The crystalline product obtained had the composition of a methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-ethyl-3-nitro-β-D-hexopyranoside (XII), but no attempt was made to elucidate its stereochemistry. This type of addition reaction should lend itself to the synthesis also of other 2-*O*-alkylated 3-nitro (and thence amino) sugars and possibly of 2-linked disaccharides.

One of the possible ways to synthesize 3-amino-2,3,6-trideoxy sugars (such as occur in certain antibiotics) was seen in a conversion of a 2,3-dideoxy-3-nitro hexoside into its 6-*O*-*p*-toluenesulfonyl and thence its 6-deoxy-6-iodo derivative, followed by reduction. To explore this route, methyl 2,3-dideoxy-3-nitro-β-D-*arabino*-hexopyranoside (XIII) (1) was monotosylated to XIV. That the tosyloxy group in XIV was indeed a primary one (i.e., located at C-6) was shown by its facile displacement by iodine on refluxing with sodium iodide in acetone. Unfortunately, reduction of the 6-iodo derivative (XV) has as yet been unsuccessful.[2]

All the experiments described above and those done previously (1) relate to the β-D-hexopyranoside series. Their performance was facilitated by the fact that I, II, and III were fairly readily available in pure, crystalline condition. It should be interesting to investigate the course of these reactions in the α-anomeric series as well. However, such undertaking remains unattractive so long as the corresponding α-glycosides, known only as amorphous mixtures of isomers (8, 9), cannot be separated into stereochemically homogeneous compounds. A first step in this direction has now been accomplished by the isolation, through column chromatography, of crystalline methyl 3-deoxy-3-nitro-α-D-glucopyranoside (XVI) and by its conversion into a crystalline 4,6-*O*-benzylidene derivative (XVII). Proof of the identity of XVI was furnished by hydrogenation and acetylation giving the known methyl 3-acetamido-3-deoxy-2,4,6-tri-*O*-acetyl-α-D-glucopyranoside.

EXPERIMENTAL

Unless otherwise indicated, evaporations were carried out *in vacuo* at 35–40° (bath temperature), petroleum ether refers to the fraction boiling at 30–60°, melting points were taken with an aluminium block apparatus and calibrated thermometer, and infrared spectra were measured using the Nujol mull technique and a Parkin-Elmer Infracord instrument.

Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-β-D-mannopyranoside (VII)

Methyl 3-deoxy-3-nitro-β-D-mannopyranoside (II; 150 mg) (4) was magnetically stirred for 15 h with 2 ml of benzaldehyde and 400 mg of anhydrous zinc chloride. The partly solidified reaction mixture was taken up with 150 ml of water and 50 ml of petroleum ether, and the heterogeneous mixture was vigorously stirred for 30 min. A solid material which separated was filtered off, washed with water and petroleum ether, and dried in a desiccator. The weight was 130 mg (62%). Recrystallization from ethanol containing a few drops of water afforded 70 mg of colorless leaflets melting at 194–196° and showing $[\alpha]_D^{23}$ −107.5° (*c*, 1 in ethanol).

Anal. Calcd. for $C_{14}H_{17}NO_7$ (311.3): C, 54.01; H, 5.51; N, 4.50. Found: C, 54.02; H, 5.62; N, 4.45.

It was not necessary to use pure II for this preparation. Rather, the material that was left in the mother liquor when methyl 3-deoxy-3-nitro-β-D-galactopyranoside (III) was prepared (4) and that consisted largely of II together with remnant III, could be utilized. Scaled-up runs could conveniently be performed. The crude benzylidenated product was then subjected to fractional crystallization from absolute ethanol, in which the *galacto* derivative VIII is less soluble than VII. Thus, in one experiment using about 25 g of a sirup of II and III there was obtained, after several recrystallizations, about 2.5 g of pure VIII from the forefractions and about 9.5 g of pure VII with m.p. 198–199° and $[\alpha]_D^{23}$ −105° (*c*, 1 in dimethylformamide). For characteristic infrared absorption bands see the second paragraph of the next section.

Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-β-D-galactopyranoside (VIII)

Pure methyl 3-deoxy-3-nitro-β-D-galactopyranoside (4) (III; 200 mg) was benzylidenated as described above for II. After recrystallization of the crude product from absolute ethanol, 140 mg (50%) of VIII

[2]*Hydrogenations using platinum catalyst or Raney nickel were tried. The choice of reducing agents was limited since alkaline conditions had to be avoided because of danger of epimerization in the nitroalcohol part of the molecule.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was obtained as colorless, long needles having m.p. 230–231° (decomp.) and $[\alpha]_D^{23}$ +24.8° (*c*, 1 in dimethylformamide). A large run using 7.7 g of crystalline but unpurified III afforded 6.0 g (56%) of pure VIII after recrystallization.

Anal. Calcd. for $C_{14}H_{17}NO_7$ (311.3): C, 54.01; H, 5.51; N, 4.50. Found: C, 54.16; H, 5.50; N, 4.70.

Infrared data:[3] The three stereoisomeric benzylidene derivatives IV, VII, and VIII show sharp hydroxyl bands at 3 450 and nitro bands at 1 560 cm^{-1}. Characteristic differences are seen in the 900–700 cm^{-1} region. IV: 880(w), 857(w), 762–755(s), 730(w), 697(s). VII: 877(s), 850(w), 815(w), 775(ms), 750(s), 725(ms), 697(s). VIII: 872(w), 827(w), 790(w), 755(w), 744(s), 697(s).

*Methyl 2-O-Acetyl-4,6-O-benzylidene-3-deoxy-3-nitro-β-*D*-mannopyranoside (IX)*

Benzylidene mannoside (VII) (200 mg) in pyridine (2 ml) was acetylated at room temperature with acetic anhydride (0.6 ml). The reaction mixture was allowed to stand overnight and was then poured into 50 ml of ice water, and the precipitate which formed was thoroughly washed with water. Recrystallization from aqueous ethanol gave 130 mg (57%) of colorless acetate IX melting at 136–137°.

Anal. Calcd. for $C_{16}H_{19}NO_8$ (353.2): C, 54.40; H, 5.42; N, 3.97. Found: C, 54.52; H, 5.55; N, 3.93.

The infrared spectrum[3] lacked hydroxyl absorption and showed a strong carbonyl peak at 1 740 and a nitro peak at 1 560 cm^{-1}. The spectrum differed from that of V in the 900–700 cm^{-1} region. IX: 917(m), 905(w), 872(m), 760–750–745(m), 722(m), 697(s), 690(w). V: 917(s), 890(m), 875(w), 763(s), 733(w), 703–697(s).

Acetylation of VII with Acetic Anhydride – Sodium Acetate

A sample of VII (300 mg) was refluxed with sodium acetate (1.2 g) in acetic anhydride (5 ml) for 6 min. Decomposition of the reaction mixture with ice water (50 ml) led to the formation of a white solid within 10 min. The solid was collected, washed thoroughly with cold water, and dried in a desiccator. The m.p. of the crude product (290 mg) was 151–154°; it was raised to 191–193° by two recrystallizations from ethyl acetate – petroleum ether. The yield of pure V was 160 mg; its infrared spectrum was identical with that of a sample prepared from IV (1) and differed from that of IX (see preceding section). The m.p. recorded (1) for V is 193–194°.

Acetoxylation of Nitroolefin (VI)

An 80 mg sample of nitroolefin (VI) from previous work (1) was refluxed for 6 min in 1 ml of acetic anhydride containing 240 mg of anhydrous sodium acetate and 40 mg of glacial acetic acid. Decomposition of the reaction mixture with 10 ml of ice water furnished 72 mg of crystals showing an unsharp m.p. of 142–148°. Since recrystallization (ethyl acetate – petroleum ether) failed to give a pure product, the whole material—crystals and evaporated mother liquor of recrystallization—was subjected once more to an identical treatment of acetoxylation, but for 2 min only. Work-up as described then afforded 60 mg of crystals melting at 152–154°. After two recrystallizations from aqueous ethanol the m.p. was 192–193° and the yield was 22 mg. The product was identified as V by its infrared spectrum.

Nitroolefin (VI) from IX

The Schmidt–Rutz elimination of acetic acid from the nitromannoside (IX) was done[4] essentially as described (1) for V. Nitromannoside (IX) (2 g) in dry benzene (50 ml) was refluxed with 10 g of finely ground, dry sodium bicarbonate. Small amounts of the solution were withdrawn from time to time, allowed to evaporate, and inspected by infrared spectroscopy. Progress of the reaction was revealed by diminution of the acetate carbonyl peak at 1 740 cm^{-1} and the nitroalkane peak at 1 560 cm^{-1} with concurrent appearance and increase of a peak at 1 533 cm^{-1} which was due to the olefinic nitro group produced. Progress was slight after 30 min, considerable after 3 and 4.5 h, and very large though incomplete after 27 h. Only VI and no more starting material was detected after 48 h when the reaction mixture was worked up by filtration, evaporation, and recrystallization of the residue from the minimum amount of ethyl acetate – petroleum ether (b.p. 60–80°). There was obtained 1.1 g of VI melting at 140–141° (yield, 70%). The infrared spectrum was identical with that of material prepared (1) from V.

Acetylation of Benzylidene Galactoside (VIII)

(a) Attempted O-Acetylation

Samples of VIII (about 50 mg each) were treated with acetic anhydride in pyridine in the manner described above for VII. The reaction mixtures turned dark brown and black on standing overnight at 0° and 23°, respectively. No crystalline acetate could be isolated, and benzaldehyde was detected during work-up. When acetylation was attempted with sodium acetate and acetic anhydride at 4° (24 h), only starting material was recovered. Under similar conditions but at room temperature a crystalline material was obtained that, according to its infrared spectrum, consisted of starting material and nitroolefin (X) (see under (*b*)).

*(b) Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-β-*D*-threo-hexopyranos-2-enide (X)*

Pure benzylidene galactoside (VIII) (3 g) was refluxed for 6 min with 12 g of anhydrous sodium acetate

[3]*Frequencies ν_{max} in cm^{-1}. Relative intensities are given in parentheses: s = strong, m = medium, w = weak.*

[4]*We are obliged to Dr. M. C. Cook of this laboratory for performing some confirmatory experiments.*

For personal use only.

in 30 ml of acetic anhydride. The slightly yellowish reaction mixture was allowed to cool under tap water and then poured into 200 ml of ice water. Stirring for 10 min resulted in the separation of a crystalline solid that was collected and washed well with water. The yield was 2.7 g (96%) of desiccator-dried, crude X which melted at 152–155° and was suitable for further experiments. An analytical sample was obtained by recrystallization from ethyl acetate – petroleum ether giving beautiful needles of m.p. 162° and $[\alpha]_D^{23}$ −47.8° (*c*, 1 in dimethylformamide).

Anal. Calcd. for $C_{14}H_{15}NO_6$ (293.3): C, 57.33; H, 5.16; N, 4.78. Found: C, 57.56; H, 5.32; N, 4.99.

When a sample of X was refluxed for 2.5 h in glacial acetic acid containing acetic anhydride, starting material was recovered and no evidence for the formation of an *O*-acetate was obtained.

Characteristic infrared bands[3]: No hydroxyl absorption; olefinic nitro group, 1 525 cm^{-1}. Comparison of X and VI in the 900–700 cm^{-1} region: X, 895(w), 877(w), 855(w), 820(m), 795(m), 752(s), 738(s), 692(s); VI, 890(w), 865(w), 802(m), 751(s), 738(w), 695(s), 675(w).

Methyl 2-O-Acetyl-3-deoxy-3-nitro-β-D-glucopyranoside (XI)

Benzylidene acetate (V) (500 mg) was refluxed for 4 h with 1.5 g of Dowex 50W-X8 (H^+) in 40 ml of methanol and 10 ml of water. The resin was removed and the filtrate was taken to dryness. Crystallization of the colorless residue (370 mg) from ethyl acetate – petroleum ether gave needles or platelets (200 mg, 54%) melting at 190–191°.

Anal. Calcd. for $C_9H_{15}NO_8$ (265.2): C, 40.76; H, 5.70; N, 5.28. Found: C, 40.31; H, 5.80; N, 5.51.

Refluxing of XI in benzene (25 parts) in the presence of solid sodium bicarbonate (5 parts) produced a dark intractable sirup.

Addition of Ethanol to Nitroolefin (VI)

Crude nitroolefin (VI) that had been obtained from 200 mg of benzylidene acetate (V) by a Schmidt–Rutz reaction as previously described (1), was refluxed for 2 h in 25 ml of ethanol. Upon addition of water and cooling there separated 120 mg (63% based on V) of needles with m.p. 122–123° and $[\alpha]_D^{23}$ −88.0° (*c*, 1.16 in ethanol). Analysis and infrared spectrum were in agreement with structure XII of a methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-ethyl-3-nitro-β-D-hexopyranoside.

Anal. Calcd. for $C_{16}H_{21}NO_7$ (339.3): C, 56.63; H, 6.24; N, 4.13. Found: C, 56.70; H, 6.22; N, 4.31.

Infrared bands (cm^{-1}): no hydroxyl; 1550, 1375 (nitroalkane); 1087, 1075, 990, 970 (ether C—O—C); 763, 700 (benzylidene).

Methyl 2,3-Dideoxy-3-nitro-6-O-p-toluenesulfonyl-β-D-arabino-hexopyranoside (XIV)

To a solution of 840 mg of methyl 2,3-dideoxy-3-nitro-β-D-*arabino*-hexopyranoside (XIII) (1) in 1 ml of pyridine was added a solution of tosyl chloride (810 mg, 1.05 molar equiv) in dichloromethane (25 ml). The mixture was left overnight at room temperature and then extracted thrice with 25 ml of 0.2 *N* hydrochloric acid, washed thrice with 25 ml of water, dried over anhydrous magnesium sulfate and finally evaporated. The colorless residue was crystallized from ethyl acetate – petroleum ether and furnished 955 mg (65%) of XIV as needles with m.p. 115°.

Anal. Calcd. for $C_{14}H_{19}NO_8S$ (361.2): C, 46.51; H, 5.31; N, 3.88; S, 8.87. Found: C, 46.75; H, 5.45; N, 4.01; S, 8.74.

Methyl 6-Iodo-3-nitro-2,3,6-trideoxy-β-D-arabino-hexopyranoside (XV)

Monotosylate (XIV) (380 mg) and sodium iodide (1.6 g) were refluxed in acetone (25 ml) for 24 h. After cooling, sodium tosylate (200 mg, 98%) was filtered off and the filtrate was evaporated. Water (25 ml) was added to the residue, and the mixture was extracted four times with 25 ml of chloroform. The combined chloroform extracts were washed once with a dilute sodium thiosulfate solution in order to remove a small amount of free iodine formed in a side reaction. Washing with water (3 × 25 ml), drying over anhydrous magnesium sulfate, and evaporation of the chloroform gave a crystalline residue which was recrystallized from ethyl acetate – petroleum ether. There was obtained 200 mg of colorless crystals, m.p. 147–148°, and a second crop (150 mg) of crystals of lesser purity. The crops were jointly recrystallized from the same solvents giving 305 mg (91%) of XV melting at 147–148°.

Anal. Calcd. for $C_7H_{12}INO_5$ (317.1): C, 26.51; H, 3.81; I, 40.03; N, 4.42. Found: C, 26.73; H, 3.92; I, 40.28; N, 4.53.

Methyl 3-Deoxy-3-nitro-α-D-glucopyranoside (XVI)

An amorphous mixture of methyl 3-deoxy-3-nitro-α-D-hexopyranosides was prepared, starting from 3.88 g (0.02 mole) of methyl α-D-glucopyranoside, in the fashion described on p. 86 of ref. 9 and relating to the nitromethane condensation in methanolic solution. The product ($[\alpha]_D^{23}$ ca. +100°, in water) was liquefied with a small amount of a chromatographic solvent mixture which consisted of the upper layer formed on mixing 1-butanol – acetic acid – water (4:1:5, v/v), and placed on a column (4.2 × 100 cm) of powdered cellulose. Elution was performed with 1.5 l of the solvent mixture, and 13-ml fractions were collected and checked polarimetrically in a 2-dm tube. Fraction No. 65 was the first to show optical activity (α_D +0.08°); maximum rotation (α_D +2.52°) was observed in fraction No. 77; then followed a gradual decrease with fraction No. 112 showing α_D +0.04° and the subsequent fractions having zero rotation. Paper chromatography using the same solvent system revealed that separation on the column had been rather unsatisfactory,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

as all the fractions gave two or three spots. Some accumulation of product and, probably, removal of impurities was nevertheless achieved resulting in the crystallization of XVI from certain fractions. Fractions 69–73 were combined and evaporated. The residue was taken up in a small amount of tetrahydrofuran, excess ethyl ether was added, and the solution was placed in a refrigerator for crystallization. The same procedure was followed for fractions 77–80. There crystallized in the course of 2 and 4 d 51 and 98 mg of products, melting at 127–133° (decomp.) and 129–133° (decomp.), respectively. Jointly recrystallized from tetrahydrofuran–ether (with an activated charcoal treatment included) the material (59 mg) melted at 136–137° (decomp.). All the other fractions were combined and, together with the mother liquors from fractions 69–73 and 77–80, were worked up in similar fashion. Seeding with the above crystals gave another crop, which upon recrystallization weighed 104 mg and also melted at 136–137° (decomp.).

Pure XVI formed colorless, elongated prisms which were chromatographically uniform; R_f 0.67; $[\alpha]_D^{23}$ +166° (*c*, 1 in water).

Anal. Calcd. for $C_7H_{13}NO_7$ (223.2): C, 37.67; H, 5.87. Found: C, 38.19; H, 5.93.

The anomeric glycosides XVI and I exhibit characteristic differences in their infrared spectra,[3] particularly in the region 950–700 cm^{-1}: XVI, 927(w), 903(m), 860(m), 800(m), 750–700(m, broad, with maximum at 725); I, 935(w), 918(m), 890(m), 790–700(m, broad, with maximum at 740).

To establish the configuration of crystalline XVI it was converted into known methyl 3-acetamido-3-deoxy-2,4,6-tri-*O*-acetyl-α-D-glucopyranoside. An aqueous solution containing 30 mg of XVI and an equivalent amount of (dilute) hydrochloric acid was hydrogenated catalytically over prehydrogenated platinum dioxide. A sirupy but chromatographically uniform amine hydrochloride was obtained; it traveled more slowly than a comparison sample of the corresponding mannoside (8, 9). Acetylation of the amine hydrochloride using 2 ml of acetic anhydride and 500 mg of sodium acetate (5 min at reflux temperature) gave after work-up in the usual manner rectangular prisms (18 mg, from ethanol) with m.p. 180–181° and $[\alpha]_D^{23}$ +108.5° (*c*, 1 in chloroform), in excellent agreement with the literature (9, 10). A mixture melting point with an authentic sample was undepressed and the infrared spectra were identical.

Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-glucopyranoside (XVII)

An amorphous mixture of methyl 3-deoxy-3-nitro-α-D-hexopyranosides (0.02 mole) was obtained according to the directions cited in the preceding section. Instead of chromatography the material was subjected to benzylidenation. The material was stirred overnight at room temperature with 4 g of anhydrous zinc chloride in 25 ml of benzaldehyde. To the reaction mixture was then added 150 ml of water and 50 ml of petroleum ether (b.p. 80–100°). When no solid had separated after 30 min of vigorous magnetic stirring, the emulsion was allowed to settle into three layers. The oily middle layer was presumed to contain the desired product. This layer was isolated, washed several times with fresh petroleum ether, then taken up in 10 ml of ethanol, and water was added to incipient turbidity. On standing at 23° for 2 d and at 4° for another day there crystallized 100 mg of XVII melting at 163–164°. Several additional crops totalling 196 mg and having slightly lower melting points were deposited by the mother liquor on prolonged standing. Recrystallization from aqueous ethanol afforded platelets of m.p. 167° and $[\alpha]_D^{23}$ +87.2° (*c*, 1 in ethanol).

Anal. Calcd. for $C_{14}H_{17}NO_7$ (311.3): C, 54.01; H, 5.51. Found: C, 54.03; H, 5.45.

The infrared spectrum shows hydroxyl (3 330 cm^{-1}) and nitro (1 550 cm^{-1}) bands and in the region 900–700 cm^{-1} the following characteristic peaks: 893(w), 865(w), 850(w), 790(m), 757(s), 697(s).

A sample of 50 mg of XVII was hydrogenated at room temperature with a platinum catalyst in 10 ml of *N*/10 hydrochloric acid. The benzylidene group was thereby removed and the nitro group reduced. The resulting amine hydrochloride failed to crystallize but gave on acetylation (as described in the preceding section) crystalline methyl 3-acetamido-3-deoxy-2,4,6-tri-*O*-acetyl-α-D-glucopyranoside, m.p. 179°, which was identified by an undepressed mixture melting point and by its infrared spectrum.

ABSTRACT

Two yellow substances were isolated from culture filtrates of the fungus *Sepedonium chrysospermum* Fries. One of these, named sepedonin, predominates in growing cultures and is believed to be the direct product of metabolism. The second, an anhydro derivative of sepedonin, was probably formed spontaneously in the culture filtrate, and during the isolation process, by chemical dehydration. Sepedonin, $C_{11}H_{12}O_5$ with one C-methyl group, gave two dimethyl ethers with diazomethane and has the spectral characteristics of a substituted tropolone. Dehydration under mild conditions afforded anhydrosepedonin, from which a monomethyl ether and two dimethyl ethers were prepared. One of the latter was unstable and rearranged slowly to a third dimethyl ether. By fusion with alkali, anhydrosepedonin was converted to a mixture from which two substituted benzoic acids and a product formulated as 6-hydroxy-4-methyltropolone were separated. The bathochromic displacement of the peaks in the ultraviolet spectrum of anhydrosepedonin compared with those in sepedonin indicated an unsaturated group conjugated to the tropolone ring, confirmed by catalytic reduction to a dihydro derivative. By careful oxidation of one of the dimethyl ethers of anhydrosepedonin with permanganate a substance believed to be a tropolone containing ester and carboxyl substituents was obtained, together with a second product formulated as the 3,4-cyclic anhydride. From these results and supporting n.m.r. and spectral evidence anhydrosepedonin is considered to be a 6-hydroxytropolone with a 2′-methylpyran ring fused at the 4,5,4′,5′-positions. Sepedonin differs only by having a 2′-hydroxy-2′-methyldihydropyran ring as the heterocyclic moiety.

Sepedonium chrysospermum (Bull.) Fr., the imperfect stage of *Hypomyces chrysospermus* (Bull.) Tul., has been isolated from soils in Europe and the American continent and is a common parasite of the fleshy fungi. The strain used in the present work was isolated from *Boletus luridus*. Cultures of this hyphomycete developed a yellow color in the broth and the surface mycelium showed patches of orange-yellow color after approximately 10 days undisturbed growth on Raulin-Thom or Czapek-Dox media. The color of the culture fluid later deepened and, in addition, gave an increasingly strong greenish-brown reaction with ferric chloride. Spectrophotometric examination of the solution showed that these changes corresponded with the appearance of a strong absorption peak at 250–275 mμ and weaker absorption in the region between 300 and 360 mμ. The wavelengths at which the maxima appeared varied with the pH of the culture filtrate. The

optical density at 271 mμ of filtrates buffered at pH 7.0 reached a maximum in cultures which had been incubated for approximately 30 days at 25°. At this time more than 90% of the glucose had been exhausted from the medium. Information on the development of cultures grown on Raulin-Thom as well as Czapek-Dox media is summarized in Table I. The main product isolated from metabolism solutions of *S. chrysospermum* was given the trivial name sepedonin.

TABLE I

	Incubation period											
	7 days			14 days			21 days			28 days		
	Batch No.

Sepedonin obtained by extracting filtrates at pH 3.5 with ethyl acetate and recrystallized from the same solvent retained ethyl acetate tenaciously in the crystals. When freed of solvent the compound gave analyses for a molecular formula of $C_{11}H_{12}O_5$, with one C-methyl but no methoxyl group. Methylation with diazomethane yielded two isomeric dimethyl ethers, the infrared spectra of which still showed hydroxyl absorption. Attempts to methylate the compound under more vigorous conditions, or to prepare other derivatives invariably led to complex mixtures and were accompanied by large bathochromic shifts in the ultraviolet absorption maxima. Similar spectral shifts could be brought about by treating sepedonin with dilute acid or alkali or even by heating a solution in ethanol.

The product obtained after acetic acid treatment was isolated and found to differ from sepedonin by loss of the elements of water. It is identical with the substance which Divekar (1) first isolated directly from culture filtrates of *S. chrysospermum* and named "sepedonin". Spectroscopic examination of the products excreted by stationary cultures of the fungus grown on Czapek-Dox medium has shown that the proportion of anhydro compound present during the early growth phase is less than 15% of the mixture, but increases later as the cultures become alkaline. This is illustrated in Figs. 1 and 2. If the pH of the cultures increases beyond 8.0, as frequently happens after growth has ceased in shaken cultures, anhydrosepedonin is usually the only product which can be isolated. Most of the sepedonin appears in the culture fluid but extraction of the mycelium with organic solvents under mild conditions afforded a very small amount which was difficult to separate in a pure form. Absorption spectra of crude mycelial extracts indicated that the proportion of anhydro form was less than in the corresponding culture filtrates. Because of the susceptibility of sepedonin to dehydration it appears likely that the presence of anhydrosepedonin in cultures is the result of a chemical change. Isolation of the anhydro form directly from culture filtrates may be due to the acidic conditions employed in this procedure, but dehydration would also occur during purification of the product by crystallization from hot ethanol and acetic acid. We now propose to reserve

use of the name "sepedonin" for the hydrated metabolite of *S. chrysospermum* and to refer in future to the compound first isolated by Divekar (1) as "anhydrosepedonin".

Anhydrosepedonin has the properties of both a weak base and a weak acid. In anhydrous media a monohydrochloride and monoperchlorate could be prepared; both were hydrolyzed rapidly in water. Since anhydrosepedonin lacks nitrogen the basicity must be due to a structural feature involving oxygen or a pseudoaromatic ring. One acidic function could be readily detected by titrating with alkali and, since no decarboxylation occurred when anhydrosepedonin was boiled with either copper chromite catalyst in quinoline or 2 *N* sulfuric acid, this is presumed to be a phenolic group. The conclusion is supported by the absence of absorption maxima in the infrared spectrum which might be assigned to a carboxyl group. Short treatment of anhydrosepedonin with diazomethane yielded a monomethyl derivative which, although no longer soluble in bicarbonate, retained some weakly acidic properties, and the characteristic ferric chloride reaction of the parent compound. Longer exposure to diazomethane gave a mixture of isomeric dimethyl ethers which were no longer acidic and showed no hydroxyl absorption maxima in their infrared spectra. Two of the oxygen functions of anhydrosepedonin are therefore phenolic in character. Attempts to prepare acetyl derivatives of sepedonin or anhydrosepedonin with either basic or acidic catalysts were unsuccessful.

No quinonoid or ketonic groups could be detected in sepedonin or its anhydro derivative by chemical tests. After reduction with zinc and acetic acid, however, anhydrosepedonin gave a copious precipitate with Brady's reagent indicating a masked ketonic function as is the case with the tropolonoid stipitatic acid (2). The infrared absorption spectra of sepedonin and its derivatives show intense maxima in the 1 500 – 1 605 cm^{-1} region with weaker maxima at 1 625 – 1 650 cm^{-1}. These are consistent with the presence of a tropolone nucleus (3–6). Further evidence has been provided by the potentiometric titration of anhydrosepedonin which showed the two acidic functions to have p*K* values similar to those reported for 4-hydroxytropolone (7). By reaction of anhydrosepedonin with fused potassium hydroxide 3-hydroxy-5-methylbenzoic acid (I) and 3,4-dimethyl-5-hydroxybenzoic acid (II) have been isolated (8). Tropolones are known to rearrange to the corresponding benzoic acids under these conditions (2, 9, 10, 11). The alkaline fusion also afforded a third product which could be obtained in better yield under somewhat milder conditions. This was a weak acid analyzing for $C_8H_8O_3$, with one C-methyl substituent, and gave a color reaction with ferric chloride similar to that of sepedonin. The ultraviolet absorption spectrum was tropolonoid rather than benzenoid in character (12) and generally similar to that of sepedonin itself. From the analyses it is assumed that one methyl and one hydroxyl substituent are present on the tropolone ring, and the most plausible structure, in view of the concomitant production of 3-hydroxy-5-methylbenzoic acid during alkaline fusion, would be (III).

If the formation of 3,4-dimethyl-5-hydroxybenzoic acid is also taken into account, anhydrosepedonin may be formulated as a 6-hydroxytropolone with carbon substituents

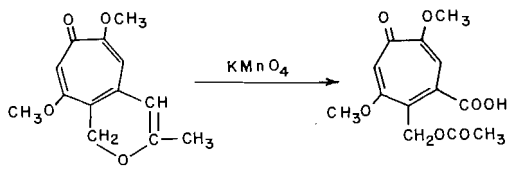
in the 4 and 5 positions. The ultraviolet absorption spectrum of sepedonin with a strong maximum in 0.01 *N* ethanolic HCl at 258 mμ (ϵ = 51 800) and a weaker peak at 329 mμ (ϵ = 9 310) is comparable with that of 4-hydroxytropolone for which the principal absorption maximum is reported to be just below 250 mμ (13). In the spectrum of anhydrosepedonin measured in acidic ethanol the principal maximum is at about 305 mμ and the longer wavelength maximum at 383 mμ is also bathochromically displaced by comparison with the corresponding maximum of sepedonin. It is apparent that dehydration of sepedonin has introduced additional unsaturation which is conjugated to the tropolone chromophore. A more complete discussion of the absorption spectrum of anhydrosepedonin, for which we are indebted to Dr. G. Aulin-Erdtman, can be found in the experimental section.

The remaining part of the C_4H_6O fragment unaccounted for in anhydrosepedonin must contain one C-methyl group and an inert oxygen atom. Information about this portion of the molecule has come from the oxidation of one of the methyl ethers of anhydrosepedonin with permanganate. From the mixture of products there was isolated an acid, $C_{13}H_{14}O_7$ which retained the two methoxyl and one C-methyl substituents as well as all carbon atoms of the parent compound. The ultraviolet spectrum of this product had reverted to the type of tropolone absorption represented by sepedonin, suggesting that oxidation had resulted in loss of the conjugated double bond of the anhydro compound. Infrared spectral evidence indicated that a carboxyl (ν_{max} 1 720 cm^{-1}) and an ester (ν_{max} 1 738 cm^{-1}) function had been generated. Treatment of the acid with diazomethane afforded a nonacidic ester (ν_{max} 1 725 cm^{-1}).



V VI

A second product, obtained in very small yield from the oxidation, analyzed for $C_{11}H_8O_6$ and is considered to be the anhydride (IV) or the isomeric methyl ether. Infrared maxima at 1 850 and 1 775 cm^{-1} attributed to the cyclic anhydride structure are comparable with those at 1 824 and 1 746 cm^{-1} in stipitatonic acid (6), and at 1 830 and 1 770 cm^{-1} in puberulonic acid (3, 4). The reaction with permanganate may be explained as the oxidative fission of a pyran ring fused to the tropolone as in (V), which would represent one of a number of possible isomeric structures of anhydrosepedonin dimethyl ether A. Cleavage of the double bond in (V) would give the acid ester (VI). An analogous reaction has been shown to occur when methyl di-*O*-methylanhydrofulvate (14) is oxidized with permanganate. The presence of a fused pyranotropolone ring system would account for the basicity of anhydrosepedonin, which is greater than expected for a tropolone system alone. It would also explain adequately the formation of formic, acetic, and malonic acids when anhydrosepedonin is oxidized with alkaline hydrogen peroxide. Anhydrosepedonin could be reduced over a suitable catalyst with the uptake of 1 mole of hydrogen. The product, deoxysepedonin, showed ultraviolet absorption maxima similar to those of sepedonin and consistent with the structure (VII) or an isomer.

The mass spectrum of anhydrosepedonin gave peaks above the highest expected molecule–ion peak at 206. This anomalous behavior disappeared upon hydrogenation,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

when the highest molecule–ion peak was at 208, provided the inlet temperature was not above 200°. The nuclear magnetic resonance (n.m.r.) spectrum of anhydrosepedonin measured in a 1:1 mixture of deuterated acetone and deuterated chloroform gave signals at τ values of 2.88 and 3.15 (two tropolone ring hydrogens); 4.15 (vinylmethine), 4.70 (methylene), and 7.89 (methyl). The assignments are consistent with the structure (VIII) or the isomer with reversed substitution at C_4 and C_5. A similar interpretation arrived at independently by Professor H. Erdtman is given in the experimental section. Structure (VIII) is preferred since the formation of 3-hydroxy-5-methylbenzoic acid (I) and 6-hydroxy-4-methyltropolone (III) during alkaline fusion may be then accounted for as the elimination of a hydroxymethyl group β- to the tropolone C_6 ring hydroxyl by means of a reversed aldol reaction. Formation of three isomeric dimethyl ethers by the action of diazomethane on anhydrosepedonin is unexpected. However, one of these, dimethyl ether A, is an unstable product which rearranges slowly to the stable derivative, dimethyl ether A_1. The type of rearrangement involved and the structure of the three products is not yet understood.

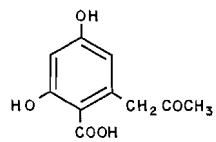
IX



X

The facile dehydration of sepedonin is similar to the conversion of the fungal metabolites fusarubin (15) and fulvic acid (14, 16) to their anhydro derivatives and is presumed to be due to the presence of a similar 2′-hydroxy-2′-methyldihydropyrane ring fused to the aromatic system. Like fusarubin and fulvic acid, sepedonin is optically inactive at the wavelength of sodium light and we propose for it the structure (IX). Assuming that its biosynthesis follows the pathway suggested for other fungal tropolones and now supported by considerable experimental evidence (17), sepedonin should be formed by condensation of acetyl coenzyme A with four units of malonyl coenzyme A. By analogy with the route proposed for stipitatonic and puberulonic acids in which orsellinic acid is an intermediate (18, 19), the phenolic acid (X) which has been isolated by Raistrick (20, 21) from cultures of *Penicillium brevicompactum* may represent an intermediate in the biosynthesis of sepedonin.

EXPERIMENTAL

Culture

The culture of *Sepedonium chrysospermum* Fries used in this work was purchased in July 1939, from the Centraalbureau voor Schimmelcultures, Baarn, Holland, who received it in July 1923 from Boedijn, Hortus Botanicus, Amsterdam, by whom it was isolated from *Boletus luridus*. It was maintained in two separate culture collections under the London School of Hygiene and Tropical Medicine (L.S.H.T.M.) catalogue numbers Ag 39 and B.B. 166. These collections were subcultured at different times and on different media. Nevertheless, comparative experiments have shown no appreciable difference in the yields of anhydrosepedonin obtained from the two cultures.

A transfer of Ag 39 is maintained on Difco malt agar slopes in the Prairie Regional Laboratory culture collection under the catalogue number PRL 1707.

Production, Isolation, and Properties of Sepedonin

Medium

The nutrient used routinely for production of sepedonin was Czapek-Dox solution of the following composition: glucose, 50 g; $NaNO_3$, 2 g; KH_2PO_4, 1 g; KCl, 0.5 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; $FeSO_4 \cdot 7H_2O$,

For personal use only.

0.01 g; distilled water, 1 l. Portions (350 ml) were dispensed into 1 l Erlenmeyer flasks and autoclaved for 20 min.

Inoculum and Conditions of Culture

A few drops of a spore suspension obtained by shaking an agar slope culture with 10 ml of sterile water proved satisfactory as inoculum only when the nutrient solution was supplemented with biotin at the rate of 5 μg per l. With a large spore inoculum sufficient biotin was introduced to give satisfactory growth without the vitamin supplement. Equally vigorous and more uniform growth was obtained with a vegetative inoculum produced by inoculating a medium consisting of Difco yeast extract (1%) and D-glucose (1%) at pH 7.2–7.4 with a spore suspension of *S. chrysospermum* and incubating at 25° on a rotary shaker at 150 r.p.m. for 3 days. These cultures were macerated in a Waring blendor and 1 ml of the suspension used for each 350 ml of production medium.

The inoculated cultures were left undisturbed in the dark at ambient temperature for 30–35 days.

Estimation of Sepedonin and Anhydrosepedonin in Culture Filtrates

Cultures were grown in triplicate in 1 l Erlenmeyer flasks constructed with a small sidearm below the surface of the 350 ml of nutrient solution. This fitting was closed with a rubber hypodermic cap, through which a sterile hypodermic needle was inserted at intervals and samples (2 ml) withdrawn for analysis of the culture fluid. A portion of the filtered metabolism solution was diluted with 0.1 *M* phosphate buffer pH 7.0, and its ultraviolet absorption spectrum recorded. Fig. 1 shows the spectrum of a 30 day old culture and, for comparison, those of sepedonin and anhydrosepedonin recorded under similar conditions. The quantities of sepedonin and anhydrosepedonin in the culture fluid were calculated by Vierordt's method (22) from the optical densities at 271 and 296 mμ. Glucose remaining in the culture filtrate was estimated with the Somogyi reagent (23). Changes in these values observed during the growth of the fungus are plotted in Fig. 2.

Isolation, Purification, and Properties of Sepedonin

The mycellium was separated by filtration through glass wool. The broth was adjusted with hydrochloric acid to pH 3.5 and allowed to remain overnight at 4°. The clear supernatant was decanted and the remaining turbid portion filtered. The clarified culture fluid was extracted six times with half volumes of ethyl acetate. Partition into ether or chloroform was less favorable, and the use of more polar solvents, such as *n*-butanol or methyl ethyl ketone into which the product was more readily extracted, resulted in decomposition.

The extracts were combined and the solvent removed at 40° *in vacuo*. Sepedonin crystallized from the concentrated solution and was purified by three additional crystallizations from the same solvent as pale-yellow prisms, m.p. 190–205° (decomp.). Found in a sample of this material dried in high vacuum at room temperature: C, 58.58; H, 5.85; OC_2H_5, 3.11. $C_{11}H_{12}O_6 \cdot \frac{1}{6}CH_3COOC_2H_5$ requires C, 58.68; H, 5.63; OC_2H_5, 3.14%. ν_{max} (KBr disk) at 1 730 cm^{-1}. Drying the sample at 80° caused decomposition. However, when the crystals were redissolved in ethanol and immediately evaporated to dryness at 40° *in vacuo*, and this procedure repeated twice, the preparation no longer absorbed energy at 1 730 cm^{-1}. The ultraviolet absorption spectrum was not appreciably changed, and showed $\lambda\lambda_{max}$ 253 mμ (ϵ = 36 800) and 327 mμ (ϵ = 6 400) in ethanol. Principal ν_{max} (KBr disk) at 3 265, 2 920, 2 850, 1 656 (shoulder), 1 600, 1 573, 1 525, 1 462, 1 378, 944, 870, 796, and 705 cm^{-1}. Found: C, 59.11; H, 5.63; OCH_3, nil; CCH_3, 11.83; mol. wt. (osmometer in ethanol) 226; $[\alpha]_D^{26°}$ nil (*c*, 0.2 in ethanol). $C_{11}H_{12}O_6$ requires: C, 58.92; H, 5.40; 1-CCH_3, 12.06%; mol. wt. 224.2.

Sepedonin is insoluble in petroleum ether, carbon tetrachloride, and benzene, poorly soluble in chloroform, ethyl acetate, acetone, or water, and fairly soluble in ethanol, pyridine, or dioxane. It is insoluble in dilute $NaHCO_3$ but dissolves easily in dilute Na_2CO_3 or NaOH solution. It is also soluble in *N* HCl giving a straw-colored solution which rapidly turns bright yellow. The solution in concentrated H_2SO_4 is also yellow. Ferric chloride added to an alcoholic solution gives a deep-green color. Tests with ketonic reagents are negative.

Derivatives of Sepedonin

Methylation of Sepedonin

Sepedonin (123 mg) in a mixture of chloroform (10 ml) and ethanol (10 ml) was treated with a distilled ethereal solution of diazomethane (from 0.5 g of nitrosomethylurea) at 0° for 18 h. The reaction products were adsorbed from chloroform solution on to a column of silicic acid which was developed first with chloroform and then with a gradient of ethyl acetate in chloroform. Two main bands, pale yellow in color, were eluted. The appropriate eluates were evaporated to dryness *in vacuo* at 40° and the residue crystallized from ethyl acetate to give the following. *(a) Sepedonin dimethyl ether A* as pale-yellow silky needles, m.p. 150–158° (decomp.), $\lambda\lambda_{max}$ in ethanol at 252 mμ (ϵ = 23 120) and 322 mμ (ϵ = 5 980), ν_{max} (KBr disk) at 3 270, 1 635 (w), 1 602, 1 592, 1 555, 1 527, 996, 946, 863, and 793 cm^{-1}. Found: C, 61.63; H, 6.50; OCH_3, 24.74. $C_{13}H_{16}O_6$ requires: C, 61.89; H, 6.39; 2-OCH_3, 24.61%. *(b) Sepedonin dimethyl ether B* as pale-cream prisms, m.p. 140–148° (decomp.), $\lambda\lambda_{max}$ in ethanol at 252 mμ (ϵ = 21 700) and 326 mμ (ϵ = 5 600), ν_{max} (KBr disk) 3 290, 1 645 (shoulder), 1 598, 1 555, 1 527, 990, 962, 938, 864, and 789 cm^{-1}. Found: C, 61.71; H, 6.24; OCH_3, 24.87%.

Anhydrosepedonin (by Direct Isolation from S. chrysospermum)

Two culture media were used for the preparation of anhydrosepedonin. (*a*) Czapek-Dox solution without addition of biotin and (*b*) Raulin-Thom solution: glucose, 75.0 g; tartaric acid, 4.0 g; ammonium tartrate, 4.0 g; $(NH_4)_2HPO_4$, 0.60 g; $(NH_4)_2SO_4$, 0.25 g; K_2CO_3, 0.60 g; $MgCO_3$, 0.40 g; $FeSO_4 \cdot 7H_2O$, 0.07 g; $ZnSO_4 \cdot 7H_2O$, 0.07 g; distilled water, 1.5 l.

These solutions (350 ml/flask) were distributed in 1 l conical flasks which were plugged with cotton wool and sterilized. The contents of the flasks were inoculated with a spore suspension, in sterile water, prepared from mature cultures of *Sepedonium chrysospermum* (strain Ag. 39 or B.B. 166) grown on wort agar, four flasks being inoculated from one slope. The inoculated flasks were incubated at 24° in the dark.

Initially the fungus grew slowly on Czapek-Dox solution, the surface of which was covered after 1 week with a white mycelium which changed to various shades of orange by the middle of the second week. Growth became very luxuriant and brownish orange in color by the end of the fourth week. The culture fluid, initially colorless, was then dark brown.

Growth on Raulin-Thom solution was not quite as heavy as on Czapek-Dox solution but showed a similar range of color. After 4 weeks incubation both mycelium and culture fluid were deep orange in color.

In order to follow the course of metabolism and to determine the optimum time of harvesting the flasks for the preparation of anhydrosepedonin, batches of 25 flasks of each culture medium were inoculated with *Sepedonium chrysospermum.* One flask culture of each medium was harvested after 7, 14, 21, and 28 days incubation. The culture fluid was then separated by filtration from the mycelium and examined. The results obtained in three separate experiments are summarized in Table I. The culture filtrate from each medium gave no color with $FeCl_3$ after 7 days incubation, pale brown after 14 days, brown after 21 days, and deep brown after 28 days, the intensity of the ferric color being a rough measure of the amount of anhydrosepedonin present.

The contents of the remaining 21 flasks of each culture medium after 28 days incubation were filtered and the separated mycelium was washed with water, dried *in vacuo* at 45°, and weighed. The respective weights of mycelium from batches I, II, and III were 78 g, 80 g, and 92 g on Czapek-Dox medium and 58 g, 50 g, and 60 g on Raulin-Thom medium. The respective culture filtrates and washings were evaporated *in vacuo* to about 1/10 volume, acidified with concentrated HCl to pH about 2.0 and exhaustively extracted with ether to separate anhydrosepedonin. The ether extracts were evaporated to dryness and the resulting dark-orange gums weighed. The respective weights of crude anhydrosepedonin from batches I, II, and III were 3.7 g, 3.5 g, and 3.9 g on Czapek-Dox medium and 3.2 g, 3.0 g, and 2.8 g on Raulin-Thom medium.

Hence Czapek-Dox medium was used for the subsequent bulk preparation of anhydrosepedonin and the flasks were harvested after 28 days incubation. The orange-colored ether extract obtained as described above from 100 such flasks was evaporated to dryness. The resulting gum was weighed and triturated with cold acetone, giving an orange solid, m.p. 190–197° (decomp.), which was separated by filtration and purified by crystallization either from absolute ethanol or glacial acetic acid. From four batches, each consisting of 100 flasks of Czapek-Dox medium, there was obtained 16.6, 17.2, 15.3, and 15.8 g of crude ether extract yielding respectively 5.8, 6.2, 4.3, and 4.9 g of pure crystalline *anhydrosepedonin.* From three batches, each consisting of 100 flasks of Raulin-Thom medium, there was obtained 3.9, 3.5, and 3.2 g of pure anhydrosepedonin.

Extraction of the dried and defatted mycelium with a variety of organic solvents failed to yield any crystalline material. However, small amounts of crystalline anhydrosepedonin were obtained from the extraction of Raulin-Thom mycelium with cold dilute aqueous NaOH or Na_2CO_3. The alkaline extracts were acidified and extracted with ether and the residue obtained on removal of the solvent was crystallized from acetone. Yield of anhydrosepedonin, melting point and mixed melting point 203–205°, 50 mg from 25 g of dried mycelium.

Anhydrosepedonin forms glistening yellow needles, m.p. 205° (decomp. and not resetting on cooling). It contains no N, Cl, or S. Found: C, 64.0, 64.2; H, 5.52, 5.29; O, by direct estimation, 31.2; OCH_3, nil; CCH_3, 5.5; active H atoms in pyridine, 0.86%; titration equivalent to phenolphthalein, 204. $C_{11}H_{10}O_4$ requires: C, 64.1; H, 4.89; O, 31.0; 1-CCH_3, 7.3; 2 active H atoms, 0.98%, equivalent titrating as a monobasic acid, 206; $\lambda\lambda_{max}$ in ethanol at 249 mμ (ϵ = 15 750), 286 mμ (ϵ = 29 400), 302 mμ (inflection, ϵ = 18 700), 354 mμ (inflection, ϵ = 8 270), 375 mμ (ϵ = 7 250), and 386 mμ (ϵ = 8 130). Principal ν_{max} (Nujol) at 1 660, 1 607, 1 465, 1 430, 1 370, 1 340, 1 310, 1 230, 1 170, 1 140, 1 105, 885, 835, and 725 cm^{-1}.

Anhydrosepedonin shows no optical activity. It sublimes unchanged in high vacuum at 170°. It is sparingly soluble in water and ether, but appreciably soluble in acetone, ethanol, methanol, ethyl acetate, dioxane chloroform, and benzene. It is insoluble in light petroleum (b.p. 40–60°). It dissolves slowly in aqueous $NaHCO_3$ but readily in aqueous NaOH. It also dissolves readily in concentrated HCl from which it is precipitated unchanged on dilution with water. It gives a strong-brown color in aqueous or ethanol solution with either aqueous or ethanolic $FeCl_3$. It gives no precipitate with Brady's reagent (0.32% 2,4-dinitrophenylhydrazine in aqueous 2*N* HCl). Its yellow ethanolic solution is not decolorized with sodium dithionite, $Na_2S_2O_4$, nor is ammoniacal $AgNO_3$ reduced. It gives a negative color test for primary and secondary alcohols (24).

Anhydrosepedonin (from Sepedonin)

Sepedonin (100 mg) was heated under reflux for 1 h in glacial acetic acid (5 ml). On cooling, bright-yellow needles (47 mg) separated slowly from the solution. After two recrystallizations from ethanol they had m.p.

203–205° (decomp.), unchanged when a specimen was mixed with anhydrosepedonin obtained directly from culture filtrates of *S. chrysospermum*. Found: C, 63.93; H, 5.05; CCH_3, 5.5%; neutralization equivalent by potentiometric titration in 80% ethanol against 0.1 *N* NaOH, 207 ± 3 (p*K* of acid function titrated, 7.15).

Physical Properties of Anhydrosepedonin (by H. Erdtman and G. Aulin-Erdtman)

The sample used for these studies had been obtained through repeated recrystallizations of an old specimen. It may have been slightly impure, as indicated by the fact that it showed lower ultraviolet absorption maxima and a higher minimum at 275 mμ in ethanolic hydrochloric acid than a pure specimen, later obtained from Dr. Vining. The mass spectra of the two specimens, however, were very similar.

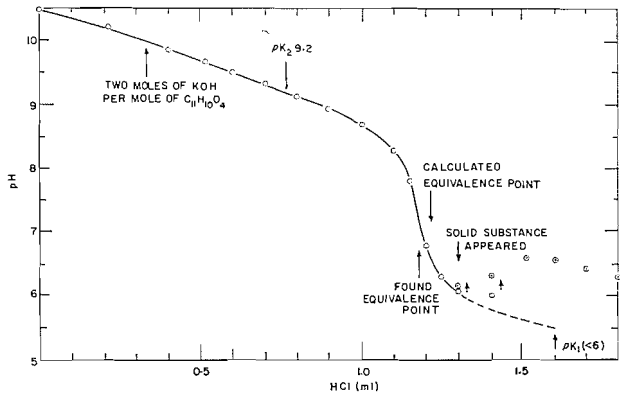

FIG. 3. Potentiometric titration of anhydrosepedonin (see text for details).

Potentiometric titration.—The potentiometric titration in aqueous solution presented difficulties because of the low solubility not only of anhydrosepedonin itself, but also of the presumed monosodium salt. The compound (10.7 mg) was dissolved by keeping it overnight at room temperature in excess (15.0 ml of 0.0084 *M*) aqueous potassium hydroxide solution containing a drop of octanol to wet the crystals, and back-titrated with 0.0613 *M* hydrochloric acid. Since solid precipitated after the first equivalence point had been passed the pK_1 could not be measured. From the titration curve (Fig. 3) an approximate upper limit of 6 is found for the pK_1 and pK_2 can be estimated as 9.2. The two values are in agreement with the dissociation constants of 4-hydroxytropolone for which Yui (7) quoted pK_1 (4-hydroxyl) 5.7 and pK_2 (2-hydroxyl) 9.5.

Ultraviolet absorption.—The absorption curve of anhydrosepedonin, measured in ethanol in the presence of a strong acid to suppress ionization of the acidic functions, showed three principal maxima (Fig. 4). The one at 250–251 mμ (log ε 4.3) may be compared with the nearly twice as high maximum just below 250 mμ reported by Nozoe and Kitahara (13) for 4-hydroxytropolone. The second high maximum, at 305 mμ (log ε 4.5, for the pure preparation 4.6), is probably a property of the entire chromophoric system, for which no close analogies yet seem to exist to enable comparison. β-Isopropenyltropolone shows no strong band in this region (25). The third, long wavelength maximum of anhydrosepedonin occurs at 386 mμ (383 mμ for the pure specimen, log ε 4.0 for both). It is bathochromically displaced and intensified compared with the

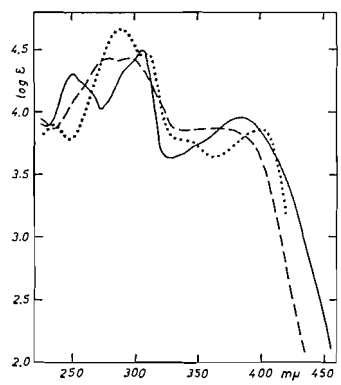

FIG. 4. Ultraviolet absorption curves for anhydrosepedonin: (—) in 0.1 *N* hydrochloric acid in 95% ethanol; (---) in phosphate buffer pH 7.2 (no ethanol added); (...) in 0.1 *N* potassium hydroxide in 95% ethanol.

For personal use only.

long wavelength maxima of tropolones not containing an extended conjugated system. The solution of anhydrosepedonin in 0.1 *M* ethanolic hydrochloric acid showed only very slight spectral changes during the period of measurement but deteriorated when kept for 24 h.

The absorption of anhydrosepedonin in 0.1 *M* ethanolic potassium hydroxide solution should be that of the doubly ionized molecule. This solution was stable for at least 24 h and gave an absorption curve generally similar to that of fully ionized stipitatic acid (12) except for the maximum at 310 mμ (log ε 4.5), which seems to correspond to the 305 mμ peak of the acidic solution. The other maxima were: 236 mμ (log ε 3.9), 289 (4.7), and 401 (3.9).

To measure the absorption of the singly ionized molecule the substance was dissolved in aqueous phosphate buffer of pH 7.2. The solution is calculated to contain only 1% of doubly ionized and not more than 6% of unionized anhydrosepedonin. The difference in absorption between this and the acidic solution, however, is not only due to ionization of the 5-hydroxyl group but also to the change of solvent from ethanol to water. Thus, the hypsochromic shift of the long wavelength absorption on passing from the acidic to the near-neutral solution seems to be caused by the change of solvent. The following maxima were found: 279–280 mμ (log ε 4.4), 295 (4.4), and 350–370 (3.9).

The ultraviolet absorption of the deoxysepedonin, whose mass spectrum is discussed below, is shown in Fig. 5. The 305 mμ peak of anhydrosepedonin has disappeared and the overall absorption is now similar to that of tropolones without extended conjugation, although the absorption does not extend as far into the long wavelength region. The maxima for the acidic solution are: 259–260 mμ (log ε 4.7) and 333 (4.0); for the alkaline solution: 281–282 (4.7), 341 (3.9), and 368 (3.9).

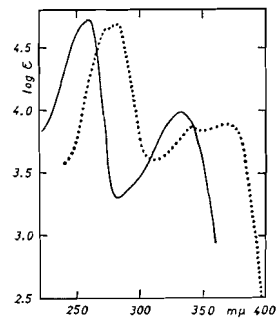

FIG. 5. Ultraviolet absorption curves for hydrogenated anhydrosepedonin (deoxysepedonin): (—) in 0.1 *M* ethanolic hydrogen chloride; (...) in 0.1 *M* ethanolic potassium hydroxide.

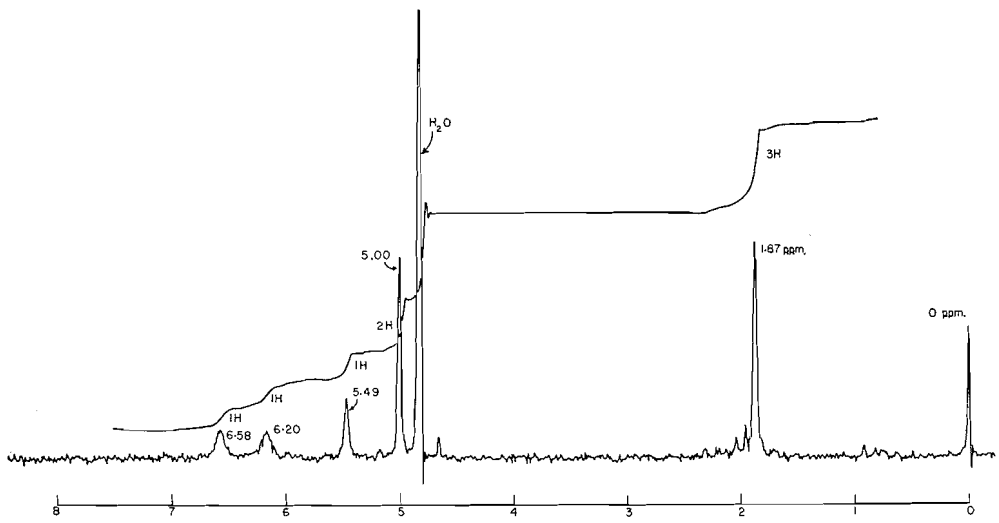

FIG. 6. Nuclear magnetic resonance spectrum of anhydrosepedonin in D_2O containing NaOD at a concentration of approximately 2 *N*. Trimethylsilyl acetic acid was the internal reference.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Nuclear magnetic resonance spectrum.—The spectrum (Fig. 6) was recorded for a solution in deuterium oxide containing approximately 2 *N* sodium deuteroxide. Trimethylsilyl acetic acid was the internal reference. The two hydrogen atoms of the tropolone ring exhibited resonance at 6.58 and 6.20 p.p.m. The signal at 6.20 p.p.m. is tentatively assigned to the hydrogen atom in position 3. As found for other tropolones examined under similar conditions the peaks were slightly broadened. Signals at 5.49, 5.00, and 1.87 p.p.m. are attributed to the olefinic, methylene, and methyl protons, respectively. An integration of the peaks supports these assignments.

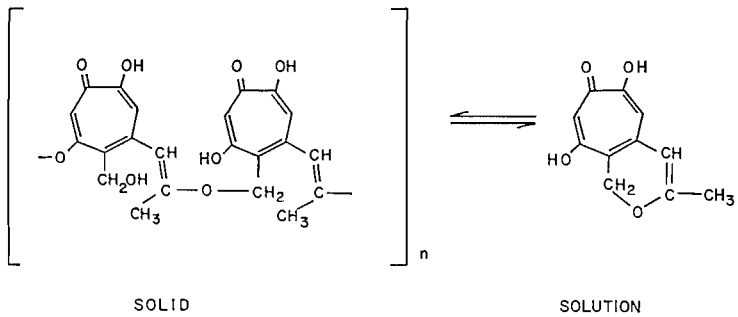

FIG. 7. Suggested oligomerization of anhydrosepedonin in the solid state.

Mass spectrum.—The two preparations of anhydrosepedonin used in these studies invariably gave mass peaks higher than the expected molecule–ion peak at 206 when examined at a range of temperatures. On the assumption that this behavior might be due to the existence of oligomers in the solid state (cf. Fig. 7) one of the samples, of which only a very small amount was available, was hydrogenated over 10% palladium on charcoal catalyst. The product, after purification by repeated sublimation and crystallization, melted in the temperature range 217–224°, with some needles remaining unchanged and sintering with decomposition up to 250°. A mass spectrum on this material at 200° gave the expected molecule–ion peak at 208, and additional peaks at 206, 178, 165, 152, 135, 121, 109, 93, 79, 77, 65, 53, and 43. At a higher temperature (250°) the result was essentially similar, except for the appearance of a lot of small peaks above 208.

Derivatives of Anhydrosepedonin

Hydrochloride.—Concentrated HCl (1 ml) was added to a filtered hot solution of anhydrosepedonin (0.5 g) in glacial acetic acid (35 ml). On cooling, *anhydrosepedonin hydrochloride* (0.35 g) crystallized from the greenish-yellow solution. It was collected and crystallized from acetic acid – concentrated HCl giving yellowish-green prisms (0.30 g) which blackened on heating above 205° but did not melt. Found: C, 54.5; H, 4.66; Cl, 14.7. $C_{11}H_{10}O_4 \cdot HCl$ requires: C, 54.4; H, 4.57; Cl, 14.6%.

The hydrochloride is immediately decomposed by water giving anhydrosepedonin and HCl. It (0.0162 g) was suspended in water for some time and shaken occasionally. The undissolved material was then separated by filtration, and the filtrate and washings were titrated against 0.02 *N* NaOH to phenolphthalein. Found: 3.40 ml 0.02 *N* NaOH = 14.9% Cl in the hydrochloride. The undissolved yellow crystalline material melted at 203–205° unchanged by admixture with anhydrosepedonin.

Perchlorate.—Aqueous $HClO_4$ (60%; 1 ml) was added to a suspension of anhydrosepedonin (0.5 g) in glacial acetic acid (15 ml). The substance dissolved and, on standing, *anhydrosepedonin perchlorate* crystallized out from the orange-colored solution. It was collected and recrystallized from acetic acid – perchloric acid as long yellow needles (0.36 g), m.p. 180–183° (decomp.). Found: C, 41.0; H, 4.22; Cl, 11.5. $C_{11}H_{10}O_4 \cdot HClO_4 \cdot H_2O$ requires: C, 40.7; H, 4.04; Cl, 10.9%. The perchlorate is immediately decomposed by water giving anhydrosepedonin and perchloric acid. Treatment of the perchlorate (0.0180 g) with water and titration as described for the hydrochloride required 2.86 ml of 0.02 *N* NaOH for neutralization to phenolphthalein = 11.3% Cl in the perchlorate. The undissolved residue was collected and dried. It melted at 203–205° unchanged by admixture with anhydrosepedonin.

Methylation Products of Anhydrosepedonin

Monomethyl ether.—An ether solution of diazomethane (from 5 g of nitrosomethylurea) was gradually added to a suspension of anhydrosepedonin (1 g) in methanol (50 ml). After 4 h a clear, greenish-yellow solution was obtained and was then evaporated to 30 ml and held overnight at 0°. The resulting crystals were collected (0.75 g), m.p. 158–160° (decomp.), and recrystallized from ethanol giving *anhydrosepedonin monomethyl ether* as canary-yellow needles (0.50 g), m.p. 163–164° (decomp.), which showed a marked green fluorescence in ultraviolet light. $\lambda\lambda_{max}$ in ethanol at 248.5 mμ (ϵ = 17 400), 285 mμ (ϵ = 28 700), and 383 mμ (ϵ = 5 430). ν_{max} (KBr disk) at 3 190, 3 100 – 2 350 (broad), 1 662, 1 614, 1 590, 1 543, 884, 845, 829, 800, and 770 cm^{-1}. Found: C, 65.15; H, 5.63; OCH_3, 14.2. $C_{12}H_{12}O_4$ requires: C, 65.5; H, 5.49; 1-OCH_3, 14.1%. The ether is insoluble in $NaHCO_3$ but is soluble in Na_2CO_3 and NaOH. Its ethanolic solution gives a brown color with ethanolic $FeCl_3$ which is very similar to that given by anhydrosepedonin itself.

For personal use only.

Dimethyl ether A.—An ether solution of diazomethane (from 10 g of nitrosomethylurea) was added to a suspension of anhydrosepedonin (2 g) in acetone (25 ml) and the mixture was held at room temperature for 24 h. The resulting reddish-brown solution was then evaporated to dryness giving a gum which was dissolved in benzene (50 ml) and passed through a column of alumina (B.D.H. for chromatographic absorption analysis). The column was eluted with ether (3 l) and the eluate was evaporated to dryness. The yellow residue (0.95 g), m.p. 148–151° (decomp.), was crystallized once from benzene and then from toluene giving *anhydrosepedonin dimethyl ether A* as bright-yellow needles, m.p. 153–155° (decomp.). Found: C, 66.1; H, 5.91; OCH_3, 27.0; mol. wt. (Rast), 225. $C_{13}H_{14}O_4$ requires: C, 66.65; H, 6.02; 2-OCH_3, 26.5%; mol. wt. 234. $\lambda\lambda_{max}$ in ethanol 250.5 mμ (ϵ = 15 400), 271 mμ (inflection; ϵ = 18 750), 280.5 mμ (ϵ = 23 600), 370 mμ (ϵ = 16 950). ν_{max} (KBr disk) at 1 650, 1 588, 1 550, 1 504, 902, 841, and 826 cm^{-1}. Dimethyl ether A is readily soluble in water and $CHCl_3$ and moderately soluble in benzene, acetone, ethanol, and methanol. An ethanolic solution gives a clear-orange color with ethanolic $FeCl_3$. An aqueous solution gives a copious precipitate with an aqueous solution of picric acid. Dimethyl ether A is unstable and is converted slowly during storage in the solid state, or in solution, to dimethyl ether A_1.

Ferric chloride complex of dimethyl ether A.—A solution of anhydrous $FeCl_3$ (100 mg) dissolved in concentrated HCl (0.5 ml) was added to a solution of anhydrosepedonin dimethyl ether A (100 mg) in glacial acetic acid (2 ml). The $FeCl_3$ complex separated as orange crystals which were collected, dried, m.p. 150–153°, and recrystallized from glacial acetic acid containing a little concentrated HCl. The complex formed beautiful orange needles (60 mg), m.p. 156–158°, which turned brick red when kept for a few days. Found: OCH_3, 14.4. $C_{13}H_{14}O_4 \cdot HFeCl_4$ requires: 2-OCH_3, 14.3%.

Dimethyl ether B.—The ether-extracted alumina column was further eluted with $CHCl_3$ (200 ml). The eluate was dried *in vacuo* and the gummy residue (0.20 g) was crystallized twice from water giving *anhydrosepedonin dimethyl ether B* as pale-cream-colored needles (80 mg), m.p. 146°. A mixed melting point with dimethyl ether A was 120–125°. Found: C, 66.6; H, 6.2; OCH_3, 26.5. $C_{13}H_{14}O_4$ requires: C, 66.65; H, 6.02; 2-OCH_3, 26.5%. $\lambda\lambda_{max}$ in ethanol: 227 mμ (inflection; ϵ = 7 620), 249 mμ (ϵ = 11 400), 298 mμ (inflection; ϵ = 30 600), 308.5 mμ (ϵ = 38 000), 354 mμ (inflection; ϵ = 10 750), 369 mμ (inflection; ϵ = 9 700), 388 mμ (inflection; ϵ = 6 500). ν_{max} (KBr disk) at 1 648, 1 585, 1 533, 975, 901, and 838 cm^{-1}. Dimethyl ether B is only slightly soluble in water, but its other properties are very similar to those of dimethyl ether A.

Dimethyl ether A_1.—Anhydrosepedonin (2 g) suspended in acetone (25 ml) was treated with a dry ethereal solution of diazomethane prepared from *N*-methyl-*N*-nitroso-*N'*-nitroguanidine (15 g). The reaction mixture, after 16 h at room temperature, was evaporated to dryness, then redissolved in benzene and applied to a column of alumina (Merck, chromatographic grade). The column was developed with a benzene–chloroform (1:1) mixture and fractions collected. Three partially resolved yellow zones were eluted. Thin-layer chromatography (t.l.c.) using silica-gel G (Merck) with chloroform containing 5% glacial acetic acid as solvent was used to follow the separation and appropriate fractions pooled, evaporated, and crystallized to give, in the order of their elution from the column: (*a*) *anhydrosepedonin dimethyl ether A_1*, obtained as clusters of yellow needles (214 mg), m.p. 157–159°, after several recrystallizations from benzene–petroleum ether (b.p. 60–80°); mixed melting point with dimethyl ether A, 140–149°. $\lambda\lambda_{max}$ in ethanol: 226 mμ (ϵ = 12 850), 232 mμ (ϵ = 12 650), 253 mμ (inflection; ϵ = 13 400), 261.5 mμ (ϵ = 17 400), 300 mμ (ϵ = 18 150), 309 mμ (ϵ = 18 700), 340 mμ (ϵ = 7 480), 352 mμ (inflection; ϵ = 7 000), 379 mμ (inflection; ϵ = 4 200). ν_{max} (KBr disk) at 1 658, 1 615 (w), 1 575, 1 553, 1 530, 1 010, 984, 868, 846, and 828 cm^{-1}. Found: C, 66.67; H, 6.27; OCH_3, 26.75; mol. wt. (osmometer with acetone) 242. $C_{13}H_{14}O_4$ requires: C, 66.65; H, 6.02; 2-OCH_3, 26.5%; mol. wt. 234. (*b*) Anhydrosepedonin dimethyl ether A, obtained as glistening bright-yellow needles (80 mg), m.p. 153–155° (decomp.), after recrystallization from toluene or carbon tetrachloride. (*c*) Anhydrosepedonin dimethyl ether B, obtained as pale-cream needles (240 mg), m.p. 146°, by crystallization from toluene and then water.

Methylation with dimethyl sulfate.—Anhydrosepedonin (0.5 g) suspended in dry acetone (30 ml) was heated under reflux for 6 h with anhydrous K_2CO_3 (0.5 g) and dimethylsulfate (0.3 ml). The solution became green after 2 h and then changed slowly to reddish brown. It was filtered and the filtrate evaporated to dryness *in vacuo*. The residue, redissolved in water (25 ml), was extracted continuously with ether. The extract upon evaporation gave a residue (260 mg) from which, in the manner described above, dimethyl ether A (80 mg) and B (3 mg) were obtained.

Methylation with methyl iodide.—Anhydrosepedonin (0.5 g) suspended in dry benzene (50 ml) was heated under reflux for 8 h while seven additions of methyl iodide (1 ml) and silver oxide (200 mg) were made. The reddish-brown reaction mixture was filtered, the filtrate evaporated to dryness and re-extracted into ether. The ethereal solution gave, on evaporation, a residue (280 mg) from which dimethyl ether A (120 mg) and B (6 mg) were obtained in the manner described above.

Dehydration of sepedonin dimethyl ethers A and B.—Sepedonin dimethyl ether A (24 mg) in glacial acetic acid (3 ml) was heated on a steam bath for 1 h. The solvent was removed and the residue, in chloroform, chromatographed on a column of alumina. The yellow band eluted with chloroform was collected and the solvent removed *in vacuo*. Crystallization of the residue gave anhydrosepedonin dimethyl ether A (4 mg).

Sepedonin dimethyl ether B (16 mg) treated similarly gave anhydrosepedonin dimethyl ether B (7 mg).

Deoxysepedonin

Anhydrosepedonin (23 mg) in ethanol (15 ml) was hydrogenated at 29° and atmospheric pressure over

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Adams' catalyst (10 mg). The rate of hydrogen uptake decreased abruptly after the absorption of 1.06 moles per mole. The catalyst was removed and the solution concentrated to a small volume. Buff-colored needles (14 mg) of *deoxysepedonin*, m.p. 234–235°, separated. $\lambda\lambda_{max}$ in ethanol 254.5, and 329 mμ with inflections at 268 and 352 mμ. ν_{max} (KBr disk) at 3 240, 3 100 – 2 550, 1 630 (shoulder), 1 606, 1 568, 1 533, 1 515, 930, 884, 816, and 720 cm^{-1}. Found: C, 63.41; H, 6.07. $C_{11}H_{12}O_4$ requires: C, 63.45; H, 5.81%.

Degradative Studies

Alkaline Degradation of Anhydrosepedonin

Anhydrosepedonin (200 mg) was stirred quickly into a fusion mixture of KOH (7 g) and water (0.5 ml) at 200°. The amber solution was immediately cooled, acidified with concentrated HCl, and extracted five times with ether. The combined ether extracts were washed with 5% $NaHCO_3$ solution, dried over anhydrous Na_2SO_4, and evaporated to dryness. The residue was crystallized from water, sublimed in high vacuum, and finally crystallized from aqueous methanol as colorless plates, m.p. 230–232°. $\lambda\lambda_{max}$ in ethanol: 251.5 mμ (ϵ = 36 500); 267 mμ (inflection; ϵ = 21 400), 331 mμ (ϵ = 7 820), 343 mμ (ϵ = 8 000). ν_{max} (KBr disk) at 3 200–2 600, 1 655 (w), 1 563, 1 478, 1 435, 1 393, 1 370, 1 345, 1 208, 1 045, 920, 870, 852, 778, 723, and 700 cm^{-1}. Found: C, 63.27; H, 5.53; CCH_3, 9.62. $C_8H_8O_3$ requires: C, 63.15; H, 5.30; 1-CCH_3, 9.86%.

The compound is insoluble or sparingly soluble in petroleum ether and benzene, only slightly soluble in water or methanol but more soluble in acetone, chloroform, or dioxane. It is insoluble in dilute $NaHCO_3$ solution but dissolves readily in *N* NaOH. With $FeCl_3$ in ethanolic solution it gives a greenish-brown color.

Oxidation of Anhydrosepedonin with Alkaline Hydrogen Peroxide

Anhydrosepedonin (1 g) was dissolved in *N* sodium hydroxide (40 ml) in a closed reaction vessel through which a slow stream of nitrogen was passed. Hydrogen peroxide (10 ml of 30% aqueous solution) was added and a slow exothermic reaction began. Gases issuing from the vessel were led through traps containing solutions of Brady's reagent and of baryta. After 10 h the reaction mixture had become colorless and was neutralized with *N* hydrochloric acid (40 ml). When carbon dioxide evolution had ceased the yield of barium carbonate in duplicate experiments was equivalent to 1.5 and 1.6 moles of carbon dioxide per mole of anhydrosepedonin used. No precipitation appeared in the trap containing Brady's reagent.

The reaction mixture was distilled *in vacuo* at temperatures not exceeding 50° and the distillate collected. In duplicate experiments the total yields of volatile acids, estimated by titration with 0.1 *N* sodium hydroxide, were 0.97 and 1.00 moles per mole of anhydrosepedonin.

Formic acid was detected by the test with chromotropic acid (26) and isolated as the lead salt. The distillate from one experiment was boiled with lead carbonate (0.75 g) and filtered. The filtrate was concentrated *in vacuo* to 10 ml and diluted with ethanol (50 ml). The product which separated was recrystallized from water as glistening colorless needles (95 mg) which became black on heating above 245°. Found by conversion to lead sulfate: Pb, 67.6, 67.9. Calcd. for $PbC_2H_2O_4$, 69.71%. A similar measurement of the lead content in an authentic sample of lead formate gave 68.4%. The amount of formic acid in the distillate was estimated by allowing it to reduce mercuric chloride. The total volatile acids from an experiment were neutralized and concentrated *in vacuo* to a small volume. Sodium acetate (3 g), mercuric chloride (3 g), and sodium chloride (2.25 g) were added, and the solution filtered, made to 150 ml, and heated on a water bath for 2 h. The yield of mercurous chloride (1.00 g) was equivalent to 0.42 mole formic acid per mole of anhydrosepedonin.

The presence of acetic acid in the volatile acids was established by preparing a *p*-bromophenacyl ester. The neutralized distillate from one experiment was evaporated *in vacuo*. The residue (0.2 g) redissolved in water (2 ml) and made acid with two drops of *N*-hydrochloric acid was heated under reflux with a solution of *p*-bromophenacyl bromide (0.75 g) in ethanol (10 ml). On cooling for several hours at 4° a crystalline product (200 mg), m.p. 70–74°, separated. This, when twice recrystallized from ethanol, had m.p. 85°, undepressed on admixture with an authentic specimen of *p*-bromophenacyl acetate. Found: Br, 31.0. Calcd. for $C_{10}H_9O_3Br$: 31.1%.

The nonvolatile fraction from the oxidation was evaporated to dryness *in vacuo* at 45–50° and the last traces of moisture removed over phosphorus pentoxide. The residue was continuously extracted with dry ether and the ether removed to give from duplicate experiments 0.59 and 0.64 g of ether-soluble material. The product from one such experiment was crystallized from chloroform and twice sublimed in high vacuum at 80° to give colorless plates, m.p. 135°, undepressed by an authentic specimen of malonic acid. Found: C, 34.9; H, 3.8. Calcd. for $C_3H_4O_4$: C, 34.6; H, 3.9%. The substance gave the color changes with acetic anhydride expected of malonic acid and formed fluorescein when heated with resorcinol and sulfuric acid.

Oxidation of Anhydrosepedonin Dimethyl Ether A with Permanganate

To a well-stirred solution of anhydrosepedonin dimethyl ether A (50 mg) in acetone (20 ml) at 0° powdered potassium permanganate (150 mg) was added in small portions over a period of 30 min. The precipitate was removed by filtration, washed with acetone, then extracted with several 2 ml portions of ice-cold water. The combined aqueous extracts were washed twice with chloroform, then acidified and re-extracted with chloroform (5 × 25 ml). The acidic product remaining after evaporation of solvent was washed with a small volume of cold acetone then twice crystallized from water to give feathery white needles (8 mg), m.p. 205–206°. $\lambda\lambda_{max}$ in ethanol at 259 mμ (ϵ = 30 300) and 324 mμ (ϵ = 6 890). ν_{max} (KBr disk) at 3 100 – 2 450,

For personal use only.

1 738, 1 720, 1 600, 1 540, 1 240, 1 028, 997, 891, 875, 788, 742, and 690 cm^{-1}. Found: C, 55.3; H, 5.3; OCH_3, 23.9; CCH_3, 4.6; neutr. equiv., 288. $C_{13}H_{14}O_7$ requires: C, 55.33; H, 5.00; 2-OCH_3, 22.00; 1-CCH_3, 5.33%; mol. wt. 282.

A methyl ester was prepared by treating an ethereal solution of the acid with diazomethane. After sublimation in high vacuum it had m.p. 132°. $\lambda\lambda_{max}$ in ethanol at 251 mμ (ϵ = 29 600), 256 mμ (inflection; ϵ = 20 700) and 323 mμ (ϵ = 7 560). ν_{max} (KBr disk) at 1 738 (shoulder) and 1 725 cm^{-1}. Found: C, 56.4; H, 5.5; OCH_3, 36.4. $C_{14}H_{16}O_7$ requires: C, 56.74; H, 5.44; 3-OCH_3, 31.41%. The ester was insoluble in dilute $NaHCO_3$ but dissolved slowly in dilute NaOH solution.

The acetone soluble fraction of the acidic oxidation products gave, on concentrating and cooling the acetone solution, a crop of orange plates (15 mg). These were recrystallized from acetone to a constant melting point of 221–222° (decomp.). $\lambda\lambda_{max}$ in ethanol at 254 mμ and 353 mμ with an inflection at 414 mμ. ν_{max} (KBr disk) at 1 850, 1 775, 1 632, 1 565, 988, 907, 883, 825, 756, 731, and 700 cm^{-1}. Found: C, 55.8; H, 3.2; OCH_3, 26.5. $C_{11}H_8O_6$ requires: C, 55.9; H, 3.4; 2-OCH_3, 26.3%.

ACKNOWLEDGMENTS

We thank Dr. R. H. Haskins and Mr. L. R. Nesbitt of the Prairie Regional Laboratory for assistance in growing and extracting cultures of *S. chrysospermum*. P. V. Divekar also thanks the Council of Scientific and Industrial Research (India) for the award of an Assam Oil Company Scholarship (1953–1956). The nuclear magnetic resonance spectrum of anhydrosepedonin in deuterated acetone – chloroform was provided by Dr. H. J. Bernstein, Division of Pure Chemistry, National Research Council of Canada, Ottawa.

We are very grateful to Professor Holger Erdtman and Dr. Gunhild Aulin-Erdtman of the Department of Organic Chemistry and the Department of Wood Chemistry, respectively, Royal Institute of Technology, Stockholm, Sweden, for their expert examination of anhydrosepedonin which they assure us is a tropolone.

ON THE USE OF NUCLEAR MAGNETIC RESONANCE FOR THE DETECTION, ESTIMATION, AND CHARACTERIZATION OF N-METHYL GROUPS

J. C. N. MA[1] AND E. W. WARNHOFF[2]
Department of Chemistry, University of Western Ontario, London, Ontario
Received December 18, 1964

ABSTRACT

A useful n.m.r. technique for the detection, estimation, and characterization of N-methyl groups is described. The method depends on the decreased shielding of N_{basic}-methyl protons when the solvent is changed from deuterochloroform to perdeuteroacetic (PDA) (or acetic) acid to trifluoroacetic acid (TFA). The decreased shielding results in a downfield shift of the N-methyl resonance of ca. 0.3–1.3 p.p.m. depending on the type of amine. Most N-methyl groups on neutral nitrogen atoms show little movement. For the majority of aliphatic amines in trifluoroacetic acid the NH exchange rate is slow enough at 38° to permit observation of coupling of H(N) with the N-methyl protons, and thus determination of whether the amine is secondary or tertiary. In some cases information can be obtained about methylene and methine groups attached to basic nitrogen. In acid solution compounds with basic nitrogen attached to, or part of, an aromatic ring show considerable shift of the aromatic proton resonance signals to lower magnetic field. Combination of the n.m.r. technique with the Herzig-Meyer analysis can also reveal the number of methyl groups attached to neutral nitrogen.

INTRODUCTION

The determination of N-alkyl groups in compounds of unknown structure is normally done by the Herzig-Meyer analysis (1) or by means of nuclear magnetic resonance (n.m.r.) spectroscopy (2, 3*a*, 3*b*). To a lesser extent infrared spectroscopy (3*c*), the isolation of a smaller known degradation fragment containing an N-alkyl group, or else Conroy's method (4) have also served. However, all of these methods have limitations.

Occasionally low or negligible values are obtained in the Herzig-Meyer analysis of compounds which do contain N-alkyl groups. Examples are the alkaloids ajaconine (44% of one NCH_3) (5), tazettine (65% of one NCH_3) (6), and α- and β-obscurine (no NCH_3 found in ref. 7*a*, but see ref. 7*b*). On the other hand there are a number of compounds which are known not to have a C_{1-4} N-alkyl group, but which do give rise to a volatile alkyl iodide under the conditions of the Herzig-Meyer reaction. The alkaloids atisine (8), veatchine, garryine (9), aspidospermine (10), aspidosine (4), hetisine, heteratisine (11), undulatine (12), decamine, decodine, decaline, vertaline (13), cassine (14), quebrachamine (15), the alkaloid derivative yohimbol (15), and 3-hydroxypiperidine (14) all have given appreciable N-alkyl values.

The Herzig-Meyer procedure does not distinguish N-methyl from N-ethyl or higher alkyl groups unless the volatile alkyl iodide is isolated as a derivative, usually the trimethylammonium salt. In the past this has led to the assumption that certain compounds possessed an N-methyl group, whereas in fact an N-ethyl group was present. The alkaloids lycoctonine (16), delpheline (17), napelline (18), and ajacine (19) are cases in point. Nor does the analysis reveal whether the N-methyl group is bonded to basic or to neutral nitrogen in those compounds with both types of nitrogen atom present.

The infrared method is complicated by overlapping absorption, while the isolation of a known fragment containing the N-alkyl group may be difficult or tedious. Conroy's

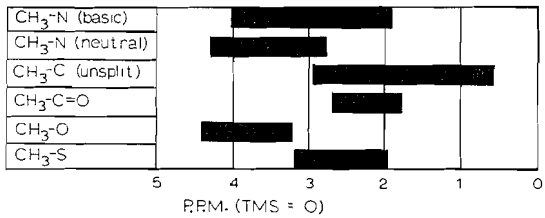

FIG. 1. Ranges of methyl n.m.r. absorption peaks for the compounds in the Varian catalogs 1 and 2, The range given for the CH_3—S group also includes the compounds reported by G. R. Pettit, I. B. Douglass, and R. A. Hill. Can. J. Chem. 42, 2357 (1964), except for methanesulfonyl chloride.

method (4) for proving the presence or absence of N-methyl groups (quaternization with labelled methyl iodide, regeneration of the original free base, and its examination for label incorporation) is restricted to those basic nitrogen-containing compounds which can be reformed from their quaternary metho salts by pyrolysis, reduction, or Hofmann degradation.

Nuclear magnetic resonance spectroscopy is potentially a much better means of detecting the N-methyl function, but it also suffers from a weakness. Several different types of methyl groups give rise to unsplit 3-hydrogen n.m.r. peaks, and their rather broad ranges of absorption overlap considerably as seen from Fig. 1. Moreover, in a complex molecule there is always the possibility of mistaking any sharp peak for a methyl group as happened in the case of aspidospermine (4, 20).

In the present work a simple and useful modification of the n.m.r. method for N-methyl analysis is described. It depends on the pronounced downfield shift of the resonance peak of basic N-methyl groups in solvents of increasing acidity. This effect, due to the decreased shielding of the methyl protons of the positively charged ammonium ion relative to those of the amine, is well known (21). The n.m.r. spectra of a series of 116 compounds containing N-methyl and (or) other methyl groups exhibiting apparent singlet n.m.r. peaks have been recorded in deuterochloroform, perdeuteroacetic acid, and trifluoroacetic acid. These two acidic solvents were chosen for the absence of hydrogen, great difference in acid strength (acetic acid $pK_a^{H_2O}$ 4.76, trifluoroacetic acid $pK_a^{H_2O}$ −0.26), and powerful solvent action on most organic compounds. Perdeuteroacetic acid, while expensive, is not inordinately so, and for most compounds acetic acid is equally satisfactory.[3] Comparison of the peak positions and chemical shift changes for the methyl protons of the compounds studied reveals that the N-methyl groups can be arranged in six and the C-methyl compounds in three categories. There is little variation among the O-methyl groups. These peak positions and chemical shift changes (Δ) are collected in Table I, A–J. Table II summarizes the range of δ values found for the resonance position of each category of methyl group together with the range of differences (Δ) in chemical shift for each two solvents. Chart 1 is a graphical presentation of the ranges for each group in each solvent in the manner of a Colthup chart.

DISCUSSION

For mono-, di-, and tri-methylamine it has been shown that in aqueous acid solution the chemical shift of the methyl protons is a linear function of the concentration of protonated amine (21*a*). Although one might thus expect a linear correlation of the Δ values

[3]*On the Varian A-60 spectrometer the region of the spectrum effectively blocked by the methyl protons in acetic acid is 2.0–2.05 p.p.m. at spectrum amplitude (s.a.) 0.1, 1.95–2.1 p.p.m. at s.a. 1, 1.9–2.2 p.p.m. at s.a. 10, and 1.85–2.25 p.p.m. at s.a. 40 (the appreciable* ^{13}C *satellite peaks at higher s.a. must be taken into account).*

[c]present as dimethylammonium ion; see Discussion.
[d]Present as II; see Discussion.
[e]Present as the equilibrium mixture of axial and equatorial protonated ions XXI. The ratio (32:68 in TFA, 43:57 in PDA) of the two species eliminates the possibility of one of the ions having a *cis*-diaxial-2,6-dimethyl chair conformation; see Discussion.
[f]Has undergone reaction.
[g]Probably present as a mixture of *cis* and *trans* isomers of X, or, less likely, a mixture of the two conformations of *cis* X whose interconversion is slow. In perdeuteroacetic acid one of the two N-methyl peaks might conceivably arise from uncyclized IX; see Discussion.
[h]Present as XII; see Discussion.
[i]Measured on a Varian DP-60 at 27°.
[j]The epoxide ring has undoubtedly been opened.
[k]The infrared spectrum in chloroform has little or no NH absorption.
[l]Present as XVII; see Discussion.
[m]Present as a mixture of XVIII and XIX; see Discussion.
[n]Value taken from the Varian NMR Spectra catalogs.
[o]Solvent was a 2:1 mixture of $CD_3COOD:CDCl_3$.
[p]Assignment uncertain.
Note: The value of 4.17 for compound No. 139 is probably for methyl trifluoroacetate.

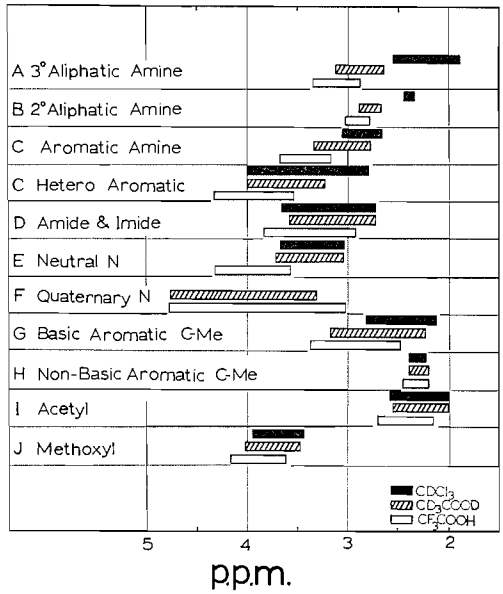

CHART 1. Normal chemical shift ranges for the methyl groups of compounds in the present study (values for compounds that react with a solvent are not included).

with base strength of the amine, perdeuteroacetic or acetic acid is sufficiently strong and is present in sufficient excess that most of the molecules of an aliphatic amine will be present as ammonium ions. Over the range of basicities for which this is true, there should be little variation in the chemical shift increments. Fig. 2, in which are plotted N-methyl chemical shift increments in perdeuteroacetic acid vs. $pK_a^{H_2O}$ values for some of the amines in the present study, bears out this conclusion. Only when the base is as weak as an aromatic amine does the downfield shift decrease considerably. Closer inspection reveals that secondary N-methylamines fall into a group separate from tertiary N-methylamines; a reason for this effect is considered later.

Under the subheadings that follow are discussed generalizations for each of the methyl types. It should be emphasized that these generalizations will be most useful for compounds containing more than one nitrogen atom and (or) unsplit methyl groups, and the following has been written with this point in mind.

Aliphatic Tertiary Amines (Table I, A)

Of the compounds studied, the N-methyl protons of aliphatic tertiary amines show the largest movement in acid toward lower magnetic field ($\sim$ 0.6–0.8 p.p.m. in TFA), and most of this shift ($\sim$ 0.5–0.6 p.p.m.) is already present in perdeuteroacetic acid. There was no difference between tertiary amines with one or two N-methyl groups. Furthermore, the shift is fairly constant regardless of the absorption position in deuterochloroform which varies from 1.97 to 2.56 p.p.m. Not surprisingly, molecules with a second basic nitrogen near the basic methyl-bearing nitrogen atom (Table I, Nos. 6, 17, 18, and 25) give somewhat greater ($\sim$ 0.9–1.0 p.p.m.) downfield increments in the stronger acid. Other electron-attracting atoms or groups in the vicinity of the basic N-methyl function do not have any regular effect on the Δ values provided they are not conjugated (compounds rendered neutral by conjugation are notable exceptions; see Table I, E). In most cases any shielding or deshielding effect of a substituent or group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

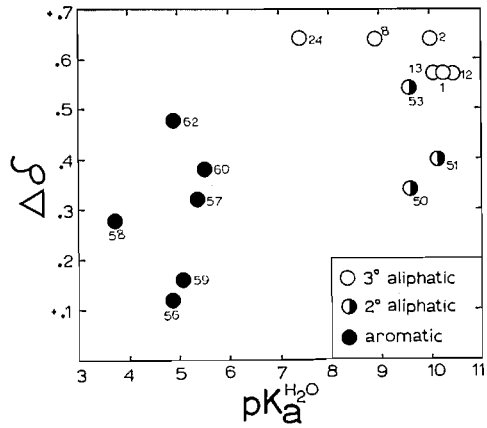

FIG. 2. Variation of N-methyl chemical shift increments ($\Delta_{CD_3COOD-CDCl_3}$) with amine basicity.

would be expected to be present in both unprotonated and protonated amine and therefore to be cancelled. Thebaine (No. 33), cryptopine (No. 34), and protopine (No. 35) are exceptions and these alkaloids are discussed later.

Aliphatic Secondary Amines (Table I, B)

N-Methyl protons in most secondary aliphatic amines are decidedly less deshielded in strong acid (~ 0.45–0.6 p.p.m. in TFA) than N-methyl protons in tertiary amines with about half of this shift occurring in the weaker acid. This can be seen best by comparing values in Table I for secondary and tertiary amines with the same structure: Nos. 2 and 44, 4 and 46, 7 and 49, 8 and 50. The values are sufficiently lower to allow tentative differentiation of secondary and tertiary N-methyl groups, whereas the N-methyl absorption in deuterochloroform alone does not distinguish the two types. A more secure distinction between secondary and tertiary N-methyl groups is possible by noting the coupling between the nitrogen protons and the N-methyl group in trifluoroacetic acid solution (see below).

Although the downfield N-methyl shift in acid will be proportional to the concentration of protonated amine (21), the cause of the discrepancy in shift between secondary and tertiary amines cannot lie in different extents of protonation of the two types, for the aliphatic secondary amines are in general stronger bases than the tertiary amines in hydroxylic solvents. A reasonable explanation is that, since the protonated secondary amine is better solvated (chiefly by hydrogen bonding of the NH protons), the positive charge is more dispersed (23); therefore, the smaller effective positive charge on nitrogen will have a smaller deshielding effect on the N-methyl protons (24).

This effect may be responsible for some of the variations in shift increments within the series of tertiary amines. Of the five dimethylaminocholestanes examined, those (2β, 7α, 6β) with axial dimethylamino groups gave larger $\Delta_{CD_3COOD-CDCl_3}$ shifts (+0.67, +0.69, +0.81 p.p.m., respectively) than those (2α, 6α) with equatorial groups (+0.58, +0.64 p.p.m.). Protonated axial amines are less accessible to solvation than their equatorial epimers as supported by pK_a measurements (22), and therefore the axial ions should have the greater effective positive charge on nitrogen. Furthermore, the axial 6β-dimethylamino derivative, which would be expected to have the most severe steric hindrance to ion solvation (C-10 axial methyl, C-4 and C-8 axial hydrogens), shows the largest shift increment (+0.81 p.p.m.).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Aromatic and N-Heteroaromatic Amines (Table I, C)

The chemical shift differences for secondary or tertiary aromatic N-methyl groups (~ 0.5–0.8 p.p.m. in TFA) do not differ from each other appreciably and are much the same as those for N-methyl aliphatic amines, except that the shift in perdeuteroacetic acid is somewhat smaller (~ 0.1–0.2 p.p.m.) for most of the aromatic amines. The rather procrustean classification of N-heteroaromatic amines exhibits similar effects in both acids but with wider variations. The fact that the resonance position of aromatic and N-heteroaromatic N-methyl groups in deuterochloroform is at lower field than for aliphatic N-methyl amines permits the former to be distinguished from the latter.

Amides and Imides (Table I, D)

The range of absorption for N-methyl amides and imides in deuterochloroform overlaps most of the values for aromatic amines. However, these compounds give even smaller shift increments (−0.09 to +0.07 p.p.m.) in perdeuteroacetic acid than N-methyl aromatic amines, and, moreover, do not show coupling in trifluoroacetic acid solution as most aromatic N-methyl amines do. Of course, infrared and ultraviolet spectra may also distinguish these functional types.

N-Methyl-2-pyridone (No. 84) and N-methyl-2-quinolone (No. 85) are exceptions and show much larger shifts (0.60 and 0.66 p.p.m.) than normal amides in strong acid. The reason for this behavior is that both types of compound exist largely as hydroxypyridinium derivatives XX at low pH, and the methyl resonance position in trifluoroacetic acid approaches that of N-methylpyridinium salts such as Nos. 94 and 97 in Table I, F. Both of these "amides" show greater similarity to other resonance neutralized nitrogen compounds and have been included in part E of Table I.

Other Compounds with Neutral Nitrogen (Table I, E)

The combination of the low field position (3.02–3.68 p.p.m.) of the N-methyl resonance in deuterochloroform and the negligible change in perdeuteroacetic acid allows this type of N-methyl group to be distinguished from normal aliphatic and aromatic methylamino groups. The greater change (~ 0.5–0.6 p.p.m.) in trifluoroacetic acid differentiates this group from the N-methyl amides and imides. Ultraviolet and infrared spectra will be a useful adjunct in distinguishing these types.

Quaternary Ammonium Salts (Table I, F)

The few examples of this kind were insoluble in deuterochloroform. They are characterized by relatively low field N-methyl absorption in perdeuteroacetic acid (3.30–4.77 p.p.m.) with negligible change (< 0.05 p.p.m.) in trifluoroacetic acid. The latter fact also distinguishes quaternary N-methyl from methoxyl groups which move 0.1–0.3 p.p.m. downfield.

C-Methyl Groups on Aromatic Rings Containing or Attached to Basic Nitrogen (Table I, G)

In deuterochloroform the methyl peaks of this type spread over a range which includes or overlaps categories A–D of N-methyl group. Furthermore, many of them exhibit downfield shifts in perdeuteroacetic and trifluoroacetic acids of the same magnitude as basic aromatic or secondary aliphatic N-methyl groups. For these compounds a negative Herzig-Meyer determination and (or) a positive Kuhn-Roth C-methyl analysis could provide reasonable certainty of the absence of an N-methyl group.

In addition to these aromatic C-methyl compounds, two nonaromatic compounds were found whose methyl groups are unusually sensitive to acid although they are not on basic nitrogen atoms. Acetone 2,4-dinitrophenylhydrazone and O-methyl caprolactim

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(Table I, Nos. 128 and 139) show no shift in deuteroacetic acid, but in trifluoroacetic acid the changes (+0.77, +0.80, and +0.62 p.p.m.) are those expected of tertiary aliphatic amines, the O-methyl caprolactim probably having been solvolyzed to methyl trifluoroacetate.

All of these examples demonstrate that the deshielding effect of a protonated nitrogen atom can be transmitted through several bonds in a conjugated system.

C-Methyl Groups on Nonbasic Aromatic Nuclei (Table I, H)

The narrow range and high field resonance position of these methyl groups in deuterochloroform coupled with their negligible movement in perdeuteroacetic acid and trifluoroacetic acid (unless reaction occurs; see discussion later of Nos. 116 and 117) distinguish them from N-methyl groups and most C-methyl groups on basic N-heterocyclic aromatic nuclei.

Acetyl and Methoxyl Groups (Table I, I and J)

Methoxyl groups and acetyl groups attached to C, N, and O atoms show negligible shifts (−0.03 to +0.11 p.p.m.) on changing from deuterochloroform to perdeuteroacetic acid and only a small (+0.08 to +0.37 p.p.m.) further downfield shift in trifluoroacetic acid. If the acetyl methyl changes are considered in conjunction with the resonance positions in deuterochloroform, the only methyl groups with which they might be confused from n.m.r. data alone are C-methyl groups on nonbasic aromatic compounds. Methoxyl groups are not differentiated from certain N-methyl amides and imides. However, if the n.m.r. data are considered with infrared spectra, Zeisel, Kuhn-Roth and Herzig-Meyer analyses, there need be no ambiguity.

Coupling in Strong Acid

It has been noted previously, e.g. refs. 25 and 26, that hydrogen atoms on the α-carbon atoms of amines are coupled to the NH protons of amine salts of strong acids. In the present study it was found that at 38° in trifluoroacetic acid a proton remains on the nitrogen atom of most aliphatic and aromatic amines long enough to give observable coupling with $J \sim 5$–5.5 c.p.s. (see Table I). The splitting pattern is very useful in the further characterization of basic N-methyl groups. Thus the combination of a methyl n.m.r. peak at higher field than 2.56 p.p.m. in deuterochloroform, a downfield shift of $\sim$ 0.5–0.6 p.p.m. in perdeuteroacetic acid, a $\sim$ 0.6–0.8 p.p.m. shift in trifluoroacetic acid, and splitting of the methyl peak into a doublet (Fig. 3*a*), all taken together provides strong evidence for the N-methyl group of a tertiary aliphatic amine. The two peaks do result from coupling rather then merely from non-equivalent methyl groups or from stereoisomers protonated on opposite sides of the nitrogen atom since some symmetrical molecules with only one N-methyl group have a doublet N-methyl absorption with equal area under each peak. More conclusively, double irradiation of N,N-dimethylbenzylamine in trifluoroacetic in the low field HN^+ region caused the N-methyl doublet (and N-methylene doublet) to collapse to a singlet. In the case of some N,N-dimethylamines with an asymmetric carbon in the α- or β-position, the N-methyl absorption appeared as a pair of doublets in trifluoroacetic acid. These non-equivalent methylamino groups are analogous to the non-equivalent methyls of similarly situated isopropyl groups (27).

Secondary N-methylamines give a symmetrical triplet in trifluoroacetic acid. (Fig. 3*b*) A methyl group which absorbs in the range $\sim$ 2.3–2.4 p.p.m. in deuterochloroform, shifts $\sim$ 0.2–0.3 p.p.m. in perdeuteroacetic acid, shifts $\sim$ 0.4–0.6 p.p.m. in trifluoroacetic acid, and is split into a triplet in the latter solvent is in all probability the N-methyl group of a secondary aliphatic amine.

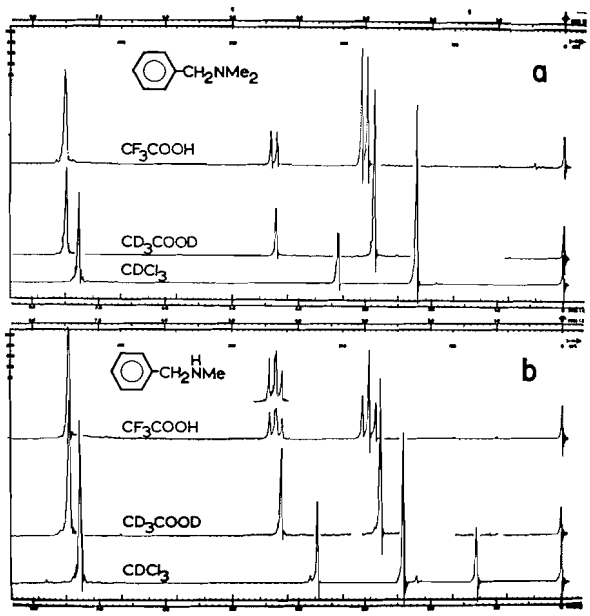

FIG. 3. (*a*) N,N-Dimethylbenzylamine and (*b*) N-methylbenzylamine.

A few aliphatic and aromatic amines gave broadened but unresolved N-methyl peaks in trifluoroacetic acid. Since this situation must be a consequence of too rapid NH exchange rate, the spectra of several of these compounds were recorded at 27° instead of 38° in an attempt to decrease the proton exchange rate. At this temperature the previously broad N-methyl peak of N-methyl-N-benzylaniline (No.61) was resolved into a doublet, and the methyl peak of N-methylaniline (No. 56) was a partially resolved triplet. No resolution of the N-methyl peak of nicotine was observed, but if the temperature were lowered still further, the coupling should become apparent. None of the other types (Table I, D–F) of N-methyl group gave any indication of coupling or peak broadening in trifluoroacetic acid at 38°. Although in trifluoroacetic acid the methyl and methylene peaks of N,N-dimethylbenzylamine (Fig. 3*a*) are symmetrical doublets, in *acetic* acid at 38° there was no resolution or broadening of the singlet peaks from the methyl or methylene groups.

Other Information

In some cases the n.m.r. spectra in weak and strong acid provide more information than just the type of methyl group. The fact that tetramethylmethylene diamine (No. 5) gives a triplet in trifluoroacetic acid is in accord with the molecule being solvolyzed to dimethylamine. Similarly, the appearance of the N-methyl resonance of caranine anhydromethine (No. 11) as a triplet in trifluoroacetic acid shows that the *o,m'*-bridge has been broken with formation of the N-methyl secondary amine II (28). This is corroborated by the appearance of a 2-H singlet at 5.29 p.p.m. due to the methylene group of the benzylic trifluoroacetate.

The anomalously large shift of the N-methyl group of cryptopine and protopine can be attributed to two factors. In deuterochloroform this methyl group is apparently shielded by the long range anisotropic effect of the carbonyl group through space to give an abnormally low δ value, compared to those for other tertiary N-methyl groups, while in acid the compounds exist largely, if not exclusively, as the quaternary ammonium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

salts X (29). The latter point was demonstrated by the identity of the ultraviolet absorption spectrum of cryptopine in ethanol containing either acetic or trifluoroacetic acids with the published spectrum of protopine hydrochloride (29). Thus not only is the shielding effect of the carbonyl group removed, but the methyl absorption is moved toward the lower field region of quaternary N-methyl groups ($\delta > 3$ p.p.m., see Table I, F).

Physostigmine (eserine, No. 36) is another compound having an unusually large Δ value in strong acid because of chemical reaction. The chemical shifts of its aromatic N-methyl group in deuterochloroform and perdeuteroacetic acid are normal values (see Table I, C), but the marked low field δ value in trifluoroacetic acid is that expected of some aromatic quaternary ammonium salts (cf. Table I, F). This is entirely reasonable since in strong acid structures of the physostigmine type are opened to imonium compounds, i.e. XII (30).

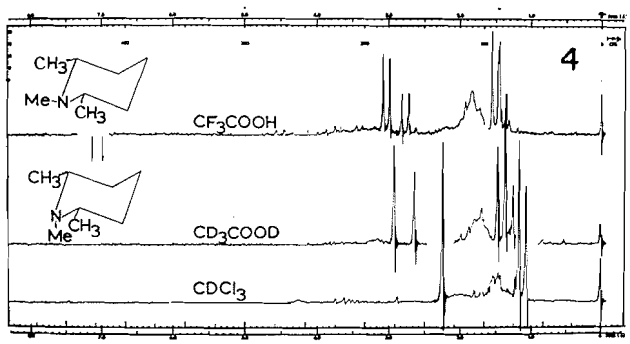

FIG. 4. *cis*-1,2,6-Trimethylpiperidine.

cis-1,2,6-Trimethylpiperidine is an example of a piperidine derivative in which the axial and equatorial N-methyl protonation isomers XXI have long enough life times to permit their observation in perdeuteroacetic and trifluoroacetic acid (Fig. 4). The more intense N-methyl peak (peak ratios 43:57 in PDA) presumably corresponds to the equatorial methyl isomer as found in the case of tropane derivatives (26). The purity of the *cis* amine was assured by reductive methylation of *cis*-2,6-dimethylpiperidine purified through its crystalline hydrochloride.

The large downfield shift (+0.69 p.p.m.) in trifluoroacetic acid reveals that 2-methylindole (No. 116) is protonated at C-3 to form XVII in trifluoroacetic acid, just as in sulfuric acid (31). Confirmation is provided by the peak (2H) at 4.47 p.p.m. arising from the C-3 protons. On the other hand 3-methylindole (No. 117) in trifluoroacetic acid is partly protonated at C-3 (XVIII) (methyl doublet at 1.52 p.p.m., $J \sim 6.5$ c.p.s.) and partly on nitrogen (XIX) (methyl singlet at 2.43 p.p.m.).

Thebaine is known to react with strong acid at room temperature; since its N-methyl resonance in trifluoroacetic acid is not near those of codeine and sinomenine, it has obviously undergone chemical change.

In molecules with more than one basic nitrogen a larger $\delta_{CF_3COOH}-\delta_{CD_3COOD}$ shift ($\sim$ 0.25–0.5 p.p.m.) than usual ($\sim$ 0.1–0.2 p.p.m.) for aliphatic amines may be evidence for close proximity of the basic nitrogen atoms, for in such cases the inductive effect of the second positively charged nitrogen atom will come into play only in strong acid where both nitrogen atoms are appreciably protonated (see Nos. 6, 17, 18, 25).

Methylene and Methine Hydrogens

Methylene and methine groups attached to basic nitrogen also show the same downfield shift as methyl groups, but since they usually appear as complex multiplets which overlap other absorption (see Fig. 5) particularly in deuterochloroform, assignment is often difficult. The unambiguous cases among the compounds studied are set forth in Table III. In so far as the limited number of examples permits, the following generalizations can be made.

In perdeuteroacetic acid methylene groups adjacent to tertiary aliphatic nitrogen are shifted almost twice as far downfield ($\sim$ 0.8–0.9 p.p.m.) as methylene groups adjacent to secondary aliphatic nitrogen ($\sim$ 0.4–0.5 p.p.m.). The reason for the difference is presumably the same as that discussed earlier for the difference between secondary and tertiary basic N-methyl groups.

In trifluoroacetic acid and in dilute perdeuteroacetic acid solution, the absorption from methylene protons within an N-heterocyclic ring and adjacent to a tertiary (but not secondary) nitrogen atom is separated into two groups of multiplets (see Fig. 6). One group presumably corresponds to the α,α' protons on the same side of the ring as the NH, while the other group arises from the α,α' protons on the side opposite the NH group. This separation could be useful in deciding whether a basic tertiary nitrogen is part of a ring.

Aromatic Hydrogens

Aromatic rings with basic nitrogen as part of the nucleus or bonded to the nucleus exhibit pronounced shifts of the aromatic protons to lower field in acid solution. The shifts are difficult to specify exactly because of the unsymmetrical nature of most of the bands and the compression of the overall bandwidth which usually takes place in acid (see Fig. 7).[4] For basic N-heterocyclic rings in trifluoroacetic acid the shift is $\sim$ 1 p.p.m. for pyridines and $\sim$ 0.5–1 p.p.m. for the other N-heteroaromatic compounds of Table I, G. For the aromatic amines of Table I, C the downfield shift in trifluoroacetic acid is somewhat less, $\sim$ 0.3–0.5 p.p.m. The aromatic protons of N-methyl-α-pyridone also move downfield more than 1 p.p.m. in trifluoroacetic acid where the molecule is present as the hydroxy pyridinium ion (XX).

EXPERIMENTAL

The compounds used in this work were commercial products, specimens from the authors' file, compounds prepared in this laboratory, or else samples generously donated by other laboratories. In each case the n.m.r. spectrum in deuterochloroform was in agreement with the structure. A few commercial products were contaminated with small amounts of impurities whose effect, if any, was assumed to be negligible.

Eastman 2,6-dimethylpiperidine was converted to the hydrochloride. This salt was recrystallized from methanol to constant m.p. 286–292° (reported (32) for *cis*-2,6-dimethylpiperidine, m.p. 281°). The regenerated pure *cis* amine was methylated by catalytic reduction in the presence of aqueous formaldehyde and 5% palladium-on-carbon catalyst. The perdeuteroacetic acid (99% d_4, Merck, Sharp and Dohme of Canada) and trifluoroacetic acid (Matheson, Coleman and Bell) were used without further purification.

Unless otherwise noted the spectra were recorded on a Varian A-60 spectrometer (measured probe temperature 38°). Concentrations varied between 10% and 20% w/v (g/ml) except for a few compounds whose low solubility or short supply obliged the use of more dilute solutions. Variations in concentration within the range used had little effect on peak positions. Dilution of a 1:3 v/v N-methyl pyrrolidine: chloroform solution to 1:30 v/v moved the N-methyl peak only 1 c.p.s. to lower field. The same control experiment with N-methyl pyrrolidine: trifluoroacetic acid gave an N-methyl downfield shift of only 2 c.p.s.; for N,N-dimethylbenzylamine in acetic acid the downfield shift was 1.5 c.p.s. Peak positions are believed accurate to $\pm$1 c.p.s. For the 19 examples run which were also in the Varian catalogs 1 and 2, the agreement in the

[4] *Although in deuterochloroform the aromatic protons of a compound may give rise to a complex pattern, in trifluoroacetic acid (and to a lesser extent in perdeuteroacetic acid) the chemical shifts of the aromatic hydrogens of some compounds are so closely spaced as to give the appearance of a broadened singlet.*

[a]The compound numbers are the same as in Table I.
[b]The protons whose absorption is given are indicated by Greek letters or an arrow in ambiguous cases.
[c]Peak positions are given in p.p.m. from internal tetramethylsilane (= 0). If the peak is not a singlet, the multiplicity is given after the peak position (d = doublet, dd = doublet of doublets, t = triplet, q = quartet, m = multiplet with well-defined peaks, bm = broad multiplet with ill-defined or no peaks). The apparent coupling constant is given in parentheses. The symbol ~ means that the band center could not be determined exactly.
[d]Assignment uncertain.
[e]Both methylene groups happen to have the same chemical shift.

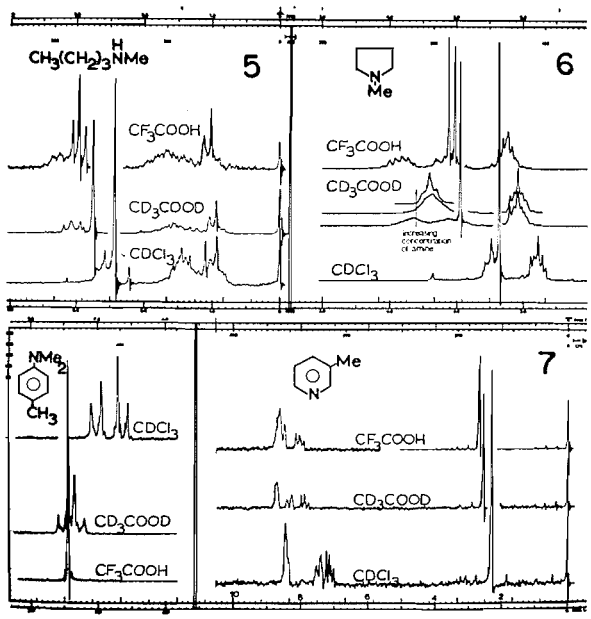

FIG. 5. N-methyl-*n*-butylamine.
FIG. 6. N-Methylpyrrolidine.
FIG. 7. (*a*) N,N-Dimethyl-*p*-toluidine and (*b*) β-picoline.

methyl resonance position in deuterochloroform was within 0.02 p.p.m. for 12 cases, and with one exception (dicentrine −0.06 p.p.m.) all agreed within 0.04 p.p.m. Several spectra were recorded in both acetic acid and perdeuteroacetic acid, and no change in methyl resonance position was observed.

Assignment of peaks in compounds with more than one kind of unsplit methyl signal presented little or no difficulty. The unsplit methyl peaks of such compounds differed in the numbers of similar methyl groups (e.g. Nos. 16, 66, 102) and (or) differed sufficiently in δ to allow clear-cut designation (e.g. Nos. 10, 19, 20, 21, 31, 65, 83), or else differed unambiguously in effect of acid on the methyl peaks (e.g. Nos. 14, 21, 57, 60). Specific assignments to the methyl groups of caffeine, theobromine, and theophylline (Nos. 68, 69, 80, 81, 82) were made by comparing the values of all three bases. The present assignments are the same as those made elsewhere (33) by comparing the spectra of caffeine, ethyl theobromine, and ethyl theophylline. The N-acetyl-*p*-toluidine methyl peaks were assigned by comparison with acetanilide. Thebaine methyl positions were based on comparison with codeine and sinomenine.

ACKNOWLEDGMENTS

Most of the funds for purchase of the Varian A-60 n.m.r. spectrometer were generously provided by the National Research Council. The support of the U.S. National Heart Institute under Grant HE-07394 is gratefully acknowledged. The authors would like to thank Mr. W. D. Chambers for preparation of some of the compounds, and Dr. R. J. Highet and Professor R. C. Cookson for donation of other compounds. Professor J. B. Stothers kindly obtained several spectra on the Varian DP-60 instrument.

THE SULFUR–CHLORINE STRETCHING BAND IN SULFONYL CHLORIDES

J. F. KING AND DAVID J. H. SMITH

In connection with some questions arising from our general study of the chemistry of sulfenes (1, 2), we wished to have information on the nature of the sulfur–chlorine stretching absorption in sulfonyl chlorides. Studies of the Raman spectra had been reported previously (3–7) and these had concurred in assigning the strong band around 375 cm^{-1} to the sulfur–chlorine stretching mode. But in order to use the corresponding infrared region for the purposes of structural elucidation, we required more information than was already available. To obtain this we have measured the spectra of a number of sulfonyl chlorides, along with a few other sulfonyl halides, using an infrared spectrophotometer equipped with cesium iodide optics. The data are listed in Table I.

Most of the spectra are of methylene chloride solutions using potassium bromide cells, which under the conditions used are limited to frequencies down to about 300 cm^{-1}. The spectra of a number of sulfonyl chlorides in the region above 420 cm^{-1} have been discussed by other investigators (6, 8) and will not be treated here. In the hope of being able to describe the intensities of the bands more precisely than merely as "strong" or "weak", we attempted to measure their extinction coefficients. In many cases this could not be done accurately because, among other things, of the presence of overlapping bands or strong background absorption. As can be seen from Table I, the value of the apparent extinction coefficient in the case of the 375 cm^{-1} band of *p*-toluenesulfonyl chloride apparently varies somewhat with change in concentration; the variation over the range of concentrations commonly used in infrared spectroscopy is, however, not large (if, in fact, real). In the most favorable cases the apparent extinction coefficients are probably accurate to $\pm 10\%$, but with those values indicated as only approximate the error is larger. In some of these cases error is introduced because the sample did not completely dissolve (probably because of partial hydrolysis). The shape of the S—Cl stretching band of *p*-toluenesulfonyl chloride was not changed significantly by running the spectra under conditions of higher resolution, and it seems likely that the uncertainties in the ϵ_{app} values (for bands above 340 cm^{-1} at any rate) deriving from overly large spectral slit widths are of minor significance.

Inspection of Table I reveals that virtually all of the sulfonyl chlorides show a band within the range 380 $\pm$ 10 cm^{-1} which may be assigned to the sulfur–chlorine stretching vibration. It is also evident that the introduction of electron-withdrawing substituents is accompanied by a shift to higher frequencies. Though the S—Cl stretching frequencies of the aromatic sulfonyl chlorides show no precise correlation with the ordinary Hammett substituent parameters, they do give a reasonably good linear plot with Taft's σ_I values (Fig. 1), indicating a direct connection between the stretching frequency and the *inductive* effect of the substituent. With the aliphatic sulfonyl chlorides the same tendency of electron-withdrawing substituents to raise the frequency of the absorption maximum is found, but the correlation with σ^*, for example, is only approximate. The effect of electron-

§Spectrum determined using CsBr cells.

withdrawing substituents leads one to suggest the possibility that the band at 416 cm^{-1} in the spectrum of trichloromethanesulfonyl chloride is the sulfur–chlorine stretching mode and not the band at 379 cm^{-1}, even though the latter falls well within the normal range and might at first glance appear to be the more likely choice.

The position of the S—Cl stretching band does not appear to be particularly sensitive to change in solvent. This is indicated by the following data for the position of this band

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

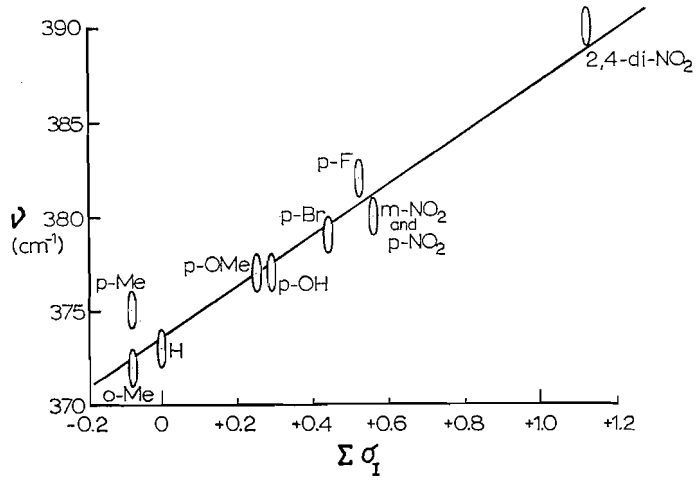

FIG. 1. Plot of the S—Cl stretching frequency for sulfonyl chlorides vs. the Taft inductive substituent parameter, σ_I. The values for σ_I used are those for "normal" solvents obtained from ^{19}F shielding values (9). The straight line was obtained from a least squares fit of the data and corresponds to the equation $\nu = 373.6 + 13.56 \sum\sigma_I$.

in the spectrum of methanesulfonyl chloride in various solvents: acetone, 374 cm^{-1}; benzene, 375 cm^{-1}; nitrobenzene, 375 cm^{-1}; carbon tetrachloride, 376 cm^{-1}; nitromethane, 378 cm^{-1}; methylene chloride, 377 cm^{-1}.

Referring again to Table I it is evident that most of the apparent extinction coefficients fall within the range 20 ± 10, though with a few compounds they lie outside this range. The compounds showing the lowest extinction coefficients, namely chlorosulfonylacetyl chloride and 2,4-dinitrobenzenesulfonyl chloride, both show somewhat broader bands than most of the other materials. Comparison of the integrated absorptions of these bands with those of the more typical cases diminishes the discrepancy in the intensities somewhat, though even by this measure the bands are only about half as intense as the weakest of the other S—Cl stretching absorptions.

Included also in Table I are the spectra of a few sulfonyl fluorides and bromides and one sulfonyl iodide. These compounds, in general, do not absorb in the region assigned to the S—Cl stretching mode, an observation which, of course, supports that assignment. *p*-Toluenesulfonyl fluoride and *p*-nitrophenylmethanesulfonyl bromide, however, do have bands in that region though the origin of these bands is obscure.

Neither the infrared nor the Raman spectra of sulfonyl bromides or iodides seem to have been investigated previously in this region. Though the number of examples is too few to establish any generalizations, it is of interest to note that the three sulfonyl bromides show a band close to 275 cm^{-1}. This is close to the band at 270 cm^{-1} in the spectrum of sulfuryl bromofluoride (SO_2FBr) which has been assigned by Gillespie and Robinson (10) to the sulfur–bromine stretching mode. *p*-Toluenesulfonyl iodide, however, also shows a similar band, and at this juncture any conclusions about the S—Br stretching position in sulfonyl bromides would seem premature.

One of the problems to which it was hoped that these data would be pertinent was concerned with the structure of the product derived by treatment of 2-methylanthraquinone-1-sulfonic acid with inorganic acid chlorides (2, 11). This compound has been assigned the sulfonyl chloride structure (I), but another structure (II) is also readily conceivable and has analogy in the chlorosultone (III) formed by the action of thionyl

III

chloride on sodium 2-formylbenzenesulfonate. Structure III had been proved by the absence of a carbonyl maximum in the infrared spectrum (12), but an attempt to distinguish between one or two carbonyl groups with the anthraquinone derivative was inconclusive. The compound does, however, show a band at 384 cm^{-1} (see Table I) in excellent agreement with structure I. The compound obtained analogously from anthraquinone-1-sulfonic acid also shows absorption in the same region (see Table I) and is therefore probably anthraquinone-1-sulfonyl chloride, as postulated by previous investigators (13).

EXPERIMENTAL

The spectra were determined using a Beckman IR-7 grating spectrophotometer equipped with cesium iodide optics. Potassium bromide cells were used to obtain the spectra of the sulfonyl chlorides. Control experiments showed that under the conditions used, the spectra obtained with the potassium bromide cells were indistinguishable down to 310 cm^{-1} (and perhaps slightly lower) from those obtained using cesium bromide cells. Cesium bromide cells were used for the spectra of all compounds for which bands below 300 cm^{-1} are listed in Table I. The data in Table I refer to solutions in methylene chloride (Fisher Spectranalyzed, distilled from calcium hydride). The spectrophotometer was calibrated using the water vapor bands in the region from 369 to 401 cm^{-1} as recommended by Blaine, Plyler, and Benedict (14); the frequencies quoted in Table I are believed to be accurate to within ± 1 cm^{-1}. The apparent extinction coefficients were calculated from optical density values obtained directly by double beam operation; control experiments using single beam operation gave essentially identical values.

Most of the compounds were commercial materials; all of these were purified by crystallization or distillation prior to running the spectrum. The following compounds were prepared as described in the accompanying references: 2-phenylethenesulfonyl chloride (15); camphor-10-sulfonyl chloride (16); phenylmethanesulfonyl-*1-d* chloride and phenylmethanesulfonyl-*1,1-d*$_2$ chloride (1); *p*-toluenesulfonyl fluoride (17); phenylmethanesulfonyl fluoride (18); chlorosulfonylacetic acid (19); 1-anthraquinonesulfonyl chloride (20); 2-methyl-1-anthraquinonesulfonyl chloride (2); *p*-nitrophenylmethanesulfonyl chloride (21); 2-phenylethanesulfonyl chloride (22); 1,4-butanedisulfonyl chloride (23). *p*-Hydroxybenzenesulfonyl chloride was prepared by the action of phosphorus pentachloride on sodium *p*-hydroxybenzenesulfonate; m.p. 90–92°. 2-Anthraquinonesulfonyl chloride was prepared by refluxing the corresponding acid with phosphorus pentachloride in chloroform for 1 h; m.p. 210° (vacuum capillary); reported m.p. 193° (24), 197° (25). Benzenesulfonyl bromide and *p*-toluenesulfonyl bromide were prepared by the reaction of bromine with an aqueous solution of the sodium salt of the corresponding sulfinic acid, instead of the sulfinic acid itself as described by Otto and co-workers (26, 27). Benzenesulfonyl iodide was prepared as described by Whitmore and Thurman (28); m.p. 90–92°. Details of the preparation and characterization of *p*-nitrophenylmethanesulfonyl bromide and its deuterated analogue, as well as that of *p*-nitrophenylmethanesulfonyl-*1-d* chloride will be described elsewhere. In a number of instances compounds which had been allowed to stand for some time in the laboratory or which had been obtained from commercial sources were not completely soluble in nonpolar solvents; the residue was found to be water soluble. These observations were taken to indicate that the sample had suffered partial hydrolysis and it was accordingly refluxed for a short time with thionyl chloride prior to recrystallization.

ACKNOWLEDGMENTS

This work was supported by a grant from the Petroleum Research Fund administered by the American Chemical Society. We wish to express our thanks to Dr. T. Durst who prepared some of the compounds, and to Professor D. C. Bradley who kindly lent us the infrared cells used in this study.

GLUCOPUTRANJIVIN

M. H. BENN AND D. MEAKIN

Long known as a synthetic product (1), isopropyl isothiocyanate was first isolated from natural sources by Puntambekar (2) who obtained it[1] from seeds of the Indian tree *Putranjiva roxburghii* Wall. (Euphorbiaceae). Puntambekar named the (assumed) glucosidic precursor of this mustard oil glucoputranjivan (2).

Although *P. roxburghii* still remains the only well-established example of the occurrence of mustard oils in the family Euphorbiaceae,[2] isopropyl isothiocyanate was subsequently found to be quite widely distributed (5), particularly within the Cruciferae, and in 1959 Kjaer succeeded in isolating glucoputranjivin from seeds of *Lunaria annua* L.[3] and characterized it as the crystalline tetraacetate (6).

[1]*Together with (+)-2-butyl isothiocyanate and a third mustard oil originally identified (2) as phenyl isothiocyanate, but later shown by Kjaer and Friis (3) to be (S)-2-methylbutyl isothiocyanate.*

[2]*The family Euphorbiaceae is normally regarded as taxonomically remote from the order Rhoeadales, which contains the families Cruciferae and Capparidaceae. (Mustard oil glucosides are widely distributed amongst the species of these two families.) However, Hutchinson (4) regards the Euphorbiaceae as a heterogeneous family, probably derived from several stocks, including the Bixales, which he also regards as the ancestral stock from which the Capparidaceae were derived; i.e. the occurrence in the Euphorbiaceae of species containing mustard oil glucosides is not to be entirely unexpected.*

Long known as a synthetic product (1), isopropyl isothiocyanate was first isolated from natural sources by Puntambekar (2) who obtained it[1] from seeds of the Indian tree *Putranjiva roxburghii* Wall. (Euphorbiaceae). Puntambekar named the (assumed) glucosidic precursor of this mustard oil glucoputranjivan (2).

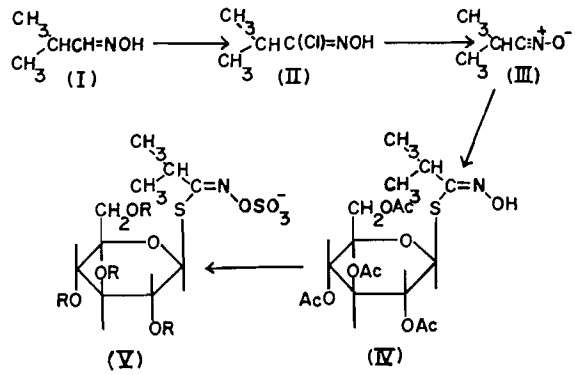
Although *P. roxburghii* still remains the only well-established example of the occurrence of mustard oils in the family Euphorbiaceae,[2] isopropyl isothiocyanate was subsequently found to be quite widely distributed (5), particularly within the Cruciferae, and in 1959 Kjaer succeeded in isolating glucoputranjivin from seeds of *Lunaria annua* L.[3] and characterized it as the crystalline tetraacetate (6).

[1]*Together with (+)-2-butyl isothiocyanate and a third mustard oil originally identified (2) as phenyl isothiocyanate, but later shown by Kjaer and Friis (3) to be (S)-2-methylbutyl isothiocyanate.*

[2]*The family Euphorbiaceae is normally regarded as taxonomically remote from the order Rhoeadales, which contains the families Cruciferae and Capparidaceae. (Mustard oil glucosides are widely distributed amongst the species of these two families.) However, Hutchinson (4) regards the Euphorbiaceae as a heterogeneous family, probably derived from several stocks, including the Bixales, which he also regards as the ancestral stock from which the Capparidaceae were derived; i.e. the occurrence in the Euphorbiaceae of species containing mustard oil glucosides is not to be entirely unexpected.*

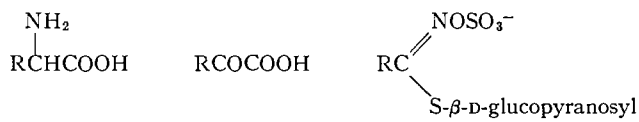
[3]*Synonym, L. biennis Moench.*

The now classic studies of Ettlinger and Lundeen (7, 8) established the general structure of the mustard oil glucosides and the mechanism by which they are enzymatically decomposed to mustard oils; thus glucoputranjivin is assigned the structure (V, R = H). We have confirmed this structure by synthesis, using the same approach as that which we developed for the synthesis of glucotropaeolin (9) and subsequently successfully applied to the synthesis of a number of other mustard oil glucosides (10).



Isobutyraldoxime (I) was chlorinated; the isobutyrohydroxamoyl chloride (II) was converted to the nitrile oxide (III) and condensed, *in situ*, with tetra-*O*-acetyl-β-D-glucopyranosyl mercaptan to give tetraacetylproglucoputranjivin (IV). Sulfonation of this with pyridine – sulfur trioxide, followed by isolation of the product as the potassium salt, gave tetraacetylglucoputranjivin (V, R = $COCH_3$), identical with a sample of natural origin. We deacetylated this material, but although the product, glucoputranjivin (V, R = H) was chromatographically homogeneous it refused to crystallize as either the potassium or tetramethylammonium salt.[4]

Our original and main interest in the mustard oil glucosides was (and remains) in their biogenesis. Inspection of the structures of the glucosides, general structure (VIII), reveals that in many cases the aglycone skeleton is that of commonly encountered α-amino acids,[5] from which the carboxyl groups have been lost. Other aglycones correspond to unknown α-amino acids,[6] implying either that these amino acids remain to be discovered or that alternative biosynthetic pathways exist, which do not necessarily involve α-amino acids.



To date, experiments have revealed that some of the mustard oil glucosides are indeed derived from α-amino acids.[7] Glucotropaeolin (VIII, R = $PhCH_2$) is derived from

[4]*The tetramethylammonium salts of the mustard oil glucosides often crystallize better than the potassium salts (7, 8, 10c).*

[5]*For example glucocapparin (VIII,* R = CH_3*) and alanine (VI,* R = CH_3*), glucocochlearin (VIII,* R = $CH_3CH_2CH(CH_3)$*), and isoleucine (VI,* R = $CH_3CH_2CH(CH_3)$*) with the same configuration at the asymmetric center in the side chain (11), and several other examples in addition to those cited in the text (5).*

[6]*For example glucohirsutin (VIII,* R = $CH_3SO(CH_2)_8$*) and a series of sulfides, sulfoxides, and sulfones of closely related structure (5).*

[7]*In addition, gluconasturtiin (VIII,* R = $C_6H_5CH_2CH_2$*) is partly derived from phenylalanine (13). However, the best precursor yet discovered for sinigrin (VIII,* R = CH_2=$CHCH_2$—*) is acetate although there was some conflict in the results reported by the two groups (13, 17).*

For personal use only.

phenylalanine (VI, R = $PhCH_2$) (12, 13, 14), glucobrassicin (VIII, R = β-indolylmethyl) from tryptophan (VI, R = β-indolylmethyl) (15) and sinalbin (VIII, R = p-$HOC_6H_4CH_2$) (16). Interestingly, there appear to be two pathways from α-amino acids, one in which the nitrogen of the α-amino acid is lost (16), biosynthesis proceeding via the keto acid (VIII), and the other in which the nitrogen of the α-amino acid is incorporated directly into the aglycone (14).[8]

In terms of the "α-amino acid hypothesis", glucoputranjivin can be visualized as derived from valine (VI, R = $(CH_3)_2CH$) (5, 19).

T. peregrinum[9] plants fed DL-valine-4-^{14}C were worked up and the mustard oil aglycones isolated as the thiourea derivatives. Paper chromatography revealed that a spot identical with isopropylthiourea contained the bulk of the radioactivity, corresponding to 0.12% incorporation of activity into the mustard oil. This initial result strongly suggests that glucoputranjivin is in fact biosynthesized in *T. peregrinum* from valine.[10]

EXPERIMENTAL

Tetraacetylproglucoputranjivin (IV)

Isobutyrohydroxamoyl chloride, freshly prepared from isobutyraldoxime (2.0 g) (20) and dissolved in ice-cold ether (50 ml), was added to a solution of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl mercaptan (1.0 g) in cold, dry ether (100 ml) and was followed by triethylamine (2.8 ml) dissolved in dry ether (10 ml). Triethylamine hydrochloride precipitated and the blue color of the solution was discharged. After 30 min the reaction mixture was washed with ca. 0.6 *N* dilute aqueous sulfuric acid (50 ml); the ether extract was separated, dried, and evaporated to yield a colorless oil which crystallized from concentrated ethereal solution upon addition of petroleum ether. Recrystallization from ether – petroleum ether gave colorless needles of tetraacetylproglucoputranjivin, m.p. 93–95° (0.75 g, 60%). Further recrystallization raised the m.p. to 98–100°. $[\alpha]_D^{25}$ –29° (*c*, 3 in $CHCl_3$). Anal. Calcd. for $C_{18}H_{27}NO_{10}S$; C, 48.10; H, 6.06; N, 3.12. Found: C, 48.31, H, 6.09; N, 3.29.

Tetraacetylglucoputranjivin (V, R = CH_3CO)

Tetracetylproglucoputranjivin (0.37 g) was dissolved in dry pyridine (5 ml), reshly prepared sulfur trioxide – pyridine complex (0.42 g) added and the reaction mixture stirred at room temperature overnight, with exclusion of moisture. The reaction mixture was poured into water (ca. 20 ml) containing potassium bicarbonate (0.75 g). After effervescence ceased the aqueous solution was extracted with ether (2 × 20 ml), the combined ether extracts washed with water (2 × 20 ml), and the combined aqueous extracts freeze dried. The residual solids were extracted with boiling 95% aqueous ethanol (v/v) and filtered hot. On cooling the filtrate deposited fine colorless needles, m.p. 180.5–182° (0.220 g, 47%), $[\alpha]_D^{25}$ –18.3° (*c*, 1.6, H_2O); lit. (6), $[\alpha]_D^{23}$ –15.4° (c, 1.2, H_2O). The infrared spectrum in a KBr disc was superimposable on that of an authentic specimen of natural origin.

Glucoputranjivin (V, R = H).

Tetraacetylglucoputranjivin (0.93 g) was dissolved in anhydrous methanol, previously saturated with ammonia, and kept at room temperature overnight. The solution was evaporated to dryness under reduced pressure to give a gum which refused to crystallize. The gum was taken up in water and passed through a Dowex-50 ion exchange column (in the tetramethylammonium form) and the aqueous eluates freeze dried. Again, the gummy residue of tetramethylammonium glucoputranjivin which was chromatographically homogeneous (21) refused to crystallize.

Biosynthesis of Glucoputranjivin from DL-*Valine-4-*^{14}*C*

The freshly cut stems of the above-ground portion of young *T. peregrinum* plants (27 g) were dipped into an aqueous solution of DL-valine-4-^{14}C(50 μcuries). After 50 h the uptake of radioactivity amounted to 33 μcuries The plants were removed, washed, homogenized in a Waring Blendor, and, after standing at

[8]*We have also performed experiments with doubly labelled phenylalanine-2-*^{14}C,^{15}N *similar to those described by Underhill and Chisholm (14), as well as with phenylpyruvic acid oxime-2-*^{14}C,^{15}N, *and also concluded that the nitrogen of the phenylalanine is retained during incorporation into glucotropaeolin.*

[9]*Synonym T. canariense Hort., the canary bird vine. The seeds of this plant are reported to produce glucocochlearin in addition to glucoputranjivin, but both compounds are only present in small amounts (18).*

[10]*We had insufficient material to carry out the degradation of the thiourea necessary to establish this absolutely. Further, as yet, we have no evidence which permits discrimination between the two possibilities of the nitrogen atom of the valine being lost or retained during incorporation into glucoputranjivin. Since the plant is in the same genus as T. majus in which glucotropaeolin is biosynthesized from phenylalanine with retention of the nitrogen atom, we favor the same process here. However, it is quite possible that in the Cruciferae, e.g. L. biennis, the biosynthesis might proceed by the alternative pathway via the keto acid (VII,* R = $(CH_3)_2CH$*).*

room temperature for 1 h, steam distilled into ethanolic ammonia. The distillate was kept at room temperature overnight and then freeze dried. The residue (a very small amount of dark-brown solid) was taken up in ethanol and examined by paper chromatography (22). No spot appeared on spraying with Grote's reagent (23) but a radioactive spot could be detected with a Nuclear-Chicago Actigraph II chromatogram scanner in the approximate position expected for isopropylthiourea. The chromatography was repeated with the addition of authentic isopropylthiourea. The chromatogram was examined with the scanner prior to spraying and 95% of the activity was located in the position exactly corresponding to the spot which appeared on spraying. The activity of this spot was further measured by cutting out the area on the paper chromatogram and, after a complete wet combustion (24), counting as carbon dioxide, using a Dynacon 6000 ionization chamber system. The total activity of the isopropylthiourea was calculated to be 0.04 μcuries, an incorporation of 0.12%.

ACKNOWLEDGMENTS

We wish to thank the National Research Council for financial support of this research and Professor Anders Kjaer for an authentic sample of tetraacetylglucoputranjivan. We are also grateful to the Golden West Seed Co. of Calgary for a generous gift of *T. peregrinum* seeds.

THE HEAT OF FORMATION OF BORON TRIBROMIDE–ACETONITRILE

J. M. MILLER AND M. ONYSZCHUK

Laubengayer and Sears (1) were the first to suggest that BF_3 is not the strongest electron-pair acceptor in the boron trihalide series. They found that heats of formation of the solid adducts from their gaseous components were 33.8 and 26.5 kcal mole^{-1} for $CH_3CN{\cdot}BCl_3$ and $CH_3CN{\cdot}BF_3$, respectively, in good agreement with their heats of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dissociation, 34.4 and 26.5 kcal mole^{-1}, respectively. These results were interpreted as indicating that BCl_3 is a stronger electron-pair acceptor than BF_3, assuming that crystal lattice energies of the adducts are similar. Unfortunately, they did not extend their measurements to $CH_3CN{\cdot}BBr_3$. We have now determined the heat of formation of $CH_3CN{\cdot}BBr_3$ with the object of (*i*) establishing the trend in heats of formation of acetonitrile – boron trihalide adducts, and (*ii*) comparing heats of formation with proton nuclear magnetic resonance (n.m.r.) shifts (2).

The heat of formation of $CH_3CN{\cdot}BBr_3$ was obtained by measuring its heat of hydrolysis using a precision calorimeter (3). The details of these measurements are summarized in

TABLE I

Heat of hydrolysis data for $CH_3CN{\cdot}BBr_3$

Trial	$CH_3CN{\cdot}BBr_3$ (mmole)	Temp. rise $\Delta T - \mu v$	Calibration $\Delta T - \mu v$	Calibration cal μv^{-1}	Heat of hydrolysis (kcal mole^{-1})
1	0.3491	77	48	0.27063	59.6
2	0.5043	108	43	0.29503	63.2
3	0.3176	68	44	0.28781	61.6
				Average	61.5±1.2

Table I. Calculation of the heat of formation of the solid adduct from its gaseous components, following Laubengayer and Sears (1), was based on the reaction

$$CH_3CN(g) + BBr_3(g) \rightarrow CH_3CN{\cdot}BBr_3(s)$$

for which, $-\Delta H = A + B + C + D - E$,

where $-\Delta H$ = heat of formation of the solid adduct from its gaseous constituents; A = heat of hydrolysis of BBr_3 = 83.6 kcal mole^{-1} (4); B = heat of vaporization of BBr_3 = 8.2 kcal mole^{-1} (5); C = heat of vaporization of CH_3CN = 8.0 kcal mole^{-1} (1); D = heat of solution of CH_3CN in H_2O = 1.1 kcal mole^{-1} (1); E = heat of hydrolysis of $CH_3CN{\cdot}BBr_3$ = 61.5 kcal mole^{-1}.

Substitution of these values into the equation gives $-\Delta H = 39.4 \pm 1.2$ kcal mole^{-1}. This value together with those of Laubengayer and Sears (1) for $CH_3CN{\cdot}BF_3$ and $CH_3CN{\cdot}BCl_3$ confirms that heats of formation decrease in the order: $BBr_3 > BCl_3 > BF_3$. Since it seems reasonable to assume that crystal lattice energies will not vary appreciably in this series of closely related adducts, we conclude that the order of acceptor power toward acetonitrile is also $BBr_3 > BCl_3 > BF_3$. Brown and Holmes (6) made the same assumption and drew the same conclusion for pyridine – boron trihalide complexes. Other physical measurements on a variety of donor – boron trihalide complexes have also been interpreted as indicating the above order of boron trihalide acceptor power (ref. 7, and references cited therein).

EXPERIMENTAL

Boron tribromide (Anderson) was purified of bromine by shaking the crude sample with mercury followed by several vacuum distillations at −78°, and its purity was checked by molecular weight (M) and vapor pressure (v.p.) measurements (M: found, 252.0; calcd., 250.6; v.p. at 32.0°: found, 82.8 mm; lit. (5), 84.0 mm). Reagent grade acetonitrile (Fisher) was distilled twice from calcium hydride (b.p.: found, 81.7°; lit. (5), 81.8°).

The complex $CH_3CN{\cdot}BBr_3$ was prepared by reacting BBr_3 with an excess of CH_3CN in a vacuum at 25°, followed by removal of excess CH_3CN by distillation at 233–255°. The resulting white solid complex melted with decomposition at 233–235°. Its heat of hydrolysis was determined with a precision calorimeter (3) designed for measurements of heats of formation of addition compounds.

COORDINATION COMPLEXES OF NIOBIUM PENTACHLORIDE WITH TRIPHENYL DERIVATIVES OF GROUP V ELEMENTS

JEAN DESNOYERS AND ROLAND RIVEST

The reactions of niobium pentachloride and triphenyl derivatives of group V elements have been investigated. If a coordination number of VI is assumed for niobium, only the 1:1 complexes would be expected, but it has been found experimentally that two types of coordination compounds are possible. Complexes with the 1:1 and the 2:1 compositions have been obtained.

Preparation of the 1:1 Complexes

Carbon tetrachloride, *n*-hexane, and cyclohexane were used as solvents. A solution of the ligand was added to a solution of niobium pentachloride and a clear solution having a different color for every ligand was obtained. The intensity of the coloration progressively decreased with time and completely vanished in 4 h. During this time a colored precipitate appeared. It was washed several times with the solvent and dried under vacuum for 4 h. It was then analyzed for carbon, hydrogen, niobium, and chloride. Carbon and hydrogen determinations were made by Schwakzkopf Microanalytical Laboratory, 56–19 37th Ave., Woodside, N.Y. Niobium and chloride were determined gravimetrically by the following method. A solid sample of the complex was treated with water and decomposed, and a suspension of the ligand and of niobium pentoxide was obtained. It was heated to boiling, filtered, and washed with water. The filtrate thus obtained was kept for the determination of chloride as silver chloride. The precipitate was then washed with acetone to remove the ligand, calcined, cooled in a desiccator, and weighed as niobium pentoxide. The analytical results and the color of the 1:1 complexes are included in Table I and compared with the theoretical values.

Preparation of the 2:1 Complexes

Using benzene instead of the solvents mentioned above, it has been possible to prepare a series of mixed solutions containing one ligand and niobium pentachloride. The color of these solutions remained almost unchanged after 24 h, but slight precipitation occurred.

JEAN DESNOYERS AND ROLAND RIVEST

The reactions of niobium pentachloride and triphenyl derivatives of group V elements have been investigated. If a coordination number of VI is assumed for niobium, only the 1:1 complexes would be expected, but it has been found experimentally that two types of coordination compounds are possible. Complexes with the 1:1 and the 2:1 compositions have been obtained.

Preparation of the 1:1 Complexes

Carbon tetrachloride, *n*-hexane, and cyclohexane were used as solvents. A solution of the ligand was added to a solution of niobium pentachloride and a clear solution having a different color for every ligand was obtained. The intensity of the coloration progressively decreased with time and completely vanished in 4 h. During this time a colored precipitate appeared. It was washed several times with the solvent and dried under vacuum for 4 h. It was then analyzed for carbon, hydrogen, niobium, and chloride. Carbon and hydrogen determinations were made by Schwakzkopf Microanalytical Laboratory, 56–19 37th Ave., Woodside, N.Y. Niobium and chloride were determined gravimetrically by the following method. A solid sample of the complex was treated with water and decomposed, and a suspension of the ligand and of niobium pentoxide was obtained. It was heated to boiling, filtered, and washed with water. The filtrate thus obtained was kept for the determination of chloride as silver chloride. The precipitate was then washed with acetone to remove the ligand, calcined, cooled in a desiccator, and weighed as niobium pentoxide. The analytical results and the color of the 1:1 complexes are included in Table I and compared with the theoretical values.

Preparation of the 2:1 Complexes

Using benzene instead of the solvents mentioned above, it has been possible to prepare a series of mixed solutions containing one ligand and niobium pentachloride. The color of these solutions remained almost unchanged after 24 h, but slight precipitation occurred.

SYNTHESIS AND REACTIVITY OF SOME ORTHO-SUBSTITUTED DIPHENYL SULFONES

O. Francis Bennett[1]

The influence of the sulfone group on the reactivity of substituents (including hydrogen) at the ortho positions in diaryl sulfones has been noted in several cases. For example, 5-nitro-2-(*p*-nitrophenylsulfonyl)benzaldehyde fails to cyclize to the corresponding thiaxanthone dioxide, whereas 5-nitro-2-(*p*-nitrothiophenoxy)benzaldehyde readily ring closes to the corresponding thiaxanthone. The resistance of the former towards cyclization has been attributed to the oxidation state of sulfur (1). Furthermore, the sulfone group which is normally considered a meta directing substituent in electrophilic substitution reactions, promotes ortho substitution when diphenyl sulfones are metalated by *n*-butyl lithium (2). Resonance and inductive effects of the sulfone group have been invoked to

explain the observed orientation in this latter example (2*a*). Indeed, these effects adequately explain the reactivity found for a variety of substituted diphenyl sulfones.*

Many years ago, Weedon and Doughty (4) gave brief mention to their observation that 2-carbomethoxyphenyl phenyl sulfone was resistent to alkaline saponification. They offered no explanation for these findings. Since that time, as far as we are aware, no further observations of the effect of the sulfone group on the reactivities of 2-carboalkoxyphenyl phenyl sulfones towards saponification have been reported. Moreover, the susceptibilities of substituted 2-carboxyphenyl phenyl sulfones to esterification have also been neglected.

Recently we had occasion to prepare a number of substituted diphenyl sulfones for use as intermediates. Several of these new compounds clearly demonstrated that for diaryl sulfones, a carboxyl group or carbomethoxy group in the 5-position—which is not affected by neighboring groups—is much more reactive than the corresponding group in the 2-position in esterification and saponification reactions, respectively. Thus, methanolic esterification of the mixture obtained from nitric acid oxidation of 2,5-dimethylphenyl phenyl sulfone (5) afforded 5-carbomethoxy-2-methylphenyl phenyl sulfone, I, and 5-carbomethoxy-2-carboxyphenyl phenyl sulfone, V, in a weight ratio of 1:10, respectively. Compounds I and V were readily converted to their corresponding acids, II and VI, by treatment with dilute base. To demonstrate the difference in reactivity of the 2-carbomethoxy group relative to the 5-carbomethoxy group, 2,5-dicarbomethoxyphenyl phenyl sulfone, III, prepared by reaction of either V or VI with diazomethane, was reacted with 1 equiv of aqueous base. As expected, 2-carbomethoxy-5-carboxyphenyl phenyl sulfone, IV, was the principal product.

Our findings parallel the reactivities found for ortho- and meta-nitrobenzoic acids (6) and their esters (7) as well as the reactivities found for 2-nitroterephthalic acid (8) and its esters (9) in esterification and saponification reactions, respectively. For these latter cases, the refractory nature of the ortho groups has been attributed primarily to steric effects (6–11). It appears likely that similar effects, attributable to the large sulfone group, provide a major contribution to the observed reactivities reported in this paper.

The equations on the next page summarize this work.

EXPERIMENTAL†

2,5-Dimethylphenyl Phenyl Sulfone

This compound (5) was prepared in 92% yield by reaction of benzenesulfonyl chloride with excess *p*-xylene in the presence of aluminium chloride; m.p. 109–110°.

Nitric Acid Oxidation of 2,5-Dimethylphenyl Phenyl Sulfone

Aqueous nitric acid (580 ml, 35%) and 2,5-dimethylphenyl phenyl sulfone, 187.3 g (0.762 mole) were charged into a 2 l stainless steel pressure vessel. An initial pressure of 150 p.s.i.g. of nitrogen was placed on the system which was heated at 190° until no further increase in pressure was evident (3 h). The pressure vessel was cooled, vented to the atmosphere, and the contents allowed to degas overnight. The insoluble materials were collected by suction filtration, washed with cold water, and air dried. Attempts to separate and purify the oxidation products by crystallization from common solvents were not successful.

Separation of Principal Oxidation Products as Methyl Esters

The above oxidation mixture (10.0 g) was treated with 300 ml of methanol containing 10 drops of concentrated sulfuric acid. The stirred reactants were heated to reflux with occasional distillation of methanol until the volume of the reaction mixture was about 75 ml (6 h). Ether (150 ml) was added to the methanolic solution, and the resulting ethereal solution was washed with three 50 ml portions of 10% sodium bicarbonate and two 50 ml portions of water. The combined washings were set aside for subsequent work-up.

**An excellent discussion of both the resonance and the inductive effects of the sulfone group in diphenyl sulfones may be found in ref. 3.*

†*All melting points are corrected. Infrared spectra were obtained on a Perkin-Elmer model 221 spectrophotometer.*

5-Carbomethoxy-2-methylphenyl Phenyl Sulfone (I)

The neutral ethereal solution obtained from the esterification described above was dried over anhydrous magnesium sulfate and filtered, and the ether was removed by evaporation. The oily residue crystallized to a yellow solid (0.85 g) after gentle scratching with a glass rod. Three crystallizations from methanol–water afforded a white solid with m.p. 106–108°.

Anal. Calcd. for $C_{15}H_{14}O_4S$: C, 62.0; H, 4.86; S, 11.0. Found: C, 61.8; H, 4.88; S, 10.71.

Saponification of I in 0.1 *N* sodium hydroxide gave the corresponding acid, 5-carboxy-2-methylphenyl phenyl sulfone, II, m.p. 230.5–231.5°.

Anal. Calcd. for $C_{14}H_{12}O_4S$: C, 61.0; H, 4.38; neut. equiv, 276. Found: C, 60.74; H, 4.53; neut. equiv, 278.

Independent Synthesis of Compounds I and II; 3-Chlorosulfonyl-4-methylbenzoic Acid (VII)

This compound was prepared by modifying the procedure used by Hansch and co-workers (12) to make 3-chlorosulfonyl-4-ethylbenzoic acid.

Chlorosulfonic acid, 200 g (1.71 moles), was added to 66 g (0.426 mole) of *p*-toluoyl chloride at such a rate that the reaction temperature did not exceed 40°. After complete addition of the chlorosulfonic acid, the reactants were heated to 80° for 3 h and then poured cautiously, with stirring, onto cracked ice. The solid was collected by suction filtration and washed thoroughly with cold water. Crystallization of the air-dried product from toluene gave VII as a white solid in 74% yield; m.p. 166–167.6°.

Anal. Calcd. for $C_8H_7O_4SCl$: C, 41.0; H, 3.02; neut. equiv, 78.2. Found: C, 41.07; H, 3.29; neut. equiv, 79.3.

The Friedel–Crafts procedure starting with 100 g (1.28 moles) of benzene, 30 g (0.127 mole) of VII, and 38 g (0.286 mole) of aluminium chloride gave II as silvery plates after crystallization of the crude reaction product from methanol; m.p. 229–231°.

Anal. Calcd. for $C_{14}H_{12}O_4S$: C, 61.0; H, 4.38; neut. equiv, 276. Found; C, 60.68; H, 4.69; neut. equiv, 280.

Methanol esterification of this acid afforded the methyl ester, identical to I in all respects, in 89% yield, m.p. 106.4–108°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

5-Carbomethoxy-2-carboxyphenyl Phenyl Sulfone (V)

Acidification with 5% sulfuric acid of the combined bicarbonate–water washings from the esterification of the oxidation products afforded 8.5 g of crude V. This product, after crystallization from methanol–water, had m.p. 182.2–183.6°.

Anal. Calcd. for $C_{15}H_{12}O_6S$: C, 56.2; H, 3.78; S, 10.0; neut. equiv, 320. Found: C, 55.93; H, 4.09; S, 9.73; neut. equiv, 323.

Alkaline saponification readily converted V to the known 2,5-dicarboxyphenyl phenyl sulfone, VI (5); m.p. 265–266.5°.

Treatment of both V and VI with ethereal diazomethane gave the known 2,5-dicarbomethoxyphenyl phenyl sulfone, III (5); in each instance, m.p. 110.4–112°. In addition, reaction of both V and VI with thionyl chloride followed by treatment with excess methanol afforded III in each case.

Structure Proof of V

3-Carbomethoxyphenyl Phenyl Sulfone (VIII); Polymorphs of VIII

One gram (0.00313 mole) of V was heated at 180° with 10 ml of quinoline containing a trace of copper powder until gas evolution ceased (½ h). Ether (100 ml) was added to the cooled reaction mixture and the ethereal solution was filtered. The filtrate was washed successively with four 30 ml portions of 3% hydrochloric acid, one 30 ml portion of water, two 50 ml portions of 10% sodium bicarbonate, and one 50 ml portion of water. The neutral ethereal solution was dried over anhydrous magnesium sulfate and filtered, and the ether was evaporated. The dark residual oil crystallized from methanol–water, following treatment with Norite, as a white solid; m.p. 64.5–66.5°. A yield of 50% (0.43 g) was obtained.

Anal. Calcd. for $C_{14}H_{12}O_4S$: C, 61.0; H, 4.38. Found: C, 61.11; H, 4.40.

The following data show that this compound was an unstable polymorphic form (A) of VIII:

When A was heated above its melting point, 64.5–66.5°, solidification occurred at about 68° and the new solid (B) melted at 84–85.2°. Subsequent decarboxylations of V, performed as above, gave only the stable form of VIII, B, m.p. 84–85.2°; the unstable form, A, was not isolated in later preparations.

Anal. Calcd. for $C_{14}H_{12}O_4S$ (B): C, 61.0; H, 4.38. Found: C, 60.88; H, 4.38.

A mixture melting point of forms A and B showed no depression of the melting point of the stable form, B (m.p. of B, 84–85.2°; mixed m.p. 84–85°). The solid phase (Nujol mull) infrared spectrum of A was different from that of B. However, their solution spectra (carbon tetrachloride) were identical in all respects. The unstable form, A, spontaneously converted to the more stable form, B, after standing at room temperature for several months as shown by its m.p. (84–85.2°), and by its solid phase infrared spectrum.

3-Carboxyphenyl Phenyl Sulfone (IX) (2a)

This substance was prepared in almost quantitative yield by saponification of VIII in 0.1 *N* sodium hydroxide, m.p. 184–185.2°.

Infrared and melting point comparisons of IX with a sample of 2-carboxyphenyl phenyl sulfone showed them to be different compounds.

The m.p.'s of VIII and IX were not depressed, in either case, when mixed with authentic samples prepared by the procedures described below. In addition, infrared comparison showed VIII and IX to be identical with the authentic samples.

The Friedel–Crafts procedure starting with 20 g (0.0884 mole) of 3-chlorosulfonyl benzoic acid (13) m.p. 132–133°, 100 g (1.28 moles) of benzene, and 28 g (0.21 mole) of aluminium chloride gave a 43% yield of 3-carboxyphenyl phenyl sulfone; m.p. 184.5–185.5°.

The corresponding methyl ester had a m.p. of 84–85°.

2-Carbomethoxy-5-carboxyphenyl Phenyl Sulfone (IV)

Saponification of 2,5-dicarbomethoxyphenyl phenyl sulfone (2.0 g, 0.0006 mole) in 55 ml of 0.1067 *N* sodium hydroxide afforded this compound in 84% yield; m.p. 200.3–201° from methanol.

Anal. Calcd. for $C_{15}H_{12}O_6S$: C, 56.3; H, 3.78; S, 10.0. Found: C, 56.16; H, 3.84; S, 9.72.

Structure Proof of IV

5-Bromo-2-carbomethoxyphenyl Phenyl Sulfone (X)

2-Carbomethoxy-5-carboxyphenyl phenyl sulfone, IV, 2.7 g (0.0084 mole), was neutralized with 1 equiv of cold 0.3325 *N* sodium hydroxide, and the resulting solution was treated with 10% excess of aqueous silver nitrate solution. The silver salt of IV precipitated at once and was collected by suction filtration, washed with water, and air dried. An 81% yield of the silver salt was obtained.

The procedure of Barnes and Prochaska (14) was followed to convert the silver salt of IV to X.

The silver salt of IV (2.9 g, 0.0068 mole), 50 ml of dried carbon tetrachloride, and 1.085 g (0.0068 mole) of dry bromine were refluxed for 1 h. The warm pale-orange reaction mixture was filtered. Ether (200 ml) was added to the cooled filtrate and the ethereal solution was washed successively with 50 ml of water, two 50 ml portions of 10% sodium bicarbonate, and 50 ml of water. The dried (anhydrous magnesium sulfate) organic solution was evaporated to dryness, and the white solid residue was crystallized from methanol–water. The resultant white needles (55% yield) had m.p. 131.5–133.5°.

Anal. Calcd. for $C_{14}H_{11}O_4SBr$: C, 47.3; H, 3.13. Found: C, 47.3; H, 3.35.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

5-Bromo-2-carboxyphenyl Phenyl Sulfone (XI)

Heating under reflux (5 h) of 0.8 g (0.00225 mole) of X with 60 ml of 0.5 *N* sodium hydroxide containing 40 ml of methanol gave the known (3*a*) XI in 89% yield, m.p. 195–196.3°.

A mixture m.p. of XI and an authentic sample was not depressed; the infrared spectra of both samples were totally superimposable.

THE STRUCTURE OF BIS-DIMETHYLAMINOBERYLLIUM

Neil R. Fetter and Frances M. Peters

INTRODUCTION

In connection with other work, bis-dimethylaminoberyllium was prepared from the reaction of dimethylamine with diethylberyllium. Although the method of preparation was slightly different from that described by Coates and Glockling (1), it was noted on several occasions that the melting points of our preparations did not agree with those (1, 2) reported by these authors. Also, nuclear magnetic resonance (n.m.r.) data indicate that $Be(NMe_2)_2$ is not cyclic, but is trimeric as reported by Coates and Glockling (1).

EXPERIMENTAL

We prepared bis-dimethylaminoberyllium by two slightly different methods and with one of them it was possible to obtain $Be(NMe_2)_2$ with the literature (1) melting point.

In the first method, a typical preparation involved adding, under vacuum, a large excess of $HNMe_2$ in four equal portions to 2.5 g (37 mmole) of Et_2Be at 25 °C. After removal of the ethane formed and the excess dimethylamine, the solid product was vacuum sublimed (0.01 mm) at 90 °C onto a cold surface

THE STRUCTURE OF BIS-DIMETHYLAMINOBERYLLIUM

Neil R. Fetter and Frances M. Peters

INTRODUCTION

In connection with other work, bis-dimethylaminoberyllium was prepared from the reaction of dimethylamine with diethylberyllium. Although the method of preparation was slightly different from that described by Coates and Glockling (1), it was noted on several occasions that the melting points of our preparations did not agree with those (1, 2) reported by these authors. Also, nuclear magnetic resonance (n.m.r.) data indicate that $Be(NMe_2)_2$ is not cyclic, but is trimeric as reported by Coates and Glockling (1).

EXPERIMENTAL

We prepared bis-dimethylaminoberyllium by two slightly different methods and with one of them it was possible to obtain $Be(NMe_2)_2$ with the literature (1) melting point.

In the first method, a typical preparation involved adding, under vacuum, a large excess of $HNMe_2$ in four equal portions to 2.5 g (37 mmole) of Et_2Be at 25 °C. After removal of the ethane formed and the excess dimethylamine, the solid product was vacuum sublimed (0.01 mm) at 90 °C onto a cold surface

For personal use only.

(−15 °C). The sublimate turned yellow slowly at 25 °C and was resublimed under the same conditions. The second sublimate (m.p. 83–130 °C*) also turned yellow slowly at 25 °C.

Anal. Calcd. for $C_4H_{12}N_2Be$: C, 49.44; H, 12.45; N, 28.84; Be, 9.27. Found: C, 49.18; H, 12.31; N, 28.70; Be, 9.54.

In the second method 0.970 g (14.5 mmole) of Et_2Be (prepared by the method of Gilman and Schulze (3)) was dissolved in 15 ml of *n*-heptane and the portions of $HNMe_2$ were condensed on the solution at −78 °C. After each addition, the mixture was allowed to warm to 25 °C and the evolved ethane was removed. A total of 40 mmole of $HNMe_2$ was condensed on the Et_2Be solution. After the solvent was removed at 25 °C via vacuum transfer, the crude product was vacuum sublimed (0.01 mm) at 65 °C yielding approximately 50 mole % of the calculated yield as a white sublimate, I, (m.p. 86–88 °C, lit. (1) 88–90 °C. (2) 94 °C). Anal. Found: C, 49.30; H, 12.58; N, 28.59; Be, 8.97. By continuing the sublimation at 100 °C another 30 mole % of the calculated $Be(NMe_2)_2$ was obtained as a white solid, II, which commenced melting at 85 °C and finally liquefied at 175 °C. Anal. Found: Be, 8.99. The remaining material which did not sublime at 100 °C was a fluffy yellow powder insoluble in benzene. No analysis was made of this material.

The n.m.r. spectra of the N—Me protons were all made at 42 °C on a Varian A-60 spectrometer with the samples 15% by weight in benzene. Molecular weight determinations were made with a Bender-Hobein freezing point apparatus using benzene as the solvent. The differential thermal analyses were made with a du Pont Model 900 DTA apparatus under a nitrogen atmosphere. The samples weighed approximately 5 mg and the heating rate was 20 °C/min. Molecular weight and differential thermal analysis (d.t.a.) data were obtained only from samples of $Be(NMe_2)_2$ prepared by the second method described above.

RESULTS AND DISCUSSION

The differential thermograms obtained from I and II sublimates of the second method explain to some extent the anomalous melting points obtained for many of our preparations of $Be(NMe_2)_2$.

The thermogram of I shows sharp endotherms at 86 and 250 °C, the former being the melting point and the latter either a boiling point or a decomposition temperature as indicated by the deposition of a white substance on the bell-jar cover of the d.t.a. cell. The endotherm at 86 °C was found to be reproducible by stopping the heating cycle at 100 °C and, after cooling, restarting the thermogram at 30 °C on the same sample.

The thermogram of II has four endotherms, sharp ones at 85, 175, and 278 °C and a broad one at 254 °C. The endotherms at 85 and 254 °C indicate the presence of I and the endotherms at 175 and 278 °C indicate the presence of at least one other form of $Be(NMe_2)_2$, if one assumes the endotherms at 254 and 278 °C represent boiling points or decomposition temperatures. A deposit of white material appeared on the bell jar at about 250 °C. Compound II appears, therefore, to be a mixture of at least two components and to obtain one of these in a pure state, the crude product must be vacuum sublimed at a temperature near 65 °C. A thermogram of the crude product also shows the same four endotherms as II, indicating a mixture is obtained during the initial reaction of Et_2Be with $HNMe_2$ between −78 and 25 °C. A thermogram of the nonsublimable yellow powder was featureless to 500 °C. The n.m.r. data are summarized in Table I.

TABLE I

Nuclear magnetic resonance spectra of $Be(NMe_2)_2$

Sample	Resonance peaks (p.p.m., δ benzene = 0)	Peak area ratio
1st Method		
Crude product	4.26, 4.23 (sh)* ; 4.87, 4.77 (sh)	1:2
90 °C sublimate	4.26 ; 4.87, 4.77 (sh)	1:2
2nd Method		
65 °C sublimate I	4.28 ; 4.90	1:2
100 °C sublimate II	4.30, 4.25 ; 4.90, 4.80	1:1:2:2
Crude product	4.28, 4.25 ; 4.87; 4.78	2:1:4:2

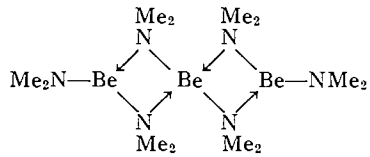
**Melting points are uncorrected.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

These data show that I from the second method has two NMe proton peaks in a ratio of 1:2 at $\delta = 4.28$ and 4.90 upfield from benzene. All the other spectra contain these two peaks in the same ratio, but other peaks are also present. In the spectra of crude products and in the 90 and 100 °C sublimate from both methods, another pair of peaks is located at approximately $\delta = 4.25$ and 4.78 upfield from benzene and in the ratio of 1:2. These two closely spaced pairs suggest the presence of two forms of $Be(NMe_2)_2$ of similar structure.

If $Be(NMe_2)_2$ were a cyclic trimer as suggested by Coates (1), there should be two types of NMe protons in a ratio of 1:1, that is, there should be 18 methyl protons bonded to terminal NMe_2 groups and 18 protons on the bridging NMe_2 groups. Since the ratio of the two types of NMe protons is 1:2, a trimeric structure of the type



is indicated to achieve a maximum coordination for beryllium. The other form of $Be(NMe_2)_2$ may be another configuration of this trimer; for example, there may exist *cis* and *trans* forms for the terminal NMe_2 groups.

Only I of the second method appears to be a pure compound; hence, the molecular weight of this substance was the only one measured. The values 308 and 311 (calcd. 291.3 for $Be(NMe_2)_2$ trimer) indicate this material is trimeric in freezing benzene; therefore, the form of $Be(NMe_2)_2$ obtained by sublimation at 65 °C is more accurately represented by the structure shown above than by the cyclic form.

THE PHOTOLYSIS OF CARBON DISULFIDE AND CARBON DISULFIDE – OXYGEN MIXTURES

M. de Sorgo, A. J. Yarwood, O. P. Strausz, and H. E. Gunning

The ultraviolet absorption spectrum of carbon disulfide indicates at least two electronic transitions. The absorption at 1 900 Å to 2 100 Å is strong and has been assigned (1) to the transition of $^1B_2 \leftarrow {}^1\Sigma_g^+$. Some of the moderately intense bands in the region 2 800 – 3 600 Å have recently been suggested to be due to the transition from the ground $^1\Sigma_g^+$

state to the B_2 multiplet component of the $^3A_2$ state (2). Heicklen (3) has observed luminescence from carbon disulfide vapor irradiated with light between 2 800 and 3 600 Å. The vibrational energy of the excited state was not dissipated by collision before emission and the lifetime of the excited state was estimated to be 3.3×10^{-6} s. Predissociation in carbon disulfide vapor has been reported (4) to set in at $\lambda = 2\,068$ Å. In previous flash photolysis studies (5, 6, 7) the possible role of long-lived excited molecules has not been considered and although the presence of atomic sulfur was demonstrated only in the careful work of Callear (5), predissociation was invoked as the sole photolytic act in every case.

The aim of the present study was to examine the mechanism of the luminescence-quenching reaction and to establish whether chemical reaction can occur from the luminescent state.

EXPERIMENTAL

Continuous Photolysis

The vacuum technique, product handling, and analytical procedures were in general similar to those described in other communications (8). The light source was a Hanovia, model 30620, medium-pressure mercury arc, in conjunction with either an interference filter which had a transmission of about 25% at 2 100 ± 150 Å, or a 6 mm thick Vycor 7910 filter, which had a short wavelength cutoff at $\lambda = 2\,290$ Å. The reaction vessel was made of fused quartz.

Flash Photolysis

A 41 μF capacitor, at 9 kV, was discharged through two 55 cm long quartz flash lamps connected in parallel. The two lamps were joined near the ends. The photolysis lamp was filled with 7 Torr N_2 and 80 Torr krypton while the spectroscopic lamp contained 100 Torr krypton. The 3 μF capacitor for the spectroscopic flash was usually charged to 10 kV. The photolysis flash reached its maximum intensity in about 35 μs and the intensity was greater than 50% of the peak value for about 55 μs. The corresponding times for the spectroscopic flash were 10 μs and 40 μs. Transient ultraviolet absorption spectra were recorded on Kodak 103 a-O plates exposed in a Hilger medium quartz spectrograph. Two reaction vessels, both 50 cm long and 4.3 cm in diameter, were used. One was constructed of Vycor 7910 (transmitted wavelength > 2 200 Å), the other of pyrex glass. Both had plane parallel quartz windows.

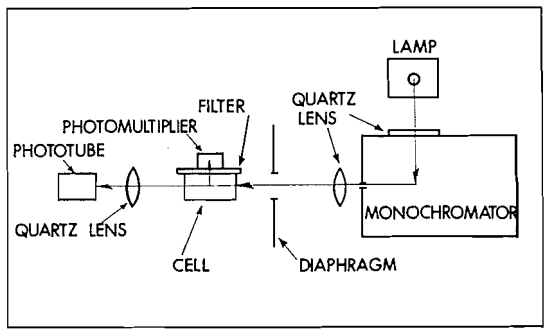

FIG. 1. A schematic illustration of the apparatus for the measurement of luminescence intensities.

Luminescence Intensity Measurements

The apparatus is illustrated schematically in Fig. 1. The lamp was an Osram, type HBO 250, high-pressure mercury arc. The light passed through a Bausch and Lomb 500 mm monochromator with a 1 200 groove/mm grating which was blazed at 5 000 Å. The entrance and exit slits were 1.00 mm wide. The cylindrical quartz cell was 5.0 cm long and 5.3 cm in diameter and was irradiated along its axis. The emerging luminescence was measured perpendicular to the incident beam by an E.M.I. 6256 photomultiplier, operated at 1900 V, from a Jarrell-Ash Recording Electronic System No. 82-110. Only the luminescence in the region 3 350 to 6 500 Å was determined. The short wavelength cutoff was set by an appropriate filter and the long wavelength limit was defined by the response of the photomultiplier. The transmitted radiation was focused by a quartz lens onto a Photovolt 501-M electronic photometer. The incident wavelength was 3 000 Å and the intensity of the luminescent radiation was taken as the difference between the photomultiplier outputs with the cell full and empty.

Materials

The carbon disulfide used was Baker 'Analyzed' reagent which was purified by low temperature distillation. The carbonyl sulfide (Matheson) was purified by bubbling through caustic soda solution, followed by low temperature distillation. Nitrogen, oxygen, and carbon dioxide were Airco 'Analyzed' reagents and the hydrocarbons were Philips 'Research' grade. The products were fractionated by low temperature distillation and analyzed by gas chromatography and mass spectrometry.

RESULTS AND DISCUSSION

The long wavelength ($\lambda > 2\,300$ Å) continuous photolysis of carbon disulfide vapor (or liquid) yielded only a brown, solid polymeric material. When the photolysis in the vapor phase was carried out in the presence of an excess of hydrogen, ethylene, butene, or propane, the polymer yield decreased but no additional product was observed. However, addition of oxygen (200 Torr to 20 Torr CS_2) resulted in the formation of carbonyl sulfide and sulfur dioxide in a ratio of about 1 to 2, with a simultaneous decrease in the polymer yield. When the effective wavelength region was 1 950 – 2 250 Å, the photolysis of a mixture of 20 Torr CS_2 and 200 Torr C_2H_4 yielded ethylene episulfide. However, no volatile product could be detected from a mixture of 20 Torr CS_2 and 200 Torr propane. Since triplet, ground-state sulfur atoms add readily to ethylene to form episulfide, but do not react with paraffins (8, 9), it follows that the photodissociation of carbon disulfide in this wavelength region leads to S (^3P) atom formation. This conclusion is in agreement with Callear's results (5). By kinetic absorption spectroscopy in the vacuum ultraviolet he demonstrated that the sulfur atoms are formed in the ^3P and not in the ^1D state. From these data it is evident that the photopolymerization and photooxidation of carbon disulfide in the absorption region of $\lambda = 2\,800 - 3\,600$ Å involve long-lived excited CS_2 molecules as the reactive intermediates.

To investigate the mechanism of the reactions, further studies were made in the flash apparatus, and the spectra of transient species recorded photographically. Spectra of both CS and S_2 were obtained when 7 Torr CS_2, with 380 Torr N_2, were flashed in either the pyrex or Vycor 7910 reaction vessel. The 2 600 – 3 000 Å band of S_2 reached its maximum intensity with the photolytic flash (35 μs) and lasted for about 300–500 μs. The prominent band of CS at 2 575.6 Å (0, 0) was visible for several minutes after the photolytic flash and the band at 2 589.6 Å (1, 1) was observed at short delay times. It is quite clear at this point that CS and S_2 must form via an excited CS_2 and atomic sulfur is absent. Further support for the excited molecule mechanism was provided by the results of the following experiments. When 2 Torr of COS with 410 Torr of N_2 were flash photolyzed the transient spectrum of S_2 molecules was detected. However, no S_2 spectrum could be detected when 2 Torr COS with 80 Torr ethylene and 300 Torr N_2 were flash photolyzed. This demonstrated that ethylene is an efficient scavenger for sulfur atoms. When this latter experiment was repeated, but with 20 Torr of added CS_2, the absorption spectrum of S_2 was again detected. (It was shown that flash photolysis of 20 Torr of CS_2 yielded approximately the same amount of S_2 as did 2 Torr of COS.) From the flash photolysis of a mixture of 3 Torr COS, 30 Torr CS_2, 90 Torr butene-2, and 280 Torr N_2, butene-2 episulfide was isolated. However, with 30 Torr CS_2, 90 Torr butene-2, and 280 Torr N_2, no episulfide was formed. The S_2 spectrum was observed in both of the latter two experiments.

The data suggest the following reaction,

$$[1] \qquad CS_2^* + CS_2 \rightarrow 2CS + S_2,$$

and also suggest that the brown polymer observed in the reaction is a mixture of CS and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sulfur polymers. Taking $D(SC{=}S) \leqslant 90$ kcal/mole, [1] will be energetically possible even at the onset of the absorption (about 3 800 Å).

In the flash photolysis of CS_2 the S_2 spectrum is completely suppressed by oxygen while the CS spectrum is only slightly affected, even at high oxygen pressures (90 Torr O_2, 22 Torr CS_2, and 280 Torr N_2). Sulfur dioxide is the only volatile product and its spectrum only appeared at delay times greater than 1 ms, suggesting its formation via the sulfur superoxide (SOO) intermediate (10). The spectrum of sulfur monoxide, SO, was not detected. In the absence of inert gas, the CS_2–O_2 mixtures exploded, yielding CO_2 and SO_2 in stoichiometric proportions. The experimental results are summarized in Table I.

TABLE I
Results of photolyses

Reactants	Illumination	Products	Conclusions
CS_2	Continuous $\lambda > 2\,300$ Å	Brown polymer	—
CS_2 + hydrocarbon	Continuous $\lambda > 2\,300$ Å	Polymer only product found	No S atom formation
$CS_2 + O_2$	Continuous $\lambda > 2\,300$ Å	COS and SO_2	
$CS_2 + C_2H_4$	Continuous $\lambda = 1\,950 - 2\,250$ Å	$H_2C{-}CH_2$ \S/	S (^3P) atoms produced
$CS_2 + N_2$ + olefin	Flash $\lambda > 2\,200$ Å	CS and S_2 No C—C formed \S/	Products come from CS_2^* and not from predissociation
$CS_2 + O_2$	Flash $\lambda > 2\,200$ Å	$CS + SO_2$ S_2 suppressed No SO observed	$CS_2^* + O_2 \rightarrow CS + SO_2$

A reaction consistent with the experimental observations is

[2] $$CS_2^* + O_2 \rightarrow CS + SOO.$$

The sulfur superoxide then isomerizes to SO_2. The fact that COS is formed in continuous but not in flash photolysis and that the intensity of the CS spectrum decreased only by a factor of less than two upon addition of oxygen could be explained if it is assumed that ground state CS does not react with O_2 but that the electronically excited CS, formed by secondary absorption does.

[3] $$CS + h\nu \rightarrow CS^*,$$
$$CS^* + O_2 \rightarrow COS + O.$$

Step [3] would be possible on both energetic and spin conservation grounds. This mechanism is also supported by the observation that COS is not formed in the continuous photolysis, when the irradiation is carried out in the pyrex vessel (CS does not absorb in the ultraviolet above 2 589.6 Å).

If [1] and [2] are assumed to be the only fluorescence-quenching reactions, the relative rate constant, k_1/k_2, could be determined by the measurement of the luminescence intensities. Figures 2 and 3 show reciprocal Stern–Volmer plots for the intensity of luminescence I_F, vs. the pressure of CS_2 and O_2 respectively. The luminescence intensities were corrected approximately for absorption by dividing the measured intensity by the total percentage of light absorbed. From the ratio of the slopes, $k_1/k_2 \simeq 7.6$.

In the flash photolysis experiments it was observed that a 4.5-fold excess of oxygen was sufficient to suppress S_2 formation below the limit of detectability, when [2] could account only for a decrease of $(7.6 \times 100)/(7.6 + 4.5) \sim 50\%$. Two alternative explanations can be offered. (*a*) S_2 is rapidly removed by oxygen. In this connection it should be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

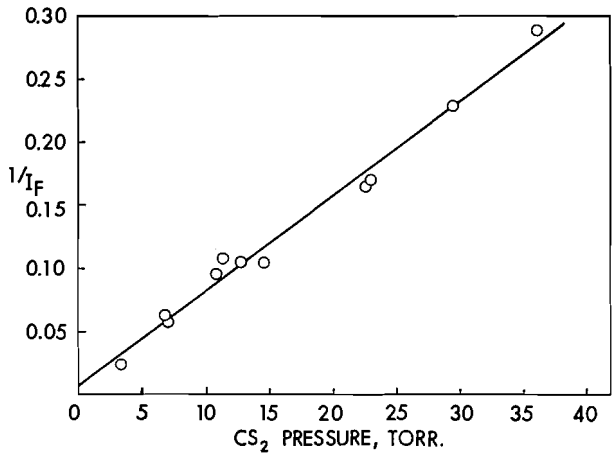

FIG. 2. Reciprocal Stern–Volmer plot for the luminescence intensities vs. carbon disulfide pressure.

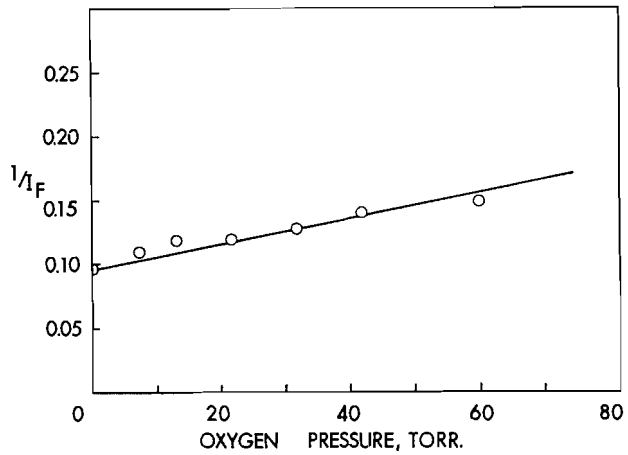

FIG. 3. Reciprocal Stern–Volmer plot for the luminescence intensities vs. added oxygen pressure. (Pressure of CS_2 = 10 Torr.)

mentioned that Wright (6) could not detect any change in the rate of S_2 disappearance upon addition of small amounts of oxygen in the flash photolysis of CS_2. (*b*) There are more than one kind of CS_2* involved. Indeed, the near-ultraviolet absorption system of CS_2 is made up of transitions from the ground state to three or four excited electronic levels (2). Some of these excited species may react with ground state CS_2 as indicated by [1], while others may react according to

$$CS_2^* + CS_2 \rightarrow 2CS_2, \qquad [4]$$

as suggested by Heicklen (3). O_2 on the other hand could react with any of the excited CS_2 molecules present.

CONCLUSION

Electronically excited carbon disulfide molecules, formed by absorption in the region $\lambda > 2\,200$ Å, may react with ground state CS_2 or O_2 molecules. Photodissociation of CS_2 to CS and S (^3P) atoms occurs at wavelength $< 2\,200$ Å.

FULLY FLUORINATED ALKOXIDES

PART I. TRIFLUOROMETHOXIDES OF ALKALI METALS[1]

M. E. REDWOOD AND C. J. WILLIS

Department of Chemistry, University of Western Ontario, London, Ontario

Received January 12, 1965

ABSTRACT

The preparation is described of the trifluoromethoxides of the heavier alkali metals, i.e. $MOCF_3$ where M = K, Rb, or Cs. These are stable, crystalline, ionic solids made by the reversible reaction of carbonyl fluoride with the appropriate metal fluoride. No trifluoromethoxides could be prepared from lithium, sodium, barium, or thallium(I) fluorides. Factors affecting the relative stability of such compounds are discussed.

Trifluoromethanol, CF_3OH, is not known, and is generally assumed to be incapable of existence because of the ease with which compounds having a fluorine atom in a position α to a hydroxyl group would eliminate hydrogen fluoride. Because of this unavailability of the parent alcohol, no metallic trifluoromethoxides have hitherto been reported. We now report the preparation of stable, crystalline trifluoromethoxides of the heavier alkali metals, i.e. $MOCF_3$, where M = K, Rb, or Cs.

A consideration of the possible formation of metallic trifluoromethoxides shows at once that they are likely to be more ionic in nature than the corresponding methoxides. The completely ionic formulation $M^+[OCF_3]^-$ would contain the trifluoromethoxide ion, isoelectronic with the fluoroborate ion, BF_4^-. The charge in the trifluoromethoxide ion rests formally on the oxygen atom, but it would be shared to some extent by the three fluorine atoms because of their greater electronegativity. The distribution of charge over the whole ion achieved in this way should therefore stabilize it, in a manner not possible in the ionic non-fluorinated methoxides of the alkali metals. The stability of a solid ionic trifluoromethoxide would clearly be influenced by the nature of the cation present, since smaller cations, or those with a high ratio of charge to size, would cause greater polarization of the anion and a correspondingly greater tendency towards decomposition to give a fluoride ion and carbonyl fluoride. In other words, the equilibrium:

$$MOCF_3 \rightleftharpoons COF_2 + MF$$

would be displaced to the left by the presence of large cations. An immediate corollary of this suggestion is that by approaching the equilibrium from the direction of formation rather than decomposition one would have available a possible synthetic route to trifluoromethoxides.

[1]*Presented in part at the 48th Annual Conference of the Chemical Institute of Canada, Montreal, May 31–June 2, 1965. For a preliminary communication, see D. C. Bradley, M. E. Redwood, and C. J. Willis. Proc. Chem. Soc. 416 (1964).*

The simple reasoning given above has now been readily confirmed by experiment. We find that visible reaction of carbonyl fluoride with suspensions of potassium, rubidium, or cesium fluorides in acetonitrile proceeds rapidly at 20°. Removal of excess carbonyl fluoride and solvent gives crystalline solids which, when kept *in vacuo*, show no sign of decomposition or evolution of carbonyl fluoride.

The molar ratio in which the carbonyl fluoride reacted with the metal fluoride was initially found to be variable in the ratio 0.5 to 0.95 mole carbonyl fluoride to 1.0 mole metal fluoride. It was therefore assumed that the reaction mixture, contained in a sealed tube, was reaching an equilibrium position, but that this equilibrium was being displaced during the subsequent removal of the volatile reactants, leading to decomposition of some of the trifluoromethoxide. It may readily be seen that the pressure of carbonyl fluoride in the system will affect the position of equilibrium. Since both the metal fluorides and the trifluoromethoxides are only very sparingly soluble in acetonitrile, we may assume their saturated solutions to be completely ionized and write the following equilibria:

$$[1] \qquad MF_{(s)} + \text{solvent} \rightleftharpoons M^{+}_{(sol)} + F^{-}_{(sol)}$$

$$[2] \qquad COF_{2(g)} + \text{solvent} \rightleftharpoons COF_{2(sol)}$$

$$[3] \qquad COF_{2(sol)} + F^{-}_{(sol)} \rightleftharpoons OCF_3^{-}{}_{(sol)}$$

$$[4] \qquad OCF_3^{-}{}_{(sol)} + M^{+}_{(sol)} \rightleftharpoons MOCF_{3(s)} + \text{solvent}$$

giving by summation the overall equilibrium:

$$[5] \qquad MF_{(s)} + COF_{2(g)} \rightleftharpoons MOCF_{3(s)}.$$

The final equilibrium is heterogeneous and the concentrations of solid metal fluoride and trifluoromethoxide are constant. Hence, when both of these solids are simultaneously present, there will be a unique pressure of carbonyl fluoride present at equilibrium at a given temperature. If this equilibrium pressure is exceeded, conversion of metal fluoride to trifluoromethoxide must occur, while at lower pressures of carbonyl fluoride the trifluoromethoxide will decompose to the fluoride. At 20°, however, these reactions only occur in the presence of a solvent, such as acetonitrile. This is demonstrated by the stability of the solid trifluoromethoxides *in vacuo*, by the observation that no reaction occurs between carbonyl fluoride and the metal fluorides in the absence of solvent, and by the fact that carbonyl fluoride is evolved when acetonitrile is added to the pure trifluoromethoxides. The equilibrium pressure of carbonyl fluoride above the solutions of the various trifluoromethoxides will clearly be a measure of their relative stabilities, and measurements of such pressures are now in progress.

In the preparation of the trifluoromethoxides, therefore, it is clear that, by having a sufficiently high pressure of carbonyl fluoride in the equilibrium mixture, the metal fluoride should be quantitatively converted to the trifluoromethoxide. However, when the volatile materials are removed, the carbonyl fluoride (b.p. −83°) must come off before the acetonitrile (b.p. 82°) and some decomposition of the trifluoromethoxide might occur while the solvent is being removed.

To minimize this decomposition, and thus obtain pure samples of the trifluoromethoxides, the reaction mixture was held below −20° while the volatile materials were removed. This had the effect of slowing down the rate of decomposition of the trifluoromethoxides, and also, presumably, of reducing their solubility in acetonitrile, and under these conditions the conversion of the fluorides of rubidium and cesium to their corresponding trifluoromethoxides was essentially quantitative. The molar combining ratio of carbonyl fluoride to metal fluoride was 0.97:1.00 and 0.94:1.00 for cesium and rubidium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

respectively and subsequent analysis of the solid products showed that their composition was that expected for 1:1 adducts. With potassium fluoride, the combining ratio was a little lower (0.82:1.00), indicating that some decomposition had occurred during solvent removal even below −20°. With sodium, lithium, barium, and thallium(I) fluorides there was no evidence of the formation of trifluoromethoxides and virtually complete recovery of unreacted carbonyl fluoride.

In the case of lithium, sodium, and barium it is presumably the greater charge to size ratio of the metal ion which leads to instability of the trifluoromethoxides. For thallium(I), the ionic size alone would lead one to expect that the trifluoromethoxide would be formed, since the ionic radius of Tl^+, given as 1.40 Å (1) or 1.44 Å (2), is between that of K^+ (1.33 Å) and Rb^+ (1.48 Å) (1, 2). However, other factors are clearly involved here, since thallium(I) fluoride differs from the alkali metals in having a distorted sodium chloride structure (3) and a lattice energy of 198 kcal/mole (4) which is higher than that of potassium fluoride (192 kcal/mole) or rubidium fluoride (183 kcal/mole) (5) and this would tend to favor thallium(I) fluoride over the trifluoromethoxide.

The influence of the cationic radius on the relative stabilities of the trifluoromethoxides was also shown in their resistance to thermal decomposition. It was found that breakdown to give carbonyl fluoride and the metal fluoride occurred readily at 80° *in vacuo* and Fig. 1 shows the relative rates of decomposition of the potassium, rubidium, and cesium salts. It is clear that the increasing size of the cation leads to a decreasing rate of decomposition.

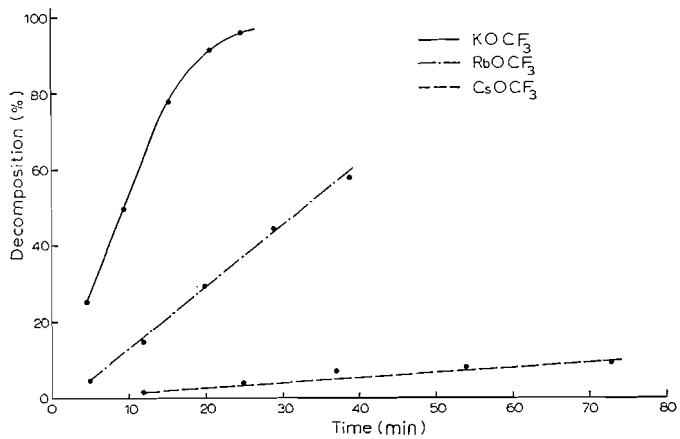

FIG. 1. Decomposition of trifluoromethoxides at 80°.

The results described above have therefore shown that carbonyl fluoride will undergo a reversible reaction with the fluorides of the heavier alkali metals to give solid 1:1 adducts. We suggest that formulation as the metal trifluoromethoxides gives the only structure consistent with the observed properties of the adducts. The only other type of bonding conceivable between carbonyl fluoride and a metallic fluoride would be coordination from the oxygen atom of the carbonyl group to the metal ion, i.e. $[M{\leftarrow}OCF_2]^+F^-$. This may be rejected in the present case for several reasons. The formation of stable complexes by coordination from oxygen to an alkali metal is very rare, and the strongest bonds are formed with the smaller ions. Hence the expected order of stability would be K > Rb > Cs, and the fact that thermal decomposition studies give the reverse order, combined with the fact that no adduct at all could be formed with the even smaller lithium and sodium ions,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

would seem to make oxygen to metal coordination most unlikely. The greater stability of the compounds containing the larger cations is, however, entirely consistent with the trifluoromethoxide formulation, where the smaller cations, having greater polarizing tendencies and yielding fluorides of higher lattice energy, would tend to favor the decomposition of the salts to the fluorides and carbonyl fluoride.

Further support for the trifluoromethoxide structure is obtained from the X-ray powder diffraction patterns of the compounds. The trifluoromethoxide ion is isoelectronic with the fluoroborate ion, and the powder patterns of the corresponding salts are very similar. Detailed indexing has been carried out for the rubidium salt, showing it to be isomorphous with rubidium fluoroborate.

The crystals are orthorhombic, cell dimensions being:

	a	*b*	*c*	Vol.
$RbBF_4$(8)	9.07 Å	5.60 Å	7.23 Å	367 Å^3
$RbOCF_3$	8.86 Å	5.79 Å	7.37 Å	378 Å^3

A density determination on rubidium trifluoromethoxide showed that, like the fluoroborate, it contains four molecules in the unit cell. It is unlikely that such a similarity in unit cells would be fortuitously shown by compounds which did not contain ions of similar shape and size.

The trifluoromethoxides are reactive compounds and are immediately hydrolyzed on contact with water. This presumably occurs by decomposition into fluoride ion and carbonyl fluoride, followed by the known, rapid hydrolysis of carbonyl fluoride.

$$2H_2O + COF_3^- \rightarrow H_2CO_3 + HF + HF_2^-$$

Analysis of solutions resulting from this hydrolysis showed the presence of ionic fluoride ion in conformity with the above stoichiometry. Similar hydrolysis occurred rapidly when samples of the trifluoromethoxides were exposed to moist air, subsequent examination by infrared spectroscopy and X-ray powder pattern showing the presence of bifluoride. It would seem unlikely, therefore, that the unknown trifluoromethanol can be produced by hydrolysis of the trifluoromethoxides, or, indeed, that it is capable of existence.

Since, among the alkali metals, the formation of stable trifluoromethoxides seems to be limited to potassium, rubidium, and cesium (and, by implication, francium), it seems improbable that purely ionic trifluoromethoxides can be formed with any other simple cation, although they are likely to be stable when combined with a large, complex cation.

The non-fluorinated alkali metal alkoxides have been used for some time as valuable intermediates in the preparation of covalent alkoxides of other elements. With the trifluoromethoxides, it is clear that this application will be restricted by the ease with which they decompose to give carbonyl fluoride, but their synthetic uses for preparing covalent trifluoromethoxides are now being investigated.

EXPERIMENTAL

Volatile materials were handled in a conventional vacuum system and separated by fractional condensation. Molecular weights were determined by Regnault's method. Moisture was rigorously excluded throughout, all reaction vessels being flamed out *in vacuo* before use and solid materials being handled in a dry controlled atmosphere enclosure.

Analysis

Fluoride was determined gravimetrically as lead chloride fluoride. Since no interfering ions were present, a preliminary "fluorosilicic acid" distillation was not necessary. Rubidium and cesium were determined gravimetrically as their tetraphenylborates (6).

For personal use only.

Metal Fluorides

The metal fluorides used were commercial samples.* Their purity was checked by analysis and by infrared examination, which showed bifluorides to be absent. They were dried before use by heating to 150° *in vacuo* for 1 h, then finely ground in a dry atmosphere, transferred to the reaction tube, and again heated *in vacuo* before other reactants were added.

Acetonitrile

Redistilled acetonitrile was stored in sealed tubes over phosphorus(V) oxide. When required for use it was transferred directly to the reaction tube, using the vacuum manifold to avoid contact with the atmosphere.

Carbonyl Fluoride

Carbonyl fluoride was prepared in 97% yield by the reaction of carbonyl chloride with sodium fluoride in acetonitrile (7). Carbonyl chloride was a redistilled commercial sample whose purity was checked by infrared examination and molecular weight determination.

In a typical preparation carbonyl chloride (1.47 g, 14.9 mmole) was condensed onto sodium fluoride (8.0 g, 180 mmole) in acetonitrile (15 ml) and the reaction mixture kept at 20° for 24 h in a sealed Pyrex tube (100 ml). Fractionation of the volatile components gave carbonyl fluoride (0.95 g, 14.4 mmole). Infrared examination showed the product to contain traces of silicon tetrafluoride and carbon dioxide but to be free of carbonyl chlorofluoride, COClF. The last compound was formed, however, if a lower ratio of sodium fluoride to carbonyl chloride was employed. The carbonyl fluoride was stored at −196° until required for use, to prevent its reaction with glass to give silicon tetrafluoride.

Reaction of Carbonyl Fluoride with Metal Fluorides

The dried metal fluoride was contained in an evacuated Pyrex tube (100 ml). Acetonitrile (15 ml) was condensed on, followed by carbonyl fluoride. The tube was sealed and allowed to warm up to room temperature with constant shaking, in the absence of which a solid layer of trifluoromethoxide rapidly formed on the surface of the metal fluoride, preventing complete reaction. After keeping at 20° for 48 h with occasional shaking the tube was opened and volatile materials removed below −20°. The unreacted carbonyl fluoride was separated from acetonitrile by fractional condensation and its purity checked by infrared examination. A blank experiment showed that, in the absence of the metal fluoride, the carbonyl fluoride could be quantitatively recovered from the reaction tube, and the amount which had reacted with the metal fluoride was therefore deduced from the weight recovered.

(a) Reaction with Cesium Fluoride

In a typical experiment carbonyl fluoride (4.26 g, 64.5 mmole) was shaken with cesium fluoride (2.50 g, 16.5 mmole). The weight of recovered carbonyl fluoride showed that 1.06 g (16.0 mmole) had reacted, giving a reacting molar ratio, COF_2:CsF, of 0.97:1.00.

Anal. Calcd. for $CsOCF_3$: Cs, 61.0; F, 26.2. Found: Cs, 60.8; F, 26.5.

In an experiment in the absence of acetonitrile, carbonyl fluoride (0.091 g, 1.37 mmole) was condensed onto cesium fluoride (0.60 g, 3.94 mmole) in an evacuated Pyrex tube (20 ml). The mixture was held at −96° for 4 h, then at 20° for 24 h. On opening the tube, unchanged carbonyl fluoride (0.089 g, 1.35 mmole) was recovered, showing that no significant reaction had occurred.

(b) Reaction with Rubidium Fluoride

In a typical experiment carbonyl fluoride (4.99 g, 75.6 mmoles) was shaken with rubidium fluoride (1.25 g, 12.0 mmoles). The weight of recovered carbonyl fluoride showed that 0.74 g (11.2 mmoles) had reacted, giving a reacting molar ratio, COF_2:RbF, of 0.94:1.00.

Anal. Calcd. for $RbOCF_3$: Rb, 50.1; F, 32.6. Found: Rb, 49.9; F, 32.7.

(c) Reaction with Potassium Fluoride

Carbonyl fluoride (5.24 g, 79.5 mmoles) was shaken with potassium fluoride (1.53 g, 26.3 mmoles). The weight of recovered carbonyl fluoride showed that 1.42 g (21.5 mmoles) had reacted, giving a reacting ratio, COF_2:KF, of 0.82:1. This ratio was reproducible.

(d) Reaction with Lithium, Sodium, Barium, and Thallium(I) Fluorides

Reaction with these fluorides was attempted under the same conditions. In all cases virtually complete recovery (96–98%) of the unreacted carbonyl fluoride was obtained.

Thermal Decomposition of Trifluoromethoxides

No evidence was found for the decomposition of the trifluoromethoxides of cesium, rubidium, or potassium at 20°. Samples kept in sealed, evacuated tubes for several weeks showed no gas pressure on opening. Qualitative experiments showed that a gas was evolved when any of the trifluoromethoxides was heated *in vacuo* at 80–100°. The gas was identified in each case by infrared examination and molecular weight measurement as carbonyl fluoride, containing traces of silicon tetrafluoride and carbon dioxide.

For quantitative measurements of the relative rates of decomposition of the potassium, rubidium, and cesium salts a continuously evacuated Pyrex tube was heated to 80°. A sample of the trifluoromethoxide was introduced from a sidearm and evolved gas led through a series of traps cooled to −196° and arranged in such a manner that the gas flow could be diverted from one to the next at regular intervals, the contents of each

**Fluorides of rubidium, cesium, and thallium were supplied by Alfa Inorganics Inc., Beverley, Mass.*

For personal use only.

trap being subsequently weighed. The temperature was finally raised to 120° and heating continued until evolution of carbonyl fluoride ceased, which was considered to represent 100% decomposition of the trifluoromethoxide present. Results are shown in Fig. 1.

X-ray Powder Patterns

These were determined on samples contained in 0.5 mm Pyrex capillaries using an 11 cm camera and Cu K_α radiation with a nickel filter. Data on rubidium trifluoromethoxide are given in Table I, together with the corresponding figures for rubidium fluoroborate as reported by Hoard and Blair (8).

THE REACTION OF ACTIVE NITROGEN WITH MIXTURES OF ETHYLENE AND NITRIC OXIDE[1]

E. FERSHT[2] AND R. A. BACK
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received December 3, 1964

ABSTRACT

The reaction of active nitrogen, produced in a condensed discharge at 1 mm pressure, with mixtures of ethylene and nitric oxide has been studied with mixtures ranging in composition from pure ethylene to pure nitric oxide. The sum of HCN + $^{14}N^{15}N$ produced from mixtures of C_2H_4 and ^{15}NO remained constant and equal to the HCN produced from pure C_2H_4 for NO concentrations up to 50 mole %. As more NO was added, this sum rose towards the value of $^{14}N^{15}N$ produced from pure ^{15}NO. These data appear to lend support to the HCN yield from ethylene as the true measure of nitrogen atom concentration. It is suggested that ^{15}NO also undergoes a concerted reaction with excited $^{14}N^{14}N$ molecules, probably in the $A^3\Sigma_u^+$ state, to produce $^{14}N^{15}N$, and that these excited molecules can be quenched by collision with ethylene or methane without consuming nitrogen or forming HCN.

INTRODUCTION

Both ethylene and nitric oxide, when present in sufficient excess, appear to react quantitatively with active nitrogen, and both have been used to measure its activity. The extent of the nitric oxide reaction, however, is consistently higher by about 50% than the maximum yield of hydrogen cyanide from the reaction with ethylene, and despite extensive studies of both systems, this discrepancy remains unexplained (1, 2, 3). It is well established that atomic nitrogen is the major reactive species in active nitrogen (2, 4, 5). There is also little doubt that excited nitrogen molecules are also present in appreciable concentrations in active nitrogen, are responsible for the decomposition of ammonia, and probably initiate the reactions with saturated hydrocarbons (2, 6–9). Suggested explanations of the ethylene–NO discrepancy fall into two general categories. In the first of these it is proposed that the reaction

[1] $$N + NO \rightarrow N_2 + O$$

is the only one of importance in the nitric oxide system, and that the lower yield of hydrogen cyanide from ethylene arises from some inherent inefficiency in the ethylene reaction (10, 11). The nitric oxide reaction has been studied by following the disappearance of nitric oxide (1, 12, 13), the appearance of N_2 (using ^{15}NO) (3), and the formation of oxygen atoms (14), and all the data are compatible with this simple mechanism, which is also apparently supported by recent estimates of atom concentration by electron spin resonance methods (5), and by measurement of the pressure change on combination (15).

In the second category of explanations, it is suggested that in the presence of a sufficient excess of ethylene, the reactions

[2] $$N + C_2H_4 \dashrightarrow HCN + CH_3$$

[3] $$N + CH_3 \dashrightarrow HCN + H_2 \text{ (or } 2H)$$

quantitatively convert nitrogen atoms to hydrogen cyanide, and that the "extra" decomposition of nitric oxide arises from some additional reaction, probably of excited

[1]*Issued as N.R.C. No. 8406. Presented at the Chemical Institute of Canada Annual Conference at Kingston, June 1964.*

[2]*National Research Council of Canada Postdoctorate Fellow, 1961–1963. Present address: Yerkes Research and Development Laboratory, E. I. duPont de Nemours and Co., Buffalo, New York.*

nitrogen molecules, in the nitric oxide system (1, 2). This view is supported by the simplicity of the products of the ethylene reaction, the absence of appreciable amounts of other nitrogenous products, and the fact that a large number of other hydrocarbons and organic compounds give approximately the same maximum yield of hydrogen cyanide (2).

A recent study of the reaction of ^{14}N-active nitrogen with ^{15}NO in this laboratory showed that $^{14}N^{15}N$ was produced in amounts approximately equal to the ^{15}NO destroyed, and that $^{15}N^{15}N$ was completely absent from the products (3). The quantitative production of $^{14}N^{15}N$ in these experiments suggested a means of measuring the extent of the nitric oxide reaction in ethylene–NO mixtures which would avoid the uncertainty, due to possible loss of NO in secondary reactions, inherent in a measurement of NO disappearance. Both $^{14}N^{15}N$ and hydrogen cyanide should be effectively inert to secondary reactions in this system (3, 16), and by simultaneous measurements of both these products from the reaction of active nitrogen with various ethylene–NO mixtures it was hoped that the origin of the ethylene–NO discrepancy might be clarified.

EXPERIMENTAL

Active nitrogen was generated by a condensed discharge in a conventional fast-flow system, previously described (3). Pressure of nitrogen was about 1 mm and the flow rate was 35 μmoles/s. Surfaces were poisoned with phosphoric acid and a trace of water vapor added to the nitrogen stream. The active nitrogen reached the reactant nozzle about 0.15 s after leaving the discharge tube.

The reaction vessel was a fused silica cylinder of 24 mm i.d. and 60 cm long. Nitric oxide and ethylene from separate flowmeters were premixed, and introduced through a nozzle mounted coaxially within the reaction vessel, designed to ensure rapid mixing of the reagent gases with the active nitrogen.

Hydrogen cyanide was trapped at −196 or −210 °C together with other condensable products and unreacted ethylene; it was dissolved in dilute sodium hydroxide solution and titrated with silver nitrate as described previously (3). Suitable blank experiments showed that none of the other products interfered with the titration. In the experiments in which $^{14}N^{15}N$ was measured, solid nitrogen traps (−210 °C) removed nitric oxide and other condensable products or reagents which might have interfered with the mass spectrometric analysis; this was also confirmed by blank experiments. Samples of noncondensable gas were removed from the flow system downstream from the traps by a Toepler pump, and analyzed by a mass spectrometer.* Straightforward corrections were made for $^{14}N^{15}N$ initially present in the isotopically natural active nitrogen, and for about 5% ^{14}NO in the ^{15}N-nitric oxide. Hydrogen, carbon monoxide, oxygen, and methane were minor noncondensable products of the ethylene – nitric oxide reaction with active nitrogen; these were analyzed by gas chromatography, and a small correction applied to the mass spectra for the contributions of carbon monoxide to the mass-28 and mass-29 peaks.

Nitric oxide titrations, based on simple visual observation of the sharp transition from a blue to a yellow–green flame, were performed before each experiment to check the activity of the active nitrogen; these always gave values within the range shown in Fig. 1, in good agreement with the $^{14}N^{15}N$ yield from pure nitric oxide.

All experiments were done at a temperature of 248 ± 2 °C. Linde "Bone dry" (99.98% pure) nitrogen was used throughout without purification. Ethylene and methane were Phillips Research grade, used after the usual degassing and bulb-to-bulb distillation. ^{14}N-Nitric oxide was obtained from Matheson and used after repeated simple distillations to remove traces of N_2O, NO_2, O_2, and N_2 impurities. ^{15}N-Nitric oxide was obtained from Merck, Sharp and Dohme of Canada Ltd., and subjected to similar purification.

RESULTS

Experiments with pure ethylene gave the usual behavior, with the yield of hydrogen cyanide becoming constant at about 3.1 μmoles/s, independent of ethylene flowrate, at ethylene flowrates above about 4 μmoles/s. Experiments with pure ^{15}NO, at flowrates beyond the end point of the flame titration, produced about 4.8 μmoles/s of $^{14}N^{15}N$, corresponding closely to the end point of the flame titration, and about 55% higher than the maximum yield of hydrogen cyanide from pure ethylene. These observations are in good agreement with previous work, and confirm the nitric oxide – ethylene discrepancy (1–3).

Figure 1 shows yields of $^{14}N^{15}N$ and HCN from NO–C_2H_4 mixtures as a function of the mole % of nitric oxide in the reagent mixture. Two sets of experiments were performed. The open squares and circles represent experiments in which the ethylene flowrate was

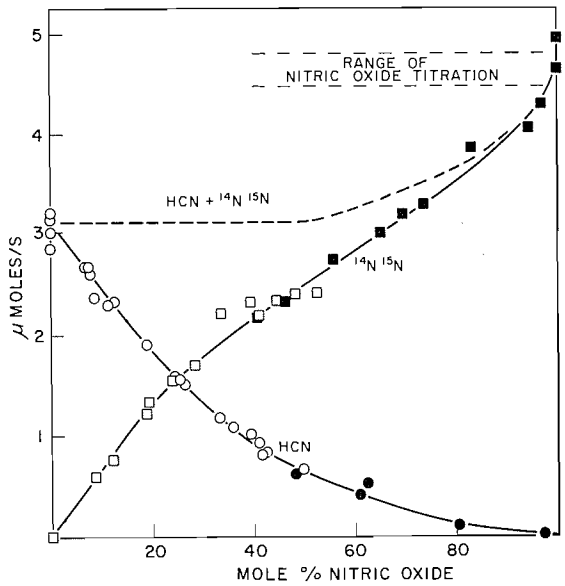

FIG. 1. Yields of HCN and $^{14}N^{15}N$ from the reaction of active nitrogen with NO–C_2H_4 mixtures ranging in composition from pure C_2H_4 to pure NO.

maintained approximately constant at values well up on the HCN "plateau", while increasing increments of nitric oxide were added. The solid squares and circles correspond to experiments in which nitric oxide flowrates were held at values somewhat in excess of the titration end point, while various amounts of ethylene were added. Thus in all the experiments there was always a sufficient excess of one reagent or the other to have ensured complete consumption of nitrogen atoms. The two sets of data overlap somewhat, and appear to lie on the same curves. In some but not all of the overlapping experiments, both reagents were in excess of the flowrates required for complete reaction. In several experiments, considerably more nitric oxide was added than the usual moderate excess; the product yields were indistinguishable from the normal experiments, indicating that nitric oxide was not being seriously depleted by any side reactions, and was always present in excess.

Also shown in Fig. 1 is a curve representing the sum of the yields of HCN and $^{14}N^{15}N$, derived from the smooth curves drawn through the HCN and $^{14}N^{15}N$ data.

Some experiments were also done with mixtures of methane with nitric oxide. Because methane reacts very slowly with active nitrogen (17), only one series of experiments, in which methane was added in increasing amounts to the NO-active nitrogen system with NO present in excess, was possible. Table I shows the effect of added methane on the yield of $^{14}N^{15}N$. There was no detectable hydrogen cyanide produced in these experiments.

DISCUSSION

As increments of ^{15}NO were added to excess ethylene (left hand side of Fig. 1), the HCN decreased from its value with ethylene alone, linearly at first and then more slowly,

1.00	4.80
0.93	4.61
0.87	4.47
0.82	4.65
0.64	4.36
0.54	4.09

and was replaced by $^{14}N^{15}N$. Because reaction [1] is probably at least 100 times faster than reaction [2] (even at 248 °C) (6, 13, 18), the initial decrease in HCN was limited by complete consumption of NO. As more NO was added, it was not completely consumed, and the relative yields of $^{14}N^{15}N$ and HCN reflected a competition between reactions [1] and [2]. This competition was complicated by reaction [3], which is probably almost as fast as reaction [1], and by the reaction of oxygen atoms, formed in reaction [1], with ethylene (19).

[4] $$O + C_2H_4 \dashrightarrow C_2H_4O^* \dashrightarrow CH_3 + CHO$$

Subsequent reactions probably account for the CH_4, CO, H_2, and C_2H_6 observed as minor products. Methyl radicals formed in reaction [4] also contribute to reaction [3], and it was probably this reaction sequence that kept the HCN yield from falling to zero as rapidly as it should have with a simple competition between reactions [1] and [2]. The abscissa scale in Fig. 1 is simply the mole % of NO initially present in the reagent mixture; it is evident from the complex nature of the competition between reactions [1], [2], and [3] that no simple significance attaches to the shapes of the curves, and that the abscissa scale merely represents a convenient empirical variable.

The most striking feature of Fig. 1 is that within the very considerable experimental error evident from the scatter of the data, the sum of HCN and $^{14}N^{15}N$ remained almost constant, and equal to the HCN yield from pure ethylene, up to about 50 mole % nitric oxide. At this point, HCN had fallen to about 20% of its initial value, and had been replaced almost quantitatively by $^{14}N^{15}N$. Despite the fact that four-fifths of the reaction was thus with nitric oxide, none of the extra reactivity shown by pure nitric oxide was yet in evidence. Only as the nitric oxide was increased beyond 50% did the extra reactivity begin to appear, as the sum of HCN + $^{14}N^{15}N$ rose gradually and then more sharply as 100% nitric oxide was approached.

Conversely, as increments of ethylene were added to the nitric oxide reaction (right hand side of Fig. 1), the yield of $^{14}N^{15}N$ decreased sharply. The decrease was at first only slightly compensated by the production of HCN, so that the sum of HCN + $^{14}N^{15}N$ fell rapidly towards the value of the HCN produced from pure ethylene.

The present observations fit most readily an explanation of the second category discussed earlier, i.e., a two-species explanation, with both ethylene and NO reacting quantitatively with nitrogen atoms, and with NO alone also reacting with a second species. The most likely second species is the metastable $A^3\Sigma_u^+$ state of N_2 (2, 8) and the lack of $^{15}N^{15}N$ in the product requires that this must react with ^{15}NO by a concerted mechanism,

[5] $$^{14}N_2(A^3\Sigma_u^+) + {}^{15}NO \dashrightarrow [{}^{14}N{}^{14}N{}^{15}NO]^* \dashrightarrow {}^{14}N + {}^{14}N{}^{15}N + O$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

rather than by an energy transfer process (3).* The effect of adding ethylene to the NO reaction would initially be the quenching of $N_2(A^3\,\Sigma_u^+)$ by ethylene, perhaps with some decomposition of the ethylene, but producing no HCN and consuming no nitrogen:

[6] $$N_2(A^3\,\Sigma_u^+) + C_2H_4 \dashrightarrow N_2(\text{ground state}) + C_2H_4 \text{ or other products.}$$

From the rapidity of the decrease in the $^{14}N^{15}N$ yield upon the addition of ethylene, it may be estimated that reaction [6] must have been from 5 to 10 times faster than reaction [5]. The data in Fig. 1 thus would represent two distinct competitions, the first for nitrogen atoms (reactions [1], [2], and [3]), in which the reaction with NO (reaction [1]) was much the faster, and the second a competition for $N_2(A^3\,\Sigma_u^+)$ (reactions [5] and [6]), in which ethylene was the faster reagent.

The effect of methane on the NO reaction (Table I) can also be explained by a similar quenching of $N_2(A^3\,\Sigma_u^+)$ by methane. It was much less efficient than ethylene, as only about half the extra $^{14}N^{15}N$ formed with pure ^{15}NO was eliminated by the addition of 50 mole % methane (cf. ethylene, Fig. 1). Allowing for consumption of NO in reaction [1], the quenching of $N_2(A^3\,\Sigma_u^+)$ by methane would have to be 2 or 3 times slower than reaction [5], and from 10 to 30 times slower than reaction [6]. This is in accord with the relative quenching efficiencies of methane and ethylene for other species (21).

It has been pointed out (2) that reaction [5] is endothermic unless the excited nitrogen molecule possesses at least one quantum of vibrational excitation. The $A^3\,\Sigma_u^+$ molecules can be formed directly by combination of nitrogen atoms or by one of several cascade processes associated with the nitrogen afterglow. In either case vibrational excitation is highly probable, and deactivation, especially below the $v = 1$ level, could be a slow process in pure nitrogen (2). This raises the possibility that ethylene and methane might be acting by deactivating $N_2(A^3\,\Sigma_u^+)$ to its lowest vibrational level rather than by electronic quenching.

The chief objection to the suggested two-species mechanism is the apparent disagreement with the recent physical measurements, mentioned previously, which yielded atom concentrations corresponding closely to the consumption of nitric oxide (5, 15). It is very difficult, however, to explain the present observations in terms of a nitrogen atom flowrate equal to the production of $^{14}N^{15}N$ from pure ^{15}NO, for whatever the data may represent, it is *not* a simple competition for nitrogen atoms. The constancy of the sum of HCN + $^{14}N^{15}N$ for reagent mixtures ranging from pure ethylene to 50% NO, with HCN production ranging from 100 to 20% of its value with pure ethylene, seems almost impossible to explain by a mechanistic inefficiency (such as catalytic combination of atoms (10, 22) for example) in the ethylene reaction. Unless this constant sum is purely fortuitous, it is difficult to avoid the conclusion that it corresponds to the flowrate of nitrogen atoms. A further argument against an explanation in terms of nitrogen atoms alone is the high efficiency of ethylene in reducing the $^{14}N^{15}N$ production from the ^{15}NO reaction, which is markedly at variance with the known (6, 18) relative rates of reactions [1] and [2], which, incidentally, are confirmed by the efficiency with which NO reduced the HCN yield when added to the ethylene reaction. The effect of methane on the production of $^{14}N^{15}N$ from the ^{15}NO reaction is similarly incompatible with its known very slow rate of reaction with nitrogen atoms (17).

**The reaction,* $NO^* + NO \rightarrow N_2 + O_2$, *following excitation of* NO *by energy transfer from* $N_2(A^3\,\Sigma_u^+)$, *suggested by Wright and Winkler (20), would still lead to* $^{15}N^{15}N$ *in the* ^{15}NO *reaction and thus may also be ruled out.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Reaction [5] at first sight may seem a rather unlikely process. However, it could be regarded as a radical–radical disproportionation reaction, with transfer of N from the weakly bonded (D_{N-N} = 85 kcal) $N_2(A^3\Sigma_u^+)$ diradical to the monoradical NO, forming N_2O with sufficient vibrational excitation to break the N—O bond; in this light it is perhaps more plausible. Simple energy transfer from $N_2(A^3\Sigma_u^+)$ to NO, with decomposition of NO, is an obvious alternative, but this is not necessarily an efficient process; experimentally it has been shown that it does not occur in the present system (3).

A further difficulty with reaction [5] is the lack of effect of ammonia, added upstream, on the nitric oxide reaction (2), since it has been suggested by several authors (2, 6–8) that ammonia reacts readily with $N_2(A^3\Sigma_u^+)$ molecules. Wright *et al.* (2) reconciled this conflict, but their arguments are not particularly convincing. However, the mechanism of the ammonia reaction is obscure and possesses several very puzzling features, and until it is better understood, any conclusions about the lack of effect of ammonia on the nitric oxide reaction should be treated with considerable reserve.

In summary, it may be concluded that the present results appear to support the HCN production from ethylene as the true measure of the nitrogen atom content of active nitrogen. A second active species that can be destroyed by ethylene or methane without producing HCN is most probably responsible for the extra reactivity shown by nitric oxide. If the second species were $N_2(A^3\Sigma_u^+)$, previous experiments in this laboratory have shown that it must react with NO by a concerted mechanism (reaction [5]), and its concentration in the present system must have been about 27% of the atom concentration. This seems well beyond the margin of error in recent physical measurements of atom concentration, and the disagreement between these and the present conclusions remain unexplained.

HALOGEN ATOM REACTIONS

III. LUMINESCENCE FROM THE RECOMBINATION OF BROMINE ATOMS[1]

D. B. GIBBS AND E. A. OGRYZLO

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received January 26, 1965

ABSTRACT

The recombination of bromine atoms has been found to result in the emission of an orange–red glow. Analysis of the banded spectrum has resulted in the identification of the transition responsible for the visible emission as $Br_2(^3\Pi_{0u}^+ \rightarrow {}^1\Sigma_{0g}^+)$. The results of a kinetic study of the glow indicate that the emission is second order in [Br] and first order in [Br_2]. Several detailed preassociation mechanisms for the reaction are discussed.

INTRODUCTION

Light emission from electronically excited states formed by the recombination of radicals is potentially an important source of information about the details of the "reactive collision process". For example, an important unanswered question for association reactions is the role of repulsive and weakly bound states. When luminescence from such states can be studied kinetically their role in the total process can be assessed. Because of the interest in reactions which are relevant to the upper atmosphere, chemiluminescence from reactions involving nitrogen and oxygen atoms has received a great deal of attention, but the mode of participation of electronically excited states in the total recombination process is still not clear (1).

Halogen atoms have received much less attention. The continuous "glow-spectrum" obtained by heating the halogens in a quartz container to temperatures in excess of 600 °C has been attributed to the two body recombination of atoms by Kondratjew and Leipunsky (2). A similar "continuous" emission from bromine dissociated in a shock tube has been reported by Palmer (3), for which he also proposed a two body recombination mechanism which can be written

$$Br(^2P_{3/2}) + Br(^2P_{1/2}) \rightleftarrows Br_2(^3\Pi_{0u}^+) \rightarrow Br_2(^1\Sigma_g^+) + h\nu$$

$$Br(^2P_{3/2}) + Br(^2P_{3/2}) \rightleftharpoons \left\{\begin{matrix} Br_2(^1\Pi_{1u}) \\ Br_2(^3\Pi_{1u}) \end{matrix}\right\} \rightarrow Br_2(^1\Sigma_g^+) + h\nu.$$

The discrete "glow-spectrum" of bromine which is obtained when the gas is at low pressures was studied by Uchida (4). The emission was found to originate from between the 4th and 12th vibrational levels of the $^3\Pi_{0u}^+$ state. The system was complicated by the fact that the walls were involved in the production of the excited molecules, and the order of the reaction with respect to bromine atoms could not be directly determined. In view of the many assumptions that Ochida was forced to make, it is doubtful if much significance should be attributed to his conclusion that the emission appears to be 4th order in the atom concentration.

In Part I (5) of this series it was shown that large concentrations of chlorine and bromine atoms could be formed with an electrical discharge in a flow system. A kinetic and spectroscopic study of the light emission accompanying the recombination of chlorine atoms was described in Part II (6). This paper described a similar study for bromine atoms.

[1]*The study was supported by the Air Force Office of Scientific Research Grant No. 158-63 and by the National Research Council of Canada.*

EXPERIMENTAL

The apparatus used for the kinetic experiments was essentially that described in Part I (5). For the spectroscopic study an optical window was inserted at the end of the reaction tube and the slit of the spectrograph placed against it. Aluminium foil was wrapped around the tube to increase the light gathered by the spectrograph. The reaction tube and gas stream were at room temperature for all experiments.

A 2 450 mc microwave discharge was used to dissociate the bromine. The pyrex walls of the discharge tube and reaction tube were coated with orthophosphoric acid. Bromine was dried with silica gel and purified by trap-to-trap distillation. The atom concentration was measured with a movable nickel wire calorimeter described previously (4). The relative emission intensity along the reaction tube was measured by photographing it with a Konica 35 mm camera with an $f/3.5$, 135 mm focal length lens. Each film was independently calibrated to relate optical density to light intensity by using a number of exposure times. Kodak high speed infrared film was used because the emission was found to peak in the infrared.

The high speed spectrophotometer was constructed from an $f/4.5$ Hilger-Watts model D285 glass prism spectrometer, an R.C.A. 7102 photomultiplier, and a 27.5 c.p.s. a-c. amplifier. For greater resolution an $f/6.3$ Jarell-Ash model 75—000 plane grating spectrograph blazed at 7 500 Å was used with Kodak 1N plates.

RESULTS

Under the usual flow-system operating conditions (p = 1 mm Hg, flow = 25 μmoles/s) a weak orange-red glow can be seen coming from the discharge products for a distance of about 1 m along the gas stream. The spectrum obtained with a low dispersion spectrophotometer is shown in Fig. 1. Comparison with the spectral response of the tube (dotted curve) indicates that the maximum in the emission intensity occurs beyond 10 000 Å under these conditions.

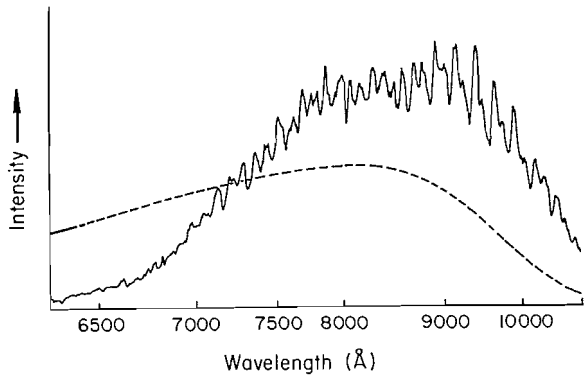

FIG. 1. Spectrum of red glow obtained with an $f/4.5$ low dispersion glass prism spectrometer and an RCA-7102 photomultiplier. Slit = 100 μ. Dotted line gives the spectral response of the photomultiplier.

Figure 2 shows the effect of pressure on the spectral distribution. A wide slit was used to remove the fine structure. It will be observed that there is a decrease in the higher energy emission intensity (relative to that at about 9 000 Å) with increasing pressure.

The spectrum was also taken on a grating spectrograph with a dispersion of 20 Å/mm. Because of the low intensity of the emission the slit width could not be decreased sufficiently to bring out the rotational structure. However, bands belonging to the system $B^3\Pi^+_{0u}$–$X^1\Sigma^+_g$ could easily be picked out. The following series were recorded between 6 200 Å and 8 300 Å:

$B^3\Pi^+_{0u}$	$X^1\Sigma^+_g$
$v' = 0$	$v'' = 5$ to $v'' = 12$
$v' = 1$	$v'' = 5$ to $v'' = 13$
$v' = 2$	$v'' = 6$ to $v'' = 12$
$v' = 3$	$v'' = 9$ to $v'' = 13$

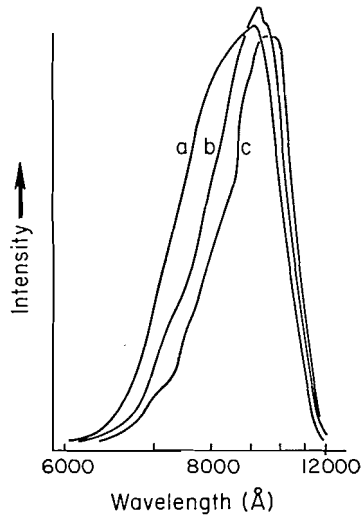

FIG. 2. Spectral distribution of the red glow obtained at three different pressures. (*a*) $P \sim 0.5$ mm Hg, (*b*) $P \sim 2$ mm Hg, (*c*) $P \sim 2.5$ mm Hg. Slit = 700 μ.

No transitions were observed involving v' greater than 3. In addition to these bands others were noted that could not belong to this system. No identification of this new system was possible because of the considerable overlap with the ${}^3\Pi_{0u}^+ - {}'\Sigma_g^+$ system. Though the new system of bands begins further into the red, bands at 7 600 Å, 7 800 Å, and 8 000 Å are quite strong. A complete analysis of this system may be possible if measurements can be extended further into the red.

The dependence of the emission intensity on the atom concentration was determined by assuming a relation of the form

$$I = k[\mathrm{Br}]^n[\mathrm{Br}_2]^m. \qquad [1]$$

At some constant pressure $[Br_2]$ = constant and eq. [1] can be written

$$\log I = n \log [\mathrm{Br}] + \text{constant}. \qquad [2]$$

A plot of log I against log [Br] in a typical experiment is shown in Fig. 3. The slope of the line is equal to 1.9 ± 0.2 which gives the order of the reaction with respect to [Br].

The order with respect to $[Br_2]$ was obtained by observing the change in light emission with the change in pressure at points in the reaction tube where [Br] is the same. Under these circumstances eq. [1] can be written:

$$m = \frac{\log (I'/I'')}{\log ([\mathrm{Br}_2]'/[\mathrm{Br}_2]'')}.$$

A typical change in conditions gave

$$\frac{[\mathrm{Br}_2]'}{[\mathrm{Br}_2]''} = \frac{0.6 \text{ mm Hg}}{1.0 \text{ mm Hg}} = 0.6$$

which resulted in a change in emission intensity (at a point where [Br]′ = [Br]″) given by

$$\frac{I'}{I''} = \frac{2.03}{2.97} = 0.68$$

$$m = 0.8 \pm 0.2.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

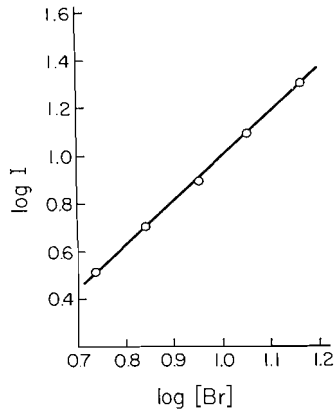

FIG. 3. A typical plot of the log of the emission intensity against the log of the bromine atom concentration (in arbitrary units). Slope ≈ 2 gives the order of the reaction with respect to bromine atoms.

The shift of the peak intensity into the infrared with increasing pressure illustrated in Fig. 2 would have the effect of making the apparent $[Br_2]$ dependence smaller than the actual value (i.e. that obtained if the entire emission were observed). A rigorously quantitative correction cannot be made until the complete spectral distribution is obtained. However, a 20% drop in intensity in the region from 7 000 Å to 9 000 Å seems quite reasonable from Fig. 2. We therefore conclude that the results indicate a first order dependence on $[Br_2]$, and that the following kinetic expression can be written for the light-emitting recombination reaction:

$$I = k[Br]^2[Br_2].$$

DISCUSSION

Some relevant potential energy curves for bromine are shown in Fig. 4. The solid curves have been spectroscopically observed and the dotted portions are drawn according to the suggestions of Rees (7) and Mulliken (8). The most significant fact is that the $^3\Pi_{0u}^+$ state does not correlate with ground state atoms.

It is possible that excited atoms form in the discharge, and direct recombination into $Br_2(^3\Pi_{0u}^+)$ could occur via the reaction:

$$Br(^2P_{1/2}) + Br(^2P_{3/2}) + Br_2 \rightarrow Br_2(^3\Pi_{0u}^+) + Br_2.$$

However, it would seem too fortuitous if the metastable $Br(^2P_{1/2})$ atoms decayed at the same rate as $Br(^2P_{3/2})$ atoms by wall and gas phase recombination to give the second order dependence on [Br] that is observed experimentally. Furthermore, if this were the mode of formation of $Br_2(^3\Pi_{0u}^+)$, emission would be expected from levels above $v' = 3$, since it is observed for chlorine (6) which has a much longer radiative lifetime. From the integrated absorption coefficient it can be established that the radiative lifetime of $^3\Pi_{0u}^+$ is shorter than 10^{-4} s. The possibility that the excited molecules themselves originate in the discharge can therefore be ruled out. It would seem more reasonable to seek an explanation which involves a collision along a potential curve which correlates with ground state atoms. There are at least two curves which might lend themselves to such a process: the $^1\Pi_{1u}$ and the $^3\Pi_{0u}^-$.

Darbyshire (9) has observed that when the rotational constant (B) for the $^3\Pi_{0u}^+$ state is plotted against the vibrational level (v') a change in slope can be seen between $v' = 3$

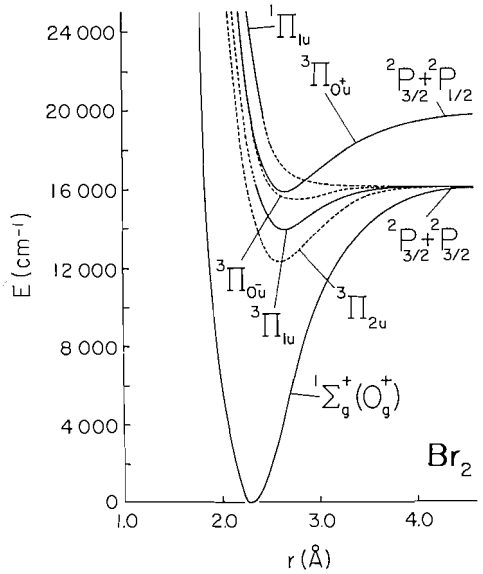

FIG. 4. Potential energy diagram for Br_2. Solid lines give spectroscopically observed states. Dotted lines give extrapolated or estimated states.

and 4. Bayliss and Rees (10) suggested that this perturbation may be due to a crossing of the $^3\Pi_{0u}^+$ curve by the $^1\Pi_{1u}$ curve as shown in Fig. 4. However, there is some evidence (11, 12, 13), that magnetic and collisional predissociation of the $^3\Pi_{0u}^+$ state in the halogens is due to the close proximity of a 0_u^- state. Rees (14) has suggested that this could be the repulsive $^1\Sigma_{0u}^-$ state which would have to intersect the right hand side of the $^3\Pi_{0u}^+$ curve. On the other hand the predissociating state could be the $^3\Pi_{0u}^-$ as suggested by Van Vleck (12) and Zener (13). Mulliken (8) has indicated that this state should lie very close to the $^3\Pi_{0u}^+$ at small internuclear distances as shown in Fig. 4. A consequence of this latter interpretation is that predissociation should occur over a large portion of the $^3\Pi_{0u}^+$ curve. The recent work of Brown and Klemperer (15) seems to indicate just such a situation. Several mechanisms therefore need to be considered.

Mechanism 1

[11] and [12] $$Br(^2P_{3/2}) + Br(^2P_{3/2}) \underset{k_{12}}{\overset{k_{11}}{\rightleftharpoons}} Br_2(^3\Pi_{0u}^- \text{ or } ^1\Pi_{1u})$$

[13] $$Br_2(^3\Pi_{0u}^- \text{ or } ^1\Pi_{1u}) + Br_2 \xrightarrow{k_{13}} Br_2(^3\Pi_{0u}^+) + Br_2$$

[14] $$Br_2(^3\Pi_{0u}^+) \xrightarrow{k_{14}} Br_2 + h\nu$$

[15] $$I = (k_{11}/k_{12})k_{13}[Br]^2[Br_2]$$

This mechanism assumes that a collision between two ground state atoms occurs along the $^3\Pi_{0u}^+$ or the $^1\Pi_{1u}$ curve. The inhomogeneous electric field of a colliding Br_2 molecule is then assumed to induce an intersystem crossing to the $^3\Pi_{0u}^+$ state. The correct kinetic order can be obtained (see eq. [15]) by assuming an equilibrium concentration of $Br_2(^3\Pi_{0u}^-)$ determined by reaction [11] and [12], and a steady state concentration of $Br_2(^3\Pi_{cu}^+)$. The mechanism can then account for all the experimental observations including the fact that emission is observed only from levels below $v' = 4$. The shift of the emission maximum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to longer wavelength shown in Fig. 2 is consistent with more rapid vibrational relaxation to lower levels of the $^3\Pi_{0u}^+$ state as the pressure is increased. From Fig. 4 it can be seen that such a shift to lower energy emission is consistent with the Franck-Condon principle.

Mechanism 2

Since the $^3\Pi_{0u}^-$ state is probably a weakly bound state, it is possible that direct recombination into that state occurs through a termolecular collision. Transitions to the emitting $^3\Pi_{0u}^+$ state could then conceivably require an additional collision. If the mechanism is written as follows,

[21] and [22] $$Br(^2P_{3/2}) + Br(^2P_{3/2}) + Br_2 \underset{k_{22}}{\overset{k_{21}}{\rightleftharpoons}} Br_2(^3\Pi_{0u}^-) + Br_2$$

[23] and [24] $$Br_2(^3\Pi_{0u}^-) + Br_2 \underset{k_{24}}{\overset{k_{23}}{\rightleftharpoons}} Br_2(^3\Pi_{0u}^+) + Br_2$$

[25] $$Br_2(^3\Pi_{0u}^+) \overset{k_{25}}{\rightarrow} Br_2 + h\nu,$$

the correct kinetic order could still result if the relative rates of the reactions are:

(*a*) [21], [22], and [25] $\gg$ [23] $\gg$ [24]

whence $$I = \frac{k_{21}}{k_{22}} k_{23}[Br_{3/2}]^2[Br_2],$$

(*b*) if reaction [21] is rate controlling

whence $$I = k_{21}[Br_{3/2}][B^2r_2].$$

Mechanism 3

There is increasing evidence that the recombination of halogen atoms occurs through the loosely bound intermediates I_3, Br_3, Cl_3 in the absence of added gases (16, 17). If these species exist in appreciable concentrations in atom-containing systems then the following series of reactions could lead to light emission with the correct kinetic dependence (eq. [35]):

[31] and [32] $$Br(^2P_{3/2}) + Br_2(+ Br_2) \underset{k_{32}}{\overset{k_{31}}{\rightleftharpoons}} Br_3(+ Br_2)$$

[33] $$Br_3 + Br(^2P_{3/2}) \overset{k_{33}}{\rightarrow} Br_2(^3\Pi_{0u}^+) + Br_2$$

[34] $$Br_2(^3\Pi_{0u}^+) \rightarrow Br_2 + h\nu$$

[35] $$I = \frac{k_{31}}{k_{32}} k_{33}[Br]^2[Br_2]$$

The symmetry requirements that prevent the direct formation of $Br_2(^3\Pi_{0u}^+)$ from ground state atoms probably do not apply to metathetical reactions such as [33], in which spin and orbital angular momentum are easily conserved.

Mechanism 3 is attractive because it is applicable to a large number of other preassociation reactions such as Cl—Cl, N—N, N—O, S—O, and S—S where preassociation has also been observed very near the dissociation limit. It is quite likely that a more detailed study of each of these reactions, which includes a determination of the temperature dependence of the emission, will allow a decision between the three mechanisms we have proposed.

AN ADIABATIC SOLUTION CALORIMETER USED FOR MEASURING THE MOLAR EXCESS ENTHALPY OF THE SYSTEM CARBON TETRACHLORIDE – BENZENE AT 25 °C[1]

J. E. BENNETT[2] AND G. C. BENSON
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received February 15, 1965

ABSTRACT

A new adiabatic calorimeter for measuring heats of mixing is described. The design of the mixing cell avoids the presence of a vapor space, and accommodates changes in volume by means of a flexible diaphragm. The apparatus is equipped with automatic adiabatic control and produces a continuous record of the temperature of the mixing cell. An extensive series of measurements was carried out for the system carbon tetrachloride – benzene at 25 °C. The maximum value of the molar excess enthalpy, 113.4 ± 0.5 J mole^{-1}, occurred at a mole fraction of carbon tetrachloride equal to 0.4907. For most of the concentration range, the results are from 1 to 2 J mole^{-1} lower than data reported recently by other investigators.

INTRODUCTION

Criteria governing the choice of a suitable pair of liquids for use in testing a new calorimeter have been discussed by McGlashan (1). He tentatively recommended the pair carbon tetrachloride – benzene for this purpose. However, values reported for the excess enthalpy at 25 °C by various authors (2–7) did not agree well; thus, for example, results for an equimolar mixture were scattered over a range of nearly 10%. Larkin and McGlashan (8) reinvestigated the system using a new calorimeter capable of much higher precision than before. Their results were systematically higher than most previous measurements and were, in fact, 4 J mole^{-1} higher for an equimolar mixture than they had expected on the basis of the earlier data. They suggested that the discrepancies arose from incomplete mixing which occurred to varying degrees in all the previous calorimeters.

More recently Lundberg (9) has also studied the carbon tetrachloride – benzene system and obtained results which are generally lower than those of Larkin and McGlashan for x, the mole fraction of carbon tetrachloride, less than 0.7 and greater for higher x-values. At the equimolar concentration the difference amounts to about 1.7 J mole^{-1} (i.e. 1.5%) and exceeds somewhat the combined estimates of the accuracies of the two calorimeters (about 1.3 J mole^{-1}).

It is clear that further careful studies of the heat of mixing of carbon tetrachloride with benzene are needed before this system can be adopted as a standard for testing calorimeters. The present investigation was undertaken to provide new independent data.

EXPERIMENTAL

The measurements were carried out in a new adiabatic calorimeter. Briefly, this apparatus consists of a stainless steel mixing cell suspended by nylon loops within a thin gold-plated copper shield. The latter is mounted on, but thermally insulated from, a framework inside an evacuated brass can immersed in an oil thermostat.

Since the calorimeter was constructed by modifying an adiabatic solution calorimeter, already described in the literature (10), the outline below is limited mainly to the changes which have been made in the previous equipment. These comprise improved instrumentation, making operation of the calorimeter more automatic, and a new vessel which is more suitable for studying small heat effects associated with the mixing of organic liquids. Reference should be made to the earlier publication (10) for details of those features of the calorimeter which remain unchanged (e.g., the adiabatic shield and can assembly).

[1]*Issued as N.R.C. No. 8434.*
[2]*National Research Council of Canada Postdoctorate Fellow 1961–1963. Present address: Imperial Chemical Industries, Agricultural Division, Billingham, England.*

(i) Automatic Adiabatic Control

The copper shield consists of two cylindrical and two conical sections bolted together, each wound with a manganin wire heater. Four 4-junction copper–constantan thermocouples are used to detect temperature differences between the parts of the shield and between the shield and the mixing cell. The oil thermostat, which is usually maintained at a temperature about 1.5 deg lower than the shield, acts as a heat sink. Heat flow between the shield and the cell is minimized by suitable adjustment of the current through the four shield heaters according to the indications of the four-difference couples. To achieve automatic control, the output of the couple between the shield and the vessel is amplified by a d-c. microvolt amplifier (Leeds and Northrup No. 9835B) and fed to a Speedomax G recorder-controller. Maximum amplification is used and full scale deflection of the recorder corresponds to a temperature difference of 0.3 °C. Deflection of the recorder auxiliary slide wire from zero actuates a Leeds and Northrup Series 60 three-action C.A.T. control unit which provides an output current of from 0 to 5 mA depending on the recorder imbalance and the control-unit settings. The output from the C.A.T. unit regulates the voltage supplied to the shield heaters by a stabilized transistorized d-c. power unit. The power to the four heaters is apportioned by individual rheostats which were adjusted once to equalize the temperatures of the four shield sections and then locked at that setting.

(ii) Cell Temperature Measurement

The temperature of the mixing cell relative to that of a water triple-point cell, external to the calorimeter assembly, is measured by a 12-junction copper–constantan thermocouple. The electromotive force (e.m.f.) of the thermocouple is balanced to the nearest microvolt on a Wenner Potentiometer (Leeds and Northrup No. 7559) and the fractional residue, amplified by a Liston-Becker DC Breaker Amplifier (Model 14) which has been modified to include feedback (11), is displayed on a second Speedomax G recorder. At the amplification normally used, a full scale deflection on the recorder corresponds to 10 μV; an e.m.f. of 0.1 μV (i.e. a temperature difference of 0.0002 °C) is easily measurable.

The coupling between the thermocouple circuit and the shield heaters is fairly high since all the leads to the calorimeter pass through a flexible metal vacuum tube for a distance of about 3 ft (from outside the oil bath to the can inside). To reduce the noise level on the recorder trace of the main thermocouple e.m.f. to an acceptable level it was found necessary to use direct current for the shield heaters.

(iii) The Mixing Cell

The new mixing cell, shown diagrammatically in Fig. 1, is basically similar to a cell used by Brown and Fock (12), but differs in details of the design. It is constructed mainly from stainless steel and consists of two cylindrical parts (A and B) held together by a ring nut (C) which clamps a 0.0005 in. aluminium foil diaphragm (D) between two machined Teflon gaskets (E and F). Part A is closed by a conical end (G) also

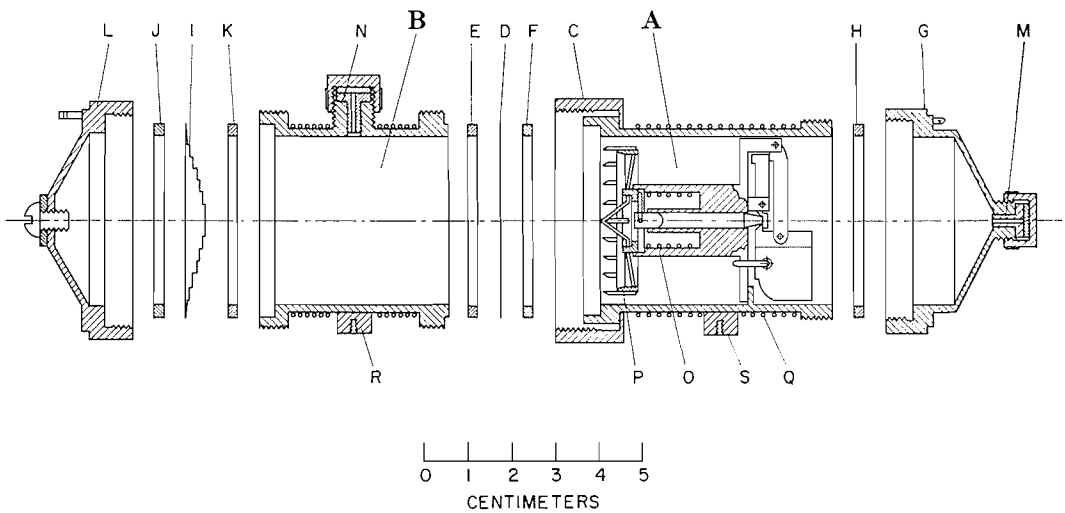

FIG. 1. Exploded sectional diagram of mixing cell.

sealed with a Teflon gasket (H). A flexible corrugated diaphragm (I), pressed from 0.003 in. beryllium–copper alloy and held in place by a pair of gaskets (J and K) and screw-end (L) complete part B. The compartments separated by the aluminium foil are filled through ports (M and N), one in end G and the other in the side of B. The walls of B are dished slightly to facilitate the escape of bubbles through the port. In use, both compartments are filled as completely as possible with the liquids to be mixed and the ports are closed by

For personal use only.

tightly fitting nylon plugs and screw caps. A strong coiled spring device (O), housed in part A, is released by gravity when the cell is rotated vertically through 180° and drives a spiked circular cutting frame (P) through the foil separator. Changes in volume which accompany the mixing are taken up by the diaphragm I; the maximum change which can be accommodated in this way is about 1.3 cm^3. A glass-fiber-insulated manganin wire heater (Q) is wound in the outside of the cell and thermocouple junctions can be screwed on to copper lugs (R and S) soldered to parts A and B. Various mixing ratios are obtained by employing several parts B of different size.

(iv) Some Operational Details

The calorimeter, with cell loaded, is left overnight in the oil thermostat (at 25 °C) to reach thermal equilibrium. About an hour before the measurements are to be started, the oil bath temperature is reduced by 1.5 deg and the C.A.T. control system is switched on to maintain the shields and the cell at the original bath temperature. When the oil bath has settled at its new control setting and the cell temperature is steady (as evidenced by the recorder trace of the main thermocouple e.m.f.), the liquids are mixed by rotating the calorimeter through 180°. Ten seconds after initiating an endothermic mixing process (as in the case of the carbon tetrachloride – benzene system) the current through a dummy resistor, similar to the cell heater, is diverted through the heater, and an amount of electrical energy very nearly balancing the expected heat of mixing is dissipated in the heater. The 10 s delay in switching the current was found to improve the C.A.T. control characteristics greatly during the mixing period. The heater voltage can range from 2 to 12 V and is chosen so that current is passed through the cell heater for about 5 min. During this period, readings of the voltage difference across the terminals of the heater and across those of a standard resistor in series with the heater are taken on a White Double Potentiometer. The calorimeter is rotated backwards and forwards 25 times during the mixing period which lasts about 20 min; after this time the cell temperature is again steady and is followed for a further 10 min. The effect of tipping is then determined by tipping the calorimeter assembly 100 times and measuring the increase in the thermocouple e.m.f. between the steady fore- and after-periods. This is usually repeated once or twice and an average is adopted. In order to allow for inexact compensation of the heat of mixing, the calorimeter is calibrated by carrying out two or three further heating periods. The heat dissipated in each of these is about 8 J; agreement between two calibrations is better than 1.5%. The heat effect associated with breaking the aluminium foil was determined in a series of separate experiments. It is exothermic and amounts to 0.18 J.

During the calibration periods and the determination of the heat of tipping, the control system keeps the temperature difference between the cell and its surroundings quite small and heat exchange is negligible. The mixing process, however, usually involves an initial rapid change in temperature and, in a measurement of a large heat of mixing, the difference between the cell and shield may be as large as 0.1 °C for a brief period. In these cases a correction is applied for the heat exchange; this is based on estimates of the net area under the recorder trace from the controller and of the cooling constant for the calorimetric system.

The heat of mixing was usually determined at a temperature differing from 25 °C by less than 0.05 °C. All results were corrected to 25.00 °C using the temperature coefficient given in ref. 8. The largest correction required was 0.25 J $mole^{-1}$ (for a temperature difference of 0.2 °C).

In a typical experiment involving about 1.317 moles of material at a mole fraction of carbon tetrachloride equal to 0.4052, the observed heat of mixing was 143.9 J. About 150.6 J were dissipated in the cell heater, of which 6.7 J gave a net rise in the cell temperature equivalent to 7.6 μV (about 0.016 °C). The energy gained by the cell as a result of exchange with the shield during the mixing period was estimated to be about 0.5 J. The temperature increases due to two lots of 100 tips were 0.54 and 0.48 μV respectively. Two determinations of the heat capacity of the system were 0.4% apart and gave a calibration factor of the order of 0.88 J μV^{-1}.

Mixtures with a final mole fraction of carbon tetrachloride from 0.3 to 0.7 were obtained directly from the pure liquids. Others outside this concentration range were made with one side of the cell filled with a mixture for which the heat of mixing was already established. The compositions were determined from weighings of the cell and components during the loading process. Weighings were made to 1 mg and all weights were corrected to *vacuo*. The total amount of material used for a measurement varied from 1.1 to 1.5 moles. At the equimolar concentration there were about 110 g of carbon tetrachloride and 54 g of benzene in the cell.

(v) Consideration of Errors

The equipment used for the electrical energy measurement is the same as that described by Benson and Benson (13). The accuracy of determination is limited primarily by the accuracy of measuring the time interval. In the present work, a 5 min period can be measured to about 0.05 s (i.e. 0.02%).

A reasonable estimate of the error in determining changes in the e.m.f. of the main thermocouple is 0.15 μV. This corresponds, for the amounts of material used, to an error of 0.1 J $mole^{-1}$. The largest energy exchange, which occurred between cell and shield during the mixing, lead to a correction of only 0.6 J $mole^{-1}$. It is believed that this correction could be estimated to better than 30%.

We feel quite certain that mixing was complete in the experiments reported in this paper. After rupture of the foil, there were pieces of the breaking mechanism loose in the cell, which acted as stirrers when the cell was rotated. The heat of tipping, measured immediately after the mixing period, was small (about 0.5 J for 100 tips) and exothermic. Repeat determinations of the heat of tipping always agreed to better than 20%.

Although the presence of a vapor space in the cell cannot be detected readily, every precaution was taken, both in the design and loading procedure, to ensure the absence of such a space. However errors arising from a vapor space (1) would be small in the present instance, due to the large quantities of material in the cell and the similarity of the vapor pressures of benzene and carbon tetrachloride as well as to the ability of the diaphragm to accommodate the increase in volume on mixing.

(vi) Materials

The carbon tetrachloride used for most of the measurements was Analytical Reagent (Mallinkrodt Chemical Works) which had been fractionally distilled 3 times; potassium hydroxide pellets were added prior to the third distillation. The density and refractive index of the final product were $d^{25} = 1.5842_5$ g cm^{-3} and $\mu_D^{25} = 1.4575$.

Reagent Grade benzene (Nichols Chemical Company) was treated with concentrated sulfuric acid, washed until neutral, and fractionally distilled 3 times after refluxing with sodium wire. The values of the density and refractive index were $d^{25} = 0.8734_5$ g cm^{-3} and $\mu_D^{25} = 1.4979$.

In addition to the above materials, some measurements were also made using Chromatoquality Reagent carbon tetrachloride (Matheson, Coleman and Bell) and Research Reagent benzene (Phillips Petroleum Company). No significant difference was detected in the results obtained with these materials.

RESULTS AND DISCUSSION

The experimental results for the mixing of carbon tetrachloride and benzene at 25 °C are summarized in Table I. This gives h^e, the molar excess enthalpy in J mole^{-1}, for various values of x, the mole fraction of carbon tetrachloride. In the previous investigations by Larkin and McGlashan (8) and by Lundberg (9), data for $h^e/x(1 - x)$ were fitted with polynomials in $(1 - 2x)$. A least square treatment of our results leads to the form

$$[1] \qquad h^e = x(1 - x)[453.5 + 15.7(1 - 2x) + 29.8(1 - 2x)^2].$$

Deviations, δ, between the experimental values and those calculated from eq. [1] are included in Table I. The root mean square value of δ is 0.5_2 J mole^{-1}, which is somewhat larger than might be expected from the above consideration of errors (i.e. about 0.3 J mole^{-1}). The values of δ show a tendency to vary systematically with x and it appears that eq. [1] gives a slightly broader and flatter curve than observed experimentally. Adding terms with higher powers of $(1 - 2x)$ did not improve the fit significantly. Alternative forms in which the mole fraction was replaced by the volume fraction, or in which $x(1 - x)/h^e$ was fitted by a polynomial in $(1 - 2x)$, were also tried, but neither of these led to a better representation of the data.

Equation [1] was adopted as a basis for comparing our results with those of other workers. The points plotted in Fig. 2 show the deviations of the experimental data from the values calculated with eq. [1]. Lundberg's results (9) are available only as an equation and the deviations of his data are represented as a dashed curve. In general, our results are much higher than the older data in the literature and in this sense confirm more recent findings (8, 9). According to eq. [1] the maximum value of h^e, 113.4 ± 0.5 J mole^{-1}, occurs at $x = 0.4907$. The standard deviations between eq. [1] and the forms given by Larkin and McGlashan (8) and by Lundberg (9) are 1.6 and 0.8 J mole^{-1} respectively. For comparison the standard deviation between these two other sets of data is 1.3 J mole^{-1}. It appears that our results agree fairly well with those of Lundberg over the lower half of the concentration scale. For larger x-values Lundberg's data are systematically higher; the maximum deviation (1.5 J mole^{-1}) occurs near $x = 0.85$. Over the central concentration range $0.25 < x < 0.75$ our results are about 2 J mole^{-1} lower than those in ref. 8. The latter difference is much larger than the combined experimental errors of the two investigations. Leakage around the gaskets of the central diaphragm in our cell would, of course, lead to premixing and the subsequent observation of smaller heat effects. In tests where a soluble dye was placed in the liquid on one side of the diaphragm, no evidence of leakage was detected over periods of several days.

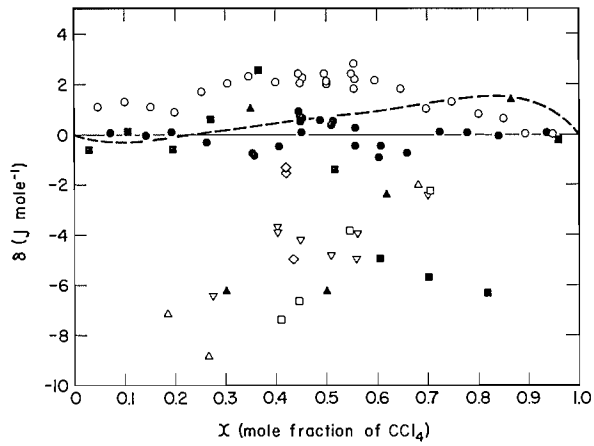

FIG. 2. Plot of the deviation $\delta = h^e$(obs.) − h^e(calcd. from eq. [1]) against the mole fraction of carbon tetrachloride. It has been pointed out that in some instances the heat of mixing of liquids may be affected by the presence of dissolved gases (1). In our work the components were loaded into the cell with pipettes and syringes; exposure to water vapor was avoided but in most cases, the liquids must have been saturated with air. However, in several experiments, an effort was made to decrease the dissolved gas content by "boiling" the components under reduced pressure just prior to the filling, and then transferring them to the cell as quickly as possible and with a minimum of turbulence. No significant difference was observed in results obtained with these partially degassed solvents.

Larkin and McGlashan noted that a few measurements made with a sample of certified high purity benzene gave higher results than those obtained with material of their own

purification. Lundberg suggested that the presence of trace impurities might account for the difference between his results and those of Larkin and McGlashan. In our work, some initial measurements were made with materials of about 99% purity; these gave heats of mixing 5 to 6 J $mole^{-1}$ lower than those reported in Table I. If, indeed, the discrepancies between the various investigations of the carbon tetrachloride – benzene system must be attributed to trace impurities which are not readily removed by normal purification procedures, the suitability of this system as a calorimetric standard seems questionable.

NOTE ADDED IN PROOF: Since this paper was written we have learned of another investigation of the carbon tetrachloride – benzene system by Van Ness and co-workers at Rensselaer Polytechnic Institute. The precision of the results appears to be very good and the values are in closer agreement with Lundberg's curve than the values reported above. We are indebted to Professor H. C. Van Ness for sending us a copy of his data.

ACKNOWLEDGMENTS

The help of Mr. G. O. Grummett in constructing the mixing cell and of Mr. B. Weston in designing the d-c. power supply for the shield heaters is gratefully acknowledged. We also wish to thank Mr. P. J. D'Arcy for invaluable technical assistance during the calorimetric measurements.

SYNTHESIS OF β-D-MANNOSE 1,2-ORTHOACETATES[1]

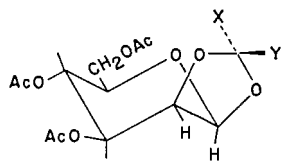
M. MAZUREK AND A. S. PERLIN
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received February 4, 1965

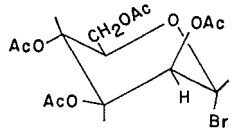
ABSTRACT

Synthesis of 3,4,6-tri-*O*-acetyl-β-D-mannopyranose 1,2-orthoacetates (I) from 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide (II) and various alcohols in the presence of pyridine and substituted pyridines is described. 2,6-Lutidine is a particularly effective acid acceptor in these condensations, and the use of chloroform as a diluent is advantageous. The lutidine-buffered system has afforded a good yield of orthoacetate (I) with several alcohols that barely react with II in the presence of silver ion; this difference is attributed to the dominance of side reactions under the latter conditions. The N-bases also promote a more highly stereoselective orthoester synthesis than does the silver-catalyzed reaction, leading to formation of the OR-*exo*-diastereoisomer almost exclusively.

An earlier paper (1) reports that the two possible diastereoisomers of 3,4,6-tri-*O*-acetyl-D-mannopyranose 1,2-(methyl orthoacetate) (I) are formed when 2,3,4,6-tetra-*O*-acetyl α-D-mannopyranosyl bromide (II) is treated with methanol in the presence of silver carbonate (2, 3, 4). The isomers co-crystallize and are not readily separable, but both were found to be present in the mixture by nuclear magnetic resonance (n.m.r.) spectroscopy. The spectral data also suggested that the OR group of the isomer giving a C-methyl signal at 1.75 p.p.m. is oriented *exo* to the fused ring system (IA), and is *endo* in the isomer that gives a C-methyl signal at 1.51 p.p.m. (IB). By preparing the benzyl analogue of I, it was possible to separate and characterize two diastereoisomeric orthoacetates as distinct crystalline entities; each of these gave only one of the orthoacetyl resonance signals shown by the mixture of IA and IB (1).



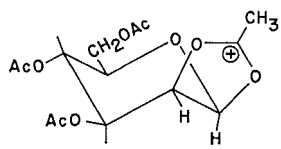
I



II

A (X = CH_3; Y = OCH_3)

B (X = OCH_3; Y = CH_3)



III

In continuing these studies, the synthesis of analogues of I containing yet other OR groups was undertaken. Since most orthoesters described in the literature (5) have been derived from primary aliphatic alcohols, it was of particular interest to test the condensation of less reactive types of hydroxylic compounds with II in the presence of silver

[1]*Presented in part at the 148th Meeting of the American Chemical Society, Chicago, Ill., August 30–September 4, 1964. Issued as N.R.C. No. 8419.*

carbonate. However, attempts to utilize several secondary alcohols and halogenated benzyl alcohols afforded little or no orthoester. Rather, side reactions (6) resulting from decomposition of the bromide (II) occurred at the expense of the condensation step. Since tetra-*O*-acetyl-α-D-mannosyl bromide is relatively stable in pyridine (6), and since the latter and various derivatives of it have occasionally been used for orthoester syntheses (5), pyridine and substituted pyridines were tested for the present purposes as acid acceptors in place of silver ion. This change in the reaction medium proved to be highly advantageous. 2,6-Lutidine was found to be especially effective, and permitted the synthesis of several new crystalline orthoester derivatives in very good yield. Among alcohols used in preparing these latter derivatives (Table I), none of which had given more than a trace of orthoester in the presence of silver carbonate, were 1,3-*O*-benzylidene-glyceritol, diphenylmethanol, *o*- and *p*-bromobenzyl alcohol, and *p*-iodobenzyl alcohol.[2]

The course of these condensations was conveniently examined by n.m.r. spectroscopy, since the intensity of the C-methyl signal provided a ready assay of orthoester yield. A striking property of the lutidine (or pyridine) buffered system was the fact that only one C-methyl signal, that at about 1.8 p.p.m., was prominent in the spectra of the reaction mixtures, whereas the signal at about 1.5 p.p.m., characteristic of IB, was usually almost completely absent. Hence each of the crystalline D-mannose 1,2-orthoacetates isolated in the current study (Table I) is essentially a single diastereomer, and is assumed to be an analogue of IA, i.e., the OR-*exo*-isomer.

Orthoester formation was more rapid and a better yield was obtained in the presence of a diluent such as chloroform, than when lutidine itself was used as the solvent. This deleterious effect of a high concentration of the N-base was particularly marked for the reaction of the mannosyl bromide with *p*-iodobenzyl alcohol: in lutidine alone the yield of orthoester was about 15%, whereas using chloroform and 2.5 molar equivalents of lutidine the yield of crystalline product was 67%. Reaction mixtures in which only 1 mole of lutidine was present per mole of mannosyl bromide, appeared to be insufficiently buffered, but 2 to 3 molar equivalents of the base was adequate to insure an optimum yield. The importance of buffering capacity was shown further by the fact that substituted pyridines having relatively low pK_a values were less effective than lutidine (pK_a, 6.7). Thus, with 3- or 4-hydroxypyridine (pK_a, 4.9 and 3.3, respectively), methanol and II gave 50–75% of the yield of I obtained in the presence of lutidine, whereas with 2-hydroxy- or 2-bromo-pyridine (pK_a 0.8 and 0.9, respectively), no orthoester was detected.

The overwhelming predominance of the diastereomer corresponding to IA in these reaction mixtures was at first attributed solely to a much more favored approach of the "hindered" alcohols towards the acetoxonium-ion intermediate (III) from a direction *exo* to the fused ring system (7). In fact, it was this expectation that partly prompted the use of these alcohols. However, in the presence of lutidine, methanol itself was found to yield IA almost entirely (the ratio of IA to IB was about 12:1), showing that the N-base induces a specific orientation effect unrelated to the reactivity of the hydroxylic component.[3] Lemieux and Morgan (8) have suggested that a transient pyridinium complex of an ion analogous to III is formed during the reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (or -β-D-glucopyranosyl chloride) with pyridine. They provided support for this

[2]*Not unexpectedly, o-bromobenzyl alcohol was the least reactive of this group, and required an elevated temperature whereas the other alcohols reacted smoothly at room temperature.*

[3]*A control experiment, in which a mixture of IA and IB was introduced at the outset of the condensation between the mannosyl bromide (II) and methanol, showed that IB remained unaltered during the succeeding reaction. Hence its virtual absence from the normal lutidine-buffered mixture is due not to its relative instability but to kinetic factors.*

proposal by showing that the addition of methanol to the reaction mixture resulted in the formation of methyl orthoacetate comprised chiefly of one diastereomer, believed to be the OR-*exo*-isomer. The current finding shows that pyridine and its analogues produce the same type of effect in the D-mannose series. However, this would not necessarily be anticipated because acetobromo-D-mannose, unlike the D-glucosyl halides, appears to be quite stable when dissolved in these bases (6). Consequently there is little reason to assume that a D-mannose pyridinium complex (analogous to the D-glucose complex) is an intermediate in the formation of diastereomer IA, although this would be required according to the mechanism of Lemieux and Morgan (8). In fact, these latter workers have now found that *sym*-collidine, which reacts far more slowly than does pyridine with D-glucosyl halides, is also more satisfactory for synthesis of D-glucose 1,2-orthoesters (9).

Although isomer IA and analogues of it may be obtained easily by the procedure described here, a stereospecific route to isomer IB and its analogues has not yet been found. Reaction conditions much more favorable to synthesis of IB were those in which II was treated with methanol and silver carbonate at relatively low temperatures.[4] Thus, at −10 °C the product contained twice as much of IB as of IA. This temperature effect was not consistent, however, for with benzyl alcohol as the hydroxylic component the direction was reversed and the relative proportion of the diastereomer corresponding to IA was even higher than at ambient temperature (i.e., 5:1 vs. 2:1). Such changes in composition with temperature suggest that the silver-catalyzed reaction may not proceed *entirely* through an intermediate such as III. With pyridine or lutidine the results are more consistent with a single, ionic, pathway: the ratio of IA to IB was the same at −10 °C as at room temperature and the rate of orthoacetate formation, as measured by changes in optical rotation or in intensity of the developing C-methyl signal, was that expected of a first-order process.

During the course of this study several other orthoesters have been synthesized with the lutidine-buffered system. Among these is a disaccharide derivative having m.p. 173 °C and $[\alpha]_D$ +18° (Table I), which was obtained from the reaction (18 h at 50 °C) of II with 1,2,3,4-tetra-*O*-acetyl-β-D-glucopyranose. This corresponds to one of two disaccharide orthoesters that have been isolated (10) from the silver-catalyzed condensation of the same compounds, an experiment that we were unable to duplicate successfully. Another derivative is one prepared for its potential use in synthesis of 2-substituted monoglycerides or 2-*O*-glycosyl-glyceritols. This is a diorthoester (Table I), undoubtedly the 1,3-diglyceride, and was obtained by treating glyceritol with two equivalents of II in dioxane–lutidine. Fischer, Bergmann, and Rabe (11) prepared 3,4-di-*O*-acetyl-β-L-rhamnopyranose (1,2-methyl orthoacetate) using quinoline as the acid acceptor and, not unexpectedly, the pure diastereomer prepared in the current study had the same physical constants as reported by them. Quinoline has been used also in a synthesis of the corresponding D-lyxose derivative (12) although its yield was only 6% whereas, now, with lutidine as base and chloroform as diluent the yield was 49%. Both of these methyl orthoacetates are analogues of IA since all three compounds give C-methyl signals at δ 1.70–1.75 p.p.m. and *O*-methyl signals at 3.25–3.29 p.p.m. However, H_1—H_2 coupling in the mannose and rhamnose derivatives ($J_{1,2}$ = 2.8 c.p.s.) is considerably smaller than in the lyxose derivative ($J_{1,2}$ = 4.7 c.p.s.). The latter value is, in fact, in the range ($J_{1,2}$ = 4.5–5.0 c.p.s.) characteristic of 1,2-orthoacetates of D-glucose (1, 9), D-galactose, and D-xylose. The apparent H_1—H_2 dihedral angles (13) represented by these two different

[4] *Variations with temperature in the relative yields of orthoester, methyl α- and β-D-mannosides, and D-mannose tetraacetate formed in this reaction have already been examined by Frush and Isbell (4).*

coupling values suggest that the chair conformation of mannopyranose (or rhamnopyranose) is distorted less by fusion of the orthoester ring than occurs with the other four sugars.

The preparation of *p*-bromobenzyl and *p*-iodobenzyl alcohol, used as hydroxylic components in this study, deserves some comment. Gilman and Melstrom (14) reported that the *p*-bromo alcohol is obtained in lower yield from *p*-bromobenzyl chloride than from *p*-bromobenzyl bromide. In addition, it has now been found that the chloride leads to a product contaminated with 15% of *p*-chlorobenzyl alcohol. This mixture was inadvertantly used initially in preparing the *p*-bromobenzyl orthoester described above. Although the orthoester also was crystalline, it too was a mixture of *p*-chloro- and *p*-bromo-derivatives, in which the ratio of the two halogens was the same as in the starting material. *p*-Iodobenzyl alcohol was prepared by lithium aluminium hydride reduction of readily available *p*-iodobenzoic acid. Fang *et al.* (15) obtained the alcohol in 25% yield from admixture with far larger amounts of benzyl alcohol. Gas–liquid chromatographic analysis of the reaction mixture showed that reduction of the carboxyl group proceeds far more rapidly than does replacement of the iodine atom. Hence, use of a relatively short reduction period affords the iodo-alcohol almost exclusively.

EXPERIMENTAL

3,4,6-Tri-O-acetyl-β-D-mannopyranose 1,2-(p-Iodobenzyl Orthoacetate)

The procedure for synthesis of this orthoester is typical of most syntheses reported herein.

A solution of *p*-iodobenzyl alcohol (250 mg) and 2,6-lutidine (0.14 ml) in chloroform (1 ml) was added to crystalline 2,3,4,6-tetra-O-acetyl-α-D-mannopyranosyl bromide (200 mg), and the reaction mixture was stored at room temperature for 24 h. Additional chloroform (15 ml) was added, the solution was washed successively with ice-cold sodium bicarbonate solution and ice water, then dried with sodium sulfate, and concentrated to dryness *in vacuo* at 55 °C. The solid residue was taken up in acetone (1.5 ml) and crystallization was promoted by addition of 1.0 ml each of ether and hexane; yield, 160 mg (69%). After recrystallization from the same solvent mixture the product had m.p. 178.5–179.0 °C; $[\alpha]_D$ 0.9° (*c*, 5.4, chloroform).

In most instances the course of the reactions was followed by n.m.r. spectroscopy, and if some unreacted acetobromo-α-D-mannose was still present (as shown by persistence of its signal for H_1) the reaction period was extended or the temperature was increased. With 1,3-*O*-benzylidene-glyceritol (m.p. 83–84 °C) for example, reaction was incomplete after 1 day but appeared to be at an end in 4 days, when the yield of crystalline product recovered was 68%. In another instance, there was little apparent reaction between II and *o*-bromobenzyl alcohol in 24 h at room temperature, but orthoester formed readily when the reaction mixture was heated under reflux. After a reflux period of 4.5 h, a 58% yield of the orthoacetate was isolated. Based on the intensity of C-methyl signals given by crude reaction products, estimated yields of orthoacetate were frequently close to 90%.

Reaction of 2,3,4,6-Tetra-O-acetyl-α-D-mannopyranosyl Bromide with Glyceritol

Glyceritol (0.44 g) was dissolved in dioxane (17 ml) containing lutidine (2.8 ml) and anhydrous calcium sulfate (6.0 g). The glycosyl bromide (4.1 g; 2.1 equivalents) was added and the reaction mixture was stored at room temperature for 5 days. Most of the dioxane was evaporated off, chloroform was added, and the chloroform solution was washed successively with ice-cold sodium bicarbonate and ice water, dried, and concentrated; yield of syrup, 2.8 g. Crystallization took place from solution in acetone–ether (yield, 0.74 g) and, after recrystallization, the solid had m.p. 164–165 °C; $[\alpha]_D$ −8.6° (*c*, 4.2, chloroform).

The mother liquor contained other orthoester material, part of which behaved chromatographically like a monosubstituted glyceryl derivative.

Reaction of 2,3,4,6-Tetra-O-acetyl-α-D-mannopyranosyl Bromide with Methanol in the Presence of 2,6-Lutidine

The glycosyl bromide (206 mg) was added to a solution (1.0 ml) of methanol and 2,6-lutidine containing 0.14 ml of the base. The reaction mixture was examined by polarimetry and also by n.m.r. spectroscopy; measurements were made over a period of 45 min of the rate of rotatory change (at 28 °C) and of the increase in intensity of the (major) C-methyl signal (probe temperature of about 35 °C). Typical of the first-order rate constant values (min^{-1}) calculated from these data are the following:

Time (min)	By n.m.r. spectroscopy	By polarimetry
10	0.0248	0.0226
15	0.0260	0.0235
20	0.0267	0.0237
40	0.0240	0.0273

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

At 40 min reaction time the yield of orthoacetate IA estimated from the intensity of its C-methyl signal was 62%.

With *sym*-collidine as base the polarimetrically estimated first-order rate constant was (average of 12 values) 0.0243 min^{-1}; with pyridine, the corresponding average value was 0.0297 min^{-1}.

p-Bromobenzyl Alcohol

Prepared from *p*-bromobenzyl bromide according to the procedure of Gilman and Melstrom (14), *p*-bromobenzyl alcohol had m.p. 77–78 °C and was analytically pure. When the starting material for its synthesis was *p*-bromobenzyl chloride (14), the alcohol obtained had the same melting point, but an incorrect elemental composition, and gave a positive test for chloride. Gas–liquid chromatographic analysis of the product showed the presence of *p*-bromobenzyl alcohol (83%) and a minor component (17%) having a shorter emergence time.

p-Iodobenzyl Alcohol

This was prepared by reduction of *p*-iodobenzoic acid with lithium aluminium hydride in ether (15). When the reduction was carried out for 1 h (15) the product was found by gas–liquid chromatographic analysis to consist of benzyl alcohol (55%) and *p*-iodobenzyl alcohol (45%). However, when the reduction period was 10 min, analysis of the product showed the presence of only 8% benzyl alcohol. The yield of *p*-iodobenzyl alcohol was 74%; after recrystallization from chloroform the melting point was 74 °C.

ACKNOWLEDGMENTS

The authors express their thanks to Dr. W. Klöker who carried out several experiments preliminary to this study, and to Dr. B. M. Craig for assistance in gas–liquid chromatographic analyses.

THE SYSTEM: BISMUTH–CADMIUM–MERCURY

A. N. Campbell and E. M. Kartzmark
Chemistry Department, University of Manitoba, Winnipeg, Manitoba
Received January 15, 1965

ABSTRACT

The liquidus surface of this ternary alloy has been determined, together with the nature of the solid phase separating from various melts. The densities and molar volumes of the binary system: Cd—Hg have been determined and it is shown that there is marked contraction when the α and β phases form from the components. X-ray powder photographs of various Cd—Hg alloys at room temperature have been made and the limits of homogeneity determined.

The binary systems from which the ternary system Bi—Cd—Hg is derived, have all been investigated previously. The system Bi—Cd is of the simple eutectic type, the eutectic lying at 144 ° and 40% Cd by weight: there appears not to be any appreciable solid solubility (1). The system Bi—Hg is also of the simple eutectic type, the eutectic lying close to the freezing point of pure mercury and containing only a trace of bismuth (2).

The system Cd—Hg is of much greater theoretical and practical interest, since the universally used cadmium standard cell makes use of a cadmium–mercury alloy of defined concentration. According to Bijl (3), Puschin (2), and Mehl and Barrett (4), this system exhibits two peritectic points, one at 190° and 50% by weight of the components, and one at −34° with a corresponding liquidus content of something less than 1% of cadmium. Corresponding to these two peritectics there are three series of solid solutions α and γ showing the cadmium and mercury lattices respectively, and β, the intermediate phase, which is said to be face-centered tetragonal. The solid solubility curves rest principally on the dilatometric work of Bijl (3). Because of the slowness with which equilibrium is established, they are highly indefinite. The careful work of Mehl and Barrett gives the limits of β and γ at the lower peritectic (−34 °) with more accuracy.

EXPERIMENTAL

The liquidus curves of the binary systems Bi—Hg and Cd—Hg, as well as certain points on the liquidus surface of the ternary system Bi—Cd—Hg, were determined, using a copper–constantan thermocouple and a Brown recorder. The system Bi—Cd is too well known to merit further attention.

All alloys were prepared by direct weighing. The mercury used was Johnson, Matthey and Mallory "technical grade", redistilled. The cadmium was "Fisher Certified Reagent", stated to contain 99.9% Cd, with traces of Cu, Pb, Fe, and Zn. The bismuth was "Fisher Certified Reagent", with traces of As, Cu, Fe, Pb, and Sb.

The weighed components were sealed in Pyrex glass containers, with inserts for the thermocouple junction. For the purposes of thermal analysis after complete fusion and shaking, the alloys were allowed to cool in the resistance furnace in which they had been prepared, after the heating current had been turned off.

The densities and molar volumes of alloys containing only cadmium and mercury were determined. The X-ray patterns of the Cd—Hg alloys were taken, using a copper anticathode and nickel filter. For this purpose, the alloys were allowed to cool over a period of 6 h in the furnace in which they were prepared. That they were in a stable state seems to be indicated by the fact that some 40 X-ray pictures of different alloys were beautifully clear and exactly reproducible. In so far as comparison is possible, our data agree with those of Mehl (5). The lattice structures of the α, β, and γ alloys had already been worked out by Mehl (5) and by Mehl and Barrett (4), but some doubt still existed as to the solid solubility curves. Our powder pictures, which reveal many more lines than those given by Mehl, indicate that the system Cd—Hg is homogeneous, at room temperature, from pure Cd up to 39 ± 3% Hg (Cd lattice), is heterogeneous from 39 ± 3% up to 45 ± 3% Hg, and after that is homogeneous (intermediate β lattice) presumably up to 92.5% Hg (Mehl and Barrett's figures). The data of our X-ray powder pictures have been accepted by A.S.T.M.

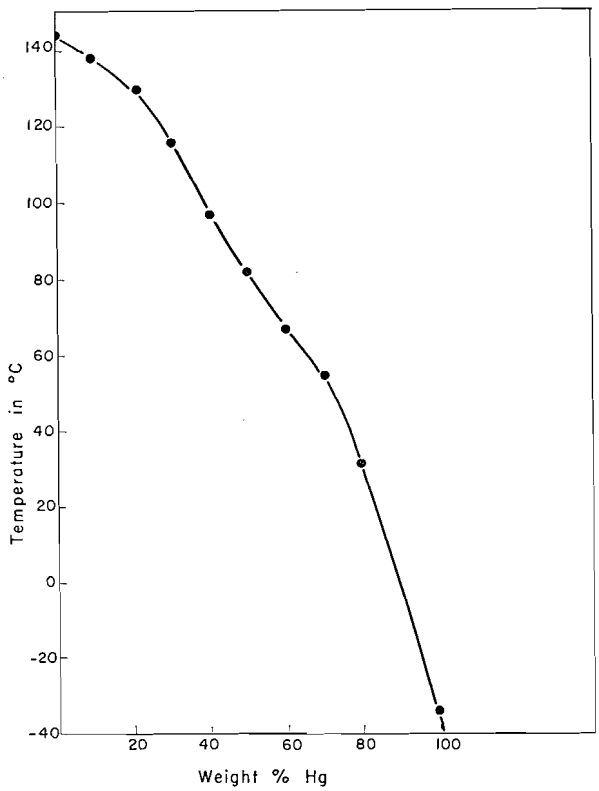

FIG. 1. Temperatures of primary crystallization vs. concentration.

The eutectic trough running across the triangular diagram from the binary eutectic of the Bi—Cd system to the low temperature (−34 °C) peritectic in the Cd—Hg system (or for that matter the eutectic of the Bi—Hg system) was determined by making up the binary eutectic of the Bi—Cd system adding increasing quantities of mercury, and submitting these pseudo-binary systems to thermal analysis. We assume that the eutectic trough is a straight line running across the diagram to the freezing point of mercury. This assumption seems to be justified by the absence of points of inflection on the cooling curve, prior to the main halt when the trough is reached.

Mixtures of the ternary system, on both sides of the eutectic trough, were made up and submitted to thermal analysis. Two halts on the cooling curves were obtained, one that of primary crystallization and the other when the eutectic trough was attained. From these data, the crystallization path and the nature of the primary crystallization were readily deduced (Fig. 1).

RESULTS

TABLE I

Densities and molar volumes of Cd—Hg alloys

Wt. % Hg	Atomic % Hg	Density at 25 °C (g/cc)	Molar volume (cc)

V	40.24	20.18	39.60	114	94
VI	19.72	20.09	60.19	88	82

DISCUSSION

The results of our thermal analysis of the system Bi—Hg are not reproduced since they are in excellent agreement with those of Puschin (2). If the solution of mercury in bismuth can by considered ideal, and in very dilute solution perhaps it can, the well-known equation

$$\Delta H/R \cdot (1/T_0 - 1/T) = \ln X_A$$

is applicable. In this formula ΔH is taken to be the molar heat of fusion of the solvent (bismuth). If, however, the solution is not infinitely dilute, the heat effect becomes the sum of the heats of fusion and the heats of mixing of molten bismuth with liquid mercury, neglecting differences in the specific heats of the component metals and the fluid amalgams. Applying this equation to our data, we obtain Table IV.

TABLE IV

Calculated heat effects

Wt. % Bi	ΔH (kcal/mole)
5	5.812
10	4.136
20	3.877
30	3.255
40	2.990
50	2.783
90.2	2.283
100.0	2.132*

*Calculated from experimental heat of fusion.

As the composition approaches that of pure bismuth, the calculated ΔH approaches the (experimental) heat of fusion of bismuth as, of course, it must. It would be unsafe to assume that the large discrepancies at lower concentrations of bismuth represent heats of mixing of molten bismuth with mercury: they more probably represent nonideality of the melt. Nevertheless, it appears that solutions containing up to 10% mercury behave in a fairly ideal manner.

Our thermal analysis figures for the system Cd—Hg confirm those of Bijl (3), who did the classical work on this system. It must be confessed, however, that our results would not reveal the existence of a peritectic at 190° and, indeed, if Bijl's own results are plotted, they could easily be interpreted as representing a smooth curve. There is no doubt of the existence of this peritectic but it does not appear very evidently as the result of thermal analysis. As the peritectic cannot be detected by thermal analysis, in the binary system, Cd—Hg, it is hopeless to attempt to determine the position of the peritectic trough by thermal analysis in the ternary system. For diagrammatic purposes we have joined the binary peritectic by a dotted line to the Bi apex, terminating it at its intersection with the eutectic trough: this intersection occurs at a composition of 21% Hg, 47.5% Bi, 31.5% Cd and corresponds to a temperature on the eutectic trough of 120° (Fig. 2).

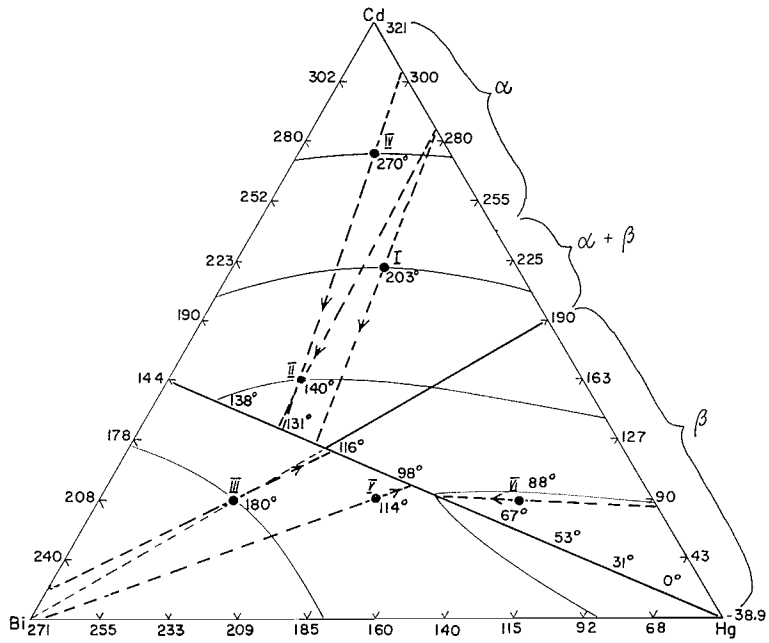

FIG. 2. Isothermal lines and crystallization paths.

When the molar volumes of cadmium–mercury alloys (Table III) are plotted against mole %, a three-branch curve, lying well below the straight line of ideal behavior, is obtained. The discontinuities correspond roughly to the limits of α and β solid solubility, as given by Mehl and Barrett (4). Since the molar volumes are always less, sometimes considerably less, than the sum of the volumes of the components, it is obvious that α and β solid solutions form with lattice contraction or, more exactly, that the cadmium lattice does not expand very greatly with the entrance of mercury atoms. The β lattice

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

is face-centered tetragonal and, therefore, different from those of cadmium or mercury. For this modification also the total volume is much less than the sum of those of the components. In fact, at the mercury limit of the β range, the molar volume differs by about 0.7 cc from the ideal (straight line) molar volume of 14.25 cc, a contraction of 5%. We did not push our measurements beyond 70 mole % mercury, i.e. we dealt only with alloys that are completely solid at room temperature.

The temperature arrests on cooling of ternary mixtures have been plotted on the triangular diagram of Fig. 2. These points have been joined by smooth curves to the corresponding temperatures on the sides of the diagram, thus generating isothermal lines, which give indications of the curvature of the liquidus surface. The compositions have been joined by straight lines to those compositions on the eutectic trough, corresponding to the observed eutectic inflections on the cooling curves. When these straight lines are produced backwards to the corresponding binary system, the nature of the primary phase separating becomes apparent, in other words these lines represent crystallization paths. This procedure is only justified on the assumption that the phase separating contains no bismuth. Tammann and Rocha (6) have shown that the solubility of Bi in Cd is less than 0.05% at the eutectic temperature. These primary phases are read off as follows.

Mixture No. (Table II)	Primary phase separating
I	α containing 18% Hg
II	α containing 12% Hg
III	bismuth
IV	α containing 7% Hg
V	bismuth
VI	β containing 81.5% Hg

PRESSURE-INDEPENDENT FLOW SYSTEM PYROLYSIS OF DIMETHYL CADMIUM

M. KRECH AND S. J. PRICE
Department of Chemistry, University of Windsor, Windsor, Ontario
Received January 26, 1965

ABSTRACT

The pyrolysis of $CdMe_2$ has been investigated in a benzene carried flow system using temperatures from 743 °K to 800 °K and pressures from 1.63 cm to 16.2 cm. High pressure limiting rate constants were obtained above approximately 8 cm pressures. The high pressure activation energy, E_0, of 48.8 ± 1 kcal/mole is identified with D(MeCd—Me) within the limits $D < E_0 < D + RT$.

INTRODUCTION

Three previous investigations of the pyrolysis of $CdMe_2$ have been reported (1, 2, 3). In the first investigation a marked surface reaction was noted but no attempt was made to isolate the homogeneous components of the reaction (1). The second study was carried out in a toluene carrier flow system by one of the present authors (2). This gave log $k = 11.9 - (45\,800/2.3RT)$ at 18 mm pressure. Under the experimental conditions used k was still a function of pressure. No appreciable surface effects were noted. The third investigation was carried out in a static system in the absence of any inhibitors (3). Rate constants were calculated on the basis of the undecomposed alkyl. A marked surface effect was again noted. To obtain the homogeneous rate, reactions were carried out at a number of surface to volume ratios and extrapolated to zero. The reaction was studied at only one temperature and a selected value of log $A = 13.08$ was used to calculate an experimental activation energy of 43.5 ± 1.4 kcal/mole.

EXPERIMENTAL

Materials

(*a*) Dimethyl cadmium was prepared from $CdCl_2$ by a procedure identical to that previously used to make dimethyl mercury (4). The fraction with b.p. 105 °C at 754 mm was collected and stored under its own vapor pressure at −78 °C.

(*b*) Spectro grade benzene was prepared for use by refluxing over sodium for 24 h and then degassing twice by bulb-to-bulb distillation. The benzene used in each experiment was freshly degassed by bulb-to-bulb distillation immediately before use.

Apparatus and Procedure

The apparatus and procedure used were similar to those previously employed in the study of dimethyl mercury (4). Contact of dimethyl cadmium vapor with mercury was minimized by replacing the mercury manometer of the alkyl injection system used in the dimethyl mercury work with a spoon gauge. The temperature control trap was kept at −100 °C so that any propane formed would be collected with the other gaseous products. Analysis of gaseous products was carried out by gas chromatography using a 1 m silica gel column at 80 °C and a flow rate of 20 cc/min. Analysis of the liquid products from the dry ice – acetone trap was carried out using a 1 m diisodecyl phthalate on diatomaceous earth column at 120 °C with a helium flow rate of 15 cc/min.

RESULTS AND DISCUSSION

The results are shown in Table I. They may be represented by a mechanism similar to that proposed for the decomposition of $Cd(CH_3)_2$ in a toluene carrier system (2):

[1] $$Cd(CH_3)_2 \rightarrow CdCH_3 + CH_3$$

[2] $$CdCH_3 \rightarrow Cd + CH_3$$

*Amount used in a given run.

[3] $CH_3 + C_6H_6 \rightarrow CH_4 + C_6H_5$

[4] $2CH_3 \rightarrow C_2H_6$

[5] $2C_6H_5 \rightarrow C_{12}H_{10}$

[6] $CH_3 + C_6H_5 \rightarrow C_6H_5CH_3$

[7] $CH_3 + C_2H_6 \rightarrow C_2H_5 + CH_4$

[8] $C_2H_5 \rightarrow C_2H_4 + H$

[9] $H + C_6H_6 \rightarrow C_6H_5 + H_2$

[10] $C_2H_6 + CH_3 \rightarrow C_3H_8$

where reaction [2] is much faster than reaction [1]. In the present investigation the extent of reaction [6] has been quantitatively determined and analyses for ethylene and propane have been made in each run. Rate constants have therefore been calculated from the usual first-order rate equation assuming fraction decomposed =

$$\frac{\frac{1}{2}(\text{moles } CH_4 + \text{moles toluene}) + \text{moles } C_2H_6 + \text{moles } C_2H_4 + \frac{3}{2}\text{ moles } C_3H_8}{\text{moles } Cd(CH_3)_2} .$$

A blank correction of 3×10^{-5} mole of methyl radicals was subtracted to allow for decomposition that occurred in the alkyl injection system.

The rate constant was studied as a function of pressure at four temperatures. From plots of log k vs. log P, it is apparent that at all temperatures used k_1 is independent of pressure above approximately 8 cm. Figure 1 shows the Arrhenius plots for the high pressure limit and for 18 mm. The lines may be represented respectively by:

$$\log k\ (s^{-1}) = 13.4 - (48\,800/2.3RT)$$

and

$$\log k\ (s^{-1}) = 12.3 - (45\,800/2.3RT).$$

The results at 18 mm are in good agreement with the previous flow system study of dimethyl cadmium if due allowance is made for the different energy transfer efficiencies of benzene and toluene.

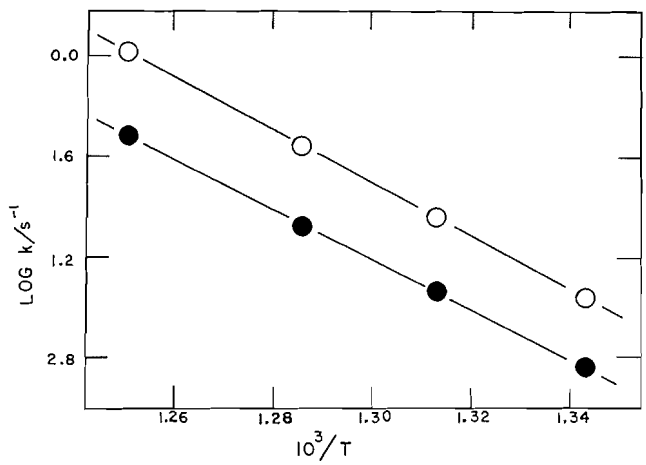

FIG. 1. Arrhenius plots for the decomposition of dimethyl cadmium at the high pressure limit (○), and at 18 mm pressure (●).

For personal use only.

The high pressure activation energy may be related to D(MeCd—Me). The best value for the sum of the two metal–carbon bond dissociation energies is 65.6 kcal/mole (5). Hence:

$$D(\text{MeCd—Me}) = 48.8 \text{ kcal/mole}$$

$$D(\text{Me—Cd}) = 16.8 \text{ kcal/mole.}$$

If the present high pressure frequency factor is used to recalculate D(MeCd—Me) from the results of Laurie and Long (3) a value of 44.3 kcal/mole is obtained. This value would seem to be too low, indicating complexities in the static system work which have not been taken into account.

THE PHOTOLYSIS OF CYCLOPENTANONE AND CYCLOBUTANONE[1]

R. F. KLEMM, D. N. MORRISON, P. GILDERSON, AND A. T. BLADES
Research Council of Alberta, Edmonton, Alberta

Received February 1, 1965

ABSTRACT

The vapor phase photolysis of cyclopentanone, cyclopentanone-d_8, and cyclobutanone have been investigated at 3 130 Å and 2 537 Å under a variety of conditions. In cyclopentanone photolysis a pressure- and wavelength-dependent "falloff" has been observed in the product ratio cyclobutane:ethylene, while a similarly dependent effect in the ratio cyclopropane:propylene exists in cyclobutanone photolysis. In the light of this data a reappraisal has been made of existing concepts regarding the photodecomposition of these ketones.

INTRODUCTION

The photochemistry of cyclic ketones has been summarized by Srinivasan (1). Thus, it has been affirmed that the photolysis of cyclopentanone vapor at temperatures up to 125° at 3 130 Å, and at shorter wavelengths up to 300°, involves a stoichiometry given by the following reactions,

$$\overbrace{CH_2CH_2CH_2CH_2CO} \xrightarrow{h\nu} 2C_2H_4 + CO$$
$$\rightarrow \text{cyclo-}C_4H_8 + CO$$
$$\rightarrow H_2C{=}CHCH_2CH_2CHO,$$

wherein the importance of 4-pentenal relative to total products increases with pressure at any given temperature. In addition, cyclopentanone exhibits fluorescence in all three phases with a maximum at 4 100 Å; however, the phosphorescence observed in condensed phases does not appear in the vapor (2).

The photolysis of cyclobutanone has not been as thoroughly studied as that of cyclopentanone; but in a similar way, the products of cyclobutanone photolysis are presumed to arise by

$$\overbrace{CH_2CH_2CH_2CO} \xrightarrow{h\nu} C_2H_4 + CH_2CO$$
$$\rightarrow \text{cyclo-}C_3H_6 + CO$$
$$\rightarrow C_3H_6 + CO.$$

Unfortunately, however, CO was found in excess of (cyclo-C_3H_6 + C_3H_6), while the equivalence of C_2H_4 and CH_2CO is difficult to establish analytically.

The important observation from the present standpoint is that the ratio cyclobutane: ethylene in cyclopentanone photolysis at 3 130 Å and 2 537 Å appears to have a constant value independent of temperature in the pressure range investigated (10–300 mm Hg). In contrast, the cyclopropane:propylene ratio in cyclobutanone ratio in cyclobutanone photolysis is wavelength sensitive and preliminary suggestions of a pressure dependence have also been reported (1). This implies a common energetic precursor for these products which may be distinct from the precursor of the other products, ethylene and ketene. Such a possibility and the seemingly dissimilar behavior in cyclopentanone prompted a reexamination of both systems with particular reference to temperature, pressure, and wavelength effects to further clarify the situation. The study of these systems also bears

[1]*Contribution No. 291 from the Research Council of Alberta, Edmonton, Alberta, Canada.*

relevantly upon the thermal reactions of cyclic molecules. Furthermore it seemed of some importance to repeat the experiments of Flowers and Frey (3), in which the ability of ethylene to react with polymethylene diradicals was described.

MATERIALS

Cyclopentanone (Eastman Kodak White Label) was distilled on a 1 m pyrex helices-packed column with a vapor takeoff. Gas chromatographic analysis using a polyethylene glycol 400 column in conjunction with a hot wire detector indicated the absence of impurities. When not in use the cyclopentanone thus prepared was stored in the dark and under vacuum at −80°. Cyclopentanone-d_8 was supplied by Merck, Sharp, and Dohme, Montreal, and was used without further purification. The cyclobutanone, an Aldrich Chemical Co. product, was treated in the same way as the cyclopentanone. Crude 4-pentenal was obtained from the thermal isomerization of allyl vinyl ether (4). It was purified by preparative scale gas chromatography on a polyethylene glycol 400 column. Toluene was prepyrolyzed, dried, distilled on an efficient column with vapor takeoff, and stored under vacuum in sealed ampoules. Ethylene (Phillips Research Grade) was distilled from −160° to −196° prior to use to ensure its purity with respect to C_5 and C_6 hydrocarbons.

APPARATUS AND PROCEDURE

The customary static vacuum system employing metal Hoke valves sufficed for experiments at 3 130 Å, while experiments at 2 537 Å were similarly conducted but in a mercury-free system. Cylindrical quartz cells of 172 cc and 535 cc were used and enclosed in lagged aluminium furnaces. The 3 130 Å radiation from a Hanovia-type SH medium pressure lamp entered the cell after passing through a 2 mm pyrex filter followed by a 2 mm Corning 0–54 filter. A low pressure mercury resonance lamp provided 2 537 Å, the 1 849 Å component being removed by a Corning 7–54 filter. The ketones were admitted to the cell either from small gas-metering volumes or weighed ampoules, or measured directly by a calibrated Pirani gauge. Exposure times ranged from a few minutes to 4 h.

After irradiation the procedure with cyclopentanone was to remove most of the substrate at −64° while distilling the more volatile products into a small U trap filled with activated silica gel at −196°. The latter trap heated to 150° formed the sample inlet to a 10 ft polypropylene glycol column which was followed by either a Gow-Mac hot wire detector or an Aerograph model 600 hydrogen-flame detector. The above chromatographic column provided an adequate separation of C_2H_4 from cyclobutane in particular and by a suitable choice of column temperature all hydrocarbons through C_6's. An essentially similar procedure was used for cyclobutanone; in this case, however, the propylene and cyclopropane were better resolved by a 20 ft squalane column. Where CO analyses were warranted, a 2 ft charcoal column at 0° was found adequate.

RESULTS AND DISCUSSION

A. Cyclopentanone

Results

It was again confirmed that over the temperature range 28-225° and the pressure interval 0.09–30 mm cyclopentanone the only hydrocarbon products appearing at low extent of reaction are C_2H_4 and cyclo-C_4H_8. The relationship $\Phi(CO) = \frac{1}{2}\Phi(C_2H_4) + \Phi(\text{cyclo-}C_4H_8)$ was also verified.

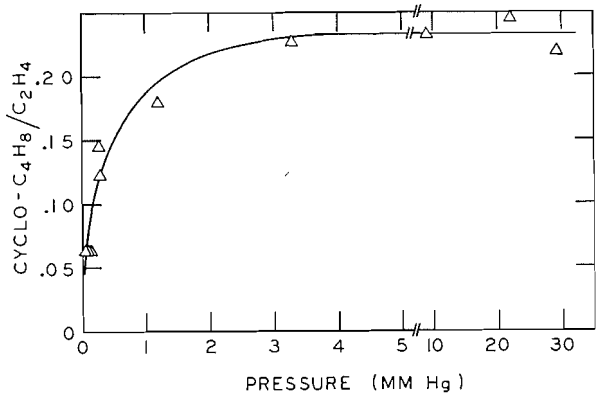

FIG. 2. Ratio of product yields, cyclo-C_4H_8:C_2H_4 vs. cyclopentanone pressure; at 2 537 Å and 100°.

The variation in R with cyclopentanone pressure at 3 130 Å presented in Fig. 1 shows R to definitely decrease at substrate pressures below 4 mm Hg for both the normal and deuterated compound, while Fig. 2 presents the more dramatic effect observed at 2 537 Å. The results with normal cyclopentanone represent overlapping data from two photolysis cells of similar geometry but differing by a factor of 3 in volume. It was further demonstrated that, over the entire pressure range studied, R was not a function of light intensity. The data in Table I also indicate that no apparent change in R with irradiation time or percent decomposition occurs over the same pressure interval. This is to be contrasted with the observations of Butler, *et al.* (5) which indicated an asymptotic decrease in R taking place from 0.075–0.75% reaction, albeit in the interval 6–10 mm cyclopentanone, where, perhaps, only the last of the three sets of data in Table I would then be a relevant comparison.

TABLE I

Effect of irradiation time on [cyclo-C_4H_8]/[C_2H_4] at 3 130 Å, 102°

Cyclopentanone pressure, mm	Duration of photolysis, min	R([cyclo-C_4H_8]/[C_2H_4])	% decomp. based on CO
0.188	30	0.19_6	0.55
0.194	18	0.19_6	0.34
0.494	30	0.20_8	0.8
0.432	90	0.21_2	2.6
13.7	10	0.24_6	0.070
19.7	180	0.23_8	0.62

Furthermore, in contrast to the work of Flowers and Frey (3), no C_6 olefins or cyclohexane were detected upon photolysis of 5–6 mm cyclopentanone in the presence of up to 850 mm C_2H_4. In fact, experiments indicate addition of C_2H_4 has little or no effect on R at this pressure other than reducing the actual amounts of C_2H_4 and cyclo-C_4H_8 formed. This conclusion rests upon the measurement of CO and cyclo-C_4H_8 in the presence of added C_2H_4 and assuming the relation [CO] = $\frac{1}{2}$[C_2H_4] + [cyclo-C_4H_8] still holds.

It seemed entirely possible that subsequent to energy absorption, cyclopentanone isomerized rapidly to either an electronically or a vibrationally excited state of 4-pentenal from which the observed hydrocarbons then arose. Consequently it was deemed relevant to look at both the photolysis and pyrolysis of 4-pentenal. Photolysis of well-characterized

samples of 4-pentenal at 3 130 Å and 100° over the range 1.0–30 mm 4-pentenal afforded butene-1 as the major (90%) hydrocarbon product along with smaller amounts ($\sim 2\%$) of C_2H_4, C_3H_6, butene-2, and pentene-1; formaldehyde and acetaldehyde were also evident. These products suggest concomitant molecular and free radical reaction modes. Pyrolysis of 4-pentenal by the toluene carrier technique at 575° and 0.1–0.2 s contact time yielded propylene and C_2H_4 as major hydrocarbon products plus smaller amounts of butene-1 and butene-2. No cyclo-C_4H_8 was evident in either photolysis or pyrolysis of 4-pentenal.

Discussion

A mechanism for the photolysis of cyclopentanone must allow for the following salient features: (*a*) variation of the 4-pentenal:CO ratio with pressure, wavelength, and temperature (6); (*b*) invariance of cyclo-C_4H_8:C_2H_4 ("*R*") with pressure and wavelength at high pressures (6); and (*c*) the wavelength-dependent decrease in *R* at low pressure. Srinivasan (6) originally suggested the vibrational energy possessed by the electronically excited cyclopentanone at the instant of its decomposition determines its mode of photolysis. His mechanism may be schematically represented as

$$\overline{CH_2CH_2CH_2CH_2CO} \xrightarrow{h\nu} (C_4H_8CO)^* \xrightarrow{k'M} \text{4-pentenal}$$
$$(C_4H_8CO)^* \xrightarrow{k_1} 2C_2H_4 + CO \qquad (C_4H_8CO)^* \xrightarrow{k_2} \square + CO$$

and is adequate to explain (*a*) and (*b*) above. To the extent that such a scheme appears to be insufficient to cope with (*c*), further definition is needed to allow for an added source of ethylene at low pressure, most likely at the expense of cyclobutane. A modification which essentially retains the concept of three independent reaction paths is the following.

$$\overline{CH_2CH_2CH_2CH_2C{=}O} \xrightarrow{h\nu} (C_4H_8CO)^* \xrightarrow{k'M} \text{4-pentenal}$$
$$(C_4H_8CO)^* \xrightarrow{k_1} C_2H_4 + C_2H_4CO \xrightarrow{k_4} C_2H_4 + CO$$
$$(C_4H_8CO)^* \xrightarrow{k_2} \square^* + CO \xrightarrow{k_3} 2C_2H_4 \qquad \square^* \xrightarrow{kM} \square$$

The species $C_4H_8CO^*$ initially presents a rather narrow spectrum of energies defined by the absorbed radiation and the thermal energy distribution of cyclopentanone. This designation may in fact include several discrete species representing various photophysical processes such as intersystem crossing and internal conversion. That the structure of $C_4H_8CO^*$ is in part like 4-pentenal might conceivably be inferred from its collisional conversion to 4-pentenal. However, the failure of 4-pentenal, on pyrolysis or photolysis, to give any trace of cyclo-C_4H_8 must be invoked against such a possibility. A diradical structure for $C_4H_8CO^*$ ties in well with its proposed unimolecular reactions; but this should not be construed as definite evidence for such a configuration. The decomposition of $C_4H_8CO^*$ into C_2H_4 and C_2H_4CO (which subsequently affords C_2H_4 and CO) is necessary to formally distinguish this route to C_2H_4, and hence k_1, from the additional source of C_2H_4 represented by the sequence involving k_2 and k_3. The reaction path utilizing k_1 has an obvious analogy to the formation of C_2H_4 and ketene in cyclobutanone photolysis. Further justification for considering such a similarity will be made in the discussion arising out of the cyclobutanone data.

Because of the energy partitioning with CO during its formation, cyclo-$C_4H_8^*$ carries a wider range of energies than its parent, $C_4H_8CO^*$. As with $C_4H_8CO^*$, no direct evidence has been obtained on its precise configuration; but one real possibility would be for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$C_4H_8CO^*$ to yield cyclo-C_4H_8 and CO directly, as Srinivasan (1) supposes. The formation of cyclo-C_4H_8 and CO from cyclopentanone requires around 26 kcal/mole. When this figure is combined with the 91 kcal/mole representing 3 130 Å radiation, one finds that 65 kcal/mole plus the thermal energy of $C_4H_8CO^*$ are to be partitioned between cyclo-C_4H_8 and CO. Because of its many more vibrational degrees of freedom it is likely that cyclo-C_4H_8 will carry away the majority of this energy. A similar energy calculation suggests even more convincingly the participation of vibrationally excited cyclo-C_4H_8 at 2 537 Å. Thus it is proposed that this species contains enough energy at both 3 130 Å and 2 537 Å to yield two molecules of C_2H_4 (a process for which an activation energy of 61 kcal/mole has been reported (7)) if it is not collisionally deactivated first.

Having thus delimited the various reactive species and their possible fates, comparison between mechanistic predictions and experimental observations opens further areas for discussion. A mathematical analysis of the mechanism with the usual steady-state assumptions gives for R, the ratio cyclo-C_4H_8:C_2H_4

$$R = \frac{k_2 k M}{2k_1 k M + 2k_3(k_2 + k_1)}.$$

At high pressure R approaches $k_2/2k_1$ independent of substrate pressure. Figures 1 and 2 indicate this high pressure limit is independent of wavelength and deuterium substitution, while Srinivasan's (6) data indicate R does not vary with temperature either. It seems possible to suggest two explanations for such behavior: either the Rice, Ramsperger, Kassel (RRK) expressions, $k = A(1 - (E_a/E))^{s-1}$, for k_1 and k_2 are congruent over the range of energies involved or C_4H_8 is already so highly excited as a result of 3 130 Å absorption that the decompositional modes represented by k_1 and k_2 are insensitive to the further gross change in energy when irradiating with 2 537 Å. A choice of explanations is not possible unless one makes the rather dubious assumption that the collisional deactivation efficiency k' does not change with wavelength. This allows one to turn to other information to resolve the point. Thus, the mechanism proposed above demands [4-pentenal]/[CO] = $k'M/(k_1 + k_2)$, a linear relationship which has been observed by Srinivasan (6) at 125° and 3 130 Å. The limited data provided by Srinivasan indicates a lower slope for [4-pentenal]/[CO] at 2 537 Å, and hence $(k_1 + k_2)$ appears to change with energy. Therefore the constancy of R would result from the former assumption, namely that of coincident RRK expressions for k_1 and k_2, at least over the energy interval 3 130 – 2 537 Å.

In the high pressure region the refined mechanism concurs additionally with the results obtained from the photolysis of cyclopentanone-2,2,5,5-d_4 where only ethylene-1,1-d_2 was found (1). Since these experiments were done above 11 mm cyclopentanone and in the region where only k_1 determines the source of C_2H_4, the more statistical distribution of deuterated ethylene which would indicate the participation of "hot" cyclobutane is not expected.

As the pressure tends to zero, R becomes a function of M, the substrate pressure:

$$R(M \to 0) \simeq \frac{k_2 k M}{2k_3(k_2 + k_1)}$$

in accord with the behavior observed. However, a strictly linear dependence of R on M in the limit is to be qualified by a concurrent decrease in k_3 with decreasing pressure. This occurs because the lower the pressure the greater is the relative contribution to the formation of ethylene from molecules of cyclo-$C_4H_8^*$ with smaller reaction probabilities,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

i.e. smaller values of k_3, so that an increasingly more positive slope is expected in the R vs. pressure plots as one approaches zero pressure. In this low pressure region the lower value of R at 2 537 Å compared to that at 3 130 Å for a given substrate pressure reflects the higher energy content of cyclo-C_4H_8* and the consequently larger value of k_3. No doubt a lower efficiency for collisional deactivation contributes to the lower values of the ratio R at 2 537 Å, also.[2]

Since the expression above for the ratio R involves k_3, the rate constant which describes the unimolecular decomposition of activated cyclo-C_4H_8, it is in this low pressure range that photolysis of cyclopentanone-2,2,5,5-d_4 might serve to support our proposal for participation of vibrationally excited cyclo-C_4H_8.

B. Cyclobutanone

Results

As in earlier literature (1) the products observed were C_2H_4, CH_2CO, C_3H_6, cyclo-C_3H_6, and CO. At 3 130 Å and 100° $[CO]/([C_3H_6] + [\text{cyclo-}C_3H_6]) = 1.1 \pm 0.1$ over the range 10–200 mm cyclobutanone, contrary to previous data indicating CO to be formed much in excess of C_3's (8). However, equivalence of CO with total C_3's is to be expected if their formation is concurrent and CH_2CO photolysis negligible. At 100 °C and over the pressure range 10–200 mm cyclobutanone the ratio C_2H_4:CO was 1.7 ± 0.1 at both 3 130 Å and 2 537 Å. A slight ($\sim$ 1 kcal/mole) temperature coefficient was noted in the latter ratio at 3 130 Å. Other than this, at a given substrate pressure, no temperature variation in the product distribution was detectable. As with cyclopentanone, irradiation of 2–5 mm cyclobutanone in a large excess of C_2H_4 failed to yield the pentenes previously attributed to the interaction of trimethylene and C_2H_4 (3). The pressure dependence of R at 3 130 Å is depicted in Fig. 3 and in Fig. 4 for data obtained at 2 537 Å, all experiments performed at 100°. Thirty-fold variation in lamp intensity again did not alter the data.

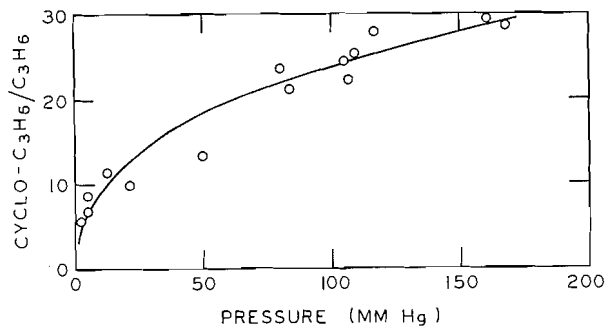

FIG. 3. Ratio of product yields cyclo-C_3H_6:C_3H_6 vs. cyclobutanone pressure; at 3 130 Å and 100°.

Discussion

Although the data obtained in cyclobutanone photolysis parallel, in general, that from cyclopentanone, the products of cyclobutanone photolysis show a number of differences: (*a*) a very minor isomerization product analogous to 4-pentenal (1); (*b*) two distinct sets of decomposition products; and (*c*) potential rearrangement rather than decomposition of the cyclic hydrocarbon if sufficient energy is available. Lack of the rearrangement product, 3-butenal, is to be expected for reasons based on the geometry of the nearly

[2]*A referee has kindly pointed out that if a single collision does not render cyclo-C_4H_8* incapable of decomposition, then the effect of a series of collisions would be to lower the average energy of cyclo-C_4H_8*, and thus lower the average k_3 with increasing pressure.*

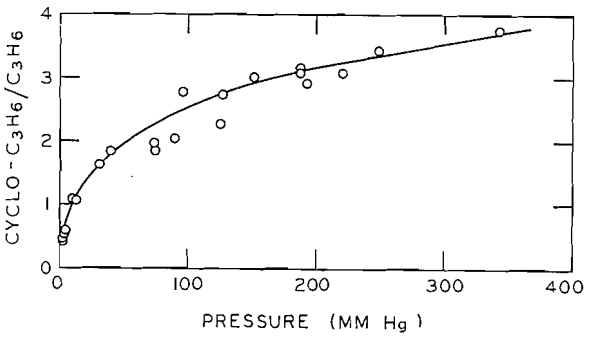

FIG. 4. Ratio of product yields, cyclo-C_3H_6:C_3H_6 vs. cyclobutanone pressure; at 2 537 Å and 100°.

planar cyclobutanone ring, provided such an isomerization is viewed as a concerted four-center process (1). In addition, compared to cyclopentanone, cyclobutanone contains half the number of β-hydrogens that are directly involved in aldehyde formation. On energetic grounds less 3-butenal would be expected simply because a comparable energy must be distributed among fewer degrees of freedom and a greater tendency exists for a 3-butenal precursor to decompose. The formation of C_2H_4 and CH_2CO may be considered a parallel to that reaction of cyclopentanone affording initially C_2H_4 and C_2H_4CO. The pressure effect shown in Figs. 3 and 4 implies that allowance must be made both for the unimolecular rearrangement of an excited cyclopropane and its deactivation or stabilization by collision.

Pursuant to this line of reasoning the following mechanism is proposed in analogy with that developed for the cyclopentanone photolysis:

$$CH_2CH_2CH_2C{=}O \xrightarrow{h\nu} (C_3H_6CO)^* \dashrightarrow H_2C{=}CH{-}CH_2CHO$$

$$(C_3H_6CO)^* \xrightarrow{k_1} C_2H_4 + CH_2O$$

$$(C_3H_6CO)^* \xrightarrow{k_2} \text{cyclo-}C_3H_6^* + CO$$

$$\text{cyclo-}C_3H_6^* \xrightarrow{k_3} C_3H_6$$

$$\text{cyclo-}C_3H_6^* \xrightarrow{kM} \text{cyclo-}C_3H_6.$$

Here $(C_3H_6CO)^*$ is considered to initially have that rather narrow energy spectrum characteristic of the absorbed radiation. The same loose definition of $(C_3H_6CO)^*$ applies here as was developed in the case of $(C_4H_8CO)^*$. The dotted arrow to 3-butenal indicates the absence, or extremely small importance, of this reaction path while preserving the analogy to cyclopentanone. According to this reaction sequence it is obvious that the ratio C_2H_4:CO is given by k_1/k_2. Experimentally a value 1.7 ± 0.1 has been found to be independent of wavelength and pressure. This is compared with the similar value from cyclopentanone of $k_1/k_2 = 2$, which is the high pressure limit of $[C_2H_4]/2[\text{cyclo-}C_4H_8]$ and is likewise wavelength independent. Such coincidence in value and behavior, though possibly fortuitous, adds a measure of reinforcement to such a unified mechanism for both ketones.

Simultaneous with its elimination of CO, $C_3H_6CO^*$ is allowed to form a cyclo-C_3H_6 structure, for which process, beginning with cyclobutanone, about 16 kcal/mole are required. At 3 130 Å cyclo-C_3H_6 and CO must partition $91 - 16 \simeq 75$ kcal/mole, which,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

if it is accepted that cyclo-C_3H_6 retains the major portion, is sufficient energy to isomerize the cyclo-C_3H_6 to propylene. The extent of this conversion is dependent upon the rate of collisional deactivation and the exact energy content of cyclo-C_3H_6*. Hence, although a steady-state treatment of the mechanism predicts

$$\frac{[\text{cyclo-}C_3H_6]}{[C_3H_6]} = \frac{kM}{k_3}$$

in fact k_3 is a function of the energy allowed cyclo-C_3H_6*, which at 2 537 Å is on the average up to 21 kcal greater than at 3 130 Å; this accords with the smaller slope depicted in Fig. 4 compared with that in Fig. 3. In the low pressure region of Figs. 3 and 4 curvature of R vs. pressure plots is expected in the direction observed because of the wide variation in the excess energy of cyclo-C_3H_6*, the exact curvature determined by the energy of excitation distribution curve and the variation of k_3 with energy.

Although the success of the present slight modifications of the original proposals of Srinivasan (1) in correlating the photochemical behavior of cyclopentanone and cyclobutanone is certainly appealing, the type and accuracy of the data accumulated to date do not prompt the more precise definition of mechanism desired. Certainly the experimental evidence definitely establishes a pressure falloff in the ratios cyclo-C_4H_8:C_2H_4 and cyclo-C_3H_6:C_3H_6. Such behavior means the interdependent formation of cyclic hydrocarbon and its decomposition or rearrangement product will require appropriate consideration in the further elucidation of the photolysis of these cyclic ketones.

THE RELATIVE SIGNS OF THE PROTON COUPLING CONSTANTS IN DIKETENE AND VINYL FORMATE

F. HRUSKA,[1] H. M. HUTTON, AND T. SCHAEFER[2]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

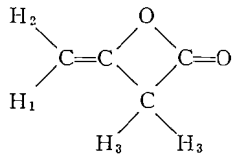
Received February 2, 1965

ABSTRACT

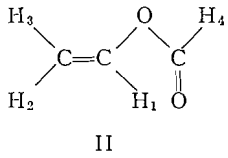
The relative signs of the proton coupling constants in diketene and vinyl formate have been determined by the field-sweep selective decoupling method. In both compounds, the couplings between protons separated by an even number of bonds are of the same sign, but of opposite sign to the couplings between protons separated by an odd number of bonds. The coupling mechanisms, especially in vinyl formate, are discussed briefly.

INTRODUCTION

In proton magnetic resonance, coupling between protons separated by more than three bonds is called "long-range coupling" and is observed in many molecules. A recent review by Sternhell collects a considerable body of data on this topic (1). One of the uses of these data will be in the establishment of configurations and conformations of organic molecules (1). Less is known about the relative signs of the coupling constants, which can be determined sometimes by the analysis of strongly coupled spectra (2). However, the method of double irradiation is more powerful in this respect (3–8).



I



II

In this paper we describe the determination of the relative signs of the coupling constants in diketene and vinyl formate (I and II) by Freeman's selective double irradiation method (4, 5). Although the magnitudes of the coupling constants are known for both diketene (9) and vinyl formate (measured in this laboratory (12)), the spectra at 40 or 60 Mc/s are not strongly coupled and the relative signs had not been determined. The long-range couplings in diketene, $H_{1,2}$—C=C—C—H_3, are known as allylic couplings (1), while the long-range couplings in vinyl formate are an example of coupling across a hetero atom, oxygen.

EXPERIMENTAL

1. Materials

Diketene was obtained from the Aldrich Chemical Company and vinyl formate from the Borden Chemical Company. Both chemicals were used without further purification. Diketene was studied as a 6 mole % solution in benzene with tetramethylsilane (TMS) as an internal reference. At this concentration the proton spectrum was approximately an AKX_2 system (11). Vinyl formate was studied with 2 mole % TMS as internal reference and the spectrum was nearly an AKRX system (11).

2. Single Resonance Measurements

The spectra of the two solutions were recorded on a Varian DP60 spectrometer at room temperature and calibrated by the side-band technique. The spectra were analyzed as ABX_2 (diketene) and ABRX (vinyl formate) systems using an average of at least 10 spectra.

[1]*Holder of a N.R.C. Studentship, 1964–1965.*
[2]*Holder of an N.R.C. Senior Research Fellowship, 1964–1965.*

3. Double Resonance Experiments

The double resonance experiments involved a Varian integrator V3521A and Hewlett-Packard 200CD audio oscillator to which a set of reduction gears was attached, allowing changes in frequency settings of 0.1 c/s at about 2 kc/s. The frequency of the 2kc/s side band of the integrator varied slightly from day to day and was remeasured before each set of experiments. The required frequency settings for the selective double irradiation experiments by field-sweep methods were obtained from the measured line positons in the single resonance spectra and are reliable to ±0.2 c/s. All calculated decoupling frequencies for various relative sign possibilities were examined for complete decoupling.

RESULTS

The chemical shifts with respect to internal TMS and the coupling constants are given in Table I. The numbering is as in I and II above. Figures 1 and 2 show the single resonance spectra obtained for these two compounds. For the convenience of tabulating the decoupling data below, the proton peaks for vinyl formate are numbered in Fig. 2, starting from high field.

TABLE I

Coupling constants and chemical shifts in diketene and vinyl formate in c/s at 60 Mc/s

Coupling constants*		Chemical shifts†	
Diketene	Vinyl formate	Diketene	Vinyl formate
$J_{12} = -3.87\ (3.92)$‡	$J_{12} = 6.4\ (6.3)$§	$H_1 = -271.5$	$H_1 = -439.8$
$J_{13} = -1.94\ (1.82)$	$J_{13} = 13.9\ (13.8)$	$H_2 = -236.8$	$H_2 = -279.5$
$J_{23} = -1.36\ (1.34)$	$J_{23} = -1.7\ (-1.7)$	$H_3 = -182.0$	$H_3 = -297.3$
	$J_{14} = -0.7\ (0.6)$		$H_4 = -484.1$
	$J_{24} = 1.6\ (1.7)$		
	$J_{34} = 0.8\ (0.8)$		

*The relative signs were determined by the double resonance experiments and are assumed to be negative for protons separated by an even number of bonds.

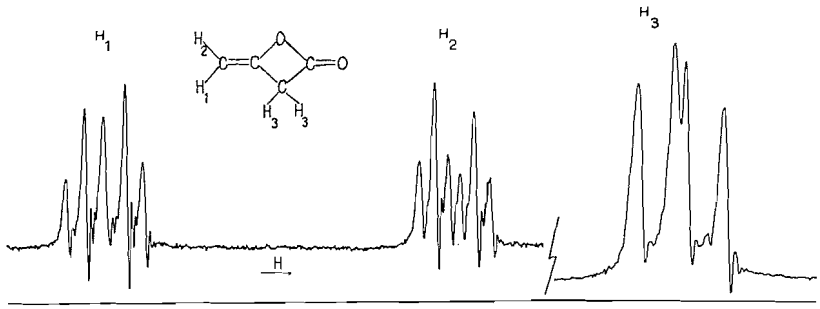

FIG. 1. Proton magnetic resonance spectrum of a 6 mole % solution of diketene in benzene at 60 Mc/s; the H_3 spectrum was obtained at a different sweep rate and gain than the H_1 and H_2 spectra.

1. Diketene

Two sets of experiments were necessary to find the relative signs of the three couplings. In the first, the peaks of proton H_3 (in the first order limit) were irradiated collapsing the multiplet due to the coupling J_{13}, while the H_1 peaks were observed with the low power modulation frequency. Figure 3*a* shows the collapse of the high-field triplet in the H_1 spectrum for a decoupling frequency of 90.7 c/s. In the second experiment, the peaks of H_3 were again irradiated collapsing the multiplet due to the J_{23} coupling, while the H_2 peaks were observed. Although other possible experiments were also performed as a check, the results of the two experiments are sufficient and are given in Table II.

2. Vinyl Formate

At least three experiments were necessary (although others were performed). Each of the three yielded the relative signs of two sets of coupling constants. In the first experiment, the H_4 peaks were irradiated to collapse the multiplet due to J_{14} while observing the H_1 peaks. A typical result for this experiment is shown in Fig. 3*b*. In the second experiment, the H_1 peaks were observed while a J_{12} multiplet was collapsed by irradiation in the H_2 spectrum. For the third experiment, the H_3 peaks were observed while a J_{34} multiplet was collapsed by irradiation of the H_4 spectrum. Figure 3*c* shows a typical result for this last experiment. The results of these experiments are given in Table III.

DISCUSSION

1. *Diketene*

The sign of the geminal coupling is of the same sign as the long-range allylic couplings. Allylic couplings are transmitted mainly through the π-electron system and are expected theoretically (10) and found experimentally to be negative and to lie in the range 0–3 c/s (1). Presumably, therefore, the geminal coupling in diketene is negative. This sign agrees with that found for geminal couplings in vinyl esters (13). The magnitude of these is about 1.5–1.7 c/s (see vinyl formate) and it would appear that ring strain in diketene causes a considerable increase in the magnitude of this coupling. This may be due to hybridization changes in the carbon atom on ring formation, but at present there is no published theory which accounts for this increase in magnitude.

The magnitude of the allylic coupling J_{23} (transoid) is generally found to be smaller in magnitude than J_{13} (cisoid). Our numbering system in I above therefore agrees with these findings (1). It also seems likely (1) that the magnitude of the allylic couplings should depend on the angle θ made by the C—H_3 bond and the plane of the double bond. This possibility depends on the amount of σ–π overlap and would be at a maximum for $\theta = \pi/2$ and a minimum for $\theta = 0$. An intermediate angle would be expected for diketene, leading to the observed finite values of the allylic couplings.

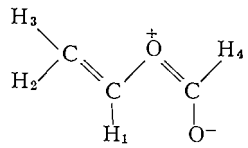
For personal use only.

2. Vinyl Formate

The two and three bond couplings have been adequately discussed for vinyl compounds elsewhere (14, 15). The vicinal proton couplings, J_{12} and J_{13}, are almost certainly positive (14, 16). In that case the signs of the couplings between protons separated by an odd number of bonds are positive and those for an even number of bonds are negative, as predicted by the Dirac vector model (17).

(a) Five Bond Couplings

Freeman and Bhacca (18) and others (1, 14) have suggested that the resonance structure III contributes, which makes vinyl formate analogous to a conjugated system. Furthermore, Rao and Curl (20) predict from microwave data that the most stable conformation

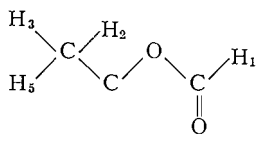


III

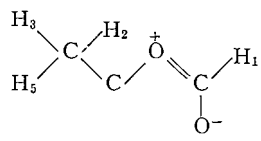
is approximately as in III, with the carbonyl oxygen near H_1. The structure III connects H_2 and H_4 by a "straighter" zig-zag path than H_3 and H_4, which appears to be particularly favorable for a five bond coupling in a number of molecules (14, 18, 19). Indeed J_{24} is about twice as large as J_{34}.

The formal structure for vinyl formate is analogous to H—C=C—C—C—H (with one carbon replaced by oxygen). For the former, a σ–π interaction is calculated to give +2.0 c/s for the proton coupling (12). This mechanism, however, predicts the same magnitude for J_{24} and J_{34}. It may be that $J_{34} = 0.8$ c/s is caused by the σ–π mechanism, while $J_{24} = 1.6$ c/s has an additional contribution from a mechanism, favored by the "straight" zig-zag path. In this connection it is interesting to note that in other molecules we know of in which this "straight" five bond coupling (analogous to J_{24}) is present, the coupling analogous to J_{34} is usually too small to measure (1, 14, 18, 19). The latter molecules are all aromatic for which valence bond theory predicts a very small (<0.2 c/s) contribution by the σ–π mechanism (21). In aromatic molecules, of course, there is no localized π bond.

On the other hand, there is a five bond coupling of about 0.5 c/s (sign unknown) in the alkyl formates (22). It is true that for ethyl formate, for instance, one could write a "straight" zig-zag structure, as in IV, and interpret this as evidence in favor of a σ mechanism in vinyl formate in addition to the σ–π mechanism. In IV there is no formal



IV



V

double bond but, of course, the resonance structure V may well contribute. There is also the question of the rotation about the C—C bond, since the measured coupling is an average of J_{15}, J_{13}, and J_{12} and not the "straight" J_{15} coupling alone. (A somewhat similar objection can be levelled against structure III for vinyl formate.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(b) Four Bond Coupling

J_{14} is formally an example of allylic coupling if III is considered (one double and three single bonds). J_{14} has the right sign for such a coupling but the C—H_4 bond in III makes an angle of $\theta = 0$ with the plane of the $^{+}$O=C bond. This minimizes the σ–π overlap and entails a small J_{14}.

$J_{14} = 0.8$ c/s is of the same magnitude as found for the analogous coupling in the alkyl formate, which range from 0.80–0.96 c/s (sign unknown (22)). If steric effects are important, as implied in the above discussion for both four and five bond couplings, then a change in conformer populations by solvent or temperature effects may lead to changes in magnitude of the long range couplings. Such experiments are being carried out on vinyl formate.

ACKNOWLEDGMENTS

We are grateful to Dr. K. McLauchlan for discussions on diketene. His unpublished sign determinations for this molecule are in agreement with ours. We are grateful to the National Research Council for financial support.

ELECTRON SPIN RESONANCE SPECTRA OF $S_2O_2^-$ IN IRRADIATED THIOSULFATE SINGLE CRYSTALS[1]

J. R. MORTON
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received February 8, 1965

ABSTRACT

Single crystals of $Na_2S_2O_3.5H_2O$ were irradiated and examined, at room temperature, with an e.s.r. spectrometer. Two radicals are present: the species present in highest concentration is $S_2O_2^-$; the other species has not yet been identified.

INTRODUCTION

It has been suggested (1), as a result of electron spin resonance (e.s.r.) experiments on microcrystalline samples, that the radical SO_2^- is trapped in thiosulfates irradiated at room temperature. In view of recent studies of this radical in dithionite systems (2–5) and the possibility of comparison with the isoelectronic species ClO_2 (6) and SeO_2^- (7), the spectra of oriented SO_2^- radicals would be of considerable interest.

It has been shown (8) that two types of radical are trapped in irradiated thiosulfate crystals. In the present work it is demonstrated that one species is $S_2O_2^-$, and also that the other radical is unlikely to be SO_2^-.

EXPERIMENTAL

Crystals of $Na_2S_2O_3.5H_2O$ tend to effloresce, and to prevent this they were coated with a film of Saran (vinylidene chloride) by dipping them into a 25% acetone solution and allowing the solvent to evaporate. The crystals were irradiated at room temperature with X rays from a Philips tube type 25623-62; they were 5 cm from the copper target and radiation times of approximately 2 h were given. The electron spin resonance spectra were examined at room temperature with a Varian V-4502 spectrometer, and a V-4012A 12 in. magnet. The magnetic field was controlled by a VFR-2100 Fieldial Hall-effect regulator and monitored with an F-8A n.m.r. fluxmeter. The frequency of the latter was measured with a C.M.C. type 707B frequency counter, which was also used to measure the frequency of an H.P. type 540B transfer oscillator from which harmonics are generated in the X band microwave region.

Crystals of $Na_2S_2O_3.5H_2O$ are monoclinic (9) having the unit-cell parameters $a = 5.94$, $b = 21.57$, $c = 7.53$ Å, $\beta = 103°58'$, $Z = 4$, in the space group $P2_1/c$. The crystals were prismatic and elongated along the a-axis, developing the faces {011} and, less strongly, {001}, {010}. The irradiated crystals were mounted on a two-circle Teflon goniometer (10) so that the a-axis was horizontal and the crystals could be rotated in the magnetic field about the a-axis or about any axis perpendicular to the a-axis. The axis-system chosen was crystallographic abc^* axis-system, to which all direction cosines therefore refer.

RESULTS

The freshly irradiated crystals of $Na_2S_2O_3.5H_2O$ were brown in color and the e.s.r. spectrum indicated the presence of two radicals, designated A and B. Radical A had an average g-value (one-third diagonal sum) of 2.0054, whereas that of radical B was 2.0143. Initially the concentration ratio A:B exceeded 20:1, but after a few days at room temperature the concentration ratio became 1:1 or less, because of the more rapid decay of the signal from radical A. During this time the brown coloration also faded. It will be shown that radical A is $S_2O_2^-$; radical B has not yet been identified, but, if an isotropic g-value of 2.005 is a prerequisite for SO_2^- (2–5), B is not SO_2^- either.

Figure 1 shows the spectrum of a freshly irradiated crystal of $Na_2S_2O_3.5H_2O$ for the orientation H_0 parallel to c^*. The hyperfine interaction of two non-equivalent ^{33}S nuclei

[1]*Issued as N.R.C. No. 8429.*

(spin 3/2, abundance 0.74%) in radical A is revealed, although for this orientation only the outer component of one quartet is visible. The tensors for the two ^{33}S hyperfine interactions in radical A were determined, using second-order theory (11) for the larger interaction. The g-tensors of radicals A and B (normal isotopic species) were also assembled. The tensors are listed in Table I together with the principal values and their direction cosines.

DISCUSSION

A comparison of the principal values of the larger ^{33}S hyperfine tensor and the g-tensor of radical A with the same parameters (12) for $^{33}SO_3^-$ suggests that the two radicals are very similar and that A is $S_2O_2^-$. In radical A the major hyperfine tensor has principal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

values 513, 407, and 406 Mc/s, whereas in $^{33}SO_3^-$ values of 428, 316, and 314 Mc/s were reported. In radical A the isotropic g-value is 2.0054, and the tensor possesses some anisotropy; the g-factor of SO_3^- was isotropic and equal to 2.0036 ± 0.0007.

The orbital scheme proposed (12) for the ground state of SO_3^-, a pyramidal radical with C_{3v} symmetry, was

$$\ldots . (3a_1)^2(3e)^4(4e)^4(1a_2)^2(4a_1)^1(5a_1)^0(5e)^0, {}^2A_1.$$

Contributions to the singly occupied $4a_1$ orbital were estimated (12) to be 0.13 from sulfur 3s and 0.49 from sulfur $3p_z$. Lowering the symmetry to C_{1h} by the substitution of a second sulfur atom for an oxygen atom, the ground state becomes $^2A'$, and approximate contributions[2] to the singly occupied orbital are 0.16 and 0.45 from central sulfur 3s and $3p_\sigma$ respectively.

The lower symmetry also removes the requirement that the central-atom hyperfine tensor and the g-tensor be coaxial and have cylindrical symmetry. It will be seen from the data in Table I that these two tensors are not diagonal in a common axis-system, and the g-tensor is not cylindrically symmetrical. One requirement of C_{1h} symmetry is that one of the principal g-values be perpendicular to the unique direction of the central ^{33}S hyperfine tensor. The principal value 2.0083 fulfills this requirement, being $\cos^{-1}$ 0.094, or 84.6° from the direction corresponding to the 513 Mc/s hyperfine interaction. The same symmetry requirement is fulfilled by the principal value 59 Mc/s of the small ^{33}S hyperfine tensor, being $\cos^{-1}$ 0.298 or 72.7° from the direction corresponding to the 513 Mc/s hyperfine interaction. The correlation in this case is less exact, owing to experimental difficulties in determining the smaller principal values and directions of the hyperfine tensor in $^{33}S^{32}SO_2^-$.

Within the experimental error, therefore, it appears that the direction normal to the symmetry plane of the radical (z) is to be associated with the largest principal g-value (2.0083) and the intermediate principal value (59 Mc/s) of the (terminal) ^{33}S hyperfine interaction, the angle between these directions being $\cos^{-1}$ 0.900 or 25.9°.

The deviation from cylindrical symmetry in the principal values (assumed positive) of the smaller ^{33}S hyperfine tensor is real, although not of great significance in view of the experimental errors involved in the determination of the smaller principal values of this tensor. It may be diagnostic of configuration interaction giving rise to positive spin-density in the terminal sulfur $3p_\pi$ orbital, and negative spin-densities in the oxygen $2p_\pi$ orbitals, the mechanism (13) for which would involve admixture into the $^2A'$ ground state of configurations involving unpaired spins in a'' orbitals. An objection to this mechanism is the large excitation energy between the $1a_2$ orbital and the $5e$ orbital, which, under C_{1h}, would correspond to the required $(a'')^2 \rightarrow (a'')^0$ promotion. An alternative possibility not quite so energetically unfavorable involves negative spin-density in a terminal sulfur $3p_\sigma$ orbital due to $(a') \rightarrow (a')$ promotion. In any event, the contributions to the singly occupied a' orbital from the terminal sulfur atom are: 3s, 0.02; and $3p_\sigma$, at least 0.23.

In SO_3^- (12) it was deduced that each oxygen $2p_z$ orbital contributed 0.13 to the singly occupied $4a_1$ orbital, and in $S_2O_2^-$ it appears that the contribution from the terminal sulfur atom has increased at the expense of that from the oxygen atoms. This can be attributed (14) to the lower electronegativity of the substituted sulfur atom.

It has been demonstrated that the largest g-shift observed in $S_2O_2^-$ corresponds to the

[2]*In calculating spin-densities for* ^{33}S *the following parameters were used (12):*

$$(8\pi g\beta\gamma/3h)\psi_{3s}^2(0) = 2\,715 \text{ Mc/s},$$
$$(2g\beta\gamma/5h)\langle r^{-3}\rangle_{3p} = 78 \text{ Mc/s}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

direction (z) normal to the symmetry plane ($\Delta g_{zz} = +0.006$). Under C_{1h}, R_z (rotation about an axis perpendicular to the symmetry plane) belongs to the representation A', and so the non-zero Δg_{zz} must arise from spin–orbit interaction between the ground $^2A'$ state and an excited A' state. The first excited $^2A'$ state in $S_2O_2^-$ probably corresponds to the configuration . . . $[(a'')^2 + (a')](a'')^2(a')^2$; where the square brackets enclose orbitals deriving from the $4e$ orbital in SO_3^-. Spin–orbit interaction between this state and the ground state would account for a positive Δg_{zz}.

The signal from radical B was too weak to allow detection of ^{33}S hyperfine structure. An identification based on the principal g-values alone is somewhat conjectural, but one possibility is that B is polyatomic sulfur biradicals. In molten sulfur (15) such radicals have an isotropic g-value of 2.024, and the spectrum of sulfur dissolved in certain amines and cooled to 77 °K (16) was indicative of principal g-values 2.055, 2.035, 2.003. Radicals can also be detected in sublimed sulfur (17) where the principal values are 2.039, 2.025, 2.000. The correlation of these data with those of radical B is not compelling, but the possibility that B is elemental sulfur in some form must be borne in mind, since colloidal sulfur is formed when irradiated thiosulfates are dissolved in water (18).

Another possibility is that B is $S_2O_3^-$. Tetrahedral radicals such as SO_4^- and PO_4^{2-} have been detected (19), and the principal g-values for SO_4^- in persulfate are 2.033, 2.008, 2.004 (average 2.0149). Such radicals are expected to possess a . . . t_1^5 ground configuration (20) under T_d symmetry. The anisotropy of the g-tensor is thought to be due to crystal-field or Jahn-Teller distortion, resulting in an effective $^2A_2$ ground state under C_{2v} symmetry. If B is $S_2O_3^-$, a similar mechanism must be operative, lowering the symmetry from C_{3v} to C_{1h}. In a monoclinic unit cell there are no three-fold axes and the environment could distort the radical.

ACKNOWLEDGMENT

The author thanks Dr. L. D. Calvert for determining the unit-cell directions of the crystals, and Dr. D. H. Whiffen for a stimulating discussion.

THE CHROMIC ACID OXIDATION OF 2-PROPANOL IN TRIFLUOROACETIC ACID

DONALD G. LEE AND DANIEL T. JOHNSON
Camrose Lutheran College, Camrose, Alberta

Received January 14, 1965

ABSTRACT

The mechanism of the chromic acid oxidation of 2-propanol in trifluoroacetic acid solutions has been studied. The general features of this reaction strongly resemble those observed in aqueous solutions of other strong acids. A "normal" primary kinetic isotope effect is observed, similar thermodynamic parameters are obtained, and the rate behaves in similar way towards changes in acidity.

An extensive study of the effect of added salts on this reaction has substantiated that the identity of added anions has a profound effect on the rate of reaction and that any complete reaction mechanism must take this into consideration.

It has been established that chromic acid is a very effective reagent for the oxidation of alcohols and that under similar conditions of acidity and temperature the rate of oxidation is much faster in acetic acid solutions than in aqueous solutions (1). The kinetics and mechanism of this reaction have been investigated quite thoroughly and it appears that the enhanced rate in acetic acid solutions is due in part to incorporation of an acetate ligand into the chromic acid ester, which acts as an intermediate in this reaction (1, 2). It seemed probable to us that the details of the mechanism of this reaction could be further exposed by undertaking a kinetic study of the chromic acid oxidation of 2-propanol in trifluoroacetic acid solutions. The following paper reports the results of this investigation.

EXPERIMENTAL

Kinetic Methods

All kinetic measurements were made spectrophotometrically using a Unicam model SP 500 spectrophotometer with a thermostated cell compartment. Solutions were made up by adding a weighed amount of anhydrous trifluoroacetic acid (Halocarbon Products) to a dilute aqueous solution of $K_2Cr_2O_7$ (Fisher Reagent). This solution was then brought to 25.0 ± 0.2° in a thermostated bath and an excess of 2-propanol was added volumetrically either from a pipet or a microsyringe fitted with a Chaney adaptor. The optical density of these solutions at 3 500 Å was then determined at intervals and a plot of log $[Cr^{VI}]$ against time was prepared. A typical rate plot is presented in Fig. 1.

pK_a Measurements

Previous work (3) has shown that the protonation of $HCrO_4^-$ does not involve simple addition of a proton to give H_2CrO_4, but that the change is accompanied by incorporation of the conjugate base of the proton-supplying acid.

$$HCrO_4^- + H^+ + HA \rightleftharpoons HCrO_3A + H_2O.$$

To determine the apparent "pK_a" for this equilibrium it is necessary to obtain a measure of the ratio of the concentration of $HCrO_4^-$ to the concentration of $HCrO_3A$ over a wide range of acidities (4).

It was found possible to obtain such a ratio by measuring the extinction coefficients at 3 500 Å of aqueous trifluoroacetic acid solutions containing Cr^{VI}. Then the ratio

$$\frac{C_{HCrO_3A}}{C_{HCrO_4^-}} = \frac{\epsilon_{HCrO_4^-} - \epsilon}{\epsilon - \epsilon_{HCrO_3A}},$$

where $\epsilon_{HCrO_4^-}$ is the extinction coefficient for $HCrO_4^-$, ϵ_{HCrO_3A} is the extinction coefficient for $HCrO_3A$, and ϵ is the extinction coefficient for solutions containing both species. The plot of ϵ against H_0 (Fig. 2) shows that at 3 500 Å a typical sigmoidal curve is obtained. The H_0 scale reported by Randles and Tedder was used (5).

Materials

Chromic acid stock solutions were prepared by dissolving weighed amounts of $K_2Cr_2O_7$ in definite volumes of distilled water. Isopropyl alcohol was refluxed over calcium oxide for 2 h and then distilled. A middle fraction boiling at 81.5–82.0° was collected and used for the kinetic experiments. The 2-propanol-2-*d* was prepared in the manner described by Leo and Westheimer (6) and was purified by use of vapor phase chromatography. Salt solutions were prepared from commercially available reagent grade salts.

Trifluoroacetic acid was distilled through an all-glass apparatus and a middle fraction boiling at 71.0–72.0° was collected and used. Attempts were made to distil trifluoroacetic acid from both $K_2Cr_2O_7$ and $KMnO_4$. When it was distilled from $K_2Cr_2O_7$ through a 14 in. all-glass Vigreux column, the distillate was observed to have a pale-yellow color that rapidly disappeared when treated with easily oxidizable substances such as alcohols or aldehydes. Such observations suggested that Cr^{VI} was forming a volatile trifluoroacetic acid complex which was being carried over into the distillate. Titration with standardized sodium thiosulfate indicated that the concentration of Cr^{VI}, though somewhat larger in the initial stages of the distillation, was about 1×10^{-5} *M* in later fractions.

When trifluoroacetic acid was distilled from $KMnO_4$ a bright green distillate was obtained. The ultraviolet–visible spectrum of the distillate was similar to that reported by Symons *et al.* (4) for $HMnO_4$. When water was added to this anhydrous trifluoroacetic acid solution the familiar purple color of permanganate was obtained. From the amount of permanganate obtained it was possible to calculate that the $HMnO_4$ concentration in the sample of CF_3COOH was 1.4×10^{-3} *M*.

From these results we have concluded that Cr^{VI} and Mn^{VII} form volatile complexes with trifluoroacetic acid. However, it is possible that H_2CrO_4 and $HMnO_4$ are themselves volatile, but so strongly solvated in water that they cannot be distilled from aqueous solutions.

RESULTS

pK_a Measurements

It has been found in previous work that a plot of the function $H_- + \log (a_{H_2O}/a_{HA})$ against $\log (C_{HCrO_3A}/C_{HCrO_4^-})$ should give a straight line of unit slope for the protonation of $HCrO_4^-$ in aqueous solutions of mineral acid HA (3). This function was used rather than the conventional H_- function because evidence had shown eq. [1] to be the correct protonation equilibrium.

$$[1] \qquad HCrO_4^- + H^+ + HA \rightleftharpoons HCrO_3A + H_2O.$$

It was also found, however, that good straight lines, though not of unit slope, could be obtained by plotting $\log (C_{HCrO_3A}/C_{HCrO_4^-})$ against H_0. Figure 3 indicates that the apparent pK_a for this equilibrium is at -0.14 on the H_0 scale. The large deviation from unit slope emphasizes that H_0 is not the best function to use in this case. However, since literature values for neither H_-, a_{H_2O}, nor a_{HA} were available for trifluoroacetic acid solutions, the latter method was used. Presumably use of the function $H_- + \log (a_{H_2O}/a_{HA})$ would give a plot with a slope closer to unity.

Reaction Rates

The rates of oxidation of 2-propanol by Cr^{VI} at 25° were determined for aqueous solutions of trifluoroacetic acid varying from 0.36 to 96.2% CF_3COOH. The logarithms of the second-order rate constants which were obtained are plotted against H_0 in Fig. 4. This plot is strongly reminiscent of the one obtained for the same reaction in aqueous solutions of other strong acids (3). In these acids the linear region at lower acidities ($+1$ to -0.3 H_0 units) was ascribed to oxidation by $HCrO_4^-$, and the other linear region at higher acidities (-0.3 to -1.9 H_0 units) was attributed to oxidation by $HCrO_3A$, where A is the conjugate base of the mineral acid used as a proton supplier.

When this reaction was previously studied in aqueous solutions of HNO_3, $HClO_4$, H_2SO_4, HCl, and H_3PO_4 it was found that in each case the slope of the plot of log k_2 against H_0 changed at an acidity near the apparent pK_a of H_2CrO_4 in that medium. In the present case the intersection of the two slopes occurred at an H_0 of -0.30 while the apparent pK_a was -0.14. This evidence suggests that in accordance with previous results the active oxidant at acidities below the apparent pK_a is $HCrO_4^-$ while at higher acidities the active species is $HOCrO_2$—$OCOCF_3$.

The rate of oxidation of 2-propanol in concentrated sulfuric acid solutions has been observed to become nearly independent of acid concentrations in solutions containing 58–100% H_2SO_4 (7, 8). In fact the slope tends to have a slight negative value. This has also been observed in the present medium where the rate is observed to remain almost constant between -1.9 and -3.2 H_0 units.

Thermodynamic Parameters

The variation of the reaction rate with temperature can be utilized to obtain the heat and entropy of activation, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ respectively. Transition state theory predicts that if log k_2/T(°K) is plotted against $1/T$(°K) (over a limited temperature range) the slope of the straight line and the intercept would give respectively $\Delta H^{\neq}$ and $\Delta S^{\neq}$ (9). The second-order rate constants for the reaction under consideration were determined at five different temperatures. The rate constants obtained are presented in Table I and a plot of log k_2/T(°K) against $1\,000/T$(°K) is presented in Fig. 5. Table II compares the thermodynamic parameters for the oxidation of 2-propanol in aqueous trifluoroacetic acid with the parameters obtained under other conditions. Since the reaction under consideration

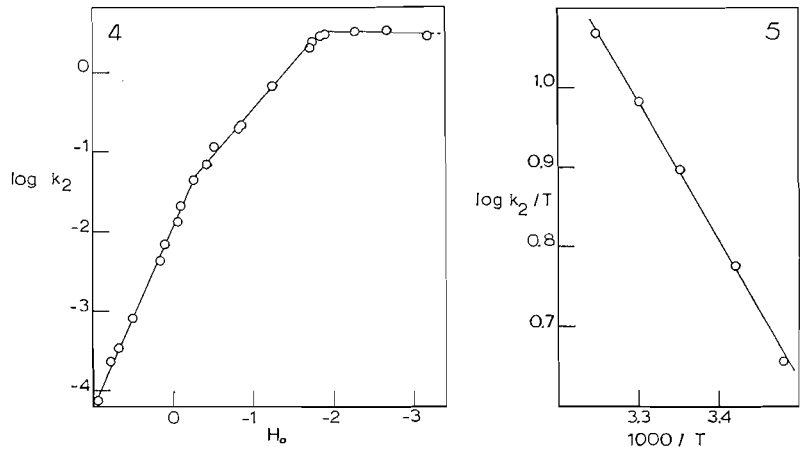

FIG. 4. Variation of rate with acidity for the chromic acid oxidation of 2-propanol in trifluoroacetic acid solutions.
FIG. 5. Plot for evaluating thermodynamic parameters.

is not a simple one (the rate-determining step follows a preliminary equilibrium) it is difficult to interpret the significance of heats and entropies which have been derived from kinetic data. However, the fact that the parameters determined in trifluoroacetic acid solutions are not greatly different from those obtained in other media would seem to substantiate accompanying evidence which indicates that use of this solvent does not produce any basic changes in the reaction mechanism.

Salt Effects

It has previously been suggested that in the region of acidity beyond the pK_a of H_2CrO_4 in a particular mineral acid, HA, the intermediate of the oxidation reaction is an ester of the type $R_2HC—O—CrO_2A$, which is formed from a molecule of alcohol and one of $HOCrO_2A$ (3). At acid concentrations below the pK_a, the active oxidant was thought to be $HCrO_3^-$. It should be possible to test these ideas by examining the effect on the reaction rate when a salt MA′ is added to the solution. If the effect of the added salt on the acidity of the solution is subtracted, then this theory would predict that above the pK_a the nature of the salt effect observed would be dependent to a large extent on the nature of A′, since there would probably be an exchange between A and A′ in the Cr^{VI} species. Below the pK_a, however, where the anion does not become intimately attached to the chromium species, the added salt would cause only medium effects and all salts would be expected to cause somewhat similar changes in rate.

In the present investigation the effect of chloride ion, nitrate ion, and perchlorate ion was studied at 0.298 *M* CF_3COOH ($H_0 = 0.60$) and at 7.35 *M* CF_3COOH ($H_0 = -0.61$). These acidities are on either side of −0.14, the observed pK_a for H_2CrO_4 in this medium. The results are summarized in Table III and are presented graphically in Figs. 6 and 7.

The values for k_{cor} were obtained by use of the formula

$$\log k_{cor} = \log k_{obs} + m\Delta H_0,$$

where k_{obs} is the observed second-order rate constant, ΔH_0 is the change in acidity caused

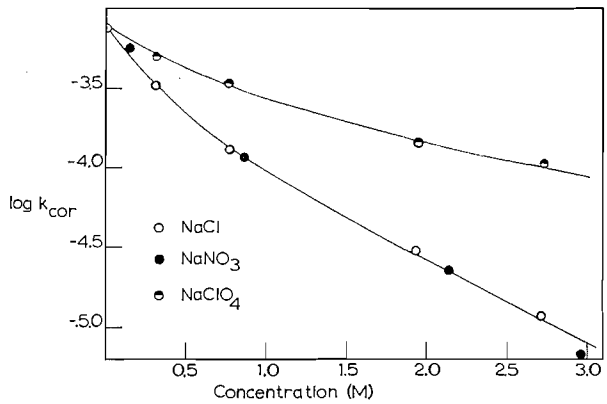

FIG. 6. Effect of added salts on the rate of oxidation of 2-propanol by Cr^{VI} in 0.298 *M* trifluoroacetic acid.

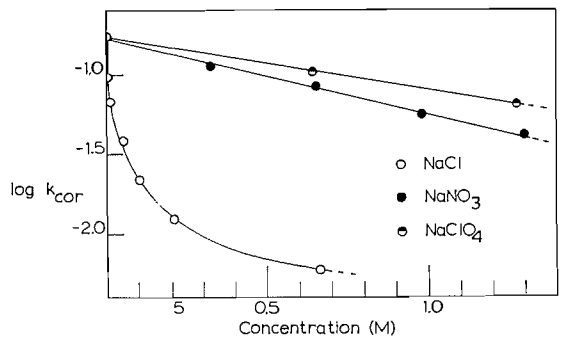

FIG. 7. Effect of added salts on the rate of oxidation of 2-propanol by Cr^{VI} in 7.35 *M* trifluoroacetic acid.

by the addition of salt, and m is the slope of the plot of log k_2 vs. H_0 taken from Fig. 4. In every case acidities were determined by use of the indicators *p*-nitroaniline, *o*-nitroaniline, and 4-chloro-2-nitroaniline. Use of the formula subtracts any increment in rate that is due to an enhanced acidity caused by the addition of salt to the solution, but it does not correct for other salt effects such as the change in ionic strength of the medium.

At low acid concentrations the results indicate that, aside from their effect on acidity, NaCl, $NaNO_3$, and $NaClO_4$ all have approximately the same effect on the rate of oxidation. In fact NaCl and $NaNO_3$ seem to be identical in their ability to depress the rate of reaction while $NaClO_4$ is slightly less effective. However, at higher acidities the salts show independent effects with small concentrations of chloride ion slowing down the reaction greatly, while nitrate and perchlorate ion also slow down the rate but to a much lesser extent. This is in accord with the work of Cohen and Westheimer (1) and of Lee and Stewart (3) who showed that formation of the species $HOCrO_2Cl$ leads to a much slower rate of reaction than does formation of the corresponding Cr^{VI} species with either acetate, nitrate, or perchlorate replacing chloride.

The dramatic decrease caused by even small concentrations of chloride ion indicates that equilibrium [2],

[2] $$HOCrO_2—OCOCF_3 + Cl^- \rightleftharpoons HOCrO_2Cl^- + CF_3COO^-,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

must lie far to the right. An attempt was made to follow this exchange spectrophotometrically in the ultraviolet–visible region of the spectrum where chromium absorbs strongly. While the most interesting part of the spectrum, below 3 000 Å, was blanked out by trifluoroacetic acid absorption it was possible to make a partial study at about 3 500 Å. The pertinent data are reported in Table IV. From the data it can be seen that as the chloride ion concentration increases the extinction coefficient steadily increases until it almost equals that observed for HCl solutions of the same acidity.

TABLE IV
Spectral data

Acid concentration	Chloride conc. (M)	ϵ	λ_{max} (Å)
7.35 M CF_3COOH	0	859	3 500
	0.0130	981	3 570
	0.0206	1 090	3 570
	0.0516	1 132	3 570
	0.103	1 190	3 580
	0.206	1 208	3 580
	0.516	1 218	3 600
2.02 M HCl	0	1 240	3 580
	0.50	1 240	3 580

In the case of nitrate and perchlorate ions the fact that significant rate changes did not occur until the concentration of these ions was quite great would seem to indicate that the equilibrium constants for nitrate or perchlorate ion exchange must be smaller than for chloride ion, i.e. chloride ion more readily forms a covalent bond with chromium.

Isotope Effects

Westheimer and coworkers have shown that a primary kinetic isotope effect of approximately 7:1 is observed for the oxidation of 2-propanol-2-*d* in either aqueous or acetic acid solutions (1, 11, 12). In the present investigation the primary kinetic isotope effect was determined at 25° for two different concentrations of trifluoroacetic acid. The results presented in Table V indicate that in this case also the rate-determining step is cleavage of the α-C—H bond.

TABLE V
Primary kinetic isotope effects on the rate of oxidation in trifluoroacetic acid solutions at 25°

DISCUSSION

The results of this investigation indicate that the general features of the chromic acid oxidation of 2-propanol in trifluoroacetic acid solution strongly resemble those observed in aqueous solutions of most other strong acids. A "normal" primary kinetic isotope effect is observed, similar thermodynamic parameters are obtained, and the rate behaves in a similar way towards changes in acidity.

The change of slope in Fig. 4 indicates, in analogy with other strong acids, that trifluoroacetic acid becomes incorporated into the Cr^{VI} species only after protonation of the monoanion, i.e., equilibrium [3] would seem to be to the right but equilibrium [4] to the left.

[3] $$H_2O + {}^-OCrO_2—OCOCF_3 \rightleftharpoons {}^-OCrO_2OH + CF_3CO_2H,$$

[4] $$H_2O + HOCrO_2—OCOCF_3 \rightleftharpoons H_2CrO_4 + CF_3COOH.$$

Results from the effect of added salts also indicate that it is possible for an exchange of conjugate base groups to take place, and that such an exchange can have a profound effect on the reaction rate.

[5] $$HOCrO_2—OCOCF_3 + Cl^- \rightleftharpoons HOCrO_2Cl + CF_3CO_2^-.$$

Current theories suggest that chromic acid oxidations involve formation of an intermediate ester which subsequently decomposes to products (13, 14). It is not clear from our results whether the presence of the conjugate base is felt more strongly in ester formation or ester decomposition, i.e., the A group could have an effect either on equilibrium [6] or on the rate-determining step [7].

[6] $$HOCrO_2A + (CH_3)_2CHOH \rightleftharpoons (CH_3)_2CH—O—CrO_2A + H_2O$$

[7] $$(CH_3)_2CH—O—CrO_2A \rightarrow (CH_3)_2C{=}O + Cr^{IV}.$$

The evidence which is available would seem to indicate that the decomposition step [7] involves intermolecular transfer of 2 electrons from the alcohol part of the ester to the chromium part, with the exact mode of transfer depending on the relative amount of overlap between the bonding orbitals in the transition state (15). Regardless of the mode of transfer an electron-attracting group attached to chromium would increase the rate of decomposition. The salt effect results presented in this paper have substantiated this idea. The second-order rate constant for oxidation of 2-propanol in HCl solutions with an H_0 of -0.61 is 1.0×10^{-3} l moles^{-1} s^{-1} (3), while the second-order rate constant for the oxidation of 2-propanol in trifluoroacetic acid solutions of the same acidity is 0.175 l moles^{-1} s^{-1}. Addition of NaCl to this trifluoroacetic acid solution steadily decreases the rate until at a salt concentration of 0.516 M the rate constant is only 7.52×10^{-3} (corrections being made for acidity changes). At the same time as the rate is being decreased spectral changes indicate the formation of a new Cr^{VI} species which has an extinction coefficient at 3 600 Å, closer to that observed for $HOCrO_2Cl$. From this it appears that chlorine is able to form a stronger covalent bond with chromium than is the trifluoroacetate group and is consequently displacing this group.

Addition of nitrate or perchlorate ions also effects a decrease in the rate of reaction after corrections are made for acidity changes. The second-order rate constant for oxidation of 2-propanol in either HNO_3 or $HClO_4$ solutions with an H_0 of -0.61 is 2.82×10^{-2} l moles^{-1} s^{-1} (3) while the second-order rate constant for the same reaction in trifluoroacetic acid solutions of the same acidity is 0.175 l moles^{-1} s^{-1}. However, addition of $NaNO_3$ steadily decreases the rate (corrected for changes in acidity) until at a concentration of

1.30 M $NaNO_3$ the rate constant is only 4.01×10^{-2} l moles^{-1} s^{-1}. Similarly addition of $NaClO_4$ decreases the rate constant until at a concentration of 1.91 M $NaClO_4$ the corrected rate constant is only 5.1×10^{-2} l moles^{-1} s^{-1}.

These results substantiate the fact that the identity of the conjugate base has a profound effect on the rate. Any complete mechanism of this reaction must take this fact into consideration.

ACKNOWLEDGMENT

The financial support of the National Research Council is gratefully acknowledged, as is a gift of trifluoroacetic acid from Halocarbon Products, Hackensack, New Jersey, U.S.A.

THE PYROLYSIS OF TRIMETHYLTHALLIUM

M. G. JACKO[1] AND S. J. W. PRICE
Department of Chemistry, University of Windsor, Windsor, Ontario
Received February 1, 1965

ABSTRACT

The pyrolysis of trimethylthallium has been studied in a toluene carrier flow system from 458 to 591 °K using total pressures from 5.6 to 33.0 mm. The progress of the reaction was followed by measuring the amount of methane, ethane, ethylene, and ethylbenzene formed and, in 21 runs, by direct thallium analysis. All preparative and kinetic work was carried out in total darkness where possible. A shielded 10 W lamp was used when some illumination was necessary.

The decomposition is approximately 80% heterogeneous in an unconditioned vessel and 14–27% heterogeneous in a vessel pretreated with hot 50% HF for 10 min. The reaction proceeds by the simple consecutive release of three methyl radicals. The rate constant depends only slightly on the total pressure in the system so that the activation energy of the homogeneous process, 27.4 kcal/mole, may be equated to $D[(CH_3)_2Tl—CH_3]$.

INTRODUCTION

No previous studies of the thermal decomposition of trimethylthallium have been reported. The pyrolysis of trimethylgallium and trimethylindium has been studied (1, 2). In each case two of the three metal–carbon bond dissociation energies were determined from the kinetic data. The reactions showed a marked surface dependence which could be substantially reduced by carrying out a number of runs to condition the reaction vessels. Somewhat similar behavior was expected in the pyrolysis of trimethylthallium.

EXPERIMENTAL

Materials

(*a*) Trimethylthallium was prepared by adding dropwise an ether solution of methyllithium to a suspension of dry powdered thallous iodide in anhydrous ether containing methyl iodide (3, 4). The methyllithium was prepared by adding methyl iodide dropwise to a suspension of finely cut lithium metal in ether (5). The thallous iodide suspension was stirred at room temperature under a dry nitrogen atmosphere. As each drop of methyllithium hit the suspension, a black dot (finely divided, highly reactive thallium) formed momentarily and then disappeared. As the addition of methyllithium progressed, the suspension became darker. After standing for 36 h the mixture cleared. The overall reaction is given by:

$$2CH_3Li + CH_3I + TlI \rightarrow Tl(CH_3)_3 + 2LiI.$$

The reaction mixture was heated in a water bath at 75 °C to distill the ether. The crude metallic alkyl was distilled into a degassing system where the remaining ether was removed by repeated bulb-to-bulb distillations with the cold trap at 0 °C. The final product had a melting point of 38.5 °C (literature value 37.5–39 °C). Trimethylthallium was handled and stored in the dark as it is sensitive to light. Vapour pressures were measured from −25 °C (1.0 mm) to 60 °C (17.5 mm).

(*b*) Toluene from sulfonic acid (Eastman Organic, X325) was dried by refluxing over sodium under vacuum and then degassed by bulb-to-bulb distillation.

Apparatus and Procedure

The toluene carrier system used was identical with that used for the study of trimethylindium (2). The volume of the reaction zone was 171 cc in the unpacked vessel and 141 cc in the packed vessel. The apparatus was operated in total darkness except for two shielded 10 W lamps which were used to take manometer readings.

In 11 runs the contents of the reaction zone were analyzed for thallium by dissolving the deposit in the reaction zone in concentrated hydrochloric acid (12 *N*). The resulting thallium trichloride solution was evaporated to 1–2 cc, diluted to 50 ml with distilled water, buffered with hexamethylenetetramine, and titrated with 0.02 *M* EDTA using xylenol orange as indicator (6). In four of these runs the contents of the

[1]*Recipient of a National Research Council of Canada Studentship. Present address: Research Division, Imperial Oil Ltd., Sarnia, Ontario.*

acetone – dry ice trap were similarly analyzed. The total moles of thallium found was always better than 99% of the moles of trimethylthallium used. Subsequently an additional 10 runs were carried out in which thallium analyses were made only on the contents of the trap.

Chromatographic analysis of the gaseous products was carried out on a 2 m silica-gel column at 80 °C with a helium flow rate of approximately 20 cc/min. The contents of the acetone – dry ice trap were analyzed using a Perkin-Elmer model 800 gas chromatograph equipped with a 150 ft Golay column, 0.02 in. i.d. coated with poly(propylene glycol).

RESULTS AND DISCUSSION

The complete experimental results are given in Tables I–V. They may be discussed in terms of the following mechanism:

[1] $$Tl(CH_3)_3 \rightarrow Tl(CH_3)_2 + CH_3,$$

[2] $$Tl(CH_3)_2 \rightarrow Tl(CH_3) + CH_3,$$

[3] $$Tl(CH_3) \rightarrow Tl + CH_3,$$

[a] $$CH_3 + C_6H_5—CH_3 \rightarrow C_6H_5—CH_2 + CH_4,$$

[r] $$2CH_3 \rightarrow CH_3—CH_3,$$

[4] $$2C_6H_5—CH_2 \rightarrow (C_6H_5—CH_2)_2.$$

The abstraction reaction [a] was a composite reaction proceeding mainly as written but with a small percentage of abstraction from the ring. The ethylene and the hydrogen observed in very small amounts (usually less than 0.05%) result from the reactions:

[5] $$CH_3 + C_2H_6 \rightarrow C_2H_5 + CH_4,$$

[6] $$C_2H_5 \rightarrow C_2H_4 + H,$$

[7] $$H + C_6H_5—CH_3 \rightarrow C_6H_5—CH_2 + H_2.$$

In runs with low toluene-to-alkyl ratios, propane, ethylbenzene, and xylenes observed in small amounts result from the reactions:

[8] $$CH_3 + C_2H_5 \rightarrow C_2H_5—CH_3,$$

[9] $$CH_3 + C_6H_5—CH_2 \rightarrow C_6H_5—CH_2—CH_3,$$

[10] $$CH_3 + CH_3—C_6H_4 \rightarrow CH_3—C_6H_4—CH_3.$$

The Arrhenius plot of $k_a/k_r^{1/2}$ shown in Fig. 1 shows no characteristic break at 33% or 67% theoretical yield of methyl radicals indicating that at all temperatures reactions [2] and [3] follow rapidly after reaction [1]. Thus the rate constants were calculated assuming that three methyl radicals were released for each trimethylthallium molecule undergoing decomposition.

Although the continuity of the Arrhenius curve of $k_a/k_r^{1/2}$ was indicative of the process outlined (2), independent tests have been made to verify the mechanism.

(*a*) In 14 runs (see Table V), the contents of the acetone – dry ice trap located at the outlet of the furnace were analyzed for thallium. Over the entire temperature range, the thallium found in this trap was equal to the quantity of undecomposed trimethylthallium expected if each alkyl molecule that decomposed liberated three methyl radicals.

(*b*) In 11 runs, the contents of the reaction vessel were analyzed for thallium. In all cases the quantity of thallium deposited in the reaction zone was in agreement with the postulated release of three methyl radicals. To insure that the deposit was actually thallium, 0.082 g of the deposit was scraped from the reaction zone while in an inert atmosphere and analyzed for thallium; 19.0 ml of 0.02 *M* EDTA were required giving a thallium analysis of 99.8%. No evidence was found for the formation of polymer of the type $(TlCH_3)_n$, as found in the pyrolysis of trimethylgallium or trimethylindium.

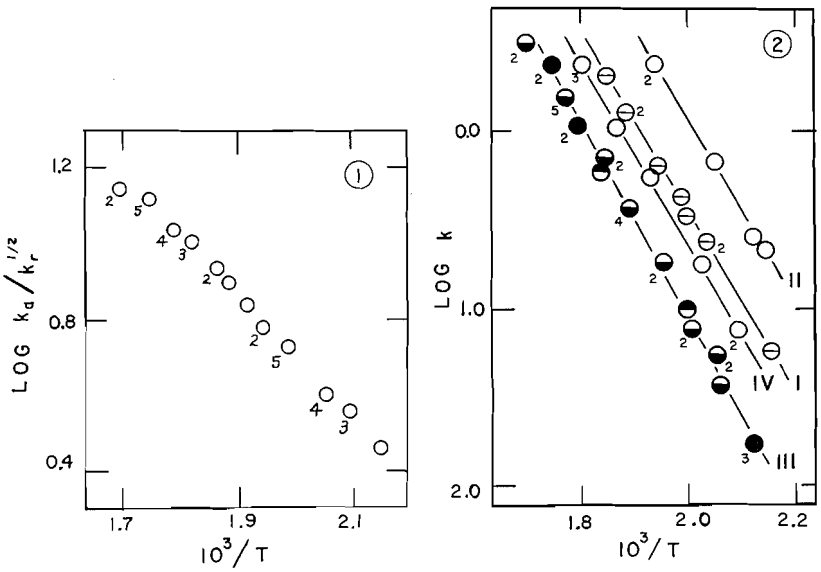

FIG. 1. Arrhenius plot for the reaction of methyl radicals with toluene when trimethylthallium is used as the source of methyl radicals. The experimental points cover 1–95% decomposition of the alkyl. Subscripts indicate the number of points averaged to obtain the given point.

FIG. 2. Arrhenius plots for the decomposition of trimethylthallium: ⊖, runs in unpacked unconditioned vessel (curve I); ○, runs in packed unconditioned vessel (curve II); ◒, runs in unpacked conditioned vessel (curve III) (◓, based on metal analysis); ○, runs in packed conditioned vessel (curve IV). Subscripts denote the number of runs averaged to obtain the given point.

Starting with a clean vessel (I), the rate constants did not decrease over several runs to a fixed minimum value as in the case of trimethylgallium or trimethylindium but remained at a constant value. These runs would have deposited enough thallium to change the surface, but no effect due to coating the surface with thallium was observed. In another series of runs, small amounts of air introduced into the reaction zone between runs produced no observable effect on the rate constants. The experimental data under these conditions (unconditioned and unpacked vessel) are given in Table I and constitute curve I in Fig. 2.

The percentage of heterogeneous reaction was estimated by carrying out a series of runs in a packed vessel (II) with a surface-to-volume ratio 12 times that of the unpacked vessel I, and the results are given in Table II and constitute curve II of Fig. 2. The rate constants obtained using vessel II were a factor 3.7 greater than those obtained in vessel I. The overall reaction in vessel I was therefore apparently about 25% heterogeneous.

In an attempt to reduce the amount of surface reaction, the unpacked vessel was treated with hot 50% hydrofluoric acid for 10 min and then baked out under vacuum at 350 °C. The experimental results are given in Table III and constitute curve III of Fig. 2. The rate constants in vessel III could never be reduced below this curve even by longer treatments with hot 50% hydrofluoric acid. Therefore, vessels treated as described above are termed conditioned vessels.

With a conditioned vessel, successive runs producing an increasing deposit of thallium metal on the surface raised the rate constant to the level of the unconditioned vessels. Consequently, conditioning with hot 50% hydrofluoric acid was required between runs to obtain reproducible results in the conditioned vessel. However, if the amount of trimethylthallium used in a run was varied from 0.5 to 2.0 millimoles, no variation in the rate constant was observed signifying that the maximum amount of alkyl used in one run did not deposit enough thallium to significantly increase the rate. Therefore the rate constants observed in the individual runs were a true indication of the decomposition in the conditioned vessel.

To estimate the percentage of heterogeneous reaction in vessel III, a packed pyrex vessel (IV) with a surface-to-volume ratio 9 times that of vessel III was treated with hot 50% hydrofluoric acid for 10 min. This gave a rate constant high by a factor of 13. Further conditioning with the hot acid reduced the rate constants to approximately a factor of 4 times those obtained in vessel III. These results are tabulated in Table IV and constitute curve IV in Fig. 2. These results indicated that the reaction in vessel III was approximately 13% heterogeneous at the highest temperatures used and approximately 27% at the lowest.

‡Run 95 (vessel only partially conditioned).
§Run 96 (vessel almost completely conditioned).
‖Run 97 (first run in fully conditioned vessel).

Comparison of curves I and III indicated that the reaction in vessel I was about 79% heterogeneous. This large percentage heterogeneous reaction is consistent with the greater than 45% heterogeneous reaction that would be indicated by comparison of curve I with the initial runs in the partially conditioned packed vessel (vessel IV before it was fully conditioned). The low estimate of percent heterogeneous reaction in vessel I obtained by comparison of runs in vessels I and II was probably due to the fact that vessel II had been washed with hydrofluoric acid before being stored at the conclusion of previous work.

The pressure dependence of $k_a/k_r^{1/2}$ is shown in Fig. 3. The falloff with increasing pressure is similar to that previously observed in similar studies with trimethylgallium, trimethylindium, and other metallic alkyls (1, 2, 7, 8, 9).

The rate constant k depended on the total pressure in the system, although the pressure dependence was very slight (Fig. 4). This slight pressure dependence was very similar to that observed for the thermal decomposition of trimethylgallium or trimethylindium.

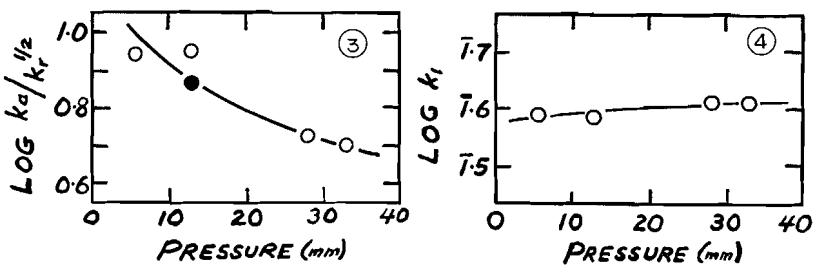

FIG. 3. Variation of $k_a/k_r^{1/2}$ with pressure at 528 °K: ○, individual runs; ●, point taken from Fig. 1.
FIG. 4. Variation of rate constant with pressure for trimethylthallium at 528 °K.

The overall reaction in the unpacked conditioned vessel may be represented by the equation:

$$\log_{10} k\ (s^{-1}) = 10.3 - (26\,000/2.303RT).$$

However, at low temperatures the heterogeneous component was 27% while at higher temperatures the heterogeneous component was only 13%. The homogeneous reaction in the unpacked conditioned vessel may therefore be represented by:

$$\log_{10} k\ (s^{-1}) = 10.8 - (27\,400/2.303RT).$$

No studies on the mean bond energy of trimethylthallium have been reported. From the known total metal–methyl bond strengths of the neighboring elements, a value of 65 ± 5 kcal/mole may be estimated.

The experimental evidence indicates that $D(Me_2Tl—Me) = 27.4$ kcal/mole, so that D_2 plus D_3 is therefore approximately equal to 38 ± 5 kcal/mole.

THE FLOW OF GASES THROUGH MICROPOROUS CARBON[1]

R. F. BARTHOLEMEW[2] AND E. A. FLOOD
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received December 14, 1964

ABSTRACT

Steady state flow rates are reported for He, Ar, N_2, Kr, methane, propane, and *n*-butane flowing through a microporous carbon rod at room temperature.

I. INTRODUCTION

Flow rates of He, Ar, N_2, Kr, methane, propane, and *n*-butane through a small circular cylinder of microporous 'saran' carbon at 25 °C have been measured. The corresponding adsorption isotherms have also been measured. The experimental results are reported below. The observed flow rates of propane and butane are compared with those calculated by means of a theoretical equation deduced previously. The theoretical equation is based on a laminar viscous flow of liquid-like films and correlates flow rates with pore dimensions and adsorption isotherms (1).

II. EXPERIMENTAL

Materials

The microporous carbon used for the permeability and adsorption measurements was a polyvinylidene or 'saran' carbon activated by heating in vacuum to about 1 100 °C for about 1 h. The sample No. 139 Plug 2A had the following properties: 99.9% carbon, surface area (B.E.T., N_2) 1 073 m^2/g, helium density 1.87 (not corrected for the adsorption), weight 56.4 mg, mean length 4.01 mm, mean diameter 4.53 mm, apparent density $\rho' = 0.872$, void volume per gram $v = 0.6112$, porosity 0.5334.

Helium.—A high grade helium for use in a helium cryostat. Minimum purity 99.99%. Supplied by Air Reduction Sales.

Argon.—Minimum purity, 99.99%. Supplied by Union Carbide, Linde Gas Division.

Nitrogen.—Super dry. Minimum purity 99.7%. Impurity mainly O_2.

Krypton.—Spectroscopically pure. Supplied by Dominion Oxygen Co.

Methane.—Phillips Research Grade. 99.58%. Lot No. 985. Probable impurities N_2, ethane, O_2, and propane.

Propane.—Phillips Research Grade, 99.99%, Lot No. 847. Main impurity, ethane.

n-Butane.—Phillips Research Grade, 99.91%, Lot No. 885. Main impurities isobutane and butenes.

Apparatus

The flow apparatus was similar to that described previously, but was provided with improved automatic input and output measuring devices. In all flow rates reported, where the output pressure was greater than zero, the input and output mass flow rates showed no trends and were the same within a few percent. An important experimental feature is the mercury seal sample or 'plug' holder which allows the carbon 'plug' to expand or contract without causing appreciable changes in leaks through the mercury–carbon interface. For samples of reasonably high permeabilities a pressure of about 40 cm of Hg is necessary to reduce the annulus leak to negligible values.

Adsorption isotherms were determined volumetrically using a microvariant of the standard volumetric equipment. In the case of the more strongly adsorbed gases, propane and butane, the volumetrically determined isotherms were checked by the McBain balance technique. The helium density of the small carbon plug was determined in the device shown in Fig. 1, the operation of which is obvious. All flow and adsorption isotherm measurements were carried out at 25.0 °C ± 0.1. All pressures quoted are in cm Hg (25 °C).

Results

Adsorption isotherm data appear in Figs. 2 to 4.

In Table I the observed flow rates in K units corresponding to various mean pressures, $\bar{p}$, are shown. K units are cc per minute measured at the input gas pressure, p_1, multiplied by this pressure, and divided by the difference between the input and output pressures, i.e., divided by $p_1 - p_2$. The mean pressure, $\bar{p}$, is $(p_1 + p_2)/2$. Molecular weight and gas viscosities in micropoise are given in Table II.

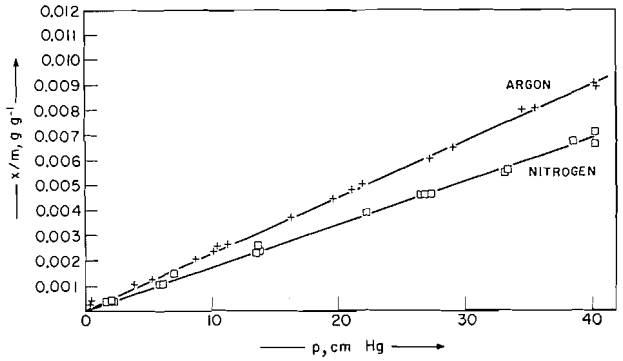

FIG. 2.

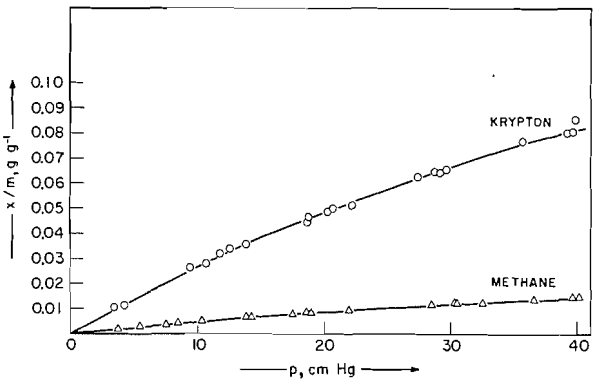

FIG. 3.

III. DISCUSSION

It has been shown by a number of investigators that flow rates of gases through microporous bodies are materially influenced by surface forces (2–5). There are two, more or less, distinct mechanisms in vogue for describing 'surface' flow rates, namely diffusion mechanisms and hydrodynamic mechanisms, the former being the more popular. Assuming that the adsorbate consists of thin liquid-like films as in Polanyi adsorption and that the dimensions of rate-controlling pores are large enough for laminar flow of these films, the following equation has been deduced (1),

[1] $$K = A\sqrt{T/M} + B\bar{p}/\eta_g + (CT^2/M^2\eta_l) \times \overline{|X^2/p|},$$

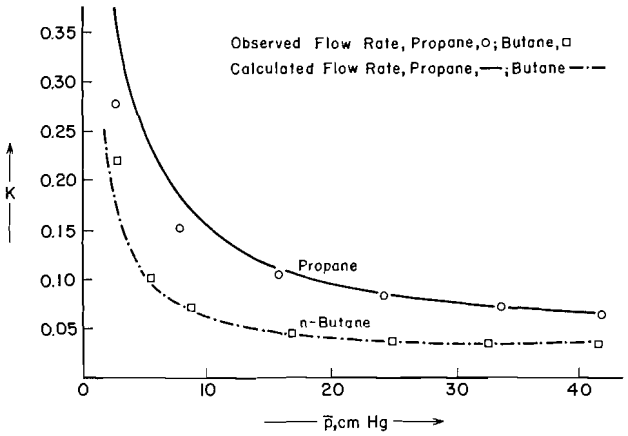

FIG. 5.

In Fig. 5 observed values of flow rates of propane and n-butane are compared with those calculated from eq. [1]. The value of $CT^2/\eta_1 M^2$ for propane is taken as 45.0 while that for n-butane is 8.63.

Since C is supposed descriptive of the pore structure only, in the absence of any molecular sieve action and other complications, the ratios of these two values should be 45/15.36 instead of 45/8.63. We believe that surface forces should increase viscosities of liquid-like films. If the differential heat of adsorption of butane (in the higher relative pressure ranges) is greater than that of propane by about 1 kcal more than the difference in their heats of evaporation, this viscosity ratio η(butane adsorbed)/η(propane adsorbed) would be about 1.78 times the ratio of their normal liquid viscosities. Hence the ratio 45/8.63 in place of 45/15.26 would be obtained.

For personal use only.

For various pore models the mean pore radii of rate-controlling pores can be estimated from eq. [1]. If these pores are more or less circular or square in cross section the pores appear to have diameters of the order of 15 to 20 Å for reasonably plausible pore models. If the pores are slit-like spaces between carbon platelets they appear to be about 10 to 15 Å apart.

The observed flow rates of Ar, N_2, Kr, and methane can be described quite well by equations where the third term on the right hand side of eq. [1] is replaced by (*a*) terms descriptive of a hydrodynamic flow with slip of gaseous adsorbate, (*b*) a term descriptive of a two-dimensional molecular random walk surface flow mechanism, i.e. a term descriptive of surface diffusion. It is difficult to distinguish between gaseous hydrodynamic flow with slip, Knudsen flow, and random walk surface diffusion mechanisms, especially in these microporous bodies, since in the lower concentration regions these mechanisms are all related more or less directly to $(RT/M)^{1/2}$ and to mean step lengths, and they all contribute to a greater or lesser extent to the net flow phenomena.

In the case of the gases Ar and N_2 we consider that the equation in which the third term of eq. [1] represents a random walk surface diffusion mechanism describes the net flow most faithfully. From our data the mean step lengths (resolved in the direction of flow) for Ar and N_2 appear to be surface controlled and of the order of 5 to 8 Å, increasing slightly with surface coverage. Thus in the cases of Ar and N_2 if we write

$$J = -\frac{1}{2}\bar{v}_x\bar{x}\frac{\mathrm{d}N}{\mathrm{d}x} = -D\frac{\mathrm{d}N}{\mathrm{d}x}$$

where J is the number of molecules passing unit length per second on the surface, $\bar{v}_x$ is the mean speed resolved in the direction of flow, the x direction, $\bar{x}$ is the mean step length resolved in the x direction and N the number of molecules per unit area, D is of the order $10^{-4}(1 + (4.59 \times 10^{-3}p_{cm}))$. If we follow Barrer (2) and write $J' = -D'\frac{dC}{dx}$ where J' refers to the number of molecules per second passing unit area of the input surface of the whole plug and C is the total number of molecules both in the gas space and on the surface that is contained in unit volume of sample, the value of D' is about the same as D.

THE REACTIONS OF 2-METHYL ETHYLENIMINE AND AZACYCLOBUTANE WITH ATOMIC HYDROGEN

J. W. S. JAMIESON, G. R. BROWN, AND W. K. HANCOCK
Department of Chemistry, St. John's College, University of Manitoba, Winnipeg, Manitoba
Received December 23, 1964

ABSTRACT

The reactions of hydrogen atoms with 2-methyl ethylenimine and azacyclobutane have been investigated at various temperatures. Between 100 and 300 °C both reactions have been found to be rapid and complete, so that the maximum disappearance of either cyclic imine under these conditions may be regarded as a satisfactory measure of atomic hydrogen flow rates. At 300 °C ethane has been found to be a major product, and it has been inferred from this and other results at this temperature that the other major product of both reactions is cyanogen, which could not be isolated since it appears to form compounds with both cyclic imines.

INTRODUCTION

The reactions of 2-methyl ethylenimine and azacyclobutane with atomic hydrogen have been studied with the hope that either or both of these cyclic imines would be capable of giving even more accurate estimates of the flow rates of atomic hydrogen in a Wood-Bonhöffer apparatus than it has previously been possible to make on the basis of the maximum extent of the reactions of ethyl chloride (1), formamide (1), or ethylenimine (2) with hydrogen atoms.

EXPERIMENTAL

A 50 g sample of 2-methyl ethylenimine (b.p. 64.0–65.5 °C) was kindly donated by Chemirad Corporation, East Brunswick, N.J., U.S.A., and azacyclobutane (1,3-propylenimine, trimethylenimine) of research grade was purchased from the Borden Company, Chemical Division, Monomer–Polymer Laboratories, Philadelphia, Pa., U.S.A. These reactants were further purified by bulb-to-bulb distillation under vacuum, the first and last fractions being discarded.

Cyanogen was prepared either by heating mercuric cyanide alone (3) or in the presence of $HgCl_2$ (4) (which did not prove to be a very satisfactory method) or by dropping saturated KCN solution into a solution of $CuSO_4$ (5).

The apparatus was a conventional fast flow system which has recently been described (1, 6). Gaseous products of the reactions have been identified by comparing temperatures for separation from a Le Roy still and retention times in gas chromatography for known gases, gases produced in the reactions studied, and mixtures of known gases and reaction products. Experimental procedures, including volumetric analysis of cyanide and analysis of ethane and ethylene by gas chromatography were as previously described (1, 6). Unreacted imine was determined by titration with standard acid to the methyl red end point. A column (7) of triacetin on Chromosorb P at 70 °C was used whenever possible to separate HCN and cyanogen by gas chromatography.

In all experiments the flow rate of molecular hydrogen was 8.82×10^{-5} mole/s, which gave a pressure in the reaction system of 1.10 mm. The atomic hydrogen flow rate was estimated at several temperatures from the reactions of ethyl chloride (1), formamide (1), and ethylenimine (2) with hydrogen atoms. At 300 °C the best estimate thus obtained is 2.1×10^{-6} mole/s, which is applicable to most of the experiments reported.

RESULTS AND DISCUSSION

The data of Table I and Fig. 1 show that 2-methyl ethylenimine reacted rapidly and completely with hydrogen atoms at 300 °C. At high imine flow rates the amount of imine reacted per second was found to be equal to the estimated hydrogen atom flow rate. The reaction was slower at 96 °C but the same maximum extent of reaction was observed at high imine flow rates, while at 36 °C (in the unheated reaction vessel) the reaction was slow and incomplete.

*All flow rates are in μmole/s.

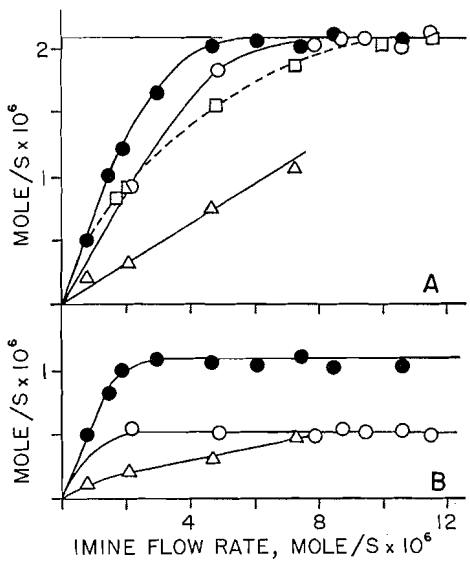

FIG. 1. The reaction of 2-methyl ethylenimine with atomic hydrogen. A. Imine reacted at 36 °C (△), 96 °C (○), and 300 °C (●); ethane produced at 300 °C (□). NOTE. The light horizontal line denotes the flow rate of hydrogen atoms. B. Cyanide produced at 36 °C (△), 96 °C (○), and 300 °C (●).

In the experiments at 300 °C the maximum amount of ethane produced was equal not only to the maximum amount of imine reacted but also to the flow rate of hydrogen atoms. The maximum amount of cyanide produced at the high temperature was about half the maximum amount of imine reacted.

A number of experiments at higher hydrogen atom flow rates (about 4 and 5 μmoles/s) and at various temperatures have given similar results, some of which have previously been reported (6).

As in the reaction of ethylenimine (2) the most probable primary reaction is abstraction of the imine hydrogen.

[1] 
It is unlikely that ethane is formed by decomposition of the imino radical thus formed, except possibly at very low imine flow rates where some HCN may be produced by reaction of the excess hydrogen atoms with imino radicals. Trace amounts of HCN were detected by gas chromatography in some experiments at very low imine flow rates, although consideration of a material balance for carbon and nitrogen at the high temperature and high imine flow rates seems to imply that the product which gives the cyanide titration is cyanogen, which during the analysis hydrolyzes to the cyanate ion and the cyanide ion. Titration of the latter ion would then give a measure of the amount of cyanogen produced in the reaction of the imine with atomic hydrogen. Thus ethane and cyanogen are probably formed mainly by combination of two of the imino radicals produced in reaction [1] so that, in agreement with the experimental results at 300 °C, one molecule of ethane and half a molecule of cyanogen are produced for each molecule of 2-methyl ethylenimine reacted with atomic hydrogen.

Cyanogen has not been positively identified among the products, except in trace amounts, either by separation from a Le Roy still at −125 °C or by gas chromatography. In an attempt to understand how cyanogen could give the cyanide titration but could not be determined by other means some cyanogen was prepared and studied. The freshly prepared cyanogen was further purified in a Le Roy still, from which it was distilled at −125 °C. The pure material was then measured in a gas burette, after which it was analyzed by gas chromatography. After passage through a suitable column (7) the cyanogen gave a distinct peak which was easily separated from HCN when it was added. The pure cyanogen was also found to give the cyanide titration with silver nitrate.

When some of either imine was added to cyanogen in the Le Roy still no gas was evolved at −125 °C. Similarly when either imine was introduced into a gas burette containing cyanogen there was an immediate and substantial drop in pressure. When some of the mixture of either imine with cyanogen was taken into the gas chromatograph no cyanogen was detected. On the other hand, when either mixture was distilled into a removable cold trap it was found to give the cyanide titration.

It appears, therefore, that there is conclusive evidence that cyanogen forms compounds in the gas phase with both 2-methyl ethylenimine and azacyclobutane. Evidently both compounds decompose either in aqueous solution or in the presence of silver nitrate solution. In view of these experiments it is hardly surprising that cyanogen could not be isolated from the mixtures of unreacted imines and other products of the reactions of atomic hydrogen with the cyclic imines.

The results for the reaction of azacyclobutane with atomic hydrogen are shown in Table II and in Fig. 2. This reaction was found to be even more rapid than the 2-methyl ethylenimine reaction. Destruction of azacyclobutane and formation of products were almost independent of temperature from 41 to 300 °C. Again, at high imine flow rates and at both temperatures, all the available hydrogen atoms were consumed by the imine. In all experiments the maximum amount of cyanide determined by titration with silver nitrate was about half the maximum amount of imine reacted.

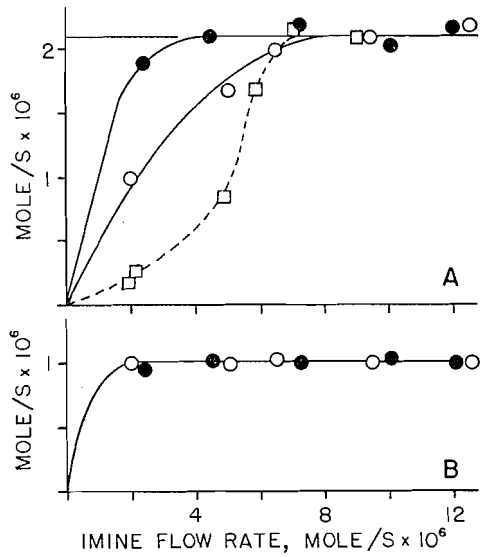

FIG. 2. The reaction of azacyclobutane with atomic hydrogen. A. Imine reacted at 41 °C (○) and 300 °C (●); ethane plus ethylene produced at 300 °C (□). NOTE. The light horizontal line denotes the flow rate of hydrogen atoms. B. Cyanide produced at 41 °C (○) and 300 °C (●).

Analysis by gas chromatography showed that both ethane and ethylene were among the products of the azacyclobutane reaction at 300 °C. Since separation of the peaks for these gases was incomplete the results are reported as ethane plus ethylene, although it is estimated that there was about twice as much ethane as ethylene. The total amount of these two products was equal to the extent of the azacyclobutane reaction at 300 °C and high flow rates.

Again, as previously reported (6), similar results were obtained in several experiments at higher hydrogen atom flow rates and at various temperatures.

By analogy with the reactions of atomic hydrogen with ethylenimine (2) and 2-methyl ethylenimine it seems likely that hydrogen atoms first attack azacyclobutane to abstract the imine hydrogen.

[2] 
Except at very low imine flow rates the main subsequent reactions would seem to involve combination of two imino radicals to give cyanogen and either ethane predominately or ethylene and hydrogen, although it has not been possible, for the reason already given, to confirm the presence of cyanogen among the products.

The formation of small quantities of HCN at very low imine flow rates might again be due to reaction of the imino radicals with any excess hydrogen atoms.

As anticipated, both 2-methyl ethylenimine and azacyclobutane reacted rapidly and completely with atomic hydrogen, particularly at temperatures above 100 °C, so that both reactants at high flow rate seem to be very suitable for the estimation of atomic hydrogen flow rates. Their use for this purpose in a study of the kinetics of the reaction of atomic hydrogen with methane has already been reported (6).

THE DISSOLUTION OF COPPER IN AMMONIACAL POTASSIUM BROMATE SOLUTIONS[1]

M. KULKARNI AND D. R. WILES
Department of Chemistry, Carleton University, Ottawa, Canada

Received January 15, 1965

ABSTRACT

The dissolution of copper in ammonia solutions was found earlier to be bimolecular in ammonia, involving a fast equilibrium adsorption of one molecule, followed by attack by a second molecule of ammonia (or an ammonium ion). The present work, differing in that potassium bromate is used as oxidizing agent rather than oxygen under pressure, shows that the dissolution process is essentially similar in many respects. The most striking difference is that the oxidation step can now be seen and proves to be quite complex. In particular two quite different oxidation mechanisms appear to operate: one is a simple adsorption of $KBrO_3$ and the other is a higher order reaction interpreted as involving a multiple adsorption on the reaction site, for which ammonia and ammonium also compete.

INTRODUCTION

The dissolution of metallic copper in aqueous ammonia solutions has been shown in earlier work (1) to involve two steps in addition to the oxidation stage. The first of these appears to be a fast equilibrium adsorption of ammonia on an oxidized site in the metal surface. The second, the rate-determining step, is an attack on the same site by either an ammonia molecule or an ammonium ion. These steps are illustrated by eqs. [1] and [2].

$$[1] \qquad Cu_o + NH_3 \overset{K}{\rightleftharpoons} Cu_oNH_3$$

$$[2a] \qquad Cu_oNH_3 + NH_3 \overset{k_1}{\rightarrow} Cu(NH_3)_2^{++}$$

$$[2b] \qquad Cu_oNH_3 + NH_4^+ \overset{k_2}{\rightarrow} Cu(NH_3)_2^{++} + H^+$$

The symbol Cu_o is used to denote a copper atom at an oxidized site in the metal surface, although the nature of this site is at present not known. Direct observation of this adsorption has recently been made by Nagi (2) using carbon-14-labelled methylamine.

The same mechanism was found to hold for the simple aliphatic amines as well as for ammonia. The reaction rate was well expressed by eq. [3], which can easily be derived from the mechanism given.

$$[3] \qquad \text{Rate} = \frac{d[Cu^{++}]}{dt} = \frac{K[NH_3]S}{1 + K[NH_3]} (k_1[NH_3] + k_2[NH_4^+])$$

The supposition that the sites for reactions [1] and [2] are the same was confirmed by the observation (3) that the same reaction is monomolecular in ethylenediamine. It is interesting to note that in 1,4-butanediamine the dissolution is bimolecular, while in 1,3-propanediamine both a bimolecular and a monomolecular reaction can be observed (3).

These studies allowed no investigation of the role of the oxidizing agent (O_2 under 8 atm pressure) because of transport problems in the solution. In the present study, oxidation was effected by the use of $KBrO_3$. This reagent was chosen as a convenient one for use in basic solutions: one which is stable toward decomposition and gives no reaction with Cu^{++}.

EXPERIMENTAL METHODS

The copper used was 99.9% pure, supplied by J. T. Baker Chemical Company. The metal was vacuum melted and cast into ingots and then stressed and annealed to effect grain refinement.* The resultant sample was a polycrystalline material whose average grain size was a few tenths of a millimeter. No determination was made of crystal orientation, which is assumed to be essentially random. After being machined to size (14.0 mm diameter) the metal samples were mounted in Bakelite to expose a constant surface area. The samples were polished by hand down to number 0 emery paper before each use. No etching treatment was used, since it was shown earlier (1) that etching makes no difference in the rate. Failure to etch the samples may lead to a variation in the true zero time, but this time was not of concern in determining the rate.

All other reagents were the best grade available. Ammonia stock solutions were kept in stoppered containers and checked frequently to detect possible changes in concentration.

The dissolution studies were done in a vessel essentially similar to the one used before, except that the use of atmospheric pressure made possible the use of a Pyrex container and Lucite internal parts. A diagram showing the essential features is given in Fig. 1.

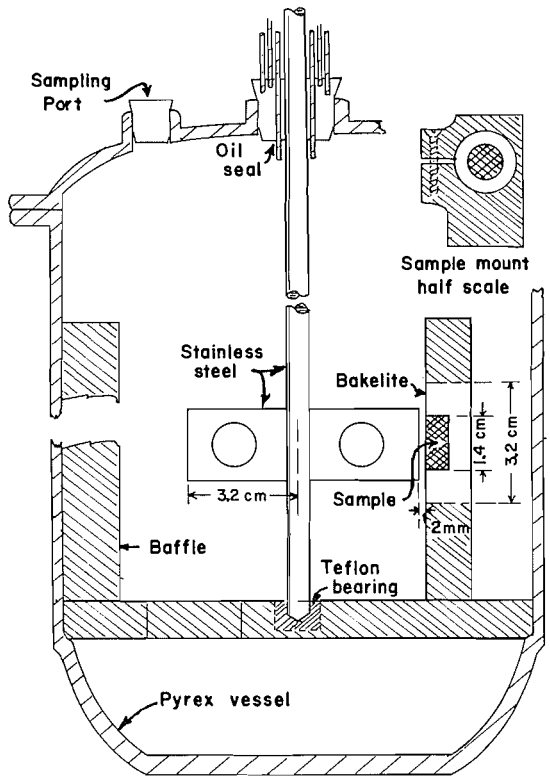

FIG. 1. Diagram of dissolution apparatus.

In any heterogeneous system, it is important to make sure that the observed rate is not merely the rate of transport of the reactants to the reaction interface (4, 5). While in the case of very slow reactions mild agitation is adequate (6, 7) in the case of more rapid dissolution the rate of stirring of the solution is occasionally of greatest importance (8, 9). We have employed two criteria to convince ourselves that transport of the reactants was not a limiting factor in the experiments described here: (i) The reaction rate was found to be essentially independent of stirring rate† between 750 r.p.m. and 1 100 r.p.m. so a stirring rate of 900 r.p.m. was used. (ii) The system was tested for transport control also by the method suggested by Bircumshaw and Riddiford (5). The dissolution was done using 0.02 M I_2 in KI solution as oxidant. A dissolution rate of ~ 250

*We are grateful to Mr. H. Weld for assistance in preparing the copper samples.

†*This is one of the criteria of King (4). Another criterion is that the activation energy not be too low, e.g.* $\Delta H^{\ddagger} > 5$ *kcal/mole. This seems to be a somewhat uncertain test, however, since some of the activation energies observed in chemically controlled dissolution reactions are disturbingly close to the suggested limit (13).*

mg Cu^{++} cm^{-2} h^{-1} was found, corresponding to a diffusion layer ~ 0.003 mm thick. Using available (10) mobility data for NH_3 and assuming the mobilities of NH_4^+ and BrO_3^- to be not greatly different, it was computed that transport control would be no problem unless the dissolution rate exceeded 500 mg Cu^{++} cm^{-2} h^{-1}. The rates observed were seldom in excess of 150 mg Cu^{++} cm^{-2} h^{-1}, and transport of reactants to the surface is concluded to play no limiting part in determining the kinetics of the reaction.

Each experiment involved stirring 3.0 l of solution of the chosen concentrations of $KBrO_3$, NH_3, and NH_4ClO_4, adjusted in advance to the proper temperature, in contact with the copper samples. The solution was sampled by withdrawing 10 ml aliquots at regular intervals. These samples were analyzed for copper by the carbamate method (11). The temperature was controlled by the use of a thermistor controller.* Temperatures were adjusted to ± 0.1 °C and controlled to about ± 0.05 of the adjusted value.

Rates were determined from the slope of the plot of $[Cu^{++}]$ vs. time. Correction was not made for the amount of solution removed in samplings and a systematic error of about 0.5% is thus introduced. In the light of other uncertainties, however, this is not of a magnitude to warrant concern. These rate plots were invariably linear, which fact was taken to indicate that (*a*) there is no reaction between BrO_3^- and NH_3 or NH_4^+ which might affect the dissolution rate, and that (*b*) the cupric ion has no effect on the reaction. Thus, autocatalytic mechanisms such as that of Lu and Graydon (12), involving some cupric species as oxidant, are not relevant here.

RESULTS AND DISCUSSION

The dissolution rates are shown, as a function of $[NH_3]$ for various values of $[NH_4^+]$, in Figs. 2 and 3.

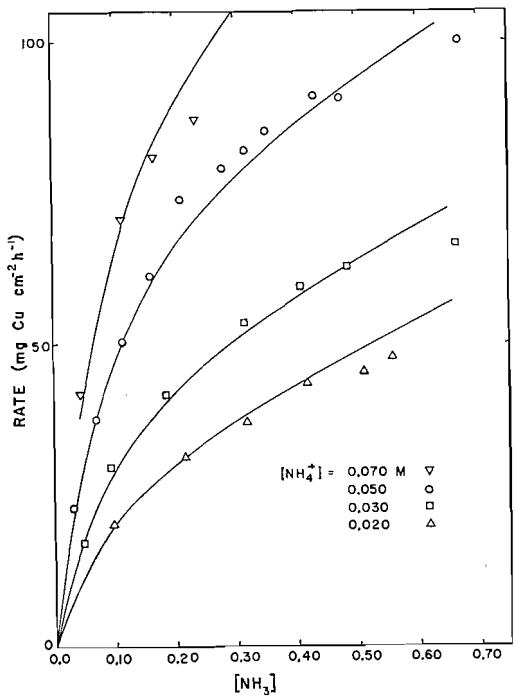

FIG. 2. Rates of dissolution as a function of $[NH_3]$. $[KBrO_3] = 0.033$ *M*, temperature 25 °C, $[NH_4^+]$ as shown on figure. Solid lines calculated using eq. [3].

The most striking feature of the rate plots is a sudden remarkable decrease in the rate which occurs as higher ammonia concentrations are reached. The "turnover point", which clearly marks the change from one reaction mechanism to another, is also a function of the ammonium ion concentration and, as is seen in Fig. 4, of the bromate concentration.

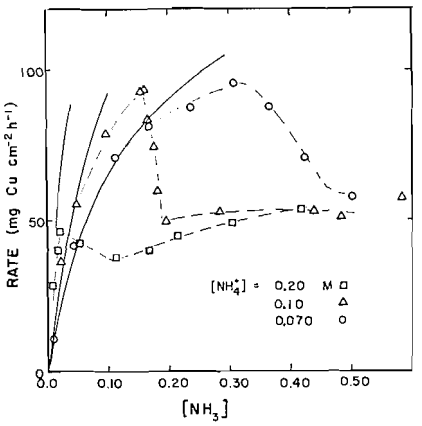

FIG. 3. Rates of dissolution as a function of $[NH_3]$. $[KBrO_3] = 0.033\ M$, temperature 25 °C, $[NH_4^+]$ as shown on figure. Solid lines calculated using eq. [3].

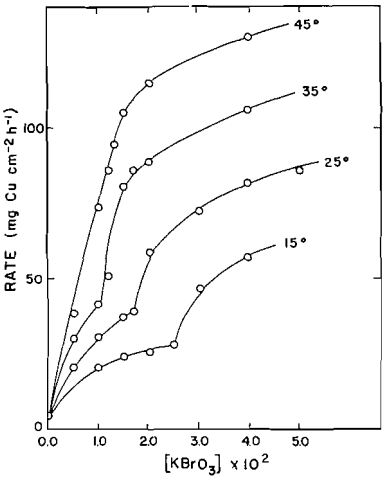

FIG. 4. Rates of dissolution as a function of $[KBrO_3]$. $[NH_3] = 0.35\ M$, $[NH_4^+] = 0.050\ M$.

We will find it convenient to refer to the "high-bromate region" and the "low-bromate region." These are quite distinct in Fig. 4.

In the high-bromate region, the dependence of the rate on the ammonia and ammonium concentrations is the same as that observed earlier using O_2 as oxidant. At constant acidity eq. [3] becomes:

$$\text{rate} = \frac{K[NH_3]^2 S}{1 + K[NH_3]} (k_1 + k_2\alpha) \qquad [4]$$

where $\alpha = [NH_4^+]/[NH_3]$. The results at constant acidity are shown in Figs. 5 and 6, for various values of α.

It is evident that the data are not precise enough to permit unequivocal computation of the constants of eqs. [3] and [4]. However, a self-consistent set is given in Table I.

It is these values which have been used in computing the solid curves drawn in Figs. 2, 3, 5, and 6. Comparison of the values for the constants determined in this work with the

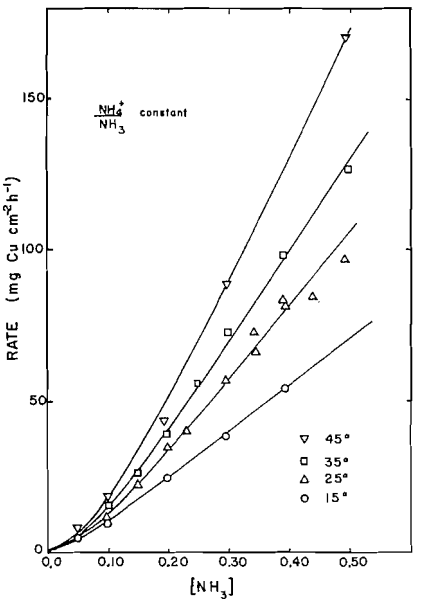

FIG. 5. Rates of dissolution at constant acidity. $[NH_4^+]/[NH_3] = 0.10$, $[KBrO_3] = 0.033$ *M*. Solid curves calculated using eq. [4].

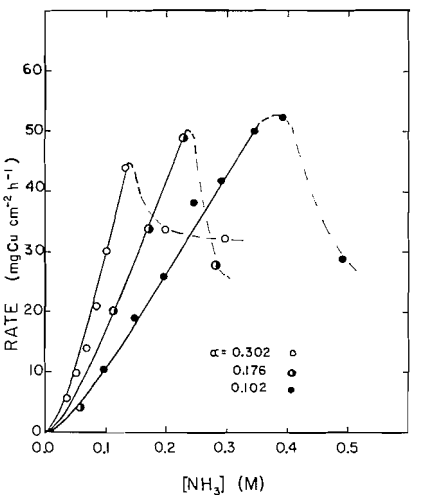

FIG. 6. Rates of dissolution at constant acidity. $[NH_4^+]/[NH_3]$ ($= \alpha$) given on graph, $[KBrO_3] = 0.011$ *M*, temperature 25 °C. Solid curves calculated using eq. [4].

values obtained by Sircar (1) shows that the adsorption and reaction mechanisms are fairly similar, although there is a quantitative dependence on both the nature and concentration range of the oxidant.

The concentration of ammonia seems to have a much smaller effect on the rate in the low-bromate region, although the nature of this effect is not clear at present. The ammonium ion appears to have a rather more pronounced effect but too few data have been obtained to make a detailed analysis possible.

TABLE I
Constants for eqs. [3] and [4]

$KBrO_3$ (M)	Temperatures (°C)	K	k_1	k_2
0.012	25	16.5	(~10)	1.6×10^3
0.033	15	22	45	0.95×10^3
0.033	25	10.0	45	1.8×10^3
0.033	35	8.0	15	3.1×10^3
0.033	45	7.0	(~25)	4.0×10^3
Activation energies (kcal/mole)		~6	—	10.7
O_2 at 8.2 atm (ref. 1)	25	4.7	80	2.5×10^3

The effect of changing bromate ion concentration (Fig. 4) suggests that the low-bromate region involves simple Langmuir adsorption of a single bromate ion, leading to the production of oxidized sites, which may then react with ammonia. Reasonable fit of the data is obtained at 25 °C by using a value $K = 140$ for the adsorption equilibrium constant. It must be emphasized that only few data are available, and a definite conclusion is not possible.

The turnover point varies in a rather complicated manner with the concentrations of bromate, ammonia, and ammonium. A sudden break in curves of this type has been observed in other cases. For example, in the dissolution of zinc in oxygenated ammoniacal solutions (14) the rate decreases suddenly as the oxygen pressure is increased. This was shown to result from the formation of a protective layer of zinc oxide.

This interpretation seems unsatisfactory in the present case, however, on the following grounds: (i) A pH-potential diagram (15) was drawn up for the copper–ammonia system, and it clearly showed that the formation of any kind of oxide layer is most unlikely under the conditions used. (ii) Zogović showed (16) that CuO, under similar experimental conditions, dissolves very slowly indeed. The present experiments show an increase in rate under conditions where formation of any sort of layer would lead to a decrease in rate.

An attractive possibility is that of a competitive adsorption at a surface site, S.

[5] $$S(NH_3)_x(NH_4^+)_y + zBrO_3^- \rightleftharpoons S(BrO_3^-)_z + xNH_3 + yNH_4^+$$

It is hoped that continuation of our carbon-14 experiments (2) may shed further light on this question. The final steps in the reaction of the oxidized site produced by this competition are the same as was found earlier for sites produced by molecular oxygen (1).

An attempt was made to apply Moelwyn-Hughes' molecular statistics (17) to the final step (i.e. eq. [2*a*] or [2*b*]). In this approach, one calculates the total number, $N^{\ddagger}$, of molecules of a given species striking the surface with energy greater than the activation energy for the reaction using the formula,

[6] $$N^{\ddagger} = n_s \sqrt{\frac{RT}{2\pi M}}\ e^{-\Delta H^{\ddagger}/RT}.$$

In cases which Moelwyn-Hughes feels the agreement is satisfactory, this number $N^{\ddagger}$ is larger than the experimental reaction rate by a factor of perhaps 40. Using this technique to look at the ammonium reaction (eq. [2*b*]) for which both the rate and the activation energy are fairly reliable, one finds the observed rate to be some 30 times the maximum theoretical rate. Considering the uncertainties involved, this may be regarded as satisfactory agreement.

THE REACTION OF UNSATURATED CARBOHYDRATES WITH CARBON MONOXIDE AND HYDROGEN

IV. STRUCTURE AND STEREOCHEMISTRY OF ANHYDRODEOXYHEPTITOLS FROM 3,4,6-TRI-*O*-ACETYL-D-GALACTAL

ALEX ROSENTHAL AND DEREK ABSON
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received February 24, 1964

ABSTRACT

3,4,6-Tri-*O*-acetyl-D-galactal reacted with carbon monoxide and hydrogen in the presence of dicobalt octacarbonyl to yield 2,6-anhydro-3-deoxy-D-*galacto*-heptitol (I) and 2,6-anhydro-3-deoxy-D-*talo*-heptitol (II). The stereochemistry of (I) and (II) has been established by correlation with 2,6-anhydro-3-deoxy-D-*gluco*-heptitol (VI) of known configuration. Evidence that both (I) and (II) are formed by the addition of a hydroxmethyl group to C-1 of the glycal is also furnished by the proton n.m.r. spectra of the normal and deuterated anhydrodeoxyheptitols.

Part I of this series (1) described the action of carbon monoxide and hydrogen on 3,4,6-tri-*O*-acetyl-D-galactal, and presented evidence for the formation of an anhydrodeoxyheptitol of unknown stereochemistry. It has since been found that 3,4,6-tri-*O*-acetyl-D-galactal reacts under oxo conditions in a manner entirely analogous to other glycals investigated (2, 3) to yield as the major products a pair of isomeric anhydrodeoxyheptitols (I) and (II), formed by the addition of a hydroxymethyl group to C-1 of the unsaturated carbohydrate. The stereochemistry of (I) and (II) has been elucidated by an analysis of their proton n.m.r. spectra and by correlation with 2,6-anhydro-3-deoxy-D-*gluco*-heptitol (VI), whose structure has been proved by crystallographic X-ray analysis (4).

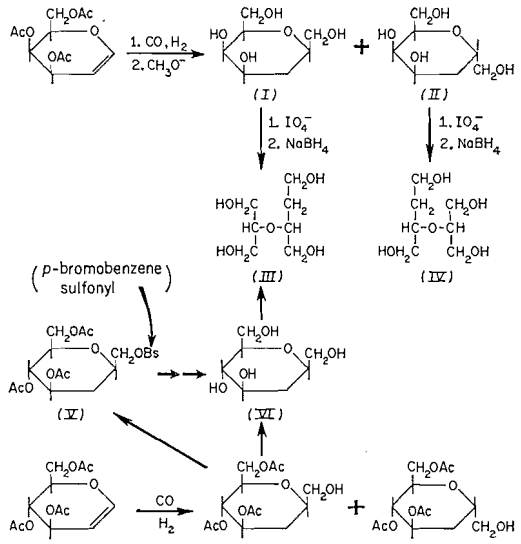
3,4,6-Tri-*O*-acetyl-D-galactal (5) was reacted in a high-pressure apparatus with carbon monoxide and hydrogen in the presence of dicobalt octacarbonyl, under conditions similar to those described previously (1). The reaction product was separated from the catalyst by chromatography on a Florisil column, and deacetylated with methanolic sodium methoxide. The two major reaction products (I) and (II), after separation by preparative paper chromatography, were obtained in approximately equal amounts.

DISCUSSION

Both (I) and (II) consumed 1 molar equivalent of periodate (0.95 and 0.98 respectively) as measured by the spectrophotometric method of Dixon and Lipkin (6). Fraction (II) reacted with acetone in the presence of sulfuric acid to form a monoisopropylidene derivative (VII), which on treatment with *p*-toluenesulfonyl chloride in pyridine gave a compound (VIII) containing two tosyloxy groups. The latter compound on heating with sodium iodide in acetone solution liberated 2 equivalents of sodium *p*-toluenesulfonate. Thus it is highly likely that (II) contains two primary hydroxyl groups and two adjacent *cis* secondary hydroxyl groups. Compound (I) was characterized as the tetra-*O*-(*p*-nitrobenzoyl) derivative.

Evidence that both (I) and (II) have unbranched carbon skeletons was furnished by their proton nuclear magnetic resonance (n.m.r.) spectra, measured in D_2O solution (Fig. 1*a* and *c*). These both show a group of signals at lower field (3.3–4.3 p.p.m.) with total area corresponding to 8 hydrogens, and a further group at higher field (1.3–2.3 p.p.m.), area = 2 hydrogens. The higher field signals can clearly be assigned to hydrogens attached

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



to C-3 of the anhydrodeoxyheptitols, this being the only carbon atom which is not directly linked to oxygen, and the fact that two such hydrogens are present in both (I) and (II) must mean that the two compounds differ only in the configuration of the hydroxymethyl group about C-2. This tentative assignment was then rigorously established by classical chemical methods in the following way. Oxidative cleavage of (I) and (II) with periodic acid followed by sodium borohydride reduction of the resulting dialdehydes gave a pair of enantiomeric tetrol ethers (III) and (IV). Each had only one asymmetric center, and the enantiomers had similar infrared spectra, and equal and opposite specific rotations. Treatment of (III) and (IV) with *p*-nitrobenzoyl chloride in pyridine afforded the enantiomeric tetra-*O*-(*p*-nitrobenzoyl) derivatives, which had identical infrared spectra and melting points and differed only in the sign of rotation.

The configuration of C-2 of both epimeric 2,6-anhydro-3-deoxyheptitols was readily established by application of proton n.m.r. spectroscopy, as previously described (2), to the 3-deoxy-3-deuterioanhydroheptitols (IX) and (X) which were produced when 3,4,6-tri-*O*-acetyl-D-galactal was reacted with carbon monoxide and deuterium. Thus, as shown in Fig. 1*b*, the narrow quartet structure (width about 17 c.p.s.) of the signal of intensity 1 at around $\delta = 1.7$ requires the C-3 proton to be in an equatorial orientation and coupled with the C-2 and C-4 axial hydrogens. On the other hand, as depicted in Fig. 1*d*, the corresponding wider multiplet of signals (width about 35 c.p.s.) of intensity 1 at the field ($\delta = 1.9$) suggests the C-3 proton of compound (X) to be in an axial orientation and coupled with the C-4 axial and C-2 equatorial hydrogens. Therefore, compounds (IX) and (X) are 2,6-anhydro-3-deoxy-D-*galacto*-heptitol-1,1,3-$^2H_3$ and 2,6-anhydro-3-deoxy-D-*talo*-heptitol-1,1,3-$^2H_3$, respectively.

Unequivocal confirmation of the C-2 configuration of the anhydrodeoxyheptitols (I) and (II) was provided by correlating (I) and (II) with 2,6-anhydro-3-deoxy-D-*gluco*-heptitol (VI). The latter compound had been produced by application of the oxo reaction to 3,4,6-tri-*O*-acetyl-D-glucal (4). The absolute configuration of the 1-*O*-(*p*-bromobenzenesulfonyl) derivative (V) had been previously proved by X-ray analysis (4), and (V) has been converted by standard procedures into (VI). The latter compound on periodate oxidation followed by sodium borohydride reduction of the dialdehyde gave a tetrol ether

For personal use only.

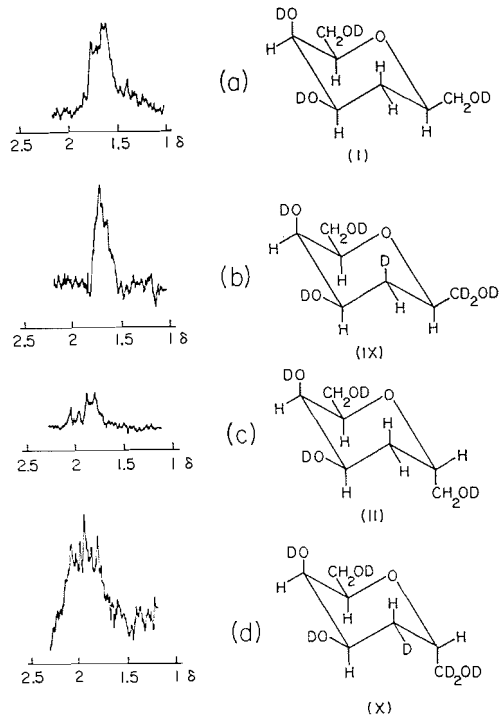

FIG. 1. Proton n.m.r. spectra in D_2O solution at 60 mc with chemical shifts given in p.p.m. from tetramethylsilane as zero; (*a*) 2,6-anhydro-3-deoxy-D-*galacto*-heptitol (I); (*b*) 2,6-anhydro-3-deoxy-D-*galacto*-heptitol-1,1,3-$^2H_3$ (*cis*) (IX); (*c*) 2,6-anhydro-3-deoxy-D-*talo*-heptitol (II); (*d*) 2,6-anhydro-3-deoxy-D-*talo*-heptitol-1,1,3-$^2H_3$ (*cis*) (X). (Only signals of protons attached to C-3 are shown.)

having an infrared spectrum and specific rotation similar to the dextrorotatory tetrol ether (III) derived from the anhydrodeoxyhexitol (1), and formed a tetra-*O*-(*p*-nitrobenzoyl) derivative identical with that obtained from (III) on the basis of melting point, mixed melting point, infrared spectrum, and specific rotation. Therefore (I), having the same configuration at C-2 as 2,6-anhydro-3-deoxy-D-*gluco*-heptitol, is 2,6-anhydro-3-deoxy-D-*galacto*-heptitol, and (II), the C-2 isomer of (I), is 2,6-anhydro-3-deoxy-D-*talo*-heptitol.

EXPERIMENTAL

General Considerations

Conditions for chromatographic separations and measurement of n.m.r. and infrared spectra have been described previously (2).

Preparation of *p*-nitrobenzoyl derivatives was carried out by a procedure similar to that of Gorin (7).

Microanalyses were by Mrs. Aldridge of this department and by Dr. A. Bernhardt, Mülheim (Ruhr), West Germany.

*Reaction of 3,4,6-Tri-O-acetyl-*D*-galactal with Carbon Monoxide and Hydrogen to Yield 2,6-Anhydro-3-deoxy-*D*-galacto-heptitol (I) and 2,6-Anhydro-3-deoxy-*D*-talo-heptitol (II)*

A solution of 3,4,6-tri-*O*-acetyl-D-galactal (15 g) and dicobalt octacarbonyl (3.5 g) in dry purified benzene (50 ml) was shaken with carbon monoxide (1 300 p.s.i.) and hydrogen (1 900 p.s.i.) in a high-pressure autoclave at a temperature of 130–135° for approximately 2 h. The resulting solution was transferred to a column (14 × 8 cm diameter) of Florisil and the catalyst was eluted with 30–60° petroleum ether. Elution with benzene–ethanol (9:1, v/v) and evaporation of solvent then gave 13.5 g of syrupy product. Deacetylation with 0.1 *N* sodium methoxide in methanol at room temperature for 18 h and removal of solvent gave a water-soluble product which, after deionization with Amberlite IR 120 (H^+) resin and freeze drying, afforded a partially crystalline mixture of (I) and (II) in approximately equal amounts, together with traces of sugars. Fractionation of the mixture of anhydrodeoxyheptitols was carried out by preparative paper chromatography. From an amount of 0.43 g of crude mixture, 0.16 g (37%) of fraction I and 0.14 g (33%) of fraction II were isolated.

Characterization of Fractions (I) and (II)

*Fraction (I) (2,6-anhydro-3-deoxy-*D*-galacto-heptitol)* was crystallized from methanol – isopropyl ether; m.p. 158–159°; $[\alpha]_D^{27}$ +24° (*c*, 0.8 in water);* R_F = 0.24.

Anal. Calcd. for $C_7H_{14}O_5$: C, 47.18; H, 7.92. Found: C, 47.50; H, 8.07.

*2,6-Anhydro-3-deoxy-1,4,5,7-tetra-O-(p-nitrobenzoyl)-*D*-galacto-heptitol*

Fraction (I) (35 mg) was treated with *p*-nitrobenzoyl chloride in pyridine to yield a tetra-*O*-(*p*-nitrobenzoyl) derivative (95 mg, 72%), which was recrystallized from ethyl acetate – petroleum ether (30–60°); m.p. 210–211°; $[\alpha]_D^{23}$ −12° (*c*, 2.0 in chloroform).

Anal. Calcd. for $C_{35}H_{26}O_{17}N_4$: C, 54.28; H, 3.38; N, 7.23. Found: C, 54.61; H, 3.50; N, 7.47.

*Fraction (II) (2,6-anhydro-3-deoxy-*D*-talo-heptitol)* was crystallized from methanol – isopropyl ether; m.p. 168°; $[\alpha]_D^{27}$ +68° (*c*, 1.1 in water); R_F = 0.21.

Anal. Calcd. for $C_7H_{14}O_5$: C, 47.18; H, 7.92. Found: C, 46.94; H, 8.22.

*2,6-Anhydro-3-deoxy-4,5-O-isopropylidene-*D*-talo-heptitol (VII)*

Fraction (II) (55 mg) in dry, purified acetone (2 ml) containing 4% H_2SO_4 was stirred at room temperature for 20 h. Neutralization with sodium hydroxide solution, filtration, and evaporation of solvent gave an oil, which was extracted with boiling carbon tetrachloride to yield the mono-*O*-isopropylidene derivative (23 mg). Further treatment of the carbon tetrachloride insoluble residue with acidified acetone gave an additional amount (21 mg) of product (66% overall yield). The combined extracts were recrystallized from carbon tetrachloride; m.p. 104–105°; $[\alpha]_D^{21}$ +12° (*c*, 1.6 in chloroform).

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.03; H, 8.31. Found: C, 54.82; H, 7.97.

*2,6-Anhydro-3-deoxy-4,5-O-isopropylidene-1,7-di-O-tosyl-*D*-talo-heptitol (VIII)*

To a solution of (VII) (33 mg) in dry pyridine (1.0 ml) was added *p*-toluenesulfonyl chloride (66 mg). After standing for 18 h at room temperature the solution was stirred with water (0.1 ml). More water was added until the solution became turbid, and on standing, crystals (50 mg, 63%) of the di-*O*-tosyl derivative formed. The product was recrystallized from methanol; m.p. 135°; $[\alpha]_D^{23}$ −42° (*c*, 1.7 in chloroform).

Anal. Calcd. for $C_{24}H_{30}O_9S_2$: C, 54.78; H, 5.74. Found: C, 55.08; H, 6.01.

When a solution of the di-*O*-tosyl derivative (VIII) (8.4 mg) and sodium iodide (25 mg) in acetone (0.4 ml) was heated in a sealed tube at 118° for 26 h sodium *p*-toluenesulfonate (6.4 mg) was precipitated in an amount equivalent to the replacement of two tosyloxy groups by iodine. When the reaction was carried out at 100° for 30 min the amount of sodium *p*-toluenesulfonate isolated was approximately equivalent to the replacement of only one tosyloxy group.

Structure and Stereochemistry of Fractions (I) and (II)

*2-Deoxy-3-O-(1,3-dihydroxy-2-propyl)-*L*-glycero-tetritol (III) from 2,6-Anhydro-3-deoxy-*D*-gluco-heptitol (VI)*

Oxidation of (VI) with 0.1 *M* periodic acid followed by reduction of the resulting dialdehyde with sodium borohydride in water, according to the procedure described previously (2), gave the tetrol ether (III), $[\alpha]_D^{22}$ +26° (*c*, 2.9 in water), which formed a tetra-*O*-(*p*-nitrobenzoyl) derivative; m.p. 151–152°; $[\alpha]_D^{21}$ +22° (*c*, 1.2 in chloroform).

Periodate oxidation and sodium borohydride reduction of (I) under similar conditions gave the tetrol ether (III); $[\alpha]_D^{25}$ +21° (*c*, 3.7 in water). This formed a tetra-*O*-(*p*-nitrobenzoyl) derivative which was recrystallized from ethyl acetate; m.p. 150–151°, undepressed on admixture with the corresponding derivative of the tetrol ether derived from (VI); $[\alpha]_D^{24}$ +23° (*c*, 0.9 in chloroform).

Anal. Calcd. for $C_{35}H_{28}O_{17}N_4$: C, 54.13; H, 3.63; N, 7.21. Found: C, 54.46; H, 3.55; N, 7.29.

In a similar manner (II) gave the tetrol ether (IV) (2-deoxy-3-*O*-(1,3-dihydroxy-2-propyl)-D-*glycero*-tetritol), $[\alpha]_D^{25}$ −23° (*c*, 3.2 in water), which formed a tetra-*O*-(*p*-nitrobenzoyl) derivative; m.p. 150–151°; $[\alpha]_D^{24}$ −23° (*c*, 1.1 in chloroform).

Anal. Calcd. for $C_{35}H_{28}O_{17}N_4$: C, 54.13; H, 3.63. Found: C, 54.55; H, 3.71.

The infrared spectra of the tetra-*O*-(*p*-nitrobenzoyl) derivatives of the tetrol ethers (III) and (IV) were identical.

*Reaction of 3,4,6-Tri-O-acetyl-*D*-galactal with Carbon Monoxide and Deuterium to Yield 2,6-Anhydro-3-deoxy-*D*-galacto-heptitol-1,1,3-$^2H_3$ (cis) (IX) and 2,6-Anhydro-3-deoxy-*D*-talo-heptitol-1,1,3-$^2H_3$ (cis) (X)*

3,4,6-Tri-*O*-acetyl-D-galactal was reacted with carbon monoxide and deuterium at 130°, under similar conditions to those used in the preparation of the normal anhydrodeoxyheptitols, to yield the above-mentioned deuterated heptitols (IX) and (X). The configuration of C-2 of both heptitols was determined by proton n.m.r. analysis (see Discussion).

LA RÉACTION DU PENTACHLORURE DE PHOSPHORE SUR LES ACYLOXY-3β-Δ⁴-CETO-6 STÉROIDES

I. SÉRIE DU PREGNANE[1]

YVON LEFEBVRE ET ROGER GAUDRY
Ayerst Research Laboratories, Montréal, Québec

Reçu le 20 janvier 1965

RÉSUMÉ

Le pentachlorure de phosphore réagit sélectivement avec la fonction carbonyle en position 6 des acyloxy-3β pregnène-4 diones-6,20, diversement substituées en 17 et 21, dans le tétrachlorure de carbone, pour donner les acyloxy-3β chloro-6 pregnadiène-4,6 ones-20 correspondantes. L'activité biologique de ces produits est rapportée.

L'influence du système Δ⁶-chloro-6 sur l'activité orale des progestérones I substituées en positions 17 et 21 est maintenant bien connue: la chloro-6 méthyl-17 pregnadiène-4,6 dione-3,20 I*a* (1, 2), la chloro-6 fluoro-21 méthyl-17 pregnadiène-4,6 dione-3,20 I*b* (1, 2), l'acétoxy-17 chloro-6 pregnadiène-4,6 dione-3,20 I*c* (3) et la chloro-6 éthyl-17 pregnadiène-4,6 dione-3,20 I*d* (2, 4) sont parmi les agents progestationnels les plus actifs actuellement connus.

Dans les cadres d'un vaste programme de recherches sur l'activité biologique en rapport avec la structure, nous avons préparé une série d'acyloxy-3β chloro-6 pregnadiène-4,6 ones-20 II, substituées en positions 17 et 21, afin de les comparer avec les cétones correspondantes I et d'étudier l'effet sur l'activité biologique de la réduction du carbonyle 3.[2,3]

Les substances de structure générale II (R′ = acyloxyles) s'obtiennent facilement par l'action du pentachlorure de phosphore, à température ambiante, dans le tétrachlorure de carbone, sur les acyloxy-3β pregnène-4 diones-6,20 III (R′ = acyloxyles). Il en résulte le remplacement du carbonyle en position 6 par un groupement Δ⁶-chloro-6.[4,5] La structure des produits formés est confirmée à l'aide des données micro-analytiques, des spectres ultraviolets et par leur transformation chimique en dicétones correspondantes I. Bien que les deux groupes carbonyles, présents dans les produits de départ III, soient susceptibles de réagir avec le pentachlorure de phosphore pour donner des substances dichlorées, les micro-analyses montrent qu'un seul atome de chlore a été introduit au cours de la chloruration. De plus, les spectres ultraviolets sont caractéristiques du système diénique 4,6, montrant un maximum d'absorption de forte intensité à 243 mμ, et deux épaulements, également de forte intensité, à 237 et 250 mμ. Par contre, les produits de départ n'ont qu'un maximum de faible intensité à 236 mμ (Tableau I). Il est par conséquent, évident d'après ces résultats que seule la cétone en position 6 a été remplacée par un groupe Δ⁶-chloro-6 et que le carbonyle en position 20 n'est pas appréciablement

[1]*Travail présenté au 31ème Congrès annuel de l'Association Canadienne-Française pour l'Avancement des Sciences, Québec, novembre 1963.*

[2]*Dans les cadres du même programme, d'autres hydroxy-3β pregnènes-4, hydroxy-3β pregnadiènes-4,6 et leurs esters ont été préparés dans nos laboratoires. Les méthodes de synthèse et les activités biologiques ont déjà été rapportées (5).*

[3]*Récemment, G. R. Allen Jr. et M. J. Weiss (6) ont obtenu la chloro-6 éthyl-17 hydroxy-3β pregnadiène-4,6 one-20 par réduction sélective du carbonyle en 3 de la dione correspondante Id.*

[4]*Une série de chloro-3 diènes-3,5 stéroides, préparée dans nos laboratoires a déjà été décrite (7).*

[5]*Bien que la réaction du pentachlorure de phosphore sur les cétones cycliques soit bien connue (8), seulement quelques céto-stéroides ont été transformés (9–12).*

TABLEAU I

Spectres ultraviolets des acyloxy-3β pregnène-4 diones-6,20 et des acyloxy-3β chloro-6 pregnadiène-4,6 ones-20

Substituants			Produits de départ III		Produits chlorés	
R	X	R′	λ_{max}(mμ)	ϵ	λ_{max}(mμ)	ϵ
CH_3-	H	CH_3CO-	236	7 400	243	24 600
CH_3-	F	CH_3CO-	236	7 700	243	24 700
CH_3COO-	H	CH_3CO-	236	7 600	243	26 200
CH_3COO-	H	$CH_3(CH_2)_4CO$-	236	8 000	243	25 500
CH_3COO-	H	 $-(CH_2)_2CO$-	236	8 220	243	26 200
CH_3COO-	H	H	241	6 800	243	24 000

effecté par le réactif. De plus les produits II (R′ = CH_3CO-) sont facilement transformés an dicétones I par hydrolyse alcaline, suivie d'une oxydation des alcools ainsi formés.

Nous avons remarqué la même sélectivité dans la réaction de l'acétoxy-3β pregnène-4 one-20 avec le pentachlorure de phosphore. Bien qu'il nous ait été impossible de purifier complètement l'acétoxy-3β chloro-6 pregnadiène-4,6 one-20 formée, sa structure ne fait aucun doute, la bande caractéristique de la fonction cétonique en 20 se voyant très clairement dans le spectre infrarouge.[6]

Le pentachlorure de phosphore réagit aussi sur les diones III dans d'autres solvants tels le benzène et l'acétate d'éthyle. Cependant les rendements en produits chlorés II sont nettement inférieurs à ceux obtenus dans le tétrachlorure de carbone. La chloruration ne se produit pas en milieu basique (pyridine, dioxane, tétrahydrofurane, *N*,*N*-diméthyl formamide), les produits de départ étant habituellement retrouvés inchangés.[7] De plus, nous n'avons pu obtenir de produits chlorés II à l'aide d'autres réactifs (chlorure de thionyle, oxychlorure de phosphore, trichlorure de phosphore et chlorure d'oxalyle (7)), les produits de départ demeurant souvent inchangés.

Quant aux acyloxy-3β pregnène-4 diones-6,20 de départ, elles sont préparées à partir des pregnénolones appropriées IV. Ces dernières sont transformées par deux voies distinctes en acétoxy-3β hydroxy-5α pregnanediones VII. D'une part les acétates de pregnénolones de départ IV (R′ = CH_3CO-) sont époxydés par l'acide peracétique et le mélange des époxydes V est traité par l'acide periodique dans l'acétone (14) ou par l'acide perchlorique dans l'acétone (15) pour donner les diols VI, qui sont ensuite oxydés par l'acide chromique en hydroxy-diones VII. D'autre part les pregnénolones IV (R′ = H) (ou leurs esters) sont transformées selon la méthode de Fieser (14) en dérivés trihydroxylés VIII, qui par oxydation sélective de l'alcool en 6 par la *N*-bromo succinimide (14), suivie d'une acétylation donnent les acétoxy-3β hydroxy-5α pregnanediones-6,20 VII. Ces dernières sont facilement déshydratées par le chlorure de thionyle dans la pyridine en acétoxy-3β pregnène-4 diones-6,20 III (R′ = CH_3CO-). Les esters III*d* et III*e* s'obtiennent par estérification de l'alcool correspondant III*f*, préparé par hydrolyse alcaline de l'acétate III*c*.

[6]*Bien que les spectres infrarouges des produits II confirment la disparition du système Δ^4-céto-6 (1 690 et 1 637 cm^{-1}), présent dans les produits de départ, ils ne sont d'aucune utilité pour déceler la présence de la fonction cétonique en 20. En effet, dans la plupart des cas la bande caractéristique coïncide avec la bande de l'acyloxyle en 3. Le cas de l'acétoxy-3β chloro-6 méthyl-17 pregnadiène-4,6 one-20 IIa est encore plus probant, la bande de la méthyl-17 cétone-20 se trouvant à 1 690 cm^{-1}.*

[7]*Ce fait est en accord avec le mécanisme général de réaction du pentachlorure de phosphore sur les cétones (13). Cependant il est intéressant de mentionner que l'addition de dioxane après le début de la chloruration dans le benzène ne nuit pas à la réaction. Bien au contraire, les rendements en produits chlorés sont sensiblement améliorés (voir Partie Expérimentale).*

Dans le test de Clauberg–McPhail (16) les acétoxy-3β chloro-6 diènes II (R′ = CH_3CO-) montrent une activité progestationnelle très puissante. Ils ont une activité comparable à celle des dicétones I. Dans le cas de la chloro-6 diacétoxy-3β,17 pregnadiène-4,6 one-20 II*c*, l'activité orale est près de trois fois celle de la dicétone correspondante I*c* (Tableau II) (17).

PARTIE EXPÉRIMENTALE[8]

*Acétoxy-3β hydroxy-5α méthyl-17 pregnanedione-6,20 VII*a

Première méthode

On agite à température ambiante pendant 4 h une solution de 31.5 g de méthyl-17 pregnénolone brute IV*a* (R′ = H) dans 155 ml d'acide formique 88%. On ajoute un volume égal d'eau et on filtre le solide qui résulte. Après lavage à l'eau et séchage, on recrystallise dans un mélange de chlorure de méthylène–hexane et on obtient 16.7 g de formiate de méthyl-17 pregnénolone IV*a* (R′ = HCO-) p.f. 187–190°. On agite pendant 2 h à température ambiante une solution de 19.2 g de ce formiate, 19.2 ml d'une solution 30% de H_2O_2 et 192 ml d'acide formique. La solution est jetée dans l'eau et la glace. Le solide formé est filtré et après lavage à l'eau est dissout dans 200 ml de méthanol. Après l'addition de 60 ml de potasse alcoolique 10%, on porte cette solution à reflux pendant 10 min. L'addition d'eau donne 15 g de triol VIII*a* p.f. 293–296°. Une solution de 15 g de ce triol dans 1 120 ml de méthanol et 720 ml d'éther est mélangée avec une solution de 20 g de *N*-bromo succinimide dans 440 ml d'eau. Après 2 h à 5°, on évapore l'éther sous pression réduite. On ajoute de l'eau et on obtient 14.1 g de diol IX*a*, qui sans autre purification sont acétylés pendant la nuit avec 140 ml d'anhydride acétique et 140 ml de pyridine. On obtient 17.25 g d'acétate brut VII*a*, purifié par plusieurs cristallisations dans un mélange de chlorure de méthylène–hexane p.f. 234–236°, $[\alpha]_D = -79°$.

Anal. Calc. pour $C_{24}H_{36}O_5$: C, 71.25; H, 8.97. Trouvé: C, 71.31; H, 9.12.

Deuxième méthode

On ajoute, en maintenant la température entre −2 et 2°, une solution de 8 g d'acétate de méthyl-17 pregnénolone IV*a* (R′ = CH_3CO-) (1, 18) dans 60 ml de chloroforme à un mélange de 700 mg d'acétate de sodium anhydre et 8 ml d'acide peracétique. Après 2 h entre 0 et 5°, la solution chloroformique est lavée successivement à l'eau, au bicarbonate de sodium et à l'eau jusqu'à neutralité. Après séchage et évaporation 8.1 g d'époxydes V*a* sont obtenus. Ce mélange d'époxydes est dissout dans 212 ml d'acétone et après l'addition de 4 ml d'acide perchlorique 70% et 28 ml d'eau, on laisse reposer à température de la pièce pendant 3 h. Le mélange réactionnel est dilué avec de l'eau et le précipité est recristallisé dans l'acétone pour donner 6 g de diol VI*a* p.f. 217–218°.

Ces 6 g de diol sont dissouts dans 70 ml de *N*,*N*-diméthyl formamide. A cette solution, on ajoute un mélange de 12 ml d'acide chromique 8 *N* (19) et 30 ml de diméthyl formamide. Après 15 min à température ambiante, l'excès d'oxydant est détruit par une solution de bisulfite de sodium. Par l'addition d'eau, on récolte 5.1 g d'un produit p.f. 234–241°, identique par comparaison des spectres infrarouges, à l'acétoxy-3β hydroxy-5α méthyl-17 pregnanedione-6,20 obtenue par la première méthode.

*Acétoxy-3β méthyl-17 pregnène-4 dione-6,20 III*a

Une solution de 5.1 ml de chlorure de thionyle dans 10 ml de pyridine est ajoutée à une solution de 5.1 g d'hydroxy-dione VII*a* dans 51 ml de pyridine, refroidie à 0°. La température est maintenue à 0° pendant

[8]*Les points de fusion ont été déterminés en tube capillaire et ne sont pas corrigés. Les rotations ont été déterminées en solution chloroformique, sauf mention spéciale, à une concentration d'environ 1% et à 23 °C. Les spectres ultraviolets ont été pris en solution dans l'éthanol 95% sur un appareil Perkin–Elmer, modèle 350, et les spectres infrarouges sur un appareil Perkin–Elmer, modèle 21, en solution chloroformique à 10%.*

For personal use only.

l'addition. Après 1 h à 0°, le mélange réactionnel est jeté dans l'eau et la glace. Le précipité est filtré et lavé jusqu'à neutralité. Par recristallisation dans un mélange de chlorure de méthylène–hexane, on obtient 3 g d'acétoxy-3β méthyl-17 pregnène-4 dione-6,20 p.f. 205–207°. L'échantillon analytique fond à 206–208°, $[\alpha]_D = -69.2°$.

Anal. Calc. pour $C_{24}H_{34}O_4$: C, 74.57; H, 8.78. Trouvé: C, 74.42; H, 8.69.

Acétoxy-3β chloro-6 méthyl-17 pregnadiène-4,6 one-20 IIa et chloro-6 hydroxy-3β méthyl-17 pregnadiène-4,6 one-20 IIf

Chloruration dans le benzène

On agite pendant 30 min à température ambiante une solution de 2.37 g de III*a*, 2.37 g de PCl_5 dans 110 ml de benzène. On jète le mélange réactionnel dans l'eau et la glace. La phase organique est lavée jusqu'à neutralité, séchée et évaporée. Le résidu est cristallisé dans le méthanol et on obtient 193 mg p.f. 119–126°. Par chromatographie des eaux-mères sur le florisil on obtient une quantité additionnelle p.f. 120–130°. La cristallisation des fractions combinées donne 224 mg d'acétoxy-3β chloro-6 méthyl-17 pregnadiène-4,6 one-20 p.f. 137–139°. Un échantillon analytique fond à 139–141°, $[\alpha]_D = -67.6°$.

Anal. Calc. pour $C_{24}H_{33}O_3Cl$: C, 71.18; H, 8.21; Cl, 8.75. Trouvé: C, 70.94; H, 8.28; Cl, 8.78, 8.67.

Chloruration dans le benzène–dioxane

On agite une solution de 1 g de III*a*, 1 g de PCl_5 dans 50 ml de benzène. Après 1 min, on ajoute 0.5 ml de dioxane et on continue l'agitation pendant 30 min. Le produit de la réaction est isolé comme précédemment. Par purification chromatographique et par cristallisation dans le méthanol, on obtient 301 mg de produit chloré II*a* p.f. 136–141°. Selon les préparations le point de fusion varie entre 136 et 145°. Par contre, l'indice de rotation se situe entre −66 et −69.5°.

Chloruration dans le CCl_4

On dissout à chaud 5 g de III*a* dans 250 ml de CCl_4. Après refroidissement à la température ambiante, on ajoute 5 g de PCl_5 et on agite le mélange pendant 45 min. On arrête la réaction par l'addition de 10 ml de pyridine. Le mélange est jeté dans une solution glacée de bicarbonate de sodium; la phase organique est séparée, lavée, séchée et évaporée. Deux recristallisations dans le méthanol donne 1.25 g d'acétoxy-3β chloro-6 méthyl-17 pregnadiène-4,6 one-20 p.f. 148–150°. L'échantillon analytique fond à 149–151°, $[\alpha]_D = -64.8°$.

Anal. Calc. pour $C_{24}H_{33}O_3Cl$: C, 71.18; H, 8.21; Cl, 8.75. Trouvé: C, 71.27; H, 8.39; Cl, 8.66, 8.69.

Une quantité additionnelle de 924 mg p.f. 146–149° est obtenue par chromatographie des eaux-mères.

Hydrolyse de IIa

On chauffe à reflux pendant 30 min sous atmosphère d'azote un mélange de 530 mg de II*a*, 137 mg de bicarbonate de potassium, 21.5 ml de méthanol et 2.5 ml d'eau. L'addition d'eau donne 415 mg de chloro-6 hydroxy-3β méthyl-17 pregnadiène-4,6 one-20 II*f* dont le point de décomposition varie entre 182 et 193° (chlorure de méthylène–hexane). Un échantillon analytique montre un point de décomposition de 182–184°. $[\alpha]_D = -45.5°$.

Anal. Calc. pour $C_{22}H_{31}O_2Cl$: C, 72.79; H, 8.61; Cl, 9.78. Trouvé: C, 72.83; H, 8.66; Cl, 9.88, 9.98.

L'acétylation de 95 mg de cet alcool, selon la méthode usuelle, avec 1 ml d'anhydride acétique et 1 ml de pyridine donne après recristallisation dans le méthanol 60 mg de II*a* p.f. 148–150°.

Chloro-6 méthyl-17 pregnadiène-4,6 dione-3,20 Ia

A une solution, agitée et maintenue à 0°, de 500 mg d'alcool II*f* dans 60 ml d'acétone on ajoute 1 ml d'acide chromique 8 *N*. Le mélange est immédiatement jeté dans l'eau et la glace et est extrait à l'éther. La solution éthérée est lavée à l'eau, séchée et évaporée. Par chromatographie du résidu sur l'alumine et par cristallisation dans l'hexane on obtient 180 mg de chloro-6 méthyl-17 pregnadiène-4,6 dione-3,20 I*a* p.f. 122–124° (point de fusion rapporté 125–126° (1)).

Acétoxy-3β fluoro-21 hydroxy-5α méthyl-17 pregnanedione-6,20 VIIb

On agite pendant 3 h à température ambiante un mélange de 16.2 g d'acétoxy-3β fluoro-21 méthyl-17 pregnène-5 one-20 IV*b* (R′ = CH_3CO-) (1), 160 ml d'acide formique et 16.2 ml d'une solution 30% de H_2O_2. Après ce temps, on dilue la solution avec de l'eau et on récolte un solide qui est lavé à l'eau et séché. Ce solide est dissout dans 240 ml de méthanol et après l'addition de 80 ml de potasse 10% on porte à reflux pendant 1 h. Par l'addition d'eau on obtient 13.6 g de triol VIII*b* p.f. 288–291°.

Sans autre purification, ce triol est dissout dans 1 000 ml de méthanol et 680 ml d'éther. Après l'addition de 17 g de *N*-bromo succinimide dissouts dans 300 ml d'eau, on laisse le mélange à 5° pendant 2 h. Le brome qui s'est formé est détruit par l'addition de 325 ml de thiosulfate de sodium 0.1 *N*. On évapore l'éther sous pression réduite en chauffant entre 40 et 50°. La solution résiduelle est mélangée avec de l'eau et on obtient 11.25 g de diol IX*b*, qui sont acétylés selon la méthode habituelle avec 110 ml d'anhydride acétique et 110 ml de pyridine. L'acétate brut est cristallisé dans un mélange de chlorure de methylène–hexane puis dans un mélange de chlorure de méthylène–ether pour donner 8.95 g d'acétoxy-3β fluoro-21 hydroxy-5α pregnanedione-6,20 p.f. 263–266°, $[\alpha]_D = -83.9°$.

Anal. Calc. pour $C_{24}H_{35}O_5F$: C, 68.22; H, 8.35; F, 4.50. Trouvé: C, 68.18; H, 8.11; F, 4.53, 4.40.

Acétoxy-3β fluoro-21 méthyl-17 pregnène-4 dione-6,20 IIIb

La déshydratation de 8.66 g de VII*b* par le chlorure de thionyle (9 ml) dans la pyridine (104 ml), selon la méthode utilisée plus haut pour le composé VII*a*, conduit à 6.96 g de produit brut, purifié par chromatographie sur le florisil. Les fractions éluées avec des mélanges benzène–ether sont combinées et cristallisées dans un mélange de chlorure de méthylène–hexane. On obtient 3.95 g d'acétoxy-3β fluoro-21 méthyl-17 pregnène-4 dione-6,20 p.f. 196–197.5°, $[\alpha]_D = -76.6°$.

Anal. Calc. pour $C_{24}H_{33}O_4F$: C, 71.26; H, 8.22; F, 4.70. Trouvé: C, 70.91; H, 7.76; F, 4.70, 4.78.

Acétoxy-3β chloro-6 fluoro-21 méthyl-17 pregnadiène-4,6 one-20 IIb

On agite à température de la pièce une solution de 4.15 g de III*b*, 4.15 g de PCl_5 dans 200 ml de benzène. Après 1 min on ajoute une solution de 1.6 ml de dioxane dans 20 ml de benzène et la réaction est continuée pendant 30 min. On ajoute 2.8 ml de pyridine et le produit de la réaction est isolé comme on a fait plus haut pour II*a*. Le résidu est cristallisé dans le méthanol et on obtient 891 mg d'acétoxy-3β chloro-6 fluoro-21 méthyl-17 pregnadiène-4,6 one-20 II*b* p.f. 170–173°. L'échantillon analytique fond à 172–173°, $[\alpha]_D = -73.5°$.

Anal. Calc. pour $C_{24}H_{32}O_3FCl$: C, 68.14; H, 7.63; F, 4.49; Cl, 8.39. Trouvé: C, 67.90; H, 7.71; F, 4.44; Cl, 8.18, 8.17.

Diacétoxy-3β,17 dihydroxy-5α,6β pregnanone-20 VIc

On ajoute une solution de 30 g de diacétoxy-3β,17 pregnène-5 one-20 IV*c* (R′ = CH_3CO-) dans 218 ml de chloroforme à un mélange de 2.67 g d'acétate de sodium et 30 ml d'acide peracétique. La température est maintenue entre −2 et 2° pendant l'addition puis entre 0 et 5° pendant 2 h. La solution chloroformique est lavée à l'eau, au bicarbonate et à l'eau jusqu'à neutralité. Après l'évaporation du solvant, on obtient 30 g d'époxydes V*c*.

On dissout ces 30 g dans 300 ml d'acétone et après addition d'une solution de 18 g d'acide periodique dans 90 ml d'eau, on porte à reflux pendant 30 min. L'addition d'eau donne 27.6 g de diacétoxy-3β,17 dihydroxy-5α,6β pregnanone-20 p.f. 301–303°. Par recristallisation dans le méthanol aqueux, on obtient l'échantillon analytique p.f. 304–306°, $[\alpha]_D = -44.5°$.

Anal. Calc. pour $C_{25}H_{38}O_7$: C, 66.64; H, 8.51. Trouvé: C, 66.85; H, 8.48.

On peut aussi obtenir ce diol à partir du mélange d'époxydes de la façon suivante. On laisse à température ambiante pendant 3 h une solution de 45 g d'époxydes, 1 020 ml d'acétone et une solution de 23 ml d'acide perchlorique et 161 ml d'eau. Pendant la réaction des cristaux de diol se forment. On ajoute un volume égal d'eau. On filtre le solide et après séchage, on obtient 45.8 g of diol VI*c* p.f. 303–305°.

Diacétoxy-3β,17 hydroxy-5α pregnanedione-6,20 VIIc

On ajoute à une solution de 2 g de diol VI*c* dans 40 ml de diméthyl formamide, une solution de 4 ml d'acide chromique 8 *N* dans 11 ml de diméthyl formamide. Après 15 min l'excès d'oxydant est détruit par l'addition de 7 ml d'une solution de bisulfite de sodium 10%. Le mélange est jeté dans l'eau et on récolte 1.78 g de diacétoxy-3β,17 hydroxy-5α pregnanedione-6,20 pf. 270–273°. Par recristallisation dans un mélange de chlorure de méthylène–hexane, on obtient l'échantillon analytique p.f. 273–275°, $[\alpha]_D = -75.2°$.

Anal. Calc. pour $C_{25}H_{36}O_7$: C, 66.94; H, 8.09. Trouvé: C, 66.68; H, 8.36.

Diacétoxy-3β,17 pregnène-4 dione-6,20 IIIc

La déshydration de 25 g de VII*c*, selon la méthode usuelle par le chlorure de thionyle dans la pyridine, donne 18.1 g de diacétoxy-3β,17 pregnène-4 dione-6,20, de pureté suffisante pour la chloruration par le pentachlorure de phosphore. On obtient un échantillon analytique, après chromatographie sur le florisil, en recristallisant dans un mélange de chlorure de méthylène–hexane les fractions éluées par des mélanges benzène–éther p.f. 200–202°, $[\alpha]_D = -70.6°$.

Anal. Calc. pour $C_{25}H_{34}O_6$: C, 69.74; H, 7.96. Trouvé: C, 69.95; H, 8.02.

Acétoxy-17 hydroxy-3β pregnène-4 dione-6,20 IIIf

On porte à reflux pendant 30 min sous atmosphère d'azote un mélange de 430 mg de III*c*, 110 mg de bicarbonate de potassium, 15 ml de méthanol et 1.5 ml d'eau. On dilue la solution avec de l'eau et on extrait par l'acétate d'éthyle. La solution organique est lavée, séchée et évaporée, laissant un résidu (387 mg) qui cristallise dans l'éther. Par recristallisation dans un mélange de chlorure de méthylène–éther on obtient un échantillon analytique d'acétoxy-17 hydroxy-3β pregnène-4 dione-6,20 III*f* p.f. 214–222°, $[\alpha]_D = 33.3°$.

Anal. Calc. pour $C_{23}H_{32}O_5$: C, 71.11; H, 8.30. Trouvé: C, 71.39; H, 8.16.

Acétoxy-17 hexanoyloxy-3β pregnène-4 dione-6,20 IIId

On laisse à température ambiante pendant 32 h une solution de 9.4 g de III*f*, 9.4 ml d'anhydride hexanoique et 94 ml de pyridine. L'hexanoate est isolé de la façon habituelle. On obtient un solide jaune purifié par chromatographie sur l'alumine. Les fractions éluées par un mélange benzène–hexane 3:1 et par le benzène pur sont combinées et cristallisées dans l'hexane pour donner 5.07 g d'acétoxy-17 hexanoyloxy-3β pregnène-4 dione-6,20 p.f. 158–159°, $[\alpha]_D = -70.2°$.

Anal. Calc. pour $C_{29}H_{42}O_6$: C, 71.58; H, 8.70. Trouvé: C, 71.45; H, 8.82.

Une quantité additionnelle de 1.13 g p.f. 155–158° s'obtient des eaux-mères.

Acétoxy-17 (cyclopentyl)-3′ propionyloxy-3β pregnène-4 dione-6,20 IIIe

On laisse à température ambiante pendant la nuit une solution de 9 g d'alcool III*f*, 9 ml de chlorure de cyclopentyl-3′ propionyle et 90 ml de pyridine. L'ester est isolé de la façon usuelle. Après chromatographie sur l'alumine, on obtient 5.78 g d'acétoxy-17 (cyclopentyl)-3′ propionyloxy-3β pregnène-4 dione-6,20 (méthanol) p.f. 163–166°, $[\alpha]_D = -60.2°$.

Anal. Calc. pour $C_{31}H_{44}O_6$: C, 72.63; H, 8.65. Trouvé: C, 72.70; H, 8.48.

Une quantité additionnelle (779 mg) p.f. 163–167° s'obtient des eaux-mères.

Chloro-6 diacétoxy-3β,17 pregnadiène-4,6 one-20 IIc

Chloruration dans le benzène-dioxane

On agite une solution de 3 g de diacétoxy-3β,17 pregnène-4 dione-6,20 III*c* et 3 g de PCl_5 dans 150 ml de benzène. Après 1 min, on ajoute une solution de 1.2 ml de dioxane dans 15 ml de benzène. Après 30 min, on ajoute 2.2 ml de pyridine. Le produit de la réaction est isolé comme à l'habitude. La cristallisation du résidu donne 1.06 g de II*c* p.f. 206–207° (décomp.). Selon les préparations le point de décomposition varie entre 202 et 215°. Un échantillon analytique fond à 202–204° (décomp.), $[\alpha]_D = -89.5°$.

Anal. Calc. pour $C_{25}H_{33}O_5Cl$: C, 66.87; H, 7.41; Cl, 7.91. Trouvé: C, 66.79; H, 8.07; Cl, 8.07, 8.06.

Chloruration dans le CCl_4

On agite pendant 30 min à température ambiante un mélange de 5 g de III*c* et 5 g de PCl_5 dans 250 ml de CCl_4. Après l'addition de 10 ml de pyridine, on isole le produit de la réaction. Par recristallisation dans le méthanol, on récolte 1.62 g de chloro-6 diacétoxy-3β, 17 pregnadiène-4,6 one-20 p.f. 203–204° (décomp.).

Acétoxy-17 chloro-6 hydroxy-3β pregnadiène-4,6 one-20 IIg

On chauffe à reflux sous azote une solution de 10 g de II*c*, 2.6 g de bicarbonate de potassium, 200 ml de tétrahydrofurane, 300 ml de méthanol et 50 ml d'eau. L'addition d'eau donne 9 g d'un solide, purifié par chromatographie sur l'alumine. On obtient par cristallisation 5.12 g d'alcool II*g* p.f. 218–221° (décomp.). Il n'a pas été possible d'obtenir un échantillon analytiquement pur. Cependant, 100 mg de cet alcool, acétylé selon la méthode habituelle, donnent après cristallisation dans le méthanol 82 mg de II*c* p.f. 213–214 (décomp.), $[\alpha]_D = -93.5°$.

Acétoxy-17 chloro-6 pregnadiène-4,6 dione-3,20 Ic

On ajoute à une solution de 1 g de l'acool II*g* dans 100 ml d'acétone, 1 ml d'acide chromique 8 *N*. Après 2 ou 3 min d'agitation, l'excès d'oxydant est détruit par l'addition d'alcool isopropylique. Le mélange est dilué avec de l'eau et est extrait par l'éther. La solution éthérée est lavée, séchée et évaporée. Le résidu est cristallisé dans le méthanol pour donner 634 mg d'acétoxy-17 chloro-6 pregnadiène-4,6 dione-3,20 p.f. 208–210°, $[\alpha]_D = -3.9°$.

Le spectre infrarouge est identique à celui d'un échantillon authentique de I*c*.

Acétoxy-17 chloro-6 hexanoyloxy-3β pregnadiène-4,6 one-20 IId

La chloruration de 5.05 g de III*d*, effectuée comme plus haut dans CCl_4, donne, après chromatographie du produit brut sur l'alumine et par cristallisation dans le méthanol du produit purifié, 3.1 g d'acétoxy-17 chloro-6 hexanoyloxy-3β pregnadiène-4,6 one-20 p.f. 94.5–98°. L'échantillon analytique fond à 95.5–98.5°, $[\alpha]_D = -80.7°$.

Anal. Calc. pour $C_{29}H_{41}O_5Cl$: C, 68.97; H, 8.32; Cl, 7.03. Trouvé: C, 68.95; H, 8.18; Cl, 7.00, 6.93.

Acétoxy-17 chloro-6 (cyclopentyl)-3′ propionyloxy-3β pregnadiène-4,6 one-20, IIe

La chloruration de 6.1 g de III*e* est faite comme plus haut. Le produit brut est purifié par chromatographie et par cristallisation dans le méthanol. On obtient 2.16 g d'acétoxy-17 chloro-6 (cyclopentyl)-3′ propionyloxy-3β pregnadiène-4,6 one-20 p.f. 106–111°. L'échantillon analytique fond à 109–112°, $[\alpha]_D = -79.3°$.

Anal. Calc. pour $C_{31}H_{43}O_5Cl$: C, 70.10; H, 8.16; Cl, 6.68. Trouvé: C, 69.85; H, 8.21; Cl, 6.69, 6.57.

REMERCIEMENTS

Nous tenons à remercier tout particulièrement Monsieur le professeur H. Favre de l'Université de Montréal dont les conseils nous ont été très utiles et Monsieur P. Abonyi dont l'aide technique nous a été très précieuse. Nous voulons également remercier le docteur G. Papineau-Couture et Madame J. Jachner pour les spectres infrarouges, Monsieur M. Boulerice pour les spectres ultraviolets et Monsieurs W. Turnbull et ses collaborateurs pour les microanalyses. Nous remercions finalement les docteurs C. Revesz et C. Chappel pour les données biologiques.

THE ALCOHOLYSIS OF TRIALKYLALKOXYSILANES

PART I. A KINETIC STUDY OF THE METHANOLYSIS OF METHYL 2,3,4,6-TETRA-*O*-TRIMETHYLSILYL-α-D-GLUCOPYRANOSIDE TO FORM METHYL 2,3,4-TRI-*O*-TRIMETHYLSILYL-α-D-GLUCOPYRANOSIDE[1]

A. G. McINNES

Atlantic Regional Laboratory, National Research Council and Dalhousie University, Halifax, Nova Scotia

Received January 29, 1965

ABSTRACT

The selective methanolysis of the trimethylsilyl group on the primary 6-position of methyl 2,3,4,6-tetra-*O*-trimethylsilyl-α-D-glucopyranoside (I) to form methyl 2,3,4-tri-*O*-trimethylsilyl-α-D-glucopyranoside (II) is catalyzed by acid or base. In the latter case the reaction follows second-order kinetics in I and methoxide ion, and the rate of reaction is independent of the nature of the cation of the metal methoxide used to catalyze the reaction. Successive replacement of the methyl hydrogens in the methoxide ion by methyl groups is accompanied by a corresponding decrease in the rate of reaction. The rate constant for removal of trimethylsilyl groups at the secondary 2-, 3-, and 4-positions of I and II is smaller by a factor of 25 than for removal of the corresponding group at the primary 6-position, and the energies of activation for the two processes are 10.8 and 9.1 kcal mole^{-1}.

When an alcohol undergoes an interchange reaction with an organosilicon alkoxide as shown in [*a*], equilibrium between the reactants and products is established slowly unless catalyzed by acid or base (1*a*).

[*a*] $$R_3SiOR' + R''OH \rightleftharpoons R_3SiOR'' + R'OH.$$

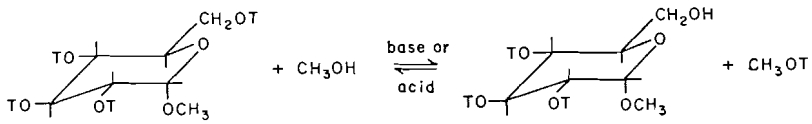
In a recent publication (2) Eaborn and co-workers demonstrated that the rate of methoxy–methoxy exchange between methanol and optically active methoxymethyl-α-naphthylphenylsilane, containing tritium in the methoxyl group, was one-half the rate of racemization regardless of whether an acidic or basic catalyst was used. Their data established that methoxide ion or methanol, depending on the nature of the catalyst, reacts with inversion of configuration at the asymmetric silicon atom. The work of Sommer and his co-workers on the stereochemistry of reactions at asymmetric silicon (3, 4, 5), on the other hand, established that organosilicon alkoxides react with solid potassium hydroxide in nonpolar solvents with retention of configuration (4). It seems probable, therefore, that if reaction [*a*] was carried out in nonpolar solvents using solid metal alkoxide and an organosilicon alkoxide, containing an asymmetric silicon atom, the reaction would also proceed with retention of configuration.

However, apart from the interesting studies described above, reaction [*a*] has been used principally to prepare organosilicon phenoxides and higher alkoxides from the corresponding methoxide or ethoxide (—OR′) derivatives (1*b*). The syntheses of the former compounds have been achieved by making the equilibrium in [*a*] favor the production of the desired product, R_3SiOR'', by removing R′OH by distillation, or by using a large excess of R″OH to shift the position of the equilibrium to the right. It should be noted that all previous investigations of this nature have been concerned only with the production of an organosilicon compound. No previous attempt has been made to carry

[1]*Presented at the 47th Annual Conference, The Chemical Institute of Canada, Kingston, Ontario, June 1–3, 1964.*
Issued as N.R.C. No. 8431.

out a detailed kinetic study of reaction [*a*], and to determine if the nature of R, R′, and R″ influences the reaction. Consequently, work was initiated in this laboratory to study this problem, and initially to make a kinetic study of the rates of methanolysis of the trimethylsilyl ethers of a variety of compounds containing different types of alcoholic hydroxyl groups. It soon became apparent that considerable differences do exist in the rates of methanolysis of different types of hydroxyl groups (primary, secondary, etc.), and that these differences in rate could be utilized for synthetic purposes in the chemistry of polyhydroxy compounds. The present communication reports a kinetic study of the methanolysis of methyl 2,3,4,6-tetra-*O*-trimethylsilyl-α-D-glucopyranoside (I) using basic and acidic catalysts. In reaction [*b*] the trimethylsilyl group on the 6-position of the glucose moiety is removed preferentially with the concomitant formation of methyl 2,3,4-tri-*O*-trimethylsilyl-α-D-glucopyranoside (II) in high yield.

[*b*]



I II

[T = $-Si(CH_3)_3$]

A description of the preparation, structure, and chemistry of II is reported in Part II of this series (6). The synthetic implications of the latter encouraged us to anticipate the results of our more general study of the alcoholysis reaction, which will be the subject of future communications.

EXPERIMENTAL

Materials

The methanol was dried by distillation from magnesium methoxide. Diphenylmethane, 4-methylquinaldine, and compounds I and II each had a purity greater than 99.5% when analyzed by gas–liquid partition chromatography (g.l.p.c.).

The preparation of I and II from methyl α-D-glucopyranoside is described elsewhere (6).

Standard Alcoholysis Reaction Conditions

An aliquot (80 μl) of a methanolic solution containing metal methoxide (0.02 millimole) was injected, by means of a calibrated micro syringe, into a methanolic solution (10 ml) of compound I (0.25 millimole) which also contained 4-methylquinaldine or diphenylmethane (0.32 millimole) as an internal standard. Both solutions were allowed to come to constant temperature in an oil bath before mixing, and care was taken to exclude moisture from the reaction solutions. The progress of the methanolysis reaction was followed by withdrawing aliquots (90 μl) of the reaction solution periodically and stopping the reaction by injecting it into a 0.9% methanolic solution (100 μl) of potassium hydrogen phthalate. An aliquot (2.5 μl) of the resulting solution was analyzed by g.l.p.c. Details of the experimental conditions and rate constants are given in Table I.

The g.l.p.c. apparatus used for the analyses was an F & M gas chromatograph, model 609, equipped with a flame ionization detector, which gave a linear response for all compounds under our reaction conditions.

RESULTS AND DISCUSSION

A typical g.l.p.c. separation of I, 4-methylquinaldine, and II is shown in Fig. 1. Compounds I and II had retention volumes relative to 4-methylquinaldine of 0.37 and 1.49, and relative to diphenylmethane of 0.53 and 2.07.

The effect of temperature on the rate of methanolysis of I is shown in Fig. 2, and the rates of alcoholysis of this compound in ethanol, isopropanol, and *tert*-butanol, using the appropriate alkoxide ion as catalyst, are depicted in Fig. 3.

Under our standard reaction conditions the disappearance of I in [*b*] follows pseudo first-order kinetics (k_1) in I (see Fig. 2). Furthermore, the magnitude of k_1 is directly proportional to the methoxide ion concentration (Table I; experiments C, D, and E). Consequently, the overall methanolysis reaction must be of second order and involve

*The solvent in each case was methanol. 4-Methylquinaldine was used as the internal standard for all experiments except J, in which diphenylmethane was used. The values for the rate constants are the mean values obtained from several experiments, and the individual rate constants could be reproduced to within ±2% of the mean values.
†Rate constant for formation of II from I.
‡There was no difference in the value of k_1 in the presence or absence of 4-methylquinaldine although it is a weak base.

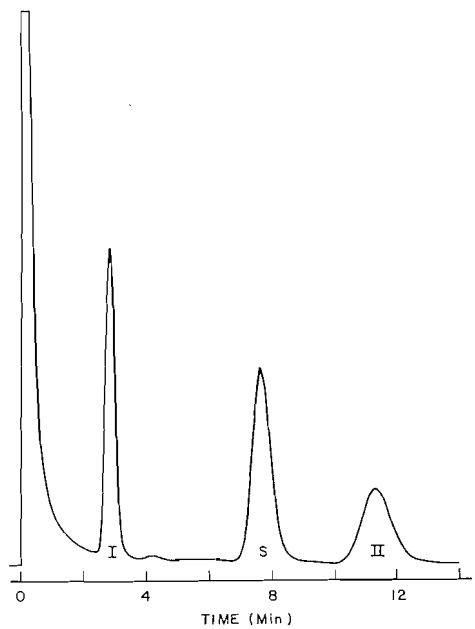

FIG. 1. The g.l.p.c. separation of methyl 2,3,4,6-tetra-*O*-trimethylsilyl-α-D-glucopyranoside (I), 4-methylquinaldine (S), and methyl 2,3,4-tri-*O*-trimethylsilyl-α-D-glucopyranoside (II) on a 5 ft column (20% w/w Carbowax 20M on Chromosorb W). Nitrogen flow rate was 84 ml/min and column temperature was 203°.

the nucleophilic attack of methoxide ion on the organosilicon compound. The rate of methanolysis of I, therefore, should be dependent only on the concentrations of methoxide ion and I. However, the observed rate of reaction will depend on the rate at which I is reformed by reaction of the anion of II with trimethylmethoxysilane, and on the rate at

For personal use only.

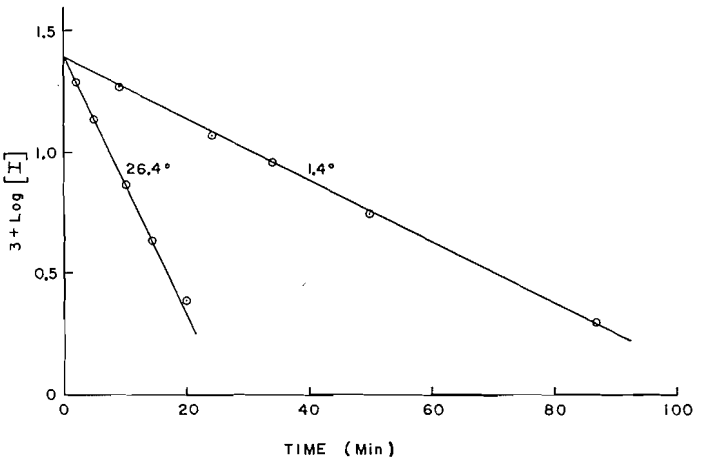

FIG. 2. The plot of the logarithm of the methyl 2,3,4,6-tetra-*O*-trimethylsilyl-α-D-glucopyranoside (I) concentration against time for the standard methanolysis reaction at 26.4° and 1.4°.

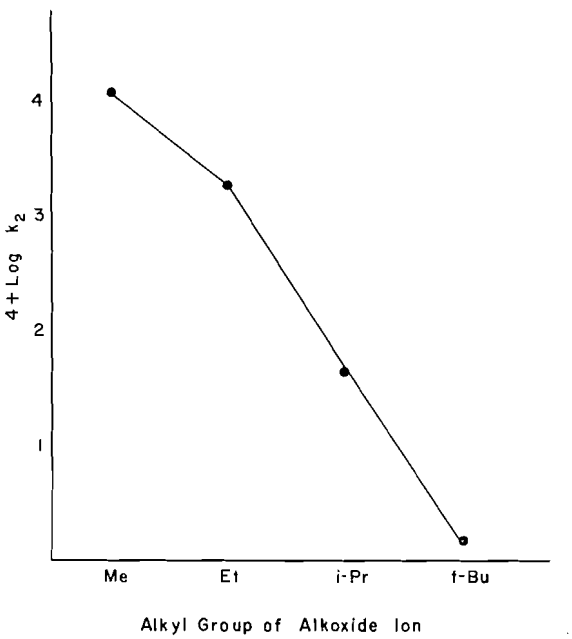

FIG. 3. The effect of structural differences in the alkyl group of the alkoxide ion on the second-order rate constant (k_2) for the alcoholysis of methyl 2,3,4,6-tetra-*O*-trimethylsilyl-α-D-glucopyranoside (I) in methanol, ethanol, isopropanol and *tert*-butanol at 30°.

which II itself reacts with methoxide ion. The latter makes only a slight contribution to the overall rate of reaction (Table I; experiments C and G). Furthermore, the linear plots in Fig. 2 require that the methoxide concentration remain constant throughout the reaction. The high methanol concentration and relative acidity of the hydroxyl proton in methanol, as compared to the corresponding proton in II, ensure that the concentration of the anion of II remains so low that the rate of reformation of I from II is negligible. Therefore, the observed second-order rate constants (k_2) for the methanolysis of I, using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

basic catalysis, reported in Table I differ only in a minor degree from the true rate constant for the conversion of I to II. It is not surprising, therefore, that the second-order rate constant for the formation of II from I (Table I; k_2') is essentially the same as for the methanolysis of I (Table I; k_2).

The nature of the metal methoxide cation, as expected, does not affect the rate of reaction (Table I; experiments A, B, and C), and the complete removal of the trimethylsilyl groups from II using base or acid catalysis yields methyl α-D-glucopyranoside. Since no change in configuration has occurred at the asymmetric centers of the latter compound during methanolysis, the reaction mechanism must involve cleavage of the Si—O bonds and not the C—O bonds. This result is in agreement with published results on the acidic or basic hydrolysis of organosilicon alkoxides containing an asymmetric carbon atom attached to the ether oxygen atom (3, 4, 5, 7).

The rate constant for removal of the trimethylsilyl groups at the *primary* 6-position of the glucose moiety of I was greater by a factor of approximately 25 than for removal of the corresponding groups at the *secondary* 2-, 3-, and 4-positions (Table I; experiments C and G). It was possible, therefore, to prepare and isolate crystalline II in high yield (6). The selectivity of this reaction appears to be quite general and has been used, for example, to prepare the derivatives corresponding to II of other methyl glycosides. Our more general studies on the methanolysis of trimethylalkoxysilanes also indicate that an even greater difference exits in the rates of methanolysis of appropriate derivatives of secondary and tertiary alcohols.

The effect of temperature on the rate of methanolysis of the trimethylsilyl group at the *primary* 6-position of the glucose moiety of I is shown in Fig. 2. This reaction was found to have an energy of activation of 9.1 kcal mole^{-1}, and an Arrhenius frequency factor of 4×10^6 l mole^{-1} s^{-1} (Table I; experiments B and F). From the transition-state theory (8) the following constants were calculated, $\Delta F^{\ddagger} = 17.5$ kcal mole^{-1}, $\Delta H^{\ddagger} = 8.5$ kcal mole^{-1}, and $\Delta S^{\ddagger} = -30$ entropy units. The large negative entropy and low frequency factor are characteristic of reactions associated with electrorestriction of solvent molecules by a highly polar activated complex (9, 10). In a similar manner the corresponding activation energy for the removal of the trimethylsilyl groups at the *secondary* 2-, 3-, and 4-positions in the glucose residue was calculated to be 10.8 kcal mole^{-1} (Table I; experiments G and H). It must be realized that there are three secondary positions in compound II and that the kinetic study measured only the rate of disappearance of II. Since the removal of any of the trimethylsilyl groups in this compound would contribute to the overall rate of reaction, and since no evidence has been found for the specific reaction at one of the secondary positions, it is probable that the value for the activation energy given above represents the average value for the secondary position in the molecule. The activation energies given above differ in magnitude by 1.7 kcal mole^{-1} and, therefore, the difference in reactivity at the primary and secondary positions in II is mainly due to a change in the enthalpy rather than the entropy of activation for the reaction.

It was also considered desirable to determine whether structural differences in the alkyl substituent of the alkoxide ion influenced the rate of alcoholysis. Figure 3 clearly illustrates that the successive substitution of the methyl hydrogens by methyl groups is accompanied by a corresponding decrease in the rate of alcoholysis of I. The relative rate constants using methoxide, ethoxide, isopropoxide, and *tert*-butoxide ion as catalysts decreased in the ratio 10^4:1.7×10^3:40:1. Compound II was not formed in the reactions using isopropoxide or *tert*-butoxide ion. Since the reaction using the latter was extremely slow, it is possible that II underwent further equilibration with the formation of lower substituted derivatives of methyl α-D-glucopyranoside. The decrease in rate of reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

on going from methoxide to *tert*-butoxide ion is undoubtedly due to an increase in steric interaction in the transition state as the number of methyl substituents is increased on the carbon bearing the basic oxygen atom. In this respect the methanolysis reaction resembles the reaction of different alkoxide ions with tri-*o*-tolylsilyl chloride (11) in which *tert*-butoxide ion in *tert*-butanol could not convert the chloride into the corresponding alkoxide.

Reaction [*b*] can be catalyzed by an organic acid instead of an alkoxide ion (Table I; experiment J). In the present experiments acetic acid was used and proved to be a less efficient catalyst than methoxide ion since the acid concentration had to be 12 times the methoxide concentration to obtain the same value for k_1 (Table I; experiments A, B, C, and J). Mineral acids such as HCl and H_2SO_4, on the other hand, were at least 4 times more efficient as catalysts for the reaction than methoxide ion. The reaction kinetics using these catalysts appeared to be more complex, and the yields of II very much poorer than when using our standard reaction conditions. Since we did not obtain consistent, reproducible rate data using these catalysts we have not included the results in this report. Nevertheless, it would appear that the methanolysis reaction is less selective if protons are used in place of alkoxide ion to catalyze the reaction. Acetic acid exists in the dissociated as well as undissociated form in methanolic solution, and it is probable that all of these species can act as catalysts for the methanolysis reaction. The yields of II using acetic acid as the catalyst are comparable with those obtained by using methoxide ion. Compound II can therefore be prepared from I under basic, acidic, or neutral conditions (Table I; experiments C, D, and J), although the rate of formation in the last case would be comparatively slow. It is interesting to note that Akerman found that the hydrolysis of trialkylphenoxysilanes proceeded much more rapidly in basic than in acidic solution (12), an observation opposite to that which we observe in the methanolysis reaction.

Although our present results do not enable us to draw conclusions about the exact nature of the mechanism of the alcoholysis reaction, it seems likely that it proceeds either by an S_N2 mechanism or by a mechanism involving a pentacovalent-silicon intermediate in which the silicon orbitals are dsp^3 hybridized. The presence of such an intermediate has been suggested by Swain, Esteve, and Jones (13) as a result of kinetic studies on the hydrolysis of triphenylsilyl fluoride and tri-*p*-tolysilyl fluoride in aqueous acetone. Eaborn has pointed out, however, that their kinetic data *do not* in fact distinguish between the two mechanisms (1*c*).

THE ALCOHOLYSIS OF TRIALKYLALKOXYSILANES

PART II. THE PREPARATION AND CHEMISTRY OF METHYL 2,3,4-TRI-*O*-TRIMETHYLSILYL-α-D-GLUCOPYRANOSIDE[1]

D. T HURST[2] AND A. G. MCINNES

Received January 29, 1965

ABSTRACT

The trimethylsilyl group on the 6-position of methyl 2,3,4,6-tetra-*O*-trimethylsilyl-α-D-glucopyranoside is preferentially removed by methanolysis, using basic or acidic catalysts, giving methyl 2,3,4-tri-*O*-trimethylsilyl-α-D-glucopyranoside in high yield (>80%). Reaction of the latter with acetic anhydride, benzoyl chloride, or phenyl isocyanate produces the corresponding 6-substituted derivatives in quantitative yield. The trimethylsilyl residues from the latter compounds are hydrolyzed by 50% aqueous methanol with the concomitant formation of 6-*O*-acetyl, 6-*O*-benzoyl, or 6-carbanilate derivatives of methyl α-D-glucopyranoside in excellent yield. Chemical and proton magnetic resonance (p.m.r.) studies established the structure of methyl 2,3,4-tri-*O*-trimethylsilyl-α-D-glucopyranoside, and of subsequent derivatives prepared from this compound. Infrared and p.m.r. evidence is offered to support conclusions regarding the conformation of the groups or atoms attached to C_6 and C_5 of the glucoside residue in some of these compounds.

INTRODUCTION

Although general methods used for the preparation of trialkylalkoxysilanes (trialkylsilyl ethers), or trialkylaryloxysilanes, have been described by Eaborn in his excellent book (1*a*), it is only the trimethylsilyl residue which has been used extensively to protect hydroxyl (2) and amino groups (1*b*). These derivatives are easily prepared, are resistant to oxidation, and have more volatility and thermal stability than the parent compound (3). Moreover, they are readily hydrolyzed under neutral conditions by hot aqueous ethanol or methanol, and the hydrolysis is catalyzed by acids or bases (1*c*). Derivatives of this type, therefore, have been used for the separation and purification of compounds containing hydroxyl groups by fractional distillation (2), and in the gas–liquid partition chromatography (g.l.p.c.) of sugars (4). The physical properties of trimethylsilyl ethers are also utilized in mass spectrometry to prevent the elimination of water from alcohols on volatilization (5).

Recently the primary hydroxyl groups in sucrose have been selectively substituted with tricyclohexylsilyl groups (6). This work, however, also established that tricyclohexylsilyl and triphenylsilyl groups are only hydrolyzed by hot solutions of a strong acid or base. Consequently, one of the advantages in using trimethylsilyl residues as blocking groups, namely their ease of hydrolysis, is lost when a tricylcohexylsilyl residue is used. Nevertheless, a literature survey reveals no other case in which advantage was taken of the relative rates of substitution of different types of hydroxyl groups by trialkylsilyl residues. Moreover, it was not realized until the present work (7) that trialkylsilyl derivatives of primary, secondary, or tertiary alcohols might have different rates of alcoholysis (or hydrolysis) and that this property could be used for synthetic purposes.

The present communication describes a method for the preparation of methyl 2,3,4-tri-*O*-trimethylsilyl-α-D-glucopyranoside in high yield by the preferential methanolysis of the

trimethylsilyl residue on the primary 6-position of the corresponding fully substituted trimethylsilyl derivative of methyl α-D-glucopyranoside. Further work has shown that this reaction can probably be applied to any polyhydroxyl compound since the trimethylsilyl groups of primary, secondary, and tertiary hydroxyl groups have significantly different rates of methanolysis under acidic, basic, and neutral conditions, and this work will be the subject of future publications. It would also be of interest to establish whether the corresponding derivatives of phenolic and carboxylic hydroxyl groups in different chemical environments also differ in their rates of methanolysis.

EXPERIMENTAL

Methyl 2,3,4,6-Tetra-O-trimethylsilyl-α-D-glucopyranoside (I) from Methyl α-D-Glucopyranoside

The procedure for the preparation and purification of I has been described previously by Hedgley and Overend (3). Methyl α-D-glucopyranoside (0.31 mole) was reacted with trimethylchlorosilane (1.8 moles) in pyridine (500 ml) at 0° to yield I (0.29 mole), b.p. 115–120° at 0.25 mm, $[\alpha]_D^{22}$ +86.7° (*c*, 0.67 in chloroform), η_D^{22} 1.4410. Reported physical constants for this compound (3) are b.p. 109–110° at 0.1 mm, η_D^{25} 1.4415, $[\alpha]_D^{20}$ +92.5° (*c*, 0.692 in chloroform).

Methyl 2,3,4-Tri-O-trimethylsilyl-α-D-glucopyranoside (II) from I

The methanolysis of I (0.105 mole) in anhydrous methanol (200 ml) at 0° using a solution of potassium carbonate (0.8 millimole in 25 ml methanol) as catalyst, with the concomitant formation of II, was followed by analyzing aliquots of the reaction mixture by g.l.p.c. (7). After 45 min the relative intensities of the peaks corresponding to I and II on the g.l.p.c. tracing indicated that the reaction was complete, so the catalyst was destroyed by the addition of an equivalent amount of acetic acid to the reaction solution. Distilled water was then added to the latter, with vigorous shaking, until the solution remained cloudy. This turbidity was carefully removed by the addition of a few drops of methanol, and the resulting solution was placed in a refrigerator at 5°. When crystallization of II (0.088 mole) was complete, the product was recrystallized from cold aqueous methanol to yield II (0.081 mole) as a white crystalline compound, m.p. 98.5–99.5°, $[\alpha]_D^{24}$ +91.48° (*c*, 5.0 in chloroform).

Anal. Calcd. for $C_{16}H_{38}O_6Si_3$: C, 46.83; H, 9.27. Found: C, 46.88; H, 9.53.

A similar yield of II was obtained when acetic acid was used instead of a base as catalyst for the methanolysis reaction. However, for a comparable reaction rate the concentration of acetic acid has to be approximately 15 times that of a basic catalyst (7).

Methyl 6-O-Acetyl-2,3,4-tri-O-trimethylsilyl-α-D-glucopyranoside (III) from II

A solution of II (10 millimoles) and acetic anhydride (11 millimoles) in anhydrous pyridine (20 ml) was heated on a steam bath for 1 h and was then taken to dryness under reduced pressure. The residue was distilled under reduced pressure to obtain III (9.3 millimoles) as a colorless oil, b.p. 145–147° at 0.34 mm, $[\alpha]_D^{23}$ +90.26° (*c*, 1.047 in chloroform), and η_D^{21} 1.4502.

Anal. Calcd. for $C_{18}H_{40}O_7Si_3$: C, 47.79; H, 8.85. Found: C, 47.51; H, 9.08.

Methyl 6-O-Acetyl-α-D-glucopyranoside (IV) from III

Distilled water was added to a solution of III (5 millimoles) in methanol (40 ml) until cloudy, and then the solution was refluxed for 4 h. Subsequently, the solution was taken to dryness under reduced pressure and the oily residue was dissolved in distilled water and filtered. The clear filtrate was taken to dryness and dried over phosphorus pentoxide *in vacuo* to yield IV (4.55 millimoles) as an oil $[\alpha]_D^{21}$ +150.1° (*c*, 1.12 in acetone).

Anal. Calcd. for $C_9H_{16}O_7$: C, 45.75; H, 6.83. Found: C, 46.10; H, 6.97.

Methyl 6-O-Acetyl-α-D-glucopyranoside 2,3,4-Tricarbanilate (V) from IV

A solution containing IV (5 millimoles) and phenyl isocyanate (17.25 millimoles) in anhydrous pyridine (10 ml) was heated on a steam bath for 1 h, and then the excess phenyl isocyanate was destroyed by the addition of ethanol (1 ml). The reaction solution was subsequently taken to dryness under reduced pressure, and the residue was crystallized several times from ethanol. Compound V (4.3 millimoles) was obtained as needles, m.p. 244–246° and $[\alpha]_D^{24}$ +73.4° (*c*, 0.105 in acetone).

Anal. Calcd. for $C_{30}H_{31}O_{10}N_3$: C, 60.70; H, 5.26; N, 7.08. Found: C, 60.73; H, 5.44; N, 7.05.

Reported physical constants for V (8) are m.p. 235–237° and $[\alpha]_D^{25}$ +71° (*c*, 0.1 in acetone). A satisfactory melting point for V could not be obtained on a hot stage micro melting point apparatus (the compound appeared to sublime) so the melting point was determined by the capillary method.

Methyl 6-O-Benzoyl-2,3,4-tri-O-trimethylsilyl-α-D-glucopyranoside (VI) from II

Compound II (10 millimoles) was reacted, overnight, with benzoyl chloride (11 millimoles) in pyridine (30 ml) at 0°, and the reaction mixture was worked up in the usual manner. However, when the chloroform solution of the reaction product was washed with acid, to remove traces of pyridine, care was taken to ensure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

that the aqueous phase did not become strongly acidic. The latter condition could lead to the hydrolysis of the trimethylsilyl groups. Distillation of the residue obtained from the chloroform solution under reduced pressure yielded VI (8.8 millimoles), b.p. 208–212° at 0.47 mm, $[\alpha]_D^{23}$ +80.12° (*c*, 0.92 in chloroform) and η_D^{22} 1.4780.

Anal. Calcd. for $C_{16}H_{38}O_6Si_3$: C, 53.70; H, 8.30. Found: C, 53.52; H, 8.30.

Methyl 6-O-Benzoyl-α-D-glucopyranoside (VII) from VI

The trimethylsilyl groups of VI (5 millimoles) were hydrolyzed in aqueous methanol by the procedure described above for the preparation of IV. Removal of the solvent under reduced pressure left a solid residue. Crystallization of the latter from ethyl acetate yielded VII (4.1 millimoles) as prisms, m.p. 132–133° (reported m.p. 174–175° (9)), $[\alpha]_D^{24}$ +104° (*c*, 1.45 in chloroform).

Anal. Calcd. for $C_{14}H_{18}O_7$: C, 56.37; H, 6.08. Found: C, 56.33; H, 6.13.

Methyl α-D-Glucopyranoside 6-Carbanilate (IX) from II

Compound II (10 millimoles) was reacted with phenyl isocyanate (11 millimoles) in pyridine (10 ml) by the same procedure described for the preparation of V above. The residue (VIII) from the reaction mixture was immediately hydrolyzed in aqueous methanol (35 ml) to remove the trimethylsilyl groups, using 1 drop of glacial acetic acid as a catalyst (see procedure described for the preparation of IV and VII above). Removal of the solvent under reduced pressure left a solid residue which crystallized from water to yield IX (8.5 millimoles) as long needles, m.p. 141–143°, $[\alpha]_D^{23}$ +126.2° (*c*, 0.93 in pyridine).

Anal. Calcd. for $C_{14}H_{19}O_7N$: C, 53.67; H, 6.11; N, 4.47. Found: C, 53.62; H, 6.16; N, 4.43.

Precipitation of IX from ethyl acetate gave an amorphous white powder, m.p. 131–132.5°. Reported physical constants for IX (10) are m.p. 131–133° (from ethyl acetate), $[\alpha]_D^{25}$ +115° (*c*, 1.0 in pyridine).

Methyl 2,3,4-Tri-O-acetyl-α-D-glucopyranoside 6-Carbanilate (X) from IX

Acetylation of IX (3.2 millimoles) with acetic anhydride (3.92 millimoles) in pyridine (20 ml) in the usual manner gave a product which crystallized from methanol to yield X (3.01 millimoles) as prisms, m.p. 146–147°, $[\alpha]_D^{24}$ +1.43° (*c*, 1.1 in chloroform).

Anal. Calcd. for $C_{20}H_{25}O_{10}N$: C, 54.66; H, 5.73; N, 3.19. Found: C, 54.57; H, 5.72; N, 3.20.

Reported physical constants for X(10) are m.p. 147–148° (from methanol), $[\alpha]_D^{24}$ +145° (*c*, 1 in chloroform).

Methyl 2,3,4-Tri-O-methyl-α-D-glucopyranoside 6-(N-Methyl)-carbanilate (XI) from IX

Compound IX (5 millimoles) was methylated (11) in anhydrous *N,N*-dimethylformamide (DMF) (20 ml) using methyl iodide (0.11 mole) and freshly prepared silver oxide (40 millimoles). The reaction was assisted by vigorous agitation of the reaction solution on a mechanical shaker for 30 h. At the end of the reaction period the solution was filtered and the clear filtrate was diluted with chloroform (250 ml) to precipitate silver iodide. The latter was removed by filtration and the chloroform/DMF solution was taken to dryness *in vacuo* on a rotary evaporator. Drying under reduced pressure over phosphorous pentoxide left an oily residue (1.29 g). The residue was further purified by distillation under reduced pressure, followed by chromatography on neutral Wöelm alumina using chloroform as the eluant. Removal of the chloroform under reduced pressure yielded XI (3.14 millimoles) as a colorless oil, $[\alpha]_D^{22}$ +89.8° (*c*, 1.314 in acetone), η_D^{21} 1.5006.

Anal. Calcd. for $C_{18}H_{27}O_7N$: C, 58.52; H, 7.37; N, 3.79. Found: C, 58.58; H, 7.63; N, 3.81.

Periodate Oxidation of IX

Compound IX (0.348 millimole) was oxidized with sodium metaperiodate (1.44 millimoles) in acetate buffer solution (100 ml; pH 4) as described by Guthrie (12). The periodate consumed by IX was determined periodically on aliquots of the reaction solution by the Fleury–Lange method (13). Aliquots of the solution (5 ml) were pipetted into a solution of saturated sodium bicarbonate (10 ml) and 0.01 *N* sodium arsenite (20 ml) and left standing in the dark for 15 min. Subsequently, a 20% solution of potassium iodide was added and the excess arsenite was titrated against 0.1 N iodine solution, using a 1% starch solution (1 ml) as indicator. The results are given in Fig. 2.

All p.m.r. spectra were taken on a Varian A60 spectrometer fitted with a variable temperature probe, and using tetramethylsilane (TMS) as an internal standard. The infrared spectra were recorded on a Perkin-Elmer model 521 spectrometer.

RESULTS AND DISCUSSION

The reaction scheme for the preparation and chemistry of II is depicted in Fig. 1.

The experimental procedures which were used to make a kinetic study of the controlled methanolysis of I to produce II have already been described in this issue (7). Essentially the same reaction conditions were used for the production of II on a preparative scale (see Experimental), apart from changes in the relative concentrations of reagents, and g.l.p.c. was again used to follow the course of the reaction. However, no g.l.p.c. internal standard (7) was present in the reaction solution since the course of the reaction could be estimated in a qualitative manner by observing the relative intensities of I and II on the g.l.p.c. tracing.

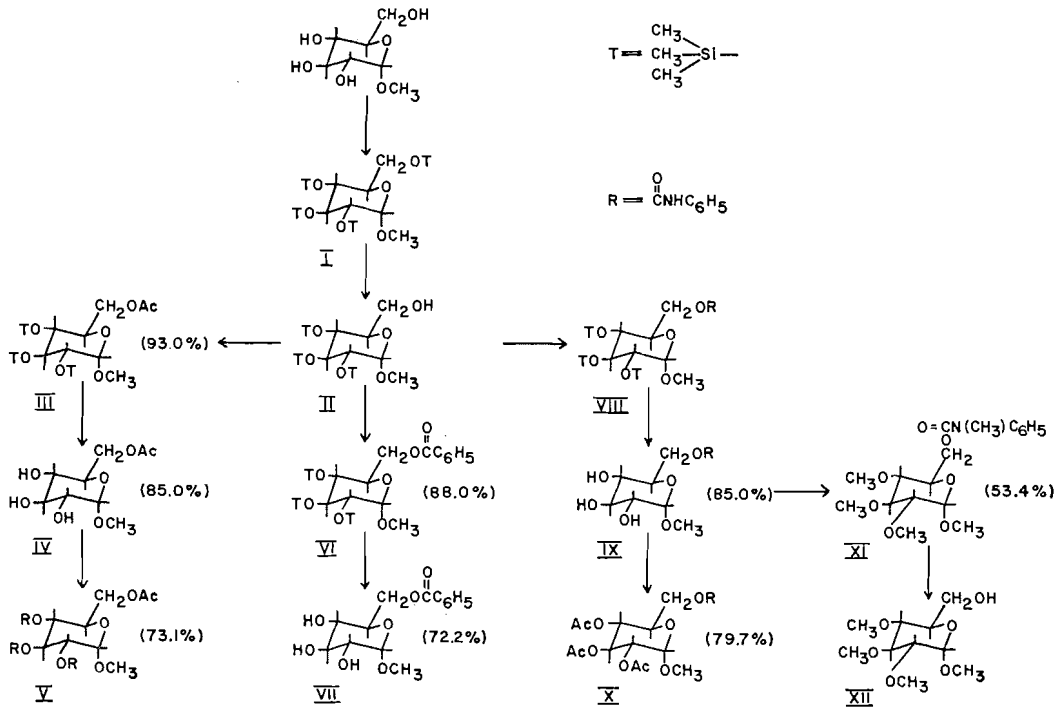

FIG. 1. The preparation and chemistry of methyl 2,3,4-tri-*O*-trimethylsilyl-α-D-glucopyranoside (II).

When the reaction was complete, II crystallized from the methanolic reaction solution on addition of water. This simple experimental procedure enabled II to be isolated in greater than 70% yield based on methyl α-D-glucopyranoside, or over 80% yield based on I. Moreover, studies in this laboratory have shown that the reaction of trimethylchlorosilane with polyhydroxy compounds in pyridine is virtually instantaneous at room temperature. Consequently, a supply of II for synthetic purposes can be obtained quickly provided it is prepared from crude (undistilled) I. The latter may be obtained sufficiently pure for this purpose by removing the pyridine under reduced pressure and dissolving I in petroleum ether, in which pyridinium hydrochloride is insoluble.

Compound II reacted with phenyl isocyanate in pyridine to form the corresponding monocarbanilate derivative VIII, which was subsequently hydrolyzed in aqueous methanol to give compound IX. The position of the carbanilate residue in IX could be determined by periodate oxidation studies. If the substituent was at carbon-6 of the glucose moiety of this compound it would consume 2 moles of periodate due to the presence of three secondary hydroxyl groups on contiguous carbon atoms, whereas the corresponding 2- and 4-derivatives, with only two secondary hydroxyl groups on adjacent carbon atoms, would require only 1 mole of the reagent. The remaining derivative with the substituent on the 3-position, and containing no secondary hydroxyl groups on adjacent carbon atoms, would not be oxidized by periodate. From Fig. 2 it can be seen that compound IX consumed 2 moles of periodate and consequently must have the substituent at carbon-6. This result requires that compounds VIII and II have the structures shown in Fig. 1, since the carbanilate residue of IX occupies the same position as the original hydroxyl group in II.

It was not possible to deduce the structure of IX by comparing its physical constants with those reported in the literature (10). Although the melting point of the latter agreed

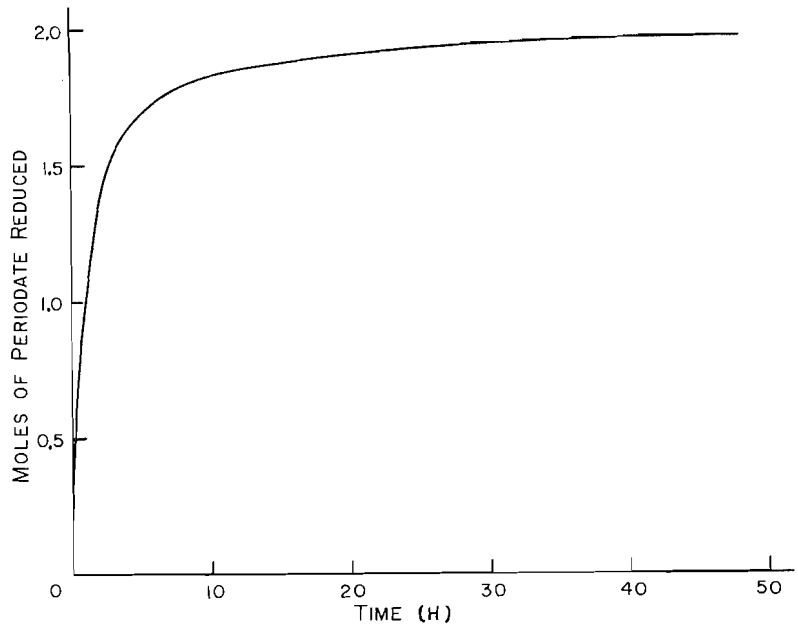

FIG. 2. A plot of the number of moles of periodate consumed by methyl α-D-glucopyranoside 6-carbanilate (IX) against time.

with the literature value it was obtained as an amorphous powder from ethyl acetate and not crystalline as reported by Hearon *et al.* Compound IX, however, could be obtained as long crystalline needles from water. Moreover, the specific rotation of our compound was 11° higher than the reported value. However, the physical constants for X, prepared by the reaction of IX with acetic anhydride in pyridine, were in excellent agreement with those reported (10). Since Hearon and co-workers prepared IX by the deacetylation of X with boiling methanolic hydrogen chloride, it seems probable that any differences in the two sets of physical constants for IX may be due to the presence of some of the corresponding β-isomer in their product which must be present after this treatment. It is of interest that Hearon *et al.* obtained IX in 15% yield using a standard five step synthesis (i.e. tritylation, acetylation, carbanilation, etc.) whereas by the present method this compound can be obtained in >60% yield based on the methyl glucoside, and without the possibility of side reactions occurring. Compound XI was prepared from IX by the Kuhn procedure (11), and the former was converted to XII when treated with ethanolic barium hydroxide. The latter (XII) was identified (14) and isolated by g.l.p.c., and the physical constants of this compound agreed with those reported in the literature for methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranoside (15). Consequently, the carbanilate residues of IX and XI, and the hydroxyl group of II, must have been attached to carbon-6 of the glucose moieties of these compounds. Moreover, the differences in the infrared spectra of IX and XI were consistent with those expected for *N*-methylation as well as *O*-methylation of IX by the Kuhn procedure. *N*-Alkylation of carbanilate groups under similar experimental conditions has been reported previously by Bouveng (16). This behavior is also observed in urethans and is in contrast to that exhibited by thiourethans which apparently can undergo *S*-alkylation (17), to produce dialkyl esters of ortho-thiocarbonic anil, RN=C(OR′)(SR″), or *N*-alkylation (18) depending on the basic catalyst.

The structure of XI was also confirmed by p.m.r. studies (see Fig. 3). At low field the five aromatic protons of the phenyl group appear as a broad singlet at 2.79, and the equatorial anomeric hydrogen occurs at 5.38 with the spacing of 3.3 c.p.s. (19) characteristic of protons in the *cis* orientation at carbon-1 and -2. The geminal hydrogens on carbon-6, which are not magnetically equivalent because of the presence of the asymmetric center at carbon-5, constitute the AB part of the ABX system shown in Fig. 4, R = —CH_3; R′ = —$OCN(CH_3)C_6H_5$, and are consequently present as two characteristic overlapping quartets centered at 5.83. Analysis of the AB multiplet gave values of 17.9 c.p.s. for the

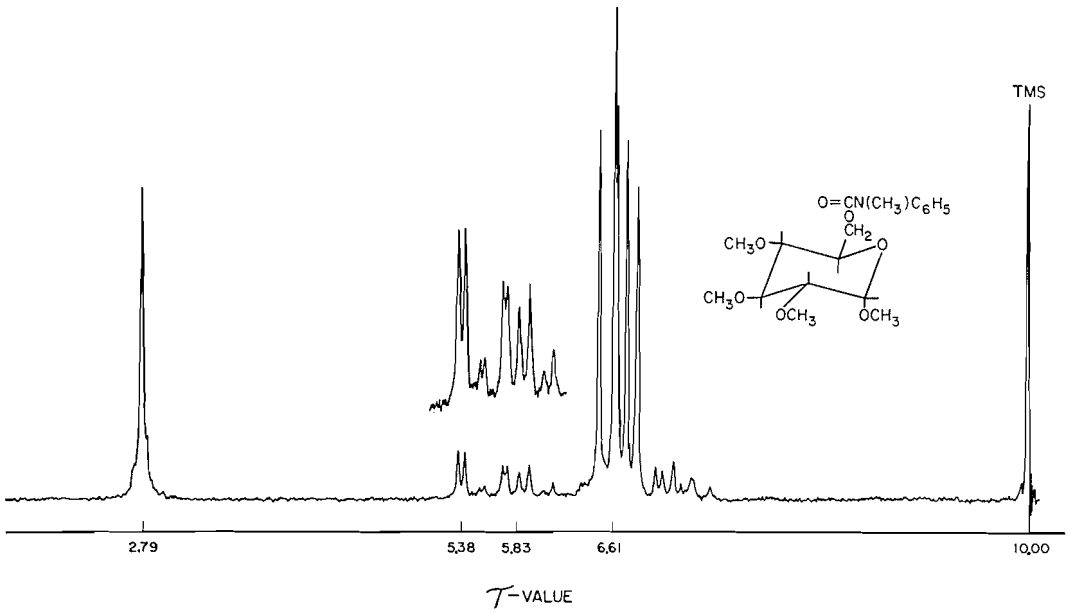

FIG. 3. The p.m.r. spectra of methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranoside 6-(*N*-methyl)-carbanilate (XI) in CCl_4 using TMS as an internal standard.

chemical shift δ_{AB}, −11.7 c.p.s. for J_{AB}, 5.4 c.p.s. for J_{AX}, and 2.0 c.p.s. for J_{BX}. Although no information can be obtained about the absolute or relative signs of these coupling constants from the p.m.r. signals for the two geminal protons, it is known that geminal coupling constants (i.e. J_{AB}) are negative (20, 21), and of opposite sign to vicinal coupling constants (i.e. J_{AX} and J_{BX}) in substituted alkanes. Consequently, the above coupling constants were arbitrarily given appropriate signs. Calculation of the theoretical line positions and intensities for the AB multiplet, using the values for the chemical shift and coupling constants given above, gave results in excellent agreement with those obtained experimentally. Furthermore, the protons of the *N*-methyl and four methoxyl groups of XI appear as singlets at 6.5, 6.61, 6.63, 6.74, and 6.83. The remaining protons of the pyranose ring are partly hidden under the latter peaks or appear on the high-field side of the singlet at 6.83.

If compound XI exists solely in conformation 1*a* (R′ = —$OCN(CH_3)C_6H_5$; R = —CH_3) (see Fig. 4) in carbon tetrachloride solution the protons H_A and H_X, which are in a *trans* relationship to one another, would be expected to have a value of from 8 to 12 c.p.s. for J_{AX} (22, 23). The low experimental value of 5.4 c.p.s. for this coupling constant therefore suggests that there is free rotation about the C_5—C_6 bond resulting in a rapid interconversion of the three possible conformations (see Fig. 4; 1*a*, 1*b*, and 1*c*) with a concomitant

1a 1b 1c

FIG. 4. The three possible conformations of the groups or atoms attached to the fifth and sixth carbon atoms in the glucose moiety of compounds XI and II.

decrease in the value of J_{AX} (22). However, the coupling constants J_{AX} and J_{BX} remained unchanged when the spectrum of XI was recorded over a temperature range of 60° to −60°, and when a solvent of high dielectric constant such as acetone-d_6 was used as a solvent instead of carbon tetrachloride. Since changes in coupling constants resulting from a changing equilibrium between conformations of different dipole moments on varying the polarity of the solvent have already been found by Sheppard (24), and since similar changes can occur by varying the temperature of the solution (25), the results only seem to be compatible with the presence of a single conformer. Consideration of the *gauche* interactions of the substituents on carbon-5 and carbon-6, together with the 1,3-interactions between the substituents on the latter and on carbon-4, leaves little doubt that 1*a* is the most stable and 1*b* the least stable conformation (see Fig. 4). Indeed the differences in non-bonded interactions in the three conformations make it unlikely that they would be equally populated in solution under all of the experimental conditions described above. Consequently, compound XI probably exists almost entirely in conformation 1*a*. The low value obtained for J_{AX} may be due to the fact that the 1,3-interactions in 1*a* would tend to repel H_A and H_4 thereby reducing the dihedral angle subtended by the C_6—H_A and C_5—O bonds. This would result in a reduction in the angle subtended by the C_5—H_X and C_6—H_A bonds, which would result in a decrease in the value of J_{AX} (23). It should also be remembered that the electronegativity of the R′ group (see Fig. 4) could also have a profound effect on the value of J_{AX} (23).

The infrared spectrum of a 5×10^{-3} *M* solution of II in carbon tetrachloride gave a single absorption band in the O—H stretching region in the infrared at 3 609 cm^{-1}. Since free primary hydroxyl groups under similar experimental conditions give absorption bands with little variation at 3 636 – 3 641 cm^{-1} (26, 27) it would appear that the primary hydroxyl group of II is involved in a *weak* intramolecular hydrogen bond corresponding to a shift to lower frequency of approximately 30 cm^{-1}. The only conformations in which the primary hydroxyl group could form a hydrogen bond are 1*a* and 1*b*, see Fig. 4; R′ = —H; R = —$Si(CH_3)_3$, and the single absorption band at 3 609 cm^{-1} implies that there is only one conformer present, or that the hydrogen bonds formed in the two conformations are of equal energy. It is unlikely, however, that II exists in conformation 1*b* since the short O—O distance (≈2.4 Å) (28) and the high electron density at the oxygen atom attached to carbon-4, due to the ionic character of the Si—O bond (1*d*), would require the presence of a much stronger hydrogen bond. Indeed, the experimental results can be explained if II exists in the same conformation as XI, namely 1*a*. In this case if the angle between the C_6—O and C_5—O bonds was increased because of the 1,3-interactions discussed above, the O—O distance in this conformation could easily be about 3 Å, and this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

large distance would of course result in a weak hydrogen bond (28) between the hydroxyl group and the oxygen atom in the pyranose ring. It is possible, however, that 3 609 cm^{-1} is the normal O—H stretching frequency for the free primary hydroxyl group in compounds such as II, although there is no evidence in the literature to support such a contention.

In conclusion compounds III and VI were prepared by the reaction of II with acetic anhydride or benzoyl chloride in pyridine, and hydrolysis of these compounds with boiling aqueous methanol gave IV, and VII, in excellent yield. The former has not been synthesized previously, and the physical constants of the latter reported in the literature (7) are in error (see Experimental). Inspection of the p.m.r. spectra of III and VI in $CDCl_3$ reveals that the signals for the two geminal protons on carbon-6 are present as two overlapping quartets centered at τ values of 5.74 and 5.50. Calculation as in the case of compound XI gave values for III of 18.5 c.p.s. for δ_{AB}, −12.2 c.p.s. for J_{AB}, 4.7 c.p.s. for J_{AX}, and 1.5 c.p.s. for J_{BX} and corresponding values for VI of 20.0 c.p.s. for δ_{AB}, −12.4 c.p.s. for J_{AB}, 5.4 c.p.s. for J_{AX}, and 1.6 c.p.s. for J_{BX}. Although V was prepared by the reaction of IV with phenyl isocyanate in pyridine, it was not possible to confirm the identity of the latter by preparing this derivative because the melting point and $[\alpha]_D$ reported for this compound (8) were lower than the values obtained in this laboratory (see Experimental). Proton magnetic resonance temperature studies on III and IV also indicate that the atoms and groups attached to carbon-5 and -6 have the same conformation as described above for XI and II.

ACKNOWLEDGMENTS

We should like to acknowledge the excellent technical assistance of Mrs. M. G. Flack and the help of our colleague Mr. D. G. Smith in recording the p.m.r. spectra.

THE STRUCTURE OF RETAMINE AND THE PARTIAL SYNTHESIS OF THE (−)-ENANTIOMORPH[1]

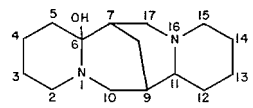
KJU HI SHIN,[2] L. FONZES,[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received March 3, 1965

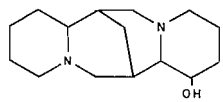
ABSTRACT

Previous work by many authors has led to the assumption that retamine might be (+)-12-hydroxysparteine. A partial synthesis of the enantiomorph of this compound has been effected by dehydration of (+)-13-hydroxylupanine and hydroboration of the product. The dehydration product consisted of two components that were separated by thin-layer chromatography and identified by the characteristics of their nuclear magnetic resonance (n.m.r.) spectra as $\Delta^{12,13}$- and $\Delta^{13,14}$-dehydrolupanine. Hydroboration of the $\Delta^{12,13}$-isomer gave rise to (−)-12-hydroxysparteine having, in thin-layer chromatography, the same R_f value as natural retamine and the same optical rotation numerically, although of opposite sign. The synthetic base had the same infrared and n.m.r. spectra as the alkaloid and the two had superimposable Debye–Scherrer patterns. Evidence is given showing the hydroxyl to be equatorial.

The lupin alkaloid retamine, $C_{15}H_{26}ON_2$, m.p. 168°, $[\alpha]_D$ +46.2°, was first isolated by Battandier and Malosse (1). It was suggested by White (2) that it was probably a hydroxysparteine, and by Ribas, Sanchez, and Primo (3) that it was likely 6-hydroxysparteine (I). Later Ribas and Fraga (4) recognized that the properties of retamine could not be accommodated by a 6-hydroxy structure and, since the base could not be oxidized to a ketone, they suggested that it was either a 7- or a 9-hydroxy-(+)-sparteine. More recently, in the light of new evidence, Ribas and his co-workers (5) abandoned the 7- or 9-hydroxy structure in favor of 8-hydroxy-(+)-sparteine, notwithstanding the fact that retamine did not produce a ketone on oxidation. Finally, Bohlmann and his co-workers (6, 7) synthesized both epimers of each 7-hydroxy and 9-hydroxy-(+)-sparteine as well as the two epimers of 8-hydroxy-(+)-sparteine and established that none of these was identical with retamine.



I

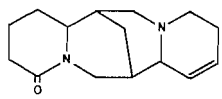


II

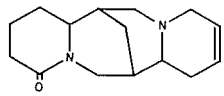
From the results of Ribas *et al.* (5) the hydroxyl in retamine can be present only in ring A or ring D. Since, however, anhydroretamine obtained by the dehydration of the base at high temperature gives rise on catalytic hydrogenation to a mixture of sparteine and α-isosparteine, it must be concluded that the hydroxyl is located in ring D. Furthermore, retamine is not a carbinolamine and, therefore, the hydroxyl cannot occupy positions 11 or 15. Also both epimers of 13-hydroxysparteine are known (8) and neither is identical with the alkaloid. Consequently, Bohlmann *et al.* (7) have suggested that retamine was either 12-hydroxysparteine II or 14-hydroxysparteine. It was assumed that the dehydration of 12-hydroxysparteine would give rise to $\Delta^{11,12}$-dehydrosparteine, and since this product on catalytic hydrogenation should form α-isosparteine exclusively (9, 10) whereas the dehydration product of retamine, depending on the temperature at which it was

[1]*Issued as N.R.C. No. 8459.*
[2]*National Research Council of Canada Postdoctorate Fellow.*

formed (5), produced on hydrogenation either sparteine or a mixture of sparteine and α-isosparteine, Bohlmann (8) considered 14-hydroxysparteine as the more likely structure for retamine.



III



IV

From a consideration of the optical activity, the possibility that retamine could be a hydroxy-α-isosparteine can be discarded. The molecular rotation of retamine is +115 and, on the assumption that it is a hydroxysparteine, the calculated molecular rotation of its hydroxy epimer, isoretamine, should be −35° in agreement with the found value (5). Were retamine a hydroxy-α-isosparteine, the molecular rotation of its hydroxy epimer should be +145.

In an attempt to establish the structure of retamine we have sought to synthesize its (−)-enantiomorph from naturally occurring (+)-13-hydroxylupanine. The dehydration of this hydroxy base would be expected to give a mixture of $\Delta^{12,13}$-dehydrolupanine III and the $\Delta^{13,14}$-isomer. In fact when 13-hydroxylupanine was dehydrated by heating at 170° with phosphoric anhydride the product showed two main spots in thin-layer chromatography.

Hydroboration of the mixed dehydrolupanines produced a mixture, one of the components of which, after purification by chromatography and sublimation, corresponded to the (−)-enantiomorph of retamine. It melted at 166–167° and depressed the melting point of the alkaloid when the two were mixed, but its infrared and n.m.r. spectra were identical, respectively, with those of retamine. It can be concluded from this result that retamine must be either 12-hydroxy- or 14-hydroxysparteine. It had been ascertained in a preliminary experiment that diborane reduced the lactamic carbonyl and converted (+)-lupanine to (−)-sparteine. Brown and Heim (11) have since shown that amides generally are reduced by diborane.

In $\Delta^{12,13}$-dehydrolupanine III the system $\rangle CH \cdot CH{=}CH \cdot CH_2-$ is present while in $\Delta^{13,14}$-dehydrolupanine IV there is the sequence $-CH_2 \cdot CH{=}CH \cdot CH_2-$. The n.m.r. spectrum of the mixture of the two dehydrolupanines isolated from the product of the dehydration of 13-hydroxylupanine contains in the ethylenic region a symmetrical quartet centered at δ 5.07 which should be assigned to the protons of the symmetrically substituted ethylenic system of $\Delta^{13,14}$-dehydrolupanine, and an unsymmetrical signal at σ 5.64, 5.48 assignable to $\Delta^{12,13}$-dehydrolupanine. The mixture of dehydrolupanines was separated into its two components by preparative scale chromatography. The component with R_f 0.49 which, in the n.m.r., showed an unsymmetrical signal (δ 5.72, 5.53, 5.32), but no symmetrical quartet, was taken to be $\Delta^{12,13}$-dehydrolupanine III while the component with R_f 0.55 containing a symmetrical quartet in its n.m.r. spectrum was considered to be $\Delta^{13,14}$-dehydrolupanine IV.[3] Hydroxylation of $\Delta^{12,13}$-dehydrolupanine by treatment with diborane yielded a product showing in thin-layer chromatography three main spots (R_f 0.64, 0.47, and 0.33), of which the intermediate one corresponded to retamine, plus four other weak spots.

[3]*Such an assignment is not always reliable, particularly when dealing with a single compound. With a mixture of two compounds, however, representing both systems and giving the coupling patterns expected of each, the assignment becomes much more reliable, especially since after separation one component gives only the unsymmetrical pattern and the other component produces exclusively the symmetrical pattern.*

The components of the reaction mixture were separated by preparative scale thin-layer chromatography with developing solvent No. 3. The band corresponding to retamine was eluted and the product after distillation *in vacuo* crystallized spontaneously. The crystals, washed with acetone and dried, melted at 166–167°. In admixture with the synthetic retamine enantiomorph described above, the melting point was unaltered, but in admixture with naturally occurring (+)-retamine (m.p. 168°)[4] it melted at 146–147.5°. The synthetic base had $[\alpha]_D^{24}$ −47.3°, which is in good agreement numerically, but of opposite sign, with the optical rotation of authentic retamine. The infrared and n.m.r. spectra and the X-ray powder pattern of synthetic (−)-12-hydroxysparteine III were identical, respectively, with those of authentic retamine, and the mobilities of the two in thin-layer chromatography were the same. It can be concluded that retamine is (+)-12-hydroxysparteine.

The direction of elimination in the dehydration of retamine is temperature dependent. If the temperature of the reaction is kept below 170° the dehydro derivative formed gives rise to sparteine on hydrogenation. When the dehydration is carried out at 200° the product gives rise to α-isosparteine on hydrogenation so that in this case the double bond must be in the $\Delta^{11,12}$ position. It is most unlikely that a 14-hydroxysparteine could give rise to $\Delta^{11,12}$-dehydrosparteine and therefore on chemical grounds can be rejected.

Since an axial hydroxyl would be expected to give $\Delta^{11,12}$-dehydrosparteine readily on dehydration, the experimental results of Ribas (5) showing that this isomer is formed only under drastic conditions and is still accompanied by the $\Delta^{12,13}$-isomer militate in favor of an equatorial hydroxyl in retamine. Such a configuration of 12-hydroxy-(+)-sparteine would favor acid-catalyzed elimination of trans-diequatorial hydroxyl and hydrogen and formation of $\Delta^{12,13}$-dehydrosparteine, whereas an axial hydroxyl would not favor the formation of this compound.

Furthermore, hydroboration proceeds preferentially from the less hindered side of cyclic or bicyclic olefins (12). An examination of a Dreiding model shows that a C-12 equatorial hydroxyl is less hindered than an axial hydroxyl, so that in accordance with the foregoing generalization the former would be favored.

In the light of the established structure of retamine the peculiarities of the dehydration of the alkaloid are readily explained. Dehydration at the lower temperature gives rise to $\Delta^{12,13}$-dehydrosparteine, which on hydrogenation produces sparteine. On the other hand at ca. 200° the predominant product is $\Delta^{11,12}$-dehydrosparteine accompanied by some of the $\Delta^{12,13}$-isomer, because of the partial rearrangement of the latter. Catalytic hydrogenation of the mixture would give rise to both α-isosparteine and sparteine.

NOTE ADDED IN PROOF: After this manuscript had been accepted for publication a paper on the structure and synthesis of retamine (F. Bohlmann, H. Overwien, and D. Schumann, Chem. Ber. 98, 659, 1965) received in Ottawa April 23 appeared in print. The constitution assigned to retamine in that paper is the same as that we have assigned, although the configuration is different. The interpretation of our evidence led us to the conclusion that the hydroxyl in retamine is equatorial.

EXPERIMENTAL

The distillations were carried out in glass bulbs blown in a tube and the temperatures cited were those of the air bath surrounding the end bulb. The n.m.r. spectra were obtained on an A-60 Varian spectrometer, in deutero-chloroform solution with tetramethylsilane as an internal indicator. For thin-layer chromatography, silica gel G was used with one of the following developing solvents: cyclohexane–chloroform–diethylamine

[4]*Very kindly sent by Professor I. Ribas, whom we thank cordially.*

7:2:1 (solvent No. 1); methanol–diethylamine 9:1 (solvent No. 2); heptane–methylethylketone–diethylamine 7.5:2:0.5 (solvent No. 3). The spots were brought out by spraying with modified Dragendorf's reagent.

Dehydration of (+)-13-Hydroxylupanine

Finely powdered (+)-13-hydroxylupanine (3.0 g) mixed with phosphorus pentoxide (17.0 g) was heated during 6 h in a metal bath at 170–175°. After cooling, cracked ice was added gradually, the reaction mixture was made strongly basic with potassium hydroxide and extracted with methylene chloride. The extract was dried over sodium sulfate and the solvent evaporated *in vacuo*. There was left a slightly colored residual oil (2.3 g). A small sample showed in thin-layer chromatography two quite close spots corresponding to the anhydrolupanines (R_f 0.49, solvent No. 1), one spot corresponding to the starting material (R_f 0.12) and three other spots that were very faint.

The residual oil was dissolved in benzene and chromatographed on neutral grade I alumina (70 g). The column was eluted and the eluate collected in 100 ml fractions. The results of the elution are given in the following table. Combined fractions 1–11 gave 1.360 g of the mixture of anhydrolupanines. This mixture

Fractions	Eluant	Residue, mg	Product
1–5	Benzene	105	Anhydrolupanines
6	Benzene–chloroform 9:1	15	,,
7	Benzene–chloroform 8:2	50	,,
8	Benzene–chloroform 7:3	75	,,
9	Benzene–chloroform 5:5	300	,,
10	Benzene–chloroform 4:6	400	,,
11	Benzene–chloroform 3:7	415	,,
12	Benzene–chloroform 2:8	50	,, and starting product
13–15	Chloroform	110	Starting product
16–18	Methanol	440	Starting product

contained in its n.m.r. spectrum in the ethylenic region a symmetrical quartet centered at δ 5.07 attributable to the protons of the symmetrically substituted ethylenic system of $\Delta^{13,14}$-anhydrolupanine and an unsymmetrical signal at δ 5.64, 5.48 assignable to $\Delta^{12,13}$-anhydrolupanine.

Synthesis of Retamine

A solution of diborane was first prepared by the addition of freshly distilled boron fluoride ethyl ether (5 ml) to a solution of sodium borohydride (5.9 g) in tetrahydrofurane (100 ml) kept magnetically stirred and cooled in an ice bath. The addition was carried out in the course of 20 min in a stream of nitrogen. The reaction mixture was then kept at room temperature for 16 h.

To the mixture of anhydrolupanines (900 mg) obtained by dehydration of (+)-13-hydroxylupanine dissolved in tetrahydrofurane (50 ml) and cooled in ice while magnetically stirred, the above solution of diborane was added in the course of 10 min in a stream of nitrogen. After 30 min the ice bath was removed and the stirring continued under an atmosphere of nitrogen for $2\frac{1}{2}$ h at room temperature. The reaction mixture was again cooled in an ice bath, made alkaline by the gradual addition of 20% aqueous sodium hydroxide, followed by the dropwise addition of 30% hydrogen peroxide (5 ml). The mixture was heated on the steam bath for 15 min, cooled, and decanted. The aqueous layer was extracted with benzene, the benzene extract combined with the tetrahydrofurane layer, dried over sodium sulfate, and evaporated to dryness under reduced pressure. The residue consisted of a slightly colored oil (900 mg) which, in thin-layer chromatography, showed two main spots (R_f 0.64 and 0.47, solvent No. 3), the second of which (R_f 0.47) was identical with that of retamine. There is also a spot (R_f 0.33) corresponding to an important quantity of unchanged starting material, and four other much weaker spots (R_f 0.54, 0.24, 0.18, 0.12).

Separation of Retamine

The above product (900 mg) obtained from the hydroboration reaction was distributed onto 10 plates (20 × 20 cm) covered with silica gel G of 0.5 mm thickness and the chromatograms were developed with solvent No. 3. The spots were brought out on strips of the chromatograms with Dragendorf's reagent and the parts corresponding to the retamine spot were scraped off, and eluted with methanol containing 5% of diethylamine. The substance obtained from this elution (200 mg) was again chromatographed on two plates (20 × 20 cm) exactly as before. It yielded on elution a crystalline residue (100 mg) that was further purified by two sublimations at 115° under 10^{-3} mm, wt. 60 mg. The substance then melted at 166–167° and in admixture with authentic (+)-retamine[4] melted at 144–148°, $[\alpha]_D^{24}$ −47.3° (c = 0.97 in 95% EtOH). Its infrared and n.m.r. spectra and X-ray powder pattern were identical, respectively, with those of (+)-retamine.

Separation of $\Delta^{12,13}$- and $\Delta^{13,14}$-Anhydrolupanine

The mixture of $\Delta^{12,13}$- and $\Delta^{13,14}$-anhydrolupanine (300 mg) was applied on five plates (20 × 20 cm) covered with silica gel and the chromatograms developed with solvent No. 1. Two fractions were obtained: fraction A ($\Delta^{13,14}$-anhydrolupanine), R_f 0.55, had a higher mobility than fraction B ($\Delta^{12,13}$-anhydrolupanine, R_f 0.49). Both fractions were located after spraying a strip on each plate with modified Dragendorf's reagent. Fraction B was scraped off and eluted with methylene chloride containing about 5% of diethyl amine. The eluate, evaporated *in vacuo*, left a residual, slightly yellow oil containing fraction B still contaminated with a very small quantity of fraction A. The separation by preparative scale thin-layer chromatography was repeated. It yielded pure $\Delta^{12,13}$-anhydrolupanine (fraction B), which produced a single spot in thin-layer chromatography. The product was distilled at 140° under 0.01 mm, wt. 102 mg. Its n.m.r. spectrum contained signals at δ 5.72, 5.53, 5.32.

Fraction A was also scraped off the plates, eluted with methylene chloride containing 5% of diethylamine. It was purified again by preparative scale thin-layer chromatography. The product thus obtained ($\Delta^{13,14}$-anhydrolupanine) showed a single spot in thin-layer chromatography and its n.m.r. spectrum contained a symmetrical quartet centered at δ 5.07.

Conversion of $\Delta^{12,13}$-Anhydrolupanine to (−)-Retamine

To a solution of $\Delta^{12,13}$-anhydrolupanine (102 mg) in tetrahydrofurane cooled in an ice-water bath and stirred under a nitrogen atmosphere, a diborane solution prepared as above (6 ml) was added in the course of 10 min. The reaction was completed exactly as described above, and the product isolated by the same procedure. It was purified by preparative scale chromatography, followed by distillation at 130° under 0.01 mm it crystallized spontaneously, m.p. 155–164°. The undistilled residue was dissolved in methylene chloride, chromatographed on grade III alumina, and eluted with chloroform. Evaporation of the eluate left a residue which was crystallized from acetone, m.p. 164–167°. Both crystalline fractions (m.p. 155–164° and 164–167°) were combined and distilled at 135° under 0.01 mm. The distillate crystallized spontaneously and was washed with a little acetone, m.p. 166–167°. The melting point was not depressed by admixture with the synthetic sample described above, but in admixture with authentic retamine, m.p. 146–147.5°. The synthetic product had the same mobility in thin-layer chromatography as authentic retamine; its infrared and n.m.r. spectra and X-ray powder pattern were identical, respectively, with those of the alkaloid.

Action of Diborane on (−)-Lupanine

(−)-Lupanine (380 mg) was dissolved in tetrahydrofurane (30 ml) and treated with diborane exactly as described above. The product, worked up as described for retamine and distilled at 150° under 0.01 mm, was an oil that formed a crystalline perchlorate. After recrystallization from methanol, the salt melted at 173° either alone or in admixture with an authentic sample of (+)-sparteine perchlorate.

ACKNOWLEDGMENTS

We express our gratitude to Mr. R. Lauzon for measuring the infrared spectra and Mr. M. Lesage for the n.m.r. spectra. We acknowledge also our indebtedness to Dr. M. Przybylska, who produced the X-ray powder patterns, and to Professor I. Ribas, who gave us a generous sample of retamine.

BIOSYNTHESIS OF BERBERINE AND BERBERASTINE

INCORPORATION OF CATECHOLAMINES[1]

IVO MONKOVIĆ AND IAN D. SPENSER

Department of Chemistry and Research Unit in Biochemistry, Biophysics and Molecular Biology, McMaster University, Hamilton, Ontario

Received February 15, 1965

ABSTRACT

Dopamine serves as a precursor of berberastine, berberine, hydrastine, and canadine in *Hydrastis canadensis* L. Noradrenaline serves as a precursor of berberastine but is not incorporated into the other three bases. It is shown that the incorporation of labelled dopamine into berberine and of labelled noradrenaline into berberastine takes place without randomization of radioactivity.

Two C_6—C_2 units, derived from tyrosine, are incorporated into the alkaloids which are biogenetically related to norlaudanosoline. The carbon skeleton of some of these bases (e.g., papaverine (3) and morphine (4)) is accounted for in its entirety by two such units. To complete the skeleton of other bases belonging to this group (e.g., hydrastine (5, 6), narcotine (7), berberine (6, 8), and chelidonine (9)) an additional one-carbon unit is required, which is derived from the S-methyl group of methionine (10).

We have presented evidence that the two C_6—C_2 units differ from one another. The first experimental indications came from our finding that even though tyrosine gave rise to both of the C_6—C_2 units which are incorporated into hydrastine the efficiency of incorporation of the two units was unequal (5), and from the results of Rapoport, Levy, and Stermitz on the nonrandom incorporation of carbon dioxide into morphine (11). We obtained direct evidence for the inequality of the two C_6—C_2 units in the biosynthesis of hydrastine with the demonstration that 3,4-dihydroxyphenylethylamine (dopamine) supplied only one of these units (12). Analogous results have now been reported by Leete and Murrill and by Battersby and Francis in studies of the biosynthesis of chelidonine (13) and of morphine (13, 14).

It appears that the conversion of tyrosine into dopa (15) and thence into two dissimilar intermediates, presumably dopamine and 3,4-dihydroxyphenylpyruvic acid, represents a common early stage of the routes leading to the different structural variants among the alkaloids related to norlaudanosoline (XII). In extension of the evidence for the generality of this biosynthetic pathway we now report that dopamine supplies only one of the two C_6—C_2 units which are incorporated into berberine.

Six small plants of *Hydrastis canadensis* L. were allowed to grow for 6 days with their roots immersed in aerated nutrient solution containing 1-^{14}C-dopamine hydrobromide (expt. 1). Berberine and hydrastine were extracted from roots and rhizomes by standard methods (6), and were found to be radioactive. Radiochemical yields in this experiment were of the same magnitude as those obtained in an earlier experiment with the same precursor (ref. 6, expt. 10), even though the duration of the feeding, the modes of administration of tracer, and the number and size of the plants and therefore also the chemical yield of alkaloids were different. In Table I the chemical and radiochemical yields obtained in these two experiments are compared.

[1]*Parts of this work have been reported in preliminary communications (1, 2).*

*Diluted with carrier.

The labelled berberine from expt. 1 was diluted with carrier, crystallized to constant activity, and degraded by the method previously reported (6) (Fig. 1). The specific activities of some of the intermediates of the degradation sequence are summarized in Table II. No loss of activity occurred in the eight-step conversion of berberine (IV) into 6-bromo-α-hydroxyhomopiperonyl bromide (VII). Oxidation of this compound, which removed a single carbon atom, led to 6-bromopiperonylic acid (VIII), which was essentially inactive. All activity of the original berberine was therefore confined to C-6 of the berberine nucleus, showing that dopamine is specifically incorporated into berberine and that only one dopamine unit enters the molecule. This result is in complete agreement with those on the incorporation of dopamine into hydrastine, chelidonine, and morphine.

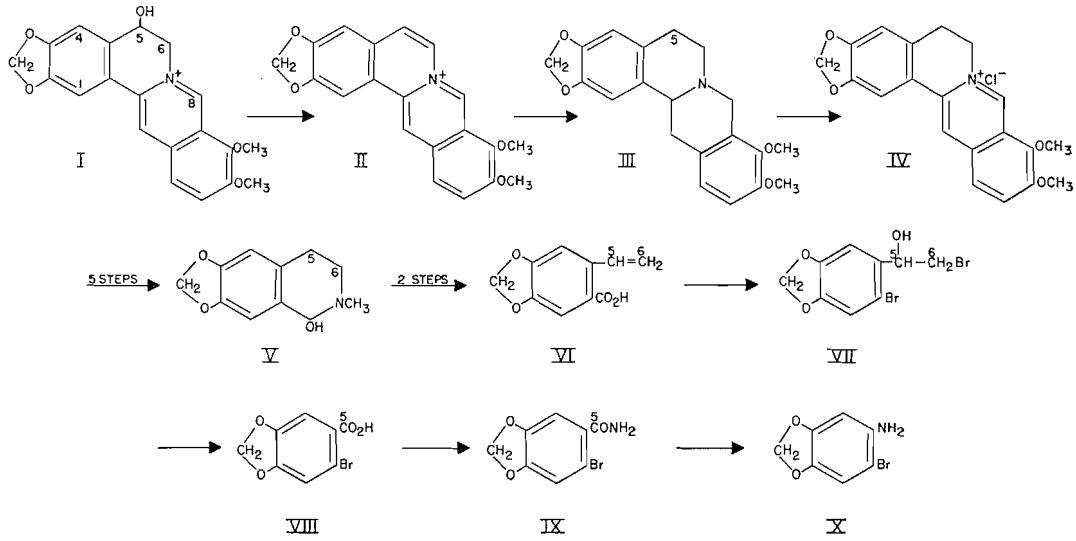

FIG. 1. Steps in the degradation of berberastine and berberine.

An outstanding experimental gap in the present understanding of the biosynthesis of the alkaloids of *H. canadensis* concerns the metabolic interrelationship of berberine (IV), hydrastine (XI), and canadine (III), which until recently were the only alkaloids known to occur in this plant. It had long been postulated that berberine is derived by partial aromatization of canadine (16), which in turn is formed from the benzylisoquinoline system of norlaudanosoline (XII) by intervention of a one-carbon unit (16). Recent evidence is consistent with this hypothesis (10, 15, 17). The third alkaloid, hydrastine, may arise from berberine (18, 19), or else directly from norlaudanosoline (XII) by a route which excludes canadine and berberine (16, cf. ref. 10). The specific incorporation of norlaudanosoline into narcotine (7) lends substance to these possibilities. Alternatively, hydrastine may originate from dopamine (6, 12) and a second tyrosine-derived C_6—C_2 unit (5, 6) by a pathway which excludes norlaudanosoline. The observation that labelled reticuline, an *O,O,N*-trimethylnorlaudanosoline, was not incorporated into hydrastine in an experiment with *H. canadensis* which yielded specifically labelled berberine (15) would appear to leave this possibility open.

One of the structural features of hydrastine, absent in berberine, is the benzylic oxygen function at C-7′. A rational biogenetic scheme for the introduction of this oxygen function in the course of the elaboration of berberine into hydrastine has been put forward (19). It was conceivable, however, that this benzylic hydroxyl group is introduced into a C_6—C_2 unit prior to formation of the benzylisoquinoline skeleton.

To test this possibility, noradrenaline (XIII), a C_6—C_2 compound which is derivable

from tyrosine (20) and contains the required structural features, was administered to *H. canadensis* by infusion into the stem in an exploratory experiment (expt. 2). Extraction of roots and rhizomes by standard methods gave crude hydrastine (339 mg) and berberine hydrochloride (564 mg), both of which, surprisingly, appeared to be highly radioactive. Recrystallization of berberine hydrochloride from water left the specific activity of the compound virtually unchanged. Paper chromatography of this sample with ethanol as the solvent appeared to give a single spot (R_f 0.18). When a portion of the berberine sample was subjected to the usual degradation procedure, however, inconsistent results were obtained. Conversion of 500 mg of the berberine, through four stages, into des-*N*-methylstyryltetrahydroberberine, led to a loss of more than half of the specific activity even though not a single carbon atom of the original alkaloid had been removed at this stage. It became clear that a re-examination of the radio-purity of the original berberine was indicated.

The remaining quantity of the berberine sample was repeatedly chromatographed on an alumina column, and a virtually inactive sample of berberine was eventually obtained. All activity was contained in a yellow fraction weighing no more than 300 μg, which closely followed, but was discrete from, the berberine fraction. The crude hydrastine lost most of its activity after repeated crystallization from ethanol.

Even though the experiment had failed in its original purpose, the use of noradrenaline as a tracer had serendipitously led to the detection of hitherto unrecognized alkaloid constituents of *H. canadensis* by a novel type of activation analysis.

At this time we became aware of the elegant work of Nijland (21) on the isolation and structure[2] of a new alkaloid, berberastine (I), from *Hydrastis* extract. We suspected that our berberine contaminant might be identical with berberastine, since the R_f value of our compound in Nijland's solvent system matched that of berberastine.[3] The berberine contaminant was isolated on a larger scale from a commercial *Hydrastis* extract by an improved method. The entire protoberberine components of the extract were precipitated in the form of their acetone adducts and the dried mixture, which also contained co-precipitated hydrastine and small quantities of other tertiary bases, was chromatographed on an alumina column, using chloroform and chloroform–methanol mixtures of increasing polarity as eluents. Chloroform eluted the acetone adduct of berberine as well as the tertiary bases. Some free berberine appeared in the effluent with chloroform containing up to 4% methanol. Chloroform of higher methanol content brought out the yellow material which was recognized as the berberine contaminant. The berberine contaminant was rechromatographed in the same manner and converted into the sparingly soluble iodide, whose infrared spectrum was identical with Nijland's published spectrum of berberastine iodide.

In this manner 120 mg berberastine iodide was isolated from 1 lb of extract.

Amongst the tertiary bases obtained from the commercial *Hydrastis* extract in trace quantity was a compound which was identical in paper-chromatographic behavior with the reduction product (21) of berberastine. This compound is presumably one of the stereoisomers of 5-hydroxycanadine. Three other unknown components of the system

[2]*Of the two possible structures for berberastine deduced by Nijland, 5-hydroxyberberine (I) was favored over the alternative 6-hydroxyberberine (21). In fact her evidence eliminates the latter. Reduction of 5-hydroxyberberine would yield 5-hydroxycanadine. The hydroxy group of 6-hydroxyberberine, a carbinolamine derivative, would not be expected to survive reduction. Reduction of berberastine with zinc/platinum (21), and also with borohydride, gave a product which retained the hydroxy group. The structure of berberastine as 5-hydroxyberberine is thus established by Nijland's work.*

[3]*We are indebted to Dr. M. M. Nijland for sending us a paper chromatogram of berberastine. In her letter she predicted independently that noradrenaline might serve as a precursor of berberastine.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were detected chromatographically in quantities too small for isolation and characterization. These fractions are under investigation.

Having gained some qualitative insight into the nature of the labelled products derived from the feeding experiment with radioactive noradrenaline, it became desirable to ascertain whether noradrenaline served as a specific precursor of berberastine, and to gather quantitative data on its incorporation into the other alkaloids. Since our earlier samples of berberine had presumably contained minute amounts of radio-berberastine as impurity, it was of importance also to obtain information on the relative efficiencies of incorporation into the alkaloids of at least one of the labelled precursors, tyrosine or dopamine, whose specific incorporation into these contaminated samples of berberine had been established by chemical degradation (6, 8).

In separate feeding experiments 1-^{14}C-dopamine (expt. 3) and DL-2-^{14}C-noradrenaline (expt. 4) were administered to *Hydrastis* plants by infusion into the stem over a period of 6 days. The alkaloids were extracted, and berberine, hydrastine, canadine, and berberastine were isolated by column chromatography on alumina, as described in the experimental section. Each alkaloid sample was purified by column chromatography and crystallized to constant activity. Chemical and radiochemical yields obtained in these experiments are summarized in Table III. Every one of the four alkaloids derived from the dopamine experiment was labelled. The noradrenaline experiment gave radioactive berberastine of high specific activity. Berberine, canadine, and hydrastine obtained from this experiment contained little radioactivity.

The incorporation figures in Table III make it abundantly clear why consistent results had been obtained in the degradation experiments with dopamine-derived berberine which was contaminated with berberastine (expt. 1), whereas contamination became immediately apparent on degradation of the contaminated noradrenaline-derived berberine (expt. 2). In the latter instance a contaminant of less than 1% by weight contained 97% of the total activity. In the former case a contaminant of less than 1% by weight contained less than 1% of the total activity.

Even though it is now recognized that the samples of berberine obtained from feeding experiments with tyrosine, dopamine, methionine, and formate, which were used in earlier degradation experiments (6, 8, 10), probably contained berberastine as a contaminant, it is not likely that the earlier results are invalidated. The tracers used in all these experiments almost certainly serve as precursors not only of berberine but also of berberastine, as is now shown to be the case for dopamine. It is probable that the relationship with respect to yield and activity between berberine and the contaminating berberastine in these earlier experiments was similar to the relationship between berberine and berberastine found in expt. 3. In the degradation experiments on these earlier berberine samples the limits of standard deviation in the radioactivity assays were higher than 1%. Within these limits all activity of the degraded samples was accounted for. Clearly, the error due to contamination was also within these limits, and does not therefore affect the results or the conclusions based on them.

Since recrystallization removed the contaminating activity from the hydrastine sample obtained in the exploratory noradrenaline experiment, the earlier results with hydrastine (5, 6, 10, 12) stand.

The noradrenaline-derived berberastine (expt. 4) was diluted with carrier and degraded. Acid-catalyzed dehydration gave 5,6-dehydroberberine (II) (21, 22) which was not isolated but was directly reduced to canadine by means of sodium borohydride (cf. refs. 21, 22). The (±)-canadine (III) so obtained was further diluted with carrier and oxidized to

*Diluted with carrier.

†The (±)-canadine (26 mg), specific activity 57.69 (±0.64) × 10^4 counts min^{-1} $mmole^{-1}$, obtained by sodium borohydride reduction of the radio-berberastine, was diluted with inactive (±)-canadine (960 mg), to yield, after recrystallization, (±)-canadine (964 mg, 98%) specific activity 1.52 (±0.021) × 10^4 counts min^{-1} $mmole^{-1}$. The relative specific activity of further intermediates of the degradation sequence, given in the table, relates to this diluted (±)-canadine.

berberine (IV) (23). This berberine was dissected in 10 steps, by the method previously reported (6), to yield 6-bromopiperonylic acid (VIII) of a specific activity identical with that of the original alkaloid. In the final step of the degradation sequence the acid was converted to the corresponding amide (IX) which, in a Hofmann rearrangement, yielded inactive 2-bromo-4,5-methylenedioxyaniline (X). The specific activities of the intermediates of the degradation sequence are tabulated in Table IV. It is evident that all activity of the original berberastine was located at C-5, indicating that noradrenaline is incorporated without randomization of activity, and that only one noradrenaline unit enters the berberastine molecule.

Because of the low yield, systematic degradation of the dopamine-derived berberastine was not feasible.

A number of conclusions regarding the interrelationship of the alkaloids can be drawn on the basis of the present experiments.

Since the specific activity of berberastine obtained in the dopamine experiment was found to be substantially higher than that of the berberine isolated from the same experiment, and since the noradrenaline experiment yielded highly active berberastine and virtually inactive berberine and canadine, neither berberine nor canadine can be precursors of berberastine.

Also excluded as a stage between noradrenaline and berberastine is norlaudanosoline (XII), whose *N*- and *O,O,N*-methyl derivatives, laudanosoline (17) and reticuline (15), have been shown to serve as specific precursors of berberine. The present evidence suggests that the benzylic hydroxyl group is generated at an early stage of biosynthesis, prior to formation of the benzylisoquinoline system. If noradrenaline is an obligatory stage of the pathway to berberastine, intermediacy of a 4-hydroxynorlaudanosoline must be postulated, which is directly derived from noradrenaline and a second C_6—C_2 unit, presumably 3,4-dihydroxyphenylpyruvic acid.

It remains to demonstrate unequivocally that the bases, whose presence in *H. canadensis* in trace amounts has now been detected for the first time by virtue of the selective incorporation of labelled noradrenaline into their skeleton, are indeed the hydroxyanalogs of hydrastine and canadine, and to show that berberastine is the first representative of a larger group of compounds, which are related to 4-hydroxynorlaudanosoline.

It will be of even greater significance to apply 'noradrenaline activation analysis' to other plants which contain alkaloids related to norlaudanosoline, e.g., the opium poppy, in order to establish whether hitherto undiscovered bases of the 4-hydroxynorlaudanosoline series, e.g., 15-hydroxymorphine, accompany the known alkaloid components. This work is in progress.

EXPERIMENTAL

Isolation of Berberastine from Commercial Plant Extract

The extract (Soft solid extract, Goldenseal root, Pennick Canada Ltd., 9–11% alkaloid content) (100 g) was dissolved in warm aqueous acetone (33%, 600 ml) and the solution was made basic by addition of 10% sodium hydroxide (100 ml). After 12 h a crystalline precipitate was obtained which consisted[4] mainly of 8-acetonylanhydrodihydroberberine (berberineacetone) and contained all the berberastine present in the original extract, either as the acetone adduct or as a co-precipitate, together with hydrastine and small amounts of other weak bases. The precipitate was washed with water and dried in air to yield crude material (20 g) which melted over a wide range (148–156°).

The dried precipitate from several duplicate experiments (80 g) was dissolved in chloroform[5] and applied to a column (3.2 cm diameter × 38 cm length) of alumina[6] (300 g) in chloroform. The column was eluted in

[4]*At every stage of the separation, product analysis was carried out by ascending paper chromatography, using Nijland's solvent, 2% aqueous potassium dihydrogen phosphate solution (21). Unless otherwise stated, R_f values in the present paper refer to this solvent.*

[5]*Commercial chloroform, containing ethanol (0.75%), was used in all experiments.*

[6]*Unless otherwise stated neutral alumina, grade I, was used in all experiments.*

succession with chloroform (1 000 ml), chloroform containing 4% methanol (1 500 ml), chloroform containing 5.5% methanol (1 500 ml), and finally with a mixture of chloroform and methanol (2:3) (500 ml). The rate of elution for the first two solvents was approximately 50 ml per hour. The elution rate with the final two solvents was increased to 150 ml per hour.

The chloroform fraction contained berberineacetone, hydrastine, and minor quantities of other tertiary bases. Free berberine was eluted with chloroform / 4% methanol, and most of the berberastine appeared in the eluent from chloroform / 5.5% methanol. The last traces of berberastine were removed from the column by the chloroform/methanol (2:3) mixture. Small quantities of phenolic bases closely preceded or followed but did not overlap with the berberastine band. The conditions which are responsible for the variation of the elution pattern of the phenolic materials have not yet been investigated.

To achieve further purification, the berberastine fraction was rechromatographed on a second alumina column (1 × 13 cm, 13 g), using the same sequence of solvents.

The berberastine so obtained was dissolved in a minimum quantity of hot methanol, and 5% aqueous ammonium iodide (20 ml) was then added. Berberastine iodide (120 mg) separated and was recrystallized from hot water containing a small amount of charcoal. The iodide does not melt, but darkens from 220°. (Found: C, 50.4; H, 4.0; I, 26.3; N, 2.7. Calcd. for $C_{20}H_{18}INO_5$: C, 50.1; H, 3.8; I, 26.5; N, 2.9%.)

The infrared spectrum of the product was identical with that reported by Nijland (21). On paper chromatography with 2% aqueous potassium dihydrogen phosphate as the solvent the material gave a single, yellow, fluorescent, elongated spot, R_f 0.20.

Isolation of the Alkaloids from Roots and Rhizomes

Hydrastine and Canadine

Dried and finely powdered roots and rhizomes (22 g) of *H. canadensis* were extracted with ether and then with ethanol, as described earlier (6).

The ether extract was evaporated and the residue dissolved in ethanol. Hydrastine, R_f 0.72, crystallized, and after two recrystallizations from ethanol, melted at 131–132°. Yield 600 mg. The combined ethanolic mother liquids were evaporated to dryness, the residue (200 mg) was dissolved in benzene (15 ml) and the solution was applied to a column (1.8 × 20 cm) prepared from 60 g alumina of 12% water content, slurried in benzene. The column was eluted in succession with benzene (100 ml), benzene containing 10% chloroform (60 ml), benzene/chloroform 1:1 (60 ml), chloroform (60 ml), chloroform containing 1% methanol (60 ml), and finally with chloroform containing 2% methanol (60 ml). (−)-Canadine (20–25 mg), R_f 0.26, melting at 132–133°, emerged with the benzene. The benzene/chloroform solutions eluted a mixture of canadine and hydrastine, contaminated by small amounts of other bases, including traces of two substances, R_f 0.30 to 0.45, which may have been isomers of hydroxycanadine, since this R_f value is identical with that of one of the reduction products of berberastine (21). Hydrastine (90–105 mg) emerged with the chloroform. The chloroform–methanol mixtures removed traces of berberine and berberastine from the column.

Berberine and Berberastine

The alcohol extract of the root material was evaporated to dryness, the residue was dissolved in 33% aqueous acetone (30 ml), and the solution was filtered through glass wool and basified with 10% aqueous sodium hydroxide (5 ml). The precipitate (805 mg), melting range 150–158°, which had separated after 12 h, was dried in air, dissolved in chloroform, and chromatographed on a column (1 × 13 cm) containing alumina (13.5 g), slurried in chloroform. Elution with chloroform (30 ml) at a rate of 10 ml per hour removed berberineacetone (650 mg). Chloroform containing 4% methanol (30 ml) then eluted most of the berberine (180 mg). By increasing the polarity of the solvent (chloroform containing 6% methanol, 30 ml) as well as the elution rate berberastine was removed. It was purified by chromatography on a second alumina column, (3 g, 0.7 × 6 cm) using the same solvent sequence, and was converted into berberastine iodide (4–6 mg) (*vide supra*).

The berberine fractions were combined and crystallized from aqueous hydrochloric acid, yielding berberine hydrochloride (960 mg).

This method for the isolation of the four alkaloids was used in the work-up of tracer experiments 3 and 4.

Conversion of Berberastine Iodide into Tetrahydroberberine ((±)-Canadine) (cf. Ref. 21)

Berberastine iodide (6 mg) was refluxed for 12 min in 2 *N* hydrochloric acid (6 ml). The solution was cooled and neutralized with 0.880 ammonia. The mixture was warmed, and methanol (7 ml) was added to redissolve the dehydroberberine which separated. Sodium borohydride (20 mg) was added in one portion to the warm solution. A vigorous reaction ensued and the solution became colorless, indicating that reduction was complete. To decompose the reduction complex the reaction mixture was acidified with 5 *N* hydrochloric acid, and was then made basic with 5 *N* ammonia. The product was extracted into ether (4 × 15 ml) and the combined ether extracts were evaporated. The residue was dissolved in *N* hydrochloric acid (1 ml), the solution was filtered and the product (3.6 mg, 81%) was precipitated by addition of 0.880 ammonia. Two crystallizations from aqueous acetone gave (±)-canadine melting at 170–172°. Reported melting point 167° (24), 174° (25).

Conversion of Berberine Hydrochloride into Tetrahydroberberine ((±)-Canadine) (cf. Refs. 26, 27)

Berberine hydrochloride (200 mg) was dissolved in methanol containing 20% water (5 ml). The solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was warmed to 50° and sodium borohydride (100 mg) was added in one portion, with stirring. After the vigorous reaction had ceased the mixture was refluxed for 5 min, cooled, acidified with 5 *N* hydrochloric acid, and warmed to redissolve the precipitate which had separated. Addition of 5 *N* ammonia gave (±)-canadine (145 mg, 88%), which after two recrystallizations from aqueous acetone melted at 170–172°. The sodium borohydride reduction of berberine has been reported (27) to yield dihydroberberine. In fact both berberine and dihydroberberine yield (±)-canadine on sodium borohydride reduction (26).

Conversion of (±)-Canadine into Berberine Hydrochloride (cf. Ref. 23)

(±)-Canadine (960 mg) was dissolved in glacial acetic acid (9 ml). Mercuric acetate (3.82 g) was dissolved in water (40 ml) to which a few drops of acetic acid had been added. The solutions were combined and the mixture was kept 3 days at room temperature. The precipitate of mercurous acetate was filtered off, the filtrate was refluxed for 30 min, cooled, and a second crop of mercurous acetate was removed. Hydrogen sulfide was passed through the filtrate, the sulfide precipitate was filtered off, and the solution was acidified with concentrated hydrochloric acid (5 ml). On cooling berberine hydrochloride (1.12 g, 97%) was obtained.

Conversion of 6-Bromopiperonylic Acid (VIII) into 6-Bromopiperonylamide (IX)

6-Bromopiperonylic acid (6) (49 mg) and thionyl chloride (0.5 ml) were heated under reflux until the acid had dissolved. Excess thionyl chloride was removed under reduced pressure and the residue was dissolved in anhydrous ether (3 ml). Anhydrous ammonia was bubbled through the ether solution for several minutes and the solvent was then evaporated. Ammonia (5 *N*, 0.5 ml) was added to the solid residue to dissolve ammonium chloride and any unchanged acid. *6-Bromopiperonylamide* (45 mg, 92%) was obtained, which after recrystallization from water melted at 170–171°. Reported melting point 163–164.5° (28). (Found: C, 39.6; H, 2.5; N, 5.6. $C_8H_6BrNO_3$ requires C, 39.4, H, 2.5, N, 5.7%.)

Conversion of 6-Bromopiperonylamide (IX) into 2-Bromo-4,5-methylenedioxyaniline (X)

Bromine (0.12 ml) was added to an ice-cold solution of sodium hydroxide (0.5 g) in water (4 ml) and the mixture was cooled and shaken until the bromine had dissolved. A portion (0.4 ml) of this hypobromite solution was added to 6-bromopiperonylamide (49 mg) and the reaction mixture was swirled in an ice bath until the amide had dissolved (15 min). The solution was heated for 30 min and was evaporated to dryness under reduced pressure. Distillation of the residue at 80° and 3×10^{-2} mm yielded *2-bromo-4,5-methylenedioxyaniline* (25 mg, 58%), melting at 83–84°. Reported melting point 80° (29). (Found: C, 39.2; H, 3.0; N, 6.3. $C_7H_6BrNO_2$ requires: C, 38.9; H, 2.8; N, 6.5%.)

A portion of the base was converted to the *picrate*, melting at 160–161°. (Found: C, 35.3; H, 2.3; N, 12.4. $C_{13}H_9BrN_4O_9$ requires C, 35.1; H, 2.0; N, 12.6%.)

Administration of ^{14}C-Labelled Compounds to Hydrastis Canadensis L. and Extraction of Labelled Alkaloids

1-^{14}C-Dopamine hydrobromide (expts. 1 and 3) and DL-2-^{14}C-noradrenaline (expts. 2 and 4) were administered to mature plants of *H. canadensis* L. either hydroponically (expt. 1) or by infusion into the stem (expts. 2, 3, and 4) by reported methods (6). Alkaloids were extracted from roots and rhizomes. In expt. 1, hydrastine and berberine were isolated by conventional methods (6). Experiment 2 demonstrated the limitations of these methods. Isolation of berberine, hydrastine, canadine, and berberastine from expts. 3 and 4 was carried out by the method described in an earlier section of this paper. Chemical and radiochemical yields from expts. 1, 3, and 4 are shown in Tables I and III.

Degradation of Radioactive Alkaloids

Labelled berberine derived from plants fed with 1-^{14}C-dopamine (expt. 1) and labelled berberastine from plants exposed to 2-^{14}C-noradrenaline (expt. 4) were degraded. The method for the degradation of berberine into 6-bromopiperonylic acid has been fully reported (6). Degradation of berberastine involved conversion of the compound into canadine and then into berberine, by the methods described above. The berberine so obtained was degraded to 6-bromopiperonylic acid as before. The final steps, conversion to the corresponding amide and Hofmann rearrangement to the aniline derivative, were carried out by the method used in the pilot experiments with inactive material. A minimum of 800 mg berberine hydrochloride was required to carry a degradation sequence to completion. To obtain sufficient material the active alkaloid samples were diluted with carrier. The specific activity of the intermediates in the two degradation sequences are tabulated in Tables II and IV. Limits shown are standard deviation of the mean.

The degradation products were crystallized to constant activity. Their radioactivity was assayed on samples of finite thickness on aluminium planchettes, using a Nuclear Chicago Corp. gas flow counter (Model 1052) in a low-background sample changer (C115). Counts were recorded on a printing timer (C111B) in association with a scaler (181B).

The usual corrections for background and self-absorption were applied. For plating a 1% solution of collodion in dimethylformamide was used as the solvent.

ACKNOWLEDGMENTS

We are grateful to Mr. R. E. Halward, Propagator of the Royal Botanical Gardens, Hamilton, for maintaining a colony of *H. canadensis* L. for our work.

SYNTHESIS IN AQUEOUS SOLUTIONS OF BINARY COMPOUNDS OF THE TRANSITION METALS WITH GROUP VA AND VIA ELEMENTS

G. E. Cranton and R. D. Heyding
Department of Chemistry, Queen's University, Kingston, Ontario
Received February 19, 1965

ABSTRACT

Some of the compounds in the systems Cu/Se, Cu/As, Cu/Sb, Ni/Se, Ni/As, Ni/Sb, and Ni/Bi have been synthesized by precipitation from aqueous solutions, following procedures similar to those described by Kulifay. The precipitates were finely divided and of relatively low purity. No new compounds were observed. None of the compounds in the Fe/As and Co/As systems were obtained, nor were any intermediate phases formed in the systems Fe/Bi, Co/Bi, and Cu/Bi.

INTRODUCTION

Transition metal pnictides and chalicides[1] are usually prepared by direct combination of the elements at temperatures above 500 °C. This method presupposes that the rate of transition in the solid to low temperature polymorphs or compounds will be appreciable in the temperature range in which these phases are stable. In the event that a transformation is slow, the stable low temperature phase may not be observed. Such polymorphs and compounds might be obtained by syntheses requiring lower temperatures.

Aqueous methods involving temperatures below 100 °C have been known for some time. These fall into four classifications: (i) reaction of a gaseous hydride (H_3Z or H_2Y) with a metal ion in solution (1–3); (ii) heterogeneous reaction of an element with ions in solution (4–14); (iii) chemical reduction of ions or complex ions of both components in solution (15–19); and (iv) electrochemical methods (20). Of the third group, the methods described by Kulifay appear to be the most promising, inasmuch as a large number of binary pnictides, chalicides, and intermetallic compounds have been prepared in this way (18, 19). Accordingly, syntheses of compounds in several binary systems were attempted using methods similar to those of Kulifay, with particular reference to new or known low temperature phases.

EXPERIMENTAL

General Procedure

Solutions of the appropriate elements as ions or complex ions were added to a solution containing a reducing agent (eg. hydrazine, hypophosphorous acid), and boiled for specified periods. Ratios of metal to metalloid ions did not necessarily correspond to those of known compounds. Quantities were used to yield approximately 0.02 mole of product. The initial and final pH of the solutions were determined, but in general no attempt was made to control the pH during the reaction. Modifications to this general procedure are given in the detailed procedures below.

The products were recovered in tared sintered glass crucibles, washed, rinsed in methanol, and dried at 70–80 °C. Chemical analyses were made by standard analytical procedures (21). Powder diffraction patterns were obtained in 11.46 cm Debye–Scherrer cameras using Ni-filtered Cu radiation ($\lambda_{K\alpha_1}$ = 1.5405 Å).

To assist in the identification of phases, 'standard' diffraction patterns were available, or were obtained for compounds prepared by mixing high purity elements in the appropriate ratios, heating, and annealing in sealed evacuated Vycor tubes in the usual manner.

The experimental conditions and product identifications are summarized in Table I.

[1]*The terms pnictide and chalicide have been proposed by Professor A. E. van Arkel for compounds of the group VA and VIA elements. Professor van Arkel has also proposed that just as 'X' is often used to denote halide atoms and ions, 'Y' and 'Z', respectively, might be used for chalicide and pnictide atoms and ions.*

TABLE I

Products formed by metal and metalloid ions in reducing media

Reducing agent	Initial metal/metalloid ratio	Total product metal/metalloid ratio	Products identified by X-ray diffraction
Copper/selenium system			
Basic hydrazine (pH 11–8)	1.00	1.01	CuSe
	1.19–1.80	0.90–1.49	CuSe + Se or Cu_2O
	1.90–2.35	1.90–2.44	$Cu_{2-x}Se$ + Cu_3Se_2 or Cu_2O
Neutral hydrazine (pH 8–5)	1.00–1.50	1.02–1.50	CuSe + Se or $Cu_{2-x}Se$
	1.80	1.86–1.89	$Cu_{2-x}Se$
	2.00	2.05	$Cu_{2-x}Se$
Ammonium sulfite (sealed tube)	1.00	1.02–1.09	CuSe + $Cu_{2-x}Se$
	1.80	1.73	$Cu_{2-x}Se$ + Cu_3Se_2
		1.83	$Cu_{2-x}Se$
Basic hydrazine on $CuSeO_3.2H_2O$	1.00	0.94–1.07	CuSe or CuSe + Se
Sulfite on $CuSeO_3.2H_2O$	1.00	1.30	CuSe + $Cu_{2-x}Se$
Nickel/selenium system			
Basic hydrazine (pH 8 or 9)	1.00	0.90–0.96	NiSe
	0.75	0.76	$NiSe_{1.30}$
	0.50	0.48–0.49	$NiSe_2$ + Se
Copper/arsenic system			
Hypophosphorous acid plus hydrazine	0.50–2.50	—	βCu_3As + Cu_2O or As_2O_3
	3.00	2.85–3.02	βCu_3As + Cu_2O
	6.00	—	βCu_3As + Cu
Hypophosphorous acid	0.50–2.50	—	βCu_3As + As_2O_3
	3.00	2.84	βCu_3As + traces Cu_2O
	6.00–9.00	—	βCu_3As + Cu, traces Cu_2O
Copper/Antimony System			
Hypophosphorous acid	1.00	—	Cu_2Sb + Sb
	2.00	2.00	Cu_2Sb
	2.75	—	Cu_2Sb
Nickel/antimony system			
Alkaline hydrazine	1.00	1.15	NiSb
	0.50–3.00	—	NiSb
Nickel/bismuth system			
Alkaline hydrazine	0.33	0.32–0.36	$NiBi_3$ + Bi
	1.00	—	$NiBi_3$ + Ni
Nickel/arsenic system			
Hypophosphorous acid plus hydrazine	1.00	0.92	NiAs
Alkaline hydrazine	0.50 (1.5 h)	—	$Ni_{2.61}As$ + $Ni_{11}As_8$

	3.00 (1.5 h)	—	$Ni_{2.61}As$

The Copper–Selenium System

(a) Reduction with Hydrazine

Solutions of copper(II) oxide in 10 ml of 6 *N* HCl and selenium in a minimum amount of 8 *N* HNO_3 were mixed and added slowly to a boiling aqueous solution consisting of 6 g of hydrazine dihydrochloride, 150 ml of distilled water, and sufficient concentrated ammonium hydroxide to give an initial pH of either 11 (basic conditions) or 8.5 (neutral conditions). The solutions were boiled for 1.5 h. The final pH of the basic solutions was 8, and of the 'neutral' solutions, 5.

In the initial stages of the reaction, the selenite ion was reduced to red selenium which transformed rapidly to the stable hexagonal (black) modification. During the reaction the red form again appeared, and was slowly replaced by a fine precipitate of the copper selenides. Relatively pure CuSe and $Cu_{2-x}Se$ were obtained for initial stoichiometric Cu/Se ratios from basic and neutral solutions, respectively. At other concentration ratios mixtures of products were obtained, with Se and Cu_2O appearing as impurities. (See Table I.) Cu_3Se_2

For personal use only.

was observed, but only in small amounts in precipitates of $Cu_{2-x}Se$. Analysis of $Cu_{2-x}Se$ samples indicated the composition $Cu_{1.85}Se$.

(b) Reduction by Sulfite in Sealed Tubes

Copper(II) chloride dihydrate and selenious acid (ca. 0.005 mole of each) were dissolved in water and mixed with a solution containing 3 g of ammonium sulfite to give a total volume of 20 to 40 ml in a heavy walled glass tube. The tube was sealed, leaving a void volume of 10 ml, and heated at 85–95 °C for 2 to 6 h. The final pH was 5. When the solutions were mixed, dark precipitates were formed which are believed to have contained red selenium. $Cu_{2-x}Se$ was the only relatively pure product obtained by this method.

(c) Reduction of Copper Selenite

Copper selenite was prepared by mixing solutions of copper(II) chloride dihydrate and sodium selenite. The solid selenite was then added to the reducing solution of either ammoniacal hydrazine or of ammonium sulfite. The solid dissolved in the former solution, and the subsequent reactions were identical to the reductions with hydrazine described above. The selenite did not dissolve in the sulfite solution, but was gradually replaced by a mixture of CuSe and $Cu_{2-x}Se$.

The Nickel–Selenium System

Solutions of nickel acetate tetrahydrate in 10 ml of water and selenium dissolved in ca. 12 ml of 8 *N* HNO_3 were mixed and added to a boiling solution of 7 g of hydrazine dihydrochloride, 45 ml of ammonium hydroxide, 2 g of tartaric acid, and 130 ml of water. Aliquots of ammonium hydroxide were added at intervals to maintain the pH between 8 and 9. The total boiling time was 2.5 h. The reactions followed the same general path observed during the reduction of copper and selenium ions with hydrazine. The compounds NiSe, $NiSe_{1.30}$, and $NiSe_2$ were observed, although Se was always present with the diselenide. There was some indication in the powder diffraction patterns that a number of compositions were formed in the $NiSe_{1+x}$ phase, with $0 \leqslant x \leqslant 0.30$. Analyses indicated that impurities in most of the precipitates were of the order of 5%.

The Copper–Arsenic System

(a) Reduction with Hypophosphorous Acid and Hydrazine

Copper(II) oxide was dissolved in 10 ml of 6 *N* HCl and added to a boiling solution of 18 ml of 50% H_3PO_2, 50 ml of water, and 30 ml of concentrated HCl. A solution containing arsenite ion, prepared by dissolving arsenious oxide in 25 ml dilute NH_4OH and acidifying with HCl, was immediately added to this mixture, and the solution returned to the boiling point. A solution containing 10 g of hydrazine dihydrochloride in 50 ml of water and 100 ml of ammonium hydroxide was added slowly, raising the pH to 11. After the solution was boiled for 1.5 h, the pH had decreased to 5. A brown precipitate (probably amorphous arsenic) formed immediately on addition of the reactants to the hypophosphorous solution. Addition of the ammoniacal hydrazine solution finally produced dark precipitates containing βCu_3As and Cu_2O, Cu, or As_2O_3.

(b) Reduction with Hypophosphorous Acid

The copper(II) and arsenite solutions, as prepared above, were added to 25 ml of 50% H_3PO_2 in 100 ml of water, and the mixture boiled for 1.5 h. The pH of the solution remained at 4 throughout the reaction. On addition to the hypophosphorous solution, the blue color due to the aquo-cupric ion disappeared, indicating reduction to copper(I). Again βCu_3As was recovered, contaminated with Cu_2O or Cu.

The Nickel–Arsenic System

(a) Reduction with Hypophosphorous Acid and Hydrazine

The procedure used in the copper–arsenic system was repeated, substituting solutions of nickel chloride for those of cupric chloride. The NiAs phase was the only arsenide formed, and that with purity less than 90%.

(b) Reduction by Hydrazine

Nickel acetate tetrahydrate was dissolved in 15 ml of water containing 2 g of tartaric acid, and arsenious oxide in 25 ml of dilute ammonium hydroxide. The nickel(II) solution was added to a boiling solution of 8 ml of hydrazine hydrate, 10 g of potassium hydroxide, 2 g of tartaric acid, and 100 ml of water. Upon reduction of nickel to the metal, the arsenite solution was added rapidly. The solution was strongly alkaline throughout the reaction. The effects of nickel/arsenic concentration ratios and boiling times were determined (Table I).

On addition of nickel ion to the alkaline hydrazine solution a blue nickel–hydrazine complex was formed, which was gradually reduced to spongy nickel metal. The reaction of this precipitate with the arsenite ions was vigorous, and yielded $Ni_{2.61}As$, $Ni_{2.50}As$, $Ni_{2.39}As$, and $Ni_{11}As_8$, depending on initial concentration and reaction times. The precipitates became progressively richer in arsenic with increasing reaction time, but neither NiAs nor higher arsenides were observed.

The Copper–Antimony System

Potassium antimonyl tartrate hemihydrate was dissolved in 40 ml of water, and copper(II) oxide in 10 ml of 6 *N* HCl. The cupric and then the arsenite solutions were added to a boiling reducing solution of 125 ml of 17% H_3PO_2, and the mixture boiled for 1.5 h. As in the copper–arsenic experiments, the Cu(II) was apparently reduced immediately to Cu(I). After a short induction period, a white precipitate formed which

darkened with boiling to produce precipitates containing Cu_2Sb, in some instances contaminated with antimony.

The Nickel–Antimony System

Solutions of nickel acetate tetrahydrate in 15 ml of water and potassium antimonyl tartrate hemihydrate in 40 ml of water were added to the hydrazine / potassium hydroxide reducing solution described in the nickel–arsenic syntheses. Boiling time was 1.5 h. The reactions were similar to those observed in the nickel–arsenic system. NiSb was the only antimonide recovered.

The Nickel–Bismuth System

Solutions of bismuth(III) oxide in 30 ml of 8 *N* HCl and of nickel acetate tetrahydrate in 15 ml of water, both containing 2 g of tartaric acid, were added to a reducing solution of hydrazine in potassium hydroxide, as used in the nickel–arsenic syntheses. Again the reactions were similar to those observed in the nickel–arsenic systems. $NiBi_3$ was the only bismuthide recovered.

The Cobalt- and Iron–Arsenic Systems, and the Cobalt–, Iron–, and Copper–Bismuth Systems

Attempts were made to prepare cobalt and iron arsenides, and cobalt, iron, and copper bismuthides using the various techniques and reagents described above. None of these attempts was successful. For systems containing iron, various hydrolysis products were obtained. In the cobalt–arsenic and cobalt–bismuth preparations, elemental arsenic (largely amorphous) and bismuth were precipitated, together with essentially all of the cobalt in such a finely divided form that no diffraction pattern registered through a nickel screen. In the copper–bismuth system the elements were precipitated, but the reduction was incomplete.

DISCUSSION

The compounds obtained are given in Table II with all of the compounds believed to exist in these binary systems at low temperatures. Several iron and cobalt diarsenides are known to exist, but none were obtained. No bismuthides of iron, cobalt, or copper have been reported, and none were formed in our experiments. The phases which were formed were found to depend on the reducing agent, pH, and reaction time, as well as initial concentrations of the reactants.

Although comments on the mechanisms involved in these reactions are largely speculative, it was obvious in nearly all instances that reduction of the metal and metalloid did not occur simultaneously. In those reactions involving nickel and hydrazine in potassium hydroxide, the metal was precipitated, and reaction apparently occurred between the metal and complex metalloid ions in solution. In the reduction of nickel and arsenite ions, for example, nickel-rich phases were first produced which became progressively richer in arsenic with increasing reaction time. These observations are reminiscent of the reaction of nickel powder with solutions of arsenic trichloride in hydrochloric acid, for which the arsenic content of the product depended on the reaction time (22). In the majority of systems involving copper, on the other hand, the metalloid was precipitated first, although the subsequent reactions may have occurred homogeneously between redissolved metalloid ions and copper ions or complex ions. In separate experiments it was observed that relatively pure $Cu_{2-x}Se$ was formed when solid CuSe and aqueous copper(II) ions were added to ammoniacal hydrazine at 100 °C; similarly some CuSe was formed when $Cu_{2-x}Se$ was treated with selenite ion under the same reducing conditions.

Known compounds which were not observed are not necessarily unstable at 100 °C. The conditions required for their appearance in appreciable quantities may not have been employed. However, compounds which did appear must be stable at 100 °C. Hence Cu_3Se_2, believed to be unstable at some temperature below 170 °C (23), is still stable at 100 °C. Similarly, these syntheses confirm the contention that the trigonal β modification of Cu_3As is stable at relatively low temperatures (24).

The products, as one might expect, were all finely divided. In many instances the diffraction patterns were so diffuse that accurate determinations of lattice dimensions were impossible. For those compounds whose patterns could be indexed at high Bragg angles, the calculated lattice dimensions agree well with those reported in the literature (Table III).

Two anomalies observed in the diffraction studies should be mentioned. The diffraction pattern of precipitated $NiBi_3$ was indexed assuming the orthorhombic unit cell given by Zhdanov (25). However, $NiBi_3$ prepared from the elements in the conventional manner at 720 °C, annealed at 230 °C, and air quenched, had the somewhat smaller unit cell recorded in Table III. Since the pattern of this specimen also contained reflections due to bismuth, the implication is that $NiBi_3$ may have a small range of variable composition on the nickel-rich side. Secondly, the diffraction patterns of a precipitated $Cu_{2-x}Se$ phase and of $Cu_{1.80}Se$ prepared in the conventional way, annealed at 230 °C, and air quenched, showed two very weak reflections at relatively low orders, which may be indicative of ordering in this compound.

In no instances, even when only one component was evident in the diffraction pattern, could the precipitated phases be regarded as pure in the semiconductor sense. Quite aside from the adsorbed impurities to be expected in any finely divided precipitate, analyses and microscopic examinations indicated the presence of phases not revealed by X-ray diffraction. Moreover, reproducibility of the syntheses was less than satisfactory. It is our opinion that the synthesis of semiconductor grade compounds by these methods, as suggested by Benzing *et al.* (17), would be most difficult, if not impossible.

TERPENOIDS

X. PRE-SENEGENIN, A QUITE NORMAL TRITERPENOID

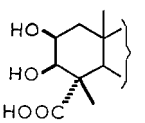
J. J. DUGAN AND P. DE MAYO
Department of Chemistry, University of Western Ontario, London, Ontario
Received February 22, 1965

ABSTRACT

Pre-senegenin has been obtained by a combination of oxidative and hydrolytic cleavage of the saponin, and has been shown to be a member of the normal and unrearranged oleanolic acid series: 2β,27-dihydroxy-23-carboxyoleanolic acid (XXII). On treatment with ethanolic hydrochloric acid it is converted quantitatively to a mixture of polygalic acid (XXI) and senegenin.

Previous work (1) has shown that senegenin is a triterpenoid of empirical formula $C_{30}H_{45}O_6Cl$ with a 2β,3β-glycol system and a 4α-carboxyl group. A second carboxyl group is also present. It has now been found to be a member of the β-amyrin-oleanolic acid series in which a carbon atom at C_{14} has migrated to C_{12} with concomitant movement of the double bond to the C_{13}—C_{14} position, and that it has the structure (XX).*

In our earlier study of the triterpenoid senegenin, we showed that, surprisingly, it contained chlorine and that it had the empirical formula $C_{30}H_{45}O_6Cl$. Four of the oxygen atoms were found to be present as shown in the part-structure (I), and the remaining two, in agreement with the conclusions of previous workers (3, 4), formed part of a carboxyl function.



(I)

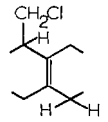
By heating senegenin with quinoline a substance, de(hydrochloro)senegenin, was obtained which showed the ultraviolet absorption spectrum of a conjugated diene. This compound could also be obtained, under defined conditions, as the product of the alkali treatment of senegenin, the "extra", and third, equivalent of alkali required in the titration of senegenin being consumed by the liberated hydrochloric acid.

The ultraviolet absorption spectrum of de(hydrochloro)senegenin (λ_{max} 243, 249, 256 mμ) was clearly indicative of a heteroannular diene and the nuclear magnetic resonance (n.m.r.) spectrum, which showed a multiplet (one proton) at τ 4.65 and a broad singlet (ca. three protons) at τ 8.19 suggested that a methyl group and a proton were substituents on this diene. However, none of the methyl groups of senegenin, of which there were clearly five, provided the methyl group of the diene, and indeed the mere presence of but five methyl groups in senegenin derivatives suggested that the biogenetically to be expected sixth bore the chlorine atom. This could give rise, eventually, to the vinylic methyl group.

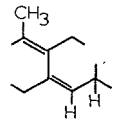
The n.m.r. spectrum of senegenin esters was obscured by the signals from the methoxyl groups in the region where —CH_2Cl signals were to be expected. The spectrum of senegenin itself, determined in pyridine, showed a multiplet in the expected region of about two

**Part of this material formed a preliminary communication (2).*

protons. The fact that a complex pattern was observed further suggested that there was at least one proton attached to the terminus of the chloromethyl group. Since senegenin derivatives showed no vinyl proton signal in their n.m.r. spectra, these observations suggested, though subject to other interpretations in detail, that the changes observed in the conversion of senegenin to de(hydrochloro)senegenin could be represented as (II) → (III). An obvious point requiring clarification was the nature of the prototropic shift apparently occurring under basic conditions. This will be returned to later.



(II)



(III)

These experiments at least indicated the proximity of the chlorine to the one double bond present in senegenin. It was also necessary to relate these functions, spatially, to the remaining carboxyl group.

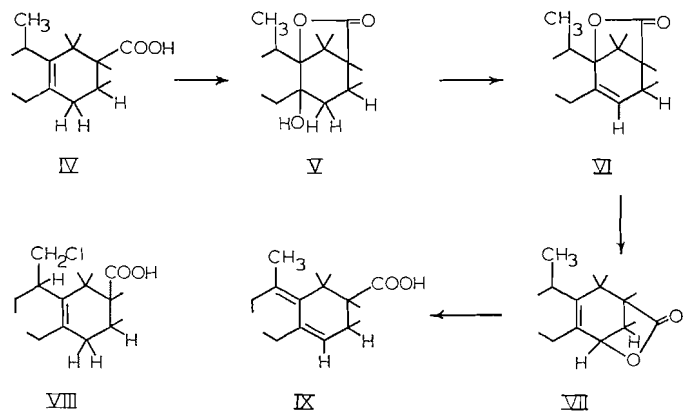
For these experiments dechlorosenegenin (1), obtained from senegenin monoacetate by reduction with lithium and liquid ammonia, was used.

Oxidation of dechlorosenegenin diacetate with hydrogen peroxide in acetic acid gave, after esterification with diazomethane, an oily lactonic ester. This showed absorption in the infrared compatible with the presence of a hydroxyl group (3 500 cm^{-1}) and of a γ-lactone (1 767 cm^{-1}). The tertiary alcohol in this compound (no methine proton on carbon bearing an oxygen) could be dehydrated with thionyl chloride in pyridine to give an anhydro lactone (VI) which appeared to contain a vinylic proton.

Merely on heating in methanol, this unsaturated lactone was isomerized into a new lactone (VII), likewise a γ-lactone (ν_{max} 1 773 cm^{-1}). This isomeric lactone, however, had no vinylic proton, but had, instead, a doublet (one proton) at τ 5.19 suggestive of the presence of a proton on carbon bearing an oxygen.

The mildness of the isomerism conditions (the isomerism was also achieved by hydrolysis of the anhydro lactone with base followed by reacetylation) seemed only compatible with an allylic rearrangement. This required that both ends of the allylic system be γ to the carboxyl group. The sequence of reactions could then be represented as in (IV) → (VII).

The ready isomerism of VI to VII, presumably through an allylic cation, suggested that if this cation could be induced to lose a proton the familiar chromophore of III would



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

be obtained. When the unacetylated ester of (VII) was allowed to stand in 5% methanolic hydrochloric acid at room temperature the diene was indeed rapidly formed and the monocarboxylic acid (IX) could be obtained in quantitative yield. This, when converted to the ester with diazomethane, gave the dimethyl ester of de(hydrochloro)senegenin.

The spatial relationship of the three functional groups in senegenin under discussion appeared to be as represented in (VIII). It was in addition, because of the difficulty of hydrolysis of the corresponding ester, probable that the carboxyl was attached to quaternary carbon. However, the mode of fusion of the remaining ring systems onto the ring in (VIII) remained to be ascertained.

One method by which information could be obtained appeared to be, in principle, by partial aromatization. Should the carboxyl be the only blocking group, then its removal should engender ready aromatization. The route selected was that used by Barton in the study of tomentosolic acid (6) and for this purpose it was desirable to have an unsaturated derivative of senegenin in which the ring A carboxyl was esterified and the other was not. Partial hydrolysis of a diester could not serve since the ring A carboxyl was the more readily hydrolyzed, but such a compound was available, by a devious route, in IX, which after acetylation gave de(hydrochloro)senegenin diacetate monomethyl ester. Conversion of this to the acid chloride, followed by pyrolysis, with loss of carbon monoxide and hydrogen chloride, gave the desired aromatic product represented now in terms of the completed structure as (X). Some difficulty was experienced in the purification of X until it was found that brief treatment with ozone after partial separation removed some olefinic contaminant.

The nature of X rests on the following evidence, other than its mode of genesis. It has the ultraviolet absorption of an alkylated benzene (λ_{max} 269 mμ). Two, and only two, aromatic protons are present in the n.m.r. spectrum as a near singlet at τ 3.05 (indicating their nearly identical environment). All four remaining positions of the benzenoid ring must be occupied by carbon (there is no aromatic methyl group) and represent the points of fusion of the adjacent rings. Part-structure (VIII) can therefore be expanded to (XI) or (XII*a*, *b*). Of these (XII*a*) may be excluded since (IX), aside from the mechanistic requirements of its genesis, does not have the properties of a β,γ-unsaturated acid.

Although there were suggestions that (XI), and therefore (X), was correct (the vinylic proton in (IX) was not a clean doublet, for instance) this sequence of reactions did not provide unequivocal evidence which allowed a decision between (XI) and (XII*b*) to be made.

Whilst the conversion of (II) to (III) under the influence of quinoline at high temperatures could be envisaged (the quinoline hydrochloride could supply a proton for a prototropic shift) the same change under the action of dilute sodium hydroxide would be impressive. The action of base was re-investigated and, indeed, in alkaline solution a new heteroannular diene could be observed. This was partly, or wholly, destroyed by casual acidification but by careful adjustment of pH to near 6 with phosphate buffer and extraction followed by esterification, an isode(hydrochloro)senegenin dimethyl ester could be obtained. Rearrangement into the de(hydrochloro) series was easily effected at room temperature with hydrochloric acid in dioxane.

Isode(hydrochloro)senegenin (XIII) showed the presence of the expected exocyclic methylene group by exhibiting bands at τ 5.13, 5.40. Ozonolysis gave, in agreement, an α,β-unsaturated ketone (λ_{max} 253 mμ) (XIV). Reduction of this gave an allylic alcohol which was readily dehydrated to a heteroannular diene absorbing at shorter wavelength than in the de(hydrochloro) series. Acetylation of the unsaturated ketone gave the expected keto-diacetate which was characterized as the allylic alcohol.

This conjugated ketone was a suitable substance for the introduction of further unsaturation in a classical procedure for structural elucidation. Bromination of the keto-diacetate resulted in the uptake of two atoms of bromine. Direct dehydrobromination of the crude dibromo compound with lithium chloride in dimethyl formamide then gave a trienone (XV).

The ultraviolet absorption spectrum of XV was characteristic of a cross-conjugated carbonyl system which, to a first approximation, shows the absorption of the separate chromophores. In the present case, excellent analogy was available in the lanosterol derivative (XVI) (5) which showed λ_{max} 258, 326 mμ (ϵ 8 500 and 8 500) as against λ_{max} 260, 320 mμ (ϵ 8 200, 7 200) for (XV) (see also (14)). The n.m.r. spectrum of (XV) showed all the signals to be expected of such a molecule. In particular, five singlets for the methyl groups were observable (Fig. 1) as were appropriate signals for three vinyl protons, two of which were strongly coupled. One of the latter shows weak long-range coupling probably with the methine proton at C_{18}.

The existence of the chromophore also requires that a blocking group, represented in (XV) by the C_8 methyl group, be present to prevent the formation, by tautomerism, of a phenol.

The summation of the part-formula (1) and the requirements for senegenin itself implied by (XV) leads, most plausibly, to the structure (XVII) for senegenin, where the weaker lines are those for which no direct evidence has been adduced. It should be noted that, in fact, only six carbon atoms have not been specifically located, and that of these three are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

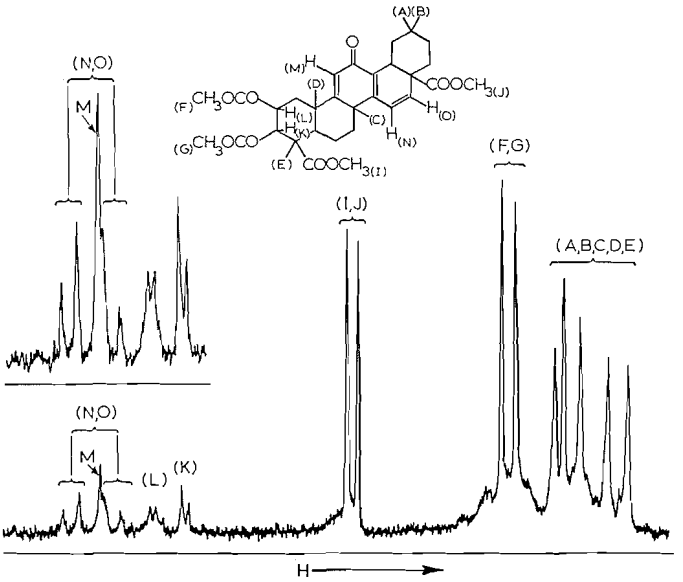

FIG. 1. Nuclear magnetic resonance spectrum of trienone (XV), with expanded inset of the vinyl region.

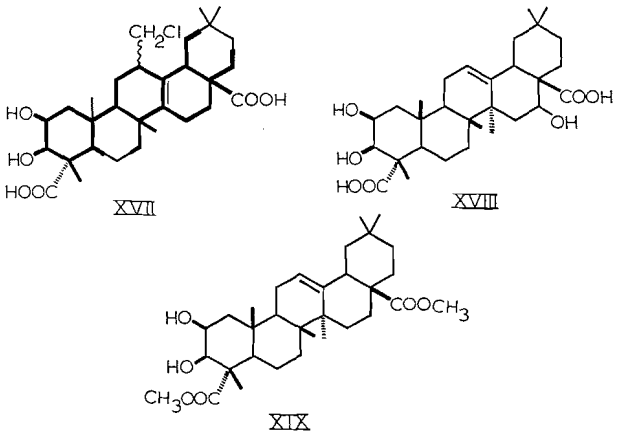
methyl groups attached to quaternary carbon. The formulation (XVII), that of a simply modified oleanane derivative, acquired added verisimilitude with knowledge that polygalacic acid, (XVIII) another oleanane derivative, has recently been isolated and characterized from a related species of polygala, *Polygala paenea* L., by Polonsky and her collaborators (7).



In the hope of obtaining direct evidence for the original ring system in senegenin, and in particular the location of the double bond in it, the mass spectrum of dechlorosenegenin dimethyl ester was obtained. For comparison that of dimethyl medicagenate (XIX) was also recorded.

Dimethyl medicagenate showed peaks at *m/e* values to be expected for an oleanolic acid derivative. These peaks, following the interpretation of Budzikiewicz, Wilson, and Djerassi (8), and irrespective of the accuracy of the interpretation of the sources of certain

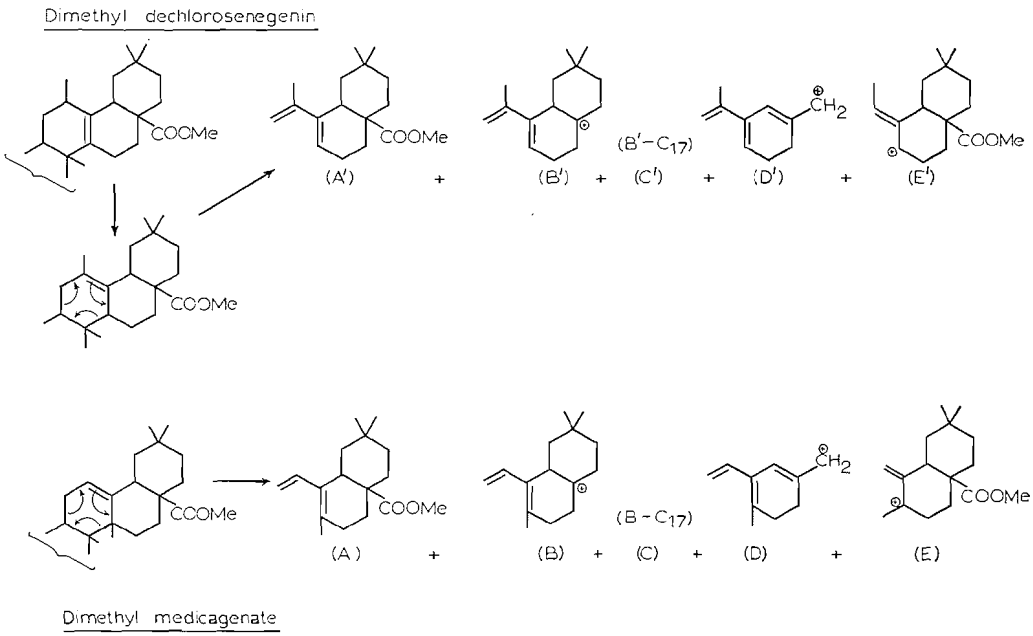

SCHEME 1. Breakdown scheme for dimethyl dechlorosenegenin and dimethyl medicagenate.

of these peaks, are to be attributed to the fragments illustrated in Scheme 1 (A–E). In this sense the pattern fully confirms the suggested importance of the retro-Diels–Alder reaction in this series, with the retention of the charge in the D/E system.

The spectrum of dechlorosenegenin dimethyl ester up to $m/e \sim 300$ is shown in Fig. 2. Comparison with the spectrum of dimethyl medicagenate shows a striking similarity in the ratios and, with one exception, an identity of position of the more important peaks. The only important difference is the presence, in dechlorosenegenin dimethyl ester, of an additional peak at 241.

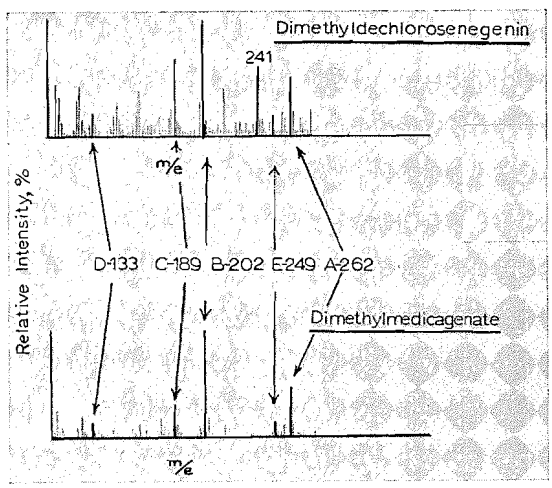

FIG. 2. Mass spectra of dimethyl dechlorosenegenin and dimethyl medicagenate.

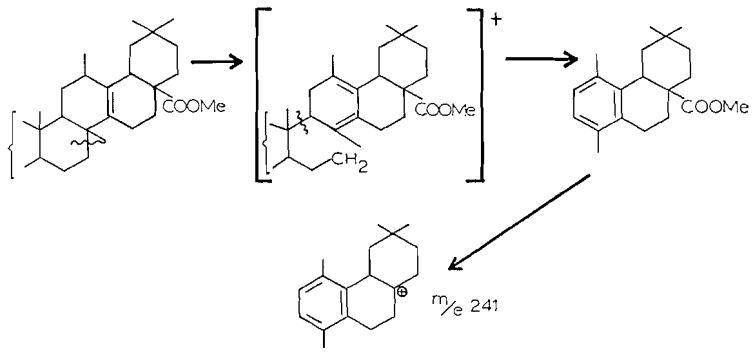
This impressive identity would suggest (8) that senegenin belonged to the Δ^{12}-unsaturated oleanene or ursene series, a conclusion which would be, in view of the facts already presented, totally unacceptable. This seeming contradiction, however, serves to complete the structure of senegenin.

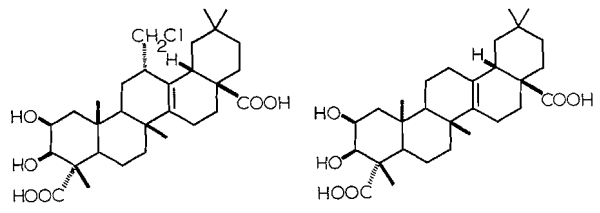
If it be assumed that after impact the ion produced may transfer the hydrogen atom at C_{12}, either in one or two stages, to C_{14} then (without charge indication) a series of fragments (A′–E′) may be written differing from, but isomeric with, the series (A–E) from dimethyl medicagenate, which will produce a series of peaks of identical *m/e* with those of that series.* If it be assumed, as appears reasonable, that the retro-Diels–Alder is energetically the most desirable mode of fragmentation other modes may be sufficiently slow to permit hydrogen transfer and breakdown by this route.



SCHEME 2. Possible origin of the peak at *m/e* 241 in the mass spectrum of dimethyl dechlorosenegenin.

The remaining feature requiring explanation is the peak at *m/e* 241 in the spectrum of dechlorosenegenin dimethyl ester. Since this has no equivalent in dimethyl medicagenate it could arise from fragmentation in the unrearranged molecule. Such a scheme is represented in Scheme 2. If this interpretation be correct the peak at *m/e* 241 should be independent of substitution in ring A. The spectrum of dechlorosenegenin diacetate was accordingly obtained and the same series of peaks, including that at *m/e* 241 was observed.†

These observations suffice, therefore, to permit the attribution of the structure (XX) to senegenin. No evidence has been provided for the stereochemistry of the methyl group at C_8, but it seems probable that it is β as in all known members of the oleanene series.



XX XXI

The stereochemistry of the chloromethyl group will have been determined by the mechanism of transfer of what was evidently the C_{14} methyl in a precursor to C_{12}. On the assumption, for the moment, that the migration is intramolecular, then the chloromethyl

Thermal rearrangement prior to ionization is also conceivable.
†*Mass spectra by Dr. R. Ryhage, Karolinska Institutet, Stockholm, Sweden.*

group surely lies on the same face of the molecule as did the original methyl group (or equivalent); that is, α. The configuration at C_{18} follows from the relationship to polygalic acid (see below).

At this point it was possible to direct attention to the structure of pre-senegenin the presumed precursor of senegenin. The structure of polygalic acid (XXI), the substance (as the monoethyl ester) accompanying senegenin when prepared by the normal isolation procedure, has been determined by conversion into the unsaturated ketone (XIV) (9). From other evidence Professor Pelletier and his colleagues have arrived at the same conclusion (10).* It seemed most probable that the carbon atom transferred in the formation of senegenin from pre-senegenin was lost in the concomitant formation of polygalic acid by a reverse Prins reaction or some equivalent on a different oxygen level.

The saponin from *polygala senega*, as already demonstrated, contains no halide (1), but attempts to hydrolyze the saponin under milder acid conditions in an attempt to isolate pre-senegenin were, in our hands, unavailing. It seemed possible, as an alternative approach, that preliminary cleavage with periodic acid might produce carbonyl functions in a suitable position for activated release of the ethereal linkage retaining the sapogenin. The cleavage might then be induced by the action of base through some process such as β-elimination. Even if not suitably placed, then, by ketol equilibration, the carbonyl function might reach such a position.

Whilst the details of the reaction are unknown the overall result was that desired. The saponin, after cleavage with sodium metaperiodate (the excess oxidant being destroyed reductively) was heated with 5% potash under nitrogen. From this medium, after adjustment to pH $\sim$ 3, the sapogenin could be extracted and was obtained crystalline as the dimethyl ester. It had the empirical formula $C_{32}H_{50}O_7$ and on acetylation gave a triacetate. By another chromatographic procedure, pre-senegenin was itself obtained crystalline. The material was accompanied by *p*-coumaric acid identified by comparison with an authentic specimen.†

When pre-senegenin was heated with ethanolic hydrochloric acid it was converted in high yield into a mixture of senegenin and polygalic acid which was separated, after methylation, and the individual components identified spectroscopically and, in the case of dimethyl polygalate, also by mixed melting point. The new sapogenin was, therefore, the sought-for precursor.

Pre-senegenin differed in composition from polygalic acid by the elements of formaldehyde. If the concept of a reverse Prins were correct, formaldehyde itself should be eliminated during the conversion of pre-senegenin into polygalic acid. By conducting the acid treatment in the presence of 2,4-dinitrophenylhydrazine the 2,4-dinitrophenylhydrazone of formaldehyde could, in fact, be isolated. The yield of polygalic acid remained unaffected by the presence of the reagent as it was when the acid treatment was conducted in the presence of a large excess of formaldehyde. The structure of pre-senegenin could then be represented by (XXII) or (XXIII), the former being a normal derivative of the oleanene series whilst (XXIII) would be that of a member of taraxerene series. In either case, the geometry of ring C, it was considered, should be such as to facilitate a Cope rearrangement through a six-center transition state including C_{12}, C_{13}, C_{14}, and the primary hydroxyl group (as in (XXIV)) with the eventual transfer of the hydroxyl proton to C_{12} and the

Professor Pelletier has used the term 'senegenic acid' for polygalic acid. Aside from observing the slight confusion possibly engendered between, for instance, dimethyl senegenin and dimethyl senegenate, we have no particular preference. The term 'polygalic acid' coined by Shamma and Irwin (18) was used in our earlier publication and we use it here for simplicity.

†*We thank Dr. A. Stoessl (Department of Agriculture) for a specimen of this substance.*

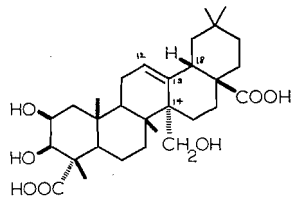
For personal use only.

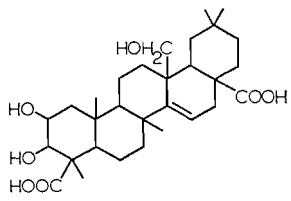
liberation of formaldehyde. Under these conditions untoward migration of the double bond prior to the reverse Prins could be discounted, a possibility which could not be excluded in the more vigorous acid treatment.

At 220° the dimethyl ester of pre-senegenin smoothly underwent the desired rearrangement and entrainment of the volatile material into aqueous dimedone gave a 73% yield of the dimedone derivative of formaldehyde. The other product was identified as dimethyl polygalate. Since, in this transformation, no possibility of inversion at C_{18} is presented this must be the same in polygalic acid as in pre-senegenin.

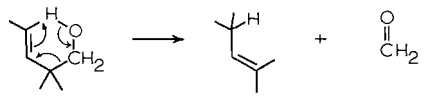
The identity of pre-senegenin as either (XXII) or (XXIII) was thus confirmed. In agreement there was a single vinyl proton in the n.m.r. spectrum of the pre-senegenin esters. The rearrangement just discussed offered a simple means of distinguishing between these formulations. Equilibration of pre-senegenin dimethyl ester with deuterium oxide in dioxane converted the hydroxyl proton in (XXIV) to a deuteron. Removal of the solvents and pyrolysis in a sealed tube under high vacuum gave after crystallization dimethyl polygalate, as previously, in which deuterium (1.4% excess) had been incorporated. Since the incorporation of one deuterium atom (at C_{12} or C_{15}) should have resulted in about 2% excess deuterium, inefficient exchange or insufficiently vigorous exclusion of water may be responsible for its incompleteness.



XXII



XXIII



XXIV

To distinguish between structures (XXII) and (XXIII) for pre-senegenin it was necessary only to ascertain the position of the introduced deuteron. Oxidation of the deuteriopolygalate ester diacetate to the unsaturated ketone (XIV) gave material containing no excess deuterium. The deuteron was therefore required to be at C_{12} unless during the oxidation, by equilibration with the solvent, a deuteron had been removed from C_{15}. This was intrinsically unlikely since this would require enolization, and such an enol would be expected to be trapped by the oxidant to give the transoid cross-conjugated ene-dione. However, the possibility was rendered even more remote by performing an equivalent oxidation of dimethyl polygalate in chromium trioxide – acetic acid-*d*. No deuterium was incorporated into the unsaturated ketone obtained. The structure of pre-senegenin is thus (XXII); bathetically, that of a normal oleanene triterpenoid.

Three points remain for discussion. Under the original isolation procedure (4) senegenin was obtained largely as the free dicarboxylic acid whilst polygalic acid was obtained in a partly esterified condition. Since normal oleanane derivatives would not be expected to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

esterified significantly under Fischer-Speier conditions, some explanation is required. The simplest is that the change in geometry implied by the introduction of a C_{13-14} ethylenic linkage may reduce hindrance to a point where partial esterification may take place under, what are for this type of procedure, forcing conditions. In agreement, use of milder conditions for the transformation of pre-senegenin gave senegenin and polygalic acid which were only $\sim 10\%$ esterified.

Treatment of polygalic acid diacetate and senegenin monoacetate with refluxing methanolic hydrochloric acid (2.4 *N*) for 6 h resulted in $\sim 100\%$ and 24% esterification respectively, as estimated by n.m.r. measurements of the methoxyl signal. Under the same conditions oleanolic acid was 7% esterified. The difference in rate between senegenin and polygalic acid may be attributed to interaction of the bulky chloromethyl group with ring E resulting in slight torsional movement of the 17-carboxyl towards ring C and somewhat increased difficulty of steric access.

Secondly, since the configuration at C_{18} in pre-senegenin is presumably β as in other oleanene derivatives this configuration must obtain in polygalic acid (because of relationship through the Cope rearrangement) and in senegenin (because of its relationship to polygalic acid through the unsaturated ketone (XIV)).

The last point, the mechanism of the evidently intramolecular conversion of pre-senegenin to senegenin is discussible in terms of cyclobutonium ions, but such discussion will be deferred until present investigations in this area are completed. It should be noted that the solvolysis of the system present in pre-senegenin has been studied (for instance refs. 11, 12) and has in fact been used for the synthesis of the triterpenoid phyllanthol (13). However, these studies were performed under essentially irreversible conditions.

The isolation of substances apparently closely related to senegenin (15–17) from *Polygala* species suggests that these, too, contain substances of the type of pre-senegenin.

NOTE ADDED IN PROOF: Professor Pelletier has very recently reported* the formation of a cyclosenegenin by the action of alkali on senegenin: a reaction with ample analogy. With hydrochloric acid senegenin (but not polygalic acid) is formed. The title of the communication requires that cyclosenegenin be present in *Polygala senega*, and the text suggests that it may be the precursor. We have also noted the formation of cyclosenegenin, but an n.m.r. study of the saponin failed to show any signals near τ 10.0 of an intensity sufficient to render possible the presence of a combined cyclosenegenin.

EXPERIMENTAL

Unless otherwise stated the following are implied: light petroleum refers to the fraction of b.p. 60–80°, rotations and infrared spectra are in chloroform solution, ultraviolet spectra are in 95% ethanol solution, and melting points were determined in evacuated capillaries. Thin-layer chromatography was done using Camag silica gel DF-5 with fluorescent indicator. The n.m.r. spectra were determined in deuteriochloroform using 1% tetramethylsilane as internal standard using a Varian D.P. 60 spectrometer (peak positions being determined using an audio oscillator calibrated with a Hewlett Packard 522-B frequency counter) or a Varian A-60. Band positions are in tau (τ) units.

Senegenin

The Anhydro Lactone Methyl Ester Diacetate (VI)

Dechlorosenegenin diacetate (290 mg) was heated in acetic acid (10 ml) containing hydrogen peroxide (4.5 ml, 30%) at 85° for 1.5 h. Dilution with water and extraction into ether followed by methylation (diazomethane) gave, after thin-layer chromatography (t.l.c.) (eluant: ether : isopropyl ether, 3:7) and extraction of the appropriate band, the hydroxy lactone (V) as an oil (250 mg), $[\alpha]_D$ +38° (*c*, 2.05), ν_{max} 3 500, 1 767, 1 742 cm^{-1}, n.m.r. bands at 9.09, 9.05, 8.85, 8.63, 8.07 (3H, singlet), 7.96 (3H, singlet), 6.32 (3H, singlet), 4.64 (2H, multiplet), which was used directly for dehydration.

The hydroxy lactone (115 mg) was dissolved in dry pyridine (8 ml), thionyl chloride (0.5 ml, purified)

added dropwise with stirring, and the solution allowed to stand at room temperature for 1 h. Pouring into sodium acetate (75 ml, 10%) with stirring, extraction into ether, and washing with dilute hydrochloric acid to remove pyridine followed by careful evaporation in the cold gave crystalline anhydro lactone. Crystallization from methanol (in the cold) gave pure material, m.p. 187–192° (decomposition, rapid heating), m.p. 180–185° (decomposition, slow heating), $(\alpha)_D$ +50° (*c*, 1.94), ν_{max} 1 742 cm^{-1} (broad band), λ_{max} 200 (ϵ 5 000), n.m.r. bands at 8.98, 8.77, 8.57, 8.04 (3H, singlet), 7.94 (3H, singlet), 6.34 (3H, singlet), and near 4.7 (3H, complex multiplet).

Isoanhydro Lactone Ester Diacetate (VII)

Anhydro lactone ester diacetate (60 mg) was refluxed for 35 min in methanol (25 ml). Evaporation of the solvent and crystallization from methanol, after separation by t.l.c. (eluant: ether:benzene, 1:1), gave the isoanhydro lactone ester diacetate (30 mg), m.p. 223–225°, $[\alpha]_D$ +10° (*c*, 1.20), ν_{max} 1 745 cm^{-1} (broad band), ν_{max} 1 773, 1 745 cm^{-1} (dioxane), n.m.r. bands at 9.05, 8.93, 8.88, 8.76, 8.61, 8.05 (3H, singlet), 7.96 (3H, singlet), 6.35 (3H, singlet), 5.19 (1H, doublet $J \sim 5$ c.p.s.), 4.62 (2H, multiplet).

Anal. Calcd. for $C_{35}H_{50}O_8$: C, 70.20; H, 8.42. Found: C, 69.98; H, 8.34.

Isoanhydro Lactone Ester

Anhydro lactone ester diacetate (115 mg) was refluxed for 10 min in methanolic potassium hydroxide (15 ml, 5%) under nitrogen. Dilution with water and extraction into ether followed by crystallization from acetone gave the isoanhydro lactone ester (90 mg), m.p. 215–219°, $[\alpha]_D$ −4° (*c*, 1.32), ν_{max} 3 500, 1 760, 1 721 cm^{-1}, n.m.r. bands at 9.02, 8.91, 8.85, 8.81, 8.75, 8.65, 6.28 (3H, singlet), 5.90 (2H, multiplet), 5.17 (1H, doublet $J \sim 5$ c.p.s.).

Anal. Calcd. for $C_{31}H_{46}O_6$: C, 72.34; H, 9.01. Found: C, 71.70; H, 8.63.

Isoanhydro lactone ester (50 mg) was acetylated (pyridine – acetic anhydride, 3:1) by heating for 2.5 h at 90° under nitrogen. Isolation of the product and crystallization from methanol gave a diacetate, m.p. 223–225°, $[\alpha]_D$ +10° (*c*, 1.20) showing no melting point depression on admixture with a sample prepared by refluxing the unrearranged lactone in methanol and having an n.m.r. spectrum identical with that sample

Monomethyl(A) De(hydrochloro)senegenin (IX)

Isoanhydro lactone ester (30 mg) was allowed to stand at room temperature for 15 min in methanol – hydrochloric acid (5%). Isolation of the product and crystallization from acetone gave a quantitative yield of monomethyl (A) de(hydrochloro)senegenin. Recrystallization from acetone gave material which softens at 200°, resolidifies, and melts at 299–301°, $[\alpha]_D$ +71° (*c*, 1.05), λ_{max} 242, 249, 258 mμ (ϵ 14 000, 16 100, 10 100), n.m.r. bands at 9.21, 9.06, 8.95, 8.75, 8.63, 8.23, 6.31 (3H each, all singlets), 5.96 (2H, multiplet), 4.66 (1H, multiplet).

Anal. Calcd. for $C_{31}H_{46}O_6$: C, 72.34; H, 9.01. Found: C, 71.74; H, 8.82.

Methylation with diazomethane and crystallization from acetone gave de(hydrochloro)senegenin dimethyl ester, m.p. 234–235°, $[\alpha]_D$ +82° (*c*, 1.12), showing no melting point depression on admixture with an authentic sample and having an n.m.r. spectrum identical with that of the authentic material.

Monomethyl (A) de(hydrochloro)senegenin (140 mg) was acetylated (pyridine – acetic anhydride, 3:1) by heating 2.5 h at 95° under nitrogen. Isolation of the product and crystallization from acetone – light petroleum gave a diacetate, m.p. 175–180°, $[\alpha]_D$ +60° (*c*, 1.43), ν_{max} 1 739, 1 695 cm^{-1}, λ_{max} 242, 249, 256 mμ (ϵ 15 000, 16 900, 11 700), n.m.r. bands at 9.22, 9.08, 8.97, 8.80, 8.58, 8.25, 8.05, 7.95, 6.35 (3H each, all singlets), 4.56 (3H, multiplet).

Anal. Calcd. for $C_{35}H_{50}O_8$: C, 70.20; H, 8.42. Found: C, 69.60; H, 8.11.

Acid Chloride (IX, COCl Instead of COOH) Formation and Pyrolysis

Monomethyl (A) de(hydrochloro)senegenin diacetate (57 mg) was refluxed in a dry atmosphere for 45 min in carbon tetrachloride (10 ml, dried) containing thionyl chloride (1 ml). Evaporation to dryness gave an oily acid chloride, ν_{max} 1 745, 1 792 cm^{-1}, which on contact with wet solvents was hydrolyzed to the corresponding acid. The freshly made acid chloride (350 mg total) was heated in five equal portions under nitrogen at 265° for 30 min. Separation by t.l.c. (eluant: ether:benzene, 3:7) gave a major portion (130 mg) (R_f near 0.5) which was treated in ethyl acetate solution with a stream of ozone for 5 min at −70°. Nitrogen was then blown through (15 min) to remove excess ozone. Reseparation by t.l.c. and crystallization from methanol gave the pure benzene derivative (X) (53 mg), m.p. 302–303°, ν_{max} 1 739 cm^{-1}, $[\alpha]_D$ +50° (*c*, 0.91), λ_{max} 269 (ϵ 535), n.m.r. bands at 9.06, 9.00, 8.89, 8.85, 8.58, 8.02, 7.91, 6.35 (3H each, all singlets), 4.6 (2H, multiplet), 3.05 (2H, broad singlet).

Anal. Calcd. for $C_{34}H_{48}O_6$: C, 73.88; H, 8.75. Found: C, 73.49; H, 8.96.

Isode(hydrochloro)senegenin Dimethyl Ester

Senegenin monoacetate (495 mg) was refluxed for 18 h under nitrogen in aqueous alcoholic (1:3) sodium hydroxide (85 ml, 5%). Dilution with water and neutralization with saturated KH_2PO_4 solution to pH ~ 6 and extraction into ether gave material which, after methylation (diazomethane) and crystallization from methanol, gave isode(hydrochloro)senegenin dimethyl ester (XIII) (250 mg), m.p. 228–230°, $[\alpha]_D$ +23° (*c*, 1.17), λ_{max} 249 mμ (ϵ 13 100), ν_{max} 3 500, 1 715, 1 616, 1 592 cm^{-1}, n.m.r. bands at 9.13, 8.98, 8.83, 8.70, 6.48 (3H, singlet), 6.36 (3H, singlet), 6.0 (2H, multiplet), 5.40 (1H, singlet), 5.13 (1H, singlet).

Rearrangement of Isode(hydrochloro)senegenin Dimethyl Ester

The ester (50 mg) was allowed to stand for 15 min at room temperature in dioxane (5 ml) containing hydrochloric acid (0.5 ml, concentrated). Isolation of the product and crystallization from methanol gave de(hydrochloro)senegenin dimethyl ester, melting point and mixed melting point 221–223°, λ_{max} 243, 249, 258 mμ (ϵ 12 700, 14 700, 10 300). The n.m.r. spectrum was identical with that of an authentic sample.

The α,β-Unsaturated Ketone (XIV)

Isode(hydrochloro)senegenin dimethyl ester (99 mg) was dissolved in methanol (5 ml), the solution cooled to −70°, and ozone bubbled in for 2 min. Nitrogen was blown through the solution for 15 min and acetic acid (0.5 ml) and potassium iodide (0.5 ml, 50% aqueous) was added. The solution was then allowed to warm up to room temperature and after 30 min it was poured into dilute sodium thiosulfate (5%) and extracted into ether. Separation by t.l.c. (eluant: ether:benzene, 3:7) and crystallization from methanol gave the α,β-unsaturated ketone (32 mg), m.p. 228–230°, $[\alpha]_D$ +41° (*c*, 1.38), λ_{max} 253 mμ (ϵ 9 400), ν_{max} 3 500, 1 721, 1 653, 1 613 cm^{-1}.

Anal. Calcd. for $C_{31}H_{46}O_7$: C, 70.16; H, 8.74. Found: C, 70.81; H, 8.50.

The ketone (90 mg) was acetylated (pyridine – acetic anhydride, 3:1) by heating for 3 h at 95° under nitrogen. Extraction into ether and crystallization from methanol gave a diacetate (85 mg), m.p. 245–247°, $[\alpha]_D$ +46° (*c*, 1.88), λ_{max} 253 mμ (ϵ 9 400), ν_{max} 1 745, 1 661, 1 613 cm^{-1}, n.m.r. bands at 8.97, 8.78, 8.62, 8.06, 7.94, 6.44, 6.33 (3H each, all singlets), 4.6 (2H, multiplet).

Reduction of the α,β-Unsaturated Ketone

The unsaturated ketone dimethyl ester diacetate (72 mg), in three equal portions, was allowed to stand at room temperature for 20 min in methanol (5 ml) containing sodium borohydride (120 mg). The product was poured into dilute acetic acid, neutralized with sodium carbonate (5%), and extracted into ether. Crystallization from methanol gave an alcohol, m.p. 223–224°, $[\alpha]_D$ +33° (*c*, 1.17), λ_{max} 205 mμ (ϵ 7 000), ν_{max} 3 450, 1 733 cm^{-1}. The compound had n.m.r. bands at 9.06 (~ 9H, singlet), 8.86 (3H, singlet), 8.66 (3H, singlet), 8.10 (3H, singlet), 7.97 (3H, singlet), 6.36 (6H, singlet), 5.84 (1H, multiplet), 4.58 (2H, multiplet).

Anal. Calcd. for $C_{35}H_{52}O_9$: C, 68.15; H, 8.50. Found: C, 68.56; H, 8.61.

Norde(hydrochloro)senegenin Dimethyl Ester

The unsaturated ketone dimethyl ester (19 mg) was allowed to stand at room temperature for 15 min in methanol (4 ml) and sodium borohydride (89 mg). The product was isolated as above and dehydrated by warming on a steam bath for 15 min in methanolic hydrochloric acid (10 ml, 5%). Isolation and crystallization from methanol gave the diene (15 mg), m.p. 200–210°, $[\alpha]_D$ +58° (*c*, 1.40), λ_{max} 238, 246, 254 mμ (ϵ 11 800, 13 800, 9 750), n.m.r. bands at 9.17, 9.10, 9.02, 8.77, 8.65, 6.46, 6.31 (3H each, all singlets), 5.99 (2H, multiplet), 5.60 (2H, multiplet).

Anal. Calcd. for $C_{31}H_{46}O_6$: C, 72.34; H, 9.01. Found: C, 71.91; H, 9.00.

Bromination of the Unsaturated Ketone

The unsaturated ketone dimethyl ester diacetate (16.0 mg) was dissolved in 10 ml of a bromine solution (232 mg Br_2 / ml of acetic acid containing 0.05% HBr). Aliquots (1 ml) were withdrawn and dropped into a solution containing potassium iodide (1 ml, 5%), water (5 ml), thiodene indicator (1 ml, 5% aqueous) and titrated with standard *N*/100 sodium thiosulfate. After 90 min the uptake was 1.99 atoms of bromine which increased to 2.05 atoms after a further 90 min.

Preparation of the Trienone (XV)

The unsaturated ketone dimethyl ester diacetate (175 mg) was brominated by allowing it to stand for 2.25 h at room temperature in a mixture of acetic acid (10 ml) and a bromine solution (4 ml, acetic acid containing 46 mg Br_2 / ml and 0.05% HBr). Pouring into sodium thiosulfate solution (25 ml, 10%) and neutralization with bicarbonate (5%), followed by extraction into ether and evaporation in the cold gave the crude dibromo compound (212 mg).

The material so obtained was heated at 105–110° under nitrogen for 5.25 h in dimethyl formamide (12 ml) containing lithium chloride (180 mg). Dilution with water, extraction into ether, and separation by t.l.c. (eluant: ether:benzene, 1:3) followed by crystallization from methanol gave the trienone (88 mg), m.p. 312–314°, $[\alpha]_D$ +136° (*c*, 1.44), λ_{max} 260, 320 mμ (ϵ 8 200, 7 200), ν_{max} 1 742, 1 650, 1 623, 1 570 cm^{-1}. The n.m.r. spectrum showed bands at 9.16, 8.97, 8.68, 8.52, 8.43, 8.05, 7.91, 6.47, 6.36 (3H each, all singlets), 4.73 (1H, doublet $J \sim 4.5$ c.p.s.), 5.40 (1H, complex multiplet), 3.88 (1H, singlet), 3.77 (2H, AB pattern, $J_{AB} = 10$ c.p.s., $\delta_B - \delta_A = 20.7$ c.p.s.).

Anal. Calcd. for $C_{35}H_{46}O_9$: C, 68.83; H, 7.59. Found: C, 69.11; H, 7.55.

Pre-senegenin

Cleavage of the Saponin and Isolation of the Sapogenin

The saponin (30 g) was dissolved in water (1 l) and sodium metaperiodate (41 g) was added over a period of ½ h while the solution was being stirred and cooled in an ice bath. The solution was allowed to stand in the dark at room temperature for 24 h. Then while the solution was stirred, potassium iodide was added (20 g) and then sodium arsenite until the iodine color disappeared. The mixture was neutralized with solid potassium hydroxide, and then an additional 50 g were added. The solution was heated at 100° under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

nitrogen with stirring for 1 h, cooled, and carefully acidified with hydrochloric acid to pH ~ 3. Extraction with ether gave 4.5 g of crude sapogenin. Methylation (diazomethane) and chromatography on silica gel (100 g, BDH) gave a crystalline sapogenin ester (1.5 g). Several recrystallizations from ethyl acetate gave the sapogenin dimethyl ester, m.p. 214–215°, $[\alpha]_D$ +78° (*c*, 2.22), ν_{max} 3 500, 1 718 cm^{-1}, n.m.r. bands at 9.37, 9.12, 9.07, 8.82, 8.68, 6.38, 6.32 (3H each, all singlets), 5.98 (2H, multiplet), 4.16 (1H, multiplet).

Anal. Calcd. for $C_{32}H_{50}O_7$: C, 70.30; H, 9.22. Found: C, 70.42; H, 9.28.

Acetylation of Pre-senegenin Dimethyl Ester

The ester was acetylated (pyridine – acetic anhydride, 3:1) by heating at 95° for 3 h under nitrogen. Evaporation and extraction into ether gave a triacetate which, on crystallization from methanol, had m.p. 219–220°, $[\alpha]_D$ +110° (*c*, 2.32), ν_{max} 1 727, 1 739 cm^{-1}, n.m.r. bands at 9.30, 9.13, 9.07, 8.80, 8.60, 8.07, 7.98, 7.96, 6.26, 6.23 (~ 3H each, all singlets), 5.90 (2H, broad singlet), 4.56 (3H, complex multiplet).

Anal. Calcd. for $C_{38}H_{50}O_{10}$: C, 67.83; H, 8.39. Found: C, 67.85; H, 8.45.

Isolation of Pre-senegenin

The crude sapogenin (1.4 g) was separated by t.l.c. (eluant: acetic acid : chloroform, 1:4) to give 450 mg of sapogenin. Crystallization from aqueous alcohol (care being taken not to heat the solvent excessively) gave pure pre-senegenin, m.p. 310–311°, $[\alpha]_D$ +91° (*c*, 1.16, MeOH).

Anal. Calcd. for $C_{30}H_{46}O_7 \cdot 0.5H_2O$: C, 68.28; H, 8.98. Found: C, 67.95; H, 8.82.

Identification of p-Methoxy Cinnamic Acid

Chromatography of the methylated crude sapogenin mixture on silica gel (BDH) yielded, besides the terpenoid ester, *p*-methoxy methyl cinnamate as identified by melting point, mixed melting point, and infrared spectrum. Separation of the crude sapogenin gave, besides the sapogenin, *p*-methoxy cinnamic acid as identified by melting point and mixed melting point.

Conversion of Pre-senegenin to Senegenin and Polygalic Acid

The sapogenin (167 mg) was refluxed for 1.25 h in a mixture of ethanol (10 ml), water (3 ml), and hydrochloric acid (1.35 ml, concentrated). Dilution with water and extraction into ether followed by re-extraction into aqueous sodium bicarbonate (5%) gave neutral (17 mg) and bicarbonate-soluble material (140 mg). Methylation of the latter with diazomethane and separation on t.l.c. (eluant: ether:benzene, 3:1) gave senegenin dimethyl ester (61 mg), $[\alpha]_D$ +14° (*c*, 1.12) and dimethyl polygalate (50 mg), m.p. 211–212°, $[\alpha]_D$ +23° (*c*, 1.11). The dimethyl senegenin was identified by comparison of the n.m.r. spectrum, infrared spectrum, and R_F (t.l.c.) with an authentic specimen. The dimethyl polygalate was identified by melting point and mixed melting point determination with an authentic specimen prepared from polygalic acid by esterification with diazomethane. Crystallized from methanol this had m.p. 211–212°, $[\alpha]_D$ +22° (*c*, 1.00).

Anal. Calcd. for $C_{31}H_{48}O_6$: C, 72.06; H, 9.36. Found: C, 71.62; H, 8.93.

No other product could be detected by t.l.c.

Treatment of Pre-senegenin Dimethyl Ester with HCHO:HCl

(*a*) The ester (4 mg) was refluxed 1.25 h in a mixture of ethanol (1.5 ml), water (0.5 ml), and hydrochloric acid (0.2 ml, concentrated). The product was diluted with water and extracted into ether.

(*b*) The ester (4 mg) was refluxed 1.25 h in a mixture of ethanol (1.5 ml), water (0.18 ml), formaldehyde (0.32 ml, 3.7% aqueous solution), and hydrochloric acid (0.2 ml, concentrated). The product was isolated as above.

Running a series of spots of various concentrations, from the above experiments, using t.l.c. (eluant: ether:benzene, 3:1) indicated no detectable difference in the ratio of senegenin ester to polygalic acid ester in the two experiments (the plates were sprayed with 50% H_2SO_4 and charred).

Pyrolysis of Pre-senegenin Dimethyl Ester

The ester (75 mg) was heated at 220° for 30 min under a stream of nitrogen that bubbled into an aqueous dimedone solution (40 ml, 0.45%). A precipitate formed immediately. The solution was allowed to stand for 2 h and the precipitate collected. The product (29 mg, 73% yield) was identified as the dimedone derivative of formaldehyde by melting point and mixed melting point comparison with an authentic sample; t.l.c. (eluant: ether:benzene, 3:1) showed only one pyrolysis product which, on crystallization from methanol, was identified as dimethyl polygalate (57 mg) by melting point, mixed melting point, and rotation.

Acid Treatment of Pre-senegenin Dimethyl Ester in the Presence of 2,4-Dinitrophenylhydrazine

Pre-senegenin dimethyl ester (86 mg) and 2,4-dinitrophenylhydrazine (89 mg) were refluxed for 2.5 h in a mixture of methanol (13 ml), water (4 ml), and hydrochloric acid (2 ml, concentrated). Isolation of the products and separation by t.l.c. (eluant: chloroform) gave formaldehyde 2,4-dinitrophenylhydrazone (4.7 mg) identified by melting point and mixed melting point comparison with an authentic sample.

*Deuterium Experiments**

Pre-senegenin dimethyl ester (215 mg) was dissolved in dried dioxane (1 ml), D_2O (10 drops, 99.65%) added, and the mixture evaporated to dryness. This process was repeated three times, the tube sealed under high vacuum and heated at 220° for 20 min. The product was separated by t.l.c. (eluant: ether:benzene, 3:1) and crystallized from methanol to give dimethyl polygalic acid-d_1 (106 mg).

**Deuterium analyses by Josef Nemeth, 303 Washington St., Urbana, Illinois.*

Anal. Calcd. for $C_{31}H_{47}O_6D$: 2.08% excess deuterium. Found: 1.40% excess deuterium.

Dimethyl polygalate-d_1 (80 mg) was acetylated (pyridine – acetic anhydride) to give the diacetate. The product was dissolved in acetic acid (1 ml), chromic acid (5 ml, 0.4 *N* in acetic acid) added, and the solution allowed to stand for 1 h at room temperature. The product was poured into a bisulfite solution and extracted into chloroform. Separation by thin-layer chromatography and crystallization gave the α,β-unsaturated ketone (XIV) (10 mg), m.p. 245–247°.

Found: 0.00% excess deuterium.

Dimethyl polygalate diacetate (87 mg) was allowed to stand 1 h at room temperature in 5 ml of 0.5 *N* chromic acid in acetic acid-d_1. The solution was poured into D_2O (30 ml), bisulfite added, and the solution extracted into chloroform. Purification in the usual way gave the α,β-unsaturated ketone (XIV) (16 mg).

Found: $< 0.04\%$ excess deuterium.

Esterification Experiments

Polygalic acid diacetate (113 mg) was refluxed for 6 h in a mixture of methanol (20 ml) and hydrochloric acid (5 ml, concentrated). This was poured into water and extracted into ether. The n.m.r. was taken in pyridine indicating $\sim 100\%$ methylation.

Senegenin monoacetate (87 mg) was treated under exactly the same conditions as above and the n.m.r. spectrum of the crude product was taken in pyridine showing $\sim 24\%$ methylation.

Oleanonic acid (91 mg) was treated as above and the n.m.r. spectrum of the crude product, taken in deuteriochloroform, indicated $\sim 7\%$ methylation.

INFRARED EMISSION SPECTRA OF FATTY ACIDS ON STEEL SURFACES[1]

M. J. D. Low and H. Inoue
School of Chemistry, Rutgers, The State University, New Brunswick, New Jersey
Received March 5, 1965

ABSTRACT

Infrared emission spectra of oleic, linoleic, linolenic, and stearic acids, and of methyl linolenate, on the surfaces of steel plates were measured at 100, 150 and 200° from 5 to 10 microns. Reactions occur to produce complex iron soaps.

The study of molecular species chemisorbed on infrared-transmitting solids has advanced markedly since the application of infrared absorption techniques to surface problems (1). However, relatively little work has been done with surfaces of bulk materials that are opaque to infrared radiation. Although reflection techniques have been developed (2, 3), these are delicate and tedious. Little attention has been paid to the alternate technique of infrared emission spectroscopy.

Some exploratory emission experiments were made by Eischens and Pliskin (1), but with little success. More recent experiments (4), however, indicated that emission methods could be used in special cases for the examination of the surface of opaque bulk solids. Infrared emission spectra of fatty acids on steel surfaces have now been obtained.

EXPERIMENTAL

A Perkin–Elmer Model 521 spectrometer fitted with a high sensitivity thermocouple* was used. Samples were placed between NaCl or CaF_2 plates for absorption spectra. Soft steel plates 1 mm thick were used as emitters for emission spectra, in conjunction with a heating device described elsewhere (4). All emission spectra shown are differential spectra obtained with slits fixed at 290 microns. The calculated spectral slit width at 1 600 cm^{-1} was 3 cm^{-1}. Units of emission and absorption ordinates are arbitrary. The fatty acids and methyl ester were of 99+% purity, obtained from The Hormel Institute.

The emitter plates were polished with grade 000 sandpaper, dipped in dilute nitric acid polished with alumina, and were washed and dried prior to use. A pair of plates was brought to constant temperature, and a thin layer of fatty acid was then quickly spread on one plate with a filter paper or glass-wool brush. Excess acid was wiped off, so that the plate surface appeared to be dry. Emission spectra were then recorded.

EXPERIMENTS, RESULTS, AND DISCUSSION

A pronounced feature of an infrared spectrum of oleic acid is a carbonyl stretching mode at about 1 700 cm^{-1} that is characteristic of C=O associated with the acid hydroxyl group. Ionization of the carboxyl group brings about bands at higher frequencies, spectra of ionic oleates showing bands near 1 555 cm^{-1} as well as in the region 1 470 – 1 400 cm^{-1}, corresponding to antisymmetrical and symmetrical vibrations of the ionized carboxyl group, respectively. Attention is therefore focused on the region from 1 800 cm^{-1} to about 1 300 cm^{-1}, on the assumption that a surface reaction would involve the formation of a carboxylate species. That region is shown in the figures presented.

Figure 1 shows examples of emission spectra of oleic acid coated steel, as well as an absorption spectrum of oleic acid. Greater detail is shown by the spectra of Fig. 2. These and similar results showed that stable spectra were obtained with the emitter plates at

100°. At 150° and 200°, however, some evaporation of oleic acid from the emitter plates occurred initially and, also, some changes occurred in the spectra with the passage of time. Slight decreases in intensity of all bands occurred at 200°, but even after 5 h the spectra could be readily observed. The emitter plates initially were and remained bright during the experiment, so that the oxide coating was minimal. Satisfactory emission spectra could not be obtained with plates deliberately oxidized to a great extent.

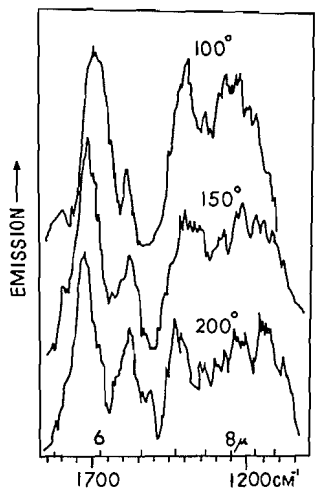

FIG. 2. Emission spectra of oleic acid on steel. Each spectrum was measured immediately after oleic acid addition, at 5× ordinate scale expansion.

For personal use only.

The results of similar experiments at 100, 150, and 200° with linoleic and linolenic acids were like those obtained with oleic acid and need not be discussed separately. The position of emission bands observed at 100° with stearic acid were like those of oleic acid, but satisfactory spectra could not be obtained at higher temperatures because band intensities declined rapidly.

Similar experiments were made with methyl linolenate. Emission and absorption spectra are shown in Fig. 3. Emission band intensities declined rapidly even at 100°, so that structure could not be observed in the spectrum after about 20 min. This suggests that relatively rapid evaporation occurred. Also, the stearic acid and ester spectra were comparatively "noisy". This could be caused by cooling of the emitter surface through evaporation.

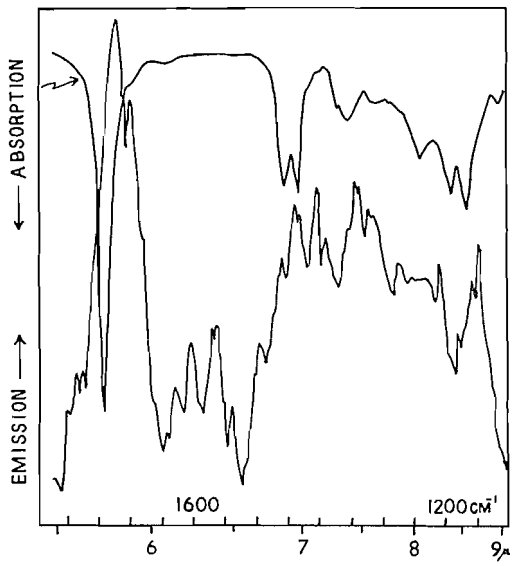

FIG. 3. Spectra of methyl linolenate. The emission spectrum was obtained at 100° immediately after ester addition, at 5× ordinate scale expansion.

The greater retention on the surface of oleic, linoleic, and linolenic acids than of methyl oleate would imply that the reaction at double bonds alone to form carbon-to-surface bonds was not significant. The relatively rapid removal of stearic acid, however, suggests that both carboxyl groups and double bonds could be involved, possibly through the formation of a surface species similar in structure to the complex zinc oleate described by Jacobsen and Gardner (5), involving a coordination of the 9,10 double bond to a Zn atom and a bond to that same atom from one of the oxygen atoms of the carboxyl group of the same acid radical. An alternative is the degeneration of the unsaturated acids to form polymers on the surface.

The 100° spectra of Figs. 1 and 2 showed strong bands near 1 700 cm^{-1}, indicating the presence of oleic acid. At 150°, however, that band gradually shifted to 1 720 cm^{-1}. If acid was placed on an emitter plate at 200°, however, a band appeared immediately at 1 720 cm^{-1}. Also, bands appeared in the region 1 120 – 1 140 cm^{-1} at 200°, as shown in Fig. 2. As this shift might be caused by the formation of degradation products, absorption spectra were obtained of oleic acid after heating in air in Erlenmeyer flasks. Heating at 140° for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

24 h caused a shoulder near 1 720 cm^{-1} to appear on the original 1 703 cm^{-1} band, and a weak band was detected at 1 170 cm^{-1}. After 48 h at 140° the shoulder had grown into a distinct band at 1 730 cm^{-1} and the 1 173 cm^{-1} band had increased. After 168 h at 140°, broad bands were found at 1 740 and 1 720 cm^{-1}, and a general loss of structure occurred in the 1 500 – 900 cm^{-1} region. Heating at 200° for 4 h had no effect, however. The spectrum obtained after heating for 48 h at 200° was similar to the 140°, 48 h spectrum. The results indicate a slow degeneration of oleic acid in air, and suggest that the 1 700 to 1 720 cm^{-1} shift is caused by the formation of a surface polymer.

It is interesting to note, however, that this shift was observed only with Fe and Co, but not with Al (4), Cu, Zn, Cd, Ag, Au, or Sn (6). There is also similarity between the 200° acid emission spectra and that of the methyl ester, which shows a strong carbonyl band at 1 720 cm^{-1} and a characteristic band at 1 170 cm^{-1} that is ascribed to the linear C—O vibration (7). The 1 700 – 1 720 cm^{-1} shift may thus be brought about through the formation of ester linkages.

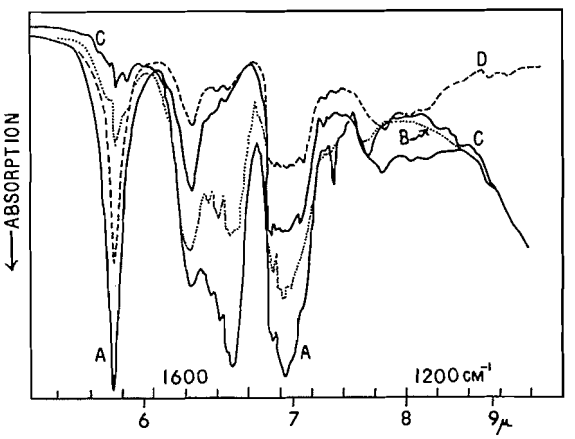

FIG. 4. Absorption spectra of iron oleates. Aqueous solution of sodium oleate (I) and $Fe(NO_3)_3$ (II) or $Fe(NH_4)_2(SO_4)_2$ (III) were mixed, and the precipitate extracted with isooctane. The mole ratios were: A, I/II = 1; B, I/II = 1/3; C, I/III = 1; D, I/II = 1/3.

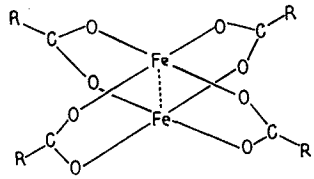
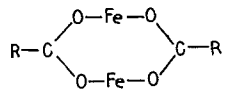
The emission spectra also show structure in the 1 650 – 1 500 cm^{-1} region that is absent in the oleic acid absorption spectrum, suggesting that reactions involving the carboxylate group had occurred. Bands and shoulders were found near 1 570 and 1 580 cm^{-1} and near 1 550 cm^{-1}. The centers of broad bands from about 1 600 to 1 500 cm^{-1} centering near 1 570 cm^{-1} were occasionally shifted to near 1 550 cm^{-1}. To obtain further information, as iron oleate spectra do not seem to have been reported, some precipitates were prepared from sodium oleates and iron salts. The absorption spectra are given in Fig. 4. The sharp bands near 1 710 cm^{-1} point to the presence of free oleic acid. The relative intensities of bands near 1 590, 1 550, and 1 530 cm^{-1} changed with the proportion of reactants, suggesting the existence of at least two iron oleate structures. As the aqueous oleate ion has a band near 1 555 cm^{-1}, the 1 550 cm^{-1} band could be ascribed to sodium oleate impurity as well as to the free oleate ion of an iron salt. The structures of the iron oleates are not known. Complex iron acetates (8) are known, however. Also, binuclear acetate complexes $Cr(ac)_4 \cdot 2H_2O$ and $Cu(ac)_4 \cdot 2H_2O$ (9) and the analogous copper oleates and stearates (10), with structure I, were reported to give bands at 1 575, 1 605, 1 588, and 1 585 cm^{-1}, respectively, assigned to the asymmetric OCO vibration. It seems possible that the 1 590

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cm^{-1} band of the precipitates and the emission bands near 1 570 cm^{-1} may be caused by the same vibration of species such as I or II.



I



II

The emission spectra are, unfortunately, not well enough resolved for adequate characterization of the carboxylate species present on the surface. The presence of shoulders and bands over a relatively wide spectral region and the shifting of the bands suggest, however, that species other than unassociated carboxylate ions are formed involving in part, the abstraction of iron atoms from the surface. The shifting of bands to lower wave numbers on heating suggests that some change occurs in the complexes, possibly a dissociation to $RCOO^-$.

CHEMISTRY OF THE COMPLEXES OF URANYL AND PLUTONYL IONS WITH ORGANIC LIGANDS

P. V. BALAKRISHNAN, S. K. PATIL, H. D. SHARMA, AND H. V. VENKATASETTY
Radiochemistry and Isotope Division, Atomic Energy Establishment, Trombay, Bombay

Received August 24, 1964

ABSTRACT

A series of complexes of uranyl and plutonyl ions with different organic ligands have been prepared and investigated by infrared spectra and magnetic susceptibility measurements. The uranyl complexes were found to be weakly diamagnetic and the plutonyl complex was found to be paramagnetic. Two ligand series are defined on the basis of the infrared asymmetric stretching frequency of the uranyl and plutonyl groups.

The chemistry of the oxometal ions is of interest because of the existence of a strong multiple metal–oxygen covalent bond persisting in various chemical environments. This can be employed as an internal molecular probe to understand more about the nature of metal–ligand bonds in the complexes of these ions (1). Many coordination compounds of uranyl ion have been prepared and their properties studied, but the problems of the coordination number of the uranium atom and the nature of binding are as yet not well understood (2–6). From the available experimental data it would seem that there is a definite preference for a coordination number of eight for the uranium atom, the axial oxygens being considered as ligands, and that all the other ligands are directly bonded to the uranium atom in a plane perpendicular to the axial U—O bonds. In the case of plutonyl ion there have been very little data in the literature both on the magnetic susceptibility and on the infrared spectra of the solid complexes (1, 2).

This paper describes the preparation of the complexes of uranyl nitrate with dimethyl sulfoxide (DMSO), pyridine (py), 2,2′-dipyridyl (dipy), 2,2′-dipyridyl-N,N′-dioxide (dipy·O_2), and *o*-phenanthroline (phen), and of the complexes of plutonyl chloride with dipy, dipy·O_2, and phen as well as the investigation of their properties by infrared spectra and magnetic susceptibility measurements.

EXPERIMENTAL

$UO_2(NO_3)_2 \cdot 2DMSO$

Uranyl nitrate hexahydrate (4.0 g) in ethanol was added to pure dimethyl sulfoxide (10 ml). On standing a yellow compound precipitated. This was filtered, washed with ethanol, and dried *in vacuo*. This compound was insoluble in benzene and carbon tetrachloride, but soluble in acetone, methanol, acetonitrile, and water. Found: U, 43.13; C, 9.04; H, 2.25. Calcd. for $UO_2(NO_3)_2 \cdot 2DMSO$: U, 43.27; C, 8.7; H, 2.2.

$UO_2(NO_3)_2 \cdot H_2O \cdot py$

Uranyl nitrate hexahydrate (4.0 g) in *n*-butyl acetate was mixed with reagent grade pyridine (2.0 g). The greenish-yellow precipitate obtained was filtered, recrystallized from ethanol, and dried *in vacuo*. It was insoluble in benzene and carbon tetrachloride, slightly soluble in acetone and acetonitrile, but more soluble in methanol and water. Found: U, 47.9; C, 11.8; H, 1.3. Calcd. for $UO_2(NO_3)_2 \cdot H_2O \cdot py$: U, 48.2; C, 12.2; H, 1.4. Thermogravimetric analysis confirmed this formula.

$UO_2(NO_3)_2 \cdot dipy$

Uranyl nitrate hexahydrate (4.0 g) in ethanol was mixed with 2,2′-dipyridyl (3.0 g) in ethanol. The resulting yellow precipitate was removed by filtration, washed with ethanol, and dried *in vacuo*. It was insoluble in benzene, carbon tetrachloride, acetone, and water, but slightly soluble in methanol and acetonitrile. Found: U, 42.5; N, 10.4; C, 22.3; H, 1.4. Calcd. for $UO_2(NO_3)_2 \cdot dipy$: U, 43.27; N, 10.21; C, 21.8; H, 1.45. Thermogravimetric analysis confirmed this formula.

$UO_2(NO_3)_2(dipy{\cdot}O_2)$

2,2′-Dipyridyl-N,N′-dioxide was prepared from 2,2′-dipyridyl as described elsewhere (7). Uranyl nitrate hexahydrate (2.0 g) in ethanol was mixed with dipy·O_2 (10.0 g) in boiling ethanol. The resulting light-yellow precipitate was filtered, washed with ethanol, and dried *in vacuo*. It was insoluble in benzene, carbon tetrachloride, and acetone, slightly soluble in methanol and acetonitrile, but more soluble in water. Found: U, 41.08; N, 9.2; C, 20.9; H, 1.34. Calcd. for $UO_2(NO_3)_2$(dipy·O_2): U, 40.88; N, 9.6; C, 20.6; H, 1.37.

$UO_2(NO_3)_2{\cdot}phen$

Uranyl nitrate hexahydrate (4.0 g) in ethanol was mixed with *o*-phenanthroline (4.0 g) in ethanol. The resulting pale-yellow precipitate was filtered, washed with ethanol, and dried *in vacuo*. It was insoluble in benzene, carbon tetrachloride, acetone, and water but slightly soluble in methanol and acetonitrile. Found: U, 40.1; N, 9.73; C, 26.9; H, 1.5. Calcd. for $UO_2(NO_3)_2$·phen: U, 41.45; N, 9.81; C, 25.1; H, 1.4. Thermogravimetric analysis confirmed this formula.

Plutonium purified by ion exchange method was oxidized by ozone to plutonium(VI) in 1 *M* HCl (8) and used for the preparation of the complexes.

$PuO_2Cl_2(dipy{\cdot}HCl)_2$

About 5 ml of a solution containing about 30 mg of plutonium as plutonium(VI) in 1 *M* HCl was mixed with about 150 mg of 2,2′-dipyridyl in acetone. The resulting clear solution was treated with excess of dioxane until a yellow, oily layer separated. This layer was separated, treated with more dioxane and alcohol, and dried. A yellowish-brown solid was thus obtained. Found: Pu, 32.3; Cl, 19.08. Calcd. for PuO_2Cl_2(dipy·HCl)$_2$: Pu, 32.8; Cl, 19.5.

$PuO_2Cl_2(phen{\cdot}HCl)_2$

About 5 ml of a solution containing about 30 mg of plutonium as plutonium(VI) in 1 *M* HCl was mixed with about 150 mg of phenanthroline. On treating the resulting clear solution with dioxane a yellowish-brown solid separated. It was thoroughly washed with ethanol and dried. Found: Pu, 29.73; Cl, 16.44; Calcd. for PuO_2Cl_2(phen·HCl)$_2$: Pu, 30.8; Cl, 18.3.

$PuO_2Cl_2(dipy{\cdot}O_2{\cdot}HCl)_2$

About 5 ml of a solution containing about 30 mg of plutonium as plutonium(VI) in 1 *M* HCl was mixed with about 150 mg of 2,2′-dipyridyl-N,N′-dioxide. The resulting clear solution gave on standing a reddish-brown precipitate. It was thoroughly washed with dioxane and ethanol and dried. Found: Pu, 27.8; Cl, 16.5; Calcd. for PuO_2Cl_2(dipy·O_2·HCl)$_2$: Pu, 30.2; Cl, 17.9. Thermogravimetric analysis of the compound confirmed the above formula.

The infrared spectra of these complexes were obtained in Nujol mull in the region 4 000 – 625 cm^{-1}, using a Perkin–Elmer Model 237 Spectrophotometer. The wave numbers in the region 2 000 – 625 cm^{-1} are accurate to ± 3 cm^{-1}. The magnetic susceptibility measurements were made in the solid phase by the Gouy method using water and nickel chloride solution as standards. The susceptibility values are accurate to $\pm 2\%$. The thermogravimetric measurements were made in a silica spring thermobalance with a sensitivity of 2.5 mm/mg. The rate of heating was maintained at 5 °C/min. About 10 mg of the sample was taken for each thermogravimetric study.

RESULTS AND DISCUSSION

Recent X-ray diffraction work (9) and the infrared (10, 11) and Raman spectral studies (12) on uranyl and plutonyl ions (11) show that these ions are linear and the strong absorption band in the region between 900–950 cm^{-1} was assigned to the asymmetric stretching mode of the metal–oxygen bonds. Not much work has been reported on the infrared spectra of the actinide complexes. Barr and Harton (13), who studied the infrared spectrum of the pyridine complex of uranyl nitrate, made some qualitative observations regarding the C=C and C=N stretching modes of the pyridine ring. Jones (14) studied the infrared spectra of the sodium acetate complexes of U(VI), Np(VI), Pu(VI), and Am(VI) and calculated the approximate values of the force constants for the metal–oxygen bonds from their symmetric and asymmetric stretching frequencies. Gatehouse, Livingston, and Nyholm (15) studied the infrared spectra of uranyl nitrate hydrates and alkalimetal uranyl nitrates in order to differentiate a coordinatively bound nitrate group from a nitrate ion.

The infrared spectra of the complexes of the uranyl and plutonyl ions with pyridine, 2,2′-dipyridyl, and *o*-phenanthroline have several absorption peaks characteristic of the

Abbreviations: S = strong; M = medium; W = weak.
*N—O stretching mode of the ligand in the complex.

C═C, C═N, and C—H groups of the ligands. These absorption bands are shifted appreciably from those of free ligands. In addition the complex $UO_2(NO_3)_2.H_2O.py$ has a peak around 1 648 cm^{-1}, characteristic of the bending vibration of the water molecule, and a pair of bands in the region 3 000 – 3 530 cm^{-1}, characteristic of the stretching modes of the bonded water molecule (16) (Table I). The asymmetric stretching mode (ν_3) of U—O bond of the uranyl group in these complexes appears at 926 cm^{-1} in $UO_2(NO_3)_2.H_2O.py$, at 937 cm^{-1} in $UO_2(NO_3)_2.phen$, and at 943 cm^{-1} in $UO_2(NO_3)_2.dipy$ (Fig. 1). McGlynn, Smith, and Nealy (17), who made similar studies on the pyridine and *o*-phenanthroline complexes of uranyl nitrate, found ν_3 at 926 cm^{-1} for the pyridine complex and ν_3 at 945 cm^{-1} for the *o*-phenanthroline complex. Similarly the infrared studies on the *o*-phenanthroline and dipyridyl complexes of the plutonyl ion show that the asymmetric stretching mode (ν_3) of the Pu—O bond of the plutonyl group appears at 912 cm^{-1} in the plutonyl phenanthroline complex and at 918 cm^{-1} in the plutonyl dipyridyl complex (Fig. 2).

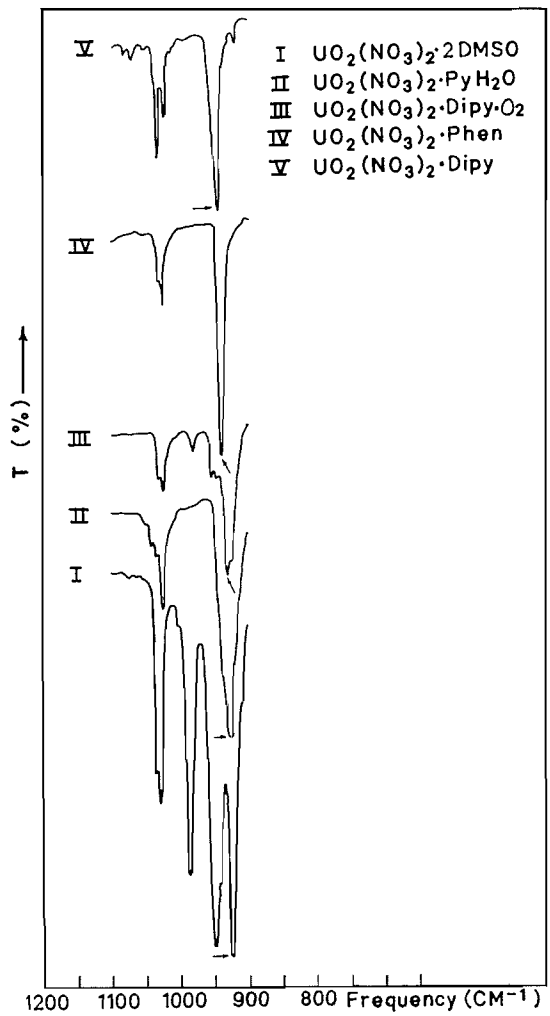

FIG. 1

In the complex $UO_2(NO_3)_2(dipy{\cdot}O_2)$, the ligand dipy-$O_2$, which forms a seven-membered chelate ring with the metal, very likely is present in a staggered conformation (7). In the spectrum of the complex, of the two ν(N—O) stretching vibrations, one appears as a sharp band at 1 222 cm^{-1} and the other appears as a medium band at 1 205 cm^{-1} (Table I). This lowering of the N—O stretching frequencies from the free ligand values of 1 262 cm^{-1} and 1 255 cm^{-1} (7) is attributed to oxygen–metal coordination. The sharp band at 929 cm^{-1} (Fig. 1) is assigned to the asymmetric (ν_3) stretching mode of the U—O bond of the uranyl group. Similarly for the plutonyl dipyridyl-N,N′-dioxide complex, the sharp band at 908 cm^{-1} (Fig. 2) is assigned to the asymmetric (ν_3) stretching mode of the Pu—O bond of the plutonyl group.

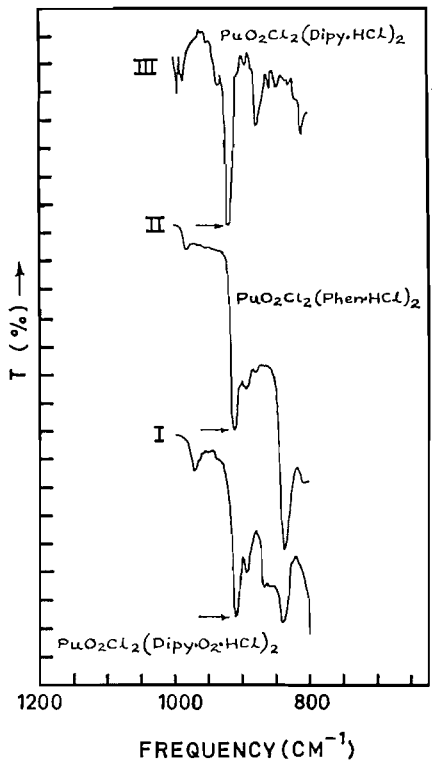

FIG. 2

The infrared spectrum of $UO_2(NO_3)_2.2DMSO$ is particularly informative because the S—O stretching frequency should indicate whether the ligand DMSO is coordinated through the oxygen or through the sulfur atom (18). Recent infrared studies on DMSO complexes of Th(IV), U(IV), and Pu(IV) show that for these metals coordination takes place through the oxygen of the ligand (19). The infrared spectrum of the complex $UO_2(NO_3)_2.2DMSO$ shows that the S—O stretching frequency is shifted to 985 cm^{-1}, from the free ligand value of 1 055 cm^{-1} (18). The strong absorption band at 922 cm^{-1} can be assigned to the asymmetric stretching mode (ν_3) of the U—O bond of the uranyl group (Fig. 1).

The infrared absorption bands assigned to the nitrate groups in the complexes indicate that these are coordinated to the metal (15, 20–23). The presence of bidentate nitrate

For personal use only.

groups and of eight-coordinated hexavalent uranium has been observed for crystalline rubidium uranyl nitrate (24), and an analogous structure has recently been established by X-ray diffraction studies (25) for the crystalline uranyl nitrate triethyl phosphate complex. By analogy with these structures it is, therefore, reasonable to propose an eight-coordination structure for the hexavalent uranium in our complexes, assuming the nitrate group to act as bidentate ligand.

In the case of plutonyl diamine hydrochloride complexes, it is very likely that each diamine is in the form of a monohydrochloride (26, 27, 28) and can act only as a monodentate ligand and therefore plutonium(VI) in these complexes can have six-coordination structure (29).

The uranium and plutonium of uranyl and plutonyl ions contain a large number of vacant orbitals (5f, 6d) available for coordination. A ligand which forms strong bonding with the metal can effectively hinder the shift of electrons from the oxygen to the metal, thus leading to a decrease in the strength of the multiple metal–oxygen covalent bond. The characteristic absorption frequency of the asymmetric vibration of the U—O bond of the uranyl ion and of the Pu—O bond of the plutonyl ion are shifted to lower values in all the complexes, from the free ion values of $965 \pm 1\ cm^{-1}$ and $962 \pm 1\ cm^{-1}$ respectively (11). Using the magnitude of this shift as a criterion of the relative complexing ability of the ligand, ligand series can be deduced (30) (Table I). The order of complexing ability of the ligands with the uranyl ion seem to be DMSO > py > dipy·O_2 > phen > dipy, and with the plutonyl ion the order is dipy·O_2 > phen > dipy. This order may also be taken qualitatively as a measure of the order of stability of these complexes.

The high stability of the uranyl dimethyl sulfoxide complex may be attributed to the ability of the oxygen atom of the ligand to form multiple bonds with atoms or groups which can readily accept π-bonding electrons available in the compact 2p level. The stability of the uranyl pyridine complex may also be attributed to the aromatic character of the nitrogen atom. The higher stability of the dipy·O_2 complex compared with that of *o*-phenanthroline and dipyridyl complexes may be attributed to the strength of the coordinative bond formed between an oxygen donor and the metal atom. In the case of phenanthroline and 2,2′-dipyridyl complexes, the highly conjugated phenanthroline is expected to form a stronger complex than that of dipyridyl.

Thermogravimetric experiments on $UO_2(NO_3)_2.H_2O$.py show that at 125 °C the water molecule is lost, giving rise to the anhydrous complex. At 195 °C the pyridine molecule is also lost and at about 550 °C the decomposition is complete, giving rise to U_3O_8. In the case of $UO_2(NO_3)_2$.dipy, at 310 °C the dipyridyl molecule is lost and further decomposition to U_3O_8 takes place at about 500 °C. The complex PuO_2Cl_2(dipy·O_2·HCl)$_2$ loses the two molecules of HCl at 170 °C and further decomposition to PuO_2 takes place at about 350 °C.

The magnetic susceptibility measurements show that the uranyl complexes are, as expected, weakly diamagnetic with X_m values ranging from -27×10^{-6} c.g.s. units to -103×10^{-6} c.g.s. units. The observed susceptibilities are $UO_2(NO_3)_2$.2DMSO, -69×10^{-6} c.g.s. units; $UO_2(NO_3)_2.H_2O$·py, -27×10^{-6} c.g.s. units; $UO_2(NO_3)_2$(dipy·O_2), -51×10^{-6} c.g.s. units; $UO_2(NO_3)_2$.phen, -103×10^{-6} c.g.s. units; and $UO_2(NO_3)_2$.dipy, -40×10^{-6} c.g.s. units. The plutonyl dipyridyl complex is paramagnetic. The magnetic susceptibility measurements were made over a limited temperature range. The X_m values are $2\,747 \times 10^{-6}$ c.g.s. units at 300 °K, $2\,649 \times 10^{-6}$ c.g.s. units at 311 °K, and $2\,483 \times 10^{-6}$ c.g.s. units at 328 °K. The effective magnetic moment is 2.6 BM. This value is much lower than that expected for $5f^2\ ^3H_4$ configuration with $\mu = 3.58$ BM. by

Russell-Saunders coupling scheme. Similar deviations have been observed for Pu(IV) and Pu(III) compounds (19, 31, 32) and are attributed to the spin–orbit interaction for 5f electrons. The greater spatial extension of the 5f wave functions results in large splitting of the 5f electrons by the crystalline field and the mixing of the ground multiplet $^3H_4$ levels of the free ion with the upper level (33, 34) and possibly to orbital angular momentum (L) reduction by covalent bonding (35).

ACKNOWLEDGMENT

SUBSTITUTIONAL AND CONFIGURATIONAL EFFECTS ON CHEMICAL SHIFT IN PYRANOID CARBOHYDRATE DERIVATIVES[1]

R. U. LEMIEUX AND J. D. STEVENS[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received January 25, 1965

ABSTRACT

The effects of long-range and virtual long-range coupling on the observed spectra of acetylated hexopyranoses and pentopyranoses are examined. Use is made of both spin decoupling and specific deuteration for the assignment of signals. It is seen that specific solvent effects on chemical shift can be superior to increasing the applied magnetic field for the resolution of the signals of closely related protons. The alteration of virtual long-range coupling effects in these ways can be useful in the diagnosis of spectra. Empirical rules are derived for estimating the long-range shielding effects which occur on changing configurations. It is seen that the inversion of a center can lead to deshielding of axial protons and to shielding of equatorial protons at other centers relative to the chemical shifts observed in reference compounds wherein all the acetoxy groups are in equatorial orientation. The effects in several cases result in equatorial protons giving their signal to higher field than chemically similar but axial protons. The conformational properties of pentopyranose tetraacetates as estimated from chemical shifts and coupling constants are seen to be in good agreement with expectations based on non-bonding interaction free energies. As expected, 2-deoxy-β-D-ribopyranose triacetate has the 1C-conformation when dissolved in chloroform.

INTRODUCTION

In 1958, Lemieux *et al.* (1) reported a study of the nuclear magnetic resonance (n.m.r.) spectra of a number of six-membered ring compounds. It was concluded that the proton of an equatorially oriented hydrogen comes into resonance at lower field than that of a chemically similar but axially oriented hydrogen. Also, the coupling constant between hydrogens on adjacent carbon atoms was observed to be two to three times greater when their projected bond angle is about 180° (anti-periplanar (2)) than when the angle is about 60° (*gauche* or syn-clinal (2)). These observations, which have since been used extensively (3–6) in structural and stereochemical studies, came primarily from a study of the acetylated aldopyranoses in which the hydrogen on C-1 (known as the anomeric carbon) is strongly deshielded, appearing as a doublet at low field, well removed from the signals produced by other hydrogens in the molecules. Although the spacing for this doublet was taken as the coupling constant, $J_{H\text{-}1,H\text{-}2}$, the spectra obtainable at that time were of poor quality by present standards and many of the signals were poorly resolved. As will be seen later on, due to virtual long-range coupling (7) the spacings were, in general, only approximately the coupling constant.

Since the time of this early study, advances in instrumentation have allowed us to examine in more detail the spectra of carbohydrate derivatives. Chemical shifts reported in this paper will be in parts per million (p.p.m.) from the internal standard, tetramethylsilane, and unless otherwise specified, spectra were recorded at 60 Mc.p.s. with a Varian A60 spectrometer.

A detailed assignment of the signals in the spectrum (Fig. 1A) of β-D-glucopyranose pentaacetate (I) in chloroform solution serves as an illustration of the chemical shifts observed for protons in this type of compound. The doublet of intensity one at lowest field

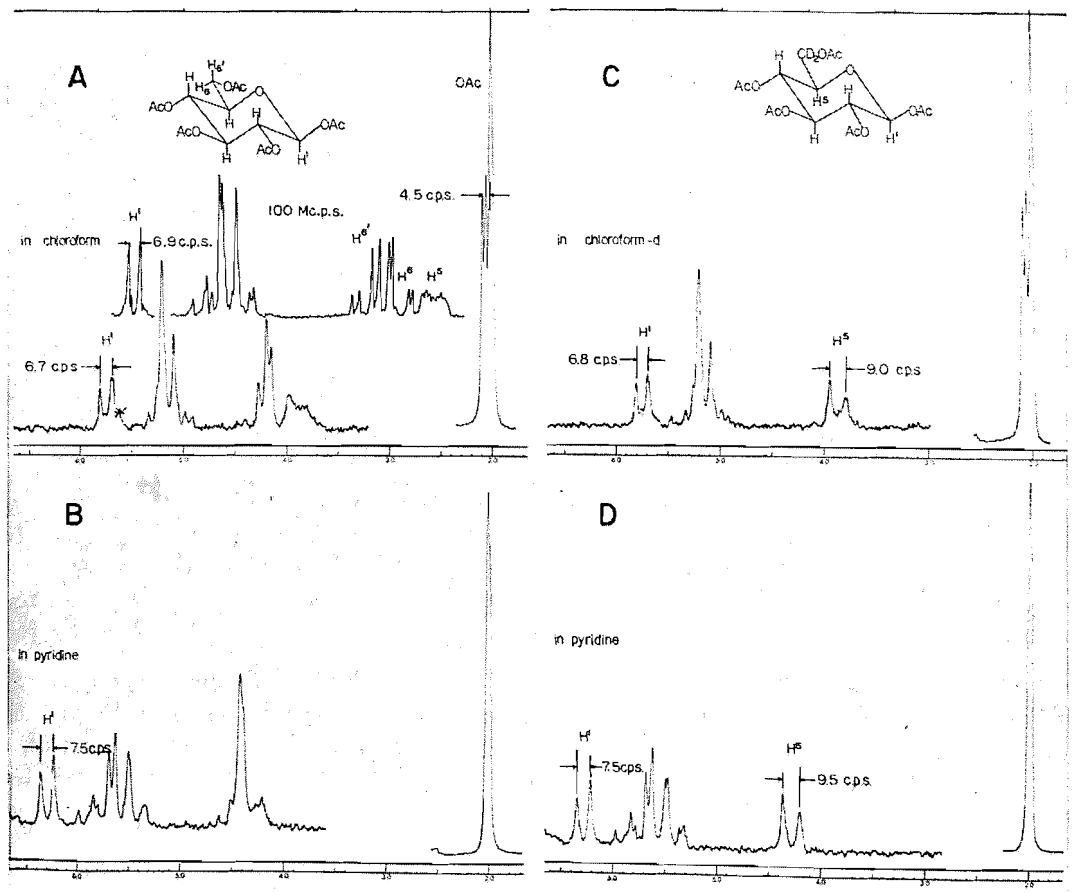

FIG. 1. Effects of solvent and deuteration on the n.m.r. spectrum of β-D-glucopyranose pentaacetate (I). A. I in chloroform. B. I in pyridine. C. 6,6′-Dideuterio-I in deuterated chloroform. D. 6,6′-Dideuterio-I in pyridine.

was assigned to the anomeric hydrogen and this assignment was verified by showing that the signal was absent in the spectrum of the C-1 deuterated derivative (1). The multiplets of total intensity three in the region 3.5–4.5 p.p.m. were assigned to the C-5 and C-6 hydrogens (1). 6,6′-Dideuterio-β-D-glucopyranose pentaacetate was now prepared from D-glucurone (8) and, as seen in Fig. 1C, the signal in this region was in fact reduced to a one-proton doublet arising from the H-5 proton. The spacings observed are in the range expected for the anti-periplanar arrangement of H-4 and H-5. The n.m.r. spectrum of I in deuterated chloroform at 100 Mc.p.s. is also shown in Fig. 1A. It is seen that the signals for the H-5, H-6, and H-6′ protons are now well shifted chemically. However, the group of signals arising from H-2, H-3, and H-4 in the region 4.8–5.5 p.p.m. remained virtually unchanged. That some increased shift between H-2 and H-3 took place is indicated by the change in the spacing of the signal for H-1 from 6.7 c.p.s. at 60 Mc.p.s. to 6.9 c.p.s. at 100 Mc.p.s. Furthermore, it is seen that the spacing for the H-1 signal increased to 7.5 c.p.s. when the spectrum (Fig. 1B) was measured at 60 Mc.p.s. using pyridine as solvent and, therefore, this solvent must have increased the chemical shift between H-2 and H-3.

Although the change in the solvent from chloroform to pyridine shifted H-3 from H-2,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

the change caused a decrease in the chemical shifts between H-5, H-6, and H-6′. It is seen therefore that specific solvent effects on chemical shift (c.p.s.) complement those obtained by changing the applied magnetic field. The signals for H-6′ and H-6 in the 100 Mc.p.s. spectrum (Fig. 1A) appear as an octet to lower field than the signal for H-5 at 3.87 p.p.m. Treating these three protons as an isolated ABX system, the following n.m.r. parameters were obtained, $\delta_A - \delta_B = 0.18$ p.p.m., $J_{AB} = 12.4$ c.p.s., $\delta_A - \delta_X = 0.4$ p.p.m., $J_{AX} = 4.7$ c.p.s., $J_{BX} = 1.9$ c.p.s. with $\delta_A = 4.27$ p.p.m. If one assumes staggered conformations for the substituents on C-5 and C-6 and that the conformation wherein the 4- and 6-acetoxy are opposed has negligible population, the A-proton can be assigned to the proton at C-6 which is anti-periplanar with H-5 in one of the conformations wherein the 6-acetoxy group is *gauche* (syn-clinal) to the ring-oxygen, namely H-6′. As can be seen in Fig. 4A, the signals for H-6′ and H-6 of β-D-mannopyranose pentaacetate show, as would be expected, a very similar pattern. The H-6 and H-6′ protons are well resolved in the 100 Mc.p.s. spectrum for α-D-gulopyranose pentaacetate (Fig. 2D). The coupling constants calculated for these protons (5.3 and 7.6 c.p.s.) are of magnitudes which require a low population for the conformation wherein the 4- and 6-acetoxy groups are in opposition and H-5 is *gauche* to both H-6 and H-6′.

Virtual long-range coupling (7) refers to second-order effects on the signal of X in a system of protons, ABCX (9), wherein J_{AB} is large as compared to δ_{AB} and B is not appreciably coupled to X. Under these circumstances, B has a long-range effect on the spin states of X although it may not be directly coupled to X. Anet (10) has described this effect in connection with the structure of signals of *C*-methyl groups. The occurrence of this phenomenon is well displayed in the spectra of the 6,6′-dideuterio derivative of I. It is seen that both the signals for H-1 and H-5 are not well defined in the spectrum (Fig. 1C) obtained using chloroform as solvent. On the other hand, these signals are better defined sharper doublets in the spectrum (Fig. 1D) using pyridine as solvent. That virtual long-range coupling effects were probably still present in the latter spectrum is suggested by the larger spacing of 8.0 c.p.s. observed for the signal of H-1 in the spectrum of 3-*O*-methyl-β-D-glucopyranose tetraacetate in the same solvent (see Fig. 2A). The signal for H-3 ($\delta_{H\text{-}3}$ = 3.87 p.p.m.) is now well shifted from those for H-2 and H-4 ($\delta_{H\text{-}2} \simeq \delta_{H\text{-}4} \simeq$ 5.42 p.p.m.). The signals for H-2 and H-4 remained virtually superimposed in the spectrum which was obtained using pyridine as solvent. This may be related to their both being in axial orientation on the same side of the ring. This type of phenomenon, like that observed (11) for specific deshielding by chloride ions, may prove of value in stereochemical studies. For example, it could be speculated that, in the spectrum for I in pyridine (Fig. 1A), it is the signal for H-3 that is shifted downfield from the signals for H-2 and H-4 which are on the same side of the pyranose ring.

As seen in Fig. 2B, the signal for the anomeric proton of β-D-galactopyranose pentaacetate appears at 60 Mc.p.s. as a quartet with the smaller spacing amounting to 1.0 c.p.s. Superficially, this spacing could be considered to arise from long-range coupling. However, when the spectrum was measured at 100 Mc.p.s., the signal for the anomeric proton appeared as a sharp doublet with a spacing of 8.4 c.p.s. with the two branches of much more nearly the same intensity. Obviously, therefore, the anomeric proton is not long-range coupled but, instead, the quartet structure of the signal observed at 60 Mc.p.s. must have arisen from virtual long-range coupling. This observation renders it clear that caution must be exercised in assigning long-range coupling to spectra subject to the phenomenon of virtual long-range coupling. The occurrence of virtual long-range coupling in this compound was not surprising in view of the fact that H-2 and H-3 were estimated to be chemically shifted by only about 0.2 p.p.m. and coupled to an extent of 10.2 c.p.s. In the case of α-D-gulopyranose pentaacetate (Fig. 2D), H-1 appeared definitely long-range coupled (about 1.3 c.p.s.) to H-3. This observation is not surprising in view of the equatorial orientations for both these hydrogens (12). Similarly, the equatorial H-5 of α-D-ribopyranose tetraacetate was found to be long-range coupled (about 0.7 c.p.s.) to the equatorial H-3 (see Fig. 5B). Irradiation of H-1 of α-D-gulopyranose pentaacetate caused the complex multiplet due to H-4 to collapse to a quartet. This coupling, about 0.7 c.p.s., over five bonds appears less commonly observed than the coupling over four bonds. It is noteworthy that spin-decoupling experiments at 100 Mc.p.s. (see Fig. 3B) showed the axial H-3 of 6,6′-dideuterio-α-D-glucopyranose pentaacetate to be weakly long-range coupled to both the equatorial H-1 and the axial H-5.

In contrast to the case of β-D-glucopyranose pentaacetate (I), the signal produced by H-1 in α-D-glucopyranose pentaacetate (II) did not change in spacing, 3.3 c.p.s., or sharpness on changing the solvent from chloroform to pyridine (compare Figs. 3A and 3C). This is not surprising since there was virtually no change in the structure of the band of signals arising from H-2, H-3, and H-4. That the signal for H-3 in these spectra is centered at about 5.5 p.p.m. (chloroform) and 5.89 p.p.m. (pyridine) and about 0.4 p.p.m. to lower

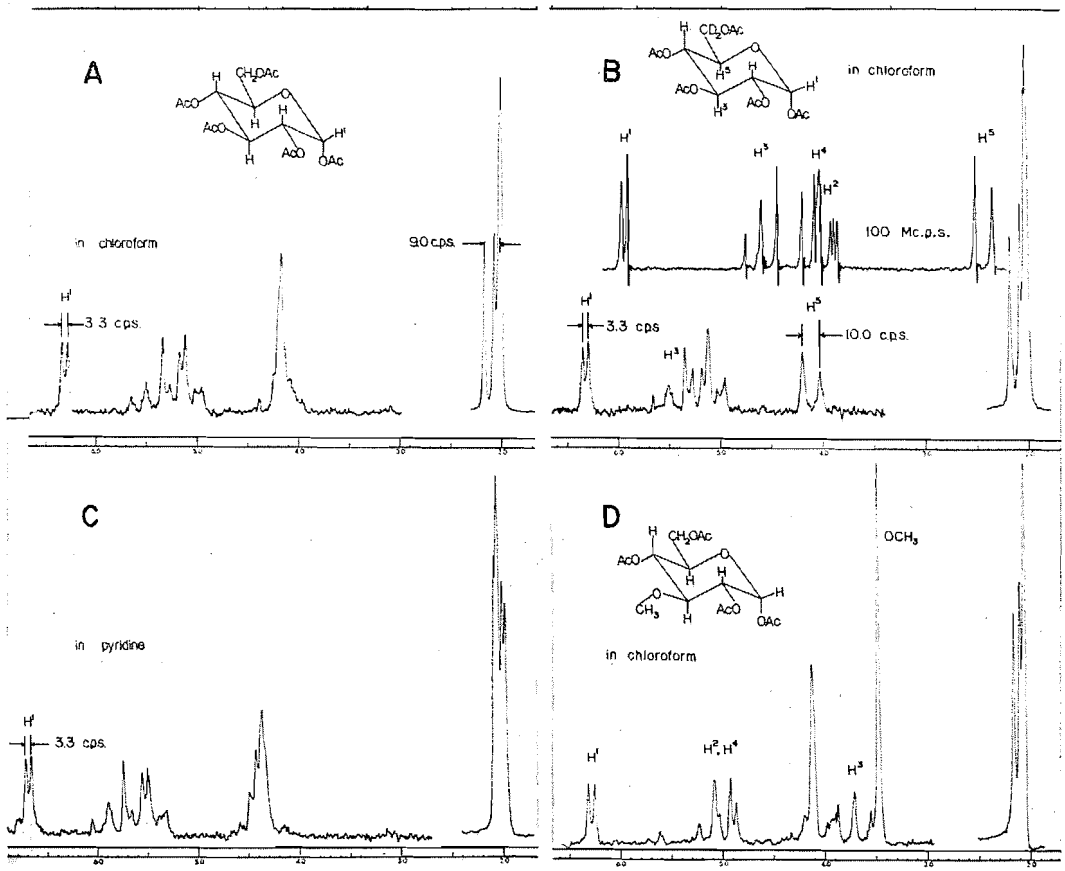

FIG. 3. Substitutional and solvent effects on the n.m.r. spectrum of α-D-glucopyranose pentaacetate (II). A. II in chloroform. B. 6,6′-Dideuterio-II in chloroform. C. II in pyridine. D. 3-*O*-Methyl-α-D-glucopyranose tetraacetate.

field than the signals for H-2 and H-4 in both spectra was deduced from the effect of the change in configuration on the chemical shift for H-5. This is best considered on the basis of the spectra obtained for the 6,6′-dideuterio derivatives of I and II. It is seen that the signal for H-5 is at 3.88 p.p.m. for the β-anomer (Fig. 1C) and at 4.12 p.p.m. (Fig. 3B) for the α-form. This deshielding effect by an axial oxygen on opposing axial hydrogens was consistently observed in all the pyranose compounds examined. It is on this basis that the above-mentioned assignment of the signal for H-3 could be made. In accordance with this assignment, irradiation of the H-5 signal in the 100 Mc.p.s. spectrum of 6,6′-dideuterio-α-D-glucopyranose pentaacetate in chloroform caused the collapse of a triplet signal at 5.13 p.p.m., with a spacing of 10.0 c.p.s. which must arise from H-4. Therefore, the now well-defined quartet at 5.5 p.p.m. with spacings of 9.4 and 10.0 c.p.s. must indeed arise from H-3. In the spectrum, H-2 appeared as a quartet centered at about 5.08 p.p.m. with spacings of 4.0 and 10.0 c.p.s. The signal for H-3 of 3-*O*-methyl-α-D-glucopyranose tetraacetate (III) was 0.22 p.p.m. to lower field than the signal for the corresponding hydrogen in the β-anomer (compare Figs. 2A and 3D). The signal for H-5 in III was obscured by the signals for the two hydrogens at the 6-position but evidently to substantially lower field than the corresponding signal in the spectrum, under the same conditions, for the β-anomer.

This deshielding effect by axial oxygen in opposing axial hydrogens has proven very useful in this laboratory for the assignment of configurations to anomeric pairs of compounds and is particularly useful when the signals for the anomeric protons are obscured or when the coupling constants for the anomeric protons do not allow an unequivocal conclusion. An example of the latter situation is provided by the anomeric pair of the D-mannopyranose pentaacetates (see Figs. 4A and 4B). For both these compounds, H-1 and H-2 are in *gauche* relationship and an assignment of the anomeric configurations based on the spacings of the signals for the anomeric proton would not be feasible. An assignment could be made on the basis of their relative chemical shifts by assigning the equatorial orientation (α-configuration) to the anomer with the signal for H-1 at lower field (1). However, as will be seen later on, this generalization that equatorial protons produce their signals at lower field than chemically similar but axial protons can have exceptions depending on the overall shielding effects operating in the molecule. Therefore, it is useful to note that the configurational assignment is supported by the relative positions of the signals for H-5 in this pair of anomers. As expected, the axial 1-acetoxy group of the α-anomer has a deshielding effect on H-5.

The chemical shift of an equatorial proton in acetylated pyranose structures is strongly influenced by the orientation of the acetoxy groups at the neighboring centers. The chemical shifts for the anomeric protons of α-D-glucopyranose pentaacetate (II) and α-D-mannopyranose pentaacetate are 6.33 and 6.07 p.p.m., respectively. Thus, inversion of the 2-position from the equatorial to the axial orientation for the acetoxy group shielded the equatorial 1-proton by 0.26 p.p.m. It is seen in Fig. 4A that one of the protons at the 2-, 3-, or 4-position of β-D-mannopyranose pentaacetate produced its signal at substantially lower field (about 0.25 p.p.m.) than the other two protons. Spin decoupling at 100 Mc.p.s. showed the low field signal to arise from H-2. It is seen that this signal moved to higher field on changing the configuration at the 1-position to form the α-anomer. Thus, again we see a greater shielding effect on an equatorial proton by a neighboring axial acetoxy group than by an equatorial acetoxy group.

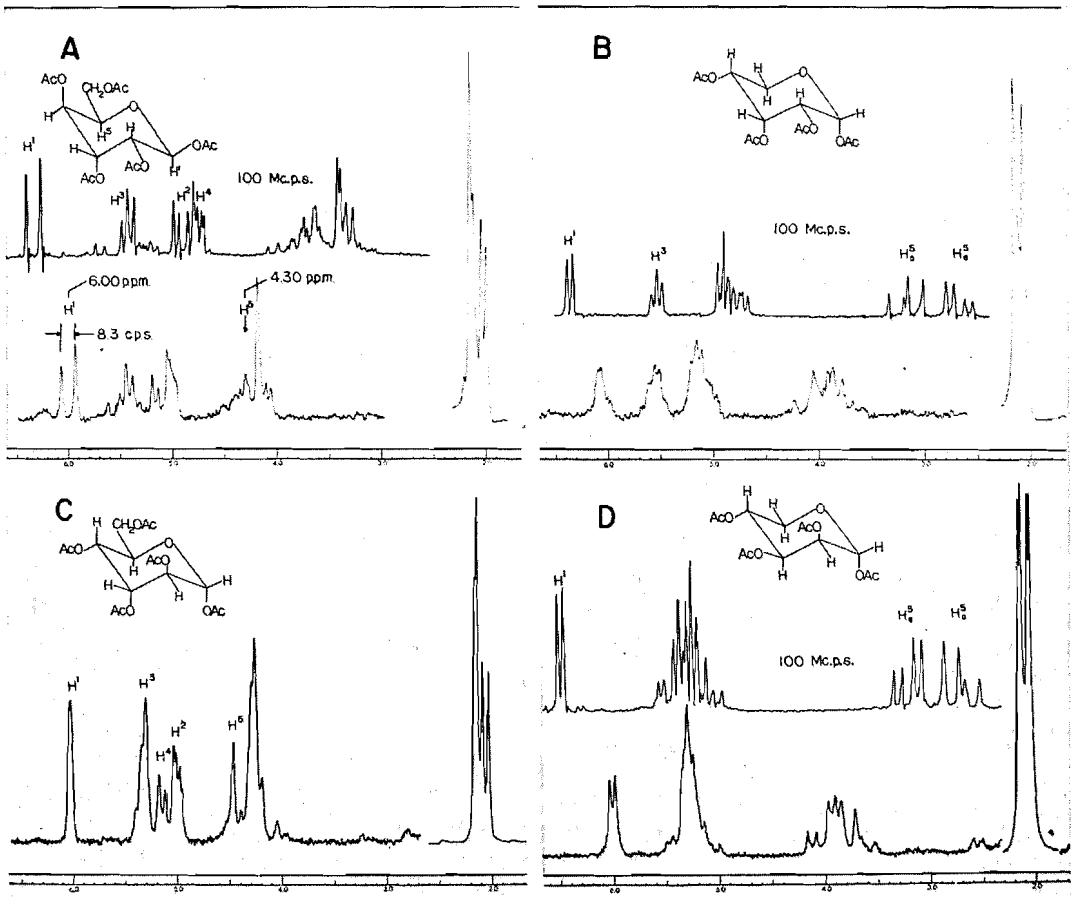

FIG. 5. Nuclear magnetic resonance spectra of sugar acetates in chloroform solution. A. β-D-Gulopyranose pentaacetate. B. α-D-Ribopyranose tetraacetate. C. α-D-Altropyranose pentaacetate. D. α-D-Lyxopyranose tetraacetate.

The spectra for the pentaacetates of β-D-allopyranose, β-D-gulopyranose, and α-D-altropyranose are presented in Figs. 4C, 5A, and 5C, respectively. The sharp triplet at 5.69 p.p.m. in the spectrum of the allose derivative is readily assigned on the basis of the spacings, 2.8 c.p.s., to the equatorial H-3. When the configuration was changed at the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

4-position to produce the gulose derivative, as expected, the signal for the 3-proton shifted upfield by at least 0.25 p.p.m. When the configuration of the allose derivative was changed at both the 1- and 2-positions to form the α-altrose derivative, the position of H-3 was shifted from 5.69 p.p.m. to 5.34 p.p.m. The position of H-3 in the spectrum for the altrose derivative was established by detailed examination at 100 Mc.p.s. The position of the equatorial H-2 was found to be at 5.00 p.p.m. Thus, the axial acetoxy groups at both the neighboring positions have strongly shielded this equatorial proton, to such an extent that it produces its signal to substantially higher field than the chemically similar but axial proton at the 4-position. This exception to the rule for the chemical shifts of chemically similar axial and equatorial protons arises mainly because of the superposition in this molecule of deshielding of the axial H-4 by the axial 2- and 3-acetoxy groups and the shielding of the equatorial H-2 by the axial acetoxy groups at the 1- and 3-positions. That an equatorial acetoxy has a greater shielding effect on a neighboring axial proton than has a neighboring axial acetoxy group is apparent from a comparison of the chemical shifts for the anomeric protons of β-D-glucopyranose pentaacetate, 5.75 p.p.m., and β-D-mannopyranose pentaacetate, 5.93 p.p.m. Also, the signal for H-5 in β-D-glucopyranose pentaacetate is 0.25 p.p.m. to higher field than the signal for the corresponding proton in β-D-galactopyranose. The n.m.r. spectra of both the anomeric pairs of the tetraacetates of methyl D-glucopyranuronate and methyl D-galactopyranuronate were measured in chloroform solution. The signals for the H-5 protons in these compounds appeared as doublets with spacings of 9.5 c.p.s. for the *gluco*-configuration and 1.5 c.p.s. for the *galacto*-configuration. The signals for H-5 were 4.20 and 4.58 p.p.m. for the *β-gluco* and *β-galacto* compounds, respectively, and 4.41 and 4.78 p.p.m. for the α-anomers, respectively. The positions of the signals for the H-5 protons of the α-anomers to lower field (0.2 p.p.m.) than the corresponding signals for the β-forms is attributed to the deshielding effect of the axial 1-acetoxy groups in the α-compounds. It is seen that changing the configuration at the 4-position in each case caused a deshielding of the H-5 proton. Therefore, it is apparent that a change in the configuration of an asymmetric center in these compounds which brings an acetoxy group from the equatorial to the axial orientation produces a deshielding effect on a neighboring axial proton but a shielding effect on a neighboring equatorial proton. On this basis, the chemical shifts observed for the ring protons in α-D-altropyranose pentaacetate are understandable with the compound in the chair conformation with the acetoxy groups at the 1-, 2-, and 3-positions in axial orientation. This conformation is also supported by the coupling of H-4. The spacings of the signal observed in the 100 Mc.p.s. spectrum were 9.2 and 3.3 c.p.s. Therefore, H-4 must define a dihedral angle of about 180° with H-5.

The following approximate empirical rules account well for the observed effects of changes in configuration on chemical shift using the chemical shifts of the ring protons of β-D-glucopyranose pentaacetate as the reference signals.

(1) If the proton under consideration has remained axial; (*a*) add 0.20 p.p.m. for an axial acetoxy group at a neighboring position, (*b*) add 0.25 p.p.m. for an opposition of the proton by an axial acetoxy group.

(2) If the proton under consideration has achieved the equatorial orientation; (*a*) add 0.60 p.p.m. because of the change from the environment of an axial hydrogen to that of an equatorial hydrogen (1, 13), (*b*) subtract 0.20 p.p.m. for an axial acetoxy group at a neighboring position, (*c*) subtract 0.20 p.p.m. for an axial acetoxy group at the next to neighboring position. This latter rule was derived primarily from a consideration of the spectra for pentopyranose tetraacetates. Thus, it is seen that, whereas axial acetoxy

groups have deshielding effects on axial protons (relative to the effects of equatorial acetoxy groups), shielding effects are observed when the ring-proton is in equatorial orientation.

*Calculated using the empirical rules described in the text and β-D-glucopyranose pentaacetate as the reference compound.

Table I shows the agreement obtained between the chemical shifts observed for the H-1 and H-5 protons of a number of hexopyranose pentaacetates and those estimated using this procedure. It is seen that the agreement is quite good and the procedure therefore well summarizes the main conclusions reached in this study of configurational effects on chemical shift. The agreement was not nearly as good for the protons at the 2-, 3-, and 4-positions. The worst discrepancy was with the 2- and 4-protons of β-D-allopyranose pentaacetate. The above-mentioned rules would predict a chemical shift of about 5.4 p.p.m. for these protons when in fact the chemical shift was about 5.0 p.p.m. The position of the 3-proton was at 5.68 p.p.m. in better agreement with the calculated value of 5.8 p.p.m. In the case of β-D-mannopyranose pentaacetate, the above rules would require the signal for the axial H-4 to be about 0.05 p.p.m. to lower field than that for the axial H-3. Spin-decoupling experiments at 100 Mc.p.s. in fact showed this to be the case, $\delta_{H-3} = 5.21$, $\delta_{H-4} = 5.30$ p.p.m. Similarly, for β-D-galactopyranose pentaacetate, the axial H-2 was found at lower field than the axial H-3, $\delta_{H-2} = 5.34$, $\delta_{H-3} = 5.16$ p.p.m. This substantiates the conclusion that in general the deshielding of an axial hydrogen by an opposing axial acetoxy group is somewhat greater than that by a neighboring axial acetoxy group.

The readily derived n.m.r. parameters for six acetylated pentoses and 2-deoxy-β-D-ribopyranose triacetate are presented in Table II. Judging from the coupling constants between a number of the vicinal protons, it is obvious that some of the compounds when dissolved in chloroform are either in conformations other than the chair forms or have appreciable populations for both the chair conformations. There can be little doubt that none of these structures have boat conformations. Certainly, the polysubstituted six-membered pyranose rings of sugar structures cannot be expected to have exactly chair conformations. Some deviation from the precisely staggered arrangement for neighboring groups must be expected. Nevertheless, it is considered that the chair conformation provides a useful approximation of the conformations possessed by acetylated sugar structures. The following discussion of the conformations of the pentopyranose tetraacetates support this contention.

Application of the non-bonded interaction free energies derived by Lemieux and Chü (14) for the anomerization equilibria of hexose pentaacetates suggests that, except for the compounds possessing the β-D-*ribo* and β-L-*arabino* configurations, at least 90% of the pentose tetraacetates listed in Table II should exist in chloroform solution in the C1-conformation (15). On this basis, it would be expected that the configurational effects on chemical shift mentioned above in connection with the spectra of the hexose pentaacetates could be used to predict the changes in chemical shift which would result from changes in the configuration of the reference compound, β-D-xylopyranose tetraacetate. The results of the calculations for the H-1, H-5, and H-5′ protons are given in Table II. It is seen that in general the calculated chemical shifts are in good agreement with the observed chemical shifts. With the exception of the β-L-*arabino* and 2-deoxy-β-D-*ribo* compounds, the assignment of the signals arising from H-5 and H-5′ are readily made on the basis of their coupling constants with H-4. It is clear, however, from the coupling constants obtained for β-D-ribopyranose tetraacetate (the spectrum is reproduced in Fig. 4D) that this compound must exist to an appreciable extent in the 1C-conformation. In fact, an estimate of the position of the chair–chair equilibrium based on the non-bonded interaction energies (14) suggests that this compound should exist to about equal extents in the C1- and 1C-conformations. On this basis and using $J_{H\text{-}1,H\text{-}2} = 7.0$, $J_{H\text{-}4,H\text{-}5} = 12.0$, and $J_{H\text{-}4,H\text{-}5'} = 5.2$ c.p.s. for the C1-conformation and $J_{H\text{-}1,H\text{-}2} = 2.8$, $J_{H\text{-}4,H\text{-}5} = 2.3$, and $J_{H\text{-}4,H\text{-}5'} = 1.6$ c.p.s. for the 1C-conformation, the expected coupling constants are 4.7, 7.2, and 3.4 c.p.s., respectively, in fairly good agreement with the observed values. The above expected coupling constants are estimated from the data for the xylose tetraacetates and the 2-deoxy-β-D-ribose triacetate given in Table II. No greater precision is expected from this treatment other than to show that the two chair conformations are in fact abundant for this compound. That the compound exists in chair conformations seems evident from the values for $J_{H\text{-}2,H\text{-}3}$ and $J_{H\text{-}3,H\text{-}4}$. The predicted chemical shifts for H-1, H-5, and H-5′ for the compound in the 1C-conformation are 6.15, 3.8, and 4.05, respectively, and therefore virtually the same as those anticipated on the basis of the C1-conformation. The agreement found between the observed and calculated chemical shifts for this compound given in Table II is therefore not surprising. On the basis of the conformational properties of β-D-ribopyranose tetraacetate and of β-L-arabinopyranose tetraacetate [about 80% C1-conformation (14)], 2-deoxy-β-D-ribopyranose triacetate must be expected to exist in solution virtually completely in the 1C-conformation. In fact, the chemical shifts and coupling constants observed for this compound can only be rationalized using the 1C-conformation.

The data given in Table II require that, in the case of α-D-ribopyranose tetraacetate, the signal for the equatorial hydrogen at the 5-position is at higher field than that for the similar but axial geminal hydrogen. It seems probable that the same situation exists for the β-L-*arabino* and 2-deoxy-β-D-*ribo* compounds. The assignments given for these compounds in Table II are made on this basis. As was seen above in the spectrum of α-D-altropyranose pentaacetate, long-range shielding effects arising from substituents at other positions can more than compensate for the shift normally found between similar hydrogens differing in orientation. A similar situation was encountered in the spectra for the anomeric D-gulopyranose pentaacetates. In each case the signal for the axial H-2 was at lower field than that for the equatorial H-4 as shown by spin-decoupling experiments at 100 Mc.p.s. Nickon and co-workers (16) have observed a similar phenomenon for the α-protons of steroidal α-haloketones. Thus, it is abundantly clear that the assignment of configurations based on the simple generalization that equatorial hydrogens produce

signals at lower field than chemically similar but axial protons is a hazardous procedure when applied to complex structures. On the other hand, it is apparent that with the development of sufficient insight on the nature of long-range effects on chemical shift, the chemical shift data will prove as valuable as coupling constants for the determination of points of configuration. Hall (17) has recently reviewed and commented on the effects of changes in the configuration at the 2-position of sugar structures on the chemical shifts of the anomeric protons.

A consideration of the signals for the protons of the acetoxy groups in the spectra of the sugar acetates presented in Figs. 1–5 shows that, as previously noted (1), axial acetoxy groups tend in general to produce their signal to lower field than equatorial acetoxy groups. It is clearly evident, however, that there is no definite regularity to the chemical shift involved and, indeed, exceptions to the rule are seen in several instances. Also, the spectra in Fig. 1 show the effect to be strongly solvent dependent. Therefore, although useful as guides toward the determination of configurations, these chemical shifts are unreliable as evidence for configurational assignments. Any doubts thus cast on the assignment of the signals for the acetyl groups in 1-trideuterio-*O*-acetyl-β-L-arabinose triacetate (14) seem dispelled by the chemical shift data given in Table II.

EXPERIMENTAL

Except for β-D-gulopyranose pentaacetate and 3-*O*-methyl-α-D-glucopyranose tetraacetate, the compounds used in this investigation were prepared by well-established procedures (1). The preparation of the 6,6′-dideuterio-D-glucose is reported elsewhere (8).

β-D-Gulopyranose pentaacetate was prepared as a sirup, $[\alpha]_D$ +2.4° (*c*, 5 in chloroform), by reaction of sirupy tetra-*O*-acetyl-D-gulopyranosyl bromide with silver acetate in acetic acid.

Sirupy 3-*O*-methyl-α-D-glucopyranose tetraacetate was prepared by anomerization of the crystalline β-form (18) by the standard procedure using sulfuric acid in acetic anhydride and was purified by chromatography on silicic acid using chloroform as eluant.

The 100 Mc.p.s. spectra were measured on a Varian HR-100 spectrometer and the spin-decoupling experiments were performed as previously described (13, 19).

ACKNOWLEDGMENTS

The 60 Mc.p.s. spectra were measured by Mr. R. Swindlehurst and Mrs. G. Conway and those at 100 Mc.p.s. by Mr. G. Bigam of this department.

TRIDENTATE COMPLEXES OF PERIODATE AND SOME FURANOSE DERIVATIVES[1]

A. S. PERLIN AND E. VON RUDLOFF
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received March 4, 1965

ABSTRACT

1,2-*O*-Isopropylidene-α-D-glucofuranose (I) is highly resistant to glycol scission by periodate in alkaline solution. This atypical effect is caused by preferential formation of a stable periodate complex. Proton magnetic resonance spectroscopy shows that the 3-, 5-, and 6-protons of I (and the 3- and 5-protons of I-6,6′-d_2) become strongly deshielded during this process, which, together with accompanying changes in proton–proton coupling, establishes that the complex (II) has a 3,5,6-tridentate structure. Variations in the stability of II with pH suggest that it can exist either as a monoanion or dianion. A complex analogous to II is formed by ethyl α-D-thioglucofuranoside, whereas methyl β-D-galactofuranoside forms a complex that probably has the 2,5,6-structure. The characteristics of these tridentate complexing reactions support the general concept that a five-membered cyclic complex is a transient intermediate of α-glycol oxidation by periodate.

For personal use only.

During recent studies (1) on the oxidation of various *vic*-diols with a weakly alkaline solution of periodate containing a small proportion of permanganate (2), it was found that the 5,6-diol group of 1,2-*O*-isopropylidene-α-D-glucofuranose (I) is cleaved far more slowly than it is by periodate in acid solution (Table I, Nos. 1 and 2). Although the rate of glycol scission by periodate may be retarded as the pH is raised (3, 4), the lessened reactivity of I appeared far too marked to be attributed to such a cause.[2] Another effect of pH has been encountered (5) with some sugars possessing a *cis*,*cis*-1,2,3-triol grouping on a six-membered ring. Several moles of periodate are consumed rapidly by these sugars at pH 4.5, but only 1 mole is taken up quickly at pH 7. This periodate is not actually *reduced*, but is complexed so strongly with the polyol that it is not backtitrated by arsenite. Although the isopropylidene derivative (I) did not show an *apparent* uptake of this kind, the likelihood has been examined that its slow oxidation rate in the presence of alkali is due to the competitive formation of a stable periodate complex.

The type of complex discovered by Barker and Shaw (5) requires proper orientation of three hydroxyl groups and hence probably has a tridentate structure. It appeared feasible that the 3-, 5-, and 6-hydroxyl groups of I might also satisfy steric requirements of a tridentate complex in which iodine is the central atom, as illustrated in II (the periodate moiety is only partially represented here for simplicity). Thus, for example, triorthoesters of I are known (6, 7). In such an event, the fact that the 5,6-diol group is not oxidized at higher pH, whereas numerous structurally related *vic*-diols are, could be attributed to the presence in I of a suitably positioned 3-hydroxyl group. Therefore, it is pertinent that 3-*O*-ethyl-1,2-*O*-isopropylidene-α-D-glucofuranose (III) behaves normally, rapidly consuming 1 mole of periodate under alkaline conditions (Table I, No. 8).

A clear demonstration that a tridentate complex such as II is formed between the isopropylidene derivative (I) and periodate at a pH of 8.5 is afforded by n.m.r. spectroscopy. The spectrum of I in deuterium oxide containing potassium carbonate (Fig. 1A) is altered drastically when sodium metaperiodate is added (Fig. 1B). That these changes are not due to oxidation is readily apparent from the different sort of spectrum obtained when

TABLE II

Reaction of complex II* with arsenite (19). Apparent periodate uptake (mole/mole)

	Reaction time (min) 15	30	60	120
At 25°	0.67†	0.35	0.18	0.12
At 95°	0.10†	—	—	—

*Formed by 5 min reaction at pH 8.5 as in experiment No. 4, Table I.
†The uptake according to the thiosulphate method was 0.05 mole/mole (No. 3, Table I).

I is oxidized at pH 4.5 (see ref. 8), or when the 3-*O*-ethyl derivative (III) is oxidized at pH 8.5.[3] To preclude appreciable oxidation of I at pH 8.5, the interaction must be not only extremely rapid but also essentially quantitative; its quantitative nature can be assessed independently, in fact, since the various resonance signals in Fig. 1B are integer values. A particularly noticeable difference between Figs. 1A and 1B is the marked displacement towards lower field in the latter spectrum of signals for the 3-, 5-, and 6-protons such as occurs when hydroxyl groups in α-position are acylated (9) or are involved in borate complexing (10). Although these signals are well differentiated and hence readily identified with the corresponding protons in II, a clear confirmation of these assignments was obtained by using 1,2-*O*-isopropylidene-D-glucofuranose-6,6′-d_2.[4] The complex now

[3]*Compound I was oxidized slowly under these conditions, however, this reaction being easily detectable by the appearance of a sharp singlet due to the protons of liberated formaldehyde (C_6) at 12 c.p.s. downfield from the* DOH *signal. The intensity of this signal increased progressively over a period of 24 h, at which time 1 mole of periodate per mole of I had been reduced and the spectrum had become closely similar to that obtained in the oxidation at pH 4.5 (8).*

[4]*This di-deuterio- derivative was kindly provided by Dr. W. Mackie.*

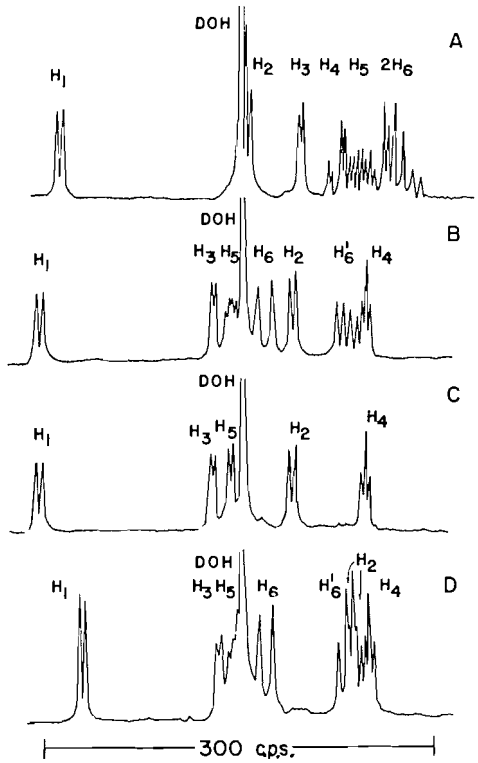

FIG. 1. Nuclear magnetic resonance spectra (100 Mc/s) in deuterium oxide – potassium carbonate solution (pH 8.5) of (A) 1,2-*O*-isopropylidene-α-D-glucofuranose, (B) 1,2-*O*-isopropylidene-α-D-glucofuranose *plus* 1 molar equivalent of sodium periodate, (C) 1,2-*O*-isopropylidene-α-D-glucofuranose-6,6′-d_2 *plus* 1 molar equivalent of sodium periodate, (D) ethyl α-D-thioglucofuranoside *plus* 1 molar equivalent of sodium periodate. In A, B, and C the two signals for the protons of the two C-methyl groups are omitted, and in D signals for the ethyl protons are omitted; the chemical shift of these protons is virtually unaffected by complexing.

afforded a spectrum (Fig. 1C) in which the signals that had been ascribed to H_6 and H_6' (Fig. 1B) are absent. Also, the quartet ascribed to H_5 in Fig. 1B is reduced to a doublet, as is to be expected when detectable coupling with H_6' has been eliminated. Hence the spectral data show that compound I forms a complex with the periodate ion at high pH and also, by directly implicating the 3-, 5-, and 6-hydroxyl groups, clearly demonstrate that this complex has a tridentate structure.

In contrast to the strong deshielding of the 3-, 5-, and 6-protons, H_2 and H_4 experience a notable increase in shielding as I is converted into II. Noteworthy also is the fact that the signal for one of the 6-protons (6′ in II) is not displaced nearly so far towards lower field as is that of the other. This intermediate result could conceivably be due to an interplay of two opposing effects: i.e., the proton may be subjected not only to the intense deshielding introduced when complexing occurs at the α-position, but also to the moderate shielding influence such as evident for H_2 and H_4.

Proton–proton coupling values in Fig. 1 agree well with measurements of carbon–hydrogen bond dihedral angles in molecular models of I and II. In making these comparisons the model of I was oriented so that C_2 was below and C_3 above a plane defined by the C_1, ring O, and C_4 atoms. Such a conformation has been depicted by Abraham *et al.* (11) for various derivatives of I, and should apply equally well for I itself since the ring

I (R = H)
III (R = C_2H_5)

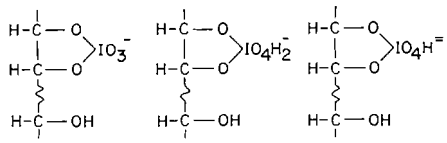
II

proton coupling values in spectrum 1A are very close to those reported in ref. 11. According to the models the reaction I → II need involve little change in H_1—H_2 coupling and H_3—H_4 coupling, and a comparison of the pertinent signals in Figs. 1, A, B, and C shows that these values do, in fact, remain constant. Hence, the conformation of the fused 1,3-dioxalane and furanose rings in II is probably the same as in I. The fact that complexing occurs does not in itself serve to define this conformation, because a model of II can be constructed readily when the rings are puckered in the opposite sense (i.e., with C_3 down and C_2 up). However, the 3-, 4-, and 5 protons of the complex must be staggered in a nearly symmetrical fashion since H_3 and H_5 are coupled equally with H_4 (Fig. 1, B or C). Such an arrangement is found in the conformation depicted, with C_3 above the plane of the furanose ring, but is not possible in the alternative conformation.

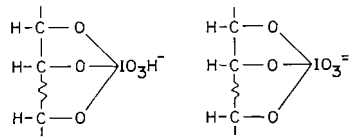
The major change to be expected when the complex is formed is a realignment of the 5- and 6-carbinol groups from an orientation in which they likely are directed away from the furanose ring in I (perhaps as in formula I) to an arrangement (as in II) in which they have been rotated upon the C_4—C_5 bond in an arc of about 120° towards the ring. The spectral data are in good agreement on this point with what would be predicted by the Karplus relationship (12, 13). Thus, the change in $J_{4,5}$ (evident most clearly in the H_4 signals of Fig. 1, A and B and the H_5 signal of Fig. 1C) corresponds to a decrease in the C_4H–C_5H dihedral angle from a value of perhaps 180° in I to a value of 40–50° in II. Similarly, the data are consistent regarding the orientation of the 5- and 6-protons in the complex. According to the model of II, H_5 subtends an angle of 90° with H_6 and 30° with H_6' and the corresponding dihedral angles estimated from the observed values of J (i.e., 0 and 5 c.p.s.) are 90° and 35° (12, 13).

The tridentate type of structure (II) may be regarded as one of a variety of cyclic periodate complexes that can arise as a result of changes in the degree of dissociation and hydration of periodate at different hydrogen ion concentrations (14). According to Bunton and colleagues (4, 15) the monocyclic type formed as a transient intermediate in glycol-scission reactions (3, 16, 17) is a singly charged anionic species (IV, V) in weakly acid or neutral media, but exists largely as a dianion (VI) at pH 9. These workers contend also that the entity that actually decomposes to products must be the *dehydrated* form, i.e. IV. Therefore, they regard dianion VI as highly stable because it cannot likewise suffer dehydration (thus accounting for the relatively slow rate of periodate oxidations at high pH (4, 15)). Tridentate complexes corresponding to V and VI are represented by VII and VIII. All four species are considered to be in equilibrium if the third hydroxyl group of the polyol can readily be accommodated within the octahedral structure of the periodate anion. We do not know if these tridentate complexes can decompose to yield products, but if they can, their rates of decomposition are exceedingly slow. It is possible that the tridentate type of structure cannot undergo an internal rearrangement with the ease that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



IV V VI



VII VIII

characterizes the decomposition of IV to a dialdehyde (15, 16), and hence is inherently more stable than a monocyclic complex. However, an extension of Bunton's views on the mechanism of periodate oxidation would suggest that neither VII nor VIII fulfills the requirements of a decomposing entity, since neither can be converted into a dehydrated form.

There is no indication that tridentate complexing takes place at pH 4.5. Glycol-cleavage rates are usually optimal in this region (3, 4) and, therefore, if IV, V, and VII are in equilibrium with each other the irreversible process IV $\rightarrow$ products should rapidly displace the system at the expense of tridentate complexing. As the pH is raised and the rate of the oxidation reaction is thereby retarded (3, 4) the formation of tridentate complexes should be progressively favored. It appears possible also that the stability of anion VII is increased at a higher pH because the complexing reaction competes effectively with oxidation in the region of pH 7 (5) to 7.5, where glycol scission can still be relatively vigorous (4). In more strongly alkaline media, a high yield of dianion VIII would be ensured by the now sluggish behavior of the competing oxidation process.

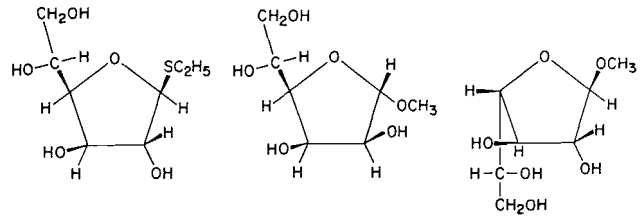
Some evidence has been obtained that, in fact, two different tridentate complexes of 1,2-*O*-isopropylidene-α-D-glucose (I) are formed as the pH is raised. As noted above, a very slow reaction takes place between I and periodate at pH 7.5, as measured titrimetrically by the arsenite method (Table I, No. 2). However, at a pH of 8.5 an immediate uptake of about 0.65 moles of periodate per mole of I was detected by the same titration method (Nos. 4 and 5). Such a result was clearly at variance with the spectral data (Fig. 1B) and, in addition, iodimetric analysis of the reaction mixture showed that no reduction of periodate had actually taken place (No. 3).[5] Hence, this spurious uptake indicated that part of the complex formed at pH 8.5 is relatively stable in the presence of added arsenite (see ref. 5). This was confirmed readily by treating the reaction mixture with the arsenite for more than the usual 15 min reduction period or at an elevated temperature (Table II), which showed that under relatively vigorous conditions the complex is broken down with release of the periodate. Since the complex that is formed at pH 7.5 did not exhibit such stability towards the arsenite reagent it must represent a second species of II. Accordingly, this latter complex probably corresponds to VII and the more stable complex, to the dianion VIII.

The arrangement of the 3,5,6-triol grouping in ethyl α-D-thioglucofuranoside (IX) or methyl α-D-mannofuranoside (X) appears to be closely similar to that in I, although the

[5]*Similar results were obtained at pH 9.0 with the use of disodium hydrogen phosphate as the base (Table I, compare No. 6 with No. 7).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

3-hydroxyl group of these compounds is itself part of a second *vic*-diol located on the five-membered ring. A *cis*-diol as in X usually is extremely reactive towards glycol-cleaving agents, whereas a *trans*-diol as in IX is relatively sluggish. At pH 7.5, in contrast to the behavior of I, both of these glycosides were rapidly oxidized (Table I, Nos. 9 and 12). When the pH was raised to 8.5, the thioglucoside now reacted much more slowly (Table I, Nos. 10 and 11) and n.m.r. spectroscopy (Fig. 1D) showed that complex formation occurs



IX X XI

under these conditions. Moreover, the structure of this complex must be closely similar to that of tridentate II, because signals for the 3-, 4-, 5-, and 6 protons in Fig. 1D are almost exact counterparts of the corresponding signals in Fig. 1B. With the manno-furanoside (X), however, oxidation of the 2,3-diol group took precedence over tridentate complex formation (Table I, Nos. 13 and 14; no formaldehyde was liberated when 1 mole of periodate was reduced). Although the complexing reaction as it applies to I and IX must be exceedingly rapid, it is not clear whether X is oxidized because scission of its 2,3-diol group is far too rapid a reaction, or because it cannot complex readily despite its presumed structural similarity to I and IX.

Molecular models suggested that a galactofuranoside also might form a stable tridentate complex with periodate, but one involving the 2-, rather than 3-hydroxyl group together with the 5,6-diol. In agreement with this possibility, it was found that methyl β-D-galactofuranoside (XI) does not readily reduce periodate at pH 8.4 (Table I, No. 17). Further, its n.m.r. spectrum was markedly altered on addition of the reagent, with several proton signals being shifted strongly towards lower field, but a detailed analysis of this spectrum has not yet been completed. However, the galactofuranoside was rapidly oxidized at pH 7.5 (Table I, Nos. 15 and 16) so that, like the thioglucofuranoside, it requires more strongly alkaline conditions for stable tridentate complexing. Presumably the complex of both these compounds attains sufficient stability only in the dianionic form (VIII).

From the current and earlier (5) data it is seen that the stability of periodate tridentate complexes varies over a wide range. D-Ribose forms a complex at the relatively low pH value of 7 (5) and this complex, probably a monoanion (VII), is stable in the presence of arsenite. The complex formed between periodate and 1,2-*O*-isopropylidene-α-D-glucose at pH 7.5 is likely also of type VII, but is far more easily decomposed by arsenite, whereas the dianionic species (VIII) formed at pH 8.5 is not readily decomposed. Tridentates of the thioglucofuranoside and galactofuranoside are detected only under the more strongly alkaline conditions that favor the dianionic form, but neither of these complexes is stable towards arsenite. These variations reinforce an earlier suggestion (5) that the tridentate-complexing reaction might provide a useful basis for comparing conformation and (or) inductive effects among series of related polyols.

EXPERIMENTAL

Proton magnetic resonance (n.m.r.) spectra were recorded with a Varian HA-100 high resolution spectrometer.

Reaction of Periodate with Furanose Derivatives

(a) Nuclear Magnetic Resonance Experiments

In a typical experiment 1,2-*O*-isopropylidine-D-glucofuranose (20 mg) was dissolved in deuterium oxide (0.6 ml), anhydrous potassium carbonate (20 mg) was added, and the n.m.r. spectrum was recorded (Fig. 1A). Sodium metaperiodate (20 mg, 1 molar equivalent) was then added to the solution, after which the n.m.r. spectrum was again measured (Fig. 1B).

(b) Titration Measurements

The polyol (0.025 mmole) and base (0.0 to 0.10 mmole) were dissolved in water (1.0 ml) and to this was added 1.0 ml of 0.025 molar sodium metaperiodate (0.025 mmole) solution. After the desired time of reaction the reaction mixture was added to either (*a*) a solution (5.0 ml) of potassium iodide (5%) in 0.2 molar potassium dihydrogen (4 parts) and disodium hydrogen (6 parts) phosphate buffer (pH 7.0) (18) or, (*b*) a mixture of 0.1 *N* sodium arsenite solution (2.0 ml) containing potassium iodide (0.01%) and sodium bicarbonate (0.5 g) (19). In the former method (thiosulphate method, Table I), the liberated iodine was titrated with 0.025 *N* thiosulphate solution, and in the latter (arsenite method, Table I) the excess arsenite was titrated (after 15 min, unless otherwise indicated) with 0.025 *N* iodine solution. Starch indicator (2%) was used in both titrations for the end point.

Under the conditions of permanganate–periodate oxidation (2) the concentration of periodate was 0.1 mmole per ml and that of potassium carbonate 0.0125 mmole.

ACKNOWLEDGMENTS

The authors thank M. Mazurek for recording the n.m.r. spectra and M. Granat for technical assistance.

ACETONATION OF ALDOSE DIETHYL THIOACETALS[1]

P. A. J. GORIN
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received February 2, 1965

ABSTRACT

Acetonation of hexose diethyl thioacetals using copper sulphate catalyst gave rise to 5,6-*O*-substituted products. The exception was D-galactose diethyl thioacetal, which underwent some 4,5-*O*-substitution. D-Threose and 2,3-di-*O*-methyl-D-galactose diethyl thioacetals also underwent predominant α-terminal substitution although some β-terminal substitution took place, particularly with the latter thioacetal. Acetone – sulphuric acid caused preferential α-T acetonation of D-threose and 2,3-di-*O*-methyl-D-galactose diethyl thioacetals. The product from D-threose diethyl thioacetal contained 90% of the 2,3-*O*-isopropylidene and 10% of the 3,4-*O*-isopropylidene derivatives.

D-Glucurono-δ-lactone diethyl thioacetal in acetone – sulphuric acid acetonated mainly on the 2,4- positions although a smaller proportion of 4,5-*O*-isopropylidene derivative was present.

The synthesis of sugars with septanose rings has been recorded in the literature on only a few occasions (1, 2, 3). The starting compound used by Micheel and co-workers for preparation of a series of septanosyl derivatives was 2,3,4,5-tetra-*O*-acetyl-D-galactose hydrate. However, in view of the ready migration of acetyl groups, compounds of this type have only a limited application. Attempts have now been made to synthesize compounds with the 6-hydroxyl free, but with the 4- and 5-hydroxyls blocked as in the 4,5-*O*-isopropylidene hexoses derived from 4,5-*O*-isopropylidene hexose thioacetals.

The *O*-isopropylidene aldose thioacetals, first synthesized by E. and J. Pacsu and coworkers (4–7), required reinvestigation since structures were assigned on the basis of methylation experiments in which the products were improperly characterized. The compound obtained on treatment of mannose diethyl thioacetal with copper sulphate acetone was assigned a 2,3-*O*-isopropylidene structure (4), which now appears unlikely since it would contain a *cis*-disubstituted 2,2-dimethyl-1,3-dioxolane ring. 2,3-*O*-Substitution was also claimed for the copper sulphate catalyzed acetonation product of galactose dibenzyl thioacetal (5) and for the condensation product from methyl ethyl ketone and glucose dibenzyl thioacetal (6). The former derivative was unambiguously characterized later as a mixture of 4,5- (7) and 5,6-*O*-isopropylidene galactose dibenzyl thioacetal (8). Mono-*O*-isopropylidene glucose dibenzyl thioacetal was obtained by action of sulphuric acid (9) and copper sulphate (10) in acetone on glucose dibenzyl thioacetal. In the latter experiment, Schinle also isolated 2,3,5,6-di-*O*-isopropylidene glucose dibenzyl thioacetal. Formation of 2-*O*-methyl glucose dibenzyl thioacetal by partial methylation of the mono-*O*-isopropylidene derivative followed by partial hydrolysis led the author to assign a 5,6-*O*-isopropylidene structure.

In the present work the mono-*O*-isopropylidene diethyl thioacetals of mannose, glucose, altrose, and galactose were prepared by the action of copper sulphate in acetone on the corresponding hexose diethyl thioacetal. Optimum conditions for synthesis were found by examination of the products, at intervals, by silica gel thin-layer chromatography. *O*-Isopropylidene derivatives were isolated by crystallization except in the glucose series, which required silicic acid chromatography before crystallization was possible. Demercaptalation of the *O*-isopropylidene hexose diethyl thioacetals with mercuric chloride in

[1]*Issued as N.R.C. No. 8478.*

aqueous acetone, in the presence of cadmium carbonate, yielded the free *O*-isopropylidene hexoses. The parent *O*-isopropylidene hexose diethyl thioacetals were identified by oxidation with sodium periodate at neutral pH, followed by sodium borohydride reduction and acid hydrolysis. Formation of glycerol from the glucose, mannose, and altrose derivatives indicated 5,6-*O*-isopropylidene substitution. The galactose derivative gave rise mainly to threitol, showing 4,5- or 4,6-substitution. Of these two possibilities, the 4,5-assignment was shown to be correct by converting the thioacetal via a series of steps into methyl tri-*O*-methyl $\alpha\beta$-D-galactoside. Gas chromatographic analysis (g.l.c.) showed that the trimethyl derivative had the 2,3,6- rather than the 2,3,5-structure (see the acetonation of 2,3-di-*O* methyl galactose diethyl thioacetal described in the experimental section). Some 2,3,4-tri-*O*-methyl derivative (11%) was also detected showing that 5,6-*O*-isopropylidene-D-galactose diethyl thioacetal had been present as an impurity in the isolated crystals.

Since acetonation of the above diethyl thioacetals was complicated by the formation of di-*O*-isopropylidene derivatives, the diethyl thioacetals of 2,3-di-*O*-methyl-D-galactose and D-threose were used as substrates. Unlike D-galactose diethyl thioacetal, the 2,3-di-*O*-methyl substituted derivative gave rise, after 18 h, to 5,6-*O*-isopropylidene (63%) and 4,6-*O*-isopropylidene derivatives (37%) with the copper sulphate catalyst. These structures and percentages were deduced from a methylation experiment described in the experimental section.

The acetonation of D-threose diethyl thioacetal was followed more readily since the three possible products were separable by g.l.c. as their acetates. Acetonation was complete after 8 h and the main product was the 3,4-isomer with smaller proportions of the 2,3- and 2,4-isomer[2] (Fig. 1). It was apparent that, although the 2,4-*O*-isopropylidene derivative was formed initially, most of it was transformed at later stages of the reaction. However,

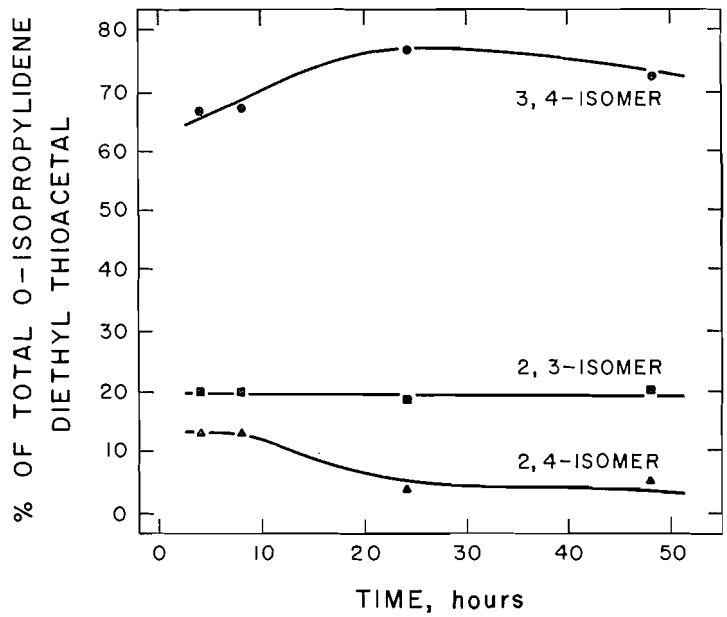

FIG. 1. Gas–liquid chromatography signal response variation with time of acetates derived from *O*-isopropylidene-D-threose diethyl thioacetals which were formed by the action of copper sulphate–acetone.

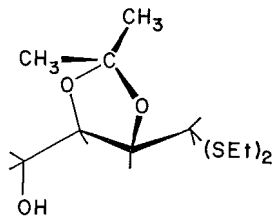
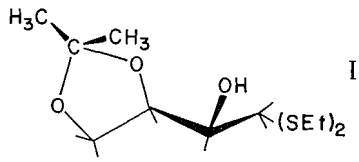
hydrolysis of the initially formed products was slow so that kinetic control of the copper sulphate catalyzed acetonation was virtually effected. Barker *et al.* (11) noted that ketones prefer to substitute primary rather than secondary hydroxyls. Rapid equilibration does not occur and since the intermediate in formation of an *O*-isopropylidene derivative should be a hemiketal, it follows that preferential substitution should take place at the more active primary hydroxyl. Since condensation depends on the reactivity of the participating groups and their relative proximity, it is not surprising that the β-terminal ring should be formed in addition to the α-terminal ring, although examples of this are rare in the ketal series (12).

In contrast, the more rapid reactions of sugar thioacetals with acetone – sulphuric acid are thermodynamically controlled and give rise to different proportions of products than the above copper sulphate catalyzed reactions. 2,3-Di-*O*-methyl-D-galactose diethyl thioacetal was converted mainly to its 4,5-*O*-isopropylidene derivative, as shown by a methylation experiment. The products from D-threose diethyl thioacetal were shown to



I



II

consist of the 2,3-*O*-isopropylidene- (90%; I) and 3,4-*O*-isopropylidene- (10%; II) derivatives by g.l.c. of their acetates. The preferential formation of an αT-ring over a corresponding terminal α-ring has been briefly rationalized by Mills (13). Known instances are the pyridinium chloride catalyzed conversion of 1,2;4,5-di-*O*-isopropylidene DL-galactitol to its 2,3;4,5-isomer (14) and the acetonation of D-galactose dibenzyl thioacetal to give the 2,3;4,5-*O*-isopropylidene rather than the 2,3;5,6-*O*-isopropylidene derivative (15).

An attempt to prepare 4,5-*O*-isopropylidene D-glucose starting from the acetonation product of D-glucurono-δ-lactone diethyl thioacetal did not succeed because of low yields. Using the acetone – sulphuric acid reagent a crystalline mono-*O*-isopropylidene derivative was obtained. The product gave a nuclear magnetic resonance (n.m.r.) spectrum which appeared to be a superimposition of two sets of signals. Reduction with sodium borohydride yielded a waxy material which was substituted mainly in the 2,4-position since demercaptalation followed by borohydride reduction gave 2,4-*O*-isopropylidene-D-sorbitol. The mother liquors contained a small proportion of 4,5-*O*-isopropylidene-D-sorbitol since periodate oxidation followed by sodium borohydride reduction and hydrolysis yielded erythritol in addition to xylitol. A crystalline sample of mono-*O*-isopropylidene D-mannurono-δ-lactone diethyl thioacetal was prepared in a similar way and also appeared to be a mixture, as indicated by its n.m.r. spectrum. The quantities of material isolated precluded a definite characterization. However, the two most likely structures are the 2,4- and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

4,5-*O*-isopropylidene derivatives since the 2,5-substituted derivative would contain a 7-membered ketal ring.

EXPERIMENTAL

Acetonation of Hexose Diethyl Thioacetals

(1) Mannose Series

The acetone derivative was prepared in a somewhat better yield than that described by Pacsu and Kary (4). D-Mannose diethyl thioacetal (11 g) was shaken for 3 h in acetone (200 ml) containing anhydrous copper sulphate (50 g). Filtration and evaporation gave material which was recrystallized from ether–*n*-hexane to give the mono-*O*-isopropylidene derivative (9.4 g). This was chromatographically pure on thin-layer silica gel plates using chloroform as solvent and 50% sulphuric acid as spray reagent.

A portion (5.5 g) was treated according to the method of Micheel and Suckfull (1) and stirred vigorously in 90% aqueous acetone (100 ml) containing cadmium carbonate (35 g) at 0 °C. Mercuric chloride (7.3 g; 1.6 moles) in acetone (30 ml) was added and the mixture was stirred at room temperature for 18 h. After heating at 50 °C for 30 min the solids were filtered off and the filtrate evaporated to a syrup in the presence of cadmium carbonate. Chromatography on cellulose (eluant, benzene–ethanol–water 500:50:1 v/v) yielded 5,6-*O*-isopropylidene-D-mannose (2.3 g), which was recrystallized twice from ethyl acetate to yield material with m.p. 76–78 °C and $[\alpha]_D$ +27° (*c*, 1.0, H_2O).

Anal. Calcd. for $C_9H_{16}O_6$: C, 49.08; H, 7.32. Found: C, 48.7; H, 7.4.

The *O*-isopropylidene mannose (100 mg) was treated with sodium borohydride (40 mg) in water (5 ml). After 1 h the pH was adjusted to 7 and the solution evaporated to a crust. The residue was dissolved in methanol, which was then evaporated. After this process was repeated three times the product was chromatographed on cellulose using benzene–ethanol–water (500:50:1 v/v) as eluant. 5,6-*O*-Isopropylidene-D-mannitol, thus isolated, was twice recrystallized from ethyl acetate and had m.p. 164–166 °C (Vargha (16) reported m.p. 167 °C for this material).

Anal. Calcd. for $C_9H_{18}O_6$: C, 48.64; H, 8.16. Found: C, 48.3; H, 8.1.

(2) Glucose Series

D-Glucose diethyl thioacetal was shown by thin-layer silica gel chromatography to acetonate rapidly and accordingly 6.0 g was shaken for 3 h in acetone (100 ml) containing anhydrous copper sulphate (25 g). The solution was then filtered, evaporated, and chromatographed on a column of silicic acid using chloroform as solvent. Initially two fractions were eluted, firstly, a di-*O*-isopropylidene-D-glucose diethyl thioacetal (0.39 g) with $[\alpha]_D$ −9° (*c*, 1.6, MeOH).

Anal. Calcd. for $C_{16}H_{30}O_5S_2$: C, 52.45; H, 8.25. Found: C, 52.1; H, 8.5.

Secondly, the major di-*O*-isopropylidene-D-glucose diethyl thioacetal (1.34 g) with $[\alpha]_D$ −44° (*c*, 1.9, MeOH), was eluted. Found: C, 52.3; H, 8.7. The above structures were probably substituted 3,4,5,6- and 2,3,5,6-respectively by analogy with the compounds obtained by Curtis and Jones in the dimethyl thioacetal series (17).

The mono-*O*-isopropylidene glucose derivative was eluted later and this was crystallized from ether–*n*-hexane. The product (3.2 g) had m.p. 68–69 °C and $[\alpha]_D$ −11° (*c*, 1.2, MeOH).

Anal. Calcd. for $C_{13}H_{26}O_5S_2$: C, 47.84; H, 8.03. Found: C, 47.8; H, 8.2.

Demercaptalation of 0.78 g by the previously described procedure provided 5,6-*O*-isopropylidene-D-glucose (0.32 g). Recrystallization from ethyl acetate gave material with m.p. 111–113 °C and $[\alpha]_D$ +17° (*c*, 0.7, H_2O).

Anal. Calcd. for $C_9H_{16}O_6$: C, 49.08; H, 7.32. Found: C, 48.9; H, 7.6.

(3) Altrose Series

D-Altrose diethyl thioacetal (18) (1.0 g) was shaken in acetone (20 ml) containing copper sulphate (5 g) for 3 h. Filtration and evaporation gave material which was recrystallized twice from ether–*n*-hexane to give a derivative with m.p. 70–71 °C and $[\alpha]_D$ +8° (*c*, 1.2, MeOH). Yield, 0.56 g.

Anal. Calcd. for $C_{13}H_{26}O_5S_2$: C, 47.84; H, 8.03. Found: C, 47.5; H, 8.1.

(4) Galactose Series

D-Galactose diethyl thioacetal (19.5 g) was treated overnight in acetone (250 ml) containing copper sulphate (25 g). The product gave two zones on silica gel thin-layer chromatography using chloroform as solvent. Filtration and evaporation gave material which appeared to be a crystalline mixture, and fractional crystallization three times from ether gave a product (6.1 g) with m.p. 82–83 °C and $[\alpha]_D$ +19° (*c*, 3.1, MeOH).

Anal. Calcd. for $C_{13}H_{26}O_5S_2$: C, 47.84; H, 8.03. Found: C, 47.8; H, 8.3.

The slower moving component on thin-layer plates was considerably concentrated by the recrystallization processes.

Characterization of Mono-O-isopropylidene Hexose Diethyl Thioacetals

(1) Mannose, Glucose, and Altrose Derivatives

These were oxidized overnight with 10 equivalents of 0.1 *M* sodium periodate in the presence of sodium bicarbonate buffer. Salts were removed with mixed Amberlite IR120 and Dowex 1 (bicarbonate form) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the filtrate treated with excess sodium borohydride. After 2 h the reducing agent was removed. Hydrolysis of the products in 5% aqueous acetic acid at 100° gave glycerol as shown by paper chromatograms (solvent: butanol–ethanol–water 40:11:19 v/v; spray: ammoniacal silver nitrate) thus indicating a 5,6-*O*-isopropylidene structure in the starting materials.

(2) Galactose Derivative

A treatment similar to that described above gave threitol and a trace of glycerol. The *O*-isopropylidene group was therefore either in the 4,5- or 4,6-position.

The *O*-isopropylidene derivative was methylated by the Haworth procedure (19) at room temperature using dimethyl sulphate and aqueous sodium hydroxide containing 5% of acetone. Excess reagent was destroyed by being heated for 3 h on a steam bath and the product was isolated by extraction with benzene. The methylated derivative was demercaptalated (1) and converted to a methylated methyl galactosidic mixture by being heated under reflux in 3% methanolic hydrogen chloride for 4 h. The product was examined by g.l.c. using 2% neopentyl glycol succinate (20) on HMDS Chromosorb W (80–100 mesh) in a 5 ft × 1/4 in. o.d. copper tube at 143 °C with helium (30 p.s.i.) as carrier gas. The g.l.c. unit was of conventional design using thermal conductivity detectors.

The following galactosides were detected, their proportion being expressed as the percentage of the total signals; the other figures in parentheses are the emergence times: methyl 2,3,6-tri-*O*-methyl-D-galactosides (89%; three signals at 1.1, 1.5, and 1.6 min), methyl 2,3,4-tri-*O*-methyl-D-galactosides (11%; one signal at 2.8 min). Identification was made by comparison of retention times and signal patterns with those of authentic glycosides.

Acetonation of D-Glucurono-δ-lactone Diethyl Thioacetal

D-Glucurono-δ-lactone diethyl thioacetal prepared by the method of Zinner and Dässler (21) was shown to be acetonated readily by 0.1% sulphuric acid in acetone. Zinc chloride and copper sulphate in acetone at room temperature gave only partial acetonation after 18 h as shown by chromatography on thin-layer silica gel plates using chloroform as solvent.

D-Glucurono-δ-lactone diethyl thioacetal (12.5 g) was treated overnight in acetone (300 ml) containing 0.1% sulphuric acid. The acid was removed with barium carbonate and the solution filtered and evaporated. Two crystallizations from ether gave the mono-*O*-isopropylidene derivative (6.7 g) with m.p. 108–111 °C and $[\alpha]_D$ +78° (*c*, 0.9, MeOH).

Anal. Calcd. for $C_{13}H_{22}O_5S_2$: C, 48.44; H, 6.88. Found: C, 48.8; H, 7.4. Examination of the product in chloroform by nuclear magnetic resonance (n.m.r.) spectroscopy showed two sets of four methylene proton signals superimposed. Absorption at 1 780 cm^{-1} in the infrared corresponded to a δ-lactone.

The mono-*O*-isopropylidene-D-glucurono-δ-lactone diethyl thioacetal (1.2 g) in dioxane (50 ml) was treated with sodium borohydride (0.3 g) in water (5 ml). After 18 h the reaction mixture was added to excess water and the solution adjusted to pH 7. Chloroform extraction removed the product, which was crystallized from ether–*n*-hexane to give a waxy product (0.73 g) with an indefinite melting point. The carbon and hydrogen analyses corresponded to those of mono-*O*-isopropylidene-D-glucose diethyl thioacetal.

Anal. Calcd. for $C_{13}H_{26}O_5S_2$: C, 47.84; H, 8.03. Found: C, 47.9; H, 8.1.

A sample of the thioacetal was demercaptalated and reduced with sodium borohydride. The product after two recrystallizations from acetone had m.p. 158–160 °C and $[\alpha]_D$ +11° (*c*, 0.9, MeOH).

Anal. Calcd. for $C_9H_{18}O_6$: C, 48.64; H, 8.16. Found: C, 48.4; H, 8.3. The mono-*O*-isopropylidene D-sorbitol after 1 h consumed 0.94 moles of sodium periodate without formation of acid.

The mother liquors (containing 30% by weight of the reduction product) were evaporated and oxidized with sodium periodate at neutral pH and the product reduced with sodium borohydride and then hydrolyzed. A small proportion of erythritol in addition to xylitol pointed to the presence of 4,5-*O*-isopropylidene-D-sorbitol.

Preparation of O-Isopropylidene-D-mannurono-δ-lactone Diethyl Thioacetal

Synthesis of the mannurono-δ-lactone derivative was carried out in a manner analogous to that used in the glucurono-δ-lactone series. After silicic acid column chromatography (chloroform 3 : hexane 2 as eluant) *O*-isopropylidene-D-mannurono-δ-lactone was obtained in very low yield. After two crystallizations from ether–*n*-hexane the product had m.p. 78–85 °C, $[\alpha]_D$ +53° (*c*, 1.1, EtOH) and an infrared absorption band at 1 785 cm^{-1} corresponded to a δ-lactone.

Anal. Calcd. for $C_{13}H_{22}O_5S_2$: C, 48.44; H, 6.88. Found: C, 48.2; H, 6.8. In the n.m.r. spectrum the methylene proton signals appeared to consist of two distinct overlapping quadruplets.

Acetonation of D-Threose Diethyl Thioacetal

D-Threose, prepared from D-galactose (5.0 g) (22), was shaken with ethanethiol (3 ml) and concentrated hydrochloric acid (3 ml) for 30 min. The reaction mixture was neutralized by addition to a stirred suspension of lead carbonate (15 g) in methanol (100 ml). Filtration and evaporation yielded a syrup which crystallized and two recrystallizations from ether gave D-threose diethyl thioacetal (1.65 g) with m.p. 69–70 °C and $[\alpha]_D$ −13° (*c*, 2.0, EtOH).

Anal. Calcd. for $C_8H_{18}O_3S_2$: C, 42.47; H, 8.02. Found: C, 42.7; H, 8.1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(1) Acetonation using Copper Sulphate

D-Threose diethyl thioacetal (1.0 g) in acetone (20 ml) was shaken with copper sulphate (5.0 g). At intervals samples were abstracted, filtered, and evaporated to residues which were acetylated with acetic anhydride in pyridine. Examination of the products by g.l.c. using a column of neopentyl glycol succinate on HMDS Chromosorb W (80–100 mesh) (see analysis of methyl tri-*O*-methyl galactosides described earlier) at 160 °C showed that tri-*O*-acetyl D-threose diethyl thioacetal had disappeared after 8 h.

The three possible acetylated *O*-isopropylidene threose diethyl thioacetal isomers had the following retention times: 3,4-*O*-isopropylidene derivative, 2.1 min; 2,4-isomer, 2.4 min;[3] 2,3-isomer, 3.2 min. The variation of the relative signals produced by these isomers with time are recorded in Table I.

TABLE I

The copper sulphate catalyzed acetonation of D-threose diethyl thioacetal

Isomer of *O*-acetyl-*O*-isopropylidene D-threose diethyl thioacetal	Time (h)					
	4	8	24	48	72	144
	% total signal response					
3,4-*O*-Isopropylidene-	66	67	77	73	65	67
2,4-*O*-Isopropylidene-	13	13	4	6	5	0
2,3-*O*-Isopropylidene-	20	20	19	21	30	33

A portion of the *O*-isopropylidene D-threose diethyl thioacetals formed after 24 h was isolated. The mixture was chromatographed on silicic acid using chloroform–hexane (1:1 v/v) as eluant. The product was syrupy and consisted of the 3,4-isomer and had $[\alpha]_D$ −18° (*c*, 1.8, $CHCl_3$).

Anal. Calcd. for $C_{11}H_{22}O_3S_2$: C, 49.61; H, 8.33. Found: C, 49.1; H, 8.3.

A small sample of the crude acetonated mixture was demercaptalated and the product reduced with sodium borohydride to *O*-isopropylidene-D-threitol. This was oxidized with excess sodium periodate and the resulting mixture reduced with sodium borohydride and the *O*-isopropylidene groups removed by hydrolysis. The product consisted mainly of glycerol arising from 3,4-*O*-isopropylidene-D-threitol diethyl thioacetal and a small amount of threitol from the other isomers.

(2) Acetonation using Zinc Chloride

The products arising from the action of zinc chloride (45 mg) in acetone (10 ml) on D-threose diethyl thioacetal were similar to those in the copper sulphate experiment. After 2 h and 8 h the relative signal responses produced by the 3,4-, 2,4-, and 2,3-isomers were 64%, 16%, 20%, and 74%, 11%, and 15%, respectively, on g.l.c. of the acetylated mixtures.

(3) Acetonation using 1% Sulphuric Acid

D-Threose diethyl thioacetal (1.0 g) was treated for 3 h with acetone (150 ml) containing sulphuric acid (0.5 ml). The mixture was added to aqueous sodium bicarbonate which was then extracted with chloroform. The extract was evaporated to a syrup which, after purification by silicic acid chromatography, had $[\alpha]_D$ +47° (*c*, 1.8, $CHCl_3$).

Anal. Calcd. for $C_{11}H_{22}O_3S_2$: C, 49.6; H, 8.33. Found: C, 49.6; H, 8.4.

The product was shown to be 2,3-*O*-isopropylidene-D-threose diethyl thioacetal by methylation with dimethyl sulphate and aqueous sodium hydroxide containing 5% acetone. The product was demercaptalated and reduced with sodium borohydride. Removal of the isopropylidene group with 5% aqueous acetic acid at 100 °C gave mono-*O*-methyl-D-threitol, which was separated from a little unmethylated threitol by cellulose chromatography (eluant: benzene–ethanol–water 200:50:1 v/v). It had $[\alpha]_D$ −6.5° (*c*, 1.5, EtOH) and on a paper chromatogram in *n*-butanol–ethanol–water (40:11:19 v/v) ran at 1.2 times the rate of glycerol. Oxidation with sodium periodate resulted in the uptake of 1.6 moles of oxidant with formation of 0.7 moles of acid. These data are consistent with slightly impure 4-*O*-methyl-D-threitol and distinguishes it from 3-*O*-methyl-D-threitol.

The above structure was confirmed by conversion to 4-*O*-methyl-D-threitol tris-*p*-nitrobenzoate, which, on three recrystallizations from ethyl acetate *n*-hexane, had melting point and mixed melting point 80–83 °C and $[\alpha]_D$ −32° (*c*, 1.0, $CHCl_3$). The product gave an X-ray diffraction pattern identical with that of authentic material.

Authentic 4-*O*-methyl-D-threitol was prepared by oxidation of 6-*O*-methyl-D-galactose with 2 moles of lead tetraacetate followed by reduction of the product with sodium borohydride. The product had $[\alpha]_D$ −9° (*c*, 1.7, EtOH) and gave a crystalline tris-*p*-nitrobenzoate with m.p. 79–83 °C and $[\alpha]_D$ −34° (*c*, 1.0, $CHCl_3$).

Anal. Calcd. for $C_{26}H_{21}O_{13}N_3$: C, 53.52; H, 3.63. Found: C, 53.6; H, 3.8.

On g.l.c. examination, 4-*O*-acetyl-2,3-*O*-isopropylidene-D-threose diethyl thioacetal gave 1.42 times the

[3]*The 2,4-isomer was identified by process of elimination after chemical characterization of the 2,3- and 3,4-isomers.*

For personal use only.

response obtained with the corresponding 2-*O*-acetyl-3,4-*O*-isopropylidene derivative. The products formed after treatment of D-threose diethyl thioacetal with acetone containing 1% sulphuric acid for 1 h and 24 h were analyzed after acetylation with pyridine – acetic anhydride. Using the above correction factor 10% of the 3,4-*O*-isopropylidene and 90% of the 2,3-*O*-isopropylidene derivatives were shown to be present in each acetonation product.

Acetonation of 2,3-Di-O-methyl-D-galactose Diethyl Thioacetal

2,3-Di-*O*-methyl-D-galactose (5.0 g) was mercaptalated by the method described previously. The product (1.4 g) was twice crystallized from ether–*n*-hexane and had m.p. 53–54 °C and $[\alpha]_D$ −25° (*c*, 1.1, EtOH).

Anal. Calcd. for $C_{12}H_{26}O_5S_2$: S, 20.40. Found: S, 20.6.

(1) Acetonation using 1% Sulphuric Acid

2,3-Di-*O*-methyl-D-galactose diethyl thioacetal was acetonated for 1 h by the method described for D-threose diethyl thioacetal. The product contained almost exclusively one compound as shown by silica gel thin-layer chromatography and had $[\alpha]_D$ +7° (*c*, 1.0, EtOH).

Anal. Calcd. for $C_{15}H_{30}O_5S_2$: C, 50.83; H, 8.53. Found: C, 51.1; H, 8.4.

Methylation and conversion to a methyl tri-*O*-methyl galactosidic mixture was carried out by the method described for 4,5-*O*-isopropylidene-D-galactose diethyl thioacetal. The products corresponded to methyl 2,3,6-tri-*O*-methyl-D-galactosides, thus indicating a 4,5-*O*-isopropylidene-2,3-di-*O*-methyl-D-galactose structure. A trace of the 2,3,4-tri-*O*-methyl isomers was present.

(2) Acetonation using Copper Sulphate

2,3-Di-*O*-methyl-D-galactose diethyl thioacetal (0.25 g) was treated with copper sulphate (1.25 g) in acetone (10 ml). After 18 h the reaction mixture was added to aqueous sodium bicarbonate, which was extracted with chloroform. The extract was evaporated to a syrup.

Anal. Calcd. for $C_{15}H_{30}O_5S_2$: C, 50.83; H, 8.53. Found: C, 50.6; H, 8.3.

The product was examined on silica gel thin-layer plates using chloroform as solvent. Two spots moving at a greater rate than 4,5-*O*-isopropylidene 2,3-di-*O*-methyl-D-galactose diethyl thioacetal were detected. These were, by process of elimination, the 5,6- and 4,6-*O*-isopropylidene derivatives.

Methylation of the *O*-isopropylidene mixture was carried out and was followed by conversion to a methyl tri-*O*-methyl galactosidic mixture. Examination by g.l.c. showed that methyl 2,3,4-tri-*O*-methyl galactosides (63%) were the main products arising from the 5,6-*O*-isopropylidene derivative. The minor component (37%) consisted of methyl 2,3,5-tri-*O*-methyl galactosides with emergence times of 1.3 min and 1.7 min. The signal pattern differed from that of the methyl 2,3,6-tri-*O*-methyl galactosides, which had emergence times of 1.1, 1.5, and 1.6 min.

ACKNOWLEDGMENTS

The author would like to thank Mr. M. Mazurek for carrying out microanalytical determinations and Mr. W. C. Haid for obtaining n.m.r. spectra.

THE CHEMISTRY OF D-APIOSE

PART II. THE CONFIGURATION OF D-APIOSE IN APIIN

R. K. HULYALKAR,[1] J. K. N. JONES, AND M. B. PERRY[1]

Department of Organic Chemistry, Queen's University, Kingston, Ontario

Received March 10, 1965

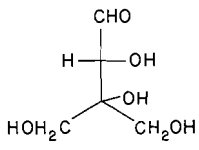
ABSTRACT

The tri-*O*-methyl-D-apiose derivative obtained from the hydrolysis products of methylated apiin was found to be identical with 2,3,4-tri-*O*-methyl-D-apio-D-furanose prepared synthetically. Periodate oxidation studies support the suggested *cis* relationship of the hydroxyl groups at C_2 and C_3 of the apiose moiety in apiin, and consideration of optical rotation data suggest that a β-type linkage unites the D-apiosyl unit to C_2 of the D-glucopyranose residue in apiin.

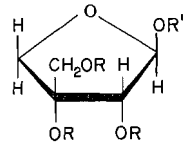
INTRODUCTION

Apiose (I) is an unusual branched-chain pentose first found in parsley, in which it occurs as the flavanoid glycoside apiin (1), and reported to occur in other plant species (2–5*a*).

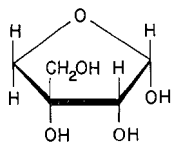
On conversion of the open-chain structural formulation of D-apiose (I) to its furanose ring forms, carbon atom 3 becomes asymmetric, giving rise to four possible isomers (II–V).



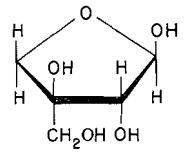
I



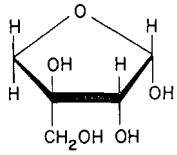
II, R = R' = H



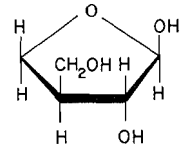
III



IV



V



VI

It may be noted that cordycepose (VI) (5*b*) can also exist in four possible forms. Although previous workers (6, 7) had shown that apiin contains a β-glycosidically linked 2-*O*-(D-apiofuranosyl)-D-glucopyranose disaccharide moiety at C_7 of the flavone residue, the absolute configuration of the D-apiofuranose residue at C_3 was not determined. The present paper describes work directed towards establishing the configuration of the D-apiofuranose residue in apiin.

DISCUSSION

Apiin was isolated from parsley (8, 9) and characterized as its crystalline octa-*O*-acetate (9). The pure apiin was fully methylated, thus fixing the configuration at C_3 of the D-apiofuranose residue, and hydrolysis of the product with an aqueous acetic acid – hydrochloric acid mixture (10) resulted in the precipitation of 5,4′-di-*O*-methyl-apigenin, leaving a solution from which 3,4,6-tri-*O*-methyl-D-glucose, characterized as its phenylosazone derivative, and 2,3,4-tri-*O*-methyl-D-apiofuranose were isolated in approximately equal molar amounts.

2,3,4-Tri-*O*-methyl-D-apio-D-furanose (II, R = Me; R′ = H) of known configuration at C_3 was synthesized. Methylation of 2,3-*O*-isopropylidene-D-apio-D-furanose (5*a*) with methyl iodide and silver oxide yielded methyl 2,3-*O*-isopropylidene-4-*O*-methyl-$\alpha+\beta$-D-apio-D-furanoside, which on treatment with methanolic hydrogen chloride, gave methyl 4-*O*-methyl-$\alpha+\beta$-D-apio-D-furanoside. Methylation of methyl 4-*O*-methyl-$\alpha+\beta$-D-apio-D-furanoside with methyl iodide and silver oxide gave methyl 2,3,4-tri-*O*-methyl-$\alpha+\beta$-D-apio-D-furanoside, which on hydrolysis with dilute sulphuric acid, yielded 2,3,4-tri-*O*-methyl-D-apio-D-furanose.

The synthetic 2,3,4-tri-*O*-methyl-D-apio-D-furanose and the tri-*O*-methyl-D-apiose isolated from methylated apiin had identical infrared spectra, and paper, thin-layer, and gas–liquid partition chromatography did not distinguish between the two products (see Tables I and II). Gas–liquid partition chromatograms of the synthetic methyl $\alpha+\beta$-glycosides from 2,3,4-tri-*O*-methyl-D-apio-D-furanose and from the tri-*O*-methyl-D-apiose isolated from apiin each showed two peaks and were indistinguishable. Gas chromatographic examination of the product obtained by direct methylation of D-apiose showed four peaks of which the faster two had the same retention times as the methyl glycosides from 2,3,4-tri-*O*-methyl-D-apio-D-furanose. The slower two peaks are probably due to the methyl α- and β-glycosides of the remaining two of the four possible isomers of D-apiofuranose. Attempts to prepare crystalline derivatives of 2,3,4-tri-*O*-methyl-D-apio-D-furanose were unsuccessful.

TABLE I

Comparison of 2,3,4-tri-*O*-methyl-D-apiose from parsley with the synthetic 2,3,4-tri-*O*-methyl-D-apio-D-furanose

Periodate oxidation (11, 12, 13) of apiin [VII, X = 7-*O*-(D-glucopyranosyl)-apigenin] was found to proceed with a rapid consumption of 2.3 moles of periodate and release of 0.7 mole of formaldehyde (30 min oxidation) followed by a slow reaction leading to a total

5. 2,3,4-Tri-*O*-methyl-1,4′-di-*O*-trimethylsilyl-D-apiitol	0.206	0.206

NOTE: T_g values are quoted relative to the retention time of methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucoside (= 1.00).

consumption of 2.93 moles of periodate and release of 0.88 mole of formaldehyde (40 hours) per mole apiin. Periodate oxidation of 1 mole of apiin with 1 mole of metaperiodate released 0.35 mole of formaldehyde, and the reduced periodate-oxidized product on hydrolysis gave a 90% recovery of glucose; paper chromatographic examination of the hydrolyzed reduced products showed the presence of glycerol, tetritol, and sorbitol. Oxidation of apiin with 2 moles of periodate resulted in the release of 0.85 mole of formaldehyde.

TABLE III

Periodate oxidation of apiin

Time, h	Uptake of periodate, moles/mole	Formaldehyde production, moles/mole
0.50	2.22	0.70
1.00	2.34	0.75
14.00	2.78	0.88
22.00	2.88	0.88
44.00	2.93	0.88

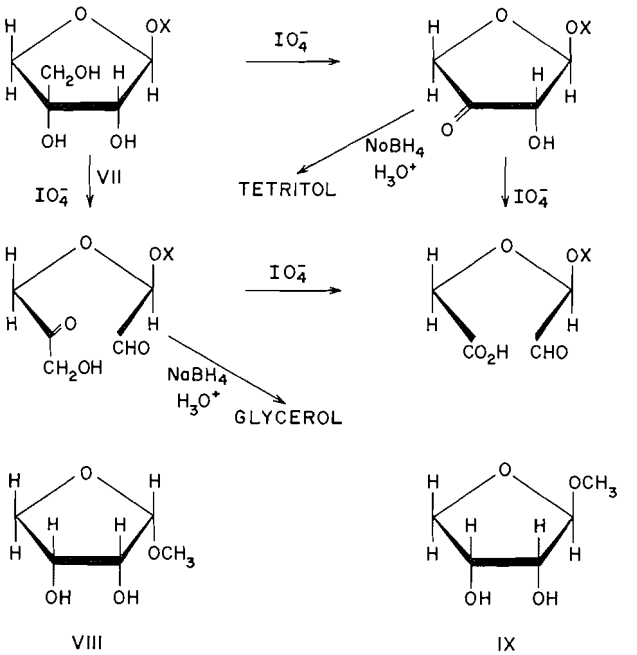
The above periodate oxidation studies support the conclusion that the secondary and tertiary hydroxyl groups at C_2 and C_3, respectively, of the apiose moiety in apiin are *cis*-related having the D-*erythro* configuration. It can be expected that, if the hydroxyl groups at C_2 and C_3 in the apiofuranose moiety were *cis*-related, their cleavage by periodate would be much faster than that of the trans C_3 and C_4 glycol system in the glucopyranose moiety. The release of formaldehyde on selective oxidation of apiin with 1 and with 2 moles of periodate suggests that the initial attack by the first mole of periodate results in about 65% splitting of the C_2–C_3 glycol system of apiose and about 35% at the C_3–C_4 bond, this latter step proceeding with the release of formaldehyde. The release of 0.85 mole of formaldehyde on oxidation of apiin by 2 moles periodate shows that the intermediates produced by the initial attack on the apiose residue are more easily oxidized than is the hexose molecule since the glucose residue is almost unaffected under these conditions.

Apiin has a molecular rotation $[M]_D$* of −754° and 7-*O*-(D-glucopyranosyl)-apigenin, which is the aglycon of apiose in apiin, has a molecular rotation $[M]_D$ of −349°. The

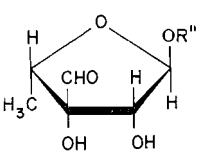
*$[M]_D = ([\alpha]_D \times m.wt.)/100$. *These values are approximate.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

molecular rotation $[M]_D$ of apiin minus the molecular rotation $[M]_D$ of 7-*O*-(D-glucopyranosyl)-apigenin is $-405°$, which is the molecular rotation $[M]_D$ of the corresponding methyl glycoside of D-apiose (14, 15, 16). It is highly improbable that the alpha form of methyl D-apio-D-furanoside would have such a high negative value as the sugar is in the D-series and the di-*O*-isopropylidene derivative, the formation of which involves an α-glycosidic hydroxyl group, has a positive rotation (5*a*). Also it may be noted that methyl α-D-erythrofuranoside (VIII) and β-D-erythrofuranoside (IX) have approximate $[M]_D$ values of $+199°$ and and $-217°$, respectively (calculated from the results of Ballou (17)).



Further evidence is given by the optical rotations of the 4-*O*-methyl- and 2,3,4-tri-*O*-methyl-D-apio-D-furanoses, which are very close to zero. It would appear therefore that methyl α-D-apio-D-furanoside should not have a negative optical rotation and hence the contribution from the anomeric linkage of the D-apiose residue corresponds to that of the β-glycoside. The evidence suggests that the D-apio-D-furanose residue in apiin is joined to C_2 of the D-glucopyranose residue by a β-glycosidic linkage. There is a structural resemblance between the glycosides of D-cordycepose (VI), D-apiose (I), and L-streptose (X, R″ = H) which may have biological significance.



X

EXPERIMENTAL

Paper chromatography was performed by the descending method on Whatman No. 1 filter paper using the following solvent systems: (*a*) butan-1-ol–pyridine–benzene–water (10:6:2:6 v/v); (*b*) butan-1-ol–ethanol–water (10:3:3 v/v); (*c*) butan-1-ol–ethanol–benzene–water (10:3:5:3 v/v); (*d*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4 v/v). Thin-layer chromatoplates were prepared using silica gel G in water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

suspension (1:2 w/v) and were dried at 110° for 10 h before use. Sugars were detected with the spray reagents 2% *p*-anisidine hydrochloride in butan-1-ol (18) and 1% silver nitrate in acetone followed by 2% sodium hydroxide in ethanol (19).

Gas–liquid partition chromatography was carried out using a Pye Argon chromatograph fitted with an ionization detector (^{90}Sr-80 μc) and employing straight glass columns (120 × 0.5 cm, I.D.) packed with either (*a*) 10% Carbowax 6000 on 80–100 mesh Chromosorb W or (*b*) 10% neopentylglycol sebacate polyester on 80–100 mesh Chromosorb W. Samples (5–10 γ) were placed on the top of the columns and development was made with dry argon at a flow rate of 100 ml per min.

Melting points were determined on a Kofler hot stage and are uncorrected. Optical rotations were measured at 22 ± 2°. Solutions were concentrated under reduced pressure below 50°.

Isolation of Apiin from Parsley

Washed fresh parsley stems and leaves (510 g) were blended with acetone (5 l) and the mixture was heated under reflux for 18 hours and filtered. The filtrate was concentrated to about 150 ml, and the resulting insoluble gelatinous material was collected and repeatedly extracted with petrol (b.p. 40–60°). The residue (15 g) was then washed with water (2 × 100 ml) and collected by filtration. The aqueous filtrate, which showed the presence of glucose, arabinose, and xylose, was discarded, and the dried insoluble residue of crude apiin (5.1 g), having m.p. 195–210°, was purified via its lead salt (9) to yield pure apiin, which, after recrystallization from ethanol, gave crystals having m.p. 228–230° and $[\alpha]_D$ −130° (*c*, 0.12 methanol).

The prepared apiin (0.5 g) was dissolved in acetic anhydride (6 ml) and pyridine (2 ml), and the solution was refluxed for 3 hours and then poured onto crushed ice. The insoluble product (0.8 g) was collected and recrystallized from a chloroform–methanol mixture to give crystalline apiin octa-*O*-acetate having $[\alpha]_D$ −53° (*c*, 1.0 chloroform) and m.p. 253–254° (lit. value m.p. 249–251° (9)).

Methylation of Apiin (20, 21)

Barium oxide (10 g) was added portionwise over 5 h to a stirred solution of apiin (5 g) in dimethyl sulphoxide (35 ml) and methyl iodide (30 ml), and after 48 hours the reaction mixture was filtered, the residue washed with chloroform, and the combined filtrate and washings were treated with more chloroform until no more inorganic material precipitated. On removal of the inorganic material the brown-colored solution was washed with 15% sodium thiosulphate solution (100 ml) and water (2 × 60 ml), and the dried (Na_2SO_4) solution was concentrated to a syrup (5.7 g). The syrup (5.7 g) was further methylated three times using methyl iodide (30 ml) and silver oxide (15 g) (22) to yield a final product (4.75 g) which showed no hydroxyl absorption at 3 500 cm^{-1} and had $[\alpha]_D$ −91° (*c*, 2.3 chloroform).

Anal. $C_{34}H_{42}O_{15}$ requires OMe, 35.5%. Found OMe, 35.1%.

Fission of Methylated Apiin

Methylated apiin (4.6 g) was heated for 8 hours on a boiling water bath with a mixture of acetic acid (50 ml) and 5% aqueous hydrochloric acid (100 ml), and after cooling, the insoluble 5,4′-di-*O*-methyl apigenin (1.4 g) (m.p. 293–295° (8)) was removed by filtration. The filtrate was neutralized by passing it through Duolite A4 (OH^-) ion-exchange resin, and the solution was concentrated to a syrup which was extracted with water (15 ml). Paper chromatographic examination of the aqueous extract using solvent system *c* showed the presence of 3,4,6-tri-*O*-methyl-D-glucose (R_G 0.82) and 2,3,4-tri-*O*-methyl-D-apiose (R_G 0.95).

Separation of 2,3,4-Tri-O-methyl-D-apiose and 3,4,6-Tri-O-methyl-D-glucose

The aqueous extracts (15 ml) of the sugars obtained from the fission of the methylated apiin were extracted with chloroform (4 × 10 ml). Concentration of the dried (anhydrous $MgSO_4$) chloroform extracts gave 2,3,4-tri-*O*-methyl-D-apiose (820 mg) having $[\alpha]_D$ −1.7° (*c*, 2.3 methanol), while concentration of the aqueous solution gave 3,4,6-tri-*O*-methyl-D-glucose (950 mg), which had $[\alpha]_D$ +70° (*c*, 1.5 water) (literature value $[\alpha]_D$ +71° (water) (23, 24)) and gave a crystalline phenylosazone derivative with m.p. 80–81° (literature value m.p. 80° (23)).

Synthesis of 2,3,4-Tri-O-methyl-D-apio-D-furanose

(A) Methyl 2,3-O-Isopropylidene-4-O-methyl-α+β-D-apio-D-furanoside

2,3-*O*-Isopropylidene-D-apio-D-furanose (1.4 g) (5*a*) in methyl iodide (75 ml) was heated under reflux while silver oxide (15 g) was added portionwise over 8 hours, and after a further 24 hours the reaction mixture was filtered, the residue was washed with chloroform, and the combined filtrate and washings were concentrated to a syrup. Thin-layer chromatographic examination of the syrup using solvent system *d* showed a major component (about 90% visual ratio) having R_f 0.68 and a minor component having R_f 0.88. Distillation of the syrup gave a fraction (1.1 g) collected at 90–95°/0.35 mm which had η_D^{23} 1.43915 and $[\alpha]_D$ −66° (*c*, 3.6 methanol).

Anal. $C_{10}H_{18}O_5$ requires: C, 55.1%; H, 8.2%; OMe 28.4. Found: C, 55.1%; H, 8.1%; OMe, 27.9.

(B) Methyl 4-O-Methyl-α+β-D-apio-D-furanoside

Methyl 2,3-*O*-isopropylidene-4-*O*-methyl-D-apio-D-furanoside (1.1 g) was heated on a boiling water bath for 3 hours with dry 2% methanolic hydrogen chloride, and, after neutralization of the cooled reaction mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with Duolite A4 (OH^-) ion-exchange resin (previously washed with methanol), the solution was concentrated to yield syrupy methyl 4-*O*-methyl-$\alpha+\beta$-D-apio-D-furanoside (0.8 g) having $[\alpha]_D$ 0° (*c*, 1.9 methanol).

Anal. $C_7H_{14}O_5$ requires: OMe, 34.8%. Found: OMe, 35.2.

(C) 4-O-Methyl-D-apio-D-furanose

Methyl 4-*O*-methyl-$\alpha+\beta$-D-apio-D-furanoside (0.8 g) was heated for 2 h at 100° with *N* sulphuric acid (10 ml) and after neutralization (Duolite A4(OH^-)) the solution was concentrated to a syrup (0.75 g) which had $[\alpha]_D$ 0° (*c*, 2.3 methanol). Paper chromatographic examination of the product using solvent system *d* showed a single spot having R_G 0.16.

Anal. $C_6H_{12}O_5$ requires: OMe, 18.9. Found: OMe, 18.5.

(D) Methyl 2,3,4-Tri-O-methyl-$\alpha+\beta$-D-apio-D-furanoside

4-*O*-Methyl-D-apio-D-furanose (0.74 g) was refluxed for 8 h with 2% methanolic hydrogen chloride (15 ml) and, after neutralization (Duolite A4(OH^-)) filtration and concentration of the filtrate, the residual syrupy furanoside was methylated in the usual way using three successive treatments with methyl iodide (25 ml) and silver oxide (10 g) to yield a final product (510 mg) which had $[\alpha]_D$ +2° (*c*, 2.2 methanol) and gave a single spot on thin-layer chromatograms.

Anal. $C_9H_{18}O_5$ requires: OMe, 60.2%. Found: OMe, 58.8%.

(E) 2,3,4-Tri-O-methyl-D-apio-D-furanose

Methyl 2,3,4-tri-*O*-methyl-$\alpha+\beta$-D-apio-D-furanoside (500 mg) was hydrolyzed with *N* sulphuric acid (15 ml) for 2 h at 100° and, after neutralization (Duolite A4(OH^-)) and concentration, the product was obtained as a syrup (450 mg) having $[\alpha]_D$ −7° (*c*, 2 methanol) and R_G 0.91 (solvent *b*).

Anal. $C_8H_{16}O_5$ requires: OMe, 48.4%. Found: OMe, 47.3%.

Periodate Oxidation of Apiin

(A) Oxidation of Apiin with Excess Periodate

Apiin (28.8 mg) dissolved in 50% aqueous ethanol (49 ml) was oxidized in the dark at room temperature by the addition of 0.3 *M* sodium metaperiodate (1 ml). At intervals, samples were withdrawn for the determination of periodate uptake (25) and release of formaldehyde (26). The results are recorded in Table III.

(B) Oxidation of Apiin with 1 Mole of Periodate

Sodium metaperiodate (32.1 mg in water (3 ml)) was added to a solution of apiin (87 mg) in 50% aqueous ethanol (72 ml) and the mixture was kept at 5° for 16 h at which time 0.35 mole of formaldehyde had been released per mole apiin. The solution was deionized by passing it through Amberlite IR-120 (H^+) and Duolite A4 (OH^-) ion-exchange resins, the eluate and washings were combined, and the oxidized apiin was reduced by addition of sodium borohydride (30 mg). After 30 min, the reduced product was hydrolyzed with *N* sulphuric acid for 3 h at 100°, and, after neutralization (Duolite A4 (OH^-)), the solution was divided into three parts. The first part, examined directly by paper chromatography, showed only the presence of glucose, and the second part, after the addition of xylose as an internal standard, showed by quantitative evaluation that 90% of the glucose present in the apiin had been recovered. The third part was reduced by $NaBH_4$ (20 mg) and subsequent paper chromatographic analysis of the product showed the presence of glycerol, tetritol, and sorbitol.

(C) Oxidation of Apiin with 2 Moles of Periodate

Oxidation of apiin as described in (B) above using twice the amount of periodate showed after 16 hours oxidation at 5° that 0.85 mole of formaldehyde was released per mole of apiin.

SURFACE EFFECTS IN THE UNINHIBITED AND THE INHIBITED PYROLYSES OF ISOMERIC HEXANES

PARTS I–III. *n*-HEXANE, 2-METHYL PENTANE, 3-METHYL PENTANE

J. CHRYSOCHOOS[1] AND W. A. BRYCE[2]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received December 9, 1964

ABSTRACT

The rates of pyrolysis of *n*-hexane, 2-methyl pentane, and 3-methyl pentane decrease with increasing S/V ratio in the pressure range of 15 to 90 mm at temperatures around 520 °C. The partial pressure of nitric oxide required for maximum inhibition which appears to be independent of the hydrocarbon pressure and is approximately constant for all isomers, namely 12–14 mm, for hydrocarbon ranging from 50 to 100 mm, increases slightly with increasing S/V ratio. Nitric oxide affects the product distribution markedly. The simultaneous increase in the yield of C_2H_4 and decrease in the yield of C_2H_6 with increasing NO pressure can be attributed to the set of competitive reactions

$$C_2H_5 + NO \rightarrow C_2H_4 + HNO$$

$$C_2H_5 + RH \rightarrow C_2H_6 + R.$$

Similarly, the slight decrease in the yield of C_3H_8 with increasing NO pressure can be accounted for by the competition

$$i\text{-}C_3H_7 + NO \rightarrow C_3H_6 + HNO$$

$$i\text{-}C_3H_7 + RH \rightarrow C_3H_8 + R.$$

Increased S/V ratios favor the formation of C_2H_6 in both the uninhibited and the inhibited pyrolyses, but has no effect on the yields of such products as C_3H_6, 1-C_4H_8, and i-C_4H_8. The analytical balance becomes less complete at higher NO pressures for the inhibited decomposition, which can be attributed to the formation of some nitrogen-containing compounds undetectable by the analytical methods used. Mechanisms are proposed accounting qualitatively for the products of the uninhibited and the inhibited pyrolyses.

INTRODUCTION

Although there has been a large number of investigations of the inhibition of the thermal decomposition of organic compounds, comparatively little work has appeared on higher hydrocarbons. Peard *et al.* (1) investigated the inhibited pyrolyses of 2-methyl pentane and 3-methyl pentane, but they focused their study on the apparent chain lengths and the kinetic parameters. The same authors have investigated the variation of the activation energy with the hydrocarbon pressure for the thermal decomposition of the above-mentioned compounds (2).

The role of nitric oxide in various decomposition reactions has not yet been completely clarified. However, a number of theories have been proposed to interpret the effects. In the early theories of Hobbs and Hinshelwood (3, 4) on the thermal decomposition of ethane and propane, nitric oxide was assumed to capture the chain-propagating radical, which inevitably causes reduction in rate. More recently, the inhibitor has been associated with both initiation and termination processes (5–8). This idea has been applied to various hydrocarbons, leading to rate expressions in good agreement with experiment.

The inhibitor is also assumed to capture β or μ radicals and to be regenerated from the bound states (βI) and (μI) (9). An attempt has been made to explain the inhibition

[1]*Present address: Department of Chemistry, Harvard University, Cambridge, Mass. 02138.*

[2]*The premature death of Professor Bryce has deprived kineticists of an able scientist and his colleagues of a trusted friend.*

phenomenon on the occurrence of degenerate chain branching of some intermediate oximes formed in the system of NO and hydrocarbon (10). The rate expressions derived on this basis also agree well with experimental results for the isomeric pentanes (11). In all of these examples inhibition was considered to be a fully homogeneous reaction. Voevodsky (12) assumed that inhibition is heterogeneous. Covering of the active centers at the wall of the vessel by the inhibitor was suggested as the cause of the rate reduction. Such surface effects have been found in the case of isopentane (13). A thorough investigation of the isomeric hexanes with respect to the effect of S/V ratio and presence of inhibitor on both reaction rates and product distributions has been carried out. The details of the decomposition of *n*-hexane, 2-methyl pentane, and 3-methyl pentane are described here.

EXPERIMENTAL

The *n*-hexane, 2-methyl pentane, and 3-methyl pentane used were Research grade (99.9, 99.7, and 99.83% respectively) obtained from the Phillips Petroleum Corp., Bartlesville, Okla. They were subjected to repeated trap-to-trap distillation at −196 and −78°. No impurities could be detected by conventional gas chromatographic methods. The nitric oxide (99%), supplied by the Matheson Co., East Rutherford N.J., was further purified by repeated trap-to-trap distillation. The absence of NO_2 in the purified NO was confirmed by infrared spectroscopy.

The pyrolyses were done in a conventional static system. For all of the inhibited and some of the uninhibited pyrolyses, a 300 ml quartz reaction vessel, held in an insulated brass block furnace, was used in which the temperature could be controlled to within 1 deg at 500 °C. Packing of the vessel was done with fire-polished quartz tubes. When necessary, hydrocarbons and NO were premixed before admitting them to the reaction vessel.

Manometric rates were obtained throughout the study, after establishing a 1:1, 0.98:1 and 0.95:1 correspondence between the initial rates so obtained and those found from the rate of disappearance of *n*-hexane, 2-methyl pentane, and 3-methyl pentane respectively by direct analysis. This correspondence was established in the uninhibited pyrolyses and it was assumed to apply to the inhibited pyrolyses too.

For some of the uninhibited pyrolyses, two 160 ml quartz reaction vessels, one packed with fire-polished quartz and the other unpacked, were placed in a well-insulated, double furnace. The increase in pressure due to decomposition was recorded for each vessel under otherwise identical conditions with a sensitive pressure transducer (9 mm recorder response per mm of mercury pressure).

Complete analytical mass balances were obtained by conventional gas chromatographic techniques supplemented by infrared analysis.

PART I. *n*-HEXANE

Results

A typical set of data for the uninhibited decomposition of *n*-hexane at 500 °C is given in Table I.

TABLE I

pressure transducer. One such pressure time curve is shown in Fig. 1. The solid line is drawn by the pen of the recorder and the discontinuities correspond to alternate connection of the transducer to the packed and unpacked vessels. In all cases, the reaction rate was lower in the packed than in the unpacked vessel. The percentage reduction in rate brought about by packing is given in Fig. 2 as a function of the initial pressure of *n*-hexane.

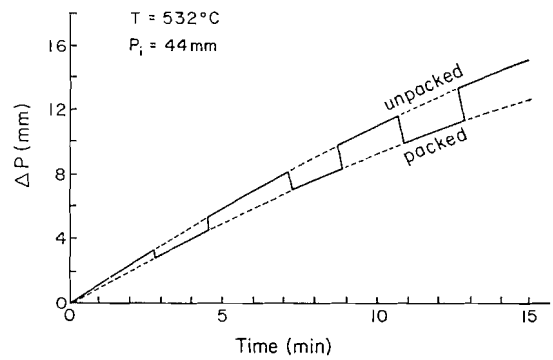

FIG. 1. Pressure–time curves for packed and unpacked vessels recorded through a pressure transducer

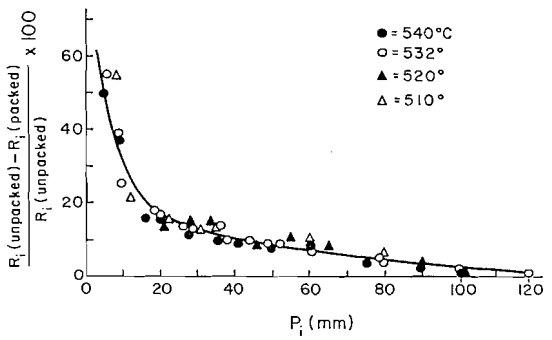

FIG. 2. Percentage reduction in rate due to packing for various initial pressures of *n*-hexane.

The data on the effect of this same increase in surface area on the product distribution are given in Table II. The ratios CH_4/C_2H_6 and C_2H_4/C_2H_6 decrease markedly when the vessel is packed.

The activation energies and frequency factors were calculated from the Arrhenius equation using rate constants obtained at the temperatures 490, 510, and 520 °C which are given in Table III. The kinetic parameters are pressure dependent yet approach constant values at high pressures. The average from 3 different determinations are given in Table IV. The rate constants can be related to the A factors and activation energies by the expressions

$$k = A(P_i) \exp -(E_{act}(P_i)/RT).$$

This in fact means that the whole mechanism depends on the initial pressure.

TABLE III

Rate constants for the decomposition of n-hexane $\times 10^2$ min^{-1}

TABLE IV

Variation of activation energies and frequency factors with initial pressure of n-hexane

P_i (mm)	E_{act} (kcal)	A (s^{-1}) $\times 10^{12}$
0–40	64.0±1.0	170.
40–60	60.0±2.0	11.
60–80	59.5±2.5	8.2
90	59.4±4.0	5.3
100	59.0±4.0	3.5
120	58.5±3.5	3.3

The overall reaction order, which was measured from the slope of the plot, log (initial rate) vs. log (P_i), was found to be unity, in fact 1.09, at the temperatures 500, 510, and 520 °C over a hydrocarbon pressure range of 10 to 120 mm (Fig. 3).

Nitric oxide reduces the reaction rate quite significantly even when present only in trace quantities. The pressure time curves were sigmoid in the presence of NO, and initial rates were obtained. The NO pressure required for maximum reduction in initial rate is 12–14 mm for the pressure range of 50 to 100 mm of n-hexane at 520 °C (Fig. 4*a*). An increase in S/V ratio from 1 cm^{-1} to 5 and 10 cm^{-1} shifts the NO pressure required for maximum inhibition from 12–14 mm to 16 and 18 mm respectively (Fig. 4*b*). Nitric oxide also changes the product distribution. The yields of C_2H_4 and CH_4 increase with increasing NO pressure while that of C_2H_6 decreases. The distribution of the products C_3H_6 and 1-C_4H_8 are independent of NO (Fig. 5).

The relationship between the yield of the products and time in the fully inhibited decompositions was found to be very nearly linear for conversions up to 40% (Fig. 6). This indicates that the inhibited reaction is not affected by the products of the reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

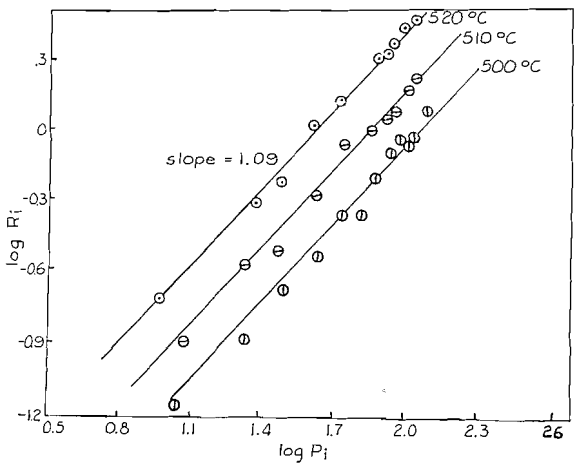

FIG. 3. Plots of the logarithm of the rate against the logarithm of the pressure for the uninhibited decomposition of *n*-hexane.

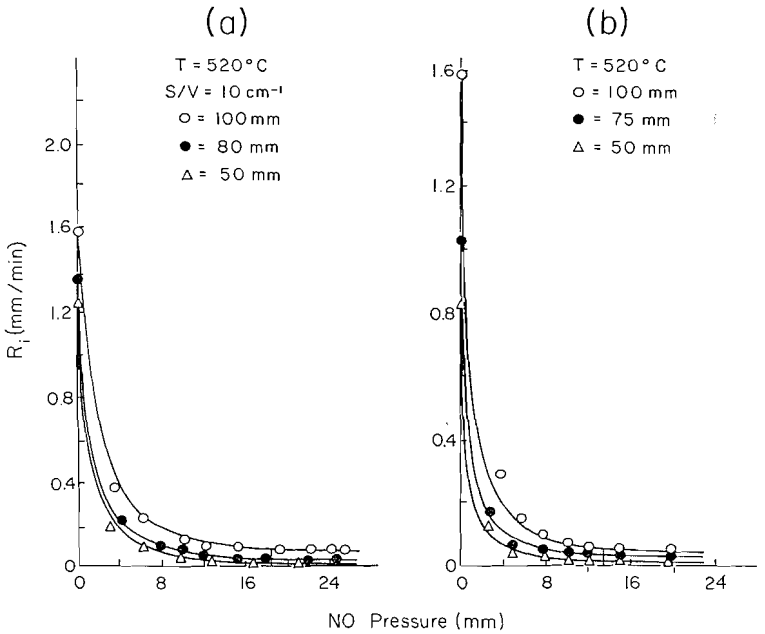

FIG. 4. Dependence of the initial rate on NO pressure in (*a*) the unpacked and (*b*) the packed vessels.

This relationship is not linear in the uninhibited decompositions at such high conversions. Thus the fully inhibited decomposition may obey a purely homogeneous mechanism.

An increase in the surface area does not affect the yields of C_3H_6 and 1-C_4H_8 as illustrated in Fig. 7. The ratio C_2H_4/C_2H_6, however, increases with increasing NO pressure and for all NO pressures decreases with increasing S/V ratio (Fig. 8).

Because of the remarkable effect of the surface on the initial rates of the decomposition, it was felt necessary to obtain some information as far as the relative adsorption of *n*-hexane and NO on quartz is concerned. Binary mixtures of *n*-hexane and NO of known

composition were passed through a thermally insulated glass tube packed with quartz wool to give an $S/V \simeq 60\ cm^{-1}$, and then analyzed by gas chromatography. Any differences in the relative adsorption of the components of the mixture on the quartz wool would change the composition of the mixture in the gas phase. However, this experiment was primitive and the results have only qualitative significance. Although it was desirable to establish the same conditions with those in the thermal decomposition of *n*-hexane, yet it was impossible because at about 400 °C decomposition was occurring rapidly, in spite of the high pressure of NO present and the short contact time (2 min). Some of the results are given in Table V. It is seen that the ratio is higher at low initial pressures of the mixture and tends to its initial value at high pressures. Therefore, at lower initial pressures, the amount of NO in the gas phase is smaller relative to the amount of *n*-hexane. In other words NO is adsorbed more than *n*-hexane on quartz wool. At higher pressures this effect fades completely.

Discussion

The following reactions are sufficient to account for the products of the uninhibited decomposition. Additional reactions which could be written only add to the complexity.

Initiation reactions:

[1*a*] $$n\text{-}C_6H_{14} \rightarrow CH_3 + n\text{-}C_5H_{11}$$

[1*b*] $$n\text{-}C_6H_{14} \rightarrow C_2H_5 + n\text{-}C_4H_9$$

[1*c*] $$n\text{-}C_6H_{14} \rightarrow 2(n\text{-}C_3H_7).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Propagation reactions:

[2*a*] $$CH_3 + n\text{-}C_6H_{14} \rightarrow CH_4 + n\text{-}C_6H_{13}$$

[2*b*] $$CH_3 + n\text{-}C_6H_{14} \rightarrow CH_4 + CH_3CH_2CH_2CH_2CHCH_3$$

[2*c*] $$CH_3 + n\text{-}C_6H_{14} \rightarrow CH_4 + CH_3CH_2CH_2CHCH_2CH_3$$

[3*a–c*] $$C_2H_5 + n\text{-}C_6H_{14} \rightarrow C_2H_6 + n\text{-hexyl radicals.}$$

Radical decompositions:

[4*a–c*] $$n\text{-hexyl radicals} \rightarrow C_2H_5 + 1\text{-}C_4H_8$$

[5*a–c*] $$n\text{-hexyl radicals} \rightarrow n\text{-}C_3H_7 + C_3H_6$$

[6] $$n\text{-}C_5H_{11} \rightarrow CH_3 + 1\text{-}C_4H_8$$

[7] $$n\text{-}C_5H_{11} \rightarrow C_2H_5 + C_3H_6$$

[8] $$n\text{-}C_4H_9 \rightarrow CH_3 + C_3H_6$$

[9] $$n\text{-}C_4H_9 \rightarrow C_2H_5 + C_2H_4$$

[10] $$n\text{-}C_3H_7 \rightarrow CH_3 + C_2H_4$$

[11] $$n\text{-}C_3H_7 \rightarrow H + C_3H_6$$

[12] $$C_2H_5 \rightarrow H + C_2H_4.$$

Termination reaction:

[13] $$2CH_3 \xrightarrow{\beta\beta M} C_2H_6.$$

The comparatively small amount of hydrogen can be accounted for by such reactions as

$$H + RH \rightarrow H_2 + R$$

which may participate to a slight extent. Hydrogen atoms are formed through reactions [11] and [12]. However, reaction [10] predominates in the competing set of reaction [10] and [11], because of a difference in activation energy of about 17 kcal (14). Thus a very small fraction of n-C_3H_7 produces H atoms. The overall order of decomposition is unity and according to the terminology of Goldfinger *et al.* (15) for first order initiations there are only two choices of termination leading to an overall order of unity: $\beta\beta$M and $\beta\mu$. The $\beta\mu$ termination is canceled because of the lack of C_4H_{10} and the only trace of C_3H_8. For second order initiation the only two choices leading to unity order, namely $\mu\mu$ and $\beta\mu$M are canceled again because of the lack of C_4H_{10} in the system.

Propylene appears in greater amounts than 1-butene, and therefore reactions [5*a–c*] must play a more important role than the competing reactions [4*a–c*].

The lower yield of C_2H_6 compared with that of CH_4 can be attributed to the difference in activation energies for the sets of the reactions [2*a–c*] and [3*a–c*]. Methyl radicals are produced mainly through reactions [5*a–c*] and [10] which are the main propagating processes and C_2H_5 are formed through reaction [4*a–c*] which play less important roles as it is revealed from the ratio $C_3H_6/1\text{-}C_4H_8$. This is the main reason for the higher yield of CH_4 over C_2H_6.

The initiation processes can take place both homogeneously and heterogeneously. A molecule chemisorbed on the walls of the reaction vessel can decompose more easily than a molecule in the gas phase because of the weakening of the various bonds due to chemisorption. In addition, termination can take place in both phases. That is, chemisorbed radicals on the walls react with other radicals more readily than if both radicals are in the gas phase. An active center on the walls can play the role of a third body, M, as well as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

molecule in the gas phase. Therefore, the surface has a twofold effect on the decomposition; acceleration because of the effect on the initiation and reduction because of the effect on the termination. The net effect can be expressed as

$$\text{net effect} = \text{effect on initiation} - \text{effect on termination.}$$

Nitric oxide is adsorbed more than *n*-hexane on quartz wool. Therefore in a competition between NO and *n*-hexane molecules for active centers, the NO molecules will expel the *n*-hexane ones. This will result in suppression of the heterogeneous initiation to a very significant extent. It is not known how much the energy of dissociation of *n*-hexane is reduced because of the chemisorption on the wall. The heat of adsorption of *n*-hexane on ferrous and ferric oxide has been found to be about 15 kcal (16). If the same value is assumed for quartz it is to be expected that the chemisorbed molecules may require 10–15 kcal less than the energy in the gas phase to dissociate. In other words the heterogeneous initiation may be more than 100 times faster than the homogeneous initiation at 500 °C.

From this point of view it is understood that NO, even in very small amounts, can reduce the rate very sharply by simply suppressing the heterogeneous initiation. However, such a heterogeneous effect of NO can be assigned only in the initial stage of the reaction. Once the initiation will take place, propagation will continue in the gas phase. In this case the effect of NO, if any, will be associated with the gas phase. The strong induction period in the initial rate of the inhibited decomposition can be attributed to this effect of NO. At maximum inhibition, an equilibrium between adsorbed and desorbed NO molecules may be established. Therefore the effect of NO on the heterogeneous initiation will cease and the rate will be independent of NO. Certainly, initiatory effects of NO will appear whose significance will increase with increasing NO pressure.

Surface-to-volume ratio has no effect on the yield of C_3H_6 or 1-C_4H_8, therefore, the propagation reactions involved in their formation must occur homogeneously. The effect of NO in causing an increase in the yield of C_2H_4 can be accounted for by the reaction

[14] $$C_2H_5 + NO \rightarrow C_2H_4 + HNO.$$

Reaction [14] would compete with reactions [3*a*–*c*] and consequently any increase in the yield of C_2H_4 would be associated with a decrease in the yield of C_2H_6.

The role of HNO in the system is not known. However, its existence has been established by flash photolysis and its lifetime was found to be about 0.1 s under these conditions (17). Some controversies exist as far as D(H—NO) is concerned. The value of 48.6 kcal was obtained from spectroscopy measurements (18, 19) while a minimum of 56 kcal was assigned from infrared chemiluminescence studies (20). In either case, reaction [14] is exothermic by at least 11 kcal (based on $D(C_2H_4\text{—H}) = 38$ kcal (21)). The HNO molecule can further participate in termination processes which regenerate nitric oxide. In addition, NO, a free readical itself, can recombine with free radicals leading to a variety of nitrogen-containing products. However, such products were not detected in the present study by the analytical method used. Slight consumption of NO was found for NO pressures above 5 mm.

It is interesting to note that the rate expressions derived by Norrish and Pratt (10) applied to the present study, gives curves approximately of the same shape as the experimental ones. However, some more or less severe assumptions have to be made because many rate constants are unknown for the *n*-hexane system.

The effect of an 11-fold increase in the S/V ratio on the decomposition rate is less marked than that observed with *n*-hexane. The percentage reduction in rate due to packing is illustrated in Fig. 9. At about 110 mm of 2-methyl pentane the effect of S/V ratio disappears. No marked effect of the surface on the product distribution was observed in the uninhibited decomposition.

Overall activation energies and frequency factors were calculated from the Arrhenius equation, using rate constants obtained at three temperatures, 500, 510, and 520 °C. The rate constants are given in Table VIII. The kinetic parameters are pressure dependent and decrease at high hydrocarbon pressures as shown in Table IX. The overall order was found to be 1.3 for hydrocarbon pressures less than 40 mm and tends to unity for pressures above 40 mm (Fig. 10).

Variation of activation energies and frequency factors with initial pressure of 2-methyl pentane

P_i (mm)	E_{act} (kcal)	A (s^{-1}) $\times 10^{11}$
0–30	62.0±1.0	470
30–60	60.0±2.0	550
60–90	58.0±3.0	120
90–100	58.5±4.0	55
120	56.0±2.0	8.4

Over a large pressure range and at constant extent of decomposition (20%), the yields of CH_4, C_2H_6, C_3H_8, and H_2 increase with increasing hydrocarbon pressure. The yields of the rest of the products increase slightly with increasing hydrocarbon pressure approaching more or less constant values at higher hydrocarbon pressures (Fig. 11).

Nitric oxide, even in small amounts, reduces the rate of decomposition significantly (Fig. 12*b*). However, the reduction in rate is less sharp in the decomposition of 2-methyl pentane than in the decomposition of *n*-hexane. The nitric oxide pressure required for maximum inhibition is about 14 mm for hydrocarbon pressures in the range of 50 to 100 mm. It also shifts to higher pressures for higher S/V ratios (Fig. 12*a*). Nitric oxide also affects the product distribution. The yields of CH_4 and C_2H_4 increase while those of C_2H_6 and C_3H_8 decrease with increasing NO pressure. The yields of products such as C_3H_6 and *i*-C_4H_8 are independent of the NO pressure as shown in Fig. 13.

For personal use only.

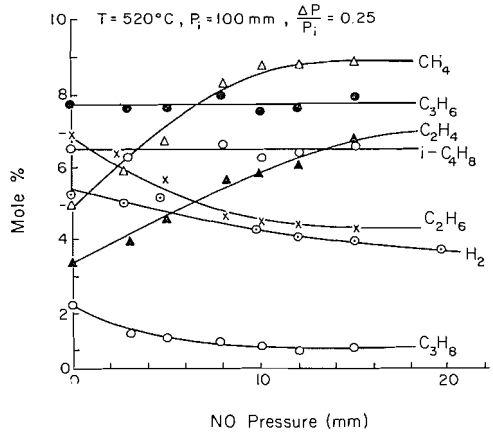

FIG. 13. Variation of the product distribution with NO pressure.

The variation of the product distribution with time is almost linear for extents of decomposition up to 40% in the fully inhibited reaction (Fig. 14). This indicates that no self-inhibition by the products occurs, at least in the fully inhibited decomposition. Self-inhibition is obvious in the case of the uninhibited decompositions under the same conditions.

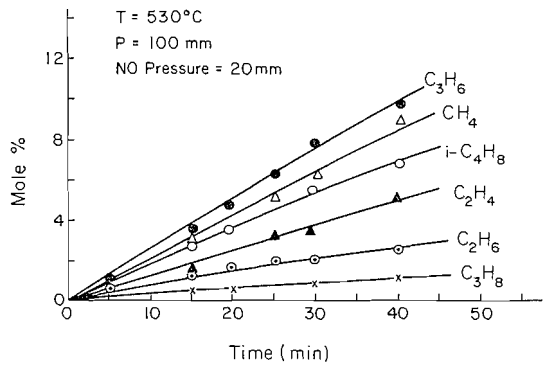

FIG. 14. Variation of the product distribution with time for the fully inhibited decomposition.

No definite effect was found on the formation of C_2H_6, C_2H_4, or C_3H_8 by the surface. The ratio C_2H_4/C_2H_6 which increases steadily with increasing NO pressure, is not significantly affected by variation in S/V ratio (Fig. 15). However, the data are scattered enough to mask any small variation in the ratio.

Results on the adsorption of 2-methyl pentane relative to NO are given in Table X. Nitric oxide is still adsorbed more than 2-methyl pentane on quartz.

Discussion

The products of the uninhibited pyrolysis at pressures of 2-methyl pentane in the range of 40 to 200 mm can be accounted for by the following reactions.

Initiation reactions:

[15*a*] $(CH_3)_2CHCH_2CH_2CH_3 \rightarrow CH_3 + (CH_3)_2CHCH_2CH_2$

[15*b*] $(CH_3)_2CHCH_2CH_2CH_3 \rightarrow CH_3 + CH_3CHCH_2CH_2CH_3$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[15c] $(CH_3)_2CHCH_2CH_2CH_3 \rightarrow C_2H_5 + (CH_3)_2CHCH_2$

[15d] $(CH_3)_2CHCH_2CH_2CH_3 \rightarrow i\text{-}C_3H_7 + n\text{-}C_3H_7.$

Propagation reactions:

[16a] $CH_3 + (CH_3)_2CHCH_2CH_2CH_3 \rightarrow CH_4 + (CH_3)_2CHCH_2CH_2CH_2$

[16b] $CH_3 + (CH_3)_2CHCH_2CH_2CH_3 \rightarrow CH_4 + (CH_3)_2CHCH_2CHCH_3$

[16c] $CH_3 + (CH_3)_2CHCH_2CH_2CH_3 \rightarrow CH_4 + (CH_3)_2CHCHCH_2CH_3$

[16d] $CH_3 + (CH_3)_2CHCH_2CH_2CH_3 \rightarrow CH_4 + (CH_3)_2CCH_2CH_2CH_3$

[16e] $CH_3 + (CH_3)_2CHCH_2CH_2CH_3 \rightarrow CH_4 + CH_3\underset{\displaystyle CH_2}{\underset{|}{C}}HCH_2CH_2CH_3.$

[17a–e] $C_2H_5 + (CH_3)_2CHCH_2CH_2CH_3 \rightarrow C_2H_6 +$ 2-methyl pentyl radicals

[18a–e] $i\text{-}C_3H_7 + (CH_3)_2CHCH_2CH_2CH_3 \rightarrow C_3H_8 +$ 2-methyl pentyl radicals

[19a–e] $H + (CH_3)_2CHCH_2CH_2CH_3 \rightarrow H_2 +$ 2-methyl pentyl radicals.

Radical decompositions:

[20a–e] 2-methyl pentyl radicals $\rightarrow C_2H_5 + i\text{-}C_4H_8$

[21a–e] 2-methyl pentyl radicals $\rightarrow i\text{-}C_3H_7 + C_3H_6$

[22] $(CH_3)_2CHCH_2CH_2 \rightarrow C_2H_5 + C_3H_6$

[23] $CH_3CHCH_2CH_2CH_3 \rightarrow C_2H_5 + C_3H_6$

[24] $(CH_3)_2CHCH_2 \rightarrow CH_3 + C_3H_6$

[25] $(CH_3)_2CHCH_2 \rightarrow H + i\text{-}C_4H_8$

[26] $n\text{-}C_3H_7 \rightarrow CH_3 + C_2H_4$

[27] $n\text{-}C_3H_7 \rightarrow H + C_3H_6$

[28] $i\text{-}C_3H_7 \rightarrow CH_3 + C_2H_4$

[29] $i\text{-}C_3H_7 \rightarrow H + C_2H_4$

[30] $C_2H_5 \rightarrow H + C_2H_4.$

Termination reaction:

[31] $2CH_3 \xrightarrow{\beta\beta M} C_2H_6.$

For first order initiation a $\beta\beta$M termination type leads to unity order (15) while for second order initiation a $\beta\mu$M termination leads to the same order. However, the $\beta\mu$M termination is canceled because no C_4H_{10} was detected among the products. For pressures lower than 40 mm the order tends to 3/2, in fact is 1.3, therefore two termination types will participate, $\beta\beta$ and $\beta\beta$M for first and second order initiation respectively. The $\beta\beta$ is canceled because β radicals are CH_3 and H whose recombination involves a third body. Therefore the above-outlined mechanism may be valid for pressures higher than 40 mm, involving a first order initiation.

Hydrogen is formed in quite significant amounts compared with those found in the decomposition of *n*-hexane. This can be attributed to the decomposition of the isopropyl radical, one of the major radicals in the mechanism. Isopropyl radical can undergo isomerization, direct decomposition, or chain propagation.

[28] $CH_3CHCH_3 \rightarrow (CH_3CH_2CH_2) \rightarrow CH_3 + C_2H_4$

[29] $CH_3CHCH_3 \rightarrow H + C_3H_6$

[18] $CH_3CHCH_3 + RH \rightarrow C_3H_8 + R$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

At temperatures around 500 °C, Jackson and McNesby (22) found that reaction [29] is faster by a factor of at least 14 than reaction [28]. Therefore reaction [29] predominates. The small amount of C_3H_8 formed indicates that reaction [18] participates to a minor extent. The dependence of the yields of CH_4, C_2H_6, C_3H_8, and H_2 on the hydrocarbon pressure can be accounted for by reactions [16] to [19] which are favored as the hydrocarbon pressure is increased. The complexity of the mechanism, however, makes any relation between the yields of products and the hydrocarbon pressure impossible.

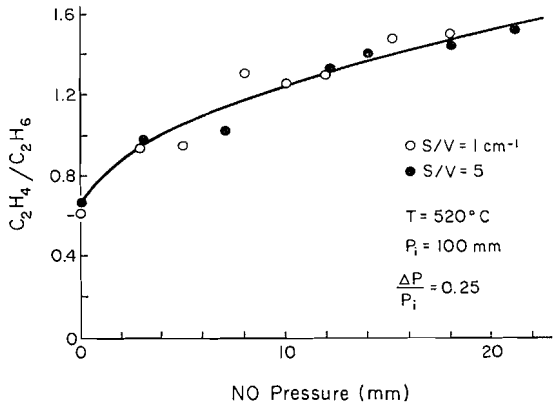

FIG. 15. Variation of the C_2H_4/C_2H_6 ratio with NO pressure.

11	2.00
31	1.94
44	1.88
61	1.86
66	1.86
96	1.80

The net effect of the surface is less marked in the decomposition of 2-methyl pentane than in the decomposition of *n*-hexane. From the mechanism of decomposition of *n*-hexane and 2-methyl pentane, it can be inferred that termination processes involve similar radicals and therefore it is rather unlikely that the effect of the surface on termination reactions would be much different in the two cases. Consequently, the less marked effect of the surface on the decomposition of 2-methyl pentane can be associated with the initiation rather than the termination processes. From Tables V and X we can infer that NO expels *n*-hexane from adsorption sites easier than 2-methyl pentane. Nitric oxide reduces the rate of decomposition of 2-methyl pentane also by suppressing the herogeneous initiation as in the case of *n*-hexane. For this reason the reduction in rate is also very sharp.

As the amount of NO increases, the inhibitor starts functioning in both phases. This is revealed by the effect of NO on the products of decomposition. The product distribution is markedly affected by NO. The simultaneous increase in the yield of C_2H_4 and decrease in that of C_2H_6 with increasing NO pressure can arise from the competing reactions discussed earlier in this paper.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[14] $$C_2H_5 + NO \rightarrow C_2H_4 + HNO$$

[3] $$C_2H_5 + RH \rightarrow C_2H_6 + R$$

The decrease in the yield of C_3H_8 with increasing NO pressure is attributed to similar competing reactions.

[32] $$i\text{-}C_3H_7 + NO \rightarrow C_3H_6 + HNO$$

[33] $$i\text{-}C_3H_7 + RH \rightarrow C_3H_8 + R$$

The effect of NO on the yield of CH_4 is particularly dramatic; it almost doubles from the uninhibited to the fully inhibited reaction, yet in the case of *n*-hexane there is almost no effect of NO on the yield of methane.

Although the reaction

[34] $$R + NO \rightarrow HNO + \text{olefins}$$

becomes more exothermic as the size of R increases, the instability of the larger R radicals rules out almost completely reactions of the type [34] in comparison to their unimolecular decomposition.

The fully inhibited decomposition appears to be of the same nature as that of *n*-hexane. The linearity in the relationship of the yields of the products to time indicates that the fully inhibited decomposition is not self-inhibited by any of its products either in the gas phase or adsorbed on the walls. This may indicate that the fully inhibited decomposition involves only homogeneous initiation while the heterogeneous one is completely suppressed by NO.

The analytical balance becomes less complete as the NO pressure is increased. This observation fits with the addition reaction of NO with radicals.

[35] $$R + NO \rightarrow RNO$$

These nitroso compounds can isomerize and decompose further into nitrogen-containing products which, however, were not observed here because of the analytical method used. Similar products have been observed by mass spectrometry in a system containing NO and methyl radicals (23). For low pressures of NO, at which NO was recovered completely, it is assumed that reaction [35] and subsequent isomerization are not important.

PART III. 3-METHYL PENTANE

Results

Two typical sets of analytical results are given in Tables XI and XII.

TABLE XI

Analytical results (mole %) for the uninhibited decomposition of 3-methyl pentane (T = 510 °C, $\Delta P/P_i$ = 0.20)

The effect of an 11-fold increase in S/V ratio upon the decomposition of 3-methyl pentane is the same as on the decomposition of 2-methyl pentane (Fig. 16). The percentage reduction in rate vanishes at about 100 mm of hydrocarbon. The overall reaction order obtained at 490, 500, 510, and 520 °C is a little higher than unity, namely 1.2 (Fig. 17). Rate constants obtained at the above-mentioned temperatures are given in Table XIII. The kinetic parameters are pressure dependent and tend to more or less constant values at higher pressures. Average of 6 values are given in Table XIV.

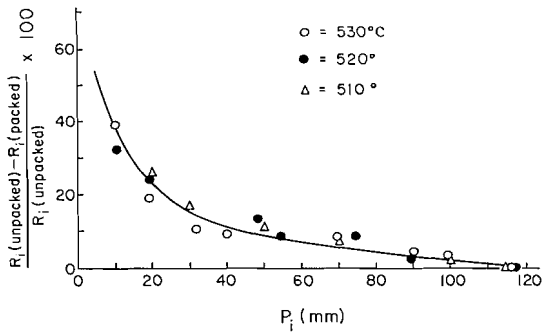

FIG. 16. Percentage reduction in rate due to packing for various initial pressures of 3-methyl pentane.

Nitric oxide inhibits the thermal decomposition of 3-methyl pentane to a similar degree as it does the decomposition of 2-methyl pentane. The NO pressure required for maximum inhibition is 12–14 mm for the hydrocarbon pressure range of 50 to 100 mm (Fig. 18*b*). This NO pressure increases slightly with increasing S/V ratio (Fig. 18*a*). Nitric oxide affects the product distribution in the thermal decomposition of 3-methyl pentane fo some extent. The yields of CH_4 and C_2H_4 increase slowly with increasing NO pressure. This result is consistent with previous investigations on isopentane (13). Finally the yield of 2-methyl butene-1 reaches a maximum with increasing NO pressure and then decreases (Fig. 19).

The variation of the product distribution of the fully inhibited decomposition is almost linear with time, with the exception of 2-methyl butene-1 which reaches a maximum and then decreases (Fig. 20), which may be attributed to further pyrolysis of this product when it is accumulated in significant amounts.

100	54.0±4	0.66
120	54.0±4	0.25

High S/V ratios favor the formation of C_2H_6 in the inhibited reaction. The C_2H_4/C_2H_6 ratio increases with increasing NO pressure and for a given NO pressure it decreases with increasing S/V ratio (Fig. 21). However, this effect is not marked. The other decomposition products are independent of the S/V rtaio. This S/V ratio independence is shown for one of the products, C_3H_6 (Fig. 22).

Nitric oxide is adsorbed on quartz wool to a similar degree as 3-methyl pentane (Table XV). Therefore both compounds will compete for adsorption sites with equal probability.

Discussion

The products of the uninhibited pyrolysis of 3-methyl pentane can be accounted for at lower pressures by the following mechanism.

Initiation reactions:

[36*a*] $CH_3CH_2CH(CH_3)CH_2CH_3 \rightarrow CH_3 + CH_3CH_2CH(CH_3)CH_2$

[36*b*] $CH_3CH_2CH(CH_3)CH_2CH_3 \rightarrow C_2H_5 + CH_3CH_2CHCH_3$

36*c*] $CH_3CH_2CH(CH_3)CH_2CH_3 \rightarrow CH_3 + CH_3CH_2CHCH_2CH_3.$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Propagation reactions:

[37*a–d*] $CH_3 + CH_3CH_2CH(CH_3)CH_2CH_3 \rightarrow CH_4 +$ 3-methyl pentyl radicals

[38*a–d*] $C_2H_5 + CH_3CH_2CH(CH_3)CH_2CH_3 \rightarrow C_2H_6 +$ 3-methyl pentyl radicals

[39*a–d*] $H + CH_3CH_2CH(CH_3)CH_2CH_3 \rightarrow H_2 +$ 3-methyl pentyl radicals.

Radical decompositions:

[40*a–d*] 3-methyl pentyl radicals $\rightarrow C_2H_5 + CH_3CH{=}CHCH_3$

[41*a–d*] 3-methyl pentyl radicals $\rightarrow C_2H_5 + CH_2{=}CHCH_2CH_3$

[42*a–d*] 3-methyl pentyl radicals $\rightarrow CH_3 + CH_2{=}C(CH_3)CH_2CH_3$

[43] $CH_3CH_2CH(CH_3)CH_2 \rightarrow CH_3 + CH_2{=}C(CH_3)_2$

[44] $CH_3CH_2CH(CH_3)CH_2 \rightarrow C_2H_5 + C_3H_6$

[45] $CH_3CH_2CHCH_2CH_3 \rightarrow CH_3 + CH_3CH{=}CHCH_3$

[46] $CH_3CH_2CHCH_2CH_3 \rightarrow C_2H_5 + C_3H_6$

[47] $CH_3CH_2CHCH_3 \rightarrow CH_3 + C_3H_6$

[48] $CH_3CH_2CHCH_3 \rightarrow C_2H_5 + C_2H_4$

[49] $CH_3CH_2CHCH_3 \rightarrow H + CH_3CH{=}CHCH_3$

[50] $C_2H_5 \rightarrow H + C_2H_4$.

Termination reaction:

[51] $2CH_3 \xrightarrow{\beta\beta M} C_2H_6$.

For first order initiation, $\beta\mu$ and $\beta\beta$M termination types lead to unity overall order (15), while for second order initiation $\mu\mu$ and $\beta\mu$M termination types lead to the same order. However $\beta\mu$, $\beta\mu$M, and $\mu\mu$ terminations are canceled because of the lack of C_4H_{10} and C_3H_8 among the products. Therefore only one choice remains, namely a $\beta\beta$M termination type leading to unity overall order. The experimental overall order was found to be slightly higher than unity. Therefore, it is not clear whether or not another mechanism will also participate leading to 3/2 order. In such a case, only one termination type can occur, $\beta\beta$M, for second order initiation. Thus we face two choices: (i) The overall order can be considered unity, so that one mechanism can account for the decomposition involving a first order initiation and a $\beta\beta$M termination. (ii) Another mechanism also participates to a smaller extent involving a second order initiation and a $\beta\beta$M termination type. The overall order in such a case will be between unity and 3/2.

The observation that the NO pressure required for maximum inhibition is approximately the same for hydrocarbon pressures of 50 to 100 mm and that it has the same magnitude to that required for maximum inhibition in the decomposition of *n*-hexane and 2-methyl pentane, indicates that NO inhibition is associated with the particular experimental conditions more than with the nature of the hydrocarbon. It must be pointed out that any small difference could be well masked, since this NO pressure is not defined accurately. However, it is rather obvious that the NO pressure required for maximum inhibition is not a fixed percentage of the hydrocarbon pressure.

Nitric oxide and 3-methyl pentane are adsorbed on quartz wool to similar extents. Therefore, NO can expel 3-methyl pentane molecules from the active sites and it can be expelled with equal probabilities. Under these circumstances, one would expect that heterogeneous initiation still exist to some extent, even in the fully inhibited decomposition. Since heterogeneous initiation is suppressed less in the decomposition of 3-methyl pentane than in the decomposition of *n*-hexane and 2-methyl pentane by NO, it is expected that

the reduction in rate due to the inhibitor will be less steep in this isomer, which is the case. On the other hand, since heterogeneous initiation participates even to a small extent, in the fully inhibited decomposition, it is expected that the initial rate of the fully inhibited decomposition of 3-methyl pentane will be larger than the corresponding initial rates of the fully inhibited decomposition of *n*-hexane and 2-methyl pentane. This has been observed too.

Nitric oxide also functions homogeneously, as can be revealed from its effect on the decomposition products.

The effect of NO on CH_4, C_2H_6, and C_2H_4 has been discussed earlier in this paper. The special behavior of 2-methyl butene-1 can be attributed to further reaction of it with NO when the latter is in significant amount. Thus

[52] $$CH_2{=}C(CH_3)CH_2CH_3 + NO \rightarrow CH_2{=}C(CH_3)CHCH_3 + HNO.$$

The C—H bond located in a β-position to the double bond is very weak, namely $D(C—H) \simeq 76$ kcal/mole. This value is assigned on the basis of the following (24, 25)

$$D(CH_2{=}CHCH_2—H) = 77 \text{ kcal/mole}$$

and

$$D(CH_2{=}C(CH_3)CH_2—H) = 76 \text{ kcal/mole}$$

and the fact that the dissociation energies in primary, secondary, and tertiary C—H bonds in molecules with infinity long side chains differ by a small quantity B (26).

$$D(C—H)_{pr} = D(C—H)_{sec} + B = D(C—H)_{tert} + 2B$$

Thus the endothermicity of reaction [52] can be estimated as follows

$$\Delta H = D(C—H) - D(H—NO) \leq 76 - 48.6 = 27 \text{ kcal/mole.}$$

Higher radicals could be attacked by NO as easily as C_2H_5, leading to olefins and HNO. However, this does not happen here because of the instability of the higher radicals for which the unimolecular decomposition must predominate.

The analytical balance becomes less complete with increasing NO pressure. It may be attributed to the possibility that reactions like

$$R + NO \rightarrow RNO \rightarrow \text{oxime} \rightarrow \text{nitrogen containing products}$$

gain significance with increasing NO pressure. In the special case of CH_3 radical we obtain

[53] $$CH_3 + NO \rightarrow CH_3NO$$

For reaction [53] it was found (27) that

$$E_A = 5.7 \text{ kcal/mole for } P \simeq 1$$

or

$$E_A = 0 \text{ kcal/mole for } P = 1.5 \times 10^{-4}.$$

Nitrosomethane is unstable and it decomposes to products such as HCN, H_2O, NH_3, CO, N_2, CO_2, CH_3CN, etc. (23).

The energy of dissociation of CH_3NO is not accurately known but it is supposed to be (28)

$$D(CH_3—NO) \simeq 30 \text{ kcal/mole.}$$

This indicates that dissociation of CH_3NO to CH_3 and NO will compete with any further isomerization of CH_3NO, but the latter cannot predominate because an activation energy of 40 kcal/mole has been found for the reaction (29)

$$CH_3NO \rightarrow CH_2{=}NOH.$$

Direct evidence for the isomerization of primary and secondary nitroso compounds has been found from the infrared spectrum of these compounds (30).

NOTES

THE PREPARATION OF ANHYDROUS ZIRCONIUM DICHLORIDE

B. SWAROOP AND S. N. FLENGAS

INTRODUCTION

The existence of zirconium dichloride was first noticed by de Boer and Fast (1) while zirconium tetrachloride was heated with zirconium metal in the presence of aluminium chloride. Later, Larsen and Leddy (2) and Turnbull and Watts (3) confirmed the formation of zirconium dichloride while studying the disproportionation of zirconium trichloride. However, the production of high purity, anhydrous zirconium dichloride was not achieved by these investigators. In the present investigation, zirconium dichloride of a purity between 95 and 99% was produced by the direct reaction between zirconium trichloride powder and zirconium metal.

EXPERIMENTAL AND RESULTS

The anhydrous zirconium trichloride was prepared by a two-step reduction of zirconium tetrachloride with zirconium metal as described in the previous investigation (4). The reduction stages are indicated by the following equations:

$$[i] \qquad Zr(s) + ZrCl_4(\text{vap. 1 atm}) = 2ZrCl_2(s) \qquad \text{at 700 °C}$$

$$[ii] \qquad 2ZrCl_2(s) + 2ZrCl_4(\text{vap. 1 atm}) = 4ZrCl_3(s) \qquad \text{at 400 °C.}$$

Hence the overall reaction is:

$$[iii] \qquad 3ZrCl_4(\text{vap. 1 atm}) + Zr(s) = 4ZrCl_3(s).$$

The direct preparation of zirconium dichloride by the reduction of zirconium tetrachloride vapor with zirconium metal, as shown in eq. [*i*], was not adopted as the procedure because of difficulty in preventing the formation of $ZrCl_3$ during the cooling cycle of the reaction cell. Zirconium dichloride was prepared by reducing zirconium trichloride with zirconium metal according to the reaction,

$$[iv] \qquad Zr(s) + 2ZrCl_3(s) = 3ZrCl_2(s) \qquad \text{at 675 °C.}$$

In order to complete the reduction of zirconium trichloride, zirconium metal in excess of the stoichiometric amount was used. The possible contamination of the product, due to the disproportionation of zirconium dichloride, as shown in reaction [*i*], was prevented by reducing the free volume of the reaction site to a minimum.

The reaction apparatus consisted of a 4 in. long quartz tube of 1 in. in diameter, closed at one end. To prevent the reaction between quartz and the charge, the tube was lined with platinum foil 0.010 in. thick. The platinum lining could be used only twice, as there was some evidence of alloy formation with zirconium.

Finely divided reactor grade zirconium metal, containing less than 70 p.p.m. hafnium and a total of other metallic impurities of 400 p.p.m, was obtained by filling the metal in a dry box containing oxygen-free argon gas. Particle sizes between −80 and +100

mesh were separated by screening and used for the experiments. About 2 g of zirconium trichloride was mixed with about 1 g of the zirconium metal powder (50% excess), and the mixture was placed in the reaction tube. The tube was then sealed under vacuum, and gradually heated to 675 °C in a vertical furnace. The reaction was allowed to continue at 675 °C for a period of 30 to 35 h, and then the tube was quenched to room temperature. The tube was opened in a dry box containing purified argon. The product was screened through a −200 mesh and a −325 mesh sieve to separate the unreacted metal, and the finely divided zirconium dichloride powder was stored in sealed containers. The −325 mesh product was analyzed as follows: (*a*) The total chlorine content was determined by a modified Volhard's method (5). To this purpose, concentrated sulfuric acid was added to the material contained in a conical flask. The flask was connected to a distillation column through ground glass joints. The chlorine of zirconium dichloride was then boiled off as hydrogen chloride, and was collected and precipitated in a standardized solution of silver nitrate. The distillation was carried out in a stream of purified argon. (*b*) The total zirconium content was determined by precipitating zirconium as zirconium phosphate following the standard method. (*c*) The reducing power of the materials in solution was determined with an $N/10$ ceric ammonium sulfate solution. (*d*) X-ray powder diffraction patterns were obtained using a 57.3 mm camera with Cu K_α radiation. The lines were indexed by the film measuring device, and the intensities were estimated visually.

The X-ray information is shown in Table II, and the results of analyses of selected batches of zirconium dichloride are given in Table I.

TABLE I

Analysis of zirconium dichloride

Batch No.	Zirconium analysis			Chlorine analysis			Atomic ratio Zr:Cl	Redox titration		
	Wt. of sample	Zr (wt. %)		Wt. of sample	Cl_2 (wt. %)			Wt. of sample	$ZrCl_2$ content	Wt. % $ZrCl_2$
		Theor.	Expt.		Theor.	Expt.				
1	0.0946	56.2	52.6	0.1010	43.7	43.5	1:2.12	0.1349	0.1332	98.7
2	0.1469	56.2	56.1	0.1513	43.7	43.3	1:1.99	0.0910	0.084	92.3
3	0.0754	56.2	61.0	0.0572	43.7	45.1	1:1.92	0.1649	0.1650	100.0
4	0.1244	56.2	58.2	0.1244	43.7	42.7	1:1.92	0.0943	0.0936	99.2

The X-ray diffraction data indicate clearly new lines that do not belong to zirconium metal, zirconium trichloride (6), or zirconium tetrachloride. Furthermore, there is no evidence that the product contains any detectable amounts of metallic platinum or platinum dichloride.

The results of the chemical analyses indicate that zirconium dichloride of a purity between 95 and 99% was produced by this method. Zirconium dichloride is a black powder which was found to be more stable in air than the trichloride. Material contaminated with zirconium metal in the form of a chemical powder appears to be much more reactive and becomes pyrophoric. Zirconium dichloride does not dissolve in water readily. The solutions after long standing produce a greyish precipitate. There is no evidence of rapid hydrogen evolution as observed with zirconium trichloride.

The overall reaction recovery after screening the product lies between 50 and 56%. This recovery is certainly dependent upon reaction temperature (675°), the reaction time (30 to 35 h), and the particle size of the reactants.

REACTIONS OF PHENYL-SUBSTITUTED HETEROCYCLIC COMPOUNDS. VI. NITRATION OF 5-PHENYLISOXAZOLE

BRIAN M. LYNCH AND LIZZIE SHIU

References cited in a recent review (1) of isoxazole chemistry indicate the possibility of some confusion between the nitro compounds derived from 5-phenylisoxazole (I) and

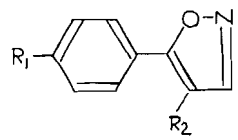
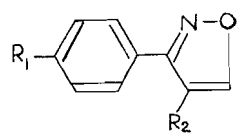
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

its 3-isomer (II). Thus, Kochetkov and Khomutova (2) report that treatment of 5-phenylisoxazole by mixed nitrating acids at 20° yields two products, having m.p. 171–172° and 115.5–116.5°: these are assigned as 5-*p*-nitrophenylisoxazole (III) and 4-nitro-5-phenylisoxazole (IV). However, Musante (3) reports that 3-phenylisoxazole is nitrated to 3-*p*-nitrophenylisoxazole (V), m.p. 174–176°, while Wieland (4) obtained 4-nitro-3-phenylisoxazole (VI), m.p. 116°, from the action of nitrous fumes on cinnamaldehyde.



I, $R_1 = R_2 = H$
III, $R_1 = NO_2, R_2 = H$
IV, $R_1 = H, R_2 = NO_2$
VII, $R_1 = R_2 = NO_2$



II, $R_1 = R_2 = H$
V, $R_1 = NO_2, R_2 = H$
VI, $R_1 = H, R_2 = NO_2$

In addition to the closely coincident melting points, doubt arises since the structures proposed by the Russian and Italian workers are based in part upon oxidative degradations to *p*-nitrobenzoic or benzoic acid, which would not distinguish between III and V, or between IV and VI. Wieland's assignment of structure VI, which is based on alkaline degradation to benzonitrile, is firmly based.

Since 5- and 3-phenylisoxazoles have quite similar physical properties (5), and syntheses from hydroxymethyleneacetophenone and hydroxylamine (6) yield mixtures of the two isomers, an obvious possibility is that the lower-melting product obtained by Kochetkov and Khomutova is VI, reflecting the presence of some 3-phenylisoxazole in their starting material. This possibility was checked by nitration of a sample of 5-phenylisoxazole prepared by a route claimed to yield only the 5-isomer (7). Our sample was homogeneous on two different gas–liquid chromatographic columns, and its retention times differed from those for a sample of 3-phenylisoxazole, prepared from benzoylvinyl benzoate and hydroxylamine (8). Our 5-phenylisoxazole was further authenticated by conversion into benzoylacetonitrile by methanolic sodium methoxide (9). Experiments using identical conditions with 3-phenylisoxazole showed that 3-phenylisoxazole was largely unaffected by sodium methoxide, although ca. 5% conversion into benzonitrile (identified by comparison of relative retention times on two different chromatographic columns, and also by its infrared absorption) occurred. Neither 3-phenylisoxazole nor benzonitrile could be detected in the reaction mixtures when our sample of 5-phenylisoxazole was treated with methanolic sodium methoxide.

Using this sample, several repetitions of Kochetkov and Khomutova's experiments, and also nitrations using acetyl nitrate (which favors substitution in the *heterocyclic ring* of arylazoles over attack at the aryl groups (10, 11)) yielded *one* mononitro compound, m.p. 176–178°, accompanied in some experiments by a dinitro compound, m.p. 115–117°. The dinitro compound was obtained readily from the mononitro compound using mixed nitrating acids at 80°.

In view of the authentication of our 5-phenylisoxazole sample, the mononitro compound is certainly 5-*p*-nitrophenylisoxazole. Unequivocal proof is furnished by its conversion into *p*-nitrobenzoylacetonitrile by brief refluxing with methanolic sodium methoxide, and is confirmed by its proton magnetic resonance (p.m.r.) spectrum. A solution in dimethyl sulfoxide at 60° shows the following proton signals: four protons in an A_2B_2 aromatic system centered at δ 8.25 (resolved (see (12)) into an A component, δ 8.37, and a B component, δ 8.13, with J_{AB} 9.1 c/s), and two 1-proton doublets (J, 2 c/s) at δ 8.73 (the 3-proton) and δ 7.25 (the 4-proton).

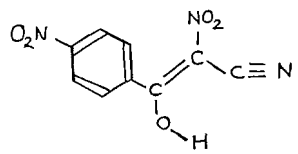
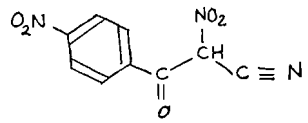
Treatment of the dinitro compound with methanolic sodium methoxide yields a high-melting solid showing both carbonyl (1 681 cm^{-1}) and nitrile (2 220 cm^{-1}) infrared absorption bands, but this information is not sufficient for a decision between a 5-(dinitrophenyl) isoxazole and 4-nitro-5-*p*-nitrophenylisoxazole (VII). The proton magnetic resonance spectrum establishes VII as the correct structure: a solution of the dinitro compound in dimethyl sulfoxide shows a 1-proton signal at δ 11.37, and a 4-proton A_2B_2 pattern from the 5-*p*-nitrophenyl group, now centered at δ 7.97 (A component, δ 8.25, B component, δ 7.69, J_{AB} 8.7 c/s). The increased shielding of all the protons of the 5-*p*-nitrophenyl group in VII as compared with III, and the increased internal chemical shift between the A and B protons, may be rationalized readily in terms of mutual twisting of the two rings resulting from the presence of the 4-nitro group, with consequent reduction of inter-ring paramagnetic effects (11, 13). The signal at δ 11.37 is assigned tentatively to the 3-proton, deshielded both by the adjacent ring nitrogen and the nitro group. Although similarly substituted compounds have highly deshielded protons (for example, the 5-proton signal from 4-nitro-1-*p*-nitrophenylpyrazole in dimethyl sulfoxide appears at δ 9.78 (11), and the 2-proton signal from 3-nitroquinoline in acetone appears at δ 9.56 (14)), the 3-proton does appear surprisingly acidic.* It is possible that the highly deshielded proton signal might reflect ring opening of VII in the dimethyl sulfoxide solvent to yield the tautomers VIII and IX: the enolic proton in VIII, or the methine proton in IX, would be expected to be highly deshielded. However, the infrared spectrum of the fission product from the dinitro compound shows little indication that the enol form is significant, while the *p*-nitrobenzoyl fragment of IX would not be expected to generate the observed A_2B_2 pattern (the chemical shifts expected for the A and B protons in *p*-nitroacetophenone (a reasonable model for IX) using parameters suggested by Corio and Dailey (15) would be δ 8.49 and 8.20). In any event, whether ring fission occurs or not, the key finding is an A_2B_2 pattern characteristic of a paradisubstituted compound, which eliminates the possibility of a 5-(dinitrophenyl)isoxazole structure.



VIII



IX

Although the melting range of the dinitro compound VII falls near that quoted by Kochetkov and Khomutova for their lower-melting nitration product, the two materials are not identical, since the Russian workers quote elementary analyses consistent with a mononitro compound, in addition to oxidative degradation to benzoic acid.

We conclude that 4-nitro-5-phenylisoxazole has yet to be prepared, and also suggest that reexamination of the nitration of 3-phenylisoxazole is in order, in view of the close agreement in melting range for our authenticated 5-*p*-nitrophenylisoxazole and Musante's claimed 3-*p*-nitrophenylisoxazole.

EXPERIMENTAL†

5-Phenylisoxazole, b.p. 246°, was prepared from the anil of benzoylacetaldehyde (anilinomethyleneacetophenone) and hydroxylamine, using Panizzi and Monti's method (7). The sample showed only a single peak on gas–liquid chromatography using either Silicone SE-52 or Cyanosilicone XF-1150 partitioning phases supported on Chromosorb P (Aerograph A-90P3 instrument, helium carrier gas, column temperatures 200°

**We are indebted to a referee for bringing this point to our attention.*

†*Analytical services, measurements of melting points, and infrared and p.m.r. spectra were as described in ref. 11.*

and 170°). Its retention time at 170° with the Cyanosilicone column (30% partitioning phase, 10 ft. × 3/8 in., flow rate 60 ml/min) was 8.0 min, while a sample of 3-phenylisoxazole, b.p. 245°, prepared by Panizzi and Sbrillo-Siena's method (8), gave a major peak (95%) with retention time 7.2 min, and a minor peak (5%) at 8.0 min. The minor peak disappeared from the sample after brief refluxing (10 min) with 0.5 *N* methanolic sodium methoxide, and a new minor peak appeared with retention time 2.0 min (area 5% of the 7.2 min component). This minor peak was identified as benzonitrile by comparison of retention times and by direct trapping and measurement of its infrared absorption spectrum. Corresponding treatment of the 5-phenylisoxazole sample with sodium methoxide, followed by acidification and collection of the resulting precipitate, yielded benzoylacetonitrile (40%), m.p. 76° (lit. (9) 81°), ν_{max} 2 247 cm^{-1} (nitrile) and 1 681 cm^{-1} (carbonyl). Neither 3-phenylisoxazole nor benzonitrile could be detected by gas–liquid chromatographic analysis of the mother liquor from the sodium methoxide treatment.

Nitrations

5-Phenylisoxazole was nitrated by mixed nitric acid (*d* 1.42) and sulfuric acid (*d* 1.84), or by nitric acid – acetic anhydride, or by mixed nitric acid (*d* 1.50) and sulfuric acid (*d* 1.84) at 15–20°, using reaction periods ranging from 0.25–1 h (these are the general conditions used in previous work on nitrations of phenyl-substituted heterocyclic compounds (10, 11, 16), and include those used by Kochetkov and Khomutova (2)). The products were collected after pouring the reaction mixtures into ice water, and were purified by careful fractional crystallization or by adsorption chromatography on alumina. 5-*p*-Nitrophenylisoxazole, m.p. 176–178° (p.m.r. spectrum, see above; nitro group infrared absorption at 1 515 and 1 333 cm^{-1}) was obtained in yields of ca. 50% starting from 1 g of 5-phenylisoxazole. The infrared spectra of all crystalline fractions were examined routinely, but there was no evidence for the presence of another mononitro compound in any of the reaction mixtures. In one experiment using mixed nitrating acids and a reaction period of 1 h, a small quantity (ca. 5% yield based on 1 g of 5-phenylisoxazole) of 4-nitro-5-*p*-nitrophenylisoxazole, m.p. 115–117°, was obtained from the fraction most readily soluble in ethanol. This material was identical with a sample prepared by nitration of 5-*p*-nitrophenylisoxazole with mixed nitrating acids for 1 h at 80°, which after crystallization from ethanol had m.p. 115–117° (p.m.r. spectrum, see above; nitro group infrared absorption at 1 504, 1 339, and 1 310 cm^{-1}; anal. calcd. for $C_9H_5N_3O_5$: C, 45.96; H, 2.14; N, 17.87%; found: C, 45.84; H, 2.38; N, 18.10%).

Fission of Nitrophenylisoxazoles by Methoxide

5-*p*-Nitrophenylisoxazole yielded *p*-nitrobenzoylacetonitrile, m.p. 133° (lit. (17) 135°) (infrared absorption: 2 273 (nitrile), 1 690 (carbonyl), 1 515, 1 351 (nitro group) cm^{-1}), when refluxed (10 min) in 0.5 *N* methanolic sodium methoxide, followed by acidification and isolation by ether extraction. Similar treatment of 4-nitro-5-*p*-nitrophenylisoxazole yielded a product, m.p. over 300°, with strong infrared absorption at 1 681, 2 220 (carbonyl, nitrile), 1 511, 1 342, and 1 310 (nitro groups) cm^{-1}.

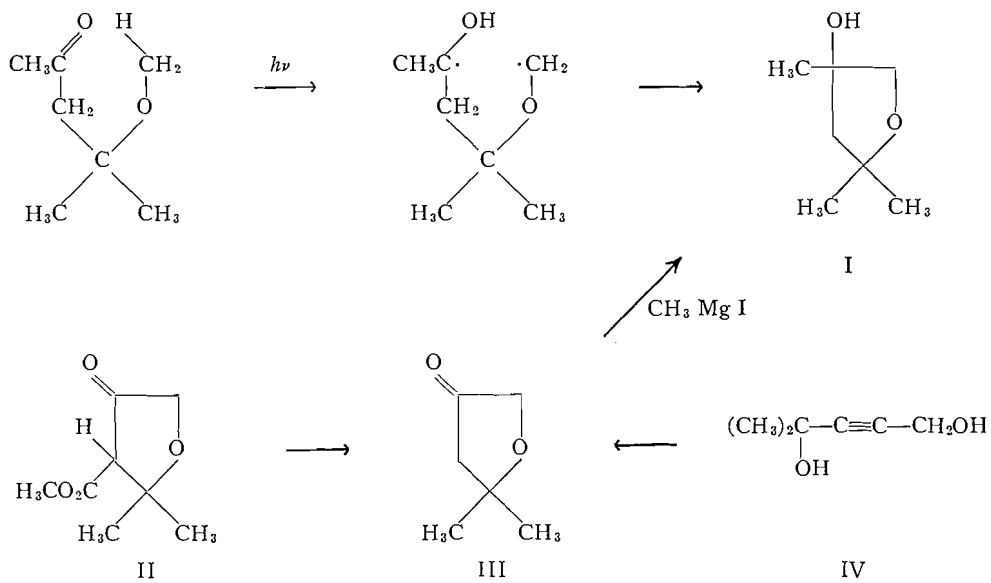
A SYNTHESIS OF 2,2,4-TRIMETHYL-4-HYDROXYTETRAHYDROFURAN, A PRODUCT OF THE PHOTOLYSIS OF 4-METHYL-4-METHOXY-2-PENTANONE

M. A. GIANTURCO AND P. FRIEDEL

It has recently been reported (1) that the photolysis of 4-methyl-4-methoxy-2-pentanone yields methanol, acetone, mesityl oxide, and a "hydroxyfuran." The elemental analysis and the spectral properties suggested that this latter substance should have structure I, which could be derived from the methoxyketone via a seven-membered ring intermediate (1). However, this important product of the photolytic reaction was not compared with a synthetic sample.

We wish to report that compound I can be conveniently obtained by reacting methyl β-methylcrotonate with the oxanion of methyl glycolate in dimethyl sulfoxide, decarboxylating the resultant β-ketoester (2,2-dimethyl-3-carbomethoxytetrahydrofuran-4-one, II) and treating the 2,2-dimethyltetrahydrofuran-4-one so obtained (III) with methylmagnesium iodide. The syntheses of the intermediates II and III were patterned after those of other tetrahydrofuranone derivatives which have been recently prepared in this laboratory (2).

When the synthesis of the intermediate III was attempted by treatment of 4-methylpent-2-yn-1,4-diol (IV) with mercuric oxide and sulfuric acid, a mixture resulted, whose main constituent was identical with a sample of III prepared from II. Two other substances, isolated from the reaction mixture by vapor phase chromatography (v.p.c.) and not submitted to elemental analysis, had infrared spectra which are compatible with the structures of two anticipated by-products of the reaction, i.e., 4-methylpent-4-en-2-yn-1-ol and 4-methylpent-4-en-3-on-1-ol. It was found, however, that the use of the less acidic catalyst described by Colonge *et al.* (3) (mercuric sulfate with no excess of sulfuric acid) suppresses the formation of these by-products and permits another convenient synthesis of III.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The identity of synthetic I with the "hydroxyfuran" obtained by photolysis of 4-methyl-4-methoxy-2-pentanone was proved by a comparison of the spectral properties of the two substances (infrared, nuclear magnetic resonance (n.m.r.), and mass spectra), effected through the courtesy of Dr. Petersen of the Aerospace Corporation, El Segundo, California (1).

The potentialities of the now easily available (2) tetrahydrofuran-3-ones as intermediates in the synthesis of 2,3-dihydrofurans (via tosylhydrazones), furans, and γ-lactones are currently being investigated.

EXPERIMENTAL

The infrared spectra were determined on CCl_4 solutions. The n.m.r. spectra were measured in CCl_4 at 60 Mc, with tetramethylsilane as internal standard; chemical shifts are in p.p.m. The mass spectra were determined on a CEC 21-103C instrument. The v.p.c. retention times (R_T) are expressed in minutes and refer to the following conditions: 2m × 0.25 in. silicone rubber column, 15% on acid-washed Chromosorb W (60–80 mesh), 75°, 70 ml He/min.

2,2-Dimethyl-3-carbomethoxytetradrofuran-4-one (II)

This compound was prepared in 40% yield from methyl glycolate and methyl β-methylcrotonate by a procedure completely analogous to that previously employed for the synthesis of other tetrahydrofuranone derivatives (2). Boiling point 41–42° at 0.1 mm; n_D^{23} 1.4497; infrared bands at 5.58, 5.69, 5.92, and 6.07 μ indicate the coexistence of keto and enol forms.

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.81; H, 7.02. Found: C, 55.87; H, 7.25.

Methyl 3-methoxyisovalerate, the only important by-product of the reaction, was isolated by v.p.c. of the forerun of distillation, and was identified by comparison of its infrared spectrum and retention time with those of an authentic sample (4).

2,2-Dimethyltetrahydrofuran-4-one (III)

The decarboxylative hydrolysis of II was effected by 1 h refluxing in 10% H_2SO_4. The usual work-up (ether extraction, drying over Na_2SO_4, removal of the solvent, and distillation) gave III in 73% yield. Boiling point 64° at 50 mm; R_T 5.6; n_D^{25} 1.4259; $\lambda_{CO}^{CCl_4}$ 5.63 μ; $\lambda_{C-O-C}^{CCl_4}$ 9.36 μ; n.m.r.: singlets at δ = 3.88, 2.23, and 1.35, in ratios of 1:1:3.

Anal. Calcd. for $C_6H_{10}O_2$: C, 63.13, H, 8.83. Found: C, 62.98; H, 8.93.

Semicarbazone, m.p. 187–188°.

Anal. Calcd. for $C_7H_{13}N_3O_2$: N, 24.55. Found: N, 24.36.

Treatment of 4-methylpent-2-yn-1,4-diol (IV) as described for the synthesis of 2,2,5,5-tetramethyltetrahydrofuran-3-one from 2,5-dimethylhex-3-yn-2,5-diol (5) resulted in a mixture, which was separated into its components by v.p.c. The main constituent (R_T 5.6) was identical (R_T, infrared) with a sample of III prepared from II. The principal infrared bands of two by-products (see text) occur at the following wavelengths: Compound A (R_T 7.6): 2.75 and 2.90 μ, free and bonded O—H stretching; 3.22 μ, asymmetric stretching olefinic CH_2; 5.54 μ, overtone of δ_{C-H} out-of-plane; 6.15 μ, C=C stretching; 9.80 and 9.90 μ, C—O stretching; 11.10 μ, δ_{C-H} out-of-plane. Compound B (R_T 13.1): 2.85 μ, O—H stretching (intramolecular bond); 5.85, 6.08, and 9.65 μ, C=O, C=C, and C—O stretching; 10.95 μ, δ_{C-H} out of plane; λ_{max}^{EtOH} 231 mμ. However, when a less acidic reaction medium was employed (see text and ref. 3), the formation of compounds A and B was suppressed, and III was obtained in 30% yield.

2,2,4-Trimethyl-4-hydroxytetrahydrofuran (I)

Refluxing for 2 h an ether solution of compound III and methylmagnesium iodide (10% excess) gave, after the usual work-up and distillation, an 87% yield of I. Boiling point 63–64° at 12 mm; n_D^{25} 1.4259; n.m.r.: doublet, 2 protons, centered at δ = 3.60; singlet, 1 proton, δ = 3.27; doublet, 2 protons, centered at δ = 1.80; singlet, 6 protons, δ = 1.30; singlet, 3 protons, δ = 1.20. The mass spectrum showed an extremely weak molecular ion peak (m/e = 130); the principal peaks were at the following m/e values: 43 (100%), 85 (69%), 57 (31%), 115 (30%), and 41 (27%).

Anal. Calcd. for $C_7H_{14}O_2$: C, 64.58; H, 10.84. Found: C, 64.68; H, 10.83.

THE EFFECT OF PHENOLS ON THE POLYMERIZATION OF VINYL ACETATE

R. A. BIRD AND K. E. RUSSELL

In studies of the effect of phenols on the free radical polymerization of styrene (1, 2) and methyl methacrylate (3), it was shown that polymer radicals attack phenols by hydrogen abstraction at the OH group. The rates of hydrogen abstraction by polystyryl radicals vary widely with the phenol; the transfer constants for simple phenols at 60 °C are in the range 0.001 to 0.008 while that for pyrogallol is 1.04. Phenols are much less reactive towards polymethyl methacrylate radicals, the transfer constant for pyrogallol being only 0.0026 at 45 °C.

The effect of phenols on the polymerization of vinyl acetate was investigated because polyvinyl acetate radicals have a much higher reactivity in transfer reactions (4) and the transfer constants for simple phenols are more easily measured. The results for such phenols provide information concerning the extent to which polar factors influence the rates of hydrogen abstraction by polymer radicals. Both deuterated and undeuterated phenols were used in the study in order to test the validity of Bagdasar'ian and Sinitsina's conclusion (5) that hydrogen atoms of phenolic OH groups do not participate directly in reactions with polyvinyl acetate radicals. A large isotope effect shows that polyvinyl acetate radicals attack almost exclusively at the OH group but a smaller effect indicates that there is a simultaneous addition to the ring to give a stabilized cyclohexadienyl radical.

EXPERIMENTAL

Vinyl acetate was fractionally distilled and prepolymerized at 70 °C under nitrogen using azobisisobutyronitrile as initiator. After approximately 10% had polymerized, the monomer was again distilled and the middle fraction retained. It was dried over calcium chloride, degassed, and distilled three times on the high vacuum line. The phenols were purified by distillation or recrystallization. Azobisisobutyronitrile was recrystallized from ether and stored at 0 °C.

The procedure was similar to that used with methyl methacrylate (3). Initiator concentrations were close to 0.004 M and phenol concentrations were usually in the range 0.002–0.02 M. In experiments with deuterated phenols, 0.05 g heavy water was added to the reaction mixture and it was shown that heavy water did not affect the rate of polymerization or molecular weight in the absence of phenol. After about 3% conversion of monomer to polymer, the reaction tubes were cooled to 0 °C on removal from the bath at 45 °C, and the contents diluted with acetone. The solution was added dropwise with vigorous stirring to 500 ml petroleum ether and allowed to stand for 5 h before filtration. The polymer was dried *in vacuo* at 60 °C, weighed, and stored in dry stoppered tubes to prevent absorption of moisture.

Intrinsic viscosities of the polyvinyl acetate samples were determined at 25 °C using acetone as solvent. Average degrees of polymerization $\bar{P}_n$ were calculated using the relationship quoted by Fuhrman and Mesrobian (6)

$$\bar{P}_n = 2.57[\eta_l]^{1.40}$$

where η_l is the limiting viscosity number.

RESULTS AND DISCUSSION

Phenols act as fairly strong retarders in the polymerization of vinyl acetate, the rate of polymerization at 45 °C being reduced to two thirds of its normal value by the addition of phenol at a concentration of 0.009 M or 2,3,4,6-tetramethylphenol at a concentration of 0.0002 M. With the exceptions of 3-acetyl- and 3-cyano-phenols, the deuterated phenols are much weaker retarders than the corresponding phenols so that the main transfer reaction occurs by attack of the polyvinyl acetate radical on the OH group.

The transfer constant C is the ratio k_{tr}/k_p where k_{tr} is the rate constant of reaction [1] and k_p is the rate constant for the propagation process. When the polymerization of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[1] 
vinyl acetate is retarded by phenols, the proportion of XO· radicals lost in cross-termination reactions with polyvinyl acetate radicals or by mutual termination is not known. Three estimates of the transfer constant for each phenol have been made from the molecular weight data, using equations derived assuming various fates for the XO· radicals (1), and the mean values are given as C_1 in Table I. The required transfer constant to monomer at 45 °C was determined experimentally to be 2.0×10^{-4}; a value of 20.5 mole l^{-1} s was used for $2k_t/k_p^2$ (7, 8), $2k_t$ being the rate constant for the mutual termination of polyvinyl acetate radicals, a process which occurs almost entirely by disproportionation (9). Transfer constants may also be derived from the rates of polymerization provided that it is assumed that none of the XO· radicals formed by reaction [1] reinitiate polymerization. Three estimates of the transfer constant have been made using equations derived by Jenkins (10) and the mean values are given as C_2 in Table I. The uncertainty in C_1 and C_2 arises largely from the lack of knowledge concerning the termination reactions, individual estimates differing by as much as 35% from the mean.

TABLE I

Transfer constants for phenols and deuterated phenols at 45 °C

	Phenols		Deuterated phenols		
	C_1	C_2	C_1	C_2	Ratios (r)
Phenol	0.019	0.024	0.002	0.005	6.1
3-Chlorophenol	0.027	0.014	0.007	0.007	2.9
3-Methylphenol	0.046	0.029	0.012	0.005	4.4
3-Acetylphenol	0.160	0.121	0.137	0.121	1.1
3-Cyanophenol	0.069	0.095	0.067	0.094	1.0
4-Chlorophenol	0.046	0.034	0.010	0.006	5.0
4-Methylphenol	0.071	0.071	0.015	0.011	5.5
2,3,4,6-Tetramethylphenol	0.94	1.32	0.075	0.085	14.1

The ratios r of the means of C_1 and C_2 for each phenol and its deuterated counterpart are given in Table I. The fairly large values of r for phenol, the chlorophenols, the cresols, and 2,3,4,6-tetramethylphenol confirm that the main rate-determining step in the transfer process is the hydrogen abstraction reaction [1]. The greatest isotope effect is observed for 2,3,4,6-tetramethylphenol and the lower value of r for phenol suggests that addition to the nucleus, which is now less sterically hindered, may compete with hydrogen transfer. A referee points out that preferential activation of the nucleus towards the addition of a polyvinyl acetate radical appears to occur when the phenol contains a meta substituent. For the electron-withdrawing substituents the ratio r decreases through chlorine ($r = 2.9$) and acetyl ($r = 1.1$) to a minimum ($r = 1.0$) with cyano in 3-cyanophenol, corresponding to the increasing importance of addition to the nucleus relative to attack at the OH group.

Analysis of the results by the method of Allen, Merrett, and Scanlan (11) shows that the efficiency of reinitiation of polymerization by XO· radicals formed in the transfer process is generally low. This conclusion is supported by the fair agreement between values of C_1 and C_2, since C_2 has been calculated on the assumption that no reinitiation occurs. In contrast, the efficiency of reinitiation of the polymerization of methyl methacrylate by XS· radicals derived from aromatic thiols is greater than 90% (3).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Of the meta-substituted phenols investigated, only 3-chloro- and 3-methyl-phenol are attacked primarily at the OH group. Their transfer constants are not greatly different from that of phenol and it is probable that inductive effects are not of great importance in this hydrogen-abstraction reaction. 4-Methyl- and 4-chloro-phenol have higher transfer constants than the corresponding meta-substituted phenols, presumably due to weak contributions to the transition state of polar structures in which an electron has been donated by the phenol to the radical (12). Inductive and resonance effects from these single substituents are small but the total effect of the four methyl groups in 2,3,4,6-tetramethylphenol is large enough to increase its transfer constant to 1.

The ratios of transfer constants for 2,3,4,6-tetramethylphenol towards polymethyl methacrylate (3), polystyryl (1), and polyvinyl acetate radicals are approximately 0.02:1:18 while those for the hydrocarbon toluene are 4:1:170. The difference in relative reactivities of polystyryl and polymethyl methacrylate radicals towards phenols and toluene is interpreted (3) in terms of contributions to the transition state of polar structures in which an electron has been donated by the radical to the phenol. Such contributions are significant in reactions between polystyryl radicals and phenols but are not important in polymethyl methacrylate reactions because of the electron-withdrawing character of the ester group (13). On this interpretation, polar structures with the polyvinyl acetate radical as donor and 2,3,4,6-tetramethylphenol as acceptor contribute to the transition state of this hydrogen-abstraction reaction but are less important than those involved in the corresponding reaction with polystyryl radicals.

Of the meta-substituted phenols investigated, only 3-chloro- and 3-methyl-phenol are attacked primarily at the OH group. Their transfer constants are not greatly different from that of phenol and it is probable that inductive effects are not of great importance in this hydrogen-abstraction reaction. 4-Methyl- and 4-chloro-phenol have higher transfer constants than the corresponding meta-substituted phenols, presumably due to weak contributions to the transition state of polar structures in which an electron has been donated by the phenol to the radical (12). Inductive and resonance effects from these single substituents are small but the total effect of the four methyl groups in 2,3,4,6-tetramethylphenol is large enough to increase its transfer constant to 1.

The ratios of transfer constants for 2,3,4,6-tetramethylphenol towards polymethyl methacrylate (3), polystyryl (1), and polyvinyl acetate radicals are approximately 0.02:1:18 while those for the hydrocarbon toluene are 4:1:170. The difference in relative reactivities of polystyryl and polymethyl methacrylate radicals towards phenols and toluene is interpreted (3) in terms of contributions to the transition state of polar structures in which an electron has been donated by the radical to the phenol. Such contributions are significant in reactions between polystyryl radicals and phenols but are not important in polymethyl methacrylate reactions because of the electron-withdrawing character of the ester group (13). On this interpretation, polar structures with the polyvinyl acetate radical as donor and 2,3,4,6-tetramethylphenol as acceptor contribute to the transition state of this hydrogen-abstraction reaction but are less important than those involved in the corresponding reaction with polystyryl radicals.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council for a grant. The vinyl acetate was a gift from Du Pont of Canada.

PREPARATION OF 4,4″-BIS(DIPHENYLAMINES) BY THE CHAPMAN REARRANGEMENT

Robert Barclay, Jr.

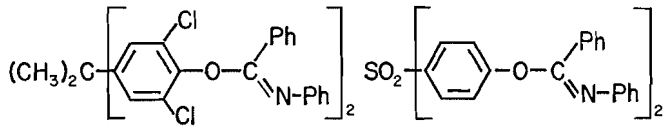
Very few applications of 4,4″-bis(diphenylamines) to the synthesis of condensation polymers have been reported. Exploratory studies in this area required the development of a convenient laboratory preparation of the diamines, preferably from the corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

diphenols. The method of choice, involving the Chapman rearrangement (1) in its key step, is a standard synthesis of diarylamines, but has apparently not previously been applied to diphenols.

Imido esters (Table I) are prepared from the phenol and the imidoyl chloride in the presence of an acid-acceptor. While anhydrous conditions are commonly employed (2), it was found at least equally convenient to carry out this reaction under conditions suitable for the preparation of polyphenyl esters by interfacial polycondensation (3). In suitable reaction media, both N-arylimidoyl chlorides (4) and acyl halides (5) undergo solvolysis by mechanisms involving a rate-determining ionization step, the rates being increased by the addition of amines; therefore, the similarity in their reactions with aqueous aryloxide ions was not unexpected. The yields were good, but not quantitative; small amounts of benzanilide and of unchanged diphenol were often recovered. Although the pure imido esters are solids with fairly high melting points, it was often difficult to obtain them in a crystalline form. It was, nevertheless, expedient to purify the imido esters, since pure benzamides could not be isolated from the products of rearrangement of crude intermediates.

Rearrangement was effected by heating the molten imido esters in a nitrogen atmosphere at temperatures in the range 220–280° (Table II). In most cases the reaction could be followed by observation of changes in the infrared spectra, especially in the C—O and C—N stretching region. The imido esters exhibited strong bands in the ranges 1206–1225 and 1266–1271 cm^{-1}, while the amides absorbed at 1326–1339 and 1289–1294 cm^{-1}. As reported by Chapman (6) and others (7), reaction is facilitated by electron-attracting substituents in the aryl groups derived from the original phenol. With the benzimidates I and II, for example, rearrangement was complete within 1 h at 240° and 3 h at 220°, respectively.



I II

The dibenzoyl derivatives were hydrolyzed to the free 4,4″-bis(diphenylamines) (Table III) by treatment with potassium hydroxide in hot aqueous ethanol. Conversion in this step appeared to be essentially quantitative. A sample of 4,4″-methylenebis(diphenylamine) prepared in this way was identical with the diamine obtained (8) by the condensation of diphenylamine with formaldehyde.

The methods described above were extended to the preparation of the polymeric substances IV and V. Since the reduced viscosities of IV and V were 0.15 and 0.12, respectively, it is probable that little change in molecular weight accompanied the rearrangement.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra (except those of the polymers) were determined on glasses obtained by cooling the molten substance or as Nujol mulls; a Beckman IR5 spectrophotometer was used. Tabulated yields refer to once-recrystallized material. Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, Tennessee. Reduced viscosities were measured in methylene chloride at 25° (0.2 g of polymer/100 ml of solution).

Diphenol N-phenylbenzimidates.—In a 250-ml, three-necked Morton-type flask with stirrer, dropping funnel, and thermometer were placed 0.04 mole of the diphenol, 0.0816 mole of sodium hydroxide, 3.3 g of

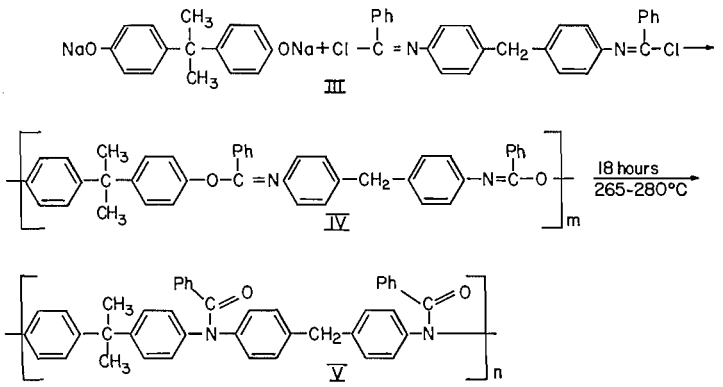
**This compound was evidently not pure. Mixture melting point with the 4,4″-isomer exhibited strong depression.



sodium chloride, 30 ml of water, and 40 ml of methylene chloride. A solution of 0.08 mole of N-phenylbenzimidoyl chloride (9) in 70 ml of methylene chloride was added with rapid stirring over 2–3 hours at 23–27°. The solution was diluted with 200 ml of water, the layers were separated, and the aqueous phase was extracted with three 100-ml portions of methylene chloride. The combined organic solution was washed with three 100-ml portions of water and dried over anhydrous magnesium sulfate. The methylene chloride was removed by distillation, leaving the crude imido ester as a residue product.

Rearrangement.—The purified imido ester was heated by means of an oil bath in a large test tube with side arm. Dry nitrogen gas was bubbled through the melt. When the reaction was complete, the cooled glassy reaction product was recrystallized from a suitable solvent.

Hydrolysis.—The preparation of 4,4″-isopropylidenebis(diphenylamine) is typical. A mixture of 32.9 g (0.0561 mole) of 4,4″-isopropylidenebis(diphenylbenzamide), 16.5 g (0.25 mole) of potassium hydroxide pellets, 135 ml of ethanol, and 15 ml of water was heated under reflux for 22 hours. The cooled reaction mass was diluted with 500 ml of water and extracted with a total of 500 ml of methylene chloride in three portions. The combined extract was washed with three 150-ml portions of water and dried over magnesium sulfate. Removal of methylene chloride by distillation left as a residue 19.84 g (94%) of crude diamine. Recrystallization from 180 ml of ethanol gave 18.10 g (85%) of 4,4″-isopropylidenebis(diphenylamine), m.p. 98–100°.

4,4″-Methylenebis(diphenylamine).—This compound was prepared via the Chapman rearrangement. However, preparation by the condensation of diphenylamine with formaldehyde (8) is more convenient.

A mixture of 2 249 g (13.29 moles) of diphenylamine, 136 g (1.68 moles) of 37% formaldehyde solution, 9 ml of concentrated hydrochloric acid, and 2.2 l of ethanol was heated under reflux (80–81°) for 1 h. The solution was cooled and divided into six portions, each of which was added to a mixture of 3 g of sodium hydroxide, 1.65 l of water, and 1.0 kg of crushed ice in a Waring Blendor. The precipitated solids were collected by filtration, washed thoroughly with water, and dried in a vacuum oven at 40°. The unchanged diphenylamine (1 700 g) was recovered by distillation to a final pot temperature of 230° (0.2 mm), and a crude product fraction was obtained by heating to a pot temperature of 358° (0.75 mm). The diamine was purified by redistillation, 294.8 g being collected, b.p. 259–286° (0.25–0.55 mm). Recrystallization from 5.75 l of ethanol gave 207.8 g (36.6%, based on diphenylamine not recovered) of 4,4″-methylenebis(diphenylamine), m.p. 121–123°.

Imidoyl chloride III.—Reaction of 4,4′-methylenedianiline with benzoyl chloride and pyridine in chloroform gave the dibenzoyl derivative, m.p. 250–251.7° (250° (10)). A mixture of 20.4 g (0.0502 mole) of the latter and 22 ml (0.30 mole) of thionyl chloride was heated under reflux for 3.5 h by means of an oil bath kept at 110–113°. Unchanged thionyl chloride was removed by distillation under reduced pressure (bath temperature 125°), giving 22.1 g (99%) of the yellow imidoyl chloride III. After two recrystallizations from toluene–heptane there remained 16.3 g (73%) of nearly pure III, m.p. 140–143°.

Anal. Calcd. for $C_{27}H_{20}Cl_2N_2$: Cl, 16.0. Found: Cl, 15.7, 15.8.

Poly-(imido ester) IV.—The polymer was prepared from 10.27 g (0.0450 mole) of bisphenol A, 19.95 g (0.0450 mole) of III and 3.72 g (0.091 mole) of sodium hydroxide essentially as described above for the N-phenylbenzimidates. Addition of III required 3 hours, the temperature being maintained at 14–16°. The polymer was precipitated by addition of the water-washed methylene chloride solution to 1.6 l of ethanol in a Waring Blendor and dried overnight in a vacuum oven at 60°. The yield of polymer, reduced viscosity 0.15, was 22.3 g (83%).

The infrared spectrum, measured as a potassium bromide pellet, included typical imido ester bands at 1 208 and 1 267 cm^{-1}.

Polyamide V.—The polymer IV was heated in a nitrogen atmosphere for 18 h at 265–270°. The resulting polymer, reduced viscosity 0.12, exhibited infrared absorption bands at 1 294 and 1 330 cm^{-1}, typical of N,N-diarylbenzamides.

THE IONIZATION OF SOME TYPICAL WEAK BASES IN CONCENTRATED PERCHLORIC ACID

KEITH YATES AND HENRY WAI

In connection with a study of the acidity of 0–80% perchloric acid, we have investigated the behavior of nine typical weak organic bases in this medium. These include representatives of the amine, carbonyl, and ether type of base. All these classes have been extensively investigated in sulfuric acid (1) but little is known of their stability, spectral changes, and basicity constants in perchloric acid. We find that the amines and carbonyl compounds are quite stable even at the highest acid concentrations used and although there is some evidence of slow decomposition of phenol and anisole in these solutions, even these compounds are quite stable within the usual time required to measure ultraviolet spectra. This is in contrast to their behavior in sulfuric acid where rapid and irreversible sulfonation of phenols and anisoles occurs at the acidities required to measure their pK values.

The ultraviolet spectra of most of the bases studied change in the expected way with increasing acid concentration. The absorption characteristics of the bases and their conjugate acids are listed in Table I. Plots of extinction coefficient against acidity (H_0) give the usual smooth sigmoid plots for the amines and carbonyl compounds, allowing pK values to be determined for these bases using standard methods (2). The upper and lower arms of these sigmoid curves should be flat in the absence of complicating medium effects which are not associated with protonation, and in fact are generally less sloping than those obtained for the same bases in sulfuric acid. This indicates that medium effects on spectra are less serious in perchloric acid. However, the spectra of anisole, phenol, and *p*-nitroanisole do not change with acidity in any simple way. The main absorption peaks in the 260 mμ region decrease continuously in intensity over a wide range of acid until by about 70% $HClO_4$ they are about half as intense as in dilute acid. It is unlikely that this change can be associated with protonation since it takes place over a range of 8–9 H_0 units and does not give any inflection point. At higher acidities new absorption bands appear as shoulders in the 285 mμ region and plots of ϵ at these wavelengths against H_0 give the beginnings of typical sigmoid ionization curves, suggesting that protonation does not occur with these bases until H_0 is less than -9.

TABLE II

Comparison of pK values* and indicator slopes of typical weak bases in perchloric and sulfuric acids at 25 °C

Base	Perchloric acid		Sulfuric acid†		Ref.	ΔpK
	pK	Slope	pK	Slope		
Benzamide	−2.03	0.77	−2.1	0.66	6	0.07
	−2.10				7	
N,*N*-Dimethyl-2,4,6-trinitroaniline	−4.54	1.22	−4.98	1.30	8	0.44
2-Chloro-4,6-dinitroaniline	−6.83	0.99	−6.68	0.98		−0.15

			−6.36		10	
Benzaldehyde	−7.90	0.72	−7.39	0.82		−0.53
			−7.47		11	
Benzoic acid	−8.85	0.83‡	−7.62	0.84‡		−1.23
			−7.66		12	
Phenol	<-9	—	−7.06	—	3	—
Anisole	<-9	—	−6.82	—	3	—
4-Nitroanisole	−10.01	0.92	—	—		—

*These were obtained by plotting log $(\epsilon_B - \epsilon)/(\epsilon - \epsilon_{BH^+})$ versus H_0. The wavelength chosen was that which gave the smoothest sigmoid titration curve on a nonlogarithmic plot. All H_0 values were taken from ref. 5.
†Values in sulfuric acid redetermined in the present work except where noted.
‡The method of Stewart and Granger (2*b*) gives somewhat higher slopes.

The pK values of the bases have been obtained, where possible, from conventional plots of log $[BH^+]/[B]$ against H_0. These resulted in good linear plots and the slopes and pK values are listed in Table II. According to the defining equation for H_0 these slopes should be equal to unity if the bases exhibit similar activity coefficient behavior to the Hammett indicators (1). This is important since if the indicator slope deviates from unity this means the base is following some other acidity function and the pK value obtained is not referred back to the same standard state as the H_0 scale, and is not a true pK value. It is clear from the indicator slopes in Table II that only 2-chloro-4,6-dinitroaniline obeys the H_0 function in its ionization. Thus the "pK" values of the other bases are not valid thermodynamic equilibrium constants. For this reason it is interesting to compare these "pK" values with those reported in sulfuric acid. (These should be the same if the pK values are

valid equilibrium constants.) It can be seen that except for 2-chloro-4,6-dinitroaniline and benzamide the agreement is not good, especially for the weaker bases. This again illustrates that caution must be used in interpreting numerical values of pK based on the H_0 function (1), unless the base in question has been shown to follow this acidity function. This is particularly true for the very weak bases which are measurably ionized only in the more concentrated acid region. Although the relative order of base strengths in Table II is the same in perchloric acid as in sulfuric acid, the absolute values of pK can only be taken as approximate estimates of basicity. Particularly striking is the discrepancy between the pK values for benzoic acid. Although the indicator slope has practically the same value in either acid, the two equilibrium constants differ by a factor of 17. We have checked our measurements of this pK carefully and have also redetermined its value in sulfuric acid and the observed difference in pK is well outside the experimental error. Arnett has already pointed out that benzoic acid is probably unusual in its activity coefficient behavior (1) and the present finding confirms this. It was not possible to obtain even approximate pK values for anisole and phenol for the reasons described above. However, our results, which have been obtained over a wider range of acid concentrations than is possible in sulfuric acid, indicate that these bases are considerably weaker than previous estimates (3). It was, however, possible to estimate a "pK" for *p*-nitroanisole by the method of Arnett and Wu (3) since this compound gave more pronounced spectral changes than anisole or phenol. This gave a value of -10.0 which is in good agreement with the value -10.26 reported for *p*-nitrophenol (4, 5) which should be very similar in base strength to the corresponding anisole.

EXPERIMENTAL

Compounds used were commercially available samples and purified by fractional distillation or repeated recrystallization. Spectra were recorded at 25 ± 0.1 °C on a Bausch and Lomb 505 Recording Spectrophotometer. Indicator solutions and acids were prepared essentially as described previously (13).

ACKNOWLEDGMENTS

This study was supported in part by a grant from the Defense Research Board of Canada. We are also grateful to the National Research Council for financial support. We are grateful to Mr. Brian Scott for redetermining the pK of benzoic acid.

HINDERED INTERNAL ROTATION IN BORON HALIDE COMPLEXES OF N,N-DIMETHYLFORMAMIDE

E. S. GORE,[1] D. J. BLEARS,[2] AND S. S. DANYLUK[2]

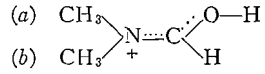
Department of Chemistry, University of Toronto, Toronto, Ontario

Received March 2, 1965

ABSTRACT

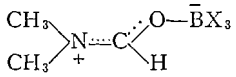
The barriers to internal rotation about the CN partial double bond in N,N-dimethylformamide (DMF) and its complex with BF_3 have been determined in tetrachloroethane (TCE) by nuclear magnetic resonance measurements. The activation energy for rotation E_a, increased from 6.2 ± 0.3 kcal mole^{-1} for DMF to 14.5 ± 1.1 kcal mole^{-1} for DMF·BF_3. Values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were also derived. Low field shifts of the methyl resonances and an increase in the relative shifts between the two methyl groups were observed on complex formation. The formyl coupling constant to the methyl groups was larger for the complex than for pure DMF. In addition, for DMF—BCl_3 evidence for the presence of two types of complex was found. The present results are compatible with BF_3 and BCl_3 complexing to the amide oxygen atom. The energy changes for internal rotation and J variation are attributed to changes in the π character of the CN bond due to stabilization of the charged resonance from $(CH_3)_2N{=}C{<}^{H}_{O}$ upon complex formation.

During the past few years the site of protonation of amides and the structure of the resulting proton adduct has been the subject of considerable controversy (1, 2, 3). Recent nuclear magnetic resonance (n.m.r.) studies confirm that protonation occurs at the oxygen atom and leads to stabilization of a planar structure of the form,



I

The amides also form relatively stable 1:1 molecular complexes with boron halides. Although the structure of such complexes has not been studied as extensively as the protonated species the infrared and n.m.r. studies of Gerrard and co-workers (4) indicate that the lone pair of the oxygen is involved in bonding to the boron halide. The planar configuration of I is presumably retained in the boron halide complex II,



II

[1]*Now at University of Illinois, Urbana, Illinois.*
[2]*Now at Argonne National Laboratory, Argonne, Illinois.*

Protonation and complex formation at the oxygen atom would stabilize resonance forms favoring a higher π-bond character in the C—N bond and it would be expected that the energy barrier for rotation about the C—N bond would increase over that for the free amide. This has been confirmed by Fraenkel and Franconi (5) who observed an increase in the rotational barrier from 9.6 kcal mole^{-1} for pure N,N-dimethylformamide (DMF) to 12.7 kcal mole^{-1} for the protonated DMF. In this work we have studied the effects of complex formation between boron halides and DMF on the parameters E_a, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ for internal rotation about the C—N bond.

Low field chemical shifts together with increases in the relative chemical shifts between the two methyl peaks are observed on complex formation. The formyl coupling constants to the methyl peaks also increase on complexing, reflecting changes in the electronic configuration at the CN bond.

EXPERIMENTAL

The N,N-dimethylformamide was Fisher Certified Reagent, dried by passing through a 50 cm column of Linde Molecular Seive 5A. The solvent, 1,1,2,2-tetrachloroethane (TCE), was washed with concentrated sulfuric acid and then with dilute sodium hydroxide solution and finally purified by distillation. The boron trifluoride and trichloride were Matheson C.P. gases and were further purified on a vacuum-transfer system.

Samples were made up by adding equimolar amounts of boron halide and DMF under vacuum to degassed TCE. The final concentration of the complex was approximately 4 mole %.

All spectra were recorded on a Varian A-60 spectrometer equipped with a variable temperature accessory. Three or four spectra were recorded at each temperature. The temperatures were accurate to ± 1 °C, chemical shifts to ± 0.10 c/s, and coupling constants to ± 0.05 c/s.

CALCULATIONS

The activation energies for rotation were calculated by the procedure of Gutowsky and Holm (6) in which the rotation about the CN bond can be regarded as a rate process which intramolecularly interchanges the two methyl groups between two environments. Solution of the Gutowsky and Holm equations yields τ from the experimental values of methyl group separations at a given temperature. Numerical calculations for τ were carried out on an IBM 7090 computer. The activation energy for the barrier to internal rotation was then computed by fitting a least squares curve to an Arrhenius equation. The computer programme also gave standard deviations in E_a and ν_0.

The free energy and entropy of activation were calculated from the Eyring equation.

RESULTS

The partial double bond character of the CN bond (4, 5) and the planar configuration of DMF (4) give rise to two separate methyl resonances of equal intensity, each split into doublets by spin–spin coupling to the formyl proton (5).

The 60 Mc/s spectrum of the methyl protons of DMF in solution in TCE at 25 °C consists of two doublets chemically shifted from each other by $\Delta_{AB} = 5.6$ c/s. The doublet at lower field has a splitting $J = 0.50$ c/s, while the higher field doublet has a splitting $J = 0.80$ c/s. This compares with the values of $J = 0.28$ c/s and $J = 0.56$ c/s obtained by Woodbrey and Rogers (7) for pure DMF. By analogy with ethylenic systems (8) the coupling of the methyl group *trans* to the formyl proton is larger than the formyl coupling to the *cis* methyl group and hence the higher field doublet is assigned to the *trans* methyl group. The relative shift of the methyl resonances would also be expected in view of the high electron density at the carboxyl oxygen atom and the high anisotropy of the carbonyl bond (9). This produces a greater shielding effect at the methyl group *cis* to the oxygen atom and results in its resonance to higher field.

The midpoint of the two methyl peaks of $DMF \cdot BF_3$ measured at 25 °C in TCE appears at 23.5 c/s to lower field from DMF. The peak separation is 7.1 c/s while the high and low field peak splittings are $J = 1.10$ c/s and $J = 0.70$ c/s respectively.

For $DMF \cdot BCl_3$ at 25 °C there are two sets of methyl doublets (Fig. 1). One set shifted by 26.5 c/s to lower field from DMF has a methyl group separation of 10.6 c/s and splitting of $J = 0.90$ c/s and $J = 1.30$ c/s for the low and high field peaks respectively. The other set is shifted by 21.3 c/s to lower field from DMF and has a methyl group separation of 8.4 c/s and splittings of $J = 0.90$ c/s and $J = 1.20$ c/s for the low and high field peaks respectively.

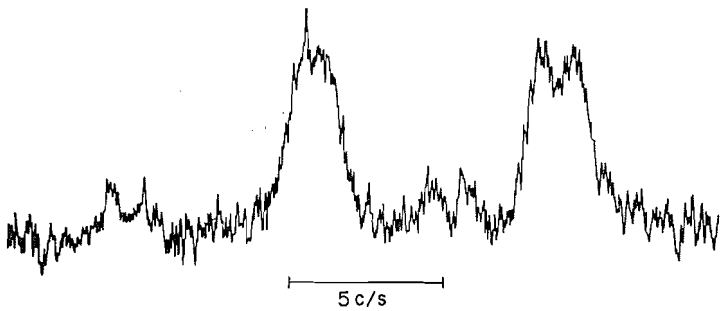

FIG. 1. Nuclear magnetic resonance spectrum of a 4 mole % solution of $DMF \cdot BCl_3$ in TCE at 25 °C.

The signals for the DMF and $DMF \cdot BF_3$ methyl groups broadened and moved closer together with increasing temperature and eventually coalesced at $T_c = 115$ °C and $T_c = 135$ °C respectively. This data is shown in Table I. Spectra were recorded under "slow passage" conditions and radio-frequency saturation avoided since the analysis is only valid provided that these conditions are maintained.

TABLE I

Collapse of the methyl group doublets in 4 mole % solutions of DMF and $DMF \cdot BF_3$ in TCE

DMF		$DMF \cdot BF_3$	
T (°C)	Δ_{AB} (c/s)	T (°C)	Δ_{AB} (c/s)

106	2.49	120	4.55
140	1.3*	122	3.75

*Line width at half height after coalescence.

Similar observations were noted for $DMF \cdot BCl_3$ complexes but in this case accurate data were not obtainable because of the overlap of the two sets of signals. An approximate coalescence temperature of 145 °C was indicated for the 1:1 complex.

The formyl coupling to the methyl groups of DMF and $DMF \cdot BX_3$ complexes in TCE is not observed at temperatures below ~ -15 °C due to a combination of freezing out of rotational isomers and signal broadening arising from viscosity effects.

A summary of the parameters E_a, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ calculated for DMF and DMF·BF_3 is given in Table II.

TABLE II

Energy parameters for internal rotation (4 mole % in TCE solutions)

	E_a (kcal mole^{-1})	ν_0 (s^{-1})	$\Delta H^{\ddagger}$ (kcal mole^{-1})	$\Delta S^{\ddagger}$ (e.u.)*	T_c
DMF	6.2±0.3	$4.02\pm0.02\times10^{4}$	6.5±1.0	−54±1.0	115
DMF·BF_3	14.5±1.1	$1.33\pm0.02\times10^{9}$	11.8±0.4	−55±1.0	135

*e.u. = entropy units.

DISCUSSION

1. *Factors Affecting Line Shape*

A variety of factors can affect the line shapes of n.m.r. spectra with the most important being intermolecular phenomena such as chemical exchange and solvent perturbations and intramolecular effects such as internal rotation.

Intermolecular exchange of the amide can occur between the free and complexed forms in solution and may result in line-shape changes with temperature. However, the stability of the BX_3 complexes (4, 15) and the good linearity obtained for plots of $(1/2\tau)$ vs. temperature indicate that changes in the equilibrium constant for complex formation are unimportant. Intermolecular solvent effects on line shapes were minimized by working with low concentrations of the complex in an inert solvent TCE. The variation of the line shapes with temperature is therefore compatible with the variation of the rate constant for the rotation of the methyl groups about the CN bond. The rate constants were evaluated from the separation between the two methyl peaks near the coalescence temperature. Although other methods of evaluation of $1/\tau$ are available (10) they are not as reliable in this region where the separation shows good sensitivity to temperature change.

2. *Coupling Constant Changes*

The long-range formyl proton–methyl group coupling constants observed for DMF in TCE in the present work are somewhat larger than the values reported earlier (7) for the neat compound. It is likely that these small differences result from solvent perturbations of the rotational and (or) H-bonding equilibrium.

The formation of DMF·BX_3 complexes significantly increases the long-range coupling between the formyl proton and the methyl group protons. A similar increase has been noted on protonation of DMF (5). In both cases the addition stabilizes the resonance form having a greater double bond (π bond) character of the CN bond and leads to an increase of the long-range coupling constant (11, 12). A similar mechanism has been evoked to explain the increase in the long-range couplings in aqueous solutions of N-methylformamide and DMF (17, 18).

The J increase for DMF·BCl_3 is slightly greater than for DMF·BF_3 as would be expected on the basis of the weaker acceptor properties of BF_3 (13). The value of J_{trans} in the 1:2 complex of DMF·BCl_3 is slightly greater than in the 1:1 complex. This would occur provided the stabilization of (II) caused by 1:1 complex formation is enhanced on 1:2 complexing. The additional increased s character of the CN bond would give rise to the larger J_{trans} value.

3. *Changes in the Rotational Barrier*

Boron trichloride is a stronger electron acceptor than BF_3 (13) and hence in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

amide–BX_3 complexes the former will stabilize from (II) more than will BF_3. The higher coalescence temperature, $T_c \gtrsim 145$ °C for the BCl_3 complex as compared with $T_c = 135$ °C for $DMF \cdot BF_3$ is in agreement with this. The enhanced stabilization and resulting increased CN double bond character is reflected in the magnitude of the activation energies for the barriers hindering internal rotation. For DMF, $E_a = 6.2 \pm 0.3$ kcal mole^{-1} and for $DMF \cdot BF_3$, $E_a = 14.5 \pm 1.1$ kcal mole^{-1}. The DMF result is compatible with previous values of $E_a = 7.3 \pm 3$ kcal mole^{-1} (ref. 6) and $E_a = 9.6 \pm 1.5$ kcal mole^{-1} (ref. 5) for pure DMF, but differs markedly from the value reported by Rogers and Woodbrey (7) of 18.3 kcal mole^{-1}. The value of E_a was found to increase on protonation to 12.7 ± 1.5 kcal mole^{-1}, in agreement with the present result for $DMF \cdot BF_3$.

The variation in the values obtained by different authors for the activation energy hindering rotation about the CN bond in DMF is probably due to solvent and concentration effects and to the presence of acidic impurities, all of which can combine to stabilize the ionic form (II) and result in an increased value of E_a.

A large increase of approximately five orders of magnitude occurs in the value of the frequency factor ν_0 on going from DMF to $DMF \cdot BF_3$. Large variations in ν_0 are also noted for similar systems, i.e. DMF, investigated under different solvent conditions by different authors (5, 6, 7). Such changes appear to be typical of these systems and are not readily interpreted at the present time. However, it seems likely that the variation of ν_0 reflects subtle influences of the solvent on the frequency of rotation about the CN bond.

The large, approximately equivalent negative values of $\Delta S^{\ddagger}$ for DMF and $DMF \cdot BF_3$ are somewhat surprising and are suggestive of a rigidly defined transition state intermediate.

4. Changes in the Chemical Shifts

Significant differences are noted between the relative shifts for the methyl groups of DMF in TCE and the values reported previously (5, 6, 7). As in the case of coupling constants these differences arise because of the influence of the solvent on the methyl shieldings. Similar solvent effects on the shifts and rotational energy barriers have been noted recently for N,N-dimethylnitrosamine (16).

Complex formation results in the low field shifts for the methyl protons in DMF in agreement with recent observations for a number of ether–BX_3 (13) and amine–BX_3 (14) addition compounds. The deshielding effect can be attributed to a flow of electron density from the donor molecule to the acceptor and would be expected to fall off with increasing number of intervening bonds. A comparison of the data for the ether and amide complexes, Table III, indicates that the deshielding effect drops off by a factor of 2 to 3 in going from the α to the β position.

Although the shift changes observed for protons on different donors upon complex formation are subject to a variety of complicating influences, the magnitudes of the shift changes for methyl protons in stable 1:1 $DMF \cdot BX_3$ complexes, ~ 0.400 p.p.m., are consistent with coordinate bond formation at the oxygen atom.

The appearance of two sets of methyl peaks in the $DMF \cdot BCl_3$ complex indicates the presence of two types of complex. The more abundant complex, -21.3 c/s downfield from DMF is due to a 1:1 adduct involving complexing at the DMF carboxyl oxygen atom. The second pair of methyl peaks at -26.5 c/s, is of much lower intensity and is probably due to a 1:2 adduct. The site of complexing in this case cannot be established unequivocally although the deshielding effect, -0.443 p.p.m., would favor the O site.

ELECTRON SPIN RESONANCE DETERMINATION OF THE RADIOLYTIC YIELDS OF TRAPPED ELECTRONS AND OTHER SPECIES IN AN ORGANIC GLASS[1]

D. R. SMITH AND J. J. PIERONI

Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratory, Chalk River, Ontario

Received April 7, 1965

ABSTRACT

The radiolytic yields, at liquid nitrogen temperature, of trapped electrons and radicals or radical-ions in 2-methyltetrahydrofuran and the yields of these species plus the biphenyl anion in solutions containing biphenyl have been determined by e.s.r. These measurements were also carried out after photolysis of the trapped electrons. The combined results are interpreted in terms of the identity of the intermediates and the reactions which they undergo. "Dual e.s.r. cavity" techniques have enabled greater accuracy and precision than is normally obtained when concentrations of paramagnetic species are determined by e.s.r.

INTRODUCTION

The work of Hamill *et al.* (1, 2) has provided convincing evidence of the role of electrons and ions in the radiation chemistry of certain organic compounds at low temperature. From optical absorption measurements, they found that electrons become trapped in the matrix during the radiolysis of 2-methyltetrahydrofuran (MTHF) at 77 °K. They also found that a solute such as biphenyl ($C_{12}H_{10}$) could compete with the solvent for electrons by forming $C_{12}H_{10}^-$. By assuming that the optical extinction coefficient of the chemically generated anion equals that of the radiolytically generated anion they determined that during radiolysis the maximum value of G(solute anion) was 2.6 to 3.0,* depending on the solute. From this they assumed that in the absence of solute, G(trapped electron) was approximately 3.0. They estimated a minimum oscillator strength $f \sim 0.8$ for trapped electrons in MTHF (3). f is expected to be close to unity and has been found to equal 0.8 to 0.9 for F centers in alkali halides (4).

In view of the importance of these results, it was decided to repeat the experiment and make observations using electron spin resonance spectroscopy (e.s.r.). Electron spin resonance measurements detect paramagnetic species and these can often be identified with greater certainty from their e.s.r. spectra than from their optical absorption spectra. In particular, and as is the case in MTHF, many free radicals which are easily detected by e.s.r. have only a weak optical absorption. A concentration measurement can be made by e.s.r. whose accuracy does not depend on any factor analogous to the extinction coefficient in optical absorption measurements. Hence this work provides a check of the results obtained by Hamill *et al.*, independent of the assumptions made by them.

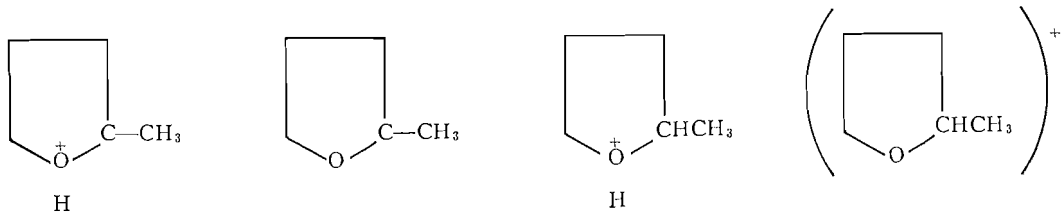
In a previous paper (5) we described results which supported Hamill and co-workers' conclusion that trapped electrons are formed by radiolysis of MTHF. From microwave saturation studies, and measurements of rates of thermal disappearance, it was concluded that the "trapped electron" in MTHF is a distinct entity distinguishable from a free radical. It was also concluded that it is trapped, along with radicals or radical-ions, in clusters or regions containing higher local concentrations than the bulk of the matrix.

[1]*AECL No. 2304.*

**G equals the number of molecules of a species formed per 100 eV energy deposited in the sample.*

The results suggested that the electron is trapped by the solvent at an average distance of about 40 Å from the parent positive ion.

The e.s.r. spectrum of another species was also detected (6, 7). Salmon (7) ascribes a weak ultraviolet absorption to this species. We choose to identify this species as the ion-radical I while Dainton *et al.* (8) suggest it is the free radical II and that the H^+ migrates to a neighboring solvent molecule to form III. Since the arguments presented earlier are not conclusive (5) this species will be referred to as I or II. Where no distinction need be made we will refer to species I or II as species A. Species IV, the primary ion, is defined here for convenience.



I II III IV

This paper reports the results of concentration measurements by e.s.r. of paramagnetic species formed and trapped during radiolysis of MTHF and solutions of MTHF containing various amounts of $C_{12}H_{10}$. These measurements have been carried out both before and after photolysis of the irradiated sample.

EXPERIMENTAL

Techniques of preparation of pure MTHF samples, ^{60}Co gamma irradiation, dosimetry, and measurement of e.s.r. spectra have been described (5, 6). A linear reproducible magnetic field scan was provided by a Varian fieldial. These experiments were all carried out at liquid nitrogen temperature. Solutions of $C_{12}H_{10}$ in MTHF were irradiated to a dose of 9.4×10^{18} eV ml^{-1}.

To prepare solutions of $C_{12}H_{10}$ of known concentration, the required amount of $C_{12}H_{10}$ was weighed into a volumetrically calibrated tube to which a spectrosil e.s.r. tube was attached. The apparatus was then evacuated while cooling the $C_{12}H_{10}$ with liquid nitrogen to avoid sublimation. A measured volume of purified degassed MTHF was then distilled under vacuum into the tube and the $C_{12}H_{10}$ dissolved. The resulting solution was subjected to several degassing cycles to ensure the absence of dissolved air. The entire apparatus was then detached from the vacuum line by sealing off at a constriction. The solution of $C_{12}H_{10}$ in MTHF was poured into the e.s.r. tube and this was in turn detached from the apparatus by sealing off under vacuum.

The chemically formed anion $C_{12}H_{10}^-$ was prepared by the method of Paul, Lipkin, and Weissman (9).

Both unknown and reference sample were present in a Varian TE_{104} "dual" cavity at the same time and both were observed at liquid nitrogen temperature. Each was in a Spectrosil tube of the same dimensions, filled and positioned so that the sample filled the vertical dimension of the cavity. The spectra were obtained consecutively without retuning the spectrometer. The reference sample spectrum was obtained both before and after that of the unknown, to check for fluctuations in spectrometer sensitivity. The reference was the stable free radical in nuclear reactor irradiated terphenyl coolant which had been stored at room temperature for 3 years. To avoid errors due to microwave saturation both samples were measured at a cavity input power of 8 μW. Identical modulation amplitudes were used for both reference and unknown sample spectra and amplifier gain switches were calibrated in terms of absorption spectrum intensity. This procedure of comparing samples in a dual cavity under identical conditions of cavity Q, cavity input power, temperature, sample dimension, etc., has considerable advantage over the more common practice of using a single cavity. The latter necessitates substitution of samples, retuning the spectrometer, etc. Unless the two samples being compared by the single cavity technique have identical dielectric properties, the spectrometer sensitivity may vary greatly between the two measurements and errors as great as $\pm 50\%$ are usually involved. In pure MTHF we estimate our precision to be $\pm 5\%$. In the series of solutions containing $C_{12}H_{10}$, the precision is poorer, $\pm 15\%$, because the graphical double integrals of spectra having different shapes are being compared. The accuracy depends on the graphical integration and on our calibration of the reference, described earlier (5). Briefly, the concentration of free radicals in the reference sample was determined by comparison

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with a solution of 2,2-diphenyl-1-picryl-hydrazl (DPPH) in CCl_4. The concentration of DPPH was determined by its optical absorption using the known optical extinction coefficient. The accuracy of the extinction coefficient is based on a measured weight of purified DPPH and on the accuracy of dilution of this material. Hence our major source of error in calibrating the reference, probably ±10%, arises from the graphical double integration of the spectra.

After irradiation, the concentrations of paramagnetic species in a sample were determined. The sample was then photolyzed by illuminating it with light of wavelength longer than about 6 000 Å. The concentrations of paramagnetic species remaining after photolysis were then determined. The total concentration of paramagnetic species was determined by comparison of the double integral (obtained graphically) of the first derivative e.s.r. spectrum with that of the free radical reference spectrum (5). In most of these measurements an absorption due to trapped electrons, $C_{12}H_{10}^-$, or both was superimposed on the central line of the septet absorption due to species A. In these cases the concentration of A was calculated from the intensity of the third and fifth absorption peaks and the measured double integral for a given intensity of these peaks. The concentration of trapped electrons, in pure MTHF, and of trapped electrons plus $C_{12}H_{10}^-$, in solutions of $C_{12}H_{10}$, was equated to the difference between the total concentration and that of A.

RESULTS

1. *Pure MTHF*

The e.s.r. spectra and the identification of the species causing them have been discussed (5). A singlet absorption due to trapped electrons is superimposed on the center line of a septet absorption due to species A and the sample is colored blue. Photolysis eliminates the blue color and the e.s.r. absorption due to trapped electrons while the e.s.r. absorption due to species A remains, although diminished in intensity. Figure 1A shows the yields of trapped electrons and of species A before and after photolysis as a function of irradiation dose up to 7.09×10^{19} eV ml^{-1}. Figure 1B is an expansion of Fig. 1A in the low dose region. Note that each graph in Fig. 1A is slightly curved and that about one-third of species A disappears when the trapped electrons are totally eliminated by photolysis. This was also observed by the e.s.r. difference spectrum method (6). Below about 5×10^{18} eV ml^{-1}, the yields are linear with dose. From the initial slopes in Fig. 1B $G(e^-_{trapped}) = 2.6$, $G(A) = 3.0$ before photolysis, and $G(A) = 2.0$ after photolysis.

We previously observed that on warming an unphotolyzed sample to 92–95 °K, the trapped electrons disappeared along with about one-third of species A (5).

2. *Solutions of $C_{12}H_{10}$ in MTHF*

Solutions containing 0.01, 0.03, 0.066, 0.098, 0.20, and 0.39 mole % $C_{12}H_{10}$ have been studied. The results are illustrated by the e.s.r. spectra in Fig. 2 and the data in Table I.

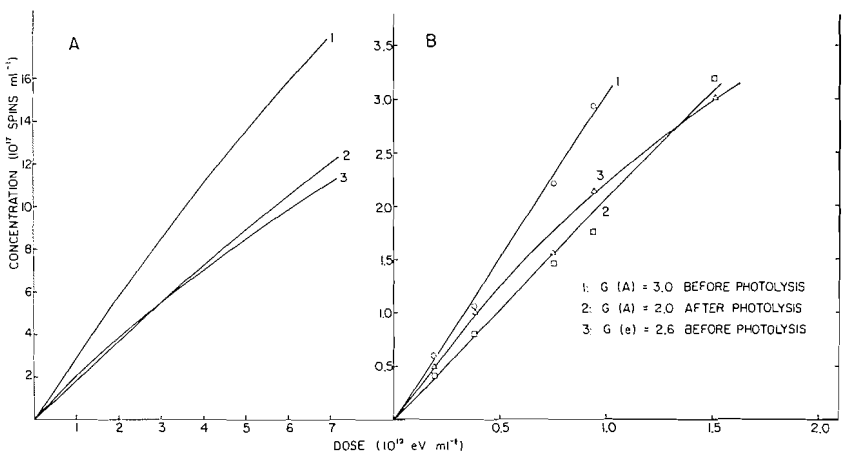


FIG. 1. Yields of trapped electrons and species A (before and after photolysis) as a function of radiation dose. Fig. 1B is an expansion of the low dose portion of Fig. 1A.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In Fig. 2 only the central absorption plus part of the third and fifth lines of the spectrum due to A is shown. The relative intensity of the spectra in the figure should be ignored, since different gain settings were used to obtain some of them.

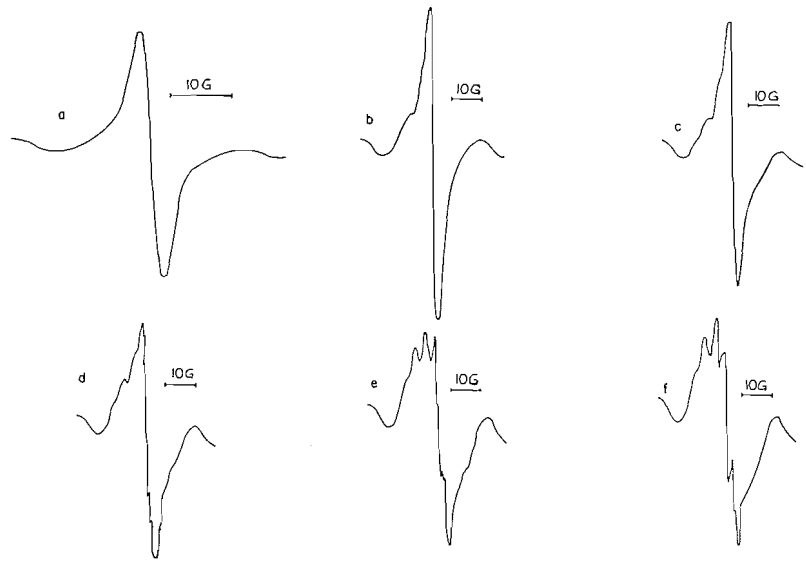

FIG. 2. Central portions of the first derivative e.s.r. spectra obtained by radiolysis of solutions of $C_{12}H_{10}$ in MTHF. Mole % $C_{12}H_{10}$ concentrations are (*a*) 0.01, (*b*) 0.031, (*c*) 0.066, (*d*) 0.098, (*e*) 0.20, (*f*) 0.39.

TABLE I

Radiolytic yields of species trapped in solutions of $C_{12}H_{10}$ in MTHF

Mole % $C_{12}H_{10}$	G(A)*	$G(e^- + C_{12}H_{10}^-)$*	G(A)†	$G(C_{12}H_{10}^-)$†

Average‡ G	3.4	2.5	3.4	2.7

*Before photolysis.
†After photolysis.
‡The averages do not include the data for the 0.01% solution.

Radiolysis generates the septet e.s.r. absorption of A. Superimposed on the center line of the septet is the sum of the absorptions due to trapped electrons and a species formed from $C_{12}H_{10}$ (concluded to be $C_{12}H_{10}^-$, see Discussion). The ratio of $C_{12}H_{10}$ species absorption to trapped electron absorption increases (the sum remaining constant) with $C_{12}H_{10}$ concentration up to 0.1 mole %. At 0.2 and 0.39 mole % only the absorption due to the $C_{12}H_{10}$ species superimposed on the central line of the spectrum of species A was observed, the absorption intensity being the same in both cases. The color of the sample changes from blue to green-blue as the absorption due to the $C_{12}H_{10}$ species increases and that due to trapped electrons decreases.

Photolysis of the samples containing up to 0.098 mole % $C_{12}H_{10}$ changed the e.s.r.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

spectrum to that obtained in irradiated samples containing 0.20 or 0.39 mole %. Photolysis did not affect the e.s.r. spectrum of the $C_{12}H_{10}$ species nor, in the presence of 0.03 mole % $C_{12}H_{10}$ or greater, was the intensity of the e.s.r. septet due to A diminished. However, photolysis did reduce the intensity of the septet in the 0.01 mole % $C_{12}H_{10}$ solution. It was qualitatively observed that much less photolysis time was required to convert the trapped electron absorption to that of the $C_{12}H_{10}$ species, compared to that required to eliminate the trapped electron absorption in pure MTHF.

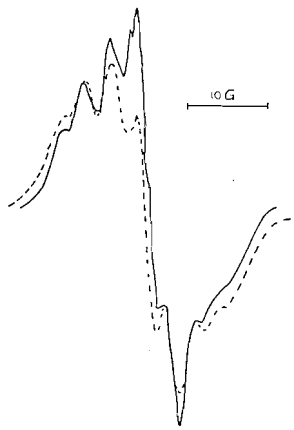

FIG. 3. (—) First derivative e.s.r. spectrum of the $C_{12}H_{10}$ species formed during radiolysis of 0.2 mole % solution of $C_{12}H_{10}$ in MTHF. (- -) First derivative e.s.r. spectrum at 77 °K of $C_{12}H_{10}^-$ formed in MTHF by reaction with Na.

The solid curve in Fig. 3 is the first derivative e.s.r. spectrum of the $C_{12}H_{10}$ species in a 0.2 mole % $C_{12}H_{10}$ solution, obtained by the e.s.r. difference spectrum technique (6). It is the difference between the absorption of the $C_{12}H_{10}$ solution, irradiated to 9.4×10^{18} eV ml^{-1} and that due to a pure MTHF sample irradiated to 14.1×10^{18} eV ml^{-1} and photolyzed. The higher dose for the pure MTHF sample was required to match the intensity of the spectrum due to A in both samples because one-third of A also disappears during photolysis. The dashed curve is the spectrum of the chemically generated $C_{12}H_{10}^-$ for comparison. The average hyperfine splitting in Fig. 3 is 3.1 G.

DISCUSSION AND CONCLUSIONS

1. *Pure MTHF*

A tentative reaction scheme to account for the results is outlined below. A possible physical mechanism for reaction [2] has been discussed (5).

[1]* $$\text{MTHF} \xrightarrow{\sim\sim} \text{IV} + e^-_{\text{untrapped}}$$

[2] $$e^-_{\text{untrapped}} \rightarrow e^-_{\text{trapped}}$$

[3*a*] $$\text{IV} \rightarrow \text{I}$$

or

[3*b*] $$\text{IV} + \text{MTHF} \rightarrow \text{II} + \text{III}$$

[4] $$e^-_{\text{trapped}} + \text{visible light or heat} \rightarrow e^-_{\text{untrapped}}$$

[5*a*] $$e^-_{\text{untrapped}} + \text{I} \rightarrow \text{II} + \text{H}\cdot$$

or

[5*b*] $$e^-_{\text{untrapped}} + \text{III} \rightarrow \text{MTHF} + \text{H}\cdot$$

**The symbol* —∿∿→ *means "produces during irradiation with γ-rays from* ^{60}Co".

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[6] $$H\cdot + II \rightarrow MTHF$$

[7] $$H\cdot + H\cdot \rightarrow H_2$$

Either reaction sequence ([3*a*] + [5*a*] + [6]) or ([3*b*] + [5*b*] + [6]) accounts for the disappearance of all the trapped electrons and a fraction of A as a result of photolysis or warming. Our arguments favoring reactions ([3*a*] + [5*a*]) over ([3*b*] + [5*b*]) were presented earlier (5). Salmon did not observe any disappearance of A by e.s.r. (7), possibly because of the errors involved in making concentration measurements with a "single" TE_{102} e.s.r. cavity. The slight optical absorption in the ultraviolet which Dainton *et al.* attributed to species II did not decrease when the trapped electrons were eliminated by photolysis (8).

$G(e^-_{trapped}) = 2.6$ is 13% less than the value deduced by Hamill and co-workers from their value of $G(C_{12}H_{10}^-) = 3.0$. If $G = 2.6$ is more nearly correct, the oscillator strength must be close to $f = 0.9$. The value $G(A) = 3.0$ suggests that a small amount of recombination competes with trapping via reactions [8] and [9] and causes the ratio $G(e^-_{trapped})/G(A)$ to be less than unity.

[8] $$e^-_{untrapped} + IV \rightarrow (MTHF)\dagger$$

[9] $$(MTHF)\dagger \rightarrow II + H\cdot$$

The thermal reaction observed at liquid nitrogen temperature (5) accounts for the curvature in Fig. 1.

2. Solutions of $C_{12}H_{10}$ in MTHF

In Fig. 3 the hyperfine splittings in the e.s.r. spectra of the radiolytically generated $C_{12}H_{10}$ species and of the chemically generated $C_{12}H_{10}^-$ ion are the same. Trace absorption by trapped electrons in the irradiated sample would account for the small difference in central peak intensity. The average value of $G(e^-_{trapped} + C_{12}H_{10}$ species) before photolysis and the average value of G(biphenyl species) after photolysis are equal within experimental error to the value of $G(e^-_{trapped}$ electrons) = 2.6 obtained in pure MTHF.

The spectra in Fig. 2 show qualitatively that the ratio of the concentration of the $C_{12}H_{10}$ species to that of trapped electrons increases in solutions containing up to 0.1 mole % $C_{12}H_{10}$. At the same time the sum of their concentrations is constant (Table I) and equals the yield of trapped electrons obtained when $C_{12}H_{10}$ is absent. Above 0.2 mole % $C_{12}H_{10}$ virtually all the electrons are captured to form the $C_{12}H_{10}$ species. Thus each $C_{12}H_{10}$ species formed results in the observation of one less trapped electron. It is concluded that the $C_{12}H_{10}$ species is $C_{12}H_{10}^-$ formed in competition with electron trapping by the solvent. The average maximum $G(C_{12}H_{10}^-)$ observed by e.s.r. is slightly lower than the value of 3.0 obtained in the optical work (2). These e.s.r. results qualitatively agree with those obtained by optical measurements (ref. 2, Fig. 2) and support the assumption of Hamill *et al.* (2) that $G(e^-_{trapped})$ in the absence of $C_{12}H_{10}$ can be equated to the maximum $G(C_{12}H_{10}^-)$ obtained in the more concentrated $C_{12}H_{10}$ solutions. However, the e.s.r. results do suggest that the value of $G(e^-_{trapped}) = G(C_{12}H_{10}^-)_{max} = 3.0$ deduced from optical measurements may be 10 or 15% high.

The yield of species A in all but the 0.01% solution was unchanged during photolysis in contrast to the behavior in pure MTHF where photolysis of the trapped electrons reduced the concentration of A by one-third via reactions ([5*a*] + [6]) or ([5*b*] + [6]). This may be due to prevention of reactions ([5*a*] + [6]) or ([5*b*] + [6]) by the $C_{12}H_{10}$ competition reaction [10].

[10] $$C_{12}H_{10} + e^-_{untrapped} \rightarrow C_{12}H_{10}^-$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

G(A) appears to be about 10% higher than in pure MTHF but this may not be significant.

Comparison of the above results with those in Fig. 2 of ref. 2 shows one difference. Our work indicates total capture of $e^-_{untrapped}$ by $C_{12}H_{10}$ during photolysis in samples containing as little as 0.031 mole % $C_{12}H_{10}$. However, optical measurements indicate considerable loss of electrons during photolysis in solutions containing as much as 0.13 mole % $C_{12}H_{10}$ (2). The only apparent difference in experimental conditions is that the optical measurements were made at a dose nearly 10 times lower than that used in our work. The explanation apparently involves an effect of dose on the competition between reaction [10] and reaction [5*a*] or [5*b*]. This is supported by our observation that at a dose of 9.4×10^{18} eV ml^{-1} photolysis of a 0.01 mole % solution does not result in quantitative capture of $e^-_{untrapped}$ by $C_{12}H_{10}$ while at the same time 20% of species A disappears.

POSSIBLE CALORIMETRIC METHOD FOR MEASUREMENT OF THE LIGAND FIELD SPLITTING ENERGIES FOR THE HEXAAQUO CATIONS OF SOME TRANSITION ELEMENTS

J. W. S. JAMIESON, G. R. BROWN, D. W. GRUENER, R. V. PEILUCK, AND R. A. LAMONTAGNE

Department of Chemistry, St. John's College, University of Manitoba, Winnipeg, Manitoba

Received November 26, 1964

ABSTRACT

High energy modifications of the lower hydrates of the divalent sulfates of manganese, iron, cobalt, and nickel have been prepared by vacuum dehydration. The heats of solution of these materials have been measured and compared with the heats of solution of the normal crystalline lower hydrates. The maximum heats of transition appear to be proportional to the ligand field splitting energies for the corresponding hexaaquo divalent cations, although theoretical justification for this correlation is not yet obvious.

INTRODUCTION

In 1930, Slonim (1) showed that certain salts can be dehydrated at low pressure to give intermediates which were thought to be amorphous. Quantitative measurements of the heat evolved when such samples change spontaneously to normal crystalline lower hydrates have been made by Volmer and Seydel (2), Khomyakov (3), and, more recently, by Frost and his co-workers (4, 5). The heat of solution method was used in all of these investigations since there is usually a substantial heat of transition. Many values may be found in the literature (6, 7, 8) for the heats of solution of anhydrous salts and their crystalline hydrates but there are few available data for the high energy forms which are obtainable from these by dehydration *in vacuo*.

The present investigation was undertaken not only to extend the data for vacuum dehydration products but also to test an approximate method, which will be proposed, for predicting the occurrence of such high energy dehydration products and estimating upper limits of the magnitude of their heats of solution, and heats of transition to normal crystalline form, from the known heats of solution of the various salts and their crystalline hydrates.

The results reported here deal with the products of dehydration of $MnSO_4.5H_2O$, $FeSO_4.7H_2O$, $CoSO_4.7H_2O$, and $NiSO_4.6H_2O$.

EXPERIMENTAL

All of the inorganic salts were J. T. Baker Analyzed reagents, except for $MnSO_4.5H_2O$ of analytical reagent grade, which was supplied by May and Baker, Ltd. Quantitative analysis of these salts has given close agreement with the analyses reported by the manufacturers. Samples of each of the salts were lightly ground in a mortar and dehydrated in various ways to obtain mixtures of the lower crystalline hydrates for measurement of heats of solution. Crystalline samples containing between 4 and 7 moles of water per mole of sulfate were usually prepared by dehydration over sulfuric acid in a desiccator for 48 h or less. Other crystalline samples containing less water were obtained by heating the higher hydrates in an oven or an Abderhalden drying apparatus, usually at 100 °C or higher. Since the iron(II) sulfate was readily oxidized, this salt was dehydrated in an atmosphere of nitrogen.

Vacuum dehydration to various water contents was carried out in a vacuum desiccator, a vacuum oven, or an Abderhalden drying apparatus, connected to a good vacuum line. The system was evacuated at ambient temperature (usually about 25 °C) and at pressures from about 30 microns to below 1 micron for sufficient time to give a product of approximately the composition desired. In some experiments barium oxide was used as desiccant. The water content of each dehydrated sample was calculated from the loss in weight.

All samples were lightly ground in a mortar before measurement of their heats of solution.

Integral heats of solution were measured in a rather crude calorimeter (9) consisting of a silvered Dewar flask equipped with a mechanical stirrer and a Beckmann thermometer. Samples which usually weighed between 0.2 and 0.5 g were dissolved in 1 000 ml of distilled water at 29.0 °C.

The heat capacity of the calorimetric system was determined from the change in temperature caused by application of a known quantity of electrical energy for a measured time to a heater made of B. and S. 28 chromel wire. Rectified power was supplied by an Eico low ripple battery eliminator (manufactured by Electronic Instrument Co. Inc., L. I. City 1, N.Y.). Throughout the heating period the current and voltage remained steady at, for example, 0.801 ± 0.002 A and 5.99 ± 0.02 V. Time was measured with a stopwatch to about 600 ± 0.1 s.

Determination of the temperature change due to either energy input or solution of a sample, which is probably the limiting factor, appears to be accurate to about ±0.002 deg, since a Beckmann thermometer can be read to the nearest 0.001 deg, and the corrections for thermal radiation, calculated from the cooling curves before and after energy input or salt addition, are probably not subject to comparable errors. For each experiment the heat capacity was calculated by dividing the energy input in calories by the temperature change caused by the energy input. An average value of 1.24×10^3 cal/deg for the heat capacity of the calorimeter, based on many individual determinations, has been used in all calculations of heats of solution.

Since measured temperature differences are probably accurate to about ±0.002 deg, it appears that individual heats of solution are known to $1.24 \times 10^3 \times 0.002$ cal or about ±2.5 cal. Independent calibrations of the calorimeter to this accuracy or better have been made with several substances, including $Na_2SO_4.10H_2O$ and oxalic acid, which have well-known heats of solution.

RESULTS

The results are given in Tables I to IV and also in Figs. 1 to 4, where it may be seen that it has been established empirically that certain linear relations are obtained by plotting the heats of solution in calories per gram of solute against the percentages of water in the samples. For convenience the various sets of results will also be expressed in the form of straight line equations, calculated by the method of least squares. The vertical lines in Figs. 1 to 4 are at the monohydrate compositions.

TABLE I

Heats of solution for various hydrates of iron(II) sulfate

% water in sample	Heat of solution (cal/g)	Nature of sample or method of dehydration
13.20	40.9	Dehydrated at 100 °C
29.69	12.1	Dehydrated at 100 °C
32.54	6.1	Dehydrated over H_2SO_4
40.81	−8.8	Dehydrated over H_2SO_4
45.36	−16.1	Crystalline heptahydrate
12.11	144.7	Vacuum dehydration
18.32	115.9	Vacuum dehydration
22.60	92.1	Vacuum dehydration
32.28	46.5	Vacuum dehydration
38.69	17.8	Vacuum dehydration
41.11	1.2	Vacuum dehydration
45.36	−16.1	Crystalline heptahydrate

Iron(II) Sulfate

The heats of solution for samples of $FeSO_4.7H_2O$ which were dehydrated by various methods are given in Table I and in Fig. 1. The line AB joins de Forcrand's values (10) for the crystalline monohydrate (10.60% water) and the anhydride. The present line BC for the higher crystalline hydrates gives close agreement with values reported by de Forcrand (10) for the monohydrate, the tetrahydrate (32.18% water), and the heptahydrate (45.36% water) and has the equation

$$y = -1.78x + 64.5.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

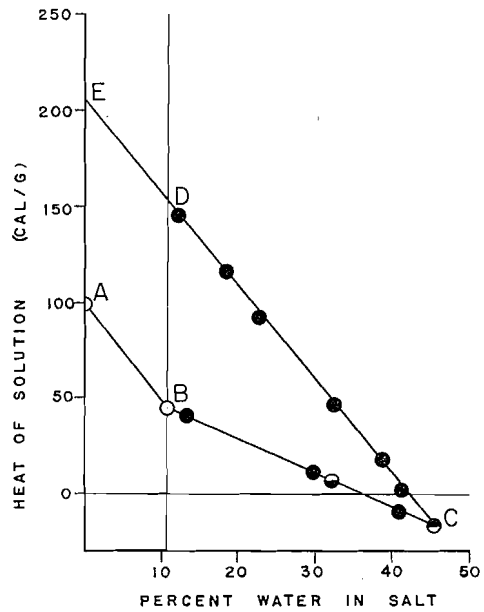

FIG. 1. Heats of solution for various hydrates of iron(II) sulfate: (○) earlier data, (●) present results.

Vacuum dehydration of $FeSO_4.7H_2O$ gave heat of solution results on the line CE with the equation

$$y = -4.86x + 203.6.$$

This line seems to be virtually parallel to the line AB for crystalline samples between the monohydrate and the anhydrous salt.

The heat of transition at any composition is just the difference in cal/g between the points on the two lines CD and BC at any desired percentage of water. Evidence that the vacuum dehydration products of $FeSO_4.7H_2O$ do revert to normal crystalline form has been reported (4). It is apparent that the maximum heat of transition DB to normal crystalline form of the high energy intermediates produced by vacuum dehydration of the heptahydrate is about 106.5 cal/g, which could be expressed as 18.1 kcal/mole of monohydrate or about 30 kcal/mole of $FeSO_4.7H_2O$. This maximum heat of transition is very much larger than the values (4, 5) which have been reported for other divalent metal sulfates.

Cobalt(II) Sulfate

Samples obtained by dehydration of $CoSO_4.7H_2O$ gave the results shown in Table II and in Fig. 2. The heat of solution of the heptahydrate (44.86% water) is in reasonable agreement with Thomsen's earlier value (6, 8). Again the lines AB and BC refer to crystalline samples. The equation of the line BC is

$$y = -2.80x + 114.7$$

while that of the line FH for samples dehydrated *in vacuo* is

$$y = -5.52x + 200.0.$$

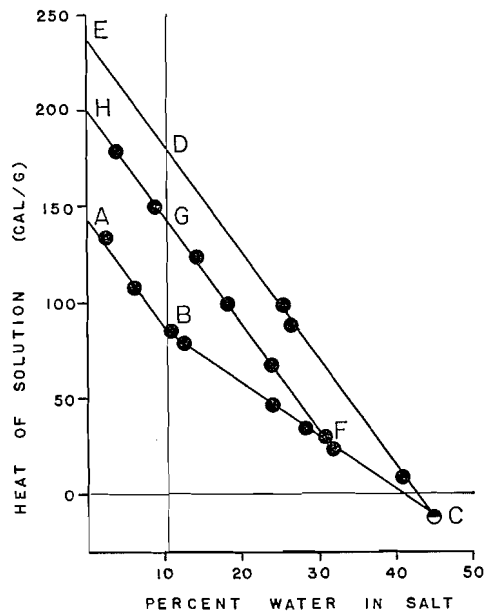

FIG. 2. Heats of solution for various hydrates of cobalt(II) sulfate: (○) earlier data, (●) present results.

Vacuum dehydration has been found to give results on this line unless barium oxide was present as desiccant, when the line CE was obtained. Again it appears that the lines AB, FH, and CE are all essentially parallel, so that the maximum heat of transition DB may be estimated as about 93.7 cal/g, which is 16.8 kcal/mole of monohydrate or about 26 kcal/mole of $CoSO_4.7H_2O$.

41.13	−6.0	Crystalline hexahydrate

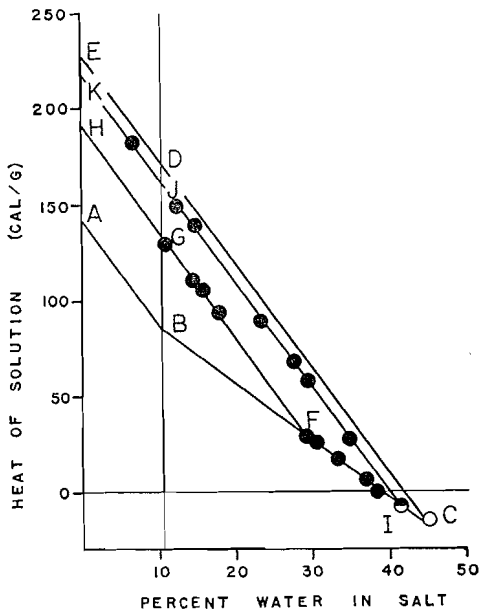

FIG. 3. Heats of solution for various hydrates of nickel(II) sulfate: (○) earlier data, (●) present results.

Nickel(II) Sulfate

The results obtained for samples of $NiSO_4.6H_2O$ dehydrated by various methods are given in Table III and in Fig. 3. Again there is reasonable agreement with previous values for the hexahydrate (11) and the heptahydrate (6, 8). The line BC for crystalline lower hydrates,

$$y = -3.00x + 116.2,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

has been calculated for samples containing more than 29% water, since it has not been possible to prepare samples which give heats of solution on this line between B and F. Attempts to make crystalline hydrates with less than 29% water have given either insoluble samples or samples with heats of solution which fell on the line FG, which has the equation

$$y = -5.55x + 191.1.$$

In a previous rather cursory study (12) of this salt it was found that samples dehydrated either at 100 °C or *in vacuo* gave heats of solution in the vicinity of the point G. The vacuum dehydration products showed the complete absence of X-ray diffraction patterns. Vacuum dehydration in this laboratory, by a technique which is not obviously different from that previously used, except that ambient temperature was used instead of 40 °C, gave samples having heats of solution on the line IK, with the equation

$$y = -5.48x + 218.0.$$

Parallel lines AB and CE have been drawn through the points for the monohydrate (10.43% water) and the heptahydrate (44.90% water). Thus the maximum heat of transition DB to normal crystalline form of the high energy intermediates produced by vacuum dehydration of the heptahydrate has been estimated as 85.7 cal/g, which is 14.8 kcal/mole of monohydrate or about 24 kcal/mole of $NiSO_4.7H_2O$.

TABLE IV

Heats of solution for various hydrates of manganese(II) sulfate

% water in sample	Heat of solution (cal/g)	Nature of sample or method of dehydration
10.66	56.5	Crystalline monohydrate
37.37	17.2	Crystalline pentahydrate
8.53	114.7	Dehydrated at 100 °C
11.02	104.4	Dehydrated at 100 °C
13.07	95.6	Dehydrated at 100 °C
9.32	123.1	Vacuum dehydration
10.12	120.7	Vacuum dehydration
11.06	116.1	Vacuum dehydration
12.25	111.2	Vacuum dehydration
16.05	98.7	Vacuum dehydration
37.37	17.2	Crystalline pentahydrate

Manganese(II) Sulfate

The heats of solution for samples of $MnSO_4.5H_2O$ which were dehydrated by various methods are given in Table IV and in Fig. 4. The line BI has been calculated from the heats of solution of commercial samples of the monohydrate (10.66% water) and the pentahydrate (37.37% water) as

$$y = -1.47x + 72.2.$$

This line for the crystalline hydrates has been extrapolated to the heptahydrate composition at C (45.51% water).

When samples of the pentahydrate were heated at 100 °C in an attempt to prepare lower crystalline hydrates it was found that this salt had a marked tendency to form lower hydrates of high energy instead. The resulting samples gave heats of solution on the line FH, which has the equation

$$y = -3.76x + 145.9.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

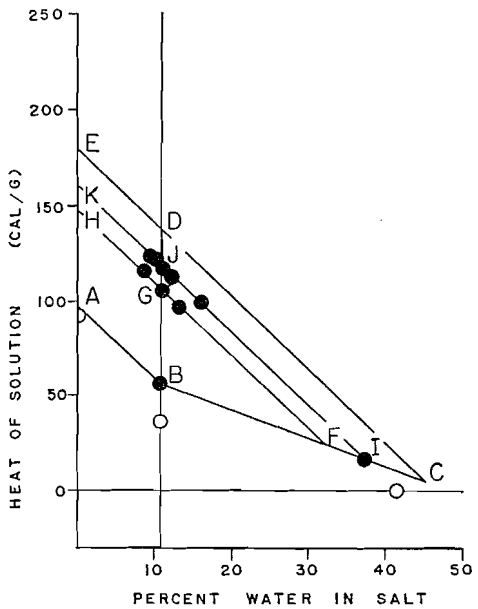

FIG. 4. Heats of solution for various hydrates of manganese(II) sulfate: (○) earlier data, (●) present results.

Similarly, vacuum dehydration of the pentahydrate gave results which fell along the line IK, with the equation

$$y = -3.77x + 158.3.$$

The lines AB and CE have been drawn parallel to FH and IK to facilitate comparison of the results for the hydrate system of manganese(II) sulfate with the results for the other three salts. Thus it is estimated that the maximum heat of transition DB for vacuum dehydration products of the heptahydrate would be about 80.2 cal/g, which could be expressed as 13.6 kcal/mole of monohydrate or about 22 kcal/mole of $MnSO_4.7H_2O$.

DISCUSSION

The maximum heats of transition DB to normal crystalline form of the high energy intermediates produced by vacuum dehydration of the heptahydrates have been directly measured for the sulfates of iron and cobalt, and obtained by extrapolation of the heat of solution data for lower hydrates of manganese sulfate and nickel sulfate. These values have been plotted in Fig. 5, from which it may be seen that the measured or calculated maximum heats of transition appear to be directly proportional to the original ligand field splitting energies of Jørgensen, quoted by Orgel (13), for the hexaaquo divalent cations of the same transition elements. The latter values are usually expressed in either cm^{-1} or kK (1 kilokayser (kK) = 1 000 cm^{-1}).

The data of Table V show that the maximum heats of transition, expressed as kcal/mole of each heptahydrate, are virtually identical with the ligand field splitting energies. It appears, however, that further study will be needed to definitely establish whether or not the correlation is valid and, if possible, to provide theoretical justification for it.

On the basis of the present results and the few other data available (2–5) it seems likely that high energy vacuum dehydration products can be obtained for any salt for which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

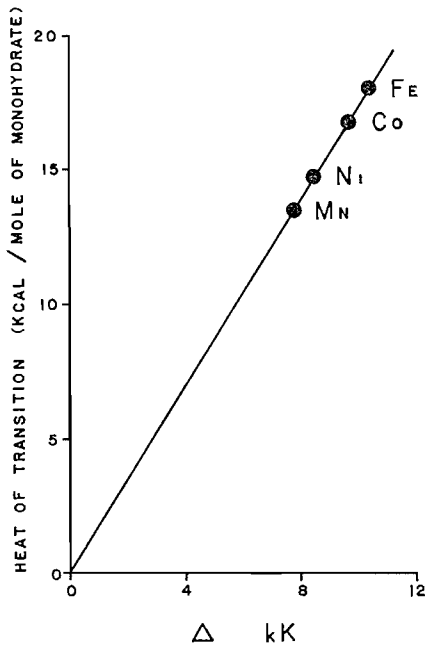

FIG. 5. Direct proportionality between maximum heats of transition and the corresponding ligand field splitting energies.

TABLE V

Ligand field deltas and maximum heats of transition

	Ligand field splitting energy		Maximum heat of transition	
Metal	kK	kcal/mole	kcal/mole	kK
Mn	7.8	22	22	7.8
Fe	10.4	30	30	10.4
Co	9.3	27	26	9.2
Ni	8.5	24	24	8.5

the heat of solution of the normal anhydride is higher than would be expected from an extrapolation of the values for the higher crystalline hydrates. For all the salts which have been found to form such high energy intermediates there has been a break in the heat of solution line for the crystalline hydrates as the anhydride has been approached. This break has usually appeared at the monohydrate composition.

When the heats of solution in cal/g are plotted against the percentages of water in various samples it may be seen that the maximum heats of transition DB for each high energy monohydrate and EA for the corresponding high energy anhydride are approximately equal. Hence, for any such simple salt for which the heats of solution of the anhydride and several crystalline hydrates are known, a line CE may be drawn (or calculated) through the point C for the heptahydrate and parallel to the line AB between the normal anhydride and the crystalline monohydrate. Points on the upper line CE may then be assumed to represent, at least approximately, the maximum possible heats of solution for vacuum dehydration products of the heptahydrate. Lower heats of solution,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and heats of transition to normal crystalline form may, however, be obtained if the method of dehydration allows the formation of one of the lower crystalline hydrates before high energy intermediates are formed.

The formation, in the presence of barium oxide as desiccant, of high energy vacuum dehydration products of $CoSO_4.7H_2O$ having heats of solution of the line CE, which seems to be the theoretical maximum high energy line, is not yet fully understood. It has, however, been established in similar experiments that vacuum dehydration of the manganese, iron, and nickel salts in the presence of barium oxide does not yield forms having higher energy, presumably because ordinary vacuum dehydration gives samples with heats of solution on the maximum possible high energy lines for the starting materials, i.e., the line IJK for $MnSO_4.5H_2O$, the line CD for $FeSO_4.7H_2O$, and the line IJK for $NiSO_4.6H_2O$.

THE DETERMINATION OF THE SATURATION VAPOR PRESSURE OF SOLID HYDROXYLAMINE USING A PISTON PRESSURE GAUGE[1]

R. A. BACK AND J. BETTS[2]
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received March 12, 1965

ABSTRACT

The saturation vapor pressure of solid hydroxylamine has been determined at temperatures from −12 to 7 °C and found to fit the equation

$$\log_{10} P \text{ (Torr)} = 11.7102 - 3352.6/T \text{ (°K)}.$$

From this have been calculated several thermochemical quantities, including a heat of sublimation of 15.34 kcal/mole, and a dissociation energy of 61.3 kcal/mole for the NH_2—OH bond. Vapor density measurements showed that hydroxylamine vapor consisted of single molecules of NH_2OH at 0.27 Torr and 25 °C.

A novel pressure gauge used in the measurements is described. Pressures were determined with an accuracy of ±0.001 Torr by measuring the force acting on a piston, moving freely in a glass cylinder, suspended on the arm of a torsion balance.

INTRODUCTION

In connection with a study of the photolysis of hydroxylamine vapor (1), an accurate knowledge of the saturation vapor pressure was required. Values for the liquid between temperatures of 39 and 110 °C are quoted in a review by Stull (2); the source of these data is not clear. They appear to be based on an extrapolation from reported boiling points of 57° at 22 Torr (3) and 70° at 60 Torr (4), and because the liquid is notably unstable at these temperatures, the data are of dubious merit. To minimize thermal decomposition both of the vapor (in which decomposition increases sharply with rising pressure (1, 5)) and of the condensed phase, our present measurements and photolysis experiments have been made with the solid well below its melting point (32 °C) and with correspondingly low vapor pressures.

The pressures involved (0.08 to 0.5 Torr) fall in a somewhat awkward region for accurate measurement of the absolute pressure of a condensable vapor. A simple gauge of novel design was devised in which the pressure of the vapor acting on a glass piston moving freely in a close-fitting glass cylinder was measured by a torsion balance. In theory such a gauge promises high sensitivity, since 1 Torr pressure with a piston of 1 cm^2 area gives a force of about 1.4 g, a quantity easily measured to one part in a thousand by a very ordinary torsion balance. In practice its performance was close to these expectations.

EXPERIMENTAL

The glass cylinder and piston used in the pressure gauge were from a 5 cc, "Super Ward" hypodermic syringe made by Becton, Dickinson and Co., taken from stock. The piston, about 12 mm in diameter, was cut to a length of about 20 mm and weighed about 3 g; its weight was approximately balanced by a counterpoise. The torsion balance was a Precision Torque Balance obtained from Vereenigde Draadfabrieken, Nijmegen, Holland, with a tungsten torsion wire, a rated capacity of 3.5 g, and a sensitivity of ±1 mg. The balance was returned to a null position by rotation of one end of the torsion wire, with 300° rotation corresponding to about 1 g. The balance was modified to permit evacuation of the chamber enclosing the balance arm, the torsion wire, and the cylinder above the piston, with the torsion wire controls operating through rubber "O" rings. Continuous pumping maintained a pressure of about 0.001 Torr which was added to all pressure readings.

[1]*Issued as N.R.C. No. 8492.*
[2]*National Research Council Postdoctorate Fellow, 1962–1964. Present address: Department of Chemistry, Carleton University, Ottawa, Canada.*

To measure the pressure of a gas or vapor, it was admitted to the cylinder below the piston, and the torsion wire was rotated to balance the force on the piston, restoring the balance to its null position. A tendency of the piston to stick slightly in the cylinder was countered by gently thumping the bench supporting the pressure gauge. The null point could be set with an accuracy corresponding to ±0.001 Torr.

The gauge was calibrated with nitrogen against a sloping (about 1 in 10) one-armed manometer filled with Octoil-S (2-ethyl hexyl sebacate) with a measured density of 0.9108 g/cc at 24.5 °C. This calibration is shown in Fig. 1, and gave a value of 0.5716 Torr for full-scale rotation of the torsion head. This value was in fair agreement with one calculated from the specified sensitivity of the balance, the area of the piston, and the length of the cross arm; the latter is a less accurate value.

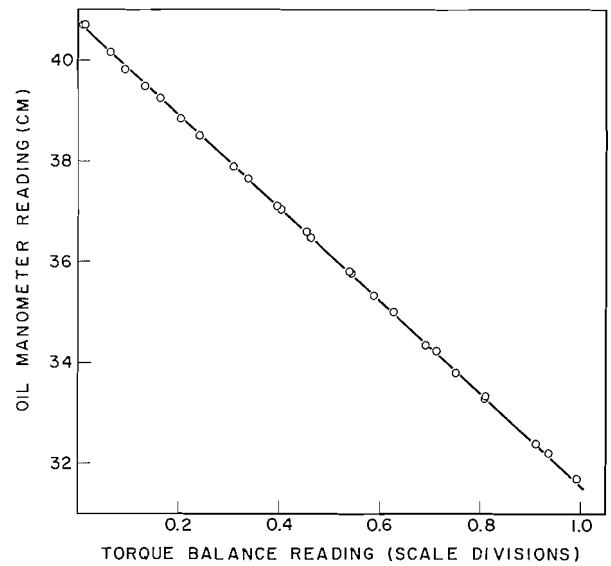

FIG. 1. Calibration of piston pressure gauge against an oil manometer.

The hydroxylamine, prepared by the method of Hurd and Brownstein (6), had a melting point close to the accepted value of 32.05 °C. It was stored in the vacuum line at −78 °C and purified as required by repeated sublimation in vacuo from 0 °C to −60 °C until the saturation vapor pressure reached a constant minimum value.

The saturated vapor pressure was measured by holding the solid at constant temperature and allowing the vapor to fill a volume of about 0.2 l. Pressure readings taken over a period of about 10 min showed a steady increase due to thermal decomposition (about 0.025 Torr/h at 0 °C); these were extrapolated to zero time to obtain the vapor pressure. The molecular weight of hydroxylamine vapor was determined by allowing it to fill a volume of 5.44 l at about 0.27 Torr pressure and room temperature, and then condensing it at −196 °C into a thin-walled Pyrex phial. The phial was sealed off, weighed, and weighed again after opening and standing over concentrated sulfuric acid in a desiccator for several days. In this way, hydroxylamine, or ammonia and water formed by its decomposition, were removed, while any mercury that had condensed out with the hydroxylamine was retained (mercury was present in the vacuum line). Buoyancy corrections were applied for the air displaced by the phial.

RESULTS AND DISCUSSION

The saturation vapor pressure data are plotted in Fig. 2. A least-squares treatment gave the equation

$$\log_{10} P \text{ (Torr)} = 11.7102 - 3352.6/T \text{ (°K)}.$$

From this equation were calculated the vapor pressures and standard molar enthalpies, free energies, and entropies of sublimation, at 0 °C and at the melting point, shown in Table I. These data are not in good agreement with those quoted by Stull (2) for liquid hydroxylamine, which gave a heat of vaporization of 17 kcal/mole and an extrapolated saturation vapor pressure of 2.6 Torr at 32.05 °C. The latter data are of uncertain origin and subject to error caused by thermal decomposition of the liquid, as discussed earlier.

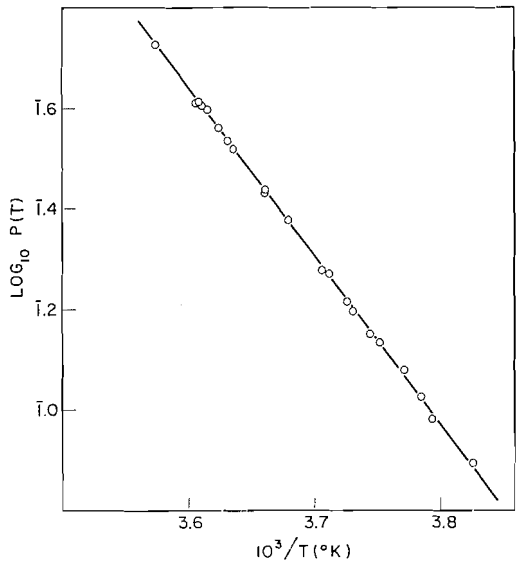

FIG. 2. Saturation vapor pressure of hydroxylamine.

TABLE I

Thermochemical data for the sublimation of hydroxylamine vapor

T (°C)	Saturated vapor pressure (Torr)	ΔH (kcal/mole)	ΔF (kcal/mole)	ΔS (cal/deg mole)
0	0.273	15.34	4.30	40.4
32.05 (m.p.)	5.31	15.34	3.01	40.4

From our extrapolated value for the vapor pressure at the melting point, combined with Bruhl's reported boiling point of 57° at a pressure of 22 Torr (3), vapor pressure data for the liquid can be computed which should be more reliable than those quoted by Stull. Estimates of the heat of vaporization (11.4 kcal/mole) and thence of the heat of fusion, and the hypothetical boiling point of the liquid at atmospheric pressure, can also be made; in Table II, these and other physical constants of hydroxylamine are compared with those of hydrazine (7) and hydrogen peroxide (8). With the notable exceptions of the high melting point and the related high heat of fusion, the properties of hydroxylamine lie, not unexpectedly, between those of the other two. The volatility of hydroxylamine as reflected in the vapor pressure, the boiling point, and the heat of sublimation, is considerably closer to that of hydrogen peroxide than to that of hydrazine.

TABLE II

Physical constants of hydrazine, hydroxylamine, and hydrogen peroxide

	N_2H_4	NH_2OH	H_2O_2
Melting point (°C)	2	32.05	−0.43
Boiling point at 760 Torr (°C)	113.5	~142 (extrapolated)	150.2
Vapor pressure at 0 °C (Torr)	2.69	0.273	0.26
Vapor pressure at melting point (Torr)	3.2	5.31	0.26
Heat of sublimation at 0 °C (kcal/mole)	14.6	15.34	15.6
Heat of fusion (kcal/mole)	3.025	3.94	2.987

The molecular weight determinations confirmed that hydroxylamine vapor at room temperature and 0.27 Torr pressure consisted largely of single molecules of NH_2OH. Experimental values, determined from the ideal gas equation, were 32.9, 34.6, and 33.9 for three samples (theoretical value = 33.03). These data also provide a rough confirmation of the purity of the hydroxylamine.

Taking the standard heats of formation of solid hydroxylamine (9) and the hydroxyl (10) and amino (11) radicals to be -25.5, $+10.1$, and $+41$ kcal/mole respectively, we can calculate a heat of formation of gaseous NH_2OH of -10.2 and thence a bond dissociation energy of 61.3 kcal/mole for the NH_2—OH bond. Cottrell (10) has calculated a value of 48 by a very similar process, using an estimated heat of sublimation. The reason for the large discrepancy is not clear; one possibility is that Cottrell took the wrong sign for the heat of solution of solid hydroxylamine (9), -3.8 kcal, and slightly overestimated the heat of sublimation. Our value of 61.3 kcal for the NH_2—OH bond may be compared with 51 for HO—OH and 60 for NH_2—NH_2 (10); it is apparent that the extreme thermal instability of hydroxylamine is not a matter of bond energy, but probably depends on a higher susceptibility to surface reaction than hydrazine or hydrogen peroxide.

Finally, the piston pressure gauge deserves some comment. This instrument showed excellent sensitivity and reproducibility (Fig. 2) which could probably be improved further. It measures absolute pressure directly, and glass is the only material in contact with the gas being measured. The cost of the gauge was about one-tenth that of commercially available diaphragm or quartz spiral gauges with about the same sensitivity. Its chief limitations are the tendency of the piston to stick in the cylinder, and leakage of gas past the piston. The latter, measured with air at a pressure of 1 Torr, was about 4 μmole/h and probably varies linearly with pressure. This was of no consequence in the present experiments, but could be inconvenient in a static system of small volume. The sticking of the piston was minimized by keeping the system free of grease and dust. Both the leakage and the sticking might be improved by more precise fitting of the piston to the cylinder. No attempt was made to do so; the piston and cylinder were simply taken from a stock hypodermic syringe without special care or selection. The piston was also heavier than it needed to be, which overloaded the torsion balance somewhat and reduced its sensitivity; this could be remedied by a specially made piston. All things considered, the gauge shows considerable promise as a convenient absolute pressure gauge for an awkward region of pressure.

Several piston pressure gauges have been described previously (12, 13, 14), with that of Ernsberger and Pitman (12) most closely resembling ours. They employed a mica-disc piston suspended on a quartz spiral whose deflection was proportional to the pressure difference across the piston. The working range of the gauge was lower than ours (0.5 to 20 microns) and leakage was probably greater. Hutton's gauge (13) operated at higher pressures than ours (0.1 to 12.5 Torr), while that of Douslin and McCullough (14) was oil-lubricated and measured pressures from 0.01 to 40 Torr. Both these latter gauges operated on a tilting deadweight piston principle, with Hutton (13) using a rotating cylinder to avoid sticking of the air-lubricated piston. The gauge of Ernsberger and Pitman could have probably been modified for our present purposes, although leakage might well have been a serious problem at the higher pressures. A compromise probably must be struck between leakage and sticking, and a quartz spiral suspension might be more affected by a sticking piston than was the torsion balance used in the present instrument.

THE MECHANISM OF THE ANOMERIZATION OF THE TETRA-*O*-ACETYL-D-GLUCOPYRANOSYL CHLORIDES

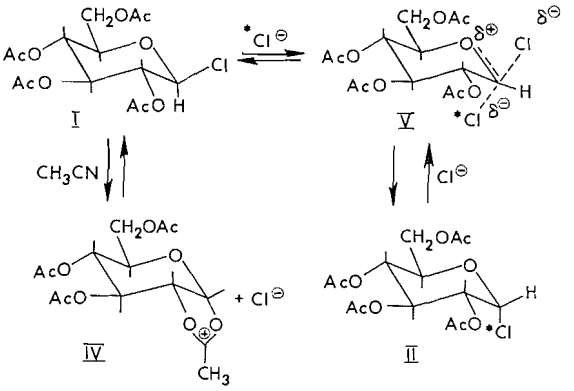
R. U. LEMIEUX AND JUN-ICHI HAYAMI[1]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received January 25, 1965

ABSTRACT

The anomerization of the tetra-*O*-acetyl-D-glucopyranosyl chlorides in acetonitrile is first order in chloride ion. Experiments with ^{36}Cl-labelled chloride ion showed the reaction to involve nucleophilic attack (S_N2) by chloride ion at the anomeric center. The reaction is accompanied by a faster dissociation of the β-anomer (I) to the 1,2-acetoxonium ion. Although the rate of anomerization was slightly accelerated by addition of benzene, the ionic reaction was strongly suppressed. Bromide ion was less effective than chloride ion in catalyzing the reaction and iodide ion was least effective. Reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide with tetraethylammonium chloride in acetonitrile rapidly gave I in high yield. The anomeric effect for chlorine appears to be about 2 kcal/mole.

INTRODUCTION

The acetylated glycosyl halides have played a central role in the chemical synthesis of a wide variety of glycosides. Although the reaction properties of these important compounds have received considerable attention (1), there has not been reported, to date, a study of the anomerization of these compounds. Such studies gained immediate importance through the observation by Lemieux and Morgan (2) that the presence of bromide ion can strongly influence the course of the reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide by catalyzing its anomerization to the β-form.



Lemieux and Brice (3) observed the anomerization of tetra-*O*-acetyl-β-D-glucopyranosyl chloride (I) to the α-anomer in the course of the reaction of β-D-glucopyranose pentaacetate with titanium tetrachloride. Recently, Korytnyk and Mills (4) anomerized I using aluminum chloride in refluxing chloroform. The reaction properties of I early indicated that the compound possesses the 1,2-*trans*-configuration and this conclusion was later fully substantiated by the nuclear magnetic resonance (n.m.r.) spectra for I and its anomer (5, 6). Furthermore, the n.m.r. spectra required the chlorine in I to be in

[1]*Postdoctorate Fellow, 1963–1964.*

equatorial orientation and to be axially disposed in the more stable α-anomer. This apparent anomaly has been termed the "anomeric effect" and is attributed to presence of strong intramolecular dipole–dipole interactions (7, 8).

Although the β-chloride (I) has often been reported to give rise to mutarotation in chloroform solution, Korytnyk and Mills (4) traced this phenomenon to hydrolysis and showed that the compound is highly stable under strictly anhydrous conditions. Tetra-*O*-acetyl-β-D-glucopyranosyl bromide was recently prepared (9) and shown to have reaction properties closely analogous to those of the β-chloride (I).

This communication is primarily concerned with the results of a detailed study of the halide-ion catalyzed anomerization of the tetra-*O*-acetyl-D-glucopyranosyl chlorides in acetonitrile. It is shown that these and closely related reactions proceed by way of a mechanism which corresponds kinetically to bimolecular nucleophilic substitution reactions.

DISCUSSION OF RESULTS

Although tetra-*O*-acetyl-β-D-glucopyranosyl chloride (I) remained virtually unchanged over several hours when dissolved in pure dry acetonitrile at room temperature, addition of chloride ion in the form of tetraethylammonium chloride produced a rapid reaction as evidenced by the change in the rotation of the solution. The course of the reaction could be followed polarimetrically and, as expected, after the optical rotation had reached a constant value the product consisted of the equilibrium mixture of I and its α-anomer (II). The equilibrium constant at 30°, starting with a 0.2 *M* solution of I in acetonitrile and 0.2 *M* in tetraethylammonium chloride, was 20.6 as determined by isotopic dilution analysis for the β-anomer (I) and 13.1 as determined by a similar analysis for the α-anomer (II). On this basis, at equilibrium, the solution contained 4.6 to 7.0% of the β-anomer I. The specific rotations of I and II under the reaction conditions were $-8.0°$ and $+162°$, respectively. On the basis of these rotations and the results of the isotopic dilution analyses of the equilibrium mixture, equilibrium specific rotations in the range 150–154° are expected. In fact, in all the equilibration studies conducted at 30°, equilibrium specific rotations in the range 141–148° were obtained. As will be seen later on, evidence was obtained that all the reactions involved some hydrolysis because of our inability to completely exclude water. Therefore, it was to be expected that the observed equilibrium rotations would be somewhat lower than those calculated from the results of the isotopic dilution analyses.

The isotopic dilution analyses require 93–95% of the α-anomer (II) in the equilibrium mixture. To calculate velocity constants from the polarimetric data, an equilibrium constant of 16 (94% of II) for the reaction I $\rightleftarrows$ II was assumed. The *A*-value [$-\Delta G$ (10)] for chlorine appears to be in the order of 0.5 kcal/mole (10, 11). On this basis, the anomeric effect for chlorine would be about 2 kcal/mole. This value may be high since the *A*-value for chlorine is probably greater for the 1-position of a pyranose ring than for a cyclohexane ring. Nevertheless, it is evident that the anomeric effect is considerably greater for chlorine than that [about 1.5 kcal/mole (8)] for the acetoxy group. This result is in accord with expectation based on the relative magnitudes of the dipole moments (12) for the C—O (1.5 D) and C—Cl (2.2 D) bonds and the theory advanced by Lemieux and Chü (7, 8) for the origin of the anomeric effect (13).

Table I reports some results of a kinetic study of the anomerizations of I and II, and the data provide an indication of the quality of the results which were obtained. It is seen that, under the conditions studied, the polarimetric data provided good first-order

*The reactions were conducted at 30° in dry acetonitrile 0.2 *M* in both I and tetraethylammonium chloride.
The specific rotations at equilibrium (t_∞) were 144.5°, 146.8°, and 141.5° for experiments 1, 2, and 3, respectively. The initial observed rotations obtained by extrapolation of the linear part of a log plot were −0.350, −0.008 and +0.195° for experiments 1, 2, and 3, respectively.
†Average values.

kinetics after the reaction had been allowed to proceed for at least 10 min. However, the rotations at zero time obtained by extrapolation of the linear part of the log plots varied considerably and, as seen from experiment 3, velocity constants calculated from the data obtained in the first few minutes of the reaction are meaningless. We attribute this initial behavior to the presence of traces of water present in the system which are involved in a fast reaction. As will be seen later on, the anomerization reaction under these conditions is accompanied by a faster dissociation of the β-chloride (I) to the 1,2-acetoxonium ion (IV). The situation is closely similar to that observed by Lemieux and Brice (3) for the anomerization of β-D-glucopyranose pentaacetate in acid media, a phenomenon which has received detailed study (14, 15). Lemieux and Cipera (16) have shown that the acetoxonium ion is an extremely effective scavenger for water. It was recently shown that the first isolable product of this reaction is 1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose (17), a strongly dextrorotatory compound, $[\alpha]_D$ +141.1° (*c*, 3 in chloroform). In fact, when the β-chloride was added to the presumably dry acetonitrile, there was observed a slight increase in the rotation of the mixture, from −0.21 (initial) to +0.10° over a period of about 12 min. The rate of the increase then diminished greatly. This initial side reaction could not be excluded by the means at our disposal and, unfortunately, precluded the achievement of highly precise measurements of certain features of the reaction. Nevertheless, as will be seen later on, the important features of the reaction were not obscured. We estimate the amounts of water required for the interference noted to be in the order of 0.02% of the reaction mixture.

	0.2	0.1	3.9
	0.2	0.2	3.9
	0.4	0	7.8
	0.6	0	10.6
40	0.2	0	12.4

Table II presents data related to the effect of the chloride ion concentration on the rate of the anomerization. It is seen that the rate was essentially doubled by doubling the concentration of the chloride ion. That this effect was not related to the increase in salt concentration is evident from the experimentally insignificant effects on rate observed on the addition of tetraethylammonium perchlorate. It is clearly evident, therefore, that the reaction is first order both in chloride ion and the acetochloroglucose (I or II). As indicated in Table II, the rate of the reaction was increased by a factor of 3.2 on raising the temperature from 30° to 40°. It was not possible at this time to obtain reliable data at other temperatures. The polarimetric rates for anomerization conducted under the conditions reported in Table I provide the sum of the velocity constants, $k_\alpha + k_\beta$, to be about 4.0×10^{-3} min^{-1}. On the basis of an equilibrium constant of $16 = k_\beta/k_\alpha$, the values for the individual velocity constants are $k_\alpha = 0.23 \times 10^{-3}$ and $k_\beta = 3.77 \times 10^{-3}$ min^{-1}.

The results of a study of the incorporation of ^{36}Cl-labelled chloride ion into both the β-chloride (I) and the α-chloride (II) are presented in Table III. In view of the inevitable small loss of the β-chloride to the traces of water, it was decided to determine its change in concentration in the course of the reaction by isotopic dilution analysis. The amounts present after 15, 30, and 90 min reaction times are given in Table III. This rate of disappearance of I requires a velocity constant of 3.6×10^{-3} min^{-1} for the reaction, in good agreement with the polarimetric rate. On the basis of these data, it is calculated that 94.2% of the β-chloride (I) survived hydrolysis. From this amount of I as the initial amount in the reaction mixture the percentages of I present after the various reaction times were calculated, and the results of these calculations are presented in Table III.

The procedure used to follow the incorporation of radioactivity from the chloride ion into the acetochloroglucoses was as follows. In view of the problem of excluding water from the system, the experiments were conducted batchwise in sealed tubes. After each of the reaction times noted in Table III, a solution was diluted with benzene and extracted four times with water under carefully standardized conditions. The fourth aqueous extract was devoid of appreciable radioactivity. The total activity in the combined aqueous extracts was then determined and the specific activity of the chloride ion calculated. The total activity in the benzene solution was also determined. The sum of the radioactivities found in the aqueous and benzene layers agreed with the amount expected from the radioactivity of the chloride ion introduced into the reaction mixture.

The experiments listed in Table III were conducted to only about 50% conversion of I since it was necessary to isolate pure I from the reaction mixture. This could only be accomplished with these relatively high concentrations of I in the reaction product. To

insure that the radioactivity found in I did not in part arise from the α-anomer (II) as a contaminant, after I had been recrystallized twice, a 10% amount of radioinactive II was added as hold-back carrier. After two recrystallizations, pure I was obtained and its specific activity was determined. The specific activities of I after various reaction times are given in Table III.

To obtain the total activity present in I after the various reaction times listed in Table III, it was necessary to be sure that the acetochloroglucoses underwent negligible hydrolysis in the course of the isolation procedure. In fact, it was found that the α-anomer (II) could be quantitatively recovered from solutions in acetonitrile. However, in repeated experiments only 95.7% of the expected radioactivity was found in the benzene layer when the β-chloride was used. Since this result was highly reproducible and had to arise from hydrolysis of I in the course of the isolation, the amounts of I in the benzene layers were taken as 95.7% of the amounts calculated to be present. From these amounts and the specific activities determined for the samples of I which were isolated, the activities expected to arise from I in each of the benzene layers were calculated. The results of these calculations are presented in Table III. The differences between these activities and the total activities found in the benzene layers were than taken as arising from the α-chloride (II). The number of millimoles of II present in each of the benzene layers was calculated from the expected extents of anomerization. On this basis, the specific activities of the samples of II present in each of the benzene layers were calculated and the results are listed in Table III. The specific activities of the chloride ions present in each of the aqueous layers could be calculated from the total activities found in the aqueous layers and the expected number of millimoles responsible for this activity. The number of millimoles was taken in each case as the initial 0.8 millimoles plus 5.8% of 0.8 mmoles due to hydrolysis of the β-chloride (I) during the first 10–15 min of the reaction. The specific activities for the chloride ion after the various reaction times are listed in Table III.

A consideration of the last two columns in Table III shows a good correspondence between the specific activity of the chloride ion and that calculated for the α-anomer (II) after each of the reaction times. Over the period of the reaction studied, only a very small amount of the α-anomer would have undergone reversion to the β-form. Consequently, unless there existed an intramolecular mechanism for the anomerization of I to II, as known to occur for methyl tetra-*O*-acetyl-β-D-glucopyranoside (18), the specific activity of the α-anomer (II) formed from I should be virtually the same as that of the ambient chloride ion. In fact, this is seen to be the case and the results exclude an intramolecular mechanism. Therefore, it is apparent that, as expected from the kinetic data, the mechanism of the anomerization involves nucleophilic attack by chloride at the anomeric center with subsequent inversion of the anomeric center. This conclusion was substantiated by a study of the relative rates of exchange and anomerization of the α-chloride (II).

The α-chloride (II) was reacted with ^{36}Cl-labelled tetraethylammonium chloride under the conditions shown in Table IV. After the various reaction times, benzene was added and the salt was removed by washing with water. The radioactivity in the benzene solution was then determined. This radioactivity was incorporated into both the β-(I) and α-(II) chlorides and is a measure of the extent to which the α-chloride (II) had reacted with chloride ion in the specified reaction time. The rate of the incorporation of radioactivity should be the same as the rate of the α to β anomerization if the process involves a nucleophilic attack by chloride ion with inversion of the anomeric center.

TABLE IV

Rate of the exchange of tetra-*O*-acetyl-α-D-glucopyranosyl chloride (II) with tetraethylammonium chloride-^{36}Cl (III) in acetonitrile at 30°*

∞	(7.50)	—	—
		Av. 2.0	

*The initial concentrations were 0.2 *M* in II and 0.2 *M* in III with a specific activity of 18.8×10^5 c.p.m./mmole and total activity of 15.0×10^5 c.p.m.

It is seen that, in fact, the velocity constant for the incorporation, average value = 2.0×10^{-4} min^{-1}, is in close agreement with the polarimetric value for $k_\alpha = 2.3 \pm 0.4 \times 10^{-4}$ min^{-1}. Table IV also contains the specific activities found for the α-chloride (II) after the various reaction times. It can be shown by obvious approximate methods of analysis that these specific activities correspond reasonably closely to those expected on the basis that the radioactive II arises from first-formed radioactive I. An exact mathematical treatment was not attempted. Nevertheless, it is clearly apparent that the α-chloride did not undergo direct exchange with the chloride ion. This was not the case for the β-anomer (I).

The specific activities found for the β-chloride (I) in the course of the exchange reaction reported in Table III are too high for the radioactivity to have been incorporated by way of the α-anomer. Therefore, the β-chloride, unlike the α-anomer, underwent exchange of the chlorine by way of mechanism other than anomerization. This exchange is readily accounted for on the basis of dissociation of I to the 1,2-acetoxonium ion (IV) followed by the return reaction of IV with chloride ion to reform I. It is seen from Table V that

the rate of the incorporation of radioactivity from the chloride ions by the β-chloride under the conditions reported in Table III is about 4 times greater than its anomerization. That the exchange resulted from dissociation of I is clear from the data reported in Table V. It is seen from experiment 3 that neither the rates of exchange nor of anomerization were affected appreciably by the addition of tetraethylammonium perchlorate. The

slight increase in rate of exchange may be a reflection of the increased ionic strength of the solution. On the other hand, the addition of benzene to reduce the dielectric constant of the medium, as seen from the results of experiment 4, reduced the rate of exchange by a factor of about 10. This is clearly in accord with the premise that the direct exchange of the β-chloride (I) involves dissociation of I and recombination of ions with overall retention of configuration. For the reasons stated above, the mechanism in all likelihood involves dissociation to the 1,2-acetoxonium ion. Of course, a 1,2-orthoacetyl chloride may have existence as a transient intermediate and would have observable properties similar to the 1,2-acetoxonium ion. However, the results of experiment 2 (Table V) show that the process is not catalyzed by chloride ion since reduction of the chloride ion concentration to one-half of that in experiment 1, while keeping the salt concentration constant, had no experimentally significant effect on the rate of exchange.

A comparison of the polarimetric rates of anomerization using both acetonitrile and mixtures of acetonitrile and benzene as solvent indicated, as seen from the experimental result reported in Table V, that the addition of benzene accelerated the reaction to a small extent. This result is consistent with the notion that the anomerization involves nucleophilic attack by chloride ion in the rate-controlling step. It would be predicted on this basis that bromide ion would be less effective than chloride ion in catalyzing the reaction and that iodide ion would be the least effective halide ion. This would follow from the established order of nucleophilicity for these ions as quaternary ammonium salts in non-hydroxylic solvents (19). The data in Table VI show this to be the case.

TABLE VI

Effect of the type of halide ion on the rate of anomerization of tetra-*O*-acetyl-β-D-glucopyranosyl chloride (I)*

Salt	Velocity constant $\times 10^4$, min^{-1} (average value)	Relative rate
Tetraethylammonium chloride	40	15
Tetra-*n*-butylammonium bromide	14	5
Tetra-*n*-butylammonium iodide	2.6	1

*The reactions were carried out at 30° using a 0.2 *M* solution of I in acetonitrile 0.2 *M* in the halide salt.

Chloride ion catalyzed the reaction 3 times more effectively than bromide ion and the latter ion was 5 times more effective than iodide ion. In all cases, the product was the equilibrium mixture of the α(II)- and β(I)-chlorides. Undoubtedly, the anomerizations catalyzed by bromide and iodide ion proceeded by way of unstable tetra-*O*-acetyl-D-glucopyranosyl bromides and iodides, respectively, and these intermediates were formed by way of both the acetoxonium ion and the bimolecular substitution processes.

The results of this investigation provide evidence that, as previously noted for reactions with thiophenoxide ion (20), replacements at the anomeric center of sugar structures can proceed by way of bimolecular nucleophilic displacement processes accelerated by the participation of the ring-oxygen in delocalization of the positive charge at the reacting center of the transition state. It is not possible to be sure of the nature of the bonding between the reacting center and the entering and leaving groups in the transition state (V). The bonding may be akin to that between ions in intimate ion-pairs (21) and thus represent an intimate ion-triplet. Lemieux and Chü (7, 22) have reported evidence that the anomerization of the acetylated aldoglycopyranoses in acetic acid – acetic anhydride mixtures catalyzed by mineral acid proceed by way of the glycosyloxocarbonium ion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

bonded (complexed) to two molecules of solvent one on each side of the reacting center. Thus, in this case, the transition state involves intimate ion–molecule complexing. Lemieux and Fraser-Reid (23) obtained evidence that the halogenomethoxylation of acetylated glycals proceeds by way of transition states wherein methanol is complexed with the anomeric center in the transition state. Therefore, it is becoming apparent that reactions at the anomeric center of glycosidic structures have a strong tendency to be bimolecular in nature although a main driving force for the reaction is participation of the ring-oxygen in delocalization of the charge at the reacting center. Thus, the high degree of inversion normally observed in reactions of acylated 1,2-*cis*-glycosyl halides is perhaps best viewed as arising not from shielding by the departing group (20) but instead from bonding (electrostatic solvation*) of the nucleophile with the reacting center in the transition state. Doering and Zeiss (24) have suggested that the greater the ability of a carbonium ion to disperse its positive charge internally the less likely is covalent bonding at the rear of the reacting center in the transition state. On this basis, the dissociation of a glycosyl halide should not be highly dependent on a stabilization of the transition state by covalent bond formation with the entering group. Instead, simple electrostatic solvation can be expected, especially for a structure approaching the glycosyloxocarbonium ion. Thus, the role of the chloride ion in the anomerization reaction can be considered to provide stabilization of the developing ion-pair by leading to an ion-triplet. To rationalize the S_N2 kinetics which were observed, the stabilization needs only to be sufficiently great (about 5 kcal/mole) to render the ion-triplet clearly a more favorable route of reaction than that provided by the ion-pair. These conclusions are of possible pertinence to a understanding of the high degree of stereospecificity observed in carbohydrase-catalyzed reactions. Also, it can be envisaged that the catalysis provided by these enzymes is to an important measure the result of specific electrostatic solvation of the transition state.

The results of a kinetic study of the halide ion catalyzed anomerization of the 3,4,6-tri-*O*-acetyl-β-D-glucopyranosyl chloride are reported in Table VII. It is seen that, except

TABLE VII

Polarimetric rates for the anomerization of 0.05 *M* 3,4,6-tri-*O*-acetyl-β-D-glucopyranosyl chloride in acetonitrile 0.1 *M* in *sym*-collidine at 25° catalyzed by halide ion

	Concentration of salt, *M*	Velocity constant, $(k_\alpha + k_\beta) \times 10^2$, min^{-1}	Relative rate

	0.01	16.0	1.85
	0.015	24.7	2.84
Tetra-*n*-butylammonium bromide	0.05	7.5	1
	0.10	15.4	2.1

for the much higher rates, the reaction has the same characteristics as that described above for tetra-*O*-acetyl-β-D-glucopyranosyl chloride. It is seen that, for the triacetate, the bromide ion was about 10 times less effective as catalyst in contrast to the factor of 3 noted above with reference to Table VI. It seems likely that the factor of 10 represents a better measure of the difference in the abilities of the chloride and bromide ions to electrostatically solvate the transition state under these conditions since, presumably, the

reaction of the triacetate was not complicated by the solvolytic reaction involving participation of the 2-substituent. Lemieux, Hayami, and Martin (6) have shown that the highly specific electrostatic deshielding (n.m.r.) of the 1, 3, and 5 protons of acetylated β-glucopyranosyl compounds by halide ions in acetonitrile most likely arises from electrostatic solvation of these hydrogens. The stabilities of the complexes increased ($Cl^- > Br^- > I^-$) with decreasing atomic radius for the halide ion present as a quaternary ammonium salt. Lemieux and Huber (25) have shown that both the α- and β-forms of 3,4,6-tri-*O*-acetyl-D-glucosyl chloride undergo replacement of the chlorine by acetate with virtually complete inversion when dissolved in acetic acid. The observation that the rate of reaction remained unchanged on the addition of potassium acetate does not preclude the possibility that the developing carbonium ion was appreciably solvated by acetic acid in the transition state. It is evident from the high stability of the biacetate ion as present in quaternary ammonium biacetates that acetic acid strongly solvates acetate ion and, as a consequence, acetate ion may not be profitably available for stabilization of the transition state by contributing to a weak ionic bond since this bond may be weaker than the bonds involved in the electrostatic solvation of the acetate ion by the acetic acid. This situation would resemble the great loss in the nucleophilicity of chloride ion on going to hydroxylic solvents (19). Similar conditions may apply to methoxide ion in methanol and be mainly responsible for the absence of an effect on the rate of the methanolysis of tetra-*O*-methyl-α-D-glucopyranosyl chloride (20). It may be noted that the mechanistic notions advanced in 1955 for the difference in the rates of acetolysis of the anomeric 3,4,6-tri-*O*-acetyl-D-glucosyl chlorides (25) must now be disregarded. The discovery of the anomeric effect (8) provides an adequate basis for explaining the 100-fold difference in reactivity based on the difference in stabilities of the ground states.

Preliminary experiments showed that reaction of tetraethylammonium acetate, as the equimolar complex with acetic acid, with the β-chloride (I) in acetonitrile led to appreciable (about 50%) replacement of the chlorine by the acetoxy group with inversion of the anomeric center. The initial reaction to yield α-D-glucopyranose pentaacetate was rapid but the reaction seemed to slow down after about 50% completion. This indication that, under appropriate conditions, I can undergo nucleophilic attack much faster than its dissociation with participation of the 2-acetoxy group suggests that it may indeed prove possible to prepare derivatives of α-D-glucose from *O*-acetylated β-D-glucopyranosyl halides, and this possibility will receive further attention. It was found in the course of this study that treatment of tetra-*O*-acetyl-α-D-glucopyranosyl bromide with tetraethylammonium chloride resulted in a rapid replacement of the bromine by chlorine with inversion of the anomeric center. The β-chloride (I) could be obtained in high yield and the reaction proved useful to prepare ^{36}Cl-labelled I.

EXPERIMENTAL

Solvents and Reagents

Unless otherwise stated, the materials used in this study were prepared by standard methods (26) and had the following physical constants: tetra-*O*-acetyl-β-D-glucopyranosyl chloride (I), m.p. 101–102°, $[\alpha]_D$ −7.2° (*c*, 4 in chloroform), −8.0° (*c*, 3.7 in acetonitrile); tetra-*O*-acetyl-α-D-glucopyranosyl chloride (II), m.p. 75–76°, $[\alpha]_D$ +166° (*c*, 2 in chloroform), +162 (*c*, 3.6 in acetonitrile); 3,4,6-tri-*O*-acetyl-β-D-glucopyranosyl chloride, m.p. 155–156°, $[\alpha]_D$ +28.9 (*c*, 1 in chloroform).

The acetonitrile was purified and dried by first distilling at least five times from phosphorus pentoxide and then distillation from anhydrous potassium carbonate. The benzene was dried by distillation and stored over sodium wire.

Tetra-*n*-butylammonium iodide and tetraethylammonium chloride were commercial reagents dried at 80° over phosphorous pentoxide. Tetra-*n*-butylammonium bromide was prepared by heating under reflux equimolar amounts of *n*-butyl bromide and tri-*n*-butylamine in an equal volume of acetonitrile for 36 h.

Evaporation left a crystalline product which was washed with acetonitrile recrystallized from ethyl acetate and dried *in vacuo* over phosphorous pentoxide.

^{36}Cl-labelled tetraethylammonium chloride was prepared by adding tetraethylammonium biacetate to a 0.3644 *N* aqueous solution of H^{36}Cl obtained from Atomic Energy of Canada and which had 4 microcuries of radioactivity per milliliter. The resulting solution was freeze dried and the residue was dried *in vacuo* at 80°. The substance was recrystallized from dry chloroform by the addition of petroleum ether. The crystals were dried *in vacuo* over phosphorus pentoxide.

Tetra-*O*-acetyl-β-D-glucopyranosyl chloride-^{36}Cl was prepared by reacting 1 mmole of tetra-*O*-acetyl-α-D-glucopyranosyl bromide with an equivalent amount of tetraethylammonium chloride-^{36}Cl (18.3×10^5 c.p.m./mmole) in 2 ml of dry acetonitrile. After 90 min at 30°, the reaction mixture was diluted with 20 ml of benzene containing 2 mmole of tetra-*O*-acetyl-β-D-glucopyranosyl chloride to serve as carrier. The resulting solution was washed four times with 5 ml volumes of water. The radioactivity of the aqueous washings indicated that 83% of the initial radioactivity remained in the benzene solution. This solution was dried by filtration through paper wetted with benzene and evaporated to a residue which was recrystallized three times from dry ether and dry petroleum ether (Skellysolve B). The yield was 800 mg (2.18 mmole) with a specific activity of 5.05 c.p.m./mmole.

Tetracetyl-α-D-glucopyranosyl chloride-^{36}Cl was prepared in the same manner as described above for the β-anomer except that the reaction mixture was kept at 30° for 60 min and then at 100° for 90 min in order to complete the anomerization of the first-formed β-chloride. The radioactive yield was near quantitative.

Methods

The polarimetric rates were determined using a Rudolph recording polarimeter operating at 589 mμ (27). In a typical experiment, 146.7 mg (0.4 mmole) of tetra-*O*-acetyl-β-D-glucopyranosyl chloride and 66.3 mg (0.4 mmole) of tetraethylammonium chloride were dissolved at zero time in acetonitrile and the solution was rapidly diluted to 2 ml and transferred to a prewarmed 0.5 dm jacketed polarimeter tube maintained at 30° by the circulation of thermostatted water. All transfers were made as quickly as possible to prevent the solvent or solutions from coming into contact with the atmosphere. The change in rotation with reaction time was provided by the chart record.

The rates of exchange were determined batchwise using sealed, double-stem tubes maintained at 30° in a water bath. In a typical experiment, 2 ml volumes of freshly prepared 0.4 *M* solutions of tetra-*O*-acetyl-β-D-glucopyranosyl chloride and of tetraethylammonium chloride-^{36}Cl were added separately one to each stem of the tube. After it had been sealed, the tube was brought to thermal equilibrium by keeping it immersed in the thermostatted bath for 30 min. The tube was then shaken to thoroughly mix the contents and the time of mixing was taken as zero time. After a given reaction time, the tube was opened and the content was immediately diluted with 20 ml of benzene. The mixture was then extracted four times with 5 ml volumes of water. The water extracts were combined in a 25 ml volumetric flask and diluted to 25ml. The resulting benzene solution was also transferred to a flask for dilution to 25 ml. The radioactivities of the solutions were determined by counting the solutions resulting on adding 1 ml samples to 15 ml volumes of an organic phosphor solution which contained 120 g of naphthalene, 7 g of PPO, and 0.05 g of POPOP per liter of dioxane. A Nuclear Chicago 700 liquid scintillation counter was used; the standard error in counting was less than 1% and the two solutions had radioactivities which totalled within 99% of that expected from the amount of radioactivity used in the experiment.

The benzene solution was evaporated to dryness and the tetra-*O*-acetyl-D-glucopyranosyl chloride-^{36}Cl was induced to crystallize from dry ether by the addition of petroleum ether. The crystalline compound (either crude I or II, depending on the experiment) was recrystallized to high purity (melting point determination) and its weight was determined. A 10% amount of the non-radioactive anomer was added to serve as hold-back carrier. The mixture was then recrystallized until the radioactive product appeared pure. Two recrystallizations normally sufficed. The compound, 18.3 mg (1 mmole), was dissolved in 1 ml of benzene for counting using 15 ml of the above mentioned organic phosphor solution.

To determine the rates of reaction by isotopic dilution analysis, reactions were conducted in the same manner as described above for the determination of rates of exchange except that non-radioactive starting materials were used. At the end of a given reaction time, the tube was opened and 100 mg of a radioactive sample of the component to be determined was added. The work-up procedure was then performed and the radioactivity of the compound isolated from the benzene layer was determined.

SYNTHÈSES DE PEPTIDES CONTENANT DES THIOACIDES

CASIMIR BERSE ET GILLES DUPUIS
Département de Chimie, Université de Montréal, Montréal, Québec
Reçu le 19 février 1965

RÉSUMÉ

L'introduction de la cystéine dans une chaîne peptidique présente toujours certaines difficultés. D'autre part, la présence des atomes de soufre dans un grand nombre de substances naturelles possédant certaines actions physiologiques permet de supposer que le remplacement de la cystéine par un autre résidu peut affecter l'activité caractéristique des peptides. Les thioacides semblent présenter une alternative intéressante pour la cystéine comme molécules remplaçantes. La présente publication décrit des condensations de *S*-benzyl thioacides (mercapto-2 acétique, (±)-mercapto-2 propionique, (±)-mercapto-2 succinique et mercapto-3 propionique) avec des esters éthyliques d'acides α-aminés (glycine, (±)-phénylalanine et L-phénylalanine) par la méthode du *N,N'*-dicyclohexylcarbodiimide.

Un très grand nombre de substances naturelles, essentielles aux différents organismes vivants, contiennent au moins une molécule de cystéine; par exemple, oxytocine, insuline, vasapressine, glutathion . . . etc. Le groupement sulfhydryle de ces substances peut être oxydé soit pour former un pont —S—S— comme dans le cas de l'oxytocine ou un dimère $(—S—R)_2$ comme le glutathion, par exemple.

Des études récentes (1) ont montré que certaines propriétés physiologiques de ces substances sont reliées à la présence de soufre dans leur structure. Du Vigneaud et ses collaborateurs ont montré que si la cystéine en position 1 de la séquence de l'oxytocine était remplacée par l'acide mercapto-3 propionique, l'hormone non naturelle ainsi obtenue (désamino-oxytocine) possède des propriétés physiologiques supérieures à celles de l'hormone naturelle (2, 3).

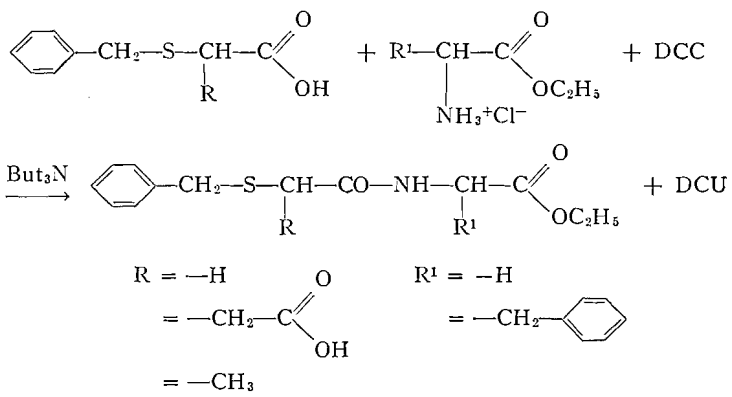
Dans ce présent travail, nous étudions les condensations de quatre thioacides différents avec les esters éthyliques de la glycine et de la phénylalanine. Les thioacides utilisés (mercapto-2 acétique, mercapto-3 propionique, (±)-mercapto-2 propionique et (±)-mercapto-2 succinique) possèdent une activité physiologique (4–10). Nous croyons que lorsque l'un de ces acides est incorporé dans une chaîne peptidique autre que celle de l'oxytocine le peptide obtenu pourrait jouer un rôle pharmacodynamique.

La méthode de condensation par formation d'anhydride mixte a été essayée sans succès. Le produit obtenu forme une huile que nous n'avons pu cristalliser. Cependant, la méthode de condensation par le *N,N'*-dicyclohexylcarbodiimide s'est avérée efficace dans la plupart des cas, sauf pour les condensations avec le glycinate d'éthyle. La fonction sulfhydryle des thioacides est bloquée par le groupement benzyle, et la fonction acide de l'acide aminé par formation de l'ester éthylique suivant la méthode de Fischer. La condensation est ensuite effectuée suivant le schéma indiqué (DDC = *N,N'*-dicyclohexylcarbodiimide, DCU = *N,N'*-dicyclohexylurée).

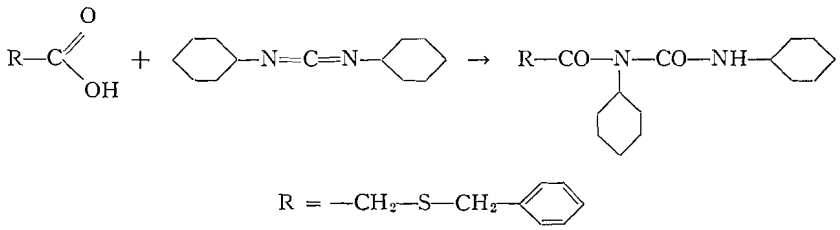
Comme nous le mentionnons précédemment, les essais de condensation du glycinate d'éthyle avec les *S*-benzyl thioacides ne donnent pas les peptides attendus (sauf dans le cas de l'acide *S*-benzyl (±)-mercapto-2 succinique).

La réaction qui a lieu est probablement la condensation du *N,N'*-dicyclohexylcarbodiimide avec le *S*-benzyl thioacide. Khorana rapporte une étude sur ce sujet (11).

Pour vérifier cette hypothèse, nous avons fait réagir équimoléculairement le DCC et l'acide *S*-benzyl mercapto-2 acétique dans le chloroforme. Le point de fusion du produit



obtenu (*S*-benzyl *N*-mercapto-2 acétyl *N,N'*-dicyclohexylurée) est le même que celui obtenu par essai de condensation de l'acide *S*-benzyl mercapto-2 acétique avec le glycinate d'éthyle en présence de DCC. L'analyse quantitative du pourcentage de carbone et d'hydrogène montre de plus l'identité des deux produits.



PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés dans des tubes capillaires, sauf indications contraires, et ne sont pas corrigés. Les indices de rotations ont été déterminés sur un appareil de Rudolph and Sons, modèle 80. Les analyses sont de C. Daesslé, Montréal, et de J. Maciak, Indianapolis.

Préparation générale des dérivés S-benzyle des thioacides

A une solution aqueuse de thioacide, dans le volume de 4 *N* NaOH calculé, refroidie à 0° sous agitation, une quantité équimoléculaire de α-chlorotoluène, dans quatre fois son volume de dioxanne est ajoutée en cinq portions approximativement égales sur une période de 30 min. Le mélange est ensuite agité 30 min à la température de la pièce. La solution aqueuse lavée à l'éther, acidifiée par 6 *N* HCl jusqu'au pH 3, concentrée in vacuo à 40°, est ensuite laissée au repos pour cristallisation. Les détails sur la recristallisation et les propriétés physiques des *S*-benzyl thioacides sont résumés dans le Tableau I.

S-Benzyl mercapto-2 acétate d'éthyle (V)

Une solution d'acide *S*-benzyl mercapto-2 acétique (6.0 g; 0.033 mole) dans de l'éthanol absolu (100 ml) saturé 0.5 h par un courant de chlorure d'hydrogène anhydre est portée à reflux pendant 2 h. La solution filtrée est ensuite évaporée in vacuo à 40°. Le *S*-benzyl mercapto-2 acétate d'éthyle est purifié par distillation sous vide; p.é. 265° à 760 mm, $n_D^{20} = 1.5352$.

Anal. Calc. pour $C_{11}H_{14}O_2S$ (210.28): C, 62.80; H, 6.67. Trouvé: C, 63.03; H, 7.17.

S-Benzyl N-mercapto-2 acétyl N,N'-dicyclohexylurée (VI)

(*a*) Une solution de glycinate d'éthyle (2.1 g; 0.015 mole) libéré de son chlorhydrate par la tributylamine (7 ml) dans le chlorure de méthylène (150 ml) est ajoutée à 0°, sous agitation, à une solution d'acide *S*-benzyl mercapto-2 acétique (2.7 g; 0.015 mole) dans le chlorure de méthylène (50 ml). La condensation est réalisée en présence de *N,N'*-dicyclohexylcarbodiimide (3.1 g; 0.015 mole) dans le chlorure de méthylène (50 ml). Le mélange est agité 0.5 h à 0° et 24 h à la température de la pièce. On sépare le précipité de DCU par filtration, puis la solution est lavée par *N* HCl (3 × 25 ml), H_2O (3 × 25 ml), 10% $NaHCO_3$ (3 × 25 ml), H_2O (3 × 25 ml), séchée sur Na_2SO_4 anhydre et évaporée à sec *in vacuo*. Le résidu cristallise d'éthanol–eau; rendement: 1.2 g (20%), p.f. 119°. Contrairement au peptide attendu (*S*-benzyl mercapto-2 acétylglycinate d'éthyle), l'analyse montre que l'on obtient le *S*-benzyl *N*-mercapto-2 acétyl *N,N'*-dicyclohexylurée.

Anal. Calc. pour $C_{22}H_{32}N_2O_2S$ (388.56): C, 68.00; H, 8.30. Trouvé: C, 68.36; H, 8.30.

†$[\alpha]_D^{26} = +68.6$ ($c = 1.0$, isopropanol).
‡$[\alpha]_D^{27} = -9.18$ ($c = 0.29$, acétate d'éthyle).

(*b*) Des quantités équimoléculaires d'acide *S*-benzyl mercapto-2 acétique (1.8 g; 0.01 mole) et de DCC (2.1 g; 0.01 mole) sont dissoutes dans le chloroforme et agitées 1 h à la température de la pièce. Après filtration du précipité de DCU (800 mg), la solution est lavée de façon habituelle, séchée et évaporée à sec *in vacuo*. Le résidu cristallise de l'éthanol–eau; rendement: 2.5 g (66%), p.f. 119–120° (bloc maquenne).

Anal. Calc. pour $C_{22}H_{32}N_2O_2S$ (388.56): C, 68.00; H, 8.30. Trouvé: C, 68.94; H, 9.08.

Le point de fusion mixte des produits obtenus en (*a*) et (*b*) est de 117° (bloc maquenne).

S-Benzyl (±)-mercapto-2 succinyl-diglycinate d'éthyle (VII)

Une solution de glycinate d'éthyle (21.0 g; 0.150 mole) libéré de son chlorhydrate par la triéthylamine (30.4 ml) dans le DMF (200 ml) est, après filtration du chlorhydrate de triéthylamine, ajoutée à 0°, sous agitation, à une solution d'acide *S*-benzyl (±)-mercapto-2 succinyl (18.0 g; 0.075 mole) dans le DMF (100 ml). La condensation est réalisée en présence de DCC (31.2 g; 0.150 mole) dans le chloroforme (100 ml). Le mélange est agité pendant 0.5 h à 0° et 2 jours à la température de la pièce. On sépare le précipité de DCU par filtration et on concentre le filtrat *in vacuo* à 50°. Le résidu est repris dans l'acétate d'éthyle; la solution obtenue est lavée de façon habituelle, séchée et évaporée à sec *in vacuo*. Le produit cristallise de l'acétate d'éthyle – éther de pétrole (60–110°); rendement: 6.0 g (15%), p.f. 121–124°.

Anal. Calc. pour $C_{19}H_{26}N_2O_6S$ (410.49): C, 55.59; H, 6.39. Trouvé: C, 55.99; H, 6.51.

S-Benzyl mercapto-2 acétyl (±)-phénylalanate d'éthyle (VIII)

Une solution de phénylalanate d'éthyle (6.9 g; 0.03 mole) libéré de son chlorohydrate par la tributylamine (7 ml) dans le chloroforme (75 ml) est ajoutée à 0°, sous agitation, à une solution d'acide *S*-benzyl mercapto-2 acétique (5.5 g; 0.03 mole) dans le chloroforme (75 ml). La condensation est réalisée en présence de DCC (6.2 g; 0.03 mole) dans le chloroforme (50 ml). Le mélange est agité pendant 0.5 h à 0° et 12 h à la température de la pièce. On sépare le DCU par filtration puis la solution est lavée de façon habituelle, séchée et évaporée à sec. Le produit cristallise de l'isopropanol; rendement: 10 g (93%), p.f. 100–101°.

Anal. Calc. pour $C_{20}H_{23}NO_3S$ (357.46): C, 67.20; H, 6.48. Trouvé: C, 67.61; H, 6.65.

S-Benzyl (±)-mercapto-2 propionyl (±)-phénylalanate d'éthyle (IX)

Ce composé est préparé de la même façon que VIII en condensant l'acide *S*-benzyl (±)-mercapto-2 propionique (9.8 g; 0.05 mole) avec le chlorhydrate de (±)-phénylalanate d'éthyle (11.5 g; 0.05 mole) en présence de DCC (10.2 g; 0.05 mole) et de tributylamine (11.6 ml) dans le chloroforme (quantité totale: 200 ml). Le produit cristallise d'éthanol–eau; rendement: 13 g (70%), p.f. 108° (bloc maquenne).

Anal. Calc. pour $C_{21}H_{25}NO_3S$ (371.49): C, 67.89; H, 6.78. Trouvé: C, 67.88; H, 7.31.

S-Benzyl mercapto-3 propionyl (±)-phénylalanate d'éthyle (X)

Ce composé est préparé de la même façon que VIII en condensant l'acide *S*-benzyl mercapto-3 propionique (5.9 g; 0.03 mole) avec le chlorhydrate de (±)-phénylalanate d'éthyle (6.9 g; 0.03 mole) en présence de DCC (6.2 g; 0.03 mole) et de tributylamine (7 ml) dans le chloroforme (quantité totale: 200 ml). Le produit cristallise de l'isopropanol; rendement: 4 g (36%), p.f. 56–57°.

Anal. Calc. pour $C_{21}H_{25}NO_3S$ (371.49): C, 67.89; H, 6.78. Trouvé: C, 67.93; H, 6.98.

S-Benzyl (±)-mercapto-2 succinyl (±)-diphénylalanate d'éthyle (XI)

Ce composé est préparé de la même façon que VIII en condensant l'acide *S*-benzyl (±)-mercapto-2 succinique (3.6 g; 0.015 mole) dans le DMF (25 ml) avec le chlorhydrate de (±)-phénylalanate d'éthyle (6.9 g; 0.03 mole) dans le chlorure de méthylène (40 ml) en présence de DCC (6.2 g; 0.03 mole) et de tributylamine (7 ml). Après filtration du précipité de DCU et évaporation *in vacuo* du filtrat, le résidu est repris dans l'acétate d'éthyle lavé, séché et évaporé. Le produit cristallise d'acétate d'éthyle – éther de pétrole (60–110°); rendement: 3.6 g (40%), p.f. 148–149°.

Anal. Calc. pour $C_{23}H_{38}N_2O_6S$ (590.70): C, 67.09; H, 6.43. Trouvé: C, 67.27; H, 6.91.

S-Benzyl (±)-mercapto-2 propionyl L-*phénylalanate d'éthyle (XII)*

Ce composé est préparé de la même façon que VIII en condensant l'acide *S*-benzyl (±)-mercapto-2 propionique (9.8 g; 0.05 mole) avec le chlorhydrate de L-phénylalanate d'éthyle (11.5 g; 0.05 mole) en présence de DCC (10.2 g; 0.05 mole) et de tributylamine (11.6 ml) dans le chlorure de méthylène (quantité totale: 200 ml). Le produit cristallise de l'isopropanol–eau; rendement: 3.7 g (20%), p.f. 76° (bloc maquenne), $[\alpha]_D^{26} = +68.6°$ ($c = 1.0$, isopropanol).

Anal. Calc. pour $C_{21}H_{25}NO_3S$ (371.49): C, 67.89; H, 6.78. Trouvé: C, 67.82; H, 6.90.

S-Benzyl (±)-mercapto-2 succinyl L-*diphénylalanate d'éthyle (XIII)*

Ce composé est préparé de la même façon que XI en condensant l'acide *S*-benzyl (±)-mercapto-2 succinique (3.6 g; 0.015 mole) avec le chlorhydrate de L-phénylalanate d'éthyle (6.9 g; 0.030 mole) en présence de DCC (6.2 g; 0.030 mole) et de tributylamine (7 ml) dans les mêmes solvants. Le produit est purifié après plusieurs cristallisations de l'acétate d'éthyle – éther de pétrole (60–110°); rendement: 2.0 (23%), p.f. 159–160°, $[\alpha]_D^{27} = -9.18°$ ($c = 0.29$, acétate d'éthyle).

Anal. Calc. pour $C_{33}H_{38}N_2O_6S$ (590.70): C, 67.09; H, 6.43. Trouvé: C, 66.92; H, 6.15.

S-Benzyl mercapto-2 acétyl (±)-phénylalanine (XIV)

A une solution de *S*-benzyl mercapto-2 acétyl (±)-phénylalanate d'éthyle (10 g; 0.028 mole) dans l'éthanol absolu (200 ml) on ajoute *N* NaOH (30 ml). Le mélange est agité 2 h à la température de la pièce, acidifié par 6 *N* HCl jusqu'à virage du tournesol et concentré *in vacuo* à 40°. Le précipité cristallise de l'éthanol–eau; rendement: 7.8 g (85%), p.f. 139–140°.

Anal. Calc. pour $C_{18}H_{19}NO_3S$ (329.41): C, 65.62; H, 5.81. Trouvé: C, 65.12; H, 6.04.

S-Benzyl (±)-mercapto-2 propionyl (±)-phénylalanine (XV)

A une solution de *S*-benzyl (±)-mercapto-2 propionyl (±)-phénylalanate d'éthyle (1.5 g; 0.004 mole) dans le dioxanne (100 ml) on ajoute *N* NaOH (6 ml). Le mélange est agité 20 h à la température de la pièce. Le précipité est filtré, dissout dans l'eau et acidifié par *N* HCl jusqu'au pH 3. Le précipité cristallise d'éthanol–eau; rendement: 1.1 g (77%), p.f. 114°.

Anal. Calc. pour $C_{19}H_{21}NO_3S$ (343.43): C, 66.47; H, 6.15. Trouvé: C, 66.45; H, 6.22.

S-Benzyl (±)-mercapto-2 succinyl (±)-diphénylalanine (XVI)

Ce composé est préparé de la même façon que XV par saponification de *S*-benzyl (±)-mercapto-2 succinyl (±)-phénylalanate d'éthyle (1.2 g; 0.002 mole) par *N* NaOH (5.4 ml) dans le dioxanne (100 ml). Le produit cristallise de l'isopropanol–eau; rendement: 0.80 g (75%), p.f. 202°.

Anal. Calc. pour $C_{29}H_{30}N_2O_6S$ (536.61): C, 64.90; H, 5.64. Trouve: C, 65.04; H, 5.24.

S-Benzyl mercapto-2 acétyl (±)-phénylalanyl (±)-phénylalanate d'éthyle (XVII)

Ce composé est préparé de la même façon que VIII en condensant le *S*-benzyl mercapto-2 acétyl (±)-phénylalanine (3.3 g; 0.01 mole) avec le chlorhydrate de (±)-phénylalanate d'éthyle (2.3 g; 0.01 mole) en présence de DCC (2.0 g; 0.01 mole) et de tributylamine (2.3 ml) dans le chlorure de méthylène (quantité totale: 125 ml). Le produit cristallisé d'éthanol; rendement: 1.8 g (36%), p.f. 124–125°.

Anal. Calc. pour $C_{29}H_{32}N_2O_4S$ (504.63): C, 69.02; H, 6.39; N, 5.55. Trouvé: C, 68.81; H, 6.46; N, 5.26.

THE ALKALOIDS OF PAPAVERACEOUS PLANTS

LIII. ESCHSCHOLTZIA CALIFORNICA CHAM.

RICHARD H. F. MANSKE AND KJU HI SHIN
Research Laboratory, Dominion Rubber Co. Ltd., Guelph, Ontario

Received November 13, 1964

ABSTRACT

Several lots of *Eschscholtzia californica* have been investigated and the following alkaloids have been identified, in addition to a new alkaloid which has been named eschscholtzine: protopine, allocryptopine, cryptopine, chelerythrine, and lauroscholtzine, which is a new name for *N*-methyllaurotetanine. Some plant lots did not yield cryptopine and not sufficient chelerythrine for positive identification.

The presence of alkaloids, and particularly of protopine and of allocryptopine, in *Eschscholtzia californica* Cham. has long been known (1, 2). Other alkaloids have been suspected and (or) reported and the author has recorded the presence of a new alkaloid, eschscholtzine (3).

More plant material has become available and a more complete examination is now reported. A small quantity of plant material (4 kg) grown locally yielded protopine, allocryptopine, cryptopine, chelerythrine, eschscholtzine, and a small amount of a phenolic base melting at 254° but not further characterized. The main lot (270 kg) did not yield this phenolic base nor cryptopine, and chelerythrine was found in only trace amounts and then evidently contaminated with sanguinarine. Eschscholtzine has now been obtained crystalline and is $C_{19}H_{17}O_4N$. The phenolic fraction yielded *N*-methyllaurotetanine for which the trivial name lauroscholtzine is now proposed.

EXPERIMENTAL

The smaller lot of material (4 kg) consisted largely of plants grown from seed of the wild plant. The large lot (270 kg) was grown from seed kindly supplied by Bodgers Seeds Limited, El Monte, California, and consisted of a mixture of cultivated varieties. The plants were grown on a plot of the Ontario Agricultural College, Guelph, Ontario, and special thanks are due to Dr. R. J. Hilton who made the necessary arrangements.

The dried and gound plant material was extracted with methanol and the extract was largely freed of solvent. The residue was then acidified with dilute hydrochloric acid (Congo test paper) and the remaining solvent was expelled in a current of steam. While still hot paraffin was added to the mixture. After settling and cooling the lower aqueous layer was withdrawn, reheated with paraffin, and after cooling once more was filtered with the aid of Filtercel. The water insoluble portions were washed with a fresh portion of acidified water and this extract was added to a subsequent methanol extract. By this countercurrent procedure it was possible to extract all of the alkaloid and do it with about 1 l of final solution per 2 kg of plant material.

The total alkaloid mixture was recovered from the aqueous solution by chloroform extraction after making alkaline with ammonia. Much non-alkaloid material was obtained in the chloroform extract and this was largely eliminated by extracting the residue from the extract with dilute hydrochloric acid. The water soluble fraction thus obtained was extracted with chloroform (4) and yielded the following fractions:

BC, bases whose hydrochlorides are extracted from aqueous solution with chloroform—eschscholtzine; some allocryptopine;

BCE and BEC, phenolic bases—lauroscholtzine;

BS, bases whose hydrochlorides are not extracted from aqueous solution with chloroform—protopine; cryptopine; most of the allocryptopine; chelerythrine; and

BSE and EES, phenolic bases—lauroscholtzine.

Eschscholtzine

The chloroform extract from the hydrochloric acid solution of the total alkaloids was evaporated to a syrupy consistency. After several days a few crystal nuclei made their appearance and the addition of a mixture of chloroform and carbon tetrachloride to incipient turbidity hastened crystallization. Filtration

and washing with the mixed solvent yielded the eschscholtzine hydrochloride in pale-yellow crystals which were recrystallized by adding chloroform to a concentrated methanol solution. Colorless well shaped needles were then obtained which effervesce slightly at 225° and melt to a colorless liquid at 246°. By reworking mother liquors there was obtained a total of 140 g of the hydrochloride from 270 kg of plant material. Analytical figures indicated a variable amount of solvent of crystallization.

Crystallization of the free base occurred only after many trials over a number of years. When nuclei were ultimately obtained, eschscholtzine crystallized with great facility from an ethereal solution which had been dried with potassium hydroxide. It will also crystallize from methanol in which, however, it is moderately soluble. The colorless stout prisms melt sharply at 128°* (λ_{max}^{EtOH} 295 mμ, log ε 4.04).

Anal. Calcd. for $C_{19}H_{17}O_4N$: C, 70.57; H, 5.30; N, 4.33. Found: C, 70.59, 70.43; H, 5.53, 5.63; N, 3.95.

The alkaloid is optically active showing $[\alpha]_D^{20}$ −202 (*c*, 1.00 in methanol).

Eschscholtzine acid oxalate crystallizes slowly from methanol and then melts with previous effervescence and sintering at 140°. A variable amount of solvent results in analytical figures of questionable value.

Protopine and Allocryptopine

The bases in the hydrochloric acid solution which had been extracted with chloroform were precipitated by adding an excess of potassium hydroxide, filtering, and washing with water until the filtrate was colorless. (The phenolic bases in the filtrate were regenerated by the addition of excess ammonium chloride and extraction with chloroform. The mixture of non-phenolic bases was redissolved in the minimum amount of dilute hydrochloric acid and the filtered solution was evaporated slightly. On cooling a copious crop of protopine hydrochloride was obtained. By reworking mother liquors it was possible to obtain a total of 58 g of protopine from the large lot of plant material. Its identity was established by melting point, mixed melting point (210°), and other characteristics.

The bases in the mother liquor from the above were regenerated by adding ammonia and extracting with chloroform. The residue from the chloroform extract crystallized readily in contact with methanol and one recrystallization from chloroform–methanol yielded pure allocryptopine melting at 160° either alone or in admixture with an authentic specimen. By reworking mother liquors there was obtained a total of 61 g of this alkaloid, but no other base, and specifically no cryptopine, could be isolated in pure form.

However, the plant material grown earlier from what was purported to be the wild species yielded cryptopine as its sparingly soluble oxalate (from methanol) and the regenerated base melted at 221° either alone or in admixture with an authentic specimen. From another lot of plant material there was obtained an oxalate which crystallized in contact with acetone. The base regenerated from this and recrystallized from chloroform–methanol melted sharply at 207°, either alone or in admixture with chelerythrine. The ψ-cyanide prepared from this melted at 257 °C.

The mother liquors from the eschscholtzine hydrochloride yielded some allocryptopine and a trace of protopine.

Lauroscholtzine

The phenolic bases from both the BC and BS fractions were worked up in parallel experiments. They were redissolved in cold aqueous sodium hydroxide, filtered to remove a turbidity, acidified with dilute acid, filtered once more, basified with ammonia, and extracted with chloroform. Further purification was effected by dissolving the residues from the chloroform extracts in aqueous oxalic acid, filtering from some amorphous residue, and repeatedly extracting the acid solutions with ether. The solutions were then diluted with water, basified with ammonia, and extracted with large volumes of ether. The residues from the ether extracts consisted of pale amber colored resins which could not be crystallized in contact with a number of solvents.

It was possible however to isolate about half of the bases in the form of glaucine perchlorate (m.p. 232–243°) from small portions which had been treated with diazomethane. It was then observed that either fraction of the phenolic bases yielded a sparingly soluble *l*-tartrate when treated with the theoretical amount of *l*-tartaric acid in absolute ethanol. Crystallization was virtually immediate. The tartrate was conveniently recrystallized by dissolving it in a small volume of hot water, evaporating to incipient crystallization, and adding hot absolute ethanol. As thus prepared the salt melted at 238–239° with some darkening. It was virtually insoluble in cold methanol or ethanol. About one half of the total phenolic fraction of alkaloids was obtainable in the form of this salt, and the yield was ca. 8 g. Though the regenerated base did not crystallize in contact with ether or with methanol it readily yielded a hydrobromide which when recrystallized once from methanol and dried at 110° melted at 237–238° and this melting point was not depressed when the salt was admixed with an authentic specimen of *N*-methyllaurotetanine hydrobromide which melted at 235–236° and which was kindly supplied by Dr. A. Rüegger of Sandoz Ltd., Basle, Switzerland (5).

The *O*-ethyl ether prepared by the action of diazoethane yielded an *l*-tartrate melting at 206° and a methiodide melting at 213°. Hofmann degradation yielded a methine whose methiodide melted at 285° and this in turn yielded 1-vinyl-7-ethoxy-3,4,6-trimethoxyphenanthrene melting at 141°. Except for the last these melting points are not always the same as reported (4) but they are of the right order. There is no doubt that lauroscholtzine is identical with the base previously described as *N*-methyllaurotetanine and the ultraviolet spectrum confirmed this identity. The maxima and their intensities were the same as those recorded by Rüegger (5).

**All melting points are corrected.*

Before it had been discovered that lauroscholtzine formed such a characteristic *l*-tartrate, attempts had been made to separate the phenolic bases by chromatography through alumina, but without success. However, the *O*-acetyl derivative, though not obtained crystalline, was obtained in ca. 50% yield as the ether eluate from a column of neutral alumina. It had R_f 0.6 in the system cyclohexane–chloroform–diethylanine (4:10:1) on thin-layer chromatography (silica gel G) and showed a phenolic acetate band at 1 760 cm^{-1} in the infrared spectrum. A hydroxyl band was absent.

Anal. Calcd. for $C_{22}H_{25}O_5N$: C, 68.91; H, 6.57; N, 3.65. Found: C, 68.77; H, 6.20; N, 3.79.

The n.m.r. spectrum of this acetyl derivative showed three methoxyl proton signals at 6.12, 6.15, and 6.31 τ, the last being undoubtedly due to the sterically hindered methoxyl at position 1 (5). Protons of the acetyl and *N*-methyl groups occurred at 6.21 and 7.50 τ respectively.

Hydrogenolysis of the acetyl derivative with lithium aluminium hydride in tetrahydrofurane regenerated lauroscholtzine characterized as its hydrobromide.

A. R. BATTERSBY AND D. F. SHAW
Robert Robinson Laboratories, University of Liverpool, Liverpool, England
Received January 22, 1965

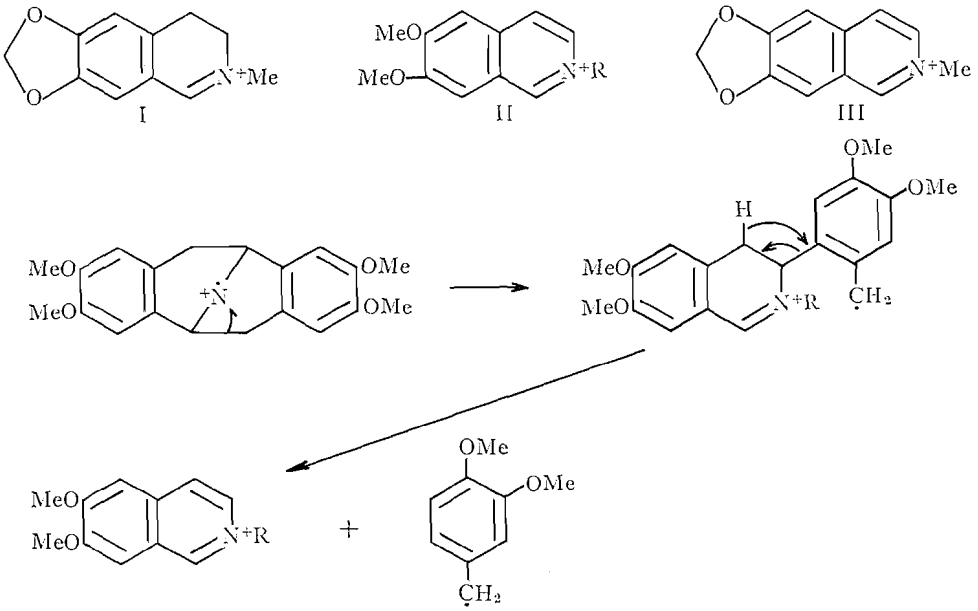
ABSTRACT

Eschscholtzine, a new alkaloid from *Eschscholtzia californica*, has been shown to be the bismethylenedioxy analogue of *N*-methylpavine (argemonine). The mass spectrometric fragmentation of alkaloids of the pavine type is discussed.

Two of us have reported the isolation of a new alkaloid, eschscholtzine, from *Eschscholtzia californica* Cham. (1) and a mass spectrum* of it showed the molecular formula to be $C_{19}H_{17}O_4N$. In the meantime, a fuller mass spectrometric study of eschscholtzine at Liverpool allowed the correct structure to be derived which had independently been determined by nuclear magnetic resonance (n.m.r.) and chemical degradation at Guelph. The mass spectrum of eschscholtzine shows a very small parent peak at *m/e* 323 when the hot inlet system was used; however, by direct inlet of the sample, the parent peak increased to about one-third the size of the base peak. In both spectra (hot inlet or direct inlet) only one intense fragment peak appeared at *m/e* 188. This behavior is similar to that of the 1-benzylisoquinoline alkaloids (2) but on this basis the only reasonable structure for the fragment ion is (I) which corresponds to *m/e* 190 and is thus unacceptable. However, the spectra of pavine (IV, R = H) and *N*-methylpavine (IV, R = Me) parallel that of eschscholtzine in showing a single intense fragment ion at *m/e* 190 and one at *m/e* 204. These ions are formulated as II (R = H) and II (R = Me) and their formation can be rationalized as shown below. The nature of the ion from eschscholtzine can now be understood as the aromatic ion (III) and its formation strongly indicated the methylenedioxy analogue (V) of *N*-methylpavine (IV, R = Me) (argemonine) as the structure of eschscholtzine.

The striking similarity of the n.m.r. spectra of argemonine (IV, R = Me) (3, 4) and eschscholtzine (V) supported this indication. Both n.m.r. spectra exhibit impressive symmetry and they are largely superimposable except for the slight shifts described in Table I. The aromatic and *N*-methyl protons call for no special comment but the protons of the two methylenedioxy groups appear as a quartet of lines of almost equal intensity: 4.17, 4.21, 4.22, and 4.26 τ. The two methylenedioxy groups are thus almost equivalent but the two protons of the O—CH_2—O system are not identical as a result of their being in different environments with respect to the aromatic rings. The eschscholtzine molecule is non-planar and may resemble a partly opened hinge. A similar non-equivalence of the methylenedioxy protons has been encountered in the aporphine alkaloids, dicentrine and bulbocapnine methyl ether (5).

**Kindly determined for us by Professor D. B. MacLean of McMaster University, Hamilton, Ontario.*



The ultraviolet spectra of argemonine and eschscholtzine are given in Table II. The bathochromic shift from 287 mμ to 295 mμ (with increase of intensity) resulting from the replacement of four methoxyl groups in the former by two methylenedioxy groups in the latter is as expected and these changes are evident in the degradation products as well.

The final proof of the structure of eschscholtzine came from chemical degradation by a route parallel to that used for *N*-methylpavine (6) to afford 2,3,8,9-tetramethoxydibenzo[*a*,*e*]cyclooctadiene (XI). The course of the degradation is outlined in the chart.

The n.m.r. spectrum of the first Hofmann degradation product (VI) exhibited a doublet centered at 3.39 τ (2H) (J = 1.5 c.p.s.) in accordance with a *cis*-stilbene structure, since *cis*- and *trans*-silbene give signals at 3.45 τ and 2.9 τ respectively (7). The n.m.r. spectrum also showed a singlet (6H) at 7.87 τ for NMe_2 and a multiplet (3H) at ca. 6.1–7.8 τ corresponding to the protons at C_{11} and C_{12}, and the aromatic protons (4H) gave signals at 3.58 τ and 3.43 τ. Finally the methylenedioxy protons appeared as singlets at 4.30 τ and 4.23 τ (2H for each) showing that now the methylenedioxy protons are equivalent. Again similar phenomena have been reported for the aporphine methines (5).

Quantitative catalytic hydrogenation of the methine (VI) yielded the dihydro derivative (VII) in which an n.m.r. multiplet (7H) corresponding to C_5, C_6, C_{11}, and C_{12} appeared between ca. 6.7 and 7.5 τ. The four protons of the two methylenedioxy groups became equivalent and appeared as a singlet at 4.33 τ. The second Hofmann degradation product (VIII) derived from the dihydromethine (VII) had a new signal as a singlet (2H) at 3.43 τ indicating once more a *cis*-stilbene. A singlet (4H) at 6.96 τ can be assigned to the protons on C_{11} and C_{12}. Reduction of the cyclooctatriene (VIII) yielded the 2,3,8,9-bismethylenedioxydibenzo[*a*,*e*]cyclooctadiene (IX) which because of symmetry gave a simple n.m.r. spectrum; singlets appeared at 7.07 τ (8H at C_5, C_6, C_{11}, and C_{12}), at 4.2 τ (4H of the methylenedioxy group), and at 3.45 τ (4H of aromatic nuclei).

The above compound (IX) was a new substance but it was possible to convert it into the known tetramethoxy derivative (XI) by converting it first into the tetrahydroxy compound (X). Reaction of the ether (IX) with phosphorus pentachloride, hydrolysis of the presumed tetrachloro intermediate, and methylation of the tetrahydroxy compound (X) with dimethyl sulfate or with methyl iodide in the presence of anhydrous potassium carbonate yielded the tetramethoxy compound (XI). Direct comparison of this compound (m.p. 200–203°) with that reported by Battersby and Binks (6) (m.p. 200–203°) proved that the two are identical. The n.m.r. spectrum was in agreement with the structure of the final product; three singlets appeared at 7.07 τ (8H of C_5, C_6, C_{11}, and C_{12}), at 6.25 τ (12H of four methoxyls), and at 3.5 τ (4H of aromatic nuclei).

In contrast to the *N*-methylpavine series (6), further Hofmann degradation of the methine (VI) yielded 2,3,8,9-bismethylenedioxydibenzo[*a*,*e*]cyclooctatetraene (XII), $C_{18}H_{12}O_4$. The structure was confirmed by the n.m.r. spectrum which exhibited three singlets at 4.18 τ (4H of the methylenedioxy groups), at 3.53 τ (4 aromatic protons), and at 3.47 τ (4 olefinic protons). The infrared spectrum of this product showed no hydroxyl band and the ultraviolet absorption (λ_{max}^{MeOH} 3.062 mμ; log ϵ = 3.97) is in keeping with the cyclooctatetraene formulation.

EXPERIMENTAL

All analytical samples were dried at room temperature *in vacuo* over phosphorus pentoxide. Thin layer chromatography was carried out using Silica Gel G, and the developing solvent was cyclohexane:chloroform:diethylamine (7:2:1). All melting points were determined with a Leitz hot-stage microscope and are uncorrected. Infrared absorption spectra were taken on a Perkin–Elmer, model 13713 spectrophotometer; ultraviolet absorption spectra were recorded using a Bausch & Lomb, spectronic 505. The n.m.r. spectra were determined in deuterochloroform with tetramethylsilane internal standard using a Varian A-60 spectrometer.

Eschscholtzine Methiodide

A solution of Eschscholtzine in methanol was treated with excess methyl iodide. Ether was added to complete the separation of the methiodide (quantitative yield) which when washed with ether and recrystallized from methanol melted at 286–287° with decomposition.

Anal. Calcd. for $C_{19}H_{17}O_4N.MeI$: C, 51.63; H, 4.33; N, 3.01; I, 27.27. Found: C, 51.78; H, 4.27; N, 2.96; I, 27.18.

Eschscholtzinemethine Hydrochloride

A solution of eschscholtzine methiodide (0.62 g) in aqueous methanol (30 ml of 50%) was reacted with silver oxide (from 1.5 g silver nitrate). The filtrate from this mixture was evaporated *in vacuo* at 40° to ca. 12 ml and heated under reflux for 5 h with 12 g potassium hydroxide. The resulting oily methine was separated by ether extraction and when dried and freed of solvent weighed 0.42 g (89%). The *hydrochloride* was obtained in colorless needles melting at 215–220° from methanol–ether. R_f: 0.51 (cf. eschscholtzine, R_f: 0.47); thin layer chromatography (t.l.c.) gives a single spot with strong fluorescence under ultraviolet lamp.

Anal. Calcd. for $C_{20}H_{19}O_4N.HCl.H_2O$: C, 61.30; H, 5.66; N, 3.58; Cl, 9.05. Found C, 61.15; H, 5.51; N, 3.19; Cl, 9.37.

Dihydroeschscholtzinemethine Hydrochloride

The catalytic hydrogenation (PtO_2 catalyst) of the methine hydrochloride in methanol proceeded to completion in 40 min. The *hydrochloride* isolated from the filtered solution crystallized readily from a small volume of methanol and the purified product melting at 275–284° (decomp.) was obtained in 80% yield. It was only very sparingly soluble in water; R_f: 0.71.

Anal. Calcd. for $C_{20}H_{21}O_4N.HCl$: C, 63.91; H, 5.90; N, 3.73; Cl, 9.43. Found: C, 63.96; H, 5.94; N, 3.35; Cl, 9.47. Nuclear magnetic resonance spectrum of free base; a multiplet (7H) at 6.7–7.5 (protons at C_5, C_6, C_{11}, and C_{12}); a singlet (4H) at 4.33 ($2CH_2O_2$=); a singlet (6H) at 7.82 (—NMe_2); and aromatic protons (4H) at ca. 3.70.

Dihydroeschscholtzinemethine Methiodide

The free base (the dihydromethine) was prepared by shaking the above hydrochloride with aqueous sodium hydroxide and ether. The dried ether solution was treated with an excess of methyl iodide and the precipitated methiodide thus formed in 60% yield melted at 180–181° with decomposition. The infrared spectrum showed a hydroxyl band at 3 500 cm^{-1} due to water of crystallization.

Anal. Calcd. for $C_{20}H_{21}O_4N.MeI.H_2O$: C, 50.51; H, 5.25; N, 2.81; I, 25.41. Found: C, 50.52; H, 5.22; N, 2.71; I, 25.73.

Dihydroeschscholtzinebismethine (VIII)

A suspension of the above methiodide (3.48 g) and fresh silver oxide (from 10 g silver nitrate) in aqueous methanol (30 ml MeOH; 10 ml H_2O) was shaken for 1 h and the clear filtrate from this was concentrated to ca. 25 ml. Potassium hydroxide (30 g) was then added and the mixture heated under reflux for 5 h and exhaustively extracted with ether. The ether extract was washed with water, with dilute hydrochloric acid, and again with water. The crystalline residue from the dried ether solution was only sparingly soluble in methanol or acetone but readily so in benzene and ethyl acetate. It was recrystallized from *n*-propanol and then melted at 146–152° (1.2 g; 59%).

Anal. Calcd. for $C_{18}H_{14}O_4$: C, 73.46; H, 4.80. Found: C, 73.45; H, 5.01. Nuclear magnetic resonance spectrum: a singlet (2H) at 3.43 (olefinic protons); a singlet (4H) at 6.96 (protons at C_{11} and C_{12}); a singlet (4H) at 4.19 ($2CH_2O_2$=); and a singlet (4H) at 3.48 (aromatic protons).

2,3,8,9-Bismethylenedioxydibenzo[a,e]cyclooctadiene (IX)

The above dihydromethine was easily hydrogenated in ethyl acetate in the presence of Adam's catalyst and crystallized from the same solvent. The colorless crystals melted at 215–218° (76% yield) and were virtually insoluble in ethanol or chloroform.

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44. Found: C, 73.14; H, 5.45.

2,3,8,9-Tetrahydroxydibenzo[a,e]cyclooctadiene (X)

A mixture of 100 mg of the foregoing substance and 300 mg phosphorus pentachloride in 25 ml benzene was heated under reflux for 90 min. The cooled solution was treated with ice and then evaporated *in vacuo*. The precipitated solid which was virtually insoluble in organic solvents was washed with water and without further treatment converted into the following.

2,3,8,9-Tetramethoxydibenzo[a,e]cyclooctadiene (XI)

(*a*) A suspension of 80 mg of the tetrahydroxy compound in 3 ml of 2 *N* sodium hydroxide and 0.5 ml methanol was treated with dimethyl sulfate (total amount, 1.7 g) in three portions. The pH was maintained at ca. 10 by the further addition of sodium hydroxide solution and the whole was stirred and maintained under nitrogen for 3 h. The mixture was then extracted with three portions of ether and the dried extract concentrated to ca. 100 ml which solution was passed through a column of alkaline alumina. Evaporation of the eluate to a small volume yielded a crop of colorless plates which when recrystallized from ethanol melted at 201–203° (lit. 201–203°).

(*b*) A mixture of the tetrahydroxy compound (50 mg), methyl iodide (1.0 g), and anhydrous potassium carbonate (0.9 g) in acetone (30 ml) was gently heated under reflux with stirring for 21 h. The acetone was evaporated, water was added to the residue, and the mixture extracted with ether. Removal of the ether from the extract yielded colorless plates (58 mg) which melted at 201–203° either alone or in admixture with the prepraration described under (*a*). Furthermore, this compound in admixture with that prepared from pavine (6) also melted at 201–203°.

Eschscholtzinemethine Methiodide

The methine was regenerated from its hydrochloride by treatment with ammonium hydroxide and ether extraction. The dried and clarified solution was treated with excess methyl iodide. The methiodide obtained in 60% yield melted at 158–161° with gas evolution. The infrared spectrum showed a band at 3 500 cm^{-1}.

Anal. Calcd. for $C_{20}H_{19}O_4N.MeI.\frac{1}{2}H_2O$: C, 51.65; H, 4.75; N, 2.87; I, 25.99. Found: C, 51.57; H, 4.96; N, 2.62; I, 25.84.

2,3,8,9-Bismethylenedioxydibenzo[a,e]cyclooctatetraene (XII)

A suspension of 0.46 g of the above methiodide in 36 ml water was shaken for 1 h with an excess of silver oxide. The filtrate from this mixture was heated under reflux after the addition of 40 g potassium hydroxide. The resulting precipitate was filtered from the cooled solution and washed with water. It was dissolved in a large volume (250 ml) of ether and the solution extracted with dilute hydrochloric acid, washed with water, dried, and evaporated. The residue (0.19 g) which was only sparingly soluble in methanol was recrystallized once from ethyl acetate – pentane and twice from benzene. It then melted at 230–233°.

Anal. Calcd. for $C_{18}H_{12}O_4$: C, 73.96; H, 4.14. Found: C, 74.26; H, 4.14.

THE SYNTHESIS OF β-D-GLUCOPYRANOSYL 2-DEOXY-α-D-*ARABINO*-HEXOPYRANOSIDE[1]

R. U. LEMIEUX AND A. R. MORGAN[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received January 25, 1965

ABSTRACT

D-Glucal triacetate reacted with iodonium and bromonium di-*sym*-collidine perchlorate complexes in the presence of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose to yield, after deacetylation, crystalline β-D-glucopyranosyl 2-deoxy-2-halogeno-α-D-mannopyranosides. The halogen was hydrogenolyzed catalytically to yield β-D-glucopyranosyl 2-deoxy-α-D-*arabino*-hexopyranoside (2-deoxy-neotrehalose) isolated as the crystalline heptaacetate. A correction of the literature is made regarding the preparation of "2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose".

INTRODUCTION

Lemieux and Levine (1)* proved that the reaction of D-glucal triacetate with iodine and silver benzoate in dry benzene (2) formed an approximately equimolar mixture of the products of *trans*-addition to the double bond, namely, 1-*O*-benzoyl-2-deoxy-2-iodo-β-D-glucopyranose triacetate and the stereoisomer with the α-D-*manno*-configuration. In a later paper (3), they extended this type of reaction to the preparation of glycosides by reacting D-glucal triacetate in benzene with equimolar amounts of an alcohol, iodine, silver perchlorate, and *sym*-collidine.

In view of the limited solubility of silver perchlorate in inert, non-polar solvents, it seemed probable that the conditions for the glycoside synthesis would be improved by the use of preformed positive halogen complexes with *sym*-collidine. For example, Carlsohn (4) prepared salts containing cationic iodine complexes with *sym*-collidine such as the hydroxide corresponding to the formula $[I(sym\text{-collidine})_{3.5}]OH$. In a later paper (5), he described the preparation of bromonium dipyridine perchlorate and referred to iodonium di-2,6-lutidine nitrate. The analogous complex with *sym*-collidine was given the formula $[I(sym\text{-collidine})_{3.5}]NO_3$. We accordingly prepared a number of complexes of "halonium perchlorates" with pyridine and substituted pyridines.

The general methods used may be summarized as follows:

$$AgNO_3 + NaClO_4 + 2B \rightarrow [Ag(B)_2]ClO_4\downarrow + NaNO_3,$$

$$[Ag(B)_2]ClO_4 + X_2 \rightarrow [X(B)_2]ClO_4 + AgX\downarrow,$$

where B is the pyridine base and X_2 is the halogen.

The first stage was carried out in aqueous solution and quantitative yields of the complexed silver perchlorate were obtained. As expected from the highly reactive state of positive halogens, the second stage, in which the halonium complex was produced, was more difficult to carry out. The stabilities and solubilities of the complexes varied widely. Colorless crystalline preparations of the bromonium and iodonium complexes with

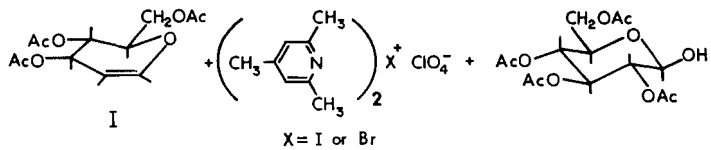
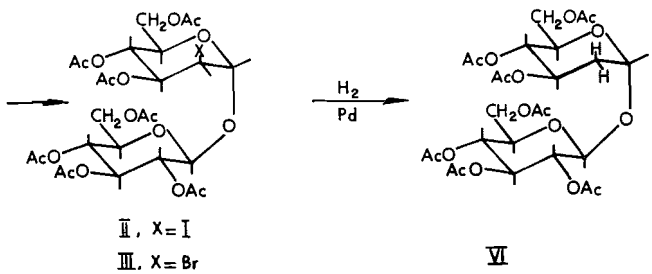
**The rotations reported in ref. 1 for methyl 2-deoxy-2-iodo-β-D-glucopyranoside and its triacetate are erroneous. The specific rotations at room temperature are* $[\alpha]_D$ *+31° (c, 0.9 in methanol) and* $[\alpha]_D$ *+61° (c, 2 in chloroform) (10), respectively. In a private communication, P. W. Kent reported* $[\alpha]_D^{25}$ *+25.4 (c, 0.92 in methanol) for the former compound.*

pyridine, 2-methylpyridine, and *sym*-collidine were readily obtained. The analyses always corresponded closely to 2 molecules of the base per positive halogen, even in the case of *sym*-collidine complexes, compounds for which Carlsohn (4, 5) usually obtained 3.5 molecules. Uschakow and Tchistow prepared various halonium complexes and later they isolated chloronium dipyridine nitrate (6). When we attempted to prepare chloronium di-*sym*-collidine perchlorate, all that was obtained was a mixture of *sym*-collidinium perchlorate and chlorinated *sym*-collidine.

As expected (3), reaction of D-glucal triacetate with equimolar amounts of methanol and either iodonium or bromonium di-*sym*-collidine complexes dissolved in chloroform gave virtually quantitative yields of acetylated methyl 2-deoxy-2-halogenoglycosides. When these halonium complexes were reacted with D-glucal triacetate in absence of the alcohol, only a very slow disappearance of the olefin took place leading to intractable materials. On the other hand, the halonium complexes with either pyridine or 2-methylpyridine rapidly gave rise to the *N*-(tri-*O*-acetyl-2-deoxy-2-halogenoglycosyl) pyridinium or 2-methylpyridinium perchlorates (7). Thus, the steric hindrance to *N*-glycoside formation provided by the methyl groups at the 2- and 6-positions of *sym*-collidine is required for a successful *O*-glycoside synthesis using these pyridine bases as buffers.

In view of the high yields obtained in the preparation of 2-deoxy-2-halogenoglycosides of simple alcohols, it was believed of interest to attempt the synthesis of non-reducing disaccharides and, for this purpose, 2,3,4,6-tetra-*O*-acetyl-β-D-glucose (8) was used as the "alcohol". The 2-deoxy-2-halogenodisaccharide heptaacetates (mainly II and III) were not obtained crystalline but deacetylation with triethylamine in aqueous methanol (9) yielded crystalline samples of both β-D-glucopyranosyl 2-deoxy-2-iodo-α-D-mannopyranoside (IV) and the corresponding bromide (V). The structures of these compounds were determined as follows.





Compound IV was hydrogenolyzed with palladium on charcoal as the catalyst, and acetylation of the product yielded the crystalline heptaacetate (VI). The deacetylated product was rapidly hydrolyzed by dilute hydrochloric acid (typical of 2-deoxyglycosides), to give D-glucose and 2-deoxy-D-*arabino*-hexose as shown by paper chromatography. A compound identical to VI was obtained on hydrogenolysis followed by acetylation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

bromo-compound V. Therefore, compounds IV and V have identical anomeric configurations. The n.m.r. spectrum of IV in deuterium oxide had signals of intensity one at τ 4.35 (spacing, <1 c.p.s.) and τ about 5.25 (obscured by another signal) which can be assigned to anomeric protons. The n.m.r. spectrum of V in deuterium oxide containing a little pyridine had signals of intensity one at τ 4.7 and τ 5.52 with spacings of <1 c.p.s. and 8 c.p.s., respectively. The low field signals in these spectra show very small coupling of the anomeric proton with the H-2 proton. This is characteristic of compounds with the *α-manno-* or *β-manno-* configurations (10). Since the 2-deoxy-disaccharide (VI) formed on hydrogenolysis of both IV and V was found to have the deoxyglucose residue in the α-configuration, both compounds IV and V must have the residue containing the halogen atom in the α-D-*manno-* configuration. This conclusion is in accord with expectations based on the experience of Lemieux and Levine as to the preferred stereochemical route in these halogenoalkoxylation reactions. The configuration of the deoxyglycoside obtained on deacetylation of VI was clearly evident from its n.m.r. spectrum in deuterium oxide. The signals for the anomeric protons appeared as two "doublets" at τ 4.6 and τ 5.3. The latter signal had a spacing of 7.0 c.p.s. and can be assigned to the β-D-glucopyranosyl portion of the compound. The low field signal was actually an ill-defined "doublet" resembling closely the signal for the anomeric proton of 2-deoxy-α-D-*arabino*-hexopyranosides (3). Well-resolved quartets are obtained for the β-D-isomers (3). Also, the structures of the signals for the protons at the 2-position were very similar to those observed for 2-deoxy-α-D-*arabino*-hexopyranosides (3). The molar rotations of compounds IV, V, and VI are approximately those which would be expected from rotations of closely related compounds. However, it is of interest to note that, according to Brewster's rules of atomic and conformational asymmetry (11), the bromo compound V should be more dextrorotatory than the iodo analog IV. In fact, V ($[M]_D$ +140°) was more dextrorotatory than IV ($[M]_D$ +123°). However, caution must be exercised in extending Brewster's rules to screw patterns involving atoms of high rotational rank. For example, according to Brewster's rules, methyl β-D-glucopyranoside ($[M]_D$ −66°) and methyl 2-deoxy-2-iodo-β-D-glucopyranoside ($[M]_D$ +94°) (1) should have the same rotation.

In preliminary experiments, when Celite chromatography (12) was used to isolate the deacetylated 2-deoxy-2-halogenodisaccharides, no crystalline material with the 2-deoxy-2-iodo-β-D-*gluco*-configuration could be obtained. Paper chromatograms also showed no evidence for the formation of stereoisomers other than the 2-deoxy-2-iodo-α-D-*manno* isomer. On the other hand, both the 2-deoxy-2-iodo- and 2-bromo-2-deoxy-disaccharides IV and V crystallized extremely slowly and incompletely from the crude syrup, possibly suggesting an impurity. Only trace amounts of glucose could be detected chromatographically as an impurity of the crude syrup. It is therefore likely that these compounds were formed in substantially higher yields than those (30–40%) calculated on the basis of the amounts of crystalline products obtained.

In attempting to extend the reaction to the formation of the α,α-linked disaccharide, it was necessary to prepare 2,3,4,6-tetra-*O*-acetyl-α-D-glucose.

Schlubach and Wolf (13) reacted 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl chloride with silver carbonate in either ether or acetone containing a little water to obtain a product melting at 107–108°, $[\alpha]_D$ +138.9°, (*c*, 0.9 in chloroform). The compound was assigned the structure of 2,3,4,6-tetra-*O*-acetyl-α-D-glucose.

Georg (14) treated tetra-*O*-acetyl-α-D-glucopyranosyl bromide with silver nitrate in ether containing a little water. He isolated material of m.p. 99–100°, $[\alpha]_D$ +135° (*c*, 4 in chloroform), and claimed its structure to be 2,3,4,6-tetra-*O*-acetyl-α-D-glucose. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

mechanism for its formation was postulated as Walden inversion at the anomeric center of the glucosyl bromide with replacement of bromide by the nitrate, followed by a second Walden inversion as water attacks the β-nitrate. Georg could not raise the melting point of his product to that of Schlubach and Wolf's material in spite of repeated recrystallization from ether – petroleum ether. Georg obtained a sample of Schlubach's material and on recrystallization from ether – petroleum ether the melting point fell to 98–99°, but when he recrystallized the compound from ether alone, the melting point rose immediately to 112–113°. He then obtained the same result with his own sample. Georg therefore concluded that dimorphic forms had been obtained.

Lemieux and Brice (15) reacted tetra-*O*-acetyl-β-D-glucopyranosyl chloride with silver acetate in 90% aqueous acetic acid and isolated crystals of m.p. 96–98°, $[\alpha]_D$ +138° (*c*, 0.44 in chloroform). The mutarotation displayed by an aqueous solution of the compound and the good agreement with Georg's values for the physical constants led them to assume they had prepared the 2,3,4,6-tetra-*O*-acetyl-α-D-glucose.

We repeated Lemieux and Brice's directions to obtain a product of m.p. 110–111°, $[\alpha]_D$ +149° (*c*, 1 in chloroform), and the n.m.r. spectrum shown in Fig. 1. The same spectrum was obtained for a product, melting in the range 90–95° obtained in second preparation. It was possible to raise the melting point to 110–111° by recrystallization from ether – Skellysolve B and seeding with the crystals of m.p. 110–111°.

The n.m.r. spectrum (Fig. 1) requires (16) the compound to be 1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose. The spacing of 3.75 c.p.s. in the signal for the anomeric proton at τ 3.77 is characteristic of protons in *gauche* orientation (17). Therefore, the anomeric configuration is α-D. The chemical shift of the proton requires the presence of an acetoxy group at the 1-position; for example, α-D-glucopyranose pentaacetate gives a signal for the anomeric proton at τ 3.63, spacing 3.3 c.p.s. The presence of a signal for an acetyl group at τ 7.82 is indicative of an axial acetoxy group. The doublet at τ 6.77 and with a spacing of 7.5 c.p.s. is assigned to the hydroxyl proton since the signal was not present in the spectrum after the chloroform solution had been shaken with deuterium oxide. The coupling of the hydroxyl proton with the 2-proton was not always observed. The signal for the 2-proton was in the region τ 5.7–6.3 and superimposed by the signals from the protons at the 5- and 6-positions.

Lemieux and Huber (18) prepared 1,3,4,6-tetra-*O*-acetyl-α-D-glucose, $[\alpha]_D$ +145° (in chloroform), m.p. 97–98°, by reacting 3,4,6-tri-*O*-acetyl-β-D-glucopyranosyl chloride with silver acetate in acetic acid. Matsuda (19) has substituted mercuric acetate for the silver acetate. His material melted at 98–100°, $[\alpha]_D$ +143° (*c*, 3 in chloroform). Recently, Helferich and Zirner (20) prepared 1,3,4,6-tetra-*O*-acetyl-α-D-glucose m.p. 98–100°, $[\alpha]_D$ +141.1° (*c*, 3.2 in chloroform), by a new route. Although Helferich and Zirner reported their compound to depress the melting point of Georg's material, it seems probable that the compounds were identical.

The formation of 1,3,4,6-tetra-*O*-acetyl-α-D-glucose from 2,3,4,6-tetra-*O*-acetyl-β-D-glucosyl chloride is most readily understood in terms of participation of the 2-acetoxy group in the solvolysis of the chloride to yield in the presence of water a transient ortho-acid, which can then rearrange to either the 1,3,4,6- or 2,3,4,6-tetra-*O*-acetyl-α-D-glucose. Our results indicate that, in the glucose series at any rate, the major first product is the 1,3,4,6-tetraacetate. That 1,3,4,6-tetra-*O*-acetyl-α-D-glucose in aqueous solution is thermodynamically less stable than the 2,3,4,6-isomer was established as follows. Although the 1,3,4,6-tetraacetate did not mutarotate in dry pyridine, the specific rotation of an aqueous solution changed from 147.5° to 71° in 12 h. That the product consisted essentially of

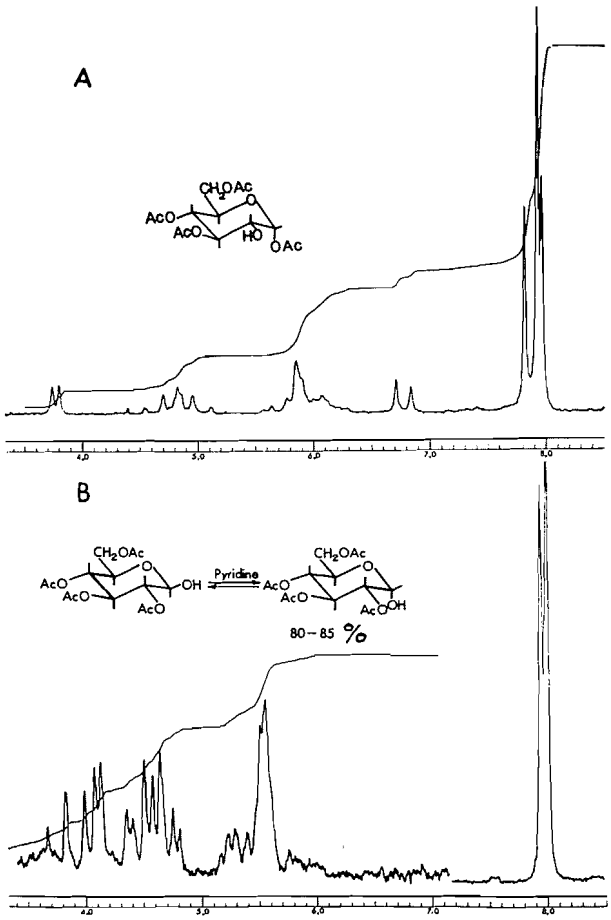

FIG. 1. A. The n.m.r. spectrum of 1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose in chloroform solution. B. The n.m.r. spectrum of the equilibrium mixture of the anomeric 2,3,4,6-tetra-*O*-acetyl-D-glucoses in pyridine solution.

2,3,4,6-tetra-*O*-acetyl-α- and -β-D-glucose in about equal amounts was evident from the n.m.r. spectrum in chloroform. The signal for the anomeric proton at τ 3.77 disappeared, and no trace of the signal at τ 7.82 characteristic of the 1-*O*-acetyl group of the 1,3,4,6-tetraacetate was present. The equilibrium mixture obtained when 2,3,4,6-tetra-*O*-acetyl-β-D-glucose was dissolved in water had the same spectrum and rotation. That the mutarotation was due to acetyl group migration followed by $\alpha \rightleftarrows \beta$ interconversion was evident since the intensity of the signals for acetyl groups required the product to be a mixture of tetraacetates.

A solution of 2,3,4,6-tetra-*O*-acetyl-β-D-glucose in pyridine displayed mutarotation. The n.m.r. spectrum (see Fig. 1) of the product in pyridine solution after equilibrium was achieved, showed a triplet with spacings of 9.5 c.p.s. at τ 3.92, and a doublet with a spacing of 3.0 c.p.s. at τ 4.16. In view of its spacing and chemical shift, the doublet is assigned to the anomeric proton of the α-anomer. This configuration is supported by the position of the triplet which is assigned to the 3-proton and which is 0.7 τ-values to lower field than the signals for the protons at the 2- and 4-positions. This decreased shielding of

the 3-proton is expected for the α-anomer wherein the 1-hydroxyl group is in axial orientation (21). The intensities of these signals relative to the total of the intensities of the other signals in the spectrum indicated that the equilibrium mixture contained about 80% of the α-anomer. The greater abundance of this isomer in the equilibrium mixture obtained from pyridine as compared to water was expected (22). Benzoylation of the product gave an 80–85% yield of 2,3,4,6-tetra-*O*-acetyl-1-*O*-benzoyl-α-D-glucose. The isomerization of the 1,3,4,6-tetraacetate of α-D-glucose in aqueous solution was independently established by Helferich and Zirner (20) during the course of this investigation.

When the syrup containing about 80% of 2,3,4,6-tetraacetyl-α-D-glucose was used as the "alcohol" in an attempt to form an α,α-linked isomer of compound IV, only IV was obtained and the yield was about the same as when pure 2,3,4,6-tetra-*O*-acetyl-β-D-glucose was used. Presumably, therefore, mutarotation took place more rapidly than did the reaction of the α-anomer, and the α-anomer reacted only very slowly as compared to the β-anomer in the iodoalkoxylation reaction.

With regard to the formation of 1,3,4,6-tetra-*O*-acetyl-α-D-glucose, it is of interest to note that Perlin (23) found the acid hydrolysis of the diastereoisomeric β-D-mannose 1,2-(benzyl orthoacetates) yielded 2-*O*-acetyl-D-mannose. Evidently, the configuration is important in determining whether the acetyl group materializes at the 1- or the 2-poisiton. Ness and Fletcher (24) showed that 1,3,5-tri-*O*-benzoyl-α-D-ribose is formed both on hydrolysis of tri-*O*-benzoyl-D-ribofuranosyl bromide and on hydrogenolysis of 3,4-di-*O*-benzoyl-α-D-ribose 1,2-(benzoyl orthobenzoate). The 1-*O*-benzoyl group was found to migrate to the 2-position in alkaline solution. The isolation by Antia (25) of 1,3,4-tri-*O*-acetyl-α-D-xylose as a product of the reaction of tri-*O*-acetyl-α-D-xylopyranosyl bromide in aqueous acetone and in the presence of silver carbonate is noteworthy.

EXPERIMENTAL

The melting points were taken on a heating stage and are uncorrected. The rotations were measured at room temperature, 23–25°.

The nuclear magnetic resonance (n.m.r.) spectra were determined, unless otherwise stated, in deuterium oxide with a Varian A60 spectrometer and the chemical shifts are reported in *tau* (τ) values with tetramethylsilane (TMS) as external standard.

Deacetylated material was chromatographed on Whatman No. 1 paper and developed with the lighter phase of 1-butanol, ethanol, and water mixture (5:1:4) (26). Silver nitrate (27), periodate–permanganate (28), *p*-anisidine hydrochloride (29), and aniline hydrogen phthalate (30) sprays were used. The R_G numbers refer to the R_f values relative to that of glucose.

Chloroform, when used in preparative procedures, was purified by passing down a column of activated alumina. A column 1.9 cm × 28 cm gave 400 ml chloroform with no trace of hydroxyl absorption in the infrared.

It is important to realize that perchlorates are potentially powerful explosives. Although none of the preparations described below caused trouble, the compounds detonated on strong heating. Due precautions must be taken (31).

Silver Di-sym-collidine Perchlorate

sym-Collidine, 20 ml, was added with vigorous stirring to a solution of silver nitrate, 9 g, and sodium perchlorate, 11 g, in 100 ml of water to give a white curdy precipitate. After washing repeatedly with water, the product was washed with ethanol and ether and finally dried under vacuum over phosphorus pentoxide. The yield was 24 g (100%).

Iodonium Di-sym-collidine Perchlorate

It is important in the preparation of halonium complexes to make sure the conditions are anhydrous. Otherwise, the halogen tends to be reliberated. Powdered iodine, 20.2 g (79.5 mmoles), was added to a suspension of the silver di-*sym*-collidine perchlorate, 35.7 g (79.5 mmoles), in about 200 ml of chloroform and 5 ml of *sym*-collidine. After shaking for 15 min, the yellow precipitate of silver iodide was removed by filtration through a bed of Celite, and the iodonium complex crystallized directly from the filtrate on standing in the cold. The mother liquors gave further fine white crystals on the addition of ether. The combined crystals were dried under high vacuum and analyzed for positive iodine by titration of the iodine liberated in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the reaction with potassium iodide in aqueous acid. The yield of iodine was 97.5% of theoretical based on the formula $(C_8H_{11}N)_2ICIO_4$.

Bromonium Di-sym-collidine Perchlorate

Silver di-*sym*-collidine perchlorate, 13.47 g (30 mmoles), was suspended in 150 ml pure chloroform and 1 ml *sym*-collidine, and 1.65 ml bromine (30 mmoles) was added. Silver bromide was rapidly precipitated and was collected by filtration on Celite. The clear faint-yellow filtrate gave a fine, white crystalline precipitate on the addition of ether. A 70% yield was obtained of a product which, on analysis contained 93% of the positive bromine expected $(C_8H_{11}N)_2BrClO_4$. The n.m.r. spectrum in methylene chloride was that expected for complexed *sym*-collidine. The intensities of the signals at τ 2.72, 7.15, and 7.57 were 2:6:3, respectively. *sym*-Collidine in methylene chloride gave signals of corresponding relative intensities at higher field τ 3.22, 7.59, and 7.77, respectively. The melting point was ill-defined but a clear liquid was obtained at 230°.

Methyl 3,4,6-tri-O-Acetyl-2-deoxy-2-iodo-α-D-mannopyranoside and the Corresponding β-Glucoside

Anhydrous methanol, 0.12 ml (2.8 mmoles), and 1.3 g of the iodonium complex (titration gave 86% of the theoretical iodine) were added to D-glucal triacetate, 0.755 g (2.78 mmoles), dissolved in 15 ml of pure chloroform. A homogeneous faint-yellow solution was obtained from which, almost immediately, *sym*-collidinium perchlorate separated. The mixture was filtered after a 20 min reaction time, and the filtrate was washed first with water, then with 2 *N* sulfuric acid, and finally with water. After drying by filtration through chloroform-wetted paper, the solution was evaporated at high vacuum to a syrup, 1.115 g (93% yield of methyl tri-*O*-acetyl-2-deoxy-2-iodoglycosides). The n.m.r. spectrum was almost identical to that obtained by Lemieux and Levine (3) except that integration of the methoxyl peaks indicated 82% of the *α-manno* and 18% of the *β-gluco*-configurations.

β-D-Glucopyranosyl 2-Deoxy-2-iodo-α-D-mannopyranoside (IV)

The iodonium complex, 12.17 g (23.7 mmoles of positive iodine as determined by titration) was added to D-glucal triacetate, 6.45 g (23.7 mmoles), and 8.25 g (23.7 mmoles) of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose dissolved in 50 ml of pure chloroform. As the iodonium salt dissolved on stirring the mixture, *sym*-collidinium perchlorate was precipitated. After 20 min, a sample of the solution was added to aqueous potassium iodide solution containing soluble starch. A strong blue color developed. After 6 h, the brownish solution was filtered to remove the *sym*-collidinium perchlorate and the filtrate was washed with 0.1 *M* sodium thiosulfate, 60 ml, to give a light-brown chloroform layer. Iodine was liberated on standing. On passing the chloroform layer down a silicic acid column (1.8 cm × 19.5 cm), a band with the violet color of iodine moved down the column followed by a brown band from which a syrup was isolated. The syrup was deacetylated by allowing a solution, in 20 ml of methanol containing 2 ml of triethylamine and water added to turbidity, to stand overnight at room temperature. A paper chromatogram of the deacetylated syrup showed a spot with R_G = 1.19 and a trace of glucose (aniline hydrogen phthalate as spray reagent). The compound, 2.84 g, crystallized from water on seeding with crystals obtained in an earlier experiment from a chromatographic purification on a Celite column using 1-butanol–water (12). A further 0.5 g was obtained by crystallization of the residual syrup from methanol. The total yield was 33%. Recrystallization from ethanol–water gave material which decomposed around 100°, $[\alpha]_D$ +26.3° (*c*, 2 in water).

Anal. Calcd. for $C_{12}H_{21}O_{10}I.1.5H_2O$: C, 30.08; H, 5.05; I, 26.48. Found: C, 30.19; H, 5.00; I, 27.94.

Further elution of the silicic acid column gave 0.6 g of syrup which, on deacetylation, gave spots corresponding to glucose and glucal on paper chromatograms.

2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl 2-Deoxy-3,4,6-tri-O-acetyl-α-D-arabino-hexopyranoside (VI)

The above described compound (IV), 0.163 g (0.36 mmoles), dissolved in 2.5 ml water and 0.3 ml triethylamine, was hydrogenolyzed with a 10% palladium-on-charcoal catalyst. After stirring for 2 h under hydrogen at slightly above atmospheric pressure, the theoretical quantity of hydrogen was taken up. The catalyst was removed by filtration using Celite. Silver carbonate, 10 mmoles, was added to the filtrate to precipitate the iodide ion. Filtration followed by passage of hydrogen sulfide to remove traces of silver salts and evaporation of the clarified solution left 0.135 g of brown residue which was acetylated in 5 ml pyridine and 5 ml acetic anhydride. After standing overnight, the solvents were evaporated to leave 0.207 g of a semicrystalline syrup. Two recrystallizations from ethanol gave fine crystals, m.p. 163.5° and $[\alpha]_D$ +66.5° (*c*, 0.8 in chloroform).

Anal. Calcd. for $C_{26}H_{36}O_{17}$: C, 50.25; H, 5.80. Found: C, 50.25; H, 5.79.

The compound was deacetylated with sodium methoxide in methanol to give a fine, white amorphous powder, R_G = 0.43. The n.m.r. spectrum in deuterium oxide had signals of intensity one (relative to the intensity of a broad band in the τ 5.6–6.9 region and taken as arising from 11 protons) at τ 4.60, 5.28, about 7.6, and about 8.2. The structures of the signals at τ 4.60, 7.6, and 8.2 were very similar to those with similar chemical shifts in the spectrum of methyl 2-deoxy-α-D-*arabino*-hexopyranoside (3). The signal at τ 5.28 was a doublet with a spacing of 7.0 c.p.s. as expected for the anomeric proton of the β-D-glucosyl portion of VII. A 0.05 g sample of the deacetylated product was dissolved in 5 ml of 0.2 *N* hydrochloric acid. The observed rotation of 0.65° (1 dm tube) after 0.5 h fell to 0.55° after 1 day. The reaction was also followed chromatographically and after 1 d essentially all the starting material, R_G = 0.43, had hydrolyzed to glucose and 2-deoxy-D-*arabino*-hexose as seen by direct comparison with authentic samples on a paper chromatogram.

Methyl 3,4,6-Tri-O-acetyl-2-bromo-2-deoxy-α-D-mannopyranoside and the Corresponding β-D-Glucoside

The bromonium complex, 0.965 g (2.12 mmoles of positive bromine as determined by titration), was added to D-glucal triacetate, 0.576 g (2.12 mmoles), and 0.2 ml methanol (4.9 mmoles) in 5 ml chloroform. The reaction was exothermic and a rapid precipitation of *sym*-collidinium perchlorate was obtained. After stirring for 10 min, the solution was washed with dilute hydrochloric acid containing potassium iodide. Iodine was liberated, but 6 ml of 0.1 *M* thiosulfate solution rendered both phases colorless. The chloroform layer was then washed with sodium bicarbonate, filtered, and evaporated overnight in a high vacuum. The residue, 0.818 g (quantitative yield) of a light-yellow syrup, had an n.m.r. spectrum which showed the presence of three methyl glycosides. From the chemical shifts of the methoxy-group signals, the compounds were identified as the methyl tri-*O*-acetyl-2-bromo-2-deoxy-D-glycopyranosides with the *β-gluco-* (25%), *α-manno-* (about 65%), *α-gluco-* (about 10%) (32) configurations.

β-D-Glucopyranosyl 2-Bromo-2-deoxy-α-D-mannopyranoside (V)

The bromonium di-*sym*-collidine perchlorate, 13.5 g (27.3 mmoles of bromonium ion by titration), was added to D-glucal triacetate, 7.17 g (26.4 mmoles), and 2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranose, 9.17 g (26.4 mmoles), in chloroform. There resulted an exothermic reaction with precipitation of *sym*-collidinium perchlorate. After 5 min, a sample did not liberate iodine when shaken with potassium iodide solution. The reaction mixture was cooled to 0° and about 6 g (27 mmoles) of *sym*-collidinium perchlorate was obtained on filtration. The chloroform filtrate was washed with dilute acid and then sodium bicarbonate.

Evaporation left a syrup which was dissolved in 40 ml of methanol containing 6.5 ml of triethylamine, and water was added to turbidity. The solution turned green and, on standing overnight, became purple. The deacetylated syrup very slowly deposited crystals from methanol, 3.5 g after a month (33% yield). Recrystallization from methanol–water mixture gave material which carbonized around 180°, $[\alpha]_D$ +39.4° (*c*, 1 in water).

Anal. Calcd. for $C_{12}H_{21}O_{10}Br$: C, 35.56; H, 5.32. Found: C, 35.46; H, 5.32.

Since the R_G value was 0.95, the compound was difficult to distinguish from glucose in the chromatogram of the crude deacetylated syrup.

The compound was hydrogenolyzed for 2 d under the same conditions as described above for compound IV using palladium-on-charcoal catalyst. The syrup obtained from the reaction was acetylated and worked up exactly as described for the preparation of the deoxy-glycoside VI. The melting point, 163°, was not depressed on admixture with VI.

1,3,4,6-Tetra-O-acetyl-α-D-glucose

2,3,4,6-Tetra-*O*-acetyl-*β*-D-glucopyranosyl chloride, 36.6 g (100 mmoles), was dissolved in about 100 ml of glacial acetic acid, and 5 ml water (110 mmoles) and 20 g silver acetate (120 mmoles) were added. The mixture was shaken vigorously for 2 min and then frozen in a dry ice and acetone mixture. The volatile components were removed *in vacuo*. The residue was finally warmed to 80° *in vacuo* to remove the last traces of acetic acid. The residue was extracted five times with ether and the silver salts were removed on Celite. To the ether filtrate was added Skellysolve B just to the point of turbidity. The crystalline precipitate, 13.7 g (40% yield), m.p. 90–95° had the n.m.r. spectrum expected for the 1,3,4,6-tetraacetate. Recrystallization from ether – Skellysolve B gave material of m.p. 110–111°, $[\alpha]_D$ +149° (*c*, 1 in chloroform). The n.m.r. spectrum (Fig. 1) is described in the above discussion.

1,3,4,6-Tetra-*O*-acetyl-*α*-D-glucopyranose did not mutarotate in dry pyridine but did in water to a final rotation of $[\alpha]_D$ +71° (*c*, 1.8 in water). 2,3,4,6-Tetra-*O*-acetyl-*β*-D-glucopyranose mutarotated in water to an equilibrium point of $[\alpha]_D$ +71° (*c*, 1.5 in water). The n.m.r. spectra of the equilibrium products dissolved in chloroform were identical and it was apparent that the *α*- and *β*-anomers were present in about equal amounts.

When the product from the equilibration in water was dissolved in pyridine further mutarotation occurred and the n.m.r. spectrum in pyridine indicated that about 80% of the mixture was 2,3,4,6-tetra-*O*-acetyl-*α*-D-glucopyranose. This was confirmed by benzoylation in the usual manner using benzoyl chloride in pyridine. The n.m.r. spectrum of the crude syrupy product, $[\alpha]_D$ +93.5° in chloroform, contained a doublet at τ 3.35, spacing 3.5 c.p.s. This signal is readily assigned to the anomeric proton of 1-*O*-benzoyl-*α*-D-glucopyranose tetraacetate, which must comprise about 80% of the product as determined from the relative intensities of the signals in the n.m.r. spectrum. The syrup readily provided a 75% yield of crystalline product from a solution in ethanol and water, $[\alpha]_D$ +74.3° in chloroform, m.p. 65–70°, and the n.m.r. spectrum indicated now only 75% of the 1-*O*-benzoyl-*α*-D-glucopyranose tetraacetate. However, a further crop of crystals was obtained from the mother liquors which, after repeated recrystallizations, melted at 67–68°, $[\alpha]_D$ +132° (*c*, 0.3 in chloroform). The n.m.r. spectrum was that expected for pure 2,3,4,6-tetra-O-acetyl-1-*O*-benzoyl-*α*-D-glucopyranose and half a molecule of ethanol of solvation. The literature values (33) for 2,3,4,6-tetra-*O*-acetyl-1-*O*-benzoyl-*α*- and -*β*-D-glucopyranoses are, respectively, m.p. 60–63°, $[\alpha]_D^{15}$ +113.5° (*c*, 3 in chloroform) and m.p. 143° $[\alpha]_D^{20}$ −28.1° (*c*, 3 in chloroform). Treatment of the benzoate with hydrogen bromide in acetic acid gave a crystalline product identical to tetra-*O*-acetyl-*α*-D-glucopyranosyl bromide.

Reaction of Syrupy 2,3,4,6-Tetra-O-acetyl-α-D-glucopyranose with Iodonium Di-sym-collidine Perchlorate and D-Glucal Triacetate

The reaction of the mixture of the α- and β-anomers of 2,3,4,6-tetra-*O*-acetyl-D-glucose, obtained by equilibration in pyridine, was performed under the same conditions as described above starting with the pure 2,3,4,6-tetra-*O*-acetyl-β-D-glucose.

On deacetylation, a 39% yield of virtually pure 2-deoxy-2-iodo-α-D-glucopyranosyl β-D-glucopyranoside was obtained as evidenced by the n.m.r. spectrum and optical rotation, and its catalytic reduction and acetylation to VI.

ACKNOWLEDGMENTS

The research was supported by grants (N.R.C.-T 172) to R. U. Lemieux and three North Atlantic Treaty Organization Studentships to A. R. M. (1961–1964). The n.m.r. spectra were determined by Mrs. Gail Conway.

THE PREPARATION AND CONFIGURATIONS OF TRI-*O*-ACETYL-α-D-GLUCOPYRANOSE 1,2-(ORTHOESTERS)[1]

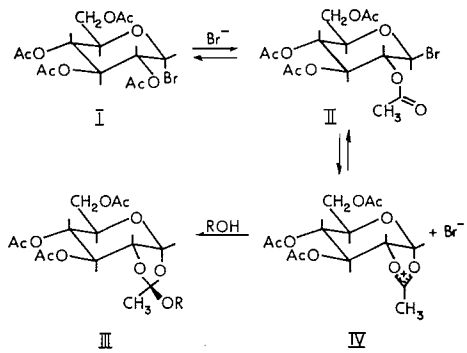
R. U. LEMIEUX AND A. R. MORGAN[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received January 25, 1965

ABSTRACT

Reaction of tri-*O*-acetyl-2-*O*-acyl (acetyl, benzoyl, pivalyl, and methoxycarbonyl)-α-D-glucopyranosyl halides with a variety of alcohols in *sym*-collidine containing a tetraalkylammonium halide gave the 1,2-orthoesters in near quantitative yields. In each case one of the two diastereoisomeric orthoesters was obtained in high yield and was shown by application of n.m.r. spectroscopy to be that isomer which has the alkoxy group on the dioxolan ring *trans* to the pyranose ring (*exo*-configuration). Participation of a methoxycarbonyloxy group allowed the preparation of a 1,2-(dimethyl orthocarbonate). 1,2-(Phenyl orthoacetates) were prepared.

INTRODUCTION

Helferich and co-workers (1, 2) observed that reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) with alcohols in the presence of *sym*-collidine (2,4,6-trimethylpyridine) gave tri-*O*-acetyl-α-D-glucopyranose 1,2-(alkyl orthoacetates). Our study of the



reaction of I with pyridine (3, 4) led to the conclusion that the orthoesters must form from the β-anomer of I which arises in the reaction mixture as a result of the liberation of bromide ion. A recent study of the equilibration of the tetra-*O*-acetyl-D-glucopyranosyl chlorides has in fact shown that the anomerization reaction is strongly catalyzed by halide ions (5). It has long been established that the reaction of tetra-*O*-acetyl-β-D-glucopyranosyl chloride with alcohols, preferably in the presence of pyridine, yields the alkyl 1,2-orthoacetates (6, 7). Tetra-*O*-acetyl-β-D-glucopyranosyl bromide (II) has recently been prepared and this highly labile compound was shown to give the 1,2-orthoacetate when reacted with methanol (8). Particularly in view of the promise that the 1,2-orthoesters of sugars will play an important role in the chemical synthesis of α-glycopyranosides (9), it seemed important to examine their preparation from the readily available *O*-acylated glycopyranosyl halides which possess a 1,2-*cis*-configuration. 1,2-Orthoesters are readily prepared from those sugars which provide the 1,2-*trans*-acylated glycopyranosyl

[1]*Presented by R. U. Lemieux at 148th Meeting of the American Chemical Society, Chicago, Illinois, August 30 – September 4, 1964.*

[2]*This research was part of a thesis submitted by A. R. M. in partial fulfillment of the requirements for the degree of Doctor of Philosophy, 1964.*

halide as the more stable anomer (10). This communication is concerned with the preparation of a variety of 1,2-orthoesters and a 1,2-orthocarbonate from derivatives of D-glucopyranose in near quantitative yield. It is apparent that the method should be generally applicable to the preparation of 1,2-orthoesters from *O*-acylated 1,2-*cis*-glycopyranosyl halides.

The preparation of orthoesters requires that the reaction medium be strongly buffered against acid. Although pyridine can be used for this purpose, its use requires the reaction to yield orthoesters to be substantially more rapid than the formation of the pyridinium glycosides (3). Since this need not generally be the case, it seemed desirable to employ a more hindered base. Since tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) did not react with *sym*-collidine after 5 d at room temperature, *sym*-collidine was chosen as a suitable base. Of course, other 2,6-disubstituted pyridines should also be useful in this regard. In fact, Mazurek and Perlin (11) have found 2,6-dimethylpyridine to be a solvent of choice in the preparation of 1,2-orthoacetates from tetra-*O*-acetyl-α-D-mannopyranosyl bromide.

Since the formation of a 1,2-orthoester from a 1,2-*cis*-glycopyranosyl halide is dependent on the epimerization of the latter compound to the 1,2-*trans*-anomer, it was evident that the anomerization reaction should be promoted by the addition of halide ion. Quaternary ammonium halide salts were used for this purpose in view of their solubilities in non-polar solvents such as *sym*-collidine and their effectiveness in promoting anomerization (5).

Reaction of I with a wide variety of alcohols using *sym*-collidine as solvent and tetra-*n*-butylammonium bromide as catalyst has provided near quantitative yields of the 1,2-orthoacetate (III). The preparations wherein R = ethyl, isopropyl, *t*-butyl, and phenyl are presented in the experimental section in order to illustrate the generality of the method. In all cases one of the diastereoisomers was formed in large excess (over 85%) except for the reaction with phenol (about 70%). Lemieux and Cipera (7) have suggested that this high degree of partial asymmetric synthesis probably arose because of a more facile approach by the alcohol to the side of the 1,2-acetoxonium ion intermediate (IV) which is *trans* to the glucopyranose ring to yield the *exo*-orthoester (the isomer with the alkoxy group in the *exo*-orientation at the 2-position of the dioxolane ring). Evidence that this is in fact the case was obtained by a comparison of the n.m.r. spectra of the 1,2-(methyl orthoacetate), 1,2-(methyl orthopivalate), and 1,2-(dimethyl orthocarbonate) derivatives of 3,4,6-tri-*O*-acetyl-α-D-glucopyranose. The orthopivalate was originally prepared in the anticipation that the bulk of the *t*-butyl group would prevent the formation of the *exo*-isomer. However, that this was probably not the case was apparent from the chemical shifts of the methoxy-group protons in the above mentioned compounds, the chemical shifts of the pyranose-ring protons in a series of 1,2-(alkyl orthoacetates), and the difference in the conformations of the pyranose rings of the orthoacetates and the orthopivalate as indicated by their n.m.r. spectra. As is seen in Table I, the major isomers in the reaction products obtained in preparing the orthoacetate and the orthopivalate both had the methoxy group signal at τ 6.71. This undoubtedly means that these isomers have the same configuration. The chemical shifts of the methoxy groups in the orthocarbonate agree well with those which would be anticipated from the chemical shifts of the methoxy groups of the diastereoisomeric orthoacetates. This is to be expected since the change in the configuration of the orthoacetates places the methoxy group in one of the environments of the methoxy groups in the orthocarbonate. The chemical shift data reported in Table II show that the change in the alkyl group from methyl to ethyl, to isopropyl, to *t*-butyl, and to phenyl had an appreciable effect on the chemical shifts of the pyranose-ring protons only at the anomeric center (H-1). Therefore, it is evident that

*The diastereoisomer formed in the greater amount.

these groups are in *cis*-relationship to H-1 and that the compounds have the alkoxy and phenoxy groups in the *exo*-orientation. It is seen in Table II that a change in the bulk of the alkoxy group of the 1,2-orthoacetates had no appreciable effect on the coupling constants for the pyranose-ring protons. It can therefore be concluded that these substitutional changes have no effect on the conformation of the ring. It is evident in view of the magnitudes of the coupling constants that these compounds have the pyranose ring distorted so that H-3 defines a dihedral angle of about 120° with both H-2 and H-4, and H-4 and H-5 define an angle of about 180°. A precise space-filling model of this conformation shows that H-5 is axially oriented and very close to the *endo*-*C*-methyl group of the *exo*-isomer. Replacement of the *C*-methyl group of the methyl 1,2-(orthoacetate) by a *t*-butyl group results in extensive interaction between the *t*-butyl group and H-5, which can only be relieved by a decrease of the dihedral angle defined by H-4 and H-5 and an increase of that defined by H-3 and H-4. Thus, it may have been predicted that $J_{3,4}$ should be greater and $J_{4,5}$ smaller for the orthopivalate than for the orthoacetate when both have the *exo*-configuration. It is seen that this was in fact the case, namely, $J_{3,4}$ increased from 2.8 to 6.5 c.p.s. and $J_{4,5}$ decreased from 9.0 to 7.0 c.p.s. Therefore, the more rapidly formed isomer in each case must have the *exo*-configuration. That the above changes in the n.m.r. parameters were not due to a change in the conformation of the dioxolane ring is clear from the constancy of $J_{1,2} = 5$ c.p.s. There is no basis to expect that an *exo*-*t*-butyl group could influence the conformation of the pyranose ring.

The 1,2-(methyl orthopivalate) and a 1,2-(isopropyl orthobenzoate) were prepared as syrups by reaction of the tri-*O*-acetyl-2-*O*-pivalyl-α-D-glucopyranosyl bromide and tri-*O*-acetyl-2-*O*-benzoyl-α-D-glucopyranosyl bromide with the appropriate alcohol in *sym*-collidine containing tetra-*n*-butylammonium bromide. Reaction of tri-*O*-acetyl-2-*O*-methoxycarbonyl-α-D-glucopyranosyl chloride with methanol in *sym*-collidine containing tetraethylammonium chloride gave the 1,2-(dimethyl carbonate). However, the syrupy product was considerably less pure than that obtained on reaction of tri-*O*-acetyl-2-*O*-methoxycarbonyl-β-D-glucopyranosyl chloride with methanol and silver di-(*sym*-collidine) perchlorate (12) using methylene chloride as solvent. Both the preparation of this β-chloride and of the orthocarbonate show that, as expected, the methoxycarbonyloxy group can participate effectively in replacements at a neighboring position. Although the methoxycarbonyloxy group is probably less nucleophilic than the acetoxy group, the delocalization of the positive charge in the resulting oxocarbonium ion is greater than in the acetoxonium ion.

EXPERIMENTAL

Tri-O-acetyl-α-D-glucopyranose 1,2-(Ethyl Orthoacetate)

Tetra-*O*-acetyl-α-D-glucopyranosyl bromide, 4.1 g (10 mmoles), was dissolved in 10 ml of *sym*-collidine and 0.6 ml of dry ethanol (10 mmoles). Tetra-*n*-butyl-ammonium bromide, 1 g (3.1 mmoles), was added, and when the mixture was heated to 50° with shaking, a homogeneous solution was obtained. Crystals of *sym*-collidinium hydrobromide soon began to separate. After 12 h at 50°, the almost solid reaction mixture was dissolved in the minimum chloroform and washed with just sufficient hydrochloric acid to neutralize the collidine, then with aqueous sodium bicarbonate, and finally water. After drying the chloroform layer by filtration through chloroform-wetted filter paper, evaporation at reduced pressure left a semicrystalline mass. The n.m.r. spectrum of this product indicated that the two diastereoisomers of the 1,2-orthoacetate had formed in theoretical yield, 3.8 g (10 mmoles). Recrystallization from hot ethanol with a drop of *sym*-collidine and water added just to turbidity resulted in a heavy crystalline precipitate. The crystals were collected by filtration, washed with water, and dried *in vacuo*. The yield of the *exo*-isomer was 85%, m.p. 95–96°; reported 97–97.5° (7), after two recrystallizations from ethanol. When a 10 *M* excess of ethanol over the tetra-*O*-acetyl-α-D-glucopyranosyl bromide was used, the product still contained only 14% of the *endo*-isomer.

Tri-O-acetyl-α-D-glucopyranose 1,2-(Isopropyl Orthoacetate)

The standard conditions above but with isopropanol in place of ethanol were used to obtain a theoretical yield of the *endo*- and *exo*-diastereoisomers. Crystallization from ethanol with a trace of *sym*-collidine, and water added to turbidity, gave an 85% yield of the *exo*-isomer, m.p. 116–117°. On repeated recrystallization, the m.p. was raised to 120–121°, $[\alpha]_D$ +30° (*c*, 2.4 in chloroform).

Anal. Calcd. for $C_{17}H_{26}O_{10}$(390.4): C, 51.8; H, 6.67. Found: 384; C, 51.54; H, 6.82.

Tri-O-acetyl-α-D-glucopyranose 1,2-(t-Butyl Orthoacetate)

Again the above conditions were employed but with *t*-butanol, except that the acid washing was omitted because of the very high sensitivity of the orthoacetate. The *sym*-collidine was finally removed *in vacuo* with warming at 80° to give a crystalline mass in theoretical yield. The pure *exo*-isomer was obtained on dissolving the crude crystals in hot ethyl acetate and adding Skellysolve B to turbidity. A 75% yield of the orthoester, m.p. 152.5–154.5°, $[\alpha]_D$ +34.5° (*c*, 1.6 in chloroform), was obtained.

Anal. Calcd. for $C_{18}H_{28}O_{10}$ (404.4): C, 53.46; H, 6.98. Found: 394; C, 53.1; H, 6.71.

Tri-O-acetyl-α-D-glucopyranose 1,2-(Phenyl Orthoacetate)

The standard conditions above with phenol as the alcohol were used to obtain a syrup which could not be induced to crystallize. The n.m.r. spectrum required the formation of the diastereoisomeric orthoacetates as the only products with 68% of the *exo*- and 32% of the *endo*-isomers as judged from the relative intensities of the signals for the orthoacetyl group at τ 8.22 and τ 8.42, respectively. The compounds are exceedingly sensitive to hydrolysis.

Tri-O-acetyl-α-D-glucopyranose 1,2-(Isopropyl Orthobenzoate)

1,3,4,6-Tetra-O-acetyl-α-D-glucopyranose (12) was benzoylated in pyridine solution using benzoyl chloride under the usual conditions. The syrupy product resisted crystallization and was treated with 30% hydrogen bromide in acetic acid to produce tri-*O*-acetyl-2-*O*-benzoyl-α-D-glucopyranosyl bromide. This product also failed to crystallize. Nevertheless, its n.m.r. spectrum was precisely that expected for this compound in that the presence of three *O*-acetyl groups and one benzoyl group was evident. The signal for the anomeric proton

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was a doublet at τ 3.23, spacing 3.8 c.p.s.; H-3 and H-4 gave triplet signals at τ 4.21 and 4.72, respectively, with spacings of 9.5 c.p.s. The signal for H-2 was a quartet centered at τ 4.90. The signals for the protons at the 5- and 6-positions were in the usual positions with the signal for H-5 to somewhat lower field, about τ 5.6. The syrup, 2.3 g, was dissolved in 4 ml of *sym*-collidine and 0.25 g of tetra-*n*-butylammonium bromide, and 0.47 ml of isopropanol were added. When the mixture was warmed to obtain a homogeneous solution, a fine precipitate appeared, and after 20 h at 42°, the solution had set solid with crystals. The chloroform solution of the reaction mixture was washed with excess 2 *N* sulfuric acid, followed by aqueous sodium bicarbonate. The n.m.r. spectrum of the syrup obtained on evaporation of the chloroform layer had doublets each of spacing 5 c.p.s. at τ 4.13 and 4.24 with relative intensities of about 2:1. This evidence that both the diastereoisomeric orthobenzoates had formed was supported by the complex structures of the signals for the acetyl groups (five signals) and the methyl groups of the isopropyl group. The pattern of signals for the protons on the pyranose ring was very similar to that observed for the tri-*O*-acetyl-α-D-glucopyranose 1,2-(alkyl orthoesters). Crystalline material was not obtained. It was apparent that these orthoesters were substantially more susceptible to hydrolysis than the corresponding orthoacetates.

Tri-O-acetyl-α-D-glucopyranose 1,2-(Methyl Orthopivalate)

1,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranose (12), 3 g (8.62 mmoles), in 9 ml of pyridine was treated with pivalyl chloride, 3.08 g (25.6 mmoles). After 3 h, the product was isolated in the normal way, and crystals were obtained from the syrup on evaporation at high vacuum. Two recrystallizations from methanol–water yielded crystal plates, m.p. 109.5–110°, $[\alpha]_D$ +93.2° (*c*, 1.2 in chloroform). The n.m.r. spectrum was in complete agreement with the assigned structure.

Anal. Calcd. for $C_{19}H_{29}O_{11}$: C, 52.77; H, 6.52. Found: C, 52.63; H, 6.20.

The above crystals, 1.486 g (3.44 mmoles), were dissolved in 5 ml of 30% hydrogen bromide in acetic acid, 1 ml of acetic acid, and 1 ml of acetic anhydride. After 9 h, the product was isolated in the normal fashion. The syrup obtained could not be crystallized, but had the n.m.r. spectrum required for tri-*O*-acetyl-2-*O*-pivalyl-α-D-glucopyranosyl bromide. The yield was quantitative.

The above syrup, 0.55 g (1.21 mmoles), was dissolved in 2 ml of *sym*-collidine and 1 ml of methanol (24.7 mmoles), and 0.2 g of tetra-*n*-butylammonium bromide were added. The reaction time required was significantly longer than that for the formation of the methyl orthoacetate. After 1 d at 60°, the reaction mixture was shaken with carbon tetrachloride and the *sym*-collidinium bromide was removed by filtration. The carbon tetrachloride filtrate was washed with water and then evaporated to a syrup, 0.3 g (61% yield). The n.m.r. spectrum of the compound is described in Tables I and II and is discussed in detail in the introduction to this paper.

Tri-O-acetyl-α-D-glucopyranose 1,2-(Dimethyl Orthocarbonate)

3,4,6-Tri-*O*-acetyl-β-D-glucopyranosyl chloride (13), 20 g (61.5 mmoles), was dissolved in 20 ml of *sym*-collidine and 100 ml of methyl chloroformate. On warming the solution, gases were evolved. Carbon dioxide and methyl chloride are presumably formed by nucleophilic attack of the chloride ion produced in the reaction on the methyl chloroformate. This reaction amounts to a decomposition of the methyl chloroformate which must therefore be added in a large excess. The reaction was carried out until almost all the methyl chloroformate had disappeared, around 4 h. The products were extracted with carbon tetrachloride, and the insoluble salts were removed by filtration. The carbon tetrachloride solution was washed with dilute sulfuric acid and aqueous sodium bicarbonate, and finally evaporated to a syrup. The n.m.r. spectrum of the product was in all respects precisely that expected for tri-*O*-acetyl-2-*O*-methoxycarbonyl-α-D-glucopyranosyl chloride. The yield was 90%.

The above syrup, 21 g (55 mmoles), was dissolved in 100 ml of acetic acid and 10 ml of acetic anhydride. Silver acetate, 15 g (89.8 mmoles), was added and the mixture was refluxed for 2 h. The silver salts were removed by filtration on Celite and the filtrate was evaporated down to a semi-crystalline mass *in vacuo*. The ethanolic solution of the crystals was decolorized with Darco G 60 and water was added to the clear solution. Shiny needle-like crystals, m.p. 129.5–130°, $[\alpha]_D$ +13.4° (*c*, 1.12 in chloroform) were obtained. The n.m.r. spectrum was that expected for tetra-*O*-acetyl-2-*O*-methoxycarbonyl-β-D-glucopyranose.

Anal. Calcd. for $C_{16}H_{22}O_{12}$: C, 47.29; H, 5.46. Found: C, 46.98; H, 5.20.

The above crystals, 0.5 g (1.23 mmoles), reacted with aluminium chloride, 0.164 g (1.23 mmoles), in 6 ml of methylene chloride over half an hour with stirring. Dry benzene, 15 ml, was added to the reaction mixture, which was passed through a bed of 1/2 g of dry silicic acid. The benzene – methylene chloride solution was washed with ice-cold water and evaporated to a crystalline mass, 0.31 g (66% yield). Recrystallization from benzene–Skellysolve B yielded material, m.p. 55–80°, $[\alpha]_D$ +5.45° (*c*, 3 in chloroform). Recrystallization did not alter the properties, but crystallization from benzene alone, followed by grinding the crystals to a fine powder before drying *in vacuo* for 1 d, raised the m.p. to 103.5–104°. The n.m.r. spectrum in deuterated chloroform indicated the presence of about one-third mole of benzene per mole of tri-*O*-acetyl-2-*O*-methoxycarbonyl-β-D-glucopyranosyl chloride.

Anal. Calcd. for $C_{14}H_{19}O_{10}Cl$. 1/3 C_6H_6: C, 47.18; H, 5.20. Found: C, 47.44; H, 5.30.

The above β-chloride, 0.765 g (2 mmoles), silver di-*sym*-collidine perchlorate (12), 0.9 g (2 mmoles), and methanol, 0.5 ml (12.13 mmoles), were allowed to react in 3 ml of methylene chloride with stirring overnight. After the removal of insoluble salts on Celite, the filtrate was washed with aqueous sodium bicarbonate and

water and finally evaporated to a syrup. The n.m.r. spectrum required that virtually pure tri-*O*-acetyl-α-D-glucopyranose 1,2-(dimethyl orthocarbonate) was the product of the reaction. The same compound was formed but in a less pure condition by reacting the syrupy tri-*O*-acetyl-2-*O*-methoxycarbonyl-α-D-glucopyranosyl chloride with methanol in *sym*-collidine containing tetraethylammonium chloride. The spacing of the signal for the anomeric proton at τ 4.32 was 5.2 c.p.s. The signal for H-3 was a quartet centered at τ 4.69 with spacings of about 4 and 6 c.p.s. which must correspond closely to $J_{2,3}$ and $J_{3,4}$, respectively. The quartet signal for H-4 was centered at τ 5.11 and showed a spacing of 9 c.p.s. which must correspond to $J_{4,5}$. Thus the *endo*-methoxy group distorts the pyranose ring from the conformation in the *exo*-1,2-(alkyl orthoacetates) toward that in the *exo*-1,2-(methyl orthopivalate).

ACKNOWLEDGMENTS

The research was supported by grants (N.R.C.-T 172) to R. U. L. and three North Atlantic Treaty Organization Studentships to A. R. M. (1961–1964). The n.m.r. spectra were determined at 60 Mc.p.s. by Mrs. Gail Conway.

THE ABNORMAL CONFORMATIONS OF PYRIDINIUM α-GLYCOPYRANOSIDES

R. U. LEMIEUX AND A. R. MORGAN[1]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received January 25, 1965

ABSTRACT

The nuclear magnetic resonance spectra for *N*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-pyridinium and 4-methylpyridinium bromides and *N*-(tri-*O*-acetyl-2-deoxy-2-iodo-α-*D*-mannopyranosyl)-pyridinium perchlorate (V) require these compounds to exist in the 1C-conformation wherein the pyridinium group is in equatorial orientation. The highly strained condition of V was evidenced by its high reactivity as compared to the β-D-*gluco* diastereoisomer (IV). It is suggested that the instability of the C1-conformation is partly attributable to the reverse of the anomeric effect, and the probable importance of this phenomenon is discussed. The optical rotatory dispersion properties of these and a number of other pyridinium glycosides are presented.

INTRODUCTION

In 1910, Fischer and Raske (1) reported the preparation of *N*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-pyridinium bromide (I). Recently, Lemieux and Morgan (2) reported the preparation of the α-anomer as a syrup. Application of these synthetic methods has now yielded both the anomers for the 4-methylpyridine analogs in pure crystalline condition. The unique conformational properties of these compounds stimulated a study of related compounds, and the results obtained are the subject of this communication.

The 100 Mc.p.s. spectrum (Fig. 1) of the crystalline *O*-acetylated 4-methylpyridinium α-glucoside (III), for reasons of the expected change in the coupling constant for protons on neighboring carbons with change in the dihedral angle defined by the protons (3, 4), appeared to require that the compound has the pyranose ring strongly distorted from the C1-conformation. It is seen that the signals for the five ring protons are all well separated and, consequently, the spectrum is subject to first-order analysis. On this basis, the coupling constants $J_{1,2} = 2.8$, $J_{2,3} = 3.1$, $J_{3,4} = 3.2$, and $J_{4,5} = 5.7$ c.p.s. are indicated. In view of these coupling constants, the compound appears to have a conformation which is close to the 1C-conformation wherein the acetoxy groups at the 2-, 3-, and 4-positions are in axial orientation. In fact, the signals for three of the acetoxy groups are in the region *normally* found for axial acetoxy groups (3). Such a strong distortion of the pyranose ring from the C1-conformation, wherein the substituents at the 2 to 5 positions would be in the equatorial orientation, must arise from powerful non-bonding interactions arising from the 4-methylpyridinium group when in axial orientation at the anomeric center. Since the *A* value for the benzene ring is believed to be in the order of only 2–3 kcal/mole (5), the distortion noted in III could not have been expected on steric grounds. However, the N—C bond length in quaternary ammonium compounds is substantially shorter, 1.48 Å (maximum), than the C—C bond in a compound such as toluene, 1.52 ± 0.01 Å (6). It is to be noted, however, that the establishment of a positively charged atom in axial orientation at the anomeric center must be expected to meet a strongly destabilizing effect (relative to when the group is in equatorial orientation) arising from the electrostatic interaction between the C-1 to N and C-5 to O bonds, when the N and C-5 atoms are in

[1]*Submitted in part by A. R. M. in partial fulfillment of the requirements for the degree of Doctor of Philosophy, University of Alberta, 1964.*

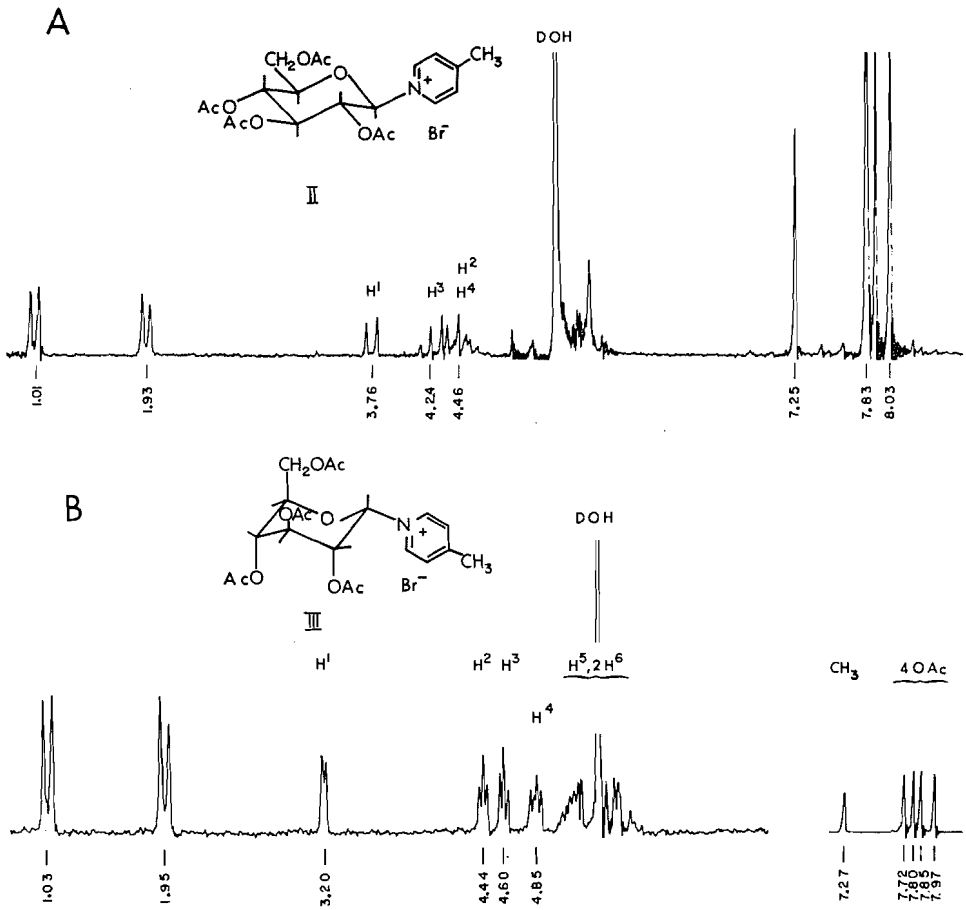

FIG. 1. N.m.r. spectra measured at 100 Mc.p.s. with deuterium oxide as solvent. A, *N*-(Tetra-*O*-acetyl-β-D-glucopyranosyl)-4-methylpyridinium bromide (II). B, *N*-(Tetra-*O*-acetyl-α-D-glucopyranosyl)-4-methylpyridinium bromide (III).

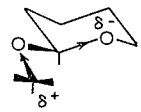
gauche relationship. This interaction amounts to the *reverse* of the anomeric effect (7, 8). Since, for example, the anomeric effect for the tetra-*O*-acetyl-D-glucopyranosyl chlorides amounts to about 3 kcal/mole in favor of the α-anomer wherein the chlorine is in axial orientation (9), it can be anticipated that the *reverse* anomeric effect may well amount to an even stronger destabilizing interaction for the 4-methylpyridinium α-glucoside (III) in the C1-conformation than that arising from the space requirements of the 4-methylpyridinium group. Thus, the fact that the n.m.r. spectrum of III requires the compound to exist in a conformation approaching the 1C-conformation in order to have the aglycone in equatorial orientation may arise from both steric and dipolar interactions, both of which destabilize the α-anomer. The n.m.r. spectrum of the syrupy preparation of the pyridinium α-glucoside (2) was virtually identical with that of III.

The above-mentioned evidence that a quaternized nitrogen at the anomeric position of a lactol ring structure is strongly demanding for an equatorial orientation could be of great importance for a number of reasons. First of all, the phenomenon would have an important bearing on the conformation and conformational rigidity of such important

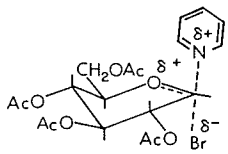
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

biological compounds as the pyridine nucleosides. Secondly, it is evident that the protonation of an axial aglycon at the atom bonded to the anomeric center will cause strong destabilization of the conformation of the sugar ring relative to that wherein the aglycon is in equatorial orientation. Thus, it can be speculated that for α-glucosides, the preferred point of protonation in the course of acid-catalyzed hydrolysis would be at the ring-oxygen atom. On the other hand, for β-glucosides, the reverse anomeric effect would tend to lead to protonation at the oxygen of the aglycon since, in this case, protonation of the ring-oxygen would have to disturb the orientation of the aglycon from the sterically and electronically most favorable position wherein the first carbon of the aglycon is *gauche* to the ring-oxygen as depicted in structure VII (10).

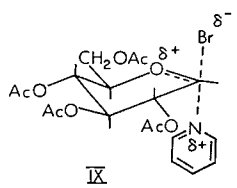


VII

Thirdly, an attack by a molecule at the anomeric center which leads to development of positive charge on the entering group must be expected to be much more favorable when the entering group leads to the equatorial product. For example, it would be expected on the basis of the reverse anomeric effect that the transition state VIII would be considerably more favorable than that represented by IX.



VIII



IX

In view of the above mentioned probable importance of the *reverse anomeric effect*, it was desirable to further examine the phenomenon. First of all, it was necessary to gain better evidence that compound III actually possesses the unusual conformation indicated by its n.m.r. spectrum. Although it seemed very unlikely, there was the possibility that the Karplus relationship for coupling constants broke down completely for this kind of structure. To test this possibility, it was of interest to determine the n.m.r. spectrum of a compound such as *N*-(tetra-*O*-acetyl-α-D-mannopyranosyl)-pyridinium bromide. Should, for the reasons outlined above, this compound exist in the 1C-conformation, then H-1 and H-2 would define a dihedral angle of about 180° and, under these circumstances, the protons should be coupled to an extent of about 9 c.p.s. However, reaction of tetra-*O*-acetyl-α-D-mannopyranosyl bromide with pyridine, with or without the addition of tetra-*n*-butylammonium bromide,* gave only the pyridinium β-mannoside. It was possible, however, to obtain pyridinium glycosides with the *α-manno* configuration by reacting D-glucal triacetate with halonium dipyridine perchlorates (11). One of these compounds, *N*-(tri-*O*-acetyl-2-deoxy-2-iodo-α-D-mannopyranosyl)-pyridinium perchlorate (V) was obtained in a pure crystalline condition. The n.m.r. spectrum of this compound is shown in Fig. 2. It is seen that, indeed, the spectrum corresponds closely with that expected for

**These experiments were conducted by Mr. M. Ponpipom.*

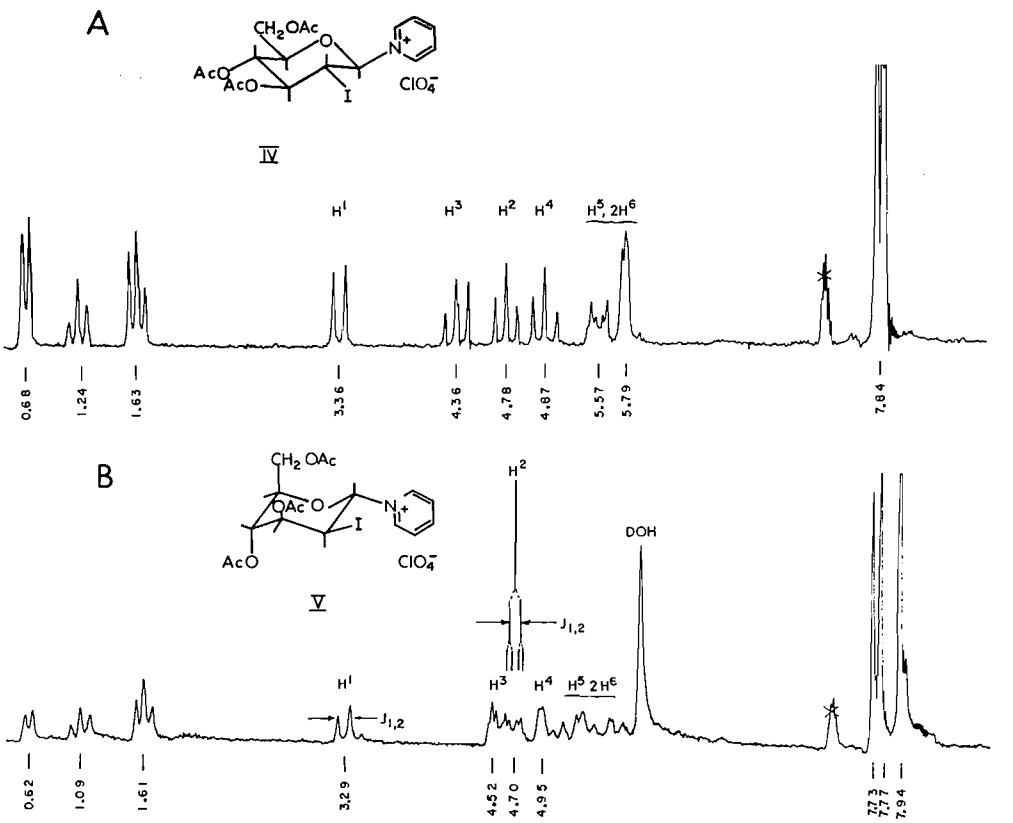

FIG. 2. N.m.r. spectra at 100 Mc.p.s. A, *N*-(Tri-*O*-acetyl-2-deoxy-2-iodo-β-D-glucopyranosyl)-pyridinium perchlorate (IV) dissolved in deuterated dimethylsulfoxide. B, *N*-(Tri-*O*-acetyl-2-deoxy-2-iodo-α-D-manno-pyranosyl)-pyridinium perchlorate (V) dissolved in deuterated dimethylsulfoxide containing a drop of deuterium oxide.

the compound in the 1C-conformation. Since there was a chemical shift of only τ 0.18 for H-2 and H-3, the structure of the doublet signal for the anomeric proton at τ 3.29 was undoubtedly affected by virtual long-range coupling (12). Nevertheless, the spacing of 9.0 c.p.s. clearly indicates that both these protons are in axial orientation. The signal for H-4 appeared at τ 4.95 as a rough singlet with a half-band width of 7 c.p.s. Therefore, the coupling of H-4 with both H-3 and H-5 must be in the range, about 3 c.p.s., expected for hydrogens in *gauche* relationship. Furthermore, the presence of signals for two acetyl groups at τ 7.73 and τ 7.77 lends support to the presence of two axial acetoxy groups as required by the 1C-conformation. The two acetyl groups gave their signals at 10–15 c.p.s. to lower field than did the other acetyl group in a variety of solvents, namely, dimethylsulfoxide, methylene chloride, acetone, pyridine, and methanol. Also, the β-D-*gluco* isomer (IV) of the above compound was prepared and the signal for the anomeric proton was found to be in almost the same position, τ = 3.36, as observed for that of the α-D-manno compound, τ = 3.29, in dimethylsulfoxide as the solvent. Also, as seen in Fig. 2, the n.m.r. spectrum of the β-D-*gluco* isomer (IV) corresponds well with that expected for the compound in the all equatorial C1-conformation. That is, the coupling constants agree well in magnitude to those normally observed in derivatives of β-D-glucopyranose (13). Therefore,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

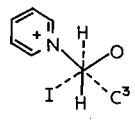
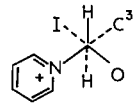
there can be no doubt that the Karplus relationship applies well enough to these compounds to allow the conclusion that definitely compounds III and V exist in conformations closely approaching the 1C-conformation. The coupling constants are not compatible with boat conformations.

In view of their highly strained conformations, compounds III and V would be expected to display somewhat abnormal properties. This was in fact the case. Compound IV was readily deacetylated in methanol using triethylamine as catalyst. On the other hand, the *α-manno* isomer (V) decomposed too readily to allow deacetylation. Although IV showed no reaction with aqueous potassium iodide solution, V rapidly decomposed to iodine and D-glucal triacetate. Furthermore, V readily isomerized to IV when dissolved in pyridine at room temperature.

Reaction of D-glucal triacetate with bromonium dipyridine perchlorate readily gave crystalline *N*-(tri-*O*-acetyl-2-bromo-2-deoxy-*β*-D-glucopyranosyl)-pyridinium perchlorate (VI). The *α-manno* isomer in the residual syrup could not be induced to cyrstallize. However, it was evident from the n.m.r. spectrum that the compound had formed and possessed the 1C-conformation of the 2-iodo analog (V). On standing in pyridine solution, the *α-manno* compound isomerized to VI.



X



XI

The optical rotatory dispersion curves for the *O*-acetylated pyridinium glycosides IV and V support the conformations assigned above on the basis of the n.m.r. spectral data. Following Brewster's rules (14) for predicting rotation on the basis of conformational asymmetry, it would be expected that the screw pattern described by the conformational unit X for compound IV in the C1 conformation would make an important contribution to rotation. Since the pyridinium group absorbs in the 260 mμ region and is present in this unit, the exhaltation of the rotation with decreasing wavelength toward the region of absorption should render the contributions to rotation by other portions of the molecule negligible as compared to contribution by the conformational unit X. On this basis, therefore, compound IV can be expected to display a Cotton effect characteristic of the conformational unit X. From Fig. 3, it is seen that IV in water provided a plain positive curve. The strong absorption prevented a measurement of the full Cotton effect. For the above mentioned reasons, the *α-manno* isomer (V) in the 1C conformation, wherein the conformational unit XI is the mirror image of that in X, would be expected to display a plain negative o.r.d. curve. Indeed, as seen in Fig. 3, this was the case. Of course, this o.r.d. data provides only circumstantial evidence for the 1C conformation of V since it is not possible to predict the rotational properties of V in the C1 conformation. The *N*-(tri-*O*-acetyl-2-bromo-2-deoxy-*β*-D-glucopyranosyl)-pyridinium perchlorate (VI) also gave a plain positive curve. The o.r.d. curves for the *α*- and *β*-anomers of the *N*-D-glucopyranosides derived from pyridine and 4-methylpyridine were very similar to those previously reported (15) for the corresponding glucosides derived from nicotinamide. For the free glucosides, both the anomers gave plain positive curves.

The addition of iodonium dipyridine perchlorate to D-glucal triacetate in chloroform gave an immediate precipitation of *N*-(tri-*O*-acetyl-2-deoxy-2-iodo-*β*-D-glucopyranosyl)-pyridinium perchlorate in 70% yield. Since the isomerization of the *α-manno* isomer did

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

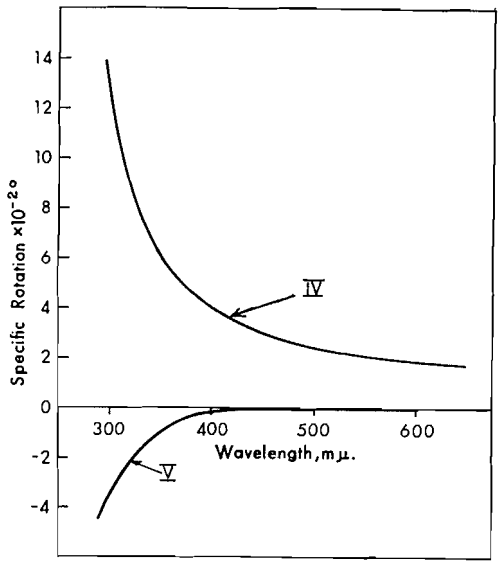


FIG. 3. The optical rotatory dispersion curves for *N*-(tri-*O*-acetyl-2-deoxy-2-iodo-D-glycopyranosyl)-pyridinium perchlorates with the *β-gluco* (IV) and *α-manno* (V) configurations.

not take place in chloroform solution, the reaction gave the product with the *β*-D-*gluco* configuration in preference to that with the *α*-D-*manno* configuration. This route of reaction is opposite to that observed in the reaction of D-glucal triacetate with alcohols in the presence of iodonium di-*sym*-collidine perchlorate (16, 17). These results support the contention (16) that the rate-controlling step in these reactions is not the formation of a 1,2-cyclic iodonium complex. Therefore, the transition state must be related to the nucleophilic attack. The reverse anomeric effect can be expected to influence the relative stabilities of these transition states. Since the reverse anomeric effect must be strong in an axial attack by pyridine and since the change in the yield of the *α-manno* product was only from about 70% for alcohols to about 30% for pyridine, it seems probable that the oxygen of the alcohol is positively charged in the transition states leading to the *O*-glycosides (18).

Although iodonium di-(2,4,6-trimethylpyridine) perchlorate did not form an isolable product when reacted with D-glucal triacetate (11), iodonium di-(2-methylpyridine) perchlorate readily formed the expected *N*-(tri-*O*-acetyl-2-deoxy-2-iodo-*β*-D-glucopyranosyl)-2-methylpyridinium perchlorate. The bromine analog was also prepared.

Reduction of IV with sodium dithionite gave a very unstable 1,4-dihydro derivative.

EXPERIMENTAL

The physical and chemical methods of analysis were described previously (15).

N-(Tetra-O-acetyl-β-D-glucopyranosyl)-pyridinium Bromide (I)

The compound, m.p. 170°, $[\alpha]_D$ −5.9° (*c*, 10 in water) was prepared following the directions of Fischer and Raske (1). The n.m.r. spectrum and o.r.d. curve of solutions in deuterium oxide were very similar to those published for the 3-carboxamido derivative (15). The signal for the anomeric proton was at τ 3.63, spacing 8.0 c.p.s.

Compound I, 3.2 g, was set aside in 320 ml of 3% hydrobromic acid for 15 h at 40° (19). Evaporation left a syrup which was crystallized from ethanol. After two recrystallizations from ethanol and water mixtures, the compound, *N*-(*β*-D-glucopyranosyl)-pyridinium bromide, melted at 176–177°, $[\alpha]_D$ +45.5° (*c*, 1.2 in water). The signal for the anomeric proton in the n.m.r. spectrum using deuterium oxide as solvent was at τ 4.10, spacing 8 c.p.s.

Anal. Calcd. for $C_{11}H_{16}NO_5Br$: C, 41.01; H, 5.01; N, 4.35. Found: C, 40.98; H, 4.87; N, 4.27.

For personal use only.

N-(Tetra-O-acetyl-β-D-glucopyranosyl)-4-methylpyridinium Bromide (II) and the α-Anomer (III)

Tetra-*O*-acetyl-α-D-glucopyranosyl bromide, 3.78 g, was dissolved in 5 ml of 4-methylpyridine, and after 2 d the solution became filled with crystals. Ethyl acetate was added and the crystals were removed by filtration. Recrystallization from 95% ethanol – ethyl acetate gave crystals, m.p. 202–203°. The n.m.r. spectrum showed that 0.5 of a molecule of each of ethanol, ethyl acetate and water per molecule of II was present in the crystals. After drying at high vacuum the crystals melted at 207–208.5°, $[\alpha]_D$ −10.2° (*c*, 1 in water). The n.m.r. spectrum of II is shown in Fig. 1. The o.r.d. curve was similar to that found for compound I and showed a plain negative curve. The specific rotations at 300, 350, 400, 450, and 500 mμ were −128, −61, −35, −22, and −17°, respectively.

Anal. Calcd. for $C_{20}H_{26}NO_9Br.0.5H_2O$: C, 46.80; H, 5.30; N, 2.73. Found: C, 46.95; H, 5.30; N, 2.62.

On standing, the filtrate from the isolation of II deposited crystals which were recrystallized from 95% ethanol – ethyl acetate. The material, m.p. 175°, $[\alpha]_D$ +43° (*c*, 1 in water), provided the n.m.r. spectrum reproduced in Fig. 1, and assigned to *N*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-4-methylpyridinium bromide (III). The assignments of signals shown in Fig. 1 are based on spin-decoupling experiments and are unequivocal. The o.r.d. gave a plain positive curve with specific rotations of 138, 121, 90, 66, and 51° at 300, 350, 400, 450, and 500 mμ, respectively.

Anal. Calcd. for $C_{20}H_{26}NO_9Br.H_2O$: C, 45.98; H, 5.40. Found: C, 46.20; H, 5.14.

N-(β-D-Glucopyranosyl)-4-methylpyridinium Bromide

Compound II, 0.65 g, was kept at 40° for 12 h in 65 ml of 3% hydrobromic acid. Evaporation left a syrup which crystallized from ethanol – ethyl acetate, m.p. 162–162.5°, $[\alpha]_D$ +38.3° (*c*, 1.2 in methanol). The n.m.r spectrum was in complete agreement with the assigned structure. A plain positive o.r.d. curve was obtained with specific rotations of 127, 92, 70, and 55° at 350, 400, 450, and 500 mμ, respectively, in methanol.

N-(α-D-Glucopyranosyl)-4-methylpyridinium Bromide

Deacetylation of III under the conditions described above for the β-anomer gave a syrup which could not be induced to crystallize. The n.m.r. spectrum required the assigned structure. The o.r.d. was a plain positive curve with specific rotations of 267, 175, 125, 94, 73, and 59° at 300, 350, 400, 450, 500, and 550 mμ, respectively.

Iodonium Di-(2-methylpyridine) Perchlorate

2-Methylpyridine, 10 ml, and sodium perchlorate, 12.2 g, in 125 ml of water were added with stirring to 5.7 g of silver nitrate dissolved in 25 ml of water. The precipitate, 13.1 g, was washed with water and dried under high vacuum over phosphorus pentoxide. The silver di-(4-methylpyridine) perchlorate thus produced, 39 g, was dissolved in the minimum amount of dry dimethylformamide, and 25.4 g of iodine and 5 ml of 2-methylpyridine were added. After being briefly stirred, the precipitated silver iodide was removed by filtration. Crystals of the iodonium salt soon began to form in the filtrate. Ether was added to provide a 21.2 g yield. The content of positive iodine as determined by iodometric titration was quantitative on the basis of the formula $(C_6H_7N)_2IClO_4$.

Iodonium Dipyridine Perchlorate

Silver dipyridine perchlorate was prepared as described above and 46.5 g was dissolved in the minimum amount of pyridine. Finely powdered iodine, 27.8 g, was added with stirring and silver iodide precipitated at once. The precipitate was removed by filtration and, on the addition of chloroform, a white crystalline product was deposited in the filtrate. The positive iodine content was 97.5% of the theoretical for $(C_5H_5N)_2IClO_4$.

Bromonium Complexes

Procedures very similar to those described above for the preparation of the iodonium complexes were used to prepare bromonium dipyridine perchlorate, $(C_5H_5N)_2BrClO_4$, and bromonium di-(2-methylpyridine) perchlorate, $(C_6H_7N)_2BrClO_4$. In each case the content of positive bromine was that expected from the formula given.

N-(Tri-O-acetyl-2-deoxy-2-iodo-β-D-glucopyranosyl)-pyridinium Perchlorate (IV) and the Corresponding α-D-manno-Stereoisomer (V)

D-Glucal triacetate, 22.2 g (81.7 mmoles), and the iodonium dipyridine perchlorate, 31.4 g (81.7 mmoles), reacted rapidly in 200 ml of chloroform. As the latter dissolved a fine precipitate of the pyridinium glucoside (IV) appeared. The reaction mixture was shaken for 1 h and the product was isolated by filtration. Fine, needle-like crystals of the pyridinium mannoside (V) were obtained from the filtrate on standing at 0°.

Compound IV, 33 g (70% yield), was recrystallized from methanol to constant physical properties, m.p. 163–164°, $[\alpha]_D$ +109.8° (*c*, 1.1 in methanol), $[\alpha]_D$ +133° (*c*, 0.4 in acetone). The n.m.r. spectrum is shown in Fig. 2 and the o.r.d. curve in Fig. 3.

Anal. Calcd. for $C_{17}H_{21}NO_{11}ClI$: C, 35.34; H, 3.66; N, 2.43; I, 22.0. Found: C, 35.55; H, 3.56; N, 2.59; I, 21.1.

The pyridinium glucoside (IV), 4.0 g, was dissolved in 100 ml of methanol and 1 ml of triethylamine. After 1 d, the solvents were evaporated and the crystalline residue was recrystallized from water. A 72% yield,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

2.25 g, was obtained. Further recrystallization from methanol with a little water gave an analytical sample, m.p. 155–157° (decomposition of the liquid phase to a black tar), $[\alpha]_D$ +132.5° (*c*, 1 in water). The n.m.r. spectrum agreed throughout with the assigned structure. The compound dissolved in water gave a plain positive o.r.d. curve with specific rotations of 1 610, 595, 301, 239, 214, and 194° at 300, 350, 400, 450, 500, and 550 mμ, respectively.

Anal. Calcd. for $C_{11}H_{15}NO_8ClI$: C, 29.25; H, 3.35; N, 3.10. Found: C, 29.01; H, 3.23; N, 3.02.

A 5.08 g sample of IV was dissolved on warming in 100 ml of water and 40 ml of methanol. Addition of anhydrous sodium bicarbonate, 5.02 g, and sodium dithionite, 5.5 g, in 40 ml of water immediately produced a yellow coloration. The solution then became turbid and a gummy precipitate was deposited. After 1 h, the gum was washed with water. It dissolved on gently warming in ethanol and, on cooling, crystals were obtained, m.p. 68.5–69.5°. The n.m.r. spectrum in chloroform initially gave a spectrum similar to that for the compound obtained on the dithionite reduction of *N*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-pyridinium bromide (I). However, the solution soon liberated iodine and the signal at about τ 7.0 disappeared in 10 min.

Recrystallization of the crude mannoside (V), m.p. 97–102°, 14 g (30% yield), from chloroform was accomplished with difficulty as there was a tendency to obtain an oil, but seeding gave crystals, m.p. 103–104°, $[\alpha]_D$ −22.6° (*c*, 1 in methanol), $[\alpha]_D$ −15.5° (*c*, 2 in acetone). The n.m.r. spectrum is given in Fig. 2 and the o.r.d. curve in Fig. 3. The iodine content, 19%, agreed well with the theoretical amount for V, 22%. The assignments of the signals shown in Fig. 2 are based on spin-decoupling experiments and are unequivocal.

When pure pyridinium mannoside (V) was dissolved in pyridine, crystals were obtained after 1 week in about 80% yield. The melting point, mixed melting point and the n.m.r. spectrum of the product were identical with those of IV. Treatment of V with aqueous potassium iodide gave a rapid liberation of iodine. The iodine was destroyed by the addition of sodium thiosulfate. Extraction with chloroform gave D-glucal triacetate, m.p. 53–54° in 94% yield. The pyridinium glucoside (IV) did not liberate iodine under similar conditions even after 1 d. Iodine was liberated when the solution was heated to the boiling point. Compound V decomposed to dark-brown products when an attempt was made to deacetylate the compound under the conditions which proved useful to deacetylate the diastereoisomer IV.

N-(Tri-O-acetyl-2-bromo-2-deoxy-β-D-glucopyranosyl)-pyridinium Perchlorate (VI)

Bromonium dipyridine perchlorate, 19.5 g, reacted rapidly with D-glucal triacetate, 15.7 g (58 mmoles), dissolved in pure chloroform to yield a fine crystalline precipitate. Recrystallization from ethanol, with a little methanol to facilitate solution, gave a product of m.p. 117–119°, $[\alpha]_D$ +78.8° (*c*, 1.2 in methanol). Cooling of the mother liquors resulted in a further crop of crystals which, when crystallized from methanol, melted at 152.5–155°. After drying *in vacuo* both lots of crystals had the same n.m.r. spectrum. Those with melting point 117–119°, on dissolving in methanol and seeding with the crystals melting at 152.5–155°, yielded crystals with the latter melting point. The n.m.r. spectrum was in agreement with the assigned structure and the specific rotation in water was 690, 377, 253, 140, 68, and 45° at 300, 350, 400, 450, 500, and 550 mμ, respectively.

Anal. Calcd. for $C_{17}H_{21}NO_{11}ClBr$: C, 38.47; H, 3.17; N, 2.64. Found: C, 38.24; H, 3.99; N, 2.81.

On adding ether to the filtrate, a syrup separated which could not be induced to crystallize. The n.m.r. spectrum of the syrup in methylene chloride was very similar to that shown in Fig. 2 for *N*-(tri-*O*-acetyl-2-deoxy-2-iodo-α-D-mannopyranosyl)-pyridinium perchlorate (IV). When the syrup was dissolved in pyridine, crystals of VI were deposited after the solution had been kept at room temperature for several days.

N-(3,4,6-Tri-*O*-acetyl-2-bromo-2-deoxy-β-D-glucopyranosyl)-pyridinium bromide, m.p. 130–133°, $[\alpha]_D$ +79.2° (*c*, 1.2 in methanol), was prepared by dissolving the syrupy mixture of tri-*O*-acetyl-2-bromo-2-deoxy-D-glucopyranosyl bromides (20) in pyridine.

The n.m.r. spectrum was very similar to that of the perchlorate VI.

Anal. Calcd. for $C_{17}H_{21}NO_7Br_2.H_2O$: C, 38.58; H, 4.38; N, 2.63. Found: C, 38.50; H, 4.30; N, 2.52.

N-(Tri-O-acetyl-2-bromo-2-deoxy-β-D-glucopyranosyl)-2-methylpyridinium Perchlorate

The compound, m.p. 223–224° (decomp.), $[\alpha]_D$ +100° (*c*, 0.5 in methanol), was prepared in a manner similar to that described above for the preparation of VI. The n.m.r. spectrum agreed with the assigned structure.

Anal. Calcd. for $C_{18}H_{23}NO_{11}ClBr$: C, 39.69; H, 4.26; N, 2.57. Found: C, 39.69; H, 4.36; N, 2.68.

N-(Tri-O-acetyl-2-iodo-2-deoxy-β-D-glucopyranosyl)-2-methylpyridinium Perchlorate

Reaction of D-glucal triacetate with iodonium di-(2-methylpyridine) perchlorate in chloroform solution gave a syrup which was extracted with hot water. On cooling, the extract deposited crystals, m.p. 186–187°. The n.m.r. spectrum was very similar, except for the signals from the 2-methylpyridine residue, to that for compound IV and left no doubt as to its identity.

ACKNOWLEDGMENTS

The research was supported by grants (N.R.C.-T 172) to R. U. L. and three North Atlantic Treaty Organization Studentships to A. R. M. (1961–1964). The n.m.r. spectra at 60 Mc.p.s. were determined by Mrs. Gail Conway and those at 100 Mc.p.s. by G. Bigam of this department.

Received January 25, 1965

ABSTRACT

Reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) with pyridine at high dilution gives a high yield of *N*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-pyridinium bromide (II). The addition of tetra-*n*-butylammonium bromide diverts the reaction to the formation of the highly strained α-anomer (III) of II. It is contended that III arises from the β-anomer (IV) of I by way of a rearrangement of an intermediate formed between pyridine and the 1,2-acetoxonium ion (VIII) which readily arises by dissociation of IV. The formation of 2-pyridyl tetra-*O*-acetyl-α-D-glucopyranoside in >60% yield in the reactions of I with either 2-ethoxypyridine or 2-pyridone in the presence of tetra-*n*-butylammonium bromide is taken as supporting evidence for this novel type of rearrangement.

INTRODUCTION

Fischer and Raske (1) prepared *N*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-pyridinium bromide (II), through the reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) with pyridine in the presence of phenol. On repeating the preparation, II was obtained in 47% yield and its anomeric configuration was confirmed by the n.m.r. spectrum (2). Since the role of the phenol in the reaction mixture was not evident, it was decided to examine the course of the reaction in its absence. When a 34.4% solution of I in pyridine was allowed to react to constant rotation, a syrupy, water-soluble product was obtained. The n.m.r. spectrum in deuterium oxide showed doublet signals at τ 3.60 (spacing 8 c.p.s.) and τ 3.12 (spacing 3 c.p.s.). These signals were found to arise from the anomeric protons of II and its α-anomer (III), respectively (2, 3). The relative intensities of the signals indicated that the two compounds were present in the ratio 11:9 in favour of the α-anomer.

The change in optical rotation during the reaction of I with pyridine was followed polarimetrically. When the initial concentration was low, 1.95% (w/v), the rate of change corresponded closely to a first-order process and virtually only the β-anomer (II) was formed. The yield was greater than 90% as judged from the n.m.r. spectrum of the product in pyridine. When the initial concentration of I was 34.4%, an induction period in the polarimetric change was noted and, therefore, it was apparent that the product of the initial reaction became involved in a faster process. The induction period was also present when the initial concentration of I was about 16%, and the anomers were formed in about equal amounts. The same course of reaction was obtained when half of the pyridine was replaced by acetonitrile, although the more polar solvent gave rise to a somewhat increased rate of reaction. When the reaction of I (16% initial concentration) was carried out in pyridine containing 1 mole of tetra-*n*-butylammonium bromide per mole of I, the rate of the reaction was greater and the induction period was not present. Virtually only the α-pyridinium glucoside (III) was formed as judged from the n.m.r. spectrum of the product. When tetra-*n*-butylammonium perchlorate was used instead of the bromide, the induction period reappeared and the product comprised a 3:2 mixture of the α- and β-forms, respectively. These results are summarized in Table I.

TABLE I

Effect of concentration and the addition of bromide ion on the rate and stereochemical route of the reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) with pyridine

Experiment	Concentration of I, % w/v	Final specific rotation, deg	Time for completion of reaction, h	Yields of *N*-glucosides, %	
				α-Anomer	β-Anomer
1	1.95	7.2	30	—	>90
2	34.4	13.4	9	55	45
3	16.3	10.3	12	50	50
4	15.8*	18.4	5	>90	—
5	15.9†	9.65	—	60	40

*The solution contained 13.5% tetra-*n*-butylammonium bromide.
†The solution contained 13.2% tetra-*n*-butylammonium perchlorate.

The most reasonable interpretation of these results was that initially I underwent nucleophilic attack by pyridine with inversion of the anomeric center to produce the β-pyridinium bromide (II). The bromide ion, thus liberated, then participated in a faster process involving a nucleophilic attack on I to form its anomer, tetra-*O*-acetyl-β-D-glucopyranosyl bromide (IV), and the latter compound was the precursor of the α-pyridinium glucoside (III). To test this hypothesis, tetra-*O*-acetyl-β-D-glucopyranosyl chloride was reacted with pyridine at room temperature. Five days were required for the rotation of the solution to reach a constant value. To the syrupy product obtained, water was added, and the mixture was extracted with chloroform. The chloroform extract gave a syrup (40% yield), the n.m.r. spectrum of which showed it to be virtually pure tetra-*O*-acetyl-α-D-glucopyranosyl chloride. Evaporation of the aqueous phase gave a syrup which was assigned the structure of *N*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-pyridinium chloride in view of the very close similarity of its n.m.r. spectrum to that of compound III. No evidence was present in the spectrum for the formation of the β-anomer. When the reaction of the β-chloride with pyridine was repeated under the same conditions, except that tetraethylammonium chloride was added, a time of about 2 d was required for the rotation to reach a constant value and the only product found in appreciable amount was that of anomerization, the α-chloride. That the bromide ion can catalyze the anomerization of the tetra-*O*-acetyl-D-glucopyranosyl bromides was supported by a recent study of the anomerization of the anomeric chloride (4). It was found that, in acetonitrile, the rate of anomerization was first-order in tetraethylammonium chloride. The more rapid exchange of the chlorine of the β-anomer with ^{36}Cl-labelled chloride ion was interpreted as resulting from

dissociation of the β-chloride to 1,2-acetoxonium ion (4). The β-bromide (IV) has recently been isolated (5), and its reaction properties correspond closely to those previously established for tetra-*O*-acetyl-β-D-glucopyranosyl chloride (6).

Since the reaction of this β-chloride in pyridine containing an alcohol leads to the formation of tri-*O*-acetyl-α-D-glucopyranose 1,2-(alkyl orthoacetate) (6, 7), the observations related to the formation of the α-pyridinium glucoside (III) led to the prediction that the addition of I to pyridine containing methanol would result in the formation of the 1,2-(methyl orthoacetate) (V). In fact, the reaction of I in pyridine containing 3 moles of methanol per mole of I, under conditions which in the absence of methanol provided the α- and β-pyridinium glucosides in the ratio 3:2, respectively, gave a mixture of the methyl orthoacetate (V) and the β-pyridinium glucoside (II). That is, the presence of the methanol blocked the route to the formation of the α-pyridinium glucoside (III), precisely the result expected should the latter compound arise from the β-bromide (IV). The n.m.r. spectrum of the crude 1,2-orthoacetate (V) showed the presence of the two possible diastereoisomers arising from a change in the configuration of the new asymmetric center in the dioxalane ring (8). It thus became apparent why Fischer and Raske (1) found it useful to add phenol to the reaction mixture to form the β-pyridinium glucoside (II). That is, the phenol prevented the formation of the α-anomer. In fact, the n.m.r. spectrum of the reaction product showed the presence of only II and the phenyl orthoesters (9).

The formation of the β-pyridinium glucoside (II) undoubtedly involves nucleophilic attack by pyridine at the anomeric center of I. Bimolecular reactions of this type at the anomeric center of glycosyl halides are known to occur (10, 11). The mechanism for the formation of the α-pyridinium glucoside (III) is more difficult to anticipate. An obvious possibility is attack by pyridine at the anomeric center of the β-bromide (IV). However, this course of reaction seems unattractive for a number of reasons. First of all, it is to be noted that compound III is highly strained (2) and must be thermodynamically considerably less stable than the β-anomer (II). Consequently, the mechanism must account for the ability of bromide ion to divert the reaction to the formation of a less stable product. That is, the formation of III is kinetically controlled. It is well established that I is more stable than the β-anomer (IV) and is the anomer with the bromine in axial orientation (n.m.r. spectrum). Judging from the yields of I obtained from reactions mixtures where it must have been at equilibrium with IV (12), the equilibrium constant for the anomerization must be at least 9. The equilibrium constant for the $\beta \rightleftarrows \alpha$ anomerization of the acetochloroglucoses is about 16 (4). Assuming that, in the presence of tetra-*n*-butylammonium bromide, compounds I and IV were at equilibrium throughout the course of reaction, then the concentration of I was at least nine times that of IV. Control experiments showed that the presence of the β-*N*-glucoside (II) in mixtures of II with its α-anomer (III) could easily be detected when II formed 10% of the mixture. Therefore, the yield of III in the experiment using tetra-*n*-butylammonium bromide as catalyst must have been greater than 90%. It is seen therefore that the reaction of IV with pyridine would have to be at least 80 times faster than the reaction of the α-anomer (I) with pyridine.

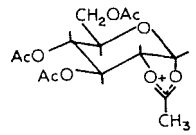
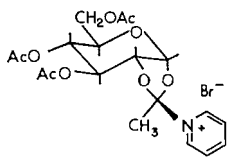
Assuming that the reactions proceed by nucleophilic attack at the anomeric centers of I and IV, the transition states depicted in VI and VII, respectively, would be anticipated and the transition state VII would have to be at least 1 kcal/mole more stable than VI. In fact, VII must be expected to be less stable than VI especially if those factors related to the anomeric effect are important in the transition states (2). Evidence in support of this contention was obtained by reaction of tri-*O*-acetyl-2-chloro-2-deoxy-α-D-glucopyranosyl bromide (13) with pyridine in the presence of tetra-*n*-butylammonium bromide. The main product of the reaction had the n.m.r. spectrum expected for 2-chloro-D-glucal triacetate. This product of dehydrobromination (11) was formed in about 78% yield. *N*-(Tri-*O*-acetyl-2-chloro-2-deoxy-β-D-glucopyranosyl)-pyridinium bromide crystallized directly from the reaction mixture in 17% yield. Therefore, if the reaction mixture contained the equilibrium amounts of the α- and β-glucosyl bromides, the reaction of the α-bromide with pyridine was substantially faster than that of the β-anomer. Although it was not possible to obtain direct evidence for the rates of anomerization of the 2-chloroglucosyl bromides under these reaction conditions, the α-bromide reacts rapidly with tetraethylammonium chloride in acetonitrile to yield tri-*O*-acetyl-2-chloro-2-deoxy-β-D-glucopyranosyl chloride and this reaction is substantially faster than the analogous reaction of I under comparable conditions (13). Thus, there is no reason to doubt that the bromide ion led to equilibration of the 2-chloroglucosyl bromides as was observed in the reactions of I with pyridine in the presence of bromide ion. On this basis, the results obtained in the reaction of tri-*O*-acetyl-2-chloro-2-deoxy-α-D-glucopyranosyl bromide with pyridine in the presence of a high concentration (0.51 *M*) of tetra-*n*-butylammonium bromide support the contention that nucleophilic attack by pyridine at the anomeric center of the β-bromide (IV) leads to a less favorable transition state (VII) than that (VI) involving attack of the α-anomer (I).

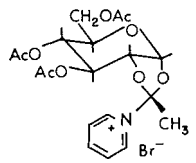


VIII

It seems more likely that the ready formation of III from IV relative to the formation of II from I is related to the ability of IV to readily dissociate to the 1,2-acetoxonium ion (VIII). This is consistent with the observation that the cation VIII is formed more rapidly than the α-glucoside (III) and can be a precursor of III. The experimental results require the reaction of the acetoxonium ion (VIII) with pyridine to form the β-glucoside (II) to be much slower than the process which leads to the formation of the α-anomer (III).



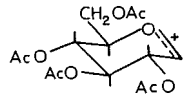
IX



X

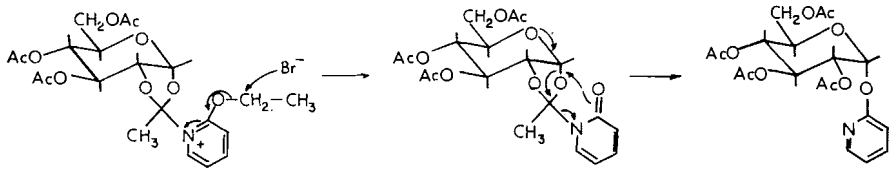
In pyridine, the 1,2-cyclic carbonium ion must lead rapidly to the complexes IX and X. In view of the ease of the acid-catalyzed hydrolysis or alcoholysis of orthoesters, these complexes must be expected to be highly labile and of only transient existence. For

example, tri-*O*-acetyl-α-D-glucopyranose 1,2-(phenyl orthoacetate) was found to be solvolyzed in *sym*-collidine saturated with water (9). Therefore, IX and X can be expected to readily revert to the acetoxonium ion.



XI

Formation of III from the acetoxonium ion (VIII) would have to involve rearrangement of the acetoxonium ion *toward* the glucosyloxocarbonium ion (XI) in the first stage of the reaction. It is reasonable to expect that this would be a facile process since it is first-order process and merely involves a reallocation of the positive charge. In contrast, the formation of the transition state VII requires charge separation in a second-order process conducted in a weakly polar solvent. It could be speculated that the ion XI is closer to the 1C- than the C1-conformation and provides α-pyridinium glucoside (III) for this reason. However it is well established that the 1,2-acetoxonium ion is formed in the anomerization of both penta-*O*-acetyl-β-D-glucopyranose (14) and tetra-*O*-acetyl-β-D-glucopyranosyl chloride (4) and that the ion does not offer a facile route to the formation of the α-anomers. For this reason, it seems best to assume that the α-glucoside (III) is formed by a rearrangement of a pyridine – acetoxonium ion complex. That is, an intimate ion–molecule pair could be involved as an intermediate in a 1,3-shift of the pyridine via the *endo*-complex X. Thus, an energetically economical route for the formation of the highly-strained α-glucoside (III) would be provided.



XII XIII XIV

In view of the unexpected conformational properties of III, it was desired to examine the conformation of *N*-(tetra-*O*-acetyl-α-D-glucopyranosyl) 2-pyridone. Therefore, I was reacted with 2-ethoxypyridine in an excess of tetra-*n*-butylammonium bromide; n.m.r. examination of the product showed the presence of a complex mixture containing about 60% of an acetylated *O*-glucoside. The compound was readily isolated by chromatography on silicic acid and found to be 2-pyridyl tetra-*O*-acetyl-α-D-glucopyranoside, m.p. 84–84.5°, $[\alpha]_D$ +147° (*c*, 0.5 in chloroform). The anomeric proton gave a doublet signal at τ 3.22 with a spacing of 3.5 c.p.s. The four aromatic protons gave signals with chemical shifts and structures very similar to those in the spectrum of 2-ethoxypyridine. The signal for H-3 was a triplet (spacing 9.5 c.p.s.) at τ 4.24, about 0.5 p.p.m. to lower field than the signals for H-2 and H-4. It was therefore evident that the compound was the α-anomer in the C1-conformation. The tetra-*O*-acetyl-α- and -β-*N*-glucosides of 2-pyridone were also formed but did not separate on the silicic acid column. The n.m.r. spectrum of the mixture isolated from the chromatogram indicated that β-anomer was formed to about three times the extent of the α-form. Spin-decoupling experiments at 100 Mc.p.s. showed the anomeric protons of the α- and β-forms to give doublet signals at τ 3.44 and τ 3.60, respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The spacings were 2.5 and 9.0 c.p.s., respectively. It was not possible to draw conclusions as to the structures of the signals for other ring-protons of the α-anomer. The spectra were devoid of signals for the ethyl group which, as expected (15), was lost in the course of the reaction. In these reactions, the ethyl group must be lost after the nitrogen has been quaternized. The quaternization which was involved in producing the α-*O*-glucoside must have taken place at a position other than the anomeric center. It seems probable *in view of the high yield of the O-glucoside*, that the 2-ethoxypyridine attacked the 1,2-acetoxonium ion to yield the intermediate (XII). This would activate the nucleophilic attack by bromide ion to remove the ethyl group and yield the *N*-orthoacetyl pyridone derivative (XIII). Such a compound can be expected to be highly labile and its rearrangement to the *O*-glucoside (XIV) following a route similar to that described above for the formation of the α-pyridinium glucoside (III) appears plausible. Reaction of I with 2-pyridone in *sym*-collidine containing tetra-*n*-butylammonium bromide gave a 70% yield of the *O*-α-glucoside (XIV) but none of the *N*-glycosides. The formation of an α-glucoside under these conditions is abnormal and presumably arose by way of the intermediate XIII. The small amount of the *N*-α-glucoside which was formed in the reaction of I with 2-ethoxypyridine in the presence of bromide ion was likely the result of nucleophilic attack by the 2-ethoxypyridine at the anomeric center of the β-bromide (IV).

EXPERIMENTAL

The experimental methods were similar to those previously described (9, 11, 16).

Reactions of Pyridine with Tetra-O-acetyl-α-D-glucopyranosyl Bromide (I)

Solutions of I in pyridine, with or without the addition of salt, were made up in the concentrations reported in Table I. The solutions were kept at room temperature and their optical rotations were determined from time to time. The initial specific rotations, 194.5°, were those expected for I. The reaction times reported in Table I correspond to the time required for the rotational change to become near asymptotic. The rotational changes observed in experiments 2, 3 and 5 showed points of inflection indicating increases in the rates of optical change in the first periods of the reactions.

After the solutions had achieved constant rotations, the pyridine was rapidly removed *in vacuo* and a sample of the residue was dissolved in deuterium oxide for analysis by n.m.r. spectroscopy. The relative amounts of the α- and β-anomers of *N*-(tetra-*O*-acetyl-D-glucopyranosyl)-pyridinium bromide were estimated from the relative intensities of the signals for the anomeric protons at τ 2.8–3.1 and 3.4–3.6, respectively, depending on the salt concentration. When the α-anomer (III) was dissolved in pyridine, the n.m.r. spectrum showed a signal for one of the acetoxy to lower field, τ 7.47, than the signals for the other acetyl groups centered at τ 7.86. Under the same conditions, the acetyl groups of the β-anomer all gave their signals above τ 7.9. The relative amounts of the anomers in mixtures could therefore be estimated by integrating over the acetyl group signals. This method of analysis confirmed in each case the results obtained by comparing the intensities of the signals from the anomeric protons.

Reactions of Tetra-O-acetyl-β-D-glucopyranosyl Chloride

(*a*) The compound, 0.25 g, was dissolved in 5 ml of dry pyridine. After 2.5 min, the observed rotation was −1.09° and the rotation steadily rose to a constant value of 4.50° after 125 h. Most of the pyridine was evaporated *in vacuo* and the product was distributed between 20 ml of water and 20 ml of chloroform. The solutions were taken to dryness. The chloroform layer gave 0.10 g of tetra-*O*-acetyl-α-D-glucopyranosyl chloride (40% yield) identified by its n.m.r. spectrum. The residue from the aqueous layer was dissolved in deuterium oxide for examination by n.m.r. spectroscopy. The spectrum was that expected for *N*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-pyridinium chloride. It was therefore concluded that the yield of this compound was about 60%. No indication of the β-anomer was present in the n.m.r. spectrum.

(*b*) The compound, 0.25 g, was taken up in 5 ml of dry pyridine saturated with tetraethylammonium chloride. After 15 min the observed rotation was −0.5° and the rotation rose to +6.52° in 45 h. The pyridine was evaporated *in vacuo* and the product was worked up as described above. The chloroform layer contained 0.19 g of virtually pure tetra-*O*-acetyl-α-D-glucopyranosyl chloride (n.m.r. spectrum). The aqueous layer gave a crystalline solid which had the n.m.r. spectrum of tetraethylammonium chloride. The spectrum indicated that a mere trace of *N*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-pyridinium chloride had formed.

Tri-O-acetyl-α-D-glucopyranose 1,2-(Methyl Orthoacetate)

Tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I), 3.03 g, was dissolved in 10 ml of pyridine containing 0.89 ml of methanol and the solution was kept at room temperature. The observed rotation after 5 min was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

47° and fell to a constant value of 2.81° after 19 h. An induction period was noted in the rotational change. The solvent was removed *in vacuo* and the residue was partitioned between water and chloroform. The chloroform layer gave a sirupy product, the n.m.r. spectrum of which showed it to be tri-*O*-acetyl-α-D-glucopyranose 1,2-(methyl orthoacetate) (9). Evaporation of the aqueous layer left a residue which was dissolved in deuterium oxide for n.m.r. spectroscopy. Except for pyridinium hydrobromide, the substance was virtually pure *N*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-pyridinium bromide (2).

Reaction of Tri-O-acetyl-2-chloro-2-deoxy-α-D-glucopyranosyl Bromide

The compound, m.p. 97–98°, $[\alpha]_D$ +250° (*c*, 3 in chloroform) (13), 0.94 g, and 0.83 g of tetra-*n*-butylammonium bromide were taken up in pyridine to give 5 ml of solution. The solution was kept at room temperature. After 40 min, the observed rotation had fallen to 11.3° at which time the solution became turbid due to deposition of a crystalline solid. After 16 h, the crystals were collected and washed with pyridine. The n.m.r. spectrum of this product required it to be *N*-(tri-*O*-acetyl-2-chloro-2-deoxy-β-D-glucopyranosyl)-pyridinium bromide contaminated by tetra-*n*-butylammonium bromide. It was estimated that the β-*N*-glucoside was formed in 17% yield based on the starting material. Recrystallization of the compound from ethanol – ethyl acetate gave material, m.p. 129.5–131.5°, $[\alpha]_D$ +67° (*c*, 0.5 in water). The n.m.r. spectrum in deuterium oxide showed the signal for the anomeric proton at τ 3.55 with a spacing of 9.2 c.p.s. The signals for H-3 and H-4 were broadly (about 9 c.p.s.) spaced triplets centered at τ 4.24 and 4.60, probably respectively. The presence of ethanol in the crystals was indicated.

The filtrate was evaporated to dryness *in vacuo* and the residue was partitioned between water and chloroform. The aqueous layer was evaporated to dryness and taken up in deuterium oxide for analysis by n.m.r. The material was mainly a mixture of tetra-*n*-butylammonium bromide and pyridinium hydrobromide. The spectrum was devoid of signals for the above mentioned β-*N*-glucoside. However, weak signals at τ 2.75 and 4.5 can be taken as evidence that some of the *N*-(tri-*O*-acetyl-2-chloro-2-deoxy-α-D-glucopyranosyl)-pyridinium bromide had formed.

The chloroform layer was taken to dryness to leave 1.19 g of syrup. The n.m.r. spectrum in chloroform showed this product to be an equimolar mixture of tetra-*n*-butylammonium bromide and 2-chloro-D-glucal triacetate. On this basis the yield of the latter compound was estimated to be 78%. The identity of the 2-chloro-D-glucal triacetate was evident from its n.m.r. spectrum which had a one-proton singlet at τ 3.22 and was otherwise virtually identical to that of 2-acetoxy-D-glucal triacetate (17).

2-Pyridyl Tetra-O-acetyl-α-D-glucopyranoside and N-(Tetra-O-acetyl-D-glucopyranosyl)-2-pyridone

(*a*) Tetra-*O*-acetyl-α-D-glucopyranosyl bromide, 5.91 g, and tetra-*n*-butylammonium bromide, 3.96 g, were dissolved in 2-ethoxypyridine, 10 ml, and the homogeneous solution obtained at 75° was allowed to react for 1 d. The volatile components were then removed *in vacuo* and the residue was dissolved in chloroform. The chloroform solution was washed three times with 2 *N* hydrochloric acid and finally with aqueous sodium bicarbonate solution. The n.m.r. spectrum of the syrup obtained from the chloroform layer showed the mixture to consist essentially of 2-pyridyl tetra-*O*-acetyl-α-D-glucopyranoside (60%) and *N*-(tetra-*O*-acetyl-D-glucopyranosyl)-2-pyridone (<40%). This was determined in the following manner. The *p*-anisidin spray reagent (18) revealed only two spots when a sample of the syrup was chromatographed on a thin layer of silicic acid. A 0.42 g sample was therefore chromatographed on a column of silicic acid, 25 g (100 mesh), with reagent chloroform as the eluant. The bands which could be observed to separate on the column were collected. The first band corresponded to ~10% yield of 2-acetoxy-D-glucal triacetate as determined by the direct comparison of n.m.r. spectra (17).

The second band showed absorptions in the ultraviolet, λ_{max} 266 mμ (ε 3 670) and 208 mμ [2-ethoxypyridine, λ_{max} 270 mμ (ε 4 500) and 214 mμ]. The n.m.r. spectrum was that expected for 2-pyridyl tetra-*O*-acetyl-α-D-glucopyranoside and this was confirmed by crystallization of the syrup. Recrystallization from ethanol–water to constant physical properties resulted in material of m.p. 84–84.5°, $[\alpha]_D$ +148° (*c*, 0.5 in chloroform).

Anal. Calcd. for $C_{19}H_{23}NO_{10}$: C, 53.64; H, 5.45; N, 3.29. Found: C, 53.70; H, 5.77; N, 3.20.

The n.m.r. spectrum contained a doublet at τ 3.22, spacing 3.5 c.p.s., and signals in the τ 1.7 to 3.2 region closely resembling those in the spectrum of 2-ethoxypyridine. The remainder of the spectrum was that expected for a tetra-*O*-acetyl-α-D-glucopyranoside.

The material in the third band absorbed in the ultraviolet, λ_{max} 300 mμ (ε 4 720) and 226 mμ (2-pyridone, λ_{max} 300 mμ (ε 6 120) and 224 mμ). The n.m.r. spectrum at 100 Mc.p.s. showed the material to be a mixture, and it was established by integration of the signals and by spin-decoupling experiments that the compounds were both *N*-(tetra-*O*-acetyl-D-glucopyranosyl) 2-pyridones. The signal for the anomeric proton of the α-anomer was a doublet at τ 3.44, spacing 2.5 c.p.s., and that for the β-form was a doublet at τ 3.60, spacing 9 c.p.s. The ratio of the α- to β-forms was estimated to be about 1:3. Pure compounds were not obtained.

(*b*) Tetra-*O*-acetyl-α-D-glucopyranosyl bromide, 0.21 g, 0.19 g of 2-pyridone, and 0.16 g of tetra-*n*-butylammonium bromide were dissolved in 0.4 ml of *sym*-collidine. The solution was kept at 75° for 18 h. Chloroform was added and the solution was washed three times with dilute hydrochloric acid and then with aqueous bicarbonate. Solvent removal gave a syrup. Integration of the n.m.r. spectrum required the material to be about 70% 2-pyridyl tetra-*O*-acetyl-α-D-glucopyranoside. There was no evidence that *N*-glycosides had formed.

ÉTUDE DES EFFETS ÉLECTROSTATIQUES SUR LE MÉCANISME D'ACTION CATALYTIQUE DE LA PHOSPHATASE ALCALINE INTESTINALE DE VEAU

MICHEL LAZDUNSKI,[1] JACQUES BROUILLARD ET LUDOVIC OUELLET
Département de Chimie, Université Laval, Québec, Québec

Reçu le 5 mars 1965

ABSTRACT

The influence of dioxane and ethanol on the rate of hydrolysis of *p*-nitrophenyl phosphate in the presence of an intestinal alcaline phosphatase can be interpreted as a dielectric constant effect, at high substrate concentration. The dielectric constant effect is a function of the pH of the medium and is maximum around pH 9.4 at 25 °C and pH 9.0 at 15 °C. An interpretation suggesting that the change in diameter of the enzyme molecule becoming an activated complex is minimum at a pH of maximum activity is proposed. The same model can take into account the influence of the ionic strength on the same reaction.

INTRODUCTION

L'étude de l'influence du pH sur l'activité de la phosphatase alcaline intestinale (1) et l'analyse cinétique de différents mécanismes d'inhibition (2) ont permis de proposer une description et un mode de fonctionnement du centre actif de l'enzyme. Pour mieux connaître l'importance des contributions électrostatiques associées au mécanisme d'action catalytique de l'enzyme nous avons étudié l'influence cinétique des effets de solvant et de force ionique.

PARTIE EXPÉRIMENTALE

A. Réactifs

Le sel disodique utilisé comme substrat provient de Mann Research Laboratories Inc. Sa richesse en phosphate de *p*-nitrophényle est de 99.7%; il a été utilisé sans purification ultérieure. Les solutions à différentes concentrations de substrat ont été obtenues par dilution du sel dans l'eau distillée. L'enzyme utilisée est la phosphatase alcaline intestinale purifiée préparée selon une méthode décrite précédemment (3). Les tampons THAM (0.01 *M*) – HCl ont été utilisés au-dessus de pH 9 et éthanolamine (0.01 *M*) – HCl pour les valeurs de pH supérieures à 9. Les pH ont été mesurés avec un pH-mètre Radiometer TTT 1-B utilisant une électrode de verre Radiometer type B.

B. Mode opératoire

(1) Détermination de la vitesse initiale d'hydrolyse, v

L'hydrolyse du phosphate de *p*-nitrophényle est suivie par mesure colorimétrique du *p*-nitrophénol libéré lors de la réaction:

$$NO_2C_6H_4OPO_3^{=} + H_2O \rightarrow NO_2C_6H_4O^- + PO_4H^{=} + H^+.$$

Des essais préliminaires ont montré que la réaction d'hydrolyse s'arrêtait par passage en milieu très alcalin.

Le déroulement des opérations est le suivant: 14 ml d'une solution de phosphate de *p*-nitrophényle, de concentration adéquate, sont ajoutés à 15 ml de solution tampon. Ce mélange est porté dans un bain à thermostat (à 15.3 °C ou 25.7 °C ± 0.1 °C) et y est laissé pendant 30 min. Ce laps de temps écoulé, la réaction est démarrée par injection d'un millilitre d'une solution de l'enzyme également à température voulue. La réaction est suivie pendant 5–10 min suivant le cas. Des prélèvement de 5 ml sont faits chaque minute et versés dans 0.3 ml d'une solution de soude 4 *N*. La réaction s'arrête. Le *p*-nitrophénol est, dans ces conditions de basicité, sous forme ionisée et les lectures sont faites au spectrophotomètre Beckman DU à la longueur d'onde de 407 mμ correspondant au maximum de densité optique.

(2) Détermination de la vitesse maximum d'hydrolyse en présence de dioxanne

Le coefficient d'extinction du *p*-nitrophénol à 407 mμ n'est pas sensiblement affecté par la présence de dioxanne.

[1]*Adresse actuelle: Institut de Chimie Biologique, Faculté des Sciences, Marseille (Bouches-du-Rhône), France.*

Chaque essai utilise 30 ml de mélange composé comme suit: 11 ml de tampon, 1 ml d'enzyme de concentration adéquate, 1 ml de phosphate de *p*-nitrophényle de concentration suffisante pour que la vitesse initiale déterminée puisse être considérée comme une vitesse maximum, le nombre de millilitres de dioxanne nécessaire à l'obtention de la concentration de dioxanne désirée dans le milieu, et la quantité d'eau distillée nécessaire pour compléter le volume à 30 ml.

Il n'existe dans la littérature aucune mention d'un tampon standard permettant de définir de façon satisfaisante l'échelle de pH dans les mélanges eau–dioxanne. Marshall et Grunwald (4) ont montré que l'électrode de verre et l'électrode à hydrogène répondent de la même manière à des variations de l'activité des ions hydrogène dans des solutions contenant jusqu'à 82% de dioxanne en poids. Inagami et Sturtevant (5) ont constaté que les appareils de mesure de pH habituels, utilisant une électrode de verre Beckman, fonctionnent parfaitement et de façon reproductible dans des solutions contenant jusqu'à 88% de dioxanne. Les pH des tampons utilisés dans cette étude ont été déterminés par la méthode déjà utilisée par Sturtevant (5) qui consiste à étalonner le pH-mètre à pH 7 avec le tampon Beckman standard, et à l'utiliser ensuite directement dans les mélanges eau–dioxanne. Les valeurs des pH apparents, lues de cette manière, sont assez peu éloignées des valeurs de pH lues en milieux purement aqueux. Le pH d'un tampon éthanolamine–HCl de force ionique 0.1 passe de la valeur 9.05 aux valeurs 8.9 et 8.65, lorsque la concentration de dioxanne dans le milieu passe de 0% à 20% puis 50% en volume. Le pH des tampons THAM–HCl est moins affecté. Un tampon THAM–HCl de force ionique 0.1 ayant un pH de 8.15 dans l'eau prend successivement des pH de 8.11 à 8.07 dans des solutions à 20% puis 50% de dioxanne en volume.

(3) Étude de l'influence de la force ionique du milieu réactionnel sur la vitesse initiale d'hydrolyse

Les vitesses de réaction ont été évaluées par titrage de l'acide phosphorique libéré par hydrolyse du phosphate de *p*-nitrophényle.

L'appareillage manufacturé par Radiometer (Copenhague) est composé d'un pH-mètre TTT 1-b muni d'une électrode à calomel et d'une électrode de verre type B, d'un enregistreur type SBr2b et d'une seringue microburette type SBU1a.

Le déroulement des opérations est le suivant: le mélange réactionnel est composé de 19 ml d'une solution contenant les quantités adéquates de phosphate de *p*-nitrophényle et de chlorure de potassium ou de bromure de tétraéthylammonium utilisés comme modificateurs de force ionique. Lorsque ce mélange a atteint la température constante de 15.3 °C, il est porté par le système pH-stat, à la valeur de pH choisie. La réaction d'hydrolyse est alors amorcée par addition de 1 ml d'une solution de phosphatase alcaline également à température de 15.3 °C. Le titrigraphe enregistre, en fonction du temps, les quantités de soude nécessaires au maintien du pH. Les pentes initiales des courbes obtenues sont utilisées à l'évaluation des vitesses initiales de réaction. La quantité de soude ajoutée au cours de la réaction représente en moyenne 1 à 2% du volume réactionnel total. La manipulation est faite en atmosphère d'air débarrassée de gaz carbonique.

PARTIE THÉORIQUE

A. Effet de solvant

Les théories de cinétique chimique s'accordent à reconnaître que la vitesse d'une réaction est déterminée par une variation de l'énergie libre $\Delta G^{\neq}$ qui se manifeste lors du passage des réactifs de l'état initial à l'état activé.

L'expression générale décrivant la constante de vitesse est:

$$[1] \qquad k = \frac{RT}{Nh} \exp\left[-\frac{\Delta G_{\text{n.e.s.}}^{\neq}}{RT}\right] \times \exp\left[\frac{\Delta G_{\text{e.s.}}^{\neq}}{RT}\right]$$

où $\Delta G_{\text{n.e.s.}}^{\neq}$ et $\Delta G_{\text{e.s.}}^{\neq}$ représentent respectivement les contributions non électrostatiques et électrostatiques à l'énergie libre d'activation, h est la constante de Planck, R, la constante des gaz et N, le nombre d'Avogadro.

Barnard et Laidler (6) ont appliqué ces concepts aux interactions entre le centre actif de l'enzyme et le substrat. Nous avons tenté de considérer toute la molécule d'enzyme comme un ion dont la charge varie avec pH du milieu.

(1) Formation du complexe enzyme–substrat

La réaction de formation du complexe enzyme–substrat est représentée schématiquement dans la Fig. 1A. La protéine est figurée par une grosse sphère de rayon R_B et de charge nette $Z_B e$ située en son centre. Le substrat est figuré par une petite sphère de rayon R_A et de charge $Z_A e$. Le complexe activé, formé par association des deux espèces ioniques,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

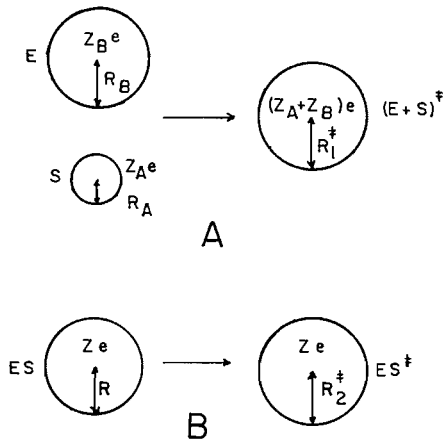

FIG. 1A. Mécanisme de formation du complexe enzyme–substrat.
FIG. 1B. Mécanisme de décomposition du complexe enzyme–substrat.

a la forme d'une sphère unique de rayon $R_1^{\ddagger}$ ayant pour charge $(Z_A + Z_B)e$. La variation d'énergie libre, $\Delta G_{e.s.}^{\ddagger}$, dérivée de l'équation de Born, est donnée par:

$$[2] \qquad \Delta G_{e.s.}^{\ddagger} = \frac{e^2}{2D}\left[\frac{(Z_A + Z_B)^2}{R_1^{\ddagger}} - \frac{Z_A^2}{R_A} - \frac{Z_B^2}{R_B}\right]$$

où e représente la charge de l'électron et D, la constante diélectrique; d'où

$$[3] \qquad \ln k_1 = \ln k_1^0 - \frac{Ne^2}{2DRT}\left[\frac{(Z_A + Z_B)^2}{R_1^{\ddagger}} - \frac{Z_A^2}{R_A} - \frac{Z_B^2}{R_B}\right]$$

k_1^0 est la constante de vitesse de formation du complexe enzyme–substrat en solution infiniment diluée.

(2) Décomposition du complexe enzyme–substrat

Le mécanisme hypothétique de cette décomposition est représenté dans la Fig. 1B. Le complexe enzyme–substrat est présenté sous la forme d'un ion sphérique de rayon R et de charge $Ze = (Z_A + Z_B)e$ qui, en passant à l'état activé, à charge constante, change de rayon $(R \rightarrow R_2^{\ddagger})$ sans changer de forme; $R_2^{\ddagger}$ peut être inférieur, égal ou supérieur à R

$$[4] \qquad \Delta G_{e.s.}^{\ddagger} = \frac{e^2}{2D} Z^2\left[\frac{1}{R_2^{\ddagger}} - \frac{1}{R}\right]$$

$$[5] \qquad \ln k_2 = \ln k_2^0 - \frac{Ne^2Z^2}{2DRT}\left[\frac{1}{R_2^{\ddagger}} - \frac{1}{R}\right]$$

k_2^0 est la constante de vitesse de décomposition du complexe enzyme–substrat en solution infiniment diluée.

Comme la suite le montrera, ces équations permettent une interprétation satisfaisante des résultats expérimentaux.

B. Effet de la force ionique

L'équation de Brönsted–Bjerrum permet d'évaluer la constante de vitesse d'une réaction dont le mécanisme serait du type:

$$A + B \rightarrow X^{\ddagger} \rightarrow \text{produits.}$$

For personal use only.

[6] $$k = k_0 \frac{\gamma_A \gamma_B}{\gamma_X}$$

γ_A, γ_B, γ_X sont les coefficients d'activité des espèces A, B et du complexe activé X; k_0 est la constante de vitesse en solution infiniment diluée. L'expression familière du coefficient d'activité est donnée par l'équation de Debye et Hückel:

[7] $$\ln \gamma_i = -\frac{Ne^2 Z_i^2}{2DRT} \frac{\kappa}{1 + \kappa a_i}$$

a_i est le rayon d'exclusion de l'espèce i qui possède une charge Z_i. Le paramètre κ représente l'inverse de la dimension de l'atmosphère ionique.

À 15 °C, l'éq. [7] peut s'écrire:

[8] $$\log \gamma_i = -0.500^* \frac{\sqrt{\mu}}{1 + a_i B \sqrt{\mu}} Z_i^2$$

où $B = 0.33 \times 10^8$ et μ est la force ionique.

Dans le cas le plus commun où A et B sont de petits ions, la quantité $a_i B\sqrt{\mu}$ peut être négligée en comparaison de 1, dans le terme $1 + a_i B\sqrt{\mu}$. L'équation [6] peut alors être écrite:

[9] $$\log k = \log k_0 + Z_A Z_B \sqrt{\mu}$$

Cette équation classique est utilisée à tort en cinétique enzymatique; la protéine a, en général, un rayon d'exclusion tel qu'il est impossible de négliger la quantité $a_i B\sqrt{\mu}$ dans le terme $1 + a_i B\sqrt{\mu}$; pour des valeurs arbitraires $a_i = 20$ Å et $\sqrt{\mu} = 0.1$, $a_i B\sqrt{\mu} = 0.66$.

(1) Formation du complexe enzyme–substrat

Cette réaction de formation, représentée schématiquement dans la Fig. 1A, fait appel à un mécanisme bimoléculaire. Les équations [6] et [8] permettent d'obtenir l'éq. [10] qui rend compte de l'influence de la force ionique sur la constance de vitesse k_1:

[10] $$\log \frac{k_1}{k_1^0} = -0.500\sqrt{\mu}\left[\frac{Z_A^2}{1 + a_A B\sqrt{\mu}} + \frac{Z_B^2}{1 + a_B B\sqrt{\mu}} - \frac{(Z_A + Z_B)^2}{1 + a_1^{\ddagger} B\sqrt{\mu}}\right]$$

a_A, a_B et $a_1^{\ddagger}$ représentent les rayons d'exclusion du substrat, de l'enzyme et du complexe activé. Les autres paramètres ont été définis dans la section précédente.

(2) Décomposition du complexe enzyme–substrat

Si la décomposition du complexe enzyme–substrat se fait selon le modèle unimoléculaire représenté dans la Fig. 1B, la vitesse de décomposition est donnée par l'équation:

[11] $$k_2 = k_2^0 \frac{\gamma}{\gamma^{\ddagger}}$$

γ et $\gamma^{\ddagger}$ sont les coefficient d'activité du complexe ES et du complexe activé ES‡. L'équation [12] rend compte de l'influence de la force ionique sur la constante de vitesse k_2.

[12] $$\log \frac{k_2}{k_2^0} = -0.500 Z^2 \sqrt{\mu}\left[\frac{1}{1 + aB\sqrt{\mu}} - \frac{1}{1 + a_2^{\ddagger} B\sqrt{\mu}}\right]$$

a et $a_2^{\ddagger}$ représentent les rayons d'exclusion du complexe ES et du complexe activé ES‡; $Z = Z_A + Z_B$.

Les équations qui ont été décrites permettent d'interpréter les résultats obtenus avec la papaine (8), la myosine (7) et l'uréase (9).

**Ce terme est égal à 0.509 à 25 °C.*

RÉSULTATS

A. Influence de la constante diélectrique sur la vitesse maximum de la réaction d'hydrolyse

Avant de traiter l'effet produit par le dioxanne sur la cinétique de la réaction enzymatique comme un effet purement électrostatique, il convient de s'assurer que les concentrations de dioxanne utilisées n'ont pas d'action spécifique tendant à supprimer l'activité phosphatasique. A 20 ml de mélange eau–dioxanne de concentration adéquate sont ajoutés 5 ml d'une solution d'enzyme à concentration de 2 / 1 000 (en poids). Le mélange est laissé à 25.7 °C pendant 30 min. Ce laps de temps écoulé, on se sert d'un millilitre de cette solution d'enzyme pour provoquer la réaction d'hydrolyse du phosphate de *p*-nitrophényle. Cette expérience a été faite à pH 9.3 en milieu d'incubation de concentration en dioxanne allant de 0 à 50%. La vitesse initiale déterminée est indépendante de la concentration en dioxanne du milieu d'incubation. Nous avons observé le même phénomène en utilisant comme solvant mixte le mélange éthanol–eau.

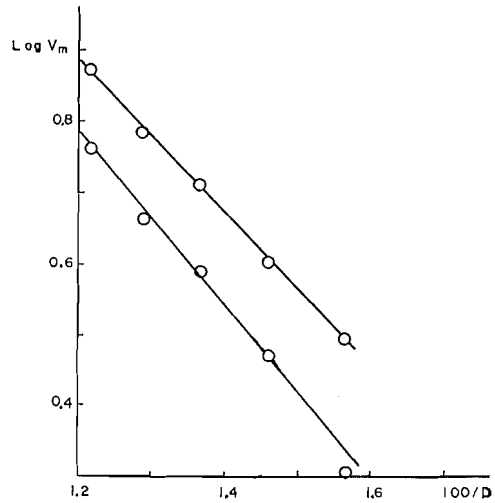

FIG. 2. Représentations de log $\bar{V}_m$ en fonction de $1/D$. Courbe supérieure: pH 7.45. Courbe inférieure: ph 10.42. Température: 15.3 °C.

La Fig. 2 représente un certain nombre de données caractéristiques obtenues à différents pH en adoptant la représentation classique qui consiste à évaluer log $\bar{V}_m$ en fonction de $1/D$. Aux deux températures, 15.3 °C et 25.7 °C, et à tous les pH étudiés, cette représentation est linéaire. Les valeurs de D utilisées sont celles d'Akerlof et Short (10).

Les valeurs des pentes d log $\bar{V}_m$/ d$(1/D)$ calculées avec les valeurs d'Akerlof ont été représentées en fonction du pH, aux températures de 15.3 et 25.7 °C dans la Fig. 3. Nous avons obtenu des résultats semblables avec les mélanges éthanol–eau à 25.7 °C (Fig. 4). Dans les deux cas, l'effet de constante diélectrique passe par un maximum pour la même valeur de pH. Des résultats semblables ont été rapportés pour la chymotrypsine par Castañeda-Agullo et Castillo (11).

B. Influence de la force ionique sur la vitesse maximum et la constante de Michaelis de la réaction d'hydrolyse

La Fig. 5 représente les résultats obtenus en portant le logarithme de la vitesse relative d'hydrolyse, v, en fonction de la racine carrée de la force ionique. L'expérience

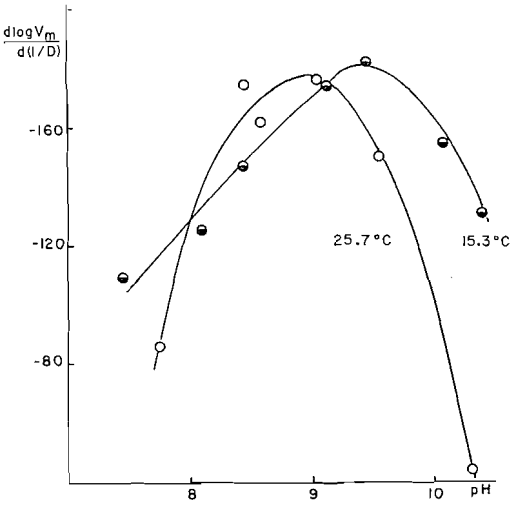

FIG. 3. Influence du pH sur la quantité $\frac{d \log \bar{V}_m}{d(1/D)}$ en présence de dioxanne.

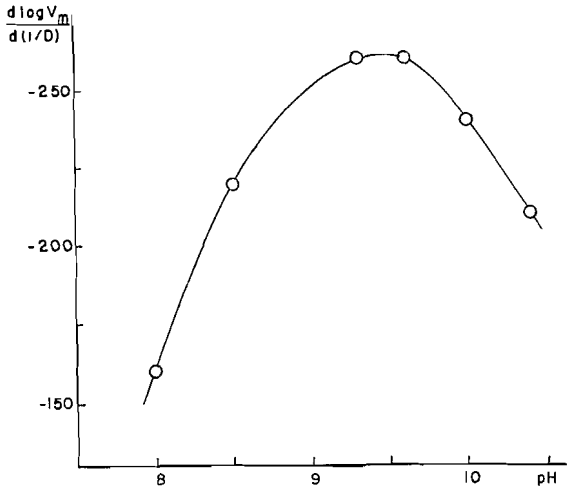

FIG. 4. Influence du pH sur la quantité $\frac{d \log V_m}{d(1/D)}$ en présence d'éthanol à 25.7 °C.

a été faite à pH 7.5, à une température de 15.3 °C et pour plusieurs concentrations de substrat. Le modificateur de force ionique utilisé est le chlorure de potassium.

La même expérience a été réalisée dans les mêmes conditions de pH et de température en utilisant le bromure de tétraéthylammonium comme modificateur de force ionique. L'accord satisfaisant entre les résultats obtenus avec les deux substances permet d'assurer que l'effet observé est bien essentiellement un effet de force ionique.

Les données représentées dans la Fig. 5 permettent d'obtenir des courbes de Lineweaver-Burk à force ionique constante. Elles permettent à leur tour l'évaluation des grandeurs $\bar{K}_m$, $\bar{V}_m$ et $\bar{K}\bar{V}_m$ en fonction de la racine carrée de la force ionique. Les résultats ainsi obtenus ont été représentés dans les Figs. 6, 7 et 8.

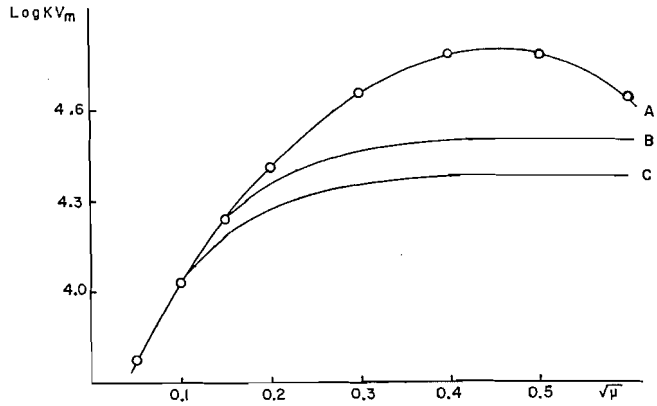

FIG. 8. Influence de $\sqrt{\mu}$ sur la quantité log $\bar{K}\bar{V}_m$ en unités arbitraires. Les points sont expérimentaux. (A) Tracé expérimental; (B) tracé théorique: $a_1^{\mp} = 20$ Å, $a_B = 19$ Å, $a_A = 4$ Å; (C) tracé théorique: $a_1^{\mp} = 20$ Å, $a_B = 18$ Å, $a_A = 4$ Å.

Influence du pH sur l'effet de force ionique

La même expérience a été faite à pH 9.55 et à 15.3 °C. L'effet de force ionique observé à ce pH est faible tant sur $\bar{V}_m$ que sur $\bar{K}_m$. La Fig. 9 traduit l'influence de $\sqrt{\mu}$ sur log $\bar{V}_m$. Les résultats ont été obtenus en présence de chlorure de potassium et de bromure de tétraéthylammonium.

DISCUSSION

A. Effet de solvant

(1) Influence des facteurs de nature non électrostatique

Si l'on a l'intention d'interpréter les données expérimentales obtenues en analysant l'effet de solvant, il convient de ne pas oublier les facteurs de nature non électrostatique dont la contribution pourrait expliquer les phénomènes observés. Les plus importants de ces facteurs sont les suivants:

(*a*) Une diminution de la concentration en eau peut provoquer une décroissance des vitesses si l'étape déterminante fait intervenir la participation de molécules d'eau (ce qui peut bien être le cas dans une réaction d'hydrolyse).

(*b*) Une inhibition possible par le composant non aqueux du solvant mixte.

(*c*) Une dénaturation de l'enzyme causée par l'addition du solvant organique.

L'influence du facteur (*a*) observée par Inagami et Sturtevant (5) par l'étude de la catalyse due à la trypsine en milieu eau–dioxanne ne se manifeste qu'à des concentrations de dioxanne supérieures à 80%. Les expériences réalisées dans cette étude, avec la phosphatase alcaline, n'ont pas fait intervenir de concentrations en dioxanne supérieures à 30%. Dans un tel milieu, la concentration en eau est encore de 39 *M* et certainement très suffisante pour que l'on puisse négliger l'influence de ce premier facteur dans l'interprétation des résultats. L'expérience exposée plus haut a montré que l'incubation de l'enzyme en présence de fortes quantités de dioxanne n'apporte aucune modification de la vitesse d'hydrolyse. Elle ôte beaucoup de son importance au facteur (*c*). L'influence du facteur (*b*) est certainement négligeable puisque les effets observés sont les mêmes avec deux molécules aussi différentes que l'éthanol et le dioxanne.

Enfin, et surtout, le fait qu'à tous les pH et températures étudiés, l'influence de $1/D$ sur log $\bar{V}_m$ se représente par une droite, comme le laissent prévoir les théories qui traitent uniquement des effets électrostatiques, enlève beaucoup d'importance aux facteurs secondaires.

For personal use only.

(2) Essai de détermination du mécanisme intime de la réaction de décomposition du complexe enzyme–substrat

Si la réaction se déroule selon le modèle monomoléculaire décrit dans la Fig. 1B, la pente théorique a pour expression:

$$[13] \qquad A' = -\frac{NZ^2e^2}{2.3 \times 2RT}\left[\frac{1}{R_2^{\neq}} - \frac{1}{R}\right].$$

La représentation la plus intéressante (Fig. 12) consiste à figurer la valeur $A = A'T$ en fonction de la charge Z du complexe enzyme–substrat évaluée à partir des courbes de titrage (Figs. 10 et 11). Ce changement de variable fait disparaître l'effet de température qui apparaissait dans la Fig. 3. Comme le prévoit l'éq. [13], l'extrapolation du côté des charges faibles indique que $A = 0$ lorsque $Z = 0$.

La pente des courbes log $\bar{V}_m$ en fonction de $1/D$ est négative quel que soit le pH d'étude; la quantité

$$\left[\frac{1}{R_2^{\neq}} - \frac{1}{R}\right]$$

doit donc être positive. Le rayon équivalent de la molécule de complexe enzyme–substrat

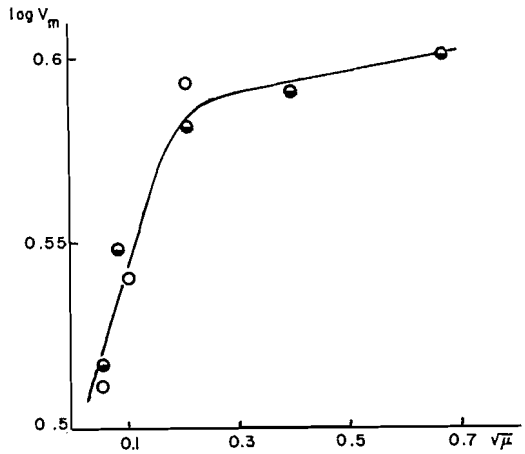

FIG. 9. Influence de $\sqrt{\mu}$ sur log $\bar{V}_m$ exprimé en unités arbitraires; pH 9.55; température 15.3 °C. ◒ KCl; ○ $(C_2H_5)_4NBr$.

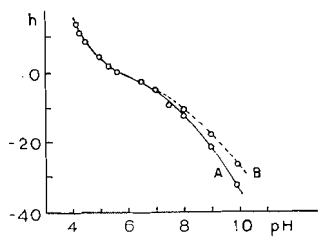

FIG. 10. Influence de la température sur la charge de l'enzyme de poids moléculaire 80 000. (A) Température 24.8 °C; (B) température 15.3 °C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

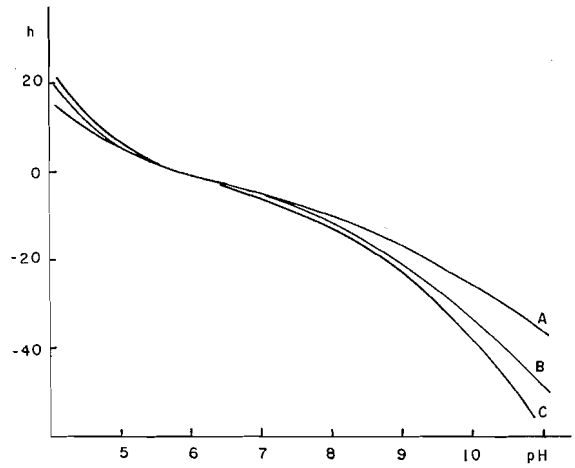

FIG. 11. Influence de la force ionique sur la charge de l'enzyme de poids moléculaire 80 000 à 24.8 °C. (A) $\mu = 0.02$; (B) $\mu = 0.1$; (C) $\mu = 0.5$.

est plus grand à l'état initial qu'à l'état activé. De toute évidence, la figure n'est pas décrite par une équation du type $y = ax^2$ (éq. [13]). La quantité

$$\frac{1}{R_2^{\neq}} - \frac{1}{R}$$

varie donc en fonction du pH. La fonction

$$\sqrt{\frac{1}{R_2^{\neq}} - \frac{1}{R}} = \sqrt{-\frac{2.3 \times 2RA}{Z^2e^2N}}$$

a été calculée pour chaque valeur de Z à partir des données expérimentales qui apparaissent dans la Fig. 12. Cette fonction ainsi obtenue est représentée par la Fig. 13, de façon

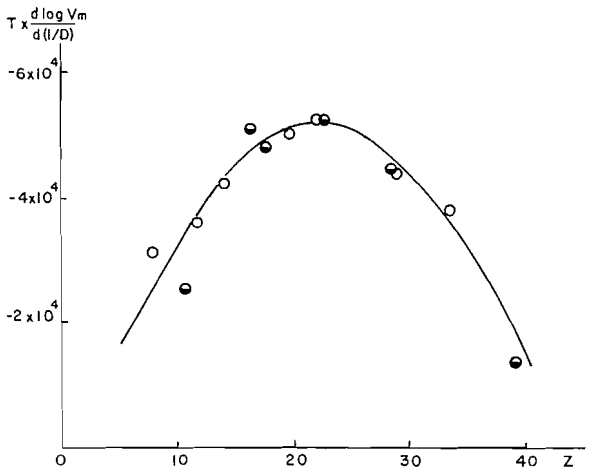

FIG. 12. Influence de la charge Z du complexe enzyme–substrat sur la quantité $T \times \frac{\mathrm{d} \log V_m}{\mathrm{d}(1/D)}$. ◒ 25.7 °C; ○ 15.3 °C.

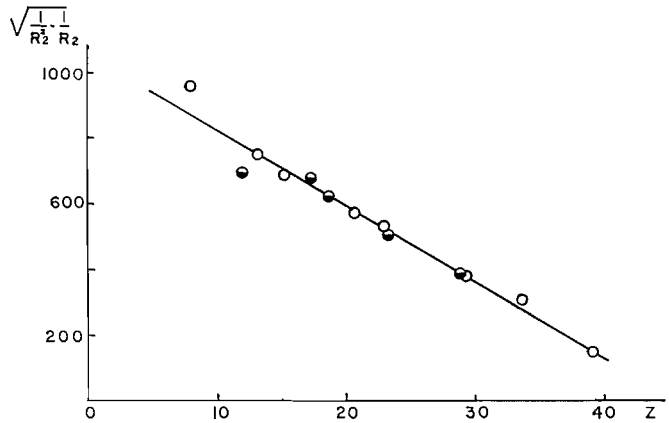

FIG. 13. Influence de la charge Z du complexe enzyme–substrat sur la quantité $\sqrt{\frac{1}{R_2^{\ddagger}} - \frac{1}{R}}$. ○ 25.7 °C; ◒ 15.3 °C.

linéaire. L'activation se fait sans changement de dimensions lorsque la charge du complexe enzyme–substrat devient $Z = -45$. Selon la température d'étude, les pH correspondants à cette charge sont compris entre 10.5 et 11. Il est intéressant de remarquer que la différence entre R et $R_2^{\ddagger}$ est minimum dans une région de pH correspondant à une vitesse maximum de décomposition du complexe enzyme–substrat (1).

Cette constatation est à rapprocher des conclusions de Bruice et Pandit (12) à l'issue d'une étude sur la catalyse intramoléculaire de l'hydrolyse des monoesters de diacides. Ces auteurs ont montré qu'une décomposition à catalyse intramoléculaire non enzymatique est d'autant plus rapide que la conformation de l'état fondamental de la molécule est plus voisine de celle de son état activé.

B. Effet de force ionique

(1) Formation du complexe enzyme–substrat

Les difficultés de mesure directe de la constante de vitesse k_1 rendent difficile, sinon impossible, l'étude systématique de l'influence de la force ionique sur la vitesse de formation du complexe enzyme–substrat. Néanmoins, si $\bar{K} = 1/\bar{K}_m$ ne représente pas, comme Michaelis l'admettait implicitement, la constante d'équilibre k_1/k_{-1} de la réaction

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES$$

mais plutôt le rapport k_1/k_2, il est évident que la quantité $\bar{K}\bar{V}_m$ est égale à $k_1[E]_0$.

Toutes les études les plus sûres, faites avec la catalase (13, 14), les trypsines (15), la peroxydase (16, 17), la carboxypeptidase (18, 19) et la myosine (20) ont montré que k_2 était très supérieure à k_{-1}, de sorte que $\bar{K} = k_1/k_2$. Nous admettrons que ceci est également vrai pour la phosphatase alcaline et interprèterons la courbe expérimentale (A) de la Fig. 8, donnant log $\bar{K}\bar{V}_m$ en fonction de $\sqrt{\mu}$, comme s'il s'agissait de la courbe log (k_1 relative) en fonction de $\sqrt{\mu}$. La courbe (A) a l'allure d'une droite aux très faibles forces ioniques entre $\sqrt{\mu} = 0.05$ et 0.2. Lorsque la force ionique augmente, ensuite, son influence sur log $\bar{K}\bar{V}_m$ devient de moins en moins considérable, passe par un maximum entre $\sqrt{\mu} = 0.4$ et 0.5 et diminue sensiblement dès que $\sqrt{\mu} = 0.6$.

For personal use only.

L'équation [10] permet de calculer les courbes théoriques log k_1/k_1^0 en fonction de $\sqrt{\mu}$.

La courbe (B) de la Fig. 8 a été calculée avec les valeurs suivantes: $a_1^{\neq} = 20$ Å, $a_B = 19$ Å et $a_A = 4$ Å; la courbe (C) avec les valeurs: $a_1^{\neq} = 20$ Å, $a_B = 18$ Å et $a_A = 4$ Å.

L'allure des courbes théoriques est très semblable à celle de la courbe expérimentale (A). Les valeurs choisies pour les rayons d'exclusion ne permettent pas d'obtenir de maximum entre $\sqrt{\mu} = 0.4$ et 0.5. On ne saurait trop attracher d'importance à cette différence; l'équation de Debye–Hückel ne s'applique plus parfaitement à des forces ioniques aussi élevées. L'expérience montre que les réactions entre petits ions ne suivent la loi décrite par l'éq. [9] que pour des valeurs de $\sqrt{\mu}$ généralement inférieures à 0.3 (21). Les courbes théoriques (B) et (C), par ailleurs, ont le mérite d'avoir entre $\sqrt{\mu} = 0.05$ et 0.2, des pentes moyennes qui sont en accord satisfaisant avec la pente 4.2 obtenue expérimentalement.

(2) Décomposition du complexe enzyme–substrat

Puisque le phosphate d'enzyme, E—$PO_3^=$, semble être l'intermédiaire le plus stable formé au cours de la catalyse phosphatasique (22–24), la courbe (A) de la Fig. 5 (log $\bar{V}_m$ en fonction de $\sqrt{\mu}$) représente en fait l'influence de la force ionique sur la vitesse k_2 de décomposition du complexe E—$PO_3^=$. Cette décomposition, qui est certainement à catalyse intramoléculaire, procède par un mécanisme unimoléculaire du type représenté dans la Fig. 1B. La courbe expérimentale (A) a l'allure d'une droite aux très faibles forces ioniques, entre $\sqrt{\mu} = 0.05$ et 0.2. Lorsque la racine carrée de la force ionique continue à augmenter, ensuite, son influence sur log $\bar{V}_m$ devient moins considérable et atteint un palier dès que $\sqrt{\mu} = 0.3$.

L'éq. [12] permet de calculer les courbes théoriques log k_2/k_2^0, c'est-à-dire log $\bar{V}_m$ en unités arbitraires, en fonction de $\sqrt{\mu}$. Pour calculer théoriquement une droite de pente positive semblable à celle obtenue expérimentalement à faibles forces ioniques, il faut nécessairement choisir des valeurs de $a_2^{\neq}$, rayon d'exclusion du complexe activé $ES^{\neq}$, inférieures à a, rayon d'exclusion du complexe enzyme–substrat ES. La courbe (B) de la Fig. 6 a été calculée en remplaçant dans l'éq. [12] les valeurs de $a_2^{\neq}$ et de a par: $a_2^{\neq} = 20$ Å et $a = 22.3$ Å.

La pente de la courbe (B) entre $\sqrt{\mu} = 0.05$ et 0.2 est en bon accord avec la pente 1.6 obtenue expérimentalement. En outre, l'allure des courbes théoriques est semblable à celle de la courbe expérimentale (A).

À pH 9.55, l'influence de $\sqrt{\mu}$ sur log $\bar{V}_m$ est beaucoup plus faible qu'à pH 7.5. Les seuls résultats qui seront interprétés sont ceux situés au-dessous de $\sqrt{\mu} = 0.4$. La pente expérimentale moyenne entre $\sqrt{\mu} = 0.05$ et 0.2 est de 0.45. En remplaçant dans l'éq. [12] les valeurs de a et $a_2^{\neq}$ par: $a = 20$ Å et $a_2^{\neq} = 19.87$ Å pour la courbe (A) et $a = 22.3$ Å et $a_2^{\neq} = 22.17$ Å pour la courbe (B), et en utilisant la charge de la phosphatase à pH 9.55 pour une force ionique de 0.02 à 15.3 °C, les pentes ainsi calculées sont respectivement 0.39 et 0.43. Elles sont en bon accord avec la valeur expérimentale.

Les interprétations données aux effets de force ionique et celles données aux effets de solvant montrent que la molécule entière de phosphatase alcaline joue, par sa charge, un rôle important dans la catalyse. Les deux études sont en bon accord; le rayon R du complexe enzyme–substrat est toujours supérieur au rayon $R_2^{\neq}$ du complexe activé correspondant; de même le rayon d'exclusion, a, du complexe enzyme–substrat est toujours supérieur au rayon d'exclusion $a_2^{\neq}$ du complexe activé correspondant. La différence $(a - a_2^{\neq})$ comme la différence $(R - R_2^{\neq})$ est d'autant plus faible que la charge de la protéine est plus élevée. Elle passe de 2.3 Å à pH 7.5 à 0.13 Å à pH 9.55. Les valeurs a_A du rayon d'exclusion du substrat utilisées dans les calculs sont nécessairement du bon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ordre de grandeur puisqu'elles ont été choisies en conséquence. Elles déterminent l'évaluation des rayons d'exclusion de l'enzyme, du complexe enzyme–substrat et des complexes activés. Ces rayons sont d'environ 20 Å; cette dimension est à peu près satisfaisante vu les simplifications faites en considérant la molécule comme sphérique et en négligeant la répartition des charges. En solution de chlorure de potassium, la valeur de $(a - R)$ pour une molécule de protéine est environ de 2.5 Å (25). À pH 7.5, le rayon d'exclusion du complexe enzyme–substrat qui permet de mieux décrire les données expérimentales est $a = 22.3$ Å. Si l'on choisit $R = 20$ Å pour que $a - R = 2.3$ Å, le rayon $R_2^{\neq}$ du complexe activé correspondant, déterminé à partir de la Fig. 13, est de 17.4 Å. Au rayon d'exclusion $a = 22.3$ Å correspond un rayon d'exclusion $a_2^{\neq} = 20$ Å (Fig. 7). La différence $(a_2^{\neq} - R_2^{\neq}) = 2.6$ Å est, elle aussi, en bon accord avec la valeur prévue (25).

CONCLUSION

Les résultats présentés peuvent s'accorder avec les schémas proposés et les équations établies dans la partie théorique. Si l'on admet ces hypothèses, les développements mathématiques décrits permettent d'interpréter les effets de force ionique et de constante diélectrique en cinétique enzymatique. Mais surtout ces résultats mettent l'accent sur un deuxième aspect de la catalyse enzymatique, sur le rôle des résidus ionisables situés en dehors du centre actif. Par la charge qu'ils confèrent à la protéine, ces résidus ont une action électrostatique directe sur les constantes de vitesses des différentes étapes de la catalyse. Cette influence électrostatique serait, en partie, le fruit d'un effet de la charge sur la configuration relative du complexe enzyme-substrat en de son état activé. La différence de rayon entre le complexe activé et son état fondamental est fonction du pH du milieu réactionnel.

Depuis deux ans, un certain nombre de preuves directes s'accumulent qui montrent que la conformation des enzymes est profondément affectée par la fixation du substrat. Tels sont les résultats de Parker et Lumry (26), obtenus par étude du système chymotrypsine – *p*-nitrophényl – triméthylacétate par dispersion rotatoire, qui sont d'ailleurs confirmés par les travaux de Hess (27). Les conformations de l'α-chymotrypsine et les acyl-chymotrypsines dépendent du pH de façon différente. Les différences de conformation entre enzyme et complexe enzyme–substrat sont minimum aux environs de pH 7.5. Avec la chymotrypsine comme avec la phosphatase alcaline, la différence entre l'état fondamental et l'état activé du complexe enzyme–substrat est minimum à un pH voisin du domaine d'activité maximum des enzymes.

THE THERMAL DECOMPOSITION OF METHYL HYDROPEROXIDE

ALEXANDER D. KIRK
Department of Chemistry, University of Victoria, Victoria, British Columbia
Received March 1, 1965

ABSTRACT

The thermal decomposition of methyl hydroperoxide has been studied in solution and in the gas phase. The decomposition was found to be partly heterogeneous in solution in dimethyl phthalate and no reliable rate constants were obtained. Use of the toluene carrier method for the gas phase work enabled measurement of the rate constant for the homogeneous decomposition. The first order rate constants obtained range from 0.19 s^{-1} at 292 °C to 1.5 s^{-1} at 378 °C, leading to log A, 11 ± 2, and activation energy, 32 ± 5 kcal/mole. These results are compared with the expected values of log A, 13–14, and activation energy, 42 kcal/mole. The significance of these findings is discussed.

Although the mechanism of its production has not been unambiguously established, and indeed may not be unique, methyl hydroperoxide has now been recognized as a significant product in the low temperature (1), radiolytic (2), and mercury photosensitized oxidation (3) of methane, the photooxidation of azomethane (4, 5), acetone (6), and methyl iodide (7), and the oxidation of methyl radicals (8). Although frequently not found in the products, it seems likely to be formed in any system involving methyl radicals and oxygen below about 400 °C. The possibility that methyl hydroperoxide acts as a chain-branching agent in the low temperature oxidation of methane has been in dispute and appears to be still uncertain (9). This uncertainty exists largely because the rate of homogeneous decomposition of the hydroperoxide is not known.

Early work (10) showed that decomposition of methyl hydroperoxide in a stream of nitrogen led to a complex mixture of products, almost certainly arising from simultaneous homogeneous and heterogeneous reaction. Recently, Fisher and Tipper (9) have studied the decomposition of the pure vapor in a static system and found the half-life of the peroxide to be up to 30 s at 395 °C depending on the condition of the reaction vessel surface. The lack of more complete data may be due to the difficulty of obtaining the hydroperoxide pure and its fairly ready heterogeneous decomposition. In this work, it was found that pure methyl hydroperoxide could be obtained safely by fractionation at reduced pressure and could be reliably estimated by iodine liberation and thiosulfate titration. The latter contrasts with other literature reports (11, 9). Details are given in the Experimental section.

This research was undertaken to obtain evidence for the homogeneous decomposition of methyl hydroperoxide into radicals

[1] $$(M +) CH_3OOH \rightarrow CH_3O\cdot + OH\cdot (+ M)$$

and to measure the rate constants and Arhennius parameters both in solution and in the gas phase. For the gas phase work, the toluene carrier method was adopted despite the criticisms which may be levelled against it (12). The facile heterogeneous decomposition of methyl hydroperoxide with low activation energy necessitates working at high temperature and short reaction times if the homogeneous reaction is to be favored. In addition, the relative effectiveness of toluene as a radical scavenger reduces secondary reactions and gives a measure of radical concentration by dibenzyl production.

EXPERIMENTAL

Materials

Methyl hydroperoxide was best prepared as described by Eggersglüss (13) with the slight modification that the product was removed directly from the reaction mixture by continuous ether extraction. The extract, after removal of the ether, was fractionated at reduced pressure in a Fenske helix column. Yields were only of the order of 5%, but, in the best case, the middle fraction of 1.5 g, with b.p.$_{184mm}$ 45.5–46.5° C, $n_D^{21} = 1.3654$, had a purity of 99% by iodimetric titration.

The dangers associated with low alkyl peroxides are well known, but the two explosions that occurred in this work are both notable in their spontaneity. In the first, dimethyl sulfate had been added over 4 h to alkaline H_2O_2, stirring through a mercury seal. The system vented through a small tube into a well-ventilated fume hood. The flask exploded violently when the temperature of the reaction mixture was only 19 °C. In retrospect, it seems certain that the explosion was caused by dimethyl peroxide and that the gas was not ignited. It has been observed previously that violent agitation may cause dimethyl peroxide vapor to detonate (14). In the second explosion, three containers containing methyl hydroperoxide samples, of purity 99%, 80%, and 50%, were allowed to warm to room temperature in a Dewar flask after being stored in liquid nitrogen for some weeks. The samples exploded completely spontaneously after about a 1 h interval. Since samples of methyl hydroperoxide of 80–90% purity were treated similarly for every run without mishap, it seems very probable that the 50% sample contained some dimethyl peroxide which initiated the explosion.

Unpurified Eastman Kodak dimethyl phthalate was used as solvent in the solution work.

Eastman Kodak sulfur-free toluene was used without purification as it gave no dibenzyl when pyrolyzed at 400 °C.

Analysis

Methyl hydroperoxide was estimated by a modification of the iodimetric method of Wagner, Smith, and Peters (15). The hydroperoxide was dissolved in 50 ml isopropanol; 1 ml glacial acetic acid and 1 g of sodium iodide was added and dissolved while warming gently. When the sodium iodide was in solution, the mixture was heated and maintained just at the boiling point for 10 min. Water (50 ml) was then added and the cooled solution titrated with 0.05 *M* sodium thiosulfate. No problem was experienced with air oxidation, and toluene, dimethyl phthalate, and formaldehyde did not interfere. Erratic results were obtained when the solutions were rapidly heated before the sodium iodide was completely in solution, but the temperature and the time of heating were not critical. No loss of iodine occurred when a standard solution of iodine in isopropanol was maintained at 82 °C in an open Erlenmeyer flask for 30 min.

In a few runs, the dibenzyl was analyzed for impurity by gas chromatography on a 3 ft silicone column at 200 °C.

Gases volatile at −196 °C were analyzed for oxygen, methane, and carbon monoxide using a 4 ft molecular sieve column at 60 °C. In one run, a 4 ft alumina column was used to analyze the gases volatile at −130 °C.

Apparatus and Procedure

(a) Decomposition in Solution

A degassed solution of methyl hydroperoxide was used to fill six calibrated 10 ml ampoules which were then sealed off under vacuum leaving just sufficient vapor space to fill them on heating to the reaction temperature. They were then heated in an oil bath thermostatted to 1 °C, removed at intervals, quenched in ice water, and analyzed iodimetrically. The first was taken as time zero and all times measured from its removal. Experiments with an ampoule having a thermocouple sealed into its center showed that the ampoules came up to bath temperature in 3 min and quenched in 30 s.

(b) Decomposition in the Gas Phase

A conventional flow system was used for the work (16); the cylindrical reaction vessel was 28 mm in outside diameter and 134 ml in volume and was heated by an aluminium block furnace. The rates of flow of toluene and methyl hydroperoxide and the overall contact time were controlled by capillaries. The pressure was measured with a Bourdon gauge and the reaction vessel temperature with a thermocouple. Degassed samples of methyl hydroperoxide and toluene were stored in containers removable for weighing.

The duration of a run was generally 10–20 min and toluene alone was passed through the apparatus for 2 min at the beginning and the end to stabilize the flow and sweep out the products. The concentration of methyl hydroperoxide was calculated from the loss in weight of the container and the exact percentage purity (about 90%) and, except for one run, was always about 0.5 mole % or less. After reaction, the products and reactants were collected in two removable traps, a small double U trap at −5 to −10 °C to collect dibenzyl and a large trap to collect all other products except permanent gases. The latter were collected in a Teopler pump and analyzed by gas chromatography. The undecomposed hydroperoxide was estimated by iodimetric titration.

RESULTS

(a) Decomposition in Solution

A conventional paraffin solvent could not be used due to the limited solubility of the polar methyl hydroperoxide. Initial runs with glycerin showed that methyl hydroperoxide

reacted with the solvent and that glycerin interfered with the iodimetric estimation of the hydroperoxide. Dimethyl phthalate was found to be a suitable solvent.

Figure 1 shows a plot of methyl hydroperoxide concentration versus time for typical data obtained for the decomposition in dimethyl phthalate. Packing experiments showed the scatter evident in the data to be due to heterogeneous decomposition. A degassed solution of methyl hydroperoxide was placed in six ampoules, three unpacked (surface/volume ≈ 4 cm^{-1}), two packed with glass tubing (surface/volume ≈ 13 cm^{-1}), and one packed with glass wool (surface/volume unknown), and heated at 155 °C for 30 min. Titration of the hydroperoxide remaining gave thiosulfate titers (corrected to 10 ml of solution) of 12.9, 12.4, and 12.0 ml for the unpacked vessels, 1.93 and 1.31 ml for the glass tube packed vessels, and 0.17 ml for the glass wool packed vessel.

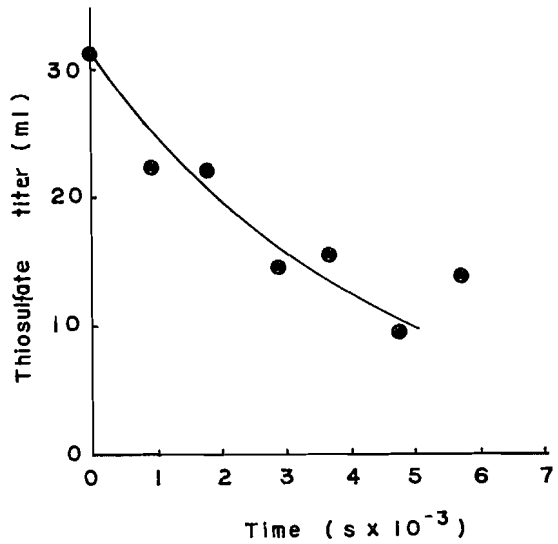

FIG. 1. Plot of undecomposed methyl hydroperoxide versus time. Solid line calculated for a first order reaction. Solvent dimethyl phthalate. Volume of solutions 10 ml. Temp. 153 °C. $[S_2O_3^{2-}] = 0.055$ *M*.

The first order rate constants obtained in unpacked vessels ranged from 3×10^{-5} s^{-1} at 112 °C to 2×10^{-4} s^{-1} at 153 °C, but, in view of the irreproducibility and the fact that heterogeneous reaction was clearly contributing to the rate, these values are of little significance. In agreement is the observation that the rate constants are much larger than would be expected by extrapolation of the gas phase data for the homogeneous reaction.

(b) Decomposition in Gas Phase

The main results are shown in Table I. Analyses were carried out primarily for dibenzyl and undecomposed hydroperoxide, but methane, carbon monoxide, oxygen, and ethane were minor products (together about 6% of the total decomposition). Analysis of the liquid products for methanol, formaldehyde, and water would have precluded titration of the unchanged hydroperoxide. Analysis of the dibenzyl showed no impurities (limit of detection $< 1\%$). The identity of the dibenzyl was confirmed by comparison of the infrared spectrum with that of an authentic sample. Test runs with toluene alone and toluene with small amounts of oxygen gave no dibenzyl.

Table I shows that the percentage decomposition rose from 15 to 75% over the temperature range 290 °C to 380 °C while the ratio mole dibenzyl / mole hydroperoxide

ϕ = mole dibenzyl / mole MeO_2H decomposed.

decomposed (ϕ) rose from 0.05 to 0.80 over the same range. This suggests competition between a heterogeneous decomposition of low activation energy and a homogeneous decomposition of higher activation energy. The ready heterogeneous decomposition of methyl hydroperoxide is well known and packing experiments were regarded as superfluous. The production of dibenzyl is unambiguous evidence for the decomposition of methyl hydroperoxide into radicals.

The total first order rate constants were calculated from the contact time and the initial and final concentrations of methyl hydroperoxide. If the mechanism presented in the discussion is assumed, the total first order rate constant may be divided into a heterogeneous and a homogeneous rate constant by

$$k_1 = k_{tot}\,\phi$$

$$k_{het} = k_{tot} - k_1.$$

DISCUSSION

Since the gas phase decomposition of methyl hydroperoxide in the presence of toluene gave dibenzyl in yields up to 85%, reactions [1]–[4] must occur.

[1] $(M +)\ CH_3OOH \rightarrow CH_3O\cdot + OH\cdot\ (+ M)$

[2] $CH_3O\cdot + C_6H_5CH_3 \rightarrow CH_3OH + C_6H_5CH_2\cdot$

[3] $OH\cdot + C_6H_5CH_3 \rightarrow H_2O + C_6H_5CH_2\cdot$

[4] $2C_6H_5CH_2\cdot \rightarrow C_6H_5CH_2CH_2C_6H_5$

The other possible reactions of methyl hydroperoxide and methoxyl, hydroxyl, and benzyl radicals must also be considered.

[5] $C_6H_5CH_2\cdot + OH\cdot \rightarrow C_6H_5CH_2OH$

[6] $C_6H_5CH_2\cdot + CH_3O\cdot \rightarrow C_6H_5CH_2OCH_3$

[7] $(M +)\ CH_3O\cdot + OH\cdot \rightarrow CH_2O + H_2O$ (or CH_3OOH) $(+ M)$

[8] $CH_3O\cdot + CH_3O\cdot \rightarrow CH_3OH + CH_2O$ (or CH_3OOCH_3)

[9] $M + OH\cdot + OH\cdot \rightarrow H_2O_2 + M$

[10] $CH_3OOH + CH_3O\cdot \rightarrow CH_3OH + CH_3OO\cdot$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

[11] $$CH_3OOH + OH\cdot \rightarrow H_2O + CH_3OO\cdot$$

[12] $$CH_3OOH \xrightarrow{\text{walls}} CH_3OH,\ CH_2O,\ O_2,\ H_2O,\ \text{etc.}$$

Alternate ring abstraction reactions from toluene are suggested by the recent work of Cher (17).

[13] $$CH_3O\cdot + C_6H_5CH_3 \rightarrow CH_3OH + \cdot C_6H_4CH_3$$

[14] $$OH\cdot + C_6H_5CH_3 \rightarrow H_2O + \cdot C_6H_4CH_3$$

Several pieces of evidence suggest that the recombination reactions involving methoxyl and hydroxyl radicals are unimportant. First, no benzyl alcohol or benzyl methyl ether was found in the dibenzyl, direct evidence against reactions [5] and [6]. Secondly, the higher temperature runs consistently gave dibenzyl in 80% yield which, remembering the likelihood of heterogeneous decomposition, indicates quantitative conversion of methoxyl and hydroxyl into dibenzyl. Since the reactions of methoxyl and hydroxyl radicals are all of zero or low activation energy, this situation probably carries over to the low temperature runs. Finally, reaction [8] will be faster than [7] or [9] since the hydroxyl radical almost certainly reacts more rapidly with toluene than methoxyl. It is interesting then to compare the relative rate of reaction of methoxyl with toluene [2] and with methoxyl [8]. Assuming $E_8 = 0$, $A_8 = 10^{11}$ l mole^{-1} s^{-1}, $k_1 = 0.3$ s^{-1} (this work), $A_2 = 10^{11}\ P_2$ l mole^{-1} s^{-1}, and $E_2 = 5.0$ kcal/mole (the value for hydrogen abstraction by methoxyl from methyl acetate (18)), then at 610 °K, if P_2 is 10^{-2}, reaction [8] accounts for only 0.1% of the methoxyls, if P_2 is 10^{-3} it accounts for 10%. Thus it seems likely that no serious error is incurred by the neglect of reactions [5], [6], [7], [8], and [9].

The experimental evidence does not entirely preclude the possibility of some chain reaction, [10] and [11], particularly at the lower temperatures. Benson has indeed suggested (19) that previous work (20) on alkyl hydroperoxides has led to high rate constants due to chain decomposition. It must be noted, however, that in this study the molar concentration of hydroperoxide was always less than or equal to 0.5% of the toluene. Since $D(CH_3OO—H) \simeq 87$ kcal/mole (19) and $D(C_6H_5CH_2—H) \simeq 83$ kcal/mole (21), one would expect a slightly lower activation energy for hydrogen abstraction from toluene. Thus, unless the steric factor for abstraction from hydroperoxide is markedly greater than from toluene, chain reaction does not occur.

Reactions [13] and [14] are unimportant since no dimethyl diphenyl or phenyl tolyl methane was found, indicating, as Cher has suggested (17), that the tolyl radical rapidly reverts to the benzyl radical when excess toluene is present. Even if this were not so, the results of this study would not be affected.

If the main reactions in the system are [1], [2], [3], [4], and [12], and if [1] and [12] are assumed to be first order, then the first order rate constants for reaction [1] may be calculated as described in the previous section. These rate constants are shown in Table I together with the total first order constants. The latter show the greater scatter confirming that the method of calculation is in fact correcting for an irreproducible heterogeneous contribution to the decomposition.

Figure 2 is the Arhennius plot of the homogeneous rate constants for reaction [1], and leads to

$$k_1 = 10^{11\pm2} \exp \frac{-(32 \pm 5) \times 10^3}{RT}$$

The 95% error limits were obtained by least squares treatment excluding the single point at the low temperature extreme.

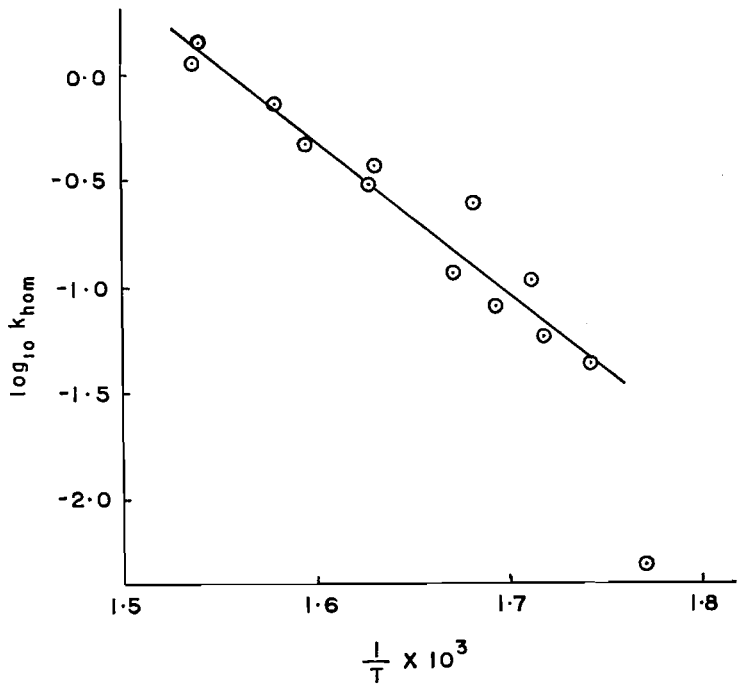

FIG. 2. Arhennius plot for the homogeneous gas phase decomposition of methyl hydroperoxide. $k_{hom} \equiv k_1$.

If the recombination of methoxyl and hydroxyl radical is assumed to have zero activation energy, then E_1 may be equated with $D(CH_3O—OH)$. The value obtained of 32 kcal/mole is much lower than would be expected on the basis of thermochemical calculations. Using group energy values (22), the heat of formation of methyl hydroperoxide is calculated to be −32.1 kcal/mole. Together with $\Delta H_f(OH) = 8$ kcal/mole (19) and $\Delta H_f(CH_3O) = 2.0$ kcal/mole (rather than −0.5 kcal/mole (23) since it is more consistent with the data on dimethyl peroxide), then $D(CH_3O—OH) = 42$ kcal/mole.

The combination of low activation energy and low A factor suggests that the rate constants are of the correct order of magnitude but are sufficiently in error to lead to these large errors in E and log A. Benson (24) has emphasized the high precision required to measure Arhennius parameters.

If this is so, it is likely that the fault lies with the data obtained at the lower end of the temperature range as there the heterogeneous reaction predominates and the mechanistic uncertainties are most important. It is significant in this regard that the high temperature rate constants are of the magnitude to be expected for a reaction of activation energy 42 kcal/mole and a "normal" A factor. Thus, using the rate constant obtained at 649 °K and assuming $E = 42$ kcal/mole, we find log $A = 14.2$. Thus the disagreement lies not in the magnitude of the rate constants but in their interrelationship.

The rate constants are lower by a factor of about three than the values previously obtained for ethyl and isopropyl hydroperoxides (20). At these temperatures, this is equivalent to an activation energy difference of 0.9 kcal/mole.

Fisher and Tipper have recently reported the half-life of methyl hydroperoxide as up to 30 s at 395 °C (9). The present work suggests a value of 0.2 s. One is tempted to favor the longer lifetime for obvious reasons. However, the following considerations support our

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

value. 1. The longer half-life corresponds to a minimum activation energy for reaction [1] of 45–48 kcal/mole for the normal range of A factors while our value corresponds to 38–41 kcal/mole, in better agreement with the thermochemical data. 2. Our value was obtained in circumstances where 80% of the hydroperoxide decomposed led to dibenzyl, leaving little doubt about the mechanism of that proportion of the decomposition. Any errors in the assumptions regarding the remaining 20% do not affect the homogeneous rate constants significantly.

One may conclude that, in the temperature range 300–400 °C, methyl hydroperoxide will cause branching in oxidation systems if formed, but that its lifetime is too short for it to be involved in degenerate chain branching.

Because of the relative simplicity of the methyl hydroperoxide molecule, it is quite likely that, at the pressures used in this work, the rate constants are pressure dependent. Unfortunately, the experimental technique was unsuitable for any study of the pressure dependence of the rate constant. As the runs reported were all at approximately the same pressure of toluene, the present results would not be affected.

ACKNOWLEDGMENTS

The author wishes to thank W. Hyslop for assistance with the solution work, W. R. Newman for much of the gas phase work, and the National Research Council and the University of Victoria for research grants. The author would also like to thank one of the referees for drawing attention to the work of Barnard and Honeyman (25) who obtained an estimate of the lifetime of methyl hydroperoxide at 284 °C as 1–4 min, consistent with the present results.

KINETICS OF VAPOR-PHASE HYDROCARBON–OZONE REACTIONS

J. J. BUFALINI AND A. P. ALTSHULLER

Laboratory of Engineering and Physical Sciences, Division of Air Pollution, and Robert A. Taft Sanitary Engineering Center, Public Health Service, U.S. Department of Health, Education, and Welfare, Cincinnati, Ohio

Received August 10, 1964

ABSTRACT

The reactions of nine olefinic and aromatic hydrocarbons with ozone in the vapor phase have been investigated in static and dynamic systems. Some of the rate constants for the olefin–ozone reactions are in good agreement with previously published data, whereas others are larger than values previously reported. Rate constants for *trans*-2-butene–, isobutene–, and ethylene–ozone reactions were measured between 30 and 100 °C. The activation energies for the reaction of ozone with *trans*-2-butene, isobutene, and ethylene are 0.2 ± 0.3, 2.8 ± 0.4, and 4.2 ± 0.4 kcal/mole. In general, the reactions of hydrocarbons with ozone are non-stoichiometric. However, these reactions do appear to be second order. The rates of reaction between alkylbenzenes and ozone are too low to be of importance in air pollution studies.

INTRODUCTION

The ozonization of hydrocarbons in the liquid phase has been the subject of considerable investigation (1). The vapor-phase counterpart has received less attention. Since Haagen-Smit (2) observed that eye irritation and plant damage resulted from ozone–hydrocarbon reactions, considerable effort has been directed toward a better understanding of the role of ozone–hydrocarbon reactions in air pollution. In the ensuing investigations numerous disagreements have arisen concerning the stoichiometries and magnitudes of the rate constants for many of the ozone–olefin reactions.

Hydrocarbons that are present in the atmosphere are generally thought to react with atomic oxygen, ozone, and free radicals. Since accurate rate constants are necessary for determining the relative importance of each of these reactants in polluted air, the present study was undertaken.

EXPERIMENTAL

Reactions were carried out in dynamic and in static systems. For the dynamic system the volume of the reaction vessel depended upon the particular hydrocarbon under consideration. (Reaction vessels of 0.5, 1, 2, 6, and 12 l capacity were employed.) For the static system a 12 l round-bottom flask and a Teflon (FEP) bag were used. Except for a few butt-to-butt glass connections jointed by Teflon tubing, an all-glass system with ball and socket connectors was employed. Fluorocarbon grease was used sparingly as a lubricant for the stirrer employed with the 12 l flask. Most dynamic experiments were conducted at 30 ± 0.1 °C. Several of the reactions also were studied at temperatures between 30 and 100 °C. The static runs were conducted at room temperatures ($T = 25 \pm 2$ °C).

Prepurified air was metered at a rate of 400 cc/min through the ozone generator. The ozone-producing lamps were of the small mercury vapor type operating on 4 W (G.E. 0Z4S11). The ballasts for the lamps were connected to a constant-voltage transformer to ensure steady ozone output. Because the 1 849 Å line is extremely dependent upon voltage, it was imperative that a steady line voltage be maintained. The ozone produced in this manner was stored in a double-walled 100 l FEP (fluorinated ethylene propylene copolymer) plastic container and was either used in test runs or vented into the air (3).

The hydrocarbons were introduced by means of syringes into a previously evacuated 34 l stainless steel tank equipped with a silicon rubber septum. The 34 l tank was then pressurized with tank air to approximately 200 p.s.i. (gauge pressure) and placed in an oven (~ 75 °C) overnight. This operation was necessary to ensure proper mixing under the high pressure.

For dynamic reactions known mixtures of hydrocarbon and ozone were metered through a venturi and into the reaction flask. The total inlet volume was checked against the total outlet volume. Enough time was allowed for the dynamic chamber to reach steady-state conditions. The calculated value for charging was in excellent agreement with the experimental value.

For static reactions the 12 l flask was evacuated with a mechanical vacuum pump. The specified amount of hydrocarbon was introduced through a silicon rubber septum by means of a syringe. A known volume of ozone was then introduced from the FEP bag.

For personal use only.

The ozone concentration was measured by the usual procedure involving the oxidation of iodide to triiodide in neutral solution. In some instances the Mast ozone meter was employed. The meter value was multiplied by a factor of 1.48 to equal the colorimetric value. Hydrocarbons were measured by a gas–liquid chromatograph (g.l.c.) equipped with a flame-ionization detector. Selection of the column material depended upon the hydrocarbon to be reacted. A column packed with medium-activity silica gel was used for the lighter olefins; a column packed with bis-2(2 methoxyethyl)adipate (BMEA) on C-22 firebrick was used for the higher olefins but was later replaced by a column packed with 10% silicon fluid (SF96) on C-22 firebrick. Aromatic hydrocarbons were separated on a column packed with 5 to 10% Carbowax 1540 on C-22 firebrick. The gas flow rates for the gas chromatograph were H_2, 22 cc/min; air, 300 cc/min; and He, 31 cc/min.

Most of the hydrocarbons were obtained from Phillips Petroleum Company. 1,3,5-Trimethylbenzene was obtained from Aldrich Chemical Company; styrene from Matheson-Coleman Company; *tert*-butyl hydroperoxide from K and K Laboratories; peracetic acid from the FMC Corporation; *n*-butyl hydroperoxide was prepared by the method of Williams and Mosher (4); and the tank air for ozone generation was obtained from the Matheson Company.

METHOD OF CALCULATION

The dynamic reaction flask was treated as a continuous stirred flow reactor. With such a reactor, materials leave at a constant concentration at steady state.
At steady state

$$F(x_0 - x) = kVxy \quad [1]$$

where F is the flow rate, x_0 is the hydrocarbon concentration entering the reactor, x is the hydrocarbon concentration leaving the reactor, y is the ozone concentration leaving the reactor, V is the reactor volume, and k is the rate constant.

In the static method, the integrated second-order rate equation was employed.

$$k = \frac{2.303 \log (C_0/C)}{\int_0^t [O_3]\, dt} \quad [2]$$

RESULTS

The values for the absolute rate constants for various hydrocarbons are shown in Table I for the dynamic system and Tables II and III for the static system.

The rate constant for mesitylene was calculated on the basis of its detectability with the gas chromatograph, i.e., it was based on the fact that if 5% of the mesitylene had reacted, the gas chromatographic analysis would detect this difference.

TABLE III

Experimental data for the reaction of 0.40 p.p.m. of *trans*-2-butene with 0.34 p.p.m. of ozone in the presence of 1.6 p.p.m. of hexene-1 at 27 °C

Time (min)	Log $\frac{C_1}{C_2}$	$\int_{t_1}^{t_2}[O_3]\,dt$ (p.p.m. min)	k (l mole^{-1} s^{-1} $\times$ 10^{-5})
0–2	0.1265	0.605	2.0
2–6	0.217	0.890	2.3
6–12	0.187	0.930	1.9
12–16	0.105	0.504	2.0

The olefin-to-ozone consumption ratios increased with increasing olefin concentration. These ratios did level off, however, when the initial olefin concentration was in excess of the initial ozone concentration. The consumption ratios at higher olefin concentrations were 1.5 for *trans*-2-butene, 1.6 for ethylene, 1.8 for 1-hexene, 2.0 for 1-butene, 1.5 for isobutene, and 2.0 for 2-methyl-2-butene. Styrene showed 1:1 stoichiometry within experimental error. There is also some evidence that the consumption ratio decreased with increasing flow rate. The consumption ratios for equal *trans*-2-butene concentrations were 1.47 for a flow rate of 655 cc/min, 1.27 for 790 cc/min, and 1.11 for 900 cc/min. Some of the data obtained on the static runs for the olefin–ozone reactions are shown in Figs. 1, 2, and 3. The dashed line in Fig. 1 is the calculated ozone concentrations assuming 1:1 stoichiometry. It is noted that the calculated ozone concentration goes to zero at 60 min reaction time when 1:1 stoichiometry is assumed.

In Figs. 2 and 3 are shown the reactions of 1-butene, *trans*-2-butene, and 1-hexene with ozone. The data show that more ozone was consumed in the 1-hexene–ozone reaction;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

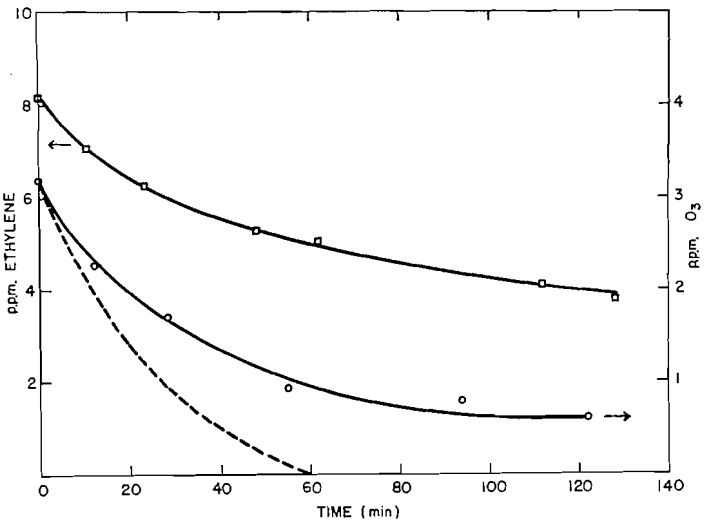

FIG. 1. Concentration vs. time curves for ozone–ethylene reaction.

however, part of the decrease in ozone concentration can be attributed to surface and thermal decomposition. It was found that 1 p.p.m. of ozone dissociated 13.6% for a period of 2 h in the Teflon bag.

Since we were primarily interested in rate constants for the ozone–olefin reactions, a thorough product analysis for reaction products was not performed. The products listed are those that were easily observed by ordinary g.l.c. analysis or by wet analysis in the case of ethylene. The reader is referred to three excellent papers (5, 6, 7) for a more complete product analysis.

The major product formed from the *trans*-2-butene–ozone reaction is acetaldehyde. Approximately 1 mole of this product is formed for every mole of olefin consumed. One

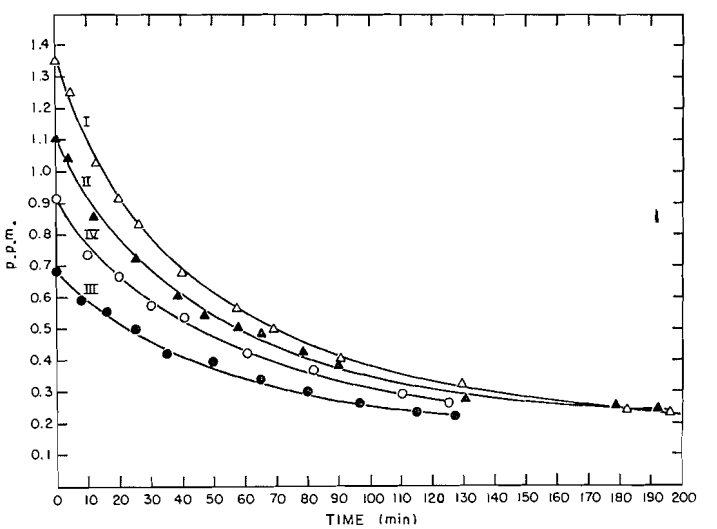

FIG. 2. Concentration vs. time curves for ozone–olefin reactions. The curves are: I and II for 1-butene and ozone, respectively; III and IV for 1-hexene and ozone, respectively.

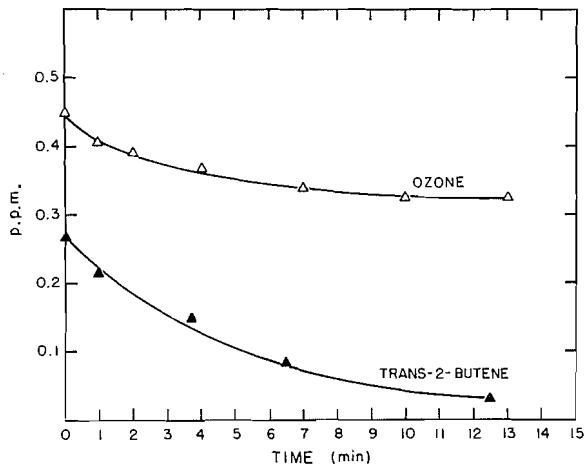

FIG. 3. Concentration vs. time curves for *trans*-2-butene–ozone reaction.

mole of acetone is formed for every 2 moles of isobutene reacted. About 0.7 mole of formaldehyde was observed for every mole of ethylene reacted. Approximately 0.2 mole of acetone was formed for every mole of 2-methyl-2-butene reacted. Because the amount of acetaldehyde formed from the 2-methyl-2-butene–ozone reaction fluctuated, a definite ratio was difficult to establish. It was noticed, however, that the reaction formed more acetaldehyde than acetone. The 1-butene–ozone reaction showed ethane to be a minor product. A quantitative study was not made on this product. The 1-hexene–ozone reaction showed pentanal as a major product and butane as a minor product. Again no quantitative studies were made.

DISCUSSION

The olefin-to-ozone consumption ratio suggests that an intermediate is formed that reacts further with the olefin. The Criegee mechanism (8) that is usually accepted for gas-phase ozone–olefin reactions is compatible with this observation. The mechanism can be written as follows.

[3] $$RHC{=}CHR + O_3 \rightarrow \text{initial product}$$

[4] $$\text{initial product} \rightarrow RH\overset{+}{C}{-}O{-}\bar{O} + RCHO$$

[5] $$RH\overset{+}{C}{-}O{-}\bar{O} + \text{olefin} \rightarrow \text{product(s)}$$

[6] $$RH\overset{+}{C}{-}O{-}\bar{O} \rightarrow RH + CO_2$$

[7] $$RH\overset{+}{C}{-}O{-}\bar{O} + O_2 \rightarrow RCHO + O_3$$

[8] $$RH\overset{+}{C}{-}O{-}\bar{O} \rightarrow ROH + CO$$

Reactions [5] and [7] can explain the high olefin-to-ozone consumption ratio that was observed. If reactions [3] and [4] are treated as one and if steady-state conditions are assumed for the zwitterion, the rate of disappearance of the olefin becomes

[9] $$-\frac{d[ol]}{dt} = k_3[ol][O_3] + \frac{k_5k_3[ol]^2[O_3]}{k_5[ol] + k_7[O_2] + k_6 + k_8}.$$

A recent study by Wei and Cvetanovic (6) in which ozone–olefin reactions were studied both in the presence and absence of molecular oxygen, seems to corroborate reaction [7].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

They found that there was an increase in aldehyde and (or) ketone concentration(s) when molecular oxygen is present. Also, they observed that in the presence of molecular oxygen the olefin–ozone consumption ratio varied between 1.4 and 2 for different olefins. The reactions were stoichiometric in the absence of molecular oxgyen, however. This observation strongly suggests that reaction [5] is unimportant. Therefore, eq. [9] was reduced to the simple second-order rate eq. [2].* The rate constants obtained from this equation by use of the data from Fig. 1, 2, and 3 are shown in the last column of Table II.

It is conceivable that other olefin-consuming reactions could occur. If a free radical were formed as an intermediate between olefin and ozone a rapid direct attack of the olefin could occur. If such a free radical were formed, a pronounced effect would be noticed when a rapid-reacting olefin is mixed with a large excess of a slower reacting olefin. Table III shows the data when *trans*-2-butene is reacted with ozone in the presence of hexene-1. Column 4 of Table III shows good agreement with the corresponding rate constant of the *trans*-2-butene–ozone reaction shown in Table III.

The presence of ethane and butane in the ozone–1-butene and ozone–1-hexene reactions can be explained by reaction [6]. The aldehyde and ketone formation can be explained by reaction [4]. We were unable with this study to determine whether the initial product resulting from reaction [3] is a four- or five-membered ring. The more acceptable form of the initial ozonide in liquid phase reactions is the five-membered ring (9).

It has been shown that the reactivity of mesitylene approaches that of many 1-alkenes in photooxidation-type reactions (10, 11, 12). Since the rate of reaction of mesitylene with ozone is very slow in the concentration range of interest, the overall rates of hydrocarbon consumption in photooxidations cannot be attributed to the reaction with ozone. The atomic oxygen – mesitylene reaction has been measured in this laboratory and found to be slow. The computed rate of reaction of atomic oxygen with mesitylene accounts for only a small fraction of the overall rate of mesitylene consumption. If the rapid photooxidation of mesitylene in the presence of oxides of nitrogen is to be explained, it must be done by introducing reacting species other than atomic oxygen and ozone. The hypothesis most compatible with these observations is that free-radical attack on the hydrocarbon is more important in the photooxidation of olefins. It would appear that electrophilic or radical species must be formed that may be capable of much more vigorous reaction with aromatic hydrocarbons than are ether ozone or atomic oxygen.

The pre-exponential factors for the three compounds studied at various temperatures are 3.6×10^8 cc mole^{-1} s^{-1} for *trans*-2-butene, 1.4×10^9 cc mole^{-1} s^{-1} for isobutene, and 1.7×10^9 cc mole^{-1} s^{-1} for ethylene.

Cadle and Schadt (13) studied ethylene–ozone and 1-hexene–ozone reactions at various temperatures. Their data showed no statistically significant change in the rate constants with increasing temperatures for both ethylene and 1-hexene. The pre-exponential factors calculated from their rate constants are 1.6×10^5 cc mole^{-1} s^{-1} and 6.1×10^6 cc mole^{-1} s^{-1} for ethylene and 1-hexene, respectively. These results are open to doubt. The largest contribution to the activation entropy comes from a loss in translational degrees of freedom. This loss in translational degrees of freedom increases with increasing masses of the reacting species. One should therefore expect that the 1-hexene–ozone reaction would have a smaller pre-exponential factor (14).

It has been suggested (15) that the nonstoichiometric behavior of olefin–ozone reactions may be due in part to oxidizing products interfering with the titration of ozone by neutral

**Other reactions can be written for the decomposition of the zwitterion (see ref. 15, pp. 175–178). However, since the rate constants for these reactions will also appear in the denominator in the last term of eq. [9], they will not contribute to the equation and have not been included.*

KI. To test this possibility, *tert*-butyl hydroperoxide, *n*-butyl hydroperoxide, and peracetic acid were tested with neutral KI solutions. The hydroperoxides liberated iodine very slowly while the peracid liberated iodine quickly. Since no slow-reacting product was observed with any of the ozone–olefin reactions, it was concluded that either hydroperoxides were absent or their reactions with olefins are so rapid that only small steady-state concentrations are present. To eliminate the latter possibility, *tert*-butyl and *n*-butyl hydroperoxides were added to isobutene in two separate experiments. No reaction was observed over a period of 12 h. It was therefore concluded that hydroperoxides are not formed from ozone–olefin reactions. It is not possible to distinguish between ozone and peracids with the neutral KI. It is possible, however, to determine whether peracids are present by appropriate kinetic experiments. Peracetic acid and 1-hexene were introduced into a Teflon (FEP) bag, and no reaction was observed over a period of several hours. Since the rate constants appearing in Table II show no trend with increasing time, it must be concluded that no peracids are formed. It is assumed that if peracids were formed, they would have to react with olefins at the same rate as ozone in order to maintain any constancy in the rate constants. Since peracids do not react quickly with olefins, if formed, they would remain in the reaction chamber. Their buildup would be appreciable over a period of time. Since this oxidant buildup would show a decrease in the rate constants by use of eq. [2] and no such decrease was observed, it must be concluded that no significant concentrations of peracids were formed.

The other possible oxidant product usually associated with ozone–olefin type reactions is an ozonide. Scott and co-workers (16) found no ozonides from the ozone–olefin reactions in the gas phase. The same group of workers in a later publication (7) did detect ozonides as minor products. A yield of 8% ozonide was observed by these workers when 20 p.p.m. each of 1-pentene and ozone were reacted. With 11 p.p.m. each of ozone and 1-hexene, 13% ozonide was detected. Little or no ozonide was observed with the lower olefins (C_2–C_4).

We did not test ozonides with neutral KI so it is entirely possible that a reaction could occur with this reagent. The rate constants given in Tables I, II, and III are dependent upon ozonides not reacting with neutral KI. Since no trend could be detected in the static studies (Column 4, Tables II and III) we feel that ozonide interference is small.

ACKNOWLEDGMENT

The authors wish to thank Dr. R. J. Cvetanovic for his valuable comments and discussions.

SYNTHESIS OF 1-ARYL SUBSTITUTED 9*H*-PYRIDO[3,4-*b*]INDOLES

W. A. SKINNER AND R. M. PARKHURST
Department of Pharmaceutical Chemistry, Stanford Research Institute, Menlo Park, California
Received March 12, 1965

ABSTRACT

A series of 1-aryl substituted 9*H*-pyrido[3,4-*b*]indoles (1,2,3,4-tetrahydro-β-carbolines) were synthesized by cyclization of tryptamine with a number of substituted benzaldehydes in the presence of hydrochloric acid. Four modifications of reaction conditions were found necessary in order to obtain the desired products containing a variety of substituents on the 1-aryl group. Nuclear magnetic resonance spectra of the products enabled definitive assignment of structure.

A number of naturally occurring β-carboline derivatives having marked physiological effects are known. Among these are harmine, harmaline, and tetrahydroharmine. A review of the synthetic methods and biological activities of these compounds was recently published (1). The psychotomimetic activity of harmine appears to be less than that of the crude extract *B. caapi* (2) leading to the suggestion that harmaline and 1,2,3,4-tetrahydroharmine may also have this type of activity (3). Yohimbine, which caused anxiety in humans (4), also contains the 1,2,3,4-tetrahydroharmine moiety.

Only a few references to the synthesis of 1-aryl-9*H*-pyrido[3,4-*b*]indoles (1-aryl-1,2,3,4-tetrahydro-β-carbolines) appear in the literature. However, quite a number of 1-alkyl-1,2,3,4-tetrahydro-β-carbolines have been reported as well as some 1-benzyl derivatives. Recently, Taborsky and McIsaac (5) reported the synthesis of some 9*H*-pyrido[3,4-*b*]indoles. None of these derivatives were 1-aryl substituted, however. Some exhibited a significant effect on the conditioned behavioral response rates of rats. A series of 6-acetyl-1,2,3,4-tetrahydro-β-carbolines were synthesized by von Strandtmann, Puchalski, and Shavel (6). The only 1-aryl derivative of this group was the phenyl-substituted compound. Protiva, Vejdělek, and Rajsner (7) reported the synthesis of 1-(3′-methoxyphenyl)-1,2,3,4-tetrahydro-β-carboline; 1-(4′-methoxyphenyl)-1,2,3,4-tetrahydro-β-carboline and 1-(4′-dimethylaminophenyl)-1,2,3,4-tetrahydro-β-carboline from the corresponding Schiff bases.

We wish to report the synthesis of a series of substituted 1-aryl-1,2,3,4-tetrahydro-β-carbolines (Table I) utilizing modifications of the Pictet and Spengler reaction (8). It was necessary to use four different reaction conditions for cyclization of tryptamine to the desired compounds.

Attempts to prepare the tetrahydro-β-carbolines from syringaldehyde and tryptamine by methods I, III, and IV failed. During isolation, the lighter colored product darkened rapidly upon contact with air indicating that rapid air oxidation was occurring, probably involving the 4′-hydroxyl group. It is interesting that the *m*-hydroxyphenyl derivative, which cannot form a quinoidal structure, and the 3′-methoxy-4′-hydroxy-5′-nitro derivative, in which the hydroxyl group is hydrogen bonded to the adjacent nitro group, were obtained without difficulty. The 2′-hydroxyphenyl derivative was also obtained. Hydrogen bonding of the hydroxyl group with the 2-nitrogen of the β-carboline moiety is probably responsible for its stability.

Nuclear magnetic resonance spectra of this series of 1-aryl-1,2,3,4-tetrahydro-β-carbolines using an A-60 instrument and TMS as an internal reference were extremely

valuable in assigning the tetrahydro-β-carboline structures to them. The absence of a band due to H—C=N at low field and the presence of a singlet 1H band at 5.00–5.20 τ assigned to the 1-position hydrogen indicated that the intermediate Schiff's base had closed to the tetrahydro-β-carboline structure. The 3,4-methylene triplets near 7 τ and the singlet NH at 8.10–8.56 τ strengthened this evidence for a saturated β-carboline ring. Addition of D_2O to the samples in the n.m.r. tubes resulted in a loss of the bands at 8.10–8.56 τ and 1.10–1.80 τ for the 9H pyrido and indole NH respectively.

EXPERIMENTAL

Method I. 1-(4'-Methylphenyl)-1,2,3,4-tetrahydro-β-carboline Hydrochloride

A mixture of 2 g (0.01 mole) of tryptamine hydrochloride, 1.2 g (0.01 mole) of 4-tolylaldehyde, and 25 ml of absolute ethanol was refluxed under nitrogen for 5 h. After this time, 0.1 ml of concentrated hydrochloric acid was added and refluxing was continued overnight. Upon cooling, a white precipitate was deposited, 1.57 g (53%), m.p. 283–286°, after recrystallization from ethanol–water; $\lambda_{max(\mu)}^{Nujol}$ 3.14 (indole NH); 6.20 (aryl); 12.2 (1,4-disubstituted benzene); 13.6 (1,2-disubstituted benzene).

The n.m.r. spectrum of the free base in $CDCl_3$ showed: NH (singlet, 1.80 τ); 8 φH (multiplet, 2.50–3.25 τ); CH (singlet, 5.20 τ); CH_2 (triplet, 7.05 τ); CH_2 (triplet, 7.30 τ); CH_3 (singlet, 7.75 τ); NH (singlet, 8.56 τ).

Method II. 1-(4'-Dimethylaminophenyl)-1,2,3,4-tetrahydro-β-carboline

A mixture of 1 g (0.005 mole) of tryptamine hydrochloride and 0.8 g (0.005 mole) of *p*-dimethylaminobenzaldehyde in 50 ml of ethanol containing a drop of concentrated hydrochloric acid was allowed to stand at room temperature for a week. The mixture was poured into excess aqueous ammonia to precipitate the product as the free base. Crystallization of the crude product from benzene – petroleum ether (b.p. 30–60°) afforded 350 mg (24%) of yellow colored platelets, m.p. 173–174°; $\lambda_{max(\mu)}^{Nujol}$ 3.15, 3.25 (indole NH and β-carboline NH); 6.18 (aryl); 6.55 (aryl); 12.2, 12.5 (1,4-disubstituted benzene); 13.3, 13.4, 13.6 (1,2-disubstituted benzene).

The n.m.r. spectrum of the free base in $CDCl_3$ showed: NH (singlet, 1.10 τ); 8 φH (multiplet, 2.50–3.25 τ); CH (singlet, 5.00 τ); CH_2 (triplet, 6.80 τ); $2CH_3$ (singlet, 7.10 τ); CH_2 (triplet, 7.20 τ); NH (singlet, 8.25 τ).

Method III. 1-(4'-Methoxyphenyl)-1,2,3,4-tetrahydro-β-carboline Hydrochloride

A solution of 2 g (0.01 mole) of tryptamine hydrochloride and 1.36 g (0.01 mole) of *p*-methoxy-benzaldehyde in 25 ml of ethanol containing 1 drop of concentrated hydrochloric acid and enough water to dissolve the tryptamine hydrochloride (5 drops) was refluxed overnight under nitrogen. Upon cooling, the product separated as colorless needles and was recrystallized from ethanol–water, 1.75 g (56)%, m.p. 283–285°; $\lambda_{max(\ )}^{Nujol}$ 3.05 (indole NH); 3.60–3.95 (NH^+); 6.12, 6.55 (aryl); 7.95 (C—O); 9.63 (C—O—C); 12.0 (1,4-disubstituted benzene); 13.5 (1,2-disubstituted benzene).

The n.m.r. spectrum of the free base in $CDCl_3$ showed: NH (singlet, 1.5 τ), 8 φH (multiplet, 2.40–3.30 τ); CH (5.10 τ); CH_3O (6.33 τ); CH_2—CH_2 (6.8–7.4 τ); NH (8.40 τ).

Method IV. 1-(3',4'-Dimethoxyphenyl)-1,2,3,4-tetrahydro-β-carboline

A mixture of 2 g (0.01 mole) of tryptamine hydrochloride, 1.66 g (0.01 mole) of veratraldehyde, 25 ml of ethanol, 0.5 ml of water, 1 drop of concentrated hydrochloric acid, and 10 ml of benzene was refluxed and the water was removed by azeotropic distillation. Upon cooling the product, 2.6 g (75%) of colorless needles precipitated. Recrystallization from ethanol–water afforded an analytical sample, m.p. 295–297°; $\lambda_{max(\mu)}^{Nujol}$ 3.00 (indole NH); 6.30, 6.66 (aryl); 8.80 (C—O—C); 12.5 (1,2,4-trisubstituted benzene); 13.5 (1,2-disubstituted benzene).

The n.m.r. spectrum of the free base showed: NH (singlet, 1.35 τ); 7 φH (multiplet, 2.20–3.20 τ); CH (singlet, 5.05 τ); OCH_3 (singlet, 6.25 τ); OCH_3 (singlet, 6.40 τ); CH_2 (multiplet, 6.90 τ); CH_2 (multiplet, 7.20 τ); NH (singlet, 8.10 τ).

α-DEUTERIUM KINETIC ISOTOPE EFFECTS IN SOLVOLYSES OF *endo*-NORBORNYL *p*-BROMOBENZENESULFONATE

C. C. LEE AND EDWARD W. C. WONG[1]

Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received February 12, 1965

ABSTRACT

endo-Norbornyl-2-*d* *p*-bromobenzenesulfonate was synthesized and the isotope effects, as measured by k_H/k_D, were determined over a range of temperatures for solvolyses in 30% water – 70% dioxane, acetic acid, and formic acid. Values of k_H/k_D are of the order of 1.20. The data appear to indicate slightly higher isotope effects as the solvents are changed from aqueous dioxane to acetic acid to formic acid, as well as somewhat higher isotope effects at lower temperatures. Possible mechanistic implications of these results are presented. Relative titrimetric acetolysis rates, k_{exo}/k_{endo}, at different temperatures, and enthalpies and entropies of activation for these acetolyses are evaluated and discussed.

INTRODUCTION

The difference in kinetic behaviors of the *endo*- and *exo*-isomers and the stereospecific nature of the products of solvolyses (1, 2), the great propensity for rearrangement (3), and the relatively recent controversy on the "equilibrating classical" or "nonclassical" structure of the norbornyl cation (4, 5) have led to intensive studies on the norbornyl (bicyclo[2.2.1]heptyl) system. Recently, the n.m.r. spectra of the norbornyl cation at various temperatures have been reported by Schleyer and co-workers (6, 7), who also adequately gave a list of the pertinent literature. Since solvolyses involving carbonium ion intermediates are known to give rise to secondary α-deuterium kinetic isotope effects (8), preliminary studies have been made (9) in an attempt to measure the kinetic isotope effects in the acetolyses of *endo*- and *exo*-norbornyl-2-*d* *p*-bromobenzenesulfonates. Because of internal returns (2, 10), which would lead to scrambling of the deuterium atom during acetolysis of the *exo*-isomer, it is difficult to interpret the overall kinetic results from solvolyses of *exo*-norbornyl-2-*d* *p*-bromobenzenesulfonate. The present paper reports more extensive measurements of α-deuterium kinetic isotope effects on the *endo*-system, the solvolyses of which are not complicated by internal returns.

RESULTS AND DISCUSSION

Reduction of norcamphor with lithium aluminium deuteride gave chiefly *endo*-norborneol-2-*d* which was converted to the *p*-bromobenzenesulfonate. The small amount (about 10%) of *exo*-isomer present was removed by selective solvolysis in aqueous acetone (3), pure *endo*-norbornyl-2-*d* *p*-bromobenzenesulfonate (I-*d*) being recovered. The n.m.r. spectrum of I-*d* showed that the absorption corresponding to the C-2 proton essentially disappeared (11) and deuterium analysis* indicated that it contained 0.94 D atoms per molecule.

The kinetics of solvolysis of *endo*-norbornyl *p*-bromobenzenesulfonate (I) and I-*d* at a number of temperatures were followed titrimetrically in 30% water – 70% dioxane (by volume), in glacial acetic acid (reagent grade, minimum 99.8% CH_3COOH), and in reagent grade 98–100% formic acid. The resulting first-order specific rate constants, together with the corresponding 95% confidence limits (standard deviation × 1.96), and the kinetic isotope effects as measured by k_H/k_D, are summarized in Table I.

While interpretations of secondary deuterium isotope effects are still of some controversy, a recent critical review has been presented by Halevi (12). Among the current hypotheses is one by Streitwieser (8, 13) who suggests that the α-deuterium kinetic isotope effect is largely due to "the decrease in a bending force constant from a starting tetrahedral C—H bending vibration to the generally lower out-of-plane bending motion in the transition state leading to the carbonium ion" (8). For a reaction involving an isolated carbonium ion, the α-deuterium kinetic isotope effect was estimated to be about 1.4 (13). The generally smaller observed effect of about 15% rate retardation per α-deuterium atom for reactions such as acetolysis is postulated as attributable to the nearby leaving group in the transition state, which impedes the out-of-plane bending motion of the C—H bond (8, 13), and possibly also to the electron-releasing inductive effect of deuterium (12, 14). For a direct displacement reaction, the α-deuterium kinetic isotope effect virtually vanishes or becomes inverse. This again may be attributed to a combination of the inductive effect of deuterium and the further stiffening of the out-of-plane C—H bending motion by the presence of the entering group at the rear (8, 13).

The data in Table I indicate that solvolyses of I and I-*d* gave an isotope effect of about 1.20 which may be regarded as normal for an S_N1 or limiting solvolysis. For the different solvents employed, the differences in k_H/k_D were very small, although the results appear to suggest a tendency towards a higher isotope effect as the solvents are changed from aqueous dioxane to acetic acid to formic acid. A similar trend for k_H/k_D has been noted in solvolyses of 2-(Δ^3-cyclopentenyl)ethyl *p*-nitrobenzenesulfonate and its 1,1-dideuterio-analog when the solvent was changed from aqueous dioxane to acetic acid (15). If this trend is real, it could be regarded as support of Streitwieser's interpretation of the α-deuterium kinetic isotope effect that, in a solvent such as formic acid, the leaving group would have receded farther from the developing carbonium ion in the transition state and would impede the out-of-plane C—H bending motion to a lesser extent, thus resulting in a higher k_H/k_D, nearer to the calculated value of 1.4 per α-deuterium atom.

The influence of varying temperature on the isotope effects recorded in Table I is very slight. The data, however, do appear to indicate somewhat higher isotope effects for lower temperatures. Leffek, Robertson, and Sugamori (16) have treated temperature effects by plotting log (k_H/k_D) against reciprocals of absolute temperature, and from the slope and intercept, $\Delta\Delta H^{\ddagger}$ (i.e. $\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}$) and $\Delta\Delta S^{\ddagger}$ (i.e. $\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}$) were evaluated. Although the precision of the present data likely may not be as high as that attained by Robertson's group, if the present results are calculated with the inclusion of one extra figure and the temperature effects are treated by the method of Leffek and co-workers, the values of $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ obtained appear to suggest that the rate retardation by α-deuterium substitution may be regarded as largely due to differences in enthalpy of activation (9, 15). This observation would be consistent with the assumption that differences in zero point energies contribute mainly to α-deuterium kinetic isotope effects (13).

Aside from the isotope effect considerations, it is of interest to compare the kinetic data for acetolysis of *endo*-isomer I (k_H, acetolysis, Table I) with the rates obtained previously (9) from acetolysis of *exo*-norbornyl *p*-bormobenzenesulfonate (II). The specific rate constants for the acetolysis of II at various temperatures are given in Table II. The activation parameters for these acetolyses, summarized in Table III, indicate that differences in rate may be largely attributable to a difference in enthalpy of activation. Professor H. C. Brown (17) has informed us that his group has also noted that the entropies of activation for the acetolyses of *endo*- and *exo*-isomers I and II do not differ very significantly, and that this would not be in agreement with expectation if anchimeric assistance

30.02	18.6±0.1
35.00	34.1±0.1
50.00	195*

*Extrapolated value.

TABLE III

Activation parameters calculated for acetolysis of *endo*-norbornyl *p*-bromobenzenesulfonate (I) at 50 °C and of *exo*-norbornyl *p*-bromobenzenesulfonate (II) at 20 °C

	ΔH^* (kcal/mole)	ΔS^* (cal/deg mole)
endo-I	25.3±0.4	−3.5±1.2
exo-II	22.3±0.1	−2.0±0.3

were associated with a higher entropy of activation (18) and if anchimeric assistance were taking place in the acetolysis of *exo*- but not *endo*-norbornyl *p*-bromobenzenesulfonate. However, Professor Winstein (19) has pointed out that entropies of activation as a criterion of anchimeric assistance have been used only *empirically* in 2-arylethyl systems (18) and that this application does not necessarily have to include the norbornyl system.

Professor Brown (17) also drew attention to the fact that relative rates calculated from k_H for acetolyses of I and II (Tables I and II) appear to be less than the well-known value of k_{exo}/k_{endo} of 350 at 25 °C reported by Winstein and co-workers (20). The latter value was based on rate constants at 25 °C calculated from experimental results obtained at two other temperatures. When the kinetic data from the present studies were extrapolated to 20 °C for the acetolysis of the *endo*-isomer I and to 50 °C for the *exo*-isomer II, the relative rate obtained for k_{exo}/k_{endo} was 330 at 20 °C but was only about 200 at 50 °C. The lower value at the higher temperature is, of course, attributable to the differences in activation parameters for the acetolyses of I and II (Table III), the predominance of a greater enthalpy of activation for the *endo*-isomer I being responsible for a proportionally greater rise in its rate constant as the temperature is increased. When this temperature effect and small differences in experimental conditions (the chief of which may be the fact that acetolyses in the present work were carried out in commercially obtained glacial acetic acid while Winstein and coworkers used anhydrous acetic acid containing about 0.2% acetic anhydride prepared from glacial acetic acid, potassium acetate, and acetic anhydride (21)) are taken into consideration, it is not surprising that absolute values of rate constants may be somewhat different. It is believed that the present results constitute a self-consistent set of data and that the relative rate of 330 for k_{exo}/k_{endo} calculated for 20 °C is in substantial agreement with the reported relative titrimetric acetolysis rates of Winstein and co-workers.

EXPERIMENTAL

endo-Norbornyl-2-d p-Bromobenzenesulfonate (I-d)

Reduction of 27.0 g (0.25 mole) of norcomphor by 3.0 g (0.071 mole) of lithium aluminium deuteride in anhydrous ether in the usual manner gave 26.5 g (96%) of norborneol-2-*d*, m.p. 148–149 °C. The alcohol was converted to the *p*-bromobenzenesulfonate which was selectively solvolyzed in 25% water – 75% acetone at 45 °C for 15 min (3). Titration of the *p*-bromobenzenesulfonic acid liberated indicated the presence of 10% *exo*-isomer. Pure *endo*-norbornyl-2-*d* *p*-bromobenzenesulphonate, m.p. 62–63 °C, was recovered in 83% yield after the selective solvolysis.

Kinetic Measurements

All reaction kinetics were followed titrimetrically. The procedures used for hydrolysis in 30% water – 70% dioxane and for acetolysis were as described earlier in analogous studies with 2-(Δ^3-cyclopentenyl)ethyl and related systems (15). For formolysis, titrations were carried out according to the method of Winstein and Heck (18). The initial concentration of I or I-*d* in all experiments was 0.0500 *M*. At each reaction temperature, corresponding protio- and deuterio-analogs were solvolysed simultaneously to minimize possible variations between experiments. The specific rate constants and the activation parameters were calculated from the slopes of least squares plots of the appropriate data (15), with the aid of a digital computer.*

FORMATION OF *O*-β-D-GLUCOPYRANOSYL- AND *O*-β-D-GALACTOPYRANOSYL-MYO-INOSITOLS BY GLYCOSYL TRANSFER[1]

P. A. J. GORIN, K. HORITSU,[2] AND J. F. T. SPENCER
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received February 2, 1965

ABSTRACT

Enzyme extracts or growing cells of *Sporobolomyces singularis* catalyzed glycosyl transfer from cellobiose or lactose to polyhydroxylic acceptors. The substituted hydroxyl, in each instance, had hydroxylic neighbors which appeared to have a role in the reaction. To show whether the pyranoid ring oxygen of glycosyl acceptors has an effect on the reaction, the substitution positions on pyranoid and myo-inositol acceptors are compared. Glucosyl transfer to the 1- and 5-positions of (1R)-myo-inositol[3] and galactosyl transfer to the 5-position occurs. The configuration of hydroxyl groups adjacent to the position substituted is the same in these products as in the corresponding pyranoid derivatives. The pyranoid ring oxygen, therefore, has little effect on the glycosyl transfer reactions.

Formation of disaccharides by transfer of β-galactopyranosyl residues from lactose to carbohydrate acceptors using growing cultures and enzyme extracts of *Sporobolomyces singularis* has been observed. When cellobiose was used in place of lactose, analogous β-glucopyranosyl transfer took place. The substituted position in the polyhydroxylic acceptor generally had a vicinal hydroxyl and it was postulated that one or more of these participated in the reaction by interaction in the transitory enzyme–substrate complex (2). In most cases the glycosyl transfer was stereospecific so that virtually only one product was formed. In acceptors containing four consecutive hydroxyl groups such as D-galactose, D-fucose, and L-arabinose the 3-positions were substituted (D-arabinose and L-fucose were poor acceptors). The 3-positions of D-glucose (using enzyme extract), 6-deoxy-D-glucose, and D-xylose were also substituted.

The reaction involved in glycosyl transfer is complex and groups in the acceptor other than neighboring hydroxyls could be involved in the enzyme–substrate complex. To establish the role of the pyranoid oxygen, if any, in the reaction, myo-inositol was tested as an acceptor. If the oxygen atom had no effect the myo-inositol molecule should be substituted in the 1- and (or) 5-positions which are similar, in respect to the configuration of the neighbouring hydroxyl groups, to the 3-positions of D-galactose and D-glucose (and configurationally similar pyranose sugars) respectively.

The products of transfer from lactose to myo-inositol in growing cultures of *Sporobolomyces singularis* were therefore examined. A mixture of galactosyl and galactobiosyl inositols was formed and the galactosyl inositol portion was isolated by chromatography. The total fraction was methylated and then hydrolyzed, and the derived penta-*O*-methyl myo-inositols were examined by gas phase chromatography (g.l.c.) (3). 1,2,3,4,6-Penta-*O*-methyl myo-inositol (74%; V) derived from 5-*O*-β-D-galactopyranosyl myo-inositol (I) was the main product and was kindly identified by Prof. C. E. Ballou.[4] Other fragments corresponded to the (1S)-1,2,4,5,6-isomer (IV) and (or) its enantiomer (3%) and other isomers (23%). 5-*O*-β-D-Galactopyranosyl myo-inositol was isolated in 23% yield (based

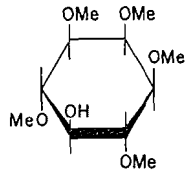
IV



V

on lactose) by crystallization of the galactosyl inositol fraction. A methylation experiment similar to that described above provided methylated fragments corresponding to methyl 2,3,4,6-tetra-*O*-methyl $\alpha\beta$-galactoside and penta-*O*-methyl myo-inositols (g.l.c.). The cyclitol portion consisted of the 1,2,3,4,6-isomer (91%) and the (1S)-1,2,4,5,6-isomer and (or) its enantiomer (9%).

Transfer of β-D-galactopyranosyl residues to myo-inositol in the presence of enzyme extract from *Sporobolomyces singularis* cells was also followed. In contrast with growing cultures the glucose liberated from lactose was not utilized. This hexose competed with myo-inositol and reduced the yields of galactosyl and galactobiosyl inositols. Analyses by g.l.c. of penta-*O*-methyl myo-inositols formed on methylation of the original reaction mixture followed by hydrolysis were obtained. Examination at intervals up to 24 h showed that only the 1,2,3,4,6-isomer was formed, and that 5-linked myo-inositol residues were present.

Transfer of β-glucopyranosyl units from cellobiose to myo-inositol was also studied in growing cultures of *Sporobolomyces singularis* and using enzyme extracts from cells. The two main β-D-glucopyranosyl myo-inositols formed in growing cultures were isolated chromatographically and crystallized. The major component was 1-*O*-β-D-glucopyranosyl-(1R)-myo-inositol, which accounted for 38% of the glucosyl inositol fraction. Methylation gave a crystalline nona-*O*-methyl derivative. It was hydrolyzed in aqueous acid and the product was treated with methanolic hydrogen chloride. The resulting mixture was examined by g.l.c. and contained materials corresponding to methyl 2,3,4,6-tetra-*O*-methyl $\alpha\beta$-glucoside and a penta-*O*-methyl myo-inositol, identified after crystallization as the 1S-1,2,4,5,6-isomer[5] (IV) (4). Because of the presence of the minor glucosyl transfer product, 5-*O*-β-D-glucopyranosyl myo-inositol (II), the mixture of penta-*O*-methyl myo-inositols obtained on hydrolysis of the permethylated product, prior to its crystallization, contained 16% of the 1,2,3,4,6-isomer (V). This glucosyl inositol crystallized as a monohydrate in 18% yield based on the total glucosyl inositol fraction and was also characterized by methylation followed by hydrolysis. The fragments corresponded on g.l.c. to methyl 2,3,4,6-tetra-*O*-methyl $\alpha\beta$-glucoside and 1,2,3,4,6-penta-*O*-methyl myo-inositol, the latter being isolated and crystallized after silicic acid chromatography.

[5]*Its specific rotation of −18° was less than that of −3.5° reported for the product derived from galactinol (4). However, repetition of the galactinol experiment showed the former value to be correct.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A small portion of the mixture of β-glucopyranosyl myo-inositols formed on glucosyl transfer was methylated. Hydrolysis of the permethylated product followed by methanolysis provided methyl 2,3,4,6-tetra-*O*-methyl αβ-glucoside and penta-*O*-methyl myo-inositols. The cyclitol mixture was examined by g.l.c. and shown to consist of the 1,2,3,4,6-isomer (30%) and the (1S)-1,2,4,5,6-isomer and (or) its enantiomer (56%). In view of the good yield of 1-*O*-β-D-glucopyranosyl-(1R)-myo-inositol, (1S)-1,2,4,5,6-penta-*O*-methyl myo-inositol should be the predominant isomer in the mixture.

The configurations of the glucosidic linkages in II and III were confirmed as β since they were readily hydrolyzed by emulsin, a β-glucosidase. The configuration of galactosyl inositol (I) was shown to be β also by using Hudson's rules of isorotation (5). The $[M]_D$ of 5-*O*-β-D-galactopyranosyl myo-inositol should equal

$[M]_D$ of II − ($[M]_D$ of methyl-β-D-glucopyranoside − $[M]_D$ of methyl β-D-galactopyranoside),

and using known $[M]_D$ values this expression comes to −560°. This value corresponds to a specific rotation of −2° which is in agreement with the found value of 0°.

β-Glucosyl transfer proceeded more rapidly than the β-galactosyl transfer in a system containing cellobiose, myo-inositol and cell enzyme extract, scission of cellobiose being virtually complete after 30 min whereas complete scission of lactose took 6 h. The reaction was complex giving glucose in addition to glucosyl inositols. Several penta-*O*-methyl myo-inositols were formed on methylation of the reaction mixture followed by hydrolysis in aqueous acid. The ratios of these derivatives compared with tetra-*O*-methyl-D-glucose and their variations with reaction time are given in Fig. 1. These results show that 5-*O*-β-D-glucopyranosyl myo-inositol is formed most rapidly but later undergoes hydrolytic exchange to give, most likely, 1-*O*-β-D-glucopyranosyl (1R)-myo-inositol, which would be represented by (1S)-1,2,4,5,6-penta-*O*-methyl myo-inositol. Although the presence of the latter material is not proven it appears likely that it is formed predominantly, at least in early stages, by analogy with the reaction with growing cultures described earlier.

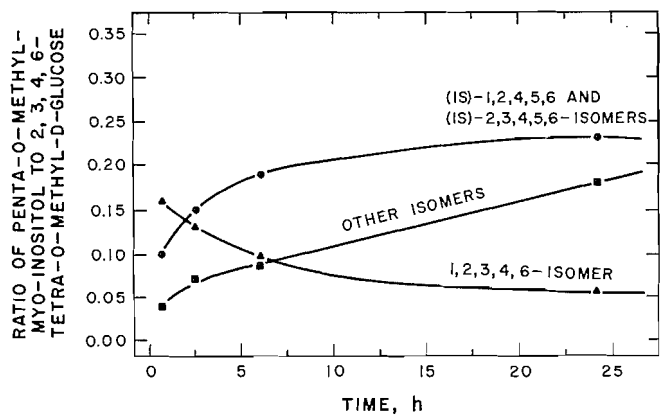


FIG. 1.

Transfer of β-galactosyl units to myo-inositol takes place preferentially at the 5-position which is configurationally analogous to the 3-positions of D-glucose, 6-deoxy-D-glucose, and D-xylose which have been shown to be prone to substitution (2). In contrast with the acceptors examined previously the products of galactosyl transfer differ from those of glucosyl transfer which are (1R)-1- and 5-substituted myo-inositol derivatives. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(1R)-1-position is analogous to the 3-position of L-arabinose, which is similarly substituted in the glucosyl transfer reaction (2). These results show that the pyranoid oxygen has little effect on the transfer reactions, and in all likelihood does not have a role in forming the intermediate enzyme–substrate complex.

EXPERIMENTAL

Preparation of β-Glycopyranosyl myo-Inositols

1. 5-O-β-D-Galactopyranosyl myo-Inositol (I)

Culture conditions used are described in a previous publication (2). The products obtained by growth of *Sporobolomyces singularis* on medium (50 ml) containing 5% lactose and 2.5% myo-inositol were examined on paper chromatograms (solvent: acetone–water (4:1 v/v), dip method: silver nitrate – sodium hydroxide (6)). In addition to myo-inositol, spots with R_I 0.88 and 0.68 (R_I refers to the mobility of the compound on a paper chromatogram compared with myo-inositol) were detected. The new products were isolated by cellulose chromatography using acetone–water (5:1 v/v) as eluant. The material with R_I 0.88 was isolated (yield 0.76 g) and was crystallized twice from aqueous methanol. The galactosyl inositol (I) (0.57 g) had m.p. 248–252° and $[\alpha]_D^{25}$ 0° (*c*, 1.0, H_2O).

Anal. Calcd. for $C_{12}H_{22}O_{11}$: C, 42.1; H, 6.5. Found: C, 42.3; H, 6.5.

Hydrolysis with 1 *N* sulfuric acid at 100° gave galactose and myo-inositol as shown by paper chromatogtography.

The fraction having R_I 0.68 was isolated (yield 0.49 g) and was probably a galactobiosyl inositol since acid hydrolysis gave a higher proportion of galactose to inositol than the above galactosyl inositol(paper chromatograms).

A complete identification of the fraction with R_I 0.68 was not carried out.

2. 5-O- and 1-O-β-D-Glucopyranosyl-(1R)-myo-inositol (II and III Respectively)

The products from 50 ml of 5% cellobiose and 2.5% myo-inositol were examined and shown to consist of materials with R_I's 0.87 and 0.95. They were isolated by cellulose chromatography using acetone–water (6:1 v/v) as eluant. The material with R_I 0.95 (0.44 g) was crystallized from aqueous methanol to give a hydrated glucosyl inositol (II) (0.13 g; 5% yield) with m.p. 158–162° and $[\alpha]_D^{25}$ −20° (*c*, 1.0, H_2O).

Anal. Calcd. for $C_{12}H_{22}O_{11}.H_2O$: C, 40.0; H, 6.7. Found: C, 40.2; H, 6.7.

The fraction with R_I 0.87 (0.35 g) which was crystallized from aqueous methanol was also a glucosyl inositol (III; 0.27 g; 11% yield) and had m.p. 256–260° and $[\alpha]_D^{25}$ −17.5°. Anal. Calcd. for $C_{12}H_{22}O_{11}$: C, 42.1; H, 6.5. Found: C, 41.8; H, 6.5.

Compound II (10 mg) was dissolved in water (0.2 ml) and almond emulsin (2.5 mg) was added. Examination of the solution, at intervals, on a paper chromatogram (solvent: *n*-butanol–ethanol–water 40:11:19 v/v; spray: ammoniacal silver nitrate) showed that hydrolysis was almost complete after 30 min. Compound III was similarly hydrolyzed using identical proportions.

Method of Characterization of β-Glycopyranosyl myo-Inositols

These were methylated at room temperature by the sodium hydroxide – dimethyl sulfate procedure of Haworth (7). After destruction of dimethyl sulfate by heating at 100° the solutions were neutralized and extracted continuously for 3 d with chloroform. The extracts were further methylated with treatment for 4 d with silver oxide in refluxing methyl iodide (8). Hydrolysis for 24 h in 1 *N* hydrochloric acid at 100° converted the fully methylated products to a mixture of 2,3,4,6-tetra-*O*-methyl-D-hexose and penta-*O*-methyl myo-inositols. Full methylation was attained under the above conditions as shown by examination of the products on silica gel thin layer plates (solvent: chloroform–methanol 50:1 v/v; spray: 50% aqueous sulfuric acid at 130°). Tetra-*O*-methyl hexoses and penta-*O*-methyl myo-inositols ran at virtually the same rates, and complete methylation was shown by absence of slower moving spots. Treatment of the fragments with refluxing 5% methanolic hydrogen chloride for 3 h converted the hexose derivative to its αβ-methyl glycoside, thus rendering the mixture more readily separable by g.l.c. and silicic acid chromatography.

Gas phase chromatography was carried out using 2% neopentyl glycol succinate (3) on HMDS Chromosorb W (80–100 mesh) in a 5 ft × 1/4 in. o.d. copper tube at 143° and 160° with helium as carrier gas injected at 30 p.s.i. The g.l.c. unit was of conventional design using thermal conductivity detectors.

Identification of 1,2,3,4,6-penta-*O*-methyl myo-inositol (V) was kindly carried out by Prof. C. E. Ballou (see footnote 4 in the theoretical section). This compound had a different retention time from other penta-*O*-methyl myo-inositols (3).

Characterization of Total O-β-D-Galactopyranosyl myo-Inositols Formed on Glycosyl Transfer

Methylated fragments were obtained from a sample of the total galactosyl inositol fraction which was formed on glycosyl transfer from lactose to myo-inositol in growing culture. These were shown by g.l.c. to consist of methyl 2,3,4,6-tetra-*O*-methyl αβ-D-galactoside and a mixture of methylated inositols consisting of 1,2,3,4,6-penta-*O*-methyl myo-inositol (V; 74%), the (1S)-1,2,4,5,6-isomer (IV) and (or) its enantiomer (3%) and other isomers (23%).

Characterization of 5-O-β-D-Galactopyranosyl myo-Inositol (I)

Fractional crystallization of the *O*-β-D-galactopyranosyl myo-inositol mixture from aqueous methanol yielded compound I. A methylation experiment gave rise to methyl 2,3,4,6-tetra-*O*-methyl αβ-D-galactoside and 1,2,3,4,6-penta-*O*-methyl myo-inositol (91%), the (1S)-1,2,4,5,6-isomer and (or) its enantiomer (5%) and other isomers (4%). Three recrystallizations of the galactosyl inositol from aqueous methanol resulted in the formation of a less pure sample. The penta-*O*-methyl myo-inositols obtained consisted of 83% of the 1,2,3,4,6-isomer and 17% of the (1S)-1,2,4,5,6-isomer and (or) its enantiomer.

Characterization of Total O-β-D-Glucopyranosyl myo-Inositols Formed on Glycosyl Transfer

The mixture of glucosyl inositols was isolated by chromatography from the culture medium as described earlier in the experimental section. Methylation followed by hydrolysis and methanolysis yielded as the only products methyl 2,3,4,6-tetra-*O*-methyl αβ-D-glucoside and a mixture of penta-*O*-methyl myo-inositols consisting of the (1S)-1,2,4,5,6-isomer and (or) its enantiomer (56%), 1,2,3,4,6-isomer (30%), and other isomers (14%). The major methylated fraction, the (1S)-1,2,4,5,6-isomer was derived from 1-*O*-β-D-glucopyranosyl-(1R)-myo-inositol (III; R_I 0.87). This material was isolated crystalline in 38% yield from the total glucosyl inositol fraction.

Characterization of 5-O-β-D-Glucopyranosyl myo-Inositol (II; R_I 0.95)

Methylation (as before) of II (0.18 g) gave 0.16 g of fully methylated glucosyl inositol. This was hydrolyzed in aqueous acid and the product was treated with methanolic hydrogen chloride. The g.l.c. analysis showed that it contained as the only products methyl 2,3,4,6-tetra-*O*-methyl αβ-D-glucoside and 1,2,3,4,6-penta-*O*-methyl myo-inositol. The mixture was fractionated on silicic acid. Chloroform eluted the glycosides (70 mg) and chloroform–acetone (4:1 v/v) eluted the inositol derivative (57 mg). Two recrystallizations of the latter from *n*-hexane gave material (29 mg) with m.p. 85–86° and $[\alpha]_D^{25}$ 0° (*c*, 1.0, H_2O).

Anal. Calcd. for $C_6H_7O.(OCH_3)_5$: OCH_3, 62.0. Found: OCH_3 61.75.

Characterization of 1-O-β-D-Glucopyranosyl-(1R)-myo-Inositol (III; R_I 0.87)

Methylation of III (0.31 g) yielded 0.18 g of fully methylated glucosyl inositol, a small portion of which was hydrolyzed and the product treated with methanolic hydrogen chloride. The penta-*O*-methyl myo-inositols consisted of 84% of the (1S)-1,2,4,5,6-isomer and 16% of the 1,2,3,4,6-isomer. Crystallization from *n*-hexane yielded the nona-*O*-methyl ether (0.12 g) of the major glucosyl inositol with m.p. 95–98° and $[\alpha]_D^{25}$ −10° (*c*, 1.0, EtOH). Anal. Calcd. for $C_{21}H_{40}O_{11}$: C, 53.8; H, 8.6. Found: C, 54.1; H, 8.45.

Hydrolysis of the nona-*O*-methyl derivative (91 mg) followed by treatment with methanolic hydrogen chloride gave a mixture of methyl 2,3,4,6-tetra-*O*-methyl αβ-glucoside and a penta-*O*-methyl myo-inositol as shown by g.l.c. The latter was crystallized from *n*-hexane (yield 31 mg) and a further crystallization gave material with m.p. 111–114° and $[\alpha]_D$ −18° (*c*, 1.0, H_2O). Anal. Calcd. for $C_{11}H_{22}O_6$: C, 52.8; H, 8.9. Found: C, 53.2; H, 8.9.

The material gave an X-ray diffraction diagram identical with that of (1S)-1,2,4,5,6-penta-*O*-methyl myo-inositol (4). The material prepared in this laboratory in a similar manner from galactinol had $[\alpha]_D$ −19° (*c*, 0.8, H_2O).

Formation of Glycosyl Inositols Using Enzyme Extract from Sporobolomyces Singularis

To a mixture of lactose (2.5 g) and myo-inositol an extract (14 ml) from wet *Sporobolomyces singularis* cells (2) isolated from 250 ml of medium was added. The reaction mixture was examined at intervals up to 24 h on a paper chromatogram with acetone–water (4:1 v/v) as solvent. After 30 min only a small amount of galactosyl inositol had been formed, but after 6 h most of the lactose originally present had been utilized in forming galactose, glucose, galactosyl inositols (R_I 0.88), and galactobiosyl inositols (R_I 0.68). The reaction was also followed by methylation of portions of the mixture. The products, on hydrolysis with aqueous acid and examination by g.l.c., provided 1,2,3,4,6-penta-*O*-methyl myo-inositol as the only cyclitol derived from galactosyl and galactobiosyl inositols.

Greater complexity was observed in the reaction of cellobiose and myo-inositol. Paper chromatography showed that most of the cellobiose had been hydrolyzed after 30 min and that glucose and two glucosyl inositols with R_I 0.87 and 0.95 were formed. The relative amounts of penta-*O*-methyl myo-inositols formed on methylation followed by hydrolysis are shown in Fig. 1. The amount of penta-*O*-methyl myo-inositols is expressed as a ratio by comparison with the 2,3,4,6-tetra-*O*-methyl glucose formed simultaneously from glucose.

ACKNOWLEDGMENTS

The authors would like to thank Dr. H. G. Fletcher, Jr. for a sample of galactinol, and Prof. C. E. Ballou for authentic (1S)-1,2,4,5,6-penta-*O*-methyl myo-inositol. Thanks are also due to Mr. M. Mazurek for carrying out microanalytical determinations and Mr. N. R. Gardner for technical assistance.

REACTIVITIES IN PHOTOSENSITIZED OLEFIN OXIDATIONS

KARL R. KOPECKY AND HANS J. REICH
University of Alberta, Edmonton, Alberta

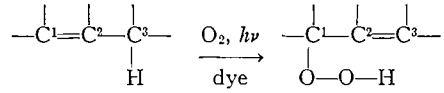
Received January 15, 1965

ABSTRACT

The rate of the methylene blue photosensitized oxidation of olefins increases in the order: 1-nonene < 4-methylcyclohexene < cyclohexene < 2,3-dimethyl-1-butene < 2-hexene < cyclopentene < 1-methylcyclohexene < 2,3-dimethylcyclohexene < 1-methylcyclopentene <1,2-dimethylcyclohexene < 2,3-dimethyl-2-butene. The last compound is oxidized 5 500 times as fast as cyclohexene. Comparison of this reactivity sequence with those obtained in other reactions confirms that the reactive intermediate in the photosensitized oxidations is electrophilic. The relative rates (k_A/k_B) of photo-oxidation of 1-methylcyclopentene (A) and of 1-methylcyclohexene (B) are 10 and do not vary significantly with five different sensitizers. Thus the same reactive intermediate, presumably singlet oxygen, is formed using each of the five sensitizers.

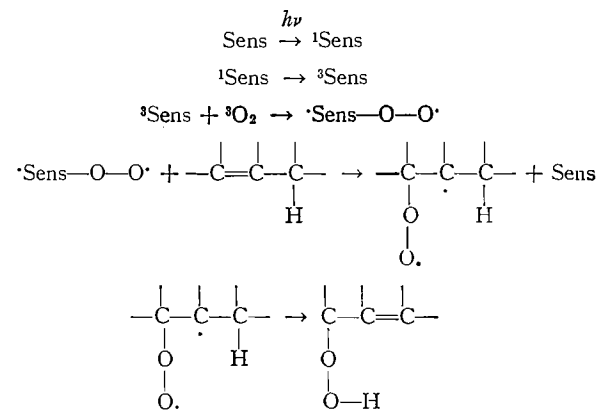
INTRODUCTION

The dye-photosensitized oxidation of olefins to allylic hydroperoxides has been studied extensively by Schenck and his co-workers (1). A shift of the double bond was reported always to take place. The reaction is stereospecific in cyclic systems (2) and has recently been used to advantage in several synthetic studies (3–5).



Two mechanisms for this transformation are currently popular.

Schenck, adapting a mechanism suggested by Schönberg (6) has proposed the following mechanism for the photosensitized oxidation of mono-olefins (1).



In this mechanism a sensitizer molecule (Sens) is excited by radiation (light absorbed only by the dye molecule is sufficient for reaction) to an excited singlet state which undergoes internal conversion to give the triplet (7). This reacts with oxygen to give a "diradical" adduct ('Sens—O—O'). The adduct reacts with an olefinic double bond, regenerating the sensitizer and forming a "diradical" adduct of oxygen and olefin. Hydrogen transfer then yields the allylic hydroperoxide.

Kautsky (8), and, more recently, Sharp (9) and Foote (10, 11) have suggested that the metastable $^1\Delta_g$ state of the oxygen molecule is the reactive intermediate involved in photosensitized oxidations.

$$^3\text{Sens} + {}^3\text{O}_2 \rightarrow \text{Sens} + {}^1\text{O}_2$$
$$^1\text{O}_2 + \text{olefin} \rightarrow \text{hydroperoxide}$$

Energy transfer from triplet sensitizer to triplet oxygen yields the ground state sensitizer and singlet oxygen, because of conservation of electron spin angular momentum during energy transfer (12, 13). Singlet oxygen then reacts with the olefin to produce the hydroperoxide.

In support of the second mechanism Foote (10) has shown that products identical to those formed in dye photosensitized photo-oxidations are produced when sodium hypochlorite is added to solutions containing hydrogen peroxide and an oxidizable substrate. Singlet oxygen has been observed spectroscopically when sodium hypochlorite was added to hydrogen peroxide (14–17). In addition, singlet oxygen generated by electrodeless discharge oxidizes anthracenes to the corresponding endoperoxides (18).

The rate of disappearance of the reactive intermediate in the sensitized oxidation of α-terpinene to ascaridole is independent of sensitizer used (19*a*). It has been suggested that a common intermediate is thus involved when different sensitizers are used (11). However, the activation energy for this reaction is only ca. 0.5 kcal/mole (19*a*), and the only conclusion one may safely make regarding any intermediates in these reactions is that they are all very reactive.

Schenck (19*b*) and Sharp (9) have measured the rate of sensitized oxidation of several olefins and found that increasing substitution of the double bond greatly increased reactivity. We report here similar reactivity studies but find that the response of the reactive intermediate to variation in olefin structure is much greater than that reported by Sharp but similar to that found by Schenck. We also compare the relative rates of photo-oxidation of olefins with the relative rates of their reactions with a number of free radicals and electrophiles. In addition, it is shown that the relative rates of photo-oxidation of two mono-olefins, a reaction which must proceed with activation energy (19*a*), does not vary with several sensitizers.

RESULTS AND DISCUSSION

Schenck's adduct would be expected to show radical reactivity while singlet oxygen

$$(:\ddot{O}{=}\ddot{O}: \leftrightarrow :\ddot{O}{-}\overset{\oplus}{\ddot{O}}:\overset{\ominus}{})$$

(9) may be electrophilic. A number of studies have been made in which the relative reactivities of a number of olefins toward a variety of reagents have been measured. A comparison of the relative reactivities of olefins of different structural types toward photosensitized oxidation and towards the other reagents can thus be made.

We have measured the relative rates of the photo-oxidation, sensitized by methylene blue, of a number of olefins. These were measured by oxidizing olefins in pairs, thus allowing them to compete for the reactive intermediate, and measuring the amounts of olefin remaining at various intervals by g.l.c. analysis. The relative rates are summarized in Table I along with the relative rates of the reactions of a variety of olefins with peracetic acid (20), phthaloyl peroxide (21), bromine (22), methyl radical (23), trifluoromethyl radical (24), and trichloromethyl radical (25, 26). The photo-oxidation reaction is seen to be extremely sensitive to structure. Indeed, the reactive intermediate involved is the most discriminating reagent of those listed in Table I. There is a close similarity in the

variation of rate with structure between the photosensitized oxidation of olefins and their reaction with peracetic acid, bromine, and phthaloyl peroxide. No such similarity exists at all between the rate of the photosensitized oxidation of olefins and the rate of addition of any of the radical reagents listed in Table I to olefins. Even the electrophilic trifluoromethyl radical (24) does not respond to structural changes in the manner that the reactive intermediate in the photosensitized oxidation reaction does. This intermediate thus has strong electrophilic character and does not exhibit any radical properties. It is quite unlikely that the intermediate has the structural features of the diradical described by Schenck (29). The reactivity is best explained by the suggestion (9–11) that singlet oxygen is the reactive intermediate.

Product formation is best described by the suggestion of Sharp (9) that an intermediate perepoxide is formed which rearranges with a concurrent proton shift to yield the allylic hydroperoxide (Chart I). However, our data do not provide evidence against a concerted cycloaddition as proposed by Nickon (30).

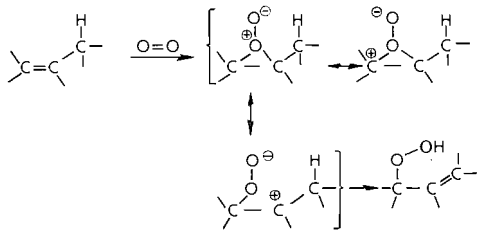

CHART I.

Sharp reports that the relative rates of tetraphenylporphine sensitized photo-oxidation of 1-hexene, 2-methyl-2-butene, and 2,3-dimethyl-2-butene are 1, 94, and 100, respectively. We find a much greater difference in reactivity with comparably substituted olefins, as does Schenck (19*b*). The relative rates of photo-oxidation of 1-nonene, 1-methylcyclohexene, 1-methylcyclopentene, and 2,3-dimethyl-2-butene are, from Table I, 1, 450, 3 900, and 55 000, respectively. The reason for this discrepancy is not clear. It is probably not due to a difference in sensitizer. The relative rates of photo-oxidation of 1-methylcyclohexene and 1-methylcyclopentene with a variety of sensitizers are listed in Table II and do not vary with sensitizer. It may be that Sharp's relative rates were measured indirectly. If so, the relative errors may have accumulated to yield the data reported.[1]

TABLE II

Effect of sensitizer on relative reactivities

Sensitizer	k_A/k_B*
Methylene blue	8.6±0.9
Eosin Y	10.8±1.4
Rose bengal	11.5±1.9
Erythrosin B	8.8±1.6
Hematoporphyrin	9.4±1.8

*A = 1-methylcyclopentene, B = 1-methylcyclohexene.

The oxidation reactions reported in this paper must have an activation energy significantly different from zero. The data of Table II therefore provide the first evidence that a common reactive intermediate is formed in oxidations involving different sensitizers.

[1]*A referee has pointed out that reactivity depends upon concentration, and that the descrepancies may be due to this factor.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

The activation energies of the rose bengal sensitized photo-oxidation of dicyclohexylidene and β-pinene are reported to be 1.3 and 4.5 kcal, respectively (19*a*). Dicyclohexylidene is thus about 700 times as reactive as β-pinene at 25°. This is in good agreement with the reactivity difference to be expected on the basis of the data in Table I.

EXPERIMENTAL

Preparation of Olefins

Cyclohexene (Eastman Kodak White Label), 2-hexene (Phillips 66 Pure Grade) and 4-methylcyclohexene (Eastman Kodak White Label) were distilled from lithium aluminium hydride. Pyrolysis of 1-nonylacetate yielded 1-nonene. The remaining olefins were obtained from the phosphoric acid catalyzed dehydration of the appropriate alcohols. The physical properties of those olefins obtained in the pure state were (boiling points in this study were obtained at 700 mm unless otherwise indicated and are uncorrected; the boiling points cited in the literature references are all for 760 mm unless otherwise indicated): cyclohexene b.p. 79–80°, n_D^{25} 1.4441 (reported (31) b.p. 82.9°, n_D^{25} 1.4438); cyclopentene b.p. 43°, n_D^{25} 1.4199 (reported b.p. 44° (32), n_D^{25} 1.4194 (33)); 1-methylcyclopentene b.p. 72–74°, n_D^{25} 1.4293 (reported (34) b.p. 75.8°, n_D^{20} 1.4330); 1-methylcyclohexene b.p. 106–107°, n_D^{25} 1.4478 (reported (31) b.p. 110°, n_D^{25} 1.4478); 4-methylcyclohexene b.p. 98–99°, n_D^{25} 1.4392 (reported (31) b.p. 102.7°, n_D^{25} 1.4389); 2-hexene b.p. 65–66°, n_D^{25} 1.3941 (reported for *cis*-2-hexene (35) b.p. 68.8°, n_D^{25} 1.3948; for *trans*-2-hexene (35) b.p. 67.8°, n_D^{25} 1.3907); 2,3-dimethyl-2-butene b.p. 70–71°, n_D^{25} 1.4098 (reported (35) b.p. 73°, n_D^{25} 1.4094); 1-nonene b.p. 61–62° at 48 mm, n_D^{25} 1.4136 (reported b.p. 33.5° at 11 mm (36), n_D^{25} 1.4133 (37)). These olefins were shown to be more than 97% pure by g.l.c. analysis.

Dehydration of 1,2-dimethylcylohexanol produced a mixture, shown by g.l.c. analysis to consist of 58% 1,2-dimethylcyclohexene, 37% 2,3-dimethylcyclohexene, and 5% of an unidentified compound. This mixture was used as such in the rate studies. The small amount of 2,3-dimethyl-1-butene, which was formed along with 2,3-dimethyl-2-butene upon dehydration of 2,3-dimethyl-2-butanol and which was used in the rate studies, was shown by g.l.c. analysis to contain 16% ether and 9% 2,3-dimethyl-2-butene as the only detectable impurities. The results obtained from these impure compounds fit well into the general pattern and are considered accurate enough for the present purpose.

Determination of Relative Reactivities of Olefins

Pairs of olefins were chosen for the competition reactions on the basis of suitable reactivity. Approximately equimolar amounts of the two olefins (0.5 to 2.0 ml), 1.0 ml of an internal standard (benzene, toluene, or ethylbenzene) and 30 mg of methylene blue were dissolved in 200 ml of redistilled methanol. The resulting solution was poured into an immersion photochemical reactor (38) just filling the annular space. A slow stream of oxygen was passed through the solution which was kept at 15 °C while it was being irradiated. The light source was a 200 W Hanovia mercury vapor lamp, type S, No. 654A. A filter sleeve, Hanovia No. 516-27-116 was used to cut off all radiation below 3 600 °A. Samples were withdrawn from the solution initially and at intervals, after mixing, during the irradiation until one component had decreased to about 10% of its original concentration. The samples were analyzed by g.l.c. using the internal standard method of Keulemans (39). A Wilkins Aerograph 202 gas chromatographic instrument was used with a 5 ft column packed with Apiezon M on 60–80 Chromosorb W which gave good separation between methanol and all the olefins. From the relative amounts of olefins remaining, the relative rate constants were calculated by the method of Ingold and Shaw (40). The results are summarized in Table III. The relative rates given represent the average of several determinations and the average errors are indicated. Control experiments showed that no olefin was consumed in the absence of light or in the absence of dye when the lamp was on for the time required for 90% oxidation of the more reactive component except in the case where 1-nonene was a

TABLE III

Relative rates of photosensitized oxidation of olefins

Expt. No.	Olefin A	Olefin B	k_B/k_A
1	1-Nonene	Cyclohexene	10*
2	4-Methylcyclohexene	Cyclohexene	1.5±0.2
3	Cyclohexene	2-Hexene	8.5±0.2

competitor. In another control experiment a solution containing 0.4 g of 2,3-dimethyl-3-hydro-peroxy-1-butene (41) and 1.0 g of 2,3-dimethyl-2-butene were photolyzed in the above apparatus. After 15 min 5% of the olefin had been consumed. Thirty mg methylene blue was added and the photolysis was continued. After 15 min 90% of the olefin had been consumed. The relative reactivities reported in Table II were determined in the manner described above using solutions made up from 2.0 ml ethylbenzene, 1.0 ml each of 1-methylcyclopentene and 1-methylcyclohexene, 30 mg of sensitizer, and 200 ml of distilled methanol.

RAMAN SPECTRUM OF CRYSTALLINE AND LIQUID SO_2

A. Anderson and R. Savoie
Frick Chemical Laboratory, Princeton University, Princeton, New Jersey
Received February 8, 1965

ABSTRACT

The Raman spectrum of crystalline sulfur dioxide has been recorded at several temperatures between 9 and 185 °K. The main features are in accord with those predicted from the factor group analysis for the known structure of the crystal. Additional peaks were also observed, some arising from isotopic species and lattice fundamentals. As an aid to the assignment of several other bands, the spectrum of the liquid has also been recorded to distinguish the specifically crystalline features. Possible causes of these extra peaks, such as combinations with lattice modes, crystalline defects, and impurities, are briefly discussed.

INTRODUCTION

The infrared spectrum of solid SO_2 at liquid air temperature was first reported by Wiener and Nixon (1), and a somewhat more detailed investigation was independently published by Giguère and Falk (2). In both cases, extra peaks occurring close to the main bands were assigned as combination or difference bands involving lattice modes with frequencies of 10 to 25 cm^{-1}. The far infrared spectrum (20 to 400 cm^{-1}) recently measured (3) has shown, however, that these optically active lattice modes have much higher frequencies (67 to 160 cm^{-1}). In an attempt to clarify the situation, Raman spectra of the crystal at 9, 77, and 185 °K, and of the liquid at 225 °K have been recorded.

EXPERIMENTAL

The cryostats and techniques used to grow crystals for investigation at liquid helium and nitrogen temperatures in a Cary 81 Raman spectrophotometer have been described elsewhere (4). The spectrophotometer was calibrated with mercury vapor lines from the lamp, and the frequencies given below are estimated to be correct to ± 2 cm^{-1}. Anhydrous SO_2, from the Matheson Co., was used without further purification. This was stated to be 99.98% pure, and a mass spectrometric check showed only small traces of N_2 and CO_2.

It was remarkably easy to grow transparent crystals, 3 in. long and $\frac{1}{2}$ in. in diameter, around the cold finger of the Raman cryostat in about 30 min. Little cracking of these samples occurred on cooling to the temperatures of the refrigerants, and the resultant low Rayleigh scattering made it possible to scan as close as 30 cm^{-1} to the exciting line. Spectra were recorded with the crystal either immersed in liquid nitrogen or cooled by a flow of cold helium gas escaping from the main refrigerant chamber. In the latter case, the temperature measured by a calibrated carbon resistor embedded in the crystal was about 7 °K, rising to 9 °K when the tail section of the cryostat was placed inside the Toronto arc lamp.

The crystal at 185 °K and the liquid at 225 °K were obtained by condensing the gas in a simple cell inside a glass Dewar vessel, using a flow of cold nitrogen gas as coolant. The solid formed in this way was polycrystalline and highly scattering. Besides the observation of the frequency shifts with temperature, another purpose of this experiment was to see if there was any dependence of the spectrum on the crystalline quality. The Raman spectrum of the liquid has been measured previously (5), but in the present work, special emphasis was placed on the possible presence of the weaker bands observed in the solid.

RESULTS

A typical spectrum of the crystal, recorded at 9 °K, is shown in Fig. 1. There are four regions of interest, corresponding to the lattice vibrations (translational T, and librational R), bending mode (υ_2), symmetric stretch (υ_1), and asymmetric stretch (υ_3). Apart from shifts in frequency (more marked for the lattice modes) and the broadening of the lines, no significant changes are seen at 77 °K and 185 °K. The spectrum of the liquid at 225 °K is shown in Fig. 2. The observed frequencies of the three main peaks are in good agreement with those obtained by Gerding and Nijveld (5). Frequencies at maximum intensity

for both phases, together with the infrared data and possible assignments are listed in Table I. The spectral slit widths for the different regions scanned are shown in Figs. 1 and 2.

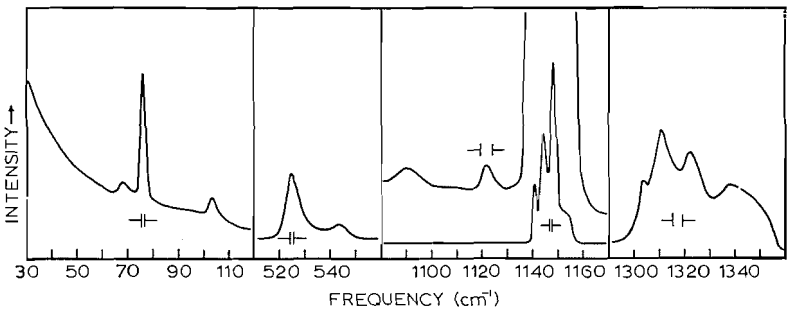

FIG. 1. Raman spectrum of crystalline SO_2 at 9 °K.

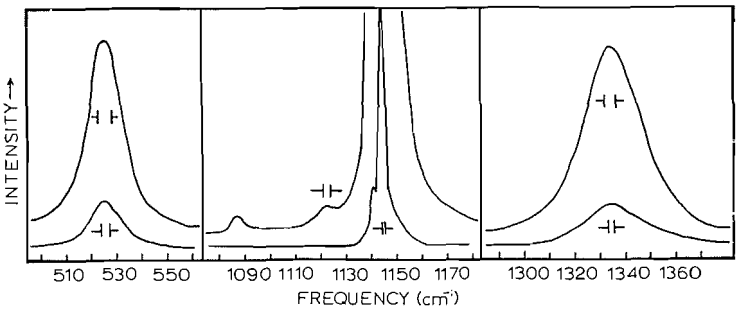

FIG. 2. Raman spectrum of liquid SO_2 at 225 °K.

DISCUSSION

Intramolecular Fundamentals

An X-ray diffraction study of a single crystal of sulfur dioxide (6) has shown the unit cell to be orthorhombic with space group C_{2v}^{17} (Aba), thus confirming earlier results obtained from powder diagrams (7). There are four molecules per unit cell (two per primitive cell) on sites of symmetry C_2. From this result, by usual group theoretical procedures (8, 9), it is easy to deduce the number of infrared and Raman components of the intramolecular and lattice modes, as shown in the correlation diagram, Fig. 3. It is seen that all of the observed infrared fundamental bands should have their Raman counterparts at the same frequencies. Comparison of the two spectra with the predictions from the factor group analysis shows only partial agreement. However, as will be shown, the extra features observed can be explained by effects other than the breakdown of the selection rules.

The doublet expected for ν_1 in Raman is nicely resolved at 1 144 and 1 148 cm^{-1} (the Raman frequencies referred to in the text are those at 77 °K for better comparison with the corresponding infrared values at 93 °K). The first component has exactly the same frequency as the singlet observed in the infrared (2). On the basis of this coincidence, the band at 1 144 cm^{-1} would belong to the A_1 species, although it is somewhat surprising that the one at 1 148 cm^{-1} is more intense, since completely symmetric modes are usually stronger in the Raman effect. In the other infrared study (1), the ν_1 peak is at 1 147 cm^{-1}, and this would support the alternative assignment $\nu_1(A_1)$ = 1 148 cm^{-1}. However, in

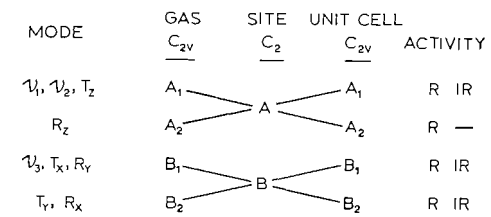

FIG. 3. Correlation between the gas and crystal symmetries for SO_2.

general our frequencies are in better agreement with those of Giguère and Falk. One of the components of the expected doublet for ν_2 is observed at 524 cm^{-1} (521 cm^{-1} in the infrared). The weaker band at 542 cm^{-1} is assigned to the second component of the bending mode (A_2), although a splitting of 18 cm^{-1} seems abnormally large in this case. No further splitting was observed in this region, even at the lowest temperature.

The ν_3 region is more complicated. The predictions for infrared and Raman are identical (two active components) and the two spectra are indeed very similar, but four or five maxima are observed in the broad band in this region. Comparison with the infrared spectrum would suggest that the bands at 1 312 and 1 324 cm^{-1} are the fundamental components, the lower frequency band (at 1 304 cm^{-1}) arising from an isotopic species. This, however, leaves the medium intensity band at 1 341 cm^{-1} (presumably the counterpart of the weaker band observed at 1 334 cm^{-1} in the infrared) unexplained. It is believed that this region is complicated by Fermi resonance between ν_3 and the combination ($\nu_1 + R_x$) with subsequent frequency shifts and intensity redistribution.

The weak peaks at 1 141 and 1 304 cm^{-1} on the low frequency side of ν_1 and ν_3 have almost the same frequency at the corresponding bands observed in the infrared and have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

been assigned by Giguère and Falk to the isotopic molecule $^{34}SO_2$ (natural abundance: 4.2%). However, the very weak band at 1 122 cm^{-1} cannot be a difference between ν_1 and a lattice mode, as was previously assigned, since it appears in the spectrum of the liquid. Furthermore its frequency and intensity in the Raman spectrum makes it a reasonable choice for the isotopic species $S^{16}O^{18}O$ (natural abundance: 0.4%).

Lattice Modes

Only three lattice modes were observed instead of the nine predicted, although careful scans to within 30 cm^{-1} of the exciting line were made. The peak at 74 cm^{-1} is the strongest in the entire spectrum and is probably characteristic of an A_1 representation. One component of the R_z libration falls in this class. The other two bands are very close in frequency to two of the five observed in the far infrared (3). In that spectrum, bands at 141 and 160 cm^{-1} were assigned to the R_x librational doublet, since the principal moment of inertia about the x axis (in the molecular plane, perpendicular to the C_2 or z axis) is much less than the other two. The same doublet should appear in the Raman, but was not observed, possibly because this region is complicated by two spurious peaks characteristic of the spectrometer. These peaks are always present, but their intensity is dependent upon the sample quality, so that exact compensation is difficult. On the basis of the relative moments of inertia, the band at 67 cm^{-1} could be assigned to the R_y librational mode, but it may also be either the second component of R_z or a translational mode. The band at 100 cm^{-1} has been tentatively assigned as translational by Anderson and Walmsley (3) by comparison with the spectrum of crystalline CO_2 (10). In any case, an exact separation of translational and librational modes may not be meaningful here, because of possible mixing between like symmetric species.

In both infrared investigations (1, 2) peaks or shoulders on the high frequency side of the fundamentals were assigned to combinations with lattice modes in the frequency range 10 to 25 cm^{-1}, and in one paper (1) a calculation was made to support this. Although these bands are also observed in Raman, there is no direct evidence from the lattice regions of either the Raman or the far infrared spectrum to support the existence of lattice fundamentals at such low frequencies. However, the evidence is not complete, since even in the far infrared only five of the total of nine bands were observed. In an attempt to resolve this difficulty, the specific heat of the crystal has been calculated according to the Einstein model, using the frequencies observed spectroscopically, as suggested by Ichijima (11). This method will be described in some detail since the original paper is not readily available in English.

A crystal containing N molecules has $6N$ fundamental intermolecular vibrations, the frequency distribution of these being obviously very complicated. Ichijima has shown that although the frequencies of the lattice modes should have a continuous distribution, they have a tendency to concentrate around the optically active modes. His treatment leads to the conclusion that fairly good values can be obtained for the specific heat and entropy of molecular crystals by calculating the contributions of the six degrees of freedom (three translational, three rotational in character) of each molecule, as well as those of the internal modes. The calculation is done using spectroscopically observed frequencies and the Einstein function for a harmonic oscillator in the usual way. Furthermore, the contribution arising from the thermal expansion of the lattice is taken into account in the treatment by using a correction factor based on the temperature dependence of the lattice modes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The specific heat at a given temperature T is given by:

$$C_p = C_v(\mathrm{i}) + \sum_{n=1}^{6} C_v(\mathrm{l})_n \left(\frac{\upsilon_n^0}{\upsilon_n}\right)$$

where $C_v(\mathrm{i})$ is the contribution from the internal modes of vibration, and $C_v(\mathrm{l})$ that of the lattice modes. υ_n^0 is the frequency (obtained by extrapolation) at 0 °K of a lattice vibration corresponding to one of the six degrees of freedom, whilst υ_n is the frequency of the same mode at a temperature T. The frequency of a lattice mode can usually be expressed as a linear function of the temperature:

$$\upsilon_n = \upsilon_n^0 - a_n T$$

where T is the temperature in °K, and a_n the temperature coefficient of the frequency.

In the case of crystalline SO_2, the coupling between the vibrations of the two molecules in a unit cell can give rise to two components for a particular mode. For example, R_x is observed as a doublet (141, 160 cm^{-1}) in the far infrared spectrum. Thus, an average value of 150 cm^{-1} was chosen for the degree of freedom corresponding to the libration around the x axis. The band at 100 cm^{-1} was chosen as corresponding to another degree of freedom; whether it is a rotational or translational mode is of no consequence in the calculation. As for the two bands observed at 67 and 74 cm^{-1}, they may be the two components of the R_z libration and an average value of 70 cm^{-1} was chosen for this degree of freedom.

The frequencies of the three bands observed in the lattice region of the Raman spectrum (Table I) have almost the same temperature dependence: the ratio of their frequency at 9 and 185 °K is close to 1.21 in all three cases. It was assumed that the R_x libration, which is seen only in the infrared, and the unseen lattice vibrations follow this trend. Thus three of the six degrees of freedom required for the calculation of the heat capacity have been obtained from spectroscopically observed lattice vibrations. The frequencies were expressed as a function of the temperature.

$$R_x = 163 - 0.1591T \ (cm^{-1})$$

$$T? = 105 - 0.1027T$$

$$R_z = 73 - 0.0703T$$

The contributions of these to the specific heat were then calculated for various temperatures between 20 and 180 °K and added to those of the internal modes (of which only the bending mode at 524 cm^{-1} contributes appreciably). The contributions from the three other degrees of freedom, taken as having the same frequency, were next calculated for various frequencies between 20 and 80 cm^{-1}, and the results added to the first to give the total specific heat. It was found that a value of 70 cm^{-1} (at 0 °K), with the same temperature dependence as the observed modes, yields a curve which agrees very well with the experimental one (12) between 20 and 150 °K (Fig. 4). The small deviation at higher temperatures could possibly be caused by the anharmonicity of the lattice modes. It should also be noted that replacing several or all of the Einstein distributions by Debye functions would increase the contribution to the specific heat at low temperature, thus yielding even worse agreement with experiment in the 25 cm^{-1} case. Because of the approximations involved, particularly the treatment of acoustic modes, one should be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

wary of concluding too much from these calculations alone, especially since in SO_2 the intermolecular interactions are quite strong and may invalidate some of Ichijima's premises. The good agreement for the 70 cm^{-1} case could be fortuitous, and it is felt that the method gives only a crude representation of the true lattice spectrum. Nevertheless, so great is the descrepancy for the assumption of three (or even two) 25 cm^{-1} vibrations (and as it is most unlikely that only one lattice mode is at 25 cm^{-1} and all the others above 60 cm^{-1}) that it is felt that the thermal data supports the conclusion from the Raman studies that the structure on the intramolecular fundamentals is not caused by combinations with lattice modes, and the explanations given in Table I are preferred.

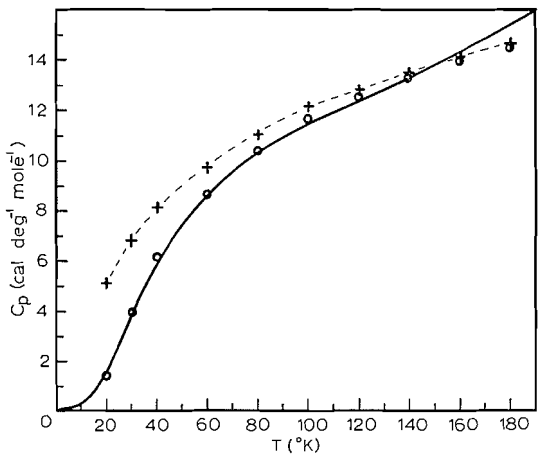

FIG. 4. Heat capacity curve of SO_2: experimental (solid curve, ref. 12), and calculated with three of the six degrees of freedom having experimentally determined frequencies, and the other three equal frequencies of 25 cm^{-1} (+) and 70 cm^{-1} (○).

Other Bands

Several weak bands, none of which was observed in the infrared spectrum, remain to be discussed. The peak at 1 044 cm^{-1}, which was only detected in the spectrum of the liquid, is readily assigned to $2\upsilon_2$, the only overtone observed in this work. Like the first overtone of υ_1 (2), the anharmonicity is quite small. The peak at 1 090 cm^{-1} is believed to arise from an impurity since its intensity is many hundred times weaker than υ_1 and it is impossible to find an overtone or combination that can fit this frequency. Weak bands at 1 153 and 1 351 cm^{-1}, on the high frequency side of υ_1 and υ_3 respectively, are more difficult to explain. Since both frequencies are close to those of the gaseous molecule, it is possible that they are caused by imperfect crystallization of the samples or by lattice defects. The same explanation could hold for the shoulder observed on the high frequency side of υ_2 in the infrared spectrum. If a finite fraction of the domains of the crystal have alternative or disordered structures, a relaxation of the selection rules and a broadening of the band is to be expected (13), and the inactive A_2 component may become active under these circumstances. In the case of crystalline CO_2, an unexpected shoulder was also observed on the high frequency side of υ_2 (14). It was shown by Osberg and Hornig to be a reflection peak since its intensity was strongly dependent upon the film thickness. It was ascertained by Giguère and Falk that no similar effect occurred in the case of crystalline SO_2, and therefore the hypothesis of partial disorder as an explanation for the complicated structure of υ_2 in the infrared is preferred.

For personal use only.

The Spectrum of the Liquid

In the Raman spectrum of liquid SO_2, the ν_2 and ν_3 bands are broad and structureless. The symmetric stretch, ν_1, is, however, remarkably sharp (half width less than 3 cm^{-1}) showing that this vibration is much less perturbed by intermolecular interactions. The corresponding band from the isotopic species $^{34}SO_2$ is readily resolved, although it is separated from the main peak by only 4 cm^{-1}. Another striking feature is the presence of a shoulder on the high frequency side of ν_1. Careful surveys have shown that this becomes more pronounced as the temperature is lowered. The band appears to be somewhat broader than ν_1 itself, and is comparable in intensity (at −70 °C) to the isotopic band at 1 141 cm^{-1}. It is therefore too strong to arise from an impurity, nor can it be accounted for as a combination or overtone, or as another isotopic species. Its temperature dependence eliminates rotational structure as a possible explanation.

The shoulder must therefore arise from the particular structure of the liquid. If one regards a liquid as an ever rearranging framework of molecular aggregates, regions would exist where the molecules are closely packed and have frequencies close to those of the crystal. Also, some molecules would be on sites adjacent to holes and defects, and these would have frequencies intermediate between those of the crystal and gas. This picture, however attractive, is inadequate here since one would expect more holes and defects at higher temperatures, so that the high frequency shoulder, contrary to experiment, should become more intense with increasing temperature. A liquid can also be regarded as made of a large number of regions, some highly ordered, with a crystal-like structure, and some more or less disordered, with a glass-like type of structure. Molecules in the latter type of environment would have an average frequency of 1 145 cm^{-1} in SO_2. Those with a crystal-like type of environment on the other hand would have a frequency distribution more or less similar to that of the crystal. The shoulder could then be explained as the band corresponding to the 1 148 cm^{-1} peak in the crystal, the weaker component (at 1 144 cm^{-1}) being obscured by the main liquid peak. Ordering of molecules in the liquid would then explain the growth in intensity of the shoulder as the temperature is lowered. The weak point in this argument is that different explanations are needed for what appear to be similar features in both liquid and solid.

SUMMARY

The general features of the Raman spectrum of crystalline sulfur dioxide show good agreement with infrared studies and have been assigned using a factor group analysis based on the known structure of the crystal. However, neither direct spectroscopic observation nor comparison with thermal data supports the assignment of very low frequency lattice modes previously postulated.

ACKNOWLEDGMENTS

We are indebted to the Office of Naval Research for its financial support and to Prof. D. F. Hornig for several helpful discussions. We are also grateful to Mr. S. Chubachi for translating the paper by Ichijima, and to Dr. J. A. Morrison for his constructive criticism of the original manuscript.

THE ROLE OF Hg 6^3P_0 ATOMS IN MERCURY PHOTOSENSITIZATION

III. REACTIONS WITH Hg 6^1S_0 ATOMS

J. E. McAlduff and D. J. Le Roy
Department of Chemistry, University of Toronto, Toronto, Ontario

Received February 9, 1965

ABSTRACT

Metastable Hg 6^3P_0 atoms were produced in a flow system by reaction of Hg 6^3P_1 atoms with nitrogen. Concentrations of the metastable atoms were studied as a function of Hg 6^1S_0 and N_2 concentration by absorption spectrometry. Rate constants have been obtained for the deactivation of Hg 6^3P_0 to the ground state and for its activation to the 6^3P_1 state by collisions with nitrogen, as well as for its reaction with Hg 6^1S_0 atoms to form a relatively long-lived diatomic species, presumably in the $A(^3O_u^-)$ state. The last process involves stabilization by collision with nitrogen.

In a previous paper (1) we described the results of an investigation of the steady-state concentration of $Hg(6^3P_0)$ as a function of nitrogen pressure in mixtures of mercury vapor and nitrogen irradiated with 2 537 Å mercury resonance radiation. Definite evidence was found for, among other reactions, a first-order disappearance of $Hg(6^3P_0)$. A measure of the steady-state concentration was obtained by observing both the absorption of 4 047 Å ($7^3S_1 - 6^3P_0$) and the emission of the forbidden line 2 656 Å ($6^3P_0 - 6^1S_0$). At nitrogen pressures up to about 10 mm the emission and absorption measurements correlated reasonably well and the first-order decay was attributed to the reaction,[1]

[6] $$Hg^0 = Hg + h\nu^0.$$

From the value obtained for k_6 the radiative lifetime of Hg^0 was calculated to be 4.2×10^{-4} s, considerably shorter than the value of 5 s calculated by Garstang (2).

Callear and Norrish (3), in flash photolysis experiments, also observed a first-order decay of Hg^0. Although radiative decay had been unequivocally established under our conditions (1), they argued that their observed first-order process could not be reaction [6] because if it were, the forbidden line would have been observed with an intensity comparable with that found for the emission of 2 537 Å fluorescence when argon–mercury mixtures were flashed. They assumed that in the presence of argon most of the Hg* atoms would disappear by reaction [2],

[2] $$Hg^* = Hg + h\nu^*,$$

whereas in the presence of nitrogen most of them would disappear by [4],

[4] $$Hg^* + N_2 = Hg^0 + N_2.$$

Although they used a constant mercury pressure (1.2×10^{-3} mm) they assumed that the observed first-order rate constant (5.4×10^3 s^{-1}) was actually the product of a second-order rate constant and the mercury concentration. The second-order constant calculated in this way was 8.2×10^{13} cm^3 mole^{-1} s^{-1}.

More recently, Callear and Williams (4), again using the flash photolysis technique, have varied the mercury vapor pressure from 3.8×10^{-4} to 23.8×10^{-4} mm and the nitrogen pressure from 500 to 1 000 mm and obtained evidence for their hypothesis. They found the second-order rate constant for the deactivation of Hg^0 by Hg to be

[1]*We are numbering the various reactions by the scheme used previously (1), and using* Hg, Hg^0, *and* Hg* *to represent* 6^1S_0, 6^3P_0, *and* 6^3P_1, *respectively.*

3.4×10^{13} cm^3 mole^{-1} s^{-1}; they also found evidence for a similar deactivation by N_2 with a rate constant of 8.7×10^7 cm^3 mole^{-1} s^{-1}.

Our previous measurements (1) were made at a constant mercury pressure of 7.7×10^{-4} mm. In the light of the more recent work it would seem reasonable to assume that Kimbell and Le Roy had observed the pseudo-first-order reaction [10] in addition to [6],

[10′] $$Hg^0 + Hg = ?$$

and that reaction [11] may have been involved in addition to, or instead of [7],

[11′] $$Hg^0 + Hg + N_2 = ?$$

[7] $$Hg^0 + N_2 = Hg + N_2.$$

We are now able to report the results of a detailed study of the steady-state concentration of Hg^0 over a wide range of mercury pressures up to 12×10^{-4} mm and over a range of nitrogen pressures up to 8 mm. Under these conditions pressure broadening effects should be small and corrections for imprisonment of resonance radiation can be made with some confidence.

EXPERIMENTAL

Little modification was required in the apparatus and procedures used previously (1). For increased stability and precision a Curtis-Wright Dynamic Capacitor electrometer was used in the double-beam photoelectric bridge circuit. The cell was of all-quartz construction and consisted of an outer tube 28 cm long and 5.5 cm o.d. and an inner tube 20 cm long and 3.1 cm i.d.; polished quartz windows were sealed to each end of the outer tube. An aqueous nickel sulfate solution was circulated through the annular space between the two tubes. This served to remove essentially all of the 4 047 Å radiation arising from the primary lamps and to keep the reaction cell at a constant temperature of 25 °C. The elimination of the 4 047 Å radiation was necessitated not simply to avoid the possibility of it appearing as scattered light, but to avoid depletion of Hg^0 by the process

$$6^3P_0 \xrightarrow{4\,047} 7^3S_1,$$

which has been observed previously in this laboratory. Because of the very low intensity of the 4 047 Å analysis beam no appreciable error arises from this cause.

The 4 047 Å analysis beam was derived from a microwave discharge through natural mercury (5). A special shutter was designed to cut off all light from the primary lamps while making the 100% transmission reading. The analysis beam passed down the axis of the cell. It had a diameter of 6 mm, defined by apertures at each end.

Close fitting metal cylinders covered each end of the reaction cell, leaving a central portion 18 cm long exposed to the light from the primary lamps. Thus the path length L of the analysis beam was effectively approximately 18 cm. The path length x, for the absorption of 2 537 Å from the primary lamps, was set at 1.5 cm, the internal radius of the cell.

The rate of formation of Hg* by reaction [1],

[1] $$Hg + h\nu^* = Hg^*,$$

can be defined as I_a^*, and if the absorption of 2 537 Å radiation can be fitted to a Beer's Law expression (see below) then

[i] $$I_a^* = 2.303K^*I_0^*[Hg]10^{-K^*[Hg]x},$$

where K^* is the decadic extinction coefficient, I_0^* is the intensity of the incident resonance radiation, and x is the path length (1.5 cm). The quantity K^* is an *effective* extinction coefficient, dependent on the nature of the emission line from the primary lamps as well as on the conditions in the reaction cell.

The value of K^* for the present experiments was measured by placing one of the primary lamps in the position usually occupied by the 4 047 Å lamp; the intensity of 2 537 Å transmitted was then determined for a series of mercury concentrations at various nitrogen pressures. For these particular measurements a Westinghouse WL-775 photocell was used. Tests using a monochromator to isolate 2 537 Å radiation from the primary lamp showed that this photocell was not sensitive to other radiation from the primary lamp.

The path length provided by the reaction cell for the absorption of 2 537 Å in these particular experiments was 28 cm. For any given nitrogen pressure up to 8 mm the logarithm of the transmitted intensity was linear in [Hg] over the range 0.6×10^{-4} mm to 1.8×10^{-4} mm and independent of nitrogen pressure. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

value of K^* calculated was 80 mm^{-1} cm^{-1} or 2.5×10^{-15} cm^2 $atom^{-1}$. At higher mercury pressures the points lay above the Beer's Law line. At higher nitrogen pressures K^* gradually increased, reaching a value of 230 mm^{-1} cm^{-1} at a nitrogen pressure of 80 mm (7.2×10^{-15} cm^2 $atom^{-1}$). For a somewhat similar lamp Pinder and Le Roy (6) found K^* equal to 6.5×10^{-15} cm^2 $atom^{-1}$ in the presence of 300 mm of propane. A constant value of $K^* = 80$ mm^{-1} cm^{-1} was assumed throughout the present work since the maximum pressure of nitrogen did not exceed 8 mm and the value of $[Hg]x$ did not exceed the value $1.8 \times 10^{-4} \times 28$.

RESULTS AND DISCUSSION

The results were interpreted in terms of the following reactions:

[1] $$Hg + h\nu^* = Hg^*$$

[2] $$Hg^* = Hg + h\nu^*$$

[4] $$Hg^* + N_2 = Hg^0 + N_2$$

[5] $$Hg^0 = Hg \text{ (on the wall)}$$

[6] $$Hg^0 = Hg + h\nu^0$$

[7] $$Hg^0 + N_2 = Hg + N_2$$

[8] $$Hg^0 + N_2 = Hg^* + N_2$$

[10′] $$Hg^0 + Hg = ?$$

[11′] $$Hg^0 + Hg + N_2 = ?$$

The rate of [1] is equal to I_a^*, which is given by eq. [i]. Nitrogen is assumed to deactivate Hg* mainly to the Hg^0 state, and so reaction [3] of the previous scheme (1) (quenching to the ground state) is not included. The rate of [5] is assumed to be diffusion-controlled and equal to $k_5 [Hg^0]/[N_2]$. Reaction [9] of the previous scheme (1) (collision-induced emission of the forbidden line ν^0) has not been included because it is kinetically indistinguishable from [7] in the present experiments. The possible products of [10′] and [11′] will be discussed below.

It was necessary to take into consideration the imprisonment of resonance radiation, which has the effect of decreasing k_2 with increasing Hg concentration. It might be noted that this correction was not required in the work of Callear and Williams (4) because the nitrogen pressures used by them were orders of magnitude larger than those used in the present work so that the rate of [2] was negligible compared to that of [4].

If τ is the true lifetime of Hg* with respect to radiation (1.08×10^{-7} s (7)), then in the range of mercury pressures used here we may write

[ii] $$k_2 = (1 - q[Hg])/\tau.$$

By assuming steady state concentrations for [Hg*] and $[Hg^0]$ one readily obtains an expression for $1/[Hg^0]$. However, the latter is not directly observable, and it is more convenient to use, instead, a quantity which is directly proportional to it, namely $K^0[Hg^0]L$, where L is the path length of the analysis beam in the region of the cell containing Hg^0 atoms (18 cm) and K^0 is the decadic extinction coefficient for the absorption of 4 047 Å by Hg^0 atoms. The latter quantity is assumed to be constant throughout the experiments, and hence

[iii] $$K^0[Hg^0]L = -\log_{10} (I_T/I_0)_0,$$

in which the right hand side is an observable, namely the negative of the logarithm of the fraction of analysis beam absorbed.

Further simplification of the steady state expression yields the relation,

$$[\text{iv}] \qquad \Psi = \frac{1}{\tau\alpha}\{k_5/[N_2]^2 + (k_6 + \tau k_4 k_5)/[N_2] + (\tau k_4 k_6 + k_7 + k_8) + \tau k_4 k_7[N_2] + [Hg](k_{10'}/[N_2] + (k_{11'} + \tau k_4 k_{10'}) + \tau k_4 k_{11'}[N_2] - qk_5/[N_2]^2 - qk_6/[N_2] - q(k_7 + k_8)) - [Hg]^2(qk_{10'}/[N_2] + qk_{11'})\},$$

in which Ψ is an experimental quantity,

$$\Psi = \frac{[Hg]}{K^0[Hg^0]L}\, 10^{-K^*[Hg]z};$$

α is not a directly observable quantity but its value can be obtained as described below; it is defined by the relation $\alpha = 2.303K^*K^0I_0^*Lk_4$.

To evaluate q and α a series of measurements was made at various constant Hg pressures at nitrogen pressures below 0.5 mm, where only the smallest powers of $[N_2]$ in [iv] are effective. These data are given in Table I. In Fig. 1 the corresponding values of $\Psi[N_2]^2$ are plotted against $[N_2]$. It follows from [iv] that the intercepts should be equal to $k_5(1 - q[Hg])/\tau\alpha$, and hence linear in [Hg]. The intercepts are plotted against [Hg] in Fig. 2, and while the precision is not high the predicted form is indicated. A least squares treatment gave $k_5/\tau\alpha = 2.0 \pm 0.3 \times 10^{-4}$ mm^3, and since $\tau = 1.08 \times 10^{-7}$ s and $k_5 = 206$ mm s^{-1} at room temperature (1), it follows that $\alpha = 9.5 \pm 1.5 \times 10^{12}$ mm^{-2} s^{-2}.

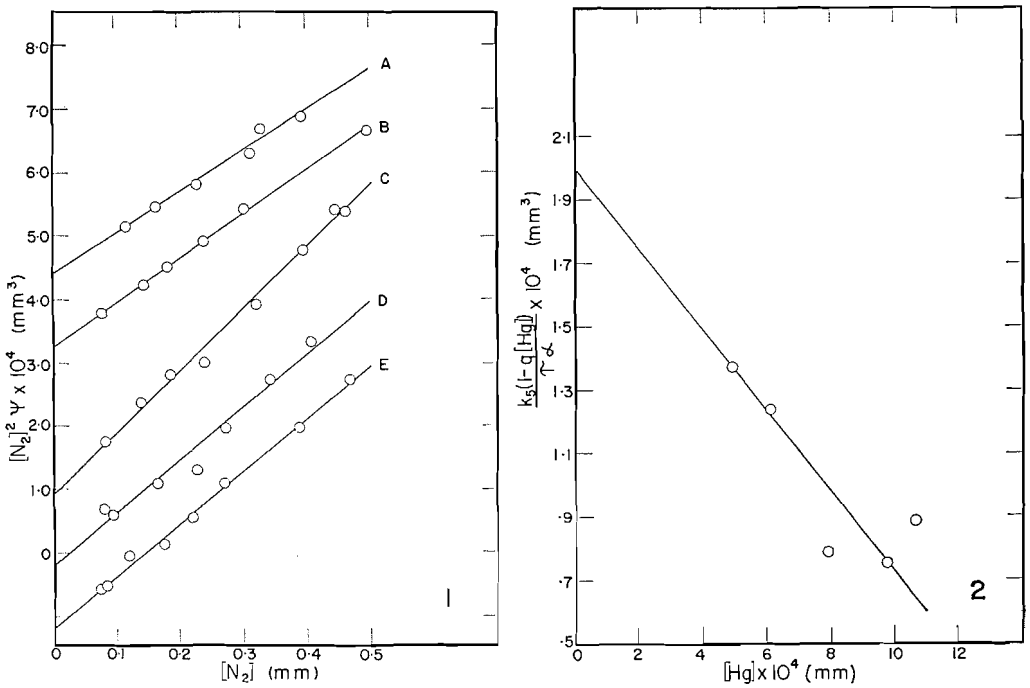

FIG. 1. $[N_2]^2\Psi$ vs. $[N_2]$ for various values of [Hg]. A, [Hg] = 4.94×10^{-4} mm, ordinates increased by 3.0; B, [Hg] = 6.15×10^{-4} mm, ordinates increased by 2.0; C, [Hg] = 10.65×10^{-4} mm; D, [Hg] = 9.75×10^{-4} mm, ordinates decreased by 1.0; E, [Hg] = 7.90×10^{-4} mm, ordinates decreased by 2.0.

FIG. 2. Intercepts of Fig. 1 plotted as function of [Hg].

For personal use only.

The value of q derived from the ratio of the slope to the intercept of Fig. 2 is 640 ± 100 mm^{-1}. This would correspond to a doubling of the effective lifetime of Hg* at a mercury pressure of 8×10^{-4} mm, about one third of the imprisonment effect observed by Webb and Messenger (8). The magnitude of the effect will, of course, depend on the dimensions of the reaction cell as well as on the nature of the 2 537 Å source.

Equation [iv] predicts that the slopes of Fig. 1 should have a parabolic dependence on [Hg]. However, the precision with which $(I_T/I_0)_0$ could be measured at these low nitrogen pressures (*v.* Table I) placed a limitation on the range of Hg pressures that could be used, so that these measurements were not designed to test this aspect of the mechanism or to evaluate the constants involved. Values of the other constants in [iv] were evaluated from a series of experiments at higher nitrogen pressures. The experimental data are given in Table II.

In Fig. 3 the experimental quantity Ψ is plotted against [Hg] for a series of nitrogen pressures above 0.5 mm. From [iv] it is evident that these curves should be of the form

$$\Psi = a + b[\mathrm{Hg}] + c[\mathrm{Hg}]^2, \qquad [v]$$

where

$$a = \frac{1}{\tau\alpha}\{k_5/[\mathrm{N_2}]^2 + (k_6 + \tau k_4 k_5)/[\mathrm{N_2}] + (\tau k_4 k_6 + k_7 + k_8) + \tau k_4 k_7[\mathrm{N_2}]\}, \qquad [vi]$$

$$b = \frac{1}{\tau\alpha}\{-qk_5/[\mathrm{N_2}]^2 + (k_{10'} - qk_6)/[\mathrm{N_2}] + (k_{11'} + \tau k_4 k_{10'} - qk_7 - qk_8) + \tau k_4 k_{11'}[\mathrm{N_2}]\}, \qquad [vii]$$

$$c = \frac{1}{\tau\alpha}\{-qk_{10'}/[\mathrm{N_2}] - qk_{11'}\}. \qquad [viii]$$

It is evident from Fig. 3 that the terms in $[Hg]^2$ in [v] are not important in the range of Hg pressures used. It was not considered desirable to use higher Hg pressures because of the deviations from the Beer's law expression that would occur, as mentioned earlier.

As the nitrogen pressure is increased, the contribution of the term $k_5/[N_2]^2$ in eq. [vi] becomes relatively unimportant and it is convenient to use the value of $k_5/\tau\alpha$ found previously and plot $a[N_2] - (k_5/\tau\alpha)/[N_2]$ against $[N_2]$ in order to evaluate the other constants in the expression for a. This has been done in Fig. 4. No deviation from linearity is indicated, showing that the term $\tau k_4 k_7[N_2]$ in [vi] is negligible at the nitrogen pressures used. It was not desirable to use higher nitrogen pressures because of the possibility of pressure-broadening effects.

From the intercept of Fig. 4, $k_6/\tau\alpha + k_4 k_5/\alpha$ was found to be $1.3_5 \pm 0.6_1 \times 10^{-4}$. Using the value of k_4 given by Matland (9) (2.1×10^5 mm^{-1} s^{-1}) and the values of τ, α, and k_5 used previously, k_6 was calculated to be 133 ± 80 s^{-1}. The major part of the probable error in k_6 arises in the intercept of Fig. 4. It should be pointed out that the value obtained was not derived from observations on the forbidden line. However, the positive intercept of Fig. 4 does indicate the occurrence of a first-order process leading to the removal of Hg^0 atoms which can probably be identified with the emission of the forbidden line, since this has been observed (1). The radiative lifetime of Hg^0 obtained from the present results ($1/k_6 = 7.5 \times 10^{-3}$ s) is about 18 times larger than the value calculated by Kimbell and Le Roy (1). Their value would, of course, be in error because of the occurrence of [10′], which would be pseudo-first order under their conditions and hence indistinguishable from

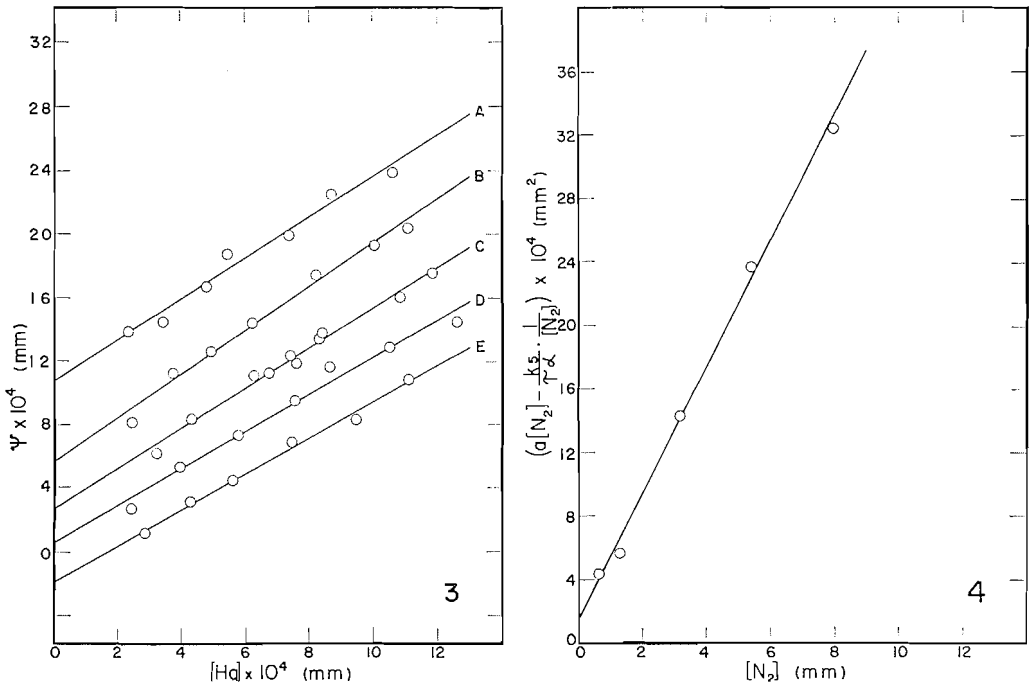

FIG. 3. Ψ as a function of [Hg] for various values of [N_2]. A, [N_2] = 0.68 mm; B, [N_2] = 1.30 mm; C, 3.18 mm, ordinates decreased by 2.0; D, [N_2] = 5.40 mm, ordinates decreased by 4.0; E, [N_2] = 7.95 mm, ordinates decreased by 6.0.

FIG. 4. Evaluation of $(k_6 + \tau k_4 k_5)$ and $(\tau k_4 k_6 + k_7 + k_8)$ from the intercepts of Fig. 3 (*v.* eq. [vi]).

[6]. The present value would seem to be not out of line with the criterion used by Callear and Williams (4) in criticizing our previous value.

The slope of Fig. 4 can be identified with the quantity $(1/\tau\alpha)$ $(\tau k_4 k_6 + k_7 + k_8)$, the least squares value of which was found to be $4.0 \pm 0.1_3 \times 10^{-4}$ mm. With the values of τ, α, k_4, and k_6 given above we obtain the value $(k_7 + k_8) = 7.6 \times 10^9$ cm^3 mole^{-1} s^{-1} with a probable error of $\pm 1.5 \times 10^9$. Since the term $\tau k_4 k_6$ is less than 1% of the value found for $k_7 + k_8$, any error in k_6 will have a negligible effect.

As mentioned previously, Callear and Williams obtained a value of 8.7×10^7 cm^3 mole^{-1} s^{-1} for the rate constant for the second-order removal of Hg^0 by N_2, almost 100 times smaller than our value of $k_7 + k_8$. The explanation would seem to lie in the difference between the experimental methods used. Whereas in our experiments we observe the steady state concentration of Hg^0, Callear and Williams observed the rate of decay of Hg^0 concentration after the removal of the primary radiation. At the high pressures of nitrogen used by them (ca. 780 mm), Hg* atoms formed in [8] would immediately re-form Hg^0 atoms by [4] so that the occurrence of [8] could not be detected from measurements of the rate of decay. Their value of 8.7×10^7 can therefore be attributed solely to reaction [7]. Using this value for k_7 we obtain $k_8 = 7.5 \times 10^9$ cm^3 mole^{-1} s^{-1}.

Reaction [8] is the reverse of reaction [4], and hence k_8/k_4 should be equal to

$$\frac{g^*}{g^0} e^{-(E^*-E^0)/RT}.$$

Using our value for k_8 and Matland's value (9) for k_4, $k_8/k_4 = 1.9 \times 10^{-3}$ at 300 °K;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the theoretical value calculated from the electronic degeneracies and the energy difference for the two energy levels of mercury involved is 0.7×10^{-3} at 300 °K. The agreement is remarkably good.

The values of $k_{10'}$ and $k_{11'}$ were obtained from the slopes of Fig. 3 as expressed in eq. [vii]. As in treating the intercepts, it was convenient to plot the quantity $b[N_2]$ plus the relatively small correction term $(qk_5/\tau\alpha)/[N_2]$ against $[N_2]$. This has been done in Fig. 5. The linearity of the curve shows that the last term in [vii] is negligible at the pressures of nitrogen used. The intercept of Fig. 5, $(k_{10'} - qk_6)/\tau\alpha$, is equal to 0.47 ± 0.10 mm. The term $qk_6/\tau\alpha$ contributes only 14% to this value so the value of $k_{10'}$ ($1.05 \pm 0.5 \times 10^{13}$ cm^3 mole^{-1} s^{-1}) is not greatly affected by uncertainties in k_6. The probable error in $k_{10'}$ arises largely from that of the intercept itself and from that of α.

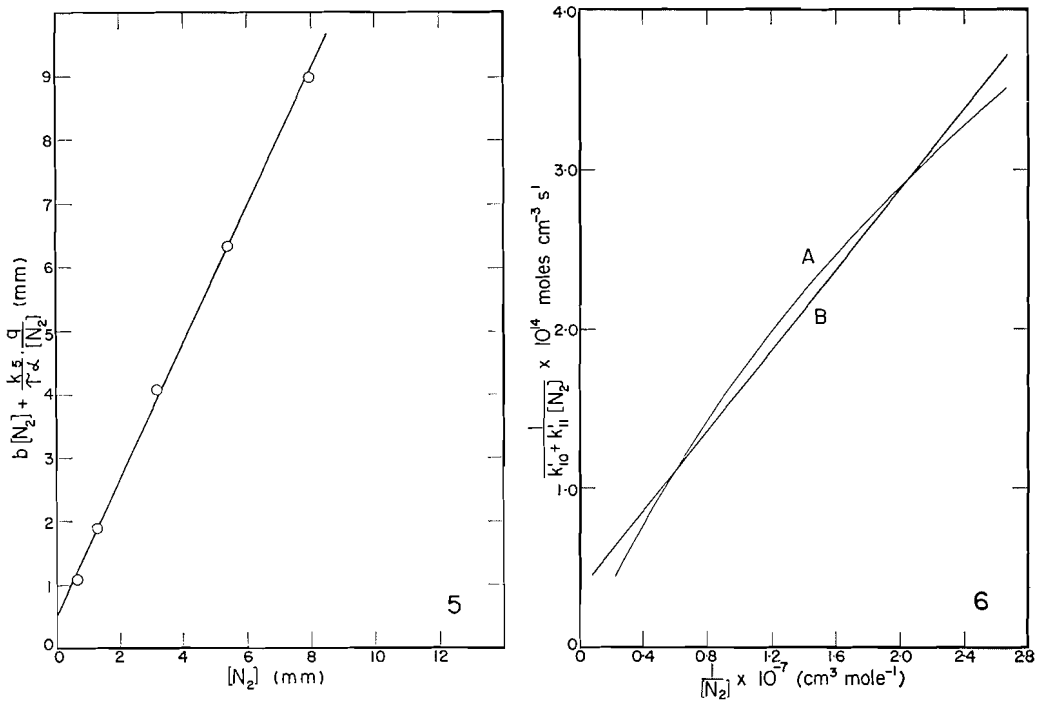

FIG. 5. Evaluation of $(k_{10'} - qk_6)$ and $(k_{11'} + \tau k_4 k_6 - qk_7 - qk_8)$ from the slopes of Fig. 3. (*v.* eq. [vii]).
FIG. 6. A, Experimental curve of $(k_{10'} + k_{11'}[N_2])^{-1}$ vs. $1/[N_2]$; B, Least squares linear approximation to curve A for the range $[N_2] = 0.7$ to 8.0 mm.

From the slope of Fig. 5 we obtain the value $(k_{11'} + \tau k_4 k_{10'} - qk_7 - qk_8)/\tau\alpha = 1.08 \pm 0.02$. The term $k_4 k_{10'}/\alpha$ contributes less than 2% and the term $qk_8/\tau\alpha$ about 25%; the term $qk_7/\tau\alpha$ contributes a negligible amount. The value of $k_{11'}$ obtained is $4.8 \pm 1.0 \times 10^{20}$ cm^6 mole^{-2} s^{-1}; the probable error is largely determined by that of α.

Our value of $k_{10'}$ is about one third of that given by Callear and Williams (4) for the bimolecular removal of Hg° by collision with Hg atoms. However, they found no evidence for the trimolecular reaction [11']. A possible explanation lies in a re-interpretation of both their mechanism and ours. Instead of reactions [10'] and [11'] we will postulate the following:

[10] $$Hg^0 + Hg = Hg_2\dagger^*,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[12] $$Hg_2\dagger^* = Hg^0 + Hg,$$

[13] $$Hg_2\dagger^* + N_2 = Hg_2^* + N_2.$$

The rate of disappearance of Hg^0 by these reactions will be given by $k_{10}k_{13}[Hg^0][Hg][N_2]/(k_{12} + k_{13}[N_2])$. Callear and Williams' measurements were made at high pressures of nitrogen (780 mm, except one at 500 mm and one at 1 000 mm), and under these conditions the term $k_{13}[N_2]$ could be considerably greater than k_{12}. The rate of disappearance of Hg^0 by these reactions would then be equal to $k_{10}[Hg^0][Hg]$, or second order, as found by them. However, our present measurements were made at pressures of nitrogen two or three orders of magnitude smaller than theirs, so it is not surprising that we found evidence for a third-, as well as a second-order process while they did not.

If reactions [10], [12], and [13] are substituted for [10′] and [11′] in the mechanism given previously, eq. [vi] remains the same and the values of α, q, k_6, and k_8 are unchanged. However, eq. [vii] takes a more complex form. Rather than using this it will be assumed that the expression given above is correct (reactions [10], [12], [13]) and that the expression $k_{10'}[Hg^0][Hg] + k_{11'}[Hg^0][Hg][N_2]$ is an approximation to it in the experimental pressure range 0.7 to 8.0 mm of nitrogen. Thus,

[ix] $$\frac{1}{k_{10'} + k_{11'}[N_2]} \approx \frac{1}{k_{10}} + \frac{k_{12}}{k_{10}k_{13}[N_2]}.$$

Using the values of $k_{10'}$ and $k_{11'}$ obtained previously, the left hand side of [ix] was fitted by the method of least squares to a linear function of $1/[N_2]$. The deviation from linearity is not large in the range 0.7 to 8.0 mm, as can be seen from Fig. 6. The least squares calculation gave $k_{10} = 2.7_0 \times 10^{14}$ cm^3 mole^{-1} s^{-1} and $k_{12}/k_{13} = 3.4 \times 10^{-7}$ mole cm^{-3}. The value obtained for k_{10} is about eight times larger than the high-pressure value obtained by Callear and Williams. In view of the considerable difference in experimental conditions, particularly with regard to the nature and possibly spacial dependence of the light absorption by Hg in the experiments of Callear and Williams, we do not consider that their results are in disagreement with the mechanism proposed here.

The value of k_{10} derived from the present experiments corresponds to a collision cross section of 6×10^{-15} cm^2. This is some orders of magnitude larger than collision cross sections for the quenching of Hg^0 by other gases (4), where deactivation to the ground electronic state is indicated. It is for this reason that we have postulated the formation of $Hg_2\dagger^*$, a highly vibrationally excited state of the $A(^3O_u^-)$ electronic state of Hg_2, the products of dissociation of which are Hg^0 and Hg (10).

If we assume a conventional collision cross section for reaction [13] our value of k_{12}/k_{13} predicts a natural lifetime for $Hg_2\dagger^*$ of the order of 3×10^{-7} s. On the other hand, the stabilized Hg_2^* molecule is believed to have a rather long lifetime (11) since the visible fluorescence coming from it persists for some distance downstream in a flowing stream of gas. Berberet and Clark (12) have studied this fluorescence and have concluded that the species responsible is formed by a process such as [11′]. Kimbell and Le Roy (13) have reached a similar conclusion. Further work is now being done in this laboratory in an attempt to establish a correlation between the intensity of the band fluorescence and the mechanism proposed in the present paper.

ACKNOWLEDGMENTS

The authors are pleased to acknowledge the financial assistance of the National Research Council. They would like to thank Dr. Callear for giving them his results (4) before publication.

INFRARED SPECTRA AND STRUCTURE OF POLYALDEHYDES

VI. POLYFLUORAL[1]

W. K. BUSFIELD[2] AND E. WHALLEY
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received March 18, 1965

ABSTRACT

The infrared spectrum of oriented polyfluoral is reported. The number and polarization of the bands suggest that the chain is helicoidal.

I. INTRODUCTION

It was reported first by Shechter and Conrad (1) that fluoral polymerizes to a waxy solid on standing, and Husted and Ahlbrecht (2) studied the free-radical and cationic polymerization. More recently Cairns, Clyne, and Graham (3) have described a copolymer of formaldehyde and fluoral, but no other work appears to have been reported on these polymers. In this paper, earlier work (4, 5) on the infrared spectra of polyaldehydes is extended to polyfluoral.

II. METHODS AND RESULTS

Polymer Preparation

Fluoral (b.p. −20 °C) was prepared by dehydrating fluoral methyl hemiacetal, obtained from Columbia Organic Chemical Company Inc., with concentrated sulfuric acid, and was purified by several vacuum distillations from —78 to −196 °C. Its infrared spectrum was identical with that recorded in the literature (1). The fluoral was stable indefinitely at low temperature. Even at room temperature in an air-free ampoule, solid polymer did not separate for at least 3 weeks.

Fluoral was polymerized in six ways using typical free-radical, cationic, and anionic catalysts. Details of the methods are given in Table I and some of the properties of the

TABLE I

Preparation of the polyfluoral samples

Polymer	Catalyst	Solvent	Temp. (°C)	Time	Approx. yield
RB	0.1 mole % Bz_2O_2 with respect to monomer	None	22	18 hours	90%
RS	None	None	22	3 weeks	30%
AN	0.5 mole % BuLi with respect to monomer	None	−78°	<1 second	100%
AH	0.5 mole % BuLi with respect to monomer	*n*-Hexane [monomer] = 10% by volume	−78°	<1 second	100%
CM	1 mole % H_2SO_4 with respect to monomer	Methylene chloride [monomer] = 7% by volume	22	7 days	50%
CT	0.5 mole % H_2SO_4 with respect to monomer	Toluene [monomer] = 5% by volume	22	2 weeks	10%

resulting polymers are summarized below. The rate of formation, the crystallinity of the polymer, and its physical properties depended on the catalyst and the solvent. None of the polymers melted on heating, but all depolymerized to monomeric fluoral at various temperatures which are summarized below.

Polymer	Appearance	Solvent action	Crystallinity	Decomposition temp.
RB	Deformable, stiff solid, low elongation	Unaffected by alcohol, ether, or chloroform	Moderate	Negligible decomposition below 300 °C
RS	Similar to RB	Similar to RB	Similar to RB	Similar to RB
AN	Deformable solid, softer and higher elongation than RB	No action by chloroform or alcohol; swells and slowly depolymerizes in acetone; small fraction dissolves in ether	Low	Negligible decomposition below 300 °C
AH	Soft and foamy solid, low elongation	No action by chloroform; swells and slowly depolymerizes in alcohol or acetone	Moderate	Negligible decomposition below 300 °C
CM	Brittle solid, easily ground, transformed into solid similar to RB on standing for several days	Depolymerizes in alcohol	High	Begins to depolymerize at ~150 °C
CT	Similar to RB	Similar to RB	Similar to RB	Similar to RB

X-ray Measurements

X-ray diffraction photographs were taken with a Debye-Scherrer 114.7 mm camera using nickel-filtered copper radiation. The patterns ranged from two diffuse halos in sample AN to a number of sharp rings in sample CM. The relative positions of the lines were the same for each sample. The approximate intensities of the lines in the sharpest spectrum (sample CM), and the corresponding interplanar spacings are listed in Table II. There appear to be at least two phases; the spacings marked with an asterisk in Table II appear to be characteristic of one phase. The strongest line of the second phase is at 4.3 Å. The other lines are characteristic of both phases. It seems likely that the variations in the patterns are due to variations in morphology or in stacking faults.

Spectroscopic Measurements

Samples of polyfluoral were rolled in a set of jeweller's rollers to form films suitable for infrared investigation. Samples thinner than about 0.001 in. were unable to support themselves, and were prepared by rolling in a silver chloride sandwich. Sample CM, which was a brittle solid, was examined in a potassium bromide disc.

The spectra were recorded on a Perkin-Elmer model 21 in the range 4 000 to 650 cm^{-1} with a rock salt prism, a Beckman IR7 in the range 4 000 to 250 cm^{-1} with gratings and

fore prisms, and a Perkin-Elmer model 301 in the range 550 to 160 cm^{-1} with gratings and filters. A silver chloride polarizer was placed in the sample beam of the spectrophotometer so that the plane of polarization of the light was at $\pm 45°$ to the instrument vertical to reduce polarization effects of mirrors, prisms, and gratings within the instrument. Oriented specimens of polyfluoral were mounted so that the plane of polarization of the incident light was either parallel or perpendicular to the direction of rolling. In the interpretation, the chains are assumed to be oriented in this direction. The frequency range investigated for each sample was: RB and AN, 4 000 to 450 cm^{-1}; AH, 4 000 to 160 cm^{-1}; CM and CT, 4 000 to 600 cm^{-1}. Various thicknesses were used as required. The thinnest rolled samples were well oriented, and the polarization of the strong bands in the range 1 450 to 500 cm^{-1} was easily determined. Oriented samples of about 0.001 in. thickness were not produced, and the polarization of most of the weaker bands was not determined.

The spectra of all samples studied were identical, except for an absorption band at 1 403 cm^{-1} whose relative intensity varied from sample to sample. A composite spectrum is shown in Fig. 1, and the wave numbers, the relative intensities, and the polarization of the strong bands are listed in Table III.

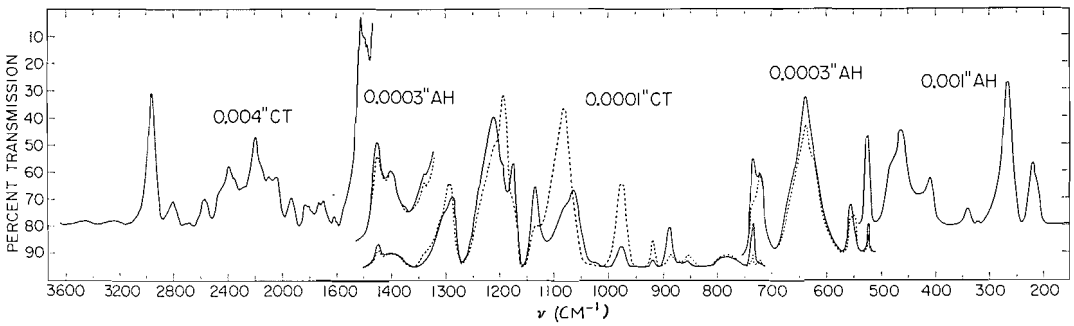

FIG. 1. Infrared spectrum of polyfluoral in the range 4 000 to 160 cm^{-1} showing the polarization of bands in the range 1 500 to 500 cm^{-1}. Full line: electric vector perpendicular to the direction of rolling. Broken line: electric vector parallel to the direction of rolling. There is a change of scale at 1 450 cm^{-1}.

A 0.0003 in. thick specimen of polyfluoral AH was well oriented, as shown by the spectrum in Fig. 1. Nevertheless, the transmission of the 2 963 cm^{-1} band was unaffected by rotation of the polarizer. It is likely, therefore, that the band is a superposition of a π (parallel to chain) band and a σ (perpendicular to chain) band, which could not be resolved in the unpolarized spectrum.

The band at 1 403 cm^{-1} was absent from the most crystalline specimen CM, and increased in intensity relative to the 1 422 cm^{-1} band with decreasing crystallinity as measured by the sharpness of the X-ray diffraction patterns. Its intensity is almost certainly caused by a breakdown in selection rules due to the presence of disorder.

III. DISCUSSION

The chemical structure of polyfluoral is doubtless $(CHCF_3 \cdot O)_n$. The main evidence for this is that when it is heated it depolymerizes to fluoral, and that the infrared spectrum, which is discussed in detail below, can be well interpreted on the basis of this structure. The spectrum of a thick sample of CT had weak absorption at 3 460 and 3 250 cm^{-1}. This indicates that there are OH end groups, as expected for a polymer prepared by sulfuric acid catalysis.

In contrast to the X-ray diffraction photographs, the infrared spectra of the various samples were very similar, except for the 1 403 cm^{-1} band. In particular, the breadths of the bands in the spectra of the most and the least crystalline sample are nearly the same. This indicates that the order within the chains is essentially preserved in the non-crystalline specimens, although the presence of the 1 403 cm^{-1} band shows that it is not perfectly preserved. This probably means that the polyfluoral chains, like polychloral chains (*4b*), are fairly stiff at room temperature, and indicates why it is difficult to find a good solvent for polychloral and polyfluoral. Part of sample AN was soluble in ether, and was probably of low molecular weight. The infrared spectrum of the ether-soluble fraction was similar to that of the other samples except that the bands were much broader, particularly in the region 1 350 to 800 cm^{-1}, and there were small differences in other bands. This indicates that in sample AN the order within the chain is considerably less than in the other samples, as would be expected if the chains are short.

We now consider in detail the spectrum of the polymer. The crystal structure is not known; in particular it is not known how many chains pass through the unit cell. We must, therefore, assume that the interaction between the chains can be neglected and that the spectrum can be interpreted on the basis of a single chain. The fact that the infrared spectra of samples of widely different crystallinity are almost identical suggests that interaction between the chains does not affect the spectrum very much. The general arguments are similar to those used previously for polychloral and are given here only briefly; more detail can be obtained from ref. *4b*.

The physical structure of the chain of polyfluoral is not known, but some information can be obtained from the infrared spectrum. Only those fundamentals can be optically active in which all repeating units move in phase. If there is one monomer unit $(CHCF_3 \cdot O)$ in the repeat unit, then the number of potentially infrared-active fundamentals is 17, excluding the rotation about the chain axis. They can be divided approximately into one CH stretching, two CH bending, six skeletal (CF, CO, CC) stretching, and eight skeletal bending vibrations.

The CH stretching bands are expected to be near 2 900 cm^{-1}. There is one band at 2 963 cm^{-1} which is assigned to a CH stretching fundamental; the polarization measurements (Section II) indicate that this may in fact be a superposition of two bands.

Two CH bending frequencies are expected if there is one monomer unit in the repeat, one approximately in the local symmetry plane, and one perpendicular to it. One is expected in the region 1 450 – 1 300 cm^{-1} and the other below 1 200 cm^{-1}. Only one band, the σ-polarized band at 1 422 cm^{-1} can be identified as a CH bending band with any assurance. In polychloral (*5b*), by contrast, there were two CH bending bands in this region, one π-polarized and one σ-polarized.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

CF_3 stretching vibrations are expected in the region 1 350 to 1 050 cm^{-1} (6). The CO and CC stretching bands are expected to be between 1 250 and 750 cm^{-1}, and no doubt the CF, CO, and CC stretching motions are well mixed. There are 15 bands in this region, of which 4, at 1 376, 1 334, 1 025, and 854 cm^{-1} are weak and of uncertain origin. There are therefore 11 skeletal stretching bands compared with the 6 expected for a one-monomer repeating unit.

Below 750 cm^{-1}, bands due to the bending vibrations are expected. These are the CF_3 symmetrical and asymmetrical deformations; the CF_3 rocking, wagging, and twisting vibrations; the CF_3 torsional vibration; and the COC and OCO bending vibrations. Sixteen bands were observed in this region, most of them being probably fundamentals, compared with the eight expected for a one-monomer repeating unit.

The fact that there are more skeletal stretching and bending fundamentals than are expected for one monomer unit in the repeat unit strongly suggests that there is more than one monomer unit in the repeat. The alternative explanation, that many of the bands arise because of interaction between the chains, is unlikely. A planar zig-zag carbon–oxygen backbone with isotactic (same side) placement of the CF_3 groups can therefore be eliminated.

A planar zig-zag carbon–oxygen backbone with syndiotactic (alternate) placement of the side groups, and a helicoidal carbon–oxygen backbone with isotactic placement of the side groups, and p (where $p \geqslant 3$) monomer units in m turns of the coil in the repeat unit, are the simplest structures that are consistent with the observed number of bands. The polarization of the bands allows one to obtain more information.

The symmetry of the isotactic plane zig-zag is such that few π-polarized bands are expected in the spectrum. In particular, only three should occur in the range 1 400–850 cm^{-1} due to CF_3 and skeletal stretching and CH bending vibrations. Seven, of which five were very strong, were observed in this frequency range, and consequently the spectrum is inconsistent with a planar zig-zag syndiotactic structure.

The helicoidal structure, on the other hand, predicts equal numbers of σ-polarized and π-polarized bands. In the range 1 450 – 800 cm^{-1}, eight σ- and eight π-bands are expected for this structure. Seven σ- and seven π-bands, which are almost certainly fundamentals, and two other weak bands of doubtful polarization which may be combinations, were observed, in good agreement with the prediction. Below 750 cm^{-1} there are approximately equal numbers of σ- and π-polarized bands, and, while detailed interpretation is not possible, the numbers are consistent with the helicoidal isotactic structure. The lack of polarization of the 2 963 cm^{-1} CH stretching band, which is probably due to its being a superposition of a σ- and a π-band, is also consistent with a helicoidal chain.

A tentative assignment of the bands, based on the assignments of smaller molecules, is given in Table III.

ACKNOWLEDGMENT

We are indebted to Dr. L. D. Calvert for the X-ray diffraction.

THE ACID HYDROLYSIS OF GLYCOSIDES

II. EFFECT OF SUBSTITUENTS AT C-5

T. E. TIMELL, W. ENTERMAN, F. SPENCER, AND E. J. SOLTES

Received March 5, 1965

ABSTRACT

First-order rate coefficients at three temperatures, and energies and entropies of activation, have been determined for the acid-catalyzed hydrolysis of methyl glucopyranosides containing various substituents at C-5 and for glycopyranosiduronic acids with different aglycones. Substitution at C-5 increased the stability towards acids of methyl α- and β-D-glucopyranosides, but there was no correlation between either the polarity or the size of the substituent and the rates of hydrolysis. The operation of either an inductive or a conformational effect alone was accordingly deemed unlikely.

Methyl α- and β-D-glucopyranosiduronic acids and methyl α-D-galactopyranosiduronic acid were only slightly more stable towards acids than the glycoside analogs, while benzyl β-D-glucopyranosiduronic acid was three times more stable. The presence of a methyl ester group at the carboxyl function increased the stability of the glycuronide bond. Isopropyl, *n*-butyl, isobutyl, and neopentyl β-D-glucopyranosiduronic acids were hydrolyzed approximately twice and cyclohexyl β-D-glucopyranosiduronic acid five times as fast as the corresponding glucosides. This appears to be the first time that glycuronides have been found to be hydrolyzed by dilute acid at a higher rate than their glycoside analogs.

The energies and, especially, the entropies of activation were, throughout, lower for the glycuronides than for the glycosides. The difference in entropy suggests that the two classes of compounds are hydrolyzed by different mechanisms.

INTRODUCTION

The mechanism of the acid hydrolysis of glycosides containing a carboxylic acid group at C-5 (glycopyranosiduronic acids, glycuronides) has attracted considerable attention in recent years, partly, no doubt, because polysaccharides with uronic acid residues are common in nature.

The glycuronide linkages have, so far, always been found to be hydrolyzed by moderately concentrated acids at a lower rate than the corresponding glycosidic bonds. Several investigators have attributed this to an inductive effect of the electron-attracting carboxyl group (1–8). Two alternatives are possible in the case of a glycopyranosiduronic acid. Either the polar effect is transmitted via one oxygen and two carbon atoms, which does not appear very likely, or, as has recently been suggested (8), the electrons at the ring oxygen are pulled by the carboxyl groups towards C-5, thus decreasing the ability of the ring oxygen to release electrons to the exocyclic oxygen. It is interesting in this connection to note that xylothiapyranosides are hydrolyzed faster than their oxygen analogs, apparently because of the ability of the less electronegative sulfur to furnish electrons to the glycosidic oxygen (9).

Alternative explanations for the stability of the glycuronide linkage have also been offered. Easty (10) noted that both the energy and the entropy of activation were lower for the acid hydrolysis of methyl α-D-glucopyranosiduronic acid as compared to methyl

α-D-glucopyranoside.[1] This was not considered compatible with the operation of an inductive effect, and Easty concluded that the mechanisms by which the two compounds hydrolyzed probably differed in some unknown manner. McKee and Dickey (11) have recently suggested that the entire uronic acid residue but not the carboxyl group, as such, stabilizes the xylosidic bond in *O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-(1 → 2)-*O*-β-D-xylopyranosyl-(1 → 4)-D-xylose. A conformational rather than a polar effect was accordingly assumed to operate.

In a previous paper in this series, the general conditions for the acid-catalyzed hydrolysis of glycosides were discussed, as well as the influence of the nature of the aglycone (12). The present investigation is concerned with the influence on the rate parameters of substituents at C-5, and especially with the acid hydrolysis of glycopyranosiduronic acids. A brief account of some preliminary results has been given elsewhere (13).

RESULTS AND DISCUSSION

Hydrolyses were carried out with 0.05 *M* glycoside solutions in 0.5 *M* aqueous sulfuric acid. The extent of hydrolysis was determined polarimetrically. Kinetic parameters and deviations from the mean were calculated as described previously (12). All compounds studied were chromatographically pure, and all except five were crystalline.

TABLE I

Rate coefficients and kinetic parameters for the hydrolysis of methyl α-D-glucopyranosides with different substituents at C-5 (0.05 *M*) in 0.5 *M* sulfuric acid

Compound	$k \times 10^{-6}$ s^{-1}			*E*, kcal mole^{-1}	$\Delta S^{\ddagger}$ at 60 °C, cal deg^{-1} mole^{-1}
	60 °C	70 °C	80 °C

Methyl 6-*O*-methyl-α-D-glucoside	0.449	1.90	8.52	34.2	+13.5

Kinetic data for a series of eight methyl α-D-glycopyranosides carrying different substituents at C-5 are presented in Table I. The greater stability of the glucoside as compared to the xyloside is well known (14). The stability towards acids of the 6-iodo- and the 6-amino glucosides has also been noted previously (15, 16). In view of the postulated inductive effect of the carboxyl group, it is of interest to compare the electron affinity of the C-5 substituents with their rate coefficients. Such a comparison is seen in Table II, where the rate constant at 60° and Taft's (17) polar substituent constant σ^* are used as parameters.

There is obviously little or no correlation between the polarity of the C-5 substituents and the rate coefficients, an inverse correlation being expected if the inductive effect alone were operating. The carboxymethyl and the chloromethyl groups, for example, have the

[1]*In Part I of this series (Table III), the rate coefficient reported by D. B. Easty in ref. 10 was erroneously stated to be 6.79 × 10^{-6} s^{-1}, when it was assumed that the original value was given in min^{-1} and 10-logarithms, while actually min^{-1} and natural logarithms had been used. The correct value, 2.95 × 10^{-6} s^{-1} is in excellent agreement with the corresponding value found in these studies, namely 2.85 × 10^{-6} s^{-1}. The authors are thankful to Dr. Alexander Meller, Australian Paper Manufacturers Limited, Melbourne, Australia, for drawing his attention to this error.*

TABLE II

Rate coefficients at 60 °C and polar substituent constants (σ^*) for some C-5-substituted methyl α-D-glucopyranosides

Substituent	$k \times 10^{-6}$ s^{-1}	σ^*
—CH_2CO_2H	0.572	+1.05
—CH_2Cl	0.092	+1.05
—CH_2I	0.099	+0.85
—CH_2OH	0.637	+0.56
—CH_2OCH_3	0.449	+0.52

same σ^* -values, yet the glucuronide was hydrolyzed more than six times faster than the 6-deoxy-6-chloro compound. The glucoside and the 6-*O*-methylglucoside were both hydrolyzed at approximately the same rate as the glucuronide, yet the σ^* -value for the hydroxymethyl and methoxymethyl groups is only about half of that of the carboxymethyl substituent. It is obvious that in these cases an inductive effect is not the only factor involved. The stability of the 6-deoxy-6-amino compound could be at least partly due to the electrostatic shielding effect of the positive ammonium ion present in acid solution.

TABLE III

Rate coefficients and kinetic parameters for the hydrolysis of methyl β-D-glucopyranosides with different substituents at C-5 (0.05 *M*) in 0.5 *M* sulfuric acid

Compound	$k \times 10^{-6}$ s^{-1}			E	$\Delta S\ddagger$
	60 °C	70 °C	80 °C		
Methyl β-D-xyloside	6.56	28.6	121	33.9	+17.9
Methyl β-D-glucoside	1.38	6.25	24.1	32.5	+10.6
Methyl β-D-glucuronide	1.16	4.14	14.4	29.3	+0.8
Methyl 6-*O*-methyl-β-D-glucoside	0.840	3.88	16.1	34.9	+16.8
Methyl 6-*O*-ethyl-β-D-glucoside	1.01	4.22	18.2	34.4	+15.8
Methyl 6-*O*-isopropyl-β-D-glucoside	1.11	5.08	20.6	34.8	+17.1

Corresponding data obtained for a series of six methyl β-D-glucopyranosides are given in Table III. Again, the difference in rate of hydrolysis between the glucuronide and the glucoside is quite small. All three 6-*O*-alkyl glucosides were hydrolyzed more slowly than the glucuronide.

There can be little doubt that some of the present results can be more rationally explained in terms of conformational rather than of polar effects. As first pointed out by Edward (14), the carbonium–oxonium ion present as an intermediate in the hydrolysis will tend to assume a half-chair conformation, a transformation which will be hindered by any substituent at C-5 relative to C-4. Rates of hydrolysis should thus decrease with increasing size of a C-5 substituent. This would explain the well-known increase in stability towards acids in the series pentosides, hexosides, and heptosides. It is evident, however, from the data in Tables I and III that this conformational effect cannot be adduced to explain all of the present results. The C-5 substituents are not of the same size in the 6-deoxy-6-chloro and 6-deoxy-6-iodo compounds, yet their rates of hydrolysis are almost the same. The methyl 6-deoxy-α-D-glucoside is hydrolyzed as rapidly as the methyl α-D-xyloside, which is also unexpected. The increase in rate of hydrolysis is less than the increase in size of the C-5 substituents in the series 6-*O*-methyl, 6-*O*-ethyl, and 6-*O*-isopropyl β-D-glucosides.

With a view of obtaining more information on this point, a number of methyl α- and β-D-glycopyranosiduronic acids were synthesized, and their kinetic parameters were compared with those previously obtained for their glycopyranoside analogs. Similar data were also established for a series of seven β-D-glucopyranosiduronic acids containing different aglycones. The results are presented in Tables IV and V.

TABLE IV

n-Butyl β-D-glucuronide	4.20	14.4	49.2	29.3	+3.3
Isobutyl β-D-glucoside	1.90	8.21	34.4	33.8	+15.2
Isobutyl β-D-glucuronide	3.74	14.9	51.4	29.5	+3.7
Neopentyl β-D-glucoside	2.41	10.6	39.9	36.2	+22.9
Neopentyl β-D-glucuronide	4.65	16.9	57.2	30.0	+5.6
Cyclohexyl β-D-glucoside	3.25	13.9	56.4	33.5	+15.3
Cyclohexyl β-D-glucuronide	18.5	63.7	217	28.7	+4.5
Benzyl β-D-glucoside	1.56	6.75	28.3	33.6	+14.2
Benzyl β-D-glucuronide	0.587	2.29	8.44	30.9	+4.1

The methyl α-D-glucuronide and methyl α-D-galacturonide were hydrolyzed at a rate which was only slightly lower than that of the corresponding neutral glycosides, which is in agreement with the previous observations of Morell and Link (18), Nakano and Rånby (7), and Easty (10). The same applies to the methyl β-D-glucuronide, while the methyl β-D-galacturonide was hydrolyzed approximately seven times more slowly than the galactoside. The methyl α-D-mannuronide was hydrolyzed 2.5 times faster than the mannoside.

In the series of β-D-glucuronides, the benzyl β-D-glucuronide was approximately three times more stable than the corresponding glucoside. The isopropyl *n*-butyl, isobutyl, and neopentyl compounds were all hydrolyzed about twice as fast as their glucoside analogs, while the cyclohexyl β-D-glucuronide reacted five times more rapidly than the β-D-glucoside. The fact that certain glucuronides are less stable towards dilute acids than their neutral analogs does not seem to have been observed previously. Nakano and Rånby (7) noted that methyl α- and β-D-glucopyranosiduronic acids were both hydrolyzed more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

rapidly in 81% phosphoric acid than the corresponding glucopyranosides. The activation energies were unusually low, however, and it was also found that the acid solutions quickly became colored, indicating the occurrence of secondary reactions.

During the acid hydrolysis of methyl esters of glycuronides the ester groups are rapidly eliminated. When the hydrolysis of methyl (methyl α-D-galactosid) uronate was followed with the aid of thin-layer chromatography, the results showed that ester linkage was hydrolyzed at a much higher rate than the galacturonide bond. The rate coefficients increased gradually during the initial stage of the reaction, indicating that the methyl ester group stabilized the galacturonide. After this period, the rate coefficients became constant and were those of methyl α-D-galacturonide, as can be seen from Table IV. Similar results were obtained with methyl (methyl β-D-galactosid) uronate and methyl (methyl β-D-glucosid) uronate. This is in agreement with the data of Dyer, Glaudemans, Koch, and Marchessault (6), who have shown that ethyl tetrahydro-6-methoxypyran-2-carboxylate is hydrolyzed in 0.001 *N* hydrochloric acid at 30 °C 7.4 times faster than is tetrahydro 6-methoxypyran-2-carboxylic acid. In this case, the extremely labile nature of the 6-methoxy group made it possible to establish quantitatively the effect of the ester group. The electron affinity of an ester group is greater than that of a carbylate ion, and the above investigators attributed the stabilization exerted by the ethyl ester group to an inductive effect. It seems more likely, however, that also in this case conformational factors are involved.

Inspection of the data in Tables I and III shows that nearly all values for the activation energy of the neutral glycosides fall within the range of 33 to 35 kcal $mole^{-1}$. The entropy of activation of the neutral glycosides ranges from +10 to +18 cal deg^{-1} $mole^{-1}$, indicating that the reaction is unimolecular (19). With the single exception of the β-D-galacturonide, all glycuronides and the methyl 6-amino-6-deoxy-α-D-glucoside have energies of activation which are 3 to 5 kcal $mole^{-1}$ lower than those of their neutral analogs, and the entropies of activation are in the range of +0.5 to +8 cal deg^{-1} $mole^{-1}$.

It is clear that the lower rate coefficients of the methyl and benzyl glucuronides and of the methyl galacturonides are entirely due to their lower entropies of activation. Differences in entropies of activation for the acid hydrolysis of esters, acetals, and lactones have previously been found to be associated with differences in reaction mechanisms (20). Whether the present glycosides and glycuronides differ in this respect cannot be decided on the basis of the evidence now available.

The energies of activation of the larger alkyl and the cyclohexyl β-D-glycuronides are 1 to 2 kcal $mole^{-1}$ lower than those of the methyl glycuronides. It is possible that this decrease in activation energy is sufficient to overcome the influence of the low entropy values, thus causing an increase rather than a decrease in rate of hydrolysis. It is interesting to note that these aglycones are all groups with a low electron affinity, while the benzyl group is electron-attracting. Semke, Thompson, and Williams (8) have recently reported that the phenyl, *p*-cresyl, and *p*-chlorophenyl β-D-glucopyranosiduronic acids, all compounds with an electron attracting aglycone, are hydrolyzed 16, 19, and 13 times more slowly, respectively, at 95 °C than the corresponding glycosides. In this case both glucuronides and glucosides had entropies of activation of +10 cal deg^{-1} $mole^{-1}$, and the authors concluded that both classes of compounds were hydrolyzed by the same mechanism.

CONCLUSIONS

The present data indicate that the effect of a carboxyl substituent at C-5 in a glycopyranosiduronic acid, whether deactivating or activating, is probably due to neither polar nor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

conformational factors alone. Instead, both effects might be operative, each contributing to a different extent under different conditions. A reaction mechanism other than that by which most neutral glycosides are hydrolyzed might, however, also be involved. In view of their conspicuously low entropies of activation it is, for example, possible that glycopyranosiduronic acids might be at least partially hydrolyzed by a bimolecular reaction mechanism, which would then involve the participation of a mole of water (19, 20).

A more definite rationalization of the present experimental evidence does not appear feasible at the moment. More data for glycopyranosiduronic acids containing aglycones with different steric and polar characteristics would be particularly desirable. Investigations with such compounds are now in progress.

EXPERIMENTAL

Most experimental conditions were the same as in the previous study in this series (12). One-third of the polarimetric measurements were carried out at 436 mμ with a Perkin–Elmer model 141 photoelectric polarimeter.

Thin-layer chromatography was carried out with Silica Gel H and pyridine – ethyl acetate – acetic acid – water (5:5:1:3). One set of chromatograms was sprayed with 72% sulfuric acid and the other with *o*-aminobiphenyl. After hydrolysis for 6 h at 60 °C, methyl (methyl α-D-galactosid) uronate had been completely replaced by methyl α-D-galacturonide. Galacturonic acid was observed after 24 h and onward. Data for the hydrolysis of methyl (methyl α-D-galactosid) uronate at 60 °C are found in Table VI.

MATERIALS

Methyl 6-Deoxy-β-D-glucopyranoside

Methyl α-D-glucopyranoside was treated with *p*-toluenesulfonyl chloride in pyridine (16, 21), giving methyl 6-*O*-*p*-toluenesulfonyl-α-D-glucopyranoside, m.p. 122–124 °C and $[\alpha]_D$ +95° (*c*, 1.0 in water) (22). The compound was reduced with lithium aluminium hydride in tetrahydrofuran (23, 24) to give methyl 6-deoxy-α-D-glucopyranoside (methyl α-D-quinovoside) with m.p. 96-98° and $[\alpha]_D$ +145° (*c*, 1.0 in water) (25).

Methyl 6-Amino-6-deoxy-α-D-glucopyranoside

This compound was prepared from methyl 6-*O*-*p*-toluenesulfonyl-α-D-glucopyranoside by treatment with methanolic ammonia at 120° (22). The hydrochloride of methyl 6-amino-6-deoxy-α-D-glucopyranoside melted with decomposition at 180–190° and had $[\alpha]_D$ +136° (*c*, 1.0 in water) (16).

Methyl 6-Chloro-6-deoxy-α-D-glucopyranoside

This compound was prepared by a combination of the methods reported by Helferich and his co-workers (26, 27). Methyl 2,3,4-tri-*O*-acetyl-6-*O*-trityl-α-D-glucopyranoside on treatment with phosphorus pentachloride and subsequent removal of the trityl group with hydrogen bromide in acetic acid gave methyl 2,3,4-tri-*O*-acetyl-6-chloro-6-deoxy-α-D-glucopyranoside. Saponification with aqueous barium hydroxide yielded methyl 6-chloro-6-deoxy-α-D-glucopyranoside with m.p. 108–110° and $[\alpha]_D$ +141° (*c*, 1.0 in water) (25, 26).

Methyl 6-Deoxy-6-iodo-α-D-glucopyranoside

The method of Compton (21) was followed. Methyl 6-*O*-*p*-toluenesulfonyl-α-D-glucopyranoside on acetylation in pyridine gave methyl 2,3,4-tri-*O*-acetyl-6-*O*-*p*-toluenesulfonyl-α-D-glucopyranoside in a yield of 41%, m.p. 169–170° and $[\alpha]_D$ +7.4° (*c*, 3.7 in chloroform). Treatment with sodium iodide in boiling cyclopentanone gave methyl 2,3,4-tri-*O*-acetyl-6-deoxy-6-iodo-α-D-glucopyranoside in a yield of 70%, m.p. 148.5–149.5° and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$[\alpha]_D$ +111° (*c*, 1.3 in chloroform) (15, 27). The compound was treated with alcoholic hydrochloric acid and crystallized from ethanol – ethyl acetate to give methyl 6-deoxy-6-iodo-α-D-glucopyranoside in a yield of 50%, m.p. 136–137° and $[\alpha]$ +102° (*c*, 1.0 in water).

Methyl 6-O-Methyl-α-D-glucopyranoside

This compound was prepared essentially as described by Helferich and co-workers (25, 28), namely by methylation, according to the method of Kuhn, Trischmann, and Löw (29), of methyl 2,3,4-tri-*O*-benzoyl-α-D-glucopyranoside. The crystalline compound had m.p. 146–149° and $[\alpha]_D$ +143.5° (*c*, 1.0 in water).

Anal. Calcd. for $C_8H_{14}O_6$: OCH_3, 29.8. Found: OCH_3, 29.1.

Methyl 6-O-Methyl-β-D-glucopyranoside

1,2; 3,5-Di-*O*-methylene-D-glucofuranose (14 g, m.p. 57–58°, $[\alpha]_D$ +51° in water) (30) was methylated with methyl iodide (100 ml) and silver oxide for 24 h at room temperature. After addition of chloroform, filtration through Celite, treatment with Darco G-60 charcoal, and concentration, a sirup (13 g) was obtained which could not be induced to crystallize; $[\alpha]_D$ +52° (*c*, 1.4 in water).

Anal. Calcd. for $C_9H_{14}O_6$: OCH_3, 14.2. Found: OCH_3, 14.3.

The 6-*O*-methyl bismethylene glucose was refluxed with *N* sulfuric acid (400 ml) for 5 h. After neutralization with barium carbonate and treatment with Amberlite IR-120 exchange resin, an aqueous solution of the reaction mixture was extracted with chloroform. The water layer was concentrated to a sirup. Crystallization from ethanol gave 6-*O*-methyl-D-glucose (5.5 g), m.p. 141–143.5° and $[\alpha]$ +55° (*c*, 1.0 in water) (31, 32).

6-*O*-Methyl-D-glucose (4.0 g) was acetylated in the usual way with hot acetic anhydride in the presence of anhydrous sodium acetate. Yield of crude, crystalline product: 8.1 g. After recrystallization from absolute ethanol the 1,2,3,4-tetra-*O*-acetyl-6-*O*-methyl-β-D-glucose (5.1 g) had m.p. 92–94° and $[\alpha]_D$ +20° (*c*, 1.0 in chloroform) (32, 33). The compound (5.0 g) was treated with glacial acetic acid (30 ml), saturated at 0° with hydrogen bromide to give the sirupy α-acetobromo compound (6.4 g) which was not characterized.

The 6-*O*-methyl acetobromoglucose (6.0 g) was dissolved in anhydrous methanol (50 ml) and shaken overnight with silver oxide (6.0 g) in the presence of some Drierite and iodine. After filtration through Celite, treatment with charcoal, and concentration, the reaction product was recrystallized from ethyl ether – petroleum ether to give 4.3 g of methyl 2,3,4-tri-*O*-acetyl-6-*O*-methyl-β-D-glucopyranoside, m.p. 103–105° and $[\alpha]_D$ −14.8° (*c*, 1.0 in chloroform) (32, 33). The compound (4.2 g) was deacetylated with anhydrous methanol (150 ml) containing sodium methoxide (1 g). After 2 h at room temperature, sodium ions were eliminated with Amberlite IR-120, and the solution was decolorized with charcoal and concentrated to dryness, yielding 2.9 g of a crude product which was crystallized from ethyl acetate. The methyl 6-*O*-methyl-β-D-glucopyranoside (1.5 g) had m.p. 133–135° and $[\alpha]_D$ −27.8° (*c*, 1.0 in water).

Anal. Calcd. for $C_8H_{16}O_6$: OCH_3; 29.9. Found: OCH_3, 30.5.

Methyl 6-O-Ethyl-β-D-glucopyranoside

Bismethylene glucose (14 g) was treated with ethyl iodide and silver oxide in the presence of dimethyl formamide (29). The sirupy product obtained (9.0 g) gave an infrared diagram with no hydroxyl band. Hydrolysis with *N* sulfuric acid yielded, after crystallization from absolute ethanol, 6-*O*-ethyl-D-glucopyranose (7.9 g), m.p. 163–167° and $[\alpha]_D$ −51.6° (*c*, 1.3 in water). The product (7.5 g) was acetylated with hot acetic anhydride in the presence of anhydrous sodium acetate, giving 1,2,3,4-tetra-*O*-acetyl-6-*O*-ethyl-β-D-glucose (12 g) as a sirup. After deacetylation of a portion of the sirup (8 g) with methanol – sodium methoxide, contaminating glucose was removed by fermentation with baker's yeast. The 6-*O*-ethyl-D-glucopyranose, after crystallization from ethanol (5.0 g) had m.p. 166–168° and $[\alpha]_D$ −53° (*c*, 1.3 in water) (34). Another portion of the crude product (4 g) was converted to the acetobromo compound, which was condensed with methanol in the usual way, giving methyl 2,3,4-tri-*O*-acetyl-6-*O*-ethyl-β-D-glucoside (2.7 g), m.p. 102–102.5° and $[\alpha]_D$ +1.2° (*c*, 1.3 in chloroform). Deacetylation of 1.5 g of this material gave methyl 6-*O*-ethyl-β-D-glucopyranoside (0.8 g) with m.p. 125.5–127.5° and $[\alpha]$ −25.5° (*c*, 1.5 in water).

Methyl 6-O-Isopropyl-β-D-glucopyranoside

Bismethylene glucose (20 g) was dissolved in dimethyl formamide and treated with silver oxide and isopropyl iodide in the usual way, giving the 6-*O*-isopropyl compound (9 g). Hydrolysis with *N* sulfuric acid, removal of glucose with yeast, and crystallization from ethanol gave 6-*O*-isopropyl-D-glucose (4.9 g) m.p. 128–130° and $[\alpha]_D$ +49° (*c*, 1.1 in water) (34). The 1,2,3,4-tetra-*O*-acetyl-6-*O*-isopropyl-β-D-glucose, after recrystallization from ethanol had m.p. 120–121° and $[\alpha]_D$ +16.6° (*c*, 1.0 in chloroform).

Condensation of the acetobromo derivative (3.0 g) with methanol yielded a sirup (2.7 g) which crystallized from ethyl ether – petroleum ether (1.8 g). The methyl 2,3,4-tri-*O*-acetyl-6-*O*-isopropyl-β-D-glucoside had m.p. 57–59° and $[\alpha]_D$ +12.2° (*c*, 1.5 in chloroform). This compound (1.7 g) was deacetylated in the usual way. After crystallization from ethyl acetate – petroleum ether, methyl 6-*O*-isopropyl-β-D-glucopyranoside (1.0 g) had m.p. 83.5–84° and $[\alpha]_D$ −24.1° (*c*, 1.0 in water).

Methyl α-D-Glucopyranosiduronic Acid

Methyl 2,3,4-tri-*O*-benzoyl-α-D-glucopyranoside (15 g) was oxidized with potassium permanganate (16 g) in a solution consisting of 150 ml each of acetone, glacial acetic acid, and water (35). After 3 days at room temperature, the solution was treated with potassium sulfite and extracted with chloroform to yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

11.3 g of a crude product. Benzoyl groups were eliminated by treatment with methanol and sodium methylate, and the methyl benzoate formed was removed by extraction with chloroform. The crude uronic acid was purified by adsorption on a column containing Dowex 1-X4 (acetate form) exchange resin. Neither the free acid nor the potassium salt of methyl α-D-glucopyranosiduronic acid could be induced to crystallize. The chromatographically pure product had $[\alpha]_D$ +129° (*c*, 1.0 in water).

Anal. Calcd. for $C_7H_{12}O_7$: OCH_3, 14.9. Found: OCH_3, 14.6.

Methyl β-D-Glucopyranosiduronic Acid

Methyl 1,2,3,4-tetra-*O*-acetyl-α-D-glucuronate and the corresponding β-anomer were prepared as described by Bollenback and co-workers (36). The α-compound had m.p. 111–112° and $[\alpha]_D$ +98° (*c*, 1.0 in chloroform). The β-anomer had m.p. 177–178° and $[\alpha]_D$ +8.6° (*c*, 1.0 in chloroform) (37, 38). Methyl 2,3,4-tri-*O*-acetyl-1-bromo-1-deoxy-α-D-glucuronate was obtained in a yield of 82% with m.p. 104–105.5° and $[\alpha]_D$ +198° (*c*, 1.0 in chloroform) (36, 38).

The acetobromo sugar (18 g) was dissolved in methanol (300 ml), and the solution was shaken in the dark with silver carbonate (20 g) in the presence of Drierite (10 g) and some iodine. After 40 h at room temperature, the solids were removed by filtration, and the methanol solution was decolorized with charcoal and evaporated to dryness. After recrystallization from ethanol, the methyl (methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranosid) uronate (10.5 g) had m.p. 153–155° and $[\alpha]_D$ −30° (*c*, 1.0 in chloroform) (39). A portion of the product (6.2 g) was treated with barium hydroxide (14 g) in water (100 ml) at 60° for 3 h. The reaction mixture was neutralized with carbon dioxide, filtered through Celite, treated with charcoal and Amberlite IR-120, and evaporated to dryness. The methyl β-D-glucopyranosiduronic acid was crystallized from acetone containing some methanol to give 3.1 g, m.p. 68–70° and $[\alpha]_D$ −55.3° (*c*, 1.0 in water).

Anal. Calcd. for $C_7H_{12}O_7$: OCH_3, 14.9. Found: OCH_3, 14.9.

Methyl (Methyl β-D-Glucopyranosid) Uronate

This compound was obtained by treating methyl (methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranosid) uronate with methanol – sodium methylate, followed by re-esterification with diazomethane. It had $[\alpha]_D$ −45° (*c*, 1.0 in water).

Anal. Calcd. for $C_8H_{14}O_7$: OCH_3, 27.9. Found: OCH_3, 26.0.

Methyl α-D-Galactopyranosiduronic Acid

This compound was prepared from D-galacturonic acid in a yield of 50%, essentially as described by Jones and Stacey (40). After two recrystallizations from ethanol, the methyl α-D-galactopyranosiduronic acid sintered at 88–90° and melted at 107–108°. It had $[\alpha]$ +128° (*c*, 1.4 in water) (41).

Methyl (Methyl α-D-Galactopyranosid) Uronate

D-Galacturonic acid (30 g) was boiled under reflux for 15 h with 0.7 *N* methanolic hydrogen chloride (300 ml) in the presence of Drierite (20 g). After neutralization with silver carbonate, treatment with charcoal, and filtration through Celite, evaporation of the solution gave a pale yellow sirup which was dissolved in a minimum amount of boiling methanol. The crystals deposited on cooling to room temperature were recrystallized from hot methanol, giving methyl (methyl α-D-galactopyranosid) uronate (4.0 g) with m.p. and mixed m.p. 147–148 °C and $[\alpha]_D$ +128° (*c*, 2.0 in water) (42–44).

Anal. Calcd. for $C_8H_{14}O_7 \cdot H_2O$: OCH_3, 25.9. Found: OCH_3, 25.9.

Methyl β-D-Galactopyranosiduronic Acid

Methyl (methyl 2,3,4-tri-*O*-acetyl-β-D-galactopyranosid) uronate, prepared from methanol and the acetobromo derivative of D-galacturonic acid, was saponified with barium hydroxide. The resulting methyl β-D-galactopyranosiduronic acid, after crystallization from acetone–chloroform, had m.p. 161–163° and $[\alpha]_D$ −40.2° (*c*, 1.1 in water) (42, 45).

Methyl (Methyl β-D-Galactopyranosid) Uronate

The above compound was obtained on deacetylation of the triacetate derivative with methanol – sodium methylate. It had $[\alpha]_D$ −27.5° (*c*, 1.0 in water).

Methyl α-D-Mannopyranosiduronic Acid

Methyl 2,3,4-tri-*O*-acetyl-α-D-mannopyranosiduronic acid (46) was oxidized with potassium permanganate as described for the corresponding glucoside derivative (35). The methyl α-D-mannopyranosiduronic acid had m.p. 114–115° and $[\alpha]_D$ +57° (*c*, 1.4 in water) (42, 47). The potassium salt had $[\alpha]_D$ +52° (*c*, 1.0 in water) (42).

Anal. Calcd. for $C_7H_{11}O_7K$: K, 15.8. Found: K, 14.9.

Both the mannuronide and the derived mannuronic acid gave only one sharp peak on ion exchange resin chromatography (48).

Cyclohexyl β-D-Glucopyranosiduronic Acid

Methyl 2,3,4-tri-*O*-acetyl-1-bromo-1-deoxy-α-D-glucuronate (12.1 g) (36) was added to a suspension of silver carbonate (10 g), Drierite (20 g), and a little iodine in cyclohexanol (150 ml). The mixture was shaken in the dark at room temperature for 24 h. The crystalline product was recovered in the usual way. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

recrystallization from 75 ml of absolute ethanol, the long needles of methyl (cyclohexyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranosid) uronate (10.6 g, 83%) had m.p. 140–141.5° and $[\alpha]_D$ −31.7° (*c*, 1.5 in chloroform) (49). Use of mercuric cyanide instead of silver carbonate, as suggested by Helferich and Berger (49), gave the same crystalline compound in a yield of 70%.

The above compound (10.3 g) was treated with barium hydroxide (20 g) in water (200 ml) at 60° for 3 h. The reaction product was recovered in the usual way and crystallized from ethanol to give cyclohexyl β-D-glucopyranosiduronic acid (4.0 g) with m.p. 168–170° and $[\alpha]$ −59° (*c*, 1.0 in water) (51).

Neopentyl β-D-Glucopyranosiduronic Acid[2]

Methyl 2,3,4-tri-*O*-acetyl-1-bromo-1-deoxy-α-D-glucuronate (12.0 g) was condensed with neopentyl alcohol (20 g) in benzene (125 ml) in the presence of silver carbonate (10 g), Drierite (20 g), and some iodine. After it was shaken at room temperature for 24 h, the solution was recovered by filtration through Celite. Filtrate and washings (benzene) were evaporated to dryness, leaving a crystalline residue which was recrystallized from ethanol. The methyl (neopentyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranosid) uronate (11.0 g) had m.p. 153–154° and $[\alpha]_D$ −51.3° (*c*, 3.0 in chloroform). A portion of the product (10.0 g) was treated with barium hydroxide (22 g) in the usual way, giving neopentyl β-D-glucopyranosiduronic acid (5.1 g); m.p. 149–151° and $[\alpha]_D$ −51.3° (*c*, 3.0 in chloroform).

Isopropyl β-D-Glucopyranosiduronic Acid[2]

The methyl (isopropyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranosid) uronate, obtained as described above in a yield of 71%, had m.p. 143.5–145.5° and $[\alpha]$ −33.4° (*c*, 1.5 in chloroform). The isopropyl β-D-glucopyranosiduronic acid had $[\alpha]$ −45° (*c*, 1.0 in water). It could not be induced to crystallize.

n-Butyl β-D-Glucopyranosiduronic Acid[2]

The methyl (*n*-butyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranosid) uronate was obtained in a yield of 68% and had m.p. 92–93° and $[\alpha]_D$ −26.1° (*c*, 1.3 in chloroform). The sirupy *n*-butyl β-D-glucopyranosiduronic acid had $[\alpha]_D$ −44° (*c*, 1.0 in water).

Isobutyl β-D-Glucopyranosiduronic Acid[2]

The methyl (isobutyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranosid) uronate, obtained in a yield of 38%, had m.p. 138.5–139.5° and $[\alpha]_D$ −24.3° (*c*, 1.3 in chloroform). The isobutyl β-D-glucopyranosiduronic acid, which could not be induced to crystallize, had $[\alpha]_D$ −51.8° (*c*, 1.4 in water).

ACKNOWLEDGMENTS

The authors express their gratitude to Mr. N. Roy for the gift of methyl (methyl α-D-galactopyranosid) uronate and to Mr. B. W. Simson for technical assistance. This investigation was supported by a United States Public Health Service Research Grant (AM 07193 MCHA) from the National Institute of Arthritis and Metabolic Diseases, Public Health Service.

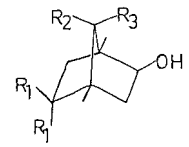
1,4-DIMETHYLBICYCLO[2.2.1]HEPTANE DERIVATIVES

PETER YATES AND THOMAS R. LYNCH[1]
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario
Received April 15, 1965

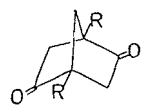
ABSTRACT

The product from the action of methylmagnesium iodide on bicyclo[2.2.1]heptane-2,5-dione gave 2-exo-5-endo-diacetoxy-1,4-dimethylbicyclo[2.2.1]heptane on treatment with sulfuric acid in acetic acid. This has been converted to 1,4-dimethylbicyclo[2.2.1]heptane-2-exo-5-endo-diol, to 1,4-dimethylbicyclo[2.2.1]heptane-2,5-dione, and to 1,4-dimethylbicyclo[2.2.1]heptane-2-endo-5-endo-diol. The stereochemical assignments have been made on the basis of the interpretation of the nuclear magnetic resonance spectra of these compounds. The exo–endo diacetoxy compound is shown to be the expected product from a double Wagner–Meerwein rearrangement.

In the course of other work, we required 1,4-dimethylbicyclo[2.2.1]heptane derivatives with functional groups in both of the two-carbon bridges. The only bicyclo[2.2.1]heptane derivatives with methyl groups at both bridgeheads which had been prepared previously were compounds I–III, obtained from compounds of natural origin (1, 2, 3). Since none of these was suitable for our purpose we investigated other routes to 1,4-dimethylbicyclo-[2.2.1]heptane derivatives. We report now the preparation of such compounds from bicyclo[2.2.1]heptane-2,5-dione (IV). After the completion of this work (4) the preparation of 1,4-dimethylbicyclo[2.2.1]heptane-2,5-dione (V) by a different route was reported (5).



I, $R_1=R_3=H, R_2=CH_3$
II, $R_1=H, R_2=R_3=CH_3$
III, $R_1=CH_3, R_2=R_3=H$



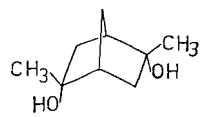
IV, R=H
V, $R=CH_3$

The diketone IV was prepared from bicyclo[2.2.1]heptadiene by the method of Meinwald, Crandall, and Gassman (6). Treatment of IV with a large excess of methylmagnesium iodide gave a viscous, colorless liquid which decomposed on attempted distillation or chromatography. This product is considered to consist largely of the 2-exo-5-exo-dimethyl-2,5-diol VI[2] (the presence of a small amount of a carbonyl compound was indicated by a very weak band in the infrared spectrum of the product at 5.7 μ). Its gross structure is assigned on the basis of its mode of formation and its reactions (*vide infra*). Its n.m.r. spectrum shows a single methyl signal, consistent with its consisting largely of a single diastereomer with both methyl groups either exo or endo. The preponderance of the stereoisomer VI would be expected on mechanistic grounds. Thus Sauers (7) has found that the product obtained by the action of methylmagnesium iodide on norcamphor is the exo-methyl compound VII, "substantially free" of the corresponding endo-methyl compound. It would be anticipated that the steric factors which favor attack by the Grignard

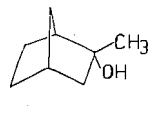
[1]*Sir Joseph Flavelle Fellow, 1961–62; Union Carbide Research Fellow, 1962–63.*
[2]*All products are racemic, and no absolute configuration is implied by this and other formulae.*

reagent on the less hindered exo side of norcamphor would favor similar attack on each of the carbonyl groups of IV (8); electrostatic effects would also be expected to favor *exo* attack in the case of the introduction of the second methyl group via the intermediate VIII. It may further be noted that the positions of the methyl proton signals in the n.m.r. spectra of VI (δ 1.28) and VII (δ 1.24) are very similar.

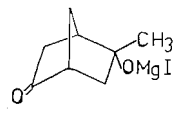
Treatment of the diol VI with 75% sulfuric acid in acetic acid at 70–80° for 2 h gave a colorless liquid, $C_{13}H_{20}O_4$. This product is assigned the structure IX on the basis of the



VI

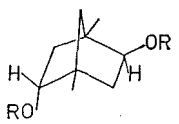


VII



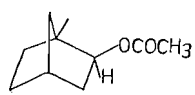
VIII

following evidence. Its infrared spectrum includes bands at 5.74 and 8.1 μ, characteristic of the acetate group and shows no bands attributable to a hydroxyl group. Its n.m.r. spectrum shows signals due to two methyl groups in slightly different magnetic environments at δ 0.95 and 1.09 (cf. X, δ 1.07). The methyl groups of the acetoxyl groups give a

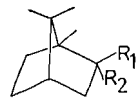


IX, R=COCH3

XI, R=H



X



XII, R1=OH, R2=H

XIII, R1=H, R2=OH

single signal at δ 1.97 (cf. X, δ 1.95). Multiplets due to the hydrogen atoms at C.2 and C.5 partially overlap to give a complex pattern in the region δ 4.5–4.8 (cf. X, multiplet centered at δ 4.5 due to the C.2 hydrogen atom).

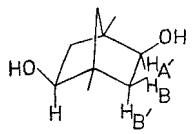
Removal of the acetyl groups with methanolic sodium methoxide gave the exo–endo diol XI, m.p. 98.5–99.5°. The n.m.r. spectrum again shows two methyl group signals at slightly different positions (δ 1.05 and 1.09). The hydroxyl protons give rise to a singlet at δ 1.70; this assignment is confirmed by the shift of this signal to δ 2.05 in the spectrum of a sample dissolved in deuteriochloroform containing a small amount of ethanol. The multiplets due to the hydrogen atoms at C.2 and C.5 again overlap, but they are sufficiently distinct in this case to permit approximate resolution of the overlapping signals into two multiplets, centered at δ 3.58 and 3.83, which are assigned to the C.2 and C.5 protons, respectively (cf. the corresponding proton signals in isoborneol (XII) (multiplet centered at δ 3.52) and borneol (XIII) (multiplet centered at δ 3.91) (cf. ref. 9).

Oxidation of the diol XI with chromium trioxide in acetone gave the diketone V, m.p. 127.5–128°. This was shown to have two carbonyl groups by the preparation of a bis-2,4-dinitrophenylhydrazone. That these are not in a β relationship is evident from the stability of the diketone under basic conditions. The situation of both carbonyl groups in five-membered rings was confirmed by the infrared spectrum of V, which shows a single carbonyl-stretching band at 5.70 μ (cf. IV, 5.68 μ). This spectrum also has a band at 7.10 μ, characteristic of a deformation vibration of a CH_2 group adjacent to a C=O group, and a band at 7.22 μ characteristic of a symmetrical deformation of a CH_3 group not adjacent to a C=O group (as anticipated, the infrared spectrum of IV shows the former band, but not the latter). The ultraviolet maximum of the diketone V (287.5 mμ (ϵ 47))

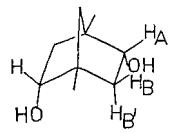
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is similar in position and intensity to that of IV (291 mμ (ε 44)) (6). Its n.m.r. spectrum shows apparent singlets at δ 1.22, 1.79, and 2.09, whose positions and relative intensities are in accord with their assignment to the protons of the two CH_3 groups, the C.7 methylene group, and the C.3 and C.6 methylene groups, respectively. Under very high resolution fine splittings of the 2.09 signal and broadening of the 1.79 signal can be observed; these effects are attributable to the non-equivalence of the exo and endo protons on the C.2 and C.5 methylene groups, and long-range coupling of the C.7 methylene protons with the endo C.3 and C.6 protons (9, 10).

Reduction of the diketone V with lithium aluminium hydride gave a syrupy crude product from which a crystalline diol, m.p. 124.5–125°, was isolated in low yield. This was shown to be a stereoisomer of the exo–endo diol XI by its re-oxidation to the diketone V. Although reduction by lithium aluminium hydride of bicyclo[2.2.1]heptan-2-ones without substituents at C.7 normally occurs by attack from the less hindered exo side (*vide supra*) to give the endo alcohol, it has been observed that reduction of the diketone IV with lithium aluminium tri-*t*-butoxy hydride gives, in addition to the corresponding endo–endo diol as the major product, detectable amounts of the exo–endo diol (6). The fact that the tri-*t*-butoxy hydride, which should be particularly susceptible to steric effects, does not react stereospecifically suggests that lithium aluminium hydride might give significant amounts of products derived by endo attack in related cases. Thus caution must be exercised in the assignment of stereochemistry to the product isolated on reduction of V, particularly since it is obtained in low yield. Nevertheless, the n.m.r. spectrum of the crude product, which was obtained in high yield, showed it to consist largely of the isomer, m.p. 124.5–125°, together with less than 20% of another product whose n.m.r. signals correspond to those of the exo–endo diol. Now, it may be counted highly unlikely that endo attack would predominate at both carbonyl groups of V to such a degree that the exo–exo diol (XIV) would be formed to the virtual exclusion of the endo–endo diol (XV). It is therefore concluded that exo attack largely preponderates and that the reduction product is the endo–endo diol XV. This view is corroborated by the following interpreta-



XIV



XV

tion of the n.m.r. spectrum of the reduction product. A sharp singlet of relative intensity six at δ 1.01 is assigned to the two equivalent bridgehead methyl groups. A broadened singlet at δ 1.25 of relative intensity two is assigned to the equivalent C.7 methylene protons coupled weakly to the C.3 and C.6 endo protons (cf. refs. 9, 10). A signal at δ 2.55 (in 2.5 mole % solution in $CDCl_3$) of relative intensity two can be attributed to the hydroxyl protons since its position is concentration dependent. The remaining signals consist of an unsymmetrical doublet (97 and 104 c.p.s.)[3] and triplet (226, 233, and 240 c.p.s.)[3] of relative intensities four and two, respectively. These can be interpreted in terms of two identical systems of the ABB′ type (11) with the low-field triplet assigned to the C.2 and C.5 protons (A) coupled respectively with the C.3 and C.6 pairs of protons (BB′). This interpretation requires that $|J_{BB'}|$ be large, as is expected, and that $\delta_B \simeq \delta_{B'}$. Restricted first-order analysis (11) gives the following approximate values: $\delta_A = 3.89$,

[3]*Down-field shifts from Me_4Si (int.) in $CDCl_3$ at 60 Mc.*

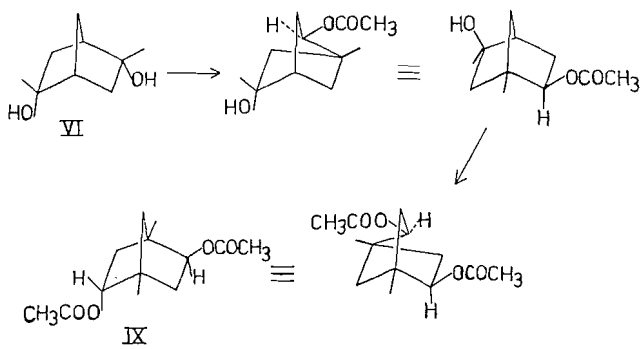
$\delta_B = \delta_{B'} = 1.68$, $|J_{AB} + J_{AB'}| = 14$ c.p.s. Now, Musher's studies of the spectra of a series of bicyclo[2.2.1]heptan-2-ols (9) indicate that for XIV and XV the AB coupling constants should have the following approximate absolute magnitudes: $J_{A'B} = 3$, $J_{A'B'} = 6.5$, $J_{AB} = 9.5$, $J_{AB'} = 3.5$ c.p.s. Thus, the observed value for the sum of the coupling constants confirms that the reduction product is the endo–endo diol XV, for the expected sum in the case of the exo–exo diol, XIV, would be $|J_{A'B'} + J_{A'B}| \simeq 9.5$ c.p.s. Indeed, Musher (9) has observed a triplet signal for the endo >CHOH proton of the exo alcohol, isoborneol (XII) with $|J_{A'B'} + J_{A'B}| = 9.3$ c.p.s. These comparisons are approximate only because of (i) approximations inherent in the restricted first-order analysis, (ii) band broadening or splitting due to further, long-range spin couplings,[4] (iii) changes in the coupling constants of the bicyclo[2.2.1]heptan-2-ols engendered by the introduction of a second hydroxyl group at C.5. However, any inaccuracies arising from these factors are expected to be relatively small and unlikely to jeopardize the structural assignment.

We turn finally to the consideration of the reaction pathway for the formation of the exo–endo diacetate IX by the acid-catalyzed rearrangement of the diol VI. It has been found (8, 12) that similar rearrangement of the corresponding monohydric tertiary endo alcohol VII, or its exo epimer, gives the exo acetate X. It may readily be seen that two successive rearrangements of this type would necessarily lead to a product with the exo–endo stereochemistry, as observed:[5]



EXPERIMENTAL

Melting points were determined on a Fisher-Johns hot stage and are uncorrected. Solutions in organic solvents were dried with anhydrous sodium sulfate and evaporated on a rotary evaporator, unless otherwise stated.

2-exo-5-exo-Dimethylbicyclo[2.2.1]heptane-2,5-diol (VI)

Bicyclo[2.2.1]heptan-2,5-dione (6) (15.4 g, 0.124 mole) in anhydrous ether (50 ml) was added with mechanical stirring to a Grignard solution made from methyl iodide (88.7 g, 0.629 mole) and magnesium (15.1 g, 0.62 g atom) in anhydrous ether (500 ml). After it had been left to stand for 7 days, with intermittent stirring, the solution was poured into ice-water (310 ml) containing ammonium chloride (40 g). The aqueous solution was extracted four times with ether, and then subjected to continuous extraction for 2 days. Combination of the ethereal extracts, followed by drying and removal of the solvent gave a viscous yellow liquid (15. 8 g, 82%). This was dissolved in ether, washed with aqueous 10% sodium sulfite, dried, and freed of solvent to give a colorless, viscous liquid (15.0 g, 78%); λ_{max} (CCl_4):2.79, 5.72 (v.w.), 7.30, 8.95 μ; δ (CCl_4):1.28 (singlet), 1.95, 2.95 p.p.m.

Attempts to purify this compound by distillation and chromatography were unsuccessful.

[4]*Strong long-range spin coupling involving the C.7 protons of norbornane derivatives of the type reported recently (13) cannot be operative here since the signal due to these protons is unsplit.*

[5]*It may be noted that this result is independent of the stereochemistry assigned to VI.*

2-exo-5-endo-Diacetoxy-1,4-dimethylbicyclo[2.2.1]heptane (IX)

Compound VI (10.0 g, 64 mmoles) was dissolved in glacial acetic acid (80 ml), and sulfuric acid (75%; 3 ml) was added. The solution was heated at 70–80° for 2 h on the steam bath and when cool, poured into ice-water (150 ml). A solution of sodium hydroxide (43 g) in water (150 ml) was added with rapid stirring to the reaction solution immersed in an ice bath, and neutralization was completed with solid sodium bicarbonate. The aqueous solution was thoroughly extracted with ether and the combined ethereal extracts were washed with saturated brine and dried. Removal of the solvent was effected by distillation through a column of glass helices, and the residue was distilled through a spinning band column to give IX as a colorless liquid (12.15 g, 50%), b.p. 74–75° (0.2 mm), $n_D^{25.6}$ 1.4560; λ_{max} (CCl_4):5.74, 8.1 μ; δ (CCl_4):0.95, 1.09, 1.97, 4.64 (multiplet) p.p.m.

Anal. Calcd. for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39. Found: C, 64.97; H, 8.39.

1,4-Dimethylbicyclo[2.2.1]heptane-2-exo-5-endo-diol (XI)

To a solution of IX (9.8 g, 41 mmoles) in anhydrous methanol (50 ml) was added sodium (200 mg) and the resulting solution was slowly distilled to dryness through a column of glass helices. The last traces of solvent were removed on the rotary evaporator and ether (200 ml) was added. The ethereal solution was washed with water (2 × 10 ml) and dried, and the solvent was distilled as above to give the crude diol as a gum (5.88 g). Crystallization from ether/hexane gave crystalline material (5.0 g, 86%) in crops with melting point ranging from 85–95° to 93–95°. Six further crystallizations gave an analytical sample, m.p. 98.5–99.5°; λ_{max} (CCl_4):2.78, 9.0, 9.72, 11.06 μ; δ ($CDCl_3$):1.05, 1.09, 1.70, 3.58 (multiplet), 3.83 (multiplet) p.p.m.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.32. Found: C, 69.24; H, 10.34.

1,4-Dimethylbicyclo[2.2.1]heptane-2,5-dione (V) from XI

A solution of the diol XI (m.p. 93–97°; 200 mg, 1.2 mmoles) in acetone (20 ml) was cooled in an ice bath. A solution of chromium trioxide (760 mg) in sulfuric acid (96%; 0.63 ml) and water (2.2 ml) was added dropwise with rapid stirring until a yellow-brown color persisted. The solution was stirred for a further 3 h, and ether was added and the solution was dried over anhydrous sodium carbonate. Removal of the solvent, followed by one sublimation and crystallization from ether–hexane gave the diketone as long needles (120 mg, 60%), m.p. 127.5–128°; λ_{max} (CCl_4):5.70, 7.10, 7.22, 8.85, 9.35 μ; λ_{max} (MeOH):287.5 mμ (ϵ 47); δ (CCl_4):1.22, 1.79, 2.09 p.p.m.

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.02; H, 7.95. Found: C, 70.94; H, 7.99.

The diketone was recovered unchanged when treated for 24 h with aqueous ethanolic potassium hydroxide.

A *bis-2,4-dinitrophenylhydrazone*, m.p. 280–282°, was prepared in dioxane/aqueous hydrochloric acid, and recrystallized three times from dioxane/ethanol.

Anal. Calcd. for $C_{21}H_{20}N_8O_8$: C, 49.21; H, 3.91; N, 21.87. Found: C, 48.88; H, 4.11; N, 22.09.

1,4-Dimethylbicyclo[2.2.1]heptane-2-endo-5-endo-diol (XV)

A solution of the dione V (110 mg, 0.72 mmole) in anhydrous ether (10 ml) was added dropwise to a solution of lithium aluminium hydride (50 mg) in ether (5 ml) and the solution was stirred overnight under a flow of nitrogen. Water (1 ml) was added and the mixture was vigorously shaken, dried, and filtered. Removal of the solvent gave the crude diol (108 mg) from which pure material (22 mg, 20%), m.p. 124.5–125°, was obtained after two crystallizations from ether/hexane; λ_{max} (CH_2Cl_2):2.80, 7.18, 8.20, 11.50 μ; δ ($CDCl_3$):1.01, 1.25, 1.68 (doublet, 'J' = 7 c.p.s.), 2.55, 3.89 (triplet, 'J' = 7 c.p.s.) p.p.m.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.32. Found: C, 68.98; H, 10.31.

1,4-Dimethylbicyclo[2.2.1]heptane-2,5-dione (V) from XV

To a solution of the diol XV (7.5 mg) in acetone (2 ml) were added, with rapid stirring, two drops of a solution of chromium trioxide (260 mg) in water (2.2 ml) and sulfuric acid (96%; 0.63 ml). After 5 min, ether was added and the solution was dried over sodium carbonate. Removal of the solvent gave a white solid (4.5 mg), m.p. 120–122°, which, on crystallization from ether/hexane, gave material (2 mg), m.p. 127–128°, whose infrared spectrum was identical with that of V prepared from XI. A mixed melting point with a sample of V prepared from XI showed no depression.

NUMERICAL SOLUTIONS OF SMOLUCHOWSKI'S EQUATIONS FOR THE COAGULATION OF UNCHARGED AEROSOLS

J. M. BEECKMANS

Department of Physiological Hygiene, School of Hygiene, University of Toronto, Toronto, Ontario

Received March 3, 1965

ABSTRACT

Smoluchowski's equations for the coagulation of uncharged aerosol particles were programmed for solution by electronic computer. Terms representing differential sedimentation, turbulence, and mean aggregate density in solid aerosols were included. The effect of heterogeneity in the particle-size distribution of the aerosols on their rate of coagulation was illustrated by means of a slip-corrected coagulation factor F_c, which assumes a value of unity in all non-turbulent homogeneous aerosols. Curves of F_c vs. σ_g, the geometrical standard deviation, were calculated for aerosols of various mean particle-size. The effects due to turbulence, and to differential sedimentation, were illustrated in a similar manner. It was also found that the process of coagulation gives rise to a degree of dispersion which is independent of the original dispersion parameter, and depends only slightly on the mean particle-size of the aerosol over a wide range of particle-sizes. In the particle-size range in which differential sedimentation is inappreciable, the relatively constant value of the dispersion parameter implies that heterogeneous aerosols must obey the simplified integrated form of Smoluchowski's equation, which is applicable to homogeneous aerosols. The coagulation constant exceeds that predicted by the simple theory by about 10% for liquid aerosols of 0.1 μ or less.

INTRODUCTION

The theory of coagulation on uncharged and monodispersed colloid particles developed by Smoluchowski (1) is applicable to aerosols when the appropriate correction is made for slip. It has been reasonably well substantiated by experiment when the effects due to wall losses, turbulence, and differential sedimentation are taken into account (2, 3). Essentially, the theory consists of a basic differential equation concerning the rate of coagulation between two different species of particles (i.e., of differing particle-sizes), which must then be integrated over all pairs of species present in the aerosol. The solution consists of a family of particle-size distribution curves, each corresponding to a certain time following the start of coagulation. If the assumption is made that the aerosol is intially homogeneous, and remains homogeneous during the course of coagulation, then a simple analytical solution to the problem is obtained. If this assumption is not made, then numerical solutions must be sought. The success of the simplified treatment, particularly with homogeneous liquid aerosols (2), is taken as evidence that the basic differential equation is essentially correct. Observed deviations from this simple theory are ascribed to three causes, viz., electrical charges, the non-spherical nature of solid aerosol particles, particularly where there exists a tendency to form chain-like agglomerates, and heterogeneity in the particle-size distribution. In this paper the latter factor will be investigated by means of numerical solutions of the basic differential equation, which are compared with the analytical solutions applicable to homogeneous aerosols. In addition, terms representing turbulence and differential sedimentation, which cannot be taken into account in the simple treatment, have been included.

METHOD OF CALCULATION

A. Basic Equations

The derivation of Smoluchowski's equations will not be given here, since this subject has been given adequate treatment in numerous books and papers. (See, e.g., Whytlaw-Gray and Patterson (4) and Green and Lane (5) for expositions in English.) The differential

equation for collisions between particles of species i and particles of species j, including turbulence and differential sedimentation terms, is as follows:

$$[1] \quad -\left(\frac{dn_i}{dt}\right)_j = -\left(\frac{dn_j}{dt}\right)_i = \{K_D\left(\frac{C_i}{d_i} + \frac{C_j}{d_j}\right)(d_i + d_j) + K_c(d_i^2 C_i - d_j^2 C_j)(d_i + d_j)^2 + K_T(d_i + d_j)^3\} n_i n_j \quad (d_i \geqslant d_j).$$

n_i is the concentration of particle species i, C_i the Cunningham slip correction factor for particle species i (see eq. [5]), and d_i is the diameter of particle species i.

The values of the constants are as follows:

$$[2] \quad K_D = \frac{kT}{3\mu} \quad \text{(diffusional collision constant)},$$

μ being the viscosity of the medium.

At 25 °C in air, $K_D = 7.38 \times 10^{-11}$ cm^3 s^{-1}.

$$[3] \quad K_c = \frac{2\pi\rho g}{9\mu} \quad \text{(differential sedimentation collision constant)}.$$

At 25 °C in air, for unit density particles, $K_c = 3.7 \times 10^6$ s^{-1} cm^{-1}.

$$[4] \quad K_T = \frac{4}{3}\left(\frac{\overline{du}}{dz}\right) \quad \text{(turbulence collision constant)}.$$

$\frac{\overline{du}}{dz}$ is the mean rate of shear due to turbulence. The Cunningham slip correction factor was calculated by the equation

$$[5] \quad C_i = 1 + (10^{-4}(0.1664 + 0.053 \exp(-8.325 \times 10^4 d_i))/d_i).$$

This particular form of Cunningham's equation is due to Davies (6).

B. Numerical Integration

Goldman (7) published the complete integro-differential equation based on eq. [1], without the differential sedimentation and turbulence terms. A similar equation was published by Zebel (8), who presented a solution derived on an electronic computer. He did not, however, systematically investigate the effects of heterogeneity, or of any other factor.

In the calculations, 80 particle-sizes were represented in the computer. The particle-size of the smallest particle class, and its density, served as input parameters. The masses of all other particle species were integral multiples of that of the first particle species. The range of masses between the smallest and the largest was 1.58×10^8. Intermediate particle masses were spaced at approximately equal logarithmic intervals. Their diameters were calculated by an equation proposed by Beeckmans (9) for aerosol agglomerates.

$$[6] \quad d_i = d_1(m_i/m_1)^\psi$$

The value of 0.333 for ψ gives the correct diameter for coalescing liquid droplets. Solid particle agglomerates generally have a value between 0.33 and 0.55, if chain formation is not too pronounced.

The procedure followed, after reading in the initial boundary conditions, and the initial particle-size distribution, was to compute values of dn_i/dt for all i by direct summation.

$$[7] \quad \frac{dn_i}{dt} = \sum_{j=1}^{i}\left(\frac{dn_i}{dt}\right)_j$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(The values for $(dn_i/dt)_i$ were multiplied by one-half to correct for duplication implied in the above counting scheme.)

Each collision between species i and species j produced an increase in the concentration of particles of species k, the value of k being determined by the equations

$$\begin{cases} m_k \leqslant m_i + m_j \\ m_{k+1} > m_i + m_j. \end{cases} \quad [8]$$

During the summation [7], the computer made additions to the values of the appropriate (dn_k/dt)'s corresponding to each combination of i and j.

$$\left(\frac{dn_k}{dt}\right)_{i,j} = -\left(\frac{dn_i}{dt}\right)_j (1 - Q_{i,j}) \quad [9]$$

$$\left(\frac{dn_{k+1}}{dt}\right)_{i,j} = -Q_{i,j}\left(\frac{dn_i}{dt}\right)_j \quad [10]$$

$$Q_{i,j} = \frac{m_i + m_j - m_k}{m_{k+1} - m_k} \quad [11]$$

The factor $Q_{i,j}$ partitions the particles produced by collisions between particles i and j in such a way as to conserve mass on averaging over many collisions. If $m_k = m_i + m_j$, then $Q_{i,j} = 0$.

All terms of the type of eqs. [9], [10], and [7] were summed to give the total net rate of particle diminution in the aerosol.

$$\frac{dn}{dt} = \sum_{i=1}^{80} \frac{dn_i}{dt} \quad [12]$$

The fractional decrease in total particle number per cycle was held constant, equal to a parameter β.

Thus

$$\frac{dn}{dt}\frac{t_c}{n} = \beta, \quad [13]$$

where

$$n = \sum_{i=1}^{80} n_i$$

and t_c is the cycle time, or the time required to reduce the particle concentration by a fraction β. Equation [13] allows its value to be calculated for a given β. The particle-size distribution was then adjusted as follows in each class.

$$n_i \rightarrow n_i + \left(\frac{dn_i}{dt}\right)t_c \quad [14]$$

Finally, the values of n_i in classes 71–80 were set equal to zero at each cycle. This was necessary to avoid collisions of the type which would produce new particles outside the size range under consideration. The computer reported on the percent of the total mass originally present in the system and removed in this manner. A number of parameters derivable from the altered particle-size distribution were calculated at certain selected cycles. They included the arithmetic and geometrical mean diameters, and the geometrical standard deviation. The following parameters were also calculated:

(i) Coagulation constant. (Calculated with n at its mid-cycle value.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[15] $$K = \left(\frac{dn}{dt}\right) \Big/ n^2(1 - \beta/2)^2$$

(ii) Coagulation factor.

[16] $$F = K/4K_D$$

(iii) Slip-corrected coagulation factor.

[17] $$F_c = \frac{F}{C_g} = \frac{K}{4K_D C_g}$$

C_g is the Cunningham slip correction factor for a particle with diameter equal to d_g, the geometrical mean diameter, and was calculated by means of eq. [5]. It may be noted that F_c equals unity for a homogeneous aerosol in which turbulence and differential sedimentation contribute to a negligible degree to the total rate of coagulation. Thus, in aerosols of relatively small particle-size, F_c is essentially a measure of the effects of heterogeneity on the coagulation constant.

RESULTS

Figure 1 shows the effect of heterogeneity, expressed as σ_g, the geometrical mean diameter, on the corrected coagulation factor F_c, for various values of d_g. K_T equalled zero for all curves. The parameter β equalled 0.001, and only one cycle was completed for each value of σ_g, and d_g, since temporal effects were not under consideration. Figure 2 shows the same data plotted as F vs. σ_g, and Fig. 3 shows F_c vs. σ_g in the presence of turbulence ($K_T = 500\ s^{-1}$ in Fig. 3, and $\psi = 0.333$ for all figures).

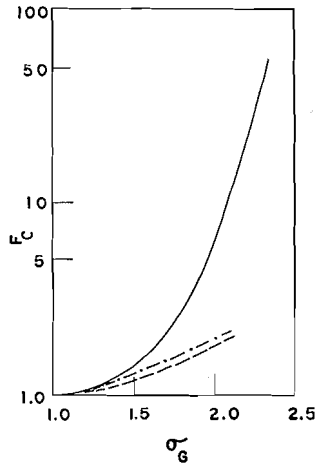

FIG. 1. Corrected coagulation factor F_c vs. σ_g; (—) $d_g = 1\ \mu$, (- -) $d_g = 0.1\ \mu$, (···) $d_g = 0.01\ \mu$.

In runs involving the effect of time on the particle-size distribution, it was first necessary to select a value for β, the fractional particle concentration decrease per cycle. Ideally this number should be as close to zero as possible. On the other hand, since the smaller, the value of β, the greater the amount of time required to compute the course of a given degree of coagulation, practical considerations made it desirable to use the largest value of β giving substantially correct results. In order to test the effect of variations in β, the course of coagulation was computed with three successive values of β and the same starting

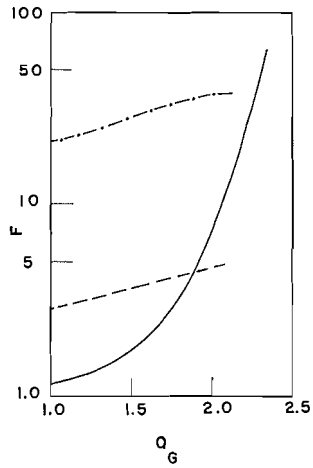

FIG. 2. Coagulation factor F vs. σ_g; (—) $d_g = 1\,\mu$, (- -) $d_g = 0.1\,\mu$, (···) $d_g = 0.01\,\mu$.

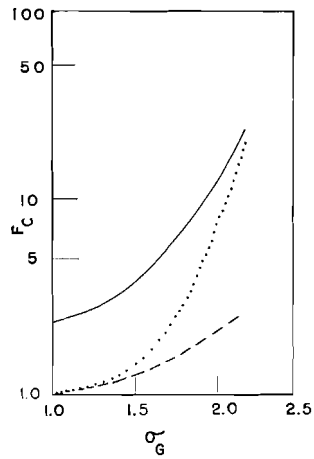

FIG. 3. Corrected coagulation factor F_c vs. σ_g for a turbulent aerosol ($K_T = 500\ s^{-1}$); (—) $d_g = 1\,\mu$, (- -) $d_g = 0.1\,\mu$, (··) $d_g = 1\,\mu$ and $K_T = 0$. (Same curve as in Fig. 1.)

conditions. The results are given in Table I, and indicate that values of β in the range 0–0.1 give substantially similar results. Consequently, a value of 0.05 was used in all subsequent runs involving time.

A preliminary inspection of the particle-size curves of coagulating aerosols showed that they were approximately logarithmically normal in shape, and, for this reason, the geometric-mean parameters have been preferred for characterization purposes in this paper. It was also found that within relatively wide ranges of mean particle-sizes the geometrical standard deviation of the coagulating aerosol tended to assume a constant value. This is illustrated in Fig. 4, which shows the effect of time on σ_g in three aerosols, each with an initial geometrical mean diameter of 0.1 μ and with geometrical standard deviations of 1.0, 1.3, and 1.5, respectively. It is seen that all three aerosols eventually attain a value of approximately 1.35 for σ_g. The equilibrium values of σ_g for liquid non-turbulent, liquid turbulent, and solid non-turbulent aerosols of three particle-sizes are given in Table II.

DISCUSSION OF RESULTS

For a homogeneous aerosol, the simplified treatment predicts

$$K = \frac{4kTC_g}{3\mu} = 4K_D C_g. \qquad [18]$$

Since C_g increases with decreasing particle-size, K must also increase with decreasing particle-size, as must F, to which it is proportional. This is borne out in Fig. 2, where F is greater than unity, even in homogeneous aerosols. On the other hand, F_c equals unity for all particle-sizes in non-turbulent aerosols, since $F_c = F/C_g$ (Fig. 1). Values of F_c

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

exceeding unity in non-turbulent heterogeneous aerosols arise because the term proportional to K_D in eq. [1] is at a minimum for $d_i = d_j$, irrespective of the values of C_i and C_j, so that the sum of all such terms in a heterogeneous aerosol always exceeds the corresponding sum in the homogeneous case. In addition to this factor, if the mean particle-size of the aerosol is sufficiently large so that differential sedimentation effects come into play, this will also increase the value of F_c. These points are illustrated in Fig. 1. The curves for $d_g = 0.1\ \mu$ and $d_g = 0.01\ \mu$ are very similar because at this particle-size the effects of differential sedimentation are negligible. A curve for $d_g = 1\ \mu$, and $K_c = 0$, and not shown in the figure, was also found to be very similar. On the other hand, the curve for $d_g = 1\ \mu$, with K_c having its proper value, diverges sharply, due to differential sedimentation effects.

Figure 3 shows that even strong turbulence has little influence on F_c for aerosols of 0.1 μ or less. On the other hand, aerosols of a particle-size of 1 μ or more, whether homogeneous or not, coagulate much more rapidly under turbulent conditions.

The relative constancy in σ_g attained in coagulating aerosols presumably derives from the fact that the natural tendency towards widening the distribution which arises through chance collisions of particles is countered by the greater collision rate between particles of differing sizes relative to the collision rate between particles of similar size. This would tend to make the aerosol more homogeneous, since particles differing greatly from the mean size would collide more rapidly than most. It may also be noted that the success of the simplified treatment in predicting the course of coagulation follows as a consequence of the temporal constancy in σ_g. By reference to Fig. 1, it is seen that the value of F_c for an aerosol 0.1 μ or 0.01 μ in mean particle-size, having a value of 1.35 for σ_g, is approximately 1.1. This implies that the rate of coagulation of a heterogeneous, aged aerosol in this particle-size range is approximately 10% greater than the rate predicted by the simplified theory for a homogeneous aerosol of the same mean particle-size. Since this factor is constant, the form of the relation between time and the particle concentration is the same in both cases. Unfortunately, accurate measurements of the particle-size distribution of coagulated aerosols do not appear to have been made, so that the calculated pseudo-equilibrium values of σ_g cannot be directly confirmed.

THE THERMODYNAMIC PROPERTIES AND PHASE DIAGRAM OF THE GOLD–CADMIUM SYSTEM BY THE ISOPIESTIC METHOD[1]

L. J. BARTHA[2] AND W. A. ALEXANDER
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received September 2, 1964

ABSTRACT

Activities of cadmium in gold alloys with up to 50 atom % Cd have been determined by an isopiestic method. The partial molar free energy, entropy, and heat of solution in the alpha and beta phases are calculated between 500 and 600 °C. The phase boundaries have been observed between 16 and 60 atom % above 400 °C. The boundaries of the two-phase regions $\alpha_2 + \beta$ and $\beta + \delta'$ are found at somewhat different concentrations than before, but the two-phase region $\alpha + \alpha_2$ was not observed.

INTRODUCTION

Measurements of the vapor pressure of the volatile element in alloys having only one volatile component may be used to calculate the thermodynamic properties of these alloys using well-known relations. These properties furnish a detailed picture of the alloy's energic quantities. The method is restricted by the requirement that only one component be significantly volatile, but several procedures have been developed for this purpose (8, 16, 17). Advantages are that the vapor pressure is very sensitive to changes in temperature or composition and that a clear interpretation of the results is possible.

A limited amount of information has been published on the thermochemical data for the gold–cadmium system. The first investigation of this system was by Ölander (1) using electromotive force measurements of a suitable cell. He calculated the heat effects at only a few phase transitions. Schneider and Schmid (2) made calculations from vapor pressure measurements over four liquid alloys above 45 atom % cadmium. These data are summarized and discussed by Kubaschewski and Catterall (3). Calorimetric measurements of heats of formation have been made for a number of alloys at 450 °C by Kleppa (10). Vapor pressure measurements of this system by Herasymenko are referred to in the literature (9) and are available as a report of limited circulation. In this report indications of ordering at a number of compositions are stressed for both the gold–cadmium and the silver–cadmium systems. However, Kleppa's results for gold–cadmium (10) and Filby and Pratt's work on silver–cadmium (11) did not show any such ordering, so its presence in the gold–cadmium system is questionable.

There is also disagreement in the literature on the gold–cadmium phase diagram, especially on the low cadmium side. Ölander's electromotive force measurements (1) indicate an alpha phase up to about 34 atom % Cd, and a two-phase region from 34 to 42% at temperatures of 500–600 °C. Below 420 °C an alpha prime phase was shown between about 18 and 28% Cd. Owen *et al.* (4, 5) found four alpha phases and suggested that the beta phase begins at 50% Cd. Hansen's more recent summary (6) does not show an alpha three phase. This phase was not found in a reinvestigation of the whole system by Rivlin *et al.* (7). On the above information then the phases present at 500–600 °C up to 55 atom % Cd should be: alpha, alpha two and beta, and two two-phase regions between them.

[2]*National Research Council Postdoctorate Fellow, 1962–1964. Present address: Kossuth Lajos Tudományegyetem, Fizikai-kémiai Intézete, Debrecen 10, Hungary.*

From both these points of view then a further investigation of this system by the vapor pressure method appeared desirable.

APPARATUS, MATERIALS, AND EXPERIMENTAL PROCEDURE

The apparatus was essentially the same as that used by Herasymenko (8) with some minor modifications as described in ref. 12. In the present work the silica tube was horizontally disposed so that the liquid cadmium distilled to the temperature minimum, which determines its pressure in the system. The equilibrium concentration of cadmium in its gold alloys is determined by this cadmium pressure and by the temperature of the alloy. The gold absorbs cadmium until the cadmium vapor pressure of the alloy is the same as that of the pure cadmium at the temperature minimum. The data for each experiment or vapor pressure are plotted as alloy temperature versus alloy composition. Isobaric curves of alloy temperature versus composition obtained in this manner will show horizontal sections in the two-phase regions of the phase diagram.

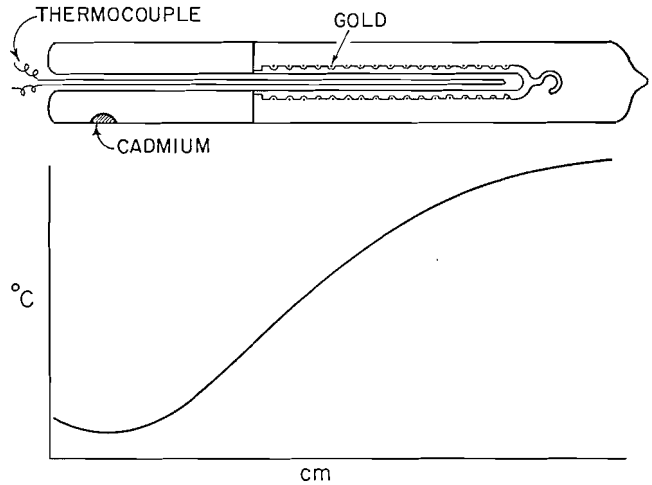

FIG. 1. Quartz vessel and temperature distribution.

The silica vessel used is shown in Fig. 1 with a schematic temperature gradient. The furnace heated by three separate windings was large enough to contain two reaction vessels with different cadmium pressures. The temperature was controlled by electronic instruments actuated by platinum resistance elements placed close to the heating windings. The desired temperature gradient was achieved by placing variable resistances in parallel with portions of the heating elements. The temperatures were measured daily by a platinum–rhodium thermocouple calibrated before and after each experiment.

Gold wire was drawn from doubly electrolyzed gold crystals cast into a bar. The cadmium was used as filings from a high purity bar with any iron particles removed by a strong magnet. Analyses of these materials showed:

Gold.—Impurities close to those in commerical samples of spectroscopically pure material. Au $\geqslant$ 99.999%.

Cadmium.—Lead, copper, and silver— one to two tenths p.p.m. Other elements not detected and therefore less than this level. Cd $\geqslant$ 99.9999%.

The vessels were charged with accurately weighed gold wires 0.254 mm diameter and 4.2 cm long and about twice the calculated amount of cadmium. Degassing was effected by evacuating to about 2×10^{-4} mm Hg while the portion of the vessel containing the gold wires was heated to about 500 °C and the remainder gently warmed. Then the vessel was sealed off under vacuum. The tubes were charged in the furnace near the required temperature and final temperature adjustments made during the next 2 or 3 days. At temperatures of this work annealing times of 3 weeks or more were employed to ensure attainment of equilibrium, although calculations from the available diffusion data (14) would indicate that a considerably shorter time should be sufficient. The vessels were air cooled to about 600 °C and then quenched in oil. Oil quenching much above 600 °C produced a light deposit, probably of carbon or tar, inside the quartz tube. The composition was determined by reweighing the wires or by chemical analysis in the few cases where the ends were fused after alloying.

The cadmium vapor pressure equation used is that of Maier (15):

$$\log p = 12.2870 - 5819.4T^{-1} - 1.2572 \log T.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

This is the equation quoted in recent summaries of vapor pressure data and is the result of a critical survey and recalculation of earlier data (cf. ref. 11).

Besides the errors in the original determination of the vapor pressure of cadmium, the following errors apply. The error in weight of the gold wires was $\pm 2\ \mu g$ in a total weight of about 50 mg. The potential of the thermocouple was read to the nearest $\frac{1}{2}\ \mu V$, or 0.05 deg. The distribution of the sample wires in the grooves along the carrier tube was determined to about ± 0.02 mm by a travelling microscope. The location of the thermocouple was measured by a steel meter rule to ± 0.25 mm, which at the maximum temperature gradient was equivalent to about ± 0.3 deg. The day-to-day error or variation in temperature of the furnace was about ± 1 deg at the maximum temperatures and about ± 0.5 deg at the minimum temperatures. This amounts to about $\pm 1.5\%$ error in the cadmium vapor pressure. The radial temperature gradient in the furnace tube was examined. It is believed that this is insignificant under experimental conditions.

EXPERIMENTAL RESULTS AND DISCUSSION

The internal consistency and the reproducibility of the data indicate that final equilibrium was attained. The consistency of the data is shown by the smooth curve obtained when the logarithm of the vapor pressure is plotted against temperature for a given alloy composition, each point being determined from a separate experiment. As should follow from the Clausius–Clapeyron equation, the curve obtained by plotting the logarithm of the vapor pressure of an alloy versus temperature is approximately a straight line. The slope and slight curvature of these curves plotted for a few representative alloy compositions were very close to those of the curve for pure cadmium. The vapor pressures found by Schneider and Schmid (2) for liquid alloys are considerably lower than we observed for the solid alloys. The reproducibility is indicated by the isobars of Fig. 3.

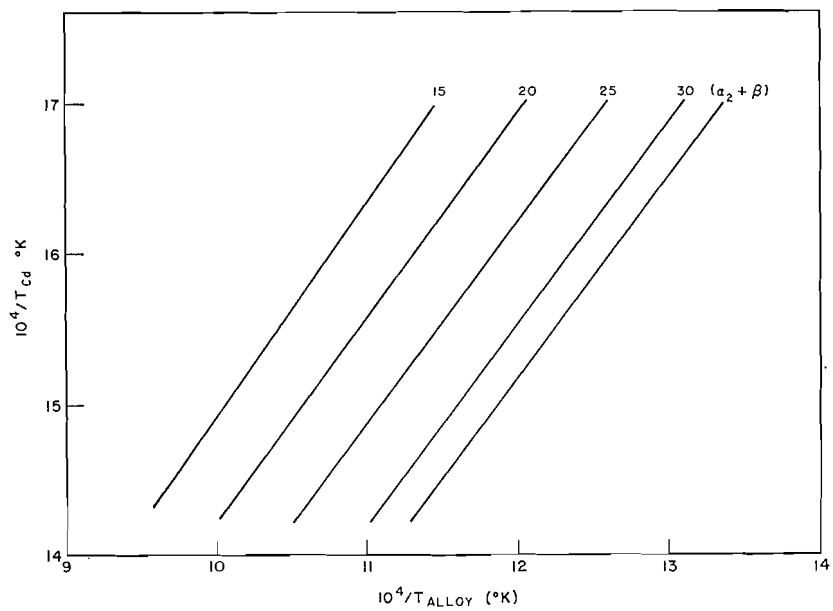

FIG. 2. Relationship between the reciprocal temperatures of the gold-cadmium alloys and of pure cadmium.

Further, two curves obtained at cadmium vapor pressures of 1.74 and 1.75 mm, only one of which is shown, lay close together and parallel over their whole course, indicating a high sensitivity for this method. The self-consistency of the data may also be checked by the method used by Birchenall and Cheng (13) with the following equation derived

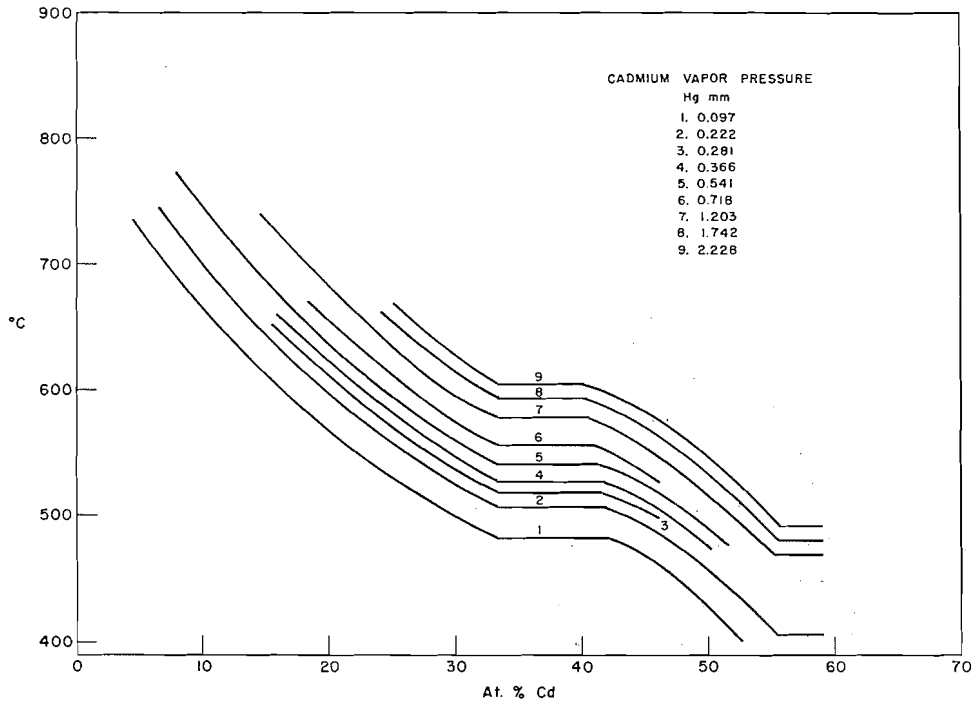

FIG. 3. Experimental isobars for the gold–cadmium alloys.

from the Clausius–Clapeyron relation, which will hold at equilibrium:

$$\frac{1}{T_0} = \frac{\Delta H_1}{\Delta H_0}\frac{1}{T_1} + (C_0 - C_1)\frac{R}{\Delta H_0},$$

where T_0 and T_1 are the absolute temperatures of the pure cadmium and of the alloy at equilibrium at a common pressure, ΔH_0 and ΔH_1 the respective heats of vaporization, C_0 and C_1 the integration constants, and R is the gas constant. The values $1/T_0$ and $1/T_1$ will be proportional if the heats of vaporization are independent of temperature or if their temperature coefficients are the same. In Fig. 2 a few of these curves are shown for some concentrations between 15 and 42 atom % cadmium. These are straight lines within experimental error.

The experimentally determined isobars obtained by plotting temperature against atomic percent showed two sections parallel to the concentration axis corresponding to the two-phase regions $\alpha_2 + \beta$ and $\beta + \delta'$, but no indication of the two-phase region $\alpha + \alpha_2$. Herasymenko (9) also found no indication of this region. The experimental results are shown in Fig. 3 where some isobars lying close together are omitted. X-ray examination of suitable samples showed that the hexagonal alpha two phase was present in these alloys. It is possible that the two-phase region $\alpha + \alpha_2$ is much narrower than shown on current diagrams in which case it would not be evident on the isobars. The phase boundaries from 0 to 60 atom % cadmium based on our results and on those of other investigators are shown in Fig. 4.

From the isobars of composition and temperature (Fig. 3) the activities of cadmium at each integral alloy composition were calculated over the temperature range using the

equation given above for the relation of cadmium vapor pressure to temperature. To eliminate errors of estimation, the results were tabulated and the equation of the best straight line through the points for each percent cadmium was determined by a least squares machine computation. The results are shown in Fig. 5. From a larger scale plot of these lines the values for log a were read off at 500, 550, and 600 °C, and the partial molar free energy $\Delta\bar{G}$ was calculated from the equation

$$\Delta\bar{G} = RT \ln a.$$

The free energy of the reference state G_0 is taken as the value for pure liquid cadmium at the temperatures of the experiments. From the same values of log a the partial molar heat of formation and partial molar entropy were calculated using the following relations:

$$\Delta\bar{H} = -RT^2 \, \mathrm{d} \ln a / \mathrm{d}T,$$

$$\Delta\bar{S} = -R(T \, \mathrm{d} \ln a / \mathrm{d}T + \ln a).$$

It is important to note that small experimental errors in the activity values are greatly magnified in the values of $\Delta\bar{H}$ and $\Delta\bar{S}$. The above-mentioned least squares calculation to obtain the best curve of log a vs. temperature was undertaken to minimize this error. Calculations have been made by standard methods (18) of the error in $\Delta\bar{G}$, $\Delta\bar{H}$, and $\Delta\bar{S}$ caused by the various experimental errors mentioned above. The errors in the calculated quantities when the relatively large day-to-day furnace temperature variation is included as an error are considerably greater than the observed scatter of the experimental points. Since these variations are probably cyclic in nature with a period which is relatively short compared with the diffusion time of cadmium through the gold wire, it is apparently safe to neglect them. The errors in the calculated quantities shown in Table I were estimated on this basis and are close to the scatter of the experimental points. The maximum values of the various experimental errors were used in this calculation, while the minima would give about one-half these errors. The data of Table I are plotted in Fig. 6. The gaps in the curves are due to the two-phase region from 34 to 42 atom % cadmium. An inflection in the $\Delta\bar{S}$ curve which is still present at 28–30 atom % cadmium might be caused by an ordering of the atoms related to the alpha two phase formation mentioned above. As would be anticipated, the $\Delta\bar{S}$ curve also shows a sharp minimum at about 47 atom % cadmium which is undoubtedly due to the superlattice formation in the Cd–Au beta phase (19). Our values of $\Delta\bar{S}$ agree reasonably with those of Herasymenko and of Ölander (9) for this phase. Otherwise, all the curves show a smooth variation with composition, in some contradiction to the results of Herasymenko (9) for the partial heat of formation and for the partial entropy. The integral heats of formation appeared to involve a large extrapolation to low cadmium contents and therefore have not been estimated.

Activity isotherms of these alloys are shown in Fig. 7 for 500 and 600 °C compared with the ideal isotherm. Our results depart strongly from the ideal in the direction of lower activities. However, the curves show a pronounced swing towards the ideal curve at 45–50 atom % cadmium.

Comparison with the vapor pressures found by Herasymenko (9) shows our data to be consistently higher by some 25–35%. Our partial free energy values are about 10% lower than those of Herasymenko. The $\Delta\bar{H}$ values found by Herasymenko and those calculated from Ölander's data (9) are both approximately 0 to 15% lower than those found here. Using the method suggested by Lumsden (21), we have estimated the partial heats of formation from 0–50 atom % Cd from the integral calormetric data of Kleppa (10). These

49	4 594	8 800	−4.75
50	4 284	6 460	−2.64

estimated values show a considerably smaller decrease with increasing cadmium content than our results. They are all less than our data, but at the point of nearest approach (32 atom % Cd) Kleppa's value is only about 1.2 kcal lower. Our $\Delta\bar{S}$ values for the alpha phase are generally somewhat lower than those of both Ölander and Herasymenko (9). These differences are nearly all greater than the experimental errors estimated in Table I.

ADDENDUM: Since the above work was completed and prepared for publication, a paper by Filby and Pratt (20) has appeared in which the vapor pressures of solid Au–Cd alloys from 8.4–25.1 atom % Cd only are measured by the dew-point method at temperatures largely coinciding with those reported here. Seven liquid alloys from 11.1–31.8 atom % Cd were also measured at higher temperatures. The ΔH values of Filby and Pratt show a much greater scatter and a different variation with increasing Cd content than those reported here, but they are approximately equal at about 15 atom % Cd. The $\Delta\bar{S}$ values also show a large scatter in contrast to our data, and are notably more positive. However, Filby and Pratt do not definitely suggest that these variations are associated with ordering.

THE H_A ACIDITY FUNCTION AND THE MECHANISM OF AMIDE HYDROLYSIS IN HYDROCHLORIC ACID

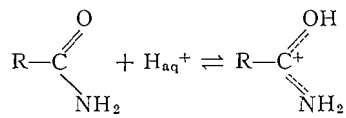
KEITH YATES AND J. C. RIORDAN
Department of Chemistry, University of Toronto, Toronto, Ontario
Received March 16, 1965

ABSTRACT

Values of the H_A acidity function have been determined for 0–35% hydrochloric acid using a set of amide indicators. The indicator pK values agree with those previously obtained in sulfuric acid. The H_A scale decreases less steeply than H_0 in the high concentration region, but the difference between the two functions is less marked than in sulfuric acid. The reasons for this are discussed. The values of H_A have been combined with available rate and water activity data to obtain information about the mechanism of amide hydrolysis. Eleven sets of rate data, consisting of 64 rate constants obtained under a variety of experimental conditions, give similar hydration parameters for this reaction. The temperature dependence of hydration parameters is discussed.

INTRODUCTION

An acidity function based on the ionization of amide indicators has recently been determined (1) for aqueous sulfuric acids. This amide-based acidity scale is significantly different numerically from other well-known Hammett type acidity functions, and has been shown (2) to be generally applicable to equilibria of the type



It is defined in an analogous way to other acidity functions,

$$H_A = -\log a_{H^+} f_A / f_{AH^+} = pK_{AH^+} - \log [AH^+]/[A],$$

where A and AH^+ refer specifically to amides and their conjugate acids. An attempt was made (2) to use the H_A scale to explain the dependence of amide hydrolysis rates on the acidity and water activity of the reaction medium in terms of the hydration requirements of the transition state. We have now extended these investigations of the ionization behavior of amides to aqueous hydrochloric acids because in addition to providing useful acidity function data in another medium, there is available a greater amount of appropriate kinetic data in this acid. This has been used to develop rate–acidity relationships for a wider range of amide hydrolysis reactions and provide more general information about the reaction mechanism.

EXPERIMENTAL

Reagents

The indicators used were 2-nitroaniline, 2-pyrrolecarboxamide, and 4-methoxy-, 3,4,5-trimethoxy-, 3-nitro,3,5-dinitro-4-methyl-, and 2,3,6-trichloro-benzamides. These were obtained and purified as described previously (1). Hydrochloric acid solutions from 0–35% by weight were prepared by diluting Fisher reagent grade concentrated acid (36.5% min.) and concentrations determined by titrating weighed samples with standard base.

Indicator Measurements

Solutions of indicators were prepared and their indicator ratios ($[AH^+]/[A] = I$) were determined spectrophotometrically as described previously (2) using a Unicam SP500 instrument thermostatted at 25 ± 0.1 °C. The spectral data were treated essentially as described previously (2) to obtain a set of indicator pK values and from these and the log I values a final set of H_A values was calculated. As before,

only log I values in the range -1.0 to $+1.0$ were used in calculating pK and acidity function values. It was necessary to use the method of Arnett and Wu (3) to obtain ϵ_{AH^+}, the conjugate acid extinction coefficient, and hence pK, for the last indicator, 2,3,6-trichlorobenzamide.*

Treatment of Kinetic Data

Data for the rates of hydrolysis of amides were taken directly from the literature in most cases. We are also grateful to Professor J. T. Edward for supplying us with some unpublished data. Water activity data at 25 °C was taken from Randall and Young (4). Data were used only if the rates had been measured in at least three different acid concentrations, and only if there was a significant change in the measured water activity over the acid range studied. All data were subjected to the standard least mean squares treatment to obtain slopes and correlation coefficients. In cases where a reaction rate had been followed in five or more different acid concentrations, the standard deviation of the slope (5) was also calculated.

RESULTS AND DISCUSSION

Indicator pK Values

The pK values of the six amide indicators were determined spectrophotometrically using changes in ultraviolet absorption on protonation, essentially as described previously (1). These were based on the reference indicator, 2-nitroaniline, whose pK is well established (6). The validity of the standard stepwise method of measuring pK values of very weak bases (6, 7) is shown by the parallelism of the indicator curves in Fig. 1. This indicates that the Hammett activity coefficient postulate (7) is being obeyed for each pair of indicators whose ionization ranges overlap, including 2-nitroaniline and the strongest amide base used, 2-pyrrolecarboxamide. As a check, the pK of the former was determined in the present study and a value of -0.31 was obtained, in excellent agreement with previously reported values in several different mineral acids (6). The pK values and absorption maxima are listed in Table I, along with the corresponding pK values obtained in sulfuric acid solutions. If these pK's are to be considered as valid thermodynamic dissociation constants† the value for each base should be independent of the acid used to establish it. That this is nearly the case can be seen by the agreement between the two sets of values. In view of the fact that the usual estimate of the uncertainty in any pK value measured in concentrated acids is about 0.05 to 0.1 pK unit, depending on the acid range used, the agreement is good.

The H_A Scale in Hydrochloric Acid

Using the above pK values and measured ionization ratios, values of the H_A function were obtained for 20 different hydrochloric acid concentrations in the range 0–35% by weight acid. Because of good ionization range overlap between the various indicators, the H_A value in any one acid solution is an average of values based on measurements involving several different indicators. Thus no part of the scale is based too heavily on any particular indicator. All the H_A values fall on a smooth curve when plotted against acid concentration. Values of H_A are listed in Table II at small concentration intervals, with the corresponding H_0 values of these solutions for comparison. It can be seen that up to about 15% acid there is essentially no difference between the two scales, but after this the H_A scale becomes significantly less negative than H_0 with increasing acid concentration, the difference amounting to 0.55 log units at the highest concentration studied. This means

*We are grateful to Miss Caroline Haynes for running duplicate spectrophotometric measurements on most of the compounds studied.

†*It has been pointed out by a referee that criteria such as indicator slope values, parallelism of successive indicator curves, and equality of pK values obtained in different acids are necessary but not in themselves* sufficient *conditions for the pK values to be accepted as thermodynamic dissociation constants. The question of the validity of pK values obtained by the standard stepwise method has been discussed in detail previously by ourselves (2) and other workers (7, 16). Since the data needed to answer this question are not experimentally accessible at present, we are forced to assume that in the absence of evidence to the contrary, amides do not show anomalous activity coefficient behavior in regions where their ionization ratios are too small to measure.*

that HCl can be up to three or four times less effective at transferring a proton to an amide than it is towards a corresponding aniline type base. This is qualitatively the same type of difference between the two acidity functions as found for sulfuric acid (1, 8), but is much less pronounced in hydrochloric acid. For example in 66.5% sulfuric acid, which has roughly the same H_A acidity as 35% hydrochloric acid, $(H_0 - H_A)$ has a value of −1.77 log units. The H_A scale in hydrochloric acid is also linear in acid concentration over a wide range, as found for sulfuric acid, $dH_A/d\%HCl$ being nearly constant at −0.1 from 8–35% HCl.

The possible reasons for the difference in the ability of an aqueous mineral acid to protonate primary amides and primary amines have been discussed previously (1) in terms of the hydration requirements of the various indicator species. It is again concluded that the changes in hydration requirements on protonating amides are greater than the corresponding changes on protonating anilines. Whether or not this is primarily due to differences in the hydration numbers of the conjugate acids is not known, but recent measurements of the activity coefficients of *neutral* amides in this laboratory (9) suggest strongly that contributions of the f_A and f_B terms to the overall behavior of H_A and H_0 respectively are significantly different and therefore cannot be ignored. It is clear that

differences in the behavior of the two types of base are not as marked in hydrochloric acid as they are in sulfuric acid. The only explanation we are able to offer is that the competition for "free" water is less severe in the former acid, resulting in smaller variations in individual activity coefficients. This may be because the indicator species are able to compete more effectively with chloride ion for available water than they are with bisulfate ion. This explanation receives some support from the fact that over a wide range, a_{H_2O} decreases less steeply with acid concentration in hydrochloric acid than it does in sulfuric acid (4). Wyatt has also concluded that chloride ion is considerably less hydrated than bisulfate (10). When one considers the water activity dependence of acidity functions it is a striking fact that H_0 in sulfuric, perchloric, hydrochloric, and nitric acids is a unique function of a_{H_2O} for these acids. This was first pointed out by Wyatt (10) and has recently been confirmed for the first two acids over a very wide concentration range to a remarkable degree of precision (11). However, plots of H_A versus a_{H_2O} for sulfuric and hydrochloric acids result in two separate curves. Although these curves are similar in appearance they diverge by up to 1.7 H_A units. We have also checked the water activity dependence of the H_R function using published data for sulfuric, perchloric, and nitric acids (12, 13) and find again that similar but clearly separate curves result for each acid. It is therefore apparent that although acidity functions in general are strongly dependent on a_{H_2O} of the medium, the unique character of the H_0–a_{H_2O} relationship for different acids must at least be partly fortuitous.

Dependence of Amide Hydrolysis Rates on Acidity and Water Activity

The following relationships between the rate constant and the acidity and water activity of the reaction medium have been derived previously (2) for amide hydrolysis in concentrated acid solutions. For the hydrolysis of weakly basic amides, which are present in

the reaction medium essentially as unprotonated amide, the relationship is

$$\log k_{obs} + H_A = r \log a_{H_2O} + \text{constant.} \quad [1]$$

For more basic amides, which are present as a mixture of the amide and its conjugate acid, the corresponding relationship is

$$\log k_{obs} - \log (h_A/K_{AH^+} + h_A) = r \log a_{H_2O} + \text{constant.} \quad [2]$$

In these equations k_{obs} is the observed pseudo first order rate constant, K_{AH^+} is the dissociation constant of protonated amide, and r is a hydration parameter which gives a direct measure of the number of water molecules needed to convert a protonated substrate molecule to transition state in the general hydrolysis scheme.

$$A(H_2O)_s + H(H_2O)_n^+ \overset{\text{fast}}{\rightleftharpoons} AH(H_2O)_p^+ + (s + n - p)H_2O$$

$$AH(H_2O)_p^+ + rH_2O \overset{\text{slow}}{\rightarrow} A^+(H_2O)_t \rightarrow \text{products.}$$

If the assumptions involved in the derivation of eqs. [1] and [2] are justified, plots of either ($\log k_{obs} + H_A$) or $\log k_{obs} - \log (h_A/K_{SH^+} + h_A)$ against $\log a_{H_2O}$ should be linear. We have tested this by using 64 reported rate constants obtained by measuring the rates of hydrolysis of six different amides in solutions ranging from 0.6 to 10.1 M hydrochloric acid. Good linear plots resulted in every case. The least squares slopes and correlation coefficients of the 11 linear relationships obtained are listed in Table III. The reactions

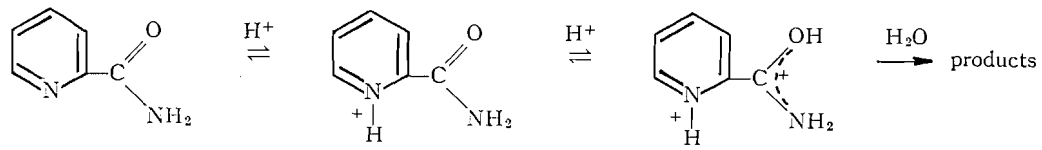
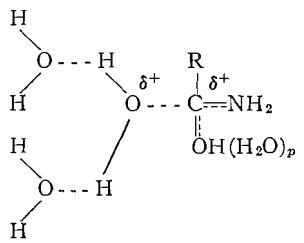
fall into two series. For simple amides like acetamide, propionamide, and benzamide, which are measurably protonated in the acids used for kinetic measurements, eq. [2] was used. For heterocyclic amides like picolinamide, eq. [1] for weakly basic substrates was used. Although the latter are in fact completely protonated in most of the acids used, it is presumably the ring nitrogen which is protonated first. However, the hydrolysis reaction requires preliminary protonation of the amide group as well.



Since it is unlikely that the second protonation equilibrium is established to any measurable extent even in moderately concentrated acids, these amides can be treated as weakly basic substrates. Hence eq. [1] is more appropriate, and in fact does give very good linear plots. It can be seen from Table III that the r-values are all similar in magnitude, particularly for the simple amides which have an average r-value of 2.91 ± 0.27. This would be expected if r is a useful indicator of mechanism since all these compounds presumably react in a very similar way. The above value compares very well with r-values of 2.6 and 2.7 obtained for the hydrolyses of benzamide and p-nitrobenzamide in sulfuric acid (2), and again suggests that in the rate-determining step one water molecule attacks the conjugate acid as a nucleophile and two more water molecules on the average assist by hydrogen bonding. The transition state for acid-catalyzed hydrolysis can thus be represented by the following structure:



The higher r-values obtained for the heterocyclic amides may reflect a somewhat different mechanism, but it seems more probable that this small difference is due to the fact that H_A is based on the ionization of uncharged amides whereas strictly speaking some acidity function of the $H+$ type should be used for the pyridine derivatives. In any event the range of hydration parameters for all 11 cases studied is fairly narrow (r = 3.1 ± mean deviation 0.3).

The theoretical relationships represented by eqs. [1] and [2] are formally equivalent to the empirical w-parameter treatment of Bunnett (14). However, the present treatment is a modification of the Bunnett approach in which the acidity of the reaction medium is based on a function strictly appropriate to the type of substrate whose reaction mechanism is being considered. This is preferable to the use of only one acidity function, namely H_0, for reactions of all types of basic substrates as is the case with the w-parameter treatment, particularly since it is now clear that many organic bases do not follow H_0 even approximately (1, 15, 16). It is noteworthy that the w-values for the reactions listed in Table III range from 1.18 to 4.94.

Effect of Temperature on Hydration Parameters

Ideally, in any treatment of rate dependence on acidity and water activity, it would be desirable to have all the data measured at the same temperature. However, such data are not always available in practice, since acidity functions and water activities are usually measured at 25 °C whereas rate constants are obtained at whatever temperature affords a conveniently measurable rate. For example, of the 158 sets of rate data in

moderately concentrated acids listed by Bunnett (14), only 78 had been studied at or near 25 °C and the rest at temperatures ranging from 0 to 131 °C. However, it can easily be shown that it is not a serious disadvantage if the kinetic data can not be obtained at 25 °C. If we let t_1 correspond to 25 °C and t_2 to some other temperature, then in the ideal case we have, for weakly basic substrates,

$$\log k_{t_1} + (H_A)_{t_1} = r \log (a_{H_2O})_{t_1} + C.$$

This can be combined with the Arrhenius relationship

$$\log k_{t_1} = \log k_{t_2} + E_a/2.3R(1/T_2 - 1/T_1)$$

to yield

$$\log k_{t_2} + (H_A)_{t_1} = r \log (a_{H_2O})_{t_1} + C^1$$

providing E_a is temperature independent over the range t_1–t_2. In the case of more strongly basic substrates the equation

$$\log k_{t_2} - \log [(h_A)_{t_1}/K_{AH^+} + (h_A)_{t_1}] = r \log (a_{H_2O})_{t_1} + C^1$$

can be arrived at in a similar way, providing K_{AH^+} for the substrate in question does not change appreciably over the range t_1–t_2. Thus, correlating kinetic data at one temperature with acidities and water activities obtained at a different temperature should just mean that each curve is shifted vertically by a constant amount $E_a/2.3R(1/T_2 - 1/T_1)$ and that the slope r is unaffected by the temperature at which the rates were measured. The data in Table III and the earlier observations of Bunnett appear to bear this out, since variations of hydration parameters with temperature appear to be small and random. However, it would be interesting to test this experimentally in a more systematic way, and we are at present investigating this.

Finally, in view of the fact that all available amide hydrolysis data, obtained under a wide variety of reaction conditions, yield good linear relationships when treated as described above, with approximately the same r-value in all cases, it is concluded that this treatment provides a useful criterion of reaction mechanism and can be extended to yield detailed information about transition states in other acid-catalyzed reactions.

ACKNOWLEDGMENTS

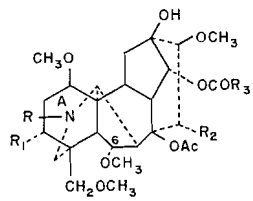
THE OXIDATION OF DITERPENOID ALKALOIDS[1]

O. ACHMATOWICZ, JR.,[2] Y. TSUDA,[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received March 12, 1965

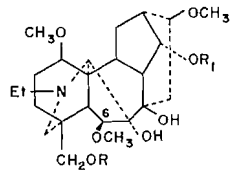
ABSTRACT

The highly oxygenated diterpenoid alkaloids possessing the same C—N ring structure fall into two groups: group A containing the aconitine-like bases in which the C-6 methoxyl is α-oriented, and group B containing the lycoctonine-like bases in which the C-6 methoxyl is β-oriented. The alkaloids of both groups are oxidized rapidly at room temperature by neutral potassium permanganate. The oxidation dealkylates the amino group in the bases of group A giving rise to secondary bases while it converts the bases of group B to the corresponding lactams. The different course of the oxidation from one group to the other is due to the different orientation of the C-6 methoxyl, and can be used to determine the stereochemistry at C-6.

The highly oxygenated diterpenoid alkaloids can be classified into two groups: group A containing the aconitine-like alkaloids I and group B or the lycoctonine-like bases II. The latter contain a ditertiary vicinal glycol and the former do not. More particularly in I the C-6 methoxyl is α whereas in II it is β.



I



II

There has been no method reported of determining the orientation of this group except X-ray crystallography. We now wish to report a method of ascertaining the stereochemistry at C-6 through an oxidation of the bases.

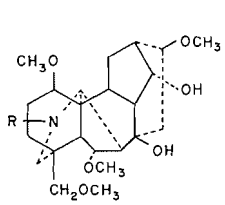
Oxidation of these alkaloids involving the attack of the reagent on the nitrogen is complicated and gives variable results depending on reaction conditions and the structure of the alkaloids. Of the various oxidizing agents tried, potassium permanganate proved the most promising. In the presence of acid, however, the oxidation gave rise to mixtures. The oxidation of aconitine with potassium permanganate in acetone containing acetic acid produced several neutral compounds and from the mixture oxonitine was isolated in 20% yield. Although oxonitine is N-formyl-N-deethylaconitine (1) it was not possible to find N-deethylaconitine among the reaction products. Under identical conditions mesaconitine I (R = Me, $R_1 = R_2 = OH$, $R_3 = C_6H_5$) is oxidized to oxonitine, and delphinine to α-oxodelphinine, which is N-formyl-N-demethyldelphinine I (R = CHO, $R_1 = R_2 = H$, $R_3 = C_6H_5$) and β-oxodelphinine claimed to be delphinine lactam (2).

In contrast, lycoctonine II (R = H; $R_1 = CH_3$) is oxidized under the same acidic

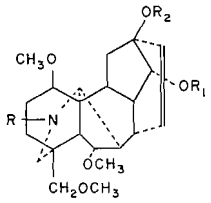
[1]*Issued as N.R.C. No. 8516.*
[2]*National Research Council of Canada Postdoctorate Fellow.*

conditions to a mixture of the lactam oxolycoctonine, deoxymethylene oxolycoctonine, and lycoctonamic acid (3). Similarly delpheline and acetylbrowniine are oxidized to oxodelpheline (4) and acetyloxobrowniine (5) respectively. In neither group of alkaloids was the formation of a secondary base observed.

In the absence of acid, however, the course of the oxidation with potassium permanganate was quite different and straightforward. In the course of the work that led to the determination of the structure of chasmanine, $C_{25}H_{41}O_6N$, III (R = Et), it was found that the alkaloid could be smoothly dealkylated when treated at room temperature for



III



IV

5 min with potassium permanganate in acetone–water solution (6). The product no longer showed the signal characteristic of the ethyl group in the n.m.r. spectrum and hence the product is III (R = H). That dealkylation was the only change brought about by the oxidation was shown by reconversion of the product (N-deethylchasmanine) to chasmanine with the aid of ethyl iodide and to the lower homologue, N-methyl-N-deethylchasmanine $C_{24}H_{39}O_6N$, III (R = CH_3) by treatment with methyl iodide.

In connection with an attempted correlation of chasmanine with bikhaconine (6) a derivative of the latter, diacetyldemethoxyisopyrobikhaconine IV (R = Et, $R_1 = R_2 = Ac$) (7), was found to undergo ready dealkylation in good yield when oxidized for 5 min with potassium permanganate in aqueous acetone at room temperature. A single product was obtained, m.p. 200–204°, which was the deethyl derivative IV (R = H, $R_1 = R_2 = Ac$). It still showed signals from the olefinic protons in the n.m.r. spectrum but no longer showed the N-Et signal. On acetylation, the product gave the neutral N-acetyl derivative IV (R = $R_1 = R_2 = Ac$), which, when treated with lithium aluminium hydride, produced demethoxyisopyrobikhaconine IV (R = Et, $R_1 = R_2 = H$). Direct ethylation of the oxidation product gave back the starting material IV (R = Et, $R_1 = R_2 = Ac$). The triacetyl derivative IV (R = $R_1 = R_2 = Ac$), when hydrogenated catalytically and subsequently saponified with methanolic sodium hydroxide, was converted to N-acetyl-N-deethyldihydrodemethoxyisopyrobikhaconine $C_{24}H_{35}O_6N$, showing an N-acetylcarbonyl band at 1 600 cm^{-1} in the infrared. Hence oxidation under the conditions described does not affect any part of the molecule besides removing the N-alkyl group. This interesting result prompted us to examine systematically the diterpenoid alkaloids of group A and group B.

First we studied the effect of the reaction on the alkaloids of group A, related structurally to aconitine and, like chasmanine, bearing an α-methoxyl group at C-6. With these ester alkaloids the reaction was slower and was allowed to proceed for a somewhat longer time. In spite of this the oxidation was not complete and for all except bikhaconitine an appreciable quantity of unchanged starting material was recovered. The predominant product was the N-dealkyl ester alkaloid accompanied by a small quantity of the neutral

N-dealkyl oxobase (Table I). All the N-dealkyl ester bases prepared except N-demethyldelphinine (identical with N-deethyldeoxyindaconitine, I, R = R_1 = R_2 = H; R_3 = C_6H_5)[3] were amorphous. The lowest yield of N-dealkyl ester base obtained was 40% and the highest was 91%, calculated after subtraction of the recovered unchanged starting material.

The neutral product in each case was the N-deethyl-oxobase. Those obtained in the oxidation of the various ester alkaloids are listed in Table IV (see experimental). The N-deethyl-ester alkaloids obtained in each case as the main product were all smoothly methylated to the corresponding N-methyl derivatives. Thus the N-deethyl derivatives of aconitine (I, R = H; R_1 = R_2 = OH; R_3 = C_6H_5), deoxyaconitine (I, R = R_1 = H; R_2 = OH; R_3 = C_6H_5), and deoxyindaconitine (I, R = R_1 = R_2 = H; R_3 = C_6H_5) yielded respectively mesaconitine, hypaconitine, and delphinine, while the N-deethyl derivatives of pseudaconitine, indaconitine, and bikhaconitine yielded lower homologues which have not yet been reported as occurring in nature (see Table III). The N-methyl bases having properties very similar to those of the corresponding N-ethyl alkaloids are not separable from the latter in thin-layer chromatography, and to obtain them pure it is essential to purify the secondary base before methylation.

The C-3 hydroxyl in ring A seems to have no effect on the course of the oxidation nor on the yield of deethyl base produced. The presence of a double bond in ring A, however, probably because of the half-chair conformation assumed by the ring, complicated the reaction. Oxidation of anhydropseudaconitine, for instance, gave only 64% yield of combined N-deethyl compound and unreacted starting base, while no oxoderivative was present.

TABLE II

Oxidation of alkamines

Alkamine	Wt., mg	Time, min	N-dealkyl base		Recovered starting base		Net yield, %	Neutral product
			mg	%	mg	%		
Chasmanine	245	5	215	94	—	—	94	
Bikhaconine	312	5	208	69	80	25	90	Trace
Pseudaconine	150	5	95	65	45	30	95	Trace
Diacetyl-demethoxy-isopyrobikhaconine	396	5	320	90	Trace	Trace	90	—
Monoacetyl-demethoxy-isopyrobikhaconine	113	5	101	95	—	—	95	Trace

Naturally occurring alkamines of group A and those obtained by saponification of the corresponding ester alkaloids underwent oxidation to the dealkyl base under the same conditions not only more rapidly but more completely in better yield and without the accompanying formation of the oxoderivative (Table II). Owing to their higher solubility in water, however, the products were more difficult to isolate. The dealkyl alkamines also were methylated smoothly to the corresponding N-methyl compounds. In most cases the product was acetylated. Thus bikhaconine gave triacetyldelphonine, and pseudaconine was converted into the new N-methyl-N-deethyl-pseudaconine tetraacetate ($C_{32}H_{47}O_{12}N$).

The bases of group B, which contain a β-C-6 methoxyl were rapidly oxidized by potassium permanganate in aqueous acetone, but with quite different results. With the

[3]*N-Deethyldeoxyindaconitine crystallized readily from ether, although when prepared previously by a different method it could not be induced to crystallize (8).*

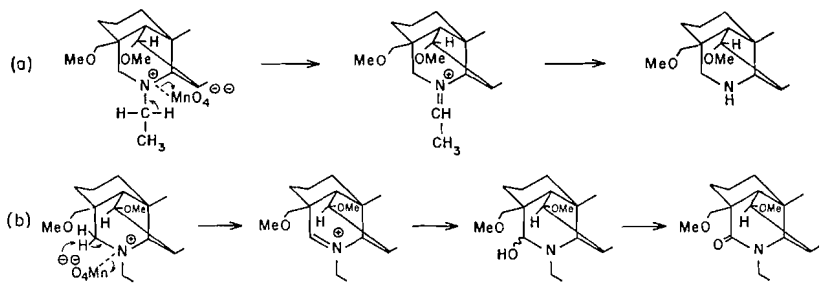
three bases of this group that were oxidized, the main product was the oxoderivative. Lycoctonine (II, R = H; $R_1 = CH_3$) produced oxolycoctonine exclusively. Browniine (II, R = CH_3; R_1 = H) gave mostly oxobrowniine accompanied by 7.5% of deethylbrowniine. Delcosine produced mainly anhydrohydroxydelcosine, a carbinolamine ether, accompanied by 15% of deethyldelcosine. As described already (9) delcosine carries a hydroxyl at C-1 of ring A oriented on the same side of ring A as the nitrogen ring, and readily forms a carbinolamine ether by condensation of this hydroxyl with the carbinolamine hydroxyl initially produced in the oxidation. Hence in the oxidation now described, the formation of anhydrohydroxydelcosine is equivalent to the formation of a lactam, but the reaction is stopped half way by the formation of the stable ether.

The characteristic difference between the alkaloids of group A and those of group B is that the C-6 methoxyl is α in the former and β in the latter. Without exception it has been found that the oxidation product of the group A alkaloids is predominantly the N-dealkyl derivative with the oxoderivative as a minor product, whereas the oxidation product of the group B alkaloids is predominantly the oxoderivative with the dealkyl base as a minor product.

The results obtained show that the ease of oxidation of a highly oxygenated diterpenoid alkaloid possessing the C—N-skeleton I or II to either a dealkyl derivative or to the oxo-base can be taken as an indication of the orientation of the C-6 methoxyl, which must be α in the first case and β when the product is mostly the lactam.

An examination of models shows that when the C-6 methoxyl is α it sterically hinders the vulnerable C-16 methylene group and prevents or restricts its oxidation to a lactamic carbonyl, thus favoring the attack on the imino-ethyl group. In contrast the β-oriented C-6 methoxyl in the alkaloids of group B does not interfere with the C-16 methylene, which is normally oxidized to a lactam carbonyl.

A possible mechanism of the oxidation reaction involves an initial complexing of MnO_4^- with the free pair of electrons on the nitrogen. The presence or absence of steric hindrance then determines the observed specificity of the reaction.



The ring methylene being more reactive is the favored point of attack, but if it is sterically hindered by the α-oriented C-6 methoxyl, as in the alkaloids of group A, the attack is on the ethyl group as in scheme *a* with the resulting elimination of that group. If there is no steric hindrance as in the group B alkaloids in which the C-6 methoxyl is β-oriented, the attack occurs as in scheme *b* and results in the production of the lactam. In the latter case there is a *trans* proton elimination with formation of an anhydronium intermediate which, in the basic medium, is rapidly oxidized, probably via the carbinolamine, to the lactam.

EXPERIMENTAL

Unless otherwise stated Analar acetone was used as a solvent in the oxidations, grade IV Woelm neutral alumina for column chromatography, and Merck's silica gel G as adsorbent and cyclohexane–chloroform–diethylamine as developing solvent for thin-layer chromatography. Infrared spectra were measured in nujol mulls for crystalline substances and in chloroform solution for amorphous compounds. The n.m.r. spectra were all measured on an A-60 instrument in $CDCl_3$ solution with tetramethylsilane as an internal standard. All melting points have been taken on a Kofler hot stage and are uncorrected.

Oxidation of Group A Alkaloids (General Procedure)

Oxidation of Bikhaconitine

Bikhaconitine (I, R = Et; $R_1 = R_2 = H$; $R_3 = C_6H_3(OCH_3)_2$) (183 mg) was dissolved in 80% acetone–water (50 ml) and potassium permanganate (160 mg) in 50% acetone–water (70 ml) was added all at once. The mixture was stirred for 10 min at room temperature and the excess permanganate reduced with sulfurous acid. The acetone was evaporated under reduced pressure and the residual aqueous solution after addition of sodium carbonate was extracted with chloroform. The dried chloroform extract on evaporation left a residue (192 mg) that was dissolved in 1% sulfuric acid (10 ml) and extracted with benzene to remove neutral substances. The aqueous solution was made basic with sodium carbonate and extracted with chloroform. Evaporation of the dried chloroform extract left a foam (180 mg) that was dissolved in benzene and chromatographed on alumina. The chromatogram was eluted first with benzene and then with 50% chloroform benzene. The benzene eluate gave unchanged bikhaconitine (101 mg) while the chloroform–benzene eluate yielded N-deethylbikhaconitine (65 mg), both homogeneous in thin-layer chromatography. The n.m.r. spectrum of the product no longer contained the triplet characteristic of the N-ethyl group. For analyses of N-methyl derivatives, see Table III.

The benzene extract containing the neutral fraction left, on evaporation, a residue that crystallized on contact with ethanol, m.p. 220–222°, wt. 2 mg. This product proved to be N-deethyloxobikhaconitine (cf. Table IV). This lactam becomes the main product of oxidation when the time of reaction is prolonged to 50 min.

Oxidation of Aconitine

Aconitine (1.950 g) in acetone (200 ml) was oxidized at room temperature with potassium permanganate (2.0 g) dissolved in 50% acetone–water (400 ml) for 20 min. The product was treated with 1% sulfuric acid and separated as above into a neutral and a basic fraction. The neutral fraction yielded N-deethyloxoaconitine (600 mg, see below) and the basic fraction gave N-deethylaconitine (578 mg) and unchanged aconitine (522 mg), which were separated by chromatography on alumina.

Oxidation of Anhydropseudaconitine

Anhydropseudaconitine (7) (568 mg) was oxidized with potassium permanganate (616 mg) in 50% acetone–water. The product (598 mg) in thin-layer chromatography showed the presence of two main compounds and five minor ones. The two main compounds were unchanged starting material and N-deethylanhydropseudaconitine. The product was chromatographed in benzene solution on alumina. Elution with benzene gave the unchanged starting material (174 mg) and elution with 20% chloroform–benzene gave a mixture (109 mg) of starting material and the N-deethyl base in which the latter predominated. Further elution with the same solvent yielded pure N-deethyl base (26 mg) as a gum. Final elution with chloroform gave material (80 mg) which included the N-deethyl base and the other minor products of low mobility. In the n.m.r. spectrum N-deethylanhydropseudaconitine produced signals at δ 6.20–5.80 (ethylenic protons), δ 3.91, 3.89 (veratroyl methoxyls), δ 3.54, 3.33, 3.30, 3.17 (four methoxyls), δ 1.33 (O-acetyl), but showed no imino ethyl signals.

N-Deethyl Bases

N-Deethylaconitine (I, R = H; $R_1 = R_2 = OH$; $R_3 = C_6H_5$), N-deethyldeoxyaconitine (I, R = R_1 = H; R_2 = OH; $R_3 = C_6H_5$), N-deethylindaconitine (I, R = R_2 = H; R_1 = OH; $R_3 = C_6H_5$), N-deethylanhydropseudaconitine, N-deethylpseudaconitine (I, R = R_2 = H; R_1 = OH; $R_3 = C_6H_3(OCH_3)_2$) and N-deethylbikhaconitine (I, R = $R_1 = R_2$ = H; $R_3 = C_6H_3(OCH_3)_2$) were amorphous. They all lacked the N-ethyl signal in the n.m.r. spectrum. N-Demethyldelphinine, identical with N-deethyldeoxyindaconitine (I, R = $R_1 = R_2$ = H; $R_3 = C_6H_5$) crystallized from ether as fine colorless needles, m.p. 162–164°. The compound obtained from two different sources also lacked the iminoethyl signal in the n.m.r. spectrum. Gilman and Marion (8), who had previously obtained this substance, reported it to be amorphous.

Methylation of N-Deethyl Bases

The N-deethyl base was refluxed in 50% methanol–ether with excess methyl iodide and powdered potassium carbonate for 1 h. In each case the product was purified by chromatography on alumina. Every one of the N-methyl-N-deethyl bases prepared showed an imino-methyl signal at δ 2.30 in the n.m.r. spectrum. They are listed in Table III together with their analytical figures.

N-Dealkyloxo Bases

The neutral fraction of the product of oxidation of the ester alkaloids mentioned above was in each case the N-dealkyloxo-derivative. It was purified by chromatography over alumina. The crystal forms, melting points, and analytical figures are given in Table IV.

Oxidation of Group A Alkamines

Oxidation of Chasmanine

Chasmanine (245 mg) was dissolved in 80% acetone–water (60 ml) and a solution of potassium permanganate (242 mg) in 50% acetone–water (200 ml) was added. The resulting solution was stirred at room temperature for 5 min and the product worked up as usual. It gave N-deethylchasmanine (215 mg), crystallizing as colorless prisms from chloroform–hexane, m.p. 230–231°.

Anal. Calcd. for $C_{23}H_{37}O_6N$: C, 65.22; H, 8.81. Found: C, 64.71; H, 8.67.

On treatment with ethyl iodide by the method described above, the product gave back chasmanine, while treatment with methyl iodide by the same method yielded N-methyl-N-deethylchasmanine, which separated from *n*-hexane as colorless prisms, m.p. 90–92°. In the n.m.r. spectrum: δ 2.29 ($N\text{-}CH_3$) (6).

Anal. Calcd. for $C_{24}H_{39}O_6N$: C, 65.87; H, 8.98; N, 3.20. Found: C, 65.64; H, 9.10; N, 3.19.

Oxidation of Diacetyldemethoxyisopyrobikhaconine

To a stirred solution of the compound (7) (396 mg) in acetone (72 ml) and water (8 ml), potassium permanganate (214 mg) dissolved in acetone (40 ml) was added all at once. After 5 min stirring at room temperature, the excess permanganate was decomposed by the addition of sulfurous acid ($Na_2SO_3 + H_2SO_4$) and the acetone evaporated under reduced pressure below 40°. Extraction of the acid liquor with chloroform removed 5 mg of neutral material which was not further investigated. The solution was made basic with sodium carbonate and extracted with chloroform. Evaporation of the dried extract yielded a colorless gum (440 mg) showing in thin-layer chromatography one strong spot (N-deethyl compound) and two weak spots, one of which corresponded to the starting material.

Crystallization of the product from ether gave N-deethyldiacetyldemethoxyisopyrobikhaconine as fine colorless needles (320 mg) m.p. 200–204°. In the n.m.r. spectrum signals at δ 6.20–5.45 (olefinic protons), δ 3.30, 3.29, 3.21 (three OMe), δ 2.05, 2.01 (two acetyl groups).

Anal. Calcd. for $C_{26}H_{35}O_7N\cdot H_2O$: C, 63.52, H, 7.59. Found: C, 63.83, H, 7.62.

Some of the N-deethyl compound (200 mg) in pyridine (5 ml) and acetic anhydride (2.5 ml) was heated on the steam bath for 4 h. The product of the reaction, a triacetate (200 mg) was a gum that could not be induced to crystallize. In the n.m.r. spectrum signals at δ 6.20–5.40 (olefinic protons), δ 3.29 (6H), 3.19 (3 OMe), δ 2.11, 2.09, 2.03 (three acetyl groups).

Reduction of the triacetate (50 mg) with lithium aluminium hydride in tetrahydrofurane (5 ml) overnight gave a product that was dissolved in benzene and chromatographed on alumina. The chloroform eluate yielded demethoxyisopyrobikhaconine, which crystallized from ether-*n*-hexane as colorless fine needles, m.p. 147–150°, identical with an authentic sample (8).

Some of the triacetate (300 mg) dissolved in ethanol (20 ml) was hydrogenated over platinum oxide (200 mg). The product, worked up as usual, was a colorless gum. It was saponified by refluxing with 3% sodium hydroxide in methanol, the methanol was evaporated, water added, and the solution extracted with chloroform. Evaporation of the extract left N-acetyl-N-deethyldihydrodemethoxyisopyrobikhaconine as a colorless gum (290 mg) which crystallized from methanol–ether as colorless prisms (256 mg), m.p. 242–245°.

Anal. Calcd. for $C_{24}H_{35}O_6N\cdot 0.5H_2O$: C, 65.01; H, 8.13. Found: C, 65.36; H, 8.42.

Oxidation of Bikhaconine

Bikhaconine (312 mg) oxidized with potassium permanganate by the procedure already described gave N-deethylbikhaconine (120 mg) and unchanged starting material (80 mg) separated by chromatography, together with a small quantity of neutral material.

A quantity of N-deethylbikhaconine (90 mg) was methylated with methyl iodide and acetylated. There was obtained a triacetate that crystallized from methanol as colorless prisms (64 mg) m.p. 182–184°.

Anal. Calcd. for $C_{30}H_{45}O_{10}N$: C, 62.16; H, 7.83. Found: C, 61.66, H, 7.41.

The triacetate was identical with triacetyldelphonine, m.p. 182–184°, prepared by hydrolysis and acetylation of delphinine.

Oxidation of Pseudaconine

Pseudaconine (150 mg) was oxidized as above for 5 min and the excess permanganate was reduced with sulfurous acid. After evaporation of the acetone under reduced pressure and extraction with chloroform to remove any neutral product, the solution was made basic with sodium carbonate and extracted for 3 days with chloroform in a liquid–liquid extractor. Evaporation of the extract left N-deethylpseudaconine (140 mg) as a gum. The gummy residue was treated with methyl iodide as described above and the product acetylated. This gave rise to the tetraacetate of N-methyl-N-deethylpseudaconine obtained as colorless prisms from ethanol, m.p. 235°.

Anal. Calcd. for $C_{32}H_{47}O_{12}N$: C, 60.19; H, 7.36. Found: C, 59.61; H, 7.08.

Oxidation of Group B Alkaloids

Oxidation of Lycoctonine

Lycoctonine (380 mg) was oxidized with potassium permanganate (380 mg) for 4 min under the conditions described above. It yielded a single product (386 mg) which crystallized on standing, m.p. 93–95°, and proved identical in every respect with an authentic sample of oxolycoctonine (3).

Oxidation of Browniine

Browniine (213 mg) liberated from its perchlorate was oxidized with potassium permanganate (220 mg) for 3 min under the conditions already described. The excess permanganate was decomposed with sulfurous acid. After evaporation of the acetone under reduced pressure, the aqueous solution was extracted with chloroform to remove the neutral fraction (170 mg). The aqueous solution was made basic with sodium carbonate and extracted with chloroform. This second chloroform extract yielded the basic fraction (43 mg). The neutral fraction crystallized immediately and after recrystallization from ether was obtained as colorless needles, m.p. 170–171°, identical by melting point, mixture melting point, and infrared spectra with an authentic sample of oxobrowniine (5).

The basic fraction still contained oxobrowniine. On chromatography in benzene solution on alumina and elution with benzene and then chloroform–benzene (1:1), it yielded a further crop of oxobrowniine (27 mg) and amorphous N-deethylbrowniine (16 mg).

N-Deethylbrowniine (76 mg) was methylated with methyl iodide by the method already described and the resulting amorphous N-methyl-N-deethylbrowniine (28 mg) was characterized as its perchlorate, colorless needles from methanol – ethyl acetate, m.p. 215°.

Anal. Calcd. for $C_{24}H_{39}O_7N \cdot HClO_4$: C, 51.99; H, 7.40. Found: C, 51.89; H, 7.28.

Oxidation of Delcosine

Delcosine (212 mg) was oxidized with potassium permanganate (150 mg) for 7 min under the conditions described and the product worked up as usual. By means of chromatography the product was separated into anhydrohydroxydelcosine (165 mg), m.p. 186–188°, unchanged delcosine (15 mg), and N-deethyldelcosine (30 mg), m.p. 240–241° (decomp.). The identity of these compounds was confirmed by direct comparison with authentic specimens (9).

ACKNOWLEDGMENT

The authors acknowledge their indebtedness to Mr. H. Seguin for the microanalyses, Mr. M. Lesage for the n.m.r. spectra, and Mr. R. Lauzon for the infrared spectra.

CARBOHYDRATES CONTAINING NITROGEN IN A FIVE-MEMBERED RING AND AN ATTEMPTED SYNTHESIS OF A CARBOHYDRATE WITH NITROGEN IN A SEVEN-MEMBERED RING[1]

W. A. SZAREK[2] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 18, 1965

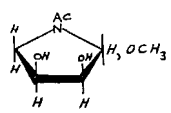
ABSTRACT

Lead tetraacetate oxidation of 6-acetamido-6-deoxy-D-galactose (IX) yielded a syrup which was converted to a compound formulated as 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-D-threofuranose (XII). The same syrup was obtained by alkaline degradation of the product of oxidation of 5-acetamido-5-deoxy-D-xylose diethyl dithioacetal (XVII) with peroxypropionic acid. Treatment of compound XII with *p*-toluenesulfonyl chloride yielded crystalline 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-3-*O*-*p*-tolylsufonyl-D-threofuranose (XIII).

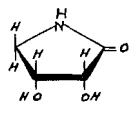
Demercaptalation of 6-acetamido-2,3,4,5-tetra-*O*-acetyl-6-deoxy-D-galactose diethyl dithioacetal (XX) with mercuric chloride and cadmium carbonate in aqueous acetone did not yield a nitrogen-containing septanose ring but an acyclic derivative.

CARBOHYDRATES CONTAINING NITROGEN IN A FIVE-MEMBERED RING

In a previous paper (1) from this laboratory the synthesis of methyl 4-acetamido-4-deoxy-L-erythrofuranoside (I), the first example of a sugar with nitrogen in a five-membered ring, was described. Very shortly after this announcement, Hanessian and Haskell (2) reported that they had obtained syrupy 4-acetamido-4-deoxy-L-erythrofuranose by the alkaline degradation of 5-acetamido-5-deoxy-L-arabinose diethylsulfonal. In the same paper Hanessian and Haskell reported the preparation of a novel sugar derivative, 4-amino-4-deoxy-D-erythronolactam (II). In the present publication we describe the synthesis by two different routes of derivatives of 4-acetamido-4-deoxy-D-threofuranose (XI).



I

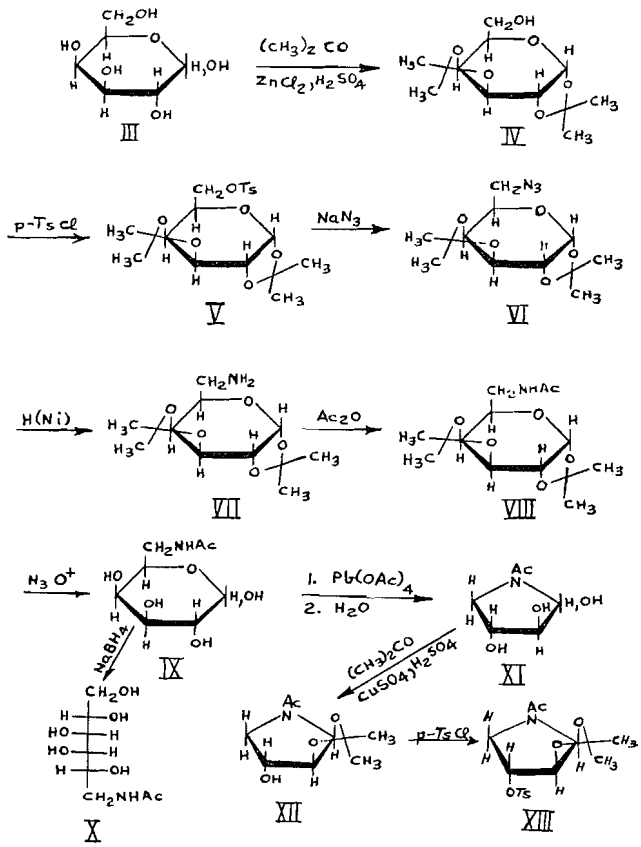


II

1,2;3,4-Di-*O*-isopropylidene-α-D-galactopyranose (IV) (3) was prepared from D-galactose (III) and treated with *p*-toluenesulfonyl chloride in pyridine to give 1,2;3,4-di-*O*-isopropylidene-6-*O*-*p*-tolylsulfonyl-α-D-galactopyranose (V) (4). Compound V reacted with sodium azide in *N*,*N*-dimethylformamide to afford a homogeneous pale yellow oil, the infrared spectrum of which showed the highly characteristic azide group absorption at 2 100 cm^{-1} but no aromatic ring and sulfonate group absorptions. The new substance is therefore 6-azido-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (VI). This derivative could be reduced to 6-amino-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (VII) (5) by merely stirring it with an excess of Raney nickel, a procedure described by Wolfrom *et al.* (6). Treatment of compound VII with acetic anhydride in pyridine afforded a glass which gave a negative ninhydrin reaction. The glassy product

[1]*Presented in part at the International Symposium on Carbohydrate Chemistry, Münster, July 13–17, 1964.*
[2]*Present address: Ohio State University, Columbus, Ohio.*

showed amide I and amide II bands in the infrared, and thus is 6-acetamido-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (VIII). Hydrolysis of VIII with Amberlite IR-120 (H form) resin yielded glassy 6-acetamido-6-deoxy-D-galactose (IX), which was characterized by its conversion to crystalline 6-acetamido-6-deoxy-D-galactitol (X) on sodium borohydride reduction.



It has been known for some time that aldohexoses, when treated with lead tetraacetate, rapidly consume 2 moles of oxidant, after which the reaction becomes very slow (7, 8). Thus, Perlin and Brice (8) were able to degrade D-glucose selectively to di-*O*-formyl-D-erythrose by oxidation with 2 moles of lead tetraacetate. The ester groups were easily hydrolyzed, giving D-erythrose in an overall yield of at least 80% of theory. D-Galactose showed similar behavior, but the product formed was D-threose esterified with 1.8 formate groups per molecule (9). Significantly, substitution of the C-6 hydroxyl group in D-glucose did not alter the rate of uptake of lead tetraacetate (10). This result implies that the primary carbinol group is not involved in the oxidation of D-glucose itself.

The results cited above suggested that oxidation of 6-acetamido-6-deoxy-D-galactose (IX) with 2 moles of lead tetraacetate would yield a 4-acetamido-4-deoxy-D-threose derivative in which there existed the possibility of formation of a nitrogen-containing furanose ring. Oxidation of compound IX with 2 moles of lead tetraacetate followed by hydrolysis of the ester groups by heating of the product in water afforded a syrup which was reducing towards Fehling's solution and whose infrared spectrum showed absorption

For personal use only.

attributable to *OH* and a very broad amide I band, but no significant amide II band. The infrared data suggested that the new substance exists primarily in the furanose form (XI). The results of periodate oxidation in unbuffered aqueous solution were consistent also with the proposed structure. The n.m.r. spectrum in deuterium oxide (Fig. 1) could

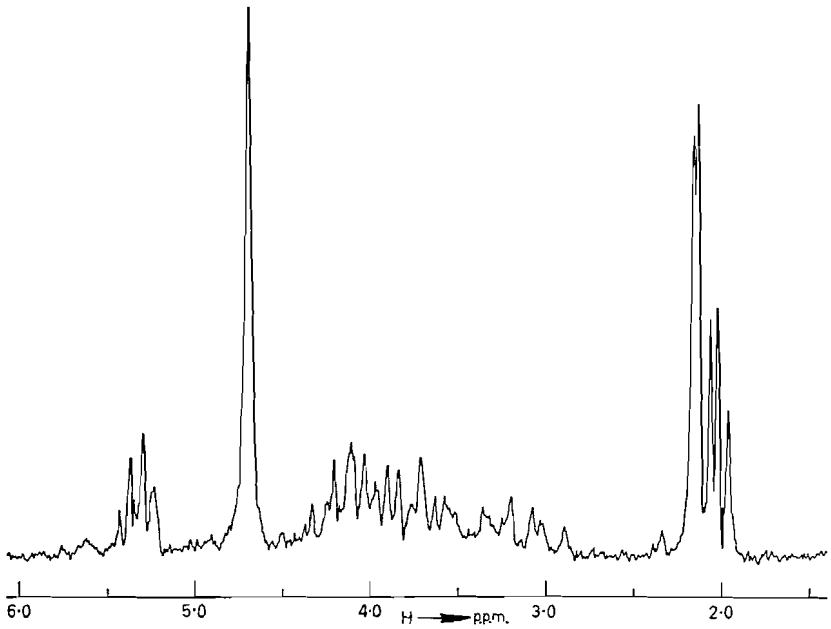

FIG. 1. Nuclear magnetic resonance spectrum of "4-acetamido-4-deoxy-D-threofuranose" at room temperature.

not be satisfactorily interpreted, however, on the basis of this formulation. In the region 1.96–2.15 p.p.m., characteristic of the protons of an *N*-acetyl group (11), there are five peaks. The portion of the spectrum from 5.24 p.p.m. to 5.43 p.p.m., which can be attributed to anomeric protons (12), is also unusually complex. An attractive suggestion is that the new substance is a mixture of α- and β-anomers, and that each anomer displays restricted rotation about the *CO—N* bond. Such hindered internal rotation has been demonstrated in methyl 4-acetamido-4-deoxy-L-erythrofuranoside and in two nitrogen-containing pyranose sugars (13). In addition there may be present a small amount of the acyclic form of the compound.

The new substance appeared on both paper and thin-layer chromatograms as two spots which moved very close to one another. A separation of the two components by preparative paper chromatography was attempted. The zones were located and extracted with methanol. Examination of the two extracts on paper chromatograms still showed in each case, however, the presence of the two original components. This observation indicated that a transformation of one component into the other occurred during the extraction or chromatography process.

Treatment of the oxidation product with dry acetone in the presence of anhydrous copper (II) sulfate and concentrated sulfuric acid afforded a pale yellow syrup. In contrast to the starting material, the product migrated as a homogeneous spot on a thin-layer chromatogram. The infrared spectrum of this material showed a doublet of approximately equal intensity attributable to a $C(CH_3)_2$ grouping, absorption attributable to *OH*,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and an amide I band but no amide II band. This evidence is consistent with structure XII for the new compound, which is named 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-D-threofuranose. The n.m.r. spectrum in deuterium oxide at room temperature (Fig. 3) shows two peaks at 1.36 and 1.41 p.p.m. which may be assigned to the protons of an isopropylidene group, and two peaks at 2.08 and 2.16 p.p.m. in the region characteristic of the protons of *N*-acetyl groups. Since there is no possibility of anomers in 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-D-threofuranose, the two signals in the *N*-acetyl region may

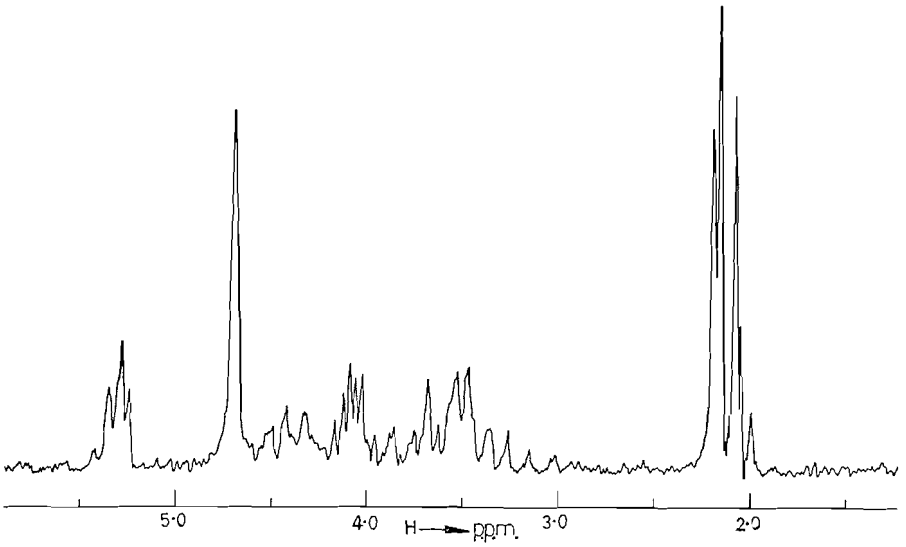

FIG. 2. Nuclear magnetic resonance spectrum of "4-acetamido-4-deoxy-L-erythrofuranose" at room temperature.

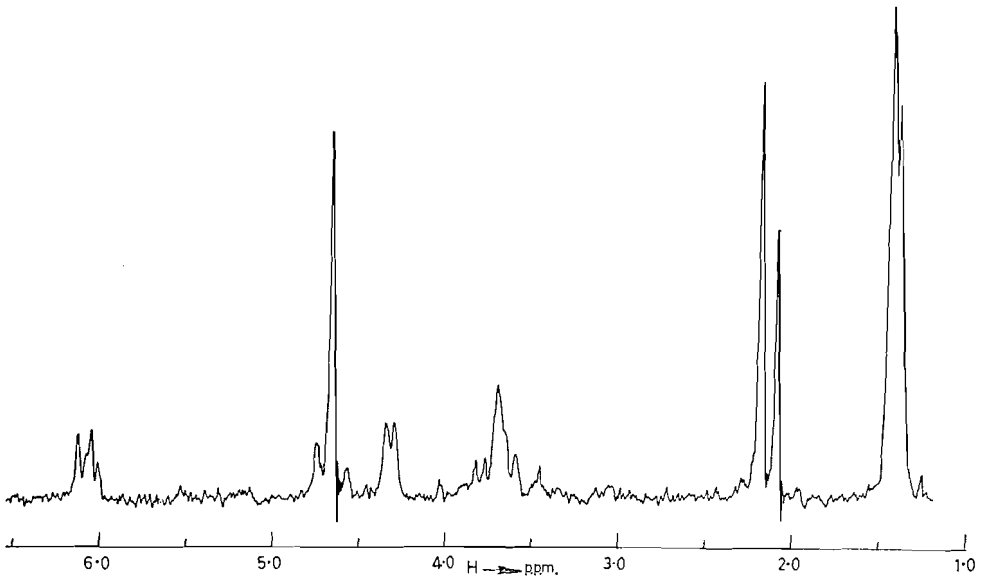

FIG. 3. Nuclear magnetic resonance spectrum of 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-D-threofuranose (LXXXVI) at room temperature.

arise from restricted rotation about the *CO*—*N* bond. At 80°, however, there was no measurable merging of the two signals. Treatment of compound XII with *p*-toluenesulfonyl chloride in pyridine yielded crystalline 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-3-*O*-*p*-tolylsulfonyl-D-threofuranose (XIII). The five-membered ring structure of XIII was indicated by the absence of the amide II band in its infrared spectrum. The n.m.r. spectrum of 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-3-*O*-*p*-tolylsulfonyl-D-threofuranose in deuterochloroform at room temperature is presented in Fig. 4. The group of peaks centered at 7.60 p.p.m. with an intensity corresponding to four protons may be assigned to tosyl ring protons. The peak at 2.47 p.p.m., corresponding to three protons, is assigned to the tosyl methyl group. The n.m.r. spectrum shows also two peaks at 1.35 and 1.39 p.p.m. attributable to the protons of an isopropylidene group. Evidence in favor of restricted rotation about the *CO*—*N* bond was obtained by the appearance of two peaks at 2.00 and 2.17 p.p.m. which may be assigned to the protons of the *N*-acetyl group, and two doublets at 5.90 and 6.20 p.p.m. in the general region characteristic of anomeric protons.

In the present work the preparation of the syrupy product obtained by lead tetraacetate oxidation of 6-acetamido-6-deoxy-D-galactose was accomplished also by a different approach. 1,2-*O*-Isopropylidene-5-*O*-*p*-tolylsulfonyl-D-xylose (XIV) was prepared from D-xylose by the method of Levene and Raymond (14). Treatment with sodium azide in *N*,*N*-dimethylformamide gave crystalline 5-azido-5-deoxy-1,2-*O*-isopropylidene-D-xylose (XV). This compound was readily reduced with Raney nickel at room temperature to give a crystalline product which, when treated with aqueous acetic anhydride, gave 5-acetamido-5-deoxy-1,2-*O*-isopropylidene-D-xylose (XVI) (15). The furanose ring of XVI could be opened by treatment with ethanethiol and hydrochloric acid to give crystalline 5-acetamido-5-deoxy-D-xylose diethyl dithioacetal (XVII). Oxidation of compound XVII with peroxypropionic acid afforded a glass, probably 5-acetamido-5-deoxy-D-xylose diethylsulfonal. Treatment of this material with aqueous ammonia afforded crystalline bis (ethylsulfonyl) methane and a syrup. The infrared and proton magnetic resonance spectra and chromatographic properties of this material were the same as those of the syrup obtained from the lead tetraacetate oxidation.

For personal use only.

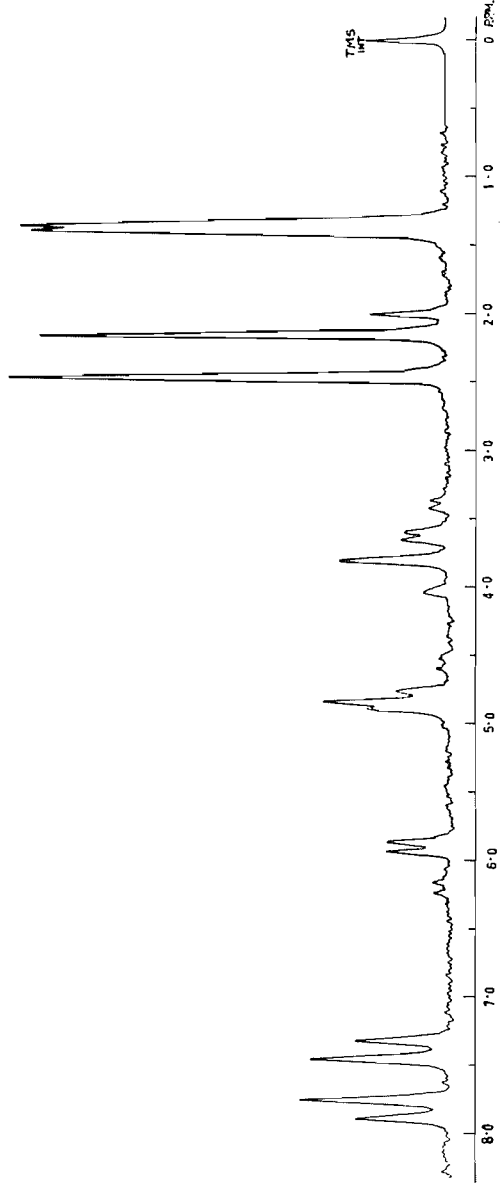

FIG. 4. Nuclear magnetic resonance spectrum of 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-D-threofuranose 3-*p*-tolylsulfonate.

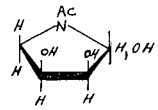
It is of interest to note that hydrolysis with Amberlite IR-120 (H form) resin of methyl 4-acetamido-4-deoxy-L-erythrofuranoside (I) (1) afforded a reducing syrup which exhibited behavior entirely analogous to that shown by the product derived from the two degradation procedures described above. The infrared spectrum of the syrup showed absorption attributable to *OH* and a broad amide I band, but no significant absorption in the region characteristic of an amide II band. On the basis of the infrared data and the structure of the precursor I, a reasonable formulation of the new syrup would be that shown by XVIII.



XVIII

The results of periodate oxidation in unbuffered aqueous solution could be accommodated also by this structure. The n.m.r. spectrum in deuterium oxide (Fig. 2), however, is very complex but resembles closely the spectrum shown in Fig. 1. Two spots were detected again by both paper and thin-layer chromatography, and an attempted separation of the components by preparative paper chromatography indicated that they are interconvertible.

ATTEMPTED SYNTHESIS OF A CARBOHYDRATE CONTAINING NITROGEN IN A SEVEN-MEMBERED RING

The synthesis of derivatives of seven-membered ring sugars or septanoses has been achieved by Micheel *et al.* (16–18). By a series of reactions α- and β-1,2,3,4,5-penta-*O*-acetyl-D-galactoseptanose were prepared. The septanose structure was confirmed by conversion of the pentaacetate to a methyl tetra-*O*-methyl-D-galactoseptanoside which, upon oxidation with nitric acid, gave tetra-*O*-methylmucic acid (17). In the present work the synthesis of a sugar derivative with nitrogen as the hetero atom in a seven-membered ring was attempted by a method analogous to that described by Micheel and Suckfüll (16).

Treatment of 6-acetamido-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (VIII) (*vide supra*) with ethanethiol and hydrochloric acid gave crystalline 6-acetamido-6-deoxy-D-galactose diethyl dithioacetal (XIX). Acetylation of XIX with acetic anhydride in pyridine then afforded crystalline 6-acetamido-2,3,4,5-tetra-*O*-acetyl-6-deoxy-D-galactose diethyl dithioacetal (XX). Demercaptalation of compound XX with mercuric chloride and cadmium carbonate in aqueous acetone, by the method employed by Wolfrom (19) to prepare the monoethyl alcoholate of 2,3,4,5,6-penta-*O*-acetyl-*aldehydo*-galactose, gave a crystalline product XXI which, on heating, reduced Fehling's solution. The infrared spectrum of this material showed strong absorption attributable to *OH*, absorption owing to *O*-acetyl groups, an amide I band, and an amide II band. Thus compound XXI is presumably the aldehydrol of 6-acetamido-2,3,4,5-tetra-*O*-acetyl-6-deoxy-*aldehydo*-D-galactose. Accordingly, compound XXI was allowed to stand in dry pyridine for 24 h and then treated with acetic anhydride. The presence of an amide II band in the infrared spectrum of the product indicated, however, that the desired cyclization to form a nitrogen-containing septanose ring had not occurred.

EXPERIMENTAL

Melting points were determined on a Fisher-Johns melting point apparatus. Optical rotations were measured with a Hilger standard polarimeter. Infrared spectra were measured with a Perkin–Elmer model 21 spectrophotometer. The n.m.r. spectra were determined at 60 Mc/s with a Varian A-60 n.m.r. spectrometer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

using approximately 10% by weight solutions; chemical shifts were determined as p.p.m. downfield from tetramethylsilane as an external standard for the deuterium oxide solutions and as an internal standard for the deutero chloroform solutions. Paper chromatography was carried out by the descending method at room temperature on Whatman No. 1 filter paper for qualitative purposes or on Whatman 3 MM filter paper for preparative purposes in the following solvent systems (v/v): (A) butan-1-ol:ethanol:water, 3:1:1; (B) ethyl acetate:acetic acid:formic acid:water, 18:3:1:4. Sugars were detected on paper chromatograms by the following spray reagents: (i) alkaline silver nitrate (20); (ii) *p*-anisidine hydrochloride (21); (iii) sodium metaperiodate – potassium permanganate (22). Rates of movement of the sugars on paper chromatograms are given relative to that of rhamnose (R_{rh}). Thin-layer chromatography was carried out on Silica Gel G supplied by Research Specialties Company, Richmond, California. The developed plates were dried in air, sprayed with concentrated sulfuric acid, and then heated in an oven at about 150°. Raney nickel catalyst in water was supplied by Aldrich Chemical Co., Inc., Milwaukee, Wisconsin.

1,2;3,4-Di-O-isopropylidene-6-O-p-tolylsulfonyl-α-D-galactopyranose (V)

1,2;3,4-Di-*O*-isopropylidene-α-D-galactopyranose (IV) was prepared from D-galactose (36 g) according to Tipson (3). The crude product (33 g) was dissolved in dry pyridine (65 ml) and *p*-toluenesulfonyl chloride (36.8 g, 1.5 moles) was added at room temperature. After 3 h the mixture was poured into 400 ml of ice-water and the precipitated product (44.1 g, 84%) was isolated in the usual way. After two recrystallizations from methanol the compound had m.p. 101.5–102.5° and $[\alpha]_D^{25} = -62°$ (*c*, 4.33 in chloroform containing 0.75% ethanol). Foster *et al.* (4) report m.p. 89–91° and $[\alpha]_D = -63.4°$ (chloroform); Freudenberg and Raschig (23) report m.p. 102–103°.

6-Azido-6-deoxy-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose (VI)

To a solution of 1,2;3,4-di-*O*-isopropylidene-6-*O*-*p*-tolylsulfonyl-α-D-galactopyranose (V) (27.0 g) in *N*,*N*-dimethylformamide (230 ml) was added water (12 ml), sodium azide (6.38 g, 1.5 moles), and urea (0.8 g). The mixture was heated for 19 h at 120° under a stream of nitrogen. The cooled solution was poured into 600 ml of ice water and extracted several times with chloroform. The combined extracts were washed with aqueous sodium hydrogen carbonate, then with water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to leave a pale yellow oil (15.6 g, 84%), $[\alpha]_D^{21} = -92.1°$ (*c*, 1.48 in chloroform containing 0.75% ethanol). Thin-layer chromatography in methanol:benzene, 1:9 (v/v), showed only one component. The infrared spectrum of this material in chloroform showed azide absorption at 2 100 cm^{-1}, but no aromatic ring and sulfonate group absorptions, and no hydroxyl group absorption.

6-Amino-6-deoxy-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose (VII)

A solution of 6-azido-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (VI) (14.4 g) in methanol (300 ml) was treated with Raney nickel (80 g) for 44 h, filtered, and concentrated to give a pale yellow syrup (13.7 g). The infrared spectrum of this material in chloroform showed *N*—*H* deformation vibration at 1 587 cm^{-1} and *N*—*H* stretching vibration in the 3 300 cm^{-1} region, but no absorption attributable to an azide grouping. The product was distilled to yield a mobile colorless syrup which had $[\alpha]_D^{23} = -44.0°$ (*c*, 1.31 in methanol). Veksler *et al.* (5) report $[\alpha]_D^{21} = -40.1°$ (in methanol) for syrupy 6-amino-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose.

6-Acetamido-6-deoxy-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose (VIII)

To a solution of 6-amino-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (VII) (12.2 g) in reagent pyridine (45 ml) was added acetic anhydride (17 ml) portionwise with ice-cooling. After 20 h at room temperature the solution was poured into 400 ml of ice water, and the mixture was extracted several times with chloroform. The combined chloroform extracts were washed with water, then shaken with an aqueous solution of cadmium chloride (to remove pyridine). The pyridine – cadmium chloride complex was filtered, the chloroform solution washed with water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to leave an almost colorless glass (15.5 g). This material gave a negative ninhydrin reaction and had $[\alpha]_D^{23} = -8.3°$ (*c*, 1.81 in chloroform containing 0.75% ethanol). The infrared spectrum in chloroform showed *N*—*H* stretching vibration absorption at 3 440 cm^{-1}, an amide I band at 1 663 cm^{-1}, an amide II band at 1 520 cm^{-1}, and a doublet at 1 387 cm^{-1} and 1 376 cm^{-1} attributable to *C*—*H* deformation vibrations of a $C(CH_3)_2$ grouping.

6-Acetamido-6-deoxy-D-galactose (IX)

A suspension of 6-acetamido-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (VIII) (1.5 g) in water (225 ml) was stirred with 7.5 g of Amberlite IR-120 (H form) resin at 60° for 3½ h. The resin was then removed by filtration, and the filtrate was shaken briefly with a small amount of Duolite A-4 (OH form) resin to remove any trace of acid. The resin was removed, and the clear colorless solution was concentrated under reduced pressure to leave a colorless glass (1.2 g). This material was reducing towards Fehling's solution, and had $[\alpha]_D^{22} = +81°$ (constant, during 24 h) (*c*, 1.24 in water). Thin-layer chromatography in 2-propanol:benzene, 1:2 (v/v), showed only one component; paper chromatography also showed only one component with R_{rh} 0.50 (solvent A, sprays i and ii).

For personal use only.

*6-Acetamido-6-deoxy-*D*-galactitol (X)*

To a cold solution of 6-acetamido-6-deoxy-D-galactose (IX) (0.26 g) in water (10 ml) 0.26 g of sodium borohydride was added, with shaking. The solution was allowed to stand in a refrigerator for 3 h and then 30 min at room temperature. Excess sodium borohydride was destroyed by the addition of acetone, and the solution was then passed through Amberlite IR-120 (H form) exchange resin. The eluate and washings were concentrated to dryness under reduced pressure. Boric acid was removed by repeated distillation with methanol. A white crystalline material was obtained which was recrystallized from methanol to give crystals (0.12 g) which had $[\alpha]_D^{21} = +20.4°$ (*c*, 1.38 in water), R_{rh} 0.6 (solvent A, spray i), and m.p. 183–183.5°. The infrared spectrum in Nujol mull showed strong absorption at 3 280 cm^{-1} attributable to *OH* and *NH*, an amide I band at 1 645 cm^{-1}, and an amide II band at 1 557 cm^{-1}.

Anal. Calcd. for $C_8H_{17}O_6N$: C, 43.04; H, 7.68; N, 6.28. Found: C, 42.78; H, 7.58; N, 6.48.

*Lead Tetraacetate Oxidation of 6-Acetamido-6-deoxy-*D*-galactose (IX)*

To a rapidly stirred solution of 6-acetamido-6-deoxy-D-galactose (0.53 g, 0.00238 mole) in 2 ml of water and 50 ml of acetic acid was added lead tetraacetate (2.2 g, 0.00497 mole), prepared according to the procedure of Vogel (24), over a period of 3 to 4 min. After 18 min oxalic acid dihydrate (ca. 0.7 g), dissolved in glacial acetic acid, was added, and the suspension was stirred for an additional 30 min; a negative potassium iodide – starch test was then obtained. The precipitate was filtered off and washed with acetic acid, and the filtrate was concentrated under reduced pressure at 35° to a volume of a few milliliters. Ethyl acetate was added and the precipitate which formed was triturated with several portions of ethyl acetate. The extracts were combined, filtered, and concentrated to a syrup which was further purified by extraction with ethyl acetate. The product was a pale yellow syrup (0.40 g).

The yellow syrup was taken up in water (25 ml) and heated on a stream bath for 3 h. The solution was then concentrated under reduced pressure to yield a light brown syrup (0.26 g) which was examined on paper chromatograms. Sprays i and ii showed the presence of 6-acetamido-6-deoxy-D-galactose at R_{rh} 0.5 and two closely moving components at R_{rh} 1.05 and 1.32 (solvent A). The two components having R_{rh} 1.05 and 1.32 were separated as one fraction from the 6-acetamido-6-deoxy-D-galactose by preparative paper chromatography in solvent A. The syrupy fraction was purified by dissolving it in water and washing the solution with chloroform. Concentration of the aqueous phase under reduced pressure gave an almost colorless syrup (ca. 0.14 g) which reduced Fehling's solution in a few minutes on heating, and had $[\alpha]_D^{24} = -15.5°$ (*c*, 1.68 in methanol). In solvent B the syrup was revealed as two spots at R_{rh} 1.06 and 1.13 (sprays i and ii). Two spots were detected also by thin-layer chromatography in 2-propanol:benzene, 1:2 (v/v). The infrared spectrum of this material (smear between "IRTRAN-2" plates) showed strong absorption at 3 380 cm^{-1} attributable to *OH*, and a very broad band at 1 627 cm^{-1} attributable to *N*-Ac.

A separation of the two components was attempted by preparative paper chromatography using solvent A. The zones were located (spray i), cut, and extracted with methanol. Examination of the two extracts on paper chromatograms still showed in each case the presence of the two original components.

*4-Acetamido-4-deoxy-1,2-O-isopropylidene-*D*-threofuranose (XII)*

To a portion (0.096 g) of the lead tetraacetate oxidation product were added dry acetone (20 ml), anhydrous copper sulfate (2 g), and concentrated sulfuric acid (1 drop). The mixture was shaken mechanically for 24 h and filtered, and the filtrate was then poured into a rapidly stirred saturated aqueous solution (ca. 24 ml) of sodium hydrogen carbonate. Most of the acetone was removed by evaporation under reduced pressure and the solution was then continuously extracted with chloroform overnight. The chloroform extract was dried over anhydrous magnesium sulfate and concentrated under reduced pressure to leave a pale yellow syrup (0.058 g). This material was distilled under vacuum to yield a syrup which had $[\alpha]_D^{25} = +162°$ (*c*, 1.64 in methanol). Thin-layer chromatography in methanol:benzene, 1:9 (v/v), showed only one component. The infrared spectrum of this material in chloroform showed absorption at 3 420 cm^{-1} attributable to *OH*, a doublet of approximately equal intensity at 1 382 and 1 391 cm^{-1} caused by an isopropylidene grouping, and an amide I band at 1 645 cm^{-1} but no amide II band.

Anal. Calcd. for $C_9H_{15}O_4N \cdot \frac{1}{2}H_2O$: C, 51.5; H, 7.62; N, 6.68. Found: C, 51.9; H, 7.28; N, 6.15.

*4-Acetamido-4-deoxy-1,2-O-isopropylidene-3-O-p-tolylsulfonyl-*D*-threofuranose (XIII)*

Syrupy 4-acetamido-4-deoxy-1,2-*O*-isopropylidene-D-threofuranose (0.51 g) was dissolved in dry pyridine (10 ml) and *p*-toluenesulfonyl chloride (0.57 g, 1.2 moles) was added at room temperature. After 24 h the solution was poured into ice water; a crystalline material separated after a few min. The product (0.61 g) was recrystallized from ether to give crystals which had m.p. 129–129.5° and $[\alpha]_D = +84°$ (*c*, 1.73 in chloroform containing 0.75% ethanol). The infrared spectrum in (KBr) showed absorption at 1 600 cm^{-1} attributable to an aromatic ring, and an amide I band at 1 653 cm^{-1}, but no absorption attributable to *OH*, nor an amide II band.

Anal. Calcd. for $C_{16}H_{21}O_6NS$: C, 54.07; H, 5.96; N, 3.94. Found: C, 53.86; H, 5.76; N, 4.05.

*1,2-O-Isopropylidene-5-O-p-tolylsulfonyl-*D*-xylose (XIV)*

This compound was prepared from D-xylose (33 g) by the method of Levene and Raymond (14). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

crystalline product (44 g, 58)% was recrystallized from ethyl acetate and it then melted at 133–134° and had $[\alpha]_D = -12.4°$ (*c*, 2.9 in chloroform containing 0.75% ethanol). Levene and Raymond report m.p. 133–134° and $[\alpha]_D^{20} = -13.0°$ (*c*, 2.0 in chloroform).

*5-Azido-5-deoxy-1,2-O-isopropylidene-*D*-xylose (XV)*

To a solution of 1,2-*O*-isopropylidene-5-*O*-*p*-tolylsulfonyl-D-xylose (14.0 g) in *N*,*N*-dimethylformamide (125 ml) was added water (6.5 ml), sodium azide (3.4 g), and urea (0.25 g). The mixture was heated overnight at 110° under a stream of nitrogen. The cooled solution was poured into 150 ml of ice water and extracted with chloroform. The combined extracts were washed with aqueous sodium hydrogen carbonate, then with water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to leave a yellow syrup (9.2 g) which appeared as one spot on a thin-layer chromatogram run in methanol:benzene, 1:9 (v/v). This syrup was crystallized from chloroform:*n*-hexane, ca. 1:15 (v/v), as long needles. A further recrystallization gave material of m.p. 58.5–60° and $[\alpha]_D^{21} = 44°$ (*c*, 1.55 in methanol). The infrared spectrum in chloroform showed absorption at 3 480 cm^{-1} attributable to *OH*, a doublet of approximately equal intensity at 1 382 and 1 391 cm^{-1} caused by an isopropylidene grouping, and strong absorption at 2 115 cm^{-1} caused by an azide group, but no aromatic absorptions.

Anal. Calcd. for $C_8H_{13}O_4N_3$: C, 44.64; H, 6.09; N, 19.53. Found: C, 44.66; H, 6.07; N, 19.62.

*5-Acetamido-5-deoxy-1,2-O-isopropylidene-*D*-xylose (XVI)*

To a solution of 5-azido-5-deoxy-1,2-*O*-isopropylidene-D-xylose (2.0 g) in methanol (60 ml) was added Raney nickel (35 g). The mixture was shaken mechanically overnight, fresh catalyst (10 g) was added, and, after it was shaken for an additional 4 h, the solution was filtered and concentrated under reduced pressure to give a crystalline product (1.1 g). This material could be readily recrystallized from ether. A sharp melting point was not obtained, however, but rather the crystals started to soften at 104° and finally melted at 107.5–109°. The substance is hygroscopic, and satisfactory analytical results were not obtained. The infrared spectrum in chloroform showed absorption at 3 350 cm^{-1} attributable to *OH* and *NH* and absorption at 1 382 and 1 392 cm^{-1} caused by an isopropylidene grouping, but was devoid of azide absorption.

A portion (0.95 g) of the crystalline compound obtained above was dissolved in water (7.7 ml) and treated with acetic anhydride (1.1 ml). The solution was allowed to stand for 20 min with occasional shaking, then was concentrated under reduced pressure to leave a light brown syrup (0.98 g) which crystallized on standing. Recrystallization from chloroform–hexane–ether gave rectangular plates with the same melting point and infrared spectrum as those of the previously reported (15) 5-acetamido-5-deoxy-1,2-*O*-isopropylidene-D-xylose.

*5-Acetamido-5-deoxy-*D*-xylose Diethyl Dithioacetal (XVII)*

5-Acetamido-5-deoxy-1,2-*O*-isopropylidene-D-xylose (0.4 g) was suspended in ice-cold concentrated hydrochloric acid (2.8 ml). Cold ethanethiol (2.8 ml) was then added, and the mixture was stirred in an ice-water bath for 7 h and finally left to stand in a refrigerator overnight. The mixture was then diluted with cold methanol and neutralized with lead carbonate and filtered, and the filtrate concentrated under reduced pressure to leave a clear colorless syrup which crystallized immediately (0.4 g, 78%). This material was recrystallized from methanol–ether to give white glistening crystals which had m.p. 106–107°, $[\alpha]_D^{23} = 0°$ (*c*, 2.50 in methanol), and R_{rh} 2.3 (solvent A, spray iii and iodine vapor). The infrared spectrum in chloroform showed absorption at 3 460 cm^{-1} attributable to *OH* and *NH*, an amide I band at 1 662 cm^{-1} and an amide II band at 1 525 cm^{-1}.

Anal. Calcd. for $C_{11}H_{23}O_4NS_2$: C, 44.4; H, 7.80; N, 4.71. Found: C 44.33; H, 7.85; N, 4.73.

Sulfone Degradation

To a solution of 5-acetamido-5-deoxy-D-xylose diethyl dithioacetal (0.30 g) in dioxane (5 ml) was added, dropwise with shaking, peroxypropionic acid (25) (15% excess over the required 4 molar equivalents) over a period of 10 min. The solution was allowed to stand for 10 min and then cooled in ice for 1 h. The clear solution was then concentrated under reduced pressure to a syrup which was repeatedly dissolved in methanol and reconcentrated until only traces of peroxypropionic acid remained. The syrup was dried over potassium hydroxide in a desiccator to yield a colorless glass (0.38 g), the infrared spectrum (chloroform) of which showed amide bands at 1 653 and 1 545 cm^{-1}. Spray iii showed the presence of only one component at R_{rh} 2.02 (solvent A).

The preceding product (0.33 g) was dissolved in dilute aqueous ammonia (5 ml, pH 8–9). After 5 min the pH fell to 5 and was restored with more ammonia solution. Paper chromatography indicated that degradation was nearly complete in 5 h. The solution was allowed to stand at room temperature overnight. A small amount of a fine precipitate appeared which was removed by filtration. The pH of the filtrate was adjusted to 3–4 with dilute acetic acid, and the solution was then passed through Amberlite IR-120 (H form) and Duolite A-4 (OH form) ion exchange resins. The eluate was extracted three times with chloroform, and the combined extract was dried over anhydrous magnesium sulfate and concentrated under reduced pressure to yield a white solid (0.087 g). After recrystallization from water this material melted at 101–102°, and showed no depression on the melting point on admixture with an authentic sample of bis-(ethylsulfonyl)-methane. The aqueous phase was concentrated under reduced pressure to leave a syrup (0.10 g) whose infrared and

n.m.r. spectra and chromatographic properties were the same as those of the product from the lead tetraacetate oxidation.

Hydrolysis of Methyl 4-Acetamido-4-deoxy-L-erythrofuranoside (I)

An aqueous solution (25 ml) of methyl 4-acetamido-4-deoxy-L-erythrofuranoside (I) (0.094 g), purified through the di-*O*-acetyl derivative (1), was stirred with 1 g of Amberlite IR-120 (H form) resin at 60° for 1 h. The resin was then removed by filtration, and the filtrate was shaken briefly with a small amount of Duolite A-4 (OH) form) resin to remove any trace of acid. The resin was removed, and the solution was concentrated under reduced pressure to leave an almost colorless syrup (0.075 g) which was examined on paper chromatograms. Sprays i, ii, and iii showed the presence of components at R_{rh} 1.00 and 1.18 (solvent A). In solvent B an elongated spot at R_{rh} 1.12 (possibly two spots) was detected. Two spots were detected also by thin-layer chromatography in 2-propanol:benzene, 1:2 (v/v). The syrup was reducing towards Fehling's solution and had $[\alpha]_D^{24} = -6.6°$ (*c*, 1.54 in methanol). The infrared spectrum of this material (smear between "IRTRAN-2" plates) showed strong absorption at 3 360 cm^{-1} (*OH*) and a very broad band at 1 617 cm^{-1} (*N*-Ac). Attempts were made to separate the two components by preparative paper chromatography using solvents A and B. The zones were located (spray i), cut, and extracted with methanol. Examination of the extracts on paper chromatograms still showed in every case the presence of the two original components.

Periodate Oxidations

The compound under examination (10–15 mg) was dissolved in water containing 0.3 *M* sodium metaperiodate solution (1 ml). The total volume was made up to 25 ml with additional water. A blank experiment was carried out at the same time. The oxidation was carried out in the dark and at room temperature. Formic acid yield and periodate uptake were determined in the usual fashion (26). The results are summarized in Table I.

TABLE I

Periodate oxidations

	(*a*) "4-Acetamido-4-deoxy-D-threofuranose"

6-Acetamido-6-deoxy-D-galactose Diethyl Dithioacetal (XIX)

A solution of 6-acetamido-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (VIII) (7.7 g) in concentrated hydrochloric acid (45 ml) at 0 °C was stirred with ethanethiol (45 ml) for 12 h at 0 °C. The mixture was then diluted with cold methanol and neutralized with an excess of lead carbonate. The solution was filtered and concentrated under reduced pressure to a volume of about 100 ml, whereupon a white crystalline material separated from solution (5.0 g). This solid was recrystallized from methanol–ether to give crystals which had m.p. 182.5–184°, $[\alpha]_D = +16.6°$ (*c*, 1.00 in methanol), and R_{rh} 2.18 (solvent A, spray iii, and iodine vapor). The infrared spectrum (Nujol mull) showed strong absorption at 3 270 cm^{-1} attributable to *OH* and *NH*, and amide I band at 1 645 cm^{-1} and an amide II band at 1 564 cm^{-1}.

Anal. Calcd. for $C_{12}H_{25}O_5NS_2$: C, 44.0; H, 7.64; N, 4.28. Found: C, 44.2; H, 7.82; N, 4.68.

6-Acetamido-2,3,4,5-tetra-O-acetyl-6-deoxy-D-galactose Diethyl Dithioacetal (XX)

A solution of 6-acetamido-6-deoxy-D-galactose diethyl dithioacetal (4.7 g) in dry pyridine (100 ml) was cooled in an ice-water bath and treated with acetic anhydride (28 ml). The clear colorless solution was left to stand in a refrigerator for 22 h, then at room temperature for 1 h and poured into ice water (800 ml), and the mixture extracted several times with chloroform. The combined extracts were washed with water, then shaken with an aqueous solution of cadmium chloride. The pyridine – cadmium chloride complex was filtered, and the chloroform solution was washed with water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to leave a white crystalline material (6.9 g, 97%). Two recrystallizations from methanol–water gave crystals which melted at 131°, and had $[\alpha]_D = 84°$ (*c*, 1.73 in chloroform containing 0.75% ethanol). The infrared spectrum in chloroform showed *NH* stretching vibration at 3 430 cm^{-1}, absorption at 1 743 cm^{-1} caused by *O*-acetyl groups, an amide I band at 1 675 cm^{-1}, and an amide II band at 1 520 cm^{-1}.

Anal. Calcd. for $C_{20}H_{33}O_9NS_2$: C, 48.48; H, 6.71. Found: C, 48.36; H, 6.53.

Demercaptalation of 6-Acetamido-2,3,4,5-tetra-O-acetyl-6-deoxy-D-galactose Diethyl Dithioacetal

6-Acetamido-2,3,4,5-tetra-*O*-acetyl-6-deoxy-D-galactose diethyl dithioacetal (1 g) was dissolved in acetone (14 ml). Water (6 ml) and an excess (2 g) of cadmium carbonate were added, and under rapid stirring a

For personal use only.

solution of mercuric chloride (1.96 g, 3.6 moles) in acetone (8 ml) was gradually added. Stirring was maintained at room temperature for 24 h with occasional additions of cadmium carbonate. The solution was then filtered, an excess of fresh cadmium carbonate being placed in the suction flask, and the precipitate was washed with acetone. The filtrate and washings were then concentrated under reduced pressure (water bath temperature 35°) and in the presence of excess cadmium carbonate. The residue was extracted several times with warm chloroform; the combined extracts were then cooled and filtered. The chloroform filtrate was washed with water, with aqueous solution of potassium iodide and again with water. The chloroform solution was dried over anhydrous magnesium sulfate and concentrated under reduced pressure to leave a thick syrup (0.35 g). Thin-layer chromatography of this material in 2-propanol:benzene, 1:2 (v/v), showed an elongated spot (possibly two spots) which moved at a slower rate than the starting material. The syrupy product crystallized on contact with ether. The ether was evaporated and the crude product was dissolved in acetone:ether, 2:1 (v/v); hexane was then added to opalescence. The crystals (XXI) which separated (0.10 g) reduced Fehling's solution on heating and migrated as a single spot with slight tailing on a thin-layer chromatogram. The mother liquors had trace quantities of two faster moving components. The crystals did not melt sharply, but rather started to soften at 90° and finally melted at 116°. The infrared spectrum (Nujol mull) showed strong absorption at 3 400 cm^{-1} attributable to *OH*, absorption at 1 753 cm^{-1} caused by *O*-acetyl groups, an amide I band at 1 663 cm^{-1}, and an amide II band at 1 553 cm^{-1}.

Attempted Cyclization of XXI

The preceding product XXI (0.072 g) was allowed to stand in dry pyridine (5 ml) for 24 h at room temperature. In a few hours the solution assumed a yellow color and finally darkened to orange. The solution was then cooled in an ice bath and treated with acetic anhydride (0.75 ml). After 1 h at 0° and at room temperature overnight, the solution was poured into ice water, and the product extracted with chloroform. The extract was washed with water, then shaken with an aqueous solution of cadmium chloride. The pyridine – cadmium chloride complex was filtered off, the chloroform filtrate washed with water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to leave a slight brown syrup (0.026 g). This material was distilled under vacuum to yield a yellow syrup. Thin-layer chromatography in 2-propanol:benzene, 1:2 (v/v), showed the presence of only one component which migrated faster than XXI. The infrared spectrum in chloroform showed weak absorption at 3 525 cm^{-1} attributable to *NH* stretching vibrations, strong absorption at 1 757 cm^{-1} caused by *O*-acetyl groups, an amide I band at 1 685 cm^{-1}, and an amide II band at 1 528 cm^{-1}.

ACKNOWLEDGMENTS

The authors thank the National Research Council for a grant (N.R.C. T-19) which made this work possible, and for a scholarship (to W. A. S.). They also wish to thank Miss Anne P. Fletcher for excellent technical assistance during the summers of 1963 and 1964.

SUR LE SPECTRE INFRAROUGE DE SO_2 À HAUTE TEMPÉRATURE

PAUL A. GIGUÈRE ET RODRIGUE SAVOIE
Département de Chimie, Université Laval, Québec, Québec
Reçu le 8 mars 1965

ABSTRACT

The infrared spectra of SO_2 have been recorded both in absorption and emission over the range 400 to 3 000 cm^{-1} at atmospheric pressure and at temperatures up to 700 °C. Two weak bands were found at 1 075 and 1 290 cm^{-1} which represent a downward shift of some 75–80 cm^{-1} from the fundamental stretching vibrations of the SO_2 molecule. They cannot fit the hypothetical isomer SOO, suggested sometime to account for the perturbations in the ultraviolet spectrum at high temperature. Other possibilities, such as "hot" bands involving a low-lying, electronically excited state of SO_2 are discussed. A third, very weak band at about 680 cm^{-1}, detected in emission only, must be due to the formation of traces of disulfur monoxide S_2O.

RÉSUMÉ

On a mesuré en absorption et en émission le spectre infrarouge de SO_2 entre 400 et 3 000 cm^{-1} à pression atmosphérique et à des températures allant jusqu'à 700 °C. Deux faibles bandes sont apparues à 1 075 et 1 290 cm^{-1}, soit à quelque 75–80 cm^{-1} de moins que les vibrations de valence de SO_2. Elles ne sauraient provenir d'un isomère hypothétique SOO, invoqué parfois comme cause des perturbations dans le spectre ultraviolet à haute température. On discute la possibilité d'un état électronique excité, mais relativement bas, de la molécule SO_2. Une troisième bande, très faible, à 680 cm^{-1}, décelée en émission seulement révèle la formation de traces d'hémioxyde S_2O.

INTRODUCTION

On sait depuis longtemps déjà (1) que le spectre ultraviolet de SO_2 subit des transformations importantes à des températures au-dessus de 450 °C. Ces dernières années diverses études de spectroscopie cinétique ont confirmé et précisé la nature de ces transformations. Ainsi Norrish et Zeelenberg (2) ont remarqué que dans la photolyse éclair de SO_2, le spectre d'absorption dans le proche ultraviolet s'effaçait temporairement pour réapparaître graduellement sur une période de plusieurs millisecondes. Un phénomène semblable a été noté par Myerson et ses collaborateurs (3) dans les explosions de mélanges de CS_2 et O_2. L'apparition du spectre électronique de SO_2 était d'abord masquée par une absorption continue à partir de 2 100 Å apparemment causée par quelque intermédiaire. Après avoir écarté la possibilité d'un état excité de SO_2, à cause de la vie moyenne relativement trop longue (10^{-2} s) de cet intermédiaire, ces auteurs en ont conclu à l'existence d'un isomère de formule probable SOO. Par ailleurs Norrish et Oldershaw (4) ont montré que l'absorption continue résultant de la photolyse éclair est un phénomène thermique et non photochimique. Sans se prononcer sur la nature de l'intermédiaire ils admettent la possibilité d'une forme isomère de la molécule. Enfin plus récemment McGarvey et McGrath (5) ont poussé l'examen spectroscopique des réactions de combustion de H_2S et CS_2 jusque dans l'ultraviolet lointain; ils sont observé un nouveau spectre transitoire dont la structure fine pourrait d'après eux s'interpréter selon le spectre de vibration de l'isomère hypothétique SOO.

Etant donné que ces phénomènes sont d'origine thermique et qu'ils apparaissent déjà à des températures de l'ordre de 500 °C, ils nous a semblé utile de les étudier en système statique par spectroscopie infrarouge. En effet, l'isomère mentionné plus haut devrait avoir un spectre de vibration passablement différent de celui de SO_2 normal. Ce travail

préliminaire (6) a également montré que l'émission produite par SO_2 au-dessous de 500° est suffisamment intense pour être enregistrée avec un spectromètre infrarouge conventionnel.

MÉTHODE EXPÉRIMENTALE

Du point de vue expérimental la principale difficulté résidait dans la construction d'une cellule d'absorption appropriée. En effet, cette cellule devait permettre de chauffer l'échantillon de gaz de façon aussi uniforme que possible, et jusqu'à des températures de l'ordre de 700 °C. De plus, elle devait être relativement étanche et inerte vis-à-vis de SO_2, assez longue pour réaliser une absorption mesurable, même aux plus hautes températures, et enfin transmettre l'infrarouge jusqu'à 20 μ. Ces objectifs ont put être assez bien satisfaits, sauf pour ce qui est de l'étanchéité. Le corps de la cellule se composait d'un tube de Pyrex (Fig. 1) de quelque 13 cm de long et 25 mm de diamètre, portant deux tubulures latérales, l'une de diamètre moyen (3 mm) pour l'entrée du gaz, l'autre, capillaire, pour la sortie. Les fenêtres étaient des disques de NaCl ou KBr, selon la région étudiée. Faute de trouver un matériau de garniture à la fois souple et réfractaire pour étancher le joint, les fenêtres ainsi que les extrémités du tube d'absorption ont été polies pour donner des surfaces de contact aussi planes que possible. Les fenêtres elles-mêmes étaient protégées par des manchons de verre pouvant glisser à frottement doux sur le tube central et son prolongement. Le tout était maintenu ensemble sous faible pression par quatre minces tiges d'acier munies de ressort à un bout.

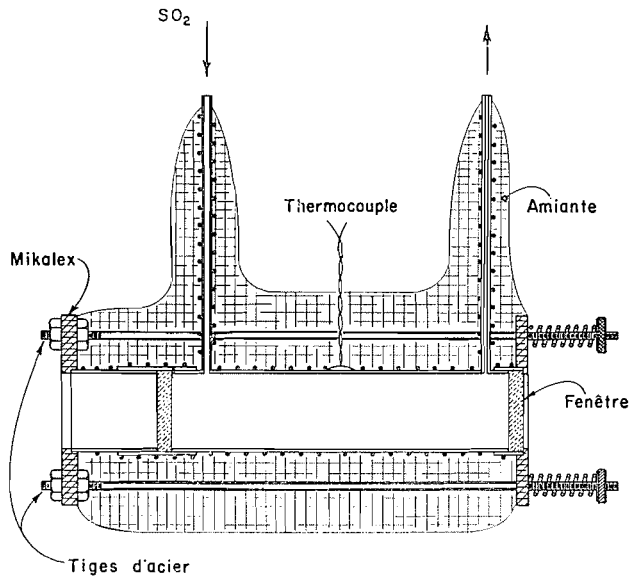

FIG. 1. Cellule d'absorption infrarouge pour les gaz à haute température.

La cellule était chauffée électriquement par un enroulement de fil de résistance (Chromel "A") de 25 Ω (environ 4.5 m) recouvert de plusieurs tours de ruban d'amiante tressé. Ce dernier avait au préalable été flambé pour éliminer le liant qui brûle à haute température et dégage des vapeurs qui auraient pu nuire à l'enregistrement des spectres. Pour atteindre un maximum de 700 °C il fallait un courant de près de 2 A sous 75 V; le chauffage devait se faire très graduellement (jusqu'à 1.5 h) pour éviter l'éclatement des fenêtres de sel. Pour cette même raison, et aussi pour empêcher les courants de convection trop violents à l'intérieur de la cellule, la température des fenêtres était maintenue assez près de celle de la cellule même. A cette fin le manchon de chauffage avait été prolongé de quelque 3 cm à une extrémité, tandis que l'autre fenêtre était montée tout près de la source (Globar) du spectromètre.

La température était mesurée à l'aide d'un petit thermocouple fer–constantan fixé sur la paroi externe du tube d'absorption, et un potentiomètre de précision (Leeds and Northrup, modèle 8662). Le thermocouple avait été calibré au point d'ébullition de l'eau ainsi qu'au point de fusion de l'étain (232 °C) et du zinc (419.5 °C). On avait également vérifié que la température à l'intérieur de la cellule était uniforme partout à 10 deg près, de sorte que la limite d'erreur sur les valeurs données ici ne dépasse pas 3%.

Le bioxyde de soufre (Mathieson 99.7% min.) passait directement de la bouteille à la cellule sans purification préalable. Le courant gazeux sortant de la cellule circulait à travers un flacon laveur contenant de

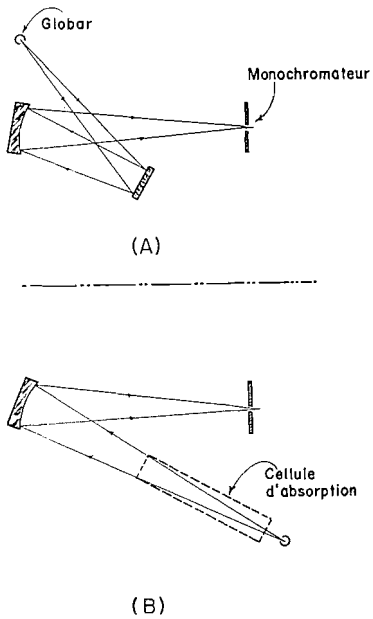

FIG. 2. Schéma du montage optique original (A) et modifié (B) du spectromètre infrarouge.

'lacide sulfurique concentré et se condensait ensuite dans un piège à carboglace. Le débit du gaz était ajusté à peu près à une bulle par seconde à travers un tube de 3 mm de diamètre intérieur. Des traces de SO_2 parvenaient toujours à s'échapper de la cellule autour des fenêtres, ce qui a necessité une ventilation très active au-dessus de l'appareil. Le spectromètre (Perkin–Elmer, modèle 12-C, avec prismes de NaCl ou de CsBr) a dû être légèrement modifié (Fig. 2) pour accommoder la cellule.

RÉSULTATS

Quelques spécimens des spectres obtenus sont reproduits dans la Fig. 3 à côté du spectre d'absorption de SO_2 à température ordinaire pour fin de comparaison. Ce dernier est tiré du travail de Pierson, Fletcher et Gantz (7). On sait que les fréquences fondamentales de la molécule sont $\nu_1 = 1\,151.38$, $\nu_2 = 517.69$ et $\nu_3 = 1\,361.76$ cm^{-1} (8). A haute température, la densité du gaz étant naturellement moindre, l'absorption infrarouge s'en trouvait diminuée d'autant. De plus l'émission sélective par le gaz contribuait à réduire davantage l'intensité apparente des bandes d'absorption. En effet, il était malheureusement impossible de séparer ces deux phénomènes avec notre système optique vu la position, juste en avant du thermocouple, de l'interrupteur de faisceau. De façon générale on vois que les bandes sont élargies par l'agitation thermique; ainsi on ne peut plus discerner let branches P et R des deux bandes de valence même lorsque l'absorption ne dépasse pas 50%. Quant à la bande de déformation, son intensité est considérablement réduite et son contour mal défini, bien que le maximum (vers 520 cm^{-1}) ne soit pas déplacé de façon notable. Phénomène tout à fait inattendu, deux nouvelles bandes apparaissent à ces températures: l'une assez faible, mais très nette à 1 075 cm^{-1}, l'autre qui se confond avec la bande ν_3 de SO_2, et dont le maximum doit correspondre assez bien au minimum à 1 290 cm^{-1} dans le spectre à température ordinaire.

En émission les bandes de valence S—O ont *grosso modo* la même allure qu'en absorption, sauf que la bande additionnelle à 1 290 cm^{-1} se détache bien de la fondamentale ν_3, et la bande de déformation est beaucoup plus intense. Ses branches P et R sont maintenant

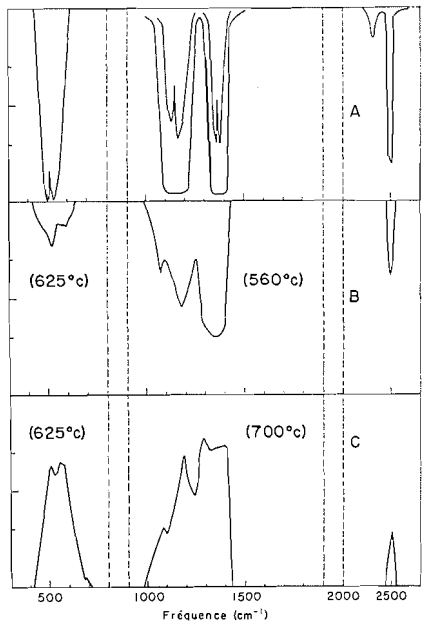

FIG. 3. Spectres infrarouges de SO_2. A. Absorption à température ordinaire (7). B. Absorption à température élevée. C. Emission.

bien visibles, et leur séparation au maximum, 505–560 cm^{-1}, est nettement plus large qu'en absorption à température ordinaire à cause, entre autre, du déplacement de population vers les niveaux de rotation supérieurs. Enfin, du côté des hautes fréquences le contour semble indiquer un pic additionnel à 620–640 cm^{-1} (tout comme en absorption quoique moins nettement) en plus d'un faible épaulement vers 680 cm^{-1} au pied de la bande principale. A propos des intensités relatives des bandes rapportées ici il convient de noter que, outre le fait que dans nos expériences l'absorption et l'émission par l'échantillon s'annulaient en partie, d'où l'impossibilité de mesures quantitatives de l'intensité en fonction de la température, l'énergie admise par la fente dans le monochromateur était contrôlée, en émission comme en absorption, par un servomécanisme basé sur le rayonnement du corps noir.

Une dernière observation faite au cours de ce travail a trait aux fenêtres de sel de la cellule d'absorption qui finissaient par se couvrir d'une fine poudre blanchâtre sous l'action de SO_2 à chaud. Le spectre d'absorption de cette poudre pris une fois les fenêtres refroidies a montré deux bandes de faible intensité à 1 110 et 640 cm^{-1} et deux autres encore beaucoup plus faibles à 1 045 et 965 cm^{-1} attribuables à des sulfites et des bisulfates (9). Comme ces bandes ne se formaient que très lentement, il était assez facile d'écarter cette cause d'erreur en repolissant les fenêtres périodiquement.

DISCUSSION

Plusieurs possibilités sont à considérer pour rendre compte des nouvelles bandes. D'abord la formation à haute température de quelque composé à partir des impuretés contenues dans le gaz SO_2 semble fort peu probable étant donné la faible concentration (moins de 0.3%) et la nature de celles-ci (O_2, N_2 et SO_3). De même on peut écarter toute réaction avec les gaz atmosphériques vu que SO_2 était sous une légère surpression dans la cellule.

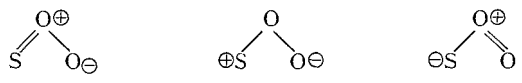
Autres oxydes de soufre

Des divers oxydes de soufre connus, et dont certains sont sans doute présents, du moins en traces, dans notre système, aucun n'a un spectre de vibration correspondant aux nouvelles bandes. Ainsi l'hémioxyde S_2O, dont la formation a déjà été rapportée dans la photolyse éclair de SO_2 (4), et se trouve confirmée ici par la faible bande d'émission vers 680 cm^{-1}, possède deux autres vibrations fondamentales à 1 165 cm^{-1} (10), donc submergée par la forte bande de SO_2, et à 387 cm^{-1} (11) au-delà de la région couverte ici. Le monoxyde SO, qui lui aussi est produit dans la photolyse éclair de SO_2 (2, 4), n'a évidemment qu'une seule vibration fondamentale dont la fréquence est de 1 138 cm^{-1} d'après l'analyse de Norrish et Oldershaw (4). Quant au trioxyde SO_3, ses bandes infrarouges se confondent assez bien avec celles de SO_2 (13). Deux de ses fréquences fondamentales à 1 271 et 1 068 cm^{-1} appartiennent à des modes symétriques, et donc ne sont actives qu'en Raman (14), bien que la dernière ait été signalée dans le spectre infrarouge du liquide (15) sans doute à cause des interactions moléculaires.

L'isomère hypothétique SOO

Qualitativement la grande stabilité thermique (16) de SO_2 milite contre l'hypothèse d'un isomère quelconque. La formule SOO proposée par Myerson pour cet isomère apparaît également assez improbable du point de vue des théories de la valence. En effet, la liaison O—O devrait être passablement plus faible que les liaisons S—O dans SO_2. Des trois formules canoniques que l'on peut imaginer, seule la première contribuerait de façon



I II III

appréciable à la structure de cet isomère, car la seconde ne donne pas un octet à l'atome de soufre, tandis que la troisième conduit à une séparation de charges formelles sur le soufre et l'oxygène médian à l'encontre de leur électronégativité respective (2.5 et 3.5 selon l'échelle de Pauling). D'ailleurs on ne connaît à peu près pas d'exemple de molécule triatomique ABC dont l'atome médian soit notablement plus électronégatif que l'un des deux autres. Enfin l'existence d'orbitales d sur l'atome de soufre, qui participent effectivement aux liaisons π dans la molécule SO_2 (17), favorise sa position au milieu de la molécule.

Malgré que l'isomère hypothétique SOO soit peu favorisé des points de vue thermodynamique et structure électronique, on peut quand même spéculer sur la nature de son spectre moléculaire. La vibration de valence S—O devrait se situer dans la même région que celles de SO_2. Par contre la liaison O—O étant essentiellement simple, sa fréquence de vibration devrait être de l'ordre de 900 cm^{-1} (v.g. 880 cm^{-1} dans H_2O_2). Or cette région était parfaitement libre dans nos spectres; pas la moindre absorption n'y a été décelée en aucun cas.

État excité de SO_2

La possibilité d'un état excité de SO_2 a déjà été considérée (3, 5) pour expliquer les modifications dans le spectre ultraviolet au cours de la photolyse éclair; c'est-à-dire l'apparition d'un continuum à partir de 3 000 Å et un nouveau système de bandes entre 1 840 et 1 740 Å (5). Cette hypothèse a dû être écartée à cause de la vie moyenne beaucoup trop longue de cette espèce (représentée par la formule $[SO_2]$) soit quelques millisecondes. Mais il se peut que cette valeur soit fictive et ne dépende que du taux de refroidissement du gaz après la photolyse. Il est également possible que la même espèce moléculaire $[SO_2]$ soit à l'origine, et des spectres supposés transitoires en ultraviolet, et des nouvelles

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

bandes de vibrations rapportées ici; d'autant plus que les deux phénomènes apparaissent vers la même température. Cependant la nature de l'excitation de [SO_2] soulève de sérieuses difficultés. En effet, elle ne saurait être d'origine vibrationnelle vu le décalage considérable des fréquences observé ici. Le spectre de vibration de SO_2 ne révèle qu'une anharmonicité assez faible (8), de l'ordre de quelques cm^{-1}, comme on peut s'y attendre.

D'autre part l'existence d'un niveau électronique excité qui serait suffisamment bas pour être peuplé de façon appréciable déjà vers 750–800 °K semble assez problématique au premier abord. La transition correspondante devrait apparaître dans le proche infrarouge, à moins qu'elle ne soit interdite. Dans son analyse de la structure électronique de SO_2, Walsh (18) a conclu à l'existence d'une première transition

$$.. (a_2'')^2 (b_2')^2 (a_1') (b_1'') \, {}^1B_1 \leftarrow ..... (a_2'')^2 (b_2')^2 (a_1')^2 \, {}^1A_1 ..$$

Or cette transition est permise et elle devrait donner en ultraviolet un système de bandes perpendiculaires. En outre elle conduirait à une légère augmentation, et de l'angle au sommet, et de la longueur des liaisons S—O. Il est vrai que les décalages rapportés ici sont bien dans ce sens; ils correspondent à un allongement de quelque 0.03 Å de ces liaisons d'après la règle de Badger.

CONCLUSIONS

Les résultats de ce travail préliminaire sont intéressants, mais forcément incomplets. En particulier ils ne permettent pas d'identifier l'espèce moléculaire responsable des nouvelles bandes infrarouges, et peut-être aussi, des anomalies dans les spectres électroniques de SO_2 à haute température. Il apparaît cependant que l'hypothèse d'un isomère de formule SOO doive être écartée. Nous nous proposons de poursuivre cette étude avec un appareil différent de façon a pouvoir distinguer entre l'absorption et l'émission. Il serait également souhaitable de reprendre les mesures de Wieland (1) sur les spectres ultraviolets à température élevée en système statique. Notons enfin qu'une situation analogue semble exister dans le cas du composé SeO_2. Ainsi la fluorescence jaune-verdâtre qui apparaît en chauffant au-dessus de 300 °C (19) a peut-être la même origine que les nouvelles bandes décelées récemment à la même température en infrarouge (20).

THE MAGNETIC ANISOTROPY OF THE CARBONYL BOND

D. L. Hooper and R. Kaiser

Departments of Chemistry and Physics, University of New Brunswick, Fredericton, New Brunswick

Received September 21, 1964

ABSTRACT

The magnetic susceptibility components of the carbonyl bond have been determined from chemical shift differences in the n.m.r. spectra of amides. Correction of the experimental chemical shift differences for the effect of internal electric fields is found to overestimate the shielding of groups close to the carbonyl bond and it is shown that the sets of susceptibility components determined without this correction give a satisfactory correlation of structure and chemical shifts in amides, α,β-unsaturated ketones, and exo-methylene cycloketones.

Four sets of susceptibility components are derived from formamide or acetamide spectra and depending on whether the effect of the carbonyl bond is assumed to be shielding or deshielding. These sets are, in units of 10^{-6} cm^3 mole^{-1}:

	$\chi_{xx}^{C=O}$	$\chi_{yy}^{C=O}$	$\chi_{zz}^{C=O}$
From acetamide spectra			
Shielding assumed	18	−14	−19
Deshielding assumed	−38	0.6	23
From formamide spectra			
Shielding assumed	0.5	−9	−7
Deshielding assumed	−12	−0.7	−3

Spectra of 1-ethylpyrrolidinone-2 are interpreted as showing that the effect of the carbonyl bond is to shield distant protons in the plane of the carbonyl group and its substituents.

INTRODUCTION

A knowledge of the anisotropy of the magnetic susceptibility of the carbonyl bond is of importance in the interpretation of the nuclear magnetic resonance (n.m.r.) spectra of large molecules (1). If the bond lengths and bond angles of a molecule are known, the contribution of each magnetically anisotropic bond to the chemical shift of protons in the molecule may be calculated (2). Conversely, Narasimhan and Rogers (3) determined the magnetic susceptibility components of the carbonyl bond from measured chemical shift differences in the n.m.r. spectra of amides.

When the susceptibility components determined by Narasimhan and Rogers are used to calculate chemical shift differences in some of the substituted acetamides discussed below, the results differ considerably from experimental values. A similar discrepancy between calculated and observed chemical shifts has been reported for the exo-methylene protons of α-methylene cycloketones (4, 5). We wish to report the results of an investigation which had as its aim the determination of susceptibility components suitable for the calculation of chemical shift differences in a variety of molecules containing carbonyl bonds.

THEORY

The effect of the magnetic anisotropy of the carbonyl bond on the screening constants $\sigma(A)$ and $\sigma(B)$ of protons H_A and H_B of a substituted acetamide (Fig. 1) is given by the theory of Narasimhan and Rogers in the form

$$[1]\qquad 3L_0(\sigma(A) - \sigma(B)) = f_1(\varphi_A,\varphi_B)\chi_{xx}^{C=O} + f_2(\varphi_A,\varphi_B)\chi_{yy}^{C=O} + f_3(\varphi_A,\varphi_B)\chi_{zz}^{C=O} + f_4(\varphi_A,\varphi_B)\Delta\chi^{C-C}.$$

x, y, and z are the axes of a right-handed coordinate system with its origin at the point in the carbonyl bond at which a magnetic dipole is assumed to be induced. The system is

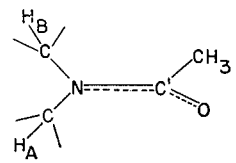

FIG. 1. Symmetrically disubstituted acetamide.

chosen such that the susceptibility tensor is diagonal, with z axis directed along the bond toward the oxygen atom, the y axis in the NC'O plane and directed away from the C'—CH_3 bond, and the x axis perpendicular to the NC'O plane. φ_A and φ_B are the rotation angles of the N-alkyl bonds with respect to the plane of the N-acetyl group. For a given choice of the origin of the coordinate system, the functions f_1, f_2, f_3, and f_4 are easily calculated from the known molecular geometry (6).

One of the four equations necessary to solve for the four unknowns $\chi_{xx}^{C=O}$, $\chi_{yy}^{C=O}$, $\chi_{zz}^{C=O}$, and $\Delta\chi^{C-C}$ was obtained from a recent quantum mechanical calculation (7) of the value of $\chi_{av}^{C=O}$, the mean bond susceptibility. For a carbonyl bond with bond order between 1 and 2, a reasonable value is $\chi_{av}^{C=O} = -5.0 \times 10^{-6}$ cm^3 mole^{-1} which leads to the equation

$$[2] \qquad \chi_{av}^{C=O} = \tfrac{1}{3}(\chi_{xx}^{C=O} + \chi_{yy}^{C=O} + \chi_{zz}^{C=O}) = -5.0 \times 10^{-6} \text{ cm}^3 \text{ mole}^{-1}.$$

Further simplification is obtained if the number of unknowns is reduced to three by treating $\Delta\chi^{C-C}$ (or $\Delta\chi^{C-H}$ for formamides) as a parameter with one of the many reported values (8–13). The remaining two equations must be obtained from experimental chemical shift differences between protons with known φ_A and φ_B values, i.e. from the spectra of molecules of known configuration. Such spectra normally show a pair of signals that may be assigned to hydrogen atoms A and B, but a decision on which signal arises from H_A and which from H_B is frequently ambiguous. Only the absolute value of the chemical shift difference can then be determined and thus the question of the sign of $(\sigma(A) - \sigma(B))$ arises. This is equivalent to the question of whether the effect of the carbonyl bond is shielding or deshielding. In Part A of the Results both possibilities are considered, while Part B discusses an experiment designed to permit a choice to be made.

EXPERIMENTAL

The n.m.r. spectra were obtained on a Varian V-4302 spectrometer operating at 56.4 Mc/s and equipped with a Varian temperature control assembly. The temperature at the sample was monitored by a copper–constantan thermocouple.

Five factors known to affect the chemical shifts of amide protons were initially taken into account in the planning and evaluation of the n.m.r. measurements: (i) interaction between amide molecules in solution (14), (ii) amide–solvent interactions (14), (iii) the averaging of chemical shifts caused by rotation of the central C'—N partial double bond (15), (iv) the possibility of structural differences between acetamides and formamides which is suggested by the differences in barriers to internal rotation (16), (v) the effect of internal electric fields arising from the polar structure of amides.

The first three factors were minimized by the extrapolation of chemical shift differences to the freezing point at infinite dilution in CCl_4. Factor iv was taken into account by considering separately the data for acetamides and formamides, and the electric field shift was estimated by means of the relation

$$[3] \qquad \sigma_E = 2 \times 10^{-12} E_z$$

derived by Buckingham (17) where σ_E is in p.p.m. and E_z is the component of the field at the H atom parallel to the C—H or N—H bond in electrostatic units.

RESULTS

Part A. Determination of the Susceptibility Components

The components of the carbonyl bond susceptibility in acetamides were determined from the chemical shift difference between the N—CH_3 groups in N,N-dimethylacetamide and that between the two sets of CH_2 protons α to the acetyl group in N-acetylpyrrolidine. Similarly, the carbonyl bond susceptibility components in formamides were determined from the corresponding chemical shift differences in N,N-dimethylformamide and N-formylpyrrolidine. The experimental chemical shift differences between the two N-substituents of these compounds are given in the second column of Table I. The values result from extrapolation of a series of measurements to low temperature and infinite dilution in CCl_4. The third column gives the electric field shift difference estimated by means of eq. [3]. E_z was assumed to be the sum of contributions originating from an electric dipole of moment 2.3 D located 1.20 Å from C′ on the axis of the C′=O bond, and from a point charge of −0.1 e located on the oxygen atom (18). Columns 4 and 5 give the difference between the experimental values in column 2 and the calculated electric field contribution in column 3, and this differential shift is assumed to be caused by the bond magnetic anisotropy. The anisotropy shift difference derived in this manner is seen to depend on whether the experimental values are taken as positive or negative, i.e. whether the signal of the A substituent is at higher or lower field respectively than that of the B substituent. The following computations were carried out for both choices.

TABLE I

Experimental chemical shift differences of amides in CCl_4 solution and electric field correction. All values are in p.p.m.

Compound		Experimental shift difference	$\sigma_E(A) - \sigma_E(B)$	Anisotropy shift difference: A at higher field	Anisotropy shift difference: B at higher field
1. N,N-Dimethylacetamide*	(CH_3)	±0.150	−0.024	+0.174	−0.126
2. N-Acetylpyrrolidine*	(CH_2)	±0.090	−0.088	+0.178	−0.002

TABLE II

Values of the orientation functions for substituted amides in units 10^{22} cm^{-3}

Compound		f_1	f_2	f_3	f_4
N,N-Dimethylacetamide	(CH_3)	1.72	−6.82	4.96	−7.09
N-Acetylpyrrolidine	(CH_2)	1.64	−8.08	6.33	−9.29
N,N-Dimethylformamide	(CH_3)	1.72	−6.82	4.96	−6.70
N-Formylpyrrolidine	(CH_2)	1.64	−8.08	6.33	−8.90
N-Acetylnortropine	(CH)	5.22	−15.78	10.54	−12.51
Formamide	(NH)	2.99	−7.82	4.84	−16.77

Table II shows the values of the orientation functions used in eq. [1]. The magnetic dipole was assumed to be induced on the C′=O bond at a point 1.20 Å from the carbon atom. This location was chosen because it is believed that the strong electronegativity of

oxygen places the electronic center of charge very near the oxygen nucleus. Free rotation of the methyl group was assumed for the N,N-dimethylamides, while for the pyrrolidine derivatives the values $\varphi_A = \varphi_B = 60°$ were substituted. Equation [1] was combined with eq. [2] for compounds 1 and 2 and separately for compounds 3 and 4 to solve for the three susceptibility components of acetamides and formamides separately, with $\Delta\chi$ as a parameter. Selected values of $\Delta\chi$ (8–13) were then substituted to obtain the results listed in columns 2, 3, and 4 of Tables III and IV.

TABLE III

Susceptibility components in units 10^{-6} cm^3/mole for acetamides and calculated anisotropy shift difference in p.p.m. for N-acetylnortropine for several values of $\Delta\chi^{C-C}$. Electric field correction applied

	$\Delta\chi^{C-C}$	$\chi_{xx}^{C=O}$	$\chi_{yy}^{C=O}$	$\chi_{zz}^{C=O}$	$\delta(A) - \delta(B)$	
A at higher field						
	1.21	+2.0	−10	−6.7	+0.48

	10.0	−51	+3.6	+32	−0.59	∩

TABLE IV

Susceptibility components in units 10^{-6} cm^3/mole for formamides and calculated anisotropy shift difference in p.p.m. for formamide for several values of $\Delta\chi^{C-H}$. Electric field correction applied

	$\Delta\chi^{C-H}$	$\chi_{xx}^{C=O}$	$\chi_{yy}^{C=O}$	$\chi_{zz}^{C=O}$	$\delta(A) - \delta(B)$	
A at higher field						
	−0.74	−13	−5.0	+3.2	+0.15	∩
	0	−14	−5.3	+4.1	+0.11	
	+0.48	−14	−5.4	+4.7	+0.08	
B at higher field						
	−0.74	−25	+3.0	+7.1	−0.29	∩
	0	−26	+2.8	+8.0	−0.33	
	+0.48	−26	+2.6	+8.6	−0.36	

In order to select an optimum set of values from those given in Tables III and IV, the anisotropy difference was calculated by means of eq. [1] for N-acetylnortropine (Fig. 2) and for formamide. Hydrogen atoms A and B in N-acetylnortropine have rotation angles $\varphi_A = \varphi_B = 0$ and the corresponding values of the orientation functions are included in Table II. When these calculated values in column 5 of Tables III and IV are compared with the corresponding anisotropy shift differences in Table I, it is seen that only a very poor agreement results. The optimum values are those marked ∩ in the last column.

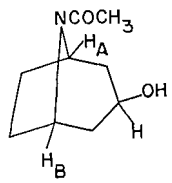

FIG. 2. N-Acetylnortropine.

It appears that the principal source of error is an overestimation of the electric field effect, especially at small values of φ_A and φ_B when the protons are close to the charges. The determination of the electric field shift by means of eq. [3] is apparently not very accurate at small distances although the field strengths are still small enough to make the quadratic term in Buckingham's equation (17) negligibly small in comparison with the linear term.

Better agreement between calculated and observed shift differences for N-acetylnortropine and formamide is obtained when the electric field effect is disregarded entirely, as was done by Narasimhan and Rogers (3). The entire experimental shift difference in column 1 of Table I is then assumed to be caused by the bond magnetic anisotropy. The resulting susceptibility components are listed in Tables V and VI, and the optimum values are marked ∪. It will be shown in the Discussion that these values are successful in the interpretation of the spectra of a variety of molecules.

Part B. Determination of the Sign of the Experimental Shift Difference

In Part A, both choices $\sigma(B) > \sigma(A)$ and $\sigma(A) > \sigma(B)$ were used in calculating susceptibility components. There is evidence for each choice. The argument of Narasimhan and Rogers (3) leads to the acceptance of only those sets which were calculated with the assumption that B is at higher field. It has been shown (19) that the largest contribution to the diamagnetic susceptibility of urea is directed perpendicular to the carbonyl bond, i.e. in the x direction. Pople (20) has postulated paramagnetic circulations in the plane of a carbonyl bond and its substituents. These ought to give a positive contribution to $\chi_{yy}^{C=O}$ and $\chi_{zz}^{C=O}$, while the results observed for urea indicate that $\chi_{xx}^{C=O}$ should be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

negative. Only the sets of components derived with the assumption that B is more shielded than A satisfy these requirements.

On the other hand, the opposite choice is favored by consideration of the magnitude of the long range spin couplings through the C—N partial double bond. The analogous long range coupling H—C=C—C—H has been analyzed (21) as the sum of a positive contribution $J(\sigma)$ through the σ-bond frame and a negative contribution $J(\pi)$ through the π electrons of the C=C double bond. The first part is different for the *cis* and *trans* configurations with $J(\sigma)_{trans} > J(\sigma)_{cis}$, while for the second part $J(\pi)_{trans} = J(\pi)_{cis}$. The magnitude of the total coupling constants $|J_{cis}|$ and $|J_{trans}|$ thus depends on the magnitude of $J(\pi)$, and if $|J(\pi)| < \frac{1}{2}(J(\sigma)_{cis} + J(\sigma)_{trans})$ then $|J_{trans}| > |J_{cis}|$. The magnitude of $J(\pi)$ may be expected to depend on the double bond character of the central bond, and this dependence may be the cause of the observed variation of the total coupling constants of amides in solvents of high dielectric constant (22). It appears permissible to assume that the double bond character of the central bond in amides is sufficiently small to warrant the conclusion that $|J_{trans}| > |J_{cis}|$. This conclusion is confirmed by recent work on unsymmetrically disubstituted amides (23) in which the spectral assignments based on the assumption $|J_{trans}| > |J_{cis}|$ were corroborated by the differential solvent shift in benzene (24). In all cases that allow observation of the long range coupling it is the signal at higher field that shows the stronger coupling. If $|J_{trans}| > |J_{cis}|$ this signal must be assigned to the group *cis* to the carbonyl group, i.e. the A substituent must be more shielded than the B substituent.

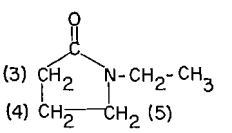

FIG. 3. 1-Ethylpyrrolidinone-2.

We have attempted to reach a decision between the two alternatives by means of the following experiment. In 1-ethylpyrrolidinone-2 (Fig. 3) the —CH_2— protons of the ethyl group and those on C_5 may be compared to the —CH_2— protons of ethyl groups *cis* and *trans* to the carbonyl bond of an acetamide. In the acetamide the two —CH_2— groups can be distinguished only by making an assumption about the relative magnitude of *cis* and *trans* coupling across the C—N partial double bond. However, in 1-ethylpyrrolidinone-2 they can be distinguished by the coupling patterns of their signals, a quadruplet being expected for —CH_2— protons of an ethyl group and a triplet for those on C_5. The relative positions of the centers of these multiplet signals enables us to decide which CH_2 group is more shielded.

The low field multiplets in the spectra of dilute solutions of 1-ethylpyrrolidinone-2 in CCl_4 and benzene are shown in Figs. 4*a* and 4*b* respectively. Figure 4*a* shows the expected seven peaks, but it is impossible to decide which four peaks are those of the quadruplet and which belong to the triplet. Figure 4*b* shows the strong separation of the quadruplet and triplet structures produced by benzene dilution of the compound. Since all four peaks of the quadruplet must be shifted identically by the change of solvent, as must the three peaks of the triplet, the peaks in the spectrum of the CCl_4 solution were assigned by the measurement of spectral positions of individual peaks in each spectrum. The peaks are labelled in order of increasing field strength in the spectrum of the benzene solution.

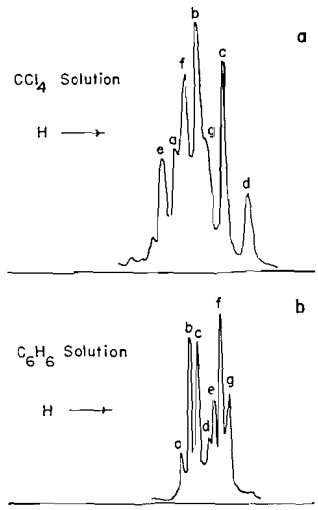

FIG. 4. (*a*) Low field peaks in the n.m.r. spectrum of 1-ethylpyrrolidinone-2 in CCl_4. (*b*) Low field peaks in the n.m.r. spectrum of 1-ethylpyrrolidinone-2 in C_6H_6.

Table VII summarizes the assignment of the peaks of the CCl_4 solution and shows agreement with the rule developed by Hatton and Richards (24) in that the group farthest from the carbonyl group (—C^5H_2—) experiences additional shielding in benzene solution.

TABLE VII

Room temperature spectral positions of low field 1-ethylpyrrolidinone-2 peaks with respect to benzene as internal standard

Peak	$-\delta$ (c.p.s.) CCl_4 soln.	$-\delta$ (c.p.s.) C_6H_6 soln.	$\delta_{CCl_4} - \delta_{C_6H_6}$ (c.p.s.)
a	220.3	218.3	−2.0
b	227.1	225.3	−1.8
c	234.2	232.3	−1.9
d	241.4	239.3	−2.1
e	218.1	247.9	29.8
f	224.8	254.9	30.1
g	231.1	261.9	30.8

A double resonance experiment in which the quadruplet was collapsed by irradiation of the high field methyl triplet confirmed that the peaks *a*, *b*, *c*, *d* are the signal of the —CH_2— protons of the ethyl group.

Table VII shows that in CCl_4 solution the signal of the A substituent (center of the quadruplet) is located at higher field than the signal of the B substituent (center of the triplet) by 6.08 c.p.s. = 0.108 p.p.m., confirming the assumption made for the long range spin coupling.

DISCUSSION

The results presented in Tables III–VI must be criticized because of the failure to achieve consistency when the shift caused by the electric field is taken into account. The discrepancy between calculated and observed shift differences is greatest for protons close to the carbonyl bond. This suggests that at distances of 1 to 2 Å the approximation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of a continuous electronic distribution by localized charges and dipoles is inadequate. Indeed, values from 0 (25) to 0.4 e (6) have been suggested for the charge on the oxygen atom in amides, and the decomposition of the electric field into a polar and dipolar part is somewhat ambiguous. The same criticism, of course, applies also to the description of the magnetic effect of the carbonyl bond in terms of an induced magnetic dipole. A calculation for the C—C bond (26) indicates the complexity of the actual physical situation.

The reaction field caused by polarization of the solvent surrounding the amide molecule has been neglected in the calculation of the electric field shift, and the values given in Table I must therefore be too large. A detailed consideration of this effect is probably of little significance in view of the use of a single model for a variety of molecules of different shapes and sizes.

It does appear, however, that the susceptibility components derived by neglecting the effect of the electric field are useful for correlating chemical shift differences with the structure of molecules containing a carbonyl bond. For example, the optimum results given in Table V have been used to explain the dependence of the chemical shift difference for the exo-methylene protons of α-methylenecycloketones on ring size (5). It was shown that the *s-trans* conformation is preferred unless the *s-cis* conformation is required by small ring size. Similar results are obtained for the open chain α,β-unsaturated ketones $CH_3CO—C{=}CRR'$. The calculated and observed shift differences $|\delta(R) - \delta(R')|$ in p.p.m. are for

		Calculated		
		s-cis	*s-trans*	Observed
methyl vinyl ketone	(R, R′) = H	0.63	0.15	0.13
mesityl oxide	(R, R′) = CH_3	0.55	0.33	0.27

To give another application, the spectra of a series of disubstituted acetamides may be considered. The observed shift differences may be rationalized by distinguishing two groups of compounds:

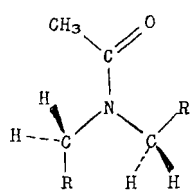
Group I with N—CH_2R substituents show

$$|\delta(H_A) - \delta(H_B)| \simeq 0 \text{ and } |\delta(R_A) - \delta(R_B)| \simeq 0.09 \text{ p.p.m.;}$$

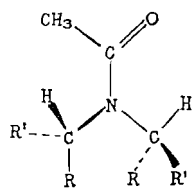
Group II with N—CHRR′ substituents show

$$|\delta(H_A) - \delta(H_B)| \simeq 0.58 \text{ p.p.m. and } |\delta(R_A) - \delta(R_B)| \simeq 0.$$

The shift differences calculated with the optimum susceptibility components of Table V agree with these observations if it is assumed that the two groups of compounds exist mainly in the following conformations:



Group I



Group II

We have not been able to prove the existence of distinct rotational isomers, but a similar proposal (27) for the closely related nitrosamines lends some support to this hypothesis.

The magnitude of the calculated shift difference is in these cases nearly independent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of whether the susceptibility components derived for A at higher field or those for B at higher field are used. The results reported in Part B, however, indicate that the assumption that A is at higher field is the better choice. Although this conclusion is in agreement with deductions made from long range spin coupling patterns and also with results for the isoelectronic nitroso group (28), it does contradict Narasimhan and Rogers' argument based on the sign of the individual susceptibility components. It is also contrary to the empirical rule that in complex molecules protons are deshielded by the influence of neighboring carbonyl bonds (1).

The susceptibility components derived for formamides differ considerably from those derived for acetamides. It appears possible that some fundamental difference in the electronic structure between formamides and acetamides is reflected in both the susceptibilities of the carbonyl bond and in the barriers for internal rotation (16).

REACTIONS OF SUGAR CHLOROSULFATES

PART V. THE SYNTHESIS OF CHLORODEOXY SUGARS[1]

H. J. JENNINGS[2] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 1, 1965

ABSTRACT

The reaction of sulfuryl chloride with reducing sugars and their methyl glycopyranosides was shown to produce fully substituted pyranose derivatives containing both chlorodeoxy and chlorosulfate ester groups. It was demonstrated that the chlorodeoxy groups were formed by nucleophilic displacement (S_N2) by chloride ion of specific reactive chlorosulfate groups in fully chlorosulfated intermediates. The degree of chloro-substitution was shown to be determined by both steric and electronic effects in the individual pyranose derivatives.

INTRODUCTION

The first direct nucleophilic substitution (S_N2) at a secondary carbon atom in a pyranose ring was achieved by Helferich (1) through the use of sulfuryl chloride. Proof of the expected change of sterochemistry at C_4 of methyl α-D-glucopyranoside when it reacts with sulfuryl chloride to give methyl 4,6-dichloro-4,6-dideoxy α-D-galactopyranoside 2,3-cyclic sulfate was given later (2). When a reduced pyridine – sulfuryl chloride ratio was employed, both D-glucose (3) and methyl α-D-glucopyranoside (4) also gave 4,6-dichloro-4,6-dideoxy-D-galactopyranoside derivatives but with positions C_2 and C_3 substituted by chlorosulfate ester groups. Most of the work recorded to date on the reaction of sulfuryl chloride with pyranose sugars (1–7) has been concerned with those in the xylo- or arabino-configuration and has indicated that position C_4 is the only secondary hydroxyl group to be converted readily to a chlorodeoxy group, with inversion of configuration. This inversion of configuration probably occurs via intermediate chlorosulfate ester groups (1–7). Positions C_2 and C_3 were found to be comparatively unreactive to chloro-substitution. This result is analogous to the substitution of the tosyl esters of methyl glucopyranosides with chloride ion (8), although the conclusion of the authors that the C_4 secondary tosyl ester group is more prone to nucleophilic substitution than the primary exocyclic C_6 tosyl ester in monosubstitution is probably incorrect. The isolation of chloro-sulfate esters under conditions which suppressed the formation of the cyclic sulfate ester derivatives (3) prompted a further study of the individual reactivities of all the chloro-sulfate esters of pyranose sugars in regard to competitive nucleophilic substitution. Besides the obvious objective of the synthesis of chlorodeoxy sugars, it was hoped to relate the high degree of selectivity found in the substitution of chlorosulfate esters in the pyranose ring structures to steric effects in each individual molecule.

DISCUSSION

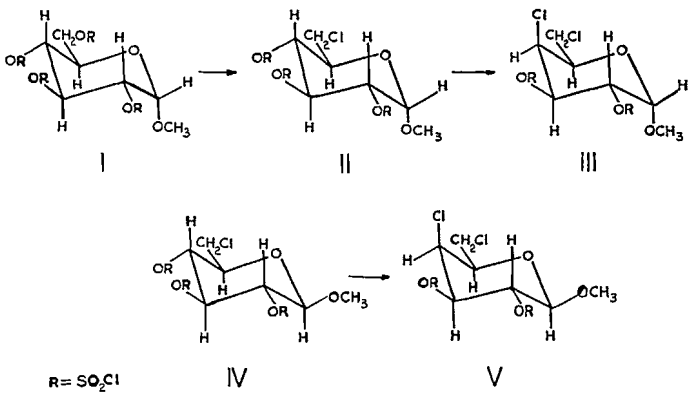
Structural Determinations

In a previous communication (4) it was reported that methyl α-D-glucopyranoside when treated with sulfuryl chloride gave, at room temperature, methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-dichlorosulfate (III). When the above reaction was repeated, except that the product was isolated from the reaction mixture at low temperature (−70°), a crystalline tetrachlorosulfate ester derivative (I) was obtained. It was

[1]*Part IV in this series was a paper by H. J. Jennings and J. K. N. Jones. Can. J. Chem. 41, 1151 (1963).*
[2]*Present address: Department of Chemistry, The University of Bristol, Bristol, England.*

shown to be a derivative of methyl α-D-glucopyranoside because, on treatment with 1 mole of pyridine hydrochloride, it gave crystalline methyl 6-chloro-6-deoxy-α-D-glucopyranoside 2,3,4-trichlorosulfate (II). Compound II had been obtained previously from the product when the reaction of methyl α-D-glucopyranoside with sulfuryl chloride was carried out at 0°. The structure of II was ascertained by removal of the chlorosulfate ester groups (4) to give crystalline methyl 6-chloro-6-deoxy-α-D-glucopyranoside (9). Periodate oxidation of this monochloro-hexoside led to an uptake of periodate (1.99 mole) and the production of acid (1.07 mole). These figures are those expected from the oxidation of a 6-chloro-substituted derivative.

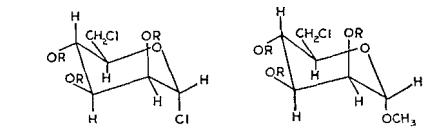
Methyl β-D-glucopyranoside, when treated with sulfuryl chloride, using the conditions which previously gave III, yielded a crystalline product which was shown to be methyl 6-chloro-6-deoxy-β-D-glucopyranoside 2,3,4-trichlorosulfate (IV), since dechlorosulfation gave crystalline methyl 6-chloro-6-deoxy-β-D-glucopyranoside (10). Periodate oxidation of this monochloro-hexoside gave results consistent only with those expected from a 6-chloro-substituted pyranose derivative. When IV was heated with pyridine hydrochloride in chloroform solution, there resulted further chloro-substitution, and the major product was shown to be V. The syrupy reaction product was dechlorosulfated and gave a non-reducing crystalline mixture from which a pure component could not be isolated. The major component of this mixture was methyl 4,6-dichloro-4,6-dideoxy-β-D-galactopyranoside (3) since its acid hydrolysis gave three reducing components (paper chromatography), the major and fastest running of which was characterized as crystalline 4,6-dichloro-4,6-dideoxy-D-galactose (2).



D-Mannose, when treated with sulfuryl chloride, gave a crystalline product (VI) which was shown to be 6-chloro-6-deoxy-α-D-mannosyl chloride 2,3,4-trichlorosulfate on the following evidence. The compound (VI) was considered to be the α-anomer by the similarity of its specific rotation to that of α-tetra-*O*-acetyl-D-mannopyranosyl chloride (11). Methanolysis and subsequent dechlorosulfation of VI gave a non-reducing syrupy mixture, the major component of which was shown to be methyl 6-chloro-6-deoxy-α-D-mannopyranoside. Hydrolysis of the syrupy mixture gave another syrup, which was shown to be a mixture containing three reducing components (paper chromatography), one of which (major component) was characterized as 6-chloro-6-deoxy-D-mannose in the following manner. The syrupy mixture of reducing compounds gave a crystalline 3,5-dichlorophenylhydrazone in good yield, from which a chromatographically pure monochloro-hexose was regenerated (12). The pure monochloro-hexose did not crystallize, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

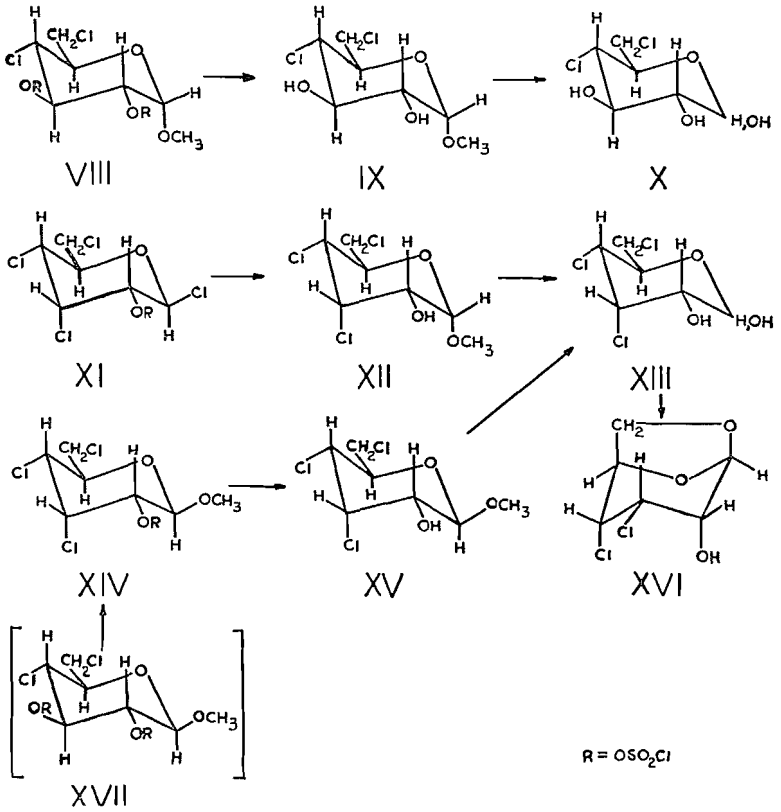
gave a crystalline phenylhydrazone, which, on further heating with phenylhydrazine, gave a crystalline phenylosazone identical with the phenylosazone of authentic 6-chloro-6-deoxy-D-glucose (3). Dechlorosulfation of the crystalline derivative (VII) obtained from the reaction of sulfuryl chloride with methyl α-D-mannopyranoside gave a syrupy non-reducing mixture which had the same specific rotation as the mixture of glycosides obtained previously by the methanolysis and dechlorosulfation of VI. The syrupy mixture obtained from VII was converted to crystalline methyl 3,6-anhydro-α-D-mannopyranoside (13) by base, while hydrolysis of the mixture gave 6-chloro-6-deoxy-D-mannose as the major product (characterized as its crystalline phenylhydrazone).



Methyl α-D-galactopyranoside, when treated with sulfuryl chloride, gave methyl 4,6-dichloro-4,6-dideoxy-α-D-glucopyranoside 2,3-dichlorosulfate (VIII), the structure of which was proved by dechlorosulfation of VIII to give crystalline methyl 4,6-dichloro-4,6-dideoxy-α-D-glucopyranoside (IX) (2). Hydrolysis of IX, which required vigorous conditions, gave crystalline 4,6-dichloro-4,6-dideoxy-D-glucose (X). D-Galactose, when treated with sulfuryl chloride, gave a syrupy product which was shown to contain 3,4,6-trichloro-3,4,6-trideoxy-D-allopyranosyl chloride 2-chlorosulfate (XI). Methanolysis and subsequent dechlorosulfation of XI gave a crystalline derivative (XII) which was shown to have the structure methyl 3,4,6-trichloro-3,4,6-trideoxy-α-D-allopyranoside on the basis of the following evidence. Elemental analysis of XII and of its crystalline tosyl ester and methyl ether derivatives proved it to be a trichloro-substituted compound. Hydrolysis of XII gave a crystalline trichlorohexose (XIII), which was also obtained directly from the syrupy mixture containing XI, by treatment of an aqueous acetone solution of the syrupy mixture with sodium iodide. The trichlorohexose (XIII) gave a crystalline *p*-nitrophenylhydrazone also containing three chlorine atoms. The same crystalline trichlorohexose was also formed in the hydrolysis of XV, which was obtained by dechlorosulfation of the reaction product (XIV) of methyl β-D-galactopyranoside with sulfuryl chloride. This implied that XV was the β-anomer of XII. That chloro-groups were present on C_6 and C_4 of XII, the one at C_4 having been introduced with inversion of configuration, was ascertained by the fact that further reaction of 4,6-dichloro-D-glucose (X) with sulfuryl chloride gave a syrupy product, which, on methanolysis and subsequent dechlorosulfation, gave XV as the major product of a mixture of methyl glycosides (thin-layer chromatography). Hydrolysis of the mixture of methyl glycosides also gave crystalline XIII as the major component of the hydrolysate. Evidence that XII was a 3,4,6-trichloro-trideoxy-D-allose derivative was obtained, although some preliminary experiments had suggested that the third chloro-group was in fact situated at C_2 of XIII. These later experiments included (*a*) the inability to reform the methyl glycoside of XIII using methanolic hydrogen chloride; (*b*) the failure to obtain a phenylosazone or a 1;2-*O*-isopropylidene derivative of XIII; (*c*) the failure to form a trichlorotrideoxy hexitol by reduction under acidic conditions of XIII; (*d*) the unusually slow uptake of periodate by XIII (14); and (*e*) a negative tetrazolium red test (15) on XIII. A probable explanation for some of these anomalous reactions can be attributed to an axial chloro-group on C_3 of XIII which is in close proximity to C_1, and could hinder reactions at this site. That the third chloro-group was,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

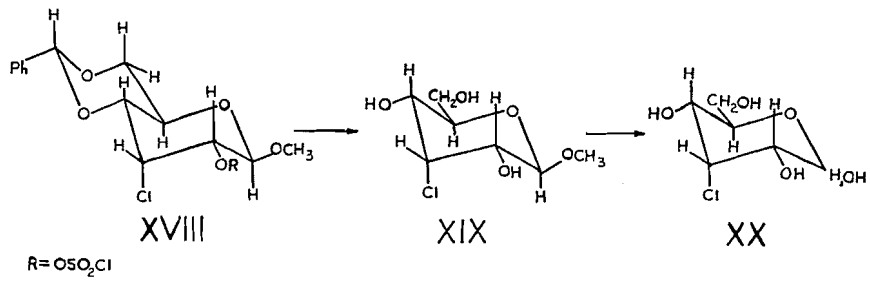
in fact, at C_3 of XII was established by paper electrophoresis of XIII in borate buffer, where XIII had a comparable electrophoretic mobility to 3,4,6-tri-*O*-methyl-D-glucose, whereas 2,4,6-tri-*O*-methyl-D-glucose is known not to move under these conditions (16). Evidence for chloro-substitution having occurred with inversion of configuration on C_3 of XII (allo-configuration) is the fact that elimination of chloride ion did not take place under basic conditions and this is consistent with the chloro-group at C_3 of XII being cis to the hydroxyl group at C_2 (2). Also the trichlorohexose (XIII) obtained from XII was immediately converted to a crystalline non-reducing derivative (XVI) by 1 mole of sodium hydroxide. The elemental analysis of XVI was consistent with the structure 1,6-anhydro-3,4-dichloro-3,4-dideoxy-β-D-allopyranose, and as the formation of the 1,6-anhydro derivative (XVI) requires the trichlorohexose (XIII) to change to the Cl conformation, it is likely that the axial chloro-group on C_3 of XIII facilitated this change.



Although the structure of XII has been fairly well established, a further experiment was performed to avoid the complication of three-chloro-groups being attached to the product. A configurational analogue of X methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (17) was treated with sulfuryl chloride on the assumption that chloro-substitution with inversion of configuration would take place at C_3 of the 4,6-*O*-benzylidene derivative. The product of the reaction was a syrup, which on dechlorosulfation gave a mixture of two components, the minor component of which was characterized as the crystalline starting compound. The major component was characterized as syrupy methyl 3-chloro-3-deoxy-4,6-*O*-benzylidene-β-D-allopyranoside (XVIII) on the following evidence. Mild hydrolysis of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

XVIII gave a syrupy derivative (XIX) which had lost the benzylidene group and was shown to be pure by gas–liquid chromatographic analysis of its triacetate derivative. The triacetate derivative of XIX did not crystallize but analyzed as a monochloro-triacetate methyl glycoside. That the chloro-group of XIX was on C_3 was indicated by the fact that XIX remained resistant to periodate oxidation and also that hydrolysis of XIX gave a syrupy monochlorohexose (XX), the electrophoretic mobility of which in borate buffer was comparable to that of 3-*O*-methyl-D-glucose and not to that of 2-*O*-methyl-D-glucose (16). Finally, XIX was assigned the allo-configuration as treatment of XIX with base gave no elimination of chloride ion; it is known that 3-chloro-3-deoxy-α-D-glucopyranoside as its 4,6-*O*-benzylidene derivative eliminates chloride ion under basic conditions (18). It might be supposed, however, that XIX might eliminate chloride ion under more drastic conditions to give methyl 3,6-anhydro-β-D-glucopyranoside. To check this possibility, XIX was heated in sodium hydroxide solution but was recovered unchanged. The triacetate derivative of the product had the same retention time as the triacetate derivative of XIX (gas–liquid partition chromatography). Also, hydrolysis of the recovered product gave a compound which had the same electrophoretic mobility as XX in borate buffer and a different mobility from that of 3,6-anhydro-D-glucose (13) in molybdate buffer.



Mechanism of the Substitution Reaction

In all the cases studied so far (2–4) and in the evidence submitted in this publication, the chlorodeoxy products formed from secondary pyranose ring hydroxyl groups have been shown to be formed with inversion of configuration. Thus the reaction seems to fall into the category of a bimolecular nucleophilic substitution reaction (S_N2) on stereochemical grounds. That the chlorosulfate ester group is the precursor of the chlorodeoxy groups is well established. Low temperature isolations of the products of the reaction of methyl α-D-glucopyranoside with sulfuryl chloride in the presence of pyridine gave the tetrachlorosulfate (I) and the 6-chloro-trichlorosulfate (II) intermediates (isolated at −70° and 0° respectively), whereas the usual reaction conditions (3) gave the 4,6-dichloro-dichlorosulfate derivative (III). It is probable therefore that at higher temperatures the reactive chlorosulfate groups on C_6 and C_4 of I are replaced by chloride ion (pyridine hydrochloride), which is itself formed in the esterification of the hydroxyl groups. Both the intermediates (I and II) were converted smoothly to the 4,6-dichloroderivative (III) by excess pyridine hydrochloride in chloroform solution and also the tetrachlorosulfate derivative (I) was converted to the 6-chloro derivative (II) by 1 mole of pyridine hydrochloride using similar conditions. The latter experiment eliminates the possibility of the regeneration of pyridine hydrochloride in the substitution reaction (catalytic effect) and also the thermal decomposition of the chlorosulfate ester group under the conditions used.

It is interesting to note that treatment of the chlorosulfate ester derivatives with iodide ion (sodium iodide) in 6% aqueous methanol solution did not give the corresponding iododeoxy compounds. For example, the 6-chloro-trichlorosulfate derivative (II) gave only methyl 6-chloro-6-deoxy-α-D-glucopyranoside (9) on treatment with sodium iodide. This removal of chlorosulfate ester groups to give the corresponding hydroxyl groups with retention of configuration was found to be of wide application and constitutes an efficient and fast method of dechlorosulfation. Only one exception to this general reaction pattern has been recorded (4) where vicinal chlorosulfate ester groups in the open-chain hexitol series gave a cyclic-sulfate ester derivative when treated with sodium iodide.

Steric Effects

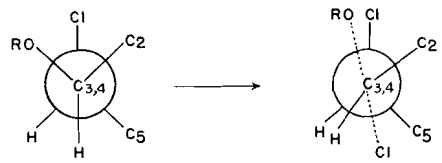
In all the experiments carried out on the reaction of sulfuryl chloride with hexopyranoses and hexopyranosides, chloro-substitution on the primary C_6 position (via the intermediate 6-chlorosulfate ester) was facile. That the C_6 chlorosulfate ester was also the most reactive one was demonstrated by the fact that methyl α-D-glucopyranoside tetrachlorosulfate (I) gave only the 6-chloro-substituted derivative (II) when treated with 1 mole of pyridine hydrochloride. These results were expected on the basis of previous work (19) and a probable explanation is that the approach of the chloride ion to the exocyclic C_6 position is not sterically hindered by other large groups in the pyranose ring.

Only the derivatives in the D-manno-configuration failed to give chloro-substitution at position C_4 under the normal conditions of the reaction (3). This result could be interpreted as due to 1;3-diaxial interaction between the approaching chloride ion at C_4 and the large axial chloro-sulfate group at C_2 in VI and VII. This is supported by the fact that II, which differed from VII only in the configuration of the C_2 chlorosulfate group, gave good yields of the methyl 4,6-dichloro-D-galactoside derivative (III) under similar experimental conditions. Further evidence of these 1;3-diaxial interactions was found in the D-galacto-series. Both D-galactose and methyl β-D-galactopyranoside gave 3,4,6-trichloro-D-allose derivatives (XI and XIV respectively) whereas methyl α-D-galactopyranoside under similar reaction conditions gave only a 4,6-dichloro-D-glucose derivative (VIII), which was shown to be resistant to further chloro-substitution even when heated at 50° with pyridine hydrochloride in chloroform solution. Crystalline VIII was recovered from the reaction mixture and examination (g.l.p.c.) of the dechlorosulfated residual syrupy product indicated a preponderance of the 4,6-trichloro-derivative (IX) and only a very minor quantity of the 3,4,6-trichloro-derivative (XII). This evidence indicated an effect that was due to the anomeric substituent of VIII, which could be interpreted as 1;3-diaxial interaction to the approach of the chloride ion to C_3 by the axial methyl-glycosidic group of VIII. This effect is not present in XIV (methyl β-glycoside) and there is some evidence that is not present in XI since it is probable that XI is the β-chloro anomer ($[\alpha_D] = -30°$). In any event, even if XI were the α-chloro anomer, it is likely that anomerization could occur under the reaction conditions used. Another example of the 1;3-diaxial interaction effect, concerning the methyl glycosidic group, is found in the reaction of sulphuryl chloride with the 4,6-*O*-benzylidene derivatives of methyl α- and β-D-glucopyranosides. The α-anomer has been shown to give a 2,3-dichlorosulfate derivative (4), whereas under similar reaction conditions the β-anomer gave mainly a 3-chloro-substituted D-alloside derivative (XVIII).

Although nucleophilic substitution by chloride ion at position C_3 is controlled by the configuration of the anomeric substituent, other factors have to be considered. Both methyl α- and β-D-glucopyranoside gave only 4,6-dichloro-substituted derivatives (III

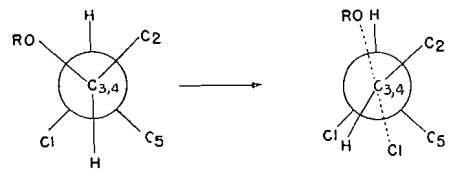
and V respectively), whereas it might have been expected that the methyl β-glycoside would have given a 3,4,6-trichloro-D-gulose derivative. The fact that no substitution by chloride ion occurred on C_3 of V indicated a deactivating effect by the axial chloro-group at C_4 of V. This deactivating effect by an axial substituent at C_4 was also observed in the reaction of sulfuryl chloride with D-glucose and 4,6-*O*-ethylidene-D-galactose: the former gave a 4,6-dichloro-D-galactose derivative (3) and the latter only a 2,3-dichloro-sulfate derivative. In contrast, compounds which had a configuration identical with that of V except for an equatorial substituent at C_4 (methyl 4,6-*O*-benzylidene-β-D-glucopyranoside and 4,6-dichloro-4,6-dideoxy-D-glucose (X)) gave facile chloro-substitution at C_3. In view of this evidence it is also probable that XVII was the unidentified intermediate in the formation of XIV.

The deactivation of an equatorial chlorosulfate ester group by a vicinal axial substituent cannot be explained by steric affects because of the approach of the chloride ion at C_3 of V, as an examination of a model of V indicates that there are no large groups in proximity to this approach. However, a possible explanation can be found by consideration of the transition state in the substitution reaction. Reaction of V with Cl^- would involve the formation of a transition state possessing considerable skew interactions due to the near-eclipsed conformation of the large substituents on C_3 and C_4. This is illustrated in XXI



XXI XXII

and XXII, representing the end-on views (20) of the C_3—C_4 bond of V and of the transition state respectively. This could raise the energy requirements of the transition state (XXII) considerably. When the chloro-group on C_4 is equatorial as in X and in the intermediate XVII, similar skew interactions would be avoided, giving a transition state (XXIV) of lower energy than XXII. This is indicated by the end-on representations of the C_3—C_4 bond of XVI in the ground state (XXIII) and in the transition state (XXIV). Similar skew interactions have been postulated to explain the large differences in the rates of nucleophilic substitution of highly substituted erythro- and threo-bromobenzenesulfonate derivatives (21).



XXIII XXIV

$R = SO_2Cl$

All of the derivatives discussed so far have, as a common feature, the relative inertness of the C_2 chlorosulfate ester group to nucleophilic substitution by chloride ion. This observation cannot be justified on the basis of steric interactions as it might be expected that the chlorosulfate ester groups on C_2 and C_4 of IV would be equally active as they are

both in a similar conformational environment. However, compound IV gave mainly a 4,6-dichloro-D-galactoside derivative (V), when heated with pyridine hydrochloride in chloroform solution. This might be explained by the fact that the ester groups on C_2 and C_4 of IV are in different electronic environments. Thus position C_2 of IV is in the proximity of two β-oxygen atoms (ring oxygen and anomeric group) whereas C_4 is only in the proximity of one (ring oxygen). This explanation has some credence as it is known that β-methoxyl substituents do retard considerably the rate of nucleophilic substitution (22). However, it is possible that C_2 chloro-substitution may have occurred in D-mannose as discussed below. The 6-chloro-substituted derivative (VI), obtained from the reaction of D-mannose with sulfuryl chloride, gave a tetrachloro-substituted derivative on further heating with pyridine hydrochloride in chloroform solution, whereas VII was resistant to further chloro-substitution. It could be argued that to obtain further substitution of VI the deactivating influence of the axial C_2 chlorosulfate ester group would have to be removed. This could be achieved by chloro-substitution at C_2 of VI to produce an equatorial chlorodeoxy group at this position. This would then allow the normally reactive C_4 ester group VI to be substituted and thus one might postulate a 1,2,4,6-tetrachloro-D-galacto-configuration for the product. Further structural studies on this tetrachloro-substituted product are being carried out.

EXPERIMENTAL

Optical rotations were measured at 21 ± 3°. Melting points were determined on a Kofler hot stage and were uncorrected. All solutions were concentrated under reduced pressure below 50°. Aqueous solutions were deionized by passage through Amberlite I.R. 120 (H form) and Duolite A.4 (OH form) ion exchange resins. Paper chromatography was carried out by the descending method on Whatman No. 1 filter paper using the following solvent systems (v/v): (*a*) butan-1-ol, ethanol, water (3:1:1), (*b*) ethyl acetate, acetic acid, formic acid, water (18:3:1:4). The rates of movement of the sugars are quoted relative to that of D-xylose (R_x). Paper electrophoresis was performed using Whatman 3 MM filter paper impregnated with buffer solutions: (i) 0.05 *M* borate solution (23) and (ii) 2% aqueous solution of sodium molybdate (24). The rates of movement of sugars in (i) are given relative to that of D-glucose (M_g) and in (ii) relative to that of sorbitol (M_s). Sugars were detected on paper chromatograms and electrophoretograms by *p*-anisidine hydrochloride (25) and (or) alkaline silver nitrate (26) spray reagents. Thin-layer chromatographic analysis (t.l.c.) was carried out on prepared silica gel G plates.

Analytical gas–liquid chromatographic analysis (a.g.l.c.) was carried out using a Pye Argon gas chromatograph with the following column packings: (A) 1:1:2 intimate mixture of 20% w/w butanediol–succinate polyester on 60–80 mesh Chromosorb W, 20% w/w Apiezon M grease on 60–80 mesh silver-coated Chromosorb W, 0.3% w/w Apiezon M grease on 60 plus mesh silver-coated glass beads, at 175° with a flow rate of 145 ml per min; (B) 10.7% of LAC-4R-886 on 100–120 mesh Chromosorb W at 207° with a flow rate of 160 ml per min.

Anhydrous pyridine hydrochloride was made by passing dry gaseous hydrogen chloride into a petrol solution of anhydrous pyridine. The precipitated pyridine hydrochloride was collected by filtration, quickly washed with petrol, and stored in a desiccator over phosphoric oxide.

Periodate oxidations were carried out in the dark at 25°, using a small sample (20 mg) of the compounds in distilled water (25 ml) containing 0.3 *M* sodium metaperiodate (1 ml). Aliquots (1 ml) were removed at intervals and the consumption of periodate (27) and the production of acid (28) were measured.

Methyl α-D-Glucopyranoside 2,3,4,6-Tetrachlorosulfate (I)

Methyl α-D-glucopyranoside (10 g) was treated with sulfuryl chloride (26 ml) and pyridine (40 ml) in chloroform solution as described in a previous communication (3), except that the reaction mixture, while still at the temperature of the acetone – solid carbon dioxide bath (ca. −70°), was quickly poured into a vigorously stirred solution of ice-cold 10% sulfuric acid (1 000 ml). The product (8.7 g, 29%) was recrystallized from chloroform–petrol (b.p. 50–60°) and gave colorless needles (7 g, 23%) of m.p. 118° and $[\alpha]_D$ +92° (*c*, 0.8 in chloroform).

Anal. Found: C, 14.6; H, 1.7; Cl, 24.6; S, 22.5. Calcd. for $C_7H_{10}Cl_4O_{14}S_4$: C, 14.6; H, 1.7; Cl, 24.2; S, 21.8.

Methyl 6-Chloro-6-deoxy-α-D-glucopyranoside 2,3,4-Trichlorosulfate (II)

The above reaction was repeated using methyl α-D-glucopyranoside (10 g), except that the reaction mixture was allowed to warm up slowly to 0° and then was poured, at this temperature, into a vigorously stirred

solution of ice-cold 10% sulfuric acid (1 000 ml). The crystalline chloroform-soluble product was recrystallized twice from chloroform–petrol (b.p. 35–60°) and gave large colorless prisms (15.5 g, 59%) of m.p. 90–91° and $[\alpha]_D$ +115° (*c*, 0.9 in chloroform).

Anal. Found: C, 16.3; H, 1.9; Cl, 28.2; S, 19.0. Calcd. for $C_7H_{10}Cl_4O_{11}S_3$: C, 16.5; H, 2.0; Cl, 27.9; S, 18.9.

Methyl 6-Chloro-6-deoxy-α-D-glucopyranoside

The compound II (5 g) was dissolved in methanol and dechlorosulfated as described previously (4). The product (2.5 g, 60%) was recrystallized from benzene–methanol to give colorless plates (1.5 g, 36%) of m.p. 110–111° and $[\alpha]_D$ +187° (*c*, 1.25 in water). The physical constants are consistent with those reported for methyl 6-chloro-6-deoxy-α-D-glucopyranoside (9).

Periodate Oxidation of Methyl 6-Chloro-6-deoxy-α-D-glucopyranoside

The moles of periodate consumed and the moles of formic acid produced were respectively as follows: 0.57, 0.26 (1 h); 1.60, 0.71 (7 h); 1.91, 1.05 (21 h); 1.99, 1.07 (46 h).

Methyl 6-Chloro-6-deoxy-α-D-glucopyranoside 2,3,4-Trichlorosulfate (II)

Methyl α-D-glucopyranoside 2,3,4,6-tetrachlorosulfate (8 g) was dissolved in chloroform (70 ml) and anhydrous pyridine hydrochloride (1.6 g, 1 mole) was added, and the solution was heated at 40–50° for 2 h. The chloroform solution was then washed with sodium bicarbonate solution and distilled water and dried over anhydrous sodium sulfate. Concentration of the chloroform solution gave a syrup which crystallized. Recrystallization from chloroform–petrol (b.p. 40–60°) gave large colorless plates (4.5 g, 65%) of m.p. 90–91°, undepressed on admixture with previously prepared methyl 6-chloro-6-deoxy-α-D-glucopyranoside 2,3,4-trichlorosulfate.

Methyl 4,6-Dichloro-4,6-dideoxy-α-D-galactopyranoside (III)

Compound I (1.1 g) was dissolved in chloroform (20 ml) and after the addition of anhydrous pyridine hydrochloride (1 g, 4.4 mole) the solution was heated at 40–50° for 8 h. The product isolated as described above was dechlorosulfated (4) and the resulting solid was recrystallized from chloroform–petrol (b.p. 40–60°) to give needles (0.42 g, 84%) of m.p. 158°, undepressed on admixture with authentic methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside (2).

Methyl 6-Chloro-6-deoxy-β-D-glucopyranoside 2,3,4-Trichlorosulfate (IV)

Methyl β-D-glucopyranoside (4.5 g), prepared from acetobromglucose (29), was treated with sulfuryl chloride (12 ml) and pyridine (18 ml) in chloroform solution (3). Removal of the solvent gave a product (6 g, 54%) which was recrystallized from chloroform–petrol (b.p. 40–60°) to give colorless needles (1.1 g, 10%)* of m.p. 134–135° and $[\alpha]_D$ +1.7° (*c*, 1.2 in chloroform).

Anal. Found: C, 16.7; H, 2.0; Cl, 27.5; S, 18.9. Calcd. for $C_7H_{10}Cl_4O_{11}S_3$: C, 16.5; H, 2.0; Cl, 27.9; S, 18.9.

Methyl 6-Chloro-6-deoxy-β-D-glucopyranoside

The crystals of IV (0.5 g) were dechlorosulfated as described previously (4) and the product (0.2 g, 95%) was recrystallized from benzene–methanol to give large colorless crystals of m.p. 157–159° and $[\alpha]_D$ −50° (*c*, 1.0 in water) (10).

Periodate Oxidation of Methyl 6-Chloro-6-deoxy-β-D-glucopyranoside

The moles of periodate consumed and the moles of formic acid produced per mole of sugar were respectively as follows: 0.60, 0.28 (1 h); 1.65, 0.75 (7 h); 1.90, 0.98 (21 h); 1.98, 1.00 (46 h).

Methyl 4,6-Dichloro-4,6-dideoxy-β-D-galactopyranoside (V)

The crystals of methyl 6-chloro-6-deoxy-β-D-glucopyranoside 2,3,4-trichlorosulfate (4 g) were dissolved in chloroform and anhydrous pyridine hydrochloride (4 g) was added to the solution. The chloroform solution was heated at 50° for 14 h and the syrupy product (3 g) isolated in the usual way had $[\alpha]_D$ −5.5° (*c*, 0.9 in chloroform). Dechlorosulfation (4), followed by continuous extraction with chloroform, gave a crystalline residue of m.p. 142°. Recrystallization from chloroform–petrol (b.p. 35–60°) gave colorless needles (1.2 g, 75%) of m.p. 144–146° and $[\alpha]_D$ −16° (*c*, 1.2 in water). Successive recrystallizations from ether did not raise the melting point to that of authentic methyl 4,6-dichloro-4,6-dideoxy-β-D-galactoside (m.p. 154°) (3).

4,6-Dichloro-4,6-dideoxy-D-galactose

A solution of the above impure preparation of V (0.4 g) was refluxed in *N* sulfuric acid (50 ml) for 16 h. The acidic solution was neutralized ($BaCO_3$) and filtered. Concentration of the aqueous solution gave colorless, syrupy crystals (0.3 g), paper chromatographic analysis in solvent *a* indicated the presence of three reducing components at R_x 1.4 (slight), R_x 2.2 (slight), and R_x 2.9 (intense). The component at R_x 2.9 was found to be chromatographically indistinguishable from 4,6-dichloro-4,6-dideoxy-D-galactose (5). Recrystallization of the syrupy crystals from methanol–water gave colorless crystals (0.1 g, 27%) of m.p. 184–186°, undepressed in admixture with authentic 4,6-dichloro-4,6-dideoxy-D-galactose (5).

**A repetition of this experiment, by Mr. A. Cottrell, showed (t.l.c.) that the non-crystalline material was mainly the 4,6-dichloro-4,6-dideoxy-β-D-galactopyranoside derivative.*

6-Chloro-6-deoxy-α-D-mannosyl Chloride 2,3,4-Trichlorosulfate (VI)

D-Mannose (25 g) was treated with sulfuryl chloride (63 ml) and pyridine (100 ml) in chloroform solution (3), and the reaction mixture was allowed to stand at room temperature for 7 h before isolation of the product as described above. Concentration of the chloroform extracts and recrystallization of the residue (31 g,) 44% from chloroform–petrol (b.p. 40–60°) gave large colorless crystals (15 g, 21%) of m.p. 156° and $[\alpha]_D$ +52° (*c*, 1.2 in chloroform).

Anal. Found: C, 14.3; H, 1.2; Cl, 34.5; S, 18.5. Calcd. for $C_6H_7Cl_5O_{10}S_3$: C, 14.1; H, 1.3; Cl, 34.6; S, 18.6.

Methyl 6-Chloro-6-deoxy-α-D-mannopyranoside

A solution of VI (10 g) in anhydrous methanol (100 ml) was refluxed for 8 h. The resulting glycoside(s) were dechlorosulfated (4) and the product, a colorless syrup (4.0 g, 96%) had $[\alpha]_D$ +60° (*c*, 1.0 in water). Paper chromatograms developed in solvent *a* and sprayed with periodic acid – *p*-anisidine hydrochloride (30) indicated that the syrup contained three components at R_x 2.1 (trace), R_x 2.5 (slight), and R_x 3.0 (intense). All of the components were non-reducing (negative test with *p*-anisidine hydrochloride).

6-Chloro-6-deoxy-D-mannose

The above syrup (3.0 g) was dissolved in *N* sulfuric acid and the solution was boiled for 7 h. The solution was neutralized with barium carbonate and filtered. Concentration of the aqueous solution gave a syrup (2.5 g). Paper chromatographic analysis in solvent *a* indicated three reducing components at R_x 0.7 (trace), R_x 1.6 (slight), and R_x 2.1 (intense). The syrup (0.8 g) gave a crystalline 3,5-dichloro phenylhydrazone which was recrystallized from chloroform–ethyl acetate to give yellow plates (0.9 g, 62%) of m.p. 149° (decomp.).

Anal. Found: C, 39.9; H, 4.1; Cl, 29.6; N, 8.0. Calcd. for $C_{12}H_{15}Cl_3N_2O_4$: C, 40.2; H, 4.2; Cl, 29.8; N, 7.8.

The 3,5-dichlorophenylhydrazone (0.8 g) was converted to the reducing sugar by the procedure of Sowden and Fischer (12). Concentration of the water-soluble fraction gave a colorless syrup (0.35 g, 79%) $[\alpha]_D$ +18° (*c*, 1.0 in water) which was shown to be chromatographically pure in solvents *a* and *b*. The syrup with phenylhydrazine in the cold gave a crystalline phenylhydrazone, m.p. 141–142° (decomp.).

Anal. Found: C, 50.1; H, 6.1; Cl, 12.3; N, 9.7. Calcd. for $C_{12}H_{17}ClN_2O_4$: C, 49.9; H, 5.9; Cl, 12.3; N, 9.7.

The phenylhydrazone, on further heating with phenylhydrazine acetate, gave a crystalline phenylosazone. Two recrystallizations from ethanol–water gave yellow needles of m.p. 165–168° (decomp.), undepressed on admixture with 6-chloro-6-deoxy-D-glucose phenylosazone (3). The infrared spectra of the two phenylosazones were also identical (0.8% in potassium bromide).

Further Chloro-substitution of 6-Chloro-6-deoxy-α-D-mannosyl Chloride 2,3,4-Trichlorosulfate (VII)

The crystals of the 6-chloro-6-deoxy-D-mannosyl chloride derivative (8 g) were dissolved in chloroform (150 ml) and anhydrous pyridine hydrochloride (6 g) was added to the solution. The chloroform solution was heated at 50° for 20 h the product isolated in the usual way, was recrystallized from chloroform–petrol (b.p. 40–60°) yielding large prisms (1.5 g, 27%) of m.p. 147° (decomp.) and $[\alpha]_D$ +65° (*c*, 1.2 in chloroform).

Anal. Found: C, 20.5; H, 2.1; Cl, 50.5; S, 9.4. Calcd. for a tetrachloro-monochlorosulfate derivative $C_6H_7Cl_5O_4S$: C, 20.4; H, 2.0; Cl, 50.0; S, 9.1.

Methyl Trichloro-trideoxy-α-D-hexoside

A solution of VII (2.5 g) in anhydrous methanol (200 ml) was boiled under reflux. The resultant glycoside was dechlorosulfated (4) and the product was crystallized from chloroform–petrol (b.p. 40–60°) to give colorless needles (0.4 g, 33%) of m.p. 122–123° and $[\alpha]_D$ +81° (*c*, 0.9 in chloroform), and +122° (*c*, 0.9 in methanol).

Anal. Found: C, 33.5; H, 4.1; Cl, 43.1. Calcd. for $C_7H_{11}Cl_3O_3$: C, 33.6;H, 4.4; Cl, 42.6.

Hydrolysis of the Methyl Trichloro-trideoxy-α-D-hexoside

The above glycoside was unaffected by boiling *N* sulfuric acid during 16 h. Hydrolysis in 25% sulfuric acid for 5 h yielded a complex mixture of reducing components as was indicated by thin-layer chromatographic analysis. All attempts to obtain a crystalline derivative of the hydrolysis product have so far failed.

Methyl 6-Chloro-6-deoxy-α-D-mannopyranoside 2,3,4-Trichlorosulfate (VII)

Methyl α-D-mannopyranoside (20 g) was treated with sulfuryl chloride (52 ml) and pyridine (80 ml) in chloroform solution (3). The chloroform extracts were concentrated to give a syrup which rapidly crystallized. Recrystallization from chloroform–petrol (b.p. 40–60°) (×2) gave large colorless prisms (15 g, 29%) of m.p. 134° and $[\alpha]_D$ +19° (*c*, 1.2 in chloroform).

Anal. Found: C, 16.7; H, 2.0; Cl, 27.8; S, 18.9. Calcd. for $C_7H_{10}Cl_4O_{11}S_3$: C, 16.5; H, 2.0; Cl, 27.9; S, 18.9.

Methyl 6-Chloro-6-deoxy-α-D-mannopyranoside

Compound VII (10 g) was dechlorosulfated and the syrupy product (4 g, 100%) which was isolated in the usual way had $[\alpha]_D$ +59° (*c*, 1.1 in water). Paper chromatograms developed in solvent *a* and sprayed with periodic acid – *p*-anisidine hydrochloride (30) indicated that the syrup contained two components at R_x 2.5 (slight) and R_x 3.0 (intense). Hydrolysis of the syrup (*N* sulfuric acid, 7 h at 100°) gave a reducing syrupy product, which yielded a crystalline phenylhydrazone derivative of m.p. 140° (decomp.), undepressed on admixture with an authentic sample.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Methyl 3,6-Anhydro-α-D-mannopyranoside

The syrupy methyl 6-chloro-6-deoxy-D-mannoside (0.5 g) (above) was dissolved in *N* sodium hydroxide (5 ml), and the solution was allowed to stand at room temperature for 10 h. The solution was deionized and concentrated to a syrup (0.4 g, 100%) which crystallized when seeded with authentic methyl 3,6-anhydro-α-D-mannopyranoside. Recrystallization from benzene gave colorless crystals (0.15 g, 36%) of m.p. 129°, undepressed on admixture with the authentic compound (13).

Attempt to Obtain Further Chloro-substitution of Methyl 6-Chloro-6-deoxy-α-D-mannopyranoside 2,3,4-Trichlorosulfate (VII)

The crystals of the methyl glycoside (6 g) (VII) were dissolved in chloroform (40 ml) and anhydrous pyridine hydrochloride (4 g) was added to the solution. After the solution had been heated at 50° for 12 h the product was recrystallized from chloroform–petrol (b.p. 40–60°) to yield colorless prisms (4.5 g, 75%) of m.p. 134°, undepressed on admixture with the starting material.

Methyl 4,6-Dichloro-4,6-dideoxy-α-D-glucopyranoside 2,3-Dichlorosulfate (VIII)

Methyl α-D-galactopyranoside (31) (10 g) was treated with sulfuryl chloride (26 ml) and pyridine (40 ml) in chloroform solution (3). The reaction mixture was allowed to stand at room temperature for 12 h before the chloroform-soluble product was isolated. It was recrystallized from chloroform–petrol (b.p. 40–60°) to give large colorless prisms (6 g, 27%) of m.p. 122–124° and $[\alpha]_D$ +68° (*c*, 2.66 in chloroform).

Anal. Found: C, 19.6; H, 2.2; Cl, 32.9; S, 14.6. Calcd. for $C_7H_{10}Cl_4O_8S_2$: C, 19.6; H, 2.3; Cl, 33.2; S, 15.0.

Methyl 4,6-Dichloro-4,6-dideoxy-α-D-glucopyranoside

Compound VIII (6 g) was dechlorosulfated (4) and the product isolated in the usual way. It (3 g, 93%) was recrystallized from chloroform–petrol (b.p. 40–60°) and had m.p. 119–121°, undepressed on admixture with authentic methyl 4,6-dichloro-4,6-dideoxy-α-D-glucopyranoside (2).

4,6-Dichloro-4,6-dideoxy-α-D-glucose

The crystalline methyl glycoside was unaffected by hot *N* sulfuric acid. Therefore, more drastic conditions were tried.

The glycoside (3 g) was dissolved in 3 *N* sulfuric acid and the solution was refluxed for 24 h. The solution was neutralized ($BaCO_3$) and filtered and the filtrate was concentrated to a solid. Recrystallization from chloroform gave colorless needles of m.p. 136–137° and $[\alpha]_D$ +49° (10 minutes) → +25° (24 h, equilibrium) (*c*, 1.1 in water). The crystals reduced Fehlings' solution and gave a positive tetrazolium red test (15).

Anal. Found: C, 33.0; H, 4.6; Cl, 32.9. Calcd. for $C_6H_{10}Cl_2O_4$: C, 33.2; H, 4.6; Cl, 32.8.

The crystals formed a crystalline phenylosazone which, when recrystallized from ethanol–water, had m.p. 129–131° (decomp.).

Anal. Found: C, 54.4; H, 4.8; Cl, 18.0; N, 14.4. Calcd. for $C_{18}H_{20}Cl_2N_4O_2$: C, 54.6; H, 5.1; Cl, 18.0; N, 14.2.

Attempt to Obtain Further Chloro-substitution of Methyl 4,6-Dichloro-4,6-dideoxy-α-D-glucopyranoside 2,3-Dichlorosulfate

The crystals of the 2,3-dichlorosulfate (4.5 g) were dissolved in chloroform (25 ml) and anhydrous pyridine hydrochloride (4 g) was added to the chloroform solution. The solution was heated at 50° for 18 h, and the products were then isolated in the usual way. Recrystallization from methanol–water gave large crystals (1.5 g, 33%) of m.p. 124°, undepressed on admixture with the starting compound. The mother liquors were concentrated to a syrup (2.5 g) which was dechlorosulfated (4). The dechlorosulfated products were examined by gas–liquid chromatographic analysis using a column (A) and the results are shown in Table I.

TABLE I

Gas–liquid chromatographic analysis of the dechlorosulfated products from VIII

Compound or mixture	Components	Retention time relative to compound 1	Estimated % of individual compounds in mixture
(1) Methyl 4,6-dichloro 4,6-dideoxy-α-D-glucopyranoside	1	1.000	—
(2) Methyl 3,4,6-trichloro 3,4,6-trideoxy-α-D-allopyranoside	1	0.545	—
(3) Syrup from experiment above	1	0.246	3–4
	2	0.324	3–4
	3	0.545	1
	4	1.000	90

3,4,6-Trichloro-3,4,6-trideoxy-D-allosyl Chloride 2-Monochlorosulfate (XI)

D-Galactose (10 g) was treated with sulfuryl chloride (26 ml) and pyridine (40 ml) in chloroform solution (3). Concentration of the chloroform extracts gave a syrup (9.5 g) which had $[\alpha]_D$ −7° (*c*, 5.0 in chloroform).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Paper chromatograms developed in solvent *a* and sprayed with aniline-pyridine reagent (3) indicated that the syrup was a mixture of two components.

*Methyl 3,4,6-Trichloro-3,4,6-trideoxy-β-*D*-allopyranoside (XII)*

The above syrup (XI) (9 g) was dissolved in anhydrous methanol and the solution was refluxed to form the methyl glycoside(s). The methyl glycoside(s) was dechlorosulfated (4) and the product was crystallized from water to give colorless needles (1.5 g, 11%) of m.p. 116° and $[\alpha]_D$ +159° (*c*, 1.8 in methanol).

Anal. Found: C, 33.6; H, 4.4; Cl, 42.3. Calcd. for $C_7H_{11}Cl_3O_3$: C, 33.6; H, 4.4; Cl, 42.6.

The overall yield of this product could be increased to 36% by first dissolving the original syrup, obtained from the reaction of sulfuryl chloride with D-galactose, in chloroform, and heating the resultant solution with anhydrous pyridine hydrochloride at 50° for 16 h, followed by the methanolysis and dechlorosulfation of the product. Methylation of the methyl trichlorotrideoxy glycoside by the method of Purdie (32) gave a crystalline monomethyl derivative which, when recrystallized from *n*-hexane, gave colorless needles of m.p. 68–69° and $[\alpha]_D$ +116° (*c*, 1.12 in methanol).

Anal. Found: C, 36.7; H, 4.8; Cl, 39.7. Calcd. for $C_8H_{13}Cl_3O_3$: C, 36.5; H, 4.9; Cl, 40.0.

The methyl trichloro-trideoxy glycoside also gave a crystalline monotosylate which, when recrystallized from ethanol, had m.p. 120–121°.

Anal. Found: C, 41.9; H, 4.2; Cl, 26.6; S, 8.1. Calcd. for $C_{14}H_{17}Cl_3O_5S$: C, 41.6; H, 4.2; Cl, 26.4, S, 7.9.

*Attempted Reaction of Methyl 3,4,6-Trichloro-3,4,6-trideoxy-α-*D*-allopyranoside (XII) with Sodium Hydroxide*

The crystals of the methyl glycoside (0.05 g) were dissolved in methanol (5 ml) and 0.1 *N* sodium hydroxide (5 ml) was added to the solution. The reaction mixture was left at room temperature for 8 h, and then was deionized. The solution was concentrated to a solid which was recrystallized from water. It had m.p. 116°, which was undepressed on admixture with the starting compound.

*3,4,6-Trichloro-3,4,6-trideoxy-*D*-allose (XIII)*

The original syrup obtained from the reaction of sulfuryl chloride with D-galactose (10 g) was dissolved in acetone (200 ml) and barium carbonate (30 g) was added and the heterogeneous mixture was stirred. Sodium iodide solution (5 g in 20 ml water) was added drop by drop until the formation of iodine had ceased. The solution was filtered and the filtrate was concentrated. The residue was dissolved in water and the aqueous solution was continuously extracted with chloroform for 10 h. Concentration of the chloroform solution and recrystallization from chloroform gave colorless crystals (1.9 g, 29%) of m.p. 170–171°. The crystals reduced Fehling's solution and gave a negative tetrazolium red test (15). The same crystalline compound was also obtained by the hydrolysis of methyl 3,4,6-trichloro-3,4,6-trideoxy-α-D-alloside with *N* sulfuric acid under reflux for 10 h.

The crystals failed to give a phenylosazone or a *p*-nitrophenylosazone but gave a crystalline *p*-nitrophenylhydrazone, which, when recrystallized from methanol–water, had m.p. 105° (decomp.) and $[\alpha]_D$ −58° (*c*, 0.75 in methanol).

Anal. Found: Cl, 28.5; N, 11.4. Calcd. for $C_{12}H_{13}Cl_3N_3O_4$: Cl, 28.8; N, 11.3.

Paper electrophoresis of the crystalline trichlorohexose in buffer solution i gave the results shown in Table II.

TABLE II

Paper electrophoresis of 3,4,6-trichloro-3,4,6-trideoxy-D-allose (XIII)

Compound	Electrophoretic mobility, mg × 10^2
3,4,6-Trichloro-3,4,6-trideoxy-D-allose	23
3,4,6-Tri-*O*-methyl-D-glucose	29
2,4,6-Tri-*O*-methyl-D-glucose	0

The crystalline trichlorohexose failed (*a*) to form an 1,2,-*O*-isopropylidene derivative, (*b*) to re-form the methyl glycoside by refluxing the sugar in a 2% (w/w) anhydrous solution of hydrochloric acid in methanol, and (*c*) to be reduced to the trichloro-trideoxy-hexitol (33). In each case the crystalline starting material was obtained.

*1,6-Anhydro-3,4-dichloro-3,4-dideoxy-*D*-allose (XVI)*

The crystals of the trichlorohexose (0.5 g) were dissolved in water and treated with 0.1 *N* sodium hydroxide (21 ml, 1 mole). The alkali reacted rapidly and the neutral solution was then continuously extracted with chloroform. The chloroform extracts were concentrated to a solid which, on recrystallization from benzene–petrol (b.p. 60–80°), gave colorless crystals (0.3 g, 77%) of m.p. 94° and $[\alpha]_D$ −96° (*c*, 1.1 in methanol). The crystals did not reduce Fehling's solution and did not appear as reducing spots when paper chromatograms developed in solvent *a* were sprayed with *p*-anisidine hydrochloride, or with the alkaline silver nitrate spray.

Anal. Found: C, 36.3; H, 4.0; Cl, 35.4. Calcd. for $C_6H_8Cl_2O_3$: C, 36.2; H, 4.0; Cl, 35.7.

Methyl 3,4,6-Trichloro-3,4,6-trideoxy-β-D-allopyranoside 2-Monochlorosulfate (XIV)

Methyl β-D-galactopyranoside (5 g) was treated with sulfuryl chloride (13 ml) and pyridine (20 ml) in chloroform solution (3). The reaction mixture was allowed to stand at room temperature for 12 h. The chloroform extracts on concentration gave a dark-colored syrup which was decolorized (5 g, 56%).

Methyl 3,4,6-Trichloro-3,4,6-trideoxy-β-D-allopyranoside (XV)

The above syrup (XIV) (5 g) was dechlorosulfated (4) and the syrupy product (2.5 g, 71%) of $[\alpha]_D$ −12.8° (*c*, 1.18 in methanol) was isolated in the usual way.

Anal. Found: C, 34.4; H, 4.3; Cl, 41.7. Calcd. for $C_7H_{11}Cl_3O_3$: C, 33.6; H, 4.4; Cl, 42.6.

The syrup appeared homogeneous by thin-layer chromatographic analysis, also hydrolysis of the syrupy glycoside in 2 *N* sulfuric acid gave a crystalline trichlorohexose of m.p. 170°, undepressed on admixture with the previously isolated 3,4,6-trichloro-3,4,6-trideoxy-D-allose.

Formation of 3,4,6-Trichloro-3,4,6-trideoxy-D-allose from 4,6-Dichloro-4,6-dideoxy-D-glucose

Crystalline 4,6-dichloro-4,6-dideoxy-D-glucose (0.15 g) was treated with sulfuryl chloride (0.4 ml) and pyridine (0.6 ml) in chloroform solution (3). The chloroform soluble product was redissolved in chloroform and heated at 50° for 8 hours with anhydrous pyridine hydrochloride (0.2 g). The syrupy product (0.2 g), isolated from the reaction mixture in the usual way, on methanolysis and dechlorosulfation (4) gave a syrup (0.1 g) which was shown by thin-layer chromatography to be chromatographically indistinguishable from methyl 3,4,6-trichloro-3,4,6-trideoxy-β-D-allopyranoside. Hydrolysis of the syrupy glycoside in *N* sulfuric acid gave a crystalline trichlorohexose of m.p. 171°–172°, undepressed on admixture with 3,4,6-trichloro-3,4,6-trideoxy-D-allose.

Reaction of Sulfuryl Chloride with 4,6-O-Ethylidene-D-galactopyranose

4,6-*O*-Ethylidene-D-galactose (10 g) (34) was treated with sulfuryl chloride (21 ml) and pyridine (40 ml) in chloroform solution (3). Concentration of the chloroform extracts gave a solid which was recrystallized from chloroform–petrol (b.p. 40–60°) to give large colorless prisms (6 g, 30%) of m.p. 133–135° and $[\alpha]_D$ +207° (*c*, 1.12 in chloroform).

Anal. Found: C, 22.7; H, 2.5; Cl, 25.4; S, 15.1. Calcd. for $C_8H_{11}Cl_3O_9S_2$: C, 22.8; H, 2.6; Cl, 25.3; S, 15.2.

A small quantity of the crystals were dechlorosulfated (4), and paper chromatographic analysis of the resultant methanol solution in solvents *a* and *b* indicated two reducing components which were chromatographically indistinguishable from D-galactose and 4,6-*O*-ethylidene-D-galactose (34).

Methyl 4,6-O-Benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (XVIII)

Methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (4 g) (17) was treated with sulfuryl chloride (10.4 ml) and pyridine (16 ml) in chloroform solution (3). The chloroform extracts were concentrated to a syrup (6 g) (XVIII). The substance was dechlorosulfated (4) in the presence of barium carbonate to prevent the removal of the benzylidene group. The resulting syrupy product (4 g) was extracted with a solution of benzene–petrol (b.p. 40–60°) (1:2) leaving a crystalline residue (0.2 g). Recrystallization of the residue from acetone gave needles of m.p. 199°, undepressed on admixture with authentic methyl 4,6-*O*-benzylidene-β-D-glucoside (7). The benzene–petrol extract was concentrated to a syrup (2.8 g) which had $[\alpha]_D$ −30° (*c*, 1.05 in methanol) and was shown to be homogeneous by thin-layer chromatographic analysis (XVIII, R = H).

Methyl 3-Chloro-3-deoxy-β-D-allopyranoside (XIX)

The above syrup (XVIII) (2.8 g) was dissolved in methanol (15 ml) and 0.1 *N* sulfuric acid (15 ml) was added to the solution. The solution was heated at 50° for 2 h, neutralized ($BaCO_3$) and filtered, and the filtrate was extracted with ether to remove the liberated benzaldehyde. The aqueous solution was deionized and concentrated to a syrup (1.5 g, 75%) of $[\alpha]_D$ −49° (*c*, 1.0 in water) which was shown to be homogeneous by thin-layer chromatographic analysis. Periodate oxidation of the syrup resulted in no consumption of periodate up to a reaction time of 60 h.

The syrup gave a syrupy triacetate derivative which had $[\alpha]_D$ −21° (*c*, 1.15 in methanol).

Anal. Found: C, 46.1; H, 6.0; Cl, 10.4. Calcd. for $C_{13}H_{19}ClO_8$; C, 46.1; H, 5.6; Cl, 10.5.

Gas liquid chromatographic analysis of the triacetate using column (B) gave one sharp peak which had a retention time of 12.3 min.

3-Chloro-3-decxy-D-allose (XX)

The syrupy monochloro methyl glycoside (XIX) (0.3 g) was refluxed in 2 *N* sulfuric acid for 16 h. The solution was neutralized and concentrated to a syrup (0.25 g, 89%), which had $[\alpha]_D$ +5.4° (*c*, 0.92 in water). Attempts to form phenylosazone, *p*-nitrophenylosazone, and *p*-nitrophenylhydrazone derivatives were unsuccessful. Paper chromatographic analysis of the syrup in solvent *a* indicated one reducing component at R_x 1.5. The syrup also gave a negative tetrazolium red test (15). Paper electrophoresis of the syrup in buffer solutions i and ii gave the following results shown in Tables III and IV respectively.

Effect of Sodium Hydroxide on Methyl 3-Chloro-3-deoxy-β-D-allopyranoside

The syrupy monochloro methyl glycoside (0.25 g) was dissolved in *N* sodium hydroxide (5 ml) and the solution was allowed to stand for 16 h at room temperature. It was deionized, and concentrated to a syrup (0.2 g) which had $[\alpha]_D$ +28° (*c*, 1.0 in methanol). It was hydrolyzed by the same method used in the previous

experiment and gave another syrup. Paper chromatography in solvent *a* and paper electrophoresis in buffer solutions i and ii of the syrup, all indicated one component indistinguishable from 3-chloro-3-deoxy-D-allose.

The reaction with *N* sodium hydroxide solution was repeated and the solution was heated at 50–60° for 10 h and then allowed to stand at room temperature for a further 16 h. The solution was deionized, and concentrated to a syrup (0.22 g) which had $[\alpha]_D$ −27° (*c*, 0.93 in methanol). The syrup gave an acetate derivative which did not crystallize and had $[\alpha]_D$ −22° (*c*, 1.32 in methanol). Gas–liquid chromatographic analysis of the derived acetate gave one sharp peak with a retention time (12.3 minutes) identical with that of methyl 3-chloro-3-deoxy-β-D-allopyranoside triacetate, when carried out using similar conditions.

ACKNOWLEDGMENTS

The authors thank the National Research Council (N.R.C. T-19) for a grant. They also thank Dr. E. Buncel for helpful discussions and Dr. H. G. Jones for carrying out the gas–liquid chromatographic analysis and for a gift of 3,4,6-tri-*O*-methyl-D-glucose.

THE NATURE OF ASSOCIATION BETWEEN MOLECULES OF N-METHYLPYRROLE

HUGH J. ANDERSON
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland
Received April 2, 1965

ABSTRACT

The dilution of N-methylpyrrole by an inert solvent causes a change in the values of the proton chemical shifts which has been interpreted to support a "closed cyclic dimer" type of association between molecules. Equilibrium constants have been computed for the monomer–dimer system at two temperatures. The proton chemical shifts have been determined for the pure liquid at a series of temperatures covering a wide range. The effects of dilution in several different solvents have also been investigated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

There has been some dispute over the nature of the association which takes place between pyrrole molecules in the pure liquid as related to the interpretation of infrared spectra (1, 2). However, the investigations of dipole moments by Lumbroso (3) and of nuclear magnetic resonance spectra by Happe (4) lend much support to their view that the association involves two molecules in the form of a "closed cyclic dimer" where the N-H of each molecule is hydrogen bonded by the π-electron cloud of the other molecule. Since these hydrogen bonds are non-linear, the force of attraction involved is far less than that of the usual hydrogen bond, probably of the order of 20–30% of the energy according to dipole moment calculations. Values for the self-association constant, as determined by the two methods, using a series of concentrations approaching infinite dilution in cyclohexane, were found to be in reasonable agreement when converted to the same units (5), and temperature differences were considered.

A dipole moment study of N-methylpyrrole (3(*a*)) indicated that this compound was also associated to some extent in an apparently similar spatial arrangement. This equilibrium system was found to have roughly similar self-association constants in both cyclohexane and carbon tetrachloride solutions to those found for the pyrrole equilibrium by the same method.

While assembling data on the n.m.r. chemical shifts of pyrrole derivatives in carbon tetrachloride we observed a variation with dilution of all of the proton signals of N-methylpyrrole. The changes of δ involved were of a magnitude similar to those observed during the dilution of pyrrole itself. To provide a comparison with the dipole moment results a series of measurements was carried out on N-methylpyrrole at increasing dilution in cyclohexane at the normal probe temperature (38 °C).

Table I shows the change in chemical shifts observed for the protons of N-methylpyrrole as this compound was diluted with cyclohexane. A similar series of measurements on solutions at 0 °C are shown in Table II. The assumption was made that the only associated form present was the dimer and that, with dilution, its concentration would decrease until at infinite dilution only monomeric N-methylpyrrole would be present. Thus the chemical shifts at infinite dilution would be those of the pure monomeric form, while in more concentrated solutions increasing amounts of the dimer would be present.

Following the arguments of Happe and of Lumbroso it was decided to assume the simplest possible situation where the only association was a dimeric one. Although other polymeric forms might well be present in liquid N-methylpyrrole, calculations involving

them would be too complex. It was found (Tables I and II) that the plots of concentration vs. the signal position of the N-methyl group were smooth curves with no abrupt change of curvature. The values of K were computed through extrapolation to infinite dilution and thus it seemed probable that at these low concentrations the only important associated species would be the dimer.

Using the series of shifts observed for the N-methyl group protons at the various dilutions as listed in Tables I and II, as well as the assumptions mentioned above, it was possible to compute, for each temperature, an infinite dilution equilibrium constant for the dissociation: dimer $\leftrightharpoons$ monomer. It was also possible to obtain the chemical shift of the N-methyl protons of both pure monomer and pure dimer.* The values at 0° are somewhat less reliable than those at 38° since the solution froze when at a concentration of 0.05 M. Nevertheless the computed chemical shifts for pure monomer and dimer at the two temperatures are in quite close agreement. These were found to be 213.5 c.p.s. for the monomer, and 153.4 c.p.s. for the dimer at 38 °C; and 213.1 c.p.s., monomer, and 150.1 c.p.s., dimer, at 0 °C. The values of K_{diss} were 15.7 $\pm$ 1.7 mole/liter at 38 °C and 10.6 $\pm$ 1.9 mole/liter at 0 °C. These values differ from the value obtained by Lumbroso

*These computations were carried out by Dr. S. Ehrenson and by Professor R. L. Taft, Jr., using a program developed to determine these values in a series of fluorinated aromatics.

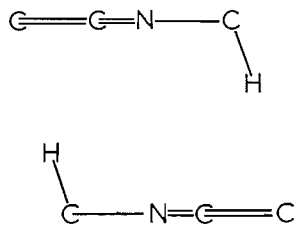
at 25 °C in cyclohexane (inverted to give a K_{diss} of 18.2 moles/liter). However, they are of similar magnitude. From the values for K_{diss} at the two temperatures it was calculated that for this equilibrium $\Delta S_0 = 11.2 \pm 4.4$ e.u. and $\Delta H_0 = 4 \pm 3$ kcal/mole. These values are consistent with the weak association expected in the "closed cyclic dimer" structure.

Qualitatively, the change in the n.m.r. spectrum observed on dilution of N-methylpyrrole with cyclohexane (or with carbon tetrachloride) is similar to that for pyrrole and may be explained in the same way. It is evident that, with dilution, some of the N-methyl protons are being removed from the environment of the dimer where they are strongly shielded. This is consistent with the N-methyl group lying in the π-cloud of another molecule while in the associated form, and the breaking up of this dimer with dilution (4, 6, 7). The smaller downfield shift of the α-protons and the even smaller upfield shift of the β-protons in cyclohexane solution may be deduced from an examination of the location of these protons in scale models where two molecules form an associated pair with the aromatic rings antiparallel and face-to-face (see the figure). Here the α-protons are inside but close to the edge of the shielding zone above, or below, the aromatic ring of the other molecule. The β-protons lie just outside this zone and are thus partially deshielded. This arrangement would produce the observed changes with dilution of the signal positions.



As Lumbroso has pointed out the arrangement of N-methylpyrrole molecules must be in an antiparallel face-to-face rather than an "open" or perpendicular arrangement since the dipole moment of the neat liquid is less than that of the vapor. The assemblages may be dimeric or multimeric in the neat liquid but at low concentrations the dimer is probably the most important associated species.

Hatton and Richards (6) observed a similar downfield movement of the methyl group signal in 4-picoline when it was diluted with carbon tetrachloride. The actual change was about 5.1 c.p.s., but this was from pure liquid to 0.10 mole fraction rather than to infinite dilution. These authors suggested the same sort of antiparallel face-to-face arrangement of molecules in the pure liquid to explain the change observed on dilution. It is most interesting to note that the doublet signal of the protons ortho to the methyl group (i.e. 3- and 5-) moved, on the average, 0.9 c.p.s. to higher field and the doublet of the protons meta to the methyl (i.e. 2- and 6-) moved, on the average, 4.5 c.p.s. to higher field on dilution with carbon tetrachloride. These positions approximate our α- and β-positions in their location with respect to the methyl group. However, it would appear that in 4-picoline the shape of the 6-membered ring and the arrangement of the molecules in space is such as to place the 3- and 5- protons just outside the shielding zone, and the 2- and 6-protons in the deshielding zone of the other molecule of the pair.

A series of measurements, shown in Table III, has been carried out on pure liquid N-methylpyrrole at temperatures from $-70°$ (supercooled) to $+100$ °C. These samples contained tetramethylsilane (TMS) as an internal reference. At higher temperatures it was necessary to use larger amounts of TMS; however, the dilution involved was relatively

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

very small. A plot of temperature vs. the chemical shift of the N-methyl protons was a straight line throughout this range of temperatures. It is possible that if several multimeric species were present there would be breaks in this curve. As the temperature increased, the values for chemical shift of the N-CH_3, α-, and β-protons all changed in the same fashion as they did when the pure liquid was diluted with cyclohexane at a given temperature. That is, N-CH_3 and α- moved to lower field while β- shifted only very slightly and to higher field. It is felt that this represents a change in the equilibrium in favor of a higher concentration of monomer at higher temperature. This should not have been caused by the expansion of the liquid since an internal standard was used. It must have been caused by the effect of the thermal energy on the weak binding forces between the molecules in the dimeric form. The values for the K_{diss} given above are indicative of the instability of dimer formed. Hatton and Schneider (7) reported a similar change of shift in methyl group protons arising from the effect of temperature on the toluene–acetonitrile complex.

TABLE III

The effect of temperature on the chemical shifts for pure N-methylpyrrole

Temp.	N-CH_3, c.p.s.	α-, c.p.s.	β-, c.p.s.
−70°	175.8	376.7	369.0
−50°	178.2	377.5	367.7
−30°	180.2	378.0	366.9
−10°	182.5	378.6	366.1
+10°	184.1	379.2	365.4
+30°	186.7	380.2	365.7
+38°	188.0	381.4	366.0
+40°	187.9	381.0	365.5
+60°	189.7	381.9	365.6
+80°	191.6	382.4	365.4
+100°	193.4	383.7	366.0

Values for the chemical shifts of all the protons in solutions of N-methylpyrrole at concentrations approaching infinite dilution were found for other solvents and are listed in Table IV. The changes taking place on dilution with carbon tetrachloride, though in the same direction, were larger than those for dilution in cyclohexane. This may well be caused by the different reaction fields of these solvents, carbon tetrachloride shifting all the signals to lower field than cyclohexane did. However, the β-proton signal is moved, instead, to higher field and to a greater extent than in cyclohexane. This cannot be explained by our simple picture. It should be noted, however, that there is also a difference in the values for K_{diss} calculated by dipole moment measurements for both N-methylpyrrole and pyrrole in these two solvents (3 (*a*)).

TABLE IV

The effect of solvent on signal positions of N-methylpyrrole*

Solvent	N-CH_3, c.p.s.	α-, c.p.s.	β-, c.p.s.
Reference cyclohexane	213.1	386.0	362.0
CCl_4	−8.0	−2.4	+3.0
Mesitylene	+28.0	+7.0	−6.5
Nitrobenzene	−3.3	−16.0	−10.6
N-Methylpyrrole (pure liquid)	+25.1	+4.6	−4.0

*A + value means a shift to higher field.

For personal use only.

Dilution in mesitylene caused all signals to be moved in the opposite direction to those observed in cyclohexane, but only to a small extent. This would be expected if the N-methylpyrrole molecule had been transferred from the environment of the dimer suggested above into a different and slightly greater induced field belonging to the other aromatic molecule, mesitylene.

This picture of associating N-methylpyrrole molecules corresponds to that suggested by Lumbroso. The chemical shifts obtained by Happe for pyrrole in cyclohexane over the range from 0.9675 to 0.0000 mole fraction change by N-H = -0.455, α-H = -0.215 and β-H = $+0.088$ p.p.m. These values are quite close to the observed changes for the corresponding protons in N-methylpyrrole in cyclohexane, over about the same concentration range. For these reasons it is felt that all our observations on N-methylpyrrole fit well with the picture of self-association for both pyrrole and N-methylpyrrole molecules in the pure liquid and in concentrated solutions suggested by Happe and by Lumbroso. That is, the "closed cyclic dimer" type of structure, involving in N-methylpyrrole some sort of dipole–dipole or charge transfer attraction, is an important associated form, and probably the most important one at lower concentrations.

Finally, dilution with nitrobenzene shifted all the proton signals of N-methylpyrrole to lower field in amounts that are in the order of their presumed polarizability: $\alpha- > \beta- > CH_3-$, as shown in Table IV. Thus, while mesitylene appears to associate with N-methylpyrrole by forming a complex similar to that formed by N-methylpyrrole with itself, the same does not seem to be true for nitrobenzene. The latter solvent apparently is acting in a selective manner on individual protons, possibly through the nitro group (8). Schneider (9) has observed a similar shift to low field of the protons of benzene in a nitrobzenene solution. He reported the change in shift from cyclohexane to be 12.9 c.p.s., the same order as observed here for the difference in chemical shift at infinite dilution of the aromatic protons of N-methylpyrrole in these two solvents.

EXPERIMENTAL

The nuclear magnetic resonance spectra were determined at 60 Mc/s using a Varian A-60 spectrometer with tetramethylsilane as internal reference. The variable Temperature Probe was calibrated against ethylene glycol above, and methanol below, ambient.

ACKNOWLEDGMENT

The author is deeply indebted to Professors J. M. W. Scott and E. Bullock for many stimulating discussions. He also thanks Dr. S. Ehrenson and Professor R. L. Taft, Jr., for the computations, and the National Research Council for continued financial support.

CONCERNING THE ORTHO SHIFT IN PROTON AND FLUORINE MAGNETIC RESONANCE OF SOME CONJUGATED HYDROCARBONS

F. HRUSKA,[1] H. M. HUTTON, AND T. SCHAEFER[2]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received February 25, 1965

ABSTRACT

A linear correlation with Q is found for the shifts of protons or fluorines placed ortho or *cis* to the substituent in monosubstituted benzenes, ethylenes, propenes, monofluorobenzenes, and perfluorobenzenes. The substituent X corresponds to H, F, Cl, Br, I, and Q equals P/Ir^3 where P is the polarizability of the C—X bond, r is the C—X bond length, and I is the first ionization potential of atom X. The correlation is useful for predicting some as yet unknown shifts in the above compounds. The significance of this correlation is discussed in an inconclusive manner.

INTRODUCTION

The observed proton shifts in the ortho position correlate well with the para proton shifts and reactivity parameters in monosubstituted benzenes (1). The exceptions are iodo-, bromo-, and chloro-benzenes. As pointed out by Wu and Dailey (2), factors other than pi electron densities are important in determining the observed shieldings in this position. It has been suggested (1) that these anomalies are caused by the magnetic anisotropy $\Delta\chi$ of the halogens, but it appears that a consistent assignment of $\Delta\chi$ cannot be made (3). This is perhaps not surprising since a shift of about 1 p.p.m. would be expected from $\Delta\chi$ effects of this sort, while the anomalous ortho fluorine shifts in the substituted fluorobenzenes are about 20 times as large as the analogous proton shifts (4, 5, 6).

There has been the suggestion (7) that the origin of the ortho shift lies in an increased paramagnetic term in Ramsey's equation (8), arising from smaller values of the electron excitation energies associated with a fluorine atom at a position ortho to a substituent. This explanation agrees with the increasing magnitude of the ortho effect as the substituent increases in size or when it is a transition metal with low-lying excited states of suitable symmetry. The appropriate ΔE values are, however, not known.

Others (6, 9, 10) have suggested that the ortho effect has its origin in the presence of time-dependent electric fields arising from the substituent. These electric fields are taken to be those which give rise to the van der Waal's forces between non-bonded atoms. Raynes *et al.* (11) calculate the intermolecular time average fields as $E^2 = 3PIr^{-6}$ where P is the polarizability of the molecule, I is the first ionization potential, and r is the intermolecular distance. This equation represents the long-range contribution to the shielding but in molecular collisions shorter range effects may be appreciable. Although there appears to be no real justification for it, Boden *et al.* have applied this equation in an attempt to explain the ortho effect for C_6F_5X (X = halogen) compounds with some success (6). In this intramolecular situation one may well question the use of this long-range equation, and it is interesting to note that it failed badly when applied to X = H.

As there appears to be no adequate theoretical model at present, it may be worthwhile to have an empirical correlation of the ortho shifts with some properties of the substituent. Such a correlation should be capable of predicting presently unknown shifts and

[1]*Holder of a N.R.C. Studentship, 1964–65.*
[2]*N.R.C. Senior Research Fellow, 1964–65.*

should be easy to use. The halogens (and hydrogen) are the substituents for which considerable shift data are available. We report here that we find a linear correlation of the low-field ortho shift with the quantity $Q = P/Ir^3$. P is the polarizability of the C—X bond (X = H, F, Cl, Br, I), r is the C—X bond length, and I is the first ionization potential of X.

The shift has been correlated with Q for (1) ortho protons in monosubstituted benzenes, (2) *cis* protons in the vinyl halides, (3) protons *cis* to the substituent in 1- or 2-halopropenes, (4) ortho fluorines in ortho-substituted monofluorobenzenes, (5) ortho fluorines in monosubstituted perfluorobenzenes.

Correlation of Shifts with $Q = P/Ir^3$

In Table I the bond and atom parameters for X = H, F, Cl, Br, I are given. The ionization potentials for the free atoms are given since no data are available on bond

excitation energies (see the discussion below). In Table II, experimental data are given for the types of compounds indicated above. The data were selected from the literature with the criterion that, if possible, the shift measurements were made in a common inert solvent for each set and that an internal reference was used. In this way, solvent effects (12) and bulk susceptibility corrections (12) were either small or nonexistent.

1. Proton Shifts

In Fig. 1*a* the ortho proton shifts in C_6H_5X are plotted versus Q. The largest deviations from the linear relationships are about 1.5 c/s in a range of over 40 c/s. In Fig. 1*b* the

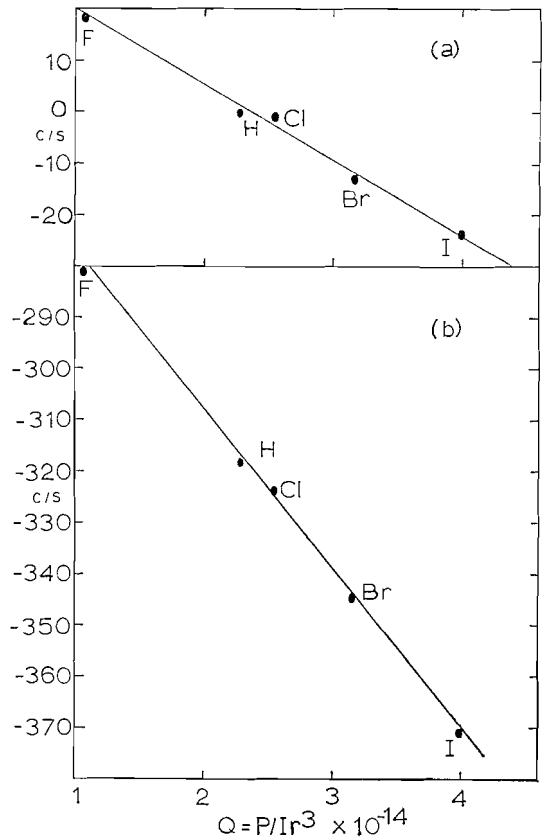

FIG. 1. In (*a*) the ortho proton shifts in c/s at 60 Mc/s in monosubstituted benzenes are plotted versus P/Ir^3. In (*b*) the shifts of the protons *cis* to the substituent are similarly plotted for monosubstituted ethylenes. Data are taken from Tables I and II.

cis proton shift in ethylene and the vinyl halides is similarly plotted. The largest deviation is about 2 c/s in a range of 90 c/s.

In Fig. 2 the shift of the protons *cis* to the substituent in the 1- and 2-halopropenes is plotted against Q. The shift for propene itself (14) was measured in carbon tetrachloride but the other values are for the neat compound (15) or cyclohexane or tetramethylsilane solutions (16). Again, the maximum deviation is about 1 c/s in the 1-halopropenes. The predicted shifts for 2-iodopropene is −337.5 c/s from internal tetramethylsilane. Similarly, the predicted shift for 1-iodopropene is −384 c/s. (The 1-iodo compound does not appear to have been made and we are presently engaged in its synthesis.)

2. The Fluorine Shifts

In Fig. 3*b* the ortho fluorine shifts in C_6F_5X are plotted versus Q. The linear correlation is considered satisfactory, although the deviation for X = H is 3.7 p.p.m. in a range of 43 p.p.m. (Boden *et al.* found a deviation as large as 23 p.p.m. for their calculation (6)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

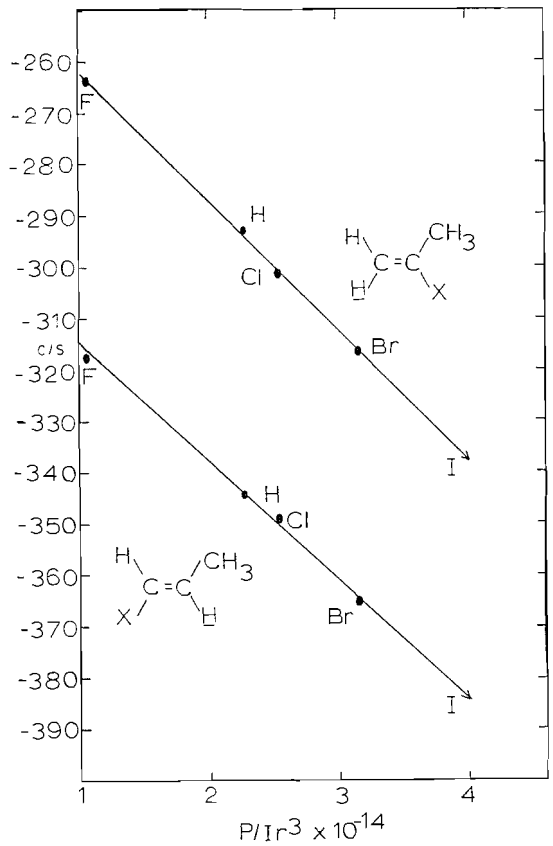

FIG. 2. The shifts, in c/s relative to internal tetramethylsilane, of the protons *cis* to the substituent in 1- and 2-substituted propenes are plotted versus P/Ir^3. The arrowheads indicate the predicted values for the iodo compounds. Data are taken from Tables I and II.

Part of the deviation of 3.7 p.p.m. may be a result of the CCl_4 solvent. Intermolecular van der Waals shifts in halogenated solvents are particularly large (12) and since hydrogen is such a small substituent it may allow a closer approach of the solvent molecules to the ortho fluorine atoms. The deviation is in fact to low field in Fig. 3*b*.

In Fig. 3*a* the ortho fluorine shifts in ortho-substituted monofluorobenzenes are plotted versus Q. The deviation for X = H from the very good straight line of X = halogen is 6.3 p.p.m., again to low field. The measurements were made on the pure compounds and not in an inert solvent (4).

DISCUSSION

1. Range of Observed Shifts

The range of proton shifts in the monosubstituted benzenes is 0.7 p.p.m. while for the *cis* proton in vinyl halides it is 1.5 p.p.m. For the *cis* proton in the 2-substituted propenes it is 1.2 p.p.m. and it is 1.1 p.p.m. for the *cis* proton in the 1-substituted propenes (using the predicted values for the 1- and 2-iodopropenes). The range of fluorine shifts is 45 p.p.m. for the mono- and 43 p.p.m. for the per-fluorobenzenes.

It is therefore fairly certain that the cause of the ortho effect is not $\Delta\chi$ of the substituents. On the other hand, it is impossible to decide whether the paramagnetic term

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

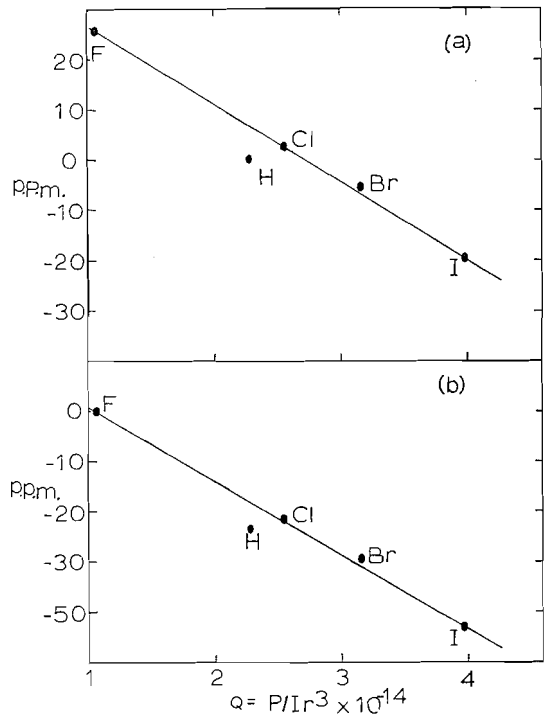

FIG. 3. In (*a*) the shifts in p.p.m. of the ortho fluorines in ortho-substituted fluorobenzenes, *o*-C_6H_4FX, are plotted versus P/Ir^3. In (*b*) the ortho fluorine shifts of monosubstituted perfluorobenzenes are similarly plotted. Data are taken from Tables I and II.

in Ramsey's equation or the intramolecular van der Waals effect is the origin of these low field shifts (but see below).

2. Correlation of Other Shifts with $Q = P/Ir^3$

The shift of the proton *trans* to the substituent in the vinyl halides and the ethylene itself gives a very good linear correlation with Q (it has not been plotted here). Furthermore, the range of shifts is 2.2 p.p.m. and is therefore larger than the 1.5 p.p.m. for the *cis* proton. This fact argues against an intramolecular van der Waals effect as the origin of the ortho shifts. The gem proton shifts do not correlate with Q.

The protons *trans* to the substituent in the 1- and 2-substituted propenes also correlate linearly with Q and we have used this correlation to predict the unknown shifts in 1- and 2-iodopropenes. The gem proton shifts do not correlate with Q.

Other shifts which do not correlate with Q are the meta and para proton shifts in the monosubstituted benzenes, monofluoro- and perfluoro-benzenes.

3. Significance of the Correlation with $Q = P/Ir^3$

If one treats the correlation function P/Ir^3 seriously, then it predicts that a perfectly hard C—X bond ($P = 0$, $I = \infty$) is to be taken as the reference and that low-field shifts will be observed for any real C—X bond in the molecules under consideration. This is reasonable in that a perturbation usually causes a low-field shift in nuclear magnetic resonance. Normally, in these compounds, the reference point is taken as the C—H bond, and the shifts in Figs. 1 to 3 are then all to high field for the C—F bond. This is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

usually interpreted as due to conjugative electron release from the fluorine substituent. We consider that since the linear correlation holds for the halogens *and* for hydrogen, it is something more than a coincidence.

One rationalization of Q is as follows. The paramagnetic contribution (second term in Ramsey's equation) should be roughly inversely proportional to a mean excitation energy ΔE. Since ΔE is not known, we are forced to use the first ionization potential, I, of the substituent X. The quantity P/r^3 (dimensionless) is then a factor which corrects for the use of I.

On this view, the ortho shifts are closely related to the paramagnetic contribution and then the linear correlation with Q of, for instance, the *trans* protons in the vinyl halides is not entirely unreasonable.

CYCLOHEXANE COMPOUNDS

V. THE REACTION OF 1-METHOXYCYCLOHEXENE-2 WITH AQUEOUS N-BROMOSUCCINIMIDE. THE 1-METHOXY-2-BROMO-3-HYDROXYCYCLOHEXANES[1]

R. A. B. BANNARD, A. A. CASSELMAN, AND L. R. HAWKINS
Defence Chemical Biological and Radiation Laboratories, Defence Research Board, Ottawa, Canada
Received April 6, 1965

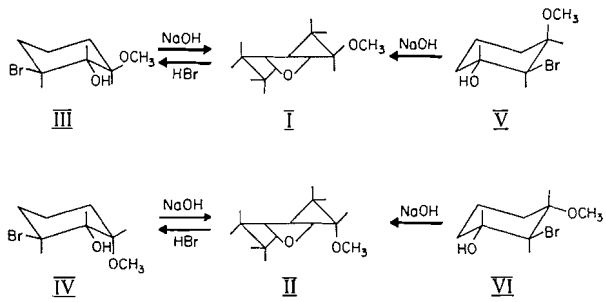
ABSTRACT

Interaction of 1-methoxycyclohexene-2 and aqueous N-bromosuccinimide gave a mixture of stereoisomeric bromohydrins, which, on treatment with aqueous sodium hydroxide, furnished 1β-methoxy-2α,3α-epoxycyclohexane (I) and 1α-methoxy-2α,3α-epoxycyclohexane (II) in the ratio 3:1. The mixture from the N-haloimide-olefin reaction was separated by preparative vapor phase chromatography into three isomeric bromohydrins, 1α-methoxy-2α-hydroxy-3β-bromocyclohexane (IV), 1α-methoxy-2α-bromo-3β-hydroxycyclohexane (V), and 1α-methoxy-2β-bromo-3α-hydroxycyclohexane (VI) in the relative proportions 1:10:4. The 3-bromo isomer IV was identified by comparison with an authentic specimen prepared by the action of hydrobromic acid on the oxide II. Compounds V and VI were shown to have the indicated structures by deetherification to the corresponding bromodiols VII and VIII in high yield, followed by debromination of the latter to *trans*- and *cis*-1,3-cyclohexanediol respectively. The product distribution is considered in relation to the intervention of electronic and steric factors in a possible mechanism suggested for the reaction between aqueous N-bromosuccinimide and 1-methoxycyclohexene-2.

Several years ago (1) we reported that the action of hydrobromic acid on the stereoisomeric 1-methoxy-2,3-epoxycyclohexanes I and II led to the formation of 1α-methoxy-2β-hydroxy-3α-bromocyclohexane (III) and 1α-methoxy-2α-hydroxy-3β-bromocyclohexane (IV) respectively. The structures of these substances were established by a variety of chemical means (1) because we wished to determine their relationship to the mixture of bromohydrins resulting from the action of aqueous N-bromosuccinimide upon 1-methoxycyclohexene-2. The latter bromohydrin mixture furnishes the oxides I and II in the ratio of 3:1 on treatment with aqueous sodium hydroxide and since 1,2-halohydrin to oxide conversions involve a *trans* ring closure (3, 4), it is apparent that the trans oxide I could have arisen from either or both of 1α-methoxy-2β-hydroxy-3α-bromocyclohexane (III) and 1α-methoxy-2α-bromo-3β-hydroxycyclohexane (V). Likewise the *cis*-oxide II would be formed if the mixture contained either 1α-methoxy-2α-hydroxy-3β-bromocyclohexane (IV) or 1α-methoxy-2β-bromo-3α-hydroxycyclohexane (VI) or both. The present communication describes the manner in which the composition of the bromohydrin mixture from the olefin-N-haloimide reaction was determined and provides an unequivocal proof of structure for 1α-methoxy-2α-bromo-3β-hydroxycyclohexane (V) and 1α-methoxy-2β-bromo-3α-hydroxycyclohexane (VI).

Attempts to separate the components of the bromohydrin mixture by fractional distillation *in vacuo* and by column chromatography on alumina were unsuccessful. We therefore explored chemical separations based upon the formation of crystalline derivatives. In this connection, the possible utility of acetate, *p*-toluenesulfonate, 2,4-dinitrobenzenesulfenate, dichloroacetate, 3-nitrophthalate, phenylurethane, and naphthylurethane derivatives was examined, but only by means of the latter was a partial separation of the isomers achieved. The crude solid resulting from the prolonged action of 1-naphthylisocyanate on the bromohydrin mixture was fractionally crystallized furnishing two methoxycyclohexene bromohydrin 1-naphthylurethanes, m.p. 151° and 196–197.5°, in 64.1% and

[1]*Issued as DCBRL Report No. 457.*



10.5% yield respectively. These compounds were shown to be completely different from the 1-naphthylurethanes of the 3-bromo compounds III and IV (1) (Table II) by mixture melting points and comparison of infrared spectra. Preparative paper chromatography of the mixture on Whatman seed test paper using hexane saturated with 90% methanol also gave a partial separation into two fractions, R_F 0.14 and 0.35. The slower-moving band (66.6%) consisted of the two 2-bromo compounds V and VI as shown by conversion to the 1-naphthylurethanes mentioned above. The faster-moving band accounted for 8.5% of the mixture and was identified as 1α-methoxy-2α-hydroxy-3β-bromocyclohexane (IV) by its infrared spectrum and its conversion to the 1-naphthylurethane of m.p. 122–124° (Table II).

These experiments demonstrated the presence of the bromohydrins IV, V, and VI in the mixture and indicated the great predominance of the 2-bromo compounds. From the ratio of the oxides I and II obtained from the bromohydrin mixture by the action of alkali (1), it was also concluded that the 1-naphthylurethanes of m.p. 151° and 196–197.5° are derived from V and VI respectively. However, these partial separations did not eliminate the possibility that III is also present as a minor component and, moreover, did not provide us with the bromohydrins V and VI which we wished to obtain for comparison of their physical properties and chemical reactivity with those of the 3-bromo isomers III and IV. Although it was considered probable that a satisfactory separation of the components of the mixture might be achieved using another solvent system for paper chromatography or thin-layer chromatography (and this actually proved to be the case later (5)) such separations on a preparative scale are frequently unduly tedious (6, 7) in comparison to those obtainable with a variety of preparative vapor phase chromatographic (v.p.c.) equipment which is now commercially available.

Preparative vapor phase chromatography at 150° on the Wilkens Autoprep Model A-700 gas chromatograph, using a column packed with 30% XF-1150 on Chromosorb P as described in the experimental section, gave the fractions shown in Table I. Fraction 1 consisted of two very minor components with retention times of 12 and 30 min. These substances differed from the four bromohydrins in question as shown by their infrared spectra, which contained a prominent carbonyl band at 1 700 cm^{-1}, which was not, of course, present in those of the bromohydrins. Fraction 2 was identified as 1α-methoxy-2α-hydroxy-3β-bromocyclohexane (IV) by its infrared spectrum. Fractions 3 and 4 were the pure 1-methoxy-2-bromo-3-hydroxycyclohexanes. From the relative amounts of fractions 3 and 4 it was deduced that the former, which is a crystalline solid, m.p. 55.5–57.0°, is 1α-methoxy-2β-bromo-3α-hydroxycyclohexane (VI)* and that the latter, which is a liquid

*We are indebted to Prof. R. Y. Moir, Mr. T. McMullen, and Mr. E. J. Langstaff for first isolating this compound during a partial v.p.c. separation of V and VI obtained using 20% butane-1,4-diolsuccinate as the substrate on a column packed with Chromosorb W.

TABLE I

Vapor phase chromatographic separation of the 1-methoxycyclohexene-2 bromohydrins

Fraction No.	Retention time (min)	Weight* (mg)	% of total recovery
1	0–36	64.5	1.04
2	41	414	6.73
3	69	1 570	25.6
4	91	4 100	66.7

*Total recovery 6 150 mg (84.0%), weight of mixture processed 7.33 g.

n_D^{25} 1.5145, is 1α-methoxy-2α-bromo-3β-hydroxycyclohexane (V). These deductions were confirmed by unambiguous chemical methods as indicated later.

The two new bromohydrins V and VI were characterized by preparation of their 1-naphthylurethanes and acetyl derivatives, the physical constants of which are recorded in Table II together with the corresponding data for the 3-bromo compounds. It is noteworthy that the structural assignments which were tentatively made on the basis of the proportions of the 1-naphthylurethanes isolated from the bromohydrin mixture were completely confirmed when these derivatives were prepared from the pure bromohydrins.

That 1α-methoxy-2β-hydroxy-3α-bromocyclohexane (III) can be formed to the extent of only 0.5% or less was established in two ways after it was discovered that the chromatographic column used in the work just described would *not* separate III from V.* Thin-layer chromatography of the bromohydrins III, IV, V, and VI on silica gel G in hexane: N,N-dimethylformamide: 90% methanol, (100:25:100) gave the R_F values 0.27, 0.40, 0.21, and 0.36 respectively, and it was demonstrated that as little as 0.5% of III could be detected in the presence of the other three by this means (5). Likewise, vapor phase chromatography at 150° in the same apparatus used previously, but employing a 5 ft column packed with 10% Versamid-900 on 45/60 mesh acid-washed and silanized Chromosorb P gave a clean separation of a synthetic mixture of the four isomers with retention times of 23, 14.5, 28, and 17 min respectively (5). Similar treatment of the bromohydrin mixture from the N-bromosuccinimide–olefin reaction failed to reveal the presence of the 3-bromo isomer III. It is therefore concluded that the bromohydrin mixture consists of compounds IV, V, and VI in the relative amounts 1:10:4, together with minor amounts of two other unidentified compounds which are not bromohydrins.

It was previously shown (1) that the most straightforward chemical method for establishing the structures of the alkoxycyclohexene bromohydrins is by deetherification and debromination to the cyclohexanediols, the structures of which, together with the predictable behavior of *trans*-1,2-bromohydrins (3, 4) provide an unambiguous configurational proof. Accordingly, the deetherification of compound VI with 68% aqueous hydrobromic acid at 65–68° gave the bromodiol VIII, m.p. 136.5–138° in 98% yield. The latter substance was converted to *cis*-1,3-cyclohexanediol (X), m.p. 85.0–86.5° (8) in 87% yield by debromination with Raney nickel and hydrogen in the presence of Amberlite IR-4B (OH) resin (9, 1). Since the bromine atom must have been *trans* to the hydroxyl group in the original bromohydrin to give the *cis*-oxide II on treatment with alkali, it follows that the structure of the bromodiol is 2β-bromo-1α,3α-cyclohexanediol (VIII) and that of the

**Difficulties encountered in the separation of the chloro analogues of III and V during their preparative v.p.c. separation were brought to our attention by Prof. R. Y. Moir and E. J. Langstaff. It was then found that the XF-1150 substrate would not separate a prepared mixture of III and V.*

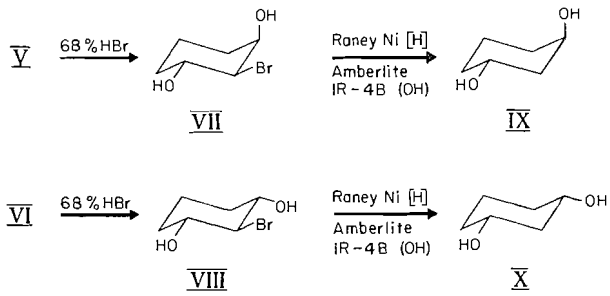
TABLE II

Physical properties of the 1-methoxy-2(3)-bromo-3(2)-hydroxycyclohexanes and their derivatives

	Cyclohexane		Derivative (m.p. or b.p. °C)			
			1-Naphthylurethane	Acetate	Diol	Diol diacetate
III	1α-Methoxy-2β-hydroxy-3α-bromo-	68.5–69	185–186	56–56.5	98–99	65–66.5
IV	1α-Methoxy-2α-hydroxy-3β-bromo-	62–63/0.01 n_D^{25} 1.5080	122–124	63–65/0.01 n_D^{25} 1.4828	70.5–71	85–86/0.1 n_D^{25} 1.4810
VI	1α-Methoxy-2β-bromo-3α-hydroxy-	55.5–57	196–197.5	44–45	136.5–138	80.2–81.2
V	1α-Methoxy-2α-bromo-3β-hydroxy-	61–61.5/0.04 n_D^{25} 1.5145	151	69–70/0.03 n_D^{25} 1.4861	104–105	82–83/0.05 n_D^{25} 1.4817

bromohydrin is 1α-methoxy-2β-bromo-3α-hydroxycyclohexane (VI). Similarly, deetherification of the liquid bromohydrin (V), n_D^{25} 1.4145, gave the bromodiol VII, m.p. 104–105°, in 91% yield. Debromination of VII furnished *trans*-1,3-cyclohexanediol (IX), m.p. 118.5–119.5° (8), in 93% yield. Since the liquid bromohydrin leading to IX yields the *trans*-oxide I it must have the structure 1α-methoxy-2α-bromo-3β-hydroxycyclohexane (V) and the corresponding bromodiol must be 2α-bromo-1α,3β-cyclohexanediol (VII). That the two bromodiols in question are not 1,2-diols was shown by the fact that they are not oxidized by sodium metaperiodate as are their isomers derived from the bromohydrins



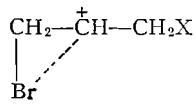
III and IV (1). The bromodiols VII and VIII were further characterized by preparation of their diacetyl derivatives, some physical constants of which are shown in Table II, together with those of the corresponding 3-bromo compounds.

The structural assignments which were made on chemical grounds as described above were fully confirmed by first-order analysis (10, 11, 12) of the multiplet patterns of the C_2 methine protons in the nuclear magnetic resonance spectra of the bromohydrin acetates and bromodiol diacetates. These spectra will be discussed in a forthcoming paper.

The composition of the bromohydrin mixture is of considerable interest from the standpoint of the mechanism of the reaction which leads to its formation. The synthetic utility of N-bromoimides in aqueous, alcoholic, or acetic acid media for adding the elements of hypobromous acid, alkyl hypobromite, or acetyl hypobromite across double bonds has been recognized for many years (13–20). No detailed studies appear to have been conducted on the mechanism of additions to double bonds via the use of N-bromoimides in polar solvents (or on the addition reactions which often accompany allylic brominations of olefins by N-bromosuccinimide in non-polar solvents). However, it has been generally assumed that such reactions proceed by a polar mechanism (14, 15, 18, 19, 21, 23, 24) involving attack by a brominium ion or another electrophilic species containing bromine to yield a cyclic bromonium ion (14, 18, 23, 24), a pi-complex (14, 25), or a carbonium ion (14, 25), which reacts subsequently with a nucleophile to form the final product. Some evidence in favor of this mechanism is derived from the *trans* stereochemistry of the resultant addition products. It has also been stated (21, 22) that when N-bromosuccinimide reacts in water or alcohols, it is converted by hydrolysis or alcoholysis to hypobromous acid or alkyl hypobromite and this viewpoint is strengthened by Traynham and Pascual's observation (25) that the substitution of aqueous N-bromosuccinimide for aqueous hypobromous acid in reactions with methylene cycloalkanes causes no change in product distribution. If the function of aqueous N-bromosuccinimide is indeed to generate hypobromous acid, there is good reason to believe that the mechanism just referred to is valid, since the extensive work of de la Mare and co-workers (26–29) on the addition of aqueous hypohalous acids to olefins has produced convincing evidence in favor of an electrophilic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

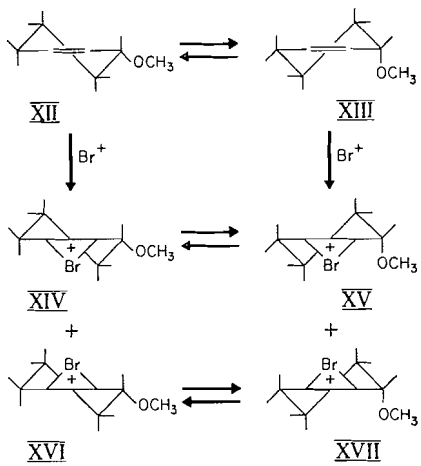
mechanism. These workers, however, favor, as an intermediate, a carbonium ion which is shielded against configurational equilibration by participation of the neighboring halogen atom during the subsequent attack by the nucleophile, as depicted in formula XI.



XI

If the viewpoint is accepted that the first stage in the reaction under consideration involves the electrophilic addition of a brominium ion or its equivalent to 1-methoxycyclohexene-2, then it could be considered that a pi-complex is first formed then transformed to the bromonium ion or shielded carbonium ion which represent slight variations of the reactive intermediate undergoing subsequent nucleophilic attack. For convenience in the subsequent discussion we shall designate the cyclic bromonium ion as the postulated intermediate. We shall then examine the products obtained from the reaction in relation to those predicted on opening the bromonium ring in a manner analogous to the nucleophilic scission of epoxides.

1-Methoxycyclohexene-2 should exist in two conformations XII and XIII, the first of which is the more stable (30). The inversion free energy change for the methoxyl group has been estimated as 0.74 kcal/mole (31) from which it follows that the percentage population of XII should be at least 75% (32). The use of Courtaulds molecular models indicated that the formation of the *trans* bromonium ions XVI and XVII and the *cis* bromonium ion XIV would not be appreciably hindered by steric interactions during the approach of the brominium ion to XII and XIII. However, the formation of the *cis* bromonium ion XV from XIII is severely hindered by the quasi-axially oriented oxygen atom of the methoxyl group. From these considerations it may be assumed that XVI and XIV will be formed in almost equal amounts and that XVII will be formed in considerably greater quantity than XV. Also, the sum of XIV and XVI should be appreciably larger than the sum of XVII and XV.*



**In this analysis the possibility that approach of the brominium ion cis to the methoxyl group in XII or XIII might be electronically assisted to a degree sufficient to overcome the less favorable steric ease of approach from that side was considered but rejected on the grounds that such electronic assistance did not intervene during the addition of hypobromous acid to 5α-cholest-1-en-3β-ol (18).*

It was mentioned previously (1) that no completely satisfactory picture of the role of polar and steric effects in determining the point of attack by nucleophiles on 1,2-epoxides has emerged. Moir and coworkers (10, 33) have pointed out that ring opening at C_3 in the 1-alkoxy-2,3-epoxycyclohexanes is to be expected if it is recognized that bond-breaking is more important than bond-making in the transition state of S_N2 epoxide scissions (34–37) and that the electron-withdrawing effect of the alkoxyl group predominates over steric factors. This interpretation predicts major attack at C_3, but not exclusive (1, 2, 10) opening at that point, since some of the experiments which led to its evolution (35–37) gave mixtures containing large amounts of isomeric products. The system was thought to be so mobile (due to the low conformation-holding energy barrier provided by the methoxyl group (33)) that it could readily accommodate itself to the polar demands of the bonds being made and broken without violating the steric requirements for diaxial opening of the ring to yield a chair form (38–39). In our view, steric factors such as the ease of approach of the nucleophile and the energy needed to bring the molecule into a reacting conformation suitable for diaxial opening to the chair form should be more carefully considered, both in the reaction of the alicyclic oxides under consideration, and in the scission of their bromonium ion analogs XIV–XVII. If it is assumed that polar and steric factors are both important, with the former slightly predominant, it seems reasonable to expect that major products will be formed when these effects operate in unison and that minor products will result when they are opposed.

In the reaction of XIV according to these principles, attack at C_3 is favored by both the polar effect of the methoxyl group and the unhindered approach of the nucleophile to yield a chair on diaxial opening, while attack at C_2 is unfavorable on both electronic and steric grounds. Consequently, XIV reacts rapidly to produce the 2-bromo compound V in major amount. In the reaction of the other major conformer XVI, opening at C_3 is favored electronically but is opposed by the steric condition that a less stable boat form would result. On the other hand, the unhindered approach of the nucleophile at C_2 would give a chair form, but is opposed by the unfavorable polar effect of the methoxyl group. The result is a decreased rate of reaction for XVI. Since XVI is in equilibrium with its conformer XVII and the latter can react more rapidly to yield VI as indicated below, the latter substance is produced at a rate faster than attack at C_2 yields the 3-bromo isomer IV. Consequently, IV is only a minor product of the reaction. In conformer XVII, diaxial opening at C_3 to yield a chair form is facilitated by the inductive effect of the methoxyl group and although the approach of the nucleophile to C_3 is impeded by 1,3-interaction with the axial methoxyl group, the hindrance is not as severe as that caused by approach to C_2. Consequently, rapid reaction at C_3 ensues, yielding the 2-bromo isomer VI. The latter compound is obtained in major amount since it is also formed from XVI via XVII as mentioned earlier. In the least abundant bromonium ion XV, opening at C_3 is favored by polar but opposed by steric factors, and for attack at C_2 the interplay of these effects is reversed. The rate of reaction of XV is thereby decreased and since its conformer XIV can react by a more favorable pathway to produce the 2-bromo isomer V, only a negligible amount of the 3-bromo compound III resulting from attack of XV at C_2 would be expected.

According to these predictions it would be anticipated that the relative amounts of the isomeric bromohydrins would be in the order V $\approx$ VI $>$ IV $>$ III. The proportions found experimentally were 10:4:1:0 and thus agree qualitatively with the above interpretation except that the presence of III could not be established by the methods employed. Also, Moir and co-workers (33) in studying the reaction between 1-methoxycyclohexene-2 and

aqueous N-chlorosuccinimide obtained a similar distribution of the corresponding chloro-isomers and demonstrated the absence of the 3-chloro analogue of III. These results provide some support for the mechanistic interpretation just presented, but it is difficult to reconcile the exclusive formation of 3-substituted products from scission of the oxides I and II under acidic and alkaline conditions (1, 2, 10) with the results presented above if the analogy in the behavior of epoxides and cyclic bromonium ions used herein is valid. It was mentioned earlier (1), however, that the methods of analysis which established 3-substituted derivatives as exclusive products in the oxide openings just referred to may not have been sufficiently sensitive to reveal the presence of minor amounts of the 2-substituted derivatives. Now that the more sensitive methods afforded by vapor phase chromatography can be brought to bear on the problem, reinvestigation of the ammonlysis and hydrobromic acid scission of these oxides is warranted to establish whether the 2-substituted products predicted by the above interpretation are actually formed.

EXPERIMENTAL*,†

1-Methoxycyclohexene-2 Bromohydrin

The mixture of positionally and stereoisomeric bromohydrins was prepared by the action of aqueous N-bromosuccinimide on 1-methoxycyclohexene-2 as described by Bannard and Hawkins (2).

Partial Separation of the 1-Methoxycyclohexene-2 Bromohydrins via 1-Naphthylurethane Formation

A portion of the bromohydrin mixture (1.00 g, 4.79 $\times$ 10^{-3} mole) and 1-naphthylisocyanate (1.0 g) were mixed and kept at 65–68° for 2 days in an apparatus protected from entry of moisture, after which a further portion of 1-naphthylisocyanate was added and the heating was repeated. The resultant crude solid product was collected and washed with heptane. A portion of this material proved to be soluble in hot carbon tetrachloride, and after separation, was recrystallized from ether–heptane, yielding 1.16 g (64.1%) of *dl*-1α-methoxy-2α-bromo-3β-hydroxycyclohexane 1-naphthylurethane, as colorless needles, m.p. 151°.

Anal. Calcd. for $C_{18}H_{20}NO_3Br$: C, 57.15; H, 5.33; N, 3.70; Br, 21.13. Found: C, 57.38; H, 5.35; N, 3.91; Br, 21.02.

The carbon tetrachloride insoluble material was recrystallized from acetone–heptane, yielding 0.19 g (10.5%) of *dl*-1α-methoxy-2β-bromo-3α-hydroxycyclohexane 1-naphthylurethane as colorless needles, m.p. 196–197.5°.

Anal. Calcd. for $C_{18}H_{20}NO_3Br$: C, 57.15; H, 5.33; N, 3.70; Br, 21.13. Found: C, 57.41; H, 5.54; N, 3.82; Br, 20.86.

In admixture the compounds had m.p. 143–182° and the infrared spectra (KBr pellet) were quite different.

Partial Separation of the 1-Methoxycyclohexene-2 Bromohydrins via Chromatography on Seed Test Paper

The bromohydrin mixture (1.5 g in 1 ml 95% ethanol) was applied as a streak to a sheet (18 in. $\times$ 22 in.) of Whatman seed-test paper which had been washed chromatographically with the following solvents in the order named: 0.01 *N* hydrochloric acid (3 days), water (2 days), 95% ethanol (2 days). The chromatogram was developed by the descending technique in a "Chromatocab" for 10 h using hexane saturated with 90% methanol. After air-drying the chromatogram was sprayed with 95% ethanol until damp and pressed against a sheet of Whatman No. 1 paper to produce a print. The print was sprayed with 2 *N* potassium hydroxide followed by 0.05 *N* silver nitrate and placed under ultraviolet light for 3.5 min. The bromohydrins were revealed as two dark brown bands against a light brown background at R_F values of 0.14 and 0.35. The bands were cut from the chromatogram and eluted with 95% ethanol. Corresponding eluates from four such chromatograms were combined, evaporated to dryness *in vacuo*, and distilled *in vacuo* in a Späth tube. The colorless oil obtained from the material of R_F 0.14 weighed 4.00 g (66.6%); b.p. 55–60° (air-bath temperature) /0.005 mm; n_D^{25} 1.5137. This material was shown to be a mixture of *dl*-1α-methoxy-2α-bromo-3β-hydroxycyclohexane (V) and *dl*-1α-methoxy-2β-bromo-3α-hydroxycyclohexane (VI) by separation and identification of the 1-naphthylurethanes of m.p. 151° and 196–197.5° as described above. The colorless oil obtained from the material of R_F 0.35 weighed 0.51 g (8.5%), b.p. 50–55° (air-bath temperature)/0.005 mm, n_D^{25} 1.5080; and was identified as *dl*-1α-methoxy-2α-hydroxy-3β-bromocyclohexane (IV) (1) via its infrared spectrum and conversion to the corresponding 1-naphthylurethane, m.p. 122–124°.

Separation of the 1-Methoxycyclohexene-2 Bromohydrins by Vapor Phase Chromatography

The bromohydrin mixture was separated into three major components by vapor phase chromatography on the Wilkens Autoprep Model A-700 gas chromatograph, using a 5 ft 3/8 in. diameter, aluminium column packed with 30% XF-1150 (cyanosilicone) on acid-washed and dimethyldichlorosilane-treated 45/60 mesh

**All melting-points are uncorrected.*

Chromosorb P. Optimum conditions for the separation were column and collector temperature 150°, injector temperature 168°, detector temperature 175°, helium flow rate 300 ml/min, filament current 200 mA. Serial injections of the neat bromohydrin mixture 150 μl (221 mg) were made every 2 h and the fractions recovered from processing 7.33 g of the mixture in this manner gave the results shown in Table I. Fraction 2, which was a liquid, n_D^{25} 1.5080, was identified as *dl*-1α-methoxy-2α-hydroxy-3β-bromocyclohexane (IV) by comparison of its infrared spectrum with that of an authentic specimen (1). Fraction 3 was redistilled in a Späth tube at 0.04 mm pressure at an air bath temperature of 30°, yielding a colorless oil, which crystallized on standing. Recrystallization from *n*-pentane furnished colorless prisms, m.p. 55.5–57.0°, which were shown to have the structure *dl*-1α-methoxy-2β-bromo-3α-hydroxycyclohexane (VI) (see below).

Anal. Calcd. for $C_7H_{13}O_2Br$: C, 40.22; H, 6.27; Br, 38.22. Found: C, 40.34; H, 6.44; Br, 38.06.

Fraction 4 was redistilled in a micro Bantamware still yielding a colorless liquid, b.p. 61–61.5°/0.04 mm n_D^{25} 1.5145, which was identified as *dl*-1α-methoxy-2α-bromo-3β-hydroxycyclohexane (V) (see below).

Anal. Calcd. for $C_7H_{13}O_2Br$: C, 40.22; H, 6.27; Br, 38.22. Found: C, 40.24; H, 6.26; Br, 38.12.

The infrared spectra of the two 1-methoxy-2-bromo-3-hydroxycyclohexanes taken in carbon tetrachloride solution were quite different from one another and from those of the isomeric 1-methoxy-2-hydroxy-3-bromocyclohexanes.

Derivatives of dl-1α-Methoxy-2β-bromo-3α-hydroxycyclohexane (VI)

The acetyl derivative was obtained in 90.5% yield, m.p. 44–45° as colorless prisms after recrystallization from anhydrous ether.

Anal. Calcd. for $C_9H_{15}O_3Br$: C, 43.04; H, 6.02; Br, 31.82. Found: C, 42.85; H, 5.84; Br, 32.02.

The 1-naphthylurethane was obtained in 96.0% yield, m.p. 196–197.5°, as colorless needles after recrystallization from acetone. This substance was identical in all respects with the 1-naphthylurethane, which was isolated in the smaller amount from the bromohydrin mixture.

Derivatives of dl-1α-Methoxy-2α-bromo-3β-hydroxycyclohexane (V)

The acetyl derivative, b.p. 69–70°/0.03 mm, n_D^{25} 1.4861, was obtained in 96.2% yield as a colorless viscous oil.

Anal. Calcd. for $C_9H_{15}O_3Br$: C, 43.04; H, 6.02; Br, 31.82. Found: C, 43.20; H, 6.01; Br, 31.67.

The 1-naphthylurethane was obtained in 91.6% yield as colorless needles, m.p. 151°, after recrystallization from anhydrous ether. This substance was identical in all respects with the 1-naphthylurethane, which was isolated in the larger amount from the bromohydrin mixture.

Deetherification of dl-1α-Methoxy-2β-bromo-3α-hydroxycyclohexane (VI) to dl-2β-Bromo-1α,3α-cyclohexanediol (VIII)

dl-1α-Methoxy-2β-bromo-3α-hydroxycyclohexane (2.09 g, 0.01 mole) was heated for 1½ h in a sealed tube at 65–70° with 68% hydrobromic acid (2.0 ml, 2.14×10^{-2} mole). The pale yellow solution was transferred quantitatively to a 500 ml round-bottomed flask in ca. 40 ml of water, the excess acid was neutralized by the addition of solid sodium bicarbonate (3.0 g), and the solution was evaporated to dryness *in vacuo*. The colorless residue was ground in a mortar, transferred to a Soxhlet extractor, and extracted for 16 h with anhydrous ether, and the extract was evaporated to dryness. Crystallization of the product from anhydrous ether furnished 1.91 g (97.4%) of *dl*-2β-bromo-1α,3α-cyclohexanediol (VIII) as colorless needles, m.p. 136.5–138°.

Anal. Calcd. for $C_6H_{11}O_2Br$: C, 36.94; H, 5.68; Br, 40.97. Found: C, 37.17; H, 5.55; Br, 40.73.

dl-2β-Bromo-1α,3α-diacetoxycyclohexane

This substance was obtained in 94.5% yield as colorless needles, m.p. 80.2–81.2°, after recrystallization from ether–heptane.

Anal. Calcd. for $C_{10}H_{15}O_4Br$: C, 43.03; H, 5.42; Br, 28.63. Found: C, 43.29; H, 5.44; Br, 28.70.

Debromination of dl-2β-Bromo-1α,3α-cyclohexanediol (VIII) to cis-1,3-Cyclohexanediol (X)

dl-2β-Bromo-1α,3α-cyclohexanediol (390 mg, 2.0×10^{-3} mole) was dissolved in ethanol (50 ml), Raney nickel W-7 (40) catalyst (10 g), and Amberlite IR-4B (OH) resin (3 ml) were added and the mixture was shaken at 50 p.s.i. hydrogen pressure for 18 h at room temperature. The catalyst was separated from the solution by centrifugation and decantation and was washed thrice with 50-ml portions of ethanol. The combined solutions were filtered, taken to dryness *in vacuo*, dissolved in ethanol (5 ml), and transferred to a 25 ml flask. The ethanol was removed *in vacuo* and the residue was heated at 60°–90° at 0.001 mm pressure in a stirred oil bath. The colorless sublimate which collected during this process was recrystallized from anhydrous ether yielding 203 mg (87.4%) of colorless platelets, m.p. 85.0–85.6°, alone, and 84.8–85.5° in admixture with an authentic specimen of *dl-cis*-1,3-cyclohexanediol of mp. 84.5–85.5°. The infrared spectra (KBr pellet) of the specimens were also identical.

Deetherification of dl-1α-Methoxy-2α-bromo-3β-hydroxycyclohexane (V) to dl-2α-Bromo-1α,3β-cyclohexanediol (VII)

The procedure was identical with that described above for the stereoisomeric bromohydrin. Recrystallization of the product from anhydrous ether gave 1.63 g of *dl*-2α-bromo-1α,3β-cyclohexanediol (VII) as colorless

For personal use only.

rosettes, m.p. 104–105°. The yield was 90.6% based on the bromohydrin used; 0.16 g of unreacted starting material was recovered and identified by its infrared spectrum.

Anal. Calcd. for $C_6H_{11}O_2Br$: C, 36.94; H, 5.68; Br, 40.97. Found: C, 36.85; H, 5.70; Br, 40.92.

dl-2α-Bromo-1α,3β-diacetoxycyclohexane

This compound was obtained in 96.8% yield as a colorless mobile oil, b.p. 82–83°/0.05 mm, n_D^{25} 1.4817.

Anal. Calcd. for $C_{10}H_{15}O_4Br$: C, 43.03; H, 5.42; Br, 28.63. Found: C, 43.00; H, 5.58; Br, 28.79.

Debromination of dl-2α-Bromo-1α,3β-cyclohexanediol (VII) to trans-1,3-Cyclohexanediol (IX)

The procedure was identical with that described above for the stereoisomeric bromodiol. Recrystallization of the sublimate from anhydrous ether furnished 215 mg (92.6%) of colorless rosettes, m.p. 118.5–119.5°, which was undepressed on admixture with an authentic sample of *dl-trans*-1,3-cyclohexanediol of m.p. 118–119.5°. The infrared spectra (KBr pellet) of the specimens were also identical.

ACKNOWLEDGMENTS

We are indebted to Mr. J. H. Parkkari and Mr. J. Legari for assistance with the preparative v.p.c. separation of the bromohydrins; to Prof. R. Y. Moir and Mr. E. J. Langstaff for helpful discussions and access to their results on the analogous chlorohydrins prior to publication; and to Dr. G. Rigby for providing us with authentic samples of *cis*- and *trans*-1,3-cyclohexanediol.

STUDIES IN THE CYCLIZATION OF THE PRODUCTS OF STOBBE CONDENSATION WITH PROPIOPHENONE

A. M. El-Abbady and S. H. Doss

Department of Chemistry, University College for Girls, Ain Shams University and National Research Centre, Cairo, U.A.R.

Received August 7, 1964

ABSTRACT

The isomeric mixture of the half-esters resulting from the Stobbe condensation of propiophenone with diethyl succinate is cyclized with stannic chloride as well as with sodium acetate in acetic anhydride. Cyclization of the ethyl half-ester chlorides with stannic chloride gives the keto-ester "4-carbethoxy-2-methyl-3-phenylcyclopent-2-enone." This on acid hydrolysis and decarboxylation yields 2-methyl-3-phenylcyclopent-2-enone, from which 2-methyl-3-phenylcyclopentanone is prepared by catalytic reduction. The keto-ester on Clemmensen reduction gives the corresponding unsaturated ester from which 3-methyl-2-phenylcyclopentane-1-carboxylic acid is obtained by catalytic hydrogenation and hydrolysis. 2-Methyl-3-phenylcyclopentanone and 3-methyl-2-phenylcyclopentane-1-carboxylic acid are of interest as intermediates for analogues of steroid hormones. From the latter 3-methyl-2-phenylcyclopentyl hydroxymethyl ketone and its acetate are prepared.

Cyclization of the isomeric mixture of the ethyl half-esters with sodium acetate in acetic anhydride gives methyl 4-acetoxy-1-ethyl-2-naphthoate which is converted into 1-ethyl-4-methoxy-2-naphthoic acid.

In previous studies propiophenone was shown to condense with diethyl succinate in the presence of sodium ethoxide (1) or potassium *tert*-butoxide (2) giving a quantitative yield of an oily isomeric mixture of the half-esters (I*a*, main product, and I*b* *cis* and *trans*; R = C_2H_5). Stobbe (1) was able to separate and identify the three isomeric dibasic acids (I*a*, 80% and I*b* *cis* and *trans*, 9%; R = H). In the present investigation the cyclization of this isomeric mixture of half-esters was carried out aiming to synthesise a cyclopentenone by the use of anhydrous stannic chloride as well as a mixture of fused sodium acetate in acetic anhydride as cyclizing agents. The Stobbe condensation products from alicyclic (3) and aliphatic ketones (4) give normally cyclopentenones on cyclization, but as far as we are aware, no alkyl aryl ketone products have been cyclized in this way.

Stannic Chloride Method

The mixture of the ethyl half-esters was converted into its acid chlorides (II*a* and *b*) by the action of thionyl chloride in the presence of one molecular proportion of pyridine (5). Cyclization of the crude half-ester chlorides was achieved with anhydrous stannic chloride (4). The mixture of products thus obtained was completely neutral to carbonate but partially soluble in cold dilute sodium hydroxide solution. The alkaline solution was acidified and the solid product obtained was acidic to carbonate and melted over a wide range. This mixture when boiled with aqueous caustic soda gave a single substance which was identified as γ-ethyl-γ-phenylisoitaconic acid (I*b* *trans* Ph—CH_2COOH, R = H) (1). This result showed that the alkali-soluble fraction was exclusively the anhydride mixture (III) which was hydrolyzed by the cold alkali to the corresponding known dibasic acid mixture (I*b* *cis* and *trans*, R = H) and then converted by the boiling alkali to I*b* *trans* Ph—CH_2COOH, (R = H). This same isomerization and a similar one were previously reported (1, 6). Now the possibility of the formation of the phenolic ester (XI) can be excluded. The neutral fraction was an oil, which showed bands in the infrared region at 1 750 (m), 1 720 (s), 1 690 (s); 1 610 (m); 765 (s), and 700 (s) cm^{-1}, characteristic of the stretching frequencies of the carbonyl groups of esters, ketones, and conjugated esters and

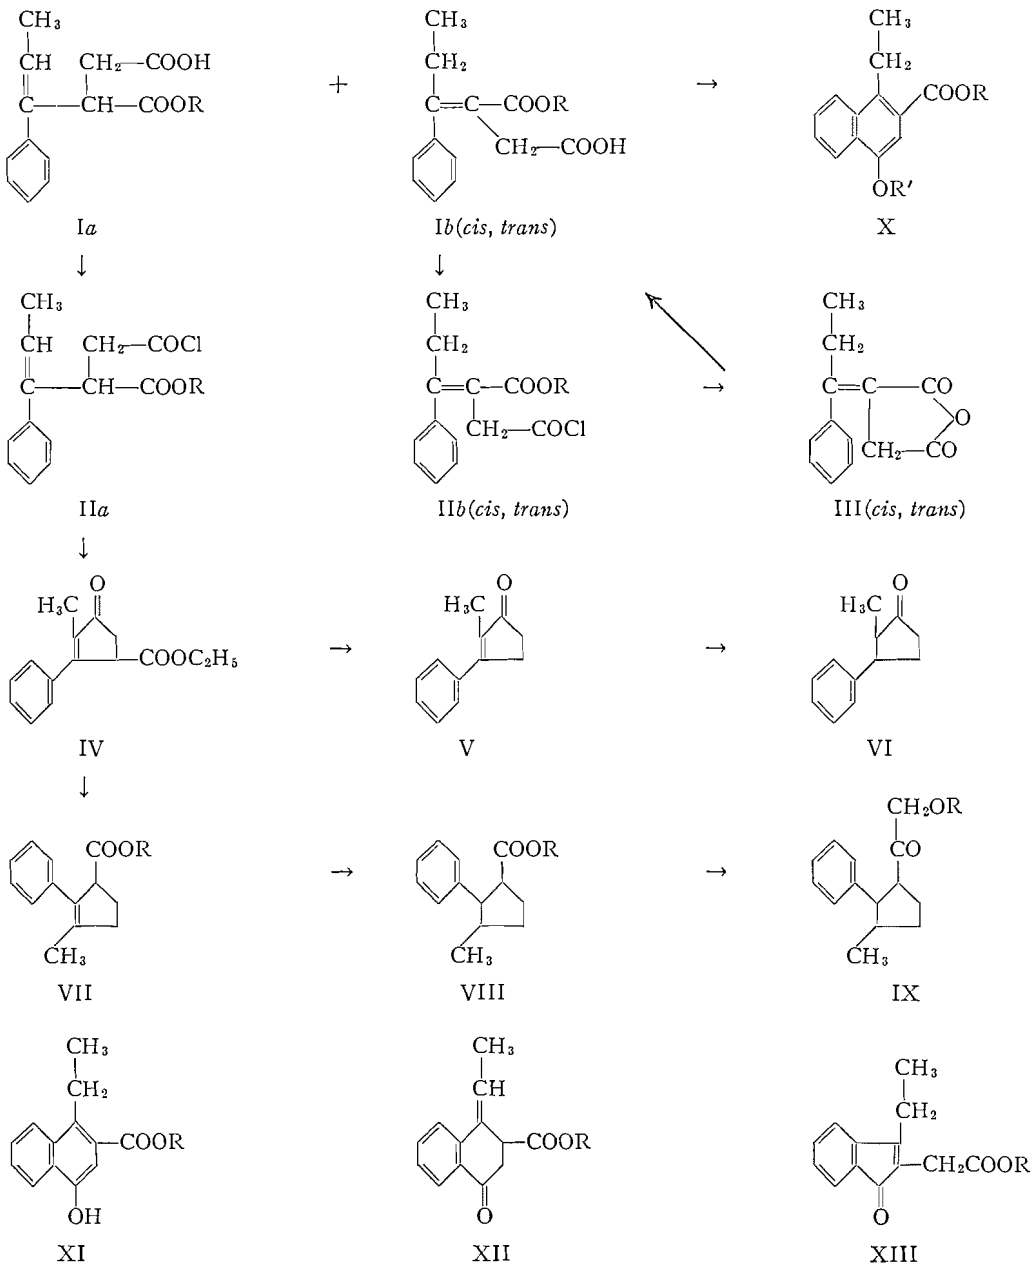
For personal use only.

ketones; the stretching frequencies of olefinic linkages; and the bending frequencies (out of plane) of aromatic 5H atoms adjacent respectively (7, 12). It gave a single semicarbazone and one 2,4-dinitrophenylhydrazone. Theoretically, such a product may be an unsaturated γ-keto-ester which can have any one of the structures IV, XII, or XIII. Acid hydrolysis and decarboxylation of the product was effected by refluxing with a mixture of glacial acetic acid, constant-boiling hydrobromic acid, and water (8) to yield the previously reported unsaturated ketone (V), as a crystalline solid, m.p. 53–55° (cf. ref. 9*a*, *b*, *c*, *d*, m.p. 50–51°, 47–48°, 49–50°, 51–52° respectively). This ketone gave a semicarbazone, m.p. 251–253° (cf. ref. 9*b*, m.p. 238°), and a 2,4-dinitrophenylhydrazone, m.p. 232–233° (cf. refs. 9*a*, *c*, *d*, m.p. 232–233°, 232–232.5°, 218–220° respectively). Since there are some variations in the published melting points of this ketone and its derivatives, it was thought necessary to confirm its structure through oxidation with concentrated sulfuric acid and mercuric sulfate (10). Benzoic acid was found to be the only insoluble product from this experiment. This indicated that the cyclization took place on the olefinic linkage and not on the aromatic ring, giving 4-carbethoxy-2-methyl-3-phenylcyclopent-2-enone (IV) from the half-ester chloride (II*a*, R = C_2H_5). This agrees with the findings of Dahn (11) in a similar cyclization. The infrared spectrum of the unsaturated ketone showed the expected stretching frequencies at 1 700 and 1 620 cm^{-1} (cf. ref. 9*c*, *e*) and aromatic γ-CH at 765 and 700 cm^{-1}, characteristic of 5H adjacent (12) which further confirmed structure V. Both the unsaturated keto-ester and ketone showed absorption maxima in the ultraviolet spectra at 270, 243, 236 mμ (log ε 4.06, 4.02, 4.00), and 275 mμ (log ε 4.23) respectively (for the unsaturated ketone, cf. ref. 9*c* and *d*, λ_{max} 279.5, 242 mμ (log ε 4.013, 3.18) and 278 mμ (log ε 4.28) respectively; for similar compounds, cf. ref. 13, λ_{max} 276 mμ (log ε 4.20)).

The unsaturated ketone (V) was then hydrogenated at a platinum oxide catalyst, absorbing 1 mole of hydrogen and giving the known 2-methyl-3-phenylcyclopentanone VI (9*a*, *b*), as a colorless oil. Its infrared spectrum showed the expected stretching frequencies at 1 745 cm^{-1} and bending frequencies (out of plane) at 765 and 700 cm^{-1} (7, 12). It gave a semicarbazone, m.p. 220–221° (cf. ref. 9*b*, m.p. 209–210°) and a 2,4-dinitrophenylhydrazone, m.p. 199–200° (cf. ref. 9*a*, m.p. 203–204°).

Clemmensen reduction of the keto-ester (IV) yielded a mixture of neutral (main product) and acid fractions. The neutral fraction consisted mainly of the unsaturated ester (VII; R = C_2H_5), which on alkaline hydrolysis gave the corresponding acid (VII; R = H). This was characterized as *p*-toluidide. The acid fraction was found to be the unsaturated acid (VII; R = H), as it gave the same *p*-toluidide derivative. The structure of the unsaturated ester and its acid was inferred from their ultraviolet spectra ($\lambda_{max}^{ethanol}$ 248.5 mμ; log ε 3.57 and 243 mμ; log ε 3.58, respectively) which showed a styryl structure (14).

The unsaturated ester (VII; R = C_2H_5) was then hydrogenated with Adam's catalyst. It absorbed 1 mole of hydrogen to yield the ester (VIII; R = C_2H_5), whence alkaline hydrolysis gave the corresponding acid (VIII; R = H). 2-Methyl-3-phenylcyclopentanone (VI) and 3-methyl-2-phenylcyclopentane-1-carboxylic acid (VIII; R = H) are of interest, as they could serve as intermediates in the preparation of analogues of steroid hormones. 3-Methyl-2-phenyl-cyclopentane-1-carboxylic acid on treatment with thionyl cloride (15) yielded the corresponding acid chloride, which with diazomethane (16) gave the corresponding diazomethyl ketone. This when treated with glacial acetic acid or with 2 *N* sulfuric acid gave 3-methyl-2-phenylcyclopentyl acetoxymethyl ketone (IX, R = $COCH_3$) or 3-methyl-2-phenylcyclopentyl hydroxymethyl ketone (IX, R = H) respectively. Both compounds (IX, R = H and R = $COCH_3$) reduced ammoniacal silver



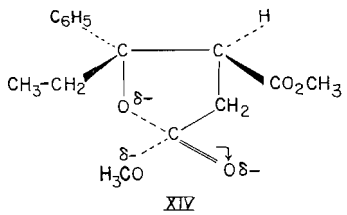
nitrate solution, and their infrared spectra showed the expected stretching frequencies at 3 600 (—OH), 1 720 (>C=O) and 1 730 (—$COCH_2OCO$—) cm^{-1} respectively. They also showed the aromatic γ-CH at 765 and 700 cm^{-1}.

Sodium Acetate Acetic Anhydride Method

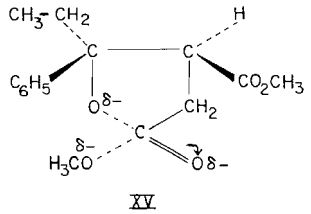
Cyclization of the crude mixture of the half-esters using fused sodium acetate in acetic anhydride (17) gave a mixture of acid and neutral fractions. The acid fraction, probably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

unreacted half-ester, was a viscous brownish oil, which on hydrolysis with baryta solution gave the known dibasic acid (I*a*, R = H) (1). The neutral fraction was a viscous oil and found to be ethyl 4-acetoxy-1-ethyl-2-naphthoate (X, R = C_2H_5, R′ = CH_3CO) formed from the half-ester I*b cis* (Ph—CH_2COOH). Trials to isolate any trace of the half-ester I*b trans* (Ph—CH_2COOH) were unsuccessful, indicating that it is present in a very small amount. The fact that the *cis* isomer in the *cis–trans* mixture of the alkylidene succinic half-ester (I*b*) is predominant can be explained by consideration of the two conformations which are favorable for the formation of the two intermediate paraconic esters. These two conformers are represented by XIV and XV. It is clear that the conformer XIV, which leads to the *cis* isomer, is more stable because of the eclipse of the bulky phenyl group with the small hydrogen atom (18).



XIV



XV

The crude acetoxy ester (X, R = C_2H_5, R′ = CH_3CO) on alkaline hydrolysis afforded 1-ethyl-4-hydroxy-2-naphthoic acid (X, R = R′ = H) in a higher yield than expected. Although Stobbe (1) stated that the ratio of I*a* to I*b* is 9:1, yet the above cyclization yield evokes the possibility of partial conversion of I*a* to I*b* under the conditions of the experiment. The hydroxynaphthoic acid was then treated with dimethyl sulfate and potassium carbonate in acetone to give the methoxy methyl ester (X, R = R′ = CH_3), which on alkaline hydrolysis yielded the methoxynaphthoic acid (X, R = H, R′ = CH_3) as a colorless crystalline solid.

EXPERIMENTAL*

4-Carbethoxy-2-methyl-3-phenylcyclopent-2-enone (IV)

The crude ethyl half-ester (14 g) obtained from the Stobbe condensation of propiophenone with diethyl succinate (2), in dry benzene (140 ml) was treated with pyridine (7 ml) and then redistilled thionyl chloride (6 ml) at 0° for half an hour. The benzene solution of the acid chlorides (II*a* and II*b*) was decanted from the solid cake, which was then pulverized and washed by decantation with benzene. The acid chlorides solution and washings were treated with stannic chloride (10 ml) for 15 h at 0°; the benzene solution was then poured on ice and concentrated hydrochloric acid (40 ml) and shaken. The benzene layer was separated and the aqueous layer washed with ether. The combined ether–benzene extract was washed with saturated sodium bicarbonate solution. Acidification of the bicarbonate washings gave no products. The organic layer was then extracted with cold 10% sodium hydroxide solution. Acidification of the sodium hydroxide washings with cold dilute hydrochloric acid gave a colorless solid, m.p. 158–175° (2.2 g). This mixture was completely soluble in $NaHCO_3$ solution and when refluxed in 10% sodium hydroxide solution (30 ml) for 1.5 h it gave after acidification γ-ethyl-γ-phenylisoitaconic acid (*Ib trans* Ph—CH_2COOH, R = H), m.p. 184–185° (from water) (cf. ref. 1).

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.65; H, 6.02. Found: C, 66.36; H, 5.85.

The organic layer after drying (Na_2SO_4), evaporation of the solvents, and distillation gave 4-carbethoxy-2-methyl-3-phenyl-cyclopent-2-enone, IV, (6.8 g, 52% crude yield), b.p. 120–122° at 0.3 mm. Infrared spectrum (liquid): 1 700, 1 690, 1 610, 765, 700 cm^{-1}. Ultraviolet spectrum: $\lambda_{max}^{ethanol}$ 270, 243, 236 mμ (log ε, 4.06, 4.02, 4.00).

2-Methyl-3-phenylcyclopent-2-enone (V) (9)

The keto-ester IV (12 g distilled) was refluxed with glacial acetic acid (120 ml), constant-boiling hydrobromic acid (80 ml) and water (40 ml) for 1 h, during which carbon dioxide was evolved. The acidic mixture was cooled and poured carefully on crystalline sodium carbonate (320 g) in sufficient water to form a slurry. The ketone was extracted with ether and dried over Na_2SO_4, and the solvent was evaporated to give a brown oily residue (8.4 g). This after distillation, b.p. 101–103° at 0.35 mm, solidified on standing giving 2-methyl-3-phenylcyclopent-2-enone (V) as colorless needles, m.p. 53–55° (from petroleum ether, b.p. 40–60°). Infrared spectrum (Nujol mull): 1 700, 1 620, 765, 700 cm^{-1}. Ultraviolet spectrum: $\lambda_{max}^{ethanol}$ 275 mμ (log ε 4.23).

Anal. Calcd. for $C_{12}H_{12}O$: C, 83.69; H, 7.02. Found: C, 83.86; H, 7.04.

It gave a semicarbazone, m.p. 251–253° (from ethanol).

Anal. Calcd. for $C_{13}H_{15}ON_3$: N, 18.33. Found: N, 17.74.

Its 2,4-dinitrophenylhydrazone melted at 232–233° (from acetic acid).

Anal. Calcd. for $C_{18}H_{16}O_4N_4$: C, 61.36; H, 4.58; N, 15.90. Found: C, 61.11; H, 4.81; N, 15.51.

The unsaturated ketone (1 g) was treated with mercuric sulfate (0.6 g) and concentrated sulfuric acid (8 ml) at 250° for 10 min, then at 300–310° for 50 min using a metal bath and an air condenser. A colorless solid sublimed and was collected from the air condenser, m.p. 119–121°. This on admixing with an authentic specimen of benzoic acid, m.p. 122° (B.D.H.), gave no depression.

2-Methyl-3-phenylcyclopentanone (VI) (9a, b)

A solution of 2-methyl-3-phenylcyclopent-2-enone (2.5 g) in glacial acetic acid (30 ml) was shaken with hydrogen in presence of Adams platinum oxide (0.2 g) until the absorption of hydrogen was ceased. After filtration, the acetic acid was neutralized with sodium carbonate solution. The product was extracted with ether and dried over Na_2SO_4, and the solvent was evaporated to give an oily residue. This on distillation yielded 2-methyl-3-phenyl-cyclopentanone as a colorless liquid (2.3 g), b.p. 81–82° at 0.25 mm. Infrared spectrum (liquid): 1 745, 765, 700 cm^{-1}.

Anal. Calcd. for $C_{12}H_{14}O$: C, 82.72; H, 8.10. Found: C, 82.24; H, 8.54.

It gave a semicarbazone, m.p. 220–221° (from methanol).

Anal. Calcd. for $C_{13}H_{17}ON_3$: C, 67.50; H; 7.41; N, 18.17. Found: C, 67.56; H, 7.37; N, 18.15.

Its 2,4-dinitrophenylhydrazone melted at 199–200° (from acetic acid).

Anal. Calcd. for $C_{18}H_{18}O_4N_4$: C, 61.01; H, 5.12; N, 15.81. Found: C, 60.93; H, 5.38; N, 15.92.

Clemmensen Reduction of the Keto-ester (IV)

To amalgamated zinc wool (80 g) in water (70 ml) and concentrated hydrochloric acid (160 ml) was added the ethyl keto-ester (IV) (20 g) in toluene (150 ml). The whole was refluxed for 30 h; every 6 h, 30 ml of hydrochloric acid was added. After cooling, the toluene layer was separated from the aqueous layer, the latter was extracted with ether, and then the ether–toluene mixture was extracted with sodium bicarbonate solution. The organic layer, after washing with water and drying (Na_2SO_4), afforded a pale-yellow oil (13.4 g), which on distillation gave ethyl 3-methyl-2-phenylcyclopent-2-ene-1-carboxylate (VII; R = C_2H_5), b.p. 97–101° at 0.2 mm. Ultraviolet spectrum: $\lambda_{max}^{ethanol}$ 248.5 mμ (log ε 3.57).

Anal. Calcd. for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88. Found: C, 78.44; H, 7.84.

The bicarbonate solution after washing with ether and acidification afforded a viscous oil (6.2 g) which on distillation yielded 3-methyl-2-phenylcyclopent-2-ene-1-carboxylic acid (VII; R = H), b.p. 130–135° at 0.45 mm. Ultraviolet spectrum: $\lambda_{max}^{ethanol}$ 243 mμ (log ε 3.58).

Anal. Calcd. for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98. Found: C, 76.67; H, 6.48.

It gave a *p*-toluidide, m.p. 131–133° (from methanol).

Anal. Calcd. for $C_{20}H_{21}ON$: C, 82.41; H, 7.26; N, 4.81. Found: C, 82.70; H, 7.25; N, 4.47.

Alkaline hydrolysis of the unsaturated ester (VII; R = C_2H_5) (1.2 g) for 2 h yielded an unsaturated acid (1 g), which gave the same *p*-toluidide as that obtained directly from the Clemmensen reduction, m.p. and mixed m.p. 130–133°.

Ethyl 3-Methyl-2-phenylcyclopentane-1-carboxylate (VIII; R = C_2H_5)

A solution of the unsaturated ethyl ester (VII; R = C_2H_5) (3.6 g) in glacial acetic acid (40 ml) was shaken with hydrogen in presence of Adams platinum oxide (0.3 g). The hydrogenation was ceased when 1 mole of hydrogen absorbed. After filtration and removal of acetic acid under reduced pressure, the residual oil was distilled at 92–96° at 0.2 mm, to give ethyl 3-methyl-2-phenylcyclopentane-1-carboxylate (VIII; R = C_2H_5) as colorless liquid (3.3 g);

Anal. Calcd. for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68. Found: C, 77.76; H, 8.38.

The ester failed to decolorize bromine in carbon tetrachloride.

3-Methyl-2-phenylcyclopentane-1-carboxylic acid (VIII, R = H)

A mixture of the ester (VIII; R = C_2H_5; 5.3 g) and 10% sodium hydroxide solution (70 ml) was refluxed for 3 h; after cooling it was ether-extracted. The ice-cold alkaline solution was acidified with hydrochloric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

acid and was then ether-extracted. The ethereal solution was dried over sodium sulfate and the solvent was removed. The residue (4 g) gave the acid (VIII; R = H) as a colorless viscous oil, b.p. 132–135° at 0.7 mm.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90. Found: C, 76.13; H, 7.63.

3-Methyl-2-phenylcyclopentyl Acetoxymethyl Ketone (IX, R = CH_3CO)

3-Methyl-2-phenylcyclopentane-1-carboxylic acid (VIII; R = H; 2.2 g) in dry benzene (20 ml) was allowed to stand 3 d at room temperature with redistilled thionyl chloride (20 ml). Excess thionyl chloride and benzene were removed *in vacuo*, and the final traces of thionyl chloride were removed by addition and subsequent removal of two 10 ml portions of dry benzene. The dry residue was then dissolved in dry ether (30 ml) and added to an ethereal solution of diazomethane (350 ml) (from 20 g of *N*-nitrosomethyl urea) at 0°; after standing for 30 min at 0° and then overnight at room temperature, removal of ether and excess diazomethane *in vacuo* left the corresponding diazoketone as a residual oil (3.5 g). This was dissolved in glacial acetic acid (50 ml); and gradually heated on a water bath. After 45 min (nitrogen evolution complete), the contents of the flask were diluted with water and ether-extracted. After the ether solution was washed with 5% sodium carbonate and then water, it was dried (Na_2SO_4) and evaporated to give a pale-yellow oil (2.5 g). This on distillation gave 3-methyl-2-phenylcyclopentyl acetoxymethyl ketone, b.p. 130–135° at 0.4 mm, which darkens on keeping. This oil reduced ammoniacal silver nitrate. Infrared spectrum (liquid): 1 730, 765, 700 cm^{-1}.

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74. Found: C, 73.35; H, 7.42.

3-Methyl-2-phenylcyclopentyl Hydroxymethyl Ketone (IX, R = H)

The diazoketone from 1.7 g 3-methyl-2-phenylcyclopentane-1-carboxylic acid, as in the previous experiment, was dissolved in 40 ml pure dioxane, and 20 ml 2 *N* sulfuric acid was added. The evolution of nitrogen started when the mixture was warmed on a water bath and ceased after 45 min. The mixture was then diluted with water and thoroughly extracted with ether. The ethereal solution was washed with small amounts of 5% sodium bicarbonate solution, then with sodium chloride solution. After drying, the ether was removed *in vacuo* and the residual oil (1.8 g) distilled at 112–115° at 0.2 mm. This oil reduced ammoniacal silver nitrate solution.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31. Found: C, 77.21; H, 8.42.

1-Ethyl-4-hydroxy-2-naphthoic Acid (X, R = R′ = H)

The crude ethyl half-ester (10 g) and anhydrous sodium acetate (5 g) in acetic anhydride (80 ml) were refluxed for 5 h and then worked up by removing the acetic anyhdride under reduced pressure, adding water, and extracting the precipitate with ether. The ethereal solution was washed with sodium bicarbonate solution, washed with water, and dried (Na_2SO_4). Evaporation left crude methyl 4-acetoxy-1-ethyl-2-naphthoate (X; R = CH_3, R′ = CH_3CO) as a brown viscous oil (5 g), which on hydrolysis with 10% sodium hydroxide solution (100 ml; 2 h refluxing), gave after acidification pale brownish needles (2.5 g). This on crystallization from aqueous ethanol yielded 1-ethyl-4-hydroxy-2-naphthoic acid (X; R = R′ = H), m.p. 189–191°.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59. Found: C, 72.34; H, 5.83.

This phenolic acid gave a violet color with alcoholic ferric chloride solution. Acidification of the carbonate washing gave a viscous brown oil (3.6 g), which on treatment with hot saturated barium hydroxide solution (100 ml; 2 h refluxing), gave after acidification γ-ethylidene-γ-phenyl methylsuccinic acid (I*a*; R = H) (1) as colorless crystals (2.4 g), m.p. 136–138° (from water). Its mixed melting point with an authentic specimen, m.p. 137–138°, which had been prepared by alkaline hydrolysis ($Ba(OH)_2$) of the crude half-ester followed by fractional crystallization, gave no depression.

Methyl 1-Ethyl-4-methoxy-2-naphthoate (X; R = R′ = CH_3)

The phenolic acid (X, R = R′ = H; 6 g), dimethyl sulfate (18 g), and anhydrous potassium carbonate (24 g) in acetone (180 ml) were refluxed for 12 h, affording a solid (5.8 g). This after crystallization from methanol gave methyl 1-ethyl-4-methoxy-2-naphthoate (X; R = R′ = CH_3) as colorless plates, m.p. 92–93°.

Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60. Found: C, 73.79; H, 6.57.

1-Ethyl-4-methoxy-2-naphthoic Acid (X; R = H, R′ = CH_3)

Hydrolysis of the ester (X; R = R′ = CH_3; 0.9 g) using 10% sodium hydroxide solution (20 ml) for 1.5 h refluxing, gave a solid (0.7 g). This on crystallization from methanol afforded 1-ethyl-4-methoxy-2-naphthoic acid as colorless crystals, m.p. 199–200°.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.02; H, 6.13. Found: C, 73.15; H, 6.26.

ACKNOWLEDGMENT

The authors thank Dr. F. G. Baddar, Professor of Organic Chemistry, Faculty of Science, Ain Shams University, for spectral determinations.

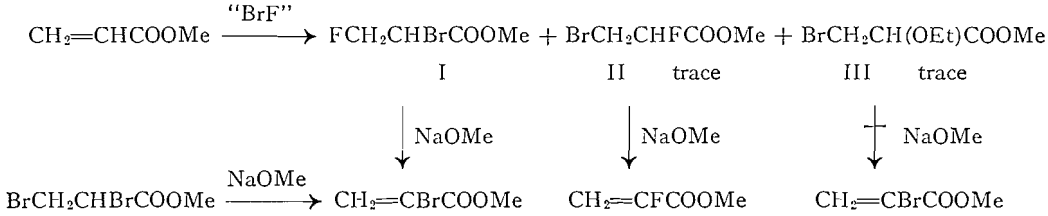
NOTES

SYNTHESIS OF THE ISOMERIC METHYL *vic*-BROMOFLUOROPROPANOATES

F. H. DEAN[1] AND F. L. M. PATTISON

The two isomeric methyl *vic*-bromofluoropropanoates I and II were required for a detailed n.m.r. study involving heteronuclear spin decoupling (1). Our recent work on the "BrF" addition to aliphatic alkenes (2) provided a route to these esters.

Initially we examined "BrF" addition to methyl acrylate.[2] This addition proceeded in low yield using *N*-bromoacetamide and anhydrous hydrogen fluoride in ether–pyridine at −20°. In addition to the expected methyl 2-bromo-3-fluoropropanoate (I), small quantities of the unexpected methyl 3-bromo-2-fluoropropanoate (II) and a methyl bromoethoxypropanoate (III) were formed; formation of ethers in this addition reaction has been discussed earlier (2). The yield of the required product was later raised to 45% by using 1,3-dibromo-5,5-dimethylhydantoin (in place of *N*-bromoacetamide) in ether – carbon tetrachloride or in chloroform at −30°. The structure of the main product I was proved by elemental analysis, n.m.r. spectroscopy (1), high-resolution infrared spectroscopy, and dehydrohalogenation to methyl α-bromoacrylate. The methyl bromoethoxypropanoate was tentatively assigned the structure III on the basis of dehydrohalogenation experiments; moreover, the isomer, methyl 2-bromo-3-ethoxypropanoate, has been reported to be unstable (5).

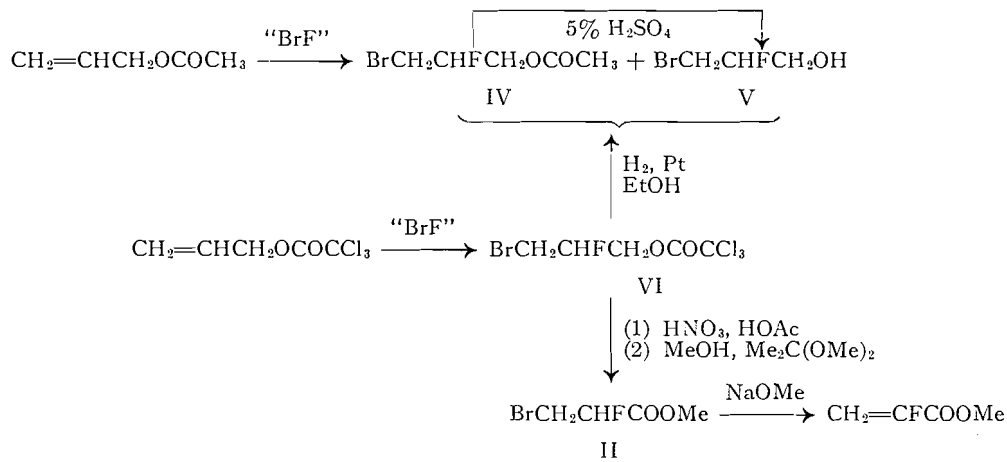


The addition of "BrF" to methyl methacrylate proceeded in good yield to give methyl 3-bromo-2-fluoro-2-methylpropanoate as the single product. The n.m.r. spectrum provided unequivocal proof of structure, as described in the Experimental section.

To obtain methyl 3-bromo-2-fluoropropanoate (II) in reasonable yield, it was necessary to select a precursor which did not have the electronic features of the α-alkenoic acids. Allyl acetate was first examined, and was found to give in low yield a mixture of the required 3-bromo-2-fluoropropyl acetate (IV) and the corresponding hydrolyzed product (V); the similarity in boiling points of these two materials caused difficulty in separation. The ester IV on acid hydrolysis gave the alcohol V. The presence of 3-bromo-2-fluoro-1-propanol was undesirable in the next step in the synthesis, so allyl trichloroacetate was chosen as an alternative precursor; trichloroacetates have been reported to undergo acid-catalyzed hydrolysis 115 times more slowly than acetates (6). Moreover, the large difference in boiling point between the resultant saturated trichloroacetate and the hydrolyzed product would simplify the isolation of the pure products even if some hydrolysis did

[1]*Present address: Department of Chemistry, University of Delaware, Newark, Delaware.*
[2]*While the work was in progress, Bose et al. reported the same reaction (3, 4).*

occur. The "BrF" addition gave a good (69%) yield of pure adduct (VI), which was found to be unstable at room temperature; it was therefore stabilized with 0.05% of pyridine and stored in a refrigerator. Its relationship to the ester from allyl acetate was proved by hydrogenolysis in ethanol; during the hydrogenation, some ethanolysis occurred, thus giving a mixture of the same two products (IV and V) which were isolated from the allyl acetate reaction. The ester VI was converted to the required methyl 3-bromo-2-fluoropropanoate by treatment with nitric acid (7) followed by esterification. Analysis by β-elimination gave methyl α-fluoroacrylate, thus proving the course of the reaction sequence. A very small amount of methyl α-bromoacrylate was isolated, indicating that some anti-Markovnikov addition had also occurred.



EXPERIMENTAL

The n.m.r. spectra were obtained with Varian A-60 and DP-60 spectrometers. Fractionations were carried out on a 23-plate platinum-plated spinning-band column. Infrared spectra were obtained with Beckman IR-7 and IR-5 infrared spectrophotometers.

Methyl 2-Bromo-3-fluoropropanoate (I)

Methyl acrylate (30 g, 0.35 mole) was added dropwise over 30 min to a stirred mixture of 1,3-dibromo-5,5-dimethylhydantoin (50 g, 0.175 mole), hydrogen fluoride (50 g, 2.5 moles), and chloroform (200 ml) at −40°. After being stirred at −30° for 4 h, the mixture was worked up in the usual way (2) to give the required ester (29.0 g, 45%), b.p. 49.5° at 10.5 mm, n_D^{25} 1.4408, d_4^{20} 1.646; (lit. (8, 9) gives b.p. 80–81.5° at 46 mm, 92–94° at 80 mm; n_D^{24} 1.4432, n_D^{30} 1.4389). The infrared spectrum (4.3% in CCl_4) showed bands at 1 760 (C=O) and at 1 013 and 1 044 (C—F) cm^{-1}. Dehydrohalogenation (see below) gave methyl α-bromoacrylate and a trace of methyl α-fluoroacrylate.

Anal. Calcd. for $C_4H_6BrFO_2$: C, 25.97; H, 3.27; Br, 43.20. Found: C, 25.85; H, 3.31; Br, 43.37.

When the reaction was carried out using *N*-bromoacetamide and anhydrous hydrogen fluoride in ether–pyridine, a higher boiling fraction was ultimately obtained (6%), b.p. 70° at 3.7 mm, n_D^{25} 1.4510, d_4^{20} 1.383. Dehydrohalogenation gave no methyl α-bromoacrylate. The infrared spectrum (CCl_4) showed bands at 1 753 (s; C=O) and 1 110 (v.s.; ether C—O) cm^{-1}.

Anal. Calcd. for $C_6H_{11}BrO_3$: C, 34.14; H, 5.25; Br, 37.86. Found: C, 34.15; H, 5.32; Br, 38.10. Structure III is therefore reasonable for this product.

Dehydrohalogenation of I and II

Absolute ether (0.3–0.5 ml) was added to dry sodium methoxide (50–100 mg) and hydroquinone (5 mg) in a 5-ml pear-shaped flask. One or two drops of the test compound were added, the flask was stoppered and the mixture was swirled. A small sample of the ether solution was then withdrawn using a microliter syringe and injected into the gas chromatograph. The retention times of the products were compared with authentic samples of methyl α-bromoacrylate and methyl α-fluoroacrylate, using both polar (DEGS) and non-polar (Apiezon-L) columns. A temperature of 90–125° was used for the fluoroacrylate and of 125–155° for the bromoacrylate.

Methyl 3-Bromo-2-fluoro-2-methylpropanoate

A solution of methyl methacrylate (70 g, 0.70 mole) in chloroform (100 ml) was added over 10 min to a stirred solution of 1,3-dibromo-5,5-dimethylhydantoin (100 g, 0.35 mole) and hydrogen fluoride (50 g, 2.5 moles) in chloroform (400 ml) at −50°. The resulting slurry was then stirred at −20° for 4 h. Work-up in the usual way (2) gave unchanged methyl methacrylate (17 g) followed by methyl 3-bromo-2-fluoro-2-methylpropanoate (82.5 g, 78% yield, 59% conversion), b.p. 80.5° at 14 mm, n_D^{25} 1.4423. Gas chromatography indicated a single product.[3] The n.m.r. spectrum was measured in $CDCl_3$ solution, positions being relative to tetramethylsilane. The CH_2Br absorption appeared as the AB portion of an ABX pattern between 200 and 250 c.p.s., and the 2-methyl group as a doublet centered at 1.68 p.p.m. (J_{HF} 21 c.p.s.). The ester CH_3 appeared as a singlet centered at 3.83 p.p.m. The structure of the product is therefore unambiguous.

Anal. Calcd. for $C_5H_8BrFO_2$: C, 30.17; H, 4.05; Br, 40.15. Found: C, 30.37; H, 3.93; Br, 40.14.

3-Bromo-2-fluoropropyl Acetate (IV) and 3-Bromo-2-fluoro-1-propanol (V)

Allyl acetate (50 g, 0.5 mole) and *N*-bromoacetamide (69.7 g, 0.505 mole) were added in the usual way (2) to a solution of hydrogen fluoride (95 g, 4.75 moles) in ether (200 ml). The reaction mixture was stirred at −80° for 75 min, and the products (40.0 g) were isolated in the usual way. From this was isolated crude V (see below) and, in very low yield, pure IV, b.p. 85° at 12 mm, n_D^{25} 1.4521, d_4^{20} 1.515. The infrared spectrum (CCl_4) showed a C=O band at 1 752 cm^{-1}.

Anal. Calcd. for $C_5H_8BrFO_2$: C, 30.17; H, 4.05; Br, 40.15. Found: C, 30.34; H, 4.09; Br, 40.30.

The alcohol V was obtained pure by hydrolyzing a portion of the mixture of IV and V. Using this pure product as a standard, we then proved the presence of V in the original mixture by vapor phase chromatographic analysis on two different columns (polar DEGS and non-polar Apiezon-L) and by infrared spectroscopy. The mixture (11 g) was heated under reflux with 4% sulfuric acid in 60% aqueous dioxane (52 ml), until homogeneous (ca. 30 min). Isolation by ether extraction, washing, drying, and fractionation[4] gave V (4.4 g), b.p. 73–75° at 12 mm, n_D^{25} 1.4683, d_4^{20} 1.770. The infrared spectrum (CCl_4) showed bands at 3 613 (free OH) and 3 408 (hydrogen-bonded OH) cm^{-1}.

Anal. Calcd. for C_3H_6BrFO: C, 22.95; H, 3.85; Br. 50.90. Found: C, 22.93; H, 3.79; Br, 50.79.

3-Bromo-2-fluoropropyl Trichloroacetate (VI)

Anhydrous hydrogen fluoride (120 g, 6.0 moles) was diluted (*caution*!) with a solution of pyridine (17 g) in ether (140 ml). Allyl trichloroacetate (47.3 g, 0.232 mole) and *N*-bromoacetamide (36.0 g, 0.261 mole) were then added at −80° over 10 min. The mixture was stirred at −80° for 1 h and then was gradually warmed to 0° with stirring. Neutralization, isolation, and purification in the usual way[4] gave VI (48.33 g, 69%), b.p. 60° at 0.025 mm, n_D^{25} 1.4895, d_4^{20} 1.760. The infrared spectrum showed a C=O band at 1 776 cm^{-1}.

Anal. Calcd. for $C_5H_5BrCl_3FO_2$: C, 19.86; H, 1.67. Found: C, 20.08; H, 1.73. Treatment of VI with hydrogen (atmospheric pressure) and platinum catalyst in ethanol for 8 h at room temperature gave a mixture of IV and V (by hydrogenolysis of the α-chlorine atoms and considerable ethanolysis of the ester).

Methyl 3-Bromo-2-fluoropropanoate (II)

3-Bromo-2-fluoropropyl trichloroacetate (16.1 g, 0.053 mole) was dissolved in a mixture of glacial acetic acid (35 ml) and nitric acid (35 ml). The solution was warmed at 50° for 32 h and then was allowed to stand at room temperature for 44 h. The nitric and acetic acids were removed by distillation at 11 mm pressure. The residual crude acid was esterified by adding methanol (7.92 g, 0.25 mole), 2,2-dimethoxypropane (20.8 g, 0.20 mole), and *p*-toluenesulfonic acid (10 mg) and allowing the mixture to stand at room temperature for 19 h. The excess methanol and 2,2-dimethoxypropane were distilled off at atmospheric pressure. The residual dark liquid was dissolved in ether, washed with 5% $NaHCO_3$, and dried (Na_2SO_4). Removal of the ether and fractional distillation of the residue gave II (4.15 g, 42%), b.p. 65° at 3.5 mm, n_D^{25} 1.4468, d_4^{20} 1.642. The infrared spectrum (4% in CCl_4) showed bands at 1 747, 1 764 and 1 775 (C=O), and at 1 020 and 1 090 (C—F) cm^{-1}. Dehydrohalogenation gave methyl α-fluoroacrylate and a trace of methyl α-bromoacrylate.

Anal. Calcd. for $C_4H_6BrFO_2$: C, 25.97; H, 3.27; Br, 43.20. Found: C, 26.16; H, 3.41; Br, 42.99.

ACKNOWLEDGMENTS

We wish to express our indebtedness to Canadian Industries Limited, Montreal for the award of a Fellowship (F. H. D.); to the National Research Council for financial support; to Dr. J. B. Stothers of this department for help with the nuclear magnetic resonance spectra; to Dr. D. A. V. Peters of this department for help with some of the preparations; and to Dr. J. J. Baron, Jr., Central Research Laboratory, General Aniline and Film Corporation, Easton, Pa., for a gift of methyl α-fluoroacrylate.

[3]*This ester contains no α-hydrogen atom and is therefore stable to gas chromatographic analysis; α,β-dihaloesters bearing an α-hydrogen atom decompose when this type of analysis is attempted, so are best studied by dehydrohalogenation (see above).*

[4]*Dry, powdered* $CaCO_3$ *should be added to the fractionation flask to prevent autocatalytic decomposition.*

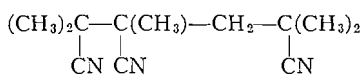
THE N.M.R. SPECTRUM OF 2,3,5-TRIMETHYL-2,3,5-TRICYANOHEXANE. UNUSUAL TEMPERATURE DEPENDENCE OF MAGNETIC NONEQUIVALENCE*

P. SMITH AND J. J. MCLESKEY III†

The n.m.r. spectra of short- and long-chain polymers have drawn considerable recent attention (1–4). The compound 2,3,5-trimethyl-2,3,5-tricyanohexane, I, may be regarded as a simple example of a short-chain polymer. Moreover, I is interesting in its own right,



I

since it has an asymmetric carbon atom, the effect of which might show up in its n.m.r. spectrum (5–9). The n.m.r. spectrum of I was first reported for a benzene solution at about 25 °C as part of another study (10). All five methyl groups of I were magnetically nonequivalent, but the protons of the methylene group appeared magnetically equivalent.

Presented here are results of a comprehensive solvent and temperature dependence study of the n.m.r. spectrum of I. In 9 of the 18 solvents employed the methylene group protons of I appeared magnetically nonequivalent at 36 °C. A representative selection of 11 solvents was employed for the temperature dependence investigation. An interesting feature of the results obtained is that for those solvents displaying methylene group nonequivalence which were subjected to a temperature dependence study, this nonequivalence increased with increase in temperature in every case except one. A possible interpretation for this unusual temperature dependence is given.

EXPERIMENTAL

Compound I was prepared and purified as before (11) (m.p. 81 ± 2 °C uncorr.). The 18 solvents employed were reagent grade or better and showed no significant impurities in the n.m.r. region of interest. Spectra were obtained on a Varian A-60 spectrometer equipped with a V-6057 variable temperature accessory, tetramethylsilane (TMS) being used as internal standard. Unsealed sample tubes were employed. Concentrations were 0.2 *M* and, unless otherwise indicated, the probe temperature was 36 ± 1 °C. A minimum of two spectra were run for each solution for each temperature. In the case of the temperature dependence studies, measurements were taken about every 15 °C depending on the observed spectral changes for the following 11 representative solvents listed together with the corresponding temperature range in °C: acrylonitrile (−40 to +74); benzonitrile (−9 to +176); carbon tetrachloride (−9 to +74); chloroacetonitrile (−40 to +114); chlorobenzene (−40 to +123); chloroform (−40 to +63); *o*-dichlorobenzene

(−9 to +162); formamide (+33 to +163); methanol (−40 to +62); pyridine (−40 to +106); toluene (−40 to +106). The solvents examined only at 36 °C were acetonitrile, benzaldehyde, benzene, benzotrichloride, dioxane, hexachloroacetone, and *p*-toluonitrile.

RESULTS

At 36 °C the results were as follows. All five methyl groups appeared nonequivalent only in benzene, benzotrichloride, chlorobenzene, toluene, and pyridine. In the remaining solvents, as many as three of the methyl groups appeared equivalent.* The methylene group protons appeared nonequivalent only in acetonitrile, acrylonitrile, benzaldehyde, benzonitrile, chloroacetonitrile, formamide, methanol, pyridine, and *p*-toluonitrile. When an AB quartet† was observed for the methylene group protons the low-field half of the quartet was noticeably broadened, except in the case of formamide.

The temperature dependence of the spectrum of I for the six solvents representative of those in which the methylene group protons appeared nonequivalent at 36 °C, i.e., acrylonitrile, benzonitrile, chloroacetonitrile, formamide, methanol, and pyridine, was as follows: in every case the nonequivalence of the methylene group protons of I increased with increase in temperature over the temperature interval investigated. For the five solvents representative of those in which the methylene group protons appeared equivalent at 36 °C the investigation of the temperature dependence of I gave the following results: in both chloroform and carbon tetrachloride I showed apparently magnetically equivalent methylene group protons over the entire temperature range; however, for the spectrum of I in chlorobenzene and *o*-dichlorobenzene as the temperature was increased above about 100 and 45 °C, respectively, and in toluene as the temperature was decreased below about −10 °C the methylene group protons became increasingly magnetically nonequivalent. A selection of the temperature dependence data is summarized in Table I.

DISCUSSION

The results mentioned above provide a further example of magnetic nonequivalence in a molecule containing an asymmetric carbon atom (5–9, 13, 14). Their most interesting feature is the *increase* in $\delta_{1,2}$ with *increasing* temperature illustrated in Table I and fully tabulated elsewhere (12). This increase occurs for each solvent showing nonequivalent methylene group protons in the temperature range investigated, with one exception. For solutions of I in toluene, $\delta_{1,2}$ fell with rising temperature. In the case of formamide there is only a slight increase in methylene nonequivalence with increase in temperature, which, when considered with the apparent absence of long-range broadening of one of the methylene proton resonances, might be construed as supporting relatively free rotation. However, as may be inferred from the discussion below, this may be an oversimplification. It seems that an increase in $\delta_{1,2}$ with increase in temperature for nonequivalent methylene group protons has not been previously described for any compound. As far as we are aware, in every case so far reported the temperature dependence of $\delta_{1,2}$ for nonequivalent methylene group protons (5, 9, 13, 14) has been a slow reduction in $\delta_{1,2}$ with increasing temperature.

An explanation of this novel temperature dependence of $\delta_{1,2}$ in terms of conformational effects in an asymmetric system would postulate that as the temperature is lowered, for a majority of solvents, the conformation in which the methylene group protons are most

**The methyl resonances are incidental to the present report and are discussed elsewhere (12). These resonances could not be definitely assigned on the basis of available model compounds, e.g., tetramethylsuccinonitrile (10) and 2,4-dicyanopentane (1).*

†The AB nature of the methylene resonance was confirmed by a 100 Mc spectrum of I in benzonitrile kindly provided by Dr. S. G. Levine, North Carolina State University, Raleigh, N.C.

*Protons 1 and 2 refer to the methylene group protons and ν_1 and ν_2, respectively, are their calculated chemical shifts. The quantity $J_{1,2}$ is the measured coupling constant and $\delta_{1,2}$ is the difference in the 1,2-proton chemical shifts. The data are all in c.p.s., downfield from TMS. Coupling constants and chemical shifts are expressed to the nearest 0.1 c.p.s. Each coupling constant value is the arithmetical mean of all data taken; single measurements for each constant varied from the reported value by as much as a few tenths of a cycle per second.

The methyl resonances each had a width at half height of about 1.0 c.p.s. compared against a corresponding value of about 0.6 c.p.s. for internal TMS.

†Temperature, ±2 °C.

‡When an apparent singlet appeared for protons 1 and 2, this is indicated by no entry for $\delta_{1,2}$. For these cases, the full width of this peak at half height was about 0.9 c.p.s., compared with about 0.6 c.p.s. for internal TMS. This suggests that $\delta_{1,2}$ may be as large as about 4 c.p.s.

equivalent is preferred. But as several contributions to the observed nonequivalence are thought to be important in systems of this kind (7), a final explanation of these results is impossible at present. Nevertheless, the observed temperature dependence of $\delta_{1,2}$ is sufficiently unusual to merit special attention and may serve to warn against too simple explanations of the temperature dependence of the magnetic nonequivalence of methylene group protons.

LIGNIN MODEL COMPOUNDS. III. DETECTION OF 1-HYDROXY-1-(4-HYDROXY-3-METHOXYPHENYL)-2-PROPANONE IN THE ACIDOLYSIS PRODUCTS OF LIGNIN

J. A. F. Gardner and Harold MacLean

INTRODUCTION

In previous papers of this series (1, 2) and in the results of Adler (3) and Lundgren (4), strong experimental support was provided for Hibbert's proposal that the ethanolysis ketones are derived from lignin via the ketols 1-hydroxy-3-(4-hydroxy-3-methoxyphenyl)-2-propanone (ω-hydroxy-guaiacylacetone) (I) and 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone (α-hydroxyguaiacylacetone) (II) by a series of rearrangements. If this explanation is accepted, then, in the absence of etherification conditions during an acidic hydrolysis of lignin, both of these ketols as well as ketol III, 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (α-hydroxypropioguaiacone), should be formed and, if conditions are not severe, be detectable in the reaction mixture. Ketols I and III have previously been shown to be present in the acidolysis products of Bjorkman lignin (3), but ketol II has not been detected heretofore.

An examination of lignin acidolysis products for the presence of II was made possible by the preparation of reference samples reported in the previous paper (2). Since II has been found to be unstable in basic solution, being quantitatively converted thereby to the ketol III, care was taken in working up the acidolysis products to avoid any contact with even mildly basic solutions.

Extractive-free, native lignin-free western hemlock (*Tsuga heterophylla* (Raf.) Sarg.) sapwood sawdust meal was treated with dioxane–water containing hydrochloric acid according to Pepper *et al.* (5). The pH of the filtered dioxane–water media was adjusted to 6.5 with sodium carbonate solution and evaporated under reduced pressure to a heavy oil. The higher molecular weight lignin fraction was precipitated by diluting the oil with acetone and adding it dropwise to a large volume of vigorously stirred water. The lignin low molecular fraction was reclaimed from the aqueous layer by extraction with chloroform. The resulting oil was separated by partitioning between ether and bisulfite solution, as outlined in the preparation of the synthetic ketol II (2).

Comparison with authentic samples using descending paper chromatography in three different solvent systems (Table I) showed the bisulfite soluble oil to be mainly ketol I together with a small amount of ketol II. Final proof of identity of these products was obtained by thick-paper chromatography separations and infrared spectral comparisons with authentic samples.

The isomeric ketol III was identified in the ether-soluble fraction by a similar procedure. The remaining possible isomeric ketol, 3-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (ω-hydroxypropioguaiacone) could not be detected in the acidolysis products.

Goldschmid's study (6) of the mild aqueous hydrolysis of western hemlock lignin suggested the presence of ketol II by its detection color with diazotized sulfanilic acid

(DSA) in paper chromatography. This suggestion has now been shown to be correct. However, he was unable to confirm the presence of ketol I.

EXPERIMENTAL

Air-dried western hemlock sapwood was reduced in a Wiley mill to approximately 40–80 mesh and made extractive-free, native-lignin free by soxhlet treatment with alcohol–benzene (1:2) for 48 h, water for 120 h, and absolute ethanol for 48 h, the wood meal being air-dried between each treatment.

Hemlock wood meal (150 g) in dioxane–water (9:1 v/v) (1 200 ml) containing concentrated HCl (19.95 ml) was refluxed with stirring for 2 h under a nitrogen atmosphere. After filtering of the wood meal residue, the reddish dioxane–water solution was partially neutralized to pH 6.5 with sodium carbonate (10%) and evaporated under reduced pressure to a dark brown oil. The oil was thinned with acetone (20 ml) and sprayed in a fine stream into vigorously stirred water (4 liters). The lignin may also be precipitated by using hexane as solvent, giving a smaller yield of a much lighter colored oil. The flocculent lignin precipitate was filtered and the water extracted with chloroform (6 × 50 ml), the emulsion residues being broken by centrifuging. The chloroform extracts were combined, dried over sodium sulfate, and evaporated to a brownish oil (1.23 g).

The oil was taken up in ether (25 ml), separated from additional lignin precipitate by decanting, and treated as outlined in the preparation of synthetic ketol II (2) using half quantities of solvent. This procedure yielded bisulfite-soluble (48 mg) and bisulfite-insoluble (210 mg) fractions.

Paper chromatography of the bisulfite-soluble oil in tetrahydrofuran – petroleum ether (65–110 °C) – water (3:7:5 v/v) (THF), butanol – ethanol – ammonia – water (40:10:1:49 v/v) (BEAW), and the organic phase of benzene – petroleum ether (80–100 °C) – methanol – water (50:50:1:50 v/v) (Lindstedt) (7) together with synthetic samples showed the two main components to be ketol I and ketol II.
