VOLUME 43 JANUARY 1965 NUMBER 1

THE SYNTHESIS OF GLUCOSINALBIN AND GLUCOAUBRIETIN[1]

M. H. BENN

Department of Chemistry, University of Alberta, Calgary, Alberta

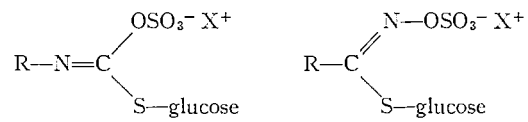
Received August 10, 1964

ABSTRACT

The first synthesis of the glucosinalbin and glucoaubrietin anions has been achieved by sulfonation and deacetylation of the thiohydroximates obtained by addition of tetraacetylglucopyranosyl mercaptan to *p*-acetoxyphenylacetonitrile oxide and *p*-methoxyphenylacetonitrile oxide.

The mustard oil glucosides form a group of natural compounds widely distributed through the plant kingdom and particularly common in the order Rhoeadales, especially within the families Cruciferae and Capparidaceae of this order (1). Eminent amongst these compounds is sinalbin, the glucosidic precursor of the mustard oil responsible for the well known flavor of white mustard, *Sinapis alba* L., a plant which has been used for medicinal and condimental purposes for some 25 centuries (2).

Sinalbin was first isolated from *Sinapis alba* in 1831 by Robiquet and Boutron (3). In 1897 Gadamer (4) proposed the general structure (I) for the mustard oil glucosides, sinalbin being (I)(R = *p*-$HOC_6H_4CH_2$, X = sinapinium cation).[2]



(I) (II)

In spite of the failure of this structure to account for several of the observed reactions of the mustard oil glucosides,[3] it was accepted until 1956, when Ettlinger and Lundeen (6) pointed out that all the observed properties and reactions were consistent with the structure (II).[4] New degradative evidence supported this structure, the correctness of which was conclusively established (7) by the synthesis of a compound with the structure (II)(R = $C_6H_5CH_2$, X = $(CH_3)_4N$) which proved to be identical with the tetramethylammonium salt[5] of the naturally occurring mustard oil glucoside, glucotropaeolin.

[1]*Presented in part at the 47th Canadian Chemical Conference, Kingston, Ontario, June 2, 1964.*

[2]*As isolated from plant material, the cation commonly associated with the mustard oil glucoside anion is potassium. Sinalbin is unique in that it is the cation of the choline ester of 3,5-dimethoxy-4-hydroxycinnamic acid (the sinapinium ion) which is associated with the anion (glucosinalbin). Occasionally, it is convenient to isolate the mustard oil glucosides as tetramethylammonium salts (see footnote 5).*

[3]*In particular, the formation under certain circumstances of nitriles, sulfur, and carbon disulfide. See ref. 5 for a discussion of these reactions.*

[4]*Glucose = β-D-glucopyranosyl residue.*

[5]*Ettlinger and Lundeen (6) found the tetramethylammonium salts to have superior crystallizing properties to the potassium salts.*

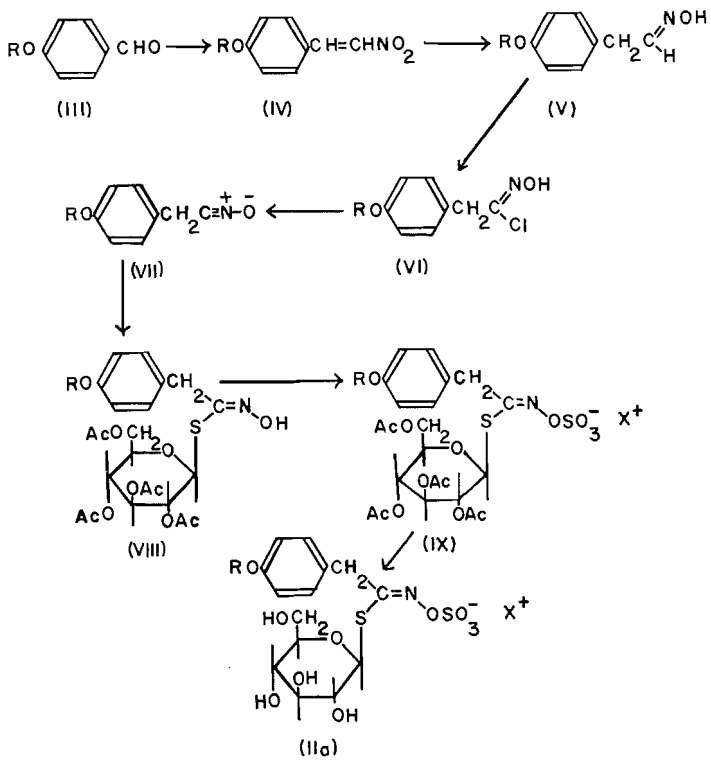
Recently, in connection with certain biosynthetic and biochemical studies, we developed a new synthesis of the mustard oil glucosides, the key feature of which was the construction of the thiohydroximate skeleton by the addition of a thiol to a nitrile oxide (8). This synthesis has been used to prepare several of the simple mustard oil glucosides[6] and we now describe its successful application in the synthesis of glucosinalbin and the related mustard oil glucoside, glucoaubrietin[7] (II)(R = p-$CH_3OC_6H_4CH_2$, X = K).



p-Hydroxy-ω-nitrostyrene (IV, R = H), produced by the ammonium acetate catalyzed condensation of p-hydroxybenzaldehyde (III, R = H) and nitromethane (12), was acetylated and then hydrogenated, in pyridine solution, over palladium–charcoal,[8] to produce p-acetoxyphenylacetaldoxime (V, R = CH_3CO). However, in contrast to the hydrogenation of p-methoxy-ω-nitrostyrene, the yield of oxime was poor and this step was the worst in the entire synthesis of glucosinalbin. The oxime was converted to the crystalline hydroxamoyl chloride (VI, R = CH_3CO) upon treatment with chlorine. Reaction of 2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl mercaptan with the nitrile oxide

[6]*Glucotropaeolin (9a), glucocapparin (II) (R = CH_3, X = K) (9b), glucolepidiin (R = CH_3CH_2, X = K) (9c), glucoputranjivin (II)(R = $(CH_3)_2CH$, X = K) (9c), and gluconasturtiin (II, R = $C_6H_5CH_2CH_2$, X = K)(9d). A very similar synthesis has been developed by Dr. Ettlinger and used to synthesize glucocapparin and glucotropaeolin. This work is described in "Final Report on Contract DA-19-129-QM-1059, Project 7-84-06-032, Simplified Food Logistics" by G. Dateo and M. G. Ettlinger.*

[7]*Glucoaubrietin occurs in plants of the genus Aubrieta (10). It may be recognized as glucosinalbin in which the phenolic hydroxyl has been methylated and it will be interesting to see whether or not glucosinalbin is the biogenetic precursor of glucoaubrietin. A recent study by Kindl (11) has shown that glucosinalbin is biosynthesized, in Sinapis alba, from phenylalanine more efficiently than from tyrosine. The biosynthesis apparently proceeds via the degradation of these α-amino acids to p-coumaric acid.*

[8]*Conditions established by Reichert and Koch (13) for the preparation of substituted phenylacetaldoximes from ω-nitro styrenes.*

(VIII, R = CH_3CO), produced *in situ*, in ether solution, by the action of triethylamine upon the hydroxamoyl chloride, afforded S-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)-*p*-acetoxyphenylacetothiohydroximate ("pentaacetylproglucosinalbin") (VIII, R = CH_3CO). Sulfonation of this compound with pyridine – sulfur trioxide, followed by treatment with potassium bicarbonate, gave potassium pentaacetylglucosinalbate (IX, R = CH_3CO, X = K).

Deacetylation with methanolic ammonia gave potassium glucosinalbate which was converted by cation exchange chromatography to the tetramethylammonium salt (II*a*, R = H, X = $(CH_3)_4N$). This crystallized well and proved to be identical with a sample of natural origin.[9]

Glucoaubrietin was synthesized by an analogous set of reactions, starting with anisaldehyde (III, R = CH_3), and isolated as the well crystalline tetramethylammonium salt.

These are the first reported syntheses of the glucosinalbin and glucoaubrietin anions.

EXPERIMENTAL

p-Acetoxy-ω-nitrostyrene (IV) (R = CH_3CO)

p-Hydroxy-ω-nitrostyrene (12)(10 g) was dissolved in acetic anhydride (100 ml) containing fused anhydrous sodium acetate (3 g), the solution refluxed gently for 4 h, then poured into crushed ice (1 kg). The fine, light-yellow precipitate was filtered off and recrystallized from acetone – petroleum ether to give the acetate as long, silky, pale-yellow needles, m.p. 161–162° (11.2 g, 88%). Lit. (14) m.p. 158–159°.

p-Acetoxyphenylacetaldoxime (V)(R = CH_3CO)

p-Acetoxy-ω-nitrostyrene (10 g) was dissolved in pyridine (100 ml), palladium–charcoal catalyst (0.5 g) added, the reaction mixture warmed to 50°, and then hydrogenated in a Parr apparatus at 30 p.s.i. Uptake of hydrogen was complete in 15 min and was slightly less than the theoretical amount. The reaction mixture was filtered through Celite, the pale-yellow filtrate poured into ice-cold, dilute sulfuric acid (4 *N*, 750 ml) and extracted with ether (4 × 150 ml).

The ether extracts were combined, dried ($MgSO_4$), and filtered. Fine colorless crystals separated, m.p. 183–184°, apparently dimeric[10] material. The ether extracts were concentrated under reduced pressure to a thin slurry of crystals in a light-brown oil. Addition of benzene, followed by filtration, gave a further yield of the dimer (total 0.58 g). The benzene solution was concentrated somewhat and petroleum ether added to the warm solution until a permanent opalescence was produced. Upon standing, an oil separated, accompanied by pale-yellow, needle-shaped crystals. The crystals were separated and the oil redissolved in benzene and the solution again treated with petroleum ether. In this way, a total of three crops of crystals was obtained (1.7 g). These were combined and twice recrystallized from benezene – petroleum ether to give pale, straw-colored needles of the oxime, m.p. 92–94° (1.35 g, 14%).

Anal. Calcd. for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25. Found: C, 62.62; H, 5.75; N, 7.05.

p-Acetoxyphenylacetohydroxamoyl Chloride (VI)(R = CH_3CO)

p-Acetoxyphenylacetaldoxime (250 mg) was dissolved in ether (30 ml), the solution cooled to 0° in an ice–salt bath, and a slow stream of chlorine was bubbled through the solution. Careful removal of solvent (bath < 10°) from the azure-colored solution left a white crystalline residue which was twice recrystallized from ether to give fine needles with a blue–green tint, sintering at 90°, m.p. 116° (206 mg, 70%).

Anal. Calcd. for $C_{10}H_{10}ClNO_3$: C, 52.76; H, 4.45; Cl, 15.58. Found: C, 53.03; H, 4.70; Cl, 15.56.

S-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)p-acetoxyphenylacetothiohydroximate (pentaacetylproglucosinalbin) (VIII)(R = CH_3CO)

p-Acetoxyphenylacetaldoxime (0.80 g) was converted to the hydroxamoyl chloride as above, the entire product was dissolved in dry ether (250 ml) and added to a stirred solution of 2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl mercaptan (1.6 g) in dry ether (100 ml), followed by triethylamine (2 ml) in ether (10 ml). There was immediate separation of triethylamine hydrochloride and the pale-blue color of the solution was discharged. After 30 min at room temperature, the reaction mixture was poured into ice-cold, dilute aqueous sulfuric acid (500 ml, 1 *N*) and shaken. The ether layer was separated, dried ($MgSO_4$), and evaporated to yield a colorless oil which crystallized and recrystallized from ether – petroleum ether in small colorless prisms, m.p. 157–158° (1.30 g, 60%). $[\alpha]_D^{25}$ −9.5° (*c*, 2 in $CHCl_3$).

Anal. Calcd. for $C_{24}H_{29}NO_{12}S$: C, 51.88; H, 5.26; N, 2.52. Found: C, 51.82; H, 5.36; N, 2.50.

Tetramethylammonium Glucosinalbate (IIa) (R = H, X = $(CH_3)_4N$)

Pentaacetylproglucosinalbin (300 mg) and freshly prepared pyridine – sulfur trioxide complex (200 mg) were stirred together in dry pyridine (3 ml) at room temperature for 24 h. The reaction mixture was poured into water (50 ml) containing potassium hydrogen carbonate (500 mg). The homogeneous, deep-orange-colored solution was freeze dried, the residue extracted with boiling 95% (v/v) aqueous ethanol (3 × 20 ml), and the extracts filtered hot. The combined orange-colored extracts deposited discolored and rather amorphous solids on cooling, the infrared spectrum of which (in KBr disc) suggested that they were the desired potassium pentaacetylglucosinalbate accompanied by partially deacetylated material. Accordingly, the combined ethanol filtrates were evaporated to dryness and the residue combined with the solids which had separated from solution. The total solids were dissolved in methanol (40 ml) previously saturated with ammonia and the solution kept at room temperature over night. Removal of solvent under reduced pressure left a brown glass which was taken up in water (5 ml) and applied to the top of a column (1 × 15 cm) of Dowex-50 cation exchange resin in the tetramethylammonium form. The column was eluted with water (30 ml) and the brown eluates were adjusted to pH 8 by addition of a drop of glacial acetic acid and freeze dried. The residual glassy solids were taken up in a little methanol and the solution filtered and diluted with absolute ethanol until a rather dirty and gummy precipitate separated. This was filtered off and the filtrate treated with 2 drops of water and absolute ethanol until turbid. On standing, first at room temperature and then at 0°, small off-white prisms separated from the solution. These were collected and recrystallized from aqueous ethanol to give almost colorless prisms of tetramethylammonium glucosinalbate, m.p. 192–195° (decomp.) (open capillary) (96 mg, 36%). The infrared spectrum (KBr disc) was identical with that of an authentic specimen of tetramethylammonium glucosinalbate of natural origin and the melting point was undepressed on admixture with this salt. $[\alpha]_D^{24}$ −20° (*c*, 2 in H_2O). Lit. (6) m.p. 191–192° (decomp.), $[\alpha]_D^{35}$ −19° (in H_2O). The product was also homogeneous when examined by paper chromatography (16).

p-Methoxyphenylacetaldoxime (V)(R = CH_3)

p-Methoxy-ω-nitrostyrene (12) (5.0 g) in pyridine (100 ml) was hydrogenated over 10% palladium–charcoal at room temperature and 30 p.s.i. Hydrogen uptake was rapid and ceased after 15 min. The reaction mixture was worked up as described above for *p*-acetoxyphenylacetaldoxime to yield a yellow oil containing suspended crystals. The oil was taken up in ether, in which the crystals were insoluble, and filtered. The residual crystals of *dimer* were recrystallized from ethanol–benzene in colorless, felted plates, m.p. 232–234°.

Anal. Calcd. for $C_{18}H_{20}N_2O_4$: C, 65.83; H, 6.11; N, 8.53. Found: C, 65.77; H, 6.33; N, 8.51.

Evaporation of the ether extract gave a yellow oil which crystallized from benzene-petroleum ether. Recrystallization with a single treatment with animal charcoal from ethanol gave colorless plates, m.p. 120° (3.5 g, 77%). Lit. (13) m.p. 120°.

S-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)p-methoxyphenylacetothiohydroximate (tetraacetylproglucoaubrietin) (VIII)(R = CH_3)

p-Methoxyphenylacetaldoxime (1.0 g) was dissolved in dry chloroform (25 ml), the solution cooled to 0°, and a slow stream of dry chlorine bubbled through the solution for 20 min. The initially blue, now green solution was worked up in the usual manner (bath < 40°). The product was an off-white mass of crystals of *p*-methoxyphenylacetohydroxamoyl chloride, which readily decomposed on standing at room temperature. The hydroxamoyl chloride was taken up in ether (10 ml) and added to a gently stirred solution of 2,3,4,6-tetra-O-acetyl-β-D-glucosyl mercaptan (2.0 g) in ether (200 ml), followed by a solution of triethylamine (2.5 ml) in ether (10 ml). After 30 min at room temperature, the reaction mixture was worked up in the usual fashion to yield a pale-brown oil. The oil was taken up in ethanol, treated with animal charcoal, and the hot, filtered solution diluted with petroleum ether until just turbid. On cooling, long, colorless, felted needles separated, m.p. 160–163°, raised to 164–166° after two further recrystallizations from ethanol. (1.9 g, 54%). $[\alpha]_D^{25}$ −12° (*c*, 2 in $CHCl_3$).

Anal. Calcd. for $C_{23}H_{29}NO_{11}S$: C, 52.36; H, 5.54; N, 2.66; S, 6.08. Found: C, 52.76; H, 5.86; N, 2.60; S, 6.15.

Tetraacetylglucoaubrietin (IX) (R = CH_3)

Tetraacetylproglucoaubrietin (410 mg) was dissolved in dry pyridine (5 ml), pyridine – sulfur trioxide (180 mg) added, and the reaction mixture stirred at room temperature for 18 h. (A homogeneous solution was obtained after 3 h.) The reaction mixture was poured into water (30 ml) containing potassium hydrogen carbonate (250 mg) and the homogeneous solution was then freeze dried. The residue was extracted with boiling 95% (v/v) aqueous ethanol (5 × 15 ml), and the extracts filtered hot. Colorless, fine, needle-shaped crystals separated, m.p. 185–190°, and recrystallized from 95% ethanol as colorless needles, m.p. 187–190° (277 mg, 55%). $[\alpha]_D^{27}$ −14° (*c*, 2 in 1:1 (v/v) aqueous ethanol).

Anal. Calcd. for $C_{23}H_{28}NO_{14}S_2K.2H_2O$: C, 40.52; H, 4.73; N, 2.05; S, 9.41; K, 5.74. Found: C, 39.96; H, 4.31; N, 1.99; S, 9.37; K, 5.74.

Glucoaubrietin (IIa) ($R = CH_3$, $X = (CH_3)_4N$)

Tetraacetylglucoaubrietin (220 mg) was dissolved in anhydrous methanol (10 ml) saturated with ammonia and the solution kept at room temperature overnight. Removal of solvent under reduced pressure left an ethanol-insoluble gum. The gum was taken up in a little methanol and 1 drop of water added, followed by absolute ethanol. The white, hygroscopic, amorphous precipitate was taken up in a few drops of water and absolute ethanol added to the warm solution until a permanent turbidity was produced. After storing at 0° overnight, the fine, colorless, granular precipitate was filtered off. It again proved to be hygroscopic, setting to a hard, powderable glass, m.p. 148–155° (decomp.). Paper chromatography revealed that the product was homogeneous with R_F 0.33.

Anal. Calcd. for $C_{15}H_{20}NO_{10}S_2K$: C, 37.22; H, 4.22; S, 13.43. Found on an undried sample: C, 37.73; H, 4.99; S, 13.80.

Evaporation of the mother liquors yielded more solid which was combined with the crystallized material and converted to the tetramethylammonium salt as described for glucosinalbin. In this case, the freeze-dried eluates yielded a residue which crystallized directly from aqueous ethanol in small colorless prisms, m.p. 187–189° (88 mg, 41%). $[\alpha]_D^{27}$ −21° (*c*, 2 in H_2O). The product was homogeneous when examined by paper chromatography (16).

Anal. Calcd. for $C_{19}H_{32}N_2O_{10}S_2$: C, 44.52; H, 6.29; N, 5.47; S, 12.51. Found: C, 44.45; H, 6.36; N, 5.19; S, 12.50.

ACKNOWLEDGMENTS

We are grateful to the National Research Council for financial support of this work and to Miss Patricia Wales who prepared the *p*-methoxy-ω-nitrostyrene.

SUPERSONIC MOLECULAR BEAMS

II. THEORY OF THE FORMATION OF SUPERSONIC MOLECULAR BEAMS

J. P. VALLEAU AND J. M. DECKERS
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario

Received June 19, 1964

ABSTRACT

Supersonic molecular beams may be isolated from gas which has been allowed to expand through a nozzle. This paper concerns the kinetic theory of the isolation of such beams, taking into account the effect of collisions in the region between the skimmer and the collimator. These collisions turn out to be important. In particular, they offer an explanation of two interesting phenomena: (*a*) the existence of a *maximum* beam intensity as the distance is varied between the nozzle and the collimating system and (*b*), in a mixed beam, large increases in the intensity of the heavy gas as its initial concentration is reduced by replacement with a much lighter gas. The theory is compared with various experimental results. Although severe approximations have been introduced into the theory, it appears to predict the above phenomena in a way that is better than qualitative.

1. INTRODUCTION

A considerable amount of data is accumulating on the behavior of supersonic molecular beams formed by expansion through a nozzle. The experimental setup for such a beam is shown schematically in Fig. 1. Gases, initially at a pressure p_0 (number density n_0), are allowed to expand through a nozzle into a region of much lower pressure. The gas in the core of the nozzle exhaust is thereby accelerated to supersonic velocities. A beam is isolated from this core by two small apertures known as the skimmer and the collimator.

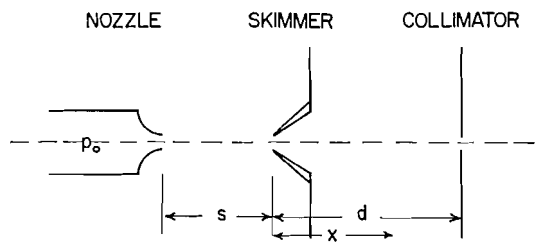

FIG. 1. Schematic diagram of beam-forming apparatus.

Two results of these experiments appear very surprising at first sight. As the distance s between the nozzle and the skimmer is increased from small values, one might expect a monotonic decrease in beam intensity. One might also expect a beam intensity roughly proportional to p_0. This is the behavior, in both respects, predicted by the original analysis of the beam problem, according to Kantrowitz and Grey (1). In practice it is found (2) that with increasing s the intensity *increases* in a certain range, then passes through a maximum, and finally decreases. Furthermore, at s-values below the maximum the intensity depends very little on p_0.

The other observation concerns mixed beams. If a beam is made from a mixture of a heavy gas and a light gas, it is usually found that the beam is very much enriched in the heavier gas. This is easy to explain (cf. Section 3), but it is more surprising that at fixed

p_0 a *dilution* of heavy gas with light gas leads to a large *increase* in beam intensity, although the beam consists almost entirely of the heavy gas.

We believe that these effects are due largely to the effect of collisions, occurring in the region between the skimmer and the collimator, between the beam molecules. The theoretical problem of taking account of these collisions is not a simple one, so that we have had to be satisfied for the moment with a theory involving several approximations. Nonetheless, the above effects are described in a way that is better than qualitative (cf. Section 4).

In an earlier paper (3) we examined the effects of collisions in the isolated beam (i.e. downstream from the collimator). We showed that in a mixed beam collisional depletion of light molecules would be more rapid than that of heavy molecules. One can expect this collisional enrichment of heavy molecules to be far more effective in the higher density region between the skimmer and collimator.

The only suggestion previously put forward to account for these effects involved the consequences of a postulated shock wave set up before the skimmer aperture. We discuss later (Section 5) some recent experimental work of Reis and Fenn (4) on this matter. Evidently, mass separation effects due to such shock waves can occur in molecular beams under some conditions, though those are not yet established. At the same time it appears certain that the collisional effect discussed in this paper is large and generally important and may well explain many of the observations on beams.

2. THEORY

The theoretical development is based on the approximation that the flow of the gas forming the beam remains "hydrodynamic" up to the skimmer, where it becomes "molecular". This approximation is implicit in the analysis of Kantrowitz and Grey (1) and others (5, 6) and allows one to estimate the Mach number $\mathscr{M}$ of the beam from the distance between the nozzle and the skimmer. It is obvious that the flow does not in practice change instantly from one regime to the other; the present picture is that, because the skimmer suddenly removes the outer envelope of flowing gas, the transition takes place rather rapidly. The approximation appears to be a useful one.

There are evidently cases where this approximation will not be suitable. If the gas at the skimmer is sufficiently dense, the expansion region will penetrate into the region between the skimmer and the collimator; the present theory cannot describe this situation. At the other extreme, for very low densities, the expansion may quit before the gases reach the skimmer; it should be possible to adapt the theory to describe this situation (cf. Section 5).

According to the above basic approximation, the Mach number at the skimmer is determined by the distance s, between the nozzle and the skimmer, measured in nozzle diameters. In the limit of low background pressure, $\mathscr{M}$ is given by Woolf's (7) generalizations of the calculations of Owen and Thornhill (8). The temperature T and the mean velocity $\bar{v}$ in the beam are then given by the laws of isentropic expansion:

$$T_0/T = 1 + (\gamma - 1)\mathscr{M}^2/2, \qquad [2.1]$$

$$\bar{v} = (2C_p(T_0 - T)/M)^{1/2} = \mathscr{M}(\gamma RT/M)^{1/2}, \qquad [2.2]$$

where T_0 is the stagnation temperature, C_p the molar heat capacity, γ the specific heat ratio C_p/C_v, M the molecular weight of the gas, and R the gas constant per mole. We have shown previously (3) that as a result of collisions in the beam there is a small decrease in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

T and increase in $\bar{v}$ in moving down the beam; we take no account here of this second-order effect.

We wish to calculate the number density n_c of the gas at the collimator and hence the beam intensity $n_c\bar{v}$. To do this it is only necessary to consider a cylindrical region based on the skimmer aperture and stretching a distance d to the collimator. Molecules enter this region at the skimmer with a density n_s. The density n_c at the collimator is much less than n_s for two reasons:

(*a*) the natural trajectories of most of the molecules at the skimmer carry them across the boundary of the cylinder before they reach the collimator; this may be called the convective or diffusive loss of molecules;

(*b*) most collisions between pairs of molecules throw the colliding molecules out of the cylindrical region rather quickly; this may be called the collisional loss.

If there were no collisions the density could be calculated from purely geometrical considerations; let us call this "collision free" density, at a distance x from the skimmer, $n'(x)$. Due to collisions the density $n(x)$ will be less than $n'(x)$ and this will reduce the convective loss by a factor of roughly n/n'. We may therefore write an approximate equation for the attenuation of the density $n(x)$, taking account of collisions, as follows;

$$\frac{dn}{dx} = \frac{n}{n'}\frac{dn'}{dx} - \frac{\lambda n^2}{\bar{v}}, \qquad [2.3]$$

where $\lambda n^2/2$ is the collision frequency per unit volume at a density n. This equation implicitly assumes that the density is uniform across the cylinder, which is not strictly the case. It also ignores the effect of collisions on the flow pattern of the gases and the fact that some collisions will in fact knock molecules *into* the beam.

We can easily solve [2.3] to obtain

$$n(X) = n'(X) \Big/ \left[1 + (1/\bar{v}) \int_0^X \lambda n'(x)\, dx\right], \qquad [2.4]$$

where X is some particular value of x. It is therefore necessary to estimate n', the density in the collision-free case.

To do this we require the Maxwellian probability distribution,

$$p(w) = \frac{mw}{kT} \exp\left\{-\frac{mw^2}{2kT}\right\}, \qquad [2.5]$$

for a molecule of mass m, in the skimmer, to have a transverse speed w. If we disregard the thermal spread of the velocities parallel to the axis (by comparison with the mean velocity $\bar{v}$), we can show that

$$n'(X) = \frac{2n_s}{\pi}\int_0^{a\bar{v}/X}\left[\arccos\frac{wX}{a\bar{v}} - \frac{wX}{a\bar{v}}\left(1 - \frac{w^2X^2}{a^2\bar{v}^2}\right)^{1/2}\right]\frac{mw}{kT}\exp\left\{-\frac{mw^2}{2kT}\right\}dw, \qquad [2.6]$$

where a is the diameter of the skimmer. Unfortunately, this cannot be integrated analytically, so we have turned to a rougher approximation. We treat the diffusive problem as though all the molecules entered at the center of the skimmer. Then all molecules with a transverse speed less than $a\bar{v}/2X$ will remain in the beam at X. Thus

$$\begin{aligned} n'(X) &\approx n_s\int_0^{a\bar{v}/2X}\frac{mw}{kT}\exp\left\{-\frac{mw^2}{2kT}\right\}dw \\ &= n_s\left[1 - \exp\left\{-\frac{ma^2\bar{v}^2}{8kTX^2}\right\}\right]. \end{aligned} \qquad [2.7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This approximation is rather drastic for small values of X, where it will somewhat overestimate the density; it becomes a very good approximation for large X, of course. It may be noted that [2.7] becomes an inverse square law for large X. It is convenient to introduce a quantity α, having the dimensions of length, as follows;

$$[2.8] \qquad \alpha = \left(\frac{m\bar{v}^2}{8kT}\right)^{1/2} a = \left(\frac{\gamma}{2}\right)^{1/2} \frac{\mathscr{M}}{2} a,$$

where the second form comes from [2.2].

We now wish to use the result [2.7],

$$n'(x) = n_s[1 - \exp(-\alpha^2/x^2)],$$

to evaluate the density $n(X)$, [2.4], and in particular the density $n_c \equiv n(d)$, at the collimator. There is some difficulty concerning the collision coefficient λ. Strictly speaking this should be regarded as a function of x; it will change with position because the transverse velocity distributions are constantly truncated as a result of the convective effect discussed earlier. Thus the molecules very near the skimmer may have considerable transverse velocities, and a three-dimensional collision problem arises. This is, however, rapidly converted into an approximately one-dimensional problem on moving away from the skimmer orifice, since only those molecules having small transverse velocities will remain in the core of the beam. In this conversion, λ will decrease by a factor of two. For the present approximate development we ignore this variation. The integration may then be carried out (cf. Appendix) to give

$$[2.9] \qquad n(X) = \frac{n_s[1 - \exp(-\alpha^2/X^2)]}{1 + (\lambda n_s/\bar{v})\{\pi^{1/2}\alpha[1 - \operatorname{erf}(\alpha/X)] + X[1 - \exp(-\alpha^2/X^2)]\}},$$

which is the desired result. The density in the skimmer n_s, is related to the stagnation density n_0 by the isentropic expansion law

$$[2.10] \qquad \frac{n_0}{n_s} = \left(1 + \frac{\gamma - 1}{2}\mathscr{M}^2\right)^{\frac{1}{\gamma-1}}.$$

For a typcial molecular beam experiment, (a/d) is usually 10^{-2} or less, and (cf. 2.8) α/d is small compared to unity. In estimating the density n_c at the collimator, one will thus usually, to a good approximation, be in the inverse square region of [2.7]:

$$[2.11] \qquad n_c \approx \frac{n_s\alpha^2/d^2}{1 + (\lambda n_s/\bar{v})\{\pi^{1/2}\alpha - \pi^{1/2}\alpha \operatorname{erf}(\alpha/d) + \alpha^2/d\}}.$$

Some further simplification is possible in practical cases. The second and third terms in the bracket of the denominator are small compared to the first, and furthermore they partially cancel. For $(\alpha/d) \lesssim 0.1$, $\pi^{1/2}\operatorname{erf}(\alpha/d) \approx 2\alpha/d$ very closely, so that

$$[2.12] \qquad n_c \approx \frac{n_s\alpha^2/d^2}{1 + (\lambda n_s/\bar{v})\{\pi^{1/2}\alpha - \alpha^2/d\}},$$

where the final term of the bracket is small compared to the first.

To estimate the magnitude of the collisional effect, one requires the ratio $\lambda/\bar{v}$, and we use here the value $\lambda = 2\sigma^2(\pi RT/M)^{1/2}$ calculated previously (3) for collisions in the beam; σ is the collision diameter of the molecules. With [2.2] this gives

$$[2.13] \qquad \lambda/\bar{v} = (2\sigma^2/\mathscr{M})(\pi/\gamma)^{1/2}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Inserting [2.10] and [2.13] into [2.12] and recalling the definition [2.8], we obtain

$$[2.14] \qquad n_c \approx \frac{n_0 \mathscr{M}^2 a^2 \gamma / 8d^2}{[1 + (\gamma - 1)\mathscr{M}^2/2]^{1/(\gamma-1)} + [\pi\sigma^2 a n_0/(2)^{1/2}][1 - (\gamma/2\pi)^{1/2}(\mathscr{M} a/2d)]}.$$

It is evident from this expression that the collisional effect, described by the second half of the denominator, should be important. For typical beam experiments ($a \sim 10^{-1}$ cm, $n_0 \sim 10^{17}$ molecules/cc, $\sigma \sim 10$ Å), this term will be $\sim 10^2$ to 10^4 and certainly not negligible compared to the other term. At low Mach numbers the collisional term will in fact dominate the denominator, so that the intensity, $n_c\bar{v}$, of the beam will *increase* with $\mathscr{M}$. At high Mach numbers the other term will dominate, and the intensity will fall off with $\mathscr{M}$ as expected according to the Kantrowitz and Grey analysis. The existence of the maximum in the intensity curve is thus explained qualitatively. Evidently, at low Mach numbers the intensity will depend very little on the nozzle density n_0, as observed experimentally. In Section 4 the above expression is compared with some experimental data.

3. ENRICHMENT AND INTENSITY IN MIXED BEAMS

If a beam is formed from a mixture of a light and a heavy gas, a large concentration enrichment of the heavy gas is to be expected. Suppose only that the mean velocities and temperatures of the two gases remain the same up to the skimmer. The light gas will accordingly have a higher transverse velocity than the heavy gas and will therefore diffuse out of the core of the beam, between the skimmer and the collimator, more rapidly than the heavy gas. We shall see that this convective effect is sufficient to give the separation ratios observed by Greene, Brewer, and Milne (9). Waterman and Stern (10) invoked somewhat similar ideas in attempting to explain the mass separation effects they have observed.

What is more surprising is that, for a fixed nozzle pressure p_0, a reduction of the mole fraction of the heavy gas leads to a very much *increased* intensity in the beam of heavy gas produced. This cannot be explained by the convective effect mentioned above, so we turn again to studying the effects of collisions. Suppose the two gases are labelled 1, 2. Then by analogy with [2.3] we can write

$$[3.1] \qquad \frac{dn_1}{dx} = \left(\frac{n_1}{n_1'}\right)\frac{dn_1'}{dx} + \frac{\lambda_{11} n_1^2}{\bar{v}} + \frac{\lambda_{12} n_1 n_2}{\bar{v}},$$

$$[3.2] \qquad \frac{dn_2}{dx} = \left(\frac{n_2}{n_2'}\right)\frac{dn_2'}{dx} + \frac{\lambda_{21} n_1 n_2}{\bar{v}} + \frac{\lambda_{22} n_2^2}{\bar{v}}.$$

Since not all collisions will be effective in removing molecules from the beam, we now think of the λ's as describing only "effective" collisions. In particular, collisions between light and heavy molecules will affect the paths of the heavy molecules much less than those of the light, as discussed elsewhere (3); thus we may expect $\lambda_{12} \ll \lambda_{21}$, where 1 is the heavy gas.

Equations [3.1,2] are not easy to solve. If, however, we make the approximation $\lambda_{12} = 0$, eq. [3.1] for the heavy gas takes the form [2.3] found for a pure beam. In doing this we ignore the effect of collisions with light molecules in removing heavy ones from the beam. The argument can then proceed exactly as for a pure heavy gas, except that the density of the heavy gas in the nozzle is only $X_1 n_0$, where X_1 is the mole fraction of the heavy gas in the stagnation gas mixture, while $\bar{v}$ in the mixed beam will be given by

$$[3.3] \qquad \bar{v} = \mathscr{M}(\bar{\gamma} RT/\bar{M})^{1/2},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where

$$\bar{M} = X_1 M_1 + X_2 M_2, \tag{3.4}$$

and

$$\bar{\gamma} = \frac{X_1 C_{p_1} + X_2 C_{p_2}}{X_1 C_{v_1} + X_2 C_{v_2}}. \tag{3.5}$$

By making the appropriate modifications to the argument of the preceding section (Section 2) we can write an approximate expression for the intensity of the heavy gas in a beam formed from a mixture of gases of very different masses. If we drop, from the denominator (cf. [2.14]), the small term containing a/d, we obtain

$$n_{1c}\bar{v} = \frac{X_1 n_0 \mathscr{M}^3 \bar{\gamma}^{3/2} a^2 M_1 (RT)^{1/2}/8\bar{M}^{3/2} d^2}{[1 + (\gamma - 1)\mathscr{M}^2/2]^{1/\gamma-1} + \pi\sigma_1^2 a X_1 n_0/(2)^{1/2}}, \tag{3.6}$$

where σ_1 is the collision diameter of the heavy gas. This is the result we shall compare with experiment. It has some interesting features. For low Mach numbers the collisional term again dominates the denominator. As a result the explicit dependence of the intensity on X_1 practically disappears, and the intensity will be roughly proportional, at fixed $\mathscr{M}$ and n_0, to $(\bar{\gamma}/\bar{M})^{3/2}$. However, $\bar{M}$ will decrease rapidly as X_1 is reduced. This explains the very high intensities of heavy gas obtained with mixed beams for low Mach numbers. For *high* Mach numbers the beam temperature T becomes small so that the collision rate is reduced. Under these conditions the collisional term no longer dominates the denominator and the intensity behaves more like $X_1(\bar{\gamma}/\bar{M})^{3/2}$; less dramatic intensity increases on dilution are to be expected in this case.

4. COMPARISON WITH EXPERIMENTS

The above predictions are here compared with some measurements already reported in the literature or obtained in this laboratory.

Deckers and Fenn (2) have measured the absolute intensity of some nitrogen beams for various stagnation pressures and over a wide range of nozzle–skimmer distances; the results show the typical maxima of intensity as this distance is varied. For the conditions of these beams (cf. [2.14]), $(\gamma/2)^{1/2}(\mathscr{M}a/2d) \ll 1$, and we may, as before, drop the final term of the denominator:

$$n_c \simeq \frac{n_0 \mathscr{M}^2 \gamma a^2/8d^2}{[1 + (\gamma - 1)\mathscr{M}^2/2]^{1/\gamma-1} + can_0}. \tag{4.1}$$

The factor c as given by the above approximate theory is $\pi\sigma^2/(2)^{1/2}$. It therefore depends rather strongly on the collision diameter σ, which is not easy to estimate closely for the beam collisions, since these take place at a very low temperature and therefore at low relative velocities. The numerical factor $\pi/(2)^{1/2}$ is also rather suspect in view of the approximations we have introduced into the theory. For these reasons we have regarded c as an adjustable parameter in fitting experimental results, but we shall check that the value obtained leads to a reasonable value for σ. We have determined c from the position of the maximum intensity, as follows. By differentiating [4.1] with respect to the Mach number $\mathscr{M}$ we obtain a relation between c and the Mach number at which the *maximum* beam intensity occurs, for a fixed stagnation density. Woolf's relation (7) was used to obtain this Mach number from the measured nozzle–skimmer distance s. When this was done for nitrogen, at a stagnation pressure of 10 torr, it was found that $can_0 = 1\,050$; this corresponds to a collision diameter σ of 8.8 Å, which is of the expected magnitude.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Using this single value of c, we can predict the dependence of the beam intensities $n_c\bar{v}$ on both s and p_0. The predictions are compared with experiment (2) in Fig. 2. It is apparent that the pressure dependence of the peak position has been explained semiquantitatively (cf. Table I); we regard this as a strong argument for the correctness of the theoretical explanation. In Fig. 2 the theoretical curves have been plotted on one scale, the experimental curves on a different scale; this was done to allow a better comparison of the shapes of these curves. It is possible, however, to predict the *absolute* intensities on the basis of the theory, and these are compared with experiment for the three peak heights in Table I. No new parameters are introduced in making this comparison, and it is worth recalling that the one parameter c was determined without using the value of any intensity. The predicted intensities are too high by a factor of about three, possibly as a result of further attenuation due to scattering by background molecules and by those reflected from the skimmer, as was suggested by Anderson and Fenn (11).

A completely independent determination of the parameter c for nitrogen was obtained using the molecular beam apparatus in this department (12). Not only was a different pressure (20 torr) used, but the geometry of the beam was rather different. The two estimates differed by less than 5%. It might be mentioned that one may expect the mean collision diameters to be temperature-dependent, and we have taken no account of this in making these experimental comparisons.

TABLE I

	Peak position s (nozzle diameters)		10^{-16} peak height (molecules/cm^2 s)	
p_0	Experimental	Theoretical	Experimental	Theoretical
10	9	9	2.7	6.3
50	18	19	4.3	12.7
100	24.5	26	4.9	17.1

The increasing intensity at very low s-values for the higher pressures is presumably due to a continuation of the hydrodynamic expansion into the region downstream from the skimmer. It was mentioned earlier that the model cannot cope with this situation. At high s-values, for the high pressures, the intensity appears to fall off more rapidly than predicted, leading to sharper peaks than the theoretical ones. This behavior seems to be typical and is not yet explained. It may arise from a breakdown of the isentropic expansion law [2.10] and perhaps from the higher background pressures that must be tolerated with higher stagnation pressures p_0.

In Fig. 3 is shown the result of similar calculations for some results on argon reported by Greene, Brewer, and Milne (9); only the shapes of the curves may be compared, since the results for each stagnation pressure have been reported on their own arbitrary scale. In drawing the theoretical curves the parameter c was chosen to roughly match the position of the peak which occurs for $p_0 = 760$ torr; this value of c corresponds to $can_0 = 25 \times 10^3$ at that pressure. The authors have not made clear the precise size of the skimmer used in these experiments, and this makes it impossible* to determine the value of the collision diameter σ implied by the derived value of can_0; a similar determination for argon based on results taken in this laboratory led, however, to $\sigma = 5.6$ Å. Because of the larger value of γ for argon, as compared with nitrogen, much higher Mach numbers must be reached before

**It also makes it impossible to apply the more accurate expressions [2.12] or [2.9], which would be preferable where such high Mach numbers are involved.*

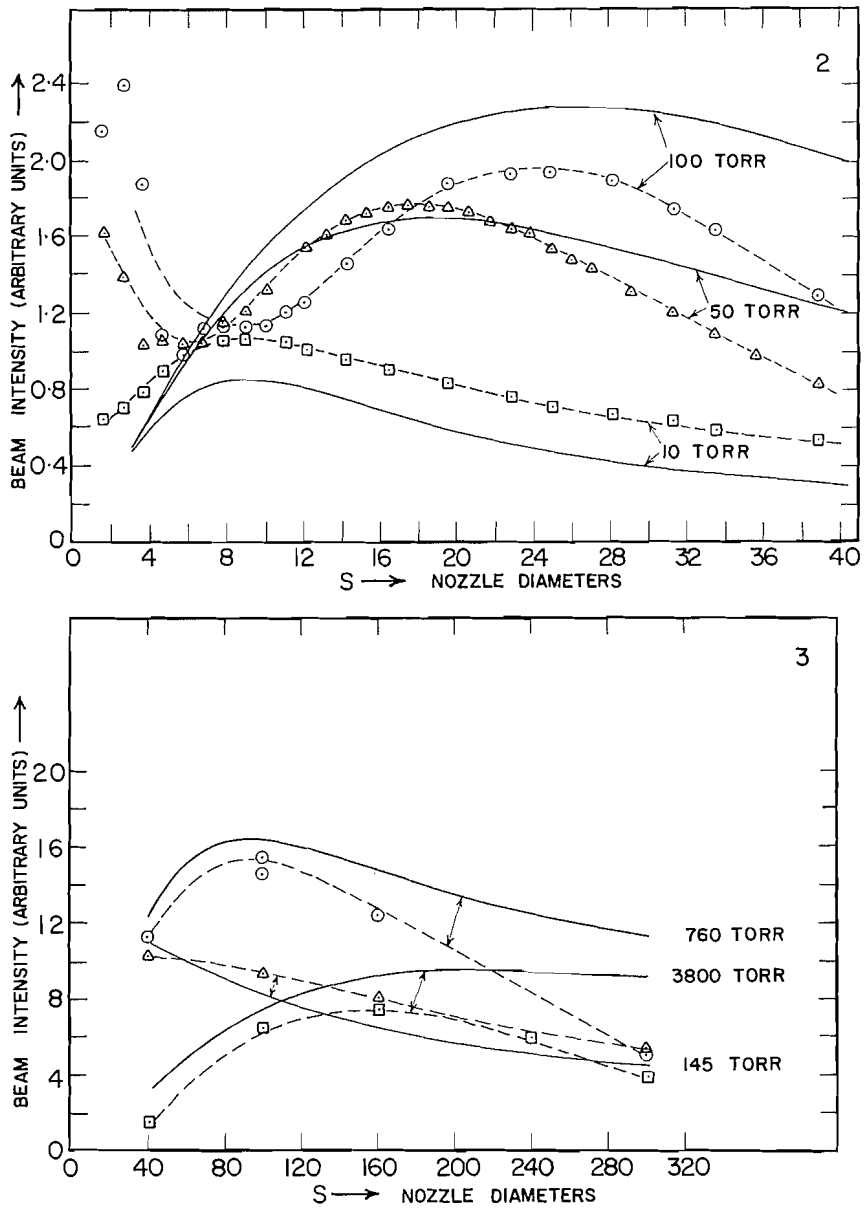

FIG. 2. Dependence of beam intensity on the distance s between the nozzle and the skimmer. The experimental points (2) are for nitrogen, and the solid lines show the intensity variations predicted by [4.1].

FIG. 3. Dependence of beam intensity on the distance s between the nozzle and the skimmer for argon beams (9). The solid curves show the variations predicted by [4.1].

the domination of the collisional term in [4.1] is overcome. This explains why the peaks occur at much larger nozzle-to-skimmer distances for argon than for diatomic gases. One can see again the characteristic fall-off of intensity with large s-values, which probably accounts for the shift of the peak position from that predicted for $p_0 = 5$ atm. It is very likely that this is connected here with a "quitting" of the expansion before it reaches the very high ratios implied by the large s-values.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

However, a more interesting test of the theory may be made using the results reported by Greene, Brewer, and Milne (9). The authors have published curves of beam intensity as a function of p_0, for fixed beam geometry, with two different nozzle sizes (cf. Fig. 4). The nozzle-to-skimmer distance was 3 mm. The intensity is proportional to p_0 over a wide range, but gradually becomes less dependent on p_0 at high pressures. It is easy to understand this behavior by reference to our result [4.1]. The Mach number is now fixed by the unvarying geometry of the beam. When p_0 and hence n_0 are small the collisional term is small, and the density and intensity will be proportional to n_0. At high pressures, on the other hand, the collisional term will dominate the denominator, so that the intensity will become independent of n_0. The only effect of changing to a larger nozzle diameter is, in this view, that of reducing the ratio of nozzle–skimmer distance s to the nozzle diameter, and thus reducing the Mach number of the beam. In Fig. 4 we have plotted the predictions of our theory, using the value of c derived above, along with the experimental points. It can be seen that the behavior is qualitatively correct, and that the two curves cross at about the pressure for which this crossing is observed experimentally.

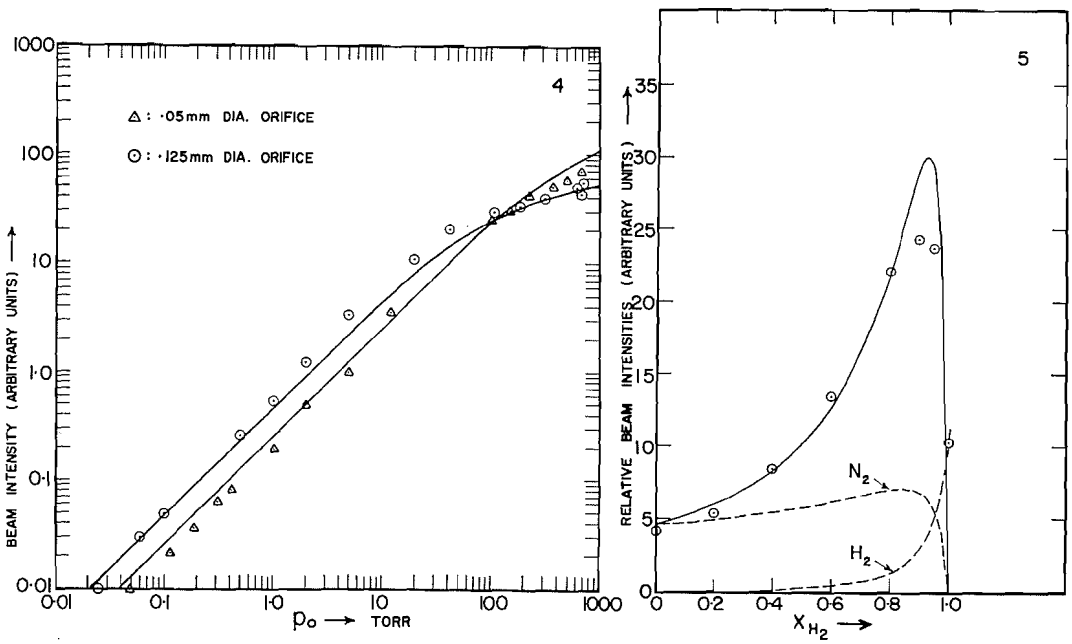

FIG. 4. Experimental (9) and predicted [4.1] pressure dependences of argon beam intensities for two different nozzle diameters.

FIG. 5. Predicted concentration dependence [3.6] of nitrogen intensity in beams formed by expanding mixtures of nitrogen and hydrogen (p_0 = 20 torr, s = 5.5 nozzle diameters), along with some experimental beam intensity values (12). The dashed lines show the intensity variations to be expected for the two gases if no collisions occurred.

Turning to mixed beams, we show in Fig. 5 the nitrogen intensity predicted by [3.6] in nitrogen–hydrogen beams of various compositions, for a stagnation pressure p_0 of 20 torr and with a fixed nozzle–skimmer distance s of 5.5 nozzle diameters. No account has been taken of the temperature dependence of the specific heat of hydrogen. The only parameter involved is the value of the nitrogen collision diameter σ, obtained from experiments on pure nitrogen beams. The figure also shows some experimental results obtained in this

laboratory (12); the agreement is very heartening. It is not surprising to find the experimental peak intensity lower than the theoretical, since the effect of mixed collisions on the intensity of the heavy gas, which we have ignored, is bound to become important for beams rich in the light gas; i.e. λ_{12} in [3.1] is not really zero.

The dashed curves show the concentration variations of the intensities of the nitrogen and hydrogen, predicted in the *absence* of any collisions. It is evident that the purely convective effect mentioned earlier leads by itself to a large enrichment of the heavy gas, but that the high intensities obtained cannot be so explained. When collisions are taken into account, the curve for the *light* gas will lie near to or below the collision-free curve shown. The relative inefficiency of mixed collisions in removing heavy molecules has therefore, according to the present argument, led to a substantial extra enrichment of the heavy gas.

These collisional effects are, of course, important only for beams with Mach numbers sufficiently low that the collisional term in the denominator of our expression [3.6] is not negligible. For beams of high Mach numbers one would therefore expect a less marked peak in the observed intensities, and this has been found to be the case (12).

Greene, Brewer, and Milne carried out many experiments on mixtures of gases, and measured the separation ratio α,

$$\alpha = \frac{(I)_1/(I)_2}{X_1/X_2}$$

where $(I)_i$ is the intensity of i molecules in the beam. It was found that α was very closely proportional to M_1/M_2, the ratio of the molecular weights. This is easy to explain in terms of our theoretical development. One can see from [3.6] that, providing the Mach number of the beam is high enough that the collisional term does not dominate the denominator, the intensity of a particular component i will be proportional to X_iM_i. This conclusion will not be affected by taking account of the mixed collisions. It leads to $\alpha = M_1/M_2$, the result obtained by Greene, Brewer, and Milne.

5. DISCUSSION

It is evident from the above that the effects of post-skimmer collisions on beam intensity and composition cannot be ignored. The theoretical development of this paper offers, in spite of the approximations involved, a description of beam intensities and composition which is better than qualitative.

There is evidently room for improvement in the theoretical development. In particular the "point source" approximation used in deriving the collision free density $n'(x)$ should be removed, and the position dependence of the collision parameter λ should be taken into account. These two approximations are only serious for small values of x, and as it happens they tend to cancel each other out in this region. This is because the former approximation overestimates the density, while the other underestimates the number of collisions which result from this density.

The theory is in an even less satisfactory position for mixtures. An effort should evidently be made to take some account of collisions between unlike molecules by solving equations like [3.1,2].

For very large values of s it is, of course, likely that the expansion will "quit" before the gases reach the skimmer, the gases going over to virtually molecular flow. This could be treated in a rough way by supposing a definite distance s_q at which the flow (suddenly) goes over from a hydrodynamic expansion regime to molecular flow. For values of s

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

greater than this it would be supposed that the Mach number is that corresponding to s_q. This is not simply equivalent to moving the skimmer back to s_q, however, since the collimator can now scavenge molecules from an area at s_q larger than the area of the skimmer. It should, however, prove possible to extend the theory to cover such cases.

Some most interesting work was reported recently by Reis and Fenn (4). They have measured mass separation effects in supersonic expansions sampled with impact probes. It was found (cf. Waterman and Stern (10, 13)) that the heavier gas was enriched in the probe. Reis and Fenn ascribe this separation to the existence of a detached shock wave ahead of the probe; the greater directional persistence of the heavier molecules leads to their enrichment in the probe. It should be emphasized that the experimental arrangement here is quite different from that involved in the beam experiments described earlier. In particular, the existence of substantial pressures in the "stagnation" probes will encourage the formation of shock waves; in the beam experiments the region behind the skimmer is not geometrically confined and is strongly pumped, so that the background pressure is normally in the region of 10^{-5} torr. The formation of shock waves is therefore much less likely. The mass separations we predict in beams are, for most conditions, much larger than those observed with impact probes and behave rather differently with the parameter s. It is clear that under certain conditions of dense beams, shocks may occur in front of the skimmer with accompanying mass separation; no evidence of this behavior has been identified under usual beam conditions.

A second interesting observation of Reis and Fenn was made with a "static" probe. With this, the composition of the beam was sampled by withdrawing gas *laterally* into a needle-shaped probe. No mass separation was observed. This confirms the contention of Reis and Fenn (cf. also Chow (14)) that the separation effects they observed are due to the probe, rather than intrinsic to the gas expansion. It also confirms the similar assumption made in our theoretical development: we explain separation effects in beams as due to the collimating system, not to the expansion.

APPENDIX

According to the approximation whereby the variation of λ with x is ignored (Section 2), we may write [2.4] in the form

$$[A.1] \qquad n(X) = n'(X) \Big/ \left\{1 + (\lambda n_s/\bar{v}) \int_0^X [1 - \exp(-\alpha^2/x^2)]\, dx\right\}.$$

The integral in the denominator is easily evaluated. It can be written

$$X - \int_0^X \exp(-\alpha^2/x^2)\, dx,$$

and integrating once by parts we obtain

$$X - X \exp(-\alpha^2/X^2) + 2\alpha^2 \int_0^X [\exp(-\alpha^2/x^2)/x^2]\, dx.$$

Making the substitution $y = \alpha/x$ in the final integral we obtain

$$[A.2] \qquad X[1 - \exp(-\alpha^2/X^2)] + (\pi)^{1/2}\alpha[\operatorname{erf}(\infty) - \operatorname{erf}(\alpha/X)],$$

where

$$[A.3] \qquad \operatorname{erf}(t) = \frac{2}{(\pi)^{1/2}} \int_0^t e^{-y^2}\, dy$$

and accordingly erf $(\infty) = 1$. When [A.2] is combined with [A.1] we arrive at the result [2.9].

SYNTHÈSES DE LA *TERT*-BUTYL-4 DIMÉTHYL-2,2 CYCLOHEXANONE ET DE SES DÉRIVÉS[1]

JEAN-CLAUDE RICHER ET GUY PERRAULT[2]
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 25 mai 1964

RÉSUMÉ

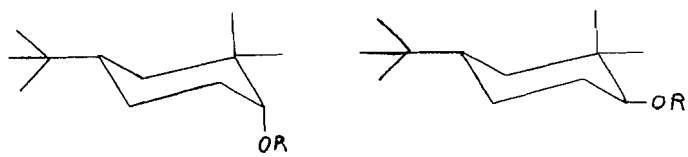
Deux méthodes sont proposées pour la synthèse de la *tert*-butyl-4 diméthyl-2,2 cyclohexanone. Les configurations des alcools isomères qui dérivent de cette cétone ont été déterminées. La différence d'énergie libre entre ces deux alcools s'établit à 0.28 kcal/mole. La stéréochimie des réductions de cette cétone est examinée.

INTRODUCTION

De nombreuses études sur l'équilibre conformationel du cyclohexanol (I) ont été rapportées (voir ref. 1). Ces travaux faisant appel à des techniques directes comme l'équilibration des *tert*-butyl-4 cyclohexanols (2) ou indirectes telles que la mesure de vitesses de réaction de dérivés (3, 4), la position de bandes dans les spectres de résonance magnétique nucléaire (r.m.n.) (5) et l'examen des spectres infrarouges (6) ont permis d'établir que la différence d'énergie libre entre le cyclohexanol axial et le cyclohexanol équatorial s'établit entre 0.33 et 0.96 kcal/mole. La valeur la plus probable serait d'environ 0.8 kcal/mole (7).

I II

Aucune étude de ce genre n'a toutefois été rapportée au sujet du diméthyl-2,2 cyclohexanol (II). La synthèse des *tert*-butyl-4 diméthyl-2,2 cyclohexanols *cis* (III*a*) et *trans* (IV*a*), modèles conformationnellement fixés des triterpènes et des stéroïdes-4,4 diméthylés, a donc été réalisée et l'équilibre conformationel du diméthyl-2,2 cyclohexanol (II) a été examiné.



III IV

a, R = H.
b, R = *p*—NO_2—C_6H_4—COO—.
c, R = *o*—COOH—C_6H_4—COO—.

[1]*Ce travail, extrait du mémoire de maîtrise soumis par Guy Perrault à la Faculté des sciences de l'Université de Montréal, a été présenté en partie lors du 46ème congrès annuel de l'institut de Chimie du Canada, Toronto, Juin 1963.*

RÉSULTATS ET DISCUSSION

Synthèses de la tert-butyl-4 diméthyl-2,2 cyclohexanone (VIII)

Le *tert*-butyl-4 diméthyl-2,2 cyclohexanone (VIII) est préparée suivant les deux séquences de réactions résumées dans le schéma I.

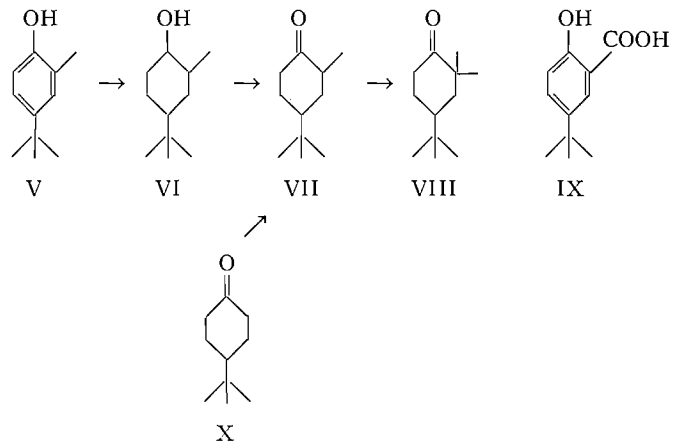

SCHÉMA I

L'hydrogénation du *tert*-butyl-4 méthyl-2 phénol (V) selon le procédé de Adams (8) conduit, après saponification du produit brut, aux divers isomères du *tert*-butyl-4 méthyl-2 cyclohexanol (VI). La stéréochimie des alcools obtenus est établie grâce aux temps de rétention rapportés par Sicher et ses collaborateurs (7), pour chacun des alcools VI. Les pourcentages relatifs de chacun des isomères sont résumés au Tableau I. Il est à noter que la stéréochimie des produits isolés par Sicher *et al.* (9) lors de l'hydrogénation de l'acide *tert*-butyl-4 salicylique (IX) est identique à celle des produits formés en prépondérance dans le présent travail.

TABLEAU I

Stéréochimie de l'hydrogénation catalytique du *tert*-butyl-4 méthyl-2 phénol (V)

Produit	Temps relatif de rétention		% formé
	Sicher	Présent travail	
cis-cis (a,e,e)*	0.630	0.680	62
trans-trans (e,e,e)*	0.775	0.800	30
trans-cis (a,a,e)*	0.833		
cis-trans (e,a,e)*	1.000	1.000	8

*Les substituants ( ) sont dans l'ordre (alcool, méthyle, *tert*-butyle).

L'oxydation du mélange des alcools épimères (VI) selon la technique de Brown et Garg (10) fournit la *tert*-butyl-4 méthyl-2 cyclohexanone (VII) n_D^{25} 1.4580, qui est caractérisée par sa semicarbazone;[3] Darzens et Rost (11) avaient rapporté que cette semicarbazone ne se forme pas. La méthylation de la *tert*-butyl-4 méthyl-2 cyclohexanone (VII) par l'iodure de méthyle en présence d'amidure de sodium selon la méthode de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Haller (12) conduit à la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (VIII),[3] p.é. 61–63° à 1.5 mm Hg et n_D^{25} 1.4558.

Des expériences ayant pour but d'introduire directement deux groupements méthyles sur la molécule de *tert*-butyl-4 cyclohexanone (X) ont été tentées sans succès: la méthylation par un excès d'iodure de méthyle en présence d'amidure de sodium dans l'éther ou le benzène a toujours conduit à des mélanges réactionnels où la *tert*-butyl-4 méthyl-2 cyclohexanone (VII) est présente en prépondérance. La *tert*-butyl-4 diméthyl-2,2 cyclohexanone (VIII) peut toutefois être obtenue en procédant à deux méthylations successives de la *tert*-butyl-4 cyclohexanone (X); la cétone désirée (VIII) est obtenue aux côtés de la *tert*-butyl-4 méthyl-2 cyclohexanone (VII) dans le rapport de 72:28.

Le spectre infrarouge de la cétone *gem*-diméthylée (VIII) montre une bande cétonique à 1 708 cm^{-1} alors que pour la cétone monométhylée (VII) la bande carbonyle apparaît à 1 715 cm^{-1}; Mazur et Sondheimer (13) ont déjà noté un déplacement bathochrome semblable dans les spectres de cétones terpéniques. Dans le spectre de résonance magnétique nucléaire (r.m.n.) des cétones (VII et VIII), le groupe méthyle de la cétone (VII) se présente sous forme de doublet ($J = 4.5$) centré à 0.94 p.p.m. alors que les deux méthyles de la cétone (VIII) apparaissent respectivement à 0.97 et 1.10 p.p.m.

La réduction de la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (VIII) par le sodium et l'éthanol (14) conduit au *tert*-butyl-4 diméthyl-2,2 cyclohexanol *trans* (IV*a*);[3] cet alcool de point de fusion 87–88° est purifié par l'intermédiaire de son *p*-nitrobenzoate (IV*b*) de p.f. 116.5–117.5°. L'alcool *cis* (III*a*)[3] p.f. 87–88° est obtenu par chromatographie sur alumine ou en phase gazeuse préparative du produit de réduction de la cétone selon la méthode de Meerwein-Pondorf-Varley (15); le *p*-nitrobenzoate (III*b*) de cet alcool fond à 112–113°. Il est à noter que les phtalates acides (III*c* et IV*c*) de chacun de ces alcools ont été préparés et que leurs points de fusion sont identiques à 155–156°; un mélange de ces deux phtalates acides fond à 120–125° alors qu'un mélange de deux alcools isomères fond à 65–70°.

La configuration *trans* proposée pour l'alcool obtenu par réduction de la cétone VII à l'aide du sodium et de l'éthanol est basée sur son mode de formation (14), sa rétention plus grande lors de la chromatographie sur alumine (14) et en phase gazeuse, la présence d'une bande à 1 035 cm^{-1} dans son spectre infrarouge (16), le déplacement chimique (−187 c.p.s.) de son hydrogène carbinolique (calculé d'après Eliel (17) −180 c.p.s.), la vitesse relative de saponification de son phtalate acide (4, 18, 19) et sa vitesse relative d'oxydation chromique (4, 19–22). Les propriétés respectives des alcools isomères sont résumées dans le Tableau II.

TABLEAU II

Propriétés des alcools III*a* et IV*a*

Grâce aux vitesses d'oxydation et utilisant l'équation proposée par Sicher (7),

$$\Delta F = RT \ln k_{ax}/k_{eq},$$

pour relier l'énergie libre entre les alcools isomères et leurs vitesses d'oxydation, il est possible d'établir à 0.30 kcal/mole la différence d'énergie libre entre les alcools; l'équilibration directe (2) dont les résultats sont résumés au Tableau III et la r.m.n. (5) nous permettent d'établir cette valeur à 0.28 et 0.26 kcal/mole respectivement. Pour l'ensemble des méthodes employées la différence d'énergie libre entre l'alcool axial (III*a*) et l'alcool équatorial (IV*a*) est donc estimé à 0.28 ± 0.02 kcal/mole.

TABLEAU III

Équilibration des alcools (2)

Produit de départ	% *cis*	% *trans*
Alcool *cis* (III*a*)	38	62
Alcool *trans* (IV*a*)	43	57
Cétone (VIII)	40	60
Moyenne	40	60

L'examen des modèles moléculaires des alcools isomères nous montre que dans l'alcool *trans* (IV*a*), le groupe —OH équatorial est soumis à deux interactions gauches de groupes CH_3 alors que dans l'alcool *cis*, (III*a*), le groupe hydroxyle axial n'est gauche que par rapport à un seul groupement méthyle. La différence de 0.52 kcal/mole qui existe entre la valeur de 0.8 kcal/mole acceptée (7) pour le ΔF entre un OH axial et équatorial dans un cyclohexane simple et la valeur de 0.28 kcal/mole trouvée ici pour la différence d'énergie dans un cyclohexanol *gem*-diméthylé en position α doit donc être assignée à une interaction gauche entre un OH et un CH_3. Cette valeur de 0.52 kcal/mole se rapproche beaucoup des valeurs 0.5 et 0.4 kcal/mole rapportées respectivement par Sicher (7) et Noyce (23) pour l'interaction entre un groupe —OH équatorial et un groupe CH_3 axial.

Considérant que l'alcool équatorial (IV*a*) dans le système décrit ici est moins stable que le *tert*-butyl-4 cyclohexanol *trans* non substitué, les résultats obtenus (voir Tableau IV) lors de la réduction de la cétone (VIII) par les hydrures complexes peuvent difficilement s'accommoder avec la notion de "product development control" (24) et se comprennent facilement lorsqu'il est réalisé que l'un des groupes méthyles (axial en position 2) "cache" la face équatoriale du groupement carbonyle et favorise une attaque du côté le moins empêché de la molécule, à savoir la face axiale du groupement carbonyle. Le même raisonnement expliquerait la surprenante quantité d'alcool *trans* (IV*a*) (voir Tableau IV) formée au cours de l'hydrogénation catalytique de la cétone (VIII).

PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés en tubes capillaires ouverts au moyen d'un thermomètre étalonné avec des substances pures de pointe de fusion connus. Les spectres infrarouges ont été mesurés sur un appareil Perkin–Elmer modèle 21, double faisceau avec prisme de NaCl. Les indices de réfraction ont été déterminés à l'aide d'un réfractomètre Abbé 60. Les analyses par chromatographie en phase gazeuse sont effectuées sur un appareil Kromo-Tog, modèle K-2 de la compagnie Burrel; des colonnes de 2.5 m de polyester de Craig sur Kromat-FB 20% p/p ont été utilisées pour ces analyses. Les spectres r.m.n. ont été mesuré à l'aide d'un appareil Varian A-60 pour des solutions dans CCl_4; la position des bandes (échelles δ) en p.p.m. se réfère au tétraméthylsilane utilisé comme standard interne. Les analyses élémentaires sont de C. Daesslé, Organic Microanalysis, Montréal.

La chromatographie en phase gazeuse préparative a été effectuée sur un appareil Fisher Prep Partitioner utilisant 6 colonnes de 50 cm chacune chargées de 20% de polyester de Craig sur Chromosorb P à 160 °C.

Les 2,4-dinitrophenylhydrazones, semicarbazones, phtalates acides et *p*-nitrobenzoates ont été préparés selon les méthodes usuelles (27).

Les vitesses de saponification sont obtenues par mesure de conductivité dans une cellule de type "Freas" branchée à un pont de comparaison de la compagnie Electro-Measurements Inc, modèle 260. La cellule est immergée durant toute l'expérience dans un bain à température constante maintenue à 50 ± 0.1°.

TABLEAU VI

Vitesse de saponification des phtalates acides III*c* et IV*c* à 50 °C

Phtalate acide		Concentration (mmole/l)	10^5k (l mole^{-1} s^{-1})	
trans (IV*c*)		40.0	27.41	
		36.1	27.00	
		36.1	27.78	
	Moyenne			27.40
cis (III*c*)		36.1	7.88	
		40.0	7.40	
	Moyenne			7.64

Les mesures sont effectuées sur des solutions aqueuses équimoléculaires en soude et en sel sodé du phtalate acide à saponifier et les constantes de vitesse sont calculées d'après la méthode du temps infini (28) et les résultats sont résumés dans le Tableau VI.

REMERCIEMENTS

Les auteurs remercient vivement le Conseil National de Recherches du Canada pour l'aide financiaire apportée sous forme d'octroi de recherches (A-1295) et de bourse d'étude; la compagnie Dow Chemicals of Canada, Ltd., pour un généreux échantillon de *tert*-butyl-4 cyclohexanone et la compagnie Pitt-Consol Chemical Company, Library, Pa., pour un généreux échantillon de *tert*-butyl-4 méthyl-2 phénol.

THE OXYMERCURATION OF 4-METHYLENECYCLOHEXANEMETHANOL

N. L. WEINBERG AND GEORGE F WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ontario
Received August 24, 1964

ABSTRACT

The oxymercuration of 4-methylenecyclohexanemethanol in *tert*-butyl alcohol yields 1-chloromercurimethylnorcineole which may be converted to 1-methylnorcineole by borohydride reduction or to 4-chloromercurimethyl-4-↑-hydroxycyclohexane-↓-carboxylic acid. This may be deoxymercurated to 4-methylenecyclohexanecarboxylic acid and reduced with borohydride to 4-↓-methyl-4-↑-hydroxycyclohexane-↓-carboxylic acid.

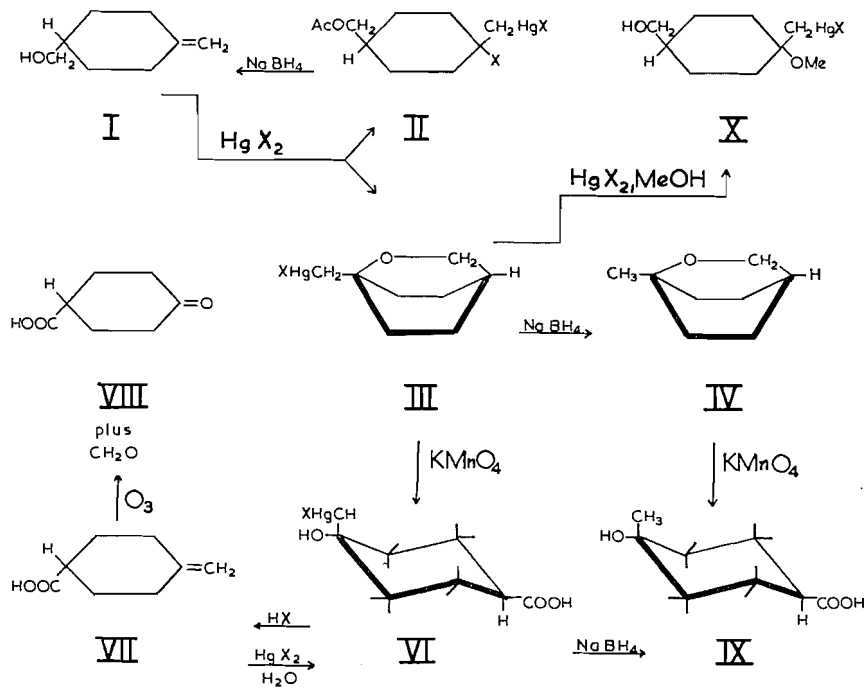
The oxymercuration of alkenols has been accomplished before. Sand and Singer (1, 2), as well as others (3), found that the hydroxyl group in 2,6-dimethylheptene-5-ol and in α-terpineol (1, 2, 4) is involved in the reaction with the consequences that cyclic ethers are formed. The same type of reaction has now been carried out with 4-methylenecyclohexanemethanol to ascertain the effect of a terminal double bond in this reaction.

When mercuric acetate in an excess of 4-methylenecyclohexanemethanol, I, is stirred for 3 days according to the method used for preparation of chloromercuricineole (4), the results are unpleasant. An unworkable gum is formed which is probably a mixture of the geoisomers of 4-acetoxymercurimethyl-4-acetoxycyclohexanemethanol, II. However, the expected product, chloromercurimethylnorcineole (III, 4-chloromercurimethyl [2,2,2,]-bicyclo-8-oxaoctane) can be obtained in 33% yield with difficulty. Dilution of the reaction system with 2,5-dioxahexane does not improve the situation, but the yield of III is doubled when *tert*-butyl alcohol is used to dilute the reaction system.

The reduction of the gum by use of sodium borohydride leads only to 4-methylenecyclohexanemethanol but reduction of III to 1-methylnorcineole, IV, occurs smoothly. The correspondence of the infrared spectrum of IV with that of 1,8-cineole which it resembles in odor leaves little doubt about its [2,2,2] bicyclic structure but it does not designate the position of the chloromercuri group in III.

This group might be linked to C-2 or C-9, depending on whether the double bond does or does not shift during oxymercuration. Two pieces of evidence show that chloromercuri is on C-9. First the substance III is recovered configurationally unchanged when it is subjected to reaction with hydrazine hydrate under conditions (5) to promote epimerization, which would be possible only at C-2. Secondly it undergoes permanganate oxidation, not to give a norcineolic acid V comparable with the cineolic acid from 2-chloromercuricineole, but instead 4-chloromercurimethyl-4-hydroxyhexanecarboxylic acid, VI. This acid can be deoxymercurated to 4-methylenecyclohexanecarboxylic acid VII and the latter may be re-oxymercurated to VI. Since VII has been characterized by ozonization to formaldehyde and the known 4-ketocyclohexanecarboxylic acid, VIII (6), it seems to be highly probable that oxymercuration of I leads to the primary chloromercurial.

Evidently the alkaline permanganate oxidation of III is accompanied by prototropic rearrangement of the carboxyl group in the product VI, probably during saponification of the lactone that is formed initially. This rearrangement is revealed when VI undergoes reduction with sodium borohydride reduction. The reduction product seems to be 4-↑-hydroxy-4-↓-methylcyclohexane-↓-carboxylic acid, IX, which is also the product when



1-methylnorcineole, IV, is oxidized by means of potassium permanganate. This acid corresponds with that defined by Vila and Coll (7) as the *cis*-geoisomer. Like their acid of slightly lower melting point ours will not form a lactone (6, 8) but, instead, is dehydrated to 4-methyl-Δ^3-cyclohexanecarboxylic acid.

Besides the chemical evidence for the structure of III there is confirmation from the proton magnetic resonance spectrum. The simple spectrum of Fig. 1 shows clearly that band 3 is due to the methylene group attached to the 4-chloromercuri group because the spin interaction with ^{199}Hg gives rise to the side bands 2 and 6 spaced equally at 1.5 p.p.m. The chemical shift of the methylene portions represented by band 3 is somewhat greater (5.1 p.p.m. relative to benzene) than the values of 4.3 and 4.5 p.p.m. quoted by Cotton and Leto (9) for the chloromercurimethyl group in β-hydroxyethylmercuric acetate and the analogous anhydride respectively; this upfield shift must be attributed to the greater electrofelicity of the chlorine substituent. The 3.4 p.p.m. shift for oxymethylene (band I) and 5.3 p.p.m. for ring methylene are within the ranges 3.4–3.9 and 5.3–5.8 quoted by Chamberlain (10) for bicylic systems, while the 5.5 p.p.m. shift upfield from benzene for tertiary hydrogen is higher, probably in consequence of the cyclic distortion, than that specified (11) for this linkage in isobutane and 2,3-dimethylbutane.

It is of interest that treatment of the acetate analogue of III (X = OAc) with mercuric acetate in methanol leads to a single geoisomer of the methoxy derivative VIII rather than the expected mixture of two isomers.

EXPERIMENTAL

Physical Constants

Melting points have been corrected against reliable standards. The infrared spectra have been determined by use of a Beckman IR-4 spectrometer using polyethylene wax wafers (12 000 p.s.i.) and in carbon tetrachloride in the 900 – 3 000 cm^{-1} region and absorptions are recorded in cm^{-1} at extinctions (E) calculated from peak heights. Nuclear magnetic resonance (n.m.r.) spectra in carbon tetrachloride were determined by use of a Varian HR-60 spectrometer with the aid and advice of Professor S.S. Danyluk.

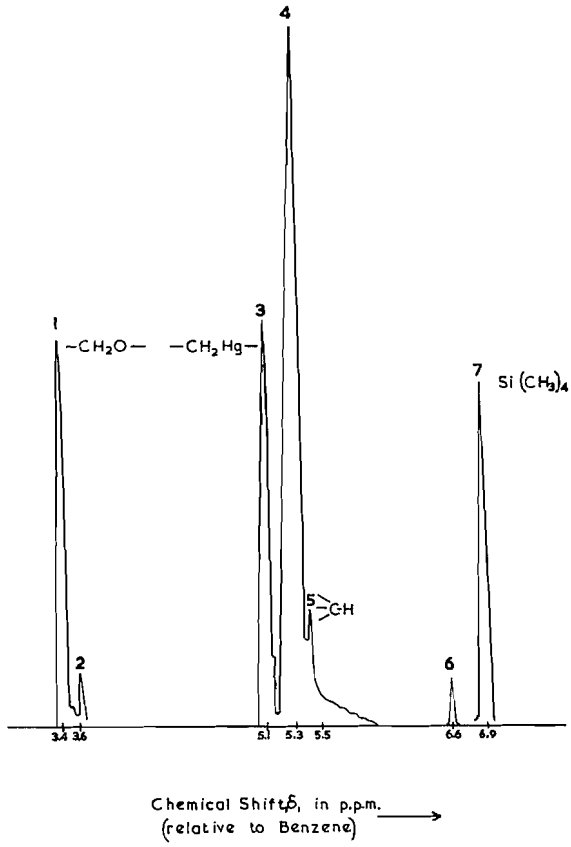

FIG. 1.

Reagents

Tertiary butyl alcohol was twice distilled from sodium wire under nitrogen (40), b.p. 82.8° at 760 mm, m.p. 25.5°. Glycol ether was distilled, after a positive benzophenone test under nitrogen, b.p. 85.5°, n_D^{20} 1.3792. Reagent grade B.D.H. mercuric acetate was recrystallized from glacial acetic acid, washed with 95% ethanol on a suction funnel, and dried at room temperature at 15 mm for 48 h. The alkene, 4-methylenecyclohexanemethanol, I, courtesy of Tennessee Eastman Company, was distilled at 40–41 °C at 0.001 mm. A heart-cut was taken, m.p. 19.5–18.5°, n_D^{20} 1.48275.

1-Chloromercurimethylnorcineole, III

(a) Use of Excess 4-Methylenecyclohexanemethanol I

Following the method of Brook and Wright (4) for the preparation of α-2-chloromercuricineole, a suspension of 82 g (0.65 mole) of 4-methylenecyclohexanemethanol I and 21 g (0.065 mole) of mercuric acetate was shaken at room temperature for 3 days. The system on filtration yielded 0.08 g of mercurous salt. Distillation of the filtrate at 0.001 mm, 28–40°, yielded 66 g (about 0.5 mole) of excess 4-methylenecyclohexanemethanol contaminated with acetic acid. The residue was suspended in 200 ml of petroleum ether (60–70°) in a separatory funnel and, on shaking, a gummy layer separated and was removed. The petroleum ether layer was then extracted with 1 × 200 and 3 × 50 ml portions of 10% aqueous sodium hydroxide, followed by 3 × 50 ml water. To the combined filtered aqueous extracts was added 12.0 g (0.2 mole) of sodium chloride, and carbon dioxide was bubbled into this solution for 12 h at 4°. Filtration by suction gave 9 g (0.25 mole), 38%, of chloromercurimethylnorcineole III, m.p. 95–97°. After three crystallizations from 95° ethanol (6 ml/g) followed by treatment with Darco, a white solid melting at 101.1–102 °C was obtained.

Anal. Calcd. for $C_8H_{13}ClHgO$: C, 26.6; H, 3.63, Found: C, 26.7; H, 3.82.

The infrared spectrum (10% in P.E. wax) is (306) 15.3, (316) 15.9, (394) 9.28, (419) 8.94, (512) 9.37, (531) 9.19, (578) 9.18, (623) 9.33, (749) 10.3, (783) 9.22, (813) 9.48.

The gum produced in this reaction seems to be a mixture. Treatment of its ether solution with an excess of mercuric chloride or with aqueous sodium chloride failed to produce a crystalline product. When 50 g was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

added to 50 ml of concentrated hydrochloric acid this system underwent complete solution within 2 min. After 15 min the system was neutralized by means of 40% aqueous sodium hydroxide and the mercuric oxide was filtered off into a celite bed in a tared Buchner funnel, water washed, and air dried, weight 32 g, 0.148 mole.

The filtrate from the removal of mercuric oxide was steam distilled and the distillate was extracted 4 times with 50 ml portions of chloroform. The combined extract, dried over magnesium sulfate was distilled, finally at 8 mm, to yield 190 g (0.151 mole) b.p. 90–91°. The infrared spectrum showed that this distillate was 4-methylenecyclohexanemethanol, I, in high purity. The same compound was obtained when II was treated with sodium borohydride.

The use of 500 ml of 2,5-dioxahexane as a diluent did not diminish the formation of gum, and 11 g of mercurous salt was formed during the otherwise comparable reaction.

(b) Use of tert-Butyl Alcohol as Reaction Medium

To 19.1 g (0.06 mole) of mercuric acetate in 400 ml (4.4 mole) of tertiary butyl alcohol was added 7.7 g (0.061 mole) of 4-methylenecyclohexanemethanol, I. After stirring for 48 h at room temperature, the milky suspension was filtered giving 1.0 g of mercurous salt. The filtrate was added to 200 ml of 3% (0.1 mole) aqueous sodium chloride solution. After evaporation of the *tert*-butyl alcohol at 30–35° and 20 mm, the mercurial was filtered off by suction and dried at 40° and 15 mm, for 24 h to yield 14.4 g (0.04 mole, 67%) of chloromercurimethylnorcineole III, m.p. 98–99.5°. Two crystallizations from 95% ethanol raised the m.p. to 101–102°. A mixture melting point with a sample from part (*a*) was not depressed.

The mercurial III was deoxymercurated by treatment of 3.69 g (0.01 mole) with 25 ml of 10% hydrochloric acid. When solution was complete after 5 min the system was extracted with three 25 ml portions of petroleum ether (b.p. 60–70°). The combined extract, washed with 30 ml of water, was dried over magnesium sulfate. Evaporation of the solvent left 1.2 g (96%) which was converted to the dinitrobenzoate, m.p. 97–98°, identified by mixture melting point with an authentic sample (12).

When the mercurial III in alkaline solution was heated with an excess of 100% hydrazine hydrate an oil was formed. This oil is evidently a 40% yield of the bis-mercurial because it may be converted quantitatively to III, m.p. 98.5–99°, by treatment with an equivalent of mercuric acetate in diethyl ether and then with aqueous sodium chloride.

4-↓-Chloromercurimethyl-4↑-hydroxycyclohexane-↓-carboxylic Acid, VI

A solution of 7.6 g (0.02 mole) of chloromercurimethylnorcineole, III, in 30 ml of 10% aqueous sodium hydroxide was added to 3.2 g (0.02 mole) of potassium permanganate in 200 ml of water. After 1 day at 20–25° the excess permanganate was destroyed by addition of 5 ml of ethanol. After 1 h the system was filtered. The filtrate was vacuum evaporated to a volume of 140 ml, then treated with 1 g (0.02 mole) of sodium chloride. This solution cooled to 0° was slowly acidified by means of 1.8% hydrochloric acid until precipitation was complete. The product, filtered, water washed, and dried at 35° (15 mm), weighed 3.0 g (38%) m.p. 145° (decomp.) when the sample was inserted at 130°.

Anal. Calcd. for $C_8H_{13}ClHgO_3$: C, 24.4; H, 3.33. Found: C, 24.7; H, 3.59.

The infrared spectrum of a sample 10% in polyethylene wax is 311 (1.6), 390 (2.9), 413 (2.9), 432 (2.0), 498 (1.8), 521 (5.2), 594 (1.6), 628 (0.2), 645 (1.5), 756 (3.4), 181 (1.9), 844 (3.2).

This acid may be obtained also by treatment of 0.5 g (0.0036 mole) of 4-methylenecyclohexanecarboxylic acid, VII, with 1.29 g (0.0036 mole) of mercuric acetate in 50 ml of water for 12 h at 20–25°. Then the milky suspension was treated with 2 ml of saturated aqueous sodium chloride. The product was filtered and crystallized from 50 ml of 1:1 methanol–acetone, 0.8 g, (56%) m.p. 141–143°. The mixture melting point with the oxidation product was not lowered and the infrared spectrum was identical.

4-Methylenecyclohexanecarboxylic Acid, VII

A quantity of 7.86 g (0.02 mole) of 4-chloromercurimethyl-4-hydroxycyclohexanecarboxylic acid was dissolved in 20 ml of 6% hydrochloric acid and then was extracted 5 times with 50 ml portions of chloroform. The combined extract, washed twice with 50 ml portion of water was dried with magnesium sulfate and vacuum evaporated to leave 2.69 g (93%) of vile-smelling 4-methylenecarboxylic acid, VII, m.p. 56°. Crystallization from 16 ml of 1:7 ethanol–water raised this m.p. to 57.5–58°; Neutralization equivalent: calcd. 140; found, 141.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.6; H, 8.63. Found: C, 68.4; H, 8.65.

The infrared spectrum, 4% in carbon tetrachloride is 890 (41.4), 905 (10.6), 930 (broad, 9.85), 995 (1.24), 1 085 (3.88), 1 180 (9.76), 1 230 (30.2), 1 305 (214), 1 410 (21.1), 1 440 (16.1), 1 635 (11.3), 1 700 (74.8), 1 740 (6.59), 2 650 (broad, 15.1), 2 950 (broad, 46.0).

4-Ketocyclohexanecarboxylic Acid, VIII

Into 20 ml of sodium-dried *tert*-butyl alcohol was dissolved (0.231 g, 0.00165 mole) of 4-methylenecyclohexanecarboxylic acid XIII. Ozone (9%) was passed into this solution for 60 min at room temperature and then the ozonide was reduced with solid sodium borohydride (added pinchwise until no more oxidizing materials were present). The solution was then steam distilled into 20 ml of 95% ethanol containing 0.5 g (0.0036 mole) of dimethyldihydroresorcinol. After standing for 2 h the organic solvents were evaporated off,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

leaving a solid which was filtered by suction, washed with a little methanol, and dried; weight of solid 0.11 g (0.0038 mole, 23% yield), m.p. 190°. A mixed melting point with an authentic sample of formaldehyde–dimedone was not lowered.

The steam distillation residue was examined for the other product of the ozonolysis, 4-ketocyclohexanecarboxylic acid, VIII. The solution was acidified to pH 2 and extracted with 8 × 25 ml diethyl ether. These combined ether extracts were then washed with 2 × 10 ml water and dried over magnesium sulfate. On filtration and subsequent evaporation of the ether, an oil was obtained as residue. An oxime was prepared from it and crystallized from benzene, weight 20 mg (0.00013 mole, 8% yield), m.p. 146–147° (6).

1-Methylnorcineole

A solution of 10.8 g (0.030 mole) of chloromercurimethylnorcineole, III, in 20 ml of 10% aqueous sodium hydroxide was stirred at room temperature. A second solution consisting of 0.3 g (0.006 mole) of sodium borohydride in 50 ml of 10% aqueous sodium hydroxide was added dropwise over 30 min. After 1 h, the aqueous supernatant liquid was extracted with 5 × 25 ml of diethyl ether, and the combined ether extracts washed with 3 × 10 ml water and then dried over calcium chloride for 12 h. Filtration with subsequent evaporation of the diethyl ether at 20° (15 mm) left 3.0 g (0.024 mole, 80%) of a colorless oil having an odor similar to 1,8-cineole but more penetrating. The oil was distilled at 31° (8 mm) or 155° (750 mm); n_D^{20} 1.42685; d_4^{26} 0.962.

Anal. Calcd. for $C_8H_{14}O$: C, 76.2; H, 11.2. Found C, 76.0; H, 11.3.

The infrared spectrum of this 1-methyl-1,8-norcineole is shown in Table I in comparison with the spectrum

TABLE I

of 1,8-cineole, both 0.128 *M* in carbon tetrachloride. The parenthetical values are extinction coefficients for the indicated wave numbers.

4-↓-Methyl-4↑-hydroxycyclohexane-↓-carboxylic Acid, IX

(a) From 1-Methylnorcineole, IV

To a solution of 2.5 g (0.016 mole) of potassium permanganate in 150 ml of water was added 0.5 g (0.004 mole) of methylnorcineole, IV. After 1 day at 20–25° the system was treated with 2 ml of ethanol. When the pink color had disappeared the mixture was filtered. The filtrate, concentrated to a volume of 50 ml by evaporation, was chilled to 0° and acidified by means of 16% hydrochloric acid. The precipitated acid weighed 0.4 g (63%), m.p. 156–156.5°. Crystallization from hot water raised this m.p. to 156.2–156.5°.

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.7; H, 8.92. Found: C, 60.6; H, 8.95.

When this acid was heated at 90° for 30 min (8) the lactone, m.p. 60–70°, was not formed. Instead 4-methyl-Δ^3-cyclohexenecarboxylic acid, m.p. 99–100°, was obtained by chloroform extraction. It formed a dibromide, m.p. 104°.

(b) From 4-Chloromercurimethyl-4-hydroxycyclohexanecarboxylic Acid, VI

A solution of 0.8 g (0.002 mole) of VI in 10 ml of 1% aqueous sodium hydroxide was heated with 0.10 g (0.0026 mole) of solid sodium borohydride during 15 min. One hour later 0.35 g (0.0018 atom) of metallic mercury was filtered off. The filtrate was evaporated to a volume of 3 ml and then was acidified by use of 5% aqueous sulfuric acid. With cooling to 0°, the crude acid 0.3 g (94%), m.p. 149–155°, was crystallized from water for mixture melting point (not depressed) with IX from the oxidation procedure.

4-Chloromercurimethyl-4-methoxycyclohexanemethanol, X

To a solution of 4.45 g (0.012 mole) of chloromercurimethylnorcineole, III, in 100 ml of pure, dry, oxygen-free methanol was added 2.0 g (0.012 mole) of silver acetate. After stirring for 0.5 h under nitrogen, the silver chloride was filtered off and 2 ml of glacial acetic acid was added along with 3.8 g (0.0012 mole) of mercuric acetate. The solution was shaken for 95 h at room temperature, but still tested positive for mercuric salt with 10% sodium hydroxide solution. Then the solution was basified with 10% aqueous sodium hydroxide and filtered by suction, using Celite, to remove mercuric oxide. On addition of 5 ml of saturated aqueous sodium chloride solution, carbon dioxide was bubbled into the system. After 1 h, 2.3 g of fluffy white solid was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

filtered off, m.p. 156–158°. The solid was recrystallized from 50 ml of 50% aqueous ethanol and dried over KOH pellets for 24 h at 65°(10 mm), m.p. 157–158°.

This methoxymercurial was soluble but stable in 10% aqueous sodium hydriodide. It was recovered almost completely after 0.30 g was dissolved in 10 ml acetic anhydride although 12 mg of mercurous chloride precipitated during the process.

Anal. Calcd. for $C_9H_{17}ClHgO_2$: C, 27.3; H, 4.36. Found: C, 27.3; 4.45.

The infrared spectrum, 3% in potassium bromide, was 2 925 (220), 2 850 (200), 2 925 (220), 2 850 (200), 1 625 (58.2), 1 450 (77.5), 1 430 (86.4), 1 320 (87.6), 1 265 (76.0), 1 220 (46.8), 1 200 (49.3), 1 170 (77.5), 1 145 (71.8), 1 135 (71.8), 1 097 (80.4), 1 060 (284), 1 045 (250), 997 (48.0), 970 (86.4), 950 (104), 925 (83.3), 877 (134), 798 (29.2), 755 (63.5), 705 (64.8).

The formation of this single methoxymercurial from acetoxymercurimethylnorcineole is in contrast to the pair of methoxymercurials obtained from I and mercuric acetate in methanol. One of the pair melted at 157–158 and the other at 118–119°, after separation by crystallization from methanol.

Received September 18, 1964

ABSTRACT

A group of polysaccharides, called galactomannans I, were precipitated as their insoluble copper complexes from aqueous solutions of the crude polysaccharides obtained from each of the organisms designated in the title. The five galactomannans I were homogeneous under conditions of electrophoresis and ultracentrifugation and had high positive specific rotations. The major constituent monosaccharide was D-mannose; amounts of D-galactose ranged from nil for the polysaccharide from *T. rubrum* to 13% for that from *T. schönleinii*. Methylation and hydrolysis of the five galactomannans I yielded varying amounts of the following: 2,3,5,6-tetra-*O*-methyl-D-galactose (not present in the products from *T. rubrum*), 2,3,4,6-tetra-*O*-methyl-D-mannose, 2,3,4-tri-*O*-methyl-D-mannose, 2,4,6-tri-*O*-methyl-D-mannose, 3,4-di-*O*-methyl-D-mannose, and 3,5-di-*O*-methyl-D-mannose. Periodate oxidation results agreed with the methylation studies. The gross structural features of each galactomannan I appear to be the same, namely, a basic chain of $1 \rightarrow 6$ linked α-D-mannopyranose units for approximately every 22 of which there is a $1 \rightarrow 3$ linked α-D-mannopyranose residue. Branch points occur along the $1 \rightarrow 6$ linked chain at the C_2 positions of the D-mannopyranose units and once in every 45 units at the C_2 position of a $1 \rightarrow 6$ linked D-mannofuranose residue. The D-galactose in the polysaccharides is present exclusively as non-reducing terminal furanose units; non-reducing terminal units of D-mannopyranose are also present. The variations in the identities and relative amounts of the non-reducing terminal units were the only apparent differences in the gross structural features within this group of polysaccharides.

The objective of this continuing program on polysaccharides of dermatophytes is to relate polysaccharide structure to species differences and immunological properties. As reported previously (1), preliminary examination of five dermatophytes showed that each had a similar pattern of water-soluble polysaccharides, specifically, two galactomannans and a glucan. At present the investigations will be limited to comparisons of gross structural features of the polysaccharides in each of the above three groups as revealed by methylation and periodate oxidation studies. The results of immunochemical tests may necessitate more detailed studies of fine structure at a later stage.

The present paper describes the isolation and gross structural features of one group of galactomannans (called galactomannan I) from *Trichophyton granulosum* Sabouraud, 1909, *Trichophyton interdigitale* Priestley, 1917, *Microsporum quinckeanum* (Zopf) Guiart and Grigorakis, 1928, *Trichophyton rubrum* (Castellani) Sabouraud, 1911, and *Trichophyton schönleinii* (Lebert) Langeron and Milochevitch, 1930.

Crude polysaccharides were extracted from powdered cells of the organisms in yields of 5–10% as described previously for *T. granulosum* (2). The products were tan-colored

[1]*Issued as N.R.C. No. 8201.*

powders which contained significant amounts of ash and nitrogen, yielded mannose, glucose, and galactose on hydrolysis, and showed at least three migrating components on moving-boundary electrophoresis in borate buffer. Fehling solution, added to aqueous solutions of the crude polysaccharides from each organism, precipitated the first group of polysaccharides as insoluble copper complexes (3). Recovery of the polysaccharides from their insoluble copper complexes yielded ash-free, nitrogen-free products, each of which showed a single, sharp, symmetrical peak under conditions of electrophoresis and ultracentrifugation. Table I shows some of the properties of this group of polysaccharides,

TABLE I

Properties of galactomannans I from dermatophytes

Organism	$[\alpha]_D$ (in water)	Hydrolysis products, %		$\mu \times 10^{-5}$ ($cm^2\ V^{-1}\ s^{-1}$)
		D-Galactose	D-Mannose	
T. granulosum	+78°	7.5	92.5	8.4
T. interdigitale	+80°	12.0	88.0	8.4
M. quinckeanum	+78°	4.5	95.5	8.4
T. rubrum	+80°	0.	100.	8.4
T. schönleinii	+64°	13.0	87.0	8.4

called galactomannans I. The specific rotations were high and positive and the only one which differed significantly from the others was that of the galactomannan I from *T. schönleinii*. Because the constituent sugars were identified as the D-enantiomorphs, the high, positive specific rotations indicated that the majority of glycosidic linkages in the galactomannans I were in the α-configuration. The major constituent monosaccharide was D-mannose and the amount of D-galactose in the polysaccharides ranged from 13% for the one from *T. schönleinii* to 0 for that from *T. rubrum*. This latter polysaccharide must therefore be classified as a mannan; for comparative purposes and because of its obvious association with the other polysaccharides in this group, it is included in the galactomannans I. The polysaccharides in Table I were indistinguishable by electrophoresis, having identical mobilities in borate buffer.

The galactomannans I were methylated fully and then hydrolyzed to yield mixtures of D-mannose and D-galactose methyl ethers. These mixtures were analyzed by a combination of gas–liquid, paper, and thin-layer chromatography. The gas–liquid chromatogram of one typical mixture is shown in Fig. 1. The two components in peak 1 were resolvable on another liquid phase and also by paper chromatography. Some 3,5-di-*O*-methyl-D-mannose was also present in the hydrolysis products but in amounts too small to be shown in Fig. 1. The relative amounts of *O*-methyl sugars in the mixtures were determined by integration of the peaks on the gas–liquid chromatograms and these results were checked by preparative paper chromatography. The amount of 3,5-di-*O*-methyl-D-mannose was determined, as a percentage of the di-*O*-methyl fraction, by the quantities isolated from thin-layer chromatograms. The quantitative results for each of the galactomannans I are given in Table II; each of the *O*-methyl sugars was characterized by isolation of a crystalline derivative. The molar ratios are based on a degree of polymerization of 45 which was the value found for the methylated galactomannans I by osmometry.

From these results it is clear that the polysaccharides in this group contain the same structural units with some variations in the relative amounts of such units. Thus, branch points occur in each polysaccharide at the C_2 and C_6 positions of D-mannopyranose and to a lesser extent of D-mannofuranose units, giving rise to the 3,4- and 3,5-di-*O*-methyl-D

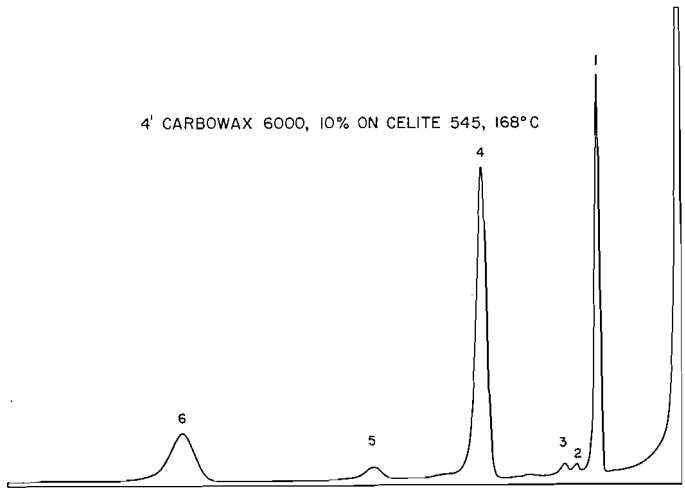

FIG. 1. Gas–liquid chromatograph of methyl glycosides of hydrolysis products from methylated galactomannan I of *T. interdigitale*. (1) Methyl 2,3,4,6-tetra-*O*-methyl-α-D-mannoside and methyl 2,3,5,6-tetra-*O*-methyl-α-D-galactoside, (2) methyl 2,3,5,6-tetra-*O*-methyl-β-D-galactoside, (3) methyl 2,3,4,6-tetra-*O*-methyl-β-D-mannoside, (4) methyl 2,3,4-tri-*O*-methyl-α-D-mannoside (shoulder following peak 4 is methyl 2,4,6-tri-*O*-methyl-α-D-mannoside), (5) methyl 2,3,4-tri-*O*-methyl-β-D-mannoside, (6) methyl 3,4-di-*O*-methyl-α-D-mannoside.

mannoses respectively. The unbranched portions of the galactomannans I are formed predominantly by 1 → 6 linked D-mannopyranose units yielding 2,3,4-tri-*O*-methyl-D-mannose in the methylation study. For every 20–22 of such linkages there is one D-mannopyranose unit which participates in a 1 → 3 linkage as shown by the presence of 2,4,6-tri-*O*-methyl-D-mannose. Some of the non-reducing terminal units are D-mannopyranose giving 2,3,4,6-tetra-*O*-methyl-D-mannose; others are formed by D-galactofuranose residues which give 2,3,5,6-tetra-*O*-methyl-D-galactose. The latter was the only derivative of D-galactose found in the products from methylation and showed that this sugar was present in the polysaccharides exclusively as non-reducing, terminal furanose residues. This conclusion was supported by an earlier, more detailed investigation (4) of one of these galactomannans I where it was shown that all of the D-galactose could be removed by mild acid hydrolysis leaving an undegraded mannan. The amount of 2,3,5,6-tetra-*O*-methyl-D-galactose in the products from two of the galactomannans I, those from *T. granulosum* and *M. quinckeanum*, did not account for all of the D-galactose present in the polysaccharide (cf. Table I). These losses could not have occurred by evaporation of this volatile product after hydrolysis of the methylated polysaccharide because the amount of end-group corresponded to the branch points as required by theory. The D-galactofuranose units must therefore have been lost during the methylation, possibly by oxidative degradation or hydrolysis under alkaline conditions. Similar loss of D-galactofuranose units during methylation has been reported in the investigation of a galactomannan-peptide fraction from *T. mentagrophytes* (5).

The methylation results showed that each of the five polysaccharides in this group contained the structural units I–VI and were very similar indeed. The range of numbers given for each unit indicates the maximum variation in the amounts of that unit within the group of polysaccharides; it does not represent the limits of error in its estimation. Table III shows the results of periodate oxidation of the galactomannans I and the values calculated from structural units I–VI for each polysaccharide. The agreement was good and the results therefore supported the conclusions based on the methylation studies.

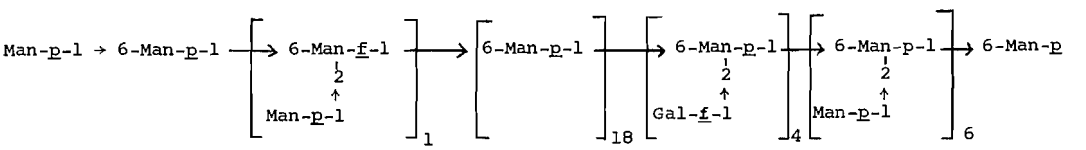

FIG. 2. General structure for galactomannans I.

The simplest general structure that can be proposed for this group of polysaccharides is shown in Fig. 2. This visualizes a basic chain of $1 \rightarrow 6$ linked α-D-mannopyranose units, with approximately one α-D-mannofuranose unit in every 45 residues. Single unit side chains of D-mannopyranose and D-galactofuranose are attached at intervals along the basic chain through the C_2 position of the D-mannose units. The structure in Fig. 2 is based on a polysaccharide of 45 units because that was the degree of polymerization found for the methylated galactomannans I by osmometry. The differences between the individual polysaccharides in this group then arise in the identity and number of non-reducing terminal units which form or terminate the side chains. The present evidence does not permit any conclusions about the length or distribution of side chains but variations in this aspect of the structure cannot be great because infrared spectra of each of the polysaccharides were superimposable.

It is tempting to speculate that polysaccharides with such similar structural features would display the same serological characteristics. However, it has been shown (6, 7) that the nature of non-reducing terminal units, and the structural units adjacent to them, are important factors in determining the specificity of a polysaccharide in serological reactions. The variations in non-reducing terminal units found in the galactomannans I may therefore be sufficient to confer serological specificity. Immunochemical tests presently

For personal use only.

being done in the laboratory of one of the authors (F.B.) should provide definitive evidence on this point. Although it is possible that the structural variations found in this group of polysaccharides were caused by partial degradation to different extents during isolation, this is considered unlikely because exactly the same conditions were used throughout. Fuke (8) reported that polysaccharides from six pathogenic fungi (only one of which, *T. interdigitale*, is included in the present study) gave cross-serological reactions and were therefore not specific for the organism. However, the crude polysaccharide preparations used in that work were not tested for homogeneity and cross reactions of non-specific components could have interfered with the tests. Barker and co-workers (5) have studied the structure of a galactomannan-peptide allergen from *T. mentagrophytes* and have attributed the "immediate" and "delayed" hypersensitivity responses elicited by the molecule to the carbohydrate and protein moieties respectively. The carbohydrate portion was shown to contain D-galactofuranose non-reducing terminal units as in the galactomannans I described in the present paper. However, the D-mannose units in the glycopeptide from *T. mentagrophytes* were joined predominantly by $1 \rightarrow 2$ and $1 \rightarrow 4$ linkages while those in the galactomannans I were linked predominantly $1 \rightarrow 6$ with $1 \rightarrow 2$ glycosidic bonds occurring only at branch points. Since the aim of the present work is to relate structure to serological properties in the *polysaccharides* from dermatophytes the products were freed of protein which would undoubtedly interfere in the serological tests.

Gross structures of the two other groups of polysaccharides, the glucans and the galactomannans II, will be described in subsequent papers; a study of one of the glucans has already been published (1). The galactomannan from *T. granulosum* that was described earlier (2) is now known to have been a mixture. The criteria of homogeneity used in that work were (*a*) a single fraction by chromatography on diethylaminoethyl cellulose (9) and (*b*) a single peak on moving boundary electrophoresis (10). Since that time it has been found that the galactomannans I and II from a single organism are not separable by method (*a*) but can be resolved by precipitation of galactomannan I as its insoluble copper complex. The two galactomannans thus separated had very similar electrophoretic mobilities, 8.4×10^{-5} and 8.1×10^{-5}, requiring prolonged electrophoresis to see even a partial separation.

The structural relation between the polysaccharides described here and those isolated from other sources have been adequately discussed in other papers (2, 4, 5).

EXPERIMENTAL

Paper chromatograms were run by the descending method using the following solvent systems (v/v):
(*a*) pyridine : ethyl acetate : water—1:2.5:2.5 (upper phase).
(*b*) butanone saturated with water.
(*c*) butan-1-ol : ethanol : water—3:1:1.

R_g values represent movement relative to 2,3,4,6-tetra-*O*-methyl-D-glucose. Whatman 3MM paper was used for paper electrophoreses (11) in 0.1 *M* sodium tetraborate at 750 V (potential gradient, 25 V/cm) and 25–40 mA for 1.5 h; M_g values represent movement relative to glucose. A Tiselius-type, Spinco model H apparatus was used for moving boundary electrophoresis in 0.05 *M* borate buffer (10). A Pye Argon Chromatograph and an F and M Model 500 chromatograph were used for gas–liquid chromatography (12); the column packings were (A) 10% carbowax 6 000 on Chromosorb W, 100–120 mesh, 150 °C, (B) 15% polyphenyl ether on Gas Chrom A, 100–120 mesh, 150 °C. Thin-layer chromatograms were on silica gel G using benzene : acetone—1:1 as developing solvent (13). Preparative thin-layer chromatography was done on 0.6 mm layers of silica gel G on 20 × 20 cm glass plates. Zones on the preparative thin-layer chromatograms were detected by a transfer technique: guide strips of thoroughly wet Whatman No. 1 paper were pressed onto the plate which had been sprayed with methanol. The strips were then removed, air dried, and sprayed to provide a template of the chromatogram. The separate zones were then marked, scraped from the plate, and the products were recovered by elution with methanol. Sugars on paper chromatograms, electrophoretograms, and thin-layer templates were detected by the *p*-anisidine hydrochloride spray

For personal use only.

reagent (14). Solvents were evaporated at 35–40 °C under diminished pressure; melting points are corrected; specific rotations are equilibrium values unless otherwise specified.

Isolation of Crude Polysaccharides

T. granulosum was grown in a liquid medium containing 4% maltose (2); *T. interdigitale, M. quinckeanum, T. Rubrum,* and *T. Schönleinii* were grown on a solid medium consisting of 4% cerelose (glucose), 1% neopeptone "Difco", 0.05% yeast extract "Difco", 0.001% thiamine, 0.005% inositol, and 1.5% agar made up in tap water. The polysaccharides were extracted from the dried mycelia as described previously for *T. granulosum* (2). The polysaccharide preparations were light brown powders containing 0.5–0.7% of nitrogen and 5–8% of ash. Yields based on the weight of dried mycelium ranged from 4.7% for *M. quinckeanum* to 10% for *T. granulosum* and the total amounts of crude polysaccharides obtained were between 80 and 100 g. Hydrolysis of samples (5 mg) of each preparation by *N* sulfuric acid (1.5 ml) at 97 °C in a sealed tube for 12 h yielded glucose, galactose, and mannose as shown by paper chromatography of the hydrolysate in solvent A.

Isolation of Galactomannans I

The crude polysaccharides from each organism were fractionated by addition of Fehling solution according to the following typical experiment. Crude polysaccharide (60 g) was suspended in water (250 ml); to the stirred mixture was added Fehling solution B (600 ml) in which the polysaccharides dissolved completely. Addition of Fehling solution A (600 ml) caused formation of a blue, curdy precipitate and the mixture was stirred for a further 1/2 h. The precipitate was removed by centrifugation, washed three times with water (600 ml each time) in a Waring Blendor, and suspended in ice water (300 ml). The copper complex was decomposed by addition of acetic acid at such a rate that the temperature never rose above 10 °C. The clear solution was diluted with methanol until precipitation was complete. The gummy precipitate, which was allowed to settle out overnight, was dissolved in water (200 ml) and the solution was deionized by passage through columns of Amberlite ion-exchange resins IR-120 and IR-45. The deionized solution was concentrated to a thin sirup to which ethanol was then added until precipitation was complete. The precipitate was removed by centrifugation, washed successively with ethanol, ether, and light petroleum (b.p. 30–60 °C), and then dried to yield galactomannan I. Yields based on the crude polysaccharide preparations were as follows: *T. granulosum* (32.2%), *T. interdigitale* (27.0%), *M. quinckeanum* (13.7%), *T. rubrum* (37.2%), and *T. schönleinii* (32.0%). Samples (150 mg) of each of these galactomannans I were dissolved separately in 0.05 *M* sodium tetraborate (15 ml), equilibrated with the same buffer by dialysis, and examined by moving boundary electrophoresis (10). Each sample showed a single, sharp, symmetrical peak throughout the test which ran for 6.5 h (mobilities are given in Table I). The sample solutions were recovered from the electrophoresis experiments and centrifuged in a model E Spinco ultracentrifuge at 20 °C for 80 min at a rotor speed of 59 000 r.p.m.; only a single component was detected in each sample.

Estimation and Identification of Constituent Sugars

Hydrolysis of each of the above polysaccharides, under conditions given for hydrolysis of the crude preparations, yielded mannose as the major constituent sugar with smaller amounts of galactose as shown by paper chromatography in solvent A. Samples (20 mg) of each galactomannan I in *N* hydrochloric acid (1 ml) had the initial specific rotations given in Table I. These rotations changed when the solutions were heated on a boiling water bath and reached the following constant values after 4.5 h: *T. granulosum* (+19.5%), *T. interdigitale* (+22.5°), *M. quinckeanum* (+17.4°), *T. rubrum* (+14.6°), and *T. schönleinii* (+23°). The percentages of D-mannose and D-galactose given in Table I were calculated from the final specific rotations of the hydrolysates. They were confirmed (mean deviation ±1.0 in 100) by the phenol–sulfuric acid method (15) after separation of the sugars by paper chromatography (solvent A) and by gas–liquid chromatography of the acetylated alditols derived from the sugars in the hydrolysate (16).

The sugars in hydrolysates of 100 mg of each polysaccharide were isolated by preparative paper chromatography (solvent A) and characterized as D-galactose and D-mannose by preparation of the phenylosazone (17), m.p. 194–196 °C, and the *p*-nitroanilide (18) m.p. 217–218 °C, respectively. Melting points of mixtures of these two products with their respective authentic samples were not depressed.

Methylation of Galactomannans I

The galactomannans I from *T. granulosum* (4.5 g), *T. interdigitale* (5.0 g), *M. quinckeanum* (5.0 g), *T. rubrum* (4.5 g), and *T. schönleinii* (4.0 g) were each dissolved in water (25 ml) and methylated by the dropwise addition of dimethyl sulfate (25 ml) and 40% aqueous sodium hydroxide (50 ml) (19). Four additions of the same amounts of reagents were made in the first 10 h and then a further five additions were made, one every 24 h. The partially methylated products were recovered in good yield by extraction into chloroform; yields, *T. granulosum* (4.4 g), *T. interdigitale* (5.4 g), *M. quinckeanum* (5.1 g), *T. rubrum* (4.6 g), and *T. schönleinii* (3.8 g). These products contained 37–40% of methoxyl groups and were further methylated by Purdie reagents (20) to yield fully methylated galactomannans I having no hydroxyl absorption in the infrared. Yields and methoxyl contents: *T. granulosum* (3.6 g; OCH_3, 45.6%), *T. interdigitale* (5.0 g; OCH_3, 44.5%), *M. quinckeanum* (4.4 g; OCH_3, 46.2%), *T. rubrum* (3.8 g; OCH_3, 45.0%), *T. schönleinii* (3.5 g; OCH_3, 44.5%); theoretical methoxyl content is 45.6%. Each methylated galactomannan I had a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

degree of polymerization of 45 as determined by osmometry in chloroform solution using a Mechrolab vapor pressure osmometer.

Hydrolysis Products from Methylated Galactomannans I

Quantitative estimation.—The methylated galactomannans I were each hydrolyzed by the following procedure. Methylated galactomannan I (1.0 g) was dissolved in ice-cold 72% sulfuric acid (8.0 ml) and the solution was left at room temperature for 45 min. Water (50 ml) was added and the solution was heated on a steam bath for 4 h (21). The hydrolysate was neutralized with barium carbonate, barium salts were removed by filtration, and water was removed from the filtrate by azeotropic distillation with ethanol at atmospheric pressure. Ethanol was removed by azeotropic distillation with benzene. This procedure avoided the losses of fully methylated sugars that occur during evaporation under diminished pressure.

A small portion (ca. 50 mg) of the mixture of hydrolysis products was heated under reflux overnight with 1% methanolic hydrogen chloride. The solution was neutralized by Duolite A4 ion-exchange resin and then examined by gas–liquid chromatography. The separation of one of the mixtures, that from the methylated galactomannan I from *T. interdigitale*, on column A is shown in Fig. 1 and is typical of the chromatograms given by each of the five mixtures of hydrolysis products. Relative amounts of the separated components were estimated by triangulation of the peaks on the gas–liquid chromatogram. The response of the β-ionization detector was the same for methyl tetra-*O*- and methyl tri-O-methyl hexosides which, however, gave 1.3 times greater response than the methyl di-*O*-methyl hexosides on a molar basis. The values obtained by direct triangulation of peaks for the methyl di-*O*-methyl hexosides were therefore multiplied by 1.3 as a calibration factor.

As a check on the quantitative data from gas–liquid chromatography another portion of each hydrolysate was separated by preparative paper chromatography (solvent B). The comparative results are shown below for one of the mixtures; the others gave very similar results.

Preparative paper chromatography		Gas–liquid chromatography
1.0 (parts)	tetra-*O*-methyl hexose	1.0 (parts)
2.0	tri-*O*-methyl hexose	2.03
1.0	di-*O*-methyl hexose	0.92

The amounts of individual components within the tetra-, tri-, and di-*O*-methyl fractions were not compared because complete resolution of the mixture was not obtainable by paper chromatography. The amounts of 2,3,5,6-tetra-*O*-methyl-D-galactose in the mixtures were estimated by gas–liquid chromatography of the methyl glycosides on column B. Under these conditions the methyl 2,3,4,6-tetra-*O*-methyl-α-D-mannoside had a retention volume of 1.10 relative to that of the methyl 2,3,5,6-tetra-*O*-methyl-α-D-galactoside. This 10% difference in retention volumes was ample for the estimation of the two components. No 2,3,5,6-tetra-*O*-methyl-D-galactose was present in the mixture from *T. rubrum*. All of the quantitative data in Table II, except that for 3,5-di-*O*-methyl-D-mannose, was therefore obtained by gas–liquid chromatography and the ratio of tetra- : tri- : di-*O*-methyl hexoses was checked by preparative paper chromatography. The 3,5-di-*O*-methyl-D-mannose was estimated as a percentage of the di-*O*-methyl fraction after separation by thin-layer chromatography as described below.

Isolation and Identification

To avoid repetition only one description of the isolation and characterization of the *O*-methyl sugars is given. It should be emphasized, however, that each *O*-methyl sugar in each of the five mixtures of hydrolysis products was identified as described here.

The mixtures of *O*-methyl sugars from hydrolysis of the methylated galactomannans I were resolved by preparative thin-layer chromatography using 20 × 20 cm plates loaded with 50–75 mg of the mixture. The fractions obtained are given below in order of greatest mobility; in our experience, relative rates of movement on thin-layer chromatograms are not sufficiently reproducible to warrant citation.

Fraction I.—A sirup which gave a single spot (R_G 1.04) on paper chromatography (solvent B) and a grey color with the spray reagent. Bromine oxidation yielded a sirupy lactone which was converted to a crystalline amide in methanol saturated with ammonia. Recrystallization of the amide from butanone yielded a product whose melting point was 154–155 °C, unchanged when the sample was mixed with authentic 2,3,5,6-tetra-*O*-methyl-D-galactonamide (22).

Fraction II.—The sirupy product showed a single spot (R_G 0.98) on paper chromatography (solvent B) and gave a red color with the spray reagent. The product was refluxed overnight in methanol containing Amberlite IR-120 ion-exchange resin. Evaporation of the solution left a residue which crystallized from light petroleum (b.p. 30–60 °C) and had m.p. 38–39 °C, $[\alpha]_D^{21}$ +69° (*c*, 1.5 in methanol). The melting point of a mixture of this product with an authentic sample of methyl 2,3,4,6-tetra-*O*-methyl-α-D-mannoside (23) was 38–39 °C.

A further portion of this fraction was converted to its anilide which was recrystallized from butanone : ether, m.p. 145–146 °C, $[\alpha]_D^{22}$ −10° (*c*, 1.0 in methanol). The melting point was undepressed when the sample was mixed with authentic *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-mannosylamine (24).

Fraction III.—This component ran on the thin-layer chromatograms as a very small zone just ahead of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Fraction IV with which it was usually contaminated after elution of the zones. A pure product was obtained by refractionation on thin-layer chromatograms. It had R_G 0.88 on paper chromatography in solvent B and M_G 0.0 on paper electrophoresis. The derived methyl glycoside had the same retention volume on gas–liquid chromatography (column A) as an authentic sample of methyl 2,4,6-tri-*O*-methyl-α-D-mannoside. Fraction III crystallized when seeded with 2,4,6-tri-*O*-methyl-D-mannose and had m.p. 60–62 °C, unchanged on admixture with 2,4,6-tri-*O*-methyl-D-mannose monohydrate (25).

Fraction IV.—The sirupy product gave a single spot (R_G 0.72) on paper chromatography (solvent B) and on paper electrophoresis (M_G 0.0). Oxidation by bromine yielded a sirupy lactone which was converted to the derived amide in methanol saturated with ammonia. The amide crystallized and recrystallization from butanone yielded 2,3,4-tri-*O*-methyl-D-mannonamide (26), m.p. 142–143°, unchanged by admixture with an authentic sample, $[\alpha]_D^{21}$ +5° (*c*, 1.0 in water).

Fraction V.—This component ran on thin-layer chromatograms as a small zone just ahead of Fraction VI. Refractionation was required to obtain a pure product. Fraction V showed one spot (R_G 0.66) on paper chromatography in solvent C; 3,4-di-*O*-methyl-D-mannose had R_G 0.72 in the same solvent. Paper electrophoresis also showed only one component, M_G 0.56; 3,4-di-*O*-methyl-D-mannose had M_G 0.54. Fraction V crystallized spontaneously and after recrystallization from butanone had m.p. 125–126 °C, undepressed by admixture with an authentic sample of 3,5-di-*O*-methyl-D-mannose (27). Yields of fraction V and the weights of the total di-*O*-methyl sugars (fractions V + VI) respectively in the five mixtures were: *T. rubrum* (11.0 mg and 123 mg), *T. granulosum*, *T. interdigitale*, *M. quinckeanum*, and *T. schönleinii* (4.8–5.1 mg and 97–102 mg). Fraction V therefore constituted 9% of the di-*O*-methyl fraction from the galactomannan I of *T. rubrum* and approximately 5% of the di-*O*-methyl fractions from the others.

Fraction VI.—This fraction crystallized spontaneously. It showed a single spot on paper chromatograms in solvents B and C (R_G 0.40 and 0.72 respectively) and on paper electrophoresis (M_G 0.54). Recrystallization from butanone yielded 3,4-di-*O*-methyl-D-mannose (28), m.p. 71–73 °C undepressed on admixture with an authentic sample, $[\alpha]_D^{21}$ +32° (*c*, 2.0 in methanol). The di-*O*-methyl sugar was converted to its methyl glycoside which crystallized from ether to yield a product with m.p. 86–87 °C, $[\alpha]_D^{21}$ +87° (*c*, 1% in methanol); the melting point was unchanged when the product was mixed with an authentic sample of methyl 3,4-di-*O*-methyl-α-D-mannoside (29).

Periodate Oxidations

Samples (11.35 mg) of each of the galactomannans I were dissolved in 0.015 *M* sodium periodate (10 ml) and stored in the dark at room temperature. At intervals aliquots (0.1 ml) were removed and diluted to 25 ml with water and periodate was determined spectrophotometrically (30). Periodate consumptions reached the constant values given in Table III after 24 h.

To each of the remaining oxidation solutions was added 2 drops of butan-1,3-diol and the solutions were set aside for 1 h. Aliquots (4 ml) were then removed and titrated to phenolphthalein end point to give the values for formic acid produced.

ACKNOWLEDGMENT

These investigations were supported, in part, by a grant from the John A. Hartford Foundation, Inc., New York.

SECONDARY KINETIC ISOTOPE EFFECTS IN BIMOLECULAR NUCLEOPHILIC SUBSTITUTIONS

II. α-DEUTERIUM EFFECTS IN MENSCHUTKIN REACTIONS OF METHYL IODIDE[1]

K. T. LEFFEK AND J. W. MACLEAN
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia
Received July 22, 1964

ABSTRACT

Secondary deuterium isotope effects have been measured for the reactions between methyl and methyl-d_3 iodides and a series of tertiary amines in benzene solvent. Deuterium substitution increased the rate of each reaction but the rate ratios (k_H/k_D) show no systematic change with variation in the structure of the amine. The isotope effect for the reaction with 2-picoline was measured at different temperatures over a range of 40 deg and shows no change. These isotope effects may be rationalized as internal rotational effects of the methyl group or as solvation effects.

Many of the kinetic secondary deuterium isotope effects recorded in the literature have been measured in reaction systems in which solvation of the reaction site is an important, but relatively unknown, factor. For such systems it is very difficult to assess what part of the isotopic rate change is due to solvation phenomena and what part comes about as a result of internal changes in the reacting molecule. Investigations of the dependence of secondary isotope effect on solvent composition give no clear answer to this problem. Shiner and Verbanic (1) found that isotope effects produced by α-deuteration of the alkyl group in *p*-alkyl benzhydryl chlorides solvolyzing in aqueous acetone were markedly dependent on the water content of the solvent, although the isotopic rate ratios were all quite close to unity. For α-deuterated methyl and ethyl *p*-bromobenzenesulfonates, Lewis and co-workers (2) found only very small changes in the isotope effect between the two solvents, methanol and acetic acid, which they interpreted on the basis of a difference in mechanism of reaction rather than a direct solvation difference. Similar changes in isotope effect, presumably due to mechanism changes, were observed by Lewis and Boozer (3) in the solvolysis reactions of 2-pentyl-1,1,1,3,3,d_5-*p*-toluenesulfonate in acetic acid, formic acid, and 80% aqueous ethanol. Similar results were observed by Winstein and Takahashi (4) for 3-methyl-2-butyl-3*d*-*p*-toluenesulfonate solvolyzing in the same solvents.

Thus changing the solvent gives information concerning solvation isotope effects which is not separable from information concerning effects resulting from changes in mechanism. Apart from the deuterated *p*-alkyl benzhydryl chlorides, there is no clear change of isotope effect with solvent for which there is not at least the possibility of a mechanistic change.

Recently, Leffek, Robertson, and Sugamori (5) proposed that the β-deuterium isotope effects in the water solvolyses of isopropyl compounds, which are rate changes brought about by changes in the entropy of activation, were due to differences in the barriers to rotation of the methyl and methyl-d_3 groups and differences in these barriers between the initial and transition states of the reaction. Although a reasonably large part of the observed effect could be accounted for on this theory, the unimportance of solvation as the source of the effect was not proved. Halevi and co-workers have suggested that these

[1]*Presented at the 47th Annual Conference of the Chemical Institute of Canada, Kingston, Ontario, June, 1964.*

results be rationalized in terms of solvation (6) and hold that "it is still reasonable to suppose that most secondary isotope effects, at least in a nonpolar solvent, would arise substantially from zero-point energy differences" (7). This supposition is tested in the present investigation for the reaction-type

$$R_3N + CH_3I \rightarrow R_3{}^+NCH_3 + I^-$$

studied in solvent benzene.

RESULTS AND DISCUSSION

Rate constants and isotopic rate ratios are given in Table I for the reactions of six tertiary amines with methyl and methyl-d_3 iodide in benzene solvent. All rate constants are corrected for expansion of the solvent. The rate constants observed in the present work for the reactions of triethylamine and pyridine with normal methyl iodide substantially agree with the values reported by Winkler and Hinshelwood (8).

TABLE I

Secondary deuterium isotope effects for the reactions between methyl iodide and tertiary amines at 50.03 ± 0.05 °C

Tertiary amine	No. of runs	10^5k_H (l/mole s)	10^5k_D (l/mole s)	k_H/k_D ± std. error
Triethylamine	3	$454._9$	$518._6$	$0.87_7 \pm 0.004$
Tri-*n*-propylamine	2	$116._5$	$130._4$	0.89_3
Tri-*n*-butylamine	3	$127._4$	$142._2$	$0.89_6 \pm 0.001$
Pyridine	4	6.99_8	7.61_4	$0.91_9 \pm 0.002$
2-Picoline	4	3.66_8	4.18_4	$0.87_7 \pm 0.002$
2,6-Lutidine	3	0.416_9	0.475_3	$0.87_6 \pm 0.002$

The deuterated methyl iodide reacts faster than the normal compound with all of the amines studied. The direction of the rate change is thus the same as that observed for similar reactions; for instance, the solvolysis in water of methyl-d_3 iodide (9) yields a rate ratio $k_H/k_D = 0.87$ and the reaction between pyridine and methyl-*t* iodide in benzene (10) gives a tritium isotope effect $k_H/k_T = 0.96$.

The rate ratios in Table I show very little variation with the amine reactant. According to Llewellyn, Robertson, and Scott (9), the isotope effect in the solvolyses of methyl halides depends upon the proximity of the entering group to the carbon atom at which substitution is taking place. Thus they observed greater inverse isotope effects the greater the S_N2 character of the solvolysis. This generalization has been shown to fail for the bimolecular attack of thiosulfate ion on alkyl bromides (11) and therefore may not be applicable to all types of nucleophilic substitutions. If, however, it were true for Menschutkin reactions, it could be concluded that the proximity of the nitrogen atom of the attacking amine to the carbon atom of the methyl iodide was approximately the same in the transition state for all six amines. This is not an unreasonable model for the transition state despite the fact that the amount of steric hindrance to reaction changes by a very large amount in, for instance, going from pyridine to 2,6-lutidine (12). The constancy of the isotope effect for tertiary amines of widely differing steric characteristics does not prove that the isotope effect is unconnected with the steric effect as the k_H/k_D ratio measures only the difference in steric effect between CH_3 and CD_3 for a given reaction. This difference may not change significantly even though the steric hindrance to reaction changes from one amine to another.

TABLE II

Temperature dependence of α-deuterium isotope effect for the reaction between methyl iodide and 2-picoline

No. of runs	$10^5 k_H$ (l/mole s)	$10^5 k_D$ (l/mole s)	Temp. (°C)	k_H/k_D
1	1.84_0	2.09_8	40.02	0.87_7
1	2.64_1	2.96_4	45.09	0.89_1
4	3.66_8	4.18_4	50.03	0.87_7
1	5.18_1	5.89_2	55.03	0.87_9
1	7.05_8	8.09_0	60.03	0.87_3
1	9.99_7	11.2_4	65.09	0.88_9
1	13.4_0	15.2_7	70.14	0.87_8
1	18.0_9	20.6_4	75.05	0.87_6
1	23.6_4	26.8_1	80.04	0.88_2

The reaction of 2-picoline with methyl iodide was chosen to carry out a study of the dependence of the rate ratio on temperature. The results given in Table II show that the isotope effect is constant over a temperature range of 40 deg. By the method of least squares, the rate ratios were fitted to the equation

$$[1] \qquad \log_{10}(k_H/k_D) = \frac{(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})}{2.303RT} - \frac{(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})}{2.303R}$$

which is derived from the rate equation of the transition state theory. Calculation of the enthalpy of activation difference and the entropy of activation difference gave

$$(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}) = -2 \pm 36 \text{ cal mole}^{-1}$$

and

$$(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}) = +0.25 \pm 0.11 \text{ cal mole}^{-1} \text{ deg}^{-1}.$$

The limits quoted in each case are standard deviations.

Thus, the isotope effect in this Menschutkin reaction, in the nonpolar solvent benzene, is an entropy of activation effect.

The 13% inverse α-deuterium isotope effect observed by Robertson and co-workers (9) for the water solvolysis of methyl-d_3 iodide was interpreted in terms of zero-point energy changes of the C—H and C—D bonds between the initial and transition states. The observed isotopic rate ratios for other methyl-d_3 compounds led to the conclusion that the C—H and C—D bending vibrations were inhibited in the transition state relative to the initial state, either by the size of the leaving group or the degree of nucleophilic interaction of the attacking water molecule. The authors examined the possibility of a "thermodynamic" source of the effects but concluded that the zero-point energy changes were probably the origin of the rate changes. This conclusion must be reexamined in the light of the present findings.

The lack of an enthalpy of activation difference between the normal and deuterated methyl iodides for the Menschutkin reaction poses the same problem as the similar result found in the water solvolyses of isopropyl esters (5); i.e., either there are no zero-point energy changes or there is a fortuitous cancellation between opposing changes in the C—H and C—D bonds. The latter alternative seemed to be the more likely (5) because it is very difficult to find a source of entropy of activation which does not simultaneously introduce an enthalpy of activation difference. However, belief in the fortuitous cancellation can only be maintained if the number of systems in which it must be postulated is not too large compared to the total number of systems examined. With the inclusion

For personal use only.

of this investigation, six temperature dependence studies of secondary deuterium isotope effects have been published (1, 5, 13, 14, 15), and three show an entropy of activation difference as the major isotope effect. Therefore, the answer to this problem on a statistical basis must await the accumulation of more data.

Secondary isotope effects may arise if the changes in the partition functions, on going from the initial state to the transition, are not the same for the protium and deuterium compounds. The transition state theory rate expression yields eq. [2],

$$[2] \qquad k_H/k_D = \frac{Q_H^{\ddagger}}{Q_H}\frac{Q_D}{Q_D^{\ddagger}}$$

in which the partition function Q may be factorized into

$$Q_{trans} \times Q_{rot} \times Q_{vib} \times Q_{int\ rot}.$$

Here the vibration partition function is calculated with reference to the minimum of the potential energy curve and therefore contains the zero-point energy component, which may be, and usually is, discussed separately from the remaining partition function contributions. For the translational and rotational contributions, the partition functions are directly proportional to the mass and the product of the moments of inertia, respectively. For a reaction, such as the Menschutkin reaction, in which the transition state is formed by the coalition of two molecules, both the translational and rotational contributions to the rate ratio yield k_H/k_D greater than unity (9), but only of the order of 1 or 2%, if solvation is assumed to be equal for the initial and transition states. An inverse isotope effect of the same order of magnitude can be obtained only if the transition state is assumed to be unsolvated and the initial state solvated, which is an unreasonable postulate for this reaction in which charges are being developed during the activation process on initially neutral molecules.

The contribution from the vibrational partition function (excluding the zero-point energy component) to the isotope effect is probably negligibly small, since Q_{vib} for individual fundamental frequencies greater than 1 000 cm^{-1} is very close to unity (16). These are the vibrations which involve hydrogen in an important way and thus are the ones most affected by deuteration. The fundamental vibrations of the molecule with lower frequencies give values of Q_{vib} greater than one, but are changed much less by deuteration. The only manner in which an inverse vibrational isotope effect can be obtained is to apply some postulate to allow an increase in the vibration frequencies during the activation process, which, as first proposed by Lewis and co-workers (17), gives rise to inverse isotope effects as a result of zero-point energy changes. However, the results of the present investigation remove the grounds on which this explanation was based; i.e., that the observed isotope effects are necessarily zero-point energy effects.

Isotope effects resulting from internal rotation were not considered to be important in the solvolyses of methyl compounds in water (9) but were used later by Leffek, Robertson, and Sugamori to partly explain the entropy of activation isotope effects found in the water solvolyses of isopropyl compounds (5). The same theory applied to the Menschutkin reactions of methyl iodide provides one source of entropy of activation isotope effect which probably contributes to the observed rate ratio.

For an S_N2 reaction involving methyl iodide, the barrier to rotation of the methyl group about the axis of the C—I bond is zero. However, in the transition state of the reaction the carbon–nitrogen bond is partly formed and will have a barrier to internal rotation. For some time it has been thought that the transition state of a Menschutkin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

reaction was very similar to the products (18), and although recent work (19, 20) indicates that this may not be true, the carbon–nitrogen bond must be at least half-formed in the transition state. If the formation of this new barrier to internal rotation is combined with the postulate made by Leffek *et al.* (5) that the barrier to rotation of CH_3 groups is slightly higher than that of CD_3 groups, which, although not predicted by theory, is supported by a limited amount of experimental evidence (21, 22), the entropy of activation for the protium compound will be a larger negative quantity than that for the deuterium compound. Thus, $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ will be positive. With assumed reasonable values for the barriers to rotation, a semiquantitative treatment may be made, and the enthalpy and entropy of activation contributions from this source obtained from Pitzer's tables (23). Some examples are given in Table III, from which it may be seen that a significant contribution to the entropy of activation difference is obtained for assumed differences in the barrier to rotation of about 10–20% between the normal and deuterated transition states. The enthalpy of activation contribution from the source is greater for the deuterated molecule than for the protium compound, thus favoring a slower reaction by the former. This effect is in the opposite direction to the enthalpy effect proposed by Lewis *et al.* (17) and Robertson *et al.* (9) and therefore allows the possibility of cancellation of the enthalpy isotope effects.

TABLE III

Contributions to the secondary isotope effects for Menschutkin reactions of methyl iodide from internal rotational effects at 300 °K

Barrier to methyl rotation in transition state (cal mole^{-1})		$(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})_{\text{int rot}}$	$(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})_{\text{int rot}}$
H compound	D compound	(cal mole^{-1})	(cal mole^{-1} deg^{-1})
1 500	1 500	52	−0.01
1 800	1 500	54	+0.15
2 100	2 100	58	−0.02
2 400	2 100	72	+0.14

From the accumulated experimental data it appears that there is no single source of secondary deuterium isotope effects. Observed rate changes which result from the cancellation of two or more effects will therefore inevitably occur in some, and perhaps many, of the systems studied. Although only two effects are necessary to obtain a cancellation, the real situation may be more complicated. In particular, for all reactions in solution, differences in solvation between the deuterated and normal compounds are an obvious source of isotope effect, but they are very difficult to assess quantitatively. The similarity between the rate ratios for the methyl iodides reacting with tertiary amines in benzene ($k_H/k_D \approx 0.89$), and solvolyzing in water ($k_H/k_D = 0.87$), may be used as an argument against solvation effects as the origin of the rate differences, since quite different solvation effects would be expected for these two reactions. However, this argument is valid only if the isotope effect for the solvolysis reaction is also temperature independent, and even then it is still assailable.

Notwithstanding this argument, solvation may be used to explain the present results in the following manner. Although benzene is a nonpolar solvent, it is polarizable; hence solvation increases during the activation process as the charges on the forming ions are developed. Since carbon–deuterium bonds release electrons inductively slightly better than carbon–hydrogen bonds, the development of the positive charge on the ammonium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ion should be less for the deuterated compound than for the normal compound, resulting in less strong solvation for the former. Such an effect would yield a rate difference between the two isotopic compounds due to both enthalpy and entropy differences. Since the entropy of activation contributions from this source are negative for both isotopic analogues, with the term for the deuterated compound the smaller one, $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ would be positive, but its size is not easily estimated. It may be argued, however, that isotope effects arising directly from isotopic substitution within the substrate molecule should always be more important than those arising from environmental changes of the molecule as a result of the isotopic substitution, the latter being secondary with respect to the former.

In the examples presented in this work and in some other cases, but obviously not in all, changes in the barriers to rotation about single bonds offer a partial explanation of the entropy difference, although other sources of isotope effect are probably operating concurrently.

NOTE ADDED IN PROOF: Recently two important papers by Wolfsberg and Stern have appeared (Pure and Appl. Chem. 8, 255, 325 (1964)), concerning the theory of isotope effects. In particular, it was demonstrated how it is possible to obtain a temperature independent secondary deuterium isotope effect ($k_H/k_D > 1$) as a result of opposing changes in force constants during the activation process. In principle, a similar treatment could be developed for the present results as an alternative to the above interpretation. However, the problem of rationalizing the force constant changes would remain and this problem is no less than that of rationalizing the rate constant isotope effects themselves.

EXPERIMENTAL

Materials

The deuterated methyl iodide, supplied by Merck and Co. Ltd., had a minimum isotopic purity of 99%. Samples from three different batches were analyzed from their mass spectra and each was found to be 99.4% deuterated. The normal methyl iodide and the tertiary amines were reagent grade and each was dried and distilled immediately before use. Reagent grade benzene was refluxed over potassium metal for 4 h, then fractionally distilled.

*Volume of 0.0250 *N* $AgNO_3$ equivalent to 4.69 ml sample, corrected for burette errors.

Kinetic Method

Each kinetic run was carried out by immersing sets of sealed tubes, each containing an accurately known volume of reaction mixture (ca. 5 ml), in a constant temperature bath (±0.01° C). After equilibrium had been reached, three tubes were withdrawn and rapidly cooled in dry ice – acetone slush, this time marking

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the kinetic zero. Thereafter tubes were withdrawn singly at regular intervals. The contents of each tube were analyzed by potentiometric titration of the iodide ion with standard silver nitrate solution, using approximately 30 ml of wet acetone as the solvent. Rate constants were calculated from the integrated rate equation for a second-order irreversible reaction. Each isotopic rate ratio was determined by carrying out a pair of runs simultaneously, identical except for the isotopic substitution; an example is given in Table IV. The reactions were generally followed over one to two half-lives. The straight chain tertiary amines have steady second-order rate constants over two half-lives, but the pyridine derivatives gave rate constants which decreased a few per cent ($< 5\%$) during 50% reaction. The constants quoted are nevertheless average values; since the two isotopic reactions were sampled at the same relative times, any parallel errors in the rate constants cancel in the evaluation of the isotopic rate ratio. Several independent pairs of runs were made for each isotope effect determined at 50.03 °C.

ACKNOWLEDGMENTS

The authors are grateful for financial support of this work by the National Research Council and thank Dr. W. D. Jamieson for the determination of the mass spectra.

NUCLEAR MAGNETIC RESONANCE INVESTIGATIONS OF SOME GROUP V METAL FLUORIDES AND OXYIONS[1]

J. V. HATTON,[2] Y. SAITO,[3] AND W. G. SCHNEIDER
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received July 28, 1964

ABSTRACT

The nuclear magnetic resonances of ^{51}V, ^{93}Nb, ^{121}Sb, ^{123}Sb, and ^{181}Ta in solutions of the pentafluorides of these elements were measured. All of these nuclei have large electric quadrupole moments. In most cases the chemical species observed was identified by spin-multiplet splitting of the metal resonance. In aqueous 48% HF solutions the ^{181}Ta resonance could not be observed; the ^{121}Sb and ^{123}Sb resonances consist of a symmetrical septet, corresponding to the hexafluoride ion; the ^{93}Nb resonance consists of a single exchange narrowed line; and the ^{51}V resonance consists of a symmetrical quintet, corresponding to the VOF_4^- ion. In alcohol solution NbF_5 disproportionates to form NbF_6^-, whereas in ether and triethylamine solutions, the complexes $NbF_5 \cdot OEt_2$ and $NbF_5 \cdot NEt_3$ are formed. The latter complexes were confirmed by proton resonance measurements. Resonances of ^{51}V in aqueous solutions of V_2O_5 and of NH_4VO_3 as a function of pH show a parallel behavior and reveal the presence of six different oxyions of vanadium. Five of these resonances are assigned to the species, VO_4^{3-}, VO_3^-, $V_2O_7^{4-}$, $V_3O_{10}^{6-}$ and VO_2^+, on the basis of the resonance line width and the pH range in which the resonance appears.

I. INTRODUCTION

The use of magnetic resonances of heavier nuclei for structural investigations of inorganic compounds has received relatively little attention. The magnetic properties of such nuclei are generally not as favorable for n.m.r. as those of hydrogen and fluorine nuclei. For some nuclei this is primarily a question of low sensitivity due to a low isotopic abundance, but more commonly it is a question of an unfavorable nuclear relaxation time. The majority of heavier nuclei possess relatively large nuclear electric quadrupole moments which strongly couple with surrounding molecular fields and give rise to a short nuclear relaxation time. This results in an enhanced nuclear resonance line width, $\Delta\nu$, given appproximately by the relation (1):

$$\Delta\nu = 1/T_1 = Kh^2(eq)^2(eQ)^2\tau_c. \qquad (1)$$

Here T_1 is the nuclear relaxation time, K is a constant, Q is the nuclear electric quadrupole moment, q is the electric field gradient near the nucleus, and τ_c is the molecular correlation time. When both the nuclear electric quadrupole moment and the field gradient are large, the resonance line may be broadened beyond detection. However, there are many molecular systems in the realm of inorganic chemistry where the field gradient in the vicinity of the nucleus of interest may be expected to be moderately small. Numerous examples of this are to be found in solutions of complex ions where the central atom is surrounded by a number of ligand groups which tend to balance out the fields near the central atom. The complex metal fluorides of the heavier metals provide a specific example of this and, in addition, offer a further advantage. If spin coupling of the fluorine can be observed in the resonance spectrum of the central atom, this immediately identifies the particular chemical species being measured.

The present investigation was undertaken to see to what extent the resonances of nuclei with large electric quadrupole moments could be measured in various chemical species and what kind of information could be derived therefrom. For this purpose several Group V nuclei were selected. Their magnetic properties are summarized in Table I. All of these nuclei have favorable isotopic abundances and all possess large electric quadrupole moments, that for ^{181}Ta being among the largest known.

TABLE I

Magnetic properties of Group V nuclei

Nucleus	Natural abundance (%)	Frequency (Mc/s) (in a field of 14.1 kilogauss)	Magnetic moment (nucl. magnetons)	Spin	Elec. quadr. moment ($e\times10^{-24}$ cm^2)
^{51}V	99.76	15.80	5.145	7/2	0.3
^{93}Nb	100	14.73	6.167	9/2	~0.3
^{121}Sb	57.25	14.37	3.343	5/2	−1.3

^{181}Ta	100	7.18	2.1	7/2	6.5

II. NIOBIUM (^{93}Nb)

(a) NbF_5 in Aqueous HF Solution

It has been shown that in the system K_2NbF_7–HF–H_2O, the NbF_6^- ion exists in solution at concentrations of HF in excess of 40.5% (2). Accordingly, dissolution of NbF_5 (m.p. 72 °C) in 48% aqueous HF would be expected to yield the hexafluoride ion. At room temperature the ^{93}Nb resonance of this solution consists of a single, very sharp, intense line. Cooling the solution causes progressive broadening of the resonance line, with no appearance of a multiplet structure at temperatures as low as −70 °C. By analogy with the corresponding behavior of SbF_5 solutions (*vide infra*), it is concluded that in the niobium solution at room temperature the ^{93}Nb resonance is narrowed by rapid fluorine exchange.

(b) NbF_5 in Dry Ethanol

In order to limit fluorine exchange, solutions of NbF_5 in organic solvents were investigated. The ^{93}Nb resonance of a dry ethanol solution at 0 °C, shown in Fig. 1, consists of a symmetrical septet (intensities, 1:6:15:20:15:6:1). As the temperature is increased from 0 to +50 °C, or decreased from 0 to −80 °C, progressive line broadening was observed. The chemical species being observed is undoubtedly NbF_6^-, since to explain the spectrum of Fig. 1 requires that the niobium nucleus "sees" six equivalent F atoms and a small electric field gradient. A similar spectrum has been observed and assigned independently by Packer and Muetterties (3) for NbF_5 in solution in dimethyl formamide. From the multiplet splitting the ^{93}Nb–^{19}F spin coupling constant is found to be 345 ± 5 c/s.

Formation of the hexafluoride ion implies self-dissociation of the dissolved niobium pentafluoride. The ethanol solution has a deep purple color and a high electrical conductivity (10^{-4} Ω^{-1}cm^{-1} for 0.01 *M* solution). Thus it is likely the disproportionation reaction is

$$[1] \qquad NbF_5 \leftrightarrows NbF_6^- + NbF_4^+.$$

This has also been suggested to account for the high conductivity of molten niobium pentafluoride (4). If the species NbF_4^+ had a symmetrical structure it should yield a second ^{93}Nb multiplet resonance considerably displaced from that of the NbF_6^- ion.

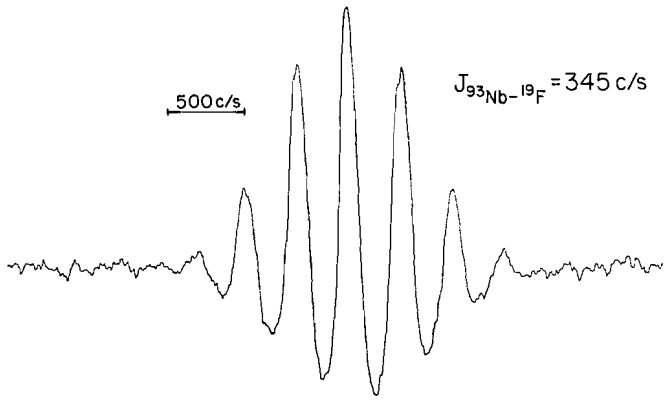

FIG. 1. ^{93}Nb resonance of NbF_5 in dry ethanol; temperature 0 °C.

Since this was not observed, an unsymmetrical structure having a large field gradient at the central atom must be assumed. Such a structure is $NbF_4(EtOH)_2^+$, in which the oxygen of the ethanol solvent takes up two of the octahedral coordination positions. Further ionic dissociation could also yield $NbF_4(OEt)_2^-$. Yet another possibility (5) involves complexing of NbF_5 with an alcohol molecule, followed by elimination of HF to yield $C_2H_5ONbF_4$, and this may proceed in successive steps to:

[2] $$6NbF_5 + 5EtOH \rightarrow 5HNbF_6 + Nb(OEt)_5.$$

The line broadening observed at temperatures above 0 °C is undoubtedly due to fluorine exchange reactions expressed by eq. [1]. The observed line broadening of the NbF_6^- ion at temperatures below 0 °C must then be attributed to possible association effects, either by ion pairing or by additional solvent coordination.

It should be noted also that the ^{93}Nb resonance position of NbF_6^- in ethanol at room temperature is very near that of NbF_6^- in aqueous HF solution (see Table II).

TABLE II

Chemical shifts of niobium and antimony in solutions of the pentafluorides

Compound	Solvent	Nucleus measured	Spectrum	Species in solution	Shift
NbF_5	48% HF	^{93}Nb	Sharp singlet	NbF_6^-	0
NbF_5	Ethanol	^{93}Nb	Sharp septet	NbF_6^- (see text)	−5
NbF_5	Ether	^{93}Nb	Broad singlet	$NbF_5 \cdot OEt_2$	−70
NbF_5	Ethanolic triethylamine	^{93}Nb	Very broad singlet	$NbF_5 \cdot NEt_3$	−155
SbF_5	48% HF	$^{121,123}Sb$	Sharp septet	SbF_6^-	0
SbF_5	Ethanol	^{121}Sb	Broad multiplet*	SbF_6^-	0±2
		^{123}Sb	Very broad multiplet*	SbF_6^-	
SbF_5	Ether	^{121}Sb	Very broad singlet	$SbF_5 \cdot OEt_2$	0±2

*The resonances were temperature dependent (see text).

(c) NbF_5 in Dry Ether

Solutions of NbF_5 in ether exhibit a single very broad resonance line at room temperature, which broadens still further as the temperature is lowered. In this case the resonance is ascribed to the coordination complex $NbF_5 \cdot OEt_2$, which is evidently favored over the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

NbF_6^- ion. The following experiment supports this conclusion. To an alcoholic solution of NbF_5, ether was progressively added until the latter was well in excess. During the course of this dilution, the ^{93}Nb septet resonance becomes progressively weaker, but shows no broadening. In the reverse experiment, i.e. by gradual addition of alcohol to an ethereal solution of NbF_5, the broad niobium resonance gives way almost immediately to the septet resonance characteristic of NbF_6^-. Thus the latter appears to require the presence of ethanol.

(d) NbF_5 in Triethylamine

Freshly prepared solutions of NbF_5 in triethylamine show a very broad resonance signal displaced to lower field with respect to the resonance of alcoholic solutions. The resonance is undoubtedly due to the amine complex, $NbF_5 \cdot NEt_3$, which in time separates from the solution as white crystals.[4] The complex can also be prepared by adding the amine to an ether solution of NbF_5.

The chemical shifts of ^{93}Nb in the NbF_5 solutions examined are summarized in Table II. There is a progressive shift of the resonance to low field in the complexes, $NbF_5 \cdot F^-$, $NbF_5 \cdot OEt_2$, and $NbF_5 \cdot NEt_3$. Because of the dominance of paramagnetic contributions to the Nb nuclear screening in these compounds, the observed order is consistent with increasing covalency in ligand bonding, as appears entirely reasonable.

III. ANTIMONY

Antimony has two magnetic isotopes, ^{121}Sb and ^{123}Sb, with natural abundances of 57% and 43%, respectively. The resonances of both isotopes were examined.

(a) SbF_5 in Aqueous 48% HF

The resonances of both antimony isotopes consist of sharp line septet spectra, confirming SbF_6^- as the stable species in these solutions. The fluorine–antimony spin coupling constants are included in Table III. In contrast to the corresponding niobium solutions, rapid fluorine exchange between SbF_5 and HF does not occur at ordinary temperatures.

TABLE III

Metal–fluorine coupling constants (c/s)

Nucleus X	$J_{M-^{19}F}$	Ion	Solvent
^{51}V	116±5	VOF_4^-	48% HF
^{93}Nb	345±5	NbF_6^-	Ethanol
^{121}Sb	1945±5	SbF_6^-	48% HF
^{121}Sb	1950±50	SbF_6^-	Ethanol
^{123}Sb	1055±5	SbF_6^-	48% HF
^{123}Sb	1050±50	SbF_6^-	Ethanol

(b) SbF_5 in Dry Ethanol

At room temperature the ^{121}Sb resonance consists of a broadened septet, the component lines of which sharpen considerably on heating to +88 °C. At +4 °C the multiplet pattern is obliterated, and only one very broad line is observable. As may be expected, ^{123}Sb, which has the larger nuclear quadrupole moment, exhibits even broader resonances.

As in the case of ethanolic NbF_5 solutions, the stable species is the hexafluoride ion.

[4] *A referee has called our attention to similar complexes formed by* SbF_5 *and* AsF_5 *with organic bases (cf. E. L. Muetterties. Advances in the chemistry of co-ordination compounds. The Macmillan Company, N.Y. 1961. p. 513).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

However, the broader resonance lines observed for the SbF_6^-, compared with the corresponding Nb resonances at similar temperatures, indicate that some additional complexing interactions must occur.

(c) SbF_5 in Ether

The room temperature ^{121}Sb spectrum consists of one broad line, which sharpens only slightly at higher temperature and broadens still further on cooling to 0 °C.

The chemical shifts of ^{121}Sb for the SbF_5 solutions in 48% aqueous HF, ethanol, and ether are the same to within 2 p.p.m. This again is in sharp contrast to the behavior of niobium solutions and provides further evidence of more complex (possibly polymeric) interactions in the case of the antimony solutions.

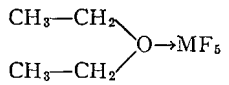
IV. TANTALUM

Since the chemistry of tantalum and niobium are generally similar, solutions of TaF_5 in 48% aqueous HF, dry ethanol, and ether were also investigated. Under the present experimental conditions no resonance of ^{181}Ta could be observed in any of these solutions. In spite of the very large electric quadrupole moment of ^{181}Ta, if tantalum were present as the simple TaF_6^- ion, its resonance should have been observed. Thus it is necessary to conclude that less symmetrical coordination complexes are formed, or else that an intermediate rate of fluorine exchange occurs so as to greatly broaden the resonance.

V. PROTON RESONANCES OF METAL FLUORIDE – ETHER COMPLEXES

Confirmatory evidence of complex formation in the metal fluoride – ether systems was obtained from proton resonances of the coordinated ether. Addition of excess metal fluoride to ether results in the formation of an immiscible viscous layer, which separates at the bottom of the solution. These layers are colored: SbF_5, dark brown; NbF_5, mauve; and TaF_5, red-brown. To remove excess ether, these layers were separated and extracted with tetramethylsilane (TMS). Finally, a small amount of the extracted complex was dissolved in TMS and the proton resonance of the ether component was measured relative to the signal of TMS. The results are summarized in Fig. 2. The proton resonance of the CH_3 (triplet) and CH_2 (quartet) groups in pure ether appear at -66.3 c/s and -201.3 c/s respectively from the TMS reference. In the metal fluoride complexes the resonances of both the CH_3 and CH_2 groups are broadened and displaced to lower field, the CH_2 group showing a larger displacement. Also the internal shift, $\Delta\nu$, between the CH_3 and CH_2 groups may be taken as a measure of relative strength of binding in the complex.

If the complex is formulated schematically as:



the observed proton resonance shifts are readily understood. Donation of electrons by the ether oxygen atom to the metal effectively makes the oxygen more electronegative. The resulting inductive effects in the bonded ethyl group will then give rise to low-field shifts of the proton resonances. Admittedly the above structure may be oversimplified. For example more complex interactions, schematically indicated by the following,

$$2(MF_5 \cdot OEt_2) \leftrightarrows \overset{-}{M}F_6 \cdot \overset{+}{M}F_4(OEt)_2$$

could also be envisaged and could contribute to line broadening.

VI. VANADIUM

Vanadium forms a greater variety of compounds than the other Group V metals so far considered, and its magnetic resonances are therefore of particular interest. While vanadium displays several characteristic valence states (not all of which are diamagnetic states), the present measurements are concerned only with the +5 state.

(a) Vanadium Fluorides

If the vanadium hexafluoride ion is a stable species, it may be expected to occur in solutions of V_2O_5 in 48% aqueous HF. The ^{51}V resonance of this solution at room temperature is reproduced in Fig. 3*a*. The line width is somewhat less than 100 c/s. On cooling the solution, the resonance is observed to broaden and ultimately yields a well resolved symmetrical quintet (Fig. 3*b*). Thus the species being observed is not the hexafluoride ion, but one with four equivalent fluorine atoms. This is undoubtedly the VOF_4^- ion, previously postulated (6, p. 817). This may be expected to have a square pyramid structure with the four equivalent fluorine atoms occupying the base position and the oxygen atom at the apex. Such a structure would not be expected to have a symmetrical field near the central vanadium nucleus.[5] However, as demonstrated by the spectrum of Fig. 3*b*, the resonance lines are fairly narrow. The vanadium–fluorine spin coupling constant is relatively small, 116 c/s (See Table III).

Other oxyfluoro ions of vanadium, for example, $VO_2F_3^{2-}$ and VOF_5^-, have been postulated (7, 8). In an attempt to observe these, solutions of V_2O_5 in 48% aqueous HF containing ammonium fluoride or containing potassium or zinc fluorides in excess were examined. Each gave spectra identical to those shown in Fig. 3, and must accordingly also contain the VOF_4^- ion. However, the presence of other species with very large field gradients at the central vanadium nucleus could conceivably escape detection because of excessive line broadening.

(b) Oxy-ions of Vanadium

Vanadium, like phosphorous, forms a series of oxy-ions in aqueous solutions (6, p. 810). The range of stability of different oxy-ions of vanadium is known to be strongly pH-dependent and to differ markedly from those of phosphorus (9). It was accordingly of some interest to what extent the vanadium resonances of different vanadate and polyvanadate species in solution could be measured. Two separate series of experiments were carried out:

(i) Starting with an aqueous solution of NH_4VO_3, which has a pH of 7.0, the ^{51}V resonance of the solution was measured as the pH was increased by addition of potassium hydroxide or decreased by addition of sulfuric acid.

(ii) A parallel series of measurements were also made starting with an aqueous solution of V_2O_5 in water.

The results are summarized in Table IV and plotted as a function of pH in Fig. 4. The ^{51}V chemical shifts (in p.p.m.) are referred to an aqueous solution of NH_4VO_3 (pH = 7.0). As is evident from Fig. 4, the two series of measurements exhibit very satisfactory agreement and consistency with respect to the chemical shift values of the observed resonances.

The results of Fig. 4 show seven separate vanadium resonances corresponding to at least six different ionic species, and in certain pH ranges two or more of these species coexist in equilibrium. The assignments indicated in Fig. 4 are to be regarded as tentative, although a considerable amount of supporting evidence is available. From pH 7 to pH 9 only one moderately sharp line is observed, and since this must correspond to the starting material, the resonance must be assigned to the metavanadate ion, VO_3^-, (or possibly to hydrated or polymeric forms of this ion). At pH 9.5 to 10, two resonances are observed, an additional rather broad line appearing about 45 p.p.m. to low field from the VO_3^- resonance. This is assigned to the pyrovanadate ion, $V_2O_7^{4-}$, known to exist in alkaline

[5]*The possibility of a trigonal bipyramid structure, with rapid exchange of fluorine atoms, cannot be ruled out.*

*The letter *a* designates aqueous NH_4VO_3 solutions, and *b* designates aqueous V_2O_5 solutions.
†Chemical shifts in p.p.m. were measured relative to aqueous NH_4VO_3 solution (pH = 7.0). Relative intensities, vw, w, m, s, vs, indicate respectively, very weak, weak, medium, strong, and very strong.

solutions (10). The resonance of the latter ion persist also in the range pH 10 to 13, and in this range the resonance of VO_3^- is no longer observable. Instead a new resonance, consisting of a very sharp line, appears at about 15 p.p.m. to lower field. The sharp resonance is indicative of a highly symmetric species and accordingly it is assigned to the orthovanadate ion, VO_4^{3-}, a tetrahedral structure.

Solutions in the acidic pH range are reported (9) to contain more complex (polyvanadate) ions, and V_2O_5 may be precipitated from solution. In the pH range 3.5 to 7.0, four separate vanadium resonances were observed. One of these arises from the VO_3^- ion, the intensity of the resonance becoming progressively weaker as the solution is acidified. Two rather broad and closely spaced lines at 60 to 80 p.p.m. to lower field also appear in the same pH range. The higher field member of this pair has an intensity about twice that of the other. The two lines are accordingly assigned to the $V_3O_{10}^{5-}$ ion. Of the three vanadium nuclei in this ion, two of them (end groups) are equivalent and are in a different environment than the third (middle group). Analagous spectra have been observed for

For personal use only.

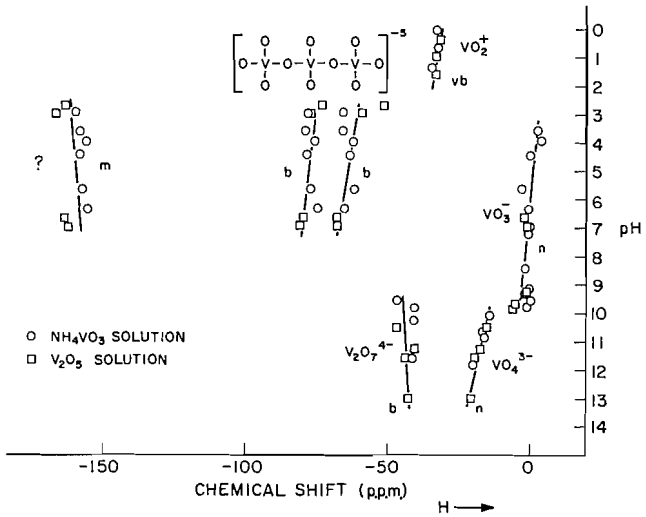

FIG. 4. ^{51}V resonance shifts of aqueous solutions of NH_4VO_3 and of V_2O_5 as a function of pH. Relative line widths of the resonances are indicated as n, m, b, and vb, corresponding to narrow, medium, broad, and very broad, respectively, covering a range of approximately 0.5 to 1.5 kc/s in line width.

^{31}P resonances of polyphosphate ions (11). Finally there is a third and completely separate species coexisting in the same pH range and having a vanadium resonance at much lower field (−160 p.p.m. from VO_3^-). The resonance line is moderately sharp indicating a fairly symmetrical species. This remains to be identified.[6]

At a pH ~ 2.2 a very sharp change in properties occurs, and the color of the solution changes. In solutions having a pH below this value only a single very broad resonance is observed about 30 p.p.m. to the low-field side of the VO_3^- resonance. The broad line is indicative of a large asymmetrical field near the vanadium nucleus. The resonance is accordingly assigned to the vanadyl ion, VO_2^+. Vanadyl sulfates are known stable salts and are obtained from strongly acid solutions (12).

It is evident from these results that a considerable amount of chemical information is derivable from nuclear resonances of complex ions. In some cases these resonances are readily observable, even though the ligand field about the quadrupolar nucleus is not spherically symmetrical. Also, the fact that several separate ionic species can coexist in the solution and their resonances are separately observable implies that exchange reactions between these species are relatively slow. Rapid exchanges (H and OH groups) between individual ions and the aqueous solvent may of course occur. The measured nuclear resonance shift of the ion is then characteristic of its exchange-averaged environment.

VII. EXPERIMENTAL

The metal resonances were measured using a Varian V4210A broad-line spectrometer incorporating a lock-in amplifier with audio phase-sensitive detection. The resonance signals were accordingly recorded as the derivative of the dispersion mode. All spectra were obtained at a magnetic field of 14.1 kilogauss.

Variable temperatures were achieved by means of a Dewar apparatus capable of operating in the range

[6]*The possibility of higher polymeric species in this pH range cannot be ruled out. Thus, for example, the metavanadate ion, VO_3^-, could conceivably be $V_4O_{12}^{4-}$ (see ref. 6, p. 810). However, unless this is a cyclic structure, two vanadium resonances should be observed because of the non-equivalence of the inner and end vanadium atoms, and the two resonances would have a constant relative intensity as the pH is varied. The further question arises whether the species, $V_5O_{14}^{3-}$, which should give three resonance lines, could account for the resonances at −160 p.p.m. and at −60 and −80 p.p.m. In this case the relative intensities of the three lines should be in the ratio of 2:2:1, whereas the observed ratio is 1:1:2.*

For personal use only.

−100 to +200 °C. In this case, the conventional 15 mm i.d. sample tube was replaced by one with i.d. of 10 mm. Accordingly the sample volume is reduced by a factor of 2 and could introduce sensitivity problems for weak resonances. No such problems were encountered here.

Chemical shifts and line separations were measured by keeping H_0 fixed and sweeping the frequency using a Hewlett-Packard frequency counter. Line intensities were measured using low r.f. power in H_1, and the mean of at least five readings was taken.

The samples were prepared by the slow addition of the pentafluoride or oxide to the solvent, which was cooled to moderate the very exothermic reactions. The fluorides of Nb, Ta, and Sb, which are sensitive to moisture, were exposed to the air only during sample preparation. Samples prepared in a dry-box gave identical spectra.

Measurements of pH were carried out using a Beckman model H2 pH meter with a fiber junction calomel reference electrode. The meter was frequently calibrated and the pH values are accurate to ±0.1 pH unit.

Addition of the pentafluorides of Nb, Sb, and Ta to the various solvents employed gave solutions with the properties described below.

Compound	Solvent	Solution properties
NbF_5	48% HF	Colorless
NbF_5	Ethanol	Pale brown if dilute; mauve if concentrated
NbF_5	Ether	Dense mauve oily layer fairly soluble in ether
NbF_5	Ethanolic triethylamine[7]	Pale brown from which white crystals separate in a few hours
SbF_5	48% HF	Pale brown
SbF_5	Ethanol	Olive green
SbF_5	Ether	Dense dark-brown oily layer
TaF_5	48% HF	Colorless
TaF_5	Ethanol	Pale brown
TaF_5	Ether	Dense brown-red oily layer fairly soluble in ether

ACKNOWLEDGMENT

We should like to express our thanks to Mr. G. Ensell for constructing the variable temperature apparatus used in the low-resolution studies.

SULFONIUM SALT SOLVOLYSIS

PART V. MODEL SYSTEMS FOR BIOLOGICAL TRANSMETHYLATION

JAMES B. HYNE AND JAMES H. JENSEN
Department of Chemistry, University of Alberta, Calgary, Alberta

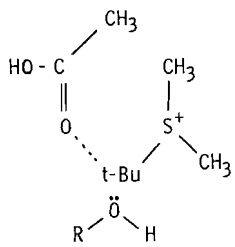
Received June 15, 1964

ABSTRACT

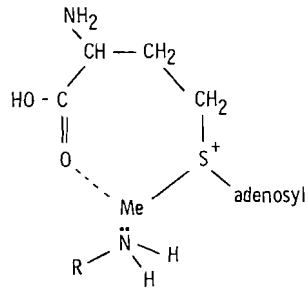
The rates of solvolysis of a series of sulfonium salts which may be considered as models for the biologically important sulfonium salt, S-adenosylmethionine, are discussed in terms of a possible anchimeric role of the carboxyl group of methionine in transmethylation reactions.

INTRODUCTION

In a previous paper in this series (1) the apparent enhancement of the nucleophilicity of the acetate anion in the solvolysis of dimethyl *t*-butyl sulfonium acetate in low-polarity solvents suggested the possibility of a similar role for the carboxylate group in biological transmethylations.



Possible participation in solvolysis



Possible participation in transmethylation

While transmethylation in the biological system normally involves S^+ to N transalkylation, the S^+ to O transalkylation in the solvolysis should be subject to similar assistance from an adjacent participating group, if such an effect is at all operative.

The comparison of the *t*-butyl and methyl group transfers requires explanation. By use of the *t*-butyl group as the transalkylating entity, competition from transfer of the other two groups on the sulfonium sulfur is eliminated. This exclusive transfer of the *t*-butyl entity in preference to either of the other functions was demonstrated by nuclear magnetic resonance (n.m.r.) studies of the products in selected cases. While transmethylation to nitrogen in the biological system cannot take place through a free methyl carbonium ion the possibility does exist for a free *t*-butyl carbonium ion in the solvolysis. However, in the low-polarity medium (0.75 mole fraction ethanol), the carbonium ion will be unstable and participation by such entities as an adjacent carboxyl group will be favored. If a *t*-butyl carbonium ion is envisaged, participation in its transfer by the carboxyl group could be envisaged as a very specific type of solvation if not actual covalent participation. The difference between the *t*-butyl and methyl cases is therefore one of degree of development of the δ^+ charge on the transferring alkyl group and participation might be expected to be operative in both cases.

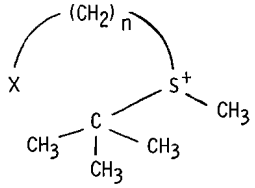
To investigate further this type of role for the carboxyl group in transalkylation reactions, we report here a rate study of a series of model compounds of the type:



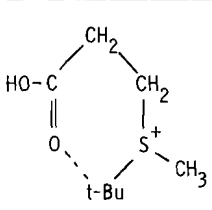
The function $X—(CH_2)_n—$ was varied by changing the value of n and by identifying X as methyl, carboxylic acid, and carboxylic ester groups.

RESULTS

The rate constants for the solvolysis (transalkylation to ROH) of the model sulfonium salts used are presented in Table I. These rate constants were obtained using a conductimetric technique with an initial concentration of the appropriate sulfonium iodide of 2×10^{-3} M in 0.750 mole fraction ethanol in water. The rate constants quoted in Table I are the average values of three determinations reproducible to better than $\pm 2\%$.

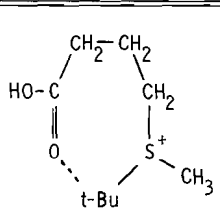
TABLE I

Rates of solvolysis of sulphonium iodides in 0.75 mole fraction ethanol-water at 60.00° (s^{-1})



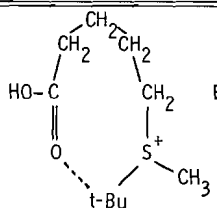
$k = 13.5 \times 10^{-4}$

I



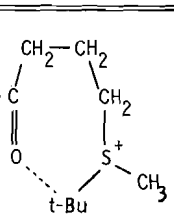
$k = 5.4 \times 10^{-4}$

II



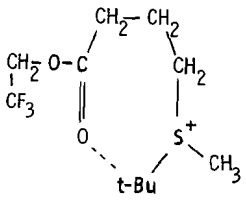
$k = 3.2 \times 10^{-4}$

III



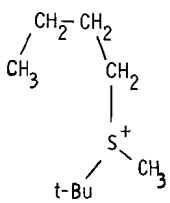
$k = 6.5 \times 10^{-4}$

IV



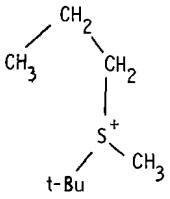
$k = 9.6 \times 10^{-4}$

V



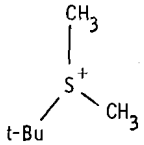
$k = 2.7 \times 10^{-4}$

VI



$k = 2.4 \times 10^{-4}$

VII

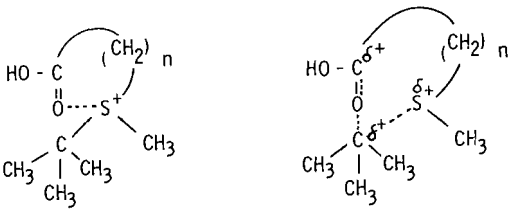


$k = 0.54 \times 10^{-4}$

VIII

DISCUSSION

It would appear from the rate data presented in Table I that the carboxyl group is significantly involved in the solvolysis of the model sulfonium salts. The carboxyl group may interact with the reactive center at the positively charged sulfur or with the developing positive charge at the *t*-butyl carbon atom:



If the predominant interaction of the carboxyl group is with the sulfonium sulfur, the initial state should be stabilized and the reaction rate reduced relative to the case where (X) is an alkyl group. If, on the other hand, the interaction is with the developing center of positive charge at the *t*-butyl carbon atom (i.e. anchimeric assistance) the transition state will be stabilized and the reaction rate should be relatively faster compared to that with an alkyl substituent. As can be seen from Table I the latter interpretation is favored since the apparent rate of solvolysis is increased 5.6 times when (X) is changed from methyl to carboxyl.

Assuming that the interaction of the carboxyl group assists in the delocalization of the developing positive charge on the tertiary carbon atom, it can be seen (Table I) that the rate of solvolysis of the carboxyl sulfonium salts are correlated with the size of the ring formed in the transition state of these sulfonium salts. Thus the solvolysis of the sulfonium salt which involves a six-membered ring, I, is 2.5 times the solvolysis rate of the sulfonium salt which must proceed through a seven-membered ring, II. Since III must form an eight-membered ring for similar participation in the transition state to be operative, the carboxyl group would not be expected to function in this manner to any large extent. In fact III solvolyzes only 20% faster than the alkyl sulfonium salt VI in which no COOH participation is possible.

It should be noted that in the simple hydrocarbon chains, where (X) is methyl, alkyl chain lengthening results in an increase in the rate of solvolysis (VIII < VII < VI). This may be due to a dominant entropy effect in these cases where no participation of the terminal entity of the alkyl chain can take place.

Under the conditions of the reaction the carboxyl group will be predominantly in the protonated form, and the anchimeric role of the carboxyl group is likely to be through the participation of the lone pairs of electrons on the carbonyl oxygen. Thus any factor which would increase the availability of these electrons should increase the amount of anchimeric assistance and therefore the rate of solvolysis of the sulfonium salt. Since the ethyl group would be expected inductively to donate electrons to the carboxyl group more readily than hydrogen, it is not surprising that the sulfonium salt with the ester substituent (IV) solvolyzes more rapidly than the corresponding acid (II).

In this case the substitution of the ethyl group for hydrogen also may give rise to a steric factor similar to the type found for the alkyl substituents. This type of explanation for the increase in rate of solvolysis for the ester group is also suggested in the case of the trifluoro ester, although differences in intramolecular inductive effects will also be important (see later). The salt V solvolyzes more rapidly than the hydrogen analogue, while the prediction based on electronegativity effects on the electron availability at the carboxyl oxygen would be a decrease in rate. Further work will be necessary to separate these various factors in the systems under study.

While the rationalization of the data to this point has been based upon an anchimeric assistance role for the various remote substituents, the possible effect of long range

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

intramolecular inductive influences cannot be unambiguously excluded. The magnitude of such effects, and in particular the manner in which they vary with the remoteness of the substituent from the reaction center, can be estimated using the Hammett-Taft type treatment, i.e. $\log k_X/k_H = \rho^*\sigma^*$ (2) Values for the appropriate ρ^* and σ^* constants are not available for the sulfonium salt systems under study here but values for $\log k_X/k_H$ can be calculated from the observed data as shown in Table II. The value of k_H for the case where two methylene groups are interposed between the COOH substituent and the reaction center is estimated from the rate values for the substituent one and three methylenes removed respectively, i.e., substrates VIII and VII. The highest possible value, namely that for VII is used in Table II. Inductive effects are frequently assumed to decrease by a factor of 1/2 per additional methylene interposed between substituent and reaction center (3). Depending upon the precise value of k_H for the case of two methylenes interposed, the decrease in $\log k_X/k_H$ and hence $\rho^*\sigma^*$ caused by increasing the number of CH_2 groups from two to three is *at least* of this magnitude and is probably larger. Increasing the number of methylenes interposed from three to four, however, results in a five-fold decrease, much larger than is predicted by the Hammett-Taft treatment. It should be noted that lack of knowledge of the appropriate values for ρ^* and σ^* in this argument is not restrictive since ρ^* is assumed constant for the reactions and hence the change in $\log k_X/k_H$ is a true measure of the change in the inductive effect σ^*. Our explanation of this observation is that in the substrates with two and possibly three interposed methylenes anchimeric assistance of the type discussed previously enhances the accelerating role of the substituent through the formation of more or less stable transient ring structures. Such participation is unlikely in the case of four interposed methylenes. The result of such additional anchimeric assistance in the case of two or three interposed methylenes will be to increase k_X and make the k_X/k_H ratios greater than predicted from purely inductive effects. While such an argument cannot be claimed to be conclusive evidence for the dominant role of anchimeric assistance it does indicate that long range inductive effects do not appear to account for all of the observed rate changes.

TABLE II

Rate ratios for COOH and unsubstituted sulfonium salts

Substrates compared	Number of interposed CH_2 groups	Log k_X/k_H	Rate change (decrease)
Estimated from VIII and VII vs. I	2	$\text{Log } \frac{13.5}{>2.4} > 0.75$	1/2
VII vs. II	3	$\text{Log } \frac{5.4}{2.4} = 0.35$	1/5
VI vs. III	4	$\text{Log } \frac{3.2}{2.7} = 0.07$	

This type of anchimeric assistance by a carboxyl function is not unusual; for example Winstein *et al.* (4) have shown that anchimeric assistance is important in the acetolysis of *trans*-2-acetoxycyclohexyl brosylate. It might be argued that in the present study the presence of the bulky *t*-butyl group might prevent participation of the type suggested. We are not, however, insisting that a covalent bond is formed between the carboxyl oxygen and the developing *t*-butyl carbonium ion, but rather that the ester or acid function is a good 'solvent' stabilizing the formation of the incipient carbonium ion. This may be

particularly important in view of the fact that the oxygen is in a preferred configuration for interaction compared with water or ethanol which must be taken from the surrounding solvation shell.

The effect of actually attaching the carboxyl group to the sulfonium salt, as opposed to having it available as a separate molecular entity, may be assessed by comparing the rate of solvolysis of the sulfonium salt I (13.5×10^{-4} s^{-1} at 60°) with the rate constant for the internal ion-pair attack by acetate ion ($1.5\text{–}3.0 \times 10^{-4}$ s^{-1} at 60°) as estimated from the value obtained in the previous paper of this series (1). The favorable entropy effect of actually attaching the participating acetate group to the reacting molecule results in a rate enhancement of some 4 to 8 times.

EXPERIMENTAL

Compounds which could be characterized by literature references were prepared by standard procedures and are listed below with the pertinent physical properties and references. Procedures for preparing new compounds are listed with the physical properties, analyses, and yields. Nuclear magnetic resonance spectra were obtained for all intermediate compounds and sulfonium salts using a Varian A-60 Spectrometer. These spectra (available on request) leave little doubt as to the nature of the products, although the analytical data for some of the sulfonium salts are not in as good agreement with theory as is normally expected. These discrepancies are probably due to the instability of the salts. The salts decomposed readily and were recrystallized immediately before use. All other reagents were "reagent grade" chemicals.

Previously Prepared Compounds

5-Bromopentanoic acid.—Boiling point 110–115° at 2 mm; lit. b.p. 125–131° at 6 mm (5). Yield 50%.

4-Bromobutanoic acid.—Boiling point 92–96° at 2 mm m.p. 31–31.5°, lit. m.p. 32° (6). Yield 90%.

3-Bromopropanoic acid.—Melting point 61–61.5°, lit. m.p. 59.5–61° (7), 62.5° (8). Yield 75%.

Ethyl-(4-bromo)-butanoate.—Boiling point 93–95° at 02 mm; lit. b.p. 96–100° at 20 mm (9), 85–87° at 14 mm (10). Yield 40%.

Dimethyl t-Butyl sulfonium iodide.—Melting point 160–160.5°, lit. m.p. 159–160.2° (11).

Intermediates

2,2,2-Trifluoroethyl-(4-bromo)-butanoate

An ether solution of 4-bromobutanoic acid was dropped into thionyl chloride (100% mole excess) and the mixture refluxed for 1 h, and distilled; b.p. of the acid chloride, 87–89° at 20 mm. The acid chloride was added to 2,2,2-trifluoroethanol (100% mole excess) over a period of 1 h at 0°. The solution was allowed to stand for 1 h at room temperature, then poured into water, extracted with ether, washed with water, sodium carbonate, and water, dried with Drierite, and distilled; b.p. 86–88° at 17 mm. Overall yield 45%.

t-Butyl-n-propyl Sulfide

Sodium hydroxide (0.22 mole) was dissolved in 50 ml of dry ethanol. The *t*-butyl mercaptan (0.11 mole) and then 1-bromopropane (0.1 mole) were added dropwise. The mixture was refluxed for 1 h and then one-half of the ethanol was removed by distillation. Water (50 ml) was added and the layers separated. The water layer was extracted twice with ether, the ether layers being added to the original organic layer. The ether solution was dried with Drierite, the ether removed, and the sulfide distilled; b.p. 133–136° at 660 mm. Yield 50%.

t-Butyl n-Butyl Sulfide

The same procedure as above, using sodium hydroxide (0.22 mole), *t*-butyl mercaptan (0.11 mole), and 1-bromobutane (0.1 mole), was followed; b.p. 159–164° at 660 mm. Yield 55%.

t-Butyl δ-Carboxy-n-butyl Sulfide

Sodium hydroxide (0.375 mole) was dissolved in 50 ml of dry ethanol. The *t*-butyl mercaptan (0.125 mole) and then 5-bromopentanoic acid (0.1 mole) were added dropwise. The mixture was refluxed for 1 h and then one-half of the ethanol was removed by distillation. Water (50 ml) was added and the layers separated. The water layer was extracted with ether twice to remove any ester which formed in the reaction. The water layer was acidified and extracted with ether twice. The ether solution was dried with Drierite, the ether removed, and the sulfide distilled under vacuum; b.p. 110–111° at 0.4 mm. Yield 40%.

t-Butyl γ-Carboxy-n-propyl Sulfide

The same procedure as above, using sodium hydroxide (0.375 mole), *t*-butyl mercaptan (0.125 mole), and 4-bromobutanoic acid (0.1 mole), was followed; b.p. 115–122° at 3 mm. Yield 45%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

t-Butyl β-Carboxyethyl Sulfide

The same procedure as above, using sodium hydroxide (0.375 mole), *t*-butyl mercaptan (0.125 mole), and 3-bromopropanoic acid (0.1 mole), was followed; b.p. 87–94° at 3 mm. Yield 45%.

t-Butyl γ-Carboethoxy-n-propyl Sulfide

Sodium hydroxide (0.25 mole) was dissolved in 50 ml of dry ethanol. The *t*-butyl mercaptan (0.125 mole) and the ethyl-(4-bromo)-butanoate (0.1 mole) were added dropwise. The mixture was refluxed for 1 h and then one-half of the ethanol was removed by distillation. Water (50 ml) was added and the layers separated. The water layer was extracted with ether. The organic layers were combined and washed with water, dried with Drierite, the ether removed, and the sulfide distilled; b.p. 93–97° at 2 mm. Yield 35%.

t-Butyl Carbo-(β,β,β-trifluoro)-ethoxy-n-propyl Sulfide

The same procedure as above, using sodium hydroxide (0.25 mole), *t*-butyl mercaptan (0.125 mole), and 2,2,2-trifluoroethyl-(4-bromo)-butanoate (0.1 mole), was followed; b.p. 120–122° at 2 mm. Yield 45%.

New Sulfonium Salts

Methyl t-Butyl n-Propyl Sulfonium Iodide (VII)

Methyl iodide (10% mole excess) was added to *t*-butyl *n*-propyl sulfide and allowed to stand for 6 h. The resulting mass was recrystallized three times by dissolving the salt in warm ethanol and then adding sufficient ether to turn the solution cloudy. The solution was then placed in the freezer until precipitation was complete. The solution yielded a white crystalline solid, 60%; m.p. 115.5–116°.

Anal. Calcd. C, 35.04; H, 6.98; S, 11.6. Found: C, 35.28; H, 7.11; S, 11.6.

Methyl t-Butyl n-Butyl Sulfonium Iodide (VI)

Methyl iodide (10% mole excess) was added to *t*-butyl *n*-butyl sulfide and allowed to stand for 6 h. The resulting mass was recrystallized four times from an ethanol–ether mixture as described previously. The mixture yielded a white crystalline solid, 45%; m.p. 96–97°.

Anal. Calcd. C, 37.50; H, 7.34; S, 11.1. Found: C, 37.63; H, 7.47; S, 11.1.

Methyl t-Butyl δ-Carboxy-n-butyl Sulfonium Iodide (III)

Methyl iodide (20% mole excess) was added to *t*-butyl δ-carboxy-*n*-butyl sulfide and allowed to stand for 4 h. The resulting mass was recrystallized three times from an ethanol–ether mixture as described previously. The mixture yielded a white crystalline solid, 35%; m.p. 106.5–107°.

Anal. Calcd. C, 36.15; H, 6.47; S, 9.65. Found: C, 37.37; H, 6.27; S, 9.51.

Methyl t-Butyl γ-Carboxy-n-propyl Sulfonium Iodide (II)

Methyl iodide (20% mole excess) was added to *t*-butyl γ-carboxy-*n*-propyl sulfide and allowed to stand for 4 h. The resulting mass was recrystallized four times from an ethanol–ether mixture as described previously. The mixture yielded a white crystalline solid, 25%; m.p. 116.5–117.5°.

Anal. Calcd. C, 33.97; H, 6.02; S, 10.08. Found: C, 34.19; H, 6.16; S, 9.65.

Methyl t-Butyl β-Carboxyethyl Sulfonium Iodide (I)

Methyl iodide (20% mole excess) was added to *t*-butyl β-carboxyethyl sulfide and allowed to stand for 3 h. The resulting mass was recrystallized three times from an ethanol–ether mixture as previously described. The mixture yielded a white crystalline solid, 25%; m.p. 87.5–89°.

Anal. Calcd. C, 31.59; H, 5.63; S, 10.5. Found: C, 30.11; H, 6.09; S, 9.68.

Methyl t-Butyl γ-carboethoxy-n-propyl Sulfonium Iodide (IV)

Methyl iodide (20% mole excess) was added to *t*-butyl γ-carboethoxy-n-propyl sulfide and allowed to stand for 2 h. The resulting mass was recrystallized three times from an ethanol–ether mixture as previously described. The mixture yielded a slightly yellow crystalline solid, 15%; m.p. 84.5–85°.

Anal. Calcd. C, 38.15; H, 6.70; S, 9.26. Found: C, 38.39; H, 6.65; S, 8.51.

Methyl t-Butyl γ-Carbo-(β,β,β-trifluoro)-ethoxy-n-propyl Sulfonium Iodide (V)

Methyl iodide (20% mole excess) was added to *t*-butyl γ-carbo-(β,β,β-trifluoro)-ethoxy-n-propyl sulfide and allowed to stand for 2 h. The resulting mass was recrystallized four times from an ethanol–ether mixture as previously described. The mixture yielded a slightly yellow crystalline solid, 15%; m.p. 84–84.5°.

Anal. Calcd. C, 33.01; H, 5.04; S, 8.01. Found: C, 33.48; H, 5.22; S, 7.44.

Solvents

Ethanol, Reliance Chemicals "100 per cent" grade was dried with magnesium turnings and distilled; n_{20}^{D} = 1.3606, lit. n_{20}^{D} = 1.3614 (12).

The water used was doubly distilled, with conductance less than 5×10^{-7} mhos.

Rate Determinations

The rate constants were measured conductimetrically using an a-c. bridge at 1 100 c.p.s. as described by Robertson. (13)

THE COPPER(II) *SYN*-PHENYL-2-PYRIDYL KETOXIME SYSTEM

PART I[1]

T. L. MEEK AND G. E. CHENEY
Department of Chemistry, Acadia University, Wolfville, Nova Scotia

Received July 13, 1964

ABSTRACT

A survey has been made of the reactions of both geometric isomers of phenyl-2-pyridyl ketoxime with metal ions. The complexes of copper(II) with the *syn*-phenyl isomer have been investigated. Acid dissociation constants of both geometric isomers, and of the 2:1 copper chelate of the *syn*-phenyl oxime have been determined.

INTRODUCTION

Since the initial report on dimethylglyoxime by Tschugaeff (1), the *vic*-dioximes have been studied extensively (2–4) as analytical reagents, and many workers (5–11) have investigated the thermodynamic stability of the chelates of some of these ligands. The abnormally short, strong intramolecular O—H—O bonds known (12, 13) to exist in the copper(II) and nickel(II) chelates of certain *vic*-dioximes are believed to contribute much to the unusual properties of these chelates. Many observers feel that the nature of these hydrogen bonds can be more conveniently studied by employing ligands which coordinate through one oxime nitrogen and one amine-type nitrogen. Reagents of this type which have been studied include 2-methyl-2-amino-3-butanone oxime and some of its N-substituted derivatives (14, 15) and pyridine 2-aldoxime (16–21).

Phenyl-2-pyridyl ketoxime has long been known to act as a chelating agent (22, 23) and has been used as an analytical reagent for various metal ions (24–28). The compound can exist in two isomeric forms, i.e. the phenyl ring may be *syn*- or *anti*- to the oxime group. Vassian and Murmann (29) have reported that the interconversion of the *syn*- and *anti*-isomers is very slow ($t_{\frac{1}{2}} > 4\,000$ min) in 1 *M* acid or alkali at 25 °C and have shown that no appreciable rearrangement occurs in solution at low temperatures. No quantitative work has been reported as yet on the equilibria pertaining to the chelation reactions of this ligand, nor have the structures of its chelates been firmly elucidated. It was thought desirable to conduct such a study, for purposes of comparison with pyridine 2-aldoxime and with the *vic*-dioximes. Therefore, following a qualitative investigation of the reactions of both geometric isomers of the ligand with numerous metal ions, the reaction of copper(II) with the *syn*-phenyl oxime was studied by potentiometric, spectrophotometric, and liquid–liquid extraction techniques.

This report is the first of a series pertaining to the reactions between *syn*-phenyl-2-pyridyl ketoxime and metal ions.

EXPERIMENTAL

Apparatus and Procedures

Potentiometric titrations were conducted on *syn*- and *anti*-phenyl-2-pyridyl ketoxime and on the copper(II) chelates of the former. The apparatus and general procedure employed are identical to those described by Haines (8). The titrant used was 0.1 *N* sodium hydroxide; the solvent system was 50 volume % dioxane–water. All titrations were performed in the presence of a known amount of perchloric acid. Varying mole ratios of ligand to metal were employed.

[1]*This work is taken from the thesis submitted by T. L. Meek to Acadia University in partial fulfillment of the requirements for the M.Sc. degree in Chemistry, April 1964.*

The acid dissociation constants of the *syn*-phenyl oxime were determined spectrophotometrically by the procedure of Flexser *et al.* (30) and by liquid–liquid extraction, using a water-anhydrous chloroform system, after the method of Jankowski and Freiser (31). The buffer solutions used were made up at an initial ionic strength of 2.0 by the addition of sodium chloride; thus after 1:1 dilution, the equilibria studied were occurring in water with an ionic strength of 1.0. All spectrophotometric measurements were taken on a Beckman model DU quartz spectrophotometer equipped with a photomultiplier attachment. Matched 1.00 cm silica cells, calibrated at the wavelengths of interest, were used. The cell compartment was equipped with thermospacers. All pH measurements were taken on a Radiometer pHM4C pH meter equipped with a saturated calomel-Beckman type E2 glass electrode pair. Both absorbance and pH measurements were made at 25.0 ± 0.1 °C.

Analyses

Microanalyses for carbon, hydrogen, and nitrogen were conducted by the Schwarzkopf Microanalytical Laboratories in Woodside, N.Y. The copper analyses were done iodometrically; the chloride analyses were done argentimetrically. In both cases the organic matter was destroyed by mild digestion with warm nitric acid.

Reagents

The two isomers of phenyl-2-pyridyl ketoxime were prepared, separated, and purified after the method of Huntress and Walter (32). The melting point of the *syn*-phenyl isomer was 153.0–153.5 °C; that of the *anti*-phenyl form was 167.0–167.5 °C. (Literature values (32) 150.5–152.5 °C and 165–167 °C respectively.)

The purity of each isomer was determined by potentiometric titration with perchloric acid in glacial acetic acid; in both cases the value obtained was 100.0 ± 0.2%.

Dichloro (syn-Phenyl-2-pyridyl Ketoxime) Copper(II)

Cupric chloride dihydrate (2 g, 0.012 mole) was dissolved in 10 ml of 1:3 hydrochloric acid. To this solution was added 2.5 g (0.0125 mole) of *syn*-phenyl-2-pyridyl ketoxime in 50 ml of 1:3 hydrochloric acid. A bright green precipitate appeared immediately; it was allowed to stand overnight, then filtered off on a glass frit and dried first *in vacuo*, then at 110 °C.

Anal. Calcd. for $Cu(C_{12}H_{10}N_2O)Cl_2$: C, 43.3; H, 3.0; N, 8.4; Cu, 19.1; Cl, 21.3. Found: C, 44.0; H, 3.1; N, 8.4; Cu, 19.2; Cl, 21.2.

Bis (syn-Phenyl-2-pyridyl Ketoxime) Copper(II) Dichloride

Cupric chloride dihydrate (2 g, 0.012 mole) dissolved in 20 ml of 2 *M* sodium chloride was added to a solution of 5 g (0.025 mole) of *syn*-phenyl-2-pyridyl ketoxime in 200 ml of 1:100 hydrochloric acid. The dark green precipitate was allowed to stand overnight, then collected on a glass frit and dried first *in vacuo*, then at 110 °C.

Anal. Calcd. for $[Cu(C_{12}H_{10}N_2O)_2]Cl_2$: C, 54.3; H, 3.8; N, 10.6; Cu, 12.0; Cl, 13.4. Found: C, 54.6; H, 3.7; N, 10.8; Cu, 12.0; Cl, 12.5.

Monohydrogen Bis (syn-Phenyl-2-pyridyl Ketoximato) Copper(II) Chloride

Cupric chloride dihydrate (2 g, 0.012 mole) was dissolved in 100 ml of 1 *M* sodium chloride and placed in a 500 ml extraction flask. A solution of 4.7 g (0.024 mole) of *syn*-phenyl-2-pyridyl ketoxime in 250 ml of chloroform was added. After equilibration, the dark green chloroform phase was drawn off and the aqueous phase was treated with 50 ml aliquots of chloroform until the organic extract was colorless. The combined extracts were boiled to dryness, and the dark green solid was dried first *in vacuo*, then at 110 °C.

Anal. Calcd. for $[Cu(C_{12}H_9N_2O)_2H]Cl$: C, 58.3; H, 3.9; N, 11.3; Cu, 12.9; Cl, 7.2. Found: C, 57.9; H, 4.0; N, 11.0; Cu, 12.4; Cl, 7.0.

Monohydrogen Bis (syn-Phenyl-2-pyridyl Ketoximato) Copper(II) Perchlorate

Cupric perchlorate hexahydrate (2 g, 0.0054 mole) was dissolved in 100 ml of 1 *M* sodium perchlorate. A solution of 2.6 g (0.013 mole) of *syn*-phenyl-2-pyridyl ketoxime in 100 ml of 95% ethanol was added and the dark green precipitate was allowed to stand overnight. The solid was collected on a glass frit and dried first *in vacuo*, then at 110 °C.

Anal. Calcd. for $[Cu(C_{12}H_9N_2O)_2H]ClO_4$: C, 51.6; H, 3.4; N, 10.0; Cu, 11.4. Found: C, 48.7; H, 3.3; N, 9.3; Cu, 11.4.

Di-(μ-hydroxo) Monohydrogen Bis [syn-Phenyl-2-pyridyl Ketoximato Copper(II)] Perchlorate

Cupric perchlorate hexahydrate (2 g, 0.0054 mole) dissolved in 100 ml of 1 *M* sodium perchlorate was treated with a solution of 1.0 g (0.005 mole) of *syn*-phenyl-2-pyridyl ketoxime in 100 ml of 95% ethanol. The dark green precipitate was allowed to stand overnight then collected on a glass frit and dried first *in vacuo*, then at 110 °C.

Anal. Calcd. for $[[Cu(C_{12}H_9N_2O)]_2H(OH)_2]ClO_4$: C, 43.9; H, 3.2; N, 8.5; Cu, 19.3. Found: C, 43.5; H, 3.1; N, 8.9; Cu, 20.3.

Bis (syn-Phenyl-2-pyridyl Ketoximato) Copper(II)

Cupric perchlorate hexahydrate (5 g, 0.014 mole) was dissolved in 50 ml of water and added to a solution of 6.5 g (0.033 mole) of *syn*-phenyl-2-pyridyl ketoxime in 500 ml of 2 *N* sodium hydroxide. The dark red-brown precipitate was allowed to stand overnight, then collected on a glass frit and dried first *in vacuo*, then at 110 °C.

Anal. Calcd. for $Cu(C_{12}H_9N_2O)_2$: C, 62.9; H, 4.0; N, 12.2; Cu, 13.9. Found: C, 59.5; H, 4.1; N, 11.1; Cu, 14.2.

RESULTS AND DISCUSSION

Preliminary Investigations

The behavior of both geometric isomers of phenyl-2-pyridyl ketoxime toward various metal ions was observed at pH values of 5, 8, and 12 by the procedure of Irving, Butler, and Ring (33). The results indicated that the *syn*-phenyl isomer forms colored complexes, extractable into chloroform, with many transition metal ions; the *anti*-phenyl oxime did not react visibly with any of the metal ions tested.

The stoichiometry of the copper chelate of the *syn*-phenyl isomer was determined by the mole ratio method of Yoe and Jones (34). The results (Fig. 1) indicated that both a 1:1 and a 2:1 chelate are formed.

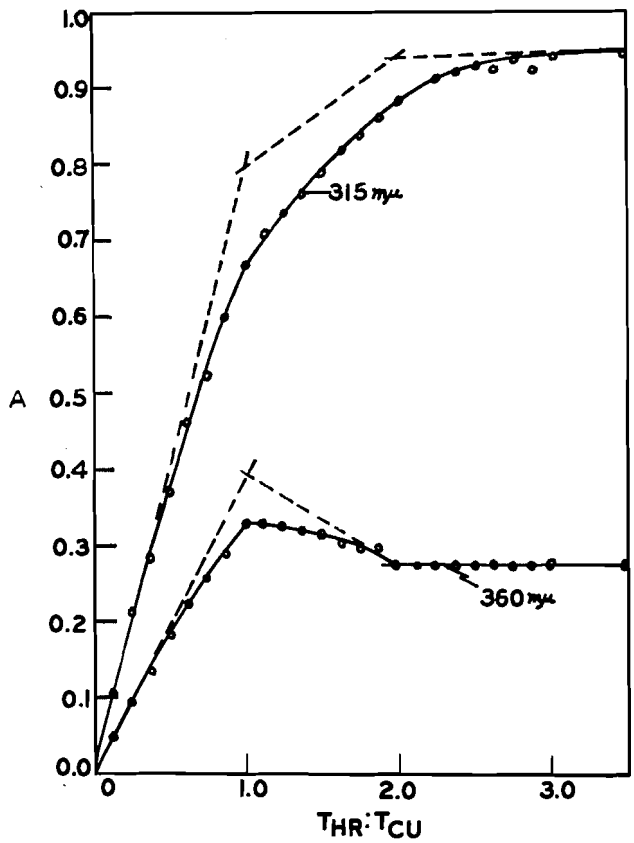

FIG. 1. Mole ratio plots, *syn*-phenyl-2-pyridyl ketoxime and copper(II); aqueous solution, $\mu = 0.1$ — pH = 5.5; A = absorbance; $T_{HR}:T_{Cu}$ = mole ratio of ligand to metal; $T_{Cu} = 8.0 \times 10^{-5}$ *M*; — experimentally obtained curve; – – extrapolated linear segments of experimental curve.

Acid Dissociation of the Reagents

The dissociation of either isomer of the ketoxime can be represented by the equilibria:

$$H_2R^+ \rightleftharpoons HR + H^+; \quad K_1 = \frac{[H^+][HR]}{[H_2R^+]}$$

$$HR \rightleftharpoons R^- + H^+; \quad K_2 = \frac{[H^+][R^-]}{[HR]},$$

where HR represents the neutral reagent molecule. The first dissociation refers to the protonated pyridine nitrogen atom, the second to the oxime group. The corresponding buffer regions do not overlap, so that K_1 and K_2 may be considered separately. The values obtained for pK_1 and pK_2 for each isomer are listed in Table I, together with values for structurally related compounds included for comparative purposes.

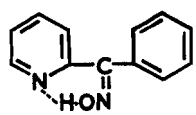
The protonated form of the *anti*-phenyl oxime was found to be somewhat more acidic ($pK_1 = 2.30$ in 50% dioxane–water) than is that of the *syn*-phenyl isomer ($pK_1 = 2.86$ in 50% dioxane–water). Furthermore the neutral form of the *anti*-phenyl isomer is slightly less acidic ($pK_2 = 12.65$) than is that of the *syn*-phenyl isomer ($pK_2 = 12.46$). This can be explained by the existence of a weak N—H hydrogen bond in the uncharged form of the *anti*-phenyl oxime; its structure could be represented by



This is analogous to the well-known effect of hydrogen bonding on the acidities of *cis-trans* isomers of α-dicarboxylic acids, first observed by Jones and Soper (35). A similar structure was proposed by Krause, Busch, and Colthup (17) for pyridine 2-aldoxime, on the basis of an infrared spectrophotometric examination.

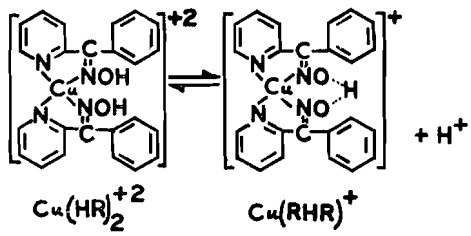
The differences between the acid dissociation constants of the *syn*-phenyl oxime in water and in 50% dioxane are in the direction that would be anticipated from consideration of the relative polarities of the two solvents. The values determined by spectrophotometry ($pK_1 = 3.84$; $pK_2 = 10.71$), and by liquid–liquid extraction ($pK_1 = 3.90$; $pK_2 = 10.71$) in the same solvent medium, are in good agreement.

The differences in acidity between *syn*-phenyl-2-pyridyl ketoxime and related compounds can be explained on the basis of structural differences. Consideration of the values listed in Table I reveals that both the pyridine ring and the oxime group are electron-withdrawing and tend to increase the acidity of conjugated functional groups, whereas the phenyl ring is electron-contributing and would cause the opposite effect. Thus the pyridinium nitrogen atom in *syn*-phenyl-2-pyridyl ketoxime would be expected to be considerably more acidic than the corresponding atom in pyridine. The difference in pK_{NH} between the ketoxime and pyridine-2-aldoxime can be attributed in part to the partial satisfaction of the electronegativity of the oxime group by the phenyl ring in the ketoxime and, in part, to the large differences in ionic strengths of the solutions in question. The relatively high pK_{NOH} of the ketoxime may be attributed to the electron-contributing properties of the phenyl ring.

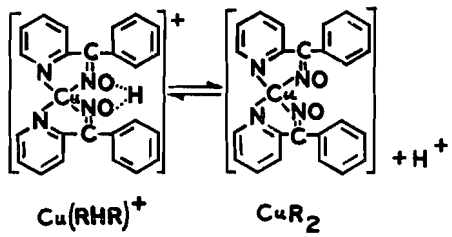
Copper Chelates, Potentiometric Study

The formation constants of the copper(II) – *syn*-phenyl-2-pyridyl ketoxime system could not be evaluated by potentiometric titration because the highest complex was completely formed prior to the addition of alkali under the experimental conditions employed. Further evidence to support the complete formation of the 2:1 *syn*-phenyl-2-pyridyl ketoxime – copper(II) complex at low pH values (pH < 2.5) may be derived from the fact that the complex $Cu(HR)_2Cl_2$ was isolated from 0.1 *M* hydrochloric acid, and an attempt to isolate the corresponding perchlorate complex $Cu(HR)_2(ClO_4)_2$ from 1.0 *M* $HClO_4$ resulted in the precipitation of the species $Cu(RHR)ClO_4$.

In the potentiometric titrations of *syn*-phenyl-2-pyridyl ketoxime in the presence of copper(II) (Fig. 2), two equivalence points corresponding to the neutralization of all the perchloric acid plus one and two protons per molecule of chelate were obtained when the ligand-to-metal mole ratio exceeded 2:1. Therefore, the equilibrium constants K_I and K_{II}, defined by the relations



$$K_I = \frac{[Cu(RHR)^+][H^+]}{[Cu(HR)_2^{+2}]},$$



$$K_{II} = \frac{[CuR_2][H^+]}{[Cu(RHR)^+]},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

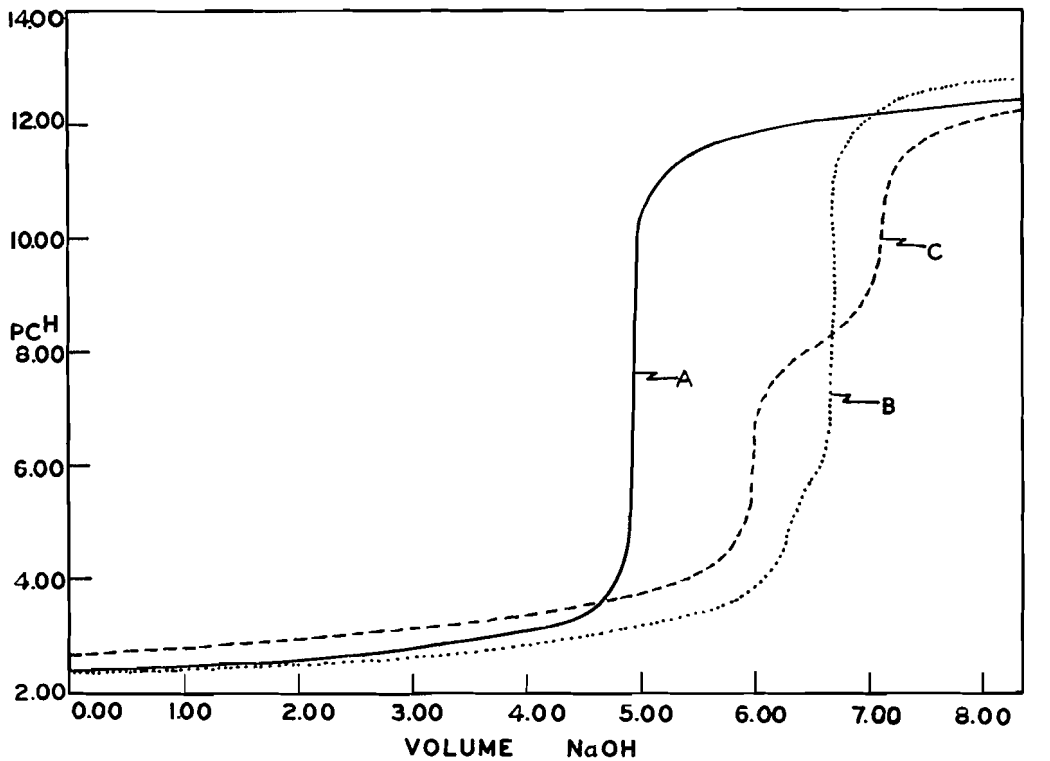


FIG. 2. Titration curves of *syn*-phenyl-2-pyridyl ketoxime and 0.50 mmole $HClO_4$, with 0.10 *N* NaOH in 50% v/v dioxane–water at 25 °C; A = 0.25 mmole HR; B = 0.10 mmole HR, 0.10 mmole copper(II); C = 0.70 mmole HR, 0.10 mmole copper(II).

could be evaluated by separately considering the first and second buffer regions, respectively.

If $\bar{n}_H$ is defined as the number of protons bound per molecule of chelate, it may be shown that, in the first buffer region,

$$[1] \qquad pK_I = p_cH - \log \frac{2 - \bar{n}_H}{\bar{n}_H - 1},$$

while in the second buffer region,

$$[2] \qquad pK_{II} = p_cH - \log \frac{1 - \bar{n}_H}{\bar{n}_H}.$$

The values obtained for pK_I and pK_{II} corresponding to each ligand-to-metal mole ratio employed are listed in Table II, together with other relevant titration data.

The values of pK_I are somewhat questionable, since the dissociation occurs at a very low pH. Thus the number of protons released is very small compared with the total number present, and cannot be measured accurately. Furthermore, the free ligand HR is a stronger base than is $Cu(RHR)^+$, so that when the ligand-to-metal ratio is high, a pseudo-buffer system may be established due to the equilibrium.

$$Cu(HR)_2^{+2} + HR \rightleftharpoons Cu(RHR)^+ + H_2R^+.$$

TABLE II

Titration data for 2:1 *syn*-phenyl-2-pyridyl ketoxime Copper(II) complex

Mole ratio $T_{HR} : T_{Cu}$	pH at $\bar{n}_H = 1.0$	pH at $\bar{n}_H = 0.5$	pH at start of precipitation	pK_I	pK_{II}
2.02:1	5.12	7.24	7.57	2.2_5	7.2_0
2.99:1	5.79	7.65	8.07	1.7_9	7.7_3
3.04:1	5.98	7.86	—	2.3_8	7.9_2
5.10:1	6.85	8.09	—	2.7_4	8.1_2
7.04:1	6.16	8.06	—	2.7_0	8.0_5
9.92:1	6.25	8.02	—	2.6_4	8.0_0

This is reflected in a virtually constant value of $\bar{n}_H$ over the first 60–80% of the first buffer region when the ligand-to-metal ratio was greater than 5:1.

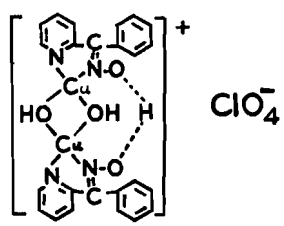
The values calculated for pK_{II} increased with increasing ligand-to-metal mole ratio until the latter reached 5:1, then remained essentially constant at a value of 8.0–8.1. At ratios of less than 3:1 a green precipitate appeared near the end of the second buffer region, while at ratios greater than 3:1 the solution gradually turned from green to red–brown beyond the first equivalence point. These phenomena are believed due to the polymerization of the sparingly soluble green species CuR_2 to the red–brown polymer $(CuR_2)_n$. As a result of this polymerization reaction, eq. [2] no longer describes the system accurately under conditions which permit the reaction, and cannot be used to evaluate pK_{II}.

Thus it appears that, with respect to both K_I and K_{II}, the values obtained at a ligand-to-metal mole ratio of 2:1 are most reliable.

The very large difference between K_I and K_{II}, both of which may be attributed to the dissociation of a coordinated oxime group, can be accounted for by the existence of a very strong O···H—O bond, analogous to those in the copper(II) and nickel(II) dimethyl glyoxime chelates, in the species $Cu(RHR)^+$. Similar effects have been observed by Murmann (15) with certain aliphatic amine oximes and by other workers (20, 21) with pyridine 2-aldoxime.

The acidity of the oxime group, as measured by the acid dissociation constants, increased markedly on chelation. Such an increase in the acidity of a functional group conjugated with a metal ion in a chelate is a very common effect (20, 21, 36, 37). It would be expected to be very pronounced in this situation inasmuch as the metal ion is directly bonded to the functional group in question.

In the titrations conducted at a ligand-to-metal mole ratio of slightly less than 1:1, the two equivalence points (Fig. 2) correspond to the neutralization of the perchloric acid plus 1.25 and 1.6 protons per ligand molecule. The complex $[(CuRHCuR)(OH)_2]ClO_4$ which could give the structure

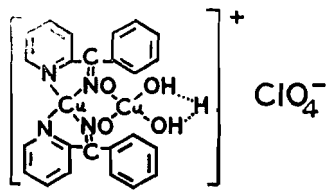


and corresponds to a complex isolated from a similar medium (see Experimental), would necessitate a loss of three protons per molecule of complex overall, or 1.5 per ligand

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

molecule. The position of the equivalence points implies that an olation process (which would require the loss of one proton per ligand molecule) occurs first, followed by the formation of the hydrogen bond (which requires the loss of 0.5 proton per ligand molecule); it also indicates that some overlap between these steps occurs. Similar bridged structures have been proposed by Murmann (15) for the species $[(CuAO')_2—H)(OH)_2]^+ClO_4^-$, where AO′ represents an N-substituted aliphatic amine oxime. Krause *et al.* (18) have postulated similar structures for palladium(II) complexes as $(PdPOX)_2Cl_2$ where POX represents the anion of pyridine-2-aldoxime.

The polynuclear structure



similar to that proposed by Liu and Liu (38) for certain copper(II) chelates of pyridine-2-aldoxime also corresponds to the analytical results. However, if it may be assumed that the stability of the species $Cu(RHR)^+$ is greater than that of the polynuclear complex, the formation of $Cu(RHR)^+$ as an intermediate would be required. This would cause an equivalence point corresponding to the neutralization of perchloric acid plus 0.5 protons per ligand molecule. The absence of such an equivalence point indicates that the species $Cu(RHR)^+$ is not formed, hence that the polynuclear structure need not be considered; it also implies that the 1:1 chelate is formed exclusively, hence that the first formation constant in this system is considerably greater than the second.

Copper Chelates, Liquid–Liquid Extraction Study

An attempt was made to study the extraction of copper(II) into chloroform by *syn*-phenyl-2-pyridyl ketoxime, employing a spectrophotometric analysis of the organic phase after 48 h equilibration at 25.0 °C. However, it proved impossible to determine the formation constant or the acid dissociation constants of the 2:1 copper chelate by this method, since both species $Cu(HR)_2Cl_2$ and $Cu(RHR)Cl$ were extractable into chloroform under the conditions employed; thus the distribution ratios could not be evaluated. Nevertheless, the data given in Table III yield some qualitative information. The increased absorbance of the organic phase with an increase in either pH or $T_{HR}:T_{Cu}$ can be interpreted in both instances as due to the conversion of $Cu(HR)_2^{+2}$ to the more strongly absorbing species $Cu(RHR)^+$. In the former case this would result from simple acidic dissociation, in the latter from the equilibrium

$$Cu(HR)_2^{+2} + HR \rightleftharpoons Cu(RHR)^+ + H_2R^+.$$

At pH values above 5.5, the red–brown polymeric species $(CuR_2)_n$ was extracted.

CONCLUSIONS

If a strongly acidic solution of copper(II) and *syn*-phenyl-2-pyridyl ketoxime at a ligand-to-metal ratio of 1:1 is neutralized, the sequence of equilibria may be represented by

[A1] $$H_2R^+ \rightleftharpoons HR + H^+$$

[A2] $$Cu^{+2} + HR \rightleftharpoons Cu(HR)^{+2}$$

5.36	0.426		

*In each case, the aqueous phase was prepared by mixing 10.0 ml of 2.132×10^{-3} *M* copper perchlorate and 10.0 ml of 0.2055 *M* sodium chloride. The pH was adjusted with hydrochloric acid. This solution was treated with 20.0 ml of a solution of *syn*-phenyl-2-pyridyl ketoxime in anhydrous chloroform. The absorbance of the organic phase was measured against anhydrous chloroform after 48 h equilibration at 25.0 °C.

[A3] $$2Cu(HR)^{+2} + 2H_2O \rightleftharpoons Cu(HR)_2(OH)_2^{+2} + 2H^+$$

[A4] $$Cu(HR)_2(OH)_2^{+2} \rightleftharpoons CuRHCuR(OH)_2^{+} + H^+,$$

in which the third and fourth steps are proposed to account for the stoichiometry as evidenced by Fig. 2, and it is probable that these equilibria are not completely distinct, or separable.

When the ligand-to-metal ratio is greater than 3:1, the equilibrium sequence may be represented by

[B1] $$H_2R^+ \rightleftharpoons H^+ + HR$$

[B2] $$Cu^{+2} + HR \rightleftharpoons Cu(HR)^{+2}$$

[B3] $$Cu(HR)^{+2} + HR \rightleftharpoons Cu(HR)_2^{+2}$$

[B4] $$Cu(HR)_2^{+2} \rightleftharpoons Cu(RHR)^+ + H^+$$

[B5] $$Cu(RHR)^+ \rightleftharpoons CuR_2 + H^+$$

[B6] $$nCuR_2 \rightleftharpoons (CuR_2)_n,$$

while at ratios between 2:1 and 3:1 the same sequence occurs, with the exception of the last step, [B6].

The formation constants of the chelates $Cu(HR)^{+2}$ and $Cu(HR)_2^{+2}$ could not be evaluated due to the very low pH at which the corresponding equilibria occur. The coexistence of two or more species throughout most of the experimental pH range made it difficult to determine the molar absorptivities of any of the species of interest; thus the evaluation of K_I and K_{II} by spectroscopic methods was precluded. Similarly, the simultaneous extraction of more than one species into chloroform imposed great difficulties on the use of liquid–liquid extraction techniques for this purpose.

The sequence of reactions outlined above raises the question as to whether the reactions between dimethylglyoxime and metal ions could not be more readily represented by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[C1] $$M^{+2} + HD \rightleftharpoons M(HD)^{+2}$$

[C2] $$M(HD)^{+2} + HD \rightleftharpoons M(HD)_2^{+2}$$

[C3] $$M(HD)_2^{+2} \rightleftharpoons MD_2 + 2H^+,$$

than by the commonly accepted sequence

[D1] $$HD \rightleftharpoons H^+ + D^-$$

[D2] $$M^{+2} + D^- \rightleftharpoons MD^+$$

[D3] $$MD^+ + D^- \rightleftharpoons MD_2,$$

particularly in view of the fact that complexes of the type $Ni(HD)_2Cl_2$ and $Ni(HD)Cl_2$ have been isolated (39, 40). This would invalidate all the previously derived formation constants for MD_2 and the chelates of other *vic*-dioximes, as the presence of charged chelates of the type $M(HD)_{1\rightarrow n}^{+n}$ was not considered in their determination; the reactions [D2] and [D3], to which these constants apply, do not actually represent the formation of the chelates, as do reactions [C1] and [C2]. An investigation of the copper(II)- and nickel(II)-dimethylglyoxime systems is presently in progress.

The structures of the polymer $(CuR_2)_n$, and of the 1:1 bridged complex $[(CuRHCuR)(OH)_2]ClO_4$, are only postulates at this time, but are currently the subject of further study, as is the mechanism of the polymerization reaction. Potentiometric titration data indicates that a 3:1 (or greater) ligand-to-metal mole ratio is a prerequisite for the formation of the polymer, and (Table III) that the reaction occurs at a higher pH than that required to titrate the hydrogen-bonded proton in the species $Cu(RHR)^+$. In addition, an investigation of the infrared and electronic spectra of all the isolated compounds as an aid in structural interpretations is currently under way.

CORRELATIONS OF PROTON COUPLING CONSTANTS IN THE CYCLOPROPANE RING WITH ELECTRONEGATIVITY

CONSIDERATION OF THE PROTON RESONANCE SPECTRUM OF CYCLOPROPYLLITHIUM

T. SCHAEFER, F. HRUSKA,[1] AND G. KOTOWYCZ[2]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received June 4, 1964

ABSTRACT

The analysis of cyclopropyllithium allows estimates to be made of all proton coupling constants. The exceptionally small couplings across carbon atoms 2 and 3 are examined in the context of correlations of coupling constants with the electronegativities of substituents. It is concluded that, although the couplings involving protons attached to the same carbon as the substituent decrease with increasing electronegativity of the substituent, the opposite is true for couplings involving the protons attached to carbons one bond removed from the substituent. Individual values are suggested for the coupling constants in cyclopropane itself and these agree with the observed ^{13}C side bands in its proton spectrum.

INTRODUCTION

A recent publication (1) gives the proton resonance spectrum of cyclopropyllithium in tetrahydrofuran. This spectrum is an example of an A_2B_2X system (2–4) but it appears to be very nearly a first-order spectrum. In view of the known values of proton coupling constants in the cyclopropane ring (5–10) and in view of our experience with first-order A_2B_2X spectra (3, 4), this is very curious. It can immediately be said that the coupling between the A and B protons in the CH_2CH_2 moiety must be not more than a cycle or two in order to give the observed spectrum (3, 4). This is rather unexpected.

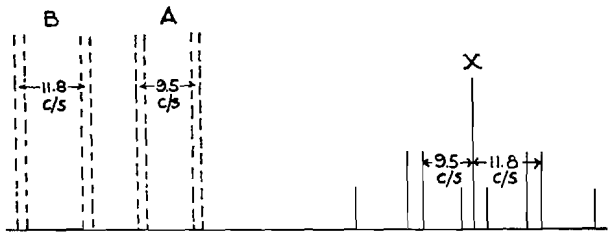
Moreover, from the correlation observed by Williamson between coupling constants and electronegativity in monosubstituted 1,1-dichlorocyclopropanes, quite different values of these couplings would be predicted at first (11). We propose to clarify this situation by showing below that the coupling between A and B protons in cyclopropyllithium is indeed small and that correlations of cyclopropyl coupling constants with electronegativity show a behavior which has not yet been noticed. Furthermore, we deduce values for all the proton coupling constants in cyclopropane itself which should be accurate to about 0.5 c/s.

The Proton Resonance Spectrum of Cyclopropyllithium

1. The Observed Spectrum

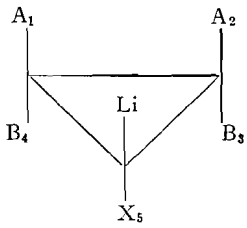
The A_2B_2 region* consists of two doublets centered at −0.46 p.p.m. and +0.05 p.p.m. with respect to internal tetramethylsilane (1). The doublet at −0.46 p.p.m. has a splitting of 11.8 c/s while that at +0.05 p.p.m. shows a splitting of 9.5 c/s. Each line of these doublets shows a further splitting of about 1 c/s. The X region at 2.5 p.p.m. consists of nine lines placed symmetrically and the intensities and splitting agree with a first-order interpretation: a triplet of triplets with splittings of 11.8 and 9.5 c/s. A schematic spectrum is shown in I. This amount of information should suffice for our purposes.

[1]*Holder of an N.R.C. Studentship, 1963–1964.*
[2]*Holder of an N.R.C. Bursary, 1963–1964.*
**We take the A proton to be more shielded than the B proton to agree with the formulation of the analysis in ref. 2.*



2. The Analysis

The ring proton spectrum can be characterized as in II:



$$\begin{aligned} \upsilon_0(1-\sigma_A) &= 0.05 \text{ p.p.m.}, \\ \upsilon_0(1-\sigma_B) &= -0.46 \text{ p.p.m.}, \\ \upsilon_0(1-\sigma_X) &= 2.5 \text{ p.p.m.} \\ &\text{at 60 Mc/s.} \end{aligned} \qquad \begin{aligned} J_{12} &= J_{34} \\ J_{14} &= J_{23} \\ J_{15} &= J_{25} \\ J_{35} &= J_{45} \\ J_{13} &= J_{24} \end{aligned}$$

II

We shall assume $J_{12} = J_{34}$, which is probably valid to at least 0.5 c/s (6). The matrix elements in the F_z representation were first written down by Richards and Schaefer and can be found in Tables I and II of ref. 2. The Hamiltonian matrix is factored into four 1×1, ten 2×2 and two 4×4 sub-matrices.

From the observed spectrum, however, it is clear that considerably greater factoring must be present in this case. In fact, we must be dealing with an A_2R_2X spectrum, in the notation of Pople and Schaefer (12). It follows from the known matrix elements (2) that the shift between A and B protons, $\upsilon_0(\sigma_A - \sigma_B)$, must be at least 10 times as large as $\frac{1}{2}(J_{23} + J_{13})$, $\frac{1}{2}(J_{23} - J_{13})$, $\frac{1}{\sqrt{2}}J_{23}$, or $\frac{1}{\sqrt{2}}J_{13}$. Normally, $J_{13} = 4$ to 10 c/s, $J_{23} = -4$ to -9 c/s in cyclopropanes and since $\upsilon_0(\sigma_A - \sigma_B) \approx 30$ c/s, this condition is not fulfilled. In the 4×4's of ref. 2, for instance, we have $H_{88} - H_{99} \approx 15$ c/s, while $H_{89} \approx 5$ c/s for normal values of coupling constants (5–10).

We present independent evidence below that both $|J_{23}|$ and $|J_{13}|$ are not much larger than 1 c/s. In that case the problem reduces to an A_2R_2X system with the largest sub-matrices being two 2×2's. Referring to ref. 2 and defining a positive constant A and an angle θ as

[1] $$A \cos 2\theta = \tfrac{1}{2}(J_{13} - J_{23})$$
$$A \sin 2\theta = J_{12},$$

we have

[2] $$\begin{aligned} E_7 &= A - \tfrac{1}{2}J_{12} + \tfrac{1}{2}\upsilon_0(1-\sigma_X) \\ E_8 &= -A - \tfrac{1}{2}J_{12} + \tfrac{1}{2}\upsilon_0(1-\sigma_X) \\ E_{11} &= A - \tfrac{1}{2}J_{12} + \tfrac{1}{2}\upsilon_0(-1+\sigma_X) \\ E_{12} &= -A - \tfrac{1}{2}J_{12} + \tfrac{1}{2}\upsilon_0(-1+\sigma_X) \end{aligned}$$

for the energies; and for the eigenfunctions we have

[3]
$$\Psi_7^1 = \cos\theta\Psi_7 + \sin\theta\Psi_8$$
$$\Psi_8^1 = -\sin\theta\Psi_7 + \cos\theta\Psi_8$$
$$\Psi_{11}^1 = \cos\theta\Psi_{11} + \sin\theta\Psi_{12}$$
$$\Psi_{12}^1 = -\sin\theta\Psi_{11} + \cos\theta\Psi_{12},$$

where Ψ_7, Ψ_8, Ψ_{11}, and Ψ_{12} are given in ref. 2.

There are 16 transitions for proton X and 24 each for protons A and B (R). They are given in Tables I and II. The 46 combination lines are ignored because their intensity is effectively zero in this case. From Table I and the observed spectrum, it is immediately clear that a first-order spectrum is expected and that $J_{35} = 11.8$ c/s, $J_{15} = 9.5$ c/s. This conclusion affirms the assignment of Seyferth and Cohen (1).

TABLE I

Transitions and intensities of proton X

	Energy, relative to $(1 - \sigma_X)$	Relative intensity		Energy, relative to $(1 - \sigma_X)$	Relative intensity

20.	$+\frac{1}{2}(J_{13} + J_{23} + J_{15})$	2	32.	$\frac{1}{2}(J_{13} + J_{23} - J_{15})$	2
21.	$+\frac{1}{2}(2J_{12} - J_{15}) - A$	$1 + \sin 2\theta$	33.	$\frac{1}{2}(-J_{13} + J_{23} + J_{15})$	1
22.	$+\frac{1}{2}(2J_{12} - J_{15}) + A$	$1 - \sin 2\theta$	34.	$\frac{1}{2}(J_{13} - J_{23} + J_{15})$	1
23.	$\frac{1}{2}(J_{13} + J_{23} - J_{15})$	2	35.	$\frac{1}{2}(-J_{13} + J_{23} - J_{15})$	1
24.	$\frac{1}{2}(-2J_{12} + J_{15}) + A$	$1 + \sin 2\theta$	36.	$\frac{1}{2}(J_{13} - J_{23} - J_{15})$	1
25.	$\frac{1}{2}(-2J_{12} + J_{15}) - A$	$1 - \sin 2\theta$	37.	$\frac{1}{2}(-J_{13} + J_{23} + J_{15})$	1
26.	$\frac{1}{2}(-J_{13} - J_{23} + J_{15})$	2	38.	$\frac{1}{2}(J_{13} - J_{23} + J_{15})$	1
27.	$\frac{1}{2}(-J_{13} - J_{23} + J_{15})$	2	39.	$\frac{1}{2}(J_{13} - J_{23} - J_{15})$	1
28.	$\frac{1}{2}(-2J_{12} - J_{15}) - A$	$1 - \sin 2\theta$	40.	$\frac{1}{2}(-J_{13} + J_{23} - J_{15})$	1

*To obtain the transitions and intensities of the B protons it is only necessary to replace J_{13} by J_{35} and $\nu_0(1-\sigma_A)$ by $\nu_0(1-\sigma_B)$ in the table.

However, from Table II it is clear that conclusions can also be reached about other coupling constants in the ring. From transitions 17 and 23, for instance, $|J_{13} + J_{23}| \approx 1$ c/s since the small splitting in the A spectrum is only about 1 c/s. From a pair of antisymmetrical transitions, i.e. 34 and 38, it follows that $|+J_{13} - J_{23}| \approx 1$ c/s. It appears that $|J_{23}| \approx 0$ or 1 c/s *or* that $|J_{13}| \approx 1$ or 0 c/s, but not both 0 or 1 c/s. In view of the resolution evident in the published spectrum, it is perhaps reasonable to put error limits of 0.5 c/s

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

on these values. These small values are consistent with the assumptions made in deducing Table II. Furthermore, from transitions like 18 and 19 and from eq. [1], we have $|J_{12} - A| \approx 0.5$ c/s and $\sin 2\theta \approx 0.9$. Consistency requires $J_{12} \approx 3$ c/s.

We suggest that the following coupling constants in c/s are consistent with the spectrum. For the X proton: $J_{15} = J_{trans} = 9.5$ c/s; $J_{35} = J_{cis} = 11.8$ c/s. For the AB(R) protons: $J_{12} = J_{cis} = 3 \pm 1$ c/s; $J_{13} = J_{trans} = 1.5 \pm 0.5$ c/s; $J_{23} = J_{gem} = -0.5 \pm 0.5$ c/s. We must now see whether these unusual values for the AB(R) protons can be rationalized.

Correlations of Coupling Constants with Electronegativity

1. Trends for J_{gem}

Williamson (11) as well as von R. Schleyer (13) have suggested that coupling constants in the cyclopropane ring are linear functions of the electronegativity (E) of the substituent In Fig. 1 the three types of proton coupling constants for compounds of the type 2-R-1,1-

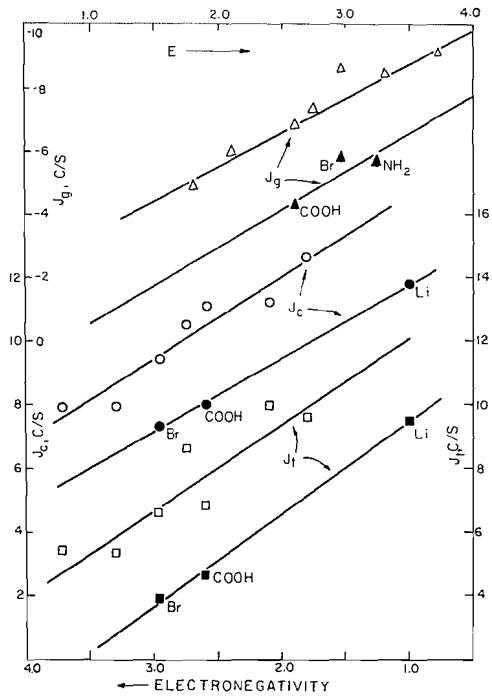

FIG. 1. Plot of proton coupling constants in c/s in 2-R-1,1-dichlorocyclopropanes versus electronegativity of R, open symbols; plot of proton coupling constants in c/s in monosubstituted cyclopropanes versus electronegativity, filled symbols. See text for discussion. Note the three different scales for the coupling constants and that the electronegativity scale decreases from left to right for J_{cis} and J_{trans} and vice versa for J_{gem}.

dichlorocyclopropane are plotted against E. They are represented by the open triangles, circles, and squares for J_{gem}, J_{cis}, and J_{trans}, respectively. The values are those measured and quoted by Williamson (11). We have also included the value for 1,1-dichlorocyclopropane itself ($E_H = 2.1$) which was taken from ref. 8. Representative straight lines have been drawn through the points which show considerable scatter for J_{cis} and J_{trans}. The correlation for J_{cis} is quite satisfactory, although the point for 2-bromo-1,1-dichlorocyclopropane falls off the line.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In Fig. 1 we have also plotted the coupling constants for a few monosubstituted cyclopropanes, represented by filled symbols. They have been taken from Wiberg and Nist for the bromo and carboxyl compounds (6), from Seyferth and Cohen for the lithium compound (1), and from Hutton and Schaefer for J_{gem} for the amino compound (4). For J_{trans} and J_{cis} the correlation is very good; for J_{gem} it is not as good.* We have taken $E_{NH_2} = 3.25$. Since all the plots are roughly parallel, we have drawn the line through J_{gem} for the monosubstituted compounds as shown. It appears from the plot that J_{gem} for Li is indeed in the vicinity of 0 c/s. We had estimated it to be -0.5 ± 0.5 c/s in the analysis above.

2. Trends for J_{cis} and J_{trans}

Another interesting conclusion from Fig. 1 is that the presence of the two chlorine atoms *increases* the coupling constants numerically by about 2 c/s. This is contrary to what one expects since E dependencies of coupling constants so far published (11, 13–17) demand that J is inversely proportional to E. In the present case, however, the chlorine atoms are situated on a *neighboring* carbon, i.e. on a carbon bonded to the carbons to which the hydrogens are bonded. In the monosubstituted cyclopropanes, as in vinyl compounds (16) or norbornene derivatives (13, 17), one is considering coupling of protons bonded to the carbon to which the substituent is attached.

The important conclusion is that substituents attached to carbon 1 in the cyclopropane ring will decrease the coupling constants between protons attached to carbons 1 and 2 (or 3) as E of the substituent increases, but will *increase* the coupling constants between protons attached to carbons 2 or 3. In cyclopropyllithium, therefore, we expect J_{12}, J_{13}, and J_{23} to be much smaller than in, e.g. bromocyclopropane. This is what we found in the analysis above.

3. Couplings in Cyclopropane

From the ^{13}C side bands in the proton spectrum of cyclopropane, Muller and Pritchard deduced a 7.5 ± 0.5 c/s coupling to adjacent protons (18). From the symmetry of the problem and the observed quintet, it is fairly clear that $J_{cis} + J_{trans} = 15.0 \pm 1.0$ c/s in cyclopropane. We can read off individual values from Fig. 1, assuming $E_H = 2.1$. We obtain $J_{cis} = 9.2$ and $J_{trans} = 6.2$ c/s, in agreement within experimental error with the ^{13}C side band (18). This agreement encourages a prediction for J_{gem} in cyclopropane. From Fig. 1 it is $J_{gem} = -5.6$ c/s. It is suggested that these values will be useful in an eventual analysis of the proton spectra of isotopically substituted cyclopropanes.

A SIMPLIFIED PROCEDURE FOR THE ANALYSIS OF COMPLEX NUCLEAR MAGNETIC RESONANCE SPECTRA

I. THE PRINCIPLES OF SUB-SPECTRAL ANALYSIS[1]

P. DIEHL,[2] R. G. JONES,[3] AND H. J. BERNSTEIN
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received August 25, 1964

ABSTRACT

A general procedure for the analysis of complex n.m.r. spectra has been developed in terms of simpler sub-spectra. The method is applicable to all possible combinations of magnetically equivalent and non-equivalent, strongly and weakly coupled groups of nuclei. It includes the special case of the composite particle model as well as the effective frequency method.

The method is applied, as an example, to the ABB'XX' spectrum of pyridine where the parameters J_{AB}, J_{AX}, the sum of $J_{BX} + J_{BX'}$, δ_{AB}, and δ_{AX} are derived without complete analysis of the spectrum, from the AB_2 sub-spectra of the problem.

INTRODUCTION

The methods which have been devised to analyze the n.m.r. spectra of complex systems have always been dedicated to the simplification of the analysis procedures. These procedures have involved a search for consistencies within the observed spectra.

The matching of observed spacings between lines taken two at a time to theoretical repeated spacings has been used extensively (1).

The composite particle method has been applied to complex systems made up of a number of groups of magnetically equivalent nuclei. The spectra of such complex systems have been attributed to the superposition of simpler spectra associated with the several groups of the system (2).

A more recent and powerful technique, that of "effective frequencies", led to the recognition of distinctive sub-spectra characteristic of the individual subgroups of the system. This method as outlined by the respective authors (3, 4) has been limited to the analysis of spectra of the type AA' . . . BB' . . . R_p . . . X_q where the prime symbol denotes magnetic non-equivalence. In those cases it leads to an impressive simplification of the analysis, and it has been possible to derive all the coupling constants and chemical shift data from the analysis of the sub-spectra of the system.

It is the purpose of this paper to expand the idea of sub-spectral analysis to the analysis of all types of nuclear magnetic resonance spectra, and it will be shown how far one can derive their properties without calculating the matrix elements of the Hamiltonian. The method of analysis to be developed is intended to be applicable to all possible combinations of magnetically equivalent and non-equivalent, strongly and weakly coupled, groups of nuclei. We shall first demonstrate the methods on the almost trivial case of two groups of magnetically equivalent nuclei, the AB_3 case (the A,B notation is that of Pople *et al.* (5)). We shall then proceed to the more complex case of three groups of nuclei partly strongly, partly weakly coupled and magnetically non-equivalent, the ABB'XX' case. We shall finally derive a general formulation of the method, giving rules which accomplish the sub-spectral breakdown.

THE METHOD OF SUB-SPECTRAL ANALYSIS

The general spin system is composed of groups of nuclei (homo- or hetero-nuclear), which may or may not be magnetically equivalent, having effective local symmetry (D_3 for $^{12}C^1H_3$) which may be used to construct basic symmetry wave functions for that group. These group wave functions can then be reclassified by their transformation properties under the covering operations of the total molecular point group.

In the following discussion we have considered only systems of spin $\frac{1}{2}$ particles.

The 2^n basic symmetry wave functions of the most general set of nuclei can be constructed by taking appropriate products of basic symmetry wave functions of the interacting groups. The 2^n molecular wave functions are then classified into the various molecular symmetry species.

In the following text the basic symmetry functions for each set of equivalent nuclei and, eventually, the total system will be schematically represented in the tables and figures by horizontal lines characterized by the appropriate quantum numbers which conveniently summarize the relevant data, e.g. $F_z(A_n)$, $F_z(B_m)$, $F_z(X_q)$. We will, for example, use the symbol $\frac{1}{2}$ to denote the single particle function α. The energy level diagram for the total system will be represented by "line patterns" also. Transitions between the various states will be indicated by tie lines. In general we shall proceed from the group basic (local) symmetry wave function diagram to the group basic (molecular) symmetry wave function diagram and then to the molecular basic symmetry wave function diagram. After having allowed mixing of the basic symmetry functions, we shall obtain the stationary state wave function diagram or the "energy level diagram".

Example 1. The AB_3 System

The AB_3 system can belong to either of the isomorphic point groups D_3 or C_{3v}. The basic symmetry functions of the B_3 nuclei can be shown to be divided into four A_1 species functions and two degenerate pairs in the E species (6).

These functions are given in Table I together with the single particle functions of the A nucleus.

TABLE I

Basic symmetry functions of the A and B_3 groups of the AB_3 system, reclassified under the molecular symmetry

Group	F_z	A_1 species functions	E species functions
A	$\frac{1}{2}$	α	
	$-\frac{1}{2}$	β	
B	$\frac{3}{2}$	$\alpha\alpha\alpha$	
	$\frac{1}{2}$	$(\alpha\alpha\beta+\alpha\beta\alpha+\beta\alpha\alpha)3^{-1/2}$	$(2\beta\alpha\alpha-\alpha\beta\alpha-\alpha\alpha\beta)6^{-1/2}$, $(\alpha\beta\alpha-\alpha\alpha\beta)2^{-1/2}$
	$-\frac{1}{2}$	$(\beta\beta\alpha+\beta\alpha\beta+\alpha\beta\beta)3^{-1/2}$	$(2\alpha\beta\beta-\beta\alpha\beta-\beta\beta\alpha)6^{-1/2}$, $(\beta\alpha\beta-\beta\beta\alpha)2^{-1/2}$
	$-\frac{3}{2}$	$\beta\beta\beta$	

The sixteen AB_3 basic symmetry functions are constructed from products of the type $A_1 \times A_1 = A_1$ and $A_1 \times E = E$ and there are therefore eight functions in each symmetry species. The construction of the product functions is schematically represented in Table II.

In this table the function $\underline{\frac{1}{2},\frac{3}{2}}$ in the A_1 species of (AB_3), for example, represents the product of $\alpha(A)$ and $\alpha\alpha\alpha(B_3)$, i.e., $\underline{F_z(A),F_z(B_3)} = \underline{\frac{1}{2},\frac{3}{2}}$. Similarly the $\underline{-\frac{1}{2},\frac{1}{2}}$ function in the E species replaces either of the two functions, $\beta(A)$ $(2\beta\alpha\alpha - \alpha\beta\alpha - \alpha\alpha\beta)6^{-1/2}(B_3)$ or $\beta(A)$ $(\alpha\beta\alpha - \alpha\alpha\beta)2^{-1/2}(B_3)$.

TABLE II

Construction of the basic symmetry product functions of the AB_3 system

F_z	A group, $F_z(A)$		B_3 group, $F_z(B_3)$			AB_3, system $F_z(A)$, $F_z(B_3)$				
	A_1 species		A_1 species	E species		A_1 species		E species		
2						$\frac{1}{2},\frac{3}{2}$				
$\frac{3}{2}$			$\frac{3}{2}$							
1						$\frac{1}{2},\frac{1}{2}$	$-\frac{1}{2},\frac{3}{2}$	$\frac{1}{2},\frac{1}{2}$	$\frac{1}{2},\frac{1}{2}$	
$\frac{1}{2}$	$\frac{1}{2}$		$\frac{1}{2}$	$\frac{1}{2}$ $\frac{1}{2}$						
0		×			→	$\frac{1}{2},-\frac{1}{2}$	$-\frac{1}{2},\frac{1}{2}$	$\frac{1}{2},-\frac{1}{2}$	$-\frac{1}{2},\frac{1}{2}$	$\frac{1}{2},-\frac{1}{2}$ $-\frac{1}{2},\frac{1}{2}$
$-\frac{1}{2}$	$-\frac{1}{2}$		$-\frac{1}{2}$	$-\frac{1}{2}$ $-\frac{1}{2}$						
-1						$\frac{1}{2},-\frac{3}{2}$	$-\frac{1}{2},-\frac{1}{2}$		$-\frac{1}{2},-\frac{1}{2}$	$-\frac{1}{2},-\frac{1}{2}$
$-\frac{3}{2}$			$-\frac{3}{2}$							
-2							$-\frac{1}{2},-\frac{3}{2}$			

The energy level diagram (the stationary state wave function diagram) can be obtained from inspection of Table II. This is because the mixing which would transform the basic molecular symmetry product function diagram into a stationary state wave function diagram does not change the transition pattern. The A and B transitions can now be picked out from the symmetry function diagram (Table II) using the selection rules, $\Delta F_z(B_3) = 0$ and $\Delta F_z(A) = 0$ respectively.

The energy level diagram is given schematically in Fig. 1.

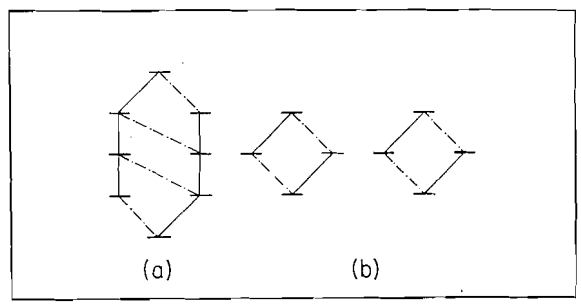

FIG. 1. Schematic energy level diagram of the AB_3 system. The solid tie lines represent B transitions and the broken tie lines represent A transitions; (*a*) A_1 species, (*b*) E species.

The result of these operations is a breakdown of the general AB_3 problem into sub-patterns which can be attributed to simpler problems. The simplicity of these patterns (the maximum determinantal order is two) arises because the molecular symmetry functions belong to the symmetry species A_1 and E are uniquely constructed from $A_1 \times A_1$ and $A_1 \times E$ products (i.e. there are no $E \times A_1 = E$ or $E \times E = A_1 + A_2 + E$ products). Hence the $A_1 \times A_1$ and $A_1 \times E$ product functions form unique groups which do not 'mix' because symmetry forbids it.

The energy level pattern isolated within the A_1 symmetry species is the typical energy level diagram of a system composed of a particle with spin $\frac{1}{2}$ and a particle with spin $\frac{3}{2}$, (composite particle model (2)). The E symmetry species energy level diagram is characteristic of the particle spin $\frac{1}{2}$, particle spin $\frac{1}{2}$ problem denoted *ab*. Lower case italic letters, e.g. *ab*, *abc*, are used to denote nuclei in sub-spectra. This *ab* subproblem can be explicitly solved, provided the correct assignment is made of observed spectral lines, to give all the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

information that can be obtained from the complete AB_3 problem, that is the chemical shift δ_{AB} and the coupling constant J_{AB}. This special case already illustrates the value of sub-spectral analysis.

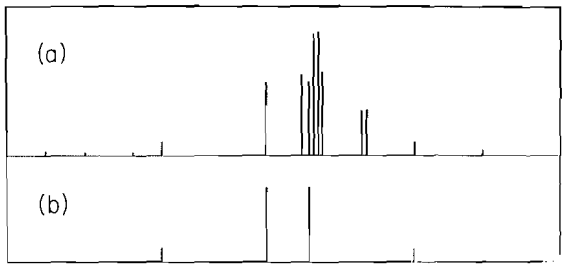

FIG. 2. Calculated spectra of AB_3 system for $J/\delta = 1$: (*a*) superposition of the ($I_A = \frac{1}{2}$, $I_B = \frac{1}{2}$) and the ($I_A = \frac{1}{2}$, $I_B = \frac{3}{2}$) sub-spectra; (*b*) the ($I_A = \frac{1}{2}$, $I_B = \frac{1}{2}$) sub-spectrum.

The spectrum of a typical AB_3 system is given in Fig. 2*a*. The *ab* sub-spectrum is indicated in Fig. 2*b*. Such a sub-spectrum can be easily picked out using previous knowledge such as the repeated spacing properties and typical relative intensity distribution. It is worthwhile pointing out here that in this simple case AB_3, where the nuclei within the groups are magnetically equivalent, the total spin quantum number F (where $F(F+1)$ is the eigenvalue of F^2 (5)) can be used to group the energy levels in a way equivalent to group theory.

Example 2. The ABB′XX′ System

The ABB′XX′ system may be regarded as being composed of three sub-groups, A, BB′, and XX′, where the nuclei within the BB′ and XX′ sub-groups respectively are chemically equivalent. It is possible to construct four basic symmetry wave functions for each of the two sets of equivalent nuclei which may be classified within the local symmetry restrictions as symmetric and antisymmetric with respect to an interchange of the two nuclei. The symmetric functions are $\alpha\alpha$, $(\alpha\beta + \beta\alpha)2^{-1/2}$, and $\beta\beta$ and the single antisymmetric function is $(\alpha\beta - \beta\alpha)2^{-1/2}$.

The overall molecular symmetry when all the nuclei lie in a plane is C_{2v}. This means that the molecule has a two-fold axis of symmetry, C_2, and two mutually perpendicular planes of symmetry σ_v and σ_v' (the plane containing all the nuclei). The possible symmetry species to which the molecular symmetry functions can belong are A_1 and B_2 (7). The functions α and β (A nucleus) as well as $\alpha\alpha$, $(\alpha\beta + \beta\alpha)2^{-1/2}$, and $\beta\beta$ (BB′ and XX′ sub-groups) are symmetric with respect to the C_2 axis, σ_v' and σ_v, and hence can be classified as A_1 functions. The functions $(\beta\alpha - \beta\alpha)2^{-1/2}$ are symmetric with respect to σ_v' but antisymmetric with respect to C_2 and σ_v. These are therefore B_2 symmetry functions. These results are summarized in Table III.

The molecular basic symmetry functions can be constructed by taking the products of all the group functions and classifying them according to their symmetry species as well as their F_z(XX′) and F_z(ABB′XX′), see Table IV.

The four species products are

$$A_1 \times A_1 \times A_1 = A_1, \qquad A_1 \times A_1 \times B_2 = B_2,$$
$$A_1 \times B_2 \times B_2 = A_1, \qquad A_1 \times B_2 \times A_1 = B_2,$$

as, for example,

$$A_1(A) \times A_1(BB') \times A_1(XX') = A_1(ABB'XX').$$

-1		$\beta\beta$		$\beta\beta$	

An alternative way of arranging the basic molecular symmetry product functions more suitable to the discussion of the X transitions would be according to their F_z(ABB′) (see Fig. 3*b*) instead of F_z(XX′).

Those functions within a given symmetry species with the same F_z(XX′) and F_z(ABB′) can mix. For example, within the ABB′XX′ system A_1 symmetry species of Table IV, the product functions $(A_1 \times A_1 \times A_1)$ $F_z(ABB') = \frac{1}{2}$, $F_z(XX') = 0$ and $(A_1 \times B_2 \times B_2)$ $F_z(ABB') = \frac{1}{2}$, $F_z(XX') = 0$ can mix.

The maximum determinantal order in the A_1 symmetry species will therefore be three. The $(A_1 \times A_1 \times A_1)$, $(A_1 \times B_2 \times B_2)$ $F_z(ABB') = -\frac{1}{2}$ and $F_z(XX') = 0$ functions also can mix. A similar degree of mixing occurs within the B_2 symmetry species. The mixing which transforms the basic molecular symmetry product function diagram into a stationary state wave function diagram does not change the transition pattern. The energy level diagram can therefore be derived from Table IV. It is presented in Fig. 3. Some of the X transitions are indicated in Fig. 3*a* to clarify the relation to Fig. 3*b*.

For personal use only.

The character (A, B, or X) of the transitions in Figs. 3*a* and 3*b* has been picked out using the convention of considering the quantum numbers of the basic symmetry functions. It is obvious from Fig. 3*a* that the A and B transitions are contained within three patterns of energy levels in both the A_1 and B_2 symmetry species which are labelled by the $F_z(XX')$ values 1, 0, and -1 respectively. These patterns are characteristic of three particles with spin $\frac{1}{2}$ having certain relations between the coupling constants and the chemical shifts within the system.

The A_1 species $F_z(XX') = 1$ levels together with the B_2 species $F_z(X) = 1$ levels constitute the typical pattern for the AB_2 system. This also is true of the A_1 species, $F_z(X) = -1$ plus the B_2 species $F_z(X) = -1$ levels. The A_1 species, $F_z(X) = 0$ and the B_2 species, $F_z(X) = 0$ independently are characteristic of the ABB′ system which has more than one effective coupling constant between the different types of nuclei. This means that the ABB′ part of an ABB′XX′ spectrum will contain *abb′* as well as simple ab_2 sub-spectra which when sorted out will help the analysis of the problem.

The XX′ transition pattern (of ABB′XX′) breaks down into sub-patterns characterized by $F_z(ABB') = \frac{3}{2}, \frac{1}{2}-\frac{1}{2}$ and $-\frac{3}{2}$ respectively in both the A_1 and B_2 species. It is possible to pick out the $F_z(ABB') = \frac{3}{2},-\frac{3}{2}$ sub-patterns as seemingly non-perturbed patterns characteristic of the two equivalent nuclei (X_2). The symmetric functions appear in the A_1 species and the antisymmetric function in the B_2 species. In Fig. 3*b* the energy levels for $F_z(ABB') = \frac{1}{2}$ and $-\frac{1}{2}$ are grouped 2,3,2 in the A_1 species and 1,3,1 in the B_2 species. On inspection of the possible transitions we find that some of these are combination lines. As a consequence there is a further breakdown possible which converts the 2,3,2 pattern into the known patterns (1,2,1)(XX′) and (1,1,1)(X_2). This breakdown does not necessarily mean that the energies of the transitions are analytical expressions in terms of chemical shifts and coupling constants, since the three wave functions of the 2,3,2 patterns can in general mix strongly.

The ab_2 sub-spectra corresponding to the $F_z(XX')$ values $+1$ and -1 discussed above have been identified as shown in the pyridine spectrum, Fig. 4. A graphical method using a plot of the relative positions of the eight AB_2 transitions as a function of J/δ has been applied. These particular sub-spectra, arising because there is a unique spin configuration where all the spins of the second strongly coupled group (XX′) are either "all up" $(\frac{1}{2},\frac{1}{2})$ or "all down" $(-\frac{1}{2},-\frac{1}{2})$, can be discussed using the effective Larmor frequency method (4). The result is that the two ab_2 patterns are characterized by the same J_{AB} and the two effective shifts,

$$\delta_{ab} = \delta_{AB} \pm \tfrac{1}{2}(J_{BX} + J_{BX} - 2J_{AX}),$$

for $F_z(XX') = +1$ and -1 respectively. Furthermore, the relative intensity of one sub-spectrum is $\frac{1}{4}$ of the total ABB′ intensity.

The identification of all the transitions of the two ab_2 sub-spectra (see Fig. 4*b* and *c*) provides the following parameters: J_{AB}, δ_{AB}, J_{AX}, and the sum of J_{BX} and J_{BX}'. These are obtained, as shown below, from the difference of line positions (δ's) in the ab_2 multiplet pattern.

(1) $J_{AB} = \frac{1}{3}[(\delta_4 - \delta_1) + (\delta_8 - \delta_6)] = \frac{1}{3}[(\delta_{4'} - \delta_{1'}) + (\delta_{8'} - \delta_{6'})]$.

(2) $J_{AX} = \frac{1}{2}(\nu_a - \nu_{a'}) = \frac{1}{2}(\delta_3 - \delta_{3'})$.

(3) $J_{BX} + J_{BX}' = \nu_b - \nu_{b'} = \frac{1}{2}[(\delta_5 + \delta_7) - (\delta_{5'} + \delta_{7'})]$.

(4) $\delta_{AB} = \frac{1}{4}(\delta_5 + \delta_7 + \delta_{5'} + \delta_{7'}) - \frac{1}{2}(\delta_3 + \delta_{3'})$.

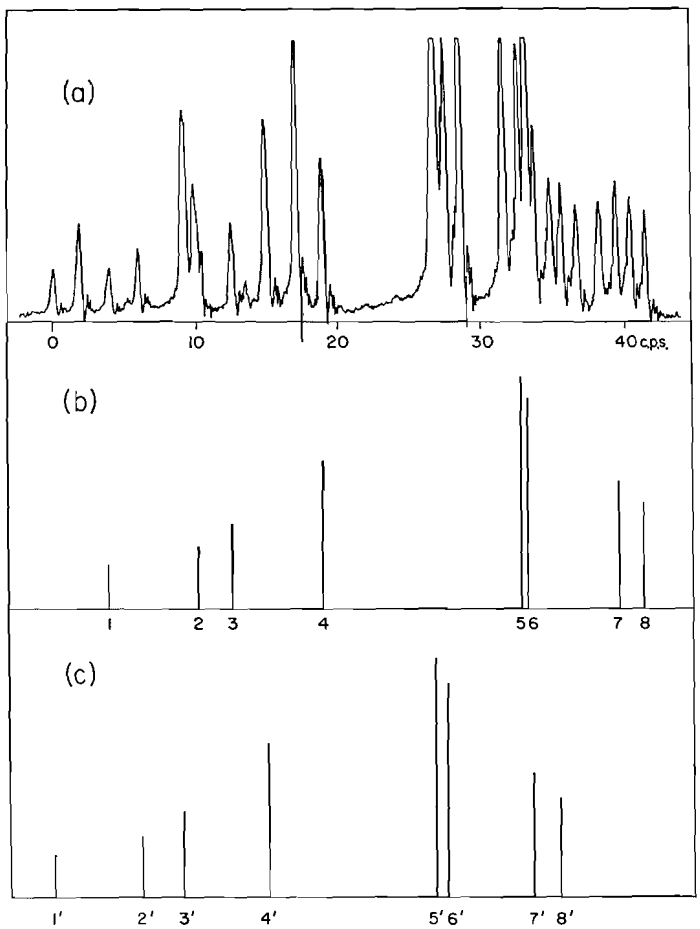

FIG. 4. The proton n.m.r. spectrum of pyridine at 60 Mc/s: (*a*) the ABB′ part of the ABB′XX′ spectrum; (*b*) the ab_2 sub-spectrum corresponding to $F_z(\mathrm{XX}') = +1$,

$$J/\delta = J_{\mathrm{AB}}/\delta_{ab} = J_{\mathrm{AB}}/\delta_{\mathrm{AB}} + \tfrac{1}{2}(J_{\mathrm{BX}} + J_{\mathrm{BX}}' - 2J_{\mathrm{AX}}),$$

(*c*) the ab_2 sub-spectrum corresponding to $F_z(\mathrm{XX}') = -1$,

$$J/\delta = J_{\mathrm{AB}}/\delta_{ab} = J_{\mathrm{AB}}/\delta_{\mathrm{AB}} - \tfrac{1}{2}(J_{\mathrm{BX}} + J_{\mathrm{BX}}' - 2J_{\mathrm{AX}}).$$

(5) The XX′ part of the spectrum will contain transitions corresponding to $F_z(\mathrm{ABB}') = \pm\frac{3}{2}$. These have an energy difference of $J_{\mathrm{AX}} + J_{\mathrm{BX}} + J_{\mathrm{BX}'}$ and their mean gives δ_{X}. The sum of their intensities is equal to $\frac{1}{4}$ of the total (XX′) intensity.

The spectra parameters obtained by the above ab_2 sub-spectral analysis are compared with those obtained in the more conventional way in Table V.

The XX′ part result for the sum $J_{\mathrm{BX}} + J_{\mathrm{BX}}' + J_{\mathrm{AX}}$ is 7.6 ± 0.2 c.p.s., the inaccuracy being due to broadening of lines.

This example shows that it is possible to derive without total analysis of the spectrum all the parameters of the strongly coupled subgroups by picking out the two sub-spectra and analyzing them. In addition, we will obtain the sums of all the intergroup coupling constants from each of the strongly coupled nuclei of one group to all the strongly coupled nuclei of the other group. This method will be of particular interest in, for example,

TABLE V

AB_2 parameters of the ABB'XX' spectrum of pyridine

$J_{BX}+J_{BX'}$	5.98	5.9–6.4
δ_{AB}	0.37 p.p.m.	0.37 p.p.m.
δ_{AX}	1.13 p.p.m.	1.14 p.p.m.

*Estimated accuracy ±0.05 c.p.s.

solvent effects, where the chemical shift as a function of dilution parameters is desired. It is evident that it is not necessary to do a full analysis of the spectrum for each dilution. The method simply involves picking out the sub-spectra from which the chemical shift can be determined directly.

In the general case where a system is composed of two sets of strongly coupled nuclei separated by a large chemical shift, (AA' . . . BB' . . .)(XX' . . . YY' . . .), we will always find spectra which are of the AA' . . . BB' . . . and XX' . . . YY' . . . type corresponding to the extreme values of F_z(XX' . . . YY' . . .), and F_z(AA' . . . BB' . . .) respectively.

The effective Larmor frequencies of the nuclei A and B, for example, in the relevant sub-spectra are given by the following relations:

$$\nu_a = \nu_A \pm \tfrac{1}{2}\textstyle\sum J_{AX} + J_{AX'} \ldots + J_{AY} + J_{AY'},$$

$$\nu_b = \nu_B \pm \tfrac{1}{2}\textstyle\sum J_{BX} + J_{BX'} \ldots + J_{BY} + J_{BY'}.$$

The effective chemical shift of the respective sub-spectra is given by,

$$\nu_a - \nu_b = \nu_A - \nu_B \pm \tfrac{1}{2}\textstyle\sum (J_{AX} - J_{BX}) + (J_{AX'} - J_{BX'}) \ldots + (J_{AY} - J_{BY}) \ldots .$$

The relative intensity of each of these two sub-spectra compared with the total AA' . . . BB' . . . intensity will be $1/2^n$, where n is the total number of XX' . . . YY' . . . nuclei. For symmetry reasons similar results can be obtained for the XX' . . . YY' . . . part by exchanging XX' . . . and YY' . . . with AA' . . . and BB' . . . .

The total intensity of any sub-spectrum can easily be obtained as the sum of the individual transitions within the sub-spectrum in the limit of magnetic equivalence and no mixing. In this limit, perturbation theory provides the result that the intensity of a transition of nucleus A in a group A_n from the state $(F_{A_n}, m_A - 1)$ to (F_{A_n}, m_A) is equal to

$$(F_{A_n} + m_A)\,(F_{A_n} - m_A + 1),$$

where F_{A_n} is the total spin quantum number which can be added as a second quantum number to the basis local symmetry functions.

As an example, let us consider an AB_3 system. The A wave function characterized by $\underline{F_z(A), F_A} = \underline{\tfrac{1}{2},\tfrac{1}{2}}$, multiplied with the two B_3 wave functions $\underline{\tfrac{1}{2},\tfrac{3}{2}}$ and $\underline{-\tfrac{1}{2},\tfrac{3}{2}}$, will form the product functions

$$\underline{F_z(A),\ F_A F_z(B_3),\ F_{B_3}} = \underline{\tfrac{1}{2},\tfrac{1}{2}\ \tfrac{1}{2},\tfrac{3}{2}} \text{ and } \underline{\tfrac{1}{2},\tfrac{1}{2}\ -\tfrac{1}{2},\tfrac{3}{2}}.$$

The B transition between the two states will, in the limit discussed above, have an intensity of $(\tfrac{3}{2} + \tfrac{1}{2})(\tfrac{3}{2} - \tfrac{1}{2} + 1) = 4$.

These zero order intensities are of additional interest because, together with the coefficients of the mixed wave functions, they determine the actual intensities of the transitions.

Example 3. The AB_2X_2 System

This example effectively shows the transition from magnetic non-equivalence ABB′XX′ to magnetic equivalence AB_2X_2 from the standpoint of symmetry.

If we choose to twist the XX group through 90° about the C_2 axis of the molecule without disturbing the ABB part, we do not change the overall molecular point group (C_{2v}). We now define σ_v' as the symmetry plane including the ABB group of nuclei and the C_2 axis. The σ_v plane includes the XX group, the A nucleus, and the C_2 axis. It is now necessary to reclassify the XX group basic symmetry functions with respect to the new covering operations. The functions $\alpha\alpha$, $(\alpha\beta + \beta\alpha)2^{-1/2}$, and $\beta\beta$ remain invariant under the covering operations C_2, σ_v, and σ_v' and therefore belong to the A_1 symmetry species. The $(\alpha\beta - \beta\alpha)2^{-1/2}$ function is invariant under the covering operation σ_v and it is transformed into minus itself by the C_2 and σ_v' operations. Hence it belongs to the B_1 symmetry species. Following the procedure outlined by Table III, the molecular symmetry functions may now be classified as indicated below,

ABB′XX′	AB_2X_2
$A_1 \times A_1 \times A_1 = A_1$	$A_1 \times A_1 \times A_1 = A_1$
$A_1 \times B_2 \times B_2 = A_1$	$A_1 \times B_2 \times B_1 = A_2$
$A_1 \times A_1 \times B_2 = B_2$	$A_1 \times A_1 \times B_1 = B_1$
$A_1 \times B_2 \times A_1 = B$	$A_1 \times B_2 \times A_1 = B_2$.

It is now apparent that symmetry forbids the mixing of wave functions observed in example 2, and Table IV represents the complete AB_2X_2 problem with the appropriate relabelling of the molecular symmetry species. The maximum determinantal order is two, and the spectra break down in exactly the way predicted by the effective frequency method (4).

Another way in which the transition from the ABB′XX′ system to the AB_2X_2 system can be made is to allow "free" rotation of the X_2 group relative to the AB_2 group about the C_2 axis of the static system (8).

SUMMARY

The general breakdown of n.m.r. spectra into simpler sub-spectral problems can be summarized as follows.

(1) Construct the basic local symmetry wave functions for the chemically equivalent groups (see Appendix).
(2) Decide on the total molecular symmetry.
(3) Reclassify the basic local symmetry functions according to their transformation properties under the covering operations of the total molecular symmetry and rewrite them in the abbreviated notation as discussed.
(4) Construct the 2^n molecular basic symmetry product wave functions by forming the 2^n possible products of the basic group symmetry functions.
(5) Derive the symmetry species of the products of basic group symmetry functions.
(6) Regroup the molecular wave functions into the molecular symmetry species.
(7) Sort out the transitions of the contributing species (e.g. ABB′ transitions (of ABB′XX′): $\Delta F_z(XX') = 0$; $\Delta F_z(ABB') = \pm 1$.
(8) Isolate the sub-spectral patterns and analyze them.
(9) Using the sub-spectra of maximum $|F_z|$ derive the parameters of the strongly coupled parts.

For personal use only.

(10) In those cases where the Hamiltonian matrix elements of n.m.r. problems are given in the literature in detail (as, for example, Schneider *et al.* (9)), steps 1 to 5 can be deleted and step 7 can be performed on the existing tables.

APPENDIX

The basic local symmetry functions which belong to the various irreducible representations of the local symmetry point group of the n chemically equivalent nuclei A_n are in the literature for two (5), three (6), and four (10) nuclei.

These wave functions are of fundamental importance in the procedures outlined and therefore will be given in this appendix together with additional tables for four and six equivalent nuclei.

The division of the basic local symmetry wave functions for groups of one, two, and three nuclei is simple since there is only one possible point group which describes the local symmetry. The results are given in Table AI using the abbreviated notation described.

TABLE AI

The basic local symmetry wave function diagram for one nucleus (I, identity operation), two nuclei ($D_{\infty h}$ symmetry), and three nuclei (D_3 symmetry)

	$A_2(D_{\infty h})$		$A_3(D_3)$	
A(I)	Symmetric	Antisymmetric	A_1 species	E species
	1		$\frac{3}{2}$	
$\frac{1}{2}$	0	0	$\frac{1}{2}$	$\frac{1}{2}$
$-\frac{1}{2}$	−1		$-\frac{1}{2}$	$-\frac{1}{2}$
			$-\frac{3}{2}$	

Four chemically equivalent nuclei may have a number of space configurations that can be encountered in n.m.r. problems. These are described by the local symmetry as:

(i) C_2, two pairs of protons twisted relative to each other by an angle $\neq 90°$ out of a plane,
(ii) C_{2v}, four protons forming a rectangle (ethylene) or two pairs of adjacent nuclei twisted through 90° relative to one another (allene),
(iii) D_{4h}, four protons forming a square (substituted cyclobutane) for which the proper point group is D_4 since a reflection in the plane of symmetry does not change the configuration as regards the spins, and
(iv) T_d, tetrahedral configuration (methane).

The configuration with T_d symmetry occurs in molecules of the type XA_4 and is a trivial n.m.r. problem. The configuration C_2 is a sub-group (7) of both D_4 and C_{2v}. This means that if the total molecular symmetry of the problem containing the four nuclei A_4 is C_2, then the reclassification of the A_4 wave functions (characterized by either D_4 or C_{2v} local symmetry) can be made direct from tables (7). The basic local symmetry function diagrams are given below in Table AII for four equivalent nuclei with the local symmetries mentioned above.

The most likely configurations which we would expect to find for six chemically

equivalent nuclei can be described by the three point groups, D_6 (planar hexagon), D_{3h} (fixed, eclipsed ethane protons), and D_{3d} (fixed, staggered ethane protons), which can be shown to be isomorphic (7). As a result of this relation between the point groups it is necessary to write down only one basic symmetry wave function diagram. It is given in Table AIII.

THE MECHANISM OF THE DEHYDROBROMINATION OF TETRA-*O*-ACETYL-α-D-GLUCOPYRANOSYL BROMIDE[1]

R. U. LEMIEUX AND D. R. LINEBACK[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received August 4, 1964

ABSTRACT

The conversion of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) to 2-acetoxy-D-glucal triacetate (II) was found to be catalyzed by secondary amines containing *n*-alkyl groups. Substitution at the α-positions of the amine reduced the catalysis. Although triethylamine and tri-*n*-propylamine did not serve as useful catalysts, the less hindered and strongly basic 1,4-diazabicyclo[2,2,2]octane was more effective than diethylamine. The reaction is strongly promoted by polar solvents and added salts—especially tetra-*n*-butylammonium bromide. The course of the reaction involves direct elimination of hydrogen bromide and this reaction is in competition with the formation of acetylated *N*-glucosides. A kinetic study of the reaction using a variety of amines led to the conclusion that the first stage of the reaction is dissociation of I to glycosyloxocarbonium ion strongly solvated by the amine. Depending on the structure of the amine, the second stage of the reaction may involve transfer of the 2-proton to the amine to form II at a faster or slower rate than the formation of the N to C_1 bond of the acetylated *N*-glucoside. Conditions were established for the near quantitative conversion of I to II in about 1/100th the reaction time reported in the literature.

INTRODUCTION

The course of reactions at the anomeric center of *O*-acylated glycosyl halides often depends on a rather delicate balance of the rates of competing reactions. An outstanding example is the formation of 2-acetoxy-D-glucal triacetate (II) in 30–50% yield (1) on reaction of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) with diethylamine in benzene. This reaction was discovered in 1927 by Maurer and Mahn (1) in the course of attempts to prepare a variety of *N*-glucosides by reaction of I with amines. It is pertinent to review some of the observations described in the literature concerning the reaction of acetylated glycosyl halides with amines in order to illustrate the strong dependence of the route of reaction on the structure of the amine. Although Micheel and Micheel (2) prepared a variety of quaternary *N*-glycosides through the reaction of trimethylamine with 1,2-*cis*-acetylated glycosyl halides (including I), the products of reactions using other trialkylamines have not been reported although the subject of *N*-glycosides has attracted much interest over several decades. The product of the condensation of I with trimethylamine is well characterized (3), as are the *N*-glucosides resulting from the reaction of I with pyridine (4, 5), with nicotinamide (6, 7), and with other substituted pyridines (8). The reactions of I with a variety of secondary amines including the ethyl ester of sarcosine (9, 10), a variety of *p*-substituted benzylmethylamines (11), and 2,4-disubstituted pyrimidines (12) have been reported to lead to *N*-glucosides in contrast to the dehydrobromination observed in the reaction with diethylamine (1). As will be seen later on, we have found that piperidine, under the conditions studied, catalyzes the elimination more effectively than diethylamine, although Baker (11) reported the preparation of two *different* *N*-(tetra-*O*-acetyl-D-glucosyl)piperidines depending on whether I reacted with piperidine alone or with piperidine in diethyl ether. Chapman and Laird (13) reported a bimolecular mechanism for the reaction of secondary amines with the

O-acetylglycopyranosyl bromides derived from glucose, galactose, and xylose and noted that substitution at C_1 is usually accompanied by elimination.

The structure of the glycosyl halide can effect the route of reaction as evidenced by formation (14) of the *N*-glucoside on reaction of tetra-*O*-methyl-α-D-glucopyranosyl bromide with diethylamine in benzene under conditions which convert I to II in about 50% yield. Diethylamine was found to cause dehydrobromination of other acetylated (15) and benzoylated (16) glucopyranosyl bromides.

The main purpose of this investigation was to attempt to gain information on the factors which are responsible for the relative rates of the competing reactions and thus help lead to a better understanding and control of reactions at the anomeric center of *O*-acylglycosyl halides.

DISCUSSION OF RESULTS

Except for the data reported in Table I, the reactions of I were followed polarimetrically. As will be seen later on, the rate of reaction is dependent on the concentrations of I, diethylamine, and bromide ion. Thus, it seems likely that the observed polarimetric rates are an expression of a rate process depressed by disappearance of amine and accelerated by the liberation of bromide ion. For these and purely practical reasons, the kinetic studies were performed as much as possible under *pseudo*-first-order conditions using up to tenfold excesses of amine and bromide ion. The rate of change of rotation was very close to a first-order process and the polarimetric data were used to calculate first-order velocity constants from the standard expression, $k = 1/t \ln [(\alpha_0 - \alpha_\infty)/(\alpha_t - \alpha_\infty)]$. In all cases, once the final rotation, α_∞, had been reached, the product was isolated and examined for content by proton magnetic resonance (n.m.r.) spectroscopy.

TABLE I

The powerful catalysis provided by diethylamine*

Concentration of diethylamine, *M*	Concentration of bromide ion, *M*	*T*, °C	*k*, min^{-1}
0	0.4	26	$<10^{-4}$
1.2	0	26	0.01
1.2	0.4	26	0.04
0	0	100	0.006
0	0.4	100	0.03

*The initial concentration of tetra-*O*-acetyl-α-D-glucopyranosyl bromide was in each case 0.4 *M* using a 2:1 *s*-collidine – acetonitrile mixture as solvent. The rates of reaction were estimated by comparing the relative intensities of appropriate signals in the n.m.r. spectra of the products.

The marked catalysis for the elimination provided by diethylamine is evident from the data shown in Table I. An excess of *s*-collidine was used to effectively buffer the reaction medium. It is seen that, in the absence of diethylamine at 26°, no observable reaction occurred. Virtually pure I was present after 24 h. However, on the addition of diethylamine, 3 moles per mole of I, the reaction was half complete in just over 1 h. The further addition of 1 mole of tetra-*n*-butylammonium bromide per mole of I increased the rate by a factor of about 4. In order to achieve reaction at a comparable rate in the absence of diethylamine, the reaction temperature had to be raised from 26° to 100°. As seen in Table VI, the rate of a reaction performed in acetonitrile was increased by a factor of 6.7 on raising the temperature from 25° to 50°. With the assumption of the same temperature coefficient under the reaction conditions given in Table I, the velocity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

constant in the presence of diethylamine and bromide ion at 100° would be about 12 min^{-1}, that is, about 400 times greater than in the absence of diethylamine (k = 0.03 min^{-1}). This amounts to the diethylamine providing a transition state with a free energy about 4.5 kcal/mole less than that which occurs in its absence.

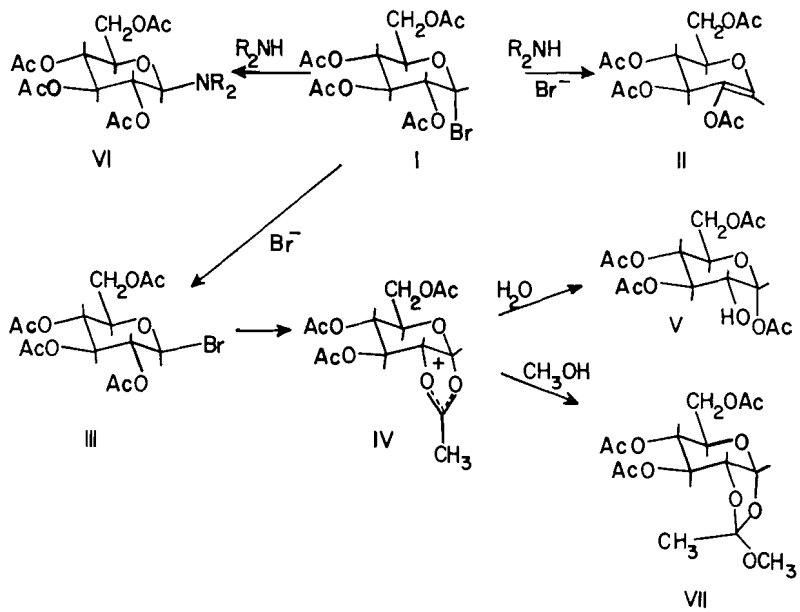

CHART 1

In view of the facts that bromide ion accelerates the formation of II from I and that the reaction of I with bromide ion can be expected to give rise to the β-anomer of I (5), it was necessary to establish whether or not II arose directly from I or from some other derivative of glucose such as the 1,2-acetoxonium ion or α-D-glucopyranose 1,2-(*N*,*N*-diethylorthoacetamide)triacetate. A decision on this matter was reached through the observation that, using diethylamine as catalyst, the 2-acetoxyglucal (II) was formed considerably more rapidly than the β-anomer (III) of I. As seen in Table II, when diethylamine was used, the presence of water in the reaction mixture had little effect on the course of the reaction. Had the elimination proceeded by way of β-acetobromoglucose (III) followed by participation of the 2-acetoxy group to yield the 1,2-acetoxonium ion (IV), in the presence of water, the product of the reaction would be 1,3,4,6-tetra-*O*-acetyl-α-D-glucose (V). The 1,3,4,6-α-tetraacetate (V) is well known to readily isomerize to the 2,3,4,6-α-tetraacetate (17) which can undergo mutarotation. The yields of V reported in Table II *in fact* refer to the total amount of glucose tetraacetate estimated to be in the product. The tetraacetates were the only products when the reaction was carried out in the presence of water but in the absence of diethylamine. That the 1,2-acetoxonium ion is a highly effective scavenger for water is demonstrated by the formation of V in about 30% yield using diisopropylamine as catalyst under conditions which were meant to be anhydrous. The trace of II which formed could only be demonstrated on paper chromatograms. In the presence of an excess of water and using diisopropylamine, as expected, virtually only V was formed. Isomerization of V was extensive in this case. When methanol was present, the methyl orthoacetate (VII) was obtained in 70% yield

together with tetraacetate V. Clearly, therefore, under the conditions given in Table II, the rate of the formation of the 2-acetoxyglucal (II) is much greater in the presence of diethylamine than is the rate of the process involving formation of the β-anomer (III) of I. It follows that the formation of II is an elimination process which proceeds directly from I. The inability of diisopropylamine to catalyze the dehydrobromination at rates competitive with either the anomerization of I or the formation of *N*-glucoside shows that the catalysis is highly demanding on the structure of the amine used as catalyst. This facet of the reaction will be considered later.

TABLE II

Effect of the nature of the amine and of the presence of either water or methanol on the course of the reaction*

Amine	Hydroxylic reagent	Composition of product
Diethylamine, 0.4 *M*	Trace of water	95% glucal (II)
Diethylamine, 0.4 *M*	Water, 0.6 *M*	80% glucal (II)
None	Water, 0.6 *M*	90% tetraacetate (V)
Diisopropylamine, 0.4 *M*	Water, 0.6 *M*	90% tetraacetate (V)
Diisopropylamine, 0.4 *M*	Trace of water	Trace of glucal (II) 30% tetraacetate (V) 60% *N*-glucoside (VI)
Diisopropylamine, 0.4 *M*	Methanol, 0.6 *M*	30% tetraacetate (V) 70% orthoacetate (VII)

*The reactions were carried to completion at 25° in acetonitrile 0.05 *M* in tetra-*O*-acetyl-α-D-glucopyranosyl bromide, 0.25 *M* in tetra-*n*-butylammonium bromide, and the amount of water or methanol indicated.

As was seen in Table II, the course of the reaction of I shifted from 2-acetoxyglucal (II) formation to the formation of *N*-glucoside (VI) on changing the amine from diethylamine to diisopropylamine. The formation of *N*-glucoside in these reactions was inferred from the n.m.r. spectra of the products. None of the *N*-glucosides (VI) were isolated in pure state for proper characterization. In view of these results, it was decided to investigate the effect of the structure of the amine on the course of the reaction. The data are listed in Table III.

TABLE III

The effect of the structure of the amine on polarimetric rate and course of reaction*

Amine	k, min^{-1}	Relative rates	2-Acetoxy glucal (II)	*N*-Glucoside (VI)	Tetraacetate (V)
Pyrrolidine	0.3	8.3	90%	—	—
1,4-Diaza[2,2,2]-bicyclooctane	0.17	4.7	90%	—	—

The largest and smallest polarimetric rates given in Table III differ by a factor of 30 but only a factor of 3 separates the polarimetric rates for the reactions involving diethylamine and triethylamine reactions which follow pronouncedly different courses. With the exception of *n*-propylamine, which led to deacetylation, the yields of 2-acetoxyglucal (II) are greater the higher the polarimetric rate. Perhaps the most striking feature of these data is the excellent correspondence between the polarimetric rate and the steric environment of the nitrogen in the amine, that is, the less hindered the amine to electrophilic attack the greater the rate. Thus, pyrrolidine is a more effective catalyst than piperidine which in turn is more effective than diethylamine. The rates decreased on increasing the lengths of the *n*-alkyl groups of secondary amines. Branching of the alkyl groups at the α-position decreased the rate as evidenced by the relative rates using piperidine, R,S-pipecoline, and R,S-coniine. With diisopropylamine, the rate was as low as that with triethylamine and of the same magnitude as that with tri-*n*-propylamine. It is to be noted that only low yields of the 2-acetoxyglucal (II) were obtained with these hindered amines and except for the reaction with the traces of water, the course of reaction changed to the formation of *N*-glucoside. In fact, the products isolated from the reactions using triethylamine and tri-*n*-propylamine proved to be mixtures of the tetraacetates of glucose. It was judged highly improbable that more than about 30% of these products of hydrolysis were formed during the course of the reaction since great care was taken to exclude water and, if substantial amounts of water had been present, the polarimetric rates should have been higher. It seemed most likely that the reactions produced *N*-glucoside (5) which underwent hydrolysis during the work-up of the reaction mixture. Evidence that this was indeed the case was obtained by observing the reactions at much higher concentrations using n.m.r. spectroscopy. It was found that the presence of the tertiary amines led to the disappearance of I without the formation of appreciable amounts of the 2-acetoxyglucal (II). Instead, products were formed, presumably *N*-glucosides, which were highly sensitive to hydrolysis. Evidence was obtained that α-D-glucopyranose 1,2-(ethyl orthoacetate)triacetate was formed on adding ethanol to the reaction mixture after all the acetobromoglucose (I) had disappeared. These labile *N*-glucosides will be further examined. The reactivities of these compounds is not surprising since it has been shown (2) that treatment of the presumably more stable N-(β-D-glucopyranosyl)-trimethylammonium bromide with base yields 1,6-anhydro-α-D-glucopyranose. Also, an attempt to tritylate the compound led to replacement of the trimethylamine by pyridine (2).

Although the polarimetric rate using *n*-propylamine was the same as that for diethylamine, no 2-acetoxyglucal (II) was detected in the product. The low yield of chloroform-extractable product together with the ready detection of *N*-*n*-propylacetamide in the product indicated that the use of primary amines leads to extensive aminolysis and, therefore, the influence of primary amines on the formation of II could not be profitably studied. It can be noted, however, that although II could not be detected in the product resulting from the use of *n*-propylamine, II was identified by paper chromatography in a reaction using isopropylamine.

In view of the above-mentioned results, it was suspected, at one stage of the investigation, that the formation of II from I resulted from a catalytic ability peculiar to secondary amines. Thus, it could be imagined that the amine not only served as a nucleophile but also engaged the active hydrogen to stabilize the transition state. Evidence that this may not be the case was suggested by the observation that *N*-deuterated diethylamine gave within 5% the same polarimetric rate as the natural diethylamine.

In view of this result, it was anticipated that the catalysis could be provided effectively by a suitably unhindered tertiary amine. In fact, 1,4-diaza[2,2,2]bicyclooctane proved to be an exceptionally good catalyst for the dehydrobromination. It is therefore concluded that the role of the amine is to help delocalize positive charge in the transition state through nucleophilic attack only. On this basis, it would be expected that for the isosteric amines piperidine and morpholine, the stronger amine would be the more effective catalyst. In fact, piperidine, $pk_b = 2.79$, was 3.5 times more effective than morpholine, $pk_b = 5.64$. The high yield of *N*-glucoside from morpholine is noteworthy.

In view of the strong steric demand made on the amine in these reactions, it was anticipated that perhaps quite different rates or routes of reaction would be observed using the enantiomeric forms of such compounds as α-pipecoline and coniine. However, as seen in Table III, the R-forms for these compounds gave polarimetric rates only barely lower than the racemic mixtures and, in each case, the products were essentially the same.

TABLE IV

Dehydrobromination of cyclohexyl bromide*

Tetra-*n*-butyl-ammonium bromide, *M*	Diethylamine	$k \times 10^3$, min^{-1}
0.25	None	1.1
0.50	None	2.2
0.50	0.05 *M*	2.3

*The reaction was carried out at 90° in acetonitrile 0.05 *M* in cyclohexyl bromide, 0.05 *M* in *s*-collidine, and the amounts of the other reagents shown.

The role of the amine in catalyzing the dehydrobromination must be, at least eventually, to accept the departing proton from I. Should this be the only role, then it would be expected that the amines would be effective catalysts under similar reaction conditions for other dehydrobromination reactions. However, as seen in Table IV, diethylamine had no effect on the rate of dehydrobromination of cyclohexyl bromide in acetonitrile containing tetra-*n*-butylammonium bromide. Clearly, the catalysis provided by the diethylamine in this reaction was in no way comparable to that observed in the dehydrobromination of I. It is concluded, therefore, that the catalysis provided by diethylamine (and the other effective amines listed in Table III) is particularly effective for the pyranosyl bromide structures. Under conditions where I was converted to II, using tetra-*n*-butylammonium bromide and diethylamine as catalysts in about 2 h, the dehydrochlorination of tetra-*O*-acetyl-α-D-glucopyranosyl chloride, substituting tetraethylammonium chloride for the tetra-*n*-butylammonium bromide, proceeded to only about 15% after 91 h. About 30% of the starting material remain unchanged. The remainder appeared to be tetraacetates of glucose which presumably arose through the intervention of water.

The ease of the dehydrobromination of I as compared to cyclohexyl bromide is undoubtedly due *mainly* to the ability of the ring-oxygen of I to help delocalize positive charge (13). It seems reasonable therefore to assume that the first stage of the reaction involves change at the anomeric center rather than attack by a nucleophile at the 2-hydrogen as is normally the case for E2 elimination. That the rate of reaction is dependent on the amine concentration is evident from the data contained in Table V. It is seen that doubling the concentration of the amine resulted in about 30% increase in the polarimetric rate. There can be no doubt, in view of the catalysis provided by the amine, that at least a mole of the amine is in the transition state. The observed fractional order

*Polarimetric rates for the conversion of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) to 2-acetoxy-D-glucal triacetate (II) at 25° in acetonitrile, 0.05 *M* in I, 0.5 *M* in tetra-*n*-butylammonium bromide, and containing varying amounts of diethylamine.

in diethylamine under conditions which are close to *pseudo*-first-order is perhaps mainly related to association of the nonpolar amine which lowers the effective concentration of monomeric amine. As seen in Table VI, changing the solvent from acetonitrile to benzene decreased the rate by a factor of about 10. This evidence for charge separation in the transition state is supported by the salt effects given in Table VII. Therefore, the fractional order must to some extent also be related to the decrease in the dielectric constant of the solvent with increasing concentration of the amine.

*Polarimetric rates for the formation of 2-acetoxy-D-glucal triacetate from 0.05 M tetra-*O*-acetyl-α-D-glucopyranosyl bromide at 25° in acetonitrile, 0.4 M in diethylamine, and with varying concentrations of salts.

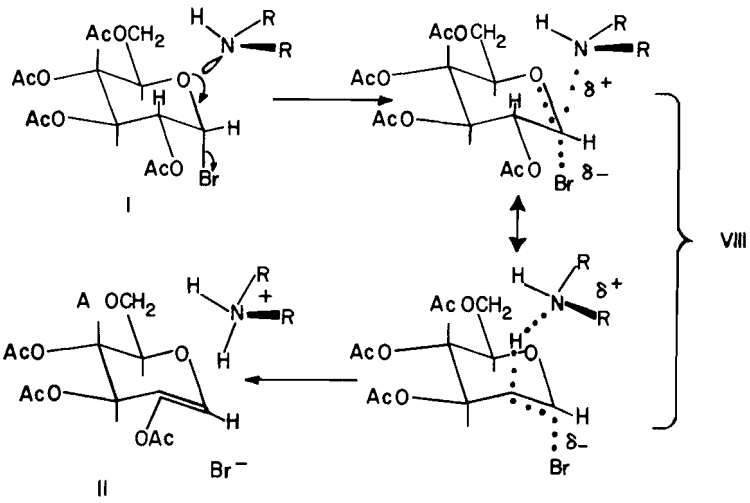

CHART 2

It seems reasonable, on the basis of the above-mentioned experimental data, that the role of the amine in catalyzing the dehydrobromination is to help stabilize the glycosyloxocarbonium bromide which results in dissociation of the glucosyl bromide (I). The positive charge is presumably distributed over the oxygen and carbon atoms and the amine in the intermediate (VIII). In view of the steric effects noted in the data listed in Table III, the bond between the nitrogen and atoms about the anomeric center must be fairly strong. However, the degree of catalysis provided by the amine does not seem large enough for the amine to play a role other than to act as an effective solvating agent for the glucosyloxocarbonium ion. The positive charge would be expected to strongly activate the 2-hydrogen. Therefore, it seems reasonable to expect that such an intermediate (VIII) could collapse to products by two different and competing routes. One route would involve establishment of a covalent N—C bond to form *N*-glucoside. The data in Table III suggest that this is the favorable route for amines with hindered nitrogen. The other route would involve loss of the 2-proton to the amine which necessarily would be well oriented in the intermediate to serve as the proton acceptor. It is conceivable,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

therefore, that the effectiveness of amines in promoting the dehydrobromination route is directly related to the allowed orientations of the amine relative to the 2-hydrogen in the intermediate. As already mentioned with reference to Table III, it is evident that the less hindered the nitrogen for amines of comparable basic strength the stronger the bonding in the transition state and the greater the yield of the acetoxyglucal (II). Clearly, for example, the non-bonding interactions in the intermediate (VIII) would be less severe for diethylamine than for either diisopropylamine or triethylamine. Furthermore, such steric interactions would tend to prevent the amine from assuming the energetically most favorable orientation coplanar with the O—C—Br atoms and very close to the 2-hydrogen. In view of the charge separation in the transition state, the roles of the solvent effects noted in Table VI and the salt effects seen in Table VII are readily rationalized. The greater effectiveness of bromide ion as compared to perchlorate ion could be assigned to the difference in charge density on these ions. It was surprising to find that the enantiomeric forms for α-pipecoline and coniine possessed almost equal catalytic abilities. It should prove possible to find enantiomers which differ substantially in their abilities to solvate the glucosyloxocarbonium ion and it is planned to examine these possibilities, since the results may help shed light on the stereoselectivity of carbohydrase-enzyme activity.

Following the proposals of Bunnett (18), the mechanism of the amine-catalyzed dehydrobromination of α-acetobromoglucose can be classified as "E2 leaning toward E1" since the breaking of the C—Br bond must be far advanced in the transition state. However, as stated above, the amine likely plays an important role in the breaking of the C—Br bond by solvating the developing cation through non-directive electrostatic bonding. Thus, in a formal sense, the mechanism of the reaction would resemble the merged bimolecular substitution and elimination mechanism proposed by Winstein, Darwish, and Holness (19). The difference would be in the ionic character of the transition state.

In conclusion, the results of this investigation have provided a deepened appreciation of the essential features of the mechanism for the dehydrobromination of tetra-*O*-acetyl-α-D-glucopyranosyl bromide and this knowledge should prove useful in arriving at conditions suitable for the dehydrohalogenation of other *O*-acylglycosyl halides in high, reproducible yields. The results also illustrate how rather small structural changes in a soluble catalyst can modify the route of reaction by changing the relative rates of competing reactions. It can be anticipated that this kind of information will prove useful in future synthetic operations.

EXPERIMENTAL

Tetra-n-butylammonium Bromide (20)

An equimolar mixture of tri-*n*-butylamine and *n*-butyl bromide was heated on the steam bath until homogeneous—about 2 weeks. On cooling, the product solidified and was recrystallized 3 times from ethyl acetate to give a 30% yield of white crystals, m.p. 111–114°, which were dried at room temperature in a high vacuum.

Tetra-n-butylammonium Perchlorate

An aqueous solution of sodium perchlorate, 2.5 *M*, was added, with stirring, to an equivalent amount of aqueous 1.25 *M* tetra-*n*-butylammonium bromide. The precipitate was washed free of bromide ion and treated with ethyl acetate. The organic layer was dried over anhydrous calcium carbonate and pentane was added. The precipitate was collected and the mother liquor was evaporated to dryness. The solids were combined and recrystallized from ethyl acetate to provide an 80% yield of white crystalline product, m.p. 207–210°. The reported melting point is 212–212.5° (21).

Amines

The amines were commercial products purified by fractional distillation through a spinning-band column and stored over potassium hydroxide.

N-Deuterated diethylamine was prepared by exchange of the active hydrogen of diethylamine with deuterium oxide. After five exchanges using equivalent amounts, the amine, which was isolated in each case by distillation through a spinning-band column, no longer produced DOH on mixing with deuterium oxide as evidenced by n.m.r. spectroscopic examination. The compound was dried over sodium metal. The extent of deuteration appeared better than 95% as judged by a comparison of the intensities of the DOH n.m.r. signals for equivalent mixtures of the deuterated and ordinary amines in deuterium oxide.

R,S-α-Pipecoline was resolved following the procedures outlined by Ladenburg (22) and by Marckwald (23). The sticky, solid mass obtained on mixing the amine with D-*dextro*-tartaric acid was triturated with cold water and the crystals twice recrystallized from water. Regeneration of the amine provided S-*dextro*-α-pipecoline, $[\alpha]_D^{25}$ +32.4°; reported (23), $[\alpha]_D$ +31.9°.

R,S-Coniine was prepared as described by Johnson (24) and partially resolved following the directions outlined by Wolffenstein (25). The tartrate, which crystallized on seeding with S-α-pipecoline D-tartrate and isolated by trituration with cold water, was decomposed directly to S-coniine of at least 50% optical purity, $[\alpha]_D^{26}$ +8.7°; reported (25), $[\alpha]_D^{19}$ +15.7°.

Solvents

The acetonitrile was twice refluxed over phosphorous pentoxide for several hours and recovered by distillation under anhydrous conditions. The benzene was dried by distillation and stored over sodium metal

Paper Chromatography

The paper chromatographic examinations of reaction products were made on dimethylsulfoxide impregnated Whatman No. 1 paper using Skellysolve B as the developing phase (26). The zones were located using alkaline silver nitrate (27). 2-Acetoxy-D-glucal triacetate moved faster than other components of the reaction products examined and smaller amounts could be detected in this way than was possible by n.m.r. spectroscopy.

Nuclear Magnetic Resonance Spectra

All spectra were measured with a Varian Associates A-60 spectrometer with chloroform as a solvent and tetramethylsilane as internal standard. The spectrum for pure 2-acetoxy-D-glucal triacetate (II) has a singlet for H-1 at 3.33 τ, a doublet with a spacing of 4 c.p.s. centered at 4.41 τ for H-3, a multiplet centered at 4.75 τ with a half-band width of about 10 c.p.s. for H-4, and a fairly sharp peak at 5.65 τ for H-5, and the two H-6's. The spectrum for tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I) has a doublet with a spacing of 3.8 c.p.s. centered at 3.40 τ for H-1, signals for H-3 and H-4 in the region 4.25 to 4.95 τ and a quartet with spacings of 3.8 and 10 c.p.s. centered at 5.19 τ for H-2. The signals for H-5 and the two H-6's formed a multiplet with the most intense peak at 5.78 τ. The relative amounts of the two compounds in a mixture could be estimated by comparing the signals for the anomeric (H-1) protons. Since the H-1 signal for II overlapped the low-field signal of the doublet for H-1 of I, the composition was estimated by subtracting the intensity of the signal at about 3.42 τ from that at about 3.33 τ and dividing the result by twice the intensity of the 3.42 τ signal. Control experiments showed that the relative amounts of compounds II and I could be estimated in this way to ±10%. The analysis could be confirmed with about the same accuracy by comparing the intensity of the signal for H-2 of I to the total intensity of the H-1 signals. In order to obtain an estimate of the amount of compounds I and II in the product, the total intensity of H-1 signals in the region of 3.3–3.5 τ was compared with the total intensity of signals arising from H-5 and H-6 protons in the region 5.5–6.2 τ, since the latter protons produced their signals in the region indicated for all the acetylated glucose derivatives encountered. The presence of 1,3,4,6-tetra-*O*-acetyl-α-D-glucose in the product was readily detected by the appearance of the signal for H-1 as a doublet with a spacing of 3.5 c.p.s. at 3.77 τ. Also, the signal for the 1-acetoxy group at 7.81 τ was highly characteristic for this compound. The presence of *N*-glucoside (VI) in the product was detected by the appearance of signals characteristic for protons of the aglycon. The amount of the *N*-glucoside (VI) was estimated by comparing the intensities of these signals with the total intensities of the signals for the H-5 and the two H-6 protons. In the reaction using diisopropylamine and in the presence of methanol, see Table II, the presence of the orthoacetate (VII) in the product was established by the characteristic signals at 4.29, 6.72, and 8.30 τ for the anomeric proton, the methoxyl-group protons, and the methyl-group protons of the orthoacetyl group, respectively (5).

Reactions Using Tertiary Amines

In the reactions involving triethylamine and tri-*n*-propylamine, see Table III, the change in specific rotation through the course of the reaction was only about 60% that observed with diethylamine. The product of the reaction using triethylamine was obviously a mixture of 2-acetoxy-D-glucal triacetate (about 15%), 1,3,4,6-tetra-*O*-acetyl-α-D-glucose (about 30%), and the equilibrium mixture of the anomeric 2,3,4,6-tetra-*O*-acetyl-D-glucoses (about 55%). It is known (17) that the 1,3,4,6-tetraacetate isomerizes readily to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the 2,3,4,6-isomer and the latter compound may have formed in this way. The product of the reaction using tri-*n*-propylamine gave the n.m.r. spectrum for the equilibrium mixture of the anomeric 2,3,4,6-tetra-*O*-acetyl-D-glucoses but no 2-acetoxy-D-glucal triacetate (II). It was therefore apparent that the reaction of I with both triethylamine and tri-*n*-propylamine led to the formation of labile compounds which decomposed during the isolation procedure. This conclusion was substantiated by the following experiments.

Tetra-*O*-acetyl-α-D-glucopyranosyl bromide (I), 0.5 g (1.22 mmoles), and tetra-*n*-butylammonium bromide, 1.96 g (6.1 mmoles), were dissolved in 5 ml of acetonitrile containing 9.8 mmoles of tertiary amine. The n.m.r. spectrum of the solution was measured within a few minutes of dissolution. Spectra were determined at varying intervals of time for the reaction mixture kept at room temperature. When the amine was triethylamine, the solution stayed nearly homogeneous and the n.m.r. spectra showed that the acetobromoglucose (I) had completely reacted within 75 min. The reaction led to the appearance of a doublet with a spacing of about 5 c.p.s. at 3.74 τ. A colorless, crystalline, water-soluble compound, 0.2 g, was deposited in the course of the reaction and identified as triethylamine hydrobromide by n.m.r. spectroscopy. The chemical nature of the carbohydrate product was not established. However, the substance was shown to be highly reactive by an examination of the chemical changes which occurred on the addition of water and dry ethanol. Water was added to one-half of the reaction mixture and, after 1 h, the product was isolated by chloroform–water extraction in the usual manner. The n.m.r. spectrum of the syrupy product in chloroform showed the presence of a compound with a signal at about 4 τ in the form of a doublet with 5.5 c.p.s. spacing. The intensity of the signal relative to the other signals in the 4.5 to 6 τ region required the compound to be the main glucose derivative in the mixture. It was evident that the product contained an appreciable amount of 2,3,4,6-tetra-*O*-acetyl-D-glucose. The syrup was dissolved in 5 ml of dioxane and 0.1 ml of 2 *N* sulfuric acid was added. No appreciable change in rotation occurred over a 10 min period. Dry ethanol was added to the other half of the original reaction solution. After 3 h, the product was isolated by chloroform–water extraction in the usual manner. The n.m.r. spectrum in chloroform showed doublets of about equal intensities at 3.92 and 4.28 τ with spacings of 5.5 and 5 c.p.s., respectively. It seemed probable that the low-field signal arose from the same compound that produced a similarly located doublet of the same spacing in the product resulting from the treatment with water. That the higher-field signal arose from an ethyl 1,2-orthoacetate derivative was clearly apparent from the following observations. α-D-Glucopyranose 1,2-(ethyl orthoacetate) triacetate in chloroform produces a signal at 4.28 τ with a spacing of 5.5 c.p.s. When the syrup was dissolved in 5 ml of dioxane and 0.1 ml of 2 *N* sulfuric acid added, the rotation of the solution changed from 1.75° to 2.63° in 3 min (28). The product was isolated by chloroform–water extraction and its n.m.r. spectrum clearly showed the presence of 1,3,4,6-tetra-*O*-acetyl-α-D-glucose (V) and the 2,3,4,6-tetra-*O*-acetyl-D-glucoses as the main products together with an abaut 5% yield of 2-acetoxy-D-glucal triacetate (II).

When tri-*n*-propylamine was substituted for the triethylamine in the above experiment, the course of the reaction as determined by n.m.r. spectroscopy appeared similar except that the reaction was much slower. The tri-*n*-propylamine was only slightly soluble in the salt solution and this may have been the main reason for the low rate of reaction.

Polarimetric Rates

Tetra-*O*-acetyl-α-D-glucopyranosyl bromide (0.500 g, 1.22 mmoles) and the desired amount of the tetra-*n*-butylammonium salt were weighed into a 25 ml volumetric flask which had been previously rinsed with dry solvent. The flask was stoppered with a serum cap and approximately 10–12 ml of dry solvent added with a syringe. Shaking produced a solution to which was added the desired amount of dry amine. The volume was then rapidly adjusted to 25 ml by the addition of dry solvent. After thorough shaking, a sample was removed with a syringe and introduced into a 0.5 dm polarimetric cell attached to a constant temperature water bath thermostatted at 25°. The remainder of the reaction solution was incubated at 25° during the course of the reaction.

The chart drive (timing mechanism) of a Rudolph Instruments Engineering Co. Automatic Recording Spectropolarimeter (Model 260/655/850/810-614) was turned on at the time the amine was added. The reaction was followed at the sodium D-line until minimum rotation was attained. At this point, the reaction solution was diluted with chloroform (100 ml) and washed successively with water, dilute hydrochloric acid, aqueous sodium bicarbonate, and water. The chloroform solution was dried over anhydrous sodium sulfate and filtered and the solvent removed under reduced pressure. The n.m.r. spectrum of the resulting syrup was determined in chloroform.

Zero-rotation base lines were placed on the chart preceding the polarimetric determination and also following it. The final rotation was verified by visual determination on a Rudolph and Sons precision polarimeter (Model 80). The change in rotation with time could be read directly from the chart record. The kinetic data presented in Table V are typical examples of the results obtained.

Dehydrobromination of Cyclohexyl Bromide

In a typical experiment, a 50 ml acetonitrile solution of cyclohexyl bromide, 0.398 g (2.44 mmoles), 2,4,6-trimethylpyridine (*s*-collidine), 0.298 g (2.44 mmoles), and tetra-*n*-butylammonium bromide, 7.84 g

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(24.4 mmoles), was prepared. Aliquots, 10 ml, were transferred to glass tubes which were sealed and incubated at 90° in an oil bath. An aliquot was kept at room temperature to serve as a control in the following analytical procedures. After varying reaction times, the tubes were cooled and analyzed for hydrogen bromide by titration with standard sodium hydroxide using phenolphthalein as indicator. The relative amounts of cyclohexene and cyclohexyl bromide were determined by gas–liquid partition chromatography using an Apiezon M column and a temperature program of 50–200°. The extents of reaction determined in both ways agreed to within 4%. When a sample of the reaction mixture was analyzed by gas–liquid chromatography, peaks assignable to *n*-butyl bromide and tri-*n*-butylamine were present. These products arose from thermal decomposition of tetra-*n*-butylammonium bromide in the inlet of the F and M Model 500 Gas Chromatograph since these compounds were not present in the volatile fraction of a sample distilled *in vacuo* in a closed system. When diethylamine was present, the amount of hydrogen bromide liberated in the reaction was determined after a fourfold dilution with water by titration to pH 4.5 with 0.05 *N* hydrochloric acid.

*Preparation of 2-Acetoxy-*D*-glucal Triacetate*

Diethylamine, 26.7 g (37.6 ml, 366 mmoles), was added to a suspension of tetra-*O*-acetyl-α-D-glucopyranosyl bromide, 50.0 g (122 mmoles), and tetra-*n*-butylammonium bromide, 39.2 g (122 mmoles), in 25 ml of acetonitrile. An orange hue developed and complete solution was obtained within a few minutes. After 20 min at room temperature, the solution was diluted with 250 ml of chloroform and washed successively with water, dilute hydrochloric acid, aqueous sodium bicarbonate, and water. The chloroform solution was dried over anhydrous sodium sulfate, filtered, and the solvent removed under reduced pressure. The n.m.r. spectrum of the resulting reddish-brown syrup showed the presence of 2-acetoxy-D-glucal triacetate only, and the conversion was therefore virtually quantitative. Crystallization from the minimum amount of ethanol required to dissolve the syrup at room temperature afforded about 80% yields of crystalline material melting at 58–60°. Further crystallizations from ethanol did not increase the uncorrected melting point to above 61° with $[\alpha]_D^{25}$ −20° (*c*, 2 in ethanol). Maurer (29) has reported the compound to melt as high as 65–66°, $[\alpha]_D^{20}$ −20.71° in ethanol.

ACKNOWLEDGMENTS

The research was supported by a Corn Industries Research Foundation grant to R. U. Lemieux. The n.m.r. spectra were measured by R. N. Swindlehurst and Mrs. Gail Conway of this department.

THE REACTIONS OF METHYLENE RADICALS WITH ACETALDEHYDE AND PROPIONALDEHYDE[1]

M. H. Back
Chemistry Department, The University of Ottawa, Ottawa, Canada

Received August 18, 1964

ABSTRACT

The reactions of methylene radicals with acetaldehyde and propionaldehyde have been studied over the temperature range 48–118 °C and over a range of pressures of aldehyde and carbon dioxide. From acetaldehyde, the main products were carbon monoxide, methane, ethane, and acetone, with small amounts of ethylene at low pressures of acetaldehyde. With carbon dioxide present, small amounts of propylene oxide were formed, but propionaldehyde was not observed. The main products from the reaction with propionaldehyde were carbon monoxide, methane, ethane, and ethylene, with small amounts of methyl ethyl ketone, butene oxide, and isobutyraldehyde. The relation of the results to the relative rates and mode of attack of methylene on the various bonds is discussed.

INTRODUCTION

The reactions of methylene radicals with hydrocarbons have been studied in some detail and a general pattern of reactivity has emerged (1). Methylene appears to be one of the most reactive radicals known and one of the most indiscriminate in its attack upon the various types of hydrocarbon bonds. Less is known about its reactivity with other types of bonds. Reactions with oxygen-containing compounds, for example, have not been extensively studied. In the gas-phase reaction of methylene with isopropyl ether (2) no evidence was found for attack of methylene on the C—O bond. The products appeared to be formed solely by abstraction of hydrogen and insertion into the various C—H bonds. The relative rate of attack on these bonds was similar to that found by Frey (3) and Knox and Trotman-Dickenson (4). This result confirmed the similar conclusion reached by von Franzen and Fikentsher (5) and Doering, Knox, and Jones (6) from a study of the reaction of methylene with aliphatic ethers and tetrahydrofuran in solution. The reaction of methylene with methanol vapor (7) produced, among other products, dimethyl ether, and it was suggested that this was formed by an insertion reaction into the OH bond. However, the possibility of its formation by radical combination reactions could not be ruled out.

The reactivity with carbonyl bonds as compared to C—H bonds is not well known. That methylene does react with carbonyl bonds has been shown by a study of the reaction with carbon monoxide (8) and carbon dioxide (9). With the former, ketene is the product, while with the latter the main product is carbon monoxide, probably initially accompanied by formaldehyde. To obtain more information on the reactivity of methylene towards carbonyl bonds, the aldehydes were chosen as reactants, since they contain three types of bonds: paraffinic C—H bonds, the labile aldehydic C—H bond, and the carbonyl bond. It was hoped that the relative rate and mode of attack of methylene on these various bonds might be measured. The photolysis of ketene was used as a source of methylene radicals.

EXPERIMENTAL

Materials

Acetaldehyde was obtained from Eastman Kodak Company. It was stored as a liquid at 0 °C and was degassed at −78 °C before use. Traces of ethane were thus removed, but a small amount of acetone remained

[1]*Presented at the 47th Canadian Chemical Conference, Kingston, June, 1964.*

as an impurity. Correction for this became large only when very high pressures of acetaldehyde were used. The same treatment was given propionaldehyde, also obtained from Eastman Kodak Company, except that it was stored at room temperature. A trace of acetaldehyde was the main impurity observed in the propionaldehyde.

Ketene was prepared by the method described by Fisher, MacLean, and Schnizer (10) with slight modifications. Nitrogen was used as a carrier gas, and one trap kept at about −40 °C served to separate most of the acetic acid and unreacted acetic anhydride from the ketone. The ketene was then degassed at −196 °C and distilled at −120 °C (*n*-propanol bath). Ethylene could not be detected by gas chromatographic analysis of a sample of the size used in most experiments. It was stored at room temperature and low pressure (< 3 cm) as suggested by Frey (11) and was found to be quite stable for periods of several months.

Carbon dioxide was a Matheson Co. product and was thoroughly degassed before use.

Apparatus

The lamp used for photolysis was a Hanovia S500 medium pressure mercury arc. A filter solution of 2,7-dimethyl-diaza-(3,6)-cycloheptadiene-(1,6)-perchlorate[2] cut off light of wavelength < 3 500 Å. A 500 cc flask, through which water flowed continuously, was placed between the lamp and filter solution and served to collimate the light roughly and to absorb much of the heat generated by the lamp.

Two reaction vessels were used, both of about 250 cc volume. The first was a spherical flask with a central cold-finger for condensing reactants, and without external heating. The second was a cylinder of diameter approximately 5 cm and was fitted inside a steel tube wound with nichrome wire. Reactants were condensed into a small U tube. In some experiments with the cylindrical vessel the reactants were allowed to stand overnight before photolysis and no change in the behavior of the system was observed. These experiments are, however, not sensitive to slight changes in homogeneity of the reactant mixtures.

The pressure in the reaction vessel was measured with a small glass diaphragm gauge used as a null-point indicator. The sensitivity was ±0.5 mm. The volume of the gauge and connecting tubing was not more than 2 or 3 cc.

Analysis

The condensable products of the reaction were fractionated through a series of four traps. The first, at −115 °C, retained most of the acetaldehyde and any higher-boiling products. This was analyzed by gas chromatography on a polypropylene glycol column, 20 ft long, at 25 °C. Acetaldehyde, propionaldehyde, acetone, and propylene oxide were well separated. The same column at 50 °C was found to separate propionaldehyde and the corresponding isomers of butyraldehyde. The second trap was a LeRoy still maintained at −196 °C and the final two traps were held at −210 °C. Except when carbon dioxide was present, the contents of these three traps were analyzed together on a 6 ft silica gel column held at 30 °C. Ethane, carbon dioxide, and ethylene were separated under these conditions. When large amounts of carbon dioxide were present, the C_2 hydrocarbons were distilled from the LeRoy still at about −162 °C.

The noncondensable gases were collected in a Toepler pump – gas burette following the traps and were analyzed by combustion in a copper oxide furnace at about 325 °C.

RESULTS AND DISCUSSION

The complexities and experimental difficulties inherent in the present system did not allow the quantitative determination of rate constants, but only a qualitative interpretation of the modes of attack of methylene on the various bonds in aldehydes. To minimize absorption of light by the aldehyde, light of wavelengths > 3 500 Å was used to dissociate ketene, and in this region the primary quantum yield for dissociation is strongly pressure dependent. Pressure effects on the reaction products were therefore obscured. Furthermore, at high pressures of aldehyde where the quantum yield for dissociation of ketene was very small, direct photolysis of the aldehyde became appreciable, especially at high temperatures where the chain length is long.

Acetaldehyde

Following the general pattern of reactivity of methylene, the possible reactions with acetaldehyde may be outlined as follows

$$[I_0] \qquad CH_2CO + h\nu \rightarrow CH_2 + CO$$

$$[a] \qquad CH_2 + CH_2CO \rightarrow C_2H_4 + CO$$

$$[1] \qquad CH_2 + CH_3CHO \rightarrow [CH_3COCH_3]^*$$

[2]*The author thanks Dr. K. O. Kutschke of the National Research Council for a sample of this compound.*

$$[S_1] \quad [CH_3COCH_3]^* + M \rightarrow CH_3COCH_3 + M$$

$$[S_2] \quad \rightarrow CH_3CH\text{—}CH_2 + M \quad (\text{O bridging CH and } CH_2)$$

$$[S_3] \quad \rightarrow CH_3CH_2CHO + M$$

$$[D_1] \quad [CH_3COCH_3]^* \rightarrow CH_3 + CH_3CO$$

$$[D_2] \quad \rightarrow CO + 2CH_3$$

$$[D_3] \quad \rightarrow CH_4 + CH_2CO$$

$$[D_4] \quad \rightarrow C_2H_6 + CO$$

$$[2] \quad CH_2 + CH_3CHO \rightarrow CH_3 + CH_3CO$$

$$[3] \quad CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO$$

$$[4] \quad CH_3 + CH_3 \rightarrow C_2H_6$$

$$[5] \quad CH_3 + CH_3CO \rightarrow CH_3COCH_3$$

$$[6] \quad 2CH_3CO \rightarrow (CH_3CO)_2$$

$$[7] \quad CH_3CO + M \rightarrow CH_3 + CO$$

For simplicity the dissociation of ketene has been represented as a single reaction although, as already mentioned, pressure and temperature effects are important in the efficiency of this step. The designation of the excited molecule formed in reaction [1] is not intended to represent its actual structure, for which several possibilities exist, and which may, indeed, be different for each of the subsequent reactions.

The main products observed were carbon monoxide, methane, ethane, acetone, ethylene, and, under certain conditions, small amounts of propylene oxide. Propionaldehyde was not detected. The yields of products as a function of acetaldehyde pressure at two temperatures are shown in Figs. 1 and 2. At 45 °C the yield of carbon monoxide dropped sharply at first as the primary quantum yield for ketene dissociation decreased, but rose again at higher pressures as the direct photolysis of acetaldehyde became important. The products were similar to those obtained by direct photolysis of acetaldehyde and the main reaction of methylene appeared to be initiation of the chain decomposition of acetaldehyde. The yields of acetone were small and the variation with pressure not pronounced. It is most likely that it was formed mainly by combination of methyl and acetyl radicals rather than by the direct insertion of methylene. The ethylene yield was also small and even at equal pressures of ketene and acetaldehyde was less than the yield of ethane. Reaction of methylene with acetaldehyde thus appears at least as fast as with ketene.

At 118 °C the drop in quantum yield for ketene dissociation with pressure is not as sharp and the rate of decomposition of acetaldehyde much faster. Thus the yields of carbon monoxide and methane rose continuously with pressure. The yield of acetone relative to the yield of ethane has decreased, a result consistent with the suggestion that acetone was formed by combination of methyl and acetyl radicals. Again, no stabilization products were observed.

The decomposition of acetaldehyde may be initiated by reaction with an excited ketene molecule rather than by direct reaction with methylene radicals. However, the maximum energy absorbed by the ketene was 3 660 Å, equivalent to 78 kcal/mole, and this is barely sufficient to cause dissociation of acetaldehyde. Furthermore, the initial drop in carbon monoxide yield as acetaldehyde pressure was increased (Fig. 1) is difficult to explain unless deactivation of ketene occurs without decomposition of acetaldehyde. At 118 °C an energy transfer process may occur to some extent. It will be seen later that the results with propionaldehyde provide additional evidence that methylene radicals are the reactive species.

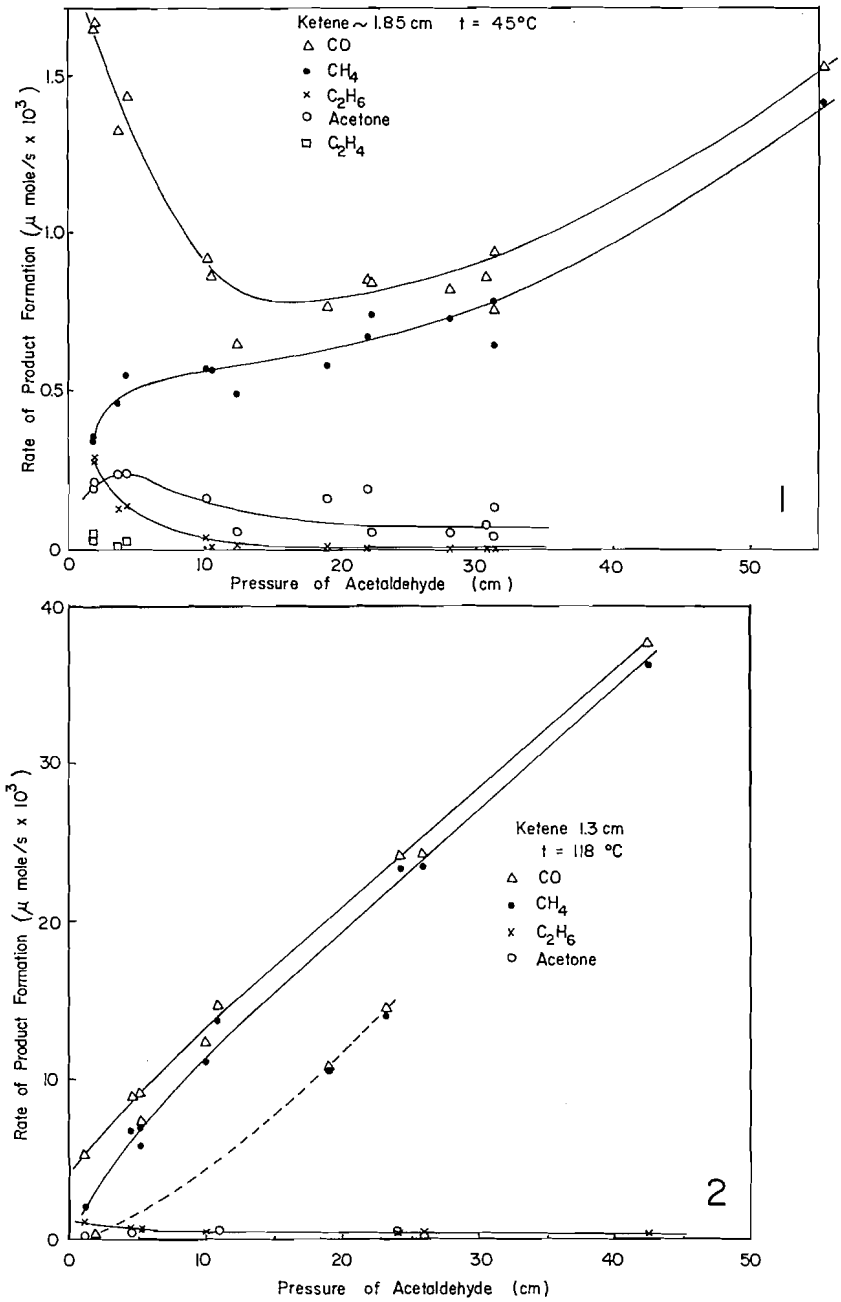
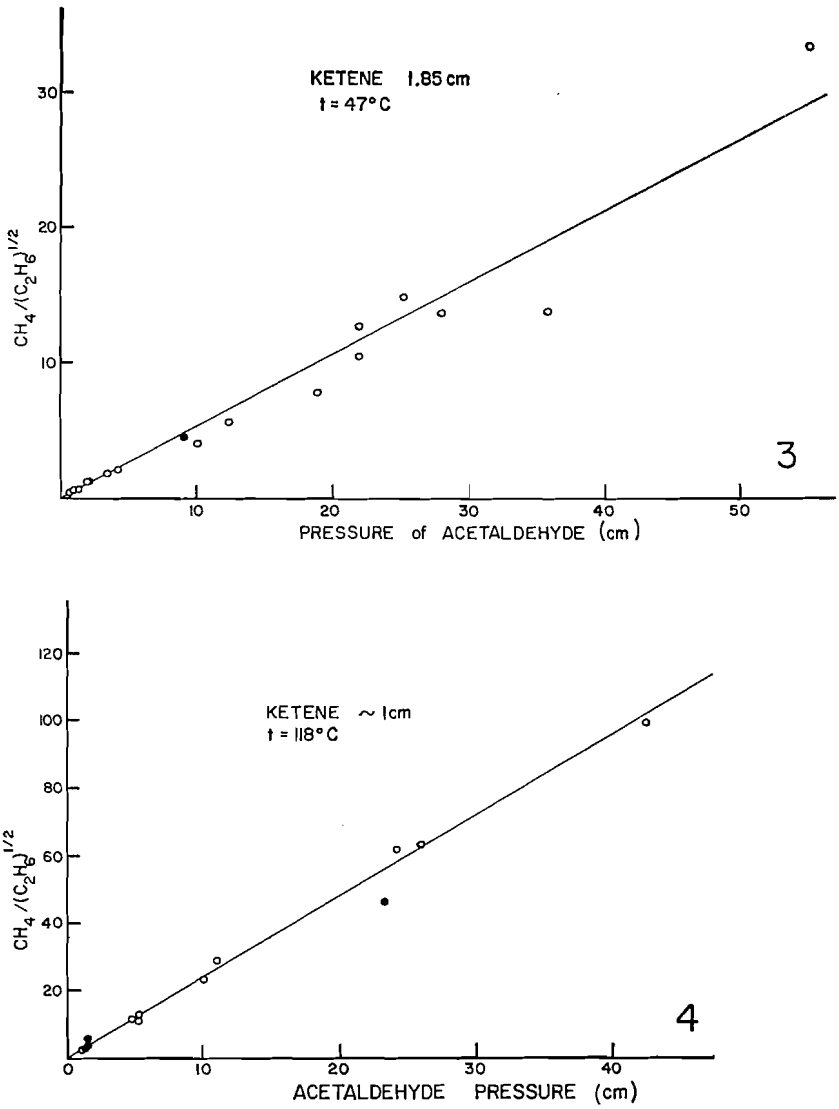


FIGS. 1 and 2. Rate of product formation from the photolysis of ketene in the presence of acetaldehyde. Dotted line shows rate of product formation from photolysis of acetaldehyde by itself.

The yield of methane divided by the square root of the yield of ethane is shown as a function of acetaldehyde pressure at the two temperatures in Figs. 3 and 4. In each case a linear relation was observed down to the lowest pressures used, showing that methane and ethane were formed from methyl radical reactions and not from a molecular decomposition of the excited molecule (reactions $[D_3]$ and $[D_4]$). From the rate constants obtained



FIGS. 3 and 4. $CH_4/(C_2H_6)^{1/2}$ as a function of acetaldehyde pressure. Filled circles are results from photolysis of acetaldehyde by itself.

from these curves an activation energy of 6.2 kcal/mole was obtained for the abstraction of hydrogen from acetaldehyde. This is in satisfactory agreement with the accepted value of 7.5 kcal/mole (12).

In order to minimize the products from the chain decomposition of acetaldehyde and at the same time increase the pressure, carbon dioxide was added to small, constant amounts of ketene and acetaldehyde. The yields of products at three temperatures are shown in Figs. 5, 6, and 7. The very pronounced increase in yields of all products at 44 °C, before the expected decrease was observed, is not readily explained by any series of reactions and may be a phenomenon associated with the absorption of light in this complex system. Another possibility is that one of the effects of carbon dioxide is to

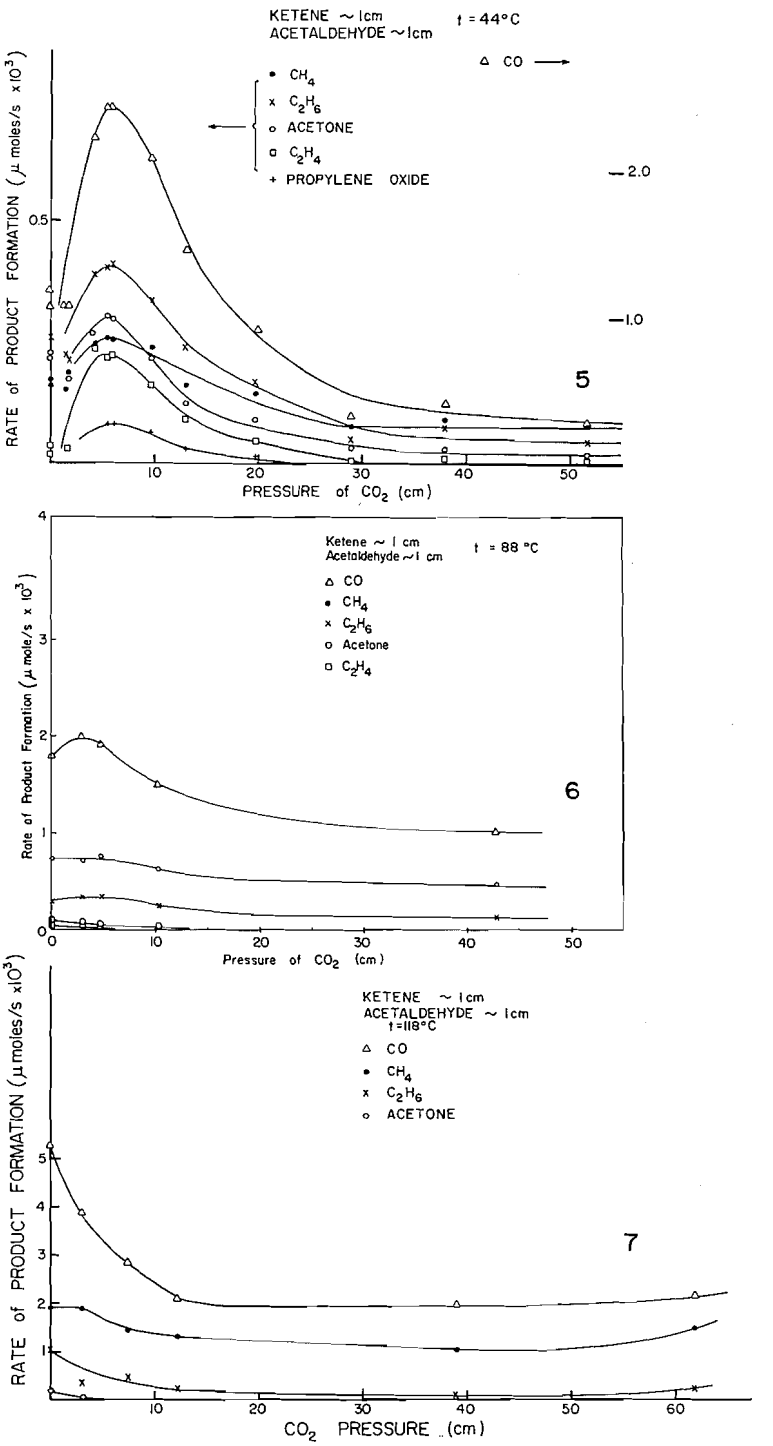

FIGS. 5, 6, and 7. Rate of product formation from the photolysis of ketene in the presence of acetaldehyde and carbon dioxide.

increase the dissociation of ketene into methylene and carbon monoxide relative to the deactivation. The increase in yields of products may thus arise from an increased yield of methylene radicals. At higher pressures deactivation finally becomes faster than dissociation and product yields fall. Since a similar effect was not observed with acetaldehyde by itself, it must be assumed that carbon dioxide is more effective than acetaldehyde in promoting dissociation of ketene rather than deactivation. The effect diminished as the temperature was increased and as the dissociation of ketene was less affected by pressure.

At 44 °C propylene oxide was observed, but in very small yields. A comparison of the variation with pressure of the yield of stabilization product, propylene oxide, and the yield of dissociation product may be made if it is assumed that the yield of radicals from reactions $[D_1]$ and $[D_2]$ may be equated to the yield of termination products from reactions [4], [5], and [6]. Since the yield of biacetyl was not measured, it was estimated by assuming $k_4 = k_5 = k_6$, which gave a total yield of termination product = [ethane + acetone + ((acetone)^2/ethane)]. Plots of these products are shown in Fig. 8. The similar effect of pressure on each type of product is difficult to explain if the yield of propylene oxide is a measure of reaction $[S_2]$ and the termination products are a measure of reactions $[D_1]$ and $[D_2]$. However, if most of the radicals were formed by reaction [2], which is a true abstraction reaction, independent of pressure, and most of the excited propylene oxide was stabilized at fairly low pressures, then the variation in pressure of both types of products will simply reflect the variation in the quantum yield of ketene dissociation. The abstraction reaction may not have been observed in the reactions of methylene radicals with hydrocarbons because in this case its rate may be slower relative to the insertion reaction. With the aldehydes, abstraction of the labile aldehydic hydrogen atom may compete favorably with the insertion.

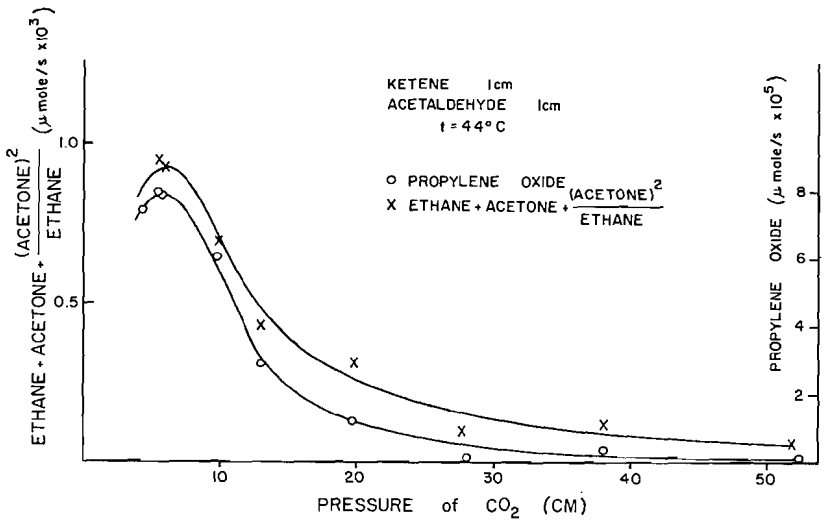

FIG. 8. Propylene oxide and radical yield as a function of carbon dioxide pressure.

An added effect of inert gas is to induce the singlet–triplet transition of the methylene radical, giving an increased concentration of triplet methylene radicals relative to singlet with rising pressure of carbon dioxide. If the triplet state radical were to react more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

readily by reaction [2] than the singlet, then the yield of radicals would not drop as sharply with pressure as expected on the basis of reactions [1], [S], and [D]. This effect may contribute to the similarity of the curves in Fig. 8, but it would be fortuitous if this alone caused the variations with pressure to be almost identical. These results, then, do not provide evidence for a difference in reactivity of singlet and triplet methylene by reaction [2].

Propylene oxide was not observed at 118 °C. From the results of Strachan and Noyes (13) it may be estimated that at this temperature the quantum yield of dissociation of ketene should be 2.5 times that at 45 °C. A yield of propylene oxide equivalent to 2.5 times that observed at 45 °C would have been easily measurable. Its absence again suggests the occurrence of an abstraction reaction which has a higher activation energy than the insertion and hence competes more favorably at the higher temperatures. The small change in temperature would not be expected to affect appreciably the amount of stabilization at any given pressure.

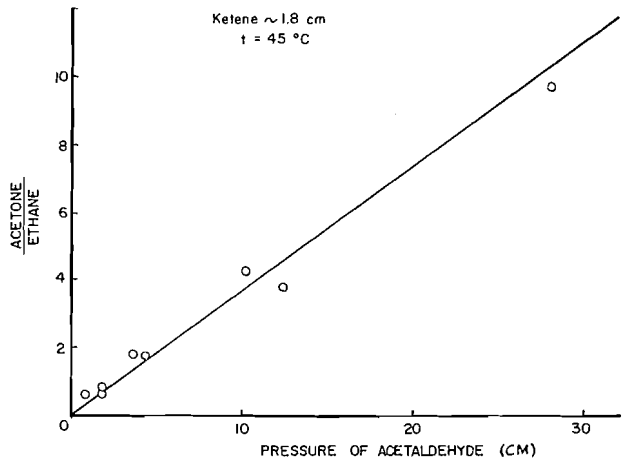

FIG. 9. Ratio of acetyl radical concentration to methyl radical concentration as a function of acetaldehyde pressure.

The ratio of acetone to ethane should be proportional to the ratio of concentration of acetyl radicals to that of methyl radicals. At 45 °C this ratio was found to be a linear function of the acetaldehyde pressure (Fig. 9). Thus for the series of experiments with constant acetaldehyde pressure the ratio would be expected to be unchanged by addition of carbon dioxide. In fact the ratio decreased with increasing total pressure (Fig. 10). This may be an indication of a pressure dependence of the decomposition of the acetyl radical.

Propionaldehyde

A series of reactions similar to those suggested for acetaldehyde would be expected to occur in the reaction of methylene with propionaldehyde. The possible stabilization products are methyl ethyl ketone, *n*-butyraldehyde, isobutyraldehyde, and α-butene oxide. Methyl, ethyl, and possibly propyl radicals may be formed by decomposition of the excited molecule, and these would initiate the chain decomposition of propionaldehyde. In accordance with this the main products observed were carbon monoxide, ethane, methane, ethylene, and small amounts of stabilization products. The results of the

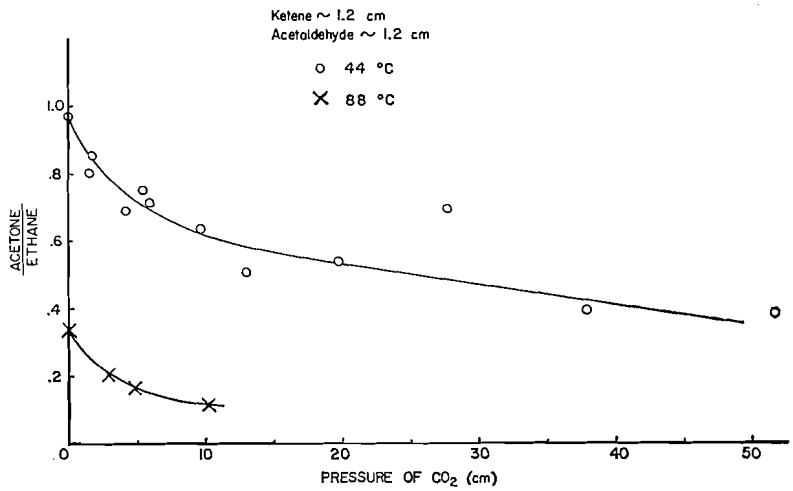

FIG. 10. Ratio of acetyl radical concentration to methyl radical concentration as a function of carbon dioxide pressure for constant acetaldehyde pressure.

photolysis of ketene in the presence of propionaldehyde and carbon dioxide at 85 °C are summarized in Table I. The yields of products at 45 °C as a function of carbon dioxide pressure are shown in Figs. 11 and 12. The yield of ethane was not plotted since it was similar at all pressures to that of methane. There is the suggestion of an inflection point in the variation of yields of the main products with carbon dioxide pressure, but the effect is much less than that observed with acetaldehyde. At 85 °C the yields of all products steadily decreased as the carbon dioxide pressure was increased. The presence of methane is good evidence that initiation of the decomposition of propionaldehyde occurs by reaction of free methylene radicals and not by energy transfer from an excited ketene molecule. Methane was not observed in the photolysis of propionaldehyde by itself.

The yields of stabilization products were still very small compared to those of the main products, carbon monoxide, methane, and ethane. *n*-Butyraldehyde was not observed under any conditions, but isobutyraldehyde was about one-third of the butene oxide. Again, methyl ethyl ketone may have been formed by stabilization or by termination.

The maximum ratio of propylene oxide to carbon monoxide found in the experiments with acetaldehyde was 0.32, but the maximum ratio of [isobutyraldehyde + butene oxide] to carbon monoxide from the reaction with propionaldehyde was 0.014. Stabilization would be expected to occur more readily with propionaldehyde than with acetaldehyde, and the apparently smaller relative yield of stabilization products may be the result of a longer chain length for decomposition of propionaldehyde than for acetaldehyde at the same temperature.

The sharp drop in yield of methyl ethyl ketone with rising pressure probably indicates that at low pressures it was formed largely by combination of radicals and not by stabilization. If the methyl ethyl ketone were formed by stabilization at higher pressures, the reactivity of the aldehydic C—H bond toward insertion of methylene is very similar to that of the secondary C—H bond. The epoxide is still the predominant stabilization product and it would thus appear that addition of methylene across the carbonyl bond is faster than insertion into a primary or secondary C—H bond.

It is of interest to compare the present results with those of Cvetanovic (14) on the reaction of oxygen atoms with olefins. In these two reactions the excited molecules formed by the addition of the diradical are isomeric, although the energy content is different in the two cases. The heat of formation of the complex formed by addition of oxygen atoms to propylene is about 64 kcal/mole, while that of the complex formed by the methylene reaction is about 51 kcal/mole[3] assuming no excess energy carried by the radicals. It

[3]$\Delta H_f(CH_2)$ *taken as 90 kcal/mole.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

might be expected, therefore, that relatively more stabilization of the excited molecule would be observed in the methylene reaction than in the oxygen atom reaction at a given pressure. The converse appears to be true. With propionaldehyde, taking methane as a measure of the dissociation and butene oxide and isobutyraldehyde as the stabilized products, the ratio of [butene oxide + isobutyraldehyde]/methane has the maximum value of 0.1 at a pressure of about 3 cm, whereas in the reaction of oxygen atoms with butene, yields of products were independent of pressure above 10 cm. However, if as suggested earlier, an abstraction reaction, independent of pressure, occurs simultaneously with the insertion reaction, the ratio given above does not represent the true ratio of stabilization to dissociation of the excited molecules formed by insertion. In fact, for these energy differences it is reasonable to assume, as already suggested, that in the addition of methylene to aldehydes stabilization may be complete at rather low pressures.

Another difference in the two sets of reactions is in the relative yields of the isomers of the stabilized molecule. These differences are most pronounced when the comparison is made with the reaction of ground state ^3P oxygen atoms with olefins. For example, with propylene, propylene oxide and propionaldehyde were formed in equal quantities, along with very small amounts of acetone, while the reaction of methylene radicals with acetaldehyde gave only propylene oxide and no propionaldehyde. Similarly, the stabilized products of the reaction of ^3P oxygen atoms with butene-1 were nearly equal yields of α-butene oxide and n-butyraldehyde, with small amounts of ketone. In the methylene radical reaction, the α-butene oxide predominated, and the aldehyde formed was isobutyraldehyde. In these systems methylene radicals were formed in the singlet state, and although some degradation to the triplet may have occurred in the presence of carbon dioxide, most of the radicals probably reacted in the singlet state. The difference in electronic state probably implies a fundamental difference in the mode of attack of the radical on the reactant and in the structure of the complex formed. For example, the addition of a ^3P oxygen atom to the double bond in an olefin forms a diradical complex, which, to form a stable molecule, may undergo migration of groups or may close the ring to form an epoxide. Excess energy may be lost before the structural changes occur. Insertion of singlet methylene, on the other hand, forms a singlet complex, which must lose energy by collisions to form a stable molecule. It is not surprising that the distribution of stabilized products is different from the two reactions.

In the reaction of ^1D oxygen atoms with butene-1 (15) the relative yield of α-butene oxide was increased to about three times that of n-butyraldehyde. The main stabilization product was thus the same for the reaction of ^1D oxygen atoms with butene-1 and the reaction of singlet methylene with propionaldehyde. However, the aldehyde from the oxygen atom reaction was exclusively n-butyraldehyde while from the methylene reaction only isobutyraldehyde was formed. This indicates there is still a difference in the mode of attack of the radicals even when both are in the singlet state and both therefore form singlet addition complexes. The oxygen atom attacks the molecule at one point only—the double bond—and subsequent products are formed by rearrangement or decomposition of the one excited molecule. Thus the excited α-butene oxide molecule initially formed may rearrange to n-butyraldehyde or methyl ethyl ketone (which was observed in small quantities), but not to isobutyraldehyde. Addition of methylene radicals, on the other hand, may occur at any bond in the molecule, usually with little discrimination. However, attack on a secondary C—H bond is usually faster than on a primary C—H bond and therefore isobutyraldehyde would be expected to predominate over n-butyraldehyde. Thus the differences between the oxygen atom reactions and the methylene radical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reactions are for the most part the result of differences in the mode of attack of each on the reactant, rather than in the subsequent behavior of the isomeric complex.

Formaldehyde

At the beginning of this research a few experiments were done with formaldehyde as reactant. No conclusive evidence for stabilization products was observed and the main reaction of the methylene radicals appeared to be the initiation of the chain decomposition of formaldehyde. The main products were carbon monoxide, methane, and hydrogen in the approximate proportion, 70%, 20%, and 10%, respectively. Small amounts of acetaldehyde were observed but these may have been formed by radical combination. Ethylene oxide was not found.

Carbon Dioxide

A few experiments were done with ketene and carbon dioxide, and these are summarized in Table II. Although the present conditions were somewhat different, the results are consistent with those found by Kistiakowsky and Sauer (9) and with their suggestion that the initial products are carbon monoxide and formaldehyde. The products formaldehyde and ethylene will be attacked more rapidly than carbon dioxide, and the minor products methane, ethane, acetaldehyde, and acetone probably arise by such secondary reactions. The number of moles of carbon monoxide which accompany each mole of minor product depends somewhat on an assumed mechanism. However, the simplest stoichiometry leads to the following. $CH_4 = 4CO$; $C_2H_6 = 5CO$; $CH_3CHO = 2CO$; $CH_3COCH_3 = 5CO$. The ratio of carbon monoxide to total products $[2C_2H_4 + 4CH_4 + 5C_2H_6 + 2CH_3CHO + 5CH_3COCH_3]$ is given in the table. The excess carbon monoxide indicates a loss of some product, which may be formaldehyde. However, the ratio increased with time of reaction (experiments 5 and 6) and extrapolated to one at zero time. This probably indicates the increasing formation of higher products which were not observed in the analysis. Loss of product as formaldehyde would be expected to be reduced at longer times of reaction, as formaldehyde is consumed by secondary reactions, so that this is not the main source of the discrepancy. Formaldehyde is probably converted to other products at very short times of reaction and has a low steady-state concentration in the reaction mixture.

THE CHEMISTRY OF THE AMINOCHROMES

PART VI. THE REACTION OF ADRENOCHROME WITH GLUTATHIONE[1,2,3]

G. L. MATTOK AND R. A. HEACOCK

Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan

Received August 10, 1964

ABSTRACT

The reaction between adrenochrome and glutathione has been studied. The main products result from the 1,4-addition of glutathione to the C_5 unsaturated carbonyl systems in adrenochrome involving the C_6—C_7 and the C_4—C_9 double bonds, and are probably 7-*S*-glutathionyl-5,6-dihydroxy-*N*-methylindole and 9-*S*-glutathionyl-2,3,6,9-tetrahydro-3,5-dihydroxy-6-oxo-*N*-methylindole respectively. 5,6-Dihydroxy-*N*-methylindole is also formed during the interaction of glutathione and adrenochrome. The mechanisms by which these compounds are formed are discussed.

INTRODUCTION

Thiols, such as glutathione, generally react with quinones by 1,4-addition across one of the α,β-unsaturated carbonyl systems. Much of the early work, dating back to 1888 (1), was reviewed by Snell and Weissberger in 1939 (2). The reaction of thiols, including glutathione, with 2-methyl-1,4-naphthoquinone has been described by several workers as a 1,4-addition process (3, 4, 5), although it has recently been suggested that this reaction proceeds by a simple nucleophilic substitution of the quinone ring by the mercaptide anion (6). Most of the previously reported additions of this type involved *p*-quinones; however, there have been a number of examples of the reported addition of thiols, including glutathione, to oxidized catechol derivatives (cf. 7–11) and recently the 1,4-addition of a thiol (1-phenyl-5-mercaptotetrazole) to several quinones, including some *o*-quinones, has been described (12, 13).

Preliminary paper chromatographic studies on the interaction of adrenochrome (I) with glutathione (free acid) in aqueous solution indicated that 5,6-dihydroxy-*N*-methylindole (II) and two other products (non-ether extractable) were formed; the major product (III) had an R_f value* of ca. 0.60 and appeared to have retained the indole nucleus and to contain an α-amino acid grouping (14, 15). Bouchilloux and Kodja subsequently reported that dopachrome solutions were decolorized by glutathione (phosphate buffer, pH = 5.5) with the formation of 5,6-dihydroxyindole, 5,6-dihydroxyindole-2-carboxylic acid, and compounds described as 4-*S*-glutathionyl-5,6-dihydroxyindole and its 2-carboxy derivative (10, 11). These latter two compounds were also reported to be obtained by the enzymatic oxidation of 5,6-dihydroxyindole or 5,6-dihydroxyindole-2-carboxylic acid respectively in the presence of glutathione (10, 11). This paper reports the results of an extensive spectroscopic and paper chromatographic examination of the products obtained by the interaction of adrenochrome and glutathione.

EXPERIMENTAL

Materials

Adrenochrome (16), *N*-ethylnoradrenochrome (17), *N*-isopropylnoradrenochrome (17), adrenochrome methyl ether (17), adrenochrome ethyl ether (17), and 5,6-dihydroxy-*N*-methylindole (18) were prepared

[1]*This investigation was supported by grants from the Department of National Health and Welfare (Ottawa) and the Government of Saskatchewan (Department of Public Health).*

[2]*Part V. Can. J. Chem. 41, 139 (1963).*

[3]*A preliminary report of part of this investigation appeared in Arch. Biochem. Biophys. 107, 352 (1964).*

**All the R_f values referred to in this paper were obtained using 2% acetic acid in water as the running solvent (see Experimental section for details).*

by the methods described in the literature. Glutathione, its monosodium salt, and oxidized glutathione were obtained from the Nutritional Biochemicals Corporation.

Spectroscopy

The spectra were recorded on either a Beckman DK-2 or Unicam SP-800 recording spectrophotometer. The reaction mixtures studied were prepared from adrenochrome (5.0 mg) and glutathione (free acid or monosodium salt) (25.0 mg) dissolved in water (1.0 ml). Suitable dilutions were prepared for measurement of the spectra. When required, ether extractions were carried out with peroxide-free ether (4 × 1 ml). In experiments designed to study the effects of added reagents, the reaction mixture was prepared by the method described above; ether extracted (if necessary) and a slight excess of the solid reagent (i.e. silver oxide, sodium hydrosulfite, sodium bisulfite, or sodium acetate) were added directly to the solution. In the experiments designed to find the optimum pH for the formation of a given product the reaction mixture was prepared as described above, except that a suitable acetate or phosphate buffer was used as the reaction medium in place of water.

Paper Chromatography

The aminochrome (10 mg) was dissolved in water (1.0 ml) and the solution was treated with a slight excess of glutathione (free acid or monosodium salt).* When the red color of the aminochrome had been completely discharged the reaction mixture was filtered and a sample (ca. 25–50 μl) of the clear filtrate applied to the chromatographic paper (acid-washed Whatman No. 1 paper). The chromatography was carried out by the descending technique, using 2% acetic acid in water as the running solvent. In all cases the solvent was allowed to descend about 15 to 16 in. (this required approximately 2.5–3 h running time). After drying (in air, at room temperature), the developed chromatograms were examined for fluorescence in ultraviolet light and individual chromatograms were sprayed with one of the following chromogenic reagents:† (*a*) Ehrlich's reagent, (*b*) cinnamaldehyde, (*c*) *p*-dimethylaminocinnamaldehyde, (*d*) Gibb's reagent, (*e*) diazotized *p*-nitroaniline, (*f*) ninhydrin/pyridine, and (*g*) ferric chloride.

In some cases the aqueous solution of the aminochrome reduction products (prepared as described above, 1.0 ml) was extracted, after filtration, with peroxide-free ether (4 × 1.0 ml). Spots consisting of ca. 120–150 μl of the dried (Na_2SO_4) ethereal extract and ca. 40–60 μl of the aqueous mother liquors were applied to the paper separately and the chromatography carried out as described above.

In the experiments designed to obtain relatively pure solutions of the individual products, the reaction mixture was prepared in the manner described above and a sample (ca. 500 μl) was applied as a "streak" across the origin on acid-washed Whatman 3 MM paper (23 cm × 57 cm). After development with 2% acetic acid, the appropriate zones were located by spraying a narrow strip, cut from the edge of the chromatogram. The zones were cut out and eluted with water.

To ascertain if any reaction occurred between 5,6-dihydroxy-*N*-methylindole (II) and glutathione (or oxidized glutathione), an aqueous solution of (II) (10 mg in 1 ml) was treated with an excess of the amino-acid and the reaction mixture examined chromtographically in the manner described above, after it had been allowed to stand at room temperature for a period of time comparable to that required for the adrenochrome–glutathione reaction to go to completion.

RESULTS

Addition of glutathione (monosodium salt) to an aqueous solution of adrenochrome (I) resulted in the discharge of the red color of the solution; the resulting pale yellow solution showed well-defined absorption maxima of approximately equal intensity in the regions of 300 mμ and 350 mμ (see Fig. 1). When the reaction was carried out using glutathione, as the free acid rather than its monosodium salt, the absorbance at 300 mμ was ca. 70% greater than that at 350 mμ (see Fig. 1). In view of the higher absorbances in the 350 mμ region of reaction mixtures obtained using the sodium salt of glutathione. the effect of pH on the relative intensities of the main absorption peaks was investigated, Reaction mixtures containing adrenochrome (I) and glutathione were prepared in a series of acetate and phosphate buffers in the pH range 1–7, and it was observed that formation of the product (λ_{max} = ca. 350 mμ) (i.e. (IV)) occurred optimally at pH = 4.7 (see Fig. 2); the amount of (IV) formed fell off sharply at pH values above and below 4.7 and did not form at all at pH values > 6.

Paper chromatograms of these reaction mixtures on Whatman No. 1 paper with 2%

**An analogous experiment was carried out using oxidized glutathione in place of glutathione, but the red color of the adrenochrome solution was not discharged in a comparable period of time.*

†The chromogenic reagents were prepared by the methods commonly described in the literature (cf. (19)).

acetic acid as the developing solvent (cf. 14, 15) showed three spots (which gave blue colors after spraying with Ehrlich's reagent) with R_f values of 0.43, 0.64, and 0.85 respectively (see Table I). A yellow spot (R_f = ca. 0.90), which appeared overnight on the sprayed chromatograms, was probably due to unchanged glutathione. The substance with an R_f of 0.85 showed a distinct yellow fluorescence in ultraviolet light; the substance with an R_f of 0.64 (i.e. (III)) did not fluoresce and the product with an R_f of 0.43 showed the weak "blue-mauve" fluorescence in "long wavelength" ultraviolet light characteristic of (II). The absorption maxima for the products were obtained by elution of the appropriate zones from a developed chromatogram of the adrenochrome–glutathione reaction mixture; these were as follows: R_f, 0.64 (i.e. (III)), 303 mμ and R_f, 0.85 (i.e. (IV)), 352 mμ. The unidentified product (III) exhibited color reactions expected for (i) an indole, (ii) a phenol, and (iii) an α-amino acid (see Table I). The color reactions of the product (IV) were a little less certain, due to the contamination of the zone (R_f, 0.80–0.90) on the chromatograms with unchanged glutathione; however, it did appear to react slowly with Ehrlich's reagent, cinnamaldehyde, diazotized *p*-nitroaniline, and ferric chloride (see Table I). The colors obtained from (IV) were similar to those given by the adrenochrome – sodium bisulfite addition product with these reagents (20).

N-Ethylnoradrenochrome and *N*-isopropylnoradrenochrome behaved similarly to adrenochrome on treatment with glutathione in aqueous solution. Paper chromatographic examination of the reaction mixtures showed that three products were formed in each case; the expected *N*-alkyl-5,6-dihydroxyindole and products probably analogous to (III) and (IV). Adrenochrome methyl ether and adrenochrome ethyl ether also behaved in a similar manner to adrenochrome on treatment with glutathione (see Table I). These results suggest that the 1- and 3-positions of the adrenochrome nucleus are not materially involved in any of the reaction sequences. There was no reaction between adrenochrome and oxidized glutathione; consequently, the thiol group of glutathione must have been involved in all these reactions. The possibility of secondary product formation by the

††5,6-Dihydroxy-*N*-isopropylindole.

interaction of 5,6-dihydroxy-*N*-methylindole (II) with glutathione (or oxidized glutathione) was also ruled out, since no reaction occurred between (II) and either glutathione or oxidized glutathione in aqueous solution, over periods of time comparable with those required for the adrenochrome/glutathione (or monosodium salt) reactions to go to completion.

It was shown by paper chromatography that ether extraction of the adrenochrome–glutathione reaction mixtures completely removed the substance with an R_f of 0.43 (i.e. (II)). The ultraviolet spectrum of the aqueous mother liquors, still showed peaks at ca. 300 mμ and 350 mμ, although the intensity of the 300 mμ peak was much reduced, because of the removal of (II) which also absorbs in this region. The reaction mixture, after removal of (II) by ether extraction, was initially yellow, but on the addition of solid sodium acetate or on the cautious addition of aqueous sodium hydroxide the solution became red. Dilution (ca. 100 times) of the ether-extracted reaction mixture with water, also led to the formation of an orange–red product, after 2 h at room temperature; the color intensified on standing overnight. These color changes did not appear to be affected by bubbling oxygen through the solution. The change in color of the solution was accompanied by a modification of the absorption spectrum; the intensity of the absorption at ca. 350 mμ was markedly reduced, and eventually disappeared; at the same time there was an increase in the absorbance at 300 mμ and a new peak at 485 mμ appeared. The red color of the modified reaction mixture was discharged on addition of excess sodium hydroxide, with the formation of a yellow product which exhibited an intense yellow–green fluorescence, usually associated with adrenolutin (5,6-dihydroxy-*N*-methylindoxyl), in ultraviolet light (cf. 21). The red product was also decolorized by the addition of sodium hydrosulfite or sodium bisulfite. In the former case an ether extractable product was obtained which was shown by paper chromatography and spectroscopy to be identical with 5,6-dihydroxy-*N*-methylindole (II), and in the latter case the red color could be restored by the cautious addition of alkali; addition of excess alklai resulted in the discharge of the red color and the formation of a fluorescent product similar to that described above. These reactions with sodium bisulfite and alkali suggests that the red product is derived from (IV) and that it is probably adrenochrome (I) (λ_{max} 300 mμ and 487 mμ (cf. 22)). The ether extracted adrenochrome–glutathione reaction mixture is capable of further modification by oxidizing and reducing agents. After treatment of the ether

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

extracted reaction mixture with silver oxide, the solution became deep yellow and the original peaks at ca. 300 mμ and ca. 350 mμ were replaced by peaks at 285 mμ* and 399 mμ; this suggests that both compounds can undergo oxidation. The peak at ca. 350 mμ (due to (IV)) disappeared and the 300 mμ peak increased in intensity on treatment of the original reaction mixture (ether extracted) with sodium hydrosulfite. Paper chromatography showed that reduction with this reagent resulted in the elimination of the faster running substance (i.e. (IV)) and the formation of (II) which could be extracted with ether and identified by chromatography and spectroscopy.

DISCUSSION

On the basis of the observed spectroscopic, paper chromatographic, and chemical data, it is possible to propose likely structures for the products obtained by the action of glutathione on adrenochrome; the formation of all the reaction products can also be explained by reasonable mechanisms.

It is well known that 5,6-dihydroxy-*N*-methylindole (i.e. (II)) is usually produced, to some extent, when adrenochrome reacts with a reducing agent (cf. 22), and it has previously been suggested that the product with an R_f value of 0.43 (i.e. (II)) was, in fact, 5,6-dihydroxy-*N*-methylindole; the results of the present investigation are in agreement with this suggestion. The paper chromatographic and spectroscopic properties of (II) were identical to those of pure 5,6-dihydroxy-*N*-methylindole. The formation of 5,6-dihydroxy-*N*-methylindole (II) could result from the direct reduction of adrenochrome (I) by glutathione. It could also result from the reduction of (I) by (III) (or possibly its immediate precursor (i.e. (VI)); the reduction of a quinone by the corresponding hydroquinone containing an electron-donating group is well known (cf. 23). To test the plausibility of the latter type of reaction occurring, a solution of *N*-isopropylnoradrenochrome was treated with (II); paper chromatography of this reaction mixture showed that interaction had, in fact, occurred, with the formation of 5,6-dihydroxy-*N*-isopropylindole (i.e. the dehydrated reduction product of *N*-isopropylnoradrenochrome). In view of the difficulty of detecting oxidized glutathione, in the presence of glutathione (with the chromatographic system used in this investigation), and the uncertainty that its presence, if found, was not merely due to autoxidation, it is not possible to be sure if the direct reduction mechanism is operating to any extent in the adrenochrome–glutathione system. However, since 5,6-dihydroxy-*N*-methylindole (II) is not the major product of the adrenochrome/glutathione reaction and the *N*-isopropylnoradrenochrome/5,6-dihydroxy-*N*-methylindole interaction resulted in appreciable formation of 5,6-dihydroxy-*N*-isopropylindole, in a time comparable to that required for the completion of the adrenochrome/glutathione reaction, it is most probable that the majority of the (II) present in the glutathione/adrenochrome system resulted from the reduction of adrenochrome by (III) or (VI) which gave "leuco-adrenochrome" (VII) which is known to dehydrate spontaneously and form 5,6-dihydroxy-*N*-methylindole (II) (cf. 24).

There are two possible ways by which glutathione could add, by a 1,4-addition mechanism, to adrenochrome. Addition could occur across the α,β-unsaturated C_5-carbonyl system, which includes the C_6—C_7 double bond, to form the adduct (V); subsequently this product could undergo an "enolization" of the polarized C_6-carbonyl

**The position of the 285 mμ peak could not be precisely determined since end absorption due to oxidized glutathione is significant below 290 mμ; this was partially compensated by the addition of oxidized glutathione to the solution in the reference beam of the spectrophotometer.*

group to give 7-*S*-glutathionyl-3,5,6-trihydroxy-*N*-methylindoline (VI). The 3,5,6-trihydroxyindoline structure is known to rapidly undergo an intramolecular dehydration to give the 5,6-dihydroxyindole structure (cf. 24), consequently, (VI) would be expected to dehydrate to give 7-*S*-glutathionyl-5,6-dihydroxy-*N*-methylindole (III). This structure is quite compatible with the observed properties of (III), i.e. the typical indole absorption maximum at ca. 300 mμ and the color reactions expected for an indole, catechol, and an α-amino acid. It is also water soluble and was not extracted from its aqueous solutions by ether as would have been expected for a molecule containing a large amino acid residue. This structure is similar to that postulated by Bouchilloux and Kodja for one of the products obtained from dopachrome by the action of glutathione, except that the French authors suggested that the glutathione residue was attached to the 4-position of the indole nucleus (11). Alternatively, 1,4-addition of glutathione to the α,β-unsaturated C_5-carbonyl system, with the double bond between the C_9-bridge-head carbon atom and C_4 would result in structure (IV), i.e. 9-*S*-glutathionyl-2,3,6,9-tetrahydro-3,5-dihydroxy-6-oxo-*N*-methylindole. This structure is similar to that proposed by Tse and Oesterling for the adrenochrome – sodium bisulfite addition product (25) and is compatible with the properties of the glutathione/adrenochrome interaction product (IV) with $R_f = 0.85$ and $\lambda_{max} = 352$ mμ. There are a number of chemical similarities between (IV) and the bisulfite addition product (cf. 25, 26) although the glutathione adduct would appear to be less stable. In the first place, there is the apparent regeneration of adrenochrome (λ_{max}, ca. 300 and 487 mμ) on treatment with mild alkali (cf. 14, 26); both products exhibit an absorption maximum in the 350–360 mμ range; both compounds show a weak yellow fluorescence in ultraviolet light and (IV) and the adrenochrome – sodium bisulfite addition product show similar paper chromatographic behavior, e.g. they both have high

For personal use only.

R_f's in 2% acetic acid and they both react relatively slowly with indole reagents, such as Ehrlich's reagent and cinnamaldehyde.

Reactions between thiols and aminochromes, such as those described above may be of considerable significance in several biological processes. A possible mode of attachment of melanins to proteins could be by a sulfide linkage formed by an interaction of one of the thiol groups in the latter with one of the indole-5,6-quinone units in the melanin structure (cf. 27, 28); such interactions could also occur with the distinct aminochrome units which are considered by some workers to be present in the melanin structure (cf. 29, 30). It has been suggested that the sulfide linkage occurs at the 4-position in the indole nucleus (11, 31), however, the present investigation would suggest that the possibility of such linkages occurring at the 7-position of the indole nucleus should not be overlooked.

The formation of aminochrome–thiol addition products such as the compound (IV) offers the intriguing possibility that some thiols could conceivably act as "aminochrome-carriers", which could readily regenerate the aminochrome under the appropriate conditions. Hadler *et al.* have recently described the somewhat analogous conjugation of cysteine during its oxidation by 2,6-dichlorophenolindophenol, and suggested that reactions of this type maybe of biological significance (32, 33).

ABSTRACT

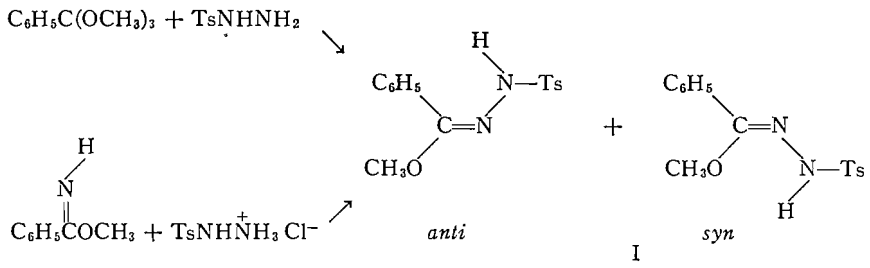
Methyl benzoate (*p*-tolylsulfonyl)hydrazone (I) was prepared from the reaction between (*p*-tolylsulfonyl)hydrazide and either methyl benzimidate hydrochloride or methyl orthobenzoate. When the potassium or sodium salt of this hydrazone was decomposed, thermally or photochemically, in the presence of alcohols, benzaldehyde mixed acetals could be isolated in good yields and of high purity. When the decomposition was carried out in the presence of piperidine, there was produced 1-(α-methoxybenzyl)piperidine (II) and α,α-dipiperidinotoluene (III). The reaction products can be explained by assuming the initial formation of phenylmethoxydiazomethane.

INTRODUCTION

Diazo compounds have proved extremely useful in synthetic organic chemistry (1). There are, however, limited types of diazo compounds available, and as an extension to this useful class of reactants, an investigation into the possible synthesis of alkoxydiazoalkanes has been undertaken. Examination of the stabilities of known diazoalkanes (2) would lead one to predict that the alkoxydiazoalkanes may be unstable, thus only *in situ* synthesis may be possible. Such *in situ* generation of alkoxydiazoalkanes would in itself be of synthetic value and thus our initial investigations have been directed at the use of the Bamford–Stevens reaction (3) on ester (*p*-tolylsulfonyl)hydrazones.

Synthesis of Ester (p-Tolylsulfonyl)hydrazones

Orthoesters have frequently been used to prepare imidate esters and Ainsworth (4) has produced ester semicarbazones from orthoesters and semicarbazide.



I

Upon refluxing an equimolar mixture of trimethyl orthobenzoate and (*p*-tolylsulfonyl)-hydrazide in methanol, methyl benzoate (*p*-tolylsulfonyl)hydrazone (I) was isolated in a 72% yield. The product consisted of a mixture of *syn* and *anti* isomers as was indicated by the presence of two signals for the methoxy protons at τ 6.22 and 6.33 in the nuclear

[1]*Presented at the 47th Canadian Chemical Conference, Kingston, Ontario, June 1–3, 1964.*
[2]*National Research Council of Canada Scholarship holder 1963–1964. Present address: R & L Molecular Research Ltd., Edmonton, Alberta.*

magnetic resonance (n.m.r.) spectrum. Upon further purification a pure isomer, m.p. 98–99°, with the signal for methoxy protons at τ 6.33, was produced.*

A second method of preparation was developed. Schmidt (6) has shown that imido esters react rapidly with hydrochloride salts of amines and hydrazines to give Schiff bases and hydrazones respectively. Methyl benzoate (*p*-tolylsulfonyl)hydrazone could be prepared in a 41% yield by adding a cold solution of methyl benzimidate in ethanol to a cold suspension of (*p*-tolylsulfonyl)hydrazide hydrochloride. The product was again a mixture of *syn* and *anti* isomers. Both methods are of general applicability, the former being preferred because of the superior yields.

Decompositions in Protic Solvents

The sodium or potassium salt of I was prepared in good yield from solutions of I (mixture of isomers) and sodium or potassium ethoxide in dimethoxyethane. These salts are stable and can be isolated in a high degree of purity as indicated by their n.m.r. spectra. Thus they were used for the majority of the reactions investigated. When the sodium salt of I was refluxed in ethanol, a reaction took place that required a 67 h reflux

$$\text{Na salt of I} + \text{ROH} \rightarrow \text{C}_6\text{H}_5\text{CH(OCH}_3\text{)OR} + \text{Na}^+ {}^-\text{O}_2\text{SC}_6\text{H}_4\text{—CH}_3(p) + \text{N}_2$$

period to complete. The only products found to be present were sodium *p*-toluenesulfinate and benzaldehyde methyl ethyl acetal. At higher temperatures the decomposition occurred much faster and in the presence of different alcohols fairly good yields of mixed acetals were obtained. A summary of these experiments is given in Table I.

The potassium salt of I decomposed photochemically in 2 h at room temperature to similarly produce benzaldehyde methyl ethyl acetal (70%).

TABLE I

Mixed acetals of benzaldehyde prepared by the thermal decomposition of salts of I

*The acetals were characterized by elemental analysis, n.m.r. spectra, and by the formation of the 2,4-dinitrophenylhydrazone of benzaldehyde upon treatment with a methanolic solution of 2,4-dinitrophenylhydrazine sulfate.
†Reported (B. Wladislaw and A. M. J. Ayres. J. Org. Chem. 27, 281 (1962).) b.p. 205° (760), n_D^{19} 1.4878.
‡1,2-Diethoxyethane was used as a solvent.

It seemed of interest to see whether the decomposition of methyl benzoate (*p*-tolylsulfonyl)hydrazone in the presence of secondary amines might give rise to compounds of the type represented by II. When the potassium salt of I was refluxed for 11 h in piperidine, the decomposition was complete. The only product that was isolated, in a 82% yield, was α,α-dipiperidinotoluene (III). It was believed that this product resulted from a reaction

**Studies by Karabatsos and Taller (5) on the n.m.r. spectra of phenylhydrazones would suggest that the isomer melting at 98–99° and having a signal at τ 6.33 should be assigned the syn configuration, using the convention outlined in ref. 5.*

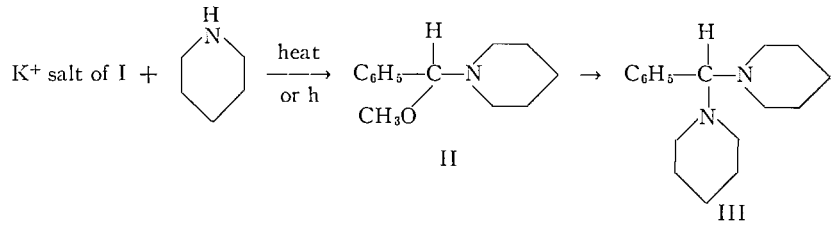
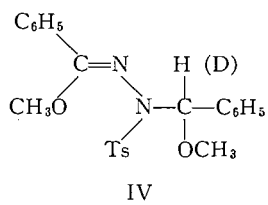
For personal use only.

between initially formed 1-(α-methoxybenzyl)piperidine (II) and piperidine. In order to test this assumption the decomposition was carried out photochemically at room temperature. When the reaction mixture was worked up, special care was taken that the temperature was kept as low as possible and II was isolated, in a yield of 30%. However



III was still the principal reaction product. The proof of structure of 1-(α-methoxybenzyl)piperidine (II) is based upon an elemental analysis, spectral data, and its conversion into α,α-dipiperidinotoluene upon heating with piperidine. Compound II is an unstable high-boiling liquid (b.p. 81–85° at 0.2 mm). Even at 0° it slowly decomposes and the smell of benzaldehyde becomes apparent. The infrared spectrum of a solution on standing also develops a carbonyl band at the same frequency as benzaldehyde (1 708 cm^{-1}). The n.m.r. spectrum shows singlets at τ 2.76, 5.33, and 6.66 ascribed to the aromatic protons, the methinyl hydrogen, and the methoxy hydrogens respectively, and broad bands at τ 7.3–7.8 and τ 8.3–8.8 ascribed respectively to the α- and β,γ-hydrogens of the piperidine ring. The ratio of integrated areas is the same as that predicted for II.

When the decomposition of the potassium salt of I was carried out in diglyme at 125–130° in the presence of a trace of water, a 15% yield of a crystalline compound, melting at 147–149°, was isolated. The infrared spectrum showed a strong absorption at 1 619 cm^{-1}, which was attributed to a carbon–nitrogen double bond, and further strong bands at 1 165 cm^{-1} and in the 1 300 – 1 350 cm^{-1} region. These latter absorptions suggested the presence of a sulfonylamido group (7). The n.m.r. spectrum showed a complicated signal pattern of aromatic protons at τ 2.0–3.3 and singlets at τ 4.14, 6.23, 7.05, and 7.59 with relative areas 14:1:3:3:3. The compound was found to have a molecular weight of 440 and to fit the empirical formula $C_{23}H_{24}N_2O_4S$ (molecular weight 424.5). The only structure that readily fits all the requirements is that of methyl benzoate (α-methoxybenzyl)-(*p*-tolylsulfonyl)hydrazone (IV).* When the experiment was repeated with a trace of



IV

D_2O instead of H_2O, the n.m.r. spectrum of IV showed that the singlet at τ 4.14 was present in only one-fifth of its original intensity, thus indicating that the proton responsible for this signal originates from the water. This type of product has recently been isolated by Nozaki *et al.* in an investigation of the reaction of phenylcarbene formed from benzaldehyde (*p*-tolylsulfonyl)hydrazone in various solvents (8).

**When an equimolar mixture of I and its potassium salt were heated in diglyme at 130° a 36% yield of IV was obtained.*

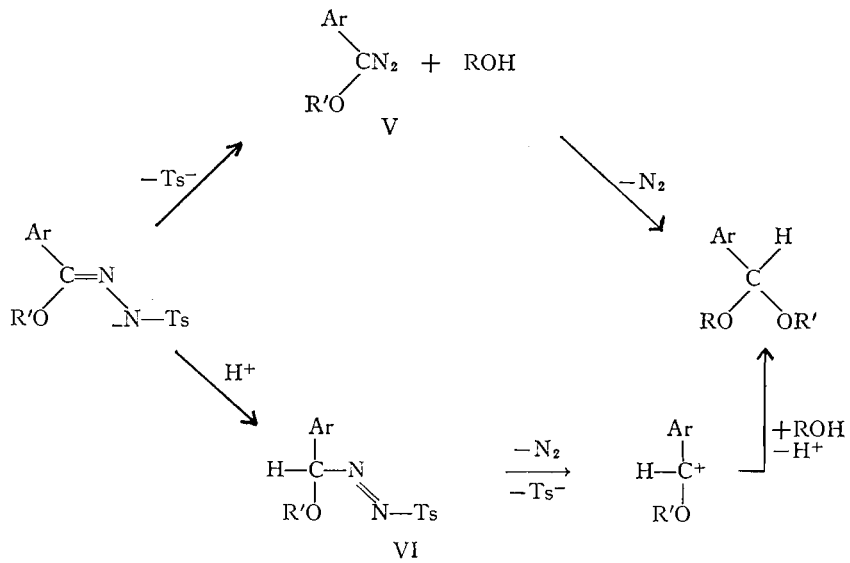
CONCLUSIONS

Salts of ester (*p*-tolylsulfonyl)hydrazones may be decomposed in protic solvents, both thermally and photochemically, to give rise to those products expected from alkoxydiazoalkanes. The results described herein are similar to those obtained by Bamford and Stevens (3) in the thermal decomposition (*p*-tolylsulfonyl)hydrazone salts of aromatic aldehydes and ketones. Therefore it seems reasonable to assume that the decomposition of an ester (*p*-tolylsulfonyl)hydrazone salt produces initially an alkoxydiazoalkane (V) which by virtue of its reactivity undergoes an immediate reaction with the solvent. However on basis of the present experiments alone the possibility of product formation via an intermediate such as VI can not be excluded.



EXPERIMENTAL

All melting points and boiling points are uncorrected.

The infrared spectra were obtained on a Perkin–Elmer Model 421 spectrophotometer equipped with grating optics. Nuclear magnetic resonance spectra were measured using a Varian Associates Model A-60 spectrometer, with tetramethylsilane as a reference. Ultraviolet spectra were obtained using a Cary Model 14M recording spectrophotometer.

Vapor phase chromatography was carried out with a Perkin–Elmer Model 154 vapor fractometer or a F. & M. Model 500 temperature-programmed gas chromatograph.

The photochemical decompositions were all carried out in a quartz reaction vessel, cooled by running tap water, with an internally situated 250 W Hanovia ultraviolet source.

The microanalyses were performed by Pascher Mikroanalytisches Laboratorium (Bonn, West Germany), Daessle Organic Microanalyses (Montreal), and the Microanalytical Laboratory of the Department of Chemistry, University of Alberta (Edmonton).

Methyl Benzimidate was prepared as described by Wheeler (9); yield, 90%; b.p. 73–74° (2.4 mm); n_D^{25} 1.5420. Reported b.p. 95–97° (14 mm).

Methyl Benzoate (p-Tolylsulfonyl)hydrazone (I) from Methyl Benzimidate

A solution of methyl benzimidate (12.2 g, 90.4 mmole) in 20 ml of absolute ethanol was added to a cold suspension of (*p*-tolylsulfonyl)hydrazide hydrochloride (20.0 g, 89.9 mmole) in 60 ml of absolute ethanol. Ammonium chloride precipitated slowly from the obtained homogeneous reaction mixture. After 3 h at room temperature the ammonium chloride was filtered off and most of the ethanol removed under reduced pressure. Diethyl ether and water were added to the residue. The ether solution was again washed with water and dried and the ether evaporated. The residue was dissolved in a mixture of 60 ml of benzene and 25 ml of *n*-hexane and cooled in the refrigerator for 2 days. The solid amounted to 8.2–11.2 g (30–41%). The n.m.r. spectrum showed that it was a mixture of the *syn* and *anti* isomer (methoxy signals at 6.23 and

6.34 with an integration ratio of 1:4 respectively). Two additional recrystallizations from a benzene – *n*-hexane mixture gave a product, m.p. 93–97°, consisting of only one isomer. However the crystals contained some benzene, as indicated by the n.m.r. spectrum and an analysis, which could not be readily removed. A pure product, believed to be the *syn* isomer, was obtained by recrystallization from diethyl ether; m.p. 98–99°.

Anal. Calcd. for $C_{15}H_{16}N_2O_3S$: C, 59.19; H, 5.30; N, 9.21; S, 10.54. Found: C, 58.87; H, 5.06; N, 9.41; S, 10.71.

When the product was heated for 0.5 h at 100–102°, a mixture of the two isomers was obtained (the integration ratio of the methoxy signals at 6.23 and 6.33 in the n.m.r. spectrum was 1:2 respectively).

Potassium Salt of Methyl Benzoate (p-Tolylsulfonyl)hydrazone

Methyl benzoate (*p*-tolylsulfonyl)hydrazone (10.0 g, 32.9 mmole) was added to a solution of potassium (1.3 g, 33.3 mg-atom) in a mixture of 6 ml of anhydrous ethanol and 70 ml of 1,2-dimethoxyethane. The solution was heated to its boiling point, then cooled. The potassium salt was filtered off and washed with ether. Yield 7.3 g (65%) of slightly yellow-colored salt which decomposes above 170°. The n.m.r. spectrum (in D_2O) indicated a complex signal pattern from the aromatic protons at 2.2–3.3, and sharp singlets at 6.55 and 8.25.

Methyl Benzoate (p-Tolylsulfonyl)hydrazone from Methyl Orthobenzoate

A solution of methyl orthobenzoate (10.0 g, 55 mmole, prepared by the method of McElvain and Venerable (10)) and (*p*-tolylsulfonyl)hydrazide (10.0 g, 54 mmole) in 60 ml of methanol was refluxed for 4 h. The solvent was removed under reduced pressure, the residual oil dissolved in 50 ml of benzene, and 25 ml of *n*-hexane added. The solution thus obtained was cooled for 2 days in the refrigerator before the crystals were filtered off. Yield, 12.2 g (73%) of white crystals, m.p. 85–95°. By an examination of the n.m.r. spectrum (in $CDCl_3$) it was clear that the solid consisted only of a mixture of the *syn* and *anti* isomer (apart from a small amount of benzene that could not be removed), as indicated by methoxy singlets at 6.22 and 6.33 (integration ratio 2:3 respectively) and aromatic methyl singlets at 7.58 and 7.63.

The Preparation of Benzaldehyde Acetals from the Thermal or Photochemical Decomposition of Alkyl Benzoates (p-Tolylsulfonyl)hydrazones (Benzaldehyde Dimethyl Acetal)*

Methyl benzoate (*p*-tolylsulfonyl)hydrazone (5.0 g, 16.4 mmole) and sodium methoxide (0.90 g, 16.6 mmole) were refluxed for 47 h in 35 ml of 1,2-dimethoxyethane. The solid (3.3 g) was collected by filtration and found to be a mixture of sodium *p*-toluenesulfinate and sodium methyl benzoate (*p*-tolylsulfonyl)-hydrazone. The filtrate was concentrated and the residue was dissolved in ether, washed with water, and dried ($MgSO_4$). The liquid residue obtained after removal of the ether consisted of only benzaldehyde dimethyl acetal (as shown by n.m.r. spectroscopy); yield, 0.8 g (50%, based on 60% starting material that had reacted); b.p. 56–57° (3.5 mm). Reported (11) b.p. 207° at atmospheric pressure.

Benzaldehyde Methyl Ethyl Acetal

(a) Methyl benzoate (*p*-tolylsulfonyl)hydrazone (10.0 g, 32.9 mmole) was added to a solution of sodium (0.8 g, 34.8 mg-atom) in 50 ml of absolute ethanol and the mixture was refluxed for 67 h. Gas evolution took place very slowly. The ethanol was distilled off and the residue was taken up in ether, washed with water, and dried with anhydrous magnesium sulfate. A vacuum distillation of the residue, obtained after removal of the ether, gave 2.0 g (37%) of the acetal; b.p. 58–59° (2.5 mm); n_D^{25} 1.4831. Reported (12) b.p. 205° (atmospheric pressure); n_D^{19} 1.4878.

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Found: C, 72.48; H, 8.40.

(b) Potassium methyl benzoate (*p*-tolylsulfonyl)hydrazone (9.0 g, 26.3 mmole) was suspended in 180 ml of absolute ethanol and irradiated at room temperature. Gas evolution took place rapidly and the potassium salt slowly dissolved. After 2 h the gas evolution ceased (calcd. amount of nitrogen at 25° and 700 mm: 693 ml; observed: 695 ml). The solution was treated as described above and yielded 3.1 g (70%) benzaldehyde methyl ethyl acetal; b.p. 60–61° (2.6 mm); n_D^{25} 1.4832.

Benzaldehyde Methyl n-Propyl Acetal

Methyl benzoate (*p*-tolylsulfonyl)hydrazone (10.0 g, 32.9 mmole) was added to a solution of sodium (0.8 g, 34.8 mg-atom) in 40 ml of 1-propanol, and the mixture was refluxed for 23 h, at which time the nitrogen evolution had ceased. Part of the sodium *p*-toluenesulfinate (4.5 g, 77%; its infrared and n.m.r. spectra were identical with those of an authentic sample) crystallized out upon cooling and was filtered off. The 1-propanol was distilled off and the residue was taken up in ether, washed with water, and dried. Removal of the ether and a vacuum distillation of the residue yielded 3.85 g (65%) of the acetal; b.p. 67–68° (2.0 mm); n_D^{25} 1.4809.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.29; H, 8.95. Found: C, 73.72; H, 8.57.

Benzaldehyde Methyl Isobutyl Acetal

The same procedure as described above was used except that 40 ml of isobutyl alcohol was used as

**All the acetals prepared reacted with a methanolic 2,4-dinitrophenylhydrazine sulfate solution to give benzaldehyde 2,4-dinitrophenylhydrazone, m.p. 241–242°.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solvent and a reflux time of only 7 h was required to effect complete decomposition. Yield, 3.9 g (61%); b.p. 77–78° (2.4 mm); n_D^{25} 1.4769.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.20; H, 9.34. Found: C, 75.24; H, 9.45.

Benzaldehyde Methyl 3-Pentyl Acetal

Potassium (1.3 g, 33.3 mg-atom) was added to a mixture of 3-pentanol (10.0 g, 0.114 mole) and 50 ml of 1,2-diethoxyethane. Methyl benzoate (*p*-tolylsulfonyl)hydrazone (10.0 g, 32.9 mmole) was added and the mixture was refluxed for 6 h. The solvent was removed under reduced pressure and the residue was taken up in ether, washed with water, and dried. The residue, obtained after removal of the solvent, was distilled *in vacuo* to give 2.4 g (35%) of the acetal; b.p. 87–88° (1.0 mm); n_D^{25} 1.4796.

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 75.18; H, 9.77.

Benzaldehyde Methyl Benzyl Acetal

Methyl benzoate (*p*-tolylsulfonyl)hydrazone (10.0 g, 32.9 mmole) was added to a solution of potassium (1.3 g, 33.3 mg-atom) in benzyl alcohol (10.0 g, 92.6 mmole) and 1,2-diethoxyethane (50 ml). The mixture was refluxed for 3.5 h and cooled, potassium *p*-toluenesulfinate (6.15 g, 97%) was filtered off and the solvent removed under reduced pressure. The residue was fractionally distilled *in vacuo* to yield 4.7 g (63%) of the product; b.p. 116–117° (0.3 mm); n_D^{25} 1.5460.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.91; H, 7.06. Found: C, 78.67; H, 6.91.

The Thermal Decomposition of Potassium Methyl Benzoate (p-Tolylsulfonyl)hydrazone in Diglyme in the Presence of a Trace of Water to Produce IV

Potassium methyl benzoate (*p*-tolylsulfonyl)hydrazone (2.0 g, 5.8 mmole) was heated for 1 h at 125–130° in 20 ml of diglyme, to which a small amount of water (0.100 g, 5.5 mmole) had been added. The reaction mixture was cooled and filtered. Addition of 50 ml of water and 75 ml benzene followed. The benzene layer was separated, after vigorous shaking, washed twice with water, and dried with magnesium sulfate. The benzene was removed and pentane was added to the residue. Upon cooling, methyl benzoate (α-methoxybenzyl)(*p*-tolylsulfonyl)hydrazone (IV) (0.18 g, 15%) slowly crystallized. The product was recrystallized from a 5:1 *n*-hexane – benzene mixture, to give white prisms, m.p. 147–149°.

Anal. Calcd. for $C_{23}H_{24}N_2O_4S$ (molecular weight 424.5): C, 65.07; H, 5.70; N, 6.60; S, 7.55. Found: C, 65.35; H, 5.76; N, 6.72; S, 7.71. Molecular weight (osmometric), 440.

The experiment was repeated using D_2O (0.093 g, 4.6 mmole) instead of H_2O. Investigation of the n.m.r. spectrum of the methyl benzoate (α-methoxybenzyl)(*p*-tolylsulfonyl)hydrazone (0.12 g, 10%; m.p. 146–148°) thus obtained revealed that the singlet at 4.14 was present in only one-fifth of its original intensity, indicating that the proton responsible for this signal had originated from the water.

The Thermal Decomposition of Potassium Methyl Benzoate (p-Tolylsulfonyl)hydrazone in Piperidine

The potassium salt (10.0 g, 29.2 mmole) was refluxed for 11 h in 50 ml of predistilled piperidine (b.p. 103–105°), at which time the gas evolution had ceased. The reaction mixture was cooled, potassium *p*-toluenesulfinate (5.5 g, 97%) was filtered off, and the solvent removed under reduced pressure. The residue was dissolved in ether, washed with water, and dried with magnesium sulfate. Removal of the ether left 6.2 g (82%), α,α-dipiperidinotoluene (III) that slowly solidified, m.p. 76–79°. Recrystallization from acetone produced white needles, m.p. 81–83°. Reported (13) m.p. 80–81°; mixture m.p. 81–83°. The infrared spectrum was also identical with that of an authentic sample.

The Photochemical Decomposition of Potassium Methyl Benzoate(p-Tolylsulfonyl)hydrazone in the Presence of Piperidine

A suspension of the potassium salt of I (9.2 g, 26.9 mmole) in a mixture of 150 ml of 1,2-dimethoxyethane and 30 ml of piperidine was irradiated for 7.5 h. The solution was filtered, the solvent mixture removed under reduced pressure and the residue taken up in ether and dried. The liquid residue obtained after removal of the ether was distilled *in vacuo* to give 1.6 g distillate, b.p. 85–100° (0.25 mm). A high-boiling residue (3.0 g) solidified upon cooling and a n.m.r. spectrum showed that it consisted mainly of α,α-dipiperidinotoluene. The distillate was almost pure 1-(α-methoxybenzyl)piperidine (II), and only a small amount of benzaldehyde dimethyl acetal was present as impurity, as was shown by n.m.r. spectroscopy. Redistillation afforded pure α,α-dipiperidinotoluene; b.p. 81–85° (0.2 mm); n_D^{25} 1.5202.

Anal. Calcd. for $C_{13}H_{19}ON$: C, 76.05; H, 9.33; N, 6.82. Found: C, 76.02; H, 9.13; N, 7.01.

A small amount of 1-(α-methoxybenzyl)piperidine (0.19 g) was dissolved in 3 ml of piperidine, heated to the boiling point of the solution, and then immediately cooled. Removal of the solvent yielded 0.24 g of a solid, m.p. 75–78°, identical in all respects with α,α-dipiperidinotoluene.

ACKNOWLEDGMENTS

The research described here was supported by the National Research Council of Canada grant to R. J. Crawford. The n.m.r. and infrared spectra were measured by R. N. Swindlehurst and Mrs. Gail B. Conway of this Department.

BIOSYNTHETIC INCORPORATION OF ONE-CARBON UNITS INTO BERBERINE AND HYDRASTINE[1]

RAM NATH GUPTA AND IAN D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ontario
Received July 23, 1964

ABSTRACT

The utilization of one-carbon precursors in the biosynthesis of hydrastine and berberine was investigated by tracer experiments with plants of *Hydrastis canadensis* L. The lactone group of hydrastine and the bridge carbon of berberine are shown to be derived from the *S*-methyl group of methionine.

Recent tracer studies have established several intermediates of the pathway leading to the phthalideisoquinoline and the protoberberine alkaloids. By systematic carbon-by-carbon degradation of the labelled products which were isolated after administration of specifically tagged precursors to intact plants, it was shown that two tyrosine (I) units are incorporated into hydrastine (VIII) (2, 3), into narcotine (IX) (4), and into berberine (VII) (3, 5), that dopamine (III) is utilized in the biosynthesis of hydrastine (3, 6) and berberine (7), and that norlaudanosoline (V) serves as a precursor of narcotine (4). Incorporation of radioactivity from dopa (II) into berberine has also been reported (8). These findings, summarized in Fig. 1, are in remarkable agreement with the biogenetic speculations which were first put forward, mainly on the basis of structural considerations, almost half a century ago (9). They establish a source of all but one of the carbon atoms in the nucleus of the phthalideisoquinoline and protoberberine alkaloids. The remaining carbon atom in the skeletons of these alkaloids, the carbonyl carbon of hydrastine and narcotine (* in VIII and IX) and the so-called bridge carbon of berberine (* in VII), has long been postulated to arise from a one-carbon unit, which was presumed to enter at the oxidation level of formaldehyde (9). In agreement with this hypothesis, radioactivity from labelled formate has been found in the carbonyl group of narcotine (4).

We have tested the incorporation of ^{14}C-formate and of methyl-^{14}C-methionine into hydrastine and berberine in intact plants of *Hydrastis canadensis* L. (Golden Seal). The results indicate that the carbonyl group of hydrastine and the bridge carbon of berberine are indeed derived from one-carbon precursors. The methyl group of methionine is incorporated into these sites more efficiently than is formate. The findings lead to the inference that the one-carbon unit, from which the carbonyl carbon of hydrastine and the bridge carbon of berberine are ultimately derived, is introduced into a precursor molecule by a transmethylation step.

In a series of seven feeding experiments, sodium ^{14}C-formate (expts. 1–3) and L-methyl-^{14}C-methionine (expts. 4–7) were administered to plants of *Hydrastis canadensis* L., either via the roots or by infusion into the stem (3). In each experiment radioactive berberine and hydrastine was isolated from roots and rhizomes. Chemical and radiochemical yields are summarized in Table I. As observed previously with other precursors (3), berberine isolated from a particular experiment invariably had a higher specific activity than hydrastine (Table I). It is noteworthy that hydroponic administration of methionine led to more efficient incorporation of tracer than wick feeding, whereas wick

[1]*A preliminary account of parts of this work has been published (1).*

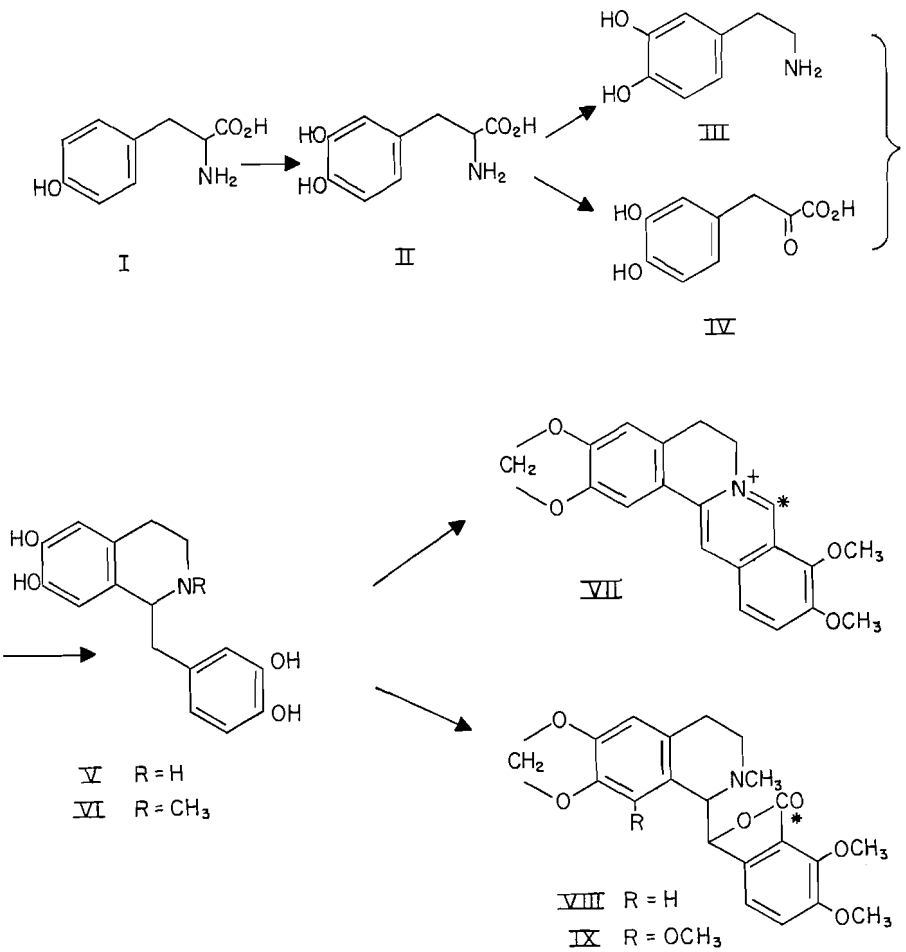

FIG. 1. Biosynthesis of berberine and hydrastine.

feeding was more efficient in the case of formate, in experiments conducted over the same time span. In terms of specific radiochemical yield, as well as in terms of recovery in the products of administered radioactivity (% incorporation), methionine was more efficiently incorporated than formate (Table II).

It was anticipated that incorporation of one-carbon precursors would yield hydrastine labelled at five centers (C=O, NCH_3, 2 × OCH_3, and CH_2O_2) and berberine labelled at four centers (bridge, 2 × OCH_3, and CH_2O_2). For an unequivocal interpretation of such multi-site incorporation of radioactivity, the labelled carbon atoms in each product had to be separated from one another, so that the extent of radioactivity at each labelled site could be determined. A method for degrading the alkaloids was worked out by pilot experiments with inactive material. The degradation sequences shown in Figs. 2 and 3 permitted determination of the radioactivity at the predicted one-carbon sites.

The labelled samples of hydrastine and berberine, obtained from six of the experiments, were degraded. The specific activities of the intermediates in the degradation sequences are shown in Tables III and IV. (Indicated limits are standard deviations of the mean.)

*Specific radiochemical yield $= \frac{\text{specific activity of product}}{\text{specific activity of precursor}} \times 100.$

†% incorporation $= \frac{\text{total activity of isolated product}}{\text{total activity of administered precursor}} \times 100.$

From these values the activity at the predicted one-carbon sites was deduced, in the manner indicated in the legend of Figs. 2 and 3. In each case these sites fully account for the activity of the original molecule. In Table V the contribution which each of these carbon atoms makes to the specific activity of the alkaloids obtained in individual experiments is expressed as a percentage of the specific activity of the intact alkaloids. The sum of the specific activities of the individual sites agrees, within experimental error, with the specific activity of the intact molecule, indicating the self-consistency of the results.

The results show that the lactone-carbonyl carbon of hydrastine and the bridge carbon of berberine, as well as the *O*- and *N*-attached one-carbon units of the two alkaloids, are specifically derived from one-carbon precursors. It is evident (Table V) that in every experiment the contribution which each of the one-carbon sites makes to the total specific activity of hydrastine and of berberine is of similar magnitude. This indicates that in each of the alkaloids all one-carbon sites are derived from the same immediate precursor. For if one of the one-carbon sites had been derived from some other immediate precursor than the other one-carbon sites in the same molecule, a different order of magnitude of the specific activity at that site, in either the formate or the methionine experiments, would have resulted. It follows that the lactone-carbonyl carbon of hydrastine and the bridge carbon of berberine are derived from the same immediate precursor which yields the extra-nuclear *O*- and *N*-attached one-carbon units.

There can be little doubt that transmethylation processes are responsible for the introduction of the one-carbon centers into the skeletons of hydrastine and berberine.

The evidence is strong that *O*- and *N*-methyl groups of alkaloids and other plant products originate in this manner (10). In a number of cases the transfer of methionine-methyl to such groups has been established by multiple labelling (11); and in others, transmethylase activity leading to the formation of *N*-methyl (12) and *O*-methyl groups (13, 14) by methyl transfer from *S*-adenosyl methionine has been demonstrated. In many further instances the methyl group of methionine proved to be more efficient than formate as a precursor of *O*-methyl (15) and *N*-methyl groups (15, 16) of plant alkaloids.

A transmethylation step is also required in the formation of the methylenedioxy group, (13, 17) which has been shown to arise from the methoxy group of an *o*-methoxyphenol (8, 18).

The origin of the bridge carbon of berberine and of the lactone group of hydrastine by a

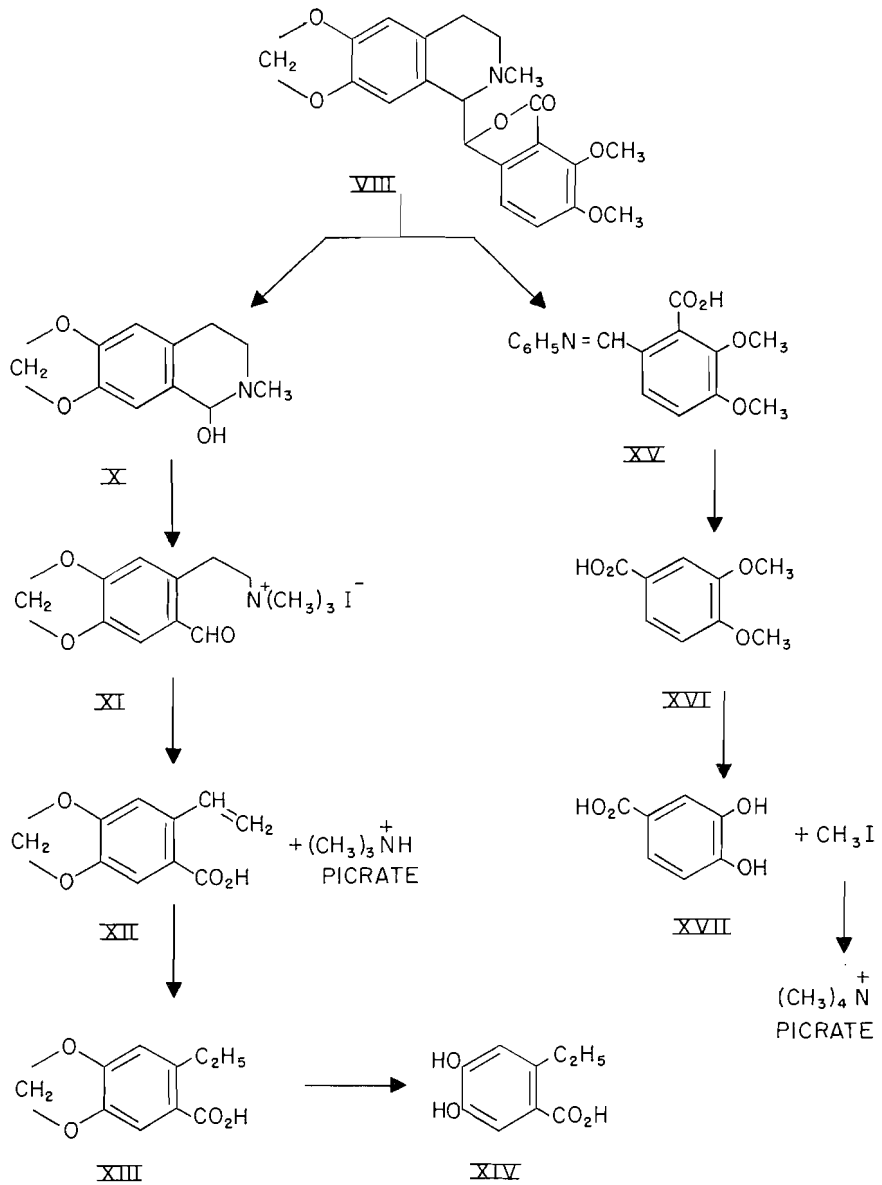

FIG. 2. Degradation of hydrastine, permitting isolation of one-carbon sites. NCH_3 = trimethylamine picrate; CH_2O_2 = 6-vinylpiperonylic acid (XII) minus 6-ethylprotocatechuic acid (XIV) (inactive) = 6-vinylpiperonylic acid (XII); $2 \times OCH_3$ = $2 \times$ tetramethylammonium picrate = veratric acid (XVI) minus protocatechuic acid (XVII) (inactive) = veratric acid (XVI); C=O = opianic acid anil (XV) minus veratric acid (XVI).

route involving transmethylation is less obvious. The early work of Sribney and Kirkwood (17) had indicated that radioactivity from methyl-labelled methionine entered the nucleus of protopine, an alkaloid structurally related to berberine. The site of activity was not determined but it was suggested that the label was located at a position corresponding to the berberine bridge. Recently it was shown that laudanosoline (VI) (19) and its di-*O*-methyl derivative, reticuline (8), are incorporated into berberine *in toto*, and that the

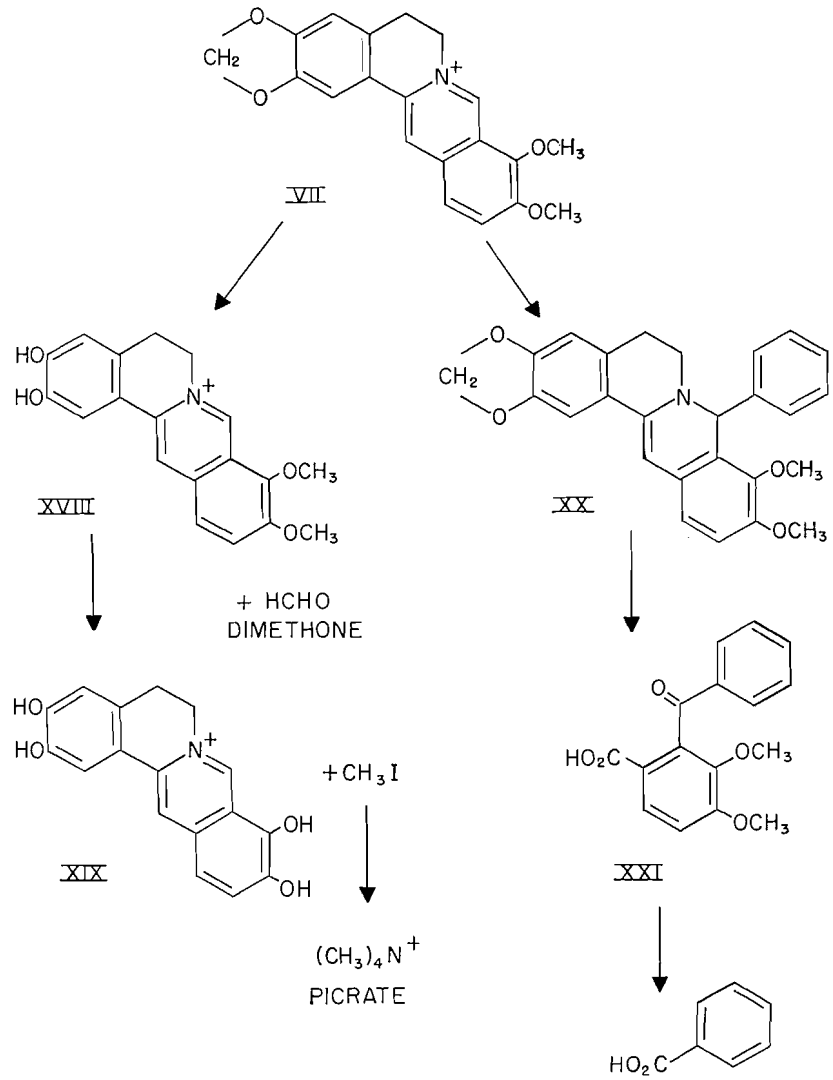

FIG. 3. Degradation of berberine, permitting isolation of one-carbon sites. CH_2O_2 = formaldehyde dimethone; 2 × OCH_3 = 2 × tetramethylammonium picrate; bridge = benzoic acid.

N-methyl group of these precursors is transformed into the bridge carbon of berberine. These results are consistent with the present findings, and with the view that the methyl group of methionine which gives rise to the bridge carbon of berberine enters the biosynthetic pathway by transmethylation onto the nitrogen atom of norlaudanosoline (V).

The present results indicate also that the lactone-carbonyl group of hydrastine, like the bridge carbon of berberine, is formed by modification of a methyl group, introduced into a precursor by transmethylation. Whether berberine and hydrastine arise from a common *N*-methylated precursor, laudanosoline (VI), by independent pathways, or whether hydrastine is formed by oxidative modification of berberine (20), or whether a *C*-methylated rather than an *N*-methylated derivative of norlaudanosoline is the intermediate of hydrastine biosynthesis, remains to be established.

EXPERIMENTAL

Degradation of Hydrastine

Conversion of Hydrastine (VIII) to Hydrastinine (X) and Opianic Acid Anil (XV) (3, 22)

Hydrastine (0.5 g) was suspended in 20% nitric acid (4 ml) and the mixture was kept at 40° for 16 h. The clear yellow solution was cooled, and cold 40% potassium hydroxide (3 ml) was added during stirring and cooling. The mixture was kept at 5° for 1 h, and the crystalline precipitate was filtered off and washed with a little cold water. Hydrastinine (227 mg, 84%), melting at 116–117° after recrystallization from ethyl acetate, was obtained; reported m.p. 116–117° (21).

Aniline (0.3 g) in ethanol (2 ml) was added to the filtrate and the solution was warmed for a few minutes at 60–70°. After the solution was cooled, cold 10% hydrochloric acid was added dropwise, with stirring, until the mixture was acidic to Congo red. The precipitate was filtered off, washed with water and with a little methanol, and crystallized from methanol. Opianic acid anil (170 mg, 45%), melting at 188–189°, was obtained; reported m.p. 191.5–192.5° (22).

Conversion of Hydrastinine to Hydrastinine Picrate (23)

Crude hydrastinine (10 mg) was dissolved in methanol (5 ml) and an excess of a hot saturated solution of picric acid in methanol was added. A red precipitate formed when the mixture was warmed and allowed to cool. This precipitate recrystallized from methanol as red crystals of hydrastinine picrate melting at 173° (reported m.p. 173° (23)).

Conversion of Hydrastinine (X) to β-[2-Formyl-4,5-methylenedioxyphenyl]-ethyltrimethylammonium Iodide (N-Methylhydrastinine Methiodide) (XI)

A one-step Hofmann degradation (3, 24) was not suitable for the present purpose, since, in the presence of excess methylating agent, methyl exchange on trimethylamine was likely to take place. Such an exchange would make the recovery of isotope in trimethylamine uncertain. *N*-Methylhydrastinine methiodide was therefore isolated.

Hydrastinine (105 mg) was suspended in water (2 ml), and potassium carbonate (100 mg) and methyl iodide (2 ml) were added. The mixture was shaken for 24 h and then kept at 40° for another 24 h. Methyl iodide was evaporated, the residue was cooled and filtered, and the product washed with a little cold water and recrystallized from aqueous methanol. *N*-Methylhydrastinine methiodide (135 mg, 75%), melting at 265–266°, was obtained; reported m.p. 267° (25) and 262–264° (26).

Hofmann Degradation of N-Methylhydrastinine Methiodide

A suspension of the above quaternary salt (180 mg) in 10% sodium hydroxide (5 ml) was kept on the steam bath for 1 h, during which time a current of nitrogen was passed through the suspension. The issuing gas was passed through an alcoholic solution of picric acid; from this solution, on concentration and recrystallization from methanol, trimethylamine picrate, melting at 216°, was isolated. Quantitative recovery of this picrate was not attempted.

The original reaction mixture was cooled, extracted with ether, and the ether extract was washed with water, dried, and evaporated. The residue was dissolved in a mixture of methanol (4 ml) and water (2 ml) and powdered silver nitrate (0.6 g) was added to the solution, followed by 20% sodium hydroxide (6 ml). The mixture was warmed on the steam bath, shaken for 2 h, filtered, and extracted with ether. The aqueous layer was warmed to remove ether and cooled and acidified with cold 50% (v/v) sulfuric acid. The precipitate, which was obtained on cooling, was washed with cold water and recrystallized from aqueous methanol. 6-Vinylpiperonylic acid (XII) (53 mg, 55%), melting at 167–168°, was obtained; reported m.p. 168° (3).

Reduction of 6-Vinylpiperonylic Acid (XII) to 6-Ethylpiperonylic Acid (XIII)

6-Vinylpiperonylic acid (100 mg) was dissolved in 10% sodium hydroxide (4 ml) and the solution maintained at 60–65°. Nickel–aluminium alloy (150 mg) was added in small portions with constant stirring. The addition of alloy was complete in 45 min. The temperature was raised to 75–80° and stirring was continued for 12 h. The catalyst was then filtered off and washed with water. The combined filtrate and washings were acidified with 50% hydrochloric acid and the product was filtered off, washed with a little cold water, and recrystallized from aqueous methanol. 6-Ethylpiperonylic acid (90 mg, 60%), melting at 125–126°, was obtained. (Found: C, 62.1; H, 5.2. $C_{10}H_{10}O_4$ requires C, 61.9; H, 5.2%.) Subsequent reductions were carried out at room temperature without affecting the yield or the nature of the reduction product. Cleavage of the methylenedioxy group, reported to take place in a number of other methylenedioxyphenyl derivatives (27), did not appear to occur with 6-vinylpiperonylic acid under these conditions.

Conversion of 6-Ethylpiperonylic Acid (XIII) to 6-Ethylprotocatechuic Acid (XIV)

6-Ethylpiperonylic acid (60 mg) and phosphorus pentachloride (180 mg) were sealed in a hard-glass test tube, which was then kept at 150–160° for 2 h. The tube was opened and the reaction mixture, after addition of water, was refluxed for 2 h in a current of nitrogen which had been purified by passing through potassium hydroxide solution. The exit gases were bubbled into *M* potassium hydroxide which was protected from atmospheric carbon dioxide by a trap of potassium hydroxide solution. The carbon dioxide

which had been swept out of the reaction mixture was converted to barium carbonate by addition of 17% barium chloride solution. The precipitate was washed with water and dried in air when barium carbonate (38 mg, 73%) was obtained.

The reaction mixture was cooled and extracted with ether. The ether extract was dried and evaporated and the residue sublimed at 130° and 1×10^{-3} mm. 6-Ethylprotocatechuic acid (24 mg, 40%), melting at 194–195°, was obtained; reported m.p. 164–165° (28). (Found: C, 59.2; H, 5.6. $C_9H_{10}O_4$ requires C, 59.3; H, 5.5%.)

Decarboxylation of Opianic Acid Anil (XV) (22)

A slow stream of nitrogen, which had been purified by passing through a saturated solution of potassium hydroxide and through sulfuric acid, was passed through the tube containing opianic acid anil (100 mg) and copper bronze (5 mg). The exit gases were bubbled through *M* potassium hydroxide, which was protected from the atmosphere by a trap of saturated potassium hydroxide solution. The reaction tube was placed in a bath of boiling ethyl benzoate (b.p. 212°) until the evolution of carbon dioxide ceased (10 min). Heating was discontinued, but passage of nitrogen was continued for another 0.5 h. Barium chloride (17%) was added to the potassium hydroxide trap which had absorbed the exit gases, to yield barium carbonate (60 mg, 90%).

The residue in the reaction tube, veratraldehyde anil, was hydrolyzed by refluxing with 5% acetic acid (1 ml) for 1 h (22). The mixture was cooled and extracted with ether. The ether extract was washed, in succession, with water, dilute potassium hydroxide solution, and water and was then dried and evaporated. The residue, veratraldehyde, was dissolved in a mixture of methanol (4 ml) and water (2 ml). Powdered silver nitrate (0.5 g) and 20% sodium hydroxide (5 ml) were added. The mixture was warmed on a steam bath for a few minutes, shaken for 2 h, and then filtered. Acidification of the filtrate with 50% (v/v) sulfuric acid yielded crude product, which was washed with water, dissolved in methanol, decolorized with charcoal, and recrystallized from aqueous methanol. Veratric acid (XVI) (34 mg, 50%), melting at 175–176°, was obtained; reported m.p. 179–181.5° (29).

Cleavage of the Methoxy Groups of Veratric Acid (cf. Ref. 30)

Veratric acid (200 mg) in freshly distilled hydriodic acid (density, 1.7, 10 ml) was gently refluxed in a current of dry nitrogen for 2 h. The exit gases were passed through a suspension of red phosphorus in 5% cadmium sulfate solution, passed over anhydrous potassium carbonate, and bubbled into a 5% methanolic solution of trimethylamine contained in a series of two tubes which were cooled in dry ice–acetone mixture. After 2 h passage of nitrogen was stopped, and the tubes containing trimethylamine solution were disconnected and allowed to stand at room temperature overnight. A crystalline precipitate of tetramethylammonium iodide was obtained. The solution was decanted and the precipitate repeatedly washed with dry methanol. The precipitate was dissolved in water, and a hot saturated aqueous solution of picric acid was added. The residue obtained on cooling was washed with ether and recrystallized twice from methanol, when pale red needles of tetramethylammonium picrate, melting at 312–313°, were obtained. No attempt was made to recover the picrate quantitatively.

The reaction mixture was diluted with water and extracted with ether. The extract was washed with cold dilute sodium thiosulfate solution to destroy iodine, and with water, dried, and evaporated. The residue sublimed at 125° and 3.5×10^{-3} mm when protocatechuic acid (XVII) (100 mg, 60%), melting at 200–202°, was obtained; reported m.p. 199°.

Degradation of Berberine

Conversion of Berberine Hydrochloride to Berberine Picrate

Berberine hydrochloride (10 mg) was dissolved in methanol and an excess of a hot saturated solution of picric acid in methanol was added. The mixture was heated and allowed to cool. An orange precipitate appeared which was filtered off, washed with methanol, and recrystallized from methanol–acetone, yielding orange needles of berberine picrate, melting at 238–239°; reported m.p. 239° (31).

Hydrolytic Cleavage of the Methylenedioxy Group of Berberine (cf. Ref. 17)

Berberine hydrochloride (100 mg) and dimedone (5,5-dimethyldihydroresorcinol) (300 mg) were suspended in dilute sulfuric acid (60 ml concentrated sulfuric acid in 100 ml water) (5ml) and the mixture was maintained at 98–100° for 18 h. The cooled reaction mixture was diluted with water (5 ml) and extracted with ether. The ether extract was washed with water, dried, and evaporated. The residue was crystallized from aqueous methanol when white silky needles of the dimedone derivative of formaldehyde (24 mg, 36%), melting at 190–191°, were obtained.

The aqueous layer, in which a precipitate had now appeared, was warmed to remove residual ether, and a saturated solution of potassium iodide (2 ml) was added. The mixture was cooled and filtered and the residue washed with a little sulfur dioxide water and dried. 2,3-Dihydroxy-9,10-dimethoxy-7,8,13,14-tetradehydroberbinium iodide (XVIII) (90 mg, 80%) was obtained (cf. ref. 32).

Cleavage of the Methoxy Groups

2,3-Dihydroxy-9,10-dimethoxy-7,8,13,14-tetradehydroberbinium iodide (XVIII) (90 mg) was refluxed with freshly distilled hydriodic acid (5 ml). Methyl iodide was isolated as tetramethylammonium picrate by the method described earlier for the cleavage of veratric acid.

For personal use only.

The reaction mixture was diluted with water, decolorized with sulfur dioxide water, filtered, and dried. Berberoline iodide (XIX) (70 mg, 74%) was obtained. This compound could not be crystallized nor converted into a crystalline derivative (cf. ref. 33).

Isolation of the Bridge Carbon of Berberine as Benzoic Acid (cf. ref. 34)

Berberine hydrochloride (700 mg) was dried at 100° under vacuum for 2 h and then suspended in 10 ml ether. Excess of an ethereal solution of phenylmagnesium bromide, prepared from magnesium turnings (0.12 g) and bromobenzene (0.6 ml) in 5 ml anhydrous ether, was added. The mixture was stirred and refluxed for 2 h. Water (5 ml) and dilute hydrochloric acid (5 ml) was added and the resulting precipitate was washed with water and a little ether.

The crude phenyldihydroberberine hydrobromide (XX) was suspended in a solution of potassium carbonate (3 g) in water (150 ml). Potassium permanganate (3 g) was added in small portions over a period of 80 h with continuous stirring. Sulfur dioxide was passed through the solution until it was clear. The solution was then acidified and boiled to expel dissolved sulfur dioxide, cooled, and extracted with chloroform. The chloroform layer was washed with water and dilute acid and extracted with 10% sodium hydroxide. The basic extract was washed with ether, acidified with 50% hydrochloric acid, and extracted with ether. The ether extract was dried and evaporated. The residue was crystallized from 50% acetic acid. 2-Benzoyl-3,4-dimethoxybenzoic acid (XXI) (120 mg, 24%), melting at 193–194°, was obtained; reported m.p. 190–191° (34) and 192° (35).

2-Benzoyl-3,4-dimethoxybenzoic acid (XXI) (100 mg) was moistened with water (0.5 ml), potassium hydroxide (1 g) was added, and the mixture was fused for 2–3 min. The cooled melt was dissolved in water and the solution was acidified with 10% hydrochloric acid and extracted with chloroform. The chloroform layer was washed with water, dried, and evaporated. The residue was sublimed at 60–70° and 1×10^{-3} mm, yielding benzoic acid (35 mg, 83%) melting at 119–120°.

Administration of ^{14}C-labelled Compounds to Hydrastis canadensis L. and Extraction of Labelled Alkaloids

Methyl-^{14}C-methionine and sodium ^{14}C-formate were administered to 4-year-old plants of *Hydrastis canadensis* L., either hydroponically or by infusion into the stem, by reported methods (3). Hydrastine and berberine were extracted from roots and rhizomes by standard methods (3). Leaves and other aerial parts were rejected. Chemical and radioactive yields from all experiments are shown in Table I.

Degradation of Radioactive Alkaloids

The radioactive alkaloids were degraded by the reaction sequences described above. When the amount of material permitted, the alkaloid was degraded without dilution after crystallization to constant activity. In most cases, however, dilution with carrier was necessary to obtain sufficient material to carry out the complete degradation sequence. A minimum of 500 mg berberine and 350 mg hydrastine was desirable for this purpose.

The degradation products were solids, or were isolated as solid derivatives, and were crystallized to constant melting point. Their radioactivity was assayed on samples of finite thickness on aluminium planchettes, using a Model 1052 gas-flow counter with "micromil" window (Nuclear Chicago Corp.) in a low-background automatic sample changer (Nuclear Chicago Corp., Model C115). Counts were recorded on a printing timer (Nuclear Chicago Corp., C111B) in association with a scaler (Nuclear Chicago Corp., 181B).

The usual corrections for background and self-absorption were applied.

For plating, a 1% solution of collodion in dimethylformamide was used as the solvent. Only berberine hydrochloride and formaldehyde dimethone could not be plated in this way. Dissolution of these samples required prolonged contact with benzyl alcohol before application of the collodion dimethylformamide solution. In the case of benzoic acid, a drop of a 5% solution of sodium hydroxide in 50% aqueous methanol was required to avoid loss of benzoic acid by evaporation.

ACKNOWLEDGMENTS

We are greatly indebted to Mr. L. Laking, Director, and Mr. R. E. Halward, Propagator, of the Royal Botanical Gardens, Hamilton, for facilities and help in the cultivation of *Hydrastis canadensis* L.

This investigation was supported by Research Grant GM-10043 from the National Institute of General Medical Sciences, United States Public Health Service, and by a grant from the National Research Council of Canada.

OXYGEN-17 NUCLEAR MAGNETIC RESONANCE STUDY OF THE CHROMATE REACTION WITH DICHROMATE[1]

B. N. FIGGIS,[2] R. G. KIDD,[3] AND R. S. NYHOLM
William Ramsay and Ralph Forster Laboratories, University College, London, England

Received July 10, 1964

ABSTRACT

The ^{17}O n.m.r. spectra from aqueous solutions containing both chromate and dichromate ions have been obtained over a range of concentrations. Signals from both the bridging oxygen and the terminal oxygens in the dichromate ion have been observed. The line widths for the dissolved species were found to be concentration dependent. The variations in line width have been ascribed to a rapid reaction occurring at equilibrium between chromate and dichromate ions. The bimolecular rate constant for the reaction is $2.3 \pm 0.4 \times 10^3$ l mole^{-1} s^{-1} at 27 °C. The reaction mechanism is discussed in the general context of nucleophilic attack on dichromate ion. A comparison of this rate constant with those for the analogous reaction using different nucleophiles indicates that it is polarizability rather than basicity which determines nucleophilic reactivity towards $Cr_2O_7^=$.

INTRODUCTION

The direct reaction between $CrO_4^=$ and $Cr_2O_7^=$ ions at equilibrium in aqueous solution, without the involvement of solvent water molecules and leading to the rapid exchange of chromium atoms between one species and the other, has never been postulated. While carrying out a nuclear magnetic resonance (n.m.r.) study of chemical shifts of oxygen-17 atoms bonded to metal atoms, we have obtained experimental evidence for the reaction

$$Cr^*O_4^= + O_3Cr—O—CrO_3^= \rightarrow O_3Cr^*—O—CrO_3^= + CrO_4^=.$$

This evidence was obtained from the widths of ^{17}O resonance lines in the n.m.r. spectra of aqueous solutions of $Na_2Cr_2O_7$ containing varying concentrations of Na_2CrO_4. The kinetic rate constant for this reaction at 27 °C has been evaluated. The reaction is viewed in terms of a nucleophilic attack by $CrO_4^=$ on $Cr_2O_7^=$ leading to substitution at a chromium(VI) atom. Its mechanism is discussed in this context.

The nature of the kinetic processes occurring in both equilibrium and nonequilibrium solutions of $CrO_4^=$ and $Cr_2O_7^=$ ions has been the subject of considerable interest for the past 35 years. This interest has manifested itself in studies of the rate at which $CrO_4^=$ and $Cr_2O_7^=$ ions exchange oxygen atoms with solvent water molecules (1–5) and studies of the rate at which $CrO_4^=$ ions dimerize to give $Cr_2O_7^=$ ions (6–10). The exchange reaction newly reported in this paper proceeds independently of and at a rate considerably greater than either of these two reactions.

EXPERIMENTAL

The n.m.r. spectra were obtained using a Varian V-4300B fixed-frequency spectrometer adapted for the observation of quadrupolar-broadened ^{17}O signals by the addition of a lock-in amplifier and phase-sensitive detector. At a frequency of 6.000 Mc/s the signals were observed in the region of 10 400 gauss. Audiofrequency field modulation of 40 c.p.s. and peak-to-peak amplitude less than 45 mgauss was applied to the Helmholtz coils of the probe assembly. The output time constant of the phase-sensitive detector was variable between 2 and 140 s. A radiofrequency power level of about 50 mgauss was found to be below the saturation level and was used for all measurements. The spectra were calibrated by passing a measured

d-c. biasing current through the Helmholtz coils of the probe, thereby shifting the position of one of the spectral signals by a known amount to provide a calibration point in each spectrum. The phase of the current leaked from the transmitter coil to the receiver coil within the probe was adjusted to give absorption mode presentation, and the signals obtained from the phase-sensitive detector were recorded in the absorption derivative form.

Water containing 2.1 atom per cent ^{17}O was obtained commercially from The Weizmann Institute, Israel. Hopkin & Williams $Na_2Cr_2O_7$ was twice recrystallized from water containing 0.1 *N* HCl. The product was dried for 6 h at 100 °C and 0.5 mm pressure. $Na_2Cr_2O_7$ (0.500 g) was placed in a 15 mm n.m.r cell and 0.870 g of the enriched water was distilled into the cell. The density of this solution was 1.42 g/cc, corresponding to a concentration of 1.98 *M* $Na_2Cr_2O_7$. Further solutions of increasing pH were prepared by the addition of weighed increments of solid NaOH to the initial solution.

In order to avoid loss of the enriched water, an identical series of solutions was prepared using natural water in place of the enriched water. The pH of each of these solutions was determined with a Cambridge potentiometer using glass and saturated calomel electrodes. The curve of *pH* vs. *weight of added NaOH* obtained from these measurements provided approximate pH values for the enriched solutions.

The sample temperature during measurement of the n.m.r. spectra was measured with a copper–constantan thermocouple and was found to be 27 ± 1 °C.

RESULTS

The ^{17}O linewidth data for the chromate and dichromate solutions are given in Table I.

TABLE I

^{17}O linewidths for $Cr_2O_7^=$ and $CrO_4^=$ solutions

Solution No.	Added NaOH, moles $\frac{NaOH}{Na_2Cr_2O_7}$	^{17}O linewidth, c.p.s.				Concentration, mole l^{-1}	
		Solvent H_2O	Terminal $Cr_2O_7^=$	Bridging $Cr_2O_7^=$	$CrO_4^=$	$[Cr_2O_7^=]$	$[CrO_4^=]$
1	0		115±15	198±9			
2	0.38		180±51	292±15			
3	0.67	199±41	321±54	872±57			0.49
4	0.84	209±17	452±12				0.86
5	1.02	227±12	534±82		554±1	1.38	1.25
6	1.11	230±10	826±61		603±56	1.27	1.45
7	1.32	230±24	923±199		570±50	1.05	1.89
8	1.40	249*			525±5	0.98	
9	1.60	245±16			380±15	0.76	
10	1.72	287±8			381±43	0.64	
11	1.95	302±14			276±67	0.39	
12	2.39	310±26			96±5		

Error limits are standard deviations.
*Single determination only.

Solution No. 1 is the initial solution containing 1.98 *M* $Na_2Cr_2O_7$ and the successive solutions were prepared from this one by addition of the amounts of NaOH indicated in the table. Each linewidth figure listed is an average value taken from at least three different spectra, except where otherwise noted.

The ionic concentration figures for the calculation of bimolecular rate constants are given in the last two columns of the table. They were obtained by a process of interpolation, making use of Fig. 1. The linewidth plots indicate that in the region between 50 and 180 mg added NaOH the concentrations of both $CrO_4^=$ and $Cr_2O_7^=$ are linear functions of the weight added. Since the initial $Cr_2O_7^=$ and the final $CrO_4^=$ concentrations are known, linear interpolation between them yields the values listed in the table. It is estimated that the inaccuracies in these figures are no greater than ±15%.

INTERPRETATION OF THE DICHROMATE ION ^{17}O SPECTRUM

The ^{17}O chemical shift for the terminal oxygen atoms in the dichromate ion has been shown (11) to be −1125 parts per million (p.p.m.) relative to water oxygens. A signal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

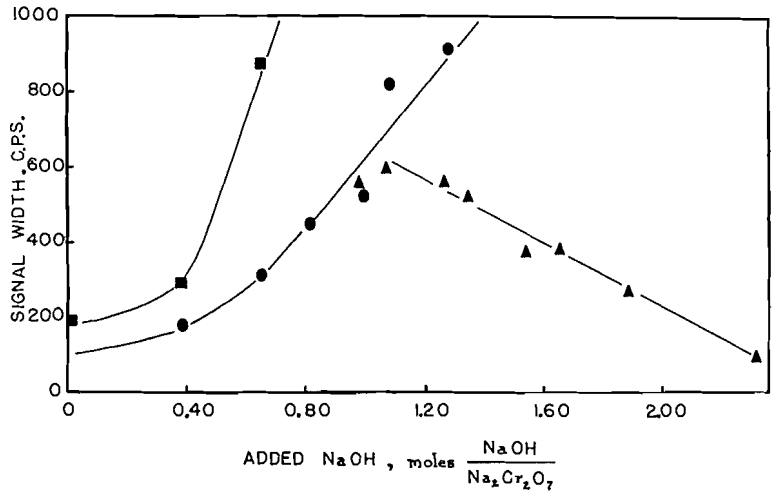

FIG. 1. ^{17}O signal widths for aqueous solutions of $Cr_2O_7^=$ and $CrO_4^=$; ■ bridging oxygen in $Cr_2O_7^=$; ● terminal oxygen in $Cr_2O_7^=$; ▼ oxygens in $CrO_4^=$.

from the bridging oxygen atom has not hitherto been reported. In order to detect the signal from the bridging oxygen it was necessary to enrich the $Cr_2O_7^=$ ion in ^{17}O. A 1.98 M aqueous solution of $Na_2Cr_2O_7$ enriched by a factor of 50 in ^{17}O yielded two ^{17}O signals apart from the solvent water line; a large signal at -1129 p.p.m. due to the terminal oxygens and a line of much lower intensity at -345 p.p.m. which was assigned to the bridging oxygens. The significant feature of this spectrum was the fact that the bridging-oxygen signal was approximately twice as wide as the terminal-oxygen signal.

The width of a nuclear resonance line having Lorentzian shape is determined by the effective transverse relaxation time T_2' of the nucleus, according to the equation (12)

$$[1] \qquad \Delta\nu = \frac{1}{\sqrt{3}\pi T_2'} \text{ s}^{-1}.$$

$\Delta\nu$ is the line width expressed in c.p.s. and defined as the horizontal separation between the points of maximum deflection of the absorption derivative curve. Where a chemical rate process causes a change in the magnetic environment of a nucleus due to exchange of the atom between two chemically different sites, then the lifetime of the spin state under investigation is limited by this process. If the lifetime of the spin state is long relative to the frequency separation of the two sites, then $\tau \cdot \Delta\omega > 1$, and the effective transverse relaxation time is given by (13)

$$[2] \qquad \frac{1}{T_2'} = \frac{1}{T_2} + \frac{1}{\tau}.$$

T_2 is the magnitude of the transverse relaxation time in the absence of any exchange process and τ is the mean lifetime for the stay of an atom at the site under investigation before it changes to another. $\Delta\omega$ is the frequency separation in radians per second between the two sites available to the nucleus. In the present study the lifetime value τ satisfies this slow exchange condition. The resonance linewidth for an ^{17}O nucleus which is not exchanged is obtained by substituting T_2 into eq. [1]. We will call this the static linewidth.

If one assumes that the static linewidths for oxygen atoms in both terminal and bridging positions of the dichromate ion are the same (and this assumption will be shown to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

have a certain measure of validity), the fact that the bridging-oxygen signal is wider than the terminal-oxygen signal indicates that $\tau_B < \tau_T$. (In the following discussion, parameters with subscript T and B refer to oxygen atoms in dichromate ion terminal and bridging sites respectively.) The equilibrium constants for the existence of $Cr_3O_{10}^{=}$ (14) and $CrO_4^{=}$ (15) in equilibrium with $Cr_2O_7^{=}$ indicate that under the experimental conditions (pH $\approx$ 4), the concentrations of each of the former two ions will be less than 10^{-3} *M*. Accordingly, we consider the solution under study to consist primarily of $Cr_2O_7^{=}$ ions and H_2O molecules; concentrations of other oxygen-containing species in chemical equilibrium with these are relatively low, as is verified by the lack of further lines in the ^{17}O spectrum. A given oxygen atom spends only a very small fraction of its time in any one of these other environments, so the contribution of these environments to the shapes of the observed lines can be neglected. When an oxygen atom leaves a bridging position, it must transfer to either an H_2O site or to a terminal site. If it transfers to an H_2O site, then oxygen atoms must leave these sites at the same rate as bridging oxygens enter. This process would result in a correlated shortening of τ_{H_2O} leading to a broadening of the H_2O signal. With solution No. 7 as an example where the broadening of the dichromate terminal signal is most marked but still measureable, the linewidth which one calculates for the water signal, assuming that terminal oxygens are exchanging with H_2O oxygens, is 300 c.p.s. The observed linewidth for the solvent water line of solution No. 7 taken from Table I is, however, 230 c.p.s. Thus the broadening of the dichromate terminal oxygen signal cannot be ascribed to exchange of oxygen between terminal and solvent H_2O sites. Since ^{17}O linewidths are known to be dependent upon solution viscosity (16), we attribute the small monotonic increase in H_2O linewidth to increasing solution viscosity, which rises steadily from 1.9 cP for solution No. 1 to 5.6 cP for solution No. 12.

A more reasonable interpretation of the linewidth discrepancy can be made in terms of exchange of oxygen atoms between bridging and terminal positions. If this exchange occurs by some mechanism as yet unspecified, then the average lifetime of a terminal oxygen is longer than that of a bridging oxygen, and $\tau_T = 6\tau_B$ by considerations of detailed balancing. On this basis we set up a pair of simultaneous equations for the effective relaxation times of oxygen atoms at the two sites.

[3]
$$\frac{1}{T_{2T}'} = \frac{1}{T_{2T}} + \frac{1}{\tau_T}$$

$$\frac{1}{T_{2B}'} = \frac{1}{T_{2B}} + \frac{1}{\tau_B}.$$

T_{2T}' and T_{2B}' values can be obtained from the experimental linewidths using eq. [1] and $\tau_T = 6\tau_B$. Then, provided that static linewidths of terminal and bridging oxygens are the same, the equations can be solved for τ_B and T_2. Diehl and his co-workers (17) have examined the ^{17}O n.m.r. spectra of acetic and propionic anhydrides, both of which contain terminal and bridging oxygens. In these molecules, exchange between the two sites is not expected. In both cases, they found the linewidths for terminal and bridging sites in the same molecule to be identical, thereby supporting the contention that the oxygen linewidth is not particularly sensitive to differences in the nature of the bonding at the oxygen atom.

From the $Cr_2O_7^{=}$ ion spectrum we get $\Delta\nu_T = 115$ c.p.s. and $\Delta\nu_B = 198$ c.p.s. which gives $1/T_{2B}' = 1\,077\ s^{-1}$ and $1/T_{2T}' = 626\ s^{-1}$. Assuming that $T_{2T} = T_{2B} = T_2$ and eliminating τ_B and τ_T from eq. [3] we obtain $T_2 = 1.85 \times 10^{-3}$ s. This corresponds to a linewidth of 98 c.p.s. in the absence of exchange.

KINETIC PATHS LEADING TO OXYGEN EXCHANGE

Two different kinetic paths may lead to exchange of oxygen atoms between terminal and bridging positions in the dichromate ion. Both of them involve scission of one of the Cr—O—Cr bonds.

[4] 
[5] 
Path [4] is an intramolecular rearrangement and path [5] is a bimolecular process involving the low concentration of $CrO_4^=$ ions present in equilibrium with $Cr_2O_7^=$ ions. It should be stressed at this point that when detailed mechanisms are discussed in this paper, no distinction is drawn between the unprotonated chromium(VI) anions and their several protonated forms. Under the experimental conditions used in the study, it is not possible to distinguish between $CrO_4^=$, $HCrO_4^-$, and H_2CrO_4. Thus, the results of experimental observations made upon $CrO_4^=$ include the effects of any $HCrO_4^-$ and H_2CrO_4 present in the system.

In order to determine whether the second of these processes makes a significant contribution to the exchange process, the chromate–dichromate equilibrium in the ^{17}O-enriched solution

$$Cr_2O_7^= + 2OH^- \rightarrow 2CrO_4^= + HOH$$

was shifted to the right by adding increments of solid NaOH until the solution was alkaline, when all chromium(IV) was present in the form of $CrO_4^=$ ions. The ^{17}O spectrum was measured after the addition of each NaOH increment and the linewidth data for each solution are given in Table I.

As the $CrO_4^=$ ion concentration increases, both the terminal- and bridging-oxygen linewidths increase markedly indicating an increase in the exchange rate. In fact the bridging signal soon becomes so broad as to be undetectable. When the $CrO_4^=$ ion concentration reaches the level where a $CrO_4^=$ resonance line can be detected, the width of this line provides further evidence for the bimolecular process. Since the $CrO_4^=$ ion takes part in the exchange path [5], the width of this line also exhibits the effects of lifetime limiting. In the pH region where the dominant chromium(VI) species is $CrO_4^=$, the width of its ^{17}O signal decreases as the concentration of $Cr_2O_7^=$ drops, as is expected for a bimolecular process. The linewidth variations for the bridging signal, terminal signal, and chromate ion signal with change in solution pH can be seen in Fig. 1.

EVALUATION OF THE EXCHANGE RATE CONSTANT

The linewidth behavior illustrated in Fig. 1 indicates that the exchange rate is markedly dependent upon the relative concentrations of chromate and dichromate ions in solution

and that the exchange process is a bimolecular one governed by a rate law of the type

$$\pm\frac{d[Cr_2O_7^{=}]}{dt} = \pm\frac{d[CrO_4^{=}]}{dt} = k[Cr_2O_7^{=}][CrO_4^{=}].$$

If we direct our attention to the pH region where $CrO_4^{=}$ ions are the predominant chromium(VI) species, then the average lifetime of a chromate oxygen, τ_C, can be evaluated from the chromate linewidths. The rate at which chromate ions react is given by

$$\frac{[CrO_4^{=}]}{\tau_C} = \pm\frac{d[CrO_4^{=}]}{dt} = k[CrO_4^{=}][Cr_2O_7^{=}]$$

and

$$\frac{1}{\tau_C} = k[Cr_2O_7^{=}].$$

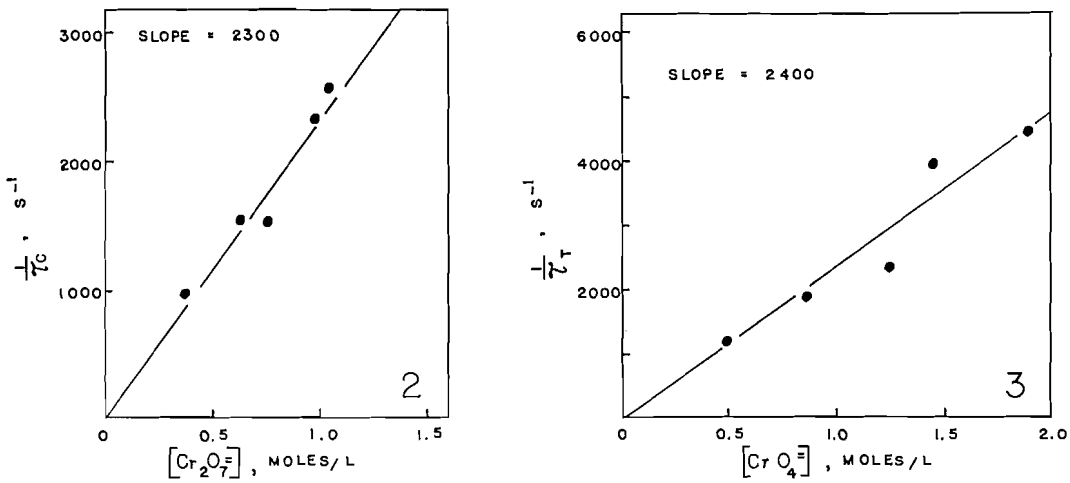

FIG. 2. Variation of $1/\tau_C$ with change in $[Cr_2O_7^{=}]$.
FIG. 3. Variation of $1/\tau_T$ with change in $[CrO_4^{=}]$.

When $1/\tau_C$ is plotted against $[Cr_2O_7^{=}]$ as in Fig. 2, a straight line with slope k and passing through the origin is obtained. The slope of Fig. 2 obtained by a least-squares treatment gives a rate constant value of $k = (2.3 \pm 0.4) \times 10^3$ l mole^{-1} s^{-1}, the error limits being the standard deviation.

The treatment of the dichromate ion linewidth data is not quite as straightforward. When a $CrO_4^{=}$ ion reacts with a $Cr_2O_7^{=}$ ion as in process [5], all four oxygens on $CrO_4^{=}$ assume new environments, but the same does not hold true for the $Cr_2O_7^{=}$ ion. Only four of these change environment to become $CrO_4^{=}$ oxygens, the other three remain as dichromate ion terminal oxygens. The average lifetime of a terminal-oxygen atom should then be twice that of a dichromate ion, since only half the terminal oxygens change their environment at each exchange event. This reasoning, however, is not confirmed by the experimental data. If one does assume that $\tau_T = \tau_{Cr_2O_7^{=}}$ then

$$\frac{[Cr_2O_7^{=}]}{\tau_T} = \pm\frac{d[Cr_2O_7^{=}]}{dt} = k[Cr_2O_7^{=}][CrO_4^{=}]$$

and

$$\frac{1}{\tau_T} = k[CrO_4^{=}].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The plot of $1/\tau_T$ vs. $[CrO_4^{=}]$ shown in Fig. 3 has the slope $k = (2.4 \pm 0.8) \times 10^3$ l mole^{-1} s^{-1}, thus lending substance to the assumption that $\tau_T = \tau_{Cr_2O_7^{=}}$. It must be concluded, therefore, that even though three of the terminal dichromate oxygens have the same environment before and after the reaction, the magnetic perturbation exerted upon them during the exchange event is sufficiently great to cause all of the terminal oxygens to lose their precessional phase correlation.

In connection with the rate constants given above, it should be mentioned that they were obtained under conditions of varying ionic strength. Since the measurements were made at electrolyte concentrations in excess of those where the ionic strength principle is applicable, it is impossible to estimate to what extent this variation affects the rate constants.

MECHANISM FOR THE EXCHANGE PROCESS

In the transfer of chromium atoms from $Cr_2O_7^{=}$ ions to $CrO_4^{=}$ ions, the ^{17}O linewidth data indicate that the largest, if not the only, contribution to the exchange process is through a mechanism the rate-determining step of which is the bimolecular reaction [5]. This being the case, the reaction can be considered as a specific example of the more general reaction

$$B + O_3Cr{-}O{-}CrO_3^{=} \xrightarrow{k_B^{II}} BCrO_3 + CrO_4^{=},$$

where B is a nucleophilic base. The case where $CrO_4^{=}$ acts as the nucleophile is unique, however, in that the products of the kinetic process are identical with the reactants. The reaction can therefore proceed with unvarying rate in a system at chemical equilibrium. Although no direct evidence concerning the detailed mechanism of this reaction has yet been obtained, the most likely reaction path involves an attack by B on the chromium atom at the center of the triangular face opposite the bridging oxygen. The transition state for this mechanism has three oxygens coplanar with the chromium atom being attacked.

The most familiar example of the general reaction is the hydrolysis of $Cr_2O_7^{=}$ with OH^- acting as the nucleophile. Saal (6) in 1928 pointed out on the basis of conductivity measurements made in a fast-flow system that the reaction

$$OH^- + Cr_2O_7^{=} \rightarrow CrO_4^{=} + HCrO_4^-$$

is a bimolecular one. However, LaMer and Read (7) two years later measured the enthalpy change accompanying the same reaction in a similar flow system and concluded that the reaction rate did not depend upon hydroxide ion concentration and obeyed a first-order rate law. This latter conclusion has been accepted until very recently when Lifshitz and Perlmutter-Hayman (9) established unambiguously, again by measurement of the enthalpy change, that the reaction is in fact bimolecular.

There is now available sufficient rate data for different donor groups reacting with $Cr_2O_7^{=}$ to attempt to assess which property of the donor determines its nucleophilic reactivity with this substrate. In Table II are listed, in order of decreasing reactivity towards $Cr_2O_7^{=}$, those nucleophiles whose rates have been determined, along with the bimolecular rate constants for these reactions. Although OH^- is the strongest base in the group listed, both NH_3 and $CrO_4^{=}$ are seen to be more reactive. Edwards and Pearson (18) have discussed recently the factors determining nucleophilic reactivity in its broadest context. They list those factors sufficient for a fundamental description of nucleophilic reactivity (defined in terms of the reaction rate with a given substrate) as being

(i) basicity, defined in terms of the equilibrium dissociation constant of the conjugate acid in water,

(ii) polarizability, defined in terms of the molar refractivity,

(iii) unshared electron pairs on the atom to which the donor atom is bonded.

It does not appear necessary to invoke the influence of unshared electron pairs in the present discussion of nucleophilic reactivity, so this factor will not be considered further.

If the relative rates for the different nucleophiles can be expressed as a linear combination of the polarizability and the basicity having the following form

$$\log \frac{k_N}{k_0} = \alpha P + \beta H, \qquad [6]$$

then it is possible to decide whether the polarizability or the basicity makes the dominant contribution to the nucleophilic reactivity towards $Cr_2O_7^=$. In this expression, (k_N/k_0) is the rate relative to water chosen as reference nucleophile, P is defined as $\log (R_N/R_{H_2O})$ with R representing molar refractivity, and H is a function of the basicity towards protons defined by the equation $H = pK_a + 1.74$. Values for all these parameters for the nucleophiles under discussion are listed in Table II. The coefficients α and β are variable parameters used to describe the substrate.

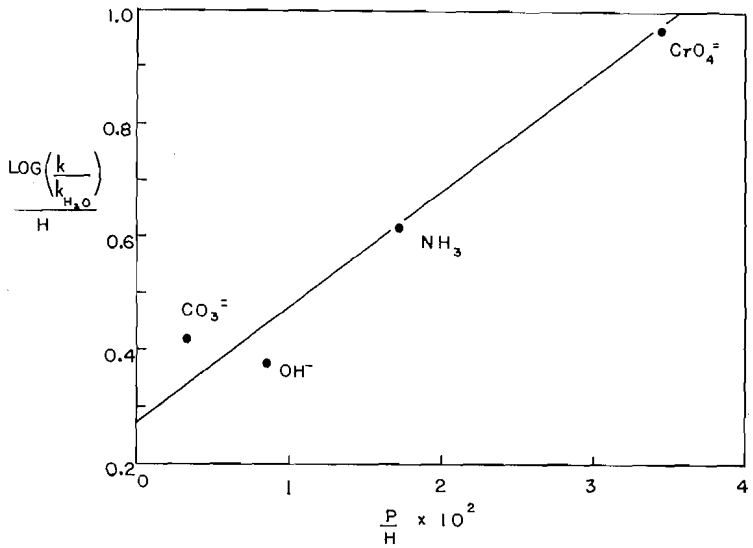

FIG. 4. Relative reactivity of nucleophiles with $Cr_2O_7^=$ as a function of basicity and polarizability.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

By writing expression [6] in the form,

$$\frac{\log (k_N/k_{H_2O})}{H} = \alpha\frac{P}{H} + \beta,$$

and plotting $\log (k_N/k_{H_2O})/H$ against P/H, we obtain the linear relation shown in Fig. 4. From this the values for the variable coefficients are obtained; these turn out to be $\alpha = 18.3$ and $\beta = 0.3$. Since the polarizability coefficient is much larger than the basicity coefficient, it is suggested that polarizability of the nucleophile is of prime importance in determining nucleophilic reactivity toward $Cr_2O_7^=$.

ACKNOWLEDGMENTS

The authors are grateful to the Ministry of Aviation for financial support including a maintenance award to one of them (R. G. K.). They also wish to thank Dr. H. W. Baldwin for making available to them some rate data prior to publication.

SOLVOLYSIS IN LIGHT AND HEAVY WATER

VI. THE ROLE OF INITIAL STATE STRUCTURE[1]

P. M. LAUGHTON[2]
Department of Chemistry, Carleton University, Ottawa, Canada
AND
R. E. ROBERTSON
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received August 14, 1964

ABSTRACT

The solubility data in light and heavy water of Swain and Thornton and of Taft and co-workers are reinterpreted to show that they support primarily the initial state origin for the kinetic solvent isotope effect. Other recent data, including the effect for *t*-butyl and α-phenethyl fluorides, are also shown to be compatible with the same hypothesis.

Papers from several different laboratories (1–4) have recently criticized our ideas ((5) and earlier papers quoted therein) attributing the major contributor to the origin of the kinetic solvent isotope effect k_{D_2O}/k_{H_2O} (KSIE) in solvolysis to differences between the initial states. The purpose of this paper is to dispose of those criticisms which have been based on solubility parameters of substrates in light and heavy water; in particular the analysis of the situation by Swain and Thornton (3), which recent reviewers (6) have accepted as negating our views.

As further evidence supporting our hypotheses, we also present solvent isotope effect data for two alkyl fluorides. These data differ little from those for other alkyl halides, while explanations based on solvation differences in the transition state would predict sharp differences between substrates generating fluoride ion and those producing other halide ions.

The main source of our disagreement with Swain and Thornton is that they have chosen as a standard state for their thermodynamic calculations one which by definition conceals any differences originally present in the solvents themselves before they undergo the change from initial state to transition state. Therefore, while relevant to the characterization of the reaction in general, their data are actually incapable of deciding the matter under contention, and in fact support our views. The same observation applies to the data of Taft and co-workers (4).

DISCUSSION

The usual practice of looking for reactivity differences only in the structures of substrates and in solvent interactions with transition states implies that differences between the various initial states may be considered negligible. Since relatively few data are available concerning the thermodynamic properties of initial states, it is hard to say how generally valid this implied approximation may be. There is, however, ample evidence that it is *not* true in water solutions ((7) and references quoted therein).

In fact, in the papers mentioned above (5), we have developed the theme that the solvent shell provides a source of structural free energy, relative changes in which during

[1]*Issued as N.R.C. No. 8202.*
[2]*Supported by a grant-in-aid of research from the National Research Council.*

the activation process account for the greater part of the KSIE. This explanation of the KSIE also implies that the structural free energy changes in the solvent during activation are themselves important parts of the free energy of activation. This view is further required by the small entropies yet large negative heat capacities of activation, which can only be generated with the involvement of many solvent molecules in processes resembling melting (8).

Arguments Based on Solubility Data

In rebuttal to our views, Swain and Thornton (3) and Taft (4) have recently offered the solubilities of several alkyl halides in light and heavy water. They confirm that the solubility ratios are near unity, representing values of $\Delta\Delta F$(gas → solution) smaller than the corresponding $\Delta\Delta F^{\ddagger}$ values for solvolysis. Their data are summarized in Table I.

TABLE I

Solubility and solvolysis parameters of alkyl halides in H_2O and D_2O

Alkyl halide	Solubility ratio D_2O/H_2O	$\Delta\Delta F^*$ (kcal/mole)	$\Delta\Delta H^*$ (kcal/mole)	$\Delta\Delta F^{\ddagger *}$,§ (kcal/mole)
MeF	1.02†	−0.01	−0.49	—
MeCl	0.96†	0.02	−0.04	−0.179
MeBr	0.93†	0.04	−0.08	−0.142
MeI	0.91†	0.06	−0.37	−0.152
t-BuCl	1.02‡	—	—	−0.172

*ΔΔ for Δ(H_2O) − Δ(D_2O).
†Reference 3; 29.4 °C.
‡Reference 4; 14.85 °C.
§Reference 14; at temperatures quoted.

Swain and Thornton evaluated their data as follows.

(1) $$\text{R—X}_{gas} + D_2O \rightleftharpoons \text{R—X in } D_2O,$$
$$\text{R—X}_{gas} + H_2O \rightleftharpoons \text{R—X in } H_2O.$$

The solubility ratio then corresponds to the equilibrium:

$$\text{R—X in } H_2O \rightleftharpoons \text{R—X in } D_2O,$$

with equilibrium constant K_{sol}.

(2) $$\text{R—X in } D_2O \rightleftharpoons \begin{matrix} D \\ D \end{matrix}\!\!>\!O\cdots R\cdots X \text{ in } D_2O;\ \text{rate constant } k_{D_2O},$$
$$\text{R—X in } H_2O \rightleftharpoons \begin{matrix} H \\ H \end{matrix}\!\!>\!O\cdots R\cdots X \text{ in } H_2O;\ \text{rate constant } k_{H_2O}.$$

(3) The kinetic solvent isotope effect is then K_{kin} for the equilibrium:

$$\begin{matrix} H \\ H \end{matrix}\!\!>\!O\cdots R\cdots X \text{ in } H_2O + \text{R—X in } D_2O + D_2O \text{ in } D_2O \rightleftharpoons$$
$$\begin{matrix} D \\ D \end{matrix}\!\!>\!O\cdots R\cdots X \text{ in } D_2O + \text{R—X in } H_2O + H_2O \text{ in } H_2O.$$

(4) They then identify as "transition state isotope effect" the equilibrium constant for the reaction:

$$\begin{matrix} H \\ H \end{matrix}\!\!>\!O\cdots R\cdots X \text{ in } H_2O + D_2O \text{ in } D_2O \rightleftharpoons \begin{matrix} D \\ D \end{matrix}\!\!>\!O\cdots R\cdots X \text{ in } D_2O + H_2O \text{ in } H_2O,$$

which is the product of K_{sol} and K_{kin}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Since K_{kln} is farther from unity than is K_{sol}, these authors then attribute the solvent isotope effect to differences in the respective transition states.

It is true that the transition states have different solubilities in the two waters. This fact does not, however, demonstrate that the transition states themselves are different. The flaw in this argument is that it ignores the differences in free energies of the two solvents, which, because K_{sol} is near unity, still exist in the two initial states. That is, the substrates have nearly the same free energies in each case, but the other reactants, the solvents, have quite different free energies. Swain and Bader (1) have estimated that nearly 1 kcal/mole of the 4.3 kcal/mole excess in free energy of H_2O over D_2O can be attributed to structural factors, i.e. libration and translation energies.

Translating equilibrium constants into free energies:

$$\delta_I\Delta F \equiv \Delta\Delta F(\text{solubility}) = -RT \ln K_{sol} = -10 \text{ to } +60 \text{ cal/mole},$$

where $\Delta\Delta F$ is the relative free energy change for the equations:

$$\Delta F_{D_2O} = F(\text{solution of RX in } D_2O) - F(\text{RX gas}) - F(D_2O),$$

$$\Delta F_{H_2O} = F(\text{solution of RX in } H_2O) - F(\text{RX gas}) - F(H_2O).$$

Since $\Delta\Delta F$ is small, F(RX gas) is common to both, and $(F_{D_2O} - F_{H_2O})$ is large and negative, then F(solution in D_2O) $-$ F(solution in H_2O) must also be large, and in the direction which is more than enough to account for K_{kln}. The solvation differences between the two transition states are therefore smaller than those between the initial states, as we have postulated.

The question of the interpretation of the solubility data is another and interesting problem. Swain and Thornton find it difficult to believe that so-called iceberg formation about a nonpolar solute can occur without a significant isotope effect on solubility. They suggest instead that these solutes utilize pre-existing holes in the water structure, especially since they are more concentrated in the aqueous than in the gas phase. Utilization of pre-existing holes would, however, imply partial molal volumes near zero for the solutes, whereas they are not, where they are known, very different from the molar volumes of the pure solutes (7). In any case, the situation is too complex to be treated on the basis of assumed H-bonding effects. The situation has been discussed by several authors, particularly Eley (9). For example, the cavitation energies $(\delta E/\delta V)_T$ of H_2O and D_2O are, of course, zero at their corresponding maximum densities, 4° and 11.2°, and appear to cross over near 100°. That is, over the whole temperature range of kinetic interest the energies required to generate holes for solutes in the two solvents lie close together. In any detailed explanation of solubilities in water, dispersion energies must be taken into account, in addition to H-bond energies and energies and entropies arising from any restricted translations and librations.

H-Bonding Models

We find it difficult to comment on the model proposed by Bunton and Shiner (2). They include in their calculations assumed frequencies for H bonds from water to neutral solutes such as alkyl halides and sulfides. More evidence will be needed to establish that such H bonds in fact exist.

Arguments from Data in Aqueous Mixtures

Recent data by Arnett and co-workers (10) highlight the role of initial state solvation in an aqueous system other than the isotopic systems considered above. They have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

measured the heat of solution of *t*-butyl chloride in aqueous alcohol mixtures and shown that the changes in enthalpy of solution, $\Delta\Delta H_{sol}$, with increasing alcohol concentration over a considerable range parallel the corresponding values of $\Delta\Delta H^{\ddagger}$ for solvolysis, i.e. $\Delta\Delta H_{sol}/\Delta\Delta H^{\ddagger} \sim -1$. Hyne has recently shown (11) that this relation does not hold so exactly for all substrates, but its existence in any instance shows the danger of attributing all kinetic differences to transition states.

Our own data for the KSIE for *t*-butyl chloride in aqueous dioxane (12) also support an initial state interpretation. The effect changes from 0.70 to 0.74 in the pure waters to 0.95 in aqueous dioxane. This is just what one would expect if the KSIE arises from a loss of initial state water structure during activation, since several lines of evidence indicate that the structure of water is broken down by diluents such as dioxane in the concentration range studied.

Alkyl Fluorides, a Possible Test Case

In Swain and Thornton's paper, the so-called transition state isotope effect is discussed in terms of the solution isotope effect on the halide ions and relative bond breaking of RX at the transition state. They do not predict the effect with fluorides, but if solvation differences in the two transition states are responsible for the KSIE, then one might expect fluorides to be unusual. Fluoride ion is the only simple ion which has a *lower* free energy in D_2O than in H_2O (1), and since the KSIE is sensitive to the anionoid portion of these substrates rather than to the alkyl group (13), one might then expect a KSIE for fluorides nearer unity or perhaps even inverted. (Uncertainty in this prediction is introduced by the compensating inversion noted in the solubility of methyl fluoride.)

We have measured the KSIE for two fluorides with the requisite precision by using 2,6-lutidine in slight excess (0.005–0.01 *M*) to delay attack on the borosilicate conductance cells. The values of k_{D_2O} and k_{H_2O} redetermined (14) for *t*-butyl fluoride at 90.00° and newly determined for α-phenethyl fluoride at 55.01° are, respectively, $4.25_1 \pm 0.004$ and $5.17_7 \pm 0.016 \times 10^{-4}$ s^{-1}, and $2.46_3 \pm 0.014$ and $2.95_4 \pm 0.004 \times 10^{-4}$ s^{-1}, leading to KSIE values of 0.82_1 and 0.83_4, respectively. These differ negligibly from those for other alkyl halides in the same temperature ranges (14).

CONCLUSIONS

We therefore believe that all the relevant data so far support our hypothesis that differences in initial state solvation energies are often significant, and should particularly not be considered negligible where the solvent is structurally ordered.

However, our hypothesis is essentially qualitative. The lack of sensitivity of the KSIE to nucleophilic involvement remains unexplained. The effect of substituents which interact with the solvent is only imperfectly understood (15). This parameter has helped to define our picture of solvent involvement near the seat of reaction, but more sensitive parameters are needed to sharpen the focus.

EXPERIMENTAL

Materials

t-Butyl fluoride was prepared in the usual way (16).

α-Phenethyl fluoride was prepared by the method of Henne and Midgely (17), using 10 g α-phenethyl bromide and mercuric oxide in 50 ml carbon tetrachloride in a Polythene bottle, and passing in HF. After careful removal of the solvent, the product was purified by Späth bulb distillation. Absence of kinetically significant impurities was evidenced by the excellent linearity of all rate plots used.

2,6-Lutidine was distilled from commercial material. Heavy water (99.7–9.8 atom % deuterium) was obtained from Merck, Sharp and Dohme of Canada Ltd.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Method

The conductance method of obtaining the solvolytic rates was that used previously.

Although the presence of 0.005 (α-phenethyl fluoride) or 0.01 (t-butyl fluoride) M 2,6-lutidine delayed attack on the cell walls such that the effect on conductance during a run was negligible, we were unable to carry on our usual practice of conditioning cells for long periods with the electrolyte to be studied without ultimate damage to the cells.

α-Phenethyl fluoride has been studied in water over the range 45–70°, but the data are not yet of the quality required for evaluation of the heat capacity of activation.

ACKNOWLEDGMENTS

We are indebted to Mr. S. Sugamori for expert technical assistance. Drs. D. N. Glew and H. S. Frank have been most generous in advising us on the properties of aqueous solutions.

A PULSED ION SOURCE FOR THE STUDY OF UNIMOLECULAR AND BIMOLECULAR REACTIONS OF GAS-PHASE IONS[1]

T. W. SHANNON, F. MEYER, AND A. G. HARRISON[2]
Department of Chemistry, University of Toronto, Toronto, Ontario

Received August 21, 1964

ABSTRACT

A pulsed ion source has been constructed for use with a magnetic-deflection mass spectrometer. With this source the time between ion formation and withdrawal for analysis can be controlled and varied in a known manner. The design and operating characteristics of the source are discussed and a technique is described for the measurement of ion withdrawal times using the pulsing technique.

The rate constant for the ion molecule reaction

$$CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$$

has been determined for the reaction of thermal energy ions using reaction time as the experimental variable. The equivalent reactions in the deuteriomethanes have also been studied. Preliminary results obtained in the study of the unimolecular fragmentation of the cyclohexadiene, toluene, and spiroheptadiene parent ions are presented.

INTRODUCTION

The quasi-equilibrium theory of mass spectra (1) considers that the fragment ions observed in the mass spectra of polyatomic molecules are formed by a series of competing and consecutive unimolecular reactions similar to the rate processes of ordinary chemical kinetics. The evidence that these fragmentation reactions can be considered as rate processes has depended almost entirely on indirect evidence and it is desirable to attempt direct measurements of the reaction rates to provide experimental tests of the theory. Such measurements require that the time between ion formation and mass analysis be varied. Some success has been achieved in varying this time by varying the repeller field which pushes the ions out of the ionization chamber and information has been obtained (2–5) on the rates of fragmentation reactions leading to metastable ion formation. However, the results obtained are not in complete agreement (5). A more difficult approach, which is not necessarily limited to the observation of fragmentation reactions leading to metastable ion formation, consists of pulsing the ionizing electron beam and varying the time between ion formation and application of the fields which abstract the ions for mass analysis. Using this technique with a time-of-flight mass spectrometer, Wahrhaftig (6), in a preliminary study, has observed directly the fragmentation reaction [1] in propane.

[1] $$C_2H_5^+ \rightarrow C_2H_3^+ + H_2.$$

In addition to unimolecular fragmentation reactions, the ions formed in the mass spectrometer ion source may undergo bimolecular reactions with neutral molecules, particularly at higher ion source concentrations. Such reactions have been extensively studied in the past 10 years (7, 8, 9). The usual technique has been to operate the ion source at a relatively high pressure with the consequence that the ions formed by the primary processes undergo reactive collisions with neutral molecules as they move out of the ionization chamber under the influence of electric fields. By varying these electric fields (particularly the repeller field) the ion-residence time can be varied and kinetic data obtained. In addition, for the bimolecular reactions kinetic data can be obtained from

[1]*Presented in part at the ASTM Committee E-14 Conference on Mass Spectrometry, Montreal, June 1964.*
[2]*Alfred P. Sloan Fellow, 1962–1964.*

pressure variation. The results obtained refer to the reactions of ions accelerated by electric fields and it is known that the cross sections for such reactions are velocity dependent. It is obviously desirable to have kinetic data for the reactions of thermal energy ions, particularly for application in radiation chemistry (8) and in combustion and discharge phenomena (10).

In 1960 Tal'roze and Frankevich (11) reported the development of a pulsed source magnetic-deflection mass spectrometer with which the time between ion formation and ion withdrawal could be varied. Using this source they studied the reactions of thermal energy ions in methane and in water vapor. While the present work was in progress Hand and von Weyssenhoff (12) briefly reported on similar experiments in methane using a time-of-flight mass spectrometer.

The present communication reports the adaptation of a commercial magnetic-deflection mass spectrometer to permit operation in the pulsed manner. The design of the pulsed source and its operating characteristics will be discussed and preliminary results obtained in the study of both unimolecular and bimolecular reactions of gas-phase ions will be presented.

DESIGN AND OPERATION OF PULSED SOURCE

The modifications necessary for operation with a pulsed ion source were made to an A.E.I. MS-2 Mass Spectrometer. The basic mass spectrometer is a 6 in. radius of curvature 90° sector-field instrument. The major changes were made to the ion source and the potentials supplied to the source. The modified source, similar in many respects to that used by Tal'roze and Frankevich (11), is shown schematically in Fig. 1. The voltages

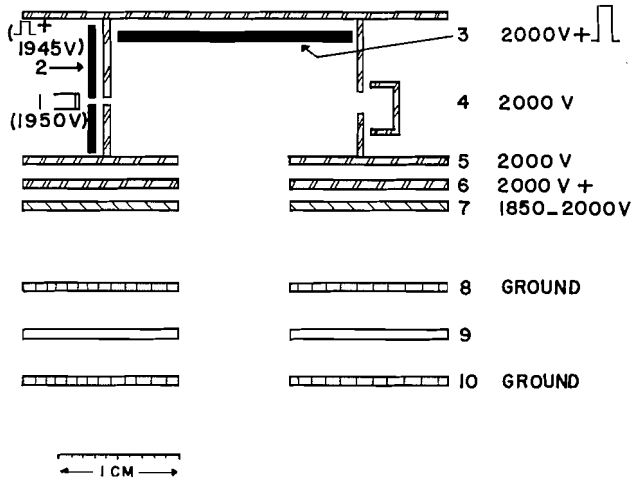

FIG. 1. Schematic diagram of ion source: 1, filament; 2, electron beam control plate; 3, repeller; 4, trap; 5, cage; 6, withdrawal plate; 7, focus; 8, 10, beam-defining plates; 9, beam centering.

given in Fig. 1 represent typical operating conditions. Essentially the modifications consisted of the installation of an electron beam control plate (plate 2) in the electron gun and the enlargement of the ionization chamber. The electrons, emitted from a directly heated tungsten or rhenium cathode, enter the ionization chamber through slits 3.0 × 0.5 mm in the two electron gun plates and are focussed by an auxiliary permanent magnet. The distances from the center of the electron beam to the exit slit and to the repeller are each

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

4.8 mm, while the distance to the side walls of the ionization chamber is 6.9 mm. The ionizing region is approximately 18 mm long with the ion exit slit having the dimensions 10×0.76 mm.

In operation, the spectrometer first was focussed on an ion beam of interest during continuous operation. The electron beam was then arrested (as indicated by the disappearance of the ion current) by applying a bias, negative with respect to the filament, to the electron beam control plate (plate 2). A positive pulse, supplied by a Datapulse Model 102 Pulse Generator, was then applied to plate 2 to provide the pulsed electron beam. With the electron beam pulsing, a small positive potential was applied to the ion withdrawal plate (plate 6) to prevent withdrawal of the ions by the main accelerating field. This potential was approximately 6 V, the magnitude being determined by the disappearance of the recorded ion current. With the present source design the main acceleration occurs between plates 7 and 8, while in the original MS-2 design the main acceleration occurred between plates 6 and 7 (plate 7 at +150 V). Under these latter conditions a positive bias of approximately 90 V on plate 6 was necessary to prevent ion withdrawal by the accelerating field and with this potential the ions were lost rapidly from the sampling region during the delay period presumably due to penetration of the field from plate 6.

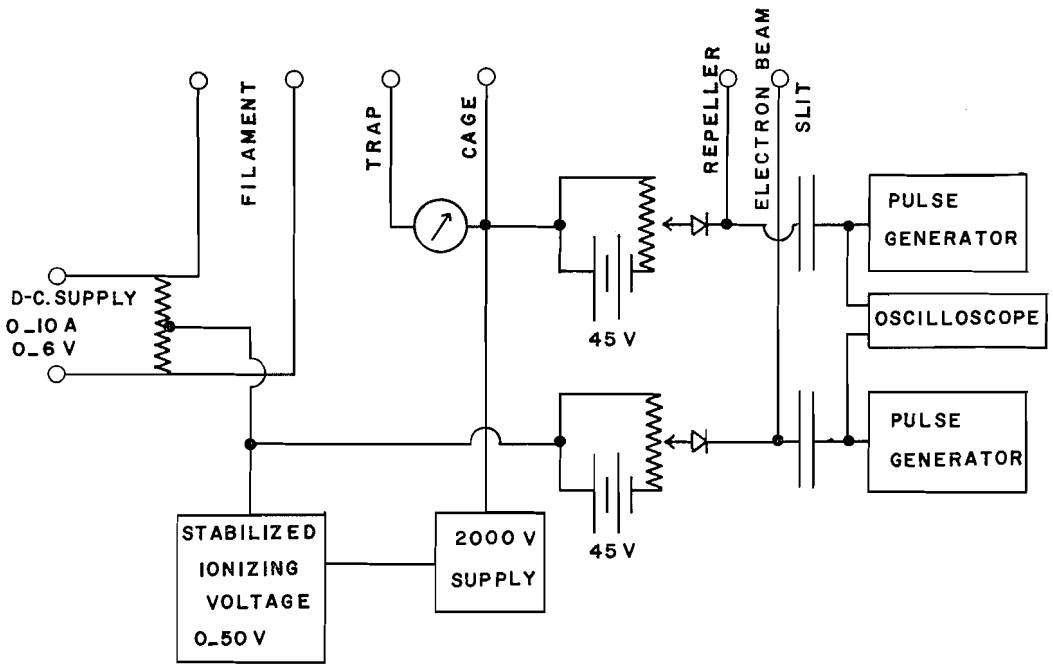

FIG. 2. Potential supplies to ion source.

The ions were pushed out of the ionization chamber by a positive pulse applied to the repeller plate (plate 3). This pulse was supplied by a Datapulse Model 100 Pulse Generator triggered by the first pulse generator with a variable time delay. The time between the ionizing and repelling pulses was determined by displaying the pulses on a two-channel oscilloscope (Tektronix Model 516). A schematic diagram of the potential supplies for the ion source is shown in Fig. 2. The filament current was initially supplied by a 6 V storage battery or, more recently, by a stabilized d-c. power supply. The ion current reaching the collector was amplified by a Cary Model 31 Vibrating Reed Electrometer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The operating characteristics were found to be primarily dependent on the potentials and pulses applied to the electron beam control plate and to the repeller plate and these points deserve more detailed comment.

Electron Beam Control Plate

A bias of 3–5 V, negative with respect to the filament, was sufficient to arrest the electron beam completely. The positive pulse applied to admit the electrons usually had an amplitude of 5–10 V and a duration of 0.1 to 1.0 μs with a rise and decay time of approximately 40 ns each. The recorded ion current was a linear function of the pulse width. However, the dependence of ion current on the pulse amplitude was somewhat variable. Usually the ion current was found to increase with the difference between the pulse amplitude and the bias voltage up to approximately 3–4 V difference and then to decrease slowly with greater differences. When operating near this maximum the major part of the electron acceleration occurs between the two plates of the electron gun and under these conditions satisfactory ionization efficiency curves, yielding appearance potentials in agreement with the literature, were obtained. Application of higher pulse amplitudes (20–30 V) frequently resulted in long tails on the ionization efficiency curves possibly because of space charge effects in the electron gun. The maximum repetition rate was limited by the duty cycle of the pulse generator to approximately 2×10^5 pulses s^{-1}.

Repeller Plate

The recorded ion current was found to depend on both the duration and amplitude of the repeller pulse. For a constant pulse amplitude the ion current increased with pulse duration up to 1.2–1.4 μs and then began to drop off slowly with longer durations, although the maximum ion current could be regained at these longer times by decreasing the pulse amplitude. Consequently the duration and amplitude of the pulse were adjusted for maximum ion current; normal operating conditions were a pulse duration of 1.4–2.0 μs and a pulse amplitude of 5–10 V.

The settings of the repeller pulse and the focus half-plate for maximum ion current were mass dependent. This fact coupled with the possibility of preferential loss of low-mass ions from the sampling region makes scanning of complete mass spectra both inconvenient and inaccurate when using the pulsed mode of operation. Consequently complete mass spectra were recorded using continuous ionization and ion withdrawal yielding mass spectra in agreement with those previously obtained.

Some experiments were carried out using a U-shaped repeller in place of the flat repeller shown in Fig. 1. The operating characteristics remained unaltered with the exception that some improvement in ion decay curves was noted presumably due to an increase in the volume sampled by the analyzing system when the repeller pulse was applied.

ION DECAY CURVES AND DISCRIMINATION EFFECTS

The usefulness of the present ion source in the study of the reactions of ions with time as the experimental variable depends on the rate at which ions are lost from the volume sampled by the analyzing system when the repeller pulse is applied. The ions will be lost from this volume due to thermal kinetic energy and under the influence of fields arising from surface potentials, space charge, and field penetration. All of these effects will lead to a more rapid loss of lighter-mass ions with increasing delay times and hence to discrimination effects which may obscure the changes anticipated from the chemical reaction under study.

Typical decay curves are shown for m/e = 16 (CH_4^+), 40 (A^+), 92 ($C_7H_8^+$), and 132

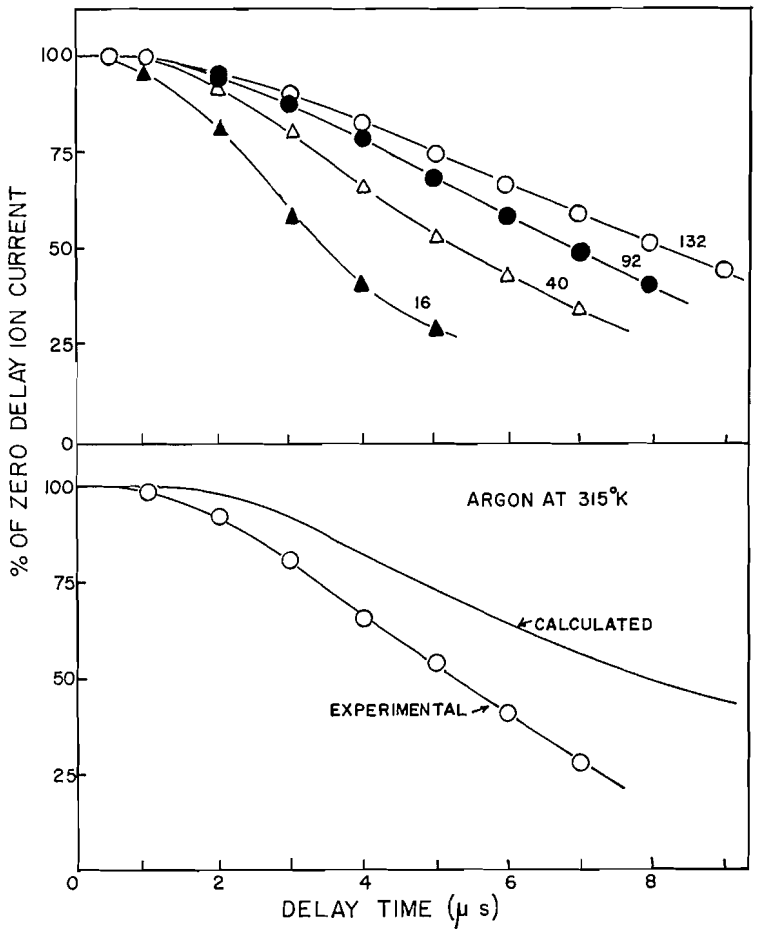

FIG. 3. (*a*) Experimental ion decay curves; (*b*) comparison of experimental and theoretical decay curves $m/e = 40$.

(Xe^+) in Fig. 3*a* where the results are plotted as percent of the zero delay ion current versus the delay time between the ionizing and repelling pulses. The mass effect is clearly demonstrated in the rather rapid loss of CH_4^+ (50% value, 3.5 μs) compared to Xe^+ (50% value, 8.3 μs).

Figure 3*b* compares the experimental decay curve for A^+ with that calculated assuming the loss of ions from the sampling region to be due to thermal kinetic energy only and assuming a Maxwell–Boltzmann distribution of energies with a temperature of 315 °K, the temperature of the ionization chamber as measured directly by a thermocouple. In view of the increased interest in the use of a pulsed source we present the details of the calculation in an appendix. It is clear from comparison of the experimental and theoretical curves that the ions are lost from the sampling volume more rapidly than would be expected from thermal effects alone indicating that small stray fields are present. To reproduce the experimental curve would require an average ion velocity about 1.8 times the thermal velocity at the temperature of the ion source. This velocity, however, would still be less than 10% of the velocity imparted to an argon ion from acceleration by a potential of 10 V (a situation common in the study of ion–molecule reactions by conventional techniques).

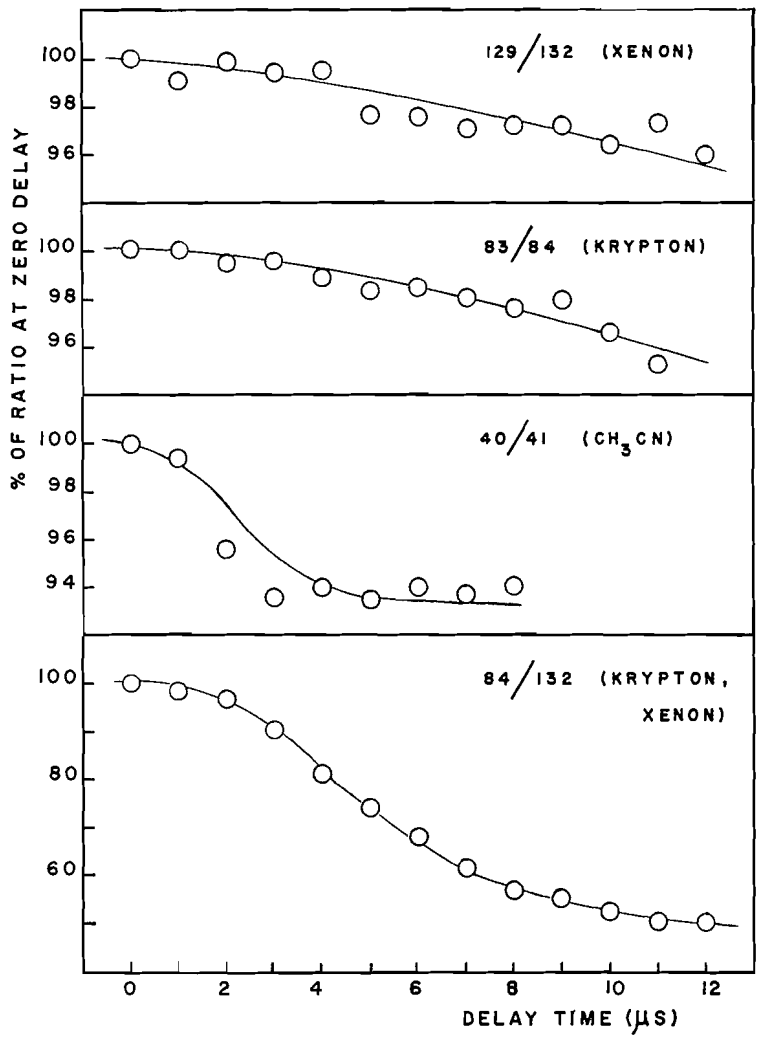

FIG. 4. Mass discrimination as a function of mass difference and delay time.

The decay curves of Fig. 3 show a much more rapid loss of the lighter-mass ions, an effect which will lead to increasing discrimination against such ions with increasing delay times. The magnitude of this discrimination effect is indicated for a number of mass regions and mass differences in Fig. 4 and also for a lower mass region in the ratio plots of Fig. 7 discussed in more detail in the section on ion–molecule reactions. For the highest masses studied the 129/132 ratio in xenon changes by less than 4% in a total of 12 μs. However, for krypton and CH_3CN the ratio of adjacent masses changes by this amount in about the same time. For a large ΔM, the 84/132 ratio in xenon–krypton mixtures, a change of 40% in the ratio is observed in 12 μs. However, in all cases the change during the first microsecond is quite small and we have found it possible to study ion–molecule reactions where the product and reactant ions differ considerably in mass by restricting the total delay time to less than 1 μs.

During operation for a period of months, the decay curves gradually deteriorated in that

the drop-off in intensity was considerably more rapid. This deterioration was presumably due to a buildup of nonconducting deposits on the electrodes. It was found that coating the surface of the ion source with colloidal graphite considerably improved the decay curves although gradual deterioration after this treatment has been observed.

MEASUREMENT OF ION RESIDENCE TIMES AND WITHDRAWAL TIMES

For the study of unimolecular fragmentation reactions the effective reaction time is the total elapsed time from initial formation of the reactant ion until it enters the main accelerating field. Any product ions formed after the reactant ion enters the accelerating field will not appear at the m/e of the product ion. Similarily a reactant ion which decomposes during acceleration, in the first drift region, or in the magnetic field will not be detected as a reactant ion nor as a product ion and, ideally, a correction should be applied to the reactant ion intensity to allow for this effect. However, calculations show that such a correction is small and lies within experimental error. To a good approximation with the present source we can take the average reaction time as the average time from formation of the ions until they reach the focus plate.

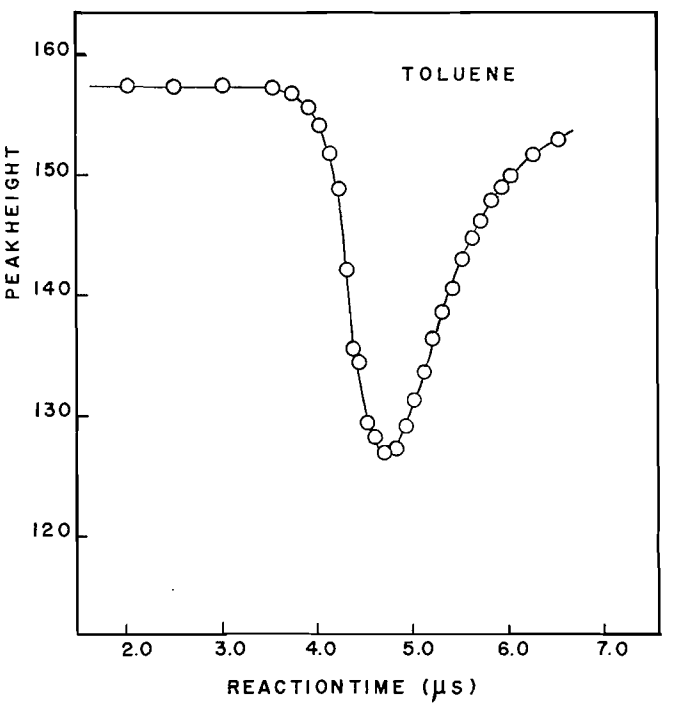

FIG. 5. Peak height vs. focus pulse delay, m/e = 92 toluene (1 μs ionizing pulse, 2 μs repeller pulse, 1 μs delay between pulses).

It was found that this time could be measured in the following manner. With the ion source operating in the pulsed mode a third pulse of short duration was applied to one-half of the focus plate. Ions passing the focus plate at the time the pulse is applied suffer a deflection and do not reach the collector causing a decrease in the recorded peak intensity. By varying the time between the ionizing and deflecting pulses a time profile of the ions passing the focus plate can be obtained. A typical deflection curve for m/e = 92 of toluene

For personal use only.

is shown in Fig. 5. This curve was obtained with a 1 μs ionizing pulse and a delay of 1 μs between the ionizing and repelling pulses. The time scale represents the time between the center of the ionizing pulse and the deflecting pulse and we have taken the minimum in the curve as the average reaction time. The width of the curve is determined by the kinetic energy of the ions, the amplitude of the repeller pulse and the spatial distribution of the ions when the repeller pulse is applied. It was found that the time from application of the repeller pulse to the minimum in the deflection curve increased slightly with increasing delay time suggesting that the ion cloud was slowly drifting away from the exit slit during the field-free time. For accurate estimation of reaction time this necessitates experimental determination of the time for each repeller pulse delay setting.

The deflection brought about by the focus plate pulse, contrary to our original expectations, does not depend primarily on the pulse amplitude but rather on the rate of voltage change during the leading and trailing edge of the pulse. With the pulses used the rate of change is approximately 10^8 V s^{-1} and it appears probable that the deflection is caused by the magnetic field associated with this potential change.

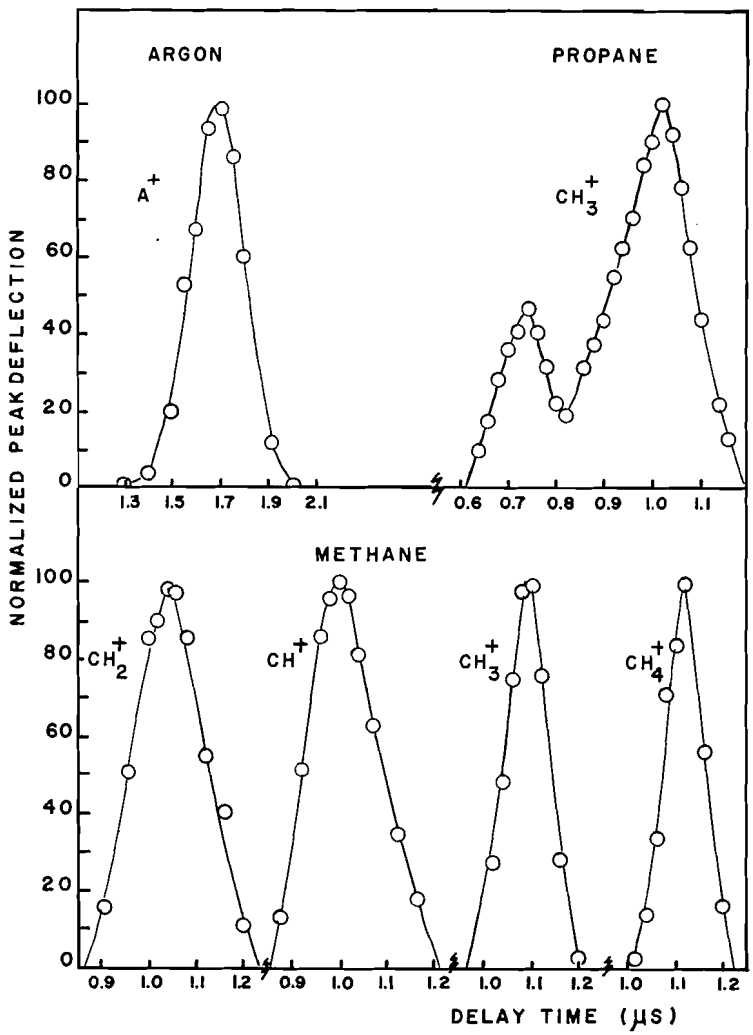

FIG. 6. Ion withdrawal curves.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The width of the curve in Fig. 5 is determined in part by the initial velocity distribution of the ions along the axis of ion withdrawal. This suggested that the technique might have application in the determination of initial ion kinetic energy and led us to make further studies of ion withdrawal times. Results obtained for the ions from methane, A^+, and CH_3^+ from propane are shown in Fig. 6 where the normalized peak deflection is plotted against the time between the ionizing and deflecting pulses. These results were obtained with an electron pulse of approximately 0.1 μs, a constant repeller voltage of 20 V and a deflecting pulse on the focus plate which was sufficiently broad that only the voltage change at the leading edge interacted with the ions. The CH_4^+ and CH_3^+ ions from CH_4 and the A^+ ions are thermal energy ions and the half-widths observed are therefore typical of such ions and indicates that the half-width increases with increasing mass. On the other hand, the CH_2^+ and CH^+ ions show a considerably larger half-width (0.17 μs compared to 0.10 μs for CH_4^+) which must be indicative of the higher initial kinetic energy of these ions. Using a rather similar technique, Taubert (13) has demonstrated that the CH_2^+ and CH^+ ions from methane do have an initial kinetic energy greater than thermal energy. The CH_3^+ ion from propane is of particular interest since it is well known (13, 14) that this ion consists of a thermal energy component in addition to a component of high initial kinetic energy. The withdrawal curve for CH_3^+ from propane shows two maxima, one at 1.02 μs which, by comparison with CH_3^+ from CH_4, corresponds to the thermal energy ion and a smaller maximum at shorter withdrawal times which must correspond to the high kinetic energy ions. This second maximum disappeared at 25–30 V electron energy consistent with a mechanism of formation from a doubly charged parent (14).

It is obvious from the foregoing that the width of the ion withdrawal curves can lead to at least qualitative information on initial ion kinetic energies. Further studies are in progress to determine whether quantitative estimates can be obtained by this method and to determine the sensitivity of the method.

ION–MOLECULE REACTIONS

The decay curves of Fig. 3 indicate that with the present ion source it is feasible to vary the ion residence time by varying the time delay between the ionizing and repelling pulses and that during this delay time the ions are in a relatively field-free region. Thus it should be possible to obtain the rates of bimolecular reactions of thermal energy ions using reaction time as the experimental variable. The total reaction time which can be used will depend on the magnitude of the discrimination between the product and reactant ion which will be determined by the decay curves for the two species.

For the general ion–molecule reaction

[2] $$P^+ + M \rightarrow S^+ + N$$

where P^+ and S^+ are the reactant and product ions respectively the integrated rate expression with time as the experimental variable becomes

[3] $$\log (1 + I_S/I_P) = k[M]t/2.303,$$

assuming the concentration of M to remain constant and assuming equal collection efficiencies for the product and reactant ion.

As a first study of ion–molecule reactions by the pulsing technique we have redetermined the rate constant for the hydrogen transfer reaction [4] in methane and have extended this work to the equivalent hydrogen and deuterium transfer reactions in the deuteriomethanes

[4] $$CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3.$$

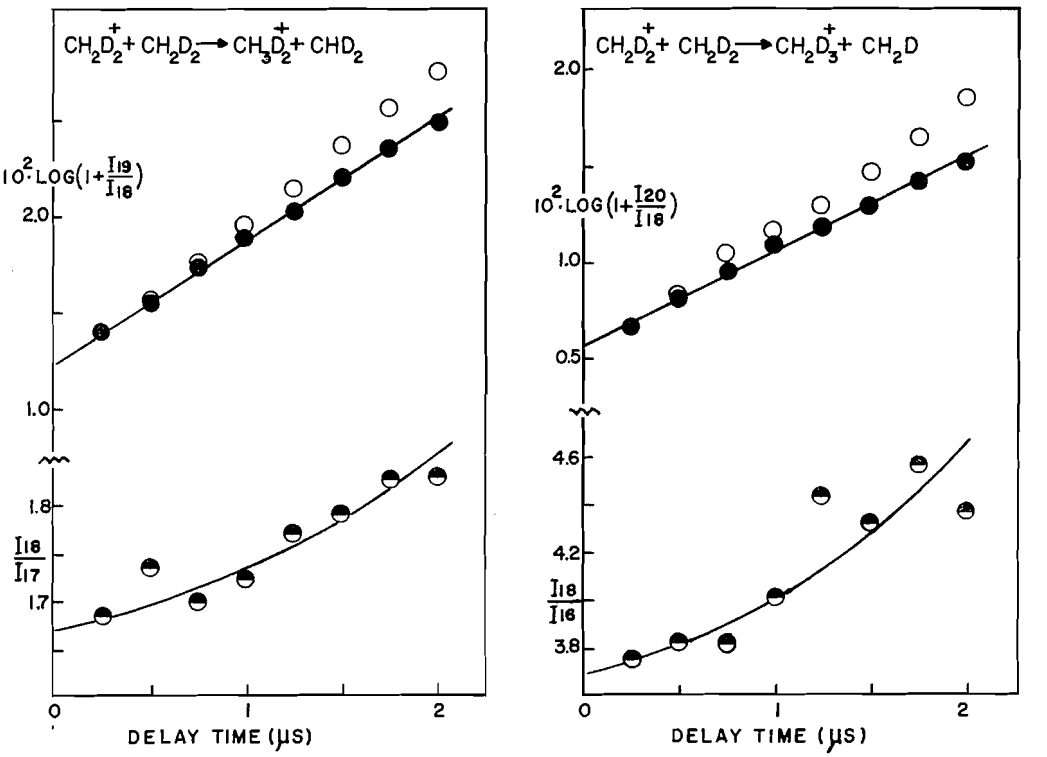

FIG. 7. Ion-molecule reactions in CH_2D_2; [M] = 5.70×10^{13} molecules cc^{-1}.

Typical plots of log $(1 + (I_S/I_P))$ versus delay time between the ionizing and repelling pulses are shown in Fig. 7 for the transfer of H and of D in CH_2D_2. The length of the ionizing pulse in this work was 0.2 μs and the electron energy was 50 V. The open circles are the log plot of the experimental I_S/I_P ratio as a function of the delay time. In general these plots showed an upward curvature which undoubtedly can be attributed to discrimination effects. The magnitude of these discrimination effects are indicated by the I_{18}/I_{17} and I_{18}/I_{16} ratios also plotted in Fig. 7. Since at the pressures used only a small fraction of the ions are reacting, we can use the change in these ratios to correct the observed I_S/I_P ratios. The log plot of the corrected data are shown by the solid points. The maximum correction amounted to about 8% for the H transfer and 17% for the D transfer. Although the corrected data in Fig. 7 possibly show a slight downward curvature which might be taken to indicate overcorrection, the points still define a reasonable straight line within experimental error and, further, such downward curvature was not observed in other cases indicating that the method of correction does not lead to serious error.

From the slopes of the corrected plots, which give k[M]/2.303, we have determined the rate constants summarized in Table I. The concentration of neutral molecules in the ion source was related to the pressure in the sample inlet system in the usual manner by total ionization measurement at 75 eV using continuous ionization. The sample inlet pressure was read by an Atlas Type MCT capacitance micromanometer, calibrated against a dibutylphthalate manometer, while the total ion current collected on the repeller was measured with a General Radio Type 1230-A d-c. Amplifier. Ionization cross sections for the methane and argon used were taken from Lampe *et al.* (15).

TABLE I
Hydrogen transfer reaction in methanes

Molecule	Rate constant $\times 10^{10}$ (cc molecule^{-1} s^{-1}) k (per H)	k (per D)	k (total)	$k_{CH_4} \times (\mu_H/\mu_D)^{1/2}$
CH_4	1.53		6.12	6.12
CH_3D	1.49	1.30	5.77	5.94
CH_2D_2	1.35	1.08	4.84	5.77
CHD_3	1.64	1.12	5.01	5.61
CD_4		1.18	4.71	5.46

Each rate constant reported is the average of at least three determinations. The overall rate constant for the reaction in methane is almost a factor of two lower than previous values of 11.6×10^{-10} and 11.0×10^{-10} cc molecule^{-1} s^{-1} obtained by Tal'roze and Frankevich (11) and Hand and von Weyssenhoff (12) respectively using similar techniques. The accuracy of the rate constant is dependent on the accuracy of the measurement of the source concentration and the delay times. A reasonable estimate of this error in both the present and previous work is 25%. Even allowing for this error the agreement is not good. It might be noted, however, that the previous workers have not made allowance for discrimination effects nor is it possible to estimate the magnitude of the discrimination from their published data. Further the results of Tal'roze and Frankevich were obtained at 370 °K compared to 315 °K in the present work and the discrepancy may indicate a small temperature coefficient. No temperature measurement was reported in the work of Hand and von Weyssenhoff. With the present instrument it is not possible to vary the temperature over a significant range. It might be noted that although absolute values of rate constants may have considerable error, relative values obtained on one instrument can be compared with greater confidence.

From columns 2 and 3 of Table I it is seen that the rate constant per H (k_H) and the rate constant per D (k_D) remain essentially constant through the series of methanes and lead to $k_H/k_D = 1.28$. Thus the total rate constant for H plus D transfer decreases with increasing deuterium substitution as shown in column 4. This decrease is considerably greater than that predicted by the effect of reduced mass on the number of collisions. This is shown by comparison of the observed total rate constants with the values calculated in column 5 by multiplying $k(CH_4)$ by the appropriate ratio of the reduced masses. We would suggest that this large effect of deuterium substitution may indicate that an appreciable fraction of the initial collision complex reverts to the reactant species (eq. [5]).

$$[5] \qquad CH_xD_y^+ + CH_xD_y \rightleftharpoons CH_xD_y \overset{+}{\ldots} CH_xD_y \begin{cases} \nearrow CH_{x+1}D_y^+ + CH_{x-1}D_y \\ \searrow CH_xD_{y+1}^+ + CH_xD_{y-1} \end{cases}.$$

With increasing deuterium substitution the transfer step in the collision complex is slowed down with the consequence that a larger fraction of the complex reverts to reactants. This implies an activation barrier in the transfer step and thus a possible temperature coefficient for the thermal rate constant. Further speculation does not appear to be justified from the limited data presently available.

While the results obtained for the methanes show that the pulsing technique can provide kinetic data for the bimolecular reactions of ions, they also serve to point out the problems encountered. As the results in Fig. 4 show, discrimination effects cause a significant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

increase in the I_S/I_P ratio with increasing delay time. For greater percentage mass differences this discrimination effect will increase and, in the extreme cases, may completely mask the changes attributed to the occurrence of ion–molecule reactions.

The pulsing technique would appear to be ideally suited for the study of charge transfer reactions of the general type

[6] $$A^+ + B \rightarrow A + B^+.$$

In principle one should be able to observe increases in the ratio B^+/A^+ with increasing reaction time which can be attributed to the charge transfer reaction. However, B^+ will also be formed by the primary electron impact process and changes in the B^+/A^+ ratio may be anticipated due to discrimination effects. Thus to obtain quantitative data one must know accurately the decay curves for A^+ and B^+. In our experience these curves cannot be obtained in separate experiments since they are quite sensitive to minor changes in operating conditions. For those cases where a third ion, C^+, with a m/e near that of B^+, is formed by the primary impact process only, simultaneous observation of the C^+/A^+ ratio should permit correction of the B^+/A^+ ratio for discrimination effects.

UNIMOLECULAR ION FRAGMENTATIONS

As mentioned previously Wahrhaftig (6), using a time-of-flight mass spectrometer in which the time between ion formation and ion analysis could be varied, observed increases in the I_{27}/I_{29} ratio in propane with increasing reaction time which he attributed to the unimolecular fragmentation of the $C_2H_5^+$ ion (reaction [1]). In a brief study we did not observe increases in this ratio probably because of excessive discrimination. To minimize such effects we have chosen to study only those reactions which involve loss of H and, in addition, we have confined our attention to reactant ions of relatively high mass.

Increases in the $(\text{parent—H})^+/\text{parent}^+(R^+/RH^+)$ ratio with increasing delay time were observed for 1,4-cyclohexadiene, spiro[2.4]hepta-1,3-diene, and toluene. Typical results for these compounds at low electron energy are shown in Fig. 8 where the ratio $R^+/(R^+ + RH^+)$ is plotted versus the delay time between the ionizing and repelling pulses. At the electron energies used, only the R^+ and RH^+ ions are present in the spectrum and the ratio plotted therefore represents the fraction of the parent ion which has undergone fragmentation in the total time available. Reproducible increases of 5–10% in the ratio were observed over the range of reaction time studied. These increases cannot be due to discrimination since the lighter $(R)^+$ ion should be lost more rapidly nor can they be caused by bimolecular reactions since the extent of the change was independent of source pressure. Therefore we conclude that we are observing directly the unimolecular fragmentation of the parent molecule–ion.

[7] $$RH^+ \rightarrow (R)^+ + H.$$

As discussed previously the total time available for fragmentation, with the event still observable experimentally, corresponds to the time taken for the ion to reach the main accelerating field in the vicinity of plate 7. Therefore zero delay time between the ionizing and repelling pulses corresponds to a finite minimum reaction time. With a repeller pulse which optimized the observed ion current, this minimum reaction time was approximately 4 μs for $m/e = 92$ (toluene or spiroheptadiene). By an increase in the amplitude of the repeller pulse and a shortening of the ionizing pulse, this minimum reaction time could be reduced to approximately 2 μs. With a minimum reaction time of 2 μs any reaction with a half-life of 0.2 μs or less will be completed before the first observations can be made. It is apparent from the curves shown that the major fraction of the ions having sufficient energy to dissociate have done so before we are able to make observations and that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

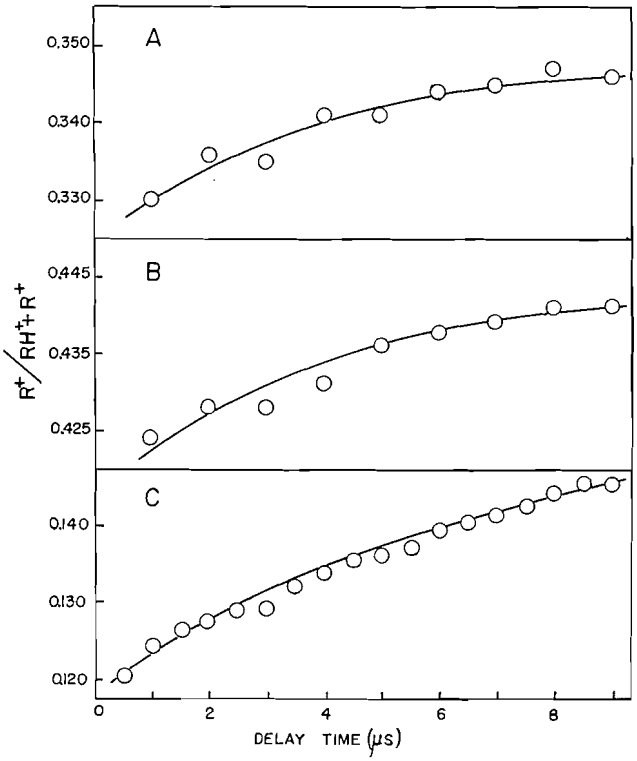

FIG. 8. Unimolecular fragmentation: (A) 1,4-cyclohexadiene 16.0 eV; (B) spiro[2.4]hepta-1,3-diene 14.0 eV; (C) toluene 13.0 eV. (All electron energies uncorrected.)

increases we are observing correspond to fragmentation of ions with a half-life of a few microseconds. Quantitative interpretation of the results is made difficult by the fact that a large and unknown fraction of the parent ions have not received sufficient energy to fragment. A more detailed study of the reaction in toluene and deuteriated toluenes will be presented elsewhere.

A considerable improvement in the minimum reaction time could be achieved by decreasing the distance from the electron beam to the exit slit. However, such a change is incompatible with the study of ion–molecule reactions where longer reaction times are required. In the time scale of unimolecular ion fragmentations, the present technique appears suitable only for those reactions which are slow. For the faster reactions the approach suggested recently by Tal'roze (16) appears more promising.

APPENDIX

Calculation of Decay Curves[3]

Essentially, the problem is to calculate the number of ions remaining in the volume sampled by the analyzing system at time τ, having initially produced ions in a volume

[3]*We are indebted to Professor J. P. Valleau for his assistance in formulating this problem.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

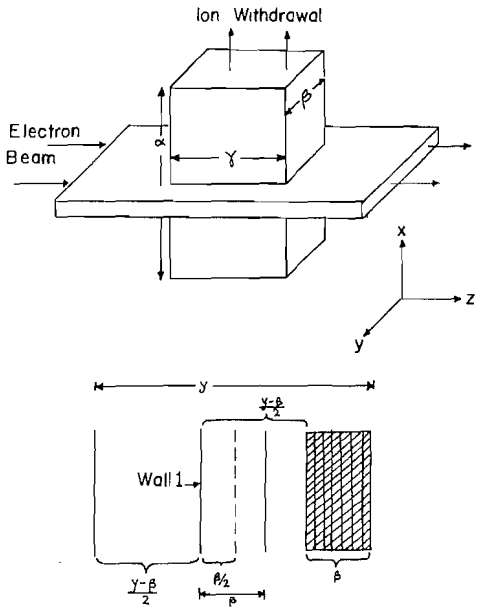

FIG. 9. (*a*) Ion formation and sampling zones. (*b*) Cross section of zones along *y*-axis.

defined by the electron beam where this initial volume intersects the sampling volume symmetrically (Fig. 9*a*). We assume free molecular flow with a temperature T.

The dimensions of the box representing the volume of initial ion formation we can take to be the dimensions of the electron beam entrance slit plus the length of the ionizing region, i.e. $x = 0.05$ cm, $y = 0.30$ cm, $z = 1.80$ cm. For the box representing the volume sampled by the analyzing system we have taken the dimension along the axis of ion withdrawal, α, to be 0.954 cm, the distance from repeller to exit slit, the dimension, γ, along the long axis of the exit slit to be 1.0 cm, the length of the exit slit, and the dimension, β, along the short axis of the exit slit to be twice the slit width or 0.152 cm. This dimension is rather arbitrary since the ions follow a curved trajectory out of the source. However, the resulting decay curves were not strongly dependent on the value chosen for β.

With the dimensions chosen $x < \alpha$, $y > \beta$, and $z > \gamma$, we have the result that ions will be lost from the sampling region by three processes:

(*a*) Loss across the plane at $-\alpha/2$. All ions travelling in $+\alpha$ direction will be collectable.

(*b*) Deficit in flow across plane at $\pm\beta/2$.

(*c*) Deficit in flow across plane at $\pm\gamma/2$.

The number of ions which survive will be given by $N_t = N_o F_a F_b F_c$ where F_i represents the fraction of ions surviving process i.

F_a

We need consider only the velocity component, u, in the $-x$ direction. All ions with $|u| > (x + \alpha)/2\tau = u_n$ will be lost while all ions with $|u| < (\alpha - x)/2\tau = u_m$ will survive. For ions where $u_m < |u| < u_n$, ions initially in a slab of thickness $((\alpha + x)/2) - u\tau$ will survive or a fraction $((\alpha + x)/2x) - (u\tau/x)$ will survive.

F_a is thus given by the equation:

$$F_a = \frac{1}{2} + \int_0^{u_m} f(u)\,du + \int_{u_m}^{u_n} \left(\frac{(\alpha + x)}{2x} - \frac{u\tau}{x}\right) f(u)\,du,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where $f(u)$ is the one-dimensional Maxwell distribution, $f(u)\,du = \pi^{-1/2}\exp(-y^2)\,dy$, $y = (M/2RT)^{1/2}u$.

Integration leads to the final expression:

$$F_a = 1/2 + 1/2[\operatorname{erf}(\sqrt{2}u_m') + \operatorname{erf}(\sqrt{2}u_n') + (\alpha/x)[\operatorname{erf}(\sqrt{2}u_n') - \operatorname{erf}(\sqrt{2}u_n')] - (2RT/\pi M)^{1/2}\tau/x[\exp(-u_m'^2) - \exp(-u_n'^2)]],$$

where $u_m' = (M/2RT)^{1/2}(\alpha - x)/2\tau$, $u_n' = (M/2RT)^{1/2}(\alpha + x)/2\tau$,

and $\operatorname{erf}(t) = \dfrac{1}{\sqrt{2}\pi^{1/2}}\displaystyle\int_0^t e^{-x^2/2}\,dx.$

F_b

The problem in this case is to calculate the net flow out of the region of length β (Fig. 9*b*), having initially produced ions in the total length y. The flow inwards across wall 1 (Fig. 9*b*) will be exactly balanced, by symmetry, by the outward flow of ions from a region of thickness $(y - \beta)/2$ to the right of the wall. The *net* flow across the wall will therefore be that arising from the region of length β, shaded in the diagram. The problem therefore is to calculate the fraction of ions in the length β which do not cross the wall in the time τ.

All ions with velocities $v_n > (y + \beta)/2\tau$ will cross wall 1 while all ions with velocities $v_m < (y - \beta)2\tau$ will be retained. For ions with velocities intermediate between v_n and v_m those in the segment of length $((y + \beta)/2) - v\tau$ will survive or a fraction $((y + \beta)/2\beta) - (v\tau/\beta)$ will survive. The formulation is thus similar to the calculation of F_a and the solution in terms of the reduced velocities

$$v_m' = (M/2RT)^{1/2}(y - \beta)/2\tau \text{ and } v_n' = (M/2RT)^{1/2}(y + \beta)/2\tau$$

becomes

$$F_b = \operatorname{erf}(\sqrt{2}v_m') + \operatorname{erf}(\sqrt{2}v_n') + (y/\beta)[\operatorname{erf}(\sqrt{2}v_n') - \operatorname{erf}(\sqrt{2}v_m')] - (2RT/\pi M)^{1/2}(\tau/\beta)[\exp(-v_m'^2) - \exp(-v_n'^2)].$$

F_c

The calculation for F_c is identical to that for F_b and leads in terms of the reduced velocities

$$w_m' = (M/2RT)^{1/2}(z - \gamma)/2\tau \quad \text{and} \quad w_n' = (M/2RT)^{1/2}(y + \gamma)/2\tau$$

to

$$F_c = \operatorname{erf}(\sqrt{2}w_n') + \operatorname{erf}(\sqrt{2}w_m') + (z/\gamma)[\operatorname{erf}(\sqrt{2}w_n') - \operatorname{erf}(\sqrt{2}w_m')] - (2RT/\pi M)^{1/2}(\tau/\gamma)[\exp(-w_m'^2) - \exp(-w_n'^2)].$$

EVIDENCE FOR $ZnF_2.2H_2O$

DEHYDRATION AND X-RAY DIFFRACTION STUDIES

E. A. Secco and Ronald R. Martin

Chemistry Department, Saint Francis Xavier University, Antigonish, Nova Scotia

Received July 22, 1964

ABSTRACT

Evidence for a dihydrate of zinc fluoride $ZnF_2.2H_2O$ from dehydration studies is reported. The structural changes accompanying the decomposition of the hydrate were followed by X-ray diffraction. The heating of the dihydrate in air was found to yield as residues (*a*) mixture of ZnF_2 and its hemihydrate, (*b*) mixture of ZnF_2 and ZnO, (*c*) the hemihydrate, and (*d*) ZnO.

INTRODUCTION

Our interest in the dehydration of zinc fluoride hydrate has been aroused by the acquisition of zinc fluoride, C.P. grade, from two independent suppliers.* These fluorides gave diffraction patterns distinct from those patterns for ZnF_2 and $ZnF_2.4H_2O$ as recorded in the ASTM file index. Our observed diffractions did show many peaks common to the reported tetrahydrate pattern and infrared spectra confirmed the presence of water. Furthermore, repeated efforts to obtain the pure anhydrous fluoride by heating in air at 100 °C as reported (1, 2, 3) and accepted as routine procedure have failed. In a literature survey on the dehydration of the tetrahydrate we were able to uncover only the early work reported in the Mellor treatise. It was desirable therefore to follow up the dehydration reactions of this unidentified zinc fluoride hydrate and to reconcile the obvious disparity between our observations and the reported data in the literature.

EXPERIMENTAL

Each fluoride sample† used for dehydration studies was placed in an aluminium weighing dish or pyrex weighing bottle, weighed, heated at the appropriate temperature for a given time interval, cooled in a dessicator containing P_2O_5, reweighed, and its resulting weight loss determined. In the reverse reaction, i.e., hydration, the product from dehydration was placed in a dessicator, without dessicant, containing distilled water at room temperature and the weight increase was measured as a function of time.

The method of preparation of the hydrate powder for the X-ray diffractometer and the procedure for recording its diffractogram after annealing have already been described (4).

The infrared spectra of the powder were obtained by using the standard KCl disc technique in a Beckman IR.8 spectrophotometer.

RESULTS

For comparison purposes the *d*-spacings corresponding to the observed peaks on the diffractograms and their relative intensities obtained with the untreated fluoride hydrate as received from the suppliers are given in Table I with those of $ZnF_2.4H_2O$.

The infrared absorption spectrum of the untreated fluoride hydrate, Fig. 1 shows the presence of the characteristic water bands in addition to bands observed with the monohydrate of HF (5) and aqueous solutions of HF (6) at −195 °C. These bands are also present in the spectrum of the residue from 20% weight loss but with their intensities reduced.

**A. D. MacKay, Inc., 198 Broadway, New York 38, N.Y. This hydrate is made by slurring zinc oxide and treating with aqueous hydrofluoride acid. City Chemical Corporation, New York, Lot G-212.*

†MacKay hydrate was used as the main source of our studies; City Chemical was used only to check what may have been judged as an anomalous result.

Table II gives the weight loss data expressed in percentage of the original sample weight at different temperatures for uncrushed and crushed samples. Fig. 2 gives the average weight loss as a function of time for three crushed samples.

Heating the crushed powder on the specimen stage of the high-temperature gonimeter for 10 min at 120 °C or in an oven at 150 °C i.e., corresponding to weight loss of 20.0 ± 0.6%, produced a diffractogram given in Fig. 3. This diffractogram remained unchanged when heated in air in the gonimeter up to 250 °C, but above 250 °C the characteristic pattern of zinc oxide was obtained. The product corresponding to Fig. 3 when left in an ambient of water vapor overnight regained the peaks observed in the original diffractograms, but with slightly lower intensities.

	500	1	29.3				
16–18	250	3	29.8±0.8				

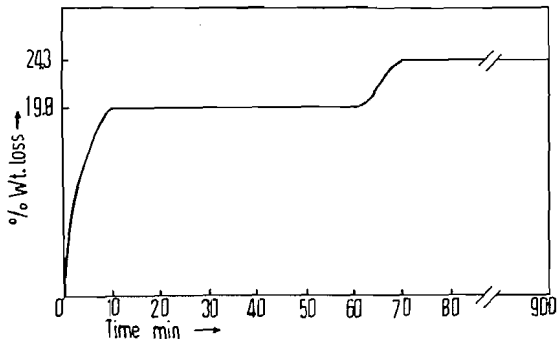

FIG. 2. Average weight loss as a function of time for three crushed samples.

The product of dehydration corresponding to ca. 26% weight loss gave a diffractogram consisting of a mixture predominant in anhydrous zinc fluoride along with evidence of zinc oxide. The product from ca. 30% weight loss gave a similar diffractogram but with stronger oxide peak intensities. On the other hand, the product from less than 26% weight loss showed a diffractogram consisting of a mixture of Fig. 3 and anhydrous zinc fluoride.

TABLE III

Run	T (°C)	Time (h)	% wt. loss	Time (h)	% wt. loss	Time (h)	% wt. gain	Time (h)	% wt. gain
28	150	2	19.4	24	93.0	72	100.2	120	102.0
29	150	2	19.8	24	91.8	72	100.1	120	101.8
30	150	2	19.7	24	92.6	72	100.1	120	101.7

Table III shows the weight losses of three samples in percentage of total water of a dihydrate along with the weight increases for those residues in an ambient of saturated water vapor. The extra weight increase, i.e., above the original, was believed due to condensation on the powder or weighing dish. These samples lost weight on exposure to the atmosphere.

Untreated fluoride was allowed to stand in distilled water at room temperature overnight with the object of preparing the reported tetrahydrate. The insoluble fluoride was filtered on No. 1 filter paper (Whatman) and allowed to dry in air for 24 h. The product gave the diffractogram in Fig. 4 and a weight loss of 20.7% was observed on heating. Another sample left in distilled water overnight, filtered, and allowed to dry in air for 1 week produced the diffractogram of Fig. 5.

DISCUSSION

It is not possible on the evidence available to elucidate completely the process of dehydration of the zinc fluoride hydrate. The dehydration of the hydrate will be discussed, however, in the light of the major points of our results.

The first important point is the variation in weight loss percentages from 100 °C to 500 °C. Since the residue from ca. 26% dehydration consists mainly of anhydrous zinc fluoride, this suggests the original compound to be a dihydrate, $ZnF_2.2H_2O$, i.e.,

$$ZnF_2.2H_2O \rightarrow ZnF_2 + 2H_2O.$$

For weight losses greater than 26%, the residue contained some zinc oxide which resulted from the reaction between the fluoride and water (1, 7). The extent of oxidation was not constant and presumably is a function of particle size, rate of heating, and humidity of the air. The oxidation reaction can conceivably go to completion under proper conditions (7). In the event of complete oxidation of the dihydrate, i.e.,

$$ZnF_2.2H_2O \rightarrow ZnO + 2HF + H_2O,$$

the stoichiometric weight loss is 41.6%, which is fortuitously identical to the value expected for the dehydration of zinc fluoride tetrahydrate.

The dehydration of 20% suggests an intermediate or lower hydrate of zinc fluoride, most probably a hemihydrate, i.e.,

$$ZnF_2.2H_2O \rightarrow ZnF_2.\tfrac{1}{2}H_2O + \tfrac{3}{2}H_2O.$$

The postulated hemihydrate is stable to 250 °C up to 3 h and its diffraction pattern is that given in Figs. 3 and 4. Mikhailov (7) has postulated an intermediate Zn(OH)F from oxidation studies. Our intermediate cannot be Zn(OH)F from two arguments. Firstly, the return of the intermediate to the original hydrate in an ambient of water vapor is not expected to be possible with Zn(OH)F. Secondly, our value of 20% weight loss is too low compared to 27.2% demanded for Zn(OH)F.

The 20.7% weight loss determined for the product after ageing in distilled water and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the diffractogram of Figs. 4 and 5 indicate that ageing promoted growth of preferred crystallographic faces of the dihydrate.

The X-ray diffractograms and thermogravimetric data were reproduced by treating anhydrous ZnF_2 in water. However, the infrared spectrum did not show the additional bands of the HF hydrate indicating that a trace of excess HF must have been present in the supplier's hydrate.

The heating of zinc fluoride dihydrate in air has yielded as residues (*a*) mixture of zinc fluoride and its hemihydrate, (*b*) mixture of zinc fluoride and zinc oxide, (*c*) the hemihydrate, and (*d*) zinc oxide. It was practically impossible to obtain pure anhydrous zinc fluoride by heating zinc fluoride hydrate in air up to 500 °C. The kinetics of the dehydration reaction in N_2 or vacuum and of hydration in controlled ambients of water vapor is planned as the subject of a future study.

SOME ANOMALOUS CARBONYL STRETCHING FREQUENCIES IN STEROID INFRARED SPECTRA[1]

R. NORMAN JONES AND J. B. DIGIORGIO[2]
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received June 22, 1964

ABSTRACT

Abnormal C=O and C=C stretching frequencies in the infrared spectra of Δ^4-3-ketosteroids containing a 19,8-lactone bridge are discussed in relation to possible conformational structures. The C=O stretching frequencies of 1,11,17-triketo-5β-steroids and Δ^2-1,11,17-triketo-5β-steroids are reported. It is noted that the anomalous C=O stretching band position previously recorded for the 11-ketone in 11,17-diketosteroids is also observed in these triketones, but no additional perturbation results from the introduction of the 1-ketone group, in spite of its proximity to the carbonyl at C_{11}.

The C=O stretching frequencies in the infrared spectra of ketosteroids and steroid esters in carbon disulfide, carbon tetrachloride, and chloroform solutions have been used extensively to characterize the type of carbonyl function. The spectra–structure correlations were summarized in 1954 (1) and again in 1958 (2). Subsequent investigations have confirmed the general applicability of these correlations to a wide range of steroids and derivatives.

This paper deals with a few recently examined cases in which the infrared carbonyl frequencies exhibit unusual features. These involve the 19:8-bridged lactone structure I and the triketones II and III. The spectra of Δ^4-3-ketosteroids containing the 8:19-epoxide bridge (IV), the 19:8-hemiacetal group (V), and the 19-methoxy-8:19-epoxide bridge (VI) will also be discussed.

have already been published (3–6). The spectra were measured on Perkin–Elmer Model 21 and Model 421 spectrophotometers with wavenumber scales calibrated with indene (8, 9) and are accurate to ± 1 cm^{-1}. The significant feature of Table I is the displacement of the C=O and C=C stretching bands by +14 and +19 cm^{-1} in chloroform solution on introduction of the lactone bridge. The spectra of I (R(β) = CO—CH_2OH) and V (R(β) = CO—CH_2OH) are compared in Fig. 1. The displacement on introduction of the epoxide or hemiacetal bridges, in contrast to that of the lactone bridge, is barely significant. These

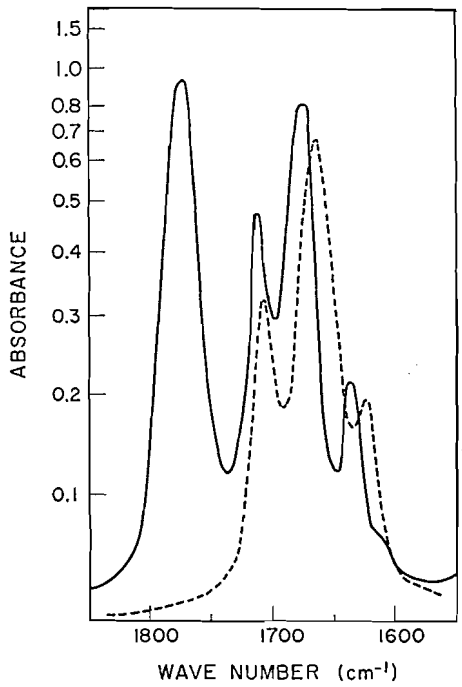

FIG. 1. Infrared spectra in chloroform solution. Concentration ~ 0.12 *M*; path length 0.1 mm; solid line, spectra of I (R(β) = CO—CH_2OH); dashed line, spectra of V (R(β) = CO—CH_2OH).

results acquire additional interest when compared with the optical rotatory dispersion (o.r.d.) curves. Djerassi has shown that the K-band Cotton effect curve for the lactone I ($R(\alpha) = COOCH_3$, and $R(\beta) = COOH$) resembles that of the unbridged Δ^4-3-ketone (3), whereas the 8:19-bridges of IV ($R(\beta) = COOH$) (4) and VI ($R(\beta) = COOCH_3$) (7) induce an inversion in the sign of the K-band Cotton effect curves. We therefore have the curious result that the type of bridge closure that induces an anomalous infrared spectrum does not perturb the o.r.d. and vice versa.

The C=C—C=O system in ring A in Δ^4-3-ketosteroids is not coplanar, and the sign of the K-band Cotton effect curve has been shown by Djerassi *et al.* (10) and by Whalley (11) to depend on the chirality of the conjugated system. The chirality is determined by the angle θ between the C_2—C_3 bond and the C=C bond. We have measured θ in Dreiding models for a variety of limiting conformations (Table II). In these measurements, the conjugated system is viewed along the axis of the C_3—C_4 bond with the C=O bond forward, horizontal, and to the left.* The o.r.d. data require that θ be positive in the lactone I and in the unbridged ketone, but negative in the other bridged compounds (IV–VI).† One cannot be so specific as to the cause of the anomalous infrared band positions of I, but the fact that both the C=O and the C=C stretching frequencies are displaced upwards could most simply be explained by a decrease in the planarity of the conjugated system: viz. an increase in the absolute value of θ without respect to sign. This would diminish the resonance coupling and increase the force constants of both the C=O and C=C bonds. It is therefore of interest to examine the effect of the bridge closure on the sign and magnitude of θ for different conformations of the A/B ring system.

The cyclohexanoid ring B can have a chair or boat form, and with each is associated two limiting conformations of ring A which we designated "C_2-up" and "C_2-down", having regard to the relation between C_2 and C_3 when the model is viewed in the conventional orientation with the angular methyl groups up and ring A to the left. The closure of the 8:19-bridge causes the C/D rings to tilt upwards and the C_{10}—C_{19} bond to deflect to the right. The flexibility of ring A is also affected in the Dreiding model, and the inter-hydrogen distances associated with C_1, C_2, C_{11}, and C_{19} are altered. In Table II the non-bonded hydrogen–hydrogen and hydrogen–oxygen distances that may influence the relative stability of the conformers are listed. These are averaged values from measurements on four sets of Dreiding models.

The following conclusions can be drawn concerning the relative stability of the four conformers of the various bridged structures.

The unbridged Δ^4-3-ketone.—The nuclear magnetic resonance (n.m.r.) coupling constants (12) and the o.r.d. data (13) indicate that ring B is in the chair form except possibly in some derivatives containing bulky substituents at the $C_6(\beta)$ position (12, 14). The ring A conformation with C_2-up is favored since the alternative C_2-down structure brings the $C_1(\alpha)$ and $C_{11}(\alpha)$ hydrogen atoms within 1.7 Å. The conformation with ring B chair and C_2-up satisfies the chirality requirements for the o.r.d. curve, and the small angle ($\theta \approx +8°$) indicates strong conjugation consistent with the observed spectrum.

The 19:8-lactone (I).—Closure of the lactone bridge in the B ring chair / C_2-up form brings the hydrogen atoms on C_1 and C_{11} into partial eclipse and 2.1–2.2 Å apart. These interactions are reduced in the C_2-down form where the hydrogens are staggered, but the $C_1(\beta)$ hydrogen and the C_{19} oxygen are then eclipsed at 2.5 Å and a choice is problematic.

*To observe this angle the model must be inverted from its conventional orientation so that the angular methyl groups point downwards.

†The o.r.d. measurements were obtained only for IV and VI, but it is tacitly assumed that V will behave similarly.

*The chirality angle was measured on the model with a protractor and the estimated precision is ±3°.

†These distances are measured to the C_{19} carbon atom and the van der Waals radius of the methyl group (2.0 Å) is subtracted.

‡This conformation is not very stable and in some of the Dreiding models it inverts spontaneously to the C_2-up form.

If ring B is in the boat form, the model indicates much greater flexibility for the A ring. With C_2-up, the $C_2(\beta)$ hydrogen and the C_{19} oxygen are eclipsed with a 2.2 Å separation, and the C_2-down conformation would probably be favored.

The o.r.d. curve requires the same chirality as for the unbridged ketone, while the infrared frequency shift, if due to diminished resonance, necessitates an increase in $|\theta|$. Both requirements are compatible with the form having ring B chair and C_2-up, since the distortion of ring A consequent to the closure of the lactone bridge changes θ from +8° to +27° in the Dreiding model. None of the other conformations is compatible with both the spectrum and the o.r.d. curve.

The 8:19-epoxide IV.—With ring B in a chair form, the hydrogen interactions on C_1 and C_{11} are similar to those in the lactone (I) and are more favorable with C_2-down than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

C_2-up. Interaction between C_1 and C_{19} is different from the lactone case and the $C_1(\beta)$ hydrogen and the C_{19} hydrogen atoms are staggered. The Dreiding model therefore suggests that of the two ring B chair forms, the C_2-down is favored. If ring B is a boat, ring A is very flexible. Of the limiting forms the C_2-up is preferred since it avoids the partial eclipsing of the hydrogens on C_2, C_1, and C_{11} which occurs with C_2-down. However the flexibility of the A ring makes intermediate structures plausible.

The o.r.d. curve requires a minus sign for θ, and the infrared spectrum, on the basis of the resonance hypothesis, requires that $|\theta|$ be approximately the same as in the unbridged ketone ($\approx 8°$). These requirements cannot be met by any of the limiting conformers. The o.r.d. measurements would fit the form with ring B chair and C_2-down ($\theta \approx -22°$), or ring B boat and C_2-down ($\theta \approx -36°$), but the large values of $|\theta|$ would be unacceptable spectroscopically. The form with ring B boat and C_2-up ($\theta \approx +3°$) would fit the spectrum best. In view of the flexibility of ring A in this conformation small repulsive forces would suffice to invert the chirality of ring A and such a distorted conformation with ring B boat and ring A "nearly up" would reconcile both the spectroscopic and o.r.d. requirements. More detailed quantitative studies of the o.r.d. spectrum and the proton magnetic resonance coupling constants should settle this question.*

Structures V and VI.—The conformations of ring A and ring B of the other 8:19-bridged structures V and VI probably resemble that of the epoxide, with the R′ substituent oriented vertically. It is not known whether the forward- or rearward-directed hydrogen atom of the C_{19} methylene group of IV is substituted in V and VI. In none of the conformations can the C_{19} hydroxyl group of V approach within hydrogen-bonding distance of the C_3 carbonyl oxygen atom, though, in the forward position, it could bond with the π-electrons of the Δ^4-double bond.

Although the arguments presented above are only rationalizations of the observed optical phenomena, they suggest that with closure of the 8:19-bridge there can be little difference between the energies of the A/B ring systems with ring B in chair or boat form and that secondary repulsive forces between C_1 and C_{11} and between C_2 and C_{19} may tip the scales in favor of one or other of the ring B conformations.

Interactions Between Carbonyl Groups

It is alternatively possible that the infrared frequency shifts for the lactone (I) result from a transannular interaction between the 3-ketone and lactone carbonyl groups, but there are reasons for thinking this effect less important than the planarity factor considered above. There are few, if any, well-established instances of carbonyl shifts in steroid infrared spectra that can be attributed to non-bonded carbonyl–carbonyl interactions. Ketone and acetate carbonyl groups in a 1:3 relation give rise to upward frequency displacements of both C=O frequencies, as has been observed in 21-acetoxy-20-ketones, 17-acetoxy-16-ketones, 16-acetoxy-17-ketones, 11-acetoxy-12-ketones, and 12-acetoxy-11-ketones and in 17*a*-acetoxy-17-ketones of D-homo steroids (2). These shifts appear to be independent of steric factors and probably result from inductive effects acting through the bond system. A mutual interaction between remote carbonyl groups in the 1:4 relation is seen in 11,17-diketosteroids, where both the C=O stretching bands are displaced to higher frequency (15); this will be discussed further below. If the 19:8-lactone

**In a personal communication, Professor Djerassi has pointed out that the inherently asymmetric nature of the α,β-unsaturated ketone is probably a function of the angle of skew and the larger the angle, the larger the intrinsic optical asymmetry; conversely, if the angle is very small, then other factors, such as vicinal effects from other substituents, may play an important part or even governing role in controlling the sign of the Cotton effect. This being the case, it is conceivable that a small amount of one conformer may control the sign of the Cotton effect by having a much more powerful rotational strength in one direction than the dominant conformer may have in the opposite one.*

carbonyl group of I were interacting transannularly with the Δ^4-3-ketone system, either by mutual dipole repulsion or π-orbital overlap, the ultraviolet spectrum would also be expected to show abnormality. The positions of the K bands in the ultraviolet spectra of similarly substituted steroids containing 19:8-lactone and 8:19-epoxide bridges are compared in Table III from which it is evident that any such effect must be quite small

TABLE III

Position of the K-band maximum in the ultraviolet spectra of 8:19-bridged Δ^4-3-ketosteroids*

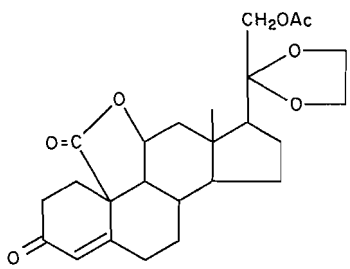
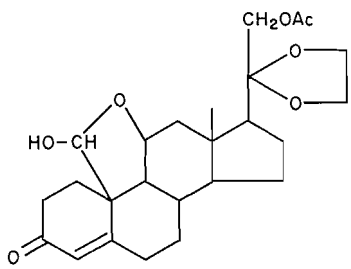
*These data are taken from refs. 3 and 4. The spectra were measured on a Beckman Model DU spectrophotometer in 95% ethanol solution.

since the untraviolet shift does not exceed 10 Å. Braude has noted (16) that *small* changes in the planarity of conjugated systems have a negligible effect on the position of the K band, but do produce a diminution of the band intensity and there is some evidence for that in the data in Table III. A transannular interaction would also be expected to perturb the C=O stretching frequency of the lactone carbonyl, but this band is observed at 1 774 ± 3 cm^{-1} in chloroform solution and is within the normal range of 1 777 ± 5 cm^{-1} established for various types of γ-lactones (17).

For the 19:11-lactone bridged Δ^4-3-ketosteroid VII, Barton and Beaton (18) report infrared bands at 1 765, 1 675, and 1 620 cm^{-1} in chloroform solution. Here $\nu_{C=O}$ for the Δ^4-3-ketone group is displaced upwards but $\nu_{C=C}$ is not. The band at 1 765 cm^{-1} must be an unresolved doublet with contributions from the lactone carbonyl and the C_{21} acetate group. A γ-lactone at the normal position of 1 777 ± 5 cm^{-1} should be separated from the ester carbonyl band, and there is a suggestion here that the lactone maximum is displaced downwards. For VII the Dreiding model allows only one stable conformation, which



VII



VIII

is rigid, with ring B in the chair form and has the two carbonyl groups approximately parallel and 3.2 Å apart.* The chirality is negative with $\theta \approx -15°$. The ultraviolet K-band maximum of VII is at 2 410 Å in methanol and is shifted some 50 Å from the 2 460 Å

**For I the closest approach of the C_3 and lactone carbonyl groups is 4.2 Å in the ring B boat / C_2-down conformation. In the other conformations the separation is 4.8–5.6 Å.*

position observed for the hemiacetal VIII in the same solvent. There is therefore stronger support for a transannular effect for the carbonyl shift in VII than in I.

Ketosteroids with Carbonyl Groups at 1, 11, and 17

The triketones II and III have recently been synthesized by Schneider (19) and the positions of the C=O and C=C stretching bands, as measured on a Perkin–Elmer 421 spectrophotometer are reported in Table IV together with relevant data for the 1-, 11-, and 17-monoketones and the 11,17-diketone in the same solvents. It is notable that the triketones exhibit the same displacements of the 11-carbonyl band as do the 11,17-diketones, but the introduction of the 1-carbonyl or the Δ^2-1-carbonyl group has little additional displacement effect. This is in spite of the fact that the oxygen atoms on C_1 and C_{11} are separated by only 2.8 Å and 3.7 Å in II and III respectively, as evaluated from Dreiding models. These figures are based on the conformations that maximize the oxygen–oxygen distance. For II this is a ring B chair conformation, but for III a ring B boat conformation must be postulated, otherwise the oxygen–oxygen distance is reduced to 2.4 Å. Both II and III are 5β-steroids. In the 5α-series the maximum C_1,C_{11} oxygen–oxygen separations are 2.4 Å for the analogue of II and 2.2 Å for the analogue of III, and the interaction effects should therefore be more severe. It would be interesting to examine these compounds.

The perturbations of the group frequencies of the 11- and 17-carbonyls in the 11,17-diketones probably depend mainly on the change in the geometry of the C and D rings. The normal coordinate analyses of Overend and Scherer (20) indicate that, for simple ketones, the C=O frequency is very sensitive to changes in the angle opposite the O=C bond, independently of any change in the C=O force constant. A small enlargement of these angles in the 11,17-diketone could bring about the observed effect.

CONCLUSION

The above results illustrate that, in dealing with small perturbations of "group" frequencies in complex molecules, the infrared spectroscopist cannot at present distinguish unequivocally among the various electronic and steric influences that can modify the band position. It must be emphasized however that the anomalies of the type discussed here are exceptional. It is important that they be noted, both to avoid errors of

interpretation when applying infrared spectroscopy to the determination of molecular structure, and to alert those investigating other physical properties of the molecules concerned.

ACKNOWLEDGMENTS

We wish to thank Dr. M. Ehrenstein and Dr. J. J. Schneider for providing the compounds discussed in this paper, and Mr. R. Lauzon for technical assistance in measuring the infrared spectra. We also wish to acknowledge the opportunity of discussing the rotatory dispersion aspects of the problem with Professor C. Djerassi.

CONCERNING THE EXISTENCE OF 2-(2-NITROVINYL)BENZOIC ACID

A CONTRIBUTION TO THE ALKALINE ELIMINATION IN β-SUBSTITUTED NITRO COMPOUNDS

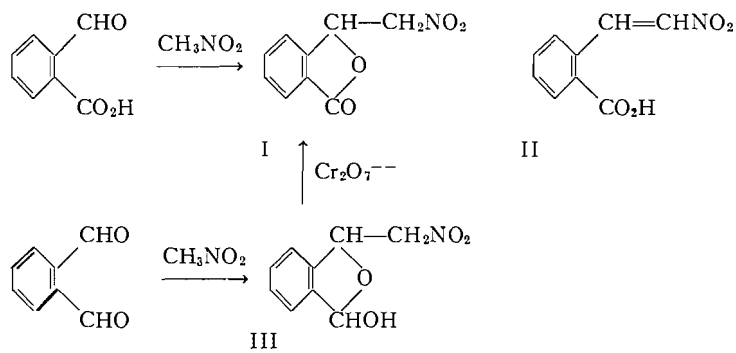
HANS HELMUT BAER AND FRANK KIENZLE
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received August 21, 1964

ABSTRACT

Action of aqueous alkali upon 3-phthalidylnitromethane (I) is shown to produce unstable 2-(2-nitrovinyl)benzoate ion (II*a*) which rapidly adds hydroxyl ion to form the dianion IV*a* of 2-(1-hydroxy-2-nitroethyl)benzoic acid. Both II*a* and IV*a* revert to I upon acidification. Substitution of methoxide for aqueous alkali converts I via II*a* into 2-(1-methoxy-2-nitroethyl)benzoate (V*a*), which is isolated as crystalline, free acid (V).

Condensations with nitromethane of isophthalaldehydic acid and terephthalaldehydic acid lead, respectively, to 3- and 4-(2-nitrovinyl)benzoic acids (1). On the other hand, *o*-phthalaldehydic acid under similar conditions has been known for many years to give a colorless compound (m.p. 130–131°) recognized to be 3-phthalidylnitromethane (I) rather than 2-(2-nitrovinyl)benzoic acid (II) (2, 3, 4). Recent work in this laboratory (5) demonstrated that the condensation of *o*-phthalaldehyde with nitromethane afforded, among other products, 2-(1-hydroxy-2-nitroethyl)benzaldehyde lactol (III). Dichromate oxidation of III gave I. The structure of I was also supported by a detailed discussion (6) of its infrared spectrum and by further chemical evidence (5).



Apparently unaware of the previous work, Hashimoto and Nagase (7) also studied the nitromethane condensation of *o*-phthalaldehydic acid and obviously obtained the same colorless product (m.p. 129–130°). They assumed, however, that it was 2-(2-nitrovinyl)-benzoic acid (II). Their assignment of this structure was based on reduction of the nitro group followed by conversion of the product into isocarbostyril. In our opinion, the experiments as described would not corroborate formula II but would in fact favor formula I. In view of this discrepancy it seemed that additional work was needed to establish the possible existence of II.

The ultraviolet spectrum of I closely resembles that of phthalide, but is completely different from the spectra reported (1) for the isomeric 3- and 4-(2-nitrovinyl)benzoic acids in that it does not exhibit the characteristic β-nitrostyrene peak in the 315 mμ

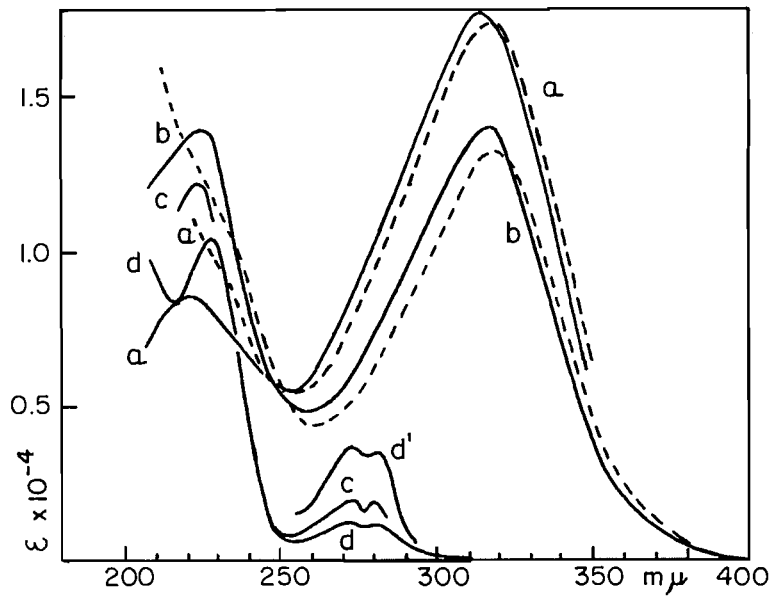


FIG. 1. Curves *a*: 4-(2-nitrovinyl)benzoic acid (solid line) and its anion (broken line) in water. Curves *b*: 3-(2-nitrovinyl)benzoic acid (solid line) and its anion (broken line) in water. Curve *c*: phthalide in methanol. Curve *d*: 3-phthalidylnitromethane, 10^{-4} *M* in methanol; in water the maxima are at about 2 mμ longer wavelengths. Curve *d'*: same as *d* but without reference to the ordinate; measured at somewhat higher concentration.—Curves *a* and *b* are redrawn from ref. 1, curve *c* from Stadtler Standard Spectrum No. 13929U.

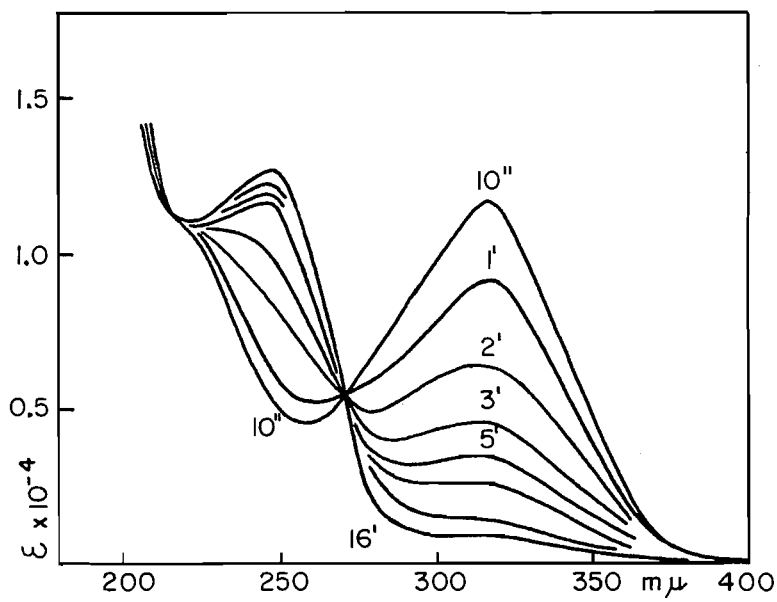

FIG. 2. Spectral changes observed in an alkalized solution of 3-phthalidylnitromethane (*c*, 10^{-4} *M*). Solvent, 1 part of methanol and 9 parts of *N*/100 aqueous sodium hydroxide.

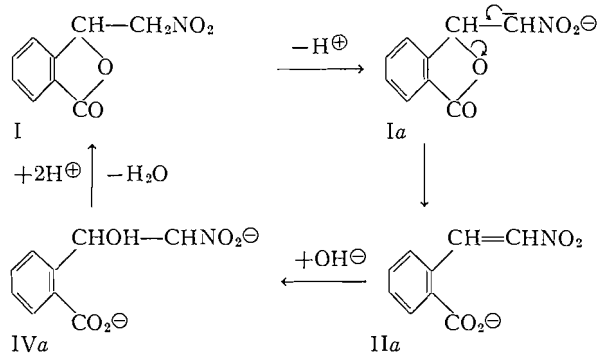
region (Fig. 1). A β-nitrostyrene chromophore is, however, instantaneously generated when aqueous alkali is added to a solution of I. The spectrum (Fig. 2) then becomes very similar to the spectra of the anions of 3- and 4-(2-nitrovinyl)benzoic acids, suggesting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

that a β-nitrostyrene carboxylate is present at this point. In $N/100$ sodium hydroxide solution the new peak at 319 mμ disappears rapidly, its half-life at 28° being about 2 min. The peak decreases more slowly in M sodium hydrogen carbonate solution at pH 8.5 (half-life, about 2 h). In phosphate buffers of pH 7.8 and 7.1 the decrease in intensity in 2 h was 9 and 6%, respectively. The spectral change occurring in alkaline solution is characterized by an isosbestic point at 271 mμ (Fig. 2). Acidification following the completion of the spectral change restores the original spectrum of I without observable recurrence of nitrostyrene absorption, and in a preparative experiment resulted in recovery of unchanged, crystalline I in 77% yield. The process may be represented by the following cyclic sequence.



This sequence involves an eliminative opening of the lactone ring in I*a*, the nitronate ion of I, which as a β-acyloxynitro compound should be unstable toward alkali.[1] The resulting product, the 2-(2-nitrovinyl)benzoate II*a*, is evidently also rather unstable in an alkaline reaction medium. Depending on the alkalinity of the solution, nucleophilic attack by hydroxyl ion takes place more or less rapidly, leading to disappearance of the nitrostyrene chromophore and the formation of the dianion IV*a* of 2-(1-hydroxy-2-nitroethyl)benzoic acid. This dianion is characterized by nitronate absorption at 248 mμ (ε, 12 500 in $N/100$ NaOH). The dianion appears to be reasonably stable in dilute alkali, but on acidification reverts to the starting compound, lactone I. There are precedents in the literature for this type of hydroxylation of β-nitrostyrene derivatives.[2]

Numerous attempts were made to liberate and, if possible, isolate 2-(2-nitrovinyl)-benzoic acid (II) by acidifying freshly alkalized solutions of I while the absorption peak at 319 mμ indicated that II*a* was still present. Acidification with hydrochloric acid or acetic acid, deionization with cation exchange resin, or indeed even addition of potassium dihydrogen phosphate to pH 4.5 resulted in instant restoration of the spectrum of I with concomitant, complete disappearance of the nitrostyrene peak. Crystalline I was the only isolable product. In phosphate buffer of pH 5 it was possible to observe spectrophotometrically that the 319 mμ peak almost disappeared within 2 min (Fig. 3). At pH 6 the peak decreased, also within a few minutes, and then remained fairly constant at a low optical density approximately equalling that of I concurrently generated. It appears, therefore, that in a narrow range around pH 6 an equilibrium I ⇌ II ⇌ II*a* is established in which an appreciable amount of II*a* is present. The molar extinction coefficient of I

[1]*The elimination of acetic acid from β-acetoxynitroalkanes leading to nitroolefins is referred to as the Schmidt–Rutz reaction (8) and is usually effected by bicarbonate in an inert solvent.*

[2]*Examples reported include β-nitrostyrene itself (9), 4-hydroxy-3-methoxy-β-nitrostyrene (10), and 2-hydroxy-1-nitroindene (5).*

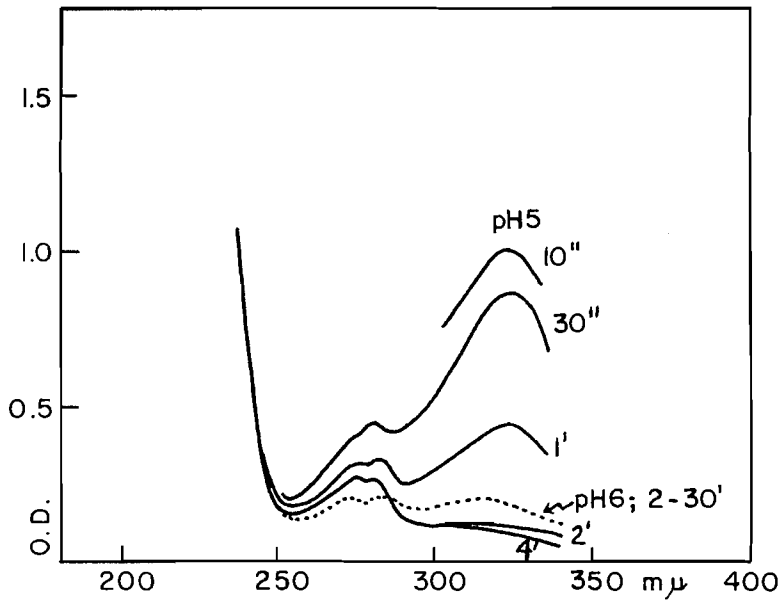

FIG. 3. Solid lines: spectral changes in a solution of 3-phthalidylnitromethane (c, approx. 2×10^{-4} M) that had been alkalized and immediately thereafter brought to pH 5 (phosphate buffer, cf. Experimental). Dotted line: final curve (after 2 and 30 min) of a similar experiment at pH 6.

(1 500) being roughly one-tenth of the values estimated[3] for II and IIa, it is evident that in this equilibrium the lactone I predominates about tenfold over the nitrostyrene system II $\rightleftharpoons$ IIa. Since any significant departure from pH 6 results in a complete shift to I (on the acid side) or to IVa (on the alkaline side), it becomes understandable that none of our attempts at isolating II was successful.

That the action of alkali upon I consists of an eliminative lactone ring opening with subsequent addition of base (I $\rightarrow$ Ia $\rightarrow$ IIa $\rightarrow$ IVa) was proved, further to the spectral evidence, by performing the same reaction with sodium methoxide in absolute methanol. Under these conditions, i.e., in the absence of aqueous hydroxide, no starting material (I) was isolated upon subsequent acidification. Instead, a colorless product melting at 140–141° was obtained in high yield. On the basis of its infrared and ultraviolet spectra, elemental analyses, and its acidic reaction toward litmus, the substance was assigned structure V, 2-(1-methoxy-2-nitroethyl)benzoic acid. This methoxy compound is stable as the free acid since, in contrast to the hydroxy analogue IV, it cannot lactonize.

If the action of methoxide upon I had consisted of lactone opening by transesterification, the methyl ester of IV would have been formed. The reaction mixture displayed transient, strong absorption at 310 mμ ascribable to IIa.[4] This intermediate, having a half-life of about 1.5 h in N/10 $NaOCH_3$, then adds methanol to give the methoxy acid V (Fig. 4). Interestingly, the final product, V, does not show nitronate absorption in the 245 mμ region in the presence of *methanolic methoxide*; it has short wavelength end absorption only. One has to conclude, therefore, that under the reaction conditions the product

[3]*By extrapolation to zero time of the IIa peak (Fig. 2) and by comparison with the ε-values given (1) for the m- and p-acids (13 900 and 18 000) and their anions (13 400 and 17 200).*

[4]*The hypsochromic shift of 9 mμ noted in methanol is explained as a solvent effect. It is in line with the fact that 4-(2-nitrovinyl)benzoic acid has* λ_{max} *307 mμ in methanol (11) and* λ_{max} *313 mμ in water (1); 2-hydroxy-1-nitroindene shows* λ_{max} *340 mμ in ethanol and* λ_{max} *355 mμ in water (5).*

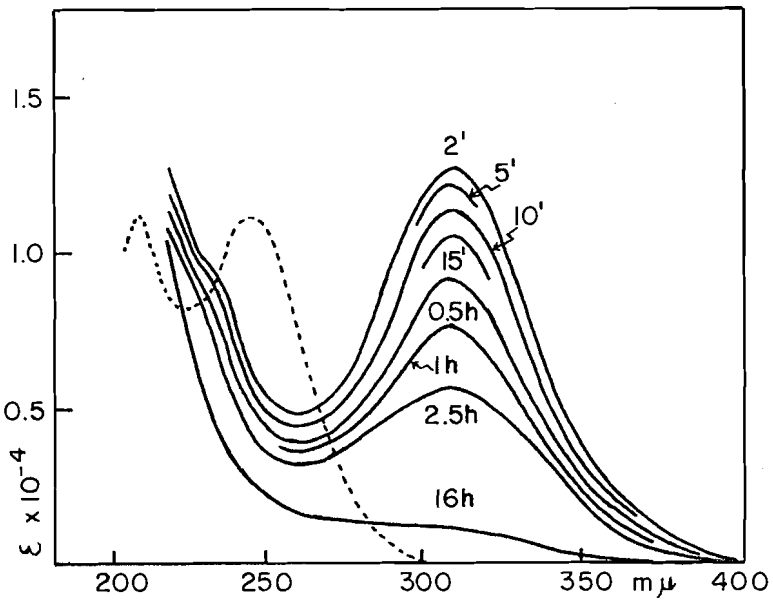

FIG. 4. Solid lines: spectral changes in a 10^{-4} *M* solution of 3-phthalidylnitromethane in *N*/10 methanolic sodium methoxide. Dotted line: a 10^{-4} *M* solution of 2-(1-methoxy-2-nitroethyl)benzoic acid in *N*/100 aqueous sodium hydroxide.

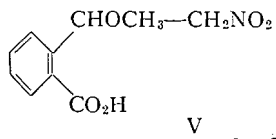
exists as carboxylate V*a* but not as a carboxylate-nitronate like IV*a*. For this reason there is no isosbestic point associated with the transformation depicted in Fig. 4, although the isolated acid (V) does produce nitronate absorption (λ_{max} 246 mμ; ε, 11 000) in the presence of *aqueous hydroxide*.



V

V*a*, $CO_2\ominus$ instead of CO_2H

Similar facile eliminations, combined with replacement by methoxyl, of substituents adjacent to a nitro group have been observed in carbohydrate chemistry (12) and have more recently been utilized for the synthesis of aliphatic nitroalkyl ethers (13). In these cases, too, there was evidence for nitroolefins playing a role as intermediates. On the other hand the lactol III when treated with aqueous or ethanolic alkali is converted instantly into a 1,3-dihydroxy-2-*aci*-nitroindane salt, with no nitroolefin intermediate observed (5). Apparently, shift in III of the mobile equilibrium toward the hydroxy aldehyde and internal Henry condensation of the latter giving the indane derivative take preference over an alternative elimination process.

EXPERIMENTAL

Spectral Determinations

The ultraviolet spectra were obtained with a Beckman DK-2 recording spectrophotometer and rechecked with a Perkin–Elmer 202 apparatus. For the runs involving action upon I of aqueous base (*N*/100 NaOH, *M* $NaHCO_3$) and (or) phosphate buffer (0.15 *M*), one part of a standard 0.001 *M* solution of I in methanol (A) was diluted with nine parts of the aqueous reagent; thus, the concentration of I was 10^{-4} *M*. The small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

changes in reagent pH that were due to the introduction of 1/9 volume of solvent methanol were neglected. The spectral curves at pH 7.8, 7.1, 6.0, 5.0, and 4.5 were taken after 0.3 ml of A had been alkalized with Na_2HPO_4 buffer component and, after a few seconds, had been made up to a volume of 3 ml with KH_2PO_4 buffer component in such proportions as to provide the desired final pH value.

3-Phthalidylnitromethane (I)

Samples of I prepared (3, 4, 7) from *o*-phthalaldehydic acid and from *o*-phthalaldehyde via III (5) were found to be identical. The identity was established by mixed melting point (130.5–132°, undepressed) and infrared (6) and ultraviolet spectra; λ_{max} in methanol, 273 mμ (ϵ, 1 550), 281 mμ (ϵ, 1 500); λ_{max} in water containing 10% of methanol, 275 and 282 mμ.

Action of Aqueous Base on I

A solution of I (96.5 mg, 0.5 mmole) in 3 ml of warm methanol was allowed to cool to about 25°, with care being taken to avoid crystallization. Then 50 ml of *N*/100 sodium hydroxide and 1 ml of *N*/1 sodium hydroxide were added quickly. After half an hour the solution was checked spectroscopically for absence of high-intensity absorption in the near ultraviolet region,[5] then acidified with 2 ml of *N*/1 acetic acid and concentrated *in vacuo* at 35° to a small volume. Excess methanol was added and sodium ions were removed by stirring with 3 ml of Rexyn RG-50(H^+). Evaporation of the filtrate gave a residue that crystallized from a small amount of aqueous methanol and was collected after standing overnight at 0°. The washed and dried, colorless crystals were identified as starting material; m.p. 131–132°. The recovery was 74 mg (77%). The mother liquor was inspected in the ultraviolet and found to exhibit absorption due to I only.

An identical experiment in which the acidification was done after 10 s furnished 78 mg (81%) of starting material. No significantly different results were obtained when ice-cold solutions were used nor when sodium bicarbonate was substituted for sodium hydroxide.

2-(1-Methoxy-2-nitroethyl)benzoic Acid (V)

3-Phthalidylnitromethane (I) (300 mg, 1.55 mmole) was dissolved in 30 ml of methanol, and 200 mg of sodium methoxide (3.12 mmole) in 10 ml of methanol was added. The slightly yellowish mixture was allowed to stand at room temperature for 24 h and then was deionized at 0° with 10 ml of methanol-washed Rexyn RG-50(H^+). The filtrate gave upon evaporation a crystalline residue which was recrystallized from 5 ml of water with the addition of a few drops of ethanol. The solution showed a pH of about 2 (indicator paper) and deposited compound V as fine needles (202 mg, m.p. 135–137°); a second crop (25 mg, m.p. 128–130°) was obtained on concentration of the mother liquor. The total yield was 64%. A recrystallization from ethanol-containing water, with activated carbon treatment, raised the m.p. to 138–139° and a further recrystallization to 140–141°. There was left 145 mg of pure V the melting point of which did not change upon further recrystallization.

Anal. Calcd. for $C_{10}H_{11}NO_5$ (225.2): C, 53.33; H, 4.92; N, 6.22; OCH_3, 13.80. Found: C, 53.29; H, 4.83; N, 6.31; OCH_3, 14.25.

The pK_a value was 3.68 (method of half titration at 25°).

Ultraviolet spectrum.—In methanol, λ_{max} 277.5 mμ (ϵ, 1 000); in *N*/10 methanolic sodium methoxide, end absorption only; in *N*/100 aqueous sodium hydroxide, λ_{max} 245 mμ (ϵ, 11 000).

Characteristic infrared bands (in cm^{-1}).—Aromatic carboxyl, 2 700 to 2 500 (group of small bands), 1 680 (strong), 920 (broad, medium). Primary nitro, 1 555 (asym., strong), 1 370 (sym., medium, superimposed on Nujol band). Methoxyl, 1 120 (strong). *o*-Substituted phenyl, 1 620, 1 600, and 1 480 (weak), 1 300, 1 285, 1 270, and 1 065 (strong), 1 030 (medium), 765 (strong).

In comparison, 3-phthalidylnitromethane (I) shows the phthalide carbonyl band at 1 760 cm^{-1} and the strained-ring =C—O—C stretching modes at 1 215 cm^{-1} (asym.) and 1 090 cm^{-1} (sym.).

ELECTROCHEMICAL STUDIES ON TITANIUM IN MOLTEN LiCl–KCl EUTECTIC

R. Baboian,[1] D. L. Hill,[2] and R. A. Bailey
Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York

Received August 7, 1964

ABSTRACT

The methods of potentiometry and polarography have been used to study the Ti(II) and Ti(III) ions in solution in the LiCl–KCl eutectic at 450 °C and 550 °C. Solutions of Ti(II) were prepared by anodic dissolution of Ti metal, and Ti(III) solutions by coulometric titration of Ti(II) by Pt(II). Apparent standard electrode potentials were measured for the Ti(II)/Ti and Ti(III)/Ti(II) couples against the Pt(II)/Pt and Ag(I)/Ag reference electrodes. Values obtained on the mole fraction scale with a Pt(II)/Pt reference electrode were

Ti(II)/Ti, −1.74 V at 450 °C; −1.73 V at 550 °C;

Ti(III)/Ti(II), −1.43 V at 450 °C; −1.43 V at 550 °C.

Polarographic waves for oxidation and reduction of Ti(II), and for reduction of Ti(III), were observed.

INTRODUCTION

The technological importance of titanium metal has led to its study at elevated temperatures and in molten salt systems. Disproportionation equilibria in alkali halide melts were studied by Mellgren and Opie (1) and Kreye and Kellogg (2) by direct analysis, and by Flengas (3) and Smirnov (4) using potential measurements in molten KCl–NaCl mixtures. These studies showed the importance of the lower states Ti(II) and Ti(III) in these systems.

Redox potential measurements of the Ti(III)/Ti(II) couple in the LiCl–KCl eutectic melt were carried out by Menzies *et al.* (5) and by Smirnov (6). Although both groups used essentially the same technique, their values differ by 0.6 V at 500 °C. Bockris *et al.* (7) studied solutions of titanium chlorides in the same melt polarographically. At 400 °C they obtained the polarographic wave for the reduction of Ti(III) to Ti(II), but no wave for the Ti(II)–Ti(0) reduction was seen at potentials less negative than that for decomposition of the melt. However, under the same conditions Okada (8) has obtained polarograms for both of these reduction processes.

The object of this work was to make a further investigation of the redox potentials of the titanium system in the LiCl–KCl eutectic melt in which the lower oxidation states of titanium were prepared *in situ*. Our approach was by way of anodic dissolution of the metal, rather than by direct addition of titanium chloride as had been done previously. In addition to the metal, three oxidation states are of importance: Ti(II), Ti(III), and Ti(IV). The last of these is volatile as the chloride and was not investigated.

when two oxidation states of titanium are present. The concentration on the mole fraction or molality scale is represented by C.

In the first case where the cell reaction is Ti + Pt(II) = Ti(II) + Pt, the cell potential is given by

$$[1] \qquad E_{\text{cell}} = E^0_{\text{Pt(II)/Pt}} - E^0_{\text{Tl(II)/Tl}} - \frac{2.303RT}{nF} \log \frac{\gamma_1 C_1}{(\gamma_2 C_2)^{n/2}},$$

where E^0 refers to the standard potential. The activity coefficient is represented by γ. Signs follow the Stockholm convention. If the Pt(II)/Pt electrode is taken as the reference, its standard potential is set at zero at all temperatures. Then, referring the cell potential to unit concentration of the reference electrode, and assuming the activity coefficients to be constant over the concentration range considered, one can rewrite for eq. [1],

$$[2] \qquad -E'_{\text{cell}} = E^{0'}_{\text{Tl(II)/Tl}} + \frac{2.303RT}{nF} \log C_1.$$

$E'_{\text{Tl(II)/Tl}}$ is the apparent standard electrode potential, referred to unit concentration but containing a term involving the activity coefficients.

When two oxidation states are present (cell B), the equation for the cell potential would reduce to

$$[3] \qquad -E'_{\text{cell}} = E^{0'}_{\text{Tl}(n')/\text{Tl}(n)} + \frac{2.303RT}{(n'-n)F} \log \frac{C_1'}{C_1}.$$

The cell reaction concerned here is Ti(II) + $\frac{1}{2}$Pt(II) = Ti(III) + $\frac{1}{2}$Pt. When $C_1' = C_1$, $-E'_{\text{cell}}$ equals the apparent standard potential of the couple.

A similar treatment would apply to the Ag(I)/Ag reference electrode.

From a theoretical point of view, the best reference electrode for chloride melts would be the chlorine electrode. Measurements referred to the platinum or silver electrodes can easily be converted to the chlorine electrode scale, since their potentials are known on this scale. For the cell

$$\text{M}\,|\,\text{MCl}_n\,|\,\text{Cl}_2,$$

the cell potential can be calculated from the free energy of formation of the pure metal chloride. Thus, one can calculate $E^0_{\text{Tl(II)/Tl}}$ on a mole fraction scale. If the activity coefficient of the reference electrode ion is known (that for Ag(I) is known to be unity

For personal use only.

in this melt (9, 10)), the activity coefficient γ_1 of the Ti(II) ion can be calculated; using this, γ_1', for Ti(III), can be found also. Potentiometric data will lead to further thermodynamic quantities through standard relations.

EXPERIMENTAL

The LiCl–KCl eutectic mixture was prepared from Baker Analyzed chemicals, purified by the method of Hill *et al.* (11). The most serious impurity was water. The oven-dried eutectic mixture was placed in a tube with a fritted glass bottom beneath which was a collecting tube. The whole was encased in an outer glass jacket and surrounded by a furnace. Dry HCl gas was passed through the mixture as the temperature was raised until the salt melted. Pure argon was then passed into the melt to remove excess HCl; magnesium turnings were added to reduce heavy metal impurities, and the salt was filtered into the collecting tube. Transfer of the purified eutectic was carried out in a dry-box.

Electrochemical measurements were carried out in a cylindrical furnace made of a steel-lined copper cylinder 20 in. long, with a $2\frac{1}{2}$ in. bore and a 1 in. wall thickness. This was electrically heated by five balanced resistance windings and enclosed in several inches of asbestos felt for insulation. Two slots for observation were cut in the furnace walls and closed with evacuated pyrex tubes imbedded in the insulation to reduce heat loss. Temperature was controlled to ± 0.5 °C by an iron–constantan thermocouple, which was enclosed in a glass sheath in the melt, and controlled a Barber-Coleman Wheelco furnace regulator.

The electrochemical cell and reference electrodes were as described by Hill *et al.* (11). The electrodes were inserted into the cell through O-ring glands which permitted them to be raised or lowered during a run. The reference electrodes consisted of a Pt or Ag foil in a pyrex compartment separated from the bulk of the melt by a glass frit. The Pt(II) or Ag(I) was prepared coulometrically using a second Pt foil in a similar compartment as cathode. The exact concentration was determined from the number of coulombs passed and the chloride content of the electrode compartment as determined at the end of the experiment. The junction potential across the frit should not be significant since the LiCl–KCl eutectic melt was present in all compartments in great excess. A check of thermal potentials arising in the electrode connections and leads showed that these were negligible in our arrangement.

Solutions of Ti(II) were prepared by anodic dissolution of a titanium rod (purity > 99.9%). Successive periods of anodization, accompanied by argon stirring, were used to give a series of Ti(II) concentrations. Concentrations were known from the number of coulombs passed and the weight of the eutectic. Equilibrium potentials were measured on unstirred solutions.

Titanium(II) was oxidized to Ti(III) by coulometric titration, using Pt(II) generated from an immersed platinum foil. Potentials were measured at intervals against a reference electrode. The Ti(III)/Ti(II) apparent standard potential could be taken from the titration curves.

Polarographic behavior was studied using platinum microelectrodes made from 15 mil Pt wire sealed into pyrex tubing. About 0.8 to 1.0 mm^2 of wire projected from the seal; the actual exposure of each one was determined with a microscope. Polarography was also used to monitor the purity of the melt.

In all experiments, a weighed amount of eutectic (about 160 g) was placed in the cell in the dry-box, and fused under *vacuo*. The electrodes were kept above the level of the salt but in the hot zone of the furnace for outgassing. The cell was then flushed with purified argon, which was also used for stirring, and the electrodes lowered to the desired depth.

The measuring equipment included a Sargent Model IV coulometric current source, a Sargent XXI recording polarograph, and a Leads and Northrup Type K-3 Universal potentiometer with electronic d-c. null detector.

Solubility of TiO_2, TiO, or Ti metal in the melt could alter the true concentrations of Ti species present. Consequently, solubilities of these substances were studied by stirring the substance in the melt for several hours, sucking a portion into a fritted glass tube, and cooling. Titanium could then be tested for by chemical analysis.

The LiCl–KCl eutectic is well known to be hygroscopic and to be appreciably hydrolyzed if melted in the presence of moisture. The presence of impurities from this source can be indicated grossly by etching of pyrex containers, and more precisely by a polarographic wave at -1.6 to -1.7 V using a platinum microelectrode and Pt(II)/Pt reference electrode. A small polarographic current (<1.5 $\mu A/cm^2$ at -2.0 V) was observed even with the most carefully purified melts; but this very small current indicates a negligible amount of impurity and compares favorably with the results of other workers (10).

When present in significant amounts, these impurities can have an important effect on the behavior of titanium metal. With inadequately purified melts, corrosion of the rod yielded a dark insoluble product immediately upon its insertion into the melt. This reaction ceased after a period of time which depended on the purity of the melt. It was more rapid at higher temperatures. In adequately purified melts, the effect was slight but still noticeable.

Henrie (12) has suggested that reaction of Ti ions with SiO_2 could take place in these systems. This did not seem to be significant in our case, since the corrosion of the rod ceased after a short time, the Ti(II) solutions prepared seemed quite stable for some time (according to their potentiometric and polarographic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

behavior), there was no trace of attack of the glass when properly purified melts were used, and there was no trace of any silicon-containing residue in the melt (by emission spectrography).

The blackish corrosion product was recovered by leaching the solidified melt with water. X-ray diffraction of the final product showed it to be a mixture of titanium dioxide and titanium monoxide. This precipitate should have no bearing on the electrochemical measurement, since independent studies showed both TiO_2 and TiO to be insoluble in the melt. Solubility studies of powdered Ti metal similarly gave no trace of a soluble corrosion product.

RESULTS AND DISCUSSION

At 450 °C, a plot of cell potential vs. log (mole fraction Ti(II)) (calculated from the number of coulombs passed on anodic dissolution of the Ti rod) was a straight line in the low-concentration region, and had a slope here of 0.06 V, close to that calculated for a two-electron transfer (0.07 V). The plot leveled out at a concentration corresponding to about 5×10^{-5} mole fraction of Ti(II). Further anodization produced a black cloudiness in the melt. Presumably this marks the limit of solubility of $TiCl_2$ in the LiCl–KCl eutectic at this temperature. These results are shown in Fig. 1.

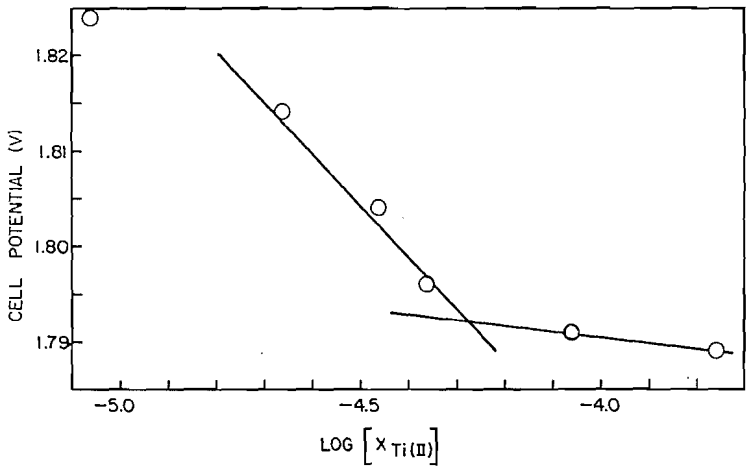

FIG. 1. Ti(II)/Ti potential in LiCl–KCl eutectic at 450 °C. Pt(II)/Pt reference electrode, 2.42×10^{-3} mole fraction of Pt(II).

Polarograms for the oxidation of Ti(II) at this temperature are shown in Fig. 2. At a fixed potential, the polarographic current increases until a Ti(II) concentration of about 5×10^{-5} mole fraction is reached, and then levels off as did the cell potential.

Similar plots of cell potential at 550 °C are shown in Figs. 3 and 4. Again, the plots are linear with a slope of 0.080V, close to the calculated value of 0.082 V for a two-electron transfer. The $TiCl_2$ was more soluble at this temperature. The calculated apparent standard potential averaged over several runs is given in Table I. Solutions of Ti(II) at this temperature were light green in color. Admission of oxygen immediately resulted in the formation of a grey precipitate.

Table I lists the apparent standard potentials determined in this work. The Ti(II)/Ti and Ti(III)/Ti(II) systems were measured directly. The uncertainties indicated here represent the observed variation from the mean of the different experiments. The Ti(III)/Ti potential is calculated from the other values. Also included are results of the Ag(I)/Ag potential against the Pt(II)/Pt electrode to aid in comparison; our value agrees very well with that of Laitinen and Liu (13), −0.637V at 450 °C on the mole fraction scale.

*Calculated values.
†Extrapolated from higher temperatures.

The temperature dependence of the apparent standard potential of the Ti(II)/Ti system against the Ag(I)/Ag electrode was strictly linear over the range 500–600 °C. (Table II).

TABLE II

Temperature dependence of apparent standard potentials

Cell	T range (°C)	$\Delta E^{0\prime}/\Delta T$ (Volts per degree)
Ag|Ag(I)||Pt(II)|Pt	450–550	3.20×10^{-4}

Pt|Ti(II), Ti(III)||Pt(II)|Pt	500–600	0

With a given concentration of Ti(II) in the melt, Ti(III) was generated in the system by the reaction

$$2\text{Ti(II)} + \text{Pt(II)} \rightarrow 2\text{Ti(III)} + \text{Pt(0)},$$

using Pt(II) generated coulometrically. A plot of the potential of the immersed platinum foil vs. a reference electrode gave a typical potentiometric titration curve. The greenish color of the Ti(II) changed to a lemon yellow, while finely divided platinum metal was formed. The Ti(III)/Ti(II) apparent standard potential could be taken from the mid-portion of the upper branch of the titration curve, which was comparatively flat. An example of such a titration is shown in Fig. 5. The results of these titrations are listed in Table III; the uncertainty represents that involved in reading the potential from the titration curve. Similar titrations could be carried out using coulometrically generated Cu(I). Each value in Table III represents the mean of several experiments.

The observed end-points of these titration curves usually occurred before the theoretical end-points which could be calculated by the number of coulombs used to generate each reactant. This effect was most significant when small concentrations of Ti(II) were used and probably was caused by reaction of the Ti(II) with traces of impurities. The initial Ti(II) content of the experiment shown in Fig. 5 was only 5×10^{-4} equivalents. Use of larger amounts of Ti(II) reduced this effect, but introduced other problems from the larger amount of platinum metal formed, and from anodic current limitations. This discrepency did not affect the reading of the Ti(III)/Ti(II) potential from the curve, nor would it have influenced the Ti(II)/Ti potential measurements since the concentrations were higher.

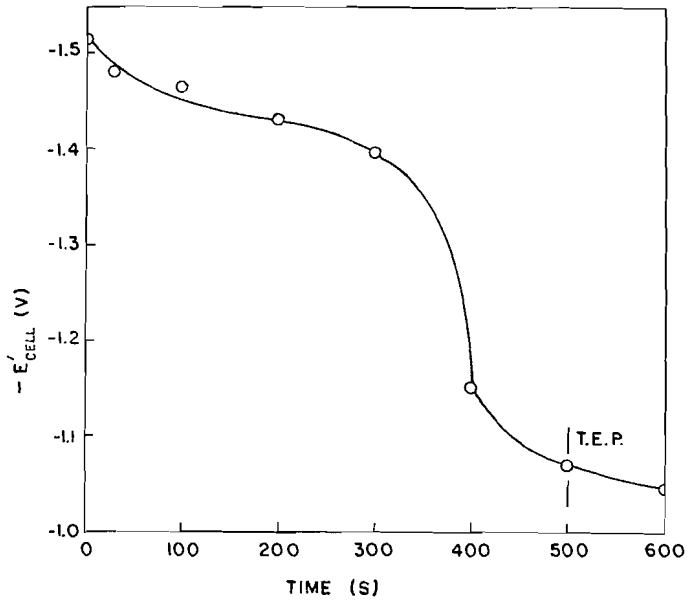

FIG. 5. Coulometric titration of Ti(II) with Pt(II) in LiCl–KCl eutectic at 550 °C. T.E.P. = theoretical end-point.

TABLE III

Standard potentials for the Ti(III)–Ti(II) couple

Cell	T (°C)	Initial concentration Ti(II) (mole fraction)	$E^{0}_{Ti(III)/Ti(II)}$ (V)	Method
(−)Pt | Ti(III), Ti(II) || Pt(II) | Pt(+)	500	9.13×10^{-5}	-1.43 ± 0.02	Back titration
(−)Pt | Ti(III), Ti(II) || Pt(II) | Pt(+)	550	8.59×10^{-5}	-1.43 ± 0.01	Coulometric titration
(−)Pt | Ti(III), Ti(II) || Pt(II) | Pt(+)	550	1.60×10^{-4}	-1.42 ± 0.02	Coulometric titration
(−)Pt | Ti(III), Ti(II) || Pt(II) | Pt(+)	600	8.26×10^{-5}	-1.43 ± 0.02	Coulometric titration
(−)Pt | Ti(III), Ti(II) || Pt(II) | Pt(+)	600	8.26×10^{-5}	-1.43 ± 0.02	Back titration
(−)Pt | Ti(III), Ti(II) || Ag(I) | Ag(+)	550	9.11×10^{-6}	-0.75 ± 0.01	Coulometric titration
(−)Cu | Ti(III), Ti(II) || Ag(I) | Ag(+)	550	3.49×10^{-4}	-0.75 ± 0.02	Coulometric titration

At the end of the titration, it was observed that immersion of the titanium rod back into the melt caused the color to revert back to green, presumably from the reaction

$$Ti + 2Ti(III) \rightarrow 3Ti(II).$$

Consequently, the potential of the platinum foil was measured against the reference electrode at successive times while the titanium rod was immersed in the argon-stirred melt, and a plot of cell potential vs. time again yielded a characteristic titration curve. The Ti(III)/Ti(II) potentials from this "back titration" procedure are also listed in Table III.

Menzies (5) has observed that the equilibrium for the above reaction lies to the right. The free energy change and equilibrium constant calculated for this reaction from the potential data, at 550 °C, are

$$\Delta G \text{ (kcal/mole)} \quad -13.4,$$
$$K_{eq} \quad 3.61 \times 10^{3}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Thus, the equilibrium does lie far to the right. The reaction Ti(III) + $e^- \rightarrow$ Ti(II) is electrochemically reversible.

Activity coefficients and partial molar free energies of solution for $TiCl_2$ and $TiCl_3$ were calculated from the potential data and are given in Table IV. Activity coefficients increase with temperature, but remain significantly less than unity. They are essentially constant over the concentration range studied. That for Ti(III) is considerably lower than the value for Ti(II); this is at variance with the conclusions of Menzies *et al.* (5) who found $(\gamma_{TiCl_2}/\gamma_{TiCl_3})_{500\,°C} = 2.7$.

TABLE IV

Activity coefficients and partial molal free energies of solution of titanium chlorides in the molten LiCl–KCl eutectic

Salt	Range of mole fraction ($\times 10^5$)	Activity coefficient (γ)		$\Delta\bar{G}_s$ (kcal/mole)	
		450 °C	550 °C	450 °C	550 °C
$TiCl_2$	5–50	0.5	0.8	−9.2	−0.46
$TiCl_3$	3–20	0.1	0.2	−2.8	−2.8

One explanation for low activity coefficients is found in the existence of complex species. Indeed, Gruen and McBeth (14) have spectroscopic evidence for Ti(III) chloride complexes in this melt at these temperatures. The more highly charged Ti(III) would be expected to be more extensively complexed than Ti(II).

The polarographic behavior of Ti(II) and Ti(III) in this melt at 550 °C is shown in Fig. 6. Polarograms (*b*) and (*c*) show waves for the oxidation of Ti(II) to Ti(III) for two concentrations of Ti(II). At a fixed potential, the polarographic currents for successive

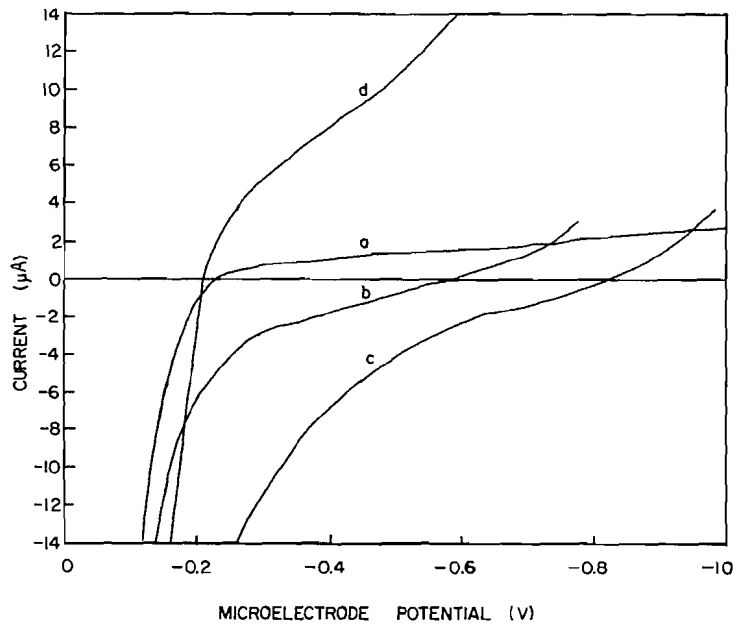

FIG. 6. Polarograms of Ti(II) and Ti(III) in LiCl–KCl eutectic at 550 °C. Pt(II)/Pt reference electrode; 2.10×10^{-3} mole fraction of Pt(II). (*a*) Residual current; (*b*) Ti(II) oxidation (4.3×10^{-5} mole fraction); (*c*) Ti(II) oxidation (8.6×10^{-5} mole fraction); (*d*) Pt(II) reduction, Ti(III) reduction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

additions of Ti(II) increased in magnitude, but no quantitative relation was observed because of the absence of well-defined plateaus. The potential at which the polarographic current attained the residual value became more negative as the Ti(II) concentration was increased.

Polarogram (*d*) in Fig. 6 shows the combined Pt(II) and Ti(III) reduction waves in solutions, prepared by coulometric titration of Ti(II) with Pt(II) beyond the end-point.

Polarographic waves for the reduction of Ti(II) to Ti(0) were not well defined or reproducible; the waves appeared at about -1.7 to -1.8 V. An approximate fit of the Ti(II) reduction waves to a linear plot of log $(i/(i_d - i))$ vs. E_{me} (where i is the current at any point on the wave, i_d is the limiting diffusion current, and E_{me} is the potential of the platinum microelectrode) was found. This is the sort of behavior expected if the reduced Ti(0) atoms diffuse into the platinum electrode. The oxidation waves fit neither this nor a log $(i_d - i)$ plot.

SYNTHESIS OF SOME ALPHA-SUBSTITUTED CYSTINES

R. J. THIBERT, J. F. G. DIEDERICH,* AND K. G. RUTHERFORD
Department of Chemistry, University of Windsor, Windsor, Ontario
Received July 14, 1964

ABSTRACT

The synthesis of α-ethyl-, α-*n*-propyl-, α-*n*-butyl-, and α-phenyl-DL-cystine via hydantoin intermediates is reported.

INTRODUCTION

Results in this laboratory on the reduction of α-methyl-DL-cystine at the dropping mercury electrode (1) have prompted further investigation into this area with other alpha-substituted cystines. It became of interest to study the steric effects of various groups in the alpha position of the cystine molecule on the half-wave potential, the diffusion current, the diffusion coefficient, and on the general shapes of the polarograms. Again, the metabolic behavior of alpha-substituted cystines and cysteines (which can be readily obtained from the corresponding cystines by reduction) should be of interest. Umbreit (2), for example, found that α-methyl-DL-glutamic acid is inert to dehydrogenation and transamination and inhibits glutamine breakdown. It has long been known, of course, that alpha-substituted amino acids such as alanine and valine are inert to metabolic reactions (2).

DISCUSSION OF EXPERIMENTAL RESULTS

Several attempts to prepare other alpha-substituted cystines in our laboratory by the Strecker route failed. However, the sequence shown here has proved quite successful for the synthesis of α-ethyl-, α-*n*-propyl-, α-*n*-butyl-, and α-phenyl-DL-cystine.

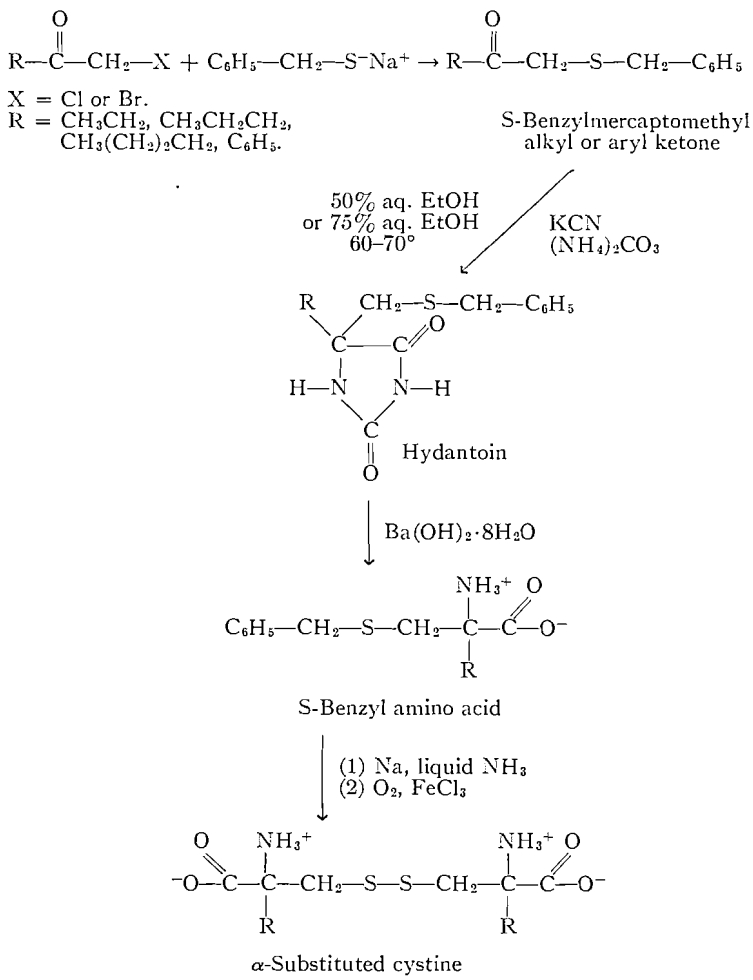
The only alpha-substituted cystine known to have been synthesized prior to this report is α-methyl-DL-cystine which was prepared by Arnstein (3) and simultaneously in this laboratory by Ottenbrite (4). The Strecker synthesis was employed in both cases. Stapleton and Swan (5) later synthesized this compound via the Bucherer-Bergs route, which involves the isolation of an intermediate hydantoin. α-Methyl-DL-cysteine hydrochloride was first reported by Connors and Ross (6). These authors reduced S-benzyl-α-methyl-DL-cysteine with sodium in liquid ammonia and isolated the final product under nitrogen. Potts (7) synthesized S-benzyl-α-methyl-DL-cysteine by the Bucherer-Bergs route but did not prepare the free mercapto-amino acid.

EXPERIMENTAL

The alpha-haloketones used as starting materials were prepared by methods previously described in the literature. 1-Bromo-2-butanone was obtained via the bromination of 2-butanone according to the procedure of Catch *et al.* (8). Both 1-chloro-2-pentanone and 1-chloro-2-hexanone were prepared by the method of Haworth (9), which involves the reaction of the appropriate acid chlorides with diazomethane followed by decomposition of the diazoketones with hydrochloric acid. Phenacyl chloride was obtained commercially.

The alpha-haloketones were condensed with the sodium salt of α-toluenethiol to yield the corresponding benzylmercaptomethyl ketones. Treatment of these ketones with potassium cyanide and ammonium carbonate in aqueous ethanol (50%) at 60–70° for several hours afforded good yields of the respective

**Taken in part from the thesis submitted by J. F. G. Diederich to the Faculty of Graduate Studies, University of Windsor, Windsor, in partial fulfillment of the requirements for the degree of Master of Science, October, 1963.*



hydantoins when R consisted of ethyl, *n*-propyl, and *n*-butyl groups. A much longer heating period (several days) and 75% alcohol were required for the preparation of the phenyl-substituted hydantoin.

Hydrolysis of the hydantoins with barium hydroxide afforded the S-benzyl amino acids. These compounds were then reduced with sodium in liquid ammonia to the corresponding sulfhydryl amino acids. Subsequent air oxidation of these latter compounds yielded the disulfides (cystines). This route then afforded α-ethyl-, α-*n*-propyl-, α-*n*-butyl-, and α-phenyl-DL-cystine in overall yields of 47%, 45%, 35%, and 31%, respectively, from the starting alpha-haloketones. It is interesting to note that Arnstein (3) obtained a 20% overall yield of α-methyl-DL-cystine via the Strecker route.

Analyses were performed by the Schwarzkopf Microanalytical Laboratory, 56–19 37th Avenue, Woodside 77, New York. Melting points are uncorrected. Some properties of all compounds prepared are presented in Table I.

Benzylmercaptomethyl Ketones

These compounds were prepared according to the procedure of Wahl (10). The preparation of benzylmercaptomethyl-*n*-propyl ketone is typical of the method used in the synthesis of ketones with R = ethyl, *n*-propyl, *n*-butyl, and phenyl. The sodium salt of α-toluenethiol was prepared by extracting α-toluenethiol (130 g, 1.05 mole) in ether (500 ml) with 10% sodium hydroxide solution (400 g). The mixture was shaken intermittently at room temperature for 2 h. The aqueous phase was then separated and heated at reflux temperature with 1-chloro-2-pentanone (60 g, 0.50 mole) overnight. The light-yellow top phase was washed with several 25 ml portions of water until it was free of chloride ions as tested by 10% silver nitrate solution. The heavy oil thus obtained (101 g) was dried over anhydrous sodium sulfate. Fractional distillation yielded benzylmercaptomethyl-*n*-propyl ketone as a colorless oil (93.5 g, 90%), b.p. 163–166° (9.5 mm).

*All compounds in the table, except for the two indicated, have not been reported in the literature.
†Prepared previously by Wahl (10).
‡Prepared previously by Long (12).
§Obtained as the disodium salt by a final precipitation at a pH of 7.5.
‖Purified by dissolution in hot 2 *N* hydrochloric acid, followed by filtration and precipitation at a pH of about 5 by concentrated ammonium hydroxide.

Benzylmercaptomethyl Alkyl Hydantoins

These compounds were prepared according to the method of Bucherer (11). The preparation of 5-benzylmercaptomethyl-5-*n*-propyl hydantoin is an example of the method used in the synthesis of the alkylated hydantoins. A mixture of benzylmercaptomethyl-*n*-propyl ketone (90 g, 0.43 mole), potassium cyanide (40 g, 0.61 mole), and ammonium carbonate (135 g, 1.40 mole) dissolved in 400 ml of 50% ethanol was heated in a 1 l, three-necked, round-bottomed flask (equipped with a condenser and mechanical stirrer) on a water bath at 60–70° for 7 h. The dark-yellow solution was allowed to partially evaporate overnight. The residue was then poured on crushed ice. The white precipitate was separated by filtration, washed with water and small quantities of ether, and dried in a vacuum dessicator. This procedure gave 52 g (97%) of hydantoin, m.p. 148–151°. After one crystallization from hot ethanol, white plates, m.p. 154°, were obtained.

Anal. Calcd. for $C_{14}H_{18}N_2O_2S$: C, 60.37; H, 6.51; N, 10.11; S, 11.51. Found: C, 60.50; H, 6.74; N, 10.17; S, 11.70.

5-Benzylmercaptomethyl-5-phenyl Hydantoin

The Bucherer-Bergs method described above was modified slightly, the reaction time was increased, and a higher percentage of ethanol was used.

A mixture of benzylmercaptomethyl phenyl ketone (125 g, 0.52 mole) and 1 500 ml of absolute ethanol was stirred at 60° until all the solid had dissolved. A solution of potassium cyanide (50 g, 0.77 mole) dissolved in 500 ml of water was added with stirring. Ammonium carbonate (300 g, 3.13 mole) was then added. A clear, light-yellow solution was obtained after this mixture had been stirred at 60–70° for about 20 h. This was allowed to react for another 28 h, decanted into a beaker, and allowed to stand at room temperature for several hours whereupon a white solid precipitated. This was recovered by filtration, m.p. 164–168°. The filtrate was poured on a mixture of ice and hydrochloric acid. The solid which separated was recovered by filtration.

All of the solid material obtained was crystallized from hot ethanol to yield 110 g of pure 5-benzylmercaptomethyl hydantoin, m.p. 175–176°. More hydantoin, 5 g, m.p. 175–176°, was recovered by partial evaporation of the combined filtrates. A total yield of 115 g (71%) of hydantoin, m.p. 175–176°, was thus obtained. Long (12) reported a melting point of 174° and a 90% yield.

Anal. Calcd. for $C_{17}H_{16}N_2O_2S$: C, 65.34; H, 5.17; N, 8.97; S, 10.27. Found: C, 65.61; H, 5.26; N, 8.63; S, 10.50.

*S-Benzyl-α-alkyl-*DL*-cysteines*

The preparation of S-benzyl-α-*n*-propyl-DL-cysteine is typical of the procedure used, where R = ethyl, *n*-propyl, or *n*-butyl.

A mixture of 5-benzylmercaptomethyl-5-*n*-propyl hydantoin (60 g, 0.27 mole), barium hydroxide (315 g, 1.0 mole) and 1 500 ml of water was heated at reflux temperature for 40 h in a 2 l round-bottomed flask. Barium was precipitated as barium carbonate at 100° using carbon dioxide generated from the reaction of marble chips with hydrochloric acid. The barium carbonate was separated by filtration and washed with boiling water and then acetone. When the filtrate was allowed to cool, unreacted hydantoin (13 g) precipitated and was removed by filtration. The filtrate was then allowed to evaporate at room temperature whereupon S-benzyl-α-*n*-propyl-DL-cysteine precipitated after several hours. It was separated by filtration and washed with small amounts of acetone. A crude yield of 72% (39 g), m.p. 218–220° (decomp.) was obtained. After the product was recrystallized from hot water, washed with acetone, and dried over phosphorous pentoxide in a vacuum dessicator, the melting point of the white powder was 229° (decomp.). The ninhydrin test gave a reddish-purple color.

Anal. Calcd. for $C_{13}H_{19}NO_2S$: C, 61.61; H, 7.56; N, 5.56; S, 12.65. Found: C, 61.47; H, 7.62; N, 5.56; S, 12.87.

*S-Benzyl-α-phenyl-*DL*-cysteine*

A mixture of 5-benzylmercaptomethyl-5-phenyl hydantoin (42 g, 0.13 mole), and 860 ml of water was heated at reflux temperature with stirring. Only part of the hydantoin dissolved. After a reaction time of 7 days a large quantity of a white solid appeared in the reaction flask. This was recovered by filtration. The barium in the filtrate was precipitated as barium carbonate and was separated by filtration. The filtrate was partially evaporated on a hot plate whereupon some S-benzyl-α-phenyl-DL-cysteine precipitated. This was separated by filtration and washed with acetone, m.p. 236–240° (decomp.). However, only a few grams of material were obtained in this manner. The solid removed previously from the reaction flask was added with stirring into 3 l of boiling water. Carbon dioxide was then passed into the mixture to precipitate barium as barium carbonate. The latter was then removed by filtration. Evaporation of the filtrate yielded a few grams of desired product, m.p. 235–239° (decomp.). Most of the amino acid was apparently adsorbed to the barium carbonate. This could be recovered by stirring the mixture of inorganic and organic materials with several 3 l quantities of boiling water, followed by filtration and evaporation of the filtrate. This process yielded a total of 30.5 g (79%) of the cysteine, m.p. 236–240° (decomp.).

The cysteine is very insoluble in hot water. In order to purify it, it was dissolved in 3 *N* sulfuric acid. Insoluble impurities were removed by filtration. Dropwise addition of concentrated ammonium hydroxide caused the amino acid to precipitate. Precipitation began at about pH 2. The final pH was 5. The material melted at 242–243° (decomp.).

α-Alkyl Cystines

A method used by Arnstein (3) and Wood and du Vigneaud (13) was followed with slight modifications. The preparation of α-*n*-propyl-DL-cystine is typical of the procedure used. Sodium metal (7.5 g, 0.33 mole), cut into small pieces and freshly dried S-benzyl-α-*n*-propyl-DL-cysteine (25 g, 0.077 mole) were added alternatively in small amounts with stirring to about 500 ml of liquid ammonia over a period of 30 min. After 1 h the blue color of the mixture was discharged with 3 g of ammonium chloride. The reaction mixture was left at room temperature overnight to allow the ammonia to evaporate. The white paste which remained was dissolved in 350 ml of cold water. The insoluble material was removed by filtration. The filtrate was then extracted with 35 ml of ether. The pH of the filtrate was adjusted to 7.5 with concentrated hydrochloric acid and a trace (about 5 mg) of ferric chloride was added. The dark-violet solution was aerated for 30 h. After this period no sulfhydryl groups were present as tested by sodium nitroprusside. The pH was then adjusted to 6. When this solution was evaporated on a steam bath to a volume of about 200 ml the α-*n*-propyl-DL-cystine precipitated as a yellow, amorphous powder. After recrystallization from boiling water which contained a small amount of decolorizing charcoal, a white solid was obtained, m.p. 260° (decomp.). The melting point was found to vary with variation in rate of heating. A yield of 11.6 g (72%) was obtained.

AN ELECTRON IMPACT STUDY OF SOME C_8H_{10} ISOMERS

F. MEYER, P. HAYNES,[1] STEWART MCLEAN, AND A. G. HARRISON[2]
Department of Chemistry, University of Toronto, Toronto, Ontario

Received August 4, 1964

ABSTRACT

The mass spectra of 1-, 2-, and 6-methylspiro[2.4]hepta-1,3-diene have been measured and found to be very similar to the spectra of 7-methylcycloheptatriene and the isomeric alkyl benzenes. It is concluded that in all cases the major part of the fragmentation occurs by identical paths involving identical intermediates. This conclusion is supported by deuterium labelling and appearance potential data. On the other hand the mass spectrum of 2,5-dimethyl-1,5-hexadien-3-yne, an acyclic C_8H_{10} isomer, shows a number of significant differences in its fragmentation pattern. These differences are reflected in the energetics of ion formation and it is concluded that in this case the fragmentation proceeds through different intermediates.

INTRODUCTION

It was pointed out recently (1, 2) that the mass spectra of a number of C_7H_8 isomers are very similar and this was explained by the assumption that all compounds decompose largely via a common intermediate, probably a seven-membered ring. The C_7H_8 isomers included toluene and cycloheptatriene (1), bicyclo[2.2.1]hepta-2,5-diene, spiro[2.4]hepta-1,3-diene, 1- and 3-ethinylcyclopentene, and quadricyclene (3). More recently the mass spectrum of bicycylo[3.2.0]hepta-2,6-diene has been recorded (4) and is again very similar. Extensive deuterium labelling has supported the assumption of a symmetrical seven-membered ring intermediate, presumably the tropylium ion (5).

We report now the mass spectra of a number of methyl-substituted analogues of these compounds, the C_8H_{10} isomers. The mass spectra of 1-, 2-, and 6-methylspiro[2.4]hepta-1,3-diene (I, II, III) have been compared with three other C_8H_{10} compounds: 7-methylcycloheptatriene, *m*-xylene, and an acyclic compound 2,5-dimethylhexa-1,5-dien-3-yne (IV). The spectra of the 1- and 2-methyl spiro compounds are identical while the 6-methyl compound shows only minor differences. The spectra of the methyl-substituted spiroheptadienes are very similar to the spectra of the xylenes and methylcycloheptatriene. Furthermore the spectra of the deuterium-labelled methylspiroheptadienes show extensive hydrogen-deuterium scrambling in the formation of $C_8H_9^+$ and $C_7H_7^+$, similar to the results reported previously for *p*-xylene (6). On the other hand the spectrum of the acyclic isomer, 2,5-dimethyl-1,5-hexadien-3-yne, differs significantly from the spectra of the other C_8H_{10} isomers and these differences are reflected in the energetics of formation of the $C_8H_9^+$ and $C_7H_7^+$ fragments.

The further decomposition of the $C_8H_9^+$ ion is shown from deuterium labelling in the methylspiroheptadienes and methylethylbenzene to involve complete scrambling of all hydrogens.

EXPERIMENTAL

All mass spectra were obtained with an A.E.I. MS-2 mass spectrometer which has been described previously (7). Mass spectra were recorded at 50 V electron energy, 20 μA ionizing current, and a repeller voltage of 3 V (7 V/cm). Appearance potentials were measured as described previously (8) using xenon to calibrate the voltage scale.

1-(I) and 2-(II)Methylspiro[2.4]hepta-1,3-diene

The synthesis of these compounds by the reaction of 1,2-dibromoethane with sodium methylcyclopentadienide in the presence of sodium amide in liquid ammonia is described elsewhere (9).

1- and 2-Methylspiro[2.4]hepta-1,3-diene-6,6,7,7-d_4

These were synthesized in the same way using 1,2-dibromoethane-d_4.

1- and 2-Methyl-d_3-spiro[2.4]hepta-1,3-diene

These were prepared by the reaction in liquid ammonia of 1,2-dibromoethane with sodium methyl-d_3-cyclopentadienide which had been prepared *in situ* by treatment of sodium cyclopentadienide with bromomethane-d_3 and then sodium amide.

6-Methylspiro[2.4]hepta-1,3-diene (III)

6-Methylspiro[2.4]hepta-1,3-diene (III) was synthesized from sodium cyclopentadienide and 1,2-dibromopropane by the procedure described for I and II (9). The product, retention time 1.65 (relative to spiroheptadiene = 1.00 (9)), $\lambda\lambda_{max}^{MeOH}$ 257, 227 mμ, formed an N-phenylmaleimide adduct, m.p. 170–171 (sealed tube). (Found: C, 77.31; H, 6.03; N, 5.13. $C_{18}H_{17}O_2N$ requires C, 77.39; H, 6.13; N, 5.01.)

2,5-Dimethyl-1,5-hexadien-3-yne(IV)

2,5-Dimethyl-1,5-hexadien-3-yne(IV) was prepared from 2,5-dihydroxy-2,5-dimethyl-3-hexyne by Nazarov's method (10). Purification of the yellow product by gas–liquid chromatography led to the isolation of its principal component as a *colorless* liquid, $\lambda\lambda_{max}^{heptane}$ 250 mμ (ϵ 14 250), 233 mμ (shoulder, ϵ 11 800), 262 mμ (shoulder, ϵ 12 100), which showed absorption at 1 613 and 895 cm^{-1} in the infrared and a complex multiplet (at least 10 narrowly spaced lines) centered at 4.78 τ (area 2) and a narrowly spaced multiplet (at least 3 lines) at 8.12 τ (area 3) in the nuclear magnetic resonance (n.m.r.) spectrum. The material rapidly became an intensely yellow oil on standing in air.

7-Methylcyclohepta-1,3,5-triene

7-Methylcyclohepta-1,3,5-triene was very kindly supplied by Mr. R. B. Medz and Professor H. J. Dauben, Jr. of the University of Washington.

Compounds used in the present study were purified by gas–liquid chromatography using a 9 ft. $\times$ $\frac{1}{4}$ in. column of 20% MEEE($(MeOCH_2CH_2OCH_2CH_2)_2O$) on Chromosorb P (60–80 mesh), typically at 75 °C with 80 ml/min helium as carrier gas.

RESULTS AND DISCUSSION

Table I shows the major peaks in the spectra of six C_8H_{10} isomers expressed as percentage of total ionization. The peaks shown account for approximately 85% of the total ionization.

The mass spectrum of 1-methylspiro[2.4]hepta-1,3-diene was found to be identical with the spectrum of the 2-methyl isomer, while the only significant difference in the spectrum of the 6-methyl isomer is the higher intensity for $m/e = 78$ (parent-28). This higher intensity may correspond to the simple loss of $CH_3CH\langle$ from the 6-methyl isomer, a fragmentation which is not possible for the other isomers without rearrangement. The spectra of the spiro compounds bear a very close resemblance to the spectra of 7-methylcycloheptatriene and the C_8H_{10} alkylbenzene isomers, of which *m*-xylene has been chosen as representative. On the other hand the spectrum of the acyclic isomer shows a greatly reduced parent-CH_3 ($m/e = 91$) intensity and an increased $C_5H_5^+$ ($m/e = 65$) intensity. The close similarity of the spectra of the monocyclic and spiro isomers suggests that for these isomers fragmentation occurs by common paths involving common intermediates. The same fragmentation paths undoubtedly apply for the acyclic isomer as well; however, the intermediates formed in this case have different structures.

For all compounds the same metastable transitions were observed (Table II), indicating the same fragmentation paths. The major decomposition path is the sequence [1]:

[1] $$C_8H_{10}^+ \rightarrow CH_3 + C_7H_7^+ \rightarrow C_2H_2 + C_5H_5^+ \rightarrow C_2H_2 + C_3H_3^+$$

TABLE II

Metastables in C_8H_{10} compounds

Reaction	Metastable
$105^+ \rightarrow 103^+ + 2$	101.0
$106^+ \rightarrow 91^+ + 15$	78.1
$105^+ \rightarrow 79^+ + 26$	59.4
$105^+ \rightarrow 78^+ + 27$	57.9*
$106^+ \rightarrow 78^+ + 28$	57.4
$91^+ \rightarrow 65^+ + 26$	46.4
$65^+ \rightarrow 39^+ + 26$	23.5

*Only one metastable observed.

A second minor path proceeds through the $C_8H_9^+$ ion to form ions in the C_6 and C_4 region. In addition several other minor paths are possible, such as that suggested above for formation of $m/e = 78$ in 6-methylspiroheptadiene.

Table III records the appearance potentials of the $C_8H_{10}^+$, $C_8H_9^+$, and $C_7H_7^+$ ions from seven C_8H_{10} isomers in addition to the appearance potential of $C_8H_9^+$ from *p*-ethyl

TABLE III

Appearance potentials and heats of formation of $C_8H_{10}^+$, $C_8H_9^+$, and $C_7H_7^+$

Compound	Appearance potential (±0.1 eV)			ΔH_f (kcal/mole)		
	$C_8H_{10}^+$	$C_8H_9^+$	$C_7H_7^+$	$C_8H_{10}^+$	$C_8H_9^+$	$C_7H_7^+$

toluene. The last three columns show the ionic heats of formation calculated from these data. The heats of formation for several of the isomers are not known and were estimated as outlined in a later section. For the cyclic isomers the appearance potential data are consistent with the spectral intensities given in Table I. Thus *m*-xylene has the highest parent ion intensity, as would be predicted since the activation energy (A(fragment) − A(molecule ion)) for further fragmentation is highest in this case. The high parent ion intensity for 2,5-dimethyl-1,5-hexadien-3-yne cannot be explained in this fashion since the activation energy for further fragmentation is lower than for any other compound studied. If fragmentation occurred through the same intermediates, one might well expect the lowest parent ion intensity for the acyclic isomer.

The $\Delta H_f(C_7H_7^+)$ from the spiroheptadienes, methylcycloheptatriene, xylene, and ethylbenzene all lead to a value of 237 ± 3 kcal/mole, suggesting that in all cases the same ion is formed through the same intermediate. For ethylbenzene, deuterium labelling (11) strongly suggests a tropylium ion structure for the $C_7H_7^+$ ion. The identity of the heat of formation suggests a tropylium structure for the $C_7H_7^+$ ion from the other isomers as well. However, in all cases the ion must be formed with excess energy, since the true heat of formation for a tropylium ion is probably considerably lower (12). The excess energy may be viewed as the energy required to raise the molecule to an excited ionized state capable of dissociating to give the cyclic $C_7H_7^+$. For 2,5-dimethyl-1,5-hexadien-3-yne a much higher value for $\Delta H_f(C_7H_7^+)$ = 278 kcal/mole is obtained. This suggests either a different (acyclic) structure or a more complicated rearrangement to form the cyclic $C_7H_7^+$ ion which requires a greater excess energy. In the absence of labelling evidence a definite conclusion cannot be reached although the former appears more likely. In any event it is evident that the fragmentation does not proceed through the same intermediate ionic state in this case.

Although the appearance potential data for the $C_7H_7^+$ ion serve to point out the similar behavior of the cyclic compounds and the rather striking difference for the acyclic isomer, the data for the $C_8H_9^+$ ion are much less clear-cut. As shown by the data in Table III the appearance potential of $C_8H_9^+$ from 1- and 2-methylspiroheptadiene, ethylbenzene, and *m*-xylene lead to $\Delta H_f(C_8H_9^+)$ = 220–225 kcal/mole, in agreement with values in this same range obtained from appearance potential measurements in the xylenes (7), the diethylbenzenes (13), the methyl-*n*-propylbenzenes (13), and *p*-ethyltoluene. On the other hand $A(C_8H_9^+)$ from 6-methylspiroheptadiene and 7-methylcycloheptatriene give a $\Delta H_f(C_8H_9^+)$ = 239–240 kcal/mole, in agreement with a value of 236 kcal/mole reported for $C_8H_9^+$ from mesitylene (13). Both these sets are much higher than the value of 202 ± 3 kcal/mole derived from the directly measured ionization potentials of the xylyl radicals (14) and from the appearance potential of $C_8H_9^+$ from the xylylbromides (7). In the latter case it was suggested, from the absence of observable substituent orientation effects, that the $C_8H_9^+$ ion had the methyltropylium structure. If such is the case the $C_8H_9^+$ formed by dissociation of the alkylbenzenes and spiroheptadienes must be formed with excess energy which, in contrast with the results for $C_7H_7^+$ formation, varies with the compound studied.

The appearance potential of $C_8H_9^+$ from 2,5-dimethyl-1,5-hexadien-3-yne leads to $\Delta H_f(C_8H_9^+)$ = 252 kcal/mole. One would expect this to correspond to an acyclic ion and the heat of formation is indeed considerably higher than that obtained from any of the cyclic isomers. However, since the total spread in values for $\Delta H_f(C_8H_9^+)$ is rather large it is probably premature to reach any definite conclusions in the absence of more conclusive evidence.

The similarity in behavior of the spiro compounds and the alkylbenzenes upon electron

impact is shown further by comparison of the spectra of deuterium labelled methylspiroheptadienes and labelled alkylbenzenes (particularly *p*-xylene (6)). Two deuterium-labelled spiro compounds methyl-d_3-spiroheptadiene and methylspiroheptadiene-6,6,7,7-d_4 were studied. In both cases spectra were obtained for mixtures of the 1- and 2-methyl-substituted isomers. Partial mass spectra in the C_8 and C_7 region are given in Table IV. The spectra are corrected for naturally occurring ^{13}C.

TABLE IV

Partial mass sepctra of 1- and 2-methylspiroheptadienes

103	7.10			89	2.00	0.99	

The C_8 region is formed from the parent ion with essentially complete scrambling of the deuterium and hydrogen just as in *p*-xylene (6). There is a preference for loss of H over loss of D, probably due to an isotope effect. The loss of D compared with the total loss of hydrogen and deuterium from the parent is 26% and 32% in the d_3- and the d_4-compound respectively compared with calculated percentages of 30% and 40% assuming complete scrambling and no isotope effect. The ratios are corrected for a small contribution for loss of H_2 which gives a peak at the same mass as loss of deuterium.

As is the case for *p*-xylene (6), the loss of methyl from the methylspiroheptadienes is a very complicated process as shown by the large intensities at *m/e* 91 to 94 in the d_3-compound and 92 to 95 in the d_4-compound. The labelling results clearly are not in accord with a simple loss of the CH_3 group and indeed they cannot be explained by any simple fragmentation scheme. Low energy scans in the C_7 region for the methylspiroheptadiene-d_4 suggested that there is more than one process for the loss of methyl from the parent ion. With lower energy the intensity at *m/e* = 95 ($C_7H_3D_4^+$) decreases with respect to 92, 93, and 94. It is interesting to note that although the 95 peak corresponds to straight loss of the original methyl group and is the biggest peak in the spectrum; it is energetically the least favored process for loss of methyl. Combining the data at 50 V for the two deuterated spectra the percentages given in Table V can be assigned to the loss of CH_3 containing hydrogen from different parts of the molecule. H_m stands for hydrogen from the original methyl group, H_r for hydrogen from the five-membered ring, and H_s for hydrogen from the three-membered ring. The solution is given between two limiting values because it was not possible to solve the equations completely. $CH_mH_rH_s + CH_rH_rH_s = 2.56\%$ and this gives the limits $CH_mH_rH_s = 2.56\%$ and $CH_rH_rH_s = 2.56\%$. Because there are probably different processes with slightly different energy requirements it is not possible to propose any general reaction mechanism but it might be noted that the results indicate a high degree of mixing of the methyl hydrogens and three-membered ring hydrogens ($CH_mH_sH_s$ and $CH_mH_mH_s$).

As mentioned previously the structure of the $C_8H_9^+$ ion is not certain. A methyl-substituted tropylium structure has been proposed for the $C_8H_9^+$ ion formed by dissociative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

TABLE V

Loss of methyl from 1- and 2-methylspiroheptadiene between two limiting values

Methyl group	% loss	Methyl group	% loss
$CH_mH_mH_m$	49.40–49.40	$CH_mH_rH_s$	0–2.56
$CH_mH_sH_s$	10.15–7.60	$CH_rH_rH_s$	2.56–0
$CH_rH_sH_s$	13.45–16.00	$CH_mH_rH_r$	0–0
$CH_mH_mH_s$	10.91–10.91	$CH_mH_mH_r$	0–0
$CH_sH_sH_s$	13.53–13.53	$CH_rH_rH_r$	0–0

ionization of the xylylbromides (7), based on the lack of effects due to substituent orientation. Labelling studies (15) on the loss of methyl from *p*-methylethylbenzene are also best explained on the assumption of a methyltropylium structure for the $C_8H_9^+$ ion. However, the results obtained for the further decomposition of the $C_8H_9^+$ ion, both in this work and in previous studies (5), cannot be reconciled with a simple methyltropylium structure for those $C_8H_9^+$ ions which undergo further frgamentation.

The $C_8H_9^+$ ion loses C_2H_2 to form the $C_6H_7^+$ ion which further loses H_2 to form $C_6H_5^+$ as shown from the metastable peaks at 59.4 and 75.1 corresponding to reactions [2] and [3] respectively.

[2] $$C_8H_9^+ \rightarrow C_6H_7^+ + C_2H_2$$

[3] $$C_6H_7^+ \rightarrow C_6H_5^+ + H_2.$$

These decomposition paths have been observed previously for *p*-xylene (6) and ethylbenzene (16) and it was observed that essentially complete scrambling of the hydrogens in $C_8H_9^+$ occurred in the formation of the C_6 ions. Similar results have been obtained for the labelled methylspiroheptadienes in the present work. Table VI compares the measured intensities in the C_6 region of the labelled methylspiroheptadienes with the intensities calculated assuming complete loss of identity in the precursor $C_8H_9^+$ ion (or deuterated equivalent). The reasonable agreement between measured and calculated intensities indicates that the assumption of complete scrambling is valid and further indicates the similarity of behavior upon electron impact of the spiro compounds and the isomeric alkyl benzenes.

TABLE VI

Mass spectra in the C_6 region for methylspiroheptadienes

In the spectrum of *p*-methylethylbenzene, $C_8H_9^+$ forms the base peak. In the fragmentation forming this ion, loss of both the α-methyl and the β-methyl occurs in the ratio 1:5 as was shown from the spectra of methylethylbenzene-α-methyl-d_3 and -β-methyl-d_3 (15). Both reactions have the same energy requirements and it was concluded that the $C_8H_9^+$ has the same structure in both cases. The mechanism for this reaction is discussed elsewhere (15).

In the spectra of the two deuterated methylethylbenzenes, $C_8H_9^+$ and $C_8H_6D_3^+$ ions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

are formed which further fragment to form the C_6 ions. In *p*-methyl-d_3-ethylbenzene, metastable peaks for reactions [4], [5], and [6] are observed.

[4] $C_8H_6D_3^+ \rightarrow C_6H_4D_3^+ + C_2H_2$, metastable 62.3

[5] $C_8H_6D_3^+ \rightarrow C_6H_5D_2^+ + C_2HD$, metastable 60.8

[6] $C_8H_6D_3^+ \rightarrow C_6H_6D^+ + C_2D_2$, metastable 59.4.

The metastable peak at mass 59.4 also corresponds to reaction [2]. In *p*-methylethyl-β,β,β-d_3-benzene only the metastable peak at 59.4 was observed because of the much lower intensity of the $C_8H_6D_3^+$ ion. Calculations based on complete scrambling of the hydrogen and deuterium atoms in $C_8H_6D_3^+$ in forming the C_6 region are in reasonable agreement with the measured intensities as shown in Table VII. In Table VII are given also the major peaks in the spectra of the two deuterated methylethylbenzenes and the corresponding intensities in methylethylbenzene-d_0.

TABLE VII

Partial mass spectra of *p*-methylethylbenzenes

		Methylethylbenzene						Methylethylbenzene			
		Methyl-d_3		Ethyl-β,β,β-d_3				Methyl-d_3		Ethyl-β,β,β-d_3	
Mass	d_0	Meas.	Calcd.	Meas.	Calcd.	Mass	d_0	Meas.	Calcd.	Meas.	Calcd.
123		38.8		35.5		80		3.25	3.52	1.35	0.68
120	36.9					79	10.50	7.86	7.12	8.47	8.45
108		100.0		20.0		78	4.23	4.66	4.58	4.51	3.70
105	120.0	18.9		100.0		77	14.49	3.74	2.78	9.04	10.27
82		2.90	3.16	0.70	0.61	76	0.83	0.48	0.18	0.68	0.58
81		4.13	4.53	1.20	0.87						

The above evidence indicates that, for those $C_8H_9^+$ ions which have sufficient internal energy to undergo further decomposition, a simple methyltropylium structure is not adequate since all hydrogens and also all carbons (6) become equivalent. It is possible to accommodate the results by postulating a number of isomerizations from a tropylium to a benzyl structure accompanied by hydrogen shifts or alternatively by expansion to an eight-membered ring with a number of intramolecular hydrogen shifts before decomposition.

Estimation of Heats of Formation

ΔH_f(7-mecylcoheptatriene) has been previously estimated (12) to be 37.2 kcal/mole using Franklin's group equivalent method (17). By the same method ΔH_f(spiro[2.4]-hepta1,3-diene) can be calculated as follows using ΔH_f(cyclo-C_5H_6) = 31.9 kcal/mole (18). ΔH_f(spiroheptadiene) = ΔH_f(cyclo-C_5H_6) − ΔH_f(—CH_2—) + ΔH_f(—$\overset{|}{\underset{|}{C}}$—) + $2\Delta H_f$(—CH_2—) + (correction for cyclopropane ring) = 52.0 kcal/mole. In a similar manner values of 44.1 kcal/mole and 45.4 kcal/mole for the 1- and 2-methyl- and the 6-methylspiroheptadienes were obtained. By Franklin's method ΔH_f(2,5-dimethyl-1,5-hexadien-3-yne) = 68.2 kcal/mole. The heats of formation of *m*-xylene, ethylbenzene, and *p*-methylethylbenzene necessary for the calculations of Table III were taken from the literature (18).

FORMATION DES DÉRIVÉS PENTAFLUOROSULFURES ÉTHYLÈNIQUES, DIÈNIQUES ET ACÉTYLÈNIQUES

MÉÜDE TREMBLAY
Centre Canadien de Recherches et Perfectionnement des Armes (CARDE) Québec, Québec

Reçu le 12 août 1964

ABSTRACT

The reaction of disulfur decafluoride with olefins, dienes, and acetylenes has been studied under pressure at 125–140 °C. The gases formed have been separated and identified with a gas chromatograph coupled to a time-of-flight mass spectrometer. Liquid pentafluorosulphur derivatives, studied by mass spectrometry, were attributed the following structures: $CH_2FCHClSF_5$, $CH_2FCHBrSF_5$, $CH_2FCHBrCH_2CHBrSF_5$, $CH_2FCHFCH_2CHFSF_5$, and $CH_2{=}CHCHFCH_2SF_5$. Addition compounds of dienes or acetylenes have structures assumed to be $FCH_2CF_2CH_2SF_5$ from propadiene and $C_2H_5CF_2CHFSF_5$ from ethyl acetylene.

RÉSUMÉ

Nous avons étudié la réaction du décafluorobisulfure (S_2F_{10}) avec les oléfines, les dièns et les acétylènes sous pression à 125–140 °C. Nous avons séparé les gaz formés par chromatographie gazeuse et les avons identifiés à l'aide d'un spectrographe de masse à temps de vol. Nous avons aussi isolé les liquides formés, qui étaient des dérivés pentafluorosulfures monosubstitués. L'étude de leur structure au moyen de la spectrographie de masse suggère que nous avons obtenu les composés suivants: $CH_2FCHClSF_5$, $CH_2FCHBrSF_5$, $CH_2FCHBrCH_2$-$CHBrSF_5$, $CH_2FCHFCH_2CHFSF_5$ et $CH_2{=}CHCHFCH_2SF_5$. A partir des dièns et des acétylènes, nous croyons avoir isolé les composés de structures suivantes: $FCH_2CF_2CH_2SF_5$ du propadiène et $C_2H_5CF_2CHFSF_5$ de l'éthylacétylène.

INTRODUCTION

Récemment, Roberts (1) a signalé l'addition du S_2F_{10} sur les oléfines. Les rendements obtenus étaient faibles. Nous nous sommes proposés d'étudier les conditions expérimentales, l'influence du substituant sur le carbone non saturé et la structure du composé d'addition. La formation de radicaux $\cdot SF_5$ à partir de S_2F_{10} a lieu sous l'action des rayons ultraviolets ou par décomposition catalytique à 150 °C. Nous avons choisi la méthode catalytique où S_2F_{10} est chauffé sous pression en présence des éthylènes, dièns ou acétylènes. Dans ces conditions, S_2F_{10} forme en premier lieu des radicaux $\cdot SF_5$ qui se décomposent rapidement en SF_4 et SF_6 (2). Ces mêmes radicaux SF_5 peuvent réagir avec les composés non saturés pour donner des produits fluorés gazeux, tel CH_2FCHF_2 isolé dans les gaz ou des produits d'oxydation comme SO_2F_2. Et, enfin, nous obtenons des dérivés pentafluorosulfures liquides qui sont partiellement ou totalement fluorés:

$$\rangle C{=}C\langle + S_2F_{10} \rightarrow \rangle \underset{\displaystyle SF_5}{\overset{\displaystyle |}{C}}{-}CF\langle$$

DISCUSSION

1. Réaction de S_2F_{10} avec les éthylènes

La réaction de S_2F_{10} avec les éthylènes substitués démontre que la liaison S—S est très faible (3), et qu'il y a rupture facile pour former des radicaux libres $\cdot SF_5$. La masse obtenue à 175 ($CHClSF_5$) dans le cas du dérivé SF_5 du chlorure de vinyle nous porte à croire que le radical $\cdot SF_5$ attaque plus aisément le centre électropositif du chlorure de vinyle,

$$\cdot SF_5 + CH_2{=}CHCl \rightarrow \cdot CH_2CHClSF_5,$$

ou que le groupe pentafluorosulfure est plus stable lorsque substitué sur un carbone déjà porteur d'halogène. Le produit isolé se formerait par décomposition du produit bisubstitué.

$$SF_5CH_2CHClSF_5 \rightarrow CH_2FCHClSF_5 + SF_4.$$

En plus d'isoler des produits partiellement fluorés, le radical $\cdot CH_2CHClSF_5$ peut ajouter une deuxième molécule d'halogénure de vinyle.

$$\cdot CH_2CHClSF_5 + CH_2{=}CHCl \rightarrow \cdot CH_2CHClCH_2CHClSF_5$$

$$\cdot CH_2CHClCH_2CHClSF_5 + \cdot SF_5 \rightarrow FCH_2CHClCH_2CHClSF_5 + SF_4.$$

En présence du radical $\cdot SF_5$, les halogénures de vinyle ont tendance à se polymériser. D'où la possibilité d'isoler un grand nombre de produits lorsque l'halogénure de vinyle est en excès. Il peut même y avoir substitution du brome ou du chlore par le fluor, pour former des vinyles fluorés, tel CH_2FCHF_2 isolé dans les gaz. Nous avons même retrouvé $ClSF_5$ à partir du chlorure de vinyle et de S_2F_{10}.

$$CH_2{=}CHCl + 4\cdot SF_5 \rightarrow CH_2FCHF_2 + ClSF_5 + 3SF_4.$$

La réaction du bromure de vinyle et de S_2F_{10} donne le 1,1,2-trifluoroéthane de la même façon. Cependant, le bromure de pentafluorosulfure qui est connu (4) n'a pas été isolé. Le fluorure de vinyle réagit avec S_2F_{10} pour donner aussi CH_2FCHF_2, ce qui indiquerait la décomposition rapide des dérivés pentafluorosulfures des halogénures de vinyle à la température de la réaction:

$$SF_5CH_2CHFSF_5 \rightarrow CH_2FCHF_2 + 2SF_4.$$

Les produits liquides obtenus sont donnés dans le Tableau I. A partir de S_2F_{10} et du chlorure de vinyle, un seul produit liquide partiellement fluoré a été isolé, i.e., $CH_2FCHClSF_5$. L'ion moléculaire dans le spectre de masse de ce produit n'est pas visible à la masse 208, mais les fragments suivants sont visibles: FCH_2CHCl, CH_2F, SF_5ClCH, Cl et SF_5. Le dérivé bisubstitué est possible et a été préparé par H. L. Roberts (1) qui lui a attribué la structure suivante: $F_5SCHClCH_2SF_5$. Il ne se forme pas dans les conditions expérimentales employées ici ou encore se décompose à la température de la réaction.

TABLEAU I

Dérivés pentafluorosulfurés (S_2F_{10}, 0.1 mole)

Réactifs				Temps de rétention sur le Prep-Partitioner à 80 °C (min)
Formule	Mole	Temp. (°C)	Structure proposée	
$CH_2{=}CHCl$	0.2	125–140	$CH_2FCHClSF_5$	67
$CH_2{=}CHBr$	0.3	125–140	$CH_2FCHBrSF_5$	38
			$CHF_2CHBrCH_2CHBrSF_5$	146
$CH_2{=}CHF$	0.3	140–150	$CH_2FCHFCH_2CHFSF_5$	27
			$CH_2{=}CHCH_2CHFSF_5$	43
$CH_2{=}C{=}CH_2$	0.3	125	$FCH_2CF_2CH_2SF_5$	8
$C_2H_5C{\equiv}CH$	0.3	125	$C_2H_5CF_2CHFSF_5$	28

Du bromure de vinyle et S_2F_{10}, nous avons isolé deux produits liquides: $CH_2FCHBrSF_5$ et $CH_2FCHBrCH_2CHBrSF_5$. L'ion moléculaire du premier n'est pas visible dans le spectre de masse, mais plusieurs fragments ont été identifiés, CH_2FCHBr, $CH_2CHBrSF_5$, CH_2CHBr, SF_5, etc. La masse 360 du deuxième composé qui est l'ion moléculaire a été identifiée ainsi que nombre de fragments: CH_2F, CH_2FCHBr, $CH_2CHBrSF_5$, $CH_2FCHCH_2CHBrSF_5$, SF_5, etc.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Le fluorure de vinyle et le S_2F_{10} donnent les produits liquides suivants: $CH_2FCHFCH_2$-$CHFSF_5$ et $CH_2{=}CHCH_2CHFSF_5$. Le premier est le dimère du fluorure de vinyle sur lequel s'est ajouté un groupe pentafluorosulfure et un fluor. Le second produit serait peut-être formé du précédent par défluoruration dans la colonne chromatographique du Prep-Partitioner. Une troisième fraction a été isolée mais n'a pas pu être identifiée d'après son spectre de masse.

La réaction de l'éthylène avec S_2F_{10} donne de grandes quantités de carbone et d'acide fluorhydrique et aucun produit d'addition.

2. Réaction avec les dienes

L'action du pentafluorobisulfure sur le propadiène, l'isoprène et le chloroprène sous pression à 125–150 °C a été étudiée. Nous avons trouvé que la température de réaction est très critique, alors qu'entre 125 et 140 °C, il se produit une polymérisation rapide en présence des radicaux libres $\cdot SF_5$ et formation d'huiles ou gommes contenant des groupes SF_5. Il se produit même dans certains cas formation de carbone et d'acide fluorhydrique. Les systèmes conjugués, tels que le chloroprène et l'isoprène, ont montré plus de tendance à se polymériser qu'à ajouter des groupes pentafluorosulfures sur les carbones 1 et 4. Le propadiène, qui possède deux doubles liaisons accumulées, a moins de tendance à se polymériser et nous avons pu isoler en trace un dérivé pentafluorosulfure. Selon toute apparence, ce dérivé se formerait de la façon suivante par l'attaque du carbone 1 et 2

$$CH_2{=}C{=}CH_2 + 2\cdot SF_5 \rightarrow CH_2{=}CFCH_2SF_5 + SF_4$$
$$CH_2{=}CFCH_2SF_5 + 2\cdot SF_5 \rightarrow CH_2FCF_2CH_2SF_5 + 2SF_4.$$

La structure ci-dessus la plus probable est en accord avec le spectre de masse qui montre une masse de 205 très intense et attribuable à l'ion $CH_2CF_2CH_2SF_5$.

3. Dérivés acétylèniques

La réaction de S_2F_{10} avec les acétylènes donne plus facilement des produits d'addition. De plus, la réactivité des acétylènes substitués croît dans l'ordre suivant:

$$H < CH_3 < C_2H_5 < C_3H_7.$$

L'acétylène non substitué donnerait le dérivé le plus intéressant ($SF_5CH{=}CHSF_5$), mais l'acétylène est décomposé en carbone. C'est pourquoi notre attention s'est portée surtout sur les dérivés méthylés et éthylés.

L'étude du spectre de masse du produit obtenu à partir de l'éthylacétylène et S_2F_{10} montre que le dérivé fluoré, $C_2H_5CF_2CHFSF_5$ de poids moléculaire 236 a été isolé selon tout probabilité. La méthode de formation serait la suivante:

$$C_2H_5{\equiv}CH + S_2F_{10} \rightarrow C_2H_5CF{=}CHSF_5 + SF_4$$
$$C_2H_5CF{=}CHSF_5 + S_2F_{10} \rightarrow C_2H_5CF_2CHFSF_5 + 2SF_4,$$

où S_2F_{10} sert d'agent fluorant.

Le radical libre $\cdot SF_5$ peut abstraire un proton pour former l'unité HSF_5 instable qui donne SF_4 et HF. Ceci explique la formation de carbone et d'acide fluorhydrique sous certaines conditions:

$$\cdot SF_5 + CH{\equiv}CH \rightarrow \cdot CH{=}CHSF_5$$
$$S_2F_{10} + \cdot CH{=}CHSF_5 \rightarrow SF_5CH{=}CHSF_5 + \cdot SF_5$$
$$SF_5CH{=}CHSF_5 \rightarrow 2C + 2SF_4 + 2HF.$$

La réaction de S_2F_{10} est beaucoup plus rapide avec les acétylènes et éthylènes ne contenant pas d'halogènes. La réaction, par exemple, de S_2F_{10} avec l'éthylacétylène est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

complète à 125 °C, alors qu'avec le fluorure de vinyle, la réaction a lieu à 140–160 °C.

Cependant, la présence d'halogène dans la molécule, après addition de SF_5, stabilise le produit formé et empêche la formation de SF_4 à partir de $\cdot SF_5$ et de l'hydrogène. Ceci explique l'isolation plus facile des dérivés des halogénures de vinyle.

PARTIE EXPÉRIMENTALE

La réaction de S_2F_{10} avec les oléfines, les diènes et les acétylènes se fait dans une bombe d'acier au chrome–vanadium de 300 ml de capacité. Après l'addition du S_2F_{10} (25.4 g, 0.1 mole) sous forme liquide, la bombe est fermée, refroidie dans l'azote liquide et évacuée à la pompe à vide. Les oléfines, diènes et acétylènes (0.2 à 0.3 mole) sont condensés dans la bombe à −196 °C. Après chauffage à la température désirée, un échantillon des produits gazeux est séparé par chromatographie et les gaz individuels identifiés par leur spectre de masse.

Le temps de rétention d'un gaz donné dépend de plusieurs facteurs dont la température, la longueur de la colonne, le débit du gaz vecteur, etc. Mais cette valeur du temps de rétention peut être donnée comme valeur relative à un gaz de référence, soit SOF_2 dans le cas présent, et en calculant le temps à partir du pic de l'air. Si tous les facteurs variables, tels que température, vitesse du gaz vecteur, etc., sont gardés constants pendant la durée de l'expérience, le temps de rétention relatif à SOF_2 est alors donné par la formule,

$$T_r = \frac{(t_x - t_{air})100}{(t_{SOF_2} - t_{air})},$$

où T_r = temps de rétention relatif à SOF_2 du gaz en question, t_x = temps de rétention du gaz en question en min, t_{air} = temps de rétention de l'air en min, t_{SOF_2} = temps de rétention de SOF_2 ou SF_4 en min.

Nous avons utilisé un chromatographe Perkin–Elmer, modèle 154 pour la séparation du mélange gazeux. Ce chromatographe possède deux colonnes consécutives. La première colonne, qui est en cuivre, mesure 9 pieds de long par 1/4 pouce de diamètre. Elle est remplie de chromosorb A (Perkin–Elmer) qui contient du diisodécyl phtalate comme phase stationnaire liquide. La deuxième colonne est aussi en cuivre, mesure 20 pieds de long par 1/4 pouce de diamètre et est remplie de brique refractaire C-22 de granulosité 35 à 80 (Johns-Manville Co.) contenant de l'huile Kel-F (Grade No. 10, Minnesota Mining and Manufacturing Co.).

Les gaz, à leur sortie du chromatographe, sont introduits avec le gaz vecteur, l'hélium, dans un spectromètre de masse à temps de vol, Bendix, Modèle 12-101, où ils sont identifiés individuellement sur l'écran d'un oscilloscope.

Les spectres de masse des liquides sont obtenus par introduction dans le spectromètre de masse à l'aide d'un appareil à introduction d'échantillon moléculaire (No. 919, Bendix Corporation) et leur spectre enregistré avec une caméra Polaroid placée devant l'écran d'un oscilloscope ou à l'aide d'un Visicorder qui enregistre le spectre sur papier photographique.

Les liquides obtenus ont été rectifiés à l'aide d'un chromatographe (Fisher Scientific Co., Prep-Partitioner, modèle 24) dont la colonne est maintenue à 80 °C, remplie de chromosorb A contenant du diisodécyl phtalate, et balayée avec de l'azote. Les liquides purifiés à l'aide de cet appareil sont donnés dans le tableau I avec les temps de rétention observés.

1. Réaction de S_2F_{10} avec le chlorure de vinyle

La réaction du décafluorobisulfure avec le chlorure de vinyle à 125–140 °C sous pression donne les gaz suivants: SF_6, SO_2F_2, SF_4, CH_2FCHF_2 et $ClSF_5$, à des temps de rétention relatifs à SOF_2 de 32, 63, 100, 141 et 209 et en pourcentage de 20.6, 5.6, 36.7, 17.8 et 2.0 respectivement. Le liquide obtenu contient le produit monosubstitué, $CH_2FCHClSF_5$, qui fut purifié à l'aide du Prep-Partitioner; temps de rétention, 67 min. Environ 2 ml (3 g) de ce liquide furent obtenus à partir de 25 g de S_2F_{10} et d'un excès de chlorure de vinyle; rendement $\simeq 7.5\%$. Son spectre de masse est donné ci-dessous, par ordre d'intensité décroissante des pics en opérant l'appareil à 50 eV. Les ions positifs identifiés sont entre parenthèses, près de leur masse respective: 81 (FCH_2CHCl), 89 (SF_3), 46 ($CH_2{=}CHF$), 27 ($CH_2{=}CH$), 127 (SF_5), 62 (CH_2CH_2Cl), 175 ($CHClSF_5$), 70 (SF_2), 51 (SF), 35 (Cl), 189 ($CH_2CHClSF_5$), 33 (CH_2F).

Anal. Calc. pour $CH_2FCH_2ClSF_5$: S, 15.4; F, 54.9. Trouvé: S, 15.4; F, 54.6.

2. Réaction de S_2F_{10} avec le bromure de vinyle

La réaction du bromure de vinyle avec S_2F_{10} dans les mêmes conditions a donné les gaz suivants, SF_6, SO_2F_2, SF_4, CH_2FCHF_2, à des temps de rétention relatifs et pourcentages respectivement de 32 et 12.8%, 63 et 5.9%, 100 et 38.3%. 141 et 8.4%. Le produit liquide séparé avec le Prep-Partitioner a donné à 38 et 146 min respectivement $CH_2FCHBrSF_5$ et $CH_2FCHBrCH_2CHBrSF_5$. Rendement: 2 ml (3 g) par 25 g de S_2F_{10}, soit environ 6%. L'analyse spectrale de masse donna les pics suivants par ordre d'intensité décroissante pour le dérivé monosubstitué: 126 (CH_2FCHBr), 127 (SF_5), 46 ($CH_2{=}CHF$), 27 ($CH_2{=}CH$), 107 (CH_2-$CHBr$), 80 (Br), 89 (SF_3), 70 (SF_2), 51 (SF), 33 (CH_2F).

Anal. Calc. pour $CH_2FCHBrSF_5$: S, 12.6; F, 45.1. Trouvé: S, 12.0; F, 44.8.

Le dérivé isolé à 146 min donna le spectre de masse suivant: 27 (CH_2=CH), 127 (SF_5), 126 (CHFCHBr), 107 (CH_2FHBr), 89 (SF_3), 360 ($CH_2FCHBrCH_2CHBrSF_5$), 70 (SF_2), 234 ($CH_2CHBrSF_5$), 80 (Br), 154 (CH_2CHSF_5), 51 (SF), 280 ($CHF{=}CHCH_2CHBrSF_5$).

Anal. Calc. pour $CH_2FCHBrCH_2CHBrSF_5$: S, 8.89; F, 31.7. Trouvé: S, 8.74; F, 29.6.

3. Réaction de S_2F_{10} avec le fluorure de vinyle

Du fluorure de vinyle et S_2F_{10}, nous avons obtenu à 140–150 °C sous pression les gaz aux temps de rétention relatifs et pourcentages respectifs suivants: SF_6, 32, 23%; SO_2F_2, 65, 0.9%; SF_4, 100, 42.1%; CH_2FCHF_2, 140, 29%. Le liquide obtenu, 5 ml (7.5 g) par 25 g de S_2F_{10} (rendement $\simeq$ 19%), se sépare en deux constituants à l'aide du chromatographe Prep-Partitioner passant respectivement à 27 et 43 min. Le spectre de masse du composé isolé à 27 min est donné par ordre d'intensité décroissante des pics: 65 ($CHFCH_2F$), 89 (SF_3), 45 (CHCHF), 127 (SF_5), 173 ($CHFCH_2SF_5$), 46 (CH_2CHF), 70 (SF_2), 51 (SF), 33 (CH_2F), 27 (CH_2=CH), 154 (CH_2CHSF_5). Ce produit donne l'analyse élémentaire calculée pour $CH_2FCHCFH_2CHFSF_5$: C, 21.9; H, 2.74; S, 14.6; F, 60.7. Trouvée: C, 22.9, H, 2.08; S, 14.2; F, 60.9. Le liquide obtenu à 43 min sur le Prep-Partitioner donne le spectre de masse suivant: 47 (CH_2CH_2F), 65 (CH_2FCHF), 51 (SF), 27 (CH_2=CH), 89 (SF_3), 33 (CH_2F), 127 (SF_5), 70 (SF_2), 154 (CH_2CHSF_5), 173 (F_5SCH_2CHF). L'analyse élémentaire calculée pour $CH_2{=}CHCHFCH_2SF_5$: C, 24.0; H, 3.00; S, 16.0; F, 56.0. Trouvée: C, 24.9; H, 2.14; S, 17.4; F, 56.1.

La réaction de S_2F_{10} avec d'autres dérivés vinylés, tel le méthyl vinyl éther donne des produits difficilement isolables et contenant de grandes quantités d'acide fluorhydrique.

4. Réaction de S_2F_{10} avec le propadiène

Lorsqu'un excès de S_2F_{10} réagit sur le propadiène à 125° sous pression, nous obtenons les gaz suivants aux temps de rétention relatifs à SOF_2 et pourcentages respectifs: SF_6, 32, 26.5%; SO_2F_2, 63, 1.0%; SF_4, 100, 10.8%. De faibles quantités de liquides, qui seraient les produits substitués, sont été isolés à l'état brut, mais un seul produit siolé en trace du Prep-Partitioner donne le spectre du produit monosubstitué: 59 ($CH_2{=}CFCH_2$ ou $CH_2{=}CCH_2F$), 40 ($CH_2{=}C{=}CH_2$), 39 ($CH_2{=}C{=}CH$), 89 (SF_3), 51 (SF), 27 (CH_2=CH), 33 (CH_2F), 70 (SF_2), 205 ($CH_2CF_2SF_5$), 127 (SF_5).

5. Réaction de S_2F_{10} avec le méthylacétylène et l'éthylacétylène

Un excès de méthylacétylène sur S_2F_{10} donne SF_6, 32, 28.5%; SO_2F_2, 63, 1.1%; SF_4, 100, 31.6% et $CH_3C{\equiv}CH$, 210, 31.1%, aux temps de rétention et pourcentage respectifs ci-dessus. Le produit d'addition liquide du méthylacétylène se décompose dans la colonne du Prep-Partitioner à 80 °C.

L'éthylacétylène en excès sur S_2F_{10} donne le gaz suivants aux temps de rétention relatifs et ppurcentages dans l'ordre suivant: SF_6, 32, 43.4%; SO_2F_2, 63, 1.3%; SF_4, 100, 30.9% et éthylacétylène, 550, 23.9%. La réaction laisse un produit qui donne le spectre de masse suivant: 28 (C_2H_4), 27 (C_2H_3). 55 ($C_2H_5CH{=}CH$), 29 (C_2H_5), 127 (SF_5), 54 ($C_2H_5C{=}CH$), 236 ($C_2H_5CF_2CHFSF_5$), 89 (SF_3), 70 (SF_2), 111 ($C_2H_5CF_2CHF$), 182 ($SF_5CH{=}CHC_2H_5$).

ELECTRON SPIN RESONANCE STUDIES OF RADICAL ANIONS AND ION PAIRS IN THE PYRAZINE SERIES

C. A. McDowell and K. F. G. Paulus
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received August 4, 1964

ABSTRACT

The alkali metal hyperfine interaction in ion pairs of sodium and potassium cations with the radical anions of some methyl-substituted pyrazines and pyridines has been investigated. The electrostatic, electronic, and steric interactions which influence the metal hyperfine splitting are discussed in detail. It is proposed that the variation of the observed hyperfine splitting is due, in some cases, to steric effects, but in the series of *m*-xylene, 3,5-dimethylpyridine, and 2,6-dimethylpyrazine, the variation is caused by a change in the energy of electronic excitations from the anion to the cation.

The results of molecular orbital calculations of the spin densities in tetramethylpyrazine and 3,5-dimethylpyridine are compared with experiment and found to give reasonable agreement.

1. INTRODUCTION

In electron spin resonance (e.s.r.) investigations of radical anions prepared by chemical reduction with alkali metals in polyethers, it is often assumed that the anions can be considered essentially as free, being surrounded individually by solvent shells. Recently improved methods of detecting free radicals have made it necessary to revise this picture. It has been found in many cases that aromatic anions prepared in the above way are associated as ion pairs with the cations of the alkali metals used in the reduction reaction. The electronic spectra of the anions exhibit this association by observed shifts of the absorption maxima, the shifts being different for different metals (1, 2). The formation of ion pairs is detectable also by e.s.r. techniques because the unpaired electron on the anion can, by various mechanisms, create unpaired electron spin density at the cation nucleus, and the resulting hyperfine interaction with the nuclear spin angular momentum appears as an additional splitting in the e.s.r. spectrum of the anion (3–8, 11).

In certain cases the e.s.r. spectra of the ion pairs can give information about their structure. Thus in the ion pairs formed by alkali metals with pyracene the cation was found to be situated near the methylene bridges of the anion (4, 5). When *m*-dinitrobenzene is reduced with alkali metals in polyethers the cation is associated with only one of the nitro groups, making the two nitro groups non-equivalent (6).

For the ion pair of 2,2′-dipyridyl with sodium, Zahlan and co-workers (7) have proposed that the cation is in proximity to the nitrogen non-bonding electron pairs. On the other hand, McDowell *et al.* (8) have suggested that in the pyrazine–sodium ion pair the sodium ion is located above the center of the ring, as in the case of the corresponding pairs with hydrocarbon anions (3). In what follows this particular viewpoint will be discussed more fully.

2. EXPERIMENTAL AND RESULTS

The preparation of the radical anions with sodium or potassium was accomplished as previously described (8, 9). The solvents were purified by distillation from anthracene and sodium–potassium alloy. The e.s.r. spectra were recorded on a Varian spectrometer with a 12 in. magnet and with 100 kc field modulation. Field measurements were made with a proton resonance magnetometer in conjunction with a frequency counter.

*From ref. 11. Values quoted are probably correct to ±0.01 G.

sodium in MeTHF were not sufficiently soluble to give a detectable e.s.r. spectrum. In all cases, the nitrogen and methyl proton coupling constants are as follows

$$a_N = 6.18 \text{ G}, a_{CH_3} = 1.73 \text{ G}.$$

The e.s.r. spectrum of the 3,5-dimethylpyridine negative ion has been investigated previously (10). We have reexamined this compound and resolved the alkali metal hyperfine structure for both the sodium and potassium complexes. Atherton *et al.* (10) have given the sodium hyperfine splitting as 0.35 G in this case. Figure 2 shows the e.s.r. spectrum of the ion pair with potassium in DME. The alkali metal hyperfine coupling constants are listed in Table I. From the above spectrum the coupling constants of the anion itself are found to be

$$a_N = 6.12 \text{ G}, a_{H_2} = 3.27 \text{ G}, a_{H_4} = 8.70 \text{ G}, a_{CH_3} = 0.92 \text{ G}.$$

These are slightly different from the previous values (10).

Table I gives a list of the alkali metal hyperfine splitting constants found in the ion pairs with the two compounds above, and also the ion pairs of pyrazine, 2,6-dimethylpyrazine, and 2,5-dimethylpyrazine with sodium or potassium in DME and THF, and of *m*-xylene with potassium only in DME (11). The e.s.r. spectra of the radical anions of pyrazine and the dimethylpyrazines have already been discussed elsewhere (8, 9).

With 2,6-dimethylpyrazine the potassium hyperfine splitting is derived from measurements of the linewidth at the onset of further resolution of the individual components of the anion spectrum. With 2,5-dimethylpyrazine the potassium hyperfine splitting is likely to be smaller than indicated. This splitting was derived from measurements of the lowest linewidth achieved in the spectrum, which was 0.075 G. Since this is near the limiting linewidth of the 100 kc instrument the splitting could possibly be less than one-third of this value. Because the potassium hyperfine splitting is detectable in all other cases and because sodium hyperfine splitting is present with 2,5-dimethylpyrazine we are confident that an ion pair is formed with potassium also, though in this case the hyperfine interaction may be too small to be resolved by our experimental apparatus at the present time.

3. DISCUSSION

(a) Anion Radicals

The e.s.r. spectra of the pyrazine and dimethylpyrazine radical anions have been discussed in earlier communications (8, 9). 3,5-Dimethylpyridine has been investigated previously by Atherton and co-workers (10) who used the e.s.r. data for the anion to derive empirically the hyperfine coupling parameters of the ring nitrogen. The tetramethylpyrazine radical anion has not been studied previously.

TABLE II

Calculated and experimental hyperfine coupling constants (G)

Compound	Substitution position	Hückel	McLachlan	Experiment
Tetramethylpyrazine	1 (N)	6.55	7.18	6.18
	2 (CH_3)	2.99	2.05	1.73
3,5-Dimethylpyridine	1 (N)	7.16	7.95	6.12
	2 (H)	3.74	4.13	3.27
	3 (CH_3)	(+)0.86	(−)0.66	(±)0.92
	4 (H)	6.62	8.73	8.70

In Table II we compare the experimental hyperfine coupling constants with those calculated using both the Hückel l.c.a.o. method, and the McLachlan method for calculating spin densities (12). In both approaches the simple inductive model was used for the methyl groups, with the Hückel parameters employed earlier (9). To reproduce the ring proton, methyl proton, and ring nitrogen coupling constants we employ here only the single constants $Q_H = -22.5$ G, $Q_{CH_3} = +19.0$ G, $Q_N = +25.3$ G.

Although the agreement between calculated and experimental hyperfine coupling constants leaves something to be desired, the calculations do at least give a fairly good approximation for the spin density distribution in the two ring systems. It is to be noted, of course, that both the Q's, and the empirical parameters of the Hückel calculations are not necessarily the best ones for the particular cases at hand. The calculations give less good results for 3,5-dimethylpyridine radical anion than for tetramethylpyrazine radical anion, and it appears likely that the parameters used previously for substituted pyrazines (9) may not be quite appropriate for the substituted pyridine radical anions.

It is noteworthy that the calculations using McLachlan's method for the pyridine radical anion indicate a negative spin density at one of the ring positions. This is in contrast to the assumption of Atherton *et al.* (10) that the spin density is everywhere positive in this radical anion.

(b) Electrostatic Interaction within the Ion Pairs

Several considerations lead us to believe that the configuration of the ion pairs formed in the present series must be such that the cation moves in a plane parallel to the plane of the anion. In the first place, the steric effect of the methyl groups would be expected to tend to keep the cation out of the plane of the ring atoms. This viewpoint is supported by the fact that the alkali metal hyperfine splitting is largest for the tetramethylpyrazine radical anion case, where the separation of cation and anion will be greatest, so that the interaction observed experimentally is unlikely to be an in-plane one.

A second point supporting our contention is that the electronic charge in the anion is distributed in orbitals of π-symmetry, so that the electrostatic interaction should be largest out-of-plane. Furthermore, the observation of a large potassium-39 interaction in

the case of the *m*-xylene ion pair by Bolton and Carrington (11) indicates that an out-of-plane interaction is taking place, assuming that the *m*-xylene radical anion can be placed in the present series by reason of the symmetry of its electron distribution.

The effect of the electrostatic interaction between cations and anions on the energy levels of the anion has been considered in detail by McClelland (1) and Hush and Rowlands (2). The energy E_j^0 of orbital j is changed by the electrostatic interaction to

$$[1] \qquad E_j = E_j^0 - e^2 \sum_s \frac{q_s^j}{r_s} + \frac{e^4}{2} \sum_{s,t} \frac{\pi_{ss,tt}^j}{r_s r_t} + 0(e^4),$$

where $\pi_{ss,tt}^j$ are the bond polarizabilities. For an approximate treatment of the electrostatic interaction between cation and anion we assume that the total electrostatic energy of interaction ϵ, can be written simply as

$$[2] \qquad \epsilon = -e^2 \sum_s \frac{q_s}{r_s},$$

where q_s is the excess π-electron charge density on atom s in the anion, and r_s is the distance between nucleus s and the center of the cation.

Making use of charge densities calculated with the inductive Hückel model we have calculated ϵ for the ion pairs of potassium with all the compounds listed in Table I. In doing so we have assumed that the cation moves at a distance of $(2.5 + r_K)$ Å above the plane of the anion (2), where r_K is the crystal radius of potassium, 1.33 Å. For simplicity, we have further assumed that in all cases the dimensions of the radical anion were the same as those of the pyrazine molecule, with the bond lengths and angles as given by Wheatley (13). We have found that the comparatively large changes in bond lengths taking place from pyrazine to tetramethylpyrazine (14) do not in any case change ϵ appreciably.

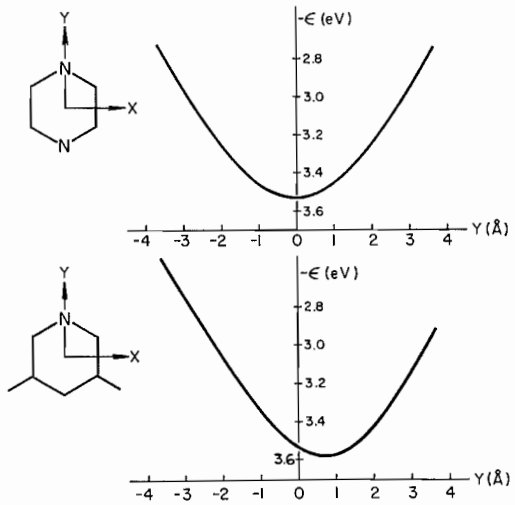

FIG. 3. Electrostatic interaction within the potassium–pyrazine (top) and the potassium–3,5-dimethylpyridine (bottom) ion pairs.

In the top portion of Fig. 3 we give the electrostatic interaction as a function of distance the cation moves along the *y*-axis. Almost identical curves are obtained for the cases of the 2,5-dimethylpyrazine and tetramethylpyrazine radical anions. The interaction as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

function of x is similar and also has a minimum at the center of the ring. The lower half of Fig. 3 shows ϵ as a function of y, with the axes indicated on the figure, for the 3,5-dimethylpyridine radical anion. The greatest attraction between cation and anion still takes place along the y-axis but the minimum is now shifted toward the nitrogen atom. ϵ as a function of y is almost identical for both the 2,6-dimethylpyrazine and the *m*-xylene radical anions, but the shift of the cation from the center of the ring along the y-axis is not as large as in the case of the 3,5-dimethylpyridine radical anion.

If the electrostatic interaction between the cation and the anion is out-of-plane it is thus clear that the most likely position for the cation will be above the center of the ring, or only slightly displaced from it along the twofold axis of symmetry of the anion. It should be noted that this follows from a consideration of the electrostatic interaction alone. In the 2,5-dimethylpyrazine and tetramethylpyrazine radical anions the effect of the methyl groups will be to increase the vertical separation of the cations and the anions compared to the pyrazine radical anion itself, while in the remaining three cases this steric effect will increase the vertical separation as well as shifting the cation horizontally in the same direction as does the electrostatic effect.

(c) Alkali Metal Hyperfine Interaction

If Ψ_0 represents the electronic ground state of the ion pair where the 4s electron is completely transferred from the potassium atom to the aromatic π-electron system, and Ψ_t represents the excited states formed when an electron is "back-donated" to the 4s level of the metal, then the potassium hyperfine splitting constant, a_K, can be written as

$$[3]\quad a_K = \frac{16\pi}{3} g_K \beta_K \left\{ \langle \Psi_0 | \sum{}' | \Psi_0 \rangle + 2 \sum_i \frac{\langle \Psi_0 | \mathscr{H} | \Psi_i \rangle}{E_0 - E_i + \epsilon} \langle \Psi_i | \sum{}' | \Psi_0 \rangle + \sum_i \left(\frac{\langle \Psi_0 | \mathscr{H} | \Psi_i \rangle}{E_0 - E_i + \epsilon} \right)^2 \langle \Psi_i | \sum{}' | \Psi_i \rangle \right\},$$

where $\sum'$ is the spin operator defined by McConnell (15), and the remaining symbols follow the usual conventions.

Excited states which could be taken into consideration are those found when an electron is promoted from any of the π-orbitals to the 4s level. Other possibilities are excitations from the nitrogen non-bonding orbital to this level or from lower levels on the metal ion itself. A similar situation exists for the other alkali metal ions.

It is expected that the zero-order term in eq. [3] will give little contribution to a_K because it depends on the probability density of the π-orbital containing the unpaired electron at the potassium nucleus, which will generally be small. It is not so straightforward to estimate the relative importance of the higher-order terms. For the naphthalene–sodium ion pair, Aono and Oohashi (16) have indeed estimated the magnitude of the second term to be only about one-tenth that of the third term and they have retained the third term only in their calculation of the sodium hyperfine splitting. It is apparent that the third term in eq. [3] will be the largest one for the integral $\langle \Psi_i | \sum' | \Psi_i \rangle$ is proportional to $|ns(r_k)|^2$, the density of the ns orbital at the alkali-metal nucleus, whereas the integrals $\langle \Psi_0 | \sum' | \Psi_0 \rangle$ and $\langle \Psi_i | \sum' | \Psi_0 \rangle$ in the other terms depend on the π-electron density at the metal nucleus. These latter are, of course, quite small.

Intuitively we may expect the exchange integrals $\langle \Psi_0 | \mathscr{H} | \Psi_i \rangle$ to decrease as the number of methyl groups increases, because the bulkiness of the methyl substituents will tend to keep anion and cation separated. The same may be said for the integrals $\langle \Psi_t | \sum' | \Psi_0 \rangle$ while

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

integrals of the type $\langle\Psi_i|\sum'|\Psi_i\rangle$ should be independent of the degree of methyl substitution. It therefore appears likely that the variation of the alkali metal hyperfine splitting in the series is not solely due to variations in these integrals, but that considerable importance must be attached to the excitation energies which occur in the denominator of both the second and third terms of eq. [3].

With respect to the excitation energies several comments may be made. If only those excitations from the π-orbitals of the anions are considered, and in particular from the π-orbital containing the unpaired electron, then it would seem reasonable that the excitation energy will decrease with increasing methyl group substitution. This should be a consequence of the decreasing electron affinity of the neutral molecules on increasing methyl substitution.

This argument, however, gives only a partial answer to the question. It is indeed seen that, as one might expect, the alkali metal hyperfine splitting increases considerably from the pyrazine radical anion to the tetramethylpyrazine radical anion. The metal hyperfine splitting constant for the dimethylpyrazines is smaller, however, than for the pyrazine radical anion itself, and the intermediate position of the pyrazine radical anion in the series remains a puzzle. A consideration of the Hückel energy levels in the series of the pyrazine radical anions is not helpful since the inductive effect of the methyl groups on the Hückel eigenvalues is very small. Steric interactions may here play some part in the variation of the hyperfine splitting constants.

If one considers the series of *m*-xylene, 3,5-dimethylpyridine, and 2,6-dimethylpyrazine radical anions, it is tempting to suggest that the increasing number of nitrogen atoms in the ring will lower the energy of the π-orbitals, and hence increase the energy of excitation from these orbitals. It is indeed found that the Hückel eigenvalues decrease considerably from *m*-xylene to 2,6-dimethylpyrazine. The change in these energies is such that the highest filled level in the neutral molecule has practically the same eigenvalue for all three molecules, while the lower filled levels and the lowest unfilled one decrease in energy with respect to this level. These considerations would then lead to the prediction that the alkali metal hyperfine splitting constant should decrease in this series, as is found experimentally.

(d) Solvent Effects

Hoijtink and co-workers (17) have made a study of ion association in solution and have found that the degree of association increases with increasing radius of the metal cation and with decreasing dielectric constant of the solvent. The dielectric constant of the solvents used in the present study decreases in the order dimethyoxyethane, tetrahydrofuran, and 2-methyltetrahydrofuran (18).

It is found in most cases (3, 5, 17) that little or no alkali metal hyperfine splitting is observable in DME, the solvent of highest dielectric constant, while larger splitting constants appears in THF and MeTHF. This observation is made also in the present investigations where the larger alkali metal splitting in the pyrazines and 3,5-dimethylpyridine is found in THF. The only exceptions to this observation are the ion pairs formed with the tetramethylpyrazine radical anion and various alkali metal cations. Here the potassium hyperfine splitting decreases in going from DME to MeTHF, in contrast to the other results. The hyperfine splitting could not be measured in 1,4-dioxane as a solvent, which has an even lower dielectric constant than MeTHF, presumably because the ion pair did not have sufficient solubility in this solvent. The sodium hyperfine splitting could be measured in DME and THF only, and the same value was obtained for the hyperfine splitting, within the limits of experimental error, in both solvents.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

If the alkali metal hyperfine splitting is divided by the atomic hyperfine coupling constant to obtain the spin density at the metal nucleus it is found that in the case of the pyrazine radical anion and the dimethylpyrazine radical anions, the spin denisty is higher for sodium than for potassium, while for the tetramethylpyrazine and 3,5-dimethylpyridine radical anions the opposite takes place. The degree of ion association is not immediately derivable from the alkali metal hyperfine splittings, however, since the unpaired electron in sodium and potassium will be preferentially in the 3s and 4s levels, respectively, which have different densities at the nucleus.

4. CONCLUSIONS

The variation of the alkali metal hyperfine splitting constants in the series of compounds investigated is rather unusual and contrary to expectations. It appears that steric effects are not the main determining factors throughout the series, nor are electrostatic effects very important as far as the magnitude of the interaction between the cation and the anion is concerned.

The hyperfine splitting in the pyrazine radical anion and the two dimethylpyrazine radical anions appears to be normal in that the effect of the methyl groups on the separation of the anion and the cation will be to lower the alkali metal hyperfine splitting in the substituted pyrazines compared to the pyrazine radical anion itself.

A different situation is found in the series *m*-xylene, 3,5-dimethylpyridine, and 2,6-dimethylpyrazine. Here the decrease of the metal hyperfine splitting is probably caused by an increase in the energies of excitation from the anion to the cation with increasing substitution by nitrogen in the ring of the radical anion.

The special position of the tetramethylpyrazine radical anion in the series is not understood at the present time. Both the magnitude of the metal hyperfine splitting, and its variation with solvent are contrary to expectation, except for a small increase in splitting above that of the pyrazine radical anion which would be expected on the basis of a decrease in the excitation energies.

5. ACKNOWLEDGMENTS

We should like to thank the National Research Council for generous financial aid in support of this research work. C. A. McD. is much indebted to the same body for the award of a Senior Research Fellowship during the 1963–1964 academic year. One of us (K. F. G. P.) wishes to acknowledge the award of a predoctoral fellowship by the Imperial Oil Company. We also thank Mr. J. A. Hebden for performing some of the experiments reported.

STUDIES ON THE RANGE OF ^{140}Ba IN PROTON-INDUCED FISSION OF ^{238}U AND A SEMI-EMPIRICAL DERIVATION OF A GENERAL RANGE–ENERGY RELATION[1]

S. MUKHERJI[2] AND L. YAFFE
Department of Chemistry, McGill University, Montreal, Quebec
Received February 14, 1964

ABSTRACT

Ranges of ^{140}Ba have been measured in the forward and backward directions with respect to the proton beam by bombarding uranium foils of normal isotopic composition with protons of 15, 30, and 60 MeV energies. Successive thin layers of aluminium were removed from the front and back catchers by an electrochemical technique, and the ranges were calculated from the relative distribution of ^{140}Ba activity in the different layers. The calculations indicate that full momentum transfer of the incident protons has taken place, suggesting that the compound nucleus mechanism is predominant at these energies.

An analysis of the existing range and energy data for fission fragments has shown that the 'effective charge' of a fission fragment, first postulated by Bohr, can be expressed as a function of the charge and the mass of the medium being penetrated. The original range–velocity relation of Bohr has been modified to include the above fact and has led to a general range–velocity relation for ranges in different metallic catchers. Similar equations seem to be applicable to the range data in gaseous media.

INTRODUCTION

Much experimental work has been done on the ranges of fragments from the thermal neutron fission of ^{235}U and ^{239}Pu and from the high-energy proton-induced fission of Bi and Ta. The thin-target thin-catcher differential technique was used by Katcoff, Miskel, and Stanley (1) for the ranges of ^{239}Pu fragments in air and by Brown and Oliver (2) for some ^{235}U fission fragments in aluminium. Finkle *et al.* (3) used a thin-target thin-catcher integral method and determined the range of ^{140}Ba in aluminium from the equation of Segrè and Wiegand (4). Thin-target methods are suitable for fragments produced from the fission of ^{235}U and ^{239}Pu by thermal neutrons because of the high fission cross sections and the fact that the targets can be conveniently irradiated inside the reactors for a long period of time.

Where the ranges of fragments from materials like ^{238}U with smaller fission cross sections are to be measured, especially if fission is induced by charged particles, thin-target thin-catcher methods become unsuitable because of the low yields of the recoils. Hence thick targets with thick or thin catchers have been used for studying the ranges of fragments from comparatively high-energy fission. Porile and Sugarman (5) used thick targets sandwiched between thick aluminium catchers for the study of fragment ranges from the fission of bismuth and tantalum. Niday (6) used the same technique for the ranges of fragments from thermal neutron fission of ^{235}U. From the ratios of the activities in the catcher foils to those in the total assembly, the ranges were calculated in terms of the target material. Sugarman, Campos, and Wielgoz (7) used thick targets and comparatively thin catchers for differential experiments to calculate the ranges in aluminium. Alexander and Gazdik (8) used a moderately thick target with comparatively thin catchers and by differential experiments calculated ranges in aluminium and in gold.

The recently developed electrochemical techniques of Davies *et al.* (9) for the removal of very thin layers of aluminium of accurately known thicknesses opened up the possibility

[1]*This work received financial assistance from the National Research Council of Canada.*
[2]*Present address: Enrico Fermi Institute for Nuclear Studies, University of Chicago, Chicago, Illinois.*

of performing differential experiments with an unprecedented degree of differentiation. The present work is essentially a thick-target thin-catcher differential experiment in which the uncertainties in the thicknesses of the commercially available foils of aluminium have been avoided.

Very few experimental data are available on the variation of the range of ^{140}Ba with energy in the low-energy proton-induced fission of ^{238}U. Douthett and Templeton (10) determined the ranges of ^{140}Ba in ^{238}U fission induced by 18 MeV deuterons and 335 MeV protons. The energies used differed widely and the fission mechanism would be presumably different so that the ranges cannot be compared on a common basis. Bombarding energies of 15, 30, and 60 MeV were chosen in the present work to see whether any change, due to reactions proceeding via mechanisms other than compound nucleus formation, could be found.

EXPERIMENTAL

(a) Target Preparation and Irradiation

A uranium foil (thickness 0.0006 in.) of normal isotopic composition was gently warmed with 6 *N* nitric acid to remove the oxide layer. A piece (1 in. × 1½ in.) was sandwiched between two 'super-pure' electropolished aluminium foils from each of which a 100 V 'thick' oxide layer had previously been removed by the technique to be described later. The aluminium foils were of slightly larger dimensions than the uranium foil. One edge of the sandwich assembly was fixed to the target holder. The other edge was vertically sheared so as to align the edges of the three foils exactly in the same vertical plane. The assembly was then attached to the water-cooled probe of the McGill Synchrocyclotron, and the foil assembly was placed perpendicular to the internally circulating proton beam. The radial distance was so chosen as to intercept the proton beam of the desired energy.

(b) Electropolishing, Anodizing, and Stripping

'Super-pure' aluminium foils of thickness 0.02 in. were first electropolished by the perchloric acid – acetic anhydride prescription of Tegart (11). The foil was anodized by dipping it for 10 min in a citrate buffer solution (3% ammonium citrate) contained in an aluminium beaker. A d-c. voltage was applied, the aluminium beaker serving as the cathode and the foil itself as the anode. The potential was always maintained at 100 V from an assemblage of 7.5 V dry batteries connected in series. The stripping of the oxide layer was carried out according to the method of Davies *et al.* (9) by a 2-min treatment with a chromium trioxide – phosphoric acid mixture maintained at 90 °C. From each catcher foil at each bombarding energy 92 layers were removed at a 100 V potential. Because of the low activity of ^{140}Ba in a single layer, two such layers were taken together and these are designated as double layers. The activity in a double layer has been assumed to be concentrated in the second of the two layers.

(c) Chemical Separation

Ba^{++} carrier, 20 mg, was added to the solution containing each alternate double layer, and the solution was then evaporated to about 4 ml. Barium was separated from the solution by the ether – hydrochloric acid method of Glendenin (12). The barium was then purified by alternate scavenging with ferric hydroxide and precipitating as barium chloride. Barium was finally precipitated as barium chromate, filtered onto glass fiber discs, dried at 110 °C, and weighed. No absolute chemical yields were determined, since only relative activities were essential for the range determination. Likewise, no activity measurement was made on the target foil itself.

(d) Measurement of Radioactivity

All the activities were determined by gross beta ray measurement, and the purity of the samples was checked by following the decay of the 12.8-d half-life activity of ^{140}Ba. Because of the low activities involved (maximum number of counts of ^{140}Ba in the 15 MeV experiment was only 40 c.p.m.) a Sharp Low Beta counter with a background of 0.5 c.p.m. was used. The counter was operated as an end-window flow type proportional counter with P-10 as the circulating gas. No self-absorption corrections were made as the weights of barium chromate did not differ appreciably in the various samples. The activities were normalized to the same sample weights, and decay corrections were made where applicable.

RESULTS

The plots of the activity of double layer against the number of the double layers removed are shown in Figs. 1 to 6 inclusive. Each double layer represents 54.3 $\mu g/cm^2$ aluminium removed from the exposed surface. The activity increases initially with increasing depth

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

from the surface and then decreases linearly with perfect regularity. The two plots at 15 MeV show considerable scatter because of the low activities involved. Extrapolation of the linear portion of the curve to zero activity gives the value of the range in any particular catcher. These are shown in Table I along with the ratios of the actual total activities in the forward and the back catchers.

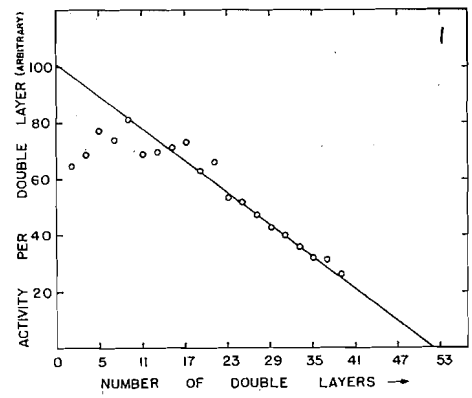

FIG. 1. Plot of activity of each double layer against the double layer number in front catcher (15 MeV protons).

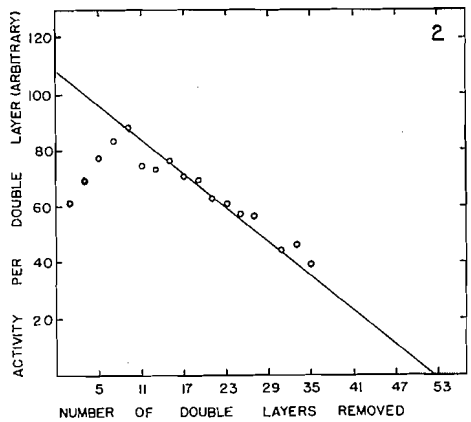

FIG. 2. Plot of activity of each double layer against the double layer number in back catcher (15 MeV protons).

The statistical errors in activity measurements and in the weight of aluminium removed by stripping are $\pm 3\%$ and $\pm 4\%$ respectively, while the error in chemical yield is $\pm 1\%$. The error in the range values is estimated to be only $\pm 3\%$, since these values are obtained by extrapolation of straight lines passing through a large number of points representing the mean values of the activities per double layer.

If one assumes that the activities should ideally have decreased linearly starting with the first double layer, then the total activity in any catcher foil can be calculated by extrapolating the linear portion backward to the original surface of the foil. The values of the ideal activities of the first few double layers were calculated by interpolation from the extrapolated initial part of the straight lines. The total ideal activities and their ratios are shown in Table I.

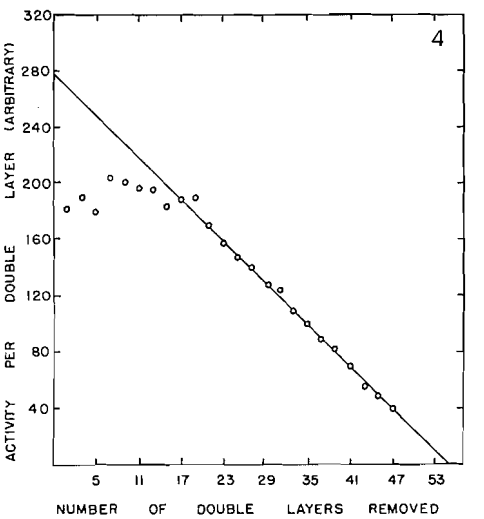

FIG. 4. Plot of activity of each double layer against the double layer number in back catcher (30 MeV protons).

DISCUSSION

(a) Evidence for Compound Nucleus Formation

As can be seen from Table I, the difference between the ranges in the front and the back catcher increases with increasing bombarding energy. If these ranges reflected fully the transfer of momentum to the struck nucleus then one could calculate quantitatively the transferred momentum. However, for reasons mentioned later, an alternative method of calculating the transferred momentum from the ratio of the activities in the front and back catchers has been used. From a modified form (Appendix B) of the equation of Sugarman *et al.* (7) we have the absorption equation

*In units of (Mev/nucleon mass)$^{1/2}$.

V = velocity of the escaping fragment,
R = range of the fragment in the catcher material from a stationary target, and
K' = constant.

The plus and minus signs refer to the front and the back catcher respectively. If R_f and R_b are the ranges in the forward and backward directions with respect to the proton beam, then

$$R_f = \frac{R(1 + \eta - \eta')}{1 - \eta'}, \qquad R_b = \frac{R(1 - \eta - \eta')}{1 - \eta'}.$$

Hence

$$\frac{R_f}{R_b} = \frac{1 + \eta - \eta'}{1 - \eta - \eta'}. \tag{2}$$

The absorption equation in the front catcher becomes

$$N_f(t) = K'(1 + \eta - \eta')^2\left[1 - \frac{t}{R_f}\right]^2. \tag{3}$$

The activity ΔN_f retained by a layer of the catcher material of thickness Δt is given by

$$\frac{\Delta N_f(t)}{\Delta t} \approx \frac{dN_f(t)}{dt} = -\frac{2K'}{R_f}(1 + \eta - \eta')^2\left[1 - \frac{t}{R_f}\right]$$

and similarly for the back catcher

$$\frac{\Delta N_b(t)}{\Delta t} \approx \frac{dN_b(t)}{dt} = -\frac{2K'}{R_b}(1 - \eta - \eta')^2\left[1 - \frac{t}{R_b}\right].$$

These relations show that the plot of the activity per double layer of aluminium against the depth of the layer should give a straight line as has been experimentally found. The total activities in the front and back catchers are obtained from the areas under the straight lines (Figs. 3–6). Hence

$$\frac{A_f}{A_b} = \frac{I_f \times R_f}{I_b \times R_b}, \tag{4}$$

where A_f and A_b are the total activities in the front and back catchers respectively, and I_f and I_b represent corresponding activities at $t = 0$ (intercepts on the activity axis). It follows (Appendix A) that

$$\frac{A_f}{A_b} = \frac{(1 + \eta - \eta')^2}{(1 - \eta - \eta')^2}. \tag{5}$$

Calculation of η from eq. [5] requires a knowledge of η'. Assuming that the mean range R_M ($= (R_f + R_b)/2$) represents the range of ^{140}Ba from a stationary target, the value of V can be calculated from eq. [19] and hence η' is known (Appendix C). The calculation of V from R_M is justified by the fact that the latter is in good agreement with the values of Douthett and Templeton (10) and of Alexander and Gazdik (8).

The value of v is then calculated from the relation $v = \eta V$. These values of v have an associated error of $\pm 20\%$ arising out of the error of $\pm 3\%$ in the values of A_f and A_b. The theoretically expected values of v, assuming full momentum transfer, have also been calculated and the relevant data are shown in Table II. The ratios of v (theoretical) to v (calculated), apart from the experimental error, are very close to unity. The calculated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

value of v obviously cannot be expected to exceed the theoretical value, and thus the calculated values of v will essentially have an error limit of -20%. Thus, at bombarding energies of 30 and 60 MeV, at least as much as 80% of the momentum of the impinging proton is transferred to the fissioning nucleus, and fission at these energies seems to proceed predominantly through the compound nucleus mechanism (13).

The calculation of η from eq. [2] has not been made for the following reasons. (*a*) The absolute values of the extrapolated ranges obtained graphically are very sensitive to the slopes of the lines (Figs. 3–6). Experimental errors of the order of $\pm 3\%$ would cause considerable error in the value of η. The total areas under the straight lines, however, are much less sensitive to these errors. (*b*) Equation [5] is independent of the straggling and scattering phenomena inside the catcher, which might add to the experimental errors in altering the slopes of the lines.

As a check on the validity of eq. [5] we have used the range values of Douthett and Templeton (10) to calculate the velocity v imparted by 18 MeV deuterons to the (^{238}U + d) nucleus. These range values have been corrected for straggling and source thickness, have a precision of 1%, and represent averaged values of R_f and R_b. The value of η' has been calculated as previously (Appendix C). The values of v obtained from $v = \eta V$ and from theoretical calculations, assuming full momentum transfer, are 0.033 and 0.0353 respectively in appropriate units. Assuming $R_f/R_b = (1 + \eta)/(1 - \eta)$, the value of v comes out to be 0.0579.

(b) Scattering and Thermal Diffusion

If one assumes isotropic distribution of the fragments, the activity per double layer should decrease linearly with increasing depth of the layer. The activity in the first few double layers is found to be consistently low in all the catcher foils, rising to a maximum in the ninth double layer and then decreasing linearly. The effect might be due to a combination of scattering and thermal diffusion. Although scattering plays a large role near the interface between the catcher and the target, because of the increasing number of nuclear collisions (14), one would expect anomalously high activities in the first few double layers rather than the opposite. In the case of ^{140}Ba produced in the range of 30–60 MeV bombarding energies, thermal diffusion of the ^{140}Xe precursor is quite likely. Significant errors may arise when ranges are calculated from the ratio of the total activities in the front and back catchers in a thick-target thick-catcher type of experiment. The corrected total activities A_f and A_b obtained by extrapolating the straight lines to zero layer and their ratios are shown in Table II. The summed total activities A_f' and A_b' and their ratios are also shown in Table II.

(c) Range–Energy Relation for Fission Fragments

Bohr (14) dealt comprehensively with the problem of the energy loss of charged particles passing through matter and derived the following equation:

$$[6] \qquad \frac{dV}{dR} = \frac{4\pi N \epsilon^4 (Z_1^{eff})^2}{m_0 M V^3} \sum_s \ln \frac{m_0 V^3}{2\pi \nu_s \epsilon^2 Z_1^{eff}} + \frac{4\pi \epsilon^4 Z_1^2 Z_2^2}{mMV^3} \ln \left[\left(\frac{mM}{m+M} \right) \frac{V^2 a_{sc}}{Z_1 Z_2 \epsilon^2} \right],$$

where

dV/dR = rate of velocity loss per unit path length,
N = number of atoms of the absorber per unit volume,
m_0 = electronic mass,
ϵ = electronic charge,
M = mass of the penetrating particle,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

m = mass number of the absorber,
Z_1 = nuclear charge of the penetrating particle,
Z_2 = nuclear charge of the absorber,
V = velocity of the penetrating particle,
ν_s = frequency of the sth electron,
Z_1^{eff} = effective charge of the penetrating particle (which is related to the rate of capture and loss of electrons by the penetrating particle), and
a_{sc} = screening constant.

The first term on the right-hand side of the equation represents the energy loss due to electronic collision while the second is that due to nuclear collisions. For fission fragment ranges in solid absorbers, as a first approximation, we may neglect the second term in comparison to the first and write

$$[7] \qquad \frac{dV}{dR} = \frac{4\pi\epsilon^4 N(Z_1^{eff})^2}{m_0 M V^3} \sum_s \ln \frac{m_0 V^3}{2\pi\nu_s \epsilon^2 Z_1^{eff}}.$$

It was further argued by Bohr (14) that the effective charge of the fission fragments is given by

$$[8] \qquad Z_1^{eff} = K\frac{V}{V_0},$$

where

V = velocity of the fragment,
V_0 = velocity of the electron in the hydrogen orbit, and
$K = kZ_1^{1/3} = kZ_p^{1/3}$, where
k = a constant and was taken by Bohr (14) as unity for gaseous absorbers, and
Z_1 = probable nuclear charge of the fragment and equals the most probable charge Z_p.

Since the logarithmic term within the summation bracket would be proportional to V, by substituting the value of Z_1^{eff} from eq. [8], we have

$$\frac{dV}{dR} = C' \times \frac{Z_p^{2/3}}{M}$$

where C' is a constant and, since $V = \sqrt{(2E/M)}$, we can write

$$[9] \qquad R = C \times \frac{E^{1/2}M^{1/2}}{Z_1^{2/3}},$$

where C is a constant and E is the kinetic energy of the fission fragment. Brown and Oliver (2) utilized this form of Bohr's equation to calculate the kinetic energies of some ^{235}U fission fragments. The constant C was first evaluated. The kinetic energy values for some nuclides were taken from the velocity data of Milton and Fraser (15) and the range data were taken from the work of Niday (6) for ranges in uranium and those in air from the data of Katcoff, Miskel, and Stanley (1). The 'constancy' of the constant C was then checked by plotting the value of C for the different nuclides obtained from eq. [9] against the mass number of the nuclides. The constant was found to show a definite drift, the values for mass numbers 92 and 134 being approximately 0.295 and 0.275 respectively. However, the plot gives a straight line up to mass number 133 for the range data in air, and the value of C for a particular nuclide could be obtained by suitable interpolation from the straight

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

line. This form of the range–energy equation cannot be regarded as a general one, as the value of the constant must be determined for each absorber material, and there is no way of theoretically comparing the range values of the same nuclide in different absorbers.

Alexander and Gazdik (8), by a different procedure, showed that the range could be related to the energy by the expression:

$$R = KE^{2/3}, \tag{10}$$

where K is not a true constant in the sense that it depends both on the absorber and on the fission product being considered. To determine the value of the constant, K, known values of the kinetic energies of some nuclides were taken from the data of Stein (16). The known ranges were taken from their own data in aluminium and the range data in air from Katcoff, Miskel, and Stanley (1). The values of K, obtained from these and from eq. [10], were plotted against the mass number of the nuclides. The plot shows that, like the constant C of the previous equation, K also does not have a unique value for all the nuclides penetrating a particular medium, although it seems to be a smooth function of the mass number of the nuclides. Consequently, to determine the kinetic energy of a nuclide from its experimentally determined range, the value of K has to be determined first by proper interpolation from the plot of the known values of K against the mass number and substituted in eq. [10].

Niday (6) determined the ranges of a large number of nuclides from the slow neutron fission of ^{235}U. From a simplification of another form of Bohr's (14) energy-loss equation, he obtained a relation between the range in uranium and the initial fragment velocity:

$$R_U = \frac{A(v_i - v_0)}{2.411(K + 4.7622K^{5/3})} \tag{11}$$

where

R_U = the range in uranium in mg/cm^2,
v_i = velocity of the nuclide in units of 10^8 cm/s,
A = mass number of the nuclide, and
v_0 = electron velocity in the hydrogen orbit in units of 10^8 cm/s.

The constant K for a particular nuclide is the same as that described previously (i.e. $K = kZ_p^{1/3}$). By an empirical choice of $k = 1$, Niday found that all his range data could be accurately reproduced when Stein's (16) kinetic energy values were substituted in this equation. This disagrees with the suggestion of Bohr and Lindhard (17) that a value of $K = 1.5 \times Z_p^{1/3}$ should be chosen for fragments passing through solids, which is close to the value of $1.4 \times Z_p^{1/3}$ found by Lassen (18) and Cohen *et al.* (19). This fact pointed towards the possibility that the value of k may not be a constant for all the absorbers but may be a function of the catcher material itself.

To investigate the applicability of eq. [11] in the case of absorbers other than U, it may be rearranged to bring out the dependence on the nuclear charge and mass number of the absorber:

$$R = \frac{A(v_i - v_0)}{126\left(\frac{Z^{1/3}}{A}\right)[K + 4.7622K^{5/3}]}. \tag{12}$$

For ease of manipulation, K was neglected in comparison to $4.7622K^{5/3}$ in the denominator of the right-hand side of eq. [12].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[13] $$R = \frac{A(v_i - v_0)}{126\left(\frac{Z^{1/3}}{A}\right)_{abs}(4.7622K^{5/3})}.$$

To find out if there is a unique value of k for aluminium as in the case of uranium, a set of nuclides was chosen with known range values in aluminium (8). Their energies were taken from ref. 14, after correction for neutron emission, with the exception of that for ^{111}Ag which is taken from ref. 8. These values were substituted in eq. [13] and values of K were calculated for each nuclide. The ratio of $K/Z_p^{1/3}$ is tabulated in Table III. The

TABLE III

value of Z_p for ^{111}Ag was obtained from Milton (20). All other values are those of Wahl (21). It seems that for aluminium there is a constant k value for all the nuclides. With range data in gold (8) a similar calculation gave constant k values, as shown in Table III. Range data in some gases were then chosen from the work of Petrzhak *et al.* (22). In spite of the fact that Bohr's equation was derived for particles penetrating into heavy media and consequently no unique value ought to have been expected, Table IV shows that k, for

TABLE IV

Values of k calculated from the equations

$$k = \frac{K}{Z_p^{1/3}}, \qquad K^{5/3} = \frac{A(v_i - v_0)}{126 \times 4.7622\left(\frac{Z^{1/3}}{A}\right)_{abs} \times R_{abs}}$$

each of the gases H_2, N_2, He, Ne, and Ar, has a constant value for all the nuclides considered. In the light of the preceding facts, we can express the range of a nuclide in any absorber by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[14] $$R = \frac{A(v_i - v_0)}{126\left(\frac{Z^{1/3}}{A}\right)_{abs} 4.7622(k \times Z_p{}^{1/3})^{5/3}},$$

provided the value of k, which is a constant for a particular absorber, is empirically determined. The next step was to find out if k could be related to some fundamental constants of the absorbers. Such a relation would eliminate the arbitrariness involved in the choice of k by empirical means. An intuitive guess was that k might be a function of $(Z^{1/3}/A)$ of the catcher material, and the values of log k for uranium, gold, and aluminium were plotted against the log $(Z^{1/3}/A)$ value of the corresponding catcher. All the three points were found to fall on a straight line. Values of log k plotted against log $(Z^{1/3}/A)$ for the other absorbers are also shown in Fig. 7. The points for the rare gases fall on a straight line

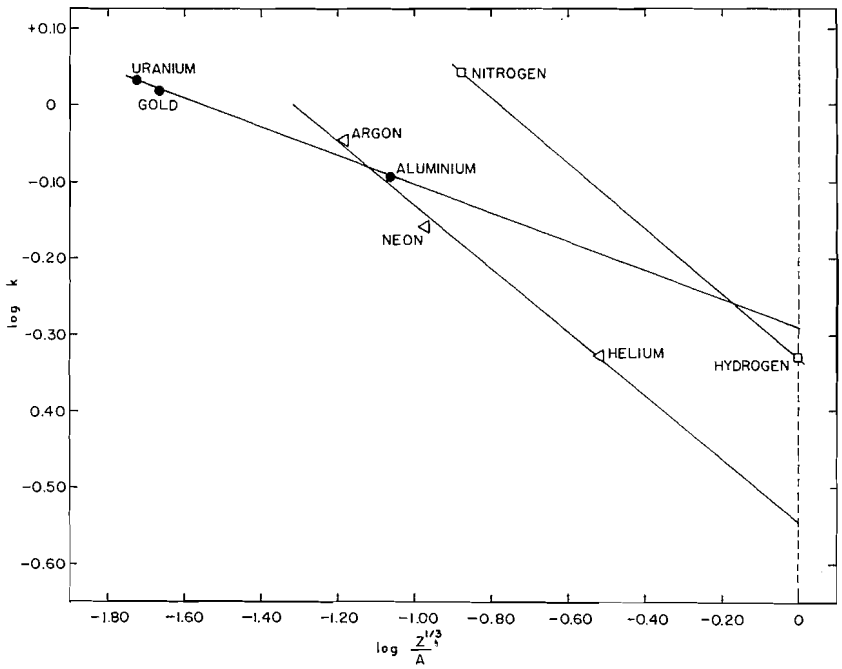

FIG. 7. Plot of log k vs. log $(Z^{1/3}/A)$ of the catcher.

whose slope is almost the same as that of the line joining the points for nitrogen and hydrogen. Thus the difference in the nature of the absorbers appears to be visibly reflected in their alignment along three different straight lines. The relation between k and $Z^{1/3}/A$ can now be expressed as:

[15] $$k_{met} = c\left(\frac{Z^{1/3}}{A}\right)^{\alpha}_{cat}$$

$$k_{mon} = c'\left(\frac{Z^{1/3}}{A}\right)^{\beta}_{cat}$$

$$k_{dl} = c''\left(\frac{Z^{1/3}}{A}\right)^{\gamma}_{cat}$$

where met = metal, cat = catcher, mon = monatomic gas, and di = diatomic gas. If

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

these are substituted in eq. [14], we have the generalized form of range–velocity relation for the three different types of catcher materials:

$$[16] \qquad R_{\text{met}} = \frac{A(v_i - v_0)}{(c^{5/3} \times 126) \times \left(\frac{Z^{1/3}}{A}\right)_{\text{cat}}^{(5\alpha/3)+1} \times 4.7622 Z_p^{5/9}}$$

$$[17] \qquad R_{\text{mon}} = \frac{A(v_i - v_0)}{126(c')^{5/3} \times \left(\frac{Z^{1/3}}{A}\right)_{\text{cat}}^{(5\beta/3)+1} \times 4.7622 Z_p^{5/9}}$$

$$[18] \qquad R_{\text{dl}} = \frac{A(v_i - v_0)}{126(c'')^{5/3} \times \left(\frac{Z^{1/3}}{A}\right)_{\text{cat}}^{(5\gamma/3)+1} \times 4.7622 Z_p^{5/9}}.$$

Evaluations of c, c', and c'' were made by taking the intercepts of the three lines in Fig. 7, on the log k axis. The values of α, β, and γ are the slopes of the straight lines. These values were substituted into eqs. [16], [17], and [18] to obtain the final forms of the general range–velocity relations, from which the kinetic energies may be conveniently calculated.

$$[19] \qquad R_{\text{met}} = \frac{A(v_i - v_0)}{195\left(\frac{Z^{1/3}}{A}\right)_{\text{cat}}^{0.6870} Z_p^{5/9}}$$

$$[20] \qquad R_{\text{mon}} = \frac{A(v_i - v_0)}{74\left(\frac{Z^{1/3}}{A}\right)_{\text{cat}}^{0.3097} Z_p^{5/9}}$$

$$[21] \qquad R_{\text{dl}} = \frac{A(v_i - v_0)}{168\left(\frac{Z^{1/3}}{A}\right)_{\text{cat}}^{0.2880} Z_p^{5/9}}.$$

From these equations, and the known energy values used previously, the ranges have been recalculated and are shown in Table V. A good correlation is evident.

(d) Interconversion of Range Values

From eq. [19] for ranges in metallic catchers, we have

$$[22] \qquad \frac{R_2}{R_1} = \left(\frac{Z_1^{1/3}}{Z_2^{1/3}} \cdot \frac{A_2}{A_1}\right)^{0.6870},$$

where R_1 and R_2 represent the ranges of the same nuclide in catchers of nuclear charges Z_1 and Z_2 and mass numbers A_1 and A_2 respectively. It was interesting to see if this formula holds for range ratios in fission at higher energies. Panontin and Sugarman (23) have determined the range values in aluminium and in the target materials of some fission fragments in the fission of ^{238}U, ^{209}Bi, and ^{181}Ta induced by 450 MeV protons. The ratios of the ranges in the target materials to those in aluminium are shown in Table VI. The same ratios calculated from eq. [22] are also shown. The agreement is fairly good.

ACKNOWLEDGMENTS

The authors are deeply indebted to Dr. J. A. Davies for his advice on electropolishing and to Mr. D. Marsden for a great deal of assistance in various ways. One of us (S. M.)

APPENDIX A

Niday (6) has given a generalized expression for calculating the number of fission fragments escaping from a thick target:

$$[1] \qquad N_c = \frac{1}{4\pi}\int_{x=0}^{R}\int_{\theta=0}^{\cos^{-1}(x/R)}\int_{\phi=0}^{2\pi} I(x)J(\theta,\phi)\sin\theta\,\mathrm{d}\phi\,\mathrm{d}x,$$

where

$I(x) \propto$ beam intensity,
$J(\theta,\phi)$ = factor to take into account any anisotropy in the emission of the fragments,
R = range of the fragments in target matter,
x = perpendicular distance between the point of origin of the fragment and the catcher surface,
$\mathrm{d}\theta$ = angle increment with respect to the normal to the foil surface, and
$\mathrm{d}\phi$ = angle increment with respect to the plane of the foil surface.

Assuming uniform beam intensity over the target area undergoing fission and isotropic emission of fragments:

$$[2] \qquad N_c = \frac{1}{2}\int_{x=0}^{R}\int_{\theta=0}^{\cos^{-1}(x/R)} I\,\mathrm{d}x\,\mathrm{d}\theta\sin\theta$$

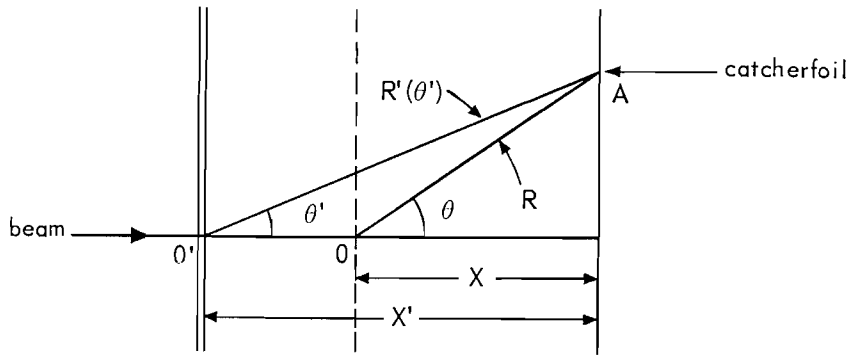
$$= \frac{I}{2}\int_{x=0}^{R}\int_{\theta=0}^{\cos^{-1}(x/R)} \sin\theta\,\mathrm{d}\theta.$$

In the case of a moving target there would be no unique range since the forward momentum would be shared to varying extents by the fragments depending on the angle θ at which they are emitted. Hence the new range $R'(\theta')$ would have an angular dependence. Further, the modified equation has to take into account the range–velocity relationship of the type $R = k(V - v_0)$ which has been found to hold for a wide number of fission fragments (eq. [19]). The modification is simple as seen from the diagram below.

From a stationary target, fragments from a thin layer $\mathrm{d}x$ situated at distance x from the catcher surface would have escaped if $R\cos\theta = 0\mathrm{A}\cos\theta \geq x$, or $k(V - v_0)\cos\theta \geq x$. Because of the forward momentum, in the case of a moving target, fragments situated at a depth x' and making an angle θ' would be just able to escape. If v is the velocity imparted to the struck nucleus in the beam direction, then

$$R'(\theta')\cos\theta' = k[(V - v_0)\cos\theta + v].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



Hence

$$\cos\theta = \frac{\frac{R'}{k}\cos\theta' \pm v}{(V - v_0)},$$

$$\sin\theta\,\mathrm{d}\theta = -\mathrm{d}(\cos\theta) = -\frac{1}{k(V - v_0)}\,\mathrm{d}[R'(\theta')\cos\theta'].$$

Using this in eq. [2] and shifting to appropriate limits of integration, we have

$$N_c = -\frac{I}{2k(V - v_0)}\int_{x'=0}^{R'(0)}\int_{\theta'=0}^{\cos^{-1}(x'/R'(\theta'))}\mathrm{d}[R'(\theta')\cos\theta']\mathrm{d}x'$$

$$= \frac{I}{4k(V - v_0)}[x'^2]_{x'=0}^{R'(0)},$$

where $R'(0)$ indicates range at zero angle to the beam direction. If A_f and A_b are the total activities in the front and the back catcher respectively, then

$$A_f = \frac{I}{4k(V - v_0)}[x'^2]_{x'=0}^{R'(0)=k(V+v-v_0)}$$

$$A_b = \frac{I}{4k(V - v_0)}[x'^2]_{x'=0}^{R'(0)=k(V-v-v_0)}.$$

Hence

$$\frac{A_f}{A_b} = \frac{(V + v - v_0)^2}{(V - v - v_0)^2} = \frac{(1 + \eta - \eta')^2}{(1 - \eta - \eta')^2},$$

where $\eta = v/V$ and $\eta' = v_0/V$.

APPENDIX B

Assuming $R = kV$, the absorption equation of Sugarman *et al.* (7) is given by

$$N(t) = K[1 \pm \eta - (t/R_0')],$$

where

$N(t)$ = number of fragments penetrating beyond a thickness t of the catcher material,
R_0' = range of the fragment in the catcher material if the target were stationary,
K = constant,
$\eta = v/V$,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

V = velocity of the fragment from a stationary target, and
v = velocity imparted to the struck nucleus by the projectile.

Assuming $R = k(V - v_0)$, the above equation takes the form

$$N(t) = K'\left[1 \pm \eta - \eta' - \frac{t}{\left(\frac{R}{1-\eta'}\right)}\right]^2$$

$$= K'(1 \pm \eta - \eta')^2\left[1 - \frac{t}{R\left(1 \pm \frac{\eta}{1-\eta'}\right)}\right]^2,$$

where R = range in the catcher material from a stationary target and K' = a constant.

APPENDIX C

(i) From eq. [19] we have $R = k(V - v_0)$. From known values of R and V, the value of k in aluminium for ^{140}Ba is found to be 0.42. Putting

$$R = R_M \qquad \left(R_M = \frac{R_t + R_b}{2}\right),$$

$$V = \frac{R_M}{0.42} + v_0 = 2.381\,R_M + v_0$$

$$\eta' = \frac{v_0}{2.381\,R_M + v_0} = \frac{2.2}{2.381\,R_M + 2.2}.$$

The velocities are all in units of cm/s $\times 10^8$.

(ii) Calculation of v from conservation of momentum is straightforward. If E is the energy of the proton in MeV, m_p is its mass, and M is the mass of the struck nucleus, then from conservation of momentum,

$$\frac{1}{2}(m + M)v^2 = \frac{E}{m_p + M}$$

$$v = \frac{\sqrt{2E}}{m_p + M},$$

where v is in units of (MeV/nucleon mass)$^{1/2}$.

MASS DISTRIBUTION IN THERMAL NEUTRON FISSION OF ^{239}Pu[1]

D. A. MARSDEN AND L. YAFFE
Department of Chemistry, McGill University, Montreal, Quebec
Received July 6, 1964

ABSTRACT

Improved radiochemical techniques have been used to study the distribution in mass of the fission fragments resulting from thermal neutron fission in ^{239}Pu.

Disintegration rates and half-lives were determined by measurement with a $4\pi\beta$ gas flow proportional counter. Further identification of the nuclides was obtained by gamma scintillation spectrometry. The flux intensity during irradiation was monitored by the $^{59}Co(n,\gamma)^{60}Co$ reaction.

The absolute fission yields of ^{89}Sr, ^{90}Sr, ^{91}Y, ^{95}Zr, ^{99}Mo, ^{103}Ru, ^{106}Ru, ^{105}Rh, ^{109}Pd, ^{112}Pd, ^{111}Ag, and ^{115}Cd in the light mass peak and ^{127}Sb, ^{131}I, ^{133}I, ^{132}Te, ^{137}Cs, ^{140}Ba, ^{141}Ce, ^{143}Ce, ^{144}Ce, ^{147}Nd, and ^{156}Eu in the heavy mass peak have been measured. In addition, the independent yields of ^{82}Br, ^{124}Sb, ^{126}Sb, and ^{136}Cs were obtained.

INTRODUCTION

The results of the only comprehensive radiochemical study of the fission product yields of ^{239}Pu were summarized by Steinberg and Freedman (1) in 1951. In this study Geiger-Müller counters had been used for activity measurements; the number of fission events were not determined directly in each experiment and the yields were often expressed relative to an internal standard—usually ^{140}Ba. The estimated accuracy was of the order of 10–20%. Since that time Bunney *et al.* (2) have determined relative yields radiochemically for the heavy rare earths with an accuracy of better than $\pm 10\%$ and Bartholomew *et al.* (3) have radiochemically determined relative yields for ^{89}Sr, ^{91}Sr, ^{139}Ba, and ^{141}La with an accuracy comparable to that obtained by using mass spectrometric techniques. Absolute cumulative yields obtained by the latter technique have been published by Fickel and Tomlinson (4, 5), Fritze *et al.* (6) and Anikina *et al.* (7).

Evaluations of all published yield data have been made by Steinberg and Glendenin in 1955 (8) and by Katcoff in 1958 (9) and 1960 (10).

The purpose of the present work was to reexamine carefully the cumulative chain yields from the thermal neutron fission of ^{239}Pu by using improved measurement techniques and by determining absolute yields.

EXPERIMENTAL

(a) Irradiation

The ^{239}Pu was in the form of a plutonium–aluminium alloy containing 3.81% ^{239}Pu by weight. Amounts of this alloy equivalent to ~1 mg ^{239}Pu were accurately weighed and then sealed in quartz vials. Weighed amounts (0.5 to 1.00 mg) of "spec. pure" (0.005 in. diameter) cobalt wire were sealed into similar vials to serve as flux monitors. The capsules containing the Pu–Al alloy and the cobalt wire were then irradiated together for a period of 48 h in a position in the NRX reactor at Chalk River where the neutron flux was predominantly thermal.

(b) Treatment of Pu–Al Alloy

On account of the low concentration of ^{239}Pu in the alloy, ~0.5 atom %, recoil losses of fission products into the quartz tube were expected to be small. Nevertheless, during the dissolution of the alloy, the quartz vial was leached as described below. The quartz tube was covered with conc. hydrochloric acid to which was added 1 ml of a solution containing 1 μg each of Cs^+, Ba^{++}, La^{+3}, and I^- ions. The quartz capsule was crushed and the alloy allowed to dissolve. When bromine or iodine were to be separated, dissolution was carried out in the cold by immersing the solution in ice water; otherwise dissolution was allowed to proceed

[1]*This work received financial assistance from the National Research Council of Canada.*

at room temperature. After the sample had dissolved, the solution was transferred to a volumetric flask. The crushed pieces of the quartz tube were washed several times with small portions of conc. hydrochloric acid, the washings being transferred each time to the volumetric flask. Several washings with distilled water were done in a similar manner. Aliquots were removed from the fission product stock solution and the fission products of interest were separated by standard radiochemical procedures (Appendix I) and their activities measured. Chemical yield recoveries in general were determined spectrophotometrically by standard methods (Appendix I).

(c) Treatment of Flux Monitor

The irradiated cobalt wire was removed from the quartz capsule and dissolved in nitric acid. The crushed vial was repeatedly leached with small volumes of dilute nitric acid until the remaining activity was negligible. The combined solutions were made up to volume and known aliquots were removed for disintegration rate determinations.

(d) Disintegration Rate Determinations and Identification of Nuclides

All disintegration rates were determined using the $4\pi\beta$-counting techniques described by Pate and Yaffe (11–15). Aliquots of the samples were deposited on calibrated gold-coated VYNS films (15–20 $\mu g/cm^2$) and dried under infrared radiation. The films were pretreated with a 5% insulin solution to ensure even deposition of the source on a known area. Corrections for absorption of radiation in the source mount and self-absorption losses were determined from absorption curves of Pate and Yaffe (13, 15) and Yaffe and Fishman (16). The half-lives of the nuclides were determined by $4\pi\beta$-counting and the nuclides were further identified by γ scintillation spectrometry both with respect to γ-ray energies and the half-lives of γ-ray decay.

RESULTS

(a) Neutron Flux Determinations

The neutron flux was calculated by means of the equation

$$(N\lambda)_{^{60}Co} = N_{^{59}Co} I\sigma_c(1 - e^{-\lambda T})e^{-\lambda t},$$

where $(N\lambda)_{^{60}Co}$ = ^{60}Co disintegration rate at a time t after an irradiation, $N_{^{59}Co}$ = no. of ^{59}Co atoms, I = thermal neutron flux, σ_c = thermal neutron capture cross section for ^{59}Co, and T = time of irradiation. The half-life of ^{60}Co was taken as 5.26 yr (17). The neutron flux is attenuated to 0.97 of its initial value by the 0.005 in. diameter cobalt wire (18) and corrections were made for this. The thermal neutron capture cross section used for ^{59}Co was 37.5 barns (19, 20).

(b) Fission Rate Determinations

On account of the low atom concentration, ~0.5% of ^{239}Pu in the alloy, the attenuation of the neutron flux in the fissile material was small enough to be neglected. The fission rates were calculated from the equation

$$R = N_{^{239}Pu} I\sigma_f,$$

where N = no. of ^{239}Pu atoms, I = thermal neutron flux, and σ_f = thermal neutron fission cross section for ^{239}Pu. The value of σ_f used was 742 barns (21).

(c) Activities Isolated

1. Bromine

The decay data for the bromine sample could be resolved into a 34-h activity with longer-lived components having half-lives of 4.2 d and 37 d and of roughly equal activities at time of separation. It was not possible to identify the longer-lived activities by γ-ray spectrometry.

^{82}Br, a shielded nuclide, occurs in very low yield and this undoubtedly accounts for the divergence from the 36-h literature value.

2. Strontium

The elapsed time from the end of bombardment to the time of separation was such

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

that only ^{89}Sr and ^{90}Sr were expected to be present. The decay data were resolved into 50-d ^{89}Sr and a long-lived component, which was taken to be ^{90}Sr (27.7 yr) and ^{90}Y (64 h) in equilibrium.

3. Yttrium

Yttrium samples were measured several days after the radiochemical separation so that all the 64-h ^{90}Y had decayed. The remaining yttrium activity decayed with a half-life of 59 d over a period of 5 half-lives and corresponded to ^{91}Y.

4. Zirconium

The zirconium activity decay curve was observed to increase to a maximum at about 30 d then to die away into a long-lived tail. The amount of this long-lived activity was estimated and subtracted from the gross counting rates to give a decay curve which grew to a maximum and then decayed with a 65-d half-life. A gamma ray spectrum of the zirconium fraction showed a prominent photopeak at 728 keV which shifted to 767 keV as the decay was followed. The decay of this gamma peak also increased to a maximum and then died away with a 65-d half-life. This was consistent with the growth of ^{95}Nb from a freshly separated ^{95}Zr parent. The long-lived activity was not identified. Disintegration rates to determine fission yields were obtained by extrapolating the $4\pi\beta$-counting data back to the time of separation, where the ^{95}Nb daughter was absent.

5. Niobium

The niobium fraction decayed with a half-life of 36.5 d measured over a period of 6 half-lives. The gamma spectrum contained a very prominent 758 keV photopeak which decayed with a 34.2-d half-life. This is consistent with the decay of ^{95}Nb. The 90-h ^{95m}Nb was not detected. In the β^--disintegration measurements, very large absorption corrections had to be applied because of the large amount of oxalic acid necessary to keep the niobium oxide in solution. Since ^{95}Nb is only one charge unit away from stability, its independent yield will be extremely small and all the niobium activity results from the decay of ^{95}Zr during and after the irradiation up to the time of separation. The ^{95}Nb disintegration rates were therefore used in growth and decay equations to calculate the ^{95}Zr fission yields.

6. Molybdenum

Freshly separated molybdenum activities showed an initial growth followed by decay with a half-life of 68.2 h lasting for about 6 half-lives. Thereafter the decay curves began tailing off, indicating the presence of a long-lived activity. These data together with gamma spectra and the decay of the gamma peaks were consistent with the growth of ^{99m}Tc and ^{99}Tc from a freshly separated ^{99}Mo parent. Since the complexity of the decay schemes involved did not allow direct calculation of ^{99}Mo disintegration rates, counting data were obtained as soon after separation as possible, and the ^{99}Mo disintegration rates were then obtained by extrapolating back to the time of separation.

7. Ruthenium

The gross decay curve obtained from $4\pi\beta$-measurements was resolved graphically into two components, one with a 1.01-yr half-life and the other with a 38-d half-life. The gamma spectrum of the ruthenium fraction showed a very prominent 508-keV gamma peak. The decay curve of this peak could be resolved into a 1.0-yr half-life and a 37-d half-life. These two activities were assigned to ^{103}Ru and ^{106}Ru respectively.

To determine the disintegration rate of ^{103}Ru, corrections have to be made for the contribution of the conversion electrons from 57-min ^{103m}Rh to the counting rate. Similarly the $4\pi\beta$-counter will measure the contributions from both ^{106}Ru (1 yr) and ^{106}Rh (30 s)

and corrections have to be made. Details for obtaining these corrections are given in Appendix II.

8. Rhodium

The β^--decay curve of the rhodium activity, measured on the $4\pi\beta$-counter, showed a single component with a half-life of 36 h measured over 7 half-lives. The gamma spectrum contained one photopeak at 315 keV which decayed with a half-life of 36 h, confirming the fact that the rhodium activity was ^{105}Rh.

9. Silver

The decay curve of the silver activity fraction was resolved into a 7.5-d component (over 7 half-lives) and a 3.2-h component (over 4 half-lives). The energy and decay of gamma peaks observed in the gamma spectra were consistent with the assignment to ^{111}Ag and ^{112}Ag respectively. Since the separation of the silver activity had taken place when all the independently formed ^{112}Ag had already decayed, this activity results from the decay of ^{112}Pd.

10. Palladium

The gross β^--decay curve was resolved into a 21-h component and a 12-h component. The early portion of the decay due to the 21-h component was calculated assuming that the later section of the decay represented an equilibrium mixture of ^{112}Pd (21 h) and ^{112}Ag (3.2 h). The resolved decay curve and the original data are shown in Fig. 1. A gamma ray spectrum of the palladium activities showed gamma peaks at 20, 90, and 626 keV. The decay of the 626-keV peak showed an initial growth and subsequent decay with a 21-h half-life. The decay of the 20-keV peak was resolved into a 12.5-h component and a 21-h component, while the 90-keV peak decayed with a half-life of 12.8 h. These data confirmed the presence of ^{109}Pd and ^{112}Pd.

In determining the disintegration rate of ^{109}Pd, it was necessary to take into account the conversion electrons emitted by ^{109m}Ag; the calculations for this are shown in Appendix II*c*.

For ^{112}Pd it was necessary to consider the growth of ^{112}Ag which contributes to the equilibrium counting rate. The data and calculations are given in Appendix II*d*.

11. Cadmium

The gross β^--decay curve was resolved graphically into a 43-d component and a 53.4-h component (over 9 half-lives). This corresponded to ^{115m}Cd and ^{115g}Cd. A gamma ray spectrum taken several hours after the separation showed an X-ray to be present, together with gamma rays of energies 255, 333, and 526 keV. This was almost identical with the gamma spectrum for 54-h ^{115}Cd in equilibrium with 4.5-h ^{115}In given by Heath (22) and compared well with gamma rays for ^{115}Cd listed in the Nuclear Data Sheets (23). The 333-keV gamma ray was observed to grow and then to decay with a half-life of 54 h, while the 527-keV gamma ray decayed with a similar half-life. The absence of gamma rays characteristic of ^{115m}Cd resulted from the very small amount of this activity present in the sample and from the fact that about 97% of the beta disintegrations (23) lead directly to the ground state of ^{115}In.

Since ^{115g}Cd decays to metastable ^{115m}In (4.5 h), the measured disintegration rate had to be corrected for the additional counts registered as a result of conversion electron emission. The details of this calculation are shown in Appendix II*e*.

12. Antimony

The gross β^--decay curve was resolved into 3.73-d ^{127}Sb, 12.8-d ^{126}Sb, 61-d ^{124}Sb, and a long-lived activity considerably above the background rate, probably due to ^{125}Sb.

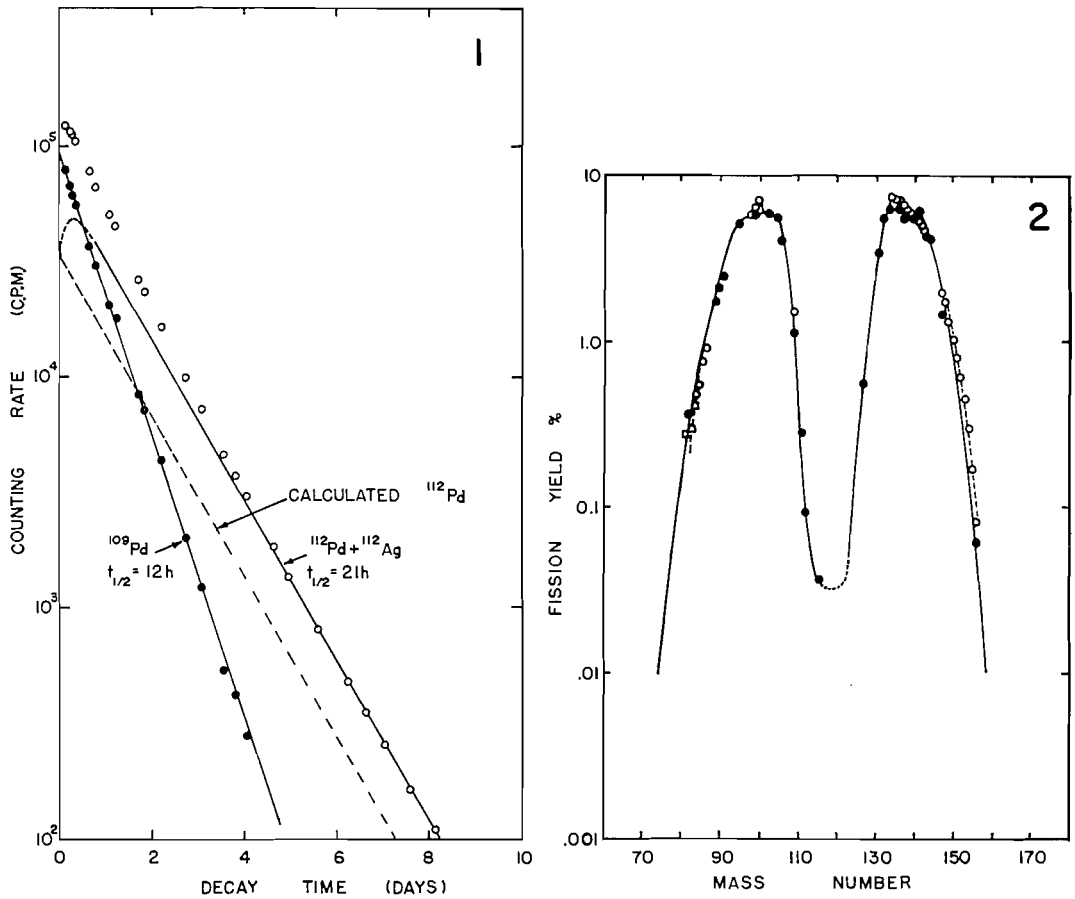

FIG. 1. Palladium activity decay curve.
FIG. 2. Mass distribution curve for thermal neutron fission of ^{239}Pu. ●This work, ○Fickel and Tomlinson (4, 5), □Croall and Willis (29).

Identification by means of gamma ray spectra was not attempted because of the complexities of the decay schemes involved.

Disintegration rate determinations for ^{124}Sb and ^{126}Sb are straightforward. These are shielded nuclides and thus are primary fission products. For ^{127}Sb it was necessary to take into account the amount of the ^{127}Te activity which would be in equilibrium with its parent. The calculations and data used in the correction factors are shown in Appendix II*f*.

13. Tellurium

The decay curve for the tellurium fraction was resolved into 105-d, 33-d, and 3.27-d components corresponding to ^{127m}Te, ^{129m}Te, and ^{132}Te in equilibrium with ^{132}I respectively. The ^{132}Te was identified by the decay of the ^{132}Te 230-keV gamma peak and the growth and decay of the 675-keV gamma peak of ^{132}I. The disintegration rate of ^{132}Te was calculated using standard growth and decay equations. No yield data were calculated for ^{127m}Te and ^{129m}Te since not sufficient information about conversion coefficients was available.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

14. Iodine

Sources for beta disintegration determinations were prepared by pipetting aliquots of the final lithium iodide solution on to gold-coated VYNS films and drying them under an infrared lamp. Kjelberg *et al.* (24) have used this technique in preparing iodide sources for $4\pi\beta$-measurements. The lithium iodide continuously released the xenon formed by the decay of iodine activity, and no measurable evaporation losses of iodine activity were found.

The decay curve was resolved graphically into 8.05-d ^{131}I, 21-h ^{133}I, and 2.4-h ^{132}I, and the assignments were confirmed by following the decay of the 360-keV γ-ray of ^{131}I, the 530-keV γ-ray of ^{133}I, and the 675-keV γ-ray of ^{132}I.

The ^{132}I disintegration rates were used to calculate ^{132}Te fission yield data since all independently formed ^{132}I had decayed at the time of the iodine separation.

15. Cesium

The gross β^--decay curve of the cesium activity was resolved graphically into a 12.9-d component and a long-lived component which had a counting rate considerably above background. A gamma ray spectrum taken a few hours after separation showed gamma peaks consistent with the presence of 12.9-d ^{136}Cs. A subsequent spectrum taken about 100 d after the first showed only a 662-keV gamma peak indicating the presence of ^{137}Cs. In determining the disintegration rate of ^{137}Cs it is necessary to take into account the internal conversion of the 662-keV gamma ray. The data and calculations are shown in Appendix II*g*.

16. Barium

The barium activity was measured immediately after separation, at half-hour intervals during the first 5 h after separation, and then less frequently. Since the growth of ^{140}La is linear during the first few hours, accurate back-extrapolation to the separation time to determine the ^{140}Ba disintegration rates could be made.

The decay curve was seen to rise to a maximum and then die away with a half-life of 12.8 d. Gamma ray energies and the decay of the gamma peaks were consistent with the decay of ^{140}Ba and the growth of ^{140}La from this parent.

17. Cerium

The gross β^--decay curve was resolved by subtracting a long-lived background activity from the experimental counting rates. A 33-d component and a 35.4-h component were then observed. The background activity, as drawn, had a half-life of about 2 yr and by trial and error was resolved into a long-lived activity considerably above background and a 285-d component. The 35.4-h activity was taken to be ^{143}Ce, the 33-d to be ^{141}Ce, and the 285-d to be ^{144}Ce. The γ-ray spectra of the cerium fraction were quite complex, and therefore γ-ray decays were not followed. For ^{144}Ce it was necessary to correct for the contribution of ^{144}Nd (17 min) daughter activity. Because of the short half-life of the latter, at equilibrium the disintegration rates of parent and daughter are equal. Furthermore, since absorption in the source mount and source material of both activities was negligible, the observed counting rates are equal.

18. Rare Earths

(i) Neodymium.—The β^--decay curve of the neodymium fraction was seen to die away with an 11-d half-life and then to tail off into a long-lived activity. The neodymium activity expected to be present at the time of separation occurs in the chain

$$\text{short-lived } ^{147}\text{Nd}(11.1\text{ d}) \rightarrow ^{147}\text{Pm}(2.6\text{ yr}) \rightarrow ^{147}\text{Sm}(1.3 \times 10^{11}\text{ yr}).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The time required for the ^{147}Pm daughter to reach maximum activity is 72 d. From the decay curve this time was about 44 d. Thus some other long-lived activity was present, in an amount estimated to be 4% of the counting rate of ^{147}Nd at separation time. This was subtracted from the ^{147}Nd counting rate for the disintegration rate determination. A gamma ray spectrum of the neodymium fraction showed photopeaks with 33, 93, 308, 416, 530, and 685-keV energies. This compared well with the gamma ray spectrum given by Heath (22) for ^{147}Nd. The 530-keV peak was seen to decay with a half-life of 11.5 d.

(ii) Europium.—The β^--decay of the europium activity was resolved into a 71.5-d component and a 15.3-d component. The activities expected to be present were 1.7-yr ^{155}Eu and 15.4-d ^{156}Eu. Since, at the end of the counting period, 120 d, the ^{156}Eu activity would have decayed through about 8 half-lives, its contribution to the counting rate would be negligible at that time. It would seem then that an activity with a half-life between 15 d and 1.7 yr, in addition to the 1.7-yr ^{155}Eu, remained in the europium sample. A gamma ray spectrum of the europium activities showed photopeaks with energies of 45, 93, 624, 806, 1160, and 1940 keV respectively, consistent with gamma ray spectra of ^{155}Eu and ^{156}Eu shown by Heath (22).

ERRORS

(a) Systematic Errors

These errors arise in weighing, diluting, and pipetting and in chemical yield analyses. A sensitive microbalance was used for all weighings, while calibrated volumetric glassware and micropipettes were used for dilutions and pipetting. Chemical yield determinations were done either by spectrophotometry, by titration, or by weighing. A Beckman DU spectrophotometer was used in making the absorbance measurements, while in the titrations calibrated pipettes and microburettes were used. The estimated errors from the above causes were less than ±3%. By the use of very thin films the source mount absorption errors were kept to ±0.2%. In order to make self-absorption losses as small as possible, only 5 to 10 mg of carrier was added before the chemical separations, the amount used depending upon the reported efficiency of the separation scheme employed. Errors associated with self-absorption losses were assessed at 0.1 to 2%, depending upon the energy of the β^--radiations. The loss of activity due to fission recoil was assumed to be negligible because of the low concentration of plutonium in the alloy used and the chemical treatment of the quartz vial.

(b) Statistical Errors

For all measurements on the 4π proportional counter, more than 10 000 counts were recorded per counting period, so that these errors were less than ±1%. Sources were prepared at least in duplicate, and only those whose counting rates agreed within 1% were used for disintegration rate determinations.

(c) External Errors

These arise in the decay schemes and decay constants of the nuclides of interest and influence the fission yields when used. Each fission yield was determined using the observed half-life and the decay scheme, as discussed.

In connection with saturation activity calculation, the pile power was constant during all the irradiations.

The calculated fission yields depend upon the ratio of the capture cross section for cobalt and the thermal neutron fission cross section for ^{239}Pu. The values used for these were obtained from the literature. Where several values were obtained for a fission yield,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

an average value was calculated assuming equal statistical 'weights' for the individual values. The error quoted for the average fission yield is the standard deviation.

Where a single determination of a fission yield was made an error of ±5% is quoted, while for two yield values the calculated average is given with the limits of the two values as the quoted error.

DISCUSSION

The fission yields are given in Table I along with previous literature values for the yields of masses measured in this work. Isobaric yields were determined for the non-shielded nuclides by calculating Z_p, the most probable nuclear charge, according to the equal charge displacement hypothesis (25) for the mass numbers concerned and then interpolating on the charge distribution curve of Wahl *et al.* (26) to obtain the fractional cumulative yield. The isobaric yields calculated in this way were identical with the experimental values except in the case of ^{133}I where the isobaric value is 6.14%.

TABLE I

Absolute thermal neutron fission yields for ^{239}Pu

*Mass spectrometrically determined yields.
†Radiochemically determined yields.
‡Independent yields.
§Interpolated yields.

Independent yields for four shielded nuclides, ^{82}Br, ^{124}Sb, ^{126}Sb, and ^{136}Cs, have been measured. Of these only the ^{136}Cs yield has been measured previously. The value obtained, 0.083%, is in excellent agreement with that of Glendenin (0.089%) reported by Steinberg and Glendenin (8) and that of Grummitt and Milton (27) (0.0835%). The independent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

yields were converted to isobaric yields by obtaining the fractional yields from the charge distribution curve (26). The isobaric yields for ^{82}Br and ^{136}Cs were found to be 0.35% and 6.30% respectively. However, the values obtained for ^{124}Sb and ^{126}Sb are too high by several orders of magnitude when plotted on the mass distribution curve. This seems to be in accord with the observation of Kennett and Thode (28) that, for masses A = 128–132, Z_p remains near 50. The influence of the 50-proton shell seems to maintain itself in the case of antimony (Z = 51).

In general, the agreement with other radiochemically determined yields is good. The yield values in column 4 have an associated error of ±10–20% (8). The agreement with mass spectrometric data is good on the rising and falling wings of each peak but poor at the maxima of the peaks. The ^{99}Mo yield of 5.61% is some 1% lower than the yield obtained by interpolation from the mass spectrometric data. This interpolated value is, however, a reflection of the very high yield, 7.05%, obtained mass spectrometrically for ^{100}Mo. It was not possible in this work to determine radiochemically the yield at mass 100 since the radioactive members of the chain are short-lived.

Discrepancies in the yields of ^{133}I, ^{136}Cs, ^{137}Cs, and ^{141}Ce occur in the heavy peak. The chain yield for masses 133 and 136 depend upon the fractional yields interpolated from the charge distribution hypothesis and would reflect the uncertainties involved in determining Z_p. The ^{137}Cs yield of Fickel and Tomlinson (5) was obtained using 26.6 yr for the half-life of this nuclide. A recently reported value for this half-life is 29.68 yr (17), but this should only affect their result very slightly. The ^{141}Ce yield reported in the present work is only the result of a single determination and cannot be regarded as confirmed.

The isobaric yields obtained in the present work are plotted as a function of the mass number to give the mass distribution curve shown in Fig. 2. Also included are the results of the mass spectrometric determinations (4, 5) at masses where the yields differ. Recent data for masses 81, 83, and 84 by Croall and Willis (29) are also included in order to delineate better the wing of the curve. The mass distribution is seen to be symmetrical about mass 118 with the two maxima representative of asymmetric fission. The width at half height is approximately 16 mass units for both peaks, and the peak-to-valley ratio is about 160. The sum of the yields in the light peak is 97%, while that of the heavy peak is 93%. The yields in each peak should sum up to 100%. The difference is seen to be mainly in the yields at the top of the peaks.

APPENDIX I
CHEMICAL TREATMENT OF SAMPLES

(a) Bromine

Bromine was separated by the method of Glendenin *et al.* (30). Bromate and iodate carriers were added to an aliquot of the fission product solution, which was then treated with hydrogen sulfide to ensure exchange between active bromine and the carrier. The bromine was oxidized with potassium permanganate and extracted with carbon tetrachloride; several oxidation–reduction cycles were performed together with extractions into and out of carbon tetrachloride to purify the bromine. Finally, the bromine was reduced to bromide by sulfurous acid, warmed to remove excess sulfur dioxide, and then neutralized with dilute lithium hydroxide solution. The active solution was made up to a known volume. Chemical yields were determined according to Volhard's method.

(b) Strontium

The method of Glendenin (31) was used to separate strontium. Barium and strontium carriers were added to an aliquot of the fission product solution and their mixed nitrates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

were precipitated with fuming nitric acid. Barium was removed as the chromate after the nitrates had been dissolved in water, leaving the strontium behind in solution. The strontium was purified by precipitating the oxalate from ammoniacal solution, dissolving the oxalate precipitate in dilute nitric acid, and again precipitating the nitrate. The nitrate was washed with ethyl alcohol, dissolved in water, and made up to volume. The chemical yield was determined by titration with EDTA (ethylenediaminetetraacetic acid) in a 50% alcoholic solution, using phthalein complexone as indicator (32).

(c) Yttrium

Yttrium was separated from an aliquot of the fission product solution by the method of Ballou (32). Carriers for cerium, yttrium, lanthanum, and zirconium were added to the solution from which yttrium and the rare earths were precipitated as fluorides. After the fluorides were dissolved in a boric acid – nitric acid mixture, cerium was removed, as recommended by Boldridge and Hume (33), by oxidation with sodium bromate and precipitation of the iodate. The rare earths were removed from the supernate by precipitating the potassium – rare earth carbonates. The yttrium, left in solution, was precipitated as the hydroxide, dissolved in dilute hydrochloric acid, and made up to volume. Chemical yields were determined spectrophotometrically using the sodium alizarin sulfonate method (34).

(d) Zirconium

With slight modifications, Moore's solvent extraction method (35), which makes use of the solubility of zirconium–TTA (2-thenoyltrifluoroacetone) complexes in xylene was used. A preliminary separation of barium fluozirconate (36) was necessary since plutonium is extracted along with zirconium in this method. Zirconium was recovered from the $BaZrF_6$ precipitate by dissolving it in dilute H_3BO_3–HNO_3 mixture, removing the barium as sulfate, and precipitating zirconium hydroxide. The hydroxide was dissolved in dilute nitric acid and extracted into a xylene solution of TTA. The organic phase was scrubbed with 1 *M* nitric acid and the zirconium removed with 0.25 *M* hydrofluoric acid. Barium fluozirconate was again precipitated and the zirconium was recovered as before. The precipitate was dissolved in dilute nitric acid and made up to a volume of 10 ml. Chemical yield was determined by developing the colored zirconium–'Thoron' [1-(*O*-arsonophenylazo)-2-naphthol-3,6-disulfonic acid] complex (37).

(e) Niobium

Niobium was separated by Glendenin's method (38) in which the oxide is precipitated from an oxalic acid solution with chloric acid. Purification from zirconium was achieved by adding zirconium hold-back carrier and repeatedly precipitating the oxide. The final precipitate was dissolved in saturated oxalic acid solution and made up to volume. Chemical yields were determined on the spectrophotometer by the thiocyanate method (34) in which the yellow niobium thiocyanate complexes are extracted into peroxide-free ethyl ether.

(f) Molybdenum

The method of Scadden (39) was used to separate molybdenum from the other fission products. Molybdenum carrier was added to an aliquot of the fission product mixture. The acidity was adjusted to about 1 *M* and molybdenum precipitated with α-benzoinoxime in ethanol. The precipitate was dissolved in fuming nitric acid and the molybdenum reprecipitated as before, after the acid solution was diluted and partially neutralized.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The α-benzoinoxime was destroyed by dissolving the precipitate in fuming nitric acid and fuming with perchloric acid. After a ferric hydroxide scavenge was made, the molybdenum was precipitated as lead molybdate from the buffered solution. The precipitate was dissolved in dilute nitric acid and made up to volume. Chemical yields were determined spectrophotometrically on the colored molybdenum thiocyanate complex extracted with a carbon tetrachloride – *n*-amyl alcohol mixture (34).

(g) Ruthenium

Ruthenium was separated from the other fission products by distilling the volatile ruthenium oxide, RuO_4 (40). Ruthenium(III) iodide and bromide carriers were added, and ruthenium was oxidized to volatile RuO_4 with sodium bismuthate and perchloric acid. The ruthenium oxide was then distilled into a sodium hydroxide solution from which it was precipitated by adding ethanol. Further purification was obtained by repeated precipitations of the RuO_4 from alkaline solution with ethanol. The final precipitate was dissolved in 6 *M* hydrochloric acid and made up to volume. Chemical yields were determined by developing the strongly colored ruthenium–thiourea complex (34).

(h) Rhodium

By a method of Ballou (41) the pyridine complex of rhodium was extracted into pyridine from a strongly alkaline solution to separate rhodium from a fission product aliquot. Decontamination from tellurium is achieved by adding Te^{+4} hold-back carrier along with Rh^{+3} carrier before the extraction. The rhodium was recovered from the pyridine layer by precipitating the sulfide. The precipitate was dissolved in aqua regia, ruthenium was removed by adding Ru^{+3} carrier and distilling the ruthenium by fuming with perchloric acid, and finally halogens were removed by adding iodide carrier and again fuming with perchloric acid. Rhodium sulfide was again precipitated, dissolved in a minimum of aqua regia, and made up to volume. Chemical yields were determined spectrophotometrically by the stannous chloride method (42).

(i) Silver

The method of Glendenin (43) was used to separate silver. Silver chloride was precipitated by adding silver carrier to an aliquot of the fission product solution which had been diluted so that the chloride concentration was about 0.3 *M*. Exchange between the carrier and any silver activity was ensured by gentle boiling and brisk stirring. After the silver chloride was dissolved in ammonium hydroxide, purification was achieved by performing two cycles of ferric hydroxide scavenging followed by precipitation of silver sulfide, the sulfide being dissolved in nitric acid between cycles. Silver was finally precipitated as silver chloride, dissolved in ammonium hydroxide, and made up to volume. Chemical yields were determined by titrating with EDTA the Ni^{+2} liberated on reacting Ag^+ with tetracyanonickelate ion, $[Ni(CN)_4]^{-2}$, in ammoniacal solution, muroxide being used as indicator (44).

(j) Palladium

A method of Seiler (45) was used to separate palladium from the other fission products. Palladium dimethylglyoxime was precipitated from acid solution. Repeated scavenging with lanthanum and zirconium hydroxides and silver chloride provided further purification. The final dimethylglyoxime precipitate was dissolved by boiling with a small amount of aqua regia and made up to volume. Chemical yields were determined in a procedure similar to that used for silver (44).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(k) Cadmium

Cadmium was separated from an aliquot of the fission product solution by the method of Glendenin (46). This consisted of repeated precipitations of cadmium sulfide interspersed with ferric hydroxide and palladium sulfide scavenging precipitations. The final cadmium sulfide precipitate was dissolved in a small amount of dilute hydrochloric acid. The solution was boiled to remove hydrogen sulfide and then made up to volume. Chemical yield determinations were made by titrating aliquots of the solution with EDTA using Eriochrome Black T (+ methyl red) as an indicator (44).

(l) Antimony

Exchange between carrier and the antimony activity was assured by adding Sb^{+3} carrier to an aliquot of the fission product solution and then oxidizing Sb^{+3} to Sb^{+5} with bromine water. Metallic antimony was precipitated with chromous chloride (47). The precipitate was dissolved in aqua regia and further purified by precipitating the sulfide. The final precipitate was dissolved in a minimum of hydrochloric acid, boiled to remove excess hydrogen sulfide, and made up to volume. Chemical yields were determined by precipitating metallic antimony with chromous chloride and weighing.

(m) Tellurium

Tellurium was recovered by precipitating the metal with sulfur dioxide in acid solution. The precipitate was dissolved in 6 *M* nitric acid and fumed with hydrobromic acid to volatilize selenium. Further decontamination was achieved by repeated ferric hydroxide scavenges. The tellurium was finally recovered as the metal, dissolved in nitric acid, and made up to volume. Chemical yields were determined by precipitation of the metal and weighing.

(n) Iodine

Iodine was separated from the fission products by the solvent extraction method of Glendenin and Metcalf (48). Iodine carrier was added and the iodide was oxidized to periodate by sodium hypochlorite in alkaline solution. Exchange between active iodine and the carrier was ensured by heating or by allowing oxidation to proceed at room temperature followed by reduction to I_2 with hydroxylamine hydrochloride in acid solution. The iodine was then extracted with carbon tetrachloride followed by extraction with sulfurous acid. Another oxidation–reduction cycle followed in which sodium nitrite was used to oxidize I^- to I_2 and sulfurous acid was used to reduce I_2 to I^-. The solution was then boiled to remove excess sulfur dioxide, after which the I^- was neutralized with a dilute lithium hydroxide solution and made up to volume. The chemical yield was determined by oxidizing the I^- to I_2 from an aliquot of the solution, extracting with a fixed volume of CCl_4, and measuring the absorbance at 517 mμ (49).

(o) Cesium

Cesium activity was separated from an aliquot of the fission product mixture by the method of Glendenin and Nelson (50). Cesium carrier was added and a silicotungstate precipitation was performed. The precipitate was dissolved in sodium hydroxide and the cesium converted to the perchlorate by boiling the solution with perchloric acid. Upon dilution, silica and tungstic acid were precipitated and removed by centrifugation. The supernate was again fumed with perchloric acid from which, after cooling, the cesium perchlorate was precipitated by the addition of absolute alcohol. The cesium perchlorate was dissolved in water, and the resulting solution was scavenged by precipitating ferric hydroxide with ammonia from the heated solution. After removing the ferric hydroxide,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the supernate was boiled with a small amount of sodium hydroxide to remove ammonia completely. From this solution the cesium was precipitated as perchlorate. The precipitate was washed several times with absolute alcohol, dissolved in water, and made up to volume. Chemical yields were obtained by precipitating the cesium as chloroplatinate and weighing.

(p) Barium

Barium was separated from the fission product mixture by the method of Glendenin (31). After the addition of carriers, barium and strontium were isolated by precipitation of the nitrates with fuming nitric acid. The barium was then separated from strontium by precipitating the chromate from a buffered solution of the mixed nitrates. Further purification was obtained by repeated precipitations of barium chloride with an HCl–ether mixture. The final chloride precipitate was dissolved in water and made up to volume. Chemical yields were determined by titration with EDTA in a 50% alcoholic solution using *o*-cresolphthalein complexone as indicator (44).

(q) Cerium

Cerium was isolated from the other fission products by oxidation with bromate in nitric acid and precipitation of the iodate with iodic acid (33). Repeated cycles of this operation were performed to separate cerium from the other rare earths. Further purification was obtained by reducing Ce^{+4} to Ce^{+3} and precipitating zirconium iodate. The cerium was finally precipitated as the hydroxide, dissolved in a minimum of hydrochloric acid, and made up to volume. Chemical yields were determined by the alizarin sulfonate method (34).

(r) Rare Earths

The rare earth activities, europium and neodymium, were separated by a combination of the methods of Nervik (51) and Smith and Hoffmann (52). Europium and neodymium carriers were added and the rare earth fluorides were precipitated. These were dissolved, scavenged by zirconyl phosphate and barium sulfate precipitations, and separated by elution from a Dowex-1 anion exchange column with conc. hydrochloric acid. After elution, the rare earth hydroxides were precipitated and dissolved in a small amount of conc. hydrochloric acid. Europium and neodymium were separated by elution at room temperature from a Dowex-50 cation exchange column with a 0.3 *M* α-hydroxyisobutyric acid solution adjusted to pH 4.1 with concentrated ammonia. The individual rare earths were then precipitated as the hydroxides, dissolved in a minimum of dilute hydrochloric acid, and made up to volume. Chemical yields were determined on the spectrophotometer by the sodium alizarin sulfonate method (34).

APPENDIX II

DETERMINATION OF DISINTEGRATION RATES

(a) Correction for Contribution of the Conversion Electrons from 57-min ^{103m}Rh to the Determination of the ^{103}Ru Disintegration Rate

The number of extra events counted per beta disintegration of ^{103}Ru is given by

$$N_{e^-} = \left(\frac{\alpha_T}{1+\alpha_T}\,\text{B.R.}\right) + \left(e\,\frac{1}{1+\alpha_T}\,\text{B.R.}\right),$$

where α_T = total internal conversion coefficient, e = efficiency for detecting the unconverted gamma rays, and B.R. = branching ratio. From the following data α_T is calculated to be 484. The value of α_K is 40 and $\alpha_K/\alpha_L = 0.09$ (53), where α_K and α_L are the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

conversion coefficients for the K and L shells respectively. The efficiency for detecting the unconverted 40-keV gamma rays is less than 0.14% (54) so that the second term can be neglected. Therefore

$$N_{e^-} = \left(\frac{484}{485} \times 0.995\right) = 0.993.$$

The energies of these conversion electrons are given by

$$E_{e^-} = E_\gamma - \text{B.R.},$$

the difference between the gamma ray energy and the binding energy of the electron in the K or L shell. Strominger *et al.* (55) gives 23.2 and 3.4 keV for the K and L electron binding energies respectively. This results in 9% of the conversion electrons having energies of 17 keV and 91% having 37-keV energy. Since these conversion electrons are monoenergetic, they will be absorbed to a different extent in the source mount and in the source itself than β^--rays of the same maximum energies. It was assumed that the absorption of conversion electrons was equivalent to the absorption of β^--rays having maximum energies of twice the energy of the conversion electrons (56). If ^{103}Ru and ^{103m}Rh are represented by subscripts 1 and 2 respectively, then since $\lambda_1 < \lambda_2$, at equilibrium

$$N_1\lambda_2 + N_2\lambda_2 = N_1\lambda_1(1.993)$$

that is

$$N_2\lambda_2 = 0.993\ N_1\lambda_1.$$

Putting $A_1 = c_1N_1\lambda_1$ and $A_2 = c_2N_2\lambda_2$, where A_1 and A_2 are the observed counting rates of ^{103}Ru and ^{103m}Rh and c_1 and c_2 are detection efficiencies given by the product of the self-absorption factor and the source mount absorption factor, then

$$\frac{A_1 + A_2}{A_1} = \frac{c_1N_1\lambda_1 + c_2N_2\lambda_2}{c_1N_1\lambda_1}$$

$$= \frac{c_1N_1\lambda_1 + 0.993\ c_2N_1\lambda_1}{c_1N_1\lambda_1}$$

$$= 1 + 0.993\frac{c_2}{c_1},$$

and

$$A_1 = \frac{A_1 + A_2}{1 + 0.993\frac{c_2}{c_1}}.$$

That is, the counting rate of ^{103}Ru is given by dividing the observed counting rate of ^{103}Ru + ^{103m}Rh by the factor $1 + 0.993\ c_2/c_1$. From this, $N_1\lambda_1$, the disintegration rate, for ^{103}Ru is given by

$$N_1\lambda_1 = \frac{A_1}{c_1} = \frac{A_1 + A_2}{c_1 + 0.993\ c_2}.$$

(b) Determination of the Disintegration Rate of ^{106}Ru

A computation, similar to the above, where subscripts 1 and 2 refer to ^{106}Ru (1 yr) and ^{106}Rh (30 s), gives the following:

$$\frac{A_1 + A_2}{A_1} = \frac{c_1N_1\lambda_1 + c_2N_2\lambda_2}{c_1N_1\lambda_1}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In this case, at equilibrium, since $\lambda_1 \ll \lambda_2$,

$$N_1\lambda_1 = N_2\lambda_2,$$

and therefore

$$\frac{A_1 + A_2}{A_1} = \frac{c_1N_1\lambda_1 + c_2N_1\lambda_1}{c_1N_1\lambda_1} = 1 + \frac{c_2}{c_1}.$$

The β^--rays of ^{106}Rh all have energies >2 meV and would therefore be absorbed to a negligible extent. Thus $c_2 = 1$ and

$$\frac{A_1 + A_2}{A_1} = 1 + \frac{1}{c_1}$$

$$N_1\lambda_1 = \frac{A_1}{c_1} = \frac{A_1 + A_2}{1 + c_1}.$$

The disintegration rate for ^{106}Ru is therefore given by dividing the observed counting rate of ^{106}Ru + ^{106}Rh by the factor $1 + c_1$.

(c) Correction for Contribution of Conversion Electrons from ^{109m}Ag to the Determination of the Disintegration Rate of ^{109}Pd

From the K shell conversion coefficient of 10.5 and the K/LM ratio of 0.84 for the 88-keV gamma ray (23), the total conversion coefficient, α_T, is calculated to be 22.6. This gives a value of 0.958 for the number of conversion electrons emitted per beta disintegration:

$$N_{e^-} = \frac{\alpha_T}{1 + \alpha_T} = 0.958.$$

The detection efficiency for the 88-keV unconverted gamma rays is less than 0.1% (54). The energy of these conversion electrons is the difference between the gamma ray energy and the electron binding energy. Strominger *et al.* (55) list the following for Ag: K electron binding energy 25.5 keV, L_1 and M_1 electron binding energy 5.8 and 0.7 keV respectively. Therefore 44% of the conversion electrons have energies of about 62 keV and 56% have energies of about 84 keV. The absorption determined as being equivalent to β^--rays with maximum energies of double the conversion electron energies gives a detection efficiency of 0.964 for the ^{109m}Ag disintegrations while the ^{109}Pd 1.025-keV β^--rays are negligibly absorbed, so that

$$\frac{\text{observed counting rate}}{^{109}\text{Pd counting rate}} = 1 + (0.958 \times 0.964) = 1.924.$$

(d) Correction for Growth of ^{112}Ag

For the determination of the disintegration rate of ^{112}Pd it was necessary to consider the growth of ^{112}Ag, which contributes to the equilibrium counting rate. At equilibrium the ratio of the disintegration rates is given by

$$\frac{N\lambda_{^{112}Ag}}{N\lambda_{^{112}Pd}} = \frac{\lambda_{^{112}Ag}}{\lambda_{^{112}Ag} - \lambda_{^{112}Pd}}.$$

If the half-life values are substituted, then

$$\frac{N\lambda_{^{112}Ag}}{N\lambda_{^{112}Pd}} = 1.180.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Now putting $A = cN$, where A is the observed activity and c is the detection efficiency,

$$\frac{A_{^{112}Ag} + A_{^{112}Pd}}{A_{^{112}Pd}} = \frac{c_{^{112}Ag}N\lambda_{^{112}Ag} + c_{^{112}Pd}N\lambda_{^{112}Pd}}{c_{^{112}Pd}N\lambda_{^{112}Pd}}$$

$$= 1 + \frac{c_{^{112}Ag}}{c_{^{112}Pd}}\frac{N\lambda_{^{112}Ag}}{N\lambda_{^{112}Pd}}$$

$$= 1 + 1.180\frac{c_{^{112}Ag}}{c_{^{112}Pd}}.$$

Since the efficiency for detecting ^{112}Ag is 1.00 and for ^{112}Pd is 0.991,

$$A_{^{112}Pd} = \frac{\text{observed counting rate}}{2.191}.$$

(e) Contribution of Conversion Electrons from ^{115m}In to the Determination of the Disintegration Rate of ^{115}Cd

From the data $\alpha_K = 0.83$ and $K/L_1M = 3.85$ (57), the total internal conversion coefficient, α_T, is calculated to be 1.05. From this the number of conversion electrons is given by

$$N_{e^-} = \frac{\alpha_T}{1 + \alpha_T} = 0.512,$$

and the number of unconverted gamma rays is therefore 0.488. Since ^{115m}In decays 94.5% by isomeric transition to ^{115}In and 5.5% by 840-keV β^--emission to ^{115}Sn, the observed β^--disintegration rate is related to the ^{115}Cd disintegration rate by

$$\text{observed D.R.} = {}^{115}\text{Cd D.R.}[1 + (0.512 \times 0.945) + 0.055].$$

Therefore

$$^{115}\text{Cd D.R.} + {}^{115m}\text{In D.R.} = {}^{115}\text{Cd D.R.}(1.539).$$

The efficiency of the 4π-counter for the 333-keV unconverted gamma rays is less than 0.14% (54), and the contribution due to these may therefore be neglected. At equilibrium, the disintegration rates of ^{115}Cd and ^{115m}In are related by

$$\frac{N_2\lambda_2}{N_1\lambda_1} = \frac{\lambda_2}{\lambda_2 - \lambda_1} = 1.093.$$

Here the subscripts 1 and 2 refer to ^{115}Cd and ^{115m}In respectively. Putting $A = cN\lambda$, where A is the observed counting rate and c is the detection efficiency,

$$\frac{A_1 + A_2}{A_1} = \frac{c_1N_1\lambda_1 + c_2N_2\lambda_2}{c_1N_1\lambda_1}$$

$$= 1 + \frac{c_2}{c_1} \times \frac{N_2\lambda_2}{N_1\lambda_1}$$

$$= 1 + \frac{c_2}{c_1} \times \frac{\lambda_2}{\lambda_2 - \lambda_1}.$$

The value of c_1 is 1.00 and c_2 is given by the product of the factor 0.539, calculated above, and the absorption factor of the conversion electrons which was estimated to be 0.996. Therefore

$$(A_1 + A_2)/A_1 = 1 + (0.539 \times 0.996 \times 1.093) = 1.587.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The observed counting rate for $^{115}Cd + {}^{115m}In$ was divided by this factor to give the ^{115}Cd counting rate.

(f) Correction for Contribution by ^{127}Te to the Determination of the Disintegration Rate of ^{127}Sb

From growth and decay considerations

$$\frac{N\lambda_{^{127}Te}}{N\lambda_{^{127}Sb}} = \frac{\lambda_{^{127}Te}}{\lambda_{^{127}Te} - \lambda_{^{127}Sb}} = 1.116.$$

From a consideration of actual activities measured on the 4π-counter,

$$\frac{A_1 + A_2}{A_1} = \frac{c_1N_1\lambda_1 + c_2N_2\lambda_2}{c_1N_1\lambda_1},$$

where subscripts 1 and 2 refer to ^{127}Sb and ^{127}Te respectively, A is the observed activity, and c is the detection efficiency, so that

$$\frac{A_1 + A_2}{A_1} = 1 + \left(\frac{c_2}{c_1} \times 1.116\right).$$

Since only 80% of the ^{127}Te activity assumes equilibrium with ^{127}Sb (the other 20% results from the isomeric transition from 105-d ^{127m}Te) and since both ^{127}Sb and ^{127}Te activities are negligibly absorbed in the source mount and the source material, then

$$(A_1 + A_2)/A_1 = 1 + (0.80 \times 1.116) = 1.895.$$

The observed counting rate of the combined activities was divided by this factor to give the counting rate of ^{127}Sb.

(g) Correction for Conversion Electrons from ^{137}Ba to Determination of Disintegration Rate of ^{137}Cs

The number of conversion electrons per disintegration of ^{137}Cs is given by $\alpha_T/(1 + \alpha_T)$, which is calculated to be 0.1066 from $\alpha_K = 0.0976$, $\alpha_K/\alpha_L = 5.66$, $\alpha_L/\alpha_{M,N} = 3.85$ (58). From this the number of unconverted gammas is 0.8934. The disintegration rate of ^{137}Cs is then given by

$$\text{observed D.R.} = {}^{137}\text{Cs D.R.}[1 + (0.1066 \times 0.95) + (0.8934 \times 0.95 \times 0.0018)],$$

where 0.95 is the branching ratio and 0.0018 is the estimated detection efficiency of the 4π-counter for the unconverted gamma rays. Thus

$$\text{observed D.R.} = 1.1028 \times {}^{137}\text{Cs D.R.}$$

Since the observed disintegration rate is the sum of the ^{137}Cs and the ^{137m}Ba disintegration rates, then

$$N\lambda_{^{137m}Ba} = 0.1028\, N\lambda_{^{137}Cs}.$$

But

$$\frac{A_1 + A_2}{A_1} = 1 + \frac{c_2N_2\lambda_2}{c_1N_1\lambda_1},$$

where the subscripts 1 and 2 refer to ^{137}Cs and ^{137m}Ba respectively, A is the observed counting rate, and c is the detection efficiency of the 4π-counter determined from the total absorption in the source mount and the source itself. Therefore

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$\frac{A_1 + A_2}{A_1} = 1 + \frac{0.1028\, c_2}{c_1}$$

and the ^{137}Cs counting rate is given by

$$A_1 = \frac{\text{observed counting rate}}{1 + (0.1028\, c_2/c_1)}.$$

Hence the ^{137}Cs disintegration rate is given by

$$N_1\lambda_1 = \frac{A_1}{c_1} = \frac{\text{observed counting rate}}{c_1 + 0.1028\, c_2}.$$

ACKNOWLEDGMENTS

1. We express our appreciation to Atomic Energy of Canada Ltd. for loan of the Pu–Al alloy used in this investigation.

2. One of us (D. A. M.) wishes to record his appreciation to Canadian Industries Ltd. for Fellowships given in 1959–1960 and 1961–1962 and to the Graduate Faculty of McGill University for award of the Alexander McFee Fellowship in 1960–1961.

KINETICS AND MECHANISMS OF THE THERMAL DECOMPOSITION OF PROPIONALDEHYDE

PART I. THE UNINHIBITED REACTION

K. J. LAIDLER AND M. EUSUF
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 4, 1964

ABSTRACT

The propionaldehyde pyrolysis was studied in the temperature range 520–560 °C and at pressures from 20 to 360 mm Hg. The reaction was followed by pressure change and by gas chromatography. The overall order was between 1.25 and 1.30 over the whole range of temperatures and pressures studied. Inert gases have no effect on the rates of formation of the products of reaction. The results are consistent with a mechanism consisting of first-order initiation, $C_2H_5CHO \rightarrow C_2H_5 + CHO$, and second-order termination, $C_2H_5 + C_2H_5 \rightarrow C_4H_{10}$ or $C_2H_6 + C_2H_4$. The overall rate can be expressed as $v = k[C_2H_5CHO]^{3/2} + k'[C_2H_5CHO]^{1/2}$. The molecular reaction, $C_2H_5CHO \rightarrow C_2H_6 + CO$, appears to be of minor importance. The reaction $C_2H_5 \rightarrow C_2H_4 + H$ was found to take place in its first-order high-pressure region under the conditions of the present investigations.

INTRODUCTION

Hinshelwood and Thompson (1) studied the thermal decomposition of propionaldehyde in the temperature range 450–600 °C; they reported that the reaction was completely homogeneous and approximately first-order with respect to propionaldehyde. Winkler, Fletcher, and Hinshelwood (2) also reported that the reaction was approximately first order. They analyzed the products of decomposition and found that the major products were CO and C_2H_6, and that considerable amounts of C_2H_4, H_2, and CH_4 were also produced. Sworski and Burton (3), studying this decomposition in the temperature range 850–950 °C, detected both CH_3 and C_2H_5 radicals and concluded that the C_2H_5 radicals are the principal chain carriers. Boyer and Niclause (4) investigated the thermal decomposition of propionaldehyde at somewhat lower temperatures (427–486 °C) and reported that the overall order of the decomposition was three-halves with respect to propionaldehyde. In a recent investigation Márta (5) observed that the overall order of decomposition was three-halves in the temperature range 515–565 °C and pressure range 100–250 mm Hg; he suggested a simple mechanism of the Rice–Herzfeld (6) type to explain his results. Recently Ho (7) compared the thermal decompositions of different aldehydes. His results show that the order of the propionaldehyde decomposition is significantly lower than that of acetaldehyde, which is known to be accurately three-halves (8). The presence of appreciable amounts of C_2H_4 and H_2 (2) shows that the C_2H_5 radical may not be as stable as suggested by Márta (5); in that case, since the chain carrier has some μ-character, the order of the propionaldehyde decomposition is expected to be lower than that of acetaldehyde, whereas in the latter case the stable CH_3 radical is the principal chain carrier.

In view of these uncertainties in the overall order of the decomposition and the stability of the C_2H_5 radical a reinvestigation of the thermal decomposition of propionaldehyde (both uninhibited and inhibited by NO) was felt to be desirable. The present experimental work was mainly concerned with establishing the order of reaction and the effect of inert gas. Other matters, such as mass balances, have been adequately dealt with by previous investigators.

EXPERIMENTAL

The apparatus used was essentially the same as described in a previous paper (8). The reaction was carried out in a quartz vessel 20 cm long and 4 cm wide having a dead space of about 1% of the total volume. The vessel was confined in a metal block, the temperature of which was controlled to within 0.2 °C. Analyses were made using a Perkin–Elmer Vapor Fractometer containing a thermal conductivity detector and a 4-metre silica gel column; dry helium was used as carrier gas.

The propionaldehyde was an Eastman Kodak product; it was purified by several distillations from 0 to −76 °C and stored in the dark. The inert gases used were Matheson research grade chemicals and were purified by several distillations.

RESULTS

Rates of Carbon Monoxide Formation

Several previous investigations (1, 2, 4, 7) have shown that the rate of pressure increase is a good measure of the rate of disappearance of propionaldehyde, and it was not considered necessary to confirm this. It was thought to be of interest, however, to relate the rate of pressure increase to the rate of carbon monoxide formation; since this substance is the only oxygen-containing product that has been detected, the rate of its formation should be equal to the rate of disappearance of the aldehyde. Figure 1 shows a plot of the

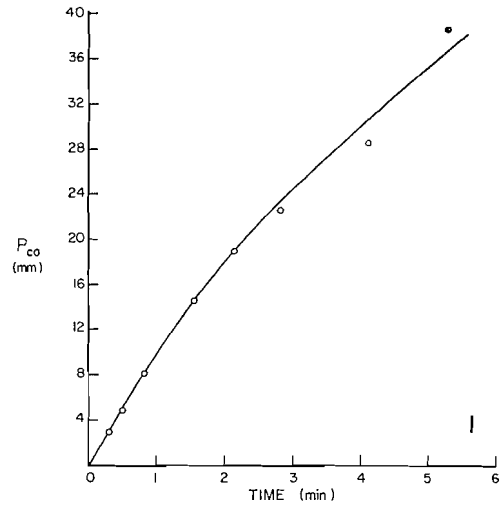

FIG. 1. Plot of the pressure of carbon monoxide formed against time with 100 mm of propionaldehyde at 540 °C.

pressure of the CO formed against time, at 540 °C and 100 mm pressure. The initial rate of appearance of CO is found from these results to be 0.154 mm per s, and this agrees satisfactorily (within 6%) with the value of 0.145 mm per s for the rate calculated from the pressure increase under the same conditions.

Ratios of Other Decomposition Products

Table I shows ratios of decomposition products corresponding to 6% decomposition at an initial pressure of 100 mm Hg. It is to be seen that there is a significant variation of the ratios with temperature and that ethane is a much more important product than ethylene and hydrogen over the entire temperature range. The fact that the ratios vary with temperature means that the correlations between pressure change and amount of aldehyde decomposed cannot be strictly valid over the entire range; however, since C_2H_4 and H_2 are minor products, the variation in their relative importance does not have a significant effect on the correlations.

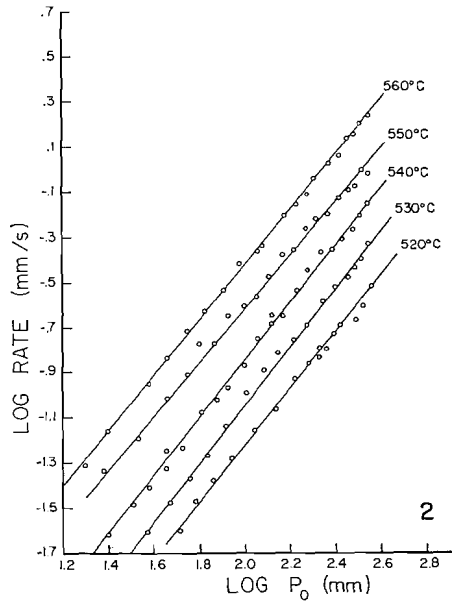

FIG. 2. Double logarithmic plots of initial rate against initial pressure of propionaldehyde at different temperatures.

TABLE I

Ratios of decomposition products
Initial pressure = 100 mm Hg; 6% decomposition

Temperature (°C)	C_2H_6/C_2H_4	H_2/C_2H_4
560	5.86	1.80
560	5.73	1.80
540	7.47	1.33
540	7.56	1.50
540	8.50	1.50
520	10.25	1.25
520	10.62	1.30

Some *n*-butane was detected in the products by the use of a 2,5-hexanedione column; the quantity formed is very small, being about 0.05% of the total products.

Order of Reaction

In view of the above results it is justifiable to determine the order of reaction and related parameters on the basis of pressure measurements. Figure 2 shows a double logarithmic plot of initial rates against initial pressures of propionaldehyde at different temperatures. The order is between 1.25 and 1.30. This result is in apparent disagreement with the work of Márta (5), but is consistent with the results of Ho (7). Our results are not directly comparable with those of Boyer and Niclause (4) because of the much lower temperature used by the latter. Figure 3 shows that added CO_2 and C_2H_6 has no effect on the rate at 520 °C. This is in agreement with the results of Márta (5) and of Hinshelwood and Thompson (1) at high pressure. Figure 4 shows the effect of 100 mm of CO_2 added to 100 mm C_2H_5CHO on the rate of formation of ethylene and ethane at 540 °C. It is clear that added inert gas has little effect on the rate of formation of ethylene and ethane. In this connection, it may be mentioned that in a study of the pyrolysis of *n*-butane by Purnell and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

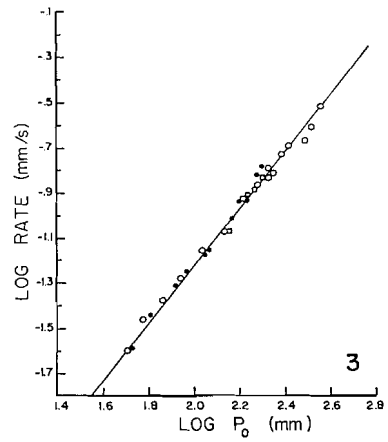

FIG. 3. Plot of log (rate) against log (pressure of propionaldehyde) showing the effects of adding CO_2 and C_2H_6. Rates with no inert gas are shown as ○, those with CO_2 added (CO_2/C_2H_5CHO = 0.5) as □, and those with C_2H_6 added (C_2H_6/C_2H_5CHO = 0.5–2.0) as ●. Temperature = 520 °C.

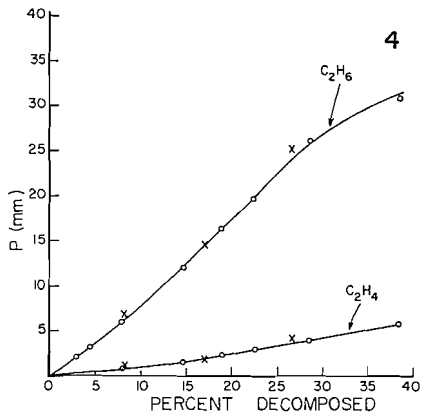

FIG. 4. Plots of the pressures of C_2H_6 and C_2H_4 formed against the percentage of propionaldehyde decomposed showing the effect of adding 100 mm of CO_2 to 100 mm of propionaldehyde. Without CO_2, ○; with CO_2, ×. Temperature = 540 °C.

Quinn (9) the ratio $v_{C_2H_4}/v_{C_2H_6}$, was found to increase with the addition of inert gas at *n*-butane pressures below 24 mm Hg.

Figure 5 shows a plot of $P_{C_2H_6}/P_{C_2H_4}$ against $P_{C_2H_5CHO}$ at 540 °C and 6% decomposition. The curve shows a slight negative curvature. In Fig. 6 is shown a plot of $v_{C_2H_6}/v_{C_2H_4}$ $[C_2H_5CHO]^{1/2}$ against $[C_2H_5CHO]^{1/2}$. At the initial stage of decomposition $P_{C_2H_6}/P_{C_2H_4}$ will be equal to $v_{C_2H_6}/v_{C_2H_4}$.

It will be shown later that the overall reaction can be divided into two parts, one in which the rate varies as $[C_2H_5CHO]^{1/2}$ and the other as $[C_2H_5CHO]^{3/2}$. Figure 7 shows a plot of $v_0/P^{1/2}_{C_2H_5CHO}$ against $P_{C_2H_5CHO}$ at different temperatures. The intercepts give the rate constants corresponding to one-half order and the slopes give those corresponding to three-halves order. In Fig. 8 is shown an Arrhenius plot, the rate constants being obtained from Fig. 7. The activation energy corresponding to the one-half-order reaction is 70.8 kcal per mole and that corresponding to the three-halves-order reaction is 57.1 kcal per mole.

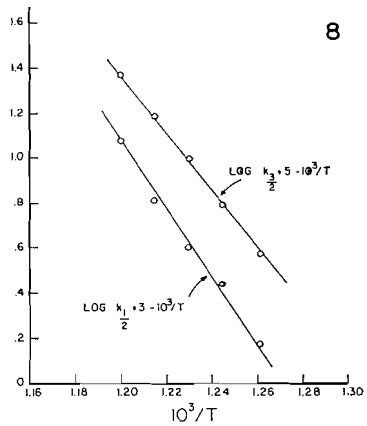

FIG. 8. Arrhenius plots. The lower curve shows the plot of $10^3 k_{1/2}$ $mm^{1/2}$ s^{-1} and the upper one that of $10^5 k_{3/2}$ $mm^{-1/2}$ s^{-1}, $k_{1/2}$ and $k_{3/2}$ being the one-half and the three-halves order rate constants respectively.

DISCUSSION

The Overall Mechanism

It is generally agreed (3–5, 7) that in the thermal decomposition of propionaldehyde C_2H_5 is the most abundant radical and that the combination of C_2H_5 radicals is the predominant chain-ending step. Since the combination of C_2H_5 radicals is a pressure-independent process (10, 11) and inert gas has no effect on the rate of decomposition (Figs. 3 and 4), chain initiation must be the first-order process

[1] $$C_2H_5CHO \rightarrow C_2H_5 + CHO.$$

Since the ratio $[C_2H_6]/[C_2H_4]$ decreases with a decrease in pressure (Fig. 5), but increases with a decrease in temperature (Table I), the two reactions producing ethane and ethylene must be in competition with each other. The same conclusion has been drawn by Purnell and Quinn (9) from their experimental results on the pyrolysis of *n*-butane.

The mechanism to which the above considerations lead is

[1] $$C_2H_5CHO \rightarrow C_2H_5 + CHO$$

[2] $$X + CHO \rightarrow CO + H + X$$

[3] $$C_2H_5 + C_2H_5CHO \rightarrow C_2H_6 + C_2H_5CO$$

[4] $$C_2H_5CO \rightarrow C_2H_5 + CO$$

[5] $$H + C_2H_5CHO \rightarrow H_2 + C_2H_5CO$$

[6] $$C_2H_5 \rightarrow C_2H_4 + H$$

[7] $$C_2H_5 + C_2H_5 \rightarrow C_4H_{10} \text{ or } C_2H_6 + C_2H_4.$$

This mechanism, without reaction [6], is very similar to that proposed by Boyer and Niclause (4) and Márta (5). Application of the steady-state treatment to this mechanism gives rise to the following expressions for the radical concentrations:

[i] $$[C_2H_5] = \left(\frac{k_1}{k_7}\right)^{1/2} [C_2H_5CHO]^{1/2}$$

[ii] $$[H] = \frac{k_1}{k_5} + \frac{k_6}{k_5}\left(\frac{k_1}{k_7}\right)^{1/2} [C_2H_5CHO]^{-1/2}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

With the assumption of large chain lengths (see below) the rate of disappearance of C_2H_5CHO is given by

[iii] $$v = k_3\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{3/2} + k_6\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{1/2}.$$

A similar rate equation has been suggested by Ho (7) to fit his experimental results for the pyrolysis of isobutyraldehyde.

The Chain Length

The fact that the amount of *n*-butane formed is 0.05% of the total products indicates, if reaction [7] is the main chain-ending step, a chain length of $\sim 1 \times 10^3$. Márta (5) has given a value for the rate constant of reaction [1], and, using his value, the chain length at 100 mm *P* and 540 °C is 8.5×10^3. There seems therefore to be no doubt that the chains are long.

Formation of Ethane and Ethylene

In equation [iii] the first term represents the rate of formation of ethane and the second that of ethylene. The ratio of the two terms at 540 °C and 100 mm pressure is

[iv] $$\frac{v_{C_2H_6}}{v_{C_2H_4}} = \frac{k_3}{k_6}[C_2H_5CHO] = 2.9,$$

the values for the rate constants k_3 and k_6 being taken from Volman and Brinton (12) and Bywater and Steacie (13), respectively. The agreement of this calculated result with the experimental value 8.1 (Fig. 5) within a factor of less than 3 must be considered satisfactory in view of the fact that a change of 1 kcal per mole in the value of *E* changes this ratio by a factor of about 2.

The predominance of the chain-termination reaction $X + H + C_2H_5 \rightarrow C_2H_6 + X$ over $2C_2H_5 \rightarrow C_4H_{10}$ at low pressures does not affect the order of ethane formation. The former process is regarded as being in its pressure-dependent region, because the excited species $C_2H_6^*$ has at least 12 kcal more than required to form two CH_3 radicals (14). If the decomposition of the C_2H_5 radical is a pressure-dependent process, the order of ethylene formation will tend towards 3/2 as the pressure is lowered, and a plot of $P_{C_2H_6}/P_{C_2H_4}$ against $P_{C_2H_5CHO}$ should show a positive curvature. The reverse character of such a plot (slight negative curvature, see Fig. 5) is attributed to the formation of some ethane by the molecular process

[1*m*] $$C_2H_5CHO \rightarrow C_2H_6 + CO.$$

The contribution of this reaction may be estimated in the following way:

[v] $$v_{C_2H_6} = k_{1m}[C_2H_5CHO] + k_3\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{3/2}$$

[vi] $$v_{C_2H_4} = k_6\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{1/2}$$

[vii] $$v_{C_2H_6}/v_{C_2H_4} = \frac{k_{1m}}{k_6}\left(\frac{k_7}{k_1}\right)^{1/2}[C_2H_5CHO]^{1/2} + \frac{k_3}{k_6}[C_2H_5CHO]$$

[viii] $$\frac{v_{C_2H_6}/v_{C_2H_4}}{[C_2H_5CHO]^{1/2}} = \frac{k_{1m}}{k_6}\left(\frac{k_7}{k_1}\right)^{1/2} + \frac{k_3}{k_6}[C_2H_5CHO]^{1/2}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

From Fig. 6, at 540 °C,

[ix] $$\frac{k_{1m}}{k_6}\left(\frac{k_7}{k_1}\right)^{1/2} = 3.4 \times 10^3.$$

If the values of k_1 (5), k_6 (13, 15), and k_7 (16, 17) are inserted into this equation, k_{1m} is calculated to be 11.7×10^{-5} s^{-1}. On the basis of this value the contribution of the molecular reaction to the rate is found to be less than 10% under the conditions of the present experiments. Because of uncertainties in the mechanism and in the rate constants, however, this conclusion could be in serious error.

Formation of Hydrogen

The fact that, as shown in Table I, the rate of production of hydrogen is significantly greater than that of ethylene requires some comment. Reaction [8*b*] gives rise to H_2, and the radical CH_3CHCHO can give rise to H_2 following a split into $CH_2CHCHO + H$. Also, radicals will add on to ethylene formed in the reaction,

$$C_2H_4 + R \rightarrow CH_2CH_2R,$$

and the resulting radical may abstract a hydrogen atom to form a hydrocarbon; alternatively it will split off a hydrogen atom or other radical which will subsequently abstract a H atom to form H_2 or a hydrocarbon. The net effect is to increase H_2 and diminish C_2H_4.

Activation Energies

The predicted activation energies for the one-half and three-halves-order reactions are given by the expressions

[x] $$E_{1/2} = E_6 + \tfrac{1}{2}(E_1 - E_7)$$

[xi] $$E_{3/2} = E_3 + \tfrac{1}{2}(E_1 - E_7).$$

Insertion of the values for E_1 (5), E_3 (12), E_6 (13), and E_7 (16, 17) leads to 80.9 kcal per mole for $E_{1/2}$ and 49.0 kcal per mole for $E_{3/2}$. The experimental values are 70.8 and 57.1, so that the agreement is not good. The mechanism proposed is necessarily oversimplified, and the inclusion of other possible chain-ending steps appears to explain the discrepancy. At lower pressures the reaction

[7*a*] $$X + H + C_2H_5 \rightarrow C_2H_6 + X$$

will become more and more important. If, hypothetically, this reaction were predominant, the rate expression would become

$$v = k_3\left(\frac{k_1k_5}{k_6k_{7a}}\right)^{1/2}[C_2H_5CHO]^{3/2} + \left(\frac{k_1k_5k_6}{k_{7a}}\right)^{1/2}[C_2H_5CHO]^{1/2}.$$

With E_5 taken as 8 kcal per mole, E_{7a} as zero and with the other values taken from Table I of Part II it is found that $E_{1/2} = 65.1$ kcal per mole and $E_{3/2} = 33.3$ kcal per mole. The experimental value of $E_{1/2}$ is between the two values given on the basis of the two chain-ending steps, and this suggests that [7*a*] does play some role. The $E_{3/2}$ values predicted by both of the mechanisms are lower than the experimental value. This suggests that ethane is formed by some other process which has a high activation energy and a low order in C_2H_5CHO. A possible process is the molecular process, which has been seen to contribute perhaps 10% of the rate; this contribution will increase with temperature.

Comparison with Acetaldehyde Pyrolysis

The overall rate of decomposition of propionaldehyde is significantly lower than that of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

acetaldehyde (7, 8), and the activation energy for the overall propionaldehyde decomposition is about 7 kcal higher than that of the acetaldehyde decomposition. The following suggestions may be made to explain the above facts.

(1) The chain-termination reaction in the acetaldehyde pyrolysis is a third-order process, whereas that with propionaldehyde is a second-order process and therefore more rapid.

(2) C_2H_5 and H radicals may abstract hydrogen atoms other than those attached to the carbonyl groups, e.g.

$$C_2H_5 + CH_3CH_2CHO \xrightarrow{[8a]} C_2H_6 + CH_3CHCHO$$

$$H + CH_3CH_2CHO \xrightarrow{[8b]} H_2 + CH_3CHCHO.$$

The CH_3CHCHO radical will mainly be involved in a chain-ending step because of its higher stability. Higher temperature may, however, favor the following reactions

$$CH_3CHCHO \overset{[9]}{\rightleftarrows} CH_3CH_2CO \xrightarrow{[10]} CH_3CH_2 + CO$$

$$CH_3CHCHO \overset{[11]}{\rightleftarrows} CH_2CH_2CHO \xrightarrow{[12]} C_2H_4 + CHO$$

which will lead to a larger chain length and consequently a higher activation energy than predicted.

One important difference between the present reaction and the decomposition of acetaldehyde is that initiation is first-order rather than second-order. It has been suggested (8) that the abstraction reaction

$$CH_3CHO + CH_3CHO \rightarrow CH_3CHOH + CH_3CO$$

is an important initiation reaction in the acetaldehyde pyrolysis, and it might be asked why the corresponding reaction

[1a] $$C_2H_5CHO + C_2H_5CHO \rightarrow C_2H_5CHOH + C_2H_5CO$$

does not play a role in the propionaldehyde pyrolysis. Using thermal data quoted by Steacie (18), Szwarc (19), and Benson (14) and estimating entropies using Benson's procedure (14), we conclude that

$$\frac{v_1}{v_{1a}} = \frac{e^{29.6/R} e^{-27000/RT}}{[C_2H_5CHO]}.$$

This ratio is 8.6 at 800 °K and 1 atm, and 18.1 at 800 °K and 360 mm (the highest pressure of the present investigation); it is higher at highest temperatures. These estimates are undoubtedly crude, but may be significant in throwing light on the difference between the initiation processes in the two reactions.

General Conclusions

It is evident from the preceding discussion that the propionaldehyde pyrolysis is even more complex than decompositions of acetaldehyde and the lower paraffins. The mechanism arrived at as representing the main features of the reaction is undoubtedly an oversimplification, and other reactions should be included. In particular, the discussion of activation energies has suggested that an additional chain-ending step is needed. The steady-state equations become quite intractable, however, if more than one chain-ending step is included. The point of view of the present paper is that it is most useful to propose an oversimplified mechanism, as a basis for discussion, and later to amend it in various particulars.

KINETICS AND MECHANISMS OF THE THERMAL DECOMPOSITION OF PROPIONALDEHYDE

PART II. THE REACTION IN THE PRESENCE OF NITRIC OXIDE

K. J. LAIDLER AND M. EUSUF
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 4, 1964

ABSTRACT

The decomposition of propionaldehyde in the presence of various amounts of nitric oxide has been studied in the temperature range 520–560 °C and at propionaldehyde pressures from 30 to 300 mm Hg. The reaction is inhibited by small amounts of nitric oxide, and larger amounts give rise to strong catalysis. The order of the maximally inhibited reaction is 1.5 and the degree of inhibition decreases with an increase of propionaldehyde pressure. In the catalytic region the order of the overall reaction is 1.25 with respect to propionaldehyde, and the relative rate (the ratio of rates in the presence and absence of nitric oxide) is independent of propionaldehyde pressure. The overall rate in the catalytic region can be expressed as

$$v = 8.38 \times 10^{12}\, e^{-36800/RT}[C_2H_5CHO][NO] + 2.35 \times 10^{14}\, e^{-42300/RT}[C_2H_5CHO]^{3/2}[NO]^{1/2}\ s^{-1},$$

the unit of concentration being mole per cc. A mechanism in which nitric oxide initiates chains by the reaction $C_2H_5CHO + NO \rightarrow C_2H_5CO + HNO$, propagates them by $C_2H_5NO + C_2H_5CHO \rightarrow C_2H_6 + C_2H_5CO + NO$, and terminates them by $C_2H_5 + C_2H_5NO \rightarrow C_4H_{10} + NO$ and $C_2H_5 + C_2H_4 + NO$ and $C_2H_5NO + C_2H_5NO \rightarrow C_4H_{10} + 2NO$ or $C_2H_6 + C_2H_4 + 2NO$ is proposed and is shown to be consistent with the results.

INTRODUCTION

Although a number of investigations have been carried out on the thermal decomposition of propionaldehyde in the presence of nitric oxide, the mechanism of the reaction has been a matter of controversy. Staveley and Hinshelwood (1) investigated the thermal decomposition of propionaldehyde; they found that the reaction was inhibited by small amounts of nitric oxide and that there was catalysis at high nitric oxide pressures. They suggested that the maximally inhibited reaction was a non-chain molecular process. Smith and Hinshelwood (2) found that both nitric oxide and propylene reduced the rate by the same amount, and also concluded that the maximally inhibited reaction was a molecular process. A recent investigation by Szabó and Márta (3, 4) showed that the overall order of the reaction in the presence of nitric oxide was three-halves with respect to propionaldehyde and approximately one-half with respect to nitric oxide at high nitric oxide pressures. These workers attempted to explain the above facts by adding the reactions

[8]	$C_2H_5 + NO \rightarrow C_2H_5NO$
[3*i*]	$C_2H_5NO + C_2H_5CHO \rightarrow C_2H_6 + C_2H_5CO + NO$
[7*i*]	$C_2H_5NO + C_2H_5 \rightarrow$ products
[7*i*′]	$C_2H_5NO + C_2H_5NO \rightarrow$ products

to the scheme of the uninhibited reaction originally suggested by Boyer and Niclause (5). Analysis of the results of Szabó and Márta (3, 4) on the basis of their mechanism reveals that $E_{7i} - E_{3i} = 2.4$ kcal per mole and $E_{7i} - 2E_{3i} = -2.9$ kcal per mole. These relationships indicate unreasonably high activation energies for the chain-ending steps, and suggest that the mechanism does not represent the complete picture. Recently Ho (6) studied the thermal decomposition of different aldehydes in the presence of nitric oxide, propylene,

and isobutene and found that in the thermal decomposition of propionaldehyde the limiting rate was lower with nitric oxide than with isobutene and propylene, in disagreement with the results of Smith and Hinshelwood (2).

Wojciechowski and Laidler (7, 8) have suggested that in the thermal decomposition of organic substances nitric oxide starts chains by abstracting a hydrogen atom and ruptures them by being involved in chain-ending reactions. The thermal decompositions of various compounds (9–14) have been explained satisfactorily on the basis of the above suggestion. Aldehydes present an additional interesting feature in that they contain a labile aldehyde hydrogen atom. It has been shown (14) on the basis of experimental results and of calculated activation energies that the following chain-propagating reaction involving a species containing nitric oxide,

$$RNO + M \rightarrow RH + R' + NO,$$

is significantly more important in the acetaldehyde pyrolysis than in that of the hydrocarbons. Szabó and Márta have suggested this reaction in the thermal decomposition of propionaldehyde, but their omission of the chain initiation by nitric oxide leads, as shown above, to unreasonably high activation energies for the chain-ending steps in order for their mechanism to be consistent with their experimental results.

The present paper describes an experimental reinvestigation of the pyrolysis of propionaldehyde in the presence of nitric oxide and interprets the results on the basis of the above ideas.

EXPERIMENTAL

The apparatus used was the same as that described in the preceding paper (15). The reaction was carried out in the same vessel as was used for the uninhibited reaction. The nitric oxide used was Matheson C.P. grade and was purified by the method of Hughes (16). The procedure followed to ensure complete mixing of propionaldehyde and nitric oxide was the same as described previously (14).

RESULTS

Rate of Carbon Monoxide Formation

It has been shown by Staveley and Hinshelwood (1) and Ho (6) that in the maximally inhibited region 1 mm pressure increase corresponds to the reaction of 1 mm of propionaldehyde. In Fig. 1 is shown a plot of the pressure of carbon monoxide formed against time, with 100 mm propionaldehyde and 14 mm nitric oxide at 540 °C. The rate of formation of carbon monoxide (0.149 mm per s) obtained from Fig. 1 agrees within 3% with the overall rate (0.145 mm per s) obtained from the pressure increase. All of the rate measurements were therefore made from the pressure increases, which were recorded automatically.

Methane Formation

A few measurements were made on the rate of methane production. Very little is formed in the uninhibited reaction, and the rate is increased by addition of nitric oxide. Table II shows the ratios of the amounts of CH_4 and CO produced, at different percentages of conversion at 540 °C; the ratio is seen to be independent of the extent of decomposition.

Orders With Respect to Propionaldehyde and Nitric Oxide

Figure 2 shows the effect of nitric oxide on the products of reaction in the catalytic region at 540 °C. The overall rate is equal to that in the absence of nitric oxide. Ethylene production shows a marked increase and hydrogen production appears to decrease slightly.

In Fig. 3 is shown a plot of relative rate, v_{NO}/v_{uninh}, against the pressure of nitric oxide

at different propionaldehyde pressures and at 540 °C. It is seen that small amounts of nitric oxide inhibit the reaction but that larger amounts produce strong catalysis. The ratio v_{min}/v_{uninh} increases with an increase of propionaldehyde pressure; this result does not agree with the results of Szabó and Márta (3, 4) but is in agreement with those of Ho (6). At higher nitric oxide pressures the relative rate is approximately independent of the propionaldehyde pressure. This result is in agreement with the results of Szabó and Márta (3, 4) but apparently in disagreement with those of Ho (6).

Figure 4 shows a double logarithmic plot of initial rates against initial pressures of

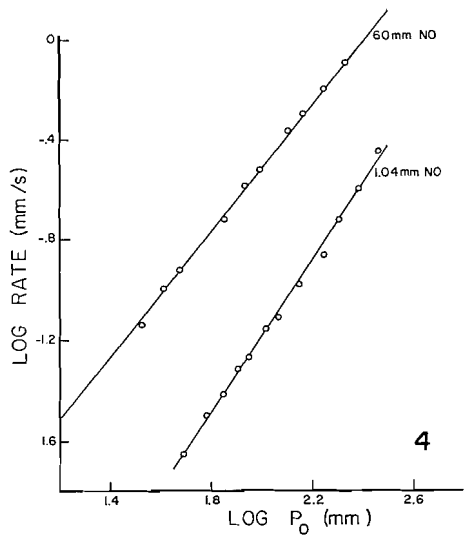

FIG. 4. Plots of log (rate) against log (pressure of propionaldehyde) showing the effect of nitric oxide pressure on the order with respect to propionaldehyde. Temperature = 540 °C.

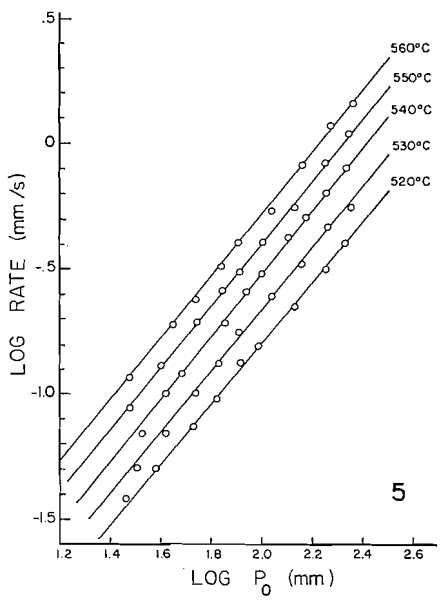

FIG. 5. Plots of log (rate) against log (pressure of propionaldehyde) with 60 mm of nitric oxide at different temperatures.

propionaldehyde at 1 mm and 60 mm of nitric oxide at 540 °C. The lower curve with 1 mm of nitric oxide represents approximately the maximally inhibited rate and gives an order of 1.5. From the upper curve, with 60 mm nitric oxide, an order of 1.25 is obtained. Figure 5 shows a double logarithmic plot of initial rates against initial pressures of propionaldehyde with 60 mm NO. The order of the reaction is seen to be 1.25 with respect to propionaldehyde. Since the orders of the reaction in the absence (Part I) and presence of large amounts of nitric oxide are the same, the relative rate must be independent of propionaldehyde pressure (Fig. 3) in contrast to the conclusion of Ho (6). In Fig. 6 is shown a plot of log (relative rate) against log (pressure of nitric oxide) at 50, 100, and 200 mm pressures of propionaldehyde. The order of the reaction is seen to be about 0.65 with respect to nitric oxide.

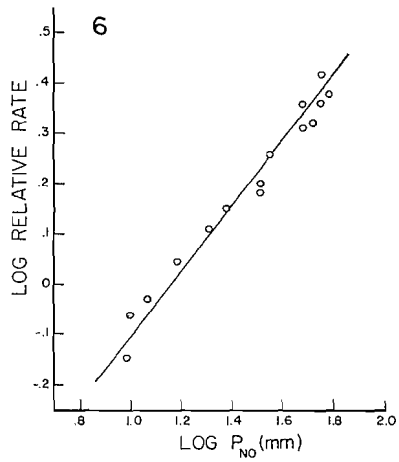

FIG. 6. Plot of log (relative rate) against log (pressure of nitric oxide) in the region where relative rates are independent of propionaldehyde pressures (Fig. 3). Temperature = 540 °C.

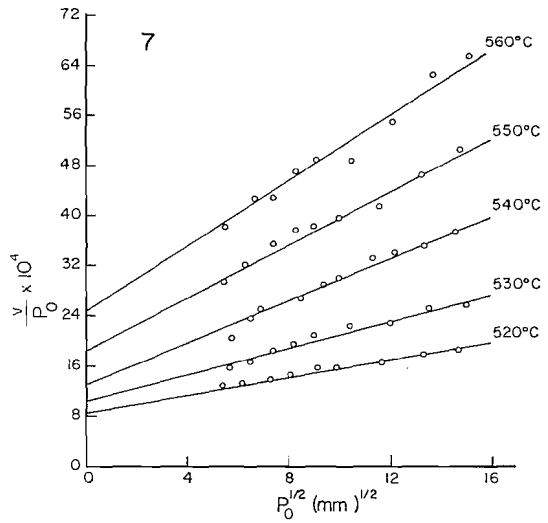

FIG. 7. Plot of $v/P_{C_2H_5HO}$ against $P^{1/2}_{C_2H_5CHO}$ with 60 mm of nitric oxide at different temperatures.

The overall rate at higher nitric oxide pressures can be represented as

[i] $$v = 2k_{1i}[C_2H_5CHO][NO] + k[C_2H_5CHO]^{3/2}[NO]^{1/2}.$$

The dependence on $[C_2H_5CHO]$ is demonstrated in Fig. 7, which is a plot of $v/P_{C_2H_5CHO}$ against $P^{1/2}_{C_2H_5CHO}$ with 60 mm of nitric oxide at different temperatures; $P_{C_2H_5CHO}$ is the initial pressure of propionaldehyde in mm. Plots of this kind were made at four nitric oxide concentrations, ranging from 0 to 100 mm; as shown in Fig. 8 the intercepts vary approximately with the first power of the nitric oxide concentration and the slopes with the one-half power. From these results values of k_{1i} and k were calculated, and Fig. 9 shows Arrhenius plots for the rate constants. The rate constants k_{1i} and k can be expressed as

$$k_{1i} = 4.19 \times 10^{12}\ e^{-36800/RT}\ \text{cc mole}^{-1}\ \text{s}^{-1}$$

$$k = 2.35 \times 10^{14}\ e^{-42300/RT}\ \text{cc mole}^{-1}\ \text{s}^{-1}.$$

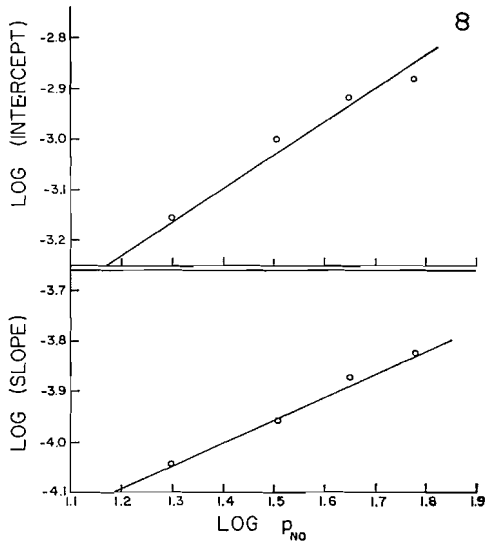

FIG. 8. Plots of log (intercept), upper curve, and log (slope), lower curve, against log (pressure of nitric oxide). Temperature = 540 °C.

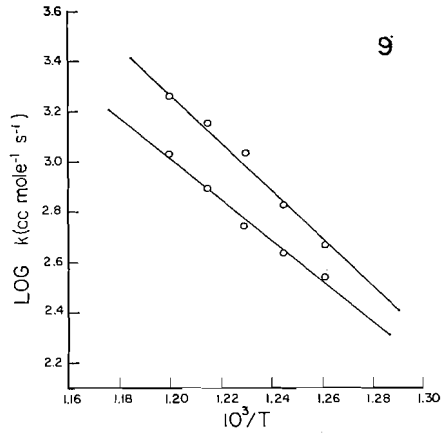

FIG. 9. Arrhenius plots. The upper curve shows a plot of $k_{3i}(k_{1i}/k_{7i}')^{1/2}$ and the lower one that of k_{1i} (cf. eq. [vii]), the rate constants being those obtained from Fig. 7.

DISCUSSION

Overall Reaction Mechanism

That the maximally inhibited reaction is not a simple non-chain unimolecular process is suggested by the following facts.

(1) The maximally inhibited reaction has a non-integral order (1.5).

(2) The degree of inhibition decreases with increase of propionaldehyde pressure.

(3) In the catalytic region, the order of the reaction is non-integral with respect to both propionaldehyde and nitric oxide, indicating that the latter must be involved in the chain reaction. The maximally inhibited reaction must, therefore, be the resultant of two opposing reactions—acceleration as well as inhibition by nitric oxide.

(4) The increase of the ratio C_2H_4/H_2 with increase in nitric oxide pressure is consistent with a chain mechanism.

(5) In the uninhibited reaction (cf. Part I), the contribution of a molecular process appears to be unimportant in comparison with that of a chain reaction.

In line with previous work in this laboratory (7–14) it is suggested that nitric oxide initiates chains by the reaction

[1*i*] $$C_2H_5CHO + NO \rightleftarrows C_2H_5CO + HNO.$$

and that the most abundant radical C_2H_5 is involved in the following equilibrium:

[8] $$C_2H_5 + NO \rightleftarrows C_2H_5NO.$$

In order for the overall order of the maximally inhibited reaction to be three-halves, an important chain-ending step must be

[7*i*] $$C_2H_5 + C_2H_5NO \rightarrow C_4H_{10} + NO \quad \text{or } C_2H_6 + C_2H_4 + NO.$$

In the catalytic region the order of the reaction with respect to propionaldehyde falls below three-halves and a plot of relative rate against nitric oxide concentration gives a negative curvature. In line with previous suggestions (14) and the work of Szabó and Márta (3, 4) it is proposed that the reactions

[3*i*] $$C_2H_5NO + C_2H_5CHO \rightarrow C_2H_6 + C_2H_5CO + NO$$

[7*i*] $$C_2H_5NO + C_2H_5NO \rightarrow \text{products}$$

become important at high nitric oxide pressures.

As in the case of acetaldehyde, in the present decomposition there is no flat region when rate is plotted against nitric oxide concentration. One must, therefore, take into consideration all the processes in the uninhibited reaction in addition to those involving nitric oxide.

The complete scheme may be written as

[1] $$C_2H_5CHO \rightarrow C_2H_5 + CHO$$

[1*i*] $$C_2H_5CHO + NO \rightarrow C_2H_5CO + HNO$$

[2] $$X + CHO \rightarrow CO + H + X$$

[2*i*] $$X + HNO \rightarrow NO + H + X$$

[3] $$C_2H_5 + C_2H_5CHO \rightarrow C_2H_6 + C_2H_5CO$$

[3*i*] $$C_2H_5NO + C_2H_5CHO \rightarrow C_2H_6 + C_2H_5CO + NO$$

[4] $$C_2H_5CO \rightarrow C_2H_5 + CO$$

[5] $$H + C_2H_5CHO \rightarrow H_2 + C_2H_5CO$$

[6] $$C_2H_5 \rightarrow C_2H_4 + H$$

$$C_2H_5 + NO \overset{[8]}{\rightleftarrows} C_2H_5NO \overset{[9]}{\rightleftarrows} C_2H_4{=}NOH \overset{[10]}{\rightarrow} \text{products}$$

[7] $C_2H_5 + C_2H_5 \rightarrow C_4H_{10}$ or $C_2H_6 + C_2H_4$

[7i] $C_2H_5 + C_2H_5NO \rightarrow C_4H_{10} + NO$ or $C_2H_6 + C_2H_4 + NO$

[7i'] $C_2H_5NO + C_2H_5NO \rightarrow C_4H_{10} + 2NO$ or $C_2H_6 + C_2H_4 + 2NO$

The numbering is consistent with the mechanism in Part I; X represents a third body, which may be propionaldehyde itself. The same type of mechanism has been used to explain the results of the acetaldehyde pyrolysis (14). Without reactions [1i], [2i], and [6] the above mechanism is very similar to that proposed by Szabó and Márta (3, 4) in the thermal decomposition of propionaldehyde.

Application of the steady-state treatment, with the usual approximations, leads to the following expressions for the radical concentrations and for the rate of decomposition:

$$[C_2H_5] = \left(\frac{k_1 + k_{1i}[NO]}{k_7 + k_{7i}k_8[NO] + k_{7i'}k_8^2[NO]^2}\right)^{1/2}[C_2H_5CHO]^{1/2}$$

$$[C_2H_5CO] = \frac{[C_2H_5CHO]k_1 + 2k_i[NO] + k_3[C_2H_5] + k_{3i}[C_2H_5NO] + k_6[C_2H_5]}{k_4}$$

$$[C_2H_5NO] = K_8[C_2H_5][NO] \qquad (K_8 = k_8/k_{-8})$$

[ii] $$v = 2k_1[C_2H_5CHO] + 2k_{1i}[C_2H_5CHO][NO] + k_3[C_2H_5][C_2H_5CHO] + k_{3i}[C_2H_5NO][C_2H_5CHO] + k_6[C_2H_5]$$

$$= 2k_{1i}[C_2H_5CHO][NO] + k_3\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{3/2}\frac{\left(1 + \frac{k_{3i}}{k_3}K_8[NO]\right)\left(1 + \frac{k_{1i}}{k_1}[NO]\right)^{1/2}}{\left(1 + \frac{k_{7i}}{k_7}K_8[NO] + \frac{k_{7i'}}{k_7}K_8^2[NO]^2\right)^{1/2}}$$

$$+ k_6\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{1/2}\frac{\left(1 + \frac{k_{1i}}{k_1}[NO]\right)^{1/2}}{\left(1 + \frac{k_{7i}}{k_7}K_8[NO] + \frac{k_{7i'}}{k_7}K_8^2[NO]^2\right)^{1/2}}$$

Important special cases follow.

(1) If [NO] is zero, eq. [ii] reduces to

[iii] $$v = k_3\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{3/2} + k_6\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{1/2},$$

which is the rate expression for the uninhibited reaction (cf. Part I).

(2) In the presence of nitric oxide, ethylene production increases but not at the expense of ethane production (Fig. 2); in the uninhibited reaction, on the other hand, the ethane and ethylene productions are in competition with each other. In the uninhibited reaction the rates of formation of ethylene and hydrogen are within a factor of two, but in the presence of nitric oxide the rate of formation of hydrogen is much less than that of ethylene (Fig. 2). These facts suggest that the reaction

[6] $$C_2H_5 \rightarrow C_2H_4 + H$$

is unimportant in the presence of nitric oxide. This is understandable in view of the fact that using the kinetic parameters of Table I the equilibrium constant K_8 is calculated to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

be 1.7×10^{10} at 540 °C, and of the fact that the relative concentrations of C_2H_5NO and C_2H_5 increase with an increase in NO concentration. Thus, at 540 °C and with 1 mm NO, the ratio $[C_2H_5]/[C_2H_5NO] = 1/340$. It is suggested therefore that most of the ethylene formed in the presence of nitric oxide comes from the chain-ending steps [7*i*] and [7*i'*]. On the basis of the above considerations eq. [ii] reduces to

$$[iv] \qquad v = 2k_{1i}[C_2H_5CHO][NO] + k_3\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]_{3/2}\frac{\left(1+\frac{k_{3i}}{k_3}K_8[NO]\right)\left(1+\frac{k_{1i}}{k_1}[NO]\right)^{1/2}}{\left(1+\frac{k_{3i}}{k_7}K_8[NO]+\frac{k_{7i'}}{k_7}K_8^2[NO]^2\right)^{1/2}}.$$

(3) At sufficiently low nitric oxide concentrations

$$1 \gg \frac{k_{3i}}{k_3}K_8[NO], \qquad \left(1+\frac{k_{7i}}{k_7}K_8[NO]\right) \gg \frac{k_{7i'}}{k_1}K_8^2[NO]^2.$$

Equation [iv] then reduces to

$$[v] \qquad v = 2k_{1i}[C_2H_5CHO][NO] + k_3\left(\frac{k_1}{k_7}\right)^{1/2}[C_2H_5CHO]^{3/2}\frac{\left(1+\frac{k_{1i}}{k_1}[NO]\right)^{1/2}}{\left(1+\frac{k_{7i}}{k_7}K_8[NO]\right)^{1/2}}.$$

Approximately 1 mm of nitric oxide gives maximum inhibition and the first term of the above equation can then be neglected. In the maximally inhibited region the rates of the chain-initiating steps [1] and [1*i*] and chain-terminating steps [7] and [7*i*] may be compared on the basis of the following ratios, which refer to 540 °C and 1 mm of NO and are based on the rate constants in Table I:

$$\frac{v_{1i}}{v_1} = \frac{k_{1i}}{k_1}[NO] \approx 130,$$

$$\frac{v_{7i}}{v_7} = \frac{k_{7i}k_8[NO]}{k_7} \approx 20,$$

$$\frac{v_{7i}}{v_{7i'}} = \frac{k_{7i}}{k_{7i'}k_8[NO]} \approx 5.$$

TABLE I

Kinetic parameters for elementary reactions

Reaction	Frequency factor (s^{-1} or cc $mole^{-1}$ s^{-1})	Activation energy (kcal $mole^{-1}$)	Reference
[1]	1.7×10^{15}	82.8	Marta (18)
[1*i*]	4.19×10^{12}	36.8	See text
[3]	2.36×10^{11}	7.6	Volman and Brinton (19)
[3*i*]	1×10^{13}	26.0	Estimated
[8]	3.0×10^{11}	0	Estimated
[−8]	5.0×10^{14}	50.0	Estimated

[7*i*]	1×10^{12}	0	Estimated
[7*i'*]	9.0×10^{9}	4.2	*A* estimated; for *E* see text

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

These ratios justify one in writing the expression for the maximally inhibited rate as

[vi] $$v \approx k_3 \left(\frac{k_{1i}}{k_{7i}k_8}\right)^{1/2} [C_2H_5CHO]^{3/2},$$

which is in complete agreement with experiment (Fig. 4.).

(4) At high nitric oxide pressures

$$\frac{k_{1i}}{k_1}[NO] \gg 1, \qquad \frac{k_{7i'}}{k_7}K_8{}^2[NO]^2 \gg \left(1 + \frac{k_{7i}K_8[NO]}{k_7}\right),$$

and

$$\frac{k_{3i}}{k_3}K_8[NO] \gg 1.$$

Equation [iv] reduces to

[vii] $$v = 2k_{1i}[C_2H_5CHO][NO] = k_{3i}\left(\frac{k_{1i}}{k_{7i'}}\right)^{1/2}[C_2H_5CHO]^{3/2}[NO]^{1/2}.$$

The inequalities imply that at high nitric oxide pressures reactions [3] and [7*i*] are unimportant in comparison with [3*i*] and [7*i*'] respectively, and the justification for this is as follows:

$$\frac{v_{3i}}{v_3} = \frac{k_{3i}}{k_3}\frac{[C_2H_5NO][C_2H_5CHO]}{[C_2H_5][C_2H_5CHO]} = \frac{k_{3i}K_8}{k_3}[NO],$$

$$\frac{v_{7i'}}{v_{7i}} = \frac{k_{7i'}[C_2H_5NO]^2}{k_{7i}[C_2H_5NO][C_2H_5]} = \frac{k_{7i'}K_8}{k_{7i}}[NO].$$

Insertion of the values of the rate constants from Table I gives, at 540 °C and 60 mm NO,

$$v_3/v_{3i} \approx 10 \text{ and } v_{7i'}/v_{7i} \approx 12.$$

The validity of eq. [vii] was demonstrated above (cf. Fig. 7).

Activation Energies

Further support for eq. [vii] can be obtained from a comparison of the observed and predicted activation energies. Activation energies corresponding to the first and the second terms of eq. [vii] are 36.8 and 42.3 kcal per mole respectively (Fig. 8). The observed activation energy of 36.8 kcal for reaction [1*i*] compares well with its endothermicity, which is 36.4 kcal per mole (calculated on the basis of D(H—NO) = 48.6 kcal and D(C_2H_5CO—H) = 85 kcal per mole; the latter value is assumed by comparison with D(CH_3CO—H) = 85 kcal per mole (17)). The activation energy expression for the second term is

$$E_{3i} + \tfrac{1}{2}(E_{1i} - E_{7i'}) = 42.3 \text{ kcal (experimental value)}.$$

Insertion of values of E_{3i} and E_{1i} from Table I leads to 4.2 kcal per mole for $E_{7i'}$. This value may be compared with 3.9 kcal per mole obtained for the similar reaction

$$CH_3NO + CH_3NO \rightarrow C_2H_6 + 2NO$$

in the pyrolysis of acetaldehyde (14).

The Production of Methane

In the uninhibited reaction only a trace of methane was detected, and it was observed that nitric oxide increases the rate of production of methane. This fact may be explained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

through the occurrence of the following reactions:

$$NO + CH_3CH_2CHO \rightarrow CH_3NO + CH_2CHO$$
$$CH_2CHO \rightarrow CH_3 + CO.$$

Inclusion of these reactions in the scheme of reactions suggested above leads to the same overall kinetics.

According to Norrish and Pratt (22) methane may arise from the oxime decomposition in the following way:

$$C_2H_5NO \rightarrow CH_3CHNOH$$
$$CH_3CHNOH + NO \rightarrow CH_3CHN + HNO_2$$
$$CH_3CHN \rightarrow CH_3 + HCN$$
$$HNO_2 \rightarrow OH + NO.$$

The data in Table II, however, show that methane is produced mainly as a primary product, so that an explanation other than that of Norrish and Pratt is required to account for its formation.

TABLE II

Ratios of CH_4 produced to CO produced
Temperature = 540 °C, $P_{C_2H_5CHO}$ = 100 mm, P_{NO} = 14 mm

% decomposed	CH_4/CO
7.0	0.048
11.7	0.055
16.5	0.044
21.6	0.052
29.7	0.054

The Termination Steps

An important feature of the proposed mechanism is that chain termination in the presence of nitric oxide involves interaction between C_2H_5 and C_2H_5NO, reaction [7*i*], and between two C_2H_5NO molecules, reaction [7*i*']. It has been shown by Pratt and Purnell (23) that, in the decomposition of tetraethyl lead in the presence of nitric oxide at 252 °C, reaction [7*i*] is unimportant in comparison with reactions [9] and [10] and that reaction [10] is entirely heterogeneous. Szabó and Márta (3, 24) have found that nitric oxide is not consumed in the pyrolysis of propionaldehyde at 55 °C; they found that after a reaction was completed a new dose of aldehyde was inhibited to the same extent. This fact suggests that, under the conditions of the pyrolysis of propionaldehyde, reactions [9] and [10] are unimportant in contrast to the suggestion of Pratt and Purnell (23) and that nitric oxide is regenerated in some way. The occurrence of the surface reaction [10] to any significant extent in the pyrolysis of propionaldehyde is also excluded by the fact that the contribution of any heterogeneous reaction in this pyrolysis is negligible (6). Figure 2 shows that the ratio C_2H_4/C_2H_6 is increased by the addition of nitric oxide. Since reaction [6] is, as shown above, unimportant in the presence of nitric oxide, the increase of C_2H_4/C_2H_6 in the presence of nitric oxide and the regeneration of the latter are attributed to the occurrence of reactions [7*i*] and [7*i*']; in other words the removal of ethyl radicals in the presence of nitric oxide takes place by the radical–molecule complex mechanism which has recently been considered theoretically by Eusuf and Laidler (25).

General Conclusions

As in the case of the uninhibited reaction the propionaldehyde pyrolysis in the presence of nitric oxide is a very complex process, and the mechanism proposed is necessarily an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

oversimplification. In our view the general behavior can be explained on the basis of the type of mechanism first proposed by Wojciechowski and Laidler (7), in which initiation involves H abstraction by NO and termination involves species like HNO, CH_3NO, and C_2H_5NO.

A completely different theory of the effect of NO has been proposed by Norrish and Pratt (22), emphasis being placed on the part played by the decomposition of oximes formed as intermediates. In our view this theory is inconsistent with the experimental results on the aldehyde decompositions and does not lead to any general interpretation of the many results that have been obtained on the effect of NO in pyrolysis. In particular it seems impossible to explain, on the basis of the Norrish and Pratt theory, the following important results:

(1) The activation energies for pyrolysis in the presence of excess NO, for a whole series of compounds, are consistent with the view that they relate to the H atom abstraction process, $NO + M \rightarrow HNO + R$.

(2) The fact that a number of clear-cut equations are obtained under various conditions and that these fall into a definite pattern.

(3) The fact that in the aldehyde pyrolyses there is no consumption of NO.

All of these facts have been explained in a self-consistent manner on the basis of the mechanisms put forward from this laboratory.

ACKNOWLEDGMENTS

The authors thank Drs. Margaret H. Back, T. M. Bell, and K. O. Kutschke for extremely valuable comments and discussions. The work was supported by a grant from the American Petroleum Fund, and M. E. wishes to thank the Canadian Commonwealth Scholarships and Fellowships Committee for a scholarship under the tenure of which this work was carried out.

HYDROLYSIS CONSTANTS OF SOME PLATINUM(II) CHLORO COMPLEXES CONTAINING UNSATURATED LIGANDS

A. D. Allen and T. Theophanides[1]
Lash Miller Laboratories, University of Toronto, Toronto, Ontario
Received August 13, 1964

ABSTRACT

Hydrolysis equilibrium constants have been determined for a series of compounds of the general form $K[LPtCl_3]$, where L is a substituted dialkyl acetylene. The hydrolysis equilibrium position is only slightly affected by the nature of L, indicating that the *trans* metal–chlorine and metal–water bonds are similar in character.

It is now well established that in complexes of bivalent platinum the presence of a strongly *trans*-directing group may or may not lead to weakening of the bond in the *trans* position to this group (1). For ions of the form $[LPtCl_3]^-$, where L is an unsaturated organic ligand, the chlorine *trans* to the ligand L is extremely readily displaced by nucleophilic reagents (2, 6), and infrared studies have shown (3, 4) that the platinum–chlorine bond is weaker than the bonds to the *cis* chlorines. However, it has been found (2, 5) that the hydrolysis equilibrium constant for the reaction

$$[LPtCl_3]^- + H_2O \rightleftharpoons \textit{trans}\text{-}[LPtCl_2H_2O] + Cl^-$$

is smaller for L = ethylene than it is for L = ammonia, a weakly *trans*-directing group, showing that the extent of the hydrolysis does not necessarily depend on the lability of the chlorine displaced.

We have investigated the behavior of a series of related complexes in which L is an acetylenic ligand (ac.). When Zeise salt is dissolved in water hydrolysis occurs and an initial equilibrium is established which involves only the chlorine *trans* to ethylene. On standing, hydrolysis of the *cis* chlorines also occurs, but at a rate which is much slower than that of the *trans* chlorine (2, 14). Preliminary experiments were designed to check whether acetylenic complexes react in a similar manner. Titration of the complexes with standard alkali gives a typical weak acid – strong base titration curve with an end point corresponding to the titration of the aquo complex, *trans*-$[ac.PtCl_2.OH_2]$. This cannot be taken as an indication that one chlorine is completely displaced by water at equilibrium, since the coordinated water is converted to the hydroxide ligand during the titration and further hydrolysis takes place to restore the equilibrium. Important conclusions from this are that the equilibrium position shifts much more rapidly than one can titrate, and that the end point corresponds to the hydrolysis of only one chlorine. From these titrations an estimated value for pK_a of 7.5 was found for the aquo complex *trans*-$(Me_2C(OH)C{\equiv}CC(OH)Me_2)PtCl_2H_2O$. Direct titration with silver nitrate also gives an end point corresponding to the displacement of one chlorine, again confirming the inertness of the *cis* chlorines and the lability of the equilibrium involving the *trans* chlorine.

Equilibrium data for the hydrolysis of the *trans* chlorine were obtained by measuring the concentration of chloride ions displaced from the complex, by a potentiometric method.

EXPERIMENTAL

Materials

The compounds potassium trichloro(2,5-dimethyl-3-hexyne-2,5-diol)platinum(II), potassium trichloro-(2,5-dimethyl-2,5-dimethoxy-3-hexyne)platinum(II), and Zeise salt were prepared as reported previously (4). The following compounds were prepared in a similar manner.

Potassium trichloro(3,6-dimethyl-4-octyne-3,6-diol)platinum(II), yellow crystals 128–130° (decomp.) (lit. (6) 122–124° (decomp.)

Anal. Calcd. for $C_{10}H_{18}O_2Cl_3KPt$: C, 23.5; H, 3.55. Found: C, 23.8; H, 3.56.

Potassium trichloro(3,6-diethyl-4-octyne-3,6-diol)platinum(II), orange–yellow crystals, 114–117° (decomp.)

Anal. Calcd. for $C_{12}H_{22}O_2Cl_3KPt$: C, 26.75; H, 4.1. Found: C, 26.1; H, 4.05.

Equilibrium Measurements

The following cell was used.

$$Ag/AgCl/[ac.PtCl_3]^-, KCl, HClO_4(0.2\ M)//HClO_4(0.2\ M)//KCl, HClO_4(0.2\ M)/AgCl/Ag.$$

Solutions of the complexes in 0.2 *M* perchloric acid do not decompose during the time necessary to perform the experiments and are stable for long periods in the presence of added chloride. In the above cell the added chloride ion concentration was always the same in both half cells, so that any difference in electromotive force was due to chloride ion liberated by hydrolysis of the complex. The cell compartments were separated by small ultrafine porosity sintered glass discs. The silver – silver chloride electrodes were prepared in the manner described by MacInnes and Parker (7), with the modifications, precautions, and improvements suggested by Carmody (8) and Brown (9). The electrodes so prepared were not affected by sunlight, and they gave very low differences in e.m.f. (0.01–0.05 mV) when placed in the same solution.

The cell voltage was measured by a Leeds and Northrup K-2 potentiometer. The cell was immersed in a constant temperature bath during the measurements. "Analar" perchloric acid (70%), (1.66 specific gravity) was diluted with doubly distilled water to give a 0.4 *N* solution. It was found that this solution contained about 3×10^{-5} *M* chloride ions, and this was allowed for in the calculations. Potassium chloride was "Analar" grade, dried for 3 h at 150 °C or 1 h at 300 °C. Stock chloride solutions of 10×10^{-3}, 6×10^{-3}, and 3×10^{-3} *M* were prepared with doubly distilled water.

Determination of the Hydrolysis Constants (K_{aq})

The solutions of the complexes were prepared in small vials by pipetting known volumes of solutions of potassium chloride in 0.2 *N* perchloric acid (10 ml) onto a weighed amount of the complex. The solution was well mixed and was then transferred to one of the cell compartments. To the second compartment was added the same solution of potassium chloride in 0.2 *N* perchloric acid (10 ml). All solutions had previously been kept in the thermostat to reach the appropriate temperature.

The total chloride concentration of the cell was calculated from the formula

$$E = \frac{RT}{F} \ln \frac{(a + x)}{a},$$

where a = concentration of added chloride, and x = chloride derived from the hydrolysis. It was assumed that the activity coefficients of the chloride ion in each half cell were equal since the ionic strengths were almost the same.

The e.m.f. of the cell was measured as soon as possible (about 1 min after mixing) and every minute thereafter for 10 min. In some cases the potential was not constant but drifted slowly downwards and an extrapolation to zero time was used to obtain the e.m.f. of the cell. In most cases, changes were small and the e.m.f. did not drift, so that an average of 8 or 9 readings could be taken.

The cell was checked every time an experiment was performed, using appropriate potassium chloride solutions in 0.2 *N* perchloric acid. The e.m.f. was compared with the theoretical e.m.f. calculated from the formula

$$E = \frac{RT}{F} \ln \frac{a_1}{a_2},$$

where a_1 and a_2 are the potassium chloride concentrations in the two compartments. A small correction for the bias of the electrodes used was applied to these results and the corrected values were used to determine the chloride concentrations. Measurements were made at three temperatures, 10° or 15°, 25°, and 40°.

Equilibrium constants for the hydrolysis were calculated from the equation

$$K_{aq} = \frac{[ac.PtCl_2H_2O]^0[Cl^-]}{[ac.PtCl_3^-]} = \frac{([Cl^-]_{total} - [Cl^-]_{KCl})[Cl^-]_{total}}{([Cpx] + [Cl^-]_{KCl} - [Cl^-]_{total})},$$

where [Cpx] = initial concentration of complex.

RESULTS AND DISCUSSION

Detailed results and calculated hydrolysis constants are given in Tables I–V. These results are summarized in Table VI, and are compared with data for other platinum(II) chloro complexes in Table VII. The most obvious conclusion to be drawn from Table VII is that all the hydrolysis constants are very similar, showing that the ligand L has little effect on the extent of hydrolysis of the *trans* chlorine. In their paper on the hydrolysis of Zeise's salt (2), Leden and Chatt predicted that this situation might occur. The labilizing effect of a *trans*-directing group is obviously a kinetic one and both the *trans* chloro group in the complex and the *trans*-aquo group in the product are highly susceptible to nucleophilic displacement. The equilibrium position would be changed drastically only if the chloro and aquo groups were very differently affected by the ligand L, which would be the case if, for example, there were substantial π-bonding with one group and not with the other. Absence of large effects shows that the bonding of the chloro and aquo groups to the platinum in these compounds is similar in character.

We have been interested in the role of the hydroxyl groups in the bonding of the ligand $Me_2C(OH)C{\equiv}CC(OH)Me_2$ to the metal atom. Chatt *et al.* (10) originally attributed the unexpectedly high stability of these complexes to an interaction between the metal and the hydroxyl groups, either via hydrogen bond or by coordination of oxygen to the metal. More recently Chatt *et al.* (6) have proposed a structure in which the hydroxyl groups are linked by hydrogen bonds to the *cis* chlorines. If the formation of hydrogen bonds is an important part of the link between the unsaturated ligand and the metal, we would

$Pt(Me_2C(OMe)C{\equiv}CC(OMe)Me_2)Cl_3^-$	1.5	
$Pt(Et_2C(OH)C{\equiv}CC(OH)Et_2)Cl_3^-$	7.5	

*Leden and Chatt (2) report a value of $3.0 \pm 0.5 \times 10^{-3}$ for this compound.

expect the dimethyl ether of this glycol to form a less stable complex. It not surprising that our equilibrium results do not reveal any significant differences between the two complexes, but the complex containing the dimethyl ether of the glycol is actually the more stable in air, has a slightly higher decomposition temperature, and is just as stable in the solutions used in this work. While these observations provide only qualitative indications, it is clear that the absence of hydrogen bonding does not seriously effect the stability of the compounds.

From the variation of the equilibrium constants with temperature it is possible to obtain approximate values for the enthalpy, free energy, and entropy of these reactions. For the hydrolysis of the complex of the glycol $Me_2C(OH)C{\equiv}CC(OH)Me_2$ we find $\Delta H^0 = 3.4$ kcal, $\Delta F^0 = 3.7$ kcal, and $\Delta S^0 = -1$ entropy unit at 25°. These values are similar to those found for the hydrolysis of $[Pt(NH_3)Cl_3]^-$ (5). For the complex of the above glycol the effect of ionic strength was also determined, giving values of K_{aq} (25°) $= 2.0 \times 10^{-3}$ at 0.02 M $HClO_4$, 2.0×10^{-3} at 0.04 M $HClO_4$, and 1.0×10^{-3} at 2 M $HClO_4$. This slight decrease with increase of ionic strength is in accordance with the expected dependence of the activity coefficients on ionic strength (13).

THERMAL INDOLIZATION OF ARYLHYDRAZONES

A. H. KELLY, D. H. MCLEOD, AND J. PARRICK
Department of Chemistry, Rutherford College of Technology, Newcastle-upon-Tyne, England

Received June 22, 1964

ABSTRACT

Thermal cyclization of arylhydrazones in the absence of acid catalyst has been investigated. Indole was not obtained from acetaldehyde phenylhydrazone; aniline, N-ethylaniline, and an unidentified compound were isolated. Phenylhydrazones of cyclohexanone and cyclopentanone and their 2-substituted derivatives were cyclized, often in good yield, to the indole and indolenine; the nature of the substituent markedly influences the ratio of the two products. Gas–liquid chromatographic analysis of the reaction mixture from indolization of two arylhydrazones revealed no crossed products. Nitrophenylhydrazones do not cyclize in good yield, but thermal indolization of some pyridylhydrazones is a good method for the preparation of pyrrolopyridines.

One of the most useful methods available for the preparation of indoles is the acid-catalyzed cyclization of phenylhydrazones discovered by Fischer (1). Many Brønsted and Lewis acids have been used as catalysts. The mechanism of the reaction was investigated by Robinson and the proposed intramolecular cyclization process has been accepted by later workers, with some slight modification. A review of the mechanism and some aspects of the synthetic utility of the reaction has appeared recently (2).

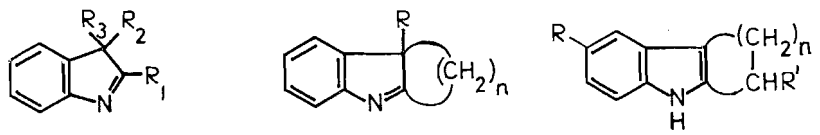
Early work led to the idea that an acid catalyst and a high temperature were essential for a successful Fischer indole synthesis. However, later work (3) has shown that the acid may assist in the first stage of the reaction, i.e. the tautomerization of the hydrazone to the enehydrazine, but is not generally essential for this or later stages of the cyclization. The early ideas may explain why an observation (4) that distillation of acetophenone phenylhydrazone gave some 2-phenylindole was ignored, until Fitzpatrick and Hiser (5) reported several phenylhydrazones were converted into the corresponding indoles on boiling a solution of the phenylhydrazone in a suitable high-boiling solvent. The reaction occurred in the absence of any acid catalyst and, indeed, in one case, in the presence of sodium hydroxide. The examples quoted by Fitzpatrick and Hiser were somewhat limited in variety. Since the reaction has obvious interest and application due to the experimental simplicity, we have investigated this thermal indolization reaction.

Indole cannot be prepared by the acid-catalyzed cyclization of acetaldehyde phenylhydrazone, though propionaldehyde and higher aldehyde phenylhydrazones do give the 3-alkylindoles (2). Fitzpatrick and Hiser (5) report the thermal cyclization of propionaldehyde *p*-tolylhydrazone but make no mention of attempts to cyclize acetaldehyde phenylhydrazone. Our efforts to obtain indole in this way were unsuccessful, though ammonia was evolved from the reaction mixture. The product consisted of a steam-volatile fraction and a nonvolatile black residue. Fractional distillation of the volatile material yielded N-ethylaniline, aniline, and an unidentified component. Since our experiments were completed, Robinson (2) has recorded that he was unable to obtain indole by this technique, though the formation of ammonia was again noted. The evolution of ammonia (possibly accompanied by other basic gas) is not a reliable indication of the formation of an indole, nor is the rate of evolution of the basic gas always a trustworthy criterion on which to judge the optimum reaction time. It seems likely that, in certain cases, two competing reactions may occur; one leading to the indole and the other giving polymeric products. Both reactions involve the evolution of basic gas.

TABLE I

Phenylhydrazone of:	Thermal cyclization		Acetic acid (7)	Sulfuric acid (7)
	Indolenine (II) (%)	Indole (III) (%)	Indole (%)	Indole (%)
Cyclohexanone	0	100	100	100
2-Methylcyclohexanone	51	49	9	68
2-*n*-Propylcyclohexanone	28	72	—	—
2-Phenylcyclohexanone	13	87	28	73
2-Cyclohexylcyclohexanone	4	96	10	63

Acid-catalyzed cyclization of phenylhydrazones from aldehydes or ketones having only one hydrogen on the α-carbon atoms give indolenines (I). Robinson (6) has used the thermal cyclization technique to prepare such compounds. Pausacker (7) has shown that the ratio of 1,2,3,4-tetrahydrocarbazolenine (II, $n = 4$, R = alkyl or aryl) to 1,2,3,4-tetrahydrocarbazole (III, $n = 3$, R = H, R′ = alkyl or aryl), formed by acid-catalyzed cyclization of 2-substituted cyclohexanone phenylhydrazones, depends on the nature of the acid catalyst: glacial acetic acid favored the formation of the tetrahydrocarbazolenine, while dilute sulfuric acid gave the tetrahydrocarbazole preferentially. We find that 1,2,3,4-tetrahydrocarbazole (III, $n = 3$, R = R′ = H) (83% yield) is obtained by boiling a solution of cyclohexanone phenylhydrazone in diethylene glycol. Thermal cyclization of 2-methyl-, 2-*n*-propyl-, 2-phenyl-, and 2-cyclohexyl-cyclohexanone phenylhydrazones gave mixtures of the corresponding 1,2,3,4-tetrahydrocarbazolenine (II, $n = 4$, R = CH_3, C_3H_7, C_6H_5, and C_6H_{11}) and 1,2,3,4-tetrahydrocarbazole (III, $n = 3$, R = H, R′ = CH_3, C_3H_7, C_6H_5, and C_6H_{11}) in the proportions shown in Table I. The high proportion of tetrahydrocarbazole resembles the results for the dilute sulfuric acid catalyzed cyclizations (7), but the steric size of the substituent has a more marked effect on the ratio of products from the thermal cyclizations than in the acid-catalyzed indolization.



I II III

When an indole shows exceptional acid sensitivity, the thermal cyclization technique appeared to offer advantages over the acid-catalyzed procedure. For example, 1,2,3,4-tetrahydrocyclopent[*b*]indole (III, $n = 2$, R = R′ = H) rapidly forms a red gum in the presence of an acid, and previous preparations (8) have used dilute sulfuric acid catalyzed indolization of cyclopentanone phenylhydrazone and extraction of the indole from the gum. 8*b*-Alkyl-1,2,3,8*b*-tetrahydrocyclopent[*b*]indoles (II, $n = 3$, R = alkyl) were not known; a reported attempt to cause indolization of 2-ethylcyclopentanone phenylhydrazone by acid-catalyzed procedure failed (9). 1,2,3,8*b*-Tetrahydrocyclopent[*b*]indole (III, $n = 2$, R = R′ = H) was now obtained in high yield by the thermal cyclization technique and was more stable than that obtained by the acid-catalyzed process. Further, 1,2,3,8*b*-tetrahydro-8*b*-methylcyclopent[*b*]indole (II, $n = 3$, R = CH_3) and the indole (III, $n = 2$, R = H, R′ = CH_3) were obtained, though in poor yield, by thermal cyclization of 2-methylcyclopentanone phenylhydrazone, while attempts to cause indolization

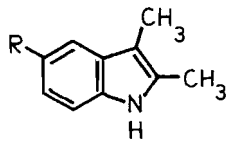
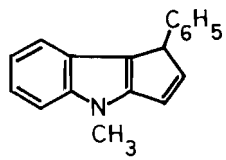
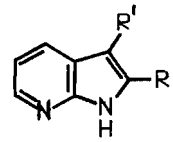
in the presence of glacial acetic acid, dilute sulfuric acid or zinc chloride gave only intractable material. However, attempts to obtain 1,4-dihydro-4-methyl-1-phenylcyclopent[*b*] indole (V) by thermal cyclization of 3-phenylcyclopent-2-en-1-one α-methylphenylhydrazone failed.



IV



V



VI

It has been suggested (10), on the basis of the isolation of crossed products, that the acid-catalyzed formation of indoles may occur by a free radical mechanism. This idea was later shown to be erroneous (11): crossed products having been formed by hydrolysis of the arylhydrazones and formation of crossed arylhydrazones, or direct transhydrazonation (12), and subsequent cyclization. Any tendency towards a free radical type of mechanism would be expected to be favored by the purely thermal cyclization technique. Consequently we have analyzed the products of the thermal cyclization of two separate pairs of arylhydrazones.

1,2,3,4-Tetrahydrocarbazole (III, $n = 3$, R = R′ = H), 1,2,3,4-tetrahydro-6-methylcarbazole (III, $n = 3$, R = CH_3, R′ = H), 1,2,3,8*b*-tetrahydrocyclopent[*b*]indole (III, $n = 2$, R = R′ = H) were prepared in high yield by thermal cyclization of the corresponding arylhydrazones. An analytical separation of these three was achieved by gas–liquid chromatography, but (III, $n = 2$, R = CH_3, R′ = H) was not separated from (III, $n = 3$, R = R′ = H). Gas–liquid chromatographic analysis of the reaction product from the thermal indolization of a mixture of cyclopentanone phenylhydrazone and cyclohexanone *p*-tolylhydrazone in diethylene glycol showed the presence of neither (III, $n = 2$, R = CH_3, R′ = H) nor (III, $n = 3$, R = R′ = H), only the expected (III, $n = 2$, R = R′ = H) and (III, $n = 3$, R = CH_3, R′ = H) were found. A similar experiment involving the indolization of cyclohexanone phenylhydrazone and ethyl methyl ketone *p*-tolylhydrazone in the same reaction mixture gave only 2,3,5-trimethylindole (IV, R = CH_3) and 1,2,3,4-tetrahydrocarbazole, no 2,3-dimethylindole (IV, R = H) or 1,2,3,4-tetrahydro-6-methylcarbazole (III, $n = 3$, R = CH_3, R′ = H) were present: in this experiment all four possible products were resolved by gas–liquid chromatography. These results, together with the high yields frequently obtained, indicate that thermal indolization of arylhydrazones does not proceed by free radical mechanism.

Arylhydrazones containing an electron-deficient aromatic nucleus undergo acid-catalyzed indolization much less rapidly than the corresponding phenylhydrazones (2). Thus, nitrophenylhydrazones cyclize with some difficulty and the choice of catalyst is critical (13). We find that thermal cyclization of cyclohexanone *p*-nitrophenylhydrazone to the nitrotetrahydrocarbazole (III, $n = 3$, R = NO_2, R′ = H) occurs in only poor yield. Addition of cuprous chloride to the reaction mixture caused a more rapid evolution of ammonia, but no increase in the yield of (III, $n = 3$, R = NO_2, R′ = H).

Pyridylhydrazones also contain an electron-deficient nucleus, but have the additional feature that in acid solution further deactivation occurs due to protonation of the pyridyl nucleus. Attempts to use acid catalysts in the cyclization of these compounds have had little success, and Robison (14) concluded that only those 2-pyridylhydrazones cyclize

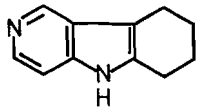
VII



VIII

to the pyrrolo[2,3-*b*]pyridine (VI, R = R′ = H), where the corresponding phenylhydrazones cyclize with extreme ease. Cyclohexanone and benzyl phenyl ketone 2-pyridylhydrazones have been cyclized, using polyphosphoric acid as catalyst, to 6,7,8,9-tetrahydro-α-carboline (VII) and 2,3-diphenylpyrrolo[2,3-*b*]pyridine (VI, R = R′ = C_6H_5); the yields were 53% and 12%. Thermal cyclization in diethylene glycol gave yields of 70% and 56% respectively.

Indolization of pyridylhydrazones by fusion with zinc chloride has been reported in some cases, the product being first obtained as the chlorozincate. Mann *et al.* (15) obtained a chlorozincate (2.8 g) on fusion of cyclohexanone 4-pyridylhydrazone (2 g) with an excess of zinc chloride, and then obtained 6,7,8,9-tetrahydro-γ-carboline (VIII) in unspecified yield. Thermal cyclization afforded the tetrahydro-γ-carboline (VIII) directly in 95% yield. The high yields obtained in these thermal cyclizations of pyridylhydrazones are surprising, and in marked contrast to the results with nitrophenylhydrazones. Details of further applications of thermal indolization to the preparation of pyrrolopyridines will be reported elsewhere.

EXPERIMENTAL

Infrared spectra were recorded on a Grubb Parsons GS3 spectrophotometer. Gas–liquid chromatography apparatus was a Pye Argon Chromatograph.

Attempted Indolization of Acetaldehyde Phenylhydrazone

Acetaldehyde phenylhydrazone (65 g) in diethylene glycol (300 ml) was boiled under reflux for 5 days. Ammonia was evolved during this time and the mixture darkened. The mixture was steam distilled to give a volatile fraction and much residual black tar, which was not investigated further. The distillate was extracted with ether and dried (Na_2SO_4), the ether removed, and the pale yellow oil (11.4 g) fractionally distilled to give fraction (i), b.p. 44–50° at 2.5 mm (3.7 g), redistilled and collected over the range 64–66° at 8 mm, n_D^{21} 1.5840, and identified as aniline by conversion to acetanilide; fraction (ii), b.p. 62–68° at 2.5 mm (5.5 g), was found to contain basic and neutral components. The basic compound was separated by extraction with acid in the usual way and distilled, b.p. 86–90° at 10 mm (0.6 g), n_D^{23} 1.5536, and identified as mainly N-ethylaniline by formation of a picrate and melting point mixed melting point with an authentic sample, 130–132°. The non-basic component was distilled, b.p. 84–88° at 10 mm (1.7 g) n_D^{21} 1.5998.

Anal. Calcd. for C_6H_6N: C, 78.3; H, 6.5; N, 15.2. Found: C, 78.2; H, 6.3; N, 15.2.

The infrared spectrum showed absorption at 3 413 cm^{-1}. The Ehrlich test was positive, but the compound was not investigated further.

Thermal Indolization of Phenyl- and p-Tolylhydrazones

The general method adopted was to prepare the arylhydrazone from the corresponding arylhydrazine and ketone by standard procedure, and to purify the product by distillation under reduced pressure or crystallization. A 10–20% solution of the arylhydrazone, in ethylene glycol or diethylene glycol, was boiled under reflux for a few hours and then poured into ice water. The solid was filtered off and recrystallized. Reaction conditions and yields are recorded in Table II. The indoles, with one exception (III, *n* = 2, R = CH_3, R′ = H), were known compounds and had melting points in accordance with the literature values.

1,2,3,4-Tetrahydro-7-methylcyclopent[b]indole (III, n = 2, R = CH_3, R′ = H) crystallized from petroleum ether (b.p. 60–80°) as colorless prisms, m.p. 116–118°.

Anal. Calcd. for $C_{12}H_{13}N$: C, 84.3; H, 7.6. Found: C, 84.6; H, 7.8.

It gave a *picrate* as brown needles from aqueous ethanol, m.p. 145–147° (decomp.).

adopted was that a phenylhydrazone (10 g), in diethylene glycol (30 ml), was gently boiled under reflux for 2 h. After pouring into water, the mixture was extracted with ether, and the ethereal solution washed with dilute hydrochloric acid (3 × 25 ml). The acid washings were added to an excess of ice-cold, dilute sodium hydroxide solution. Any solid product was filtered off and recrystallized. When an oil was formed, it was extracted with ether and the indolenine distilled under reduced pressure. The above acid-washed, ethereal solution was washed with water, dried (Na_2SO_4), and filtered, the ether distilled off, and the indole crystallized.

2-Methylcyclohexanone phenylhydrazone gave 1,2,3,4-tetrahydro-11-methylcarbazolenine (II, $n = 4$, $R = CH_3$) (3.5 g), b.p. 120–126° at 1 mm, crystallized from alcohol, m.p. 68–69° (lit. m.p. 69° (9)) and 1,2,3,4-tetrahydro-1-methylcarbazole (III, $n = 3$, R = H, R′ = CH_3) (3.4 g), recrystallized from aqueous ethanol, m.p. 66–68° (lit. m.p. 69° (7)).

2-*n*-Propylcyclohexanone phenylhydrazone yielded 1,2,3,4-tetrahydro-11-*n*-propylcarbazolenine (II, $n = 4$, R = *n*-C_3H_7) (1.2 g), b.p. 120–144° at 0.5–1 mm, crystallized from petroleum ether (b.p. 60–80°), m.p. 137–139° (lit. m.p. 139° (10)) and *1,2,3,4-tetrahydro-1-n-propylcarbazole (III, n = 3, R = H, R′ =* *n*-C_3H_7) (3.1 g), recrystallized as colorless needles from benzene, m.p. 151–152°.

Anal. calcd. for $C_{15}H_{19}N$: C, 84.6; H, 8.9. Found: C, 84.5; H, 8.9.

Picrate crystallized as brown plates from ethanol, m.p. 116–118°.

Anal. Calcd. for $C_{21}H_{22}N_4O_7$: C, 57.1; H, 5.0. Found: C, 56.8; H, 4.8.

2-Phenylcyclohexanone phenylhydrazone afforded 1,2,3,4-tetrahydro-11-phenylcarbazolenine (II, $n = 4$, R = C_6H_5), b.p. 175–186° at 1.5 mm (0.6 g), crystallized from petroleum ether (b.p. 60–80°), m.p. 122–124° (lit. m.p. 125° (7)) and 1,2,3,4-tetrahydro-1-phenylcarbazole (III, $n = 3$, R = H, R′ = C_6H_5) (3.9 g), recrystallized from petroleum ether (b.p. 40–60°), m.p. 97–99° (lit. m.p. 99° (7)).

2-Cyclohexylcyclohexanone phenylhydrazone gave 11-cyclohexyl-1,2,3,4-tetrahydrocarbazolenine (II, $n = 4$, R = C_6H_{11}) (0.2 g), recrystallized from petroleum ether (b.p. 60–80°), m.p. 76–78° (lit. m.p. 79° (7)) and 1-cyclohexyl-1,2,3,4-tetrahydrocarbazole (III, $n = 3$, R = H, R′ = C_6H_{11}) (4.9 g), b.p. 201–206° at 1 mm, crystallized from petroleum ether (b.p. 60°–80°) m.p. 137–139° (lit. m.p. 140° (7)).

1,2,3,8b-Tetrahydro-8b-methylcyclopent[b]indole (II, n = 3, R = CH_3) and 1,2,3,4-tetrahydro-3-methylcyclopent[b]indole (III, n = 2, R = H, R′ = CH_3)

2-Methylcyclopentanone (2.64 g) and phenylhydrazine (2.9 g) were mixed, and, after the initial exothermic reaction had slackened, the mixture was warmed on a water bath for 30 min. The water produced was removed by azeotropic distillation with benzene. The hydrazone, in diethylene glycol (20 ml), was boiled under reflux for 2 h and then poured into ice water. The oil was extracted with ether and quickly separated into basic and neutral fractions by extraction with dilute hydrochloric acid in the usual way. The basic fraction was distilled, b.p. 94–96° at 0.5 mm, as a colorless oil (0.57 g). Treatment with ethanolic picrolonic acid afforded *1,2,3,8b-tetrahydro-8b-methyl-cyclopent[b]indole picrolonate* as yellow prisms, m.p. 219–221° (decomp.).

Anal. Calcd. for $C_{22}H_{21}N_5O_5$: C, 60.1; H, 4.8; N, 16.1. Found: C, 59.7; H, 5.0; N, 15.6. The neutral fraction was distilled, b.p. 116–124° at 0.8 mm, as a colorless oil (0.12 g). Addition of ethanolic picric acid gave *1,2,3,4-tetrahydro-3-methylcyclopent[b]indole picrate*, recrystallized as dark-red needles from aqueous ethanol, m.p. 132–134°.

Anal. Calcd. for $C_{18}H_{16}N_4O_7$: C, 54.0; H, 4.0. Found: C, 54.2; H, 4.1.

Attempted Preparation of 1,4-Dihydro-4-methyl-1-phenylcyclopent[b]indole (V)

3-Phenylcyclopent-2-en-1-one (3.2 g) and α-methylphenylhydrazine (2.4 g) were mixed and, after the addition of glacial acetic acid (2 drops), warmed on a water bath for 30 min. Benzene was added and the water removed by azeotropic distillation. The *phenylhydrazone* was crystallized from ethanol as yellow prisms (4.4 g), m.p. 113–114°.

Anal. Calcd. for $C_{18}H_{18}N_2$: C, 82.5; H, 6.8. Found: C, 82.2; H, 7.0.

When a solution of this phenylhydrazone in ethylene glycol (or diethylene glycol) was boiled under reflux in a nitrogen atmosphere a basic gas was evolved, but, after pouring the reaction mixture into water, the only product isolated was a black, friable amorphous solid.

Indolization of Mixtures of Arylhydrazones

(i) A mixture of freshly prepared cyclopentanone phenylhydrazone (1 g) and cyclohexanone *p*-tolylhydrazone (1 g), in diethylene glycol (10 ml), was boiled under reflux for 1 h and then poured into water. The oil was extracted with benzene, washed with water, and dried (Na_2SO_4). The benzene solution was submitted to gas–liquid chromatography in a column of 4% silicone oil on celite 545 (80–100 mesh) at 150°, packed in 4 ft of 5 mm (outside diameter) glass tubing, and using argon as the carrier gas at a flow rate of 20 ml/min. Retention times were measured relative to that for 1,2,3,4-tetrahydrocarbazole (III, $n = 3$, R = R′ = H) (15 min). The two peaks obtained had relative retention time (r.r.t.) of 0.68 and 1.54 and were shown to be due to 1,2,3,4-tetrahydrocyclopent[b]indole (III, $n = 2$, R = R′ = H) and 1,2,3,4-tetrahydro-6-methylcarbazole (III, $n = 3$, R = CH_3, R′ = H). 1,2,3,4-Tetrahydro-7-methylcyclopent[b]indole (III, $n = 2$, R = CH_3, R′ = H) had r.r.t. 1.02.

(ii) A similar reaction was performed with a mixture of cyclohexanone *p*-tolylhydrazone and ethyl methyl ketone phenylhydrazone. Gas–liquid chromatography in a column of 4% Apiezon L on celite 545 at 200°, in a tube of the dimensions mentioned above and at the same gas flow rate, gave two peaks, r.r.t. 0.23 and 1.27, identified as due to 1,2,3,4-tetrahydro-6-methylcarbazole (III, $n = 3$, R = CH_3, R′ = H) and 2,3-dimethylindole (IV, R = H). 1,2,3,4-Tetrahydrocarbazole had a retention time of 22.5 min and 2,3,5-trimethylindole (IV, R = CH_3) had r.r.t. 0.59.

1,2,3,4-Tetrahydro-6-nitrocarbazole (III, $n = 3$, R = NO_2, R′ = H)

Cyclohexanone *p*-nitrophenylhydrazone (3 g), in diethylene glycol (20 ml), was boiled under reflux until evolution of ammonia ceased (10 h) and then poured into water. The solid (2.1 g) was extracted with boiling benzene (2 × 50 ml). The benzene solution was passed down an alumina column and afforded an upper brown band and a lower yellow band. The latter was eluted with more benzene, and the benzene solution concentrated to give yellow prisms (0.1 g), m.p. 176–178° (lit. m.p. 177° (13)).

6,7,8,9-Tetrahydro-α-carboline (VII)

Cyclohexanone 2-pyridylhydrazone (14) (4.25 g) in diethylene glycol (20 ml) was boiled under reflux for 7 h. Ammonia was evolved and the solution became red-brown. After cooling, the mixture was poured into ice water and the solid (2.7 g) filtered off. Recrystallization from petroleum ether (b.p. 60–80°) gave pale cream needles, m.p. 153.5–154.5° (lit. m.p. 156° (14)).

2,3-Diphenylpyrrolo[2,3-b]pyridine (VI, R = R′ = C_6H_5)

Benzyl phenyl ketone 2-pyridylhydrazone (14) (6.5 g) in diethylene glycol (20 ml) was boiled under reflux for 7 h. After cooling, the solid was filtered off and washed with water. The dry solid (3.4 g, 56%) was sublimed, 230° at 1.5 mm, to give a pale cream solid m.p. 293–295° (lit. m.p. 293.5° (14)).

6,7,8,9-Tetrahydro-γ-carboline (VIII)

Cyclohexanone 4-pyridylhydrazone (15) (3 g), in diethylene glycol (20 ml), was boiled under reflux for 11 h. After cooling, the mixture was poured into water and the solid filtered off. The light brown solid (2.6 g, 95%) was recrystallized from aqueous ethanol (charcoal) to give colorless prisms, m.p. 268.5–270° (lit. m.p. 272° (15)).

ACKNOWLEDGMENTS

Part of this work was done as a project for the diploma in Technology while employed (D. H. McL.) by Winthrop Laboratories Ltd. We gratefully acknowledge the award (A. H. K.) of a research studentship by Newcastle-upon-Tyne Education Committee and our indebtedness to Mr. R. Hindson for technical assistance.

NOTES

THE OPTICAL ACTIVITY OF FUCOXANTHIN

N. J. Antia

Fucoxanthin has been shown to be the predominant plastid carotenoid pigment of brown algae (Phaeophyceae), diatoms, and Chrysophyceae, with evidence for direct participation in photosynthesis by light activation (1). Although extensively studied by several investigators (see Jensen (2) for the most recent work and citation of the earlier literature), its chemical structure has remained undetermined and the question of its optical activity unresolved. Karrer *et al.* (3) reported the compound to be optically active ($[\alpha]_C$ +72.5°) but subsequent investigators (4) have claimed it to be inactive. The discrepancy appears to be due to the problem of making measurements in the spectral region dictated by standard polarimetric equipment but where fucoxanthin shows strong light absorption thereby necessitating the use of concentrations too low to register reliable activity readings. The recent development of spectropolarimeters has now offered an excellent opportunity to reexamine the problem by measuring the optical activity of fucoxanthin over the widest possible spectral range especially in regions where light absorption of the compound is low enough not to interfere.

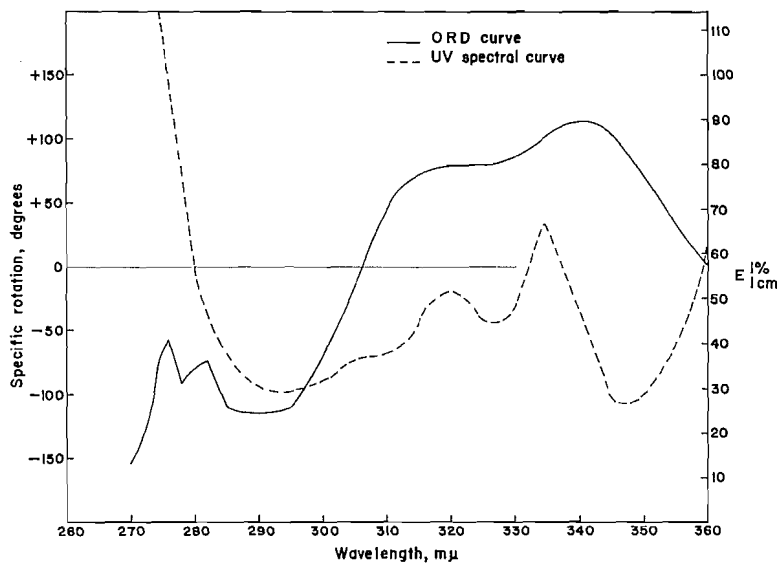

FIG. 1. The rotatory dispersion and ultraviolet absorption of fucoxanthin.

Crystalline fucoxanthin isolated from *Sargassum muticum* by Parsons and Strickland (5) was used in the present study. A sample was scanned in *p*-dioxane solution (*c*, 0.0175)

from 600 to 240 mμ and the only region showing measurable rotation was that between 360 and 270 mμ. The optical rotatory dispersion (o.r.d.) curve for this region, depicted in Fig. 1, shows a multiple Cotton effect with close correspondence between its *extrema* and the ultraviolet absorption maxima. The nature of the rotatory dispersion observed suggests the proximity of elements of asymmetry in the molecule of fucoxanthin to chromophores with λ_{max} at 334, 320, 307, and 264 mμ. The molecular asymmetry may stem from one or more carbon atoms carrying a secondary or tertiary hydroxyl or acetoxy group or from the location of the allene group in the carotenoid chain. The ultraviolet-absorbing chromophores may be carbonyl functions of the ester group and keto group conjugated with the polyene chain (or with the allene group). Evidence for the occurrence of these groups in the fucoxanthin molecule has been recently presented (2, 6). In the absence of o.r.d. studies on other carotenoids or allenes, it is not possible to make comparative inferences on the structure of fucoxanthin from the present study, which does show, however, that any structure proposed for this carotenoid will henceforth require to take cognizance of molecular asymmetry. Similar o.r.d. studies on other carotenoids are desirable to resolve controversies on their optical activity (e.g. zeaxanthin (7)).

EXPERIMENTAL

The fucoxanthin sample of Parsons and Strickland (5) was recrystallized twice from ether – light petroleum (30–60°); m.p. 151–153° (uncorrected, Kofler block).

Anal. Calcd. for $C_{42}H_{62}O_6$: C, 76.13; H, 9.36; mol. wt., 662. Found: C, 75.69; H, 9.07; mol. wt. (Rast), 649.

Solutions of the compound scanned for light absorption in the region 350–700 mμ showed maxima at the following wavelengths: ethanol, 450 mμ ($E_{1\ cm}^{1\%}$ = 1 140); chloroform, 458 mμ; light petroleum (60–80°), (426), 448, 476 mμ. The infrared spectrum (KBr disc) was identical with that of a specimen of fucoxanthin from *Fucus vesiculosus* (6) kindly supplied by Dr. B. C. L. Weedon; no band was observed in the acetylenic grouping absorption region 2 100 to 2 200 cm^{-1}, indicating the absence of any allene → acetylene rearrangement during the isolation of the pigment. Paper chromatography by the method and solvent systems of Jeffrey (8) showed the pigment to be homogeneous with the following R_F values: 4% propan-1-ol in light petroleum, 0.78; 30% chloroform in light petroleum, 0.54.

The o.r.d. was measured on a Cary Model 60 recording spectropolarimeter, with a path length of 1 cm, temperature of 25°, slit width of 25 Å (spectral band pass), and scan speed of 1 Å per second. The specific rotation at 589 mμ was too low for measurement with the high light absorption obtained at this wavelength and appears to be less than +25°. The ultraviolet absorption was measured with a Cary Model 14 recording spectrophotometer on the same solution used for o.r.d. measurement.

ACKNOWLEDGMENTS

Grateful acknowledgment is hereby made to Dr. T. R. Parsons for supplying the fucoxanthin from *S. muticum* used in this investigation as well as to Mr. N. Mitchell of Applied Physics Corporation, Monrovia, California, for making the o.r.d. measurement.

UREA INCLUSION COMPOUNDS OF ALKENOIC ACIDS AND ALKYL ALKENOATES

JACK RADELL AND B. W. BRODMAN

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Commercially obtained samples of alkenoic acids and alkyl alkenoates were examined in the infrared region to determine the geometric isomerism around the double bond. This information was required because in an earlier study (1) it was found that the effect of *cis* and *trans* isomerism on the ability of a molecule to form a urea inclusion compound was very significant. The geometric isomerism of all endocytes selected were the same, so that their behavior under complexing conditions could be compared. The *trans* rather than the *cis* isomers were chosen because it made it possible to deal with the more readily available shorter molecules which are capable of forming complexes. This would not be true of the corresponding *cis* molecules.

Some of the pertinent peaks obtained from the infrared analysis are listed in Table I.

TABLE I

$H(CH_2)_2CH{=}CHCH_2COOEt$	—	963m	1 300m	1 655w

*Intensity of peaks are described as s (strong), m (medium), and w (weak).
†Shoulder.

Most significant is the *trans* out-of-plane =CH deformation reported (2) as a strong band at 965–980 cm^{-1} for unconjugated acids with some shifts to higher frequencies observed for the α,β-unsaturated acids. This band was observed in this range for all the acids and esters, although the frequency of the absorption was consistently higher for the conjugated acids and esters than for the unconjugated acids and esters, respectively. This band alone is not conclusive evidence for the presence of the *trans* structure. The *trans* in-plane deformation which reportedly (2) appears at 1 295 to 1 310 cm^{-1} appears in all the acids and esters in Table I except for 3-*n*-hexenoic acid which has the hint of a shoulder around 1 308 cm^{-1}. The remaining absorption bands present are consistent with the structure of the molecules and have been omitted.

In Table II are listed the compounds treated by an urea–methanol solution as described in the experimental section. All compounds treated formed urea-inclusion compounds except 3-*n*-hexenoic and 3-*n*-octenic acids. All other alkenoic acids differed from these two by the presence of a double bond in the 2-position. This trend is similar to one observed in earlier studies of alkynes (3). The triple bond did not prevent complex formation in 1-, 2-, or 3-nonyne and 2- and 3-decyne but did prevent complex formation in 4-nonyne and 5-decyne. The fact that all the 3-*n*-alkenoic acid esters formed urea complexes is

*3-*n*-Hexenoic acid and 3-*n*-octenoic acid formed no crystalline material.
†Interplanar spacings in Å using Cu K_α radiation.
‡Weight of urea-inclusion compound isolated by procedure in the experimental.
§Relative intensities; 1.00 being the strongest. A dash has been used for spacing of intensity less than 0.05.
‖Other interplanar spacings for urea occurred at 2.00, 2.53, and 2.83 Å.

attributable to the added van der Waals stabilization resulting from the alkyl groups of the ester. In general for two identical compounds differing in the location and not in the geometric isomerism of the double bond, the isomer with the more centrally located double bond is less stable and forms less or no complex under the same conditions.

The interplanar spacings listed in Table II indicate that all compounds which formed crystals when treated with an urea–methanol solution formed urea-inclusion compounds. This is demonstrated by the following three most generally intense interplanar spacings 3.53–3.57 Å, 4.09–4.15 Å, and 7.04–7.19 Å. The urea–methanol-treated samples are all generally free from dissociated tetragonal urea except the 2-*n*-hexenoic acid methyl ester and 3-*n*-hexenoic acid methyl ester, both of which have a low-intensity interplanar spacing characteristic of free tetragonal urea. The 3-*n*-hexenoic and 3-*n*-octenoic acids formed no crystalline product and are therefore not listed in Table II.

EXPERIMENTAL

Urea-Inclusion Compounds

Urea-inclusion compounds of the alkenoic acids and alkyl alkenoates were prepared by a previously described procedure (4). The only exception was that 1 g of the guest compound was used in place of 30 drops.

X-Ray Powder Diffraction Measurements

The X-ray diffraction patterns were obtained by a previously described method (4).

Alkenoic Acids and Alkyl Alkenoates

The acids and esters were all obtained from the Gallard-Schlesinger Mfg. Corp., Long Island, N.Y., and their purity was established by elemental analysis and infrared data.

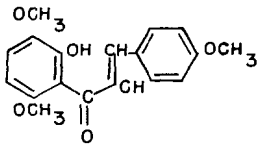
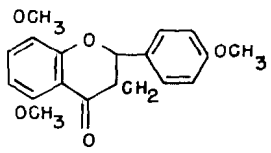
3,5,8,4′-TETRAMETHOXYFLAVONE AND THE CONSTITUTION OF PRATOLETIN

JASWINDER SINGH CHADHA[1]

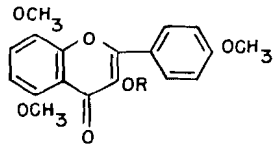
Pratoletin, a flavone, was isolated from the flowers of *Trifolium pratense* by Hattori, Hasegawa, and Simokoriyama (1). It was considered to be either (i) 3,5,6,4′-tetrahydroxy flavone or (ii) 3,5,8,4′-tetrahydroxyflavone. This was based on the following considerations: pratoletin gave an orange red color with magnesium and hydrochloric acid and produced a greenish-brown color with ferric chloride. The analysis of pratoletin and its derivatives corresponded to a tetrahydroxy flavone. It was considered to have an ortho- or a para-dihydroxylic system because an alcoholic solution of pratoletin gave a black precipitate with an aqueous solution of chloropentaaminocobaltic chloride. From a comparison of the ultraviolet spectra of pratoletin and its tetramethyl ether, it was considered to be a flavonol (1).



I



II



III, R = H

IV, R = CH_3

Because of war time difficulties, the above publication (1) was for a long time not fully known; it was abstracted in the Chemical Abstracts only in 1951 (2). Meanwhile, during studies relating to nuclear oxidation in the flavone series, Rajagopalan, Row, and Seshadri (3) prepared 3,5,6,4′-tetrahydroxyflavone and its derivatives. These do not agree with those of pratoletin and its derivatives. Consequently pratoletin has been considered to be 3,5,8,4′-tetrahydroxyflavone (4).

During work carried out relating to leucoanthocyanidins, 3-hydroxy-5,8,4′-trimethoxyflavone was prepared and methylated to yield 3,5,8,4′-tetramethoxyflavone. The synthesis was carried out following the procedure of Ahluwalia and Seshadri (5), who prepared the closely related 3,5,8,3′,4′-pentahydroxyflavone and derivatives. 2-Hydroxy-3,6,4′-trimethoxychalcone I (6) was cyclized to the corresponding flavanone II and the flavanone was converted into the flavonol III by the amylnitrite method (7). Final methylation yielded the tetramethoxyflavone IV.

3,5,8,4′-Tetramethoxyflavone IV has a m.p. 158° (anhydrous sample) and λ_{max}: 272 mμ(log ε 4.11), 299 mμ(log ε 4.13), and 321 mμ(log ε 4.16). Pratoletin tetramethyl ether is recorded to have m.p. 109° (hydrate) and 138° (anhydrous) and λ_{max}: 266 mμ and 329 mμ (1). It seems, therefore, necessary to reinvestigate the constitution of pratoletin.

EXPERIMENTAL

5,8,4′-Trimethoxyflavanone (II)

2-Hydroxy-3,6,4′-trimethoxychalcone (1 g) was dissolved in ethanol (60 ml) and aqueous hydrochloric acid (3%) was added till there was a permanent turbidity and the solution refluxed for 24 h. On cooling, part of the chalcone separated. This was filtered and the filtrate heated to expel most of the alcohol. On

[1]*Present address: Unilever Research Laboratory, The Frythe, Welwyn, Herts, England.*

For personal use only.

cooling, a mixture of the chalcone and the flavanone separated. It was filtered (600 mg) and treated with cold aqueous sodium hydroxide (1%) to dissolve the unchanged chalcone. On filtration, crude flavanone (500 mg) was obtained. It was crystallized from methanol yielding light yellow rods, m.p. 178°.

Anal. Calcd. for $C_{18}H_{18}O_5$: C, 68.8; H, 5.8. Found: C, 68.6; H, 5.8.

The mixture of the chalcone and the flavanone could also be separated by fractional crystallization from carbondisulfide.

3-Hydroxy-5,8,4'-trimethoxyflavone (III)

The trimethoxyflavanone (120 mg) was dissolved in ethanol (20 ml) and to the boiling solution concentrated hydrochloric acid (10 ml) was added. To this isoamyl nitrite (1 ml) in ethanol (10 ml) was added in small portions and with constant shaking during 3 min. The color of the reaction mixture changed to orange. It was allowed to stand for 2 h with occasional shaking. Part of the alcohol was distilled and water added. On cooling, the flavonol separated as needles (50 mg) and on crystallization from methanol, it came out as light yellow needles, m.p. 188°.

Anal. Calcd. for $C_{18}H_{16}O_6$: C, 65.8; H, 4.9. Found: C, 65.3; H, 5.3.

3,5,8,4'-Tetramethoxyflavone (IV)

A mixture of 3-hydroxy-5,8,4'-trimethoxyflavone (70 mg), dimethyl sulfate (0.1 ml), and potassium carbonate (500 mg) in dry acetone was refluxed for 6 h. The mixture was filtered and the acetone solution concentrated to small bulk and water added. On cooling, the product was obtained as a crystalline compound. It was filtered (50 mg) and crystallized from benzene – petroleum ether. It came out as light yellow needles, m.p. 158°.

Anal. Calcd. for $C_{19}H_{18}O_6$: C, 66.7; H, 5.3. Found: C, 66.3; H, 5.4.

THE PREPARATION OF THIOACETALS FROM ORTHOTHIOBORIC ESTERS

F. Bessette, J. Brault, and J. M. Lalancette

We have indicated that orthothioboric esters $(RS)_3B$ can be obtained by the action of mercaptans on boron sulfide (1). These esters were found to react with aldehydic or ketonic carbonyls to give the corresponding thioacetals and boric anhydride according to the following equation:

Anal. Calcd. for $C_{18}H_{18}O_5$: C, 68.8; H, 5.8. Found: C, 68.6; H, 5.8.

The mixture of the chalcone and the flavanone could also be separated by fractional crystallization from carbondisulfide.

3-Hydroxy-5,8,4'-trimethoxyflavone (III)

The trimethoxyflavanone (120 mg) was dissolved in ethanol (20 ml) and to the boiling solution concentrated hydrochloric acid (10 ml) was added. To this isoamyl nitrite (1 ml) in ethanol (10 ml) was added in small portions and with constant shaking during 3 min. The color of the reaction mixture changed to orange. It was allowed to stand for 2 h with occasional shaking. Part of the alcohol was distilled and water added. On cooling, the flavonol separated as needles (50 mg) and on crystallization from methanol, it came out as light yellow needles, m.p. 188°.

Anal. Calcd. for $C_{18}H_{16}O_6$: C, 65.8; H, 4.9. Found: C, 65.3; H, 5.3.

3,5,8,4'-Tetramethoxyflavone (IV)

A mixture of 3-hydroxy-5,8,4'-trimethoxyflavone (70 mg), dimethyl sulfate (0.1 ml), and potassium carbonate (500 mg) in dry acetone was refluxed for 6 h. The mixture was filtered and the acetone solution concentrated to small bulk and water added. On cooling, the product was obtained as a crystalline compound. It was filtered (50 mg) and crystallized from benzene – petroleum ether. It came out as light yellow needles, m.p. 158°.

Anal. Calcd. for $C_{19}H_{18}O_6$: C, 66.7; H, 5.3. Found: C, 66.3; H, 5.4.

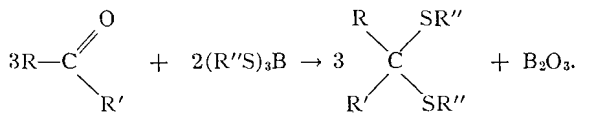
THE PREPARATION OF THIOACETALS FROM ORTHOTHIOBORIC ESTERS

F. Bessette, J. Brault, and J. M. Lalancette

We have indicated that orthothioboric esters $(RS)_3B$ can be obtained by the action of mercaptans on boron sulfide (1). These esters were found to react with aldehydic or ketonic carbonyls to give the corresponding thioacetals and boric anhydride according to the following equation:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This reaction seems general for aliphatic and aromatic molecules. It has given good yields of the thioacetals without undesirable side reactions with the molecules studied (Table I). Contrary to the usual procedure leading to the formation of thioacetals (2), this reaction proceeds smoothly in neutral medium at room temperature.

TABLE I

With some reactive aldehydes like benzaldehyde, the speed of the reaction has to be controlled by working with a diluent, such as petroleum ether or benzene. In several cases, however, the thioacetal can be obtained merely by mixing the reactants and filtering off the boric anhydride, after a contact of a few hours at room temperature.

This reaction shows some analogy with the interchange of oxygen for sulfur on the boron atoms of B_2S_3, when this sulfide is allowed to react with aldehydic or ketonic carbonyls (3). The exchange is much favored, thermodynamically, by the difference in the heats of formation of B—S and B—O bonds. This should be, in fact, the driving factor of the reaction. The reaction proceeds in neutral medium and shows an induction period, the initiation of the process being indicated by the precipitation of boron oxide, highly insoluble in the petroleum ether or benzene used as solvents. These results can be interpreted as indications of a free radical mechanism for the reaction.

EXPERIMENTAL

Benzaldehyde Thioacetal

To an ice-cold solution of 16 g (0.083 mole) of ethyl orthothioborate in 150 ml of dry petroleum ether, b.p. 40–50°, a solution of 13.8 g (0.13 mole) of freshly distilled benzaldehyde in the same amount of petroleum ether is added slowly, under stirring and nitrogen atmosphere. As the addition proceeds, a white precipitate of boric anhydride slowly appears. The reaction is completed by heating under reflux for 2 h. By filtration, 2.82 g (0.041 mole) of B_2O_3 is obtained. This solid does not melt below 300° and yields boric acid, m.p. 175–177°, on treatment with boiling water.

The organic fraction, after evaporation of the petroleum ether, leaves a pink residue which is fractionated *in vacuo*. The main fraction, b.p. 125–127° at 0.22 mm, n_D^{25} 1.5731, 19.85 g (0.093 mole), is the benzaldehyde thioacetal.

Anal. Calcd. for $C_{11}H_{16}S_2$: C, 62.18; H, 7.56; S, 30.22. Found: C, 61.97; H, 7.56; S, 30.11.

By this technique, several aldehydes and ketones have been transformed into their thioacetal (Table I). Ethyl, butyl, and pentyl orthothioborates have been shown to give the expected reaction which should be general for all orthothioboric esters.

With carbonyls of moderate reactivity, the diluent—petroleum ether or benzene—can be omitted. In such an experiment, 5.7 g (0.079 mole) of butanone was mixed with 10.0 g (0.052 mole) of ethyl orthothioborate. After 5 to 10 min, the reaction mixture starts to exhibit a gel-like appearance. After a contact

time of 18 h, at room temperature, in a dessicator containing potassium hydroxide pellets, the mass is taken up by petroleum ether, b.p. 40–50°. The boric anhydride is filtered off and the usual techniques give the butanone thioacetal, b.p. 205–208° at 750 mm, n_D^{25} 1.4955, in 76% yield.

Anal. Calcd. for $C_8H_{18}S_2$: C, 53.87; H, 10.17; S, 35.95. Found: C, 54.47; H, 10.00; S, 35.24.

THE ADSORPTION OF KRYPTON AND ETHYLENE ON EVAPORATED FILMS OF MAGNESIUM[1]

D. M. Young and C. D. Anderson

A study of the adsorptive behavior of boron halides on evaporated films of magnesium was initiated in the hope of throwing some light on the mechanism of formation of protective films on magnesium surfaces. The project was later abandoned, however, on finding that evaporated magnesium films sinter to a marked degree even at temperatures as low as −78 °C. The sintering behavior is reported here because no such information is available in the literature. Some unusual physical adsorption isotherms, obtained during surface area measurements, also merit publication.

EXPERIMENTAL

Magnesium wire of 0.025 in. diameter, extruded from sublimed magnesium of 99.96% purity, was obtained from the Metallurgical Laboratory, The Dow Chemical Co. Ethylene supplied by Imperial Oil, Ltd., was 99.99 mole % pure, the major impurity being 0.0047% ethane. Reagent grade helium and krypton supplied in glass flasks by Air Reduction Sales Co. were used as received. The only detectable impurity, according to the supplier, was 0.03 mole % nitrogen in the krypton.

The apparatus was of the constant volume type conventionally used for studies on evaporated metal films. Wide bore mercury cut-offs were used in place of stopcocks and a U trap, always kept at liquid air temperature, served to protect the metal film from mercury vapor. Measured amounts of adsorbate were admitted by means of a greaseless doser previously described (1). Equilibrium pressures were measured with a McLeod gauge for krypton or with a Pirani gauge calibrated against a McLeod gauge for helium (used for determining the dead space) and ethylene.

The temperatures of the liquid oxygen or nitrogen baths surrounding the adsorbent were measured with an oxygen vapor pressure thermometer. The correction for gas adsorbed on the walls was estimated by carrying out a blank run prior to evaporating a film, making allowance for the area later to be covered with magnesium. This correction, negligible for krypton at −195°, never exceeded 3% of the ethylene adsorbed on the film at −183°. It has been applied to the ethylene results given here. The effects of thermal transpiration, calculated by the methods of Bennett and Tompkins (2), were found negligible for all gases.

RESULTS AND DISCUSSION

A reliable method of determining surface areas was required in order to study the effect of heat treatment on sintering and to measure the porosity of the films, i.e. to establish whether the surface area increased with increasing film thickness. A number of variants on the Brunauer, Emmett, Teller (B.E.T.) method are useful for small surface areas (3), notably the use of krypton at −195° and ethylene at −183°.

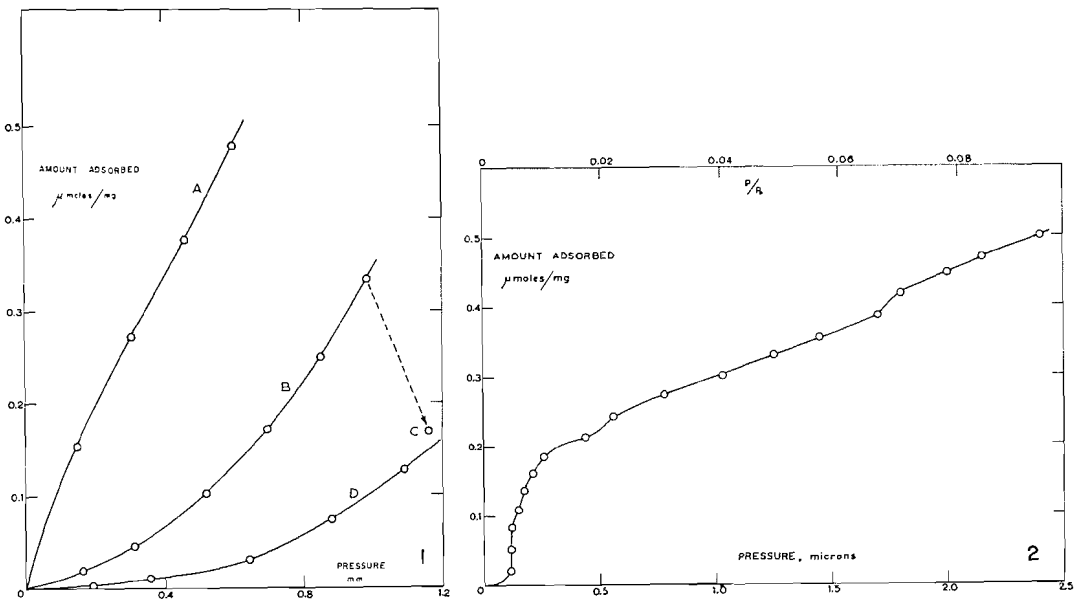

FIG. 1. Adsorption isotherms of krypton on film I at −195°, showing effects of sintering at −78°. Curve A, freshly formed film; curve B, after pumping at −78° for 2.5 h; curve C, after standing at −78° for 63.5 h; curve D, after pumping at −78° for 1 h.
FIG. 2. Adsorption isotherm for ethylene on film II at −183°.

The krypton method, due to Beebe, Beckwith, and Honig (4), was tried with film I (78.6 mg) and the results are shown in Fig. 1. Isotherm A was measured on the freshly formed film. It is characteristic of a B.E.T. type II isotherm with a very low value of the B.E.T. *c*-constant and is virtually useless for surface area determinations (3). Experiments with krypton were continued on film I, however, to determine its temperature stability. The film was warmed to −78° and pumped for 2.5 h to remove the krypton. A second krypton isotherm at −195° was measured (curve B). The diffuse knee-bend in the original isotherm has now disappeared and curve B is a typical B.E.T. type III isotherm. This, together with the lowered adsorptive capacity, shows that rapid sintering has occurred even at −78°. With the krypton left in the adsorption system, the temperature of the film was again raised to −78° and so maintained for 63.5 h. The film was then cooled to −195° and the equilibrium pressure of krypton again measured. The amount adsorbed had dropped from the final point of isotherm B to point C in Fig. 1. The adsorption vessel was warmed to −78° and evacuated for 1 h, then cooled to −195° and a third krypton isotherm measured (curve D).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The adsorption isotherms of ethylene at −183° were found suitable for B.E.T. surface area determination; this method was first suggested by Wooten and Brown (5). Equilibrium was established within a few minutes after each admission of gas and almost complete desorption occurred on pumping at −183°. A number of points were obtained at low relative pressures, revealing several "steps" in the isotherm (Fig. 2, film II). Some possible explanations for isotherms of this type are discussed elsewhere (3). In the pressure range used for the B.E.T. calculation ($p/p_0 = 0.05 - 0.3$) however, the isotherms have normal type II curvature and the B.E.T. equation fits quite accurately. The natural isotherm for film III, again showing an inflection, is plotted in Fig. 3 (upper curve) with the corresponding B.E.T. plot (lower curve).

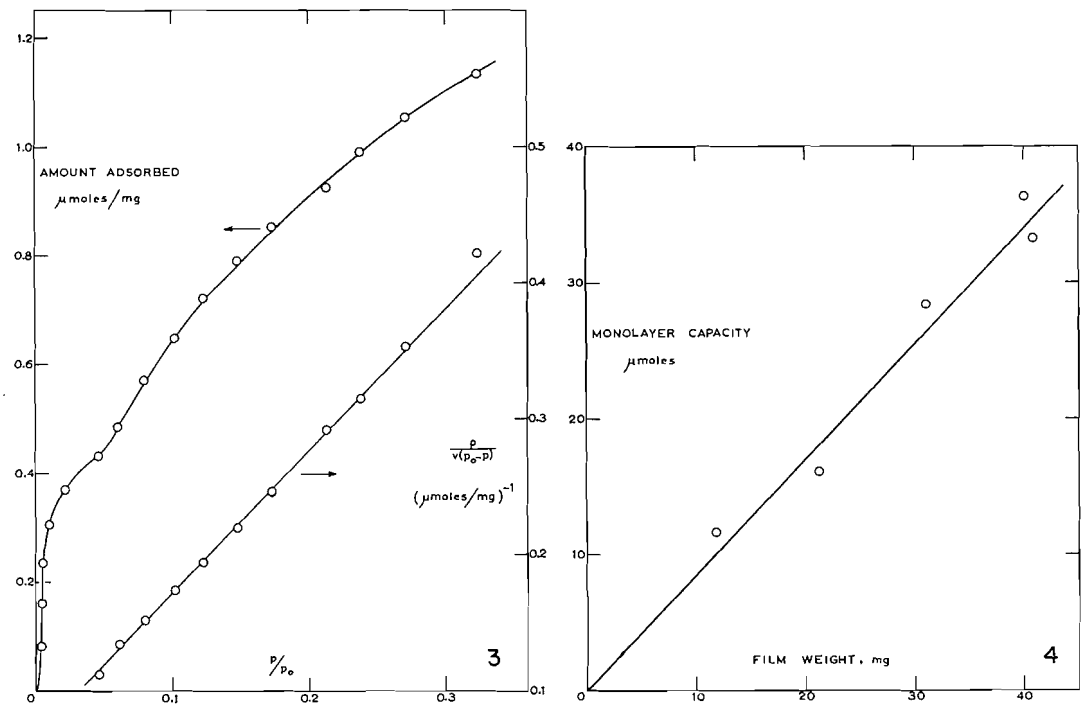

FIG. 3. The adsorption of ethylene on film III at −183°. Upper curve, natural isotherm; lower curve, plotted according to the B.E.T. equation.
FIG. 4. Monolayer capacity of films II–VI as a function of film weight.

Ethylene adsorption isotherms were measured on a series of magnesium films of different weights, and monolayer capacities calculated from the B.E.T. equation. The results are given in Fig. 4 in which the monolayer capacity is plotted against the film weight, for films II to VI inclusive. The linearity of this plot shows that the surface areas of the films are proportional to their weight and hence that the films are porous. Taking 17.55 Å² as the cross-sectional area of an ethylene molecule in the completed monolayer, following Wooten and Brown (5), the slope of the line in Fig. 4 corresponds to an average specific surface area of 89.8 m²/g for the five films studied.

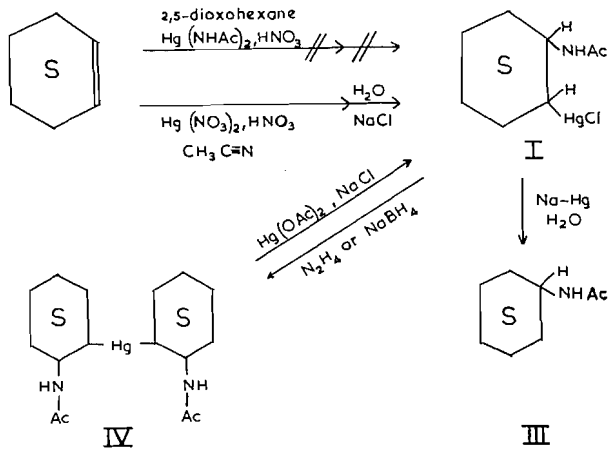
THE AMMONOMERCURATION OF CYCLOHEXENE

D. CHOW, J. H. ROBSON, AND GEORGE F WRIGHT

This is a preliminary report of a reaction in which the acetamino group and the anionomercuri group are added to the double bond. It is not the first time that a double bond has been saturated by an anionomercuri group and a nitrogen function. Previously N-β-chloromercuriethylpiperidine has been prepared from ethylene, mercuric salt and piperidine (1), diethylamine (2), and mesidine (3). However the reagents in our transformation are unique, the yields are high, and the reaction ought to be useful in syntheses.

A solution of mercuric nitrate and absolute nitric acid in acetonitrile reacts with cyclohexene within 1 min to give a nearly quantitative yield, after conversion with mercuric chloride, of 2-acetaminocyclohexylmercuric chloride, I. No configuration has been assigned because we have as yet been unable to convert I to a mixture (4) from which the other diastereomer might be isolated, nor have we been able to find the other isomer in the nearly pure product of the reaction.



We are not prepared to suggest a mechanism for this reaction but we do not believe that it involves mercuric acetamide, II, or a mixed salt of it because I is not obtained when II and nitric acid are treated with cyclohexene in 2,5-dioxahexane, diethyl ether, methanol, or acetonitrile. In each case cyclohexene and acetamide have been recovered from the hydrolysate.

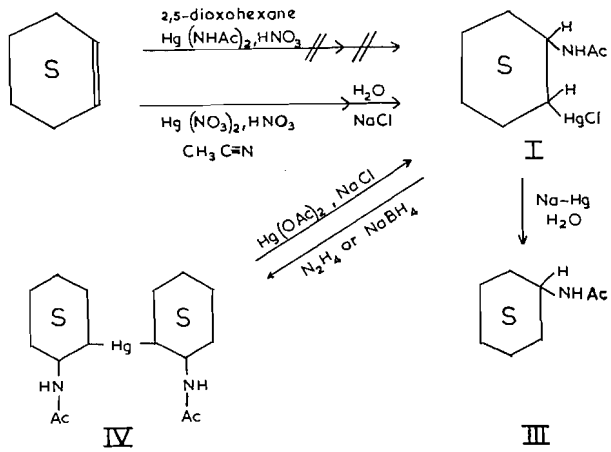
THE AMMONOMERCURATION OF CYCLOHEXENE

D. CHOW, J. H. ROBSON, AND GEORGE F WRIGHT

This is a preliminary report of a reaction in which the acetamino group and the anionomercuri group are added to the double bond. It is not the first time that a double bond has been saturated by an anionomercuri group and a nitrogen function. Previously N-β-chloromercuriethylpiperidine has been prepared from ethylene, mercuric salt and piperidine (1), diethylamine (2), and mesidine (3). However the reagents in our transformation are unique, the yields are high, and the reaction ought to be useful in syntheses.

A solution of mercuric nitrate and absolute nitric acid in acetonitrile reacts with cyclohexene within 1 min to give a nearly quantitative yield, after conversion with mercuric chloride, of 2-acetaminocyclohexylmercuric chloride, I. No configuration has been assigned because we have as yet been unable to convert I to a mixture (4) from which the other diastereomer might be isolated, nor have we been able to find the other isomer in the nearly pure product of the reaction.



We are not prepared to suggest a mechanism for this reaction but we do not believe that it involves mercuric acetamide, II, or a mixed salt of it because I is not obtained when II and nitric acid are treated with cyclohexene in 2,5-dioxahexane, diethyl ether, methanol, or acetonitrile. In each case cyclohexene and acetamide have been recovered from the hydrolysate.

The ammonomercurial, I, is more stable than the analogous oxymercurials. It may be recovered unchanged after long treatment with 5% aqueous sodium hydroxide in which it dissolves. Also it dissolves initially in concentrated hydrochloric acid but a hydrochloride is precipitated shortly. When this hydrochloride after many hours is washed with water it reverts to I. Only in boiling concentrated hydrochloric acid is I decomposed to cyclohexene, acetamide, and mercuric chloride.

Reduction with sodium amalgam in alkaline solution leads cleanly to N-cyclohexylacetamide, III, and some of this is found upon treatment of an alkaline solution with sodium borohydride or hydrazine hydrate. However, the principal product with these reagents is the bis-mercurial, IV, even though conditions of reaction with the hydrazine hydrate have been arranged to cause diastereomeric equilibration via the mercuri linkage. The bis-mercurial has been reconverted quantitatively to I by treatment with mercuric salts. The bis-mercurial, IV, is only slightly soluble in 40% aqueous sodium hydroxide and is unchanged by it after a half-hour at 110°.

EXPERIMENTAL

Physical Constants

Melting points have been corrected against reliable standards. X-ray diffraction patterns have been obtained using Cu (Ni-filtered) radiation and are recorded as *d*-spacings in Å at intensities I/I_1.

Reagents

Cyclohexene was washed peroxide free with aqueous ferrous sulfate and after drying with magnesium sulfate was distilled under nitrogen. Acetonitrile was distilled under vacuum from phosphorus pentoxide and then at 82° and 755 mm. It was subsequently dried by means of drierite. Mercuric nitrate (Merck) was used as received. Absolute nitric acid (water white) was prepared by vacuum distillation of a nitric acid – sulphuric acid mixture.

2-Acetaminocyclohexylmercuric Chloride, I

From Cyclohexene

To a stirred suspension of 1.62 g (5 mmole) of freshly ground mercuric nitrate in 5 ml of acetonitrile was added 0.021 ml (0.5 mmole) of absolute nitric acid and then with cooling 0.5 ml (5 mmole) of cyclohexene. The suspension disappeared and after 2 min a test with alkali for inorganic mercuric salt was negative; a slight amount of mercurous salt was present. After 20 min the system was poured slowly into 10 ml of water at 4° and then 1.5 ml of 5 *M* aqueous sodium chloride was added. Filtration removed 1.75 g (94%), m.p. 199°. Crystallization from methanol (11 ml per g) and finally from dimethylformamide raised the m.p. to 201.5–202°.

Anal. Calcd. for $C_8H_{14}ClHgNO$: C, 25.5; H, 3.75. Found: C, 25.5; H, 3.72.

The reaction was completed within 1 min when the amount of nitric acid was doubled, and the yellow color characteristic of the reaction system appeared correspondingly earlier. When the reaction system was diluted with 2,5-dioxahexane the yield was decreased to 30% and much mercurous salt was formed.

From Bis-2-acetaminocyclohexylmercury

A 50 mg quantity (0.104 mmole) either of one pure diastereomer (m.p. 253°) or else of the diastereomeric mixture of bis-mercurials IV and 33 mg (0.104 mmole) of mercuric acetate was dissolved in 2 ml of methanol, warmed 5 min at 50°, then cooled, diluted with 4 ml of water and 0.1 ml of 5 *M* aqueous sodium chloride solution, and finally centrifuged to remove 0.76 g, m.p. 188–191°. Crystallization of this 86% yield raised its m.p. to 200–201°. A mixture melting point with I was not depressed.

N-Cyclohexylacetamide, III

A mixture of 15 ml of water, 3.75 g (10 mmole) of I, 2 ml of 6 *M* aqueous sodium hydroxide solution, and 20 mmole of 2% sodium amalgam was shaken for 3 h. Filtration of the aqueous suspension after decanting from mercury gave a grey solid which was extracted with 10 ml of hot ethyl acetate. Concentration of this extract yielded 0.75 g (66%) of III, m.p. 102–106°. Crystallization raised this m.p. to 105–106° and a mixture melting point with an authentic sample (5) was not depressed.

Bis-2-acetaminocyclohexylmercury, IV

A solution of 2.00 g (5.3 mmole) of I, 18.3 ml (0.26 mole) 100% hydrazine hydrate, and 5 ml of 5% aqueous sodium hydroxide quickly formed a white precipitate which became orange in color within a few minutes and then successively darker, because of the deposition of metallic mercury. The temperature was raised and maintained at 70–80° for 3 h. The system was cooled; the solid was filtered off and extracted

with 30 ml of hot methanol. Concentration of this extract yielded 12.7 g (99%) m.p. 213–215°. From this mixture of diastereomers was obtained 0.27 g (22%) m.p. 256–257° of one isomer by repeated crystallization from hot methanol (16 ml per g).

Anal. Calcd. for $C_{16}H_{28}HgN_2O_2$: C, 39.9; H, 5.87. Found: C, 40.0; H, 5.50.

The X-ray diffraction pattern was (10) 5.129; (6) 2.203; (5) 2.038; (4) 2.508; 1.925; (3) 2.640, 1.795, 1.591; (2) 2.508, 2.424.

Reduction with 2 equivalents of sodium borohydride in an otherwise identical system was much less satisfactory. The yield of the diastereomic mixture of IV was only 22% but the isomer, m.p. 253–254° was identified after isolation from methanol solution by its X-ray diffraction pattern.

Cyclohexene with Mercuric Acetamide, II

Systems comprised of cyclohexene and mercuric acetamide (m.p. 197–198°) (6) in equivalent amounts dispersed in 2,5-dioxahexane, diethyl ether, and acetonitrile gave none of I whether or not nitric acid was present. The odor of cyclohexene was strong when these systems were diluted with water. Extraction of the diluate with diethyl ether yielded unchanged acetamide. Similar results were obtained, when mercuric nitrate and acetamide were treated with cyclohexene (all equimolar) in dioxahexane.

The authors are grateful to the National Research Council for grants-in-aid which made this work possible.

HYDRATION OF PURINES, PYRIMIDINES, NUCLEOSIDES, AND NUCLEOTIDES[1]

Michael Falk

Hydration is a major factor determining the structure of deoxyribonucleic acid (DNA) (1–3). It was therefore of interest to examine the hydration of the molecular constituents of DNA (purines, pyrimidines, nucleosides, nucleotides, and related compounds) and to compare it with the hydration of DNA at comparable values of relative humidity.

The 37 compounds used in the present study were the best commercial grades available. Their melting points and their infrared and ultraviolet spectra were determined and compared whenever possible with the data reported in the literature. The weight of water taken up by each compound was determned as a function of relative humidity by the procedure reported in a recent study of DNA (4). Duplicate specimens of 50 to 100 mg, in pyrex weighing bottles, were exposed to atmospheres of constant relative humidity at 21.0 ± 0.5° in glass hygrostats and were weighed daily to 0.1 mg until the weight remained constant *for at least a week*. The dry weight of each sample was obtained by drying it to constant weight in a vacuum of 10^{-3} Torr at room temperature, followed by prolonged drying in vacuum at temperatures up to 100° for those compounds that were stable under such a treatment.

For the purpose of the experiment the compounds were divided into "hygroscopic", characterized by forming at least a tetrahydrate at high relative humidity, and "non-hygroscopic", forming no higher hydrate than a dihydrate. The non-hygroscopic compounds were only subjected to one series of measurements at gradually increasing values of relative humidity. The hygroscopic compounds were subjected to several cycles of increasing and decreasing relative humidity. "Adsorption" and "desorption" values obtained in this manner often did not coincide.

The degree of hydration of the compounds investigated at various relative humidities is shown in Tables I and II. Most of the values reported are averages from several determinations. The separate determinations agreed within 0.1 moles of water per mole of compound. The results may be summarized as follows. Purines, pyrimidines, their nucleosides and nucleotides (Table I) do not as a rule become hydrated even at 93% relative humidity, which was the highest relative humidity used in this study. Those few that do, form at the most a dihydrate. On the other hand, the salts of the nucleotides and other compounds containing the *ionic* phosphate group (Table II) begin to take up water at low relative humidity and usually become highly hydrated as relative humidity increases. At 93% relative humidity all but one of the compounds in this class form hydrates higher than a dihydrate, and more than half take up 20 or more molecules of water.

Of all the compounds in Table II the most appropriate for a rough comparison with DNA are the monosodium salts of the nucleotides. Figure 1 compares the hydration

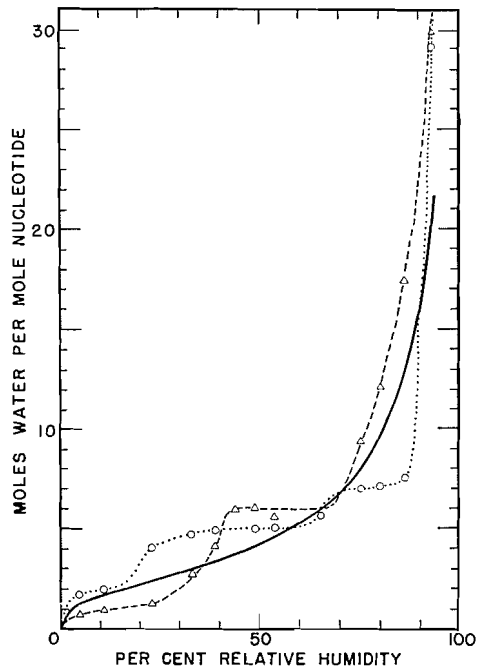

FIG. 1. Hydration curves of the sodium salt of deoxyribonucleic acid (full line), monosodium cytidine-5′-phosphate (circles, dotted line), and monosodium adenosine-5′-phosphate (triangles, broken line).

curves of the two compounds in this class with the hydration curve of the sodium salt of DNA from ref. 4, expressed in moles of water sorbed per mole of 'average nucleotide'. Figure 1 shows that the hydration of DNA is of the same order of magnitude at various relative humidities as that of the salts of single nucleotides. The hydration curves for various types of ribonucleic acid (RNA) and for several synthetic polynucleotides are similar to that for DNA (5). One difference between the hydration curves of polynucleotides and those of nucleotides may be noted; the latter often show plateaux indicating the existence of distinct hydrates, stable or metastable over certain ranges of relative humidity (cf. Fig. 1). Small environmental differences between the successive ionic phosphate groups of the polynucleotide chain can be expected to cause the merging of such plateaux. The complex sequence of four different nucleotides along the DNA or RNA chain may further smooth out the hydration curve.

The present results show that the hydration of nucleotides and of related compounds is very slight, while the hydration of their phosphate salts is high and is of the same order of magnitude as that of polynucleotides. These results suggest that the ionic phosphate groups are the primary sites for the hydration of nucleotides *and* polynucleotides and that these groups are easily accessible to water in the polynucleotides so far examined.

ABSTRACT

Diethyl sebacate was the major product obtained by ethanolysis of the ozonization products of ethyl 10-undecenoate in the temperature range 28 to 170 °C. Mixed esters of sebacic acid were similarly obtained, in poor to moderate yields, by alcoholysis of the ozonization product from an alkyl ester of 10-undecenoic acid in the appropriate alcohol. Sebacic acid half esters are prepared by a similar treatment of the ozonization products from 10-undecenoic acid itself. Ester formation has been shown to proceed mainly by rearrangement of an alkoxyhydroperoxide, with oxidative esterification of an aldehyde intermediate contributing to a minor degree.

INTRODUCTION

Ozonolytic cleavage reactions have long been used to determine the positions of the double bonds in unsaturated natural products, but relatively little was known about the mechanism of product breakdown. Knowledge concerning this mechanism has greatly increased during the last decade, largely as a result of the discovery of the reacting solvent systems, particularly aliphatic alcohols. Their use has provided considerable stimulus for current study of the alkoxyhydroperoxides and related peroxidic compounds.

It has been established, largely by the work of Criegee, that ozonization of an olefin in a reacting solvent produces an aldehyde or a ketone, an alkoxyhydroperoxide, and other peroxidic compounds (1, 2, 3). Bailey has studied the formation and decomposition of the ozonization products of phenanthrene in methanol and has reported the formation of an aldehydo–ester in good yield under the appropriate conditions (4, 5). A methyl ester was also detected among the ozonization products of camphene (6), and acenaphthylene in methanol has been found to produce a 50% yield of methyl 8-formyl-1-naphthoate (7).

Isolation of esters from ozonolytic decomposition products has principally been used to gain insight into the possible mechanisms of intermediate product breakdown. For example, ozonization of 1,2-dibenzoylethene in methanol formed the intermediate, α-hydroperoxy-α-methoxyacetophenone, which was purified and subsequently decomposed

[1]*Part II. Can. J. Chem. 40, 1189 (1962).*

[2]*Presented in part at the Edmonton Conference of the Chemical Institute of Canada, June, 1962.*

in refluxing ethanol. Isolation of acids (formic and benzoic), esters (methyl and ethyl formate and ethyl benzoate), and methanol demonstrated the complexity of the decomposition but the quantitative estimation of the constituents suggested that one major and three minor decomposition mechanisms were simultaneously operating (8, 9).

Other instances of ester by-products from ozonization reactions have been reported (10, 11, 12) but the reaction has neither been specifically investigated as a preparative method for obtaining esters from olefinic compounds, particularly the naturally occurring unsaturated fatty acids, nor have optimum reaction conditions been described. The possibility of ester formation through an aldehyde intermediate has been suggested but not explored.

In the present work, we have studied the ozonization of ethyl 10-undecenoate in ethanol and find that moderate yields of diethyl sebacate (50%) can be obtained by the thermal decomposition of the ozonization product in the same alcohol that was used for the ozonization stage. We have attempted to assess the preparative utility of such procedures for preparation of half esters and mixed esters of sebacic acid.

EXPERIMENTAL

Ozonized oxygen was obtained from a Towers apparatus at a concentration of approximately 6%. Heptanal[3] was better than 98% pure; heptanoic acid, detected as the methyl ester, was the only impurity found. The methyl and ethyl esters of heptanoic acid[4] and the ethyl ester of hexanoic acid[4] were prepared by standard procedures and fractionally distilled through a short column (Raschig rings) to give products with a purity better than 98% (g.l.c.).[5] 10-Undecenoic acid[6] had m.p. 21.6–23.2 °C (thermometer immersed) and was esterified with the appropriate alcohols without further purification. The 10-undecenoic esters were distilled through a short column and were better than 99% pure (g.l.c.).

Gas–Liquid Chromatography

Gas–liquid chromatographic analyses were carried out using the Aerograph Hy-FI model with flame ionization detection. Separations were performed on columns (copper tubing, 10 ft. × $\frac{1}{8}$ in. outside diameter) filled with Celite (60–80 mesh) coated with Apiezon L grease (10% w:w) at an oven temperature of 128 °C and a carrier gas (N_2) flow rate of 20 ml/min. Samples were injected directly as neat liquids (0.1–0.3 μl) using a Hamilton syringe. Undecenoic ester solutions were analyzed in the Burrell K3 chromatograph using a hot-wire detector. Separations were performed on columns (copper, 9 ft. × $\frac{1}{4}$ in.) filled with Embacel coated with Apiezon T (10% w:w) at an oven temperature of 215–220 °C and using helium for the carrier gas. (Fig. 1, A and C; Fig. 2, A.) Percentage yields were calculated on the amounts of emerging components and were determined by weighing the respective excised peak traces. Calibration was achieved by comparing peak areas with syringe volume readings (pure liquids and solutions). The average value from 10 runs was quoted.

Under the above conditions, an equimolar synthetic mixture of heptanal, methyl heptanoate, and ethyl heptanoate gave three well-resolved peaks of equal area, showing that the response of the instrument was linear with respect to molar concentration. Mixtures of these three substances in different relative concentrations also gave well-resolved peaks of the expected areas.

Preliminary Experiments

An ethanolic solution of heptanal was diluted with ethereal diazomethane to give a solution with a yellow color persisting for 10 min. Evaporation of the solvents left an oil that gave only two peaks (g.l.c.) that were identified as heptanal (93%) and methyl heptanoate (7%). Repeated addition of ethereal diazomethane and storage up to 12 h increased the formation of the acid derivative to 50%.

Ethyl Ester Formation from Heptanoic Acid

(*a*) Heptanoic acid (5 g) in Analar grade ethanol (50 ml) was heated in a stainless steel pressure vessel at 150–155 °C for 4 h. The ethanol was removed under reduced pressure (75 °C bath temperature and 50 mm) and the residual acid was neutralized with a slight excess of ethereal diazomethane. After removal of the solvents, the mixture was analyzed (g.l.c.). Methyl heptanoate and ethyl heptanoate were the only two constituents detected (excluding the solvent peak) and their identities were confirmed by admixture experiments with authentic specimens. Yield of ethyl heptanoate 23.5%.

Products of reaction A after esterification with ethereal diazomethane. C. Heating ozonolysis products of ethyl 10-undecenoate with Raney nickel in ethanol to 100–110 °C. D. Products of reaction C after esterification with ethereal diazomethane. Peak 1, 9-carbethoxynonanal; peak 2, methyl ethyl sebacate; peak 3, diethyl sebacate.

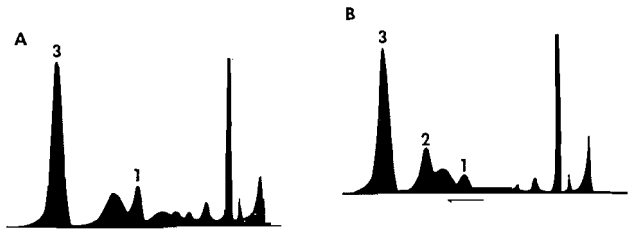

FIG. 2. A. Heating ozonolysis products of ethyl 10-undecenoate in ethanol to 150–155 °C. B. Products of reaction A after esterification with ethereal diazomethane. Peak 1, 9-carbethoxynonanal; peak 2, methyl ethyl sebacate; peak 3, diethyl sebacate.

(*b*) In a duplicate experiment, a stream of ozonized oxygen was passed through a chilled (ice bath) solution of ethanolic heptanoic acid (10% w:v) for 4 h then charged to the pressure vessel and heated as above. After an identical work-up, and analysis (g.l.c.), only the same two constituents were detected and identified. Yield of ethyl heptanoate 23.0%.

(*c*) A repeat experiment of (*b*) was carried out differing only by the heating conditions (200–220 °C, 3 h). No additional peaks were detected but the yield of ethyl heptanoate had increased to 33.9%.

Simulated Ozonolysis Products Decomposition Using a Model Aldehyde–Heptanal in Ethanol (Table I)

An ice-cold solution of heptanal (8 g, 10% w:v) in ethanol was subjected to a stream of ozonized oxygen for 2.5 h. The solution was transferred to the pressure vessel and heated at the above standardized conditions (150–155 °C, 3 h). After solvent removal, the residual oil was taken up in ether (100 ml, peroxide free). Sample 2 of Table I was a 1% aliquot of this solution treated with diazomethane and was found to contain the six components tabulated. Sample 3 was obtained from the main ether solution by sodium bicarbonate extraction followed by acid and diazomethane treatment. Sample 1 was the non-acidic fraction of the main ether solution (6.81 g after solvent removal).

Ozonization Products Decomposition Using a Model Aldehyde – Olefin Mixture – Heptanal and Ethyl 10-Undecenoate in Ethanol

Sample 4, Table I, was an ice-cold solution of ethyl 10-undecenoate (2 g) in ethanol (25 ml). It was subjected to a stream of ozonized oxygen until a test aliquot indicated the absence of unsaturation. The solution was then heated under the standardized conditions described above. Product analysis gave only a baseline trace in the region where products 1–6 (Table I) would have been expected.

TABLE I

Heptanal–ethanol–ozone reactions

Sample	Starting materials	Products* 1 (heptanal)	2	3	4 (methyl heptanoate)	5 (ethyl heptanoate)	6 (heptanal diethyl acetal)
1	Heptanal in ethanol	40	+†	31	–	14	15
2	Product from 1 treated with diazomethane	+	+	+	+	+	+
3	Methyl ester of acidic products from 1	–	–	–	+	–	–
4	Ethyl undecenoate in ethanol	–	–	–	–	–	–
5	Ethyl undecenoate and heptanal in ethanol	11.3	+	+	18.1‡	12.6	58.6

*Products 1, 4, 5, and 6 were identified as indicated by co-chromatography with authentic specimens. Product 2 was unidentified and appeared as a small shoulder on the heptanal peak. Product 3 had a retention time intermediate between that of methyl heptanoate (b.p. 172°) and ethyl hexanoate (167°) and was not identical with either; it was obtained only in small yield. The – sign means that the product was absent (below 1%); the + sign that it was present. The figures are percentage yields based on heptanal.

†Included in product 1.

‡This figure includes products 2 and 3 which were present only in small quantity.

TABLE II

*Products were detected by gas chromatography. Acids were detected as the derived methyl esters.

†Hydrogen at 60–70 p.s.i. over 5% palladium catalyst on calcium carbonate.

‡A duplicate experiment containing a stirred suspension of freshly prepared Raney nickel catalyst gave essentially an identica pattern of products (Fig. 1, A and B).

§A duplicate experiment containing a stirred suspension of powdered sodium sulfite gave an identical pattern of products and a comparable yield of diethyl sebacate.

Sample 5 was obtained from an experiment using heptanal (3 g) and ethyl 10-undecenoate (3 g) in ethanol (50 ml) ozonized and heated in the usual matter. Analysis of the syrupy product (g.l.c.) is shown in Table I.

Diethyl Sebacate

Reaction conditions and products formed in exploratory experiments on ethanolysis of ozonized ethyl 10-undecenoate are presented in Table II. In each case, 10 g samples of ethyl undecenoate in ethanol (50 ml) were ozonized to completion, purged with nitrogen, and hydrogenated as indicated. In this manner, the effect of presence and absence of catalyst and of hydrogen were explored, including trial runs employing Raney nickel W-2 catalyst (30 ml settled volume) or sodium sulfite as mild reducing agents.

A solution of ethyl 10-undecenoate (20 g, n_D^{20} 1.4390) in ethanol (200 ml) was ozonized at ice-bath temperatures. The end point of the reaction was detected by failure of a test sample to decolorize a dilute solution of bromine in glacial acetic acid. The solution was transferred to a top-stirred autoclave pressure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

vessel[7] and heated to 125–150 °C for 4 h. When the vessel was opened, a strong odor of formaldehyde was detected. The solution gave a negative peroxide test with aqueous potassium iodide solution but gave a positive Schiff test, even after prolonged boiling to expel formaldehyde. Examination by g.l.c. gave a pattern of peaks very similar to the trace obtained in the above preliminary experiments (Fig. 2). The constituent corresponding to peak 1 was identified as 9-carbethoxynonanal by co-chromatography with an authentic specimen prepared from ethyl 10-undecenoate by ozonolysis and reduction (13). The constituent corresponding to peak 3 (Fig. 2) was present in greatest yield and was identified as diethyl sebacate, by co-chromatography and by further tests described below. From four experiments, differing only in the rate of heating the autoclave to the maximum temperature (150 °C), the following yields were obtained (excluding peaks assigned to low boiling solvents) 56%, 63%, 61%, and 68%. At this column temperature (220 °C), sebacic acid half ethyl ester did not emerge. Esterification of an aliquot sample with ethereal diazomethane formed the volatile methyl ethyl sebacate and the yield of the acidic constituent could be evaluated (Fig. 2B). The last three runs were combined and fractionally distilled to give diethyl sebacate (36.4 g, 50%) with a b.p. 180–183 °C (14 mm) and n_D^{23} 1.4355 (lit. n_D^{20} 1.4366) (14). The ester gave an infrared spectrum identical to that of an authentic specimen.

Anal. Calcd. for $C_{14}H_{26}O_4$: saponification equivalent, 129. Found: saponification equivalent, 130, 131.

Alkaline hydrolysis afforded sebacic acid which was identified by its melting point, mixed melting point, and infrared spectrum.

From the forerun of the distillation, a crude semicarbazone was obtained by reaction with semicarbazide acetate. Hydrolysis with ethanolic alkali liberated the semicarbazone of 9-carboxynonanal (sebacic semialdehyde) which was recrystallized from ethanol, m.p. 169–170 °C and mixed melting point 169–170 °C. The authentic specimen was prepared from the ozonolysis and reduction of 10-undecenoic acid (13).

Mixed Esters of Sebacic Acid

Mixed esters were prepared by essentially the same procedure as was described in the preceding experiment, by carrying out the ozonization of a 10-undecenoate ester in a series of aliphatic alcohols. The products were purified by fractional distillation and their physical constants have been summarized in Table III.

TABLE III

Mixed sebacic esters

9-Carbethoxynonanoic Acid (Sebacic Acid Half Ethyl Ester)

An ethanolic solution of 10-undecenoic acid (20 g, 10% w:v) was ozonized to completion at −10 to −20 °C, and then heated to 150 °C in the usual manner. An aliquot portion was removed and analyzed as the derived methyl ester by g.l.c. (10% w:w Apiezon M on silver-coated firebrick at 225–230 °C). Three peaks were detected, excluding low boiling solvent peaks, and were identified by co-chromatography experiments with authentic specimens, as dimethyl sebacate (minor), methyl ethyl sebacate (major), and diethyl sebacate (minor) respectively. Area measurements indicated that these products were present in the ratio of 1.5:7.0:1.5 respectively. An authentic specimen of methyl ethyl sebacate was prepared from monoethyl sebacic acid, m.p. 34–35 °C, and ethereal diazomethane.

The alcoholic reaction solution was concentrated to a thin syrup under reduced pressure and diluted with ether. The ethereal solution was extracted with cold sodium bicarbonate solution. The bicarbonate extracts

were acidified and the liberated carboxylic acids were collected with ether. Concentration of the dried ether extract afforded crude 9-carbethoxynonanoic acid (12 g) as a hygroscopic semisolid. The syrupy impurity was partially separated on unglazed porcelain tile and a product of m.p. 36–40 °C was obtained. Analysis of the derived methyl ester by g.l.c. indicated a purity of 83 ± 5% with dimethyl sebacate being the major impurity.

Hydrogenolysis of the Ethanolic Ozonization Product from Ethyl 10-Undecenoate

By the previously described method, a solution of ethyl 10-undecenoate (20 g) in ethanol (200 ml) was ozonized and hydrogenated using an aged sample of Raney nickel catalyst (19). Hydrogenation was initially carried out at 2 000 p.s.i. and at room temperature (4 h). The temperature was then raised to 140 °C and held there for a further 4 h. Relative yields of diethyl sebacate and ethyl 10-hydroxydecanoate were determined using gas chromatography (oven temperature, 170 °C). In synthetic admixture and in the hydrogenolysis sample, the peaks were imperfectly resolved, but their areas were estimated by triangular approximation to be in the ratio of 2 moles of diester to 1 mole of hydroxyester. In a second run, using freshly prepared Raney W-2 catalyst and a slow rate of heating the autoclave, the yield of hydroxyester predominated and the relative peak areas were almost exactly reversed.

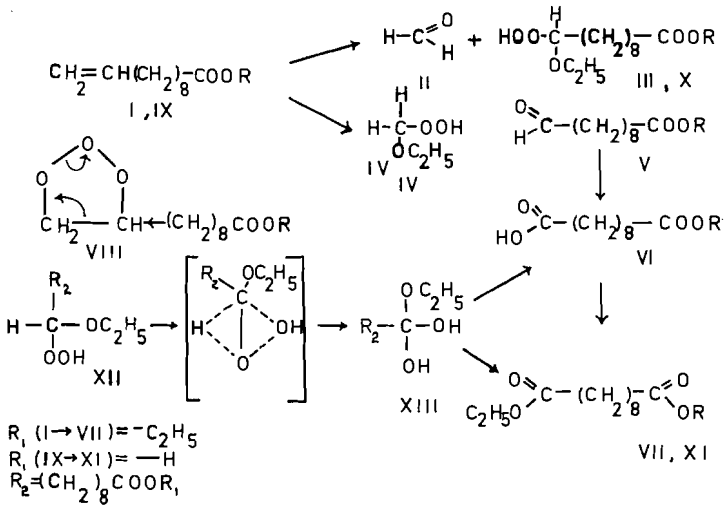
DISCUSSION

Decomposition of ozonolysis products under the appropriate conditions has resulted in the preparation of satisfactory yields of carboxylic acids (90–100%) (15, 16), aldehydes (80–90%) (17), and alcohols (75–90%) by organohydride reductions (18, 19) while moderate yields of amines (40–60%) (11, 12), esters (ca. 50%) (4–7), and alcohols (ca. 50%, by pressure hydrogenolysis) (19) have been reported. In some cases improved yields have been attributed to the use of alcohols for the ozonization solvent (17). Decomposition at low temperature has been found necessary for reactions involving a hydrogenation stage if a pure product was to be obtained. In two previous investigations, the implication has been that elevated temperatures increased side reactions (11, 17) and direct evidence that the side reactions were significant was obtained from reductive amination experiments where by-products such as aldehydes (12), acids (12), and esters (11) were identified. Since high temperatures were also employed in the ozonolysis–pressure reduction of ethyl 10-undecenoate (19), reinvestigation of this reaction, using product analysis by g.l.c., demonstrated that the product was a mixture of ethyl 10-hydroxydecanoate and diethyl sebacate. The ratio of the products was dependent upon the activity of the Raney nickel catalyst and also upon the rate of heating of the pressure autoclave. Clearly, this experiment demonstrated that a competition between hydrogenation and ester formation takes place. Palladium-catalyzed hydrogenolysis of an ethanolic solution of ozonization products from ethyl 10-undecenoate gives predominantly 9-carbethoxynonanal at 0°. By the use of similar pressure, solvent, and catalyst conditions and a temperature (28°) only slightly elevated, significant amounts of diethyl sebacate and sebacic acid half ethyl ester were concurrently formed (Fig. 1, A and B). Although esters were initially observed in all of these reduction-type reactions, a systematic elimination of reaction variables indicated that heating the alcoholic ozonolysis solution at an elevated temperature was the major factor involved in ester formation. Optimum heating conditions were obtained where the ester (diethyl sebacate) was now predominantly formed (ca. 60%) and the respective aldehyde and half acid ethyl ester were present as comparatively minor constituents (Fig. 2, A and B).

The ozonolytic fission of ethyl 10-undecenoate (I), an unsymmetrically alkylated olefin, in ethanol can be expected to take place as a competition between two reactions I → II and III and I → IV and V. Other dimeric and polymeric peroxidic products may possibly be formed.

It can be reasonably assumed that the direction of ring opening in the postulated primary ozonization product VIII, should be controlled by the inductive effect of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



chain of eight methylene groups with negligible influence expected from the terminal carbethoxyl group. Nucleophilic attack at the 10-position yielding III or X rather than at the 11-position giving V are the two possible routes of attack. We favor the former route because it best explains the observations discussed below (see also ref. 3). Scission of the ring in the direction indicated by the arrows should favor the formation of II and III in preference to IV and V (20, 21).

Ester formation could theoretically also occur via 9-carbethoxynonanal (V) by oxygen/-ozone oxidation to 9-carbethoxynonanoic acid (VI) followed by esterification to diethyl sebacate (VII), during autoclaving of the ethanolic solution.

We have checked both steps of this route using heptanal and heptanoic acid as model compounds. Autoclaving an ethanolic solution of heptanoic acid under standardized conditions formed ethyl heptanoate in 23% yield with the remainder being unchanged heptanoic acid. This figure was probably not the equilibrium concentration of ester but rather the final yield to be expected under the alcoholysis experimental conditions. The ester yield was unaffected by pretreatment with ozone, but increased by temperature increase. Similarly, heptanal in ethanol solution was partially oxidized by the oxygen/-ozone mixture to heptanoic acid, even in admixture with a competitive olefin. Autoclaving this solution afforded a complex mixture of at least six constituents with ethyl heptanoate being formed in about 12.5% yield.

Assuming that the model aldehyde will exhibit a reactivity in the preceding reactions not significantly different from that of 9-carbethoxynonanal (V), it would appear that the yield of diethyl sebacate expected from this route (V → VI → VII) would be ca. 10–20%. Since ester yields of ca. 60% were obtained (Fig. 2), the major reaction route most likely proceeded via the preferred intermediate, the alkoxyhydroperoxide (III).

Support for decomposition of the intermediate alkoxyhyroperoxide was also obtained from the thermal decomposition of ozonolyzed ethanolic 10-undecenoic acid (IX). Product analysis after treatment with diazomethane indicated that dimethyl sebacate, 9-carbethoxynonanoic acid (sebacic acid half ethyl ester), and diethyl sebacate were formed in the ratio of 1.5:7.0:1.5 respectively. These results indicated that both aldehyde oxidation to carboxyl and ethyl ester formation were occurring as comparatively minor reactions, but the major product, the half ethyl ester, could have been obtained only by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

selective ester formation at one end of the chain. Rearrangement and decomposition of (X) could provide a tentative explanation.

The preparation by classical means of half esters of such acids as sebacic offers some practical difficulty. Equilibrium partial esterification of the acid gives a low yield of half ester and it is difficult to purify because of further equilibration during isolation. The Grün and Wirth procedure of rapid partial saponification of the diester attempts to achieve kinetic control of the half-ester proportion but is only partially successful. Saponification of the diester by methanolic baryta gives good yields of insoluble barium salt of the half ester and is judged to be of comparable convenience with the method here described. The ozonide alcoholysis route is virtually independent of the vagaries of esterification equilibria, and, in the case of easily alcoholyzed ozonization products, may offer a preferred route for half-ester preparation. A suggested alternative half-ester preparation having similar advantages is oxidative work-up of ozonolysis products from esters of undecenoic acid.

Rearrangement of the alkoxyhydroperoxide (XII), according to Bailey's suggested mechanism (8), could take place through a concerted 1,2-hydrogen shift to form intermediate (XIII). Intermediate (XIII) could be decomposed by two possible routes to form the ester (VII), with loss of a molecule of water, or the carboxylic acid (VI), with loss of a molecule of ethanol. Decomposition entirely by route (XII) → (XIII) → (VI) would form the carboxylic acid (sebacic acid half ethyl ester) which has been demonstrated, by model experiments, to yield about 23% ethyl ester under standardized autoclaving conditions. Decomposition predominantly by route (XII) → (XIII) → (VII) would directly form the ethyl ester. This route of decomposition provides the only alternative, of the routes outlined, that avoids esterification of the carboxylic acid group and could possibly account most reasonably for the yields of diethyl sebacate obtained. An alternative route from the *gem*-diol (XIII) to the ester (VII) without passing through the acid (VI) is the replacement by —OEt of one of the —OH groups of (XIII). A large excess of ethanol would facilitate this process, which would if completed, give the ortho ester, $R_2C(OEt)_3$. Elimination of ethanol would then produce the ester (VII).

On the basis of this alternate route of ester formation, higher mixed esters from an unsaturated fatty acid could be prepared by esterification with the first alcohol, then the second ester group could be introduced at the double bond by ozonolysis and thermal decomposition in the second alcohol. We have selected the terminal unsaturated fatty acid, 10-undecenoic acid (IX), and have prepared a representative number of mixed esters in poor to moderate yield, by the suggested two-step synthesis.[8] Further examples of mixed and half esters will be the subject of another publication.

Our previous work on preparative ozonization has assumed that ozonization products may be regarded as aldehyde or ketone precursors. In reacting solvents this view must be somewhat modified, yet we have successfully employed the concept in synthesis of amino acids which will be the subject of a further communication.

STRUCTURAL STUDIES BY MASS SPECTROMETRY

DETERMINATION OF THE STRUCTURE OF LYCOFAWCINE (BASE L)

W. A. AYER, W. R. BOWMAN, AND P. KEBARLE

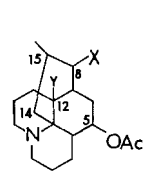
Received September 16, 1964

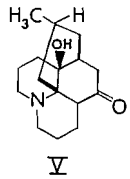
ABSTRACT

The mass spectra of lycofawcine (base L from *L. fawcettii*) and some of its derivatives are recorded and discussed. On the basis of the interpretation of the mass spectra a structure (IV) is proposed for lycofawcine. Experiments which confirm structure IV are described, and the stereochemistry of lycofawcine is discussed.

The isolation and characterization of an alkaloid designated base L from *Lycopodium fawcettii* was reported recently (1). At that time it was suggested that base L is a tricyclic tertiary base possessing a tertiary hydroxyl, a secondary equatorial hydroxyl, and a secondary axial O-acetyl grouping. An examination of the mass spectra of base L and some of the transformation products described previously (1) has now been carried out. The results, which are discussed below, permit the deduction of a structure for base L and this structure has been confirmed by means of chemical transformations. Since the relation between base O, another alkaloid of *L. fawcettii* (2), and base L has already been determined (1), this also establishes the structure of base O. For ease of reference we suggest the trivial name lycofawcine for base L, and acetyllycofawcine for base O.

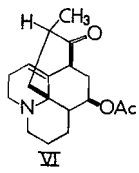


I X=Y=H
II X=OAc, Y=H

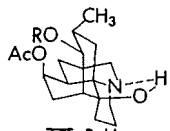


V

IV X=Y=OH

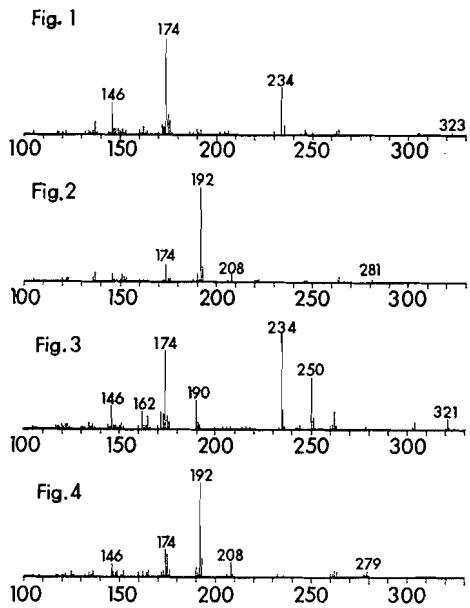


VI



VII R=H
VIII R=Ac

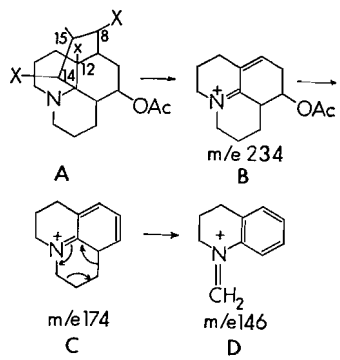
The mass spectra of lycofawcine, desacetyllycofawcine, dehydrolycofawcine, and desacetyldehydrolycofawcine are shown in Figs. 1, 2, 3, and 4, respectively. The most obvious deduction to be made from the mass spectra is that the molecular formula $C_{18}H_{31}NO_4$ (molecular weight 325) originally suggested (1) for lycofawcine is incorrect and should be changed to $C_{18}H_{29}NO_4$ (molecular weight 323). This requires that the



FIGS. 1–4. Mass spectra of lycofawcine and derivatives: 1, lycofawcine; 2, desacetyllycofawcine; 3, dehydrolycofawcine; 4, desacetyldehydrolycofawcine. Peaks with an intensity greater than 2% of the most intense peak are shown.

base be tetracyclic, nor tricyclic as originally suggested. Besides the weak molecular ion at *m/e* 323, the mass spectrum of lycofawcine (Fig. 1) shows strong peaks at *m/e* 234, 174 (base peak), and 146. This fragmentation pattern is reminiscent of that of O-acetyldihydrolycopodine (I) (3) and O-acetyllofoline (II) (4) and is consistent with structure A for lycofawcine, where two of the X's are hydroxyl and the other hydrogen, as shown in Scheme I. The appearance of a C-methyl doublet in the nuclear magnetic resonance (n.m.r.) spectra of derivatives of lycofawcine eliminates C-15 as a possible position for a hydroxyl group. Since elimination of water does not occur as readily as elimination of acetic acid (compare the mass spectra of dihydrolycopodine and O-acetyldihydrolycopodine (3)), the mass spectrum of desacetyllycofawcine (Fig. 2) has its base peak at *m/e* 192 (ion B, OH instead of OAc) rather than at 174.

Dehydrolycofawcine, in which one of the hydroxyl groups of lycofawcine is oxidized



SCHEME 1

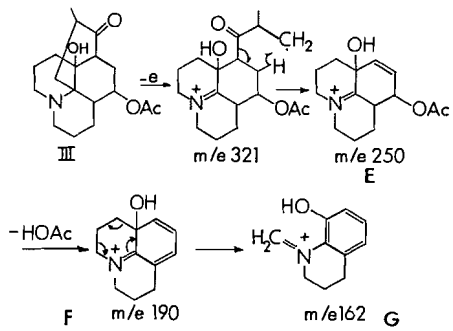
For personal use only.

to a ketone (1), again displays strong peaks in its mass spectrum (Fig. 3) at *m/e* 234, 174, and 146 corresponding to ions B, C, and D in Scheme 1, suggesting that the keto group is located on the bridge at either C-8 or C-14. Provided the absolute configuration is as illustrated in A, a decision between the two positions can be made by application of the Octant rule (5). As predicted if the ketone is located at C-8, the optical rotatory dispersion curve for dehydrolycofawcine shows a negative Cotton effect curve. If the ketone were at C-14 a positive Cotton effect would be expected. In the mass spectrum of dehydrolycofawcine, besides the peaks at 234, 174, and 146, prominent peaks are also observed at *m/e* 250, 190, and 162. These peaks are easily accounted for if the remaining hydroxyl group is located at C-12 instead of C-14, fragmentation of dehydrolycofawcine (III) occurring as shown in Scheme 2 to give ions E, F, and G. On this basis we arrive at structure IV for lycofawcine.



SCHEME 2

The mass spectrum of desacetyldehydrolycofawcine (III, OH in place of OAc) shows (Fig. 4) prominent peaks corresponding to ions of type B (*m/e* 192, OH in place of OAc), C, D, E (*m/e* 208, OH in place of OAc), and F.

In order to confirm the deductions made above dehydrolycofawcine (III) was dehydrated, using conditions similar to those used (6) in dehydrating lycodoline (V). The product was identical with O-acetylacrifoline (VI) (7), corroborating structure III for dehydrolycofawcine and hence IV for lycofawcine. Since the stereochemistry of acrifoline is known this result also establishes the stereochemistry of lycofawcine at all points except C-8, C-12, and C-15. Dehydrolycofawcine (III), like lycodoline (V), (6), has an intramolecularly hydrogen-bonded hydroxyl group (concentration independent band at 3 565 cm^{-1} in the infrared (CCl_4 solution)), and since none of the lycofawcine derivatives show "Bohlmann bands", characteristic of *trans*-quinolizidines (8), the stereochemistry at C-12 must be the same as in lycodoline (V) and as shown in the conformational drawing VII. The configuration at C-15 is not rigorously defined, but is assigned on the basis of analogy with other Lycopodium alkaloids which have, except in cases where there is a carbonyl group at C-8, the configuration shown. The assignment of configuration at C-8 is based on the earlier suggestion (1) that the secondary hydroxyl is equatorial. Base O, which is acetyllycofawcine (1), must have structure VIII.

EXPERIMENTAL

The mass spectra were determined on a AEI MS2-H mass spectrometer at an ionizing potential of 70 eV. Samples were introduced through a heated inlet system maintained at 200°. Infrared spectra were determined by Mr. R. N. Swindlehurst and his associates using a Perkin–Elmer Model 421 spectrophotometer.

Dehydrolycofawcine

Dehydrolycofawcine was prepared as previously described (1). Infrared spectrum (CCl_4): ν_{max} 3 565 (concentration independent, intramolecularly H-bonded hydroxyl), 1 736 (OAc), 1 703 cm^{-1} (ketone). Nuclear magnetic resonance spectrum ($CDCl_3$): τ 4.97 (1H, quartet, C*H*OAc), 8.02 (3H, singlet, $OCOCH_3$), 8.74 (3H, doublet, splitting 6 c.p.s.). Rotatory dispersion in methanol (*c* 0.10): $[\phi]_{589}$ −190°, $[\phi]_{400}$ −475°, $[\phi]_{305}$ −2025°, $[\phi]_{260}$ +825°.

Dehydration of Dehydrolycofawcine

Dehydrolycofawcine (55 mg) was dissolved in a 1:1 solution of phenylphosphoric dichloride : pyridine (6 ml) and maintained at 65° for 20 h. The excess phenylphosphoric dichloride was then decomposed by the slow addition of ice and water. Sodium hydroxide pellets were added until the solution was alkaline and the resulting solution was extracted with chloroform. Evaporation of the chloroform left a viscous oil (40 mg). Thin layer chromatography (t.l.c.) indicated the presence of O-acetylacrifoline as well as some starting material. The crude product was subjected to chromatography over basic alumina (4 g). Elution with ether–chloroform (7:3) yielded O-acetylacrifoline (25 mg) identical (infrared spectrum, t.l.c. behavior, mixed melting point undepressed), with an authentic sample.

The methiodide, prepared in methanol, and recrystallized from acetone–ether, melted at 278–279°. When admixed with an authentic sample of O-acetylacrifoline methiodide, m.p. 281–282°, it melted at 280–281°.

ACKNOWLEDGMENTS

We wish to thank Messrs. R. Taylor and W. Duholke for their assistance in determining the mass spectra, and the National Research Council for financial support.

β-AMINOCROTONONITRILE

I. GEOMETRICAL ISOMERISM AND SOME REACTIONS

E. BULLOCK AND B. GREGORY

Department of Chemistry, Memorial University, St. John's, Newfoundland

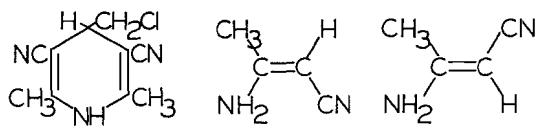
Received August 26, 1964

ABSTRACT

The low-melting form of β-aminocrotononitrile is a mixture of two components, one of which is the high-melting isomer. Isomerization reactions between the high- and low-melting forms occur very easily, reactions in solution being subject to acid–base catalysis. Self-condensation of β-aminocrotononitrile gives 4-amino-1,3-dicyano-2-methylpenta-1,3-diene which readily cyclizes to 2-amino-5-cyano-4,6-lutidine.

Condensation of β-aminocrotononitrile with 1,2-dichloroethyl ethyl ether gives the chloromethyldihydropyridine (I) and other products (1, 2). During attempts to increase the yield of (I) at the expense of by-products we examined the isomeric composition of the nitrile.

In connection with the nomenclature of the geometrical isomers of the title compound, double bonds carrying four different substituents cannot be described unambiguously by the terms *cis-* and *trans-*, without a definition. Conn and Taurins (3) define (II) as *cis-* and (III) as *trans-β*-aminocrotononitrile, presumably on the reasonable basis that CH_3— and H— are the 'most alike' of the substituents (4).



I II III

We wished to compare proton nuclear magnetic resonance (n.m.r.) spectra of the nitrile with those of crotonic acid derivatives, and it is possible to make a definition in terms of the parent nitriles. This leads to the description of (II) as *trans* and (III) as *cis* but is more convenient for the present purpose than the older nomenclature. Thus, in this paper the terms *cis-* and *trans-β*-aminocrotononitrile refer to formulas (III) and (II) respectively and are the reverse of those in ref. 3.

Two forms of β-aminocrotononitrile have been described (5, 6, 7), and recently it was suggested that the high-melting form (m.p. ca. 80°) was the *cis*-compound (III) and the low-melting material (m.p. ca. 50°) has the *trans*-configuration (II) (3).

The n.m.r. spectra of the two forms show that the low-melting material is a mixture of two components, one of which is the high-melting form. (The spectra are consistent with the assignment of structure (III) to the high-melting form; see detailed discussion of n.m.r. results.) The composition of the low-melting material is variable and depends on the method of preparation, the solvents used, and even the storage conditions. It has been noted that the melting point of the low-melting material rises on keeping in the solid phase (8) and this change corresponds to an increase in the proportion of the *cis*-isomer.

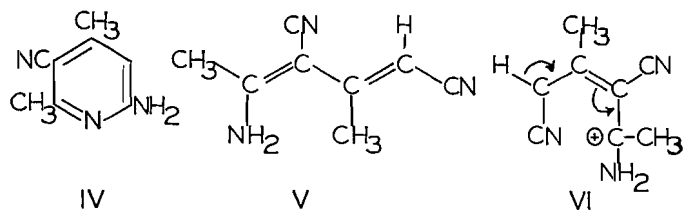
The high-melting form is isomerized on heating under reflux in benzene (6) or on attempted recrystallization from ethanol (3). The conversion is subject to acid–base

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

catalysis. Thus, acetic acid (0.1 *M* solution) in benzene accomplishes the change in less than 5 min at room temperature. A similar concentration of piperidine in benzene completes the same reaction in about 6 h. The final composition of the product of the reaction depends on the solvent used, but is insensitive to low concentrations of acid or base. If any β-aminocrotononitrile is allowed to stand in commercial chloroform for 2 days, it achieves a composition (which is somewhat concentration dependent) of about 65% of (II) and closely resembles material isolated by the literature preparation of the low-melting form (3). Melting point is a poor criterion of composition of β-aminocrotononitrile except for the very pure *cis*-form (m.p. 78–80°). In general, a material which melts below about 55° will have a preponderance of the *trans*-compound. Repeated fractional sublimation (40°, 0.1 mm) of the chloroform equilibration mixture gives material, m.p. 41–53°, which is about 90% *trans*-isomer. We have been unable to improve the purity of this isomer any further. This material rapidly equilibrates to the starting mixture when dissolved in chloroform.

The recorded solubility data for the nitrile (3) suggest that the *cis*-compound (III) is about 2.5 times more soluble in benzene in the presence of the *trans*-isomer than when it is pure. This fact, plus the marked sensitivity of the n.m.r. peak positions to concentration and the reasonably well-defined melting point of the equilibrated material, suggests that strong intermolecular complexing occurs when the two isomers are present in the same solution. Cryoscopic molecular weight determinations in benzene were limited by solubility, but even in 0.15 *M* solution, the molecular weight of the low-melting form is about 30% high. Infrared comparisons were limited (by solubility difficulties) to chloroform solutions and mulls. The only differences between the solution spectra of the high- and low-melting forms were in intensities of certain bands. The relative absorbances of these particular absorptions are noted in the Experimental section.

Clarification of the mechanism of the isomerization reactions in the solution and solid phases is being sought through rate studies.



IV V VI

The main by-product from the preparation of (I) is a white, crystalline solid, $C_8H_9N_3$, which shows two intense nitrile absorptions in the infrared spectrum. The n.m.r. spectrum (partially shown in Fig. 1) indicates the presence of two methyl groups, one of which is coupled ($J \sim 0.9$ c.p.s.) to an olefinic proton. The compound yields 2-amino-5-cyano-4,6-lutidine (IV) (6) under a variety of conditions and is thus formulated as the pentadiene derivative (V). (This formula is not intended to imply a proved stereochemistry.) In pyridine solution (9) the n.m.r. absorptions are more complex (Fig. 1) and strongly suggest that the compound is a mixture of conformational (or, less likely, geometric or tautomeric) isomers. The NH region of the infrared spectrum (in chloroform) also supports this idea, though the melting point is very sharp. Recovery of the compound from pyridine solution gives a substance which is identical in all respects with starting material. Compounds with similar melting characteristics to those of (V) have been reported previously (10, 11) from reactions involving β-aminocrotononitrile and may be identical with our material. A

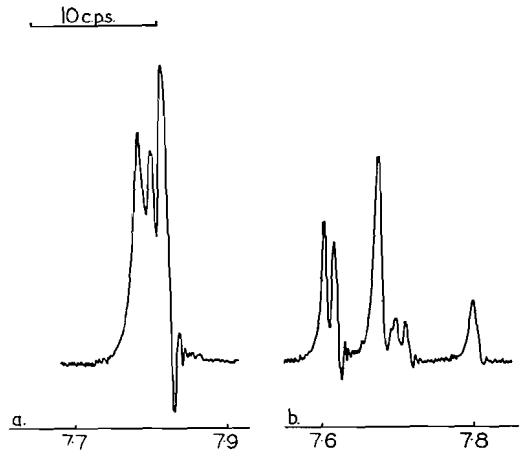


FIG. 1. Partial nuclear magnetic resonance spectra of (V): (*a*) in d_6-dimethylsulfoxide, (*b*) in pyridine.

mechanism for the self-condensation of β-aminocrotononitrile (to pyridine derivatives) has been proposed (12), and involves the formation of a carbonium ion intermediate (VI). Loss of a proton from this intermediate would give (V). This product contrasts with that from the acid-catalyzed dimerization of diphenylacetaldimine, $(C_6H_5)_2$—CH—CH=NH (or tautomer), in which attack of the enamine on the imine form gives a divinylamine $[(C_6H_5)_2C{=}CH]_2NH$ (13).

The use of pure *cis*-β-aminocrotononitrile in the preparation of (I) causes a marked decrease in the reaction rate (cf. ref. 8), but does not materially affect the composition of the product. Since formation of both (I) and (V) occurs with elimination (of the elements of ammonia) there may be a steric factor in the reaction which requires the presence of both isomers. Thus the rate of formation of products from pure *cis*-isomer would be slow and dependent largely on the rate of isomerization. A modified technique for the preparation of (I) using water as a moderator (14) gives a good yield of the desired product.

EXPERIMENTAL

Melting points (uncorrected) were determined in capillaries (for β-aminocrotononitrile samples) or on a Kofler block. Nuclear magnetic reso nance spectra were recorded on a Varian A-60 analytical spectrometer and peak positions are given on the τ-scale. Infrared spectra were recorded on a Perkin–Elmer Model 237B spectrometer.

Nuclear Magnetic Resonance Results

Nuclear magnetic resonance studies of *cis-/trans*-isomers of β-substituted crotonic acid derivatives (bibliography in ref. 15) have led to the generalization that the methyl signal of a *trans*-compound will occur to high field of the methyl signal of the corresponding *cis*-isomer. The position of the signal is relatively unaffected by the substituent on C-3. Further, olefinic protons of $CH_3.CX{=}CH.COOR$ (R = H, Me, etc.) isomers show the reverse order, i.e. the *trans*-olefinic proton occurs to low field of the corresponding *cis*-proton. This holds for a number of derivatives (15) but the position of the olefinic proton signal is very sensitive to the nature of X. In particular, the *trans*-proton appears to be more affected by electron-donating substituents on C-3 than does the *cis*-proton, through in no case is the difference large enough to reverse the generalization. The n.m.r. spectra of crotononitrile isomers have been analzyed (16) and the above generalizations still hold. In this example, however, the *cis*-2-proton is only 0.05 p.p.m. to high field of the corresponding *trans*-proton. (The corresponding difference in the methyl crotonates is 0.63 p.p.m. (17).) Table I shows that the resonance signals for the two forms of β-aminocrotononitrile do not follow the generalization for the esters since the isomer with the high field methyl signal also has the high field olefinic proton. Since chemical evidence favors (III) for the high-melting isomer (3), the n.m.r. results will be consistent with known effects if it is postulated that the primary amino-group reverses the expected order for the olefinic protons.

TABLE I

Compound	Solvent	Olefinic H	Methyl H	NH	J (c.p.s.)
cis-β-Aminocrotononitrile (III) (saturated solution)	Benzene	6.36	8.50	Not observed	$H/CH_3 = 0$
Equilibrium mixture (dilute solution)	Benzene				
(*a*) *cis* (III)		6.37	8.50	Not observed	$H/CH_3 = 0.8$
(*b*) *trans* (II)		6.64	8.97		
Equilibrium mixture (saturated solution)	Benzene				
(*a*) *cis* (III)		6.02	8.22	Broad, 5.35	$H/CH_3 = 0.8$
(*b*) *trans* (II)		6.51	8.68		
Compound (V) (see Fig. 1)	d_6-Dimethyl sulfoxide	4.70	(*a*) 7.80 (*b*) 7.82	Broad, 2.45	$H/CH_3(a) = 0.9$
Compound (V)	Pyridine				
(*a*) major component		4.30	(*a*) 7.60 (*b*) 7.65	Not observed	$H/CH_3(a) = 0.9$
(*b*) minor component		4.71	(*a*) 7.70 (*b*) 7.76		$H/CH_3(a) = 0.9$

The olefinic proton absorptions are about 1.5 p.p.m. to high field of the corresponding unsubstituted crotononitrile (16) and similar effects have been noted in vinyl ethers (18) and other enamines (19).

Molecular Weight of β-Aminocrotononitrile

The molecular weight of the low-melting form was determined cryoscopically in benzene. The variation of molecular weight with concentration is shown below.

Concentration (g/l)	Molecular weight
3.393	87.1
6.619	94.7
10.293	109.0
Theory	82.108

cis-β-Aminocrotononitrile (III)

The sodium salt was prepared by the method of Adkins and Whitman (20). The salt was decomposed with water at 0° and the product taken into ether which was washed twice with a small volume of water and dried (magnesium sulfate). The solvent was removed *in vacuo* at room temperature. It is important that all stages after decomposition of the salt are performed rapidly. The aminonitrile should not be left in solution over extended periods. The residue after removal of the majority of the ether (it is difficult to remove the ether completely) was cooled and the residual liquid decanted from the crystalline product. The solid was allowed to stand overnight at room temperature in a stoppered vessel and then recrystallized five times from benzene to give a white, crystalline solid, m.p. 78–80° (with preliminary softening above about 72°), which was homogenous (by n.m.r. spectrum in benzene).

Low-Melting β-Aminocrotononitrile

Decomposition of the above sodium salt at 30° yields material of m.p. 38–44° before crystallization and m.p. 44–46° after crystallization from a small volume of benzene (3). Alternatively, the pure *cis*-compound (above) may be kept in chloroform (10 mg/ml) for 64 h, after which removal of the solvent gives a clean, low-melting product which contains 65.4% *trans*-isomer (mean of nine integrations of n.m.r. spectrum; spread of values ±0.4%). Infrared spectrum of pure *cis*-compound (freshly prepared solution 8.1 mg per ml of chloroform) showed peaks at 3 516 (0.35), 3 417 (0.71), 3 357, 3 250, 3 219, 3 199, 2 918, 2 201, 1 637, 1 605, 1 434, 1 409, 1 365, (0.23) 1 298 (0.38) 1 123, and 1 020 cm^{-1}. After 3.5 days at room temperature, intensity changes occurred for the following bands 3 516 (0.44), 3 417 (0.54), 1 365 (0.30), 1 305 (0.16) cm^{-1}. Pure *cis*-compound (Nujol mull) showed peaks at 3 433, 3 339, 3 247, 3 219, 3 054, 2 180, 1 646, 1 594, 1 523, 1 311, 1 122, 1 023, 841, 760, and 719 cm^{-1}. The low-melting form (Nujol mull) showed peaks at 3 427, 3 332, 3 233, 3 207, 3 047, 2 172, 1 648, 1 591, 1 523, 1 309, 1 122, 1 026, 844, 764, and 722 cm^{-1}.

4-Amino-1,3-dicyano-2-methylpenta-1,3-diene (V)

(i) β-Aminocrotononitrile (29 g, 0.28 moles mixed isomers) was dissolved in benzene (30 ml) and cooled in ice, while 1,2-dichloroethyl ethyl ether (25 ml, 0.2 moles) was added. A vigorous exothermic reaction occurred. The mixture was kept for 2 h when the precipitated yellow solid (19.5 g) was separated, washed with ether and then water, and fractionally crystallized from aqueous ethanol. The more soluble product, m.p. 178–180°,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was 4-chloromethyl-3,5-dicyano-1,4-dihydro-2,6-lutidine (I:2). The less soluble compound (which was the major product) had m.p. 166–166.5° and resolidified at 167°, remelting with sublimation at 220–225°.

Anal. Calcd. for $C_8H_9N_3$: C, 65.28; H, 6.16; N, 28.55; molecular weight, 147. Found: C, 65.10; H, 6.01; N, 28.60; molecular weight (Rast), 178.

Light absorption (ethanol); λ_{max} at 219, 254, and 328 mμ; ϵ_{max} 11 300, 7 080, and 17 500 respectively. The infrared spectrum showed main maxima at 3 540, 3 511, 3 440, 3 405, 3 344, 3 244, 2 210, 2 196, 1 630, 1 598, 1 557, and 1 040 cm^{-1}.

(ii) The above reaction was repeated using pure *cis*-β-aminocrotononitrile. There was no exothermic reaction on removal of the mixture from the ice bath and development of a yellow precipitate required approximately 12 h. The same products were isolated.

4-Chloromethyl-3,5-dicyano-2,6-dimethyl-1,4-dihydropyridine (I)

β-Aminocrotononitrile (5 g, mixed isomers) was melted and then cooled almost to crystallization. 1,2-Dichloroethyl ethyl ether (5.04 g) was added and followed immediately by water (30 ml). After the reaction had subsided, the mixture was warmed on the steam bath for 5 min, cooled, and filtered. The solid was crystallized twice from aqueous ethanol to give the dihydropyridine, 3.0 g (47%), identical with that from (i) above.

2-Amino-5-cyano-4,6-lutidine (IV)

(i) The foregoing dinitrile (V) was heated to 170° and the product crystallized from ethanol to yield colorless needles, m.p. 227–228° (with sublimation).

(ii) A mixture of the dinitrile (100 mg) and potassium hydroxide (40 mg) in ethanol (5 ml) was heated under reflux for 20 min when the ethanol was removed and the residue treated with water. The crystalline solid thus obtained was crystallized from aqueous ethanol giving the product in almost quantitative yield as colorless needles, m.p. 227–228°.

(iii) The dinitrile (2.6 mg) was dissolved in ethanol (25 ml) and the solution was divided into two parts. The first was kept in the dark and the ultraviolet absorption spectrum was shown to be unchanged after 17 h. The second fraction was irradiated under an ultraviolet lamp and after 17 h, the light absorption showed maxima at 210, 271, and 295 mμ; ϵ_{max} 11 250, 17 300, and 7 470 respectively. Evaporation of the solvent gave colorless needles, m.p. 227–228°.

The same product (melting point and spectra) was obtained from all three reactions. (Calcd. for $C_8H_9N_3$: C, 65.28; H, 6.16; N, 28.55. Found: C, 65.00; H, 5.97; N, 28.40.) The infrared spectrum showed main maxima at 3 519, 3 415, 2 212, 1 615, 1 555, 1 472, 1 448, 1 378, 1 357, 1 173, and 846 cm^{-1}. Reaction of this product with sodium nitrite in dilute sulfuric acid gave 5-cyano-4,6-lutid-2-one (6, 7), m.p. 305–307° (sealed tube) with darkening ca. 280°. This was identical (melting point and spectra) with the product obtained from β-aminocrotononitrile with boiling water.

ACKNOWLEDGMENTS

This investigation was supported by an operating grant from the National Research Council. We are grateful to Memorial University for a Postdoctoral Fellowship (awarded to Brian Gregory).

A SERIES OF MODEL COMPOUNDS FOR THE STUDY OF AROMATIC REACTIONS[1]

S. Safe and R. Y. Moir
Department of Chemistry, Queen's University, Kingston, Ontario
Received September 22, 1964

ABSTRACT

A series of halogenated phthalides was prepared in which there was a systematic variation in the identity, position, and degree of activation of the halogen, and in the activation of the methylene group. A study was made of the selective reductive removal of halogen in the presence of another halogen, or of a nitro group.

Metameconine (I*a*) is admirably adapted to the study of competitive reactions. A rapid survey of its possibilities has shown that in several well-known aromatic reactions it could be used to drive currently favored theories into difficulties that were not easily resolved (1). The new compounds described in this paper formed a weapon that has since been used in a much more intensive attack upon two of these reactions.

One of these was the copper-catalyzed removal of halogen by aqueous hydroxide ion. Our previous work (1–6) had provided a set of compounds superbly suited to the study, as shown by the large number of new observations recorded in the next paper. More compounds needed in the investigation were provided in the present work. In particular, the synthesis of II*b*, II*c*, and II*d* was saved from triviality by two difficulties that had to be overcome. It was pointed out previously (1) that the nitro group in 4-amino-7-nitrometameconine (II*e*) was very easily extruded on diazotization. For example, when II*e* was diazotized in dilute aqueous hydrochloric acid, reduction of the diazonium solution gave 7-chlorometameconine (III*a*), and treatment of the diazonium solution with potassium iodide gave 4-iodo-7-chlorometameconine (III*d*) (1). The same diazonium solution has now been shown to give 4,7-dichlorometameconine (III*b*) with cuprous chloride. However, cuprous bromide gave a mixture of compounds instead of pure III*c*. Thus the diazonium cation III*e* was conventional in its relative reactivities towards chloride, bromide, and iodide under the conditions used.

When sulfuric acid was used in the diazotization of II*e* (in an attempt to avoid nucleophilic displacement of the nitro group) a diazonium salt was obtained whose resistance to thermal decomposition and to reduction has been recorded (1). The idea of using the poorly nucleophilic monovalent anions, nitrate and perchlorate, in place of sulfate, seemed most unattractive.[2] Fortunately, the diazonium sulfate prepared by the method of Hodgson and Walker (7, 8) was found to react under suitable conditions (8) with cuprous chloride, cuprous bromide, or potassium iodide to give good yields of the activated aromatic halides 4-chloro-7-nitrometameconine (II*b*), 4-bromo-7-nitrometameconine (II*c*), and 4-iodo-7-nitrometameconine (II*d*), respectively.

The study also required a knowledge of the products of hydroxydehalogenation, and these were characterized in the present work. The uncatalyzed reaction of 7-chloro-4-iodometameconine (III*d*) with aqueous potassium hydroxide gave 7-chloro-4-hydroxymetameconine (III*f*), with selective replacement of iodine. One might have expected II*b*, II*c*, and II*d* all to give 4-hydroxy-7-nitrometameconine (II*f*) in the same reaction, but in fact with one exception the reactions took a more complex course. However, the copper-catalyzed reaction of the iodo compound (II*d*) gave the expected hydroxy compound (II*f*), accompanied by some 7-nitrometameconine (II*a*); this competition between substitution and reduction is the main theme of the next paper. Phenols II*f* and III*f* and their methyl ethers II*g* and III*g* were synthesized for further comparative studies of anisoles and diphenyl ethers (9, 10).

It is odd that metameconine gives no 4-nitrometameconine on nitration (since 7-nitrometameconine readily gives 4,7-dinitrometameconine) (1), and we have now accumulated a considerable list of failures to nitrate at the 4-position. Over the course of 26 years, previous workers in this laboratory have repeatedly failed to nitrate 7-acetaminometameconine (I*b*) (3)[3] and 7-diacetylaminometameconine (I*c*) (3).[3] To this list of failures we have now added the known compound 7-chlorometameconine (III*a*) (5) and the new compound 7-formaminometameconine (I*d*). As a check, 4-formamino-7-nitrometameconine (II*h*) and 4-acetamino-7-nitrometameconine (II*j*) were made and found to be fairly stable. The difference between the 4- and 7-positions was also illustrated in another interesting way. The previous observations that 4- and 7-bromophthalides were subject to reductive dehalogenation (6) but that some related chloro compounds were not (5) led to the successful selective reduction of 7-chloro-4-iodometameconine (III*d*) to 7-chlorometameconine (III*a*) (1). We now find that 4,7-dichlorometameconine can also be selectively reduced in excellent yield, to the same 7-chlorometameconine (III*a*). Thus a difference in the identity of the two halogens is not required for selective removal of one of them.

The reductive removal of halogen in the presence of the easily reducible nitro group is of considerable interest, especially since the established method of Leslie and Turner (12) failed completely in the present series. Removal of the halogen of 4-iodo-7-nitrometameconine (II*d*) with copper and aqueous potassium hydroxide has already been mentioned; it was (in this case) overshadowed by the substitution reaction. Better, but still moderate, yields of the reduced product (II*a*) were obtained when 4-bromo-7-nitrometameconine (II*c*) was heated with copper and molten benzoic acid at about 160°, according to the

[2]*Diazotization of II*e *in hydrobromic acid gave a crystalline diazonium salt showing diazonium and nitro bands at 2 180 and 1 547 cm*$^{-1}$ *in the infrared spectrum. It failed to give the Sandmeyer reaction, and it survived attempted reduction with hypophosphorous acid. While one sample remained unmelted at 250°, another exploded with quite a lot of noise, smoke, and flame, when touched by a spatula on the Buchner funnel. An analogous salt was obtained by diazotization of II*e *in concentrated hydrochloric acid. Attempts to obtain fluoborates failed.*

[3]*Our early papers used the numbering scheme of Rây and Robinson (11), the later ones the scheme of Chemical Abstracts.*

method of Smith and Campanaro (13). In their examples bromine para to nitro was *not* removed. With the more delicate 4-iodo-7-nitrometameconine (II*d*), acetic acid was found to be preferable to benzoic acid as the source of hydrogen. Curiously, the addition of the very nucleophilic acetate ion did not appreciably lower the yield of the reduced product (II*a*); apparently the substitution reaction was much depressed in the acetic acid solvent.

Anbar, Guttman, and Friedman (14) recently found that cupric ion and ascorbic acid in neutral aqueous solutions were together very effective in the de-iodination of ortho-iodobenzoic acid. As is shown in the next paper, our experience differed sharply in nearly every respect from theirs. Nevertheless, 4-iodo-7-nitrometameconine (II*d*) was reduced smoothly and in good yield to 7-nitrometameconine (II*a*) by copper *metal* and ascorbic acid in alkaline solution. It is likely that this reduction system will prove very useful in preparative aromatic chemistry.

EXPERIMENTAL

Melting points marked (p) were determined on the precision capillary apparatus, the rest on the Kofler Micro Hot Stage; the values from the latter have been lowered 3–5° to bring them into agreement with the former (5), except for cases of polymorphism or decomposition at the melting point in which there is a real theoretical difference between the two methods. Infrared spectra for all of the new compounds and nuclear magnetic resonance (n.m.r.) spectra for some of them have been determined and are in agreement with the structures suggested.

*4,7-Dinitrometameconine (II*i*)*

The yield (70.5%) and quality (151.3–152.0°) of the crude material were considerably better than reported before (1), due to the use of relatively larger amounts of nitrating acid and of purer metameconine. Fuming nitric acid (80 ml, 90%) and concentrated sulfuric acid (20 ml) were mixed and chilled to 0°. Metameconine (16.5 g, m.p. 157.5–158.5°) was added with stirring over 45 min. More fuming nitric acid (75 ml) was added, and the stirring continued 5 h longer, the mixture then being poured onto ice and water (300 ml). Crude product was recovered, washed, and dried; yield 17.0 g.

*4-Iodo-7-nitrometameconine (II*d*)*

The method resembled that used by Chalmers, Dickson, Elks, and Hems in the synthesis of a precursor of thyroxine (8). Sodium nitrite (0.42 g) was warmed with concentrated sulfuric acid (8 ml). The solution was chilled, diluted with glacial acetic acid (8 ml), and then stirred and cooled in an ice bath while a second cold solution, made from 4-amino-7-nitrometameconine (II*e*) (1) (0.95 g, m.p. 230–231°), concentrated sulfuric acid (10 ml), and glacial acetic acid (10 ml), was added over a period of 1 h; stirring and cooling were continued for an additional 3 h. The cold *solution of diazotized 4-amino-7-nitrometameconine* was then added with stirring to a solution of potassium iodide (4 g), urea (2 g), and water (150 ml). The temperature rose to 58°. After being stirred for 0.5 h, the solution was treated with sodium bisulfite and chilled overnight; the light-yellow, crude product was recovered in a yield of 1.21 g (84%), m.p. 159.5–161.5°. When the cold solution of diazotized 4-amino-7-nitrometameconine from 3 g of the amine was poured into a mixture of water, chloroform, urea, potassium iodide, and iodine in the more elaborate procedure used in previous examples (8, 15), the total yield of once-crystallized product was only 76%. Three more recrystallizations of the first fraction of this material from ethanol gave the analytical sample, m.p. 161.3–161.9° (p).

Found: C, 32.96; 33.13; H, 2.27, 2.48; N, 3.66, 3.51; I, 35.00, 35.06. Calcd. for $C_{10}H_8O_6NI$: C, 32.88; H, 2.23; N, 3.83; I, 34.79.

4-Chloro-7-nitrometameconine (IIb)

A cold solution of diazotized 4-amino-7-nitrometameconine (made approximately as above from 2.5 g of the amine) was added with swirling to a fresh solution of cuprous chloride (made from 5 g of copper sulfate pentahydrate) in concentrated hydrochloric acid (10 ml). Urea and water were added to the dark-purple mixture which was then warmed to 60–70°. Crude product was recovered from the cooled solution in a yield of 2.41 g (94%), m.p. 130–131°. Four recrystallizations from butanol gave the pale-yellow needles of the analytical sample, m.p. 132.8–133.3° (p).

Found: C, 44.12, 44.11; H, 2.74, 2.91; N, 5.24, 5.15; Cl, 12.81, 12.71. Calcd. for $C_{10}H_8O_6ClN$: C, 43.88; H, 2.93; N, 5.12; Cl, 12.98.

4-Bromo-7-nitrometameconine (IIc)

A cold solution of diazotized 4-amino-7-nitrometameconine (made approximately as above from 1.0 g of the amine) was added with swirling to a solution of cuprous bromide (made from 2.5 g of copper sulfate pentahydrate) in hydrobromic acid (60%, 5 ml); urea was added and the mixture was warmed slightly,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

diluted with water, and cooled. The recovered product after one recrystallization from butanol had a m.p. of 141.5–142.2°, yield 1.08 g (91%). Two more recrystallizations gave white plates, m.p. 140.5–141.5° (p).

Found: C, 38.12, 38.23; H, 2.50, 2.70; N, 4.44, 4.42; Br, 25.38, 25.09. Calcd. for $C_{10}H_8O_6NBr$: C, 37.74; H, 2.52; N, 4.40; Br, 25.16.

7-Chloro-4-iodometameconine (IIId) (1)

Pure 4-amino-7-nitrometameconine (3.0 g, m.p. 230–231°) was diazotized with sodium nitrite in aqueous hydrochloric acid (cf. ref. 1); the solution was poured into a rapidly stirred mixture of potassium iodide (10 g), urea (5 g), iodine (5 g), water (110 ml), and chloroform (140 ml). Crude product was recovered (in much the same way as in the second method used for 4-iodo-7-nitrometameconine above) in a yield of 3.08 g (74%), reduced after one recrystallization from methanol to 2.61 g (m.p. 140.5–145.5°). One more recrystallization raised the melting point to that of the pure material previously obtained (1), 148.5–153.5°, the range being due to the dimorphism observed on the Kofler hot stage (1), though usually not in the capillary method (1).

4,7-Dichlorometameconine (IIIb)

Pure 4-amino-7-nitrometameconine (2.0 g) was diazotized in aqueous hydrochloric acid approximately as above. The solution was treated with urea and then added to a fresh solution of cuprous chloride (made from 5 g of copper sulfate pentahydrate) in concentrated hydrochloric acid (10 ml). After effervescence had ceased, the mixture was warmed to 60–70° and then chilled. The pale-yellow product was recovered and recrystallized from aqueous ethanol with charcoal. Colorless flat plates were obtained in a yield of 1.38 g (90%), m.p. 141.3–141.8° (with a trace at 138.8°). Four recrystallizations from butanol gave the analytical sample, m.p. 141.6–142.2° (p).

Found: C, 45.54; 45.39; H, 3.23, 3.07; (on another sample) Cl, 27.32, 27.19. Calcd. for $C_{10}H_8O_4Cl_2$: C, 45.65; H, 3.04; Cl, 27.00.

An attempt to convert the amine to the corresponding bromo compound (IIIc), using cuprous bromide in hydrobromic acid in place of cuprous chloride in hydrochloric acid, but retaining the diazotization in hydrochloric acid, gave a product which after two recrystallizations from acetic acid and two from butanol had m.p. 154.6–157.2°.

Found: C, 40.21, 40.21; H, 2.82, 2.99; Cl, 15.20, 15.39; Br, 19.25, 19.28. Calcd. for $C_{10}H_8O_4ClBr$: C, 39.09; H, 2.61; Cl, 11.40; Br, 26.06.

Reduction of this mixture yielded 7-chlorometameconine (IIIa).

Selective Dehalogenation of 4,7-Dichlorometameconine (IIIb)

4,7-Dichlorometameconine (0.10 g, m.p. 141–142°) was heated under reflux with water (15 ml), potassium hydroxide (1.5 g), and zinc dust (0.50 g) for 10 h. The mixture was filtered, the filtrate acidified with hydrochloric acid, and the long, white needles isolated in a yield of 0.075 g (79%), m.p. 193–194°. A mixture melting point with an authentic sample of 7-chlorometameconine (IIIa) (m.p. 194–195°) (5) showed no depression (194–195°). The reaction was not complete in a reaction time of 4 h.

4-Hydroxy-7-nitrometameconine (IIf)

4-Iodo-7-nitrometameconine (0.70 g, m.p. 160–161°) was dissolved in boiling 3% aqueous potassium hydroxide (35 ml, made in the proportion of 30 g potassium hydroxide (85% minimum) in 100 ml of water). Copper bronze (Kahlbaum's No. 02219, 0.34 g) was added and the mixture heated under reflux for 3 h with periodic stirring. The catalyst was removed by filtration. Then the filtrate was acidified with concentrated hydrochloric acid and cooled. Fluffy, yellow crystals, m.p. 167–197°, were recovered in a yield of 0.41 g. These were extracted with aqueous sodium bicarbonate, the insoluble material removed, and the filtrate acidified to give a white precipitate in a yield of 0.30 g (56%), m.p. 217–218° (with decomp.). Three recrystallizations from water gave the analytical sample of 4-hydroxy-7-nitrometameconine, m.p. 218.2–219° (p) (decomp.).

Found: C, 47.06, 47.02; H, 3.49, 3.70; N, 5.36, 5.26. Calcd. for $C_{10}H_9O_7N$: C, 47.06; H, 3.53; N, 5.49.

The bicarbonate-insoluble material (0.07 g) had m.p. 172–179°, raised to 178–180° after one recrystallization from glacial acetic acid; mixture melting point with authentic 7-nitrometameconine (3, 11)[3] (m.p. 181–182°) (IIa), 178–181°. In several repetitions of the experiment, the crude 7-nitrometameconine showed the same low melting point, indicating a third reaction product (see next paper).

4-Methoxy-7-nitrometameconine (IIg)

Pure 4-hydroxy-7-nitrometameconine (m.p. 219–220°, 1.0 g) was treated in ethereal solution with an excess of diazomethane. Some solid (0.21 g, m.p. 115–116.3°) deposited; more (0.72 g) was recovered by evaporation of the solvent (total yield 89%). Four recrystallizations from aqueous methanol gave the *light-sensitive* analytical sample, m.p. 113.6–114.5° (p).

Found: C, 48.64, 48.38; H, 4.12, 4.22; N, 5.26, 5.37. Calcd. for $C_{11}H_{11}O_7N$: C, 49.07; H, 4.09; N, 5.26.

7-Chloro-4-hydroxymetameconine (IIIf)

Pure 7-chloro-4-iodometameconine (0.20 g, double m.p. 148.5–153.5°) was heated under reflux with potassium hydroxide (1.2 g) and water (15 ml) for 12 h. The cooled solution was acidified and the precipitate was recovered and treated with sodium bicarbonate solution. After filtration from a small amount

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of insoluble material, the solution was acidified to give the product in a yield of 0.097 g (70%), m.p. 179.3–180.8°. Combined with a similar product from another reaction and thrice recrystallized from water, the sample gave short, white, stubby crystals, m.p. 179.3–180.0° (p).

Found: C, 48.91, 48.96; H, 3.84, 3.77; Cl, 13.93, 14.00. Calcd. for $C_{10}H_9O_5Cl$: C, 49.18; H, 3.64; Cl, 14.34.

7-Chloro-4-methoxymetameconine (IIIg)

Treatment of 7-chloro-4-hydroxymetameconine (1.0 g, m.p. 180–181°) with excess ethereal diazomethane gave glistening white plates, 0.55 g, m.p. 108–109.5° (p), and 0.44 g, m.p. 110.4–111.2° (p), a total yield of 93%. Two recrystallizations from absolute ether gave the analytical sample, m.p. 109.0–109.8° (p).

Found: C, 51.47, 51.53; H, 4.45, 4.62. Calcd. for $C_{11}H_{11}O_5Cl$: C, 51.16; H, 4.22.

4-Acetamino-7-nitrometameconine (IIj)

Pure 4-amino-7-nitrometameconine (II*e*) (1) (1.0 g, m.p. 233–234.5°) was dissolved in warm glacial acetic acid (20 ml). The solution was kept at 80–100° for 40 min with acetic anhydride (3 ml) and then diluted with water (7 ml). Long, fine, white needles were recovered in a yield of 0.94 g (85%), m.p. 187–189°. Three recrystallizations from water gave the analytical sample, m.p. 187.8–188.3° (p). The sample quickly turned purple on exposure to daylight, and poor analytical results were obtained on a sample sent away. Satisfactory results were found on a sample analyzed immediately after preparation.

Found: C, 48.71, 48.47; H, 4.36, 4.34. Calcd. for $C_{12}H_{12}O_7N_2$: C, 48.65; H, 4.18.

4-Formamino-7-nitrometameconine (IIh)

The pure amino compound (II*e*) (1.5 g, m.p. 230–231°) was heated under reflux with formic acid (90%, 25 ml) for 20 min, diluted with water (50 ml), and chilled. Fine, yellow needles were obtained in a yield of 1.42 g (86%), m.p. 188–188.5°. Three recrystallizations from water gave the analytical sample, m.p. 188.6–189.4° (p).

Found: C, 46.86, 47.01; H, 3.61, 3.67; N, 10.26, 10.03. Calcd. for $C_{11}H_{10}O_7N_2$: C, 46.83; H, 3.55; N, 9.93.

7-Formaminometameconine (Id)

7-Aminometameconine (3, 11)[3] (0.84 g, m.p. 160.5–161.5°) was heated under reflux with formic acid (90%, 15 ml) for 20 min. The solution was diluted with water (40 ml) and chilled. White crystals were recovered in a yield of 0.78 g (82%), m.p. 211.9–213.4°. Three recrystallizations from water gave the analytical sample as long, white needles, m.p. 213.2–214.0° (p).

Found: C, 55.97, 56.05; H, 4.50, 4.66; N, 6.16, 6.27. Calcd. for $C_{11}H_{11}O_5N$: C, 55.46; H, 4.20; N, 5.88.

Reductive Dehalogenations in the Presence of Nitro Groups

(a) With Copper and Benzoic Acid

The method is that of Smith and Companaro (13). Pure 4-bromo-7-nitrometameconine (0.20 g, m.p. 140–141°) (II*c*) and benzoic acid (0.61 g) were heated together on an oil bath at 150–175°. Kahlbaum's copper bronze (No. 02219, 1.0 g) was added over a period of 5–10 min. The melt soon solidified. Heating was continued for a short time. The greenish mixture was then cooled, extracted with aqueous sodium carbonate (1.0 g in 5 ml), and filtered. The insoluble material was extracted with several small portions of boiling acetone. The product was recovered by evaporation of the acetone and recrystallized from glacial acetic acid with charcoal. Light-yellow crystals, m.p. 178–180°, were recovered (some from mother liquors) in a total yield of 0.06 g (40%), mixture melting point with authentic 7-nitrometameconine (3, 11)[3] (m.p. 181–182°), 178–181°.

(b) With Copper and Acetic Acid

Pure 4-iodo-7-nitrometameconine (0.114 g, m.p. 160–161°) (II*d*) was heated under reflux for 12.5 h with glacial acetic acid (12 ml) and Kahlbaum's copper bronze (No. 02219, 0.15 g). The "catalyst" was then removed. The filtrate was concentrated to one-quarter of its original volume and diluted with water. The crude 7-nitrometameconine (II*a*) so obtained had m.p. 175–178°, undepressed by admixture with authentic material. The yield was 0.05 g (68%). No reaction occurred in the absence of the copper bronze.

(c) With Copper and Acetate

The same iodo compound (0.25 g, m.p. 160–161°) (II*d*) was heated under reflux for 6.5 h with glacial acetic acid (25 ml), potassium acetate (2.5 g), and Kahlbaum's copper bronze (0.25 g). The "catalyst" was removed. The markedly green filtrate was concentrated and then diluted with water to give a precipitate of crude 7-nitrometameconine in a yield of 0.086 g (53.5%). Its melting point of 177–179° was undepressed by admixture with authentic material.

(d) With Copper and Tetralin (12, 16)

The nitro-iodo compound (II*d*) (0.25 g) was heated about 40 min with tetralin (2.5 ml) and copper bronze (0.25 g); attempts to isolate the product gave only an intractible, green gum.

(e) With Copper and Ascorbic Acid

Pure 4-iodo-7-nitrometameconine (0.200 g) (II*d*), 4% aqueous potassium hydroxide (15 ml), ascorbic acid (0.100 g), and copper bronze (0.020 g) were heated together under reflux for 2 h. The reddish-orange solution was filtered from the catalyst (which was unchanged in appearance), and the product was isolated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in the usual way to give 7-nitrometameconine in a yield of 0.1025 g (78.6%), m.p. 179.5–182°, mixture melting point with authentic material (3, 11)[3] (m.p. 182–183°), 179–183.5°.

The method failed with the corresponding bromine compound (II*c*).

ACKNOWLEDGMENTS

The work was supported by the National Research Council of Canada with a Grant and with a Scholarship awarded to one of us. The vanillin which was the source of our compounds was donated by Dr. G. H. Tomlinson of the Howard Smith Paper Company division of Dominion Tar and Chemical Co., Ltd., Cornwall, Ontario.

RELATIVE REACTIVITY OF TOLUENE–BENZENE IN NITRONIUM TETRAFLUOROBORATE NITRATION

LIMITATION OF THE COMPETITIVE METHOD OF RATE DETERMINATION IN FAST REACTIONS*

W. S. TOLGYESI

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received August 14, 1964

ABSTRACT

A study was made to determine the relative reactivity of the toluene–benzene pair in a nitronium salt nitration, using the method of competitive rate determination. Despite difficulties encountered in ensuring homogeneous reaction conditions owing to the high speed of reaction the relative rates (toluene/benzene) obtained under certain conditions attained a range (25–30) which is considered to represent the range of relative reactivity and it corresponds to the known reactivity of toluene–benzene in nitric acid nitration. On the basis of these results there seems to be no reason to suppose that nitronium salt nitration involves a mechanism different from that of the nitric acid nitration.

INTRODUCTION

In recent years the method of competitive rate determination has been extensively used in connection with aromatic substitutions. Using nitronium salts as nitrating agents, Olah and co-workers (1–5) reported relative reactivity values much lower (e.g. toluene/benzene = 1.67 with NO_2BF_4 in tetramethylene sulfone) than those obtained with nitric acid (toluene/benzene = 21–27) (6, 7). At the same time the nitronium salt nitration retained the high positional selectivity of nitric acid nitrations, thereby invalidating the selectivity principle for these systems.

The possibility was suggested by Brown,[1] however, that non-kinetic factors had been responsible for the observed low substrate selectivity in the nitronium salt nitrations.

The competitive method, described by Francis (8) in 1926, consists of "adding to a mixture of two compounds an insufficient amount of a reagent which reacts with both; and by suitable analysis determining the extent of each reaction. From these the ratio of the two velocity constants can be calculated."

The method, though supplying less kinetic information than absolute rate measurement, has its advantages. Francis (8) applied it to determine relative reaction velocities when the rate constants were in the region of 10^6, making absolute rate determination impractical. According to Ingold and Shaw (9): "uncertainties arising from imperfect, and consequently unequal, temperature control are avoided." Another important advantage of the method was mentioned by Dewar (10) in connection with aromatic nitration: the concentration of the reagent added to the competing compounds does not need to be known. "It is of course necessary to ensure that appreciable amounts of each hydrocarbon remain unchanged." Furthermore, "the method does not require an accurate knowledge of the reaction kinetics, provided we assume that both hydrocarbons are nitrated by the same nitrating agent or agents, and that the rates of nitration are of the first order with respect to the hydrocarbon concentration" (10).

Competitive rate determination has limitations as well. The one with which the present work is concerned was first described by Francis (8), who tried to carry out competitive

*Contribution No. 123.

[1]*Reference 15 in the paper of Olah and co-workers. J. Am. Chem. Soc. 83, 4571 (1961).*

bromination using aqueous solutions of free bromine: "The difficulty arises of obtaining a homogeneous mixture of the reactants, since the reactions are so rapid that they take place at the point of entrance of the bromine water, the bromine perhaps not being properly divided between the competitors. Thus, if competitor A reacts much more rapidly than B, it would become impoverished in the layer of solution adjacent to the bromine water and allow competitor B to obtain more than its just share of the bromine. The error thus introduced would usually be on the side of making the competitors seem too nearly equal in speed and probably would be slight for well-matched competitors."

The explanation of Francis implies that in the limiting case when the rate of reaction of both competitors with reactant X is very much higher than the rate with which they are supplied in the layer adjacent to the reactant, the product ratio is equal to the concentration ratio of the competitors. Therefore the calculated relative rate is 1. One can use the two limiting values of a competitive reaction (relative reactivity under kinetic control on one end and unity under statistical control on the other) to calculate intermediate points when only portions of reactant X react according to statistical control. In Fig. 1 calculated reaction rates[2] of three hypothetical competitive reactions are plotted against percentage kinetic control of the reaction.

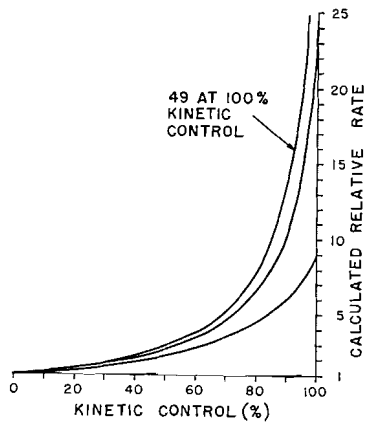

FIG. 1. Calculated relative rate: influence of statistical factors.

It is not intended to correlate the curves quantitatively with subsequent results, mainly because the assumption that the two limiting mechanisms operate simultaneously is certainly an oversimplification. However, some qualitative conclusions, drawn from these approximate calculations, seem plausible; of prime significance is the fact that even small deviations from kinetic control decrease the relative rate markedly. The higher the relative reactivity, the more marked is the decrease. On the other end, in the region nearer to statistical control, the value of the relative reactivity or the extent of influence of the statistical factor is less important in determining the relative rate.

It is known that the rate of nitration of reactive aromatics is very high in solutions

[2]*The following equation was used for the calculation of reaction rates shown in Fig. 1.*

$$\text{Reaction rate} = [y(R + 1) + 2Rx]/[y(R + 1) + 2x],$$

where R is the relative reactivity of the two competitors towards the reactant, while x and y (y = 100 − x) are % portions of the reactant consumed in kinetically and statistically controlled steps, respectively. One must, of course, assume that the concentrations of the competitors are equal and constant both in time and distribution in the reaction medium and the reactant can only be consumed according to either of the two extreme steps.

For personal use only.

where nitronium ion, the active nitrating species, is readily available, as in nitric acid. According to Hughes and Ingold (11): "A direct kinetic observation of the mononitration of benzene in nitric acid is scarcely possible, because of the very high speed of nitration of benzene in this medium. In order to obtain a measurable reaction rate one has to introduce some strongly deactivating group such as a nitro group." Ciaccio and Marcus (12) measured the rate of nitration of nitrobenzene in nitric acid and found even this to be a fast reaction (k_2 = 1.0–10.0 l mole^{-1}min^{-1}). Using nitronium tetrafluoroborate the rate constants were 0.11 in acetonitrile, 0.5 in sulfuric acid, and 1.1 in methanesulfonic acid. Benzene is estimated to be 10^5–10^7 (11, 13) times as active as nitrobenzene in nitration. After the present work had been finished, it was learned that Ritchie and Win (14) carried out nitronium fluoroborate nitration of aromatics and found that: "these reactions may not be well-behaved kinetically."

According to these references, the rate coefficient of the nitration of aromatics like benzene and toluene is large, though unknown, and competitive experiments of high velocity reactions can yield relative rates not corresponding to relative reactivities.

EXPERIMENTAL

Materials

Benzene, toluene, and chlorobenzene. Reagent grade materials, dried over calcium chloride. Fluorobenzene. Technical grade material, fractionated on an Aldershaw column and dried with calcium chloride. Nitric acid. Reagent grade, red fuming nitric acid. Specific gravity, 1.59–1.60. Sulfuric acid. Reagent grade 96% sulfuric acid. Specific gravity: 1.84.

Tetramethylene sulfone. Development product of the Shell Chemical Company. The dark-brown material, solid at room temperature, was purified by fractional distillation from solid sodium hydroxide (15) at 106–115° and 1–2 mm. After discarding the first 10–15% of the distillate, the following 50–55% was collected. The distilled material was colorless, solid at room temperature. Its water content, analyzed according to the Karl-Fischer method, was always less than 7 p.p.m., the limit of detection being 5 p.p.m. A blank reaction with the solvent did not cause a measurable increase of its water content. The material was free of butadiene sulfone—an intermediate in the production of tetramethylene sulfone—according to nuclear magnetic resonance (n.m.r.) (sensitivity 1 000 p.p.m.) and gas chromatography (g.c.) (sensitivity 100 p.p.m.) analyses. Tetramethylene sulfone was further purified for reactions in which the concentration of the nitronium tetrafluoroborate was less than 2%. The once distilled material was fractionated on a Todd column at 98–103° and 0.8–1.2 mm with 5:1 reflux ratio and 0.3–0.4 ml/min takeoff. Analytical results are shown below.[3]

FREEZING POINT	26.7 °C
REFRACTIVE INDEX AT 30 °C	1.4816
SPECIFIC CONDUCTIVITY	6.45×10^{-6} cm/ohm

Nitronium tetrafluoroborate was prepared according to the method of Kuhn (16) from fuming nitric acid, hydrogen fluoride, and boron trifluoride in nitromethane solution. The white, powdery nitronium tetrafluoroborate was filtered on a sintered glass crucible, washed four times with nitromethane, then three times with Freon 113. The material was dried at room temperature at pressures below 0.1 mm until constant weight (10–12 h) and stored in a dessicator. Filtration and all subsequent handling was carried out in dry nitrogen atmosphere.

Preparation of Solutions

Tetramethylene sulfone was used as solvent in all the experiments. The solutions were prepared by weight for each set of experiments. Sulfuric and nitric acid solutions were prepared by slowly adding the measured amount of acid into tetramethylene sulfone with cooling because of the high heat of dissolution.

Nitronium tetrafluoroborate solutions were prepared by transferring a measured amount of nitronium tetrafluoroborate into a known amount of tetramethylene sulfone at 30–35°, in dry nitrogen atmosphere. The mixture was stirred for about 3 h with a magnetic stirrer because the rate of dissolution of the salt was rather low. For saturated solutions excess amount of nitronium salt was stirred in tetramethylene sulfone for 6–7 h then it was allowed to settle overnight. The concentration of the saturated solution was determined by the following methods:[3] (1) boron determination, 6.8% (w/w); (2) specific gravity, 7.8% (w/w); (3) refractive index, 7.8%(w/w); (4) hydrolysis, 7.55% (w/w).

The solutions had a pale-yellow color probably originating from some impurity of the solvent. In one case a colorless solution was obtained using freshly distilled tetramethylene sulfone.

[3]*The analyses were carried out by Mr. D. Choksi, Dow Chemical of Canada, Limited.*

Reactions

Employing Magnetic Stirring and Dropwise Addition of the Nitrating Solution (Tables I and IV)

The reactions were carried out in a 250 ml flat bottom flask equipped with thermometer, dropping funnel, and $CaCl_2$ tube in a 25 ± 1 °C water bath. Fifty milliliters of the toluene–benzene solution was measured in the flask and 25 ml of nitronium tetrafluoroborate solution in the dropping funnel. The aromatic solution was agitated with a Teflon-coated magnetic bar (9 × 38 mm) rotated by a magnetic stirrer. Electric input of the motor was regulated by a Powerstat Voltage Regulator. The rotating speed of the magnetic bar in the aromatic solution was calibrated with a stroboscope, and the results are shown below.

Setting of Powerstat, V	42.5	45	50	55	60	65	70	75
Revolutions of magnetic bar, rev/min	79	137	198	300	410	612	778	966

The nitronium tetrafluoroborate solution was added to the aromatic solution at a rate of 30–40 drops/min, the total time of addition being between 16 and 19 min. The tip of the dropping funnel was positioned slightly off the center of the revolving magnet. After the addition of all the nitronium salt, the dark-red reaction mixture was poured into water (150 ml) which turned its color to yellow. The organic layer of the mixture was diluted with 50 ml ether.

Magnetic Stirring and Syringe Addition of the Nitronium Salt Solution (Part of Table III)

The reactions were carried out in a 50 ml Erlenmeyer flask, having a short side arm closed with a serum cap, a baffle in the form of a flattened glass rod reaching vertically to about 3 mm above the tip of the rotating magnet, and a long wide neck closed with a $CaCl_2$ tube. Forty milliliters of the toluene–benzene solution was measured in the flask filling it to the bottom of the neck. High liquid level was necessary to prevent air reaching to the the magnetic bar at the high rate of stirring and making the solution "boil". Nitronium tetrafluoroborate solution (6 ml) was measured in the barrel of a 10 ml syringe connected to a nitrogen cylinder through a pressure regulator. The nitronium salt solution was injected into the aromatic solution in the form of a fine jet, at pressures 5–15 p.s.i., through a thin hypodermic needle (20G–24G). The tip of the hypodermic needle, entering through the serum cap on the side arm of the flask, was positioned between the rotating magnetic bar and the baffle. Addition time ranged from 0.5 to 2 min depending on the size of the needle, pressure, and concentration of the nitronium salt solution. These variants were constant in comparative experiments. The temperature was not controlled, but was measured to be between 23 and 26 °C.

Vibrator Disc Agitation and Syringe Addition of the Nitronium Tetrafluoroborate Solution (Tables II, Part of III and V)

The reactions were carried out under a blanket of dry nitrogen in a jacketed test tube (28 × 200 mm) having a short side arm, closed with a serum cap, near to the bottom of the vessel. Sixty milliliters of the aromatic solution was measured in the reaction vessel and it was agitated with a laboratory type, Model E-1 Vibro-Mixer.[4] The vibrating stainless steel disc (23 mm diameter) had five Venturi-type orifices (3 mm diameter) and it was positioned about 15 mm from the bottom of the reaction tube, the orifices pointing downwards. Electric input was controlled with a Powerstat Voltage Regulator. The frequency of vibration of the disc was 7 200 cycles/min and it was independent of the power input. Voltage regulation influenced only the amplitude of vibration. The amplitudes, measured with the aid of a stroboscope and cathetometer, are given below.

Setting of Powerstat, V	40	50	60	70	80	90	100	110	120
Amplitude of vibration, mm	0.35	0.45	0.70	1.15	1.55	2.00	2.40	2.85	3.40

The vibrator disc with Venturi tube type orifices ensured a very turbulent agitation. The turbulence originates in three separate characteristics of the agitator (*a*) Non-aerodynamic shape of the disc in the direction of movement, with small localized passages for the liquid; (*b*) continuously changing speed; (*c*) reciprocal movement of the disc (7 200 cycles/min). Nitronium tetrafluoroborate solution (20 ml) was added to the aromatic solution from a 25 ml syringe at 15–20 p.s.i. nitrogen pressure through a fine hypodermic needle (1 in. long, 24G except when stated otherwise) as described above. The tip of the needle, inserted through the serum cap was positioned 1–2 mm beneath the center of an orifice. Time of addition varied between 3.5 and 4.5 min depending on the concentration of the solution and the pressure applied. The temperature was regulated by circulating water (25 ± 1 °C) in the jacket of the reaction tube. After the addition of the nitrating solution the mixture was poured into 150 ml water and diluted with 50 ml ether. "Mixed acid" nitrations were all carried out according to the above method using the Vibro-Mixer and syringe addition of the acid solution.

In the first set of five parallel experiments 20 ml of a tetramethylene sulfone solution of nitric acid (1.3 *M* for HNO_3) was injected in 10–11 min at 25 °C. into 60 ml of a tetramethylene sulfone solution which was 2.1 *M* for both benzene and toluene and 1.7 *M* for sulfuric acid.

In the second set of five parallel experiments 20 ml of a tetramethylene sulfone solution of sulfuric acid

[4] *A. G. Fur Chemie-Apparatebau, Mannedorf-Zurich.*

(4.2 *M* for H_2SO_4) was injected in 10–11 min at 25 °C into 60 ml of a tetramethylene sulfone solution which was 2.3 *M* for both benzene and toluene and 0.5 *M* for nitric acid.

Nitric Acid Nitration

(a) With Dissolved Nitric Acid

A solution of 0.08 mole of nitric acid in 60 g of tetramethylene sulfone was added dropwise in the course of 20 min to a mixture of 0.25 mole of benzene and 0.25 mole of toluene dissolved in 70 g of tetramethylene sulfone, while it was agitated with a magnetic stirrer (60 V). The solution was agitated for 11 h or 6 h at 24–26°. The mixtures were poured into 250 ml water and were diluted with 50 ml ether.

(b) With Neat Nitric Acid

Nitric acid (0.07 mole) was added dropwise in 10 min to a solution of 0.25 mole of benzene and 0.25 mole of toluene in 120 g of tetramethylene sulfone while it was agitated as above. After 6 h of further agitation at 24–26° the solution was poured into 250 ml of water and was diluted with 50 ml of ether.

Washing and Concentrating of the Reaction Mixtures

The quenched reaction mixtures were filled up to about 450 ml with water in a 500 ml separatory funnel. The aqueous layer containing most of the tetramethylene sulfone was extracted three times with 35–40 ml portions of ether after separation. The combined organic solution was washed twice more with 250–300 ml water. Each portion of the washing water was extracted twice with 30–35 ml ether, which was added back to the organic solution. In the case of "mixed acid" and nitric acid nitration the solution had to be washed with water once more to ensure neutral pH. The solutions were dried with $CaCl_2$ and the ether and part of the excess benzene was distilled off on a 30 cm packed column. The head temperature of the distillation never exceeded 95 °C (for mixtures of very low conversion) and in most cases the distillation was carried only to 50 °C. The method of washing and concentrating—checked on synthetic mixtures—did not change the composition of the reaction products.

Analyses[5]

All analyses of the nitrated samples were carried out on an F and M Model 720 Dual Column Gas Chromatograph equipped with a thermal conductivity detector. The operating conditions were cell current: 100 mA (W-2 filaments); carrier gas: helium at 10 ml per 10 s; injection port temperature: 300 °C; detector block temperature: 340 °C; injection size: 15 μl, injected with 50 μl Hamilton syringe equipped with Chaney Adaptor.

Peak areas were determined either by triangulation or with a Disc Chart Integrator. Peak heights were measured when peaks were smaller than about 10 mm in height or were incompletely resolved from other large peaks (*m*-nitrotoluene).

Calibrating standards were prepared in volumetric flasks on an analytical balance. New standards were prepared and analyzed whenever a new set of samples contained nitrated compounds at concentrations not previously encountered. Sample concentrations were based on direct comparisons of samples and standards and expressed as moles of compound per 15 μl of sample solution.

Nitrobenzene and Nitrotoluene

These compounds were determined on a 4.5 ft column of 1/4 in. outside diameter copper tubing packed with 15 w/w % 6 ring poly-*m*-phenyl ether on Chromosorb W at 180 °C.

Dinitrotoluene

Dinitro compounds were analyzed either on a 9 ft column packed with 15 w/w % silicone gum rubber SE-30 on Chromosorb W at 230 °C or on the 4.5 ft poly-*m*-phenyl ether column at 225 °C. The resolving power of the columns changed rapidly and unknown impurities started to interfere after about 20 samples.

Other columns using polar-partitioning liquids (such as Carbowax 20M, Carbowax 4000 terephthalic acid, Carbowax 4000 monostearate) were tried but all were found to be unsuitable because of inadequate resolution of the dinitro compounds, interference from unknowns, or an insufficiently high maximum column temperature.

Nitrofluoro and Nitrochlorobenzenes

Analysis was carried out on the 4.5 ft poly-*m*-phenyl ether column at 175 °C. The nitrofluorobenzene isomers were separated from one another, eluting in 4–6 min in the sequence *m*-, *p*-, *o*-. The *o*-nitrofluorobenzene isomer, however, had the same retention time as nitrobenzene. For samples containing both of these compounds their combined concentration was found using the area response of nitrobenzene as calibration. Nitrochlorobenzenes eluted in about 12 min. The isomers were not adequately separated to permit their separate determination. The area response of the *p*-isomer was used to convert the combined nitrochlorobenzene peak area to concentration.

RESULTS

Toluene–Benzene

The purpose of the following set of experiments was to investigate the possible existence

[5]*The analyses were carried out by Mr. P. Kann, Dow Chemical of Canada, Limited.*

of non-kinetic conditions in competitive nitration of benzene and toluene with nitronium tetrafluoroborate. This point was approached by determining whether non-kinetic factors, like rate of stirring, and concentration of the solutions, influenced the product ratios of the reaction.

The results show the same general trend. Increased speed of agitation or decreased concentration of the nitrating agent results in an increase of the product ratio. At the same time, however, the data of Table II show some new characteristics which can be best represented graphically. Figures 2 and 3 show the product ratios, given in Tables I and II respectively, plotted against the voltage of agitation.

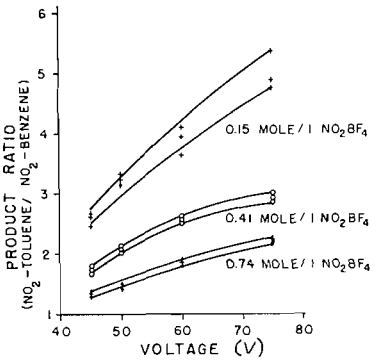

FIG. 2. Product ratio vs. voltage of magnetic stirrer using NO_2BF_4 solutions of different concentrations.

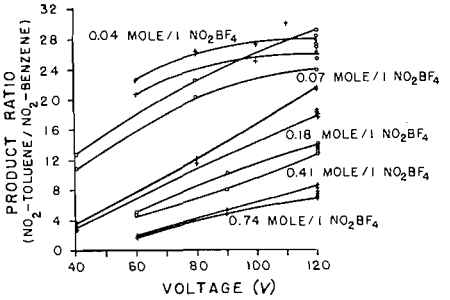

FIG. 3. Product ratio vs. voltage of vibrator motor using NO_2BF_4 solutions of different concentrations.

Two of the curves of Fig. 3 representing product ratios obtained with the two most dilute NO_2BF_4 solutions approach a constant and common value at high rate of agitation. Therefore it can be suggested that the product ratio approached independence from both stirring rate and concentration under the specific conditions. With the following set of experiments the effect of dilution of the aromatic solution was investigated. Pairs of reactions were carried out under different conditions. Within each pair, however, only the concentration of the aromatic solutions was changed. It is seen from the data of Table III that the more concentrated aromatic solution yields a higher product ratio than the less concentrated one under the investigated conditions. The change is opposite in direction to that observed when the concentration of the nitronium salt was varied.

As has already been indicated, a nitro group on the aromatic ring decreases its activity for further nitration by a factor of 10^5–10^7 (11, 13). Therefore, dinitration should not be observable in the present investigation as the conversion of the aromatics was always less than 10%. Reaction mixtures of low product ratio, however, contained measurable amounts of dinitrotoluene as identified by g.c. analysis. Amounts of dinitrotoluene found

in reaction mixtures are shown in Table IV expressed as percentage of the mononitrotoluene. Dinitrotoluene was found in similar quantity in 37 additional reaction mixtures[6] with product ratios of the mononitro compounds ranging from 1.3 to 6.5.

TABLE IV

Extent of dinitration of toluene

Product ratio	Calculated conversion of toluene* (%)	Dinitrotoluene as % of mononitrotoluene: 2,4-Dinitro	2,6-Dinitro	Estimated accuracy of analysis (±%)
1.33	9	1.0	0.5	10
5.6	6	0.4	Less than limit of	25
7.4	6	0.3	quantitative	25
10.3	6	0.4	determination	25

*Calculated from the amount of NO_2BF_4 and product ratio.

Dinitrobenzene was not found in the reaction mixtures or at least it was present in quantities smaller than the limit of detection of the analytical method, about 0.1% of the mononitrobenzene under optimum conditions. Its absence can be explained by the facts that mononitrobenzene nitrates about 330 times slower than *p*-nitrotoluene (17), and its concentration was always lower than that of nitrotoluene.

The problem of fast distribution of the nitrating agent in the reaction mixture prior to considerable degree of conversion was investigated from a different angle in the following set of experiments. The rate of consumption of the nitronium salt was decreased by using aromatics (fluorobenzene and chlorobenzene) less reactive than benzene and toluene. Reactions were carried out with vibrator disc agitation and syringe addition of 20 ml of the nitronium salt solution to 60 ml of the aromatic solution which was 2.3 *M* for each competitor. Results are shown in Table V. Data represent the average and maximum scatter of three parallel experiments.

[6]*Dinitrotoluene and mononitrotoluene were determined from separate injections; therefore, they cannot be directly compared.*

TABLE V

Competitive nitration of different pairs of aromatics

Aromatic compounds	$[NO_2BF_4]$ (mole/l)	Product ratio	Isomer distribution		
			ortho- (%)	meta- (%)	para- (%)
			of fluoronitrobenzene		
Fluorobenzene–chlorobenzene	0.17	4.3±0.1	9.9±0.3	0.31±0.05	89.8±0.3
	0.74	4.2±0.1	9.5±0.3	0.30±0.01	90.2±0.3
Benzene–fluorobenzene	0.17	6.0±0.2			
	0.74	5.0±0.5			
Benzene–chlorobenzene	0.17	22.2±3.5			
	0.74	19.7±3.3			
			of nitrotoluene		
Toluene–fluorobenzene	0.17	101 ±1	63.5±0.2	3.06±0.08	33.5±0.1
	0.74	27.8±5	62.5±0.2	3.16±0.05	34.3±0.2

It is seen from Table V that the product ratio of the fluorobenzene–chlorobenzene pair is independent of the concentration of the nitronium salt. Furthermore it corresponds closely to the relative reactivity value (4.5) obtained by Bird and Ingold (18) using acetyl nitrate in acetic anhydride solution. In the case of the more reactive benzene–fluorobenzene pair the product ratios depend on the concentration of the nitronium fluoroborate solution only slightly and are still similar to the relative reactivity value of 6.7 (18) and 7.1 (19) obtained under different conditions. The product ratio for the still more active toluene–benzene pair (Table II), however, depends markedly on the nitronium salt concentration and is increasingly lower than the relative reactivity.

The results obtained for aromatic pairs of increasingly different reactivity show the same characteristics. The product ratio of the benzene–chlorobenzene pair depends on the nitronium salt concentration only slightly and is only moderately different from the reported (18) relative reactivity of 30. In the case of the faster toluene–fluorobenzene pair, the same conclusion cannot be drawn.

Isomer Distribution of Nitrotoluene

The isomer distribution data obtained from 151 nitration experiments with NO_2BF_4 are shown in Figs. 4 and 5. The bar graph (Fig. 4) shows the reproducibility of data. The amount of ortho- and para-isomers, seems to exhibit a slight dependence on the concentration of NO_2BF_4 as shown in Fig. 5. The small but perceptible decrease in the amount of ortho-isomer might be attributed to changes in steric hindrance with increasing concentration of the nitronium fluoroborate solution.

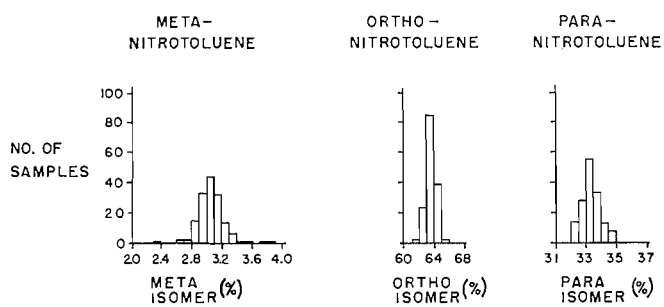

FIG. 4. Distribution diagram of the isomers of nitrotoluene in NO_2BF_4 nitration.

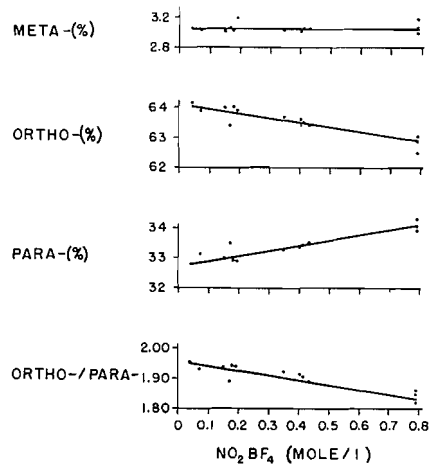

FIG. 5. Isomer distribution of nitrotoluene vs. concentration of NO_2BF_4 solution. (Each point represents the average of one set of experiments.)

As nitric acid or mixed acid nitration is reported (8, 9) to yield lower ortho-/para-values than the present ones a few further experiments were carried out with nitric acid as the nitrating agent in tetramethylene sulfone solution. In the first set of experiments a tetramethylene sulfone solution of nitric acid was added to the aromatic solution containing sulfuric acid. The product ratio was found to be 36.9 ± 2.2 while the isomer distribution of nitrotoluene (61.6 ± 0.8% *o*-, 2.91 ± 0.21% *m*-, and 35.5 ± 0.6% *p*-) gave an ortho-/para-value of 1.74 ± 0.06.

In the second set of experiments the nitric acid was dissolved in the aromatic solution and nitration was effected by the addition of a sulfuric acid solution. The product ratio was found to be 34.8 ± 4.3 in this case while the composition of nitrotoluene (61.6 ± 0.6% *o*-, 3.36 ± 0.47% *m*-, and 35.0 ± 0.5 *p*-) gave an ortho-/para-value of 1.76 ± 0.04.

Both types of nitration may be described as "mixed acid" nitration, because nitric acid alone did not yield measurable amounts of nitro aromatics under similar conditions.

The product ratio is surprisingly high in both cases even if we take into account that because of the low conversion the estimated accuracy of analysis of nitrobenzene is 10% and 20% in the first and second set of experiments, respectively.

The ortho-/para-value of nitrotoluene was checked further, using a tetramethylene sulfone solution of nitric acid in two parallel experiments omitting the sulfuric acid. The product ratio was found to be 24.7 ± 1.6 while the isomer distribution of nitrotoluene (60.2 ± 0.9% *o*-, 5.1 ± 0.9% *m*-, and 34.7 ± 0.1% *p*-) gave an ortho-/para-value of 1.73 ± 0.03. In spite of the prolonged reaction time, the conversion of the aromatics was very low and therefore the product ratio and the *m*-nitrotoluene value are indicative rather than quantitative data. Both *o*- and *p*-nitrotoluene were present, however, in easily measurable quantities (±5% estimated analytical accuracy) and show, similarly to the "mixed acid" nitration, a lower ortho-/para-value than NO_2BF_4.

The possibility of obtaining low product ratio even in nitric acid nitration was demonstrated with the following experiment. The above described experiment was repeated with the exception that neat nitric acid was added to the tetramethylene sulfone solution of benzene and toluene. After 6 h of reaction time the product ratio was found to be 3.4. The isomer distribution of nitrotoluene (59.6% *o*-, 4.7% *m*-, and 35.7% *p*-) gave an ortho-/para-value of 1.67.

DISCUSSION

On the basis of the results it is proposed that the competitive nitration of reactive aromatics with nitronium tetrafluoroborate does not proceed with kinetic control under the conditions described in the literature—magnetic stirring, dropwise addition of the reactant (1–5). Therefore, reported relative rates do not represent the relative reactivity of the competitors. The absence of kinetic control originates probably from the fact that the rate of nitration of benzene and aromatics of similar reactivity is very high with nitronium ion. Seemingly it is high enough to ensure a considerable consumption of the nitrating agent before it is homogenized in the aromatic solution. The reaction occurring prior to homogenization might be influenced by the non-kinetic factors described by Francis (8).

The absence of kinetic control and the correspondence to Francis' conclusions in the presently described nitration is shown by the following observations.

(1) Product ratios increased with increasing intensity of stirring.

(2) Product ratios increased with decreasing concentration of the nitrating solution. The two phenomena may be explained by a related effect. Both increased speed of distribution and lower concentration of the reactant decrease the extent of reaction occurring prior to homogenization in the layer adjacent to the entering nitronium salt solution.

(3) Product ratios decreased with decreasing concentration of the aromatic solution. The extent of the primary, selective depletion of the more reactive competitor in the reaction zone is higher when the concentration of the aromatic compound is low. Therefore the less reactive competitor obtains increasingly larger portions of the reactant, and the product ratio moves toward unity.

(4) Reaction mixtures of low product ratio contained measurable amounts of dinitrotoluene (Table IV). Though the extent of dinitration was small, one could calculate from the data a relative rate of nitration of toluene/nitrotoluene as being < 10 considering the low conversion. This low figure can hardly be considered as a kinetic value. The result can be explained by imperfect homogenization of the reaction mixture. If the aromatic solution were not exchanged fast enough in the layer surrounding the nitrating agent subsequent portions of the nitronium salt would be confronted with a layer rich in nitroaromatics. It seems plausible to suggest that the same factors might limit the applicability of the competitive method of rate determination for other fast reactions as well.

To diminish the influence of non-kinetic factors in the investigated system the effectiveness of agitation was increased by using a disc vibrator instead of a magnetic stirrer. By use of the vibrator stirrer in connection with nitronium salt solutions of low concentrations (0.07 and 0.04 M), the product ratios approached a range (between 25 and 30) where they became independent of both concentration and stirring rate. Because this range corresponds to that of the relative reactivity of toluene/benzene in nitric acid nitrations there seems to be no reason to suppose that nitronium salt nitration involves a mechanism different from that of nitric acid nitration, investigated in great detail by Ingold and co-workers (11). This proposal is supported further by the fact that when the absolute rate of the reaction was reduced by using aromatic pairs of lower reactivity (fluorobenzene/chlorobenzene and with certain limitations benzene/fluorobenzene) the product ratios remained independent of the concentration of the nitronium salt solution, in spite of the higher values, and corresponded to the known relative reactivities (18, 19) in nitric acid nitration as well. An alternative explanation of the results would imply the existence of separate nitrating species in the nitronium salt solutions; a highly reactive one, present when the concentration of the salt is high, and another, present in dilute solutions, with

decreased reactivity because of solvation. The former would show much lower substrate selectivity than the latter.

The validity of this type of explanation is, however, extremely doubtful considering the following.

(1) The concentration of tetramethylene sulfone is so high (93.2 mole %) even in a saturated nitronium fluoroborate solution, that further increase to 99.6 mole % seems to be insufficient to effect drastic changes in the environment of the nitronium salt.

(2) According to indicator and cryoscopic studies of Arnett and Douty (20), tetramethylene sulfone is a very weakly basic solvent, in which ions are poorly solvated. The electrical conductivity of nitronium tetrafluoroborate in tetramethylene sulfone (21), attributed to conducting ion triplets (4), varied linearly with the concentration in the range used in the present investigation.

(3) According to spectroscopic evidence the nitronium ion is insensitive to environmental changes (4, 22).

(4) Rate constants for the nitration of nitrobenzene (12) with nitronium tetrafluoroborate were independent of the concentration of the nitronium salt both in organic solution (acetonitrile) and in inorganic solution (sulfuric acid).

(5) Concentration changes of the nitronium salt affect the product ratios, in the present investigations, only in the case of highly reactive aromatics. Chlorobenzene–fluorobenzene was insensitive, benzene–fluorobenzene slightly sensitive, and toluene–benzene highly sensitive to the concentration.

(6) Dilute aromatic solution always yielded a lower product ratio than a more concentrated one.

(7) If dilution effected any change in the isomer distribution of nitrotoluene through solvation the ortho-/para-value would be expected to decrease. The results, however, point to the other direction. Toluene showed a somewhat greater ortho-steric hindrance against concentrated solutions of nitronium tetrafluoroborate than against dilute ones.

Apart from these facts solvation or some other kind of complex formation can not explain the dependence of product ratios on the rate of agitation.

Based on the foregoing arguments it seems highly improbable that separate nitronium ion species of highly different reactivities operate simultaneously in the reaction and that their relative concentration determined by dilution regulates the product ratios.

ACKNOWLEDGMENTS

It is a pleasure to thank Dr. J. W. Crump of Albion College, Michigan, and many of my colleagues for helpful discussions. I also wish to thank Mr. P. Kann for the gas chromatographic analysis.

ESTER HYDRAZONES AS POSSIBLE PRECURSORS TO ALKOXYDIAZOALKANES[1]

II. THE DECOMPOSITION OF ESTER (*p*-TOLYLSULFONYL)HYDRAZONE SALTS IN APROTIC SOLVENTS

ROBERT J. CRAWFORD AND RINTJE RAAP[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received July 10, 1964

ABSTRACT

The thermal and photochemical decomposition of methyl benzoate (*p*-tolylsulfonyl)hydrazone salts in 1,2-dimethoxyethane, 1,2-diethoxyethane, or diglyme gives rise to benzaldehyde dimethyl acetal, methyl benzoate azine (II), *meso*-1,2-diphenyl-1,2-dimethoxyethane, and methyl α-(*p*-tolylsulfonyl)benzyl ether. The thermal decomposition in the presence of diethyl fumarate produced diethyl 3-methoxy-3-phenyl-*trans*-1,2-cyclopropanedicarboxylate (XIV) in 62% yield; a low yield (4%) of the two isomeric forms of 1-methoxy-2-*n*-octyl-1-phenylcyclopropane (V) was formed in 1-decene. The thermal and photochemical decomposition of potassium 4-pentenyl benzoate (*p*-tolylsulfonyl)hydrazone (XVIII) produced 1-phenyl-2-oxabicyclo[4.1.0]heptane (XXI) in 14 and 21% yield respectively. These products provide additional evidence for the occurrence of alkoxydiazoalkanes and suggest alkoxycarbenes as possible intermediates in the decomposition of ester (*p*-tolylsulfonyl)hydrazone salts.

INTRODUCTION

Diazoalkanes undergo thermal and photochemical decomposition in aprotic solvents to give rise to a number of unique products (1). The reactions of the sodium salts of I in protic solvents was shown, in the preceding paper (2), to decompose in a manner reconcilable with an alkoxydiazoalkane intermediate. We have herein undertaken a study of the decomposition of the sodium salts of I in aprotic solvents in an attempt to gain information of a synthetic and mechanistic value.

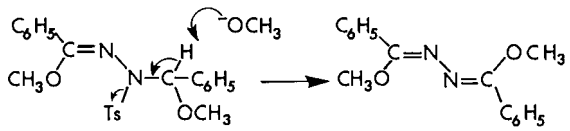
I

DISCUSSION*

The sodium salt of I was prepared by dissolving the hydrazone I in DME with an equimolar amount of sodium methoxide. The methanol was distilled off and the resulting solution refluxed for 65 h, as judged sufficient by the decreased rate of nitrogen evolution. The products were benzaldehyde dimethyl acetal (34%) and a solid, m.p. 72–73°, that was isolated by chromatography, on alumina, of the nonvolatile fraction. The infrared spectrum of the solid showed an intense absorption at 1 615 cm^{-1}, indicative of C=N. The nuclear magnetic resonance (n.m.r.) spectrum indicated aromatic protons at τ 2.0 to 2.8 and a sharp —OCH_3 singlet at τ 6.18, with relative areas of 10:6 respectively. The compound has a molecular weight of 269 and its elemental composition fits the empirical formula

[1]*Presented at the 47th Canadian Chemical Conference, Kingston, Ontario, June 1–3, 1964.*
[2]*Holder of a National Research Council of Canada Scholarship, 1963–1964. Present address: R & L Molecular Research Ltd., Edmonton, Alberta.*
**Solvents such as 1,2-dimethoxyethane(DME), 1,2-diethoxyethane (DEE), and diglyme were freed, prior to use, from hydroxylic materials by distillation from potassium metal.*

$C_{16}H_{16}N_2O_2$ (molecular weight 268.3). There is little doubt that the product is methyl benzoate azine (II), as the same product was prepared from methyl benzoate (α-methoxybenzyl)(p-tolylsulfony)hydrazone (III) (2) by refluxing with sodium methoxide in DME.



III II

An n.m.r. spectrum of the product mixture resulting from the decomposition of the potassium salt of I indicated that, apart from benzaldehyde dimethyl acetal and methyl benzoate azine (II), other products were present containing only aromatic hydrogens. Possible products such as benzonitrile, diphenylacetylene, and biphenyl could not be detected by infrared spectroscopy and (or) gas-liquid partition chromatography (g.l.p.c.), neither could any other product be isolated by elution chromatography on alumina.

When the decomposition was repeated in the presence of cyclohexene the product mixture was the same as that obtained in the absence of cyclohexene and there was no indication of the formation of 7-methoxy-7-phenylnorcarane (IV), which would have resulted from a reaction between phenylmethoxycarbene, a possible decomposition intermediate, and cyclohexene.

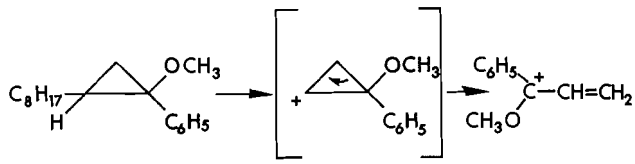
IV

The potassium salt, when heated alone in diglyme, dissolved at the boiling point, and was completely decomposed within 5 min. Benzaldehyde dimethyl acetal, although not isolated, was shown to be present by g.l.p.c. A very complicated product mixture had resulted from this decomposition as was indicated by n.m.r. spectroscopy, and only two products were isolated in small amounts, methyl benzoate azine (II) (2.5%) and *meso*-1,2-diphenyl-1,2-dimethyoxyethane (3%). That the solvent was not involved in the formation of the benzaldehyde dimethyl acetal was shown by the isolation of this product, in 30% yield, from the thermal decomposition of the potassium salt in DEE.

A further attempt to isolate a cyclopropane derivative was made by carrying out the decomposition in 1-decene. The boiling point of this olefin (168°) is such that it may be used as a 1:1 mixture with diglyme. The reaction product obtained when the potassium salt was decomposed at 158° had a n.m.r. spectrum very similar to that of the product that was obtained when the decomposition was carried out in diglyme alone. However, when the product mixture was repeatedly chromatographed on alumina, a 2.2% yield of a pure liquid was obtained. The molecular weight of the compound was found to be 260; this, together with an elemental analysis, established the empirical formula as $C_{18}H_{28}O$ (molecular weight 260.4). The infrared spectrum showed a weak band at 1 020 cm^{-1}, a position corresponding to a cyclopropane ring deformation frequency (3) and strong absorption in the region 1 050 to 1 080 cm^{-1}, indicative of an ether linkage. The n.m.r. spectrum contains singlets at τ 2.81 and 6.84 and a broad band at τ 8.3–9.4 (with a strong maximum at 8.72 and a weak maximum at 9.11) with relative areas 1.8:1.0:10.4. These findings led to the conclusion that the compound was indeed one of the isomers of the

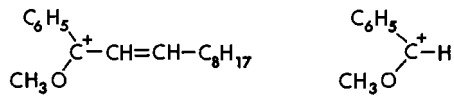
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

desired cyclopropyl derivatives V. The mass spectrum provides further evidence as the major fragment, accounting for 13.8% of the fragmentation products, has a $m/e = 147$, which corresponds with the carbonium ion VI whose presence may arise by the following sequence:



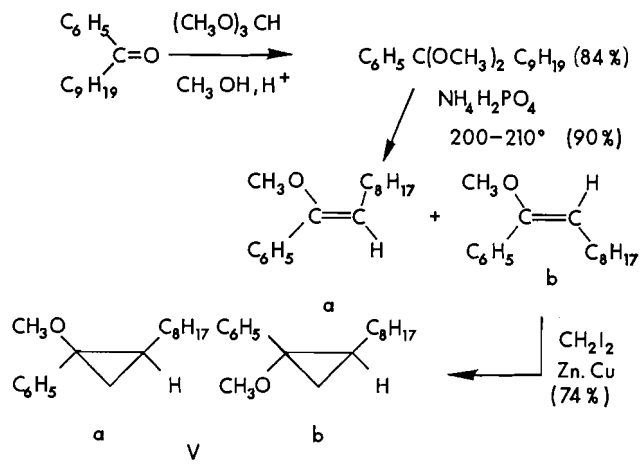
V VI

The fragment with $m/e = 259$ can similarly be explained by the initial loss of hydrogen, instead of the octyl group, to give the carbonium ion VII. The second largest fragment (6.8%), $m/e = 121$, is believed to be α-methoxybenzyl carbonium ion (VIII).



VII VIII

The configuration assignment of the isolated isomer, and the detection of the other isomer, required the synthesis of the isomers V*a* and V*b*. The mode by which this synthesis was accomplished is outlined in reaction Scheme 1, in which the yields of the individual steps are also indicated.

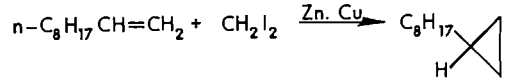


SCHEME 1

When the Simmons–Smith reaction (4) was carried out with the mixture of isomers of IX, a 5:3 mixture of the cyclopropyl isomers of V was obtained. The n.m.r. spectrum showed that the principal product has the same signal pattern as that isolated from the thermal decomposition of the potassium salt of I in the presence of 1-decene. The aromatic protons and the methoxy group appear in V*b* as singlets at τ 2.73 and 6.98 respectively, whereas the octyl group appears as a broad band at τ 8.6–9.2, with a strong maximum at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

8.83 and a smaller maximum at τ 9.04. The position of the octyl group in the n.m.r. spectrum may serve as a means for the configuration assignment. The n.m.r. spectra displayed a distinct difference in the position of the two maxima of the octyl group in the two isomers. It was felt that, due to steric and electronic interactions, the proximity of a phenyl group to the octyl group, as in V*b* and IX*b*, would alter the position of the latter more than the *cis*-methoxy group would in structures V*a* and IX*a*. Thus the octyl maxima in V*a* and IX*a* were expected to be very much the same as in the unsubstituted *n*-octylcyclopropane (X).

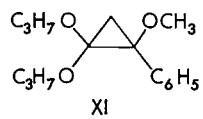


X

The n.m.r. spectrum of X shows the two octyl maxima at τ 8.78 and 9.11. As these maxima appear at the same positions in the principal product from either the dealcoholation or the methylene-transfer reaction, there is little doubt that they can also be attributed to the favored reaction products IX*a* and V*a*.

With the configurations established, it was thus possible to determine the isomeric ratio of the cyclopropanes that resulted from the thermal decomposition in 1-decene at 155–165°. The yield of 1-methoxy-2-*n*-octyl-1-phenylcyclopropane (V), determined by g.l.p.c.,* amounted to 4%; the relative ratio of V*a* and V*b* was 1.8:1 respectively.

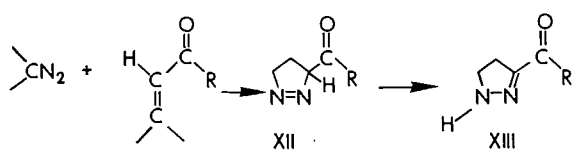
It was thought that a more electron-rich olefin would give a better yield of cyclopropane derivative. Ketene diethylacetal has been shown to act as a very efficient carbene trap (5) and thus ketene dipropyl acetal, with a boiling point of 153°, was most suitable for the present purpose. No 1-methoxy-2,2-di-*n*-propyloxy-1-phenylcyclopropane (XI) could be isolated from the complex product mixture that was obtained when the potassium salt of I was decomposed at 150–155° in a 1:1 mixture of diglyme and ketene dipropyl acetal. Although the n.m.r. spectrum of a distillation fraction boiling at 90–125° (0.2 mm) showed a complicated signal pattern at τ 8.3–9.5, which could only be due to propyl groups, no separation could be effected by elution chromatography on alumina. However it could be concluded from the n.m.r. spectrum that compound XI is certainly not formed



XI

in a yield exceeding 4%, and therefore the use of a ketene acetal does not seem to have much effect on the yield of the carbene adduct.

Diazo compounds and olefins, e.g. α,β-unsaturated carbonyl compounds, react to produce 1-pyrazolines (XII) which generally rapidly isomerize to 2-pyrazolines (XIII) and in certain instances decompose to cyclopropane derivatives (6).

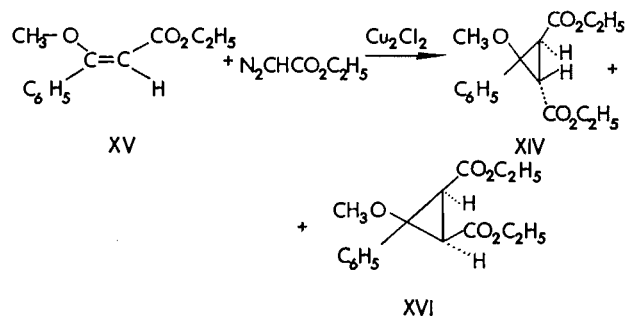


XII XIII

*A 4 ft Apiezon M column at 220° was used. It was shown that the product did not isomerize on the column, as an analysis of an authentic mixture of Va and Vb by g.l.p.c. and by n.m.r. spectroscopy gave the same result.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The formation of a pyrazoline from the decomposition of the potassium salt of I in the presence of an α,β-unsaturated carbonyl compound would provide additional evidence for the existence of the intermediate phenylmethoxydiazomethane. The potassium salt of I was decomposed at 130–135° in diethyl fumarate. A solid was isolated in 62% yield, by elution chromatography on alumina, m.p 40–41°. The infrared spectrum of the product showed an intense absorption in the carbonyl region at 1 720 cm^{-1}. The n.m.r. spectrum contained singlets at τ 2.77, 6.98, and 7.14, two methylene quartets (J = 7 c.p.s.) of the same intensity at 5.82 and 6.17, and two methyl triplets (J = 7 c.p.s.) of the same intensity at τ 8.69 and 9.02, the approximate relative areas were respectively 5:3:2:4:6. As the product did not contain any nitrogen and the infrared and n.m.r. spectra did not indicate the presence of an olefinic double bond or olefinic hydrogens, its structure was believed to be that of diethyl 3-methoxy-3-phenyl-*trans*-1,2-cyclopropanedicarboxylate (XIV), a conclusion in agreement with the elemental analysis. However a less ambiguous proof of structure appeared necessary, and therefore the cyclopropane derivative XIV was synthesized as shown in Scheme 2. Ethyl *trans*-β-methoxy cinnamate (XV), prepared by the procedure of Arndt and Loewe (7) for the methyl ester, was allowed to react with carbethoxycarbene, generated from ethyl diazoacetate under the catalytic influence of cuprous chloride. Diethyl 3-methoxy-3-phenyl-*trans*-1,2-cyclopropanedicarboxylate (XIV) and diethyl 3-methoxy-*trans*-3-phenyl-*cis*-1,2-cyclopropanedicarboxylate (XVI) were obtained in yields of 10% and 3% respectively. Compound XIV was identical in all respects with the solid obtained from the thermal decomposition of the potassium salt of I in diethyl fumarate.

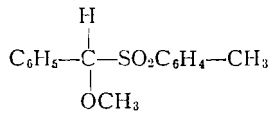


SCHEME 2

The photochemical decomposition of the potassium salt of I at room temperature in a 1:1 mixture of DME and cyclohexene was also investigated. Prior to the work-up the presence of a trace of methanol was demonstrated by g.l.p.c. Benzaldehyde dimethyl acetal was again isolated (36%), and treatment of the product mixture with *n*-hexane caused a solid to precipitate that was obtained as white needles, m.p. 101–103° (decomp.). The infrared spectrum showed strong absorption at 1 128 cm^{-1} and in the region 1 290 to 1 320 cm^{-1}, suggesting the presence of a sulfone group (7). The n.m.r. spectrum showed aromatic proton signals in the region τ 2.4–2.9, with a sharp singlet at 2.73, and further singlets at 4.82, 6.35, and 7.62, with integrated areas 9:1:3:3. The compound was found to have a molecular weight of 272 and to fit the emperical formula $C_{15}H_{16}O_3S$ (molecular weight 276.3). From this it is clear that the product is methyl α-(*p*-tolylsulfonyl)benzyl ether (XVII). This product was isolated in 3.2% yield; however, it could be isolated in as high as a 17% yield when the photochemical decomposition was carried out in DME

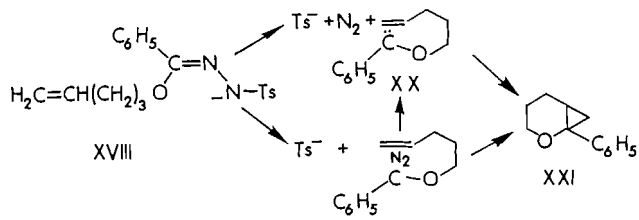
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

alone. Although a large number of other products were produced, as demonstrated both by n.m.r. spectroscopy and g.l.p.c., they could not be isolated in pure form by distillation and (or) elution chromatography.



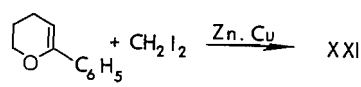
XVII

Since the phenylmethoxydiazomethane gave such such poor yields of cyclopropane products with 1-decene, it was decided to investigate the efficiency of an internally situated olefinic double bond to cyclopropane formation. Because of the availability of 4-pentenol the corresponding potassium 4-pentenol benzoate (*p*-tolylsulfonyl)hydrazone (XVIII) was prepared and reactions of it studied. Thus if cyclopropane ring formation occurred through the diazoalkane (XIX) or the carbene (XX), the olefinic double bond would be suitably disposed to trap the intermediate and lead to the formation of 1-phenyl-2-oxabicyclo[4.1.0.]heptane (XXI).



XVIII XX XXI XIX

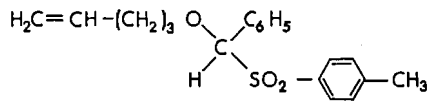
In order to facilitate the isolation and quantitative determination of XXI it was first synthesized by a Simmons–Smith reaction on 2-phenyl-2-dihydropyran (XXII) in 72% yield. The infrared spectrum of the product shows an absorption of medium intensity at 1 024 cm^{-1}, characteristic of a cyclopropyl group (3). The n.m.r. spectrum contains a singlet at τ 2.09 and complex absorption at τ 6.1–7.0 and 7.8–9.2, with relative areas 5:2:7 respectively.



XXII XXI

The thermal decomposition of XVIII was carried out in diglyme at 140–150°, at which temperature the salt readily decomposed. The amount of XXI in the product mixture was quantitatively determined by g.l.p.c. To establish its identity it was also isolated by elution chromatography. The pyran (XXI) was the major product in the thermal decomposition, its yield amounting to 11–14%. Although several modifications in the decomposition procedure were investigated in order to improve this yield, they were without success. When a dilute solution of XVIII in anhydrous diethyl ether was photolyzed at room temperature, the product XXI was formed in 20–21% yield. The photochemical decomposition also produced an appreciable amount (15%) of 4-pentenyl α-(*p*-tolylsulfonyl)benzyl ether (XXIII), as a white crystalline solid, m.p. 90–91°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



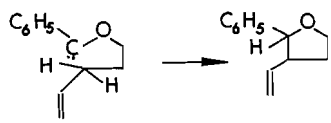
XXIII

The presence of another expected product, benzaldehyde 4-pentenyl acetal (XXIV), was shown by g.l.p.c. and its yield was estimated at 3–6% from the thermal decomposition and 1–4% in the photochemical decomposition. As this low yield did not permit an effective isolation it was only characterized by its retention time on an Apiezon M column. Authentic benzaldehyde 4-pentenyl acetal was prepared in 80% yield by the thermal decomposition of XVIII in DEE in the presence of 4-pentenol.

$$C_6H_5CH(O(CH_2)_3CH{=}CH_2)_2$$

XXIV

The possibility of carbene insertion into the allylic 3-position of the alkyl group in XVIII to form the vinyl furan (XXV) was seriously considered since the vapor phase chromatogram, of the product mixture from the decomposition of XVIII, displayed a relatively large amount (estimated at 3 to 4% in the thermal and at 5 to 7% in the photochemical decomposition) of a product with a similar retention time to that of XXI. However it was later found that this product resulted from the thermal decomposition of the sulfone XXIII, and the idea was abandoned as the chromatogram indicated that the insertion product XXV had not been formed, if at all, in a yield greater than 1%.



XXV

CONCLUSIONS

The production of benzaldehyde dimethylacetal in aprotic solution along with the formation of methanol suggests that the salts are decomposing by routes as yet not elucidated. The methanol formed in this process would appear to occur via alkoxy radicals abstracting from the solvent, since the methanol can be detected by g.l.p.c. on the anhydrous solutions before work-up.

Three possible reaction paths which may explain the cyclopropane formation with 1-decene and diethyl fumarate, are shown in Scheme 3.

Mechanism A involves a nucleophilic attack on the olefin which although reasonable for diethyl fumarate, seems less likely for 1-decene. Mechanism B involves a 1,3-dipolar addition of the diazocompound to the olefin, but requires that the loss of nitrogen be more rapid than the rate of tautomerization of 1-pyrazoline (6). Mechanism C involves the thermal decomposition of the alkoxydiazoalkane to an alkoxy carbene which may have nucleophilic properties similar to the carbene species investigated by Wanzlick (9) and Kirmse (10). Thus diethyl fumarate is a superior trap to any of the other olefins. It is not possible on the basis of existing data to discriminate among these three mechanisms, and minor variations thereof, but since phenyldiazomethane can be prepared, and isolated, by

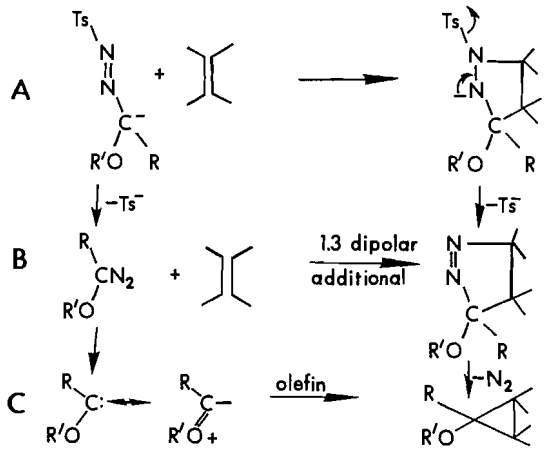

SCHEME 3

this method and since nucleophilic addition to 1-decene does not seem likely,* mechanisms B and C are favored.

EXPERIMENTAL

All melting points and boiling points are uncorrected.

The infrared spectra were obtained on a Perkin–Elmer Model 421 spectrophotometer equipped with grating optics. Nuclear magnetic resonance spectra were measured using a Varian Associates Model A-60 spectrometer, with tetramethylsilane as a reference. Ultraviolet spectra were obtained using a Cary Model 14M recording spectrophotometer. Mass spectra were obtained on a A.E.I. MS2-H mass spectrometer.

Vapor phase chromatography was carried out with a Perkin–Elmer Model 154 vapor fractometer or a F. & M. Model 500 temperature-programmed gas chromatograph.

The photochemical decompositions were all carried out in a quartz reaction vessel, cooled by running tap water, with an internally situated 250 W Hanovia ultraviolet source.

The microanalyses were performed by Pascher Mikroanalytisches Laboratorium (Bonn, West Germany), Daessle Organic Microanalyses (Montreal), and the Microanalytical Laboratory of the Department of Chemistry, University of Alberta (Edmonton).

The Decompositon of α-Alkoxy(p-tolylsulfonyl)hydrazone Salts

Solvents

1,2-Dimethoxyethane was distilled from potassium metal, b.p. 82°. A technical grade of *1,2-diethoxyethane* was distilled. The fraction boiling at 116–120° was left with potassium overnight and fractionally distilled. The fraction with b.p. 116–117° consisted of pure 1,2-diethoxyethane as was shown by g.l.p.c. *Diglyme* (diethylene glycol dimethyl ether) was left over potassium metal overnight and distilled, b.p. 157–159°.

The Thermal Decomposition of Sodium Methyl Benzoate (p-Tolylsulfonyl)hydrazone in 1,2-Dimethoxyethane

Methyl benzoate (*p*-tolylsulfonyl)hydrazone (10.0 g, 32.9 mmole) (1) was dissolved in 60 ml of 1,2-dimethoxyethane, and sodium methoxide (1.8 g, 33.3 mmole) was added. Solvent was distilled (approximately 20 ml) until the boiling point reached that of pure 1,2-dimethoxyethane. The mixture was stirred and refluxed for 65 h. After cooling, the sodium *p*-toluenesulfinate (5.3 g, 90%) was filtered off and the solvent of the orange-colored solution was removed. The residue was dissolved in ether, washed with water, and dried. Removal of the ether gave 3.1 g liquid residue. A vacuum distillation produced 0.9 g (34%) benzaldehyde dimethyl acetal, b.p. 56–57° (3.5 mm); n_D^{25} 1.4960. The high-boiling point liquid residue was chromatographed on Harshaw alumina. The product obtained by elution with a 5% ether in pentane solution was recrystallized from a small amount of *n*-hexane to give 0.5 g (12%) of methyl benzoate azine (II) as white needles, m.p. 72–73°. The ultraviolet spectrum shows a broad band with a maximum at 2 700 Å (log = 4.09).

Anal. Calcd. for $C_{16}H_{16}N_2O_2$ (molecular weight, 268.3); C, 71.62; H, 6.01; N, 10.44. Found: C, 71.87; H, 5.99; N, 10.49; molecular weight (osmometric), 269.

Although other products were formed that contained only aromatic protons, as was shown by n.m.r. spectroscopy, no other compounds could be isolated and characterized. When the experiment was repeated

**The rate of nitrogen evolution appears to be independent of the presence of the olefin substrate which would not seem reasonable for mechanism A.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in the presence of 15 ml cyclohexene, the same product mixture was obtained and there was no indication for the formation of 7-methoxy-7-phenylnorcarane as the n.m.r. spectrum of the reaction products showed no absorption above 7.0.

The Reaction of Methyl Benzoate (α-Methoxybenzyl)(p-tolylsulfonyl)hydrazone with Sodium Methoxide

Methyl benzoate (α-methoxybenzyl)(*p*-tolylsulfonyl)hydrazone (0.500 g, 1.18 mmole) (2) and sodium methoxide (0.072 g, 1.33 mmole) were refluxed in 20 ml of 1,2-dimethoxyethane. A precipitate formed slowly and after 5.5 h the mixture was cooled and sodium *p*-toluenesulfinate (0.16 g, 76%) was filtered off. The solvent was removed and the residue was dissolved in ether, washed with water, and dried. Removal of the ether produced 0.33 g of residue that slowly solidified. An infrared spectrum was identical with that of a mixture of starting material and methyl benzoate azine. Addition of *n*-hexane caused the starting material (0.08 g, 16%) to precipitate. The remaining product was chromatographed on alumina. The pure azine was obtained by elution with a 5% ether in pentane solution and amounted to 0.14 g (46%), m.p. 72–73°; mixture m.p. 72–73°.

The Thermal Decomposition of Potassium Methyl Benzoate (p-Tolylsulfonyl)hydrazone in 1-Decene

A suspension of the potassium salt (1.50 g, 4.4 mmole) in 15 ml of 1-decene was heated, while being stirred, at 155–165° until the gas evolution had ceased, which required approximately 40 min. The reaction mixture was cooled and water and diethyl ether were added. The organic layer was dried, and the ether and 1-decene distilled off, the latter under reduced pressure. It was shown by g.l.p.c. that the residue contained at least 13 different products, all present in relatively low concentrations. In order to be able to analyze for the two isomeric 1-methoxy-2-*n*-octyl-1-phenylcyclopropanes (V), the mixture was added to an alumina column and eluted with *n*-pentane until all of the desired product was removed from the column. This operation required approximately 700 ml of *n*-pentane. The pentane was removed and an accurately known amount of 2-ethoxynaphthalene was added as an internal standard. The total amount of 1-methoxy-*trans*-2-*n*-octyl-1-phenylcyclopropane and 1-methoxy-*cis*-2-*n*-octyl-1-phenylcyclopropane was determined by g.l.p.c. using a 4 ft Apiezon M column. In two separate experiments the total amount of these two isomers was 47 mg (4.1%) and 42 mg (3.8%). the isomer ratio *trans/cis* being 1.9 and 1.7 respectively. It was shown that the product did not isomerize at the column temperature (220°) as the analysis of an authentic mixture of the two isomers by n.m.r. spectroscopy and by g.l.p.c. gave the same result.

The decomposition was repeated on a larger scale in a 1:1 mixture of diglyme and 1-decene: The potassium salt (10.0 g, 29.2 mmole) was decomposed by refluxing for 10 min in a mixture of 30 ml diglyme and 30 ml 1-decene. Prior to the work-up an appreciable amount of benzaldehyde dimethyl acetal was shown to be present in the reaction mixture by g.l.p.c. on an Apiezon L column. A quantitative amount of potassium *p*-toluenesulfinate was filtered off and the solvent mixture was distilled off under reduced pressure. The highly colored residue was passed through a short alumina column with 300 ml of *n*-pentane. The pentane was removed and the residue distilled *in vacuo*. After a small amount of a low-boiling fraction, which was not further investigated, 1.35 g of a fraction with a boiling range of 110–140° (0.3 mm) distilled over. Upon addition of a small amount of *n*-hexane and cooling overnight at −15°, 0.1 g (3%) of crystals with m.p. 138–140° were obtained, identical in all respects (mixture melting point, infrared and n.m.r. spectra) with *meso*-1,2-diphenyl-1,2-dimethoxyethane. The hexane solution was chromatographed on alumina. The product that was eluted with a 5% ether in pentane solution was recrystallized from a small amount of *n*-hexane to give 0.1 g (2.6%) of methyl benzoate azine. The *n*-pentane fraction contained 1-methoxy-2-*n*-octyl-1-phenylcyclopropane. The product mixture from this fraction was again chromatographed on alumina and eluted with *n*-pentane. The first fraction contained 0.17 g (2.2%) of pure 1-methoxy-*trans*-2-*n*-octyl-1-phenylcyclopropane.

Anal. Calcd. for $C_{18}H_{28}O$ (molecular weight, 260.4): C, 83.02; H, 10.84. Found: C, 83.21; H, 11.11; molecular weight 260 (mass spectrometrically).

The following chromatographic fractions contained smaller amounts of a mixture of the two isomers and also other products.

The Photochemical Decomposition of Potassium Methyl Benzoate (p-Tolylsulfonyl)hydrazone in 1,2-Dimethoxyethane and Cyclohexene

A stirred suspension of the potassium salt (10.0 g, 29.2 mmole) in a mixture of 90 ml 1,2-dimethoxyethane and 100 ml cyclohexene was irradiated for 9 h, at which time the gas evolution had become almost negligible. A total of 570 ml of gas had evolved (theoretically 770 ml of nitrogen). The solution was filtered, the solvent removed under reduced pressure, and the residue taken up in ether. The ether solution was washed with water and dried and the ether removed. A n.m.r spectrum showed the residue was a mixture of many products. Addition of a small amount of *n*-hexane caused 0.26 g of a white solid to precipitate, that could be recrystallized from a 5:1 mixture of *n*-hexane and benzene to give white needles, m.p. 101–103°. Because of decomposition no sharp melting point could be obtained.

Anal. Calcd. for methyl α-(*p*-tolylsulfonyl)benzyl ether (XVII), $C_{15}H_{16}O_3S$ (molecular weight 276): C, 65.19; H, 6.83; S, 11.61. Found: C, 65.34; H, 6.29; S, 11.45; molecular weight (osmometric) 272, 274.

The *n*-hexane was removed and the residue distilled *in vacuo* to give 0.8 g (36%) benzaldehyde dimethyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

acetal (b.p. 58–59° at 3.6 mm), 0.9 g of a fraction with b.p. 102–109° (1.0 mm), and 0.55 g of a fraction boiling at 110–116° (0.15 mm). Both these last fractions showed a very complicated n.m.r. signal pattern. An attempt was made to separate the fraction with b.p. 102–109° (1.0 mm) into its components by elution chromatography on alumina, however no separation could be effected and each fraction that was eluted from the column contained several components as was shown by n.m.r. spectroscopy and g.l.p.c.

When the photochemical decomposition was carried out in 1,2-dimethoxyethane alone, methyl α-(*p*-tolylsulfonyl)benzyl ether was isolated in 17% yield. Prior to the work-up benzaldehyde dimethyl acetal was shown to be present by g.l.p.c., using a 2 m Apiezon L column. A trace of methanol could also be detected. It was characterized by its retention time on two columns, packed with Apiezon L, and Ucon LB-550-X respectively.

The Decomposition of Potassium Methyl Benzoate (p-Tolylsulfonyl)hydrazone in Diethyl Fumarate

The potassium salt (4.0 g, 11.7 mmole) was suspended in 40 ml of diethyl fumarate (a center distillation cut, b.p. 66–67° at 1.8 mm, of Eastman white label material) and heated, while stirred, at 130–135° for 1.5 h. The mixture was cooled, 100 ml ether added, and the ether solution washed four times with water. The pale yellow-colored ether solution was dried, the ether evaporated, and the diethyl fumarate distilled off *in vacuo*. Upon addition of a small amount of *n*-pentane to the residue, methyl benzoate (α-methoxybenzyl)(*p*-tolylsulfonyl)hydrazone (III) (0.43 g, 18%; m.p. 147–149°) precipitated. The pentane was removed and the residue purified by elution chromatography on alumina. Elution with benzene produced 2.15 g of an oil that slowly solidified to a white solid, m.p. 37–39°. The product was twice recrystallized from a small amount of *n*-hexane to give fine white needles, m.p. 40–41°, of analytical purity. The melting point was not depressed by diethyl 3-methoxy-3-phenyl-*trans*-1,2-cyclopropanedicarboxylate. The infrared and n.m.r. spectra were identical with those of an authentic sample of diethyl 3-methoxy-3-phenyl-*trans*-1,2-cyclopropane dicarboxylate. No other reaction products were detected either by n.m.r. spectroscopy or elution chromatography.

4-Pentenyl Benzimidate

Dry hydrogen chloride (25.5 g, 0.70 mole) was added to a mixture of 4-pentenol (60.0 g, 0.70 mole) and benzonitrile (68.0 g, 0.66 mole) and cooled in an ice–salt mixture. The reaction mixture was left in the refrigerator for 24 h, at which time it had almost solidified, and 200 ml of ether was added. The hydrochloride salt was collected and mounted to 77.7 g (0.36 mole, 52%), m.p. 122–123° (decomp.). Under vigorous stirring this salt was added to a solution of potassium carbonate (120 g 0.87 mole) in 300 ml of water covered with 150 ml of ether, followed by the further extraction of the aqueous layer with 60 ml of ether. The combined ether solutions were dried and the residue was distilled *in vacuo* to give 59.8 g (92%) of colorless product, b.p. 86–87° (0.3 mm); n_D^{25} 1.5252. The infrared spectrum (in CCl_4) shows an N—H band at 3 340 cm^{-1} and a strong band at 1 630 cm^{-1} due to the C=N.

Anal. Calcd. for $C_{12}H_{15}NO$: C, 76.15; H, 7.99; N, 7.40. Found: C, 76.41; H, 8.12; N, 7.38.

4-Pentenyl Benzoate (p-Tolylsulfonyl)hydrazone

A solution of 4-pentenyl benzimidate (15.9 g, 84.1 mmole) in 35 ml of absolute ethanol was added to a cold suspension of (*p*-tolylsulfonyl)hydrazide hydrochloride (18.7 g, 84.0 mmole) in 75 ml of absolute ethanol and the mixture was left at room temperature for 3 h. The ammonium chloride was filtered off, the ethanol removed under reduced pressure, and the residue dissolved in 120 ml of methylene chloride. The methylene chloride solution was washed twice with water, dried ($MgSO_4$), and filtered, and the solvent removed. The residue was immediately dissolved in 100 ml of anhydrous diethyl ether and cooled at −15° overnight to yield 14.4 g (48%) of crystals, m.p. 87–89°. One additional recrystallization produced an analytical sample, m.p. 89–90°. The infrared spectrum (in $CHCl_3$) shows N—H stretching at 3 300 cm^{-1} and a C=N— stretching band of medium intensity at 1 620 cm^{-1} with a shoulder at 1 635 cm^{-1}.

Anal. Calcd. for $C_{19}H_{22}N_2O_3S$: C, 63.66; H, 6.19; N, 7.82; S, 8.95. Found: C, 63.75; H, 6.38; N, 7.68; S, 8.81.

Potassium 4-Pentenyl Benzoate (p-Tolylsulfonyl)hydrazone (XVIII)

A solution of 4-pentenyl benzoate (*p*-tolylsulfonyl)hydrazone (10.0 g, 27.9 mmole) in 40 ml of 1,2-dimethoxyethane was added to a solution of potassium (1.1 g, 28.2 mgram-atom) in a mixture of 6 ml absolute ethanol and 40 ml of 1,2-dimethoxyethane. Cooling and the addition of *n*-pentane did not cause any salt to precipitate. Thus the solvent was removed and the residue kept *in vacuo* for 30 min, at which time the syrup had crystallized completely. The slightly yellow-colored salt, soluble in water and in most organic solvents, amounted to 11.0 g.

Benzaldehyde Di-(4-pentenyl) Acetal XXIV

Potassium 4-pentenyl benzoate (*p*-tolylsulfonyl)hydrazone (11.0 g, 27.7 mmole) was refluxed in a mixture of 10 ml 4-pentenol and 40 ml of 1,2-diethoxyethane for 3 h. Potassium *p*-toluenesulfinate (5.5 g, 100%) was filtered off, the solvent removed under reduced pressure, and the residue taken up in ether, washed with water, and dried ($MgSO_4$). Removal of the solvent, followed by a vacuum distillation, yielded 5.8 g (80%) of the product, b.p. 102–103° (0.2 mm); n_D^{25} 1.4905. The infrared spectrum shows the olefinic double bond stretching as a band of medium intensity at 1 637 cm^{-1}.

Anal. Calcd. for $C_{17}H_{24}O_2$: C, 78.42; H, 9.29. Found: C, 78.47; H, 9.19.

The Thermal Decomposition of Potassium 4-Pentenyl Benzoate (p-Tolylsulfonyl)hydrazone in Diglyme to Produce XXI

The potassium salt (1.31 g, 3.3 mmole) was dissolved in 20 ml diglyme and heated for 10 min at 145–150°. After cooling there was added 50 ml water and 75 ml *n*-pentane and the mixture was vigorously shaken. The pentane layer was again washed with water and then dried. The pentane was removed, 0.091 g of 2-ethoxynaphthalene was added as an internal standard, and the absolute amount of 1-phenyl-2-oxabicyclo[4.1.0]heptane (XXI) was determined by g.l.p.c. using a 4 ft Apiezon M column, yield 0.071 g (12.3%). The experiment was repeated, with the potassium salt slowly added, either as the solid or as a diglyme solution, to diglyme at 140–150°. The yield of XXI was 13.7% and 10.8% in two separate experiments. By carrying out the experiment on a somewhat larger scale and by eluting the product mixture with *n*-pentane from an alumina column, a pure sample of XXI could be isolated (even though the overall separation was poor) and characterized by its retention time and by comparing its infrared and n.m.r. spectra with those of an authentic sample.

The Photochemical Decomposition of Potassium 4-Pentenyl Benzoate (p-Tolylsulfonyl)hydrazone in Diethyl Ether

The potassium salt (1.571 g, 4.0 mmole) was dissolved in 190 ml of diethyl ether and irradiated for 45 min, at which time the gas evolution had ceased. The ether solution was washed with water and dried. The residue (1.0 g) obtained after removal of the ether, solidified slowly. Upon the addition of a small amount of *n*-pentane, 0.220 g of a white solid, m.p. 81–85°, was obtained. Two recrystallizations from *n*-hexane produced an analytical sample, m.p. 90–91°. The infrared spectrum (in CCl_4) showed a band of medium intensity at 1 640 cm^{-1} and strong bands at 1 320 and 1 139 cm^{-1}.

Anal. Calcd. for 4-pentenyl α-(*p*-tolylsulfonyl)benzyl ether (XXIII), $C_{19}H_{22}O_3S$: C, 69.06; H, 6.71; S, 9.70. Found: C, 68.86; H, 6.70; S, 10.01.

The pentane was removed, 2-ethoxynapthalene (0.100 g) was added as an internal standard, and the amount of XXI was determined by g.l.p.c.; yield 0.137 g (19.9%). When the experiment was repeated, the product was formed in a 20.6% yield.

The Preparation of Some Authentic Samples

Decanophenone

This compound was prepared in 77% yield by a Friedel–Crafts reaction between decanoyl chloride and benzene, according to the procedure of Breusch and Oguzer (11); m.p. 35–36°. Reported (11) m.p. 34.4–35.4°.

Decanophenone Dimethyl Ketal

Decanophenone (70.0 g, 0.30 mole), methyl orthoformate (32.0 g, 0.30 mole), and a small amount of anhydrous *p*-toluenesulfonic acid (0.40 g) were dissolved in a mixture of 200 ml of methanol and 25 ml of diethyl ether. This mixture was left at room temperature for 3 days, after which the acid was neutralized by adding sodium methoxide. The solvent was distilled off, the residue dissolved in ether, washed with water, and dried with magnesium sulfate. The ether was removed and the residue distilled *in vacuo* to give 71.4 g (84%) of the colorless liquid; b.p. 115–118° (0.3 mm); n_D^{25} 1.4804.

Anal. Calcd. for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86. Found: C, 77.85; H, 10.95.

β-n-Octyl-α-methoxystyrene

Decanophenone dimethyl ketal (27.0 g, 0.097 mole) was stirred and heated with ammonium dihydrogen phosphate (2.0 g) at 200–210° for 45 min, under slightly reduced pressure. Initially, the pressure could be reduced only slightly because of foaming. After approximately 0.5 g the foaming ceased, probably indicating the complete removal of methanol. The liquid was distilled *in vacuo* to give 21.4 g (90%) of a 2:3 mixture of the isomeric products, b.p. 107–110° (0.2 mm); n_D^{25} 1.5035. The infrared spectrum of the neat liquid shows the olefinic double bond as a band of medium intensity at 1 641 cm^{-1}. The compound was found to have a molecular weight of 241 (osmometric); calcd. for $C_{17}H_{26}O$: molecular weight 246.4.

1-Methoxy-2-n-octyl-1-phenylcyclopropane

A crystal of iodine was added to a stirred suspension of a Zn–Cu couple (3) (7.2 g, 0.11 gram-atom) in 60 ml of anhydrous ether. As soon as the brown color had disappeared, methylene iodide (29.5 g, 0.110 mole) and an isomeric mixture of β-*n*-octyl-α-methoxystyrene (18.0 g, 0.073 mole) was added. The reaction mixture was refluxed for 13 h, after which the solid was filtered off. The ether solution was washed twice with a saturated aqueous ammonium chloride solution, twice with a saturated aqueous sodium bicarbonate solution, and finally twice with water. The residue obtained after drying and removal of the ether was distilled *in vacuo* to give 14.0 g (74%) of colorless product, b.p. 114–118° (0.3 mm); n_D^{25} 1.4926. The infrared spectrum shows a cyclopropyl ring deformation band at 1 020 cm^{-1}. The n.m.r. spectrum indicated that a small amount of β-*n*-octyl-α-methoxystyrene was still present which could not be removed by either distillation or elution chromatography on alumina. The n.m.r. spectrum showed that 1-methoxy-*cis*-2-*n*-octyl-1-phenylcyclopropane and 1-methoxy-*trans*-2-*n*-octyl-1-phenylcyclopropane were present in a ratio of 3:5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

n-Octylcyclopropane

To a suspension of a Zn–Cu couple (3) (10.6 g, 0.163 gram-atom) in 75 ml of anhydrous ether was added methylene iodide (43.7 g, 0.163 mole) and 1-decene (15.0 g, 0.107 mole), and the mixture was refluxed for 20 h. After filtration and washing with a saturated ammonium chloride solution, a saturated sodium bicarbonate solution, and water, the ether solution was dried over magnesium sulfate. Removal of the ether gave a residue that still contained a large amount of 1-decene. Enough bromine was added to convert all the 1-decene into the dibromo compound. The mixture was again dissolved in ether, washed twice with an aqueous sodium thiosulfate solution, and dried. The ether was removed and the residue distilled *in vacuo* to give 4.1 g (25%) of the product, b.p. 65–66° (5.0 mm); n_D^{25} 1.4280. A large amount of a higher boiling product, that partially decomposed, was left behind in the flask. The infrared spectrum of a neat sample of *n*-octylcyclopropane shows sharp absorption bands at 3 070 and 1 009 cm^{-1} respectively due to cyclopropyl hydrogen stretching and cyclopropyl ring deformation. The n.m.r. spectrum is described in the text.

Anal. Calcd. for $C_{11}H_{22}$: C, 85.63; H, 14.37. Found: C, 85.68; H, 14.33.

1-Phenyl-2-oxabicyclo[4.1.0]heptane (XXI)

A crystal of iodine was added to a suspension of a Zn–Cu couple (13.0 g, 0.20 mole) in 80 ml anhydrous diethyl ether. As soon as the brown color had disappeared, methylene iodide (53.6 g, 0.20 mole) and 2-phenyl-Δ^2-dihydropyran (12) (25.0 g, 0.156 mole) were added and the mixture was stirred and refluxed for 20 h. A finely divided black suspension was filtered off and the ether solution successively washed with saturated aqueous ammonium chloride, saturated aqueous sodium bicarbonate, and water. After drying and removal of the ether, a yellow-colored liquid residue was obtained, that was distilled *in vacuo* to give 19.5 g (72%) of the colorless product, b.p. 75–76° (0.25 mm); n_D^{25} 1.5487. No starting material was recovered from the reaction. The infrared and n.m.r. spectra are compatible with that required by the structure XXI.

Anal. Calcd. for $C_{12}H_{14}O$: C, 82.72; H, 8.10. Found: C, 82.44; H, 8.04.

Diethyl 3-Methoxy-3-phenyl-1,2-cyclopropanedicarboxylate

A solution of ethyl diazoacetate (5.5 g, 0.048 mole; prepared in 63% yield by the method of Searle (13); n_D^{25} 1.4616; reported (12) n_D^{25} 1.4616) in 10 ml of *n*-hexane was added dropwise, in approximately 30 min, to a refluxing solution of ethyl-*trans*-β-methoxycinnamate (6) (8.0 g, 0.039 mole) in 10 ml of *n*-hexane to which a small amount of cuprous chloride (0.25 g) had been added. A vigorous nitrogen evolution took place during the addition. Some ether was added and the solution was filtered. Upon removal of the ether a darkly colored liquid residue was obtained. A n.m.r. spectrum suggested that it contained mainly diethyl fumarate and ethyl *trans*-β-methoxycinnamate. Most of these products were removed by a vacuum distillation which yielded 1.3 g of a fraction boiling at 65–80° (1.7 mm) and 4.2 g of a fraction with b.p. 95–103° (0.3 mm). The residue (4.6 g) was chromatographed on alumina. A mixture of ethyl *trans*-β-methoxycinnamate and diethyl 3-methoxy-3-phenyl-*trans*-1,2-cyclopropanedicarboxylate was eluted with a *n*-hexane–benzene (1:1) mixture. Relatively pure diethyl 3-methoxy-3-phenyl-*trans*-1,2-cyclopropanedicarboxylate was eluted with benzene. The oil was dissolved in a small amount of *n*-hexane and cooled in a dry ice–acetone mixture. The solid thus obtained was twice recrystallized from a small amount of *n*-hexane to give an analytical sample of fine white needles, m.p. 40–41°. The total amount produced in the reaction was estimated at 1.1 g (10%).

Anal. Calcd. for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90. Found: C, 65.49; H, 6.73.

Diethyl 3-methoxy-*trans*-3-phenyl-*cis*-1,2-cyclopropanedicarboxylate (0.33 g, 3%) was eluted with a *n*-hexane – diethyl ether (1:1) mixture. A relatively pure sample was obtained when this chromatography fraction was again chromatographed on alumina. The oily material, n_D^{25} 1.505, did not solidify at room temperature. Its infrared and n.m.r. spectra indicated that it was structurally similar to the isomeric material, and that it contained no olefinic hydrogens.

Anal. Calcd. for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90. Found: C, 65.56; H, 6.89.

ACKNOWLEDGMENTS

The research described herein was supported by a National Research Council of Canada grant to R. J. Crawford. The n.m.r. and infrared spectra were measured by R. N. Swindlehurst and Mrs. Gail B. Conway of this Department.

THE LIFETIME OF THE A.$^3\Sigma_u^+$ STATE OF N_2

L. F. PHILLIPS
Chemistry Department, University of Canterbury, Christchurch, New Zealand

Received September 14, 1964

ABSTRACT

The decay of the blue emission from the active nitrogen – iodine flame has been measured at iodine pressures down to 1.4×10^{-4} torr. Extrapolation of the decay rate to zero iodine pressure yields a value of 0.89 ± 0.41 s^{-1} for the first-order rate constant in absence of iodine, corresponding to a mean lifetime of 1.1 s for the A.$^3\Sigma_u^+$ state of N_2. The rate constants for the reactions

[1] $$N + I_2 \rightarrow NI + I$$

and

[6] $$N_2(^3\Sigma_u^+) + I_2 \rightarrow N_2(^1\Sigma_g^+) + I_2^*$$

are $(2.6 \pm 0.3) \times 10^{-11} \exp(-68 \pm 34/RT)$ and $(8.3 \pm 1.2) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} respectively.

INTRODUCTION

In a recent photometric study of the reaction of iodine with active nitrogen (1) it was found that the characteristic blue reaction flame is largely the result of energy transfer to molecular iodine during collisions with a metastable species that is produced by the reaction. It was suggested that the metastable species involved is a nitrogen molecule in the A.$^3\Sigma_u^+$ state, and the present results provide further support for this identification. An alternative possibility (2), that the metastable species is a nitrogen molecule in the $^3\Delta_u$ state, appears to be ruled out by the agreement between the present results and other recent estimates of the lifetime of the A state (3, 4, 5).

It has now been shown that the decay of the iodine emission in the flame does not depend markedly on the surface area of the reaction vessel, has a negligible temperature coefficient between 15 and 50 °C, and is the same whether the intensity is measured at 2 600 Å or 4 600 Å. An error due to the use of a faulty iodine saturator in the previous work has been corrected, and the lifetime of the metastable species which is responsible for most of the iodine emission has been determined by means of a short extrapolation of the decay rate to zero iodine pressure. From the variation of the decay rate with iodine pressure an improved rate constant for deactivation of the metastable species by molecular iodine has been obtained, while from the decay of the nitrogen afterglow the rate constant for reaction [1] has been redetermined in the interval 10–50 °C.

[1] $$N + I_2 \rightarrow NI + I.$$

EXPERIMENTAL

The apparatus was essentially the same as that described previously (1), except that the length of the reaction tube was 1.5 m instead of 30 cm. Active nitrogen from a microwave discharge passed a light trap and entered one end of the 18.4 mm i.d. reaction tube. Iodine vapor, carried by a stream of argon, entered through a spherical inlet jet nearby. Photometric observations were made on the last 100 cm of the reaction tube, this part being enclosed in a black box. For observations of the ultraviolet emission a plain thin-walled pyrex tube was used; otherwise the reaction tube was water-jacketed for temperature control, although most measurements were in fact carried out at room temperature (18 °C). For several sets of measurements the surface-to-volume ratio of the tube was increased by inserting a central pyrex rod of diameter 7.9 mm. From the reaction tube the gases passed to a small rotary vacuum pump protected by a cold trap.

Flow velocities in the reaction tube were between 1 and 3 m/s at pressures between 1 and 12 torr. The velocity was usually calculated from the total gas flow and the pressure in the tube, but could also be

measured directly by determining the time required for a light front to travel the length of the reaction tube when the discharge was turned on or off. For this purpose two photomultipliers were mounted 100 cm apart with their outputs connected via a capacitance to the input of a Tektronix type 564 storage oscilloscope. The oscilloscope was triggered by the signal from a photocell placed near the discharge. The flow time was obtained from the distance on the oscilloscope screen between the differentiated signals from the photomultipliers. Velocities obtained by the two methods agreed to within 3%.

Light intensities were measured with a 1P28 photomultiplier enclosed in a box which could be slid along rails parallel to the reaction tube. The photomultiplier box was fitted with collimating windows and a holder for filters. For the iodine emission a Wratten number 50 filter (λ_{max} = 4 600 Å), or a Baird-Atomic type A11 interference filter, of 100 Å half-width at 2 600 Å, was used. For the nitrogen afterglow a Spectrolab type P interference filter of 15 Å half-width at 6 250 Å was used. At the highest iodine flows the emission could only be measured in the first 20 cm or less of the reaction tube inside the black box, while at the lowest iodine flows the decay of the blue emission was affected by the presence of unreacted nitrogen atoms except in the last 15 or 20 cm.

Analytical reagent grade iodine, welding grade dry argon ($O_2 < 5$ p.p.m.) and Matheson prepurified nitrogen ($O_2 < 8$ p.p.m.) were used. The nitrogen was dried further at −196 °C and the argon at −80 °C, although the results did not seem to be affected by failure to do this. All-glass connections were used to convey nitrogen and argon to their flowmeters. With ordinary commercial nitrogen a film of I_2O_5 formed on the walls of the reaction tube near the iodine inlet and decay rates at low iodine pressures were markedly less than usual, showing that some iodine had been removed. Since oxygen is likely to be the most serious impurity, as far as the lifetime of the A state is concerned, the ability of iodine to remove it in this way is an advantage. With prepurified nitrogen the 'pink afterglow' (6) was always present but did not extend as far as the iodine inlet.

Two different iodine saturators were used. In the first the argon stream passed down a tube containing iodine crystals at ca. 50°, through a sintered glass disc and then through a glass spiral immersed in a water bath at between 0 and 20 °C, before going to the inlet jet. The walls of the spiral were coated with iodine and the emerging argon stream was assumed to be saturated at the temperature of the water bath. The second saturator consisted simply of a vertical tube of 12 mm i.d. which contained a 15 cm depth of powdered iodine packed around the stem of a thermometer, the whole being immersed in the water bath at between 0 and 20 °C. The vapor pressure data of Gillespie and Fraser (7) were used. The two saturators gave the same results within experimental error. When the iodine from the second saturator was collected in a cold trap for a known time, extracted with KI solution, and titrated with thiosulfate, the result agreed to within 2% with that predicted from the argon flow, the saturator temperature, and the pressure in the reaction tube. (The argon flow was always so small that the pressure drop across the iodine inlet to the reaction tube could be neglected.) In the present work much lower values than those obtained previously were found for the rate constant of reaction [1] and for the decay rate of the blue emission at any given iodine pressure. In the previous work saturation of the argon stream was assumed to take place above a sintered glass disc and the partial pressure of iodine in the gas which had passed through the disc was calculated by multiplying the vapor pressure by a factor for the pressure drop across the disc. It now appears that this was wrong, and that with this type of saturator the pressure at which saturation with iodine vapor actually takes place is not well defined, but may even be closest to the pressure on the exit side of the disc. Fortunately a different type of saturator was used for the recent work with chlorine and bromine (2).

Typical partial pressures in the reaction tube were: N_2 5.0 torr, Ar 0.1 torr, and I_2 0.005 torr. Nitrogen atom concentrations were not usually determined, but would have been about 0.1 torr at the iodine inlet. As in the previous work, iodine was assumed to be present almost entirely in the form of I_2 because of the speed with which iodine atoms are able to recombine on a glass surface (8).

RESULTS

1. *Iodine Emission*

Some typical graphs of log intensity vs. time for the iodine emission are shown in Figs. 1 and 2. These particular graphs show that the decay rate is the same for the blue and ultraviolet emissions and is independent of temperature.

In Fig. 3 the apparent first-order rate constant for the decay of the iodine emission is plotted against the iodine pressure in the reaction tube. Three kinds of experimental points are distinguished: those obtained with the blue filter, those obtained with the ultraviolet filter, and those obtained with the blue filter with the surface-to-volume ratio increased by the insertion of the central glass rod. There appear to be no systematic differences between the three sets of results. Nor was there any apparent effect due to variation of the nitrogen pressure in the range 1 to 12 torr.

For personal use only.

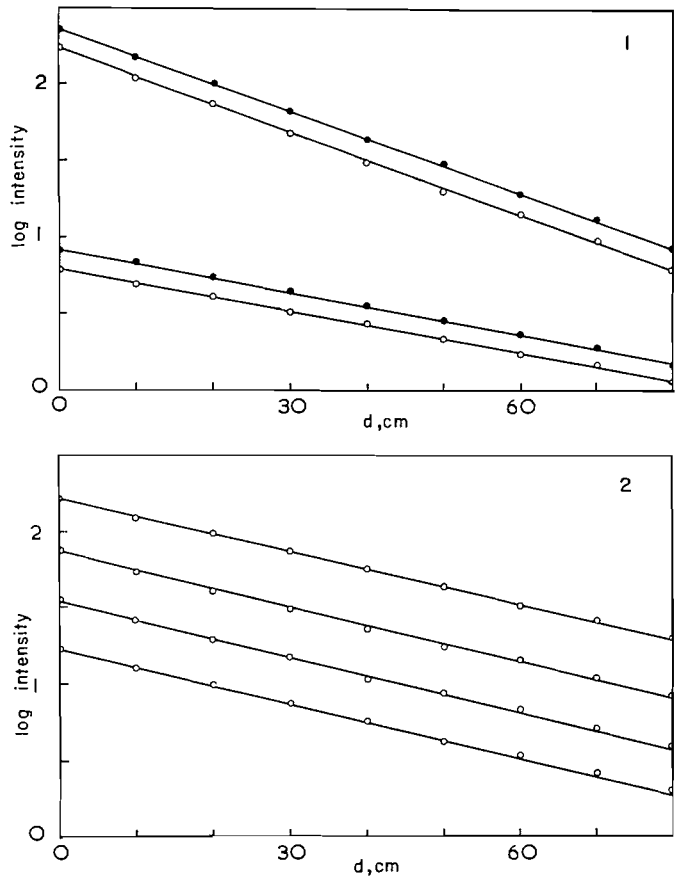

FIG. 1. Graphs of log intensity vs. time (in terms of distance along the reaction tube) for the iodine emission. ○, blue emission; ●, ultraviolet emission. Upper pair of lines 7.5 torr N_2, lower pair of lines 1.5 torr N_2.

FIG. 2. Graphs of log intensity vs. time for the iodine emission at different temperatures, at constant iodine pressure and flow velocity. Jacket temperatures, from top to bottom: 52, 38, 29, and 15 °C.

The least-squares line for the points of Fig. 3 (the regression line for $[I_2]$ in terms of k) has the equation

$$k = 0.89 + (2.72 \times 10^{-3})P_{I_2} \qquad [2]$$

so that the mean lifetime of the metastable species at zero iodine pressure is 1.1 s. The standard error of k is 0.41 s^{-1}, corresponding to an upper limit of 2.1 s and a lower limit of 0.77 s for the lifetime. The lowest observed value of k was 1.1 s^{-1}, in an experiment with impure nitrogen. The iodine pressure in this case was unknown because of formation of I_2O_5. With pure nitrogen the lowest observed value of k was 1.3 s^{-1} at an iodine pressure of 1.4×10^{-4} torr.

From eq. [2] the rate constant for deactivation of the metastable species by I_2 is $(8.3 \pm 1.2) \times 10^{-14}$ cm^3 $molecule^{-1}$ s^{-1}, where the limits of error are estimated from the possible variation of the slope of the line in Fig. 3.

2. Nitrogen Afterglow

Graphs of log intensity vs. time for the nitrogen afterglow are linear in the presence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

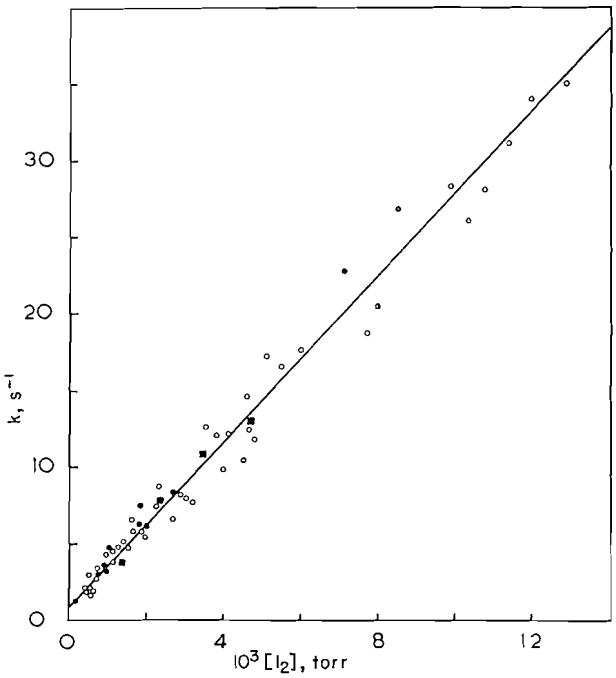

FIG. 3. Variation of the rate of decay of the iodine emission with iodine pressure. ○, blue filter; ●, ultraviolet filter; ■, blue filter with increased surface to volume ratio.

of iodine. Nitrogen atoms are believed to be removed by reaction [1], followed mainly by [3] at high atom concentrations and by [4] at low atom concentrations (1).

[3] $$N + NI \rightarrow N_2^* + I,$$

[4] $$NI + \text{wall} \rightarrow \tfrac{1}{2}N_2 + \tfrac{1}{2}I_2 + \text{wall}.$$

By the time the part of the reaction tube inside the black box is reached, the nitrogen atom concentration is expected to be so low that reaction [3] can be neglected in comparison with [4]. In all cases ordinary termolecular recombination is negligible in comparison with [1]. Results for the decay of the afterglow at low nitrogen atom concentrations are given in Table I, together with corresponding values of the rate constant for reaction [1].

The temperature coefficient of this reaction is remarkably small. In a typical experiment

the slope of the log intensity vs. time graph increased by (6 ± 3)% when the temperature of the water jacket was changed from 12 to 38 °C. Incorporation of the temperature coefficient into the results of Table I gives finally

[5] $$k_1 = 2.6 \times 10^{-14} \exp(-68/RT) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

with an estimated error of ±15% in the range 10–50 °C.

DISCUSSION

The value of 1.1 s which has been obtained for the mean lifetime of the metastable species is identical, within the experimental error, with the values of 2.0 ± 0.9 s and ca. 0.9 s found by Carleton and Oldenberg (3) and Zipf (4) respectively for the lifetime of the $A.^3\Sigma_u^+$ state of N_2. The lower values found by several previous workers (9, 10, 11) probably result either from the presence of deactivating species or from the A state molecules being in other than the ground vibrational level. (It might be expected that the nitrogen molecules produced by reaction [3] would possess vibrational as well as electronic excitation, but this does not have to be the case, as shown for example by the work of Del Greco and Kaufman (12) on the reaction of H with NO_2.)

The agreement between these lifetime values suggests very strongly that it is the A state that is produced by reaction [3], as was previously supposed. It seems unlikely that the other metastable species that might be produced by reaction [3], namely the $^3\Delta_u$ state of N_2, should have the same lifetime as the A state. If the $^3\Delta_u$ state lies above $B.^3\Pi_g$, then it should readily undergo collision-induced transitions to the B state, even if the rate of the allowed radiative transitions is low because of the ν^3 factor in the transition probability, and its lifetime should be pressure dependent and probably quite short. If, on the other hand, the $^3\Delta_u$ state lies below the B state, then the failure of spectroscopists to discover a band system analogous to the Vegard–Kaplan bands of the A state (13) would indicate that its lifetime is considerably longer than that of the A state. (It is notable that both of the possible transitions, to $A.^3\Sigma_u^+$ and $X.^1\Sigma_g^+$, are forbidden by two selection rules, and not just by one as is the case with the Vegard–Kaplan system.) The results of Kenty (14), if they do refer to the $^3\Delta_u$ state, suggest that its lifetime is several seconds even in the presence of deactivating species. Our attempts to obtain a conclusive identification of the metastable species, by observing its absorption spectrum in that of the reaction flame, have so far been unsuccessful.

We have found that reactions [1] and [6] both have very small temperature coefficients. This is not unexpected for

[6] $$N_2(^3\Sigma_u^+) + I_2 \rightarrow N_2(^1\Sigma_g^+) + I_2^*,$$

which is an energy transfer process, but reaction [1] is a simple bimolecular reaction with a rate constant 10^3 times smaller than the collision frequency, and the lack of a corresponding energy of activation indicates that the entropy of activation ($\Delta S^* = -13$ cal/mole deg) is unusually large. A factor of 50 in the rate constant can be accounted for by the loss of translational freedom on forming the activated complex; the remaining factor of 20 could be a steric factor.

REACTIONS OF AMIDES AND RELATED COMPOUNDS

I. N.M.R. (PROTON) INVESTIGATION OF *N,N*-DIMETHYLFORMAMIDE – LEWIS ACID ADDUCTS AND REMARKS ON THE RELATIVE STRENGTH OF LEWIS ACIDS[1]

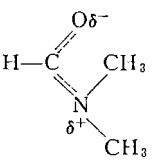
STEPHEN J. KUHN AND JOHN S. MCINTYRE
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received March 16, 1964

ABSTRACT

The proton resonance spectra of a number of Lewis acid – *N,N*-dimethylformamide adducts in 2-nitropropane and methylene chloride solutions have been investigated and an attempt has been made to correlate the relative strength of Lewis acids with the chemical shift of the methyl protons. The order obtained for the relative strength of Lewis acids shows good agreement with the results obtained by other methods. The complex formation has taken place on the carbonyl oxygen of the *N,N*-dimethylformamide in all cases. The DMF – Lewis acid mole ratios were 1:1 in $ZnCl_2$, $AlCl_3$, PF_5, $BiCl_3$, $InCl_3$, AsF_5, $SbCl_5$, SbF_5, BF_3, BCl_3, BBr_3. The 2:1 DMF – Lewis acid complexes of $ZnCl_2$, $SnCl_4$, $SnBr_4$, SnI_4, $TiCl_4$, $ZrBr_4$ have also been investigated.

INTRODUCTION

During recent years a considerable effort has been made by a number of investigators to obtain additional information about the chemical reactions and structure of carboxylic amides (1). The structure of DMF (*N,N*-dimethylformamide) has been well established by infrared and proton magnetic resonance spectroscopy (1, 2, 3). The n.m.r. spectrum shows two different kinds of methyl protons (*cis* and *trans* to carbonyl oxygen). These arise from the restricted rotation about the carbon–nitrogen bond due to its partial double bond character.



At higher temperatures the rate of rotation becomes sufficiently fast that only one type of methyl proton can be observed. The methyl peak located towards higher field has been assigned as *cis* to the aldehyde proton. Although both methyl peaks are split by the aldehyde proton (4), no definite split has been observed in the aldehyde proton but broadening indicates complex structure.

The retention of the two separate signals for the methyl protons in the n.m.r. spectra of strong acid solutions of DMF (5, 6) shows the preservation of the partial double bond character of the C—N bond and indicates oxygen coordination. The proton resonance spectrum of the $DMF \cdot BCl_3$ adduct has also shown the presence of the two chemically different methyl proton peaks (7).

The infrared spectra of *N,N*-dialkylamide complexes strongly support coordination (1, 7) at the oxygen atom. Such coordination would tend to increase the single bond character of the carbonyl group and thus shift the carbonyl stretching vibration to lower frequencies. Also, the double bond character of the C—N group would be increased, with consequent shifting of its stretching vibration to higher frequencies. If N coordination took place, the frequency shifts would be in the opposite direction to those cited

[1]*Contribution No. 108.*

above. Quite recently Cook (8) has convincingly demonstrated that protonation occurs on the carbonyl oxygen by preparing compounds from aliphatic acylhalides and tertiary amines, as shown in [1], and comparing their infrared spectra with alpihatic amide salts.

[1] 
The compounds prepared in this manner are the same as would be expected if the coordination were to take place on the N atom of the amides. Their infrared spectra show that the carbonyl stretching vibrations occur at a much higher frequency (near 1 800 cm^{-1}) than in the protonated amides.

Crystallographic studies have also shown that in complexes with metal salts the amides are bonded to the metal atom through the carbonyl oxygen (9).

In the present work a number of DMF – Lewis acid complexes have been prepared in solution and the proton resonance spectra of these compounds have been investigated.

EXPERIMENTAL

Solutions of DMF – Lewis acid adducts

(*a*) *N,N*-Dimethylformamide (0.1 mole), dissolved in 40 g of 2-nitropropane, was added in small portions to a solution of 0.1 mole of Lewis acid in 40 g of 2-nitropropane. The temperature was kept around 0 °C during the addition.

(*b*) If the Lewis acids were gases, 0.1 mole of Lewis acid gas was introduced into a solution of 0.1 mole of the amide in 80 g of 2-nitropropane.

(*c*) The $ZnCl_2$ complex was prepared by shaking a solution of 0.1 mole of dimethylformamide in 80 g of 2-nitropropane with 0.1 mole of $ZnCl_2$ until all the $ZnCl_2$ was dissolved.

(*d*) The SbF_5 salt, prepared in Freon 113, and the AsF_5 and PF_5 salt, prepared in ether, were isolated and then dissolved in 2-nitropropane.

The CH_2Cl_2 solutions were prepared in a similar manner: 0.1 mole of complex was dissolved in 80 g of CH_2Cl_2.

From $ZnCl_2$, $SnCl_4$, $SnBr_4$, $TiCl_4$, SnI_4, $ZrBr_4$, the $2DMF \cdot MX_n$ complexes have also been prepared as described above.

Nuclear Magnetic Resonance

The nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer operating at room temperature. In the series using 2-nitropropane as solvent, the chemical shifts of the methyl protons were measured relative to the second band of the nitropropane septuplet (Fig. 1), and in the series using methylene chloride, the shifts were relative to an external reference of acetonitrile (Fig. 2). These shifts were determined on the 100 cycle sweep width except in the few cases where the shift was greater than 100 c.p.s., when measurement was on the 250 cycle sweep width. The aldehyde shifts were measured relative to tetramethylsilane in both solvents.

RESULTS AND DISCUSSION

The n.m.r. results obtained in 2-nitropropane and methylene chloride solvents are summarized in Tables I and II.

The data show that the methyl protons are separated in all of the DMF – Lewis acid complexes investigated. The arguments used to substantiate O protonation in acid solutions of dimethylformamide can be used to deduce the site of coordination in DMF – Lewis acid adducts. If the coordination were to take place on the N atom of the molecule, the partial double bond character of DMF would be destroyed and the difference between the methyl protons would disappear. In coordination on the oxygen atom of the molecule, the carbon–nitrogen bond would retain its double bond character and the methyl protons

TABLE I

Proton shifts of DMF – Lewis acid complexes in 2-nitropropane

Complex	*cis* Methyl*	*trans* Methyl*	Aldehyde†
DMF	102	94	474
$ZnCl_2 \cdot 2DMF$	91	82	487
$SnI_4 \cdot 2DMF$	89	79	483
$InCl_3 \cdot 1DMF$	87	77	493
$ZnCl_2 \cdot 1DMF$	85	75	489
$ZrBr_4 \cdot 2DMF$	84	75	503
$BiCl_3 \cdot 1DMF$	82	69	507
$TiCl_4 \cdot 2DMF$	78	69	518
$SnCl_4 \cdot 2DMF$	80	69	500
$SnBr_4 \cdot 2DMF$	80	68	502
$BF_3 \cdot 1DMF$	78	68	487
$TiCl_4 \cdot 1DMF$	75	65	512
$PF_5 \cdot 1DMF$	75	64	502
$AlCl_3 \cdot 1DMF$	74	64	493
$AsF_5 \cdot 1DMF$	72	60	507
$SbF_5 \cdot 1DMF$	70	60	505
$BCl_3 \cdot 1DMF$	68	57	506
$SbCl_5 \cdot 1DMF$	68	56	519

*The shifts are in c.p.s. upfield from second peak in nitropropane septuplet. The *cis* or *trans* is with respect to aldehyde proton.
†The shifts are in c.p.s. downfield from internal tetramethylsilane.

TABLE II

Proton shifts of DMF – Lewis acid complexes in methylene chloride

$BBr_3 \cdot 1DMF$	106	113	510
$SbCl_5 \cdot 1DMF$	105	114	512

*The shifts are in c.p.s. downfield from external acetonitrile reference. The *cis* or *trans* is with respect to aldehyde proton.
†The shifts are in c.p.s. downfield from internal tetramethylsilane.

would remain separated. One can conclude from the data obtained that in DMF – Lewis acid adducts the interaction takes place on the carbonyl oxygen of the molecule.

It was anticipated that some data on the strength of Lewis acids could also be obtained by comparing the n.m.r. spectra of DMF – Lewis acid complexes. This was based on the assumption that with the individual Lewis acids the strength of the interaction with the carbonyl oxygen should be different. This interaction would affect the magnetic shielding of the methyl protons through the participation of the unshared electron pair of the nitrogen in the formation of the C=N double bond.

For the stoichiometric adducts studied no peaks were observed for the uncomplexed DMF. In the case of the $DMF \cdot BF_3$ adduct in methylene chloride solution, an excess of DMF gave two pairs of methyl signals: one pair corresponds to the methyls of the

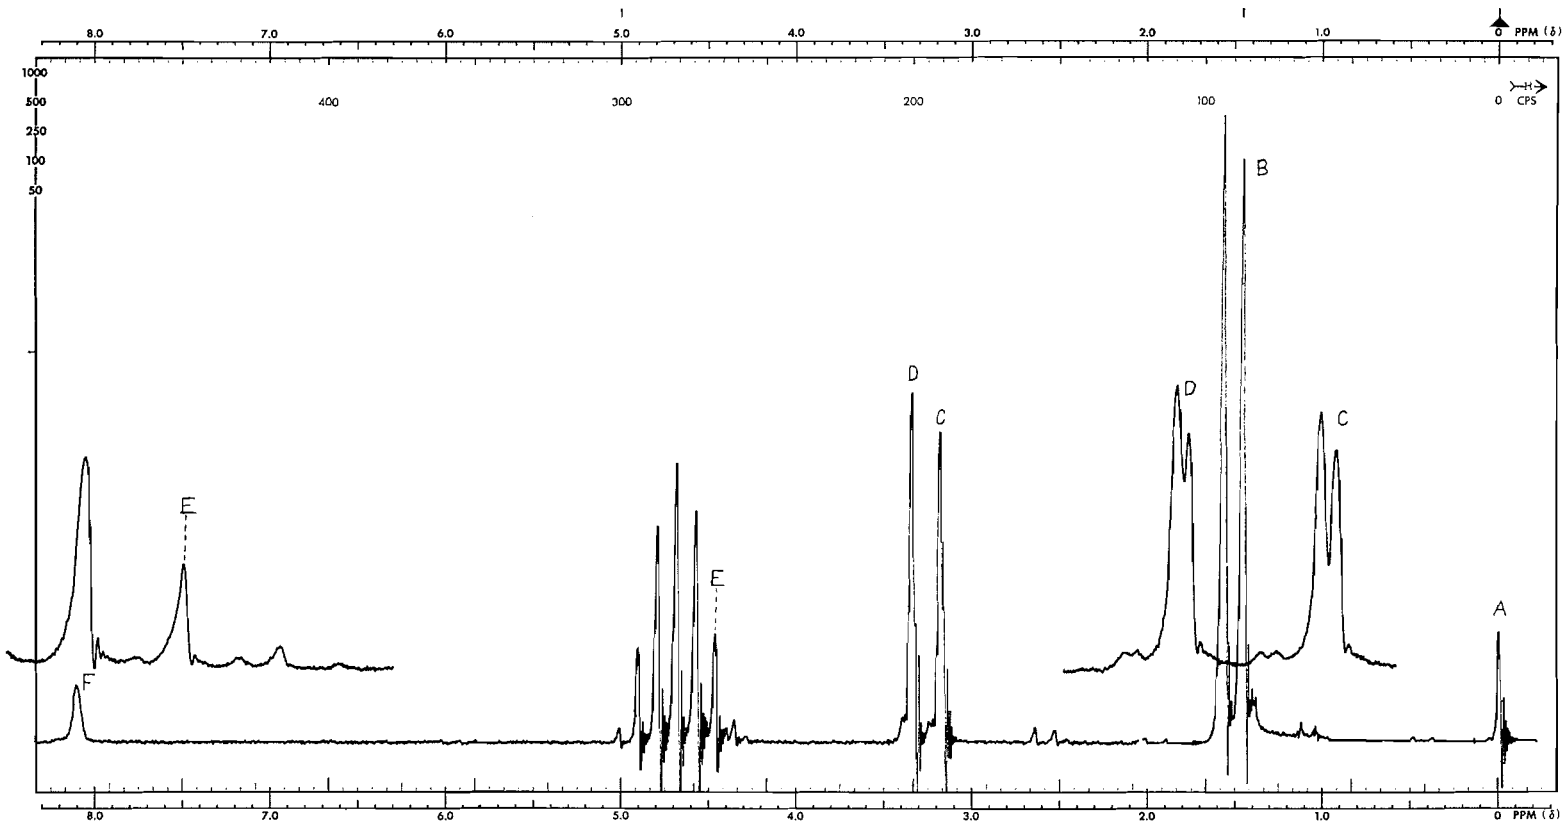

FIG. 1. The $BF_3 \cdot DMF$ complex in 2-nitropropane. The 100 and 500 c.p.s. sweep width are shown on the upper and lower spectra respectively. A, tetramethyl silane; B, 2-nitropropane doublet; C, *cis* methyl; D, *trans* methyl; E, second peak in nitropropane septuplet; F, aldehyde proton.

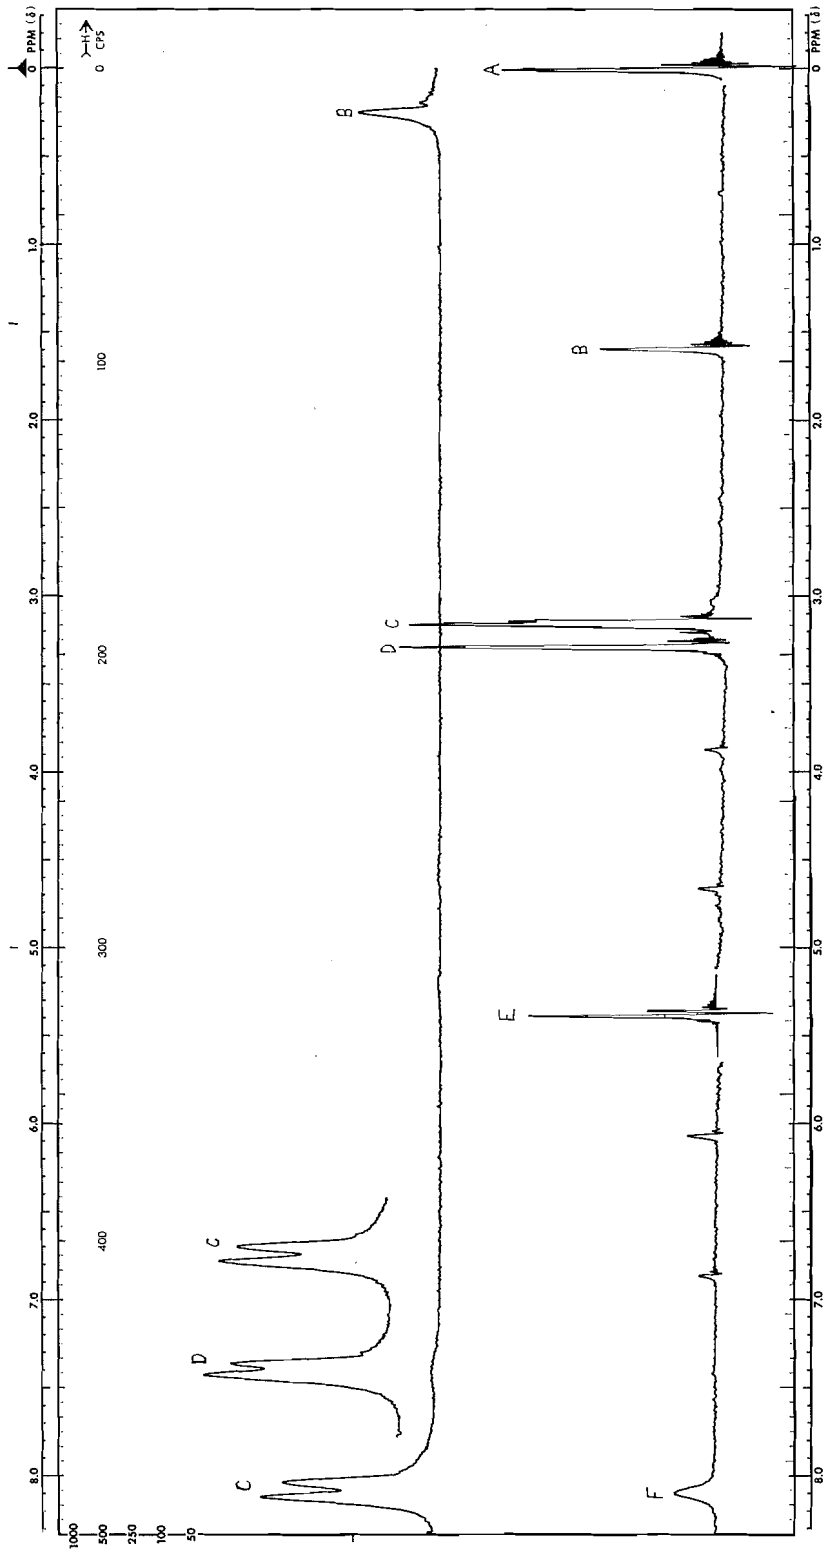

FIG. 2. The $BF_3 \cdot DMF$ complex in methylene chloride. The 100 and 500 c.p.s. sweep width are shown on the upper and lower spectra respectively. A, tetramethylsilane; B, external acetonitrile; C, *cis* methyl; D, *trans* methyl; E, methylene chloride; F, aldehyde proton.

complex and the other to the uncomplexed methyls of DMF. This shows that the equilibrium strongly favors the complex structure and allows a comparison of the Lewis acid strengths with methyl proton shifts. The relative perturbation of the stretching frequency of a carbonyl group by different Lewis acids has been used to measure Lewis acid strength: Susz and Chalandon (10) used acetophenone as a donor, Lappert (11) used ethyl acetate, and Cook (12) used xanthone. The relative order obtained for the strength of Lewis acids in this investigation shows close agreement to the order obtained by the infrared technique (Table III).

TABLE III

Comparison of Lewis acid strength* obtained by infrared and n.m.r. methods

DMF – Lewis acid† (n.m.r.)	Xanthone – Lewis acid (12) (infrared)	Acetophenone – Lewis acid (10) (infrared)	Ethylacetate – Lewis acid(11) (infrared)

$SbCl_5$			
BBr_3			

*Acid strength increases downward.
†Mole ratios in the complexes are 1:1 unless otherwise indicated.

Tables I and II also show that there is a definite difference in the methyl proton shift of complexes of $TiCl_4$, $SnCl_4$, etc. depending upon the mole ratio of $DMF \cdot MX_n$. According to these results $TiCl_4$, for example, seems to be a stronger Lewis acid in $TiCl_4 \cdot 1DMF$ complex than in $TiCl_4 \cdot 2DMF$ adducts. A number of possible structures can be written to explain this fact, but only through an X-ray investigation can the correct structure be determined.

THE RADIOLYSIS OF ETHANOL

III. LIQUID PHASE

J. J. J. Myron and G. R. Freeman
Chemistry Department, University of Alberta, Edmonton, Alberta

Received September 11, 1964

ABSTRACT

The G values of the major products of the γ-radiolysis of liquid ethanol at a dose of 2×10^{20} eV/g are: hydrogen, 4.2; acetaldehyde, 1.9; 2,3-butanediol, 2.2; $G(-C_2H_5OH) = 7.5$. At progressively lower doses $G(H_2)$ increases to a maximum of 5.0. The yield of water, $G(H_2O) = 0.5$, is equal to the sum of the yields of the C_2 fragments found in the other products.

The approximate yields of three kinetically distinguishable sources of hydrogen were found to be $G(e^-_{solv}$, free ion$) = 0.9$, $G(H) = 2.7$ and G(unscavengeable $H_2) = 1.5$. The half-life of solvated electrons with respect to reactions such as

$$e^-_{solv} \rightarrow C_2H_5O^- + H$$

is 3 μs.

Both 1,3-pentadiene and benzene inhibit hydrogen and glycol formation but neither affect the high dose yield of acetaldehyde. Pentadiene reacts with H atoms and other radicals and possibly also with e^-_{solv}. Benzene appears to inhibit hydrogen and glycol formation mainly by an unidentified activation transfer process.

INTRODUCTION

The yields of products of the γ-radiolysis of liquid ethanol that are reported in the literature show poor agreement (1–5). Values of $G(H_2)$ range from 3.7 to 5.5 and the yields of acetaldehyde and 2,3-butanediol show a similarly wide variation. The ratios of the reported yields of the products also vary greatly; for example, the value of the ratio G(acetaldehyde)/G(2,3-butanediol) has been reported to be 1.8 (3) and 0.7 (5). The discrepancies between the several sets of results are probably due partly to different experimental conditions (dose, dose rate, etc.) and partly to the presence of small amounts of impurities that act as inhibitors.

Three products, hydrogen, acetaldehyde, and 2,3-butanediol, account for 85% of the observed decomposition. Proposed mechanisms have included free radical, molecular, and ionic reactions (1–8).

The present work was done to obtain further information about the yields of the products, including water, and about the reaction mechanism.

EXPERIMENTAL

Materials

Benzene-free absolute ethanol from Reliance Chemical Company was used. The only impurity detectable by gas chromatography (g.c.) was water (0.1%). The water content was reduced to $\leqslant 0.005\%$ by treatment with sodium and diethylphthalate followed by distillation (9). The purification system was protected from atmospheric moisture. For low-dose samples ($< 1 \times 10^{20}$ eV/g), the drying was preceded by a modification of the procedure outlined by Wild (10) for the preparation of 2,4-dinitrophenylhydrazones, to remove any aldehyde present. The purified ethanol was thoroughly degassed and distilled under vacuum into a Pyrex reservoir.

Phillips Research Grade benzene was distilled, the middle third being retained and stored in the vacuum system; g.c. analysis showed no detectable hydrocarbon impurities and $<0.001\%$ water.

The 1,3-pentadiene (Columbia Organic Chemicals Company) was purified by vacuum distillation, and g.c. analysis showed it to be 95% pure.

Sample Preparation

The sample cells were cleaned with hot sulfonitric acid, rinsed several times with dilute sodium carbonate solution, then rinsed many times with doubly distilled water.

Most of the samples were 1.0–2.2 ml of liquid contained in 15 mm O.D. tubes of about 4 ml capacity.

However, for water analysis, very thin-walled spherical bulbs (capacity $\approx$ 0.5 ml) were used to contain 0.1 ml samples.

Irradiation

Co^{60} γ-irradiations were done with three different sources; the approximate dose rates were 0.9, 5, and 60×10^{18} eV/g h. The dosimetry was done with the Fricke dosimeter. Dose rates for ethanol and ethanol–inhibitor solutions were calculated using the assumption that the dose rate was proportional to the electron density of the solution. To obtain the dose rates for the 0.1 ml samples, a plot of sample volume vs. dose rate was extrapolated from 0.5 ml to 0.1 ml.

The temperature during irradiation was 25 $\pm$ 4 °C.

The ethanol–benzene solutions were given a dose of 1.5×10^{20} eV/g and the ethanol–1,3-pentadiene solutions were given 3.5×10^{20} eV/g.

Product Analysis

Gaseous products were separated into two fractions by successive distillations of the samples through traps at different temperatures (−196° and −112°). The total amount of each fraction was measured in a gas burette and each fraction was analyzed by g.c. with either a charcoal or a silica gel column.

The glycols, *sec*-butyl alcohol, and acetal were measured by g.c. using a di-*n*-decyl phthalate on Fluoropak 80 column. The glycols used were separated from each other in the following order; ethylene glycol, 1,2-propanediol, 2,3-butanediol, 1,3-propanediol, 1,3-butanediol, and 1,4-butanediol.

Acetaldehyde was determined polarographically using a 0.1 *M* aqueous lithium hydroxide supporting electrolyte solution at 0 °C. The total acetaldehyde yield was determined by adding the yields of acetaldehyde and acetal. In some samples part of the acetaldehyde reacted with ethanol to produce acetal and water. Although the amounts of acid present in the samples were less than that required to affect the radiolysis mechanism (11), only a small trace of acid is required (12) to catalyze the reaction

$$CH_3CHO + 2C_2H_5OH \rightarrow CH_3CH(OC_2H_5)_2 + H_2O.$$

Formaldehyde was analyzed by the chromotropic acid method (13).

Water analysis was effected by crushing the thin-walled bulbs directly in the carrier gas stream above the chromatographic column. After water analysis on a Carbowax 1500 on Fluoropak 80 column, the sample was led from the first detector cell *via* a heated stainless steel capillary tube to a second column (di-*n*-decyl phthalate on Fluoropak) and detector, by which the acetal yield was determined. The value of $G(H_2O)$ was obtained by subtracting the amount of acetal from the total amount of water.

RESULTS

Pure Ethanol

Gaseous Products

The yield of hydrogen decreased rapidly with increasing dose at low doses, then decreased more slowly as the dose increased above about 3×10^{19} eV/g (Fig. 1). The value of $G(H_2)$ extrapolated to zero dose was $G_i(H_2) = 5.0$. The hydrogen yield was independent of dose rate and was the same for samples that contained 0.005% or 0.2% water.

The yields of methane, carbon monoxide, ethane, ethylene, and propane are shown as a function of dose in Fig. 2. Only G(ethylene) shows an appreciable dependence on dose and dose rate (Fig. 2D). Variations in the yields of the other products with dose rate were random and were within experimental error of each other.

The initial G values of these products are given in Table I.

Liquid Products

The yields of acetaldehyde ($G = 1.9$), formaldehyde ($G = 0.13$), 2,3-butanediol ($G = 2.2$), and 1,2-propanediol ($G = 0.13$) were independent of dose over the ranges studied (Fig. 3). However, analytical difficulties prevented the measurement of liquid product yields in the dose region where the hydrogen yield increased rapidly with decreasing dose (i.e., $<10^{19}$ eV/g).

At high doses ($>5 \times 10^{20}$ eV/g) the 2,3-butanediol g.c. peak was resolved into a doublet. With the aid of authentic samples of meso- and *d,l*-2,3-butanediol[1] it was established that the doublet peak was due to approximately equal amounts of the two diasterioisomers.

[1]*We are grateful to Dr. F. A. L. Anet of the University of Ottawa for a sample of d,l-2,3-butanediol.*

TABLE I

Product yields

Product	G	Lowest dose used (10^{19} eV/g)	Dose rate (10^{18} eV/g h)
Hydrogen	5.0	0.2	0.9–60
Acetaldehyde	1.9	1.1	5–60
2,3-Butanediol	2.2	9.0	5–60
Water	0.5	58	5
Methane	0.6	0.2	0.9–60
Carbon monoxide	0.06	1.0	0.9–60
Ethane	0.24	4.0	0.9–60
Ethylene	0.14	4.0	0.9
Acetylene	$\leqslant$0.02	35	60
Propane	0.009	6.5	0.9–60
Butane	0.0004	25	5
sec-Butanol	0.08	92	5
Formaldehyde	0.13	2.2	5
Ethylene glycol	0.01	300	5
1,2-Propanediol	0.13	22	0.9–60
1,3-Propanediol	0.002	300	5
1,3-Butanediol	0.05	300	5
1,4-Butanediol	0.01	300	5

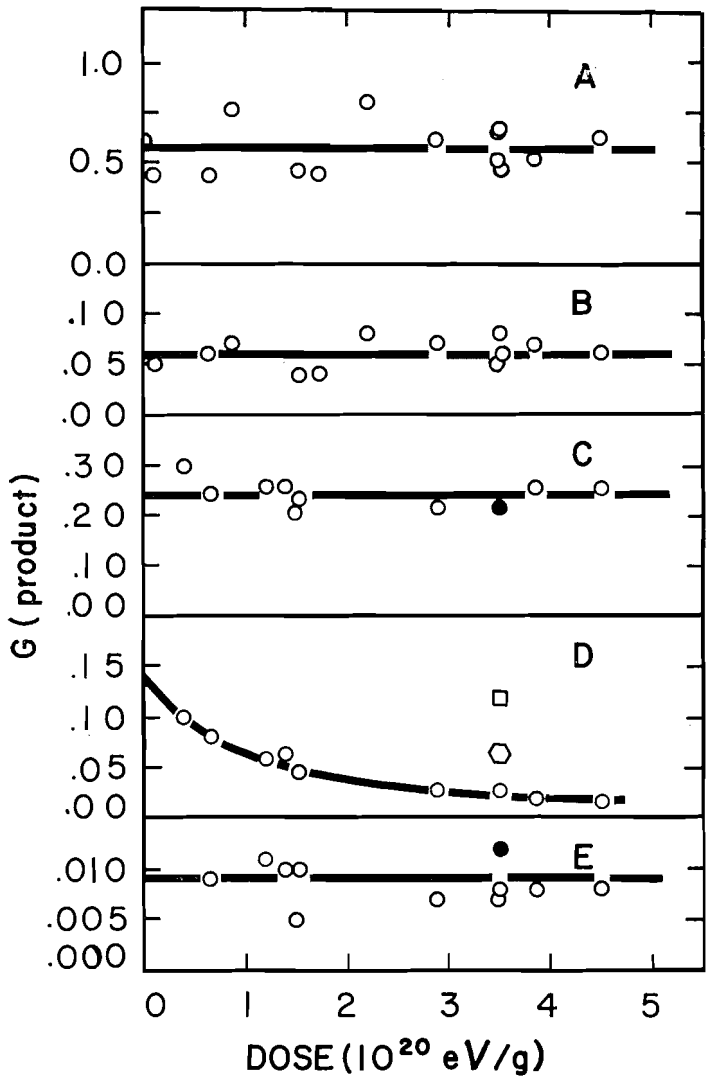

FIG. 2. Various gaseous product yields as a function of dose. A: Methane. B: Carbon monoxide. C: Ethane, ● average of four values at three different dose rates (0.9, 5, and 60 × 10^{18} eV/g h). D: Ethylene, ○ dose rate = 0.9 × 10^{18} eV/g h, ⬭ dose rate = 5 × 10^{18} eV/g h, □ dose rate = 60 × 10^{18} eV/g h (average of two values). E: Propane, ● average of two values at a dose rate of 60 × 10^{18} eV/g h.

Small yields of 1,3-butanediol, 1,4-butanediol, 1,3-propanediol, ethylene glycol, and *sec*-butanol were measured at doses greater than 10^{21} eV/g (see Table I).

The determination of the value of $G(H_2O)$ was difficult because of the hygroscopic nature of pure ethanol and because of the conversion of varying amounts of the acetaldehyde into acetal and water. For these reasons, previous values of $G(H_2O)$ from liquid phase (8) and vapor phase (13) radiolyses of ethanol were probably too high. Under the present conditions, the water yield could not be measured accurately at doses below 6×10^{20} eV/g; $G(H_2O) = 0.5$ (see Fig. 4 and Table I).

Ethanol–Inhibitor Solutions

The yields of the three major products, hydrogen, acetaldehyde, and 2,3-butanediol, are plotted as functions of the electron fraction of inhibitor, ϵ, in Figs. 5 and 6. The

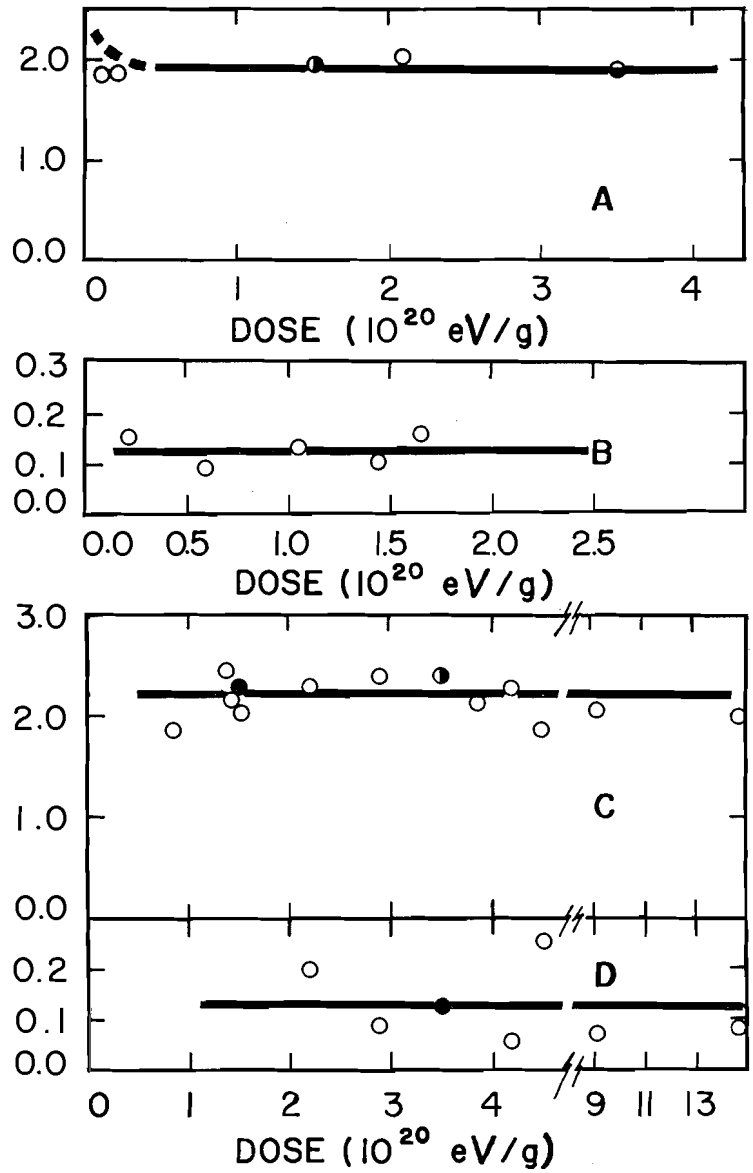

FIG. 3. Liquid product yields as a function of dose. A: Acetaldehyde, ◑ average of two values, ◒ average of three values, - - - theoretical yield. B: Formaldehyde. C: 2,3-Butanediol, ● average of two values, ◑ average of four values. D: 1,2-Propanediol, ● average of four values.

broken lines in the figures represent values of G(product) that would be expected if the radiolysis of the inhibitor and of ethanol were unaffected by the presence of each other. The most remarkable result is that both benzene and 1,3-pentadiene inhibit the formation of hydrogen and of 2,3-butanediol (Figs. 5, 6B, 6C) but neither additive appreciably inhibits the formation of acetaldehyde (Fig. 6A). Methane formation is also inhibitable by both additives (Fig. 7). Where inhibition effects occur, 1,3-pentadiene is a more efficient inhibitor than is benzene.

Three new products were measured in the pentadiene–ethanol solutions. The g.c. peaks of these products appeared in the region where C_{10} hydrocarbon peaks appeared from

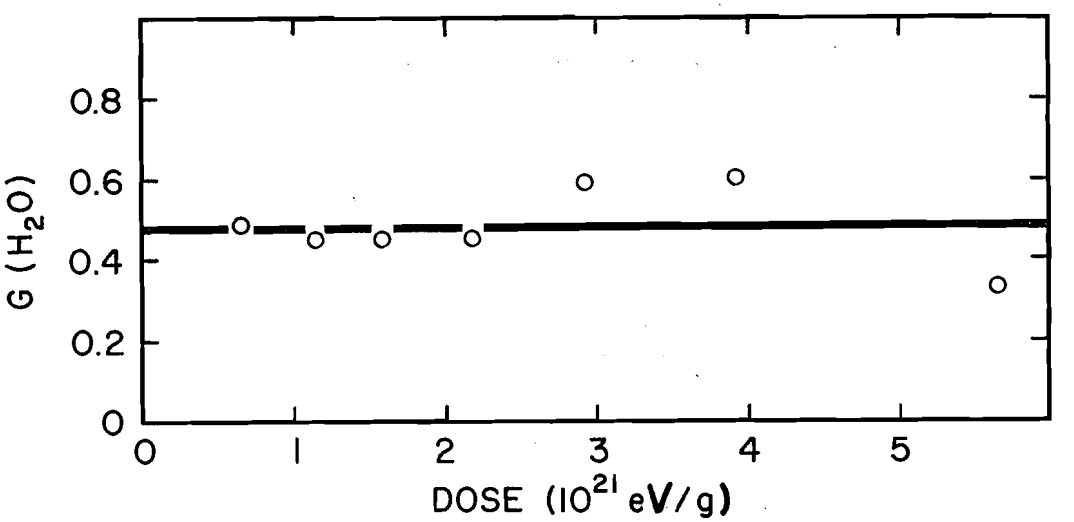

FIG. 4. Water yield as a function of dose.

the same column. The areas of the peaks are plotted against the electron fraction of 1,3-pentadiene, ϵ_p, in Fig. 8. Using a calibration factor estimated from those of other compounds that appeared in the same region, 1 area unit corresponds to a G value of 0.12 ± 0.02. Thus the maximum G value of product A (Fig. 8) was 1.8 ± 0.3, of product B was 0.5 ± 0.1, and of C was 0.7 ± 0.1. The yield of product A increased approximately linearly with increasing ϵ_p, whereas B and C passed through maxima at $\epsilon_p = 0.04$ and then decreased linearly with increasing ϵ_p.

DISCUSSION

Mass Balance

A mass balance for carbon, hydrogen, and oxygen, using product yields obtained from the graphs at a dose of 2×10^{20} eV/g, gave an empirical formula of $C_{2.00}H_{6.11}O_{1.01}$ and $G(-C_2H_6O) = 7.5$. There was a slight stoichiometric excess of hydrogen over the carbon and oxygen in the products. The excess corresponds to $G(H_2) = 0.4$.

Reaction Mechanism

The present results are consistent with many of the features of the mechanism proposed for the radiolysis of liquid ethanol by Adams and Sedgwick (4). A similar mechanism had been proposed earlier by Baxendale and Mellows for the radiolysis of methanol (14).

The main features of the overall radiolysis are: (*a*) there are three precursors of hydrogen that are distinguishable by their ease of reaction with inhibitors; (*b*) most of the butanediol is scavengeable; (*c*) the acetaldehyde produced at high doses is not scavengeable, although part of the larger yield of acetaldehyde produced at low doses is probably scavengeable.

Hydrogen

Adams and Sedgwick (4) suggested that solvated electrons and hydrogen atoms were kinetically distinguishable precursors of hydrogen and that there was also a "molecular yield" of hydrogen. The following is a refinement of their mechanism that is suggested by the present results and consideration of the yields of free ions in various kinds of liquids (15). The square brackets indicate that the entities are within a spur.

[8] $$e^-_{solv} \rightarrow CH_3CH_2O^- + H$$

[9] $$H + C_2H_5OH \rightarrow H_2 + CH_3CHOH.$$

At doses $>10^{18}$ eV/g, reactions [10] and [11] become important.

[10] $$e^-_{solv} + CH_3CHO \rightarrow CH_3CHO^-$$

[11] $$CH_3CHO^- + C_2H_5OH_2^+ \rightarrow CH_3CHOH + C_2H_5OH.$$

The mechanism does not involve excited molecules as such; however, reaction [2] is simply reaction [1] involving a more energetic precursor. Excited neutral molecule reactions cannot be excluded, but they appear to contribute less than do the ionic reactions

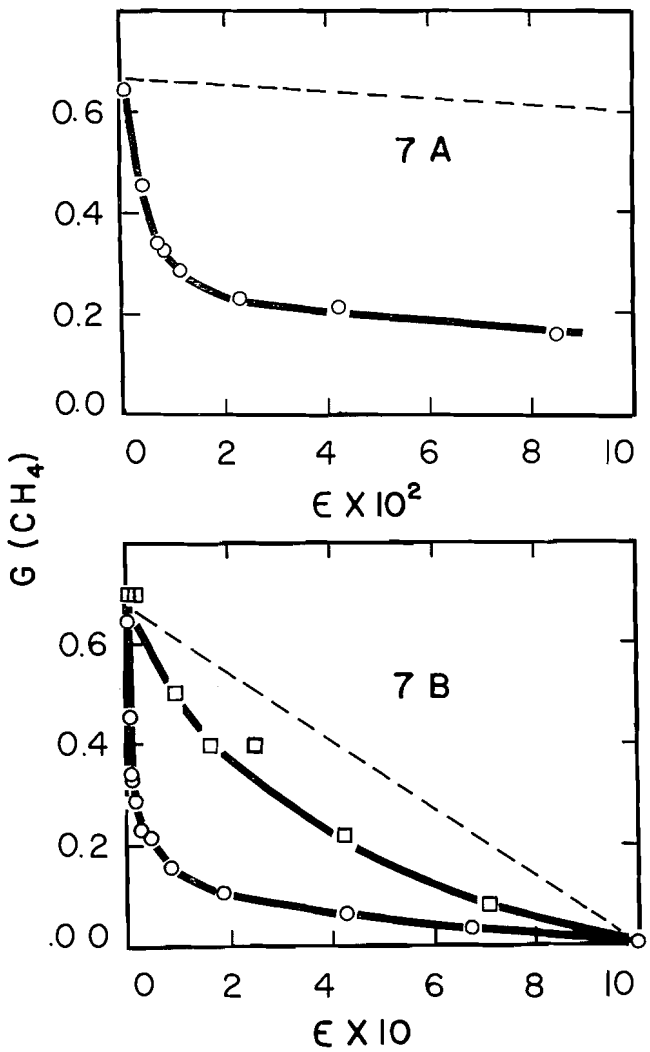

FIG. 7. Methane yield as a function of additive concentration, where ϵ = electron fraction of additive; ○ 1,3-pentadiene, □ benzene.

to the present system. The results indicate that reactions [1] and [2] occur to similar extents if G(total ionization) = 3–4.

In a mass spectrometric study of ion–molecule reactions, Ryan *et al.* (16) found that CH_3CHOH^+ was the important precursor for the formation of $CH_3CH_2OH_2^+$. Reaction [3] probably involves the shift of a hydrogen atom along a hydrogen bond in the liquid phase.

Reactions similar to [5], [6], and [7] will be discussed elsewhere (15).

An alternative to reaction [8] as a fate for the solvated electrons, e^-_{solv}, that exist as free ions in the bulk solution might be

$$[6'] \qquad e^-_{solv} + C_2H_5OH_2^+ \rightarrow nC_2H_5OH + H.$$

However, Adams and Sedgwick (4) found that reaction [6'] was not important in neutral ethanol. This conclusion is confirmed by kinetic calculations (17) involving the dose rate,

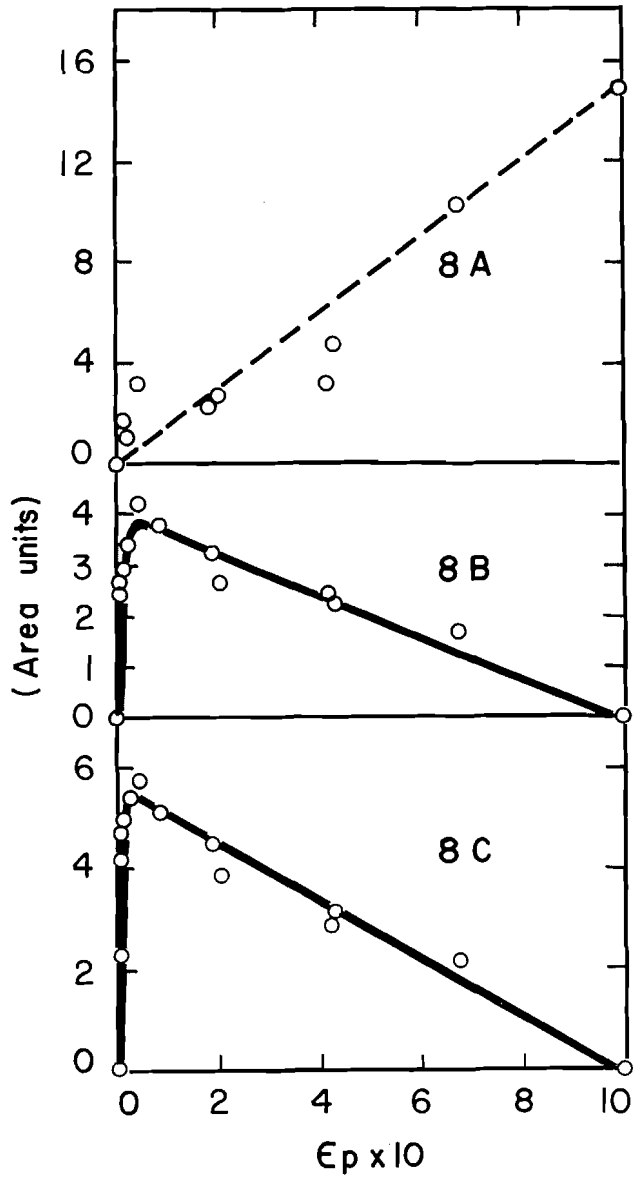

FIG. 8. C_{10} hydrocarbon products as functions of pentadiene concentration, ϵ_p. The ordinate, area units, refers to the g.c. peak area of the product. Using an estimated calibration factor, 1.0 area unit corresponds to a G value of 0.12 ± 0.02.

$G(\text{free } e^-_{solv}) = 1$, the value of the autodissociation constant of ethanol ($pK = 19.1$, ref. 18), $k_{6'} = 2.0 \times 10^{10}$ l/mole s (19*a*), $k_{10}/k_{6'} = 0.080$ (4), and the curves in Fig. 1. Briefly, the concentration of $C_2H_5OH_2^+$ from the autodissociation of ethanol (3×10^{-10} M) is more than an order of magnitude greater than that from the "free ions" generated by radiolysis. The total $[C_2H_5OH_2^+]$ is four or five orders of magnitude too small to explain the curve in Fig. 1A by a competition between reactions [10] and [6′].

The decrease in $G(H_2)$ from 5.0 to 4.2 with increasing dose can be explained by competition between reactions [8] and [10]. Thus, $G(H_2)$ is given by

[i] $$G(H_2) = 5.0 - \frac{0.8\, k_{10}\,[CH_3CHO]}{k_8 + k_{10}\,[CH_3CHO]}$$

at a particular value of $[CH_3CHO]$. Since the acetaldehyde concentration increases with increasing dose, the observed hydrogen yield at dose D is an average value:[2]

[ii] $$G(H_2)_D = \frac{1}{D}\int_0^D \left(5.0 - \frac{0.8\, k_{10}\,[CH_3CHO]}{k_8 + k_{10}\,[CH_3CHO}\right) dD$$

[iii] $$= 4.2 + \frac{0.8\ln(1+r)}{r},$$

where

[iv] $$r = k_{10}[CH_3CHO]_D/k_8,$$

and

[v] $$[CH_3CHO]_D = \int_0^D \frac{d[CH_3CHO]}{dD}\, dD.$$

The halfway point between $G(H_2) = 5.0$ and 4.2 occurs at $r = 2.6$ and $D = 1.1 \times 10^{19}$ eV/g. Equation [v] was solved graphically by assuming that $G(CH_3CHO)$ varied[3] from 2.8 to 1.9 as $G(H_2)$ varied from 5.0 to 4.2 (see later discussion). At 1.1×10^{19} eV/g, $[CH_3CHO] = 3.4 \times 10^{-4}\ M$ and

[vi] $$k_8 = k_{10} \times 3.4 \times 10^{-4}/2.6 = 2.1 \times 10^5\ s^{-1}.$$

Thus the half-life of the solvated electron in ethanol is 3.3 μs. Taub *et al.* (19*a*) measured the half-life of the solvated electron in neutral ethanol and found it to be 3 μs. They suggested that this half-life was partly due to reaction [6′]. An estimate of 4.0 μs for the half-life of the solvated electron can be obtained by combining data of Adams (4) with Taub's value of $k_{6'}$ (19*a*). It therefore appears likely that the contribution of reaction [6′] to the decay of the solvated electrons was small, even at the high dose rate in the pulse used by Taub (2×10^{23} eV/g s (19*a*)).

The value $G(e^-_{solv}) = 0.8$ is obtained from the data in Fig. 1. Adams and Sedgwick (4) reported a value of 1.02 which included a contribution of $G = 0.07$ for the reaction (transcribed into the present symbolism)

[12] $$e^-_{solv} \rightarrow C_2H_5 + OH^-.$$

Addition of this contribution to the present yield gives $G(e^-_{solv}) = 0.9$. Taub *et al.* (19*b*) reported $G(e^-_{solv}) = 1.0 \pm 0.3$. The three values are in reasonably good agreement.

The inhibition studies were done at high doses (to give measureable concentrations of liquid products) where reaction [10] was proceeding to the exclusion of reaction [8].

Pentadiene was a more effective inhibitor of hydrogen formation than was benzene in the low concentration region (Fig. 5). The shapes of the pentadiene curves in Figs. 5A and 5B indicate that there are scavengeable ($G \approx 2.7$) and unscavengeable ($G \approx 1.5$) precursors of hydrogen in addition to the solvated electrons discussed above. The results are consistent with the suggestion of Adams and Sedgwick (4) that the scavengeable precursor is atomic hydrogen (they reported $G(H) = 2.25$ and $G_m(H_2) = 1.65$). The

[2]*The following is a refinement of the treatment originally presented and was suggested by one of the referees.*

[3]*The variation in the acetaldehyde yield is expected to occur at such low doses (see Fig. 3) that the present method of analysis could not measure it. The good agreement between the two yields measured at 0.1 and 0.2 $\times$ 10^{20} eV/g is fortuitous because they were measured near the detection limit of the method.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

source of the unscavengeable hydrogen is possibly a combination of direct decomposition of ethanol to form molecular products,

[13a] $$CH_3CH_2OH^* \rightarrow CH_3CHO + H_2$$

[13b] $$\rightarrow CH_2{=}CHOH + H_2,$$

and reaction of hot hydrogen atoms generated by reactions [2] and [6].

Low concentrations of 1,3-pentadiene are roughly 20 times as efficient as benzene in inhibiting hydrogen formation and about 30 times as efficient as benzene in inhibiting methane formation. The value of the ratio of the methyl affinity of 1,3-pentadiene to that of benzene in alkane solutions is about 3 000 (20, 21) and it seems unlikely that this value would be reduced 100-fold by changing the solvent from alkane to ethanol. It therefore appears that benzene affects the product yields mainly by an activation transfer process. The activated species with which benzene interacts has several possible identities ($C_2H_5OH^+$, e^-, $[e^-_{solv}]$) among which it is not yet possible to choose. The gas phase proton affinity of benzene (6.26 eV) is much smaller than that of ethanol (8.4 eV) (22) so the species is probably not $C_2H_5OH_2^+$.

Kinetic analysis of the data according to the general mechanism[4]

[14] $$h \rightarrow \text{hydrogen}$$

[15] $$h + C_6H_6 \rightarrow \text{no hydrogen}$$

gave $k_{15}/k_{14} = 0.54$ l/mole. Other values obtained for this rate constant ratio are 0.58 for methylcyclohexane–benzene solutions (23), 0.78 for cyclohexane–benzene (24), 0.54 for cyclohexane–cyclohexene (25), 0.2 for cyclohexanone–benzene (26), and 0.2 for cyclohexene–benzene (27).

Acetaldehyde and 2,3-Butanediol

Acetaldehyde is formed by reactions [4] and [13], and both acetaldehyde and butanediol are products of reactions such as [16]–[18].

[16] $$2CH_3CHOH \rightarrow (CH_3CHOH)_2$$

[17a] $$CH_3CHOH + CH_3CH_2O \rightarrow CH_3CHO + CH_3CH_2OH$$

[17b] $$\rightarrow CH_3CH(OH)OCH_2CH_3 \text{ (hemiacetal)}$$

[18] $$2CH_3CH_2O \rightarrow CH_3CHO + CH_3CH_2OH$$

The hemiacetal from reaction [17*b*] is equivalent to acetaldehyde in the present analytical system.

Pentadiene inhibited the formation of butanediol but not the net rate of formation of acetaldehyde at the high dose used. Hayon and Weiss (3) found G(acetaldehyde) = 3.1 at a low dose (1×10^{17} eV/g), which is higher than the value found at doses in the vicinity of 10^{20} eV/g. Although reported product yields vary too much to confidently draw conclusions from differences between them, the present work indicates that a high acetaldehyde yield ($G \approx 2.8$) would be found in neutral ethanol at low doses. At high doses, solvated electrons destroy 0.9 units of the aldehyde. Since the high dose yield of aldehyde is not inhibited by pentadiene, either (i) the diene reacts both with free radicals that generate aldehyde in the bulk solution and with the solvated electrons that exist as free ions, or (ii) if the diene does not react with solvated electrons, reactions [17] and [18] occur mainly in the spurs. It appears that (i) is more likely because reaction [16] occurs mainly in the bulk medium and is readily inhibitable by the diene. It is improbable that reaction [16] would occur mainly in the bulk solution if reactions [17] and [18] occurred mainly in the spurs.

[4]*Unknown hydrogen precursors are symbolized by h.*

Methane

The results from the pentadiene solutions (Fig. 7) show that about 70% of the methane is scavengeable. Methyl radicals are probably the precursors of the scavengeable methane.

Ethane, Ethylene, and Water

Ethane is probably formed by the reaction

[19] $$C_2H_5 + C_2H_5OH \rightarrow C_2H_6 + CH_3CHOH.$$

Ethyl radicals have been detected in photolyzed solid ethanol by electron spin resonance spectroscopy (28). Possible sources of ethyl radicals in the radiolysis are reactions [12] and

[20] $$C_2H_5OH^* \rightarrow C_2H_5 + OH$$

[21] $$e^-_{solv} + C_2H_5OH_2^+ \rightarrow C_2H_5 + H_2O.$$

Ethylene may be formed by

[22] $$CH_3CH_2OH^* \rightarrow C_2H_4 + H_2O.$$

Some ethane and ethylene might also be formed by the disproportionation of ethyl radicals with other radicals.

The decrease in G(ethylene) with increasing dose can be ascribed to the reaction

[23] $$R + C_2H_4 \rightarrow RC_2H_4\cdot.$$

The average lifetime of the radicals with respect to radical–radical reactions decreases with increasing dose rate, so the dose dependence of the ethylene yield decreases with increasing dose rate.

Water can be formed by reactions [21] and [22] and by

[24] $$OH + C_2H_5OH \rightarrow H_2O + CH_3CHOH$$

[25] $$OH^- + C_2H_5OH_2^+ \rightarrow H_2O + C_2H_5OH.$$

The water yield ($G = 0.5$) equals the sum of the C_2 hydrocarbon fragments found in the other products:

$$G(C_2H_6 + C_2H_4 + C_2H_2 + C_3H_8 + C_4H_9OH + 2C_4H_{10}) = 0.48.$$

C_{10} Hydrocarbons from the Pentadiene Solutions

The maximum yield of two of the C_{10} products occurs at $\epsilon_p = 0.04$ (Figs. 8B and 8C). The hydrogen atoms are essentially completely scavenged at the same diene concentration (Fig. 5A). It appears that these C_{10} compounds are formed by the reactions

[26] $$H + CH_2{=}CH{-}CH{=}CH{-}CH_3 \rightarrow CH_3{-}\overset{\displaystyle I}{CH\cdots CH\cdots CH}{-}CH_3$$

[27] $$2I \rightarrow C_{10} \text{ isomers}$$

There is evidence that allylic radicals do not disproportionate to an appreciable extent (26). Thus,

$$G(H) \approx 2G(C_{10}) \approx 2.4 \pm 0.4,$$

where $G(C_{10})$ refers to the maximum yield of the compounds represented in Figs. 8B and 8C. This value is in good agreement with the estimates of G(H) mentioned earlier.

The C_{10} hydrocarbon represented in Fig. 8A is apparently a product of the direct radiolysis of pentadiene.

The products of reactions such as

[28] $$CH_3CHOH + C_5H_8 \rightarrow \cdot C_7H_{12}OH$$

[29] $$2 \cdot C_7H_{12}OH \rightarrow (C_7H_{12}OH)_2$$

would not have been observed with the present analytical system.

For personal use only.

Free Radicals and Glycol Formation

The ratio of $CH_3CHOH:CH_2CH_2OH$ radicals contained in the glycols is 69:1. These figures roughly reflect the relative ease of abstraction of hydrogen from the α- and β-carbons in ethanol. If this difference is attributed to the difference in the activation energies of the two abstraction reactions, then $\Delta E = 2.7$ kcal/mole. This is similar to the value $(E_{31} - E_{30}) = 2.0$ kcal/mole (29) found for the reactions

[30] $$CH_3 + C_3H_8 \rightarrow CH_4 + CH_3CHCH_3$$

[31] $$\rightarrow CH_4 + CH_2CH_2CH_3.$$

ACKNOWLEDGMENTS

This work received financial assistance from the National Research Council.

NOTE ADDED IN PROOF:

G. Dobson and L. I. Grossweiner (Radiation Res. **23**, 290 (1964)) have recently photolyzed potassium iodide in ethanol solution, and their results indicate that the solvated electrons so produced have a half-life of 21 μs. The difference between this half-life and those reported in the present paper might be due to the difference in reaction conditions, although the size of the difference is surprising.

F. S. Dainton, J. P. Keene, T. J. Kemp, G. A. Salmon and J. Teply (Proc. Chem. Soc. 265 (1964) found a half-life of 1.9 μs for solvated electrons in methanol at 20°. This is in general agreement with the present results.

PAPER CHROMATOGRAPHY OF SOME AMINE HYDROCHLORIDES AND ACETATES IN ACIDIC SOLVENT SYSTEMS[1]

R. A. B. BANNARD AND A. A. CASSELMAN
Defence Chemical Biological and Radiation Laboratories, Ottawa, Canada

Received September 4, 1964

ABSTRACT

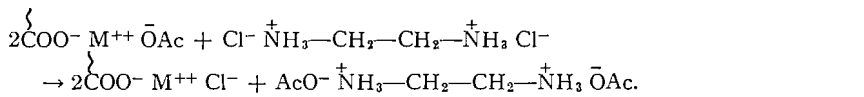
The chromatography of piperidine, cyclohexylamine, benzylamine, and morpholine hydrochlorides on unwashed Whatman No. 1 and No. 17 papers in *t*-butanol : acetic acid : water (2:1:1) leads in each case to partial conversion to the acetate salt, the mobility of which differs from that of the hydrochloride. The interconversion is reduced but is not prevented by the use of acid-washed papers and is increased again when the acid-washed papers are treated with sodium, potassium, calcium, or magnesium acetate prior to chromatography. The salt interconversion is continuous during development of the chromatograms, extended development leading to complete disappearance of the hydrochloride. Quantitative chromatography of piperidine and morpholine hydrochlorides revealed that the extent of salt interconversion is ca. 12% on unwashed and calcium ion washed Whatman No. 17 papers, ca. 6% on sodium ion washed papers, and ca. 1% on acid-washed papers. Piperidinium ions become bound to unwashed, acid-washed, and salt-washed Whatman No. 17 papers during chromatography in aqueous solution just as they do to the hydrogen, sodium, and calcium forms of the carboxylate ion exchanger Amberlite IRC-50 under similar conditions, indicating that a cation exchange mechanism involving carboxyl groups in the paper is responsible for the observed salt interconversion.

The chromatography of ethylenediamine dihydrochloride on unwashed Whatman No. 17 paper in *t*-butanol : acetic acid : water (2:1:1) gave two ninhydrin-positive bands, R_F 0.28 and 0.51, which were identified as ethylenediamine dihydrochloride (98%) and diacetate (1%) respectively (1). The multiple zoning was not observed on papers which had been deashed by acid washing but reappeared if acid-washed papers were treated with a solution of an alkaline earth metal prior to chromatography. The chromatography of ethylenediamine diacetate on unwashed or acid-washed Whatman No. 17 paper in *t*-butanol : 0.5% hydrochloric acid (3:1), on the other hand, led to quantitative conversion to the dihydrochloride due to displacement of the weak acid in the substrate by the strong acid in the solvent system.

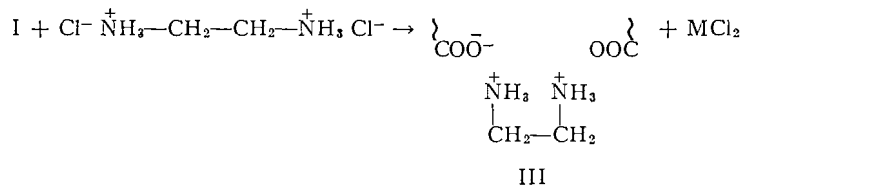
There are numerous examples in the literature in which ion exchange properties have been attributed to paper by virtue of the carboxyl groups contained in the cellulose (e.g. refs. 2–7) and in fact ion exchange processes generally form the basis for estimation of the carboxylic content of paper (e.g. refs. 8–10). Two possible ion exchange mechanisms involving carboxylic acid groups and alkaline earth metal ash constituents (11) in the papers were therefore proposed (1) to account for the observed dihydrochloride to diacetate conversion on the unwashed paper. Both mechanisms were consistent with the experimental facts but it was not possible to distinguish between them from the data at hand. In the first mechanism (which is subsequently referred to as the acetolysis – anion exchange mechanism) it was suggested that the carboxylate salt I could be converted to the mixed salt II by partial acetolysis under the influence of the solvent system. Sites of the latter type could then readily effect the observed interconversion by anion exchange. Alternatively, the dicarboxylate salt I could undergo direct cation exchange with the ethylenediammonium ion, with formation of III and liberation of the alkaline earth metal cation (M^{++}). A second cation exchange with the protons of the acidic solvent would

[1]*Issued as DCBRL Report No. 449.*

I II



free the ethylenediammonium cation again for combination with the acetate ion in the solvent. This reaction sequence is subsequently referred to as the cation exchange mechanism.



III

If ion exchange is responsible for the salt interconversion there appeared to be no reason why monoacid base hydrochlorides should not exhibit analogous behavior. Furthermore, if the acetolysis – anion exchange mechanism is operating, it should be possible to prevent the exchange reaction by replacing the divalent cationic impurity in the paper with a monovalent alkali metal. On the other hand, the cation exchange mechanism should be capable of functioning in the presence of either an alkali metal or an alkaline earth metal, although there could be a considerable difference in the extent of conversion because of the difference in ion exchange potential between these cations (12). If the cation exchange mechanism is valid, the aminium ions undergoing exchange should become temporarily bound to the carboxyl groups of the paper, accompanied by a release of cations from the binding groups; two conditions which do not obtain for the alternative mechanism. It seemed of interest, therefore, to examine the validity of these mechanisms by determining the qualitative and quantitative paper chromatographic behavior of some monofunctional amine hydrochlorides and acetates in both of the solvent systems mentioned earlier, using unwashed, acid-washed, and salt-washed papers.

Chromatography of each amine hydrochloride shown in Table I on unwashed Whatman No. 1 and No. 17 paper in *t*-butanol : acetic acid : water (2:1:1) gave two ninhydrin-positive spots, the faster moving of which is identical in R_F with the single spot resulting from similar chromatography of the corresponding acetate (Table II). Thus, the double-spotting phenomenon observed with ethylenediamine dihydrochloride in this solvent system (1) is quite general for monoacid bases and in each case examined the acetate salt has the higher R_F. Similar experiments conducted in *t*-butanol : 0.5% hydrochloric acid (3:1) demonstrated that only one ninhydrin-positive spot is obtained regardless of whether the amine hydrochloride or acetate is used. It is therefore concluded that, as in the case of ethylenediamine (1), acetate salts of monoacid bases are converted to hydrochlorides by simple acid displacement in this strongly acidic solvent system. This conclusion was readily confirmed since the quantitative chromatography of piperidine and morpholine acetates on Whatman No. 17 paper under these conditions led to recovery of the respective hydrochlorides in 97.5% and 97.0% yields.

The R_F values shown in Table II were not changed significantly when acid-washed or salt-washed papers were used. However, in contrast to the results reported for ethylenediamine dihydrochloride (1) and clam poison dihydrochloride (13) the use of acid-washed papers did not eliminate the double spotting from chromatograms of these base hydrochlorides in the acetic acid solvent system, although the extent of acetate formation was greatly reduced by the use of acid-washed papers and restored by the use of salt-washed papers, judging from the areas of the ninhydrin-positive spots. These observations confirmed that the presence of metallic ions in the paper does have an important influence on the degree of interconversion. During the chromatography of the amine hydrochlorides on unwashed paper (both No. 1 and No. 17) in the acetic acid system, silver nitrate reagent revealed the majority of the chloride ion to be coincident with the slower-moving, ninhydrin-positive spot, but there was also a diffuse chloride ion tail. It was concluded that the aminium ion and chloride ion migrate as an ion pair (cf. ref. 1) and that the diffuse tail represents chloride ion which has been released during the salt interconversion. It was found by the use of the lanthanum nitrate reagent that the acetate ion is coincident with the faster-moving, ninhydrin-positive spot. Furthermore, a diffuse ninhydrin- and acetate-positive tail extended from the faster- to the slower-moving ninhydrin-positive spot. These results were considered indicative that the aminium ion and acetate ion also migrate as an ion pair and that the interconversion is continuous during chromatographic development. That the interconversion is indeed continuous was demonstrated by prolonged chromatography of the piperidine and morpholine salts on unwashed Whatman No. 17 paper in the acetic acid solvent system, under which conditions the area of the acetate spot gradually increased with increasing time of development at the expense of the hydrochloride spot, until the latter disappeared entirely.

Piperidine and morpholine hydrochlorides were also chromatographed quantitatively on unwashed, acid-washed (0.01 *N* HCl), and salt-washed (0.01 *N* HCl, Na^+ and Ca^{++}) papers in *t*-butanol : acetic acid : water (2:1:1). Since the qualitative experiments had indicated the slower-moving hydrochloride spot to contain acetate as well, the entire ninhydrin-positive area was recovered by aqueous elution and the respective hydrochlorides and acetates were isolated by fractional sublimation *in vacuo*. From the results given in Table III it is clear that on unwashed paper 11–12% of the hydrochlorides are converted to the acetates and that the conversion is decreased by an order of magnitude when acid-washed paper is used. Thus, the extent of conversion is independent of the strength of the base, within the range of basicities examined (14). It is also evident that the conversion on calcium ion washed paper is identical with that on unwashed paper and that sodium ion washed paper is only about half as effective as calcium ion washed paper in promoting the conversion. It thus appears that alkaline earth metal impurities are more important in the conversions on unwashed papers than are alkali metal impurities. The fact that sodium ion washed papers are capable of effecting significant conversions of monoacid base hydrochlorides to acetates suggests that the cation exchange mechanism is more probable than the acetolysis – anion exchange mechanism. The much greater conversion observed on the calcium ion washed papers was unexpected, since although the ability of one cation to displace another from a carboxylic exchanger (the exchange potential) normally increases with increasing atomic number and with increasing valence (12, 15), when the ease of displacement of divalent and monovalent cations from the carboxylate group by another monovalent ion (e.g. an aminium ion) is considered, the latter are generally much more readily displaced than the former (cf. refs. 12 and 16 and the experiments with Amberlite IRC-50 resin mentioned below). That this reversal of the normal exchange potential seems general for cellulosic carboxyl groups

is shown in experiments described later on the aqueous chromatography of piperidine hydrochloride on the variously treated papers.

The occurrence of a small amount of hydrochloride to acetate conversion on the acid-washed paper was unexpected because this phenomenon had not been observed with the diacid base hydrochlorides and because of the exceedingly high affinity of the carboxylate group in resinous carboxylic exchangers (12) for protons in the presence of neutral salts such as alkali and alkaline earth metal chlorides. However, the study of methods for the estimation of carboxyl groups in paper (4–10) has revealed that protons bound to such groups will exchange to a small extent due to the equilibrium reaction

$$\text{[1]} \qquad \text{COOH} + \text{M}^+ \rightarrow \text{COO}^- \text{M}^+ + \text{H}^+$$

which is kept well shifted in favor of the undissociated acid unless the protons freed in the exchange are continuously removed (17). Thus, the fact that a small but measurable conversion is observed with monoacid base hydrochlorides during chromatography is consistent with an ion exchange mechanism. The apparent failure of ethylenediamine dihydrochloride to yield the diacetate under similar conditions is readily explicable when differences in the extent of conversion of the mono- and di-acid bases on unwashed paper are considered. Calculation of the probable concentration (10 γ/in.^{2}) of ethylenediamine diacetate produced by exchange from the dihydrochloride revealed that it would have been insufficient for detection by the ninhydrin reagent. This interpretation does not explain why the extent of exchange with ethylenediamine dihydrochloride is so much lower than that observed with the monoacid base hydrochlorides and no firm explanation can be offered at this time. However, the presence of a third ninhydrin positive spot corresponding to a mixed salt (e.g. ethylenediamine monohydrochloride monoacetate) or a mixture of ethylenediamine dihydrochloride and diacetate has never been observed on chromatograms on unwashed paper. Moreover, the recovery in these experiments of 98% dihydrochloride and 1% diacetate virtually excludes the possibility of the presence of mixed salt or salt mixtures. The suggestion is offered, therefore, that conversion of the diacid base dihydrochloride to diacetate may require simultaneous exchange at the two aminium ions. Such a requirement would clearly reduce markedly the extent of the phenomenon because the chances of obtaining simultaneous collisions between the reactive centers would depend on the distribution of carboxylic sites in the paper relative to the geometry of the aminium ions, a condition which would not need to be satisfied for the monoacid bases.

Evidence in support of the cation exchange mechanism was sought by experiments designed to show that a portion of the piperidinium ion remains bound to the variously treated Whatman No. 17 papers during chromatography. Since the much greater affinity of carboxyl groups for protons than for aminium ions would render the retention of the latter by carboxylate groups in the paper very small in the acidic solvent normally employed, water was used as the developing solvent. Piperidine hydrochloride was applied to strips of the variously pretreated papers as for normal descending chromatography and was eluted with freshly boiled, distilled water until no further salt could be extracted. The strips were then eluted with carbon dioxide – saturated water to displace any piperidinium ion which had remained bound to the papers and the latter was converted to piperidine hydrochloride for recovery by sublimation *in vacuo*.[2] It is quite

[2]*In experiments in which unwashed or calcium ion washed papers were used, it was necessary to basify the eluate and extract with ether prior to regeneration of the hydrochloride to effect quantitative recovery, due presumably to complex formation between the amine and calcium chloride (18).*

TABLE III

Hydrochloride to acetate conversion in *t*-butanol : acetic acid : water (2:1:1) on Whatman No. 17 paper

Hydrochloride applied	Weight applied (mg)	Type of paper	Acetate recovered (mg)	Hydrochloride recovered (mg)	% recovered	% conversion to acetate
Piperidine	1 000	Unwashed	133	798	96.4	12.1
	500	Acid washed (0.01 *N* HCl)	6.0	451	96.6	1.1
	500	Salt washed (0.01 *N* HCl, Na^+)	36.8	434	98.5	6.7
	400	Salt washed (0.01 *N* HCl, Ca^{++})	51.0	323	96.8	11.7
Morpholine	500	Unwashed	60.5	411	97.8	11.1
	500	Acid washed (0.01 *N* HCl)	5.4	462	98.8	1.0
	500	Salt washed (0.01 *N* HCl, Na^+)	32.0	438	98.7	5.8
	500	Salt washed (0.01 *N* HCl, Ca^{++})	61.6	406	97.2	11.4

clear from the results shown in Table IV that a significant quantity of the aminium ion remains bound to each of the papers. Furthermore, the quantity of aminium ion bound parallels the extent of hydrochloride to acetate conversion observed during chromatography on the same papers in the acetic acid solvent system (Table III) when the results from the binding experiments are calculated on the basis of an 18 × 22 in. sheet of paper (Table IV, column 5). Thus, the greater ease of displacement of calcium than of sodium ion from the cellulosic carboxylates noted in the acidic solvent system is also observed during aqueous chromatography. The amount of piperidinium ion bound during aqueous chromatography of piperidine hydrochloride on a column prepared from mechanically dispersed acid-washed Whatman No. 17 paper was an order of magnitude greater than that bound by the same weight of this paper in strip chromatograms. This result strongly suggests that many of the exchange sites in the paper are made less accessible during the sheeting process.

TABLE IV

Aqueous chromatography of piperidine hydrochloride on Whatman No. 17 paper

Paper pretreatment	Salt bound (meq)	Ion liberated (meq)	% salt bound	% salt bound (18 × 22 in. sheet basis)
Unwashed	0.070	0.140 Ca^{++} 0.112 Na^{+}	2.8	11.2
Acid washed	0.021	0.031 H^{+}	0.8	3.2
Sodium ion washed	0.041	0.102 Na^{+}	1.7	6.8
Calcium ion washed	0.076	0.170 Ca^{++}	3.1	12.4

For comparison with the results mentioned above, the behavior of piperidine hydrochloride during aqueous chromatography on the hydrogen, sodium, and calcium forms of the carboxylic cation exchanger Amberlite IRC-50 was also examined, and the unbound and bound salt was recovered as mentioned earlier. It is evident from Table V that a significant amount of piperidinium ion exchanges with the protons of the carboxyl groups and that, as anticipated, much more exchange occurs with the calcium and sodium forms of the resin. As predicted from the cation exchange potential series (12, 15), sodium ion is much more readily displaced from the resin than is calcium ion. These results contrast sharply with those given in Tables III and IV for chromatography of amine hydrochlorides on the variously pretreated papers.

That ion exchange involving carboxyl groups is indeed involved in the binding of piperidinium ions to acid-washed papers as well as to the hydrogen form of Amberlite IRC-50 appears certain since during both processes the pH of the effluent at first fell abruptly, indicating the liberation of protons in agreement with eq. [1], then slowly increased to a pH more alkaline than that of the water used for elution, signifying the anticipated slow hydrolysis of the salt of a weak acid and a weak base formed during the cation exchange. Only the cation exchange mechanism could lead to the observed binding of piperidinium ions to acid-washed paper since this paper would be virtually free of the divalent metallic impurity required for intervention of the acetolysis – anion exchange mechanism. That cation exchange is also involved on unwashed, sodium ion washed, and calcium ion washed papers is supported by the concomitant liberation of metal ions and the binding of piperidinium ions during the experiments on the chromatography of piperidine hydrochloride in aqueous solution which are summarized in Table IV. It is, therefore, concluded that the cation exchange mechanism is the only one which receives

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

support from the quantitative data available. The reversal of exchange potential observed for sodium and calcium ions on cellulosic carboxyl groups does not invalidate the conclusion reached regarding the mechanism of the salt interconversion since numerous examples of such behavior are known (ref. 16, p. 57).

TABLE V

Aqueous chromatography of piperidine hydrochloride on Amberlite IRC-50 resin

Form of resin	Recovery from aqueous elution (mg)	Recovery from acid elution (mg)	Total recovery (%)	% bound to resin
H^+	228	12.0	98.4	4.9
Na^+	42.0	196	97.6	80.4
Ca^{++}	192	45.6	97.6	18.7

As a result of these studies the following practical considerations should be borne in mind during the paper chromatography of amine salts. It is essential not to use a solvent which contains an acid weaker than that in the salt if double zoning is to be prevented. A solvent system which contains an acid much stronger than that present in the salt will cause complete conversion to the salt of the stronger acid, but the minimal difference in acid strength necessary to produce this effect has not been delineated. It is, therefore, highly desirable to use a solvent system which contains the same acid as is present in the salt if complications are to be avoided.

EXPERIMENTAL[3,4]

Preparation of Amine Salts

The amine hydrochlorides and acetates were prepared by dropwise addition of a solution of the appropriate acid (0.12 mole) in ether or acetone to a stirred cold (0°) solution of the amine (0.10 mole) in the same solvent. The reaction mixture was allowed to come to room temperature and was evaporated to dryness *in vacuo* and the resultant solid was purified by recrystallization from a suitable solvent. Analytical and pertinent experimental data for these compounds are given in Table I.

Pretreatment of Papers for Chromatography

The Whatman No. 1 and No. 17 papers used in these studies were either unwashed, acid washed, or salt washed. Acid-washed papers ($18\frac{1}{4} \times 22\frac{1}{2}$ in.) were prepared from unwashed papers by chromatographic elution with (*a*) 0.01 *N* hydrochloric acid (3 days) and water (3 days) or (*b*) 0.6 *N* acetic acid (3 days) and water (3 days). Salt-washed papers were prepared by similarly washing *each* type of acid-washed paper with a 0.1% solution of sodium, potassium, calcium, or magnesium acetate (2 days) and water (2 days).

Qualitative Paper Chromatography

(1) Normal Development

Whatman No. 17 papers were supported by means of a Whatman 3MM stirrup (27) and a single wick of the latter paper was used as solvent feed. The amine salts were spotted from 4% aqueous solutions, 200 γ and 1 mg being applied per spot on the No. 1 and No. 17 papers respectively. After chromatographic development with either *t*-butanol : acetic acid : water (2:1:1) or *t*-butanol : 0.5% hydrochloric acid (3:1) by descending flow, the No. 1 papers were dried in a forced air oven at 55° for 30 min (No. 17 papers, 1.5 h), sprayed with ninhydrin reagent (1), and heated for 5 min (No. 17 papers, 10 min) for detection of the amines. For detection of chloride ion, the chromatograms, dried as mentioned above, were sprayed with 5% aqueous silver nitrate and exposed to ultraviolet light to develop the color. Acetate ion was detected by the lanthanum nitrate reagent (1) after chromatograms on No. 1 paper (acetic acid solvent system only) had been air dried for 96 h at room temperature to remove excess acetic acid. Acetate ion was not detectable in this manner when the hydrochloric acid solvent system was used due to interference by chloride ion with the lanthanum nitrate test. The results of these experiments are given in Table II.

(2) Extended Development

On two separate sheets ($18\frac{1}{4} \times 22\frac{1}{2}$ in.) of unwashed No. 17 paper, 1 mg spots of piperidine and morpholine were each applied as pairs of their hydrochloride and acetate salts and developed for 7 h in a

[3] *Melting points are uncorrected.*

For personal use only.

Chromatocab using *t*-butanol : acetic acid : water (2:1:1). A strip containing one pair of salt spots was then removed, dried, and sprayed with ninhydrin. The remaining portion of the chromatogram was developed for a further 20 h, following which a second strip was removed and sprayed with ninhydrin. The remaining spots on the unsprayed portion of the chromatogram were removed in a horizontal strip, to which was sewn a new 3MM stirrup and a new long strip of unwashed No. 17 paper. This paper was developed for two additional periods of 20 h following each of which a strip was removed and sprayed with ninhydrin. Upon completion of the final development, each chromatogram contained only acetate spots, i.e. the hydrochlorides had been completely converted to the acetates.

Quantitative Paper Chromatography

(a) Amine Acetate to Amine Hydrochloride Conversion, Chromatography in t-Butanol : 0.5% Hydrochloric Acid (3:1)

Piperidine or morpholine acetate was applied as a 100 mg streak from 20% aqueous solution to the start line of each of two or three sheets ($18\frac{1}{4} \times 22\frac{1}{2}$ in.) of unwashed Whatman No. 17 paper. The papers were developed simultaneously in a Model A 300 Chromatocab by the descending method in *t*-butanol : 0.5% hydrochloric acid (3:1) for 60 h, using a single wick of Whatman 3MM paper as solvent feed. The papers were air dried for removal of the solvent and 1 in. reference strips were cut and sprayed with ninhydrin (0.4% in water-saturated *n*-butanol). The band bearing the salt was removed and eluted chromatographically with water (200 ml). The eluate was taken to dryness *in vacuo* and the residue was sublimed at 1×10^{-3} mm pressure at 110–120° for piperidine hydrochloride and at 80–90° for morpholine hydrochloride. The sublimates were identified by their melting points alone and in admixture with authentic specimens (see Table I) and also by their infrared spectra (KBr pellet). Piperidine and morpholine hydrochlorides were obtained in 97.5% and 97.0% yield respectively.

(b) Amine Hydrochloride to Amine Acetate Conversion, Chromatography in t-Butanol : Acetic Acid : Water (2:1:1)

Experiments were conducted in the same manner as described in (*a*) above except that unwashed, acid-washed (0.01 *N* HCl), and salt-washed (0.01 *N* HCl, Na^+ and Ca^{++}) papers were used; 400–500 mg of piperidine or morpholine hydrochloride was applied per paper, and development was for 40 h in *t*-butanol : acetic acid : water (2:1:1). Since qualitative chromatograms had indicated that the slower-moving hydrochloride band contains some of the acetate, the entire ninhydrin-positive area was eluted with water (400 ml). The eluates were taken to dryness *in vacuo* and the residues were fractionally sublimed at 1×10^{-3} mm pressure. Under these conditions piperidine acetate and hydrochloride sublimed at 40–50° and 110–120° respectively and morpholine acetate and hydrochloride at 35–45° and 80–90° respectively. The sublimates were identified by their melting points, alone and in admixture with authentic specimens, and by their infrared spectra (KBr pellet). Results are given in Table III.

(c) Evidence for the Binding of Piperidinium Ions to the Paper During Chromatography of Piperidine Hydrochloride in Water

Piperidine hydrochloride (300 mg) was applied as a single streak from 10% aqueous solution to a strip of unwashed Whatman No. 17 paper (6.0 × 16.7 in., 100 sq. in.) to one 6 in. edge of which a Whatman 3 MM stirrup and single wick had been affixed. The paper was eluted with freshly boiled distilled water (pH 6.4, 4 × 100 ml) in a nitrogen atmosphere. The unbound salt (290 mg) was all contained in the first 100 ml of eluate and was recovered by sublimation at 1×10^{-3} mm pressure at 100–120°. However, when the residue from the sublimation was taken up in water (10 ml), basified to pH 11–12 with sodium hydroxide, and extracted with ether and the dried ether solution treated with dry hydrogen chloride, a small amount of precipitate resulted. Removal of the ether *in vacuo* followed by sublimation as before gave a further 5.6 mg of piperidine hydrochloride. Further elution of the paper with carbon dioxide saturated water (pH 3.95, 100 ml) followed by evaporation to dryness *in vacuo* furnished an additional 5 mg of piperidine hydrochloride. Identifications were made by comparison of melting points and infrared spectra.

The experiment was repeated using acid-washed, sodium ion washed, and calcium ion washed papers. It was not necessary to resort to basification and ether extraction to recover all of the amine when sodium ion washed or acid-washed papers were used, but was quite essential to effect quantitative recovery in the presence of calcium ions. An aliquot of the eluate containing the unbound salt was removed and (*a*) titrated to pH 6.3 with 0.02 *N* sodium hydroxide in a carbon dioxide free atmosphere to determine the acid liberated during binding of the salt, or (*b*) analyzed for sodium ion content by the micro magnesium uranyl acetate method (28), or (*c*) analyzed for calcium ion content by the complexon method (ref. 28, p. 117). Results are given in Table IV.

Acid-washed Whatman No. 17 paper (100 sq. in.) was dispersed in 0.001 *N* hydrochloric acid by mechanical stirring and transferred to a chromatographic column 3.1 cm in diameter. After elution with freshly boiled distilled water until the pH of influent and effluent were identical (6.4), piperidine hydrochloride (300 mg) was added and the column was washed with freshly boiled distilled water (300 ml) to remove the unbound salt. During this process the pH of the effluent first decreased rapidly to 4.10, then rose again slowly to 6.86. Elution was resumed with carbon dioxide saturated distilled water (500 ml) to remove the bound salt and the latter was recovered in the usual manner, yielding 14.1 mg of piperidine hydrochloride.

Column Chromatography on Amberlite IRC-50 Resin with Piperidine Hydrochloride

(a) With Amberlite IRC-50 (H^+)

An Amberlite IRC-50 (H^+) column (7.5 × 0.75 cm) containing 3 ml (9 meq) of the resin was prepared and washed with distilled water at the rate of 10 drops per min until the pH of influent and effluent were identical (5.8). Piperidine hydrochloride (244 mg, 2 mmoles in 10 ml of distilled water) was started through the column, followed by distilled water. The pH of the effluent dropped rapidly to 2.0, then rose gradually to 6.4, at which point the fraction was cut (20 ml) and collection was resumed in a second receiver. As elution was continued, the pH rose gradually to 6.7, then fell again and leveled off at 6.0. This eluate was designated as fraction 2 (70 ml). The column was then eluted with 0.01 *N* hydrochloric acid until the effluent pH decreased to 2.0 (20 ml, fraction 3). The fractions were taken to dryness *in vacuo* after acidification to pH 1 with hydrochloric acid and the residues were sublimed *in vacuo* yielding 244, 4.1, and 12 mg of piperidine hydrochloride respectively. Identifications were made by comparison of melting points and infrared spectra.

(b) With Amberlite IRC-50 (Na^+)

An Amberlite IRC-50 (Na^+) column containing 3 ml (9 meq) of the resin was prepared and washed with distilled water. Piperidine hydrochloride (244 mg, 2 meq) was added in 10 ml of distilled water and the column was washed with distilled water (50 ml). The eluate was taken to dryness *in vacuo* yielding 42 mg of piperidine hydrochloride. The column was washed with 0.1 *N* hydrochloric acid until the pH of the effluent decreased to 1. The solution thereby collected (150 ml) was evaporated to dryness *in vacuo*, yielding 196 mg of piperidine hydrochloride.

(c) With Amberlite IRC-50 (Ca^{++})

The above-described experiment was repeated using 3 ml (9 meq) of Amberlite IRC-50 (Ca^{++}) resin. The aqueous eluate furnished piperidine hydrochloride (161 mg) by sublimation as in the experiment described above but the acidic eluate failed to give any sublimate under the normal conditions used. However, when the dry residue was dissolved in water (10 ml), basified, and extracted with ether, and the extract dried and treated with dry hydrogen chloride, a colorless precipitate was obtained. Removal of the ether *in vacuo*, followed by sublimation *in vacuo* yielded 45.6 mg of piperidine hydrochloride. Similar treatment of the residue from vacuum sublimation of the aqueous eluate furnished a further 30.7 mg of piperidine hydrochloride. Results of all the experiments with Amberlite IRC-50 resin are given in Table V.

SIMULTANEOUS POLAROGRAPHIC DETERMINATION OF SMALL AMOUNTS OF BISMUTH AND LEAD IN COPPER-BASE ALLOYS

C. H. McMaster

Mineral Sciences Division, Department of Mines and Technical Surveys, Ottawa, Canada

Received September 22, 1964

ABSTRACT

The extraction of metal diethyldithiocarbamate complexes into chloroform from an alkaline solution containing cyanide and citrate ions is a convenient means of separating small amounts of bismuth and lead from copper and uranium, and from the elements normally found in copper-base alloys. After the separation, bismuth and lead are determined polarographically using an acidic tartrate solution as the supporting electrolyte.

The method is applicable to the determination of bismuth and lead, in the concentration range from 0.0005–0.05%, in copper-base alloys of widely different composition.

INTRODUCTION

Small amounts of bismuth and lead seriously affect the hot workability of copper and brass by producing a characteristic known as "hot shortness". Generally, this condition exists when the impurity has a low melting point and is insoluble in the base material; during cooling the impurity segregates at the grain boundaries and causes cracking. As little as 0.005% bismuth and 0.02% lead can cause hot shortness in brass (1). During an investigation into the uses of depleted uranium, carried out by the Physical Metallurgy Division of the Mines Branch and the Canadian Uranium Research Foundation, it was found that uranium metal added to molten brass baths acts as a scavenger for bismuth and lead and results in the restoration of normal hot working conditions (2). In the course of this project, samples of brass containing up to 0.5% uranium were submitted for bismuth and lead analyses.

Polarography is a particularly attractive technique for the analysis of small amounts of bismuth and lead as the two metals can be determined simultaneously by using a slightly acidic tartrate solution as the supporting electrolyte (3). In this medium copper and uranium interfere and must be removed by chemical separation. The separation technique must result in complete elimination of uranium since the reduction of uranyl ion occurs at the same potential as lead. Copper is reduced at a more positive potential and interferes by limiting the amounts of bismuth and lead that can be determined with a conventional direct current polarograph. It is necessary, therefore, to decrease the amount of copper to about the same order as the bismuth and lead.

The usual methods of separation, involving precipitation of the hydroxides from ammoniacal solution (4) or coprecipitation with manganese dioxide (5), are not applicable in the present case as part or all of the uranium remains with the bismuth and lead. Uranium also interferes in the methods proposed by Eve and Verdier (6) in which bismuth is precipitated with ammonium carbonate and lead is separated from copper by controlled potential electrolysis.

A colorimetric procedure for the determination of bismuth is based on the extractability of the yellow-colored complex of bismuth diethyldithiocarbamate with chloroform or carbon tetrachloride (7, 8). Many interfering elements are rendered innocuous by carrying out the extraction from an alkaline solution containing cyanide ions and citrate or tartrate ions. Under these conditions lead diethyldithiocarbamate is also extracted. The utilization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of this extraction procedure as a means of isolating small amounts of bismuth and lead from cast iron, prior to the polarographic determination of the two elements, is described by Rooney (9). After extraction of the bulk of the iron with ethyl acetate, bismuth and lead are separated from the remaining iron, and other impurities by extraction of the diethyldithiocarbamates.

In the work described herein, the diethyldithiocarbamate separation technique is applied to the polarographic determination of small amounts of bismuth and lead in samples of brass containing uranium. Investigations also show that the method is applicable to copper-base alloys of widely different composition.

EXPERIMENTAL

Apparatus

Polarograph: Leeds and Northrup Electrochemograph, Type E.

Polarographic cell: An H-type cell was used with a saturated calomel electrode (s.c.e.) serving as the reference electrode, and a dropping mercury electrode as the indicating electrode (10). All polarographic measurements were made at 25 ± 0.1 °C. pH meter: Leeds and Northrup.

Reagents

Ammonium citrate: 40% (w/v) aqueous solution.

Potassium cyanide: 20% (w/v) aqueous solution. The salt used to prepare this solution should contain little or no sulfide. Analar potassium cyanide (British Drug Houses) was found to be suitable.

Sodium diethyldithiocarbamate: 0.1% (w/v) aqueous solution (freshly prepared).

Wash solution: Mix 50 ml of 40% ammonium citrate solution with 50 ml of 20% potassium cyanide solution and dilute with water to about 425 ml. Adjust the pH to 10.1 with ammonium hydroxide and make up to 500 ml with water.

Chloroform: c.p. grade.

Supporting electrolyte: Dissolve 23 g sodium tartrate in about 150 ml of water, adjust the pH to 4.5 with hydrochloric acid, add 2 ml of 0.1% Triton X-100, and dilute to 200 ml with water.

Procedure

Weigh out 1 g of the sample and dissolve in 5 ml of hydrochloric acid and about 10 ml of 30% hydrogen peroxide added in small portions. Heat the solution in a covered beaker to drive off the excess peroxide, and evaporate to a small volume. Cool and add 25 ml of ammonium citrate solution. Adjust the pH to 10.1 with ammonium hydroxide. Add 25 ml of potassium cyanide solution and transfer quantitatively to a 250 ml separatory funnel. Add 20 ml of sodium diethyldithiocarbamate solution and mix. Add 10 ml of chloroform, shake for 1 min, allow the layers to separate, and transfer the chloroform layer to a 125 ml separatory funnel containing 50 ml of wash solution. Shake for about 15 s, allow the layers to separate, and transfer the chloroform layer to a 50 ml beaker. Carry out a total of three extractions in identical fashion, and evaporate the combined fractions to dryness. Add 3 ml of nitric acid and 3 ml of perchloric acid, cover the beaker, and heat until fumes of perchloric acid are evolved. Remove the cover and evaporate to dryness. Cool and dissolve the residue in exactly 5 ml of supporting electrolyte solution, added from a pipette, and transfer to a polarographic cell. Deaerate with nitrogen gas and electrolyze at the dropping mercury electrode from 0.1 to 0.7 V.

In 0.5 M tartrate solution of pH 4.5 bismuth is reduced at −0.29 V and lead at −0.48 V vs. s.c.e.

RESULTS AND DISCUSSION

Dissolution of Sample

The mixture of hydrochloric acid and hydrogen peroxide, used to dissolve the samples, was selected in order to prevent the precipitation of metastannic acid when dealing with copper-base alloys containing tin.

Samples containing appreciable amounts of silicon, such as silicon bronzes, should be treated with a few drops of hydrofluoric acid to achieve complete dissolution.

Extraction

The extraction of bismuth and lead diethyldithiocarbamates with chloroform is quantitative at any pH between 9 and 10.5. The extraction at pH values outside of this range was not investigated.

The extraction of bismuth and lead is complete up to at least 0.05% of each, using the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

quantities of sodium diethyldithiocarbamate and chloroform specified in the procedure. Above this value it is preferable to decrease the size of the sample. An excess of sodium diethyldithiocarbamate does not present any problems as the reagent is not extracted above a pH of 8 (11).

Washing of the chloroform layer was implemented as a means of obtaining more complete isolation of bismuth and lead from copper. The chloroform extract, before washing, was found to contain as much as 0.05% copper; after washing, the amount of copper was decreased to less than 0.0005%.

Inteferences

The extraction procedure provides a satisfactory separation of bismuth and lead from copper and uranium. Typical recoveries, obtained with synthetic samples, are shown in Table I.

TABLE I

Recovery of bismuth and lead

Composition of synthetic sample	Bismuth (%)		Lead (%)	
	Added	Found	Added	Found
Cu, 70%, Zn, 29.5%, U, 0.5%	0.0020	0.0021	0.020	0.020
	0.0050	0.0051	0.010	0.011
	0.010	0.010	0.0050	0.0052
	0.020	0.020	0.0020	0.0021

The combination of cyanide and citrate ions prevents the precipitation or extraction of a large number of elements including the major alloying constituents, viz. silver, zinc, aluminium, tin, manganese, iron, and nickel. Iron appears to be partially extracted as evidenced by the dark-amber color of the initial chloroform extract. This coloration, however, disappears on washing the organic layer.

Of the many elements associated with copper, only antimony(III) and tellurium(IV) are extracted from an alkaline cyanide solution (11).

Trivalent antimony forms a white precipitate with diethyldithiocarbamate that is extracted by chloroform at pH 9–9.5. In the present procedure antimony is oxidized to the pentavalent state during dissolution of the sample and does not interfere.

Tellurium(IV) is extracted completely from an alkaline cyanide solution at pH 8.5. Tests carried out in this laboratory showed that tellurium is partially extracted up to pH 9.6, but is without effect at pH 10–10.5. Since tellurium interferes with the polarographic determination of bismuth and lead, it is essential that the extraction be performed at a pH of 10 or above.

Application to Copper-Base Alloys

There appears to be a lack of standard copper-base alloys containing certificate values for both bismuth and lead. Three bronze samples and a copper–nickel–zinc alloy from the National Bureau of Standards contained lead in the desired range, but none of the samples contained bismuth. Instead of preparing completely synthetic samples, the above-mentioned N.B.S. alloys were used and known amounts of bismuth were added to each. The bismuth was added during dissolution of the sample and was carried through the entire procedure. Table II shows the results obtained with the N.B.S. alloys and with a sample of cupro-nickel (British Chemical Standards) in which the bismuth was reported as $< 0.0005\%$ and the lead as $< 0.01\%$.

B.C.S. 180–1	67.36	—	30.85	—	—	0.82	—	0.81

The copper-base alloys listed in Table II contain wide ranges of alloying elements and, thus, are ideally suited to illustrate the application of the proposed method. Table III shows the percentages of the constituents that are present in these alloys in amounts greater than 0.1%.

The procedure, as described in this report, can be used for the determination of bismuth and lead in the concentration range from 0.0005–0.05%. Reagent blanks are negligible at 0.002% and above, but should be taken into consideration at lower concentrations. The elements normally found in copper-base alloys do not interfere in the proposed method.

PYRROLE CHEMISTRY

IV. THE PREPARATION AND SOME REACTIONS OF BROMINATED PYRROLE DERIVATIVES

HUGH J. ANDERSON AND SHU-FAN LEE
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received September 21, 1964

ABSTRACT

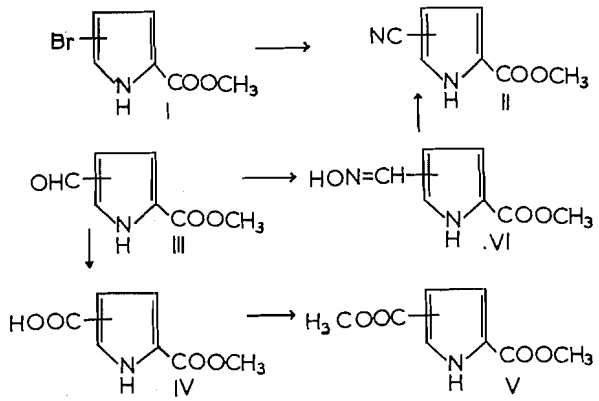
Methyl 2-pyrrolecarboxylate and 2-pyrrolecarboxaldehyde have been brominated under a variety of conditions and the isomer ratios determined. The products have been identified as the 4-bromo, 5-bromo, and 4,5-dibromo derivatives and their structures proved. It has been shown that the bromine group in these products is not easily displaced by nucleophiles although this has been accomplished with the cyanide ion. The bromine has been removed easily by catalytic hydrogenation.

In our survey of the reactions of relatively simple pyrrole derivatives (1) it appeared likely that bromination might prove both useful and interesting. A selection of types of brominating agents including molecular bromine, the bromonium ion, and the bromine atom is available (2). In turn it might prove possible to replace the bromine group by others such as cyanide or methoxyl as has been done in the thiophene and furan series (3, 4, 5). The most satisfactory starting materials appeared to be methyl 2-pyrrolecarboxylate and 2-pyrrolecarboxaldehyde. The electron-withdrawing groups would provide a 4-directing effect. Thus a mixture of 4- and 5-isomers would be formed (1, 6) which might be made to favor one or the other position by a choice of the type of brominating agent. In addition, both ester and aldehyde can be converted to the acid group which then might be removed by decarboxylation. Finally, the deactivation of an electron-withdrawing group would be necessary to allow the isolation of monobrominated products in reasonable yields (7). From the reaction products we isolated 4-bromo, 5-bromo, and 4,5-dibromo derivatives for both the 2-ester and the 2-aldehyde. A small amount of the 3,4,5-tribromo-2-ester (8) was also found in one reaction. Methyl 4,5-dibromo-2-pyrrolecarboxylate (9) has been reported previously.[1]

Identification of the monobrominated-2-esters (I) was accomplished by a series of reactions. First, nucleophilic displacement of the bromine group was carried out using cuprous cyanide in hot dimethyl sulfoxide. The yields of methyl 4- and 5-cyano-2-pyrrolecarboxylate (II) were not good but in each case a single product was obtained and characterized. Then methyl 2-pyrrolecarboxylate was formylated by the Vilsmeier-Haack technique (3) producing a mixture (III), containing mostly the 4-formyl-2-ester along with some of the 5-formyl-2-ester. Pinder (10) has formylated the corresponding ethyl ester but obtained a considerably greater proportion of 5-formylation. Each formyl-2-ester was then subjected to two operations. First, it was oxidized (IV) and esterified (V) to the known methyl 2,5- or 2,4-pyrroledicarboxylate (11), thus proving the orientation of substituents. A second portion of each formyl-2-ester was converted to the oxime (VI), dehydrated to the corresponding 4- or 5-cyano-2-ester and used for mixed melting point and comparison of infrared spectrum with the products (II) obtained above. Further

[1]*Dr. R. W. Rickards of the University of Manchester has kindly informed us that he and P. Hodge have brominated the 2-ester with bromine in acetic acid and obtained and identified the same products. The physical properties of the products are in agreement with ours.*

bromination of either monobrominated ester led to the same dibrominated product. The same was true for the monobrominated aldehydes. The monobromo-2-aldehydes were oxidized and esterified to the corresponding monobromo-2-esters (I) for identification. The dibromo-2-aldehyde was treated similarly.



In addition, the nuclear magnetic resonance (n.m.r.) spectra of the brominated esters and aldehydes had already provided quite adequate identification. As has been observed for the benzene series (12), bromination does not greatly alter the positions of the signals of the remaining aromatic protons from those of the parent compounds. These results will be discussed in a forthcoming paper.

After isolation of all the pure substances from the bromination reactions using column chromatography on alumina and fractional crystallization, further trials were analyzed by gas–liquid partition chromatography. A series of trials with known mixtures showed that the triangulation method of analysis could be applied to the gas chromatograms with an accuracy of about 2%. The results were converted to mole % and are recorded in the tables. It was soon found that from a preparative point of view bromination in carbon tetrachloride, with a trace of iodine, was by far the best reaction. No other method approached the greater than 90% conversions possible for the ester. Although the acetic acid reaction was satisfactory the work-up was more laborious.

Several conclusions may be drawn from Table I, which lists a representative selection from a large number of trials on ester and aldehyde. Bromination at the 4-position predominates at room temperature and below, where the 4- : 5- substitution ratio is usually from 6:1 to 10:1. At the boiling point of carbon tetrachloride the attack is much less selective and the amount of 5-bromo product present approaches that of the 4-bromo. The former may then be isolated easily by column chromatography. Increasing the relative amount of bromine raises the percentage of dibrominated product and may produce almost a quantitative yield of it if desired. Conversions are generally lower for the aldehyde brominations than for those of the ester. There is little destruction of the pyrrole nucleus under these conditions.

Of the variety of other reagents listed in Table II none proved to be a selective reagent for attack at the 5-position. The only satisfactory procedures found by us for obtaining 5-bromo derivatives involve the most vigorous reagents and conditions. Under these circumstances the amounts of 4- and 5-bromination are about equal. The free radical reagent N-bromosuccinimide in carbon tetrachloride, with some benzoyl peroxide, was equally random. No 3-bromination was detected in any of our experiments.

The bromonium ion from acidified hypobromous acid (13) or from bromine and silver perchlorate in perchloric acid (prepared analogously to the chloronium ion of ref. 14), was neither very selective nor very successful. Basic reagents such as bromine in dilute aqueous sodium hydroxide and pyridinium bromide perbromide in pyridine (15) favored 4-substitution fairly strongly. The latter reagent was quite successful for the preparation of the 4-bromo-2-ester, although less so for the corresponding aldehyde. The only similar monobrominated pyrrole has been prepared by Ciamician (16) through the action of bromine in acetic acid on 2-acetylpyrrole, and later identified as the 4-bromo derivative by n.m.r. (17). The same compound has also been obtained by the action of the dioxane–bromine complex (18). It seems surprising that although some dibrominated product was isolated none of the 5-isomer was found. The contrast with the thiophene series, where bromination of the 2-aldehyde (19) and the 2-acid (20) using bromine produced the 5- but not the 4-bromo derivative, points up the selectivity of the bromination reaction.

It was found in general that nucleophilic substitution of the bromine in these compounds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was difficult. The displacement of bromine by cyanide in the ester series was not a satisfactory conversion. This is in agreement with results reported for thiophene derivatives (3). Attempts to replace the bromine with methoxyl by refluxing the monobromo-2-ester with sodium methoxide in methanol for 30 h were unsuccessful. It appears that much more drastic conditions would be necessary to make this conversion successful. The reaction takes place moderately well in the thiophene and furan series (4, 5).

It was found that the bromines could be removed from the ring by reduction. Catalytic hydrogenation was much more successful than zinc and acetic acid or other chemical means. The 5-bromine was removed more rapidly than the 4-bromine. It was thus possible to reduce the 4,5-dibromo compounds to a mixture in which the 4-bromo compound predominated. However, this seemed to have little preparative value since some complete reduction also took place. Bromine was less readily removed from the aldehydes than from the corresponding esters. Although the corresponding bromo-2-acids were obtained, from the ester and from the aldehyde, it was found that their purification was very difficult and they rapidly blackened. Various attempts to isolate the products of decarboxylation using a variety of conditions were all unsuccessful. These included dry distillation from a mixture with copper–bronze and from a mixture with soda–lime, as well as distillation from quinoline and copper powder.

EXPERIMENTAL

General

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded by a Perkin–Elmer 237-B grating spectrophotometer using the potassium chloride disc technique (2 mg of sample in 200 mg KCl). Ultraviolet spectra were determined with a Beckman DK-2A recording spectrophotometer at a concentration of 10 mg per liter in ethanol (95%). Elemental analyses were determined by Alfred Bernhardt, Mülheim (Ruhr), Germany.

Analyses of reaction mixtures were carried out by means of gas–liquid partition chromatography using a Beckman GC-2A gas chromatograph, equipped with an 18 in. column (No. 70008) packed with Apiezon L on fire brick. For the pyrrole esters operation was at 220° using helium as carrier gas at 20 p.s.i.g. inlet pressure. Retention times established for pure compounds were: methyl 2-pyrrolecarboxylate, 0.9 min; 5-bromo derivative, 2.1 min; 4-bromo derivative, 3.5 min; 4,5-dibromo derivative, 6.5 min. For the pyrrole aldehydes operation was at 190° using helium as carrier gas at 20 p.s.i.g. inlet pressure. Retention times established for pure compounds were: 2-pyrrolecarboxaldehyde, 1.3 min; 5-bromo derivative, 3.3 min; 4-bromo derivative, 4.7 min; 4,5-dibromo derivative, 12.5 min.

Starting Materials

Methyl 2-pyrrolecarboxylate was prepared and purified as described in ref. 1. 2-Pyrrolecarboxaldehyde was prepared by the method of Silverstein, Ryskiewicz, and Willard (21).

General Procedure for Bromination with Bromine

In a 100 ml three-necked round bottom flask equipped with a sealed stirrer, a condenser, and a dropping funnel, was placed 0.004 mole of starting material along with 2–3 mg of iodine dissolved in 30 ml of carbon tetrachloride. A solution of bromine (0.004 mole) in 10 ml of carbon tetrachloride was added dropwise, with stirring. The mixture was neutralized with 20% sodium carbonate solution, the layers separated, and the aqueous layer extracted with ether. The combined organic layers were dried over sodium sulfate and the solvents were removed by flash evaporation. The residue was injected into the gas chromatograph in ether solution. The results of the analyses, together with conditions of time, temperature, and concentration are listed in Table I.

Isolation of Bromination Products

The solid material, after flash evaporation of solvents, was chromatographed on neutral alumina (Woelm, No. 1), following the progress of elution by means of gas chromatography. Homogeneous fractions were isolated, and the solids sublimed and recrystallized from petroleum pentanes to obtain purified products.

Bromination with Other Reagents

In each trial 0.004 mole of starting material was treated with 0.004 mole of the brominating reagent. The reaction time was usually judged on the basis of a color change. Working-up involved standard procedures for the removal of by-products, depending on the reagent. This was followed by flash evaporation of the solvent, and gas chromatographic analysis. The results are listed in Table II. (*a*) The bromination in carbon tetrachloride was carried out at 70° for 60 min using a small amount of iron powder as catalyst. (*b*) The bromination was carried out in carbon tetrachloride at room temperature for 120 min in the presence of an excess (0.008 mole) of anhydrous aluminium chloride. (*c*) The bromine–dioxane complex (22) was used in dioxane solution at 60° for 30 min. (*d*) Bromination was carried out at 60° in a solution of 30 ml glacial acetic acid containing 0.75 g sodium acetate. (*e*) N-Bromosuccinimide was used at the boiling point of the carbon tetrachloride solution and in the presence of about 0.1 g benzoyl peroxide. Reaction time was 90 min. (*f*) The bromonium ion was prepared by the action of bromine on silver perchlorate (0.012 mole) in aqueous perchloric acid solution (3 ml, 72%). The reaction proceeded at room temperature over 30 min. (*g*) Hypobromous acid solution (0.079 *N*) was prepared by the action of freshly prepared mercuric oxide on bromine in an excess of water (23). The reaction was carried out at room temperature in the presence of 72% perchloric acid (0.10 mole) over 30 min (13). (*h*) Pyridinium bromide perbromide was used in pyridine solution at room temperature over 1 h (15). (*i*) The sodium hypobromite solution was prepared by dissolving bromine in 40 ml 6 *N* aqueous sodium hydroxide. (*j*) The mixture of cupric bromide and starting material together with 0.0005 mole of lithium bromide was heated at 150° for 2 h in 25 ml of dimethylformamide (24).

Preparation of Brominated Acids and Their Esterification

(*a*) The brominated ester (0.008 mole) was refluxed with a mixture of 25 ml of 20% aqueous potassium hydroxide and 20 ml of methanol for 2 h. The methanol was removed under vacuum and unreacted ester extracted with ether. The aqueous layer was acidified with dilute hydrochloric acid and extracted with ether. After drying, the ether solution was evaporated and the crude solid was sublimed and recrystallized.

(*b*) The brominated aldehyde (0.0002 mole) in 2 ml of ethanol was added to a suspension of silver oxide (from 50 mg of silver nitrate, 5 ml of water, and 10 ml of 1 *N* sodium hydroxide solution). The mixture was shaken mechanically for 1 h at room temperature and filtered (25). The filtrate was acidified and extracted with ether. The extract was dried and the product was isolated by evaporation.

Products obtained by methods (*a*) and (*b*) were: 4-bromo-2-pyrrolecarboxylic acid, m.p. 155–165°; 5-bromo-2-pyrrolecarboxylic acid, which decomposed in air after a short time; 4,5-dibromo-2-pyrrolecarboxylic acid, m.p. 165–175°. All attempts to purify these compounds caused extensive decomposition.

The addition of an ethereal solution of diazomethane (26) to the ethereal solution obtained by method (*b*), followed by keeping overnight at room temperature converted the crude acids directly to the corresponding esters. The products were proved identical to those from direct bromination of the 2-ester by mixed melting points and comparison of infrared spectra.

Reductive Removal of Bromine

(*a*) A solution of methyl 4,5-dibromo-2-pyrrolecarboxylate (0.004 mole) in 30 ml of glacial acetic acid was refluxed gently while zinc dust (0.001 mole) was added slowly. After a further 3 h heating the solution was cooled, neutralized with base, and extracted with ether. Gas-chromatographic analysis of the dried extract indicated: methyl 2-pyrrolecarboxylate, trace; methyl 4-bromo-2-pyrrolecarboxylate, 5.9%; methyl 5-bromo-2-pyrrolecarboxylate, 2.1%; starting material, 92%.

(*b*) A solution of brominated ester or aldehyde (50 mg) was dissolved in 25 ml of glacial acetic acid containing 10 mg sodium acetate. After adding 20 mg of 5% palladium-on-charcoal catalyst the reaction mixture was shaken in a heavy-wall glass bottle under 3 atm of hydrogen at 60° for from 10 min to 2 h depending on the compound. After removal of the catalyst, neutralization, extraction, and drying, gas-chromatographic analysis showed quantitative removal of bromine.

(*c*) With the same starting materials the reductions were carried out at room temperature and pressure while agitating the reaction mixture with a magnetic stirrer. Again quantitative reduction was observed over times ranging from 15 min to 3 h.

Products were isolated from all these reductions and identified.

Replacement of Bromine with Cyanide

A mixture of the bromopyrrole ester (0.01 mole) and freshly prepared cuprous cyanide (0.015 mole) (27) in 50 ml of dimethyl sulfoxide was refluxed for 5 h. Most of the solvent was removed by vacuum distillation and the dark residue was washed with 30 ml of 20% aqueous ammonium chloride and extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. After evaporation of the ether the nitrile was obtained by crystallization from petroleum pentanes and sublimation. Yields averaged about 20%. The products were: methyl 5-cyano-2-pyrrolecarboxylate, m.p. 165–166°. Calcd. for $C_7H_6O_2N_2$: C, 56.00; H, 4.03; N, 18.66. Found: C, 55.82; H, 4.11; N, 18.57. Methyl 4-cyano-2-pyrrolecarboxylate, m.p. 169–170°. Calcd. for $C_7H_6N_2O_2$: C, 56.00; H, 4.03; N, 18.66. Found: C, 55.96; H, 4.19; N, 18.71.

Formylation of Methyl 2-Pyrrolecarboxylate

Following the procedure of Silverstein *et al.* (21) methyl 2-pyrrolecarboxylate (0.04 mole) was formylated with 3.5 g of dimethylformamide and 7.0 g of phosphorus oxychloride in 25 ml of ethylene chloride. After working-up, the product was distilled at 120° and 5 mm giving a product which, after sublimation, melted at 92–93°. The undistilled residue was purified by recrystallization from pentane, and sublimation, to m.p. 121–122°. Over 90% of the ester was converted to products.

Identification of Formylated Pyrrole Esters

Each of the formyl-2-esters was oxidized with alkaline silver oxide following the procedure outlined above for the brominated aldehydes. Each crude acid in ether was then esterified by the addition of an ethereal solution of diazomethane. Yields were very good. From the formyl-2-ester, m.p. 92–93°, was obtained: methyl 2,4-pyrroledicarboxylate, m.p. 126–127°; λ_{max} 264 mμ (ϵ 13 700). (Reference 11 gives m.p. 126–127°; λ_{max} 267 mμ in aqueous solution.) Calcd. for $C_7H_7NO_3$: C, 54.90; H, 4.61; N, 9.15. Found: C, 54.97; H, 4.71; N, 9.21; From the formyl-2-ester, m.p. 121–122°, was obtained methyl 2,5-pyrroledicarboxylate, m.p. 128.5–129.5°; λ_{max} 274 mμ (ϵ 24 400). (Reference 11 gives m.p. 129–130°; λ_{max} 277 mμ in aqueous solution.) Calcd. for $C_7H_7NO_3$: C, 54.90; H, 4.61; N, 9.15. Found: C, 54.97; H, 4.72; N, 9.32.

Conversion of Formyl Derivatives to Cyano Derivatives

The now proven methyl 4-formyl-2-pyrrolecarboxylate (m.p. 92–93°) was converted to its oxime, m.p. 204–205°, and dehydrated with hot acetic anhydride (28) to the corresponding methyl 4-cyano-2-pyrrolecarboxylate. Similarly the 5-formyl-2-ester was converted by way of its oxime, m.p. 123–124°, to methyl 5-cyano-2-pyrrolecarboxylate. These compounds were then used to prove the structures of the same compounds obtained above by displacement of bromine by cyanide. Mixed melting points were undepressed and infrared spectra corresponded.

THE OXYGENATED FATTY ACIDS FROM THE OIL OF THE SPORES OF LYCOPODIUM SPECIES[1,2]

A. P. TULLOCH
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received October 1, 1964

ABSTRACT

The oil from the spores of commercial *Lycopodium*, mainly *L. complanatum*, contains *cis*-9,10-epoxyoctadecanoic acid (2%), (+)-8-hydroxyhexadecanoic acid (7%), and (±)-*threo*-9,10-dihydroxyoctadecanoic acid (4%). Smaller amounts of 8-oxohexadecanoic acid and an epoxyhexadecanoic acid also seem to be present.

The oil from the spores of species of the clubmoss *Lycopodium* has been examined by a number of workers, most of whom (1–5) agreed that it contained a small amount of a 9,10-dihydroxyoctadecanoic acid. The present investigation of the spore oil was undertaken because it was thought that the dihydroxy acid might have been produced in the spore by enzymatic hydrolysis of a hitherto unobserved epoxyoctadecanoic acid. The enzymatic conversion of *cis*-9,10-epoxyoctadecanoic acid to (+)-*threo*-9,10-dihydroxyoctadecanoic acid had earlier been found to occur in the uredospores of the wheat stem rust fungus (6). It was hoped that *Lycopodium* spores might prove to be a more convenient source of epoxide-hydrolyzing enzyme than wheat stem rust spores.

A further reason for reinvestigating *Lycopodium* spore oil was that the early workers disagreed about the melting point of the dihydroxy acid. Thus Bukowsky (1) gave 92 °C, Rathje (2) 140 °C, Bauer and Piners (3) 98 °C, Riebsomer and Johnson (4) 93 °C, and Hirai and Toyama (5) 130 °C. These melting points indicate that different stereoisomers had been isolated; the higher melting acids probably were *erythro* forms (racemic form has melting point 130 °C and the (+) or (−) form 140 °C) and the lower melting probably *threo* forms (racemic form has melting point 95 °C and the (+) or (−) form 99 °C). One possible explanation for these results is that the spores had been obtained from different species of *Lycopodium*. The above workers seem to have used commercial "lycopodium powder", and though it has been assumed that this consists of the spores of *L. clavatum*, it is most probable that other species are also present in considerable proportions. The spores of the "lycopodium powder" used in the present work belonged to the species *L. complanatum*.

Methyl esters of the oil were prepared, and analyzed by gas–liquid chromatography (g.l.c.) using a silicone SE-30 column. The g.l.c. separation of the esters is shown in Fig. 1A and the separation, after the esters had been treated with acetic acid to open epoxide rings and acetylated to convert hydroxy esters to acetates (6, 7), is shown in Fig. 1B. The small peak in the C_{20} region in A is still smaller in B, indicating the presence of C_{18} epoxy ester (7). A diacetate peak has appeared in B, part of which should be derived from epoxy ester and the rest from dihydroxy ester in the original oil. Also in B an acetoxy palmitate peak has appeared just beyond the C_{18} peak. In A the original hydroxy palmitate would be obscured by the larger C_{18} peak, since previous work has shown that the

[2]*Issued as N.R.C. No. 8236.*

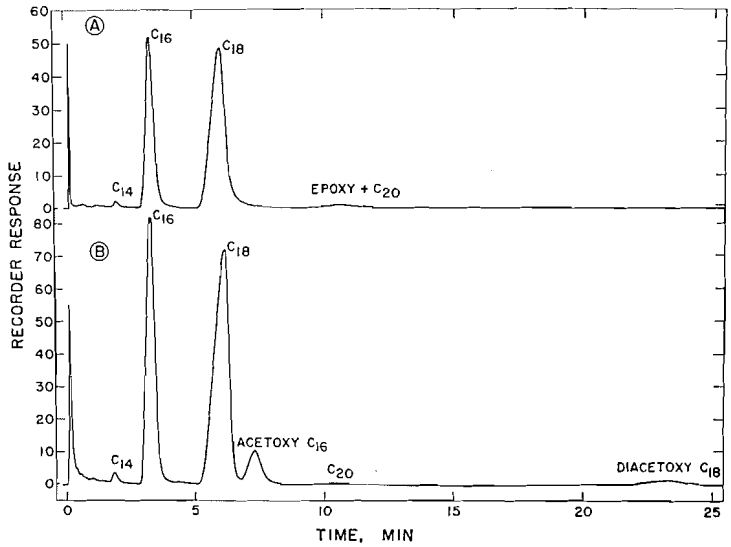

FIG. 1. (A) Gas–liquid chromatographic separation of the methyl esters of *Lycopodium* spore oil; (B) g.l.c. separation of esters after treatment with acetic acid and acetylation.

carbon number (8) of a hydroxy ester changes by 0.5 to 1.0 units on acetylation, the size of the change depending on the location of the hydroxyl group on the fatty acid chain (9).

Using a silicic acid column the esters were separated into non-oxygenated, epoxy, hydroxy, and dihydroxy ester fractions (10). The non-oxygenated esters were examined by g.l.c. and separated into saturated monoene and diene fractions by chromatography on a silver nitrate – silicic acid column (11, 12) and the fractions oxidized to determine the positions of the double bonds. 9-Hexadecenoic acid was present in the unusually large amount of 29%, as found by Riebsomer and Johnson (4), the other acids were oleic (21%) and linoleic (19%). The less common 11-octadecenoic acid, the presence of which was suggested by Riebsomer and Johnson, was also found (8%). The infrared spectra indicated that these unsaturated acids had the *cis* configuration.

Saponification of the epoxy ester fraction yielded an epoxy acid identical with the optically active *cis*-9,10-epoxyoctadecanoic acid previously isolated from the oil of wheat stem rust uredospores (13). Since the specific rotation of the epoxy ester was lower than that of epoxy ester derived from rust spores some racemic ester may also have been present in *Lycopodium* spore oil. The epoxy ester fraction also contained a lesser amount of a slightly more polar second component which was isolated after conversion of the accompanying epoxy ester to dihydroxy acid. The infrared spectrum indicated that it was an oxo ester (14); the carbon number, using a silicone QF-1 column, was 21.03 which suggested an 8- or 9-oxohexadecanoate (9). The acid could not be isolated in a sufficiently pure form for comparison with synthetic 8-oxohexadecanoic acid, but chromic acid oxidation yielded suberic and pimelic acids, confirming that it was 8-oxohexadecanoic acid. The fraction also contained a very small amount of a methyl epoxyhexadecanoate which had about the same carbon number, using the SE-30 column, as the above oxo ester but, using the QF-1 column, the carbon number was 20.2 (methyl *cis*-9,10-epoxyoctadecanoate had a carbon number of 22.2 using this column). This component could not be detected after acetic acid treatment (7).

Gas–liquid chromatography showed that the hydroxypalmitate fraction contained only

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

a single component. The ester was optically active and chromic acid oxidation at 100 °C yielded suberic and pimelic acids, indicating that the hydroxyl group was at carbon 8. Chromic acid oxidation at 25 °C gave an oxo ester which was shown to be methyl 8-oxopalmitate by comparison with the synthetic ester prepared by chain elongation of 6-oxotetradecanoic acid (9). The hydroxy ester is thus (+)-methyl 8-hydroxyhexadecanoate; (±)-methyl 8-hydroxyhexadecanoate was synthesized for comparison by reduction of the oxo ester. This hydroxy acid does not seem to have been isolated previously. The (±) ester has been synthesized before (15), but the route used and the physical properties of the ester and acid have apparently not been disclosed. The other hydroxyhexadecanoic acids which have been found in nature are 3-D-hydroxyhexadecanoic in the extracellular glycolipids produced by species of *Rhodotorula* (16), (+)-11-hydroxyhexadecanoic in the seeds and roots of convolvulaceous plants (17), 14- and (or) 15-hydroxyhexadecanoic in beeswax (18, 19), and 15- and 16-hydroxyhexadecanoic acids in the glycolipid produced by *Torulopsis magnoliae* (20).

The dihydroxy ester fraction was shown by comparison with synthetic material to be racemic methyl *threo*-9,10-dihydroxyoctadecanoate. Since the residue obtained after crystallization of the racemic *threo* ester had a low rotation ($[\alpha]_D$ +4°), the amount of (+)-*threo*-dihydroxy acid isomer ($[\alpha]_D$ +24° (13)) present in the oil, if any, must have been very small. The finding of a *threo* dihydroxy acid is in agreement with the results of Riebsomer and Johnson (4), who carried out the most thorough of the previous investigations.

The overall percentage fatty acid composition of the oil was calculated to be: myristic, 1; palmitic, 6; 9-hexadecenoic, 29; stearic, 1; 9-octadecenoic, 21; 11-octadecenoic, 8; linoleic, 19; *cis*-9,10-epoxyoctadecanoic, 2; 8-oxohexadecanoic, 0.4; (+)-8-hydroxyhexadecanoic, 7; *threo*-9,10-dihydroxyoctadecanoic, 4; and unidentified, 1.6.

The presence of racemic dihydroxy acid is surprising, particularly since the other two oxygenated acids are optically active. This acid could not have been produced by enzymatic hydrolysis of the epoxy acid as occurs in wheat stem rust spores unless it is assumed that some type of racemizing enzyme is also present in *Lycopodium* spores. The dihydroxy acid could not have arisen by hydrolysis of epoxy acid during preparation of methyl esters from the oil since it was previously shown that methanolysis with a weak solution of sodium methoxide in methanol did not affect the epoxide group (7, 26). It is unlikely that the oxygenated acids are produced by autoxidation since some are optically active and since only a few specific acids are produced. If random autoxidation occurred epoxy- and dihydroxy-hexadecanoic acids derived from 9-hexadecenoic acid would be expected.

It is interesting that about 2% of racemic *threo*-9,10-dihydroxyoctadecanoic acid was recently found in the oil of *Onguekoa gore* (isano oil) (21). This oil was also reported to contain 1.4% of *cis*-9,10-epoxyoctadecanoic acid, apparently mainly as the racemic form (22). The epoxy acid also occurs in small quantity in the seed oil of *Tragopogon porrifolius* (23). However, no explanation of the presence of these small amounts of oxygenated acid has been put forward. Epoxy and hydroxy acids have also been found in sulfur olive oil and it has been suggested that they are produced by the action of microorganisms (24, 25). At least some of the oxygenated acids in *Lycopodium* spore oil and the other oils may have been produced in the same way.

EXPERIMENTAL

Optical rotations were measured at 25 °C in a 1 dm tube. Light petroleum refers to a fraction of boiling range 60–80 °C.

Isolation of the Oil

The *Lycopodium* spores were purchased from Canadian Laboratory Supplies, Ltd., Winnipeg, and were found to consist mainly of spores of *Lycopodium complanatum* by Dr. M. Steeves of the Department of Geology, University of Saskatchewan. The spores were extracted by grinding in a ball mill with light petroleum for 48 h, the yield of oil was about 50%. The oil was treated with diazomethane to esterify free fatty acids, and, using methyl eicosanoate as a marker, the free fatty acids were estimated by g.l.c. to be less than 0.5%. Methyl esters were prepared by methanolysis with 0.02 *N* sodium methoxide in methanol (26)

Gas–liquid Chromatographic Analysis

Silicone SE-30 and QF-1 columns were prepared and operated as described earlier (9), and the ethylene glycol phthalate column used to analyze the esters and their oxidation products was employed as described by Tulloch and Craig (27).

Column Fractionation of the Methyl Esters of the Oil

Methyl esters (24.8 g) were dissolved in light petroleum and applied to a column (5 × 40 cm) of silica gel (Davison, 60–200 mesh). Non-oxygenated esters (20.5 g) were eluted with light petroleum containing 3% ether, and an epoxy ester fraction (1.1 g) with light petroleum containing 4% acetone; increasing the acetone content to 8% eluted a hydroxy ester fraction (1.5 g), and to 15% gave a dihydroxy ester fraction (1.1 g).

The Non-Oxygenated Ester Fraction

The following composition (in weight %) was obtained by g.l.c.: 14:0, 0.8; 14:1, 0.2; 16:0, 7.5; 16:1, 31.0; 16:2, 0.4; 18:0, 0.6; 18:1, 34.4; 18:2, 23.4; 20:0, 0.4; 20:1, 0.3; 22:0, 0.4; 22:1, 0.3. Chromatography on a silver nitrate – silicic acid column (11, 12) gave saturated esters (9.0), monoenes (65.9), and dienes (25.1%). Gas–liquid chromatography showed that the diene fraction contained some 16 carbon monoene but rechromatography on a shorter column yielded an almost pure diene fraction. The monoene fraction was separated, in batches, into C_{16} and C_{18} monoenes by g.l.c., using the SE-30 column. A portion of the C_{16} monoene was converted to *threo*-9,10-dihydroxyhexadecanoic acid by performic acid oxidation (26); the acid had melting point and mixed melting point 88–89 °C. The two monoene fractions and the diene fraction were oxidized with the permanganate periodate reagent (28) and the oxidation fragments analyzed by g.l.c. (27). The results are summarized below, only the major products are shown.

	C_{16} monoene (mole %)	C_{18} monoene (mole %)	Diene (mole %)
Dibasic acids			
C_9	94.2	69.4	93.6
C_{11}	1.2	26.9	1.3
Monobasic acids			
C_6	1.6	—	89.5
C_7	95.9	27.7	6.2
C_9	1.2	72.3	—

Epoxy Ester Fraction

Ester (0.90 g) was rechromatographed on a short silicic acid column and elution with light petroleum containing 6% ether gave almost pure epoxy ester (0.54 g). After crystallization from light petroleum the ester had melting point 22.5–24.5 °C and $[\alpha]_D$ +0.4° (*c*, 12.5, MeOH). A freshly prepared sample of methyl *cis*-9,10-epoxyoctadecanoate from the oil of wheat stem rust uredospores had melting point 23–25 °C and $[\alpha]_D$ +0.7° (*c*, 17.5, MeOH). The *Lycopodium* epoxy ester was saponified and the acid obtained after acidification was crystallized from acetone. The melting point and mixed melting point with *cis*-9,10-epoxyoctadecanoic acid from wheat stem rust was 57.5–58.5 °C and the mixed melting point with synthetic racemic *cis*-9,10-epoxyoctadecanoic acid was 53–57 °C. The infrared spectra of the acid from *Lycopodium* spores and the acid from wheat stem rust spores were indistinguishable.

A later fraction (0.21 g), obtained during the rechromatography of the epoxy ester, which seemed from g.l.c. analysis to be a mixture of an oxo C_{16} ester (40%) and the epoxy ester, was refluxed with acetic acid, the product hydrolyzed, and the acids isolated. The oxo acid was extracted with light petroleum and had melting point 72–77 °C, oxidation with chromic acid at 100° gave pimelic and suberic acids. The dihydroxy acid produced from the epoxy acid was crystallized from ethyl acetate and the melting point and mixed melting point with synthetic racemic *threo*-9,10-dihydroxyoctadecanoic acid was 93–94.5 °C.

Hydroxy Ester Fraction

Saponification of the ester yielded (+)-8-hydroxyhexadecanoic acid which, after crystallization from acetone, had melting point 78.5–79.5 °C and $[\alpha]_D$ +0.3° (*c*, 19.5, $CHCl_3$).

Anal. Calcd. for $C_{16}H_{32}O_3$: C, 70.5; H, 11.8. Found: C, 70.5; H, 11.9.

Methyl (+)-8-hydroxyhexadecanoate was prepared by treating the acid with diazomethane. Crystallization from light petroleum gave the pure ester with melting point 44–45.5 °C and $[\alpha]_D$ +0.8° (*c*, 14, MeOH).

Anal. Calcd. for $C_{17}H_{34}O_3$: C, 71.3; H, 12.0. Found: C, 71.4; H, 12.1.

The mixed melting point with the racemic ester was 42.5–45 °C.

Methyl ester (0.01 g) was oxidized with a solution of chromic acid in glacial acetic acid (2%, 1 ml) for 30 min at 100°. Sodium metabisulfite and dilute sulfuric acid were added and the products extracted with ether and converted to methyl esters with diazomethane. Gas–liquid chromatographic analysis on the polyester column showed that the major dibasic products were pimelic and suberic acids.

Methyl 8-oxohexadecanoate was prepared by oxidation of the hydroxy ester with chromic acid in acetic acid at 25 °C. The melting point of the oxo ester and the mixed melting point with synthetic methyl 8-oxohexadecanoate was 36–36.5 °C. 8-Oxohexadecanoic acid was obtained on hydrolysis and had melting point and mixed melting point 75.5–77 °C.

Synthesis of 8-Oxo- and 8-Hydroxyhexadecanoic Acids

6-Oxotetradecanoic acid (6 g) (9) and methyl hydrogen succinate (6.6 g) were electrolyzed in 0.022 *N* sodium methoxide solution (30 ml). After 1.5 h a further 3 g of half ester was added in sodium methoxide solution (10 ml) and the electrolysis continued for another 1.5 h when the solution was alkaline. Methanol was added to give a volume of 75 ml and insoluble dioxohexacosane was filtered off. The residue was acidified with acetic acid, the methanol removed, and the product taken up in ether and washed with sodium bicarbonate. After removal of the ether the esters were distilled and crude oxo ester collected at 130–150 °C and 0.1 mm. The distillate was saponified and crystallization of the acid from acetone yielded 8-oxohexadecanoic acid (1.35 g) with melting point 76–77 °C (lit. (29) gives 77.4–78.9 °C). The methyl ester had melting point 36–36.5 °C (lit. (29) gives 36.5–37.1 °C).

Hydrogenation of the oxo acid (30) yielded 8-hydroxyhexadecanoic acid with melting point 73.5–74.5 °C.

Anal. Calcd. for $C_{16}H_{32}O_3$: C, 70.5; H, 11.8. Found: C, 70.5; H, 12.0.

The methyl ester had melting point 45–46 °C.

Anal. Calcd. for $C_{17}H_{34}O_3$: C, 71.3; H, 12.0. Found: C, 71.5; H, 12.0.

Dihydroxy Ester Fraction

Crystallization from light petroleum gave methyl *threo*-9,10-dihydroxyoctadecanoate with melting point 67.5–68.5 °C, undepressed by admixture with the synthetic ester of melting point 68–69 °C. After removal of several optically inactive crops of crystals from the mother liquors the residue (0.17 g from 1.16 g) had $[\alpha]_D$ +4° (*c*, 3.4, MeOH). *threo*-9,10-Dihydroxyoctadecanoic acid was obtained by saponification of the ester and had melting point and mixed melting point of 93–94.5 °C.

ACKNOWLEDGMENTS

The author is grateful to Dr. M. Steeves for the identification of the *Lycopodium* spores. The author also thanks Mr. L. L. Hoffman for able technical assistance, Mr. M. Mazurek for the microanalyses, and Mr. W. C. Haid for the infrared spectra.

CONSTITUTION OF AN ARABINOGALACTOMANNAN FROM HONEY[1]

I. R. SIDDIQUI
Food Research Institute, Canada Department of Agriculture, Ottawa, Canada
Received August 14, 1964

ABSTRACT

An arabinogalactomannan isolated from honey consisted of D-mannose, L-arabinose, and D-galactose in molar proportions of 1.0:2.04:4.04 respectively. Electrophoretic and sedimentation results indicated that the arabinogalactomannan was homogeneous. Methylation studies showed a highly branched structure. Hydrolysis of the methylated polysaccharide gave 2,3,4,6-tetra-*O*-methyl-D-mannose (3 molecular proportions); 2,3,4,6–tetra-*O*-methyl-D-galactose (2 molecular proportions); 2,3,5-tri-*O*-methyl-L-arabinose (1 molecular proportion); 2,3,4-tri-*O*-methyl-D-galactose (6 molecular proportions); 2,3-di-*O*-methyl-L-arabinose (4 molecular proportions); 2,5-di-*O*-methyl-L-arabinose (1 molecular proportion); 2,4-di-*O*-methyl-D-galactose (5 molecular proportions). The general structural features of the arabinogalactomannan are discussed.

Although many extensive investigations have been made on the composition of honey, practically nothing is known about its polymeric constituents. The presence of polysaccharide in honey has been recognized for many years and it has been pointed out that the removal of these colloidal components results in the elimination of turbidity and production of brilliant clarity; caramelization and tendency to crystallization are also greatly lessened (1, 2, 3). The only report on the nature of these colloidal constituents appeared in 1953. On the basis of electrophoretic and sedimentation analyses of buckwheat honey the presence of three polymeric constituents has been claimed (4); the major components were proteins and the minor component appeared to be a polysaccharide.

In the present investigation, a number of honey samples were examined for their polysaccharide content. The polymeric material, in every instance, on hydrolysis produced small amounts of sugars and large amounts of amino acids. Among the sugars, glucose, galactose, mannose, arabinose, and xylose were invariably present; in some cases rhamnose and traces of uronic acids were also detected. Following this preliminary investigation, a detailed study was made of the polysaccharide isolated from honey collected at the Central Experimental Farm, Ottawa.

The crude polymer was precipitated from a 50% aqueous solution of honey by ethanol in a yield of about 0.2% of honey. Attempts to fractionate the crude material by the conventional methods such as precipitation with Fehling solution (5), precipitation with Cetavlon and borate (6), and phenol–water partition (7), were largely unsuccessful. The procedure which proved successful consisted of acetylation (8) of the crude material, extraction with acetone, and deacetylation to yield two fractions (I and II yield; ca. 1% based on the crude polymer and 0.002% of honey respectively).

There was undoubtedly more polysaccharide present in the acetylated acetone-insoluble residue as was evident by the paper chromatographic analysis of the deacetylated hydrolyzed product. However, the present technique did not permit its isolation. Fraction I on acid hydrolysis yielded galactose, glucose, mannose, arabinose, xylose, and rhamnose. Fraction II produced galactose, mannose, and arabinose, and showed a single symmetrical mobile peak on boundary electrophoresis (9) and sedimentation analysis (10) (Figs. 1 and

[1]*Issued as Contribution No. 18 of the Food Research Institute.*

2). On the basis of these observations, this material appeared to be a chemically homogeneous polysaccharide and was the subject of further investigations as reported in this paper.

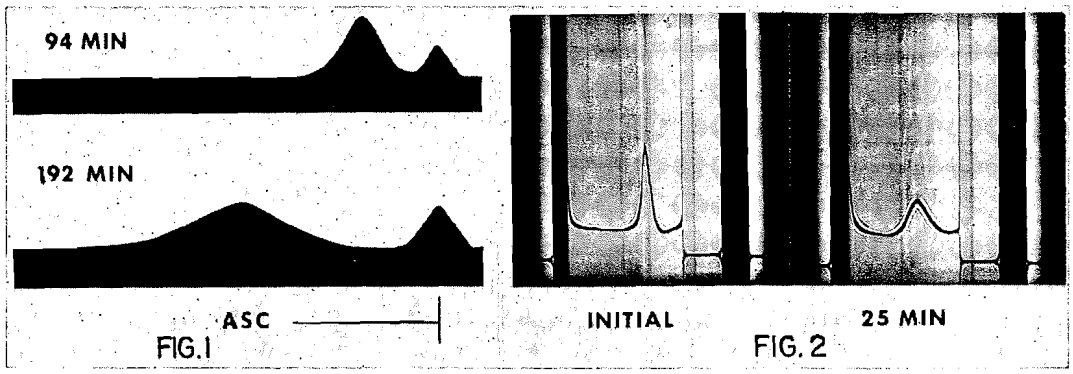

FIG. 1. Electrophoretic pattern of polysaccharide in borate buffer pH 9.2.
FIG. 2. Sedimentation pattern of polysaccharide in borate buffer pH 9.2.

After acid hydrolysis of the polysaccharide, mannose, arabinose, and galactose were found (11) in a ratio of 1.0:2.04:4.04. From the hydrolysis products, D-galactose and L-arabinose were obtained in the crystalline form and D-mannose was identified as *N*-*p*-nitrophenyl-β-D-mannosylamine, dihydrate (12).

The polysaccharide was methylated and the fully methylated product was subjected to methanolysis and hydrolysis. The *O*-methyl sugars were quantitatively determined, in a portion of the hydrolysate, by gas–liquid partition chromatography (13) of their methyl glycosides. The overall quantitative ratio of (di-*O*-methyl-hexosides) to (di-*O*-methyl-pentosides and tri-*O*-methyl-hexosides) to (tri-*O*-methyl-pentosides and tetra-*O*-methyl-hexosides) was 1:2:1. Analytical data are summarized in the following table.

Hydrolysis products from methylated arabinogalactomannan

Component No.	Component	Molar ratio	Structural feature indicated
1	2,3,4,6-Tetra-*O*-methyl-D-mannose	3	D-Man*p* 1 →
2	2,3,4,6-Tetra-*O*-methyl-D-galactose	2	D-Gal*p* 1 →
3	2,3,5-Tri-*O*-methyl-L-arabinose	1	L-Ara*f* 1 →
4	2,3,4-Tri-*O*-methyl-D-galactose	6	→ 6-D-Gal*p* 1 →
5	2,3-Di-*O*-methyl-L-arabinose	4	→ 5-L-Ara*f* 1 → and (or) → 4-L-Ara*p* 1 →
6	2,5-Di-*O*-methyl-L-arabinose	1	→ 3-L-Ara*f* 1 →
7	2,4-Di-*O*-methyl-D-galactose	5	→ 3 → 6 -D-Gal*p* 1 →

All of these sugars, with the exception of 2,3,5-tri-*O*-methyl-L-arabinose and 2,5-di-*O*-methyl-L-arabinose, were characterized by the isolation of crystalline aniline derivatives. The ratio of mannose : arabinose : galactose calculated from the proportion of methylated sugars was 1.0:2.0:4.3 in good agreement with that found for the original polysaccharide. All of the mannose was accounted for as nonreducing terminal units and, therefore, could not have arisen from an admixed mannan.

The methylation analysis showed that the molecule had a highly branched structure. Thus, of the 22–23 sugar residues which make up an average unit of the polysaccharide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

there are 6 terminal nonreducing end groups consisting of 3 units of mannose, 2 of galactose, and 1 of arabinose. There are also 5–6 residues of galactose at which branching occurs, in the polysaccharide, through the 3 and 6 positions. The remaining 11 nonterminal residues consist of 6, 1 → 6 linked galactose units; 4, 1 → 5 and (or) 1 → 4 linked and 1, 1 → 3 linked arabinose units.

Although no attempt was made to determine the molecular weight of the polysaccharide, the rapid rate of diffusion (Fig. 2) indicated a low molecular weight. The use of a synthetic boundary cell for sedimentation analysis suggested this to be less than 10 000. The value quoted (4) for the molecular weight of buckwheat honey polysaccharide is 9 000.

The present data do not permit formulation of a unique structure, as the sugar residues can be arranged in several different ways. At present only the linkages between the various sugars are known with certainty. Fragmentation studies are necessary to reveal the detailed structure of the polysaccharide. Such a study might also be useful in providing additional evidence for the triheteropolymer nature of this polysaccharide.

EXPERIMENTAL

Paper chromatography was performed by the descending method on Whatman No. 1 paper using the organic phases of the following solvent systems: (A) 1-butanol : acetic acid : water (4:1:5); (B) ethyl acetate : pyridine : water (8:2:1); (C) 1-butanol : ethanol : water (40:11:19); (D) 2-butanone saturated with water containing 2% ammonia. Chromatograms were sprayed with (A) aniline hydrogen phthalate for reducing sugars (14) and (B) ninhydrin (15) for amino acids. Evaporations were carried out at 35 °C using a rotary film evaporator. Melting points are corrected and rotations are equilibrium values.

Isolation of the Polymer

Honey (100 lb) diluted with an equal volume of water was added to 95% ethanol (50 gal) agitated mechanically. The precipitate was removed using a Sharples centrifuge, suspended in water, and dialyzed for 3 days against running tap water. The soluble and insoluble material (80 g) was recovered by ethanol precipitation. The polymer (80 g) was extracted successively with benzene, ether, and chloroform. The resulting material (73 g) showed N, 11.02% and ash, 2.4%. Chromatography of a hydrolysate (solvents A and B) (sprays A and B) showed galactose, mannose, arabinose, xylose, small amounts of rhamnose, and large amounts of amino acids.

Acetylation of the Polymer

Honey polymer (53 g) in formamide (500 ml) was shaken for 3 days. The gel-like product was warmed to 68 °C and pyridine (700 ml) was added with vigorous shaking followed by acetic anhydride (600 ml) in ten 60 ml portions. After shaking for 3 days the reaction mixture was poured into a mixture of water and ice (20 l). The insoluble material was removed by decantation and centrifugation and was extracted with acetone in a Soxhlet for 24 h. Evaporation of the acetone-soluble material gave the acetylated product. The residue was treated in this manner altogether four times, giving a total of acetylated product (6.3 g).

Deacetylation and Fractionation of the Polysaccharide

The acetylated product (6.3 g) was dissolved in acetone (1 500 ml), *N* sodium hydroxide (150 ml) was added, and the mixture was stirred magnetically for 20 h. The mixture was neutralized with glacial acetic acid, with cooling, and an oily precipitate was separated from the solution. This oily precipitate which was still alkaline was dissolved in water (200 ml) and the solution was mixed with methanol (4 volumes). The solution on neutralization with glacial acetic acid gave a precipitate and a supernatant solution A. The precipitate was dissolved in *N* sodium hydroxide and the solution was mixed with methanol (1 volume). The precipitate which formed was removed from the supernatant solution B, was suspended in water, dialyzed, and freeze dried to yield fraction I, 560 mg.

The acetone extract left after removal of the oily precipitate as described above was freed from the solvent by distillation and the residual solution (150 ml) was made *N* with respect to sodium hydroxide and mixed with methanol (4 volumes). A small amount of precipitate was discarded and the supernatant liquid was combined with supernatants A and B. The combined supernatant was adjusted to pH 7, concentrated to 200 ml, and dialyzed. The dialyzed solution was centrifuged to remove small amounts of insoluble material and the dark turbid solution was mixed with methanol (1 volume). The precipitate (145 mg) was centrifuged off and the clear solution was decolorized with charcoal, filtered, concentrated, and freeze dried to yield fraction II, 520 mg.

Paper chromatography of the hydrolysates prepared from the two fractions showed the presence of galactose, mannose, glucose, arabinose, xylose, and rhamnose in fraction I and galactose, arabinose, and mannose in fraction II.

Analysis of Arabinogalactomannan (Fraction II)

The arabinogalactomannan $[\alpha]_D^{22}$ −21.4° (*c*, 0.84 water) on analysis gave the following: N, 1%; ash, nil. Electrophoretic examination of a 1% solution in a Spinco apparatus model H in 0.5 *M* borate buffer pH 9.2 showed a single symmetrical peak (Fig. 1). The sedimentation pattern, using a synthetic boundary cell, of a 1% solution in borate buffer pH 9.2; ionic strength, 0.2; rotational speed 59 780 rev/min is shown in Fig. 2. The polysaccharide (2.5 mg) was hydrolyzed with 2 *N* sulfuric acid for 3 h at 100 °C. The sugars were recovered and determined quantitatively according to Nelson (11), giving a ratio of mannose : arabinose : galactose of 1.0:2.04:4.04.

Acid Hydrolysis of Arabinogalactomannan

Polysaccharide (250 mg) was hydrolyzed with 2 *N* sulfuric acid (5 ml) for 3 h at 100 °C. After neutralization with barium carbonate, filtration, and evaporation, the sugars were recovered and separated on paper chromatograms in solvent B. Location and elution of appropriate strips gave galactose, mannose, and arabinose as syrups.

(i) D-*Galactose.*—The syrup crystallized from ethanol to give D-galactose, m.p. 164–165 °C and $[\alpha]_D^{22}$ +81.05 ± 1° (*c*, 0.95 water).

(ii) L-*Arabinose.*—The syrup crystallized from ethanol to give L-arabinose, m.p. 150–152 °C and $[\alpha]_D^{22}$ +105.8 ± 2° (*c*, 0.51 water).

(iii) D-*Mannose.*—The syrup was refluxed for a total of 12 h with an aliquot (1 ml) of a solution containing *p*-nitroaniline (9 g), methanol (200 ml), and concentrated hydrochloric acid (0.14 ml). The *N*-*p*-nitrophenyl-β-D-mannosylamine dihydrate, which settled out from the solution, was washed with methanol and had m.p. 219 °C and $[\alpha]_D^{22}$ −335° (*c*, 0.1 dry pyridine). Reported values (12): m.p. 219 °C, $[\alpha]_D^{22}$ −333°.

Methylation of Arabinogalactomannan

An ice-cooled solution of arabinogalactomannan (250 mg) in water (5 ml) was methylated by adding 30% sodium hydroxide (14 ml) and dimethyl sulfate (5 ml). The reagents were added at such a rate that the reaction mixture remained alkaline but as close to neutral as possible for the first few hours. The additions took place over 2 h after which the solution was stirred for 24 h. After four such methylations the reaction mixture was cooled and neutralized with glacial acetic acid to pH 7.0 and the solution extracted with chloroform (7 × 100 ml portions). The chloroform extract was dried (sodium sulfate), filtered, and evaporated to a syrup. The chloroform-soluble fraction gave some methanol-insoluble material (100 mg) which was combined with the residue recovered by freeze drying from the dialyzed aqueous solution. The combined material after nine further additions of 30% sodium hydroxide (7 ml) and dimethyl sulfate (3 ml) was recovered in the usual way. The partially methylated product (175 mg) was methylated 10 times by Purdie's method, using methyl iodide (30 ml) and silver oxide (3 g) per methylation, to yield a product (150 mg), $[\alpha]_D^{22}$ −42.0° (*c*, 1.0 chloroform), which showed no hydroxyl absorption in its infrared spectrum.

Hydrolysis Products from Methylated Arabinogalactomannan

The methylated polysaccharide (150 mg) was refluxed with 3% methanolic hydrogen chloride (25 ml) for 24 h. The solution was neutralized with silver carbonate, filtered, and evaporated to a syrup, which was hydrolyzed with *N* sulfuric acid (10 ml) at 100 °C for 24 h. The hydrolysate was neutralized with barium carbonate, filtered, and evaporated to a syrup (90 mg). A portion of this syrup was refluxed with 2% methanolic hydrogen chloride for 6 h, neutralized with silver carbonate, and the resulting methyl glycosides in the solution were examined by gas–liquid partition chromatography (13) using a 4 ft column of 10% neopentylglycol sebacate on Chromosorb W at 180 °C and an argon flow rate of 100 ml/min. The areas under the peaks, measured by triangulation, gave the overall quantitative ratios of di-*O*-methyl-hexosides to (di-*O*-methyl-pentosides and tri-*O*-methyl-hexosides) to (tri-*O*-methyl-pentosides and tetra-*O*-methyl-hexosides) to be 1:2:1. Molar ratios of individual components were determined by gas–liquid partition chromatography of *O*-methyl-glycosides with the exception of 2,3,4-tri-*O*-methyl-galactose and 2,3-di-*O*-methyl-arabinose. The ratio for the latter components was evaluated from the combination of gas–liquid partition chromatography data and the actual weights of the fractions isolated. These ratios converted to the nearest whole number were 2,3,4,6-tetra-*O*-methyl-D-mannose, [3]; 2,3,4,6-tetra-*O*-methyl-D-galactose, [2]; 2,3,5-tri-*O*-methyl-L-arabinose, [1]; 2,3,4-tri-*O*-methyl-D-galactose, [6]; 2,3-di-*O*-methyl-L-arabinose, [4]; 2,5-di-*O*-methyl-L-arabinose, [1]; 2,4-di-*O*-methyl-D-galactose, [5].

The remaining mixture of sugars was separated on eight chromatograms (7 × 22 in.) using solvent C. Location and elution of appropriate strips gave the following fractions:

Fraction 1

The syrup showed two components having R_f values (solvent D) and color reactions identical with authentic specimens of 2,3,4,6-tetra-*O*-methyl mannose and 2,3,5-tri-*O*-methyl arabinose. It was separated on three chromatograms (6 × 22 in.) giving

*(a) 2,3,4,6-Tetra-O-methyl-*D-*mannose.*—The syrup (4 mg) in ethanol (0.25 ml) containing aniline (2 mg) was refluxed for 5 h. On evaporation of ethanol at room temperature crystals appeared which after recrystallization from ether in the cold gave 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-mannosylamine m.p. 153–155 °C. Reported value: 142–143 °C (19). An authentic sample of 2,3,4,6-tetra-*O*-methyl-D-mannose was treated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with aniline in exactly the same manner. The resulting crystals showed the same melting point undepressed on admixture with the former sample.

*(b) 2,3,5-Tri-O-methyl-*L*-arabinose.*—The syrup (ca. 3 mg) was oxidized with bromine. The resulting lactone was recovered in amounts too small to permit identification.

Fraction 2

The syrup on paper chromatography in solvent D showed a mixture of 2,3,4,6-tetra-*O*-methyl galactose and 2,5-di-*O*-methyl arabinose (one spot) and faint traces of an unidentified component. It was purified on two chromatograms (6 × 22 in.) using solvent D. The mixture of sugars (6 mg) was refluxed with aniline (3 mg) in ethanol (0.5 ml) for 5 h. Evaporation of ethanol gave crystals which were recrystallized from ethanol giving 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-galactosylamine, melting point and mixed melting point 195–197 °C. Reported value: 196 °C (16).

Fraction 3

The syrup showed two components, R_f values (solvent D) and color reactions identical to those given by authentic samples of 2,3,4-tri-*O*-methyl galactose and 2,3-di-*O*-methyl arabinose. The mixture was separated on four chromatograms (6 × 22 in.) using solvent D. Location and elution of appropriate strips gave

*(a) 2,3,4-Tri-O-methyl-*D*-galactose.*—The syrup (10 mg) was refluxed with aniline (5 mg) in ethanol (1 ml) for 5 h. On cooling, crystals separated which after recrystallization from ethanol gave 2,3,4-tri-*O*-methyl-*N*-phenyl-D-galactosylamine melting point and mixed melting point 167–168 °C. Reported value: 167 °C (17).

*(b) 2,3-Di-O-methyl-*L*-arabinose.*—The syrup (6 mg) in ethanol (0.5 ml) was refluxed with aniline (3 mg) for 5 h. Crystallization of the ether-soluble portion in the cold gave 2,3-di-*O*-methyl-*N*-phenyl-L-arabinosylamine having m.p. 135–138 °C. Reported value: 138 °C (18).

Fraction 4

Fraction 4 (15 mg) showed R_f value (solvent D) and color reactions identical with an authentic sample of 2,4-di-*O*-methyl galactose. The syrup was mixed with aniline (8 mg) in ethanol (1 ml) and the solution was refluxed for 4 h. Slow evaporation gave crystals which were washed and recrystallized from ethanol giving 2,4-di-*O*-methyl-*N*-phenyl-D-galactosylamine melting point and mixed melting point 216–217 °C. Reported value: 214-217 °C (16).

ACKNOWLEDGMENT

The author is grateful to Mr. F. P. Cooper for the gas–liquid chromatographic analysis.

ADDITION COMPOUNDS OF TITANIUM(IV) CHLORIDE CONTAINING ELEMENTS OF GROUPS V AND VI AS DONOR ATOMS

ALAN D. WESTLAND AND LIESELOTTE WESTLAND
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received August 20, 1964

ABSTRACT

Complexes $TiCl_4.L$ where L is a mono- or bi-dendate ligand having P, As, S, or Se as donor atom were prepared. Triphenylphosphine and dialkyl sulfide also form complexes $TiCl_4.2L$. Far infrared data are presented for certain of the complexes.

Organo derivatives of the heavier elements of groups V and VI, that is, phosphorus, arsenic, antimony, sulfur, selenium, and tellurium serve frequently as ligands in addition complexes with transition elements in low valence states. Few complexes of these elements have been reported in which the central atom is a transition element from one of the earlier groups in its highest valence state. However, H. Rose (1) reported over a century ago that phosphine forms an adduct with titanium(IV) chloride and hydrogen sulfide is known to form an adduct at low temperatures (2). Challenger and Pritchard (3) reported in 1924 that triphenylarsine forms an addition compound with $TiCl_4$ but they did not identify the resulting substance. In recent years, Clarke and co-workers (4) have shown that *o*-phenylenebisdimethylarsine forms the complexes MCl_4.dias and MCl_4.2dias where M = Ti, Zr, Hf. Fairbrother and Nixon (5) have shown that alkyl sulfides, R_2S, where R = CH_3, C_2H_5, will form complexes with pentahalides of niobium and tantalum. Chatt and Hayter (6) have prepared a few complexes of titanium(IV) chloride and mono- and di-tertiary phosphines. We have extended the list of known adducts formed by tertiary phosphines and arsines with tetrahalides of group IV elements and have shown that even the very weak Lewis bases, dialkyl sulfide and dialkyl selenide, form stable complexes with these elements. The present paper deals with complexes of titanium(IV) chloride.*

RESULTS AND DISCUSSION

All of the alkyl and aryl compounds of the elements N, P, As, Sb, O, S, Se, and Te which were tested were found to react with $TiCl_4$. Fowles has reported an investigation of the reaction of tertiary amines with $TiCl_4$ (7). We shall restrict ourselves here to the behavior of tertiary phosphine, arsine, and stibine and organo-sulfide, -selenide, and -telluride.

When pure components were allowed to react, fairly exothermic reactions occurred. The reaction of $TiCl_4$ with pure triethylphosphine is violent. For preparative purposes, the components were dissolved in dry benzene and allowed to react. In all cases, a yellow or deep-red coloration appeared. In one case studied more closely, that of triphenylarsine, the red color did not obey Beer's law indicating that the equilibrium,

$$TiCl_4 + AsPh_3 \rightleftharpoons TiCl_4.AsPh_3,$$

does not lie strongly to the right at low concentrations. It follows that the complex formed is not particularly stable with respect to the solvating effect of benzene upon the

**Note added in proof: Professor G. W. A. Fowles described the dialkyl sulfide complexes at the 8th International Conference on Coordination Chemistry, Vienna, September 1964.*

component substances. This solvation energy is presumably not large in the case of each component as there is no sensible heat effect when they are dissolved alone. However, Elliot, Evans, and Owen (8) report that $TiCl_4$ forms a 1:1 complex with benzene but it is a very weak one.

The compounds which were prepared are listed with colors, melting points, and analyses in Table I. It may be seen that 1:1 complexes only are found with monodentate arsine and selenide while triphenylphosphine and alkylsulfide formed 2:1 addition compounds. We have found a 1:1 complex as well with triphenylphosphine. This gave a Debye–Scherrer X-ray pattern which was almost identical with that of the corresponding arsine but which differed from that of the 2:1 complex. The 2:1 phosphine complex has been reported by Chatt and Hayter (6).

TABLE I

Properties and analyses of complexes of $TiCl_4$

Compound	Color	Melting point (°C)	Percentage composition			
			Found		Calcd.	
			Ti	Cl	Ti	Cl
$(Ph_3P)TiCl_4$	Red–violet	147.5–149	11.2	31.1	10.6	31.4
$(Ph_3P)_2TiCl_4$	Red–black	149–151	6.77	19.4	6.75	19.8

$(Ph_2Se_2C_3H_6)TiCl_4$	Red–black	83 (decomp.)	8.20	25.3	8.81	26.1

Triphenylstibine and diethyltelluride reacted with $TiCl_4$ in two stages. A deep-violet color was observed in each case, upon mixing benzene solutions of the components. After some seconds or minutes a black, somewhat gummy solid appeared. Evaporation of the mother liquor yielded a gum which crystallized poorly upon standing for a few days. Benzene solutions of these gums were brown rather than violet. Although the chlorine to titanium ratio in these residues was 4:1, the products were thought to consist of a complex or mixture of $TiCl_2$ and dichlorinated diethyltelluride. That it was not a simple mechanical mixture was indicated by the failure to remove tellurium, e.g. as dichlorodiethyltellurium, by extraction with carbon tetrachloride.

The possibility that all of the compounds contained titanium in a reduced valence state was considered, for all of the ligand substances are reducing agents to some degree. The molar magnetic susceptibility of one of the compounds, $TiCl_4.AsPh_3$, was found to be $\chi_M = -0.26 \times 10^{-3}$ c.g.s. units. The estimated value for the compound assuming an oxidation state of +4 for the titanium is -0.27×10^{-3}. The similar color and behavior of the remaining compounds allows us to extend analogous formulations to them.

Attempts were made to discover compounds with apparently different coordination numbers. The use of a ditertiary arsine and a selenodiether allowed us to produce complexes with two donor atoms in the coordination shell. Variation of the proportions of the components in the reaction mixture led to the formation of more than one product in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the cases of triphenylphosphine and the ditertiary phosphine. As Clarke and co-workers (4) were successful in preparing an eight-coordinate complex of $TiCl_4$ with o-$C_6H_4(AsMe_2)_2$, similar complexes with $C_2H_4(PPh_2)_2$ and $C_2H_4(AsPh_2)_2$ were sought. However, addition occurred in each case only to the extent of 3 moles of ligand to 2 moles of $TiCl_4$ which, if the compounds are not molecular mixtures, indicates a coordination greater than six. The 3:2 phosphine compound was formed when a benzene solution containing n moles of $TiCl_4$ was mixed with a solution containing $5n$ moles of the base. The 3:2 and the 2:3 adducts appear from the analyses to be somewhat contaminated with the 1:1 compound. The ditertiary arsine formed only the 3:2 complex.

It remains undecided whether the 1:1 complexes are five-coordinate monomers or more highly coordinated polymers. Many of the complexes are not sufficiently stable to yield definitive results from molecular weight determinations. It is likely that both 1:1 and 2:1 complexes occur in varying proportions in solution. Attempts to detect spectrophotometrically the existence of a 2:1 complex in the system Ph_3As–$TiCl_4$ were limited, because of the intense color, to work on systems containing very low concentrations of the components and perhaps for this reason were unsuccessful.

The dialkyl sulfide complexes were sufficiently soluble in benzene to measure depression of the freezing point. Good agreement with the molecular weights indicated that these complexes are stable monomers in benzene solution. The chelated compounds were all too sparingly soluble to afford sufficient accuracy in freezing point determinations.

An examination of far infrared spectra provided values of various metal–ligand stretching frequencies and thereby some comparison of the bonding was possible. Sulfide and selenide complexes gave broad absorptions of little interpretive value. About all that could be seen with certainty was the fact that this absorption reached a maximum at ca. 410 cm^{-1} for sulfur compounds and continued to lower frequencies while the maximum was reached at 395 cm^{-1} for the ethyl selenide complex. The upper limit is certainly associated with sulfur and selenium stretching rather than chlorine stretching.

Titanium–phosphorus stretches, where identifiable, are shown in italics.
Abbreviations: s, strong; vs, very strong; w, weak; sh, shoulder; b, broad.

It was possible to identify stretching bands with reasonable certainty in the case of the simpler phosphine complexes. A summary of frequencies in the region 260–520 cm^{-1} is given in Table II and where possible titanium–phosphorus stretching frequencies are shown in italics. These were assigned easily because of their relative isolation in compounds of various transition metals.* A sample spectrum is shown in Fig. 1. A single phosphorus stretch appears in the spectrum of $(Ph_3P)TiCl_4$ as expected but two bands are found for $(Ph_3P)_2TiCl_4$. The conclusion drawn is that these are symmetric and antisymmetric

**Unpublished work.*

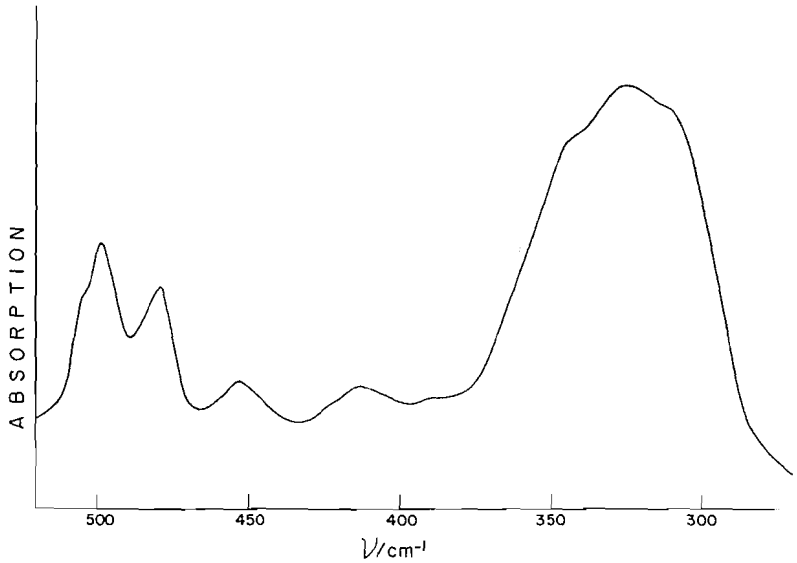

FIG. 1. Infrared spectrum of the compound $(Ph_4P_2C_2H_4)TiCl_4$.

modes which arise in the case of complexes having the *cis* configuration. The frequency values reported by Coates and Parkin (9) for the bonds formed between phosphorus and palladium, platinum, and gold are comparable with those found here. A force constant calculation which takes account only of the two atoms forming the bond shows that the values for the Ti—P bond in $(Ph_3P)_2TiCl_4$ are just about the same as for the Pt—P bond in *cis*-$(Me_3P)_2PtCl_2$, a typical phosphine complex of high stability. Table III presents the force constants so estimated for the symmetric and antisymmetric modes of these compounds. The force constants are designated k_1 and k_2 because it is not certain which belongs to the symmetric and which to the antisymmetric mode. The comparison

TABLE III

Comparison of force constants

	Force constants (dyne $cm^{-1} \times 10^{-5}$)	
Compound	k_1	k_2
$(Ph_3P)_2TiCl_4$	2.18	2.07
$(Ph_4P_2C_2H_4)TiCl_4$	2.27	1.90
cis-$(Me_3P)_2PtCl_2$	2.22	2.05
$(Ph_4P_2C_2H_4)PtCl_4$	2.96	2.87

shows that $TiCl_4$ is just as effective as an acceptor toward a phosphine as $PtCl_2$. It will be remembered that platinum is regarded as one of the most strongly bonding elements towards phosphines. However, it is seen that when the valence state of the platinum is made to equal that of the titanium, platinum is then the better acceptor.

It is interesting to observe that the Ti—P stretching frequency is greater for $(Ph_3P)TiCl_4$ than for either mode of the 2:1 adduct. A similar but rough comparison can be made for the 2:3 and the 3:2 complexes. Although it is not certain how many bands in each case should be attributed to metal–phosphorus and metal–chlorine stretching, it is at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

least likely that the band at 465 cm^{-1} for $L_2Ti_3Cl_{12}$ is due to Ti—P stretching and this is higher than the highest corresponding frequency, 436 cm^{-1}, for $L_3Ti_2Cl_8$. In the latter compound, additional bands, e.g. at 416 and 393 cm^{-1} are evidently due to Ti—P stretching, which indicates the complexity of the compound structure. A similar complexity is observed for the arsine $(Ph_4As_2C_2H_4)_3Ti_2Cl_8$.

EXPERIMENTAL

Infrared spectra of Nujol mulls between caesium iodide plates were obtained with a Perkin–Elmer Model 13G spectrometer set for double beam operation and fitted with a 30 micron grating. The fore-prism index was adjusted continuously throughout the spectral range. Analyses of complexes were carried out gravimetrically following preparation of the sample by Parr bomb combustion.

Titanium(IV) chloride was purified by the method of Clabaugh and co-workers (10). Triphenylphosphine, triphenylarsine, and triphenylstibine, obtained from M and T Chemicals, Inc., were recrystallized from ethanol until the melting points were constant. Dimethylsulfide and diethylsulfide, supplied by Distillation Products Industries, were distilled prior to use. The compounds 1,2-bis(diphenylphosphino)ethane and 1,2-bis(diphenylarsino)ethane were prepared by the method of Chatt and Hart (11).

1,3-Bis(phenylseleno)propane.—Phenylselenol (55.4 g) was added to a solution prepared by adding sodium (8.18 g, 1 mole) to ethanol (50 cc). To this, 1,3-dibromopropane (71.6 g, 0.5 mole) dissolved in ethanol (50 cc) was added dropwise with stirring. The solution was heated under reflux in a nitrogen atmosphere for 2 h. The solution was separated from sodium bromide by filtration and the alcohol removed by distillation. The resulting brown oil was distilled at 0.1 mm Hg pressure to yield an amber oil (37.2 g, 59%) with b.p. 185–188 °C.

Anal. Found: C, 50.7; H, 4.32. Calcd. for $C_{15}H_{16}Se_2$: C, 50.9; H, 4.55.

Preparation of complexes.—The addition complexes were all prepared by essentially the same procedure of which the following is representative.

Tetrachlorotriphenylphosphinetitanium.—The content of an ampoule of titanium(IV) chloride (3.84 g) was introduced to a nitrogen-filled Schlenk tube containing carefully dried, sulfur-free benzene (8 cc). To this solution was added triphenylphosphine (2.7 g, 0.5 mole) dissolved in benzene (10 cc). There was immediate appearance of a dark-red coloration with the formation of dark crystals. These were removed by filtration in an apparatus similar to that described by Fritz and co-workers (12). The product (2.3 g) was washed on the filter with a small quantity of benzene and dried at room temperature under vacuum. As the compound was attacked by moist air, it was stored in ampoules. This was true of all other complexes as well.

The other complexes were best prepared from stoichiometric quantities of the components except in the cases of the 3:2 and 2:3 compounds of the diphosphine. For the former, a fivefold excess of diphosphine was used and for the latter, a fivefold excess of $TiCl_4$.

It was possible to recrystallize the compounds prepared from monodentate ligands by dissolving in benzene and removing the solvent by distillation under reduced pressure. The bidentate ligands formed compounds which were only sparingly soluble. However, the analyses reported in Table I refer to preparations which had not been recrystallized.

One compound, $(Ph_2S_2C_2H_4)TiCl_4$, appeared as a mixture of bright-red needles and darker-red granules. As shown in Table I these forms when separated melt at different temperatures, the darker one under non-equilibrium conditions, of course.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Mrs. Astrid Benn for assistance in obtaining the infrared spectra and to the National Research Council for financial aid.

DIFFUSION IN MULTICOMPONENT GASEOUS MIXTURES

PART 2. DIFFUSION OF XENON-133 IN BINARY MIXTURES OF XENON WITH HELIUM, NEON, ARGON, AND KRYPTON

HARRY WATTS[1]

South Australian Institute of Technology, Adelaide, South Australia

Received September 21, 1964

ABSTRACT

The diffusion coefficient of trace amounts of xenon-133 has been measured in binary mixtures of xenon with helium, neon, argon, and krypton. Measurements were made over the complete composition range in the pressure range 10–300 Torr at 302.6 °K. These systems are the first studied in which the results do not agree with the equation:

$$\frac{1}{D_{iM}} = \sum_{j \neq i} \frac{x_j}{\mathscr{D}_{ij}},$$

which relates the effective diffusion coefficient of a trace in an ideal gas mixture to binary diffusion coefficients and the composition of the mixture. Deviation from this equation can not be accounted for in terms of the known deviation of xenon from ideal gas behavior.

The self-diffusion coefficient of xenon was 0.060 and the binary diffusion coefficients Xe–He 0.535, Xe–Ne 0.230, Xe–Ar 0.127, Xe–Kr 0.0823, in $cm^2\ s^{-1}$ corrected to 1 atm pressure.

INTRODUCTION

Kinetic theory predicts, and several recent experimental investigations confirm (1–4), that the effective diffusion coefficient D_{iM} of a trace component i in a dilute gas mixture is given by the equation:

[1] $$\frac{1}{D_{iM}} = \sum_{j \neq i} \frac{x_j}{\mathscr{D}_{ij}}.$$

In eq. [1] the x_j are mole fractions and the $\mathscr{D}_{ij}$ are binary diffusion coefficients. This paper presents results of a further experimental investigation in which xenon-133 is the diffusing trace component in binary mixtures of xenon with the other group 0 gases. These systems are a special case of diffusion in a three-component mixture. Equation [1] then takes the form:

[2] $$\frac{1}{D_{A^*M}} = \frac{x_A}{\mathscr{D}_{A^*A}} + \frac{x_B}{\mathscr{D}_{A^*B}},$$

where x_A, x_B are the mole fractions of xenon and the second major component, $\mathscr{D}_{A^*A}$ is the self-diffusion coefficient of xenon and $\mathscr{D}_{A^*B}$ is the binary diffusion coefficient of xenon-133 with the other major component. This last quantity is approximated by the binary diffusion coefficient of normal xenon with the other major component.

RESULTS

All measurements were made in the same apparatus and by the same technique as previously described (4). Xenon-133 was obtained from the Radiochemical Centre, Amersham, England through the Australian Atomic Energy Commission.

The effective diffusion coefficient of xenon-133 in mixtures of xenon with each of the other group 0 gases was measured at several mole fractions. The self-diffusion coefficient of xenon and the binary diffusion coefficient of xenon with each of the other gases were also measured. All measurements were made at pressures in the range 10–300 Torr and

[1]*Present address: Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario.*

at 302.6 °K. The diffusion coefficients listed in Table I have been converted to 1 atm pressure assuming that the diffusion coefficient is inversely proportional to pressure; the actual experimental pressures are recorded in the table. It was previously shown that there is a significant difference of 2.5% between the results of duplicate experiments performed in the two diffusion cells (4). (This was shown by the application of "Student's *t* test", see, for example, Youden (5).)

Further, over the pressure range used, results obtained in the same cell may differ by 1.5%. The standard deviations given in Table I are those calculated for a single experiment; they vary from under 5% to over 10%. When allowance is made for the difference between cells and pressures, the standard deviations vary from about 1 to 6%. The standard deviation on the means should thus be better than 6%.

DISCUSSION

The predictions of eq. [2] are: (i) $1/D_{A^*M}$ varies linearly with x_A; (ii) at $x_{Xe} = 0$, $1/D_{A^*M} = 1/\mathscr{D}_{AB}$; (iii) at $x_{Xe} = 1$, $1/D_{A^*M} = 1/\mathscr{D}_{A^*A}$. Figure 1 shows that the reciprocal of the effective diffusion coefficient is a linear function of mole fraction over the greater part of the composition range for each system. The intercepts at $x_{Xe} = 0$ are given by the experimental binary diffusion coefficients. Straight lines through the points for each system extrapolate to the same intercept at $x_{Xe} = 1$. This intercept, however, does not agree with the experimental value of the self-diffusion coefficient of xenon from which it differs by 10%; this difference is significantly greater than the measuring error.

Before concluding that eq. [2] is invalid for these systems it is well to be certain that systematic experimental errors are not present. Errors in making up gas mixtures or contamination of the gases with impurities could lead to the observed results. It is unlikely that the same errors could have been made consistently with each mixture to give a common intercept at $x_{Xe} = 1$. Further, the technique for making mixtures was as used in the previous measurements (4) of the effective diffusion coefficient of krypton-85 in mixtures. Three different samples of xenon-133 and several different samples of normal xenon and the other gases were used in preparing mixtures, so errors due to impurities are unlikely.

The observed self-diffusion coefficient of xenon may be in error. The six measurements tabulated, however, were not all performed with the same sample of normal xenon or of xenon-133. The results in Table I*e* have a standard deviation of about 5%, less than 2% when allowance is made for the difference between cells and pressures. Thus these measurements are self-consistent. In Table II a comparison is made between the self and binary diffusion coefficients of xenon found in this work and values recorded in the literature.

The self-diffusion coefficient of xenon is consistent with those of Visner (6) and Amdur and Schatzki (7), but not with that of Groth and Harteck (8). The value of Groth and Harteck, however, is even less in agreement with that calculated from the intercept of Fig. 1. The binary diffusion coefficients agree with those in the literature. Thus it must be concluded that eq. [2] is not valid for the present systems. A detailed investigation in the composition range 0.8–1.0 mole fraction of xenon would be necessary to discover the relation between diffusion coefficient and composition.

The observed self-diffusion coefficient is significantly smaller than the value given by extrapolation of the concentration dependence; 0.06 $cm^2\ s^{-1}$ compared with 0.07 $cm^2\ s^{-1}$. A possible cause of this lower value is association of the diffusing species. Bernardes and Primakoff (10) investigated the possibility of stable diatomic molecule formation in the group 0 gases and derived an equation from which the degree of association might be calculated. Their equation predicts about 0.4% association in xenon under the conditions of these experiments. This is insufficient to affect the diffusion results significantly.

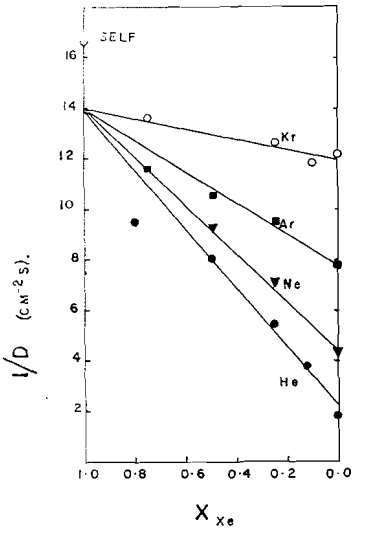

FIG. 1. Reciprocal of the effective diffusion coefficient of xenon-133 in the various mixtures plotted against mole fraction.

The formation of diatomic molecule ions, such as Xe_2^+, caused by ionizing radiation from the decay of xenon-133, was calculated to occur to less than 1 part in 10^{14}. This would not influence the diffusion results. The calculation was made on the basis of data in the literature (11–13) and the known amount of xenon-133 used in an experiment.

The effect of nonideal gas behavior was calculated to be insufficient to cause deviations from eq. [2]. The calculation was performed on the basis of the association model for the second virial coefficient given by Fowler and Guggenheim (14) and the second virial coefficients tabulated by Beattie (15).

The systems reported here are the first for which eq. [2] is not valid. No simple explanation for the failure of this equation can be offered. The need for further investigation of these systems in the xenon-rich region is obvious. The author is no longer in a position to carry out such an investigation and suggests that others may care to do so.

THE CRYSTAL STRUCTURE OF α-$Zn_3(PO_4)_2$

CRISPIN CALVO
Department of Chemistry, McMaster University, Hamilton, Ontario
Received July 28, 1964

ABSTRACT

α-$Zn_3(PO_4)_2$ crystallized in the monoclinic space group $C2/c$ with lattice parameters $a = 8.14 \pm 0.02$ Å, $b = 5.63 \pm 0.01$ Å, $c = 15.04 \pm 0.04$ Å, $\beta = 105°08' \pm 05'$, and $Z = 4$. The cations are found in two types of tetrahedrally coordinated sites. One-third of the cations lie on twofold axes within an oxygen tetrahedron. The remaining cations are found in a pair of edge-sharing oxygen atom tetrahedra. The green emission of Mn^{++} in α-$Zn_3(PO_4)_2$ is consistent with Mn^{++} substituting for Zn^{++} in either tetrahedral site.

INTRODUCTION

The probable phase diagram of anhydrous zinc orthophosphate has been determined by Hummel and co-worker (1). The α-phase was shown to be stable below 942 °C and to transform above this temperature to a new phase, labelled β. No further transitions occur between 942 °C and the melting temperature (1 060 °C). Upon the addition of Mn^{++} (2), Mg^{++} (3, 5), Cd^{++} (4) as orthophosphates a third phase was found. This phase, generally called γ, has been shown to be in fact a solid solution (2). The composition range over which the γ-phase is stable varies with the nature of the added cation. The crystal structure of γ-$Zn_3(PO_4)_2$ has been resolved (6) and, in addition, it appears to be isostructural with the end member $Mg_3(PO_4)_2$. Some crystallographic data are available on other phases that may be important in understanding the phase behavior of $Zn_3(PO_4)_2$. Mackay has discussed the crystallography of $Ca_3(PO_4)_2$ (7) and unpublished data have been obtained for $Mn_3(PO_4)_2$, $Cd_3(PO_4)_2$, and β-$Zn_3(PO_4)_2$ (8).

Studies related to the luminescence of suitably activated $M_3(PO_4)_2$ has led to the discovery of a large number of polymorphs. Here temperature and composition are to be regarded as the variables. Two stable phases are reported to occur in each of $Zn_3(PO_4)_2$ (1), $Sr_3(PO_4)_2$ (9), $Ca_3(PO_4)_2$ (7), and $Pb_3(PO_4)_2$ (10). Recently two phases of $Mn_3(PO_4)_2$ have been identified and a third is suspected on crystallographic grounds. Similarly a second phase is suspected to occur in $Cd_3(PO_4)_2$ at high temperatures. $Ba_3(PO_4)_2$ on the other hand shows only one phase up to its melting temperature. Additional new compounds of the type $Ba_2Y(PO_4)_2$, $BaY_2(PO_4)_2$, and $SrY_2(PO_4)_2$ for Y = Zn or Mg (9, 11) have been reported. Differential thermal analysis studies of these phases indicate new polymorphic forms in the zinc-containing members at high temperature. In addition three distinct solid solutions are found in the $(Cd,Zn)_3(PO_4)_2$ system. One of these phases appears to be an isostructure of γ-$Zn_3(PO_4)_2$ (4). In contrast only a limited number of anhydrous orthophosphates are found as minerals in nature. These minerals are whitlockite, graftonite (12), scarscopside, and hurlbutite. Crystal structures of the last two have been published (13, 14). Finally the crystal structures of the room-temperature forms $Ba_3(PO_4)_2$ and $Sr_3(PO_4)_2$ have been determined and are identical (15). It is clear that a great deal of crystallographic information remains unresolved and that without such a resolution the crystal chemistry of the orthophosphates will remain a bibliographic indexing.

It has been widely suggested that the emission energy of Mn^{++} is related to its coordination number. The luminescence of α-$Zn_3(PO_4)_2$:Mn is green whereas both

β-$Zn_3(PO_4)_2$:Mn and γ-$Zn_3(PO_4)_2$:Mn emit red when suitably excited. In detail a green emission is said to arise from tetrahedrally coordinated Mn^{++} while the red emission arises from an octahedrally coordinated environment. The theoretical basis for this proposed correlation lies in the Sugano–Tanabe (16) diagram of the energy level splittings versus the ratio of the octahedral component of the crystal field energy to the electron correlation as measured by the parameter DQ/B. Assuming that the crystal field term DQ increases with the number of ligands and further that a similar diagram is also valid for the emission states, one can understand the proposed correlation. In γ-$Zn_3(PO_4)_2$ one finds both tetrahedral and octahedral cation sites and some evidence exists for the preferential solubility of Mn^{++} into the octahedral site. Thus a consistent model can be obtained in this system.

The present crystal structure study has been undertaken, in part, to determine whether the tetrahedrally coordinated cation sites, as suggested by the emission, actually exist. The consequences of direct Mn^{++} substitution for Zn^{++} are considered and this manner of substitution is the basis for a discussion of the relative free energies of the α- and γ-phases.

EXPERIMENTAL

Single crystals of α-$Zn_3(PO_4)_2$ suitable for X-ray crystallographic studies were grown from $ZnCl_2$ melt (17). A mix containing about tenfold molar excess of the solvent was placed in an open vycor tube plugged at the open end with quartz wool. At 650 °C all the zinc orthophosphate had dissolved. Crystals were then grown by slow cooling of this mix from 650 °C to room temperature. The α-$Zn_3(PO_4)_2$ crystals were easily recovered from the slurry formed upon the addition of water. The crystals were needle-shaped with the needle axis coinciding with the crystallographic b-axis. Since X-ray reflections indexed as $h0l$ with l = odd and hkl with $h + k$ = odd were not observed, the space group choice then lay between $C2/c$ and Cc. The centered space group was chosen as the trial space group.

Lattice parameters were obtained from rotation photographs calibrated for the effective camera radius by superimposing NaCl powder lines. The parameters so obtained were $a = 8.14 \pm 0.02$ Å, $b = 5.63 \pm 0,01$ Å, $c = 15.04 \pm 0.04$ Å, $\beta = 105°08' \pm 05'$. These values are in good agreement with those obtained by Amick from powder data (18). The measured density of 3.88 g/cm³ compares well with the calculated density of 3.85 g/cm³ for a unit cell containing four molecules. Since the $C2/c$ space group requires that atoms in the general position occur in the unit cell as multiples of 8, at least 4 of the 12 Zn^{++} must occur in special positions. The available sites of fourfold multiplicity are on the twofold axis and at the center of symmetry.

Intensity data visually estimated from Weissenberg photographs were obtained for the 0th and 1st layer lines about the b-axis. These data were taken with Cu K_α radiation using a crystal of breath 0.1 mm × 0.1 mm perpendicular to the needle axis and 0.3 mm along this axis. Patterson function projections were prepared from these intensity data after suitable corrections for Lorentz and polarization effects. These functions were readily interpreted for the x- and z-parameters of Zn and P atoms. The ambiguity with regards to the special site occupied by one-third of the cations was resolved in favor of a twofold axis site by the interpretation of the generalized Patterson function, prepared with the data from the 1st layer line, together with the trial x- and z-parameters; x- and z-parameters from the oxygen atoms were determined from Fourier and difference Fourier projections. Trial y-parameters for the oxygen atoms were found by distributing these atoms tetrahedrally about the P atom on a spherical shell of radius equal to 1.5 Å. Subsequent refinement of these parameters yielded a value for the reliability index of 0.18 for the $h0l$ and 0.27 for the $h1l$ data. At this stage the dispersions in the value of the P—O and O—O bond distances about the PO_4 group suggested the need for additional data. Therefore $hk0$ and $0kl$ data were taken with Mo K_α radiation on the precession camera and in addition the first three layer lines about the b-axis were also recorded with this radiation using the Weissenberg camera. No absorption corrections were necessary for the data taken with Mo K_α radiation. Additional refinements using difference Fourier series and least-squares procedures with this new data included has led to the atomic parameters tabulated in Table I. A modified Busing, Martin, and Levy program (19) for the IBM 7040 (20K) was used in this least-squares refinement. The overall reliability index for the 750 independent observations including unobserved reflections is 0.12. The reliability index for the individual zones is shown in Table II and the observed and calculated structure factors are compared in Table III.

THE CRYSTAL STRUCTURE

The crystal structure is seen in projection onto the $x - z$-plane in Fig. 1. The Zn^{++} in the special site and the one in the general position show tetrahedral coordination to surrounding oxygen atoms. However, only in the former case is the symmetry of a

regular tetrahedron actually approached. These zinc ions (Zn_I^{++}) lie on twofold axes and share one oxygen atom with each of four neighboring phosphorus atoms. The average Zn_I—O bond distance is found to be 1.98 ± 0.05 Å and the O—O near neighbor distance around this cation is 3.27 ± 0.13 Å. The near neighbor oxygen atom distribution about Zn_{II}^{++} is quite irregular but still roughly tetrahedral. The Zn_{II}—O bond distances range from 1.86 to 2.03 Å with an average of 1.96 ± 0.05 Å. Again each oxygen atom is shared with an unique phosphorus atom. The Zn_{II}^{++} occur as a centered pair of edge-sharing tetrahedra with O_{III} as the common oxygen atom. Only one oxygen atom (O_{IV}) is shared between the cations in the general position and the special site.

The phosphate groups are slightly irregular independent tetrahedron with each of its oxygen atoms coordinated with at least one Zn^{++}. The average P—O bond distance is 1.53 Å with an estimated standard deviation (e.s.d.) of 0.03 Å in agreement with the accepted value of 1.54 Å for a P—O bond with a double bond order of 0.5 (20). However, the values obtained range from 1.50 to 1.58 Å. There is no doubt that the lack of high resolution along the *y*-direction will limit the accuracy with which these oxygen atoms can be located. The relatively large e.s.d. on all the *y*-parameters illustrates this point. The O—O bond distances around the tetrahedron average 2.52 Å and the bond angles

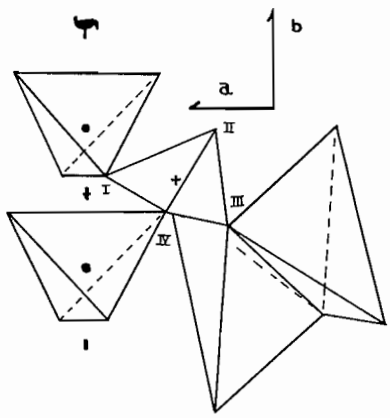

FIG. 1. α-$Zn_3(PO_4)_2$ crystal. Structure projected onto the $x = 0$ plane. The PO_4 group and Zn_IO_4 are represented by tetrahedra and the $Zn_{II_2}O_6$ group is depicted as an edge-shared pair of tetrahedra. The oxygen positions are at the corners of these polyhedra. The positions of the phosphorus atoms are shown by the crosses, and the full circles are the positions of Zn_I^{++}.

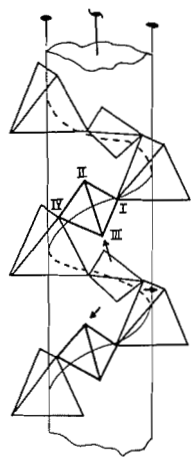

FIG. 2. The coordination among the PO_4 and Zn_IO_4 groups. The axis of the cylinder corresponds to the 2_1 axes of the structure whereas the twofold axes lie in the surface. The smaller tetrahedron represents the PO_4 group. The oxygen atoms are labelled for one of these tetrahedra. The three oxygen atoms which are bonded to a given Zn_{II}^{++} are indicated by arrows.

The phosphate ion and the $Zn_{II}O_4$ group alternate in generating the spiral unit shown in Fig. 2. This spiral has a pitch equal to the length of the *b*-axis and its axis coincides with the twofold screw axis. The structure near the $c/4$-planes parallel to the *a*-axis and containing the twofold axes consists of spirals of this sort. The spirals in this plane are related by the twofold axes lying in the conceived surface that encloses the spiral. Adjacent sheets of these spirals are generated by the centers of symmetry lying in the $z = 0$ plane. These near neighbor sheets are joined by the coordination of the Zn_{II}^{++}. Of the

four oxygen atoms bonded to a given Zn_{II}^{++} three are shared with phosphorus atoms in one set of spirals. The arrows in Fig. 2 indicate these oxygen atoms. Zn_{II}^{++} can be considered to control the pitch of the spiral. The fourth oxygen atom (O_{III}') is used to join adjacent spirals. An alternate description of the structure is presented below where the α- and γ-phase structures are compared.

α- TO γ-PHASE BOUNDARY

For temperatures near but below 900 °C and upon the addition of 5 or more mole % of the orthophosphates of Mn, Mg, or Cd to $Zn_3(PO_4)_2$, the γ-phase is found to be stable. In the case of added Mn^{++} this phase boundary has a negative temperature versus composition slope. The α-phase on the other hand is stable to the addition of only a very small percentage of Mn^{++}. Any composition between these limits of solubility of Mn^{++} in the two phases results in fact in a mixture of α-$(Zn,Mn)_3(PO_4)_2$ and γ-$(Zn,Mn)_3(PO_4)_2$. The low solubility of Mn^{++} must mean that the free energy of the α-phase must increase rapidly upon adding Mn^{++}, for finite concentration of the added impurity. This in turn indicates a relatively unfavorable site for the added Mn^{++}. The phase diagram of $Cd_3(PO_4)_2$ or $Mg_3(PO_4)_2$ with $Zn_3(PO_4)_2$ leads one to a similar conclusion in these cases. We will examine the differences in the two structures in some detail in the hope of gaining some understanding of the large dependence of the chemical potential of Mn^{++} on its concentration in the α-phase.

These structures have the following points of similarity. The phosphate groups occur as independent tetrahedra with each oxygen atom shared with at least one Zn^{++}. The cations are found in two different types of sites with the less symmetrically coordinated cation (Zn_{II}^{++}) occurring at twice the frequency of the more symmetrically bonded cation (Zn_I^{++}). The cations in the low symmetry site are found as a discrete centered pair of edge-sharing ZnO_4 groups. In each phase a pair of symmetry-related oxygen atoms (O_I) are shared only between phosphorus atoms and the higher symmetry cations site.

The near neighbor bonding in the two structures differ on the following points. Zn_I^{++} in the α-phase lies on a twofold axis and is tetrahedrally coordinated with each of the four oxygen atoms shared with a different phosphorus atom. In contrast the more symmetrical cation site in the γ-phase lies on a center of symmetry and is octahedrally coordinated with each of the six oxygen atoms contributed by a different PO_4 group. In the α-phase only one oxygen atom is shared between the type I and type II cations while in the γ-phase two oxygen atoms are so shared.

We would expect that if the transition between α and γ were to be direct, the structural features that these phases have in common would be preserved. Thus the tetrahedrally coordinated Zn_I^{++} in the α-phase would transform into the octahedrally coordinated Zn_I^{++} in the γ-$Zn_3(PO_4)_2$. The two new oxygen atoms coordinated with Zn_I^{++} must have been contributed by two PO_4 groups not previously sharing oxygen atoms with the particular cation site under consideration. Unfortunately when we consider further neighbors we find that a more drastic rearrangement is necessary than that required to transform the tetrahedrally to the octahedrally coordinated site. In each structure the Zn_2O_6 groups about the type II cation site share oxygen atoms with two pair of PO_4 to form a linear hexagonal chain (Fig. 3*a*). In the α-phase these ribbons are joined through O_{III} to form the set of steps shown in Fig. 3*b*. Adjacent sheets are generated by the twofold axes passing through the cations. Thus in one sheet the steps run along the

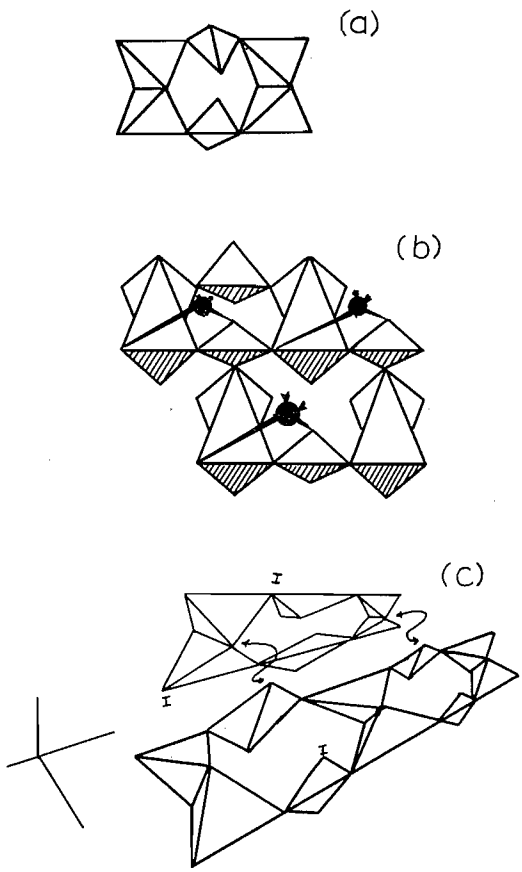

FIG. 3. A comparison of the structures of γ- and α-$Zn_3(PO_4)_1$. (*a*) Coordination of PO_4 and $Zn_{II_2}O_6$ groups. The edge-shared tetrahedra represented by the $Zn_{II_2}O_6$ groups and the tetrahedra represented by the PO_4 groups form a one dimensional ribbon. (*b*) The arrangement of adjacent ribbons in the α-$Zn_3(PO_4)_2$ structure. The special site cation is represented by the open circle. (*c*) The arrangement of adjacent ribbons in the γ-$Zn_3(PO_4)_2$ structure. Two ribbons are shown and these are bond through sharing the common O_{III} indicated by the arrows. The cations at the special site is coordinated to the oxygen atoms at the positions indicated by I and those related to it by the center of symmetry at the cation.

$\vec{a} + \vec{b}$ direction while in the next neighboring sheet they run in the $\vec{a} - \vec{b}$ direction. The bonding across adjacent sheets is solely through these special site ions.

Similar ribbons occur in the γ-phase but here they all run parallel. The bonding of adjacent ribbons in the γ-phase is depicted in Fig. 3*c*. The cations at the center of symmetry lie within tubes of diamond cross section formed from four of these $(Zn_2O_6PO_2)_n$ chains. Here adjacent sheets are bonded both by the special site cations and by O_{III}. The conceived phase transformation therefore must involve a change from the crossed ribbons of the α-form to the parallel ones of the γ-form. This requires that alternate cations break Zn_{II}^{++}—O_{IV} bonds in alternate sheets of the α-phase and that these bonds reform with O_{IV} in adjacent cells translated one unit along the *b*-axis. Such a transformation would require such large cooperative motions that a solid state transformation is to be judged as unlikely although the structural similarity suggests a small free energy difference between the phases.

DISCUSSION

Divalent manganese substituted in either cation site would be consistent with the Linwood–Weyl–Schulman (21, 22) proposal that the green emission of Mn^{++} indicates that it is tetrahedrally coordinated. Unfortunately at present we do not know which site, if either, is occupied by the Mn^{++}. Although the crystallographic studies of the γ-phases did indicate a large relative nonpreference on the part of Mn^{++} for the edge-shared tetrahedral site, we can not deduce from this any reason for a preferred site in the α-phase. Fortunately this question can be answered by the examination of the electron paramagnetic resonance (e.p.r.) spectra of α-$Zn_3(PO_4)_2$:Mn. If Mn^{++} dissolves into the site on the twofold axis one should see one e.p.r. active site and further, one of the magnetic axes of the spin Hamiltonian tensor should lie along the twofold axis in this space group as in β-$Zn_2P_2O_7$ (23) and β-$Mg_2P_2O_7$ (24). Note that a positive result would confirm the space group chosen here. This study is presently in progress.

The role of divalent metal ions (Ca^{++}, Cd^{++}, Mn^{++}, or Mg^{++}) in causing the instability of the α-phase must involve a chemical specificity of either the Zn^{++} or the impurity ion, since a scalar variable like temperature as a perturbing influence results in yet another phase (β-$Zn_3(PO_4)_2$). This role, because of the diverse nature of the impurities, cannot be simply attributed to a "single" cause such as the difference in ionic radii or electronegativity between the added divalent metal ion and the Zn^{++}. Unfortunately the crystal structure of α-$Zn_3(PO_4)_2$ offers no clear-cut clue to indicate why this structure is so critically sensitive to the characteristics of the Zn^{++}. The fact that the spiral consisting of the Zn_IO_4 and PO_4 tetrahedra is locked laterally and vertically by the Zn_{II}^{++} may preclude the substitution of divalent cations into the general cation site. On the other hand the strain introduced by the cations substituting into the special site seems readily relaxable. The structure regarded as steps of ribbons joined by these special site cations seems easily adaptable to distortions. Unfortunately the crystallographic method emphasizes just geometric considerations and one must speculate about other factors, such as electron effects, which probably are very important in this question.

In contrast γ-$Zn_3(PO_4)_2$ appears to be a "compromise" structure since it appears so often as a solid solution. Thus ions such as Mg^{++} and Mn^{++} that have a high site preference for the octahedral site, can gain enough stabilization to compensate for the relatively unfavorable tetrahedra site. This suggests that entropy of mixing in the γ-$(Zn,Mn)_3(PO_4)_2$ will be near ideal and this further suggests, because of the nature of the phase diagram, that the α- and γ-$Zn_3(PO_4)_2$ have free energies of formation nearly the same. In particular assuming $Mn_3(PO_4)_2$ to dissolve ideally into the γ-phase, one would expect the α-phase to be stable by about 0.2 kcal/mole at the temperature of interest in the limit that the Mn concentration goes to zero. Inexact phase boundary curves, however, prevent one from directly determining the composition or temperature dependence of the chemical potential of $Mn_3(PO_4)_2$ in this phase. It is hoped that the study of the crystal structures of β-$Zn_3(PO_4)_2$, $Mn_3(PO_4)_2$, and $Cd_3(PO_4)_2$ will shed light upon site sensitivity of the ions.

ACKNOWLEDGMENTS

The early portions of this work were performed while the author was associated with the Radio-Corporation of America at Princeton, N.J. Special thanks are extended to Dr. W. H. McCarrol of that corporation who helped with the growing of the crystals and to the National Research Council of Canada which supported this work.

CONSIDERATIONS OF ADSORBED IONIC INTERMEDIATES ON THE AgO/Ag_2O ELECTRODE IN AQUEOUS ALKALINE SOLUTION

R. G. BARRADAS AND G. H. FRASER[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received July 21, 1964

ABSTRACT

An experimental study of the kinetics for the electrochemical formation of AgO from Ag_2O in aqueous alkaline solutions was reported in an earlier paper (1). The proposed mechanism for the rate-determining step was suggested to be the transfer of oxide ions across the mixed oxide interface. Further theoretical possibilities under Langmuir and Temkin conditions of surface coverages are considered here in the light of the previously obtained experimental data. In particular we examine the possibilities of the rate-determining step involving adsorbed ionic intermediates on the AgO/Ag_2O electrode at the oxide/electrolyte interface. For the Temkin conditions, the intrinsic and induced heterogeneity models of Conway and his co-workers have been applied to our calculation of Tafel slopes. None of the mechanisms at the oxide/electrolyte interface were found to be rate-controlling.

INTRODUCTION

In a previous paper (1) the relations between current and potentials were obtained by galvanostatic and potentiostatic experiments for the anodic oxidation of Ag_2O to AgO in normal and $N/40$ aqueous potassium hydroxide solutions. The stoichiometric reaction is

[1] $$2OH^- + Ag_2O = 2AgO + H_2O + 2e.$$

At high overpotentials a Tafel relation was obtained:

[2] $$\eta = a + 2.303(RT/F) \log i.$$

The results were fitted over the entire range of overpotentials studied (1 to 170 mV) to a hyperbolic sine relationship

[3] $$i = 2i_0 \sinh (\eta F/RT).$$

No dependence of rate on the extent of conversion of Ag_2O to AgO was noted, indicating that the rate-determining step occurs at an interface and is not a migration process within one of the oxides.

From these results it was concluded that the rate-determining step occurred at the AgO/Ag_2O interface, and was either

[4] $$Ag^+ = Ag^{+3} + 2e$$

or, more probably, the transfer of O^{-2} ions across the mixed oxide interface.

It was proposed that oxide ions were formed from adsorbed hydroxyl ions according to

[5] $$(OH^-)_{aq} = (OH^-)_s$$

followed by either proton abstraction

[6] $$(OH^-)_{aq} + (OH^-)_s = H_2O + (O^{-2})_s$$

or surface recombination

[7] $$2(OH^-)_s = H_2O + (O^{-2})_s$$

[1]*Holder of a Province of Ontario Government Fellowship for 1963–1964.*

or surface dissociation

[8] $$(OH^-)_s = (H^+)_{aq} + (O^{-2})_s, \qquad (H^+)_{aq} + (OH^-)_{aq} = H_2O.$$

The subscripts "aq" and "s" refer to an ion dissolved in solution and adsorbed on the electrode surface. It must be emphasized that our mechanisms involve adsorbed *ionic* intermediates. We do not consider intermediates covalently adsorbed on the electrode surface, e.g. OH and O species formed by the discharge of hydroxyl ions. It is improbable that O atoms would migrate through a semiconductor film independently of the electrons removed from the ion.

REACTION MECHANISMS AT THE OXIDE/ELECTROLYTE INTERFACE

We now examine the possibility that either reactions [5], [6], [7], or [8] occurring at the AgO/electrolyte interface is the correct rate-determining step of reaction [1]. For Langmuir conditions, i.e. limitingly low or limitingly high surface coverage by the intermediates, the Tafel slopes to be expected if any of the steps [5] to [8] were rate-controlling can be easily calculated. Reactions [5], [6], and [7] can be treated analogously to

[9] $$M + OH^- = MOH + e,$$

[10] $$OH^- + MOH = MO + H_2O + e,$$

and

[11] $$2MOH = MO + M + H_2O$$

respectively. Reactions [9] to [11] concern formation and reaction of covalently adsorbed surface species by neutralization of the adsorbing ions. In reactions [5] to [8], however, the surface species contain ionic and not covalent bonds, i.e. the adsorbing ions are not neutralized. Similar rate equations can be applied to both cases (2). Hence, we can calculate the Tafel slopes reported in Table I. The calculations show that under Langmuir conditions none of the reactions listed except [8] could be the rate-controlling step. However, in alkaline solutions it is rather unlikely that reaction [8] should occur. For this reason we rule out [8] as a possible rate-determining step.

TABLE I

Langmuir conditions of surface coverage

Rate-determining step	Slope	Analytical condition
[5]	$2RT/F$	$[OH^-]_s \rightarrow 0$
[6]	$2RT/3F$	$[OH^-]_s \rightarrow 0$
	$2RT/F$	$[OH^-]_s \rightarrow 1$
[7]	$RT/2F$	$[OH^-]_s \rightarrow 0$
	∞	$[OH^-]_s \rightarrow 1$
[8]	RT/F	$[OH^-]_s \rightarrow 0$
	∞	$[OH^-]_s \rightarrow 1$

TEMKIN CONDITIONS OF SURFACE COVERAGE

When the surface coverage (θ) is neither limitingly high nor limitingly low, the Tafel slopes can be calculated using two models proposed by Conway and Gileadi (3). For an induced surface heterogeneity model, the variation of the heat of adsorption is given by

[12] $$\Delta H_A = \Delta H^0{}_A - r_A\theta_A - r_B\theta_B, \qquad \Delta H_B = \Delta H^0{}_B - r_A\theta_A - r_B\theta_B,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

whereas for the intrinsic heterogeneity model,

[13] $$\Delta H_A = \Delta H^0{}_A - r_A(\theta_A + \theta_B), \qquad \Delta H_B = \Delta H^0{}_B - r_B(\theta_A + \theta_B),$$

where $\Delta H^0{}_A$ and $\Delta H^0{}_B$ refer to the heat of adsorption of species A and B respectively at zero coverage. In our mechanisms r_A and r_B refer to O^{-2} and OH^- species. In the intrinsic heterogeneity model r is directly associated with the variation of the forces of interaction between adsorbent and adsorbate with coverage as preferred sites for adsorption are occupied. In the induction model it is associated with the variation with coverage of the effect of the adsorbed dipole double-layer on the surface potential of the electrode. Hence the r terms are not the same in the two models.

Equations [12] and [13] assume a linear variation of the heat of adsorption with surface coverage (Temkin isotherm). However, the actual form of the variation does not affect the kinetic parameters for the induced model nor, if the form of the variation is the same for all intermediates, for the intrinsic model (3, 4). Equations [12] and [13] were originally proposed by Conway and Gileadi (*loc. cit.*) for reactions involving the chemisorption of neutral species at a metal electrode. The interactions between the adsorbent and adsorbate will be quite different in the case of ions adsorbed on the surface layers of an oxide such as AgO. Nevertheless, the nature of the interaction can reasonably be expected to fall into one or other of the categories described by [12] and [13].

Using the two models mentioned above we can calculate the slopes which are listed in Table II. Except for steps [5] and [7] in Table II it will be noted that the other slopes do not correspond to the observed experimental slope of RT/F (1), and hence cannot be rate-controlling. It may be further noted that eq. [2] would be obeyed if

$$r_{[OH^-]_s} > 5r_{[O^{-2}]}$$

and that eq. [3] would be valid if the surface coverage of $(O^{-2})_s$ as well as that of $(OH^-)_s$ is appreciable. The parameter r may differ for two intermediates for steric reasons alone (5). In the case of O^{-2} and OH^-, however, these will have a negligible effect, since the *radii* of the two ionic species are nearly the same (6).

TABLE II

Temkin conditions of surface coverage

Rate-determining step	Slope	
	Induced heterogeneity model	Intrinsic heterogeneity model
[5]	$2RT/F$	$2RT/F$
[6]	$2RT/F$	$(RT/F)\ 2r_{[OH^-]_s}/(2r_{[OH^-]_s} - r_{[O^{-2}]_s})$
[7]	$2RT/F$	$(RT/F)\ 2r_{[OH^-]_s}/(2r_{[OH^-]_s} - r_{[O^{-2}]_s})$
[8]	∞	$(RT/F)\ 2r_{[OH^-]_s}/(r_{[OH^-]_s} - r_{[O^{-2}]_s})$

The following arguments can be applied (7, 8) to resolve the probable contributions to the r parameters from the adsorption of O^{-2} and OH^-. When ions adsorb on a uniform ionic dielectric, the most important contribution to the energy of interaction is due to the electrostatic induction of the dielectric (7, 8)

[14] $$E = -(n_1{}^2e^2/4R_0)(K - 1)/(K + 2),$$

where K is the static polarizability of the dielectric, e is the charge on the electron, n_1 is the valency of the adsorbing ion and R_0 is the equilibrium distance from the ion to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

surface. Assuming that R_0 is reasonably constant, the variation of heat of adsorption with coverage will be in the term $(K - 1)/(K + 2)$. This type of interaction will obviously make

$$r_{[O^{-2}]_s} > r_{[OH^-]_s}$$

since n_1 is twice as great for O^{-2} as for OH^-. It follows therefore that steps [6] and [7] cannot be rate-determining ones.

The properties of the oxide are not uniform as implied in the intrinsic heterogeneity model which we are using here. In this case the value of K varies from site to site on the surface. The energy of interaction (E) is greater at large values of K since E represents the energy of the bond between the adsorbed ion and the surface. Preferential adsorption will occur at those sites for which E is higher (i.e. K large). The value of K which appears in eq. [14] is not the average value for the oxide but is that for the site at which adsorption is taking place. When the most favorable sites are covered, adsorption then takes place at sites with lower K values. Therefore, as coverage increases, the value of K to be used in eq. [14] decreases. This means that E (and also the heat of adsorption) decreases as surface coverage increases. The properties of the surface, i.e. the K values of individual adsorption sites, do not change with coverage; only the value of K to be used in eq. [14] changes with coverage.

In summary, it appears that none of the reactions involving adsorbed ionic intermediates taking place at the oxide/electrolyte interface are rate-controlling steps for the electrolytic formation of AgO from Ag$_2$O. This supports our original conclusion (1) that the rate-determining step occurs at the mixed oxide interface.

THE *C*- AND *O*-BENZYLATION OF L-ASCORBIC ACID

K. G. A. JACKSON AND J. K. N. JONES
Chemistry Department, Queen's University, Kingston, Ontario
Received May 11, 1964

ABSTRACT

Alkylation of sodium L-ascorbate with benzyl chloride yielded a 2-*C*-benzyl-3-keto-hexulosonic acid lactone and 3-*O*-benzyl-L-ascorbic acid, the yield of each being dependent on reaction conditions. Other products obtained from the alkylations were 2,3-di-*O*-benzyl-L-ascorbic acid and a 1-deoxy-1-*C*-phenyl-2-hexulose. Treatment of 3-*O*-methyl-5,6-*O*-isopropylidene-L-ascorbic acid with benzyl chloride and sodium methoxide yielded the 2-*O*-benzyl derivative.

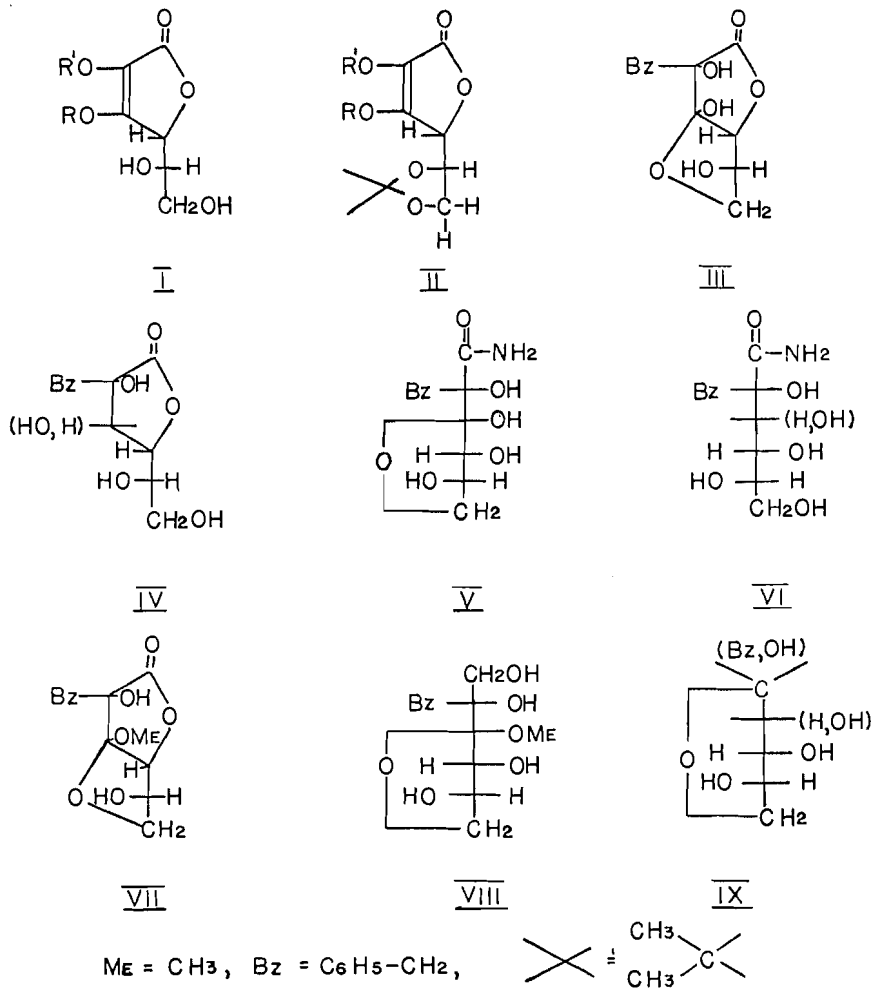
INTRODUCTION

A 2-*O*-methyl-3-hexulose has been prepared from L-ascorbic acid (1). It was argued that preparation of the corresponding *O*-benzyl derivative and subsequent hydrogenolysis of the resultant 2-*O*-benzyl-3-hexulose should yield the parent 3-hexulose.

The reaction of sodium-L-ascorbate with benzyl chloride in aqueous acetone resulted in a mixture of products; the two major components of which were identified as syrupy 3-*O*-benzyl-L-ascorbic acid (I, R = Ph—CH_2, R′ = H) and a crystalline 2-*C*-benzyl-3-keto-hexulosonic acid lactone (III). Derivatives of I, II, and III were prepared.

The lactone (III) did not affect ferric chloride solution and therefore did not contain enolic hydroxyl groups. Aqueous solutions of III were acidic to litmus and gave an instantaneous positive test with Wallenfels reagent (2). The infrared spectrum of III indicated the presence of a lactone and a benzene ring; the absorption of the ascorbate structure was absent. Periodate oxidation revealed the uptake of 5 moles of periodate and the release of 3 moles of titratable acid per mole of lactone. The detection and characterization of phenylacetic acid in the reaction mixture indicated the presence of a *C*-benzyl residue which was attached as a tertiary carbinol. Reduction of III with sodium borohydride provided a neutral product which gave a negative test with Wallenfels reagent. This new crystalline compound showed an absorption corresponding to lactone carbonyl in the infrared and was formulated as a 2-*C*-benzyl-hexonic acid lactone (IV). The amide (VI) of IV was prepared, as well as the amide (V) of III. The optical rotation of each was positive, lending weight to the assignment of the L-*lyxo* configuration to III by Hudson's rules (3). Furthermore the optical rotation of sodium L-ascorbate in acetone–water did not change appreciably over a period of 2 days, indicating that change of configuration at C_4, as experienced by Brenner *et al.*, did not occur (4).

The methyl glycoside (VII) of III was formed in methanolic hydrogen chloride. It did not react with sodium metaperiodate. Molecular models show that only one strain-free glycoside (alpha-L) can be produced. Reaction of the glycoside (VII) in ether with lithium aluminium hydride produced two crystalline compounds, one of which analyzed correctly for the expected alcohol (VIII). Periodate oxidation of VIII caused the formation of 0.6 mole of formaldehyde per mole of VIII; a small amount of acid was also produced. These results indicated that III was 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone and ruled out the isomeric structure, a 3-*C*-benzyl-2-keto-hexulosonic acid lactone. On treatment with acetic anhydride in pyridine, VIII readily gave a crystalline triacetate in which all of the secondary groups were acetylated.



The sodium salt of III spontaneously decomposed in water giving a crystalline 1-deoxy-1-*C*-phenyl-2-hexulose (IX). This was more easily prepared on a larger scale when L-ascorbic acid and 2 moles of sodium hydroxide per mole were stirred with benzyl chloride. The product was neutral to litmus paper, reduced Fehling's solution, and showed no absorption in the infrared in the interval 1 605 to 2 000 cm^{-1}. Quantitative periodate oxidation of IX resulted in the uptake of 3 moles of periodate per mole and the release of 2 moles of acid per mole. Analysis of the product revealed the presence of glycolaldehyde phenylacetate, both alcohol and acid portions of which were characterized. This substance originates presumably from a 3-hexulose derivative which isomerizes to the 2-hexulose under the influence of base. This wandering of the keto group has been observed to occur in other furano-ketoses and in acyclic ketoses (unpublished results) when a stable ring derivative can be produced.

3-*O*-Benzyl-L-ascorbic acid (I, R = Ph—CH_2, R′ = H) was isolated from the reaction mixture containing 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone. The separation of I (R = Ph—CH_2, R′ = H) from the amide of III was effected by cellulose column chromatography. On weighing the concentrated fractions of 3-*O*-benzyl-L-ascorbic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and V, the amide of III, we found the relative amounts of *C*-benzylation and *O*-benzylation to be in the approximate ratio of 1:1.

A solution of III in chloroform–acetone, after an interval of 3 weeks, crystallized to yield a new lactone which was considered to be an isomorph of III. The isomorph had a lower melting point and a lactone absorption in the infrared (KBr disc) 15 cm^{-1} higher than that of III. Both compounds had similar optical rotations in water, as well as in methanol, and had similar rates of movement on thin layer chromatograms. It was found that the isomorph could be recovered from deuterium oxide by evaporation of the solvent at room temperature. Furthermore, recrystallization of the isomorph from chloroform–acetone solution at 60° gave III only, whereas recrystallization from chloroform–acetone solution at room temperature yielded starting material. The nuclear magnetic resonance (n.m.r.) spectra of each were indistinguishable from one another.

Alkylation reactions in which there is a choice between two reactive sites have been investigated (5–8). It has, in general, been found that *C*-alkylation is favored in media of high hydrogen-bonding power and that *O*-alkylation is favored in media of low hydrogen-bonding power and high dielectric constant such as dimethylsulfoxide and dimethylformamide (9). When dimethylsulfoxide was used as a reaction solvent, a high yield of 3-*O*-benzyl-L-ascorbic acid was obtained.

The crude product so obtained partially crystallized but the crystals proved to be the isomorph of III. Higher substituted derivatives of L-ascorbic acid were removed from the residue by chloroform extraction and 3-*O*-benzyl-L-ascorbic acid (I, R = Ph—Ch_2, R′ = H) was separated from the remaining material by formation of the amide (V) from any III present, followed by chromatography of the mixture on a cellulose column. The weights of *C*-benzylated amide (V) and 3-*O*-benzyl-L-ascorbic acid were in the ratio of 1:3. Syrupy 3-*O*-benzyl-L-ascorbic acid gave a light green color with ferric chloride reagent and showed absorptions at 1 675 and 1 750 cm^{-1} in the infrared. These absorptions were present in all the ascorbic acid derivatives examined. The crystalline isopropylidene derivative (II, R = Ph—CH_2, R′ = H) was readily formed in anhydrous acetone – zinc chloride. 3-*O*-Benzyl-L-ascorbic acid, in excess ethereal diazomethane, gave a syrupy product that did not affect ferric chloride reagent. This was assumed to be 2-*O*-methyl-3-*O*-benzyl-L-ascorbic acid (I, R = Ph—CH_2, R′ = CH_3) and was proved to be such by conversion to crystalline II (R = Ph—CH_2, R′ = CH_3) with anhydrous acetone-zinc chloride reagent.

2-*O*-Benzyl-3-*O*-methyl-5,6-*O*-isopropylidene-L-ascorbic acid (II, R = CH_3, R′ = Ph—CH_2) was prepared from syrupy 3-*O*-methyl-5,6-*O*-isopropylidene-L-ascorbic acid (II, R = CH_3, R′ = H) by treatment of the latter with sodium methoxide followed by benzyl chloride. The melting point and optical rotation of the product obtained (II, R = CH_3, R′ = Ph—CH_2) were found to be significantly different from those of the compound assumed to be 3-*O*-benzyl-2-*O*-methyl-5,6-*O*-isopropylidene-L-ascorbic acid. The infrared spectra were indistinguishable from each other.

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 filter paper by the descending method using the following solvent systems (v/v): (A) butan-1-ol – ethanol – water (3:1:1); (B) butan-1-ol – pyridine – water (10:3:3); (C) ethyl acetate – acetic acid – formic acid – water (18:3:1:4). The sugars were located on paper chromatograms using the following spray reagents: (O) a spray solution of 1% silver nitrate in acetone followed by 2% sodium hydroxide in ethanol (10); (P) a spray solution of 3% *p*-anisidine hydrochloride in butan-1-ol (11) followed by heating the chromatogram in an oven at 115° for 2 min; (Q) a spray solution of 0.01 *M* sodium metaperiodate in water. After 5 min the sugars were located with spray reagent (P). Also used was (R), a spray solution of 2% ninhydrin in butan-1-ol (12). The final detection system, (S) consisted of a glass tank filled with iodine vapor. The chromatograms were suspended in the vapor.

Thin layer chromatography was carried out on glass plates coated with Silica Gel G (Research Specialties Co.). The plate was developed in benzene–isopropanol (2:1, v/v) solvent and then dried in air. Compounds were located as black spots by spraying the plate with concentrated sulfuric acid, followed by heating it at 140–170° in an oven.

Infrared spectra were determined on a Perkin–Elmer Model 21 infrared spectrophotometer. Formaldehyde formation in periodate oxidations was measured by the chromotropic acid method (13). All periodate oxidations were carried out using sodium metaperiodate solutions. Melting points were taken on a Fisher block and are uncorrected. All evaporations were carried out under reduced pressure at 40–60° on a water bath.

C-Benzylation of L-*Ascorbic Acid*

*2-C-Benzyl-3-keto-*L-*lyxo-hexulosonic Acid Lactone (III)*

L-Ascorbic acid (20 g, 0.113 mole) dissolved in water (200 ml) and partially neutralized by potassium hydroxide (5.8 g, 0.105 mole) in water (50 ml) was treated with benzyl chloride (14.4 g, 0.114 mole) in acetone (200 ml). The mixture was shaken mechanically for 60 h at room temperature and concentrated to remove acetone and the residue was washed with petrol (b.p. 60–80°). The residue was then exhaustively extracted with hot ethyl acetate. The extracts were dried (magnesium sulfate), filtered, and the filtrate was concentrated to yield a light-yellow oil. Yields varied from 8.1 g (27% theoretical) to 21.85 g (69% theoretical). The syrup crystallized in one preparation and on recrystallization from chloroform–acetone (8:1) the product had m.p. 156–156.5° with solvent of crystallization eliminated between 70 and 80° and $[\alpha]_D^{23} = +7 \pm 1°$ (*c*, 1.0 in methanol). The crystalline material had R_f 0.76, R_{Rh} 2.50 (spray reagent (O), (P), (Q)) in solvent (A) and R_f 0.82, R_{Rh} 2.04 (spray reagent (O)) in solvent (B). A strong absorption at 1 775 cm^{-1} (lactone carbonyl) was present in the infrared. The material was acidic to litmus; it gave an instantaneous Wallenfels test (2) but did not affect ferric chloride.

Anal. Calcd. for $C_{13}H_{14}O_6$: C, 58.6; H, 5.3. Found: C, 58.5; H, 5.4.

The analysis was performed on solvent-free material, obtained by heating the lactone at 80° for 10 min.

*The Periodate Oxidation of 2-C-Benzyl-3-keto-*L-*lyxo-hexulosonic Acid Lactone (III)*

Oxidations were carried out quantitatively and qualitatively on solvent-free material. In the qualitative oxidation 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone (200 mg) was dissolved in 0.10 *M* sodium metaperiodate solution (25 ml) in the absence of light. After 4 h the solution was extracted with chloroform (50 ml) and the extracts were evaporated to a gum that crystallized immediately. After recrystallization from petrol (b.p. 60–80°) thin plates of m.p. 74–76° were obtained. The mixed melting point with authentic phenylacetic acid was 75–77°. The infrared spectrum was indistinguishable from that of phenylacetic acid (KBr disc).

In the quantitative oxidation, periodate uptake and acid release were determined from an unbuffered aqueous solution shielded from light. The results are tabulated below.

TABLE I

The periodate oxidation of 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone

Time (h)	Periodate uptake (moles/mole)	Acid release (moles/mole)
0.25	2.80	1.65
0.75	3.30	2.09
2.33	4.15	2.62
5.25	4.73	2.83
8.25	5.00	3.03
11.00	5.00	3.03

*2-C-Benzyl-3-keto-*L-*lyxo-hexulonamide (V)*

2-*C*-Benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone (1.87 g) in anhydrous methanolic ammonia was kept at −20° for 7 h. Paper chromatography of the solution at the end of this time revealed only one component, moving at R_f 0.62, R_{Rh} 2.00 (solvent (A), spray reagents (Q), (R)) and at R_f 0.74, R_{Rh} 1.50 (solvent (C)). Crystallization occurred when the solution was concentrated to 20 ml and the amide was recrystallized from methanol to give needle-shaped crystals (1.91 g) of m.p. 137–138.5° and $[\alpha]_D^{23} = +7 \pm 1°$ (*c*, 1.0 in methanol).

Anal. Calcd. for $C_{13}H_{17}O_6N \cdot MeOH$: C, 53.3; H, 6.7; N, 4.4. Found: C, 53.3; H, 6.7; N, 4.5.

*2-C-Benzyl-(*L-*idono or* L-*talono)-lactone (IV)*

2-*C*-Benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone (2.69 g, 1.01×10^{-2} mole) in water (100 ml) was added dropwise over a period of 4 h to sodium borohydride (0.404 g, 1.3×10^{-2} mole) in water (100 ml). After it had been stirred for 14 h the solution was still reducing to Benedict's reagent although paper chromatography (solvent (A)) revealed mainly one component of R_f 0.70, R_{Rh} 2.06 with spray reagent

(O). The reaction mixture was treated with acetone (10 ml) and passed through a column of IR-120 (acidic) resin. The effluent was evaporated to a syrup and treated with successive portions of hot methanol (3 × 50 ml) followed by evaporation of the methanol in order to remove boric acid. The syrup so obtained crystallized and recrystallization from chloroform afforded needle-shaped crystals, neutral to litmus and of m.p. 174–175° and $[\alpha]_D^{23} = +39 \pm 2°$ (*c*, 1.0 in methanol).

Anal. Calcd. for a 2-*C*-benzyl-hexonolactone, $C_{13}H_{16}O_6$: C, 58.2; H, 6.0. Found: C, 58.5; H, 6.1. The infrared spectrum was almost identical with the spectrum of the starting material, except for a new absorption at 3 200 cm^{-1} (hydroxyl).

2-C-Benzyl-(L-idonamide or L-talonamide) (VI)

2-*C*-Benzyl-(L-idono or L-talono)-lactone (100 mg) in methanolic ammonia (25 ml) was kept at 0° for 48 h. Paper chromatography (solvent A) revealed the gradual disappearance of starting material and the appearance of a new slower moving component R_f 0.62 and R_{Rh} 1.70 (spray (O), (Q), (R)). The solution was filtered and concentrated to give a light-yellow syrup of $[\alpha]_D^{23} = +24 \pm 2°$ (*c*, 1.0 in methanol).

The Optical Rotation of Sodium L-Ascorbate in Aqueous Acetone (4)

L-Ascorbic acid (1.0 g) was titrated to equivalence (phenolphthalein) with aqueous sodium hydroxide (2.0 *N*) and the solution was diluted with water to a volume of 30 ml. Acetone (30 ml) was then added to bring the total volume to 60 ml. The optical rotation of this solution was measured at various times over a period of 2 days at room temperature.

TABLE II

Optical rotation of sodium L-ascorbate in aqueous acetone

Time (h)	$[\alpha]_D^{23}$
0.16	+132
1.5	+129
24	+127
48	+129

Thin layer chromatography (4) of the product showed the presence only of L-ascorbic acid.

Methyl Glycoside of 2-C-Benzyl-3-keto-L-lyxo-hexulosonic Acid Lactone

A solution of 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone (1.87 g) in methanolic hydrogen chloride (2% w/v, 100 ml) was heated for 11 h at 55–60°. The solution was neutralized with silver carbonate, filtered, and the filtrate was evaporated to yield a light-yellow syrup that crystallized. The product was recrystallized from hot water to give 0.96 g of needle-shaped crystals of $[\alpha]_D^{23} = +12 \pm 1°$ (*c*, 1.0 in methanol) and m.p. 139–140°.

Anal. Calcd. for $C_{14}H_{16}O_6$: C, 60.0; H, 5.8; OMe, 11.1. Found: C, 59.8; H, 5.6; OMe, 9.0.

The glycoside was not detectable on paper chromatograms (sprays (O), (P), (Q), or in iodine vapor (S)).

Methyl 2-C-Benzyl-L-lyxo-3-hexuloside (VIII)

A solution of the methyl glycoside of 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone (0.90 g) in anhydrous ether was added slowly to lithium aluminium hydride (1.0 g) in ether (50 ml). Reaction took place immediately with the formation of a precipitate. After 5 min ethyl acetate (5 ml) was added followed by distilled water (50 ml) and the mixture was filtered through Celite. The filtrate was extracted exhaustively with ethyl acetate, to yield, on evaporation of the extracts, a light-yellow oil (0.73 g). This crystallized and recrystallization was effected with ether–petrol b.p. 60–80° (85:15). Two different crops were collected, the first crop (150 mg) having m.p. 144–148° and the second crop (110 mg) having m.p. 115–117°. The product having m.p. 115–117° was recrystallized from ether–petrol b.p. 60–80° (85:15) to give long needles of m.p. 116–118° and $[\alpha]_D^{23°} = -23 \pm 1°$ (*c*, 1.0 in methanol).

Anal. Calcd. for $C_{14}H_{20}O_6$: C, 59.1; H, 7.1. Found: C, 59.4; H, 6.9.

The infrared spectrum showed absorptions at 3 420 and 3 550 cm^{-1} (hydroxyl) and no absorption in the region 1 605 to 1 800 cm^{-1}.

The initial crop of crystals having the melting point 144–148° were recrystallized from water, to give plates of m.p. 149–150° and $[\alpha]_D^{23} = -5 \pm 2°$ (*c*, 1.0 in methanol).

Anal. Calcd. for $C_{14}H_{20}O_6$: C, 59.1; H, 7.1. Found: C, 60.3; H, 6.8.

The infrared spectrum was practically identical with that of the alcohol m.p. 116–118° except for the absence of the absorption at 3 550 cm^{-1} (hydroxyl). The structure of this compound remained unknown.

Periodate Oxidation of Methyl 2-C-Benzyl-L-lyxo-3-hexuloside (VIII)

After 18 h the periodate uptake was determined as 2 moles/mole and formaldehyde release as 0.7 mole/mole. Slow overoxidation resulted in a total periodate consumption of 2.56 moles/mole and an acid realse of 0.63 mole/mole after 60 h.

For personal use only.

Methyl 1,4,5-Tri-O-acetyl-2-C-benzyl-L-lyxo-3-hexuloside

The triacetate was prepared by dissolving VIII (100 mg) in pyridine (50 ml) and acetic anhydride (1 ml) and storing the solution at 0° for 10 h. Water (300 ml) was then added and the solution was extracted with chloroform (100 ml). The extract was washed successively with sulfuric acid solution (2 *N*, 2 × 50 ml), saturated sodium bicarbonate solution (50 ml), and water (100 ml) and then dried over calcium sulfate. Concentration of the dried solution afforded a syrup that crystallized immediately. After two recrystallizations from methanol–water the crystals had m.p. 152–154° and $[\alpha]_D^{23} = +14 \pm 1°$ (*c*, 0.62 in chloroform).

Anal. Calcd. for $C_{20}H_{26}O_9$: C, 58.5; H, 6.4. Found: C, 58.3; H, 6.2.

The infrared spectrum (KBr disc) revealed a single hydroxyl absorption at 3 600 cm^{-1}.

Decarboxylation of 2-C-Benzyl-3-keto-L-lyxo-hexulosonic Acid Lactone (III)

The lactone (III) (3.0 g, 1.1 × 10^{-2} mole) in water, was titrated to 77% equivalence (phenolphthalein) with aqueous sodium hydroxide (15 ml, 1.02 *N*). Paper chromatography in solvent (A) revealed mainly one component; R_f 0.19, R_{Rh} 0.60 (spray reagents (O), (P)). The component of R_f 0.19 gradually disappeared over a period of 2 days and was replaced by a substance with R_f 0.62, R_{Rh} 2.15 (solvent (A), spray (O)). After 3 days the solution was evaporated to dryness, extracted with butan-1-ol, and the butan-1-ol solution was filtered, and the solvent evaporated. The heavy oil so obtained was passed through a cellulose column (eluent; butan-1-ol – water, 10:1) and fractions of ca. 6 ml were collected automatically every 15 min. The fractions on which paper chromatographic examination (solvent (A), spray (O)) were shown to contain only the component of R_f 0.62, R_{Rh} 2.15, were combined and evaporated to a light-yellow syrup (1.28 g). The syrup crystallized after 3 weeks and on recrystallization from chloroform–acetone, crystals of m.p. 126–128° were obtained. This was subsequently shown to be a 1-deoxy-1-*C*-phenyl-2-hexulose.

1-Deoxy-1-C-phenyl-L-(lyxo or xylo)-2-hexulose (IX)

L-Ascorbic acid (20 g, 0.113 mole) in water (150 ml) was treated with aqueous potassium hydroxide, (12.8 g, 0.228 mole, 50 ml) benzyl chloride (28 g), and acetone (250 ml) and the system was shaken for 8 h at room temperature. After this interval paper chromatography (solvent A) and spray (O) revealed the presence of only one main component, with R_f 0.62, R_{Rh} 2.15. The solution was evaporated to remove the acetone and washed with petrol (b.p. 60–80°). Exhaustive extraction with hot ethyl acetate and evaporation of the combined extracts provided a syrup, yields of which varied from 11 to 14 g. The syrup crystallized spontaneously only once and further crystallizations were effected by dissolving the syrup in hot acetone (7.1 ml per gram of syrup) and chloroform (1.2 ml per gram of syrup) and seeding the solution. After recrystallization the melting point increased from 115–117° to 127–128° with $[\alpha]_D^{23} = -31 \pm 1°$ (*c*, 1.0 in methanol). The infrared spectrum showed no absorption in the region 1 605 to 1 800 cm^{-1} and was indistinguishable from that of the crystalline product isolated from the decarboxylation of 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone with alkali.

Anal. Calcd. for $C_{12}H_{16}O_5$: C, 60.0; H, 6.7. Found: C, 59.9; H, 6.8.

Periodate Oxidation of 1-Deoxy-1-C-phenyl-L-(lyxo or xylo)-2-hexulose (IX) and Isolation of Products

The quantitative oxidation on 100 mg of the hexulose (IX) resulted in 3 moles/mole of periodate uptake and 2 moles/mole of acid release after 0.25 h. Little further oxidation occurred after 36 h and no formaldehyde was detected.

In order to isolate the oxidation products the hexulose (0.63 g) was oxidized with sodium metaperiodate solution (0.2 *M*, 7.0 ml) in the absence of light. Chloroform extraction of the reaction mixture after 12 h afforded, after concentration of the extracts, a light-yellow fragrant oil (440 mg) that did not crystallize. The infrared spectrum showed absorptions at 1 740 and 1 720 cm^{-1} (ester, carbonyl). A portion of the syrup (58 mg) was saponified with sodium hydroxide (0.01 *N*, 2.92 ml), acidified with hydrochloric acid, and then extracted with chloroform. The extracts on concentration crystallized immediately and recrystallization from petrol (b.p. 60–80°) afforded plates of m.p. 74–76°. The infrared spectrum was indistinguishable from that of phenylacetic acid (0.8% KBr). A second portion of the syrup (200 mg) was hydrolyzed in aqueous sulfuric acid (0.5 *N*, 10 ml) for 2.5 h, neutralized with sodium hydroxide (phenolphthalein), and evaporated to dryness. Extraction of the salts and organic material with hot acetone yielded, on concentration, a brown gum. A portion of the gum so obtained was dissolved in hot ethanol (60°) containing 2,4-dinitrophenylhydrazine reagent, to give a red-orange product of m.p. 310–320°. The melting point of glycolaldehyde-bis-2,4-dinitrophenylhydrazone prepared from authentic glycolaldehyde was 320–325°. The infrared spectra of the product and of the authentic specimen were indistinguishable from each other.

Isolation of an Isomorph of 2-C-Benzyl-3-keto-L-lyxo-hexulosonic Acid Lactone (III)

The syrupy product from the reaction of L-ascorbic acid with sodium hydroxide and benzyl chloride was dispersed in chloroform–acetone and allowed to stand. After 3 weeks large needle-shaped crystals had formed, with m.p. 142–143° and $[\alpha]_D^{23} = +6 \pm 1°$ (*c*, 0.6 in methanol), $[\alpha]_D^{23} = 13.5 \pm 1°$ (*c*, 2.0 in water) in the unrecrystallized state. The isomorph gave an instantaneous Wallenfels test (2), was acidic to litmus, and revealed an absorption at 1 788 cm^{-1} (lactone) in the infrared and had the same rate of movement as III on thin layer chromatograms. The n.m.r. spectrum, taken with a Varian A-60 spectrometer, D_2O solvent, was found to be identical to that of 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone. Evaporation of D_2O at room temperature afforded crystals that had m.p. 142–145° with instantaneous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solidification at 145° to a glass that melted at 154–156°. When the isomorph was recrystallized by cooling a solution in hot chloroform–acetone the melting point rose to 154–155° with solvent of crystallization being given off at 70–80°. *Analysis* of the isomorph. Found: C, 58.9; H, 5.5. 2-*C*-Benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone has the following constants. *Analysis*: C, 58.6; H, 5.3; m.p. 156–156.5°, $[\alpha]_D^{23} = +7 \pm 1°$ (*c*, 1.0 in methanol), $[\alpha]_D^{23} = +15.5 \pm 1°$ (*c*, 2.0 in water).

*Isolation of 3-O-Benzyl-*L*-ascorbic Acid (I, R = Ph—CH₂, R′ = H)*

The filtrate after isolation of 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone gave a light-green color with ferric chloride solution. In a typical separation 5.8 g of crude reaction product gave 0.83 g of crystalline lactone. The filtrate was concentrated, dissolved in methanolic ammonia (100 ml) and left at 0° for 4 days. On concentration of the solution a dark-brown syrup (4.55 g) was recovered. A portion of the syrup (1.77 g) was fractionated on a cellulose column (usual eluent) to yield two main fractions considered to be 3-*O*-benzyl-L-ascorbic acid (800 mg) and 2-*C*-benzyl-3-keto-L-*lyxo*-hexulonamide (580 mg). The infrared spectrum of the former fraction was indistinguishable from that of 3-*O*-benzyl-L-ascorbic acid. The percentage of 3-*O*-benzyl-L-ascorbic acid calculated from the above data was 50%.

O-Benzylation of L-*Ascorbic Acid*

*3-O-Benzyl-*L*-ascorbic Acid (I, R = Ph—CH₂, R′ = H)*

The sodium salt of L-ascorbic acid (17.84 g, 0.09 mole) was dissolved in dimethylsulfoxide (350 ml) containing benzyl chloride (11.43 g, 0.09 mole) and shaken for 1 week at room temperature. Dimethylsulfoxide was removed at 70° *in vacuo* to yield a dark gum. This was dissolved in water (300 ml), washed with petrol (b.p. 60–80°, 100 ml), and exhaustively extracted with hot ethyl acetate. The extracts on evaporation gave a light-brown syrup (19.45 g). Absorptions at 1 690, 1 730, 1 760, and 1 790 cm^{-1} were present in the infrared and indicated the presence of two or more components.

Chloroform extraction of a solution of crude 3-*O*-benzyl-L-ascorbic acid (7.44 g) in water (200 ml) and evaporation of the extracts yielded 1.13 g of dark gum assumed to contain higher substituted derivatives of L-ascorbic acid. The aqueous layer on evaporation gave a syrup of $[\alpha]_D^{23} = +8 \pm 1°$ (*c*, 1.0 in methanol). A portion of the syrup (1.34 g) was dissolved in anhydrous methanolic ammonia and kept at 0° for 48 h. The solution was then concentrated and passed through a cellulose column (usual eluent) to yield two syrupy fractions of total weight 800 mg. The first fraction; R_f 0.77, R_{Rh} 2.63 in solvent (A) (spray (O)) was assumed to be 3-*O*-benzyl-L-ascorbic acid and the second fraction to be 2-*C*-benzyl-3-keto-L-*lyxo*-hexulonamide. 3-*O*-Benzyl-L-ascorbic acid had $[\alpha]_D^{23} = +15 \pm 2°$ (*c*, 1.0 in methanol) and showed absorptions at 1 760 and 1 685 cm^{-1} in the infrared (typical pattern for ascorbate derivatives). There was no shoulder at 1 790 cm^{-1}. The syrup gave a light-green to light-blue color with ferric chloride in methanol and was acidic to litmus. In the above fractions the ratio of 3-*O*-benzyl-L-ascorbic acid to amide was 3:1.

*2,3-Di-O-benzyl-5,6-O-isopropylidene-*L*-ascorbic Acid (II, R = R′ = Ph—CH₂)*

The chloroform extract (1.13 g) (see above) was dispersed in anhydrous acetone (30 ml) containing crushed zinc chloride sticks (2.0 g) and the solution was shaken for 24 h at room temperature. After neutralization with 10% aqueous potassium carbonate (75 ml), extraction of the aqueous solution with diethyl ether, and evaporation of the ether, a light-yellow oil that crystallized immediately was obtained. Recrystallization from ether afforded needle-shaped crystals (0.052 g) of m.p. 125–126° and $[\alpha]_D^{23} = +23 \pm 1°$ (*c*, 1.15 in chloroform). The infrared spectrum showed strong absorptions at 1 755 and 1 675 cm^{-1}. No absorption was present in the region 3 100 to 3 600 cm^{-1}.

Anal. Calcd. for $C_{23}H_{24}O_6$: C, 69.7; H, 6.1. Found: C, 69.4; H, 6.3.

*3-O-Benzyl-5,6-O-isopropylidene-*L*-ascorbic Acid (II, R = Ph—CH₂, R′ = H)*

The isopropylidene derivative was prepared in the usual way (see above) from 3-*O*-benzyl-L-ascorbic acid (1.0 g, $[\alpha]_D^{23} = +8 \pm 1°$). The product crystallized and after recrystallization from diethyl ether – petrol (b.p. 60–80°) afforded needle-shaped crystals (374 mg) of m.p. 109–111° and $[\alpha]_D^{23} = +36 \pm 1°$ (*c*, 1.0 in methanol). The infrared spectrum (KBr disc) showed strong absorptions at 1 750 and 1 690 cm^{-1} with a medium absorption at 3 310 cm^{-1} (enolic hydroxyl).

Anal. Calcd. for $C_{16}H_{18}O_6$: C, 62.7; H, 5.9. Found: C, 62.6; H, 6.0.

*Isolation of the Isomorphous Form of 2-C-Benzyl-3-keto-*L*-lyxo-hexulosonic Acid Lactone (III) from the Experiment with Dimethylsulfoxide*

On standing 4 weeks, the crude reaction product ($[\alpha]_D^{23} = +8 \pm 1°$, (*c*, 1.0 in methanol)) had partially crystallized. The syrupy crystalline mass was dispersed in chloroform – ethyl acetate (4:1) and allowed to crystallize further to yield needles of m.p. 142–144° showing an absorption at 1 790 cm^{-1} (lactone) in the infrared. Except for the lactone peak the infrared spectrum was indistinguishable from that of 2-*C*-benzyl-3-keto-L-*lyxo*-hexulosonic acid lactone.

*3-O-Benzyl-2-O-methyl-*L*-ascorbic Acid (I, R = Ph—CH₂, R′ = CH₃)*

Crude 3-*O*-benzyl-L-ascorbic acid (3.42 g) was dissolved in absolute methanol (25 ml) containing excess ethereal diazomethane and kept at 0° for 2 days. The solution on evaporation yielded a syrup. The syrup was dispersed in chloroform and washed with water. The chloroform layer was dried and evaporated to yield a neutral gum (1.73 g) of $[\alpha]_D^{23} = +21 \pm 2°$ (*c*, 1.0 in methanol). The infrared spectrum of the gum showed strong peaks at 1 758 and 1 672 cm^{-1}.

3-O-Benzyl-2-O-methyl-5,6-O-isopropylidene-L-ascorbic Acid (II, R = Ph—CH_2, R' = CH_3)

The isopropylidene derivative was prepared from 3-*O*-benzyl-2-*O*-methyl-L-ascorbic acid in the usual way. The product was recrystallized from diethyl ether to give needles of m.p. 99.5–100.5° and $[\alpha]_D^{23}$ = +36 ± 1° (*c*, 1.0 in methanol).

Anal. Calcd. for $C_{17}H_{20}O_6$: C, 63.7; H, 6.3. Found: C, 63.9; H, 6.3.

Two strong absorptions at 1 675 and 1 750 cm^{-1} and no hydroxyl absorption were present in the infrared spectrum.

3-O-Methyl-5,6-O-isopropylidene-L-ascorbic Acid (II, R = CH_3, R' = H)

The isopropylidene derivative was prepared from 2.0 g of 3-*O*-methyl-L-ascorbic acid (14) in the usual way except that the product was extracted with ethyl acetate. The yield was 1.32 g of a colorless syrup of $[\alpha]_D^{23}$ = +18 ± 1° (*c*, 1.0 in methanol). Paper chromatography (solvent (A)) revealed one component moving at R_f 0.84, R_{Rh} 2.81 (spray (O), iodine vapor).

2-O-Benzyl-3-O-methyl-5,6-O-isopropylidene-L-ascorbic Acid (II, R = CH_3, R' = Ph—CH_2)

3-*O*-Methyl-5,6-*O*-isopropylidene-L-ascorbic acid (1.32 g) in anhydrous methanol (50 ml) was treated with sodium methoxide (0.7 ml, 4.0 *N*) and the solution was concentrated to a syrup. Benzyl chloride (30 ml) was added and the mixture heated for 1 h to give a dark-brown solution. The reaction system was removed from the bath, treated with water (200 ml), and steam distilled to remove the benzyl chloride. Crystallization commenced after the removal of the benzyl chloride and after recrystallization from ether the product had m.p. 86–87° and $[\alpha]_D^{23}$ = +41 ± 1° (*c*, 1.0 in methanol).

Anal. Calcd. for $C_{17}H_{20}O_6$: C, 63.7; H, 6.3. Found: C, 63.45; H, 6.3.

The infrared spectrum was indistinguishable from that of 3-*O*-benzyl-2-*O*-methyl-5,6-*O*-isopropylidene-L-ascorbic acid.

ION–SOLVENT INTERACTION IN MIXED SOLVENTS

PART III. THE MOLAR REFRACTION OF ELECTROLYTES

J. PADOVA[1]

The Northern Polytechnic, London, England, and
Soreq Research Establishment, Israel Atomic Energy Commission, Yavne, Israel

Received July 13, 1964

ABSTRACT

The apparent Lorenz–Lorentz molar refractions of Na_2SO_4, $MgSO_4$, $MnCl_2$, $NaOCOCH_3$, $Ba(OCOCH_3)_2$, $Mg(OCOCH_3)_2$, and $KOCOCH_3$ have been determined at 25 °C in mixtures of ethanol and acetone with water. The molar refraction of the solvated ions has been defined, and the values were calculated and found to be a linear function of the reciprocal of the dielectric constant of the bulk solvent.

INTRODUCTION

The refractive indices of sodium sulfate, magnesium sulfate, manganese chloride, sodium acetate, barium acetate, magnesium acetate, and potassium acetate have been determined at 25 °C with a view to investigating the variation of the molar refraction of the salts with the composition of the mixed solvents. These determinations may be expected to give some indication of the ion–solvent interaction in the immediate vicinity of the ions, since the refractivity of the salt is determined by the polarizability of the ions themselves and the change in the polarizability of the solvent produced by their presence. Although a large amount of data is available in aqueous solutions, only little is known on mixed solvents. Butler and Lees (1) have previously investigated the behavior of lithium chloride in ethanol–water mixtures using the Lorenz–Lorentz expression, whereas Bottcher (2) used glycerol–water mixtures as solvents to confirm his modified Lorenz–Lorentz equation. A number of references (unavailable to the writer) to work on molar refractions of salts may be found in the article on "Refractometry" (3).

EXPERIMENTAL

The solutions examined were the same as before (4), and were placed in a thermostat at 25° for half an hour before measurements were commenced. The refractive indices were then determined using a thermostated Abbé refractometer at 25 °C. The refractometer was checked using water and standard test specimens.

RESULTS AND DISCUSSION

For all the salts examined the refractive index increases with the concentration of the salts and of the organic components of the mixed solvents. On the assumption that the apparent molar refraction of electrolytes is given by the Lorenz–Lorentz expression for mixtures, Geffcken (5) derived relation [1] for the apparent molar refraction R

$$[1] \qquad R = \frac{n_0^2 - 1}{n_0^2 + 2} \cdot \left[\frac{1\,000}{c} \left(\frac{n^2 - 1}{n^2 + 2} \cdot \frac{n_0^2 + 2}{n_0^2 - 1} - 1 \right) + \phi_v \right],$$

where n_0 is the refractive index of the solvent, n is the refractive index of the solution, c is the molar concentration of solute, and ϕ_v is the apparent molar volume of solute. The molar refraction R is called the apparent molar refraction as it is calculated on the assumption that solution of the electrolyte causes no change in the solvent. Equation [1]

[1]*Present address: Radiochemistry Department, Soreq Research Establishment, Israel Atomic Energy Commission, Yavne, Israel.*

may be reduced to the form

$$[2] \qquad R = \frac{3\,000(n^2 - n_0^2)}{c(n^2 + 2)(n_0^2 + 2)} + \frac{n_0^2 - 1}{n_0^2 + 2}\,\phi_v.$$

Merland (6) has shown that in electrolyte solutions the relation

$$[3] \qquad n - n_0 = a(1 - e^{-bc})$$

is sometimes valid up to saturation. Here a and b are constants for the salt considered, where a is specific to the wavelength used and b is suggested to be the volume of the dissolved ions (6). Using [3] in eq. [2] when $c \rightarrow 0$,

$$[4] \qquad R^0 = \frac{6\,000abn_0}{(n_0^2 + 2)^2} + \frac{n_0^2 - 1}{n_0^2 + 2}\,\phi_v^0.$$

Table I compares the values of R^0 at 18 °C calculated using eq. [4] with those from the literature. The agreement is especially good for potassium salts and justifies the use of eq. [4] in the calculation of R^0 from Merland's expression.

TABLE I

Apparent molar refraction at infinite dilution

Salt	R^{0a}	R^{0b}
KNO_3	13.30	13.28
KCl	11.03	11.31
$BaCl_2$	21.37	22.00
$MgCl_2$	16.00	16.52
K_2SO_4	19.00	19.03
KBr	14.87	14.73
KI	21.28	21.55
$KOCOCH_3$	16.41 (25 °C)	16.53

[a]From eq. [4].
[b]See refs. 11 and 7.

For all electrolytes used in the experiments it has been found possible to extend the application of eq. [3] to mixed solvents. For a given salt, the constant a is the same irrespective of the nature of the solvent but the constant b varies with the solvent, usually decreasing with increasing concentration of non-aqueous solvent in the mixture (see Table II). The agreement between the calculated and experimental values of $(n - n_0)$ was well within the accuracy obtainable with the refractometer (± 0.0001).

It is proposed to use the solvated molar volume ϕ_s to arrive at a better representation of the molar refraction of the solvated complex R_s.

Assuming no further interaction between the solvation shell and the rest of the solvent, the Lorenz–Lorentz equation may be used and one obtains an equation similar to eq. [2],

$$[5] \qquad R_s = \frac{3\,000(n^2 - n_0^2)}{c(n_0^2 + 2)(n^2 + 2)} + \frac{n_0^2 - 1}{n_0^2 + 2}\,\phi_s.$$

Comparing [5] and [2], the relation between R_s and R at any concentration is

$$[6] \qquad R_s = R + h\,\frac{M_0}{d_0}\,\frac{n_0^2 - 1}{n_0^2 + 2},$$

where M_0 is the molar weight of solvent, d_0 is the density of pure solvent, and h is the

solvation number corresponding to the relation between ϕ_s and ϕ_v:

[7] $$\phi_s = \phi_v + h\frac{M_0^2}{d_0}.$$

Let

$$\frac{M_0}{d_0}\frac{n_0^2 - 1}{n_0^2 + 2} = R_0'.$$

Then at infinite dilution

[8] $$R_s^0 = R^0 + h^0 R_0'.$$

The molar refractions were calculated for sodium sulfate, magnesium sulfate, manganese chloride, potassium acetate, sodium acetate, barium acetate, and magnesium acetate in ethanol–water and acetone–water mixtures. In Figs. 1 and 2 the results are plotted against the reciprocal of the dielectric constant of the solvent. It is seen that the molar refraction of solvated ions varies linearly, in a similar manner to the solvated molar volume (3).

According to Merland (6) the constant b should be regarded as the volume of the ions. However, since

$$R_s^0 = \phi_s^0 \frac{n_s^2 - 1}{n_s^2 + 2},$$

where n_s is the refractive index of the solvated complex,

[9] $$\phi_s^0 \frac{n_s^2 - 1}{n_s^2 + 2} = \frac{6\,000abn_0}{(n_0^2 + 2)^2} + \phi_s^0 \frac{n_0^2 - 1}{n_0^2 + 2}$$

or

[10] $$b = \phi_s^0 \frac{(n_s^2 - n_0^2)(n_0^2 + 2)}{2\,000an_0(n_s^2 + 2)}$$

and is only proportional to ϕ_s^0.

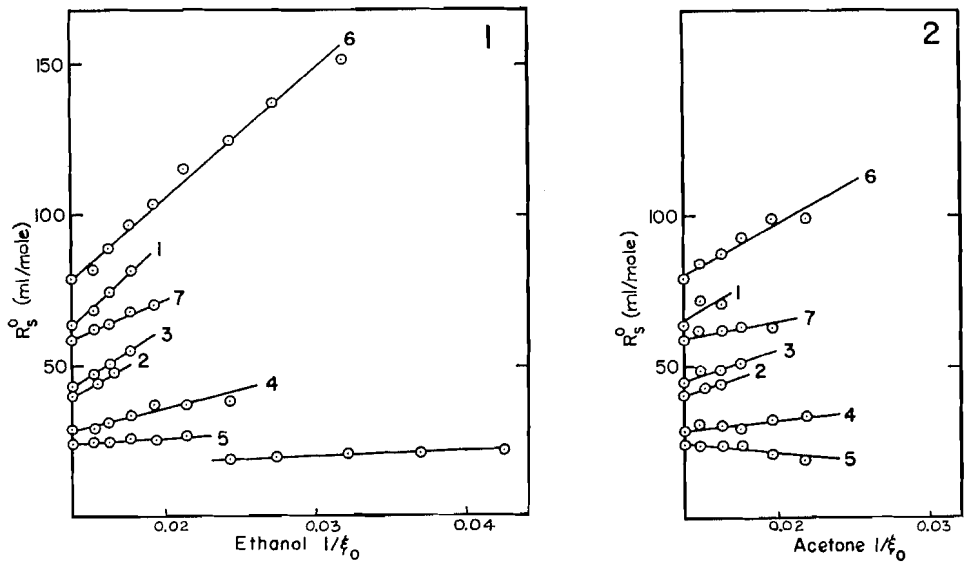

FIG. 1. Molar refraction in ethanol–water mixtures. (1) $MgSO_4$, (2) Na_2SO_4, (3) $MnCl_2$, (4) $NaOCOH_3$, (5) $KOCOCH_3$, (6) $Mg(OCOCH_3)_2$, (7) $Ba(OCOCH_3)_2$.

FIG. 2. Molar refraction in acetone–water mixtures. (1) $MgSO_4$, (2) Na_2SO_4, (3) $MnCl_2$, (4) $NaOCOCH_3$, (5) $KOCOCH_3$, (6) $Mg(OCOCH_3)_2$, (7) $Ba(OCOCH_3)_2$.

The polarizability data compiled from the published values of the apparent molar refraction data for electrolytes are not accurate (2), and only from eq. [9] is it possible to obtain the correct polarizability of the solvated ion complex. Bottcher (2) proposed a corrected Lorenz–Lorentz expression to account for the deviation in the apparent molar electrolyte refraction, and its application entails the assumption that the polarizability of Li^+ is zero. Fajans and his coworkers (7) tried to explain the deviations by assuming that the polarizability of a particle would depend to a large extent upon the properties of the surrounding media. The polarizability of water molecules which are subjected to polarization from surrounding ions has been calculated (8), but a later analysis did not indicate whether the Bottcher or Lorenz–Lorentz method is more appropriate (9), although theoretical considerations (10) seem to favor the former method. The above relation shows that the polarizability of solvated complex changes with the mixed solvent used. From the various values of ϕ_s and R it has been found that in a given solvent, the refractive index of the solvated complex is constant, in like manner to the constancy found for the dielectric constant (11) of the solvated complex determined assuming the additivity of the molar polarization at infinite dilution.

These data tend to show that with respect to certain properties, a solvated complex seems to behave as if it were a true particle and not merely an effective entity.

ACKNOWLEDGMENT

The experimental work was carried out in the laboratories of the Chemistry Department, The Northern Polytechnic, London. The author wishes to express his sincere appreciation for the help and encouragement he received from Dr. C. G. Smith during the course of this work.

MOLECULAR FORCE FIELD FOR SULFUR TETRAFLUORIDE

M. G. KRISHNA PILLAI, K. RAMASWAMY,[1] AND R. PICHAI
Department of Physics, Annamalai University, Annamalainagar, South India

Received September 1, 1964

ABSTRACT

An attempt has been made to modify the UBFF for SF_4 by taking into account the presence of the lone pair of electrons. It has been found that the bond pair – lone pair interactions become of importance only when the angle between the bond pair and the lone pair approaches 90°. The equatorial S—F stretching force constant (4.0146 mdyn/Å) is greater than the axial stretching force constant (3.6237 mdyn/Å), which is consistent with the form of the relationship between the force constant and bond length.

INTRODUCTION

Gillespie (1) has shown that the shapes of molecules of the non-transition elements can be readily understood in terms of the repulsive interactions between the electron pairs in the valency shell of the central atom. On this basis all molecules of the type AX_4E, where X is a ligand and E is a lone pair, will have a general shape based on a trigonal bipyramidal arrangement. SF_4, which has one lone pair of electrons, belongs to this category. The microwave spectral data for SF_4 determined by Tolles and Gwinn (2)—namely, that the equatorial bonds (1.545 Å) are shorter than the axial bonds (1.646 Å) and the angle between the equatorial bonds is 101° 33′ while the angle between the axial bonds is 186° 56′—was satisfactorily, at least qualitatively, explained on the basis of the valency shell electron pair repulsion theory (3).

It is of interest to see whether the presence of the lone pair has any influence on the bond force constants and also to determine the lone pair interactions. This can be effected by suitably modifying the molecular force field for SF_4 by taking into account the presence of lone pair of electrons. Such an attempt was made by Pariseau *et al.* for NH_3 (4) and for ClF_3 by the authors (5).

The Raman and infrared spectra of SF_4 was reported by Dodd *et al.* (6) and a tentative assignment was given on the basis of a C_{2v} model. The vibrational wave numbers are

$$a_1 = 889, 715, 557, 235 \text{ cm}^{-1}$$

$$a_2 = 401 \text{ cm}^{-1}$$

$$b_1 = 867, 532 \text{ cm}^{-1}$$

$$b_2 = 728, 463 \text{ cm}^{-1}.$$

Using this assignment a force field calculation was made by Chantry and Ewing (7). They concluded that the relation between the bond force constant and the internuclear distance was not affected by the introduction of d-electrons as in SF_4. They also indicated the possibility of inversion in sulfur tetrafluoride.

In the present study an attempt was made to calculate the molecular force constants for SF_4, taking into account the presence of the lone pair of electrons, in the usual Urey–Bradley force field (UBFF).

MODIFIED UBFF FOR SF_4

As pointed out earlier (1) SF_4 will have a trigonal bipyramidal arrangement with the lone pair occupying one of the equatorial positions as shown in Fig. 1. The internuclear distances (a, d, and R) and the interbond angles (α, β, η, and γ) used for the construction of F and G matrices are as defined in Fig. 1. The numerical values were taken from ref. 2.

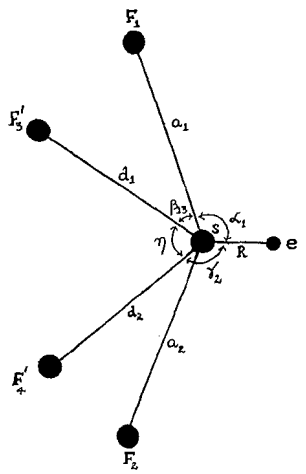

FIG. 1. Internal coordinates for SF_4.

In the usual UBFF for SF_4, there are six force constants (K_a, K_d, H_β, H_η, $F_{F'F'}$, and $F_{FF'}$ (see Fig. 1) and nine vibrational frequencies. Hence they can be determined uniquely. Therefore, it is not difficult to extend the UBFF to take into account the non-bonded interactions between the lone pair of electrons and the fluorine atoms. The coordinates R and α for the lone pair may be noted.

Using the internal coordinates defined in Fig. 1, the complete expression for the potential energy was written in the usual way (4, 5) and the expressions for the valence force constants were obtained. They are:

$$f_a = K_a + 2(S_{FF'}^2 F_{FF'} + t_{FF'}^2 F_{FF'}') + (S_{Fe}^2 F_{eF} + t_{Fe}^2 F_{eF}')$$

$$f_d = K_d + 2(S_{F'F}^2 F_{F'F} + t_{F'F}^2 F_{F'F}') + (S_{F'F'}^2 F_{F'F'} + t_{F'F'}^2 F_{F'F'}') + (S_{F'e}^2 F_{eF'} + t_{F'e}^2 F_{eF'}')$$

$$f_R = K_R + 2(S_{eF}^2 F_{eF} + t_{eF}^2 F_{eF}') + 2(S_{eF'}^2 F_{eF'} + t_{eF'}^2 F_{eF'}')$$

$$f_\alpha = H_\alpha - S_{eF} S_{Fe} F_{eF}' + t_{eF} t_{Fe} F_{eF}$$

$$f_\beta = H_\beta - S_{FF'} S_{F'F} F_{FF'}' + t_{FF'} t_{F'F} F_{FF'}$$

$$f_\gamma = H_\gamma - S_{eF'} S_{F'e} F_{eF'}' + t_{eF'} t_{F'e} F_{eF'}$$

$$f_\eta = H_\eta - S_{F'F'}^2 F_{F'F'}' + t_{F'F'}^2 F_{F'F'}$$

$$f_{aR} = S_{Fe} S_{eF} F_{eF} - t_{Fe} t_{eF} F_{eF}'$$

$$f_{dR} = S_{F'e} S_{eF'} F_{eF'} - t_{F'e} t_{eF'} F_{eF'}'$$

$$f_{ad} = S_{FF'} S_{F'F} F_{F'F} - t_{FF'} t_{F'F} F_{F'F}'$$

$$f_{dd} = S_{F'F'}{}^2 F_{F'F'} - t_{F'F'}{}^2 F_{F'F'}'$$
$$f_{R\alpha} = t_{eF} S_{Fe} F_{eF} + t_{Fe} S_{eF} F_{eF}'$$
$$f_{R\gamma} = t_{eF'} S_{F'e} F_{eF'} + t_{F'e} S_{eF'} F_{eF'}'$$
$$f_{a\beta} = t_{FF'} S_{F'F} F_{F'F} + t_{F'F} S_{FF'} F_{F'F}'$$
$$f_{a\alpha} = t_{Fe} S_{eF} F_{eF} + t_{eF} S_{Fe} F_{eF}'$$
$$f_{d\gamma} = t_{F'e} S_{eF'} F_{eF'} + t_{eF'} S_{F'e} F_{eF'}'$$
$$f_{d\beta} = t_{F'F} S_{FF'} F_{FF'} + t_{FF'} S_{F'F} F_{FF'}'$$
$$f_{d\eta} = t_{F'F'} S_{F'F'} F_{F'F'} + t_{F'F'} S_{F'F'} F_{F'F'}'$$

$$S_{ij} = \frac{r_i - r_j \cos \alpha_{ij}}{q_{ij}}$$

and

[1] $$t_{ij} = \frac{r_j \sin \alpha_{ij}}{q_{ij}}.$$

Here the subscripts refer to pairs of atoms; the qs represent the non-bonded distances; the symbols K, H, and F represent, respectively, the stretching, bending, and repulsive force constants. The Ks represent the linear terms which vanish in the equilibrium configurations. The constants F' were set equal to -0.1 times the corresponding F values, assuming that the energies associated with the qs are proportional to q^{-9}.

The following set of symmetry coordinates was formed from the internal coordinates.

For a_1 species.—$S_1 = (\Delta a_1 + \Delta a_2)/\sqrt{2}$
$S_2 = (\Delta d_1 + \Delta d_2)/\sqrt{2}$
$S_3 = \Delta\eta$
$S_4 = (\Delta\beta_{13} + \Delta\beta_{23} + \Delta\beta_{14} + \Delta\beta_{24})/2$
$S_5 = \Delta R$
$S_6 = (\Delta\gamma_1 + \Delta\gamma_2)/\sqrt{2}$
$S_7 = (\Delta\beta_{13} + \Delta\beta_{23} + \Delta\beta_{14} + \Delta\beta_{24} + \Delta\alpha_1 + \Delta\alpha_2)/\sqrt{6}$

For b_1 species.—$S_8 = (\Delta d_1 - \Delta d_2)/\sqrt{2}$
$S_9 = (\Delta\beta_{13} + \Delta\beta_{23} - \Delta\beta_{14} - \Delta\beta_{24})/2$
$S_{10} = (\Delta\gamma_1 - \Delta\gamma_2)/\sqrt{2}$

For a_2 species.—$S_{11} = (\Delta\beta_{13} - \Delta\beta_{23} - \Delta\beta_{14} + \Delta\beta_{24})/2$

For b_2 species.—$S_{12} = (\Delta a_1 - \Delta a_2)/\sqrt{2}$
$S_{13} = (\Delta\beta_{13} - \Delta\beta_{23} + \Delta\beta_{14} - \Delta\beta_{24})/2$

[2] $S_{14} = (\Delta\alpha_1 - \Delta\alpha_2)/\sqrt{2}.$

The coordinate S_7 is redundant and S_4 and S_7 are not orthogonal.

This set of symmetry coordinates gives a non-orthogonal U matrix and the unsymmetrized G matrix is constructed by the standard methods. The matrices are then symmetrized by the following transformations.

[3] $$\boldsymbol{F} = (U^{-1})' f U^{-1}$$

[4] $$\boldsymbol{G} = U G U'.$$

Owing to the presence of the atom of zero mass (electron) certain elements of G are infinite. The rows and columns containing these elements are now dropped from G and the residue G^0 is taken with modified F^0 matrix to give for each symmetry block a reduced secular equation by the method outlined earlier (4, 5, 8). The modified F^0 matrix elements thus obtained are as follows.

For a_1 species.—$$F_{11}^{\,0} = f_a - \frac{2f_{aR}^{\,2}}{f_R}$$

$$F_{12}^{\,0} = 2f_{ad} - \frac{2f_{aR}f_{dR}}{f_R} - \frac{f_{aR}f_{d\gamma}}{f_{R\gamma}}$$

$$F_{13}^{\,0} = 0$$

$$F_{14}^{\,0} = \sqrt{2}(f_{a\beta} - f_{a\alpha}) + \frac{2\sqrt{2}f_{aR}f_{R\alpha}}{f_R}$$

$$F_{22}^{\,0} = f_a + f_{dd} - \frac{2f_{dR}^{\,2}}{f_R} - \frac{f_{d\gamma}^{\,2}}{f_\gamma} - \frac{2f_{dR}f_{d\gamma}}{f_{R\gamma}}$$

$$F_{23}^{\,0} = \sqrt{2}f_{d\eta}$$

$$F_{24}^{\,0} = \sqrt{2}f_{d\beta} + \frac{2\sqrt{2}f_{dR}f_{R\alpha}}{f_R} \frac{\sqrt{2}f_{d\gamma}f_{R\alpha}}{f_{R\gamma}}$$

$$F_{33}^{\,0} = f_\eta$$

$$F_{34}^{\,0} = 0$$

$$F_{44}^{\,0} = f_\beta + 2f_\alpha - \frac{4f_{R\alpha}^{\,2}}{f_R}$$

For b_1 species.—$$F_{55}^{\,0} = f_d - f_{dd} - \frac{f_{d\gamma}^{\,2}}{f_\gamma}$$

$$F_{56}^{\,0} = \sqrt{2}f_{d\beta}$$

$$F_{66}^{\,0} = f_\beta$$

For a_2 species.—$$F_{77}^{\,0} = f_\beta$$

For b_2 species.—$$F_{88}^{\,0} = f_a - \frac{f_{a\alpha}^{\,2}}{f_\alpha}$$

$$F_{89}^{\,0} = \sqrt{2}f_{a\beta}$$

[5] $$F_{99}^{\,0} = f_\beta.$$

After removing the coordinates which have infinite values for the G matrix, we are left with the usual G^0 matrix and an F^0 matrix which contains extra terms involving the lone pair.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

To facilitate computations the F^0 matrix given above was modified to a new $\mathfrak{F}$ matrix through the transformation

[6] $$\mathfrak{F} = U' F^0 U,$$

where U is the matrix of transformation from the real internal coordinates (without considering the lone pair) to the symmetry coordinates. The $\mathfrak{F}$ elements are given by

$$\bar{f}_a = f_a - \frac{f_{aR}^2}{f_R} - \frac{f_{a\alpha}^2}{2f_\alpha}$$

$$\bar{f}_d = f_d - \frac{f_{dR}^2}{f_R} - \frac{f_{d\gamma}^2}{f_\gamma} - \frac{f_{dR}f_{d\gamma}}{f_{R\gamma}}$$

$$\bar{f}_{dd} = f_{dd} - \frac{f_{dR}^2}{f_R} - \frac{f_{dR}f_{d\gamma}}{f_{R\gamma}}$$

$$\bar{f}_{ad} = f_{ad} - \frac{f_{aR}f_{dR}}{f_R} - \frac{f_{aR}f_{d\gamma}}{2f_{R\gamma}}$$

$$\bar{f}_\eta = f_\eta$$

$$\bar{f}_{d\eta} = f_{d\eta}$$

$$\bar{f}_\beta = f_\beta + \frac{f_\alpha}{2} - \frac{f_{R\alpha}^2}{f_R}$$

$$\bar{f}_{d\beta} = f_{d\beta} + \frac{f_{dR}f_{R\alpha}}{f_R} + \frac{f_{d\gamma}f_{R\alpha}}{2f_{R\gamma}}$$

[7] $$\bar{f}_{a\beta} = f_{a\beta} - \frac{f_{a\alpha}}{2} + \frac{f_{aR}f_{R\alpha}}{f_R}.$$

With these expressions for the force constants, the problem was treated as a simple UBFF calculation, but with the following modified Urey–Bradley force constant (UBFC),

[8] $$\bar{K}_a = K_a + (S_{Fe}^2 F_{eF} + t_{Fe}^2 F_{eF}') - \frac{f_{aR}^2}{f_R} - \frac{f_{a\alpha}^2}{2f_\alpha}$$

[9] $$\bar{K}_d = K_d + (S_{F'e}^2 F_{eF'} + t_{F'e}^2 F_{eF'}') - \frac{f_{dR}^2}{f_R} - \frac{f_{d\gamma}^2}{f_\gamma} - \frac{f_{dR}f_{d\gamma}}{f_{R\gamma}}$$

[10] $$\bar{H}_\beta = H_\beta + \frac{f_\alpha}{2} - \frac{f_{R\alpha}^2}{f_R}$$

[11] $$\bar{H}_\eta = H_\eta$$

[12] $$\bar{F}_{FF'} = F_{FF'}$$

[13] $$\bar{F}_{F'F'} = F_{F'F'},$$

and with additional non-Urey–Bradley cross terms,

[14] $$\bar{F}_{dd} = -\frac{f_{dR}^2}{f_R} - \frac{f_{dR}f_{d\gamma}}{f_{R\gamma}}$$

[15] $$\bar{F}_{ad} = -\frac{f_{aR}f_{dR}}{f_R} - \frac{f_{aR}f_{d\gamma}}{2f_{R\gamma}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[16] $$\bar{F}_{d\beta} = \frac{f_{dR}f_{R\alpha}}{f_R} + \frac{f_{d\gamma}f_{R\alpha}}{2f_{R\gamma}}$$

[17] $$\bar{F}_{a\beta} = -\frac{f_{a\alpha}}{2} + \frac{f_{aR}f_{R\alpha}}{f_R}.$$

The force constants in eqs. [8]–[17] were adjusted by Danielewsky's method of successive approximation (9). The set which gives the best reproduction of frequencies was obtained. The agreement between the observed and calculated frequencies may be seen from Table I. The vibrational assignments and the microwave data given earlier were used in the present calculations. The distance between the nucleus and the lone-pair electrons (R) was assumed to be 0.54 Å.

The modified Urey–Bradley force constants obtained using the transformation equations are presented in Table II along with F^0 matrix elements.

[a]The F^0 matrix elements containing only stretching constants are in mdyn/Å, those containing only angle–angle constants are in mdyn Å/rad^2 and those containing bond angle interaction constants are in mdyn/rad.

[b]This number of significant figures is retained to secure internal consistency in the calculations and to obtain the best agreement with the observed wave numbers.

DISCUSSION

It is seen from Table II that the S—F axial stretching force constant is less than that for the equatorial bond. The magnitude is consistent with the variation in the bond

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

length. The S—F stretching force constants ($\bar{K}_a$ and $\bar{K}_d$) for axial and equatorial bonds (1.646 Å and 1.545 Å) are 3.6237 mdyn/Å and 4.0146 mdyn/Å respectively. Hiraishi *et al.* (10) reported the UBFC for S—F stretch in SF_6 to be 3.75 mdyn/Å. The S—F bond length in SF_6 is 1.58 Å (11). This value is intermediate between the values obtained in the present study for the axial and equatorial S—F bonds. This is to be expected on the basis of the empirical relations suggested for the variation of bond force constant with internuclear distance (12, 13).

It is possible to calculate the value of the lone pair – bond pair interaction constants ($F_{eF'}$ equatorial and F_{eF} axial) and stretching force constant (K_R) of the lone pair. The values obtained for the lone pair – bond pair interactions ($F_{eF'} = -0.2056$ mdyn/Å and $F_{eF} = -0.6167$ mdyn/Å) indicate that the lone pair – bond pair interactions become of importance only when the angle between them approaches 90°. This result is consistent with earlier statements (11). The value for K_R (2.0179 md/Å) seems to be in agreement with the value reported by Pariseau *et al.* (4) for ammonia (3.62 mdyn/Å).

The value of the equatorial $\overset{\frown}{F\ S\ F}$ bending constant ($\bar{f}_\eta$) as well as $F_{F'F'}$ equatorial non-bonded interaction constant are considerably lower than those for the axial $\overset{\frown}{F\ S\ F}$ bending constant ($\bar{f}_\beta$) and $F_{FF'}$ axial–equatorial non-bonded interaction constant. This shows that there is lack of strain in the trigonal plane due to fluorine–fluorine repulsion as pointed out by Ewing and Chantry.

ACKNOWLEDGMENT

REACTIONS OF PALLADIUM COMPOUNDS WITH ACETYLENES

II. TETRAKIS(*p*-CHLOROPHENYL)CYCLOBUTADIENE PALLADIUM COMPLEXES

P. M. MAITLIS, D. POLLOCK, M. L. GAMES, AND W. J. PRYDE
Department of Chemistry, McMaster University, Hamilton, Ontario

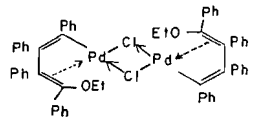
Received September 30, 1964

ABSTRACT

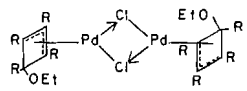
It is found that both diphenylacetylene and bis(*p*-chlorophenyl)acetylene on reaction with bis(benzonitrile)palladium chloride in benzene give the benzenoid trimer (R_6C_6) as well as a new type of cyclobutadiene complex $[(R_4C_4)(PdCl_2)_x]_2$ (R = Ph and *p*-ClC_6H_4) for which structure IV is proposed. *p,p'*-Dichlorotolan reacts with bis(benzonitrile)palladium chloride in ethanol – methylene chloride to give a complex $[(R_4C_4OC_2H_5)PdCl]_2$ (II) which is converted into the normal cyclobutadiene complex $[(R_4C_4)PdBr_2]_2$ (V) on treatment with hydrogen bromide. This can also be obtained from IV. The tetrakis(*p*-chlorophenyl)cyclobutadiene palladium halides on treatment with tri-*n*-butylphosphine give a dimer of tetrakis(*p*-chlorophenyl)cyclobutadiene which is probably octakis(*p*-chlorophenyl)cyclooctatetraene. Tetrakis-(*p*-chlorophenyl)cyclobutadiene iron tricarbonyl has also been prepared from IV and V by a ligand-transfer reaction.

INTRODUCTION

We recently communicated (1) the results of a reinvestigation of the reaction between diphenylacetylene (tolan) and palladium(II) compounds originally discovered by Malatesta *et al.* (2). This reaction we found to give products, the nature of which depended largely on the conditions and solvent used for the reaction. For example, tolan and bis(benzonitrile)palladium chloride in benzene gave mainly hexaphenylbenzene, while the same reaction carried out in ethanol–chloroform or with sodium chloropalladite and tolan in aqueous ethanol gave mainly a complex $[C_{30}H_{25}OPdCl]_2$. This was originally assigned structure I, but an X-ray structure determination by Dahl and Oberhansli (3) has now shown it to be the *endo*-4-ethoxy-π-1,2,3,4-tetraphenylcyclobutenyl palladium chloride dimer (II, R = Ph).



I



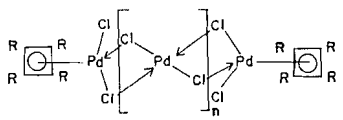
II

Reaction of II, R = Ph with hydrogen halides gave the π-tetraphenylcyclobutadiene palladium halides, $[\pi\text{-}Ph_4C_4]PdX_2$ (III). It was originally hoped that this reaction would lead to a simple general synthesis of cyclobutadiene palladium complexes from the appropriate acetylenes. However, it is now well established that acetylenes react with palladium(II) compounds to give a wide variety of oligomers and complexes, the nature of which depends largely on the acetylene used (4). We are currently, therefore, engaged on a detailed investigation of these reactions with the aim of correlating the structure of the acetylene with the nature of the products obtained and hope, on completion of this project, to be able to present a comprehensive theory of the reaction of acetylenes with palladium(II) and other transition metal compounds. Since there is such a wide variation in the nature of the reaction of palladium compounds with acetylenes we decided to start by examining the effect of a very simple change in the structure of the acetylene used, i.e., by using *p,p'*-dichlorotolan in place of tolan. The effect of this will be almost entirely

electronic since the para-chlorines will not be expected to exert any appreciable steric influence on the course of the reaction. We find that *p,p'*-dichlorotolan reacts qualitatively in a very similar fashion to tolan, but a sufficient number of points of interest have arisen during the course of this work to prompt us to publish our results now.

RESULTS

The reaction of tolan with bis(benzonitrile)palladium chloride in non-hydroxylic solvents gave, as mentioned, mainly hexaphenylbenzene. A careful reexamination of this reaction has now, however, shown that some tetraphenylcyclobutadiene palladium chloride is also formed in addition. The amount of this and the exact structure of the complex, however, vary with the ratio of tolan:bis(benzonitrile)palladium chloride used and with the method of addition. Thus, using a 2:1 ratio, 18% of a cyclobutadiene complex was obtained, whereas with a 1:1 ratio and slow addition of the tolan to the bis(benzonitrile) palladium chloride in high dilution a 34% yield of a related complex was obtained. The former complex analyzed for $[(Ph_4C_4)(PdCl_2)_{2.5}]_2$, the latter for $[(Ph_4C_4)(PdCl_2)_3]_2$.[1] As these were both definitely complexes of tetraphenylcyclobutadiene palladium chloride from their infrared spectra and their reactions, we conclude that their structure must involve the existence of two $(Ph_4C_4)PdCl_2$ units bridged by a series of $PdCl_2$ units as in IV, R = Ph, the former complex having $n = 3$ and the latter $n = 4$. This structure is



IV

V, R = *p*-ClC_6H_4

similar to that for solid palladium chloride itself and can be thought of as a short segment of the palladium chloride polymer terminated by a $(Ph_4C_4)PdCl_2$ group at each end. The formation and also the stability of such structures is quite surprising.

This type of complex is also formed by reaction of *p,p'*-dichlorotolan and bis(benzonitrile)palladium chloride in benzene, but the yields of the cyclobutadiene complexes under comparable conditions are rather better for the *p,p'*-dichlorotolan (43%) than for tolan (34%). In this case complexes of type IV, R = *p*-ClC_6H_4 with analyses corresponding to $n = 2$ and $n = 4$ have been obtained, depending on the conditions, together with hexakis-(*p*-chlorophenyl)benzene. Attempts to remove the excess palladium chloride from these complexes (e.g., by treatment with Cl^-, benzonitrile, or other solvents) were not successful, and the complex was either recovered unchanged or else had been completely destroyed. However, IV, R = *p*-ClC_6H_4 could be converted into tetrakis(*p*-chlorophenyl)cyclobutadiene palladium bromide (V) by treatment with hydrogen bromide in methylene chloride.

The presence of a π-bonded cyclobutadiene ring in these complexes was also indicated by their conversion to the known tetrakis(*p*-chlorophenyl)cyclobutadiene iron tricarbonyl (VI) by the ligand-transfer reaction recently described by Maitlis and Games for the tetraphenylcyclobutadiene complexes (5). The complex VI had originally been prepared by Braye and Hübel (6) and the infrared spectrum has been studied by Fritz (7).

Tetrakis(*p*-chlorophenyl)cyclobutadiene palladium bromide (V) was found to be a

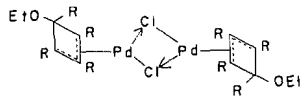
[1]*Since these complexes are too insoluble for molecular weight determinations, the dimeric structures which we are assigning to them are by analogy with other structures described below.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

stable red crystalline solid, decomposing only above 300°. The solubility of this complex was sufficient for an osmometric molecular weight determination to be possible in chloroform; this showed that V was dimeric even in a 0.0053 *M* solution and hence must have the bromine-bridged structure (V). This is similar to that of Criegee's tetramethylcyclobutadiene nickel chloride (8), an X-ray structure determination of which showed it to be dimeric with bridging halogens and formally five-coordinate Ni(II) (9).

Reaction of *p*,*p*′-dichlorotolan with bis(benzonitrile)palladium chloride in ethanol – methylene chloride yielded the ethoxy-π-cyclobutenyl complex (II, R = *p*-ClC_6H_4) by analogy to the tolan reaction already described above. The ethoxy complex (II, R = *p*-ClC_6H_4) on treatment with hydrogen bromide in methylene chloride also gave the tetrakis(*p*-chlorophenyl)cyclobutadiene palladium bromide (V) and, as in the tetraphenylcyclobutadiene series, this represents the best route to V. Attempts to prepare II, R = *p*-ClC_6H_4 by using aqueous ethanolic sodium chloropalladite and acetylene were not successful, and other variations in the method invariably gave low yields of II, R = *p*-ClC_6H_4 together with hexakis(*p*-chlorophenyl)benzene from which it was difficult to separate.

As reported previously (1), tetraphenylcyclobutadiene palladium chloride can be converted by treatment with ethanol into a geometric isomer of II which has now been shown (3) to have the structure VII, R = Ph, the isomers only differing in the orientation of the ethoxy and phenyl groups on the saturated carbon of the four-membered ring with respect to the metal.



VII

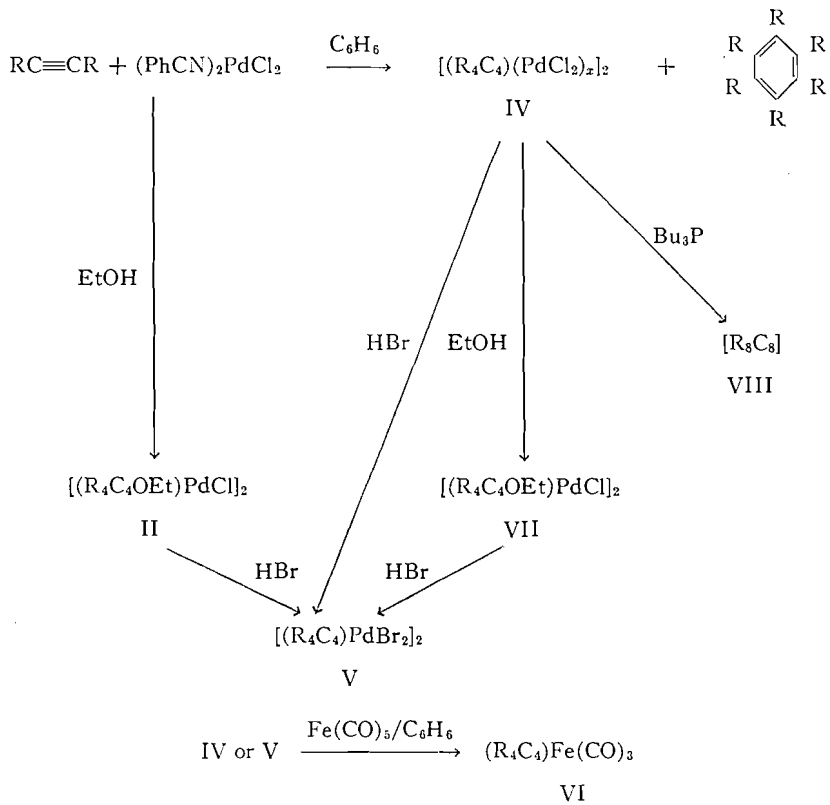
In a similar manner the *p*-chlorophenyl complex (VII, R = *p*-ClC_6H_4) was formed by treatment of IV, R = *p*-ClC_6H_4 with ethanol. As in the tetraphenylcyclobutadiene series, VII, R = *p*-ClC_6H_4 could be reconverted into the tetrakis(*p*-chlorophenyl)cyclobutadiene palladium bromide by treatment with hydrogen bromide in methylene chloride. However, neither II nor VII, R = *p*-ClC_6H_4 formed the simple tetrakis(*p*-chlorophenyl)cyclobutadiene palladium chloride (IV, R = *p*-ClC_6H_4, $n = 0$) by reaction with hydrogen chloride or hydrochloric acid under a variety of conditions. The reactions and interconversions are summarized in the chart.

Maitlis and Stone (10) showed that reaction of tetraphenylcyclobutadiene palladium halides with *t*-phosphines gave high yields of the tetraphenylcyclobutadiene dimer, previously described by Freedman and Petersen (11). The latter authors suggested that this dimer was octaphenylcubane (VIII*a*, R = Ph) on the evidence of the absence of a C=C stretching mode in the Raman spectrum at ca. 1 650 cm^{-1} and on the preliminary results of an X-ray structure determination (but see below). Tetrakis(*p*-chlorophenyl) cyclobutadiene palladium halides (IV, R = *p*-ClC_6H_4) on treatment with *t*-phosphines, especially tri-*n*-butylphosphine, gave bis(tributylphosphine)palladium chloride and 54–73% yields of the tetrakis(*p*-chlorophenyl)cyclobutadiene dimer (VIII, R = *p*ClC_6H_4). This was at first also assumed to have the cubane skeleton. However, although this compound had no double-bond peak in the infrared, a very strong band was found in the solid state Raman spectrum at 1 642 cm^{-1}, in the region expected for a C=C stretching mode in these compounds (11) as well as a phenyl band at 1 597 cm^{-1} (corresponding to the one

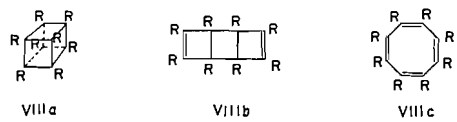
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

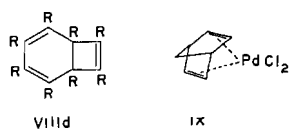
CHART I

Reactions of *p,p'*-dichlorotolan and the complexes derived from it (R = *p*-ClC_6H_4)



observed in "octaphenylcubane" at 1 605 cm^{-1}). The ultraviolet spectrum of our dimer showed a single band centered around 2 730 Å (ϵ = 34 000) and a plateau at about 2 375 Å (ϵ = 42 100), and is reminiscent of that of the *cis*-stilbene chromophore (bands at ~2 800 Å, ϵ = 10 500 and 2 240 Å, ϵ = 24 400 (12)). These results suggest strongly that our dimer has not the cubane skeleton.





DISCUSSION

Because we have as yet no quantitative data on other substituted tolans with which to compare these results, this discussion is confined to some of the novel structural features encountered in this work.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Due to their insolubility in solvents with which they do not react, molecular weight determinations for the tetraphenylcyclobutadiene palladium halides have not been possible. However, this insolubility and the fact that tetraphenylcyclobutadiene palladium chloride readily dissolves in chloroform saturated with hydrogen chloride, an obvious halogen-bridge-splitting reaction (1), together with the known dimeric structure for V and tetramethylcyclobutadiene nickel chloride, suggests that they are all halogen-bridged dimers with 5-coordinate Pd(II). This tendency for cyclobutadiene palladium and nickel complexes to achieve 5-coordination and, incidentally, the electronic configuration of xenon and krypton respectively, deserves some comment since it is at first sight surprising in view of the known 4-coordinate monomeric structures for diene palladium dihalides. The crystal structure of one of these, norbornadiene palladium chloride (IX), has been determined and shown unambiguously to have a square planar arrangement of the four ligands about the palladium (13). However, in this complex the diene system subtends an angle of 72° at the metal, whereas it can easily be shown that in tetramethylcyclobutadiene nickel chloride (9) the angle subtended by the four-membered ring is only about 45°. This angle will, of course, be even somewhat less for the tetraphenylcyclobutadiene palladium complexes. As a result there will be less crowding around the metal in a cyclobutadiene complex than in a "normal" diene complex (since the phenyl rings are bent back (14), they will not interfere greatly) and thus to achieve the desired highest coordination number, halogen bridges with another molecule will be formed. This argument may also partly explain the high stability of the similarly 5-coordinated π-tetraphenylcyclobutadiene iron tricarbonyl and (π-cyclopentadienyl)(π-tetraphenylcyclobutadiene)cobalt complexes by comparison with the very reactive diene iron tricarbonyl and diene (π-cyclopentadienyl)cobalt analogues.

Since this paper was originally prepared we have been informed by Lipscomb (15) that a complete X-ray structure determination of Freedman and Petersen's "octaphenylcubane" (VIII*a*, R = Ph) now shows it to be octaphenylcyclooctatetraene (VIII*c*, R = Ph). This suggests that our tetrakis(*p*-chlorophenyl)cyclobutadiene dimer will also have this structure, in agreement with the observed presence of a C=C stretching mode in the Raman spectrum. More conclusive evidence is necessary, however, since structures VIII*b*, VIII*c*, and VIII*d* would all be expected to show this band. Since chemical evidence is difficult to obtain because of the steric hindrance of the phenyl groups, the best evidence would be from the intensities of the main peaks in the ultraviolet spectrum. Braye, Hübel, and Caplier (16) already observed some years ago that the ratio of the extinction coefficient for the tetraphenylcyclobutadiene dimer to that of *cis*-stilbene is nearly 4, and on this basis suggested the octaphenylcyclooctatetraene structure for it. Unfortunately such a direct comparison is not possible for our dimer (VIII, R = *p*-ClC_6H_4) since *cis*-*p*,*p*′-dichlorostilbene is unknown. Even using a "reasonable" value for the expected extinction coefficient (extrapolated from the difference between *trans*-stilbene and *trans*-*p*,*p*′dichlorostilbene) a result suggesting the presence of three double bonds is obtained for our molecule. While such a structure is quite possible (VIII*d*, R = *p*-ClC_6H_4, for example) we still prefer the cyclooctatetraene (VIII*c*, R = *p*-ClC_6H_4). Freedman and Petersen (11) also obtained an isomer of octaphenylcyclooctatetraene, which showed a strong Raman-active C=C stretching mode at 1 650 cm^{-1}, from the reaction of 3,4-dibromo-1,2,3,4-tetraphenylcyclobutene with butyl-lithium. This was an unstable material which on standing at room temperature isomerized to the octaphenylcyclooctatetraene. This compound is probably now best regarded as the *syn*- or anti-isomer of octaphenyltricyclooctadiene (VIII*b*, R = Ph), and the reaction

VIII*b*, R = Ph → VIII*c*, R = Ph

For personal use only.

exactly parallels the reactions recently described by White and Dunathan (17). These authors found that in reactions in which diphenylcyclobutadienes were plausible products, tetraphenyltricyclooctadienes were isolated when the reactions were run at low temperatures, while at higher temperatures the products were tetraphenylcyclooctatetraenes. The latter were also formed by thermal isomerization of the tetraphenyltricyclooctadienes. That our dimer (VIII, R = p-ClC_6H_4) is not the one corresponding to Freedman and Petersen's unstable isomer is shown by it being unchanged even after melting at 375° or vacuum sublimation over a free flame. This again suggests that our dimer is the "stable" isomer and hence octakis(p-chlorophenyl)cyclooctatetraene. We are, however, unable to account for the fact that VIII*c*, R = Ph shows no Raman active C=C stretching mode whereas VIII*c*, R = p-ClC_6H_4 does.

NOTE ADDED IN PROOF:

Hüttel and Neugebauer (20) have also recently reported a tetraphenylcyclobutadiene palladium chloride complex with high Pd and Cl analyses. They propose a structure for it with one bridging $PdCl_2$ group, identical with that proposed here, IV, R = Ph, n = 1.

EXPERIMENTAL

Preparation of p,p'-Dichlorotolan

This was conveniently prepared in a 2 g scale by a modification of the method of Jonas (18) from the readily available insecticide 1,1-bis(p-chlorophenyl)-2,2-dichloroethane (DDD).

An amount of 10 g of DDD (0.312 moles) was mixed with 10 g potassium hydroxide in a 2 l flask. This was arranged horizontally, so that the product could be recovered more easily, and carried a glass tube which came nearly to the base of the flask and through which a slow stream of nitrogen was passed. The contents of the flask were heated with a flame until an oil distilled out; this oil was washed out, the flask was dried, and the contents were reheated vigorously. A white solid now sublimed out into the neck and was collected. This was the fairly pure p,p'-dichlorotolan. Additional quantities were obtained by reheating twice more. After crystallization from methanol, a total of 1.8 g (23%) was usually obtained. This had m.p. 174.5–176° (lit. 175–176° (18)) and analyzed correctly.

Anal. Calcd. for $C_{14}H_8Cl_2$: C, 68.07; H, 3.26; Cl 28.79%. Found: C, 68.19; H, 3.39; Cl, 28.65%.

Attempts to improve the yield by changing conditions or by the use of other bases were not successful. For example refluxing DDD with a large excess of potassium t-butoxide in t-butanol for 14 h only gave 2,2-bis(p-cholorophenyl)-1-chloroethylene in 47% yield.

Tetrakis(p-chlorophenyl)cyclobutadiene Palladium Chloride Complexes (IV, R = p-ClC_6H_4)

(1) A solution of 6 g (24.2 mmoles) of p,p'-dichlorotolan in 550 ml benzene was added slowly with stirring over 10–15 h to a solution of 3.88 g (10.1 mmoles) bis(benzonitrile)palladium chloride in 275 ml benzene. After about 50 ml of the solution had been added, a red-brown precipitate began to form. On completion of the reaction this precipitate was filtered off and digested thoroughly with two portions of 150 ml of boiling benzene to remove any trimer present. A crystalline residue of 1.91 g of the cyclobutadiene complex (IV, R = p-ClC_6H_4, n = 2) remained, m.p. 244–248° decomp.[2]

Anal. Calcd. for $[(C_{28}H_{16}Cl_4)(PdCl_2)_2]_2$: C, 39.58; H, 1.90; Cl, 33.38; Pd, 25.12%. Found: C, 39.65; H, 1.86; Cl, 33.30; Pd, 25.20%.

A molecular weight determination was not possible due to the insolubility of the compound. The yield of complex, based on the amount of acetylene used, was 18%. Evaporation of the benzene solution gave the crude trimer which was chromatographed on silica in benzene – light petroleum to remove other impurities and then crystallized from benzene as colorless prisms. Yield of analytically pure hexakis(p-chlorophenyl)-benzene 2.95 g (45%), m.p.[2] 433° (lit. 404–405° (19)).

Anal. Calcd. for $C_{42}H_{24}Cl_6$: C, 68.03; H, 3.26; Cl, 28.68%; mol. wt. 741. Found: C, 68.16; H, 3.36; Cl, 28.91%; mol. wt. (mass-spectroscopically) 740.

(2) A solution of 3.21 g (13 mmoles) of p,p'-dichlorotolan in 800 ml benzene was added to 5 g (13 mmoles) bis(benzonitrile)palladium chloride dissolved in 800 ml benzene, with stirring over 15 h. After the crystalline precipitate had been washed with benzene as above, it weighed 2.80 g and had m.p.[2,3] 232–234° (decomp). The compound analyzed correctly for the complex IV, R = p-ClC_6H_4, n = 4 and had identical infrared spectrum in the 2–16 μ range.

Anal. Calcd. for $[(C_{28}H_{16}Cl_4)(PdCl_2)_3]_2$: Pd, 31.1%. Found: Pd, 30.4; 31.0%. Yield, based on the amount of acetylene used: 43%.

From the benzene mother liquors 1.02 g (32%) of hexakis(p-chlorophenyl)benzene was obtained.

[2]*Melting point taken in an evacuated capillary.*

[3]*The melting point obtained depends on rate of heating and values as high as 256–258° have been obtained.*

Reaction of Tolan with Bis(benzonitrile)palladium Chloride

A solution of 0.5 g (2.81 mmoles) diphenylacetylene in 50 ml of benzene was added to a solution of 0.54 g (1.40 mmoles) bis(benzonitrile)palladium chloride in 50 ml benzene, and the solution was stirred for 16 h at 25°. A pinkish solid was slowly formed which consisted of a mixture of mainly hexaphenylbenzene and a little tetraphenylcyclobutadiene palladium chloride complex. The former was removed by repeatedly boiling the mixture with benzene until the residue was homogeneous. This left 0.20 g of the tetraphenylcyclobutadiene palladium chloride complex (IV, R = Ph, $n = 3$).

Anal. Calcd. for $[(C_{28}H_{20})(PdCl_2)_{2.6}]_2$: Pd, 33.2%. Found: Pd, 33.2%.

The infrared spectra (KBr disc, 2–16 μ) was identical to that of an authentic sample of tetraphenylcyclobutadiene palladium chloride. The yield of IV based on the amount of tolan used was 18%.

A solution of 1.0 g (5.56 mmoles) of diphenylacetylene in 345 ml benzene was added to a solution of 2.16 g (5.56 mmoles) bis(benzonitrile)palladium chloride in 345 ml benzene over 4 h at 25°. The solid product was filtered off and was boiled repeatedly with benzene until all the hexaphenylbenzene had been removed. This left 0.84 g of a red solid, (IV, R = Ph, $n = 4$).

Anal. Calcd. for $[(C_{28}H_{20})(PdCl_2)_3]_2$: Pd, 33.9%. Found: Pd, 33.6%. Yield, based on the amount of acetylene used: 34%.

Di-μ-chloro-di[π-(endo-4-ethoxy-1,2,3,4-tetrakis(p-chlorophenyl)cyclobutenyl)palladium] (II, R = p-ClC$_6$H$_4$)

A solution of 0.78 g (2.03 mmoles) of bis(benzonitrile)palladium chloride in 50 ml methylene chloride was added with stirring to a suspension of 1.00 g (4.05 mmoles) of *p,p'*-dichlorotolan in 100 ml of ethanol. After stirring for 30 min a clear solution resulted which slowly began to deposit a copious yellow precipitate. This was filtered off after a further hour at room temperature and was recrystallized from methylene chloride – ethanol. Yield: 0.90 g (66%). Thin-layer chromatography showed the material to be homogeneous and different to the exo-isomer (VII). The pure material gradually decomposed above 280° and finally melted[2] about 310°. The n.m.r. spectrum showed the presence of phenyl (2.58 τ), CH_2 (5.72 τ), and CH_3 (8.50 τ) protons in the expected ratio.

Anal. Calcd. for $[C_{30}H_{21}Cl_5OPd]_2$: C, 52.82; H, 3.11; Cl, 25.99; Pd, 15.7%; mol. wt. 1 362. Found: C, 52.99; H, 3.38; Cl, 26.06; Pd, 15.5%; mol. wt. 1 380.

Tetrakis(p-chlorophenyl)cyclobutadiene Palladium Bromide (V)

(1) Dry hydrogen bromide gas was bubbled through a solution of 0.50 g of di-μ-chloro-di[π-endo-4-ethoxy-1,2,3,4-tetrakis(p-chlorophenyl)cyclobutenyl]palladium (II, R = p-ClC$_6$H$_4$) in 100 ml of methylene chloride for 10 min. There was an immediate darkening of the color. On completion of the reaction the solution was evaporated to dryness, and the resultant solid was redissolved in methylene chloride, filtered, and crystallized by the addition of ligroin (b.p. 80–100°). Yield of tetrakis(*p*-chlorophenyl)cyclobutadiene palladium bromide: 0.46 g (82%). The red, crystalline complex was stable in air and had no sharp melting point[2] but slowly decomposed on heating to above 300°.

Anal. Calcd. for $[(C_{28}H_{16}Cl_4)PdBr_2]_2$: C, 44.22; H, 2.12; Br, 20.95; Cl, 18.65; Pd, 14.0%; mol. wt. 1 521. Found: C, 43.89; H, 2.05; Br, 21.37; Cl, 18.30; Pd, 14.0%; mol. wt. 1 517 (0.0053 *M* in chloroform).

(2) Dry hydrogen bromide gas was passed into a suspension of 0.84 g of the tetrakis(*p*-chlorophenyl)-cyclobutadiene palladium chloride complex (IV, R = p-ClC$_6$H$_4$, $n = 4$) in methylene chloride for 10 min. The suspended solid mostly dissolved after a few minutes and was replaced by a precipitate of $PdBr_4^{2-}$ which was then filtered off. The solvent and excess hydrogen bromide were removed on a rotary evaporator, and the residue was crystallized from methylene chloride – ligroin. Yield of pure tetrakis(*p*-chlorophenyl)-cyclobutadiene palladium bromide (V) was 0.17 g (23%), and was shown to be identical to the above prepared sample by thin-layer chromatography and infrared spectra.

Tetrakis(p-chlorophenyl)cyclobutadiene Dimer (VIII, R = p-ClC$_6$H$_4$)

A solution of 0.63 g (3.2 mmoles) of tri-*n*-butylphosphine in 10 ml benzene was added to a well-stirred refluxing suspension of 0.60 g (0.71 mmoles) of the tetrakis(*p*-chlorophenyl)cyclobutadiene palladium chloride complex (IV, R = p-ClC$_6$H$_4$, $n = 2$) in 90 ml of benzene under nitrogen. The red suspension rapidly dissolved to give a green solution which then turned yellow and finally pale yellow on refluxing. It was refluxed for a total of 30 min and then filtered and the solvent was taken off. Addition of ethanol to the oily residue gave 0.26 g (73%) colorless crystals of the dimer, whicle concentration of the ethanol solution yielded 0.443 g of yellow crystals of bis(tributylphosphine)palladium chloride identified by comparison with an authentic sample. The dimer was purified by crystallization from benzene–ligroin, and had m.p.[2] 371°. A slightly higher m.p. (373–375°) was obtained after vacuum sublimation of the sample over a free flame; the compound analyzed correctly for the dimer (VIII, R = p-ClC$_6$H$_4$).

Anal. Calcd. for $C_{56}H_{32}Cl_8$: C, 68.03; H, 3.26; Cl, 28.68%; mol. wt. 988.5. Found: C, 68.07; H, 3.29; Cl, 28.59%; mol. wt. 1 038 (osmometric in benzene) 982 (mass spectroscopic). The compound underwent no significant change on vacuum sublimation. The same compound, VII, was also obtained in 54% yield by an identical reaction from the tetrakis(*p*-chlorophenyl)cyclobutadiene palladium chloride complex (IV, R = p-ClC$_6$H$_4$, $n = 4$). The tetrakis(*p*-chlorophenyl)cyclobutadiene dimer (VIII) shows the following spectral bands.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(i) Ultraviolet: peak at 2 730 Å (ϵ = 34 000); plateau at 2 375 Å (ϵ = 42 100) in hydrocarbon solvent.
(ii) Infrared (KBr disc): 491(s), 769(s), 787(s), 829(s), 1 013(s), 1 092(s), 1 398(m), 1 487(vs), and 1 588(m) cm^{-1}.
(iii) Raman (solid state): 621, 641, 854, 869, 1 000, 1 036, 1 161, 1 196, 1 292, 1 341, 1 447, 1 498, 1 542, 1 597, and 1 642 cm^{-1}.

Tetrakis(p-chlorophenyl)cyclobutadiene Iron Tricarbonyl (VI, R = p-ClC_6H_4)

A solution of 1.0 g (0.975 mmoles) of the tetrakis(*p*-chlorophenyl)cyclobutadiene palladium chloride complex (IV, R = *p*-ClC_6H_4, n = 4) was refluxed in 100 ml benzene under nitrogen for 10 min. An amount of 6 ml (44.5 mmoles) iron pentacarbonyl was added and refluxing was continued for a further 10 min.[4] The solution was then filtered, all the solvent was removed, and the residue was taken up in 5 ml benzene and chromatographed in alumina in 15% benzene – 85% light petroleum (b.p. 30–60°). The first, yellow, fraction to be eluted contained the desired compound which after crystallization from methylene chloride – ethanol gave 0.27 g of yellow crystals of tetrakis(*p*-chlorophenyl)cyclobutadiene iron tricarbonyl (VI) (44%). This had m.p.[2] 242°, showed terminal carbonyl bands in the infrared at 1 978 and 2 025 cm^{-1} (CCl_4 solution) and 2 040, 1 986, and 1 965 cm^{-1} (KBr disc); the whole spectrum was identical with that of a sample prepared by Braye (6).

Anal. Calcd. for $C_{31}H_{16}Cl_4O_3Fe$: C, 58.71; H, 2.54; Fe, 8.81; Cl, 22.36%; mol. wt. 634. Found: C, 58.72; H, 2.88; Fe, 8.79; Cl, 22.26%; mol. wt. 647 (osmometric). The same compound was also obtained in an identical ligand-transfer reaction from tetrakis(*p*-chlorophenyl)cyclobutadiene palladium bromide (V) in 46% yield, identified by m.p. and mixed m.p. as well as infrared spectra.

Di-μ-chloro-di-[π-exo-(4-ethoxy-1,2,3,4-tetrakis(p-chlorophenyl)cyclobutenyl)palladium] (VII, R = p-ClC_6H_4)

A suspension of 1 g (0.975 mmoles) of the tetrakis(p-chlorophenyl)cyclobutadiene palladium chloride complex (IV, R = *p*-ClC_6H_4, n = 4) in 150 ml absolute ethanol was stirred for 48 h at 25°. This gave 0.61 g of the crude complex (VII) contaminated with some palladium metal. The complex was dissolved in methylene chloride, filtered, and crystallized by the addition of ligroin to give 0.35 g (53%) of the yellow π-cyclobutenyl complex (VII, R = *p*-ClC_6H_4), m.p. 201–202° decomp.[2]

Anal. Calcd. for $[C_{30}H_{21}Cl_5OPd]_2$: C, 52.82; H, 3.11; Cl, 25.99; Pd, 15.65%; mol. wt. 1 362. Found: C, 53.16; H, 3.25; Cl, 26.21; Pd, 15.44%; mol. wt. 1 347 (osmometric). The n.m.r. spectrum agreed with this formulation and showed the presence of C_6H_5 (2.70 τ), CH_2 (6.51 τ), and CH_3 (9.02 τ) protons. Treatment of this complex with hydrogen bromide in methylene chloride solution in a similar manner tp that used above converted it into tetrakis(*p*-chlorophenyl)cyclobutadiene palladium bromide (V) in 62% yield, identified by infrared spectrum and thin-layer chromatography with an authentic sample. Attempts to convert the complex into tetrakis(*p*-chlorophenyl)cyclobutadiene palladium chloride were unsuccessful. Even under very drastic conditions products were obtained for which the n.m.r. spectra still showed the presence of ethoxy groups, showing that neither hydrogen chloride nor hydrochloric acid is a powerful enough reagent to cleave the ether link here.

ACKNOWLEDGMENT

We wish to thank the National Research Council of Canada and the Research Corporation of New York for supporting this research, and Mr. D. Clugston for determining some of the n.m.r. spectra and mass-spectroscopic molecular weights.

^{13}C N.M.R. STUDIES

PART III.[1] CARBON-13 N.M.R. SPECTRA OF SUBSTITUTED ACETOPHENONES[2]

K. S. DHAMI[3] AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ontario

Received September 24, 1964

ABSTRACT

The 15.1 Mc/s ^{13}C n.m.r. spectra of 55 substituted acetophenones have been examined and the chemical shifts of the various carbon nuclei determined. This series included a variety of monosubstituted cases (ortho, meta, and para) as well as several polysubstituted examples. The factors contributing to the observed shieldings of all carbon nuclei are considered. The aromatic shieldings are compared with previous results for other aromatic derivatives. The application of the carbonyl shifts to the study of steric inhibition of resonance in these derivatives is examined critically. The shieldings of the acetyl methyl and para-carbon nuclei are found to offer confirmatory evidence for the existence of steric hindrance to coplanarity of the acetyl group in several ortho-substituted cases.

INTRODUCTION

Earlier papers in this series have presented the data and our interpretations of the carbon-13 nuclear magnetic resonance (n.m.r.) signals of carbonyl groups in a wide variety of organic carbonyl compounds (1) and some ortho-substituted acetophenones (2). To investigate some of the features noted in these studies in more detail, a series of 55 substituted acetophenones has been examined by ^{13}C n.m.r. spectroscopy at 15.1 Mc/s. Examples of a number of monosubstituted derivatives (ortho, meta, and para) as well as several polysubstituted compounds having at least one ortho-substituent have been included. Chemical shift values for all carbon nuclei in these compounds have been obtained except for a few cases in which the upper solubility limit was insufficient to obtain a satisfactory signal:noise ratio to allow measurements in the aromatic region. Analyses of the aromatic portions of the spectra were accomplished by intercomparisons of the variously substituted derivatives and by assuming an additive relation for the substituent effects on the aromatic nuclei on the basis of the careful studies by Lauterbur (3*a*–*e*). The resonances of the alkyl carbons were readily identified by comparisons of the observed positions with those observed for the simpler benzenoid hydrocarbons or monosubstituted benzene derivatives. The assignment of the carbonyl peaks, of course, is the easiest of all and presents no difficulty (1).

The results of this study afford a further test of the additivity of substituent effects on aromatic shieldings, first noted by Lauterbur (3*b*). Since the series includes 36 compounds with at least one ortho-grouping, the variations in the spectral parameters with increasing steric hindrance are easily followed and potential application of ^{13}C n.m.r. techniques to the study of hindered systems is clearly indicated. In particular, an extensive test is possible for our proposed method (2) of estimating angles of twist between the planes of the aromatic ring and the carbonyl group based on the variation of the carbonyl carbon resonance position with ortho-substitution. Variations of the acetyl methyl and para-carbon shieldings also follow the trends expected for sterically hindered systems on the basis of the most probable changes in the π-electron distributions with increasing steric

[1]*Part I, ref. 1. Part II, ref. 2.*

[2]*These results were reported in part at the 46th Annual Conference of the Chemical Institute of Canada, Toronto, June, 1963.*

[3]*Petroleum Research Fund Predoctoral Fellow, 1962–1964.*

interference of the acetyl grouping. Further evidence for the effects of hydrogen bonding by both intra- and inter-molecular mechanisms are presented and, since the latter may involve the solvent, some results of more detailed studies of solvent effects are given to support our arguments, although a fuller discussion of these is deferred for a later publication. The spectral data for a few alkylbenzenes were required to provide estimates of the shielding properties of the ethyl, isopropyl, and *t*-butyl groups and are reported in full for the first time, although their spectra have been published (4).

EXPERIMENTAL

Nuclear Magnetic Resonance Spectra

All spectra were obtained at 15.085 Mc/s using compounds containing carbon-13 in natural abundance. In most cases, the reference was either external CH_3I (enriched to 58% ^{13}C) or CS_2 contained in a 5 mm outside diameter tube inserted in the larger 15 mm sample tube, although in a few instances CS_2 was used as both solvent and internal reference. The spectra were calibrated by the generation of audio side bands of the reference signal on the spectrum so that peak positions could be measure by interpolation (5). The output of the audio oscillator was continuously monitored with a Hewlett Packard 522B counter. A minimum of eight separate spectra were measured in each case. The position of the CS_2 resonance signal was assigned as the origin of the chemical shift scale and no corrections for bulk susceptibility differences were included. The data are judged to be accurate to within ±0.5 p.p.m. Other details of the experimental procedure have been reported (3*a*). Where possible the spectra were obtained on the neat liquids, otherwise solutions in appropriate solvents were used as noted in the text and tables. These conditions were employed to produce a maximum signal:noise ratio and sufficient model studies have been carried out to show that solvent effects, although not always negligible, are of secondary importance for any of the comparisons discussed herein.

In a few cases, double irradiation experiments were performed to assist in the spectral analysis. In these experiments, the protons coupled to the carbon nuclei under examination were irradiated at their resonance frequency near 60 Mc/s to reduce the carbon signals to singlets by heteronuclear spin-decoupling. The technique has been reviewed (6) and a detailed description of the procedure has been given (7). In the present case, a NMR Specialties, Inc. Model SD-60 decoupler was employed.

Typical traces are illustrated in Fig. 1 to show the general features of the 15.085 Mc/s carbon-13 spectra obtained.

Materials

Acetophenone was a B.D.H. Ltd. product and the following substituted acetophenones were obtained from the Aldrich Chemical Company, Inc.: 2-hydroxy, 4-hydroxy, 2,4-dihydroxy, 2,6-dihydroxy, 2,4,6-trihydroxy, 4-methoxy, 2,4-dimethoxy, 2,4,5-trimethyl, 2,6-dimethyl-4-*t*-butyl, 4-bromo, 2,4-dichloro, 2-nitro, and 2-amino. The 3-nitro- and 4-nitro-acetophenones were Eastman-Kodak products. A sample of 2,5-di-*t*-butylacetophenone was kindly supplied by Professor L. R. C. Barclay. The rest of the materials examined in this investigation are known compounds, with one exception, and all were prepared by established procedures. In each case, infrared and proton spectra were obtained to check their purity. Their physical properties and the syntheses employed are outlined in Table I together with the previously reported physical constants. All melting points were determined on a Kofler hot stage and are uncorrected. For the most part, the liquids were purified by distillation through an 18 in. Nester-Faust platinum-plated spinning band column and the refractive indices were determined on a Bausch and Lomb refractometer. The microanalysis of 2,6-diisopropylacetophenone was performed by Alfred Bernhardt and Associates, Mulheim, Germany.

DISCUSSION

To facilitate the discussion and to emphasize their similarities the results for the meta- and para-substituted acetophenones are discussed together, while the ortho-substituted compounds are considered in a separate section. To permit an easier intercomparison of the figures for the various compounds, each type of carbon nucleus is discussed under a separate subheading. Finally, considerations of the application of the ^{13}C n.m.r. technique to the study of sterically hindered ketones are described in the last section.

meta- and para-Substituted Acetophenones

(a) Aromatic Carbons

The shieldings observed for the aromatic carbons in acetophenone itself may be compared with those reported previously by Spiesecke and Schneider (35) and which are

included in Table II in parentheses. The agreement is within experimental error and it may be noted that the earlier data were measured using a concentric spherical cell arrangement which eliminates bulk susceptibility differences. Part of the difference between the two sets of data may be due to this factor. While these authors have unequivocally established the assignments for acetophenone by deuterium labelling, the method used for assigning specific bands in the spectra of the substituted compounds requires some explanation. The problem is twofold, (i) the bands which form portions of multiplets must be distinguished from the singlet peaks and all chemical shifts measured and (ii) the observed shifts must be assigned to specific carbon nuclei. For the first distinction, the problem is simplified by virtue of the fact that, in general, only direct ^{13}C—^{1}H spin couplings are resolved in the spectra obtained under these experimental conditions. Thus, bands due to the aromatic nuclei bearing substituents appear as singlets, while the unsubstituted carbons give rise to doublets having coupling constants in the range, 161 ± 3 c/s.[3] A further aid for selecting the components of a multiplet within a spectrum is given by the relative intensities of the bands, since the multiplets are generally skewed owing to magnetization transfer (36) so that the first peak of a doublet, for example, is more intense than the second. A scan in the opposite direction gives the reverse behavior, while

[3]*No specific coupling constants have been included in the tables, since all were within the expected range and the present experimental method does not allow their measurement to better than ±8 c/s.*

the singlet peaks are unaffected. Since the intensity of a band is directly proportional to the number of contributing nuclei, measurements of relative intensities offer an additional aid. In each case, the carbonyl peak serves as a reference, representing one carbon nucleus. Many of the general features of a typical 15.085 Mc/s ^{13}C spectrum are illustrated in Fig. 1*a* for *p*-methoxyacetophenone. Finally, confirmation of which particular bands constitute multiplets may be gained by heteronuclear spin-decoupling experiments to eliminate the effects of spin coupling with protons in the observed carbon spectrum. A typical result is shown in Fig. 1*b*. Thus, the observed chemical shifts for the various nuclei may be determined.

The assignment of particular shieldings to specific nuclei within the molecule is based primarily on the previous results of extensive investigations of several aromatic series. Lauterbur (3*a*–*e*) has been the principal contributor to this field and was the first to point out the apparent additivity of substituent effects on aromatic carbon shieldings (3*b*). His studies of several polysubstituted benzenes show that the combined effects of a methyl group with other methyls (3*a*), methoxyl (3*b*), iodo (3*c*), amino and dimethylamino (3*d*), and nitro groups (3*e*) are additive to a high degree of precision (ca. ±1 p.p.m.) provided the substituents are not ortho with respect to each other. (It may be noted that the aromatic carbons for these various series absorb over a total range of almost 70 p.p.m.) More recently, Savitsky (37) has shown that comparable results are obtained for some para-disubstituted benzenes, *p*-X-C_6H_4-X, where X = F, Cl, Br, and Ac, and with somewhat less precision (ca. 2 p.p.m. maximum deviation) for some para-substituted anisoles, *p*-Y-C_6H_4OMe, where Y = Br, Cl, CHO. Comparable results were obtained from an extensive survey of the spectra of 40 substituted anisoles (38), the full details of which will be published in due course.

Assuming that an additive relation holds for the meta- and para-substituted acetophenones, we have assigned the observed shifts as shown in Tables II and III utilizing the substituent effects which are available for the appropriate monosubstituted benzenes

(3*b*, 35). For the effects of the acetyl group, we have employed values obtained by averaging the present results and those reported by Spiesecke and Schneider (35). Since the necessary shielding data for the alkylbenzenes, R—C_6H_5 where R = Et, *i*-Pr and *t*-Bu, were not available, although their spectra have been published (4), these spectra were determined and the figures appear in Table IV. For the most part, the deviations between the calculated and observed shifts are less than ±1.3 p.p.m. and those cases for which the differences are larger are indicated in the tables. It may be that a part of these discrepancies arises from the fact that our observed shieldings are not corrected for bulk susceptibility differences. In general, however, it appears that the combined substituent effects on the aromatic carbon nuclei for the meta- and para-substituted acetophenones are additive to a reasonable approximation. Some typical results for this comparison are shown in Fig. 2 in which the difference between the calculated and observed shifts is given beside the various aromatic nuclei.

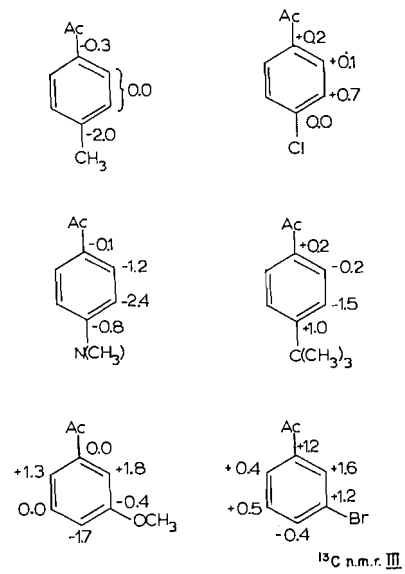

FIG. 2. Deviations between observed and calculated shielding data for aromatic carbon nuclei in some meta- and para-substituted acetophenones.

*The reader is referred to ref. 4 for typical spectra of these compounds.

(b) Carbonyl Carbons

The assignment of the carbonyl peak in these spectra is straightforward in all cases since it appears as a clear single band at the lowest field position. The most striking feature of the carbonyl carbon resonance positions for the meta- and para-substituted acetophenones is the apparent lack of sensitivity toward the variety of polar substituent groups examined. All carbonyl peaks fall in the range, -3.2 ± 0.6 p.p.m., with the exception of the two hydroxy derivatives at -4.6 and -4.9 p.p.m. which constitute separate cases and are discussed in conjunction with their corresponding ortho-derivatives in a later section. While the present series is more extensive, our earlier reports (1, 2) have noted the absence of substituent effects on the carbonyl resonance position and this feature has been discussed in detail (2). Although it is conceivable that solvent effects may mask a weak substituent effect, the influence of the substituent on the carbonyl shielding must be very small since the observed difference between the *p*-NO_2 and *p*-NMe_2 derivatives is only 0.7 p.p.m. (both in $CHCl_3$). An indication that chloroform tends to lower the carbonyl shielding relative to that in a less polar medium has been given for acetophenone (1) and, as a further example, we find the carbonyl peak for the *p*-NMe_2 derivative at 0.8 p.p.m. higher field in benzene solution relative to chloroform solution. Thus, it is clear that our original observation of no pronounced substituent effect holds.

(c) Acetyl Methyl Carbons

In all of these spectra a quartet appears centered at 167 ± 1.0 p.p.m. with a coupling constant of 127 ± 2 c/s (the highest field multiplet in Fig. 1*a*, for example) and for most cases an unambiguous assignment of this multiplet to the acetyl methyl carbon nucleus can be made directly. Since the compounds bearing polar groups exhibit no large changes in the resonance position for the acetyl methyl quartet, it follows that its shielding is also unaffected by alkyl groups in the meta- and para-positions. In the case of alkylated derivatives with other bands in this region, the acetyl methyl resonance was assigned to correspond with the other cases. The increased shielding of the acetyl methyl carbon in conjugated ketones by ca. 4 p.p.m. relative to saturated analogues has been noted and discussed (1). It is possible that the total range of these shifts listed in Tables II and III is increased somewhat by a small effect of the chloroform solvent relative to the pure liquids but this effect would not appear to exceed ca. 1 p.p.m. (see Table VII, ref. 1).

(d) Other Carbons

The observed shieldings and coupling constants for the various nuclei in the substituent groupings are found to be in close agreement with the data obtained for the corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

monosubstituted benzenes. The figures in Table II for the ethyl, isopropyl, and *t*-butyl groups may be compared with those in Table IV while the results for the different types of methyl carbons agree closely with those given by Lauterbur for toluene, 171.8 (3*a*), anisole, 138.4 (3*b*), and N,N-dimethylaniline, 152.6 p.p.m. (3*d*). The observed coupling constants for these various carbons were OCH_3, 147 ± 2; $N—CH_3$, 134 ± 2; $C—CH_3$, $C—CH_2—C$, and C—CH—, 127 ± 2 c/s, in close agreement with other results (3*a*–*e*).

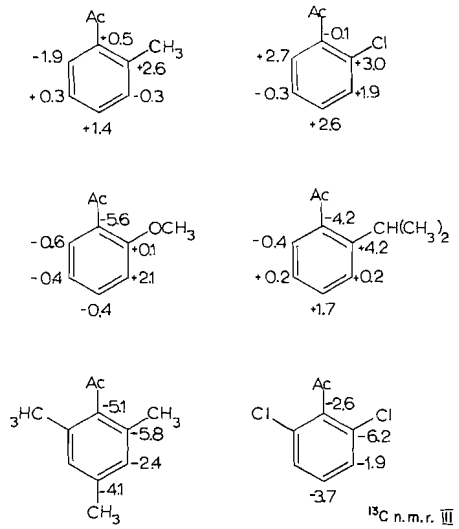

FIG. 3. Deviations between observed and calculated shielding data for aromatic carbon nuclei in some ortho-substituted acetophenones.

ortho-Substituted Acetophenones

(a) Aromatic Carbons

Following the procedure outlined above for the meta- and para-substituted cases, the assignments of the observed spectral bands to the various aromatic carbons in the ortho derivatives have been made as listed in Tables V and VI. As Lauterbur has established for several other examples, the additivity of the indirect effects of substituents on the ring carbons appears to break down with ortho substitution. In the present series of monosubstituted acetophenones the differences between the observed and calculated shifts are appreciably larger, on the average, than those discussed for the meta- and para-derivatives. In addition these differences appear to increase with increasing size of the group ortho to acetyl, clearly suggesting the existence of steric interference between substituent groups. To indicate the magnitude of these differences, some examples are shown in Fig. 3 together with a few more highly substituted compounds. While the larger deviations from the calculated values tend to introduce a greater uncertainty in the specific assignments, intercomparison of the data for the monosubstituted derivatives with those for the more highly substituted cases provide some support for our assignments. Examination of ortho-derivatives labelled with deuterium would, of course, allow unequivocal assignments but this has not been done. The assignments for the symmetrically substituted cases (i.e., 2,6-disubstituted) are unambiguous.

Four of the examples, having similarly positioned substituents, display particularly striking deviations of the observed chemical shifts from those calculated by the additivity relation. These are 2,3-dimethyl-, 2,3,4,6-tetramethyl-, 2,3,5,6-tetramethyl-, and 2,3,4,5,6-pentamethylacetophenone, each of which has three or more contiguous, substituted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

aromatic carbons. It can be seen that for each of these compounds, at least one of the aromatic nuclei bearing a methyl group absorbs at considerably higher field than the less highly methylated compounds. For the four examples, these signals appear at 58.5, 59.9, 64.8, and 65.1 p.p.m., respectively. The last two figures are virtually the same as that of benzene itself although the effect of a methyl group is usually ca. −9 p.p.m. Lauterbur has noted this remarkable change in durene and hexamethylbenzene (*3a*). While this particular case is perhaps an extreme example, it serves to illustrate the complexity of the problem which must be solved before a rational explanation of the origins of these substituent effects can be offered.

Apart from the changes in chemical shift for the para-carbon (C-4), the observed trends are difficult to interpret on the basis of present knowledge and further discussion does not seem warranted. A detailed discussion of the para-carbon shieldings is included in the section on steric inhibition of conjugation below.

(b) Carbonyl Carbons

The striking feature of the carbonyl shieldings for the ortho-substituted acetophenones is the wide range over which these peaks absorb, −2.8 to −15.3 p.p.m., in direct contrast to the results for the meta- and para-derivatives. The values listed in Tables V and VI serve to extend the number of examples included in our previous report (2) in which a detailed discussion of the earlier observations was presented. The application of these

carbonyl results to the estimation of the extent of steric inhibition of conjugation in these hindered systems is illustrated in the final section of this paper.

Further comments, however, regarding the different media employed are in order. Since it was impossible to obtain all of the spectra using the neat liquid, solutions in various solvents were required for examination. Since preliminary solvent studies had indicated that data obtained in either dioxane or carbon disulfide solution are in close agreement with the neat liquid values (1), these were the solvents employed, if possible. In the case of the former, recent work has confirmed our conclusion (39). To examine the effect of chloroform, which was employed in a few cases to obtain concentrations sufficient for detection of the spectra, on the carbonyl carbon resonance position, some compounds were measured in different solvents. These figures in Table VII indicate clearly that, although there is a small but definite deshielding of the carbonyl carbon, the effect of chloroform as a solvent is much smaller than the changes caused by ortho-substitution. It seems likely that the effect of chloroform is due to hydrogen bonding of the carbonyl oxygen and the proton of the solvent.

(c) Acetyl Methyl Carbons

The shieldings of the acetyl methyl carbons in the ortho-substituted acetophenones follow trends similar to those exhibited by the carbonyl carbon nuclei as the results in Tables V and VI show. The resonance position of these nuclei moves to lower field, relative to that of acetophenone, as the bulk and (or) number of the ortho-substituents increases such that this carbon absorbs over the range, 159.3–168.9 p.p.m. The variation of these shifts roughly follows that of the carbonyl carbon for this series of ortho-substituted compounds. The trend is illustrated in Fig. 4, for a number of the alkyl-substituted

acetophenones examined. The apparent slope of this plot indicates that the shielding of the acetyl methyl carbon is somewhat less sensitive to the influence of the ortho-grouping than the carbonyl carbon shielding. The possible significance of the variation of the acetyl methyl chemical shift with the nature of the ortho-group is discussed in a later section.

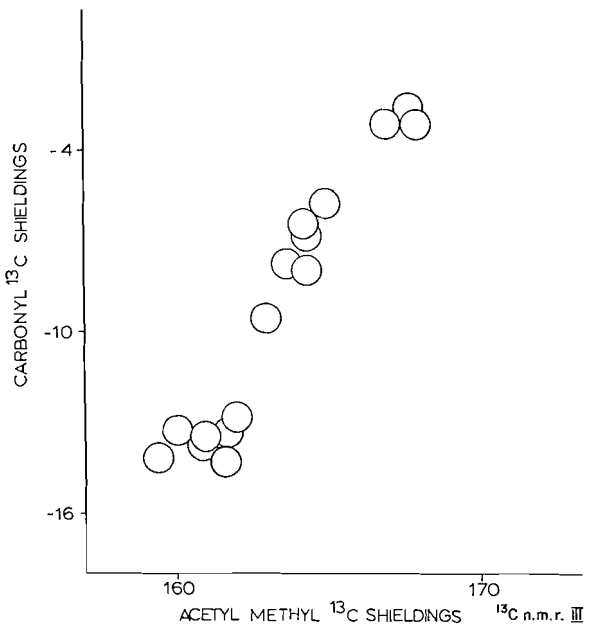

FIG. 4. Plot of observed resonance positions of carbonyl carbon nuclei vs. those of the acetyl methyl carbon nuclei for a number of ortho-alkylated acetophenones.

(d) Other Carbons

The observed chemical shifts for the methoxyl carbon nuclei are in the range, 137.8 ± 0.5 p.p.m. in agreement with the data for the meta- and para-derivatives above and with the results reported by Lauterbur previously (3*b*). Apparently there is no effect of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ortho-substitution on these shieldings. A more extensive study of the spectra of substituted anisoles has shown that substitution at both positions ortho to the methoxyl group is required to change its shielding from the typical value near 138 p.p.m. (38).

In the case of the alkyl substituent groups, however, the chemical shifts of the carbons bonded directly to the aromatic ring and flanked by one or more ortho-groups show small but significant differences from those in the corresponding meta- and para-substituted compounds. In general, the effect of ortho-substitution is one of shielding at these α-carbons. Intercomparisons of the figures in Tables V and VI with those in Tables II, III, and IV show that this effect on primary carbon is ca. 1 p.p.m., on secondary carbon, ca. 2 p.p.m., and on tertiary carbon ca. 4 p.p.m. for methyl, ethyl, and isopropyl groups, respectively. In the last two cases, the β-carbons do not appear to be affected. For the more highly substituted compounds, the data indicate that this trend is accentuated in compounds bearing three substituents on contiguous aromatic carbons (i.e., 1,2,3-trisubstitution). For example, for 2,3-dimethylacetophenone, the two aromatic methyl carbons appear at 177.2 and 173.0 p.p.m., the first of which may be assigned to the 2-methyl carbon flanked by two substituents. Similar shifts were found for acetyldurene (2,3,5,6-tetramethylacetophenone).

Hydroxy-Substituted Acetophenones

A number of derivatives bearing hydroxyl groups have been included in this series and the results obtained differ somewhat from those found for the other examples. One would expect that hydrogen bonding involving the hydroxyl proton and the carbonyl oxygen is probably responsible for these differences. In the monosubstituted cases, the ortho-hydroxyl group is seen to lower the carbonyl shift substantially (by ca. 7 p.p.m.) relative to the meta- and para-derivatives, while the acetyl methyl shielding is unaffected. Presumably the slightly lower carbonyl peak position in the meta- and para-derivatives relative to acetophenone is due to electron-withdrawing intermolecular hydrogen bonding while much more effective intramolecular interaction occurs in the ortho-case. The carbonyl carbon absorbs at significantly lower field for the ortho-amino derivative relative to acetophenone. Although the appropriate model compounds (3-NH_2— and 4-NH_2—) were not examined, it is reasonable that the intramolecular hydrogen bonding of the type, N—H---O=C, is responsible, at least in part, for the observed shift. In those compounds bearing two ortho-hydroxyl groups, the acetyl methyl shielding is reduced indicating steric interference between the acetyl methyl and the second substituent. The carbonyl resonance position is little affected by the second ortho-hydroxyl grouping. It does seem reasonable that hydrogen bonding between a carbonyl group and an ortho-hydroxyl would not be seriously affected if the carbonyl group was hindered from attaining coplanarity with the ring provided it was not twisted too far from this plane. For reasons that are presented in detail below, we would suggest that the second hydroxyl group does not cause a severe twist of the carbonyl group away from the aromatic ring plane although there is little doubt that these two groups are not coplanar. While both inter- and intramolecular H bonding will contribute to the shift of the carbonyl carbon nucleus in these cases, it is not possible to show with the present evidence the extent of the contribution of the former factor for the ortho-substituted cases. Studies of the dilution effect on these shifts are required but these present a practical difficulty due to the low sensitivity of the present technique.

Steric Inhibition of Conjugation

In the preceding section, some spectral features pointing to the existence of steric interference between substituent groupings in the compounds having ortho-substitution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

have been mentioned. A number of these observations suggested the possibility of a semiquantitative approach to the estimation of the extent of steric inhibition of conjugation in these derivatives. In the preceding part of this series (2), a method has been proposed which is alternative to, and possesses certain advantages over, the more usual means of predicting angles of twist between the carbonyl group and the aromatic ring. With the results for a larger number of derivatives now in hand, a critical assessment of this proposed method may be undertaken.

We have already demonstrated the variation of the carbonyl carbon shielding with the size of the ortho-grouping, as estimated by van der Waal's radii or covalent radii (see Fig. 2, ref. 2) and the additional data in Tables V and VI offer further support for this relation. The rationale of the arguments leading to the conclusion that the carbonyl resonance position reflects the degree of steric interference in these ketones has been given and need not be reiterated. Secondary and confirmatory evidence for these ideas derived from other observed trends in these spectra was not presented in detail previously, however, and requires further amplification.

The deviations from additivity of substituent effects on the aromatic carbon shieldings in the ortho-substituted acetophenones were noted above and the difficulty of presenting a clear evaluation of all of these differences was mentioned. One possible exception, however, is the variation of the para-carbon (i.e. C-4) chemical shifts with changes in the substituent group. There are two reasons which suggest that a rational interpretation of these shieldings is possible. First, Spiesecke and Schneider (35) have demonstrated that there is a good correlation of the para-carbon shifts with the Hammett σ_P parameter for a number of monosubstituted benzenes. This result indicates that these ^{13}C shifts reflect the π-electron density distribution at this position and Lauterbur has confirmed this conclusion by comparing the calculated π-electron densities with the para-carbon shifts for several examples (3*a*–*e*, 40). Secondly, the effect of various substituents at the meta-carbon in monosubstituted benzenes is small, less than 1 p.p.m. for the substituents included in our series with the exception of the halogens and hydroxyl. These two facts suggest that the shielding of the para-carbon in the acetophenones will reflect variations in the extent of electron withdrawal at this position by the acetyl group, which would be caused by steric hindrance to co-planarity of the carbonyl group and the aromatic ring. In acetophenone, the para-carbon absorbs ca. 4 p.p.m. toward lower field from the resonance position of pure benzene and it is reasonable that this low field shift is primarily due to conjugative electron withdrawal by acetyl from the para-position. Thus, any factor hindering this conjugation would be expected to reduce the effect of the acetyl group at the para-carbon which would mean an increased shielding and, therefore, a shift to a value closer to that of pure benzene.

An examination of the data for the para-carbon nuclei, however, does not necessarily support this proposal unless the effects of the other substituents are taken into account. To allow an easier comparison, the pertinent shielding data are collected in Tables VIII and IX and the "corrected" figures, allowing for the effects of the other substituents, are included. In general, the para-carbon shifts move to higher field with increasing size and (or) number of ortho-groups, in agreement with expectations. Probably the most reliable data are those for the mono- and 2,6-di-substituted compounds, since the "corrections" for the substituents in these positions are relatively small. Because of the breakdown of the additivity relation for ortho-substituted derivatives, the significance of the "corrections" used for the examples having groups at the 3-, 4-, and 5-positions is questionable. As an example, the corrected figures for tetramethyl- and pentamethyl-acetophenone do not agree well with those for less highly substituted examples. It is interesting that this

analysis of the data for the 2-methoxyl derivatives indicates no steric interference between the acetyl and methoxyl groups, but there is an indication of crowding for the 2,6-dimethoxyl case. Another feature is that the "corrected" para-carbon shielding is similar for each of the three mono-halo derivatives (Cl, Br, I), but the "corrections" for two of these cases are relatively large (i.e., 2.2 p.p.m. for Br, 2.6 p.p.m. for I) and these could be in error, although there is no obvious way to check this point. A further disadvantage to the use of the para-carbon shifts for estimating the extent of steric hindrance in these systems is the relatively small range of 4 p.p.m. over which one can expect to observe

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

changes. This consideration of para-carbon shieldings, however, does show that the general trends are consistent with those expected for steric inhibition of conjugation and that the observed shifts might be used to support evidence from other spectral features.

The observed shifts for the acetyl methyl carbons have been included in Tables VIII and IX to show more clearly the regular reduction in shielding with increasing bulk and number of ortho-groups mentioned above (see Fig. 4). While this trend to lower field is qualitatively reasonable, the maximum change observed is larger than expected, if the extent of conjugation of the carbonyl group with the aromatic ring were the dominant factor, indicating that longer range substituent effects contribute to these shieldings as well. Approximate estimates of the ring anisotropic effects indicate a maximum difference of 0.2 p.p.m. between the planar and perpendicular orientation of an acetyl methyl carbon with the ring, following the method of Johnson and Bovey (41) and, of course, this change is in the opposite direction to that observed.

Qualitatively, however, the observed variation of the acetyl methyl shieldings appears to indicate the extent of steric interference of the ortho-substituents with the acetyl group. In contrast to the para-carbon shieldings, these data indicate appreciable steric hindrance by *one* ortho-methoxyl group which is only slightly increased by the introduction of a second ortho-methoxyl.

While a full discussion of the probable significance of the carbonyl shieldings has been presented (2), further evidence in support of these ideas is given by the data in Tables VIII and IX for 30 examples and which are completely consistent with our original interpretation. The empirical expression, $\cos^2\theta = (\delta_C{}^X + 23.2)/20$ (where θ is the angle of twist for the acetophenone bearing the X substituent and $\delta_C{}^X$ is its ^{13}C carbonyl chemical shift), which was developed previously, permits one to estimate the dihedral angle between the planes of the carbonyl group and the aromatic ring and the calculated angles for the examples included in this study are given in Table X.

On the basis of Lauterbur's results for several aromatic series, there seems little doubt that closely neighboring groups can exert certain "ortho" effects on the shielding of the carbonyl nuclei which are independent of, and simultaneously operative with, any effects whose origins are steric in nature. The cause or causes of this mysterious effect are obscure. Although the most popular interpretation attributes these "ortho" effects to neighbor–anisotropy phenomena, it appears unlikely that this is the sole, or even the most important, factor for all cases. The problem has been discussed for particular cases, e.g. I (3*c*). The estimation of the magnitude of the non-steric "ortho" effect presents a difficult problem but, as a first approximation, we have examined the possibility of using estimates based on the data for various substituted toluenes (42, 43). At first, this approach seemed a reasonable one since the variation of the ^{13}C methyl shift with polar substitution is very small for meta- and para-substituted toluenes but there are significant changes from these in the ortho-derivatives. We assumed that this change is primarily due to a non-steric "ortho" effect of uncertain origin. By taking the difference between the observed methyl carbon shift for an ortho-substituted toluene and the averaged methyl shift for the corresponding meta- and para-substituted toluenes, we calculated "correction" factors for the various substituents. Applying these factors to the observed carbonyl carbon shielding data, we obtained "corrected" shielding values which are listed in the last column of Tables VIII and IX. Because of the unavailability of the required ethyl-, isopropyl-, and *t*-butyltoluenes, the "correction" factor for methyl carbons, found from the xylene data, were used for the first two cases since both can adopt conformations which would tend to minimize steric interactions and which would be approximately similar to those for methyl substitution. A factor for the *t*-butyl group, however, is more difficult to estimate and we hesitate to hazard a guess as to its magnitude. For the same reasons, "correction" factors for the ortho-phenyl and iodine nuclei have been omitted. For the tables, the following "correction" factors were employed: CH_3, -1 p.p.m., Cl, -1.2 p.p.m., Br, $+0.7$ p.p.m., NO_2, -0.9 p.p.m., and CH_3O, -4.8 p.p.m. Two immediate surprises in these figures appear to be the value for the methoxyl group and the opposite signs of the factors for chlorine and bromine. Substitution of the "corrected" carbonyl shieldings in the expression given above yielded the angles of twist, θ, listed in Table X and termed "corr." For most cases, the "corrected" angles are only slightly different from the original values. These estimates seem to be satisfactory for the alkyl groups, but some of the results for the polar groups are dubious.

Support for the inclusion of the "correction" factor for methyl groups in the ortho-position(s) was noted in our earlier report, based on the results for substituted benzaldehydes. In the present series, the results give no reason to change this conclusion for the alkyl groups. No supporting evidence, however, can be put forward for the other substituents. In fact, in view of the apparent discrepancies in the results obtained using the "corrected" carbonyl data, it would seem more desirable to accept the uncorrected figures as a better indication of the geometry of the molecules. Clearly more information on the nature of the indirect effects of these polar groups on the shielding of carbon nuclei is required to allow a full understanding of the present results. The main difficulty which must be overcome is by no means trivial and clear approaches to its resolution are difficult to suggest. This problem is the estimation of the contribution to the observed effect of that portion which is operative through space, the so-called field effect. The usual approach employed is an application of the point dipole model (44) to evaluate the so-called neighbor–anisotropy contribution (44, 45) due to the field induced circulation of electrons on the X atom. Several examples, however, are known for which inclusion of the neighbor–anisotropy effect is insufficient to rationalize the observed data, the case of iodine, for

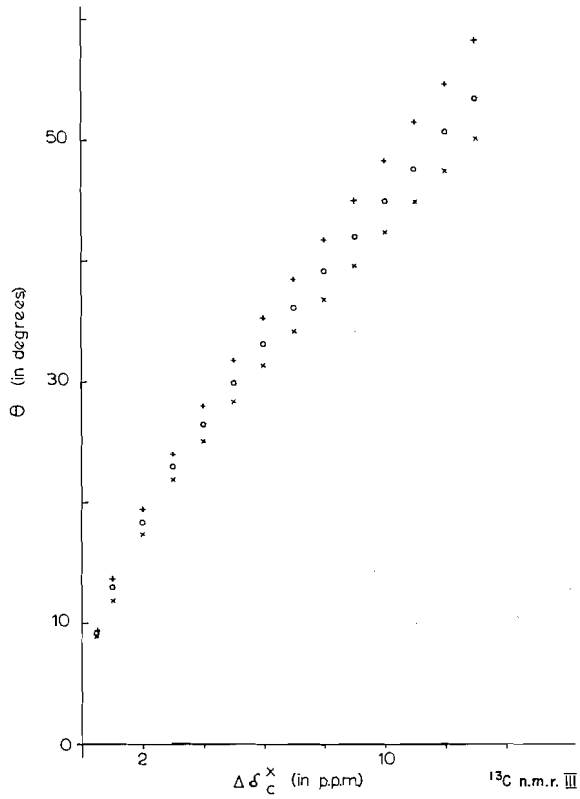

FIG. 5. Variation of the calculated angle of twist, θ, with $\delta_C{}^X$ values for various ortho-substituted acetophenones, assuming different values for the contribution by the phenyl group on the carbonyl chemical shifts (+, 15 p.p.m.; ○, 17 p.p.m.; ×, 19 p.p.m.).

example (3*c*). With the present state of knowledge, we would favor neglecting these "correction" factors until a more rational method for their estimation is suggested.

A weakness of this overall approach to θ values may appear to be the estimation of the shielding of the carbonyl carbon nucleus for the 90° case. To show that an estimated value of 17 p.p.m. for the conjugative shielding effect of the phenyl group is not extremely critical, we have plotted the variation of θ with $\delta_C{}^X$, the difference between the carbonyl shielding in acetophenone and that for an X-substituted compound, for other values of the phenyl conjugative effect, viz. 15 and 19 p.p.m. (see Fig. 5). Only for the highly hindered cases is there an appreciable change in θ, although $< 8°$ at 50°. Hence, we feel that this weakness is not a strong objection to the proposed approach to estimates of angles of twist.

An examination of the data in Table X indicates that the estimates of θ based on the observed shieldings are in substantial agreement with simple stereochemical considerations. In general, these estimates tend to be somewhat smaller than those obtained from analyses of ultraviolet spectral data or dipole moments (22, 46), comparisons with which were given previously (2). Estimates of θ for the 2,4,6-trimethyl- and 2,3,5,6-tetramethylacetophenones have recently appeared derived from determinations of the Kerr constants (47) and are found to be 90° for each of these cases. Clearly, these values are greatly different from any of the previous estimates and seem to be much too large.

An additional example of the buttressing effect of a second methyl group has been found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(2,3-dimethylacetophenone) and the observed change in θ by ca. 4° is comparable to that found for acetyldurene. No additional hindrance appears to be associated with the introduction of a fifth methyl group in the latter case.

The order observed for the three ortho-haloacetophenones using the uncorrected data also is in agreement with that expected on steric grounds but, since the observed carbonyl ^{13}C shielding may be strongly affected by an "ortho" effect of iodine (3*c*), the internal agreement of these estimates may be fortuitous. The results for the group of compounds bearing the methoxyl group in the ortho-position(s) may also be suspect. It was pointed out above that the other trends indicating steric interference in most of the cases (the acetyl methyl and para-carbon shieldings) are in direct contradiction and, in addition, the non-steric "ortho" effect of oxygen nuclei (from the toluene data) is appreciably larger than that for the other groupings examined. The estimates using the observed carbonyl data (i.e. uncorrected) appear reasonable with the exception of the 2,4-dimethoxy-derivative, but the "corrected" values seem unduly large (note especially the 2,6-$(CH_3O)_2$ case). At the present time, no clear explanation of these discrepancies can be offered apart from the suggestion that a smaller angle of twist might be expected for a compound bearing a para-methoxyl group due to conjugative electron release by oxygen. The slightly reduced θ in the alkylated examples having para-methyl groups may be ascribed to a similar electron release by the methyl group.

In general, the proposed method for the estimation of angles of twist in these carbonyl-containing systems yields reasonable and, most importantly, consistent results for the alkylated examples and for a number of other polar substituents. The approach possesses distinct advantages over the method based on the intensities of electronic transitions since the observed spectral band is characteristic of the ground state of the molecule. Furthermore, this transition can be assigned unambiguously and measured accurately. In addition, confirmatory evidence is provided by measurements of two other transitions in the spectrum. The results of an extension of our study of carbonyl compounds and a consideration of this approach for the estimation of steric hindrance in a series of alkyl phenyl ketones and the results of a detailed examination of several aliphatic conjugated carbonyl compounds will be reported shortly.

ACKNOWLEDGMENTS

We gratefully acknowledge the support of the Petroleum Research Fund, administered by the American Chemical Society, in the form of operating funds and the Ontario Research Foundation for a grant to purchase the 15.1 Mc/s rf unit. We also thank Professor L. R. C. Barclay for a sample of 2,5-di-*t*-butylacetophenone.

^{13}C N.M.R. STUDIES

PART IV.[1] CARBON-13 N.M.R. SPECTRA OF SOME ALKYL PHENYL KETONES[2]

K. S. DHAMI[3] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario

Received September 24, 1964

ABSTRACT

The 15.1 Mc/s ^{13}C n.m.r. spectra of 21 substituted alkyl phenyl ketones, ArCOR, have been determined and the ^{13}C chemical shifts measured. This group of compounds included examples of each of the ethyl, isopropyl, and *t*-butyl phenyl ketone series. Variations of the chemical shifts with structure are analyzed and compared with the results for substituted acetophenones. The study of steric inhibition of conjugation in these compounds by means of their ^{13}C data is discussed in detail. The parameters for the acetyl carbons for a few methyl aryl ketones have been determined as well to examine the effect of orientation of this group on a polycyclic aromatic skeleton.

INTRODUCTION

As an extension of our investigations of the carbon-13 nuclear magnetic resonance spectra of organic carbonyl groups (1, 2, 3), we have prepared a number of alkyl phenyl ketones and determined their ^{13}C spectra at 15.085 Mc/s. Seven examples in each of the propiophenone, isobutyrophenone, and pivalophenone series have been included and, since our interest has centered primarily on the ^{13}C shieldings in hindered systems, most of these compounds bear at least one ortho-substituent. As models for comparison with the results for these hindered systems, the parent ketone of each series and its para-methoxyl derivative were examined. Analyses of the spectra were carried out by the methods which have been described in detail in Part III of this series (3). The aromatic shieldings for the methoxyl derivatives permit an additional test of the additive relation of combined substituent effects on the chemical shifts of these nuclei (4).

The results for the hindered ketones show that variations of the ^{13}C chemical shift parameters for the carbonyl carbon, the para-carbons, and the α-carbon of the acyl group provide indications of the existence of steric interference to coplanarity of the acyl grouping. Application of the carbonyl shieldings to semiquantitative estimates of the angles of twist in these systems has been attempted, using an approach similar to that described for the analysis of the carbonyl data for the acetophenones. The limitations of the approach for these compounds place greater uncertainties on the calculated values, but the results are reasonable and appear to yield satisfactory estimates as a first approximation.

EXPERIMENTAL

Nuclear Magnetic Resonance Spectra

All spectra were determined at 15.085 Mc/s using the compounds described below containing ^{13}C in natural abundance. Details of the experimental procedure have been presented (3).

Materials

All of the compounds were prepared from readily available commercial products. Most of the ketones are well known and all were obtained by established procedures. In each case, infrared and proton spectra were determined to check their purity. The observed physical constants and the syntheses employed are collected

[1]*Part III, ref. 3.*
[2]*These results were reported in part at the 46th Annual Conference of the Chemical Institute of Canada, Toronto, June 1963.*
[3]*Petroleum Research Fund Predoctoral Fellow, 1962–1964.*

in Table I together with the reported constants. The analytical data are included for the new compounds: 2,3,4,5,6-pentamethylpropiophenone, 2,3,5,6-tetramethyl-, 2,3,4,5,6-pentamethyl-, and 2,4,6-triisopropylisobutyrophenone. The microanalyses were performed by Alfred Bernhardt and Associates, Mulheim, Germany. All melting points, determined on a Kofler hot stage, are uncorrected. The liquids were purified by distillation through a platinum-plated, spinning band column. The solvents used for spectral studies were Fisher "Spectro-Grade" reagents.

DISCUSSION

The results for the three closely related series of alkyl phenyl ketones are considered together to facilitate discussion and to emphasize the common features. The observed chemical shifts for each type of carbon nucleus are discussed under separate subheadings to allow ready intercomparison of the data from each series. The shieldings of the carbons of the acetyl group in a few polycyclic aryl methyl ketones are presented in a separate section. In the final section, the application of these ^{13}C spectral results to the estimation of the extent of steric inhibition of conjugation of the acyl grouping is considered in detail.

The majority of the data have been obtained using the neat liquids or solutions of the ketones in carbon disulfide. In the latter cases, however, the maximum concentrations attainable were not sufficient to permit satisfactory measurements for all band positions and consequently certain data do not appear in the tables. Measurements for some of

For personal use only.

these bands were possible in chloroform solution and these figures are indicated in the tables. On the basis of our previous results (1, 3), it seemed unlikely that chloroform causes appreciable changes in the shielding of any but the carbonyl carbons, but, to confirm this point, a few examples were studied in both carbon disulfide and chloroform solutions.

Alkyl Phenyl Ketones

(a) Aromatic Carbons

The chemical shifts of the aromatic carbon nuclei in the propiophenone, isobutyrophenone, and pivalophenone series are given in Tables II, III, and IV, respectively. The analyses and assignments in the aromatic regions of these spectra were accomplished by the methods which were described in detail in the preceding part of this series (3). The data for the parent ketone for each of these series show that the substituent effects of the three acyl groups are similar and not greatly different from those caused by an acetyl group. To compare the effects of various carbonyl-containing groups on the aromatic shieldings, the relevant data are listed in Table V in which the substituent

effects are given relative to benzene. The figures for the formyl group are from Spiesecke and Schneider (17). The effects of the acyl groups at the ortho- and meta-positions are slightly less than those of the formyl and the differences between the effects for the various R—C(=O)— groups are within experimental error. For these acyl groups, appreciable differences are found, however, at the C-1 and C-4 nuclei, but there is no apparent trend for these changes at either position. No explanation can be offered to account for the small, but distinct, variations.

The para-methoxyl derivative of each parent ketone was examined to test for additivity of substituent effects, since an additive relation has been found to hold to a good approximation for several meta- and para-substituted aromatic compounds (3, 4, 18, 19). The methoxyl group was chosen since the effect of this grouping differs considerably at the various aromatic nuclei and thus provides a more definitive test. The agreement between the observed and calculated chemical shifts for the ring carbons was found to be within 1.3 p.p.m. with one exception, the 2- and 6-positions (which are equivalent) in 4-methoxypivalophenone. These differences are comparable to those found for acetophenones (3). We have assumed that these results confirm our peak assignments.

The remaining compounds were examined primarily to study the variations of the chemical shifts of nuclei in the substituent groups of other hindered systems to compare with our previous results and to test conclusions drawn therefrom. The shieldings of the aromatic carbon nuclei of these compounds are listed in the tables (II, III, and IV) but little comment can be offered at this time. As before, ortho-positioning of substituent groupings on the ring produces marked deviations of the observed shifts from the values calculated by assuming an additive relation. Remarkable differences are also observed for those cases in which an aromatic methyl group is flanked on both sides by substituents. The acyl derivatives of durene and pentamethylbenzene exhibit this behavior as does 2,3,4,6-tetramethylpivalophenone. For each of these examples, one of the methyl-substituted aromatic nuclei absorbs in the range, 63.1–65.3 p.p.m., indicating that the usual deshielding effect of ca. 9 p.p.m. due to methyl substitution is largely overcome by some other factor. As before (3), we have assigned this signal to the aromatic carbon(s) bearing the most crowded methyl group(s) which for the durene derivatives are the C-2 and C-6 nuclei. The other methyl-substituted aromatic nuclei in these derivatives are also abnormally shielded but to a lesser degree. Evidence suggesting that this shielding effect is due, at least in part, to the acyl group comes from the observation that only *two* aromatic carbons absorb near 65 p.p.m. in the pentamethyl derivatives. Thus, this effect would not appear to arise merely from a simple crowding of the methyl substituents and consequently the highest field signal in the aromatic region has been assigned to the C-2 and C-6 nuclei in these compounds. By the same reasoning, the signal at 64.3 p.p.m. in the spectrum of 2,3,4,6-tetramethylpivalophenone has been assigned to carbon-2. Similar effects have been noted for the polymethylated acetophenones (3). Further indication that the acyl group is largely responsible for this up-field shift is given by the shieldings for the aromatic nuclei of hexamethylbenzene at 60.4 p.p.m. (20) and pentamethylbenzene in which the substituted ring carbons appear at 60.8 p.p.m. (21). Clearly both show a shift to higher field relative to less highly substituted compounds, but the relative change is considerably less than that observed for the ketones.

The chemical shifts for the C-4 aromatic nuclei in the ortho-substituted derivatives exhibit variations similar to those found for the acetophenone series (3) in that substitution at the ortho-position(s) tends to reduce the deshielding effect of the acyl group at the para-position. A comparison of the observed C-4 shifts for propiophenone or isobutyrophenone and the corresponding 2-methyl derivative illustrates the trend without allowing for the small effect of the methyl group at C-4. The observed changes are consistent with previous observations in the acetophenone series, even the exceptions are similar (i.e. the 2,3,4,5,6-pentamethylated derivatives) and these have been discussed (3). We attribute the increased shielding at the para-carbon to steric inhibition of conjugation in the ortho-substituted compounds relative to compounds lacking ortho-substituents.

Apart from the observations and interpretations noted above, present knowledge of aromatic shieldings in general does not permit a fuller evaluation of our results.

(b) Acyl Groups

(i) Carbonyl carbons.—The easily recognized singlet peaks due to the carbonyl carbon nuclei are the lowest field bands in all of these spectra and the observed resonance positions (Tables II, III, and IV) clearly show that methyl substitution on the α-carbon of the acyl group tends to deshield the carbonyl carbon. These bands appear at -3.2, -5.6, -10.3, and -14.4 p.p.m. for the acetyl, propionyl, isobutyryl, and pivaloyl groups, respectively. These changes are in *qualitative* agreement with those found for

the comparable series of alkyl methyl ketones (1) as well as the differences in chemical shift of the unsaturated carbon in the system =C—R, where R = ethyl, isopropyl, *t*-butyl for both aromatic (3) and aliphatic (22) hydrocarbons. In the latter case, the assignments for the appropriate olefinic carbon nuclei have not been made by the original authors, but, by analogy with their other results the most probable assignment supports the above claim. There are significant *quantitative* differences, however, between these effects and those found for methyl substitution in the aliphatic and aromatic ketones. In the present series, successive substitution on the α-carbon tends to deshield the carbonyl nucleus by ca. 4 p.p.m. per methyl group whereas, in the aliphatic ketones the carbonyl carbon shift difference between the isopropyl methyl and *t*-butyl methyl ketones is only 0.8 p.p.m. Further discussion of this point is presented in the final section.

In each series, there are distinct variations in the carbonyl shieldings with substitution on the aromatic ring. In contrast to the results for the acetophenone series, the para-methoxyl group shifts the carbonyl resonance to higher field relative to its position for the parent ketone. These differences of 0.9, 1.8, and 3.4 p.p.m. for the propiophenone, isobutyrophenone, and pivalophenone derivatives, respectively, appear to increase with increasing size of the acyl group suggesting that the origin of the effect is probably steric. The results of the study of the acetophenone series established that the polar nature of substituent groups was of minor effect on the carbonyl shieldings in planar systems while some evidence for a shielding effect operative in hindered systems was obtained for certain electron-releasing groups in the para-position. The present results, therefore, seem consistent with the latter condition.

The remaining examples in each of the three series bear one or two ortho-substituents and a comparison of the changes in carbonyl chemical shift with substitution shows that similar variations are found for each series. For example, introduction of an ortho-methyl group produces an average change of -4.2 ± 0.6 p.p.m. for each carbonyl carbon shift relative to that observed for the parent ketone, while a second ortho-methyl substituent gives an additional average change of -4.5 ± 0.7 p.p.m. The observed changes for these and other substitutions are collected in Table VI. The average effects are given in the last column of Table VI, and, although the deviations are slightly larger than experimental error, the effects are closely similar. A more important observation is probably the fact that the order throughout each series is the same. This order follows that expected on the grounds of increasing steric interference of the substituents with the acyl groups thus hindering the carbonyl group from attaining coplanarity with the aromatic ring.

(ii) Alkyl carbons.—The observed chemical shifts of the alkyl carbon nuclei of the three acyl groups of the parent ketones (Tables II, III, and IV) may be compared to the shifts observed for ethyl, isopropyl, and *t*-butyl groups directly bonded to aromatic

*Difference between shifts for ketone and hydrocarbon.

rings (3). In each case, the α-carbon is deshielded and the β-carbons (methyl) are shielded for the ketone relative to the values for the corresponding alkylbenzene. These figures are collected in Table VII for comparison. The largest difference for the α-carbon shielding is found for the *t*-butyl group and is much greater than any of the others. Indeed, this difference appears to break the trend (compare the figures in Table VII). The shielding effect at the β-methyl carbons decreases with increasing size of the alkyl group. Apart from this variation for the β-methyl carbon shifts, however, the shielding of these nuclei is relatively insensitive to the introduction of substituents in the aromatic ring. It appears that the methyl carbon shieldings are not sensitive to changes in the polarization of the carbonyl bond, at least in the first approximation. With the exception of the pivalophenone series, a similar behavior is not observed for the α-carbon shieldings. One would expect the α-carbon shift to reflect changes in the carbonyl polarization since this nucleus is directly bonded thereto. The fact that the α-carbon shieldings are decreased with increasing ortho-substitution is completely consistent with the existence of steric interference to coplanarity of the carbonyl group and the observed changes are strikingly similar to those observed for the acetyl methyl carbon in similarly substituted acetophenones (3). For example, the average change caused by the introduction of a 2-methyl group is -3.2 ± 0.5 p.p.m. for the acetophenone, propiophenone, and isobutyrophenone systems, while substitution of a second ortho-methyl group (from the results for the 2,4,6-trimethyl derivatives) produces an average shift of -6.25 ± 0.25 p.p.m. relative to the parent ketone in each of these three systems. It is reasonable to suggest that these changes arise from a common origin which is steric inhibition of conjugation of the carbonyl grouping.

Other Carbons

The observed chemical shifts for the various types of carbon nuclei in the substituent alkyl groups are similar to those reported earlier in the acetophenone series. As before, an increased crowding of the methyl groups on an aromatic ring tends to shift the methyl carbon resonance toward higher field. It is important to note that in view of considerable overlapping of the bands for the various alkyl carbons in these spectra, their data are the least precise. The methoxyl carbons, however, absorb in a region of the spectrum which is uncluttered and their signals are easily measured. The shieldings of 138.1 ± 0.1 p.p.m. are unexceptional (3, 4).

Methyl Polycyclic Aryl Ketones

The shieldings of the carbonyl carbon nuclei for a few methyl aryl ketones having polycyclic aryl groupings have been reported (3) and these data together with those for the methyl carbon nuclei are collected in Table VIII. The figures for acetophenone are

included for comparison. The variations in these results clearly indicate that there are steric interactions between the acetyl group and the aromatic ring system for those cases in which *peri*-hydrogens could interfere with the rotation of the acetyl group, namely, 1-naphthyl, 9-phenanthranyl, and 9-anthranyl. The latter case exhibits the most pronounced deshielding effect at both the carbonyl and methyl carbons presumably owing to the fact that two *peri*-hydrogen interactions may be involved. Although three of these examples were studied in chloroform solution only, the observed chemical shifts would not be expected to differ greatly from values for comparable concentrations in less polar media. An upper limit for the solvent effect on the resonance positions of these carbons would, in all probability, not exceed 2 p.p.m. on the basis of previous results (1, 3). The chemical shifts of certain nuclei in chloroform solution relative to those in carbon disulfide are listed in Table IX, and it is evident that the solvent effects are relatively small. Thus, there is clear evidence for steric inhibition of conjugation for these three cases. Owing to the complexity of the aromatic regions in these spectra, and, for the solids, the relatively low concentrations of the solutions obtainable, satisfactory analyses of the aromatic patterns were not possible and the chemical shift measurements are limited to the carbons of the acetyl grouping. In the case of 9-acetylanthracene, spin-decoupling experiments were carried out to locate and measure the position of the acetyl methyl signal.

Steric Inhibition of Conjugation

A number of the variations in the chemical shift results for alkyl aryl ketones which provide evidence for the existence of steric inhibition of conjugation in several cases

have been noted in the preceding sections. Our previous studies of the ^{13}C spectra of substituted acetophenones permitted the development of a semiquantitative approach to an estimation of the magnitude of the steric interference in terms of the angles of twist, θ, between the planes of the carbonyl group and the aromatic ring. The present series affords an opportunity to investigate the use of this method for similar estimates in some closely related systems.

Of the four series of compounds included in this study, the polycyclic aryl methyl ketones are perhaps the least different from the acetophenones, if one is to judge on the basis of the observed chemical shifts of the acetyl carbon nuclei. These shieldings for the 2-naphthyl and 3-phenanthranyl systems are the same, within experimental error, as those found for acetophenone (Table VIII). The other examples exhibit deshielding effects which we attribute to steric interference with the *peri*-hydrogens. Assuming that the empirical expression (2, 3) relating θ with the carbonyl carbon shift is applicable, substitution of the observed values yields the following angles of twist for these hindered cases: 1-naphthyl, 25°; 9-phenanthranyl, 28°; 9-anthranyl, 49°. All of these values seem to be reasonable estimates although figures with which comparisons might be made are lacking. The effect of varying contributions due to ring currents in these aromatic skeletons have been neglected in these calculations but any differences arising from this effect are small relative to the overall changes observed for the hindered and planar cases. An estimate, using the calculated values for ring current contributions from Johnson and Bovey (23) and assuming independent contributions by each ring in the polycyclic system (24), of the additional ring current effect for the most extreme case, 9-acetylanthracene, relative to acetophenone is calculated to be -1.02 p.p.m. for the carbonyl carbon shielding. Clearly, the ring current contributions, as estimated by the generally accepted models, are of secondary importance, although the calculated angles of twist may be somewhat larger than the actual angles. Differences due to varying ring current contributions at the various acetyl methyl carbons will be even smaller than those at the carbonyl nuclei owing to their greater distance from the aromatic ring systems and the fact that these methyl groups are not in the plane of the aromatic skeleton.

A direct comparison of the carbonyl carbon shifts for acetophenone, propiophenone, isobutyrophenone, and pivalophenone clearly shows that the effect of methyl substitution on the α-carbon is substantial, as pointed out above. Since the ethyl and isopropyl groups in propiophenone and isobutyrophenone, respectively, can adopt conformations which have the same non-bonded interactions as the methyl group in acetophenone, it is generally assumed that the carbonyl group is coplanar with the aromatic ring in each of these compounds (25, 26). The observed differences in the shieldings, therefore, must be primarily due to polar effects of methyl substitution. Attention has been drawn to the similarities of these changes with those observed for the corresponding methyl alkyl ketones and olefins, although no clear explanation for these changes can be offered. Assuming that these effects are entirely due to the alkyl substituents bonded to the carbonyl groups, the variations in carbonyl carbon shielding caused by alkyl substitution on the ring may be employed to calculate the angles of twist, θ, for the hindered systems. For this purpose, the original expression must be modified to, $\cos^2\theta = (\delta_C{}^X + 20)/20$ where $\delta_C{}^X$ represents the difference in carbonyl shielding for the X-substituted compound relative to the corresponding parent ketone. The necessary data are given in the first two columns of Table VI. Using these figures, angles of twist have been calculated for the propiophenone and isobutyrophenone series and these are listed in Table X. As

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

described in previous papers (2, 3), there is evidence that an ortho-methyl substituent tends to shield the carbonyl carbon nucleus by ca. 1 p.p.m. and, taking this effect into account, "corrected" estimates of θ have been calculated and included in Table X. A detailed discussion of the significance of these "corrections" has been presented (3) and need not be repeated. The estimates in this table seem reasonable although, again, other estimates for these systems are not available for comparison. Two interesting features are apparent from these results: (*a*) the hindrance of two ortho-isopropyl groups is apparently slightly greater than that caused by two ortho-methyls, and (*b*) there are indications of a buttressing effect by the additional methyl groups in durene and pentamethylbenzene derivatives relative to the acylmesitylenes. Both of these observations are in agreement with the results from the acetophenone study.

TABLE X

Estimated angles of twist, θ, for some hindered alkyl phenyl ketones (given in degrees)

	Alkyl group

2,3,5,6-$(CH_3)_4$	48	55	44	49
2,3,4,5,6-$(CH_3)_5$	49	55	44	50
2,4,6-(i-C_3H_7)$_3$	47	53	43	48

As noted in a previous section, the carbonyl shielding of pivalophenone is towards lower field by −4.1 p.p.m. relative to isobutyrophenone, while the difference in carbonyl carbon shifts for methyl isopropyl and methyl *t*-butyl ketones is only 0.8 p.p.m. and this difference is even less (0.2 p.p.m.) for diisopropyl and di-*t*-butyl ketones. This distinct difference for pivalophenone indicates that its carbonyl carbon is deshielded by an effect in addition to that of the *t*-butyl group. The most probable interpretation of this observation appears to be the presence of steric inhibition of conjugation due to interference between the aromatic protons and the β-methyls of the *t*-butyl grouping since it cannot assume a conformation having non-bonded interactions similar to those of methyl, ethyl, or isopropyl. If this is a valid explanation, the magnitude of the angle of twist for this system may be estimated using the empirical expression given above and the figure −3.6, for δ_C^X, since this is the difference between the observed change in pivalophenone and the average of the two *t*-butyl aliphatic examples, all relative to the corresponding isopropyl derivatives. In this way, the angle of twist is found to be 25° which may be compared to the value of 34°, estimated from ultraviolet spectral data (25). Both of these estimates agree well with those found for ortho-methylacetophenone by the corresponding methods (3, 25). Although this analysis of the ^{13}C chemical shift data is crude, it is interesting that the estimated angle is not unreasonable for this system. For the substituted pivalophenones, the observed variations of the carbonyl shieldings are comparable to those for the related series and estimates of the extent of steric inhibition can be made in a similar fashion. In view of the uncertainties of the approach to the estimated value for the parent compound, however, the significance of such estimates is questionable. For the 2-methyl and 2,4,6-trimethyl derivatives, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

calculated angles are found to be 40° and 51°, respectively, and the figures for the other derivatives correspond closely with these values, for the mono- and di-ortho-substituted examples, respectively. In any event, the differences in the carbonyl shieldings for the pivalophenone series are qualitatively consistent with the other findings.

Another feature of these spectra of the alkyl phenyl ketones, which was mentioned earlier but deserves further comment, is the effect of the para-methoxyl group on the carbonyl carbon shieldings. For each of the three series, a shift of the resonance position of the carbonyl carbon toward higher field is observed upon the introduction of this substituent and is most pronounced for pivalophenone (3.4 p.p.m.). This change provides supporting evidence of steric interference in pivalophenone itself since it may reasonably be attributed to an increased conjugation of the carbonyl group with the ring due to the strong electron-releasing tendency of the methoxyl group. In other words, it is suggested that the conjugative interaction of the methoxyl oxygen with the carbonyl group, acting through the aromatic ring, reduces the angle of twist in the substituted case relative to the parent ketone. Support for this conclusion is provided by the very much reduced effect of the methoxyl group on the carbonyl shielding in 2-methyl-4-methoxypivalophenone (relative to that for the 2-methyl derivative) for which it would appear that any conjugative interaction is not sufficient to overcome the more pronounced nonbonded interactions. The effect of the para-methoxyl substituent on the isobutyrophenone carbonyl shielding (1.8 p.p.m.) is appreciable and it follows, therefore, that there is some hindrance to coplanarity of the carbonyl group in the unsubstituted ketone. Some evidence for minor steric interference in secondary alkyl phenyl ketones has been noted from ultraviolet studies (25), but no appreciable hindrance to coplanarity would be expected since conformations similar to those for acetophenone may be adopted. In the event there is some interference, the estimated angles of twist collected in Table X for the isobutyrophenone series will be low by a few degrees. There is no compelling evidence to suggest that steric inhibition of conjugation occurs in propiophenone, since the observed effect of the para-methoxyl group, while directionally similar to the other series, is much smaller, 0.9 p.p.m., and is not outside the limits of experimental uncertainty. No evidence from other sources which would indicate deviations from coplanarity has been found.

In summary, the ^{13}C spectral results for the present examples of alkyl phenyl ketones and methyl aryl ketones support the conclusions drawn from the previous results for the acetophenones and are in good agreement with expectations based on simple steric considerations. Although the proposed semiquantitative approach to estimates of the angles of twist in these systems may be subject to some error due to presently unrecognized effects, there is no question that the variations of the chemical shifts are qualitatively reasonable and provide a potentially useful method for investigating related systems.

^{13}C N.M.R. STUDIES

PART V.[1] CARBON-13 SPECTRA OF SOME SUBSTITUTED STYRENES[2]

K. S. DHAMI[3] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario

Received September 30, 1964

ABSTRACT

The 15.1 Mc/s ^{13}C n.m.r. spectra of 23 substituted styrenes have been examined and the shieldings of the various carbon nuclei determined. Several meta- and para-substituted derivatives were included to study the effects of polar substituents on the vinyl carbon chemical shifts. In agreement with previous proposals, a linear correlation with the Hammett σ parameter is found for the β-carbon shieldings, but not for those of the α-carbons. Nine ortho-substituted examples and two α-substituted compounds were investigated to compare their chemical shifts with results for related carbonyl compounds. While the ^{13}C data exhibit marked differences in the hindered compounds, the variations differ from those observed in the more polar carbonyl systems.

INTRODUCTION

In previous papers of this series we have presented the results of an extensive survey of organic carbonyl compounds by carbon-13 nuclear magnetic resonance (n.m.r.) spectroscopy (1, 2, 3). These investigations have revealed a number of factors which contributed to the shieldings of carbon nuclei in groups bonded to aromatic rings. To gain a fuller understanding, and to test previous interpretations (1), of the effects of polar substituents on these chemical shifts, we have chosen to study a series of substituted styrenes which will allow an examination of two unsaturated centers in a group capable of conjugative interaction with the ring. Ten monosubstituted meta- and para-derivatives were included to compare variations of the vinyl carbon shieldings with the polar character of substituents covering the range p-NMe_2 to p-NO_2. Another facet of this investigation was the examination of the chemical shift parameters for nine compounds, bearing one or two ortho-groups, and two examples with α-substituents. The analyses of these spectra were performed by methods which have been described (2). More extensive use of spin-decoupling experiments, however, was required than in the previous work, particularly to establish the location of the vinyl carbon signals with certainty for several cases.

The results for the meta- and para-substituted styrenes show that the β-carbon shieldings are sensitive to the effects of polar substituents and a linear correlation of these values is obtained with the Hammett σ parameters. These shifts also correlate with the ^{19}F shieldings for similarly substituted fluorobenzenes (4), although different slopes are found for the meta- and para-cases. While the variation in the shieldings for the α-carbon nuclei are slightly larger than the experimental uncertainty, no similar correlations were found. The ortho-substituted examples extend our studies of hindered systems and the results are qualitatively comparable to those found for the carbonyl compounds. There are significant quantitative differences, however, and estimates of the extent of steric inhibition of conjugation for these styrenes are not possible by the methods previously proposed (2, 3, 5). An approximate correlation has been found for the chemical shifts of the β-carbon nucleus in the hindered compounds with the molar extinction coefficient of

the electronic transition involving the conjugated chromophore (6, 7). In addition, these examples provide further tests of the applicability of the additive relation of substituent effects on aromatic carbon shieldings, originally noted by Lauterbur (8). Since the only previously reported study of unsaturated hydrocarbons did not include styrene (9), this paper represents the first investigation of aromatic olefins.

EXPERIMENTAL

Nuclear Magnetic Resonance Spectra

The ^{13}C spectra were obtained at 15.085 Mc/s using samples which contained carbon-13 in natural abundance. The detailed procedure employed in this study has been described (2).

Materials

Most of the substituted styrenes were obtained from commercial sources as listed in the following: Matheson, Coleman and Bell, styrene and α-methylstyrene; Aldrich Chemical Co. Inc., the 4-methyl-, 3-nitro-, 2,4-dimethyl-, 2,5-dimethyl-, 2,6-dimethyl-, 2,4,6-trimethyl-, and 2,3,5,6-tetramethyl-derivatives; Columbia Organic Chemicals, 2-bromo-, 3-bromo-, 4-bromo-, 2-chloro-, 3-chloro-, 4-chloro-, 2-methyl-, and 3-methyl-derivatives. A sample of 3,4-dichlorostyrene was kindly provided by Prof. K. Yates. The remaining examples included in this investigation, one of which is a new compound, were prepared by well-known methods. The physical constants (uncorrected) and the syntheses employed for these materials are outlined in Table I together with their reported physical data and the analytical results for 2,4,6-triisopropylstyrene. The microanalysis was performed by Alfred Bernhardt and Associates, Mulheim, Germany. Infrared and proton spectra were determined for each sample before its ^{13}C spectrum was obtained as a check of the purity. The ultraviolet spectra for a few examples were determined to measure their molar extinction coefficients. These were obtained with a Bausch and Lomb 505 spectrophotometer.

†Methods used: A-1, Grignard reaction of MeMgI + ArCHO, spontaneous dehydration of carbinol (10). A-2, Grignard reaction of MeMgI + ArCHO, followed by dehydration on $KHSO_4$ (14). B, dehydration of carbinol on $KHSO_4$ (14). C, from ϕCH_2CH_2Br, following the method of Strassbourg, Gregg, and Walling (10). D, from $CH_3CH_2CH(\phi)COOH$ by reduction followed by dehydration over KOH (12, 13).

RESULTS AND DISCUSSION

The observed chemical shifts for the carbon nuclei in the meta- and para-substituted styrenes are listed in Table II, while the data for the ortho-derivatives appear in Table III. For purposes of the discussion, these will be considered separately. For clarity, the various types of nuclei will be discussed under individual subheadings in the following. Finally, the evidences provided by the spectra of the ortho- and α-substituted cases for the existence of steric inhibition of conjugation of the vinyl group in the hindered systems are considered.

Meta- and Para-Substituted Styrenes

Aromatic Carbons

The assignments of chemical shifts for the aromatic nuclei in styrene shown in Table II have been made by analogy with the results for other aromatic hydrocarbons (2, 15, 16).

While the assignment for C-1 is unambiguous, the others are not unequivocal although support for the present assignment is provided by the results for the meta-substituted cases. The values for styrene indicate that the substituent effect of the vinyl group on the aromatic shieldings is very similar to that of the methyl group. At the para-position, an up-field shift of 2.5 p.p.m. relative to benzene is observed, whereas the C-1 nucleus is deshielded by 8.6 p.p.m. The comparable figures for the methyl group are +2.8 and −9.1 p.p.m., respectively, (16). Directionally the effects at the ortho- and meta-positions are opposite for these two groups but the changes are less than 1 p.p.m. and, therefore, within experimental uncertainty. According to previous results (16, 17), the observed shielding for the para-carbon indicates an increased π-electron density at this position which is due, presumably, to electron release by the vinyl group to the ring.

An examination of the aromatic shieldings for the meta-derivatives given in Table II

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

shows that bands are observed whose positions are in good agreement with calculated values assuming additivity of substituent effects at these nuclei. The latter values may be calculated from the substituent effects found for monosubstituted cases (16) and the present styrene data. In general, the differences are less than 1.5 p.p.m. with two exceptions, the C-4 and C-3 nuclei in the 3-methyl and 3-bromo derivatives, respectively. The present assignments are based on the assumption that additivity of substituent effects holds. For the para-derivatives, the situation is significantly different. In general, the observed transitions appear at positions which are up to 3.5 p.p.m. from those calculated. To compare the results for the meta- and para-substituted systems, the deviations between the observed and calculated chemical shifts are shown in Fig. 1 for the methyl, bromo, and nitro groups. The assignments indicated in Table II for the aromatic nuclei have been made by assuming a minimum difference between the calculated and observed values, since no other approach is available without resorting to the use of labelled compounds. It is possible, of course, that the deviations are even larger than these but evidence is lacking.

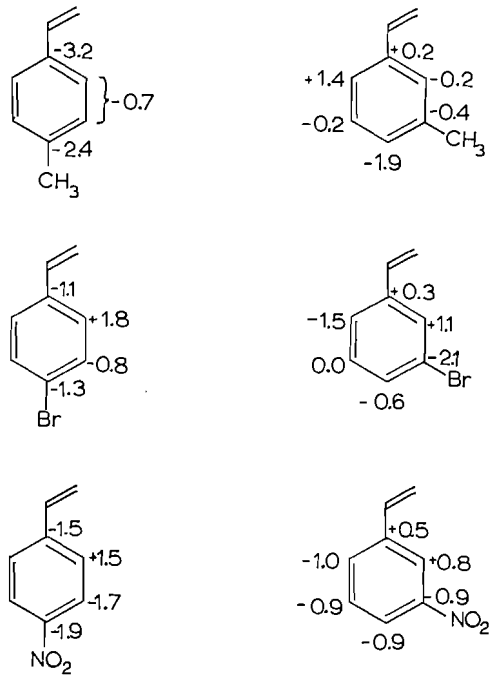

FIG. 1. Differences between the observed and calculated chemical shifts for the aromatic carbon nuclei of some meta- and para-substituted styrenes.

The fact that much better agreement is found for the meta-substituted compounds seems entirely reasonable, since conjugative interactions between the vinyl group and a meta-substituent will be minimal. In cases with significant resonance interaction between two groups on an aromatic ring, it would not be surprising to find greater deviations for the aromatic shieldings, since one or both of the substituent effects could be altered by conjugation. This situation has been discussed in general (18). In the present system, the vinyl group is capable of either electron release to, or withdrawal from, the ring depending on the influence of other polar substituents in conjugation with it. Consequently, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

substituent effects of the vinyl group at the aromatic carbon nuclei would be expected to depend strongly on the demands of para-substituents. In styrene itself, it appears that the vinyl group releases electrons to the ring, but this tendency may be reversed if an electron-releasing group is at the para-position such that the vinyl group tends to gain electrons from the ring. Support for this argument is provided by the chemical shift results for the β-carbon of the vinyl group discussed below. Since the electronic characteristics of the vinyl substituent are subject to these two extremes, it is hardly surprising that the observed values for the aromatic carbons in the para-substituted examples differ from those calculated by substantially greater amounts than the corresponding figures for the meta-systems. For each example having a para-substituent capable of electron release by resonance, the deviations at the C-4 nucleus are large, ranging up to 3.5 p.p.m. for the para-methoxyl case, and all are negative (i.e. the observed shift is at *lower* field than that calculated). This observation is consistent with the reversal of the polar tendencies of the vinyl group in these compounds relative to styrene and reflects a reduced π-electron density at this position.

Vinyl Carbons

The first investigation of ^{13}C spectra of olefins, reported by Holm (19), established that olefinic carbons absorb in the same general region as aromatic carbon nuclei. A recent detailed study of ^{13}C olefinic n.m.r. absorption (9) in aliphatic compounds has clearly defined the effects of alkyl substitution on these shieldings. Since the conjugated systems examined in the aliphatic series showed no marked differences from the corresponding non-conjugated cases, these results suggest the most probable regions of absorption for the vinyl carbons in styrene. Without exception, the bands overlap with the aromatic signals but the patterns due to spin coupling provide an essential clue for the detection of the β-carbon absorption since it is a triplet with a coupling constant in the range 161 ± 4 c/s. The α-carbon band is a doublet with a similar spacing. In most instances, the triplet is readily distinguished since it appears in the higher field portion of this spectral region and overlap with other bands was found to be less serious. The α-carbon resonances, however, present a problem in several instances, due to their appearance in a more congested region of the spectrum and the presence of other doublets with comparable coupling constants. Spin-decoupling experiments proved to be extremely valuable in aiding identifications and allowing more precise measurements of these bands. Owing to the above complications, it is necessary to note that the assignments given in Table II appear to be the most reasonable and internally consistent, but they are not unequivocal for all cases, and, lacking measurements of labelled materials, it is conceivable that a few of these figures may be interchanged with certain of the aromatic shifts, the rationale for which was discussed in the previous section. To illustrate the type of spectrum which is obtained for these compounds, that of 4-methoxystyrene is illustrated in Fig. 2 and the assignments are indicated. This case was chosen to show an example in which the β-carbon signals are not well separated and to illustrate the effect of double irradiation at the proton resonance frequency for the aromatic region (Fig. 3). The origins of the singlets in the decoupled spectrum are indicated since the two traces were obtained at slightly different sweep rates. The effect of sweep direction on the shapes of multiplets is apparent in Fig. 2 and the signal enhancement due to a nuclear Overhauser effect (20) may be seen in Fig. 3 by comparison of the intensities of the absorption due to the C-4 and α-C nuclei, for example. Both of these effects prove to be useful as aids for the analyses of these spectra.

The chemical shift values for the vinyl carbons in styrene have been found to be 57.0

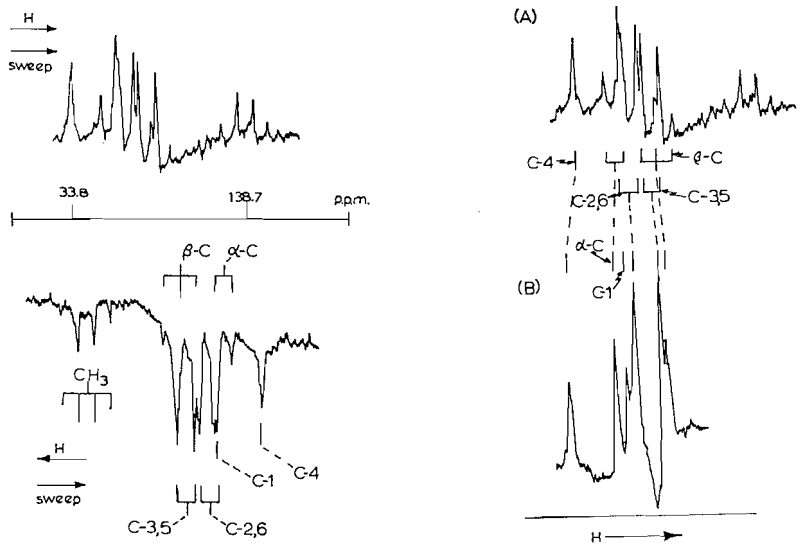

FIG. 2. 15.085 Mc/s ^{13}C spectra of para-methoxystyrene.
FIG. 3. (A) Normal 15.085 Mc/s ^{13}C spectrum of para-methoxystyrene; (B) decoupled ^{13}C spectrum of aromatic region obtained by simultaneous irradiation at the resonance frequencies of the various protons (near 60 Mc/s).

(α-C) and 80.5 (β-C) p.p.m., which may be compared to shifts of 55.2 and 79.3 p.p.m. for the C-2 and C-1 nuclei, respectively, of 1-pentene and 55.6 and 76.2 p.p.m. for C-2 and C-1 in 1,3-butadiene (9). Clearly, the aliphatic shifts are comparable with those for the aromatic system although the latter appear at slightly higher field. Any contribution from a ring-current effect in styrene, an effect which is absent in the other systems, would tend to decrease the vinyl shieldings; thus these data provide another piece of evidence indicating that ring-current effects in carbon spectra are of secondary importance.

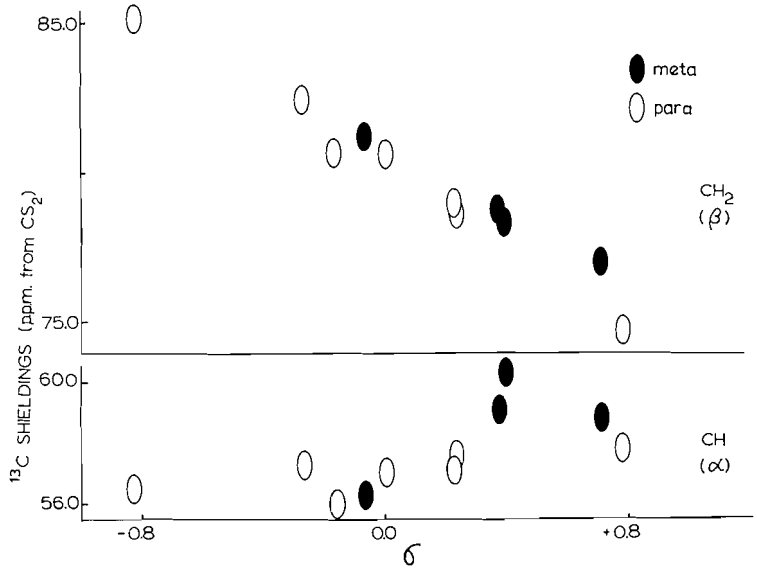

FIG. 4. Plot of vinyl ^{13}C shieldings of meta- and para-substituted styrenes vs. Hammett σ parameters.

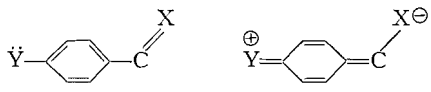
An inspection of the β-carbon shieldings for the meta- and para-substituted compounds reveals that these nuclei absorb over a total range of 10.3 p.p.m. and that the shifts appear to be dependent on the polar characteristics of the substituent groups. A reasonably linear correlation of the β-carbon chemical shifts with the Hammett σ parameters is obtained as illustrated in Fig. 4. The variation of the α-carbon shifts with the same parameters is included to show the marked difference for this nucleus. The scatter of the α-carbon shielding values is significantly larger than the experimental error of the measurements but there is no apparent trend with polarity of substituent. In fact, the total variation for the para-derivatives is just greater than the experimental uncertainty while the meta-substituted examples exhibit somewhat larger differences. Perhaps this indicates the presence of a field effect operative at the α-carbon due to groupings at the meta-position. The uniform change in the β-carbon shifts, however, fits well with our previous interpretation of the observed absence of substituent effects on carbonyl carbon shifts in acetophenones (1, 2). The explanation of the latter result was based on a consideration of the contributions to the ground state of conjugated molecules by various resonance forms. As an example, consider a conjugated molecule (I) bearing an electron-releasing group in the para-position. Resonance form II (as well as others) will contribute to the



I II

electronic distribution in the ground state. Analogous structures with reversed charges may be written for examples bearing electron-withdrawing substituents. The polarized form (II) illustrates an important difference between the α- and β-nuclei of the sidechain (i.e. C and X, respectively) in that the latter nucleus is at a terminus of the resonance system while the α-carbon is not. It appears reasonable to suggest, therefore, that the electron density changes will be most pronounced at the β-position and minimal at the α-nucleus. Our present investigation was prompted by this proposal which was used to explain the carbonyl shieldings of acetophenones, since the styrene series provides a close analogy to the carbonyl systems and permits ^{13}C studies of the β-nucleus. ^{19}F spectral studies (4, 21) on an extensive series of substituted fluorobenzenes has established the marked dependence of ^{19}F shieldings on substituent polarities. It is interesting to compare the β-carbon chemical shift values with the ^{19}F results for the corresponding fluorobenzene derivatives as illustrated in Fig. 5. The meta and para cases appear to follow different correlations. Taft (4) has shown that ^{19}F data for the two types of substituted systems require different correlation equations using the separated parameters σ_I and σ_R, and therefore, the present result is not unexpected, although difficult to explain. One surprising feature is the excellent plot obtained for the para-substituted derivatives except for the result for styrene itself. The range of values which the meta-series includes is small. The available evidence, however, indicates that the β-carbon shieldings are approximately one-third as sensitive to substituent polarity as the ^{19}F nuclei in the para-derivatives, but in the meta-compounds the β-carbon and ^{19}F nuclei respond similarly.

Other Carbons

The observed chemical shifts for the methyl carbon nuclei in the various substituents agree well with those reported previously by Lauterbur for the corresponding mono-substituted benzenes: toluene, 171.8 (15), anisole, 138.4 (4), and N,N-dimethylaniline, 152.6 p.p.m. (22). It is evident that the vinyl group exerts no significant effect on these

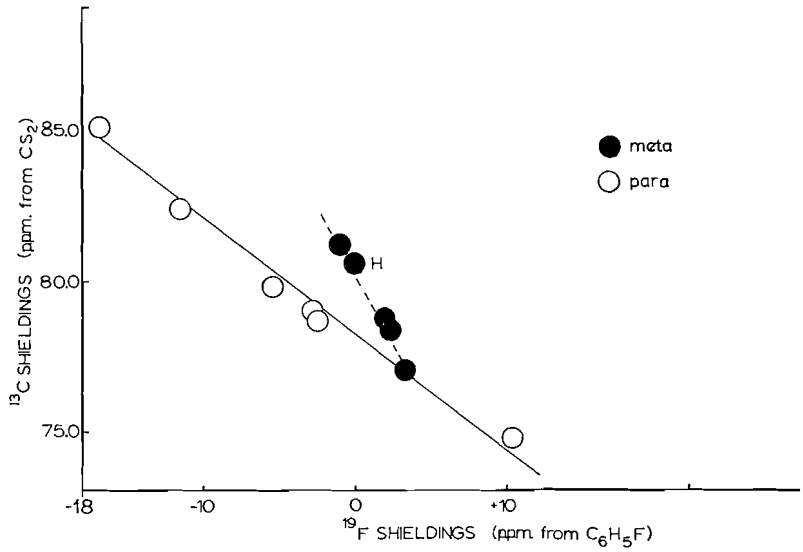


FIG. 5. Plot of β-carbon shieldings for meta- and para-substituted styrenes vs. ^{19}F shieldings of similarly substituted fluorobenzenes.

nuclei for the meta- and para-derivatives. The observed coupling constants are also similar to the earlier results (4, 15, 22).

Ortho-Substituted Styrenes

Aromatic Carbons

We have assigned the chemical shifts for the aromatic carbons as listed in Table III by again assuming an additive relation for substituent effects. Since the deviations are greater for ortho-substituted compounds in general (2, 3, 8, 15, 22, 23), there is more uncertainty in all of these cases. Qualitatively, two features are consistent with previous results for the carbonyl systems. Ortho-substitution tends to reduce the deshielding effect of the vinyl group at C-1. To show this for each example it is necessary to allow for the effects of the other substituents but, having done this, it can be seen that for most cases the observed shift is at higher field than that calculated. While the opposite effect is not found consistently for the C-4 nucleus, its absence is not particularly surprising in view of the relatively small change at this position in styrene itself relative to benzene. The second point concerns the aromatic shieldings in vinyldurene for which the "normal" deshielding effect of methyl at the substituted aromatic nuclei is absent. It is curious that the shielding at the C-1 nucleus, however, is very close to that expected if the substituent effects were additive. As in our other recent investigations, present knowledge does not permit an adequate explanation of these aromatic shieldings to be offered.

Vinyl Carbons

From the data for the first four entries in Table III, it can be seen that the α-carbon chemical shifts for the ortho-substituted styrenes show small variations with the nature of the ortho-group relative to the value for styrene itself, but no pronounced changes are found. These results are similar to those for the meta- and para-derivatives. The α-carbon shieldings for the compounds bearing two or more alkyl substituents are the same within experimental error and indicate that these nuclei are slightly shielded by the ortho-alkyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

carbons, although to a lesser extent than carbonyl or methyl carbons in corresponding environments (2, 15). The situation at the β-carbon in these compounds is distinctly different, since the signals due to these nuclei appear at lower fields than those for the β-carbon in styrene. For the 2-chloro-, 2-bromo-, and 2-methyl-derivatives the observed shieldings are reduced by 0.5–2 p.p.m. relative to the corresponding 3- and 4-substituted examples. In the diortho-substituted systems, a further reduction of ca. 5 p.p.m. is apparent. This trend is consistent with the presence of steric interference to coplanarity of the vinyl group in this series. In the alkylated cases, for example, the aromatic ring is electron-rich relative to styrene due to electron release by the alkyl substituents and, in the absence of steric inhibition of conjugation, the vinyl group would be expected to act as an electron-withdrawing substituent from the results discussed above for the meta- and para-derivatives. In this event, the β-carbon nucleus should exhibit an increased shielding with the signal shifted to higher field. In fact, the observed effect is the reverse and, therefore, would appear to indicate that there is steric inhibition of resonance in these systems. It is unfortunate that ^{13}C data are not available for lower molecular weight olefins with which the values for the hindered styrenes might be compared.

A closer examination of the trends exhibited by the β-carbon shifts of the methylated derivatives shows the following pattern. The β-carbon nucleus in 2-methylstyrene appears at 79.1 p.p.m., which is 1.4 p.p.m. to lower field from its position in styrene. The introduction of the 4-methyl group tends to increase its shielding by 1.3 p.p.m. suggesting that this substituent increases the conjugative interaction of the ring with the vinyl group, an effect that was found for the carbonyl carbon resonances in similarly substituted aromatic ketones. A second ortho-methyl group (e.g. 2,6-dimethylstyrene) shifts the β-carbon signal to 74.3 p.p.m. Further methyl substitution on the ring does not affect the observed shift, nor does this shielding differ for the 2,4,6-triisopropyl derivative. These variations of the β-carbon shieldings are similar to those observed for the carbonyl carbon in the corresponding acetophenones with two important differences. These two nuclei are in different positions relative to the aromatic ring and the carbonyl carbon in the poly-substituted cases is affected by increased substitution. The α-carbon shielding which might be expected to undergo changes similar to those exhibited by the carbonyl carbon nucleus remains essentially constant for this series. In the case of the ketones, however, the α-nucleus (carbonyl carbon) is doubly bonded to an electronegative element, oxygen, whose polarizing effect on the C=O bond will be more pronounced at the α-position for the hindered ketones since the electron supply from the ring is reduced by steric inhibition of conjugation. In the styrene system, both nuclei of the vinyl carbon have comparable electronegativities and no strong polarization of the C=C bond would result from a reduced conjugative interaction with the ring, instead, the shielding at the β-carbon would be decreased relative to the unhindered systems since the conjugative electron release by the ring to the vinyl group is less efficient. We suggest, therefore, that the nature of the double bond in conjugation with the aromatic system is the major controlling factor for determining the shieldings at these side-chain nuclei in the hindered systems and is responsible for the observed differences between the carbonyl and olefinic systems.

Correlations of the shieldings of the β-carbon vinylic grouping with other physical properties would be expected if the above interpretations are valid. In particular, the intensities of the electronic transitions for the fully conjugated chromophores are believed to reflect the extent of steric inhibition of resonance in hindered systems such as these (6, 7, 24). While only limited data are available, an approximate correlation between these two parameters is found as illustrated in Table IV. There is a marked decrease in the

TABLE IV

Comparison of β-^{13}C shielding and ultraviolet data for some substituted styrenes

Substitution	$\delta_c^{\beta-C}$ (p.p.m.)	ϵ_{max}	Estimated angle of twist* (°)	
Nil	80.6	15 600	0	0
2-CH_3	79.1	12 000	28	31
2,6-$(CH_3)_2$	74.3	5 400	—	54
2,4,6-$(CH_3)_3$	74.7	7 000	54	49
2,3,5,6-$(CH_3)_4$	74.2	4 000	—	—
2,4,6-(*i*-Pr)$_3$	74.6	5 800	—	—

*First column from ref. 6, second column, ref. 24.

extinction coefficients with increased ortho-substitution which roughly parallels the change in β-carbon chemical shifts, although the ϵ_{max} values vary somewhat for the various diortho-substituted derivatives. All of the latter variation may not be real due to the difficulty in locating and measuring the appropriate ultraviolet band precisely. A few of the intensity figures were not available in the literature and were determined for this comparison. The ultraviolet spectral data have been utilized by others to calculate the angles of twist for sterically hindered systems (6, 24) and these estimates are included in Table IV. Lacking the figures for suitable model compounds, we hesitate to perform a similar analysis of the ^{13}C data. Qualitatively, however, the observed ^{13}C shifts provide strong evidence of steric inhibition of conjugation of the vinyl group.

Other Carbons

The chemical shifts for the carbon nuclei of the substituent groups are found to correspond well with those observed for the corresponding substituted acetophenones (2). The carbons bonded directly to the ring and ortho to the vinyl group tend to absorb at slightly higher field than those in less hindered positions. The most striking example of this feature is provided by vinyldurene for which two methyl groups appear at 177.3 p.p.m. and these signals have been assigned to the 2- and 6-groups, for reasons discussed previously (2).

α-Substituted Styrenes

Aromatic Carbons

The effects of the isopropenyl and 2-butenyl groups on the aromatic shieldings are found to be closely similar to those exhibited by the vinyl group (last two entries in Table III). The major difference is a greater decrease in shielding at the substituted carbon (C-1) which is found to be 13 p.p.m. for these two groups compared to the −8.6 p.p.m. decrease caused by the vinyl substituent. Apart from this change, the effects at the other aromatic nuclei are the same within experimental error.

Vinyl Carbons

The shielding effects at the olefinic carbon nuclei by methyl substitution on double bonds have been established by Friedel and Retcofsky (9) for aliphatic systems. In general, the changes are opposite at the two centers with the signal for the substituted nucleus moving to lower field and the β-carbon absorption to higher. Qualitatively, the vinyl carbon shifts for 2-methylstyrene undergo similar changes. The closest model system included in the aliphatic series, is that of 1,3-butadiene and 2,3-dimethyl-1,3-butadiene for which the shift of the internal olefinic carbon (C-2 and C-3) change by −5.2 p.p.m. and the terminal nuclei (C-1 and C-4) are shielded by +5.0 p.p.m. by methyl substitution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(9). For α-methylstyrene relative to styrene, the corresponding changes are −6.4 and +0.8 p.p.m. Introduction of the ethyl group instead of methyl was found to cause changes of -6.5 ± 1.3 and $+1.1 \pm 1.1$ p.p.m. for the substituted and β-carbon nuclei, respectively, relative to the shifts in the methyl derivative, in some aliphatic olefinic systems (9). Although none of these are closely related to the present cases, the observed changes for α-ethylstyrene are remarkably close to these values, −6.9 and +1.5 p.p.m., respectively. The two α-substituted styrenes, therefore, are additional examples showing the same general variations as aliphatic olefins.

The most interesting feature of these observations is the very much reduced shielding at the β-carbon caused by α-methyl substitution. A possible explanation of this could invoke steric inhibition of conjugation such that there is a reduced effect of the aromatic ring at this center. Suzuki has concluded this to be the case from the ultraviolet spectra and has estimated the angle of twist to be 33°(24). Our study of the ^{13}C results for this system, however, is not nearly extensive enough to corroborate or refute his conclusion.

ACKNOWLEDGMENTS

We thank the donors of the Petroleum Research Fund, administered by the American Chemical Society, for generous support of this investigation through the provision of operating funds and the Ontario Research Foundation for a grant to purchase the 15.1 Mc/s oscillator unit.

ESSENTIAL OILS AND THEIR CONSTITUENTS

XXVII.[1] COMPOSITION OF OIL OF GINGERGRASS

M. C. NIGAM,[2] ISHWAR C. NIGAM, AND LEO LEVI
Pharmaceutical Chemistry Division, Food and Drug Directorate, Ottawa, Canada

Received September 2, 1964

ABSTRACT

Oil of gingergrass was found to contain the following as yet unreported constituents: *trans-p*-menthene-8-diol-1,2; *cis*- and *trans*-carveol; *cis*- and *trans*-dihydrocarvone; piperitenone and limonene oxide. The presence of an aromatic compound for which gas chromatographic and infrared criteria of identity were determined was also demonstrated. Limonene oxide is probably the most important precursor of these and related monoterpenoids of the essential oil.

INTRODUCTION

Oil of gingergrass (*Cymbopogon martini* Stapf var. *sofia*) has been the subject of a number of chemical investigations (1, 2, 3). These established the presence of the following constituents: limonene, dipentene, α-phellandrene, perillyl alcohol, carvone, and geraniol. Recently Naves and Grampoloff, studying a genuine sample of Indian origin, established the occurrence of four alcohols: *cis*- and *trans-p*-menthadiene-2,8-ol-1, *cis-p*-menthadiene-1(7),8-ol-2, and isopiperitenol. They did not detect the presence of geraniol (4, 5). Swaleh, Bhushan, and Sidhu confirmed subsequently the occurrence of several compounds already reported (6). The present investigation was undertaken to identify hitherto unknown constituents, establish the presence or absence of geraniol and reflect on the biogenesis of some of the components of the essential oil.

EXPERIMENTAL

Column Chromatography of the Essential Oil

An authentic sample (2 g) was chromatographed over alumina (Woelm Grade I; 40 g) using as eluants petroleum ether (b.p. 40–60 °C), benzene, ether, and methanol. Effluents (50 ml) were collected and elutions continued until evaporation of fractions left no residue. Following removal of solvent each fraction was examined by gas chromatography. Recoveries are shown in Table I.

TABLE I

Column chromatography of oil of gingergrass

Fraction No.	Eluant	Volume of eluant (ml)	Weight of fraction (%)
A	Hexane	200	13.5
B	Benzene	200	3.0
C	Ether	50	37.5
D	Ether	150	42.0
	Methanol	100	
		(Recovery	96.0%)

Rechromatography of Fraction D

Fraction D (0.84 g) was chromatographed over neutral grade II alumina (40 g). Ether was used as eluant and subfractions were recovered by evaporating 10 ml portions of effluents collected. Product yields are shown in Table II.

[1]*Paper XXVI: J. Org. Chem. (In press.)*

TABLE II

Rechromatography of fraction D

Fraction No.	Weight of fraction (g)	Essential oil (%)
D-1	0.19	9.5
D-2	0.22	11.0
D-3	0.18	9.0
D-4	0.13	6.5
D-5	0.08	4.0
D-6	0.02	2.0

Gas Chromatography of Essential Oil and Isolated Fractions

Apparatus and general procedures have been described (7). Reoplex 400 (20%) deposited on Chromosorb W (acid washed; 60–80 mesh size) was used as column packing. Analyses were carried out at the following column temperatures: fraction A: 110 °C; fractions B, C, and D-1 to D-4: 170 °C; fractions D-5, D-6, and the essential oil: 200 °C.

Identification and Determination of Constituents

Constituents were identified by the serial dilution technique and comparison of infrared spectra of effluents (deposited directly on a salt plate (8) or collected in carbon tetrachloride and purified by rechromatography) with those of pure reference standards or published data. Quantitative estimations were carried out by the sigma method (9, 10).

Isomerization of Limonene Oxide to Terpenoids Present in Oil of Gingergrass

Limonene oxide (180 mg) and pyridinium bromide were refluxed for 1 h with 3 ml of pyridine. The reaction mixture was cooled, diluted with excess of ether, and filtered. Following evaporation of the filtrate 125 mg of material was recovered and analyzed by gas chromatography. Effluents corresponding to main peaks and shoulders were collected in carbon tetrachloride following repeated sample injections, the fractions repurified by chromatography, and constituents identified on the basis of gas chromatographic and infrared spectral data.

RESULTS AND DISCUSSION

The gas chromatogram of the essential oil is reproduced in Fig. 1A. It is more complex than one would expect on the basis of existing compositional data. The presence of compounds already reported was confirmed and some constituents giving rise to distinct peaks and shoulders were identified for the first time.

Constituents

Limonene.—This terpene was identified as the only constituent of fraction A.

cis- and trans-Dihydrocarvone, carvone, and piperitenone.—These ketones were found to be present in fraction B.

Isopiperitenol and cis-p-Menthadiene-1(7),8-ol-2.—These two alcohols made up fraction C. They were also present in sub-fractions D-1 to D-4. Small quantities of isopiperitenol were also found to occur in fraction B.

trans-p-Menthadiene-2,8-ol-1, cis- and trans-carveol, and perillyl alcohol.—These compounds were present in varying proportions in sub-fractions D-1 to D-4.

trans-p-Menthene-8-diol-1,2.—This glycol formed the chief constituent of sub-fraction D-5 and was also present in sub-fraction D-6.

Aromatic compound.—Sub-fraction D-6 contained, in addition to the glycol, an aromatic compound, displaying characteristic infrared absorptions at 3 420, 1 680, 1 615, 1 508, 1 095, 968, 930, 910, and 895 cm^{-1}.

Limonene oxide.—A small peak (relative retention time 0.72; reference, isopiperitenol) (see Fig. 1A) was identified as limonene oxide by the serial dilution technique. The terpenoid (2.1% of the oil) could, however, not be recovered in any chromatographic fraction which observation suggested its decomposition during column chromatography on active alumina.

For personal use only.

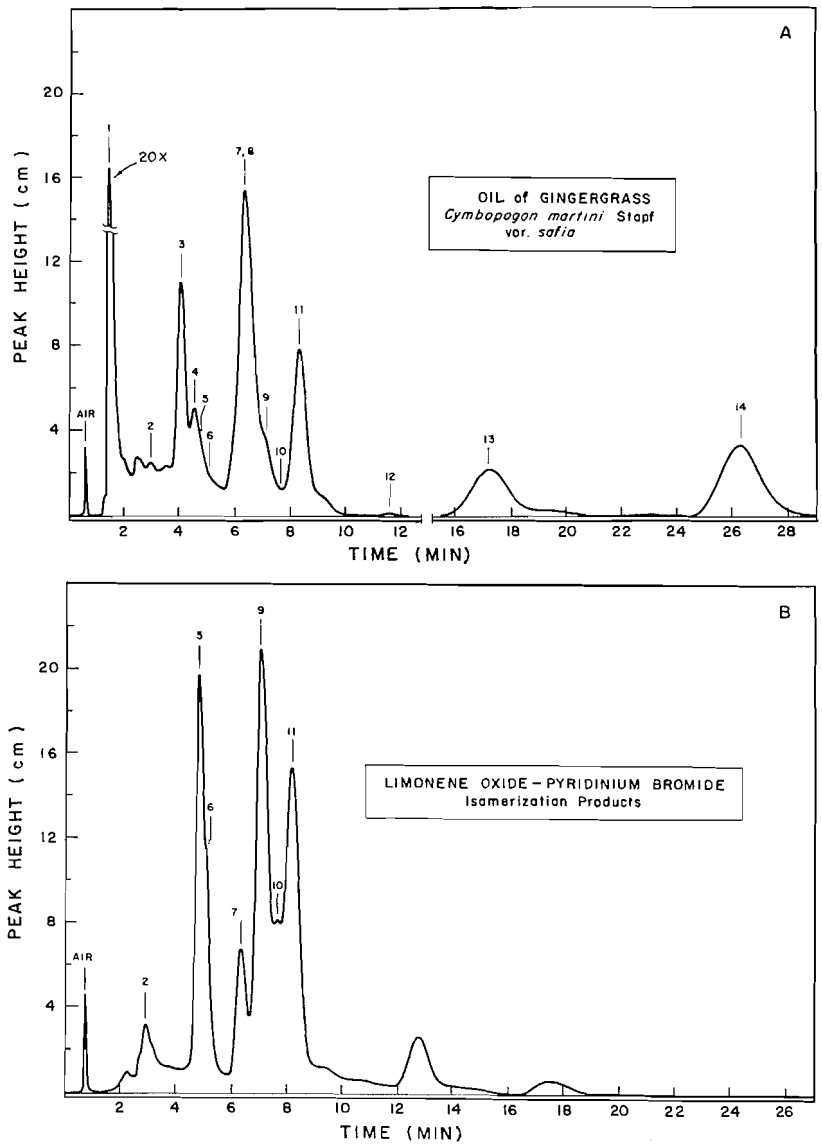

FIG. 1. Gas chromatograms: A, oil of gingergrass; B, limonene oxide–pyridinium bromide isomerization products. Column temperature, 200 °C; helium, 75 ml/min.

Geraniol.—The presence of geraniol in oil of gingergrass reported by earlier workers was questioned by Naves and Grampoloff (4, 5), who showed that the alcohol does not occur in the essential oil at concentration greater than 0.25%. Using preparative gas and thin layer chromatography, the present authors failed to detect even minute traces ($< 0.001\%$) of the alcohol in the essential oil. Evidently, genuine gingergrass oil does not contain geraniol. Quite likely the occurrence of small amounts of the alcohol in the essential oil is due to contamination with trace amounts of palmarosa oil which admixture may occur if plants are not raised or harvested under expert supervision (11).

For personal use only.

Composition of Essential Oil

Quantitative results were obtained by correlation of gas chromatographic data assembled for the various fractions isolated. They are shown in Table III.

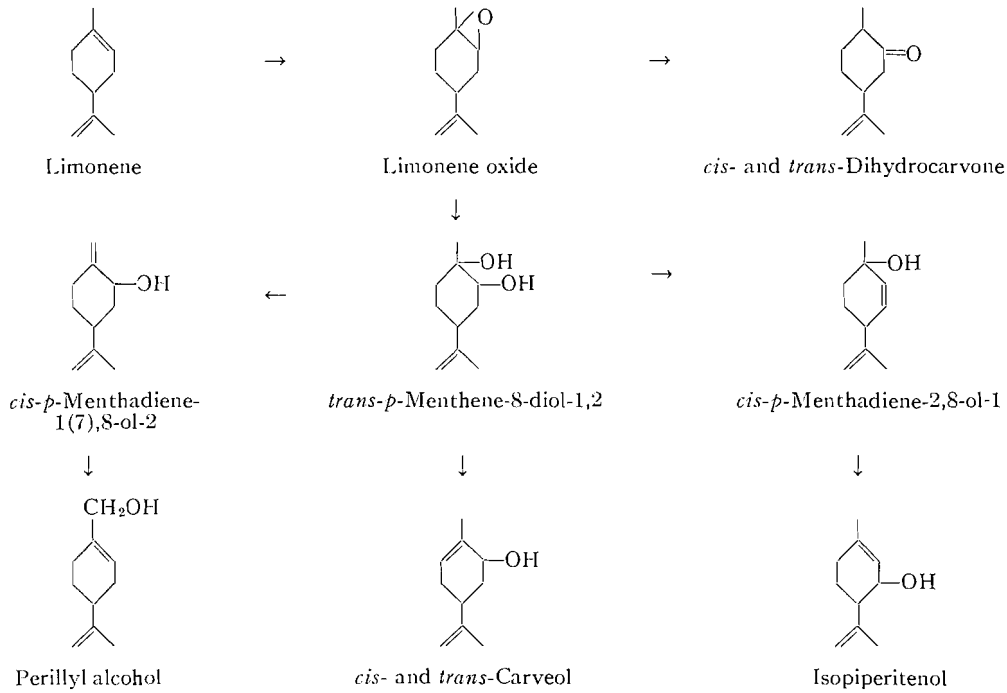

FIG. 2. Biogenetic relationships of monoterpenoids derived from limonene oxide.

TABLE III

Composition of gingergrass oil

Peak No.	Constituent	Relative retention time	% (w/w)
1	Limonene	0.36	13.5
2	Limonene oxide	0.72	2.1
3	Isopiperitenol	1.00	13.4
4	*trans*-*p*-Menthadiene-2,8-ol-1	1.12	8.6
5	*trans*-Dihydrocarvone	1.18	0.3*
6	*cis*-Dihydrocarvone	1.28	
7	*cis*-*p*-Menthadiene-1(7),8-ol-2	1.53	31.1
8	Carvone	1.65	1.1
9	*trans*-Carveol	1.71	2.7*
10	*cis*-Carveol	1.90	
11	Perillyl alcohol	2.05	15.0
12	Piperitenone	2.81	0.1
13	Aromatic compound	4.23	0.6
14	*trans*-*p*-Menthene-8-diol-1,2	6.46	2.4
	Unidentified		9.1

*These pairs of isomers were not sufficiently resolved by column and gas chromatography to permit quantitative measurements of either component.

Biogenetic Significance of Analytical Data

Epoxy compounds of mono- and sesqui-terpenes occur in many essential oils (12) and they have been considered as precursors of related constituents. Oil of gingergrass is of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

particular interest in this regard since it was shown to contain limonene oxide as well as a number of structurally closely related monoterpenes. Biogenetic transformations of the epoxide to other constituents may take place in accordance with the scheme of rearrangements outlined in Fig. 2. The ease with which such transformations can be brought about was demonstrated by the authors who succeeded in synthesizing a mixture containing most of these compounds by merely refluxing the epoxide with pyridinium bromide. The resulting product was found to be composed of *cis*- and *trans*-dihydrocarvone, *cis*-*p*-menthadiene-1(7),8-ol-2, *cis*- and *trans*-carveol as well as perillyl alcohol, as shown in Fig. 1B.

ACKNOWLEDGMENTS

The authors are indebted to Excel Traders, Bombay, Sri. G. N. Gupta, H. B. Technological Institute, Kanpur, Manaunlal Ram Narain, Kannauj, and Dr. M. Swaleh, Regional Research Laboratory, Hyderabad, India, for courteously supplying authentic samples of oil of gingergrass for this study.

NOTES

REARRANGEMENT STUDIES WITH ^{14}C. XXII. SOLVOLYSES OF 1-^{14}C-ETHYL *p*-TOLUENESULFONATE

C. C. Lee and Moira K. Frost

Roberts and Yancey (1) have reported that the nitrous acid deamination of 1-^{14}C-ethylamine gave rise to 1.5% 2-^{14}C-ethanol resulting from 1,2-hydride shift. This finding has been confirmed by Sixma and Hendriks (2). It is of interest to ascertain whether any analogous 1,2-shift would take place in solvolytic reactions with 1-^{14}C-ethyl *p*-toluenesulfonate (I). Solvolysis of I was carried out in 75% dioxane – 25% water (by volume), glacial acetic acid, or anhydrous formic acid. The ethanol produced from the reaction in aqueous dioxane, or obtained after hydrolysis of the ethyl acetate or formate from acetolysis or formolysis, was degraded to iodoform. The activity in the iodoform would be a measure of the extent of rearrangement of the ^{14}C-label from the C-1 to the C-2 positions of the ethyl group. The results, summarized in Table I, show that there were no significant amounts of ^{14}C-rearrangement, indicating the absence of 1,2-hydride shift, in any of the solvolyses studied. These results are consistent with the expectation that such solvolyses with the primary ethyl system likely proceed by a direct displacement or an S_N2 mechanism. The present findings are also in agreement with the conclusion of Winstein and Marshall (3), arrived at from kinetic studies, that solvolysis of ethyl *p*-toluenesulfonate is not close to "limiting" in type.

TABLE I

Data from solvolyses of 1-^{14}C-ethyl *p*-toluenesulfonate

	Specific activity (c.p.m./mmole) × 10^{-3}					
	C_2H_5OTs		CHI_3		% rearrangement	
Solvent	Run 1	Run 2	Run 1	Run 2	Run 1	Run 2
None (blank degradation)	300	830	0.2	0.2	0.07	0.02
Dioxane–water	300	830	0.3	0.3	0.1	0.04
Acetic acid	300	830	0.3	0.4	0.1	0.05
Formic acid	300	830	0.4	0.6	0.1	0.07

EXPERIMENTAL

1-^{14}C-Ethyl *p*-toluenesulfonate (I), m.p. 32 °C (lit. (4) m.p. 32 °C), was prepared from 1-^{14}C-ethanol* by treatment with *p*-toluenesulfonyl chloride in pyridine (4).

A solution of 10 g (0.05 mole) of I in 20 ml of 75% dioxane – 25% water, glacial acetic acid, or anhydrous formic acid was heated under reflux for 24 h. For the reaction in aqueous dioxane, an ethanol–water solution was distilled directly from the reaction mixture, 6–7 ml of distillate being collected. For acetolysis and formolysis, the reaction mixture was cooled in an ice bath, 50 ml of water added, and the solution neutralized with solid sodium carbonate. The product was recovered by continuous extraction with alcohol-free ether for 48 h. After the extract was dried over magnesium sulfate and the ether removed, the residual ester was hydrolyzed directly by heating over a steam bath for 2 h with 10 ml of 20% sodium hydroxide solution. The ethanol produced, together with water, was distilled from the hydrolysate, 6–7 ml of distillate being collected. In preliminary trials, the yields of ethyl acetate or formate were found to be in the order of 50%.

**Purchased from New England Nuclear Corp.*

The aqueous ethanol obtained from each solvolysis run was degraded to give iodoform according to a procedure previously described (5).

The activities of I and of iodoform were measured using a liquid scintillation counter. Samples weighing about 10 mg dissolved in 20 ml of toluene were counted. The iodoform solutions caused considerable quenching and correction factors were determined with ^{14}C-toluene as internal standard. The actual observed activities, together with background, of all the iodoform samples recorded in Table I were less than twice background.

THE IONIZATION BEHAVIOR OF AMIDES IN CONCENTRATED SULFURIC ACIDS

II. APPLICATIONS OF THE H_A FUNCTION TO RATES AND EQUILIBRIA

KEITH YATES AND JOAN B. STEVENS

Department of Chemistry, University of Toronto, Toronto, Ontario

Received October 16, 1964

ABSTRACT

The newly determined H_A scale of acidity has been tested against ionization ratio data for 33 amides. Twenty-nine of these compounds give log I vs. H_A slopes of 0.9–1.1 and most are within 0.95–1.05. The average slope for these is 1.001 ± 0.051. The H_A function is thus considered to be generally applicable to the ionization of this type of base, and the significance of previously reported amide pK values is discussed in the light of these results. Previously reported basicity – substituent constant relations have been reexamined using thermodynamically significant pK data and earlier conclusions confirmed. Appropriate equations are derived in an attempt to explain the rate–acidity dependence of amide hydrolysis directly in terms of the water activity of the reaction medium. The picture of the hydrolysis transition state which results is in accord with that obtained using methods described by other workers.

INTRODUCTION

In Part I of this series (1) values of a new acidity function H_A were reported. This scale was based on a set of structurally related amide indicators. The usefulness of such a scale depends on the extent to which it can be applied to the ionization of other bases, therefore any tests of ionization behavior with respect to the H_A scale are important. Although it is not expected that the applicability of the H_A function will be any wider than is that of the H_0 function (2) for example, it is important for any such function that it be obeyed at least by bases of similar structural type to those used to establish the scale. Only in this way can the function be expected to yield quantitative information about base strengths. In the present paper we wish to report the results of such tests of the H_A scale using all presently available data on the ionization of amides in sulfuric acid.

Two of the principal uses of the acidity function approach have been in the study of structure–reactivity relations and rate–acidity correlations. We have therefore reexamined such relations involving amide protonation and hydrolysis in the light of information provided by the new amide acidity scale.

EXPERIMENTAL

Measurement of Ionization Ratios

Ionization ratios ($I = [BH^+]/[B]$) for the following amides were obtained spectrophotometrically as described previously (1): *p*-bromobenzamide, *p*-toluamide, 4-bromo-3-nitrobenzamide, 3,5-dinitrobenzamide, and 3-hydroxyphenylurea. These were all commercially available compounds which were recrystallized to constant melting point before use.

Calculation of pK Values and Indicator Slopes

All pK values and slopes of log I versus H_A plots were obtained by the standard least mean squares treatment. Only values of log I in the range ± 1.0 were selected since the experimental uncertainty in this quantity increases very rapidly outside this range (3). At least 6 and up to 20 experimental points were used to calculate each pK value and indicator slope. Values of log I were measured in the present work or taken directly from the literature, or, where the log I values were not actually reported, they were supplied by the authors. We are very grateful to Professors R. Stewart and J. T. Edward and Dr. R. B. Moodie for access to unpublished material. The log I versus H_A plots showed good linearity in most cases, correlation coefficients in the range 0.980–0.999 being obtained. In one case only, that of N,N-dimethyl-*p*-phenylbenzamide, were the points too widely scattered ($r = 0.925$) to allow estimates of pK and the slope to be made. In cases where the necessary log I data was not available, estimates of pK were made by converting the reported pK values (based on the H_0 scale) to values based on the new H_A scale by simple interpolation.

RESULTS AND DISCUSSION

The Generality of the H_A Scale and Significance of Derived pK Values

The basicities of a large number of amides have been measured previously. These were based on spectrophotometric determination of ionization ratios ($I = [BH^+]/[B]$) and plots of log I against the Hammett acidity function H_0. However, as Arnett (4) has pointed out, unless the base in question can be demonstrated to adhere to the H_0 function in its ionization behavior, any pK value so derived has no thermodynamic significance. Such pK values are simply equal numerically to the H_0 value of the acid in which they are half protonated and are not true equilibrium constants. That amides as a class do not follow H_0 even approximately has been shown previously (5) by the fact that slopes of log I vs. H_0 plots for amides are far from unity, as required by the defining equation for H_0.

$$H_0 = pK_{BH^+} - \log I = -\log a_{H^+} f_B / f_{BH^+}.$$

The H_0 slopes for a large number of amides for which data is available are in the range 0.4–0.8 (5, 6). Thus all previously reported pK values for amides cannot be considered as valid thermodynamic equilibrium constants.

In order to investigate the possibility of obtaining amide pK values of thermodynamic significance and at the same time to test the validity of the recently determined H_A scale of acidity, we have plotted log I versus H_A using all the data presently available on the ionization of this type of base. The H_A function is defined in an analogous way to H_0, except that A and AH^+ refer to an amide and its conjugate acid,

$$\begin{aligned} H_A &= pK_{AH^+} - \log [AH^+]/[A] \\ &= pK_{AH^+} - \log I = -\log a_{H^+} f_A / f_{AH^+}, \end{aligned}$$

where $K_{AH^+} = a_{H^+} a_A / a_{AH^+}$ is the thermodynamic dissociation constant of the conjugate acid. Values of this function were based on a set of eight primary amide indicators, using the standard stepwise technique (2). It is therefore of importance to investigate the adherence of other amides to this function to determine how adequately it represents the ionization behavior of amides in general. We have obtained slopes of log I versus H_A for 25 amides which were not used as indicators in establishing the scale. These slopes are listed in Table I. It can be seen that they are generally close to unity, as required by the defining equation for H_A. Excluding for now four widely deviating cases, the slope values are all in the range 0.9–1.1. If one includes the 8 amides used as H_A indicators, which naturally have slopes close to unity, 29 out of 33 amides listed have slopes within this range and most are in the range 0.95–1.05. The average value for these 29 bases is 1.001 with a standard deviation of ± 0.051. Thus the H_A function appears to be quite generally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

applicable to the ionization of amide type bases. A similar test of the behavior of aniline type bases with respect to H_0 has not been carried out. However, if the 10 new aniline indicators used in the recent re-investigation of the H_0 scale (7) are subjected to the same treatment, it is found that their log I vs. H_0 slopes are in the range 0.94–1.06, with a mean value and standard deviation of 0.995 $\pm$ 0.040. Since these anilines were actually used as indicators in determining H_0, the comparable degree of agreement of the large majority of the amides with respect to H_A is very satisfactory evidence that this function represents the ionization behavior of aromatic amides as well as H_0 represents that of anilines.

Taking a log I – acidity function slope of 0.95–1.05 as a reasonable criterion of whether a particular base is following that particular function, we can assess the quantitative significance of the pK values listed in Table I. These fall into several groups. Those listed for compounds having log I vs. H_A slopes within the above range can be considered to be valid thermodynamic pK values based on dilute aqueous solution as standard state, within the usual limits of experimental uncertainty. In a few cases where the slopes are outside this range, but still fairly close to unity (0.9–1.1), the pK values have less significance but can be taken as approximate pK values. Those for which no slope is given may be valid pK's, but this remains to be demonstrated. In the cases where the slope deviates widely from unity, the pK value has no thermodynamic significance and only corresponds numerically to the H_A value of the acid in which the base is half protonated.

Although the criterion of unit slope is a necessary condition for a derived pK value to be taken as a valid equilibrium constant, Arnett (4) has pointed out that this is not always in itself a sufficient condition. The possibility cannot be ruled out that a given base may exhibit anomalous activity coefficient behavior in an acid region where ionization ratios are too small to be experimentally accessible. This has been observed for at least two supposedly Hammett type bases, with the result that although their indicator curves have unit slope, the pK values are not referred to the same standard state as the H_0 scale, and hence are not true pK values. We are at present investigating the activity coefficient behavior of typical amides and have not yet observed any similar cases of anomalous solubility increase. Thus in the absence of evidence to the contrary, we are assuming that the criterion of unit slope is a satisfactory one.

The only amides so far investigated which do not follow H_A very closely are propionamide (0.70), *p*-nitrobenzamide (0.75), *o*-toluamide (0.81), and N,N-dimethyl-2-naphthamide (0.77). The deviation of propionamide is perhaps not surprising since this is an aliphatic compound and it is now evident that Hammett-type acidity functions can be quite sensitive to large changes in base structure. The anomalous behavior of *p*-nitrobenzamide is probably attributable to uncertainty in the spectrophotometric determination of ionization ratios. The ultraviolet absorption characteristics of this compound are not very suitable for obtaining precise log I data, since both forms of the amide absorb at almost the same wavelength and the increase in absorption on protonation is not very large. The reason for the deviation of *o*-toluamide is less easy to account for. It is difficult to see how the steric effect of an *o*-methyl group on solvation of the amide group could produce this effect, since both 2,6-dimethylbenzamide (0.95) and 2,4,6-trimethylbenzamide (0.92) do not show similar large deviations. We are unable to explain this at present. In view of a recent study of the non-Hammett-type behavior of N,N-disubstituted anilines (8), it might be expected that alkyl substitution on the amide nitrogen would produce similar large deviations from an acidity function based on primary amides. However, of the seven secondary and tertiary amides in Table I for which indicator ratio

slopes are available, only one deviates widely from unity. This provides a further indication (1) that hydration of the protonated carbonyl oxygen of the amide group is much more important that hydration of the $—NH_2$ group. It is interesting that the four secondary amides in Table I have indicator slopes somewhat greater than unity (1.02–1.11), whereas the three tertiary amides show less than unit slope (0.77–0.90). Considering

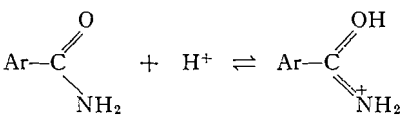
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the number of acidic protons available for hydrogen bonding to solvent molecules, and making the usual assumption that hydration of the conjugate acid forms is more important than that of the neutral bases, it would be predicted that f_{AH^+}/f_A would rise most rapidly with acid strength (i.e. diminishing water activity) for primary, less rapidly for secondary, and least rapidly for tertiary amides. Thus the rate of change of log $[AH^+]/[A]$ with acidity would be in the order tertiary > secondary > primary. Plots of log I against H_A should therefore give greater than unit slopes for both secondary and tertiary amides with the latter having the highest slopes. It can be seen from Table I that the secondary amides behave as predicted but the tertiary amides do not. Although the data on N-substituted amides is somewhat limited, it is again evident that differences in activity coefficient behavior cannot be explained solely in terms of the *number* of acidic protons available for hydration, even in a qualitative way. A similar conclusion has been reached by Moodie (9) on the basis of the water activity dependence of ionization ratios.

In conclusion, the results of the above tests show that aromatic amides follow the H_A function remarkably well in view of the large differences in structure of some of the bases investigated. This agreement is probably due in part to the fact that the H_A function is not based too heavily on polynitro-substituted indicators. This is a consequence of the inherently weaker basicity of amides when compared with anilines. However, there are indications that aliphatic amides do not follow H_A with anything like the same precision, but further work is needed to test this.

Linear Free Energy Relations

A good linear correlation between Hammett σ-values and pK values of *m*- and *p*-substituted benzamides was reported previously (10). Since this was better than the correlation between σ^+ and pK, it was taken as evidence of a lack of conjugation between the protonated carboxamide group and phenyl ring. However, as pointed out in the previous section, the pK values used were not true equilibrium constants, and this conclusion might not be valid. We have therefore re-investigated these relations using the pK values in Table I. Using only the pK data for which the log I vs. H_A slope is 1.00 ± 0.05, a fairly good linear relation ($r = 0.978$) between pK and σ still holds. The corresponding plot of pK versus σ^+ shows poor linearity ($r = 0.896$) and further, all seven points for *p*-substituted benzamides deviate in the same direction from a line drawn through the points for non-conjugating substituents. This confirms the earlier conclusion. Several suggestions have been advanced (6, 10) to explain this lack of conjugation in amides but as yet there is no evidence to indicate which, if any, is correct. From the above pK–σ relation, the correct Hammett ρ-value for the equilibrium is -0.92, which is appreciably lower than previously reported. This is a more reasonable value for an



ionization in which unit positive charge is developed and essentially localized at a distance of two atoms from the phenyl ring (11).

It was suggested in Part I of this series that the last indicator of the H_A set might not be too reliable due to the small spectral changes produced by protonation. The pK of this base, 2,4,6-trinitrobenzamide, was found experimentally to be -4.08. Using the above linear free energy relation, one can estimate roughly the effect of three nitro groups on the basicity of benzamide. Assuming additivity of substituent effects and that

o-nitro has a similar electronic effect to *p*-nitro, the equation $\log K/K_0 = \rho\sum\sigma$ yields a rough pK value of -3.9 for 2,4,6-trinitrobenzamide, which is in good agreement with the experimental value.

Rate–Acidity Correlations

Bunnett (12) has shown for a large number of reactions in moderately concentrated acids that the following relation between the rate constant, acidity, and water activity is generally obeyed,

$$\log k + H_0 = w \log a_{H_2O} + \text{constant}.$$

The values of w obtained can be used to classify reactions according to mechanism. Although this relation is empirical, Bunnett (13) has also shown that by considering hydration of all species involved, these w-parameters can be related to the change in hydration in going from reactants to transition state. However, this hydration treatment involves the extreme assumption that activity coefficient ratios* for species of like charge are medium independent. This assumption results in cancellation of a term $f_{S(H_2O)_s} f_{BH(H_2O)_c^+}/f_{B(H_2O)_b} f_{\ddagger(H_2O)_t^+}$ (Bunnett's notation (13)) which appears in the rate expression derived on the basis of transition state theory. In this activity coefficient ratio S and ‡ refer to a wide variety of substrates and their transition states and B and BH^+ refer to the Hammett indicators used to measure the acidity of the reaction medium. For substrates such as amides, whose ionization behavior does not follow H_0, the similar ratio $f_{S(H_2O)_s} f_{BH(H_2O)_c^+}/f_{B(H_2O)_b} f_{SH(H_2O)_p^+}$ is clearly strongly medium dependent and it is therefore extremely unlikely that the Bunnett assumption is valid for acid-catalyzed reactions of this type of substrate. Hence the w-parameters for reactions of substrates which have not been demonstrated to follow H_0 as bases cannot be simply related to the hydration changes involved in the rate-determining step. It is possible, however, to obtain direct information about the nature of the transition state in the following way. The generalized mechanism for acid-catalyzed reactions, in terms of fully hydrated species, can be written

$$S(H_2O)_s + H(H_2O)_n^+ \rightleftharpoons SH(H_2O)_p^+ + (s + n - p)H_2O$$
$$SH(H_2O)_p^+ + rH_2O \rightleftharpoons S^{\ddagger}(H_2O)_t \rightarrow \text{products}.$$

For reactions in which the protonation step is rapidly reversible, this scheme leads to the rate equation

$$[1] \qquad v = k/K_{SH^+} \cdot [S(H_2O)_s] f_{S(H_2O)_s}/f_{S^{\ddagger}(H_2O)_t} \cdot a_{H(H_2O)_n^+} \cdot a_{H_2O}^{r-(s+n-p)} = k_{obs}[S]_{st},$$

where K_{SH^+} is the dissociation constant of the substrate conjugate acid, k_{obs} is the observed pseudo-first-order rate constant (the acidity remaining effectively constant in any given kinetic experiment) and $[S]_{st}$ is the stoichiometric substrate concentration. Consider now the generalized indicator equilibrium, also in terms of fully hydrated species

$$In(H_2O)_b + H(H_2O)_n^+ \rightleftharpoons InH(H_2O)_c^+ + (b + n - c)H_2O.$$

This can be used to define the acidity of the medium in terms of a general acidity function:

$$[2] \qquad h_x = a_{H(H_2O)_n^+}/a_{H_2O}^{b+n-c} \cdot (f_{In(H_2O)_b}/f_{InH(H_2O)_c^+}).$$

If we now substitute for the hydronium ion activity in eq. [1] in terms of the relation given in eq. [2] and indicate by a subscript h that each species referred to is fully hydrated, we obtain the rate expression

$$[3] \qquad v = k/K_{SH^+} \cdot [S_h](f_{S_h} f_{InHh^+}/f_{S^{\ddagger}h} f_{In_h}) \cdot h_x \cdot a_{H_2O}^{r+(b-c)-(s-p)}.$$

**All activity coefficients in this section refer to fully hydrated and not formal species.*

This gives a general relation between the rate, acidity, and water activity similar to that derived by Bunnett (13). Now if the substrates and indicators are of the same structural type, i.e. if both are amides, this expression can be simplified by a much less extreme assumption. The terms f_{S_h} and f_{In_h} refer to the same type of species and will approximately cancel in all solutions. For the same reason $(b - c) - (s - p)$ will be effectively zero. Since the amide conjugate acid and the transition state have the same charge and are very similar structurally, it is reasonable to assume that the ratio of their activity coefficients will be nearly medium independent. Thus the rate equation for amide hydrolysis becomes

$$v \approx (k/K_{SH^+}) \cdot [S_h] h_A a_{H_2O}{}^r.$$

For weakly basic amides which are protonated to a very small extent in the reaction medium, $[S_h] = [S]_{st}$ and the rate constant is given by

$$k_{obs} = k/K_{SH^+} h_A a_{H_2O}{}^r.$$

Taking logarithms and rearranging, this gives

$$\log k_{obs} + H_A = r \log a_{H_2O} + \text{constant}. \quad [4]$$

For more basic substrates which are protonated to an appreciable extent, $[S_h] = [S]_{st} \times (h_A/K_{SH^+} + h_A)$, and the rate constant is given by $k_{obs} = k(h_A/K_{SH^+} + h_A)a_{H_2O}{}^r$. The corresponding logarithmic relation between rate, acidity, and water activity is thus

$$\log k_{obs} - \log (h_A/K_{SH^+} + h_A) = r \log a_{H_2O} + \text{constant}. \quad [5]$$

Equations [4] and [5] are formally very similar to the empirical relations discovered by Bunnett (12), except that an acidity function strictly appropriate to the substrate is involved and r can now be more directly related to the number of water molecules needed to convert protonated substrate to its transition state.

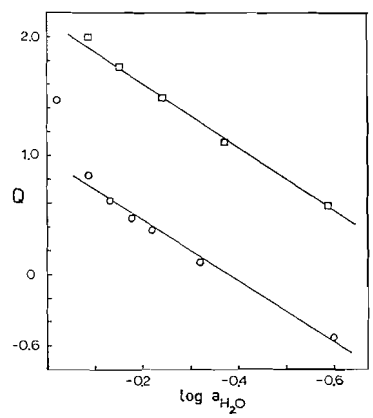

FIG. 1. Plot of $Q(= [\log k_{obs} - \log(h_A/h_A + K_{SH^+})] + 3)$ against $\log a_{H_2O}$ for the hydrolysis of benzamide (circles) and *p*-nitrobenzamide (squares) in sulfuric acid at 25 °C. Data taken from refs. 1, 12, and 14.

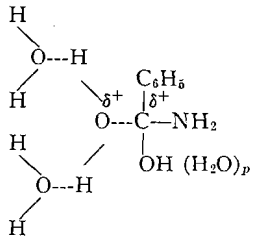
In Fig. 1 the quantity $\log k_{obs} - \log (h_A/K_{SH^+} + h_A)$ is plotted against $\log a_{H_2O}$ for the hydrolysis of benzamide (15) in sulfuric acid. The plot is reasonably linear over a wide range of acid giving a slope $r = 2.6$ (correlation coefficient = 0.994) if the point in dilute acid is omitted. This deviation may be due to the fact that in the dilute region

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

there is plenty of "free" water available for solvation. Average hydration numbers in this region may be significantly different from those in more concentrated acids where competition for available water is more serious. The only other amide for which appropriate data (14) is available is *p*-nitrobenzamide, and although this base does not follow H_A as well as benzamide, a similar plot is also linear with slope $r = 2.7$ (correlation coefficient = 0.998). These results suggest that over a wide range of acidity an amide conjugate acid is converted to its transition state by the attack of three additional water molecules on the average. This transition state can be reasonably represented by the following structure.



Moodie (15) has already reached a similar conclusion concerning the nature of this transition state using a different treatment which involves the water activity but does not involve either the pK of the base or any acidity function values. An alternative approach is the recent ϕ-parameter treatment of Bunnett (16), which does not involve any water activity data. In this method quantities such as the left hand sides of eqs. [4] or [5] are plotted against (log $[H^+] + H_0$) as a reference standard for all reactions and equilibria. By this approach excellent linear plots are also obtained in the present case, yielding ϕ-values of 0.71 (correlation coefficient 0.993) and 0.69 (correlation coefficient 1.000) for the hydrolysis of benzamide and *p*-nitrobenzamide respectively. On the basis of acidity – water activity variation over a wide range of hydrochloric, sulfuric, and perchloric acids, Bunnett (16) assigns a value of 4.5 ϕ to the average hydration change accompanying any reaction. This again indicates that three additional water molecules are involved in the rate-determining step of amide hydrolysis. Thus all three approaches described above yield essentially the same picture of the transition state.

At present the scarcity of appropriate acidity function and kinetic data does not allow the present approach to be tested further to see if similar results are obtained for other amides. We are at present evaluating the H_A function in other acids in an attempt to test the general usefulness of this method of obtaining detailed information about transition states.

CONTRIBUTION A L'ÉTUDE DU MÉCANISME D'OXYDATION CHROMIQUE DES ALCOOLS SECONDAIRES[1]

JEAN-CLAUDE RICHER ET CLAUDE GILARDEAU[2]
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 28 septembre 1964

RÉSUMÉ

Cette étude montre que lorsqu'il n'y a que des effets stériques qui influencent les vitesses de réaction d'oxydation chromique d'alcools secondaires, toutes les réactions passent par un état de transition semblable et que l'enthalpie et l'entropie d'activation se compensent; d'autre part le rapport des vitesses d'oxydation d'alcools épimères est égal au rapport de la concentration de ces derniers à l'équilibre.

INTRODUCTION

Le mécanisme d'oxydation chromique des alcools secondaires a fait l'objet de nombreux travaux (1–10). Au cours des années récentes, deux relations linéaires ont été proposées (6, 9) pour relier les vitesses d'oxydation chromique d'alcools secondaires épimères et la stabilité relative des alcools oxydés. Les résultats rapportés dans le présent travail indiquent que la différence d'énergie libre entre deux alcools épimères (ΔF_{ox}) est reliée aux vitesses d'oxydation des alcools d'après l'équation [1] proposée par Sicher et ses collaborateurs (6).

$$[1] \qquad \Delta F_{ox} = RT \ln k_a/k_e.$$

RÉSULTATS ET DISCUSSION

Les vitesses d'oxydation par l'acide chromique, de plusieurs monoalcools alicycliques secondaires ont été mesurées et les résultats obtenus sont résumés au Tableau I.

TABLEAU I

Vitesses d'oxydation par l'acide chromique*

Alcool	17 °C	25 °C	33 °C
tert-Butyl-4 cyclohexanol *trans* (I)	1.266	2.50	4.95
Triméthyl-3,3,5 cyclohexanol *cis* (II)	1.864	4.25	7.42
Cyclohexanol (III)	2.02	3.72	6.58
Diméthyl-4,4 cyclohexanol (IV)	2.24	4.22	7.23
tert-Butyl-4 cyclohexanol *cis* (V)	5.46	9.70	16.15
Cyclopentanol (VI)	3.86	6.96	11.79
Triméthyl-3,3,5 cyclohexanol *trans* (VII)	100.8	143.2	198.4
tert-Butyl-4 diméthyl-2,2 cyclohexanol *trans* (VIII)		11.73	
tert-Butyl-4 diméthyl-2,2 cyclohexanol *cis* (IX)		19.5	
Diméthyl-3,5 cyclohexanol *cis,cis* (X)		3.30	
Diméthyl-3,5 cyclohexanol *trans,trans* (XI)		18.4	
Diméthyl-3,3 cyclohexanol (XII)		6.82	

*10^3 k_2 (l mole^{-1} s^{-1}). Les vitesses d'oxydation rapportées sont la moyenne de 3–4 mesures; l'erreur moyenne sur ces mesures est de ±0.6%.

A l'aide des vitesses d'oxydation à plusieurs températures, les paramètres thermodynamiques d'activation, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ et $\Delta F^{\ddagger}$, ont été calculés. Ces valeurs sont rapportées au Tableau II.

[1]*Communication présentée en partie lors du XIXeme Congrès de l'Union Internationale de Chimie Pure et Appliquée, Londres, juillet 1963.*
[2]*Détenteur de la Bourse C.I.L. pour les années 1963–1965.*

TABLEAU II

Facteurs thermodynamiques d'activation

Alcool*	$\Delta H^{\ddagger}$†	$\Delta S^{\ddagger}$‡	$\Delta F^{\ddagger}$†
I	13.80	24.20	21.02
II	13.23	25.17	20.74
III	12.14	28.95	20.78
IV	12.06	29.01	20.71
V	10.91	31.20	20.22
VI	10.35	33.73	20.41
VII	5.79	42.49	18.46

*Les alcools auxquels on se réfère ici sont nommés dans le Tableau I.
†En kcal/mole, l'erreur moyenne sur ces valeurs est de 0.05 kcal/mole.
‡En unités entropiques, erreur moyenne de 0.03 u.e.

Dans le présent travail, tous les facteurs thermodynamiques ne dépendent que de la structure des alcools employés, c'est-à-dire que les effets polaires des substituants alkyles sont nuls ou négligeables (11). De plus l'enthalpie et l'entropie d'activation sont reliés d'une façon linéaire. Cette relation qui peut être décrite par une équation (éq. [2]) du type proposé par Leffler (12) indiquerait que, dans tous les cas étudiés ici, les états de transition sont semblables.

[2] $$\Delta H = \Delta H_0 + B\Delta S.$$

Dans une étude rapportée récemment, Wilcox (9) a proposé une corrélation linéaire entre les $\Delta(\Delta F^{\ddagger})$ d'oxydation des alcools et la stabilité relative calculée de ces alcools. Grâce aux vitesses d'oxydation de ces alcools et utilisant l'éq. [1] proposée par Sicher (6), il est possible d'évaluer la différence d'énergie libre entre deux alcools épimères. Les valeurs (ΔF_{ox}) calculées de cette manière à l'aide des résultats rapportés ici ainsi que dans le travail de Richer, Pilato et Eliel (3) sont rapportées dans le Tableau III en regard des différences d'énergie libre (ΔF) mesurées par équilibration des alcools par l'isopropylate d'aluminium. Ces données présentées sous forme de graphique montrent une relation linéaire avec pente de 0.97 et passant par l'origine. Ce résultat indique que les états de transition des oxydations des alcools épimères examinés ont atteint une équivalence énergétique dépassant même la valeur de 90% proposée par Wilcox (9) et confirme la validité de l'éq. [1] pour déterminer la différence d'énergie libre entre deux alcools épimères.

TABLEAU III

PARTIE EXPÉRIMENTALE

Préparation des alcools

Les diméthyl-3,5 cyclohexanols nous ont été gracieusement fournis par le Dr. E. L. Eliel, Département de Chimie, Notre Dame University, alors que les *tert*-butyl-4 diméthyl-2,2 cyclohexanols ont été synthétisés

par M. Guy Perrault de ce département (13). Les autres alcools utilisés dans cette étude ont été préparés et purifiés par des méthodes connues. Leur pureté a été vérifiée par c.p.g. (Colonne de 2.5 m de Carbowax 20 M sur Chromat FB à 20% et à une température variant entre 160 et 170°) et par spectrophotométrie infrarouge.

Cinétique

La méthode employée ici est semblable à celle d'Eschenmoser (4). Une solution d'acide acétique 75% v/v et environ 10^{-3} M en $HCrO_4^-$ est gardée dans un bain à température constante. L'alcool est pesé de façon à obtenir une solution environ 10^{-2} M en alcool. Les mesures cinétiques sont effectuées spectrophotométriquement à 348 mμ. L'enregistrement automatique de la disparition de l'acide chromique en fonction du temps est fait sur un appareil Perkin-Elmer, modèle 4000A. La constante de vitesse est trouvée en faisant le graphique du log $(a - x)$ en fonction du temps. Une relation linéaire est obtenue au delà de 60% de la réaction.

REMERCIEMENTS

Les auteurs remercient sincèrement la compagnie C.I.L. (1954) et le Conseil National de Recherches pour l'aide financière apportée sous forme de bourse prédoctorale (C. G.) et d'octrois de recherches (J. C. R.)

THE REACTION OF SOME AROMATIC ACIDS WITH SODIUM AZIDE IN A TRIFLUOROACETIC ACID - TRIFLUOROACETIC ANHYDRIDE MEDIUM

K. G. RUTHERFORD, SANDRA YUEN-SHUN ING (YU), AND R. J. THIBERT
Department of Chemistry, University of Windsor, Windsor, Ontario

Received October 26, 1964

ABSTRACT

Some commercially available aromatic acids have been treated with sodium azide using a mixture of trifluoroacetic acid and trifluoroacetic anhydride as the reaction medium. Benzoic, ortho-, meta-, and para-toluic, ortho-bromo-, and ortho-nitro-benzoic acids were converted to corresponding N-substituted trifluoroacetamides in good yields. 1-Naphthoic acid was converted to N-(1-naphthyl)-trifluoroacetamide in near quantitative yield. Meta- and para-bromobenzoic and meta- and para-nitrobenzoic acids did not undergo this modified Schmidt reaction under these conditions. The conversion of aromatic acids to N-substituted trifluoroacetamides is discussed and evidence is presented for the mechanism.

INTRODUCTION

The normal Schmidt reaction involves the conversion of an organic acid to an amine with the use of sodium azide in a sulfuric acid medium. The mechanism of the reaction has been well established and is known to involve the following sequence of steps (1):

$$\mathrm{RCOOH} \xrightarrow{HN_3} \mathrm{RCON_3} \xrightarrow{H^{\oplus}} \mathrm{R{-}N{=}C{=}O} \xrightarrow[H_2O]{H^{\oplus}} \mathrm{R{-}\overset{H}{\overset{|}{N}}{-}COOH} \longrightarrow \mathrm{RNH_2} + \mathrm{CO_2}$$

Rutherford and Newman (2) reported that 4-phenanthroic acid underwent sulfonation under the normal conditions of the Schmidt reaction but was converted in almost quantitative yield to 4-phenanthryl isocyanate when a mixture of trifluoroacetic acid (TFA) and trifluoroacetic anhydride (TFAn) was used as the reaction medium. It was decided then to investigate the scope and limitations of these modified Schmidt conditions with some commercially available aromatic acids.

RESULTS AND DISCUSSION

Table I indicates the organic acids which were subjected to the modified Schmidt reaction. Wherever possible a comparison with the normal Schmidt reaction is shown. As can be seen from the table, trifluoroacetyl derivatives of the corresponding amines were obtained in all cases of those acids which proved amenable to the TFA–TFAn system with the exception of 2-naphthoic acid which afforded the azide in quantitative yield. The N-substituted trifluoroacetamides could be readily hydrolyzed in excellent yields to afford the amines. It is important to note, however, that these modified conditions of the Schmidt reaction are not to be considered general, since attempted conversion of meta- and para-bromobenzoic and the analagous nitrobenzoic acids failed. The normal Schmidt reaction proves ideal for the conversion of the nitrobenzoic acids to amines.

The presence of trifluoroacetic anhydride in the reaction medium is as previously reported (2) imperative. In no case did the reaction proceed in 100% trifluoroacetic acid. Table II indicates the effect on the yield of N-(1-naphthyl)-trifluoroacetamide with varying amounts of TFA and TFAn. Even the presence of 10% (by volume) of TFAn has a pronounced effect on the success of the reaction. The yields, however, are reduced quite drastically when the amount of TFAn exceeds 60%.

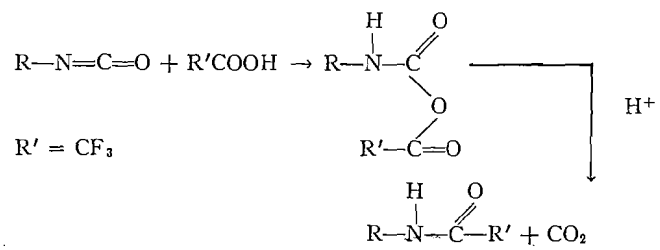
o-Nitrobenzoic	35–40	N-(*o*-Nitrophenyl)-trifluoroacetamide	89–90	62	83
m-Nitrobenzoic	35–40	Starting material	—	—	83
p-Nitrobenzoic	35–40	Starting material	—	—	83

TABLE II

The influence on the yields of the Schmidt reaction with 1-naphthoic acid with a varying ratio of trifluoroacetic acid and its anhydride

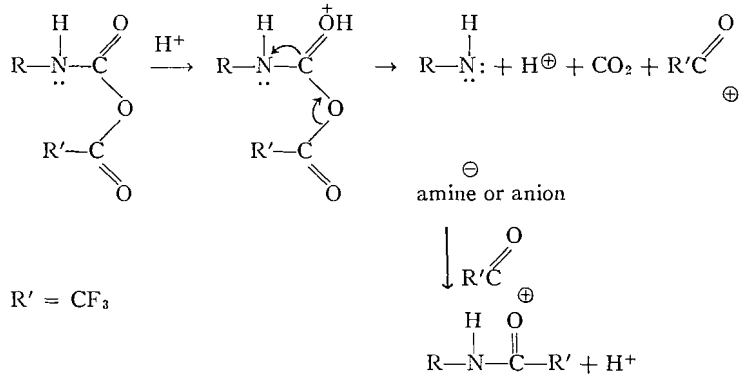
Volume % CF_3COOH	% yield of trifluoroacetyl 1-naphthylamine	% acid recovered
100	—	100
90	75.8	—
80	84.7	—
70	97.8	—
60	97.0	—
50	97.6	—
40	92.3	—
30	57.0	30
20	27.6	59.3
10	19.1	78.4
0	—	100

Of special interest to us was the formation of the trifluoroacetamide derivatives in all cases in which the reaction was successful, especially in view of the fact that 4-phenanthroic acid yielded an isocyanate which was stable in the reaction medium. Evidently, the isocyanate intermediates arising from the acids studied in this investigation underwent rapid reaction with trifluoroacetic acid according to the well-known sequence:

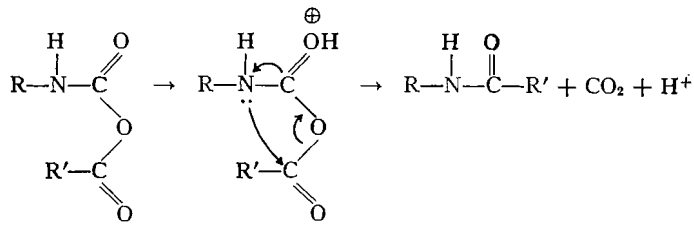


Fry (3) had previously shown that the CO_2 which is liberated in such a reaction contains the carbon atom which is adjacent to the R—NH group of the mixed anhydride. The acid-catalyzed breakdown of the mixed anhydride can be rationalized in the following two ways:

[1]



[2]



Although it is obvious that either the free amine or its anion (path [1]) could result from a slightly different route from the one depicted above, there is a distinct difference between paths [1] and [2]. The latter route involves a concerted path which would be independent of the presence of extraneous anhydride. Although intuitively one might expect path [1] to be operative, it was found that when phenyl isocyanate was treated with trifluoroacetic acid in the presence of an equimolar amount of acetic anhydride, N-phenyl-trifluoroacetamide was obtained in 84% yield. None of the expected acetanilide was obtained. Under the same conditions, 1-naphthyl isocyanate afforded the trifluoroacetyl derivative of 1-naphthylamine in 91% yield. The expected N-(1-naphthyl)-acetamide was not detected.

The reaction of these isocyanates with trifluoroacetic acid to yield N-substituted trifluoroacetamides via the concerted process (path [2]) is probably unique, since, when phenyl isocyanate was treated with an equimolar mixture of trichloroacetic acid and acetic anhydride, only acetanilide was isolated (92%). Again, when phenyl isocyanate was treated with an equimolar mixture of acetic acid and trifluoroacetic anhydride only trifluoroacetanilide was obtained (87%). Clearly, in these latter cases then, the formation of the intermediate amine or its anion (path [1]) is evident.

The uniqueness of the concerted path in the case of the reaction of phenyl and naphthyl isocyanates with trifluoroacetic acid is undoubtedly a manifestation of the exceptional carbonyl character of the trifluoroacetyl group of the mixed anhydride. Other analogous mixed anhydride intermediates may be expected to undergo decomposition under the reaction conditions to yield the transient amine or its anion prior to amide formation. A study of the reaction of substituted aryl and alkyl isocyanates with strong organic acids

in order to determine electrical and steric effects on the course of the reaction is in progress.

It is of interest to note that acetophenone was converted to acetanilide in 80% yield using sodium azide in the TFA–TFAn medium. This compares quite favorably with that reported by Briggs and De Ath (4) who obtained a yield of 70% using the sulfuric acid medium.

EXPERIMENTAL

Melting points were taken on the Fisher-Johns melting point apparatus and are uncorrected. Analyses were performed by the Schwarzkopf Microanalytical Laboratory, 56–19 37th Avenue, Woodside 77, New York.

The Schmidt Reaction in the Trifluoroacetic Acid – Anhydride Medium

The reaction apparatus used throughout consisted of a 100 ml, three-necked, round-bottomed flask which was equipped with a mercury-sealed stirrer, a small oblong flask which allowed the portionwise addition of sodium azide simply by rotation of the flask at the appropriate angle, and a reflux condenser. The outlet of the condenser was connected via a rubber tube to an inverted graduated cylinder which was used to collect gas by the downward displacement of water. When required, the reaction flask was immersed in an oil bath which was heated to facilitate reaction. The conversion of benzoic acid to N-phenyl-trifluoroacetamide exemplifies the reaction.

Benzoic acid (3.0 g, 0.0246 mole) was dissolved in a solution of trifluoroacetic acid (25 ml) and trifluoroacetic anhydride (10 ml). Sodium azide (1.6 g, 0.0492 mole) was added portionwise with stirring over a period of 48 h whereupon 700 ml of gas was collected. The volatile materials were removed *in vacuo* and the remaining portion of the reaction mixture was poured on crushed ice. The crude N-phenyl-trifluoroacetamide was collected by filtration, washed with cold water, and air dried. Recrystallization from a chloroform – petroleum ether (b.p. 60–110°) solvent pair gave colorless crystals (3.3 g, 72%), m.p. 87–89°, recorded 87–89° (5).

Anal. Calcd. for $C_8H_6F_3NO$: C, 50.81; H, 3.19; F, 30.11; N, 7.40. Found: C, 50.92; H, 3.19; F, 30.39; N, 7.42.

An authentic sample of N-phenyl-trifluoroacetamide was prepared by the addition of trifluoroacetic anhydride to freshly distilled aniline at ice-bath temperature. The mixture was allowed to stand for 20 min and was poured on crushed ice. Recrystallization from chloroform – petroleum ether (b.p. 60–110°) yielded colorless crystals, m.p. 87–89°. There was no depression in melting point on admixture with the N-phenyl-trifluoroacetamide isolated from the Schmidt reaction with benzoic acid.

The following analytical data is recorded for the N-substituted trifluoroacetamides listed in Table I.

N-(ortho-Tolyl)-trifluoroacetamide

Anal. Calcd. for $C_9H_8F_3NO$: C, 53.20; H, 3.96; N, 6.89; F, 28.05. Found: C, 53.17; H, 4.21; N, 6.59; F, 27.77.

N-(para-Tolyl)-trifluoroacetamide

Anal. Calcd. for $C_9H_8F_3NO$: C, 53.20; H, 3.96; N, 6.89; F, 28.05. Found: C, 53.34; H, 4.17; N, 7.05; F, 28.02.

N-(meta-Tolyl)-trifluoroacetamide

Anal. Calcd. for $C_9H_8F_3NO$: C, 53.20; H, 3.96; N, 6.89; F, 28.05. Found: C, 53.46; H, 3.98; N, 6.73; F, 28.11.

N-(ortho-Bromophenyl)-trifluoroacetamide

Anal. Calcd. for $C_8H_5F_3NOBr$: C, 35.43; H, 1.88; Br, 29.82; N, 5.22; F, 21.22. Found: C, 35.57; H, 2.02; Br, 30.06; N, 5.19; F, 21.13.

N-(ortho-Nitrophenyl)-trifluoroacetamide

Anal. Calcd. for $C_8H_5F_3N_2O_3$: C, 41.03; H, 2.15; N, 11.96; F, 24.34. Found: C, 41.33; H, 2.33; N, 11.82; F, 24.18.

N-(1-Naphthyl)-trifluoroacetamide

Anal. Calcd. for $C_{12}H_8F_3NO$: C, 60.21; H, 3.42; N, 5.81; F, 23.92. Found: C, 60.28; H, 3.52; N, 5.74; F, 23.80.

The above N-substituted trifluoroacetamides were prepared independently from the reaction of the corresponding amine with trifluoroacetic anhydride. The corresponding infrared spectrograms were identical as were melting points of appropriate admixtures with the corresponding derivatives obtained from the Schmidt reaction.

The Reaction of Phenyl Isocyanate with Trifluoroacetic Acid

Phenyl isocyanate (2.97 g, 0.025 mole) was dissolved in 10 ml of anhydrous chloroform. The solution was placed in a filter flask (100 ml) which was fitted with a dropping funnel. The side outlet was connected to a rubber tube which was led into an inverted graduated cylinder (1 000 ml) such that gas could be collected by the downward displacement of water. A solution of trifluoroacetic acid (2.7 g, slightly less than 0.025 mole) and chloroform (10 ml) was added dropwise over a period of 20 min through the funnel with occasional shaking while the reaction flask was maintained at a temperature of −20° by means of dry-ice – acetone bath. The resultant yellow solution was allowed to warm to room temperature whereupon gas evolved quite rapidly. The volatile material was removed *in vacuo* and the residue was poured on crushed ice whereupon N-phenyl-trifluoroacetamide solidified. The compound was recovered by filtration and air dried (3.13 g, 67.3%), m.p. 85–87°. A mixture melting point determination with an authentic sample was not depressed.

Reaction of Phenyl Isocyanate with a Mixture of Trifluoroacetic Acid and Acetic Anhydride

A solution of phenyl isocyanate (5.0 g, 0.042 mole), freshly distilled acetic anhydride (4.28 g, 0.042 mole), and 10 ml of anhydrous chloroform was cooled externally by means of an ice-water bath. Trifluoroacetic acid (4.8 g, 0.042 mole) was added dropwise with stirring over a period of 30 min. The reaction mixture was allowed to stir for an additional 30 min whereupon the chloroform was removed *in vacuo* and the remaining portion was poured on crushed ice. The N-phenyl-trifluoroacetamide was collected by filtration, air dried, and recrystallized from chloroform – petroleum ether (b.p. 60–110°). A yield of 6.67 g (84.1%), m.p. 89–90°, was obtained. The melting point was not depressed on admixture with an authentic sample of N-phenyl-trifluoroacetamide. The infrared spectrograms were identical.

Reaction of 1-Naphthyl Isocyanate with a Mixture of Trifluoroacetic Acid and Acetic Anhydride

A solution of 1-napthyl isocyanate (5.0 g, 0.0296 mole), freshly distilled acetic anhydride (3.38 g, 0.0296 mole), and 10 ml of anhydrous chloroform was mechanically stirred while trifluoroacetic acid (3.38 g, 0.0296 mole) was added dropwise rapidly at room temperature. The reaction mixture was allowed to stand overnight whereupon the volatile components were removed *in vacuo*. The residue was poured on crushed ice and N-(1-naphthyl)-trifluoroacetamide was collected by filtration. Recrystallization from a chloroform – petroleum ether (b.p. 60–110°) solvent pair afforded 6.4 g (90.6%) of pure material, m.p. 96–97°. The melting point was not depressed on admixture with an authentic sample.

Reaction of Phenyl Isocyanate with a Mixture of Trichloroacetic Acid and Acetic Anhydride

A three-necked, round-bottomed flask (250 ml) was equipped with a stirrer, a dropping funnel, and a reflux condenser outfitted with a rubber tube which led to a gas-measuring cylinder. Phenyl isocyanate (5.0 g, 0.042 mole) was added to the flask. Stirring was commenced and a solution of trichloroacetic acid (6.84 g, 0.042 mole) and 10 ml of anhydrous chloroform was added. The reaction mixture was heated to 40° by means of a water bath and was allowed to stir at this temperature for 24 h. The chloroform was removed *in vacuo* and the remaining contents of the flask were poured on crushed ice. The product which precipitated was collected by filtration, washed twice with cold water, and air dried. Recrystallization from a chloroform – petroleum ether (b.p. 60–110°) solvent pair afforded 5.2 g (92%) of pure acetanilide, m.p. 114–115°. The melting point was not depressed on admixture with an authentic sample. The infrared spectrograms were identical.

Reaction of Phenyl Isocyanate with a Mixture of Acetic Acid and Trifluoroacetic Anhydride

A solution of trifluoroacetic anhydride (8.8 g, 0.042 mole) acetic acid (2.35 g, 0.042 mole), and phenyl isocyanate (5.0 g, 0.042 mole) was stirred at 45–50° for 24 h. The volatile components were removed *in vacuo* and the remaining contents were poured on crushed ice. The resultant precipitate was collected by filtration, washed with cold water, and air dried. Recrystallization from a chloroform – petroleum ether (60–110°) solvent pair gave pure N-phenyl-trifluoroacetamide (6.9 g, 87.2%), m.p. 89–90°. The melting point was not depressed on admixture with an authentic sample. The infrared spectrograms were identical.

Reaction of Acetophenone with Sodium Azide in a Mixture of Trifluoroacetic Acid and Trifluoroacetic Anhydride

A solution of acetophenone (3.0 g, 0.024 mole), trifluoroacetic acid (25 ml), and trifluoroacetic anhydride (10 ml) was placed in a reaction flask. Sodium azide (3.16 g, 0.048 mole) was added portionwise with stirring over a period of 15 min. The reaction mixture was allowed to stir for an additional 4 h whereupon the volatile components were removed *in vacuo* and the remaining portion was poured on crushed ice. The acetanilide was recovered by filtration and recrystallized from chloroform – petroleum ether (b.p. 60–110°). A yield of 2.72 g (80.4%), m.p. 114–115° was obtained. The melting point was not depressed on admixture with an authentic sample.

SOLVOLYSIS OF ALKYL CHLOROSULFATES

PART I. REACTION OF *n*-PROPYL CHLOROSULFATE WITH NUCLEOPHILES[1]

E. BUNCEL AND J. P. MILLINGTON
Department of Chemistry, Queen's University, Kingston, Ontario

Received July 31, 1964

ABSTRACT

The effect of various reagents on the rate of hydrolysis of *n*-propyl chlorosulfate in 10 *M* aqueous dioxane is reported. Halide ions increase the rate of reaction ($I^- > Br^- > Cl^-$) but perchlorate is without effect. Hydroxide and pyrrolidine have a strong accelerating effect, but only at higher concentrations. These observations support a bimolecular mechanism: rate-determining displacement by nucleophile on carbon, with OSO_2Cl^- as the leaving group. The present results are not in accord with a previous proposal that alkyl chlorosulfates react by rate-determining sulfur–chlorine bond fission followed by fast displacement by nucleophile on carbon.

INTRODUCTION

Alkyl chlorosulfates,[2] $ROSO_2Cl$, comprise a class of acyl halide which has been only slightly studied in the past, in comparison with, for example, the structurally related chlorosulfites, ROSOCl, or the sulfonyl chlorides, RSO_2Cl. It is only recently that the diverse reactions of chlorosulfates have been utilized in organic synthesis, by Jones and co-workers (1) of this laboratory in the field of carbohydrate chemistry. The complexity of these reactions have pointed to the necessity of detailed studies of relatively simple compounds and it is with this purpose that this series of studies was initiated. The present paper reports the results of perhaps the simplest and most basic study, that of aqueous hydrolysis of a typical primary alkyl chlorosulfate.

Early studies (2) of the hydrolysis of methyl chlorosulfate in water ascribed three concurrent modes of reaction to the ester, to give the hydrogen sulfate, chloride, and methanol (eqs. [1]–[3]); in addition some dimethyl ether was often observed. These reactions were heterogeneous, due to insolubility of the chlorosulfates in water.

$$[1] \qquad CH_3OSO_2Cl + H_2O \rightarrow CH_3OSO_3H + HCl,$$

$$[2] \qquad CH_3OSO_2Cl + H_2O \rightarrow CH_3Cl + H_2SO_4,$$

$$[3] \qquad CH_3OSO_2Cl + 2H_2O \rightarrow CH_3OH + H_2SO_4 + HCl.$$

More recently Hall (3) found that under homogenous conditions, in a medium of aqueous dioxane, reaction occurred only according to eq. [3]. Hall also carried out the first kinetic study on this class of acyl halide and compared their reactivity with the related sulfonyl chlorides and sulfamyl chlorides. He studied methyl and ethyl chlorosulfates and came to certain conclusions concerning their mechanism of reaction. However, these conclusions needed a reevaluation in view of the recent work by Jones *et al.* (1). In the present work, carried out in 10 *M* aqueous dioxane, the effect of a variety of reagents has been investigated to ascertain the intimate nature of the hydrolysis.

RESULTS

Rate of Neutral Hydrolysis

The products of reaction of a 0.01 *M* solution of *n*-propyl chlorosulfate in 10 *M* aqueous dioxane were first examined. The ionic products are H_2SO_4 and HCl, formed in

[1]*Presented in part at the 47th Annual Conference of the Chemical Institute of Canada, Kingston, Ontario, June 1964.*

[2]*Also known as alkyl chlorosulfonates or alkoxysulfonyl chlorides.*

quantitative yield. The only organic product detected by vapor-phase chromotography was *n*-propyl alcohol. The stoichiometry of reaction is hence that of a simple hydrolysis, as in eq. [3].

The rate of neutral hydrolysis in 10 *M* aqueous dioxane at 25° was measured conductimetrically; the pseudo-first-order rate constant calculated from the usual plot, linear over 90% reaction,[3] is $(38.6 \pm 0.3) \times 10^{-4}$ s^{-1}. As a check, the rate was also determined by electrochemical measurement of chloride ion; this gave the rate constant value $(37.4 \pm 2.8) \times 10^{-4}$ s^{-1}.

Effect of Added Nucleophiles

In Table I are presented the effects of added perchloric acid, sodium perchlorate, some halide ions, sodium hydroxide, and pyrrolidine on the rate of hydrolysis of *n*-propyl chlorosulfate in 10 *M* aqueous dioxane at 25 °C. These data were obtained by the conductivity method. In the presence of halide, hydroxide, and pyrrolidine the first-order plot was linear over 1–2 half-lives but showed a moderate deviation from linearity thereafter. The variation in the individual rate constants during a given run was also markedly greater than in the absence of added reagents (±1%), particularly at the higher ionic strengths. Thus with added halide the highest error was ±5%, with added hydroxide, pyrrolidine, and perchloric acid, ±10%; with added perchlorate, a smaller error was observed.

DISCUSSION

Mechanism of Hydrolysis

In early work with methyl and ethyl chlorosulfate a variety of products was observed, which would suggest rather complex reactions with water. The more recent work of Hall (3) showed that in dilute solution in aqueous dioxane the only products are the alcohol, H_2SO_4, and HCl. Hall's results are confirmed in the present study. The principal reaction is therefore that of a simple hydrolysis (eq. [3]). The other products in the early work were due in part to heterogeneous reaction conditions. At the same time the early studies used very vigorous conditions, e.g. heating to 100° for several hours when the present work shows that hydrolysis at 25° would be complete in several minutes. In the acidic reaction mixture the alcohol formed in the primary reaction would give rise to alkyl hydrogen sulfate, alkyl chloride, and dialkyl ether by straightforward reaction paths.

Discussion of the mechanism of hydrolysis must consider whether the sulfur or the carbon of the alkyl chlorosulfate suffers attack by a water molecule, and also the nature of the leaving group. In the case of displacement on sulfur, there are two possible leaving groups, chloride and alkoxide. Since it is known that chloride ion is a much better leaving group than alkoxide (4), the latter possibility is extremely unlikely. Attack on sulfur with chloride as the leaving group would yield the intermediate alkyl hydrogen sulfate, which may subsequently hydrolyze to ROH and H_2SO_4. However, it is known (5) that alkyl hydrogen sulfates are hydrolyzed with difficulty and would certainly be stable under the reaction conditions. Hence this reaction path can be eliminated.

A variation of the above pathway is possible, if it is postulated that the rate-determining step is ionization at the sulfur–chlorine bond to give an intermediate alkoxysulfonylium ion, $ROSO_2^+$, followed by a fast step involving reaction of the nucleophile at carbon (eq. [4]). The displaced SO_3 would react instantaneously with the water of the medium.

[4*a*] $$ROSO_2Cl \xrightarrow{\text{slow}} Cl^- + R{-}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S^+}} \xrightarrow{\text{fast}} \begin{cases} \xrightarrow{H_2O} HOR + H^+ + SO_3 \\ \xrightarrow{Y^-} Y{-}R + SO_3 \end{cases}$$

[4*b*]

An alternative to the reaction paths considered above is a rate-determining displacement on carbon by a water molecule or a nucleophile (eq. [5]). The leaving group in this displacement would be OSO_2Cl^- which is expected to react with a water molecule in a fast step with formation of $SO_4^=$, Cl^-, and $2H^+$.

[5] $$Y^- + ROSO_2Cl \rightarrow Y{-}R + {}^-OSO_2Cl.$$

Hall concluded (3) that although methyl and ethyl chlorosulfates may undergo some reactions which are S_N2 displacements on carbon, the usual reaction mode is the ionization mechanism at sulfur (eq. [4]). The main evidence on which Hall based this conclusion was that hydrolysis of ethyl chlorosulfate in presence of pyrrolidine in concentrations "too low to affect the rate significantly" yielded 20% of 1-ethylpyrrolidine as reaction product. Reaction sequence [4], with Y^- = pyrrolidine, was proposed to account for this result.

Our data on the effect of added reagents (Table I) are consistent with bimolecular displacement on carbon (eq. [5]). Perchloric acid and sodium perchlorate have no effect on the rate of hydrolysis of *n*-propyl chlorosulfate. A lack of acid catalysis or salt effect

has been noted in other bimolecular solvolytic reactions (6), even though theory (7) would predict a small accelerating affect. On the other hand, chloride, bromide, and iodide ions have a substantial accelerating effect on the rate (Fig. 1). The relative rate sequence $I^- > Br^- > Cl^-$ has been observed in many past studies of displacement reactions at carbon in aqueous media (4). Clearly in presence of these nucleophiles there are two competing reactions at hand: solvolysis and bimolecular displacement at carbon by the added nucleophile.

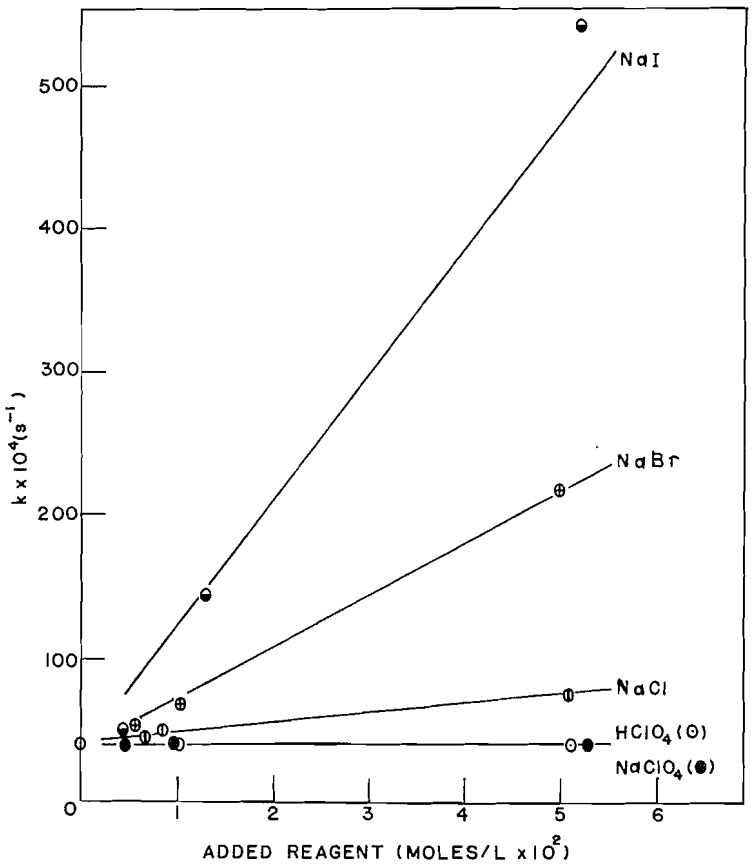

FIG. 1. Effect of added reagents on rate of hydrolysis of *n*-propyl chlorosulfate.

The effect of hydroxide ion and of pyrrolidine on the rate of hydrolysis of *n*-propyl chlorosulfate (Fig. 2) follow a different pattern from the effect of halide ions. No effect on the rate is observed at low concentrations, but a very large accelerating effect is observed at higher concentrations of these reagents. Figure 2 shows the results with hydroxide ion and pyrrolidine, expressed as rate constants as a function of the concentration ratios $[OH^-]/[ROSO_2Cl]$ and $[C_4H_8NH]/[ROSO_2Cl]$. Pyrrolidine is seen to have a much greater effect on the rate than does hydroxide. An explanation of these results must first consider the derivation of the rate constants. As stated previously, the rate data are obtained by the conductivity method, which clearly is based on the number and type of ions formed in the reaction. When neutral solvolysis is studied, these ions are H_3O^+, Cl^-, and $SO_4^=$ (or HSO_4^-). When the reaction is conducted in presence of added

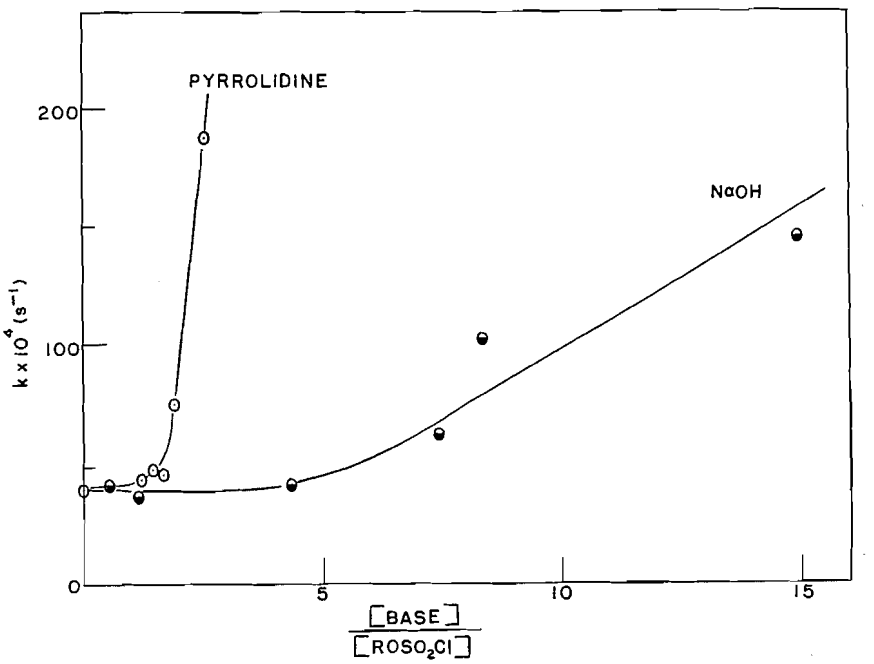

FIG. 2. Effect of added sodium hydroxide and pyrrolidine on rate of hydrolysis of *n*-propyl chlorosulfate.

hydroxide ions these make themselves felt in several ways. Firstly, they will have an effect on the neutral solvolysis, by neutralizing the hydrogen ions thus liberated. In this process three hydroxyl ions are consumed and a chloride and a sulfate ion are formed; this has no effect on the conductimetrically measured neutral solvolytic rate constant. Secondly, hydroxyl ions themselves undergo nucleophilic displacement on the substrate, the stoichiometry of this reaction being given by eq. [6].[4]

$$[6] \qquad 3HO^- + ROSO_2Cl \rightarrow ROH + SO_4^{=} + Cl^- + H_2O.$$

Since hydroxide ion is a more effective nucleophile than water, this reaction will manifest itself in an increased rate constant. At sufficiently low concentrations hydroxide ion cannot effectively compete with neutral solvolysis, but as the hydroxide ion concentration is increased it is increasingly able to compete with the neutral solvolytic reaction, until eventually this reaction (eq. [6]) becomes dominant. This accounts for the greatly increasing rate at higher concentrations of hydroxide. Since three hydroxyl ions are consumed according to each act of the hydroxide displacement (eq. [6]) and three more in neutral solvolysis (eq. [3]), the reaction is strongly dependent on the hydroxide ion concentration and the ratio $[OH^-]/[ROSO_2Cl]$ must be considered when the chlorosulfate concentration is varied, as in this series of runs.

The lyate ion effect, k_{OH^-}/k_{H_2O}, calculated by means of eq. [7] from the last three points of Fig. 2, is 380 ± 30.

$$[7] \qquad \text{Rate} = k_{H_2O}[ROSO_2Cl] + k_{OH^-}[ROSO_2Cl][OH^-].$$

A lyate ion effect of this magnitude is added evidence for the normal solvolytic nature of this reaction. Typical values for other solvolytic reactions range between about 10 and several thousand, depending on the nature of substrate and solvent (e.g. ethyl bromide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in 80% aqueous ethanol, 1 230 (9); 1-bromohexane in 50% aqueous dioxane, 124 (10); ethyl *p*-toluenesulfonate in 60.7% aqueous dioxane, 45 (11)).

In the presence of added pyrrolidine a parallel situation arises. In neutral solvolysis the liberated hydrogen ions are again neutralized in formation of pyrrolidinium ions, and the conductimetric rate constant remains unaltered since it now reflects the formation of sulfate, chloride, and pyrrolidinium ions. Competing with neutral solvolysis is the displacement of pyrrolidine on carbon of $ROSO_2Cl$ with formation of N-propylpyrrolidine and HSO_3Cl. Since the latter will be hydrolyzed by water to H_2SO_4 and HCl, three more moles of pyrrolidine will be consumed in neutralization of the acids. The stoichiometry of the process is given in eq. [8].

$$[8] \qquad 4C_4H_8NH + ROSO_2Cl + H_2O \rightarrow R{-}NC_4H_8 + 3C_4H_8NH_2^+ + SO_4^{=} + Cl^-.$$

The pyrrolidine displacement is able to compete with neutral solvolysis more effectively than in the case of hydroxide displacement, since pyrrolidine is expected to be the better nucleophile (4); this in turn is reflected in a greater accelerating effect by pyrrolidine than by hydroxide, for a given [base]/[$ROSO_2Cl$] concentration ratio, as shown in Fig. 2.

According to Hall's observations added hydroxide significantly affected the rate of hydrolysis of ethyl chlorosulfate and pyrrolidine was without detectable effect, yet the product contained 20% of 1-ethylpyrrolidine. Our data, however, would indicate that with the concentrations used (3), $[C_4H_8NH]/[C_2H_5OSO_2Cl] = 2.3$, one would have expected a significant increase in rate. Although the effect of the amine : chlorosulfate concentration ratio on the rate may vary with the alkyl group and with the medium, methyl chlorosulfate in 86.1% water – 13.9% dioxane was found (3) to exhibit a significant increase in rate constant at $[C_4H_8NH]/[CH_3OSO_2Cl] = 1.5$. According to our work (12) ethyl chlorosulfate fits well into the reaction series of primary chlorosulfates, and a change in mechanism between methyl and propyl is extremely unlikely.[5]

The evidence presented in this paper supports a solvolytic mechanism analogous to that of other alkyl derivatives, except that in chlorosulfate solvolysis the leaving group, OSO_2Cl, is composite. That this leaving group, although unfamiliar, should be a chemically feasible one is shown by the stability of salts having OSO_2Cl as the anionic portion, e.g., $NaSO_3Cl$, Me_4NSO_3Cl, PCl_4SO_3Cl; the infrared assignments are fully in accord with the $^-O{-}SO_2{-}Cl$ structure (13). The ionization of these salts into M^+ and OSO_2Cl^- is also shown by conductivity data in liquid hydrogen chloride (13). Chlorosulfonic acid in sulfuric acid also ionizes in this manner (14). In aqueous medium the anion OSO_2Cl^- is unstable and becomes rapidly hydrolyzed to $SO_4^{=}$, Cl^-, and $2H_3O^+$.

Further discussion of the mechanism of solvolysis of alkyl chlorosulfates is presented in Part II of this series (12).

EXPERIMENTAL

Materials

n-Propyl chlorosulfate was prepared after the method of Binkley (15). Dioxane, analytical reagent grade, was purified by refluxing over sodium for 24 h, followed by fractional distillation. The fraction having a boiling point of 101.5° was collected. The dioxane was stored in the absence of light and was used within 2 weeks of distillation. The pyrrolidine was a commercial sample and was fractionally distilled twice, b.p. 88.5°. Water was distilled and deionized using a commercial mixed bed ion-exchange resin. All inorganic

[4]*Although one would expect the conductivity to decrease during this process, it actually increases, due to the very low conductance of hydroxide ion in the medium 85.3% dioxane – 14.7% water (8).*

[5]*Experimental difficulties in measuring rate constants for ethyl chlorosulfate were reported by Hall (3), apparently due to incomplete solubility of the compound in the more aqueous medium. It is possible that this accounted for the insensitivity of rate to pyrrolidine concentration with ethyl chlorosulfate. Methyl chlorosulfate was completely soluble in that medium and gave good rate constants (3).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

salts used were of analytical reagent quality. The 10 *M* aqueous dioxane was made up by weight (85.3 wt. % dioxane – 14.7 wt. % water).

Product Analysis

The ionic products were analyzed by standard methods. The concentrations used for the product analysis were the same as those in the kinetic experiments, 0.01 *M* in the chlorosulfate. The reaction mixtures were allowed to stand in the thermostat bath for at least six half-lives.

The total acid was determined by titrating aliquots (5 ml) with standard sodium hydroxide (0.01 *N*). The chloride was determined by adding an aliquot (5 ml) to distilled water containing finely powdered barium carbonate, which neutralized the acid, bringing the solution to the correct pH for titration, and removed sulfate ions as barium sulfate. The solution was then titrated with standard silver nitrate (0.01 *N*) using Mohr's method. Sulfate was obtained as the difference between the total acid and the chloride concentrations.

The determination of the alcoholic product of reaction was done by vapor-phase chromatography (v.p.c.). The reaction product was saturated with sodium chloride and extracted exhaustively with ether. Evaporation of the ether yielded a solution of the alcohol in dioxane, carried from the original reaction mixture. This solution was diluted to the original volume with dioxane and was analyzed by v.p.c. using calibration curves prepared from the authentic alcohol. The recovery of product ranged between 75 and 90%. No olefinic product could be detected by the method of Davis *et al.* (16).

Measurement of Rates

The reaction vessel was placed in a thermostat which gave temperature control to ±0.01°. Temperature was measured using an N.B.S. calibrated thermometer. In all the determinations, unless stated otherwise, the reaction solution was initially in the range of 0.01 *M* chlorosulfate in 10 *M* aqueous dioxane. All volumes and concentrations were measured at the temperature of the reaction.

Conductivity Method

A commercial direct-reading conductivity bridge, accurate to 1%, and a dip-type conductivity cell (cell constant approximately 0.6) were used.

A calibration curve (Fig. 3) of conductivity as function of concentration was determined as follows. As the chlorosulfate under the conditions of the hydrolysis yields 1 mole of sulfuric acid and 1 mole of hydrochloric acid, a standard solution of 0.01 *M* hydrochloric acid and 0.01 *M* sulfuric acid in 10 *M* aqueous dioxane was successively diluted. The measurement of the conductivity of these diluted solutions gave a plot of concentration of total ionic product (derived from the chlorosulfate) as a function of conductivity. From this curve values of concentration at various time intervals of any run could be interpolated.

It was found that, over the conductivity range measured during the runs, concentration was a linear function of conductivity. Hence rates calculated from conductivity were within the limits of experimental error, the same as those calculated from the interpolated values of concentration. A typical result is shown in Table II. Thereafter rates were normally determined graphically. The error in determining rates in the presence of added ions is rather large due to the small relative increase in conductivity during a run at the higher ionic strengths.

The experimental values of the specific conductivity obtained from rate measurements in the presence of hydroxide and pyrrolidine were related to concentration in a similar manner as described above for

TABLE II

Rates of hydrolysis of *n*-propyl chlorosulfate in 10 *M* aqueous dioxane, calculated from specific conductivity and from concentration (temperature = 24.97°; initial concentration of *n*-propyl chlorosulfate 0.00935 mole/l)

neutral solvolysis (Fig. 3). Again it was found that concentration was approximately proportional to conductivity. With added hydroxide, as with other reagents, the conductivity of the reaction solution during a run increased continuously with time. This rather surprising result is due to the very small conductance of hydroxide ion in 10 *M* aqueous dioxane (8).

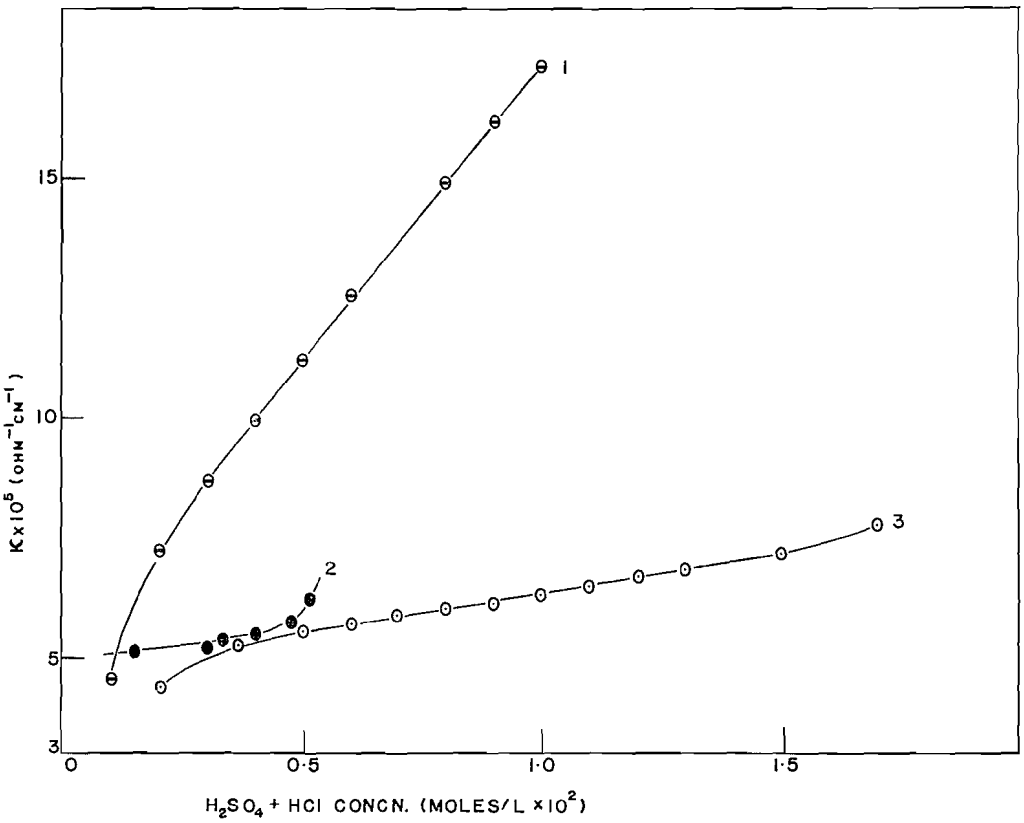

FIG. 3. Typical calibration curves of conductivity as function of added reagent for solvolysis of *n*-propyl chlorosulfate in 10 *M* aqueous dioxane: 1, H_2SO_4 + HCl only, with no added reagent; 2, with added NaOH (0.045 *M*); 3, with added pyrrolidine (0.0327 *M*).

Electrochemical Method for Chloride

A modification of the end-point cell described by Swain and Scott (17) was used. The cell was an H-type electrochemical cell with two compartments separated by an agar – potassium perchlorate salt bridge. Each compartment contained a silver / silver chloride electrode and a small air-driven stirrer. Several electrodes were prepared initially and before each run the two electrodes which had the least potential difference were chosen. The run was initiated by the addition of the chlorosulfate by means of a weight pipette to one compartment of the cell. A solution of hydrochloric acid in the same solvent equivalent to one-quarter half-life was then added to the other compartment. The potential difference (p.d.) between the two electrodes was then measured and when this approached zero the electrodes were shorted across the galvanometer; the time at which the p.d. was zero was noted. A further volume of the acid was then added and the time at which the p.d. was zero was again noted. Hence at these times the concentrations of chloride ion present in the reaction mixture was known, and the rate constant could be calculated.

HYDROLYSIS OF A SERIES OF PRIMARY ALKYL CHLOROSULFATES

ENTROPY OF ACTIVATION AS A CRITERION OF FRAGMENTATION IN SOLVOLYTIC REACTIONS[1,2]

E. BUNCEL AND J. P. MILLINGTON
Department of Chemistry, Queen's University, Kingston, Ontario

Received October 13, 1964

ABSTRACT

The solvolysis of the series of alkyl chlorosulfates, $ROSO_2Cl$, where R = methyl, ethyl, *n*-propyl, isobutyl, and neopentyl, has been studied in 10 *M* aqueous dioxane. The relative reactivities fit well a solvolytic mechanism involving displacement by water on carbon, with OSO_2Cl as the leaving group. The change in mechanism of solvolysis from bimolecular with the straight-chain chlorosulfates to unimolecular with neopentyl chlorosulfate is shown by the absence of the lyate ion effect and the observation of rearrangement in the latter case.

The entropies of activation in chlorosulfate solvolysis appear to be abnormally large. It is proposed that the abnormal $\Delta S^{\ddagger}$ indicates a transition state in which both carbon–oxygen and sulfur–chlorine bond weakening occurs. It is shown that some other solvolytic reactions that are characterized by abnormally high entropies of activation may be interpreted on the basis of multiple bond fission (fragmentation). The mechanism of S_Ni reactions is considered in this context.

The preceding paper (1) considered in detail the reaction of a typical primary alkyl chlorosulfate with nucleophiles. Here we report the results of a solvolytic study on the series of primary alkyl chlorosulfates $ROSO_2Cl$, where R is methyl, ethyl, *n*-propyl, isobutyl, and neopentyl.

The products of reaction of dilute solutions (0.01 *M*) of the alkyl chlorosulfates in 10 *M* aqueous dioxane were determined (Table V, Experimental section). The ionic products are H_2SO_4 and HCl, formed in quantitative yield. The major organic product in each case was the alcohol, with a trace of olefin as side product. The major reaction is therefore that represented by eq. [1], i.e. a simple hydrolysis, the olefin being formed most probably by a minor competing elimination reaction. In the case of neopentyl chlorosulfate, the alcohol formed is that from rearrangement, viz. *t*-pentyl alcohol.

$$ROSO_2Cl + 2H_2O \rightarrow ROH + H_2SO_4 + HCl. \quad [1]$$

The kinetic data were measured in 10 *M* aqueous dioxane, 85.3% dioxane – 14.7% water, by weight. The concentration of chlorosulfate employed was 0.01 *M*. Rates were measured conductimetrically. The half-lives of the hydrolyses were found to vary from the order of a minute in the case of the methyl compound to several hours for the neopentyl. The pseudo-first-order rate constants were calculated from usual plots which were linear over at least 75% of reaction and usually over 90% of reaction. Results for hydrolysis at several temperatures are given in Table I. Rate constants when calculated for each point individually within a run agreed to ±1% (standard deviation). The reproducibility between runs was generally also ±1%. The rate constants given in Table I are the values from two separate runs. E_a and log *A* were obtained from a least-square plot. The error in E_a is estimated as ±0.35 kcal/mole, and in $\Delta S^{\ddagger}$, ±1.0 entropy units (e.u.).

The Bimolecular and the Unimolecular Mechanism

One of the criteria used in evaluating the mechanism of solvolysis is the lyate ion

effect (2). The large lyate ion effect with *n*-propyl chlorosulfate ($k_{OH^-}/k_{H_2O} = 380 \pm 30$) was strongly indicative of a bimolecular mechanism of solvolysis. Since a change in mechanism along the series might be anticipated, it was of interest to determine how the lyate ion effect might vary. The rate of hydrolysis of neopentyl chlorosulfate was totally unaffected by base. The absence of a lyate ion effect in this case is indicative of a unimolecular carbonium ion mechanism (2). This is confirmed by the observation of rearrangement; *t*-pentyl alcohol was the only product formed, apart from a trace of olefin, in solvolysis of neopentyl chlorosulfate.

The relative reactivities of the series of alkyl chlorosulfates studied is informative. The results, relative to ethyl chlorosulfate as standard, are shown in Table II which also gives the results of some other nucleophilic substitutions of primary compounds containing displaceable groups. The reactions are arranged in a decreasing order of magnitude of the rate ratio of methyl (or ethyl) to neopentyl.

Reactions 1 and 6 represent two extremes in the effect of environment on reactivity. In reaction 1, which is a bimolecular displacement reaction, steric hindrance plays a dominant role and is responsible for the extremely low relative reactivity of the neopentyl compound. In reaction 6, solvolysis of the neopentyl compound actually proceeds at a faster rate than that of the methyl, so that clearly steric hindrance has now no importance; a limiting mechanism is indicated, that is a unimolecular carbonium ion mechanism with no participation by nucleophile in the transition state. However, even in formolysis some nucleophilic participation in the transition state must occur, since optically active 1-deutero primary systems react with inversion (3). In solvolysis of neopentyl derivatives there is no evidence for nucleophilic participation, but whether or not a migrating methyl group participates in the rate-determining transition state has not been settled (4, 5). An excellent discussion of this topic has been given (6).

The hydrolysis of alkyl chlorosulfates appears between the solvolysis of alkyl *p*-toluenesulfonates in pure ethanol and the solvolysis of alkyl bromides in 50% aqueous ethanol, in the reactivity order of Table II. Now solvolysis in ethanol (reaction 2) is considered (6) to be closely similar to the bimolecular displacement with ethoxide ion (reaction 1), so that in ethanolysis participation by the solvent molecule in the transition state must be very extensive (with the exception of the neopentyl case). By analogy, in the hydrolysis of alkyl chlorosulfates in 85.3% aqueous dioxane, solvent must likewise play an important role in the rate-determining transition state. Thus the above constitutes strong evidence in support of our view that alkyl chlorosulfates react with water in aqueous dioxane by

bimolecular displacement on carbon, with the exception of neopentyl chlorosulfate which reacts by a unimolecular carbonium ion mechanism.

It is also noteworthy that the sequence of reactions 2–6, obtained by arranging these in the order of decreasing magnitude of the rate ratio methyl:neopentyl, also represents the order of increasing ionizing power of the medium, and the chlorosulfate hydrolysis fits exactly into this sequence on both accounts. This gives added weight to the above argument.

Activation Parameters

In the series ethyl, *n*-propyl, isobutyl, neopentyl, there is a steady change in both $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, the former increasing in magnitude and the latter becoming more positive (Table III). A plot of $\Delta H^{\ddagger}$ against $\Delta S^{\ddagger}$ is shown in Fig. 1. The slope of the straight line drawn through the points representing the above compounds, but excluding methyl, is 443.4 °K, which is the isokinetic temperature. Since the isokinetic temperature has a value far above the temperature of the experimental, interpretation of the data is free from the uncertainties arising when the isokinetic temperature is close to the experimental range (8). The enthalpy–entropy compensation effect observed in this reaction series is paralleled by the behavior of many other solvolytic reactions, for instance the solvolysis in water of alkyl methanesulfonates and bromides (9*a*). For one member of the series to deviate from this relationship is also not uncommon and in the present could be caused by the greatly reduced steric requirements of the transition state of the methyl case. It is also noteworthy that the neopentyl case falls on the isokinetic line with the alkyl chlorosulfates, methanesulfonates, and bromides (9*a*), even though neopentyl derivatives hydrolyze with rearrangement. Thus neopentyl derivatives seem to provide an exception to the general rule that a change in mechanism along a reaction series should be reflected by a deviation from the isokinetic relationship.

Entropy of Activation as a Criterion of Fragmentation

Further insight into the mechanism of chlorosulfate solvolysis is gained by consideration of the actual magnitudes of the activation parameters. A discussion of activation parameters must consider their dependence on the medium and on the mechanism of reaction. Thus the entropy of activation of solvolytic reactions conducted in aqueous organic solvents becomes rapidly more negative as the water content of the medium decreases (10) and a unimolecular mechanism is in general associated with a more positive entropy of activation, by 20 or more e.u., than a bimolecular reaction (11). The last point is well illustrated in the present series; $\Delta S^{\ddagger}$ for neopentyl chlorosulfate is 20–26 e.u. more positive than for the straight-chain chlorosulfates.

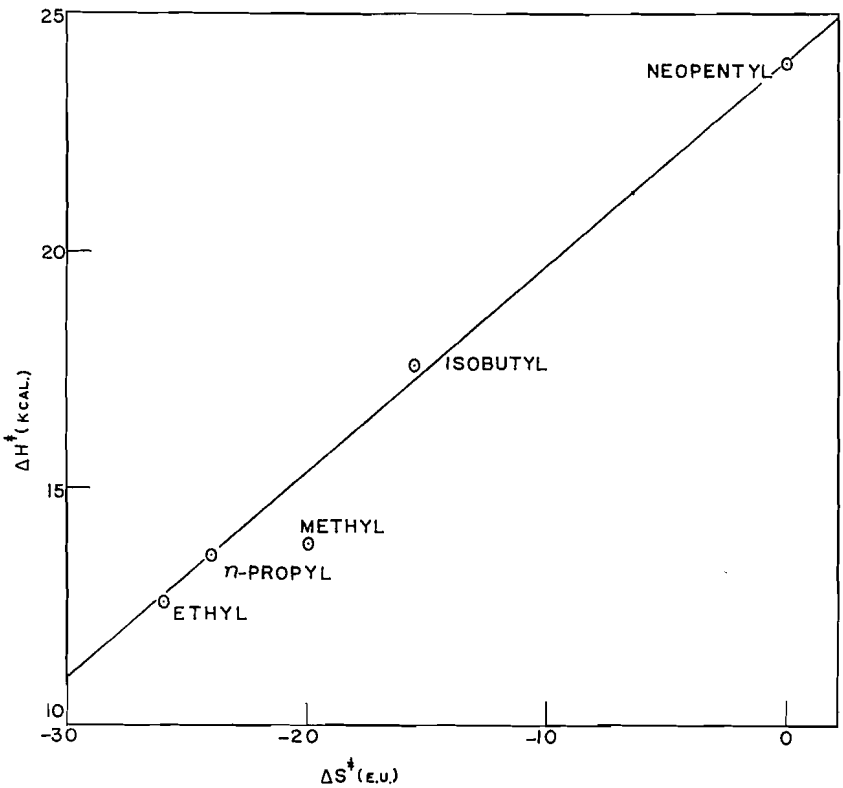

FIG. 1. Plot of $\Delta H^{\ddagger}$ vs. $\Delta S^{\ddagger}$ for solvolysis of chlorosulfates.

Comparison of the rates and activation parameters in chlorosulfate solvolysis with other solvolytic reactions, in the same reaction medium (Table III), shows at first glance that chlorosulfates react considerably faster and that in general lower enthalpies and greater entropies of activation are responsible for this enhanced reactivity. For a more searching comparison heed must be taken that two compared substrates should solvolyze by the same mechanism. It then becomes apparent that chlorosulfate solvolysis is associated with a more positive $\Delta S^{\ddagger}$, by 10–15 e.u. Considering first unimolecular solvolysis, *t*-butyl chloride, *t*-butyl bromide, α-phenylethyl chloride, α-phenylethyl bromide, and benzhydryl chloride all solvolyze with $\Delta S^{\ddagger}$ varying between −11 and −15 e.u., while $\Delta H^{\ddagger}$ varies between 20 and 22 kcal (12). Similarly, isopropyl benzenesulfonate, with $\Delta S^{\ddagger} = -13.3$ e.u. and $\Delta H^{\ddagger} = 22.0$ kcal, reacts by the unimolecular mechanism (13). No data have been found for neopentyl derivatives in this medium. For a comparison with activation parameters in bimolecular solvolysis, fewer data are available in the literature covering the present reaction medium. The solvolysis of a number of sulfonyl chlorides (14) provides comparable data: a typical example is ethane sulfonyl chloride, with $\Delta S^{\ddagger} = -37.4$ e.u. and $\Delta H^{\ddagger} = 12.8$ kcal. It appears then that in unimolecular as well as in bimolecular solvolysis, when $\Delta H^{\ddagger}$ is comparable ($EtOSO_2Cl$ vs. $EtSO_2Cl$) or when the reverse order obtains (neoPeOSO_2Cl vs. *t*-BuCl), chlorosulfates react with a more positive $\Delta S^{\ddagger}$. While this relationship has not been rigorously established, particularly in view of the many factors which can influence entropies of activation (9, 11, 12), yet it seems to be sufficiently well documented to warrant consideration of its possible mechanistic significance.

The relative reactivities, the lyate ion effect and the effect of added nucleophiles (1) in chlorosulfate solvolysis are entirely consistent with a normal solvolytic mechanism, which can be unimolecular or bimolecular, with the leaving group being —OSO_2Cl. On this basis, the transition state, for the unimolecular mechanism, would be as shown in eq. [2]. For comparison, the transition state of solvolysis of alkyl benzene sulfonates is shown in eq. [3], which is chosen due to the similarity of the two structures.

[2] $$R{-}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Cl \rightarrow R{\cdots}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Cl \rightarrow R^+ + {}^-O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Cl$$

[3] $$R{-}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Ar \rightarrow R{\cdots}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Ar \rightarrow R^+ + {}^-O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Ar$$

One would predict a slightly greater charge separation in the chlorosulfate than in the arenesulfonate on account of the electronegative chlorine, though this could be to some extent counteracted by the conjugating ability of the aryl group in the sulfonate. On the whole then, the polarities of the two ground states are rather similar and the same would be expected for the two transition states. Since the differential solvation of initial and transition states is generally accepted (10) as the major factor governing entropies of activation, one would expect both reactions to have similar $\Delta S^{\ddagger}$ values, which is not the case.

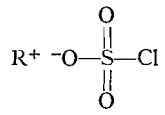
Another transition state may be considered for chlorosulfate solvolysis, one in which carbon–oxygen as well as sulfur–chlorine bond weakening occurs (eq. [4]):

[4] $$R{-}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Cl \rightarrow R{\cdots}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{\cdots}Cl \rightarrow R^+ + SO_3 + Cl^-.$$

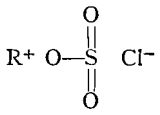
In this transition state there is a greater charge separation and also an incipient sulfur trioxide molecule is forming, to a degree which depends on progress along the reaction coordinate. Both these factors should give rise to an increased solvation of the transition state, and consequently a more negative $\Delta S^{\ddagger}$ compared with the situation in eq. [2]. However, the simultaneous fission of two bonds with formation of three fragments would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

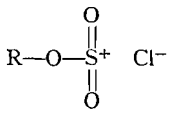
result in an increased $\Delta S^{\ddagger}$ due to the gain of translational, rotational, and vibrational degrees of freedom. The balance of the two effects, a smaller $\Delta S^{\ddagger}$ due to solvation and a larger $\Delta S^{\ddagger}$ due to dissociation, is difficult to estimate a priori. Gas-phase reactions provide a parallel: abnormally high entropies of activation, by 10–20 e.u., are believed to be due to simultaneous rupture of two bonds (15). The fragmentation process in chlorosulfate solvolysis may, therefore, well result in an abnormally large entropy of activation. On this basis the transition state in chlorosulfate solvolysis may be represented by the following resonance structures:



I



II



III

Analogous structures may be written for the bimolecular mechanism. The importance of structures II and III is indicated by the reported (16) relative inertness of alkyl fluorosulfates.[3] That I and II are contributing structures is further suggested by the fact that there are only very few examples of simple secondary chlorosulfate in the literature and that a tertiary chlorosulfate has never been reported.

Application to Other Systems

The hypothesis of the fragmentation process in chlorosulfate solvolysis is germane to the problem of the possible generality of multiple bond fission. The classical S_Ni reaction provides an example of this possibility. For instance, the decomposition of alkyl chlorosulfites and chloroformates to alkyl halides may in theory proceed by alkyl–oxygen fission, by acyl–chlorine fission, or by both modes simultaneously. There is considerable evidence that in inert solvents these processes have a predominantly carbonium ion character (alkyl–oxygen fission) (17), and that in the gas phase a cyclic four-centered, possibly polar, transition state obtains (18). The entropies of activation of these processes appear to be normal, generally ranging between -10 and -20 e.u. A recent study (19) of another S_Ni reaction, the decomposition of aralkyl thiocarbonates ROCOSR′ to RSR′ and CO_2, has provided evidence for simultaneous fission of the alkyl–oxygen and acyl–sulfur bonds, through the observation of specific electronic effects of R and R′ on the rate of reaction. No entropies of activation were reported for the reaction.

The solvolysis of alkyl chloroformates in formic acid appears to be associated with an unusually high $\Delta S^{\ddagger}$: ethyl and isopropyl chloroformates have $\Delta S^{\ddagger}$ values of -1.8 and -0.4 e.u. respectively (20). In contrast formolysis of the corresponding arenesulfonates proceeds with more negative $\Delta S^{\ddagger}$, by 5–15 e.u. (4). It is therefore noteworthy that in the solvolysis of alkyl chloroformates there is evidence of both alkyl–oxygen and acyl–chlorine bond fission (20, 21).

The solvolysis of γ-aminoalkyl halides (IV) yields products of substitution, elimination, cyclization, and fragmentation at the C_β—C_γ bond (22). The proposed mechanism (22) is rate-determining ionization of the C—X bond to give V, followed by fast product-forming steps.

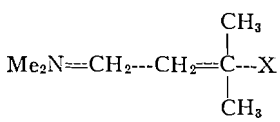
V



VI

[3]*Work is in progress to establish this point on a quantitative basis.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The entropies of activation in 80% ethanol – 20% water, −1.2 e.u. for X = Cl, and 1.6 e.u. for X = Br are 4 e.u. greater than for the corresponding *t*-butyl halides (12*a*, 12*c*). Further, on substitution of the Me_2N group of IV (X = Cl) by Me_2CH, $\Delta S^{\ddagger}$ becomes again 5 e.u. smaller and only products from substitution and elimination are obtained. Now the Me_2N group does not play a role in the transition state by anchimerically assisting ionization of C—X, since there is no rate acceleration compared with the isopropyl analogue. If significance can be attached to a difference in $\Delta S^{\ddagger}$ of only 4–5 e.u., an explanation for the greater $\Delta S^{\ddagger}$ with IV is that in the transition state for solvolysis there is partial C_β—C_γ bond weakening (VI).

The hypothesis that entropies of activation may provide an indication of multiple bond fission in solution processes must be advanced with considerable caution, in view of the intricate nature of the activation process (23) and the many factors which can influence activation parameters. Further entropy data, for S_Ni and other solvolytic processes, are needed and corroboration by other criteria which afford a direct measure of the extent of bond weakening (e.g. isotope effects) is desirable before the validity of this hypothesis can be fully evaluated.

EXPERIMENTAL

Preparation of Chlorosulfates

The chlorosulfates were prepared by a modification of the method described by Binkley (24). Sulfuryl chloride (1 mole) was placed in a three-necked flask equipped with a gas inlet tube, a dropping funnel, and a drying tube. The flask was cooled in a bath of solid carbon dioxide and acetone and the solution agitated by means of a stream of dry nitrogen, which also removed most of the hydrogen chloride produced in the subsequent reaction. The anhydrous alcohol (1 mole) was then added by means of the dropping funnel, over a period of 1 h; in the neopentyl case the alcohol was dissolved in anhydrous ether before addition. At the end of this time the mixture was allowed to warm up to approximately 0 °C. The crude product was then washed three times with ice water, and dried over magnesium sulfate. The products were all purified by repeated fractional distillation under reduced pressure. The chlorosulfates were stable for prolonged periods at 0 °C but at room temperature they gradually decomposed.

The physical properties are shown in Table IV. The infrared spectrum of each compound showed the characteristic absorption bands in the region of 1 190 and 1 410 cm^{-1} due to the —OSO_2Cl group (25); there was no hydroxyl absorption. The nuclear magnetic resonance spectrum of neopentyl chlorosulfate showed only two peaks, one at τ = 8.97, of area 9 units corresponding to the methyl group and one at τ = 5.80, of area 2 units corresponding to the methylene group. This proved that no rearrangement had occurred during the synthesis.

Product Analysis

This was carried out as previously (1), Table V. It was found (vapor-phase chromatography (v.p.c.)) that methyl, *n*-propyl, isobutyl, and neopentyl chlorosulfates yielded methyl, *n*-propyl, isobutyl, and *t*-pentyl alcohol, respectively. No *t*-butyl alcohol was detected in the hydrolysis of isobutyl chlorosulfate. Whether reaction of neopentyl chlorosulfate also yielded some unrearranged neopentyl alcohol could not be determined by v.p.c., since neopentyl alcohol had the same retention time as dioxane under the conditions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

TABLE V

Products of the hydrolysis of chlorosulfates (0.01 *M*) in 10 *M* aqueous dioxane

Chlorosulfate	H_2SO_4 produced (Mole %)	HCl produced (Mole %)	Olefin produced (Mole %)
Methyl	96.8	99.5	—
Ethyl	101.4	97.7	—
n-Propyl	99.4	99.6	—
Isobutyl	99.4	98.3	—
Neopentyl	98.8	98.3	4.5

used. To obtain information on this point a method of estimating a mixture of neopentyl and *t*-pentyl alcohol from their infrared spectra was developed.

The infrared spectrum of *t*-pentyl alcohol in dioxane showed a strong band at 940 cm^{-1} while neopentyl alcohol under the same conditions showed strong absorption at 1 017 cm^{-1}. Infrared spectra of mixtures of these alcohols in varying ratios but with the same total concentration (0.02 *M*) gave a calibration curve of concentration against % absorbance for each alcohol. Three reaction mixtures were then analyzed in this way and showed a total recovery of 88%, 87%, and 90% respectively of *t*-pentyl alcohol and 0% neopentyl alcohol, with an error in estimation of ±5%.

Measurement of Rates

The kinetic data were obtained by the conductivity method already described (1). The data for the lyate ion effect with neopentyl chlorosulfate are as follows:

$[ROSO_2Cl] \times 10^2$ (*M*)	$[NaOH] \times 10^2$ (*M*)	$k \times 10^4$ (25 °C) (s^{-1})
1.00	0.54	0.174
1.00	0.90	0.171
1.00	5.4	0.172
1.02	9.0	0.170
0.50	4.5	0.171
0.52	9.0	0.172

ACKNOWLEDGMENTS

The authors wish to thank Dr. R. E. Robertson for a stimulating discussion and the National Research Council for a Studentship (to J. P. M.) and a grant.

FREE RADICALS BY MASS SPECTROMETRY

XXXII. THERMAL DECOMPOSITION OF CYCLOPENTYL RADICALS[1]

T. F. PALMER[2] AND F. P. LOSSING
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received July 15, 1964

ABSTRACT

At low pressures and elevated temperatures cyclopentyl radicals are found to dissociate mainly by two modes of reaction: about 34% by loss of H atom to form cyclopentene, and about 66% by a C—C bond rupture to form ethylene and allyl radicals. Under the conditions employed no evidence for a third possible mode, the loss of H_2 to form cyclopentenyl radical, could be found. It is estimated that an incidence of 2% of the latter could have been detected.

INTRODUCTION

Three modes have been postulated for the thermal decomposition of cyclopentyl radicals:

[1]

[2] 
[3]

The occurrence of reaction [2] for cyclopentyl radicals produced by abstraction of H from cyclopentane has been observed (1). In later work (2) reaction [3] was proposed, on the basis of the CD_3H/CD_4 ratios found when CD_3 radicals were used as the abstracting species. The occurrence of reaction [2] above 250° has recently been confirmed (3) and a value of 36.9 ± 1 kcal/mole for its activation energy has been obtained. In the same work the occurrence of reaction [1] at about 300° has been proposed.

In the present work the modes of thermal decomposition of cyclopentyl radicals have been investigated, using a low-pressure thermal reactor coupled to a mass spectrometer (4). Although this apparatus is not suitable for accurate measurements of rate parameters, it enables a direct observation to be made on unstable intermediates and their decomposition products. It was thought therefore that a search for allyl and cyclopentenyl radicals, and measurements on the non-radical products of the decomposition of cyclopentyl radicals would provide information on the relative rates of reactions [1]–[3].

EXPERIMENTAL

The cyclopentyl radicals were generated by the thermal decomposition of cyclopentyl methyl nitrite in a fused-silica furnace leading directly to the ionization chamber of a mass spectrometer (4). The purified nitrite was held in a trap immersed in a freezing bath of suitable temperature, and admitted to the reactor through an adjustable stainless-steel valve. Also connected to the reactor was a conventional "leak" backed by a sample-handling system and micromanometer, by which calibration of the sensitivity coefficients for the nitrite and the stable reaction products could be made.

[1]*National Research Council Contribution No. 8143.*
[2]*National Research Council Postdoctorate Fellow, 1960–1962.*

The reactions leading to the formation of cyclopentyl radicals were:

[4] 
[5] 
The partial pressure in the reactor was kept as low as practicable ($\sim 10^{-3}$ mm) to minimize the occurrence of bimolecular radical reactions in the contact time (~ 1 ms) available. No evidence for a significant lifetime for the cyclopentylmethoxy radical could be found even at the lowest temperature (300°) at which the nitrite began to decompose. Evidently reaction [5] occurs very rapidly at this temperature.

A special problem was posed in measuring the ethylene and cyclopentene yields in the presence of the cyclopentyl radical, whose mass spectral contributions at mass 68 and 28 could not be determined. To avoid this difficulty, all analyses were made using an ionizing electron beam of sufficiently low energy that the peaks at *m/e* 68 and 28 contained no contributions from the ionized cyclopentyl radicals. Since under these conditions the sensitivity coefficients are extremely dependent on small changes in ion-source contact potential, it was necessary to perform a calibration *in situ* for each measurement. Each measurement of the peak height of the product at mass 68 and 28 was accompanied by a calibration made by means of additions to the reaction stream of known partial pressures of cyclopentene and ethylene from the sample-handling system. The increase in peak height caused by the known increase in partial pressure of the component could then be used to calculate the equivalent partial pressure of product. This method of calibration was found to be rapid and accurate. A correction of $M^{1/2}$ for molecular flow in the reactor was required in order to express equivalent partial pressures in the reactor in terms of the known partial pressures in the sample-handling system. The reason for this is clear if one considers a component AB entering the reactor at a diffusion rate corresponding to a molecular weight M_{AB}, and dissociating there to A and B, which are then pumped out of the reactor independently at rates corresponding to M_A and M_B. The observed amounts of A and B in the reactor must therefore be multiplied by the ratios $(M_{AB}/M_A)^{1/2}$ and $(M_{AB}/M_B)^{1/2}$ to place them on the same basis as standard gases A and B admitted through the leak from the sample-handling system. The standard gases A and B flow through the leak into the reactor at rates corresponding to M_A and M_B and are pumped away unchanged.

TABLE I

Confirmation of calibration procedure: acetone yield from the thermal decomposition of di-*t*-butyl peroxide (DTBP)

Electron accel. potential (V)	DTBP decomposed (equiv. microns)	Acetone formed (equiv. microns)	Acetone yield % Ac/2DTBP × 100
50.0	24.6	50.0	101.6
12.0	24.6	49.7	101.0
50.0	62.9	127	101.0
11.5	62.9	124	98.6
50.0	107	224	104.7
11.2	107	213	99.5

This assumption of molecular flow, and the method of calibration, were checked by measuring the yield of acetone formed by the thermal decomposition of di-*t*-butyl peroxide. As shown in Table I, the yield of acetone measured, using the low electron energy method, agreed closely with the yield measured using 50 V electrons, and is within ±2% of the theoretical yield. The yield is independent of pressure, showing that no flow interaction occurred between the peroxide and the added acetone standard over the pressure interval employed. The observed amounts of acetone have been corrected by $(146/58)^{1/2}$ to give the values in Table I.

Materials

Cyclopentylmethyl nitrite was prepared from a commercial sample of cyclopentylmethanol by the action of sodium nitrite and dilute sulfuric acid. The nitrite was washed with water, dried over anhydrous sodium sulfite, and purified by repeated distillation at reduced pressure.

RESULTS AND DISCUSSION

Preliminary investigation showed that the major products of the decomposition of cyclopentylmethyl nitrite at 300–800° were NO, formaldehyde, and cyclopentyl radicals, and that the latter decomposed to form ethylene, allyl radicals, cyclopentene, and hydrogen. Small amounts of propylene, bi-allyl, cyclopentane, and bi-cyclopentyl were also detected using higher concentrations of the nitrite. With low energy ionizing electrons used for detection, the parent peak for the cyclopentyl radical (mass 69) rose from zero at 250° to a maximum at about 450°, and then fell with increasing temperature to nearly zero at 708°. No evidence for the formation of cyclopentenyl radical (mass 67) could be found over this temperature range, although it might be expected to be quite stable at these temperatures and contact times.

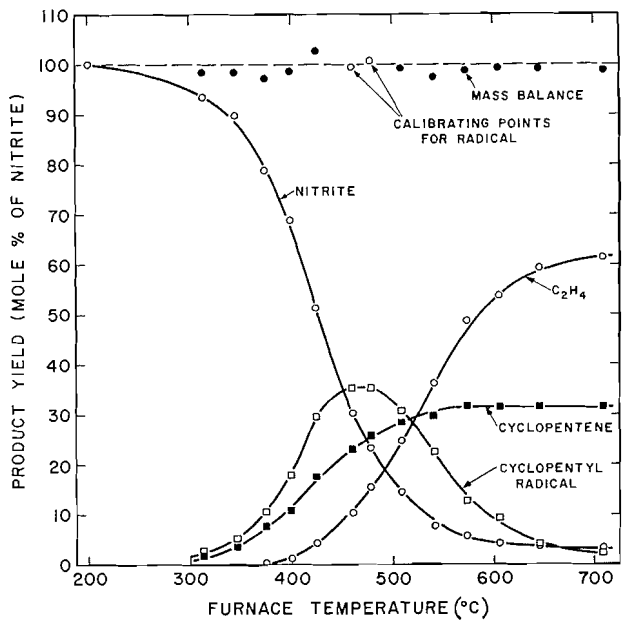

FIG. 1. Product yields in the thermal decomposition of cyclopentylmethyl nitrite.

The extent of decomposition of the nitrite as a function of furnace temperature, and the yields of ethylene, cyclopentene, and cyclopentyl radicals are shown in Fig. 1. It is evident that the nitrite decomposes to give cyclopentyl radicals (reactions [4] and [5]) and that the cyclopentyl radicals decompose subsequently by reaction [1] to give cyclopentene (and a hydrogen atom) and by reaction [2] to give ethylene and an allyl radical. Although allyl radicals were easily detected, the yield was not measured since it would be very nearly equal to that of ethylene. At the partial pressure of nitrite used in this experiment the amounts of cyclopentane and bi-cyclopentyl were too small to be shown in Fig. 1, although they are included in the calculation of mass balance. The cyclopentylmethyl nitrite, ethylene, and cyclopentene were measured by the calibration procedure described above. The sensitivity coefficient for cyclopentyl radicals was derived as follows. At 708°, at which temperature nearly all cyclopentyl radicals were decomposed,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the amounts of ethylene and cyclopentene (and including about 1% made up of cyclopentane and bi-cyclopentyl) amounted to 98% of the nitrite decomposed. It could be assumed consequently that at any temperature:

[original nitrite] − [nitrite decomposed] = [cyclopentyl] + [cyclopentene] + [ethylene] + 2[bi-cyclopentyl] + [cyclopentane].*

Since all these quantities except [cyclopentyl] could be determined by calibrations with standard gases, a solution for the sensitivity coefficient for cyclopentyl could be made at any temperature. For greatest accuracy this was done for the two temperatures (463° and 479°) at which the cyclopentyl concentration was greatest. At these temperatures the cyclopentyl yields were 34.8% and 34.5% respectively of the original nitrite. From the sensitivity coefficient (peak height / partial pressure) derived from the average yield at these two temperatures the observed peak heights for cyclopentyl radical were converted to the radical yield curve shown. The mass balance was found to be 100 ± 2% over the whole temperature range as shown at the top of Fig. 1. Since the radical yield varies from 0% to 35%, the constancy of the mass balance shows that a correct value for the sensitivity coefficient for the radical has been chosen.

These results indicate that at the lower temperatures cyclopentyl radicals dissociate faster by reaction [1] than by reaction [2], but with increasing temperature reaction [2] predominates.† The implication that the activation energy E_1 is less than E_2 is not in accord with estimates from thermochemistry. From ΔH_f(cyclopentane) = −18.46 kcal/mole and ΔH_f(cyclopentene) = 7.87 kcal/mole (5) and ΔH_f(H) = 52.1 kcal/mole, the sum of the two bonds $D(c\text{-}C_5H_9\text{—H}) + D(c\text{-}C_5H_8\text{—H}) = 130.5$ kcal/mole. There seems no reason why $D(c\text{-}C_5H_9\text{—H})$ should be much different from other secondary C—H bonds in alkanes, i.e. 93 kcal/mole at 25 °C (6). $D(c\text{-}C_5H_8\text{—H})$ in cyclopentyl radical is therefore close to 37.5 kcal/mole. The activation energy E_1 will be 37.5 kcal/mole plus the activation energy for the reverse reaction. A lower value for E_1 can be assigned only at the expense of increasing D(C—H) in cyclopentane by a corresponding amount. For example, $E_1 = 28$ kcal/mole (7) would require $D(c\text{-}C_5H_9\text{—H}) = 102.5 + E_{-1}$. Values of 4–5 kcal/mole for E_{-1} in gas phase reactions have been generally found (8), although the reaction of H atoms with olefins in the solid state suggest a lower value of 1.5 kcal/mole (9). Even with this lower value, D(C—H) in cyclopentane would have to be 104 kcal/mole. This seems unreasonably high.

The overall heat of reaction [2] to give C_2H_4 + allyl is about 22 kcal/mole, assuming ΔH_f(allyl) ~ 32 kcal/mole. E_2, presumably corresponding to the initial ring rupture, has, however, been found experimentally to be 37–38 kcal/mole by Gunning and Stock (3) and by Gordon (7). From these considerations it would appear that E_1 should be somewhat larger than E_2. Two possible reasons for the apparent reversal of this order in the present work may be considered. The first is that reaction [1] is accompanied at low temperatures by an abstraction of H by NO formed by the nitrite decomposition:

[6] $$c\text{-}C_5H_9 + NO \rightarrow HNO + c\text{-}C_5H_8.$$

A significant contribution by this reaction seems improbable, however, since [NO] ≈ [cyclopentyl] and even the presumably faster combination and disproportionation reactions of two cyclopentyl radicals are negligibly slow at the low pressures employed in the

*Assuming the cyclopentane to be formed from disproportionation of two cyclopentyl radicals.

†The flattening of the cyclopentene yield curve above 575° suggests that some cyclopentene may be disappearing by a secondary reaction. However, no evidence for products such as cyclopentadiene could be found.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

present experiment. A second possibility is that reaction [1] is considerably accelerated by reaction at the wall. The pressure in the reactor is so low ($\sim 10^{-3}$ mm) that most radicals have several collisions with the wall. Any catalytic activity favoring a C—H split over a C—C split would cause a large increase in k_1/k_2 at the lower furnace temperatures. It is possible therefore that the ratio of k_1/k_2 observed at the highest temperature is also larger than would be observed at higher reaction pressures. With this reservation, the present findings show that at 700°, in a reaction time of around 1 ms some 66% of cyclopentyl radicals decomposing do so by reaction [2], about 34% by reaction [1], and less than 2% by reaction [3].* The uncertainties in contact time and temperature in the present apparatus preclude calculation of the rates on any but a relative basis.

A STUDY OF SOME REACTIONS OF THE CYCLOPENTYL RADICAL

ALVIN S. GORDON
Chemistry Division, Research Department, USNOTS, China Lake, California
Received October 26, 1964

ABSTRACT

The specific rate constant for opening the cyclopentyl radical has been determined to be $10^{14.5}$ exp $-37\,700/RT$ s^{-1}. The energy of activation indicates that any eclipsed pairs of H atoms in the cyclic radical are not de-eclipsed in the activated complex. No evidence for the resulting five-membered linear radical can be found, only evidence for its breakdown products, allyl radical and ethylene.

The disproportionation/combination ratio for methyl and cyclopentyl radicals is about 0.3. The energy of activation for methyl abstracting a hydrogen atom from cyclopentane has been confirmed as about 9.5 kcal/mole.

Cyclopentyl radical also loses a hydrogen atom to form cyclopentene. The kinetic parameters are difficult to obtain because of radical–radical reactions which form cyclopentene. An analysis of the results indicates an energy of activation at least equal to that for opening the cyclopentyl ring.

Evidence is presented to support the view that the cyclopentyl radical loses a molecule of hydrogen to form the resonance-stablized cyclopentenyl radical with an energy of activation close to that for opening the ring, and a pre-exponential factor about 1/10 of that for the opening of the ring.

INTRODUCTION

In a study of cyclopentyl radicals from the Hg-sensitized photolysis of cyclopentane, Gunning and Stock (1) have recently published a value of 36.9 ± 1.4 kcal/mole for the E_{act} for opening the cyclopentyl radical. By use of a different experimental approach, the value found in this work is in excellent agreement. Also, the experiment makes it possible to monitor other reactions of the cyclopentyl radical.

In this study the cyclopentyl radicals are generated via abstraction of H from cyclopentane by methyl radicals.

MATERIALS AND PROCEDURE

Cyclopentane purchased from Phillips Company was at least 99.9% pure. There is a cyclopentene impurity which barely shows above the baseline of our gas chromatography unit at concentrations of cyclopentane used in this work. The acetone is Eastman Spectroscopic Grade with no detectible impurity. Merck acetone-d_6 has a D/D + H = 0.995.

Experiments were made in a 45 cc cylindrical quartz reaction cell set into a furnace with a quartz window. Full intensity medium pressure mercury arc, Hanovia SC-100, was the photolysis source, although the effect of intensity and wavelength were checked by using a filter which filtered linearly starting at 2 900 Å, cutting out about 65% of the 3 130 Å radiation.

Portions of a master mix of acetone and cyclopentane were metered into the reaction vessel to a desired pressure. The mix was photolyzed for a time such that less than 10% reacted. The reacted mixture was transferred to a gas chromatographic unit. Two 5% anthracene on silane columns in tandem were used to separate the constituents. The first column was held at 100 °C which retains the ketones in the products but had no effect on the remaining constituents. These constituents were then separated on the second column which was temperature programmed from −195 to 100 °C. Provision was made so that any fraction could be trapped for identification by a mass spectrometric analysis.

The mass spectrometer was also employed to analyze for hydrogens (H_2, HD, and D_2), and methanes by introducing the sample via a trap of copper wool at 77 °K.

RESULTS AND DISCUSSION

Disproportionation/Combination of Methyl and Cyclopentyl Radicals

The following reaction scheme accounts for the major products at temperatures up to 325 °C.

[1] $$CD_3COCD_3 \xrightarrow{h\nu} 2\dot{C}D_3 + CO$$

[2] $$\dot{C}D_3 + \bigcirc \rightarrow CD_3H + \bigcirc\cdot$$

[3] $$\dot{C}D_3 + CD_3COCD_3 \rightarrow CD_4 + \dot{C}D_2COCD_3$$

[4] $$\bigcirc\cdot + \dot{C}D_3 \rightarrow \bigcirc\!\!\!\!\begin{matrix}CD_3\end{matrix}$$

[5] $$\bigcirc\cdot + \dot{C}D_3 \rightarrow CD_3H + \bigcirc\!\!=$$

As seen in Table I, at temperatures up to about 300° cyclopentyl radical mostly reacts with other radicals since neither C_2H_4 nor H_2 (products of the cyclopentyl radical pyrolysis) appear in the products.

The ratio k_5/k_4 = cyclopentene / methyl cyclopentane is shown in Table II. Up to 220 °C the ratio is a constant ($\simeq 0.3$). At higher temperatures other radicals build up relative to methyl radical and give cyclopentene by disproportionation with cyclopentyl radical. At still higher temperatures, as will be discussed in a later section, cyclopentene is produced by loss of an H atom from a cyclopentyl radical, which rapidly becomes an important source for cyclopentene with increasing temperature.

Abstraction of an H Atom from Cyclopentane by Methyl Radical

The energy of activation for abstraction of H from cyclopentane by methyl radical has previously been published (2) using the method of competitive methyl radical abstraction from cyclopentane and acetone-d_6. In this work the experimental results contain the methane data necessary to determine the E_{act} reported above, as well as the ratio of pre-exponential factors for the methyl abstracting from cyclopentane and from acetone. The Arrhenius plot for the methane data is shown in Fig. 1. From the data, $E_D - E_H = 2.1$ kcal/mole where E_D is the abstraction of D from acetone-d_6 and E_H is the abstraction of H from cyclopentane. Since E_D has been established (3) as 11.6 kcal/mole, $E_H = 9.5$ kcal/mole, in excellent agreement with the previously published value. The ratio of pre-exponential factors $A_H/A_D = 1.2$; the value based on the number of H atoms and D atoms in the two compounds would give $A_H/A_D = 1.7$. The results indicate that the pre-exponential factor for a methyl radical to abstract an H atom is 50% of that for the abstraction of a D atom. Since the volume of a D atom is somewhat smaller than that of an H atom, the results cannot be explained by the cross-sectional area of the attacked atom. The eclipsing of the hydrogen atoms in the cyclic compound and the position of D atoms α to the carbonyl group are probably unimportant, since McNesby and Gordon (4) studied the abstraction of H and D from 2,2,3,3-butane-d_4 by methyl radicals and reported that the pre-exponential factor for abstraction is also about 50% higher for D than H. The writer is not able to offer any explanation for the pre-exponential ratio.

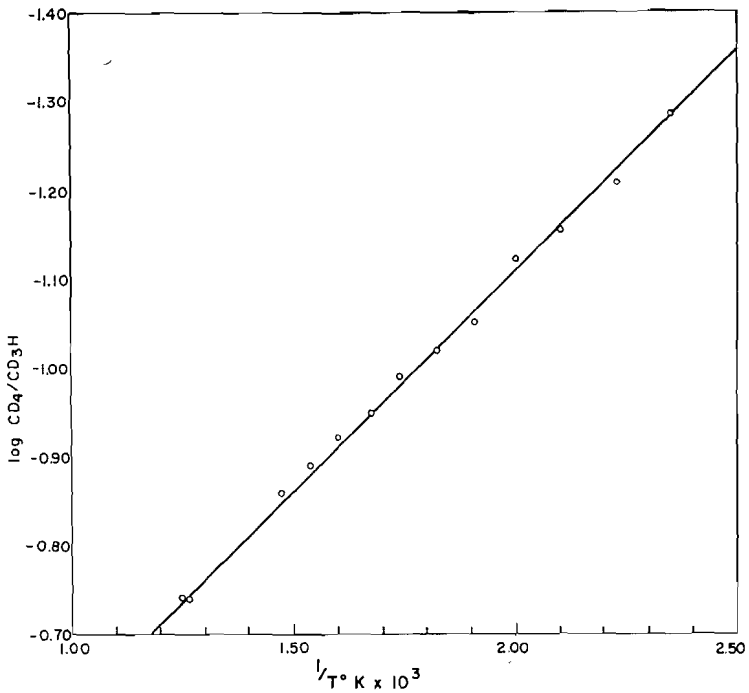

FIG. 1. Arrhenius plot for competitive abstraction of D from acetone-d_6 and H from cyclopentane.

Opening of the Cyclopentyl Radical

Starting at about 300° the cyclopentyl radical decomposes to an allyl radical and ethylene.

[6]  $\rightarrow \overline{\text{CH}_2\text{CHCH}_2} + \text{C}_2\text{H}_4.$

The products of the reaction never contain evidence that a linear C_5 pentenyl radical existed long enough to be stabilized to form hexene-1 by addition of a methyl radical, or to form pentene-1 by abstraction of H. Thus we may conclude that at temperatures where the cyclopentyl radical opens, the resultant pentenyl radical decomposes very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

rapidly compared to the cyclopentyl radical breaking a C—C bond. The most likely reason for the above behavior is that the activated complex for decomposing the linear pentenyl radical has a portion of the resonance energy of the allyl radical; the energy of activation for decomposition is lowered by the amount of resonance energy in the complex.

The kinetic parameters for the opening of the cyclopentyl radical may be monitored by reactions [2], [4], and [6]. Using acetone-d_6 as the source for methyl radicals:

[I] $$r_6 = \frac{d[C_2H_4]}{dt} = k_6\left[\bigcirc\cdot\right]$$

[II] $$r_4 = \frac{d\left[\bigcirc CD_3\right]}{dt} = k_4 \left[\bigcirc\right][\dot{C}D_3]$$

[III] $$r_2 = \frac{d[CD_3H]}{dt} = k_2[\dot{C}D_3]\left[\bigcirc\right].$$

The photolyses are carried to small percentage decomposition and r_2, r_4, and r_6 do not vary with time. Under this condition:

[IV] $$\frac{r_2 r_6}{r_4\left[\bigcirc\right]} = \frac{k_2 k_6}{k_4}.$$

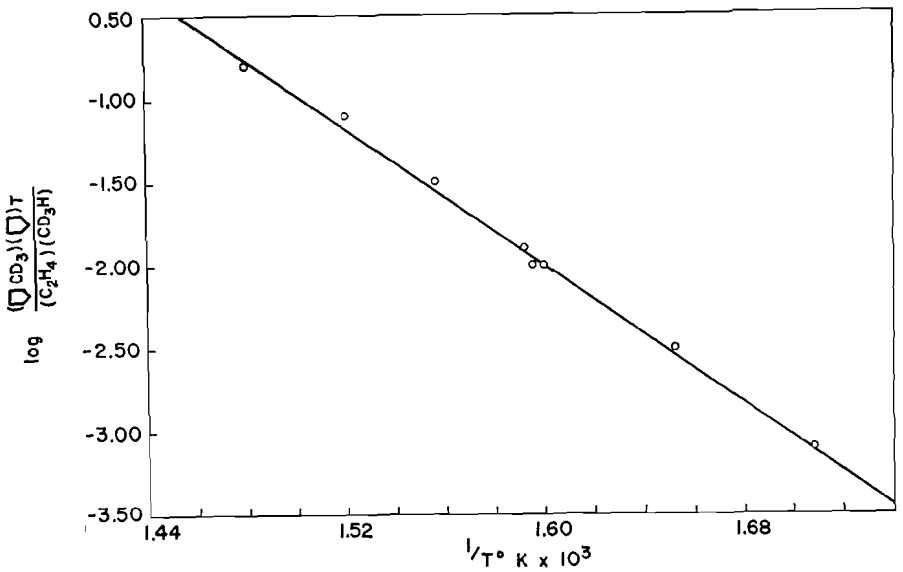

FIG. 2. Arrhenius plot for monitoring the opening of the cyclopentyl radical. T is the reaction time in seconds.

All the rates which determine the right-hand side of eq. [IV] were obtained from the results reported in Table I. The resulting ratio has been plotted in an Arrhenius plot (Fig. 2). From the slope the overall energy of activation for $E_6 + E_2 - E_4$ is determined to be 45.3 kcal/mole with a standard deviation of 1.4 kcal/mole. Since $E_4 = 0$ and $E_2 =$ 9.5 kcal/mole, $E_6 = 37.7$ kcal/mole in excellent agreement with Gunning and Stock (1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The overall pre-exponential factor is

$$A_0 = \frac{A_2 A_6}{A_4} = 10^{13.5}.$$

Trotman-Dickenson and Steacie (6) report that the pre-exponential factor for the methyl radical abstraction of cyclopentane is about 10^{-2} of that for methyl radical combination. The combination of a methyl radical and a cyclopentyl radical is probably less favorable than the combination of two methyls, a relative factor of about 10^{-1} is considered to be reasonable and leads to a value for A_6 of $10^{14.5}$, consistent with the pre-exponential factors of many first order processes.

Loss of H Atom from Cyclopentyl Radical

It is possible, in principle, to monitor the loss of an H atom from cyclopentyl radical,

[7] 
[6] 
by measuring the products from competitive reactions [6] and [7]. Both cyclopentene and ethylene may be measured with good precision from our gas chromatogram records. The amount of cyclopentene may be corrected for the cyclopentene formed in the disproportionation reaction of methyl and cyclopentyl radicals by the methyl cyclopentane formed in the addition reaction of the same radicals. These corrected cyclopentene/ethylene ratios, when plotted in an Arrhenius graph (Fig. 3), are seen to increase with temperature from 300° to 400° and then remain constant to 445°.

The author has indicated in private communication (1, 7) that the low temperature slope indicated the E_{act} for reaction [7] to be as low as 28 kcal/mole. Based on thermodynamic values for the heat of formation for cyclopentane and for cyclopentene, with any realistic value for the C—H bond strength in cyclopentane, Palmer and Lossing (7) have shown clearly that this value is much too low. The products in Table I show an interesting trend for the hydrogen and cyclopentane. At temperatures up to 268° only small amounts of hydrogen appear in the products, probably associated with excited molecule reactions. Although there is essentially no hydrogen at 268°, substantial amounts of cyclopentene (which have been corrected for disproportionation of methyl and cyclopentyl radicals) appear in the product. The cyclopentene cannot be formed from loss of H from cyclopentyl radicals, since no hydrogen is present. The only reasonable source for the cyclopentene is via disproportionation of cyclopentyl with cyclopentyl. Above 300° H atoms, shown by the products H_2 and HD, and allyl radicals, shown by the production of ethylene from reaction [6], also participate in disproportionation reactions leading to formation of cyclopentene. Examination of the CD_3H/CD_4 ratios indicates that even at the highest temperatures, CD_3H is 85% of the total methane. Thus the rate of formation of the methanes is a good indicator of the rate of formation of cyclopentyl radicals. Against the above background the results in Table I show that methyl and cyclopentyl radicals decrease in steady-state concentration with increasing temperature since the rate of methyl cyclopentane is quite insignificant by 400 °C. Similarly the steady state concentration of H atoms probably follows the same trend. However, the steady state concentration of allyl radical, which is resonance stabilized, increases with temperature, as can

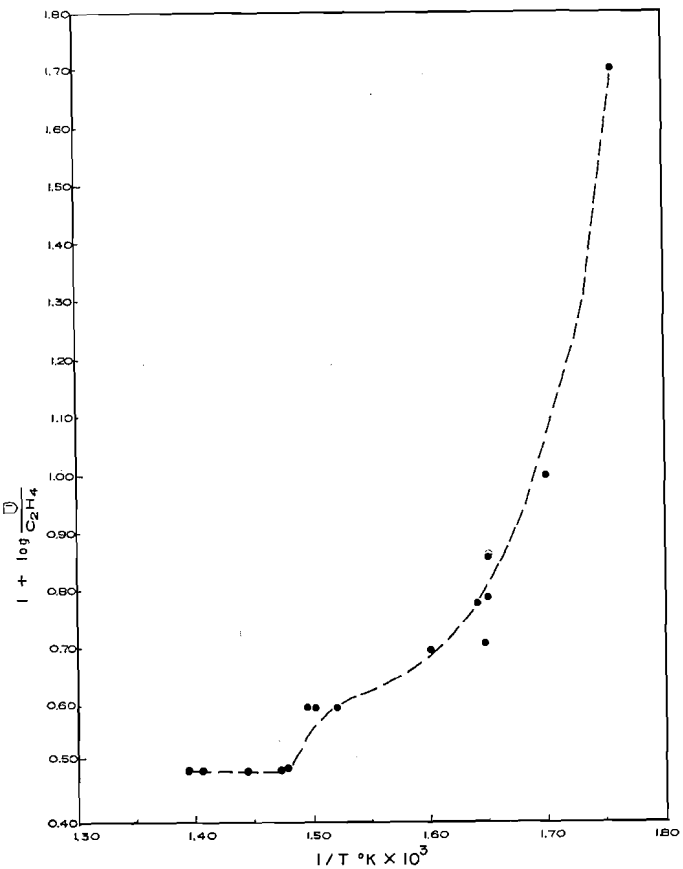

FIG. 3. Arrhenius plot for loss of H atom from the cyclopentyl radical.

be seen by the increasing rate of formation of 1.5 hexadiene, which results from the combination of two allyl radicals. Allyl cyclopentane, from the combination of allyl and cyclopentyl radicals, also increases with temperature until between 370 and 385°, and then decreases. Since the allyl radical is probably the radical of highest steady state concentration in this higher temperature range, the disproportionation formation of cyclopentene from allyl and cyclopentyl radicals also increases to 370–385° and then decreases. The rate of hydrogen (H_2 + HD) relative to the rate of formation of cyclopentene, agrees with the above analysis. The formation of hydrogen will be discussed in the next section. If we assume that the H atoms from reaction [7] will abstract H and D, then the rate of hydrogens should equal the rate of cyclopentene. The results in Table I show that the cyclopentene is always greater than the hydrogen, and that the discrepancy decreases with temperature. The results above 400 °C are probably more correct than the results at lower temperatures, and the energy of activation for reaction [7] is at least equal to 38 kcal/mole.

Loss of Molecular Hydrogen from the Cyclopentyl Radical

Gordon and Smith (8) have reported that molecular hydrogen could be eliminated from a hydrocarbon radical if an allylic radical results. According to the postulated reaction,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

cyclopentyl radical could lose molecular hydrogen to form cyclopentenyl radical. The possibility for this reaction has been surveyed over a temperature range, and evidence will be presented below which provides support for the reaction.

In a mix of acetone-d_6 and cyclopentane, the hydrogens and methanes were analyzed for various deuterium marking and rate of formation as a function of temperature. The results in Table I show that starting at 300 °C the rate of total hydrogens (HD and H_2) formation progressively increases as a function of temperature, and at 350° is 10% of the methanes.

*$\lambda > 3\,000$ Å; low flux relative to full intensity of mercury arc.

The H_2/HD ratios are considerably larger than the CD_3H/CD_4 ratios generated in the same media, as may be seen in Table III. In unreported work on H atoms and methyl-d_3 radicals in the same media (9) it has been noted that the two species show the same difference in energies of activation for abstracting H and D; however, the H_2/HD ratios from the abstraction reactions may be as much as 1.5 times the corresponding CD_3H/CD_4 ratios. The H_2/HD ratios in Table III are 2.5 to 3.0 times the corresponding CD_3H/CD_4 ratios, suggesting that molecular hydrogen may be formed without intermediate formation of H atoms.

Time of reaction does not have a large effect on the ratios of H_2/HD or CD_3H/CD_4 reported in Table III. The ratios of hydrogens are not as precise as the methane ratios since comparatively small quantities of HD appear in the products. Errors from small quantities of HD from excited molecule processes cause significant errors in the amount of HD. These errors are reflected in the calculated molecular hydrogen / ethylene ratios in Table IV.

Figure 4 shows the Arrhenius plot of the H_2/HD ratios and the CD_3H/CD_4 ratios. If only H atoms were involved, as previously noted, two parallel lines would result. The CD_3H/CD_4 ratios are well behaved, but the H_2/HD ratios may be interpreted as due to

H atoms as well as H_2 being introduced into the medium. The maximum in the H_2/HD ratio may be interpreted as resulting from a new source of H atoms at higher temperatures and increasingly important with increasing temperature. The new sources could be due to the radical reactions:

[8] $$\overline{CH_2CHCH_2} \rightarrow CH_2{=}C{=}CH_2 + H$$

[9]  + H.

If molecular hydrogen is eliminated from the cyclopentyl radical, then evidence for the cyclopentenyl radical should be seen in the products. Methyl cyclopentene is identified as such a product. However, it could be argued that the product arose from methyl radical addition to cyclopentene with subsequent elimination of an H atom from the radical. The appearance of methyl cyclopentene when only relatively small amounts of cyclopentene appear argues against the latter interpretation. Cyclopentene-d_1 is also identified in the product, and this is a strong argument that cyclopentenyl radical is present because there are no free D atoms in the reaction media; the only D in the product is that abstracted from acetone-d_6. The cyclopentenyl radical can be formed by abstraction of one of the allylic hydrogens in the cyclopentene as well as by the elimination of molecular hydrogen from the cyclopentyl radical.

An experiment to choose between the two possibilities was performed at 475 °C by generating the smallest quantity of cyclopentene that could be reliably measured. A mix of 1 cyclopentane to 3 acetone-d_6 was employed in the reaction so that the chance to form cyclopentene-d_1 by abstraction was enhanced. The gas chromatographic cut of the cyclopentene product has a small amount of cyclopentane impurity, arising from the large cyclopentane peak preceding the cyclopentene peak. To maximize the accuracy of the analysis for cyclopentene-d_1, the mass spectrometer was calibrated with pure samples of cyclopentene and cyclopentane just prior to the analysis of the gas chromatographic cut. The reaction mix consisted of 28.9 μmoles of cyclopentane. CD_3H (0.2 μmole) was formed and thus the same number of μmoles of cyclopentane are attacked. It is realistic to assume that the energy of activation of H abstracted from cyclopentene is not more than 4 kcal/mole more favorable than the abstraction of H from cyclopentane. Bearing in mind that there are 4 allylic H atoms in cyclopentene which can be abstracted to form the cyclopentenyl radical as against 10 H atoms in cyclopentane which can be abstracted to form cyclopentyl radical, then the Arrhenius calculation indicates that the H atom in cyclopentene should be abstracted five times as rapidly as the H atom in cyclopentane. Since cyclopentene is formed during the reaction, its average concentration is only one-half of the final concentration and, thus, the ratio of the rates of attack on cyclopentene and cyclopentane during the time interval is 2.5. Since 0.7% of the cyclopentane is attacked, 1.8% of the cyclopentene product should be attacked, to form cyclopentenyl radical. Experimentally 1.4% of cyclopentene-d_1 is found in the cyclopentene product.

The energy of activation for methyl radical attack on an H atom bound to carbon increases with increasing C—H bond strength even though the reactions are all exothermic. For a resonance stabilized radical the reactions are endothermic for attack on saturated compounds and the energy of activation for abstraction should be ordered the same way with bond strengths as for the methyl radical; the difference in the energies of activation for abstraction should be at least as large as that for methyl radical. The ratio of pre-exponential factors for abstractions should be quite independent of the radical, and the relative rates of abstraction have been taken to be independent of the radical. Based on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the CD_3 radical attack, the abstraction of H atom is about twice the rate for D atom abstraction. Thus, about 4.2% of the cyclopentene has been formed by abstraction, which is more than twice the calculated cyclopentenyl radical that could be formed from the cyclopentene. Also the rate of abstraction of the resonance stabilized cyclopentenyl radical is less than that for methyl radical and radical–radical processes are important in removing the cyclopentenyl radical, e.g. allyl radical steady state concentration has been noted to increase with temperature, while methyl and cyclopentyl decrease. Thus only a fraction of the calculated 1.8% cyclopentenyl radical formed from cyclopentene would abstract H or D to re-form cyclopentene.

The normal experimental errors, including the analytical error and the lack of temperature equilibration in the reaction vessel because of the small reaction time, cannot provide an escape from the conclusion that very little of the cyclopentene-d_1 results from cyclopentenyl radical generated from cyclopentene.

The molecular hydrogen is monitored from the HD concentration, since it must form from a free H atom abstracting a D atom from acetone-d_6; the H_2 which is formed by the concurrent abstraction of H atom abstracting an H atom from cyclopentane is calculated from the CD_3H/CD_4 ratio at the same temperature multiplied by a factor. As previously mentioned, the H_2/HD ratio could be as much as 1.5 times the corresponding CD_3H/CD_4 ratio. The difference between the H_2 calculated above and the total H_2 found is taken to be molecularly eliminated.

Two reactions may be used to monitor the molecular elimination process:

[10] 
[6] 
and $k_{10}/k_6 = H_2/C_2H_4$.

The resulting ratios are shown in Table IV over a temperature range. In one column the corrected H_2/C_2H_4 ratios are calculated assuming the H_2/HD ratios are 1.5 times the CD_3H/CD_4 ratios, and in the other column that the ratio of the ratios is unity. It may be seen that for both columns there is no trend in the ratio with temperature, suggesting that the E_{act} for molecular H_2 elimination is 35–40 kcal/mole, and the pre-exponential factor about 10% that for the opening of the cyclopentyl radical, or about $10^{13.5}$.

The large amounts of molecular hydrogen formed relative to the formation of ethylene may result from the eclipsing of the hydrogen on the carbon atoms α and β to the carbon atom with the odd electron. The hydrogen atoms are held in excellent position to form a molecule of H_2.*

PYROLYSIS OF CYCLOPENTANE

Gunning and Stock (1) report that cyclopentane pyrolyzes appreciably in 240 min at temperatures starting at 350 °C, and a concentration of 5.6×10^{-3} moles/l. Our reactions were done in 8 min or less and at a pressure of about 1×10^{-3} moles/l, except for one run of 1 h at 350° with filtered light. The product distribution for the long-time runs were

**Note added in proof: Palmer and Lossing (7) do not see any evidence of cyclopentenyl radical from the pyrolysis of cyclopentyl methyl nitrite at low pressures.*

The arguments for cyclopentenyl radical in this work are based on indirect evidence. The evidence against its appearance is direct but may be due to the special conditions of the work. For example, if cyclopentyl radical is the homogeneous source for ethylene and cyclopentene, the amounts of these products should increase with temperature, possibly at different rates. Since the experimental distribution of products does not conform to the prediction, it may be determined by the hot wall of the reactor.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

quite in line with the short-time runs, although it is possible that some of the products were formed in pyrolysis.

Cyclopentane was pyrolyzed for 10 min over a temperature range at the pressure employed in this work. Up to 475 °C, no hydrogen was noted above the very small background hydrogen seen at low temperatures. Above this temperature hydrogen shows in the products in increasing amounts. At 520 °C the rate of production of ethylene from cyclopentane pyrolysis is about 5% of the rate of ethylene formed in the photolysis of the 1:1 acetone–cyclopentane mix at the same partial pressure of cyclopentane. In this work experiments involving hydrocarbon products were performed below 450°, and experiments with the marked hydrogens and marked methanes, at or below 475°, so that pyrolysis of the cyclopentane does not cloud the interpretation of the results.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to Joseph H. Johnson for performing the experiments, and to Mrs. Helen R. Young for reducing the data.

CARBON-13 ISOTOPE EFFECTS IN SYSTEMS CONTAINING CARBON DIOXIDE, BICARBONATE, CARBONATE, AND METAL IONS

H. G. THODE, M. SHIMA, C. E. REES, AND K. V. KRISHNAMURTY
McMaster University, Hamilton, Ontario

Received October 19, 1964

ABSTRACT

The fractionation of ^{13}C between $CO_2(g)$ and $CO_3^{=}$--$HCO_3^{-}(aq)$ in solution has been studied in single stage experiments using carbonic anhydrase to catalyze the hydration of CO_2. Added metal ions, pH of the equilibrium mixture, and temperature are found to play important roles in the overall fractionation process. Theoretical evaluation of the $^{13}CO_2(g)$--$^{12}CO_3^{=}(aq)$ equilibrium constant (K_2) has been made using the most recent spectroscopic data on the exchanging species. The variation of the equilibrium constant K_2 with temperature has been calculated for each 25 deg interval from 0 to 975 °C with the help of the McMaster University IBM 7040 computer. It is shown that the overall ^{13}C fractionation in the system may be treated as contributions due mainly to three exchange equilibria whereby $^{13}CO_2(g)$ independently exchanges with $^{12}CO_2(aq)$, $H^{12}CO_3^{-}(aq)$, and $^{12}CO_3^{=}(aq)$, the corresponding equilibrium constants being K_0, K_1, and K_2 respectively. The best fit values for the equilibrium constants are $K_0 = 1.0009$, $K_1 = 1.0077$, and $K_2 \geqslant 1.013$, indicating the order $K_0 < K_1 < K_2$.

INTRODUCTION

The fractionation of carbon-13 between gaseous carbon dioxide and solution carbon species such as $CO_2(aq)$, HCO_3^{-} $CO_3^{=}$, has been of considerable interest since the early thirties when Urey and his co-workers (1–4) showed that carbon-13 enrichment can be achieved via the following exchange reactions:

[1] $$^{13}CO_2(g) + {}^{12}CO_2(aq) \rightleftharpoons {}^{12}CO_2(g) + {}^{13}CO_2(aq),\ K_0;$$

[2] $$^{13}CO_2(g) + H^{12}CO_3^{-}(aq) \rightleftharpoons {}^{12}CO_2(g) + H^{13}CO_3^{-}(aq),\ K_1;$$

[3] $$^{13}CO_2(g) + {}^{12}CO_3^{=}(aq) \rightleftharpoons {}^{12}CO_2(g) + {}^{13}CO_3^{=}(aq),\ K_2.$$

The exchange studies reported until now make use of two phase gas–liquid column experiments and the single stage separation factor α is obtained from the familiar expression:

[4] $$\alpha^k = \frac{n/(1-n)_{\text{bottom}}}{N/(1-N)_{\text{top}}},$$

where k is the number of theoretical plates and n and N are the mole fractions of carbon-13 in solution and gas phase respectively. Apparently no attempt is made to obtain α independently from single stage equilibrium experiments. It is, however, shown in this study that α can be related to the individual equilibrium constants K_0, K_1, and K_2.

Among the numerous experimental problems the most formidable one perhaps is the slowness of the hydration reaction:

[5] $$CO_2 + H_2O \rightleftharpoons [H_2CO_3] \rightleftharpoons CO_2 + H_2O.$$

Urey, Aten, and Keston (2), in their pioneer column experiments, demonstrated that the hydration reaction [5], in fact, can be catalyzed enzymatically using carbonic anhydrase which was just then discovered by Meldrum and Roughton (5). The enzyme used was a crude solution of bovine carbonic anhydrase and the results were not encouraging. Interest in the use of enzyme-catalyzed CO_2 hydration as a means of isotope enrichment was revived when Scott and Mendive (6) succeeded in preparing carbonic anhydrase in

a pure crystalline form. Hawkings, Graham, Harkness, and Thode (7) used this preparation of the enzyme in their study of oxygen-18 enrichment in the hydration reaction:

[6] $$\tfrac{1}{2}C^{16}O_2 + H_2{}^{18}O \rightleftharpoons \tfrac{1}{2}C^{18}O_2 + H_2{}^{16}O.$$

The problem was reopened with a view to studying it from two directions: (i) a theoretical evaluation of the equilibrium constants K_0, K_1, and K_2 using more recent spectroscopic data on the exchanging species and (ii) experimental determination of the equilibrium constants from single stage fractionation experiments using carbonic anhydrase to speed up isotopic exchange

THEORY AND CALCULATIONS

For the isotope exchange reaction:

$$aA_1 + bB_2 = aA_2 + bB_1,$$

it may be shown (4, 8) that the equilibrium constant may be expressed in terms of ratios of partition functions,

$$K_{eq} = \left(\frac{Q_{A_2}}{Q_{A_1}}\right)^a \Big/ \left(\frac{Q_{B_2}}{Q_{B_1}}\right)^b$$

and that

[7] $$\frac{Q_2}{Q_1} = \prod_i^{3n-6} \left(\frac{u_{2i}}{u_{1i}}\right)\left(\frac{e^{-u_{2i}/2}}{e^{-u_{1i}/2}}\right)\left(\frac{1 - e^{-u_{1i}}}{1 - e^{-u_{2i}}}\right),$$

where $u_i = h\nu_i/kT$ and ν_i is the i-th fundamental vibrational frequency of the molecule. The use of eq. [7] implies a number of assumptions, but since calculations are usually made by employing approximate versions of this equation, when it is used in the form quoted above it will be referred to as the "exact" expression for the ratio of partition functions.

One of the main assumptions in the derivation of [7] is that the vibrations of molecules are harmonic. The approximation is not greatly in error when considering the ratios of partition functions for isotopic molecules, provided the observed fundamental frequencies are used rather than the zero order frequencies, and that the temperature is low enough so that only low lying vibrational levels have appreciable populations. Hulston (9) has shown how anharmonicity corrections can be of significance at high temperatures.

For the majority of the molecules, only the observed fundamentals are available. In the case of CO_2(g) the anharmonicity constants have been determined, but since the corresponding information has not been reported for the $CO_3^=$ ion or CO_2(aq), calculations have been performed using only the observed frequencies rather than applying corrections to only one member of a pair involved in exchange. It has been suggested (10) that the procedure will minimize the errors involved.

Several approximations (4, 7, 25, 26) exist for expression [7], the most widely used being those of Urey (4) and Bigeleisen (8) which may be written:

[8] $$\ln (Q_2/Q_1) = \sum_i^{3n-6} \ln \frac{u_{2i}}{u_{1i}} + \sum_i^{3n-6} \delta_i \coth x_i,$$

where $$x_i = \frac{u_{1i} + u_{2i}}{4} \quad \text{and} \quad \delta_i = \frac{u_{1i} - u_{2i}}{2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and

$$[9] \qquad Q_2/Q_1 = 1 + \sum_i^{3n-6} G(u_i)\,\Delta u_i,$$

where

$$G(u_i) = \frac{1}{2} - \frac{1}{u_{2i}} + \frac{1}{e^{u_{1i}} - 1}$$

$$\Delta u_i = u_{1i} - u_{2i}.$$

While Bigeleisen's expression [9] is somewhat more convenient for purposes of computation, especially in view of the fact that values of the function $G(u)$ are tabulated (8), Urey's expression is, in fact, a more accurate approximation. Both expressions involve power series expansions in terms of a Δ_i, a number proportional to $(\nu_{1i} - \nu_{2i})$ the frequency shift, in the i-th fundamental frequency of the molecule, caused by isotopic substitution, and normally these expressions are terminated at the first-order term in Δ_i. However, in the logarithmic expansion developed by Urey, the term in Δ^2 has a zero coefficient so that the errors involved are due to terms in Δ^3 and higher, while the expansion developed by Bigeleisen has a non-zero term in Δ^2.

To demonstrate the improved accuracy of the Urey expression over the more generally used one due to Bigeleisen a sample set of calculations has been performed for the exchange reaction [3] and K_2 has been evaluated in three different ways, using expressions [7], [8], and [9]. The results of the calculations are shown in Table I.

TABLE I

Calculation of partition function ratios by the three main methods

25 °C	Exact	Urey	Bigeleisen
$Q(^{13}CO_3^=)/Q(^{12}CO_3^=)$	1.1926	1.1926	1.1750
$Q(^{13}CO_2)/Q(^{12}CO_2)$	1.1837	1.1837	1.1678
K_2	1.0075	1.0075	1.0062

In all further calculations reported below, the exact method of evaluation has been employed, using the computer program developed by Hulston (9).

Frequency Assignments for Gaseous Carbon Dioxide, $CO_2(g)$

The fundamental frequencies used in the calculations are shown in Table II and are those collected by Wentink (11). Estimates of anharmonicity constants have been made for both $^{12}CO_2$ and $^{13}CO_2$ but were not used, for the reasons discussed above.

Frequency Assignments for Dissolved Carbon Dioxide, $CO_2(aq)$

Jones and McLaren (12) measured the value of ν_3 for $^{12}CO_2$ dissolved in water. There are no experimental values available for ν_1 and ν_2 under the same conditions since ν_1 is not active in the infrared and presumably ν_2 was too low to measure on the instrument used by Jones and McLaren. ν_1 and ν_2 were estimated by assuming them to be displaced from the gaseous $^{12}CO_2$ values by the same fractional amount as in ν_3. The values for ν_1, ν_2, ν_3, for dissolved $^{13}CO_2$ were estimated by assuming the same fractional isotope shifts as for gaseous $^{13}CO_2$. These frequencies are listed in Table II.

Frequency Assignments for the Carbonate Ion, $CO_3^=$

For $^{12}CO_3^=$ the frequencies quoted by Kujumzelis (13) were used, and the $^{13}CO_3^=$ frequencies were calculated using the orbital valence force field (o.v.f.f.) treatment of Heath and Linnett (14). Both sets of frequencies are listed in Table II.

TABLE II

Vibrational frequency assignments for CO_2 and $CO_3^=$

Molecule	Frequency* (cm^{-1})			
	ν_1	ν_2	ν_3	ν_4
$^{12}CO_2$(g)	1 342.86	667.30 (2)	2 349.30	
$^{13}CO_2$(g)	1 344.66	648.65 (2)	2 283.46	
$^{12}CO_2$(aq)	1 338.70	665.20 (2)	2 342.00	
$^{13}CO_2$(aq)	1 340.49	646.61 (2)	2 276.37	
$^{12}CO_3^=$	1 063.00	1 415.00	680.00 (2)	879.00 (2)
$^{13}CO_3^=$	1 063.00	1 375.75	677.49 (2)	851.38 (2)

Degeneracy indicated in parentheses.
*Although the quoted frequencies are not by any means accurate to the degree implied by the quoted values, the computer program was designed to accommodate two places of decimals in the frequencies, and the numbers quoted above were placed straight into the expression.

Frequency Assignments for the Bicarbonate Ion, HCO_3^-

The only frequency assignments available for the bicarbonate are due to Duval, Duval, and Le Comte (15) who studied the infrared absorption spectra by the pellet method for the bicarbonates of ammonium, sodium, potassium, rubidium, and cesium. It is not possible to determine the fundamental frequencies of the ionic species from this work and since further, a force constant analysis on a XYZ_2 type molecule is difficult, no attempt was made to estimate partition function ratios in this case.

Results of Calculations

The partition function ratios for the carbonate ion and gaseous and dissolved carbon dioxide are presented in Table III together with the equilibrium constants for the exchange between $CO_3^=$ and CO_2(g) and for that between CO_2(g) and CO_2(aq).

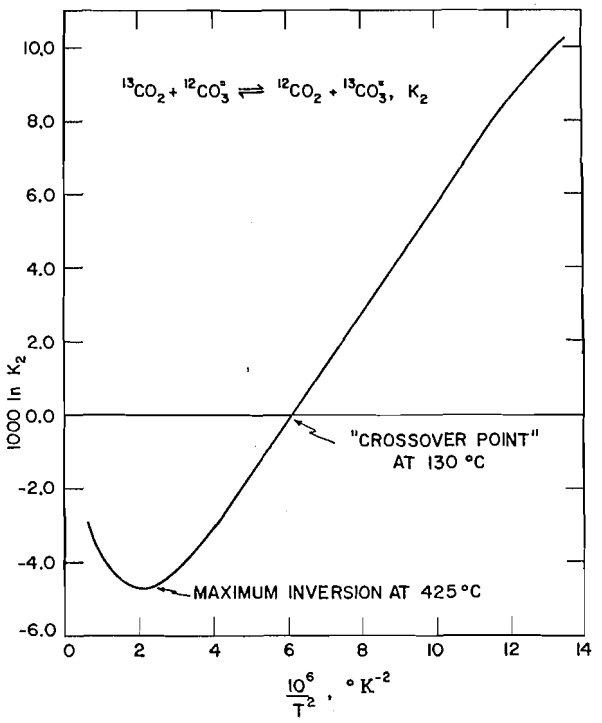

FIG. 1. Calculated temperature dependence of equilibrium isotope effect (K_2). Calculations made on McMaster University IBM 7040 Computer.

Figure 1 shows the wide temperature range behavior of K_2. In accordance with theory there is an extensive linear region in the curve and the high temperature limit for K_2 unity. Of particular interest is the fact that the equilibrium constant for this exchange undergoes inversion, is greater than unity at low temperatures and approaches unity from below at high temperatures. The "cross-over point" is 130 °C and the maximum inversion corresponding to the minimum on the curve occurs at 425 °C.

EXPERIMENTAL

A. Materials

The water used in this study was from Lake Ontario and distilled twice over $KMnO_4$. Both Na_2CO_3 (anhydrous) and $NaHCO_3$, as well as other chemicals, are of reagent grade purity. Pure crystalline bovine carbonic anhydrase was supplied to this laboratory by Professor D. A. Scott nearly 22 years ago and found to be still active as an enzyme. Stock solutions of carbonic anhydrase were prepared as and when needed by dissolving 2.16 mg of the crystalline enzyme in 1.00 ml of distilled water and 1.00 ml of 0.08% peptone solution. A working solution of the enzyme was made by diluting 0.50 ml of the stock solution with 12.25 ml of 0.08% peptone solution and 12.25 ml of water to give a concentration of 21.6 μg/ml carbonic anhydrase in 0.04% peptone solution. The 0.08% peptone nutrient solutions were prepared by dissolving 0.2 g each of the proteose–peptones in 250 ml of water. The proteose–peptones, Nos. 1, 2, 3, 4, and bactopeptone were supplied by Difco Laboratories, Inc., Detroit, Michigan.

B. Apparatus

Two different experimental procedures (I and II) were employed in the determination of the equilibrium constants.

I. Normal carbon dioxide of known isotopic composition was allowed to equilibrate with solutions of known carbonate concentration in a 60 ml round-bottom flask with a ground glass attached rotatable mixing sidearm for transfer of carbonic anhydrase solutions. The flask was thermostated while the admitted CO_2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

attained isotopic equilibrium with solution species. The gas phase was removed from the flask in the usual way as described under Procedure.

II. The apparatus used in the second procedure is shown in Figs. 2*a* and 2*b*. No carbon dioxide was let into the system. Rapid sampling of small amounts of gaseous carbon dioxide without too much perturbation of equilibrium was accomplished by increasing both the size of the reaction vessel and concentrations of carbonate solutions. The reaction vessel and the vacuum line were considerably different from those used by Cragg and Thode (16) in their preliminary studies.

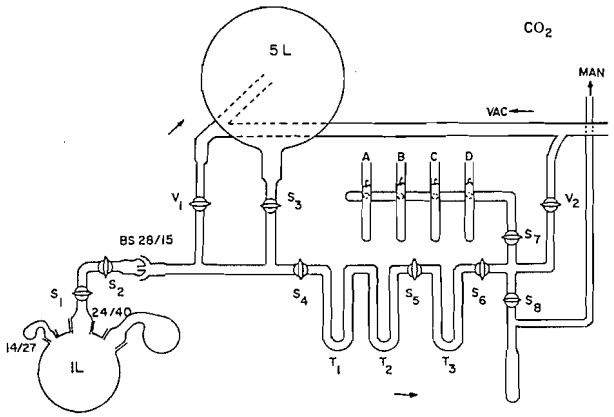

FIG. 2*a*. Gas phase sampling system.

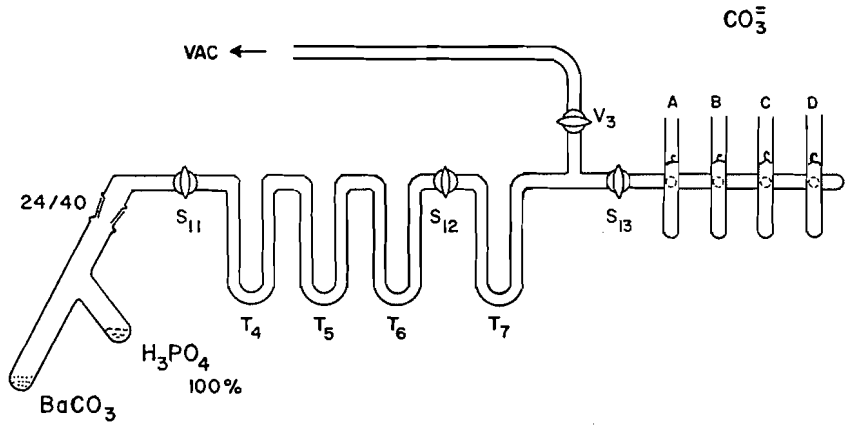

FIG. 2*b*. Solution phase sampling system.

The high precision isotope ratio mass spectrometer used in this investigation was built by Wanless and Thode (17) in 1953 and over the years it underwent several modifications to permit a good deal of flexibility in the collector system for measuring carbon, nitrogen, oxygen, and sulfur isotope ratios. Isotope ratio to an accuracy of $\pm 0.02\%$ was measured routinely on this machine using carbon dioxide samples. The 45/44 and 46/(45 + 44) peak ratios were measured in all samples against tank CO_2 as standard. Necessary corrections for differences in the O-17 content in all carbon analyses were applied using Craig's correction formulas (18).

C. Procedure

Enzymatic Activity and Choice of Stabilizer

The rates of evolution of carbon dioxide from carbonic acid – bicarbonate solutions were determined in the presence and absence of carbonic anhydrase with and without the peptone stabilizer.

In a 60 ml round-bottom reaction flask were placed 5 ml 0.4 *M* $NaHCO_3$ and 10 ml water, in the mixing sidearm 5 ml of phosphate buffer prepared by mixing equal volumes of 0.4 *M* Na_2HPO_4 and 0.4 *M* NaH_2PO_4, and the flask connected to a manometer through a stopcock. The contents of the flask were magnetically stirred at 25.0° and the phosphate buffer from the sidearm allowed to mix and react gently. The rates of CO_2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

evolution were determined manometrically. In the catalyzed reaction 1.00 ml of carbonic anhydrase (10 μg/ml) was added to the buffer solution before mixing. Similar experiments were performed using the peptone stabilizers since dilute aqueous solutions of carbonic anhydrase were found to be unstable. The effect of five different peptones on carbonic anhydrase activity was studied repeating the experiments with 5.00 ml 0.4 *M* $NaHCO_3$ and 10.00 ml of 0.08% aqueous peptone solutions and following the CO_2 evolution rates as before.

Procedure I

All experiments on the effect of metal ions, particularly Mg^{2+} ion, were carried out using this procedure as also some preliminary experiments on the effect of pH of the equilibrium mixtures. The reaction vessel as described earlier was a 60 ml round-bottom flask with sidearm for transfer of enzyme solution, and a side finger attached through a stopcock for freeze-collection of CO_2.

Varying volumes of standard Na_2CO_3, HCl, and $MgCl_2$ (or other metal chlorides) were mixed to give stock solutions that are essentially HCO_3^-–$CO_3^=$ mixtures with or without added metal ions—Mg^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Al^{3+}, Cr^{3+}. Twenty milliliters each of the mixtures were placed in the reaction vessel with the sidearm containing 1.00 ml carbonic anhydrase (21.6 μg/ml) and the solution was degassed by a repeated freezing, pumping, and thawing process. About 4.8×10^{-5} moles of previously equilibrated (with saturated Na_2CO_3 solution) CO_2 was admitted into the flask and the flask thermostated with shaking at 25.0° for ~5 h. The gaseous CO_2 after equilibration was collected in the side finger kept at liquid air temperature by opening and closing the attached stopcock. It was further purified by passing it through a trap at −80° and metered into a sample tube.

The solution in the reaction vessel was frozen to liquid air temperature and 1.00 ml 4 *N* HCl added and evacuated again. The frozen mass was allowed to melt and mix when CO_2 evolved. This was sampled as before for analysis to give the isotopic composition of solution carbon species.

Procedure II

The reaction vessel was a 1 l round-bottom flask with or without mixing sidearms connected to the vacuum line as shown in Fig. 2*a* through a detachable ball and socket joint (BS 28/15). About 500 ml of standard solutions ranging from 1 *M* to lower concentrations of $NaHCO_3$ and(or) Na_2CO_3 were taken in the flask to which 1.00 ml carbonic anhydrase stock solution was added with magnetic stirring. A small quantity of the solution was removed quickly to measure the initial pH and quench-precipitate the carbonate in solution for isotopic analysis. The reaction vessel was slowly chilled at dry ice – acetone temperature and air removed from the contents by alternately opening S_1, S_2, S_3 to the 5 l flask and evacuating the large flask with S_1, S_2 closed but V_1 open. This step was repeated several times. The reaction vessel was isolated and allowed to warm slowly, after pumping on the frozen mass for a few minutes. Thawing was accomplished by jacketing the flask with warm water. To ensure minimal mechanical and thermal strains on the reaction vessel it was replaced every two or three experiments.

The thawed contents were magnetically stirred at (27 ± 1°) room temperature and the gas phase containing the equilibrium CO_2 was sampled as follows: with S_2, S_3 open, S_1 was rapidly opened (< 6 s) to allow the gas to diffuse into the evacuated 5 l flask instantaneously. (Gas samples were thus collected in some experiments at intervals ranging from 2 to 40 h.) The collected CO_2 was transferred to the traps T_1, T_2 and kept at liquid air temperature by opening S_3, S_4 gradually until condensation in T_1 showed that the gas was slowly escaping from the large flask. With S_3, S_4, S_5, S_6, and V_2 open, the large flask and the traps were opened to the pumps for a few minutes and S_4, S_6 closed, confining the frozen CO_2 to T_1. It was purified from water by three successive distillations from T_1 to T_3 via T_2 kept at dry ice – acetone temperature. The first distillation was carried out rather slowly (1½ to 2 h) as this was found necessary to prevent interference of water contamination in the mass spectrometric analysis. After the final distillation, a suitably sized portion of CO_2 was metered into one of the break-seal sample tubes A, B, C, D.

Samples of the solution were obtained before and after the experiment to measure pH and for conversion of the carbonate to CO_2 for mass spectrometric analysis. A 2 ml aliquot of the solution was quenched in a saturated $BaCl_2$ solution and the precipitated $BaCO_3$ was centrifuged, washed successively with CO_2-free water and absolute alcohol, dried in filter paper folds, and transferred rapidly into the Y tube, shown in Fig. 2*b*, for vacuum drying. The dried $BaCO_3$ was then cautiously allowed to react with 2.5 ml 100% H_3PO_4 (prepared by dissolving P_2O_5 in 85% H_3PO_4), already taken in the sidearm, by gentle rotation-mixing. With S_{11} closed, the contents of the Y tube were left for an hour for equilibration of the evolved CO_2. The CO_2 was then condensed in T_4, T_5 at liquid air temperature by repeatedly opening and closing S_{11}. T_4 was allowed to warm to room temperature and T_5 to dry ice – acetone temperature while T_6 was kept at liquid air temperature. S_{12} was opened, T_7 kept at liquid air temperature, and T_6 allowed to warm. When the transfer was complete S_{12} was closed and a suitably sized sample was sealed in the sample tube for mass spectrometric analysis. Several Y tubes were used to facilitate rapid batch sampling of carbonate precipitates.

RESULTS AND DISCUSSION

Enzymic Activity and Choice of Stabilizer

The results calculated according to Meldrum and Roughton's method (5) from our rate data are presented in Table IV and the CO_2 evolution rates in Fig. 3. From these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

experiments it is concluded that the carbonic anhydrase preparation, although 22 years old, is still active and is effectively stabilized in aqueous solution in presence of proteose–peptone No. 4 ("Difco").

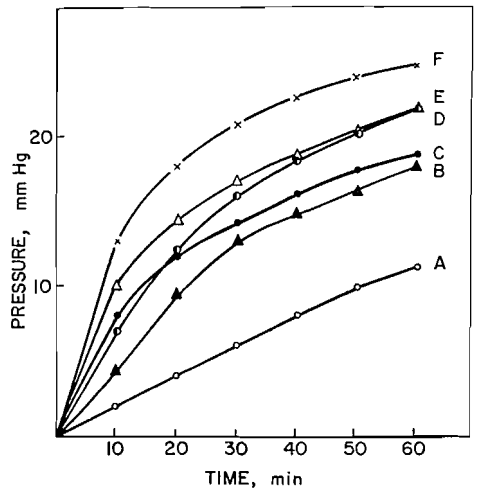

FIG. 3. Carbon dioxide evolution rates in carbonic anhydrase reactions. (A) Without enzyme; (B) enzyme + proteose–peptone No. 2; (C) with enzyme alone, and enzyme + proteose–peptone No. 1; (D) enzyme + bactopeptone; (E) enzyme + proteose–peptone No. 3; (F) enzyme + proteose–peptone No. 4.

6	Enzyme + proteose peptone No. 4	5 650	6 150
7	Enzyme + bactopeptone	2 850	3 600

Effect of Cations

Table V shows the effect of cations on the overall C-13 enrichment and the apparent equilibrium constant, K, is listed under varying experimental conditions.

Except in the case of Mg^{2+} ion, the other cations do not seem to suggest any specific effect although the K values are lower than the one with just Na^{+} ion present. The experimental difficulties are numerous when working with the transitional metal ions; one such difficulty is the extra element of heterogenity introduced into the equilibrium system as a result of precipitating hydroxides, basic carbonates, and carbonates. The same is true at higher concentrations of Mg^{2+} ion and at elevated pH's. However, with the available experimental data it can be shown that Mg^{2+} ion does participate in some way in the overall fractionation of ^{13}C, as illustrated in Fig. 4.

Furthermore, interest in the study of Mg^{2+} ion effect on ^{13}C fractionation derives mainly from its occurrence as the third major constituent in sea water. Any chemical model for sea water (19) must therefore take into consideration the various chemical species in

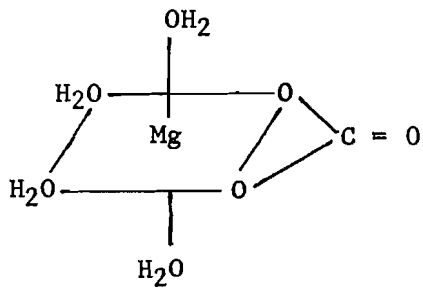
which magnesium is present. Recently Thode (20) summarized the carbonate ion anomaly in sea water and Garrels, Thompson, and Siever (21) calculated that of the total $CO_3^=$ in sea water nearly 75% is present as a neutral complex, $MgCO_3^0$. Magnesium is known to exhibit hexa-coordination, for example, in $Mg(H_2O)_6^{2+}$ (22) and $Mg(C_2O_4)_2(H_2O)_2^{2-}$ (23). A reasonable structure for the neutral complex of magnesium and carbonate in solution is



although some type of protonated carbonato complex might alter the bidentate character of the carbonate ligand. However, if we assume the neutral complex is so stable as to discriminate between free carbonate and bound carbonate then the symmetrical XY_3 form of free carbonate changes to what is in effect an XYZ_2 type of structure, resulting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in altered symmetry and perhaps changes in the characteristic vibrational frequencies. This therefore leads to isotopic discrimination and ^{13}C may be favored in the complex. Experimentally it is found to be so, as shown by the increased value of K in the presence of Mg^{2+} ions. It would be interesting, however, to make computer calculations of the normal coordinate treatment for this model and obtain band assignments and force constants which might permit evaluation of the partition function ratio, $Q_{Mg^{13}CO_3^0}/Q_{Mg^{12}CO_3^0}$, and calculation of the equilibrium constant for

[10] $$^{13}CO_2(g) + Mg^{12}CO_3^0(aq) = {}^{12}CO_2(g) + Mg^{13}CO_3^0(aq)$$

and also comparison with the experimental value ($K_{MgCO_3^0} > 1.012$). Mention may be made of an unsuccessful attempt to treat the complexed carbonate as an XYZ_2-type molecule using the vibrational frequencies of carbonyl fluoride, $^{12}COF_2$ (expt.) and $^{13}COF_2$ (calcd.) to represent $Mg^{12}CO_3^0$ and $Mg^{13}CO_3^0$ respectively for calculating $K_{MgCO_3^0}$. The calculated value gave an inverse isotope effect (0.935) indicating enrichment of carbon-13 in $CO_2(g)$. The COF_2 model may not be adequate to represent fully the bound carbonate.

Effect of pH

Preliminary experiments on the effect of pH on the carbon-13 fractionation carried out by procedure I consistently indicated a gradual, followed by steep and again gradual depletion of carbon-13 in the gas phase with increasing pH of the solution in the range 7–11. Figure 5 illustrates the trend when one plots ($^{12}C/^{13}C$) ratio in the $CO_2(g)$ vs. pH of the solution. The pH's were measured in these experiments from the change in color of the indicator present in the 60 ml reactor flask in two different sets of experiments and are less accurate than those measured by a pH meter in procedure II. Nevertheless, the S-shaped depletion curve was the case in all the experiments. A more detailed investigation was undertaken to study the effect of pH on the equilibrium isotope effect in general.

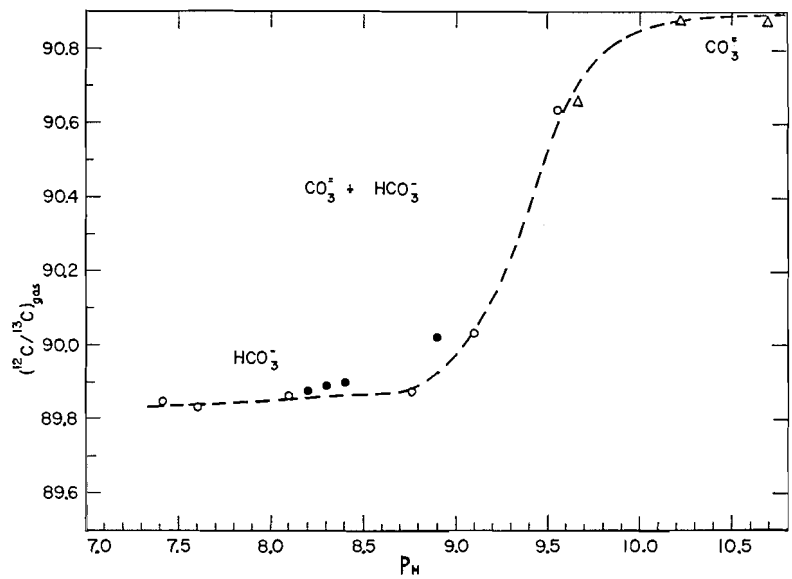


FIG. 5. Carbon-13 depletion curve: open circles and triangles indicate experimental data obtained using procedure I; solid circles are (normalized) points obtained using procedure II.

The wide fluctuations in the reported values for the single stage enrichment factor, α, obtained from column experiments are shown in Table VI. Earlier investigators have not taken into account the effect of pH nor has any further analysis been made in terms of three separate equilibria, [1], [2], and [3]. Since the magnitudes of K_0, K_1, and K_2 play an important role in the observed overall enrichment of ^{13}C in solution in a given experiment, a systematic study of the effect of pH seemed desirable and was undertaken.

TABLE VI

Figure 6 shows the relation between K and pH; the calculated curves are based on the following considerations. The $^{13}CO_2(g)$ can exchange with the solution carbon species as follows:

$$^{13}CO_2(g) + \begin{Bmatrix} l\,^{12}CO_2(aq) \\ m\,H^{12}CO_3^-(aq) \\ n\,^{12}CO_3^=(aq) \end{Bmatrix} = {}^{12}CO_2(g) + \begin{Bmatrix} l\,^{13}CO_2(aq) \\ m\,H^{13}CO_3^-(aq) \\ n\,^{13}CO_3^=(aq) \end{Bmatrix}$$

and the apparent equilibrium constant K is given by

$$K = \frac{lK_0 + mK_1 + nK_2}{l + m + n}, \qquad [11]$$

where l, m, and n represent each fraction of the total carbon present as $CO_2(aq)$, $HCO_3^-(aq)$, and $CO_3^=(aq)$ respectively and are determined by the pH of the solution. Using the ionization constants of carbonic acid it is possible to calculate $CO_2(aq)/HCO_3^-/CO_3^=$ ratios at a given pH. Also by using the best available experimental values for K_0, K_1, and K_2, the apparent equilibrium constant, K, can be calculated at different pH's with the help of eq. [11]. The values used in calculating the curves in Fig. 6 are: $K_0 = 1.0009$, obtained experimentally by Abelson and Hoering (24); $K_1 = 1.0083$ (curve I), obtained by Abelson and Hoering (24); and $K_1 = 1.0071$ (curve II) obtained by us, using

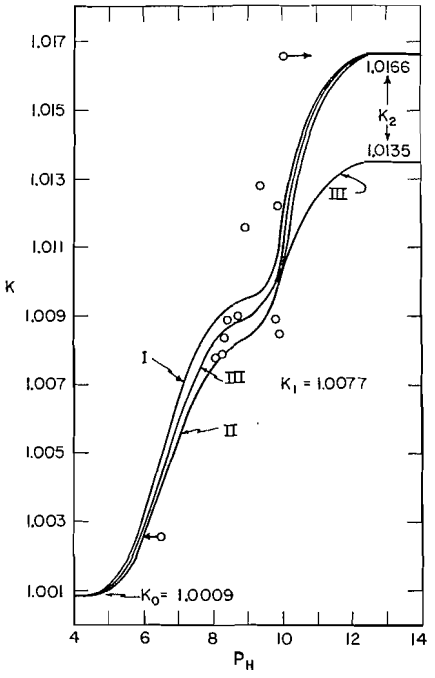

FIG. 6. pH dependence of equilibrium isotope effect. Curves are calculated using eq. [11] and for values, $K_0 = 1.0009$, $K_1 = 1.0083$ (curve I), $K_1 = 1.0071$ (curve II), $K_1 = 1.0077$ (curve III); $K_2 = 1.0166$ and 1.0135. Points shown in circles are those obtained experimentally using procedure II in all cases except the one at pH 6.5. Temperature 27 ± 1 °C.

procedure I in preliminary studies, as also a mean value 1.0077 (curve III); also two values of K_2 were used, 1.0166 the highest value obtained in our experiments and $K_2 = 1.0135$, the average value obtained (see curves in Fig. 6). The numerical values for these constants are further discussed.

At pH's greater than 7 the species in solution are predominantly HCO_3^- and $CO_3^=$ and eq. [11] becomes

$$K' = \frac{mK_1 + nK_2}{m + n}, \qquad [12]$$

where K' is the new overall equilibrium constant. If we define $c = m/n$, eq. [12] is further reduced to

$$K' = \frac{cK_1 + K_2}{c + 1}. \qquad [13]$$

The wide divergence in the apparent equilibrium constant reported from column experiments shown in Table VI is thus explained in part as due to different values of c (different pH's), in other words, mixtures of HCO_3^- and $CO_3^=$ present in the scrubbing solution. Knowing K', K_1, and K_2 it should be possible to fix the composition of the scrubbing solution used by various investigators in their column experiments.

$CO_2(g)$---$CO_2(aq)$ Equilibrium Constant, K_0

The value reported by Abelson and Hoering (24), 1.0009 at 25° and used by us in Fig. 6, agrees well with our calculated value, 1.0008 at 25° shown in Table III. It may

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

be pointed out that dissolved carbon dioxide in water is essentially present as $CO_2(aq)$ and no attention is paid to the questionable species $H_2CO_3(?)$. If the latter is at all present the ratio $(H_2CO_3)/(CO_2)$ at equilibrium is indeed small and hence its contribution to K_0 is negligible.

$CO_2(g)$---$HCO_3^-(aq)$ Equilibrium Constant, K_1

A direct measurement of K_1 is more difficult to make in view of the fact that bicarbonate solutions are never purely bicarbonate in their composition. Abelson and Hoering (24) report a value for $K_1 = 1.0083$ at 25° from their ion-exchange experiments assuming no isotope fractionation on the Dowex-1 resin used. Starting with purely bicarbonate solutions we obtained $K_1 = 1.0071$ by procedure I and somewhat higher values by procedure II (see Table VI). However, from an analysis of pH dependence data we recommend a value for $K_1 = 1.0077$. No theoretical calculation of K_1 was attempted for reasons discussed earlier.

$CO_2(g)$---$CO_3^=(aq)$ Equilibrium Constant, K_2

Although theoretical calculations have been made with a fair degree of success for this equilibrium constant over a wide range of temperature, 0 to 975 °C, there is considerable lack of reproducibility in experimental determinations and equal lack of agreement with the theoretical value. The calculated value for $K_2 = 1.0074$ at 27° seems to agree with only the lower limit set in this study. By using procedure II the observed equilibrium constant ranges from 1.0066 to 1.0166 in all the experiments at room temperature (27 ± 1 °C). The reason is not apparent. Although the experiments were intended to obtain K_2 directly, in reality, however, under the experimental conditions reported here we are not dealing with purely carbonate solutions but solutions containing significant concentrations of bicarbonate ion. In the presence of carbonic anhydrase and its nutrient solution the pH of a 1 *M* Na_2CO_3 solution was always found to be lower than the expected value of ~ 12. The problem is further complicated by the possibility of CO_2 absorption, in the course of pH measurements, which would yield spuriously low pH's. Equally important are (i) poor accuracy in analyzing small size $CO_2(g)$ samples from the gas phase, (ii) the possibility of rapid deterioration of carbonic anhydrase at pH's where $CO_3^=$ is the predominant species, and (iii) perhaps certain unknown kinetic problems associated with the hydration–dehydration reactions of carbon dioxide which are so vital in assuming isotopic equilibrium of elementic carbon between $CO_2(g)$ and $CO_3^=(aq)$. At best, therefore, one can give only an approximate value for $K_2 \geqslant 1.013$ indicating the order $K_0 < K_1 < K_2$. This is also supported by our preliminary experiments on carbon-13 depletion observed in the gas phase.

^{13}C N.M.R. STUDIES

PART VI.[1] CARBON-13 SPECTRA OF α,β-UNSATURATED CARBONYL COMPOUNDS[2]

D. H. MARR AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario

Received October 19, 1964

ABSTRACT

The 15.1 Mc/s ^{13}C n.m.r. spectra of 34 α,β-unsaturated carbonyl compounds have been obtained and the chemical shifts of the olefinic and carbonyl carbon nuclei are reported. Examples were drawn from the acyclic and five- and six-membered ring alicyclic series. A few aldehydes are included although most of the compounds are ketones. In the case of compounds assumed to be planar, variations of the olefinic shieldings with alkyl substitution parallel those observed previously for olefinic hydrocarbons. The key factor governing the chemical shifts of the carbonyl-carbon nuclei appears to be the extent of conjugation in a given system. Consequently, the ^{13}C results provide evidence for steric interference to coplanarity in the hindered systems. This approach is compared with other methods of estimating the extent of steric inhibition of conjugation and its merits are assessed.

INTRODUCTION

The investigation of the carbon-13 nuclear magnetic resonance (n.m.r.) spectra of a wide variety of organic carbonyl compounds was presented as the first part of this series (1) and included some results from a few aliphatic conjugated systems. To study in more depth the general features revealed by the earlier work, we have assembled a series of 15 acyclic and 19 alicyclic α,β-unsaturated aldehydes and ketones and measured the chemical shifts of their olefinic and carbonyl carbon nuclei. The alicyclic series included examples of the five- and six-membered cycloalkenones and a few acetylated cyclohexenes. The prime objective of the study of the effects of methyl substitution on these shieldings has been to allow a detailed comparison of chemical shift variations with those reported previously for acyclic olefins (2). No polar substituents were included. The analyses of the spectral data were, for the most part, straightforward. Intercomparisons of the chemical shift variations within a particular group generally provided a clear indication of the more reasonable assignment for the olefinic nuclei in those cases in which an unambiguous choice could not be made directly. The signals from the carbonyl carbon nuclei are at lowest field in all cases and present no difficulty (1).

The results of this study bear out the marked similarities for the olefinic shieldings in both the aliphatic (2) and aromatic olefins (3). Additivity of the effects of methyl substitution on or close to the double bond is noted for the olefinic shieldings and is compared with the earlier observations for the acyclic olefins (2). The carbonyl carbon shieldings are compared with our previous results for the acetophenones (4) and alkyl phenyl ketones (5) and similar trends found. Coplanarity of the components of the conjugated system appears to be the most important single factor governing the position of absorption of the carbonyl carbon in these systems, and, consequently, evidence for steric inhibition of conjugation in the hindered systems is given by the observed carbonyl shifts. The shieldings of the olefinic nuclei in these cases offer supporting evidence for this feature. Although no semiquantitative estimation of the extent of steric interference is attempted, the qualitative approach to the problem is compared with previous results for these

[1]*Part V, ref. 3.*
[2]*These results were reported in part at the 14th Conference on Analytical Chemistry and Applied Spectroscopy, Pittsburgh, March 1963.*

compounds obtained by the more usual techniques based on ultraviolet, infrared, and Raman spectroscopic data (6–13). The advantages and limitations of the ^{13}C method are discussed.

EXPERIMENTAL

N.M.R. Spectra

All spectra were obtained at a spectrometer frequency of 15.085 Mc/s using the pure compounds containing ^{13}C in natural abundance. The details of the experimental procedure have been given (4). The chemical shift data are judged to have a precision of ± 0.5 p.p.m. and are given on a scale relative to CS_2 (0 p.p.m.).

Materials

Some of the compounds employed are commercially available and were obtained from the following sources: Aldrich Chemical Co., Inc., isophorone, 2-cyclopentenone, 1-indanone, 9-fluorenone, 1-acetylcyclohexene; Eastman-Kodak, acrolein, crotonaldehyde, tiglaldehyde, pulegone; Louis Light and Co., piperitone. Samples of a number of the materials included in this survey were kindly supplied by Dr. Klaus Noack, who had prepared them for investigations of their infrared and ultraviolet spectra (9). The physical data for the following have been reported (9): methyl vinyl ketone; methyl isopropenyl ketone; 3-methyl-, 4-methyl-, and 3-ethyl-3-pentene-2-one; 3,4-dimethyl-3-hexen-2-one; 2-ethylidenecyclohexanone; 3-methyl-, 2,3-dimethyl-, 3,5-dimethyl-, and 3,5,5-trimethyl-2-cyclohexenone. A sample of piperitenone was donated by Mr. J. Cooper. The remaining compounds were prepared by well-known methods. The observed physical constants and the syntheses employed are outlined in Table I. In these cases the boiling points and melting points are uncorrected. One of the compounds, 3-pentenone, was isolated and purified by preparative scale vapor-phase chromatography (v.p.c.) and its boiling point was not determined. For all compounds, a small sample was examined by analytical v.p.c. before its ^{13}C spectrum was determined. These analyses were performed on a F-M model 700 instrument using a 10 ft column (outside diameter 0.25 in.) of 10% Apiezon on firebrick. The purity of most of the samples exceeded 98%, but a minimum of 96% was deemed acceptable for a few cases. Proton spectra were also obtained for most samples to check for the absence of gross amounts of impurities.

DISCUSSION

The chemical shift results for the acyclic α,β-unsaturated ketones are collected in Table II, while the data for the cycloalkenones and acetylcyclohexenes are presented in Tables

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

III and IV, respectively. The results for the few aldehydes and cross-conjugated ketones examined appear in Table V. The tabulated data are restricted to the observed shieldings of the olefinic and carbonyl carbon nuclei. Since the complexity of the spectra in the saturated carbon region does not permit a precise analysis and any assignments would be uncertain, except for the simplest derivatives, we have not attempted a detailed analysis of these absorption bands. For purposes of discussion, the carbonyl and olefinic carbon shieldings are considered separately. In the last section, the application of these results to the investigation of steric inhibition of conjugation is discussed and compared with the more usual approaches to this problem. All of the data in Tables II–V were obtained using the neat liquids, but to examine the effect of hydrogen bonding at the carbonyl oxygen on the shieldings of these nuclei some compounds were examined in methanol solution as well (Table VII).

TABLE II

^{13}C chemical shifts of the carbonyl and olefinic carbons of some acyclic α,β-unsaturated ketones (in p.p.m. from CS_2)

Compound	Chemical shifts		
	C=O	C-3 (α-C)	C-4 (β-C)
Butenone	−4.4	56.2	65.1
3-Methyl-3-butenone	−4.8	49.2	68.5

Carbonyl Carbon Chemical Shifts

For purposes of discussion it is convenient to consider the acyclic aldehydes and ketones and the cyclohexenone derivatives as a group, before examining the data for the cyclopentenones, acetylated cyclohexenes, and cross-conjugated examples. For this first group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of compounds, the ketonic carbonyl carbon signal appears over the range, −2.8 to −12.7 p.p.m., while the aldehydes exhibit this peak at 0.0–1.4 p.p.m. A comparison of the values for the simplest examples in each of these series shows that methyl substitution on the carbonyl group, i.e. RCHO → $RCOCH_3$, tends to deshield the carbonyl nucleus by ca. 5 p.p.m. as was noted previously (1). Certain consistent trends can be seen for the effects of further alkyl substitution on the α,β-unsaturated carbonyl system by comparing the rest of the data.

Methyl substitution on the β-olefinic carbon seems to increase the shielding at the carbonyl carbon nucleus by ca. 1 p.p.m. for both the aldehydes and ketones (cf. butenone with 3-pentenone; acrolein with crotonaldehyde). The effect of ethyl substitution at the β-position appears to be somewhat larger (ca. 2 p.p.m., butenone and 3-hexenone), although further extension of the chain causes no additional change. Similarly, methyl substitution at C-5 in the 2-cyclohexenone derivatives is without effect at the carbonyl carbon. Since it is well established that conjugation tends to shield carbonyl carbons (1) and that the carbonyl shieldings reflect the extent of conjugation (4, 5, 28), it is not surprising that β-methyl substitution tends to shift the carbonyl absorption toward higher field. The introduction of a second β-methyl group produces an additional shielding effect as illustrated by the values for mesityl oxide and 3-methyl-2-cyclohexenone relative to 3-pentenone and 2-cyclohexenone, respectively. For all of these comparisons, the observed effect is of the order of the experimental error but the consistency of the changes lends support to the idea that the trend may be real. The shielding at the carbonyl carbon nucleus of 2-cyclohexenone will be the resultant of the two opposing factors noted in the acyclic examples, namely, the deshielding effect of alkyl substitution on the carbonyl carbon and the shielding effect of β-alkyl substitution, and its carbonyl absorption position is virtually the same as that of butenone.

The replacement of α-hydrogens by alkyl groups tends to produce an effect opposite to that discussed above at the carbonyl carbon. For each of the five possible comparisons within this group of compounds, the α-methyl substituent reduces the carbonyl shielding by 0.4–1.6 p.p.m. Again, these changes are not large but the trend is observed for all examples without exception. The lone example bearing an α-ethyl group, 3-ethyl-3-pentenone, exhibits carbonyl absorption at −3.6 p.p.m. or 1.6 p.p.m. up-field from the 3-methyl derivative. An explanation of this observation is not evident. For the various α-methyl derivatives, however, it would appear that this grouping decreases the conjugative interaction between the olefinic and carbonyl bonds.

Marked low-field shifts of the carbonyl carbon absorption are found for the cases in which the double bond is fully substituted. Clearly the effects of the α- and β-methyl substituents at the carbonyl carbon are not additive, but rather produce an overall deshielding effect of 5.2–6.0 p.p.m. The most reasonable interpretation of this observation appears to be a pronounced interference to coplanarity for the conjugated system. We shall return to this point in the final section of the paper.

In the cyclopentenone series, the carbonyl absorption appears at much lower field than that for the six-membered cases, and the effects of monomethyl substitution on the double bond are very small, if indeed real. In addition, the carbonyl carbon for the 2,3-dimethyl derivative is 2.2 p.p.m. *more shielded* than that in 2-cyclopentenone itself. These variations would appear to reflect the geometrical differences between the five- and six-membered rings and will be considered in more detail below. We are still without explanation for the low-field position of the carbonyl absorption for five-membered ring compounds, although the problem was considered earlier (1) and further work is in progress.

TABLE IV

^{13}C chemical shifts of the carbonyl and olefinic carbons of some substituted 1-acetyl-1-cyclohexenes (in p.p.m. from CS_2)

Compound	Chemical shifts		
	C=O	C-1 (α-C)	C-2 (β-C)
1-Acetylcyclohexene	−4.6	54.1	52.4
1-Acetyl-6,6-dimethylcyclohexene	−4.7	46.7	54.4
1-Acetyl-2-methylcyclohexene	−7.6	60.6	52.5
1-Acetyl-2,6,6-trimethylcyclohexene	−12.7	65.2	49.9

The carbonyl shieldings for the four acetylated cyclohexenes (Table IV) depend strongly on the number of methyl substituents. Apparently substitution at C-6 does not alter the electronic environment about the carbonyl carbon nucleus unless the double bond is fully substituted, in which case the carbonyl shielding is decreased by 5.0 p.p.m. The effect of β-methyl substitution in this series is similar to that observed for the acyclic compounds, since this example possesses a fully substituted double bond and exhibits its carbonyl peak at 3.0 p.p.m. lower field than 1-acetyl-1-cyclohexene. Steric inhibition of conjugation would appear to be responsible for these variations in the observed carbonyl shieldings (see below).

Two ketones, phorone and piperitenone, having cross-conjugated systems were examined and both exhibit carbonyl carbon signals at considerably higher field than the simpler α,β-unsaturated derivatives. Clearly, any contribution to the carbonyl shielding arising from the magnetic anisotropy of the olefinic groups must be small, since this effect would tend to deshield in the olefinic plane (29, 30). Presumably, additional electron supply to the carbonyl group by the second double bond is responsible for the observed shift. Since few other types of carbonyl carbon nuclei absorb in this particular region, it appears that the ^{13}C spectrum may provide diagnostic evidence for the identification of cross-conjugated carbonyl systems, although several more examples are required to confirm this point. At the present time, it is known that α-halo ketones give rise to carbonyl peaks in this region (1) as do a number of substituted benzaldehydes (31). The latter would present no problem since the carbonyl band is a doublet, and there is little difficulty in distinguishing between haloketones and conjugated ketones by other means.

TABLE V

^{13}C chemical shifts of carbonyl and olefinic carbons of some α,β-unsaturated aldehydes and two cross-conjugated ketones (in p.p.m. from CS_2)

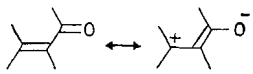
Compound	Chemical shifts		
	C=O	C-2 (α-C)	C-3 (β-C)
Propenal (acrolein)	0.4	56.4	56.8
2-Butenal (crotonaldehyde)	1.4	60.0	40.7
2-Methyl-2-butenal (tiglaldehyde)	0.0	53.5	45.2
3-Methyl-6-isopropylidene-2-cyclohexenone (piperitenone)	3.5	63.8	34.0
2,6-Dimethyl-3,6-heptadien-4-one (phorone)	4.9	68.1	41.3

Olefinic Carbons

As in the preceding section, it is convenient to discuss the acyclic carbonyl compounds and the cyclohexenones as a group. The data in Tables II, III, and V show that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

olefinic carbon nuclei absorb over a total range of 38.3 p.p.m. (31.5 → 69.8 p.p.m.) which is comparable to the 42.9 p.p.m. range (44.4 → 87.3 p.p.m.) reported for the acyclic olefins (2). Presumably the presence of the carbonyl group in conjugation with the double bond is responsible for the overall shift towards lower field for these chemical shifts. Except for the simplest cases, butenone and propenal, the first problem in the analysis of these results is the differentiation between the signals for the α- and β-olefinic carbons in the unsubstituted cases (cyclohexenone, pentenone, etc.). Due to the electron-withdrawing effect of the carbonyl grouping, however, it is reasonable to suggest that the lower field signals arise from the β-nucleus, since resonance forms of the type, II, contribute to the electronic distribution in the ground state. A shift toward lower field has



I II

been consistently observed for carbon nuclei in comparable environments [e.g. C-4 aromatic nuclei in monosubstituted benzenes (32, 33, 34), β-vinyl carbons in substituted styrenes (3)]. Closer inspection of the olefinic shieldings reveals variations caused by methyl substitution which are very similar to those observed for the olefinic hydrocarbons (2). These findings lend support to the above suggestion and provide reasonable evidence for the present assignments.

A comparison of the results for 3-methylbutenone and butenone itself shows that introduction of the methyl group tends to deshield C-3 (the α-C) by 7.0 p.p.m. and to shield C-4 (the β-C) by 3.4 p.p.m. There is no doubt about the assignments for these particular nuclei since the observed multiplicities provide a definite distinction. Similarly, the effect of the methyl group on the β-C can be found by comparing the results for acrolein and crotonaldehyde, which shows that the α- and β-carbons are shifted by +3.6 and −16.1 p.p.m., respectively. The observation that the olefinic carbon being substituted is deshielded by the introduction of a methyl group while the adjacent olefinic nucleus is shielded was found to be quite general in the hydrocarbon series (2). Further comparisons of this sort for the other monomethylated derivatives of the present series indicate that there are no exceptions to this behavior, although the magnitude of the effects differs for terminal and internal olefinic bonds. Again, this difference was found for the hydrocarbons. A summary of the changes arising from monomethyl substitution is presented in Table VI. The observed ranges are indicated and are found to be close to the experimental uncertainty except for one notable exception. The effect of methyl substitution on the β-position appears to be quite different in acyclic and alicyclic systems, but only one comparison was possible in the former case and perhaps it is anomalous. In any event, it is important to note that the consistency of these results appears to be limited to the monomethylated compounds. These trends break down for the examples having fully substituted double bonds. The possible significance of this observation is considered in more detail in the final section.

For the cyclopentenones, it is found that the effects of methyl substitution on the olefinic shieldings are qualitatively similar to those discussed above, but differ in magnitude. At both the α- and β-positions, the deshielding effect of a methyl substituent is greater (almost 50% greater for the β-methyl) than that found in the six-membered rings or the acyclic cases. Perhaps this enhancement is due to greater conjugative interactions in the more planar system, but the origin of these differences may be some unrecognized factor, since it is known that the five-membered ring affects carbonyl shieldings in a

unique manner (1). Little can be said about the olefinic shifts for 2-ethylidenecyclohexanone since no comparisons similar to the previous ones can be drawn. The methyl groups in 6,6-dimethyl-1-acetyl-1-cyclohexene appear to exert an effect at the olefinic nuclei which is appreciable for the α-C (−7.4 p.p.m.) but weak at the β-C (+2.0 p.p.m.). The remaining examples possess fully substituted olefinic bonds and a discussion of these is included in the final section.

While the overall consistency of the effects of methyl substitution tends to support the present assignments, a potential method of confirming our conclusions seemed worth investigating. It has been established that hydrogen-bonding solvents tend to reduce the shielding of carbonyl carbon nuclei relative to that measured for the pure liquid or in nonpolar solvents (1, 4, 5, 35). This reduction, although not particularly large unless protonation occurs (35), is significant and, furthermore, in aromatic systems the effect appears to be reflected at the terminal carbon nucleus as well [i.e., C-4 in acetophenone (1)]. The latter change is not unexpected since hydrogen bonding will enhance the contribution of polarized forms analogous to II. If a similar situation obtains for the aliphatic conjugated systems, one could distinguish the β-olefinic carbon from the α-nucleus by comparison of the olefinic shieldings measured for the neat liquid (or a solution in a nonpolar solvent) with those in a hydrogen-bonding solvent such as methanol. To test this idea, several samples were examined in the latter solvent and the difference in shielding for the olefinic and carbonyl carbons are listed in Table VII relative to the values for the pure liquids. Without exception, the carbonyl carbon absorption appears at lower field in methanol and the β-carbons are affected similarly, although to a lesser extent. These changes are consistent with the foregoing but the principal difficulty is that the shieldings of the α-nuclei are affected in a random fashion. With only one exception, however, the down-field shift is greater for the nucleus in the β-position and thus, further support for the present assignments is gained for the compounds having symmetrically substituted double bonds. The assignments for the lone exception, propenal, are unambiguous since the multiplicity of the absorption band differs for each olefinic carbon. While the solvent effects in several of these examples are small, within experimental error for some, it is interesting that the observed changes are qualitatively consistent with expectations based on the simple hydrogen-bonding explanation.

Steric Inhibition of Conjugation

The question of steric effects in conjugated carbonyl compounds has been the object of several investigations employing spectroscopic techniques and, although much of the

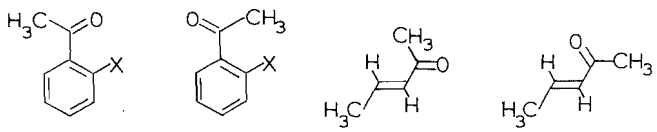
attention has been focussed on aromatic systems, a considerable effort has been expended on the study of aliphatic systems, a brief review of which has appeared (11). While the principal steric effect concerns the interference to coplanarity of the components of the conjugated systems, a secondary consideration is the orientation of these components about the single bond which joins them. This is perhaps a more important feature in the aliphatic systems since two, quite different, planar conformations are possible while differences between the planar conformations in aromatic compounds are less marked. For example, III and IV represent the planar conformations for a 2-substituted acetophenone while V and VI are the corresponding conformations for *trans*-3-penten-2-one. The latter are designated s-*trans* and s-*cis*, respectively. Since the absorption spectra of



III IV V VI

these two aromatic conformations (III and IV) would be expected to be very similar, provided each was planar or had the same degree of nonplanarity, any conclusions regarding the preferred conformation must be based on some other consideration(s) such as the space-filling characteristics of the interfering groups (a subject that is not without controversy) or measurements of another physical property. At the present time, a clear choice between these two conformations is often difficult. In the aliphatic systems, however, the optical absorption spectra for the two planar forms (V and VI) were expected to be quite distinct on the basis of studies of model compounds in which the s-*trans* and s-*cis* configurations are fixed. Recently, Noack and Jones (10*b*) have described the infrared and Raman spectra of *trans*-3-penten-2-one obtained over a temperature range and their results show that this ketone exists as an equilibrium mixture of these two conformers with the s-*trans* form predominant at room temperature. It has been well established that the ultraviolet spectra of *cis* and *trans* forms of conjugated systems exhibit different characteristics, the most striking difference being the reduced intensity of the absorption band for the *cis* isomer with or without a shift in the position of the band. These differences have been discussed in detail and a classification system for the observed effects has been proposed (13), although its acceptance has not been universal.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Similar effects in the ultraviolet spectra of conjugated carbonyl compounds and certain differences in the infrared and Raman spectra of compounds of known geometry (7–12) have been suggested to distinguish between the two planar comformations. The general characteristics of the two forms are summarized in Table VIII. The principal difficulty of these approaches is a clear distinction between the planar s-*cis* conformation and possible nonplanar conformers, since the optical absorption characteristics of these forms are very similar. The present data indicate that a determination of the ^{13}C chemical shifts in these systems provides an alternative approach which yields more striking differences between the planar and nonplanar forms.

*Units given in Can. J. Chem. 39, 2201 (1961).

On the basis of the results from extensive series of acetophenones and related compounds (4, 5, 28), it was concluded that the degree of planarity of a conjugated carbonyl system is a most important factor affecting the shielding of the carbonyl carbon nuclei. Steric interference to coplanarity of the carbonyl group is clearly shown by a down-field shift of the carbonyl absorption band, while polar factors appear to be of minor importance, as are neighbor-anisotropy effects. Thus, one would expect little or no difference in the resonance position of carbonyl carbons in s-*cis* and s-*trans* conformations of α,β-unsaturated systems. The observed carbonyl shifts for mesityl oxide and 2-ethylidenecyclohexanone, which are closely similar to the values for 3-penten-2-one and 2-cyclohexenone, support this expectation. There is no question regarding the configurations for these alicyclic compounds, while mesityl oxide is generally believed to exist largely in the s-*cis* conformation and trans-3-penten-2-one mainly as the s-*trans* form. Thus, at least as a first approximation, it would appear that the shielding of the carbonyl carbon in the *planar* form is independent of the configuration about the connecting single bond. Several of the compounds having fully substituted double bonds, however, exhibit carbonyl bands at appreciably lower fields than the less highly alkylated examples. The most reasonable explanation for these trends seems to be a departure from coplanarity of the unsaturated groups due to steric interference of the substituents. The 3,4-dimethyl derivatives of 3-penten-2-one and 3-hexen-2-one are examples showing this behavior. It is unlikely that a fully substituted double bond in the five- or six-membered rings could cause a marked departure from coplanarity for the fixed s-*trans* cases and the observed carbonyl shieldings are not greatly different from those for the unsubstituted compounds. In the fixed s-*cis* configurations for the alicyclic cases, however, there will be an effect of ring size since one of the β-methyl substituents can more closely approach the carbonyl oxygen in the six-membered ring than in the five-membered system. The carbonyl chemical shift for pulegone indicates that this conjugated system is subject to interference since the peak

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

appears at −7.8 p.p.m. relative to the carbonyl absorption at −4.9 p.p.m. in 2-ethylidenecyclohexanone and at −4.3 p.p.m. in 2-cyclohexenone. On the other hand, the carbonyl peak at −11.8 p.p.m. for 2-isopropylidenecyclopentanone is at *higher* field than that of 2-cyclopentenone (−15.3 p.p.m.) indicating that there is substantial polarization of the system by the two β-methyl substituents. The observed carbonyl shielding for piperitone could, perhaps, be interpreted to mean that the 6-isopropyl grouping disturbs the planarity of the conjugated system but such a conclusion would be rash since we know little of the effects of alkyl substitution at this position on carbonyl carbon chemical shifts.

Further support for our present proposal was obtained from an examination of the ^{13}C spectra of the series of substituted 1-acetyl-1-cyclohexenes listed in Table IV. Members of this series have been employed previously as models to illustrate the spectral characteristics of hindered conjugated aliphatic systems (7, 11, 36). From the carbonyl results for the examples studied in this work, it follows that both the parent compound and its 6,6-dimethyl derivative are essentially planar (although probably in different conformations), while the 2-methyl compound is nonplanar as illustrated by the change of −3 p.p.m. for the carbonyl shielding. Apparently the interference in the 2,6,6-trimethyl derivative is more severe since the carbonyl signal is ca. 8 p.p.m. to low field relative to the planar compounds. These conclusions based on the observed carbonyl chemical shifts are completely consistent with those drawn from the optical spectral data or an examination of molecular models for the various members of the series.

A consideration of the carbonyl carbon shieldings for the entire series, therefore, points to a valuable application of the ^{13}C technique to the study of these systems. The basic assumption that the carbonyl carbon chemical shifts for both planar conformations are the same may be an oversimplification since only a few examples of the fixed s-*cis* configuration have been examined. Recent studies have been reported to show that unsaturated carbon nuclei exhibit chemical shifts which are somewhat dependent on the configuration of substituents about the double bond (37). These effects were observed, however, for compounds of the type XCH=CHX (where X = Cl, Br, I or COOEt) and the influence of the polar substituents may well be larger than that of alkyl groups. The two available comparisons for olefinic hydrocarbons (2) show that the differences between the *cis* and *trans* isomers are indeed small. Until more results for the fixed *cisoid* configuration become available, the present assumption seems reasonable since the effects of steric interference to coplanarity appear to be larger than the differences one would expect to arise for the *cis* and *trans* configurations.

An examination of the results for the olefinic carbons in the examples exhibiting lower field carbonyl peaks indicates that these olefinic shieldings offer supporting evidence for a departure from coplanarity in these compounds. In the earlier discussion of the observed olefinic shieldings it was noted that the introduction of a methyl group on the β-carbon of the double bond produced a marked deshielding effect at that nucleus and the effect was more pronounced than the methyl effect at the α-position (Table VI). The β-carbon shieldings for 3,4-dimethyl-3-penten-2-one, 3,4-dimethyl-3-hexen-2-one, 2-methyl-1-acetyl-1-cyclohexene, and its 2,6,6-trimethyl derivative are not shifted by the amounts indicated in Table VI. In fact, with one exception, the trend is toward slightly *higher* field if these shifts are compared with the values for the compounds bearing one less methyl group (i.e., 3-methyl-3-penten-2-one, 3-methyl-3-hexen-2-one, and 1-acetyl-1-cyclohexene, respectively). 2,6,6-Trimethyl-1-acetyl-1-cyclohexene is the exception for which the β-olefinic carbon is found at −2.5 p.p.m. lower field than the parent compound, a shift which is markedly reduced from that observed for less hindered systems (−10

p.p.m.). While the assignments for the olefinic carbons in the fully methylated compounds are not obtained directly, the reverse assignment seems very unlikely and the trends just described would be even more pronounced by 6–15 p.p.m. The absence of the strong deshielding effect of the β-methyl groups for these substituted cases, is fully consistent with the existence of steric inhibition of conjugation. It was noted above that the carbonyl group tends to produce an overall deshielding effect on the olefinic chemical shifts relative to the olefinic hydrocarbons and it follows that any factor which reduces the effect of the carbonyl group will tend to produce an up-field shift of the signals for these nuclei. Since the effect of the carbonyl group at the β-position must be largely due to conjugative interactions, any factor which influences the extent of conjugation should be reflected by the β-carbon shieldings.

TABLE IX

Ranges of ^{13}C chemical shifts in α,β-unsaturated ketones (p.p.m. from CS_2)

	Conformation of molecules*	
Carbon nucleus	Planar	Nonplanar
C=O†	−5.0 to −2.5	−12.7 to −5.5
α-C	50 to 70	56 to 72
β-C	14 to 65	50 to 56

*Relative orientation of olefinic and carbonyl bonds.
†Excluding cyclopentenones.

In summary, the present results indicate that ^{13}C n.m.r. spectroscopy provides a method for distinguishing hindered α,β-unsaturated carbonyl compounds from those capable of attaining planar conformations. The distinction is based on the carbonyl carbon chemical shift and the shieldings of the olefinic carbon nuclei provide confirmatory evidence. The principal differences are listed in Table IX in a brief form. An extension of the previously proposed approach (4, 28) to the estimation of angles of twist in these systems has not been attempted owing to the scarcity of data for suitable systems, but remains as a potential refinement when the necessary data become available.

ACKNOWLEDGMENTS

The authors wish to thank the donors of the Petroleum Research Fund, administered by the American Chemical Society, and the Ontario Research Foundation for operating funds and a major equipment grant, respectively. We also thank Dr. Klaus Noack for his generous donation of a number of samples which provided sufficient results to show that a more complete study of the system would be worthwhile.

SPECTROSCOPIC STUDIES OF ORGANOPHOSPHORUS COMPOUNDS

PART I. THE CONSTITUTION OF ALKYLPHOSPHINE – CARBON DISULFIDE ADDUCTS

M. ARSHAD A. BEG AND M. S. SIDDIQUI
Central Laboratories, P.C.S.I.R., Karachi, Pakistan

Received May 19, 1964

ABSTRACT

The constitution of the alkylphosphine – carbon disulfide adducts has been investigated by the study of their infrared spectra. Certain definite features of the spectra of the adducts are the shift of the P—C asymmetric vibrations to higher frequencies and the large shifts in the fundamentals of the acceptor molecule. These features are attributed to the formation of a quadruply connected phosphorus compound. From a comparison of the spectra of the carbon disulfide adducts with those of the corresponding phosphonium compounds, phosphine oxides and phosphines, evidence is provided for the structure of these compounds which has been suggested to be of the phosphonium type.

INTRODUCTION

During an investigation on the chemistry of the trifluoromethylphosphines it was noted that the spectra of the boron trifluoride adducts of the phosphines had all the absorptions corresponding to the phosphines but those of boron trifluoride were shifted to lower frequencies on complex formation (1, 2). Similar shifts have also been observed for other BF_3 adducts (3). The other notable feature is the shift of the P—C stretching vibration to higher frequencies, and from a study of the spectra of the other organophosphorus compounds this may be associated with the formation of a quadruply connected structure. In order to further establish these features the study of the spectra of the addition compounds of carbon disulfide and alkylphosphines has been taken up. Carbon disulfide, which is also a Lewis acid, is expected to behave similarly to BF_3 and hence it was of interest to see if the change in frequency followed a similar trend.

Alkylphosphines react with carbon disulfide to form deep-red solids which can be hydrolyzed with alcoholic potassium hydroxide to give pure phosphines (4). Considerable controversy has existed regarding the nature of the bonding in these adducts (4, 5, 6). Recently the crystal structure of the triethylphosphine – carbon disulfide addition compound has been obtained from X-ray data (5) and it has been shown to be a phosphonium compound $R_3P^+CSS^-$ having the CS_2 moiety in the form of dithioformate anion. Jensen (6) has recently given a short account of the spectra of these compounds but no detailed discussion. We have furnished additional evidence in support of the idea of phosphonium compound formation and have also made tentative assignments of the absorption spectra.

EXPERIMENTAL

The phosphines, trimethylphosphine, triethylphosphine, and tripropylphosphine, were prepared by the Grignard method, using an inert atmosphere throughout the reaction. The reaction vessel was kept in a dry ice – acetone bath during the addition of phosphorus trichloride or phenyldichlorophosphine for the preparation of phenyldimethylphosphine. The yields of the phosphines were thus quite improved and ranged from 60–75% compared with 40–50% without the use of refrigerants. The CS_2 adducts were prepared by adding stoichiometric amounts of the reactants. The deep-red crystals so obtained were further purified by washing with ether, maintaining an inert atmosphere. The purity was checked from the melting point reported in the literature (6). The infrared spectra were recorded on a PE234 spectrophotometer, using both Nujol mulls and KBr pellets. For comparison purposes we have also prepared tetramethylphosphonium iodide, trimethylphosphine oxide, and phenyltrimethylphosphonium iodide.

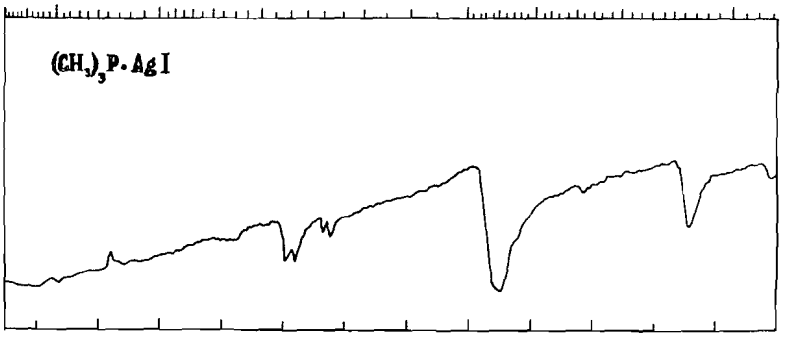

FIG. 3.

The spectra of tetramethylphosphonium iodide and the trimethylphosphine complex of carbon disulfide and silver iodide are shown in Figs. 1–3 and their infrared bands are listed in Table I. The infrared absorptions of phenyldimethylphosphine and phenyltrimethylphosphonium iodide and the CS_2 addition compounds of phenyldimethylphosphine are depicted in Figs. 4–6 and their bands are listed in Table IV.

DISCUSSION

The C—H stretching and bending vibrations in the quadruply connected compounds show small shifts in their positions compared with the corresponding triply connected structures. Shifts observed in the skeletal modes, however, are more marked than the others. The CH_3 rocking and the P—C asymmetric vibrations are seen to be quite sensitive to structural changes as would be evidenced by Table II.

P—C symmetric	653			678	664		

In the spectra of phenyltrimethylphosphonium iodide, trimethylphosphine – carbon disulfide adduct, and the phosphine oxide (7) there are two bands corresponding to the CH_3 rocking vibration, one at 860 and the other at 950 cm^{-1}. The spectrum of trimethylphosphine also records splitting but at higher frequencies. Tetramethylphosphonium iodide on the other hand does not have such split bands. It is possible that the splitting is due to the lowering of symmetry from a completely symmetrical molecule Me_4P^+ (which by analogy with molecules and cation of this type may have T_d symmetry) to a less symmetrical molecule Me_3PO or Me_3P, having an axial symmetry. In $Me_3P.CS_2$ the splitting may also be due to a lowering of symmetry. Splittings are usually the result of interaction of another species, which in the present case is the CS_2 moiety, and which in the case of $PhMe_3P^+$ is the phenyl group and in the case of Me_3P, the lone-pair electrons.

For the P—C antisymmetric vibration characteristic shifts have been found in all quadruply connected structures as compared with the corresponding phosphine. The absorption in $Me_3P.CS_2$ occurs at 772 cm^{-1} and in the Me_4P^+ the absorption occurs as a doublet at 785 and 776 cm^{-1}. It may, however, be noted here that the P—C antisymmetric stretching vibrations for the quadruply connected compounds have shifted to higher frequencies, compared with Me_3P. Such shifts are usually associated with changes in symmetry and have been reported (9) for the amine complexes containing sulfates, carbonates, etc. as ligands. The P—C symmetric vibration occurs at 678 cm^{-1} for $Me_3P.CS_2$ and at 664 cm^{-1} for Me_3PO. The P—C symmetric vibration for Me_4P^+ is reported at 571 cm^{-1} (8). It is quite likely that the intense absorption at 678 cm^{-1} in $Me_3P.CS_2$ is a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

result of the C—S single bond stretching or a possible coupling of this vibration with the P—C symmetric mode.

The most conspicuous difference between the spectrum of $Me_3P.CS_2$ and Me_4P^+ or Me_3PO is the occurrence of an intense absorption at 1 045 cm^{-1}, which is due to the C=S stretching mode and has been confirmed by a study of the spectra of the zanthates (10) and of the thiocyanates (11). The readily observable antisymmetric stretching frequency for the CS_2 molecule is totally absent in the addition compounds. If the CS_2 moiety were to preserve its identity an intense absorption would have been expected at 1 523 cm^{-1} in the infrared spectrum. However, it is noted from the X-ray data that the CS_2 group is no longer linear but has a triangular structure. Thus there is a change from $D_{\infty h}$ to C_{2v}. Such a change is also noted for the carbonyl group, e.g. from the CO_2 to the formate ion when the C=O frequency is seen to move to higher wavelengths (12). Also, in the case of the BF_3 addition compounds a similar change is noted (2). The large shifts in the characteristic frequencies of the acceptor molecule may thus be used as one of the evidences for the formation of a quadruply connected structure. The spectra of the adducts of the other trialkylphosphines also have the same features and are listed with tentative assignments in Table III.

TABLE III

Vibrational frequencies of $Et_3P.CS_2$ and n-$Pr_3P.CS_2$

	745 vs	
C—C symmetric stretch	723 m	720 m

The spectrum of the addition compound $PhMe_2P.CS_2$ is also quite interesting and one of the important features deserves to be mentioned. The single band at 739 cm^{-1} observed for phenyldimethylphosphine is split into two sharp and strong bands at 750 and 737 cm^{-1} in the case of $PhMe_2P.CS_2$ and into a sharp band at 754 and a weak one at 740 in the case of phenyltrimethylphosphonium iodide. This type of splitting seems to be characteristic of a quadruply connected aromatic phosphorus compound. Thus triply connected compounds like phenylphosphine, phenyldichlorophosphine, diphenylphosphine, diphenylchlorophosphine, and triphenylphosphine do not show any splitting in the 750 cm^{-1} region. It is only in the case of quadruply connected structures that this band is split, as is shown by a comparison with the reported spectra (13) of such compounds.

The similarity of the spectra of the phosphonium compounds and those of the carbon disulfide adducts of the alkylphosphines leads to the conclusion that the latter are phosphonium compounds with a tetrahedral structure having the constitution $R_3P^+CSS^-$.

RADIATION CHEMISTRY OF ALKALI THIOSULFATES

R. L. EAGER AND D. S. MAHADEVAPPA[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received June 29, 1964

ABSTRACT

The salts $Na_2S_2O_3$, $Na_2S_2O_3 \cdot 5H_2O$, $K_2S_2O_3$, and $K_2S_2O_3 \cdot \frac{5}{3}H_2O$ were irradiated at room temperature with ^{60}Co gamma rays. When the irradiated salts were dissolved in water, sulfite and sulfate ions, H_2S gas, colloidal sulfur, and a relatively small quantity of acid were found among the irradiation products. The dependence of yields on the absorbed dose was studied. *G*-values of approximately unity were found. Using ^{35}S as a label, it was found that the inner sulfur (the central, oxygen-bonded sulfur atom of the complex) appears in the sulfite and sulfate whereas the outer sulfur (the sulfur linked only to the central sulfur and not to oxygen) appears in the H_2S and colloidal sulfur. Annealing experiments using irradiated $Na_2S_2O_3$ and $K_2S_2O_3$ showed that the yields of sulfite, sulfate, and H_2S were decreased by heating. The sodium salts were also irradiated at 77 °K. The yields of sulfate and H_2S were higher for the low temperature irradiations as compared to room temperature irradiations, whereas the yields of sulfite were lower. A tentative mechanism which partially explains the results is proposed.

INTRODUCTION

A review of the literature shows that only limited information is available about the radiation chemistry of the inorganic compounds of sulfur. The radiation chemistry of aqueous solutions of ferrous ammonium sulfate has been extensively investigated (1–8), mainly because of the use of these solutions for dosimetry. Johnson (9) irradiated ferrous ammonium sulfate crystals with ^{60}Co gamma rays after which they were dissolved in water. Ferric and sulfite ions and hydrogen gas were found to be irradiation products. Mahlman (10) studied the yield of hydrogen from degassed concentrated solutions of sodium sulfate irradiated with ^{60}Co gamma rays. He concluded that all of the energy absorbed by the solution was effective in decomposing the water and that bisulfate and sulfate ions are not effective H-atom scavengers. Hochanadel *et al.* (11) have investigated the production of sulfur dioxide by the irradiation of sulfuric acid solutions with ^{60}Co gamma rays. Abellan (12) investigated the effect of ^{60}Co gamma rays on alkaline solutions of sodium thiosulfate. He suggested the following overall radiolytic reaction to explain the effects he observed.

$$2S_2O_3^{=} + 4OH + 2H \rightarrow HS^- + 3SO_3^{=} + 3H^+ + H_2O.$$

The present studies were undertaken to investigate the effect of ^{60}Co gamma rays on the crystalline sodium and potassium thiosulfates.

EXPERIMENTAL

Reagents

The sodium thiosulfate pentahydrate used was of reagent grade. The composition of the salt was checked by iodometric titration and by the weight loss upon dehydration. The results indicated that the sample used was quite pure. Reagent grade potassium thiosulfate was further purified by recrystallization from a hot aqueous solution. The tritapentahydrate, $K_2S_2O_3 \cdot \frac{5}{3}H_2O$, was obtained, as indicated by the weight loss upon dehydration. Crystalline anhydrous sodium thiosulfate and potassium thiosulfate were obtained by evaporating to dryness at 80 °C saturated solutions of the corresponding hydrates (13). That the salts were anhydrous was shown by the absence of a loss of weight when they were heated to 100 °C. The crystalline nature of the anhydrous sodium thiosulfate was shown by its X-ray diffraction pattern which was in good agreement with that reported elsewhere (14). Inner labelled and outer labelled sodium thiosulfates were obtained from Atomic Energy of Canada Limited. They were diluted with inactive sodium thiosulfate so as to give approximately 10^6 counts per min per g, assuming a 20% counting efficiency. Distilled water, again

[1]*Present address: Department of Chemistry, Manasagangothri, University of Mysore, Mysore, India.*

distilled from alkaline permanganate and then from an acid dichromate solution, was used for dissolving the irradiated samples. All other solutions used were prepared with deaerated double-distilled water.

Irradiations and Dosimetry

The irradiation source was a Gamma Cell 220 ^{60}Co Irradiation Unit manufactured by Atomic Energy of Canada Limited. The dose rates were of the order of 1 200 rad per min. The absorbed dose was measured using ferrous sulfate dosimetry, a *G*-value of 15.5 was used for the production of ferric ion. Allowance was made for the difference in the electron densities of the sample and the dosimeter. The samples were irradiated in the presence of air. The temperature of the samples was 25 ± 5 °C.

Counting of Radioactivity

A liquid scintillation counter was used. The scintillator used was a toluene solution of 2,5-diphenyloxazole (PPO) and 1,4-bis-2-[(5-phenyloxazolyl)]benzene (POPOP). As aqueous solutions were to be counted, a constant amount of water was always used in the counting solution. Similarly, as the H_2S was dissolved in "hyamine hydroxide" (*p*-(diisobutyl-cresoxyethoxyethyl)dimethylbenzylammonium hydroxide) prior to counting it, a constant amount of hyamine hydroxide was always used.

Analytical Procedures

The irradiated salt was dissolved in water and analyzed for acid, sulfite, sulfate, hydrogen sulfide, and colloidal sulfur. Prior to the determination of acid, sulfite, sulfate, and colloidal sulfur the hydrogen sulfide present was removed by bubbling nitrogen through the solution.

Acid was determined by a micro-titration with a standard sodium hydroxide solution using phenolphthalein as an indicator. A blank was done on a solution of the unirradiated thiosulfate.

Sulfite was determined by the decolorization of fuchsin (15). To the solution of the irradiated thiosulfate was added 0.2 to 0.3 g of sodium bicarbonate after which nitrogen was bubbled through the solution for a further 5–10 min (16). Fuchsin solution was added and the optical density of the solution was read at 542 mμ. A calibration curve was prepared by analyzing mixtures containing known amounts of sulfite and thiosulfate.

Sulfate was determined by difference using a nephelometric method (17) in which a barium sulfate precipitate is formed. Thiosulfate interferes when it is present in relatively large quantities due to the precipitation of barium thiosulfate. This interference was eliminated by oxidizing the thiosulfate to tetrathionate with iodine. The iodine also oxidized the sulfite present to sulfate. Hence the nephelometric determination gave sulfate plus sulfite and the amount of sulfate was calculated by difference. A calibration curve was prepared by analyzing solutions containing known amounts of sulfate, sulfite, and thiosulfate.

Hydrogen sulfide was estimated by the methylene blue method of Sands *et al.* (18). When hydrogen sulfide is passed into a solution containing the sulfate or hydrochloride of *p*-amino-*N*,*N*-dimethylaniline and ferric chloride, methylene blue is formed. The optical density of the solution is taken at 670 mμ. The apparatus used was similar to that described by Budd and Bewick (19). In experiments with labelled thiosulfates the hydrogen sulfide was absorbed from the nitrogen stream by bubbling it through 2 ml of hyamine hydroxide. The resulting solution was used in making up the counting solution for the scintillation counter.

The amount of colloidal sulfur present in the solutions of the irradiated salts was estimated as follows. As shown later it seems fairly definite that the colloidal sulfur is derived from the "outer" sulfur of the thiosulfates. Irradiated outer labelled $Na_2S_2O_3$ and $Na_2S_2O_3 \cdot 5H_2O$ was dissolved in water. After the removal of hydrogen sulfide the solution was filtered through a 0.22 μ pore size Millipore filter. The filter was washed free of labelled undecomposed thiosulfate by passing 500 ml of a 0.8 *M* inactive $Na_2S_2O_3$ solution through it. The dried paper was added to the scintillation counting solution and the resulting mixture counted. The paper disintegrated in the counting solution yielding a transparent gelatinous mass. A filter paper was similarly added when standard active thiosulfate solutions and when background solutions were counted.

The presence of oxygen in the irradiation products was checked using gas chromatography methods. A Linde 5A molecular sieve was used as a column packing. No oxygen was detected; the method was sensitive enough so that the presence of one μmole would have been detected.

RESULTS

The salts upon irradiation underwent the following color changes. At room temperature $Na_2S_2O_3 \cdot 5H_2O$ first turned yellow which then deepened to a dark-brown color at high doses. At 77 °K the pentahydrate turned a greenish-brown color which rapidly turned to a brown color when the solid was warmed to room temperature. The anhydrous salt, $Na_2S_2O_3$, showed little color effect at room temperature, a yellow tinge only being observed at high doses. At 77 °K the anhydrous salt assumed a violet color which was bleached upon the salt being warmed to room temperature. The potassium salts showed a yellow coloration upon irradiation. In annealing experiments with $K_2S_2O_3$ the yellow color persisted at 50 °C but it was completely bleached at 100 °C.

For personal use only.

Comparison of the infrared spectra of irradiated samples with those of unirradiated samples showed that the irradiation had produced no detectable changes in the spectra. The lack of any change may be due to the small amount of decomposition undergone by the compounds, which was less than 1%. Cunningham and Heal detected new infrared bands in KNO_3 when the salt was irradiated with a sufficient dose of gamma rays to bring about 4 to 24% decomposition (20).

When the irradiated samples were powdered the odor of H_2S could be detected. Upon solution in water an effervescence was observed, and the odor of H_2S was given off. At the same time a white turbidity developed in the solution. Attempts to identify the material causing the turbidity were not successful, presumably due to the very small amounts present. It was assumed that the turbidity was due to sulfur as had been observed by Abellan (12) when solutions of thiosulfates were irradiated.

Yields of Products Formed Upon Solution of Irradiated Thiosulfates in Water

The yields of sulfite, sulfate, and H_2S, in μmoles, and of acid, in μequivalents, produced per mole of salt are shown plotted against absorbed dose in eV per mole in Figs. 1, 2, 3, and 4 for $Na_2S_2O_3 \cdot 5H_2O$, $Na_2S_2O_3$, $K_2S_2O_3 \cdot \frac{5}{3}H_2O$, and $K_2S_2O_3$, respectively. In Table I are given some *G*-values for the products. These were calculated from the curves given in Figs. 1, 2, 3, and 4.

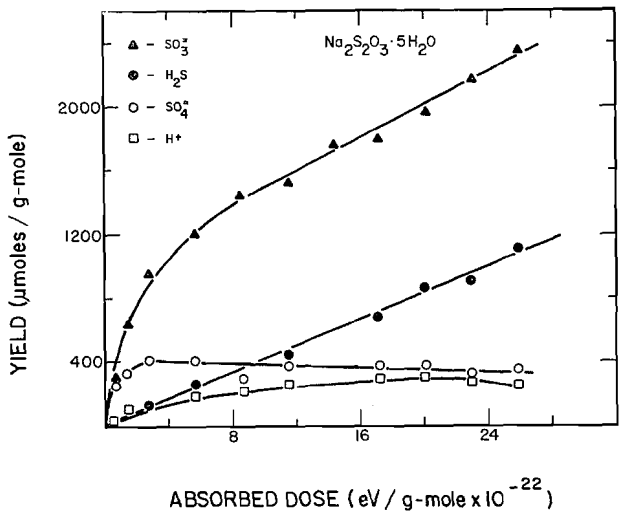

FIG. 1. Yields of $SO_3^=$, $SO_4^=$, H_2S, and acid as a function of dose for $Na_2S_2O_3 \cdot 5H_2O$.

Low Temperature Irradiations

Samples of $Na_2S_2O_3 \cdot 5H_2O$ and $Na_2S_2O_3$ were irradiated at liquid nitrogen temperatures. The salts received doses of 5.1×10^{22} and 3.1×10^{22} eV per g-mole, respectively. The results of the analyses of their aqueous solutions are given in Table II. Also given in Table II are the corresponding yields for room temperature irradiations. These yields were taken from Figs. 1 and 2.

Irradiations of ^{35}S-labelled $Na_2S_2O_3 \cdot 5H_2O$ and $Na_2S_2O_3$

The hydrogen sulfide liberated upon solution of irradiated $Na_2S_2O_3 \cdot 5H_2O$ and $Na_2S_2O_3$ labelled in the "outer" sulfur position was found to be radioactive. For both compounds

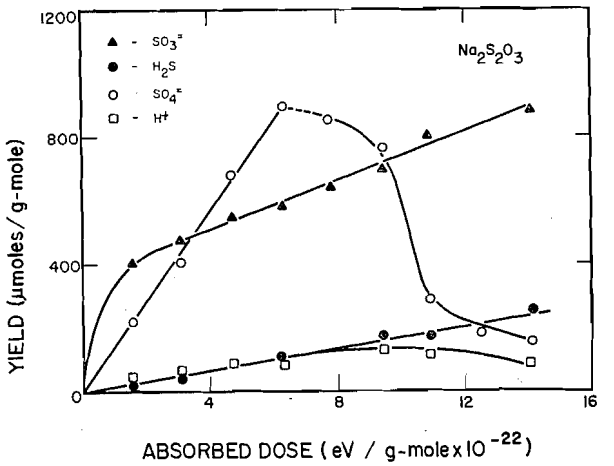

FIG. 2. Yields of $SO_3^=$, $SO_4^=$, H_2S, and acid as a function of dose for $Na_2S_2O_3$.

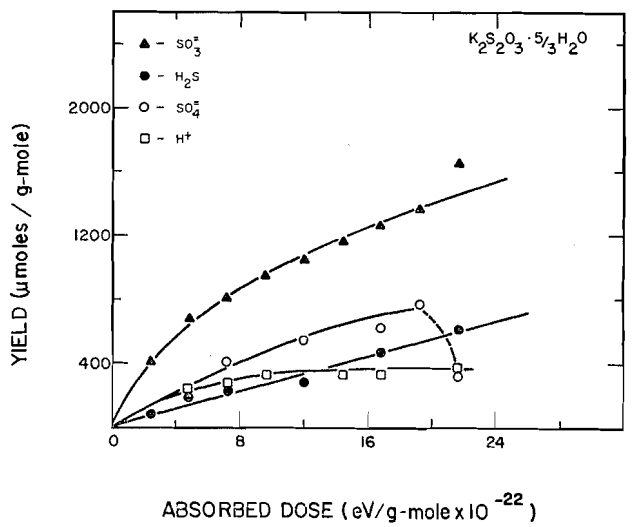

FIG. 3. Yields of $SO_3^=$, $SO_4^=$, H_2S, and acid as a function of dose for $K_2S_2O_3 \cdot \frac{5}{3}H_2O$.

it was calculated from the measured radioactivity of the H_2S and the specific activity of the outer labelled thiosulfates that the amount of H_2S possessing the label was approximately 90% of the amount of H_2S found by chemical analyses. The H_2S from inner labelled thiosulfates was found to be inactive, the observed "counts" being identical with the background. Hence, it is concluded that the only source of H_2S sulfur is from the outer sulfur atoms of the thiosulfates. The discrepancy of about 10% observed in the experiments with the outer labelled compounds must be due to errors either in the radioactivity measurements or in the chemical analyses, or in both.

Sulfite and Sulfate from outer labelled $Na_2S_2O_3 \cdot 5H_2O$ and $Na_2S_2O_3$ yielded $BaSO_4$ which was found to be nonradioactive. When inner labelled compounds were used the $BaSO_4$ was radioactive.

The colloidal sulfur retained by the 0.22 μ pore size millipore filter was found to be radioactive when outer labelled $Na_2S_2O_3 \cdot 5H_2O$ and $Na_2S_2O_3$ were used but to be non-radioactive when the inner labelled compounds were used. It was thought that this could be used as a method of determining the amount of colloidal sulfur produced. In Table III are given some of the results obtained when outer labelled compounds were used. Also given in Table III are the corresponding yields of H_2S, sulfite, and sulfate taken from Figs. 1 and 2. The last column of Table III gives the sum of the sulfur found as colloidal sulfur and H_2S as a percentage of that found as sulfite and sulfate. Since it appears that the outer sulfur of the thiosulfates forms colloidal sulfur or H_2S whereas the inner sulfur forms sulfite or sulfate, the low values in the last column suggest that some of the outer sulfur was not being found. It is possible that not all of the colloidal sulfur was retained by the 0.22 μ filter paper. When 0.45 μ filter papers were used, only about one-quarter as much colloidal sulfur was retained. An attempt was made to use 100 mμ filter papers, but with the slow filtration rates the paper could not be washed free of the radioactive thiosulfate. An attempt was made to carry down the colloidal sulfur with $Al(OH)_3$ precipitate but this did not prove to be very successful. The use of some solvent, immiscible with water, was considered for extracting the sulfur. However the method was not tried since considerable difficulty was anticipated in preventing a carry over of even a very small fraction of the relatively large amount of radioactivity present in the solution. The tendency for emulsion formation in such systems would also have caused difficulties. It should be noted that, for sample weights of 1 g, the weights usually used, the amount of sulfur unaccounted for is less than 0.0001 g.

Annealing Experiments

Irradiated samples of the anhydrous salts were annealed for varying lengths of time at 50 °C and at 100 °C. At the end of the annealing period, the salts were dissolved in water and the resulting solutions analyzed. Sodium thiosulfate samples were irradiated to a

DISCUSSION

The experiments with labelled compounds indicate that the colloidal sulfur and the H_2S originate from the outer sulfur of the thiosulfate group whereas the sulfite and sulfate originate from the inner sulfur. An implication of the above is that the sum of the yields of colloidal sulfur and H_2S should be equal to the sum of the yields of sulfite and sulfate. The fact that a sulfur balance was not obtained may be due to not all of the collidal sulfur being retained by the filter paper.

The annealing experiments show that the yields of all of the products determined decrease when the samples are heated to 50 °C or to 100 °C. After approximately 2 h at either temperature the yields of all of the products are reduced to values which remain constant at a level about one-half of those found prior to annealing. An explanation of this behavior may be that at least some of the species produced in the crystals upon irradiation remain in close proximity of one another and so may recombine to form thiosulfate ions, or perhaps some other product which was not determined. Alternately, or in addition, excited thiosulfate ions may be formed by the radiation and these may be deactivated during the annealing process.

From the information presently available it does not appear to be possible to offer a detailed mechanism for the reactions which occur when the alkali thiosulfates are irradiated with gamma rays. The following tentative scheme is proposed to account for some of the observed behavior.

Ionization and Excitation

[1] $S_2O_3^{=} \sim\sim\sim\sim\rightarrow S_2O_3^{=*}$

[2] $S_2O_3^{=} \sim\sim\sim\sim\rightarrow S_2O_3^{-}$, S_2O_3, and electrons

[3] $H_2O \sim\sim\sim\sim\rightarrow H + OH.$

Primary Dissociation

[4] $S_2O_3^{=*} \longrightarrow S + SO_3^{=}$

[5] $S_2O_3^{=*} \longrightarrow S + SO_3 + 2e$

[6] $S_2O_3^{=*} \longrightarrow S^{=} + SO_3.$

Electron Capture

[7] Na^+ or $K^+ + e \longrightarrow$ Na or K

[8] S + electrons $\longrightarrow S^-$ and $S^{=}$

[9] SO_3 + electrons $\longrightarrow SO_3^-$ and $SO_3^{=}$.

The sulfur sesquioxide, whose formation is indicated in eq. [2], would upon solution of the sample react with water to form the observed products; sulfur, sulfite, and sulfate (21).

With the hydrates the yields of sulfate are considerably lower than for the anhydrous salts whereas the sulfite yields are increased. When the salts are irradiated at liquid nitrogen temperature the yield of sulfate is markedly increased over that at room temperature. It would seem reasonable to postulate that the primary interaction of gamma rays and of at least the high energy electrons with the thiosulfate group would be the same regardless of the presence of water or of a difference in temperature. It would thus appear that the precursor for at least some of the sulfate may either survive in the solid, and eventually produce sulfate, or it may undergo reactions in the solid, or upon solution, which leads to sulfite. As an example, such a sulfate precursor may be the SO_3 molecule

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(either in the ground state or in some excited state). The SO_3 molecule may undergo an electron capture reaction [9] leading to the appearance of sulfite ions. If a large fraction of the SO_3 molecules did not undergo reaction [9] then a relatively low yield of sulfite would result, as is the case for the anhydrous salts. If, on the other hand, a further reducing agent is present when the hydrates are irradiated the rather large decrease in sulfate ions yields would be explained. Such a reducing agent may be H atoms, formed according to reaction [3]; these could react as follows,

$$SO_3 + H \longrightarrow SO_2 + OH. \quad [10]$$

Another source of hydrogen atoms in the hydrates would result from the reaction of electrons with the water of hydration. The increased yield of sulfate in the low temperature irradiations would follow from the decreased rate of diffusion of electrons and of hydrogen atoms and also from the reduced rates of reactions [9] and [10].

None of the reactions proposed so far would result in the formation of any acid in excess of that required for the formation of H_2S. A yield of acid would result if some of the sulfide ions, or their precursors, were converted into some substance which was not a volatile acid. Since this substance could not be sulfite or sulfate, as shown by the experiments with the outer labelled compounds, the sulfide would have to be changed into some product not determined in the scheme of analysis used.

Electron spin resonance spectra indicate the presence of the free radical ion SO_2^- in the irradiated salts (22). This radical could arise as the result of some dissociation reaction such as

$$S_2O_3^{-*} \longrightarrow SO_2^- + \text{other products}. \quad [11]$$

At high doses the fall-off of yield of sulfate, especially for the andhyrous salts, is very pronounced and occurs quite suddenly. Since there is no corresponding increase in the yield of sulfite the sulfate precursor, SO_3 perhaps, must disappear without being reduced to the sulfite precursor. A similar decrease was found by Johnson (9) for the yields of products from the irradiation of ferrous ammonium sulfate with ^{60}Co gamma rays. No explanation was offered as to the cause for the fall-off in yields. In the present work a simple recombination of ions or radicals to remove the sulfate precursor would only result in a leveling off of the yield of sulfate. If, however, after a certain amount of radiation had been absorbed by the crystal the recombination suddenly became more rapid, without a corresponding increase in the rate of formation of the precursor, then such a fall-off in the yield of sulfate would result. This increase in the rate of the reverse reaction might occur as a result of an increase in the rate of diffusion of electrons in the crystal after a certain threshold of "damage" has been produced in the crystal. For example, if reaction [5] were reversible then a sudden increase in the number of electrons reaching the sulfur atom – SO_3 molecule pair would result in a decrease in the amount of SO_3 present in the crystal. The sulfur atom and the SO_3 molecule could very likely be held in a cage and they may even be bonded together in an excited molecule. An alternative mechanism for the marked decrease in the yield of sulfate is that the following overall reaction becomes important in a crystal of a thiosulfate which has been subjected to high doses:

$$2SO_3 + 2e \longrightarrow S_2O_6^=.$$

Due to the lack of suitable analytical techniques no attempt was made to detect dithionate among the products.

A QUANTUM-THEORETICAL STUDY OF SOME AROMATIC NITRILES BY THE SEMIEMPIRICAL LCAO-SCF-MO METHOD

H. E. POPKIE AND J. B. MOFFAT
Department of Chemistry, University of Waterloo, Waterloo, Ontario
Received September 9, 1964

ABSTRACT

Semiempirical LCAO–SCF–MO calculations have been carried out on some aromatic nitriles in an attempt to predict spectral transitions. Mataga's approximation has been applied to the Coulomb repulsion integrals and a set of parameter values which gives a reasonable prediction of the observed singlet–singlet transition energies of pyridine and benzonitrile was used. The calculations were applied to pyridine, benzonitrile, 2-, 3-, and 4-cyanopyridine, 1,2-, 1,3-, and 1,4-dicyanobenzene, 2,6-dicyanopyridine, and 1,2,4,5-tetra cyanobenzene. Computed singlet–singlet transition energies are in fair agreement with experiment. However, calculated singlet–triplet transition energies are, in general, lower than the experimental values by about 1 eV. The SCF ground state MO's and orbital energies are reported together with the wave functions for the four lowest-energy excited singlet states for each molecule.

INTRODUCTION

The most successful application of the semiempirical LCAO–MO method as applied to π-electronic systems has been the quantitative prediction of the positions and intensities of the low-lying electronic spectral bands (1). Most of the work has been done on hydrocarbon molecules, especially alternant ones, but numerous computations on molecules containing heteroatoms are being reported. However, predicted transition energies for hetero molecules do not in general agree with experimental values as well as in the case of hydrocarbons, and Parr (1) notes that discrepancies of 0.5 eV are not uncommon. The main problem has been a judicious choice of parameter and integral values.

Several semiempirical SCF calculations have been done on aromatic nitrogen-containing molecules. The azabenzene series has been studied by Pariser and Parr (2), McWeeny and Peacock (3), and Mataga and Nishimoto (4); the azanaphthalenes by Peacock (5), Mataga (6), and Favini *et al.* (7). In addition, individual members such as pyridine and *s*-triazine have been subjected to treatments by many workers such as Anno (8), Kon (9), and Brown and Heffernan (10). Recently aniline and polysubstituted aminobenzenes have received attention from Fischer-Hjalmers (11), Bloor *et al.* (12), and Mataga (13).

A small amount of work seems to have been reported for aromatic nitriles. Peacock and Wilkinson (14) have done a semiempirical SCF study of benzonitrile and have calculated spectral transitions. Polansky and Grassberger (15) have attempted to predict the spectra of the cyanobenzenes using a Hückel-type procedure. It seemed worth while to attempt to apply a semiempirical SCF calculation to several cyanobenzenes and cyanopyridines to determine the extent to which transition energies could be predicted using the Mataga approximation (4) for Coulomb repulsion integrals and a set of parameter values which gave a reasonable prediction of the observed singlet–singlet transition energies of pyridine and benzonitrile. The molecules studied were pyridine, benzonitrile, 2-, 3-, and 4-cyanopyridine, 1,2-, 1,3-, and 1,4-dicyanobenzene, 2,6-dicyanopyridine, and 1,2,4,5-tetracyanobenzene.

METHOD OF CALCULATION

The LCAO–SCF–MO method with the simplifications introduced by Pariser, Parr (2), and Pople (16) was used. A brief outline of the principles and assumptions involved is given below.

The method begins with the assumption that the π-electrons of an unsaturated molecule can be treated apart from the σ-electrons. They are allowed to move in an effective field due to the core region composed of the σ-electrons and nuclei. Parr (1) has given a set of sigma–pi separability conditions which the wave functions of a set of molecular states must satisfy in order that the π-electrons can be treated separately. In this π-electron approximation, correlation energies between σ- and π-electrons are necessarily neglected and the σ-parts of the wave functions are assumed not to change from state to state.

The Hamiltonian for a system containing $2n$ π-electrons is written:

$$[1] \qquad H_\pi = \sum_{i=1}^{2n} H_{\text{core}}(i) + \sum_{i<j=1}^{2n} \frac{e^2}{r_{ij}},$$

where $H_{\text{core}}(i) = T(i) + U_{\text{core}}(i)$ is the kinetic energy operator for electron i plus its potential energy in the field of the core.

The ground state wave function for a molecule with a closed shell structure is represented by a single normalized Slater determinant:

$$[2] \qquad \Psi_0 = \det |\Phi_1\bar{\Phi}_1\Phi_2\bar{\Phi}_2 \ldots \Phi_n\bar{\Phi}_n|,$$

where $\Phi_i = \psi_i\alpha$ and $\bar{\Phi}_i = \psi_i\beta$ are molecular spin orbitals.

In the LCAO approximation, the molecular orbitals (MO's) ψ_i are assumed to be linear combinations of a basis set of m atomic orbitals (AO's) ϕ_μ:

$$[3] \qquad \psi_i = \sum_{\mu=1}^{m} c_{i\mu}\phi_\mu.$$

The AO's ϕ_μ are centered, one to an atom, on the various atoms contributing π-electrons to the system under consideration. They are mutually orthogonal orbitals of such a nature that differential overlap is negligible. Although their exact analytical form is unknown, they may be expected to resemble (somewhat) deformed 2p π-orbitals.

A procedure for the determination of the coefficients $c_{i\mu}$ which minimize the total π-electronic energy $E_0 = \int \Psi_0^* H_\pi \Psi_0 \, d\tau$ has been given by Roothaan (17).

However, the calculations are quite tedious. The equations can be simplified considerably by the introduction of the zero differential overlap (ZDO) approximation as suggested by Pariser, Parr (2), and Pople (16). The ZDO approximation can be expressed as:

$$[4] \qquad \phi_\mu^*(i)\phi_\nu(i) \, dv(i) = 0; \; (\mu \neq \nu).$$

It is rather difficult to determine theoretically whether or not the ZDO assumption is a justifiable approximation. For conjugated hydrocarbons it appears to be a good first approximation, but for heteroatomic molecules where the distribution of electrons is not so uniform one would expect overlap effects to play a greater role (1). Nevertheless, as Dewar (18) points out, calculations using the ZDO assumption have proved useful for extracting experimental data, as has been shown by actual quantitative applications.

With the ZDO approximation, the coefficients $c_{i\mu}$ and the MO energies ϵ_i are the eigenvectors and eigenvalues of the Hartree–Fock matrix h^F whose elements are given by:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$h_{\mu\mu}^{\mathrm{F}} = \alpha_\mu + \tfrac{1}{2}P_{\mu\mu}\gamma_{\mu\mu} + \sum_{\nu\neq\mu} P_{\nu\nu}\gamma_{\mu\nu}; \quad [5]$$

$$h_{\mu\nu}^{\mathrm{F}} = \beta_{\mu\nu} - \tfrac{1}{2}P_{\mu\nu}\gamma_{\mu\nu}; \ (\mu \neq \nu). \quad [6]$$

In these equations α_μ is the Coulomb integral

$$\alpha_\mu = \int \phi_\mu^*(1) H_{\mathrm{core}}(1) \phi_\mu(1)\, dv(1), \quad [7]$$

the quantity $\beta_{\mu\nu}$ is the resonance integral

$$\beta_{\mu\nu} = \int \phi_\mu^*(1) H_{\mathrm{core}}(1) \phi_\nu(1)\, dv(1), \quad [8]$$

the quantity $\gamma_{\mu\nu}$ is the Coulomb repulsion integral

$$\gamma_{\mu\nu} = \iint \phi_\mu^*(1)\phi_\nu^*(2)\frac{e^2}{r_{12}}\phi_\mu(1)\phi_\nu(2)\, dv(1)\, dv(2), \quad [9]$$

and $P_{\mu\nu}$ is an element of the charge and bond order matrix P defined by

$$P_{\mu\nu} = 2\sum_i C_{i\mu}^* C_{i\nu}, \quad [10]$$

where the sum is over all occupied MO's.

The integral α_μ [7] can be expanded according to Goeppert-Mayer and Sklar (19) as:

$$\alpha_\mu = W_\mu - \sum_{\nu\neq\mu} [(\mu\mu:\nu) + Z_\nu\gamma_{\mu\nu}], \quad [11]$$

where Z_ν is the number of π-electrons contributed by atom ν. In this paper, the penetration integrals $(\mu\mu:\nu)$ are neglected.

Furthermore, the energy zero for the MO energies ϵ_i is chosen as $W_{\mathrm{C}} + \frac{1}{2}\gamma_{\mathrm{CC}}^{(0)}$ as suggested by McWeeny and Peacock (3).

The form finally adopted for the H–F Hamiltonian h^{F} can be written:

$$h_{\mu\mu}^{F} = \delta w_\mu + \tfrac{1}{2}P_{\mu\mu}\gamma_{\mu\mu} - \tfrac{1}{2}\gamma_{\mathrm{CC}}^{(0)} + \sum_{\nu\neq\mu} (P_{\nu\nu} - Z_\nu)\gamma_{\mu\nu}, \quad [12]$$

$$h_{\mu\nu}^{\mathrm{F}} = \beta_{\mu\nu} - \tfrac{1}{2}P_{\mu\nu}\gamma_{\mu\nu}; \ (\mu \neq \nu), \quad [13]$$

where

$$\delta w_\mu = W_\mu - W_{\mathrm{C}}. \quad [14]$$

Because h^{F} depends on P, an iterative calculation must be used to determine the $c_{i\mu}$'s and ϵ_i's. A procedure for the direct iteration of the matrix R $(= \frac{1}{2}P)$ utilizing the method of steepest descent has been proposed by McWeeny (20). As it only involves the manipulation of matrices, it is particularly adaptable for electronic computation. The entire procedure was programmed in SPS and run on an IBM 1620 computer. The input data required consisted of numerical values for Z_μ, δw_μ, $\beta_{\mu\nu}$, and $\gamma_{\mu\nu}$ defined in equations [11], [14], [8], and [9] and an initial estimate of R. At the end of each descent the idempotency of R was restored according to McWeeny's procedure (20). The procedure was regarded as self-consistent when successive iterations did not change any of the elements of R by more than 10^{-4}. If Huckel MO's were used as starting orbitals, 6 to 8 iterations on the average were required in order to reach self-consistency. The program running time was approximately proportional to n^3, where n is the number of atoms donating π-electrons in the system under consideration. A typical run for a 10-atom molecule took approximately 4 min per descent. The eigenvectors and eigenvalues of

the self-consistent Hamiltonian h^F were determined using an SPS subroutine which diagonalized the matrix utilizing the Jacobi method of rotations.

When an electron is excited from an occupied MO ψ_i to an unoccupied MO $\psi_{k'}$, the resulting singly excited configuration, which may be a singlet or triplet, can be represented by the determinantal wave function.

$$[15] \qquad {}^{1,3}X_{i\to k'} = \frac{1}{\sqrt{2}}\left(|\Phi_1\bar{\Phi}_1 \ldots \Phi_i\bar{\Phi}_{k'} \ldots \Phi_n\bar{\Phi}_n| \mp |\Phi_1\bar{\Phi}_1 \ldots \bar{\Phi}_i\Phi_{k'} \ldots \Phi_n\bar{\Phi}_n|\right).$$

The excited states of the molecule are expressed as a linear combination of singly excited configurations:

$$[16] \qquad S_I = \sum_{i,k'} c_{S_I,ik'}\,{}^1X_{i\to k'},$$

$$[17] \qquad T_I = \sum_{i,k'} c_{T_I,ik'}\,{}^3X_{i\to k'},$$

where i is summed over all occupied MO's, and k' is summed over all unoccupied MO's.

The coefficients $c_{S_I,ik'}$, $c_{T_I,ik'}$ and the electronic excitation energies are obtained by diagonalizing a configuration interaction (CI) matrix with elements given by (21):

$$[18] \qquad ({}^1X_{i\to k'}|H_\pi|{}^1X_{j\to l'}) = \delta_{ij}\delta_{kl}(\epsilon_{k'} - \epsilon_i) + 2\langle ik|jl\rangle - \langle ij|kl\rangle,$$

$$[19] \qquad ({}^3X_{i\to k'}|H_\pi|{}^3X_{j\to l'}) = \delta_{ij}\delta_{kl}(\epsilon_{k'} - \epsilon_i) - \langle ij|kl\rangle,$$

where ϵ_i is the orbital energy of MO ψ_i and $\langle ij|kl\rangle$ is a molecular repulsion integral which can be computed from:

$$[20] \qquad \langle ij|kl\rangle = \sum_{\mu,\nu} c_{i\mu}c_{k\mu}c_{j\nu}c_{l\nu}\gamma_{\mu\nu}.$$

An SPS program was set up to calculate all the elements of the singlet and triplet CI matrices. The required input data consisted of the MO coefficients $c_{i\mu}$, the MO energies ϵ_i, and the Coulomb repulsion integrals $\gamma_{\mu\nu}$.

All configurations which did not interact to an appreciable extent with any of the four lowest-energy configurations were not included in the final diagonalization of the CI matrix. "Important" configurations $X_{j\to l'}$ were arbitrarily selected as those which satisfied:

$$[21] \qquad |(X'_{i\to k'}|H_\pi|X_{j\to l'})|/[|(X_{j\to l'}|H_\pi|X_{j\to l'}) - (X'_{i\to k'}|H_\pi|X'_{i\to k'})|] \geqslant 0.1,$$

where $X'_{i\to k'}$ is one of the four lowest-energy configurations.

CALCULATION OF INTEGRAL AND PARAMETER VALUES

The one-center core parameters δw_μ were estimated using the relationship

$$[22] \qquad \delta w_\mu = I_C - I_\mu.$$

The necessary valence-state ionization potentials I_μ were taken from the recently compiled tables of Hinze and Jaffé (22):

$$I_C(trtrtr\pi) = 11.16 \text{ eV},$$

$$I_N(di^2di\pi\pi) = 14.18 \text{ eV},$$

$$I_N(tr^2trtr\pi) = 14.12 \text{ eV}.$$

Carbon–carbon resonance integrals were evaluated with an exponential fit

[23] $$\beta_{CC}(r) = -2\,500\exp(-5r)\text{ eV} \qquad (r \text{ in Å}).$$

The two carbon–nitrogen resonance integrals were chosen so as to best reproduce the observed singlet–singlet transition energies of pyridine and benzonitrile. The values adopted were:

$$\beta_{CN}\,(\text{aza}) = -2.6\text{ eV},$$

$$\beta_{CN}\,(\text{nitrile}) = -3.5\text{ eV}.$$

One-center Coulomb integrals were evaluated according to the method suggested by Pariser (23):

[24] $$\gamma_{\mu\mu}^{(0)} = I_\mu - A_\mu.$$

The required valence-state ionization potentials I_μ and electron affinities A_μ were taken from Hinze and Jaffé (22). These gave:

$$\gamma_{CC}^{(0)} = 11.13\text{ eV},$$

$$\gamma_{NN}^{(0)}\,(\text{aza}) = 12.34\text{ eV},$$

$$\gamma_{NN}^{(0)}\,(\text{nitrile}) = 12.52\text{ eV}.$$

Two-center Coulomb integrals were computed according to the scheme proposed by Mataga and Nishimoto (4):

[25] $$\gamma_{\mu\nu}(r) = e^2/(a_{\mu\nu} + r).$$

Of course, application of Mataga's approximation to atoms that are not uniformly charged +1 in the core is not readily justifiable.

The constants $a_{\mu\nu}$ were determined from the values of $\gamma_{\mu\mu}^{(0)}$ and $\gamma_{\nu\nu}^{(0)}$ according to:

[26] $$a_{\mu\nu} = \tfrac{1}{2}e^2\left(\frac{1}{\gamma_{\mu\mu}^{(0)}} + \frac{1}{\gamma_{\nu\nu}^{(0)}}\right).$$

The interatomic distances for the various molecules studied were estimated from the molecular geometrics of pyridine (24) and benzonitrile (25).

RESULTS AND DISCUSSION

The SCF ground state MO's and orbital energies of all the molecules studied are given in Appendix I. Charge densities and bond orders computed from these orbitals are shown in Fig. 1. The wave functions for the four lowest-energy excited singlet states for each molecule are listed in Appendix II. In addition, the four lowest-energy excited triplet states of pyridine and benzonitrile are given. Table I presents a summary of the computed transition energies and compares them with experimental values. Observed transition energies were taken to correspond to the position of the band maxima and were determined from the data given in the references listed below Table I. The nature of the solvent is indicated. Appendices I and II have been placed in the depository of unpublished data.

It can be seen from Table I that computed singlet–singlet transition energies are in fair agreement with experiment. In general, singlet levels are predicted to be somewhat higher (0.1 to 0.4 eV) than is observed. However, the spacing amongst the various levels is in good accord with observed spacings. As might be expected, the largest differences

between theory and experiment occur for the most highly substituted molecule studied, namely 1,2,4,5-tetracyanobenzene. It should be noted that the observed transition energies were not corrected for solvent effects. Such corrections would raise the observed singlet levels and bring them in closer agreement with theory. The calculated energy sequences for the first two singlet levels in the isomeric cyanopyridines and isomeric dicyanobenzenes agree with experiment with one notable exception. The second singlet level in 4-cyanopyridine is calculated to lie 0.2 eV above the second levels in 2- and 3-cyanopyridine, whereas experimentally it is observed to lie 0.05 eV below.

The greatest conflict between theory and experiment occurs for the lowest singlet–triplet transition energy. In pyridine, the computed energy is 1.2 eV too low, while in benzonitrile it is 1.1 eV too low. This seems to be characteristic of the use of the Mataga

approximation for the two-center repulsion integrals. In benzene (4) it is possible to get an excellent fit with experiment for the three singlet levels by varying the carbon–carbon resonance integral β_{CC}. However, use of the "optimum" value of β_{CC} causes the calculated lowest triplet level to lie approximately 1 eV below the observed level. It is not surprising that this discrepancy lingers in calculations on substituted benzenes.

In CI calculations, the question arises as to whether or not it is sufficient to take into consideration only the singly excited configurations involving the two highest occupied and two lowest unoccupied ground state MO's. For the molecules studied, there is little change ($\approx$0.1 eV) in the singlet levels by considering all singly excited configurations. However, singly excited configuration involving the third and fourth highest occupied and lowest unoccupied orbitals were found to be important in the calculation of triplet levels, especially the lowest level as the following data illustrates:

Pyridine:—1st approximation,

$$^3E_1 = 3.11 \text{ eV},$$
$$T_1 = 0.857\ ^3X_{1\to 2'} - 0.516\ ^3X_{2\to 1'};$$

2nd approximation,

$$^3E_1 = 2.51 \text{ eV},$$
$$T_1 = 0.766\ ^3X_{1\to 2'} - 0.579\ ^3X_{2\to 1'} + 0.129\ ^3X_{2\to 3'} + 0.248\ ^3X_{3\to 3'}.$$

Benzonitrile:—1st approximation,

$$^3E_1 = 3.06 \text{ eV},$$
$$T_1 = 0.785\ ^3X_{1\to 1'} + 0.620\ ^3X_{2\to 2'};$$

2nd approximation,

$$^3E_1 = 2.26 \text{ eV},$$
$$T_1 = 0.668\ ^3X_{1\to 1'} + 0.620\ ^3X_{2\to 2'} + 0.158\ ^3X_{3\to 3'} - 0.174\ ^3X_{4\to 4'} + 0.200\ ^3X_{1\to 3'} - 0.174\ ^3X_{3\to 4'}.$$

In summary, it appears as though use of the Mataga approximation for two-center Coulomb repulsion integrals together with a judicious choice of core parameters will give a fairly reasonable prediction of singlet–singlet transition energies in aromatic nitriles. Treatment of δw_N as an empirical parameter and a careful selection of resonance integrals could undoubtedly improve the agreement between theory and experiment over that which is reported here. However, the lowest singlet–triplet transition energies are not predicted very well and lie around 1 eV below the observed energies.

REACTIONS OF THE ETHYL RADICAL

IV. ADDITION TO VINYL MONOMERS

D. G. L. JAMES

Received October 19, 1964

ABSTRACT

The Arrhenius parameters have been measured for the addition of the ethyl radical to a representative selection of vinyl monomers in the gas phase. The wide range of reactivity observed was almost entirely due to the variation of the energy of activation, from 3.4 ± 0.4 kcal/mole for acrylonitrile to 6.9 ± 0.5 kcal/mole for vinyl acetate. No significant variation was found among the values of the pre-exponential factors, indicating uniformity of steric conditions at the site of radical attack. The rate constant for the addition of the ethyl radical is considered as an alternative to the copolymerization parameter Q_0 as an index of the intrinsic reactivity of a monomer at a given temperature.

INTRODUCTION

The effect of structure upon the reactivity of monoolefins towards the addition of the ethyl radical was discussed in Part II of this series (1). This study has now been extended to vinyl monomers of the type CH_2=CHX, chosen so that diverse combinations of Q and e values should be included. The values of e for the olefins of Part II all lie within a narrow range, but in this study e varies from +1.11 for acrylonitrile to −1.64 for vinyl *n*-butyl ether (2, 3). Such a wide variation in e introduces a particular difficulty into any attempt to relate the intrinsic reactivity of the monomer to the rate constant for the addition of a chosen reference species. This is particularly clear if we consider the diverse patterns of response shown by the monomers of this study towards homogeneous polymerization under cationic, radical, and anionic conditions. Although none of these monomers is entirely unreactive towards attack by the polystyrene radical, kinetic measurements (4) reveal that vinyl *n*-butyl ether (Q = 0.014, e = −1.64) reacts far more rapidly with the polystyrene cation whereas acrylonitrile (Q = 0.58, e = 1.11) is more reactive towards the polystyrene anion. Selectivity varies from styrene (Q = 1.00, e = −0.80) which reacts freely with the polystyrene cation, radical, or anion, to vinyl acetate (Q = 0.026, e = −0.22) which reacts appreciably with the radical only. Parallel results are obtained in attempts to initiate homogeneous homopolymerization of these monomers with cationic, radical, and anionic catalysts. Selectivity is lowest with styrene, intermediate with acrylonitrile, which responds to anionic and radical catalysts but is inert to the strong cationic catalyst boron trifluoride etherate in a pure form (5), and highest with vinyl *n*-butyl ether and vinyl acetate, which yield appreciable amounts of high polymer only with cationic (6, 7) and radical (8, 9) catalysts respectively.

The examples given above show that the monomers chosen for this study encompass a wide diversity of behavior. Polar effects dominate the response of these monomers to the reaction conditions. A reliable index of the intrinsic reactivity of the monomer, independent of polar effects, is required before the reactivity of a given monomer can be

[1]*Present address: Plastics Division, Central Research Department, The Distillers Co. Ltd., Epsom, Surrey, England.*

related to its molecular structure. The rate constant for the addition of a common reference species to the monomer at a standard temperature provides a valid index of intrinsic reactivity only if this reference species is well chosen. The polyethylene radical has the virtue of possessing both a high ionization potential and a low electron affinity, so that polar effects in the addition of this radical should be particularly low. Indeed Burkhart and Zutty have recently proposed that the Q_0 value of the monomer should be used as an index of intrinsic reactivity (10). Q_0 values are based upon the choice of ethylene as the reference monomer, and the assignment to ethylene of the values: $Q_0 = 1.00$ and $e_0 = 0.00$. The Q_0 value of a monomer is then directly proportional to the rate constant for the addition of the polyethylene radical to the monomer molecule and thus provides a direct measure of monomer reactivity. The Q_0 value of a monomer (B) should be directly determined from the relationship $Q_{0B} = 1/r_A$, where r_A is the reactivity ratio of the copolymerization of monomer (B) with ethylene (A), but this has been measured accurately for only a few monomers (10, 11). Significantly these values of Q_0 are calculated on the assumption that the reactivity of the polyethylene radical is entirely determined by the terminal ethylene unit. In fact the model polyethylene radical is no more than the substituted ethyl radical, $YCH_2CH_2\cdot$, in which the nature of Y has no effect upon the reactivity. It is therefore reasonable to propose that at common temperature the rate constant for the addition of the ethyl radical itself to the monomer B should be proportional to Q_{0B}, and should therefore provide an alternative measure of the intrinsic reactivity of the monomer B. The ethyl radical also possesses a high ionization potential and a low electron affinity, so that polar effects in the addition reactions of the ethyl radical should be particularly small.
