2-Hydroxymethyl-1-methylpyridinium iodide, and the 2-acetoxymethyl analogue, cleaved readily to yield the 1-methylpyridinium ion (isolated as the sodium double picrate (7)) on refluxing with aqueous sodium hydroxide, or with an aqueous buffer of pH 9.6. 2-Formylpyridinium methiodide, in the form of its hemi-acetal, behaved similarly. However, the cleavage reaction did not occur in neutral or acidic solution, and moreover, the corresponding derivatives of the 4-pyridyl series were stable under those conditions which cleaved the 2-derivatives, indicating the lower stability of zwitterions of type III than those of type II.

The present results rationalize the formation (8) of the stilbazole derivative (VIII) on reaction of the hydroxymethyl compound (IX), and the 2-formyl analogue, with dimethylaminobenzaldehyde. In addition to proposing the mechanism favored by us,

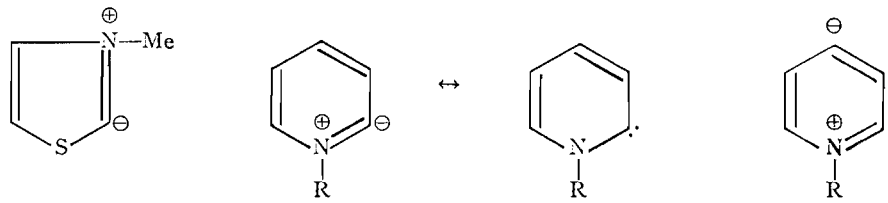
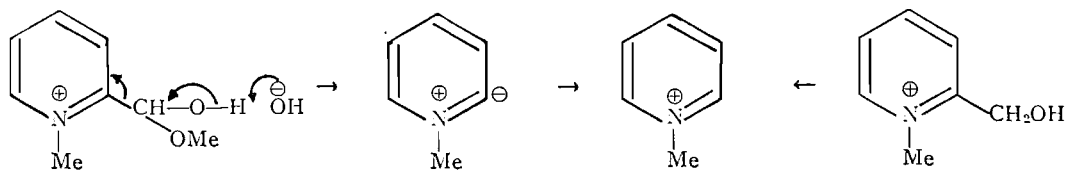
HETEROCYCLONIUMYL ZWITTERIONS. PART I. THE ALKALI-CATALYZED CLEAVAGE OF 2-HYDROXYMETHYL- AND 2-FORMYL-PYRIDINIUM CATIONS

S. GOLDING AND A. R. KATRITZKY



I II III

Heterocycloniumyl zwitterions of type I are well known to be of importance in the biological activity of thiamine (1), and recently azolonium zwitterion intermediates have received attention (2). Certain pyridinium derivatives have been shown to exchange α-hydrogen atoms by way of zwitterions of type II (3). We have now shown that the relative stability of such species facilitates the reaction sequences (IV $\rightarrow$ VI) and (VII $\rightarrow$ VI).



IV V VI VII

1-Methyl-2-formylpyridinium iodide has been previously reported as an oil (4), or as a solid of m.p. 174° (5) or 178–179° (6), but in none of these references is there mention of any analytical data. 1-Methyl-4-formylpyridinium iodide was reported (5) as a "low melting solid", but was apparently not characterized. Repetition of these procedures gave ill-defined products. Attempted preparation of the aldehyde methiodides in methanol solution gave crystalline derivatives which were shown by analysis and spectroscopy to be the corresponding methyl hemi-acetals.

2-Hydroxymethyl-1-methylpyridinium iodide, and the 2-acetoxymethyl analogue, cleaved readily to yield the 1-methylpyridinium ion (isolated as the sodium double picrate (7)) on refluxing with aqueous sodium hydroxide, or with an aqueous buffer of pH 9.6. 2-Formylpyridinium methiodide, in the form of its hemi-acetal, behaved similarly. However, the cleavage reaction did not occur in neutral or acidic solution, and moreover, the corresponding derivatives of the 4-pyridyl series were stable under those conditions which cleaved the 2-derivatives, indicating the lower stability of zwitterions of type III than those of type II.

The present results rationalize the formation (8) of the stilbazole derivative (VIII) on reaction of the hydroxymethyl compound (IX), and the 2-formyl analogue, with dimethylaminobenzaldehyde. In addition to proposing the mechanism favored by us,

IX

the previous authors suggested an alternative which involved participation of the dimethylamino group to facilitate protonation. Previous work (9, 10) by one of us, makes this alternative very unlikely.

EXPERIMENTAL

2-Acetoxymethyl-1-methylpyridinium Iodide

2-Acetoxymethylpyridine (1 g) was refluxed with methyl iodide (1ml) in methanol (2 ml) for 6 h. Addition of ether to the cooled mixture gave the methiodide which formed colorless plates, m.p. 154–155°, from ethanol–ether. Calc. for $C_9H_{12}INO_2$: C, 36.9; H, 4.1; N, 4.8. Found: C, 36.8; H, 4.1; N, 4.8.[1]

The following were similarly prepared: 2-hydroxymethyl-1-methylpyridinium iodide, m.p. 153.5–154.5° (lit. (11) m.p. 153°). Calc. for $C_7H_{10}INO$: C, 33.4; H, 4.0; N, 5.6. Found: C, 33.5; H, 4.0; N, 5.5. 4-hydroxymethyl-1-methylpyridinium iodide, m.p. 97–98° (lit. (12) m.p. 94°).

2-Acetoxymethyl-1-methylpyridinium picrate formed yellow needles, m.p. 101–102°, from ethanol. Calc. for $C_{15}H_{14}N_4O_9$: C, 45.7; H, 3.6; N, 14.2. Found: C, 45.7; H, 3.7; N, 14.4.

2-Hydroxymethyl-1-methylpyridinium picrate formed yellow needles, m.p. 121–122°, from ethanol. Calc. for $C_{13}H_{12}N_4O_8$: C, 44.3; H, 3.4; N, 15.9. Found: C, 44.3; H, 3.6; N, 16.1.

Hemi-methyl Acetals of 2- and 4-Formyl-1-methylpyridinium Iodide

2-Pyridine aldehyde on treatment as above gave the hemi-methyl acetal methiodide, m.p. 101–105°, as plates which decomposed on attempted recrystallization. Calc. for $C_8H_{12}INO_2$: C, 34.2; H, 4.3; N, 5.0. Found: C, 34.4; H, 4.5; N, 5.8. The infrared spectrum (Nujol) showed strong bands at 3 240 (bonded OH), 1 640 (pyridinium ring), and 1 100 cm^{-1} (ether). The nuclear magnetic resonance (n.m.r.) spectrum showed a multiplet at 1.35–2.35 (4 aromatic protons), and singlets at 3.7 (CH), 5.8 (O—Me), and 6.9 τ (N—Me).

The hemi-acetal methiodide from 4-pyridine aldehyde formed plates, m.p. 75–78°, which decomposed on attempted recrystallization. Found: C, 33.7; H, 4.9; N, 5.6. The infrared spectrum (Nujol) showed strong bands at 3 250 (bonded OH), 1 650 (pyridinium ring), and 1 080 cm^{-1} (ether). The n.m.r. spectrum showed doublets at 1.4 and 2.1 (4 aromatic protons), and singlets at 4.0 (CH), 5.7 (OMe), and 6.9 τ (NMe).

Cleavage Reaction Procedure

The cleavage reaction was carried out by heating the compound (0.5 g) with sodium hydroxide or sodium carbonate buffer (50 ml) on a water bath for 6 h. Sodium 1-methylpyridinium dipicrate was isolated by the addition of 10% ethanolic picric acid (10 ml); on cooling, it separated as yellow needles, m.p. 215–216°. The double picrate was synthesized independently by dissolving pyridine methiodide (0.25 g) in *N* sodium hydroxide (25 ml) and adding 10% ethanolic picric acid (5 ml). On cooling the double picrate (0.35 g, 100%) was obtained as yellow needles, m.p. 215–216° (reported, 215–220° (7)), after recrystallization from ethanol. The double picrates from the cleavage reactions were identical with those directly synthesized, as was shown by mixed melting points and infrared spectra.

THE INFRARED SPECTRUM OF AMMONIA ADSORBED ON CABOSIL SILICA POWDER

N. W. CANT AND L. H. LITTLE

Measurements of length changes and infrared spectra of Vycor porous silica glass during the adsorption of ammonia led Folman and Yates (1, 2) to propose that two types of adsorption sites existed on the surface. They showed that free surface hydroxyl groups constitute one of these sites while surface silicon or oxygen atoms were assumed to be the other. Recently (3), using thinner samples of porous glass, we showed that ammonia adsorbed on the free hydroxyl groups and gave bands at 3 400 cm^{-1} and 3 320 cm^{-1} due to the asymmetric and symmetric NH-stretching vibrations. These bands disappeared on room-temperature evacuation of gas phase ammonia. In addition, we were able to distinguish bands at 3 365 cm^{-1} and 3 280 cm^{-1} that were unaffected by room-temperature evacuation. From comparison with the spectrum of the Lewis acid–base complex $F_3B{:}NH_3$, we proposed that these bands were due to ammonia strongly held to surface Lewis acid sites, possibly boron or aluminium atoms. Roev, Filiminov, and Terenin (4) observed similar bands for residual ammonia adsorbed on a silica–alumina catalyst and attributed them to ammonia molecules chemisorbed to surface aluminium atoms.

In view of these results it was decided to study the infrared spectrum of ammonia adsorbed on Cabosil silica powder as had been suggested to us by Professor Fripiat (5). This material is extremely pure and does not contain boria, alumina, and other oxides, which occur in Vycor silica glass and which are considered to be active sites for chemisorption of ammonia (3). If the above assignments (3) are correct, only the absorption bands at 3 400 cm^{-1} and 3 320 cm^{-1}, due to ammonia molecules hydrogen bonded to surface hydroxyl groups, should appear for adsorption onto Cabosil. No evidence for chemisorption should appear.

In the infrared spectra of both types of silica sample, absorption bands appear due to surface hydroxyl groups, some of which are free and others hydrogen bonded among themselves. The former are responsible for a band at 3 747 cm^{-1}, the latter for a shoulder at 3 670 cm^{-1}. Very recently Yates (6) quoted optical densities for the free hydroxyl absorption band, before and after the adsorption of ammonia, but no ammonia frequencies or spectra were given.

EXPERIMENTAL

Cabosil powder (from Godrey L. Cabot Inc.) was compressed into thin self-supporting discs under a pressure of 10 tons/sq. in. The quantity of material in the infrared beam was approximately 12 mg/cm^2.

THE INFRARED SPECTRUM OF AMMONIA ADSORBED ON CABOSIL SILICA POWDER

N. W. CANT AND L. H. LITTLE

Measurements of length changes and infrared spectra of Vycor porous silica glass during the adsorption of ammonia led Folman and Yates (1, 2) to propose that two types of adsorption sites existed on the surface. They showed that free surface hydroxyl groups constitute one of these sites while surface silicon or oxygen atoms were assumed to be the other. Recently (3), using thinner samples of porous glass, we showed that ammonia adsorbed on the free hydroxyl groups and gave bands at 3 400 cm^{-1} and 3 320 cm^{-1} due to the asymmetric and symmetric NH-stretching vibrations. These bands disappeared on room-temperature evacuation of gas phase ammonia. In addition, we were able to distinguish bands at 3 365 cm^{-1} and 3 280 cm^{-1} that were unaffected by room-temperature evacuation. From comparison with the spectrum of the Lewis acid–base complex $F_3B{:}NH_3$, we proposed that these bands were due to ammonia strongly held to surface Lewis acid sites, possibly boron or aluminium atoms. Roev, Filiminov, and Terenin (4) observed similar bands for residual ammonia adsorbed on a silica–alumina catalyst and attributed them to ammonia molecules chemisorbed to surface aluminium atoms.

In view of these results it was decided to study the infrared spectrum of ammonia adsorbed on Cabosil silica powder as had been suggested to us by Professor Fripiat (5). This material is extremely pure and does not contain boria, alumina, and other oxides, which occur in Vycor silica glass and which are considered to be active sites for chemisorption of ammonia (3). If the above assignments (3) are correct, only the absorption bands at 3 400 cm^{-1} and 3 320 cm^{-1}, due to ammonia molecules hydrogen bonded to surface hydroxyl groups, should appear for adsorption onto Cabosil. No evidence for chemisorption should appear.

In the infrared spectra of both types of silica sample, absorption bands appear due to surface hydroxyl groups, some of which are free and others hydrogen bonded among themselves. The former are responsible for a band at 3 747 cm^{-1}, the latter for a shoulder at 3 670 cm^{-1}. Very recently Yates (6) quoted optical densities for the free hydroxyl absorption band, before and after the adsorption of ammonia, but no ammonia frequencies or spectra were given.

EXPERIMENTAL

Cabosil powder (from Godrey L. Cabot Inc.) was compressed into thin self-supporting discs under a pressure of 10 tons/sq. in. The quantity of material in the infrared beam was approximately 12 mg/cm^2.

The discs were evacuated for 3 h at 400–450 °C before recording the initial spectrum. The spectra shown in Fig. 1 were recorded with a Perkin–Elmer Model 521 spectrometer for which the spectral slit width was about 5 cm^{-1} at 3 800 cm^{-1}. The disc was enclosed in an evacuated silica test tube cell of approximately 1 cm internal diameter. This cell absorbed slightly near 3 670 cm^{-1}, for which a correction was made. The deuteration experiments quoted in the text were carried out with a Perkin–Elmer Model 137G spectrometer. A 1 cm path length cell, consisting of magnesium oxide windows attached to a Pyrex tube with epoxy resin, was used in this work. In both cases the ammonia gas band at 3 337 cm^{-1} was used for calibration.

RESULTS AND DISCUSSION

Figure 1*a* shows the spectrum of the Cabosil disc after evacuation for 3 h at 450 °C; the 3 747 cm^{-1} band being due to free surface hydroxyl groups and a shoulder at about 3 670 cm^{-1}, not clearly discernible in spectrum (*a*), to adjacent hydroxyl groups hydrogen bonded together. The spectrum is similar to that recorded by McDonald (7). Spectrum 1*b* was obtained 1 h after 6 cm pressure of ammonia had been admitted to the cell at room temperature. No changes were observed after further standing. The circles in this figure represent optical densities after evacuation of ammonia for 15 min at room temperature.

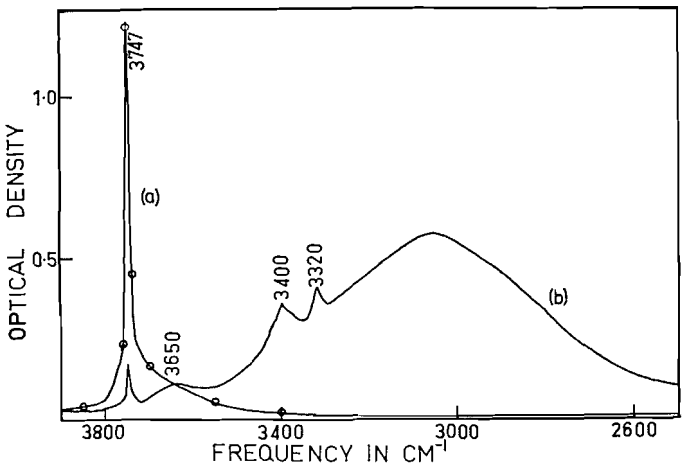

FIG. 1. (*a*) The infrared spectrum of Cabosil from 3 900 cm^{-1} to 2 500 cm^{-1} after evacuation for 3 h at 450 °C. (*b*) The spectrum 1 h after admission of 6 cm of ammonia at room temperature. The circles represent the resulting optical densities after evacuation at room temperature for 1 h. A shoulder appears at 3 670 cm^{-1} in spectrum (*a*). After adsorption of ammonia the shoulder is displaced to 3 650 cm^{-1} (spectrum (*b*)).

The great reduction in the intensity of the free hydroxyl band and the appearance of a very broad, intense band at 3 050 cm^{-1} after admission of ammonia to the cell show that adsorption has occurred by hydrogen bonding to free surface hydroxyl groups. This is confirmed by the appearance of bands at 3 400 cm^{-1} and 3 320 cm^{-1}, due to NH-stretching vibrations of ammonia. The absence of bands after room-temperature evacuation of the ammonia shows that Cabosil contains no adsorption sites of the second type found on Vycor.

As can be seen from Fig. 1*a* and 1*b* the adsorption of ammonia greatly reduced the intensity of the free hydroxyl band without appreciably affecting the intensity of the hydrogen-bonded one. When the pressure of ammonia in the cell was raised to 12 cm the free hydroxyl band was indistinguishable from background noise. This indicates that all free hydroxyl groups are able to interact with ammonia molecules and are therefore surface groups. Similar results were obtained for the free hydroxyls on Vycor glass.

Fripiat and Uytterhoeven (8) concluded that after evacuation of Degussa Aerosil (which is made by an identical process to the Cabosil used here) at 400 °C, only 30% of the total hydroxyl content was on the surface. If it is assumed, as Fripiat did, that the absorption coefficients of both types of surface hydroxyl groups are identical, then it is possible to estimate roughly the ratio of free to hydrogen-bonded groups from the relative areas beneath the bands of Fig. 1*a*. Using this method we found that the free hydroxyl groups, which all reside on the surface, represent at least 50% of the total hydroxyl content of our silica after 450 °C evacuation. It is likely that the absorption coefficient of the hydrogen-bonded hydroxyls is considerably greater than that of the free groups (9). On this basis the free surface hydroxyl content should greatly exceed 50% of the total. Although ammonia does not interact by hydrogen bonding to the hydroxyls responsible for the 3 670 cm^{-1} band of either Cabosil (Fig. 1) or Vycor (3), it can be established that a considerable proportion of these hydroxyl groups are also on the surface.

Fripiat, Gastuche, and Brichard (10) showed that both types of hydroxyl groups of Degussa Aerosil can be converted to deuteroxyl groups by room-temperature treatment with D_2O vapor. We have been able to show that these deuteroxyl groups (both free and bonded) can be reconverted to hydroxyl groups by exchange with ammonia at room temperature. These reactions are only possible if an appreciable proportion of the bonded hydroxyls (or deuteroxyls) exist on the surface. On this basis it is estimated that approximately 80% of the total hydroxyl content of the Cabosil silica resides on the surface of the particles.

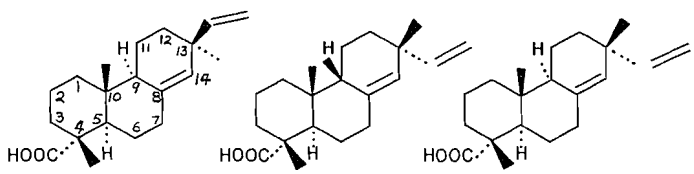
ABSTRACT

Evidence is presented for the epimeric character of the C-13 substituents in pimaric and isopimaric acids and for the nuclear double bond location in isopimaric acid. This work, coupled with recent synthetic work and rotatory dispersion evidence, permits assignment of the structure and stereochemistry IV to isopimaric acid. Hydroboration and selenium dioxide oxidation of the acid are described.

In 1948 Harris and Sanderson suggested structures for two diterpenoid constituents of pine oleoresin, pimaric and isopimaric acids (1). Extensive chemical work (2–6) appeared to confirm their assignments. In combination with arguments based on optical rotation (7) and optical rotatory dispersion (8), this led to general acceptance of the structure and stereochemistry shown in I for pimaric acid and in II for isopimaric acid. Another isomer, sandaracopimaric acid, was assigned configuration III (9). The elegant



total synthesis by Ireland and Schiess of *dl*-pimaradiene and *dl*-sandaracopimaradiene confirmed the structure of the corresponding acids (10). With reasonable assumptions regarding the steric course of the reactions, supplemented by evidence from ultraviolet absorption spectra and relative adsorption, this work provided strong support for the stereochemistry shown in I and III. Further confirmation of the structure and absolute configuration was given by Milne and Smith, who transformed a steroid degradation product into pimar-8-ene (11).[3] Finally, transformation of testosterone into sandaracopimaradiene by Bose and Harrison (12) and of 3β-hydroxyandrost-5-ene-17-one into the same diene by Fetizon and Golfier (12*a*) established beyond question the configuration at C-13 for all three acids. Thus, pimaric and sandaracopimaric acids are correctly represented in every detail by I and III.

[1]*Issued as N.R.C. No. 8297.*
[2]*National Research Council Postdoctorate Fellow.*
[3]*It seems logical to use the phenanthrene numbering system for the pimaric acids. However, because of the widespread familiarity with the steroid numbering system, most North American groups have applied this to the resin acids. For this reason we also use the latter in this paper.*

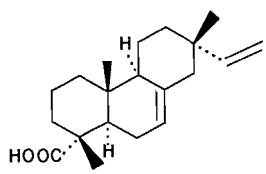
The chemistry and optical rotatory dispersion (2, 8) of isopimaric acid seemed perfectly consistent with the structure and stereochemistry denoted by II. However, Church and Ireland synthesized the corresponding pimaradiene (13) and found it to be different from isopimaradiene. This observation proved that the double bond of isopimaric acid was not in the 8,14 position. They pointed out that, since the nuclear vinyl hydrogen signal for isopimaric acid (14) was a broadened doublet, it must be coupled with adjacent hydrogens. Since the double bond migrates easily to the 8,9 position, the most logical location for it, on this and biogenetic grounds, was the 7,8 position. They hence postulated that isopimaric acid had the structure and stereochemistry illustrated in IV. This expression was also consistent with all the previous evidence except that of Harris and Sanderson.

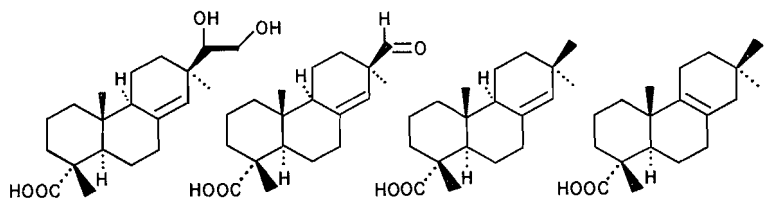
We now amplify our preliminary report on work which interrelated pimaric and isopimaric acids and proved that they are epimeric at C-13 (6), and on the experiments which proved Church and Ireland's structure IV to be correct for the latter (15).

A direct and unequivocal way of interrelating the acids and settling whether or not they were isomeric at C-13 proved to be the conversion of both to the 13,13-dimethyl compounds (6). Pimaric acid reacted with 1 mole of osmium tetroxide in dry ether to give an osmate which was decomposed by alkaline mannitol solution. A diol acid V was obtained in poor yield.[4]

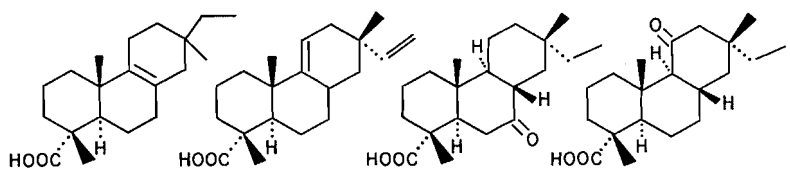
This was cleaved in aqueous dioxane solution by periodic acid to a rather sensitive aldehydo acid VI. Wolff–Kishner reduction of VI (preforming the hydrazone) gave the 13,13-dimethyl acid VII. This could be quantitatively isomerized by hydrogen chloride in chloroform to the Δ^8 acid VIII.



IV



V VI VII VIII



IX X XI XII

[4]*This diol acid does not correspond to either of the acids previously described as arising by permanganate oxidation of pimaric acid (16).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Hydroxylation of isopimaric acid in the same way gave a mixture of sparingly soluble products. Two isomeric diol acids and a triol acid were separated by fractional crystallization. The major diol acid gave an aldehydo acid when treated with periodic acid. Wolff–Kishner reduction of this gave a 13,13-dimethyl acid distinct from the one from pimaric acid. When exposed to dry HCl in $CHCl_3$ this acid was isomerized to the $\Delta^{8,9}$ isomer, which proved identical with VIII derived from pimaric acid. This confirmed the earlier conclusion (2–5) that pimaric and isopimaric acids had identical skeletons and stereochemistry at C-4, C-5, and C-10. Since the $\Delta^{8,9}$ acids (IX) derived from dihydro pimaric and isopimaric acids were different, it followed that the parent acids were epimeric at C-13.

Although structure IV for isopimaric acid seemed the most plausible one on biogenetic grounds, the chemical evidence did not exclude the $\Delta^{9,11}$ isomer X from consideration. We hence sought experiments which would clearly distinguish between these. One possibility was that of converting the acid via the keto acids XI or XII to 1,7,9- or 1,5,7-trimethyl phenanthrene or to the phenols 1,7-dimethyl-9-phenanthrol or 1,7-dimethyl-5-phenanthrol. Hydroboration of the double bond of dihydroisopimaric acid gave a mixture of alcohols[5] which on oxidation with Jones's reagent (17) have one keto acid. Since this was stable to base, the ring fusion at this point was in its most stable configuration. The nuclear magnetic resonance (n.m.r.) spectrum of the keto acid had signals between τ 7.5 and τ 8.2 corresponding to three hydrogens alpha to the ketone carbonyl. This was consistent with either XI or XII. An indication that the carbonyl was at C-7 (XI) was given by the facile formation of a 2,4-dinitrophenylhydrazone. An 11-ketone as in XII should (if the ring fusion were *trans*–anti–*trans*) be inert to the reagent by analogy to the behavior of 11-keto steroids.

The keto acid was treated with methyl magnesium iodide to give the methyl carbinol (probably configuration XIII if structure XI is correct). This, however, gave only small amounts of phenanthrenes which could not be purified when it or its sodium salt was heated with selenium. Dehydrogenation of the keto acid (XI or XII) did give a phenolic product very similar to 1,7-dimethyl-9-phenanthrol, but identity could not be rigorously established.

The second approach to location of the double bond of isopimaric acid proved more definitive. It had already been shown that photolysis of the azide of dihydropimaric acid gave a mixture of the corresponding isocyanate and the γ-lactam XIV (18). It appeared likely that the same course would be followed with isopimaric acid, and experiment confirmed this expectation. A 9% yield of γ-lactam ($\nu_{max}^{CHCl_3}$ 1 685 cm^{-1}) was produced when the azide was photolyzed in hexane solution. On the basis of structure IV this should be XV, while structure X would give rise to XVI. Only in structure XV is the amide nitrogen allylic to the double bond. Inspection of the geometry of this structure (see XVII) indicated that the 6-hydrogen should be weakly coupled, if at all, to the 7-hydrogen ($\phi \simeq 90°$) and hence should give a fairly clean doublet in the n.m.r. spectrum of the compound. In contrast, the 6-hydrogen in XVI and XVIII should give rise to a complex signal, since it should be coupled with the 5-hydrogen and the two on C-7 (see XVIII). In fact, the 6-hydrogen of the lactam from pimaric acid XVIII gave a very broad and complex signal between τ 5.95 and 6.65. The corresponding signal for the γ-lactam from isopimaric acid was a doublet centered at τ 6.17 (J = 10 c.p.s.). This observation excludes structure XV from consideration and proves that isopimaric acid has the sekeleton shown in IV.

[5]*In most experiments the carboxyl group was partially reduced by the diborane simultaneously with hydroboration of the double bond.*

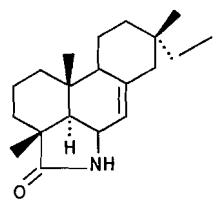
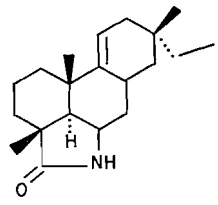
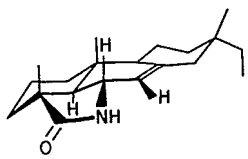
XIV



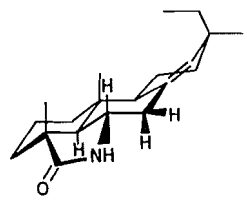
XV



XVI

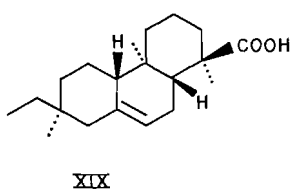


XVII

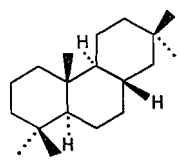


XVIII

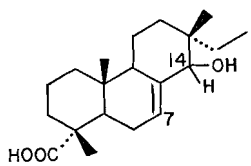
The stereochemistry of isopimaric acid can be deduced on the following grounds. C-13: The configuration at C-13 has been shown above to be epimeric to that of pimaric acid (I) whose stereochemistry is established by the syntheses of Ireland (10), Smith (11), and Bose (12). C-9: If dihydropimaric acid had a 9-α-hydrogen, it is clear from the orientation shown in XIX that its rotatory dispersion curve should be very similar to



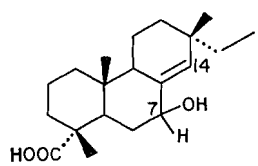
XIX



XX



XXI



XXII

that of cholest-5-ene. The O.R.D. curve for dihydroisopimaric acid is plain and negative (8), almost identical with that of the steroid (19); hence this is the correct stereochemistry.

Proof of this configuration was also provided by Ireland and Newbould (20). They converted pimaradiene to the pentamethyl *trans*–anti–*trans* perhydrophenanthrene XX.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

By a similar sequence which left the asymmetry at C-9 untouched, they converted isopimaric acid to the same hydrocarbon, proving that it has a 9-α-hydrogen. Thus, no doubt is left that the structure and absolute stereochemistry of isopimaric acid is that shown in IV.

Ukita's acid, for which a $\Delta^{7,8}$ structure was suggested (2), has since proved to be a mixture of isopimaric and sandaracopimaric acids (21). Our interest in Ukita's report that the dihydro compound derived from this mixture gave a 7-hydroxy-$\Delta^{8,9}$ derivative on oxidation with selenium dioxide led us to examine the reaction of methyl dihydroisopimarate with this reagent. In ethanol at room temperature a very complex mixture of products resulted. These appeared to be mainly dienes ($\lambda\lambda_{max}$ 235, 244, and 253 mμ). However, careful chromatography on alumina enabled isolation of small quantities of two alcohols. These appeared to be allylic, since in each case manganese dioxide oxidized them to α–β unsaturated ketones (λ_{max} 242 mμ). The n.m.r. spectrum of the first, which melted at 84°, contained a vinyl hydrogen signal as a very broad doublet (J = 4 c.p.s.) centered at τ 4.42. This appeared identical with the 7-hydrogen signal of isopimaric acid (14). A second hydrogen resonating at τ 6.44 was a singlet. These observations accord with structure XXI, the second deshielded hydrogen being the one on C-14.

The second alcohol, m.p. 92°, had a n.m.r. signal at τ 4.55 (one hydrogen, half band width 4 c.p.s.). This is consistent with structure XXII.

EXPERIMENTAL

Rotations were of solution in absolute ethanol. Infrared spectra were determined on a Perkin–Elmer model 21 spectrometer and were of Nujol mulls unless otherwise stated. Nuclear magnetic resonance spectra were obtained with Varian HR-60 and A-60 spectrometers, in chloroform or deuterochloroform with tetramethylsilane as internal standard. Melting points were determined on a Kofler hot stage unless otherwise stated.

Diol V from Pimaric Acid

Pure pimaric acid (9.17 mg, m.p. 211–214°, $[\alpha]_D$ +79°) was suspended in 5 ml of dry ether. A solution of 876 mg of osmium tetroxide in 5 ml of ether was added followed by 5 ml of ether washings. The mixture was shaken for 10 min to dissolve the pimaric acid. The dark solution was left at 5 °C for 65 h. The black precipitate recovered by filtration weighed 1.53 g. Evaporation of the filtrate gave 450 mg of dark residue. The precipitate was heated on the steam bath for 1 h with a mixture of 1 g of sodium hydroxide and 5 g of mannitol in 15 ml of water. The solution was then cooled, acidified with acetic acid, and the precipitate collected by filtration. The solid was dissolved in chloroform, the solution was washed with water, and the water layer back-extracted with chloroform. The chloroform solution was combined with a chloroform extract of the aqueous filtrate from the reaction, dried, and distilled, giving 842 mg of solid. The ether-soluble osmate, when treated similarly, gave 268 mg of solid acid. These were fractionally crystallized separately from ether, giving in each case unchanged pimaric acid, crude diol, and a small quantity of prisms, m.p. 252–257°, which gave analytic figures between those of a diol and a monohydroxy acid.

The crude diol (m.p. up to 165°) was purified by chromatography on a 20-fold ratio of silica gel, from which the main component was eluted with 50% benzene–ether mixture. After three recrystallizations from ether this had m.p. 160–163°, $[\alpha]_D^{23}$ +3 ± 2° (c, 1.11), ν_{max} 1 681 cm^{-1} (COOH) and 821 cm^{-1} (). Yield was approximately 17%.

Anal. Found: C, 71.56; H, 9.50. Calcd. for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59.

Aldehydo Acid VI

Diol acid V (70 mg) was dissolved in 5 ml of pure dioxane. A solution of 108 mg of paraperiodic acid in 1 ml of water was added, and the solution left at room temperature in the dark for 1 h. The bulk of the solvent was then removed under reduced pressure, water added, and the product extracted into methylene chloride. The organic layer was back-washed with water, dried, and distilled, giving 70 mg of crystalline residue, m.p. 195–204°. After four recrystallizations from ether this melted at 215–217° (evacuated capillary) and had $[\alpha]_D^{23}$ +119° (c, 1.60); ν_{max} 2 700, 1 720 cm^{-1} (—CHO), 1 693 cm^{-1} (COOH), 824 cm^{-1} (). A form melting at 174–177° (evacuated capillary) was obtained once.

Anal. Found: C, 75.09; H, 9.10. Calcd. for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

13,13-Dimethyl Acid VII

A solution of 55 mg of the aldehydo acid VI in 2 ml of triethylene glycol containing 0.5 ml of 95% hydrazine was heated on the steam bath for 30 min, then at 140° for 30 min. After cautious addition of 0.64 g of potassium hydroxide the bath temperature was raised slowly to 205° under a slow nitrogen stream, then maintained at this temperature for 3 h. The mixture was cooled, diluted with water, and extracted with methylene chloride. The organic layer was back-washed with dilute alkali. The combined aqueous layers were acidified with sulfuric acid, and extracted with methylene chloride. The 54 mg of acid recovered crystallized spontaneously, m.p. 228–235°. After several recrystallizations from methanol it melted at 232–238° and had $[\alpha]_D^{22}$ +17 ± 2° (*c*, 1.0), ν_{max} 1 692 and 823 cm^{-1}.

Anal. Found: C, 78.41; H, 10.10. Calcd. for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41.

Δ^8-13,13-Dimethyl Acid VIII

The 13,13-dimethyl acid VII (26 mg) was dissolved in 5 ml of dry ethanol-free chloroform and the solution cooled to 0°. Dry hydrogen chloride was then bubbled into the solution for 3.5 h. The hydrogen chloride was then removed from the chloroform by a water wash. An attempt to extract the acid into dilute sodium hydroxide failed, since the sodium salt was more soluble in moist chloroform than in water. The free acid (23 mg) crystallized from aqueous methanol as thick hexagonal plates, m.p. 156.5° after preliminary sintering at 147°, $[\alpha]_D^{24}$ +67 ± 4° (*c*, 0.725), ν_{max} 1 693 cm^{-1} (COOH).

Osmylation of Isopimaric Acid

A solution of 1.21 g of isopimaric acid (m.p. 160–163°, $[\alpha]_D$ 0° (*c*, 2.1)) in 10 ml of dry ether containing 1.0 g of osmium tetroxide quickly turned dark and deposited a precipitate. After 17 h at 5 °C the suspension was filtered and the solid washed with ether, leaving 2.28 g. This was suspended in 15 ml of water containing 1 g of sodium hydroxide and 5 g of mannitol; then the mixture was heated on a steam bath for 1 h. After cooling, the solution was acidified with acetic acid. The solid which separated was collected by filtration, and then washed with hot methylene chloride. The insoluble residue weighed 1.17 g, while the methylene chloride dissolved 14 mg.

The solid was recrystallized from absolute ethanol, giving 407 mg of diol 1, m.p. 205–223°. After four more recrystallizations this melted at 222–228° and had $[\alpha]_D^{22}$ +1° (*c*, 1.14); ν_{max} 3 420, 3 160, 2 520 cm^{-1} (OH's), 1 695 cm^{-1} (C=O), and 825 cm^{-1} (vinyl hydrogen).

Anal. Found: C, 71.66; H, 9.59. Calcd. for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59.

The main mother liquor crystallized slowly, giving blades, m.p. 205–218°, and soft feathery crystals, which were mechanically separated. After two recrystallizations from methanol the blades melted at 208–218°, markedly depressed on admixture with the above diol. Found: C, 71.75; H, 9.56. Hence, this is a second diol acid. The feathery crystals from the mother liquor were separated by crystallization into diol 1 and a new compound. The latter, when recrystallized from methanol, melted at 283°.

Anal. Found: C, 68.33; H, 8.92. Calcd. for $C_{20}H_{32}O_5$: C, 68.15; H, 9.15. This appears to be a triol acid.

Aldehydo Acid from Diol 1 (from Pimaric Acid)

To a solution of 80 mg of diol 1 in 5 ml of pure dioxane was added a solution of 122 mg of paraperiodic acid in 2 ml of water. After 1.5 h in the dark the solution was concentrated to ca. 1 ml *in vacuo*, diluted with water, and extracted with methylene chloride. The organic layer was washed with sodium thiosulfate solution, dried, and distilled, giving 78 mg of nearly pure aldehydo acid. An ether solution of this was diluted with hexane, clarified by filtration, and then concentrated. The aldehydo acid crystallized and had m.p. 145–185° on a hot stage, 166–168° in an evacuated capillary. One recrystallization from ether–hexane raised the melting point to 168–169° (evacuated capillary); $[\alpha]_D^{24}$ −3° (*c*, 1.97); ν_{max} 2 725, 1 721 cm^{-1} (CHO), 1 693 cm^{-1} (COOH), and 825 cm^{-1} (vinyl hydrogen).

Anal. Found: C, 74.85; H, 9.23. Calcd. for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27.

13,13-Dimethyl Acid (from Isopimaric Acid)

Pure aldehydo acid (69 mg) was dissolved in 2 ml of triethylene glycol containing 0.5 ml of 95% hydrazine. This was left overnight at room temperature, and then heated to 150°. After cautious addition of 0.6 g of potassium hydroxide the bath temperature was raised to 200 ± 5° and held there for 4.5 h. The mixture was cooled, diluted with water, acidified, and extracted with methylene chloride. The 80 mg of material from the methylene chloride crystallized spontaneously. After three recrystallizations from aqueous methanol the product melted at 149–154° and had $[\alpha]_D^{24}$ −7° (*c*, 1.38); ν_{max} 2 820, 1 695 cm^{-1} (COOH), and 824 cm^{-1} (vinyl hydrogen).

Anal. Found: C, 78.55; H, 10.24. Calcd. for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41.

Isomerization of the 13,13-Dimethyl Acid (from Isopimaric Acid)

Dry hydrogen chloride was bubbled through an ice-cold solution of 25 mg of the dimethyl acid in 5 ml of dry ethanol-free chloroform for 4 h. The solution was then extracted twice with cold water, dried, and distilled. The residue was dissolved in hexane and the acid extracted into dilute sodium hydroxide solution. The aqueous solution was acidified and the liberated acid extracted into methylene chloride, giving 26 mg

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of product. This was recrystallized twice from aqueous methanol, giving 14 mg of flat needles, m.p. 146–156°, $[\alpha]_D$ +69° (*c*, 0.83). This did not depress the melting point of the Δ^8-13,13-dimethyl acid from pimaric acid, and the mull spectra of the two acids were identical.

Anal. Found: C, 78.59; H, 10.29. Calcd. for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41.

Photolysis of the Azide of Dihydroisopimaric Acid

This azide was prepared as described previously (18). The hydrazide formed prisms from aqueous methanol, m.p. 153°; $[\alpha]_D$ +3° (*c*, 0.97); ν_{max} 3 380 cm^{-1} (>NH), 1 620 cm^{-1} and 1 590 cm^{-1} (amide).

Anal. Found: C, 75.29; H, 10.67; N, 8.73. Calcd. for $C_{20}H_{34}N_2O$: C, 75.42; H, 10.76; N, 8.80.

A hexane solution of the acyl azide prepared from this hydrazide (800 mg), which showed infrared absorption at 2 125 cm^{-1} and 1 700 cm^{-1}, was photolyzed as described previously (18). After 16 h all the azide absorption in the infrared spectrum had disappeared, and the solution was then evaporated to dryness and chromatographed on alumina (grade IV). Hexane eluted the isocyanate (510 mg) as a colorless oil showing infrared absorption at 2 245 cm^{-1}. Elution with benzene yielded a crystalline product (66 mg, 9%) which was purified by sublimation (160° at 10^{-4} mm pressure), yielding small prisms, m.p. 178°, $[\alpha]_D$ 32° (*c*, 0.75).

Anal. Found: C, 79.91; H, 10.17; N, 4.52. Calcd. for $C_{20}H_{31}NO$: C, 79.67; H, 10.37; N, 4.65.

Infrared spectrum: ν_{max} 3 250 cm^{-1} (>NH), 1 690 and 1 645 cm^{-1} (γ-lactam), or 1 685 cm^{-1} (γ-lactam in chloroform). Nuclear magnetic resonance spectrum: τ 1.73, one-hydrogen singlet (NH); τ 4.20, broad one-hydrogen signal, half band width 6 c.p.s. (vinyl hydrogen); τ 6.17, one-hydrogen doublet with J = 10 c.p.s. and half band width for each branch of 6 c.p.s. (hydrogen on C-6). Dihydroisopimaric acid (300 mg) in hexane (100 ml) was unchanged after photolysis for 24 h.

Hydroboration of Methyl Dihydroisopimarate

Freshly distilled boron trifluoride etherate (5 ml) in tetrahydrofuran (70 ml) was treated with sodium borohydride (5.9 g) during 10 min and the mixture was stirred overnight at room temperature before being filtered through glass wool. The diborane solution was made up to 100 ml and used as a standard solution for hydroboration. A solution of methyl dihydroisopimarate (1.5 g) in tetrahydrofuran (50 ml) at 0° under nitrogen was treated with 30 ml of the above diborane solution with vigorous stirring for 3 h. Water (20 ml) was added to the reaction mixture and the mixture evaporated under reduced pressure to about 10 ml. Ethanol (30 ml of 95%), containing sodium hydroxide (1 g), and hydrogen peroxide (2.5 ml of 10%) were added, and the mixture was heated on a steam bath for 15 min and then evaporated to dryness under reduced pressure. The residue was extracted with ether and the ether layer washed with water, dried, and evaporated to yield a colorless oil (1.6 g) which was oxidized directly with Jones's reagent (17). The oxidation product obtained by dilution of the reaction mixture with water and ether extraction was chromatographed on alumina (grade IV). Ether–benzene (1:3) eluted a crystalline solid (600 mg), m.p. 79–80°, raised to 83° on crystallization from aqueous methanol. An analytical sample was sublimed at 120° under 10^{-3} mm pressure, giving colorless prisms, m.p. 83°, $[\alpha]_D$ +10.0° (*c*, 0.37).

Anal. Found: C, 75.62; H, 10.16. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25.

Its infrared spectrum had a broad peak at 1 720 cm^{-1} (—COOMe and >C=O) and its n.m.r. spectrum contained complex signals integrating for three hydrogens between τ 7.5 and 8.2. The keto ester reacted immediately with 2,4-dinitrophenyl hydrazine at room temperature. The product formed orange needles from ethyl acetate – methanol, m.p. 193°.

Equilibrium of Keto Ester XI with Base

The keto ester XI (30 mg) in methanol (10 ml) was refluxed with 20% aqueous potassium hydroxide (2 ml) for 3 h. The mixture was cooled, acidified, and ether extracted. Evaporation of the dried extract yielded an acid (25 mg) which crystallized from benzene–hexane as prisms, m.p. 238–240°, $[\alpha]_D$ +2° (*c*, 1.0).

Anal. Found: C, 74.85; H, 9.80. Calcd. for $C_{20}H_{32}O_3$: C, 74.96; H, 10.06.

Infrared spectrum: ν_{max} at 3 150 cm^{-1} and 1 690 cm^{-1} (—COOH) and 1 725 cm^{-1} (>C=O). Nuclear magnetic resonance spectrum: three-hydrogen signals between τ 7.5 and 8.1. Methylation of this acid with ethereal diazomethane gave the same keto ester, m.p. and mixed m.p. 83°, $[\alpha]_D$ +10°, with its infrared spectrum and thin-layer mobility identical with those of the original ester described above.

Dehydrogenation of the Keto Ester

The keto ester (500 mg) and selenium (2 g) were intimately mixed and heated at 300° for 14 h. The mixture was cooled and the black solid was extracted several times with boiling benzene. The benzene extract was refluxed with freshly precipitated silver for 1 h, filtered, and refluxed again with fresh silver. The benzene extract was washed 4 times with 5-ml portions of 2 *N* sodium hydroxide. The aqueous solution was acidified and extracted with ether. The ether extract was dried and evaporated to yield a yellow oil

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(15 mg) which showed phenanthrene-like absorption in its ultraviolet spectrum. Methylation of the crude product with dimethyl sulfate and potassium carbonate in boiling acetone yielded a neutral product which gave one spot on a thin-layer chromatogram after purification by chromatography on alumina. Despite the fact that its ultraviolet spectrum and R_f in two solvents were identical with those of authentic 1,7-dimethyl-9-methoxyphenanthrene,[6] it would not crystallize when seeded with this. The infrared spectrum of the oil was nearly superimposable on that of the authentic sample.

Methyl Carbinol XIII

A solution of 400 mg of keto acid X in 40 ml of dry ether was added slowly to methyl Grignard reagent prepared from methyl iodide and 300 mg of magnesium in 10 ml of ether. The mixture was stirred overnight at room temperature, and then poured into 40 g of ice and 20 ml of 4 *N* sulfuric acid. The ether layer was washed with sodium hydrogen sulfite solution, dried, and distilled, giving 440 mg of residue. The residue was adsorbed on a column of silica gel (20 g). Hexane eluted 123 mg, but the main product (301 mg) was eluted by 30% ether in benzene. The strongly adsorbed material was converted to its methyl ester, which was distilled over a short path at 110–120°, 2×10^{-3} mm pressure. It then melted at 100–103°. After purification by chromatography on alumina the methyl ester of XIII melted at 105° and had $[\alpha]_D$ +6° (*c*, 3.0).

Anal. Found: C, 75.53; H, 10.76. Calcd. for $C_{22}H_{38}O_3$: C, 75.38; H, 10.93.

Dehydrogenation of XIII and Its Salt

A mixture of XIII (500 mg) and 2 g of selenium was heated at 300° for 17 h. The product extractable into benzene was refluxed in this solvent with freshly precipitated silver for 1 h. The filtrate gave a product showing phenanthrene-like ultraviolet absorption, but no pure product was obtained.

An intimate mixture of 800 mg of the sodium salt of XIII with selenium was covered with more selenium (total 8 g) and heated at 260° for 16 h and at 300° for 7 h. Extraction of the reaction mixture as described above did not give any pure products.

Selenium Dioxide Oxidation of Methyl Dihydroisopimarate

To a solution of methyl dihydroisopimarate (500 mg) in ethanol (20 ml) was added freshly sublimed selenium dioxide (200 mg) in ethanol (10 ml) and water (2 ml). The solution was stirred at room temperature for 8 h, after which the yellow solution was filtered to remove precipitated selenium. The solution on evaporation left a yellow oil (510 mg) which was redissolved in ethanol and filtered through active charcoal (Darco G 60). Evaporation gave a colorless oil (470 mg) showing hydroxyl absorption in its infrared spectrum. Thin-layer chromatography indicated the presence of at least seven components. The oxidation product was chromatographed on alumina (Woelm grade III). Benzene eluted a crystalline compound (40 mg) which, on rapid crystallization from the minimum amount of pentane at 0 °C, yielded colorless prisms, m.p. 84°.

Anal. Found: C, 75.16; H, 10.00. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25.

Infrared spectrum: ν_{max} at 3 510 cm^{-1} (hydroxyl), 1 710 cm^{-1} (ester), and 830 cm^{-1} (trisubstituted double bond). Nuclear magnetic resonance spectrum: a broad one-hydrogen doublet at τ 4.42, J = 4 c.p.s. (vinyl hydrogen), a three-hydrogen singlet at τ 6.36 (carbomethoxyl), and a one-hydrogen singlet at τ 6.44 (carbinol hydrogen). Chloroform eluted a further crystalline product (57 mg) which on sublimation furnished colorless prisms, m.p. 92°.

Anal. Found: C, 75.51; H, 10.13. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25.

Infrared spectrum: ν_{max} at 3 650 cm^{-1} (hydroxyl), 1 725 cm^{-1} (ester), and 820 cm^{-1} (trisubstituted double bond). Nuclear magnetic resonance spectrum: 4.55 τ (one-hydrogen singlet, half-band width 4 c.p.s., vinyl hydrogen), 5.94 τ (one-hydrogen broadened singlet, half-band width 7 c.p.s., carbinol hydrogen), 6.36 τ (three-hydrogen singlet, carbomethoxyl).

The other components of the reaction mixture could not be obtained pure but appeared to be other allylic alcohols and dienes (based upon spectra).

Oxidation of the two alcohols by manganese dioxide in chloroform yielded, in both cases, products with ultraviolet absorption at λ_{max} 242 mμ, log ϵ 3.5 (assuming molecular weight of 300) and infrared absorption at 1 665 cm^{-1}. These products could not be purified nor were derivatives obtained. Dehydration experiments with hydrochloric acid in ethanol on the allylic alcohols gave an inseparable mixture of dienes.

ACKNOWLEDGMENTS

We thank Mr. A. Knoll (N.R.C.) and Mrs. I. Lemke (Carleton University) for technical assistance. We are indebted to Mr. H. Séguin for the analyses, to Mr. R. Lauzon for the infrared spectra, and to Mr. J. Nicholson for the n.m.r. spectra. One of us (J. W. A.) thanks the National Research Council for financial support for the work carried out at Carleton University.

REACTION OF DIHYDROPYRAN WITH ETHYL AZIDOFORMATE[1,2]

I. BROWN[3] AND O. E. EDWARDS
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received November 18, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Photochemical reaction of ethyl azidoformate with dihydropyran gave a good yield of the very reactive aziridine III. The thermal reaction between the two compounds took a completely different course, via triazoline XI to 2-hydroxy-2-ethoxycarbonamidotetrahydropyran XIII.

Interest in new and reactive ring systems, in the synthesis of analogues of 2-amino-2-deoxy sugars, and in the mechanism of acyl azide reactions led us to study the photochemical and thermal reactions of ethyl azidoformate with dihydropyran.

Recent work has shown that ethyl azidoformate reacts under ultraviolet irradiation with cyclohexene (1) and with benzene (2). The products from reaction with cyclohexene were mainly the aziridine I and urethane II in the ratio 4.5:1. It was hoped that in the case of dihydropyran a reactive N-ethoxycarbonyl aziridine would be formed in good yield by attack on the double bond.

Irradiation, with ultraviolet light, of a solution of ethyl azidoformate in dihydropyran resulted in nitrogen evolution and gradual disappearance of the characteristic azide bands (ν_{max} 2 120, 2 170 cm^{-1}) in its infrared spectrum (3). The product, after removal of the bulk of the excess dihydropyran under reduced pressure, was a mobile oil, with infrared absorption at 1 710 cm^{-1}. This could be distilled over a short path at 80° under 5×10^{-4} mm, but a large high-boiling residue remained. The distilled material reacted rapidly with water or methanol to give a hydroxyurethane ($\nu_{max}^{CHCl_3}$ 1 710 cm^{-1}) or ethoxy urethane respectively. The former analyzed correctly for structure III, and its nuclear magnetic resonance (n.m.r.) spectrum[4] (see structure) was in harmony with this assignment. Attempts to obtain the pure methoxy urethane IV always resulted in partial hydrolysis to III. The vicinal nature of the hydroxyl and urethane groups in III was proved by heating the compound with 2,4-dinitrophenylhydrazine hydrochloride solution. The osazone V was formed and identified by comparison with an authentic specimen (4, 5).

Finally, the hydroxyurethane III could be oxidized to a lactone VI that retained the urethane group, thus confirming the location of the nitrogen in III and IV. We hence conclude that the reactive product from the photochemical reaction is the desired aziridine VII.

The direction of hydrolytic opening of the aziridine ring and its reactivity are normal when viewed either as attack of solvent on the zwitter ion VIII (S_N1 process) or S_N2 displacement at the most electron-deficient carbon (see IX). The nonvolatile residue produced on heating the product was probably of the type X, the polymerization being initiated by traces of III resulting from reaction with minute amounts of water. If the

photolysis was conducted in the presence of water (as a second phase), the product was III in excellent yield. The only significant products besides those derived from VII were produced from photolysis of dihydropyran itself (ca. 0.3 g from 100 ml in blank runs for 5 h). These have not been characterized.

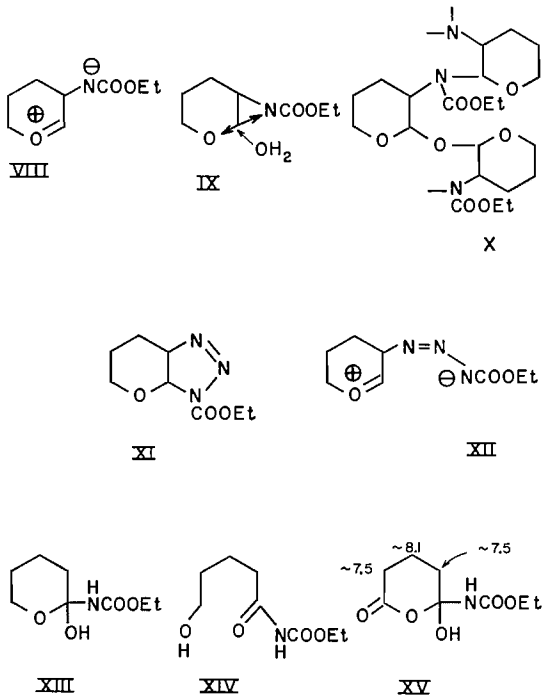
The notable selectivity of attack on the double bond suggests one of two things: (*a*) that the reaction is one involving an excited azide, giving an excited triazoline which spontaneously loses nitrogen, or (*b*) that an electrophilic singlet nitrene is the reacting entity, so that attack on the polarized double bond overshadows insertion into C—H bonds.

To examine possibility (*a*) we hoped to prepare and photolyze the triazoline XI. If the product was *not* the aziridine VII, then there would be some indication that the triazoline was not an intermediate in the photolysis of the mixture of dihydropyran and ethyl azidoformate.[5] In fact, the triazoline could not be obtained, since dihydropyran reacted at temperatures from ambient to 80° with ethyl azidoformate, with simultaneous nitrogen evolution. That the triazoline was an intermediate in the thermal reaction, however, was evident, since the rate of reaction at 80° (measured by nitrogen evolution) was 20 times the rate of decomposition of ethyl azidoformate in dioxane at the same temperature. The formal 1,3-dipolar addition seems likely to proceed via the intermediate XII.

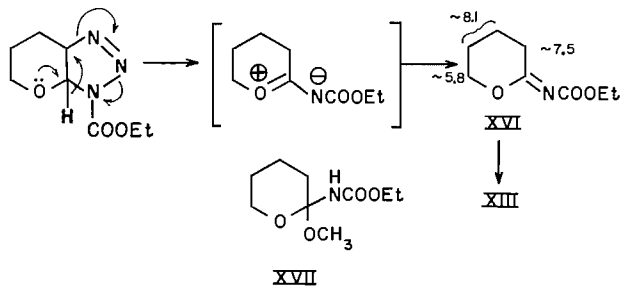
The major product from the thermal reaction followed by exposure to water at room temperature was a crystalline solid analyzing for $C_8H_{15}NO_4$. Its infrared spectrum (Nujol mull) had peaks at 1 765 cm^{-1} (urethane) and 3 265 and 3 200 cm^{-1} (OH and (or) NH). In chloroform solution, however, two carbonyl peaks at 1 760 and 1 705 cm^{-1} were evident, in addition to a broad band at 3 400 cm^{-1}. Its n.m.r. spectrum ($CDCl_3$) had signals at 1.7 (NH) and 7.3 (OH) which disappeared when D_2O was added. An ethoxy group

[5]*This involves the assumption that the excited states from the two routes would be comparable in their chemical reactivity.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



was indicated by a triplet at 8.7 and a quartet at 5.8. Two broad two-hydrogen signals at 6.4 and 7.3 corresponded to CH_2—O— and —CH_2—C(=O)— groups respectively. The hydroxyl hydrogen gave rise to a triplet centered at 5.7 in dimethyl sulfoxide; hence, it was a primary alcohol (6). On the basis of the above evidence and mechanistic considerations, structure XIII seemed plausible for the compound in the solid state, and XIV for it in solution. To test this, the compound was oxidized with Jones reagent. The product analyzed for $C_8H_{13}NO_5$ (loss of two hydrogens and addition of one oxygen). Its infrared spectrum (Nujol) showed the presence of two carbonyl groups (ν_{max} 1 760 and 1 720 cm^{-1}) and OH and (or) NH groups (ν_{max} 3 265 and 3 200 cm^{-1}). This and its n.m.r. spectrum in D_2O (see assignment on the structure) are consistent with structure XV. Finally, hydrolysis of the oxidation product gave glutaric acid, confirming the structures XIII through XV. The formation of XIII can be rationalized as shown in Reaction Scheme 1.



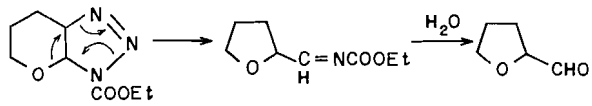
REACTION SCHEME 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The n.m.r. spectrum of the product before addition of water contained no vinyl hydrogen, as expected if it contained the intermediate XVI. Addition of methanol, rather than water, to the reaction mixture gave a new product with R_f 0.8 in a thin-layer chromatogram, compared to R_f 0.2 for XIII. A spot at R_f 0.2, however, was also present. When the component with R_f 0.8 was recovered from a preparative plate, only the hydroxy compound XIII was obtained. It seems that the methoxy compound XVII had been formed by addition of methanol to intermediate XVI, but that it was hydrolyzed fairly rapidly on the silica gel surface to XIII. The imino intermediate itself must react almost instantly with water in the silica gel, since the initial reaction mixture gave a main spot at R_f 0.2 identical with that of XIII. These observations support the suggestion that XVI is the primary product of the thermal reaction.

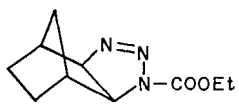
When a sample of aziridine VII was heated at 80° in dihydropyran, the dihydropyran removed under reduced pressure, and the residue treated with water, III was present among the products but there was no evidence of XIII on a thin-layer chromatogram. We conclude that VII is not an intermediate in the formation of XVI.

A search for tetrahydrofurfural, which might have been formed in the thermal reaction by the sequence given in Reaction Scheme 2 (cf. ref. 7), was fruitless.



REACTION SCHEME 2.

The contrast between the thermal and photochemical reactions described above seems at first sight to discount the triazoline as a possible intermediate in the photochemical process. However, it seems dangerous to extrapolate from the reaction of a vibrationally excited ground state in the thermal reaction to that of the probably vibrationally and electronically excited intermediate in the irradiation. This caution is reinforced by the observation that irradiation of the corresponding triazoline XVIII from norbornylene *does* give the same products as light-induced reaction of norbornylene and ethyl azidoformate.[6] We hence reserve judgment about the nature of the intermediates in the photochemical reaction.



XVIII

The apparent cyclol character of XIII and XV in the solid state has analogy in the observations of other groups on hydroxy-N-acyl lactams (8–10). Although the two compounds appear to be acyclic in solution, they only show end absorption in the ultraviolet, as contrasted with the maxima near 220 mμ reported for N-acyl lactams. A referee has suggested that this difference is due to less conjugation in N-acylcarbamates such as XIII and XV than in the N-acyl lactams. Since the excited state probably

[6] *Unpublished observations by O. E. Edwards, J. Elder, and M. Lesage.*

resembles $^{\delta-}O\cdots C\cdots \overset{+}{N}(H)\cdots C\cdots O^{\delta-}$, the higher electrical symmetry of the N-acyl lactams should lower the energy of their excited states relative to those of the carbamates.

The hydroxyurethane III is a derivative of a 2-amino-2,3,4-trideoxyaldopentose. The more oxygenated analogues of the aziridine VII, if they can be prepared from the glycals, would provide valuable precursors for the 2-amino-2-deoxy sugars and their polymers.

EXPERIMENTAL

Melting points were measured on a Kofler hot stage; ultraviolet spectra were determined in 95% ethanol, and n.m.r. spectra in deuterochloroform with tetramethylsilane as internal standard, unless otherwise stated.

Dihydropyran was purified by distillation at atmospheric pressure, irradiation with a 100-W low-pressure mercury lamp in an immersion cell with water cooling and quartz filter, drying, and distilling twice. In this way photochemically active impurities in the dihydropyran were removed.

A solution of ethyl azidoformate (11) (4 g) in purified dihydropyran (100 ml) exhibited a split azide band at 2 120 and 2 170 cm^{-1} and a carbonyl absorption at 1 730 cm^{-1}. The solution was irradiated for 5 h with agitation by a stream of dry nitrogen, after which time the azide absorption had been replaced by a band at 1 710 cm^{-1}. The excess dihydropyran was removed under reduced pressure at 50° and the residual mobile oil (5.6 g) was immediately distilled at 5×10^{-4} mm and a bath temperature of 80°. A colorless oil (1.91 g) distilled, leaving a brown high-boiling residue. The distillate was dissolved in dioxane and excess water added. After the solution had stood for 30 minutes at room temperature, the solvent was removed on a rotating evaporator at 50°. The oily product crystallized on scratching and was recrystallized from acetone to give colorless needles (0.63 g) of III, m.p. 115–117°.

Anal. Found: C, 50.73; H. 7.78; N, 7.53. Calcd. for $C_8H_{15}NO_4$: C, 50.78; H, 7.99; N, 7.40.

Photolysis in the Presence of Water

Ethyl azidoformate (6.8 g) in dihydropyran (100 ml) and water (10 ml) was irradiated as above for 5 h. The mixture was then diluted with an equal volume of methylene dichloride and dried over anhydrous sodium sulfate. The organic solvent was taken to dryness at 50° under reduced pressure and the residual oil crystallized from acetone to give colorless needles (9.5 g) of III, m.p. 115–117°.

Osazone V

The hydroxyurethane, m.p. 117°, was dissolved in a methanolic solution of 2,4-dinitrophenylhydrazine hydrochloride, and then boiled for 1 h. The orange needles which separated melted at 241° and did not depress the melting point of the derivative of 5-hydroxy-2-ketopentanal (4, 5).

Oxidation of III with Sodium Dichromate

To the hydroxyurethane III (0.50 g) dissolved in glacial acetic acid (15 ml) was added sodium dichromate (0.577 g; 1.1 mole). The mixture was swirled to effect solution and allowed to stand for 20 h. Thin-layer chromatography in silica gel with ether as developing solvent indicated disappearance of starting material and the formation of two new components. Benzene (50 ml) was added to the acetic acid solution followed by excess powdered sodium carbonate. The slurry of sodium acetate and sodium carbonate was filtered off and washed with benzene. The combined filtrates were washed with sodium bicarbonate solution, then water, and dried. Evaporation of the solvent left a yellow oil (0.217 g). A portion of this oil (0.125 g) was separated into its two components by preparative thin-layer chromatography on silica gel with ether as developing solvent, the bands being located by iodine vapor. The absorbed iodine was allowed to evaporate; the silica gel was scraped off, mixed with an equal quantity of "Celite", and eluted in a column with chloroform–methanol. The eluate was taken to dryness; the filtrate was taken up in chloroform, filtered, and the solvent evaporated off. The main component (R_f 0.4, 0.072 g) was distilled over a short path at 95°, 3×10^{-3} mm, to give a colorless oil (0.068 g) which showed only end absorption in the ultraviolet and had infrared absorption at 1 750 cm^{-1} and 1 710 cm^{-1} ($CHCl_3$ solution).

Anal. Found: C, 51.52; H, 7.18. Calcd. for $C_8H_{13}NO_4$: C, 51.33; H, 7.00.

Thermal Reaction

Ethyl azidoformate (0.57 g) in purified dihydropyran was refluxed for 10 h, after which time no more nitrogen was evolved. The excess dihydropyran was removed at 50° under reduced pressure, and the residual oil was dissolved in aqueous dioxane and allowed to stand 24 h. The solvent was evaporated. The residual oil (0.80 g) crystallized on scratching. It was recrystallized from benzene to give XIII as needles (0.60 g), m.p. 68.5–70°. It had only strong end absorption below 210 mμ.

Anal. Found: C, 50.74; H, 7.79; N, 7.68. Calcd. for $C_8H_{15}NO_4$: C, 50.78; H, 7.99; N, 7.40.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Thermal Reaction of Aziridine VII

A sample of aziridine VII was dissolved in dihydropyran and the solution boiled for 16 h. After removal of the dihydropyran under reduced pressure, the residue was dissolved in cold aqueous dioxane and left for 1 h. A thin-layer chromatogram of the product showed three spots, one of which had an R_f identical with that of III. No spot was present with the same R_f as XIII.

Oxidation of XIII with Jones Reagent

The compound (0.86 g) dissolved in 15 ml acetone was titrated with Jones reagent (12) with magnetic stirring at 20°. A color end point was observed after 1.8 moles of reagent had been added. A further 0.3 moles of reagent was added, the slurry stirred for 5 min, and then excess reagent destroyed by addition of a few drops of ethanol. The chromium salts were filtered from the acetone solution and the filtrate taken to dryness. The solid residue was taken up in benzene, filtered through charcoal, and then recrystallized first from benzene – *n*-hexane and subsequently from chloroform to give needles of XV (0.62 g), m.p. 136.5–139.5°. It had strong end absorption below 210 mμ.

Anal. Found: C, 47.36; H, 6.44; N, 6.90. Calcd. for $C_8H_{13}NO_5$: C, 47.29; H, 6.45; N, 6.89.

HBr in Acetic Acid Hydrolysis of XV to Glutaric Acid

The lactone (0.043 g) was heated on the steam bath with a mixture of glacial acetic acid (2 ml) and 47% hydrobromic acid (2 ml) for 1 h. The solution was then taken to dryness at 70° on the water pump and the solid residue was extracted with acetone to give, after recrystallization from benzene, plates (m.p. 95–99.5°) identical (infrared, mixed melting point) with authentic glutaric acid.

ACKNOWLEDGMENTS

We are indebted to Mr. M. Lesage for determination of n.m.r. spectra and Mr. H. Seguin for the analyses.

COMPLEXES OF STANNIC IODIDE WITH AROMATIC HYDROCARBONS

J. F. MURPHY[1] AND D. E. BAKER[2]
University of Idaho, Moscow, Idaho
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Spectrophotometric measurements on solutions of stannic iodide were found to provide evidence for complex formation with aromatic hydrocarbons. Calculations, based on spectra for mixed solutions of benzene and stannic iodide in carbon tetrachloride, yield values of 0.26 for the equilibrium constant (mole fraction), 28 400 l/mole cm for the molar extinction coefficient of the benzene – stannic iodide complex. Kinetic evidence indicates that the order of decreasing complex stabilities is from xylene to toluene to benzene. The formation of stannic iodide – aromatic hydrocarbon complexes provides an explanation for the discrepancy between measured solubilities of stannic iodide in benzene, toluene, and xylene, and the solubilities predicted by the Hildebrand theory of regular solutions.

INTRODUCTION

The Hildebrand theory of regular solutions has been very successful in predicting solubilities. In a few cases, however, unexpected discrepancies have appeared. For example, the solubility of iodine in benzene, toluene, and xylene was found to be in reverse order to the order of the solubilities calculated from regular solution theory. The early spectrophotometric study of iodine in aromatic hydrocarbons by Benesi and Hildebrand (1) showed that complexes were formed. Since then many other systems have been studied (2). Benesi and Hildebrand considered the complexes as examples of acceptor–donor combinations in the Lewis acid–base sense. The order of stability of the complexes, as calculated from spectrophotometric data, was such as to explain satisfactorily the disagreement between the observed order of solubility and that predicted from the theory of regular solutions. A similar disagreement of predicted and observed solubility order has been noted by Hildebrand and Scott (3) for solutions of stannic iodide. Regular solution theory predicts a decrease in solubility as the internal pressure of the solvent decreases from benzene through toluene to xylene, whereas the observed solubilities increase from benzene to toluene.

The work described in this paper was undertaken to determine whether complex formation could account for these discrepancies between theory and observation.

EXPERIMENTAL

Stannic iodide was prepared by the method of Dorfman and Hildebrand (4). Reagent grade solvents were used without further purification. Spectrophotometric measurements were made at 25 ± 2 °C with a Beckmann spectrophotometer, model DU.

RESULTS

General Nature of Spectra

Preliminary measurements were made on solutions of stannic iodide in dioxane, carbon tetrachloride, hexane, petroleum ether, benzene, toluene, and *m*-xylene (Table I). The

TABLE I

Wavelengths of absorption maxima and molar extinction coefficients for stannic iodide in various solvents

Solvent	SnI_4 concn. range $\times 10^5$	λ_1	ϵ_1	λ_2	ϵ_2
Carbon tetrachloride	4.4–9.7	365	8 500	285	4 600
Petroleum ether	1.6–7.9	365	8 300	285	4 600
Hexane	8.1	365	8 000	285	4 400
1,4-Dioxane	2.6–5.2	454	1 760	264	9 200
Benzene	5.0–10.9	365	8 500	297	8 500
Toluene	8.7–9.7	365	9 540	(300)	—
m-Xylene	4.6	365	10 100	(300)	—

molar extinction coefficient curves showed maxima at 285 and 365 mμ for carbon tetrachloride, hexane, and petroleum ether. Extinction coefficient curves for stannic iodide in these three solvents are identical. Solutions of stannic iodide in dioxane exhibited absorption maxima at 264 and 454 mμ. Solutions in benzene showed maxima at 297 and 365 while toluene and xylene solutions showed only one clearly defined maximum at 365 mμ. Representative spectra for solutions of stannic iodide in carbon tetrachloride, benzene, and toluene are shown in Fig. 1. There is an obvious difference between the spectra in carbon tetrachloride and in the aromatic compounds in the 285–300 mμ region.

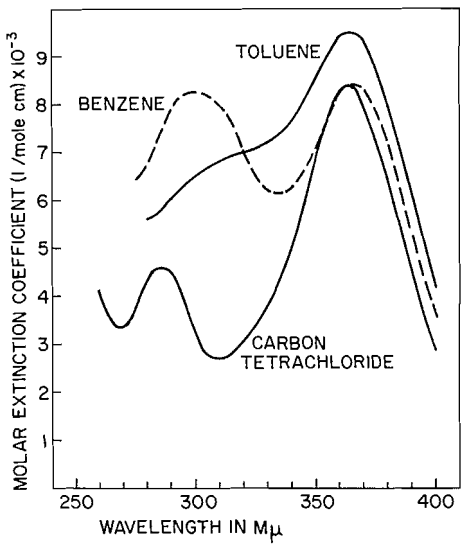

FIG. 1. Molar extinction coefficients vs. wavelength for stannic iodide. Temperature 25 ± 2 °C; concentration range 8.5–9.5 × 10^{-5} *M*.

Solutions of stannic iodide in benzene, toluene, and xylene exhibited a marked color change on standing in air while exposed to sunlight or artificial light. Figure 2 illustrates the effect of a 3 h exposure to sunlight on the spectrum of a solution of SnI_4 in benzene open to the air. A molar extinction curve for iodine in benzene is also shown for comparison. For these solutions the change in color was more rapid in sunlight than in artificial light. For the same exposure to light, the rate of color change was found to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

increase in the order: benzene, toluene, and xylene. Spectrophotometric measurements of the iodine produced by illumination of solutions of stannic iodide in benzene showed that the color change was due to a photochemically accelerated reaction of oxygen with stannic iodide to form iodine (see Fig. 2). When the reaction was allowed to go to completion, the iodine formed was equivalent to complete decomposition of the stannic iodide. Removal of oxygen by bubbling deoxygenated nitrogen through the solution decreased the rate of reaction to the point that no iodine could be detected in solutions exposed to artificial light for 5 h. Therefore, all further measurements were made on deoxygenated solutions.

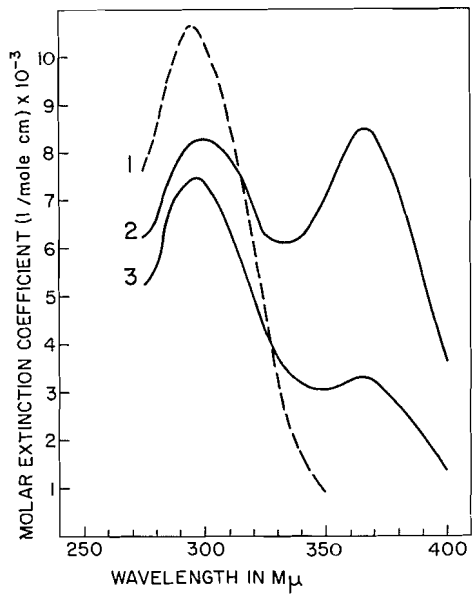

FIG. 2. Photochemical oxidation of stannic iodide in benzene at 25 ± 2 °C. Curve 1, iodine in benzene; curve 2, stannic iodide in deaerated benzene-fresh solution; curve 3, stannic iodide in benzene after 3 h exposure to sunlight.

Assignment of Absorption Peaks for Benzene Solutions

Both iodine and stannic iodide in benzene have an absorption maximum at 297 mμ (Fig. 2) and stannic iodide decomposes to form iodine. Therefore, it is important to eliminate the possibility that the peak observed for stannic iodide solutions is due to the presence of iodine from decomposition of the stannic iodide. To eliminate this possibility we were careful to use data for solutions in which the stannic iodide 365 mμ peak height was correct for the concentration of stannic iodide used.

We also considered the possibility that one or both of the peaks were due to, or modified by, an "acid–base" reaction between stannic iodide and iodine (produced by decomposition of a part of the stannic iodide). This possibility was tested by examining the spectra of solutions containing various ratios of iodine to stannic iodide at a constant total concentration of 1×10^{-4} moles/l in carbon tetrachloride. No absorption maximum was observed at 297 mμ in these solutions. Further, the extinction coefficients for iodine at 517 mμ and for stannic iodide at 365 and 285 mμ were equal to the values obtained for simple solutions of iodine and stannic iodide in carbon tetrachloride. Therefore, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

absorption maxima at 365 mμ were attributed to free stannic iodide and the enhancement and shift of the 285 mμ peak to the formation of a benzene – stannic iodide complex.

Properties of the Benzene – Stannic Iodide Complex

When benzene was added in small concentrations to a solution of stannic iodide in carbon tetrachloride, a progressive shift of the lower wavelength absorption maximum from 285 to 297 mμ was observed. The apparent extinction coefficient was found to increase as the benzene concentration was increased. Table II lists data for mixed solutions of benzene and iodine in carbon tetrachloride. The increase in extinction coefficient with benzene concentration indicates that there is interaction between the stannic iodide and the benzene.

If we assume the formation of a complex according to eq. [1], we may calculate the equilibrium constant for the formation of the complex by eq. [2].

[1] $$D + SI \rightleftarrows DSI$$

[2] $$K_C = \frac{[C_C]}{[C_D - C_C][C_{SI} - C_C]}.$$

In these equations C_C is the concentration of the complex DSI at equilibrium; C_D is the initial concentration of the donor (benzene); and C_{SI} is the initial concentration of stannic iodide. Rose and Drago (5) have shown that, in the general case, K_C is related to experimental parameters as shown in eq. [3].

[3] $$K^{-1} = \frac{A - A^0}{\epsilon_C - \epsilon_{SI}} - C_{SI} - C_D + \frac{C_D C_{SI}(\epsilon_C - \epsilon_{SI})}{A - A^0},$$

where ϵ_C and ϵ_{SI} are the molar extinction coefficients for the complex and the stannic iodide, respectively, while the absorbances A^0 and A are given by:

[4] $$A^0 = \epsilon_{SI} C_{SI}$$

and

[5] $$A = \epsilon_C C_C + \epsilon_{SI}(C_{SI} - C_C).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

When experimental conditions are such that the first two terms on the right side of eq. [3] are negligible compared to the last two terms, eq. [3] can be simplified.

$$[6] \qquad \frac{C_{SI}}{(A - A^0)} = \frac{1}{K_X(\epsilon_C - \epsilon_{SI})} \cdot \frac{1}{C_D} + \frac{1}{(\epsilon_C - \epsilon_{SI})}.$$

Equation [6] is a form of the equation derived by Ketelaar (6) for cases in which the absorption bands of the solute and complex overlap as they do in the case of stannic iodide in benzene. If C_D is expressed as a mole fraction, then the dimensionless constant, K_X, rather than K_C is used.

Experimental conditions in the present work were chosen so that eq. [6] could be used. This equation is of the form $Y = ABX + B$ where $Y = C_{SI}(A - A^0)^{-1}$, $X = (C_D)^{-1}$, $A = K_X^{-1}$, and $B = (\epsilon_C - \epsilon_{SI})^{-1}$. Therefore a plot of $C_{SI}(A - A^0)^{-1}$ against $(C_D)^{-1}$ should give a straight line with an intercept of $(\epsilon_C - \epsilon_{SI})^{-1}$ and slope of $K_X^{-1}(\epsilon_C - \epsilon_{SI})^{-1}$. Assuming that A^0 and ϵ_{SI} are equal to the absorbance and the molar extinction coefficient of stannic iodide in carbon tetrachloride, it is possible to determine K_X, the complex formation constant, and ϵ_C, the extinction coefficient of the complex. The absorbance A is calculated from the spectrum of stannic iodide in benzene.

The data shown in the last two columns of Table II give a straight line plot. A least-squares analysis of the data yields the equation

$$[7] \qquad \frac{C_{SI}}{(A - A^0)} = \frac{1.592 \times 10^{-4}}{C_D} + 0.42 \times 10^{-4}.$$

From the slope and intercept we calculate values of the dimensionless equilibrium constant based on mole fractions, $K_X = 0.264$, and the molar extinction coefficient for the complex, $\epsilon_C = 28\,400$ l/mole cm. The fit of this equation to the data may be judged to be very good on the basis of correlation coefficient of 0.955. The student "t" test on the Z score for a correlation coefficient of 0.955 (9 data points) shows significance at the 95% confidence level ($0.955\sqrt{n-1} = 2.70 > 2.306$). These results support the assumption of a 1:1 complex between stannic iodide and benzene.

DISCUSSION

In an extensive discussion of methods for the spectroscopic determination of equilibrium constants of benzene complexes, Rose and Drago (5) point out that the value of K_X in pure benzene is much more dependent on the accuracy of ϵ_C than those in dilute solution. We can assume that uncomplexed stannic iodide has the same molar extinction coefficient in benzene as in carbon tetrachloride at 297 mμ, and that the higher total absorbance of stannic iodide in benzene is due to the contribution by the complex. If $K_X = 0.26$ and $C_D = 1$ for pure benzene, then C_C and $(C_{SI} - C_C)$ may be calculated. Using $\epsilon_C = 2.84 \times 10^4$ l/mole cm, $\epsilon_{SI} = 3\,800$ l/mole cm, in eq. [5], we calculate an absorbance of 0.78, in agreement with the measured value of 0.77. This agreement indicates that the calculated K_X and ϵ_C values are correct in pure benzene as well as in carbon tetrachloride – benzene mixtures.

The values for K_X and ϵ_C for benzene – stannic iodide may be compared with those for other complexes. Benesi and Hildebrand (1) found $K_X = 1.73$ and $\epsilon_C = 15\,400$ l/mole cm for the benzene–iodine complex. Andrews and Keefer (7) found $K_X = 5.8$ and $\epsilon_C = 8\,100$ l/mole cm for iodine monochloride – benzene. Thus K_X is lower and the ϵ_C is higher for the stannic iodide complex than for related benzene complexes. If we assume that the bonding in the complex depends on two iodine atoms of the stannic iodide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

molecule acting in absorption like a diatomic iodine molecule, the low K_X and high ϵ_C are to be expected. The most probable structure for the benzene – stannic iodide complex is discussed below.

Structure of the Complex

Both iodine–benzene (1) and stannic iodide – benzene have absorption maxima at 297 mμ. Iodine–toluene solutions show an absorption maximum at 306 mμ (1) and the spectrum of stannic iodide – toluene solutions show a levelling off in the same region (Fig. 1). The stannic iodide molecule should exhibit some of the characteristics of the iodine molecule. It seems reasonable, therefore, that interpretation of the spectrum of stannic iodide in benzene should be similar to interpretation of the spectrum of iodine in benzene.

On the basis of quantum mechanical considerations, Mulliken (8) chose for the iodine–benzene complex a model in which the iodine molecule rests on the benzene molecule with its axis parallel to the plane of the benzene and its center on the sixfold axis of the benzene. A similar model for the stannic iodide – benzene complex would place two of the peripheral iodine atoms on the benzene ring with the line joining the centers of iodine atoms parallel to the plane of the benzene. Pringsheim (9) has noted that the iodine atoms in stannic iodide are tetrahedrally arranged around the tin atom. At high temperatures the amplitude of oscillation becomes sufficiently great that the two iodine atoms can approach each other so closely that they can be separated in a single act from the parent molecule as an excited iodine molecule (9). Measurements on the fluorescence of stannic iodide vapor have indicated that in the 215 to 245 mμ region the molecule decomposes photochemically to stannous iodide and iodine (10). Terenin and Tshubarov concluded that photodissociation is simultaneous with union of iodine atom sbefore they leave the molecule with the liberated iodine molecule in an excited state as evidenced by fluorescence (10). The similarity of the spectra of benzene solutions of iodine and stannic iodide may, therefore, be due to a strengthening of the residual bond between iodine atoms in stannic iodide by the formation of the complex with benzene. The observation that the rate of photochemical oxidation of stannic iodide increases in the order of increasing solvent basicity for benzene, toluene, and xylene also supports the contention that complex formation strengthens the iodine–iodine bond and weakens the iodine–tin bond. Also, if the complex bond depends on the iodine–iodine bond, then K should be lower for stannic iodide than for iodine. The evidence appears to support a model of the complex in which two of the peripheral iodine atoms in stannic iodide are involved in the bond with the aromatic hydrocarbon. Mulliken's resting model for the iodine – aromatic hydrocarbon complex is also indirectly supported.

Solutions in Toluene and Xylene

The low wavelength absorption maxima for stannic iodide in toluene and xylene were not well enough defined in our measurements to allow an evaluation of the stability and extinction coefficient of the complex. However, the order of the rates of the photochemical reaction between stannic iodide and these solvents indicates that the stability of the stannic iodide in the complexes decreases in the order: benzene, toluene, xylene (least stable). In the aromatic solvents, the formation of the complex probably increases the rate of oxidation by air to form free iodine and stannic oxide. An increased strength of bond between the iodine portion of the stannic iodide and the aromatic solvent should lead to a lowering of the activation energy for the reaction of the stannic ion with oxygen. An increase in solubility due to increased strength of complexing in the order benzene,

For personal use only.

toluene, xylene, would also seem to provide an adequate explanation for the discrepancies between observed and theoretically predicted solubilities (3).

LABELLING OF NUCLEOSIDES WITH TRITIUM

G. A. LePage and Irene G. Junga
Life Sciences Research, Stanford Research Institute, Menlo Park, California
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The synthesis of 9-(α,β-D-2′-deoxyribofuranosyl)-2-amino-6-mercaptopurine with tritium labelling in both base and sugar was attempted. At the step where a mercury salt of the base and the blocked chlorosugar were coupled in benzene, the tritium labelling was lost, apparently by an exchange with the protons of the solvent. This appeared to be catalyzed by the mercuric chloride. It was demonstrated that unlabelled nucleoside could be tritium labelled by refluxing it in benzene-T or toluene-T with mercuric chloride. By this exchange process, both base and sugar were tritiated, but a larger amount of tritium appeared in the base. Because of the availability of benzene-T and toluene-T of high specific radioactivity, this appears to be a practical means of synthesis of the labelled nucleoside. This exchange reaction may be useful for the study of carbon–hydrogen bond stabilities.

Biological investigations with the fraudulent nucleoside, 9-(β-D-2′-deoxyribofuranosyl)-2-amino-6-mercaptopurine, have shown that it has carcinostatic activity, and that its activity was also evident in several lines of experimental cancers that were resistant to 2-amino-6-mercaptopurine (1). Moreover, the unexpected result that the α-anomer of the fraudulent nucleoside had carcinostatic activity, with very low host toxicity, was obtained. When 9-(α-D-2′-deoxyribofuranosyl)-2-amino-6-mercaptopurine was labelled in the purine base with radiocarbon and administered to tumor-bearing mice, the radiocarbon appeared in the deoxyribonucleic acids of tumor cells which could not so incorporate labelled 2-amino-6-mercaptopurine. It thus became important to synthesize the α-anomer of this nucleoside with tracer labelling in both the purine base and the sugar to establish whether this α-anomer was incorporated into nucleic acids without cleavage.

The cost of the necessary radiocarbon-labelled starting materials would be prohibitive. Labelling with tritium by the Wilzbach method (2), or by commercially available catalytic methods, would be expected to involve extensive decomposition of this labile nucleoside. We therefore planned the synthesis with tritium-labelled guanine (guanine-8-T) and tritium-labelled glucose (glucose-6-T) as starting materials. These two materials were purchased from the Nuclear-Chicago Corporation. A 100-millicurie batch of D-glucose-6-T was diluted, with D-glucose monohydrate, to 1.0 millicurie/millimole. The resulting 19.8-g quantity was converted, by the procedure of Diehl and Fletcher (3), to 2-deoxyribose-5-T in approximately 5% yield. The 2-deoxyribose anilide melted at 180 °C. A 25-mcurie batch of guanine-8-T was converted to 2-amino-6-mercaptopurine-8-T, as described by LePage (4), in 65% yield and diluted to approximately 1.0 mcurie/mmole with unlabelled material. The 2.66 g of purinethiol was converted to 2-amino-6-chloropurine-8-T by the method of Davis *et al.* (5) in 50% yield, and to the 2-acetamido-6-chloro-9-Hg-purine salt by the method of Iwamoto *et al.* (6) in 31% yield. The 2-deoxyribose-5-T was converted to 1-chloro-3′,5′-di-O-*p*-toluyl-2′-deoxyribose-5-T (6). At this stage approximately 2.2 mmoles of the mercury salt of the purine derivative and an equivalent amount of the chlorosugar were available. Measurements with a Nuclear-Chicago scintillation counting system established that each derivative contained approximately 1.0 mcurie/mmole of tritium. The two labelled derivatives were refluxed together in benzene for the coupling reaction, as described by Iwamoto *et al.* (6). The resulting

blocked nucleoside was isolated and separated into α- and β-anomers. Both were found to contain negligible amounts of radioactivity. The tritium on the labelled derivatives appeared to have exchanged with the hydrogens of the solvent, which was then distilled off. The other product of the reaction, mercuric chloride, was suspected of catalyzing this exchange.

It seemed imperative to determine whether the above conclusion was correct, and whether the tritium exchange could be reversed by the use of a tritium-labelled solvent. No tritiated benzene was immediately available, but a standard solution of toluene-T at 1.09 μcuries/ml (2.39×10^6 counts per minute per milliliter) was on hand. To a 50-mg batch of 2-acetamido-6-chloro-9-(2′-deoxy-3′,5′-di-O-*p*-toluyl-D-ribofuranosyl)-9-H-purine was added 50 mg mercuric chloride and 5.0 ml of the toluene-T. These were refluxed together for 30 minutes in a 20-ml flask and cooled, and the solvent removed *in vacuo*. Addition of unlabelled solvent and removal *in vacuo* were carried out to assure removal of any labile tritium. The residue was taken up in chloroform and the mercuric chloride removed by washing twice with a 30% solution of potassium iodide, then with water. The blocked nucleoside was crystallized from chloroform and found to have the same melting point as the starting material (184 °C). Scintillation counting in a toluene system was carried out, with standards to determine any quenching. The blocked nucleoside was found to contain 650 c/min mg. A 50-mg sample of 9-(β-D-2′-deoxyribofuranosyl)-2-amino-6-mercaptopurine was refluxed 30 minutes with 5.0 ml of toluene-T and 50 mg of mercuric chloride. The solvent was removed *in vacuo*. Unlabelled solvent was added and evaporated off as before, with water used once as solvent. Scintillation counting carried out in a polar solvent system (6% efficiency), identical with that described by Bray (7), demonstrated that the mercury salt of the nucleoside contained 11 000 c/min mg. The nucleoside would therefore contain approximately 18 700 c/min mg. Removal of the mercury as sulfide led to a very low yield of nucleoside (4%), presumably because of adsorption on the mercuric sulfide.

Benzene-T was obtained commercially and found to have 0.54 mcuries/ml (1.2×10^9 c/min ml). A reaction mixture containing 195 mg of 2-acetamido-6-chloro-9-(2′-deoxy-3′,5′-di-O-*p*-toluyl-D-ribofuranosyl)-9-H-purine, 195 mg of mercuric chloride, and 10 ml of benzene-T was refluxed for 30 minutes and cooled, and the solvent removed *in vacuo*. Unlabelled solvent was added and evaporated as before. Purification was carried out as described earlier. The melting point and optical rotation indicated that the properties of the product were unchanged from those of the starting material. Scintillation counting showed that the blocked nucleoside contained 1.4×10^5 c/min mg. Removal of the blocking groups and conversion to the 9-(β-D-2′-deoxyribofuranosyl)-2-amino-6-mercaptopurine were carried out as described by Iwamoto *et al.* (6). This product was found to contain 1.4×10^4 c/min mg.

An 8.8-mg batch of the above nucleoside was suspended in 2.6 ml of 1.0 *M* perchloric acid and heated for 10 minutes at 100 °C to cleave the sugar from the base. The solution was chilled and neutralized to pH 7 with potassium hydroxide, and the potassium perchlorate removed. The solution was passed onto a Dowex-1-formate column, 5×45 mm. This would retain the base and allow passage of the sugar. The resin was washed with several portions of water. Then the base was eluted with two portions of 1.0 *M* formic acid. The eluates were analyzed for the base (by extinction at 345 mμ), and scintillation counting was carried out. The first acid eluate contained about 75% of the base, the second one about 25%. The water eluates contained no material absorbing at 345 mμ. Counts present in the two acid eluates correlated with base content, as indicated by ultraviolet absorption. The sample used contained radioactivity measured as 1.23×10^5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

c/min. That recovered in the base was found to be 1.04×10^5 c/min, and for the water eluate (sugar) 1.96×10^4 c/min. Thus the tritium was distributed 84% in the base and 16% in the sugar moiety. Initially, a large fraction of the radioactivity was in the blocking groups.

A limited study was made of the progress of the tritium exchange with time. The experiment with the blocked nucleoside and mercuric chloride in refluxing benzene-T was repeated, and at intervals samples were withdrawn through the condenser with a capillary pipette. This indicated that radioactivity in the blocked nucleoside increased only from 1 032 c/min mg after 20 minutes of refluxing to 1 440 c/min mg after 150 minutes.

Another purine nucleoside, arabinosyl adenine, was refluxed with toluene-T and mercuric chloride. The mercuric chloride was removed by extraction in methanol. The nucleoside was found to have a significant level of radioactivity.

DISCUSSION

The results of our tritium-exchange experiments support the conclusion that a catalytic exchange of tritium can occur between an aromatic solvent and the protons of a purine base or a sugar. Although more potential exchange sites were available on the sugar than on the base (7 vs. 1), the exchange was more active on the base. The higher temperature for the reaction in toluene appeared to produce a more active exchange than occurred in benzene. The difference evidenced in the stability of the protons of purine and sugar may indicate a utility of this reaction for studies of the stability of carbon–hydrogen bonds in various materials. The sensitivity of scintillation counting and the present availability of inexpensive tritiated solvents would encourage use of this as an investigative tool.

Determination of optimum conditions for this tritium exchange will require much more extensive studies, which we have initiated. The labelling of nucleosides seems to be proportional to the level of radioactivity in the solvent, and solvents such as benzene-T and toluene-T are available at relatively low price and high specific radioactivity (250 mcuries/mmole). The synthesis of the nucleosides we require, with tritium in both base and sugar, thus appears practical.

It will be important to determine the general applicability of this reaction and whether superior catalysts can be found. If it does have general applicability to tritium labelling of organic compounds, there would be a distinct advantage to the mild conditions used, since the Wilzbach (2) technique is destructive to labile materials.

ELECTRONIC EFFECTS IN E2 REACTIONS

II. *t*-BUTOXIDE-INDUCED ELIMINATIONS OF 2-METHYL-3-PENTYL ARENESULFONATES[1,2]

ALLAN K. COLTER AND DONALD R. MCKELVEY
Department of Chemistry, Carnegie Institute of Technology, Pittsburgh, Pennsylvania

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

As part of a study of the influence of electronic effects imposed by the leaving group on orientation in E2 reactions, a study of elimination in a series of 2-methyl-3-pentyl arenesulfonates (I) has been carried out. The compositions of the olefin mixtures resulting from reaction of selected members of this series with potassium *t*-butoxide in *t*-butanol (I*a*, I*d*), 50% (by volume) *t*-butanol – dioxane (I*a*–I*g*), 25% (by volume) *t*-butanol – dioxane (I*d*–I*f*), and 25% (by volume) *t*-butanol – dimethyl sulfoxide (I*a*, I*d*, I*f*, I*g*), at 50 °C, have been determined using vapor phase chromatography. Second-order rate constants were measured for these reactions in *t*-butanol (I*e*), and 50% *t*-butanol – dioxane (I*a*, I*c*–I*g*) at 50 °C and in 25% *t*-butanol – dimethyl sulfoxide (I*a*, I*d*, I*e*) at 25 °C.

The compositions of the olefin mixtures vary in a fairly regular way with changes in the electronic nature of the leaving group, the fraction of 2-methyl-2-pentene and ratio of *trans*- to *cis*-4-methyl-2-pentene for the most part increasing with increasing electron withdrawal. The E2 reactions in 25% *t*-butanol – dimethyl sulfoxide produce *trans*- and *cis*-4-methyl-2-pentene in ratios (20 to 35) considerably higher than those in an equilibrium mixture (ca. 6).

The results are discussed in terms of recent views on the E2 transition state.

INTRODUCTION

In recent years, the concept of a continuous spectrum of transition states for the E2 reaction (Fig. 1), differing in the extent to which the C_β—H and C_α—X bonds are broken, has become widely accepted (1–13). Factors expected to influence the position of an

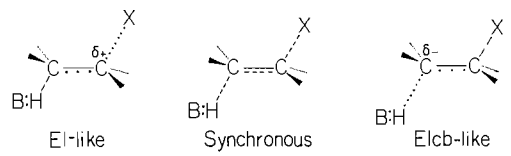

FIG. 1. Spectrum of E2 transition states.

elimination among the spectrum of transition states and methods of assessing the quality of the transition state have recently been discussed by Bunnett (12). In E2 reactions in alkyl systems having two or more constitutionally nonequivalent β-hydrogens, it is generally agreed that transition states in the E1*cb*-like region favor abstraction of the most acidic hydrogen, thereby leading to predominant amounts of the product having the smallest number of alkyl groups attached to the olefinic function (Hofmann pattern). Transition states in the synchronous to E1-like regions favor formation of the most highly alkylated olefin (Saytzeff pattern).

In this and previous work (13) we have been concerned with evaluating the importance of electronic effects imposed by the leaving group in determining orientation in E2

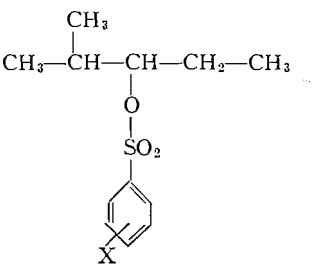
reactions. Our approach has been to examine the olefin mixtures produced from E2 reactions of a series of alkyl arenesulfonates differing only in a substituent in the meta or para position of the benzene ring in the leaving group. In this way, steric influences (14) are constant throughout the series.

Applied to a series of alkyl arenesulfonates, the model of the E2 transition state discussed by Bunnett does not lead to a clear-cut prediction about how direction of elimination should change with leaving group. Whereas a change to a leaving group of greater electron-attracting character, by increasing the acidity of the β-hydrogens, is predicted to result in a shift toward the E1*cb*-like extreme, such a change in a series of arenesulfonates, by increasing the ease of heterolysis of the C—O bond, could also produce a shift toward the E1-like extreme (12). Thus, a study of this kind allows some evaluation of the relative importance of these two effects in determining orientation.

In the first paper in this series we reported the results of a study of the reactions of a series of 2-pentyl arenesulfonates with ethanolic sodium ethoxide. There appeared to be a very small but regular increase in the percentage of 2-pentene and in the ratio of *trans*- to *cis*-2-pentene with increasing electron withdrawal in the leaving group. However, this conclusion was clouded somewhat by the fact that, under the conditions studied, observed olefin compositions had to be corrected for competing first-order elimination. The corrections were based on two assumptions (13), neither of which could be rigorously justified.

In the present work, our aim was to minimize competition by first-order elimination by appropriate choice of base–solvent system. The compounds studied were the series of 2-methyl-3-pentyl arenesulfonates (I). This system offers an advantage over the 2-pentyl system in that E1 elimination in the solvents studied produces 15–20% of the



I*a*, X = *p*-$N(CH_3)_2$
I*b*, X = *p*-NH_2
I*c*, X = *p*-OCH_3
I*d*, X = *p*-CH_3
I*e*, X = *p*-Br
I*f*, X = 3,4-di-Cl
I*g*, X = *p*-NO_2

rearranged olefin 2-methyl-1-pentene. The presence or absence of this olefin therefore provides a test for competing first-order elimination and a non-kinetic method for correcting for competing first-order elimination, if necessary.

RESULTS

Synthesis of Starting Materials

The desired arenesulfonates were synthesized by conventional methods. All except the *p*-aminobenzenesulfonate I*b* were prepared by treatment of 2-methyl-3-pentanol with the appropriate arenesulfonyl chloride in dry pyridine. The *p*-aminobenzenesulfonate was prepared by reaction of *p*-aminobenzenesulfonyl fluoride with sodium 2-methyl-3-pentoxide.

Product Studies

Product studies were carried out in the four solvents: *t*-butanol, 50% (by volume)

t-butanol – dioxane, 25% (by volume) *t*-butanol – dioxane, and 25% (by volume) *t*-butanol – dimethyl sulfoxide. All product studies, except when stated otherwise, were carried out at 50 °C. Potassium *t*-butoxide was the base employed in all the E2 reactions. The olefinic products were separated from the reaction mixtures by distillation and were analyzed by vapor phase chromatography.

Table I summarizes the results of the E1 product studies. The formation of the rearranged olefin 2-methyl-1-pentene indicates that at least part of the reaction involves a carbonium ion or ion pair intermediate. Direct analysis of the reaction mixture from solvolysis of I*d* in *t*-butanol showed, by the absence of any detectable *t*-butyl 2-methyl-3-pentyl ether, that at least 95% of the first-order reaction leads to olefinic products.

TABLE I

Products of E1 reactions of 2-methyl-3-pentyl arenesulfonates

Ester	Solvent	% 2-methyl-2-pentene	% *cis*-4-methyl-2-pentene	% *trans*-4-methyl-2-pentene	% 2-methyl-1-pentene
p-CH_3*	*t*-Butanol	77.2	0	7.0	15.8
p-$N(CH_3)_2$*†	50% *t*-butanol – dioxane	65.5	1.9	15.5	17.0
p-Br‡	50% *t*-butanol – dioxane	71.4±0.4	0.9±0.1	8.3±0.1	19.4±0.3

*Single run; estimated uncertainties ±0.4%.
†Temperature = 100.0°.
‡Average of three runs listed with average deviations.

The results of the E2 product studies are shown in Table II. Corrections for competing first-order elimination were made whenever 2-methyl-1-pentene was present in the olefinic products. In such cases, two sets of values are listed; the values in parentheses are uncorrected percentages based on the E2 products alone.

In correcting E2 product mixtures for E1 reaction, the fraction of the total olefin product arising from first-order elimination was taken as a fraction of 2-methyl-1-pentene in the mixture divided by the fraction of 2-methyl-1-pentene in the E1 product. The olefin composition from the E1 reaction of I*e* in 50% *t*-butanol – dioxane was used in making all corrections, with the single exception of the E2 reaction of I*d* in *t*-butanol, in which case the E1 product of the same compound in *t*-butanol was used. The use of a single E1 product composition cannot lead to any significant error, since the E1 product mixtures are expected to be quite insensitive to leaving group and the corrections are very small.

The method of correcting for first-order elimination is based on the assumption that the carbonium ion intermediate leads to the same product mixture in the presence of base as in the absence of base. While this assumption is unlikely to be completely valid, the corrections are probably approximately correct for the following reason. In the basic media a carbonium ion is expected to yield an olefin mixture which is intermediate in composition between the E1 and E2 mixtures. Thus, while the fraction of 2-methyl-1-pentene in the basic reaction product would then underestimate the amount of competing E1 reaction, the E1 product composition used in the correction tends to make the correction too large. Most important, the corrections in all cases are much too small to change the general trends in product composition. The correction procedure is described in detail, with an example, in the Experimental section.

With the exception of the two *p*-amino esters, I*a* and I*b*, in *t*-butanol and 50% *t*-butanol – dioxane, the percentage of 2-methyl-2-pentene and the ratio of *trans*- to *cis*-4-methyl-2-pentene increase in a regular way with increasing electron withdrawal in the leaving group. The changes are substantial, the percentage of Saytzeff elimination increasing from 48.9% (*p*-OCH_3) to 59.3% (*p*-NO_2) in 50% *t*-butanol – dioxane and from 47.9% (*p*-$N(CH_3)_2$) to 61% (*p*-NO_2) in 25% *t*-butanol – dimethyl sulfoxide. The *trans* to *cis* ratio in the Hofmann olefins increases from 1.48 (*p*-OCH_3) to 3.20 (*p*-NO_2) in 50% *t*-butanol – dioxane and from 20.7 (*p*-$N(CH_3)_2$) to 34.8 (3,4-di-Cl) in 25% *t*-butanol – dimethyl sulfoxide. Aside from elimination of competing E1 reaction, replacement of *t*-butanol by dioxane mixtures has almost no effect on the E2 products. However, whereas the E2 reactions in 25% *t*-butanol – dimethyl sulfoxide yield a similar fraction of 2-methyl-2-pentene as the reactions in *t*-butanol and the *t*-butanol – dioxane mixtures, the ratio of *trans*- to *cis*-4-methyl-2-pentene is dramatically increased.

Rate Studies

Substituent and solvent effects on rates of elimination could provide information about the extent of C—O bond fission and charge separation in the transition states. Consequently, second-order rate constants for reaction of selected esters with potassium *t*-butoxide were measured in *t*-butanol and 50% *t*-butanol – dioxane at 50° and in 25% *t*-butanol – dimethyl sulfoxide at 25°. The results are listed in Table III. Although certain of these reactions are known from the product studies to be accompanied by first-order reaction, no observable regular trend in calculated second-order rate constants was observed in any instance. Order of magnitude corrections for competing first-order elimination can be made where complementary product studies have been carried out. It seems safe to assume that no appreciable substitution occurs in either the first- or second-order reaction, since it was demonstrated that at least 95% of the reaction of I*d* in *t*-butanol at 50° leads to olefin (see above). Therefore, the fraction of the total reaction occurring via a first-order process under the conditions of the product runs can be

p-NO$_2$‖	$1.07\pm0.10 \times 10^{-3}$
25% *t*-butanol – dimethyl sulfoxide, 25.00±0.02 °C	
p-N(CH$_3$)$_2$	$1.01\pm0.06 \times 10^{-3}$
p-CH$_3$	$1.24\pm0.05 \times 10^{-2}$
p-Br	$1.00\pm0.04 \times 10^{-1}$

*Rate constants listed with average deviations.
†First-order correction would reduce this value by ca. 0.27 × 10^{-5} l mole^{-1} s^{-1}.
‡First-order correction ca. 0.36 × 10^{-5} l mole^{-1} s^{-1}.
§First-order correction ca. 0.06 × 10^{-4} l mole^{-1} s^{-1}.
‖First-order correction ca. 0.15 × 10^{-3} l mole^{-1} s^{-1}.

estimated as already described. This value can then be used to estimate the relative magnitudes of the first- and second-order rate constant (k_1/k_2) under the conditions of the product run (13) and, if one assumes that the same ratio prevails under the conditions of the rate measurements, an approximate correction can then be applied to the observed second-order rate constant.[3] Corrections for the rate constants in 50% *t*-butanol – dioxane estimated in this way are listed as footnotes to Table III. The correction for the single E2 rate in *t*-butanol was estimated as described in ref. 13 by using an approximate first-order rate constant in *t*-butanol (see below).

The rate measurements were carried out at moderately high (0.15–0.38 *M*) base concentrations to approximate the conditions of the product runs. The extent of aggregation of the base will, of course, be concentration dependent. Second-order behavior was assumed; however, an appreciable fraction of the reaction could depend on a higher-than-first power of the base concentration without producing noticeable trends in calculated second-order rate constants. An increase in base concentration from 0.145 *M* to 0.352 *M* produced an increase of about 20% in the second-order rate constant for the *p*-N(CH$_3$)$_2$ ester (the one listed corresponds to 0.145 *M* base). This increase could be a result of elimination induced by higher aggregates of base, complex formation between the potassium ion and the amino group (see Discussion), or less specific salt effects. Further studies of the effect of base concentration on rates and products of elimination in these systems are in progress; at present, a measure of the effect of base concentration on the rates of elimination of the other arenesulfonates is not available. It is clear, however, that such effects are not large enough to affect the general nature of the results reported, and are unlikely to change appreciably the slopes of the Hammett plots (see below).

[3]*Such corrections are only very approximate for two reasons. First, the method assumes that the ratio (k_1/k_2) is unaffected by the base concentration. Secondly, we must assume that the fraction of 2-methyl-1-pentene gives an accurate measure of the fraction of the reaction proceeding by first-order reaction.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Hammett plots[4] for the E2 rates in 50% *t*-butanol – dioxane at 50 °C and 25% *t*-butanol – dimethyl sulfoxide at 25 °C are shown in Figs. 2 and 3. The range of log *k* shown graphically for each point includes the uncertainty introduced by the competing first-order reaction. A least squares fit of the plot shown in Fig. 1 gives $\rho = 1.51$, a value not too different from that (1.35) obtained for the E2 reactions of 2-pentyl arenesulfonates in ethanolic sodium ethoxide at 50 °C (13). In contrast, the E2 rates in 25% *t*-butanol – dimethyl sulfoxide show an unusual sensitivity to substitution in the leaving group, ρ here being 2.40. The reactivity of the *p*-bromobenzenesulfonate relative to the *p*-toluenesulfonate in this system (8.1) is, to our knowledge, the largest ever reported in any substitution or elimination reaction of arenesulfonates (16, 17).

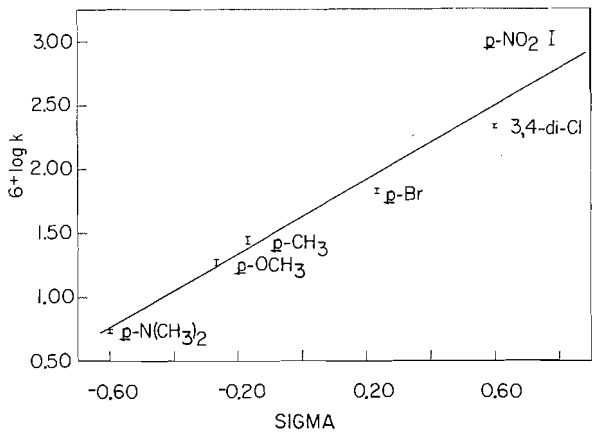

FIG. 2. Hammett plot for E2 rates in 50% *t*-butanol – dioxane.

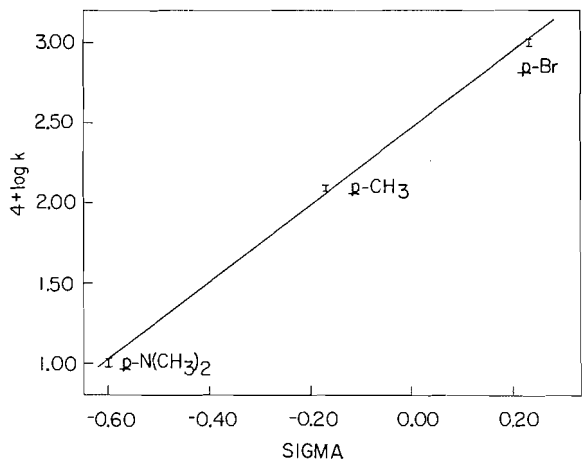

FIG. 3. Hammett plot for E2 rates in 25% *t*-butanol – dimethyl sulfoxide.

For purposes of comparison, it would be instructive to have a measure of solvent and substituent effects for the E1 reactions of compounds I in the solvents studied. For this reason, several first-order rates were run in *t*-butanol and 50% *t*-butanol – dioxane (18). However, accurate determination of first-order rate constants was made very difficult

[4]*Hammett sigma values are taken from H. H. Jaffé, Chem. Rev. 53, 191 (1953).*

by the enormous salt effects in these nonpolar solvents (19), especially in 50% *t*-butanol – dioxane, so that first-order rate constants increase sharply with extent of reaction. From the measurements made, it can be estimated that first-order rates in *t*-butanol are faster than those in 50% *t*-butanol – dioxane by a factor of about 10. This is to be compared with a factor of 1.35 for the E2 reaction of the *p*-bromobenzenesulfonate.

Control Experiments

The stability of the olefin mixtures under the conditions of the product studies was demonstrated for all reaction media. The absence of any significant fractionation of olefins accompanying their distillation from the reaction medium was demonstrated by showing that identical olefin compositions were obtained by direct analysis of a product mixture without separation of olefins and by a method involving separation of olefins by toluene extraction. The E2 product from reaction of I*d* with potassium *t*-butoxide in 50% *t*-butanol – dioxane was unaffected by 0.52 *M* aniline. (See Discussion for the significance of this control.) The possibility that an appreciable portion of the E2 products in 25% *t*-butanol – dimethyl sulfoxide arises through a prior displacement of the leaving group by dimethyl sulfoxide can be ruled out on the basis of our E2 rates and rates of dimethyl sulfoxide displacements reported by Smith and Winstein (20).

DISCUSSION

With the exception of the *p*-amino esters I*a* and I*b* in *t*-butanol and 50% *t*-butanol – dioxane, the E2 product compositions show two important trends. First, as substitution in the leaving group is made increasingly electron withdrawing, the fraction of 2-methyl-2-pentene increases. Second, paralleling this increase in the proportion of Saytzeff elimination is an increase in the ratio of *trans*- to *cis*-4-methyl-2-pentene. Both trends are consistent with the suggestion (13) that increasing the ease of heterolysis of the C—O bond should result in a shift in the character of the transition state toward the E1-like extreme (Fig. 1). Consequently, it appears that, in the systems studied in this work, electronic influences on the ease of heterolysis of the C—O bond have a greater effect on the character of the transition state than changes in the acidities of the β-hydrogens. It must be emphasized, however, that this picture is oversimplified, since we have neglected a dimension in the spectrum of transition states. Thus, one can visualize a spectrum of synchronous transition states, for example, with little C_β—H and C_α—X bond stretching at one extreme to nearly complete bond fission at the other.

It is, of course, also possible to explain the trends in product composition in terms of changing proportions of elimination arising from two competing processes. Two such processes could be, for example, one involving a fairly synchronous E2 transition state and one involving reaction of base with an ion pair which, to account for the second-order rate law, returns to covalent ester more often that it reacts with base. The latter mechanism does not seem unreasonable for E2 reactions of secondary arenesulfonates in ethanol, *t*-butanol, or *t*-butanol – dioxane mixtures. Since competing E1 reaction occurs in most of these solvents, it seems logical to assume that the E2 transition states lean toward the E1-like extreme (11, 21).

Two features of the results deserve particular comment. The first is the dramatic difference in the character of the E2 product in 25% *t*-butanol – dimethyl sulfoxide from that in the other solvents. Although the proportion of Saytzeff elimination is similar in all solvents, elimination in the dimethyl sulfoxide containing solvent leads to remarkably high (21:1 to 35:1) ratios of *trans*- to *cis*-4-methyl-2-pentene. Equilibration of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

mixture containing the two olefins with potassium *t*-butoxide in dimethyl sulfoxide at 55 °C leads to a *trans* to *cis* ratio of about 6:1 (22). Thus, if one assumes a similar ratio in 25% *t*-butanol – dimethyl sulfoxide at 50 °C, the difference in the standard free energies of the activated complexes leading to *cis*- and *trans*-4-methyl-2-pentene is greater than the difference in the standard free energies of the olefins themselves. It is apparent, then, that the simple view that the proportion of Saytzeff elimination and the *trans* to *cis* ratio are both simple functions of the amount of double bond character in the transition state is incorrect, or at least not the whole story.

Several possible reasons for the abnormally high *trans* to *cis* ratio come to mind. One possibility is that the assumption of *trans* elimination through a pure symmetrical staggered transition state is incorrect. This problem is being investigated further. Whatever the reason, this result is not a general characteristic of E2 reactions in dimethyl sulfoxide. Hofmann *et al.* (23) report that reaction of 2-chlorobutane with potassium *t*-butoxide yields *trans*- and *cis*-2-butene in a ratio of 3.46:1, which is close to the equilibrium value.

The reason for the "anomalous" behavior of the *p*-amino compounds in *t*-butanol – dioxane is not known, but some of the possible causes have been eliminated by control experiments. The amino groups, through more effective solvation of the potassium cation, could conceivably alter the nature of the base enough to throw the product composition out of line. This possibility was eliminated, however, by showing that the E2 product composition from I*d* in 50% *t*-butanol – dioxane in the presence of 0.52 *M* aniline is identical with that obtained in the absence of added aniline. It was also considered that a unimolecular *cis* elimination (24, 25) could be occurring in competition with the E2 reaction. To account for the anomalous E2 products, however, such a process would have to be comparable in rate to the E2 reaction. Since the absence of 2-methyl-1-pentene in the base-induced reaction product indicates that the normal E1 process does not compete with the E2 reaction, the cyclic process would have to be much faster than the normal E1 process. However, the E1 product for I*a* in 50% *t*-butanol – dioxane at 100° (Table I) is normal in every respect; hence, no other type of unimolecular reaction can be important under E2 conditions. A third possible reason for the irregular behavior of the *p*-amino esters is complex formation between the *p*-amino or *p*-dimethylamino group and the potassium cation. This explanation could account for the "normal" behavior of I*a* in 25% *t*-butanol – dimethyl sulfoxide, because complex formation should occur to a much smaller extent in this solvent, since dimethyl sulfoxide is an effective cation-solvating solvent (26). If a small fraction of the substrate, say 1%, were complexed in this way and the complexed leaving group were more reactive by a factor of 100, the observed rate constant would be approximately doubled, while about 50% of the product would arise through the complexed leaving group. The E2 rate constant for I*a* in 50% *t*-butanol – dioxane did indeed show a substantial increase with an increase in base concentration (see Results), but this may simply be a normal salt effect. A more complete study of the effect of base concentration on the E2 products is needed to answer this question. Such a study is in progress. Finally, it is possible that changes in the character of the E2 transition state brought about by substitution in a series of benzenesulfonates may be more complex than those predicted on the basis of our simple model.

EXPERIMENTAL

Preparation of Esters

2-Methyl-3-pentanol was prepared from 2-bromopropane and propionaldehyde by a procedure similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to that of Krollpfeiffer and Seebaum (27). The crude material was fractionated and the portion boiling at 127.1 °C (at 734 mm pressure) collected. Analysis by gas chromatography showed this material to be greater than 99% pure.

Commercially available *p*-methyl-, *p*-bromo-, and *p*-nitro-benzenesulfonyl chlorides were purified as previously described (13). *p*-Aminobenzenesulfonyl fluoride and *p*-methoxybenzenesulfonyl chloride were prepared as previously described (13). Commercially available 3,4-dichlorobenzenesulfonyl chloride was purified by two fractional freezings.

p-N,N-Dimethylaminobenzenesulfonyl chloride was prepared by reaction of phosphorus pentachloride with sodium N,N-dimethylsulfanilate (28) in refluxing toluene. Dry recrystallized sodium N,N-dimethylsulfanilate (0.1 mole) and phosphorus pentachloride (0.1 mole) were refluxed in 150 ml of reagent grade toluene until the theoretical amount of hydrogen chloride was liberated (4–6 h). The reaction mixture was filtered and the filtrate washed thoroughly with aqueous sodium carbonate and water. After it was dried over magnesium sulfate, the toluene was evaporated under reduced pressure and crystallization induced by addition of pentane. The yellow crystals (70% yield) melted at 109–110 °C (lit. (29), 110°) and were not purified further.

With the exception of 2-methyl-3-pentyl *p*-aminobenzenesulfonate, the esters were prepared by reaction of the appropriate acid chloride with a stoichiometric amount of 2-methyl-3-pentanol in enough dry pyridine to effect solution. In preparing the 3,4-dichloro and *p*-nitro esters it was necessary to moderate the reaction by addition of an equal volume of dry benzene. The tightly stoppered reaction flask was left overnight in the refrigerator, after which the ester was extracted into ether and washed twice with dilute hydrochloric acid, twice with dilute aqueous sodium hydroxide, and twice with water. After it was dried over magnesium sulfate and treated with Norite A, the ether was evaporated under reduced pressure. The *p*-methyl-, *p*-bromo-, *p*-methoxy-, and 3,4-dichloro-benzenesulfonates are liquids at room temperature. The *p*-nitrobenzenesulfonate first appeared as a yellow oil but crystallized upon addition of a small amount of *n*-pentane. This ester had m.p. 51–52 °C and decomposed within a few hours at room temperature. The *p*-N,N-dimethylbenzenesulfonate was obtained as a white solid, m.p. 84–86 °C.

2-Methyl-3-pentyl *p*-aminobenzenesulfonate was prepared by reaction of *p*-aminobenzenesulfonyl fluoride with sodium 2-methyl-3-pentoxide in ether as previously described (13) for the corresponding 2-pentyl ester. The product was obtained as white plates, m.p. 99–100 °C.

The *p*-nitrobenzenesulfonate (I*g*) was very unstable and, for this reason, it was not possible to obtain an elemental analysis. The infrared spectrum showed strong absorption at 6.52 μ, 7.41 μ, and 11.68 μ (characteristic of aromatic nitro) and at 7.32 μ and 8.45 μ (characteristic of sulfonates (30)).

Reaction Media

t-Butanol (Fisher certified reagent grade) was distilled twice over sodium. Dimethyl sulfoxide (Fisher certified reagent grade) was distilled over calcium hydride under reduced pressure, b.p. 50 °C at 3 mm pressure, and was freshly prepared for each experiment. Dioxane was purified by Fieser's method (31). The reaction media were prepared by first dissolving, under nitrogen, clean potassium metal in an accurately known volume of *t*-butanol and then adding an accurately known volume of either dioxane or dimethyl sulfoxide. An aliquot of this mixture was then titrated with standard hydrochloric acid to determine, in moles per liter, the concentration of potassium *t*-butoxide and, hence, the amount of *t*-butanol consumed by reaction with potassium. The appropriate weight of *t*-butanol was then added to an accurately known volume of the mixture to obtain an accurately known volume ratio of the two solvents.

Product Studies

A weighed portion of ester was dissolved in 100 ml of the reaction medium in a 200-ml round-bottomed flask. The flask was swept out with nitrogen, sealed, and immersed in a constant temperature bath maintained at 50.06 ± 0.02 °C. In cases where the rate of reaction was very rapid, i.e. all reactions involving the 3,4-dichloro- and *p*-nitro-benzenesulfonates and all reactions in 25% *t*-butanol – dimethyl sulfoxide, the reaction medium was preheated to 50.06° before addition of the ester. After the reaction was calculated to be at least 99% complete, the mixture was transferred to a 500-ml round-bottomed flask containing about 350 ml of water. The olefinic materials were then concentrated by careful distillation through an 18-inch tantalum-wire spiral column fitted with an ice condenser. The methylpentenes were chased through the column with a small volume of *t*-butanol – water azeotrope (b.p. 80°). Everything distilling up to 80 °C was collected.

The olefins were analyzed by vapor phase chromatography at room temperature, using helium carrier gas at a pressure of 20 p.s.i.g. and a 35-ft column packed with tricresyl phosphate (Burrell Corp., catalogue No. 341-139). The individual methylpentenes were identified by comparison of retention times with those of authentic samples.

The E2 reactions in *t*-butanol and *t*-butanol – dioxane mixtures were accompanied by precipitation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

potassium arenesulfonate. Rate measurements showed, however, that no appreciable coprecipitation of base occurs and that no appreciable reaction occurs at the surface of the precipitate. E1 product runs always contained an excess of 2,6-lutidine to neutralize the arenesulfonic acid formed.

Correction of E2 Product Compositions

The E2 reaction of I*e* in 50% *t*-butanol – dioxane will serve to illustrate the procedure for correction for competing E1 reaction. The analysis gave four peaks of area listed in the second column in Table IV. Since the pure E1 process yields 19.4% 2-methyl-1-pentene (Table I), 1.7 cm^2 represents 19.4% of all the E1 products and 1.7/0.194 = 8.76 cm^2 represents 100% of all the E1 products. The area of the *cis*-4-methyl-2-pentene peak should then be corrected by 0.009 × 8.76 = 0.1 cm^2, the area of the *trans*-4-methyl-2-pentene peak by 0.083 × 8.76 = 0.7 cm^2, and the area of the 2-methyl-2-pentene peak by 0.714 × 8.76 = 6.3 cm^2. The uncorrected and corrected areas and percentages are listed in Table IV.

TABLE IV

Correction of E2 product from I*e* in 50% *t*-butanol – dioxane

Olefin	Uncorrected area, cm^2	Uncorrected %*	Corrected area, cm^2	Corrected %
cis-2-Methyl-2-pentene	64.8	17.5	64.7	17.8
trans-2-Methyl-2-pentene	113.6	30.7	112.9	31.1
2-Methyl-2-pentene	191.2	51.8	184.9	51.0
2-Methyl-1-pentene	1.7	—	0.0	—

*Based on the E2 products alone.

Kinetic Studies

In *t*-butanol and 50% *t*-butanol – dioxane, 5-ml samples of the reaction mixture were sealed in monax glass ampoules under a nitrogen atmosphere and immersed in a constant temperature bath at 50.06 ± 0.02 °C. After thermal equilibrium, 2–3 tubes were withdrawn for the initial (zero) point. At appropriate time intervals additional tubes were withdrawn, leaving two for infinity measurements. Upon withdrawal from the bath the tubes were quenched by plunging in ice water and broken open, and the contents quantitatively transferred to a flask containing crushed ice. The mixture was then titrated with standard aqueous HCl to a phenolphthalein end point. Initial ester and base concentrations were, respectively: I*e* in *t*-butanol, 0.076 *M*, 0.223 *M*; in 50% *t*-butanol – dioxane: I*a*, 0.131 *M*, 0.145 *M*; I*c*, 0.202 *M*, 0.323 *M*; I*d*, 0.100 *M*, 0.158 *M*; I*e*, 0.103 *M*, 0.236 *M*; I*f*, 0.314 *M*, 0.380 *M*; and I*g*, 0.20 *M*, 0.34 *M*.

In 25% *t*-butanol – dimethyl sulfoxide, a weighed quantity of ester was dissolved in the reaction medium in a volumetric flask already immersed in a constant temperature bath maintained at 25.00 ± 0.02 °C. By using a 5-ml pipette, aliquots were transferred at appropriate time intervals to flasks containing cracked ice. The mixtures were then titrated with standard aqueous HCl using phenolphthalein indicator. Initial ester and base concentrations were, respectively: I*a*, 0.100 *M*, 0.162 *M*; I*d*, 0.095 *M*, 0.162 *M*; and I*e*, 0.106 *M*, 0.162 *M*.

Rate constants were calculated using the integrated second-order rate expression

$$k_2t = [1/(b - a)] \ln[a(b - x)/b(a - x)],$$

where a and b are initial ester and base concentrations, respectively, and $(a - x)$ and $(b - x)$ are the ester and base concentrations at time t.

Control Experiments

The stability of the olefin mixtures in 50% *t*-butanol – dioxane – 0.47 *M* potassium *t*-butoxide at 50 °C was demonstrated by reaction of I*a* for periods ranging from 33 to 90 days. Product compositions were identical within experimental uncertainty.

A 1-ml sample of olefin consisting of 90.4% *cis*-4-methyl-2-pentene and 9.6% *trans*-4-methyl-2-pentene was added to 50 ml of 25% *t*-butanol – dimethyl sulfoxide, 0.20 *M* in potassium *t*-butoxide. After 96 min at 50 °C (twice the longest reaction time for this medium), the olefin mixture was analyzed by the usual procedure. The composition was unchanged.

A sample of the reaction mixture from solvolysis of I*d* in *t*-butanol was analyzed by injecting it directly into the gas chromatograph. The analysis gave the same results, within experimental error, as those obtained by first concentrating the olefins via distillation. The spectrum showed no detectable (estimated less than 5%) *t*-butyl 2-methyl-3-pentyl ether.

In the E2 reaction of I*b* in 50% *t*-butanol – dioxane, the olefins were separated from the reaction mixture by the usual distillation procedure and also by extraction with toluene. The reaction mixture from one run (100 ml) was washed three times with 10-ml portions of toluene. The toluene extract was washed

For personal use only.

twice with 10-ml portions of 2 *N* HCl. The olefins were then concentrated by distillation. Analysis of the two olefin samples gave identical results.

The runs carried out in the presence of aniline were carried out in the usual manner, except that aniline was added to the reaction medium before addition of the ester.

THE PREPARATION OF 3-ALKYLTHIOINDOLES[1]

R. V. JARDINE[2] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

3-Ethylthioindole has been prepared by Fischer cyclization of the condensation product of phenylhydrazine and ethylthioacetaldehyde diethyl acetal, and also by a route involving the reaction of ethyl iodide with the sodium borohydride reduction product of 1,2-dithiolo[4,3-*b*]indole-3-(4H)-thione. The last-named compound was obtained by reaction of 2-carbethoxyindoxyl with phosphorus pentasulfide.

INTRODUCTION

The need for a quantity of 3-indolylthioacetic acid evoked interest in the general problem of preparing 3-alkylthioindoles. Information in the literature concerning such compounds is meager. Several attempts have been made to prepare 3-mercaptoindole, from which, via a Williamson ether synthesis, the requisite 3-alkylthioindole might then be made. When indole magnesium bromide was treated with sulfur, 3,3′-diindolyl sulfide was obtained rather than the expected 3-mercaptoindole (1). Oddo and Mingoia (2) have recorded the preparation of 3- as well as some 2-benzoylthioindole when the indole Grignard reagent was allowed to react successively with sulfur and then benzoyl chloride. Hydrolysis of the resulting thiol esters led to 3- and 2-mercaptoindole.

The formation of thioethers from 3-mercaptoindole does not appear to be straightforward. Grant and Snyder (3), upon hydride reduction of 3,3′-diindolyl disulfide followed by addition of 2,4-dinitrochlorobenzene, quite readily obtained 3-(2,4-dinitrophenylthio)-indole, but when ethyl bromoacetate was used instead of the dinitrochlorobenzene there was obtained mainly unchanged 3,3′-diindolyl disulfide with only a trace of the expected 3-indolylthioacetic acid. These same authors were unable to isolate 3-mercaptoindole from hydride reduction of the disulfide, presumably because of the remarkably easy oxidation of 3-mercaptoindole back to the disulfide. Grant and Snyder, furthermore, have pointed out the similarity of the melting point of their 3,3′-diindolyl disulfide (m.p. 217–218°) to that of the reported (2) 3-mercaptoindole (235°). The 3,3′-diindolyl disulfide prepared by Woodbridge and Dougherty (4) is reported to melt at 227–229.5°. Hence, a doubt exists that 3-mercaptoindole (2) has actually been obtained. The 2-mercaptoindole, however, seems to be more readily isolated, since the compound reported by Oddo and Mingoia (2) melted at 148–150°, very close to that found for 2-mercaptoindole (m.p. 145°) easily prepared in 70% yield by treatment of oxindole with phosphorus pentasulfide (5).

Two reports of the preparation of 3-substituted 2-methylthioindoles have appeared (6, 7), but to our knowledge there is no account, other than those mentioned above, of the synthesis of 3-alkylthioindoles.

[1]*Taken from the thesis of R. V. Jardine, submitted to the Faculty of Graduate Studies, University of Alberta, Edmonton, Alberta, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

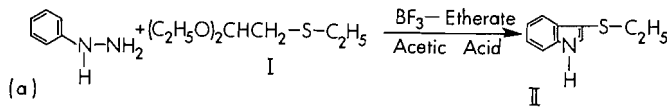
RESULTS AND DISCUSSION

3-Alkylthioindoles via the Fischer Indole Synthesis

When ethylthioacetaldehyde diethyl acetal (8) was condensed with phenylhydrazine in acetic acid in the presence of boron trifluoride etherate catalyst, a smooth exothermic reaction occurred (eq. [*a*]) and yielded 3-ethylthioindole (~60%). Elemental analysis,



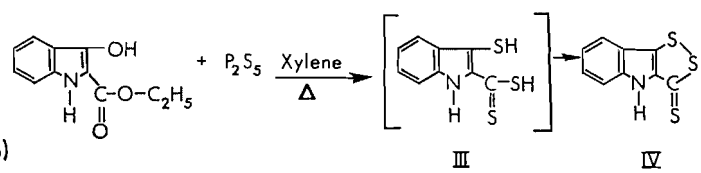
molecular weight (by mass spectrometry), and infrared and nuclear magnetic resonance (n.m.r.) spectra, as well as the method of synthesis, showed conclusively that the product was 3-ethylthioindole (II).

Attempts to form the N-acetyl derivative with either acetic anhydride in benzene or acetyl chloride in pyridine gave only unchanged thioether. This agrees with a similar resistance to N-acylation shown by 3,3′-diindolyl sulfide (1). When II was treated with an alcoholic solution of mercuric chloride, a precipitate of ethylthiomercuric chloride (9) was obtained, a reaction characteristic of a number of alkyl aryl and aryl aralkyl thioethers (10).

The utility of this reaction in preparing 3-alkylthioindoles is obviously dependent upon the availability of the appropriate alkylthioacetaldehyde diethyl acetal (I).

3-Alkylthioindoles via Reaction of P_2S_5 with 2-Carbethoxyindoxyl

Since the reaction of oxindole with phosphorus pentasulfide is known to produce 2-mercaptoindole (5), 2-carbethoxyindoxyl was treated with phosphorus pentasulfide in boiling xylene (eq. [*b*]). From the reaction mixture was isolated in 11% yield the compound 1,2-dithiolo[4,3-*b*]indole-3(4H)-thione (IV).*

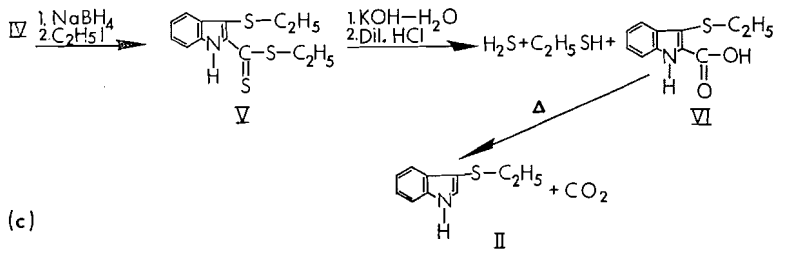


The isolation of IV (the oxidized form of III) rather than the 3-mercaptoindole (III) is analogous to the reported isolation of 3,3′-diindolyl disulfide rather than the expected 3-mercaptoindole upon reduction of this disulfide (3). Elemental analysis, molecular weight, and infrared and nuclear magnetic resonance spectra, as well as a negative Ehrlich test (11, 12), supported structure IV for this product. In addition, Raney nickel desulfurization (13) of IV afforded a compound whose infrared spectrum was identical with that of authentic 2-methylindole (14).

Reduction of IV, with sodium borohydride in ethanol, followed by reaction of the product with ethyl iodide (eq. [*c*]) gave an 84% yield of ethyl 3-ethylthio-2-indoledithiocarboxylate (V), whose structure was corroborated by elemental analysis and infrared and

**The reaction of β-ketoesters (N. Lozac'h and L. Legrand, Compt. Rend. 234, 1291 (1952); A. Luttringhaus, H. Trefzger, and U. Schmidt, Angew. Chem. 67, 274 (1955)) and of aromatic o-hydroxycarboxylic acids (L. Katz, W. Schroeder, and M. Cohen, J. Org. Chem. 19, 711 (1954)) with P_2S_5 has been shown to produce the stable 1,2-dithiolo-3-thione structure found in compound IV.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



nuclear magnetic resonance spectra. Hydrolysis of V gave hydrogen sulfide, ethyl mercaptan, and 3-ethylthioindole-2-carboxylic acid (VI). Compound VI readily decarboxylated and distilled when heated under vacuum, producing 3-ethylthioindole (II), identical with that prepared by the Fischer reaction.

EXPERIMENTAL

Infrared spectra were obtained with Perkin–Elmer instruments, models 21, 221G, and 421. Nuclear magnetic resonance spectra were provided by a Varian Associates instrument, model A-60. Mass spectra were obtained with a MS2-H Metropolitan-Vickers instrument. Gas–liquid chromatography was carried out on a Burrell K-2 Kromo-Tog using a 2½-m column containing a packing of 20% Apiezon L on Kromat F.B. (30–60 mesh) and employing helium as carrier gas.

3-Ethylthioindole (II) by Fischer Cyclization

A mixture of 17.8 g (0.1 mole) of ethylthioacetaldehyde diethyl acetal (8) and 10.8 g (0.1 mole) of phenylhydrazine was added to 100 ml of glacial acetic acid at room temperature. A slightly exothermic reaction took place. Addition of 15.1 g (0.1 mole) of boron trifluoride etherate caused a rise in temperature to 90°. The mixture was maintained at this temperature for 1 h, then poured into 1 l of cold water, and extracted with ether (3 × 200 ml). The combined ether extracts were neutralized with sodium bicarbonate and then washed successively with water (1 × 300 ml), 1 *N* HCl (3 × 300 ml), and water (3 × 300 ml). The dried ethereal solution ($MgSO_4$) was freed from solvent and afforded 12 g (67.5%) of red oil which was shown by gas–liquid chromatography to be reasonably pure 3-ethylthioindole.

An analytical sample was prepared by passing a portion of the oil through a column of neutral alumina (activity grade 1)* using benzene as eluant. The benzene eluate was freed from solvent and the residual oil distilled at 95° at 1.5 mm pressure. Much decomposition accompanied distillation but the product came over as a light yellow oil, η_D^{24} 1.6285.

Anal. Calcd. for $C_{10}H_{11}NS$: C, 67.8; H, 6.26; N, 7.95; S, 18.07. Found: C, 67.54; H, 6.19; N, 7.74; S, 18.27.

Infrared absorption (neat) at 3 405 cm^{-1} indicated N—H stretching characteristic of indoles (15). Aliphatic C—H absorption occurred at 2 885, 2 910, and 2 985 cm^{-1}. The n.m.r. spectrum obtained in deuterochloroform showed a triplet centered at 8.80 τ (J = 7 c.p.s.) and a quartet centered at 7.3 τ (J = 7 c.p.s.), both characteristic of an ethyl group. Signals at 2.0–3.0 τ were attributed to aromatic protons and, according to the integrated area, also included the C_2 proton signal shifted downfield from its normal position at about 2.9–3.4 τ (16, 17) as a result of the combined inductive effects of the nitrogen and the C_3 sulfur substituent. Analysis of the compound by mass spectrometry gave a molecular weight of 177. The empirical formula calculated from mass spectrometric data by the method of Silverstein and Bassler (18) was $C_{10}H_{11}NS$.

Acetylation of 3-ethylthioindole with either acetic anhydride in benzene or acetyl chloride in pyridine failed. Only unchanged 3-ethylthioindole was recovered.

Treatment of 3-ethylthioindole with an ethanolic solution of picric acid gave an amorphous precipitate; attempts at crystallization failed to improve this precipitate. The substance melted over the range −10 to 0°.

When 55 mg (2.55 × 10^{-4} mole) of pure 3-ethylthioindole was treated with 69 mg (2.55 × 10^{-4} mole) of mercuric chloride in 1 ml of 95% ethanol and the solution allowed to stand overnight at room temperature, 50 mg of ethylthiomercuric chloride was deposited. This gave an infrared spectrum in Nujol identical with that of an authentic specimen (9). Thin-layer chromatography of the remaining ethanolic solution showed spots, developed by Ehrlich's reagent (11, 12), whose R_f values were identical with those of authentic samples of indole and 3-ethoxyindole (19, 20).

3-Ethylthioindole via Reaction of P_2S_5 with 2-Carbethoxyindoxyl

1,2-Dithiolo[4,3-b]indole-3(4H)-thione (IV)

To 10 g (0.028 mole) of 2-carbethoxyindoxyl (20) in 150 ml of practical grade xylene was added 20 g (0.09 mole) of phosphorus pentasulfide and the resulting mixture heated to reflux for 2.5 h. The solution was

**Alupharm Chemicals, P.O. Box 755, New Orleans, Louisiana, U.S.A.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

then filtered hot, and the filtrate reduced in volume to 50 ml and chromatographed on a column of neutral alumina (activity grade 1) using ether as eluant. Removal of the ether from the eluate deposited deep orange crystals which were recrystallized from toluene. Yield, 1.2 g (11%); m.p. 208° (decomp.). Molecular weight by Rast, 231; by mass spectrometry, 223.

Anal. Calcd. for $C_9H_5NS_3$: C, 48.40; H, 2.24; N, 6.28; S, 43.10. Found: C, 48.53; H, 2.35; N, 6.42; S, 43.07.

The infrared spectrum showed absorption at 3 310 cm^{-1} (indolic NH) (14) but no carbonyl absorption between 1 600 and 1 735 cm^{-1} (21). No absorption bands could be clearly discerned as being due to $\diagup C{=}S$, usually found at 1 050 – 1 200 cm^{-1} (15, p. 357). The n.m.r. spectrum in dimethyl sulfoxide showed a N—H signal at $-2.34\ \tau$ and aromatic absorption at 1.83–3.0 τ, while in pyridine a signal at $-2.79\ \tau$ occurred for N—H, and between 2 and 3 τ for aromatic absorption, but no signals were found above 3.0 τ.

Compound IV gave a negative Ehrlich test, indicating that both C_2 and C_3 positions of the indole ring were blocked by substituents (11, 12).

A solution of 300 mg (0.0013 mole) of 1,2-dithiolo[4,3-*b*]indole-3(4H)-thione in 200 ml of 95% ethyl alcohol, containing 40 g of active Raney nickel (13), was refluxed for 24 h. The hot solution was separated from the nickel by filtration and the sludge extracted with hot alcohol (3 × 100 ml). The combined alcohol solutions were freed from solvent, giving 10 mg of a compound whose infrared spectrum was identical with that of authentic 2-methylindole (14).

Ethyl 3-(Ethylthio)-2-indoledithiocarboxylate (V)

A solution of IV (0.445 g, 0.0021 mole) in 12.5 ml of 95% ethyl alcohol and 2.5 ml of water containing 0.2 g of sodium carbonate was treated with 0.25 g (0.0066 mole) of sodium borohydride under an atmosphere of nitrogen. The mixture was then heated to reflux for 30 min and cooled. To this ice-cold solution was then added 1 ml of ethyl iodide and the resulting mixture brought to reflux for an additional 30 min. The originally dark red solution became light orange. The reaction mixture was then filtered free from solid, and the filtrate diluted with water and extracted with ether (2 × 50 ml). The ether extract was washed with water and dried ($MgSO_4$). Upon removal of the ether the residue was taken up in hexane and the solution chromatographed on 20 g of neutral alumina. Elution with a benzene–hexane mixture (1:1) gave 440 mg of a red-orange oil upon removal of the solvent. On standing, it solidified. Recrystallization was best accomplished from a minimum amount of toluene (2 ml) diluted with *n*-pentane (25 ml). Upon standing overnight at −20°, the solution deposited fine orange needles melting at 49–50°. Yield, 0.356 g (61%).

Anal. Calcd. for $C_{13}H_{15}NS_3$: C, 55.50; H, 5.34; N, 4.98; S, 34.15. Found: C, 55.66; H, 5.15; N, 4.86; S, 34.50.

The infrared spectrum (Nujol) showed a band at 3 340 cm^{-1} for indolic N—H (15). The signals and integrated area of the n.m.r. spectrum in deuterochloroform were consistent with structure V, showing two triplets centered at 8.58 τ (J = 7.5 c.p.s.) and 8.8. τ (J = 7.5 c.p.s.) and two quartets centered at 6.6 τ (J = 7.5 c.p.s.) and 7.1 τ (J = 7.5 c.p.s.) respectively, thereby indicating two differently located ethyl groups. Aromatic proton absorption occurred at 2–3 τ.

Hydrolysis of V to 3-Ethylthioindole-2-carboxylic Acid (VI)

To a solution of ethyl 3-(ethylthio)-2-indoledithiocarboxylate (V) (0.362 g) in 10 ml of 95% ethanol was added 1 ml of water containing 1 g of potassium hydroxide. The mixture was stirred and refluxed for 7 h under an atmosphere of nitrogen. Ethyl mercaptan was evolved and could be detected by the white precipitate which occcurred when it was passed through a solution of mercuric chloride. The reaction mixture was then cooled, diluted with a small amount of water, and then filtered to remove suspended particles. The cooled filtrate (ice) was acidified with 4 ml of 6 *N* hydrochloric acid. Hydrogen sulfide was liberated. After the solution had stood for an hour, 245 mg (86%) of crude yellow material, m.p. 97–100°, was deposited. Solution of this material in 5 ml of benzene followed by addition of hexane (35 ml) and cooling of the resulting solution gave dark yellow needles melting at 105–106°. Yield, 185 mg (65%). The solid was soluble in dilute aqueous sodium hydroxide. A 10-mg sample required 9.9 ml of 0.00441 *N* sodium hydroxide, giving a neutral equivalent of 229 (theoretical, 221).

An infrared spectrum in Nujol showed indolic N—H absorption at 3 310 cm^{-1} and carbonyl absorption at 1 710 cm^{-1}.

Anal. Calcd. for $C_{11}H_{11}O_2NS$: C, 59.72; H, 5.01; N, 6.33. Found: C, 59.51; H, 5.26; N, 6.47.

3-Ethylthioindole (II)

3-Ethylthioindole-2-carboxylic acid (380 mg) was heated at 150° at 6 mm pressure. A gas was evolved (CO_2) and a liquid was distilled under these conditions, giving 85 mg (26.6%) of pure 3-ethylthioindole identical in boiling point and infrared and n.m.r. spectra with those of an authentic sample prepared by Fischer cyclization.

ANOMALOUS REACTIONS IN ATTEMPTS TO PREPARE 3-ALKYLTHIOINDOLES[1]

R. V. JARDINE[2] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Indole magnesium bromide reacting with ethanesulfenyl chloride produces ethyl mercaptan, diethyl disulfide, indole, 3-ethylindole, 3-ethylthioindole, and 3,3′-diindolyl sulfide, along with at least three compounds not yet identified.

The reaction of ethyl mercaptan with N-benzoyl-3-bromoindole in dimethylformamide containing potassium carbonate produces indole, 3-bromoindole, ethyl thiolobenzoate, 3-ethylindole, diethyl disulfide, and 3-ethylthioindole.

In both of these reactions a substance (or substances) which caused strong allergenic reactions in persons exposed to the reaction mixtures was produced. 3,3′-Diindolyl disulfide was found to be allergenic in minute amounts.

INTRODUCTION

A recent publication (1) has described two routes for the preparation of 3-alkylthioindoles, one involving initially the reaction of phosphorus pentasulfide with carbethoxyindoxyl while the other and preferred method employed the Fischer indole synthesis. This paper reports the results from attempts to obtain 3-ethylthioindole from the reaction between indole magnesium bromide and ethanesulfenyl chloride on the one hand and of ethyl mercaptide with N-benzoyl-3-bromoindole on the other. Although neither scheme was suitable for the thioether preparation, the anomalous product formation was interesting.

RESULTS AND DISCUSSION

Reaction between Indole Magnesium Bromide and Ethanesulfenyl Chloride

The reaction between sulfenyl halides and Grignard reagents is known to yield thioethers (2–5). In view of this, ethanesulfenyl chloride was added slowly to an ethereal solution of indole magnesium bromide at $-10°$ and the reaction worked up as described in the Experimental section. A number of compounds, at least three of which still remain unknown, were formed, as shown by gas–liquid chromatography (g.l.c.) and thin-layer chromatography (t.l.c.). Actually isolated by precipitation were ethyl mercaptan (as the silver salt) and 3,3′-diindolyl sulfide, while by distillation of the mother liquor were obtained both indole and 3-ethylindole. The same ethylindole was obtained as its picrate by treatment of the ether extract of the reaction mixture, before distillation, with picric acid; hence, it was an actual product of the original reaction and not a result of pyrolysis during distillation.

Gas–liquid chromatography of the ether extract of the original mixture, first freed from mercaptan, showed the presence of indole and 3-ethylindole as well as diethyl disulfide

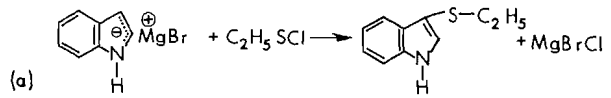
and 3-ethylthioindole. Attempts to isolate 3-ethylthioindole failed, but further evidence for its presence was obtained by precipitation of ethylthiomercuric chloride when an ether extract of the reaction mixture, freed from ethyl mercaptan, was treated with ethanolic mercuric chloride. This reagent is known to react readily with unsymmetrical thioethers to produce the characteristic alkyl or arylthiomercuric chlorides (6). In trial runs under our room temperature conditions, no visible reaction occurred between ethanolic mercuric chloride and diethyl disulfide (a compound found in our reaction mixture), although such a reaction has been reported (7). The same precipitate was obtained when ethanolic mercuric chloride was added to the traces of 3-ethylthioindole collected by g.l.c. Thin-layer chromatography also indicated the presence of 3-ethylthioindole as well as 3,3′-diindolyl.

Identification of the isolated compounds was made by comparing infrared spectra, nuclear magnetic resonance (n.m.r.) spectra, melting points, or boiling points with those of authentic samples, while those compounds not isolated were identified by their retention times or R_f values compared with those of known compounds. The 3,3′-diindolyl (8) could be readily identified by its R_f value (t.l.c.) and by its characteristic strong blue-white fluorescence, first noted by Gabriel *et al.* (9).

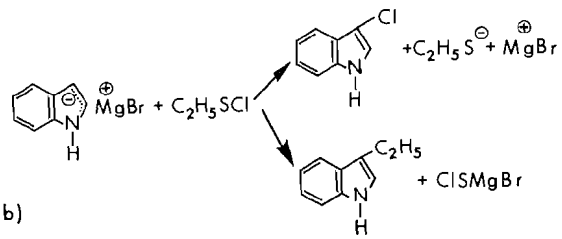
3-Ethylthioindole occurs, no doubt, via the known reaction (5, 10, 11) indicated by



eq. [*a*]. Indole and diethyl disulfide could arise from hydrolysis of unreacted indole magnesium bromide and ethanesulfenyl chloride. The latter compound is known to hydrolyze to a mixture of products, one of which is diethyl disulfide (12, 13).

A possible source of 3,3′-diindolyl was indicated by the next experiment. Chromatographically pure indole was converted to indole magnesium bromide and the ethereal solution stirred for several hours without precaution for exclusion of air. When the mixture was treated with water and worked up as usual, indole was found to be the main product as expected. However, in addition, there was obtained evidence by t.l.c. for 3,3′-diindolyl and at least nine other unidentified compounds, each giving a positive Ehrlich test for the 2- and (or) 3-unsubstituted indole nucleus (14).

The formation of ethyl mercaptan, 3-ethylindole, or 3,3′-diindolyl sulfide is not at all clear. The possibility that indole magesium bromide and ethanesulfenyl chloride will



react to form 3-ethylindole or 3-chloroindole (eq. [*b*]) is unlikely, since in our hands phenyl magnesium bromide and ethanesulfenyl chloride gave only ethyl phenyl sulfide and no indication of ethylbenzene or chlorobenzene.

For personal use only.

It is reported that Grignard reagents are capable of cleaving thioethers, but this occurs usually at higher temperatures (15). When 3-ethylthioindole was treated with indole magnesium bromide at room temperature or below (our conditions), only unchanged starting materials were found in the product. Furthermore, although it is known that phenyl magnesium bromide reacts with diphenyl disulfide to produce diphenyl sulfide (10) and that disulfides are cleaved by nucleophilic species (5, 16), our attempts to produce a similar reaction between indole magnesium bromide and 3,3′-diindolyl disulfide resulted in nearly complete recovery of starting material. The possibility that 3,3′-diindolyl disulfide might have been formed, even though this highly insoluble and readily isolable substance was not in fact obtained, was entertained because of pronounced and characteristic allergic effects experienced during experiments involving the reaction of indole magnesium bromide with ethanesulfenyl chloride.* Of the available pure compounds tested for this allergenic reaction, only 3,3′-diindolyl disulfide was found to be active and, even in minute amounts, gave rise to acute allergic symptoms. Because of these undesirable physiological effects, further work on this reaction was discontinued.

Reaction between Ethyl Mercaptide and N-Benzoyl-3-bromoindole

The high nucleophilicity of the alkali salts of mercaptans (17) and the reported facile reaction of alkyl halides with 6-mercaptopurines in dimethylformamide containing potassium carbonate (18) suggested the possibility of a similar reaction between 3-bromoindole and ethyl mercaptan to form 3-ethylthioindole.

To avoid the spontaneous decomposition and polymerization which 3-bromoindole undergoes during its isolation and purification if conditions are not carefully controlled (19), N-benzoyl-3-bromoindole was employed. It was hoped that the presence of the N-benzoyl group might result in increased nucleophilic attack at C_3 of the indole ring.

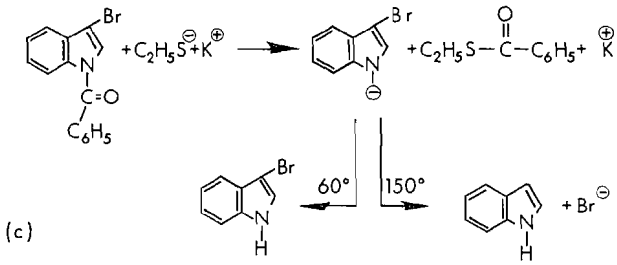
A mixture of equimolar amounts of N-benzoyl-3-bromoindole, dry powdered potassium carbonate, and ethyl mercaptan was heated in previously distilled dimethylformamide at reflux (150°) for 12 h. This high temperature was chosen because preliminary experiments revealed that one of the products was 3-bromoindole, which, because of its characteristic decomposition, complicated the isolation procedure. It had also been found that, when 3-bromoindole was heated at 150° in dimethyl formamide containing potassium carbonate, all of it was converted smoothly to indole and bromide ion, neither of which presented any problem during isolation.

An ether extract of the reaction mixture, which was first washed with aqueous silver nitrate to remove unreacted mercaptan, then dried, and freed of solvent, gave, upon distillation, ethyl thiolobenzoate (48%), indole (28%), and 3-ethylindole (25%) plus a tarry residue. No 3-ethylthioindole was obtained, but this is not unexpected, since this thioether does tend to decompose upon distillation even when it is reasonably pure (1). When an ether extract from a second reaction was first freed from mercaptan as above, then reduced in volume, and subjected to gas–liquid chromatography using either a column packed with Apiezon L on Kromat B or silicone rubber on Kromat B, several peaks were noted. Identified by comparison of retention times with those of authentic samples were diethyl disulfide, 3-ethylindole, indole, ethyl thiolobenzoate, and 3-ethylthioindole. At least three other unidentified peaks were present. The detection of 3-ethylindole in this case showed that it was an actual product of the original reaction.

If the mixture of equimolar quantities of N-benzoyl-3-bromoindole, ethyl mercaptan,

Exposure to this substance caused urticaria, edema, and finally a serious case of serum sickness. Other persons in the same room, when in contact with equipment contaminated by this substance, also developed mild symptoms.

and potassium carbonate in dimethylformamide was heated for 2 h at 60° rather than 150° and if the ether extract, purified as above, was reduced in volume with simultaneous addition of benzene to displace the ether, followed by chromatography of this solution on neutral alumina (activity grade 1), indole and 3-bromoindole were eluted initially, using pentane. Further elution with additional pentane gave oils which could not be crystallized. Subsequent elution with benzene gave an oil which reacted with mercuric chloride in ethyl alcohol to give ethylthiomercuric chloride, indicative of 3-ethylthioindole.



(c)

The formation of ethyl thiolobenzoate (20) by reaction of ethyl mercaptide occurs, no doubt, by the expected reaction (eq. [*c*]). Diethyl disulfide could arise via oxidation of ethyl mercaptan (21). The origin of 3-ethylindole is unknown. Although 3-ethylindole is obtained from the reaction of indole with ethyl alcohol in the presence of acid or base and at a temperature of 180–200° (22), we found no 3-ethylindole when indole, ethyl mercaptan, and potassium carbonate were heated in dimethylformamide to 150° for 6 h. Furthermore, when ethyl thiolobenzoate was distilled with 3-bromoindole, there was obtained only unchanged ester and dark greenish product as a result of decomposition of 3-bromoindole.

Further experiments designed to clarify this reaction were discontinued when allergic reactions, similar to those noted previously, developed from exposure to some factor(s) in the products of this reaction.

EXPERIMENTAL

All melting points and boiling points are uncorrected.

Gas–liquid chromatography was accomplished with a Burrell K-2 Kromo-Tog using a 2.5-m column packed with 20% Apiezon L on Kromat F.B. (30–60 mesh) and a similar column packed with 20% silicone rubber on Kromat F.B. (30–60 mesh). The column temperatures employed depended upon the boiling point of the compounds analyzed. The carrier gas was helium.

Compounds were identified by comparison of their retention times with those of authentic samples. In several cases compounds were also isolated and identified according to usual procedures.

Analyses were also made via thin-layer chromatography using aluminium oxide as the adsorbant and Ehrlich's reagent (14) to detect the position of indole compounds.

Infrared spectra were obtained with Perkin–Elmer instruments, models 21, 221G, and 421. Nuclear magnetic resonance spectra were made with a Varian Associates model A-60 spectrometer. X-ray diffraction patterns were obtained with a Philips Electronics Inc. X-ray diffraction unit, type No. 12045.

Source or Preparation of Reagents

N-Benzoyl-3-bromoindole

N-Benzoylindole was prepared by a modification of the method of Weissgerber (23). A mixture of indole (117 g, 1 mole) and 23 g (1 g-atom) of sodium in 1.5 l of purified dry dioxane (24) was refluxed for 48 h. To the cooled solution, freed from unreacted sodium, was slowly added 140.5 g (1 mole) of benzoyl chloride. The resulting mixture was refluxed for an additional 12 h and then poured into 4 l of water. The precipitated crude N-benzoylindole was collected and extracted with pentane to remove unreacted indole. Crystallization of the crude amide from ethyl alcohol gave the pure product in 55% yield, m.p. 67–68° (lit. m.p. 67–68° (23)).

N-Benzoylindole was converted to N-benzoyl-3-bromoindole according to published directions (23). Yield, 82%; m.p. 97–98° (lit. m.p. 97–98°).

3-Bromoindole was prepared from N-benzoyl-3-bromoindole by the method of Weissgerber, or preferably by direct bromination of indole with pyridinium bromide perbromide (19).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Ethyl thiolobenzoate was prepared by a modification of a literature synthesis (20). A solution of 6.2 g (0.1 mole) of ethyl mercaptan in 50 ml of anhydrous dimethylformamide (24) containing 13.8 g (0.1 mole) of anhydrous potassium carbonate was treated with 14.0 g (0.1 mole) of benzoyl chloride. The resulting mixture was refluxed for 2 h and then poured into 200 ml of water. The aqueous mixture was extracted with ether (3 × 100 ml) and the combined extracts dried over magnesium sulfate. The ether was removed under reduced pressure and the remaining oil distilled, b.p. 146° at 31 mm pressure (lit. b.p. 146° at 31 mm pressure (20)).

Ethylthiomercuric chloride was prepared by the method of Challenger and Rawlings (7).

2-Ethylindole was prepared according to published directions (25).

3-Ethylindole

The published procedure (26) was modified as follows. N-Butyraldehyde (14.4 g, 0.2 mole) was treated with 21.6 g (0.2 mole) of phenylhydrazine in 200 ml of glacial acetic acid. The resulting solution was warmed to 50° and stirred at this temperature for 2 h. The reaction mixture was allowed to cool to room temperature and 30.2 g (0.2 mole) of boron trifluoride etherate added carefully. When the ensuing exothermic reaction had subsided, the mixture was stirred for an additional half hour and then poured into 1 l of water, and the whole extracted with ether (3 × 100 ml). The combined ethereal extracts were neutralized with sodium bicarbonate, washed with water (2 × 100 ml), and dried ($MgSO_4$). The ether was removed on a rotary evaporator and the residual oil distilled at 175° at 6 mm pressure (lit. b.p. 282–284 (26)). The picrate (from ethanol) melted at 143° (lit. m.p. 143° (26)).

3,3′-Diindolyl disulfide was prepared according to published directions (27). Yield, 23%; m.p. from toluene 227–229° (lit. m.p. 217–218° (28), 227–229.5° (27)).

Diethyl disulfide and sulfuryl chloride were obtained from Eastman Kodak Co.

Ethanesulfenyl Chloride

This was prepared by a modification of literature directions (29). Diethyl disulfide (60 g, 0.41 mole), in a 1-l flask protected with a calcium chloride tube, was cooled to −70° in a dry ice – acetone mixture. To the flask was added dropwise 55 g (0.41 mole) of sulfuryl chloride. The solution became orange immediately upon addition of the first portion of the sulfuryl chloride. During the addition, the solution was allowed to warm slowly to room temperature, thus preventing precipitation of solutes. Upon completion of the addition, the reaction mixture was heated on a steam bath for 20 min to remove dissolved sulfur dioxide, and then distilled. Yield, 70% of material boiling at 51° at 74 mm pressure (lit. b.p. 51° at 74 mm pressure (29)).

3,3′-Diindolyl was prepared according to known directions (8), m.p. (from toluene followed by drying for 20 h at 25° at 0.2 mm pressure) 284–286° (lit. m.p. 286–287° (9), 284–286° (8)).

3,3′-Diindolyl sulfide was prepared according to published directions (30), m.p. (from toluene) 232°.

3-Ethylthioindole was prepared as described previously (1).

Attempted Reaction of N-Sodio-3-bromoindole with Sodium Ethyl Mercaptide

3-Bromoindole (5.0 g, 0.025 mole) in 50 ml of anhydrous dioxane (24) was treated with 0.6 g (0.026 g-atom) of sodium to form N-sodio-3-bromoindole. To the reaction mixture was added a solution of sodium ethyl mercaptide (0.6 g, 0.026 g-atom of sodium in 10 ml of anhydrous ethanol followed by addition of ethyl mercaptan to the cooled sodium ethoxide). The resulting dioxane – ethyl alcohol mixture was heated at 60° for 2 h and then poured into 250 ml of cold water. 3-Bromoindole was recovered in 86.5% yield. No indication of 3-ethylthioindole was found.

Decomposition of 3-Bromoindole in Dimethylformamide Containing Potassium Carbonate

3-Bromoindole (5.0 g, 0.025 mole) and 3.52 g (0.025 mole) of dry powdered potassium carbonate in 100 ml of anhydrous dimethylformamide (24) were heated at 150° for 12 h, during which time carbon dioxide was evolved. The mixture was then poured into 500 ml of cold water and the resulting mass was extracted with ether (3 × 100 ml). The dried ($MgSO_4$) ethereal extract was freed from solvent. Crystallization of the residue from pentane gave 2.6 g (87.4%) of indole, m.p. 52°. Addition of excess aqueous silver nitrate (1 *N*) to the acidified (HNO_3) aqueous phase gave 4.65 g of silver bromide, accounting for 97.5% of the theoretical amount of bromine in this 3-bromoindole.

When the above experiment was repeated, but at the reaction temperature of 60° rather than 150°, only 17.5% of the 3-bromoindole had decomposed, as indicated by the amount of silver bromide precipitated from the aqueous phase after ether extraction. The 3-bromoindole and indole could be recovered from the ether if care was taken in its isolation (see latter portion of the next experiment).

Reaction of N-Benzoyl-3-bromoindole with Ethyl Mercaptan in Dimethylformamide at 150° Containing Potassium Carbonate

A mixture of N-benzoyl-3-bromoindole (10 g, 0.035 mole) in 150 ml of anhydrous dimethylformamide (24), containing 4.8 g (0.035 mole) of anhydrous potassium carbonate and 2.17 g (0.035 mole) of ethyl mercaptan, was heated at 150° for 12 h. The cooled solution was extracted with peroxide-free ether (2 × 200 ml), and the combined ethereal extracts were washed with 0.2 *N* aqueous silver nitrate (2 × 100 ml) to remove unreacted mercaptan, then washed with water (2 × 200 ml), and finally dried ($MgSO_4$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A small part of this dried ethereal extract was subjected to gas–liquid chromatography (g.l.c.) using a column packed with 20% Apiezon L on Kromat F.B. (30–60 mesh). Peaks with retention times identical with those of diethyl disulfide, indole, ethylthiolobenzoate, 3-ethylindole, and 3-ethylthioindole were observed. At least three other unidentified compounds were indicated.

A 10-ml portion of the ethereal extract was treated with 2 ml of ethyl alcohol saturated with mercuric chloride and gave a precipitate of ethylthiomercuric chloride, identified by its characteristic infrared spectrum and its X-ray diffraction pattern.

The remainder of the above ethereal extract was freed from solvent and the residue distilled under vacuum. There was obtained 1.6 g of indole (24% based upon the N-benzoyl-3-bromoindole used), b.p. 105° at 5 mm pressure; 2.6 g of ethyl thiolobenzoate (48%), b.p. 108–110° at 5 mm pressure; and 1.23 g of 3-ethylindole (24%), b.p. 138–140° at 1.5 mm pressure. Considerable decomposition occurred during the distillation. The indole and 3-ethylindole were identified by melting point, mixed melting point, and comparative infrared spectra of the respective picrates with those of authentic compounds. That the ethylindole was actually 3-ethylindole and not the 2-isomer was verified by synthesis of both 3-ethylindole (26) and 2-ethylindole (25).

The reaction of N-benzoyl-3-bromoindole with ethyl mercaptan in dimethylformamide containing potassium carbonate was repeated, but at 60° rather than 150°, and a portion of the ether extract was reduced in volume. A spontaneous exothermic reaction occurred, yielding hydrogen bromide and a green amorphous material—a reaction characteristic of the behavior of 3-bromoindole under these circumstances, thus indicating that 3-bromoindole had been formed during this reaction. When the solvent was removed from the remainder of the ether extract, but with simultaneous addition of benzene to replace most of the ether, this decomposition of the 3-bromoindole could be avoided. Chromatography of the benzene solution on neutral alumina (activity grade 1*), with pentane as eluant, removed first the indole and then 3-bromoindole from the column. The indole and 3-bromoindole could be obtained from the separate fractions and were crystallized from pentane and *n*-heptane respectively (19). The remaining fractions obtained with the eluant pentane were oils which could not be induced to crystallize. Subsequent elution with benzene gave an oil which yielded ethylthiomercuric chloride when treated with ethanolic mercuric chloride (7), indicative of the presence of 3-ethylthioindole.

Attempted Reaction of Indole with Ethyl Mercaptan in Dimethylformamide

A mixture of indole (6.9 g, 0.059 mole), 3.64 g (0.059 mole) of ethyl mercaptan, and 8.1 g (0.059 mole) of anhydrous potassium carbonate in 100 ml of anhydrous dimethylformamide (24) was refluxed for 6 h at 150°. The cooled reaction products were poured into 1 l of cold water. The aqueous mixture was extracted with ether (2 × 200 ml), and the combined ethereal extracts were washed with 0.2 *N* aqueous silver nitrate (3 × 100 ml) and then dried ($MgSO_4$). Gas–liquid and thin-layer chromatography of this solution indicated only unreacted indole, with no evidence of ethylindole.

Attempted Reaction between 3-Bromoindole and Ethylthiolobenzoate

A mixture of 3-bromoindole (5 g, 0.029 mole) and ethyl thiolobenzoate (5 g, 0.03 mole) was distilled at 146° at 31 mm pressure. Much decomposition occurred, attributed to 3-bromoindole. The distillate contained only ethylthiolobenzoate as shown by infrared spectroscopy, with no evidence of 3-ethylindole.

Attempted Reaction between Ethylthiolobenzoate or Diethyl Disulfide and Mercuric Chloride

A sample (1 g) of each of ethylthiolobenzoate and diethyl disulfide was added to separate 10-ml quantities of saturated ethanolic mercuric chloride. On standing for 48 h, the solutions deposited no ethylthiomercuric chloride.

Reaction of Indole Magnesium Bromide with Ethanesulfenyl Chloride

Ethyl bromide (26.1 g, 0.26 mole) in 600 ml of anhydrous ether was treated with 6 g (0.25 mole) of magnesium turnings. When the reaction was complete 27 g (0.23 mole) of indole in 50 ml of dry ether was added as quickly as refluxing permitted and the solution then gently refluxed for 10 min. To the resulting indole magnesium bromide (now cooled to −15°) was added dropwise 23.1 g (0.26 mole) of ethanesulfenyl chloride in 50 ml of anhydrous ether so that the temperature of the reaction was maintained at −10°. The mixture slowly became deep red. When the addition of the halide was completed, the vessel and contents were allowed to attain room temperature and then the solution was refluxed for 3 h. The mixture was cooled and poured into 2 l of water, and the pH adjusted to 7 with acetic acid. The ether layer was separated and the aqueous layer extracted with ether (2 × 200 ml). The volume of the combined ethereal solutions was reduced to about 400 ml. This solution was extracted with water (3 × 200 ml) and washed with 0.2 *N* aqueous silver nitrate (2 × 100 ml), from which was obtained 1.5 g of silver ethyl mercaptide whose infrared spectrum (halo oil mull) was identical with that of a sample prepared from aqueous ethyl mercaptan and silver nitrate. The remaining ether filtrate was freed from solvent and the brown oil, when taken up in ethyl alcohol and kept overnight at −20°, afforded 5.1 g of 3,3′-diindolyl sulfide. One recrystallization from toluene gave a melting point of 232° (lit. m.p. 232° (30)).

Anal. Calcd. for $C_{16}H_{12}N_2S$: C, 72.73; H, 4.65; N, 9.44; S, 12.12. Found: C, 72.76; H, 4.61; N, 9.47; S, 11.94.

**Alupharm Chemicals, P.O. Box 755, New Orleans, Louisiana, U.S.A.*

The filtrate obtained after removal of the 3,3′-diindolyl sulfide was freed of solvent and the resulting oil divided into two equal portions. One portion was subjected to vacuum distillation and gave 2.1 g of indole, b.p. 110° at 6 mm pressure, and 3.8 g of 3-ethylindole, b.p. 170° at 3 mm pressure. These compounds were identified by melting points of their respective picrates as well as by comparative infrared spectra with those of authentic samples. Portions of the remaining half of the above filtrate were analyzed by gas–liquid chromatography. Peaks with retention times identical with those of authentic indole, 3-ethylindole, 3-ethylthioindole, and diethyl disulfide appeared. At least three other unidentified compounds were indicated by peaks in the gas–liquid chromatography. A portion of this filtrate, treated with saturated ethanolic mercuric chloride, precipitated ethylthiomercuric chloride (7). Thin-layer chromatography yielded similar results but showed, in addition, the presence of 3,3′-diindolyl, identified by its R_f value and the characteristic blue-white fluorescence (9).

Attempted Reaction of Indole Magnesium Bromide with 3-Ethylthioindole

Magnesium turnings (1.2 g, 0.05 mole) in 50 ml of dry ether were treated at 5° with 5.5 g (0.05 mole) of ethyl bromide in 10 ml of dry ether. On completion of the reaction, 6 g (0.05 mole) of indole in 25 ml of dry ether was added as quickly as the reaction permitted. When the evolution of ethane had ceased (about 0.5 h later) the mixture was cooled to 0° and 8.55 g (0.05 mole) of 3-ethylthioindole (1) in 10 ml of anhydrous ether was added dropwise so that the reaction temperature remained between 0–5°. The solution was then warmed to reflux and maintained at this temperature for 3 h. It was then worked up in the same manner as in the reaction of indole magnesium bromide with ethanesulfenyl chloride to the point of silver nitrate wash. It was dried ($MgSO_4$) and reduced in volume. Gas–liquid chromatography indicated the presence of only two products whose retention times were identical with those of indole and 3-ethylthioindole. The ether was removed and the oil taken up in ethanol, from which products could not be induced to crystallize.

A repetition of this experiment, using enough magnesium and ethyl bromide to form indole dimagnesium bromide, gave the same results.

Air Oxidation of Indole Magnesium Bromide

An ether solution of indole magnesium bromide, prepared as described above, was stirred at room temperature for 26 h, in a flask equipped with a drying tube but with no precaution taken for the exclusion of dry air. The mixture was then treated with ice and water, followed by sufficient acetic acid to convert the solution to a pH of 7. The solution was washed with water, dried ($MgSO_4$), and freed from ether. Thin-layer chromatography indicated that the main product was indole. It was also accompanied by a small amount of 3,3′-diindolyl, as shown by the strong blue-white fluorescence (9), a positive Ehrlich test (14), and comparison of its R_f value with that of an authentic specimen (8). Also, at least nine other indole compounds were indicated by the Ehrlich spray on the thin-layer chromatogram.

Reaction of Phenyl Magnesium Bromide with Ethanesulfenyl Chloride

Magnesium turnings (1.2 g, 0.05 mole) in 50 ml of dry ether at 5° were treated with 8 g (0.05 mole) of bromobenzene in 10 ml of ether. When the reaction was completed, the solution was cooled to 0° and 4.8 g (0.05 mole) of ethanesulfenyl chloride in 10 ml of dry ether was added dropwise so that the temperature remained between 0 and 5°. The solution was then refluxed for 2 h, cooled, and worked up as described for the reaction of indole magnesium bromide with ethanesulfenyl chloride to the point of silver nitrate and subsequent water wash. The dried ($MgSO_4$) solution was reduced in volume and subjected to g.l.c. analysis. Only benzene and ethyl phenyl sulfide were present, identified by comparison of the retention times with those of authentic samples. There was no evidence of ethyl benzene or chlorobenzene.

Attempted Reaction of Indole Magnesium Bromide with 3,3′-Diindolyl Disulfide

Magnesium turnings (1 g, 0.0416 mole) in 50 ml of dry ether were treated with 6.16 g (0.0395 mole) of ethyl iodide in 10 ml of dry ether. On completion of the reaction, 4.68 g (0.06 mole) of indole in 10 ml of dry ether was added dropwise. Twenty minutes after the addition of the indole, 4.0 g (0.00135 mole) of 3,3′-diindolyl disulfide (27) in 10 ml of dry tetrahydrofuran was added dropwise. The resulting mixture was refluxed for 2 h, then poured into 400 ml of ice water, and filtered. The filtrate, dried ($MgSO_4$) and extracted in a Soxhlet extractor with pentane, gave a recovery of 3.75 g of the 3,3′-diindolyl disulfide. No 3,3′-diindolyl sulfide was detected.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council of Canada for their generous financial support during the course of this work.

Grateful acknowledgment is also made to Dr. T. H. Aaron of the Baker Clinic, Edmonton, for his generous medical assistance when allergic reactions developed, and for his cooperation in conducting tests on potential allergenic substances.

AUTOXIDATION REACTIONS CATALYZED BY COBALT ACETATE BROMIDE

ALLAN S. HAY AND HARRY S. BLANCHARD
General Electric Research Laboratory, Schenectady, New York

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Cobalt acetate bromide in acetic acid solution is an extraordinarily active catalyst for the autoxidation of hydrocarbons. Carboxylic acids and ketones are readily prepared in high yields at moderate temperatures and at atmospheric pressure. In addition, benzylic and allylic groups can be converted to esters of the corresponding alcohols, and the oxidation of tetralin can be controlled to give either α-tetralone or 1,2-dihydronaphthalene as the major product. A mechanism for these reactions is postulated.

INTRODUCTION

The autoxidation of aralkyl hydrocarbons has received considerable attention in recent years, and the mechanism (eqs. [1]–[5]) is now well understood (1).

[1] $$\text{Initiator} \xrightarrow{k_i} 2R'\cdot$$

[2] $$R'\cdot + O_2 \rightarrow R'OO\cdot$$

[3] $$R'OO\cdot + RH \rightarrow R'OOH + R\cdot$$

[4] $$R\cdot + O_2 \rightarrow ROO\cdot$$

$$ROO\cdot + RH \xrightarrow{k_p} ROOH + R\cdot$$

[5] $$2ROO\cdot \xrightarrow{k_t} \text{nonradical products}$$

In the presence of heavy metal salts this reaction sequence is modified principally by reactions [6] and [7], which increase the rate of free radical production (2) and have a profound effect on the products of the reaction.

[6] $$Co^{+2} + ROOH \rightarrow Co^{+3} + RO\cdot + OH^-$$

[7] $$Co^{+3} + ROOH \rightarrow Co^{+2} + ROO\cdot + H^+$$

For compounds having a methyl group on an aromatic ring, these degradation reactions eventually result in a carboxyl group, and this is the basis of some commercial processes for the production of such acids.

In a previous report (3) we described the ozone-initiated cobalt-catalyzed autoxidation of aralkyl hydrocarbons. Ozone oxidizes cobalt(II) to cobalt(III) and thus serves to initiate the cyclic sequence in eqs. [6] and [7]. As soon as oxidation of the aralkyl hydrocarbon begins, the ozone may be stopped since the peroxy intermediates will reoxidize cobalt(II) efficiently. Thus, ozone serves the same function as acetaldehyde and methyl ethyl ketone in the processes described by Hull (4) and Brill (5).

In this system, *p*-xylene and *m*-xylene are readily oxidized to the corresponding toluic acids. Continued oxidation results in high yields of corresponding dibasic acids. However, when *o*-xylene is subjected to this system, the principal product is *o*-toluic acid, and

o-phthalic acid is formed only in amounts equivalent to the cobalt ion in solution. Apparently *o*-phthalic deactivates the catalyst, since the reaction proceeds only very slowly.

We hypothesized that *o*-phthalic acid was influencing the oxidation potential of the Co(II)–Co(III) couple by chelation with cobalt ions. If so, the propagation reactions (eqs. [6] and [7]) would be affected and the rates decreased. To circumvent this retardation by *o*-phthalic acid, we decided to run the reaction in the presence of acids stronger than acetic and *o*-phthalic. Among the many acids tried, α-bromoacetic acid was unique in that it allowed *o*-xylene to be rapidly oxidized in high yield to *o*-phthalic acid. The reaction mixture became deep blue and the effect was soon found to be due to a bromine ion presumably formed via reaction with cobalt acetate.

[8] $$BrCH_2CO_2H + Co(Ac)_2 \rightarrow CoAcBr + AcOCH_2CO_2H$$

No ozone was necessary in this reaction.

This paper describes the scope of cobalt acetate bromide (CAB) catalyzed autoxidations and the results of our study on the mechanism of the reaction. The effect of bromine on metal-catalyzed autoxidations, principally as a route to the phthalic acids, has been the subject of intensive work in other laboratories (6), and a comparison with these results is made.

DISCUSSION AND RESULTS

The addition of an equimolar amount of hydrogen bromide to cobalt(II) acetate in acetic acid solution gives a catalyst that is extraordinarily active for the autoxidation of methylene or methyl groups adjacent to an aromatic ring to ketones or carboxylic acids, respectively (7). Thus, *p*-xylene can be readily oxidized to terephthalic acid at atmospheric pressures and at temperatures as low as 60–100 °C. Tetralin is oxidized rapidly at room temperature to α-tetralone. Phenacyl esters can be prepared from the corresponding β-phenethyl esters and oxidation of methylphenyl acetate yields methylphenyl glycoxylate. Further examples are described in the Experimental section. All of these reactions are performed at atmospheric pressure and moderate temperatures (25–120 °C) and thus are readily adaptable to conventional equipment in the laboratory.

Most metal-catalyzed autoxidation reactions require only trace amounts of catalyst and, in fact, the catalytic effect reaches a maximum value at relatively low concentrations (8). In the CAB system, concentrations of catalyst of at least 0.1 *M* are necessary for optimum reaction rates. Below this concentration the rates drop off rapidly. This can be qualitatively demonstrated by oxidizing *p*-xylene at various catalyst concentrations and observing the point at which terephthalic acid, which is insoluble in the reaction mixture, first precipitates (Fig. 1).

In most metal ion autoxidation systems, the anion associated with the metal ion is of minor importance in determining the activity of the metal ion as a catalyst. Obviously, the anion can play a role in aiding solubility of the salt or in increasing or decreasing the oxidation–reduction potential of the metal ions. In general, however, these effects are small. Bromine, however, is unique in that, when used in conjunction with cobalt(II) ion, it yields a catalyst of increased activity. Other metal ions such as manganese and cerium also show this effect, but to a more limited extent. Moreover, we discovered that the ratio of the atoms of bromine to the atoms of cobalt in the catalyst system and the molar concentration of the catalyst have a profound and unexpected effect on the low-temperature oxidation reaction. Therefore, we have devoted considerable study to defining the scope of the reaction and to elucidating the mechanism of the reaction.

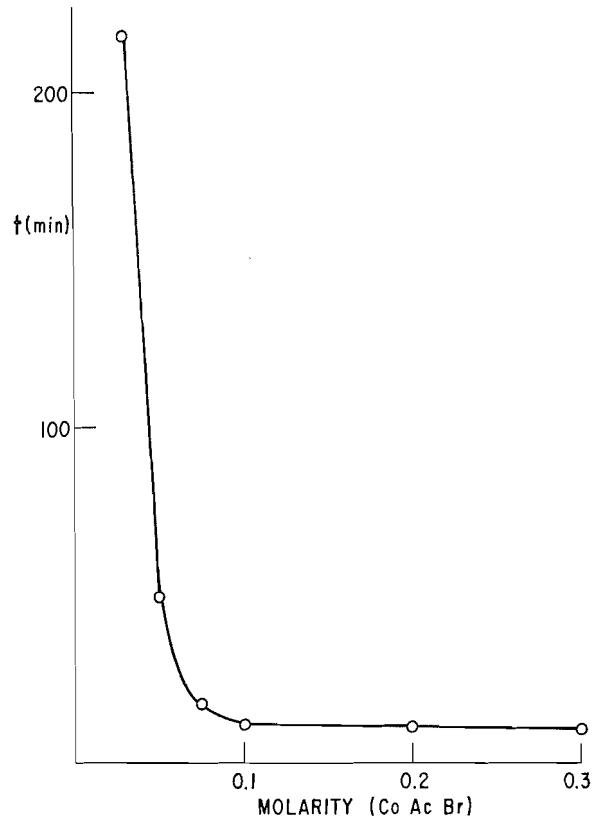

FIG. 1. Oxidation of *p*-xylene (0.4 *M*) at 90 °C in acetic acid. [CoAcBr] = 0.1 *M*; *t* = time in minutes for the appearance of terephthalic acid.

Any explanation devised to account for the uniqueness of the CAB system must account for the following facts. (i) The rates of autoxidation are greatly enhanced by the presence of the bromine, much more so than if the metal ions were present alone. (ii) The nature of the products in a given autoxidation can be profoundly altered. Thus, for example, *p*-xylene is converted easily and at temperatures as low as 60 °C to terephthalic acid. (iii) Bromine is unique in its effect. None of the other halogens or their compounds approach it in activity.

Since bromine has such a profound effect on autoxidations it seemed important to establish unequivocally that the free-radical nature of the reaction was preserved in the presence of the bromine-containing catalyst. It might be imagined, for example, that the addition of bromine had completely changed the reaction to such an extent that we were no longer dealing with a free-radical chain reaction. Indeed, in the early phases of the investigation, it was found that hydrocarbons such as toluene, xylene, and cumene could be autoxidized in the presence of CAB without the addition of the usual free-radical initiator. However, when highly purified hydrocarbons were treated in this manner, induction periods were observed which were apparently dependent on the degree of purity. Moreover, these induction periods could be removed by (*a*) exposing the purified hydrocarbons to air and light before the oxidation or (*b*) adding hydroperoxides or α,α-azo-bisisobutyronitrile (AIBN) as an initiator. Further, and significantly, it was found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that addition of such a typical free-radical chain inhibitor as 2,6-di-*t*-butyl-*p*-cresol (DBPC) inhibited the oxidations. These findings offer strong support to the idea that the autoxidations in the presence of CAB follow the typical free-radical chain mechanism operative in normal initiated autoxidations.

Since the mechanism for initiated autoxidations is composed of three distinct parts, namely, initiation, propagation, and termination, it is conceivable that CAB could have an effect on any or all of these steps. To determine its effect on the initiation step, we have studied rates of initiation in the AIBN-initiated autoxidation of cumene in the presence and in the absence of CAB. The results of this phase of the investigation, which was carried out as described in ref. 9 for cobalt(II) ions themselves, are presented in Table I.

†Rate following the inhibition period.
‡Initial concentration of cobaltous acetate chloride.

As is evident from the data in Table I, the lengths of the inhibition periods in the presence and in the absence of CAB are identical within experimental error. From this fact, the important conclusion can be drawn that the rate of free-radical production is the same in the presence as it is in the absence of the added CAB, and therefore the CAB has no effect on the initiation reaction. Stated somewhat differently, it can be concluded that there is no direct reaction between CAB, oxygen, and hydrocarbon which leads directly to free-radical production, and therefore an enhanced rate of oxidation (10). It follows that the explanation for the bromine effect must be sought either in the propagation reaction and (or) the termination reaction.

First, let us consider the possibility that the main function of the CAB is to enhance the rate of autoxidation by speeding up the propagation reaction. As shown in Table I, the rates of oxidation in the presence of CAB are substantially faster than those in the absence of CAB. Moreover, this rate enhancement must be intimately bound up with the bromine since, as shown by the data in Table I, those runs containing cobalt(II) ions with no bromine show only a slight rate enhancement. Moreover, as shown by the last experiment in Table I, cobaltous acetate chloride shows virtually no rate enhancement. Based on the earlier work of Vaughan, Rust, and their co-workers (11) we were led to consider the possibility that bromine could enhance the rate of autoxidations independent of the metal ion. To this end we studied the effect of anhydrous hydrogen bromide on the initiated oxidation of cumene. The results of this phase of the study are presented in Fig. 2.

As shown in Fig. 2, anhydrous hydrogen bromide enhances the rate of oxidation of cumene markedly. Indeed, in the initial stages of oxygen absorption the rates are increased

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

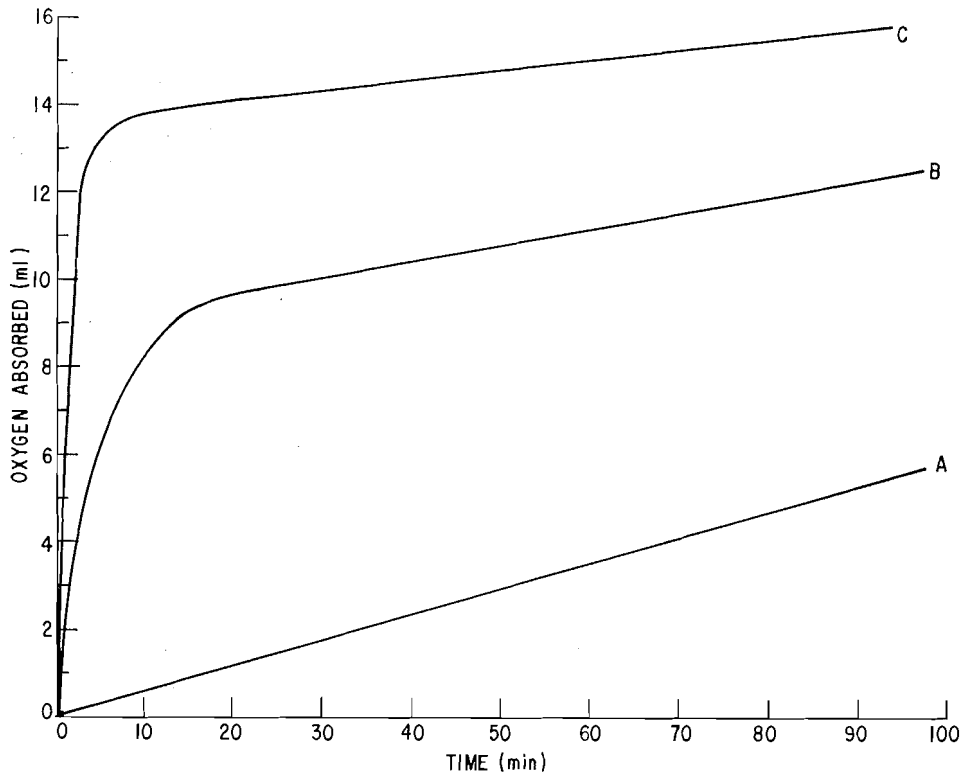

FIG. 2. The effect of hydrogen bromide on the AIBN-initiated oxidation of cumene. Curve A, AIBN-initiated rate, no HBr; curve B, AIBN plus 0.022 *M* HBr; curve C, AIBN plus 0.04 *M* HBr.

by 3–4 orders of magnitude. This rate enhancement is best explained on the basis of eqs. [9], [10], and [11] as postulated by Vaughan, Rust, and co-workers.

[9] $$ROO\cdot + HBr \rightarrow ROOH + Br\cdot$$

[10] $$Br\cdot + RH \rightarrow HBr + R\cdot$$

[11] $$R\cdot + O_2 \rightarrow ROO\cdot$$

Moreover, reaction [9] would not be expected to be important in the case of anhydrous hydrogen chloride since the bond energy for this substance is some 15 kcal/mole higher than that for anhydrous hydrogen bromide (12). Obviously, hydrogen iodide possesses a low enough bond energy to participate in the propagation step. However, because of the facile oxidation of iodide ion to molecular iodine, a well-known scavenger of free radicals, this substance actually functions as an inhibitor. Thus, the oxidation curves presented in Fig. 2 show that the rates of oxygen absorption can be greatly enhanced quite independently of the cobalt(II) ions.

As shown in Fig. 2, the initially fast rates continue only for a relatively short time and ultimately approach a value which is, in fact, slower than the AIBN-initiated rate of oxidation of cumene. This is due, at least in part, to the production of phenolic inhibitors, apparently arising from the heterolytic rearrangement of cumene hydroperoxide (eq. [12]). As pointed out earlier, the reaction is a free-radical chain process and, hence, is subject to inhibition by phenolic-type inhibitors. However, this is not the whole story, because even

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[12] 
triptane shows this same kind of behavior and the products of the acid-catalyzed rearrangement of triptane hydroperoxide (*tert*-butyl alcohol and acetone, eq. [13]) are not oxidation inhibitors. Rather, what appears to be the case is that the bromine is actually consumed, causing the reaction to "run downhill."

[13] 
Support for this idea is gained by the fact that addition of more hydrogen bromide to a triptane oxidation where the rate has fallen off to a very low value causes a resumption in the rate. Thus, a solution of triptane (1.03 *M*) in benzene containing anhydrous hydrogen bromide (0.06 *M*) and AIBN (0.097 *M*) absorbs approximately 15 ml of oxygen in 10 min, after which oxidation virtually ceases. If, at this point, the solution is again made 0.06 *M* with respect to anhydrous hydrogen bromide, oxidation can be resumed and an additional 15 ml of oxygen will be absorbed in 10 min time. This cycle can be repeated several times. To account for this behavior, we suggest the following reactions.

[14] $$Br\cdot + Br\cdot \rightarrow Br_2$$

[15] $$R\cdot + Br_2 \rightarrow RBr + Br\cdot$$

Each time reaction [15] takes place, bromine will be "lost" as a catalyst and, providing those reactions are efficient enough, all of the bromine can be used up in reactions of this kind.

More recently, McIntyre and Ravens (13) have oxidized aralkyl hydrocarbons to carboxylic acids in high yield in aqueous hydrogen bromide with oxygen in the temperature range 180–200 °C. These reactions, in all probability, proceed by the same mechanism as those described by Rust and Vaughan. The intermediate hydroperoxides formed in both cases would be thermally decomposed to the aldehyde and alcohol. Lorand and Edwards (14) have, for example, prepared *p*-methylbenzyl hydroperoxide and find it rapidly decomposes above 130 °C. In reactions studied by Rust and Vaughan, a significant side reaction is the formation of the benzyl bromide; however, in the aqueous system, as pointed out by McIntyre and Ravens (13), any bromides formed would be rapidly hydrolyzed to the alcohol and subsequently oxidized to the acid under the reaction conditions.

From the results described, it appears that the rate enhancement can be explained on the basis that the rate of the propagation reaction is greatly increased by the presence of bromine atoms. It remains, however, to assign a role to the metal ions. From the nature of the products (phthalic acid from xylene, acetophenone from ethyl benzene, etc.) it is clear that reactions [6] and [7] are operative in this system and one function of the metal ions is to degrade the intermediate hydroperoxides. This will, of course, lead to rate enhancement since the rate of free-radical production is increased. However, as shown previously (9) for cobalt(II) ions, this rate enhancement is not strikingly large. We feel that the major function of the metal ions in this system can best be explained on the basis of equilibrium [16]. As shown, this equilibrium is shifted well to the right and thus one

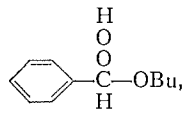
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

function of the cobalt(II) ions is to keep the concentration of free hydrogen bromide at a

[16] $$Co(OAc)_2 + HBr \rightleftharpoons Co\begin{matrix}OAc\\ \diagup\\ \\ \diagdown\\ Br\end{matrix} + HOAc$$

very low value, thus preventing any heterolytic rearrangement of hydroperoxides to phenol.

It is interesting to note that in the oxidation of benzyl *n*-butyl ether an appreciable by-product is benzaldehyde. Increasing the concentration of bromide ion (and hence increasing the acidity of the reaction mixture) increases the amount of benzaldehyde formed. The intermediate hydroperoxide,



which has an acetal structure, would be expected to be readily cleaved by acid to benzaldehyde in competition with the cobalt-catalyzed decomposition to butyl benzoate. Secondly, cobalt(II) must also have the ability of preventing bromine from being consumed by reactions such as [14] and [15]. Since the above equilibrium is shifted to the right, the concentration of free hydrogen bromide will be low and, thus, the concentration of bromine atoms will be low. This situation will make the recombination reaction [14] slow. Addition of cobalt(II) acetate to a warm solution of benzyl bromide in acetic acid immediately generates the intense blue color caused by cobalt acetate bromide. Thus, the cobalt acetate is able to reconvert benzylic bromide back to ionic bromine and keep the catalyst active.

[17] $$Co(OAc)_2 + \phi CH_2Br \rightarrow CoAcBr + \phi CH_2OAc$$

Interestingly, it was observed that when these reactions became too anhydrous the catalyst rapidly lost its activity, as evidenced by the change in color of the solution from blue to pink and the presence of lachymatory materials in the reaction mixture, presumably benzyl bromides. Also, if the reactions were deliberately performed under anhydrous conditions with sodium acetate added, the blue color of the reactions was maintained and a major product was the allylic or benzylic ester, e.g.

[18] 
[19] 
A useful method for the preparation of allylic and benzylic esters in moderate yields using inexpensive reagents is thus afforded.

The oxidation of tetralin is of particular interest. This oxidation takes place rapidly at room temperature to give α-tetralone as the major product. However, on distillation of the product the fraction containing unreacted tetralin also contained appreciable amounts of 1,2-dihydronaphthalene and naphthalene. The intermediate α-tetralyl radical can react in either of the following ways.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[20] 
[21]

The reaction with oxygen eventually gives α-tetralone; however, under the present reaction conditions the bromotetralin would dehydrohalogenate to 1,2-dihydronaphthalene. Subsequent oxidation of 1,2-dihydronaphthalene could give, in the same manner, naphthalene or α-naphthol. The latter would inhibit the oxidation and consume bromine, and indeed in the latter stages of the reaction the blue color of the active catalyst is invariably lost. When the oxidation is starved for oxygen the major product then becomes 1,2-dihydronaphthalene. Presumably, if the reaction were performed at higher oxygen pressures, this side reaction could be eliminated.

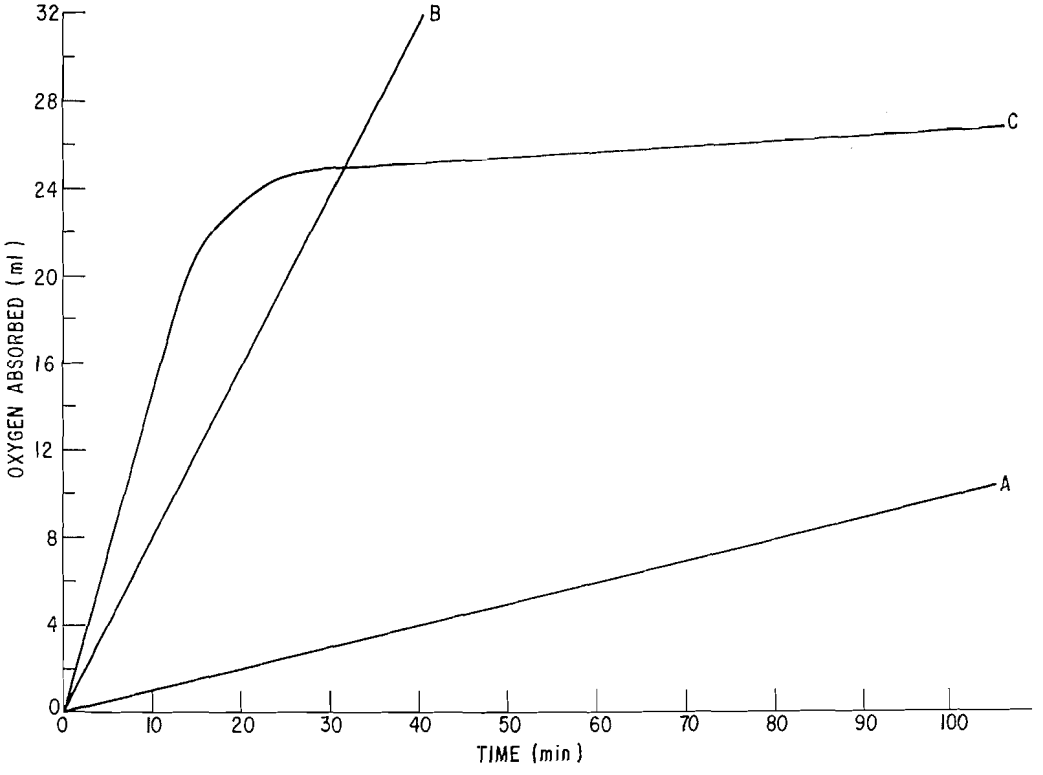


FIG. 3. Oxidation of cumene. (A) AIBN-initiated oxidation; (B) AIBN plus CAB; (C) AIBN plus cobalt(II) bromide.

If the equilibrium situtation depicted in eq. [16] actually prevails, it should follow that increases in the bromine to cobalt ratio should cause increases in the rates of oxygen absorption. As shown by the typical oxidation curves in Fig. 3, this prediction is borne out. Thus, curve A shows the AIBN-initiated rate of oxidation of cumene in the absence of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

cobalt(II) acetate bromide. Curve B shows the marked rate enhancement observed in the presence of cobalt(II) acetate bromide (prepared from equimolar amounts of cobalt(II) acetate and anhydrous hydrogen bromide). Finally, curve C shows the even greater enhancement observed in the *initial* rate of oxygen absorption caused by cobalt(II) bromide. However, as shown in Fig. 3, the initially rapid oxidation observed in the presence of cobalt(II) bromide is sustained for only a very short period and quickly falls to a value lower than the AIBN-initiated rate of oxidation itself. We interpret this result to mean that the concentration of hydrogen bromide present in the equilibrium depicted in eq. [15] has now increased to such an extent that phenolic inhibitors are formed and the oxidation will not proceed to completion. By way of comparison, it should be noted that curve B shows no evidence of departure from linearity and, in fact, oxidations in the presence of equimolar amounts of cobalt(II) acetate and hydrogen bromide proceed readily to completion. Thus, from a practical standpoint, when the reaction is run below 120 °C the optimum catalyst is obtained when quantities of cobalt(II) acetate and hydrogen bromide are in the range encompassing equimolar amounts.

EXPERIMENTAL

Most of the reactions described represent only one experiment and no attempt has been made to optimize the reactions.

The general reaction conditions employed are illustrated by the oxidation of *o*-bromotoluene to *o*-bromobenzoic acid.

The reaction flask consisted of a 1-l round-bottomed flask equipped with an oxygen inlet tube and thermometer and a condenser which also served as a gas exit tube. Efficient oxygen–liquid mixing was obtained with a Vibromixer stirrer. Flowmeters were attached to the inlet and exit tubes to measure the oxygen consumption to indicate when the reactions were completed.

Oxidation of R—CH_3 to R—COOH

To the reaction flask was added 25 g (0.1 mole) of cobalt(II) acetate, 27 g (0.1 mole) of 30% hydrogen bromide in acetic acid, 500 ml of acetic acid, and 86.5 g (0.5 mole) of *o*-bromotoluene. Oxygen (600 ml/min) was bubbled through the vigorously stirred reaction mixture, which was initially heated to 90°, at which point the reaction became exothermic and kept the reaction at the temperature of reflux. The reaction was continued for 2 h, during which time the temperature rose to a maximum of 112°. At the end of this period, oxygen was no longer being absorbed. The reaction mixture was cooled and made up to 1 l with ice water. From the solution, *o*-bromobenzoic acid (90.5 g, 91% yield) separated, m.p. 146.5–148°. There was no depression in a mixed melting point with an authentic sample. In a similar fashion the carboxylic acids in Table II were prepared.

TABLE II

Oxidation of 
R	Product	Yield	m.p.	N.E.
H-	Benzoic acid	86	121	
p-Cl-	*p*-Chlorobenzoic acid	88	240	
o-Cl-	*o*-Chlorobenzoic acid	86	141	
p-Me-	Terephthalic acid	71.5*	>300	86.3
p-Me 	Oxydibenzoic acid	87*	>300	131.2
p-Me 	Benzophenone dicarboxylic acid	76*	>300	132.2
m-Me-	Isophthalic acid	67*	>300	86.5
p-Et-	4-Acetylbenzoic acid	78		157

*The dibasic acid is insoluble in the reaction mixture. By dilution of the filtrate with water the monocarboxylic acid is obtained.

Phenacyl Benzoate

To a 250-ml flask was added 5 g (0.02 mole) of cobalt acetate, 4 ml (0.02 mole) of 30% hydrogen bromide in acetic acid, 22.6 g (0.1 mole) of β-phenethylbenzoate, and 100 ml of acetic acid. Oxygen (600 ml/min) was passed through the vigorously stirred solution for 75 min, during which time the temperature of the reaction mixture was raised from 60 °C to 80 °C. The reaction mixture was poured into 1 l of ice water and the solid removed by filtration. The solid was dissolved in ether and washed with potassium carbonate solution to remove benzoic acid. The ether layer was dried and evaporated to yield 17.0 g (0.071 mole, 71% yield) of phenacyl benzoate, m.p. 121 °C.

n-Butyl Benzoate

Oxygen (600 ml/min) was passed through a vigorously stirred solution of 5 g (0.02 mole) of cobalt acetate, 4 ml (0.02 mole) of 30% hydrogen bromide in acetic acid, and 32.8 g (0.2 mole) of benzyl-*n*-butyl ether in 100 ml of acetic acid. Over a period of 11 min, the temperature rose from 30 to 100 °C. The reaction was continued for a further 50 min and then poured into 1.5 l ice water and extracted with ether. The ether was washed with potassium carbonate solution and then dried, evaporated, and distilled to yield 21.5 g (0.12 mole, 60% yield) of *n*-butyl benzoate, b.p. 60° at 0.5 mm, n_D^{20} 1.4975. From the potassium carbonate layer after acidification there was obtained 7.5 g (0.61 mole, 31% yield) of benzoic acid.

A series of three reactions were run in a similar fashion except that the temperature was kept below 45 °C and at different bromine to cobalt ratios, and the neutral portion of the product was examined by vapor phase chromatography for benzaldehyde.

Br/Co	Benzaldehyde, % yield
1	13.7
1.5	15.2
1.9	28.5

n-Hexyl Caproate

To a 500-ml flask equipped as previously described with the addition of a Dean–Stark trap was added 150 g (1.47 moles) of *n*-hexanol, 50 g of benzene, 5 g (0.02 mole) of cobalt acetate, and 3.27 g (0.01 mole) of cobalt bromide. Oxygen (1 000 ml/min) was passed through the vigorously stirred solution at reflux and water was collected in the Dean–Stark trap. Over a 2-h period the temperature of the reaction mixture rose from 89 to 143 °C and a total of 24 ml of water was collected. The reaction mixture was cooled and dissolved in 300 ml of ether, then washed with cold dilute hydrochloric acid to remove the cobalt salts. The ether layer was washed with cold dilute potassium carbonate solution, then dried, and distilled to yield 14.9 g (0.15 mole) of *n*-hexanol and 56.9 g (0.28 mole) of *n*-hexyl caproate. The potassium carbonate layer was acidified and after distillation there was obtained 26.7 g (0.23 mole) of caproic acid.

Methylphenylglyoxylate

To a 1-l flask was added 600 ml of acetic acid, 10 g (0.04 mole) of cobalt(II) acetate, 2.6 g (0.008 mole) of cobalt(II) bromide, and 75 g (0.5 mole) of methylphenylacetate. Oxygen (800 ml/min) was bubbled through the vigorously stirred reaction mixture at the temperature of reflux for 80 min. The reaction mixture was flooded with ice water and extracted with ether. The ether layer was washed with cold potassium carbonate solution, dried ($MgSO_4$), and distilled. There was obtained 46.5 g (0.31 mole) of methylphenylacetate, b.p. 77° at 6 mm, and 12.7 g (0.08 mole, 41% yield) of methylphenylglyoxylate, b.p. 102.5–106° at 6.5 mm, DNP m.p. 175.5–176° (lit. (15) 174°).

Benzyl Acetate

To a 1-l three-necked round-bottomed flask equipped with gas inlet tube, Vibromixer stirrer, thermometer, and water condenser which also served as a gas exit was added 20 g (0.08 mole) of cobalt(II) acetate, 8 g (0.08 mole) of sodium bromide, 3.3 g (0.04 mole) of sodium acetate, 200 ml of acetic acid, 186 g (1.82 moles) of acetic anhydride, and 138 g (1.5 moles) of toluene. Oxygen was bubbled through the vigorously stirred solution. The temperature was raised and, when the reaction mixture reached about 70°, it became exothermic and rose rapidly to 109°, and oxygen was absorbed by the solution at a rate of 600 ml/min. The reaction was continued for 65 min and then poured into ice water and extracted with ether. The ether layer was washed with sodium bicarbonate solution to remove acetic acid (and any benzoic acid present), then dried over anhydrous magnesium sulfate, and filtered. The ether was distilled off on the steam bath and 158.9 g of a light yellow oil remained. This was examined quantitatively by vapor phase chromatography (v.p.c.) using known solutions for calibration. The product contained 97.2 g of unreacted toluene, 30 g of benzyl acetate (44.7% yield), 10.1 g of benzaldehyde (21.5%), and 15.6% of an unidentified product. The remainder (19.2%) probably is principally benzoic acid which was not isolated.

p-Methylbenzyl Acetate

In a similar fashion 160 g (1.5 moles) of *p*-xylene was oxidized for 160 min to yield 185.4 g of a yellow oil containing 102 g (0.96 mole) of *p*-xylene, 23 g of *p*-tolualdehyde (0.21 mole, 39%), and 52 g (0.31 mole, 57%) of *p*-methylbenzyl acetate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

α-Methylbenzyl Acetate

Oxidation of ethylbenzene (159 g, 1.5 moles) gave 35 g (0.33 mole) of ethyl benzene, 35 g (0.29 mole, 25% yield) of acetophenone, and 25 g (0.15 mole, 13% yield) of α-methylbenzyl acetate. The products isolated by v.p.c. were identified by comparison of their infrared spectra with those of the known compounds.

3-Acetoxycyclohexene

To a 500-ml three-necked round-bottomed flask equipped with thermometer, Vibromixer stirrer, and water condenser which also served as a gas exit was added 200 g (0.08 mole) of colbalt(II) acetate, 8 g (0.08 mole) of sodium bromide, 26.5 g of sodium acetate, 200 ml of acetic acid, 186 g of acetic anhydride, and 123 g (1.5 moles) of cyclohexene. Oxygen was bubbled through the vigorously stirred solution (600 ml/min) at reflux temperature. Over a period of 5 h the pot temperature rose from 80 to 111 °C.

The reaction mixture was flooded with water and extracted with ether. The ether layer was washed with sodium bicarbonate solution, then dried over magnesium sulfate, filtered, and evaporated. There was obtained 96.0 g of a sweet-smelling oil which was distilled to yield 23 g of 3-acetoxycyclohexene, b.p. 53 °C at 6 mm, n_D^{20} 1.4618 (literature n_D^{20} 1.4609). Vapor phase chromatography showed it was a pure material.

α-Acetoxymethylstyrene

Oxidation of α-methylstyrene (177 g, 1.5 moles) gave by v.p.c. 98 g (0.83 mole) of α-methylstyrene, 54 g (0.45 mole, 62% yield) of acetophenone (identified by comparison of infrared spectrum), and 28 g (0.16 mole, 24% yield) of α-acetoxymethylstyrene. A sample was isolated for anlysis; n_D^{20} 1.5329 (lit. 1.5281).

Anal. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86. Found: C, 74.75, 74.61; H, 6.61, 7.04.

α-Tetralone

To a 2-l round-bottomed flask equipped as described previously was added 750 ml of acetic acid, 25 g (0.1 mole) of cobalt(II) acetate tetrahydrate, and 30 g (0.092 mole) of cobalt(II) bromide hexahydrate. Oxygen in excess was kept passing through the vigorously stirred solution maintained at 40° with an ice bath and "jackomatic". Over a 30-min period was added 330 g (2.5 moles) of tetralin dissolved in 255 g of acetic anhydride. The reaction was very exothermic and up to 1 200 ml/min of oxygen was absorbed during this period. The reaction was continued for 30 min,* then flooded with ice water, and extracted with ether. The ether layer was washed with cold sodium carbonate solution, then dried ($MgSO_4$), and distilled. A fraction (86 g), b.p. 40–50 °C at 0.5 mm, and 168 g (1.15 moles), b.p. 90–95 °C at 0.5 mm, were obtained. The latter fraction was α-tetralone, m.p. 6.5 °C.

A number of smaller scale runs were performed and analyzed by vapor phase chromatography (Perkin–Elmer K column). In all cases, in addition to α-tetralone and unreacted tetralin, naphthalene (0.5–3%) and 1,2-dihydronaphthalene (10–15%) were identified. The latter was isolated by preparative vapor phase chromatography, b.p. 63 °C at 3.2 mm, n_D^{20} 1.5829, m.p. −8 °C.

Oxidation of Tetralin to 1,2-Dihydronaphthalene

To a 500-ml wide-mouthed Erlenmeyer flask equipped with a gas inlet tube, thermometer, and a Vibromixer was added 10 g (0.04 mole) of cobalt(II) acetate tetrahydrate, 10.8 g (0.04 mole) of 30% hydrogen bromide in acetic acid, 250 ml of propionic acid, and 66 g (0.05 mole) of tetralin. Air (50 ml/min) was bubbled through the stirred reaction mixture for 16 h. The reaction mixture was then flooded with water, extracted with ether, washed with cold sodium bicarbonate solution, and dried ($MgSO_4$), and the ether removed on the steam bath to leave 67 g of a light orange oil.

The oil was analyzed by vapor phase chromatography and contained tetralin, 67%; 1,2-dihydronaphthalene, 21%; naphthalene, 5%; and α-tetralone, 5%. This is a 71% yield of 1,2-dihydronaphthalene based on the tetralin consumed.

Rate and Inhibition Studies

The rate and inhibition studies were carried out exactly as described in ref. 10.

ACKNOWLEDGMENTS

Distillations and vapor phase chromatographic analyses were performed by Mr. E. M. Hadsell. It is a pleasure to acknowledge the capable assistance of Mr. R. J. Flatley.

SYNTHESIS OF ANHYDRODIDEOXYHEXITOLS RELATED TO ANHYDRODEOXYHEXITOLS FROM OXO REACTION OF 3,4-DI-*O*-ACETYL-D-XYLAL

ALEX ROSENTHAL AND D. ABSON
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

2,3-Di-*O*-acetyl-1,5-anhydro-4,6-dideoxy-D-*arabino*-hexitol (VI) and 2,3-di-*O*-acetyl-1,5-anhydro-4,6-dideoxy-L-*xylo*-hexitol (VII) were prepared by reaction of methyl magnesium bromide with 3,4-di-*O*-acetyl-D-*xylo*-pyranosyl chloride. An independent synthesis of compounds (VI) and (VII) was also achieved from the 6-*O*-tosyl derivatives of the oxo products from 3,4-di-*O*-acetyl-D-xylal, thus confirming that the configuration of the secondary hydroxyls of glycals is not inverted during the oxo reaction.

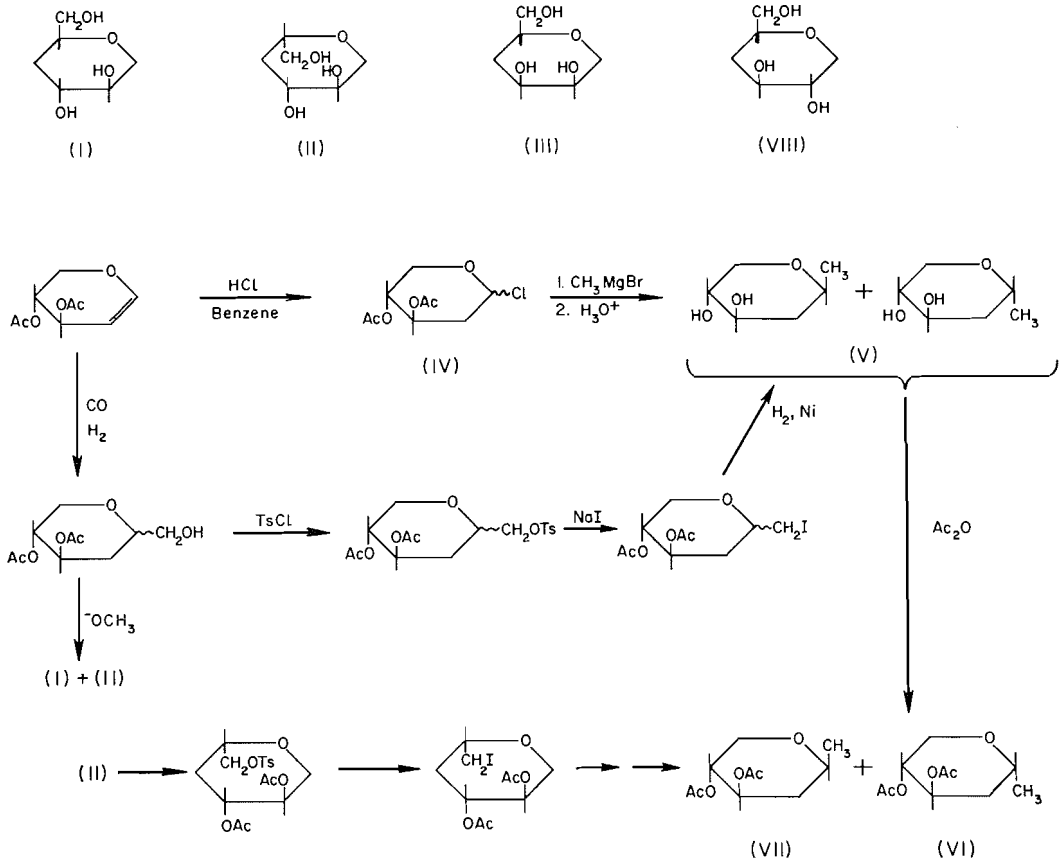
Part II of this series (1) showed that application of the oxo reaction to 3,4-di-*O*-acetyl-D-xylal, followed by deacetylation, gave 1,5-anhydro-4-deoxy-D-*arabino*-hexitol (I) and 1,5-anhydro-4-deoxy-L-*xylo*-hexitol (II). The L-configuration of C-5 of (II) was established by correlation with C-4 of 1,4-anhydro-5-deoxy-D-*arabino*-hexitol; the C-5 configuration of (I) must therefore be D, as this anhydrodeoxyhexitol, on cleavage of the α-glycol bond and reduction, formed a triol ether which was the mirror image of that derived from (II). The remaining asymmetric centers of (I) and (II), at C-2 and C-3, were assumed to be unchanged in configuration from the parent polyol.

Von Rudloff *et al.* (2) carried out the hydrogenolysis of methyl-α-D-glucopyranoside at 240° to give 1,5-anhydro-4-deoxy-hexitol along with other products. Gorin (3) subsequently showed that the hexitol consisted of two 1,5-anhydro-4-deoxy-D-hexitols. On the bases of comparative rates of lead tetracetate oxidation and comparison of observed specific rotations with those calculated from application of the principle of optical superposition, these hexitols were postulated to have structures (I) and (III) (1,5-anhydro-4-deoxy-D-*lyxo*-hexitol). The compound to which they assigned the D-*arabino* configuration ($[\alpha]_D$ +19°; tris-*p*-nitrobenzoate, m.p. 115–119°, $[\alpha]_D$ +59°) is clearly different from our compound (I) ($[\alpha]_D$ −13°; tris-*p*-nitrobenzoate, m.p. 215°, $[\alpha]_D$ −50°). We have accordingly carried out a series of reactions correlating the secondary hydroxyl configurations of (I) and (II) with those of D-xylal, thereby confirming our assignments of structures (I) and (II).

Bonner (4) has shown that the hemiacetal halogen of polyacetylglycosyl halides undergoes a metathetical reaction with Grignard reagent when the latter is present in sufficient excess, and has, moreover, provided adequate experimental proof to show that decomposition of the Grignard adduct to the ester group does not involve rupture of asymmetric bonds, and therefore no change of configuration takes place during reaction with the Grignard reagent. Using the Grignard synthesis we have been successful in preparing the diacetates of the two 6-deoxy analogues of (I) and (II), namely 2,3-di-*O*-acetyl-1,5-anhydro-4,6-dideoxy-D-*arabino*-hexitol (VI) and 2,3-di-*O*-acetyl-1,5-anhydro-4,6-dideoxy-L-*xylo*-hexitol (VII).

Hydrogen chloride readily adds across the double bond of 3,4-di-*O*-acetyl-D-xylal (cf. ref. 5), as was evidenced by complete disappearance of the characteristic C=C

stretching vibration at ca. 1 640 cm^{-1} in the infrared spectrum. The unstable product, 3,4-di-*O*-acetyl-2-deoxy-D-*xylo*-pyranosyl chloride (IV), was immediately caused to react



with about 10 molar equivalents of methyl magnesium bromide, according to the general procedure outlined by Bonner (4), except that the product was isolated in the deacetylated form since it was hoped to effect a separation by paper chromatography. However, only one zone was detected on spraying of the samples with sodium periodate – Schiff reagent (6), although a variety of solvent systems was tried. Nevertheless, the sirupy product isolated from the Grignard reaction and purified by preparative paper chromatography undoubtedly consisted of a mixture of the two anhydrodideoxyhexitols (V), as was clear from the proton nuclear magnetic resonance (n.m.r.) spectrum, which showed a pair of overlapping "*C*"-methyl doublets (J = 6 c.p.s.) at δ = 1.14 p.p.m. and δ = 1.17 p.p.m. By acetylation and gas–liquid partition chromatography (g.l.p.c.), the two components of the mixture could be separated in sufficient amounts for characterization. The faster-moving component (relative retention time 1.00), $[\alpha]_D$ −21°, was identified as 2,3-di-*O*-acetyl-1,5-anhydro-4,6-dideoxy-L-*xylo*-hexitol (VII) by preparation of (VII) from 1,5-anhydro-4-deoxy-L-*xylo*-hexitol (II) as described in the Experimental section. The slower-moving component (relative retention time 1.10), $[\alpha]_D$ −82°, was therefore 2,3-di-*O*-acetyl-1,5-anhydro-4,6-dideoxy-D-*arabino*-hexitol.

3,4-Di-*O*-acetyl-D-xylal was caused to react with carbon monoxide and hydrogen as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

described previously (1). After removal of the catalyst, a portion of the sirupy product was deacetylated, and separated by paper chromatography into fractions (I) and (II). A further portion of the catalyst-free product was treated with *p*-toluenesulfonyl chloride in pyridine to give a mixture of 2,3-di-*O*-acetyl-6-*O*-tosyl derivatives of (I) and (II), which without purification was heated with sodium iodide in acetone solution, whereby the tosyloxy groups were replaced by iodine. The crude mixture of 2,3-di-*O*-acetyl-1,5-anhydro-4,6-dideoxy-6-iodo-hexitols was then shaken in basic solution with hydrogen in the presence of Raney nickel (7), effecting simultaneous reduction of $-CH_2I$ to CH_3, and deacetylation. Paper chromatography of the product showed only one zone identical in R_f value with that of the mixture of 1,5-anhydro-4,6-dideoxyhexitols (V) obtained by the action of methyl magnesium bromide on (IV). Confirmation that the product was a mixture of 1,5-anhydro-4,6-dideoxy-D-*arabino*- and -L-*xylo*-hexitols was obtained on acetylating the mixture and separating it by g.l.p.c. into two pure components, identical with (VI) and (VII) by virtue of their relative retention times, optical rotations, and nuclear magnetic resonance and infrared spectra.

The D-*arabino* and L-*xylo* configurations of the anhydrodeoxyhexitols (I) and (II) are thus confirmed unambiguously; consequently, the polyol of R_{Rh} 1.3* (denotes distance moved on paper relative to rhamnose in 1-butanol – ethanol – water (40:11:19 v/v/v) solvent) isolated by Gorin (3) from the hydrogenolysis products of methyl-α-D-glucopyranoside is not 1,5-anhydro-4-deoxy-D-*arabino*-hexitol. Both this and the other polyol of R_{Rh} 1.1 are known to be of the D series, as they gave 2-deoxy-3-*O*-(2-hydroxyethyl)-L-*glycero*-tetritol on oxidative cleavage followed by reduction with sodium borohydride (1). Furthermore, as the rate of oxidation by lead tetracetate indicated a *trans*-α-glycol group in the faster-moving polyol (3), we concluded that this compound was probably 1,5-anhydro-4-deoxy-D-*xylo*-hexitol (VIII). This was confirmed on examination of a sample of the compound kindly made available by Dr. P. A. J. Gorin, which proved to be enantiomeric with (II). Thus, the n.m.r. spectra were identical, the specific rotations were equal and opposite, and the compound formed a crystalline tri-*O*-acetyl derivative enantiomeric with 2,3,6-tri-*O*-acetyl-1,5-anhydro-4-deoxy-L-*xylo*-hexitol (1).

Comparison of a sample of the crystalline anhydrodeoxyhexitol of R_{Rh} 1.1, also furnished by Dr. Gorin, with 1,5-anhydro-4-deoxy-D-*lxyo*-hexitol (III), one of the products obtained by the oxo reaction of 3,4-di-*O*-acetyl-D-arabinal (8), confirmed the identity of the two compounds.

EXPERIMENTAL

General Considerations

Gas–liquid partition chromatography separations were carried out on an Aerograph "Autoprep" model A-700 employing a column (10 ft × 1/4 in.) of 20% Silicone GE-SF-96 on firebrick at a temperature of 180°, with helium as the carrier gas at a flow rate of 40 ml/min. Samples (3–4 mg in chloroform solution) were injected directly onto the column using a 6-in. needle. Conditions for paper chromatographic separations, isolation and deacetylation of oxo products, and measurement of infrared spectra have been described (1). The n.m.r. spectra of the acetates were obtained on a Varian A-60 instrument using tetramethylsilane as the internal standard (set at $\delta = 0$).

Microanalyses were carried out by Dr. A. Bernhardt, Mülheim (Ruhr), West Germany.

Preparation of 2,3-Di-O-acetyl-1,5-anhydro-4,6-dideoxy-D-arabino-hexitol (VI) and 2,3-Di-O-acetyl-1,5-anhydro-4,6-dideoxy-L-xylo-hexitol (VII)

(a) By Reaction of 3,4-Di-O-acetyl-D-xylopyranosyl Chloride with Methyl Magnesium Bromide

A cooled solution of 3,4-di-*O*-acetyl-D-xylal (2.5 g) in dry benzene (5 ml) was saturated with dry hydrogen chloride. After 1 h, the solvent was removed under reduced pressure at 30° to give a colorless oil. An infrared spectrum of the product showed no absorption at ca. 1 640 cm^{-1}. The product loses hydrogen chloride on standing and must be used immediately.

For personal use only.

To a stirred solution of methyl magnesium bromide in dry ether, prepared by the slow addition of methyl bromide gas to a stirred suspension of magnesium (3.2 g) in dry ether (50 ml) under an atmosphere of dry nitrogen, was added dropwise over 45 min a solution of 3,4-di-*O*-acetyl-2-deoxy-D-*xylo*-pyranosyl chloride (prepared from the 2.5 g of 3,4-di-*O*-acetyl-D-xylal as described above) in dry ether (30 ml). After it had been heated under reflux for 5 h, the solution was cooled and added slowly to a large volume of ice water containing 5 ml of acetic acid. The aqueous phase was filtered through Celite, neutralized with 2 *N* sodium hydroxide, and evaporated to a white solid. The reaction product was separated from inorganic material by repeated extraction, filtration, and evaporation with ethanol (and subsequently with acetone) to yield a yellow sirup (0.95 g). Paper chromatography (water-saturated 1-butanol containing 5% ethanol, v/v) showed one zone, $R_f = 0.69$, on spraying of the samples with sodium periodate–Schiff reagent (6). A portion of the product (0.33 g) was purified by chromatography on paper to yield a sirup (0.22 g); n.m.r. spectrum (D_2O solution, relative areas in parentheses): complex multiplet 3.0–4.2 p.p.m. (5); pair of overlapping doublets ($J = 6$ c.p.s.) centered at 1.14 and 1.17 p.p.m. (3) caused by C—CH_3.

A portion of the purified mixture of 1,5-anhydro-4,6-dideoxy-D-*arabino*- and -L-*xylo*-hexitols (100 mg) was acetylated with acetic anhydride (1 ml) and anhydrous pyridine (1 ml) overnight. The mixture was poured into ice water, and after 30 min stirring, the resulting homogeneous solution was extracted three times with chloroform. The combined chloroform extracts were washed successively with sodium hydrogen sulfate solution, sodium hydrogen carbonate solution, and water, and dried over anhydrous magnesium sulfate. Under reduced pressure the extracts were evaporated to a sirup (110 mg) which, when fractionated by g.l.p.c., yielded two pure components (VI) and (VII), the latter identified as 2,3-di-*O*-acetyl-1,5-anhydro-4,6-dideoxy-L-*xylo*-hexitol by independent synthesis from 1,5-anhydro-4-deoxy-L-*xylo*-hexitol (II) as described below.

*Fraction (VI) (2,3-di-O-acetyl-1,5-anhydro-4,6-dideoxy-*D*-arabino-hexitol).*—Relative retention time 1.10; a colorless liquid of $[\alpha]_D^{24}$ −82° (*c*, 1.0, chloroform). N.m.r. spectrum (CCl_4 solution): multiplets at 4.75–5.00 p.p.m. (2), 4.4–4.65 p.p.m. (1), and 3.35–3.9 p.p.m. (3); two sharp signals at 2.02 p.p.m. (3) and 2.06 p.p.m. (3) caused by acetyl hydrogens; multiplet at 1.5–1.85 p.p.m. (2) caused by C—CH_2—C; doublet ($J = 6$ c.p.s.) centered at 1.13 p.p.m. (3) caused by C—CH_3.

Anal. Calcd. for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46. Found: C, 55.61; H, 7.55.

*Fraction (VII) (2,3-di-O-acetyl-1,5-anhydro-4,6-dideoxy-*L*-xylo-hexitol.*—Relative retention time 1.00; a colorless liquid of $[\alpha]_D^{24}$ −21° (*c*, 0.9, chloroform). N.m.r. spectrum (CCl_4 solution): multiplets at 4.65–5.00 p.p.m. (2), 3.8–4.2 p.p.m. (1), and 3.0–3.65 p.p.m. (3); sharp signal at 1.97 p.p.m. (6) caused by acetyl hydrogens, superimposed on multiplet (2) caused by C—CH_2—C; doublet ($J = 6$ c.p.s.) centered at 1.20 p.p.m. (3) caused by C—CH_3.

Anal. Calcd. for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46. Found: C, 55.47; H, 7.42.

*2,3-Di-O-acetyl-1,5-anhydro-4,6-dideoxy-*L*-xylo-hexitol (VII) from 1,5-anhydro-4-deoxy-*L*-xylo-hexitol (II).*—To an ice-cold solution of anhydrodeoxyhexitol (II) (70 mg) in anhydrous pyridine (0.5 ml) was added over 20 min a solution of *p*-toluenesulfonyl chloride (105 mg, 1.1 molar equivalents) in anhydrous pyridine (1.0 ml). After the mixture had been allowed to stand at 5° for 18 h, acetic anhydride (1.0 ml) was added and the mixture was kept at room temperature for 12 h. Isolation of the product by an isolation procedure identical with that described above gave a sirup (140 mg) which contained approximately 80% of 2,3-di-*O*-acetyl-1,5-anhydro-4-deoxy-6-*O*-tosyl-L-*xylo*-hexitol, as judged by the amount of sodium *p*-toluenesulfonate liberated therefrom. The crude product in acetone (2 ml) was heated with sodium iodide (140 mg) in a sealed tube at 140° for 3 h. After cooling, sodium *p*-toluenesulfonate (58 mg) was removed by filtration and the solution was evaporated to dryness. Extraction with refluxing ether and evaporation of solvent gave a sirup (125 mg). The crude 6-deoxy-6-iodo derivative was dissolved in methanol (10 ml) containing 0.5 ml 5 *N* sodium hydroxide, and shaken with hydrogen in the presence of Raney nickel (15 mg) for 30 min. Filtration, neutralization with carbon dioxide, and evaporation gave a white solid, which was acetylated by being heated at 100° for 3 h with acetic anhydride (2 ml) and anhydrous sodium acetate (0.4 g). Isolation of the product in the usual way gave a brown sirup (50 mg). Gas–liquid partition chromatography of the product showed one zone whose retention time was identical with that of fraction (VII). The infrared spectrum of a portion of the product purified by g.l.p.c. was identical with that of fraction (VII).

*(b) From Oxo Products Obtained by Reaction of 3,4-Di-O-acetyl-*D*-xylal with Carbon Monoxide and Hydrogen*

3,4-Di-*O*-acetyl-D-xylal was converted into a mixture of 2,3-di-*O*-acetyl-1,5-anhydro-4-deoxy-D-*arabino*-hexitol and 2,3-di-*O*-acetyl-1,5-anhydro-4-deoxy-L-*xylo*-hexitol by the method previously described (1). To a portion of this oxo product (1.5 g) in anhydrous pyridine (6 ml) was added *p*-toluenesulfonyl chloride (1.8 g). After the mixture had been allowed to stand at room temperature for 18 h, water (5 ml) was added in small portions over a period of 20 min, with cooling in ice. The mixture was then poured into ice water and the product was isolated by extraction with chloroform. The combined chloroform extracts were washed successively with sodium bisulfate solution, water, sodium bicarbonate solution, and again with water, and dried over anhydrous magnesium sulfate. Evaporation under reduced pressure gave a sirup (1.6 g) whose n.m.r. spectrum indicated approximately 75% of 2,3-di-*O*-acetyl-1,5-anhydro-4-deoxy-6-*O*-tosyl-hexitols to be present. This mixture was converted into a mixture of 1,5-anhydro-4,6-dideoxy-L-*xylo*- and -D-*arabino*-hexitols by the procedure described in the preceding section, and then purified by preparative paper chromatography. A portion of the purified product (110 mg) was acetylated to yield a syrup (140 mg) which was

fractionated by g.l.p.c. into (VI) and (VII), identical with the two fractions isolated as described in Section *a* on the basis of retention times, specific rotations ($[\alpha]_D^{24}$ −81° and −23° (*c*, 1.2, chloroform) respectively), and n.m.r. and infrared spectra.

Identification of Anhydrodeoxyhexitol of R_{Rh} 1.3 from Hydrogenation of Methyl α-D-Glucopyranoside (3)

The tris-*p*-nitrobenzoate of this compound (170 mg), kindly supplied by Dr. P. A. J. Gorin, was debenzoylated by heating it under reflux with 0.1 *N* methanolic sodium methoxide for 1 h. Isolation of the product in the usual way gave a colorless sirup (38 mg), $[\alpha]_D^{22}$ +40° (*c*, 2.0, chloroform), whose n.m.r. spectrum was identical with that of the levorotatory L-isomer (II) (1), and which formed a tri-*O*-acetyl derivative, m.p. 80–82°; $[\alpha]_D^{22}$ +40° (*c*, 2.0, chloroform), whose infrared spectrum was identical with that of 2,3,6-tri-*O*-acetyl-1,5-anhydro-4-deoxy-L-*xylo*-hexitol (1).

ACKNOWLEDGMENTS

The authors gratefully acknowledge the financial assistance of the National Research Council and the University of British Columbia Research Grant. One of us (D. A.) gratefully acknowledges the Standard Oil Fellowship and the University of British Columbia Research Fellowship.

The authors thank Dr. P. A. J. Gorin for making available samples of his two anhydrodeoxyhexitols.

SYNTHESIS OF 8-AZA-D-HOMO-18-NORESTRONE METHYL ETHER

NORMAN A. NELSON[1] AND YASUMITSU TAMURA
Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Alkylation of the potassium salt of 1,4-dihydro-2,6-dimethoxybenzene with 2-(2-bromoethyl)piperidine yielded the bis-enol ether I, which, on acid hydrolysis, afforded the crystalline vinylogous amide II. Lithium aluminium hydride reduction of II gave two isomers of 1,2,3,4,4*a*,5,6,6*a*,8,9,10,10*a*-dodecahydro-7H-benzo[*c*]quinolizin-7-one (III). A similar series of reactions starting with 1-(2-chloroethyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride (V) gave two isomers of 2,3,4,4*a*,6,7,11*b*,12,13,13*a*-decahydro-9-methoxy-1H-dibenzo[*a*,*f*]quinolizin-1-one (8-aza-D-homo-18-norestrone methyl ether) (IX).

In an earlier report (1) we described some nitrogen-containing tricyclic analogues of 18-nor-D-homoestrone having anti-inflammatory activity. This pharmacological finding prompted us to prepare some of the corresponding tetracyclic analogues. The preparation of two isomers of 2,3,4,4*a*,6,7,11*b*,12,13,13*a*-decahydro-9-methoxy-1H-dibenzo[*a*,*f*]-quinolizin-1-one (8-aza-D-homo-18-norestrone methyl ether) (IX) is the subject of this paper.

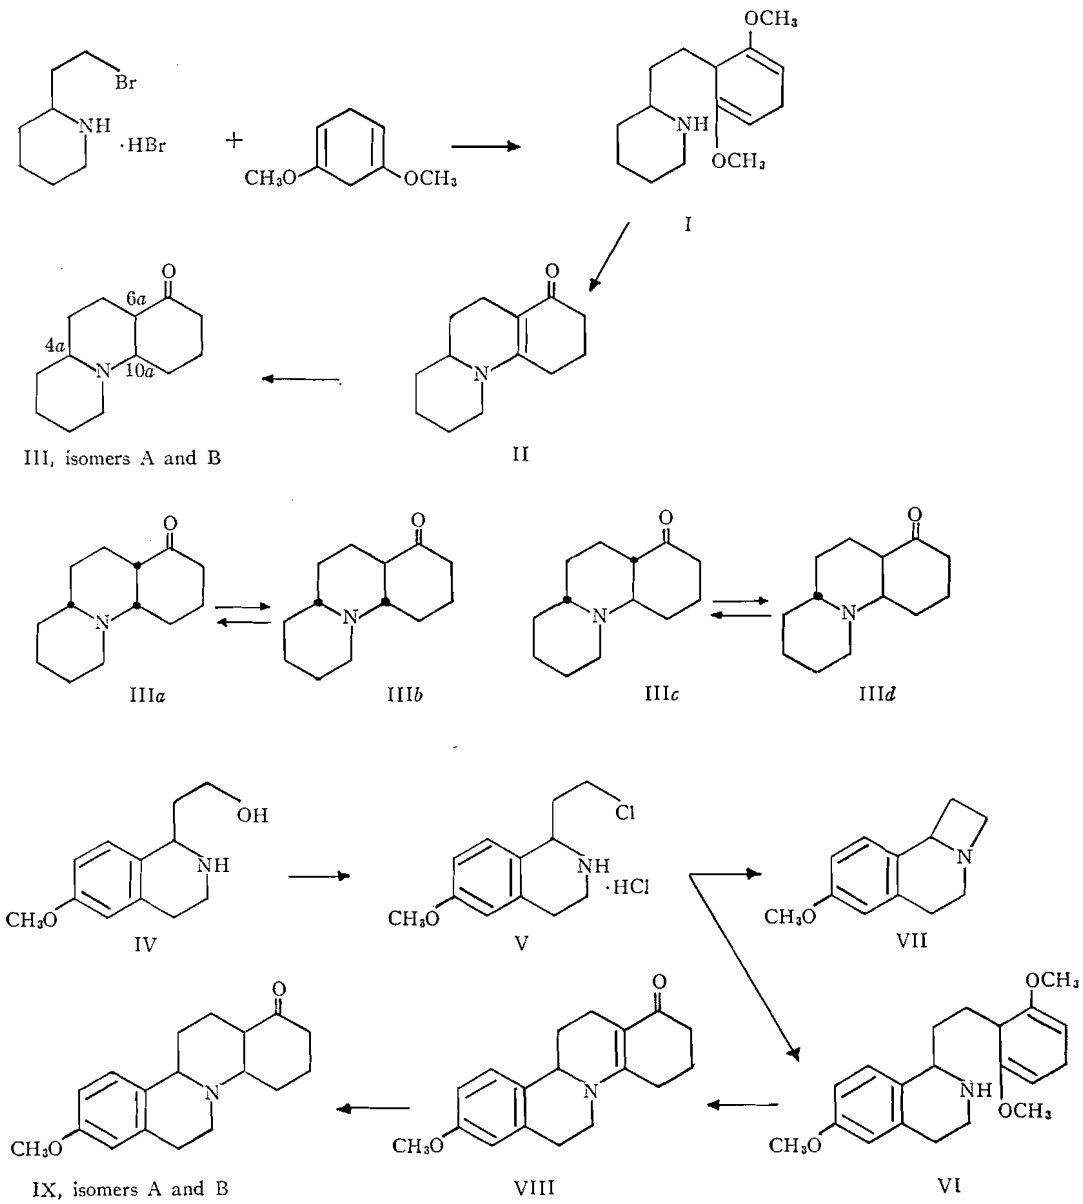
A number of years ago we (2) prepared 1-(2-hydroxyethyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline (IV) in anticipation of utilizing it as an intermediate in the preparation of IX. At the outset of the present work we utilized the more readily available 2-(2-hydroxyethyl)piperidine (3) as a model of IV in our effort to elaborate two additional rings corresponding to the C and D rings of a steroid.

2-(2-Hydroxyethyl)piperidine was converted to 2-(2-bromoethyl)piperidine hydrobromide in 83% yield using hot 48% hydrobromic acid. Conversion of 2-(2-hydroxyethyl)piperidine hydrobromide to the corresponding 2-bromoethyl derivative was also effected using phosphorus tribromide (29% yield) or thionyl bromide (69% yield).

Alkylation of the potassium salt of 1,4-dihydro-2,6-dimethoxybenzene (4) with 2-(2-bromoethyl)piperidine in liquid ammonia proceeded smoothly, giving 2-[2-(1,4-dihydro-2,5-dimethoxyphenyl)ethyl]piperidine (I). Hydrolysis of the bis-enol ether was accompanied by cyclization of the intermediate diketone, yielding the tricyclic vinylogous amide II in 71% yield. Treatment of II with lithium aluminium hydride resulted in a net reduction of the carbon–carbon double bond, thereby giving a crystalline isomer (isomer A) of III in 44% yield and a liquid believed to represent a second isomer (isomer B) of III in 36% yield. The two isomers were characterized as their picrates. Lithium aluminium hydride reduction of vinylogous amides may lead to loss of the carbonyl oxygen (5, 6) or to the production of aminoalcohols or aminoketones (7–9).

The conversion of II to III can be pictured as a 1,4-reduction or a 1,2-reduction followed by hydrolysis of the enamine to a 3-hydroxycyclohexenone, elimination of water, and finally a Michael addition of the nitrogen to the intermediate 2-substituted cyclohexenone. On the basis of a closely related example (9), the 1,4-reduction mechanism is to be preferred.

[1]*To whom inquiries should be addressed. Present address: Department of Chemistry, The Upjohn Company, Kalamazoo, Michigan.*



The crystalline isomer A of III, on treatment with ethanolic sodium ethoxide, was isomerized to the corresponding oily isomer B. The infrared spectra of the two isomers of III both exhibit infrared absorption bands at 2 790 and 2 754 cm^{-1}. Such bands have been attributed to amines which have at least two α-hydrogens *trans*-diaxial to the unshared electron pair of the nitrogen (10–12). On this basis, it would appear that the two isomers of III exist in carbon tetrachloride solution as *trans*-fused quinolizidines (at least to a considerable extent). The various conformations that are possible for III and which have a *cis*-fused quinolizidine system have only one α-hydrogen *trans*-diaxial to the unshared electron pair on nitrogen.

The isomers of III are believed to be epimeric at the asymmetric center alpha to the carbonyl function. If such is the case, isomer A should be III*a* or III*c*, while isomer B should be III*b* or III*d* respectively. The prediction of stabilities of the various conformations of III is based on the known stabilities of the corresponding perhydrophenanthrenes (13) and the similar stereochemical requirements of tetrahedral carbon and nitrogen (see refs. 14 and 15 for recent papers regarding the steric requirements of the lone electron pair on nitrogen). The possibility that isomers III*c* and III*d* could also be isomerized to III*b* (through the substituted cyclohexenone formed by β-elimination of nitrogen) cannot be ruled out.

1-(2-Hydroxyethyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline was converted to 1-(2-chloroethyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride (V) in 93% yield using thionyl chloride. Treatment of V with an excess of the potassium salt of 1,4-dihydro-2,6-dimethoxybenzene in liquid ammonia yielded the bis-enol ether VI, in addition to a small amount of material having properties consistent with 1,4,5,9*b*-tetrahydro-7-methoxy-2H-azeto[2,1-*a*]isoquinoline (VII). The formation of VII is analogous to the formation of conidine from 2-(2-chloroethyl)piperidine (3).

Acid hydrolysis of VI and cyclization of the intermediate gave the tetracyclic vinylogous amide VIII. Lithium aluminium hydride reduction of VIII yielded two crystalline isomers of IX which were separated by chromatography on Florisil. The isomer with m.p. 158.5–160° (isomer A) was isomerized in the presence of methanolic sodium methoxide to isomer B (m.p. 143.5–144°). As in the model series, these isomers are believed to be epimeric at the asymmetric center alpha to the carbonyl group. The isomers exhibit infrared absorption bands characteristic of *trans*-quinolizidine systems; however, it is not possible to say whether or not one of the isomers of IX (8-aza-D-homo-18-norestrone methyl ether) corresponds in configuration with naturally occurring estrone.

Recently, the hydrobromide salt of an isomer of IX was described (16), but unfortunately it was not possible to relate it with our isomers because the supplies of the various compounds had been exhausted. Since this work was completed, the synthesis of 8-aza-estrone (17) and other 8-azasteroids (18) has appeared.

EXPERIMENTAL

Infrared spectra were determined with a Baird model B spectrophotometer fitted with a sodium chloride prism unless otherwise specified. Ultraviolet spectra were determined in 95% ethanol with a Cary recording spectrophotometer (model 11 MS). The microanalyses were performed by Dr. S. M. Nagy and his associates. Melting points are uncorrected.

2-(2-Bromoethyl)piperidine Hydrobromide

A solution of 38.7 g of 2-(2-hydroxyethyl)piperidine (3) in 120 ml of 48% hydrobromic acid was refluxed for 1 h before 70 ml of distillate was collected. An additional 100 ml of 48% hydrobromic acid was added to the residue and the resulting solution was refluxed for 6 h before the excess acid was removed *in vacuo*. The residue was washed with ethyl acetate and recrystallized from ethanol, giving 59 g (72%) of product, m.p. 167–168°, and 9.2 g (11%) of material with m.p. 166–167°. The analytical sample had m.p. 167–167.2°.

Anal. Calcd. for $C_7H_{15}Br_2N$: C, 30.77; H, 5.49; Br, 58.61. Found: C, 30.77; H, 5.49; Br, 58.39.

Initial attempts to prepare 2-(2-bromoethyl)piperidine hydrobromide using phosphorus tribromide gave a 29% yield of product, while thionyl bromide gave a 69% yield.

2-[2-(1,4-Dihydro-2,5-dimethoxyphenyl)ethyl]piperidine (I)

Potassium amide was prepared from 8 g of the metal, 700 ml of liquid ammonia, and a trace of ferric chloride. To this mixture was added with stirring 21 g of 2,5-dihydro-1,3-dimethoxybenzene (4) and 7 ml of ether (rinse solution). The resulting red solution was stirred for 10 min before 24.9 g of powdered 2-(2-bromoethyl)piperidine hydrobromide was added over a period of 17 min to discharge the red color. Most of the ammonia was evaporated, 200 ml of water was added, and the product was extracted with ether. The ether extract was washed with water and saturated sodium chloride solution, dried, and concentrated. Distillation of the residue gave 18.8 g of product, b.p. 138–140° at 5.0 mm pressure. The analytical sample

had b.p. 105° at 0.25 mm pressure, α_D^{26} 1.5104, and infrared absorption bands (in CCl_4) at 1 694 and 1 662 cm^{-1} (unconjugated enol ether double bonds).

Anal. Calcd. for $C_{15}H_{25}NO_2$: C, 71.71; H, 9.96; N, 5.58. Found: C, 71.44; H, 9.96; N, 5.61.

1,2,3,4,4a,5,6,8,9,10-Decahydro-7H-benzo[c]quinolizin-7-one (II)

A solution of 12.5 g of 2-[2-(1,4-dihydro-2,5-dimethoxyphenyl)ethyl]piperidine in 40 ml of 2 *N* hydrochloric acid was heated to 60° for 30 min, cooled, and neutralized with 2 *N* sodium hydroxide solution. The water was removed from the reaction mixture by azeotropic distillation with benzene–ethanol. The product was separated from sodium chloride by trituration of the residue with cold ethanol. Evaporation of the ethanol gave a residue which, after crystallization from ether and then ether–hexane (3:4), gave 7.4 g (71%) of product, m.p. 76.5–77.5°. The ultraviolet spectrum has a maximum absorption at 316 mμ (ϵ 31 900). The infrared spectrum shows a strong maxima at 1 620 and 1 580 cm^{-1} associated with the conjugated ketone–enamine grouping.

Anal. Calcd. for $C_{13}H_{19}NO$: C, 76.05; H, 9.33; N, 6.82. Found: C, 75.89; H, 9.43; N, 6.69.

1,2,3,4,4a,5,6,8,9,10-Decahydro-7H-benzo[c]quinolizin-7-one Picrate

This was prepared in the usual way and recrystallized from ethanol, m.p. 153.5–154°.

Anal. Calcd. for $C_{19}H_{22}N_4O_8$: C, 52.53; H, 5.10; N, 12.90. Found: C, 52.60; H, 5.20; N, 13.03.

1,2,3,4,4a,5,6,6a,8,9,10,10a-Dodecahydro-7H-benzo[c]quinolizin-7-one (III); Isomers A and B

To a mixture of 170 mg of lithium aluminium hydride in 5 ml of dry tetrahydrofuran was added with stirring 410 mg of 1,2,3,4,4*a*,5,6,8,9,10-decahydro-7H-benzo[*c*]quinolizin-7-one (II) in 2.5 ml of tetrahydrofuran. The mixture was refluxed under a nitrogen atmosphere for 4.5 h and cooled, and 1 ml of ethyl acetate was added before the mixture was poured into 20 ml of dilute sodium hydroxide solution. The mixture was extracted with ether, and the ether extract was dried and then concentrated. Trituration of the residue with ether and recrystallization of the solid several times from hexane gave 280 mg (44%) of an isomer (isomer A) of III, m.p. 124–125°, and infrared absorption peaks (in CCl_4) at 1 709 (C=O) and 1 060 cm^{-1} (characteristic of this isomer). The infrared spectrum (using a CaF_2 prism) shows peaks at 2 790 and 2 754 cm^{-1} (characteristic of a *trans*-quinolizidine system).

Anal. Calcd. for $C_{13}H_{21}NO$: C, 75.31; H, 10.21; N, 6.76. Found: C, 75.32; H, 10.33; N, 6.80.

The *picrate* of III (isomer A) was crystallized from ethanol, m.p. 154° (decomp.).

Anal. Calcd. for $C_{19}H_{24}N_4O_8$: C, 52.29; H, 5.54; N, 12.84. Found: C, 52.29; H, 5.53; N, 12.84.

The filtrate from the trituration of the crystalline isomer A of III above yielded an additional small amount of isomer A and 150 mg (36%) of an oily residue (presumably an isomer B of III) whose infrared spectrum (carbonyl absorption at 1 712 cm^{-1} and 2 790 and 2 754 cm^{-1} using a CaF_2 prism) was different from that of isomer A and which was converted to a different *picrate* derivative of III, crystallized from ethanol, m.p. 185° (decomp.).

Anal. Calcd. for $C_{19}H_{24}N_4O_8$: C, 52.29; H, 5.54; N, 12.84. Found: C, 52.33; H, 5.56; N, 12.78.

Chromatographic purification of the oily isomer B on Florisil did not yield any additional isomers and indicated that it was probably a single substance.

Isomerization of Isomer A of 1,2,3,4,4a,5,6,6a,8,9,10,10a-Dodecahydro-7H-benzo[c]quinolizin-7-one (III)

To a solution prepared from 25 mg of sodium and 5 ml of absolute ethanol was added 100 mg of the crystalline isomer A of III and the mixture was refluxed in a nitrogen atmosphere for 1 h. The mixture was diluted with 20 ml of water, most of the alcohol was removed *in vacuo*, and the product was extracted with ether. Concentration of the dried ether extract *in vacuo* gave 90 mg of an oil whose infrared spectrum was essentially identical with the liquid isomer B described above.

In a similar isomerization experiment involving 150 mg of the liquid isomer B of III, only unchanged starting material was recovered.

1-(2-Chloroethyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline Hydrochloride (V)

A solution of 10.4 g of 1-(2-hydroxyethyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline in 40 ml of chloroform was cooled in a water bath while it was saturated with hydrogen chloride. To the mixture at 0° was added 8.3 g of thionyl chloride. The mixture was allowed to stand at room temperature for 30 min before it was refluxed for 105 min. The reaction mixture was cooled, diluted with 5 ml of water, and concentrated *in vacuo*. The residual solid was recrystallized from ethanol, giving 12.2 g (93%) of product, m.p. 165–166.5°.

Anal. Calcd. for $C_{12}H_{17}Cl_2NO$: C, 55.00; H, 6.50; Cl, 27.06; N, 5.35. Found: C, 55.02; H, 6.72; Cl, 26.69; N, 5.14.

1-[2-(1,4-Dihydro-2,5-dimethoxyphenyl)ethyl]-6-methoxy-1,2,3,4-tetrahydroisoquinoline (VI) and 1,4,5,9b-Tetrahydro-7-methoxy-2H-azeto[2,1-a]isoquinoline (VII)

To a mixture of potassium amide (prepared from 7.8 g of the metal) in 1 l of liquid ammonia was added 28 g of 2,5-dihydro-1,3-dimethoxybenzene and, after the resultant red solution was stirred for 10 min, 10.4 g of 1-(2-chloroethyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride was added over a period of 30 min. The mixture was stirred for 50 min, most of the ammonia was evaporated, and the residue

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was shaken with ether and water. The residue obtained from the washed and dried ether layer was distilled *in vacuo*. The fraction with b.p. 88–90° at 0.02 mm pressure amounted to 2.5 g and is presumably VII. The infrared spectrum (in CCl_4) has the characteristic aromatic (C=C) absorption bands at 1 610, 1 575, and 1 500 cm^{-1}.

Anal. Calcd. for $C_{12}H_{15}NO$: C, 76.15; H, 7.99; N, 7.40. Found: C, 76.14; H, 7.93; N, 7.51.

Treatment of VII with picric acid in the usual way gave a *picrate derivative*, recrystallized from ethanol, m.p. 133.5–134.5°.

Anal. Calcd. for $C_{18}H_{18}N_4O_8$: C, 51.67; H, 4.34; N, 13.39. Found: C, 51.72; H, 4.38; N, 13.54.

The residue from the above distillation amounted to 6.6 g and was largely the desired product VI. An analytical sample of 1-[2-(1,4-dihydro-2,5-dimethoxyphenyl)ethyl]-6-methoxy-1,2,3,4-tetrahydroisoquinoline (VI) was prepared by evaporative distillation at 0.006 mm pressure and a bath temperature of 150°.

Anal. Calcd. for $C_{20}H_{27}NO_3$: C, 72.92; H, 8.26; N, 4.25. Found: C, 72.63; H, 8.04; N, 4.42.

9-Methoxy-2,3,4,6,7,11b,12,13-octahydro-1H-dibenzo[a,f]quinolizin-1-one (VIII)

A mixture of 6.0 g of 1-[2-(1,4-dihydro-2,5-dimethoxyphenyl)ethyl]-6-methoxy-1,2,3,4-tetrahydroisoquinoline (VI), 20 ml of 2 *N* hydrochloric acid, and 10 ml of water was warmed to 50° for 15 min with occasional stirring. The mixture was cooled, neutralized with 20 ml of 2 *N* sodium hydroxide solution, and extracted with chloroform. The chloroform extract was washed, dried, and concentrated to give 6.2 g of a brown oil. A portion of this oil was purified for analysis by evaporative distillation at a bath temperature of 180° and at 0.003 mm pressure. The ultraviolet spectrum of a different sample has an inflection at 286 mμ (ε 7 100) and a maximum at 316 mμ (ε 21 000).

Anal. Calcd. for $C_{18}H_{21}NO_2$: C, 76.29; H, 7.47; N, 4.94. Found: C, 76.05; H, 7.65; N, 4.84.

The *picrate of 9-methoxy-2,3,4,6,7,11b,12,13-octahydro-1H-dibenzo[a,f]quinolizin-1-one (VIII)* was crystallized from ethanol, m.p. 174–175° (decomp.).

Anal. Calcd. for $C_{24}H_{24}N_4O_9$: C, 56.25; H, 4.72; N, 10.93. Found: C, 56.34; H, 4.72; N, 10.79.

2,3,4,4a,6,7,11b,12,13,13a-Decahydro-9-methoxy-1H-dibenzo[a,f]quinolizin-1-one (IX); Isomers A and B

A solution of 5.6 g of crude 9-methoxy-2,3,4,6,7,11*b*,12,13-octahydro-1H-dibenzo[*a*,*f*]quinolizin-1-one (VIII) in 35 ml of dry tetrahydrofuran was added dropwise with stirring to a mixture of 4.2 g of lithium aluminium hydride in 60 ml of tetrahydrofuran. The mixture was refluxed for 4 h, cooled, treated dropwise with 10 ml of ethyl acetate, and then poured into 600 ml of cold 1% potassium hydroxide solution. The mixture was extracted with benzene–ether (5:1) and the extract was washed with water, dried, and concentrated to give 4.5 g of a brown oil. Chromatographic purification of the oil on 100 g of Florisil with benzene as the eluent gave, as the first band, 960 mg of a white solid. Several recrystallizations of this material from ether–benzene (3:1) gave 170 mg of isomer A of IX, m.p. 158.5–160°. The infrared absorption spectrum (in $CHCl_3$) shows bands at 2 780 and 2 700 cm^{-1} (characteristic of a *trans*-fused quinolizidine) and 1 708 cm^{-1} (C=O).

Anal. Calcd. for $C_{18}H_{23}NO_2$: C, 75.75; H, 8.12; N, 4.91. Found: C, 75.73; H, 8.20; N, 5.03.

Further elution of the column gave a mixture of substances followed by a second band of 850 mg of a solid. Recrystallization of this material from benzene–ether (3:1) gave 110 mg of isomer B of IX, m.p. 143.5–144°. The infrared spectrum (in $CHCl_3$) shows a peak at 1 705 cm^{-1} (C=O) and 2 790 cm^{-1} (poor resolution).

Anal. Calcd. for $C_{18}H_{23}NO_2$: C, 75.75; H, 8.12; N, 4.91. Found: C, 75.72; H, 7.90; N, 5.01.

Isomerization of 2,3,4,4a,6,7,11b,12,13,13a-Decahydro-9-methoxy-1H-dibenzo[a,f]quinolizin-1-one (IX); Isomer A to Isomer B

A solution of 28 mg of isomer A (m.p. 156–160°) in 5 ml of sodium methoxide solution (prepared from 25 mg of sodium and 5 ml of methanol) was refluxed under a nitrogen atmosphere for 2 h. The mixture was cooled and diluted with water, and the product extracted with ether. The ether extract was dried and concentrated, giving white crystals which were recrystallized from ether to give 17 mg of isomer B, m.p. 135–139° (mixed m.p. with isomer A, 125–130°, and mixed m.p. with pure isomer B, 136–140°).

ACKNOWLEDGMENT

This investigation was supported in part by research grants CY-2999 (C2 and C3) from the National Cancer Institute, Public Health Service.

THE Hg 6($^3P_1$) PHOTOSENSITIZED DECOMPOSITION OF CYCLOHEXENE VAPOR

G. R. De Maré, O. P. Strausz, and H. E. Gunning
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The reaction follows the pattern established for the triplet state reactions of olefins in general. The major products, ethylene, 1,3-butadiene, vinylcyclobutane, cyclohexane, various C_{12}-compounds, and polymer, can best be accounted for by the allylic C—H and C—C bond cleavage of the primary triplet biradicals and the ring closure and fragmentation reactions of the resulting open chain biradicals. At least three types of triplet state species must be involved in the mechanism. The rate equations, developed on the assumed mechanism, satisfactorily describe the observed product distribution and kinetic features of the system and permit the estimation of the elementary rate constant values and the lifetimes of the various transient biradicals involved. Preliminary experiments with cycloheptene indicate that vinylcyclopentane is an important product.

INTRODUCTION

It is well established that the interaction of triplet mercury atoms with olefinic hydrocarbons, through a π–π transition, results in the formation of a vibrationally excited triplet biradical. The main features of these processes along with the variety of reactions which these excited species may undergo have recently been reviewed by Cvetanović (1). Previous studies on monoolefins were mainly concerned with open chain molecules and among the cyclic structures only cyclopentene has been dealt with briefly (2). The basic differences in behavior between the linear and cyclic olefins arise from the fact that in the latter case the characteristic allylic C—C bond cleavage leads to an allylic-type biradical with widely separated free spins which, according to indications (2), exhibits some unique reactivity. To test the generality of the ring contraction reaction found for cyclopentene (2) and to get a deeper insight in its mechanism a detailed study was made of the cyclohexene reaction and a brief examination of the cycloheptene system.

EXPERIMENTAL

The static reaction system consisted of a cylindrical quartz cell, 2 cm long and 5 cm in diameter, connected to a differential manometer. A mercury float valve isolated the reaction system from a conventional high vacuum apparatus. The mercury resonance radiation source was a Hanovia 87A45 low-pressure Hg-lamp. The use of such a short reaction cell was necessitated by the gas chromatographic (g.c.) technique employed.* The absorption of the incident radiation was incomplete in this cell and furthermore it varied with gas pressure, owing to Lorentz broadening of the Hg-resonance line. It therefore became necessary to determine the amount of light absorbed in the cell as a function of substrate gas pressure. To this end a 1P28 photomultiplier tube, powered by a 225 V battery, and equipped with a 2 537 Å interference filter was placed behind the reaction cell at a distance of 3.8 cm. The light inlet to the photomultiplier was 1.3 cm in diameter.

The total response (T) of the photomultiplier was measured by freezing all mercury out of the cell with liquid nitrogen. The response (R) with Hg or with Hg + added gas was measured after time was allowed for equilibration. The difference ($T - R$) divided by T was then taken as a measure of the fractional absorption in the cell. Plots of $(1 - (R/T))$ vs. added gas pressure are given for propane and cyclohexene in Figs. 1 and 2 respectively. All the data reported here, unless otherwise stated, are corrected on this basis.

Light intensities, 3.0×10^{16} and 1.7×10^{15} quanta/s were determined by propane actinometry. A.P.I. cyclohexene, standard sample 522-5S, with a stated maximum impurity level of 0.023 ± 0.020 mole % was stored at -196 °C and used without further purification. Airco Assayed Reagent CO_2 was degassed

**Good resolution of the vinylcyclobutane, cyclohexane, and cyclohexene peaks could be obtained only with limited quantities of substrate.*

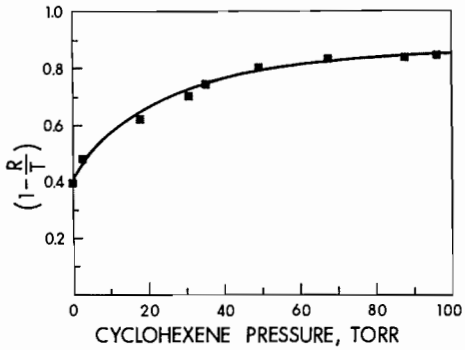

FIG. 2. Plot of fractional absorption, $(1 - (R/T))$, vs. cyclohexene pressure.

before use. Nitric oxide (Matheson C.P.) was purified by triple distillation from liquid oxygen. Ethane-d_6 (Merck) was thoroughly degassed by trap-to-trap distillation. Mass spectral analysis indicated the presence of ca. 2.5% C_2D_5H, but no other impurity could be detected by g.c. analysis on a silica gel column.

At the conclusion of irradiation the noncondensable products were removed at liquid nitrogen temperature by a Toepler pump, measured in a gas buret and subsequently analyzed by mass spectrometry for H_2 and C_2H_4. The remaining products and substrate were transferred to a g.c. unit for analysis. Good resolution of the C_2H_4, C_4H_6, vinylcyclobutane (VCB) and cyclohexane products, and the substrate was achieved on a 10 ft column of 20% diisodecyl phthalate on 60/80 Ultraport (A.W.). After each experiment the reaction vessel was cleaned by flaming.

With added CO_2 and C_2D_6, the addend and products noncondensable at -130 °C were removed and analyzed only for butadiene by g.c. as above. (C_2H_4 could not be separated from the large excess of added gas.) With the exception of VCB, the C_2 to C_6 products were identified by comparison of their mass spectra and g.c. retention value with those of authentic samples.

The characterization of VCB was made on the basis of mass spectrometric, infrared, and n.m.r. analysis.* The mass spectrum confirmed the molecular weight and the cracking pattern discounted the 1,5-hexadiene structure. The absence of allylcyclopropane was concluded from g.c. retention time measurements. The vapor phase infrared spectrum indicated the absence of methyl groups (1 385 ± 10 cm^{-1}) and the presence of a terminal vinyl group (1 820, 1 638, 1 420 – 1 440, 990, 910, etc. cm^{-1}). Strong methylene absorption was indicated by the broad bands at 2 880 and 2 975 cm^{-1}. The characteristic ν_{CH_2} ring vibration band at 900–950 cm^{-1} (3) was indicated by the absorption at 915 cm^{-1}, which, however, coincides with the δ_{CH} absorption of the terminal vinyl group at 910 cm^{-1}. The spectrum was entirely consistent with those obtained with an A.P.I. certified sample of vinylcylopentane, and reported for vinylcyclopropane (4). Now the presence of a double bond, the absence of methyl groups, and a molecular weight of 82, taken in conjunction with the mass spectral cracking pattern data, allow only two structural possibilities: vinylcyclobutane and methylene cyclopentane with a strong preference for the former.

The n.m.r. spectrum of this product determined in CS_2 using TMS as an internal standard was found to be consistent with the vinylcyclobutane structure but not with methylene cyclopentane. Thus the spectrum showed four multiplet resonances: a heptet centered at τ-value of 4.2 for the vinyl proton, two complex

**The synthesis of VCB has been reported by C. G. Overberger et al. J. Polymer Sci. Part A, 2, 755 (1964). The infrared and n.m.r. spectra are in good agreement with those reported here.*

For personal use only.

doublets of the terminal vinyl protons centered at $\tau = 5.1$, while the complex multiplets of the ring bridgehead proton and the ring methylene protons appeared at $\tau = 7.1$ and 8.1 respectively. Also the integrated peak areas were in the right proportions, that is 1:2:1:6.

Bicyclohexyl and the other C_{12} products were tentatively identified by g.c. retention time comparisons. Product determinations were obtained from calibrated g.c. peak areas with the exception of VCB in which case the detector response was based on cyclohexene. The vinylcyclopentane formed in the decomposition of cycloheptene was identified by comparison of its mass spectrum, infrared and n.m.r. spectra with those of vinylcyclopentane (A.P.I.). All runs reported were performed at 26 ± 2 °C.

RESULTS

The products of the reaction were hydrogen, acetylene, ethylene, 1,3-butadiene, VCB, cyclohexane, and bicyclohexyl. Traces of 1,3-cyclohexadiene were also detected. Two additional isomers of butadiene, in minor yields, as well as a heavy oil, mainly C_{12} compounds, were also found. A specific search for methane and ethane in the fraction noncondensable at −160° proved the absence of these materials. It is not possible to state with certainty that no C_6 isomers other than VCB were formed in the reaction since some of these isomers could have eluted from the g.c. column with the substrate which was always present in large excess. However, the fact that no inconsistency was observed in the results on successive reuse of the substrate recovered by g.c. would argue against this possibility. For a number of the possible C_6 isomers, the g.c. retention time values were specifically checked, and as a result their absence in the reaction mixture can be regarded as proved. These were: 1,3-, 1,5-, and 2,4-hexadiene; allylcyclopropane; bicyclo[2.1.1]-hexane; 1-methylcyclopentene; 1-hexyne; 2,3-dimethyl-1,3-butadiene; 2-ethyl-1,3-butadiene; and bicyclo[3.1.0]hexane. In all runs reported the ethylene yield includes a small amount of acetylene and the butadiene yield some C_4-isomers. However, ethylene and butadiene comprised over 95% of their respective fractions.

Five main series of experiments were carried out.

I. Product yields were studied as a function of substrate pressure at an incident light intensity of 3.0×10^{16} quanta/s. The results are shown in Fig. 3. At substrate pressures exceeding 20 Torr, the exposure time was 10 min while at the lower pressures it was proportionally shorter. As can be seen from the figure, the yield of ethylene equals that of butadiene except at pressures below ca. 10 Torr where a deficiency in the butadiene yield appears. The suppressing effect of pressure on the ethylene-, butadiene-, and VCB-forming reactions is evident from the data. The yield of cyclohexane on the other hand shows no pressure dependency above ca. 5 Torr.

II. The quantum yields of ethylene, butadiene, VCB, and cyclohexane at a substrate pressure of 26 Torr were examined as a function of exposure time. According to the data

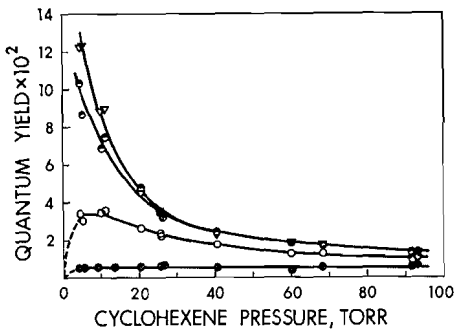

FIG. 3. Quantum yield for ethylene ▽, butadiene ◓, vinylcyclobutane ○, and cyclohexane ● formation as a function of cyclohexene pressure. $I_a = 3.0 \times 10^{16}$ quanta/s.

For personal use only.

appearing in Fig. 4 all of these species are primary reaction products. The quantum yield of cyclohexene disappearance, as determined directly from substrate consumption, was ca. 0.2. The difference between yields of substrate consumption and the combined yields of product formation was largely due to the formation of the oily polymer, bicyclohexyl, and other C_{12}-compounds, which were not determined quantitatively.

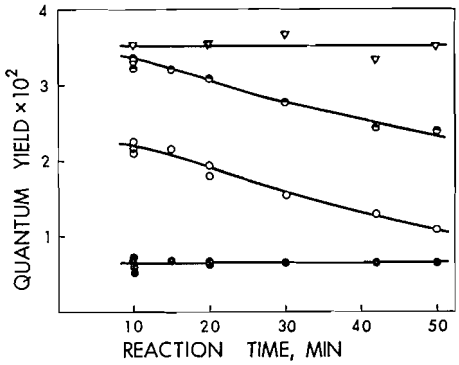

FIG. 4. Quantum yield for ethylene ▽, butadiene ◓, vinylcyclobutane ○, and cyclohexane ● formation as a function of exposure time.

III. To extend the range of pressure study which was limited by the low vapor pressure of the substrate, two series of experiments were performed with varying amounts of added inert gas at a constant pressure of cyclohexene. The data obtained with carbon dioxide as inert gas are presented in Fig. 5. and those with C_2D_6 in Fig. 6. For both cases a pressure effect similar to that found for cyclohexene itself is evident. The order of effectiveness in collisional deactivation for the three molecules is cyclohexene > C_2D_6 > CO_2.

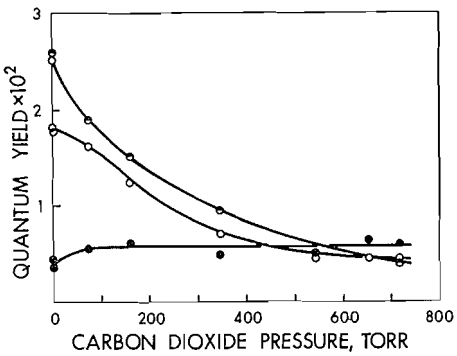

FIG. 5. Quantum yield of butadiene ◓, vinylcyclobutane ○, and cyclohexane ● formation as a function of added carbon dioxide pressure. P(cyclohexene) = 26 Torr. Uncorrected for incomplete absorption.

IV. To examine the effect of light intensity on the reaction, the pressure study with the pure substrate was repeated at the lower intensity of 1.7×10^{15} quanta/s. The results are plotted in Fig. 7. The reaction time was 100 min in experiments at pressures above 17 Torr, and 50 min at lower pressures.

V. Finally, a few experiments were done with a small amount of added nitric oxide. While cyclohexane formation was completely suppressed, the yields of butadiene and VCB were not affected by nitric oxide. In separate experiments carried out in a single pass

system, a white solid product deposited on the walls, which by infrared and n.m.r. analyses was found to be mainly cyclohexenone oxime.

DISCUSSION

The nature of the products, the lack of an inhibiting effect by nitric oxide on butadiene and VCB formation, and the kinetic characteristics of the reaction dictate that the primary reaction between triplet mercury atoms and cyclohexene molecules leads to a long-lived excited cyclohexene molecule, which on the basis of the generally accepted view on olefin reactions, is assumed to be a vibrationally excited triplet biradical. Also the pressure independence of the hydrogen and cyclohexane yields above ca. 30 Torr (cf. Figs. 3, 5, 6, and 7) suggests a minor paraffinic C—H scission by direct quenching at the methylene groups of the molecule. Thus the primary steps of the reaction may be represented by the sequence

[1a] $\quad Hg^* + \bigcirc \rightarrow Hg + \dot{\bigcirc}$

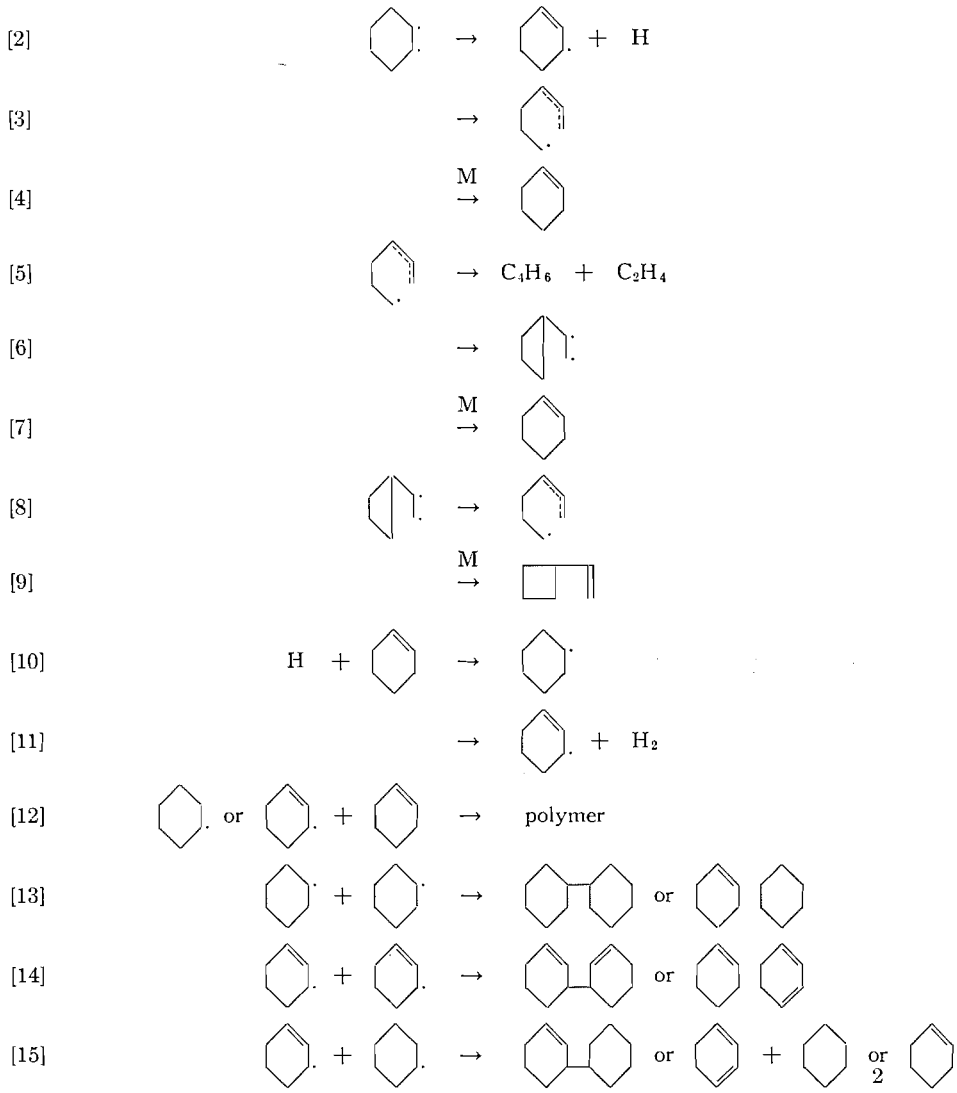
[1b] $\quad Hg^* + \bigcirc \rightarrow Hg + H +$ cyclo-$C_6H_9\cdot$

where cyclo-$C_6H_9\cdot$ represents a cyclohexenyl radical with the odd electron at the α- or β-position. It has been shown that paraffinic quenching reactions exhibit a large H/D kinetic isotope effect, but the olefinic reactions do not (5). Now if step [1b] is operative,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the quenching cross section of cyclo-C_6H_{10} should be somewhat larger than that of cyclo-C_6D_{10}. This was indeed borne out by experiment: $*\sigma_Q^2$(cyclo-C_6H_{10}) = 48.2 and σ_Q^2(cyclo-C_6D_{10}) = 42.9 Å^2 (6).

The following further reactions of the species formed in [1*a*] may be envisaged.



Step [2] is the familiar allylic C—H and [3] is the C—C bond cleavage which latter in the present case results in an open chain biradical with widely separated free spins. This open chain, resonance-stabilized biradical has an appreciable lifetime and may undergo unimolecular C—C bond cleavage yielding ethylene and butadiene, [5], or unimolecular isomerization to a triplet vinylcyclobutane, [6]. The mode of cleavage of the allylic biradical in step [5] was confirmed in studies on methyl-labelled cyclohexenes, currently in progress. Thus 4-methylcyclohexene and 3-methyl cyclohexene gave propylene + 1,3-butadiene, and ethylene + 1,3-pentadiene, respectively, in the corresponding reactions.

**For the lower olefins where the* Hg*—(C—H) *interaction is presumably negligible the following* σ_Q^2 *values were obtained:* C_2H_4 *(26.0 Å^2),* C_2D_4 *(25.5 Å^2),* C_3H_6 *(29.8 Å^2), and* C_3D_6 *(28.7 Å^2) (7, 5).*

For personal use only.

The overall reaction to $C_2H_4 + C_4H_6 - 1,3$ is exothermic to about 71 kcal (8) and since the lowest triplet state for butadiene has been estimated to lie 60 kcal above the ground state (9) it is possible that the observed deficiency in butadiene yield at low pressures is due to some triplet state reaction.

The fate of the triplet vinylcyclobutane biradical is either reversal to the open chain biradical, [8], or alternatively as with the other excited species present, collisional deactivation to the ground state [9]. Other modes of decomposition of the excited VCB may also be operative leading to some additional products which could have been lost in the analysis. Without product evidences, such reactions would be speculative and are therefore omitted from the mechanism. The appearance of hydrogen, cyclohexane, and the C_{12} compounds in the products as well as the formation of polymer would probably be adequately accounted for by steps [10] to [15].

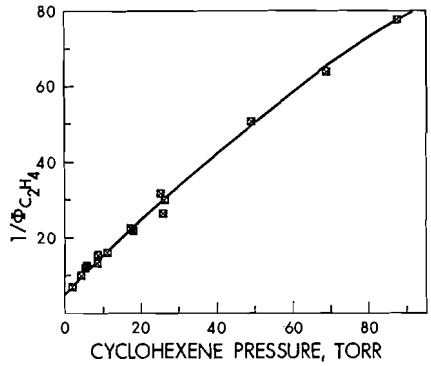

FIG. 8. Plot of $1/\Phi(C_2H_4)$ vs. cyclohexene pressure.

On the basis of a steady-state treatment of the above mechanism it can be shown that the plot of $1/\Phi(C_2H_4)$ vs. P, (Fig. 8), on extrapolation to $P = 0$, gives the expression:

$$[I] \qquad 1/\Phi(C_2H_4)_{at\ P=0} = 1 + \frac{k_2}{k_3},$$

from which $k_2/k_3 = 4.0$.

If the above mechanism is correct the following relation should also hold:

$$[II] \qquad P.\frac{R(C_2H_4)}{R(VCB)} = \frac{k_5k_8}{k_6k_9} + \frac{k_5}{k_6}.P,$$

where P is the substrate pressure.

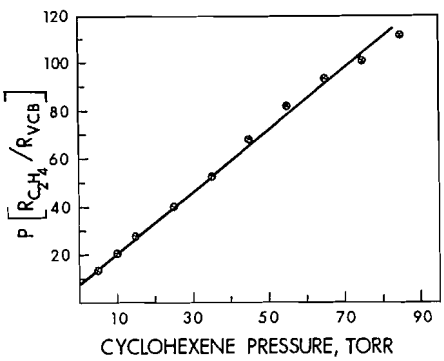

FIG. 9. Plot of $P[R(C_2H_4)/R(VCB)]$ vs. cyclohexene pressure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In Fig. 9 the L.H.S. of eq. [II] is plotted against pressure and a good linear relation is obtained. Rearranging [II] we obtain

$$[III] \qquad \frac{R(C_2H_4)}{R(VCB)} = \frac{k_5k_8}{k_6k_9}P^{-1} + \frac{k_5}{k_6}.$$

From the slopes of [II] and [III] (which can be obtained with better accuracy than the ordinate intersections) from a least-mean-squares calculation we obtain: $k_5k_8/k_6k_9 = 6.7_5$ Torr and $k_5/k_6 = 1.2_5$. Assuming perfect collision efficiency for all deactivation reactions and taking $k_4 = k_7 = k_9 = 1.0 \times 10^{-10}$ cc molecule^{-1} s^{-1}, k_8 equals 1.7×10^7 s^{-1} and the lifetime of the excited VCB molecule is 5.8×10^{-8} s. It should be pointed out that this value of k_8 includes the rate constant values of other modes of decomposition if operative.

For the yield of ethylene formation, (Φ), the steady-state treatment results in the following equation:

$$[IV] \qquad Ak_3k_5 - Bk_5 - Ck_3 - \alpha^2 = 0,$$

where $\alpha = k_4P = k_7P = k_9P$; $A = (\Phi)^{-1} - 5 - [4\alpha/(k_8 + \alpha)]$; $B = \alpha[0.80\alpha/(k_8 + \alpha) + 1]$; $C = 5\alpha$. Equation [IV] cannot be solved explicitly, but only by approximation, because the rate constant values, k_3 and k_5, exhibit a small pressure trend. In the pressure interval of 10 to 80 Torr, k_3 and k_5 have nearly equal values which monotonously increase with pressure from about 3×10^7 s^{-1} at 10 Torr to about 5×10^7 s^{-1} at 80 Torr. Taking the mean value we obtain $4 \pm 1 \times 10^7$ s^{-1}. (The approximation method would in actual fact tolerate a variation in the ratio k_5/k_3 from 1 to 4.) Thus the lifetimes of the vibrationally excited triplet cyclic biradicals formed in [1*a*] and the open chain allylic biradicals formed in [3] are 0.5×10^{-8} and 1.4×10^{-8} s, respectively, which values are close to that obtained for the excited vinyl cyclobutane molecule, 5.8×10^{-8} s. The reason for the apparent small pressure trend in k_3 and k_5 is not clear but in addition to a systematic experimental error the following possibilities should be considered: *a*) in the estimation of $\Phi(C_2H_4)$ step [1*b*] was neglected which introduces a small systematic error in the calculation; *b*) the calibration of g.c. detector response for VCB was based on cyclohexene; *c*) the assumption that $k_4 = k_7 = k_9$ may not be valid and also their numerical value was chosen arbitrarily; *d*) some other reactions not considered in the mechanism may be operative; *e*) finally, the exposure time dependence of some of the products could not properly be taken into consideration.

Substituting the values of k_5 and k_3 in the ratios $k_5/k_6 = 1.2_5$ and $k_2/k_3 = 4.0$, we obtain $k_6 = 3.2 \times 10^7$ s^{-1} and $k_2 = 1.6 \times 10^8$ s^{-1} and for the lifetimes, $\tau_6 = 3.1 \times 10^{-8}$ and $\tau_2 = 6.3 \times 10^{-9}$ s. If we consider the rate constant values per bond we conclude that C—H cleavage is twice as fast as C—C cleavage, in spite of the fact that the C—C bond is the weaker. This indicates a higher frequency factor for the hydrogen-scission reaction.

It may be instructive now to compare the lifetimes for the various excited species obtained here to those available in the literature for 1-butene (10) and 2-butene (11). The relevant data are summarized in Table I. The species listed have equal total excitation energies (electronic + vibration) of 112.7 kcal, the electronic energy of Hg $6(^3P_1)$ atom, and all lifetimes were obtained on the generally accepted, but experimentally yet unverified, assumption that every collision of the excited species leads to deactivation, i.e. complete loss of reactivity. If we take τ to be inversely proportional to the number of available allylic bonds in the radical and take τ(C—C)/τ(C—H) = 2, we obtain a 'normalized' lifetime value for the triplet molecules which is taken as the reciprocal of the ratio of rate constants for the allylic C—C cleavage to the number of allylic C—C

TABLE I

Lifetime values for excited triplet olefins

Process	τ (s $\times 10^9$)	τ(normalized) (s $\times 10^9$)
C_2H_5—$\dot{C}H$—$\dot{C}H_2$ → decomposition	6.3	32
CH_3—$\dot{C}H$—$\dot{C}H$—CH_3 → decomposition	3.3	40
→ decomposition	5.0	50(100)*
→ decomposition	58	232

*This value was obtained by taking $k_3 = 2.0 \times 10^7$ and $k_5 = 8.0 \times 10^7$ s^{-1}.

bonds in the molecule. It is seen from the table that these normalized τ-values are nearly equal for the two butenes, 1.3 to 3 times larger for cyclohexene and still higher for VCB. The higher values for the latter two can be explained by the increased number of bonds present. However, it is not clear why the normalized lifetime of VCB is so much larger than that of cyclohexene.

A preliminary study on cycloheptene has indicated that this reaction is considerably more complicated than with the smaller ring homologs. The reaction products are more numerous and there are at least four isomeric C_7H_{12} compounds formed in comparable yields, one of which is vinylcyclopentane.

Combining the results of the present study with those obtained earlier on the cyclopentene reaction it may be concluded that ring contraction is a general, characteristic reaction of cyclic monoolefins, and that the mechanism of this reaction involves an allylic-type, open-chain triplet biradical with widely separated free spins.

ABSTRACT

Two methods of preparing diethyl(diphenylphosphinyl)aluminium have been investigated. This compound exists as a dimer which can be cleaved to monomeric complexes by a variety of Lewis bases. The structure of the dimer and its chemical transformations are discussed.

INTRODUCTION

Considerable effort has been expended examining the chemistry of inorganic molecules which are isoelectronic with olefins. These studies have involved the formation of compounds by the bonding of an atom from group III with one from group V of the periodic table, both atoms often carrying organic substituents. Interest has centered on the chemical and physical properties of such systems but it has focused especially on the nature of the bonding between the group III and group V atoms. The major efforts in this area have involved studies of the B—N system (mainly trimeric) (1) and the B—P system (mainly trimeric) (2). Less is known about the Al—N system (3, 4). No "double bonding" has been observed to date.

When our work was started only three reports could be found on the chemistry of compounds containing aluminium–phosphorus bonds. Davidson and Brown (5) observed that trimethylphosphine and trimethylaluminium formed a stable adduct which eliminated methane, but only at high temperatures, to form dimethyl(dimethylphosphinyl)-aluminium, $Me_2Al—PMe_2$.[5] This compound was reported to be trimeric and not subject to cleavage by trimethylamine or dimethyl ether. In 1960 Burg and Mödritzer (6) attempted to prepare dimethylphosphinylalane, $Me_2P—AlH_2$, by a variety of methods but failed. Fritz and Trenczek (7) found that treatment of aluminium chloride with lithium diethylphosphide afforded dichloro(diethylphosphinyl)aluminium. They reported that this substance existed as a trimer but it must be noted that this conclusion was based on cryoscopy in phosphorus oxychloride, a solvent with which the compound in question reacted, albeit slowly.

Our purposes in studying the chemistry of aluminium–phosphorus compounds were: 1, to develop useful and general methods of synthesis of the compounds; 2, to investigate the nature of the bonding in these systems; and 3, to study the chemical behavior of aluminium–phosphorus compounds. Since the ultimate goal of most of the work in this field has been to detect the presence or absence of double bonding in the inorganic systems,

that became one of our goals as well. There was virtually no information available about the chemical properties of the aluminium–phosphorus compounds. In fact, most compounds reported were, at best, poorly characterized and nothing was known of their reactions.

RESULTS

In our study of the chemistry of aluminium–phosphorus compounds we decided to use diethyl(diphenylphosphinyl)aluminium (I), $Et_2Al—P(Ph)_2$, as our model compound. This choice was dictated primarily by the availability of starting materials but it was thought its chemistry would be typical nonetheless.

Lithium diphenylphosphide was required for one of our synthetic approaches to I. The only previous reports regarding the preparation of lithium diphenylphosphide involved either the cleavage of triphenylphosphine with metallic lithium (8) or the reaction of phenyllithium with diphenylphosphine (9). The former method has the distinct disadvantage of cost and the presence of phenyllithium. The latter method is tedious since the diphenylphosphine usually has to be prepared from the metal phosphide or from diphenylphosphinous chloride (8, 10). Methods are known for the preparation of sodium or potassium diphenylphosphide directly from the diphenylphosphinous chloride (11, 12) but these involved the use of the molten metals.

It was found that metallic lithium would react with diphenylphosphinous chloride in tetrahydrofuran solution to afford lithium diphenylphosphide. This reaction appeared to be rather specific in that it would not occur in diethyl ether or in dioxane solution. A convenient method of assaying for the phosphide was to react an aliquot with methyl iodide and isolate the diphenyldimethylphosphonium iodide. By this method, it was determined that the yield of the phosphide was normally 95%. The diphenylphosphinous chloride was shown not to react under these conditions. The solution of phosphide was stable for several hours and gave no indication of reacting with the solvent (13).

Diphenylphosphine at first was prepared according to literature procedures by the reduction of diphenylphosphinous chloride with lithium aluminium hydride (10). However, this reduction took place in only 47–67% yields. We found that conversion of the chloride into lithium diphenylphosphide followed by treatment of the latter with gaseous hydrogen chloride until the color of the phosphide was discharged led to the formation of diphenylphosphine in 83% overall yield. No attempt was made to maximize this yield. These methods developed for the synthesis of diphenylphosphine and lithium diphenylphosphide are much simpler, experimentally, than those presently in the literature (14). In addition, the yields are high and the products uncontaminated. They appear to be the methods of choice.

Reaction of lithium diphenylphosphide with diethylaluminium bromide (15) gave lithium bromide (91%) and an amorphous tetrahydrofuran etherate of I. Reaction of the potassium diphenylphosphide with diethylaluminium bromide initially afforded uncomplexed I but crystallization from ether gave an etherate of I. Issleib and Deylig (12) first carried out this reaction and obtained the etherate directly. Microanalytical data indicated that the etherate was converted to its uncomplexed dimer before analysis. However, ethane analysis and cryoscopy in benzene confirmed the monomeric etherate structure.

[1] $$Ph_2P^-Li^+ + Et_2AlBr \rightarrow Ph_2P—AlEt_2 + LiBr.$$

Mixing diphenylphosphine and triethylaluminium either neat or in a solvent led to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the instantaneous evolution of ethane and the formation of dimeric diethyl(diphenylphosphinyl) aluminium (eq. [2]). The dimer gave satisfactory aluminium and phosphorus analyses but the carbon and hydrogen values were consistently low, probably due to hydrolysis. The compound also gave satisfactory ethane analyses and cryoscopy in benzene confirmed the dimeric structure.

[2] $$Et_3Al + Ph_2PH \rightarrow [Et_3\bar{A}l—\overset{+}{P}HPh_2] \rightarrow Et_2Al—PPh_2 + EtH.$$

The dimer of I was very sensitive to moisture. Protolysis with ethanol then water led to the evolution of ethane and the formation of diphenylphosphine. The latter was not isolated as such but was permitted to oxidize during the work-up to diphenylphosphinic acid. The yield of this acid could be increased by the addition of dilute hydrogen peroxide to the hydrolysis mixture prior to work-up. The dimeric structure could be cleaved by the action of a variety of Lewis bases. Simple crystallization of the dimer from diethyl ether at low temperatures led to the isolation of the diethyl etherate of monomeric I. This sample was identical to one prepared directly from diethylaluminium chloride and potassium diphenylphosphide (12).

In a similar manner the dimer (I) reacted with acridine to form a 1:1 complex between the acridine and the monomeric aluminium–phosphorus compound. This complex was an amorphous material but after purification it gave satisfactory phosphorus, aluminium, and ethane analyses. The dimer appeared to form complexes with a variety of amines but most were not crystalline. Evidence was obtained for some reaction between the dimer and trimethylamine in the form of a color change but only unreacted dimer could be isolated from the reaction mixture.

The dimer (I) was cleaved readily by *n*-butyllithium to *n*-butyldiethylaluminium and lithium diphenylphosphide. The presence of the latter was confirmed by trapping it in a reaction with iodobenzene to form triphenylphosphine (eq. [3]). Authentic lithium diphenylphosphide was shown to afford triphenylphosphine upon reaction with iodobenzene. The dimer was shown not to react with iodobenzene.

[3] $$\underset{\text{I}}{Et_2Al—P(Ph)_2} + C_4H_9Li \rightarrow Et_2AlC_4H_9 + (Ph)_2P^-Li^+ \xrightarrow{Ph—I} (Ph)_3P$$

Diethyl(diphenylphosphinyl)aluminium (I) also was shown to react with methyl iodide and the resulting diphenyldimethylphosphonium iodide was isolated in 90% yield. No attempt was made to isolate the aluminium-containing product.

DISCUSSION

When we began our work on the aluminium–phosphorus system the only known compounds of this type, $Me_2Al—P(Me)_2$ (5) and $Cl_2Al—P(Et)_2$ (7), had been reported to be trimeric. These observations appeared somewhat anomalous in view of Gillespie's arguments that valency-angle deformation from the tetrahedral (109°) hybridization to a square (90°) hybridization should occur rather readily with elements of the second and lower periods (16). Nonetheless, only trimeric aluminium–phosphorus compounds had been reported, those presumably having a six-membered ring structure.

Since our work was undertaken there have been three publications, including this one, reporting studies on aluminium–phosphorus compounds. Interestingly, all three of these independent reports indicated that the substances under study existed as *dimers* rather than trimers as had been reported earlier. Issleib and Deylig (12) prepared $Et_2Al—P(Et)_2$, Coates and Graham (17) prepared $Me_2Al—P(Ph)_2$, and we have prepared $Et_2Al—P(Ph)_2$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

It should be noted that Issleib and Deylig (12) earlier had failed to obtain the dimer of $Et_2Al—P(Ph)_2$ and had reported only the monomeric etherate. It would appear that the recent trend in the aluminium–phosphorus compounds is in accord with Gillespie's arguments (16) favoring the dimeric structures as the most common.

The aluminium atom in the dialkyl(disubstitutedphosphinyl)aluminium compounds obviously is very acidic and tends to be complexed by a Lewis base. In spite of the presence of an adjacent phosphorus atom with an unshared pair of electrons potentially available for sharing with the vacant orbital of aluminium, thereby satisfying the electron demand of the aluminium, there has been no evidence provided for the existence of a free monomeric structure (III). In other words, there is no evidence to indicate that multiple bonding exists in the aluminium–phosphorus series.

$$R_2Al—\ddot{P}R_2 \leftrightarrow R_2\bar{A}l=\overset{+}{P}R_2$$

III

Instead, the compounds dimerize (e.g. IV) and a phosphorus atom acts as a Lewis base to complex with the aluminium atom of another molecule, both atoms probably being tetrahedrally hybridized. This apparent lack of double bonding is in spite of the fact that the size relationship of the two atoms, phosphorus and aluminium, should be favorable for overlap and double bonding. Lack of appreciable overlap may be due to the hybridization of the two atoms being incompatible with pi bonding.

We have been able to demonstrate that the dimer of I is readily converted into the monomeric etherate. It appears that the ether is sufficiently nucleophilic to displace the diphenyl(diethylaluminio)phosphine molecule as a complexing group for the other aluminium atom (eq. [4]). Such was not the case for the tetraethyl analog of IV, $(Et_2Al—PEt_2)_2$, since Issleib and Deylig (12) reported obtaining only the dimer with no mention made of a monomeric etherate. This is to be expected since the diethylphosphorus group in the latter case should be a stronger nucleophile than the diphenylphosphorus group in IV and more difficult to displace with ether.

[4] $$\underset{\text{IV}}{\begin{matrix}Et_2Al—P(Ph)_2\\ \diagdown\ \diagup\\ (Ph)_2P—Al(Et)_2\end{matrix}} \xrightarrow{Et_2O} \left[\begin{matrix}Et_2Al—P(Ph)_2\\ \diagdown\\ (Ph)_2P—Al(Et)_2\\ \uparrow\\ Et—O—Et\end{matrix}\right] \xrightarrow{Et_2O} 2\ \begin{matrix}Et_2Al—P(Ph)_2\\ \diagdown\\ Et—O—Et\end{matrix}$$

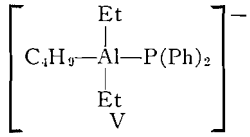
It was somewhat surprising to find that our dimer (IV) appeared to react only slightly with trimethylamine, a stronger nucleophile than ether. Under no conditions could a stable complex be isolated. In contrast, Coates and Graham (17) reported that $Me_2Al—P(Ph)_2$ would complex with trimethylamine (stable to 65°) but there was no indication of the stoichiometry of the product. We did find, however, that acridine would cleave the dimeric form of I and form a stable complex with the monomeric form. It may be that the steric requirements of a trimethylamine complex were too large and that acridine, while even less basic, does have a lower steric requirement.

Very little work has been published on the reactions undergone by aluminium–phosphorus compounds. We have found that diethyl(diphenylphosphinyl)aluminium (I) is very sensitive to moisture. Hydrolysis of I led to the initial cleavage of the aluminium–carbon bonds and then to the cleavage of the aluminium–phosphorus bond, resulting in the formation of ethane and diphenylphosphine. In view of our observations on the hydrolytic instability of I it is interesting to note that Fritz and Trenczek (18) recently reported, in a communication devoid of experimental data, that $H_2Al—P(Et)_2$, thought

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

to exist as a trimer, was stable in the atmosphere. This is particularly surprising since the indications from all previous work on aluminium–phosphorus compounds are that all of these compounds are very moisture sensitive.

We have found that I is subject to cleavage by other nucleophiles, especially organolithium reagents. Reaction of I with *n*-butyllithium apparently proceeded by nucleophilic attack of the butyl carbanion on the aluminium atom resulting in the formation of *n*-butyldiethylaluminium and lithium diphenylphosphide (eq. [3]). Since the solution containing the colorless dimer acquired the orange coloration typical of the diphenylphosphide anion immediately upon the addition of *n*-butyllithium and it exhibited reactions characteristic of that anion (reaction with iodobenzene to form triphenylphosphine), it appears unlikely that an intermediate of the type V had an appreciable lifetime. This observation is somewhat surprising in view of the acidity of the aluminium atom. However, credence was lent to our observation by the recent report that $Et_3Ge—P(Ph)_2$ reacted similarly, affording *n*-butyltriethylgermane and the diphenylphosphide ion (19).



In accord with the observation initially made by Issleib and Deylig (12) we have confirmed that the aluminium–phosphorus bond is cleaved readily by methyl iodide, compound I forming diphenyldimethylphosphonium iodide and, presumably, diethyliodoaluminium. Again the reaction is not unique for the aluminium–phosphorus system since $Et_3Ge—P(Ph)_2$ was cleaved in an analogous manner (19). These cleavages most likely occurred by initial quaternization of the phosphorus atom followed by nucleophilic attack of the iodide on the aluminium or germanium atom (eq. [5]).

[5] $$Et_2Al—P(Ph)_2 + MeI \rightarrow [Et_2Al—\overset{+}{P}(Me)(Ph)_2\ I^-] \rightarrow Et_2Al—I + MeP(Ph)_2,$$
$$MeP(Ph)_2 + MeI \rightarrow Me_2\overset{+}{P}(Ph)_2\ I^-.$$

EXPERIMENTAL

General Manipulative Methods

All operations were carried out under a blanket of oxygen-free nitrogen. Mechanical manipulations were done in a nitrogen-filled plastic "dry bag" (available from I²R, Inc., Cheltenham, Penna.). All solvents were meticulously purified and dried by standard procedures. Molecular weights were determined cryoscopically in benzene. It was necessary to degas the solvent thoroughly before use. Samples for elemental analysis were first oxidized with sodium peroxide in a Parr bomb. The oxidation solution was acidified with nitric acid, then an aliquot was analyzed for phosphorus essentially as described by Bachofer and Wagner (20). A second aliquot was analyzed for aluminium using the 8-hydroxyquinoline reagent in a standard manner. Ethane analyses were carried out by treating the compounds with *n*-butyl alcohol then 6 *N* hydrochloric acid and determining the volume of the liberated ethane.

Aluminium Starting Materials

Ethylaluminium sesquibromide was obtained by the procedure of Grosse and Mavity (15) in 73% yield as a colorless liquid, b.p. 140° (10 mm).

Using the procedure of the same authors we obtained diethylaluminium bromide in 75% yield as a colorless liquid, b.p. 64° (1.0 mm).

Anal. Calcd. for $C_4H_{10}AlBr$: Al, 16.35; Br, 48.5; ethane, 35.7. Found: Al, 15.65; Br, 48.0; ethane, 34.9.

Triethylaluminium was at first prepared by treatment of diethylaluminium bromide with sodium (15) but was later purchased from Texas Alkyls, Inc. It was redistilled as a colorless liquid, b.p. 54° (0.5 mm).

Anal. Calcd. for $C_6H_{15}Al$: ethane, 83.6. Found: ethane, 83.4.

Lithium Diphenylphosphide

To a stirred slurry of 2.0 g (0.29 g-atoms) of finely divided lithium metal in 250 ml of dry tetrahydrofuran was added 25 g (0.11 mole) of diphenylphosphinous chloride over a period of 30 min. After heating under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

reflux for 30–45 min the solution was siphoned away from the excess lithium and stored under nitrogen until needed. To 1.0 ml of the above orange solution was added excess methyl iodide in 2 ml of THF. The color rapidly disappeared and a colorless precipitate appeared simultaneously. After the mixture was warmed for a few minutes under a hot water tap the precipitate was filtered and dried. The yield of diphenyldimethyl phosphonium iodide was 0.135 g (95%) and it crystallized from ethanol–water as colorless needles, m.p. 240° (lit. (21) m.p. 241°).

Diphenylphosphine

To the stored solution of lithium diphenylphosphide prepared exactly as described above was added gaseous hydrogen chloride through a straight bore adapter until the orange color of the phosphide had just disappeared. A distillation head was then attached to the flask and the THF was removed. Distillation under vacuum afforded 17.5 g (83%) of diphenylphosphine as a colorless liquid, b.p. 84–86° (0.5 mm), n_D^{20} 1.6279, λ_{max} 4.5 μ (lit. (21) b.p. 280°).

Diethyl(diphenylphosphinyl)aluminium (I)

A solution of lithium diphenylphosphide was prepared as described above from 20.9 g (0.095 mole) of diphenylphosphinous chloride and 3.8 g (0.55 g-atom) of lithium. To this stirred solution was gradually added 15.6 g (0.095 mole) of diethylaluminium bromide, during which time the color faded to a golden yellow. The solvent was evaporated and replaced by benzene then the lithium bromide (7.5 g, 91%) was removed by filtration. Evaporation of the benzene left an oily residue which was taken up in ether. After 24 h a precipitate appeared which could not be recrystallized and which did not afford a satisfactory melting point.

Anal. Calcd. for $C_{16}H_{20}AlP \cdot C_4H_8O$: Al, 7.9; P, 9.06. Found: Al, 7.76; P, 8.1.

To a cold solution of 8.25 g (0.05 mole) of diethylaluminium bromide in 120 ml of diethyl ether was added slowly 20 g (0.05 mole) of $(Ph)_2PK \cdot (dioxane)_2$ (9). After the mixture was stirred for 2 h the potassium bromide was removed by filtration and the ether filtrate evaporated, leaving 8.0 g (60%) of crude diethyl-(diphenylphosphinyl)aluminium (I), m.p. 121–122°. The solid crystallized from diethyl ether at −70° as colorless needles of the monomeric diethyl etherate of I, m.p. 148° (lit. (12) m.p. 151°).

Anal. Calcd. for $C_{16}H_{20}AlP \cdot (C_2H_5)_2O$: P, 9.02; Al, 7.85; mol. wt. 344; ethane, 16.8. Found: P, 11.31; Al, 9.66; mol. wt. 340, 358, 340, 345; ethane, 16.6.

To 15.1 g (0 081 mole) of diphenylphosphine cooled to 0° was added, with stirring, 9.27 g (0.081 mole) of triethylaluminium over a period of 30 min. Some gas was evolved but the rate of evolution increased when the temperature was raised to 90°. After 2 h at this temperature the oily mass solidified. The crude solid (21 g, 96%) was taken up in warm benzene, then the dimer of diethyl(diphenylphosphinyl)aluminium (I) was crystallized as colorless needles upon the addition of petroleum ether, m.p. 124–126°.

Anal. Calcd. for $(C_{16}H_{20}AlP)_2$: C, 71.2; H, 7.42; P, 11.5; Al, 10.0; mol. wt. 540; ethane, 21.5. Found: C, 66.6; H, 6.74; P, 11.39; Al, 9.96; mol. wt. 540, 550, 555; ethane, 20.9.

Dimeric I was dissolved in a minimum of warm diethyl ether. After cooling for 1 day the monomeric etherate of I crystallized as colorless needles, m.p. 148–150°, shown to be identical to the sample prepared above by admixture melting point and a comparison of the infrared spectra.

To a solution of 5.0 g of the dimer (I) in 25 ml of benzene was added 3.4 g of freshly sublimed acridine. The solution became a green-brown but it was warmed gently until all of the acridine had dissolved. After the solution stood overnight at room temperature the benzene was evaporated *in vacuo* and the residue was washed with a benzene – petroleum ether solution to remove unreacted acridine. Additional unreacted acridine was removed by heating the residue to 120° *in vacuo*. The presumed complex of monomeric I and acridine remained as a black porous solid, m.p. 130–145°.

Anal. Calcd. for $C_{29}H_{29}AlPN$: Al, 6.03; P, 6.91; ethane, 12.92. Found: Al, 5.95; P, 6.67; ethane, 13.0.

Hydrolysis of I

A solution of 3.0 g of I in 5 ml of benzene was treated with 10 ml of ethanol then 20 ml of water. A very strong phosphine odor was evident. The solvent mixture was replaced with pure benzene and this solution was extracted with dilute sodium hydroxide. Acidification of the aqueous layer afforded 0.4 g (20%) of crude diphenylphosphinic acid, m.p. 175–190°. The acid crystallized from ethanol–water as colorless needles, m.p. 190–193° (lit. (21) m.p. 195°). The yield of acid was increased to 43% when the additon of water was followed by the addition of 10% aqueous hydrogen peroxide.

Reaction of I with Methyl Iodide

To a solution of 5.0 g (9.3 mmoles) of dimeric I in 10 ml of cold benzene was added 11.5 g of methyl iodide. No visible reaction occurred but upon allowing the mixture to warm to room temperature and stand overnight a mass of colorless needles precipitated. When the supernatant liquid was treated with ethanol or dilute hydrochloric acid a gas was evolved. The precipitate was filtered, affording 7.0 g (90%) of crude diphenyldimethylphosphonium iodide, m.p. 235–239° (lit. (21) m.p. 241°).

Reaction of I with n-Butyllithium

To a solution of 6.0 g (0.22 mole) of I in 10 ml of benzene was added 0.07 mole of *n*-butyllithium in 20 ml of hexane. The solution immediately became yellow and the color darkened to orange with gentle warming.

A 10 ml aliquot of this solution was treated with excess iodobenzene whereupon the orange color gradually disappeared. The addition of ethanol and then water led to the evolution of a gas. The organic layer was separated, the aqueous layer extracted with benzene, and the combined organic layers were chromatographed on alumina to afford 0.7 g (38%) of crude triphenylphosphine, m.p. 65–72°. The phosphine crystallized from benzene–ethanol as colorless plates, m.p. 77–78°. It was identified by admixture melting point with an authentic sample, a comparison of its infrared spectrum with that of an authentic sample, and oxidation to triphenylphosphine oxide, m.p. 151–152°.

ACKNOWLEDGMENTS

We gratefully acknowledge the financial support of the Olin Mathieson Chemical Corporation throughout this work. We would like to thank the Victor Chemical Division of the Stauffer Chemical Co. for generous gifts of diphenylphosphinous chloride. The senior author acknowledges his personal debt to an inspiring teacher, Reuben B. Sandin.

PHOTOCHEMICAL TRANSFORMATIONS OF SOME 4′-AMINO-2-STYRYLPYRIDINES AND THEIR SALTS

J. L. R. Williams, J. M. Carlson, R. E. Adel, and G. A. Reynolds

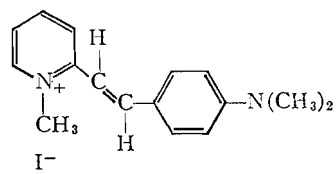
ABSTRACT

The photochemical behavior of 4′-amino-, 4′-dimethylamino-, 4′-diethylamino-, and 4′-di-*n*-propylamino-substituted *trans*-2-styrylpyridine were studied. Ultraviolet irradiation of aqueous solutions of the bishydrochlorides and methiodide–hydrochlorides for moderate periods of time produced mixtures of the corresponding *cis* and *trans* isomers. Long irradiation times produced the corresponding dimers in all cases except that of *trans*-4′-di-*n*-propylamino-2-styrylpyridine. The *cis* isomers of the free bases and methiodides were isolated from the *cis–trans* mixtures. The *trans*-methiodides are not photochemically labile. The spectra of each pair of isomers were determined in water and in 50% methanol–water, with the exception of the 4′-di-*n*-propylamino derivative, which is not sufficiently water soluble. In addition, the spectra of the corresponding methiodides, hydrochlorides, bishydrochlorides, and methiodide–hydrochlorides were determined. The basic strengths of the nitrogens in the *cis–trans* isomer pairs of the free bases and methiodides have been determined spectroscopically in water and in 50% methanol–water.

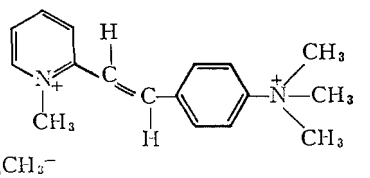
INTRODUCTION

Earlier papers (1, 2) discussed the photoisomerization and photodimerization of some substituted styrylpyridines. When dimethylamino groups were placed in the 4′-position (4-position in the phenyl group), dimerization of *trans*-2-styrylpyridine methiodide (I*a*) in the solid state did not take place.



I*a*

This effect appearing in the solid state was attributed to improper spacing of the double bonds in the crystal lattice. The corresponding bismethosulfate (XII) did, however, photodimerize in the solid state.



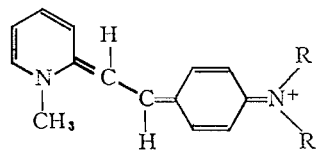
$SO_4CH_3^-$ XII

Furthermore, dimerization and photoisomerization of *trans*-4′-dimethylamino-2-styrylpyridine methiodide (I*a*) and *trans*-5-ethyl-4′-dimethylamino-2-styrylpyridine (XI) failed to occur in aqueous solution. On the other hand, the 4′-methyl- and 4′-methoxyl-substituted *trans*-2-styrylpyridine methiodides gave *cis–trans* mixtures and dimers when irradiated in water solution. The photochemical behaviors of the hydrochlorides of the

monobasic styrylpyridines were analogous to those of the monoquaternary salts (2). Tables I and II summarize the symbols which represent the various derivatives studied in the present work.

DISCUSSION

The fact that I*a*, II*a*, and III*a* do not photoisomerize in solution suggests that extreme structures in which the ethylenic double bonds do not exist as such contribute greatly to the ground state of the molecules. One such example would be:



I⁻

I*a*–III*a*.

The lack of double-bond character at the ethylenic bond could be responsible for the failure of I*a*, II*a*, and III*a* to undergo photochemical change.

In the present work the spectra and photochemical behavior of 4′-dimethylamino-2-styrylpyridine (I), 4′-diethylamino-2-styrylpyridine (II), 4′-(di-*n*-propyl)-2-styrylpyridine (III), 4′-amino-2-styrylpyridine (IV), and their salts were studied. A second purpose was to study the base strengths of the *cis* and *trans* isomers prepared during the work. Base strengths were determined by the method of Hammett (3), as modified for difunctional compounds by Rosenblatt (4). The use of the Rosenblatt scheme was necessary, since during determinations of base strength the monohydrochlorides I*b* to IX*b* never exist in their pure form. The wavelengths of λ_{max} and molecular extinction coefficients of these monohydrochlorides were obtained from the ultraviolet absorption curves measured at various values of pH and by calculation. Both the spectra and the base strength values were determined in water and in 50:50 methanol–water, since III is not water soluble. Table I summarizes the ultraviolet absorption data of the *trans* forms of the free bases and salts of I, II, III, and IV. The free bases (I–IV) show wavelengths of λ_{max} in the range of 337–380 mμ, whereas the *trans*-methiodides (I*a*–IV*a*) and *trans*-monohydrochlorides (I*b*–IV*b*) show corresponding absorptions in the range of 385–470 mμ. Under the same conditions, the *trans*-bishydrochlorides (I*c*–IV*c*) and the *trans*-methiodide–hydrochlorides (I*d*–IV*d*) show wavelengths of λ_{max} in the range of 324–328 mμ. Thus, it appears that the ethylenic linkage in the *trans* free bases (I–IV), the *trans*-bishydrochlorides (I*c*–IV*c*), and the *trans*-methiodide–hydrochlorides (I*d*–IV*d*) possesses greater double-bond character than in the *trans*-methiodides (I*a*–IV*a*) and monohydrochlorides (I*b*–IV*b*). As a result, photochemical change takes place when compounds I–IV, I*c*–IV*c*, and I*d*–IV*d* are irradiated. The unsubstituted salt, *trans*-2-styrylpyridine methiodide (V*a*), absorbs at a wavelength of λ_{max} of 340 mμ. In all the other cases we have examined, including 4′-CH_3–, 4′-OCH_3–, 4′-chloro-, and 4′-nitro-substituted *trans*-2-styrylpyridine methiodides, a bathochromic shift of the wavelength of λ_{max} occurred upon introduction of a substituent into the 4′-position of *trans*-2-styrylpyridine methiodide (V*a*). The charged group —$\overset{+}{H}N(CH_3)_2Cl^-$ caused the reverse effect, a hypsochromic shift due to the high electrophilicity of the positive group. A similar difference was noted by Phillips (5) between the spectra of the bismethiodide of *trans*-4′-dimethylamino-2-styrylpyridine (I), I, and I*a*.

The values of the red shifts produced in the *trans*-methiodides (I*a*–IV*a*) when the

*Calculated. The monohydrochlorides do not exist as such in dilute acid solution, since they are in equilibrium with free base and bishydrochloride. Their complete ultraviolet absorption curves cannot be determined but the values of λ_{max} and their corresponding molecular extinction coefficients can be determined by calculation.

alkyl group of the amino group was changed from hydrogen to methyl, ethyl, and propyl are 45 mμ, 64 mμ, and 67 mμ. Thus, there seems to be very little steric interference of the dialkylamino groups with the phenyl ring, and coplanarity of the dialkylamino groups and the phenyl ring is possible. The molecular extinction coefficients increase in the same order. On the basis of absorption spectra, the methyl group appears to be less effective in promoting the release of electrons into the conjugated system via the amino nitrogen than does ethyl or propyl.

Furthermore, there is little or no solvent shift when the spectra of I*c*–IV*c* and I*d*–IV*d* are determined in water or in 50% methanol–water. The localized electron pairs of the amino groups of I–IV, I*a*–IV*a*, and I*b*–IV*b* do participate in solvent interactions, as evidenced by the shifts of wavelengths of λ_{max}. These species, I*a*–IV*a* and I*b*–IV*b*, undergo photochemical change only after extremely long irradiation times. Since the species I–IV,

I*c*–IV*c*, and I*d*–IV*d* do undergo rapid photoisomerization, the *cis* isomers were prepared by solution irradiation according to the sequence shown in Reaction Scheme 1. The scheme involving bishydrochlorides, I*c*–IV*c*, was analogous.

Difficulty was at first encountered during the isolation of the *cis* isomers. Since the *cis* isomers are readily thermally isomerized to their *trans* forms, all operations were carried out at room temperature or below. At the same time, it was necessary to carry out manipulations under dark conditions to avoid photoequilibration of the products. Table II summarizes the absorption spectra data of the *cis* isomers. In general, the changes

of wavelengths of λ_{max} of the *cis* isomers with substitution on the nitrogens and acidity conditions follow those of the *trans* forms. However, the *cis* forms consistently show wavelengths of λ_{max} at shorter wavelengths than do the *trans* isomers.

Each pair of *cis* isomers of the free bases (VI–IX) required a different method of separation because of the changes in physical properties resulting from the variation of substituents on the amino nitrogen. The methods used were cold extraction, column chromatography, and fractional crystallization. The *cis*-methiodide salts (VI*a*–IX*a*) were even more sensitive to heat and light than VI–IX and thus their melting points were of no use in characterization. Further irradiation of the methiodide–hydrochloride photoequilibrium mixtures did not produce dimers. However, when the irradiations of the bishydrochloride photoequilibrium mixtures were continued, the dimers of I*c*, II*c*, and IV*c* were produced and were subsequently treated with base to give the dimers of I, II, and IV. Long irradiation of III*c* gave several unidentified products but no dimers.

The base strengths of the various 4′-amino substituents are influenced by the conjugated 2-styrylpyridyl group. At the same time, the base strengths of the pyridine nitrogens are interdependent with those of the 4′-amino nitrogen through the conjugated system. Both nitrogens can therefore alter their base strength by the interaction of their lone-pair electrons in the π-system. In all cases examined, the 4′-amino nitrogens possessed lower basic strengths than aniline, indicating donation of the electron pairs from the 4′-amino group into the π-system of the 2-styrylpyridyl group. Table III demonstrates that,

TABLE III

Base strengths of 4′-amino-substituted 2-styrylpyridine methiodides

R	In water	
	trans, pK_{a_2}	*cis*, pK_{a_2}
NH_2	2.83	3.20
$N(CH_3)_2$	3.10	3.44
$N(C_2H_5)_2$	4.48	4.83
$N(n\text{-}C_3H_7)_2$	4.67	4.42

when the lone pair of the pyridine nitrogen is tied up by quaternization to form the methiodide, the difference between the base strength values of the 4′-amino nitrogen of the *cis* isomers and *trans* isomers of 4′-dimethylamino- (I*a* and VI*a*), 4′-diethylamino- (II*a* and VIII*a*), 4′-amino- (IV*a* and IX*a*), and 4′-di-*n*-propylamino- (III*a* and VIII*a*) 2-styrylpyridines is a constant value of 0.35 ± 0.02 pH unit. The basic strengths of the amino groups are in the same relative order as reported (6) in the aniline–dialkylaniline series:

$$N(C_2H_5)_2 > N(C_3H_7)_2 > N(CH_3)_2 > NH_2.$$

Furthermore, in the methiodide series, the 4′-amino nitrogens of the *cis* isomers (VI*a*, VII*a*, VIII*a*, and IX*a*) have higher base strengths than those of the corresponding *trans* isomers (I*a*, II*a*, III*a*, and IV*a*), indicating reduced interaction between the pyridinium and phenyl rings via the double bond. Jaffé and Orchin (7) attributed the reduced interaction between the two phenyl rings of *cis*-stilbene to steric interference and resulting noncoplanarity of the rings. The same effect can operate in the case of the *cis*- and *trans*-methiodides (V*a*–IX*a* and I*a*–IV*a*) to cause changes in the basicity of the amino nitrogens. This effect was noted earlier in the differences of absorption spectra between the *cis* isomers (V*a*–IX*a*) and the *trans* isomers (I*a*–IV*a*).

The base strength value of the pyridine nitrogen in *trans*-2-styrylpyridine (V), pK_a 5.23, is slightly larger than that of pyridine, pK_a 5.15. This indicates that the unpaired electrons of the pyridine nitrogen in V are not donated to the styryl system and that, in fact, a shift in the reverse direction occurs. The pK_a value for the nitrogen in *cis*-2-styrylpyridine is 5.20. Table IV summarizes the base strength figures determined for the *cis* and *trans* free bases (I–IX).

The contribution of the electron pair from the pyridine nitrogen via the conjugated system can reduce the value of pK_a of the amino nitrogen. The value of pK_a of the 4′-amino group in *trans*-4′-amino-2-styrylpyridine (IV) is 2.92, compared to 4.58 for aniline. The pK_a value of the pyridine nitrogen in IV is 5.72, compared to 5.23 for V and 5.15 for pyridine. Replacement of the amino-group hydrogens by alkyl groups which donate electron character increases the base strength of the 4′-amino and pyridine

nitrogens by a factor similar to that seen for the base strengths in the aniline–dialkylaniline series (6). Methyl groups are generally accepted to be superior in their electron-donating ability to ethyl or propyl groups because of hyperconjugation effects (8).

In the present work, the superior release of electron character by the methyl group is evident when the relative base strengths of the 4′-amino groups in the methiodide series or the free bases are compared in water and in 50% methanol–water solution (Table IV). Quaternization causes the pyridine nitrogen to become very electron attracting. Since the methyl groups donate electron character, there is a greater decrease in the base strength of the 4-dimethylamino group in the methiodide salt (I*a*), compared to the free base (I), than occurs in the other pairs of 4′-amino-substituted derivatives (II*a* and II, III*a* and III). A similar situation exists when the base strengths of the free bases (I, II, III, and IV) are compared in water and in 50% methanol–water. The base strengths of all free amino groups are dependent on the number of hydrated ($—N \overset{+}{\rightarrow} HOH$) bonds associated with the nitrogen (9). In aqueous solution, the pyridine nitrogen is preferentially ionized and stabilized by solvation. Such solvation causes the nitrogen to act as an electron-withdrawing group similar to that of the quaternary methiodide group. The fact that the 4′-dimethylamino group is the superior electron-releasing group explains the fact that the pyridine nitrogen in I has the highest base strength (pK_a 6.40) of any amino group in the present series of compounds. In 50% methanol–water the solvation effects are much reduced, causing all the nitrogen atoms to have lower base strengths than in water.

As already pointed out, solvation effects are seen in the absorption spectra. By changing the system from 50% methanol–water to water, more hydrogen bonding can occur. Accordingly, the wavelengths of λ_{max} of the free bases (I–IV) and of the monohydrochlorides (I*b*–IV*b*) shift to shorter wavelengths. The greatest shift occurs with I and I*b*. The shift of both is equal and corresponds to an energy increase of approximately 2.6 kcal/mole. This value represents the energy necessary to break the hydrogen bond so that a nonbonding electron of the amino group or molecule can be raised to the first excited state. Therefore, hydrogen bonding cannot be maintained in the excited state (10).

In 50% methanol–water solution, the absence of large solvation effects changes the order of magnitude of the effect of the groups that contribute the most electron character to the conjugated system. The absence of strong solvation effects involving the pyridine nitrogen of the *trans* free bases (I) lowers its electron-attracting power, and electron character is not drawn to the conjugated system as readily from the 4′-amino group.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Therefore, the base strength of the pyridine nitrogens of I–IV becomes directly proportional to the base strength or electronegativity of the 4′-amino groups.

The base strength of the nitrogens becomes weaker in all cases when the solvent is changed from water to 50% methanol–water. The largest change occurs in I, the smallest in IV.

CONCLUSIONS

The *trans*-methiodides, I*a*–IV*a*, are not photochemically isomerized in solution to the *cis* isomers (V*a*–IX*a*) because of the lack of double-bond character at the ethylenic bond. The corresponding bishydrochlorides (I*c*–IV*c*) and methiodide–hydrochlorides (I*d*–IV*d*) absorb light at wavelengths shorter than those of I*a*–IV*a* or even the corresponding free bases I–IV and can be photoisomerized and photodimerized. The photochemical susceptibility is due to the tying-up of the lone-pair electrons on the positively charged nitrogens, thereby imparting sufficient double-bond character to the ethylenic bonds. The molecules under these conditions become more stilbene-like. Under highly acid conditions, existence of the bishydrochloride (I*c*–IV*c*) and methiodide–hydrochloride (I*d*–IV*d*) species would promote $\pi \rightarrow \pi^*$ transitions at the ethylenic bonds. The excited molecule can then rotate about the ethylenic bond. The excitation of the monohydrochlorides (I*b*–IV*b*) and the methiodides (I*a*–IV*a*) would not involve promotion of an electron at the same site in the molecule, making rotation about the ethylenic bond impossible. Currently, we are undertaking measurements of basic strengths, in their excited states, of the nitrogens in these compounds to provide a truer picture of the role of the lone-pair electrons in the excited state. The solvent shifts (between water and 50% methanol–water) of wavelengths of λ_{max} indicate that electrons are available on the amino groups for hydrogen bonding. Comparison of the double-salts series (I*c*–IX*c*, I*d*–IX*d*) (no solvent shift) with the free bases (I–IX) and the monosalts (I*a*–IX*a*, I*b*–IX*b*), which do show a solvent shift, illustrates this fact.

Interaction of the lone-pair electrons of the two nitrogens via the conjugated system in both isomers is indicated by the fact that the free bases of both *cis* and *trans* isomers (I–IX) absorb at longer wavelengths than do the double salts (I*c*–IX*c*, I*d*–IX*d*). This effect is also illustrated by the interdependent changes of value of base strength of the two nitrogens in the free bases (I–IX). However, release of electron character to the conjugated system by the amino group is more striking in the case of the methiodide salts (I*a*–IX*a*). The values of pK_a of the amino nitrogen of the methiodide *cis* isomers (VI*a*–IX*a*) are all greater than those of the *trans* isomers (I*a*–IV*a*) by 0.35 ± 0.02 pH unit.

EXPERIMENTAL

Determination of the Basic Strength of cis- and trans-4′-Amino-substituted 2-Styrylpyridines

A 5×10^{-4} *M* stock solution in dilute hydrochloric acid of each compound was prepared. Such stock solutions were diluted further, to 2.5×10^{-5} *M* for the *trans* compounds or to 5×10^{-5} *M* for the *cis* compounds in a solution of the desired pH made by the addition of hydrochloric acid or sodium hydroxide solutions. The total ion concentrations were kept low and did not exceed 5×10^{-3} *M*, except for the measurements made in strong acids. The pH measurements were made by using a Beckman pH meter equipped with a calomel reference cell and a glass electrode. The absorption spectra were measured at several pH values ranging between 1 and 10. All measurements involving the *cis* compounds were obtained in red safelight illumination because of the sensitivity of the co-derivatives to yellow light.

From such data a plot of absorption of the different λ_{max} vs. pH was drawn. For a monobase, the pK_a can be determined by finding the point on such a curve halfway between the free base value and the value for 100% salt. However, when a dibase of which the ΔpK_a is less than 4 is considered, this method does not give a true pK_a value. The incorrect pK_a value results from the fact that the molecule will never

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

exist as a 100% monosalt. Therefore, the absorption spectra of the monosalts remain unknown. By extrapolation of the straight-line portions of absorbance vs. pH curves, a better approximation of the pK_a value is found. For a more accurate determination, the pK_a's of the compounds were also calculated using the method described by Rosenblatt (4). The absorption of all three species (free dibase, monosalt, and disalt) and the two equilibrium constants can be calculated by setting up five simultaneous equations using measurements at five different pH values. The general form of the equations is as follows:

$$a_n\epsilon_n\left(\frac{1}{K_2}\right) + \frac{\epsilon_n}{a_n}(K_1) - a_n\frac{(\epsilon_\alpha)}{K_2} - \frac{1}{a_n}(\epsilon_\gamma K_1) - \epsilon_\beta = -\epsilon_n,$$

where a_n = hydrogen activity, ϵ_n = extinction coefficient at the measured pH, K_2 = second equilibrium constant, K_1 = first equilibrium constant (Note: K_1 and K_2 are interchanged from Rosenblatt's equation since his applied to dibasic acids rather than to bases), ϵ_α = extinction coefficient of double salt, ϵ_γ = extinction coefficient of free base, and ϵ_β = extinction coefficient of monosalt.

Since points were found at which addition of more acid did not change the absorption spectra of the double salt or the addition of base did not change the absorption spectra of the free base, the extinction coefficients were thereby determined. These constants can then be placed in the equation, which can be simplified to the following:

$$a_n(\epsilon_n - \epsilon_\alpha)\frac{1}{K_2} + \frac{(\epsilon_n - \epsilon_\gamma)}{a_n}K_1 - \epsilon_\beta = -\epsilon_n.$$

Since the total concentration and the same cell path length were used for all measurements, these two values will cancel out. $\epsilon = A/Cl$, where A = absorption, ϵ = excitation coefficient, C = concentration, and l = cell thickness. Thus, the absorption value can be used rather than the extinction coefficient. The equation then becomes

$$a_n(A_n - A_\alpha)\frac{1}{K_2} + \frac{(A_n - A_\gamma)}{a_n}K_1 - A_\beta = -A_n,$$

where a_n = hydrogen activity, A_n = absorption of solution at a_n, A_α = absorption of double salt, A_γ = absorption of free base, and A_β = absorption of monosalt.

For the present calculation, $[H^+]$ was used rather than a_n, but the error introduced is small, since the calculations were carried out using values obtained for solutions where the ion concentrations would be about 10^{-3} M. Thus, the activity coefficients would be very close to unity. The fact that the ultraviolet absorption curves all passed through isosbestic points at these ion concentrations is further evidence of the insignificant effect of ion concentration. Therefore, the equation was further modified to

$$[H^+](A_n - A_\alpha)\frac{1}{K_2} + \frac{(A_n - A_\gamma)}{[H^+]}K_1 - A_\beta = -A_n.$$

The values were calculated at the three wavelengths corresponding to the absorption maxima of each form and using three different pH values for each calculation.

trans-4'-Dimethylamino-2-styrylpyridine (I)

This was prepared as described previously (11).

trans-4'-Diethylamino-2-styrylpyridine (II)

A mixture of 56 g (0.6 mole) of 2-picoline, 106 g (0.6 mole) of 4-diethylaminobenzaldehyde, and 2 g of anhydrous $ZnCl_2$ was placed in an autoclave and heated at 200 °C for 16 h. The cooled reaction mixture was poured into ether and stirred at room temperature for a short time. The solid was collected by filtration and crystallized from ethanol to yield 74 g (50.3%) of a yellow solid (II), m.p. 319–141°.

Anal. Calcd. for $C_{17}H_{20}N_2$: C, 81.0; H, 8.0; N, 11.1. Found: C, 81.4; H, 7.9; N, 10.8.

trans-4'-Di-n-propylamino-2-styrylpyridine (III)

A mixture of 56 g (0.6 mole) of 2-picoline, 82 g (0.4 mole) of 4-dipropylaminobenzaldehyde, and 2 g of anhydrous $ZnCl_2$ was placed in an autoclave and heated at 200 °C for 16 h. The reaction mixture was then distilled using a pot temperature of 142–167°/8 μ to give 70.5 g (63%) of a red oil (III) which could not be crystallized.

Anal. Calcd. for $C_{19}H_{24}N_2$: C, 81.4; H, 8.6; N, 10.0 Found: C, 81.1; H, 8.6; N, 10.1.

trans-2-(4'-Aminostyryl)pyridine (IV)

The following procedure is an adaptation of that used for the preparation of 4-(4'-aminostyryl)pyridine (12).

A solution of 22.6 g (0.1 mole) of 2-(4'-nitrostyryl)pyridine in 200 ml of hot 5% hydrochloric acid was added over a 10-min period to a stirred solution of 60 g of stannous chloride in 100 ml of concentrated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

hydrochloric acid while the solution was heated on a steam bath. The heating and stirring were continued and hydrogen chloride was passed through the reaction mixture for 1 h. The mixture was cooled and 20% sodium hydroxide solution was added until the mixture was strongly basic. The solid was collected, washed with water, dried, and extracted with acetone in a Soxhlet extractor. The extract was cooled to room temperature and filtered, and the filtrate was diluted with water and chilled to yield 16 g of crude product which was recrystallized from toluene to give IV, 15.1 g (77%), m.p. 137–138° (lit. (13) m.p. 138–139°).

Anal. Calcd. for $C_{13}H_{12}N_2$: C, 79.6; H, 6.1; N, 14.3. Found: C, 79.8; H, 6.3; N, 14.1.

trans-4′-Dimethylamino-2-styrylpyridine Methiodide (Ia)

This was prepared as previously described (11).

trans-4′-Diethylamino-2-styrylpyridinium Methiodide (IIa)

A mixture of 23.5 g (0.1 mole) of 2-picoline methiodide, 35.4 g (0.2 mole) of 4-diethylaminobenzaldehyde, 150 ml of methanol, and 5 ml of piperidine was refluxed on a steam bath for 1 h. The reaction mixture was chilled and the product isolated by filtration. The solid was crystallized from acetonitrile to yield IIa, 33 g (84.5%), m.p. 242–245° (lit. (5) m.p. 246–247°).

Anal. Calcd. for $C_{18}H_{23}IN_2$: C, 54.8; H, 5.9; I, 32.2; N, 7.1. Found: C, 54.7; H, 5.7; I, 32.4; N, 7.0.

trans-4′-Di-n-propylamino-2-styrylpyridine Methiodide (IIIa)

A mixture of 11.8 g (0.05 mole) of 2-picoline methiodide, 11.3 g (0.055 mole) of 4-dipropylaminobenzaldehyde, 50 ml of methanol, and 2.5 ml of piperidine was refluxed on the steam bath for 1 h. The reaction mixture was chilled, and the product isolated by filtration and then crystallized from ethanol to yield IIIa, 3.9 g (66%), m.p. 209–211°.

Anal. Calcd. for $C_{20}H_{27}IN_2$: C, 57.0; H, 6.5; I, 30.1; N, 6.6. Found: C, 56.8; H, 6.2; I, 30.4; N, 6.4.

4′-Amino-2-styrylpyridine Methiodide (IVa)

A mixture of 7.4 g (0.02 mole) of 4′-nitro-2-styrylpyridine methiodide, 14 g of stannous chloride, and 50 ml of concentrated hydrochloric acid was heated on the steam bath, with stirring, for 1 h. The mixture was cooled and the solid collected. The solid was added to 250 ml of water and 10 ml of concentrated hydrochloric acid. Hydrogen sulfide was passed through the mixture, with heating, until no further tin sulfide was precipitated. The hot mixture was filtered and the filtrate was neutralized with solid sodium bicarbonate to yield 4.1 g (61%) of IVa, m.p. 260°.

Anal. Calcd. for $C_{14}H_{15}IN_2$: C, 49.7; H, 4.4; N, 8.3. Found: C, 49.5; H, 4.3; N, 8.2.

Purification of cis Isomers

The irradiation mixtures containing primarily the *cis* isomer were subjected to column chromatography or fractional crystallization. The various fractions from elution of the column or from crystallization were analyzed by determination of their ultraviolet absorption spectra. The fractions which contained material exhibiting the shortest wavelength of λ_{max} were selected as the pure *cis* fractions. We have found that the accuracy of infrared spectroscopy for determining the present *cis–trans* ratios is less than that of ultraviolet absorption spectroscopy methods. Further evidence of the purity of the *cis* isomers is found when their ultraviolet absorption spectra are determined at several values of pH (14). When such a series of ultraviolet absorption spectra are plotted, a precise isosbestic point is obtained only if the free base and the conjugate acid of a single species are present. The presence of *trans* isomer in *cis* isomer would cause the junction of the series of curves to scatter and give a number of scattered isosbestic points. The *cis* isomers isolated and purified as reported below gave precise isosbestic points when subjected to the above method.

cis-4′-Dimethylamino-2-styrylpyridine (VI)

A solution of 5 g (0.0223 mole) of *trans*-4′-dimethylamino-2-styrylpyridine (I) in 2 l of 1 *N* hydrochloric acid was placed in an irradiation flask equipped with a nitrogen inlet tube at the bottom. A 450-W medium-pressure Hanovia mercury arc lamp equipped with a Pyrex glass water jacket was then immersed in the solution. The solution was stirred by a Teflon-covered stirring bar, driven magnetically through the bottom of the flask. Nitrogen was bubbled through the solution while the irradiation was conducted for 25 min, with stirring. The irradiated solution was made alkaline with potassium carbonate and was extracted with three 250-ml portions of chloroform. The chloroform solutions were dried over anhydrous potassium carbonate. The dried chloroform extracts from five such irradiations were combined and the chloroform evaporated at room temperature and reduced pressure, using a rotary evaporator and an ice-chilled collection flask. The residue was triturated with 400 ml of cold petroleum ether (b.p. 66–75°) for 30 min, after which time the solids were removed by filtration. The solid weighed 5.0 g, and consisted principally of I. The petroleum ether extract was evaporated at room temperature and reduced pressure to give 19.5 g *cis*-4′-dimethylamino-2-styrylpyridine (VI): λ_{max} (MeOH) 348 mμ, ϵ 9 100; λ_{max} (1 *N* hydrochloric acid) 308 mμ, ϵ 7 920.

This material was further purified by column chromatography by means of an activated alumina column with ethyl acetate as the solvent and eluent. The ultraviolet absorption spectra of each fraction were determined and the fractions containing material having λ_{max} of 347 mμ were combined. The ethyl acetate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was evaporated at room temperature and reduced pressure to give VI, a pale yellow liquid, λ_{max} (MeOH) 347 mμ, ϵ 10 300.

Anal. Calcd. for $C_{15}H_{16}N_2$: C, 80.3; H, 7.2; N, 12.5. Found: C, 80.5; H, 7.3; N, 12.4.

cis-4′-Diethylamino-2-styrylpyridine (VII)

The procedure used was the same as that used for VI. Five runs using 5.72 g of II yield 22.4 g (78%) of VII, λ_{max} 359 mμ, ϵ 13 100. A 5-g sample was further purified by column chromatography, as described for VI, to give 2.6 g of VII, a yellow oil, λ_{max} (MeOH) 359 mμ, ϵ 13 500.

Anal. Calcd. for $C_{17}H_{20}N_2$: C, 80.9; H, 8.0; N, 11.1. Found: C, 80.9; H, 8.3; N, 11.4.

cis-4′-Di-n-propylamino-2-styrylpyridine (VIII)

Three 5-g portions of III were irradiated and combined as described for VI. The residue from the combined chloroform extract was dissolved in 400 ml of ethyl acetate. The solution was then passed through an activated alumina column, as described for VI. Eluate samples of approximately 20 ml were taken and the one containing a sample of VIII, which showed the shortest wavelength of λ_{max}, was selected. Its characteristics were λ_{max} (ethyl acetate) 355 mμ; λ_{max} (CH_3OH) 359 mμ, ϵ 14 400, and 330 mμ, ϵ 12 000.

Anal. Calcd. for $C_{19}H_{24}N_2$: C, 81.5; H, 8.5; N, 9.7. Found: C, 81.2; H, 8.4; N, 9.7.

By combination and evaporation *in vacuo* of the eluates containing VIII of wavelength λ_{max} 355–360 mμ (ethyl acetate), there was obtained 4.0 g of VIII showing λ_{max} (CH_3OH) 362 mμ, ϵ 14 400; 330 mμ, ϵ 11 000, which corresponded to 95% *cis* isomer (VIII). The remaining elates, which were the first to traverse the column, were combined to give 0.5 g of essentially *trans* isomer (III), λ_{max} (ethyl acetate) 362–372 mμ.

cis-4′-Aminostyrylpyridine (IX)

Three 5-g portions of IV were irradiated and the product was extracted as described for the preparation of VI. The residue from the combined, dried, and evaporated chloroform extracts was triturated with 400 ml of cold cyclohexane. The volume of the cyclohexane solution was reduced at room temperature *in vacuo* to 40 ml and chilled to 1 °C. The yellow crystals (IX) which separated and were collected weighed 0.06 g, m.p. 80–83°, λ_{max} (CH_3OH) 330 mμ, ϵ 12 350. The residue from the cyclohexane trituration was triturated with 250 ml of cold diethyl ether. The undissolved material which was collected and dried weighed 5.2 g, m.p. 113–135°, and consisted principally of *trans* isomer (IV). The diethyl ether solution was cooled at 1 °C to give 0.2 g of a dimer – *trans* isomer mixture which melted at 169–188°. On longer storage, two crops of essentially *cis* isomer (IX) separated: m.p. 78–82°, 0.7 g, λ_{max} (CH_3OH) 332 mμ, ϵ 7 140; and m.p. 79–81°, 0.1 g, λ_{max} (CH_3OH) 342 mμ, ϵ 12 100. The diethyl ether solution was then evaporated to dryness and the residue dissolved in 90 ml of 50:50 benzene–heptane. After the solution had cooled to 1 °C, the oil which separated crystallized to give 4 g of IX melting at 73–80°, λ_{max} (CH_3OH) 337 mμ, ϵ 13 500. On evaporation, the mother liquors yielded 1.5 g of IX, m.p. 71–85°, λ_{max} (CH_3OH) 330 mμ, ϵ 11 750. The 4-g sample of IX was dissolved in 50 ml of diethyl ether. When the solution was cooled to 1 °C, 1.9 g of IX, m.p. 80–100°, λ_{max} (CH_3OH) 337 mμ, ϵ 13 500, was collected. The diethyl ether was evaporated, leaving 2.0 g of IX, m.p. 70–75°, λ_{max} (CH_3OH) 333 mμ, ϵ 12 200.

Anal. Calcd. for $C_{13}H_{12}N_2$: C, 79.6; H, 6.1; N, 14.2. Found: C, 79.2; H, 6.2; N, 13.9.

The yield of combined fractions containing greater than 97% *cis* isomer (XI) was 4.1 g.

cis-4′-Dimethylamino-2-styrylpyridine Methiodide (VIa)

A solution of 10 g (0.0274 mole) of *trans*-4′-dimethyl-amino-2-styrylpyridine methiodide in 2 l of 0.5 *N* hydrochloric acid was placed in a Pyrex glass irradiation flask. The solution was irradiated during 2 h in the same manner as already described for the preparation of *cis*-4′-dimethylamino-2-styrylpyridine (VI). The solution was concentrated to 500 ml at room temperature and reduced pressure and made alkaline with sodium bicarbonate. The resulting solution was warmed gently to dissolve all material and then cooled to room temperature. The first crop of crystals collected was principally *trans* isomer (I*a*), weighing 4.0 g, m.p. 253–264°, λ_{max} (H_2O) 437 mμ, ϵ 25 100. The second crop consisted of red prism-like crystals weighing 2.6 g and was *cis*-4′-dimethylamino-2-styrylpyridine methiodide (VI*a*), λ_{max} (H_2O) 404 mμ, ϵ 8 400. The sample of VI*a* melted at 268–270°, since, when it was heated, it reverted to the *trans* isomer (I*a*). This was confirmed by ultraviolet absorption data.

Anal. Calcd. for $C_{16}H_{19}IN_2$: C, 52.4; H, 5.2; I, 34.7; N, 7.7. Found: C, 52.1; H, 5.2; I, 34.9; N, 7.5.

The remaining material in the mother liquors was the *trans* isomer (I*a*).

cis-4′-Diethylamino-2-styrylpyridine Methiodide (VIIa)

A solution of 10.0 *g* of *trans*-4′-diethylamino-2-styrylpyridine methiodide (II*a*) in 2 l of 1 *N* hydrochloric acid was irradiated for 1 h. The irradiation conditions and product isolation were carried out as described for VI*a*. However, the first material which crystallized from aqueous solution consisted of 75% inorganic salts. The expected product (VIII*a*) did not crystallize from water. Therefore, the inorganic salts and mother liquors were extracted with chloroform. The chloroform extract was concentrated at room temperature and reduced pressure until the solid began to crystallize. The crops of crystals collected were the *trans* isomer (II*a*). The solubility of the *cis* isomer was so high in chloroform that it was necessary to add diethyl ether to cause crystallization. In this manner, a yield of 4.8 g of *cis*-4′-diethylamino-2-styrylpyridine methiodide, m.p. 238–241°, λ_{max} (H_2O) 437 mμ, ϵ 10 100, was obtained.

Anal. Calcd. for $C_{18}H_{23}IN_2$: C, 54.9; H, 5.8; I, 32.2; N, 7.1. Found: C, 54.5; H, 5.4; I, 31.9; N, 6.9.

For personal use only.

cis-4'-Di-n-propylamino-2-styrylpyridinium Methiodide (VIIIa)

A single 5-g sample of IIIa was irradiated as described for VIIa. The aqueous solution was made basic with sodium bicarbonate and concentrated at reduced pressure and room temperature to 600 ml. The aqueous solution was extracted with 60 ml of chloroform (extract A). The aqueous solution was then extracted with three 60-ml portions of chloroform, which were then combined and evaporated to 80 ml (extract B). To both extracts there was added 100 ml of diethyl ether. When both solutions were cooled to 1 °C, *trans* isomer (IIIa) separated from them: A, 1.3 g, B, 0.6 g. On addition of 80 ml of diethyl ether to solution B, an additional 0.3 g of IIIa was obtained. Both solution A and solution B were then evaporated to dryness at room temperature and reduced pressure. The residues were held *in vacuo* for several hours at 0.3 mm pressure. Sample A weighed 1.0 g, λ_{max} (H_2O) 440 mμ, ϵ 11 100.

Anal. Calcd. for $C_{20}H_{27}N_2$: C, 57.0; H, 6.4; N, 6.6. Found: C, 56.7; H, 6.6; N, 6.4.

Sample B weighed 1.5 g, λ_{max} 448 mμ, ϵ 8 320.

cis-4'-Amino-2-styrylpyridine Methiodide (IXa)

A solution of 2.5 g of IVa in 1 l of 1 *N* hydrochloric acid was irradiated for 1 h as described earlier for VIa. The irradiated solution was made alkaline with sodium bicarbonate and evaporated to dryness at room temperature and reduced pressure.

The residue was triturated at room temperature with three portions of acetone: 150 ml, 400 ml, and 250 ml. The acetone solutions were successively concentrated and cooled to yield fractions of crystalline materials consisting of *cis-* and *trans*-isomer mixtures. The fractions containing IXa, which exhibited λ_{max} (H_2O) 374 mμ, ϵ 9 000, and which totaled 1.4 g, were selected to be essentially pure IXa.

Anal. Calcd. for $C_{14}H_{15}IN_2$: C, 49.7; H, 4.4; I, 37.6; N, 8.3. Found: C, 49.6; H, 4.4; I, 37.3; N, 8.0.

Dimerization of trans-4'-Dimethylamino-2-styrylpyridine (I)

A solution of 5 g of I in 1 l of 1 *N* hydrochloric acid was irradiated for 27 h in the manner described for the preparation of VI. The irradiation solution was made basic with potassium carbonate and extracted with two 200-ml portions of benzene and one 200-ml portion of diethyl ether. The combined extracts were dried over anhydrous potassium carbonate and evaporated at room temperature and reduced pressure. The residue was stirred with 40 ml of cold diethyl ether for 20 min. The crude dimer which was isolated by filtration weighed 1.7 g, m.p. 246–253°. Recrystallization from 50 ml of benzene gave 1.2 g of dimer, m.p. 255–257°. An earlier sample (see ref. 2) melted at 248–250°. The ultraviolet spectra of the two samples of dimer I were identical. The combined mother liquors were evaporated to give 3.3 g of a mixture of I and VI.

Dimerization of 4'-Diethylamino-2-styrylpyridine (II)

A solution of 5.0 g of II in 1 l of 1 *N* hydrochloric acid was irradiated during 30 h as described for VII. The solution was made basic with potassium carbonate and extracted with four 125-ml portions of chloroform. The extracts were combined and dried over anhydrous potassium carbonate. The chloroform solution was evaporated at room temperature and reduced pressure and the residue was triturated with 200 ml of cold low-boiling petroleum ether. The material not soluble in the petroleum ether was separated by filtration (1.5 g) and recrystallized from 40 ml of a 50:50 mixture of diethyl ether and methanol. Thus, 0.9 g of dimer, m.p. 184–185°, λ_{max} 268 mμ (methanol), ϵ 40 400, was obtained.

Anal. Calcd. for $C_{34}H_{30}N_4$: C, 80.9; H, 8.0; N, 11.1; mol. wt., 504. Found: C, 80.6; H, 8.1; N, 11.5; mol. wt., 510.

The petroleum ether mother liquor was evaporated at room temperature and reduced pressure, leaving 3.3 g of a mixture of II and VIII, λ_{max} (MeOH) 363 mμ, ϵ 8 000.

Dimerization of 4'-Amino-2-styrylpyridine (IV)

A solution of 5.0 g of IV in 2 l of 1 *N* hydrochloric acid was irradiated during 43 h in the manner described for VI. The solution was made basic and the solids were separated by filtration. The crude product was dried *in vacuo* and melted at 160–187°; yield, 4.3 g. The solid was recrystallized from a 100 ml 50:50 benzene–chloroform solution. The first crop of crystals, which melted at 207–209° and weighed 2.5 g, λ_{max} (MeOH) 243 mμ, ϵ 23 200, was recrystallized from benzene to give 2.2 g of dimer IV, m.p. 213–214°, λ_{max} (methanol) 243 mμ, ϵ 24 800.

Anal. Calcd.: C, 79.6; H, 6.1; N, 14.3; mol. wt., 392. Found: C, 80.1; H, 6.4; N, 13.8; mol. wt., 428.

The mother liquors were evaporated and 1.8 g of a mixture of *cis-* and *trans*-4'-amino-2-styrylpyridine was obtained, λ_{max} 342 mμ, ϵ 7 160.

Attempted Photoisomerization of Ia–IVa

For irradiation purposes a 1-cm quartz spectrophotometer cell was filled with a 2.5×10^{-5} *M* aqueous solution of the *trans* isomer of the compound to be studied. The absorption spectrum of the starting solution was first determined. The cell was then irradiated sequentially using the light sources tabulated below. After each irradiation (A and D) the ultraviolet absorption spectra were determined.

A. The sample cell was placed at a distance of 10 cm from a 500-W Hanovia water-cooled medium-pressure mercury arc lamp. A Kodak Wratten 18A filter was interposed between the sample cell and the light source. (The 18A filter transmits light of wavelengths 310–390 mμ.)

B. The sample cell was placed at a distance of 10 cm from the source used in A. The 18A filter was not used.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

C. The sample cell was placed at a distance of 10 cm from the source used in A. A Kodak Wratten 2A filter was interposed between the sample cell and the source. (The 2A filter transmits all wavelengths of light longer than 410 mμ.)

D. The sample cell was placed at a distance of 10 cm from a 100-W (80 W at 253°) Hanovia mercury resonance lamp.

Prolonged irradiation of solutions of I*a*–IV*a* with any of the above sources failed to produce significant changes in their ultraviolet absorption spectra. Thus, I*a*–IV*a* were considered to be photochemically stable in dilute aqueous solution.

Received November 13, 1964

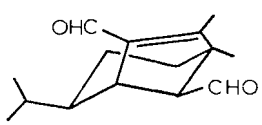
Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

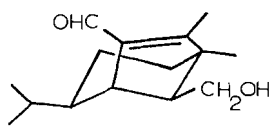
An earlier investigation had shown that helminthosporal, the toxin isolated from growths of *Helminthosporium sativum*, does not exist as such in the culture, but is formed from a precursor on subsequent mild treatment with acid, base, or heat. What is believed to be the immediate precursor of helminthosporal has now been isolated, as the acetal (IV), from an aged fungus extract. The corresponding precursor of helminthosporol, also as the acetal (V), accompanied it. Hydrolysis of the latter gave prehelminthosporol (also isolated from fresh extracts), which was converted into helminthosporol. Hydrolysis of the acetal of prehelminthosporal gave helminthosporal directly.

Although prehelminthosporol exists in the fresh extracts, it appears that more exists, together with prehelminthosporal, in the form of unstable complexes, possibly dimeric hemiacetals, which break down under very mild conditions. One of these has been obtained in moderately pure condition.

Previous investigations from these laboratories (1, 3) have established that helminthosporal, the toxin produced by *Helminthosporium sativum* (4), has the structure and stereochemistry shown in (I). This structure has recently been confirmed by a synthesis which has provided the absolute stereochemistry (5). This substance, which along with the fungus is responsible for seedling blight, foot and root rot, and leaf spot of cereals, has similar growth-inhibiting activity possessed by the crude extract, but as has been pointed out (1) the unpurified toxin does not show the characteristic carbonyl absorption of the dialdehyde. These bands (at 1 715 and 1 685 cm^{-1}) only appear on heat treatment of the extract, as in distillation, or on treatment with acid or base. More recently we have demonstrated, by thin-layer chromatography (t.l.c.), the total absence of helminthosporal (I) and of helminthosporol (II) (2) from the extracts.



(I)



(II)

It was surmised that the precursors present in the extract, in view of their ready conversion to (I) and (II), were probably present as some form of hemiacetal.

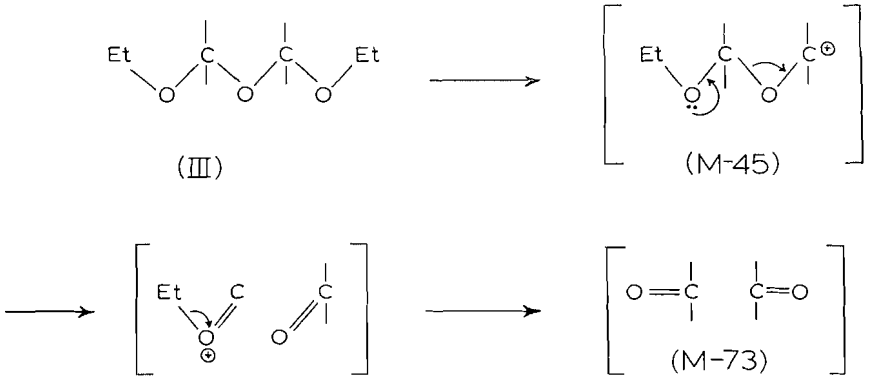
There was available to us, from an early isolation, a chloroform extract of the active

[1]*University Sub Post Office, London, Ontario.*

material (1) which had been standing for several months. Careful evaporation of the solvent from this material, and examination of the residual oil by thin-layer chromatography, showed the absence of (I) and (II) and the presence of two fast-running main components. These substances were isolated in pure form by a combination of chromatography in liquid and vapor phases.

One of these, designated acetal A, was crystalline and gave analytical figures compatible with the empirical formula $C_{19}H_{32}O_3$. In agreement, the molecular weight (M), determined by mass spectrometry, was 307 ± 1. Since some relationship to helminthosporal was required, a surplus of four carbon atoms remained. Alkoxyl estimation indicated that they should be attributed to two ethoxyl groups.

The mass spectrum also showed peaks at (M-45) and (M-73). These would be compatible with the loss of ethoxyl and the loss of ethoxyl + ethyl, as would be expected from the breakdown of an acetal (III) as indicated below.



The infrared spectrum of acetal A, while indicating the absence of carbonyl functions, showed, by absorption at 3 060, 1 657, and 885 cm^{-1}, the probable presence of an exocyclic methylene group. This led to the consideration of (IV) as a representation of acetal A.

The nuclear magnetic resonance (n.m.r.) spectrum of acetal A was informative (Fig. 1). The two low-field protons (at τ 5.32 and 5.16), very weakly coupled together, provided added confirmation of the presence of the exocyclic methylene group. In addition, there could be discerned a singlet methyl, two partly superimposed doublets for the isopropyl group, and the methyls of two ethoxyl groups. Two doublets, at τ 5.38 and 5.63, were attributed to the acetal methine protons. That at τ 5.63 was coupled to the allylic proton at τ 7.48, as shown by double irradiation, whereas that at τ 5.38 was coupled with an unresolved proton near τ 9.0. The bridgehead proton at τ 7.02, normally found at such low-field positions in helminthosporal derivatives, was coupled to an unresolved proton near τ 8.9. The pattern was complicated by the four protons of the ethoxyl methylene groups. In these the methylene protons were not equivalent, because of the attachment of the oxygen atom to an asymmetric center (6) resulting in the production of a large number of lines.

As would be expected from this formulation, acetal A on treatment with aqueous acid was converted into helminthosporal, further characterized as the bis-oxime (1). In the absence of acid, acetal A was stable under conditions which would convert the sought-for precursor of helminthosporal to helminthosporal.

It thus appeared that acetal A was an artifact produced from the precursor of helminthosporal during the prolonged standing in solution. The method of isolation (1) involved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

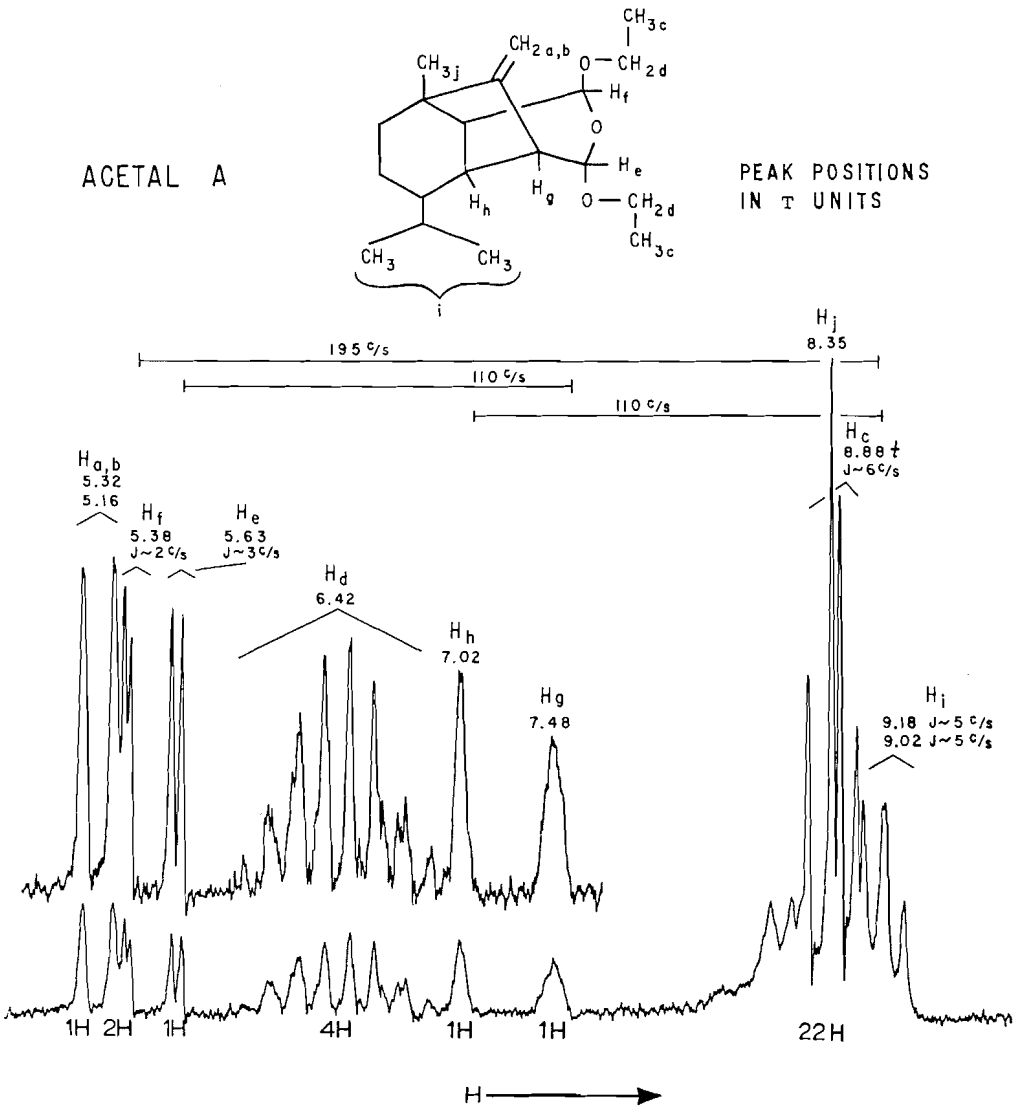


FIG. 1.

washing the charcoal cake, on which the toxin was adsorbed, with ethanol before extraction with chloroform. The chloroform extract would, therefore, contain significant amounts of ethanol.

The second substance, acetal B, isolated from the aged chloroform extract had an analysis compatible with the empirical formula $C_{17}H_{28}O_2$, containing a surplus of two carbon atoms over that required for a sesquiterpenoid. These were contained in an ethoxyl group as was shown by alkoxyl determination and the lack of a methoxyl signal in the n.m.r. spectrum.

In view of the structure of acetal A it was presumed that acetal B would have some relationship to helminthosporol. The presence of an exocyclic methylene group was signalled by appropriate absorption in the infrared spectrum, and by the presence in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

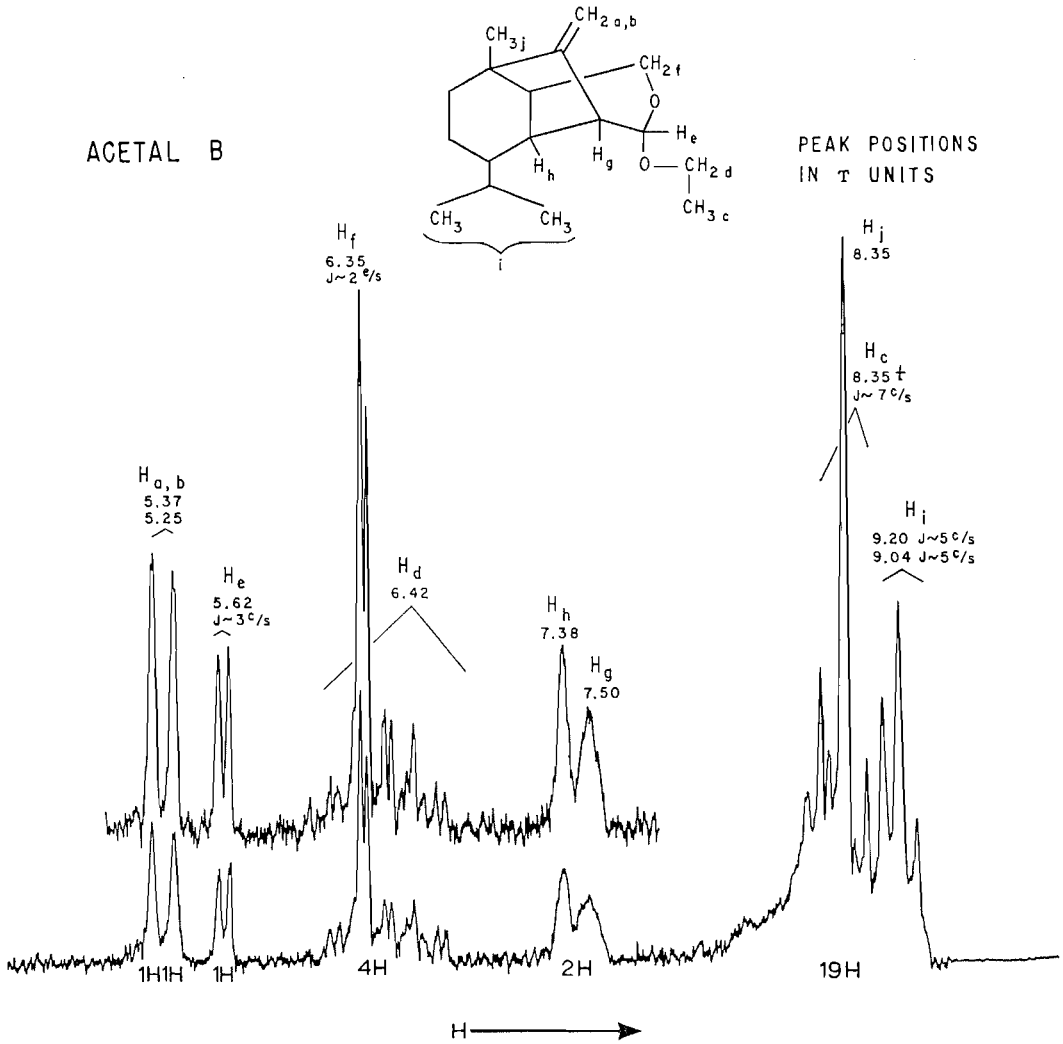

FIG. 2.

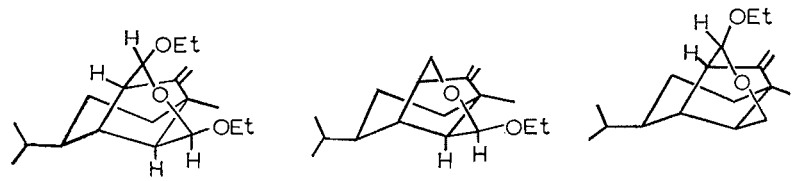
n.m.r. spectrum (Fig. 2) of two singlets at τ 5.37 and 5.25. Signals caused by only one acetal methine proton (at τ 5.62) could be observed, and the presence of four protons in the τ 6.0–6.5 region required that there be an oxymethylene group (in addition to that of the ethoxyl) present in the molecule. Acetal B could thus be provisionally formulated



(IV) (VI) (V)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

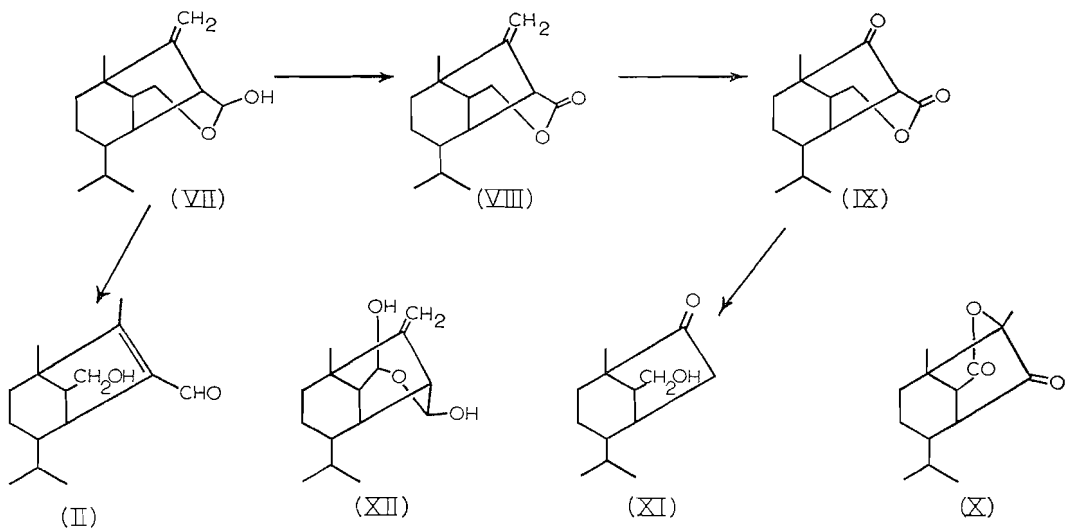
as (V) or (VI). Of these (V) would be favored since the acetal methine proton (τ 5.62) corresponds closely in signal position with the corresponding proton (at τ 5.63) in (IV).

Treatment of acetal B with aqueous acid resulted in hydrolysis of the acetal to the hemiacetal and no further change. Two formulations, corresponding to (V) and (VI), were possible for the hemiacetal; however, it was possible to discriminate between them by the sequence of reactions shown below.

Oxidation of the hemiacetal, now formulated as (VII), gave a δ-lactone (ν_{max} 1 754 cm^{-1}) (VIII). The signals in the n.m.r. spectrum at τ 5.24 and 4.90 were attributed to the exocyclic methylene group (attested to also by absorption at 3 060, 1 680, and 860 cm^{-1}), whereas those at τ 7.63 and 6.83 were attributed to the bridgehead and allylic protons respectively. The methylene group of the lactone appeared as two superimposed non-equivalence quartets between τ 5.59–6.08.

Ozonolysis of the lactone (VIII) gave the keto-lactone (IX) showing absorption at 1 773 and 1 742 cm^{-1}. The higher value for the δ-lactone is attributed to the adjacent carbonyl function. A similar observation was made in the case of the keto-lactone (X) (3) which absorbed at 1 802 and 1 767 cm^{-1}.

Alkaline hydrolysis of the keto-lactone, with opening of the lactone, resulted in spontaneous decarboxylation to give the ketol (XI). The ketone carbonyl now absorbed in the normal position at 1 739 cm^{-1}. The carbonyl of the lactone in (VIII), and therefore the acetal function in (V), is thus required to be β to the trigonal carbon atom; (VI) is thus excluded as an adequate formulation.



The above considerations rendered the correctness of the structure (V) for acetal B a matter of considerable probability as regards the functional groups and their relationship, but direct evidence about the nature of the carbon skeleton was lacking. This was obtained by the direct conversion of (VII) to helminthosporol (II) by the action of triethylamine. The helminthosporol so obtained was identical in every way with a specimen obtained from Professor Tamura* (Tokyo) which has, in turn, been correlated with helminthosporal.

The serendipitous isolation of the two acetals suggested that the immediate precursors

*We are glad to express our thanks to Professor Tamura for this specimen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of helminthosporal and helminthosporol were (XII) and (VII) respectively, and in sanguine expectancy these substances were termed prehelminthosporal and prehelminthosporol respectively.

Attention was now directed to fresh chloroform extracts of the toxin in which the ethanol wash had been omitted. Thin-layer chromatography revealed, as expected, the absence of helminthosporal and helminthosporol and also of acetals A and B. Prehelminthosporol was present and could be isolated directly, but, even though (XII) would be expected to run more slowly than (VII) on the plate, it appeared to be absent. The main bulk of the material was present as material running considerably ahead of (VII). This material appeared to be unstable and attempts at purification led to the appearance of carbonyl absorption. By preparative thin-layer chromatography a small amount of one of the materials was isolated in almost pure form.

Although insufficient data are available to permit the ascribing of specific structures to these substances, the following observations are pertinent.

First, at least four of these compounds appear to be present; yet, after passage through alumina (an effective mode of disrupture) only helminthosporal, prehelminthosporol, and traces of helminthosporol can be detected. A hemiacetal such as (XII) would be expected to be dehydrated under these conditions. Secondly, the n.m.r. spectrum of the purified material was roughly compatible with that of the addition of the spectrum of (VII) to what would be expected for the spectrum of (XII). The infrared spectrum, while indicating hydroxyl absorption, did not have absorption in the 3 600 cm^{-1} region of the intensity to be expected by comparison with that of (VII). This was borne out by the high R_f on thin-layer chromatography.

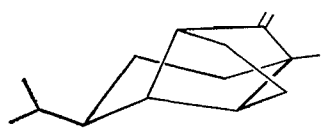
In view of the mildness of the conditions required to disrupt the complexes some form of acetal between (VII) and (XII) seemed likely. Determination of the molecular weight of the purified complex by the method of isothermal distillation gave, with appropriate controls, values somewhat less than dimeric.

It thus appears that, while prehelminthosporol is the immediate precursor of helminthosporol and prehelminthosporal may be the immediate precursor of helminthosporal, these substances, at least in the chloroform extracts obtained, are present as loose complexes.

We suggested previously (7) that helminthosporal was derived from a tricyclic precursor (XIII) by oxidative cleavage, and have provided some evidence for this view. The structures of the presently described immediate precursors are compatible with this concept, since the ethylenic linkage occupies the biogenetically prescribed position.

In our search for earlier presursors of helminthosporal the culture medium was examined at daily intervals up to the 5 days normally necessary for optimum production. The composition of the extract showed little change, after the appearance of activity as determined by the inhibition of germination of *Monilinia fructicola*, although the total amount of material increased. The results are tabulated in the Experimental section.

From the extract of the first day's growth a small amount of a crystalline solid was



(XIII)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

isolated. This was present—a trace—in the extract from the second day's growth, but not subsequently. By examination of its absorption and mass spectra it was identified as anthraquinone, and its identity confirmed by melting point and mixed melting point with an authentic specimen. Anthraquinone has previously been isolated from *Penicillium islandicum* (8).

EXPERIMENTAL*

Isolation of Acetal A (IV) and Acetal B (V)

A chloroform extract, obtained during the normal isolation procedure for helminthosporal by washing the charcoal cake on which the active agents were adsorbed (1), was allowed to stand for about 9 months before use. It was then evaporated under reduced pressure at 40° to give 25 g residual oil.

The oil (4 g) was chromatographed on alumina (Woelm, neutral, grade I; 300 g) and the fractions eluted with light petroleum, combined, and evaporated. Partial crystallization occurred and the crystals (ca. 0.5 g) were collected and recrystallized from light petroleum to give prehelminthosporal diethyl diacetal (acetal A), m.p. 60.5–61.5°; $[\alpha]_D$ −68° (*c*, 0.86); $\nu_{max}^{CCl_4}$ 3 060, 1 657, 885 cm^{-1}; n.m.r. spectrum: Fig. 1.

Anal. Calcd. for $C_{19}H_{32}O_3$: C, 73.98; H, 10.46; OEt (2), 29.2. Found: C, 74.01; H, 10.22; OEt, 29.3.

The fractions (0.7 g) eluted with benzene were combined with the mother liquors from the crystallization of acetal A and separated by g.l.c. on Carbowax 20M (20% on Chromosorb P, 190°) into two fractions. The second g.l.c. fraction crystallized to give a further 0.5 g acetal A. The first g.l.c. fraction was further purified by g.l.c. on the column indicated above to give prehelminthosporol ethyl acetal (acetal B) as an oil, $[\alpha]_D$ +1° (*c*, 2.56); $\nu_{max}^{CCl_4}$ 3 068, 1 657, 886 cm^{-1}; n.m.r. spectrum: Fig. 2.

Anal. Calcd. for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67; OEt, 17.0. Found: C, 76.98; H, 10.40; OEt, 14.8.

Prehelminthosporol

(*a*) A sterile infusion (100 l), prepared using 22 g dehydrated potatoes and 100 g sucrose per liter, was directly inoculated with spores of *Helminthosporium sativum* obtained by washing moist sterile barley seed which had been inoculated with spores and then incubated at 22–24° for 14 days. The infusion growth was allowed to proceed for 6 days. The active materials were adsorbed on 400 g charcoal, as previously, and the main portion (300 g) of the charcoal was extracted with chloroform (but without ethanol washing as previously (1)). The extract was evaporated below 40° under reduced pressure to give an oil (16 g).

The extract (660 mg) was chromatographed on alumina (Woelm, neutral, grade IV; 30 g). The fractions eluted with benzene (160 mg) were combined and separated by t.l.c. on silica gel. The prehelminthosporol obtained (10 mg) was identified by comparison of its infrared spectrum with that of an authentic specimen (see below) and by its conversion with triethylamine into helminthosporol, m.p. 91–92°.

(*b*) Acetal B (58.2 mg) was dissolved in hydrochloric acid – dioxane – water (1:36:18; 10 ml) and heated at 70° under nitrogen for 45 min. After neutralization with 5% aqueous sodium bicarbonate the product was isolated with ether (51.3 mg). This was separated by preparative t.l.c. on silica gel to give prehelminthosporol (30 mg), $[\alpha]_D$ −91° (*c*, 1.31); $\nu_{max}^{CCl_4}$ 3 608, 3 067, 1 656, 884 cm^{-1}; n.m.r. spectrum: 9.10 (6H, two superimposed doublets, $J \sim 5$ c.p.s.), 8.85 (3H, singlet), 7.52 (1H, multiplet), 7.36 (1H, multiplet), 6.23 (2H, multiplet), 6.02 (1H, multiplet), 5.37 (1H singlet), 5.23 (1H, singlet), 5.16 (1H, doublet, $J \sim 2$ c.p.s.).

Anal. Calcd. for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24. Found: C, 76.26; H, 10.41.

The Prehelminthosporal Complex

The extract described in the previous section (*a*) (3.5 g) was applied to silica gel (B.D.H.; 110 g) in light petroleum solution. The fraction (2.3 g) eluted with benzene–ether (17:3) was collected. On thin-layer chromatography this showed the presence of prehelminthosporol (R_f 0.4), but most of the material was contained in a number of spots (R_f 0.6–0.8) running ahead of the prehelminthosporol. Further, the presence of acetal A and B (R_f 1.0) and substantial amounts of material running behind the prehelminthosporol could not be detected. A 1.8-g quantity of this material was separated repeatedly by preparative thin-layer chromatography. During the separation, decomposition occurred with the formation of helminthosporal and prehelminthosporol. The product was an apparently homogeneous oil (75 g) whose R_f (0.7) on the thin-layer plate (benzene–ether 4:1) was different from that of acetals A and B (R_f 1.0) and that of prehelminthosporol (R_f 0.4), $\nu_{max}^{CCl_4}$ 3 608 (w), 3 065, 1 659, 1 075, 922, 885 cm^{-1}; n.m.r. spectrum: 9.14 (6H, doublet, $J \sim 5$ c.p.s.); 9.07 (6H, doublet, $J \sim 5$ c.p.s.); 8.87 (3H, singlet); 8.84 (3H, singlet); 7.45 (4H, complex); 7.09 (2H, complex); 6.33 (2H, broad); 5.33 (2H, broad singlet); 5.18 (2H, broad singlet); 4.96 (2H, complex). Mol. wt. 457 ± 46 (isopiestic method using acetal A as reference).

The complex (11.4 mg) was applied to a column of alumina (Woelm, neutral, grade I; 1 g) in light petroleum solution and allowed to remain on the column for 4 h. The column was then washed with ether and the eluate separated by t.l.c. on silica gel using benzene–ether (4:1) as developing solvent. Unreacted starting material (1.9 mg, R_f 0.7), helminthosporal (1.9 mg, R_f 0.5, identified by R_f and infrared spectrum),

**For general directions, see Part IV (3).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and a mixture (2.1 mg) of prehelminthosporol (R_f 0.4) and helminthosporol (R_f 0.1) (identified by comparison of R_f and infrared spectra) were obtained.

The Conversion of Prehelminthosporol to Helminthosporol

Prehelminthosporol (8.5 mg) was heated under reflux (nitrogen atmosphere) in triethylamine (2 ml) for 7½ h. The triethylamine was removed under reduced pressure and the residue separated by t.l.c. on silica gel to give helminthosporol (2.8 mg), m.p. 93–93.5°, undepressed on admixture with an authentic specimen. The infrared spectra were also identical.

Conversion of Acetal A to Helminthosporal

Acetal A (54.8 mg) was dissolved in dioxane (3 ml) containing 2% (v/v) sulfuric acid and the mixture allowed to stand (nitrogen atmosphere) at room temperature overnight. After dilution with water and neutralization with 5% aqueous sodium bicarbonate the product (47 mg) was isolated with ether and separated by t.l.c. on silica gel using ether–benzene (1:4) as developing solvent. Two fractions were obtained. One (16.7 mg) was identified as helminthosporal, $[\alpha]_D$ −43° (*c*, 1.23), by comparison with an authentic specimen (infrared spectrum) and by conversion to the bis-oxime, m.p. 167–169°, undepressed on admixture with an authentic specimen.

The other fraction (12.5 mg) was a product derived from helminthosporal and ethylene glycol (5) (a contaminant of the dioxane), as was shown by the appropriate control experiments. It was not further investigated.

Oxidation of Prehelminthosporol

The alcohol (11.4 mg) and chromium trioxide (85 mg) in pyridine (1 ml) were shaken at room temperature for 3½ hours. The slurry was warmed briefly to 80° and poured into cold dilute aqueous sodium bisulfite solution. After acidification the product was isolated with ether to give the δ-lactone (VIII), m.p. 78.5–79.0°; $[\alpha]_D$ −119° (*c*, 1.09); $\nu_{max}^{CCl_4}$ 3 060, 1 754, 1 680, 860 cm^{-1}; n.m.r. spectrum: 9.13 (3H, doublet, $J \sim 5$ c.p.s.); 9.03 (3H, doublet, $J \sim 5$ c.p.s.); 8.78 (3H, singlet); 7.60 (1H, multiplet); 6.73 (1H, multiplet); 5.83 (1H, AB system, $\delta_B-\delta_A = 14.9$ c.p.s., $J_{AB} = 10$ c.p.s.); 5.80 (1H, AB system, $\delta_B-\delta_A = 7.1$ c.p.s., $J_{AB} = 11.5$ c.p.s.); 5.20 (1H, singlet); 4.87 (1H, singlet).

Anal. Calcd. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46. Found: C, 76.77; H, 9.43.

Ozonolysis of Prehelminthosporol δ-Lactone (VIII) (with Dr. R. W. White)

The lactone (60 mg) was dissolved in ethyl acetate and a stream of ozonized oxygen passed through at −70° for 20 min. After evaporation of the solvent, water (5 ml) was added and the solution boiled briefly. Removal of the water under reduced pressure gave a partially crystalline gum which was chromatographed on silica gel (5 g). The fraction eluted with benzene gave, after crystallization from ether – light petroleum, the nor δ-lactone (IX), m.p. 100–101.5°; $[\alpha]_D$ −4° (*c*, 0.99); $\nu_{max}^{CCl_4}$ 1 773, 1 742 cm^{-1}.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53. Found: C, 70.93 ;H, 8.14.

Decarboxylation of the Nor δ-Lactone (XI) (with Dr. R. W. White)

The keto-lactone (IX) (51 mg) was added to aqueous sodium hydroxide (10%; 10 ml) and the mixture refluxed for 30 min. After acidification the product was isolated with ether and chromatographed on silica gel (5 g). The fraction eluted with benzene–ether (9:1) was sublimed (120°; 2 torr) to give the ketol (XI) (22 mg), m.p. 56–58°; $[\alpha]_D$ +35° (*c*, 1.18); $\nu_{max}^{CCl_4}$ 3 610, 1 739, 1 410 cm^{-1}; n.m.r. spectrum: 9.12 (3H, doublet, $J \sim 5$ c.p.s.); 9.08 (3H, singlet); 9.04 (3H, doublet, $J \sim 5$ c.p.s.); 8.7–7.79 (9H, complex); 7.42 (1H, complex); 7.04 (1H, singlet); 6.46 (2H, complex).

Anal. Calcd. for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54. Found: C, 74.55; H, 10.48.

Isolation of Anthraquinone

A sterile infusion (100 l) was prepared and inoculated with *Helminthosporium sativum* as described above. Samples of the infusion were taken after 24, 48, 72, 96, and 120 h and worked up as described previously (Table I). The evaporated chloroform extracts were examined by t.l.c. on silica gel, but showed relatively little variation in composition of the extract after the appearance of toxicity as determined by inhibition of germination of *Monilinia fructicola* (Table II).

TABLE I

h after inoculation	Sample volume, l	Weight evaporated chloroform extract, g
24	20	1.27
48	20	1.68
72	20	2.30
96	20	7.75
120	28	8.47

TABLE II

h after inoculation	% inhibition					
	Culture filtrate dilution:					
	1:2	1:4	1:8	1:16	1:32	1:64
24	0	0	0	0	—	—
48	100	100	68	11	—	—
72	100	100	91	33	—	—
96	100	100	100	63	20	0
120	100	100	100	52	20	0

After they had been allowed to stand overnight at 4°, both the evaporated chloroform extracts obtained after 24 and 48 h of growth contained small amounts (ca. 15 and ca. 1 mg respectively) of a crystalline material. None was present in any of the later extracts. This crystalline material was identified as anthraquinone, m.p. 280–282° (sealed capillary), undepressed on admixture with an authentic sample, by its infrared and mass spectra.

THE SOLVOLYSIS OF ARENESULFINATES, SULFUR–OXYGEN VERSUS CARBON–OXYGEN BOND FISSION[1,2]

DAVID DARWISH AND JOHN NOREYKO
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The base-catalyzed solvolysis of *p*-methoxyneophyl benzenesulfinate and the corresponding 2,6-dimethyl-, 2-methyl-, 4-methyl-, and 2-chloro-benzenesulfinates has been studied in ethanol and aqueous ethanol. The reactions involve sulfur–oxygen bond fission. The rate of sulfur–oxygen bond fission is decreased by the introduction of two methyl groups ortho to the sulfur. The rate decrease may be partly due to steric hindrance to nucleophilic attack on the sulfinate sulfur, but this effect is very small compared to the effect in carboxylate ester hydrolysis. The reactions are catalyzed by ethoxide, acetate, and pyridine. Reaction is very slow in the presence of 2,6-lutidine. With certain arenesulfinate esters one can control the reaction to give sulfur–oxygen or carbon–oxygen bond fission by choice of an appropriate base.

INTRODUCTION

The solvolysis of arenesulfinates can involve either sulfur–oxygen or carbon–oxygen bond fission. Kenyon and co-workers (1, 2) have shown that (−)-α-phenylethyl *dl*-*p*-toluenesulfinate yields α-phenylethyl alcohol of retained configuration on hydrolysis and ethanolysis, indicating that sulfur–oxygen bond cleavage has taken place. The ethoxide ion catalyzed ethanolysis of the diasterioisomeric (−)-menthyl (+)-*p*-iodobenzenesulfinate and (−)-menthyl (−)-*p*-iodobenzenesulfinate both yield (−)-menthol in a concentration equivalent to the amount of ester originally present, indicating essentially exclusive sulfur–oxygen bond cleavage (3). Methyl *p*-toluenesulfinate undergoes a slow neutral hydrolysis as well as a rapid reaction in alkaline solution and an acid-catalyzed hydrolysis in dioxane–water mixtures. The base- and acid-catalyzed reactions have been shown (4) by the use of ^{18}O tracers to involve sulfur–oxygen bond fission. Similarly, the sulfur–oxygen bond is broken on alkaline hydrolysis of diphenylmethyl *p*-toluenesulfinate (5). The formation of sulfones and substitution products on solvolysis of arenesulfinates (6, 7, 8) indicates that under certain conditions carbon–oxygen bond fission must occur.

Our interest in the reaction of arenesulfinates centered mainly on reactions involving carbon–oxygen bond fission (8, 9). However, it was necessary to investigate the sulfur–oxygen bond cleavage reactions to choose conditions under which sulfur–oxygen bond fission would not take place as an undesirable side reaction. Two general approaches were followed. First, an examination of the effect of substituents upon the rate of sulfur–oxygen bond fission was made. Secondly, the effect of various nucleophiles upon the rate of reaction was investigated.

Different products are obtained from alcoholysis of arenesulfinates involving sulfur–oxygen and carbon–oxygen bond fission. Sulfur–oxygen bond fission gives rise to ester interchange and yields a new arenesulfinate ester as shown in eq. [1]. Carbon–oxygen

[1] $$R{-}O{-}\overset{\overset{O}{\uparrow}}{S}{-}Ar + R'OH \rightarrow R'{-}O{-}\overset{\overset{O}{\uparrow}}{S}{-}Ar + ROH$$

[2] $$R{-}O{-}\overset{\overset{O}{\uparrow}}{S}{-}Ar + R'OH \rightarrow ArSO_2H + ROR' \ (+ \text{olefin})$$

bond fission gives rise to an arenesulfinic acid and solvolysis products as shown in eq. [2]. Thus, product analysis provides information on the type of bond cleavage. If water is the substituting agent, a sulfinic acid and an alcohol are produced by both sulfur–oxygen and carbon–oxygen bond fission. One must then use other criteria to determine the type of bond fission which has occurred.

The systems chosen for this study were arenesulfinate esters of *p*-methoxyneophyl alcohol. Since these esters have a neophyl type of structure, one can rule out direct nucleophilic displacement on the primary carbon as a major route for carbon–oxygen bond fission. If carbon–oxygen bond fission were to occur, the reaction should involve neighboring *p*-anisyl participation (10), giving rise to products from the rearranged carbonium ion as shown in eq. [3]. Sulfur–oxygen bond fission would yield the unrearranged alcohol, *p*-methoxyneophyl alcohol. Therefore, with this system one can distinguish between carbon–oxygen and sulfur–oxygen bond fission by product analysis, even with water as the nucleophile.

[3] $$H_3C{-}\overset{\overset{An}{|}}{\underset{\underset{CH_3}{|}}{C}}{-}CH_2{-}O{-}\overset{\overset{O}{\uparrow}}{S}{-}Ar \rightarrow CH_3{-}\overset{\overset{+}{|}}{\underset{\underset{CH_3}{|}}{C}}{-}CH_2{-}An + ArSO_2^- \rightarrow \text{products}$$

RESULTS

Preparation of Esters

The 2,6-dimethyl-, *o*-chloro-, and *o*-methyl-benzenesulfinic acids were prepared by a method described by Hanke (11) which involved diazotization of the corresponding substituted aniline and treatment of the solution with sulfur dioxide in the presence of copper powder. Benzene- and *p*-toluene-sulfinic acids were prepared by reduction of the corresponding sulfonyl chlorides with zinc powder.

The arenesulfinic acids were treated with thionyl chloride in pentane to obtain the corresponding acid chlorides. The acid chlorides were dissolved in pyridine and treated with the appropriate alcohol to yield the arenesulfinate esters after work-up.

Rate Measurements

A summary of the rate constants for the reaction of a number of *p*-methoxyneophyl arenesulfinates is presented in Table I. In most cases the reactions were followed by measuring the increase in absorption of the band at ca. 11.35 μ where the corresponding ethyl arenesulfinates have an intense absorption band. These reactions were therefore studied by measuring the rate of formation of the product of sulfur–oxygen bond fission. In the cases where the solvent was an ethanol–water mixture the disappearance of absorption at ca. 10.4 μ, associated with the *p*-methoxyneophyl arenesulfinate, was measured.

In every case first-order rate constants were calculated within any run. Good first-order rate constants were obtained with ethoxide or acetate as the added base, except for the reactions of *p*-methoxyneophyl 2,6-dimethylbenzenesulfinate in the presence of acetate ion. These rate constants showed a marked upward drift as the reaction progressed. The initial rate constants reported for these reactions are obtained from the slope of the curve obtained by plotting log $(a - x)$ versus time. When 2,6-lutidine and pyridine were

the added bases the reactions were very slow, and again only initial rate constants were estimated. The rate constants estimated for the reaction of the 2,6-dimethylbenzenesulfinate in the presence of added acetate ion and for all the reactions with added pyridine and 2,6-lutidine are very crude. These rate constants may be in error by as much as a factor of two. As shown in Table I the reactions were second order: first order in ester and first order in added ethoxide or acetate. The order of the reaction with respect to added pyridine and lutidine was not determined.

Titrations for acid were also carried out at each point in the rate determinations when ethoxide or acetate was the base. In the reactions involving anhydrous ethanol as solvent, acid production would indicate reaction via carbon–oxygen bond fission. No change in acid titer was detected in the course of the reactions in solvent ethanol. Therefore, only sulfur–oxygen bond fission occurred.

Reaction Products

In solvent ethanol the reaction product was the corresponding ethyl arenesulfinate as shown by the kinetic studies. A product run was carried out on the reaction of methoxyneophyl 2,6-dimethylbenzenesulfinate in 60% ethanol–water with 2,6-lutidine as added base. The reaction mixture was heated for 46 days at 90.0°, corresponding to ca. 20% reaction. The reaction mixture was separated into ester and alcohol fractions by chromatography. The ester was unreacted *p*-methoxyneophyl 2,6-dimethylbenzenesulfinate and the alcohol was *p*-methoxyneophyl alcohol as shown by infrared spectroscopy.

DISCUSSION

The displacement reaction must involve sulfur–oxygen bond fission as shown by the reaction products.

The reaction is second order: first order with respect to the ester and first order with respect to the base when ethoxide or acetate is the added base. The order of the reactions with respect to pyridine and 2,6-lutidine has not been determined.

There are four types of mechanisms which are consistent with the data. These four mechanisms can be divided into two categories. (i) Catalysis, which involves a nucleophilic displacement on sulfur by the base to yield a substitution product. In the case of ethoxide ion the substitution product would be the product ethyl arenesulfinate. In the case of acetate ion a mixed anhydride would be formed. The mixed anhydride would be converted rapidly to the ethyl arenesulfinate by reaction with the solvent. (ii) General base catalysis, which involves attack by the solvent on the ester concerted with transfer of a proton to the added base. The ethyl arenesulfinate would be produced directly regardless of the nature of the base.

Within each of the mechanistic schemes described above a further subdivision can be made. Substitution could involve concerted bond-making and bond-breaking to yield the substitution product in a manner analogous to that for a nucleophilic displacement on saturated carbon. Alternatively, displacement could occur in a stepwise fashion involving, first, addition of the nucleophile to sulfur followed, in a second step, by loss of the leaving group. In the hydrolysis of cyclic sulfite esters Bunton *et al.* (12) have reported that ^{18}O exchange with the solvent does not occur in significant competition with hydrolysis. Davis (14) suggested that the small amount of exchange observed by Bunton (12) indicated that there was evidence for an intermediate. However, de la Mare *et al.* (13) have indicated that the exchange may represent experimental error.

The data here reported cannot distinguish between these four alternative mechanisms. For the amines, one can exclude mechanisms in which the lyate ion of the solvent is formed in a rapid preequilibrium step by reaction with the added base followed by a slow reaction of the lyate ion with the substrate as shown in eqs. [4] and [5].

$$\text{B:} + \text{C}_2\text{H}_5\text{OH} \overset{K}{\rightleftarrows} \text{C}_2\text{H}_5\text{O}^{\ominus} + \text{BH}^{\oplus} \qquad [4]$$

$$\text{C}_2\text{H}_5\text{O}^{\ominus} + \text{RO}_2\text{SAr} \overset{k}{\rightarrow} \text{C}_2\text{H}_5\text{O}_2\text{SAr} + \text{RO}^{\ominus} \qquad [5]$$

The latter alternative is ruled out as follows. 2,6-Lutidine is a stronger base than pyridine. If reaction occurred by the above scheme, then the reaction should be faster in the presence of 2,6-lutidine than in the presence of pyridine. The opposite result is observed and, therefore, this alternative can be excluded.

Within the framework of the four mechanisms the effects of substituents, solvents, and bases are consistent and are discussed below.

Substituent Effects

A summary of the relative rates of ethanolysis of a number of arenesulfinates is presented in Table II. It is instructive to compare these relative rates with the relative rates of base-catalyzed hydrolysis of the correspondingly substituted ethyl benzoates in 85% aqueous ethanol (25). One ortho substituent has a small and roughly equivalent effect on both reactions. Two ortho methyl groups have a much smaller effect on the rate of reaction of the arenesulfinate ester than on the rate of hydrolysis of the benzoate ester.

TABLE II

Relative rates of reaction of various *p*-methoxyneophyl arenesulfinates at 90° in anhydrous ethanol with potassium acetate as added base

Benzenesulfinate	Ester (*M*)	Base (*M*)	$10^4 k$ (s^{-1})	Relative rates
2-Chloro	0.02486	0.0478	4.05	1.45
4-Methyl	0.02465	0.0478	1.60	0.58
2-Methyl	0.02510	0.0478	1.15	0.41
Unsubstituted	0.02502	0.0478	2.78	1.0
2,6-Dimethyl	0.02422	0.0478	0.075	0.028

If the decrease in rate on changing from the benzenesulfinate to the 2-methybenzenesulfinate is ascribed entirely to an electronic effect and if it is assumed that the electronic effect of a second ortho methyl group would reduce the rate by a similar amount, then the 2,6-dimethylbenzenesulfinate reacts at a rate which is ca. 1/6 of the anticipated value. This extra rate decrease may be associated with steric hindrance to attack on the sulfinate sulfur. Even if all of the rate reduction observed in comparing the benzenesulfinate and 2,6-dimethylbenzenesulfinate is ascribed to a steric effect, the difference in rates is less than a factor of 40. In contrast, the hydrolysis of ethyl benzoate is nearly five powers of 10 faster than the hydrolysis of ethyl 2,6-dimethylbenzoate.

Any increase in non-bonded interactions at the transition state relative to the ground state must be very small for the arenesulfinate esters as compared to the large effect for the carboxylate esters. The carbon–sulfur bond in the arenesulfinates is longer (ca. 1.8 Å) than the carbon–carbon bond of the Ar—C=O system (1.5 Å). Therefore, the region of greatest size of the transition state may effectively be removed further from the ortho methyl groups in the arenesulfinate than in the benzoate ester reactions and may account for much of the difference in behavior of the two systems.

The arenesulfinate esters appear to be more nearly analogous in behavior to the sulfonate esters than to the benzoate esters. Thus, Bunnett and Bassett (15) have observed that there is no detectable steric hindrance on the rate of sulfur–oxygen bond fission of a number of arenesulfonate esters.

Solvent Effects

The change of solvent from anhydrous ethanol to 80% ethanol and 60% ethanol reduced the rate constant for 2,6-dimethylbenzenesulfinate ester disappearance with ethoxide and acetate ion, respectively, as added bases. The reaction in the presence of 2,6-lutidine was faster in 60% ethanol–water than in anhydrous ethanol. These observations are consistent with all four mechanisms. The reaction of the negatively charged bases with the ester must involve charge dispersal at the transition state and, hence, increasing the polarity of the medium should hinder reaction (16). The reaction of neutral bases with the ester must involve charge formation at the transition state and will be facilitated by increasing the polarity of the solvent.

The above discussion of solvent effects must be qualified, since it considers only changes in charge distribution and solvent polarity. Other factors, such as the extent of ion pairing of the salts, and the change from ethoxide to hydroxide ion as the water content of the solvent is increased, may also be of importance. Bunton and co-workers (5) have reported that the hydroxide ion catalyzed hydrolysis of methyl *p*-toluenesulfinate is 40 times faster in 40% dioxane–water than in 60% dioxane–water. This reaction would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

be expected to be faster in 60% dioxane–water than 40% dioxane–water, if only the effect of solvent polarity on changes in charge distribution were important.

Effect of the Base

The rate of sulfur–oxygen bond fission varies enormously with the nature of the added base. The esters are particularly susceptible to attack by the strongly basic ethoxide ion; the nitrogen bases 2,6-lutidine and pyridine are much less effective than acetate ion at facilitating the reaction. Edwards and Pearson (17) have suggested that basicity is of prime importance for nucleophilic character towards tetrahedral sulfur. On this basis, if the reactions of the arenesulfinates involved nucleophilic attack on sulfur by the added base, then one would predict the observed reactivity order. Similarly, if the reactions of the esters involved general base catalysis, the observed order of reactivity would be anticipated. The fact that pyridine is a more effective catalyst than 2,6-lutidine would, in the first case, reflect the steric hindrance of the methyl groups to attack on sulfur by the nitrogen base. In the latter, it would be required that steric hindrance to general base catalysis be invoked to explain the greater effectiveness of pyridine than 2,6-lutidine. Westheimer and co-workers (18, 19) have reported a number of examples of reactions which exhibit steric hindrance in general base catalysis.

The difference in rates for ethanolysis of the arenesulfinates with pyridine and 2,6-lutidine as added bases may be larger than it appears from an examination of the data in Table I. The 2,6-lutidine used in these experiments contained a small amount of a methylpyridine. The observed reaction may have involved catalysis by the impurity and not by the 2,6-lutidine. If the reaction in the presence of pure 2,6-lutidine were significantly slower than the value reported, it would tend to suggest that the reactions of the other bases involve a nucleophilic substitution on sulfur by the added base.

The most important result of these experiments is the demonstration that one can greatly reduce the rate of sulfur–oxygen bond fission in arenesulfinate esters by the use of weak bases. In systems which can undergo facile carbon–oxygen as well as sulfur–oxygen bond fission, it is possible to control the type of bond cleavage by choosing the appropriate base. A remarkable illustration of this behavior is found in the ethanolysis of allyl 2,6-dimethylbenzenesulfinate (20). In anhydrous ethanol at 90.0° with acetate ion as the added base, allyl 2,6-dimethylbenzenesulfinate yielded ethyl 2,6-dimethylbenzenesulfinate plus a trace of allyl 2,6-dimethylphenylsulfone. Under the same conditions but with 2,6-lutidine as the added base, the reaction was slower and allyl 2,6-dimethylphenyl sulfone was the only detectable reaction product.

EXPERIMENTAL

α,α-Dimethyl-p-methoxybenzyl Cyanide

This compound was prepared by the method of Heyningen (21, 10) from *p*-methoxybenzyl cyanide (22). The yield of product, b.p. 110–113° at 2 mm pressure, η_D^{25} 1.5142 (reported (10), b.p. 110° at 3 mm pressure, η_D^{25} 1.5143), was 50%.

p-Anisyldimethylacetic Acid

α,α-Dimethyl-*p*-methoxybenzyl cyanide was hydrolyzed by the method described by Heyningen (21). The acid, recrystallized from aqueous methanol, melted at 88–89.5° (reported (10), 88–89.5°).

p-Methoxyneophyl Alcohol

Lithium aluminium hydride reduction of the above acid produced *p*-methoxyneophyl alcohol, m.p. 46.5–48.5° (reported (10), m.p. 45–46.5°) after recrystallization from Skellysolve B.

Arenesulfinic Acids

Benzene- and *p*-toluene-sulfinic acids were prepared by reduction of the corresponding sulfonyl chlorides with zinc dust by the method described by Vogel (23).

§The bands at lower frequency, where recorded, were used in the rate determinations.

The 2,6-dimethyl-, 2-chloro-, and 2-methyl-benzenesulfinic acids were prepared by the method described by Hanke (11) from the correspondingly substituted anilines. In a typical experiment 31 g of 2,6-dimethylaniline yielded 32.6 g of 2,6-dimethylbenzenesulfinic acid, m.p. 95–98°.

Arenesulfinates

All the arensulfinates were prepared by the same general procedure. In a typical preparation 4.6 g of 2,6-dimethylbenzenesulfinic acid was treated with 15 ml of thionyl chloride in 50 ml of pentane. After vigorous reaction had subsided, the solution was filtered through a glass wool filter. The solution was warmed on a steam bath to remove the pentane. The thionyl chloride was removed by pumping under vacuum overnight. The residual 2,6-dimethylbenzenesulfinyl chloride, an oil, was dissolved in 15 ml of anhydrous pyridine and cooled in a dry ice – acetone bath. A solution of 5 g of *p*-methoxyneophyl alcohol in 25 ml of pyridine was added. The reaction mixture was then allowed to warm up to room temperature. The mixture was poured into a mixture of ice and 35 ml of concentrated hydrochloric acid and extracted with ether. The ether extract was washed 3 times with water, then with dilute hydrochloric acid, again with water, and then 6–8 times with 10% sodium carbonate solution or until no yellow color appeared in the aqueous layer. After the extract was dried over magnesium sulfate, the ether was removed by warming the solution on a steam bath. The residue was recrystallized from 10% ether–pentane to yield 4.5 g of *p*-methoxyneophyl 2,6-dimethylbenzenesulfinate, m.p. 57–58.5°.

Analyses and physical properties of the arenesulfinates are summarized in Table III. The nuclear magnetic resonance spectra of these and other arenesulfinates are of interest and will be described in a subsequent paper.

Solvents

Ethanol was dried by treatment with magnesium ethoxide as described by Fieser (24).

Ethanol–water (80% by volume) was prepared by mixing 8 volumes of anhydrous ethanol to which the appropriate amount of base had been added and 2 volumes of boiled distilled water which had previously been equilibrated at 25°.

Ethanol–water (60% by volume) was prepared by mixing 6 volumes of ethanol to which the appropriate amount of base had been added and 4 volumes of boiled distilled water which had previously been equilibrated at 25°.

Kinetic Measurements

A sample of ester was accurately weighed into a 100-ml volumetric flask. A stock solution of the solvent containing the appropriate base was added and the solution was made up to the mark with the solvent. For rates at 90° the sealed ampoule technique was employed. Ampoules were removed from the constant temperature bath controlled to ±0.03° and quenched in ice water. The ampoules were equilibrated to 25° and a 5-ml aliquot was removed by means of a calibrated 5-ml automatic pipette. The 5-ml aliquots were delivered into a 60-ml separatory funnel containing 25 ml of pentane and 10 ml of water. The pentane layer was washed 4 times with 10 ml of water. The pentane layer was dried over anhydrous granular potassium carbonate. The combined water washings were titrated with standard hydrochloric acid (for reactions in which ethoxide was the base) or standard sodium methoxide in methanol using phenolphtholein as the indicator. The residual oil, obtained by removal of the pentane from the dried pentane solution, was diluted with two 1-ml aliquots of carbon disulfide using a 1-ml automatic pipette. The infrared spectrum of the

solution was recorded in the region from 10 to 12 μ with the 20 cm per micron scale using a Perkin–Elmer model 21 infrared spectrophotomer. The reference cell containing carbon disulfide was of the variable spacer type. The values of log (I_0/I) were measured using the base line technique. For rates at 25° the volumetric flask was immersed in the constant temperature bath. Aliquots were removed using a 5-ml automatic pipette and quenched by transferring to a 60-ml separatory funnel containing 25 ml of pentane and 10 ml of water. The rest of the procedure was as described for reactions at 90°.

Controls were run on all the esters to ensure that a linear relationship between absorbance and concentration was obeyed after the extraction procedure had been carried out. A sample rate run is presented in Table IV.

Product Run

A 0.844-g quantity of *p*-methoxyneophyl 2,6-dimethylbenzenesulfinate and 0.447 g of 2,6-lutidine were dissolved in 100 ml of ethanol (60% by volume) and transferred to a 250-ml flask having a constricted neck. The flask was sealed and placed in the 90° constant temperature bath for 46 days. The cooled reaction mixture was poured onto ice containing 1 ml of 6 *N* hydrochloric acid. The mixture was extracted twice with ether. The combined ether extracts were washed twice with saturated aqueous sodium bicarbonate and dried over magnesium sulfate. The ether was removed by careful distillation through a Vigreux column. The residue was separated into ester and alcohol fractions by chromatography on 30 g of alumina. The infrared spectrum of the ester fraction (0.72 g, 85%) showed it to be the starting material, *p*-methoxyneophyl 2,6-dimethylbenzenesulfinate. The infrared spectrum of the alcohol (25 mg, 6%) corresponded to the spectrum of authentic *p*-methoxyneophyl alcohol. The presence of less than 5% of ethyl 2,6-dimethylbenzenesulfinate or 1-*p*-anisyl-2-methyl-2-propanol in the ester and alcohol fractions respectively would not have been detected.

THE REACTION OF UNSATURATED CARBOHYDRATES WITH CARBON MONOXIDE AND HYDROGEN

V. ABSOLUTE STEREOCHEMISTRY OF ANHYDRODEOXYHEPTITOLS FROM 3,4,6-TRI-*O*-ACETYL-D-GLUCAL. STEREOCHEMISTRY OF HYDROFORMYLATION. CONFORMATIONAL ANALYSIS

ALEX ROSENTHAL AND HANS J. KOCH
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

3,4,6-Tri-*O*-acetyl-D-glucal reacted with carbon monoxide and hydrogen in the presence of dicobalt octacarbonyl to yield a mixture of two epimeric anhydrodeoxyheptitols, namely, 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptitol (I) and 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*gluco*-heptitol (II). De-*O*-acetylation of the mixture, followed by chromatographic separation, yielded crystalline 2,6-anhydro-3-deoxy-D-*manno*-heptitol (III) and 2,6-anhydro-3-deoxy-D-*gluco*-heptitol (IV). Reaction of the mixture of heptitols (I) and (II) with *p*-bromobenzenesulfonyl chloride, followed by fractional crystallization of the brosylates, gave pure 4,5,7-tri-*O*-acetyl-2,6-anhydro-1-*O*-(*p*-bromophenylsulfonyl)-3-deoxy-D-*gluco*-heptitol (VII). The absolute configuration of (VII) has been previously established by X-ray crystallographic analysis. The absolute configuration of (III) was established by correlation with that of (VII). The conversion of compound (II) into various derivatives is described.

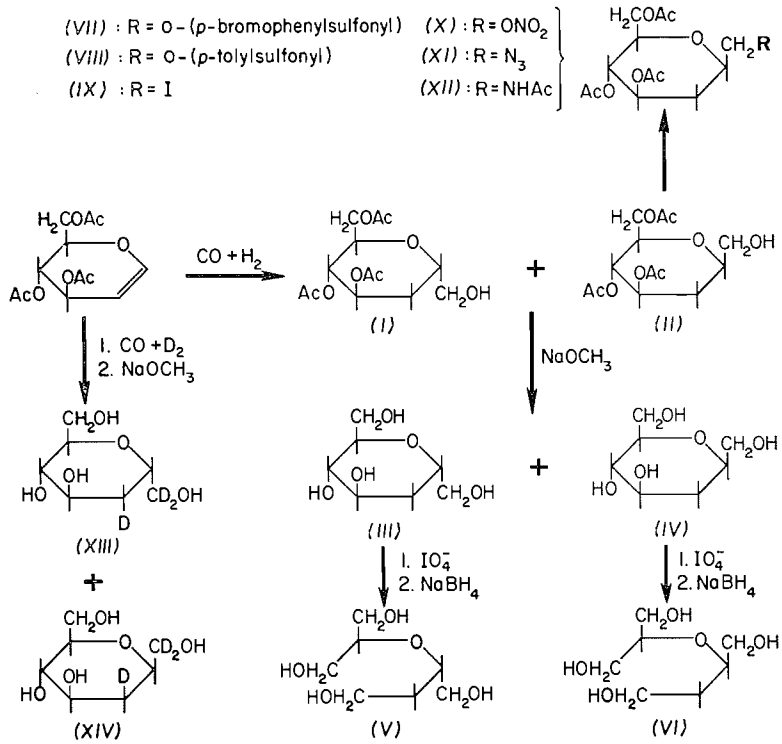
Reaction of 3,4,6-tri-*O*-acetyl-D-glucal with carbon monoxide and deuterium afforded 2,6-anhydro-3-deoxy-D-*manno*-heptitol-1,1,3-$^2H_3$ (XIII) and 2,6-anhydro-3-deoxy-D-*gluco*-heptitol-1,1,3-$^2H_3$ (XIV). Examination of the nuclear magnetic resonance (n.m.r.) spectra of the normal and deuterated anhydrodeoxyheptitols confirmed the structural assignments and showed that *cis* addition to the double bond took place to give (XIV).

Comparison of the exchange reaction of sodium iodide with 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*gluco*-heptitol (VIII) and with 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*manno*-heptitol (XV) revealed that the equatorial primary tosyloxy group of (VIII) was exchanged by iodine twice as readily as the axial primary tosyloxy group of (XV).

Preceding papers in this series (1, 2) have reported that pentals react preferentially at C-1 with carbon monoxide and hydrogen to yield epimeric anhydrodeoxyhexitols. This paper deals with the extension of the oxo reaction to 3,4,6-tri-*O*-acetyl-D-glucal. A preliminary report of part of this work has already appeared (3).

When 3,4,6-tri-*O*-acetyl-D-glucal was subjected to the oxo reaction at a temperature of about 130°, an almost quantitative yield of a mixture of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptitol (I) and 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*gluco*-heptitol (II) was obtained. De-*O*-acetylation of this mixture with methanolic sodium methoxide afforded the crystalline parent anhydrodeoxyheptitols (III) and (IV) which were readily separated by paper chromatography or cellulose column chromatography. Both heptitols were also converted into crystalline acetates.

Alternatively, the oxo product mixture was separated in the following ways. Tosylation of the mixture of (I) and (II) yielded the monotosylate esters (VIII) and (XV), which, on fractional crystallization, afforded pure crystalline 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*gluco*-heptitol (VIII). Chromatographic separation of the monotosylates by thin-layer chromatography (t.l.c.) gave both epimers. Similarly, treatment of (I) and (II) with *p*-bromobenzenesulfonyl bromide, followed by fractional crystallization of the



brosylates, produced pure 4,5,7-tri-*O*-acetyl-2,6-anhydro-1-*O*-(*p*-bromobenzenesulfonyl)-3-deoxy-D-*gluco*-heptitol (VII). The purity of the tosylate and brosylate esters was established by their conversion into 4,5,7-tri-*O*-acetyl-2,6-anhydro-1,3-dideoxy-1-iodo-D-*gluco*-heptitol (IX), which, on treatment with silver nitrate, yielded the 1-*O*-nitro derivative (X). Reduction of the latter substance with hydrogen over palladium, followed by de-*O*-acetylation, gave the crystalline anhydrodeoxyheptitol (IV).

In order that the point of attachment of the hydroxymethyl group to the glycal might be ascertained, the heptitols (III) and (IV) were first oxidized with periodate (1 mole consumed by each) and the resulting dialdehydes were then reduced with sodium borohydride. The fact that enantiomeric tetrol ethers (V) and (VI) were produced established that the heptitols (III) and (IV) are epimers which differ in the configuration of C-2. This assignment of structure was confirmed by analysis of the n.m.r. spectra of the heptitols. The spectra of both heptitols (see Fig. 1, *a* and *c*) exhibit a multiplet of peaks at $\delta = 1.5$ to 2 having an area which corresponds to the two methylenic hydrogens on C-3.

The configuration of C-2 of both epimeric 2,6-anhydro-3-deoxyheptitols was then readily established by application of n.m.r. spectroscopy, as previously described (1), to the 3-deoxy-3-deuterioanhydroheptitols (XIII) and (XIV) which were produced when 3,4,6-tri-*O*-acetyl-D-glucal was caused to react with carbon monoxide and deuterium. Thus, as shown in Fig. 1, *b*, the chemical shift and quartet structure (width of 17.7 c.p.s.) of the signal of intensity one at around $\delta = 1.7$ require the C-3 proton to be in an axial orientation and coupled with the C-4 axial and C-2 equatorial hydrogens. On the other hand, as depicted in Fig. 1, *d*, the corresponding narrower quartet of signals (width 7.3 c.p.s.) of intensity one at the lower field ($\delta = 1.94$) necessitates that the C-3 proton of compound (XIV) is in an equatorial orientation and coupled with the C-4 and C-2 axial hydrogens.

For personal use only.

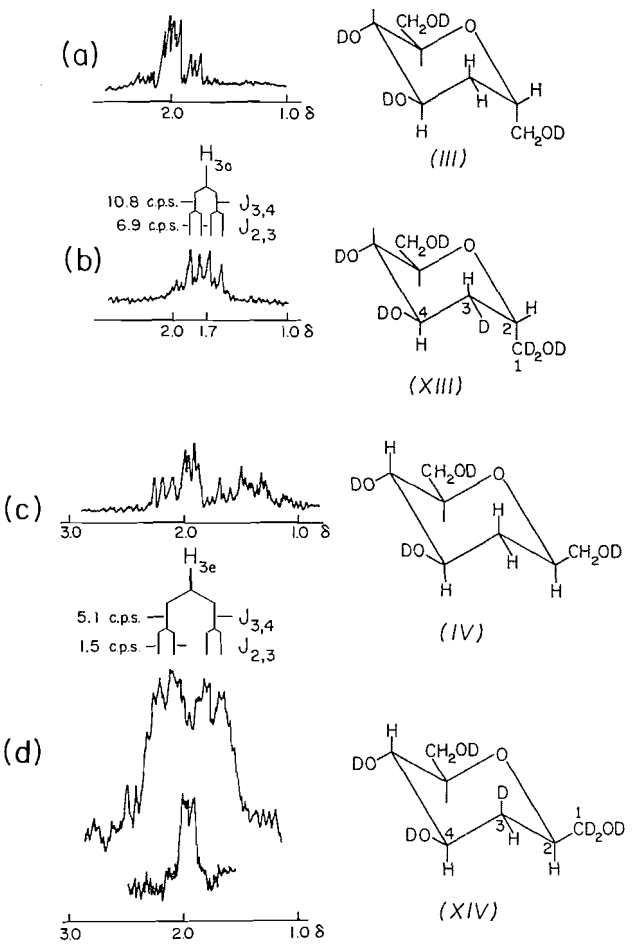

FIG. 1. Proton n.m.r. spectra in D_2O solution at 60 Mc/s with chemical shifts given in p.p.m. from tetramethylsilane as zero: (*a*) 2,6-anhydro-3-deoxy-D-*manno*-heptitol; (*b*) 2,6-anhydro-3-deoxy-D-*manno*-heptitol-1,1,3-$^2H_3$; (*c*) 2,6-anhydro-3-deoxy-D-*gluco*-heptitol; (*d*) 2,6-anhydro-3-deoxy-D-*gluco*-heptitol-1,1,3-$^2H_3$. (Only signals of protons attached to C-4 are shown.)

Therefore, compounds (XIII) and (XIV) are 2,6-anhydro-3-deoxy-D-*manno*-heptitol-1,1,3-$^2H_3$ (*cis*) and 2,6-anhydro-3-deoxy-D-*gluco*-heptitol-1,1,3-$^2H_3$ (*cis*), respectively. Evidently, the deuterated heptitols (XIII) and (XIV) must have been formed by a *cis* addition of the hydroxymethyl group and of the deuterium to the 1,2-unsaturated bond of 3,4,6-tri-*O*-acetyl-D-glucal. Unequivocal confirmation of the structures of the heptitols was provided by carrying out an independent X-ray crystallographic analysis (4) of a derivative of compound (II), namely, 4,5,7-tri-*O*-acetyl-2,6-anhydro-1-*O*-(*p*-bromobenzenesulfonyl)-3-deoxy-D-*gluco*-heptitol (VII).

The utility of the monotosylate ester (VIII) in synthesis was demonstrated by its conversion into the 1-amino derivative. Treatment of compound (VIII) with ammonia in methanol afforded the 1-amino derivative, which was isolated in the fully acetylated form (XII). Attempts to convert the tosylate ester (VIII) into the amino derivative via the monoiodo derivative (IX), thence into the azido derivative, followed by catalytic reduction of the azido compound to (XII), were not successful and were abandoned.

Very little work has been reported (5) on correlating the reactivity of primary hydroxyl groups of carbohydrates with their orientation. From this work, which has dealt mainly with the polyol bicyclic acetal derivatives, it has been adduced that the axially oriented tosyloxy group reacts with sodium iodide with greater ease than the equatorial group when both groups are in similar environments (5). Preferential reaction at the axial tosyloxy group would not be expected in a reaction that seems to be (6) rather strongly retarded by an increase in the size of substituents in the vicinity of tosyloxy groups.

Since an acetal ring is known to greatly reduce the chemical reactivity of adjacent tosyloxy groups (7–9), we believed that carbohydrates possessing the pyran ring and only one tosyloxy group would be suitable model substances for correlating chemical reactivity of the tosyloxy group and its orientation. The mono-1-*O*-tosylate derivative of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*gluco*-heptitol and of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptitol appeared to be ideal model compounds because these epimers differ in one aspect only, namely, one possesses an equatorial tosyloxy group whereas the other has an axial tosyloxy group. X-ray crystallographic studies have definitely established that 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*gluco*-heptitol (VIII) exists in the chair conformation with all groups in equatorial positions (4). On the bases of the facts that 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*manno*-heptitol (XV) was prepared by tosylation of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptitol following the same procedure as utilized in the preparation of its epimer, and the n.m.r. spectra of the two tosylates were similar, the tosyl group was assumed to be on C-1. If there had been acetyl migration before the tosylation, then the tosyl group would have been on a secondary hydroxyl group. Because replacements by iodide of a tosyloxy group on a secondary hydroxy under the conditions used in our work are not known to occur (10), the assumption that compound (XV) had its tosylate group on C-1 appears to be valid.

Samples of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*gluco*-heptitol (VIII) and of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*manno*-heptitol (XV) were allowed to react with sodium iodide in acetone at 100° in closed tubes for varying periods of time as shown in the Experimental section. The solutions were equimolecular with respect to each other. The extent of the exchange reaction was determined by weighing the sodium *p*-toluenesulfonate precipitated. In the figures quoted in the Experimental section, the solubility of sodium *p*-toluenesulfonate in a solution of acetone and sodium iodide was taken into account. The results clearly show that the equatorial tosyloxy group at C-1 of (VIII) was replaced at about double the rate by iodine than was the axial tosyloxy group at C-1 of (XV).

When a 0.01-mole mixture of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptitol (I) and 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*gluco*-heptitol (II) was allowed to react with 0.011 mole of *p*-toluenesulfonyl chloride at room temperature for 22 h, all of compound (II) was tosylated, whereas only a trace of compound (I) was converted into the tosylate (XV).

EXPERIMENTAL

General Considerations

General conditions for chromatographic separations have been described previously (1). Preparation of *p*-nitrobenzoyl derivatives was carried out by a procedure similar to that described by Gorin (11).

Reaction of 3,4,6-Tri-O-acetyl-D-glucal with Carbon Monoxide and Hydrogen to Yield 2,6-Anhydro-3-deoxy-D-manno-heptitol (III) and 2,6-Anhydro-3-deoxy-D-gluco-heptitol (IV)

3,4,6-Tri-*O*-acetyl-D-glucal (12) was caused to react with carbon monoxide and hydrogen in the presence of preformed dicobalt octacarbonyl according to a procedure previously described (1). The product was de-*O*-acetylated with sodium methoxide to yield a mixture of compounds (III) and (IV). Fractionation of

the mixture of anhydrodeoxyheptitols was carried out by preparative paper chromatography or by cellulose column chromatography at 37°.

The ratio of (I) and (II) depended on the temperature of the reaction. At 130° it was almost equimolar.

Characterization of Fractions (III) and (IV)

*Fraction (III) (2,6-anhydro-3-deoxy-*D*-manno-heptitol).*—This fraction was crystallized from methanol – isopropyl ether; m.p. 152–153°, $[\alpha]_D^{20}$ +60° (*c*, 1.4, water), R_F = 0.21.

Anal. Calcd. for $C_7H_{14}O_5$: C, 47.18; H, 7.92. Found: C, 47.30; H, 7.82.

*1,4,5,7-Tetra-O-acetyl-2,6-anhydro-3-deoxy-*D*-manno-heptitol.*—Fraction (III) was acetylated with acetic anhydride in the presence of sodium acetate to yield a tetra-*O*-acetyl derivative which was first purified by chromatography on silica gel using 2.5% methanol in benzene as developer and then crystallized from ether – light petroleum ether; m.p. 123–124°, $[\alpha]_D^{20}$ +28° (*c*, 0.5, acetone).

Anal. Calcd. for $C_{15}H_{22}O_9$: C, 52.02; H, 6.40. Found: C, 52.53; H, 6.55.

*Fraction (IV) (2,6-anhydro-3-deoxy-*D*-gluco-heptitol).*—This fraction was crystallized from methanol – isopropyl ether; m.p. 137–138°, $[\alpha]_D^{20}$ −1° (*c*, 3.5, water), R_F = 0.30.

Anal. Calcd. for $C_7H_{14}O_5$: C, 47.18; H, 7.92. Found: C, 47.19; H, 7.63.

*1,4,5,7-Tetra-O-acetyl-2,6-anhydro-3-deoxy-*D*-gluco-heptitol.*—Fraction (IV) was acetylated and purified in the same way as described above to yield a tetra-*O*-acetyl derivative; m.p. 79–80°, $[\alpha]_D^{21}$ +2° (*c*, 0.5, acetone).

Anal. Calcd. for $C_{15}H_{22}O_9$: C, 52.02; H, 6.40. Found: C, 52.48; H, 6.50.

Structure and Stereochemistry of Compounds (III) and (IV)

*2-Deoxy-3-O-(1,3-dihydroxy-2-propyl)-*D*-glycero-tetritol (V) from 2,6-Anhydro-3-deoxy-*D*-manno-heptitol (III)*

Oxidation of 2,6-anhydro-3-deoxy-D-*manno*-heptitol with 0.1 *M* periodic acid (1 mole consumed), followed by reduction of the resulting dialdehyde with sodium borohydride in water according to the procedure described by Gorin (11), gave the tetrol ether (V) as a sirup; $[\alpha]_D^{19}$ −25° (*c*, 0.7, methanol). This sirup was converted into a tetra-*O*-(*p*-nitrobenzoyl) derivative; m.p. 149–150.5°, $[\alpha]_D^{22}$ −22° (*c*, 1.5, chloroform).

Anal. Calcd. for $C_{35}H_{28}O_{17}N_4$: C, 54.13; H, 3.63; N, 7.21. Found: C, 54.55; H, 3.71; N, 7.30.

*2-Deoxy-3-O-(1,3-dihydroxy-2-propyl)-*L*-glycero-tetritol (VI) from 2,6-Anhydro-3-deoxy-*D*-gluco-heptitol (IV)*

Periodate oxidation and sodium borohydride reduction of the dialdehyde from (IV) under similar conditions to those described above gave the tetrol ether (VI); $[\alpha]_D^{22}$ +26° (*c*, 2.9, water). This formed a tetra-*O*-(*p*-nitrobenzoyl) derivative which was recrystallized from ethyl acetate – petroleum ether; m.p. 151–152°; $[\alpha]_D^{21}$ +22° (*c*, 1.2, chloroform).

Anal. Calcd. for $C_{35}H_{28}O_{17}N_4$: C, 54.13; H, 3.63; N, 7.21. Found: C, 54.50; H, 3.94; N, 7.50.

The infrared spectra of the tetra-*O*-(*p*-nitrobenzoyl) derivatives of the tetrol ethers (V) and (VI) were identical.

Alternative Methods of Separation of the Heptitols (I) and (II) by Conversion to 1-O-Sulfonate Esters (VII) and (VIII)

*A. 4,5,7-Tri-O-acetyl-2,6-anhydro-1-O-(p-bromophenylsulfonyl)-3-deoxy-*D*-gluco-heptitol (VII)*

p-Bromobenzenesulfonyl bromide (2.6 g) was added to 2 g of an ice-cold anhydrous mixture of oxo product (I) and (II) dissolved in anhydrous pyridine (15 ml). After the mixture was left at room temperature for 30 h, 20 ml of water was added and the mixture left to stand for 24 h. The solution was then extracted with three portions of chloroform. The combined chloroform extracts were washed with water and then dried over anhydrous sodium sulfate. Evaporation of the chloroform left a residue which was twice recrystallized from methanol, and then from methanol–water; yield 1.01 g; m.p. 104°; $[\alpha]_D^{22}$ −10° (*c*, 3, chloroform).

Anal. Calcd. for $C_{19}H_{23}O_{10}SBr$: C, 43.58; H, 4.43; S, 6.13; Br, 15.27. Found: C, 43.57; H, 4.47; S, 6.32; Br, 15.26.

The proof of structure of compound (VII) by X-ray crystallographic studies has been described previously (4).

*B. 4,5,7-Tri-O-acetyl-2,6-anhydro-3-deoxy-1-O-tosyl-*D*-gluco-heptitol (VIII)*

The tosylate ester (VIII) was prepared by tosylation of the mixture of compounds (I) and (II) following the same procedure as used in the preparation of the brosylate ester (VII). Fractional crystallization of the tosylates gave compound (VIII) in pure form; m.p. 117–118°, $[\alpha]_D^{20}$ −5° (*c*, 0.5, chloroform); n.m.r. (given in δ units; spectra obtained in deuterated chloroform): 2.0 (acetyl and CH_2, area = 11H), 2.37 (CH_3, area = 3H), 3.55 (area = 2H), 3.95 (multiplet, area = 4H), 4.85 (area = 2H), 7.17 (doublet, area = 2H), 7.61 (doublet, area = 2H).

Anal. Calcd. for $C_{20}H_{26}O_{10}S$: C, 52.50; H, 5.52. Found: C, 52.20; H, 5.51.

*4,5,7-Tri-O-acetyl-2,6-anhydro-3-deoxy-1-O-tosyl-*D*-manno-heptitol (XV)*

An amount of 4.8 g of the oxo products (I) and (II) was allowed to react with 6.0 g of *p*-toluenesulfonyl chloride in 125 ml of anhydrous pyridine at room temperature for 12 h and then heated at 100° for 1 h. Work-up of the product in the usual way gave 5.06 g of a mixture of compounds (VIII) and (XV). Thin-layer chromatographic separation of this mixture (0.45 g) on silica gel using toluene–ether (2:1, v:v), or isopropyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ether, as developer afforded 0.30 g of (VIII) and 0.08 g of (XV). The tosylates were detected by spraying the samples with diphenylamine in methanol (1% solution) and viewing them under ultraviolet light.

4,5,7-Tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*manno*-heptitol (XV) was obtained as an oil; $[\alpha]_D^{23}$ +30° (*c*, 1.7, chloroform); n.m.r.: 2.0 (11H), 2.40 (3H), 3.55 (2H), 4.00 (multiplet, 4H), 4.90 (multiplet, 2H), 7.17 (2H), 7.65 (2H).

Anal. Calcd. for $C_{20}H_{26}O_{10}S$: C, 52.50; H, 5.52. Found: C, 52.36; H, 6.18.

Comparative Rate of Tosylation of Oxo Products (I) and (II)

An amount of 0.010 mole of oxo product mixture (70% of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*manno*-heptitol (I) and 30% of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*gluco*-heptitol (II)) was allowed to react with 0.011 mole of *p*-toluenesulfonyl chloride (0.011 mole) at room temperature for varying periods of time and the product analyzed by t.l.c. on silica gel using isopropyl ether as developer. Compound (II) was completely tosylated after 22 h whereas only a trace of compound (I) was converted into the tosylate (XV) during the same time.

4,5,7-Tri-O-acetyl-2,6-anhydro-1,3-dideoxy-1-iodo-D-gluco-heptitol (IX)

4,5,7-Tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*gluco*-heptitol was allowed to react with sodium iodide in acetone in a closed tube at 100° for 6 h to afford 4,5,7-tri-*O*-acetyl-2,6-anhydro-1,3-dideoxy-1-iodo-D-*gluco*-heptitol; m.p. 100°, $[\alpha]_D^{22}$ −13° (*c*, 0.1, chloroform).

Anal. Calcd. for $C_{13}H_{19}O_7I$: C, 37.69; H, 4.62; I, 30.64. Found: C, 37.58; H, 4.35; I, 30.58.

Treatment of the brosylate (VII) with sodium iodide in acetone also yielded compound (IX).

4,5,7-Tri-O-acetyl-2,6-anhydro-3-deoxy-1-O-nitro-D-gluco-heptitol (X)

4,5,7-Tri-*O*-acetyl-2,6-anhydro-1,3-dideoxy-1-iodo-D-*gluco*-heptitol dissolved in acetonitrile was caused to react with silver nitrate according to a procedure previously described (10). The product (X) was recrystallized from ether – light petroleum ether; m.p. 79°, $[\alpha]_D^{22}$ −8° (*c*, 0.7, acetone).

Anal. Calcd. for $C_{13}H_{19}O_{10}N$: C, 44.71; H, 5.48; N, 4.08. Found: C, 44.58; H, 5.12; N, 4.06.

Conversion of 4,5,7-Tri-O-acetyl-2,6-anhydro-3-deoxy-1-O-nitro-D-gluco-heptitol (X) into 2,6-Anhydro-3-deoxy-D-gluco-heptitol (IV)

An amount of 30 mg of compound (X) dissolved in anhydrous methanol (10 ml) was hydrogenated over palladium black (3 mg) at atmospheric pressure and room temperature for 75 min. After removal of the catalyst, the solvent was evaporated under vacuum and the product then dried. De-*O*-acetylation of the residual sirup with methanolic sodium methoxide gave a compound having a melting point, R_F value, and infrared spectrum identical with those of authentic 2,6-anhydro-3-deoxy-D-*gluco*-heptitol (IV).

1-Acetamido-4,5,7-tri-O-acetyl-2,6-anhydro-1,3-dideoxy-D-gluco-heptitol (XII)

An amount of 0.148 g of 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-1-*O*-tosyl-D-*gluco*-heptitol was added to an ammonia-saturated solution of methanol (12 ml). The reactants were heated in a sealed tube at 100° for 65 h. After the ammonia evaporated, the methanol was removed under reduced pressure and the product then dried. Acetylation of the product with 4 ml of acetic anhydride and 4 ml of pyridine in the usual way gave the fully acetylated amino compound (XII). Purification of (XII) was achieved by column chromatography on silica gel using benzene–methanol (96:4, v:v) as developer. Recrystallization of the product (0.065 g) from acetone – isopropyl ether – heptane gave pure (XII); m.p. 136–137°, $[\alpha]_D^{22}$ −3° (*c*, 1.8, chloroform); n.m.r.: 2.05 (multiplet, area = 14H), 3.5 (multiplet, area = 4H), 4.1 (multiplet, area = 2H), 4.82 (multiplet, 2H), 5.75 (broad, area = 1H).

Anal. Calcd. for $C_{15}H_{23}O_8N$: C, 52.17; H, 6.71; N, 4.06. Found: C, 51.94; H, 7.01; N, 3.94.

Attempt to Prepare 1-Acetamido-2,6-anhydro-1,3-dideoxy-D-gluco-heptitol from Compound (IX)

An amount of 0.24 g of 4,5,7-tri-*O*-acetyl-2,6-anhydro-1,3-dideoxy-1-iodo-D-*gluco*-heptitol (IX) was caused to react with sodium azide (0.5 g) in acetone (3 ml) and water (2 ml) for 10 h at a temperature of 110–120 °C in a sealed tube. After the tube was opened, 5 ml of ether was added. The ether layer was washed with water, dried over an anhydrous sodium sulfate, and then evaporated. The resulting azido compound (XI), dissolved in acetone, was decolorized by passage through a short column of charcoal; yield 0.083 g. Compound (XI) showed an azide peak at 2 120 cm^{-1} in the infrared spectrum. After it was dissolved in ethanol (20 ml), it was hydrogenated at atmospheric pressure for 6 h over platinum oxide (0.022 g) according to a procedure previously described (13). After removal of the catalyst, the solvent was evaporated under reduced pressure. The product was then acetylated in the usual way using acetic anhydride and pyridine. Addition of water to the reaction product gave a trace of crystalline product which was removed by filtration. After removal of the volatile components, the product was analyzed by thin-layer chromatography and shown to contain a trace of compound (XII).

Reaction of 3,4,6-Tri-O-acetyl-D-glucal with Carbon Monoxide and Deuterium to Yield 2,6-Anhydro-3-deoxy-D-manno-heptitol-1,1,3-$^2H_3$ (cis) (XIII) and 2,6-Anhydro-3-deoxy-D-gluco-heptitol-1,1,3-$^2H_3$ (cis) (XIV)

3,4,6-Tri-*O*-acetyl-D-glucal was caused to react with carbon monoxide and deuterium at 130°, under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

conditions similar to those used in the preparation of the normal anhydrodeoxyheptitols, to yield the above-mentioned deuterated heptitols (XIII) and (XIV). The stereochemisty of the deuterium atom on C-3 of both heptitols was determined by proton n.m.r. analysis (see Discussion).

Comparative Iodine Exchange Experiments of Tosylates (VIII) and (XV)

In each experiment each Carius tube contained 9.1 mg of the tosylate, 9.1 mg of sodium iodide, and 1.4 ml of acetone. After the tubes were cooled in solid carbon dioxide, they were sealed and then heated at 100° (±0.1) for varying periods of time. The amount of sodium *p*-toluenesulfonate was collected in a sintered-glass crucible, washed with 2 ml dry acetone, and dried under reduced pressure before they were weighed. A correction of 0.20 mg of sodium *p*-toluenesulfonate was added to each weight as this amount dissolved in the acetone at room temperature. The results are as follows: % exchange of tosylate by iodine of compound (VIII) 14 (5 min), 18 (10 min), 41 (23 min), 46 (41 min), 51 (60 min), 59 (90 min), 93 (162 min); % exchange of tosylate by iodine of compound (XV) 20 (30 min), 32 (60 min), 41 (120 min), 47 (300 min), 56 (420 min), 73 (630 min).

ACKNOWLEDGMENTS

The authors gratefully acknowledge the financial assistance of the National Cancer Institute of Canada, the National Research Council of Canada, the University of British Columbia Research Grant, and the Petroleum Research Fund administered by the American Chemical Society for support of this work.

Part of the preliminary experimental work was done by Mr. T. Field and Mr. R. Bolster.

The senior author (A. R.) expresses his gratitude to University Chemical Laboratory, University of Cambridge, for use of its facilities during the writing of this manuscript.

SOME TRANSFORMATIONS OF TETRACYCLINE AT THE 4-POSITION[1]

ROBERT K. BLACKWOOD AND CHARLES R. STEPHENS
Medical Research Laboratories, Chas. Pfizer and Co., Inc., Groton, Connecticut
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Reactions leading to the replacement of the 4-dimethylamino group of tetracycline by keto, hydroxy, hydroxyimino, hydrozono, and amino groups are reported.

INTRODUCTION

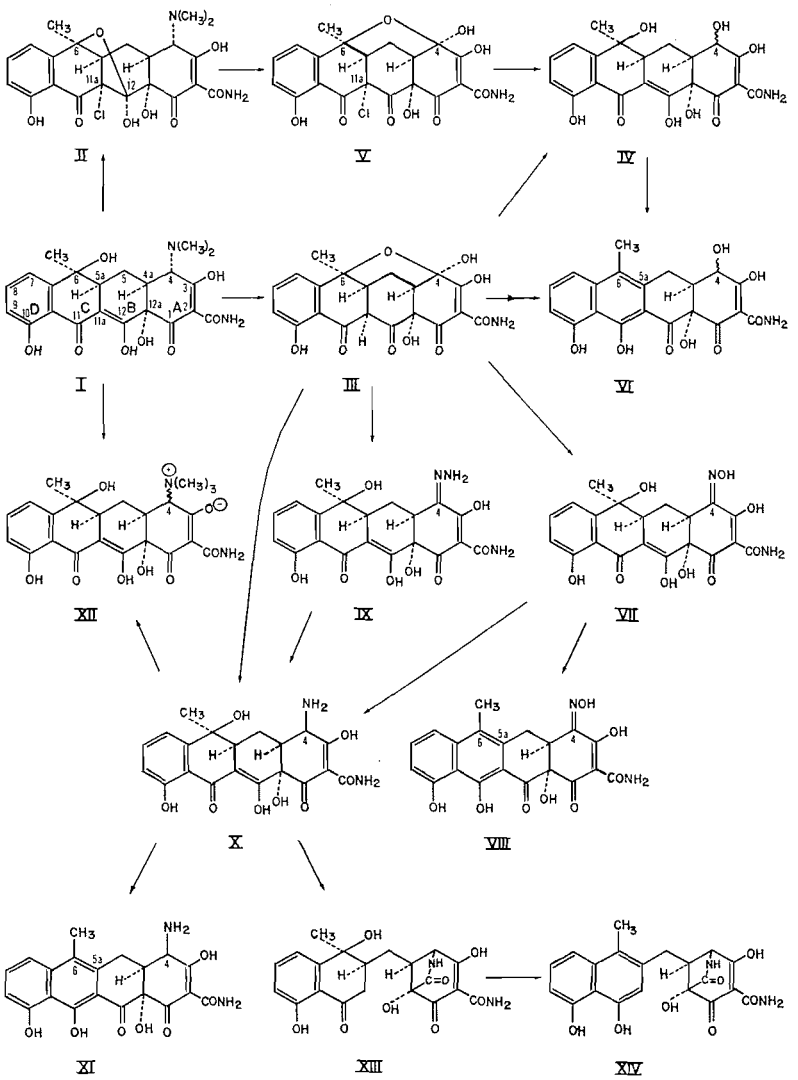
Only a limited number of transformations of tetracycline at C-4 have been previously reported: 4-dedimethylaminotetracyclines (3, 4), 4-epitetracyclines (5), and tetracycline methiodides (4, 6). An extension of earlier halogenation studies (7) has provided an entrée to further modification at this position. The chemistry investigated should be adaptable to the preparation of a broad variety of related derivatives.

DISCUSSION

The reaction of *amphoteric* tetracycline (I) with N-chlorosuccinimide in aqueous solvents to yield 11*a*-chlorotetracycline-6,12-hemiketal (II) has been described (7). A less-than-drastic change in reaction conditions—treatment of tetracycline *hydrochloride* with N-chlorosuccinimide in water—leads to rapid precipitation of a very different product, which we have characterized as 4-oxo-4-dedimethylaminotetracycline-4,6-hemiketal (III). Carbonyl absorption at 5.7 μ and ultraviolet absorption in acid (8-hydroxytetralone and unmodified A-ring chromophores) at first suggested possible close structural analogy to 11*a*-substituted tetracyclines (e.g. XV, cf. ref. 7). However, in excess methanolic sodium hydroxide, the ultraviolet absorption indicated that III is enolic, suggesting alternative analogy to 12*a*-epi-4-dedimethylamino-5-hydroxytetracycline (XVI, cf. refs. 6 and 8), which is isolated in the completely ketonic form, but is also enolized under basic conditions. Analyses on III confirmed suspected loss of the dimethylamine, and, further, showed that it contains additional oxygen, *but no chlorine*. The chemical properties of III, detailed below, demonstrate the presence, or potential presence, of a ketone group at C-4 and retention of the *cis* A- to B-ring juncture. No additional infrared absorption beyond that seen with compounds such as XV and XVI is noted in the carbonyl region. This and the unmodified A-ring ultraviolet chromophore in acid lead to the conclusion that the C-4 ketone is not free. By employment of the now firmly established stereochemistry of tetracycline (I, cf. ref. 9), model studies clearly indicate that the only reasonable structure which will account for all of the facts is that depicted in structure III, which results from formation of an internal hemiketal between the 6-hydroxyl and the newly formed 4-oxo group.

The same reaction has been applied successfully to 11*a*-chlorotetracycline-6,12-hemiketal (II) to provide the 11*a*-chloro-4-oxo analogue (V). Structural assignment is based

[1]*Much of the work described herein has been the subject of a preliminary communication (1). Similar independent studies employing 6-demethyltetracyclines have been reported by a group at Lederle Laboratories (2).*



on ultraviolet absorption in methanol – hydrochloric acid (virtually identical with that of the precursor, II), infrared absorption in the carbonyl region (closely analogous to those of III, XV, and XVI), and catalytic reduction to the alcohol (IV) with uptake of 2 equivalents of hydrogen.

The reaction which leads to formation of the 4-oxotetracyclines (III and V) appears to be of a novel type insofar as ketone formation is concerned, although aldehydes have been reported as products in prior studies on the interaction of tertiary amines with N-bromosuccinimide (10) and with hypochlorous acid (11). In the case of the N-bromosuccinimide reaction, initial bromination on carbon adjacent to nitrogen has been indicated (13). We would, therefore, suggest that, in the case of tetracycline, formation of the 4-oxo derivative occurs as shown in Reaction Scheme 1. Esse *et al.* (2), on the basis of additional evidence, have also proposed an imine intermediate in connection with their analogous studies on 6-demethyltetracyclines.

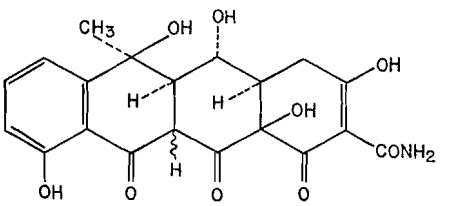
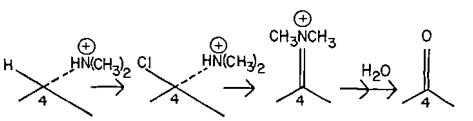
XV



XVI

4-Dedimethylamino-4-oxotetracycline-4,6-hemiketal (III) is readily reduced to the alcohol (IV, e.g. by sodium hydrosulfite, zinc combination, or catalytic hydrogenation). The latter shows the typical ultraviolet chromophores of tetracycline and no infrared carbonyl bands below 6 μ. The alcohol in turn is converted by acid degradation to its 5a,6-anhydro derivative (VI). Preliminary evidence indicates that the same anhydro alcohol is obtained by degradation of the 4,6-hemiketal in anhydrous hydrogen fluoride followed by reduction.



REACTION SCHEME 1.

Reaction of hydrazine and of hydroxylamine with the 4-oxo derivative (III) produces hydrazone (IX) and oxime (VII) respectively. The C,D-β-diketone system in these compounds is enolic, with the now more highly conjugated A-ring ultraviolet chromophores shifted to longer wavelengths. Both compounds are readily reduced to 4-epi-N^4,N^4-didemethyltetracycline (X). Under the conditions which we have employed (sodium hydrosulfite, zinc – acetic acid, or catalytic hydrogenation), it appears that the primary sight of reduction is the N—N or the N—O bond, rather than the C=N double bond. Thus, we have seen no evidence of intermediate hydrazines or hydroxylamines in these reactions. Furthermore, a major by-product in the case of sodium hydrosulfite reduction of VII or IX in aqueous solvents is the 4-hydroxy derivative (IV). Since there is no apparent hydrolysis in the absence of the reducing agent, it is proposed that there is initial reduction to an imine, part of which is reduced to amine and part of which is hydrolyzed to ketone (III) and then reduced to alcohol (IV). The amine (X) may also be obtained directly from the 4-ketone by reductive amination.[2]

[2]*Esse et al. (2) have reported extensively on reductive amination of the 6-demethyl analogue of III. They employed a variety of primary amines, although they did not describe use of ammonia. They have also assigned the 4-epi configuration to their alkylamino products and have shown them to contain the normal more active epimer as a minor component.*

Assignment of stereochemistry at C-4*a* in the 4-amino derivative (X) and its precursors is based on smooth conversion of X to tetracycline methyl betaine (XII) by reaction with methyl iodide, in the presence of excess propylene oxide as an acid scavenger.[3] Tentative assignment of stereochemistry at C-4 was earlier (1) deduced from the short wavelength ultraviolet absorption (almost identical with that of 4-epitetracycline) and from the presence of a minor more antibacterial substance in all preparations of the amine.[2] Unequivocal assignment of stereochemistry at C-4 in compound X derives from degradation studies in hot aqueous bicarbonate, which followed earlier studies by Korst and Butler (12) using an N^4-demethyltetracycline prepared by an unrelated reaction sequence. Under these conditions, the normal epimer persists, and can be readily separated from the degradation product, which has been characterized as the lactam, XIII. This non-basic compound is isomeric with its precursor and possesses 8-hydroxytetralone—A-ring ultraviolet chromophores and infrared absorption at 5.7 μ. It is degraded in acid to compound XIV, which displays ultraviolet absorption typical of 1,8-dihydroxynaphthalene and A-ring chromophores as well as retention of lactam carbonyl absorption. Formation of the lactam (XIII) from X undoubtedly occurs by transannular attack of the 4-amino group on the 12-carbonyl. Such an interaction requires that the amine be *trans* to C-4*a*-hydrogen (4-epi configuration). The undegraded minor component, which was not isolated in analytical pure form, shows the ultraviolet absorption characteristics of tetracycline, and, like the latter, is epimerized at C-4 in pyridine – acetic acid.

EXPERIMENTAL

4-Oxo-4-dedimethylaminotetracycline-4,6-hemiketal (III)

Tetracycline hydrochloride (10 g) was dissolved in 500 ml of water containing 2 ml of concentrated hydrochloric acid. (Initial experiments without added hydrochloric acid gave somewhat lower yields of crude product contaminated by greater amounts of tetracycline.) To the solution, with stirring at room temperature, was added 7 g of powdered N-chlorosuccinimide. The crude product began to precipitate within a few minutes. It was recovered by filtration, with water wash, after 30 min reaction time. Partial purification of the crude air-dried product (6.7 g) was achieved by distributing it between 150 ml of water and 400 ml of ether. The aqueous phase and five 40-ml water washes of the ether phase were discarded. The ether phase was stripped to dryness, the residue treated with water, and the product recovered by filtration. The yield of partially purified product, suitable for further transformations, was 5.6 g (65% overall).

For analysis, partially purified product (1 g) was dissolved in 4 ml of methanol, treated with Darco G-60, and filtered. The product crystallized as the monopotassium salt upon the addition of 0.40 ml of 5 *N* potassium hydroxide. The yield of material, dried *in vacuo* at 50° for 48 h, was 0.50 g (46%). It showed λ_{max}^{KBr} 5.7 μ; $\lambda_{max}^{MeOH\ -\ 0.01\ N\ HCl}$ 268 and 346 mμ (log ϵ 4.40 and 3.72); in MeOH – 0.01 *N* NaOH the compound is very unstable—a rapidly determined spectrum includes $\lambda_{max} \sim 370$ mμ (log $\epsilon \sim 4.4$).

Anal. Calcd. for $C_{20}H_{16}O_9NK \cdot 0.5H_2O$: C, 52.0; H, 3.7; N, 3.0; Cl, 0.0; K, 8.4; H_2O, 1.9. Found: C, 52.0; H, 3.8; N, 3.2; Cl, 0.0; K, 8.2; H_2O, 1.7.

Compcund III shows the typical acid instability of tetracyclines having a hydroxyl group at C-6 and unblocked at C-11*a*. For example, when the potassium salt of III was dissolved in liquid hydrogen fluoride, allowed to stand for 1.5 h, and then evaporated to dryness, it gave a crude product, presumed to be 5*a*,6-anhydro-4-oxotetracycline, possessing the expected ultraviolet spectral properties. The latter, on reduction with sodium hydrosulfite, is indicated by spectral and paper chromatographic evidence to yield the same anhydro–hydroxy derivative (VI) obtained by the alternative reduction–dehydration sequence.

4-Hydroxy-4-dedimethylaminotetracycline (IV)

Crude 4-oxo-4-dedimethylaminotetracycline-4,6-hemiketal (III, 25 g) was dissolved in 300 ml of methanol. A solution of sodium hydrosulfite (10 g) in 200 ml of water was added. The temperature rose from 25 °C to 35 °C during this process. The mixture was stirred for 40 min at room temperature. Water (250 ml) was added and the solution extracted twice with 1.25-l portions of ether. The combined ether layers were

[3]*Under these conditions tetracycline and 4-epitetracycline yield the same betaine. Without the acid scavenger, the reaction of X with methyl iodide ceases with uptake of 1 equivalent of the reagent to produce a mixture which is indicated by paper chromatography to include appreciable amounts of starting material, presumed 4-epi-N^4-demethyltetracycline, and 4-epitetracycline, as well as a minor quantity of tetracycline.*

back washed with five 50-ml portions of water, dried over anhydrous sodium sulfate, filtered, and evaporated to dryness in a rotating evaporator. The residue was treated with ca. 250 ml of water and the amorphous product (19.1 g) recovered by filtration. The product was crystallized from hot ethylene dichloride (recovery in three crops, 10.7 g, 33% overall from tetracycline). It shows λ_{max}^{KBr}, no carbonyl bands below 6 μ; $\lambda_{max}^{MeOH - 0.01\,N\,HCl}$ 257 mμ and 362 mμ (log ϵ 4.42 and 3.68); $\lambda_{max}^{MeOH - 0.01\,N\,NaOH}$ 246, 264, and 378 mμ (log ϵ 4.26, 4.23, and 4.28).

Anal. Calcd. for $C_{20}H_{19}NO_9$: C, 57.6; H, 4.6; N, 3.3. Found: C, 57.3; H, 4.6; N, 3.2.

The same 4-hydroxy compound (IV) is also obtained by sodium hydrosulfite reduction of partially purified, or the potassium salt of, 4-oxo-4-dedimethylaminotetracycline. Alternatively, it may be obtained by zinc dust reduction (e.g. in 50% aqueous acetic acid with excess zinc, with stirring for 30 min at room temperature) or catalytic hydrogenation (e.g. H_2, Pd/C in methanol at atmospheric pressure and room temperature) of either IV or the corresponding 11*a*-chloro derivative (V).

11a-Chloro-4-oxo-4-dedimethylaminotetracycline-4,6-hemiketal (V)

11*a*-Chlorotetracycline-6,12-hemiketal (II, ref. 2, 2.3 g) was slurried in 110 ml water containing 0.7 ml of concentrated hydrochloric acid. Powdered N-chlorosuccinimide (1.6 g) was added and the mixture stirred for 1 h at room temperature. The crude product was isolated by filtration with water wash. It crystallized on trituration with methanol. The yield was 11 g. For analysis, 1 g was dissolved in excess ether and filtered. The filtrate was washed with dilute hydrochloric acid and water, dried over anhydrous sodium sulfate, filtered, and finally stripped to dryness, and the residue triturated with methanol. The material, dried *in vacuo*, showed λ_{max}^{BKr} 5.77 μ; $\lambda_{max}^{MeOH - 0.01\,N\,HCl}$ 258 and 343 mμ (log ϵ 4.42 and 3.68).

Anal. Calcd. for $C_{20}H_{16}O_9NCl$: C, 53.4; H, 3.6; N, 3.1; Cl, 7.9. Found: C, 53.0; H, 3.7; N, 2.8; Cl, 8.0.

5a,6-Anhydro-4-hydroxy-4-dedimethylaminotetracycline (VI)

A solution of 4-hydroxy-4-dedimethylaminotetracycline (V, 0.5 g) was boiled in 5 ml of acetone containing 1.0 g of *p*-toluene sulfonic acid until the volume was reduced to ca. 1.5 ml. The product crystallized when the solution was cooled. It was recovered by filtration and dried *in vacuo* for analysis. It showed $\lambda_{max}^{MeOH - 0.01\,N\,HCl}$ 222, 262, 310, and 423 mμ (log ϵ 4.46, 4.70, 3.68, and 4.01).

Anal. Calcd. for $C_{20}H_{17}O_4N$: C, 60.1; H, 4.3; N, 3.5. Found: C, 59.8; H, 4.5; N, 3.3.

4-Hydroxyimino-4-dedimethylaminotetracycline (VII)

Partially purified 4-oxo-4-dedimethylaminotetracycline-4,6-hemiketal (III, 7.5 g) was dissolved in 30 ml of methanol. Potassium bicarbonate (15 g) and hydroxylamine hydrochloride (3.13 g) were added and the slurry stirred for 15 min. The mixture was filtered. Water (120 ml) was added to the mother liquor and the pH was adjusted to 2.0. The partially precipitated product was extracted into excess ether and recovered by evaporation dryness. The residue was slurried with 100 ml of benzene and the insoluble product (4.7 g, 60%) recovered by filtration. The crude product (2.1 g) was recrystallized by dissolving it in 6.3 ml of toluene and 4.2 ml of isopropyl alcohol, filtering it, adding 5.0 ml toluene to the mother liquor, and allowing the mixture to stand at room temperature overnight. The yield of product recovered by filtration and dried *in vacuo* at 50 °C was 1.0 g (48%). It showed $\lambda_{max}^{MeOH - 0.01\,N\,HCl}$ 222, 276, 308, and 359 mμ (log ϵ 4.25, 4.07, 4.23, and 4.19); $\lambda_{inf}^{MeOH - 0.01\,N\,HCl}$ 237 and 268 mμ (log ϵ 4.17 and 4.06); $\lambda_{max}^{MeOH - 0.01\,N\,NaOH}$ 235, 245, and 373 mμ (log ϵ 4.25, 4.24, and 4.28); $\lambda_{inf}^{MeOH - 0.01\,N\,NaOH}$ 256 and 325 mμ (log ϵ 4.21 and 4.16).

Anal. Calcd. for $C_{20}H_{18}O_9N_2$: C, 55.8; H, 4.2; N, 6.5. Found: C, 55.7; H, 4.4; N, 6.2.

5a,6-Anhydro-4-hydroxyimino-4-dedimethylaminotetracycline (VIII)

4-Hydroxyimino-4-dedimethylaminotetracycline (VII, 500 mg) was dissolved in 3 ml of 4% methanolic hydrogen chloride. The solution was boiled about 3 min and left to crystallize overnight at room temperature. The product (240 mg, 51%) was recovered by filtration with methanol wash and dried *in vacuo* at room temperature. It showed $\lambda_{max}^{MeOH - 0.01\,N\,HCl}$ 225, 263, 302, and 422 mμ (log ϵ 4.48, 4.64, 4.26, and 4.07).

Anal. Calcd. for $C_{20}H_{16}O_8N_2 \cdot 0.5CH_3OH$: C, 57.6; H, 4.2; N, 6.6. Found: C, 57.7; H, 4.1; N, 6.8.

4-Hydrazono-4-dedimethylaminotetracycline (IX)

Partially purified 4-oxotetracycline (III, 11.5 g), dissolved in 80 ml of 95% ethanol, was added to a solution of 1.7 ml of hydrazine hydrate in 80 ml of the same solvent. The mixture, which began to precipitate immediately, was stirred for 1 h and then left to stand overnight. The product was recovered by filtration and the crude air-dried product reslurried in an additional 100 ml of 95% ethanol for 1 h at room temperature. The yield of crystalline product, air-dried at room temperature, was 6.0 g (37%). For analysis, a sample was recrystallized from tetrahydrofuran–water. It showed $\lambda_{max}^{MeOH - 0.01\,N\,HCl}$ 264 and 335 mμ (log ϵ 4.16 and 4.53); $\lambda_{max}^{MeOH - 0.01\,N\,NaOH}$ 261, 323, and 373 mμ (log ϵ 4.33, 4.25, and 4.29).

Anal. Calcd. for $C_{20}H_{19}O_8N_3 \cdot H_2O$: C, 53.6; H, 4.7; N, 9.4. Found: C, 53.8; H, 4.6; N, 9.0.

4-Epi-N^4,N^4-didemethyltetracycline (X)

4-Hydrazono-4-dedimethylaminotetracycline (8.7 g) was dissolved in 350 ml of acetone. Water (260 ml) and then 17.4 g of sodium hydrosulfite were added to the stirred solution. The temperature rose from 25 °C to 32 °C. After it was stirred for an additional 30 min at room temperature, the now heterogeneous mixture was treated with charcoal and filtered through a Supercel pad with 1:1 acetone–water wash. The mother

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

liquor was stripped of acetone. The pH was adjusted to 4.5 and nonamphoteric by-products, including very considerable presumed 4-hydroxy-4-dedimethylaminotetracycline, were removed from the aqueous phase by thorough extraction with ethyl acetate. The desired product was then extracted into butanol (four times with 100-ml portions). The butanol was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness *in vacuo* in a rotating evaporator. The residue was slurried with and filtered from 33 ml of ethyl acetate. The yield of crude air-dried product was 2.6 g. This crude product was dissolved in 100 ml of dimethylformamide. The solution was clarified and 35 ml of water added to the mother liquor. When the solution was stirred slowly for 2 h, the product crystallized. The yield of vacuum-dried 4-epi-N^4,N^4-didemethyltetracycline, solvated with dimethylformamide, was 2.1 g (20%). It shows $\lambda_{max}^{MeOH - 0.01\ N\ HCl}$ 260 and 360 mμ (log ϵ 4.25 and 4.17); $\lambda_{max}^{MeOH - 0.01\ N\ NaOH}$ 246, 266, and 375 mμ (log ϵ 4.23, 4.22, and 4.25). Paper chromatography – bioautography indicate the product to contain a minor, slightly less polar material which is much more active against *Klebsiella pneumonia*.

Anal. Calcd. for $C_{20}H_{20}O_8N_2 \cdot 1.5(CH_3)_2NCHO$: C, 55.9; H, 5.8; N, 9.3. Found: C, 55.8; H, 5.9; N, 9.2.

The same compound (X) may also be obtained by analogous sodium hydrosulfite reduction of the oxime (VII). Alternatively, the hydrozane and the oxime (3 g) in 50% aqueous acetic acid (100 ml) were reduced by stirring for 30 min at room temperature with 3 g of zinc dust. Excess zinc was removed by filtration and the mother liquor evaporated to low volume. Water (100 ml) was added and the pH adjusted to 7.0 with sodium hydroxide. Crude zinc complex of X (3.9 g) was isolated by filtration and air dried. The product was characterized by ultraviolet absorption, paper chromatography, and conversion to the analytically pure 5*a*,6-anhydro derivative.

Compound X was obtained directly from 4-oxotetracycline-4,6-hemiketal by reductive amination. The partially purified hemiketal (III, 2.5 g) and 1.2 g of magnesium chloride hexahydrate were added to a slurry of platinum oxide (300 mg) prereduced in a mixture of 24 ml of dimethyl formamide and 3 ml of 28% ammonium hydroxide. Approximately 5 mmoles of hydrogen was taken up in 2.5 h at room temperature and atmospheric pressure. The catalyst was removed by filtration and crude product precipitated by addition of the mother liquor to 700 ml of ether that was being stirred. The crude magnesium complex (3.1 g) was characterized by ultraviolet absorption, paper chromatography, and conversion to the 5*a*,6-anhydro derivative.

5a,6-Anhydro-4-epi-N^4,N^4-didemethyltetracycline (XI)

The 5*a*,6-anhydro derivative (XI) was readily obtained from crude zinc complex of compound X (2.5 g) by dissolving in 15 ml of tetrahydrofuran and 1.5 ml of conc. hydrochloric acid. The filtered solution was allowed to stand at room temperature for 8 days. The tetrahydrofuran solvated product, which crystallized slowly, was recovered by filtration and dried *in vacuo* at 50 °C for 48 h. The yields were 0.7 g (30% overall from oxime) and 1.2 g (55% overall from hydrazone). It showed $\lambda_{max}^{MeOH - 0.01\ N\ HCl}$ 223, 272, and 423 mμ (log ϵ 4.45, 4.79, and 3.93); $\lambda_{max}^{MeOH - 0.01\ N\ NaOH}$ 229, 271, 338, and 428 mμ (log ϵ 4.39, 4.57, 3.73, and 4.09).

Anal. Calcd. for $C_{20}H_{18}O_7N_2 \cdot (CH_2)_4O \cdot HCl$: C, 56.8; H, 5.4; N, 5.5; Cl^-, 7.0; NH_2, 3.4. Found: C, 56.7, 56.6; H, 5.4, 5.0; H, 5.6, 5.5; Cl^-, 7.1, 7.1; NH_2, 3.2.

The volatile portion was only 3.7% when the compound was dried overnight *in vacuo* at 100 °C. When the compound was dried for 48 h at 100 °C, the analysis was consistent with loss of only part of the tetrahydrofuran.

Anal. Calcd. for $C_{20}H_{18}O_7N_2 \cdot 0.25(CH_2)_4O \cdot HCl$: C, 55.8; H, 4.7; Cl^-, 8.0. Found: C, 55.6; H, 5.0; Cl^-, 7.5.

Identical product was obtained by analogous acid degradation of either the purified 4-amino compound (X, dimethylformamide solvate) or the crude magnesium complex.

Tetracycline Methyl Betaine (XII)

The 4-amino derivative (X, dimethylformamide solvate, 100 mg) was refluxed overnight in a mixture of 2 ml acetone, 0.5 ml propylene oxide, and 0.5 ml methyl iodide. When the mixture was cooled, pure crystalline N^4-methyltetracycline betaine (70 mg, 79%) was recovered by filtration. The same product is obtained by use of this process with either tetracycline or 4-epitetracycline (87% and 84% yield respectively). They show identical behavior on paper chromatography and identical infrared absorption (KBr); $\lambda_{max}^{MeOH - 0.01\ N\ HCl}$ 271 and 358 mμ (log ϵ 4.24 and 4.17).

Anal. Calcd. for $C_{23}H_{26}O_8N_2 \cdot H_2O$: C, 58.0; H, 5.9; N, 5.9. Found: C, 58.0; H, 6.0; N, 5.6.

Tetracycline methyl betaine has been previously reported as a methanol solvate (4).

Degradation of 4-Epi-N^4,N^4-didemethyltetracycline

A solution of the amino compound (X, dimethylformamide solvate, 2.0 g) in 50 ml of 40% aqueous sodium bicarbonate was heated on a steam bath under nitrogen for 30 min. The solution was cooled to room temperature, transferred to a beaker, layered with 50 ml of ethyl acetate, and carefully acidified to pH 2.0 with 5% hydrochloric acid. The aqueous phase was further extracted with six 50-ml portions of ethyl acetate. After drying over anhydrous sodium sulfate, the combined ethyl acetate extracts were evaporated to dryness *in vacuo* to yield 1.34 g of crude lactam degradation product (XIII). To free the product of traces of the 4-amino derivative (principally the normal epimer), the crude product was taken up in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

1.9 l of ether and reevaporated to dryness. The recovery was 1.14 g. For analysis, the lactam was recrystallized from hot acetone–water. The recovery in two crops, dried *in vacuo*, was 0.87 g (51%). It shows $\lambda_{max}^{MeOH - 0.01\ N\ HCl}$ 258 and 335 mμ (log ϵ 4.38 and 3.73); $\lambda_{max}^{MeOH - 0.01\ N\ NaOH}$ 249, 262, and 335 mμ (log ϵ 4.22, 4.17, and 3.71); $\lambda_{max}^{dioxane}$ 5.72 and 6.07 μ.

Anal. Calcd. for $C_{20}H_{20}O_8N_2 \cdot 2H_2O$: C, 5.31; H, 5.3; N, 6.2. Found: C, 53.2; H, 5.4; N, 6.5.

In a separate experiment 200 mg of compound X was similarly degraded in bicarbonate. The pH was adjusted to 2.0 and the mixture filtered (insoluble, 10 mg). The mother liquor was extracted with eight 15-ml portions of butanol. The combined butanol extracts were evaporated to dryness. The residue (150 mg) was taken up in 20 ml water and 20 ml of ethyl acetate. The aqueous phase, after three further extractions with ethyl acetate, was freeze dried to yield 21 mg of crude N^4,N^4-didemethyltetracycline which paper chromatography indicated to be virtually free of the 4-epi compound. It showed $\lambda_{max}^{MeOH - 0.01\ N\ HCl}$ 268 and 362 mμ, and was readily epimerized (e.g. in acetic acid – pyridine) to compound X (paper chromatographic evidence).

The lactam (XIII) was degraded to the 1,8-dihydroxynaphthalene derivative (XIV) by refluxing the former (300 mg) in 10 ml of 1:6 conc. hydrochloric acid – methanol. The solution was cooled, clarified, and evaporated to dryness. The residue was taken up in excess ether and the ether washed with several small portions of water, dried over anhydrous sodium sulfate, and evaporated to dryness, and the amorphous product dried *in vacuo* for analysis. The yield of compound XIV was 250 mg (92%). It showed $\lambda_{max}^{MeOH - 0.01\ N\ HCl}$ 232, 257, 310, 325, and 339 mμ (log ϵ 4.43, 3.94, 3.48, 3.56, and 3.59); $\lambda_{max}^{dioxane}$ 5.73 and 6.05 μ.

Anal. Calcd. for $C_{20}H_{18}O_7N_2 \cdot 0.5H_2O$: C, 59.0; H, 4.7; N, 6.9. Found: C, 59.1; H, 5.1; N, 6.4.

ACKNOWLEDGMENTS

The authors thank Prof. R. B. Woodward, Dr. L. H. Conover, and Prof. H. Muxfeldt for stimulating discussions concerning this work. They are also grateful to Mr. T. J. Toolan and his associates for physical measurements and microanalyses, Mr. P. J. DeMuria and his associates for paper chromatographic studies, and Mr. J. A. Aimetti for technical assistance.

PYRAZOLINES

IV. REARRANGEMENT OF ALKYL GROUPS DURING THE PYROLYSIS OF 4,4-DIALKYL-3-CYANO-3-CARBOMETHOXY-Δ^1-PYRAZOLINES

DONALD E. MCGREER, ROBERT S. MCDANIEL, AND MAGNUS G. VINJE

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

A number of 4,4-dialkyl-3-cyano-3-carbomethoxy-Δ^1-pyrazolines have been synthesized. Pyrolysis of these pyrazolines yielded cyclopropane and olefin products. The formation of olefin products by rearrangement of an alkyl group from C_4 to C_5 of the pyrazoline system suggests that positive charge is developed on C_5 in the transition state. Ionic character in the transition state was also indicated by the fact that the rate of pyrolysis is faster in polar than in nonpolar solvents.

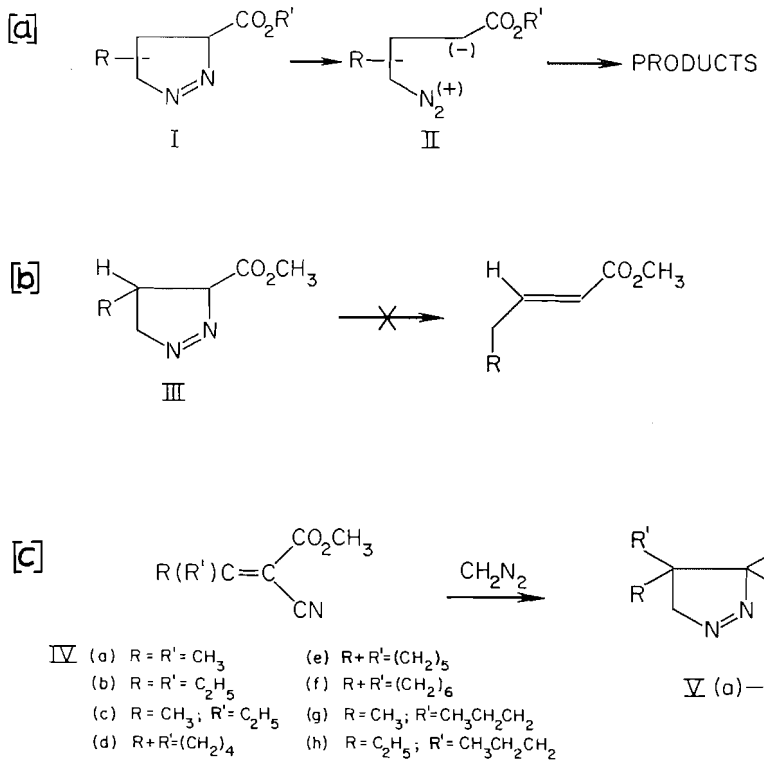
A mechanism which has been considered by a number of workers for the pyrolysis of 3-carbalkoxy-Δ^1-pyrazolines (I) and related systems has followed a form similar to the scheme shown in eq. [*a*] (1, 2). The products consist of cyclopropane derivatives and α,β- and β,γ-unsaturated olefins. The ring-opened intermediate II has been considered, since rotation around the bonds in II would explain the experimental fact (2) that cyclopropane products in which the stereochemistry in the cyclopropane is different from that in the pyrazoline are formed. As a starting point for further study we have therefore assumed II to closely represent the intermediate or transition state for this reaction. In this paper and the next paper in this series (3) we have looked for rearrangements which are characteristic of ionic compounds and which might be expected for intermediates with the ionic character shown in II.

Structure II suggests that positive charge is built up at C_5 of the pyrazoline system in the transition state. If this is the case, then rearrangements characteristic of carbonium ions should be possible for this system. Wagner–Meerwein rearrangements and related reactions clearly demonstrate that alkyl groups can readily migrate to a positive center. However, the migration of alkyl groups to a radical center or an anion center are predicted to be especially unfavorable (4). The occurrence of alkyl migration would be diagnostic of positive charge at C_5 in the transition state for the pyrolysis reaction.

In the pyrolysis of the many pyrazolines to date, there has been no observation of rearrangement of an alkyl or aryl group from C_4 of the pyrazoline ring to C_5 (see eq. [*b*]). This has been due, presumably, to the facile competitive migration of hydrogen in those pyrazolines analogous to compound III. To observe alkyl migration we therefore need two alkyl groups at C_4.

The pyrazoline from mesityl oxide is known (5, 6); however, heating this Δ^2-pyrazoline does not give an identifiable product. Attempts in this laboratory to prepare the corresponding methyl ester by reaction of diazomethane and methyl senecioate were unsuccessful. The presence of the two β-methyl groups on the acrylate system sterically hinders the system to such an extent that no reaction occurred when the reaction was carried out in a sealed tube for several days.

Successful preparation of a series of 4,4-dialkyl-Δ^1-pyrazolines was achieved by the



reaction of diazomethane with a number of methyl alkylidenecyanoacetates (IV*a*–IV*e*) (see eq. [*c*]). The required alkylidenecyanoacetates (IV) were readily prepared by the procedure of Cope (7) with modifications as developed by Widequist (8). Nuclear magnetic resonance (n.m.r.) was useful for the assignment of stereochemistry to compounds IV*c* and IV*g*. The assignments are based on the fact that the isopropylidene derivative (IV*a*) shows different peak positions for the two β-methyl groups (7.61 and 7.71 τ). In methyl *cis*- and *trans*-crotonate the β-methyls are found at 7.86 and 8.12 τ respectively (9), and in *cis*- and *trans*-crotonitrile the β-methyls are found at 8.05 and 8.20 τ respectively (10). The downfield shift is greater in the *cis* isomers and is greater for the *cis* ester than the *cis* nitrile. We therefore have assigned the β-methyl at 7.61 τ in IV*a* to that group *cis* to the carbomethoxy group and the β-methyl at 7.71 τ to that group *cis* to the nitrile.

The alkylidene derivatives IV*c*, IV*g*, and IV*h* for which R ≠ R′ are mixtures of two isomers. For IV*c* and IV*g* these mixtures contain one isomer with a β-methyl *cis* to the carbomethoxy group and one with a β-methyl *trans* to the carbomethoxy group. These compounds as isolated from the Cope reaction showed the β-methyls at 7.62 and 7.72 τ for IV*c* and 7.63 and 7.72 τ for IV*g* with intensities which indicated mixtures of about 50:50 composition. The isomers with the lower-field β-methyl were assigned the structure having the β-methyl *cis* to the carbomethoxy group and in this paper are referred to as IV*c* (methyl *cis*) and IV*g* (methyl *cis*).

Addition of diazomethane to methyl isopropylidenecyanoacetate (IV*a*) in ether at room temperature gave a solution which contained 4,4-dimethyl-3-cyano-3-carbomethoxy-Δ^1-pyrazoline (V*a*). Evaporation of the ether at 0° gave an oil which, when warmed to room temperature, decomposed exothermally to yield nitrogen and pyrolysis products.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The oil was more stable in solvents and was identified as pyrazoline (V*a*) by its n.m.r. spectrum.

Similarly, pyrazolines V*b* and V*c* were obtained from the alkylidenecyanoacetates IV*b* and IV*c*. The pyrazoline V*d* obtained from IV*d* was sufficiently less stable than the other pyrazolines that pyrolysis occurred during its preparation. A discussion of its structure is reserved until after the pyrolysis reaction has been discussed.

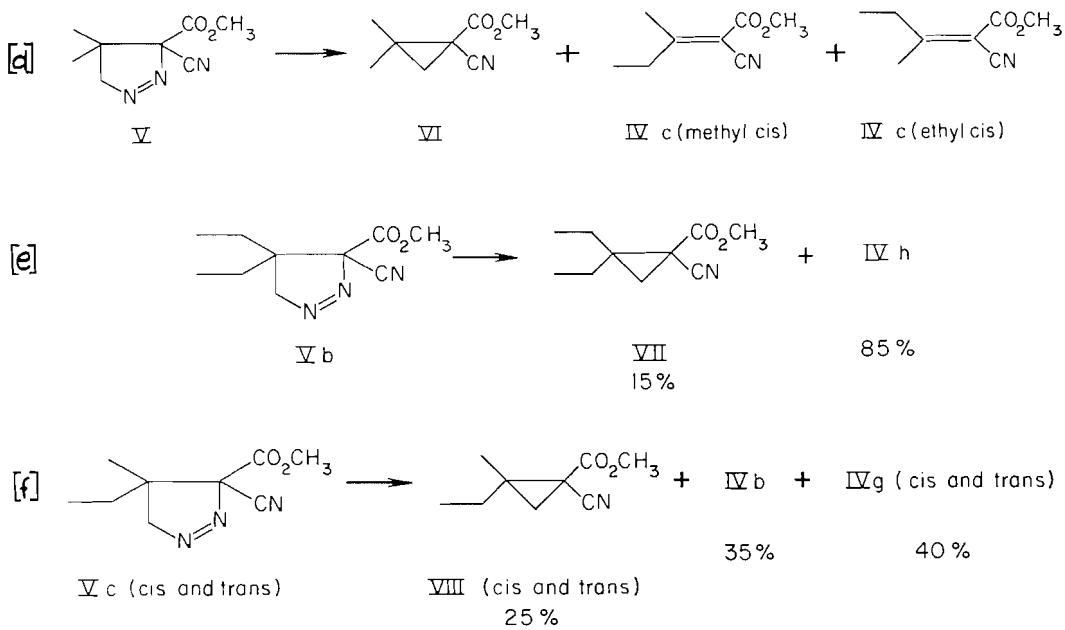
Pyrolysis of 4,4-dimethyl-3-cyano-3-carbomethoxy-Δ^1-pyrazoline (V*a*) gave a mixture of three products (see eq. [*d*]). Vapor chromatographic separation (v.p.c.) gave 2,2-dimethyl-1-cyano-1-carbomethoxycyclopropane (VI) and a mixture of the two isomeric methyl 1-methylpropylidenecyanoacetates (IV*c* (methyl *cis*) and IV*c* (ethyl *cis*)). This latter mixture could not be separated and was analyzed by n.m.r. The product analysis for pyrolysis of V*a* neat and in two solvents is given in Table I.

TABLE I

Product compositions for the pyrolysis of 4,4-dimethyl-3-cyano-3-carbomethoxy-Δ^1-pyrazoline V*a*

Solvent	VI	IV*c* (methyl *cis*)	IV*c* (ethyl *cis*)
Neat	39	39	22
Benzene	38	28	34
Tetrachloroethylene	57	5	38

Pyrolysis of the 4,4-diethylpyrazoline V*b* and the 4-ethyl-4-methylpyrazoline V*c* gave similar results with the formation of both cyclopropane and olefin products (see eqs. [*e*] and [*f*]). The olefins IV*b* and IV*g* were identical with authentic samples and IV*h* was



suggested by its analysis and n.m.r. spectrum. The cyclopropane VIII was characterized by its physical data and particularly by the absence of unsaturation as shown by n.m.r. and infrared. The cyclopropane VII could not be isolated. Instead, when attempts were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

made to isolate it, only a rearranged product which was indicated to be methyl 2-cyano-4-ethyl-4-hexenoate by its n.m.r. spectrum could be obtained. This rearrangement product was expected, since at the higher temperature needed for separation it was found that the related cyclopropanes VI and VIII were also rearranged (12). Thus, VI gave pure methyl 2-cyano-4-methyl-4-pentenoate (IX) when heated to 200° (see eq. [*g*]). The cyclopropane VII is therefore undoubtedly formed as a product from pyrazoline V*b*. The product compositions were determined for neat pyrolysis by vapor chromatography and are included in the equations for the reaction.

As mentioned above, the preparation of the pyrazoline from methyl cyclopentylidenecyanoacetate (IV*d*) was complicated by concurrent pyrolysis. Thus, methyl cyclohexylidenecyanoacetate (IV*e*), an expected product, was being formed during the reaction and also was reacting with the excess diazomethane. This reaction was readily followed by n.m.r. as shown by Fig. 1. At early stages of the reaction, removal of the ether gave an oil which showed peaks (Fig. 1A) in the n.m.r. caused by ether and methyl cyclopentylidenecyanoacetate (IV*d*) at 6.19 and 7.10 τ (ester methyl and β-methylenes respectively), and the pyrazoline V*d* at 5.12 and 5.59 τ (AB system, J = 17.8 c.p.s., for the hydrogens on C_5) and 6.11 τ (ester methyl), in addition to the ring hydrogens of IV*d* and V*d* at 8.25 τ. At later stages in the reaction (Fig. 1B) a similar sample showed peaks caused by

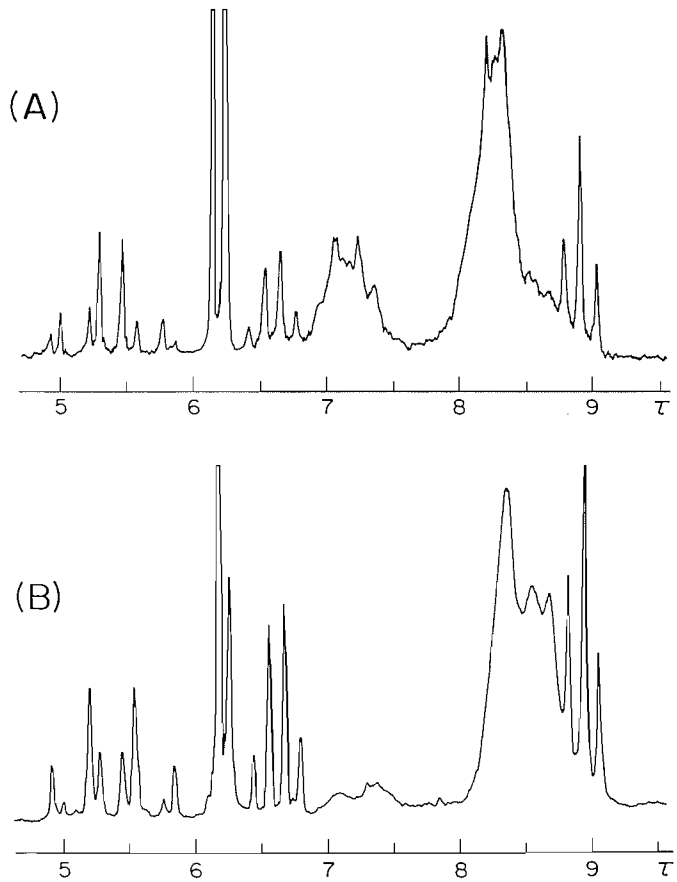


FIG. 1. A, product from reaction of IV*d* with diazomethane for 2 h at 22°; B, product for reaction time of 4 h.

For personal use only.

ether and methyl cyclohexylidenecyanoacetate IV*e* at 6.21 τ (ester methyl) and 7.06 and 7.31 τ (two broad bands for the β-methylenes), and pyrazoline V*e* at 5.04 and 5.68 τ (AB system, $J = 17.6$ c.p.s., for the hydrogens on C_5) and 6.13 τ (ester methyl), in addition to the ring hydrogens of IV*e* and V*e* at 8.3 τ. Thus, although the individual pyrazolines V*d* and V*e* were not isolated, their presence was inferred by the n.m.r. spectra in Fig. 1 and the products isolated from pyrolysis. Vapor chromatography of the pyrolysis mixtures gave the alkylidenecyanoacetates IV*d*–IV*f*. In addition, there was obtained a small fraction, which represented less than 5% of the product and for which the n.m.r. spectrum indicated the structure methyl 2-cyano-3-(1-cyclopentenyl)propanoate (XI). Again, pyrolysis of the anticipated cyclopropane product, 5-cyano-5-carbomethoxyspiro[4.2]-heptane (X), during isolation, would be expected to yield XI (12) (see eq. [*h*]).

XII IVc (ethyl cis)

In the pyrolysis of pyrazolines V*a* to V*e* we have observed alkyl migration from C_4 to C_5 of the pyrazoline system to give α,β-unsaturated esters. Such migration is diagnostic of the development of positive charge at C_5 of the pyrazoline ring (4) and is suggested by structure II. In addition, we have done some preliminary studies on the rate of pyrolysis of pyrazolines V*a* and V*d* (mixed with V*e*) in a variety of solvents. (13). Typical results are shown in Table II where the half-lives of V*a* and V*d* are estimated from the slope of the first-order plots of nitrogen evolution during pyrolysis. The kinetic data reported here are from a relatively simple and crude setup (the gas burette was not jacketed, the thermometer was not calibrated, and the solution was agitated but not stirred), but the results were reproducible to better than 5% and show the trends we might expect when measurements can be made more accurately. These results suggest a transition state for pyrolysis which is more polar than the starting material, as is also suggested by structure II, since the rate is greater in the more polar solvents.

On the other hand structure II, through rotation around the single bonds, would be

TABLE II

Calculated half-lives for pyrazolines V*a* and V*d* (mixed with V*e*) (13)

Solvent	$t_{\frac{1}{2}}$ at 53° for V*a* (min)	$t_{\frac{1}{2}}$ at 20° for V*d* (min)
Butyl ether	23	98
Tetralin	16	—
Benzene	—	65
Nitrobenzene	13	19
Formamide	≠	0.5*

*Extrapolated from 3.5° by measuring the relative rate in nitrobenzene and formamide at 3.5° and the rate in nitrobenzene at 20°. ≠, the rate in formamide was sufficiently faster than that in nitrobenzene so that the two could not be run at the same temperature.

anticipated to give a nearly 50:50 mixture of the olefins because of the migration of the groups on C_4. The data in Table I show, however, that pyrolysis of V*a* in tetrachloroethylene yielded an 8:1 mixture of the two possible olefins. In addition, this ratio was found to be solvent dependent. Also, although the results in Table II support the postulation of an ionic intermediate, the variation in the rate with solvent does not correlate with other polar reactions in nonpolar media (14). Particularly, the increase in rate in changing from the solvent nitrobenzene to formamide is not expected.

We feel that the product analysis results of Table I can best be explained by assuming that the methyl group migrates concerted with nitrogen loss. This would make the reaction analogous to that proposed for the pyrolysis of 3,5-dimethyl-3-carbomethoxy-Δ^1-pyrazolines (11), for which it was suggested that hydrogen on C_4 migrates concerted with nitrogen loss. Thus, for the pyrolysis of V*a* in the tetrachloroethylene the methyl *cis* to the carbomethoxy group appears to be in the better position for migration. This is illustrated by structure XII → IV*c* (ethyl *cis*) (see eq. [*i*]). Just how the reaction parameters are influenced by the steric and electronic factors in the pyrazoline and by the solvent to give this stereospecificity is not clear. A study is now underway to determine the importance of these individual factors on the reaction.

The rearrangements observed in this paper and the effects of solvent on the reaction discussed show many similarities to the reactions of ketones with diazomethane (15). It is hoped that further work on this reaction will help us decide whether a betaine structure is an intermediate in the reactions of ketones with diazomethane as has been proposed.

EXPERIMENTAL

The apparatus and methods are as described in Part V (3).

Methyl Alkylidenecyanoacetates (IV)

These compounds were prepared by the procedure of Cope (7) as modified by Widequist (8).

Methyl isopropylidenecyanoacetate (IV*a*), b.p. 103–105° at 8 mm, n_D^{25} 1.4720 (lit. (7), b.p. 99–101° at 9 mm, n_D^{25} 1.4696), showed peaks in the n.m.r. spectrum at 6.21, 7.61, and 7.71 τ. The peak at 7.61 τ was assigned to the methyl *cis* to the ester group, that at 7.71 τ to the methyl *trans* to the ester group, and that at 6.21 τ to the methyl of the ester group (see the text).

Methyl 1-ethylpropylidenecyanoacetate (IV*b*), b.p. 110° at 8 mm, n_D^{25} 1.4699 (lit. (7), b.p. 112–114° at 9 mm, n_D^{25} 1.4708), showed peaks in the n.m.r. spectrum at 6.13 τ, 7.18 τ (quartet, J = 7.3 c.p.s.), 7.39 τ (quartet, J = 7.6 c.p.s.), 8.77 τ (triplet, J = 7.3 c.p.s.), and 8.85 τ (triplet, J = 7.8 c.p.s.). By analogy with IV*a* it is anticipated that the 7.18 τ peak is *cis* to the carbomethoxy group.

Methyl 1-methylpropylidenecyanoacetate (IV*c*), b.p. 129–130° at 28 mm, n_D^{25} 1.4705 (lit. (7), b.p. 105–106° at 9 mm, n_D^{25} 1.4705), showed n.m.r. peaks at 6.17 τ, 7.19 τ (quartet, J = 7.6 c.p.s.), 7.40 τ (quartet, J = 7.6 c.p.s.), 7.62 τ, 7.72 τ, and 8.80 τ (triplet, J = 7.5 c.p.s.), and 8.87 τ (triplet, J = 7.6 c.p.s.). By analogy with IV*a* and because of the relative peak intensities, peaks at 6.17, 7.40, 7.62, and 8.80 τ were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

assigned to the isomer in which the β-methyl is *cis* to the carbomethoxy group (IV*c*, methyl *cis*). The ratio of IV*c* (methyl *cis*) to IV*c* (ethyl *cis*) was estimated to be 53:47 on the basis of the integral of the 7.62 and 7.72 τ peaks respectively.

Methyl cyclopentylidenecyanoacetate (IV*d*) (Aldrich) showed n.m.r. peaks at 6.18 τ, 7.12 τ (broad band,) and 8.12 τ (broad band) for the ester methyl, the β-methylenes, and the γ-methylenes respectively.

Methyl cyclohexylidenecyanoacetate (IV*e*), b.p. 93–95° at 0.1 mm, n_D^{25} 1.5033 (lit. (7), b.p. 146–147° at 9 mm, n_D^{25} 1.5035), showed n.m.r. peaks at 6.19 τ (ester methyl), 7.03 and 7.36 τ (two broad bands for the β-methylenes), and 8.28 τ (broad band for the γ- and δ-methylenes).

Methyl cycloheptylidenecyanoacetate (IV*f*), b.p. 122–123° at 0.1 mm, n_D^{25} 1.5088, showed n.m.r. peaks at 6.20 τ (ester methyl), 6.96, 7.06, 7.17, and 7.28 τ (group of four peaks for the β-methylenes), and 8.38 τ (broad band for the γ- and δ-methylenes).

Anal. Calcd. for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.82; N, 7.25. Found: C, 68.26; H, 7.83; N, 7.40.

Methyl 1-methylbutylidenecyanoacetate (IV*g*), b.p. 139–140° at 28 mm., n_D^{25} 1.4700 (lit. (7), b.p. 116–118° at 9 mm, n_D^{25} 1.4700), showed n.m.r. peaks at 6.19 τ and 7.22 τ (complex group of bands), 7.63 τ, 7.72 τ, and 8.44 τ (complex group of bands), 8.98 τ (triplet, J = 6.6 c.p.s.), and 9.00 τ (triplet, J = 6.6 c.p.s.). Two isomers were indicated by the singlets at 7.63 and 7.72 τ for the β-methyl groups of the two compounds. By analogy with IV*a* the peak at 7.63 τ was assigned to the isomer IV*g* (methyl *cis*). The ratio of the peaks at 7.63 and 7.72 τ was 54:46 respectively.

Preparation of Pyrazolines Va to Vd

Pyrazolines V*a* to V*d* were prepared by reacting an excess of diazomethane (prepared from nitrosomethylurea) in ether with the appropriate methyl alkylidenecyanoacetate (IV*a* to IV*d*) at room temperature. The excess diazomethane was either evaporated from the solution or reacted with acetic acid. Evaporation of the solution on a rotary evaporator at 0° gave a satisfactory sample for n.m.r. analysis. No other physical data were obtained as a result of the instability of the pyrazolines.

4,4-Dimethyl-3-cyano-3-carbomethoxy-Δ¹-pyrazoline (V*a*) showed n.m.r. peaks at 5.24 and 5.63 τ (AB group with J = 17.3 c.p.s.) and 6.13 τ, 8.80 τ, and 8.88 τ, in addition to minor peaks caused by ether and pyrolysis products. The peaks at 5.24 and 5.63 τ were assigned to the hydrogens on C_5, the peaks at 8.80 and 8.88 τ to the methyls on C_4, and the peak at 6.13 τ to the ester methyl.

4,4-Diethyl-3-cyano-3-carbomethoxy-Δ¹-pyrazoline (V*b*) showed n.m.r. peaks at 5.19 and 5.80 τ (AB group with J = 17.4 c.p.s.), 6.08 τ and 8.38 τ (quartet, J = 7.2 c.p.s.), 8.48 τ (quartet, J = 6.6 c.p.s.), 9.03 τ (triplet, J = 6.8 c.p.s.), and 9.21 τ (triplet, J = 7.1 c.p.s.). The presence of the AB group at 5.19 and 5.80 τ and the presence of two ethyl groups confirmed the structure as V*b*.

4-Ethyl-4-methyl-3-cyano-3-carbomethoxy-Δ¹-pyrazoline (V*c*) showed n.m.r. peaks at 5.24, 5.27, and 5.72 τ (two AB groups which overlap for which J = 17.7 c.p.s.), 6.09 τ and 8.50 τ (group of peaks not fully resolved), 8.89 and 8.95 τ (two singlets), and 9.16 τ (group of peaks not fully resolved). The presence of the two AB groups at 5.24 and 5.72 τ, and at 5.27 and 5.72 τ, for the hydrogens on C_5 was anticipated, since there would be a mixture of isomers present. Similarly, the peaks at 8.89 and 8.95 τ (intensity ratio of 51:49) would be for the methyls on C_4 for the two isomers. The ethyl groups of the two isomers were sufficiently overlapped that the spectra were not resolved; however, the assignment was clearly that for structure V*c*.

The pyrazoline V*d* from methyl cyclopentylidenecyanoacetate decomposed during its formation, and thus the n.m.r. spectrum contained considerable amounts of other products as shown in Fig. 1. The composition of the mixture is discussed in the text.

Pyrolysis of the Pyrazolines

For product analysis the pyrazolines were pyrolyzed neat at temperatures near room temperature. The products were separated using an Apiezon J column in an Aerograph A 90-P. Analytical studies were made using a 150-ft Golay column in a Perkin–Elmer 226 chromatograph.

Pyrolysis of the 4,4-dimethylpyrazoline V*a* gave a mixture which was separated by v.p.c. into two components. The first component, isolated with a column temperature of 173°, was 2,2-dimethyl-1-cyano-1-carbomethoxycyclopropane (VI), n_D^{25} 1.4479, with n.m.r. peaks at 6.21 τ, 8.26 and 8.62 τ (AB system with J = 4.8 c.p.s.), 8.53 τ, and 8.71 τ.

Anal. Calcd. for $C_8H_{11}O_2N$: C, 62.72; H, 7.24; N, 9.14. Found: C, 62.73; H, 6.91; N, 9.19.

The n.m.r. was consistent with the assigned structure with peaks at 8.53 and 8.71 τ assigned to the methyls at C_2, the peak at 6.21 τ assigned to the ester methyl, and the peaks at 8.26 and 8.62 τ assigned to the ring hydrogens. The low value of the geminal coupling constant was normal for a cyclopropane derivative (16).

The second component, n_D^{25} 1.4701, gave infrared and n.m.r. spectra identical with those found for methyl 1-methylpropylidenecyanoacetate (IV*c*). The relative proportions of the *cis* and *trans* isomers, as estimated by the 7.62 and 7.72 τ peaks respectively, depended on the solvent used for the pyrolysis, and these results are recorded in Table I.

Pyrolysis of the 4,4-diethylpyrazoline V*b* gave a mixture which was separated by v.p.c., at 240°, into two components. The first component showed n.m.r. peaks at 4.60 τ (quartet, J = 6.9 c.p.s.), 6.21 τ and 6.43 τ (four lines for one hydrogen coupled unequally to two hydrogens with J = 8.1 c.p.s. and 6.8 c.p.s.), 7.40 τ (poorly resolved group of lines), 7.91 τ (quartet, J = 7.5 c.p.s.), 8.36 τ (doublet, J = 6.9 c.p.s.), and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

9.03 τ (triplet, J = 7.5 c.p.s.). This spectrum is consistent with that expected for methyl 2-cyano-4-ethyl-4-hexenoate. It would be anticipated (12) from pyrolysis of 2,2-diethyl-1-cyano-1-carbomethoxycyclopropane (VII) under the conditions of separation (see pyrolysis of VI below). The peaks were assigned as follows: 4.60 τ (hydrogen on C_5), 6.21 τ (ester methyl), 6.43 τ (hydrogen on C_2), 7.40 τ (hydrogens on C_3), 7.91 and 9.03 τ (ethyl on C_4), and 8.36 τ (hydrogens on C_6).

The second component, n_D^{25} 1.4682, was identified by its n.m.r. and infrared spectra to be methyl 1-ethylbutylidenecyanoacetate (IV*h*).

Anal. Calcd. for $C_{10}H_{15}NO_2$: C, 66.27; H, 8.34; N, 7.73. Found: C, 66.37; H, 8.46; N, 8.12.

The n.m.r. spectrum showed three complex regions at 7.32, 8.36, and 8.90 τ in addition to the ester methyl at 6.16 τ. Integration gave values of 4.2:2.0:6.7:3.0 for the four regions, which corresponds to a hydrogen ratio of 4:2:6:3 in IV*h*.

Pyrolysis of the 4-methyl-4-ethylpyrazoline V*c* gave a mixture which was separated by v.p.c., at 173°, into two components. The first component, n_D^{25} 1.4525, gave a complex n.m.r. spectrum with no signals below 8.0 τ other than the ester methyl at 6.18 τ. Two strong singlets appeared at 8.55 and 8.76 τ.

Anal. Calcd. for $C_9H_{13}O_2N$: C, 64.65; H, 7.84; N, 8.38. Found: C, 64.15; H, 7.90; N, 8.78.

The absence of olefin stretching vibrations in the infrared and the absence of signals below 8.0 τ in the n.m.r. spectrum confirm that this compound is a cyclopropane derivative. It was assigned the structure 2-ethyl-2-methyl-1-cyano-1-carbomethoxycyclopropane (VIII) on the basis of its mode of synthesis. The complexity of the n.m.r. spectrum is partly caused by the presence of *cis–trans* isomers, which are indicated by the signals at 8.55 and 8.76 τ assigned to the methyls on C_2 in the two isomers. The relative amounts of the two isomers were about 50:50; however, overlap of some peaks prevented accurate estimation of the distribution.

The second component, which by analytical v.p.c. showed two peaks corresponding to alkylidene derivatives IV*b* and IV*g*, showed peaks in the n.m.r. attributable to all of the peaks of IV*b* and IV*g*. The proportions of VIII, IV*b*, and IV*g* in the product from the neat pyrolysis were 25:35:40 respectively.

Pyrolysis of the pyrazoline mixtures obtained from the reaction of diazomethane with methyl cyclopentylidenecyanoacetate gave the following products by vapor chromatography at 240°. The first component showed n.m.r. peaks at 4.38 τ (broad singlet), 6.18 τ and 6.31 τ (triplet, J = 7.0 c.p.s.), 7.29 τ (doublet, J = 7.0 c.p.s.), and 7.55 to 8.40 τ (complex group of peaks). The n.m.r. spectrum and the mode of synthesis and isolation suggested that this compound was methyl 2-cyano-3-(1-cyclopentenyl)propanoate (XI) (see the text). The n.m.r. peaks at 6.31 τ were very similar to the signals found in other α-cyano-γ,δ-unsaturated esters for the α-hydrogen. The peak at 4.38 τ was assigned to the vinyl hydrogen, that at 7.29 τ to the β-hydrogens, and those from 7.55 to 8.40 τ to the ring hydrogens.

The remaining three components were isolated and identified by their retention times and n.m.r. and infrared spectra to be methyl cyclopentylidenecyanoacetate (IV*d*), methyl cyclohexylidenecyanoacetate (IV*e*), and methyl cycloheptylidenecyanoacetate (IV*f*).

Pyrolysis of 2,2-Dimethyl-1-cyano-1-carbomethoxycyclopropane (VI) (12)

The cyclopropane VI, when heated above 200°, rearranged to form a new isomer with a slightly longer retention time (7.32 min vs. 7.08 min for VI) as determined at 166° on the P-E 226. The new isomer, n_D^{25} 1.4454, showed n.m.r. peaks at 5.08 τ, 6.20 τ, and 6.28 τ (four lines with J = 8.0 and 6.8 c.p.s.), 7.36 τ (doublet, J = 7.4 c.p.s.), and 8.20 τ (broad singlet).

Anal. Calcd. for $C_8H_{11}O_2N$: C, 62.72; H, 7.24; N, 9.14. Found: C, 62.92; H, 6.92; N, 9.27.

The n.m.r. suggested that the new isomer was methyl 2-cyano-4-methyl-4-pentenoate (IX) with the vinyl hydrogens at 5.08 τ, the ester methyl at 6.20 τ, the α-hydrogen at 6.28 τ, the β-hydrogens at 7.36 τ, and the γ-methyl at 8.20 τ.

ACKNOWLEDGMENTS

The authors gratefully appreciate the support received for this work from the National Research Council and from the Committee on Research of the University of British Columbia.

Thanks are also extended to Mrs. Jenkins for the microanalyses and to Mrs. A. Brewster for the n.m.r. spectra.

PYRAZOLINES[1]

V. RING CLOSURE TO OXYGEN IN THE PYROLYSIS OF 3-ACETYL-Δ^1-PYRAZOLINES

DONALD E. MCGREER, NORMAN W. K. CHIU, AND MAGNUS G. VINJE

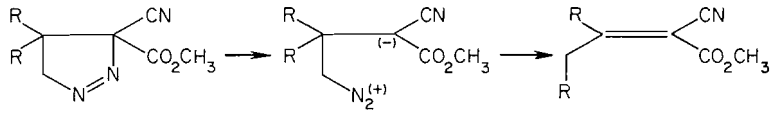
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The pyrolysis of 3-methyl-3-acetyl-Δ^1-pyrazoline (IV) and *cis*- and *trans*-3,5-dimethyl-3-acetyl-Δ^1-pyrazoline (V and VI) has been studied. Pyrolysis of IV gave 2,3-dimethyl-4,5-dihydrofuran (XI) as a minor product, indicating some ring closure to oxygen in these reactions. Pyrolysis of V gave 2,3,5-trimethyl-4,5-dihydrofuran (XVII) as 23% of the product, whereas VI yielded only a trace of XVII. This fact and other differences in the product analysis from isomers V and VI are discussed in terms of the possible mechanism for the pyrolysis reaction.

In Part IV of this series (1) we reported a rearrangement in the pyrolysis of a series of pyrazolines which supports a mechanism involving ionic intermediates (I → III) and specifically the development of a positive charge on C_5 of the pyrazoline system during reaction. If we illustrate this effect by means of structure II, we see that there is also built up in the molecule a negative charge at C_3 which is presumably delocalized into the electron-withdrawing groups attached to C_3.



I II III

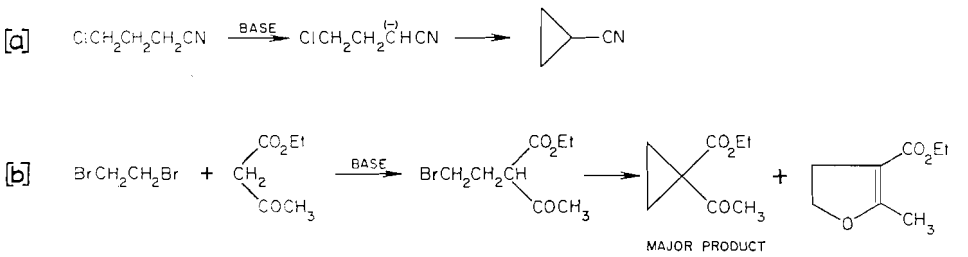
Major products from the pyrolysis of many pyrazolines are cyclopropane derivatives. It has been proposed (2) that such products arise by ring closure of an intermediate like II in a manner analogous to the many classical anionic cyclopropane-forming reactions. For example, the preparation of cyclopropyl cyanide is believed to follow the mechanism (3) illustrated in eq. [*a*].

When the acetyl group is the electron-withdrawing group in a cyclopropane ring closure, there is often also ring closure to the oxygen of the acetyl group. This was first noted by Perkin (4) in the application of the Perkin ring closure reaction to acetoacetic ester (see eq. [*b*]). More recently, related reactions have been used to synthesize dihydrofurans (5, 6). When trimethylene bromide was used by Perkin the major product was a dihydropyran caused by ring closure to oxygen (7).

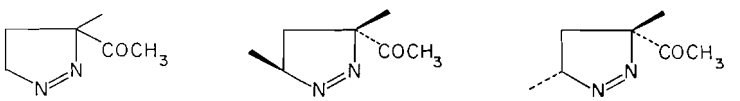
We have prepared three 3-acetyl-Δ^1-pyrazolines to see if in their pyrolysis there may also be ring closure to oxygen and in the hope that such studies will help to elucidate the mechanism of this reaction.

3-Methyl-3-acetyl-Δ^1-pyrazoline (IV) and *cis*- and *trans*-3,5-dimethyl-3-acetyl-Δ^1-pyrazoline (V and VI) were prepared by the addition of diazomethane and diazoethane to isopropenyl methyl ketone. The latter reaction gave a mixture of two pyrazolines which

[1]*Taken in part from the M.Sc. Thesis of N. W. K. Chiu and the B.Sc. Thesis of M. G. Vinje, University of British Columbia, 1964.*



were partially separated by fractional distillation using a spinning-band column. The lower-boiling isomer, which was assigned the *cis* structure V, was obtained up to 81% pure and the higher-boiling isomer, which was assigned the *trans* structure VI, was obtained up to 87% pure. These mixtures were readily analyzed by nuclear magnetic resonance (n.m.r.), for the acetyl resonance of V occurs 0.13 p.p.m. above that of VI.



IV V VI

Assignment of structure to these isomers is of particular importance for the discussion of the mechanism of pyrolysis given in Part VI (8). Although the above assignment is not unequivocal, it is based on the following three points which all suggest the same stereochemistry.

(*i*) The higher-boiling isomer is predominant (60:40 ratio) in the product from the reaction of diazoethane with isopropenyl methyl ketone. Since this reaction is quite sensitive to steric effects (9) and since the methyl group would be expected to have a larger steric requirement than the acetyl group (it is assumed that the acetyl group would have a steric requirement similar to that of the carbethoxyl group, which has been shown to have a smaller steric requirement than methyl as a substituent on the cyclohexane ring (10)), this ratio would suggest that the higher-boiling isomer is the *trans* isomer VI.

(*ii*) Photolysis of the higher-boiling isomer yielded predominantly *trans*-1,2-dimethyl-1-acetylcyclopropane in the cyclopropane portion of the product (*trans* to *cis* ratio was 3.5:1). This conversion in a previous example was found to be highly stereospecific (11) and, thus, a greater stereospecificity is expected in the photolysis than in the pyrolysis of pyrazolines.

(*iii*) The peak positions in the n.m.r. spectrum for the C_4 hydrogens in the higher-boiling isomer are at about 8.53 τ. The hydrogen *cis* to the acetyl group would be expected to appear at lower field than that *trans* to the acetyl group, since such stereochemical effects are present in olefins (see ref. 12 and see compounds VIII, IX, XIV, and XV below) and some ring compounds (13, 14, for reference to some cyclopropane systems see ref. 8). This effect is apparently offset by the anisotropy of the —N=N— group which affects the C_4 hydrogens unequally as a result of folding of the five-membered ring. The hydrogen *cis* to the acetyl would be expected to be folded towards and above the —N=N— group, giving it a greater shielding than the hydrogen remaining in the plane of the ring. This situation is closely analogous to the situation of the C_6 hydrogens in the bicycloheptene systems described by Fraser (13) for which unequivocal assignment could be made.

For the lower-boiling isomer the C_4 hydrogens appear at 7.57 τ and 9.30 τ. Thus the shift caused by the acetyl group and the —N=N— group are not counterbalanced, with the

Free valences represent methyls.

result that the hydrogen *trans* to the acetyl group has been shifted up to 9.30 τ by the —N=N— group and that *cis* to the acetyl group has been shifted down to 7.57 τ by the acetyl group.

It is interesting that the formation of a dihydrofuran product from the lower-boiling isomer and not from the higher-boiling isomer, which is reported below, also corroborates these assignments.

Pyrolysis of 3-methyl-3-acetyl-Δ^1-pyrazoline gave a mixture of five isomeric products which were separated by vapor chromatography and identified on the basis of their physical data (see eq. [*c*]). The products were 1-methyl-1-acetylcyclopropane (VII), *trans*-3-methyl-3-penten-2-one (VIII), *cis*-3-methyl-3-penten-2-one (IX), 3-methyl-4-penten-2-one (X), and 2,3-dimethyl-4,5-dihydrofuran (XI). Compounds VII and XI were synthesized by independent routes for proof of structure. The variation of the product composition with the conditions used for the pyrolysis of IV are given in Table I.

TABLE I

Product compositions for the pyrolysis of 3-methyl-3-acetyl-Δ^1-pyrazoline (IV)

Reaction conditions	Δ VII	*trans* VIII	*cis* IX	β,γ X	XI
Neat at 120°	65	14	14	4	3
Ester neat* at 120°	65	15	15	5

(XVII). 3-Methyl-3-hexen-2-one has been reported in the literature (15), but a comparison of the properties with those of our samples would indicate that the earlier prepared compound was *cis–trans* mixture. The dihydrofuran derivative XVII has also been reported in the literature (16), but our evidence for its structure and that of the other products is based mainly on the physical properties and spectral data. The stereochemical assignment to cyclopropanes XII and XIII is based on the fact that XIII, when heated 9 h at 220°, rearranged to 3-methyl-5-hexen-2-one, while XII was unchanged after 14 h at 220°. An analogous rearrangement of the related esters has been reported (17). The variation of the product composition with the conditions used for the pyrolysis of V and VI is given in Table II. These data have been corrected to represent reaction of pure V and VI.

TABLE II

Product compositions for the pyrolysis of *cis*- and *trans*-3,5-dimethyl-3-acetyl-Δ^1-pyrazoline (V and VI)

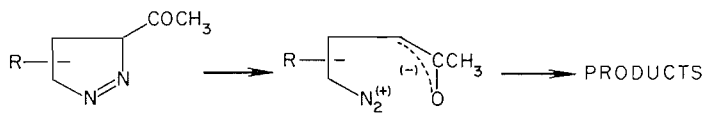
The formation of dihydrofuran derivatives from these pyrazolines can be explained if we assume an intermediate is formed with negative charge built up on C_3 of the pyrazoline system. As this negative charge is delocalized into the carbonyl oxygen, the oxygen will be able to participate in a ring closure reaction.



XIX

The results presented in Table II for pyrolysis of the isomeric 3,5-dimethyl-3-acetyl-Δ^1-pyrazolines are particularly interesting for, in general, the *cis* isomer V yields the dihydrofuran product while the *trans* isomer VI yields little or no dihydrofuran product. For such to be the case, the intermediate XIX cannot have free rotation around the C_3—C_4 bond. Restriction of this rotation infers that there is some bonding (either ionic or partially covalent) between C_3 and N in the transition state. With rotation restricted around the C_3—C_4 bond, the reaction of an intermediate like XIX will still be influenced by steric factors present in the original pyrazoline. Thus, V, which has the methyl substituents *cis*, would twist in such a way that the carbonyl group would be forced under the ring towards C_5 and in a position favorable for ring closure to oxygen. On the other hand, the *trans* isomer would twist to force the carbonyl group away from the C_5 carbon. This argument also gives further support to the original geometric assignments made for the isomeric 3,5-dimethyl-3-acetyl-Δ^1-pyrazolines V and VI.

The medium in which the pyrolysis of these pyrazolines is carried out also influences the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

amount of dihydrofuran derivative formed. The percentage of this derivative is highest in the nonpolar solvent cyclohexane and is very low in more polar solvents like acetonitrile. Pyrolysis in the vapor phase tends to give results analogous to those in a nonpolar solvent but does not give the extreme situation that one might expect. The solvent effect suggests that the structure of the transition state (or states) is sensitive to the polarity of the solvent and the product composition is altered as a result. Competing reactions through similar transition states might also explain this variation in product composition with solvent.

A similar trend has been found in the effect of solvents on the proportion of cyclopropane products to olefins. The cyclopropane formation and dihydrofuran formation appear to be very closely related. This can be illustrated by the ratio of *cis* to *trans* cyclopropane derivatives from V and VI and from their corresponding esters (8). In general, the product analysis from the ketopyrazolines correlates well with that from the ester pyrazolines. (For example, see the neat pyrolysis of the 3-methyl-3-carbomethoxy-Δ^1-pyrazoline included in Table I for comparison with the neat pyrolysis of IV.) The neat pyrolysis of VI from Table II gives a ratio of *cis* to *trans* cyclopropanes of 60:17 and no dihydrofuran, corresponding to 60:15 for the ester (8). The neat pyrolysis of V from Table II gives a ratio of *cis* to *trans* cyclopropanes of 16:24 and 23% dihydrofuran, to be compared with 18:48 for the ester (8). The dihydrofuran percentage, if added to the *trans* cyclopropane percentage, would alter the ratio from V to 16:47 and thus would give a better correspondence. This suggests that the dihydrofuran is being formed at the expense of cyclopropane products and mainly at the expense of the *trans* derivative. A further discussion of the product ratios listed in Table II is given in Part VI of this series (8).

Nominé and Bertin (18) have found that the rate of nitrogen loss from a 3-keto-Δ^1-pyrazoline is greatly enhanced by the addition of boron trifluoride. In addition, boron trifluoride catalysis appeared to increase the proportion of the cyclopropane product in their reaction.

The effect of boron trifluoride on the pyrolysis of V and VI is given in Table II. The reaction occurs readily at 5°, indicating the catalytic effect of the boron trifluoride. 3-Carbomethoxy-Δ^1-pyrazolines, on the other hand, simply precipitate as the amine–boron trifluoride salt without pyrolysis. The catalytic effect of boron trifluoride is therefore probably due to coordination with the carbonyl of the acetyl group, resulting in stabilization of the negative charge developing at C_3. In this way, this reaction is analogous to the 3-cyano-3-carbomethoxy pyrazolines (1) which also pyrolyze at low temperatures.

The catalyzed reaction does not give a greater proportion of cyclopropane derivatives, as observed by Nominé and Bertin. It does, however, considerably alter the product composition and, although the results are not readily explained, they still show that differences are present in the reactions of the isomers V and VI. The products were stable to similar treatment by boron trifluoride and thus, even under these conditions, the intermediates from V and VI must be structurally different. This conclusion is also supported by the fact that recovered pyrazoline VI, after 50% reaction, showed none of isomeric V to be present. The presence of both α,β-unsaturated olefins from the *cis*-pyrazoline and not the *trans*-pyrazoline may reflect a larger effective bulk for the acetyl group coordinated to the boron trifluoride than for the acetyl group alone, thus causing a flattening of the molecule and a change in the availability of the C_4 hydrogens for migration (8).

A reaction in the literature which may well be formally analogous to the pyrolysis of 3-acetylpyrazolines is the reaction of diazoketones with ketenes. In this reaction the product is mainly a result of ring closure to oxygen, although the intermediacy of a pyrazolone has not been demonstrated (19, 20).

EXPERIMENTAL

Melting points and boiling points are uncorrected. Boiling points were determined by the micro inverted capillary method.

Infrared spectra were measured with a Perkin–Elmer model 137 infracord. The n.m.r. spectra were recorded on a Varian A60 instrument with internal tetramethylsilane as the standard. Samples were run as 30% solutions in carbon tetrachloride and the area integration fits the assigned structure unless otherwise noted. The vapor chromatograms were obtained with an Aerograph A-90-P and a Perkin–Elmer model 226. Percentage compositions were determined by area measurements and are estimated to be accurate to ±2%. The reproducibility was generally found to give values to ±4% from different runs under the same conditions.

The pyrolyses in low-boiling solvents at 125° were carried out on 1% solutions in a sealed tube and, in work-up, the solvent was partially distilled before chromatographic analysis. The vapor pyrolysis was carried out on 3-μl samples in a 1-l flask at 1 mm pressure.

3-Methyl-3-acetyl-Δ¹-pyrazoline (IV)

Methyl isopropenyl ketone (K and K), after purification by precipitation of polymeric impurities with ether, filtration, and distillation (b.p. 95°), was reacted with a solution of diazomethane in ether prepared from nitrosomethyl urea. After distillation of the ether, the product was distilled to give 3-methyl-3-acetyl-Δ¹-pyrazoline (IV), b.p. 45° at 0.3 mm, n_D^{20} 1.4610.

Anal. Calcd. for $C_6H_{10}ON_2$: C, 57.11; H, 7.99; N, 22.20. Found: C, 57.10; H, 7.94; N, 22.30.

An infrared band at 1 720 cm^{-1} and n.m.r. peaks at 5.53 τ (triplet with splitting of 8 c.p.s. for the hydrogens on C_5), 7.73 τ (acetyl methyl), 8.57 τ (methyl on C_3), and a group of peaks from 8.0 to 8.8 τ for the non-equivalent hydrogens on C_4 were consistent with the assigned structure.

Pyrolysis of 3-Methyl-3-acetyl-Δ¹-pyrazoline (IV)

The product analysis on mixtures obtained by pyrolysis of IV under a variety of conditions are listed in Table I. The individual components were isolated by chromatographic separation using a 10-ft didecyl phthalate column of 0.25 inch diameter at 128° with a head pressure of 40 p.s.i. The properties recorded for each component are boiling point, refractive index, retention time, pertinent infrared bands, and n.m.r. peak positions.

3-Methyl-4-penten-2-one (X): b.p. 112°; retention time 10.6 min; infrared bands at 3 030, 1 725, and 1 630 cm^{-1}; n.m.r. peaks at 4.0 to 5.0 τ (group of peaks assigned to the olefin hydrogens), 6.88 τ (pentet with splitting of 7 c.p.s. for the hydrogen on C_3), 7.93 τ (hydrogens on C_1), and 8.81 τ (doublet with J = 6.9 c.p.s. for the methyl on C_3). An analysis was carried out on a mixture (approximately 50:50) of this component and the 2,3-dimethyl-4,5-dihydrofuran component.

Anal. Calcd. for $C_6H_{10}O$: C, 73.43; H, 10.27. Found: C, 73.70; H, 10.50.

2,3-Dimethyl-4,5-dihydrofuran (XI): b.p. 111°; retention time 11.5 min; infrared bands at 1 695, 1 432, and 1 375 cm^{-1}; n.m.r. peaks at 5.92 τ (triplet with splitting of 9.3 c.p.s. for the hydrogens on C_5), 7.54 τ (broadened triplet with splitting of 9.3 c.p.s. for the hydrogens on C_4), and 8.42 τ (broadened singlet for the methyls on C_2 and C_3). This sample was identical in all respects with a sample prepared by an independent route reported below.

cis-3-Methyl-3-pentene-2-one (IX): b.p. 124°; retention time 16.0 min; infrared bands at 1 685 and 1 618 cm^{-1}; n.m.r. peaks at 4.23 τ (multiplet for the hydrogen on C_4), 7.84 τ (hydrogens on C_1), 8.15 τ (methyl on C_3), and 8.19 τ (doublet with J = 7.0 c.p.s. for the hydrogens on C_5). The *cis* assignment is based on the fact that the hydrogen on C_4 appears to higher field than that in the *trans* isomer (12).

Anal. Calcd. for $C_6H_{10}O$: C, 73.43; H, 10.27. Found: C, 73.40; H, 10.14.

1-Methyl-1-acetylcyclopropane (VII): b.p. 128°; n_D^{20} 1.4332 (lit. (21), b.p. 126°; n_D^{20} 1.4330); retention time 17.3 min. This compound was identical with a sample prepared by the procedure of Julia (21) using 5-chloro-3-methyl-2-pentanone and powdered potassium hydroxide. Vapor chromatographic analysis showed less than 1.5% of 2,3-dimethyl-4-5-dihydrofuran in the latter product.

trans-3-Methyl-3-penten-2-one (VIII): b.p. 147°; n_D^{20} 1.4496; retention time 23.6 min; infrared bands at 1 668 and 1 642 cm^{-1}; n.m.r. peaks at 3.36 τ (quartet with J = 7 c.p.s. for the hydrogen on C_4), 7.82 τ (hydrogens on C_1), 8.27 τ (methyl on C_3), and 8.18 τ (doublet with J = 7 c.p.s. for the hydrogens on C_5).

Anal. Calcd. for $C_6H_{10}O$: C, 73.43; H, 10.27. Found: C, 73.59; H, 10.43.

2,3-Dimethyl-4,5-dihydrofuran

α-Methyl-α-acetylbutyrolactone, b.p. 62° at 0.04 mm, n_D^{20} 1.4561 (lit. (21), b.p. 128° at 20 mm, n_D^{20} 1.4560), was prepared by the procedure of Julia (21) from α-acetylbutyrolactone (Aldrich).

α-Methyl-α-acetylbutyrolactone (30 g) was hydrolyzed in 100 ml of 5% hydrochloric acid until the solution became homogeneous (30 min). The solution was made basic with potassium hydroxide and saturated with potassium carbonate to give 19.8 g of product which was dried over potassium carbonate and distilled to give 17.8 g (71%) of 3-methyl-2-pentanon-5-ol, b.p. 89° at 18 mm, n_D^{20} 1.4391.

Anal. Calcd. for $C_6H_{12}O_2$: C, 62.03; H, 10.41. Found: C, 61.84; H, 10.40.

3-Methyl-2-pentanon-5-ol (6.8 g) was placed in a 8-ml pear-shaped flask fitted with a short column (4 inches) and a condenser for distillation. A trace of orthophosphoric acid was added and the flask was heated in an oil bath. At a bath temperature of 140° distillation began and was steady at 155° with a head temperature of 94°. Water was removed from the distillate during distillation with a pipette. The organic layer was immediately redistilled to give 4.5 g of 2,3-dimethyl-4,5-dihydrofuran, b.p. 108–110°, n_D^{20} 1.4410.

Anal. Calcd. for $C_6H_{10}O$: C, 73.43; H, 10.27. Found: C, 73.36; H, 10.35.

cis- and trans-3,5-Dimethyl-3-acetyl-Δ¹-pyrazoline (V and VI)

A solution of diazoethane in ether was prepared from nitrosoethyl urea and 40% potassium hydroxide. Isopropenyl methyl ketone was added to this solution until the orange color disappeared and the mixture was distilled to give the pyrazoline mixture, b.p. 56–57° at 1.2 mm.

Anal. Calcd. for $C_7H_{12}NO$: C, 59.97; H, 8.63; N, 19.99. Found: C, 59.60; H, 8.22; N, 20.27.

The n.m.r. spectrum, based on the acetyl resonances, showed this to be 40% of the lower-boiling isomer and 60% of the higher-boiling isomer.

The *cis*- and *trans*-pyrazoline mixture was separated by distillation through a Nester and Faust 45-cm by 6-mm spinning-band column at 0.2 to 0.3 mm with the still pot immersed in an oil bath maintained at 65–70°. Of the various fractions obtained, the best separation gave the lower-boiling fraction 81% pure and the higher-boiling fraction 87% pure as determined by the proportion of the acetyl resonances in the n.m.r. spectra at 7.78 and 7.65 τ respectively. The lower-boiling isomer was assigned the *cis* structure V and the higher-boiling isomer the *trans* structure VI for reasons described in the text. The n.m.r. spectrum of *cis*-3,5-dimethyl-3-acetyl-Δ¹-pyrazoline (V) had peaks at 5.66 τ (sextet with splitting of 7.5 c.p.s. for the C_5 hydrogens), 7.57 τ (two doublets with J_{gem} = 13.0 c.p.s. and J_{vic} = 8.7 c.p.s. for one of the C_4 hydrogens), 7.78 τ (acetyl methyl), 8.40 τ (C_3 methyl), 8.52 τ (doublet with J = 7.0 c.p.s. for the C_5 methyl), and 9.30 τ (two doublets with J_{gem} = 12.9 c.p.s. and J_{vic} = 7.7 c.p.s. for the other C_4 hydrogens). The n.m.r. spectrum of *trans*-3,5-dimethyl-3-acetyl-Δ¹-pyrazoline (VI) had peaks at 5.67 τ (sextet with splitting of 7.4 c.p.s.), 7.65 τ (acetyl methyl), 8.48 τ (doublet with J = 6.0 c.p.s. for the C_5 methyl), 8.53 τ (multiplet for the unresolved C_4 hydrogens), and 8.63 τ (C_3 methyl).

Pyrolysis of cis- and trans-3,5-Dimethyl-3-acetyl-Δ¹-pyrazoline (V and VI)

The product analysis on mixtures obtained by pyrolysis of samples of V and VI of 81 and 87% purity have been corrected to represent compositions from pure V and VI and are recorded in Table II. The individual components were separated using a 10-ft didecyl phthalate column of 0.25 inch diameter at 140° with a head pressure of 48 p.s.i. Compounds XIII and XVI were not separted under these conditions. The combined sample was analyzed by analytical vapor phase chromatography (P-E 226) and n.m.r.

2,3,5-Trimethyl-4,5-dihydrofuran (XVII): b.p. 119–120°; n_D^{24} 1.4305 (lit. (16), b.p. 118.3–118.6° at 746 mm; n_D^{24} 1.4390); retention time 6.2 min; infrared band at 1 698 cm^{-1}; n.m.r. peaks at 5.59 τ (sextet for the hydrogen on C_5), 7.40 τ (two doublets) and 7.98 τ (two doublets) for the hydrogens on C_4, 8.43 τ (broadened singlet for the methyls on C_2 and C_3), and 8.79 τ (doublet with J = 6.1 c.p.s. for the methyl on C_5). The hydrogens on C_4 form the AB part of an $ABXM_3$ system from which the following constants are calculated without second-order corrections: Δ_{AX} = 144.5 c.p.s., Δ_{BX} = 109 c.p.s., Δ_{AB} = 35.5 c.p.s., J_{AB} = 14.5 c.p.s., J_{AX} = 8.0 c.p.s., and J_{BX} = 9.5 c.p.s.

trans-1,2-Dimethyl-1-acetylcyclopropane (XIII): b.p. 137°; n_D^{24} 1.4275; retention time 10.5 min; C=O band at 1 694 cm^{-1}; n.m.r. peaks at 7.86 τ (acetyl methyl), 8.62 τ (C_1 methyl), 9.03 τ (broad peak for the C_2 methyl), and two sets of multiplets in the region from 8.75 to 9.60 τ for the ring hydrogens. A sample (500 μl) of XIII was heated at 220° for 9 h in a sealed tube. Vapor chromatography of the product at 130° showed two peaks at 12.9 min and 21.9 min in the ratio of 85:15 respectively. The components were collected and the latter proved to be identical with *trans*-3-methyl-3-hexen-2-one (XV), while the former was a new compound which on the basis of its n.m.r. spectrum was assigned (17) the structure 3-methyl-5-hexen-2-one, b.p. 138°; n_D^{22} 1.4225; C=O band at 1 710 cm^{-1} and C=C band at 1 643 cm^{-1}; n.m.r. peaks at 4.45 τ (group of peaks from 4.1 to 4.8 τ for the hydrogen on C_5), 5.12 τ (two broadened peaks for the hydrogens on C_6 with separation of 13 c.p.s.), the hydrogens on C_3 and C_4 were not resolved and gave a group of peaks between 7.25 and 8.10 τ, 7.98 τ (singlet for the hydrogens on C_1), and 8.96 τ (doublet with J = 6.7 c.p.s. for the methyl on C_3).

Anal. Calcd. for $C_7H_{12}O$: C, 74.95; H, 10.78. Found: C, 74.97; H, 10.78.

The chromatographic separation of *trans*-1,2-dimethyl-1-acetylcyclopropane (XIII) and 3-methyl-4-hexen-2-one (XVI) could only be accomplished on the analytical P-E 226 instrument. Microanalysis was carried out on the mixture of XIII and XVI.

Anal. Calcd. for $C_7H_{12}O$: C, 74.95; H, 10.78. Found: C, 74.87; H, 10.91.

For the above data on XIII the mixture was treated with bromine in carbon tetrachloride and then separated by v.p.c. to give pure XIII. The n.m.r. spectrum of the mixture of XVI and XIII established the

structure of XVI to be 3-methyl-4-hexen-2-one through the presence of peaks at 4.57 τ (multiplet for the two vinyl hydrogens on C_4 and C_5), 7.97 τ (hydrogens on C_1), 8.32 τ (doublet with J = 4.8 c.p.s. for the hydrogens on C_6), and 8.92 τ (doublet with J = 7.0 c.p.s. for the methyl on C_3).

cis-3-Methyl-3-hexen-2-one (XIV): b.p. 145° (lit. (15), b.p. 151° for 3-methyl-3-hexen-2-one); n_D^{24} 1.4370; retention time 12.2 min; infrared bands at 1 692 and 1 620 cm^{-1}; n.m.r. peaks at 4.44 τ (broadened triplet with J = 7.2 c.p.s. for the hydrogen on C_4), 7.73 τ (multiplet for the hydrogens on C_5), 7.86 τ (hydrogens on C_1), 8.12 τ (broadened singlet for the methyl on C_3), and 9.02 τ (triplet with J = 7.3 c.p.s. for the hydrogens on C_6). The higher position of the vinyl hydrogen (4.44 τ) compared to the *trans* isomer (3.52 τ) is the basis for the *cis* assignment to this isomer (12).

Anal. Calcd. for $C_7H_{12}O$: C, 74.95; H, 10.78. Found: C, 75.02; H, 10.77.

cis-1,2-Dimethyl-1-acetylcyclopropane (XII): b.p. 152°; n_D^{24} 1.4376; retention time 15.7 min; C=O at 1 680 cm^{-1}; n.m.r. peaks at 8.00 τ (acetyl methyl), 8.72 τ (methyl on C_1), 8.88 τ (distorted doublet for the methyl on C_2), and two of the ring hydrogens centered around 8.68 τ and one centered around 9.74 τ. (See assignment under the *trans* isomer XIII.)

Anal. Calcd. for $C_7H_{12}O$: C, 74.95; H, 10.78. Found: C, 74.85; H, 10.95.

trans-3-Methyl-3-hexen-2-one (XV): b.p. 157°; n_D^{23} 1.4481; retention time 17.7 min; infrared bands at 1 680 and 1 650 cm^{-1}; n.m.r. peaks at 3.52 τ (broadened triplet with J = 7.6 c.p.s. for the hydrogen on C_4), 7.76 τ (multiplet for the hydrogens on C_5), 7.81 τ (hydrogens on C_1), 8.39 τ (broadened singlet for the methyl on C_3), and 8.93 τ (triplet with J = 7.5 c.p.s. for the hydrogens on C_5). (See assignment under the *cis* isomer XIV.)

Anal. Calcd. for $C_7H_{12}O$: C, 74.95; H, 10.78. Found: C, 75.03; H, 10.81.

Boron Trifluoride Catalyzed Pyrolysis of V and VI

A solution of 0.2 ml (0.0015 mole) of the pyrazoline in 10 ml of anhydrous ether was cooled to 15°. To this solution was added with stirring 0.21g (0.0015 mole) of boron trifluoride etherate (b.p. 126°) in 1 ml of ether. Decomposition was complete in 25 min. The ether solution was washed with ice-cold water until neutral, dried with sodium sulfate, and analyzed by chromatography. The results are reported in Table II.

The above procedure was followed with 0.5 ml of *trans*-pyrazoline VI (99% pure) and 0.5 g of boron trifluoride etherate in 5 ml of ether at 0 °C. After 50% (35 ml) of the theoretical volume of nitrogen had been evolved, the reaction was worked up as above. Removal of all of the ether and pyrolysis products on a vacuum line left a pyrazoline sample which showed no evidence of the *cis* isomer in its n.m.r. spectrum.

Photolysis of Pyrazolines IV, V, and VI

Photolyses were carried out on 5% solutions in refluxing ether in a pyrex vessel by irradiation with a 450-W Hanovia medium-pressure mercury lamp No. 79A36. The product obtained from IV contained VII, VIII, IX, X, and XI in the ratio of 78:4:3:1:14. The products obtained from V and VI, as corrected to 100% pure samples, contained XII, XIII, XIV, XV, XVI, and XVII in the ratios of 59:28:1:0:6:6 and 21:70:2:1:4:2 respectively. The products were stable to photolysis under the reaction conditions. Not more than 1% of methyl isopropenyl ketone was formed from IV, V, or VI.

ACKNOWLEDGMENTS

The authors gratefully appreciate the support received for this work from the National Research Council of Canada and from the Committee on Research of the University of British Columbia.

Thanks are also extended to Mrs. A. Aldrich for some microanalyses and to Mrs. E. Brion and Mr. P. Horn for some of the n.m.r. spectra.

PYRAZOLINES

VI. THE STEREOCHEMISTRY IN THE PYROLYSIS OF PYRAZOLINES FOR THE C_3 AND C_5 POSITIONS OF THE PYRAZOLINE MOLECULE[1,2]

ABSTRACT

cis- and *trans*-3,5-Dimethyl-3-carbomethoxy-Δ^1-pyrazoline (IV and V) have been separated, and product analysis for the pyrolysis and photolysis of these compounds has been completed. The cyclopropane products are formed with some change in the relative configuration of the *cis–trans* groups in both reactions. The α,β-unsaturated olefin product is formed stereospecifically with IV, yielding methyl 2-methyl-*cis*-2-pentenoate (XI), and with V, yielding methyl 2-methyl-*trans*-2-pentenoate (X). The results of the pyrolysis and photolysis of *cis,trans*-3,4,5-trimethyl-3-carbomethoxy-Δ^1-pyrazoline are also described. The product studies and some kinetic studies are the basis of a new mechanism proposed for the pyrolysis of pyrazolines.

Recent studies on the pyrolysis of pyrazolines have reopened the question regarding the stereochemistry of the conversion of pyrazolines into cyclopropanes (1–3). This reaction was reported by von Auwers (4) to be essentially stereospecific and this was the accepted view on the reaction for many years (stereospecific here is used to mean that the substituents on the cyclopropane ring have the same *cis–trans* relationship as on the initial pyrazoline). Van Auken and Rinehart (1) showed that the pyrolysis of a pair of isomeric pyrazolines with methyls *cis* and *trans* on C_3 and C_4 (compounds I and II) gave cyclopropanes with effective randomization of this *cis–trans* relationship. On the other hand, Overberger and Anselme (2) have found that the pyrolysis of *trans*-3,5-diphenyl-Δ^1-pyrazoline (III) gave stereospecifically the *trans*-1,2-diphenylcyclopropane, and thus the stereochemistry of this reaction is not clear.

We have prepared some new pyrazolines, which show a *cis–trans* relationship at positions C_3 and C_5, in an effort to find out more about the pyrolysis reaction. The preparation of a *cis–trans* mixture of 3,5-dimethyl-3-carbomethoxy-Δ^1-pyrazoline and its pyrolysis was reported earlier (5). This mixture has now been separated by distillation through a spinning-band column at a temperature slightly below the pyrolysis temperature. The lower-boiling isomer has been assigned the structure with the methyl groups *cis* (IV) and the higher-boiling isomer that with the methyl groups *trans* (V). The preparation and

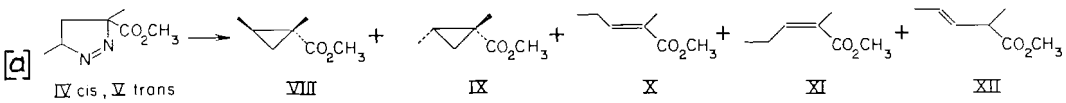
pyrolysis of a related pair of isomers having an acetyl group in place of the carbomethoxy group (VI and VII) have also been studied in this laboratory (6).

The stereochemical assignment to the pyrazolines has been discussed in detail earlier (6) and similar arguments are applicable to compounds IV and V. The predominant formation of the higher-boiling isomer (3:2) ratio suggests that it has the methyl groups *trans*. The fact that photolysis of the lower-boiling isomer gives predominantly (3:1) (see Table III) the cyclopropane with the methyls *cis*, and conversely the higher-boiling isomer gives predominantly (3:1) the cyclopropane with the methyls *trans*, suggests also that the higher-boiling isomer has the methyls *trans*, since the photolysis reaction has been found in an earlier case to be more stereospecific than the pyrolysis reaction (1). The nuclear magnetic resonance (n.m.r.) spectrum of the higher-boiling isomer shows the C_3 hydrogens at 8.28 and 8.56 τ, consistent with the suggestion made earlier (6) that the hydrogen *cis* to the carbomethoxy group is shielded by the —N=N— group and deshielded by the carbomethoxy group, with the result that its chemical shift remains close to the other C_4 hydrogen. In the other isomer, the C_4 hydrogens appear at 7.68 and 9.14 τ, consistent with deshielding of the hydrogen *cis* to the carbomethoxy group by the carbomethoxy group to give a chemical shift of 7.68 τ and with shielding of the hydrogen *trans* to the carbomethoxy group by the —N=N—. Folding of the molecule to make such differential shielding is illustrated in structures XX and XXI.

The n.m.r. spectra of mixtures of pyrazolines IV and V can readily be used to estimate the composition of these mixtures, since the ester methyl peak of V is 0.06 p.p.m. downfield from the ester methyl peak of IV. The samples of IV and V used for the product study were 83% and 100% pure respectively. The results reported in Tables I and II on material of 83% purity have been corrected for the 17% of V present.

The products from the pyrolysis of pyrazolines IV and V have been reported earlier (5). It has now been possible to confirm by n.m.r. the *cis–trans* relationship of the methyl 2-methyl-2-pentenoates to be as reported therein (see eq. [a]). The product composition has been found to be sensitive to the pyrazoline used and the conditions of pyrolysis. The results from a number of runs are given in Table I.



There are two striking features in this data. First, α,β-olefin formation is essentially stereospecific with the *cis* olefin XI being formed from the *cis*-pyrazoline IV and the *trans* olefin X being formed from the *trans*-pyrazoline V. Even the small amounts of X formed from IV could be due to errors in the estimation of the products for 100% pure IV. Second, the cyclopropane with the methyls *trans* (IX) is the predominant cyclopropane from the *cis*-pyrazoline IV and the cyclopropane with the methyls *cis* (VIII) is the predominant cyclopropane from the *trans*-pyrazoline V. The cyclopropane-forming reaction, however, does not have the high stereospecificity that the olefin-forming reaction has and *requires* inversion at *either* C_3 or C_5 during cyclopropane formation.

The effect of solvent on the reaction has been to raise the proportion of the olefins in the product as the dielectric constant of the solvent is increased. At the same time there has been little change in the stereospecificity of the reaction. In an earlier study we found (7) that the rate of pyrolysis of a 4,4-dialkyl-3-cyano-3-carbomethoxy-Δ^1-pyrazoline (XIII) was faster in polar solvents than in nonpolar solvents. For comparison we have

	81° in cyclohexane		79	14	6	0	1

TABLE II

Kinetics for the pyrolysis of a sample of 40% IV and 60% V

Solvent	Dielectric* constant (D)	$t_{\frac{1}{2}}$ (min^{-1})
n-Butyl ether	3.06 at 25°	26.2
Tetralin	2.78 at 20°	29
Nitrobenzene	34.8 at 20°	43.6
Formamide	109 at 20°	83.1

*A. C. Maryott and E. R. Smith, Table of dielectric constants of pure liquids, National Bureau of Standards Circular No. 514, 1951.

determined the kinetics of the pyrolysis of a mixture of IV and V in four solvents. The results of these runs at 100° in butyl ether, tetralin, nitrobenzene, and formamide are given in Table II. The polarity of the solvent has little effect on the rate and one must conclude that for pyrazolines related to IV and V there is no increase and possibly some decrease in the polarity of the transition state over the starting material.

The mechanism proposed for the pyrolysis of pyrazolines related to IV and V suggests that the initial step of the reaction is the breaking of the N_2—C_3 bond (1). Immediately

one anticipates free rotation around the single bonds of XV and such has been suggested (1). If the lifetime of XV is sufficiently long to permit rotations, then we would expect (A) reversal of step 1 would give some pyrazoline with inversion of geometry at C_3, and (B) the product analysis from any pair of pyrazolines isomeric at C_3 should be independent of the starting material since, because of rapid inversion of C_3 in XV or because of its planar nature (8), the intermediate from the two pyrazoline isomers would be identical.

These conditions are not satisfied. We have carried out the pyrolysis of *trans*-pyrazoline V to 50% reaction and the recovered pyrazoline was pure *trans* as determined by n.m.r. under conditions which would have detected 1% of the *cis* isomer IV. Similar results have been obtained by van Auken and Rinehart (1) on I. The product analyses from IV and V show many differences (Table I). Even in the pyrolysis of pyrazolines I and II where the cyclopropane products are formed with randomization at C_3, there is a major difference in the proportion of olefin to cyclopropane product corresponding to 3.97:1.70 and 1.31:2.22 respectively. We have repeated this reaction in the gas phase and find that this difference is still present.

The product analyses for the pyrolysis of the isomeric 3-acetylpyrazolines VI and VII also show differences which cannot be explained by an intermediate like XV (6). 2,3,5-Trimethyl-4,5-dihydrofuran (XVI) was formed from VI and not from VII. It is interesting that a comparison of the products from the 3-carbomethoxy derivatives (IV and V) and the 3-acetyl derivatives (VI and VII) has been found to suggest that the dihydrofuran (XVI) is being formed at the expense of the *trans*-cyclopropane (6).

Pertinent to the question of bond breaking in the transition state are the recent results of Seltzer on acyclic azo compounds. Kinetic studies on the pyrolysis of azo-bis-α-phenylethane (XVII) (9), α-phenylethylazo-2-propane (XVIII) (10), α-phenylethylazomethane (XIX) (11), and their α-deuterium derivatives have shown that for XVII both C—N bonds are breaking equally in the transition state, for XVIII the C—N bonds are both breaking but to a different degree, and for XIX only the C—N bond with the α-phenyl substitution is breaking in the transition state.

A similar spectrum of situations may also be present in the cyclic azo systems where symmetric pyrazolines like III would have both C—N bonds breaking equally in the transition state. Pyrazolines like I, II, IV, and V would have unequal breaking of the bonds, but would still retain some bonding for both C—N bonds in the transition state. A study on the kinetics of the pyrolysis of a number of pyrazolines related to I–VII (12) has found that substitution of H by CH_3 at C_5 causes a sevenfold increase in rate. This effect and similar substitution factors at C_3 also suggest that both C—N bonds are being broken in the transition state. For pyrazolines related to XIII the transition state is highly polar, and yet the product suggests some bonding of N_2 to C_3 in the transition state (7). This could be caused by an intermediate like XV having a short lifetime with respect to rotation.

The conformation of the pyrazolines will be controlled by the large groups present (two methyls and a carbomethoxy group), since the gauche interactions of hydrogens have little effect in locking a cyclopentene ring into a specific conformation (13). The coupling constants for the C_5 hydrogen with each of the C_4 hydrogens are almost the same (8.6 c.p.s. for the *cis* and 8.3 c.p.s. for the *trans* pair in IV and 8.0 c.p.s. for both pairs in V). If we assume a projected angle of 120° for the geminal C_4 hydrogens and that the Karplus equation (14) is applicable, with a possible upward displacement of the curve because of substituent effects (15), then equal coupling constants predict dihedral angles of 25 and 145° (calculated values of J for 25° and 145° (14) are 6.5 and 6.2 c.p.s. respectively). From the calculations of Abraham and McLauchlan (16) on a C_5 cyclopentane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

structure, this will correspond to a folding of the pyrazoline ring to the extent that the plane of atoms 3, 4, and 5 would make an angle of slightly less than 25° with the plane of atoms 5, 1, 2, and 3 in agreement with models of this system. Because of the assumptions made here, this is only an approximate result but confirms the folding of the ring assumed earlier. If results on studies on the cyclopentene system (13) can be applied to this system, we can further assume that variations from this mean by tens of degrees can occur with little increase in the potential energy.

XX XXI

Free volences represent methyls.

An explanation of the stereochemistry of the olefin-forming reaction is therefore possible, if we assume that hydrogen migration is concerted with nitrogen elimination. Hydrogen migration concerted with bond breaking has been suggested in other pyrolysis reactions (17, 18). As a result of the nonplanar conformation of the pyrazoline ring in IV and V, one of the C_4 hydrogens is in a better position to migrate to C_5 than the other as it is *trans* to the nitrogen (the C_4 hydrogen *cis* to the carbomethoxy group in XX and that *trans* to the carbomethoxy group XXI). It is just these hydrogens which must migrate to give the α,β-unsaturated systems with the geometry found experimentally. Similarly, the migration of the same hydrogen to C_3 would give, in both cases, the β,γ-unsaturated system with the *trans* geometry. It is therefore significant that the *trans* β,γ-ester is formed and none of the *cis* ester has been detected in the pyrolysis of IV and V. The relative proportion of α,β- to β,γ-unsaturated product should therefore be a measure of the relative migrational aptitude of hydrogen as a hydride or a proton. An examination of the few studies (earlier work from this laboratory primarily) which have measured both α,β- and β,γ-unsaturated products shows this ratio to be around 10:1. The charge delocalization of the anion or cation center may, however, be important in determining this ratio.

The cyclopropane-forming reaction gives such a variety of stereochemical results that a simple explanation does not present itself. The fact that the product composition changes with the conditions of the reaction suggests that the cyclopropane products are formed through a slightly different transition state (and presumably less polar) than the olefins. This transition state may well be a diradical or dipolar structure along the lines of XV, which could be expected to give the retention and inversion found for this reaction. To obtain predominant inversion at one of C_3 or C_5, one can simply require that nitrogen is lost stepwise (3) and that the second step is backside displacement.

The ring-opened intermediate as drawn in XV would be expected to be more polar and have quite a different energy from that expected for the transition state envisioned for the olefin-forming step. For these reasons and since pyrolysis gives no methyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

methacrylate (a product which should be formed by a low-energy process from a ring-opened intermediate), we favor a process which is concerted.

To obtain inversion by a concerted process, let us consider two extremes for nitrogen elimination.

(*i*) Loss of nitrogen by a stretching vibration in the plane of atoms 3, 4, and 5 would be accompanied by formation of two p-orbitals at C_3 and C_5 which, because of their orientation towards each other, would couple to give product of retained configuration.

(*ii*) Loss of nitrogen by a stretching vibration perpendicular to the plane of atoms 3, 4, and 5 would be expected to give two p-orbitals at C_3 and C_5 parallel to each other. However, the substituents on C_3 and C_5 would be sufficiently close that the parallel orientation could only be approximated. To accommodate this steric factor a greater stretching of one C—N bond in the transition state would permit a twisting of the molecule and stacking of the groups which interact sterically. Such stacking would lead to p-orbitals at C_3 and C_5 in a position to give inversion at one center.

Whether *i* or *ii* is concerted or not depends on whether the developing p-orbitals on C_3 and C_5 overlap in the transition state or not. Process *i*, if concerted, would then be identical with the process proposed for the photochemical reaction by van Auken and Rinehart (1). Process *ii*, if not concerted, simply adds a geometrical restriction to the dipolar intermediate earlier proposed.

In the actual reaction a situation between *i* and *ii* is expected, and thus both inversion and retention are anticipated, with the proportion depending on the conformations available for reaction and the substituents present. Further work on the stereochemistry of this reaction is therefore justified.

In a further pyrazoline which we have studied, we wished to examine the stereochemistry at both C_3 and C_5 relative to an independent center (at C_4) and not just relative to each other. The results are somewhat clouded by the fact that the pyrazoline used was a mixture, but the results are still informative and are described below.

Addition of diazoethane to methyl tiglate gave a pyrazoline product which by n.m.r. appeared to be a 90:10 mixture. It was assumed, on the grounds that steric effects will be important and that the geometry at C_3 and C_4 for both isomers will be that of methyl tiglate (1), that the major pyrazoline was XXII and the minor one was XXIII (see eq. [*b*]).

Pyrolysis of this pyrazoline mixture gave three products identified as methyl *cis,trans*-1,2,3-trimethyl-1-cyclopropanecarboxylate (XXIV), methyl *cis,cis*-1,2,3-trimethyl-1-cyclopropanecarboxylate (XXV), and methyl 2,3-dimethyl-2-pentenoate (XXVI) (see eq. [*c*]). Von Auwers and Konig (4) have reported that the pyrolysis of the same pyrazoline gave XXIV and XXVI in the proportion of 86:14 as estimated by bromine titration.

	XXIV	XXV	XXVI
pyrolysis	61%	32%	6%
photolysis	88%	10%	—

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The n.m.r. spectrum of XXIV was used for its structural assignment. Peaks for three ring methyl groups appear at 8.80 τ (C_1 methyl) and 8.91 and 8.94 τ (doublets). The methyl at 8.91 τ is split by a hydrogen at 9.37 τ and the methyl at 8.94 τ is split by a hydrogen at 8.67 τ. Only structure XXIV satisfies non-equivalence of the methyls and the hydrogens on C_2 and C_3. The chemical shift separation between the ring hydrogens is undoubtably due to the anisotropy of the carbonyl of the ester group, which by comparison with other cyclopropanecarboxylic acid esters (19) and cyclopropanecarboxylic acids (19–22) would be expected to deshield the hydrogen *cis* to it.

The n.m.r. spectrum of XXV shows, in addition to the C_1 methyl at 8.96 τ, a doublet at 9.07 τ for the two equivalent methyls on C_2 and C_3 and a multiplet at 8.59 τ for the two ring hydrogens. The low-field position of the ring hydrogens suggests that they are *cis* to the carbomethoxy group. This assignment would also follow if the cyclopropane formation in the photolysis reaction were assumed to be stereospecific (1).

Formation of cyclopropane XXIV requires retention at C_5 from at least 55% of XXII and formation of XXV requires inversion at C_5 from at least 25% of XXII in the pyrolysis reaction. Total inversion at C_5 therefore need not be a mechanistic requirement of the pyrolysis reaction.

Photolysis of Pyrazolines

The products from the photolysis of the *cis–trans* pair of pyrazolines IV and V under a number of conditions were analyzed and the results are recorded in Table III. When

the photolysis products are compared to the products from pyrolysis, we find a higher percentage of cyclopropane derivatives present, the formation of an additional product from cleavage of the molecule at the N_2—C_3 and C_4—C_5 bonds, and a different stereochemical result. Even when the photolysis is carried out at the same temperature and in the same solvent as the pyrolysis reaction we find that these differences are still present. In refluxing cyclohexane the rate of nitrogen evolution during photolysis was 3 times the rate of nitrogen evolution during pyrolysis only, and thus both reactions can be studied under these conditions (Tables I and III). Photolysis at −55° in ether gives essentially the same product ratio as the photolysis in refluxing ether.

Van Auken and Rinehart (1) have also observed significant differences between the pyrolysis and photolysis of I and II. They found the cyclopropanes formed by photolysis to be formed stereospecifically and suggested a molecular mechanism with bonding between C_3 and C_5 taking place concerted with nitrogen elimination.

It seems unlikely that the electronically excited molecule would decompose more readily than the ground-state molecule. Thus, photodecomposition probably results from regeneration of the ground-state molecule with excess vibrational and rotational energy. The amount of this excess energy is probably more than enough for decomposition (this is suggested by the appearance of a new mode of decomposition to give methyl methacrylate), and thus small factors like conformational preferences would have less control on this reaction. The higher energy of the reacting molecules might lead to a more nearly planar (mean conformation) transition state with a result closer to mechanism *i* than for the pyrolysis reaction. This explanation is preferred to one invoking a completely new mechanism for the photolysis reaction, since the effect of solvent and the stereospecificity in olefin formation are still present but not to the same degree as in the pyrolysis reaction.

EXPERIMENTAL

The apparatus and procedures used were the same as reported earlier (6).

cis- and trans-3,5-Dimethyl-3-carbomethoxy-Δ^1-pyrazoline (IV and V)

This pyrazoline was prepared as reported earlier (5) and fractionally distilled with a Nester and Faust 45 cm by 6 mm spinning-band still at a pressure of 1 mm and with the still pot in an oil bath held between 80 and 90°. The head temperature varied from 55 to 65° but was not an accurate measure of the boiling point, as pyrolysis occurred, to some extent, simultaneous with distillation and thus the head pressure fluctuated during distillation. The lower-boiling fraction was not obtained pure and contained 13% of the higher-boiling fraction as determined by n.m.r. The n.m.r. peaks attributable to the lower-boiling fraction were at 5.42 τ (sextet with splitting of about 7.5 c.p.s. for the hydrogen on C_5), 6.33 τ (ester methyl), 7.68 τ (two doublets with J_{gem} = 12.9 c.p.s. and J_{vic} = 8.6 c.p.s. for one of the C_4 hydrogens), 8.38 τ (methyl on C_3), 8.51 τ (doublet with J = 7.0 c.p.s. for the methyl on C_5), and 9.14 τ (two doublets with J_{gem} = 12.8 c.p.s. and J_{vic} = 8.3 c.p.s. for the second hydrogen on C_4). This isomer was assigned the structure IV with the methyls *cis* (see the text).

The higher-boiling fraction was obtained essentially pure and showed peaks in the n.m.r. at 5.43 τ (sextet with splitting of about 7.5 c.p.s. for the hydrogen on C_5), 6.27 τ (ester methyl), 8.28 τ (two doublets with J_{gem} = 12.8 c.p.s. and J_{vic} = 8.0 c.p.s. for one of the C_4 hydrogens), 8.55 τ (doublet with J = 7.0 c.p.s. for the methyl on C_5), 8.56 τ (two doublets with J_{gem} = 12.6 c.p.s. and J_{vic} = 8.0 c.p.s. for the second hydrogen on C_4), and 8.63 τ (methyl on C_3). This isomer was assigned the structure V with the methyls *trans* (see the text).

Pyrolysis and Photolysis of IV and V

Pyrolysis in the vapor phase was carried out on a 3-μl sample placed in a 1-l flask. The flask was evacuated to 1 mm with the sample cooled in a side arm in liquid nitrogen. The flask was closed with a stopcock and placed in an oven at 125°. The sample completely vaporized before its pyrolysis temperature was reached.

Pyrolyses in solvents were carried out at 125° on 200-μl samples of IV or V in 25 ml of solvent in a sealed tube. For low-boiling solvents the solvent was distilled through a spinning-band column and the concentrated solution was analyzed by vapor chromatography. For formamide the volatile products were removed from the solvent on a vacuum line.

The photolysis was carried out by placing a Hanovia 450-W medium-pressure mercury arc 6 inches from a flask containing the sample and by allowing the solvent to reflux. For the run at −55° the sample flask was cooled by an external coolant flowing through a jacket around the flask and insulated by another air jacket. Ethanol was used as the coolant and was cooled to −55° before it was pumped through the cooling jacket.

The products from the pyrolysis and photolysis of pyrazolines IV and V are listed in Tables I and III. The individual products have been previously identified. A n.m.r. spectrum has now been obtained on methyl *cis*-2-methyl-2-pentenoate and showed peaks at 4.16 τ (broadened quartet with J = 7.2 c.p.s. for the hydrogen on C_3), 6.34 τ (ester methyl), 7.55 τ (multiplet for the hydrogens on C_4), 8.15 τ (broadened singlet for the methyl on C_2), and 9.02 τ (triplet with J = 7.4 c.p.s. for the hydrogens on C_5). The higher field position (23) for the hydrogen on C_3 compared to that in the *trans* isomer (3.48 τ (5)) confirms the assignment of geometry given to these isomers earlier (5).

Kinetics of the Pyrolysis of IV and V

The apparatus used consisted of a flask heated in a constant temperature bath held at 100.5 ± 0.5°. The solvent (6 ml) was preheated in the bath and a 250-μl sample (40% IV and 60% V) was added with thorough mixing. The flask was connected to a 100-ml burette and the time for generation of each 2-ml sample was recorded until 60–80% reaction. The infinity point (≃ 40 ml) was determined by raising the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

temperature of the reaction to complete the reaction and cooling it to 100°. Plots of $\log -(V_\infty/(V_\infty - V_t))$ vs. t gave straight lines except for *n*-butyl ether which gave some divergence above 70% reaction. The $t_{\frac{1}{2}}$ values from runs in *n*-butyl ether, tetralin, nitrobenzene, and formamide are recorded in Table II.

3,4,5-Trimethyl-3-carbomethoxy-Δ¹-pyrazoline

Tiglic acid (Aldrich) was esterified with diazomethane and the methyl tiglate was distilled. To 15 g of methyl tiglate was added three portions of diazoethane in ether (prepared from 25 g of nitrosoethylurea) over a 1-week period. After the reaction was complete the mixture was distilled to give 4 g of pyrazoline, b.p. 50° at 0.005 mm, n_D^{25} 1.4536 (lit. (24), b.p. 88° at 3 mm, $n_{H_2O}^{20}$ 1.453). The n.m.r. spectrum fitted a pyrazoline structure with peaks at 6.12 τ (multiplet for the C_5 hydrogen), 6.33 τ (ester methyl), 8.30 τ (multiplet for the C_4 hydrogen), 8.62 τ (doublet with J = 7 c.p.s. for the C_5 methyl), 8.92 τ (C_3 methyl), and 9.09 τ (doublet with J = 6.5 c.p.s. for the C_4 methyl). The assignments of the methyl groups are based on the fact that the peaks of the doublet at 8.62 τ are more nearly equal in intensity and therefore coupled to a hydrogen further downfield than the doublet at 9.09 τ. There is evidence for a second pyrazoline as a result of peaks at 6.42 τ (singlet), 7.71 τ (multiplet), and 9.34 τ (doublet). By comparison of the intensity of the peaks of these two pyrazolines it is possible to estimate this to be a 90:10 mixture. The major component was assigned the structure *cis,trans*-3,4,5-trimethyl-3-carbomethoxy-Δ¹-pyrazoline (XXII) and the minor component the *cis,cis* structure (XXIII) (see the text).

Pyrolysis of 3,4,5-Trimethyl-3-carbomethoxy-Δ¹-pyrazoline

The pyrazoline was pyrolyzed by heating a sample in an oil bath at 120° and the products were separated by chromatography.

Methyl *cis,trans*-1,2,3-trimethyl-1-cyclopropanecarboxylate (XXIV): b.p. 151°; n_D^{25} 1.4308; infrared band of C=O at 1 710 cm^{-1}; n.m.r. peaks at 6.39 τ (ester methyl), 8.67 τ (quartet with J = 6 c.p.s.), 8.80 τ (methyl on C_1), 8.91 and 8.94 τ (doublets with J = 6 c.p.s.), and 9.37 τ (quartet with J = 6 c.p.s.). The assignments of the peaks are given in the text.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93. Found: C, 67.36; H, 10.15.

Methyl 2,3-dimethyl-2-pentenoate (?) (XXVI): b.p. 163°; infrared band of C=O at 1 715 cm^{-1}; n.m.r. peaks at 6.38 τ (ester methyl), 7.68 τ (quartet with J = 7.6 c.p.s. for hydrogens on C_4), 8.23 τ (methyls on C_2 and C_3 unresolved), and 9.0 τ (triplet with J = 7.6 c.p.s. for the hydrogens on C_5). Application of the mechanism herein described would predict this olefin to have the methyls *cis*.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93. Found: C, 66.99; H, 10.27.

Methyl *cis,cis*-1,2,3-trimethyl-1-cyclopropanecarboxylate (XXV): b.p. 166°; n_D^{25} 1.4410; infrared band of C=O at 1 725 cm^{-1}; n.m.r. peaks at 6.44 τ (ester methyl), 8.59 τ (multiplet for the two ring hydrogens), 8.96 τ (methyl on C_1), and 9.07 τ (doublet with J = 5.5 c.p.s. for the methyls on C_2 and C_3). The assignments of these peaks are discussed in the text.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93. Found: C, 67.38; H, 10.12.

ACKNOWLEDGMENTS

The authors gratefully appreciate the support received for this work from the National Research Council of Canada and from the Committee on Research of the University of British Columbia.

Thanks are also extended to Mrs. A. Aldrich for determining the microanalyses and to Mrs. E. Brion for determining the n.m.r. spectra.

PHOTOREARRANGEMENT OF 2,3-DIMETHYL-4,5-DIHYDROFURAN AND 2-METHYL-4,5-DIHYDROFURAN

DONALD E. MCGREER, MAGNUS G. VINJE, AND ROBERT S. MCDANIEL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Irradiation of an ether solution of the title compounds with a medium-pressure mercury arc gave in each case a rearrangement reaction, with formation of an acetyl cyclopropane isomer as the major product. This reaction is similar to that induced thermally at 450°.

2-Methyl-4,5-dihydrofurans are formed as minor products in the pyrolysis and photolysis of 3-acetyl-Δ^1-pyrazolines (1). These derivatives were found to be stable to light filtered by a pyrex vessel; however, in a silica-glass flask they were rearranged under irradiation by a mercury lamp to cyclopropane derivatives.

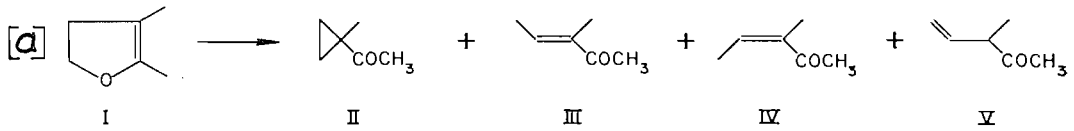
When 2,3-dimethyl-4,5-dihydrofuran (I) (λ_{max} = 218 mμ) was irradiated in an ether solution, the work-up of the reaction after 86% of I had reacted gave a mixture which contained 1-methyl-1-acetylcyclopropane (II) as the major component. Other products identified only by their retention times in the vapor chromatogram were *trans*-3-methyl-3-buten-2-one (III), *cis*-3-methyl-3-buten-2-one (IV), and 3-methyl-4-buten-2-one (V) (see eq. [*a*]). Similarly, photolysis of 2-methyl-4,5-dihydrofuran (λ_{max} = 210 mμ) gave methyl cyclopropyl ketone. This latter reaction is complicated by extensive polymerization.

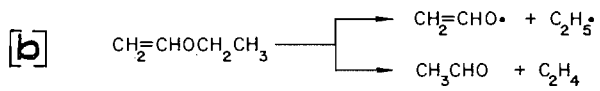
The photorearrangement of dihydrofurans is analogous to the thermally induced rearrangement (2–4). For example, 2-methyl-4,5-dihydrofuran, when heated to 450° in a flow system, is converted to methyl cyclopropyl ketone and 3-buten-2-one (2, 3).

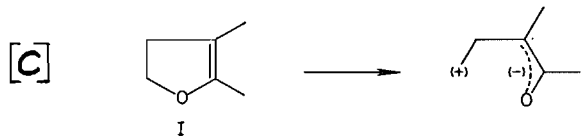
It is of interest that the product ratio for compounds II–V in the photorearrangement of I (90:5:3:2 respectively) is close to that obtained for the photolysis of 3-acetyl-3-methyl-Δ^1-pyrazoline (88:6:3:3 respectively) (1). Although this may be fortuitous, it may mean that a similar intermediate is involved in the two reactions.

The photolysis of vinyl ethers in the gas phase has been found to give two primary processes, the first caused by cleavage of the alkyl group – oxygen bond and the second caused by rearrangement and fragmentation to give an aldehyde and ethylene (5) (see eq. [*b*]). In the dihydrofuran system analogous cleavage would give a diradical intermediate which, in a dipolar form, is similar to that proposed for the pyrolysis of pyrazolines (6) (see eq. [*c*]). However, the possibility of a molecular mechanism must also be considered, since stereochemical results in the pyrolysis and photolysis of pyrazolines suggested a molecular mechanism is possible (7).

Boykin and Lutz (8) have observed that the photorearrangement of 2,3,5,5-tetraphenyl-4,5-dihydrofuran gives the valence tautomer 1-benzoyl-1,2,2-triphenylcyclopropane (these results were published while the present paper was in press). Their system is interesting in that the dihydrofuran can be reformed from the cyclopropane by treatment with acid, and more drastic conditions are needed to give ring-opened products. This might suggest also that ring opening is not involved in the dihydrofuran–cyclopropane tautomerism.







EXPERIMENTAL

Photolysis of 2,3-Dimethyl-4,5-dihydrofuran (I)

A solution of 0.5 ml of I (1) in 25 ml of ether was placed in a silica-glass flask fitted with a reflux condenser. The solution was irradiated with a Hanovia 450-W medium-pressure lamp No. 79A36 placed 3 inches from the flask. After 4 h of irradiation the solution was concentrated and analyzed by vapor chromatography (Aerograph A-90-P using a 10-ft dinonyl phthalate column at 122°). The chromatogram showed that 14% of the mixture (by areas) was I (retention time 12.2 min). Other components identifiable by their retention times as compared with those of authentic samples (1) were 3-methyl-4-buten-2-one (V) (1%, 11.3 min), *cis*-3-methyl-3-buten-2-one (IV) (1%, 17.3 min), 1-methyl-1-acetylcyclopropane (II) (74%, 19.2 min), and *trans*-3-methyl-3-buten-2-one (III) (4%, 25.1 min). The 1-methyl-1-acetylcyclopropane (II) was isolated and found to have a nuclear magnetic resonance (n.m.r.) spectrum identical with that of an authentic sample (1). II was stable under the reaction conditions.

Photolysis of 2-Methyl-4,5-dihydrofuran

The 2-methyl-4,5-dihydrofuran (Columbia Organic Chemicals) was distilled before use, b.p. 78.5–79.5°, n_D^{25} 1.4289 (lit. (9), b.p. 78.9°, n_D^{25} 1.4289). A solution of 5 ml of 2-methyl-4,5-dihydrofuran in 15 ml of ether was irradiated as above. The progress of the reaction was followed by vapor chromatography and at 25 h 10% of the volatile fraction (excluding solvent) was starting material. The product was distilled to give 0.4 ml, b.p. 80–150°. The residue (3 ml) was polymeric in nature. Vapor chromatography (P-E 226 using a 150-ft Golay polyglycol column at 103°) of the distillate showed one major component at 1.3 min in addition to starting material at 0.6 min. The 1.3-min component was collected (Aerograph A-90-P) and identified as methyl cyclopropyl ketone, b.p.111.0–111.2°, n_D^{20} 1.4241 (lit. (2), b.p. 110.2–110.4°, n_D^{20} 1.4250). The n.m.r. spectrum agreed with that of the assigned structure. The 2,4-dinitrophenylhydrazone was prepared by the procedure of Shine (10), m.p. 154–156° (lit. (3), m.p. 147.8–149.2°).

REACTIVITY AND GEOMETRY IN ALLYLIC SYSTEMS

III. PHOTOSENSITIZED OXYGENATION OF CHOLEST-4-ENE, A STEROID OLEFIN WITH A CONFORMATIONALLY FLEXIBLE RING[1,2]

A. NICKON[3] AND W. L. MENDELSON
Department of Chemistry, The Johns Hopkins University, Baltimore, Maryland
Received November 13, 1964

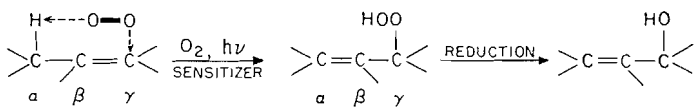
Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

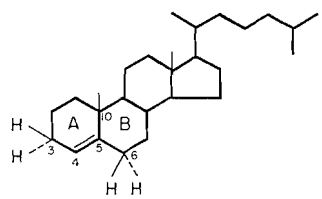
ABSTRACT

Photosensitized oxygenation of cholest-4-ene with hematoporphyrin in pyridine followed by reduction of the derived hydroperoxides gave five allylic alcohols in these relative amounts: cholest-4-en-3α-ol (V*a*, 37%); cholest-4-en-3β-ol (IV*a*, 7.5%); 5α-cholest-3-en-5-ol (VIII*a*, 29%); 5β-cholest-3-en-5-ol (VI*a*, 2%); and cholest-5-en-4β-ol (X*a*, 8.5%). A by-product from breakdown of the hydroperoxides was cholest-4-en-3-one (III, 6.5%). The Δ^4-stenols are not primary products from the photosensitized process but arose by gradual isomerization of the initially derived 5-hydroperoxycholest-3-enes. When the original hydroperoxide mixture was allowed to stand in chloroform, the rearrangement went to completion and no isolable amounts of the Δ^3-stenols remained. After rearrangement, V*a* and IV*a* were present in a ratio of about 8:1, and this sequence affords a convenient new route to cholest-4-en-3α-ol. The photooxidation products and their relative proportions are readily understood if oxygen can attack both half-chair conformations of ring A in cholest-4-ene and can cyclically abstract a quasi-axial (or an axial) allylic hydrogen. Conclusions are drawn on the importance of steric hindrance and of ring inversion on the photosensitized oxygenation reaction.

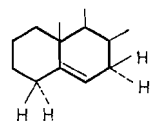
INTRODUCTION

Photosensitized oxygenation of monoolefins gives allylic hydroperoxides with a rearranged double bond (1). Work with steroids showed that the bonds formed and broken (C—O and C—H respectively) are *cis* to each other and led to the suggestion of a cyclic mechanism, with no implication about the timing of the events or the extent of participation by the sensitizer (2, 3). Geometric considerations indicate that in a half-chair cyclohexenoid ring a quasi-axial (*a'*) hydrogen is better suited than a quasi-equatorial





I



II

(*e'*) hydrogen for cyclic abstraction. All results so far are interpretable on this basis and no definitive examples have been found of *e'* hydrogen abstraction in a rigid ring system.

[1]*For Part II see ref. 15a.*
[2]*Taken from the Ph.D. Dissertation of W. L. Mendelson, Johns Hopkins University, 1963.*
[3]*Alfred P. Sloan Foundation Fellow, 1957–61.*

In those cases where the preferred ring conformation is different for the starting olefin and product, ring inversion or distortion must occur at some stage, but in one test case studied (5β-cholest-3-ene) it was shown that this factor by itself was insufficient to stop the reaction, though it may have slowed it (4). Results with steroids and simpler olefins indicate that the reaction is subject to steric hindrance. In particular, an axial alkyl group in a 1,3-relationship both to the developing C—O bond and to the allylic C—H bond inhibits the oxygenation markedly (2–5).[4] Which of these two 1,3-interactions is the more important emerges from the present study and from work to be described elsewhere (4, 5).

Although several monocyclic olefins have been photooxygenated with sensitizers (1), the only studies involving complete product analysis have been by Kenney and Fisher (6, 7) and by Schenck *et al.* (8). The former workers examined (+)-carvomenthene, and the latter group investigated (+)-carvomenthene and (+)-limonene. Both research groups satisfactorily accounted for their products on the basis of the cyclic *cis* mechanism.[5] To find out the effect of conformational flexibility in a condensed ring system we examined the photosensitized oxygenation of cholest-4-ene (I). The double-bond environment in this substrate is similar to that in Δ^5-steroids (part of structure II) but, unlike these ring B olefins, cholest-4-ene can exist in two interconvertible half-chair conformations; hence, it was of interest to learn if products could be derived from each. Furthermore, the behavior of the cholest-4-ene system would help assess other steric features of the reaction.

RESULTS

Cholest-4-ene was prepared from cholest-4-en-3β-ol acetate (or benzoate) and also from cholest-4-en-3-one (III) by reported methods (9, 10). To facilitate identification and assay of oxygenation products we separately synthesized the five allylic alcohols IV*a*, V*a*, VI*a*, VIII*a*, and X*a*, and some of their esters as follows.

Cholest-4-en-3β-ol (IV*a*) was obtained by reduction of III with lithium aluminium hydride and then separation of the epimers with digitonin. In a simplified route sodium borohydride reduction produced the 3β-ol in such preponderance that this epimer could be isolated directly by crystallization without resort to digitonide formation. Reduction of III with aluminium isopropoxide (11) gave the 1:1 complex of the epimers IV*a* and V*a*. After removal of the 3β-epimer with digitonin we obtained cholest-4-en-3α-ol (V*a*). An improved route to V*a* arose from the photooxygenation of I and will be described in the sequel. The reduction of 4β,5-epoxy-5β-cholestan-3-one with hydrazine gave us 5β-cholest-3-en-5-ol (VI*a*) as reported (24), and we applied the same reduction to 4α,5-epoxy-5α-cholestan-3-one (VII) and obtained the new allylic alcohol 5α-cholest-3-en-5-ol (VIII*a*). As expected (12) the molecular rotation increment of VIII*a* relative to 5α-cholest-3-ene for introduction of the OH group at C-5 is strongly negative. The synthesis of 4β-acetoxycholest-5-ene (X*c*) by a reported method proved unsuitable; hence, we developed a two-step procedure which involved conversion of cholest-4-ene to the diol monoacetate IX by treatment with hydrogen peroxide in acetic acid – acetic anhydride, followed by dehydration to X*c*.

We photooxygenated cholest-4-ene (I) in dilute pyridine solution (ca. 0.03 *M*) at

[4]*The formation of relatively little cis-carveol (5%) among the photosensitized oxygenation products of (+)-limonene can be rationalized on a similar basis, although alternate explanations are possible (8).*

[5]*Kenney and Fisher originally favored a concerted process for the cyclic mechanism (6) but have reinterpreted their results (7) in terms of Schenck's stepwise mechanism (1) in which* C—O *bond formation creates an intermediate diradical and precedes* C—H *cleavage.*

about 35–40° with hematoporphyrin (ca. 2×10^{-4} *M*) as sensitizer. In a typical run it underwent about 90% conversion in 25 h,[6] and the crude product (after correction for unchanged olefin) contained 6.5% cholest-4-en-3-one (III, assayed by its ultraviolet absorption at 240 mμ) and 83% mixed hydroperoxides (assayed by quantitative hydrogenation of an aliquot). The total product was reduced with sodium iodide and chromatographed on alumina. In addition to starting olefin (ca. 11%) and cholest-4-en-3-one (III) we identified five allylic alcohols IV*a*, V*a*, VI*a*, VIII*a*, and X*a*. Table I lists the alcohols, in order of elution, and their approximate relative yields after correction for recovered olefin. The compounds were identified by infrared spectroscopic comparison and, except for VI*a*, also by appropriate melting point and mixture melting point comparisons of the alcohol (or one of its esters) with the genuine samples from synthesis. In a control photooxygenation conducted in the same way except that the sensitizer was omitted, no detectable hydroperoxidic material was produced and the starting olefin was recovered entirely. When a free-radical initiator (*t*-butyl hydroperoxide) was added in nearly equivalent amount, a control run in the absence of sensitizer gave about 5% oxidation. These results reasonably exclude a radical-chain pathway as a significant source of oxygenation products.

TABLE I*

	Relative %
5α-Cholest-3-en-5-ol (VIII*a*)	29
Cholest-5-en-4β-ol (X*a*)	8.5
5β-Cholest-3-en-5-ol (VI*a*)	2
Cholest-4-en-3α-ol (V*a*)	37
Cholest-4-en-3β-ol (IV*a*)	7.5

*The total recovery from chromatography was 95%, which included about 9.5% of unidentified mixtures.

DISCUSSION

Because photosensitized oxygenation is invariably accompanied by a shift of the double bond (1), the hydroperoxides IV*b* and V*b* (corresponding to the alcohols IV*a* and V*a*)

[6]*Longer reaction times encouraged breakdown of the hydroperoxides, as evidenced from diminished infrared intensities in the* OH *region and increased intensities in the carbonyl region.*

cannot be primary products of the sensitized process. That they can arise by subsequent allylic rearrangement of the expected 5-hydroperoxycholest-3-enes in the original solution or during the iodide reduction was indicated when a chloroform solution of the crude hydroperoxidic mixture was found to mutarotate during polarimetric readings. When rearrangement in the chloforom solution was allowed to go to completion (48 h), the mixture was reduced with sodium iodide and chromatographed as before. The two cholest-3-en-5-ols (VI*a* and VIII*a*) were no longer present, and the epimeric cholest-4-en-3-ols (V*a* and IV*a*) were obtained in higher yields and in a ratio greater than 8:1 (cf. original ratio of 5:1 from Table I). These allylic rearrangements of tertiary hydroperoxides to secondary hydroperoxides have analogy,[7] and, because of the favorable final proportion of the α-epimer V*a*, we recommend photosensitized oxygenation of cholest-4-ene followed by allylic rearrangement of the hydroperoxidic mixture in chloroform as a convenient route to cholest-4-en-3α-ol (V*a*). From the *cis* stereochemistry required both for the oxygenation step (2, 3) and for the subsequent allylic rearrangement of the tertiary hydroperoxides (13, 14) it follows that the combined yield (66%) of V*a* and VIII*a* represents the total abstraction of the α-hydrogen at C-3; similarly, the combined yield (9.5%) of IV*a* and VI*a* represents the net abstraction of the β-hydrogen at C-3. The fifth alcohol X*a* (obtained in 8.5% yield) arises from removal of the β-hydrogen at C-6. These are the first cases where β-attack has been observed in photosensitized oxygenation of a steroid monoolefin. The relative ease of hydrogen abstraction for $3\alpha/3\beta/6\beta$ lies between 8.5/1.1/1 and 7.8/1.9/1.[8] The following conformational analysis satisfactorily accounts for these results and leads to some new conclusions about the oxygenation reaction.

In cholest-4-ene, ring A can adopt two half-chair conformations depicted in XI and XII. We shall first consider attack by oxygen[9] at C-5 and abstraction of hydrogen from C-3. In half-chair XI, α-attack by oxygen meets no serious steric hindrance and the 3α-hydrogen is quasi-axial (a'). Consequently, circumstances are favorable for production of hydroperoxide XIII by a cyclic mechanism. Importantly, this hydroperoxide can adopt only one half-chair conformation (shown in XIII) and no ring inversion is involved when the double bond shifts from Δ^4 (in XI) to Δ^3 (in XIII). The C—O bond in XIII is a' and therefore well disposed sterically and stereoelectronically for intramolecular allylic rearrangement to XV, which can ultimately equilibrate with its alternate half-chair conformation, XVII.

Beta attack by oxygen cannot be consummated from half-chair XI because the 3β-hydrogen is quasi-equatorial (e') and therefore relatively inaccessible for cyclic transfer.[10] The situation changes in half-chair XII, because now the C—H bonds in ring A have reversed their conformational character. The 3α-hydrogen is e' and precludes hydroperoxidation from the α-side.[11] On the other hand, the 3β-hydrogen is a' and the overall steric situation for β-attack is now similar to that noted above for α-attack on half-chair

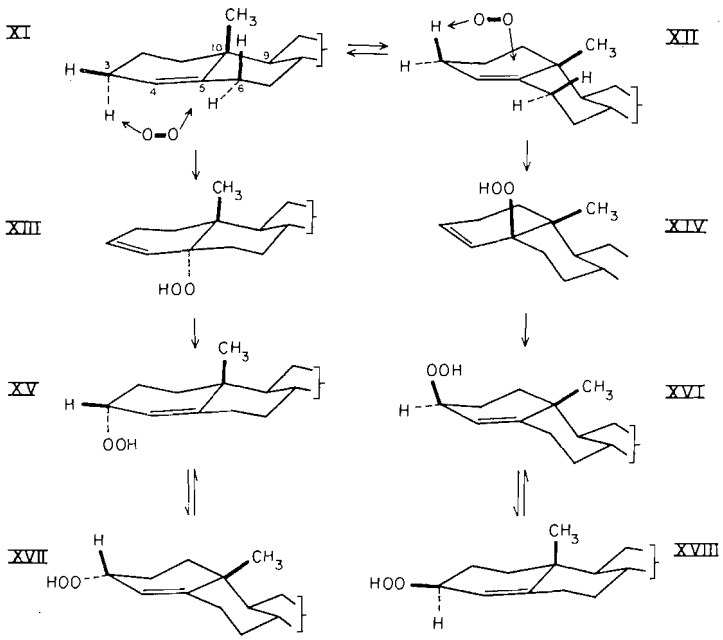
[7]*Schenck et al. (13) and Lythgoe and Trippett (14) first observed this type of isomerization with 5-hydroperoxy-5α-cholest-6-en-3β-ol, which rearranged to 7α-hydroperoxycholest-5-en-3β-ol. Schenck's mechanistic studies showed that the isomerization is both intramolecular and stereospecifically cis.*

[8]*The uncertainty in these ratios arises because a portion of the 3α- and 3β-hydroperoxides breaks down to cholest-4-en-3-one, and presently we have no way to estimate how much of the ketone is derived from each hydroperoxide. The first set of figures applies if the ketone (6.5%) arose exclusively from Vb; the second set applies if the ketone came entirely from IVb. The true figures probably lie between these extremes.*

[9]*The photochemical aspects of sensitized reactions have been discussed elsewhere (see refs. 1, 3, and 15 for leading references).*

[10]*Note also that the angular methyl group at* C-10 *would present an almost eclipsed 1,2-interaction to an incipient beta* C—O *bond at* C-5 *and might further impede β-attack.*

[11]*An added feature that could impede α-attack on XII is the* C_9—C_{10} *bond, which would eclipse a* C—O *bond being created at* C-5.



XI. On this basis, hydroperoxide XIV should arise from half-chair XII about as readily as XIII did from half-chair XI. Once formed, XIV has its hydroperoxy group suitably poised (*a'* to ring A) for allylic rearrangement to XVI. Ring inversion plays no role in the formation of XIV or in its isomerization to XVI but enters only in the final equilibration of XVI with its alternate half-chair form XVIII. The yields in Table I reveal that the fraction of XIV that rearranged (0.83 ∓ 0.04)[8] is higher than that (0.58 ± 0.02)[8] of XIII. The A/B *cis* ring fusion in XIV is probably less stable than the A/B *trans* fusion in XIII, and the drive to release strain may be correspondingly greater in the former system.

We now turn our attention to oxygenation at C-4 accompanied by hydrogen abstraction from C-6. Alpha attack is not fruitful from either half-chair XI or half-chair XII, because the 6α-hydrogen is equatorial (*e*) to ring B and unsuitably oriented with respect to the olefinic bond. Beta attack on XI is sterically blocked by the methyl group at C-10, which is axial to ring B and quasi-axial to ring A and which presents diaxial-type 1:3-interactions to a developing C—O bond at C-4 and also to the 6β-hydrogen. Other examples that attest to the difficulty of hydroperoxidation in molecules with comparable steric situations are available (2–8). In half-chair XII the offending methyl group is *e'* to ring A and no longer confronts an incipient beta C—O bond at C-4 with serious hindrance. Consequently, the cholest-5-en-4β-ol (X*a*) is most reasonably derived from half-chair XII and, concomitant with the double-bond shift from Δ^4 to Δ^5, ring A must either undergo conformational inversion or develop initially into a twist boat form. Another example where the ring-inversion factor has failed to block oxygenation has been observed with 5β-cholest-3-ene (4).

Half-chair XII contains a geometric feature not exemplified so far. The angular methyl group is quasi-equatorial to ring A but is axial to ring B and presents a diaxial 1:3-interaction to the 6β-hydrogen but not to a developing beta C—O bond at C-4. Therefore, unless X*a* is formed by some abnormal mechanism, this case illustrates that a diaxial 1:3-relationship between an alkyl group and an allylic hydrogen is insufficient by itself to block

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the reaction. Insofar as these hindrance effects can be separately evaluated, steric interactions with the developing C—O bond rather than with the allylic hydrogen appear to be of greater importance. The formation of X*a* from cholest-4-ene is of additional interest, because the double bond is initially exo to ring B and finally exo to ring A. Schuller and Lawrence have implied that a structural change of this type would involve a prohibitive amount of strain as the transition state is approached and would lead to nonreactivity (16).

EXPERIMENTAL

General

Melting points are corrected. Optical rotations refer to the sodium D-line and were taken at room temperature in chloroform. Ultraviolet spectra were taken in 95% ethanol on a Beckmann DK-2 or a Cary model 11 M recording instrument. Infrared spectra were taken in carbon disulfide solution with a Perkin–Elmer model 21 double-beam spectrophotometer. In color tests for hydroperoxide 1 drop of a saturated solution of sodium iodide in isopropyl alcohol was added to the unknown (0.002–0.003 g) dissolved in glacial acetic acid. Authentic steroid hydroperoxides were used as controls.

To assay for total hydroperoxide in a crude product we used quantitative hydrogenation with Raney nickel catalyst (17), in pyridine (13, 18). The hydrogen uptake was usually complete within 20–30 min with pre-blanked catalyst and was reproduced in a duplicate run to within 3–4%. For the determinations we used 0.015–0.030 g of the hydroperoxide and ca. 0.5 g of the ethanol-moistened Raney nickel.

Reductions of hydroperoxides with sodium iodide were conducted as soon as possible after work-up of the oxygenation. In a typical reduction, sodium iodide (ca. 0.6 g) was dissolved in a solution containing the crude hydroperoxide (0.15 g) in absolute methanol (10 ml), anhydrous ether (2 ml), and glacial acetic acid (3–4 drops). After 12 h most of the solvent was removed, an excess of ether was added, and the solution was washed with sodium thiosulfate (until the ether was clear) and then with water. The ether was dried over sodium sulfate, which was the drying agent throughout this work, and evaporation gave the allylic alcohol.

Sterols were acetylated and benzoylated by conventional procedures (3).

Photosensitized oxygenations were conducted in a vertical pyrex tube (30 cm) irradiated along its length by two standard fluorescent desk lamps (each containing two 15-W fluorescent tubes, each about 17 inches long) mounted about 1 inch away. A long glass tube with a fritted glass plate at the end was used to admit oxygen at the bottom of the solution, slowly and without interruption. The lamps kept the temperature of the solution between 35–40°. Hematoporphyrin (Mann Research Laboratories) and reagent grade pyridine were used in all of the photosensitized oxygenations. A typical work-up procedure for a 20-ml aliquot was as follows. After evaporation of the solvent under reduced pressure at 35–45°, anhydrous ether (15 ml) and charcoal (ca. 0.02 g) were added; the mixture was warmed briefly and filtered, and the filtrate was evaporated under vacuum at a temperature not exceeding 40°.

Cholest-4-en-3-one (III)

This compound, prepared as described (19), had m.p. 79–81°, $[\alpha]$ +90°, λ 241 (ϵ 16 600). Reported m.p. 79.5–80.5° (19), λ 240.5 (ϵ 18 000) (20).

*Cholest-4-en-3β-ol (IV*a*)*

(i) By Reduction with Lithium Aluminium Hydride

Reduction of cholest-4-en-3-one (III) with lithium aluminium hydride yielded a white solid, usual m.p. 125–127°. The optical rotations (three runs) ranged from +55° to +65°, which indicated about a 4:1 ratio of cholest-4-en-3β-ol to cholest-4-en-3α-ol (V*a*). Recrystallization from aqueous ethanol or methanol–acetone raised the m.p. to 129–130°. In contrast to a literature report (21*a*), the 1:1 molecular compound of IV*a* and V*a* (m.p. 141°, $[\alpha]$ +85°) could not be obtained by us this way (cf. 21*b*). However, we obtained pure IV*a* (m.p. 132–133°, $[\alpha]$ +46°) by treatment of the reaction product with digitonin as reported (21). We could not isolate cholest-4-en-3α-ol (V*a*) from the digitonide mother liquors, presumably because it was present only in small amounts.

(ii) By Reduction with Sodium Borohydride

A suspension of sodium borohydride (1.2 g) in a small volume of methanol was added to the enone (4.1 g) in methanol (300 ml) and the mixture was stirred at room temperature for 24 h, was poured into water (300 ml), and was extracted with ether, which was dried and evaporated. The product was crystallized once from ethyl acetate – methanol, m.p. 126–127° (3.5 g), $[\alpha]$ +51°. Pure cholest-4-en-3β-ol (IV*a*, m.p. 130–132°, $[\alpha]$ +46°) was obtained by one or two further recrystallizations (ca. 75% recovery) from ethyl acetate – methanol or from aqueous ethanol. Reported m.p. 131–132°, $[\alpha]$ +44° in benzene (21).

Acetylation of IV*a* gave cholest-4-en-3β-ol acetate IV*c*, m.p. 84–86°, $[\alpha]$ +6°. Reported m.p. 87–88°, $[\alpha]$ +8° (22). Benzoylation of IV*a* gave cholest-4-en-3β-ol benzoate, m.p. 125–126°, $[\alpha]$ +1°. Reported m.p. 125–128°, $[\alpha]$ ±0° (9).

Cholest-4-en-3α-ol (Va)

Reduction of enone III with aluminium isopropoxide (11) gave us the 1:1 complex of IV*a* and V*a* with m.p. 141–142°, [α] +84°. Separation of this complex with digitonin (21*a*) gave cholest-4-en-3α-ol (V*a*) as a hardened oil ([α] +121°). Two crystallizations from acetone–water gave solid with m.p. 78–82°. Reported m.p. 84°, [α] +120.8° in benzene (21).

Acetylation of V*a* (oil) gave cholest-4-en-3α-ol acetate V*c*, m.p. 83–84°, [α] +175°. Reported m.p. 82–83°, [α] +177° (22).

Cholest-4-ene (I)

Method A

This method involved the lithium–ethylamine reduction of the allylic acetate (IV*c*) (or benzoate) as reported (9). The product was purified by chromatography on alumina and then by one crystallization from ethyl acetate – methanol, m.p. 81–82°, [α] +73°. Reported m.p. 82–83.5°, [α] +76°, for olefin purified through the dibromide (20). The infrared spectrum (potassium bromide disc) of our product had bands at 1 655 and 810 cm^{-1} in agreement with those reported by Bladon *et al.* (20). The reduction proceeded equally well (yields 35–40%) with either the acetate or benzoate. In one run we carried out the reaction on a mixture (ca. 1:2) of cholest-4-en-3α-ol and -3β-ol acetates and obtained cholest-4-ene of the same purity.

Method B

This method was useful for larger scale preparations of the olefin (2.5 g); however, the product was not as pure as that from method A. This procedure involved treatment of an ether solution of the cholest-4-en-3-one (II) with aluminium chloride and lithium aluminium hydride as reported by Wheeler and Mateos (10). They reported m.p. 65°, [α] +56°, for material obtained after chromatography of the crude product and indicated that the product was a mixture of cholest-4-ene (80%) and cholestane (20%). Our product, after chromatography, had m.p. 65–70°, [α] +56°. Two crystallizations from ethyl acetate – methanol gave cholest-4-ene (25%, m.p. 78–80°, [α] +70°), whose infrared spectrum (potassium bromide) was identical in all essential respects with that of the olefin produced by method A.

4β,5-Epoxy-5β-cholestan-3-one

This synthesis was carried out by modification of the procedure of Plattner *et al.* (23). A solution of cholest-4-en-3-one (2.0 g) in 95% ethanol (500 ml, at room temperature) was treated simultaneously and dropwise with 30% hydrogen peroxide (12 ml) and 5 *N* sodium hydroxide (12 ml). After the solution had stood at 0° for 24 h, water (100 ml) was added and most of the solvent was removed in a rotary evaporator. The resulting pasty solution was extracted with methylene chloride, and the organic layer was washed several times with water and dried over sodium sulfate. Evaporation of the solvent gave a solid, which crystallized in needles from acetone–methanol, 1.3 g, m.p. 118–119°, [α] +128°. Reported m.p. 116–117°, [α] +136° (23).

5β-Cholest-3-en-5-ol (VIa)

This compound was obtained by treatment of 4β,5-epoxy-5β-cholestan-3-one with hydrazine hydrate as reported (24). The crude product (oil, 0.25 g) was chromatographed on alumina (9 g). Elution with benzene – petroleum ether yielded a clear oil (0.15 g, [α] +94°) which hardened to a semisolid. Reported m.p. 93–94.5°, [α] +98°. The infrared spectrum of our product had bands at 3 600, 3 550, 1 015, 1 000, 975, 925, 740, 720, and 625 cm^{-1}.

4α,5-Epoxy-5α-cholestan-3-one (VII)

This epoxyketone was prepared by the photosensitized oxygenation of cholest-4-en-3β-ol IV*a* as reported previously (15*a*). After chromatography on deactivated alumina and crystallization, it had m.p. 121–122°, [α] −39°. Reported m.p. 120–121°, [α] −42.5° (26).

5α-Cholest-3-en-5-ol (VIIIa)

This new allylic alcohol was prepared by treatment of 4α,5-epoxy-5α-cholestan-3-one (VII) with hydrazine hydrate (24) followed by chromatography on alumina. Elution with benzene – petroleum ether (1:1) gave a solid, m.p. 72–74°, with infrared bands at 3 600, 955, 930, 918, 895, 725, and 688 cm^{-1}. One crystallization from methanol gave crystals, m.p. 74–75°, [α] −14°. (For analysis, the material from the oxygenation of cholest-4-ene was purified (see below).)

4β-Acetoxy-cholest-5-ene (Xb)

The following procedure was found to be superior to a reported method (25). A solution of cholest-4-ene (0.5 g) in benzene (1 ml) was treated with acetic anhydride (3 ml) and acetic acid (8 ml). The reaction mixture was stirred rapidly at 40–45° while 30% hydrogen peroxide (3 ml) was added over a 2.5-h period. Stirring was continued for 14 h at 40–50°, after which several milliliters of the solution was distilled. When the solution was cool, an excess of ether was added, and the solution was washed successively with water, with 5% sodium bicarbonate (until the washings were neutral), and with saturated sodium chloride, and then dried. Removal of the ether under reduced pressure gave an oil, which was dissolved in hexane and

chromatographed on alumina (15 g). Elution with benzene–hexane (1:1) gave 4β-acetoxy-5α-cholestan-5-ol (IX) as a crystalline solid. Crystallization from methanol gave plates, m.p. 177–178°. Reported m.p. 175–176°, [α] +38° (25). This diol monoacetate was converted to 4β-acetoxy-cholest-5-ene (X*c*) by a published method (reported m.p. 108°, [α] −70° (25)). After chromatography and crystallization from acetone–methanol, we obtained X*c* with m.p. 111.5–112°, [α] −71° (20–25% overall yield from cholest-4-ene).

Photosensitized Oxygenation of Cholest-4-ene (I)

Exploratory oxygenations revealed that conversion was largely complete after 24 h. Longer reaction (e.g. 48 h, 72 h) led to diminution of hydroperoxidic infrared bands and gradual increase in the intensities of bands attributable to ketonic breakdown products (e.g. 1 710, 1 660 cm^{-1}); consequently, shorter reaction times were chosen for the definitive runs described below.

Run 1

A solution of cholest-4-ene (1.00 g, m.p. 77–79°) and hematoporphyrin (0.008 g) in pyridine (75 ml) was oxygenated and irradiated for 25 h. After normal work-up, the product contained 6% α,β-unsaturated ketone (ultraviolet intensity at 240 mμ), and quantitative hydrogenation of an aliquot indicated a hydroperoxide content of 74% (based on a molecular weight of 402). The specific rotation (+28°) of another aliquot in chloroform gradually increased with time and reached +64° after 48 h, with no further change after an additional 12 h. A portion of the original crude product (0.70 g) was reduced with sodium iodide and the resulting oil ([α] +48°) was dissolved in hexane and chromatographed on alumina (25 g). Elution with benzene–hexane (1:10) gave a clear oil (0.114 g) whose infrared spectrum indicated it was largely (at least two-thirds) cholest-4-ene, with some contamination by unidentified material having bands at 1 095, 1 080, 895, and 710 cm^{-1}.

Elution with benzene–hexane (1:4) gave crystalline fractions (0.167 g, m.p. 65–74°) shown to be 5α-cholest-3-en-5-ol (VIII*a*) from the infrared spectra. Crystallization from methanol gave m.p. 72–74° ([α] −15°) which was not depressed by VIII*a* (m.p. 74–75°) prepared as described earlier. The analytical sample (m.p. 75–76°) was obtained by rechromatography on alumina and elution with hexane. Thin-layer chromatography on silica gel gave only one spot.

Anal. Calcd. for $C_{27}H_{46}O$ (386.64): C, 83.87; H, 11.99. Found: C, 83.87; H, 11.74.

Benzene–hexane (1:2) eluted a pasty solid (0.068 g) whose infrared spectrum indicated it was a mixture of VIII*a* and cholest-5-en-4β-ol (X*a*), roughly in the ratio 1:4, along with a small amount of ketonic material. A separate photooxygenation (see run 3) was conducted to isolate and identify X*a*. Continued elution gave fractions (0.014 g) identified as 5β-cholest-3-en-5-ol (VI*a*) by infrared comparison with authentic material, followed by fractions of a clear oil (0.231 g), which was largely cholest-4-en-3α-ol (V*a*) according to its infrared spectrum. For confirmation, a portion of the clear oil was acetylated and the acetate was crystallized from acetone–methanol, m.p. 82–83°, [α] +170°. The melting point was not depressed by the authentic acetate V*c*. A second portion of the clear oil was treated with Girard's reagent (27) to remove ketonic impurity and, after chromatography on alumina, gave V*a* whose infrared spectrum was the same as that of authentic material.

Methylene chloride containing increasing proportions of acetone eluted crude crystalline cholest-4-en-3β-ol (IV*a*, 0.046 g, m.p. 113–120°) identified by infrared comparison. A portion was benzoylated and gave, after crystallization from methanol, pure cholest-4-en-3β-ol benzoate identical in all respects (melting point, mixture melting point, and infrared spectrum) with an authentic sample.

Final elution with acetone gave unidentified oily mixtures (0.024 g) containing hydroxyl and carbonyl absorption in their infrared spectra. The total recovery from the column was 0.664 g (95%). Cholest-4-en-3-one (III) was not separately isolated in this run but its presence in several of the fractions was evident from the infrared spectra.

Run 2

This photooxygenation of cholest-4-ene (0.880 g) and hematoporphyrin (0.008 g) in pyridine (75 ml) was conducted for 24 h in a cold room that maintained the solution at about 15°. The crude hydroperoxidic product had an infrared spectrum similar to those from the other runs except that carbonyl absorption was absent, an indication that the hydroperoxides underwent less breakdown at the lower temperature. However, when the product was reduced with sodium iodide, appreciable cholest-4-en-3-one was produced (ultraviolet spectrum). We believe that the inadvertent use of too much acetic acid in the reduction promoted decomposition of the hydroperoxides. Chromatography gave the same products as in run 1. In addition, cholest-4-en-3-one (III) was identified (by infrared and ultraviolet spectra) in several of the fractions eluted with benzene–hexane (1:2).

Run 3

*Identification of cholest-5-en-4β-ol (X*a*).*—Cholest-4-ene (0.350 g) was photooxygenated for 24 h as in run 1. The product was reduced with sodium iodide and then treated with Girard's reagent (27) to remove ketonic material. Chromatography on alumina gave, in some of the fractions eluted with benzene–hexane, a white solid (0.027 g) whose infrared spectrum corresponded to that of authentic X*a*. Acetylation gave cholest-5-en-4β-ol acetate (X*c*), with m.p. 108° after recrystallization from acetone–methanol. Mixture melting point and infrared determinations established its identity with authentic X*c*.

Photooxygenation and rearrangement of hydroperoxides.—A solution of cholest-4-ene (1.0 g) and hematoporphyrin (0.006 g) in pyridine was irradiated and oxygenated for 24 h. The crude product (0.950 g), which contained ca. 6% of enone (ultraviolet analysis), was dissolved in chloroform (100 ml) and allowed to stand in the dark at room temperature until the optical rotation attained a constant value (48 h). The chloroform was removed with a rotary evaporator and the residue was reduced with sodium iodide.

A portion of the reduced product (0.350 g) was treated with Girard's reagent (27) to remove the ketonic component, and the non-ketonic material was chromatographed on alumina (9 g). All fractions that contained cholest-4-en-3α-ol (V*a*) and cholest-4-en-3β-ol (IV*a*) were combined (0.170 g, eluted with benzene–hexane from 1:4 to 1:1). Infrared inspection showed that the 3β-alcohol IV*a* was only a minor component of the mixture. Neither of the cholest-3-en-5-ols (VI*a* or VII*a*) was detected during the chromatography.

A second portion of the reduced product was acetylated and 0.242 g of the derived acetate was chromatographed on alumina (12 g). Elution with petroleum ether gave 0.180 g of fractions containing only the two cholest-4-en-3-ol acetates V*c* and IV*c*. Semiquantitative assay of the epimeric ratio was obtained by comparison of the infrared spectrum with authentic mixtures of the two acetates and indicated a V*c*:IV*c* ratio greater than 8:1. No 5α- or 5β-cholestan-3-en-5-ols were detected in the chromatography.

Attempted photooxygenations without sensitizer.—(A) A solution of cholest-4-ene (0.450 g, m.p. 80.5–81.5°) in pyridine (35 ml) was irradiated and oxygenated for 26 h in the absence of sensitizer. The olefin (m.p. 79–80°) was recovered virtually quantitatively and its identity with starting material was confirmed by melting point, mixture melting point, and infrared inspection. (B) A solution of cholest-4-ene (202 mg, containing 1.6% of cholesta-3,5-diene, based on ultraviolet absorption in isooctane at 228, 235, and 244 mμ (28)) in pyridine (15 ml) was photooxygenated 25 h without sensitizer. During this period a solution of 0.9 equivalent of *t*-butyl hydroperoxide in pyridine (1 ml) was added portionwise (0.1 ml initially and every 2 hours, the remainder after 8 h). Normal work-up left a solid (quantitative yield), which gave a positive hydroperoxide test and whose infrared spectrum showed very weak absorption at 3 540 and 1 680 cm^{-1}, but which otherwise appeared identical with that of starting material. The ultraviolet absorption (isooctane) at 232 mμ indicated ca. 3.5% cholest-4-en-3-one. The product was allowed to stand for 2 days in chloroform and then was reduced with potassium iodide in the usual way. Finally, it was oxidized with manganese dioxide, after which the enone content (λ 232) was 4.3–6.8%. The range arises because of the diene, whose presence was indicated by an inflection at 244 mμ but whose contribution to the 232-mμ peak cannot be accurately evaluated.

ACKNOWLEDGMENTS

This work was supported by the National Institutes of Health (grant GM 09693), and an early phase of it was aided by the Alfred P. Sloan Foundation, and by a grant-in-aid from the Hynson, Westcott and Dunning fund of The Johns Hopkins University. We are grateful to Messrs. Richard Maffezzoli, Anthony Baum, and Maurice Brookhart for valuable assistance in the preparative work, to Mr. J. Walter for the elemental analyses, and to Drs. J. B. DiGiorgio, P. J. L. Daniels, N. Schwartz, and D. Widdowson for helpful contributions.

THE OXIDATION OF METHYL FUMAROPIMARATE WITH LEAD TETRAACETATE

W. A. Ayer and C. E. McDonald
Chemistry Department, University of Alberta, Edmonton, Alberta

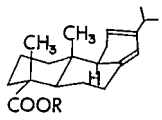
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

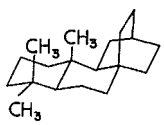
ABSTRACT

The oxidation of methyl fumaropimarate (VII) with lead tetraacetate has been found to lead to four different products, two of which have rather novel structures. The results which led to the elucidation of the structures of these products are presented, along with speculation on their mode of formation.

In connection with our studies aimed at the chemical correlation of the resin acids with the diterpene alkaloids of the atisine type (1), we became interested in the Diels–Alder adducts formed between levopimaric acid (I) and various dienophiles as intermediates in the construction of the bicyclo[2.2.2]octane ring system present in compounds such as atisine. The use of this approach for the synthesis of the hydrocarbon III has been



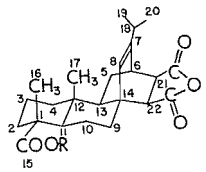
I R=H
II R=CH_3



III

reported (1, 2) and the correlation of III with a degradation product of atisine has been achieved (1).

The most readily accessible Diels–Alder adduct of levopimaric acid is the commercially available[1] maleopimaric acid (the adduct with maleic anhydride), which has been shown to possess structure IV (3–6). Since one of the problems encountered in the Diels–Alder



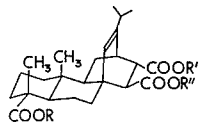
IV R=H
V R=CH_3

approach to a bicyclo[2.2.2]octane system using maleic anhydride or fumaric acid as the dienophile involves the removal of the two vicinal carboxyl groups (or anhydride function), we decided to use the readily available methyl maleopimarate (V) as a model compound for investigating methods for removal of the unwanted functional groups.

In 1952 Doering and co-workers (7) discovered that 1,2-dicarboxylic acids (and anhydrides) could be converted to olefins, albeit in low yield, by the action of lead dioxide.

[1]*Distillation Products Industries, Rochester, N.Y.*

In 1958, Grob *et al.* (8, 9) showed that the yields in this oxidative bisdecarboxylation sequence could be greatly improved by the use of lead tetraacetate in benzene or acetonitrile in the presence of an organic base. A further modification (10) involves the use of pyridine as the solvent for the lead tetraacetate oxidation. When subjected to these various conditions, methyl maleopimarate (V) was recovered unchanged. This is perhaps not surprising, however, since the anhydride ring in V is very stable (it is impossible to isolate the corresponding dicarboxylic acid) and presumably does not undergo facile mixed-ester formation by exchange with lead tetraacetate, a step which is necessary to initiate the reaction (8, 11). We therefore turned our attention to the C-15 monomethyl



VI R = R' = R'' = H

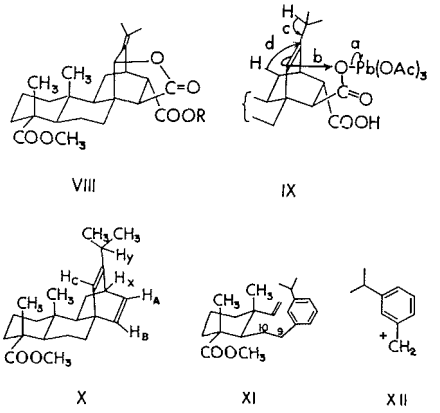
VII R = CH_3, R' = R'' = H

ester (VII) of fumaropimaric acid (VI) (12) in which the anhydride function has been replaced by a *trans*-1,2-dicarboxylic acid system. Fumaropimaric acid (VI) is the product of the reaction of levopimaric acid or rosin with fumaric acid (12), but may also be obtained from maleopimaric acid (IV) by the action of hot methanolic potassium hydroxide (3). The configuration of the carboxyls at C-21 and C-22 as shown in VI was first assigned (3) on the basis of a result to be discussed in detail below and has since been corroborated by two other groups (13, 14). The monomethyl ester VII, which will be referred to as methyl fumaropimarate, was prepared by treatment of methyl maleopimarate (V) with methanolic sodium hydroxide followed by acidification or, more conveniently, by addition of fumaric acid to either methyl levopimarate (II) or methyl abietate.

When a pyridine solution of methyl fumaropimarate was treated with a slight molar excess of lead tetraacetate at room temperature, a reaction rapidly set in as evidenced by a rise in temperature and the evolution of a gas, and a total of four different products was isolated from the reaction mixture. Three of these, separated by chromatography over silica gel, were neutral compounds, and the fourth, separated from unreacted starting material by crystallization and chromatography, was an acid. Since a knowledge of the structure of the acidic product was useful in assigning the stereochemistry at C-21 and C-22 in methyl fumaropimarate, it will be discussed first.

The acidic product (obtained in 6% yield) crystallized from benzene as a hemisolvate ($C_{25}H_{34}O_6 \cdot \frac{1}{2}C_6H_6$) and was further characterized as its methyl ester ($C_{26}H_{36}O_6$). An examination of the spectral properties of the acid and its ester led to the assignment of structure VIII. The infrared spectrum of the acid showed bands at 1 771 (γ-lactone), 1 725 (ester), 1 717 (acid), and 1 675 cm^{-1} (carbon–carbon double bond). The n.m.r. spectrum showed signals at τ 9.29 (3H, singlet, methyl at C-12 shielded by C-7, C-18 double bond (3)), τ 8.84 (3H, singlet, methyl at C-1 (3)), τ 8.20 (6H, singlet, isopropylidene methyls), τ 6.33 (3H, singlet, carbomethoxyl protons), τ 4.97 (1H, singlet, proton at C-8), and τ 2.61 (3H, singlet, benzene of solvation). The formation of the lactone acid VIII (R = H) establishes that the carboxyl at C-22 in fumaropimaric acid (VI) is *endo* to the unsaturated ring. Since the double bond in VI is extremely hindered, we feel that the formation of the lactone VIII probably does not involve direct attack by lead tetraacetate on the double bond (15), but instead involves intramolecular electrophilic attack by the C-22 carboxyl as illustrated in IX (arrows *a*, *b*, and *c*). The preparation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



ester VIII by oxidation of fumaropimaric acid with alkaline permanganate followed by esterification has recently been described (14).

The neutral products of the oxidation, as mentioned earlier, were separated by chromatography over silica gel. The first substance eluted was a compound $C_{23}H_{34}O_2$, obtained in 10% yield, which showed the properties expected of the diene X, the product of straightforward oxidative bisdecarboxylation of diacid VII. The infrared spectrum showed olefinic C—H stretching at 3 040 cm^{-1} and ester carbonyl absorption at 1 732 cm^{-1}. Evidence for the unrearranged bicyclo[2.2.2]octadiene structure X was provided by the n.m.r. spectrum, which showed the shielded C-12 methyl (τ 9.38) (3), the isopropyl group as a pair of doublets at τ 8.93 and 9.00, and the C-1 methyl as a singlet at τ 8.88. The chemical shifts and coupling constants for the protons designated by letter in X are given in Table I. The assignments, which are consistent[2] with the proposed structure, were

TABLE I

Signals for lettered protons in diene X

Proton	Chemical shift (τ)	Multiplicity
H_A	3.84	Quartet, J_{AB} 7 c.p.s., J_{AX} 6 c.p.s.
H_B	4.05	Quartet, J_{AB} 7 c.p.s., J_{BX} 1.5 c.p.s.
H_C	4.59	Triplet, J_{CY} 1.7 c.p.s., $J_{CX} \approx 1$ c.p.s.
H_X	6.75	Multiplet, not completely resolved
H_Y	7.70	Multiplet, not completely resolved

verified by appropriate decoupling experiments. Thus, irradiation of the signal at τ 6.75 greatly simplified the olefinic region, the signals for H_A and H_B then appearing as a simple AB quartet (J = 7 c.p.s.) and H_C appearing as a doublet (splitting 1.7 c.p.s.). When the signal at τ 7.70 was irradiated, H_C appeared as a poorly resolved doublet of splitting about 1 c.p.s. Simultaneous irradiation of *both* the τ 6.75 and the τ 7.70 signal caused H_C to collapse to a singlet. The diene X was thermally unstable and was transformed in part to an aromatic compound on attempted distillation. A sample of X which had been heated at 180° for 30 min showed strong signals in its n.m.r. spectrum at τ 3.0–3.3 (aromatic protons) and its ultraviolet spectrum displayed typical benzenoid absorption. We believe this to be indicative of an aromatization process similar to the thermal transformation of bicyclo[2.2.2]octadiene to benzene and ethylene (17), leading in this

[2]*For a summary of and references to recent work on the n.m.r. spectra of bridged ring compounds, see ref. 16.*

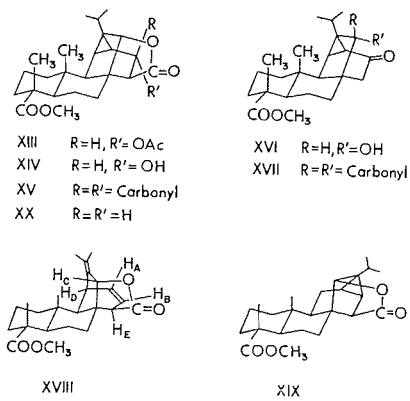
case to compound XI. The mass spectrum of the diene X provided further evidence for the facility of this aromatization process, the most intense peak in the spectrum appearing at m/e 133 corresponding to the cleavage of the C-9 to C-10 bond in an ion of structure XI with the formation of the benzylic ion XII (or its tropylium ion counterpart (18)). Hydrogenation of the diene X at atmospheric pressure yielded a dihydro derivative in which the 21,22 double bond had been reduced as revealed by the n.m.r. spectrum, which showed a single olefinic proton (τ 4.60) and a high-field methyl signal (τ 9.42) that is due to the shielded methyl group at C-12 (3).

The diene X was eluted from the silica gel column with benzene. Elution with benzene–ether yielded first a compound $C_{24}H_{34}O_4$ (lactone A) followed by a compound $C_{26}H_{36}O_6$ (lactone B). Lactone A was isolated in 7% yield and lactone B in 3% yield. When the reaction was carried out in acetic acid, in the presence of sodium acetate, lactone A was not isolated but lactone B was obtained in 11% yield.

To lactone B was assigned structure XIII on the basis of the following observations. The infrared spectrum showed absorption at 1 784 cm^{-1} (γ-lactone), 1 740 cm^{-1} (acetoxyl), and 1 722 cm^{-1} (carbomethoxyl). The n.m.r. spectrum confirmed the presence of the carbomethoxyl group (three-proton singlet at τ 6.31) and the acetoxyl group (three-proton singlet at τ 7.90) and indicated the presence of four methyl groups attached to saturated carbon. Two of these appeared as sharp singlets at τ 8.79 (methyl at C-1 (3)) and 9.05 (C-12 methyl (3)), while the other two appeared as a pair of doublets at τ 8.94 (splitting 7 c.p.s.) and 9.16 (splitting 7 c.p.s.). These latter signals are attributed to the methyls of the isopropyl group, made non-equivalent by the asymmetry of their environment (19). Both these doublets collapsed to singlets when the region τ 8.12 (isopropyl methine) was simultaneously irradiated. A one-proton singlet at τ 5.19 is attributed to the lactonic hydrogen at C-8 and a doublet at τ 4.85 (splitting 5 c.p.s.) to the proton on the acetoxyl-bearing C-21.



Methanolysis of lactone B provided the hydroxylactone XIV. The infrared spectrum of XIV exhibited, besides the lactone and ester absorption, a band at 3 610 cm^{-1} indicative of a nonhydrogen-bonded hydroxyl group. The n.m.r. spectrum of XIV was very similar to that of lactone B (XIII) except that the doublet at τ 4.85 (C*H*OAc) and the singlet at 7.90 (OCOC*H*$_3$) has been replaced by a poorly resolved peak at τ 5.80 (C*H*OH) and a concentration-dependent peak at about 7.2 (O*H*). Oxidation of XIV with chromic acid yielded the ketolactone XV, which showed carbonyl absorption at 1 790 cm^{-1} (γ-lactone), 1 725 cm^{-1} (ester), and 1 715 cm^{-1} (ketone) in the infrared. In agreement with the

formulation of XV as a cyclopropyl ketone, the ultraviolet spectrum measured in isooctane showed a maximum at 199 mμ (ε 2 400) (20). Compound XV is also a β-keto lactone and as such would be expected to be sensitive to base. In fact it was found that, when XV was heated under reflux with methanolic sodium methoxide, it underwent a reverse Claisen reaction and methanolysis to give the hydroxyketone XVI, the infrared spectrum of which showed nonbonded hydroxyl (3 610 cm^{-1}), ester (1 727 cm^{-1}), and ketone (1 687 cm^{-1}) absorption. The C-8 proton now appeared at τ 5.58 (singlet) in the n.m.r. spectrum. Oxidation of XVI with chromic acid yielded the diketone XVII, which showed a maximum at 202 mμ (ε 6 500) in the ultraviolet.

To test further the validity of structure XIII for lactone B, it was treated with *p*-toluenesulfonic acid in hot benzene in the hope that cleavage of the C_{21}–oxygen or C_8–oxygen bond would occur with concomitant opening of the cyclopropane ring in a manner analogous to that observed for the transformation of cyclopropylcarbinyl derivatives into allylcarbinyl derivatives (21). The product, formed in 90% yield, was a diene to which structure XVIII is assigned on the basis of the following information. The infrared spectrum showed absorption at 3 042 cm^{-1} (olefinic C—H), 1 765 cm^{-1} (γ-lactone), 1 720 cm^{-1} (ester), and 1 630 cm^{-1} (carbon–carbon double bond(s)). Pertinent details of the n.m.r. spectrum, including results obtained or confirmed by spin-decoupling experiments, are presented in Table II. The presence of a *cis*-disubstituted double bond is revealed by the appearance of the two strongly coupled (8.8 c.p.s.) olefinic protons. The fact that each of these protons is involved in a further large coupling (6.7 and 4.8 c.p.s.) suggests the presence of the grouping CH—CH=CH—CH. The fact that H_A is further split but H_B is not is explained by the fact that H_A and H_E fulfill the steric requirements for maximum allylic coupling (22) while H_B and H_D do not. The further splitting of H_E is attributed to long-range "tail-to-tail" coupling (22) with H_C and this has been confirmed by double-irradiation experiments. The presence of an isopropylidene

TABLE II

Details of n.m.r. spectrum of diene XVIII

Proton(s)	Chemical shift (τ)	Multiplicity
H_A	3.56	Septet, J_{AB} 8.8 c.p.s., J_{AD} 6.7 c.p.s., J_{AE} 1.7 c.p.s.
H_B	4.48	Quartet, J_{AB} 8.8 c.p.s., J_{BE} 4.8 c.p.s.
H_C	4.93	Broadened singlet
H_D	6.99	Poorly resolved doublet
H_E	7.06	Sextet, J_{BE} 4.8 c.p.s., J_{AE} 1.7 c.p.s., J_{CE} 1.7 c.p.s.
$COOCH_3$	6.33	Singlet
C-19, C-20	8.23, 8.32	Broadened singlets
C-16	8.81	Singlet
C-17	9.25	Singlet

group in the diene is indicated by the methyl signals at τ 8.23 and 8.32. The fact that the C-17 protons (τ 9.25) are somewhat more shielded than in the starting material is consistent with the location of an unsaturated function near the quaternary methyl group (3) as in structure XVIII. The diene XVIII readily formed a dihydro derivative when subjected to catalytic hydrogenation. The n.m.r. spectrum of the dihydro compound showed the isopropylidene methyls at τ 8.26 and 8.32 but no olefinic protons, clearly indicating that the unhindered (from the underside) *endocyclic* double bond had been reduced. The formation of XVIII (via the homoallylic cation formed by loss of the C-21 acetoxyl group with participation of the C-6, C-7 bond) provides evidence for the C-5 to C-7 bond in lactone B (XIII).

The acetoxyl group at C-21 in lactone B (XIII) was assigned the *exo* configuration (*trans* to the lactone group), since the infrared spectrum of the corresponding alcohol (XIV) showed no intramolecular hydrogen bonding and since the n.m.r. spectrum of XIII displayed a doublet whose splitting (5 c.p.s.) is compatible only with a *trans* arrangement of the protons on C-21 and C-22 (3).

One possible mode of formation of lactone B (XIII) is illustrated by arrows *a*, *b*, and *d* in IX. This process, which finds analogy in the lead tetraacetate induced transformation of norbornene into 3-acetoxynortricyclene (23), is either preceded by or followed by oxidative replacement of the C-21 carboxyl by acetoxyl (see below).

The third neutral product of the oxidation, lactone A, is assigned structure XIX. The presence of the γ-lactone is suggested by infrared absorption at 1 780 cm^{-1} and by a one-proton signal at τ 5.30 (—C*H*—OCO—) in the n.m.r. spectrum. The other two oxygens of lactone A are accounted for by the carbomethoxyl group, which gives rise to absorption at 1 720 cm^{-1} in the infrared and at τ 6.33 (3H, singlet) in the n.m.r. spectrum. As was the case with lactone B, the isopropyl methyls were markedly non-equivalent, giving rise to doublets at τ 8.96 (splitting 7.5 c.p.s.) and 9.24 (splitting 7.5 c.p.s.). The possibility that lactone A was 21-desacetoxylactone B (XX) was excluded when it was shown that compound XX, prepared by transformation of ketone XV to the corresponding thioketal and desulfurization, was not identical with lactone A.

Lactone A was transformed to the corresponding hydroxydiester XXI by the action

XXXI

of methanolic sodium hydroxide followed by diazomethane. Oxidation of XXI with chromic acid in acetic acid afforded the ketone XXII, which absorbed at 1 729 and 1 718 cm^{-1} in the infrared and at 202 mμ (ϵ 4 000) (cyclopropyl ketone (20)) in the ultraviolet. The formation of lactone A (XIX) from methyl fumaropimarate (VII) is closely analogous to the formation of tricyclo[2.2.2.$0^{2,6}$]octan-3-yl acetate (XXIII) from *exo*-5-carboxybicyclo[2.2.2]oct-2-ene (XXIV), which is brought about by the action of lead tetraacetate in acetic acid in the presence of potassium acetate (24). The fact that the tricyclic compound XXIII was transformed by the action of acid into *exo*-bicyclo-[2.2.2]oct-5-en-2-yl acetate (XXV) led us to attempt a similar reaction on lactone A. It was found that lactone A (XIX) was extremely sensitive to hot acetic acid and was converted in less than 20 min to an oily three-component mixture (as determined by thin-layer

chromatography (t.l.c.)), which, from n.m.r. analysis, was judged to contain ca. 80% of the acetoxy acid XXVI. Thus, restoration of the bicyclo[2.2.2]octene system was indicated by an olefinic proton at τ 4.63 (0.8H relative to the carbomethoxyl signal) and a shielded C-methyl group signal at 9.38 (2.4H). Attempts to isolate XXVI were unsuccessful. However, methanolysis of the crude solvolysis product led to the isolation of the major component in the form of the hydroxy acid (XXVII). Esterification of XXVII with diazomethane gave the corresponding ester XXVIII, which exhibited the expected infrared and n.m.r. spectral behavior. The most intense peak in the mass spectrum of XXVIII occurred at m/e 316 and is attributable to an ion of structure II formed by "retro-Diels–Alder" fragmentation of the molecular ion, a process shown previously to be important in bicyclo[2.2.2]octene derivatives (1). Oxidation of XXVIII with chromic acid yielded the corresponding ketone XXIX, which absorbed at 1 722 cm^{-1} (esters) and 1 705 cm^{-1} (ketone) in the infrared and at 296 mμ (ϵ = 139, enhanced $n \rightarrow \pi^*$ absorption of a β,γ-unsaturated ketone (25)) in the ultraviolet. In agreement with the generalized Octant rule (26) and its application to β,γ-unsaturated ketones (26, 27) the ketone XXIX displayed a strongly negative Cotton effect.

The ketone XXIX was transformed, via the thioketal and desulfurization, into the diester XXX, which was shown to be identical with the diester of the Diels–Alder adduct of levopimaric acid and acrylic acid. Since the structure of this adduct has been established as XXX (13), this result rigorously establishes the structure of the solvolysis product XXVI and thus provides further support for the structure of lactone A (XIX). The formation of lactone A is presumed to involve lactonization of the homoallylic cation XXXI, which is formed by oxidative loss of the C-21 carboxyl group (11, 24). As mentioned earlier, lactone A is not detected when the reaction is carried out in acetic acid – sodium acetate but the yield of lactone B is increased, indicating that in acetic acid XXXI reacts with acetate ion rather than undergoing lactonization. Further oxidation of the acetoxy acid XXVI could lead to lactone B (XIII).

The results obtained in this model series clearly indicated that the presence of a double bond in the bicyclo[2.2.2]octane system was undesirable when one is attempting oxidative bisdecarboxylations. This knowledge was useful in planning the preparation of the hydrocarbon III (1).

EXPERIMENTAL

Nuclear magnetic resonance spectra were measured on 5–10% (w/v) solutions in deuterochloroform (unless otherwise noted), using either a Varian A-60 or HR 100 spectrometer. Tetramethylsilane was used as an internal standard. Spin-decoupling experiments were carried out with the HR 100 spectrometer using the method described by Johnson (28). Unless otherwise noted, infrared spectra were determined in carbon tetrachloride solution using a Perkin–Elmer model 421 spectrophotometer. Ultraviolet spectra of the cyclopropyl ketones were obtained, through the courtesy of Dr. K. H. Palmer, on a Unicam SP 700 spectrophotometer. The mass spectra were determined on an AEI MS2-H mass spectrometer. Samples were introduced through a heated inlet system kept at 200°. Skellysolve B refers to Skelly Oil Company light petroleum, b.p. 62–70°. Melting points are uncorrected. Kiliani's reagent was prepared from sodium dichromate (60 g) in water (270 ml) to which concentrated sulfuric acid (80 g) was added. Microanalyses are by Pascher Mikroanalytisches Laboratorium, Bonn, West Germany, and C. Daessle, Montreal, Quebec.

Fumaropimaric Acid from Maleopimaric Acid

Maleopimaric acid (IV, 10 g) was dissolved in a solution of potassium hydroxide (16 g) in aqueous methanol (200 ml, 1:10 water–methanol) and the resulting solution heated under reflux for 1½ h. Most of the methanol was then removed at the pump, dilute hydrochloric acid was added, and the resulting precipitate filtered off and recrystallized from acetic acid. The fumaropimaric acid (4 g, 38% yield) thus obtained melted at 193–195°, and analyzed as a monohydrate after it was dried at 110° *in vacuo*.

Anal. Calcd. for $C_{24}H_{34}O_6 \cdot H_2O$: C, 66.03; H, 8.310 O, 25.65. Found: C, 66.14; H, 8.05; O, 25.90.

A sample recrystallized from aqueous ethanol melted at 244–248°. The reported melting points are 280–282° (sample dried at 152° *in vacuo* (12)) and 249–252° (hydrated form from dioxane (29)). A sample of

For personal use only.

fumaropimaric acid prepared by Diels–Alder addition of fumaric acid to rosin (12) showed identical properties.

Methyl Fumaropimarate (VII)

A. From Methyl Maleopimarate

Methyl maleopimarate (60 g) was dissolved in methanol (600 ml) containing sodium hydroxide (36 g) and the solution refluxed for 45 min; then 2 *N* aqueous sodium hydroxide (400 ml) was added and heating continued for a further 100 min. The solution was then neutralized with hydrochloric acid, most of the methanol removed at the pump, and the residue made strongly acidic with 2 *N* hydrochloric acid. The precipitate which separated was collected by filtration, washed first with water and then with benzene, and recrystallized from acetic acid to yield methyl fumaropimarate (15 g), m.p. 269–279°. The analytical sample, m.p. 274–279°, was prepared by further recrystallization from ethanol.

Anal. Calcd. for $C_{25}H_{36}O_6$: C, 69.40; H, 8.39; O, 22.20; OCH_3, 5.69. Found: C, 69.49; H, 8.35; O, 22.10; OCH_3, 4.98.

Infrared spectrum: ν_{max}^{Nujol} 3 200 (broad), 1 725, 1 705 cm^{-1}.

B. From Methyl Abietate

Crude methyl abietate (860 g, prepared by esterification of rosin) was stirred under nitrogen with fumaric acid (500 g) at 170–185° for 18 h. The mixture was then transferred to a large Erlenmeyer flask and washed with benzene (2 l, in portions). The benzene-insoluble residue was then suspended successively in 3-, 2-, and 1-l portions of hot water, the insoluble portion being collected each time by filtration. In this way methyl fumaropimarate (202 g), m.p. 269–279°, identical with that prepared above, was obtained. Further purification could be effected by recrystallization from ethanol.

Lead Tetraacetate Oxidations

A. In Pyridine

Methyl fumaropimarate (VII, 21 g, 0.049 mole) was dissolved in pyridine (250 ml) at 30° and lead tetraacetate (31 g, 0.07 mole) added. After a few minutes the temperature rose to 45° and a gas was evolved. The solution was cooled to 30° and allowed to stand at room temperature for 12 h. Excess reagent was destroyed by the addition of ethylene glycol, the solvent evaporated on the steam bath under reduced pressure, and the residue washed with four 125-ml portions of ether. The combined ether solutions were washed with water, dilute hydrochloric acid, and extracted with dilute sodium hydroxide (extract A). Evaporation of the ether yielded an oil (6.0 g) which was subjected to chromatography over silica gel (400 g). Fractions 2–4, eluted with benzene (1.5 l), gave the diene X as a colorless oil (1.7 g) which showed a single spot on thin-layer chromatography. For analysis, a sample was dried *in vacuo* at 50° for 48 h.

Anal. Calcd. for $C_{23}H_{34}O_2$: C, 80.65; H, 10.00. Found: C, 80.77; H, 9.80.

Infrared spectrum: ν_{max} 3 040, 1 732 cm^{-1}. Mass spectrum: *m/e* 342 (molecular ion), 133 (base peak). See Table I for details of n.m.r. spectrum.

Fractions 7 and 8, eluted with benzene–ether (1 l of 7:1) afforded lactone A (XIX) (1.4 g) as colorless needles which melted, after recrystallization from benzene – Skellysolve B, at 176–180°.

Anal. Calcd. for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87; O, 16.56. Found: C, 74.48; H, 8.74; O, 16.56.

Infrared spectrum: ν_{max} 1 780, 1 720 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.25 (3H, doublet, J = 7.5 c.p.s.), 9.17 (3H), 8.96 (3H, doublet, J = 7.5 c.p.s), 8.85 (3H), 7.61 (1H), 6.33 (3H, singlet), and 5.30 (1H).

Fractions 10–12, also eluted with benzene–ether (7:1, 1.5 l), gave lactone B (XIII) (0.6 g) as colorless needles which melted at 194–195° after recrystallization from benzene – Skellysolve B and then methanol.

Anal. Calcd. for $C_{26}H_{36}O_6$: C, 70.25; H, 8.16; O, 21.60. Found: C, 70.35; H, 7.88; O, 21.58.

Infrared spectrum: ν_{max} 1 784, 1 740, 1 722, 1 242 cm^{-1}.

The acidic components were present both in the free form (extract A) and as lead salts (residue from ether trituration). The latter portion was dissolved in acetic acid and hydrogen chloride bubbled in until no more precipitate formed. The precipitated lead chloride was filtered off and the filtrate concentrated under reduced pressure. Benzene was added to the partially crystalline residue and the insoluble portion (0.7 g) collected by filtration. This portion was identified by its melting point and infrared spectrum as unreacted starting material. The benzene filtrate was combined with the acids liberated by acidification of extract A and the residue (12 g) obtained by removal of the solvents was subjected to chromatography over silica gel (700 g). Elution with benzene provided only trace amounts of unidentified material. Elution with benzene–ether (3:1) provided the lactone acid VIII (R = H) which crystallized in solvated form from benzene, m.p. 189–190°.

Anal. Calcd. for $C_{25}H_{34}O_6 \cdot \frac{1}{2}C_6H_6$: C, 71.60; H, 7.95; O, 20.44; OCH_3, 6.61. Found: C, 71.21; H, 7.95; 20.60; OCH_3, 6.75.

Infrared spectrum: $\nu_{max}^{CHCl_3}$ 1 771, 1 725, 1 717, 1 675 (w) cm^{-1}. The methyl ester VIII (R = CH_3), prepared by reaction of the above acid with diazomethane, melted at 180–181° after recrystallization from methanol.

Anal. Calcd. for $C_{26}H_{36}O_6$: C, 70.25; H, 8.18; O, 21.59; OCH_3, 13.96. Found: C, 70.10; H, 8.38; O, 21.51; OCH_3, 14.48.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Infrared spectrum: $\nu_{max}^{CHCl_3}$ 1 770, 1 733, 1 725, 1 674 (w) cm^{-1}.

The later fractions from the chromatogram yielded further unchanged starting material.

B. In Acetic Acid

Methyl fumaropimarate (VII, 10 g, 0.023 mole) was suspended in hot (steam bath) acetic acid (100 ml) containing acetic anhydride (2 ml) and lead tetraacetate (12 g, 0.027 mole). The reaction mixture was kept at 90° for 10 min with no evidence of reaction. The addition of sodium acetate (3.0 g, 0.037 mole) resulted in the immediate evolution of gas and the dissolution of the suspended solids. After 7 min, additional lead tetraacetate (16 g, 0.036 mole) was added and the heating continued for 30 min. The cooled solution was diluted with a large volume of water and extracted several times with chloroform. The residue left after evaporation of the chloroform was chromatographed over acid-washed alumina (150 g). Elution with benzene gave a small amount of impure diene X, and elution with benzene–ether and ether yielded lactone B (XIII) (1.12 g) but no lactone A. Further elution (chloroform, chloroform – acetic acid) yielded acidic material which was not investigated further.

Reactions of Diene X

A. Hydrogenation

The diene X (260 mg) was dissolved in methanol (6 ml) and stirred in an atmosphere of hydrogen in the presence of finely divided platinum (from 14 mg of Adams catalyst) for 22 h. Removal of the catalyst and concentration of the filtrate yielded the dihydro derivative (220 mg) as a colorless oil, which absorbed at 1 720 cm^{-1} in the infrared. The nuclear magnetic resonance spectrum showed absorption at τ 9.42 (3H), 9.02 (6H, doublet, J = 6 c.p.s.), 8.91 (3H), 6.37 (3H), and 4.60 (1H).

B. Thermal Decomposition

The diene X (100 mg) was heated at 180° for 25 min and then distilled under vacuum. The n.m.r. spectrum of the oily distillate (80 mg) showed very little absorption at τ 9.38 (0.4H as compared to the carbomethoxyl peak taken as 3H) but strong absorption (2.5H) in the aromatic region. The ultraviolet spectrum of the distillate showed typical aromatic absorption at 254, 262, 270, and 274 mμ.

Methanolysis of Lactone B

Lactone B (XIII, 0.31 g) was dissolved in methanolic sodium methoxide (0.01 g sodium in 10 ml methanol) and kept at room temperature for 9 h. Water (100 ml) was then added and the aqueous solution extracted twice with methylene chloride. Evaporation of the methylene chloride and crystallization of the residue from benzene–Skellysolve gave the hydroxylactone XIV (0.245 g), m.p. 189–190°.

Anal. Calcd. for $C_{24}H_{34}O_5$: C, 71.61; H, 8.52; O, 19.87. Found: C, 72.25; H, 8.31; O, 19.60.

Infrared spectrum: ν_{max} 3 610, 3 480, (concentration dependent, absent in dilute solution), 1 782, 1 729 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.15 (3H, doublet, J = 7 c.p.s.), 9.06 (3H), 8.94 (3H, doublet, J = 6.5 c.p.s.), 8.80 (3H), 7.22 (concentration dependent, O*H*), 5.78 (1H), 5.24 (1H).

Ketolactone XV

The hydroxy lactone XIV (0.34 g) was dissolved in acetic acid (25 ml) and Kiliani's reagent (0.45 ml) added. The solution was left at room temperature for 60 min, then diluted with water (100 ml), and extracted 4 times with benzene. The combined benzene extracts were washed several times with water, dried, and evaporated to give an off-white foam which crystallized from benzene – Skellysolve B as fine colorless needles (0.30 g) which melted at 179–180°, then resolidified and remelted at 184–185°.

Anal. Calcd. for $C_{24}H_{32}O_5$: C, 71.96; H, 8.07; O, 19.97. Found: C, 71.80; H, 8.01; O, 20.18.

Infrared spectrum: $\nu_{max}^{CHCl_3}$ 1 790, 1 725, 1 715 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.11 (3H, doublet, J = 7 c.p.s.), 8.98 (3H), 8.88 (3H, doublet, J = 6.5 c.p.s.), 8.78 (3H), 6.35 (3H), 4.97 (1H). Ultraviolet spectrum: λ_{max}^{EtOH} 286 mμ (ϵ 82), $\lambda_{max}^{isooctane}$ 199 mμ (ϵ 2 400). Rotatory dispersion in methanol (c, 0.33): α_{589} +92°, α_{500} +210°, α_{400} +494°, α_{350} +930°, α_{318} +2060° (inflection), α_{308} +2370° (peak), α_{285} ± 0°, α_{270} −745°, α_{260} −550°.

Hydroxyketone XVI

Ketolactone XV (0.30 g) was dissolved in methanol (150 ml) in which sodium (2.1 g) was dissolved and the solution was heated under reflux for 18 h. The solution was concentrated, diluted with dilute aqueous hydrochloric acid, and extracted 3 times with chloroform. Evaporation of the chloroform left the crystalline hydroxyketone XVI (0.29 g), which, after recrystallization from benzene and then methanol, melted at 228–229°.

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.74; H, 9.16; O, 17.09. Found: C, 74.04; H, 8.93; O, 17.06.

Infrared spectrum: $\nu_{max}^{CHCl_3}$ 3 610, 3 450, 1 727, 1 687 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.05 (3H, doublet, J = 8 c.p.s.), 8.98 (3H), 8.92 (3H, doublet, J = 7 c.p.s.), 8.80 (3H), 6.32 (3H), 5.58 (1H). Ultraviolet spectrum: λ_{max}^{EtOH} 275 mμ (ϵ 50).

Diketone XVII

The hydroxyketone XVI (0.09 g) was dissolved in acetic acid (4 ml) and Kiliani's reagent (0.15 ml) added. After 60 min, excess solvent was destroyed with methanol, most of the solvent removed at the pump, and water added. Chloroform extraction provided the diketone XVII (0.07 g), m.p. 178–179° (from ethanol).

Anal. Calcd. for $C_{23}H_{32}O_4$: C, 74.15; H, 8.67; O, 17.18; molecular weight 372. Found: C, 73.99; H, 8.74; O, 17.10; molecular weight (mass spectrometry) 370 ± 2.

Infrared spectrum: ν_{max} 1 742 (sh), 1 727, 1 715 cm^{-1}. Ultraviolet spectrum: λ_{max}^{MeOH} 202 mμ (ε 6 500), 273–287 mμ (ε 90).

Thioketal of Ketolactone XV

The ketolactone XV (0.2 g, 0.5 mmole) was dissolved in freshly distilled boron trifluoride etherate (3 ml) containing ethanedithiol (0.53 g, 5.6 mmoles) and left at room temperature for 45 min. Benzene (50 ml) was then added and the solution washed several times with water and then evaporated. One crystallization of the residue from ethyl acetate afforded 0.12 g of crude thioketal, m.p. 225–236°. The analytical sample, prepared by recrystallization from ethyl acetate and then from benzene – Skellysolve B, melted at 238–239°.

Anal. Calcd. for $C_{26}H_{36}O_4S_2$: C, 65.52; H, 7.62; S, 13.45. Found: C, 65.57; H, 7.60; S, 13.61.

Infrared spectrum: $\nu_{max}^{CHCl_3}$ 1 765, 1 712 cm^{-1}. The nuclear magnetic resonance spectrum showed a four-proton multiplet at τ 6.60 assigned to the —S—CH_2—CH_2—S— protons.

Desulfurization of the Thioketal

The crude thioketal (0.17 g) prepared above was dissolved in acetone (30 ml), W2 Raney nickel (4 g) added, and the mixture heated under reflux for 8½ h. The nickel was then filtered off and washed with acetone and the filtrate evaporated. The crude deoxylactone XX (0.11 g) crystallized on trituration with methanol and was recrystallized from methanol, m.p. 135–137°.

Anal. Calcd. for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87; O, 16.56. Found: C, 74.75; H, 8.79; O, 16.97.

Infrared spectrum: ν_{max} 1 775, 1 723 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.14 (3H, doublet, J = 7 c.p.s.), 9.03 (3H), 8.87 (3H, doublet, J = 7 c.p.s.), 8.81 (3H), 6.36 (3H), 5.29 (1H).

Preparation of Diene XVIII

Lactone B (XIII, 1.74 g) was dissolved in benzene (80 ml) containing *p*-toluenesulfonic acid (0.5 g) and the solution heated under reflux for 12 h. The cooled solution was filtered through alumina (20 g) and the alumina washed with benzene–ether (200 ml of 20:1). Evaporation of the solvents and crystallization of the residue from Skellysolve B provided 1.34 g of the crude diene XVIII, m.p. 167–170°. Recrystallization from methanol and then Skellysolve gave the analytical sample, m.p. 171–172°.

Anal. Calcd. for $C_{24}H_{32}O_4$: C, 74.96; H, 8.40. Found: C, 74.72; H, 8.20.

Infrared spectrum: ν_{max} 3 042(w), 1 765, 1 720, 1 630(w) cm^{-1}. Details of the n.m.r. spectrum are presented in Table II.

Hydrogenation of Diene XVIII

Diene XVIII (0.46 g) was dissolved in ethyl acetate (50 ml) and hydrogenated over platinum (from 55 mg of Adams catalyst) at atmospheric pressure. Hydrogen uptake (1 mole) was complete in 30 min. The dihydro compound was crystallized from ethyl acetate and then from benzene – Skellysolve B and melted at 184–185.5°.

Anal. Calcd. for $C_{24}H_{34}O_4$: C, 74.56; H, 8.89; O, 16.56. Found: C, 74.62; H, 8.92; O, 16.41.

Infrared spectrum: ν_{max} 1 765, 1 722, 1 632(w) cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.29 (3H), 8.82 (3H), 8.26 (6H), 6.32 (3H), 5.00 (1H).

Methanolysis of Lactone A

Lactone A (XIX, 0.21 g) was dissolved in a solution of sodium methoxide (0.26 g) in methanol – dimethyl sulfoxide (8 ml of 1:3). Solution was effected by warming the mixture on the steam bath and the solution was then left at room temperature for 7 days, after which time benzene was added. The resulting solution was washed several times with water and the combined aqueous extracts acidified with concentrated hydrochloric acid. Chloroform extraction yielded the crude hydroxy acid (0.20 g), which was recrystallized to constant melting point (212–215°) from methanol – ethyl acetate. Infrared spectrum: ν_{max} 3 480 (broad) 3 300 – 2 400, 1 710 cm^{-1}. Esterification with diazomethane yielded the hydroxy ester XXI, m.p. 140–141° (from benzene – Skellysolve B).

Anal. Calcd. for $C_{25}H_{38}O_5$: C, 71.73; H, 9.15; O, 19.11. Found: C, 71.84; H, 9.06; O, 19.50.

Infrared spectrum: ν_{max} 3 460 (concentration independent, hydrogen-bonded hydroxyl) 1 715 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.27 (3H, doublet, J = 7 c.p.s.), 9.03 (3H), 8.95 (3H, doublet, J = 7 c.p.s.), 8.89 (3H), 6.49 (1H, doublet, J = 12 c.p.s., CHO*H*), 6.41 (3H), 6.35 (3H), 6.00 (1H, doublet, J = 12 c.p.s., C*H*OH).

Ketoester XXII

The hydroxy ester XXI (95 mg, 0.23 mmole) was dissolved in acetic acid (5 ml) and oxidized for 1 h with Kiliani's reagent (0.15 ml, 0.22 mmole H_2CrO_4) at room temperature. Excess oxidant was destroyed with methanol and the solution then diluted with water and extracted with chloroform. Evaporation of the chloroform and recrystallization of the residue from Skellysolve B and then methanol provided the ketoester XXII, m.p. 122–123°. Infrared spectrum: ν_{max} 1 729 (sh), 1 718 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.27 (3H), 9.06 (3H, doublet, J = 7 c.p.s.), 8.96 (3H, doublet, J = 7 c.p.s.), 8.88 (3H), 6.37 (6H). Ultraviolet spectrum: $\lambda_{max}^{isooctane}$ 202 mμ (ε 4 000), 288 mμ (ε 70). Rotatory dispersion in methanol (c 0.204): α_D −39°, α_{400} +34°, α_{303} +2 580°, α_{288} 0°, α_{268} −3 320°, α_{250} −2 500°.

Solvolysis of Lactone A in Acetic Acid

Lactone A (XIX, 1.26 g) was dissolved in acetic acid (50 ml) and the solution heated on the steam bath for 20 min, then diluted with a large volume of water, and extracted 4 times with benzene. Removal of the solvents left an oily residue (1.3 g) shown by t.l.c. to consist of one major and two minor components. The infrared spectrum of the mixture showed absorption at 2 500–3 300, 1 715, and 1 695 cm^{-1}. The n.m.r. spectrum showed peaks at τ 9.38 (2.4H using the carbomethoxyl signal (3H) at 6.40 as an internal standard), 8.95 (doublet, $J = 6.5$ c.p.s.), 8.89, 8.00 (3H, —OCOCH_3), 5.50 (0.8H, C*H*OAc), 4.63 (0.8H, olefinic proton). Attempts to crystallize the free acid or the derived cyclohexylamine salts were unsuccessful. The reaction product was therefore deacetylated by allowing it to stand for 10 h in methanol (25 ml) containing sodium methoxide (0.23 g), then adding dilute hydrochloric acid, and extracting the mixture with benzene. Trituration of the oily residue with Skellysolve B and seeding (seed prepared in a separate experiment via the cyclohexylamine salt) provide the crude hydroxy acid XXVII (0.55 g), which, after recrystallization from benzene–Skellysolve, melted at 161–162°. Esterification with diazomethane followed by recrystallization from benzene – Skellysolve B provided the hydroxyester XXVIII, m.p. 135–136°.

Anal. Calcd. for $C_{25}H_{38}O_5$: C, 71.73; H, 9.15. Found: C, 71.56; H, 9.20.

Infrared spectrum: ν_{max} 3 610, 1 715 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.37 (3H), 8.95 (6H, doublet, $J = 7.5$ c.p.s.), 8.87 (3H), 6.40 (3H), 6.31 (3H), 6.24 (1H, C*H*OH), 4.64 (1H, olefinic.) The mass spectrum showed a weak parent peak at m/e 418 and the base peak at m/e 316.

Ketodiester XXIX

The hydroxydiester XXVIII (58 mg, 0.14 mmole) was dissolved in acetic acid (5 ml), Kiliani's reagent (0.12 ml, 0.18 mmole H_2CrO_4) added, and the solution kept at room temperature for 70 min. Excess oxidant was destroyed with methanol, and the reaction mixture was diluted with water and extracted several times with chloroform. Evaporation of the chloroform and recrystallization of the residue from methanol and then Skellysolve B provided the pure ketodiester XXIX, m.p. 160.5–161.5°.

Anal. Calcd. for $C_{25}H_{36}O_5$: C, 72.07; H, 8.72; O, 19.21. Found: C, 72.16; H, 8.46; O, 19.28.

Infrared spectrum: $\nu_{max}^{CHCl_3}$ 1 722, 1 705 cm^{-1}. Nuclear magnetic resonance spectrum: τ 9.32 (3H), 8.95 (6H, $J = 7$ c.p.s.), 8.84 (3H), 6.38 (3H), 6.34 (3H), 4.29 (1H). Ultraviolet spectrum: $\lambda_{max}^{isooctane}$ 282 (ϵ 120), 296 (ϵ 139), 305 (ϵ 122), 318 mμ (ϵ 61). Rotatory dispersion in isooctane: α_D −120°, α_{400} −595°, α_{317} −5 620°, α_{311} −4 400°, α_{307} −4 800°, α_{300} −1 440°, α_{295} 0°, α_{280} +5 450°.

Diester XXX

The ketodiester XXIX (0.40 g) was dissolved in anhydrous chloroform (15 ml), the solution saturated with hydrogen chloride, and ethanedithiol (2.5 ml) added. After 4 days at room temperature the solution was diluted with benzene (150 ml), washed with aqueous carbonate solution, then with water, and evaporated. The oily residue was dissolved in ethanol (50 ml) and heated under reflux with W2 Raney nickel (4 g) for 10½ h. After removal of the nickel by filtration and evaporation of the solvent, the residue was triturated with methylene chloride and the soluble portion (0.33 g) subjected to chromatography over neutral alumina (10 g). Elution with Skellysolve B (200 ml) and benzene–Skellysolve B 1:20 (100 ml) and 1:10 (200 ml) provided traces of uncharacterized oils. Elution with benzene – Skellysolve B 1:3 (250 ml) and 1:1 (400 ml) and benzene (150 ml) provided the crystalline deoxy diester XXX (0.11 g), m.p. 69–69.5 (from methanol–water), identical (melting point, mixed melting point, infrared spectrum, n.m.r. spectrum) with an authentic sample of the diester of the levopimaric acid – acrylic acid adduct (13) kindly provided by R. V. Lawrence.

ACKNOWLEDGMENTS

We thank Dr. R. V. Lawrence for a sample of the levopimaric acid – acrylic acid adduct and for a gift of levopimaric acid. Thanks are also due to Messrs. R. N. Swindlehurst and G. Bigam and their associates for the determination of most of the infrared and nuclear magnetic resonance spectra, and to the National Research Council for financial support.

SUBSTITUENT EFFECTS IN THE FLUORENE SERIES

I. SYNTHESIS AND ACETOLYSIS OF SOME DINITRO-9-FLUORENYL *p*-TOLUENESULFONATES

FREDERICK F. GUZIK AND ALLAN K. COLTER
Department of Chemistry, Carnegie Institute of Technology, Pittsburgh, Pennsylvania
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

2,4-, 2,5-, and 2,7-Dinitrofluorenones (I*a*, I*b*, and I*c*) were converted to 2,4-, 2,5-, and 2,7-dinitro-9-fluorenyl *p*-toluenesulfonates (IV*a*, IV*b*, and IV*c*) through the corresponding 9-diazo compounds (III*a*, III*b*, and III*c*). These diazo compounds were converted directly to the three dinitro-9-fluorenols (VI*a*, VI*b*, and VI*c*) and 9-fluorenyl acetates (V*a*, V*b*, and V*c*).

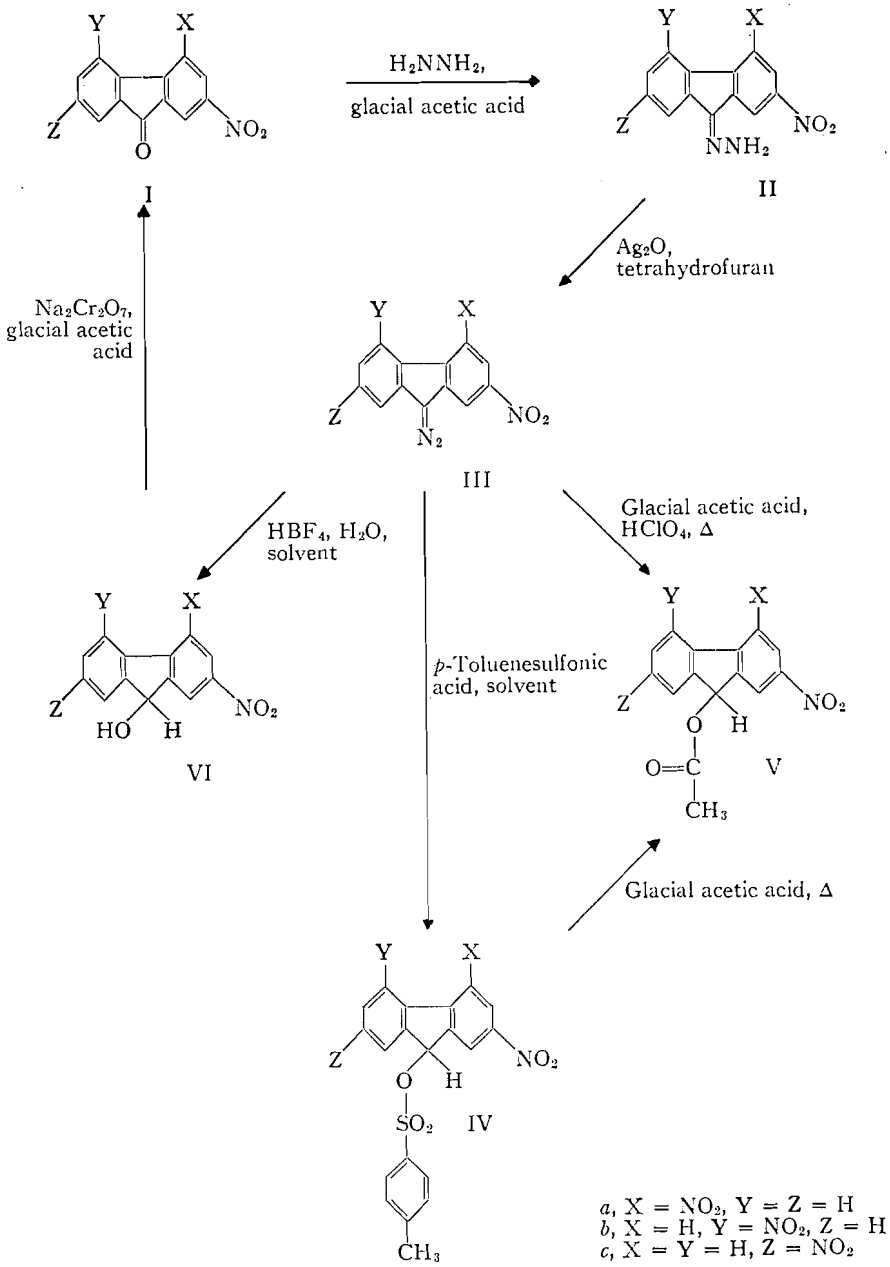
Rates of acetolysis of the three *p*-toluenesulfonates (IV*a*, IV*b*, and IV*c*) were measured in glacial acetic acid at 50.17° and 70.07°. The results are discussed.

INTRODUCTION

As part of a comprehensive study of charge-transfer complexes in solvolysis reactions (1, 2), 2,4-, 2,5-, and 2,7-dinitro-9-fluorenyl *p*-toluenesulfonates (IV*a*, IV*b*, and IV*c*) were desired. These compounds are also of interest in connection with a study of substituent effects in the fluorene series. The 2-, 4-, 5-, and 7-positions may be thought of as pseudo-meta positions with respect to the 9-position. Hence, introduction of a substituent at the 2- (or 7-) position is expected, as a first approximation, to have a similar effect on rates or equilibria involving reaction at the 9-position as introduction of the same substituent at the 4- (or 5-) position. However, no quantitative comparison of substituent effects at the two types of positions is presently available. Further, it is of interest to compare the effects of disubstitution involving two of the benzene rings in the fluorene ring system with equivalent substitution involving a single benzene ring. One might anticipate a special kind of "saturation effect" (3), possibly important in structure–reactivity correlations in polynuclear aromatic systems, whereby multiple substitution in a single benzene ring has a smaller influence than multiple substitution in more than one ring. Again, quantitative comparisons are lacking. Finally, the sequence ketone → hydrazone → diazo compound → alcohol represents a potentially useful method for selective reduction of base-sensitive carbonyl compounds (4). The present work was aimed at further defining the scope of this method.

RESULTS AND DISCUSSION

The synthetic sequence (Reaction Scheme 1) starts with the known dinitrofluorenones (I). Structures were characterized by infrared and analytical data (Table I), as well as by acetolysis of the *p*-toluenesulfonates (IV*a*, IV*b*, and IV*c*) to the corresponding acetates (V*a*, V*b*, and V*c*) and oxidation of the alcohols (VI*a*, VI*b*, and VI*c*) to the corresponding ketones. Schmidt and Bauer (5) have described the synthesis of V*c* and VI*c* by an indirect procedure starting from 2,7-dinitro-9,10-phenanthrenequinone. There is little basis for comparison of their results with those of the present work, except the reported melting points, which are in approximate agreement. These authors also reported the preparation of 4,5-dinitro-9-fluorenol and 4,5-dinitro-9-fluorenyl acetate by the same route, starting



REACTION SCHEME 1.

with 4,5-dinitro-9,10-phenanthrenequinone. However, the alleged 4,5-dinitro-9,10-phenanthrenequinone was subsequently shown to be the 2,5-isomer (see, for example, refs. 6 and 7); hence, it is likely that Schmidt and Bauer actually prepared V*b* and VI*b* (6). If the "4,5-dinitro compounds" are assumed to be the 2,5-isomers, the earlier results are inconsistent with those reported here in only one important respect. The precurser of the "4,5-dinitro-9-fluorenyl acetate", a dinitro-9-hydroxy-9-fluorenecarboxylic acid, was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

converted, by heating it in acetic anhydride in an air stream, to "4,5-dinitrofluorenone". The C, H, and N analyses for this compound were consistent with a dinitrofluorenone, but its melting point (>350°) was much higher than that reported (8) for 2,5-dinitrofluorenone.

Rates of acetolysis of IV*a*, IV*b*, and IV*c* at 50.17 °C and 70.07 °C are listed, together with activation parameters at 50.17 °C, in Table II. Comparison of the rates of acetolysis of the 2,5- and 2,7-dinitro-*p*-toluenesulfonates (IV*b* and IV*c*) reveals that a nitro group in the 7-position has a larger deactivating effect than a nitro group in the 5-position. Two factors may be responsible for the difference. First, the distribution of charge in the 9-fluorenyl cation (and hence in the transition state leading to the cation) may be such that its stability is less sensitive to substitution at the 4- (or 5-) position than the 2- (or 7-) position. Calculations designed to provide a measure of this factor are underway;

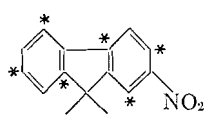
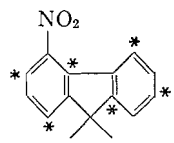
a full discussion of this point is properly postponed until more experimental data are available. A second factor to be considered is steric interference between a nitro group at the 4- (or 5-) position and a hydrogen at the 5- (or 4-) position. Calculations show that complete coplanarity would require an O—H distance of ca. 1.5 Å, considerably less than the sum of the van der Waals radii of oxygen and hydrogen (ca. 2.6 Å).

Comparison of the rates of acetolysis of the 2,4- and 2,5-dinitro-*p*-toluenesulfonates (IV*a* and IV*b*) shows that two nitro groups on a single benzene ring result in a smaller deactivating effect than equivalent substitution in two benzene rings. This result is in line with the expectation that successive substitution of strongly electron-withdrawing groups, because of a successive decrease in the polarizability of the pi electrons, should result in successively smaller substituent effects. In the fluorene ring system, such an effect can be rationalized by a simple argument involving resonance structures. For a nitro group in either the 2- or the 4-position, contributing structures having a positive charge at the 1-, 3-, 4*a*-, 5-, 7-, and 8*a*-positions (starred positions in VII*a*) can be written. A nitro group in the 5- or 7-position should produce the greatest electron deficiency at the 2-, 4-, 4*b*-, 6-, 8-, and 9*a*-positions (starred positions in VII*b*). Hence, the 5-nitro group in the 2,5-dinitro system should exert a greater influence than the 4-nitro group in the 2,4-system. Alternatively, the "saturation effect" observed here may not depend on



VII*a*



VII*b*

conjugation between the two rings. For this reason, we plan to look for effects of this kind in systems containing isolated and insulated benzene rings and in completely alternant systems.

EXPERIMENTAL[1]

2,4-Dinitrofluorenone (Ia)

This compound was prepared by the method of Ullman and Broido (11), m.p. 194–195° (reported (11), m.p. 197°).

2,5-Dinitrofluorenone (Ib)

This compound was prepared by oxidation of 2,5-dinitrofluorene with sodium dichromate in glacial acetic acid, m.p. 237–239° (reported (8), m.p. 241°). 2,5-Dinotrofluorene was prepared as described by Courtot (12).

[1]*Melting points are uncorrected. Microanalyses were performed by Galbraith Microanalytical Laboratories, Knoxville, Tenn. Infrared spectra were measured in* KBr *pellets with a Perkin–Elmer model 137B spectrophotometer.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2,7-Dinitrofluorenone (Ic)

This compound was prepared by oxidation of 2,7-dinitrofluorene (12) with sodium dichromate in glacial acetic acid, m.p. 289–290° (reported (8), m.p. 290°).

2,4-Dinitrofluorenone Hydrazone (IIa)

A 22-g quantity of I*a* was dissolved in 500 ml of boiling glacial acetic acid and a solution of 20 ml of 100% hydrazine hydrate in 50 ml of glacial acetic acid was slowly added with stirring. In about 5 min an orange precipitate began to appear. After it was heated for an additional 15 min, the mixture was allowed to cool to room temperature and suction filtered, and the product washed several times with 95% ethanol. After it was air-dried, the product weighed 17.5 g (76%) and had m.p. 255–256° (decomp.). Recrystallization from glacial acetic acid left the melting point unchanged.

Anal. Calcd. for $C_{13}H_8N_4O_4$: C, 54.97; H, 2.84; N, 19.75. Found: C, 54.77; H, 2.98; N, 19.46.

2,5-Dinitrofluorenone Hydrazone (IIb)

A 20-g quantity of I*b* was dissolved in 1 500 ml of boiling glacial acetic acid and a solution of 20 ml of 100% hydrazine hydrate in 50 ml of glacial acetic acid was slowly added with stirring. An orange precipitate began to appear in about 10 min. Heating was continued for an additional 5 min. The solution was cooled and filtered, and the product washed thoroughly with water and 95% ethanol. The dried product, 20.4 g (97%), had m.p. 260–265° (decomp.). Crystallization from glacial acetic acid yielded material of m.p. 264–266° (decomp.).

Anal. Calcd. for $C_{13}H_8N_4O_4$: C, 54.97; H, 2.84; N, 19.75. Found: C, 54.66; H, 3.18; N, 20.01.

2,7-Dinitrofluorenone Hydrazone (IIc)

A 16-g quantity of I*c* was dissolved in boiling glacial acetic acid and a solution of 16 ml of 100% hydrazine hydrate in 30 ml of glacial acetic acid was slowly added with stirring. The mixture was heated for 16 min (orange precipitate after 5 min) and the cooled solution filtered, washed with water, and dried under vacuum. The crude product weighed 15 g (89%) and had m.p. 275–278° (decomp.).

Anal. Calcd. for $C_{13}H_8N_4O_4$: C, 54.97; H, 2.84; N, 19.75. Found: C, 54.88; H, 3.08; N, 19.69.

9-Diazo-2,4-dinitrofluorene (IIIa)

In a three-necked flask equipped with an efficient power-driven stirrer and a condenser, 17.5 g of II*a* was dissolved in 1 500 ml of refluxing technical tetrahydrofuran. A 21-g quantity of powdered silver oxide was introduced in small portions over a period of 15 min. Refluxing was continued for 3 h with vigorous stirring. The silver residue was filtered while the solution was warm. The orange crystals which formed when the solution was cooled were filtered and washed thoroughly with 95% ethanol. The remainder of the product was obtained by evaporating the solution to dryness. The dried product weighed 11 g (63%). Recrystallization from nitromethane yielded reddish-orange needles, m.p. 192–192.5° (decomp.).

Anal. Calcd. for $C_{13}H_6N_4O_4$: C, 55.36; H, 2.14; N, 19.85. Found: C, 55.29; H, 2.22; N, 19.77.

9-Diazo-2,5-dinitrofluorene (IIIb)

The procedure was similar to that for III*a*. A suspension of 9 g of II*b* in 1 500 ml of technical tetrahydrofuran was oxidized with 12 g of powdered silver oxide. After it was refluxed for 4 h the mixture was filtered while warm, cooled, and diluted with an equal volume of water. The product was filtered, washed with 95% ethanol, and dried. The crude product weighed 5.7 g (64%), m.p. 207–209° (decomp.). Recrystallization from nitromethane (1 g in 250 ml) yielded orange crystals, m.p. 208° (decomp.).

Anal. Calcd. for $C_{13}H_6N_4O_4$: C, 55.36; H, 2.14; N, 19.85. Found: C, 55.34; H, 2.32; N, 19.67.

9-Diazo-2,7-dinitrofluorene (IIIc)

The procedure was similar to that for III*a*. A suspension of 15 g of II*c* in 1 800 ml of technical tetrahydrofuran was oxidized with 23 g of powdered silver oxide. After it was refluxed for 5 h the warm solution was filtered and evaporated to one-third of its original volume. The brownish-orange material which separated was filtered and washed with 95% ethanol. Additional product was obtained by diluting the filtrate with water. The crude product weighed 10 g (67%), m.p. 196–199° (decomp.).

Anal. Calcd. for $C_{13}H_6N_4O_4$: C, 55.36; H, 2.14; N, 19.85. Found: C, 55.63; H, 2.44; N, 19.84.

2,4-Dinitro-9-fluorenyl p-Toluenesulfonate (IVa)

To a warm solution (70–75°) of 10 g of *p*-toluenesulfonic acid in 500 ml of acetonitrile, 10 g of crude III*a* was slowly added with stirring. After it was heated for an additional 10 min the solution was filtered while warm. The filtrate was cooled to −25 °C for several hours, during which time the product crystallized. The peach-colored solid was filtered and washed with ether. The dried product weighed 11.5 g (76%), m.p. 106–164°. Recrystallization from acetonitrile raised the melting point to 164–166°.

Anal. Calcd. for $C_{20}H_{14}N_2O_7S$: C, 56.33; H, 3.31; N, 6.57. Found: C, 56.49; H, 3.51; N, 6.32.

2,5-Dinitro-9-fluorenyl p-Toluenesulfonate (IVb)

To a warm solution (70–75°) of 1.6 g of *p*-toluenesulfonic acid in 100 ml of acetonitrile, 1.6 g of crude III*b* was slowly added with stirring. After it was heated for an additional 5 min the reaction mixture was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

cooled and filtered. The filtrate was evaporated to about 5 ml and filtered, and the solid product washed thoroughly with ether. The crude product weighed 1.3 g (54%). Crystallization from acetonitrile gave orange crystals, m.p. 178–179°.

Anal. Calcd. for $C_{20}H_{14}N_2O_7S$: C, 56.33; H, 3.31; N, 6.57. Found: C, 56.41; H, 3.60; N, 6.29.

2,7-Dinitro-9-fluorenyl p-Toluenesulfonate (IVc)

A 2-g quantity of III*c* was added to a warm solution (90–95°) of 2 g of *p*-toluenesulfonic acid in 100 ml of nitromethane. After it was heated for an additional 5 min the reaction mixture was filtered and cooled at −25° for several hours. The crude product was filtered and washed thoroughly with ether. Additional product was obtained by evaporation of the filtrate to one-third of its original volume. The crude product weighed 1.85 g (61%). Crystallization from nitromethane afforded tan crystals, m.p. 208–210° (decomp.).

Anal. Calcd. for $C_{20}H_{14}N_2O_7S$: C, 56.33; H, 3.31; N, 6.57 Found: C, 56.55; H, 3.59; N, 6.32.

2,4-Dinitro-9-fluorenyl Acetate (Va)

A mixture of 1.0 g of III*a*, 100 ml of glacial acetic acid, and 1.5 ml of 70–72% perchloric acid was refluxed for 2 h. After the solution was cooled to room temperature, the product was precipitated by addition of 200 ml of water. Filtration and drying led to 1.0 g (90%) of crude product. Crystallization from glacial acetic acid gave orange crystals, m.p. 178–180°.

Anal. Calcd. for $C_{15}H_{10}N_2O_6$: C, 57.32; H, 3.21; N, 8.91. Found: C, 57.03; H, 3.17; N, 8.86.

2,5-Dinitro-9-fluorenyl Acetate (Vb)

To a hot solution (100–110°) of 50 ml of glacial acetic acid and 1 ml of 70–72% perchloric acid, 0.30 g of crude III*b* was slowly added with stirring. After it was heated for an additional 5 min the mixture was filtered and cooled, and the product precipitated by addition of an equal volume of water. After it was filtered, washed with water, and dried, the crude product weighed 0.30 g (90%). Crystallization from glacial acetic acid yielded material of m.p. 213–216° (reported (5), m.p. 220–221°).

Anal. Calcd. for $C_{15}H_{10}N_2O_6$: C, 57.32; H, 3.21; N, 8.91. Found: C, 57.58; H, 3.32; N, 8.67.

2,7-Dinitro-9-fluorenyl Acetate (Vc)

To a hot solution (100–110°) of 50 ml of glacial acetic acid and 1 ml of 70–72% perchloric acid, 0.75 g of III*c* was slowly added with stirring. After it was heated for an additional 5 min the solution was filtered and evaporated under reduced pressure to one-half of its original volume. The crystalline product which separated was filtered and washed with ether. Additional product was obtained by diluting the filtrate with an equal volume of water, giving a total of 0.65 g (78%) of crude product. Crystallization from glacial acetic acid gave light brown crystals, m.p. 205–208°. Several recrystallizations yielded material of m.p. 244–245° (reported (5), 244, 247 (decomp.)).

Anal. Calcd. for $C_{15}H_{10}N_2O_6$: C, 57.32; H, 3.21; N, 8.91. Found: C, 57.54; H, 3.35; N, 8.92.

2,4-Dinitro-9-fluorenol (VIa)

A 1.5-g quantity of III*a* was slowly added to a warm solution (70–75°) of 2 ml 42–45% fluoboric acid, 3 ml of water, and 60 ml of acetonitrile. After it was cooled and filtered, the solution was evaporated almost to dryness under reduced pressure. The product was filtered and washed with 95% ethanol, yielding 1.2 g (83%) of dried crude product. Crystallization from acetonitrile yielded beige crystals, m.p. 154–156°.

Anal. Calcd. for $C_{13}H_8N_2O_5$: C, 57.36; H, 2.96; N, 10.29. Found: C, 57.18; H, 3.01; N, 10.06.

2,5-Dinitro-9-fluorenol (VIb)

A mixture of 0.70 g of III*b*, 5 ml of water, 5 ml of 42–45% fluoboric acid, and 50 ml of acetonitrile was refluxed for 72 h. The mixture was cooled and filtered, and the filtrate diluted with an equal volume of water. The beige precipitate was filtered and dried, yielding 0.35 g (52%) of crude product. Crystallization from acetonitrile–water gave beige crystals of m.p. 181–184° (reported (5), m.p. 201–202°).

Anal. Calcd. for $C_{13}H_8N_2O_5$: C, 57.36; H, 2.96; N, 10.29. Found: C, 57.63; H, 3.27; N, 10.40.

2,7-Dinitro-9-fluorenol (VIc)

To a warm solution (70–75°) of 3.5 ml of water, 2.5 ml of 42–45% fluoboric acid, and 75 ml of acetonitrile, 1.5 g of crude III*c* was slowly added with stirring. The reaction was heated for an additional 5 min, filtered while warm, and kept at −25° for several hours. The tan precipitate was filtered and dried, yielding 0.9 g (62%) of crude product. Crystallization from nitromethane gave tan crystals of m.p. 210–213° (reported (5), m.p. 212°).

Anal. Calcd. for $C_{13}H_8N_2O_5$: C, 57.36; H, 2.96; N, 10.29. Found: C, 57.16; H, 3.16; N, 10.02.

Acetolysis of IVa, IVb, and IVc

Acetolysis of the *p*-toluenesulfonate esters IVa, IV*b*, and IV*c* was carried out by refluxing for 8–24 h in glacial acetic acid (ca. 100 ml per g of ester). The acetates were isolated by cooling and evaporation and filtration. In all cases, high yields (up to 95%) of acetates, shown by infrared spectra and mixed melting points to be identical with the acetate prepared from the 9-diazo compounds III*a*, III*b*, and III*c*, were obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Oxidation of VIa, VIb, and VIc

The alcohols were oxidized by refluxing for 1–2 h in glacial acetic acid (100–200 ml per g of alcohol) plus sodium dichromate dihydrate (1–3 g per g of alcohol). The ketones were isolated by cooling or addition of water, followed by filtration. In all cases, high yields (up to 90%) of ketones, shown by infrared spectra and mixed melting points to be identical with authentic I*a*, I*b*, or I*c*, were obtained.

Kinetic Measurements

Rates of acetolysis were measured as previously described (2). Ester concentrations were close to 2×10^{-3} *M*.

SUBSTITUTED QUINODIMETHANS

VIII. SALTS DERIVED FROM THE 7,7,8,8-TETRACYANOQUINODIMETHAN ANION–RADICAL AND BENZOLOGUES OF QUATERNARY PYRAZINIUM CATIONS[1,2]

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Our continued study of derivatives of the 7,7,8,8-tetracyanoquinodimethan anion–radical ($TCNQ^{-}\cdot$) has shown that the simple N-methylphenazinium salt (II*a*) exhibits a volume electrical resistivity of 7×10^{-3} Ω cm and thus is the most highly electrically conductive organic compound known. In contrast, the N-ethyl analogue has a resistivity of 10^{9} Ω cm. Electrical properties of pyrazinium, quinoxalinium, and phenazinium analogues, including phenazine-derived cation–radical salts of $TCNQ^{-}\cdot$, are discussed. Qualitative observations are made concerning the electron paramagnetic resonance of the N,N′-dimethyldihydrophenazinylium cation–radical.

In a previous publication (1) we discussed the electrical properties of salts of the anion–radical derived from 7,7,8,8-tetracyanoquinodimethan (TCNQ, I). Those derivatives included the simple salts comprising one cation and one $TCNQ^{-}\cdot$ anion–radical (e.g. $Li^{+}TCNQ^{-}\cdot$), and the complex salts wherein the unit composition requires inclusion of a formally neutral molecule of TCNQ (e.g. the triethylammonium complex salt formulated conveniently as $Et_3NH^{+}\ (TCNQ)_2^{-}\cdot$). In general the simple $TCNQ^{-}\cdot$ salts exhibit electrical resistivities in the range 10^{5} to 10^{8} Ω cm, while the more highly conducting complexes have resistivities falling in the range 10^{-2} to 10^{2} Ω cm (1).

Pursuing an inquiry into the electrical effect of the cation portion of these $TCNQ^{-}\cdot$ salts and complexes, we have examined analogues of the pyrazine ring system, including quaternized quinoxaline, acridine, phenazine, and phenazine-derived cation–radicals.

Electrical Properties

Most of the simple $TCNQ^{-}\cdot$ salts listed in Table I exhibited electrical resistivities similar to those of previously described analogues. However, the N-methylphenazinium salt II*a* exhibited the unusually low value of 7×10^{-3} Ω cm measured on single crystals in the long needle axis direction. This is the most highly electrically conductive organic compound known. In marked contrast, the N-ethyl compound II*b* had a single crystal resistivity of 10^{9} Ω cm.

*Compared with $Li^{+}TCNQ^{-}\cdot$ for which $\epsilon_{842\,m\mu}$ = 43 000 in acetonitrile (see ref. 1).
†Determined on polycrystalline compaction unless otherwise noted.
‡Determined on single crystal.

Preliminary X-ray measurements by Dr. C. J. Fritchie of this laboratory have shown that in the N-methyl salt the $TCNQ^{-}\cdot$ units are stacked one above the other. Furthermore, the compound has a remarkably high density (1.44). These observations suggest that the low steric requirement of the N-methyl group in the cation allows very efficient packing of the $TCNQ^{-}\cdot$ units which presumably mediate the electronic conduction. On the other hand, the N-ethyl derivative has a density of 1.33; the bulky N-ethyl group apparently disrupts the packing, resulting in an appreciable barrier to electron movement. Previously, the most conductive compound we have prepared is the complex quinolinium salt III. It had a single crystal resistivity of 0.01 Ω cm and a density of 1.36. However, in this case, the complex anion $(TCNQ)_2^{-}\cdot$ is thought to be the principal conducting moiety and it is apparently relatively less disturbed by cation spatial effects. In Table II are listed a number of complex salts related to the simple salts of Table I; the resistivities of the complex salts were all in the expected range.

Attention is drawn to the apparently high conductivity of the simple salt N-methylquinoxalinium $TCNQ^{-}\cdot$ (126 Ω cm). The result is believed to be specious since, although elemental analytical data were satisfactory, density measurements indicated a mixture, perhaps, of simple and complex salts. The complex component in the solid state would increase the conductivity. This was the only compound listed which was not shown convincingly to be pure by our standard criteria.

Synthesis and Spectral Data

The simple salts of $TCNQ^{-}\cdot$ were prepared by metathesis of an appropriate quaternary compound with $Li^{+}TCNQ^{-}\cdot$ as previously described (1) (illustrated in eq. [1] for the N-methylpyrazinium salt, IV). The compounds prepared in this way are listed in Table I. These salts are stable in the solid state, and most were purified by recrystallization from acetonitrile in air. Under these conditions, however, the N-methylacridinium compound (V) was completely converted to the complex salt (VI), presumably by air oxidation of a portion of the anion–radical (eq. [2]). A similar transformation apparently occurs to some extent when the N-methylquinoxalinium simple salt is recrystallized. The stability in solution of compound IV and, particularly, of the N-alkylphenazinium compounds II*a* and II*b* suggests a protecting effect on the anion by the associated cations. It is tempting to postulate some sort of ion pairing to account for this solution stability, but visible absorption spectral data point to complete dissociation of II and IV in acetonitrile solution. Thus, the pyrazinium and phenazinium compounds, and also N-methyl-1,10-phenanthrolinium $TCNQ^{-}\cdot$, showed molar extinction coefficients, $\epsilon_{842\,m\mu} \simeq 43\,000$, characteristic of the $TCNQ^{-}\cdot$ anion (reference compound $Li^{+}TCNQ^{-}\cdot$). The N-methylquinoxalinium and N-methylacridinium compounds were so unstable in solution that spectral measurement was precluded.

The corresponding complex salts were prepared by recrystallizing the simple salts from acetonitrile containing a molar equivalent of neutral tetracyanoquinodimethan (see ref. 1).

The previously unknown cation–radical salt N,N′-dimethyldihydrophenazinylium iodide (VIII) was prepared by iodine oxidation of the free base VII in acetonitrile (eq. [3]). By metathesis, the salt VIII was converted to the simple $TCNQ^{-}\cdot$ salt IX. The spectrum of this derivative showed considerable absorption attributed to neutral TCNQ and attenuation of absorption by the cation–radical, indicating an equilibrium between ion–radical and uncharged species (eq. [4]). The extinctions are given in Table III. The data indicate an equilibrium comprising about 30–40% neutral species. In the solid state this compound may more properly be represented as a π-complex rather than an ion–radical salt.*

**Similar spectral behavior was observed for the π-complex derived from N,N,N′,N′-tetramethyl-p-phenylenediamine and TCNQ (see ref. 1).*

TABLE III

Absorption spectrum of dimethyldihydrophenazinylium $TCNQ^{-}\cdot$ (IX) in acetonitrile

λ_{max} (mμ)	ϵ
842	26 000*
394	43 000†
258	58 000†

*Compare $Li^{+}TCNQ^{-}\cdot$ $\epsilon_{842\ m\mu}$ = 43 300.
†Neutral TCNQ ϵ_{391} = 64 400; $Li^{+}TCNQ^{-}\cdot$ ϵ_{391} = 21 500.
‡Compound VIII ϵ_{258} = 84 000.

Treatment of the base VII with 2 equiv. of TCNQ afforded the corresponding complex salt. In this transformation the neutral base presumably donates one electron to a molecule of TCNQ to form the anion–radical; the ionic species then precipitates with a neutral TCNQ molecule to form the complex salt. The absorption spectrum showed characteristics similar to that of the simple salt.

The electron paramagnetic resonance (e.p.r.) spectrum of the cation–radical VIII is of some interest. At a concentration of 10^{-2} *M* in ethylene glycol, this compound showed an 11-line spectrum attributed to hyperfine splitting of the electron resonance by both nitrogen nuclei and methyl-group protons. When the solution was diluted to 5×10^{-4} *M* the spectrum was resolved into over 65 lines as a result of splitting by the benzo-ring protons. These observations are similar to those of Hausser *et al.* (2) and Matsunaga and McDowell (3) on the e.p.r. of the unmethylated analogue.

In the Experimental section there is recorded a convenient preparation of the water-soluble dimethyldihydrophenazinylium chloride.

EXPERIMENTAL

Quaternary Salts

o-Phenanthroline methiodide and pyrazine methiodide were prepared by allowing concentrated ether solutions of the bases and excess methyl iodide to stand at room temperature for several days. The salts separated as yellow crystalline solids. N-Methylacridinium and N-methylphenazinium methyl sulfate were prepared by heating the respective bases and excess dimethyl sulfate in benzene at 70° for several hours. N-Ethylphenazinium ethyl sulfate was formed by heating equal weights of the base and diethyl sulfate in nitrobenzene at 120–125° for 2 h, cooling to 60°, and adding ether to precipitate the quaternary salt.

N,N'-Dimethyldihydrophenazinylium Iodide

In 10 ml of warm acetonitrile was dissolved 0.21 g (1 mmole) of dimethyldihydrophenazine (4), and a warm solution of 0.13 g (1 g-atom equiv.) of iodine in 10 ml of acetonitrile was added. The green solution was cooled in wet ice – acetone, and the black needles were collected and washed with ether. The yield of analytically pure material was 0.28 g (83%), m.p. 204–206° (decomp.).

Anal. Calcd. for $C_{14}H_{14}N_2I$: C, 50.0; H, 4.2. Found: C, 50.0; H, 4.3.

N,N'-Dimethyldihydrophenazinylium Chloride Monohydrate

In 75 ml of chloroform was dissolved 2.1 g (10 mmoles) of dimethyldihydrophenazine, and 0.25 ml of liquid chlorine was allowed to evaporate over the surface of the stirred solution. The green-black solid was collected on a filter and washed with chloroform. It was recrystallized from 100 ml of 95% ethanol to obtain 1.85 g of shiny black needles, m.p. 142–145° (decomp.).

Anal. Calcd. for $C_{14}H_{14}N_2Cl \cdot H_2O$: C, 63.8; H, 6.1; Cl, 13.4. Found: C, 64.0; H, 6.1; Cl, 13.4.

The infrared spectrum showed a strong band at 3 300 cm^{-1} attributed to water of hydration. Reduction with zinc in ethanol afforded authentic dimethyldihydrophenazine.

Preparation of Simple $TCNQ^-\cdot$ Salts (Table I)

The compounds listed in Table I were prepared by treatment of the respective quaternary iodides or methyl sulfates in hot absolute alcohol (about 0.1 *M*) with a boiling solution of 1 equiv. of LiTCNQ (1) in absolute ethanol (about 0.05 *M*). After the solution was cooled to room temperature, the products were collected on a filter and were recrystallized from acetonitrile.

Preparation of the Complex $(TCNQ)_2^-\cdot$ Salts (Table II)

One millimole of simple salt was dissolved in a boiling solution of 25 ml of acetonitrile containing 1 mmole of neutral TCNQ; the solution was filtered hot and then cooled to precipitate the product.

N,N'-Dimethyldihydrophenazinylium $(TCNQ)_2^-\cdot$

A hot filtered solution of 0.10 g (0.5 mmole) of N,N'-dimethyldihydrophenazine in 10 ml of acetonitrile was added to a hot filtered solution of 0.2 g (1 mmole) of TCNQ in 15 ml of acetonitrile. Black needles separated almost immediately. The mixture stood at room temperature for 30 min, and the product was collected on a filter and washed with acetonitrile and ether.

ACKNOWLEDGMENTS

The author thanks Dr. W. E. Mochel for helpful discussions and Drs. R. G. Kepler, H. G. Hoeve, and P. Arthur, respectively, for the electrical, electron paramagnetic resonance, and density measurements.

ABSTRACT

A series of compounds related to 1,2-dichloro-4-benzenesulfonamido-5-nitrobenzene has been synthesized. These included derivatives in which ionizable groups had been placed in the para position of the benzenesulfonamido portion to confer on the compounds water solubility at physiological pH. Thus, carboxyl and quaternary ammonium groupings were introduced in this position. Water solubility was also conferred by introduction at the same position of non-ionizable groups such as polyhydroxyalkylamido groups. Additional relatives of the parent compound in which the chlorine atoms were replaced by methyl groups, and in which para-substituted benzenesulfonamido groups replaced those in the 4 and 5 positions, were synthesized. These compounds were tested for their ability to cure permanently the spontaneous mammary cancers of two strains of mice. All compounds were tested in combination with 1,2-dimethyl-4-(*p*-carboxyphenylazo)-5-hydroxybenzene. The most active substance found was 1,2-dichloro-4-(*p*-carboxybenzenesulfonamido)-5-nitrobenzene.

INTRODUCTION

Woolley and Stewart (1) showed that some spontaneous mammary cancers of mice could be cured permanently when the animals were given a mixture of two antimetabolites of 1,2-dimethyl-4,5-diaminobenzene. The two antimetabolites were 1,2-dimethyl-4-(*p*-carboxyphenylazo)-5-hydroxybenzene and 1,2-dichloro-4-benzenesulfonamido-5-nitrobenzene (I). These compounds were noteworthy not only because they actually cured spontaneous cancers but also because they were not very toxic to the animals themselves. They destroyed the cancers but did not at the same time poison the hosts. They apparently were able to do this because of their ability to inhibit the biosynthesis of vitamin B_{12}, and because this vitamin is synthesized by the spontaneous cancers but not by the hosts (2–6).

Certain shortcomings and anomalies in the actions of these two substances were, however, pointed out by Woolley and Stewart. In the first place, the compounds were not able to cure all of the cancerous mice. At most, only 35% were permanently cured, and a further 33% experienced only a transient regression of their cancers, after which the disease progressed. Thus, 32% of the cancers were not affected detectably by the compounds.

In the second place, the dose–response curve was unusual. Small doses produced no cures, and larger ones gave greater and greater numbers of cures up to a certain point. Beyond this point no additional numbers of cures could be produced by further increases in the dose of the antimetabolites.

The purpose of the work to be described in this paper was to synthesize derivatives of 1,2-dichloro-4-benzenesulfonamido-5-nitrobenzene which might prove to be more potent than the parent compound, and might be able, in conjunction with 1,2-dimethyl-4-(*p*-carboxyphenylazo)-5-hydroxybenzene, to cure all of the mammary cancers in a group of mice.

X

The strategy followed was to introduce chemical groups into 1,2-dichloro-4-benzenesulfonamido-5-nitrobenzene which would increase its water solubility. At the pH of animal tissues this parent compound was only very slightly ionized, and was consequently rather insoluble. It was felt that if its water solubility could be increased without sacrifice of its oncolytic activity a more potent substance might result.

The ways which were explored to achieve this end were, first, to introduce carboxyl groups to solubilize the compound as an anion at pH 7.5 or cationic groups of sufficient basic strength that the cations (or their zwitterions with the acidic sulfonamide group) would exist at physiological pH. It was recognized that the conversion of the drug to an ionized derivative might destroy its chemotherapeutic potency either because the derivative might be excreted too rapidly or because it might fail to penetrate into cells.

If achievement of solubility by introduction of ionizable groups were found to lead to biologically inactive compounds, it was planned to leave the ionizability of the parent compound untouched, but instead, to introduce polyhydroxyalkyl groups to achieve the desired solubility.

The proposed structural alterations could be introduced at many different points in the molecule. However, it was thought best to make all of the modifications in the benzenesulfonamide portion, and to leave untouched the "business end" of the molecule, viz. the part which gives it its structural analogy to dimethyldiaminobenzene. This plan was followed. In addition, some derivatives of another antimetabolite of this series were also prepared and tested. These were derivatives of 1,2-dimethyl-4,5-bis-(benzenesulfonamido)-benzene (II). This compound (1) had been found to exhibit some ability to cure spontaneous mammary cancers, but suffered from the same shortcomings as did 1,2-dichloro-4-benzenesulfonamido-5-nitrobenzene. The idea pursued again in designing the derivatives was to introduce solubilizing groups into the benzenesulfonamido portions.

EXPERIMENTAL

All compounds were recrystallized to constant melting point from the solvents indicated in the text.

1,2-Dichloro-4-(p-carboxybenzenesulfonamido)-benzene, Compound III

A solution of 53 g of 3,4-dichloroaniline in 180 ml of pyridine was cooled to 0°, stirred, and slowly treated with 76 g of *p*-cyanobenzenesulfonyl chloride, prepared as described by Remsen *et al.* (7). When the addition was complete, the solution was allowed to stand at room temperature for 20 h. Without isolation of the nitrile derivative, the reaction mixture was then treated with 56 g of NaOH in 1 l of water. The resulting solution was refluxed for 2 h to hydrolyze the nitrile. The hydrolysate was diluted with 8 l of water, treated with 10 g of Norit, filtered, and acidified to pH 2 with HCl. It was necessary to have a large volume at the time of the acidification. Otherwise, an intractable gel was formed. The crystalline precipitate which formed was collected, washed with water, and recrystallized to constant melting point (255°) from 1 l hot acetone by addition of 0.5 l of water; yield 97 g.

Anal. Calcd. for $C_{13}H_9Cl_2NO_4S$: C, 45.1; H, 2.9; N, 4.0. Found: C, 45.4; H, 2.7; N, 3.9.

1,2-Dichloro-4-(p-carboxybenzenesulfonamido)-5-nitrobenzene, Compound IV

Yellow fuming nitric acid, specific gravity 1.48 (950 ml), was cooled to 20° and stirred, and 95 g of dry powdered 1,2-dichloro-4-(*p*-carboxybenzenesulfonamido)-benzene was added to it at such a rate that the temperature did not rise above 25°. A clear solution was soon produced. When the nitration was attempted at lower temperatures, the starting material was found to be so insoluble in the nitric acid that incomplete reaction occurred. The reaction mixture was held for 0.5 h at 20°, and was then poured slowly with much stirring into 6 l of ice and water. The crystalline precipitate which formed was collected, washed with water, and recrystallized to constant melting point from 1.5 l butanol, or from acetone by addition of benzene. The yield was 54.5 g; m.p. 225° (decomp.).

The position of the nitro group was inferred from the similar preparation of 1,2-dichloro-4-benzenesulfonamido-5-nitrobenzene (8), in which case the position of the group was proved by alternate synthesis.

Anal. Calcd. for $C_{13}H_8Cl_2N_2O_6S$: C, 39.9; H, 2.0; N, 7.2. Found: C, 38.7; H, 2.0; N, 7.1.

1,2-Dichloro-4-(p-carboxamidobenzenesulfonamido)-5-nitrobenzene, Compound V

The preceding compound IV (19.5 g) was dried at 100°, powdered, and suspended in 250 ml of anhydrous ether, and 11.5 g of PCl_5 was added to it. The suspension was stirred at room temperature until a clear solution was obtained. The reaction mixture was concentrated under reduced pressure to dryness, and the crystalline acid chloride was triturated with dry petroleum ether to remove $POCl_3$. The acid chloride was then dissolved in 175 ml of acetone, and the solution was added dropwise during 30 min to 100 ml of concentrated aqueous ammonia which was being stirred and cooled to 0°. The resulting solution was held at room temperature overnight and then was concentrated under reduced pressure to 100 ml and acidified to pH 6.0 with HCl. The precipitate which formed was collected, washed with water, and recrystallized from 200 ml of ethanol. The yield was 19.0 g; m.p. 222° (decomp.).

Anal. Calcd. for $C_{13}H_9Cl_2N_3O_5S$: C, 40.0; H, 2.3; N, 10.8. Found: C, 40.4; H, 2.4; N, 10.5.

1,2-Dichloro-4-[p-(N-glucosaminocarbonyl)-benzenesulfonamido]-5-nitrobenzene, Compound VI

The acid chloride of compound IV was prepared as described in the preceding section from 19.5 g of the acid and dissolved in 175 ml of acetone. This solution was then added dropwise with stirring to a freshly prepared suspension of MgO (10 g) and D-glucosamine hydrochloride (10.8 g) in 250 ml of cold (0°) water. After the reaction of the acid chloride had proceeded for 2 h at 0 °C, and overnight at room temperature, the unused MgO was filtered off and washed thoroughly with water. The filtrate was concentrated under reduced pressure to about 100 ml. This concentrated solution was then acidified to pH 4 with concentrated HCl. The desired product, which crystallized out, was collected and washed with small amounts of water. It was then dried to constant weight *in vacuo* and triturated with 250 ml of acetone to remove any unchanged compound IV. If the material had not been thoroughly dried before treatment with acetone, it became dark and gummy and some of it dissolved in the acetone, but thorough drying prevented these problems. The acetone-insoluble material (28 g) was recrystallized from water. The yield was 20 g; m.p. 170° (decomp.), with sintering from 160 °C. In boiling water it was soluble at 2 mg per ml and at 0.6 mg per ml in cold water. Crystals contained 1 mole of water which was lost at 78 °C *in vacuo*.

Anal. Calcd. for $C_{19}H_{19}Cl_2N_3O_{10}S$: C, 41.3; H, 3.5; N, 7.6. Found: C, 41.2; H, 3.5; N, 7.3.

Reaction of Compound VI with 1,2-Dimethyl-4-(p-carboxyphenylazo)-5-hydroxybenzene

It was proposed to test compound VI in combination with 1,2-dimethyl-4-(*p*-carboxyphenylazo)-5-hydroxybenzene for chemotherapeutic action against cancers. Quite unexpectedly, however, it was found that these two compounds reacted with each other in aqueous solutions. When the aqueous solutions at pH 8 were mixed at room temperature, a brownish-red precipitate slowly separated. The chemical nature of this precipitate was not established, but it was plain that the aldehydo group in compound VI was necessary for the reaction. This was shown by the fact that the corresponding compound (compound VII, see below) in which the aldehydo group had been reduced to $—CH_2OH$ did not produce a color change or a precipitate when aqueous solutions of it were added to neutral aqueous solutions of 1,2-dimethyl-4-(*p*-carboxyphenylazo)-5-hydroxybenzene.

1,2-Dichloro-4-[p-(2'-desoxy-2'-glucitolaminocarbonyl)-benzenesulfonamido]-5-nitrobenzene, Compound VII

A solution of 30 g of compound VI in 550 ml of water and 5.5 g of $NaHCO_3$, which had stood at room temperature for 2 h to allow complete mutarotation, was mixed all at once with a freshly prepared solution of sodium borohydride (6 g in 140 ml of water) (cf. ref. 9). After the mixture had stood for 2 h at room temperature it was acidified below pH 6 with acetic acid, and the precipitate which formed was collected and washed 3 times with 150 ml of water. This precipitate was dissolved in aqueous $NaHCO_3$, treated with Norit, filtered, and reprecipitated by acidification. It was then recrystallized from 0.02 *N* aqueous HCl. The yield was 15 g; m.p. 138° (decomp.). The compound was soluble in boiling water at 8 mg per ml and in cold water to the extent of 1 mg per ml.

Anal. Calcd. for $C_{19}H_{21}Cl_2N_3O_{10}S$: C, 41.2; H, 3.8; N, 7.6. Found: C, 40.7; H, 3.7; N, 7.5.

1,2-Dichloro-4-(p-cyanobenzenesulfonamido)-5-nitrobenzene, Compound VIII

A solution of 21.5 g of 3,4-dichloro-6-nitroaniline, prepared according to the directions of Beilstein and Kurbatow (10) in 75 ml of pyridine, was treated with 21 g of *p*-cyanobenzenesulfonyl chloride prepared as described by Remsen *et al.* (7). The mixture was held at room temperature in a stoppered flask for 24 h and was then poured into 1 l of ice water. The gummy precipitate which formed crystallized after several hours, was collected, and was well washed with water. Unchanged dichloronitroaniline was removed from it by trituration with 1 l of water containing 11 g Na_2CO_3 and 4 g NaOH, and by filtration. The recovered dichloronitroaniline weighed 12 g. The filtrate was immediately acidified with acetic acid, and the precipitate which formed was collected, washed with water, and recrystallized from acetic acid by the addition of water. The yield was 7.3 g; m.p. 199–201°.

Anal. Calcd. for $C_{13}H_7Cl_2N_3O_4S$: C, 41.9; H, 1.9; N, 11.3. Found: C, 41.7; H, 2.1; N, 11.0.

1,2-Dichloro-4-(p-trimethylaminobenzenesulfonamido)-5-nitrobenzene, Compound IX

The methyl betaine of sulfanilic acid was prepared by rearrangement of methyl *p*-dimethylaminobenzenesulfonate as suggested by Kuhn and Ruelius (11). The rearrangement was best carried out by heating the ester at 100° for 3 h without solvent.

The betaine was converted to its acid chloride by heating under reflux a suspension of 17 g of the betaine with 100 ml of CCl_4 and 29 g of PCl_5 for 24 h. The acid chloride which remained insoluble as its hydrochloride was filtered off and washed with CCl_4. It was then added to a solution of 3,4-dichloro-6-nitroaniline (12.4 g) (10) in 50 ml of pyridine. The mixture was held at 50° and stirred for 24 h. It was then concentrated under reduced pressure to dryness. Unchanged dichloronitroaniline and pyridine hydrochloride were removed by extraction with chloroform (200 ml). The compound IX, because it was a zwitterion, was not soluble in this solvent. All attempts to remove the dichloronitroaniline by recrystallization failed until this method was found. The chloroform-insoluble material (12 g) was then recrystallized from boiling water, or from glacial acetic acid.

Compound IX was (for an ionized salt) surprisingly insoluble in water. At 100° the solubility was approximately 0.5 mg per ml. It was also rather insoluble in acetic acid or ethanol. It was no more soluble in aqueous 1 *N* HCl or 1 *N* NaOH than it was in water. The melting point (235–238°) was a decomposition point which, in contrast to that for other compounds of this series, was of little value as a criterion of purity.

Anal. Calcd. for $C_{15}H_{15}Cl_2N_3O_4S$: C, 44.6; H, 3.7; N, 10.4. Found: C, 44.5; H, 3.6; N, 10.2.

1,2-Dichloro-4-[p-(p'-cyanobenzenesulfonamido)-benzenesulfonamido]-5-nitrobenzene, Compound X

Compound V (3.8 g) was converted to the corresponding amine (viz. 1,2-dichloro-4-(*p*-aminobenzenesulfonamido)-5-nitrobenzene) by a standard Hofmann degradation with NaOCl. The product was isolated from the alkaline aqueous reaction mixture by acidification to pH 4. The amine was weak enough that it did not form a hydrochloride at that pH and readily crystallized. The amine was then dried, dissolved in pyridine, and acylated with *p*-cyanobenzenesulfonyl chloride (10) by use of the conditions described for other acylations in this paper. The product was recrystallized from acetic acid; m.p. 136° after sintering from 115°.

Anal. Calcd. for $C_{19}H_{12}Cl_2N_4O_6S_2$: C, 43.3; H, 2.3; N, 10.6. Found: C, 43.3; H, 2.4; N, 10.3.

1,2-Dimethyl-4,5-bis-(p-cyanobenzenesulfonamido)-benzene, Compound XI

A cooled and stirred solution of 14 g of 1,2-dimethyl-4,5-diaminobenzene in 50 ml of pyridine was slowly treated with 44 g of *p*-cyanobenzenesulfonyl chloride (10), and allowed to stand at room temperature for 1 h. The reaction mixture was then poured into 1 l of ice water, and the precipitate which formed was collected, washed with water, dried, and recrystallized from 200 ml of boiling glacial acetic acid with addition of 200 ml of water. The yield was 38.5 g; m.p. 207–209°.

Anal. Calcd. for $C_{22}H_{18}N_4O_4S_2$: C, 56.7; H, 3.9; N, 12.0. Found: C, 56.7; H, 3.8; N, 11.7.

1,2-Dimethyl-4,5-bis-(p-carboxybenzenesulfonamido)-benzene, Compound XII

The dinitrile, compound XI (9.3 g), was dissolved in 200 ml of aqueous 1 *M* NaOH, and the solution was refluxed for 2 h. It was then cooled, diluted with 500 ml of water, decolorized with Norit, and acidified to pH 2 with HCl. The precipitate which formed was collected, washed, and recrystallized by suspension in 100 ml of hot glacial acetic acid and addition of 250 ml of water. The yield was 9.8 g; m.p. 255° (decomp.).

Anal. Calcd. for $C_{22}H_{20}N_2O_8S_2$: C, 52.4; H, 4.0; N, 5.6. Found: C, 52.2; H, 3.8; N, 5.6.

TABLE I

Effect of compounds on spontaneous mammary cancers of mice (all animals received 6 g 1,2-dimethyl-4-(*p*-carboxyphenylazo)-5-hydroxybenzene per kg rations in addition to the compounds listed)

		Oral dose (g per kg ration)	I.P. dose (mg per mouse per day)	SPFS mice			C3H mice		
				No. mice	Transient suppression	Permanent cures	No. mice	Transient suppression	Permanent cures
1,2-Dichlorobenzenes									
	None	0	0	33	2	2	58	1	0

*These mice received no 1,2-dimethyl-4-(*p*-carboxyphenylazo)-5-hydroxybenzene.

1,2-Dimethyl-4,5-bis-(p-amidinobenzenesulfonamido)-benzene Dihydrochloride, Compound XIII

The dinitrile, compound XI (28.5 g), was dissolved in 50 ml of acetone and 200 ml of dry chloroform and mixed with 22 ml of 10 *M* alcoholic hydrogen chloride. The mixture was allowed to stand at room temperature for 24 h. It was then concentrated under reduced pressure to dryness at 25°, and freed of acetone by addition of anhydrous ether and reconcentration. The residue was dissolved in 100 ml of absolute ethanol at 0°, and immediately mixed with 250 ml of ethanol previously saturated with NH_3. The solution which resulted was held at room temperature for 3 days, and was then concentrated under reduced pressure to dryness at 25°. The residue was triturated with 1 l of boiling chloroform, and the insoluble portion was dried and triturated with ethanol which was then diluted with water. The desired amidine remained in the water-soluble portion along with the impurities (fraction A). The water-insoluble portion was a mixture of several compounds, one of which appeared to be the cyclic amidine formed by reaction of the two bis-imino-ether groups with 1 molecule of NH_3. It was purified by suspension in ethanol, addition of chloroform, and concentration under reduced pressure to remove most of the ethanol. It melted at 187°.

Anal. Calcd. for $C_{22}H_{21}O_4N_5S_2$: C, 54.6; H, 4.3; N, 14.5. Found: C, 54.5; H, 4.5; N, 14.0.

The desired diamidine was obtained from the water-soluble fraction A by conversion to the dihydrochloride by addition of ethanolic hydrogen chloride. The dihydrochloride (3 g) crystallized from this mixture, m.p. 276° (decomp.).

Anal. Calcd. for $C_{22}H_{26}Cl_2N_6O_4S_2$: C, 46.1; H, 4.5; N, 14.7. Found: C, 45.4; H, 4.3; N, 14.3.

Effects on Spontaneous Mammary Cancers of Mice

Most of the compounds were tested for their ability to cure the spontaneous mammary cancers of two strains of mice, viz. the SPFS and C3H strains. The methods of testing, and the criteria of cure or regression were those described in the preceding paper (1). The compounds were administered both orally (mixed with the food) as well as by daily intraperitoneal injections. All compounds were tested in combination with 1,2-dimethyl-4-(*p*-carboxyphenylazo)-5-hydroxybenzene, but some were also tested without this compound.

It is important to note that the compounds were tested against spontaneous cancers, not against transplants. The importance of this distinction has been discussed in preceding papers (1, 12).

Because mice with spontaneous mammary cancers are rare, each test group contained limited numbers of animals, usually six. Any compound which showed promising potency was then retested with larger numbers of animals. In this way, the best use could be made of the limited numbers of rare animals. The precise relative potencies were thus not determined with accuracy, but this was of only secondary interest. The assay was adequate to reveal any compound which would cure *all* of the cancers. Other compounds of less potency were of less interest.

The results of the chemotherapeutic experiments are summarized in Table I. It can be seen that the most active new compound was IV. Only the SPFS cancers were susceptible to these compounds. The C3H strain showed no permanent cures with any one of them. This difficulty in causing an effect in the C3H strain accorded with the previous experience with the parent compound (1).

THE MECHANISMS OF THE HALOGENATIONS AND HALOGENOMETHOXYLATIONS OF D-GLUCAL TRIACETATE, D-GALACTAL TRIACETATE, AND 3,4-DIHYDROPYRAN[1]

R. U. LEMIEUX AND B. FRASER-REID
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The stereochemical routes of the reactions showed trends, when the halogen, the olefin, and the solvent were changed, which can be accounted for on the basis of (*a*) the relative stabilities of the halonium and oxocarbonium ions formed as intermediates, (*b*) the effect of ring conformation on the ease of formation of oxocarbonium ions involving the ring-oxygen of the pyranose ring, (*c*) the role of the anomeric effect in determining the stability of the transition state, and (*d*) the influence on the route of reaction of whether or not the intermediate cations are solvated by a nucleophile as they are formed. Proton magnetic resonance spectroscopy was extensively used to determine the compositions of products and the configurations and conformations of the compounds obtained.

The stereochemical routes of the bromination and halogenomethoxylations of D-glucal triacetate were reported in an earlier communication (1). The product of the chlorination has now been established and the reactions were extended to D-galactal triacetate (2) and 3,4-dihydropyran. The halogenations were performed at 0° in carbon tetrachloride and the halogenomethoxylations at 0° in methanol containing silver acetate. The yields and configurations of the products formed in each of the reactions are given in Table I. The bases for these conclusions are presented in the Experimental section of this paper and in the previous communications (1).

The results appear to shed light on the nature of the intermediates formed in halogenation reactions and on the stereoelectronic requirements for ring-oxygen participation in reactions at the anomeric center of sugar derivatives. This becomes apparent when the results (Table I) are considered and one keeps in mind the probable effect of the electronegativity of the halogen on the relative stabilities of the intermediates B to E, the effect of the nature and concentration of the nucleophile Y in the reactions of these intermediates, and the stereoelectronic demands for the transformations involved in the conversion of the cyclic vinyl ethers (A) to the products (L to O).

In theory, four diastereoisomeric products (L to O) can be expected to form, if the nucleophilic attack in the second stage of the reaction is restricted to the anomeric center. This route of reaction must be expected, since it allows the ring-oxygen to help delocalize positive charge at the anomeric center. That is, the intermediates B to E are expected, as shown, to possess oxocarbonium-ion character and, therefore, to undergo nucleophilic attack most readily at the anomeric center. All the results of the halogenomethoxylations are in accord with this expectation.

The exact nature of the halogenating agent is not known. Nevertheless, it suffices for the present purposes to assume that it is a form of complexed cationic halogen and that the initial interaction is with the pi-orbitals of the six-membered cyclic vinyl ethers

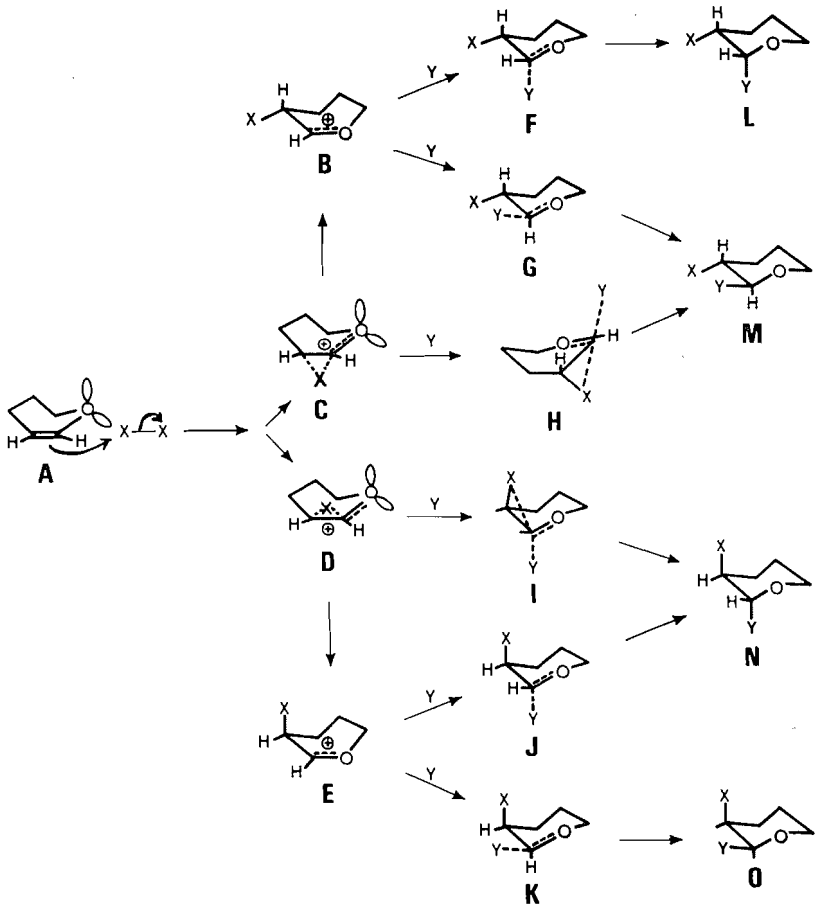
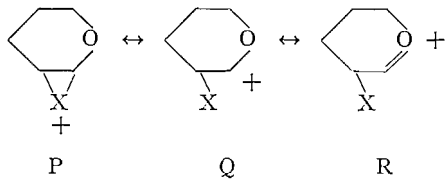
* Ref. 1.

† Products L and O are indistinguishable, as are products M and N, and both are formed as racemates. The yields are listed under the more stable conformation for these compounds.



[A (I, IV, and XVIII)] used as reactants to form cations akin to C and D. The structures of these cations can be expected to vary greatly with the nature of the halogen (X). That is, the actual structure can be expected to be a resonance hybrid of the following canonical structures.



P Q R

In view of the strong anchimeric assistance provided by the participation of iodine (3), it can be expected that structure P will contribute most strongly when X = I. On the other hand, structure P must be expected (4–6) to be of little, if any, importance when X = Cl. The cations with X = Br should be of intermediate structure and stability. De la Mare *et al.* (7) have demonstrated the migration of iodine and bromine in the reactions of hypochlorous acid with allyl iodide and allyl bromide, respectively, and pointed out that this is consistent with the facts established concerning the relative efficiency of iodine, bromine, and chlorine in neighboring group participation. Although

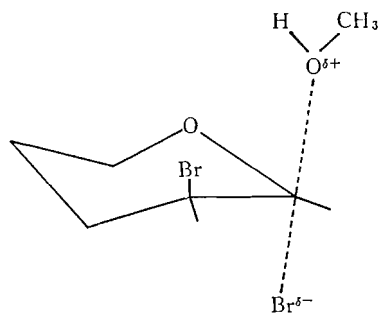
the methanolysis of tri-*O*-acetyl-2-bromo-2-deoxy-α-D-mannopyranosyl bromide proceeded without evidence for 2-bromine participation (1), the methanolysis of tri-*O*-acetyl-2-bromo-2-deoxy-α-D-talopyranosyl bromide (IX) proceeded with equal amounts of retention and inversion of the anomeric center. It is possible that the reaction proceeded, in part, with 2-bromine participation in the case of IX because formation of the 1,2-bromonium ion released the non-bonded interaction between the axial 2-bromine and the opposing axial 4-acetoxy group. Methanolysis of *trans*-2,3-dibromotetrahydropyran also appeared to proceed with extensive (50–60%) participation of the 3-bromine. Certainly, the indication is apparent that with X = Br the structure R makes an important contribution. In the absence of a contribution by structure P, the structure of the cation corresponds to Q ↔ R. The formulas for the cations B and E are considered to represent this type of ion, often referred to as an oxocarbonium ion.

The classical route for the halogenation of alkenes is to provide the *trans* adduct (8, 9), and this route is usually considered to involve cyclic halonium ions as intermediates. In cyclic systems, the diaxial adduct is *normally* formed most readily but *may* rearrange to the more stable diequatorial form (10). These aspects of the reaction have received much attention and appear to be rather well understood. Heterolytic *cis* addition of halogen to an olefin must presumably either involve the formation of an open carbonium ion as an intermediate or else proceed by way of a four-centered transition state.

The most outstanding result contained in Table I is the lack of the formation of products corresponding to structure O. The hindrance to this course of reaction cannot simply be attributed to problems inherent to *cis* addition, since *cis* addition to form the diastereoisomeric structure L was prevalent in several of the reactions. The lack of products corresponding to O must arise because either the formation of the ion E or the transition state K for its reaction with a nucleophile (or both) is unfavorable as compared to the alternate routes of reaction. That this should be the case can be appreciated on stereoelectronic grounds. Clearly, the p-orbitals of the ring-oxygen are not as well oriented for charge delocalization in ion D as in ion C. Therefore, the energy barrier should be less for the formation of ion B than that for ion E. In the absence of axial substituents at the 3- or 5-positions, an ion of structure E would be expected to react by way of transition state J rather than K, since axial approach of the nucleophile avoids interaction with the axial 2-substituent. Thus, the absence of structures corresponding to O is understandable. Structures corresponding to O were formed in the methanolysis of both the tri-*O*-acetyl-2-bromo-2-deoxy-α-D-mannopyranosyl (1) and tri-*O*-acetyl-2-bromo-2-deoxy-α-D-talopyranosyl (IX) bromides. Likely, these reactions with methanol as the solvent proceeded by way of the following transition state.



That is, in the presence of the very high concentration of methanol, some bonding of the anomeric center with methanol was established before the bromide ion had time to

depart (11). This shielding by a departing group is not present in the halogenomethoxylation reactions.

In view of the above-mentioned facts, the chlorination reactions should proceed directly to the oxocarbonium ions B and E. The ion B should form more readily and tend to accept the chloride ion by way of transition state F rather than G to form the *cis* adduct L for two reasons: (*a*) because of the anomeric effect (12), L is more stable than the anomer M and, with a negative entering group (halide ion), this effect should be felt in the transition state; and (*b*) the chloride ion most likely was formed from the chlorine molecule which made the electrophilic attack and, therefore, because of the absence of other nucleophiles in the environment, *cis* addition, by way of a process approaching a four-centered transition state, can be expected. In fact, the only products detectable in appreciable concentration (>80%) from the chlorination of both D-glucal triacetate (I) and D-galactal triacetate (IV) were those (II and V) corresponding to structure L. That the β-anomers corresponding to structure M were not first formed and rapidly anomerized seems definite, in view of the observation that tetra-*O*-acetyl-β-D-glucopyranosyl chloride was not anomerized to a detectable extent when subjected to the conditions of chlorination. Anomerization could not be detected in the bromination of D-glucal triacetate (1). The *cis* addition of nitrosyl chloride to acetylated glycals to form products corresponding to structure L has been demonstrated (13). The chlorination of 3,4-dihydropyran (XVIII) gave equal amounts of the *cis* and *trans* adducts. The course of reaction leading to the *trans* product may have resulted from a tendency of the presumably first-formed ion B to undergo conformational change before accepting the chloride ion. The energy barrier to the conformational change must be very small and, although the ion E has the chlorine in axial orientation, the charge separation (between the chlorine and the ring-oxygen) is less in E than in B. Therefore, although B must be expected to form more readily than E, the difference in stability between E and B in carbon tetrachloride solution may be small. It is possible, on the other hand, that the *trans* isomer (XX) was formed by anomerization of first-formed *cis* adduct (XIX). Unfortunately, this possibility was not examined. That the *trans* isomer is, in fact, the more stable compound was established by showing an increase in the concentration of this isomer both when the reaction mixture was heated before isolation and when the product in acetonitrile was treated with tetraethylammonium chloride. The formation of the *cis* adduct (XIX) in a concentration greater than its presence in equilibrium mixture (XIX $\rightleftarrows$ XX) suggests that, as found for the chlorinations of the acetylated glycals, the ion corresponding to B was formed more readily than that represented by E. That is, it is improbable that the less stable isomer (XIX) would have formed to an extent greater than its presence in the equilibrium mixture, had its cationic intermediate (*B*) not formed more readily.

The anomeric effect (12) favors the conformations for XIX and XX wherein the 2-chlorine is in axial orientation. In view of this effect and the conformational properties of *trans*-1,2-dichlorocyclohexane (14), it was not surprising to find (n.m.r. evidence) that the compounds in fact possessed these conformations.

A greater tendency for *trans* addition can be expected to occur in brominations than in chlorinations both for steric reasons (greater non-bonding interactions between the gauche halogens) and the established greater favorability of cyclic bromonium ions (corresponding to structures C and D). The results of the bromination reactions agree with this expectation. Thus, it is seen that, for the brominations, the rates of *trans* addition to products of structure N are close to those of *cis* addition to products corresponding to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

L. Unless the cyclic bromonium ion corresponding to C is considerably more stable than the oxocarbonium ion B, reaction initiated by formation of C would be expected to proceed by way of B to give the *cis* adduct corresponding to L. This would follow for the reasons outlined above with regard to the routes of the chlorination reactions and the fact that *trans* addition of the bromine by way of the transition state H represents a sterically unfavorable route of reaction. It is probably for these reasons that *cis* addition, to provide the products corresponding to L, occurred. However, in contrast to the chlorinations, substantial yields of the diaxial *trans* dibromides were formed in the brominations. These results suggest that, for bromine, cyclic bromonium ion intermediates are formed and, in view of the favorability of the transition state I, this route of reaction is about as favorable as that by way of ion B. The formation of these products by way of oxocarbonium ions corresponding to E seems unlikely, in view of the absence of products corresponding to O in all of the reactions studied. It must be admitted, however, that there is little basis for distinguishing between the transition states I and J.

Except for the chloromethoxylations, the halogenomethoxylation reactions using methanol as solvent must lead directly to strongly solvated (complexed) intermediate cations which can be represented by structures F to K with Y = CH_3OH. Since the formation of these complexes is expected to begin with the attack on the double bond by the halogen, the products of *trans* addition should form most readily, and this was in fact observed in all cases; *cis* addition was extensive only in special cases, namely, chloromethoxylations and the bromomethoxylation of D-galactal triacetate. That *cis* addition was prevalent in the chloromethoxylations can, of course, be attributed to the instability of chloronium ions and the consequent tendency for the reactions to proceed directly by way of oxocarbonium ions. Reactions by way of ion B should be more important, as was observed, in the chloromethoxylation of D-galactal triacetate than for D-glucal triacetate, since in the former case the oxocarbonium ion E has the axial chlorine opposing the axial acetoxy group at the 4-position. This situation would also influence the bromomethoxylations of these compounds and promote *cis* addition to D-galactal triacetate.

The formation of appreciable amounts of the diequatorial products corresponding to structure M in the halogenomethoxylations is in sharp contrast to their absence in the products of the halogenations. As already mentioned, solvation of the ion as it is forming is probably mainly responsible for this result. It should be noted, however, that the intermediates F and G must differ less in stability with Y = CH_3OH than with Y = X^-, since in the former case the oxygen in Y must possess a partial positive charge and, therefore, stabilization of F over G through the anomeric effect is precluded.

The tendency to form *trans* adducts by way of the intermediates H and I should increase with increasing stability for the cyclic halonium ion and, therefore, increase as the halogen is changed from chlorine to bromine and from bromine to iodine. The results are seen to agree with this expectation. The formation of the *trans* adducts only in the iodomethoxylations is not surprising in view of the stability of the cyclic iodonium ions, and presumably these reactions proceeded exclusively by way of the intermediates H and I. For reasons already discussed, the preference for the route leading to the diaxial product is not surprising. The slightly greater preference for this route of reaction found in the iodomethoxylation of D-galactal triacetate over that observed for D-glucal triacetate likely is due to a shielding by the axial 4-acetoxy group in D-galactal triacetate of the approach by methanol to form the intermediate H. The result could, of course, also be rationalized by assuming a stabilization of the iodonium ion of structure D by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Coulombic interaction of the positive iodine with the axial 4-acetoxy group in the case of the reaction with D-galactal triacetate. This interpretation appears less attractive in view of the results obtained in the bromomethoxylations. The iodomethoxylation of 3,4-dihydropyran gave the *trans* adduct exclusively. Of course, there was no possibility of distinguishing between the products corresponding to M and N since, in this case, these products are merely conformers.

In conclusion, although the results of this study cannot be interpreted with precision, it is seen that the stereochemical routes of the reactions studied showed trends, when the halogen, the olefin, and the solvent were changed, which can be rationalized by taking into account (*a*) the expected relative stabilities for iodonium, bromonium, and chloronium ions, (*b*) the expectation that the axially oriented p-orbital of the ring-oxygen is more favorably disposed for participation in delocalization of developing charge at the anomeric center than is the equatorially oriented p-orbital, (*c*) the expectation that axial attack at the anomeric center is more favorable for reasons of the anomeric effect by a negative ion than by a neutral molecule, and (*d*) the expectation that the route of the reaction is influenced by whether or not the intermediate cations can be solvated (complexed) by a nucleophile as they are formed. The display of the stereoelectronic demands for ring-oxygen participation is of obvious importance to an understanding of reactions at the anomeric center of glycosidic structures.

EXPERIMENTAL

Halogenations

A stirred solution of 26 mmoles of the acetylated glycal in 50 ml of carbon tetrachloride was cooled in an ice bath and protected from light. Bromine was added dropwise, or chlorine was bubbled in, until a color caused by excess halogen was present. After the solution had stood for a further 15 min, air was bubbled into the solution to remove the excess halogen, and the solvent was evaporated *in vacuo* at 40°. In all cases yields were better than 95% and samples were checked by nuclear magnetic resonance spectroscopy (n.m.r.) before work-up to ensure that the isolation procedures had not changed the product.

Tetra-*O*-acetyl-β-D-glucopyranosyl chloride (17) was recovered unchanged when subjected to chlorination under these conditions.

Methanolysis of the Acetylated 2-Deoxy-2-halogenoglycosyl Halides

The dihalide (41 mmoles) was dissolved in 50 ml of dry methanol and, after the addition of dry freshly prepared silver carbonate (0.2 mole), the mixture was stirred until a portion of the filtered reaction mixture failed to give a precipitate with ethanolic silver nitrate—usually 1 to 1.5 h. The silver salts were removed by filtration through Celite and the filter cake was thoroughly washed before the filtrate was evaporated to dryness. Decolorization of an ethanolic solution with charcoal was usually necessary and, finally, a chloroform solution of the product was eluted through a short column of silicic acid. Samples of the product so obtained were analyzed by n.m.r. before purification of the components was attempted.

Halogenomethoxylations

The acetylated glycal (37 mmoles) was dissolved in 250 ml of dry methanol containing 8.76 g (52 mmoles) of silver acetate. The mixture was cooled to 0° and 52 mmoles of bromine or iodine was added over a period of 10 min with stirring. Chlorine was bubbled into the reaction mixture until a starch–iodide paper test on the effluent gases indicated an excess. After an additional 20 min, the silver salts were removed by filtration and washed with methanol. The filtrate was evaporated *in vacuo* to a residue which was taken up in chloroform. The chloroform solution was washed with aqueous sodium bicarbonate and sodium thiosulfate solutions, and dried by passage through chloroform-wetted filter paper. Evaporation then produced clear syrups or oils, usually in better than 90% yield, and in each case a portion of the material was reserved for n.m.r. analysis before isolation or characterization of the components was attempted.

Chlorination of D-Glucal Triacetate (I)

A 92% yield of a colorless syrup, $[\alpha]_D$ +152.7° (*c*, 1.64, in chloroform), of nearly pure tri-*O*-acetyl-2-chloro-2-deoxy-α-D-glucopyranosyl chloride (II) was obtained. The n.m.r. spectrum of the syrup (which resisted crystallization for over 1 year) recovered from an ether solution which had been left at room temperature for 1 week was the same as that of the freshly prepared material (Fig. 1). The crystalline product melted at 96–97°, $[\alpha]_D$ +218° (*c*, 2, in chloroform), in good agreement with the constants reported by Fischer *et al.* (17) for their crystalline "triacetyl glucal dichloride", m.p. 92–94°, $[\alpha]_D$ +173.6° (acetylene tetrachloride). A comparison of the spectra in Fig. 1 suggested that the chlorination gave II in 80–90% yield.

For personal use only.

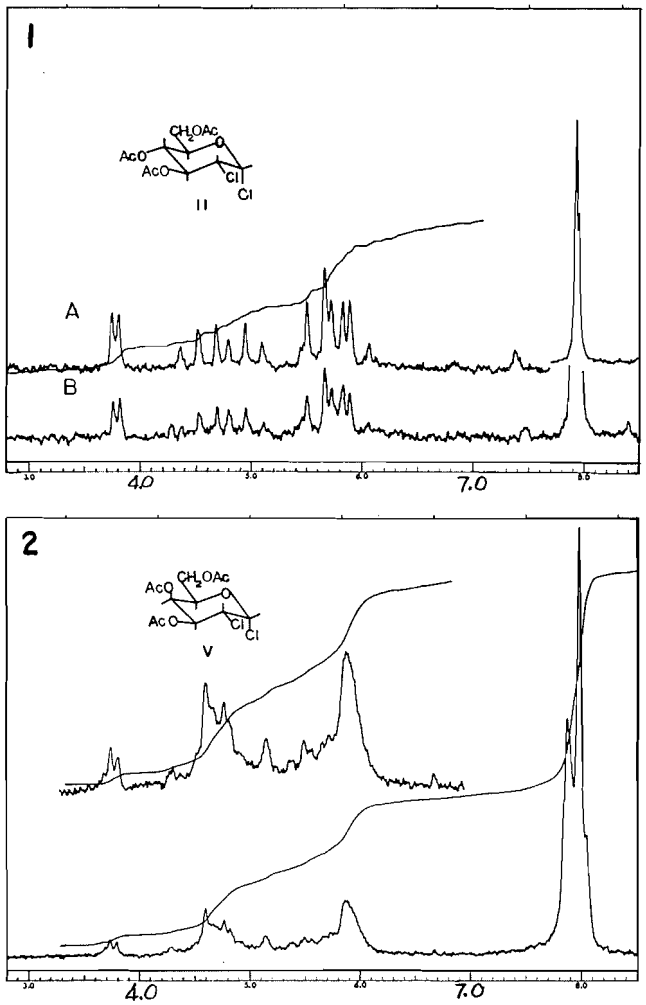

FIG. 1. The n.m.r. spectrum (B) at 60 Mc.p.s. of the product of the chlorination of D-glucal triacetate (I) in carbon tetrachloride. Spectrum A is that of pure tri-*O*-acetyl-2-chloro-2-deoxy-α-D-glucopyranosyl chloride (II).

FIG. 2. The n.m.r. spectrum at 60 Mc.p.s. of the product (V) of the chlorination of D-galactal triacetate (IV) in carbon tetrachloride.

Methyl 2-Chloro-2-deoxy-β-D-glucopyranoside Triacetate (III) (1)

Methanolysis of the syrupy dichloride (II) yielded a syrup in 86% yield. The n.m.r. spectrum indicated the formation of only one methyl glycoside. Crystalline material was readily deposited from ethanol and was characterized by mixed melting point determination with an authentic sample (1).

Reactions of D-Galactal Triacetate (IV)

(a) Chlorination.—A 96% yield of a colorless syrup which resisted crystallization was obtained, $[\alpha]_D$ +71.5° (*c*, 3.6, in chloroform). The n.m.r. spectrum (Fig. 2) required the product to be at least 80% pure tri-*O*-acetyl-2-chloro-2-deoxy-α-D-galactopyranosyl chloride (V).

Methanolysis of the dichloride (V) gave a near quantitative yield of a crystalline product, which was purified by recrystallization from ethanol, m.p. 127–129°, $[\alpha]_D$ +33.3° (*c*, 1.5, in chloroform).

Anal. Calcd. for $C_{13}H_{19}O_8Cl$: C, 46.15; H, 5.62. Found: C, 46.02; H, 5.38.

The n.m.r. spectrum of the compound (Fig. 3) required it to be methyl tri-*O*-acetyl-2-chloro-2-deoxy-β-D-galactopyranoside (VI). Deacetylation with 5% triethylamine in 50% aqueous methanol gave methyl 2-chloro-2-deoxy-β-D-galactopyranoside, m.p. 143.5–144.5°, $[\alpha]_D$ +11.0° (*c*, 1.06, in methanol).

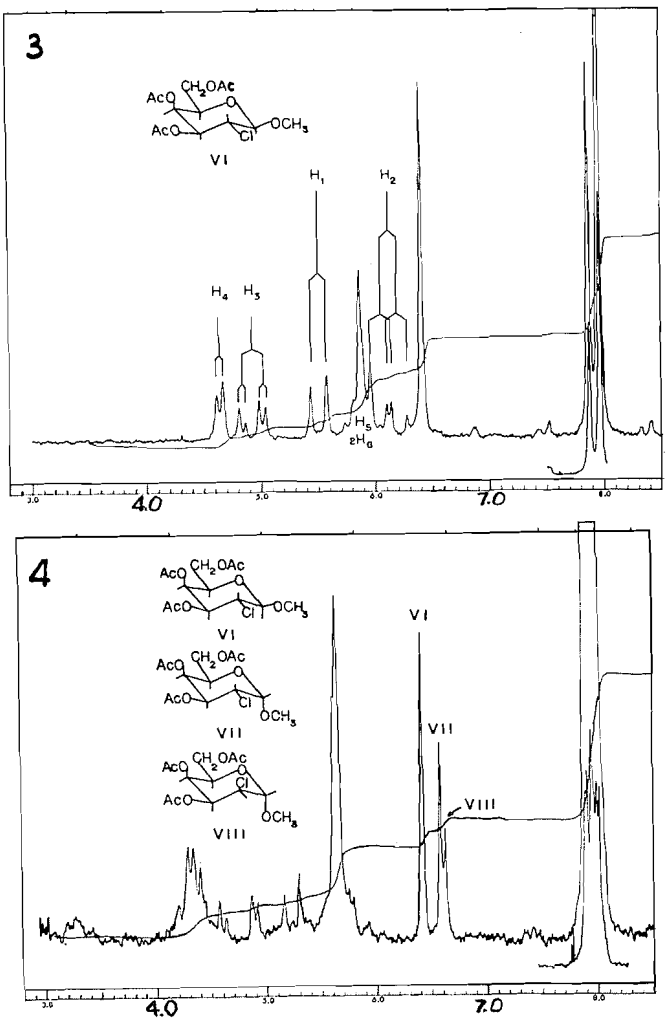

FIG. 3. The n.m.r. spectrum at 60 Mc.p.s. of methyl tri-*O*-acetyl-2-chloro-2-deoxy-β-D-galactopyranoside (VI) in chloroform.

FIG. 4. The n.m.r. spectrum in pyridine at 60 Mc.p.s. of the product of the chloromethoxylation of D-galactal triacetate.

(b) Chloromethoxylation.—The n.m.r. spectrum (Fig. 4) of the syrupy product indicated the presence of three methyl glycosides, in view of the signals for methoxy-group protons at τ 6.42, 6.58, and 6.62. The relative intensities of these signals were 53:39:8, respectively.

The syrup was dissolved in ethanol and, on standing overnight at 4°, the solution deposited 1.75 g (14% yield) of methyl tri-*O*-acetyl-2-chloro-2-deoxy-β-D-galactopyranoside (VI), identified by direct comparison.

The mother liquor from the above crystallization was evaporated to a syrup, 3.0 g of which was preparatively chromatographed on six 46 cm × 57 cm sheets of Whatman 3MM paper impregnated with dimethyl sulfoxide (18) and eluted with Skellysolve B for 7 h. Although separation was not complete, the fastest-moving zone provided 0.64 g of a syrup, the n.m.r. spectrum of which was devoid of methoxy-group signal at τ 6.42. When an ether – Skellysolve B solution of the material was refrigerated for several months, crystals were deposited, m.p. 86–88°, $[\alpha]_D$ +73.8° (*c*, 1.5, in chloroform).

Anal. Calcd. for $C_{13}H_{19}O_8Cl$: C, 46.15; H, 5.62. Found: C, 46.56; H, 5.65.

The n.m.r. spectrum of the compound showed absorption for the anomeric proton at τ 4.90 and methoxy-group protons at τ 6.58. The substance was methyl tri-*O*-acetyl-2-chloro-2-deoxy-α-D-galactopyranoside (VII), since these signals were present in the syrupy product obtained when the β-anomer was treated with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

titanium tetrachloride in chloroform under the conditions previously described (1). The extent of anomerization achieved was 37%, based on the n.m.r. spectrum of the product.

Deacetylation of VII gave a crystalline product, methyl 2-chloro-2-deoxy-α-D-galactopyranoside, m.p. 145–147°, $[\alpha]_D$ +75.4° (*c*, 0.52, in methanol).

Examination of the syrupy residue from the isolation of VII by n.m.r. spectroscopy showed the substance to be a 1:1 mixture of VII and the methyl glycoside which produced the signal for methoxy-group protons at τ 6.62 in the original reaction product. The n.m.r. spectrum of the mixture in chloroform at 100 Mc.p.s. showed two doublet signals in the region characteristic for anomeric protons of methyl glycosides. The doublet at τ 4.90 with a spacing of 3.8 c.p.s. arose from VII. The doublet of equal intensity at τ 4.88 with a spacing of 1.1 c.p.s. must, therefore, have arisen either from methyl tri-*O*-acetyl-2-chloro-2-deoxy-α-D-talopyranoside (VIII) or the β-anomer. The α-configuration was assigned to this product of the chloromethoxylation in view of the position of the signal for the methoxy group and the high specific rotation of the syrup, +67.8° (*c*, 2.22, in chloroform). Since VII has a rotation of 73.8°, the other isomer in the 1:1 mixture must have a rotation of 61.8°. This rotation agrees well with that expected on the basis of the rotation of α-D-talopyranose pentaacetate, +70.2 (*c*, 4, in chloroform) (19). Also, the rotation agrees well with that reported below for methyl tri-*O*-acetyl-2-bromo-2-deoxy-α-D-talopyranoside (XI).

(c) Bromination.—An 88% yield of colorless syrupy product was obtained. Integration of the signals for anomeric protons in the n.m.r. spectrum of a solution in deuterochloroform at τ 3.20 and 3.46 with spacings of less than 1 and of 4.0 c.p.s., respectively, required the formation of two isomers in equal amounts. In view of the chemical shifts and spacings for these signals and the expectation that for both isomers the bromine at the 1-position is axially oriented, the compounds are assigned the α-D-*talo* (IX) and α-D-*galacto* (X) configurations, respectively.

Methanolysis of the mixture of dibromides gave a 90% yield of syrup which had signals for three different methoxy groups in the n.m.r. spectrum measured in chloroform solution at 100 Mc.p.s. The signals were at τ 6.39, 6.42, and 6.58 and their relative intensities were 23:50:27, respectively. A 3.0-g portion of the syrup was chromatographed on six 46 cm × 57 cm Whatman 3MM paper impregnated with dimethyl sulfoxide (18) and the chromatograms were developed with Skellysolve B for 7 h. Two overlapped zones were located by spraying side and center cuts with alkaline silver nitrate in the usual manner. The region of overlap was discarded and the remaining strips were extracted with chloroform. The chloroform solution was washed with water and percolated through a short column of silicic acid to remove dimethyl sulfoxide. Evaporation of the extract of the faster-moving zone gave a colorless syrup, $[\alpha]_D$ +65.6° (*c*, 1.8, in chloroform), which failed to crystallize. The n.m.r. spectrum shown in Fig. 5 requires the substance (XI) to be a virtually pure compound. A portion of the substance dissolved in a 10:9:1 mixture of methanol–water–triethylamine, respectively, and was hydrogenolyzed at room temperature and atmospheric pressure using 5% palladium-on-charcoal as catalyst. The product (XIV) resisted crystallization and was identified by paper chromatographic comparison with an authentic sample of methyl 2-deoxy-α-D-galactopyranoside prepared in the following manner. Crystalline methyl 4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside, m.p. 177–178°, $[\alpha]_D$ +122° (*c*, 1.05, in chloroform), was prepared following the procedure described by Tamm and Reichstein (20). Hydrogenolysis in ethanol using 5% palladium-on-charcoal gave a syrup with the specific rotation, +69.5° in methanol, expected (21) for methyl 2-deoxy-α-D-galactopyranoside. The R_f value on Whatman No. 1 paper, using the *n*-butanol – water – ethanol (5:4:1) system, was 0.46. Treatment of D-galactal with 3% methanolic hydrogen chloride (21) gave a product with two components, the R_f values of which were 0.39 and 0.46. Hydrogenolysis of crystalline methyl 2-bromo-2-deoxy-β-D-galactopyranoside (XII), under the conditions described for the hydrogenolysis of XI, gave a product, methyl 2-deoxy-β-D-galactopyranoside, with a R_f value of 0.39. Therefore, compound XIV is methyl 2-deoxy-α-D-galactopyranoside.

The signal for the anomeric proton in the n.m.r. spectrum of XI (Fig. 5) has a spacing of 1.5 c.p.s. This spacing is incompatible with the α-*galacto* configuration, since a spacing of 3.5–4 c.p.s. is expected for this configuration. Furthermore, treatment of methyl tri-*O*-acetyl-2-bromo-2-deoxy-β-D-galactopyranoside (XII) with titanium tetrachloride in chloroform as previously described (1) gave rise to the α-anomer (XV) of XII, and this compound (XV) had the signal for its methoxy group at τ 6.54 in contrast to the position of τ 6.58 for the methoxy-group signal of XI. This small chemical shift was readily established by examining the compounds (XI and XV) together at 100 Mc.p.s. Therefore, compound XI is methyl tri-*O*-acetyl-2-bromo-2-deoxy-α-D-talopyranoside.

The slower-moving zone in the above-mentioned preparative paper chromatogram provided a syrup, 1.69 g, which deposited, from ethanol, 0.62 g of a crystalline compound. After two recrystallizations from ethanol, the melting point was 134–135°, $[\alpha]_D$ +33.2° (*c*, 1.37, in chloroform).

Anal. Calcd. for $C_{13}H_{19}O_8Br$: C, 40.73; H, 4.97. Found: C, 40.98; H, 4.88.

The n.m.r. spectrum of the compound in chloroform was completely first order at 100 Mc.p.s., and the signals for the 1-, 2-, 3-, and 4-protons were definitely assigned through double irradiation experiments. The coupling constants, $J_{1,2}$ = 8.5 c.p.s. and $J_{2,3}$ = 10.3 c.p.s., are consistent only with the structure of methyl tri-*O*-acetyl-2-bromo-2-deoxy-β-D-galactopyranoside (XII). The position of the methoxy-group signal was τ 6.42.

Hydrogenolysis, as described above, of the syrup in the mother liquor from the isolation of XII gave

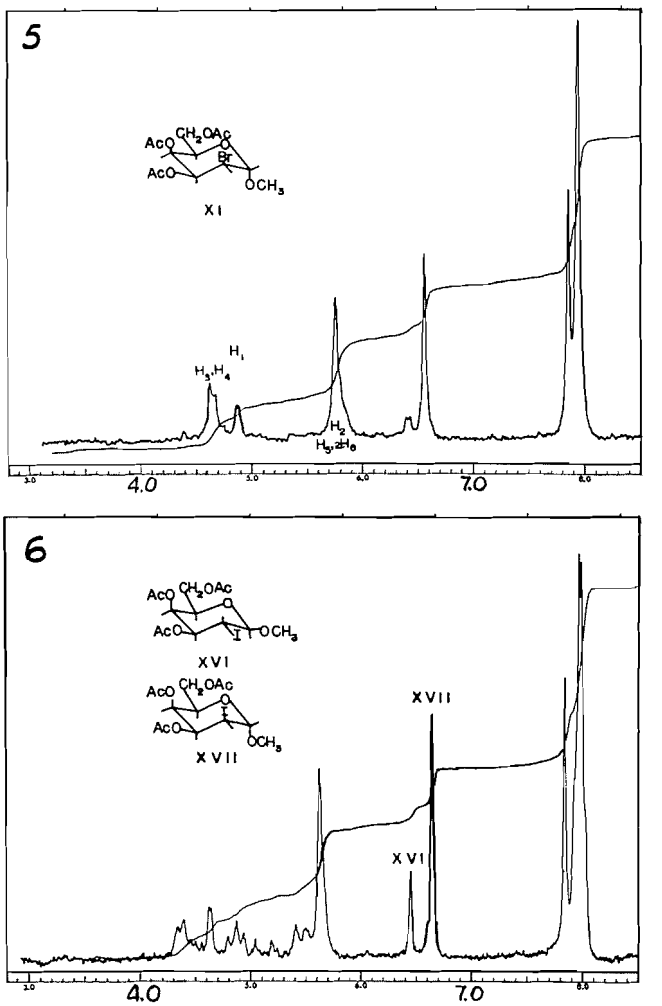

FIG. 5. The n.m.r. spectrum at 60 Mc.p.s. of syrupy methyl tri-*O*-acetyl-2-bromo-2-deoxy-α-D-talopyranoside (XI) in chloroform.

FIG. 6. The n.m.r. spectrum at 60 Mc.p.s. of a chloroform solution of the product formed on the iodomethoxylation of D-galactal triacetate (IV).

only methyl 2-deoxy-β-D-galactopyranoside, as judged by paper chromatographic examination of the product as described above. This observation, together with the chemical shift of the methoxy group, τ 6.39, for the third isomer formed in the methanolysis, requires the compound to be methyl tri-*O*-acetyl-2-bromo-2-deoxy-β-D-talopyranoside (XIII).

The assignments of the *talo* configuration to compounds XI and XIII agree with the abundance of these compounds expected in the product from the amount of IX in the dibromide mixture.

(d) Bromomethoxylation.—A 90% yield of a colorless syrupy product was obtained. The n.m.r. spectrum in chloroform solution, measured at 100 Mc.p.s., showed the presence of three methyl glycosides with the signals for the methoxy groups at τ 6.41, 6.54, and 6.58. The relative intensities were 37:11:52, respectively. It was concluded, therefore, that the product was a mixture of compounds XII, XV, and XI in the amounts indicated above, respectively. In agreement with this conclusion, deacetylation of the product for chromatography on a cellulose column (22) using *n*-butanol as irrigant followed by reacetylation of the fractions obtained provided pure samples of compounds XI and XII. Deacetylation of the product of the bromomethoxylation and paper chromatography using *n*-butanol – water – ethanol (5:4:1) (23) gave three spots with R_f values of 0.63, 0.83, and 0.89. The deacetylated forms of X and XI were shown to give spots with R_f values of 0.63 and 0.89. The deacetylated product of the titanium tetrachloride catalyzed anomerization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of XI gave spots with R_f values of 0.63 and 0.83. Thus, the assignments of structure based on the n.m.r. spectra were confirmed.

(e) Iodomethoxylation.—A quantitative yield of a syrupy product was obtained. The n.m.r. spectrum is shown in Fig. 6. The relative intensities of the methoxy-group signals at τ 6.42 and τ 6.75 established a 19:81 ratio for the two components in the product. The compounds were readily separated by preparative paper chromatography as described above using dimethylsulfoxide-impregnated Whatman 3MM paper. The well-separated zones were readily detected by exposure to ultraviolet light. Chromatography of 2.0 g of the reaction product gave 0.21 g of the slower-moving component and 0.97 g of the more mobile substance.

The minor component of the reaction mixture crystallized from ethanol and, after two recrystallizations from ethanol, melted at 125–126°, $[\alpha]_D$ +14° (*c*, 4.1, in chloroform).

Anal. Calcd. for $C_{13}H_{19}O_8I$: C, 36.28; H, 4.42. Found: C, 36.16; H, 4.54.

The n.m.r. spectrum of the compound in chloroform gave the signal for the anomeric proton at τ 5.40, spacing 8.5 c.p.s. The methoxy-group signal was at τ 6.42. The spectrum was very similar to that of the *β-galacto* bromide XII and was therefore assigned the structure of methyl tri-*O*-acetyl-2-deoxy-2-iodo-β-D-galactopyranoside (XVI). Deacetylation gave a syrup, $[\alpha]_D$ +34.6° (*c*, 0.47, in methanol), and hydrogenolysis in the usual manner gave methyl 2-deoxy-β-D-galactopyranoside.

The major component of the iodomethoxylation failed to crystallize. However, the n.m.r. spectrum shown in Fig. 7 required the syrup to be a pure compound, $[\alpha]_D$ +27.7° (*c*, 3.13, in chloroform). The n.m.r. spectrum at 100 Mc.p.s. was first order for the ring protons and provided the following parameters: H_1, τ 4.77, $J_{1,2}$ = 1.1 c.p.s.; H_2, τ 5.80, $J_{2,3}$ = 5.3 c.p.s.; H_3, τ 5.13, $J_{3,4}$ = 3.9 c.p.s.; H_4, τ 4.61, $J_{4,5}$ = 1.1 c.p.s.; CH_3O, τ 6.75. Deacetylation gave a syrup, $[\alpha]_D$ +57.0° (*c*, 2.4, in methanol), and hydrogenolysis provided methyl 2-deoxy-α-D-galactopyranoside In view of these data, the compound was assigned the structure of methyl tri-*O*-acetyl-2-deoxy-2-iodo-α-D-talopyranoside (XVII).

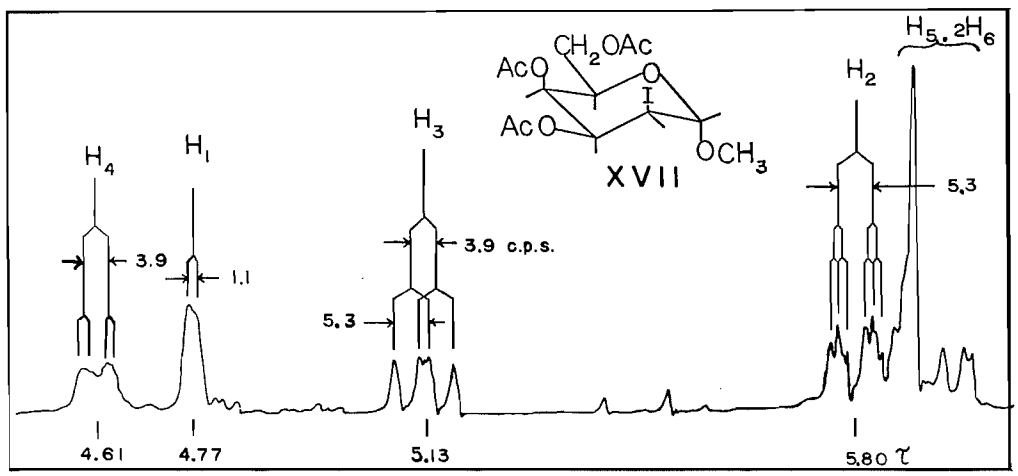

FIG. 7. The n.m.r. spectrum at 100 Mc.p.s. of syrupy methyl tri-*O*-acetyl-2-deoxy-2-iodo-α-D-talopyranoside (XVII).

Reactions of 3,4-Dihydropyran (XVIII)

(a) Chlorination (24, 25).—A product, b.p. 37° at 38 mm, n_D^{23} = 1.4935, was obtained in near quantitative yield. The n.m.r. spectrum is shown in Fig. 8A. The spectrum at 100 Mc.p.s. showed the signal at τ 3.97 to be a multiplet which could not have arisen from a single kind of anomeric proton. The product (5 g) was diluted with 5 ml of dry acetonitrile saturated with tetraethylammonium chloride. The material was isolated after 1.5 h. Prolonged treatment caused the appearance of a new signal at τ 3.4, probably as a result of dehydrochlorination. The n.m.r. spectrum of the product resulting from this treatment is shown in Fig. 8B. As expected, the structure of the signal for anomeric proton was changed, and the simpler spectrum suggested that the signal now closely represented a single kind of anomeric proton. It could therefore be concluded that the chlorination produced about equal amounts of the *cis* and *trans* adducts (XIX and XX). Both Crombie and Harper (24) and Paul (25) assumed that their preparations using ether as solvent contained only the *trans* isomer. When their preparations were repeated, it was found that the same mixture was formed as when carbon tetrachloride was the solvent. When a solution of 3,4-dihydropyran in carbon tetrachloride was saturated at 0° with chlorine and the mixture then kept at 78° for 4 h in a sealed tube (26), the product obtained was identical (n.m.r. spectra) with that resulting from the equilibration using

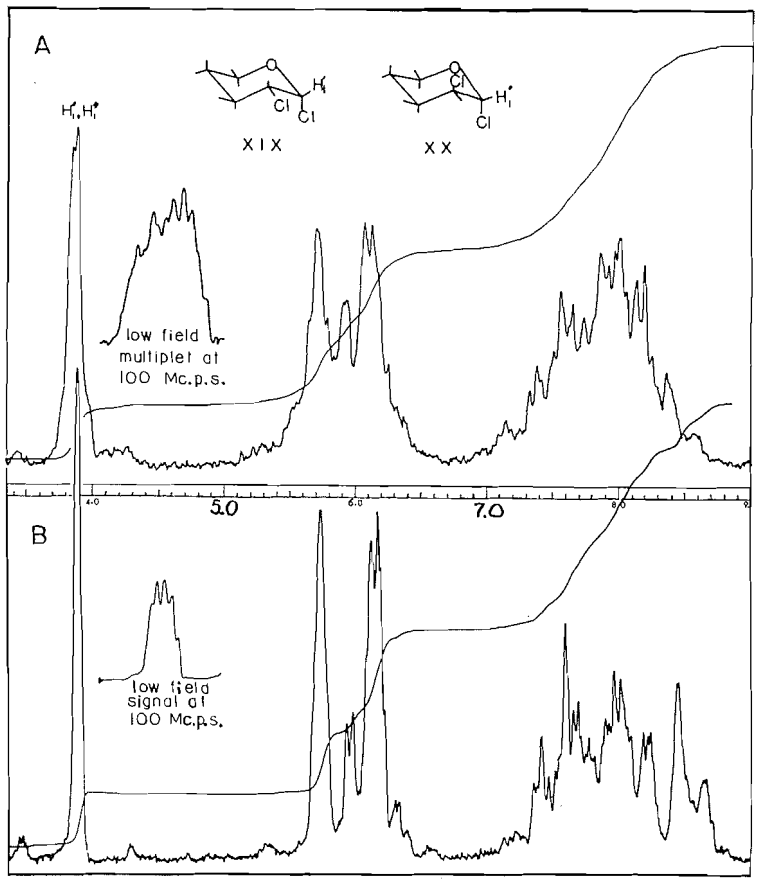

FIG. 8. The n.m.r. spectra of mixtures of the *cis* (XIX) and *trans* (XX) isomers for 2,3-dichlorotetrahydropyran. The 60 Mc.p.s. spectra were measured on the neat liquids. The 100 Mc.p.s. spectra were determined using solutions in deuterochloroform. A. The product formed on chlorination of 3,4-dihydropyran in carbon tetrachloride at 0°. B. The equilibrated mixture of compounds XIX and XX.

tetraethylammonium chloride. It should be noted that the rules for naming heterocyclic structures require that the anomeric proton in these derivatives of tetrahydropyran be designated the 2-proton.

Reaction of the product of the chlorination of 3,4-dihydropyran (XVIII) (25) with methanol gave a product with the n.m.r. spectrum shown in Fig. 9. The spectrum required the product to be a mixture of the *cis*- and *trans*-3-chloro-2-methoxytetrahydropyrans (XXI and XXII, respectively), and the relative intensities of the signals at τ 5.42 and 5.57, which must arise from anomeric 2-protons, required the isomers to be present in the same relative amounts (1:1) as the dichlorides in the starting material. It seemed probable, therefore, that both of the 2,3-dichlorides underwent methanolysis, with inversion or retention of configuration. In view of the routes followed in the methanolyses of compounds II and V, inversion was expected and was established by an examination of the route of the methanolysis of the mixture of dichlorides obtained in the anomerization reaction. That the predominant dichloride in this product possessed the 2,3-*trans* configuration (XX) was established by n.m.r. investigation of a chloroform solution at 100 Mc.p.s. with double irradiation to determine the magnitudes of the $J_{2,3}$, $J_{3,4}$, and $J_{3,4'}$ coupling constants. Irradiation at τ 1.67 upfield from the anomeric signal at τ 3.97 resulted in a collapse of the signal from a closely spaced quintet to a triplet. Therefore, the signal at τ 5.64 arose from the proton at the 3-position and the coupling constant was about 1.5 c.p.s. Therefore, H_2 and H_3 were in gauche relationship and, from the magnitude of the coupling constant, most likely (14) in the *trans*-diequatorial conformation. In view of the anomeric effect (12), the 2-hydrogen must be equatorial. That the 3-hydrogen is also equatorial was established by the magnitudes of $J_{3,4}$ and $J_{3,4'}$. Irradiation at both τ 1.57 and 1.97 upfield from the signal for the 3-proton at τ 5.64 caused collapse of the latter signal, and it could be concluded, therefore, that the signals for the 4-axial and 4'-equatorial protons were at τ 7.21 and 7.61, respectively. The changes in the structure of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

3-proton signal in these double irradiation experiments required both protons at the 4-position to be coupled to an extent of about 3.2 c.p.s. with the 3-proton. Therefore, the thermodynamically more stable 2,3-dichlorotetrahydropyran has the 1,2-*trans* configuration (XX) and prefers the conformation wherein both chlorines are axial.

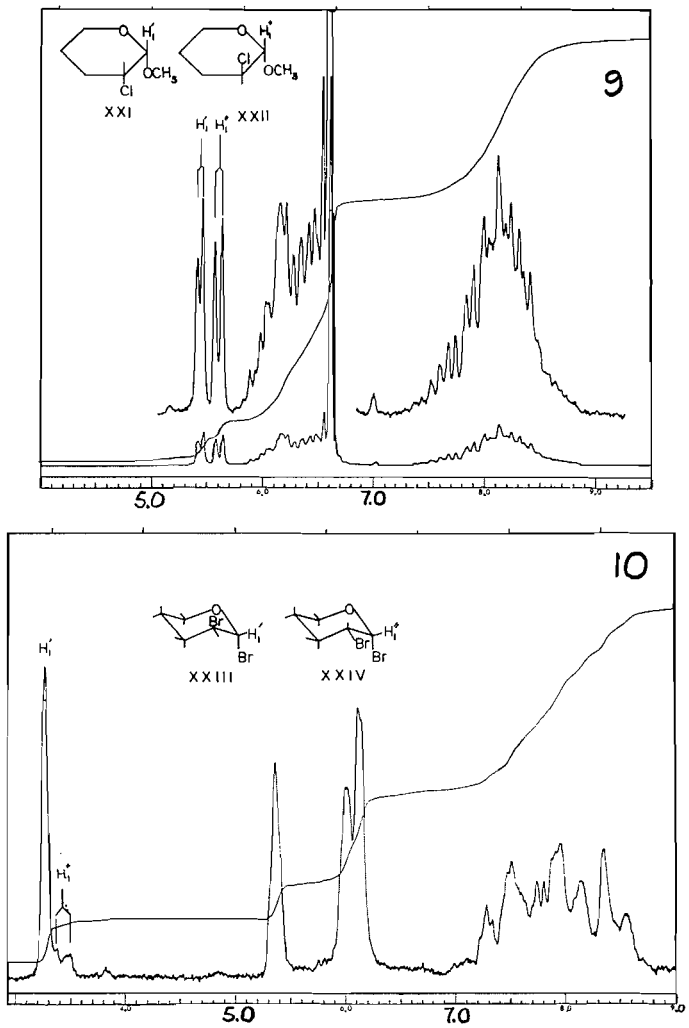

FIG. 9. The n.m.r. spectrum at 60 Mc.p.s. of the product (no solvent) formed on methanolysis of a 1:1 mixture of *cis*- and *trans*-2,3-dichlorotetrahydropyran (XIX and XX, respectively).

FIG. 10. The n.m.r. spectrum at 60 Mc.p.s. of the product (no solvent) formed on the bromination of 3,4-dihydropyran (XVIII).

Methanolysis of the equilibrated mixture of dichlorides gave a 7:3 mixture of the *cis* (XXI) and *trans* (XXII) isomers of 3-chloro-2-methoxytetrahydropyran, if one judges from the relative intensities of the signals for anomeric protons at τ 5.42 and 5.57 with spacings of 3.0 and 4.0 c.p.s., respectively. If one assumes inversion of the anomeric center in the methanolysis, the product would contain 70% of the *cis*-3-chloro-2-methoxytetrahydropyran (XXI), and the equilibrated mixture of dichlorides was therefore a 70% pure preparation of the 2,3-*trans* isomer (XX).

On this basis, the 2,3-*cis* protons are coupled to an extent of about 3.0 c.p.s. The larger coupling constant, 4.0 c.p.s., would then be associated with the 2,3-*trans* isomer and presumably arose from contributions by the compound in both the diaxial and diequatorial conformations. This conclusion is in agreement with the n.m.r. properties of the *trans*-3-bromo-2-methoxy (XXV) and *trans*-3-iodo-2-methoxy (XXVII) derivatives of tetrahydropyran to be described later on.

For personal use only.

(b) Chloromethoxylation.—The reaction gave a 93% yield of a 1:3 mixture of the *cis* (XXI) and *trans* (XXII) isomers of 3-chloro-2-methoxytetrahydropyran, respectively, as indicated by the relative intensities of the methoxy-group signals in the n.m.r. spectrum.

(c) Bromination (27).—A quantitative yield was obtained of a product, b.p. 86° at 10 mm, $n_D^{23} = 1.4642$, with the n.m.r. spectrum shown in Fig. 10. The relative intensities of the signals for anomeric protons at τ 3.24 and 3.45 required the isomer with $J_{2,3}$ less than 1 c.p.s. to be formed in 89% yield. The structure of the rather sharp signal at τ 5.36 for the 3-proton of this isomer required that the 3-proton be weakly coupled with both protons at the 4-position. Therefore, the 3-proton is in equatorial orientation and, since the 2-proton is undoubtedly also in equatorial orientation (anomeric effect), the main product of the reaction was the 2,3-*trans* isomer (XXIII). The spacing of 3.0 c.p.s. for the signal of the anomeric proton of the second isomer is that expected for the 2,3-*cis* isomer (XXIV).

Methanolysis of the mixture of dibromides proceeded in 86% yield to a product, b.p. 161° at 723 mm, 78° at 10 mm; $n_D^{23} = 1.4841$. The relative intensities of the two signals for anomeric proton (Fig. 11) at τ 5.45 (spacing 2.7 c.p.s.) and τ 5.54 (spacing 3.9 c.p.s.) required the product to consist of a 2:3 mixture of the isomeric 3-bromo-2-methoxytetrahydropyrans. The n.m.r. spectrum of the mixture in acetonitrile saturated with tetra-*n*-butylammonium bromide showed spacings of 2.7 and 5.0 c.p.s. for the signals of the anomeric protons (see Fig. 11). The change in the spacing of the signal for the anomeric proton of the major component of the mixture required it to be the 2,3-*trans* isomer (XXIII). If one assumes that the 1,2-*cis*-dibromide (XXIV) reacted completely with inversion, it followed that the 1,2-*trans*-dibromide (XXIII) reacted to an extent of 50–60% with retention of configuration.

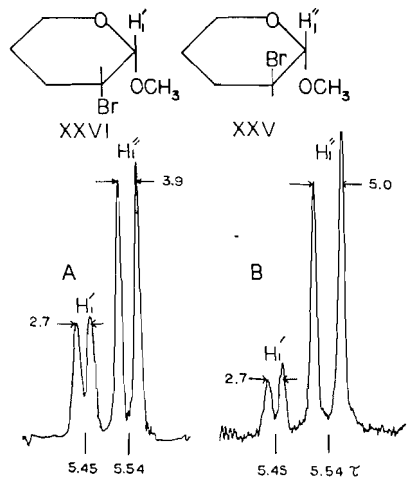

FIG. 11. The n.m.r. signals at 100 Mc.p.s. for the anomeric protons of the mixture of 3-bromo-2-methoxytetrahydropyrans formed on the methanolysis of a 9:1 mixture of the *trans* (XXIII) and *cis* (XXIV) 2,3-dibromotetrahydropyrans, respectively. A. In deuterochloroform. B. In acetonitrile saturated with tetra-*n*-butylammonium bromide.

(d) Bromomethoxylation.—A near-quantitative yield was obtained of an oily product with the physical constants reported above for the mixture of 3-bromo-2-methoxytetrahydropyrans. The n.m.r. spectrum of the mixture (100 Mc.p.s.) showed the presence of a 9:1 mixture of the *trans* (XXV) and *cis* isomers (XXVI), respectively.

(e) Iodomethoxylation.—A product which was distilled under vacuum, b.p. 84° at 9 mm, $n_D^{23} = 1.5177$, was obtained in 90% yield. The material contained a single component whose n.m.r. signal for the 2-hydrogen at τ 5.48 was a doublet with spacing 5.0 c.p.s. and, because of this spacing, it was judged to be *trans*-3-iodo-2-methoxytetrahydropyran (XXVII).

EFFECT OF ELECTROLYTE ENVIRONMENT ON DIVALENT TARTRATE ION MOBILITY[1]

JAMES C. NICHOL, DUANE G. HEIKKINEN[2], AND GARY E. GLASS[3]
Department of Chemistry, University of Minnesota, Duluth, Minnesota
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The variation of the electrophoretic mobility, u_T, of divalent tartrate ion with changing electrolyte environment has been studied. Mobilities were determined from boundary velocity measurements at 1.00 °C in the Tiselius electrophoresis apparatus. The solutions used, which were adjusted to pH 8.3–8.5, were principally either 0.04667 *M* C_2T or 0.01 *M* C_2T – 0.11 *M* CA, where C^+, $T^=$, and A^- are, respectively, a univalent cation, divalent tartrate ion, and a univalent anion. Relative viscosities, η_{rel}, of a number of these solutions were also obtained. For a given anion environment, the variation of u_T with changing cation is characterized by a minimum at sodium and a maximum at tetramethylammonium for a series of six alkali metal and tetraalkylammonium ions. For the alkali metal cations and for tetrapropylammonium ion, u_T undergoes a distinct decrease when the solution is changed from 0.04667 *M* C_2T to 0.01 *M* C_2T – 0.11 *M* CCl. For all solutions containing an anion A^-, u_T decreases with increasing hydrocarbon content of A^- for a given cation. Possible ion association, obstruction, and ion–solvent interaction effects are considered.

INTRODUCTION

In Dole's development of the steady state moving boundary theory for strong electrolytes (1), it is assumed that the mobilities of the ions in solutions of electrolytes vary by the same proportional factor with change in composition, that is, the relative mobilities are constant. This assumption makes possible an elegant mathematical treatment for the general case of *n* ions. Only the relative mobilities appear in the equations, since the ion mobilities themselves always occur in the fundamental moving boundary relationship as ratios. Thus, the much poorer assumption of constant ion mobilities is avoided. The assumed constancy of relative mobilities is justified to the extent that the final results of a moving boundary experiment (boundary velocities and refractive index gradients), predicted from the initial conditions by the Dole theory, have been found to agree to within 1% or less of the observed values for uni-univalent electrolytes (2). Also, for simple systems involving weak electrolytes, the application of moving boundary theory, which includes the assumption that the relative mobilities of the ionic subspecies are constant, yields predictions in accord with observed results to within about 1% (3). Nevertheless, especially in experiments with strong electrolyte solutions containing more highly charged ions, pronounced mobility changes can occur. For example, we have observed (Table III) that the decrease of divalent tartrate ion mobility with increasing ionic strength varies markedly with the nature of the solutions in which it is measured. The value in 0.04667 *M* disodium tartrate is about 4% lower than that in 0.03333 *M* disodium tartrate, while in a mixture of 0.11 *M* sodium acetate and 0.01 *M* disodium tartrate, the decrease is about 13%, although the change in ionic strength, 0.04 units, is the same in both cases. These

[3]*National Science Foundation Undergraduate Research Participant, 1961–1962.*

results led us to suspect a significant deviation of the relative mobility from constancy, a suspicion which was confirmed by the determination of the sodium ion mobility, u_{Na} in each of the three solutions, and the calculation of tartrate relative mobilities, r_T, therefrom on the basis of $r_{Na} = 1$ (Table III). That good agreement of moving boundary theory with experiment is obtained for such systems (4) may simply reflect an insensitivity of the predicted concentrations and boundary velocities to the values chosen for relative mobilities, rather than constancy of the latter.

To obtain an idea of how general such pronounced effects of electrolyte environment upon mobility might be, a survey of the mobility of divalent tartrate ion in a variety of electrolyte solutions was undertaken, using the Tiselius free electrophoresis method. The presentation and discussion of the results of this study is the objective of this paper. To avoid complications arising from variations in concentration and charge type, most of the experiments were performed using either 0.04667 M C_2T (in transference number type experiments, with an appropriate indicator electrolyte), or 0.01 M C_2T plus 0.11 M CA (analogous to the electrophoresis of a single protein in a buffer), where C^+, $T^=$, and A^- are, respectively, a univalent cation, divalent tartrate ion, and a univalent anion. (See experimental section for details.) In many cases, electrolyte viscosities were also determined. The determination of mobilities in a study of electrolyte behavior has the obvious advantage of singling out a property of the individual ion, rather than obtaining measurements on the solution as a whole, as in the case of conductance or viscosity determinations alone.

The Tiselius instrument, despite its limitations of accuracy (in comparison with the conventional moving boundary apparatus for transference number determinations) and of concentration range, is well suited for a survey of the type undertaken here, in which the variations being studied are large, and in which solutions containing more than one electrolyte are used. It possesses the advantage of recording accurately, both with schlieren and Rayleigh interference fringe optical systems, the diffuse boundaries frequently observed. Small convective effects, which would render a particular experimental arrangement unsatisfactory, are detected readily, and there is considerable flexibility in redesigning the experiment to produce a stable system. The sources of error and the reproducibility and accuracy of the mobility measurements are discussed in detail in the following section.

EXPERIMENTAL

All moving boundary experiments were performed at 1.00 °C with a Spinco Model H electrophoresis apparatus. Mobilities were calculated using the equation $u_T = Al\kappa/it$, where u_T is the electrophoretic mobility of divalent tartrate ion in a solution of specific conductance κ, A is the cross-sectional area of the cell limb, and l is the distance moved by the boundary with respect to the cell in time t if the electric current is i. One limb only of an 11 ml quartz Tiselius cell, equipped with reference paths, was used for all experiments. The mean cross-sectional area of the limb was 0.7654 ± 0.0002 cm², this value being determined from measurements at 5 mm intervals using a Gaertner Model M2001P comparator. The magnification factor from cell to photographic plate was 1.0000 ± 0.0007. Simultaneous schlieren (Wolter phase plate) and Rayleigh integral fringe photographs were taken at about 30 min intervals on Kodak metallographic plates. Exposures were of 15 s duration, as timed with a calibrated stopwatch. The overall error in the time intervals was estimated to be ±0.02%. Boundary displacements, l, were usually determined from the schlieren patterns as described previously (3). In some experiments, the change in field strength across the boundary was slight, so that the latter was very diffuse and failed to attain a steady state in the time required for it to move the length of the cell. In such cases, corrected fringe displacements from the Rayleigh integral fringe photographs were used (3). In all determinations, the gradients were sufficiently symmetrical that the maximum ordinate could be considered to establish the boundary position without significant error (5). Boundary velocities calculated in this manner from the five or six successive displacements which were photographed in each experiment were observed to be constant. Furthermore, in two instances, the velocities calculated from the displacements of the first moment axis were determined and found to be identical with those obtained using the maximum ordinate. The current source was one of the power supplies provided with the instrument.

The current was adjusted from run to run to give a field strength of 2 to 3 V cm^{-1}, and ranged from 4 to 10 mA. (A few test runs at as high as 16 mA and 5 V cm^{-1} yielded mobilities within the limits of reproducibility of those obtained at the lower field strengths.) Several checks on the current were made during every run by measuring the voltage drop across a calibrated 100 Ω resistance with a Rubicon Model 2780 potentiometer. When the power supply was operating properly the current was found to stay constant to within ±0.03%. Only experiments for which the electrical leakage from bath to cell was less than 0.05% of the total current at the start and finish were used for mobility determinations. It was observed that the leak remained at or below this value if not more than one experiment was done per day, and if the cell sections were rinsed thoroughly with absolute ethanol after the regular cleanup.

Solutions were prepared either from reagent grade salts or by neutralization of the acids with carbon dioxide free base. All solutions, including both leading and indicator electrolytes, were adjusted to pH 8.3–8.5, in order that hydrogen tartrate ion should not be present or formed in significant concentration. The pH values of the leading and following solutions were checked at the end of several moving boundary experiments, and were found to agree with the original values to within 0.1–0.2 pH units in all cases. Since pK_2 for tartaric acid has been determined to be 4.1 at 1.00 °C and 0.1 ionic strength (4), it is evident that an insignificant amount of hydrogen tartrate ion would be present. All mobility experiments were performed at least in duplicate, with fresh solutions being used for each run. For each system, preliminary experiments were carried out in order to establish that the proposed arrangement was stable, and to ensure that the initial following solution was within about 5% of the adjusted indicator concentration behind the boundary (6, 7), with the experiment designed so that the solution of lower density was on top. The initial boundary was compensated into view in these trial runs. Boundaries were ascending or descending, as density considerations dictated. The indicator electrolytes for transference number type experiments (all descending) were the acetate salts of the cations concerned (i.e. COAc). In experiments with Li^+, Na^+, K^+, TMA^+, and TEA^+ (see Fig. 1 for definitions of symbols), for which the COAc densities increase with increasing concentration, the proper initial COAc concentrations were found to lie in the range 0.072–0.075 *M* (i.e., about 5% lower than those of the adjusted COAc solutions generated immediately above the descending tartrate boundaries in the course of the experiments). Since the density of TPAOAc decreases with increasing concentration, a top solution concentration of 0.085 *M* (a few percent *higher* than the adjusted TPAOAc solution) was used. For the experiments analogous to the electrophoresis of a single protein in a buffer, the tartrate boundaries were descending except in those cases for which the "buffers" were the chlorides of Li^+, Na^+, K^+, TMA^+, and TEA^+ and the iodate of Na^+. The top solutions in the descending boundary experiments consisted of the "buffer" salts in the concentration range 0.11–0.12 *M*, except for TPACl (0.140 *M*) and TPAOAc (0.135 *M*), which again for density reasons had to have a higher concentration than that of the adjusted solution, and except for the sodium iodide and sodium bromate experiments. In these, to prevent density inversions, it was found necessary to use 0.1370 *M* NaI and 0.1367 *M* $NaBrO_3$ as leading solutions, behind which were generated 0.01 *M* Na_2T – 0.11 *M* NaI and 0.01 *M* Na_2T – 0.11 *M* $NaBrO_3$, respectively. The initial top solutions were 0.0095 *M* Na_2T – 0.1045 *M* NaI and 0.00996 *M* Na_2T – 0.1096 *M* $NaBrO_3$. In these experiments, the moving boundary was allowed to migrate completely out of the cell center section, in order to make possible the isolation and removal of the adjusted phases for conductance measurements needed in calculating mobilities. A similar procedure, with similar ranges of concentration to the above, was found necessary in all the ascending boundary experiments except for the one involving iodate, in which the leading (top) solution required for conductance was the original solution. For the sodium ion mobilities of Table III, lithium ion was used as the following ion in descending boundary experiments, while the mobility of acetate ion was obtained in a 0.11 *M* NaOAc – 0.01 *M* Na_2T solution generated behind 0.076 *M* Na_2T in a descending experiment.

Electrode volume corrections were made in the usual manner (6). Partial molal volumes for solutions appearing between the moving boundary and closed electrode were calculated from density measurements using Weld pycnometers, where literature values were unavailable. Bearman (8) has pointed out that if appreciable volume changes occur at the liquid junctions the electrode volume correction is suspect. A consideration of the known partial molal volume data for the electrolytes involved in the various junctions indicated that such effects were not significant in the present experiments. Furthermore, substitution of tetramethylammonium chloride for sodium chloride as the electrode electrolyte in some runs did not affect the corrected mobility values.

Conductances were measured at 0 °C, using a Jones conductance bridge and a cell of the Jones and Bollinger type. Hence, the computed mobility is the value at 0 °C, rather than 1 °C, if the transference number of the ion does not change significantly with the change in temperature (9). The best transference data available indicate that this is true to within 0.1% or better at low concentrations of simple salts (10). The reproducibility of the mobilities calculated from the several photographs taken during a single run averaged ±0.05%. However, the average agreement of values from separate identical runs was ±0.13%, which is slightly larger than the maximum error calculated from the error estimates in the individual quantities. This probably reflects the difficulty in performing experiments reproducibly, particularly as regards greasing of the rather large cell and standard taper surfaces.

Relative viscosities, η_{rel}, were determined in duplicate at 0.30 °C, using Ostwald viscometers for which the flow times were about 200 s, and for which the constants were determined in the usual manner. It was found

possible to maintain this temperature conveniently over an extended period by vigorous stirring of crushed ice and water in a large glass container. Values of η_{rel} determined with separate viscometers were found to agree to within $\pm 0.17\%$. As in the case of the transference number, an examination of the temperature dependence of η_{rel} of electrolyte solutions indicated that it should undergo no significant change between 0 °C and the bath temperature.

RESULTS AND DISCUSSION

In Table I are listed all the divalent tartrate ion mobilities, u_T, obtained in solutions of 0.04667 *M* C_2T and of 0.01 *M* C_2T plus 0.11 *M* CA. (It should be noted that the ionic strength is always 0.14, but that the cation concentration is 0.09334 *M* in the former type of solution and 0.13 *M* in the latter.) Also included are relative viscosity values, η_{rel}, and the corresponding mobility–viscosity products, $u_T\eta_{rel}$. A number of η_{rel} values for 0.11 *M* CA solutions (the "solvent") are included which show that for the most part omission of C_2T (at least at 0.01 *M* concentration) has only a small effect upon η_{rel}. In Fig. 1 the mobilities of Table I are plotted in order to show clearly the variation of u_T with changing

electrolyte environment. Consideration was given to plotting the mobility as a function of the ionic radius of the cation. However, since the significance of the crystal radius as a factor directly affecting the mobility in aqueous solution is not clear, and since reported values for hydrated radii vary so widely that their relative magnitudes change depending on which ones are chosen, it was decided simply to space the mobilities corresponding to solutions of the various cations at equal distances in order of increasing cation formula

weight. This also turns out to be the order of increasing crystal radii for the cations we have used (11). No particular significance is to be attached to the three sets of lines joining the points. They are intended to serve as an aid in distinguishing mobility trends for the three main types of solutions.

Several distinct trends are apparent upon inspection of Tables I and II and Fig. 1.

0.07	0.21	20.17	19.78	20.37

1. For a *constant* anion environment, the qualitative variation of u_T with changing cation is the same regardless of whether the solution contains only tartrate ion, a mixture of tartrate and chloride ions, or a mixture of tartrate and acetate ions (connected points in Fig. 1). In each case, there is a minimum value for u_T when the cation is sodium. Furthermore, for solutions containing only tartrate ion, the minimum becomes more pronounced with increasing concentration (Table II). This is in contrast to the frequently observed steady progression of a physical property with atomic weight and radius in the alkali metal series. The values of η_{rel}, on the other hand, decrease regularly from lithium to potassium. Also, in each case the highest mobility of u_T is observed when the cation is tetramethylammonium, and there is a steady drop in u_T with increasing size of the tetraalkylammonium ion. It will be observed in Table I that the increase in η_{rel} more than offsets the decrease in u_T in the tetraalkylammonium series, so that $u_T\eta_{rel}$ rises with increasing size of the tetraalkylammonium ions, and that the $u_T\eta_{rel}$ values as a group are distinctly higher than those for the alkali metal ions.

2. *Change* of the anion environment in the sequence pure tartrate, tartrate–chloride, tartrate–acetate results in significant variations in u_T (Fig. 1). In the case of the alkali metal cations, u_T decreases regularly in the order tartrate > tartrate–chloride > tartrate–acetate. For tetramethylammonium and tetraethylammonium ions the u_T values are essentially the same in pure tartrate and in tartrate–chloride, while for tetrapropylammonium u_T is somewhat lower in tartrate–chloride. For all three tetraalkylammonium cations, u_T is much lower in tartrate–acetate than in the other two anion environments.

3. In C_2T–CA solutions in which sodium is the cation, the nature of the anion, A^-, has a pronounced effect (Fig. 1). The tartrate mobilities in solutions containing iodide, bromate, chloride, and iodate comprise a fairly compact group, while those in the series of solutions containing formate, acetate, propionate, and butyrate decrease regularly with increasing size of the anion. Introduction of a hydroxyl group, by substitution of glycolate for acetate ion, results in an increase in u_T. The constancy of $u_T\eta_{rel}$ in the fatty acid anion series of solutions (Table I) is in marked contrast to its steady increase with increasing size of the tetraalkylammonium cations, in solutions of constant anion (tartrate–chloride) environment.

In attempting to account for these observations, we are faced with the problem of sorting out a variety of influences which may simultaneously affect the behavior of the tartrate ion. The situation is very complex, since the ion is present in electrolyte solutions, the

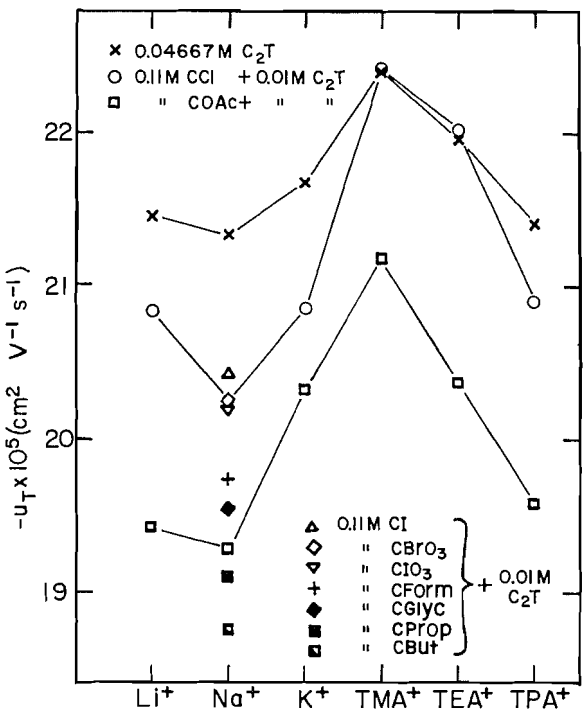

FIG. 1. Effect of ionic environment upon the mobility, u_T, of divalent tartrate ion. Symbols: $T^=$, divalent tartrate; C^+, univalent cation shown on abscissa; $Form^-$, formate; OAc^-, acetate; $Prop^-$, propionate; But^-, butyrate; $Glyc^-$, glycolate; TMA^+, TEA^+, and TPA^+, tetramethylammonium, tetraethylammonium, and tetrapropylammonium, respectively. The other symbols have their usual chemical significance.

total concentrations of which are far from infinite dilution. Therefore, the most we can hope to do is to point out some of the factors which may be involved in establishing the major trends. Among the possibilities which appear to be worth considering are ion association and the effect of the properties of the other ions present, such as size and tendency to interact with the solvent, on the forces impeding the movement of the tartrate ion.

Results reported by a number of workers indicate that the alkali metal cations form weak complexes, CT^-, with tartrate (12) and with related ions such as malate (13, 14). In the present experiments, if the concentrations of cations and tartrate should change in such a way as to increase the extent of association, then u_T would drop, since it would be a constituent mobility, related to the ion mobilities $u_{T^=}$ and u_{CT^-} and to the molar concentrations $c_{T^=}$ and c_{CT^-} by the equation

$$u_T = \frac{u_{T^=}c_{T^=} + u_{CT^-}c_{CT^-}}{c_{T^=} + c_{CT^-}} .$$

This may explain in part the decrease in u_T in going from pure tartrate to tartrate–chloride solutions of the alkali metal cations. The metal ion concentration increases from 0.09334 M to 0.13 M, while that of the tartrate ion decreases from 0.04667 M to 0.01 M. For the sodium ion, Wu and Hsu (12) report an association constant of 3.66 at 25 °C and 0.2 ionic strength. If calculations are carried out on the assumption that K_{assoc} lies somewhere between 2 and 6 under the conditions existing in our experiments, a decrease of from 3 to 6% in u_T is obtained for the concentration change under consideration. The

For personal use only.

observed drop for the sodium ion case is about 7%. It will be noted that there is very little change in u_T in going from pure tartrate to tartrate–chloride when the cation is tetramethylammonium or tetraethylammonium. This would be reasonable on the basis that if ion association is playing a role, its effect should be significantly less for the large tetraalkylammonium ions with their low charge density, than for the alkali metal ions used in this study. However, the decrease of u_T in the tetrapropylammonium case is almost as great as that when lithium is the cation. Therefore, an explanation of the above mobility changes based only upon the one effect is undoubtedly an oversimplification.

TABLE III

Mobilities and relative mobilities in various solutions

Concentration (mole l^{-1})		Ionic strength	Mobility $\times 10^5$ ($cm^2\ s^{-1}\ V^{-1}$)			Relative mobility		
Na_2T	NaOAc		u_{Na}	$-u_T$	$-u_{OAc}$	r_{Na}	$-r_T$	$-r_{OAc}$
0.03333	0	0.10	20.25	22.22		1	1.093	
0.00714	0.0785	0.10		20.41				
0.04667	0	0.14	19.24	21.34		1	1.109	
0.03	0.05	0.14		20.08				
0.01	0.11	0.14	20.80	19.29	16.44	1	0.928	0.791

With regard to effects arising from variations in ion size and ion–solvent interactions, the regular decrease of u_T with increasing amount of the hydrocarbon portion of the ions of both the fatty acid anion series and the three tetraalkylammonium cation series appears to be significant. Only a rough connection between mobility, as measured by conductance or diffusion, and the bulk viscosity can be expected, since the viscosity measured by capillary flow can be considered as the resultant of strongly varying local viscous effects (15). Nevertheless, the fact that η_{rel} rises as u_T decreases in all experiments for which data were obtained in the above series, suggests that at least there is an effect on the mobility connected with the change in viscosity. Robinson and Stokes have suggested that, where large increases in bulk viscosity occur in solutions containing big, approximately spherical ions (large viscosity B-coefficients in the Jones and Dole equation (16)), they are mainly the result of the distortion of the stream-lines (17). The ions are considered to behave hydrodynamically as though they were rigid spherical obstructions. Robinson and Stokes also draw attention to and elaborate on Wang's suggestion (18) that the increased viscosity and decreased conductance represent two parallel effects of a common cause, the obstructive action of the solute. These effects are considered to be the distortion of the stream-lines by the solute molecules or ions in viscous flow and the lengthening of the effective paths of the moving particles in conductance and diffusion. This picture accounts qualitatively for the above results on the basis that the obstructive effect increases regularly with ion size, and that the tetraalkylammonium and fatty acid ions approximate spheres, However, ion–solvent interactions, such as the postulated tightening or immobilization of the surrounding water structure by tetraalkylammonium cations and fatty acid anions (19, 20, 21), may also play a role, and it is impossible on the basis of the present experiments to distinguish between the two effects. The same uncertainties are involved in attempting to account for the consistently and distinctly higher u_T values and the lower η_{rel} values in chloride–tartrate solutions as compared to acetate–tartrate (Fig. 1). The chloride ion is both smaller than acetate and, like iodide, bromate, and iodate (in the solutions of which the u_T values are about the same), is considered to be a structure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

breaker (22). The increase in u_T and decrease in η_{rel} when glycolate is substituted for acetate recalls a solvent structure effect discussed by Frank (23) in connection with the viscosity and apparent molal heat capacity of tetraethanolammonium bromide. He regards introduction of the hydroxyl group as making the ion more water-like, so that the surrounding water is more nearly able to retain its normal, less rigid structure.

It is difficult to say whether the constancy of the $u_T\eta_{rel}$ products for the fatty acid anion series and the steady increase for the tetraalkylammonium series has any special significance. For large ions in water–sucrose mixtures, constancy is approached (24), but tartrate is not very large compared to the fatty acid anions used, and there is the added complication of the medium being an electrolyte solution. Somewhat comparable data are provided by tracer-diffusion coefficient determinations of iodide ion in aqueous alkali chloride solutions (25). At concentrations of about 0.1 M the $D\eta_{rel}$ values are much more nearly equal to one another than the D-values themselves, but, at higher concentrations, multiplication by η_{rel} overcorrects badly.

The occurrence of a minimum in u_T at sodium ion for the series in which the cation is varied again probably reflects a combination of factors such as those discussed above, rather than any single effect. Since the minimum is observed in three different types of anion environment, it would appear to be definitely related to the specific nature of the cations.

ACKNOWLEDGMENTS

The authors gratefully acknowledge helpful discussions with Dr. L. C. Thompson, and the assistance of Mrs. G. Stromme and Mr. S. Ji in carrying out a number of the experiments.

THE RADIOLYSIS OF ETHANOL

IV. DEUTERATED ETHANOLS IN THE LIQUID AND GAS PHASES

J. J. J. Myron and G. R. Freeman
Chemistry Department, University of Alberta, Edmonton, Alberta

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The value of $G(-\text{ethanol})$ in the vapor phase is nearly double that in the liquid phase. Part of the difference appears to be due to the recombination of radicals in liquid cages. Ethanol molecules, on the average, break into smaller fragments in the gas than in the liquid phase radiolysis. The isotopic compositions of the hydrogen produced from various deuterated ethanols are consistent with the suggestion that the reaction

$$CH_3CH_2OH^+ + CH_3CH_2OH \rightarrow CH_3CH_2OH_2^+ + CH_3CH_2O$$

occurs to a significant extent in the liquid but not in the gas phase. This reaction probably involves the shift of a hydrogen atom along a hydrogen bond. The reaction

$$C_2H_5OH_2^+ + e_{solv}^- \rightarrow C_2H_5O + H_2$$

does not occur to an appreciable extent in the liquid phase. In the liquid phase the relative contributions of the three different groups in the ethanol molecule to hydrogen production are in the order $CH_2 > OH \gg CH_3$. A similar trend occurs in the gas, although the contributions of the three groups are more nearly equal in this phase. Isotope effects, in the range $k_H/k_D = 2.2$–3.9 per bond, occur in the methane formation mechanism. The isotope effects are somewhat smaller in the liquid than in the vapor phase and somewhat smaller in the inhibited than in the uninhibited systems. A comparison of product distributions in the liquid and gas radiolyses of several compounds by γ-rays and by α-particles indicates that L.E.T. effects can also occur in the gas phase.

INTRODUCTION

It has been suggested that the reaction

[1] $$CH_3CH_2OH^+ + CH_3CH_2OH \rightarrow CH_3CH_2OH_2^+ + CH_3CH_2O$$

occurs in the liquid phase radiolysis of ethanol (1). Since this reaction merely involves the shift of a hydrogen atom along a hydrogen bond, it should occur to a smaller extent in the vapor than in the liquid phase. This hypothesis can be tested by irradiating C_2H_5OD and C_2D_5OH in the liquid and vapor states to determine the contributions of the hydroxyl hydrogen to the product hydrogen in the two phases. It is expected that the contribution of the hydroxyl hydrogen will be greater in the liquid phase. The present paper reports the results of this test. To increase the confidence that may be placed in the results and their interpretation, the isotopic composition of the product hydrogen from CH_3CD_2OH, CD_3CH_2OH, and C_2D_5OD is also reported.

Ryan *et al.* (2) have recently observed that reaction [1] does not occur to an appreciable extent in a mass spectrometer, but that the reaction

[2] $$CH_3CHOH^+ + C_2H_5OH \rightarrow CH_3CHO + C_2H_5OH_2^+$$

occurs very readily. However, all of the reactions [3]–[5] occurred readily under the same conditions as those used for the ethanol study, so the situation is not clear.

[3] $$CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_3O$$

[4] $$\rightarrow CH_3OH_2^+ + CH_2OH$$

[5] $$CH_2OH^+ + CH_3OH \rightarrow CHO_3H_2^+ + CH_2O$$

Since the above-mentioned experiments involved a comparison of results of the γ-radiolyses of the liquid and vapor phases of expensive deutero-ethanols, it was necessary first to compare the γ-radiolyses of the two phases using ordinary ethanol. In addition to the above, isotope effects were observed in the methane yields and are reported herein.

EXPERIMENTAL

Part of the experimental procedure has been described elsewhere (1). Only additional procedures will be reported here.

Materials

The isotopic purities of the deutero-ethanols (Merck, Sharp and Dohme, Ltd.) were measured with a Varian Associates Model A-60 Analytical NMR Spectrometer (see Table I). Phillips Research Grade ethylene was used.

TABLE I

Isotopic analysis of deuterated alcohols

Alcohol	Group	Isotopic purity (%)
C_2H_5OD	OD	>99
C_2D_5OH	CD_2	99.0
	CD_3	99.4
CH_3CD_2OH	CD_2	96.3
CD_3CH_2OH	CD_3	>99
C_2D_5OD	OD	99.5
	CD_2	99.6
	CD_3	99.6

Sample Preparation and Irradiation

The alcohols and 1,3-pentadiene were thoroughly degassed at −112°. Before introducing C_2H_5OD or C_2D_5OD into the sample preparation system, all surfaces with which the alcohol would come in contact were equilibrated with D_2O vapor. The D_2O remained in the system for 20 min, then was pumped away and the system was baked out. The process was then repeated. The nuclear magnetic resonance (n.m.r.) analyses reported in Table I were done on samples that had passed through the sample filling system. When an "OH" alcohol was used after an 'OD' compound, the system was preequilibrated with H_2O and baked out. The amount of deuterated alcohol in each sample was determined from liquid volume measurements, assuming that the density ratio for deuterated to 'light' ethanol was equal to the molecular weight ratio. This assumption is correct to within 0.3% for heavy and light water at 25°,* to within 0.1% for C_2H_5OD and C_2H_5OH at 0° (3), and would be even closer to exact for the other deuterated ethanols.

Gas phase samples were contained in 500 ml bulbs. The bulbs were placed in a heating mantle during radiolysis. Ethanol and its solutions were irradiated at a temperature of 105 ± 3° and a pressure of about 800 Torr. Ethylene, at 32° and about 900 Torr, served as the gas phase dosimeter and $G(H_2) = 1.28$ (4) was used. A stopping power correction, to convert the dosimetry from ethylene to ethanol, was calculated from the Bethe equation (5); this amounted to 1%. Liquid phase dosimetry was done with the Fricke dosimeter, using $G(Fe^{3+}) = 15.5$ and $\epsilon(Fe^{3+}, 304\ m\mu, 25°) = 2\ 225$. The liquid ethanol samples were irradiated at 28°. The dose rate in the Gammacell-220 was about 6×10^{19} eV/g h for both liquid and gas samples.

Product Analysis

The products that were volatile at −196° were separated from the sample by distillation under vacuum. The gas mixture was analyzed with a Metropolitan-Vickers MS-2 mass spectrometer.

RESULTS

The high cost of the deutero-alcohols prevented a complete study of the radiolysis of these compounds. Each alcohol was irradiated to a dose of 3.8 ± 0.4 (10^{20} eV/g) in the presence and absence of an electron fraction of 1,3-pentadiene equal to 0.20 ± 0.01. This concentration of pentadiene suppresses, essentially completely, the contributions of

*D_2O *was obtained from Bio-Rad Laboratories and the density of* D_2O *was given on the label as 1.105 g/ml at 25 °C.*

A moderately complete product analysis in the gas phase γ-radiolysis of light ethanol was made so that the product yields could be compared with those from the α-radiolysis (6). The results, listed in Table IV, are the averages from two experiments.

DISCUSSION

Comparison of the γ-Radiolyses of Ethanol in the Liquid and Gas Phases

One great difference between the results of the γ-radiolyses of liquid and gaseous ethanol is that in the liquid $G(-\text{ethanol}) = 7.5$, while in the gas phase $G(-\text{ethanol}) = 13.9$. These values refer to doses greater than 10^{20} eV/g. The value of $G(-\text{ethanol})$ increases at lower doses but the difference between the values for the two phases persists,

*ϵ_p = electron fraction of 1,3-pentadiene in the sample.
†The numbers in these columns are $G_{observed}/0.80$, i.e. they refer to the energy absorbed initially by the ethanol. The 1,3-pentadiene contributes $G(H_2) \approx 0.04$ and 0.1 to the liquid and gas phase yields, respectively.

judging from the hydrogen yields (1, 6). Larger values of $G(-\text{substrate})$ in the gas than in the liquid phase have been observed in several systems (6–9). Part of the increase might be due to the higher temperature used in most of the gas phase studies ($\sim 100°$, refs. 6, 8, 9, compared to $\sim 25°$ in the liquids). However, methanol radiolyses in the two phases at room temperature also showed greater decomposition in the vapor than in the liquid state (7). Part of this difference is probably due to the decomposition in the gas of some of the activated species that are deactivated in the liquid (this includes back reactions in liquid cages). Part might also be due to the formation of different activated states in the two phases.

Assuming that each observable C—C bond break eventually gives rise to a molecule of methane, i.e. neglecting reactions such as

[6] $$CH_3 + R \rightarrow CH_3R,$$

the ratio of $G(CH_4)/G(H_2)$ reflects the ratio of primary C—C bond breakage to the C—H and O—H breakages, i.e. (C—C)/(C—H + O—H). The values of this ratio corrected by a statistical factor of six (the ratio of the number of bonds to hydrogen to the number of C—C bonds in the molecule) are 0.7 for the liquid and 1.9 for the gas radiolysis. These figures indicate that in the radiolysis of the liquid, a large amount of C—C bond rupture may be masked by cage effects (cage recombination). Methyl radicals are more susceptible than hydrogen atoms to cage recombination because the former are larger and less mobile than the latter. The nearly twofold increase in the extent of decomposition on going from the liquid to the gas is reflected to varying degrees in the yields of each of the observed products.

The ethylene yield is an order of magnitude greater in the gas phase, while the ethane yield is unchanged. These facts are probably due to the active species having a greater amount of time to decompose before being deactivated by collisions, e.g.

[7] $$C_2H_5OH^* \rightarrow C_2H_4 + H_2O,$$

[8] $$C_2H_5^* \rightarrow C_2H_4 + H.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Ethylene formation is not appreciably inhibited by 1,3-pentadiene in either phase. Ethane formation is inhibited in both phases, probably by the scavenging of ethyl radicals.

While the acetaldehyde yield is greater in the gas than in the liquid, the unscavengeable yields of this compound are the same in the two phases. The scavengeable acetaldehyde is probably formed by the disproportionation reactions of CH_3CHOH and CH_3CH_2O radicals. It has been suggested (1) that a large part of the unscavengeable acetaldehyde in the liquid phase was formed by the reactions

[9] $$C_2H_5OH \longrightarrow CH_3CHOH^+ + H + e^-,$$

[2] $$CH_3CHOH^+ + C_2H_5OH \rightarrow CH_3CHO + C_2H_5OH_2^+.$$

It is doubtful that reaction [9] would occur with the same G value in the two phases, so the agreement between the unscavengeable acetaldehyde yields is probably fortuitous. The unscavengeable yield of hydrogen equals that of acetaldehyde in the gas phase, but the former is smaller than the latter in the liquid. Thus the reaction

[10] $$C_2H_5OH^* \rightarrow CH_3CHO + H_2$$

might be more important in the gas than in the liquid phase.

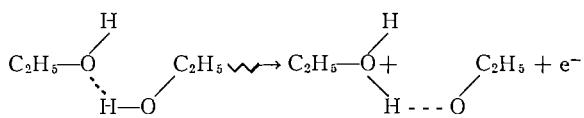
The yield of 2,3-butanediol increased by about a third while that of 1,2-propanediol increased sevenfold on going from the liquid to the gas. This is another illustration of the enhanced C—C bond cleavage in the gas phase.

Hydrogen Formation

In the uninhibited systems, the percentage of D in the product hydrogen from C_2H_5OD and the percentage of H in the hydrogen from the 'OH' alcohols decreased on going from the liquid to the gas phase radiolysis (see Table III). These results are consistent with the suggestion that reaction [1] occurs to a significant extent in the liquid but not in the vapor state (see Introduction).

[1] $$C_2H_5OH^+ + C_2H_5OH \rightarrow C_2H_5OH_2^+ + C_2H_5O$$

The reaction would be facilitated by the hydrogen bonding in the liquid.



Reaction [1] would be followed by reactions [11] and [12].

[11] $$C_2H_5OH_2^+ + e_{solv}^- \rightarrow H + nC_2H_5OH$$

[12] $$H + C_2H_5OH \rightarrow H_2 + CH_3CHOH$$

Reaction [11] probably occurs in the spurs (1). The hydrogen atoms in reaction [12] also abstract from the methyl and to a very small extent from the hydroxyl but the main portion of the abstraction is from the methylene group. This is in agreement with the findings of other workers (10, 11) and is consistent with the relative bond strengths in the molecule. The amount of D_2 in the products from C_2H_5OD was very small (Table II), so the reaction

[13] $$C_2H_5OH_2^+ + e_{solv}^- \rightarrow C_2H_5O + H_2$$

does not occur to an appreciable extent in the liquid phase. If reaction [2] is the only source of $C_2H_5OH_2^+$ in the vapor phase, reaction [13] is also unimportant in the vapor (the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

electron is probably not 'solvated' in the vapor, although the probability of formation of negative clusters is not known).

In the inhibited systems, the % D in the product hydrogen is the same for liquid and gaseous C_2H_5OD (Table III). This is in contrast to the results from the uninhibited systems and is consistent with the proposed mechanism because the hydrogen atom that results from reactions [1] and [11] is scavengeable.

[14] $$H + C_5H_8 \rightarrow C_5H_9\cdot$$

The % D in the product hydrogen from the three alcohols that were deuterated at only one of the three different groups in the molecule indicate the relative contributions of each of the groups to hydrogen formation. In the pure liquid the relative contributions from the three sites are in the order methylene > hydroxyl $\gg$ methyl. This is consistent with the results of other measurements of the isotopic composition of the hydrogen produced by the radiolysis of various deutero-alcohols (12–14) and with the fact that CH_3CHOH is the main radical observed in irradiated solid ethanol at 77 °K (15, 16).

A similar trend was observed in the pure gas phase, although the relative importance of the methyl group doubled, that of the methylene group increased by 30% and that of the hydroxyl group decreased by 40% from those in the liquid phase (see Table III). In both phases, the % D in the hydrogen from the CD_3CH_2OH–pentadiene solutions was greater than that in the hydrogen from pure CD_3CH_2OH. For all the other deutero-alcohols, the % D in the hydrogen from the pentadiene solution was smaller than that in the hydrogen from the corresponding pure alcohol. Thus the methyl group is relatively more important in the formation of unscavengeable hydrogen than it is in the formation of scavengeable hydrogen. This is consistent with the idea that the unscavengeable hydrogen is formed from a very reactive species that reacts with less selectivity than do those which form the scavengeable hydrogen (e_{solv}^- and thermal H).

Methane Formation

The methane results were sufficiently simple (Table II) that certain rate constant ratios and isotope effects could be calculated from the present data. For simplicity, both the scavengeable and the unscavengeable methane yields will be considered to be produced by the following reactions.

[15] $$CH_3 + CH_3CH_2OH \rightarrow CH_4 + CH_3CHOH$$

[16] $$\rightarrow CH_4 + CH_3CH_2O$$

[17] $$\rightarrow CH_4 + CH_2CH_2OH$$

If the unscavengeable methane were produced by the unimolecular decomposition of activated ethanol species or by the disproportionation reactions of radicals in spurs, the rate constant ratios and isotope effects reported here could be readily transferred to these types of reaction.

Values of k_{15}/k_{16}, k_{15}/k_{17}, and of the kinetic isotope effect k_H/k_D can be calculated from the isotopic compositions of the methanes obtained from the various deutero-ethanols (Table II). For example, values of k_{15}/k_{16} and k_H/k_D in the liquid phase were calculated as follows.

[15′] $$CH_3 + CH_3CD_2OH \rightarrow CH_3D + CH_3CDOH$$

[16′] $$\rightarrow CH_4 + CH_3CD_2O$$

[15″] $$CH_3 + C_2H_5OD \rightarrow CH_4 + CH_3CHOD$$

[16″] $$\rightarrow CH_3D + C_2H_5O$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

From the data in Table II, $k_{15'}/k_{16'} = 0.8$ and $k_{15''}/k_{16''} = 6.0$. The isotope effects in reactions [15] and [16] are assumed to be about the same. Thus, $k_{15}/k_{16} = (0.8 \times 6.0)^{1/2} = 2.2$ and $k_H/k_D = (6.0/0.8)^{1/2} = 2.7$. These values would not be appreciably changed by including reaction [17] in the calculations because the contributions of the corresponding reactions [17'] and [17''] would tend to cancel each other. The unscavengeable yield of methane is only 12% of the total methane yield in the gas phase and 20% in the liquid phase radiolysis of ethanol (Table IV), so little error is introduced into the calculation of the kinetic parameters by using the total methane yields in calculating the values for the scavengeable reactions.

TABLE V

Some kinetic parameters of the methane formation reactions

Radical	Phase	Methane type	k_{15}/k_{16}	k_{15}/k_{17}	k_H/k_D*
CH_3	Liquid, 28°	Scavengeable	2.2	—	2.7
CH_3	Liquid, 28°	Unscavengeable	1.8	—	2.2
CD_3	Liquid, 28°	Scavengeable	—	6.2	2.7†
CD_3	Liquid, 28°	Unscavengeable	—	3.2	2.2†
CH_3	Gas, 105°	Scavengeable	2.7	—	3.9
CH_3	Gas, 105°	Unscavengeable	1.8	—	2.5
CD_3	Gas, 105°	Scavengeable	—	8.0	3.9†
CD_3	Gas, 105°	Unscavengeable	—	6.4	2.5†

*k_H/k_D is the isotope effect per bond.
†Assumed.

The values of k_{15}/k_{16}, k_{15}/k_{17}, and k_H/k_D for liquid ethanol at 28° and gaseous ethanol at 105° are recorded in Table V. The isotope effect is smaller for the unscavengeable processes than for the scavengeable processes in both phases. This indicates that the former processes involve more energetic reactants than the latter. The results in Table II also allow calculation of the ratio $(k_H/k_D)(k_{15}/k_{16})$ when CD_3 radicals replace the free CH_3 radicals in reactions [15] and [16]. For the scavengeable and the unscavengeable methane in both the liquid and the gas phases, the results indicate that

$$\left(\frac{k_H}{k_D} \cdot \frac{k_{15}}{k_{16}}\right)^{\frac{1}{2}}_{CH_3} = 2\left(\frac{k_H}{k_D} \cdot \frac{k_{15}}{k_{16}}\right)_{CD_3}.$$

The conclusions of earlier photolytic studies in methanol (17, 18) cast some doubt upon the suggestion that the scavengeable methane is formed by methyl radical reactions during the radiolysis of ethanol. Shannon and Harrison (17) studied reactions [18] and [19] in the gas phase.

[18] $$CH_3 + CH_3OH \rightarrow CH_4 + CH_2OH$$

[19] $$\rightarrow CH_4 + CH_3O$$

Extrapolation of their results to 105° gives $k_{18}/k_{19} = 0.66$, which lies between the values $k_{15}/k_{16} = 2.7$ and $k_{17}/k_{16} = 0.34$ as would be expected. However, their results yield $k_H/k_D = 7.4$ at 105°, which is significantly larger than the present value of 3.9. Furthermore, Cher (18) studied reactions [18] and [19] in the liquid phase at 30° using CD_3 rather than CH_3 radicals. He found $k_{18}/k_{19} = 45 \pm 12$ and $k_H/k_D = 8.7 \pm 2.8$. These values are much larger than the $k_{15}/k_{16} = 2.2$, $k_{17}/k_{16} = 0.35$, and $k_H/k_D = 2.7$ found in the liquid phase radiolysis at 28°. More work is required to prove or disprove the occurrence of reactions [15]–[17] during the radiolysis of ethanol.

Comparison of the γ- and α-Radiolyses of Ethanol

The most striking difference between the α- and γ-radiolyses of ethanol vapor (Table IV) is the acetaldehyde/2,3-butanediol ratio; the value of the ratio is 1.1 for γ's and 3.8 for α's. The conditions (pressure, temperature, dose rate, surface/volume ratio of sample container) in the two studies were similar and could not account for the widely different ratios, so the difference must be attributed to the nature of the radiation. The same trend can be noted in other systems. The acetaldehyde/2,3-butanediol ratio from liquid ethanol has the value of 0.9 for γ's (1) and 2.1 for α's (19); the formaldehyde / ethylene glycol ratio from liquid methanol is 0.43 for γ's and 1.0 for α's (20).

The difference in the aldehyde/glycol ratios in the liquid systems are due to L.E.T. effects. For example, the yield of 'free ions' is very probably much smaller for α- than for γ-radiolysis. Thus reactions such as [20] and [21],

[20] $$CH_3CHO + e_{solv}^- \rightarrow CH_3CHO^-$$

[21] $$CH_3CHO^- + C_2H_5OH_2^+ \rightarrow CH_3CHOH + C_2H_5OH,$$

which destroy aldehydes, occur to a smaller extent in the α- than in the γ-radiolysis. At the doses used to measure the yields of these products reaction [20] is the main fate of the 'free' solvated electrons in liquid ethanol (1). This effect would tend to make the aldehyde/glycol ratio larger in the α- than in the γ-radiolytic systems. The relative amounts of the various free radicals produced are probably also affected by L.E.T. because the glycol yields, which are nearly unaffected by reactions [20] and [21], are different for the different radiations (1, 19, 20). It thus appears that L.E.T. effects can also occur in gas phase radiolyses. Differences in product distributions have also been noted between the α- and X-radiolyses of hydrocarbon vapors (21).

There are many possible reasons for these differences, some of which are (*a*) different states might be formed in different abundances in the two systems; (*b*) space charge along the α-particle track might cause a larger amount of local charge neutralization to occur during the α-radiolysis than would occur during γ-radiolysis; (*c*) a significant amount of charge neutralization might occur on the reaction vessel wall under the usual conditions of γ-radiolysis. The following observation leaves some doubt about reason (*a*). An extrapolation of mass spectrometric results from fast electrons (22) and protons (23) to α-particles as an ionization source indicates that the primary species formed during the α- and γ-radiolyses of the compounds would be quite similar. However, caution should be used in extrapolating conclusions from mass spectrometry to the interpretation of radiolysis systems. The above reason (*b*) is a sort of local dose rate effect. Both (*b*) and (*c*) could be checked by doing γ- or fast electron radiolyses at very high dose rates in the vapor phase.

THE METHYLATION OF THE RESORCINOLATE DIANION

I. THE EFFECTS OF SOLVENT AND BASE AND THE ALKYLATION SEQUENCE

ALLAN R. STEIN[1]

Noyes Laboratory of Chemistry, University of Illinois, Urbana, Illinois

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The alkylation of the di-alkali metal salts of resorcinol with methyl iodide under various conditions was examined. Solvent and cation effects on the mode and position of resorcinolate anion methylation are discussed. By examination of the neutral and phenolic fractions and comparison with the alkylation of methoxyphenols and mesorcinol, the principal methylation sequences are determined. The intermediacy of the various hydroxydienones, for example, 2,4,6,6-tetra- and 2,6,6-tri-methyl-1-hydroxycyclohexa-1,4-dien-3-one, in the formation of the principal product, 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione, from the methylation of the resorcinolate dianion in nonpolar solvents or water is established by the isolation of such intermediates. The 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione itself will be discussed in detail in the second paper in this series.

INTRODUCTION

Substituent effects on the alkylation of enolates (1), of oxime salts (2, 3), and of thiophenolates (4) have been examined, but the only study of the effect of substituents on the alkylation of phenoxides is that reported by Curtin *et al.* (5), who examined only the sodium salts of phenol and its 4-methyl and 4-bromo derivatives. An examination of the methylation of resorcinol was undertaken after a cursory examination of substituent effects confirmed an expectation that a meta-methoxyl group ($\sigma_{meta} = 0.115$; $\sigma_{para} = -0.268$) on phenol greatly enhanced carbon alkylation over that observed with phenol and, especially, with *p*-methoxyphenol.

The alkylation of polyhydroxylic benzene salts has been studied. Herzig and Zeisel (7), contrary to a report by Will (8), found that treatment of phloroglucinol with ethyl iodide in alcoholic alkali solution gave a pentaethylphloroglucinol which they considered to be 2,2,4,4,6-pentaethylcyclohexan-1,3,5-trione (I). Margulies (9) and Herzig and Erthal (10) both report the isolation of II from the methylation of phloroglucinol in methanolic potassium hydroxide solution. Di- and tri-methylated phloroglucinols were also obtained and were assumed to be carbon-alkylation products (9).

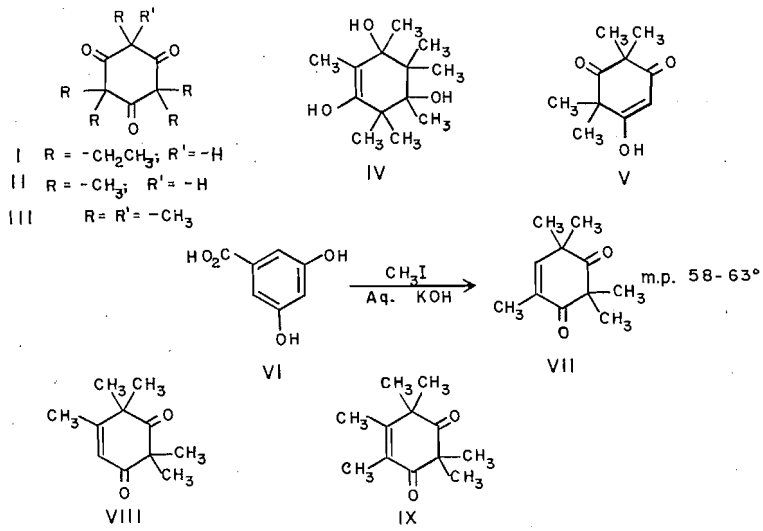
A hexamethylphloroglucinol to which was assigned the structure 2,2,4,4,6,6-hexamethylcyclohexan-1,3,5-trione (III) was first reported by Kaufler (11) and later by Herzig and Erthal (10). This material was later found to be identical with the compound formed by the base-catalyzed trimerization of dimethylketene (12). Under the reaction conditions employed, II was not further methylated to give III, nor were the usual carbonyl derivatives of either species obtained (10). Grignard reagents, however, did add to II to give IV.

Kaufler (11) obtained hexa-, penta-, and tetra-methylphloroglucinols by using methyl iodide, carefully dried phloroglucinol, and alkaline absolute methanol. In addition, he reported the monomethyl ethers of penta- and tetra-methylphloroglucinols. In aqueous solution, only assorted ethers were obtained and, in methanolic solution, varying the amount of base varied the product composition. Ethyl, *n*-propyl, and isopropyl iodide behaved similarly, but as the alkyl group increased in size, Kaufler found the amount of carbon methylation was reduced. To explain the fact that with benzyl chloride he obtained

[1]*Current address: Central Research Laboratories, Dominion Tar and Chemical Company, Ltd., Senneville, Quebec.*

almost exclusively the mono-, di-, and tri-benzyl ethers of phloroglucinol, he stated that phloroglucinol acts as a ketone towards methylation but as a phenol towards benzylation. It is, perhaps, of interest that the dianion of phloroglucinol has recently been shown to exist principally in the ketonic cross-conjugated dienone form (13).

An attempt to characterize the tetra-, penta-, and hexa-methylphloroglucinols (V, II, and III respectively) was made by Spitzer (14). In an attempt to establish the origin of the 2,2,4,4,6,6-hexamethylcyclohexan-1,3,5-trione (III), Herzig and Erthal (15) found that a mixture of II and III was formed when V was methylated with methyl iodide in 10% aqueous potassium hydroxide.



The first reported study of a resorcinolate alkylation is that of Kurzweil (16). Using orcinol carboxylic acid (VI) and methyl iodide in basic aqueous solution, he obtained, among assorted methyl ethers and esters, a compound $C_{11}H_{16}O_2$ to which he erroneously assigned the structure 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione (VII).

Herzig and Wenzel (17) studied the methylation of orcinol (i.e. 5-methylresorcinol) in basic solutions with diazomethane, dimethylsulfate, and methyl iodide. Only the last gave carbon- as well as oxygen-methylated products. Herzig and Wenzel stressed the fact that minor variations in temperature, concentration, thoroughness of drying the orcinol, or the order in which the reagents were added greatly affected the product distribution. Even supposedly identical runs gave varying product distributions.

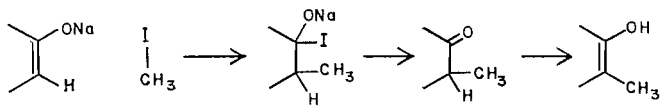
Herzig and Wenzel (18) attempted to identify their tetra- and penta-methylorcinols but met with dubious success. The tetramethylorcinol was brominated and then treated with aqueous potassium hydroxide to give fumaric acid (12%), diisopropylketone (11%), and an acid $C_{11}H_{16}O_4$ (67%), which they failed to identify. With similar treatment, the pentamethylorcinol gave only an acid $C_{12}H_{18}O_3$ (73%), again unidentified. These results are inconsistent with the proposed structures for the tetra- and penta-methylorcinol (VIII and IX respectively). Compound VIII was not further methylated by methyl iodide in 10% aqueous potassium hydroxide, conditions under which orcinol gave a mixture of VIII and IX in 10% yield (15).

In 1911, Herzig and Wenzel (18) proposed the mechanism shown in Reaction Scheme 1 for the carbon methylations observed. Applying this mechanism repetitively, they suggested a stepwise methylation for the formation of VIII and IX. Resorcinol and orcinol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were reported to behave similarly, but resorcinol was methylated somewhat less readily (15).

While reports of the alkylation and acylation of resorcinol and phloroglucinol under acid conditions (i.e. using alcohols, olefins or alkyl halides, or acid anhydrides or acyl halides and assorted protonic or Lewis acids as catalysts) are very numerous, the only recent reports of the alkylation of resorcinolates have both used allylic halides. Monroe (19) used allyl chloride in a sodium dihydrophosphate buffered solution (pH 5–7) near room temperature to obtain a diallylresorcinol, and Fitton and Ramage (20) obtained the monobenzyl ether by treating resorcinol with benzyl chloride and potassium carbonate in dry acetone.



REACTION SCHEME 1.

RESULTS AND DISCUSSION

Studies of the alkylation of the resorcinolate dianion present several difficulties. For many of the products, it is impossible to distinguish between ortho and para alkylation and it is impossible to discern which species is alkylated. More important, however, is the multiplicity of possible products. As many as 23 of the 40 possible products summarized in Table I were observed in a single product mixture from the methylation of the resorcinolate dianion with methyl iodide, and examples of each class of product were isolated and identified.

Some of the overlapping effects or factors operative in alkylations of the resorcinolate dianion will be discussed. These will be followed by a more complete examination of the neutral fraction and phenolic fraction, together with some mechanistic interpretations of these results.

Cation Effects

As is general for the alkylation of phenoxides (5, 6, 21), the sodium salts of resorcinol gave far less carbon methylation than did the lithium salts. Thus, in tetrahydrofuran the sodium salt gave a carbon-to-oxygen methylation ratio of less than 0.2 while the lithium salt gave a ratio of over 2.0. In methanolic solution where a more ionic reaction is probably occurring, little difference between the two cations was noted. Both gave a carbon-to-oxygen alkylation ratio of about 0.8–1.0.

Solvent Effects

An appreciation of the complexity of solvent effects on the alkylation of ambient anions can be gained by an examination of the tabulation of the variation of the composition of the neutral fraction with the mole % of water in tetrahydrofuran used as a solvent for the methylations of the lithium salt (Table II). Four equivalents were found to be sufficient base to convert essentially all (97–99%) of the resorcinol to neutral fraction (except in pure water where only 80% conversion was attained), so that 4 moles of lithium hydride were used for each mole of resorcinol. None of the phenolic fractions examined contained any resorcinol but were made up mainly of high-boiling tars.

It should be noted in examining the results represented in Table II that, with the concentration range employed, only 3.2 mole % of water was sufficient to convert all of the excess lithium hydride to lithium hydroxide. This change of base, together with the anticipated "solvent sorting" (22), whereby the water would collect about the ionic charge centers, could account for the drastic changes in product composition observed when

small amounts of water were present. A mechanistic change is indicated, however, as the reaction solvent is changed from tetrahydrofuran to water. A similar mechanism change was indicated by the cation effects mentioned above. This will be discussed in more detail below.

Extrapolation from the moderately nonpolar tetrahydrofuran to even less polar solvents like hexane or toluene would be expected to give far more carbon methylation. Because it was impossible to form the resorcinol salts with the metal hydrides in these solvents, they were formed in a small quantity of tetrahydrofuran, and toluene or hexane was then added. As indicated in Table III, in 16.5% (by volume) tetrahydrofuran in toluene, methyl iodide alkylations of the lithium salt gave a 68% yield of a mixture of 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione (VII) and 2,2,6,6-tetramethylcyclohex-4-en-1,3-dione (X). The former, enedione VII, is the major topic of the second paper in this series (23).

Kornblum and his co-workers have attempted to break similar solvent effects, observed in other phenoxide alkylations, into some of their component parts, i.e. hydrogen bonding (24) and dielectric constant effects. Too few solvents were tested to attempt such correlations with this system, but several of the interrelated factors are apparent from the results presented here. Thus, comparison of the relative amounts of 2,4- and 2,6-dimethoxytoluenes reported in Table II shows that, in tetrahydrofuran (THF) solution, four or five times as much 2- as 4-methylation occurs —a relative rate difference of more than eightfold when the two equivalent 4-positions are considered. This is confirmed by the relative amounts of the 2,4- and 2,6-dimethoxy-1,3-xylenes. As water is added, methylation at the 4-position becomes more and more competitive until the two relative rates are approximately equal, that is, about twice as much 4- as 2-dimethoxytoluene was formed. This product change indicates that, as water strongly solvates the two negatively charged oxygens, the di-ortho 2-position between them becomes sterically blocked to attack and the normally less favored attack at the ortho–para 4-carbons can compete on a more equal basis. Tying up oxygen with water of solvation would promote carbon attack over oxygen attack (23, 24), and hence explain the increase in the carbon-to-oxygen alkylation ratio and, thus, the amount of per-methylated products, the enediones (25), at the higher concentrations of water. To compare more meaningfully the results for the methylation of the lithium salts of resorcinol in nonpolar aprotic and in polar hydroxylic solvents, resorcinol, with 4 equiv. of lithium hydride present, was methylated with methyl iodide in several polar aprotic solvents. The analyses of the neutral fractions from methylation at 66° in dimethylsulfoxide (DMSO) and in N,N-dimethylformamide (DMF) are reported in Table III.

The comparatively small yield of carbon methylation products was anticipated, since both solvents are excellent cation-solvating solvents but are poor at solvating anions (27). The more electronegative oxygen would then be expected to be the major point of attack in methylation (26). One definite objection to working in either of these two solvents is that they apparently react with alkyl halides (28, 29) and are apparently reduced by the lithium hydride. In dimethylsulfoxide in particular, considerable quantities of iodine and of the sulfide and mercaptan reduction products of dimethylsulfoxide were liberated. In dimethylformamide, less iodine formed but reduction products of dimethylformamide were formed in quantities readily detectable by their amine odor.

Similarly, the relative amounts of carbon alkylation of the sodium salt in tetrahydrofuran and in methanol can be attributed to the greater hydrogen-bonding ability of the latter, enabling it to "tie up" the oxygens. It is interesting to note that methanol apparently was not a potent enough hydrogen-bonding solvent to cause such effects in other systems studied (24), and that such specific solvation must overcome the effect of increased resorcinolate ionization, which always favors oxygen alkylation in phenoxide systems (5, 26).

The Anionic Species

Thus far it has been assumed that the major amount of carbon methylation occurs on the dianion. That this is indeed so can be inferred from the data in Table III by comparing the amounts of the C-methylated products obtained from resorcinol and *m*-methoxyphenol under the same conditions. Under similar conditions in tetrahydrofuran solution, lithium 3,5-dimethoxyphenoxide gave 39% of 1,3,5-trimethoxybenzene, 43% of 2,4,6-trimethoxytoluene, 9% of 2,4,6-trimethoxyxylene, and only 9% of carbonyl-containing materials. (Little or no para methylation must have occurred as noted by the complete absence of trimethoxymesitylene in the product.) Thus, even the 3,5-dimethoxyphenoxide is less readily methylated than is the resorcinolate.

Since hydroxy and methoxy groups have similar Hammett "σ" constants and since electron donor substituents ortho to the alkylation site are found to greatly favor carbon alkylation (6), similar results would be expected from *m*-methoxyphenoxide and *m*-hydroxyphenoxide or the resorcinol dianion which could readily be mono-oxygen methylated to the *m*-methoxyphenoxide ion. *m*-Dimethoxybenzene and its carbon-methylated analogues are inert under the reaction conditions so that, by a process of elimination, we are left only with the resorcinolate dianion as the alkylated species. An ortho-"oxide" substituent should have a large negative "σ" value and, hence, would give much more carbon alkylation than a methoxy substituent.

Methylation Sequence

Since it is apparent that virtually all of the carbon methylation must occur before the methylation of the first "oxide", the analyses of the neutral fractions can yield some indication of the main order or sequence of the methylation, if it is assumed that the ease of oxygen methylation and particular carbon methylation are relatively independent of the carbon methylation or vary smoothly with additional carbon methylation. Thus, from the results presented in Table II, in tetrahydrofuran solution, nearly five times as much 2,6- as 2,4-dimethoxytoluene was obtained. This represents a difference in relative rate of a factor of about nine. In water, the relative rates are about equal, while in 30% tetrahydrofuran–toluene solution, the relative rate for 2-methylation is again about eight times that for 4- (or 6-) methylation. While relative rates for further methylation are more difficult to estimate, it appears that in the nonpolar solvents 2-methylation is still favored, while in water 2- and 4- (or 6-) methylation proceed at approximately the same rates.

While the examination of the neutral fraction allows some generalizations to be made concerning the sequence of the methylation of the resorcinolate dianion to the enediones, VII and X, only an examination of the acid or phenolic fraction as the reaction proceeds can lead to definite conclusions concerning the pathway of, and intermediates in, their formation. Because the methylation reaction is heterogeneous in nonpolar solvents, it was not possible to simply analyze aliquots of a single reaction. To minimize the extensive analysis requirement, only a single solvent (20% (by volume) tetrahydrofuran in toluene) at a single temperature (66.1°) with constant initial concentrations of resorcinol, methyl iodide, and lithium hydride (mole ratio of 1:12:2) was used, with reaction times varying from 5 to 1 440 min. The analysis of the phenolic fraction is reported in Table IV. The composition of the neutral fraction obtained varied randomly about that for 16.5% THF–toluene reported in Table III.

An estimate of the relative rates of the various steps indicated in Reaction Scheme 2 can be drawn from the results in Table IV. Thus, it appears that k_1 is about twice k_2 (four times k_2 if the statistical factor is included), that k_3 is approximately equal to $k_4 + k_5$ (or $(k_4 + k_5)/2$ if the statistical factor is included), and so on. Over six half-lives, the disappearance of resorcinol was first order in resorcinol with a rate constant of 1.67×10^{-3} s^{-1}. Unfortunately, when an analogue computer was used in an attempt to determine the relative rate constants and, hence, their absolute magnitude using the resorcinol disappearance as a calibration point, it was found to be impossible to get self-consistent values for k_1 and k_2, let alone for the subsequent rate constants. Apparently, other factors, such as those dependent upon heterogeneous reactions with base, rates of solution of the solid salt, or side reactions, could not be considered.

From the data presented, the sequence of the methylation in the formation of the two enedione products (VII and X) given in Reaction Scheme 2 seems quite well established. That this picture was still far from complete was apparent when mesorcinol (dihydroxymesitylene) itself was methylated under the conditions used for the resorcinol acid fraction

study. Comparison of the neutral fraction analyses of the methylation of resorcinol in tetrahydrofuran–toluene solution with those obtained for the methylation of mesorcinol reported in Table V shows that the enediones have another source, or a far larger portion of the product would have been dimethoxymesitylene.

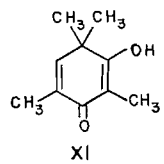
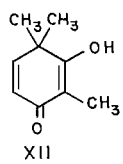
The first indication of what alternative paths could be operating in the methylation of the resorcinol dianion was the observation that some of the early fractions from the vapor phase chromatograph of the phenolic or acid fraction, which could not be sufficiently resolved for individual collection, exhibited nuclear magnetic resonance signals in the region of the geminal dimethyls in the enedione products (i.e. between 8.5 and 9.1 τ and between 7.8 and 8.2 τ) (25). By double collection on the vapor phase chromatograph, first from an Apiezon-1 and then from a polar Ucon column, it was possible to separate two components in 19 and 8% yields respectively from the acid fraction of a resorcinol methylation in 20% (by volume) tetrahydrofuran–toluene solution at 66° for 13.5 h with 6 equiv. of lithium hydride.

The nuclear magnetic resonance spectrum of the first component shows a single hydroxylic proton at 2.00 τ, a quartet (J = 1.5 c.p.s.) of area one at 3.65 τ, a doublet ($J \simeq 1.5$ c.p.s.) of area three at 8.12 τ overlapping a singlet of area three at 8.14 τ, and a sharp singlet of area six at 8.69 τ. The infrared spectrum shows a hydroxylic absorption as well as the three strong bands at 1 730, 1 675, and 1 605 cm^{-1} which are characteristic of the cyclohex-2,5-diene-1-one system. The geminal dimethyl doublets at 1 375 and 1 364, and 1 180 and 1 145 cm^{-1}, were also present. The ultraviolet spectrum showed a maximum at 236 mμ ($\epsilon = 4.1 \times 10^3$). From this spectral evidence the structure XI was assigned to the material.



XI



XII

The second component was assigned structure XII on the basis of its nuclear magnetic resonance spectrum, which showed a hydroxylic proton at 2.10 τ, two doublets (J = 10.0 c.p.s.) each of area one at 3.50 and 3.72 τ, and sharp singlets of areas three and six at 8.13 and 8.69 τ. Its infrared spectrum showed a hydroxylic proton and the same geminal dimethyl doublets as did that of XIX. In the double-bond region, strong absorptions occurred at 1 735, 1 690 (shoulder), and 1 662 and a broad band at 1 590 cm^{-1}. In the ultraviolet region a maximum at 221 mμ ($\epsilon = 4.5 \times 10^3$) was present.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

To establish that the components XI and XII are indeed intermediates in the formation of the enedione products, a portion of the acid fraction from which the two tentative intermediates were isolated was further methylated in tetrahydrofuran solution and found to be quickly converted in over 97% yield to neutral material with VII as the major constituent. Also, the fact that no hydroxydienone product was observed in the methylation of mesorcinol and 1 equiv. of lithium hydride established that the hydroxydienone intermediate must indeed be much more readily methylated at carbon than at oxygen and than mesorcinol or *m*-methoxymesitol is at either oxygen or carbon.

Since intermediates XI and XII occur in the methylation of resorcinol dianion, it is probable that the other intermediates of this type (i.e. hydroxydienones) can also occur to a greater or lesser extent. Thus, Reaction Scheme 2 should be extended to include these other intermediates, as is done in Reaction Scheme 3. Little evidence about the relative importance of the various routes to the enedione products has been obtained, but the large amount of dimethoxymesitylene formed in the methylation of the mesorcinol dianion suggests that, at least in the 20% (by volume) tetrahydrofuran–toluene solution, the route through mesorcinol is of minor importance.

Phloroglucinol Methylations

For purposes of comparison, several methylations of phloroglucinol in the presence of 6 equiv. of lithium hydride at 66° were performed. In tetrahydrofuran solution, more than 85% of neutral fraction, which was made up of yields of 49% 2,2,4,4,6,6-hexamethylcyclohexan-1,3,5-trione III, 14% 2,2,4,4-tetramethyl-5-methoxycyclohex-5-en-1,3-dione, 8% 2,4,6-trimethoxyxylene, and 2% trimethoxymesitylene, was obtained. An additional three neutral components (total yield 12%) were unassigned. In aqueous solution under similar conditions, only a 19% yield of neutral fraction was obtained. It was made up of yields of 15% of the hexamethyltrione and 4% of the tetramethylenedione. The acid fractions were not sufficiently volatile for vapor phase chromatographic analysis and consequently were not examined in detail.

In tetrahydrofuran solution, the phloroglucinol trianion was even more readily carbon methylated than was the resorcinol dianion. Just why so little neutral fraction was obtained from the aqueous methylation of phloroglucinol is not clear and perhaps warrants more study. Unfortunately, the nonvolatility of the acid fraction would necessitate the use of separation and analytical techniques other than vapor phase chromatography.

EXPERIMENTAL

The phenols employed throughout the following experiments were reagent grade materials which were doubly sublimed and stored in the dark. They melted over less than a 1° range and showed no or minuscule impurities on the vapor phase chromatograph. All organic solvents, except the alcohols, were dried over, and freshly distilled from, $LiAlH_4$. Methyl iodide was freshly distilled from calcium hydride. All manipulation of lithium and sodium hydrides was done in a nitrogen-purged dry box and reactions were run under a nitrogen atmosphere in carefully dried equipment. Water used as a reaction solvent was deionized water which was distilled, degassed under vacuum, and saturated with nitrogen before transfer. Reaction times were measured from the start of methyl iodide addition.

Cation Effects

Into a 500-ml Morton (creased) flask equipped with a reflux condenser, an equilibrating addition funnel, and a high-speed stirrer were placed 0.118 ± 0.002 mole of metal hydride (LiH or NaH) and 3.22 ± 0.05 g (0.0292 ± 0.0005 mole) of resorcinol, and 150 or 175 ml of tetrahydrofuran was slowly added. The white slurry was slowly brought to gentle reflux and 25 ml (57 g, 0.400 mole) of methyl iodide was added over several hours with vigorous high-speed stirring. After 30 ± 5 h, the reaction was stopped, the solvents were removed on a rotary evaporator, and the residue was taken up in 100 ml each of diethyl ether and 1:1 aqueous Claisen's alkali.* The ethereal layer was extracted with additional 50-ml portions of the alkali

REACTION SCHEME 3. Sequence of resorcinol dianion carbon methylation including hydroxydienone intermediates.

until the extract was colorless. The combined alkaline fractions were extracted with several 50-ml portions of ether. The combined ethereal layers were dried and the ether was removed to leave the neutral fraction. The alkaline layers were acidified with hydrochloric acid and the acid or phenolic fraction was recovered by three or four extractions with ether. The ethereal extract was dried and the ether removed to leave the phenolic fraction.

Vapor phase chromatographic analysis (v.p.c.) of the two fractions for the lithium and for the sodium salts

For personal use only.

respectively are: neutral fraction, 99%, 82%; enedione mixture, 24%, <2%; *m*-dimethoxybenzene, 4%, 55%; 2,6- and 2,4-dimethoxytoluene, 41% and 9%, 18% (total); 2,4-dimethoxy-1,3-xylene, 18%, 3%; 4,6-dimethoxy-1,3-xylene, 5%, 2%; and dimethoxymesitylene, 2%, <1%. The yields from the 18% of acid fraction in the case of the sodium salt were 11% *m*-methoxyphenol, 4% resorcinol, and at least five other components.

Solvent Effects

Aqueous Tetrahydrofuran

Into the Morton flask of the apparatus previously described was placed 0.97 ± 0.14 g (0.092–0.120 mole, 4 equiv.) of lithium hydride, and 10–25 ml of tetrahydrofuran was added (except in the pure aqueous reaction). In the addition funnel, 3.00 ± 0.45 g (0.023–0.031 mole, 2 equiv.) of resorcinol was dissolved in 25–40 ml of tetrahydrofuran (100 ml of water in the aqueous reaction) and slowly added to the lithium hydride with gentle stirring. After hydrogen evolution ceased, the remaining quantities of tetrahydrofuran and water were added to give a total of 150 ml of solvent, and then heating and vigorous stirring commenced. At reflux, 25 ml (57.0 g, 0.400 mole, >13 equiv.) of methyl iodide was added dropwise over 1–2 h.

The reaction was gently refluxed with vigorous stirring for about 10 h and without stirring for another 12 h before it was worked up by the extractive procedure presented above. The v.p.c. analyses of the neutral fractions on a polar Ucon column are presented in Table II. Except in pure water, the neutral fraction accounted for 97–100% of the resorcinol. In water, it was 80%. The resinous acid fractions were not examined in detail but no resorcinol was present and, at most, there were only small amounts of *m*-methoxyphenol present.

Other Solvents

For the other solvents presented in Table III, the quantities of lithium hydride, resorcinol, and methyl iodide were very similar to those for the aqueous tetrahydrofuran reactions. In the case of the nonpolar solvents such as hexane and toluene, the resorcinol was taken up in 25–50 ml of tetrahydrofuran and added to the lithium hydride in the Morton flask so that the resorcinol salt was formed before the addition of the nonpolar solvent. In the case of methanol, dimethylsulfoxide, and dimethylformamide, the resorcinol was dissolved in a portion of the solvent and added normally. The reaction and work-up were performed as before and the analyses of the neutral fractions are reported in Table III.

Methylation of m-Methoxyphenoxide

Into the Morton flask was placed 0.95 ± 0.08 g (0.017 ± 0.009 mole, 2 equiv.) of lithium hydride, and 5.9 g (0.050 mole, 1 equiv.) of *m*-methoxyphenol dissolved in 25 ml of the solvent employed (tetrahydrofuran or water) was slowly added with gentle stirring. After hydrogen evolution ceased, the remaining solvent (water, tetrahydrofuran, or toluene) was added to give 150 ml, and gentle reflux and vigorous stirring commenced. Over a period of 2 h, 25 ml (57 g, 0.400 mole) of methyl iodide was added. After the 30-h reaction period, the reaction mixture was worked up like the resorcinol methylations. Product analysis is reported in Table III.

Methylation of 3,5-Dimethoxyphenoxide

Following the procedure of Pratt and Robinson (30), 3,5-dimethoxyphenol was synthesized from phloroglucinol and methanol with hydrogen chloride catalysis. To 1.040 g (0.118 mole) of lithium hydride and 10 ml of tetrahydrofuran in the Morton flask, 3.820 g (0.0207 mole) of 3,5-dimethoxyphenol (b.p. 132° at 0.9 mm, m.p. 39–40°) in 40 ml of tetrahydrofuran was slowly added. After hydrogen evolution ceased, an additional 100 ml of tetrahydrofuran was added, and at gentle reflux with vigorous stirring 25 ml (57 g, 0.400 mole) of methyl iodide was added over a period of 1 h. After 24 h, the reaction was worked up by the usual extractive procedure to give 4.47 g of neutral and 0.01 g of acid fraction. Vapor phase chromatographic analysis on a polar Ucon column showed the neutral fraction to be 39% 1,3,5-trimethoxybenzene, 43% 2,4,6-trimethoxytoluene, and 9% 2,4,6-trimethoxyxylene. The remaining two unidentified fractions, in 6 and 3% yields, showed geminal dimethyl proton signals in their nuclear magnetic resonance spectrum at 7.95–8.05 τ and carbonyl absorption in the infrared, indicating that they were dienone products.

The Phenolic Fraction

The phenolic fraction from the methylation of resorcinol in tetrahydrofuran–toluene solution with 4 equiv. of lithium hydride and excess methyl iodide was examined at 66° for various times of reaction. To 1.102–1.312 g (0.125–0.148 mole) of lithium hydride in the Morton flask, 3.446–4.073 g (0.0312–0.0370 mole) of resorcinol in 25 ml of tetrahydrofuran was slowly added with gentle stirring. After hydrogen evolution had ceased, 100 ml of toluene was added, the flask was lowered into the 66° constant temperature bath, and vigorous high-speed stirring commenced. After equilibration for ¾–1 h, 25 ml (57 g, 0.400 mole) of methyl iodide was rapidly added. The reaction time was measured from the start of the methyl iodide addition to the removal of the flask from the oil bath. After the desired interval, stirring was stopped, the methyl iodide and other solvents were quickly removed on the rotary evaporator, and the reaction was worked up by the usual extraction method to give the neutral and phenolic or acid fractions.

The exact quantities of reagents used and weights of neutral and acid fractions are reported in Table VI. The compositions of the acid fractions are reported in Table IV. Structural assignment of the components of the acid fraction was by nuclear magnetic resonance and infrared spectra obtained on the materials collected from a 10-ft Apiezon-1 column of the v.p.c. and by comparison of spectra and retention times with those of knowns of all compounds identified except the two dimethylresorcinols (see Table IV). The components of the neutral fraction were also collected from a 16-ft Ucon 50-HB-5000 and identified by spectral

*Tetrahydrofuran (25 ml) and 100 ml of toluene.
†No excess LiH was evident in the work-up.

methods, but the only trend noted was a small decrease in the amounts of the intermediately methylated toluenes, xylenes, and mesitylene compared to the enediones as the reaction proceeded. The analyses of the acid fractions are reported in Table IV.

Preparation of Mesorcinol

Attempts to prepare mesorcinol (dihydroxymesitylene or 2,4,6-trimethylresorcinol) from mesitol (2,4,6-trimethylphenol) by first nitrating or sulfonating were unsuccessful because of oxidation and decomposition of the mesitol. (Judson and Kilpatrick were also unable to prepare *m*-nitromesitol directly (31).) The preparation reported by Cornforth *et al.* (32) for mesorcinol by methylation of resorcinol with sodium methoxide and methanol could not be repeated. Friedel and Crafts reactions with zinc chloride or boron trifluoride and methyl iodide in a variety of solvents were also singularly ineffective. Attempts to diazotize diaminomesitylene with sodium nitrite in hydrochloric acid or sulfuric acid solutions, either stepwise or both amine groups at once, and to decompose the diazonium salts formed gave little hydroxyl-containing material. (Morgan and Davies were able to couple both the mono- and the di-diazonium salt of diaminomesitylene with β-naphthol but no yields and few details are given (33).) Equally unsuccessful were the attempts to exchange the amino groups for hydroxyl groups in diaminomesitylene by use of the Bucherer reaction (34).

The procedure finally used for the preparation of dihydroxymesitylene was essentially that employed by Knecht (35).

Dinitromesitylene

To 350 ml of red fuming nitric acid cooled in an ice bath to 0°, 140 ml (121 g, 1.0 mole) of mesitylene (b.p. 164–165°) was very slowly added, drop by drop, with magnetic stirring. After the addition was complete (4–5 h) the reaction mixture was stirred at room temperature for 2 h and then poured onto ice (about 700 g). Water (1 000 ml) was added and the cake of dinitromesitylene was broken into small pieces before the flask was placed in a refrigerator overnight.

The aqueous acid was decanted and the solid washed with several liters of water. The solid was then taken up in hot absolute ethanol (about 700 ml) and recrystallized to give beautiful pale yellow needles. The 204.1 g of dinitromesitylene (m.p. 84.5–85.0°, lit. 86° (36)) obtained corresponds to a 96.5% yield.

Nitromesidine

In a 3-l three-necked flask, 100 g (0.485 mole) of dinitromesitylene was dissolved in 750 ml of absolute ethanol and 85 ml of concentrated aqueous ammonia was added. The solution was gently refluxed on a steam bath while hydrogen sulfide gas was slowly bubbled through it. Every few hours, the solution was saturated with ammonia. After 50 h, the hydrogen sulfide gas flow was stopped and the reaction cooled to 0° for 4–6 h to precipitate the sulfur, which was then removed by filtration. The yield of 43.3 g (0.135 mole) of monoclinic sulfur (m.p. 119.5–120.5°) corresponds to 96% of theoretical yield.

The ethanol was removed from the filtrate on the steam bath to leave a yellow-brown oil which solidified on cooling. The crude nitromesidine was purified by dissolving it in 500 ml of toluene and by precipitating the amine as the hydrochloride salt by bubbling hydrogen chloride through the solution. The amine hydrochloride was removed by filtration and the filtrate was treated with more hydrogen chloride to recover any remaining amine. The salt was washed with copious quantities of toluene and air dried (m.p. 219° (decomp.)). The nitromesidine was recovered by treating the hydrochloride salt with aqueous ammonia and by recovering the liberated amine with several 150-ml ether extractions. Removal of the ether gave 81.5 g (95%, m.p. 71–72.5°, lit. 75°) of a yellow solid. Either the hydrochloride salt or the free amine could be used in the next step.

m-Nitromesitol

To the hot solution formed by adding 50 ml of concentrated sulfuric acid to 250 ml of water, 50 g (0.277 mole) of nitromesidine was added. After all the amine went into solution, 250 ml of water was added together with about 500 g of ice. By vigorous stirring with a stirring rod, the solid amine salt was kept finely divided.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

With external cooling and occasional addition of ice, 19.70 g (0.281 mole) of sodium nitrite in 90 ml of water was slowly added while the solution was stirred and swirled. Small portions of solid sodium nitrite were added until the solution still gave a positive starch–iodide paper nitrous acid test after it had stood for 10–15 min. Several grams of urea were then added to remove the excess nitrous acid.

After it had stood for several hours at room temperature, the solution was heated on a steam bath for several hours. The nitromesitol was removed from the by-products by steam distillation. By acidifying the distillate with 5–10 ml of concentrated hydrochloric acid per liter of distillate, 41.35 g (82%) of crude nitromesitol was recovered from the 24–35 l of distillate by ether extraction. The nitromesitol was purified by extraction of an ethereal solution with 1:1 aqueous Claisen's alkali, which was then washed with several portions of ether. The alkaline material was acidified and re-extracted with ether to give 30.1 g (60%) of nitromesitol (m.p. 63–64.5° after recrystallization from toluene).

Anal. Calcd. for $C_9H_{11}NO_3$: C, 59.66; H, 6.12; N, 7.73. Found: C, 59.43; H, 6.19; N, 7.60.

Mesorcinol

Reductions of nitromesitol with lithium aluminium hydride exploded two out of three times; thus, this reduction was performed with tin and hydrochloric acid.

On a steam bath 50 g (0.277 mole) of nitromesitol was heated for several hours in 175 ml of concentrated hydrochloric acid and 65 g (0.548 mole) of granulated tin, and swirled frequently. The reaction mixture was poured into 1.5 l of water and heated on a steam bath while hydrogen sulfide was bubbled through the solution to decompose the tin salts. After the tin sulfide was removed by filtration, the filtrate was evaporated to dryness on the steam bath.

The salt was taken up in 350 ml of water and 70 ml of sulfuric acid, and the solution was cooled to 0° before 19.0 g (0.272 mole) of sodium nitrite in 90 ml of water was slowly added with stirring. After it was stirred for several hours at room temperature, the solution was heated for 3 h on the steam bath, cooled, and extracted with a number of 100-ml portions of ether. From the black tarry mess left after ether removal, 19.9 g (48%) of crude mesorcinol was obtained after two sublimations. After two recrystallizations from toluene, 9.8 g (23%) of mesorcinol (m.p. 152–153.5°, lit. 149–150°) was obtained in 12% overall yield.

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.02; H, 7.95. Found: C, 70.85; H, 7.93.

Methylation of Mesorcinol

Two methylations of mesorcinol were performed in tetrahydrofuran–toluene solution, the first with 4 equiv. and the second with 1 equiv. of lithium hydride. The procedures were parallel and, where different, the quantities of reagents or products indicated refer to the first and second reaction respectively.

To 1.25 g (0.142 mole) or 0.238 g (0.0273 mole) of lithium hydride placed in the Morton flask, 5.217 g (0.0342 mole) or 4.142 g (0.0272 mole) of mesorcinol in 25 ml of tetrahydrofuran was slowly added. After hydrogen evolution had ceased, the flask was lowered into the 66° oil bath and vigorous stirring was commenced. After equilibration for $\frac{3}{4}$–1 h, 25 ml (57 g, 0.400 mole) of methyl iodide was added over several hours.

The reaction was allowed to proceed for 23 or 8 h before being worked up by the usual extractive procedure to give 5.965 g or 1.673 g of neutral fraction and 0.065 g or 2.801 g of phenolic fraction. The analyses of the neutral fractions are reported in Table V. Of the two phenolic fractions, only the second was examined and found to be exclusively *m*-methoxymesitol and mesorcinol, representing a 36.4% yield and a 26.2% recovery respectively. The products accounted for over 97 or 99% of the starting mesorcinol.

Isolation of Hydroxydienones

Hydroxydienone intermediates were isolated from several methylations of resorcinol with 6 equiv. of lithium hydride in tetrahydrofuran–toluene solution. Thus, to 2.450 g (0.277 mole) of lithium hydride in the Morton flask, 5.073 g (0.0461 mole) of resorcinol in 25 ml of tetrahydrofuran was cautiously added. After hydrogen evolution ceased, 100 ml of toluene was added, the mixture was allowed to equilibrate at 66°, and, with vigorous stirring, 25 ml (57 g, 0.400 mole) of methyl iodide was run in. After 13.5 h, the usual work-up gave 3.940 g of neutral and 4.034 g of acid fraction. The neutral fraction contained enediones (40% yield) and another three components (10% yield). Vapor phase chromatographic analysis of the acid fraction showed it to contain, in addition to peaks assigned to the usual methylated resorcinols (each in 0.5–3.7% yield), a large unsymmetrical peak (32% overall yield) with an Apiezon-1 column. Re-separation of the collected fraction on a polar Ucon column showed it to be made up of two components in the ratio of 5:2 (i.e. in 19 and 8% yields on 39 and 16% of the acid fraction, respectively). The two components were assigned structures XI and XII, principally on the basis of spectral evidence presented above.

Intermediacy of the Hydroxydienones

To establish that the two hydroxydienones XI and XII were potential intermediates, 1.772 g of the acid fraction, containing a total of 55% of the two hydroxydienones, and 1.33 g (0.151 mole) of lithium hydride were treated in 100 ml of tetrahydrofuran at reflux with 25 ml (57 g, 0.400 mole) of methyl iodide for 25 h. (The yellow complex which immediately forms when methyl iodide comes in contact with lithium resorcinolates and which persists as long as any of the salt remains faded within 1 h to the off-white color that indicates no resorcinolates remain.) Normal work-up gave 1.868 g of neutral and 0.054 g of acid fraction. The neutral fraction was 37% 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione (VII), 19% dimethoxymesitylene, 12% dimethoxytoluenes and xylenes, and the rest unidentified products.

Methylation of Phloroglucinol in THF

To 2.194 g (0.249 mole) of lithium hydride in the Morton flask, 4.8023 g (0.0380 mole) of phloroglucinol dissolved in 125 ml of tetrahydrofuran was slowly added. Little hydrogen evolution was noted. The flask was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

lowered into the 66° bath and allowed to equilibrate for 1.5 h with vigorous stirring before 25 ml (57 g, 0.400 mole) of methyl iodide was added over a period of 1 h. The reaction was run for 30 h with stirring throughout. The solution was heterogeneous throughout and considerable lithium hydride was present at the end.

The usual extraction work-up gave 6.83 g of neutral and 1.31 g of acid fraction. The acid fraction was not sufficiently volatile to be analyzed on the v.p.c. The 85.4% by weight of neutral fraction had the following composition: 48.5% 2,2,4,4,6,6-hexamethylcyclohexan-1,3,5-trione (m.p. 80.0–81.0°, lit. 80–81° (12)), 14.1% 2,2,4,4-tetramethyl-5-methoxycyclohex-5-en-1,3-dione (m.p. 58.5–60.5°), 7.9% 2,4,6-trimethoxyxylene, and 2.0% trimethoxymesitylene. In addition, peaks of 9.2%, 2.7%, and 0.3% of the total area were unassigned.

Methylation of Phloroglucinol in Water

To 1.2610 g (0.143 mole) of lithium hydride in the Morton flask, 3.489 g (0.0276 mole) of phloroglucinol in 125 ml of water was cautiously added. After the reaction subsided, the flask was lowered into the 66° oil bath and allowed to equilibrate for 1 h with vigorous stirring before the slow addition of 25 ml (57 g, 0.400 mole) of methyl iodide was started. After 28 h the reaction mixture, which was heterogeneous only with respect to the methyl iodide phase, was worked up in the usual manner. The reaction gave 0.937 g of neutral fraction (a low-melting solid) and 4.042 g of acid fraction.

The neutral fraction (19%) consisted of yields of 14.8% of 2,2,4,4,6,6-hexamethylcyclohexan-1,3,5-trione and 4% of 2,2,4,4-tetramethyl-5-methoxycyclohex-5-en-1,3-dione. The acid fraction could not be analyzed by v.p.c.

ACKNOWLEDGMENTS

The author expresses his appreciation to Dr. R. B. Sandin for his personal interest and encouragement. The author also thanks Dr. D. Y. Curtin for his guidance, aid, and encouragement throughout the study and for reading this manuscript, and the University of Illinois and the Firestone Tire and Rubber Company for financial support while this research was undertaken.

THE METHYLATION OF THE RESORCINOLATE DIANION

II. PER-METHYLATED RESORCINOL: 2,2,4,6,6-PENTAMETHYLCYCLOHEX-4-EN-1,3-DIONE

ALLAN R. STEIN[1]

Noyes Laboratory of Chemistry, University of Illinois, Urbana, Illinois

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Structural evidence for the enedione products, 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione and 2,2,6,6-tetramethylcyclohex-4-en-1,3-dione, which are the principal products from the methyl iodide alkylation of the dilithium resorcinol salt in nonpolar aprotic or very polar hydroxylic solvents, is presented. The diimide and lithium aluminium hydride reduction products are presented and, together with the decarboxylated hydrolysis product, 2,4,6-trimethylcyclohex-2-en-5-one, constitute proof of the structure of the 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione. Some of the synthesis potential of resorcinolate alkylations is indicated.

INTRODUCTION

Earlier studies in this laboratory on the nuclear alkylation of phenoxides, and, in particular, those studies on 2,6-disubstituted phenoxides, led to the study of the alkylation of polyhydroxylic benzenes under basic conditions. Curtin *et al.* (1) first observed that the sealed-tube methylation of lithium 2,6-dimethylphenoxide with methyl iodide leads to the formation of 2,6-dimethylanisole and a carbonyl-containing species to which was assigned structure I. Some of the many factors which influence the relative amounts of carbon and oxygen alkylation have been discussed by Curtin *et al.* (1), Curtin and Fraser (2), Curtin and Dybvig (3), Kornblum and Lurie (4), Kornblum and Seltzer (5), Kornblum *et al.* (6), Kornblum *et al.* (7), and Barner and Schmid (8). A brief review of the alkylation of analogous systems (e.g. enolates, oxime salts, and thiophenolates) is given in the recent paper by Curtin and Dybvig (3).

By analogy to the phenoxide methylations, the various alkylated *m*-dimethoxybenzenes and, possibly, the dienone analogues II and III would be among the expected neutral products from the methylation of the dilithium salt of resorcinol. It is conceivable that even the higher methylation products IV and V might be formed. It is the last of these, the 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione (V), with which this paper deals.

The only previous report of the synthesis of V is the questionable work of Kurzweil in 1903 (9). The 5-methyl substituted compound, however, was reported by Herzig and Wenzel in 1906 (10) as a minor product from the methyl iodide methylation of orcinol (5-methylresorcinol). Herzig and Zeisel (11) have reported that the methylation of phloroglucinol gives 2,2,4,4,6,6-hexamethylcyclohexan-1,3,5-trione (VI), a structure which has recently been confirmed by the independent synthesis of Erickson and Kitchens (12).

This paper deals with the synthesis and structure of 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione, VI, and some of its properties and reactions.

RESULTS AND DISCUSSION

Methyl iodide methylations of resorcinol in the presence of excess base in solvents of intermediate polarity (e.g. methanol, ethanol, and tetrahydrofuran) give, among the

[1]*Current address: Central Research Laboratories, Dominion Tar and Chemical Co., Ltd., Senneville, Quebec.*

neutral products, a small carbonyl-containing fraction and all seven of the possible 1,3-dimethoxybenzenes—methylation meta to the oxygens was never observed in the products. By use of the less polar solvent mixture of 16% tetrahydrofuran in toluene, it was possible to raise the yield of the carbonyl compounds to about 70%, based upon starting resorcinol, or to about 93–98% of the neutral fraction.

Comparison of the infrared, nuclear magnetic resonance, and ultraviolet spectra of the carbonyl fraction to those of 2,6,6-trimethylcyclohexa-2,4-dienone (I) suggested a similar structure. Thus, the carbonyl fraction collected on the vapor phase chromatograph had carbonyl bands in the infrared at 1 717 and 1 676 cm^{-1} and a geminal dimethyl doublet at 1 382 and 1 362 cm^{-1} compared to those at 1 720 and 1 680 cm^{-1} and at 1 385 and 1 363 cm^{-1} for the Diels–Alder dimer of I (14). In its nuclear magnetic resonance spectrum, the carbonyl fraction had signals at 8.74 and a narrow doublet at 8.16 τ compared to those at 8.80 and 8.13 τ in I. Even the coupling constant giving rise to the doublet was about 1.45 c.p.s. for both species. The ultraviolet absorbance maxima at 231 mμ (ϵ = 8 450) and at 305 mμ ($\epsilon \simeq 57$) suggest that the fraction contains both a conjugated and non-conjugated carbonyl. This conclusion is confirmed by the infrared carbonyl absorption frequencies quoted above.

A molecular weight and elemental analysis determination gave the molecular formula $C_{11}H_{16.5}O_{2.05}$ for one carbonyl fraction. The nuclear magnetic resonance spectrum of this particular fraction showed the aforementioned signals at 8.74 τ (area = 12.97, a singlet), at 8.16 τ (area = 3.05, a doublet, $J \simeq 1.5$ c.p.s.), and at 3.47 τ (area = 1.00, a quartet, $J \simeq 1.5$ c.p.s.) and two pairs of doublets at 3.98 and 3.21 τ (area 0.09, $J \simeq 10.5$ c.p.s.). The relative intensities of the olefinic quartet and pair of doublets varied from reaction to reaction, so that they must be caused by two separate components. Indeed, the spectrum of the carbonyl fraction collected on the vapor phase chromatograph from the methylation of mesorcinol (dihydroxymesitylene) was completely free of the olefinic doublets. It showed only the signals at 3.47, 8.16, and 8.74 τ (relative areas, 1:3:12) and analyzed for $C_{11}H_{16}O_2$.

Nuclear magnetic resonance spin-decoupling studies confirmed that the pairs of olefinic doublets were coupled to each other and that the olefinic quartet at 3.47 τ and the doublet at 8.16 τ were spin coupled. Upon expansion, the 8.74 τ signal was found to be a narrow jagged doublet with separation of about 0.8 c.p.s. The signal was unaffected by temperature variations between −35° and 65°.

From the spectral evidence discussed above, it was concluded that the carbonyl-containing fraction from the methylation of resorcinolate dianion must be a mixture of IV and V. The percentage of IV present varied from 8 to 30%, with the higher end of the range occurring in the reactions with lower conversions of resorcinol to the enediones, as would be expected from the data presented in Part I of this series (13).

While attempts to make the usual derivatives of the double bond or carbonyls in V were unsuccessful, additional evidence for the structure of the enedione (V) is found in some of its reactions. By using pure V derived from the methylation of mesorcinol under conditions identical with those used in the methylation of resorcinol, a diimide reduction of the carbon–carbon double bond was performed by the procedure of van Tamelen *et al.* (15). The reduced material, 2,2,4,4,6-pentamethylcyclohexan-1,3-dione, VII, showed carbonyl absorption frequency shifts from 1 727 and 1 683 cm^{-1} to 1 695 and 1 724 cm^{-1} and disappearance of the 900 cm^{-1} vinyl proton bending frequency. In its nuclear magnetic resonance spectrum, VII showed a pair of overlapping multiplets (J = 6.5 c.p.s.) centered at 7.28 and 7.49 τ of total area one, a narrow doublet (J = 1.5 c.p.s.) at 8.15 τ

of area one, a doublet (J = 6.5 c.p.s.) at 8.30 τ of area one, and an unsymmetrical quartet at 8.84 τ of area 15. Spin-decoupling studies confirmed that the downfield multiplets were coupled both to the protons at 8.15 and 8.30 τ and to the methyl protons at 8.84 τ. The protons at 8.15 τ were also coupled with the methyl protons. Further confirmation of the structure of VII was found in its ultraviolet spectrum, which showed absorption maxima at 290 mμ (ϵ = 47) and at 214 mμ (ϵ = 725).

Lithium aluminium hydride reduction of V gave three fractions upon vapor phase chromatographic separation. The minor constituent (11% of the product) showed infrared absorptions attributed to hydroxyl and to carbonyl (1 709 cm^{-1}). No olefinic proton signal appeared on the nuclear magnetic resonance spectrum and, in the ultraviolet, maxima appeared at 280 mμ (ϵ = 44) and at 235 mμ (ϵ = 143) as a shoulder on end absorption. This spectral evidence is consistent with structure VIII, arising from V by the 1,4- or Michael addition of the hydride to the conjugated carbonyl (16) and simple reduction of the other carbonyl.

The infrared spectra of the two remaining fractions, IX and (X + XI), showed no carbonyl absorption but did show very weak carbon–carbon double bond absorption at about 1 650 cm^{-1} and very strong broad hydroxyl absorption. The ultraviolet spectra showed only weak absorptions at about 230 mμ with $\epsilon \simeq 53$ and 38, respectively, for the major (52% yield) and final (37% yield) fractions. Nuclear magnetic resonance and spin-decoupling results are summarized in Table I.

After IX had stood in d_6-dimethylsulfoxide for several weeks, or after a small amount of water had been added and the mixture had stood for a few minutes, the nuclear magnetic resonance spectrum of IX was simplified. The pair of doublets at 5.54 and 5.72 τ became a broad singlet, while the doublets at 6.56 and 6.72 τ became two singlets. The rest of the spectrum was unchanged. The low-field doublets then are caused by the hydroxylic protons, and their spin coupling to the protons on the hydroxylic carbon is confirmed.

On the basis of this evidence, the major fraction was assigned structure IX. Because of the marked similarity of the spectra of the major and final fractions, it was concluded that they were isomeric. That the third fraction was about an equal-part mixture of the two possible isomers of IX was inferred from the nuclear magnetic resonance spectrum and especially from the fact that, in the spin-decoupling studies, a narrow "doublet" was obtained from several signals, while the corresponding signals in IX decoupled to a sharp singlet. Structures X and XI were assigned to the components of this mixture.

Aqueous base cleavage of V did not give reverse aldol cleavage at the double bond but did give a quantitative yield of a sharp-melting solid with the molecular formula $C_{11}H_{18}O_3$, corresponding to the addition of the elements of water to the enedione. The infrared spectrum contained the characteristic very broad carboxylic acid hydroxyl absorption between 3 600 and 2 400 cm^{-1}. The ultraviolet spectrum showed only a strong maximum at 233 mμ ($\epsilon = 2.7 \times 10^3$).

Heating the acid above 150° resulted in decarboxylation to give $C_{10}H_{18}O$. The decarboxylated material showed a single sharp carbonyl absorption at 1 720 cm^{-1}, which is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in the region of non-conjugated carbonyl groups. At 845 cm^{-1}, a band characteristic of C—H bending in trisubstituted ethylenes was present. In the ultraviolet region absorption maxima were present at 293 mμ (ϵ = 220) and at 212 mμ ($\epsilon = 3.2 \times 10^3$). The nuclear magnetic resonance signals and the results of spin decoupling for the decarboxylated compound are summarized in Table II.

TABLE II

Nuclear magnetic resonance and double resonance studies on 2,4,6-trimethylhept-2-en-5-one (XII)

Signal	τ value	Area ratio	Multiplicity	J (c.p.s.)	Double resonance
A	5.02	1	Pair of heptets	10.0 and 1.3	At B gave a single heptet (J = 1.3) " D " " " doublet (J = 10.0)
B	6.53	1	Pair of overlapping quartets	10.0 and 7.0	" A " " " quartet (J = 7.0) " E–F " " " doublet (J = 10.0)
C	7.34	1	Heptet	7.0	" E–F " " singlet

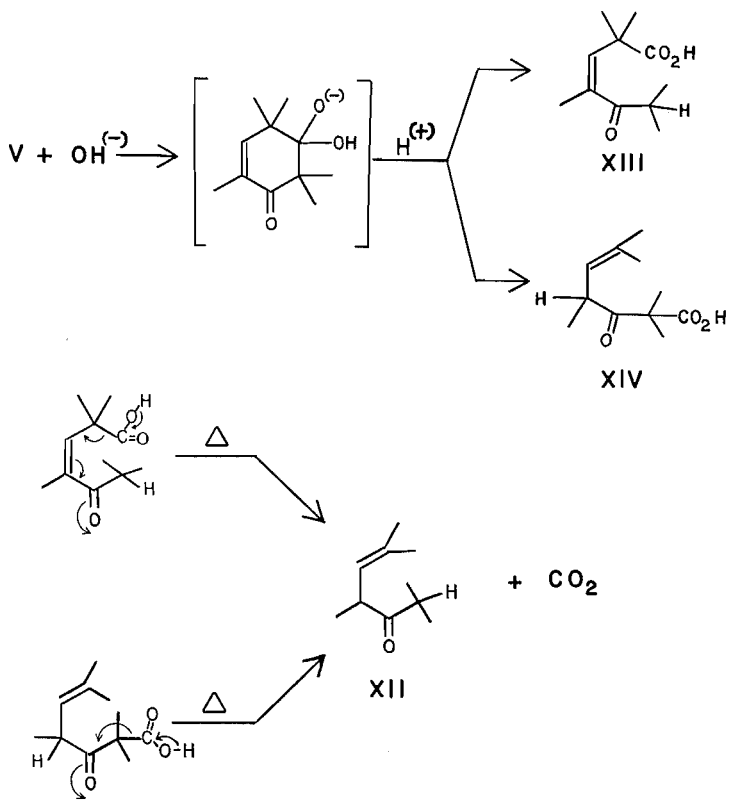
E	8.98	6	Pair of overlapping doublets	7.0	" B " an unsymmetrical triplet
F	9.02	3		6.9	" C " " " "

From this spectral evidence, the decarboxylated material was assigned structure XII. This 2,4,6-trimethylcyclohex-2-en-5-one can arise by decarboxylation of either or both of the acids derived from attack of the hydroxide ion at the 1-carbonyl in V, that is, from either XIII or XIV.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Nuclear magnetic resonance spectroscopy should readily distinguish between the two acids, XIII and XIV. Unfortunately, even the sharp-melting (88.5–88.8°) analytical sample of the acid gave a spectrum which could be either of, or more likely a mixture of, the two acids. The ultraviolet maximum at 233 mμ ($\epsilon = 2.7 \times 10^3$), corresponding to that at 231 mμ ($\epsilon = 8.5 \times 10^3$) for V, suggests that approximately 30–35% of the "enone" chromophore is present in the acid mixture. This approximately 1:2 composition of XIII and XIV is consistent with the nuclear magnetic resonance spectrum of the acids.

Analogies for the ring cleavage by aqueous base treatment are to be found in a study by Stetter (17) of the formation of δ-ketocarboxylic acids by the treatment of 1,3-cyclohexandiones with aqueous base.

All of the physical data presented for the major product from the methylation of resorcinol in basic nonpolar solution, 2,2,4,6,6-pentamethylcyclohex-4-en-1,3-dione, and some of its reaction products are consistent only with the structure proposed. Potential synthetic uses for the enedione or its analogues produced by substituting other alkyl halides for the methyl iodide at any point along the alkylation sequence, as presented in the previous paper (13), are numerous and varied.

EXPERIMENTAL

Infrared spectra reported were obtained for the most part with a Perkin–Elmer model 21 on 10% solutions in carbon tetrachloride. Nuclear magnetic resonance spectra were obtained with a Varian A-60 on 10–30% solutions in carbon tetrachloride or deuterochloroform, except in those cases (IX, X, and XI) where the sample was not soluble. d_6-Dimethylsulfoxide was then used. Spin-decoupling studies were performed on a Varian HR-60 with side-band double resonance. Ultraviolet spectra were obtained in ethanolic solution on a Bausch and Lomb Spectronic 505 spectrophotometer.

Preparation of 2,2,4,6,6-Pentamethylcyclohex-4-en-1,3-dione (Enedione)

Into a 500-ml Morton (creased) flask continually purged with dry nitrogen, 6.568 g (0.0596 mole) of resorcinol in 25 ml of tetrahydrofuran, which had been freshly distilled from lithium aluminium hydride, was very slowly added to 3.162 g (0.358 mole) of lithium hydride powder while the mixture was gently stirred. In the violent evolution of hydrogen, considerable tetrahydrofuran vapors were entrained. After hydrogen evolution had ceased, 125 ml of toluene, which had been freshly distilled from lithium aluminium hydride, was added, and heating and vigorous high-speed stirring commenced. At gentle reflux, 50 ml (114 g, 0.800 mole) of methyl iodide, which had been freshly distilled from calcium hydride, was dropped in over an 8-h period. The milky-white slurry turns brilliant yellow with the first drops of methyl iodide.

After it was refluxed and stirred for 24–30 h, the solution was allowed to settle and cool before the supernatant liquid was poured off and concentrated on a rotary evaporator. The residue from both the flask and the solvents was taken up in 100 ml each of ether and 1:1 aqueous Claisen's alkali (13). Extraction and re-extraction of each of the ethereal layers until the fresh alkali extracts were colorless, and drying and removal of the ether, gave 6.18 g of neutral fraction. Vapor phase chromatographic analysis on a 16-ft 20% liquid-phase Ucon 50-HB-2000 column at 188° showed the neutral fraction to be 98% enediones and 2% dimethoxymesitylene.

The enedione fraction collected from the vapor phase chromatograph was found to be 93% V and 7% IV. The oil (b.p. 75–82° at 2.3 mm and 62–66° at 0.9 mm) had an average molecular weight of 178.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95. Calcd. for $C_{10}H_{14}O_2$: C, 71.65; H, 8.44. Found: C, 72.91; H, 8.78.

Attempted Preparation of Derivatives of the Enedione V

2,4-Dinitrophenylhydrazone

The procedure of Shriner *et al.* (18) was followed, but the small amount of solid obtained after it had stood at 3° for 5 days melted over a 50° range, even after six recrystallizations from ethanol.

Semicarbazone

The procedure of Shriner *et al.* (19) was followed, but even after 2 months in the refrigerator no precipitate had formed.

Bromine Addition

Bromine failed to add to the double bond with carbon tetrachloride or acetic acid solutions of bromine or pure bromine. Aqueous bromine solution gave some paste-like material which failed to crystallize in 15 months.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Diimide Reduction of the Enedione

By the procedure of Thiele (20), 20 g (0.172 mole) of azodicarboxamide was hydrolyzed with 50 ml of carbon dioxide free 50% aqueous potassium hydroxide at 0° under a nitrogen blanket in a 1-l beaker. The dipotassium azodicarboxylate was vacuum-filtered in a chilled Büchner funnel, again under a blanket of nitrogen. The salt was promptly dissolved in water (100 ml) at 0° and filtered through a chilled sintered-glass funnel into 400 ml of cold absolute ethanol, where the salt again precipitated as a fine bright yellow powder. The product was recovered from the ethanolic solution by filtration and was thoroughly washed with three 400-ml portions of absolute methanol at 0° and under a nitrogen blanket. The yellow salt was transferred to a vacuum desiccator and dried overnight to yield 27.2 g or 83% of the theoretical amount of dipotassium diazodicarboxylate.

Following the general procedure of van Tamelen *et al.* (15), 3.50 g (0.021 mole) of the enedione was added to 75 ml of methanol containing 10.0 g (0.0515 mole) of dipotassium diazodicarboxylate. With magnetic stirring at 0°, 11 ml (11 g, 0.18 mole) of glacial acetic acid in 30 ml of methanol was very slowly added under a nitrogen atmosphere. After several hours at 0°, the solution was allowed to warm slowly to room temperature, where it was stirred for 6 h.

The methanol was removed on a rotary evaporator and the slurry was taken up in ether and water. The ether layer was washed twice with 50-ml portions of 1:1 aqueous Claisen's alkali to remove the excess acetic acid and then washed with water before being dried by an extraction with saturated aqueous sodium chloride and filtration through a cone of sodium sulfate.

Vapor phase chromatographic analysis showed the enedione to be only 15% reduced, so that the reduction procedure was repeated three additional times to give an overall yield of 3.35 g (90%) of a material which was 3.4% enedione, 3.4% miscellaneous products, and 93.4% 2,2,4,6,6-pentamethylcyclohexan-1,3-dione. Analysis of a fraction of VII collected on the vapor phase chromatograph follows.

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95. Found: C, 72.33; H, 9.90.

Lithium Aluminium Hydride Reduction of the Enedione

Under an atmosphere of dry nitrogen, 1.00 g (0.006 mole) of the enedione was dissolved in 75 ml of reagent grade ether, and 0.696 g (0.0183 mole) of lithium aluminium hydride was added.

After the solution was refluxed for 20 h with magnetic stirring, 1.5 ml of water was cautiously added to destroy the excess hydride and the solution was stirred overnight, before the precipitated salt was removed by filtration and washed with several portions of ether. The ethereal solution was dried with sodium sulfate and the ether removed to leave 0.95 g of white solid (m.p. 106–122°). The three components which were separated on the vapor phase chromatograph were assigned the structures 2,2,4,4,6-pentamethylcyclohexan-3-ol-1-one, VIII (10.6%), 1,3,3,5,5-pentamethylcyclohex-1-en-4*e*,6*e*-diol, IX (52.0%), and the two stereoisomers with pseudo-axial and equatorial hydroxyl groups, X and XI (37.4%).

Treatment of the Enedione with Refluxing Aqueous Potassium Hydroxide

Under a slight positive pressure of nitrogen, 1.05 g of V (b.p. 59° at 0.75 mm, m.p. 5–8°) was refluxed for 2 h in 50 ml of 10% aqueous potassium hydroxide made with freshly opened reagent grade potassium hydroxide and degassed distilled demineralized water. Still under nitrogen, the flask was allowed to cool to room temperature. The solution was extracted with two 75-ml portions of ether which were, in turn, washed with water and dried, and the ether removed to give 0.009 g of neutral fraction, all of which was recovered enedione.

The alkaline solution was acidified with hydrochloric acid and the white solid which separated was recovered with two 50-ml ether extractions. The ethereal layers were washed once with 10 ml of water and dried as usual before the ether was removed on a rotary evaporator. From the $C_{11}H_{18}O_3$ formula calculated from the analysis of a recrystallized portion of the white solid, the 1.127 g of acid fraction obtained corresponds to a 97.8% yield.

Recrystallization of 100 mg of the product from 2 ml of hexane gave 75 mg of very fluffy solid carboxylic acid mixture (m.p. 88.5–88.8°).

Anal. Calcd. for $C_{11}H_{18}O_3$: C, 66.63; H, 9.15. Found: C, 66.67; H, 9.09.

Either collection of the material which passes through the v.p.c. or heating the acid or mixture of acids above 150° for several minutes results in decarboxylation to give a colorless liquid, XII.

Anal. Calcd. for $C_{10}H_{18}O$: C, 77.84; H, 11.77. Found: C, 77.54; H, 11.74.

KETO–ENOL TAUTOMERISM IN β-DICARBONYLS STUDIED BY NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

II. SOLVENT EFFECTS ON PROTON CHEMICAL SHIFTS AND ON EQUILIBRIUM CONSTANTS

MAX T. ROGERS AND JANE L. BURDETT

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The effect of various solvents on the proton chemical shifts of a number of acyclic β-diketones and β-ketoesters has been observed by nuclear magnetic resonance spectroscopy. These shifts are discussed in terms of the dissociation of intramolecular and intermolecular hydrogen bonds on dilution. A complex of benzene with the enol tautomer of the β-dicarbonyl molecule is proposed. The effect of solvents on the position of the tautomeric equilibrium is discussed.

INTRODUCTION

Proton chemical shifts and equilibrium constants for pure β-dicarbonyls are given in the first paper of this series (1). Reeves (2), Reeves and Schneider (3), Schneider and Reeves (4), and Balta-Calleja (5) have investigated solvent effects on acetylacetone by nuclear magnetic resonance (n.m.r.), and Giessner-Prettre (6) has observed the effect of solvents on the n.m.r. spectrum of ethyl acetoacetate. The present study involves a series of β-diketones and β-ketoesters with various substituents and has been extended to include additional solvents. The effects of solvents on proton chemical shifts and on the position of equilibrium have been determined.

EXPERIMENTAL

Instrumental

Proton magnetic resonance spectra were obtained on the Varian A-60 spectrometer. Chemical shift and equilibrium constant measurements have been made at 33 ± 2 °C. Chemical shift values are reported in c.p.s. from internal tetramethylsilane to within ±1 c.p.s. Dilution chemical shifts are reported in c.p.s. relative to the pure compound. A positive shift of a resonance peak is one which occurs at a higher applied magnetic field than the corresponding peak of the pure compound. Equilibrium constants have been obtained by integration of the areas of certain keto and enol resonance peaks. At least six integrations have been performed, and reported percentages of enol tautomer are accurate to within ±2%.

Solvent Purification

Benzene, chloroform, acetic acid, and dioxane were purified according to Vogel (7). Other solvents were dried and fractionally distilled.

Sample Preparation

Solutions were weighed on an analytical balance to ±0.1 mg, and mole fractions were determined to within ±0.001. Tetramethylsilane was added as an internal reference to each solution; the quantity added was the same in each case and did not affect the calculated mole fraction to within 0.001. Spectra made with samples in unsealed tubes were compared with those for samples sealed *in vacuo*, and usually no difference in line width or shape was found. For acetic acid solutions and those using acetylacetone, tubes were evacuated and sealed, but for the other solutions unsealed sample tubes were used.

Compound Preparation and Purification

Synthesis and purification of the β-dicarbonyls used in this study have been described in the first paper of this series (1).

RESULTS AND DISCUSSION

Chemical shifts at infinite dilution for various proton groups of both the enol and keto tautomers of β-diketones and β-ketoesters are listed in Table I for carbon tetrachloride, benzene, chloroform, and hexane. Similar data are given in Table II for acetylacetone and ethyl acetoacetate in 13 different solvents. The values represent the changes in chemical shifts for given proton groups between pure compound and an infinitely dilute solution in the given solvent, measured in c.p.s., and are positive when the solution shift is at higher magnetic field. In a few cases (m = masked) the values could not be measured because of overlapping of resonances. Where hydrogen bonding occurs only a single proton resonance is seen, and its chemical shift is an average of the shifts for bonded and non-bonded protons.

Inert Solvents

There is very little effect on most of the chemical shifts on dilution in carbon tetrachloride, hexane, carbon disulfide, dioxane, or ether, and we call these solvents inert for that reason. The α-protons of the keto isomer usually move to high field by 10–15 c.p.s. This was explained by Giessner-Prettre (6) as resulting from the breaking up of intermolecularly hydrogen-bonded polymers on dilution. Variable temperature studies confirm the dissociation of intermolecular hydrogen bonds, since the α-proton resonances occur at higher applied fields at increased temperatures (8).

The α-protons of the enol tautomers also move to higher field by 2–12 c.p.s. on dilution, but the most marked effect is on the hydroxyl protons, which are shifted to higher magnetic field by about 6–21 c.p.s. These chemical shifts are illustrated in Fig. 1 where the chemical

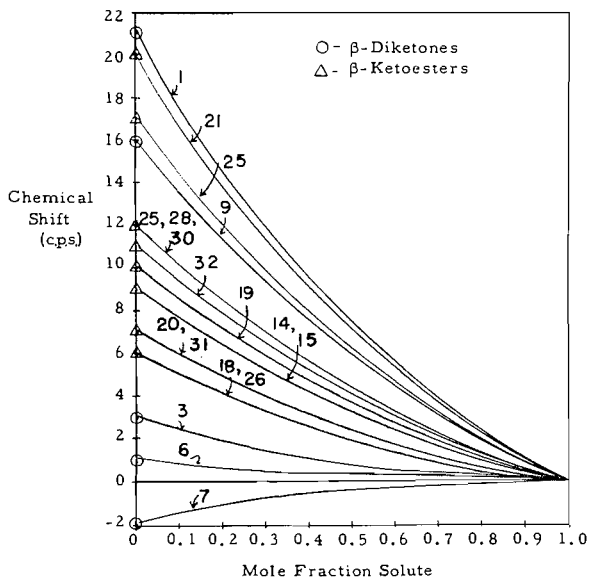

FIG. 1. Chemical shift relative to pure solute of the OH proton in β-dicarbonyls in carbon tetrachloride vs. mole fraction of solute (code numbers refer to compounds of Table I).

shift of the OH proton is plotted as a function of concentration in carbon tetrachloride solution for all the β-dicarbonyls studied. These shifts can be attributed to the breaking up on dilution of the intramolecularly hydrogen-bonded species of the enol tautomer.

*Chemical shifts are in c.p.s. relative to the pure compound. k = keto, e = enol, and m = masked.

Trifluoroacetylacetone and hexafluoroacetylacetone are exceptions. In this case the electronegative substituents may lead to the formation of stronger hydrogen bonds not appreciably broken up at the lowest dilutions used here (~0.03 mole fraction solute). However, the intramolecular hydrogen bond of these compounds is particularly sensitive to heat, and increased temperatures result in marked shifts of the hydroxyl proton to high fields (8). The small downfield shift of the hydroxyl proton of the enol tautomer of ethyl acetoacetate on dilution in ether and hexane is also an exception to the above generalizations.

Hydrogen-Bonding Solvents

When the solvent molecules are able to form hydrogen bonds with the α-protons of the keto tautomer, or with the hydroxyl proton of the enol tautomer, the chemical shifts of these protons do not tend to change much on going from pure liquid to solution. This behavior is noted, in general, for the solvents chloroform, acetonitrile, acetic acid, and ethanol, and may be the result of the simultaneous breaking up of solute–solute intermolecular hydrogen bonds and the re-forming of solute–solvent intermolecular hydrogen bonds. We might expect a shift of the α-proton to lower magnetic field on dilution if the hydrogen bond to solvent molecules were stronger than that to the carbonyl group of the β-dicarbonyl itself. Such downfield shifts are observed (Table II) particularly for acetylacetone and ethyl acetoacetate in dimethylsulfoxide and in methanol.

On the other hand, the enol hydroxyl proton chemical shifts for acetylacetone are quite variable. In going from pure acetylacetone to acetic acid or chloroform solution this proton resonance shifts upfield by 32 c.p.s. or 20 c.p.s., respectively, suggesting that the chemical shift of the hydroxyl proton is at higher field when involved in an intermolecular hydrogen bond than in an intramolecular hydrogen bond (chelated structure). Exceptions are benzene (discussed below) and acetonitrile, where there may be a particularly important long-range diamagnetic anisotropy correction. No specific conclusions can be drawn from the data for alcohol solutions of acetylacetone, since the OH peaks of solvent and solute are coalesced (whereas they are distinct in acetic acid solutions).

The enol hydroxyl proton resonance for ethyl acetoacetate is very nearly unchanged (±6 c.p.s.) in going from pure solute to solution in a hydrogen-bonding solvent. The same is true for the β-ketoesters in going to chloroform solution (with the exception of ethyl benzoyl acetate). The hydroxyl peak for the alcohol solvents is now distinct from the enol peak.

In the case of chloroform the effect of the β-dicarbonyls, considered as solvents, on the chemical shift of the chloroform proton resonance may be observed (Fig. 2). It is seen

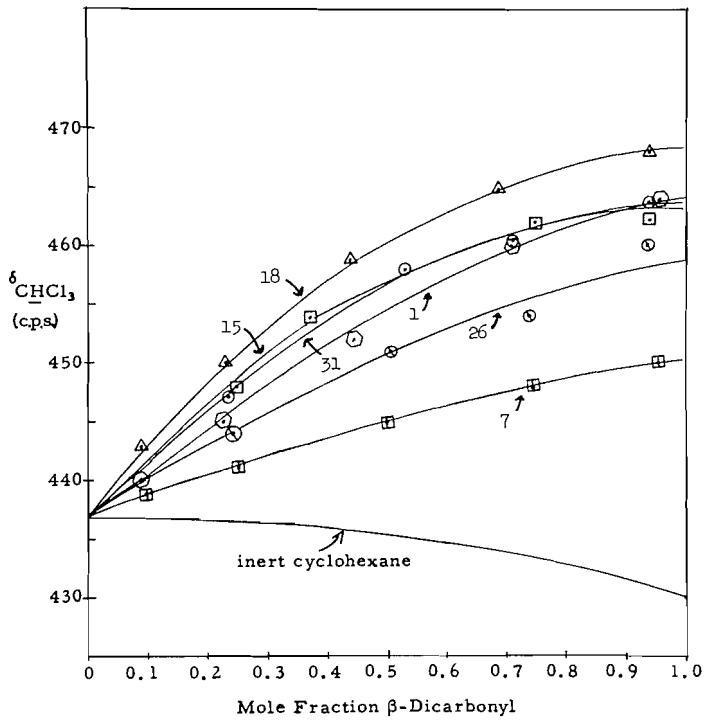

FIG. 2. Chemical shift of the chloroform proton in β-dicarbonyls as solvents (code numbers refer to compounds of Table 1).

that this resonance is shifted to higher field by 10–30 c.p.s. Korinek and Schneider (9) related this shift to the "donor strength" of the solvent molecule, and on this basis ethyl acetoacetate would be the best donor and trifluoroacetylacetone the poorest. It should be noted that the largest upfield shift of the hydroxyl proton resonance on dilution in chloroform is 31 c.p.s. for trifluoroacetylacetone and the smallest shift (nearly zero) is for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the β-ketoesters, so that trifluoroacetylacetone would also be the poorest donor on this basis.

Benzene

Chemical shifts of the various proton groups of β-dicarbonyls in benzene are given in Table I for infinitely dilute solutions (relative to pure liquid). Most of the proton resonances (alkoxy and acetyl groups and α-protons) are at higher magnetic field in benzene. However, the hydroxyl protons of the enol tautomer are shifted to lower magnetic field, while the protons of alkyl α-substituents tend to be almost unchanged (±8 c.p.s.). It seems probable that these unusual chemical shifts arise from ring current effects in a solute–solvent complex, as has been observed for a number of solutes in benzene (10, 11, 12), although no single structure for the collisional complex seems to account for all the data in this case. If the molecules are placed roughly parallel as in Fig. 3, with the benzene

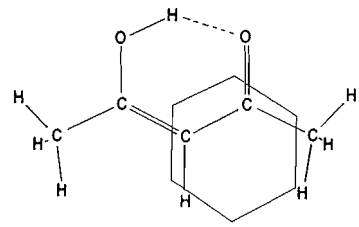

FIG. 3. Proposed complex of acetylacetone with benzene.

rings over a region of large positive charge density of the enol molecule, the high-field shifts of the methyl protons and the α-protons may be semiquantitatively accounted for by the tables of Johnson and Bovey (13). However, to obtain the observed low-field shift of the enol proton by this mechanism the rings would have to be tipped down by the methyl groups, putting the enol proton roughly in the same plane as the benzene ring and so in a paramagnetic region.

Trifluoroacetylacetone and hexafluoroacetylacetone, where there is a large negative charge density on the end groups of the enol molecules, evidently do not form this type of complex, since the hydroxyl proton and the α-proton are both now shifted to higher field, as would be expected for a complex in which the benzene ring and the six-membered ring of the enol were parallel.

Basic Solvents

In triethylamine solution the β-ketoesters tend to show peaks for only the keto tautomer and the β-diketones peaks for only the enol tautomer (2, 3). For *t*-butyl acetoacetate and ethyl α-allylacetoacetate both tautomers may be detected, but the peaks tend to be broad. Chemical shifts from pure solute to solution are generally small, but the enol hydroxyl proton of acetylacetone is shifted to higher field on dilution.

In diethylamine solutions of the β-ketoesters only the keto tautomer is detected. The esters, with the exception of methyl acetoacetate, tend to react with the amine. Acetylacetone is present only as the enol tautomer, which has been shown previously to form a complex with solvent molecules (2, 3).

Solvent Effects on Keto–Enol Equilibria

Equilibrium constants (K_e) for the equilibrium, keto $\rightleftharpoons$ enol, of acetylacetone and ethyl acetoacetate in various solvents are given in Table III. Since both enol and keto molecules may form hydrogen bonds with the solvent, the relative stability of the tautomers is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

*K_e = [enol]/[keto], and measurements are at 33 ± 2 °C.
†Measurements at 0.3 mole fraction of solute.

often solvent dependent. For comparison purposes all values of Table III have been derived from the spectra of solutions 0.1 or 0.3 mole fraction in solute at 33 °C. Figure 4 shows the percentage of enol tautomer throughout the concentration range for ethyl acetoacetate in various solvents, and similar results have been obtained for acetylacetone.

The β-diketones are principally in the enol form and the "inert" solvents favor this form, since the internally hydrogen-bonded enol molecule is less polar than the keto molecule. In polar solvents the fraction of keto molecules increases. The electrostatic repulsion between carbonyl groups of the keto form is reduced in a polar solvent. Also, the solvation energy of keto molecules is presumably greater than for enol molecules in polar solvents (14) and the solubility of the keto tautomer is greater in these solvents (15); hence, one might expect the equilibrium to shift toward the keto tautomer on dilution in polar solvents.

The β-ketoesters are principally in the keto form and the fraction of keto tautomer increases on dilution in polar solvents for the reasons mentioned above. In hydrogen-bonding solvents this effect is particularly marked and the enol tautomer becomes difficult to detect in acetic acid or dimethylsulfoxide solution.

Values for the fraction of enol tautomer reported here for acetylacetone and ethyl acetoacetate agree reasonably well, where they may be compared, with those of Meyer (16), Kabachnik *et al.* (17, 18), and Murthy *et al.* (19), but less well with the values of Conant and Thompson (20). Since many of the previous results were based on bromine titration, where errors may be large, close agreement with the n.m.r. data would not be expected.

Powling and Bernstein (21) showed that the enthalpy, and also the free energy, of tautomerization for several systems was a linear function of the solvent quantity $[(\epsilon - 1)/(2\epsilon + 1)]\rho/M$. This latter quantity, when multiplied by the difference between the squares of the dipole moments of the tautomers, gives the difference between the enthalpy of the tautomerization in dilute solution and in the gas phase. Although our measurements (Table III) are for moderately concentrated solutions, we have plotted ΔF vs.

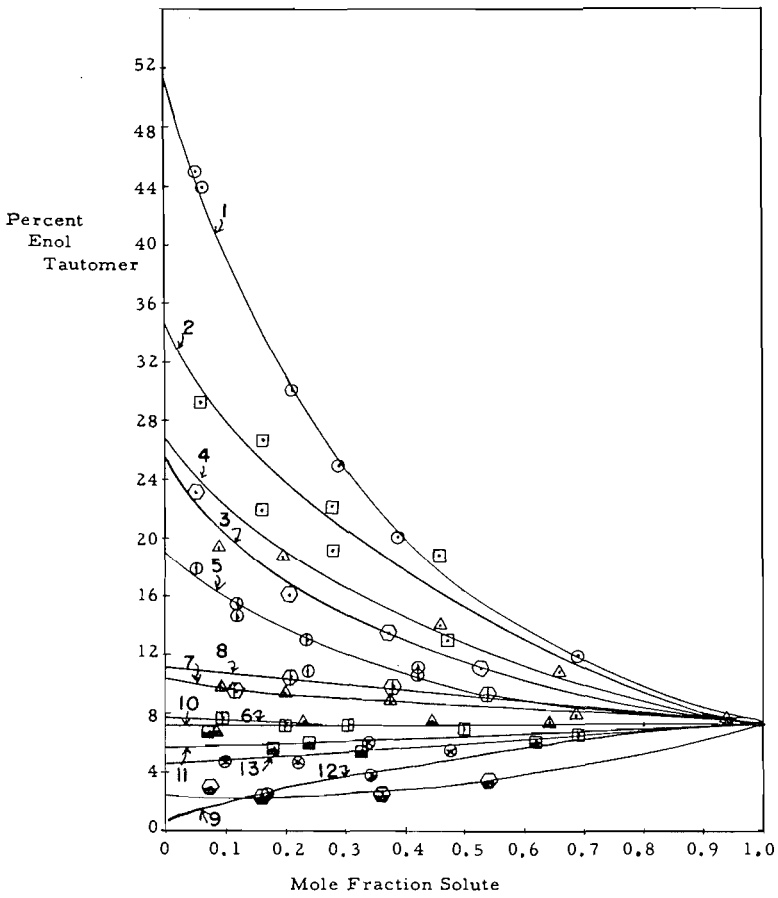

FIG. 4. Percentage of enol tautomer for ethyl acetoacetate in various solvents (code numbers refer to solvents of Table II).

$[(\epsilon - 1)/(2\epsilon + 1)]\rho/M$ for acetylacetone (Fig. 5) and ethyl acetoacetate (Fig. 6); in the former case the values for solute mole fraction 0.3 were used, since the probable error in ΔF becomes very large in the more dilute solutions where the fraction of keto isomer is low.

For ethyl acetoacetate a straight line drawn according to the method of least squares (omitting the alcohols) has an intercept at $\Delta F = 0.16$ kcal/mole, somewhat above the gas phase value of 0. The points for solvents where important specific intermolecular interactions might be expected (acetic acid, chloroform, and perhaps benzene) are scattered rather widely, but the points for a group of 'inert' solvents (hexane, carbon tetrachloride, ether, carbon disulfide, and acetonitrile) do fall close to a line extrapolating to $\Delta F = 0$.

For acetylacetone the plot (Fig. 5) is less informative. The least-squares line (omitting the points for the alcohols) has an intercept $\Delta F = -1.79$ kcal/mole, considerably higher than the gas phase value of -1.5 kcal/mole. Indeed, for two 'inert' solvents, hexane and carbon disulfide, ΔF is more negative for the solutions than for the gas phase—an unexplained anomaly previously found for several tautomeric systems (21).

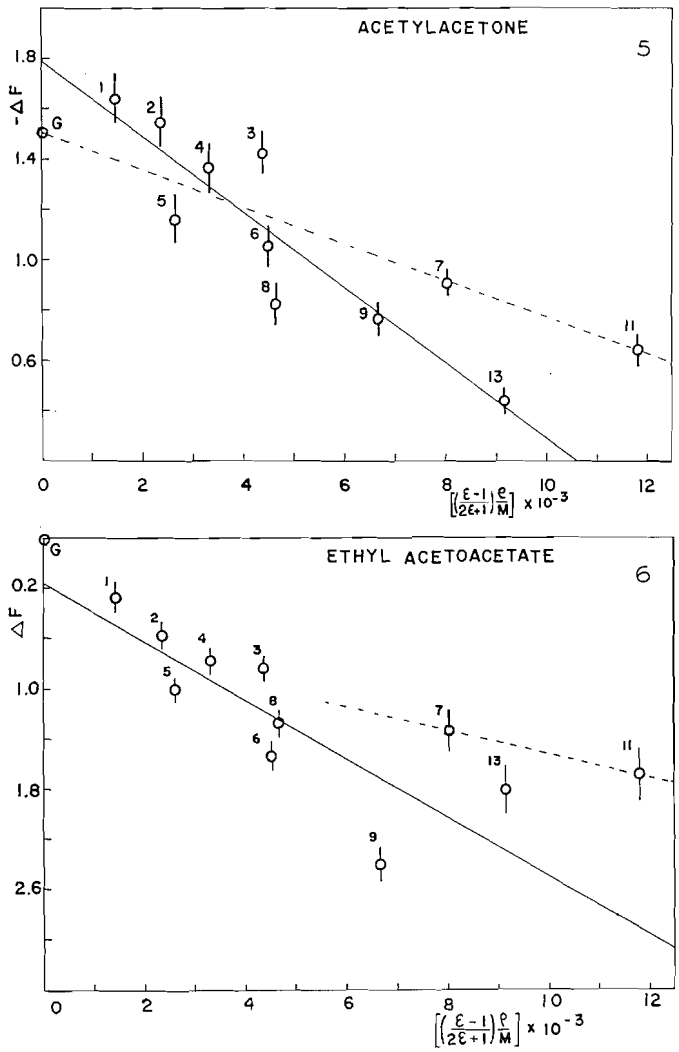

FIG. 5. Free energy of tautomerization for acetylacetone vs. solvent property (code numbers refer to solvents of Table II).

FIG. 6. Free energy of tautomerization for ethyl acetoacetate vs. solvent property (code numbers refer to solvents of Table II). The point G is the value reported for the gas phase.

It is interesting to note that the points for methyl and ethyl alcohol appear to fall on lines of different slope; in the case of acetylacetone this line extrapolates almost exactly to the gas phase value of ΔF as was observed by Powling and Bernstein (21).

The scatter of points in these graphs is perhaps not too surprising in view of the rather concentrated solutions used, the specific interactions expected in hydrogen-bonding solvents, the possible substantial entropy effects in these systems (8), and the errors at present associated with the n.m.r. method for determining K_e when the amount of one tautomer is below about 10%; further research will be required for a more complete understanding of the factors influencing tautomeric equilibria.

ABSTRACT

Condensation of β-*m*-methoxyphenethylamine with methyl coumalate followed by saponification of the ester gave N-(*m*-methoxyphenethyl)-5-carboxy-2-pyridone (I). Cyclization of the pyridone using phosphorus oxychloride gave 3-carboxy-6,7-dihydro-9-methoxybenzo[*a*]-quinolizinium chloride (II*e*), which, on catalytic reduction, afforded the two possible racemic 3-carboxy-1,3,4,6,7,11*b*-hexahydro-9-methoxy-2H-benzo[*a*]quinolizines (III*b* and IV*b*). The corresponding ethyl esters were prepared in an analogous manner and their stereochemistry was assigned on the basis of equilibration experiments. Mercuric acetate oxidation of the racemic esters gave 3-carbethoxy-1,2,3,4,6,7-hexahydro-9-methoxybenzo[*a*]quinolizinium perchlorate (V).

In continuing our work on the preparation of amino acid analogues of artificial estrogens (1), we became interested in incorporating a nitrogen atom into the skeleton of compounds related to doisynolic acid. Several isomers of the latter compound are known to be potent estrogens (2). This paper describes the preparation of some polyhydrobenzo[*a*]quinolizines (III–V) which represent 8-aza analogues of doisynolic acid.

By the method of Wiley, Smith, and Knabeschuh (3), treatment of methyl coumalate (4) with an excess of *m*-methoxyphenethylamine and saponification of the crude product gave N-(*m*-methoxyphenethyl)-5-carboxy-2-pyridone (I) in 82% yield. Cyclization of this pyridone using phosphorus oxychloride in xylene (3) followed by treatment of the intermediate acid chloride with absolute ethanol gave 3-carbethoxy-6,7-dihydro-9-methoxybenzo[*a*]quinolizinium chloride (II*a*) in 72% yield. Treatment of the crude reaction mixture with potassium iodide gave the corresponding iodide (II*b*). Hydrolysis of the intermediate acid chloride gave the quinolizinium acid salts II*d* and II*e*.

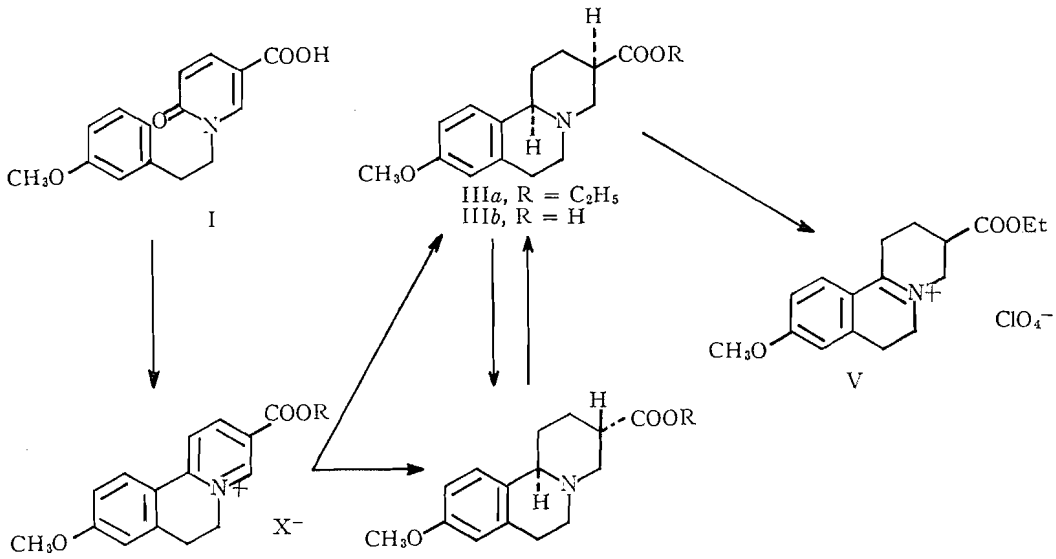
A number of attempted cyclizations of pyridones to produce substituted quinolizinium compounds have yielded simply the corresponding pyridinium salts (ref. 5 and references therein). That N-(*m*-methoxyphenethyl)-5-carboxy-2-pyridone did undergo cyclization to the quinolizinium ring system is evidenced by the fact that the products II*a*–II*e* have ultraviolet absorption spectra characteristic of this ring system (3), but different from what would be expected from a composite of the isolated *m*-methoxyphenyl and carboxychloropyridinium chromophores had cyclization not occurred. It is generally found that Bischler-Napieralski reactions of N-*m*-methoxyphenethylamides and lactams occur preferentially with cyclization para to the methoxyl group (6–8). That a para ring closure occurred in the present work is indicated by spectral means, and will be discussed later under the preparation of III*a*.

Catalytic hydrogenation of the quinolizinium ester salts II*a*–II*c* using Adams catalyst resulted in the isolation of the two possible racemic forms of the free amino ester. The best results were obtained when the chloride salt II*a* was used because of its greater

[1]*From part of the thesis presented by J. M. S. in partial fulfillment of the requirements for the Ph.D. degree, 1960.*
[2]*Author to whom inquiries should be addressed: Department of Chemistry, The Upjohn Company, Kalamazoo, Michigan.*

solubility as compared with the iodide and perchlorate salts II*b* and II*c*. Thus, when 3-carbethoxy-6,7-dihydro-9-methoxybenzo[*a*]quinolizinium chloride (II*a*) was reduced catalytically using Adams catalyst and a solvent mixture composed of 2 parts ethanol, 2 parts water, and 1 part acetic acid, 3 molecular equivalents of hydrogen were absorbed, and the product obtained in 76% yield was the hydrochloride of 3-carbethoxy-1,3,4,6,7,11*b*-hexahydro-9-methoxy-2H-benzo[*a*]quinolizine IV*a* in which the relationship of the hydrogen atoms attached to C-3 and C-11*b* is *trans*. The basis for this assignment will be given below. Also isolated from this reduction was 16% of a lower-melting hydrochloride salt which was a mixture of the two racemic forms. That the reduction took place in the pyridinium ring rather than the benzene ring is shown by the ultraviolet absorption spectrum. The hydrochloride of compound IV*a* has maxima at 277 (ϵ 1 750) and 284 mμ (ϵ 1 720) while 6-methoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride has maxima at 278 (ϵ 1 960) and 285 mμ (ϵ 1 840).

Treatment of the hydrochloride of IV*a* with dilute sodium hydroxide liberated *trans*-3-carbethoxy-1,3,4,6,7,11*b*-hexahydro-9-methoxy-2H-benzo[*a*]quinolizine IV*a* in 95% yield.



II*a*, R = C_2H_5, X = Cl
II*b*, R = C_2H_5, X = I
II*c*, R = C_2H_5, X = ClO_4
II*d*, R = H, X = ClO_4
II*e*, R = H, X = Cl

IV*a*, R = C_2H_5
IV*b*, R = H

On the other hand, catalytic reduction of II*a* using Adams catalyst in glacial acetic acid again resulted in an uptake of 3 molecular equivalents of hydrogen. After evaporation of the reduction mixture, treatment of the crude oil with dilute ammonium hydroxide resulted in the isolation of 86% of the isomeric *cis* ester III*a*. The ultraviolet spectra of compounds III*a* and IV*a* are consistent with the presence of a 6-methoxy-1,2,3,4-tetrahydroisoquinoline chromophore and are inconsistent with an 8-methoxy-1,2,3,4-tetrahydroisoquinoline chromophore (7). This rules out the possibility that cyclization of I occurred at the less favorable position ortho to the methoxy group. Further conformation for the para ring closure of I can be found in the n.m.r. spectrum of III*a*. The aromatic region of the curve is typical of a 1,2,4-trisubstituted benzene of the estrone type (cf. ref. 8).

Equilibration studies on the isomeric esters III*a* and IV*a* indicated that III*a* is the less stable isomer and that the equilibrium position lies approximately 80% on the side of IV*a*. The isomer IV*a* was therefore assigned the thermodynamically more stable configuration in which the carbethoxy group is equatorial. Treatment of both esters with mercuric acetate in aqueous acetic acid followed by the addition of perchloric acid (6) resulted in the formation of the same dehydro product, 3-carbethoxy-1,2,3,4,6,7-hexahydro-9-methoxybenzo[*a*]quinolizinium perchlorate (V), in about 90% yield. Catalytic hydrogenation of V using Adams catalyst in glacial acetic acid gave a mixture of the two esters III*a* and IV*a* with the more stable isomer IV*a* predominating in about the same ratio as found in the equilibration of the amino ester.

The ease with which the mercuric acetate oxidation proceeds under the mild conditions used for both esters is indicative of a *trans* quinolizine system having an axial hydrogen at the bridgehead (9). Further evidence for the *trans* ring juncture is given by the fact that infrared spectra of both esters show four characteristic peaks in the carbon–hydrogen stretching region when a calcium fluoride prism is used: the major band at 2 940 cm^{-1} and three peaks of medium intensity at 2 850, 2 815, and 2 780 cm^{-1}. Such bands appear to be associated with tertiary amines which have two or more adjacent hydrogens *trans* diaxial to the electron pair of the nitrogen (refs. 10, 11; see, however, ref. 12 for possible exceptions).

On the basis of the above evidence for *trans*-fused rings, and the results of the equilibration studies, the more stable low-melting material is assigned structure IV*a* with the carbethoxy group equatorial. The isomeric ester is assigned the configuration with an axial carbethoxy and is represented by III*a*. After this work had been completed, Ohki and Noike (13) published independently the structural assignment of the isomeric 3-carbethoxyquinolizidines, in which essentially the same methods of elucidation were employed.

Once the configuration of the amino esters had been determined, the preparation of the corresponding amino acids was investigated. Hydrogenation of 3-carboxy-6,7-dihydro-9-methoxybenzo[*a*]quinolizinium chloride (II*a*), using Adams catalyst in glacial acetic acid and in aqueous acetic acid solution, resulted in the formation of mixtures of amino acids as their hydrochlorides. Separation of the isomeric compounds by fractional crystallization from absolute ethanol gave 46% of the less soluble higher-melting isomer later shown to be the hydrochloride of IV*b*. The filtrate gave the lower-melting hydrochloride of III*b* in 50% yield. The homogeneity of the different isomers was shown by paper chromatography.

Treatment of the hydrochloride of IV*b* with exactly 1 equivalent of sodium hydroxide afforded the amino acid IV*b* in 94% yield. The relationship of this amino acid and therefore of its antecedent hydrochloride to the amino esters was determined by treating an ethanolic solution of the free amino acid with ethereal diazoethane. The amino acid IV*b* was converted to the amino ester IV*a* (equatorial carbethoxy) in a 93% yield.

In the same manner as above, the hydrochloride of III*b* was converted to the free amino acid III*b* in 89% yield and this in turn was transformed into the amino ester III*a* (axial carbethoxy) in 72% yield by treatment with ethereal diazoethane.

The infrared spectra of these isomeric acids are of interest, in that III*b* with its axial carboxyl group can form an intramolecular hydrogen bond while the isomeric amino acid IV*b* cannot form such a bond unless the nitrogen atom undergoes inversion to give the less favorable cisoid ring juncture with the electron pair on nitrogen oriented equatorially and the N-alkyl group oriented axially. Spectra of the amino acids in potassium

bromide pellets show that III*b* (axial carboxyl) has absorption peaks at 2 860 cm^{-1} (m, C—H stretching), 2 740–2 580 cm^{-1} (w, broad, characteristic of amine salts), and two peaks associated with carboxyl absorption: 1 675 cm^{-1} (s, broad, hydrogen-bonded associated carboxyl) and 1 590 cm^{-1} (m, ionized carboxyl).

The isomeric amino acid IV*b* shows essentially the same peaks but there are significant differences in intensity and exact location. The 2 860 cm^{-1} peak is almost nonexistent and the absorption at 2 720–2 580 cm^{-1} is more intense than in III*b*. The carboxyl absorption, however, shows the greatest change. The free-carboxyl absorption has shifted to 1 650 cm^{-1} and is present only as a shoulder. The ionized carboxyl at 1 590 cm^{-1} has increased greatly in intensity and is the most intense band in the spectrum.

Paper chromatography of the two amino acid preparations indicated that the preparations were homogeneous. The more soluble *cis* material III*b* moved faster under the conditions employed and a mixture of the two isomers was separated without difficulty.

EXPERIMENTAL

Infrared spectra were determined with a Perkin–Elmer (model 21) spectrophotometer fitted with a sodium chloride prism unless otherwise specified. Ultraviolet spectra were determined in 95% ethanol with a Cary recording spectrophotometer (model 11 MS). The microanalyses were performed by Dr. S. M. Nagy and his associates. Melting points are uncorrected.

N-(m-Methoxyphenethyl)-5-carboxy-2-pyridone (I)

A mixture of 2.0 g of methyl coumalate (4) and 5 ml of *m*-methoxyphenethylamine was converted to 3.0 g (82%) of crude product, m.p. 179–181°, by the method of Wiley *et al.* (3). Recrystallization of the material twice from 95% ethanol gave white crystals of I, m.p. 180.5–181°. The ultraviolet spectrum showed peaks at 261 mμ (ϵ 16 100) and 303 mμ (ϵ 5 310). The infrared spectrum (KBr pellet) showed carbonyl peaks at 1 700 and 1 640 cm^{-1}.

Anal. Calcd. for $C_{15}H_{15}NO_4$: C, 65.92; H, 5.55; N, 5.13. Found: C, 65.62; H, 5.54; N, 5.08.

3-Carbethoxy-6,7-dihydro-9-methoxybenzo[a]quinolizinium Iodide (IIb)

Following a known method (3), we converted 1.4 g of N-(*m*-methoxyphenethyl)-5-carboxy-2-pyridone to 1.8 g of II*b*, m.p. 215–219° (decomp.) (recrystallized from ethanol–ether). The ultraviolet spectrum showed maxima at 220 (ϵ 23 800), 291 (ϵ 6 620), and 364 mμ (ϵ 27 320) and a shoulder at 258 mμ (ϵ 5 090). The infrared spectrum showed a carbonyl peak at 1 725 cm^{-1}.

Anal. Calcd. for $C_{17}H_{18}INO_3$: C, 49.65; H, 4.41; N, 3.41. Found: C, 49.72; H, 4.37; N, 3.51.

3-Carbethoxy-6,7-dihydro-9-methoxybenzo[a]quinolizinium Chloride (IIa) and Perchlorate (IIc)

Cyclization of 5.0 g of I using phosphorus oxychloride (3) gave a product which was recrystallized from 25 ml of water to give 4.2 g (72%) of II*a*, m.p. 200–201°, raised to 208–209° after recrystallization from ethanol–ether. The ultraviolet and infrared spectra showed essentially the same characteristics as described above for the corresponding iodide salt (II*b*).

The filtrates from the above crystallizations were combined and treated with 2 ml of 72% perchloric acid to give 1.9 g (27%) of the perchlorate salt II*c*, m.p. 210–212°. An analytical sample recrystallized from aqueous methanol had m.p. 209–210° and suitable infrared and ultraviolet spectra.

Anal. Calcd. for $C_{17}H_{18}ClNO_7$: C, 53.20; H, 4.74; N, 3.65. Found: C, 53.32; H, 4.64; N, 3.50.

3-Carboxy-6,7-dihydro-9-methoxybenzo[a]quinolizinium Perchlorate (IIa)

N-(*m*-Methoxyphenethyl)-5-carboxy-2-pyridone (1.9 g) was cyclized as described above in the preparation of II*b*; however, water (20 ml) rather than ethanol was used in the reaction with the intermediate acid chloride. The aqueous mixture was allowed to stand at room temperature for 10 min, then 70 ml of water was added to dissolve the precipitate. To the solution was added 2.0 g of sodium perchlorate, a precipitate forming immediately. The suspension was cooled at 5° overnight and then filtered. Recrystallization of the precipitate from ethanol–water gave 2.0 g (81%) of product, m.p. 270° (decomp.). The ultraviolet spectrum has maxima at 220 (ϵ 23 800), 284 (ϵ 6 650), and 355 mμ (ϵ 23 400) and a shoulder at 254 mμ (ϵ 4 900).

Anal. Calcd. for $C_{15}H_{14}ClNO_7$: C, 50.80; H, 3.97; N, 3.95. Found: C, 50.78; H, 4.01; N, 3.88.

3-Carboxy-6,7-dihydro-9-methoxybenzo[a]quinolizinium Chloride (IIe)

To 5.0 g of N-(*m*-methoxyphenethyl)-5-carboxy-2-pyridone was added 25 ml of phosphorus oxychloride and 25 ml of xylene. After the mixture was heated gently under reflux for 2 h, the volatile material was removed under reduced pressure. The residue was dissolved in 125 ml of water and allowed to cool slowly.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Filtration gave 5.3 g (98%) of product, m.p. 265–266°. Maxima in the ultraviolet spectrum occur at 220 (ε 9 600), 283 (ε 7 460), and 355 mμ (ε 24 200) and a shoulder at 254 mμ (ε 5 520).

Anal. Calcd. for $C_{15}H_{14}ClNO_3$: C, 61.75; H, 4.84; N, 4.81. Found: C, 61.71; H, 4.96; N, 4.58.

trans-3-Carbethoxy-1,3,4,6,7,11b-hexahydro-9-methoxy-2H-benzo[a]quinolizine (IVa) Hydrochloride

To a solution of 3.0 g of II*a* dissolved in a mixture of 24 ml of acetic acid, 50 ml of ethanol, and 50 ml of water was added 500 mg of Adams catalyst. Hydrogen was introduced at atmospheric pressure and the suspension was stirred vigorously. After the hydrogen uptake ceased (8 h), the suspension was filtered and the filtrate was evaporated to dryness. The oil was dissolved in 15 ml of absolute ethanol, treated with Norit, and filtered. The product was crystallized from absolute ethanol–ether giving 2.3 g (76%) of IV*a* hydrochloride, m.p. 194–197°, raised to 201–202.5° after recrystallization. The ultraviolet spectrum shows maxima at 227 (ε 8 630), 277 (ε 1 755), and 284 mμ (ε 1 720).

Anal. Calcd. for $C_{17}H_{24}ClNO_3$: C, 62.66; H, 7.42; N, 4.30. Found: C, 62.55; H, 7.40; N, 4.10.

The filtrate yielded an additional 500 mg of material, m.p. 115–170°, which appeared to be a mixture of the two isomeric hydrochlorides.

trans-3-Carbethoxy-1,3,4,6,7,11b-hexahydro-9-methoxy-2H-benzo[a]quinolizine (IVa)

Treatment of a solution of 5.3 g of IV*a* hydrochloride in 25 ml of water with a slight excess of dilute sodium hydroxide solution and recrystallization of the crude product from ethanol–water gave 4.5 g (96%) of IV*a*, m.p. 47–50°, raised to 51–52.5° after one recrystallization. The ultraviolet spectrum of IV*a* has maxima at 220 (ε 9 275), 278 (ε 1 890), and 286 mμ (ε 1 840). The infrared spectrum (in CCl_4, calcium fluoride prism) shows maxima at 2 850, 2 815, 2 780, and 2 760 cm^{-1} (C—H stretching of transoid-ring system) and (with sodium chloride prism) 1 730 cm^{-1} (ester C=O) and two peaks at 1 110 and 990 cm^{-1} (characteristic of this *trans* isomer).

Anal. Calcd. for $C_{17}H_{23}NO_3$: C, 70.56; H, 8.01; N, 4.84. Found: C, 70.54; H, 7.96; N, 4.75.

cis-3-Carbethoxy-1,3,4,6,7,11b-hexahydro-9-methoxy-2H-benzo[a]quinolizine (IIIa)

A mixture of 2.5 g of II*a*, 100 ml of glacial acetic acid, and 200 mg of Adams catalyst was shaken in the presence of hydrogen at atmospheric pressure until the theoretical amount of hydrogen was absorbed (7 h). The suspension was filtered and evaporated to dryness. The residue was dissolved in 50 ml of water to which dilute ammonium hydroxide was added until the mixture was alkaline. The aqueous suspension was extracted with ether and the ether extract was washed with water until neutral. The solvent was removed under reduced pressure and the oil was crystallized from aqueous methanol yielding 1.85 g (86%) of product III*a*, m.p. 83–86°, raised to 85–86° on recrystallization from aqueous ethanol. The ultraviolet spectrum of III*a* has maxima at 220 (ε 9 720), 278 (ε 1 925), and 286 mμ (ε 1 850). The infrared spectrum (in CCl_4, calcium fluoride prism) shows maxima at 2 850, 2 815, and 2 780 cm^{-1} (C—H stretching of transoid-ring system) and (with sodium chloride prism) 1 735 cm^{-1} (ester C=O) and two peaks at 1 100 and 1 076 cm^{-1} (characteristic of this *cis* isomer). The n.m.r. spectrum of III*a* in $CDCl_3$ shows signals centered at about 6.64, 6.74, and 7.12 p.p.m. (tetramethylsilane = 0) for the 8-, 10-, and 11-hydrogens, respectively.

Anal. Calcd. for $C_{17}H_{23}NO_3$: C, 70.56; H, 8.01; N, 4.84. Found: C, 70.67; H, 7.93; N, 4.80.

The hydrochloride salt of III*a* was prepared by passing hydrogen chloride into an ethereal solution of pure III*a*. The product was recrystallized from ethanol–ether, m.p. 210–211°, and gave normal ultraviolet and infrared spectra.

Equilibration Studies of the cis and trans Isomers of 3-Carbethoxy-1,3,4,6,7,11b-hexahydro-9-methoxy-2H-benzo[a]quinolizine

Standard curves of optical density vs. concentration were prepared from infrared data of synthetic mixtures (10% solutions in CCl_4) of III*a* and IV*a* using the 987 cm^{-1} peak and 1 076 cm^{-1} peak of the *trans* and *cis* isomers respectively.

(A) To 500 mg of IV*a* (m.p. 50.5–51.5°) was added 10 ml of sodium ethoxide solution prepared from 500 mg of sodium in 50 ml of absolute ethanol. The solution was kept under a nitrogen atmosphere at room temperature for 48 h. The solution was poured into 100 ml of ice water which was then extracted with ether. The ether extract was washed until neutral and evaporated to give 450 mg of mixed amino esters. The oil was dried for 24 h at 50° *in vacuo*. An infrared spectrum of the mixture and utilization of the standard curves indicated the presence of 86% of IV*a* and 17% of III*a*. Normalization gives the equilibrium position as 83.5% IV*a* and 16.5% III*a*.

(B) To 250 mg of III*a* (m.p. 85–85.4°) was added 5.0 ml of sodium ethoxide prepared from 500 mg of sodium and 50 ml of absolute ethanol. The solution was kept under a nitrogen atmosphere at room temperature for 48 h. The solution was worked up in the same manner as above to give 240 mg of mixed amino esters. The oil was dried for 24 h at 50° *in vacuo*. From the infrared spectrum of the mixture and utilization of the standard curves the mixture appeared to consist of 86% of IV*a* and 28% III*a*. Normalization gives the equilibrium position as 75.5% IV*a* and 24.5% III*a*.

3-Carbethoxy-1,2,3,4,6,7-hexahydro-9-methoxybenzo[a]quinolizinium Perchlorate (V)

Both III*a* and IV*a* gave the same quinolizinium perchlorate after mercuric acetate oxidation. The procedure used for each isomer was exactly the same and it is described below for the equatorial isomer IV*a*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

To a solution of 4.5 g of mercuric acetate in 25 ml of 5% acetic acid was added 1.0 g of *trans* ester IV*a*. Mercurous acetate began precipitating within 3 min as the temperature of the mixture was raised to 60° and kept there for 2 h. Filtration gave 1.7 g (95%) of mercurous acetate. The filtrate was saturated with hydrogen sulfide and the suspension filtered through Celite. The solution was concentrated under reduced pressure to 10 ml, at which point it was diluted to 50 ml with absolute ethanol. The solution was again concentrated to a volume of 10 ml under reduced pressure and 15 ml of absolute ethanol containing 0.5 ml of 70% perchloric acid was added. The solution was diluted with ether giving 1.1 g of V, m.p. 131.5–132.5°, and 90 mg, m.p. 129–131°. The sample melting at 131.5–132.5° was analytically pure. The ultraviolet spectrum of V has maxima at 230 (ϵ 5 890), 237 (ϵ 7 400), and 323 mμ (ϵ 18 900) and a shoulder at 244 mμ (ϵ 5 680).

Anal. Calcd. for $C_{17}H_{22}ClNO_7$: C, 52.65; H, 5.72; N, 3.62. Found: C, 52.52; H, 5.76; N, 3.64.

The *cis* amino ester gave 90% yield of V, m.p. 131.0–132.0°. The infrared spectra of the products obtained from the isomeric esters are superimposable and mixed melting point determination showed no depression.

Reduction of 3-Carbethoxy-1,2,3,4,6,7-hexahydro-9-methoxybenzo[a]quinolizinium Perchlorate (V)

To a suspension of 1.1 g of V in 50 ml of glacial acetic acid was added 100 mg of Adams catalyst. Hydrogen was introduced at atmospheric pressure and the uptake was completed in 6 h. The suspension was filtered and the filtrate evaporated to dryness. The oil was dissolved in 50 ml of water and dilute ammonium hydroxide was added until the mixture was basic. The suspension was extracted with ether. The ether extract was washed with water to neutrality. The ether was evaporated to give an oil which was a mixture of the amino esters III*a* and IV*a*. The oil was dissolved in a methanol–water solution and 110 mg of III*a*, m.p. 80.5–83°, precipitated. Addition of water to the filtrate followed by slow cooling precipitated 300 mg of IV*a*, m.p. 46–48°.

Hydrochlorides of cis- and trans-3-Carboxy-1,3,4,6,7,11b-hexahydro-9-methoxy-2H-benzo[a]quinolizines (IIIb and IVb)

A mixture of 4.5 g of 3-carboxy-6,7-dihydro-9-methoxybenzo[*a*]quinolizinium chloride (II*e*), 400 ml of acetic acid, and 400 mg of Adams catalyst was shaken in a hydrogen atmosphere at atmospheric pressure until the theoretical uptake of hydrogen had occurred (12 h). The catalyst was removed and the filtrate evaporated to dryness. The residue was leached with 30 ml of boiling absolute ethanol. The insoluble material amounted to 2.1 g (46%) of the *trans* isomer IV*b*, m.p. 274–280°, raised to 287–288° after two recrystallizations from 95% ethanol.

Anal. Calcd. for $C_{15}H_{20}ClNO_3$: C, 60.50; H, 6.77; N, 4.70. Found: C, 60.34; H, 6.79; N, 4.71.

The ethanol leach solution above was diluted to a volume of 100 ml with ether giving 1.75 g (38%) of the *cis* isomer III*b*, m.p. 231–235°, raised to 235–239° on recrystallization from aqueous ethanol–ether.

Anal. Calcd. for $C_{15}H_{20}ClNO_3$: C, 60.50; H, 6.77; N, 4.70. Found: C, 60.58; H, 6.88; N, 4.75.

Paper chromatography of the isomeric amino acid hydrochlorides indicated that the above materials were homogeneous as far as was indicated by the development techniques used. From a spot of 100 γ of each material was obtained a single spot. A mixture of 50 γ of each was separated into two spots. The mobile phase for these experiments was methyl ethyl ketone to which 1% methanol was added. Whatman No. 1 paper was used and the spots were developed by passing the dried paper strip through a solution of iodine in carbon tetrachloride. The compounds showed up as yellow spots.

cis-3-Carboxy-1,3,4,6,7,11b-hexahydro-9-methoxy-2H-benzo[a]quinolizine (IIIb)

A solution of 1.1 g of the hydrochloride of III*b* in 10 ml of water was neutralized to pH 7 with dilute sodium hydroxide. The solution was evaporated to dryness under reduced pressure and the residue was triturated with 50 ml of absolute ethanol. The suspension was diluted to a volume of 100 ml with ether and then filtered, giving 859 mg (89%) of III*b*, m.p. 219–224°, raised to 224–225° (with sintering at 218°). The ultraviolet spectrum of III*b* has maxima at 227 (ϵ 9 110), 277 (ϵ 1 720), and 285 mμ (ϵ 1 680). The infrared spectrum (KBr pellet) exhibits a strong band at 1 675 cm^{-1} (hydrogen-bonded carboxyl) and a medium band at 1 590 cm^{-1} (ionized carboxyl).

Anal. Calcd. for $C_{15}H_{19}NO_3$: C, 68.95; H, 7.32; N, 5.36. Found: C, 68.98; H, 7.37; N, 5.41.

Paper chromatography of the material melting at 224–225° with the same system used for the hydrochloride indicated that the material was homogeneous. The *cis* isomer moves more rapidly than the *trans* isomer (described below) and a mixture of the two isomers is separated.

trans-3-Carboxy-1,3,4,6,7,11b-hexahydro-9-methoxy-2H-benzo[a]quinolizine (IVb)

Conversion of 500 mg of the hydrochloride of IV*b* by essentially the same process as described above for the preparation of III*b* gave 410 mg (93%) of IV*b*, m.p. 231–240°, raised to 240–242° on recrystallization from aqueous ethanol. The ultraviolet spectrum of IV*b* has maxima at 227 (ϵ 9 200), 277 (ϵ 1 790), and 285 mμ (ϵ 1 730). The infrared spectrum (KBr pellet) exhibits a shoulder at 1 650 cm^{-1} (hydrogen-bonded carboxyl) and a strong band at 1 590 cm^{-1} (ionized carboxyl).

Anal. Calcd. for $C_{15}H_{19}NO_3$: C, 68.95; H, 7.32; N, 5.36. Found: C, 69.10; H, 7.39; N, 5.42.

Paper chromatography of a sample of IV*b* melting at 240–242° indicated that it was homogeneous.

Mixtures of the isomeric amino acids III*b* and IV*b* could be separated effectively by leaching them with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

anhydrous benzene. The axial isomer III*b* is much more soluble in benzene and it was removed completely from the mixture. Concentration of the benzene followed by slow cooling gave III*b* in well-defined crystals.

Correlation of the Amino Acids IIIb and IVb with the Corresponding Axial and Equatorial Esters. Treatment with Diazoethane

(A) To a solution of 150 mg of IV*b* in 15 ml of 95% ethanol was added an excess of ethereal diazoethane solution (14). The solution was stirred at room temperature for 2 h and then evaporated to dryness. The residue was dissolved in 50 ml of anhydrous ether, filtered, and evaporated to dryness to give 160 mg (97.5%) of crude product. An infrared spectrum indicated that the material was the equatorial ester. Recrystallization of the oil from ethanol–water gave 145 mg (88%) of the equatorial amino ester IV*a*, m.p. 49–50°. The amino acid IV*b* and the corresponding hydrochloride therefore have equatorial carboxyl groups.

(B) To a solution of 150 mg of III*b* (softening 210°, m.p. 219–222°) in 15 ml of an ethanol–water mixture was added an excess of ethereal diazoethane. The solution was stirred for 2 h and then evaporated to dryness. The residue was dissolved in 50 ml of anhydrous ether, filtered, and evaporated to dryness to give 155 mg (93.5%) of crude product. Comparison of the infrared spectrum to that of the pure axial ester indicated that there was a small amount of the low-melting equatorial isomer present. The oil was crystallized from an ethanol–water mixture to give 119 mg (72%) of the axial ester III*a*, m.p. 83–84°. The amino acid III*b* and its corresponding hydrochloride therefore have axial carboxyl groups.

ACKNOWLEDGMENT

This investigation was supported in part by a research grant, CY-2999 (C3), from the National Cancer Institute, Public Health Service.

THE CONVERSION OF META- AND PARA-SUBSTITUTED BENZALDOXIME ARENESULFONATES TO NITRILES

ROBERT J. CRAWFORD AND CHARLES WOO[1]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received November 13, 1964

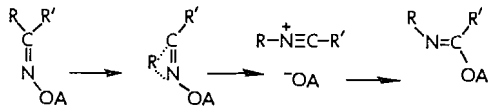
Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The meta- and para-substituted *syn*-benzaldoxime arenesulfonates were prepared from the reaction between the sodium salt of the oxime and the acid chloride in absolute ether. These oxime esters reacted in aqueous alcohol readily to yield the corresponding nitriles exclusively. The reaction rates can be correlated by a Hammett plot with a slope of −0.77. Several para-substituents tended to deviate from the line. Isotope study gives a k_H/k_D ratio of 4.51. The rate was found to be sensitive to the change in the ionizing power of the solvent, and to the change in the strength of the esterifying acid. The addition of lithium perchlorate gives rise to a normal salt effect. Sodium acetate brings about a basic elimination having a Hammett ρ value of +0.44. A mechanism is proposed in the light of these results.

INTRODUCTION

Since Beckmann (1) reported the conversion of oximes to the corresponding amides in acid media, numerous publications have appeared in an attempt to elucidate the mechanism of the transformation. Several authors, Blatt (2), Jones (3), Heldt (4), and Smith (5), have reviewed the Beckmann rearrangement up to 1963. The generally accepted view of the rearrangement involves migration of the hydrocarbon residue *anti* to the leaving group, followed by a rapid tautomerization of the intermediate. The transition state for such a reaction has been described as a pseudo three-membered ring, and the process was viewed as "an internal nucleophilic displacement, and may be described as ionization by rearrangement" (5). Although extensive work has been done on the subject of the



Beckmann rearrangement of ketoximes, the aldoximes have been less frequently investigated. Aldoximes and their derivatives usually undergo fragmentation to nitriles, under the conditions of the Beckmann rearrangement, so readily that examples of normal rearrangement to give amides are quite rare (4). For example, in the presence of phosphorus pentachloride and ether, *syn**-2-chloro-5-nitro-benzaldoxime gave rise to 2-chloro-5-nitrobenzonitrile (6); *syn*-2,6-dichloro-3-nitrobenzaldoxime yielded 2,6-dichloro-3-nitrobenzonitrile (7); and *syn*-α-bromocinnamaldoxime gave α-bromocinnamonitrile (8).

It would appear that aldoximes generally react by a different mode than do ketoximes; thus, "ionization by rearrangement" may not be operative for aldoximes. This paper initiates a general investigation about the difference of aldoxime and ketoxime esters under Beckmann conditions.

[1]*National Research Council of Canada Scholarship holder 1964–65.*

**The use of syn and anti with aldoximes is different from the common convention with ketoximes and refers to cis and trans to the hydrogen, respectively. See ref. 4a, p. 3; 4b, p. 321.*

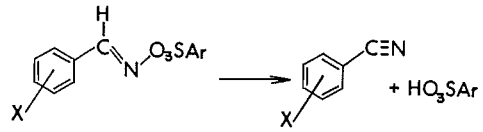
RESULTS AND DISCUSSION

Aldoxime esters react in aqueous alcohol to give rise to the corresponding nitriles as the sole product. The reaction rates were measured spectrophotometrically by following



the disappearance of the band at the wavelength of maximum absorption of the corresponding aldoxime ester. The products, the nitrile and the acid, have only a small absorption at this wavelength. A correction in the rate expression was made to accommodate this product absorption, and the first-order rate equation becomes

$$\log \frac{(A_0 - A_\infty)}{(A_{obs} - A_\infty)} = \frac{kt}{2.303},$$

where A_0 represents the optical density at the beginning of the reaction, A_{obs} is the observed optical density at time t, and A_∞ is the optical density caused by the products at the end of the reaction. The reaction was found to follow first-order kinetics in aldoxime ester to greater than 90% completion. The first-order rate constants were obtained graphically by plotting $\log (A_0 - A_\infty)/(A_{obs} - A_\infty)$ versus t, and are summarized in Tables I, II, and III. The experimental uncertainty was calculated by the method of average, and found to be ±2.3%. A sample run is given in the Experimental section.

TABLE I

An examination of the rates in Table III reveals several characteristics of the reaction. First of all, runs 1, 19, and 20 show that the rate is sensitive to solvent change. Varying the solvent from 100% methanol to 60% methanol–water increases the rate by a factor

*Extrapolated rate constant.

of 11.3. This effect can be correlated by the equation proposed by Winstein and coworkers (9), using the scale of solvent-ionizing power derived from ionization of *p*-methoxyneophyl *p*-toluenesulfonate:

$$\log k_r = a \log k_1 + b,$$

where k_r is the rate constant for the reaction being examined, k_1 is the rate constant for the ionization of *p*-methoxyneophyl *p*-toluenesulfonate, and a is a measure of relative sensitivity of the reaction to the ionizing power of the solvent. The a values for several rearrangements have been calculated (9) from data available in the literature, being 0.690 for the ionic rearrangement of 9-decalyl perbenzoate; 0.569 for the allylic rearrangement of 1-phenylallyl 3,4,5-tribromobenzoate; and 0.119 for the Curtius rearrangement of benzoyl azide. In the latter, sensitivity to solvent change is low. Figure 1 shows a

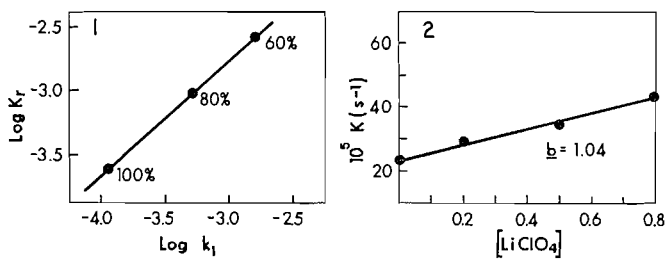

FIG. 1. Plot of log k_r for reaction of *syn*-*p*-methoxybenzaldoxime *p*-toluenesulfonate vs. log k_1 for solvolysis of *p*-methoxyneophyl *p*-toluenesulfonate in methanol at 50 °C.

FIG. 2. Plot of rate constant vs. lithium perchlorate concentration in the reaction of *syn*-*p*-methoxybenzaldoxime *p*-toluenesulfonate in 95% ethanol at 50 °C.

plot of log k_r versus log k_1 in methanol at 50°. The relatively high a value (0.950) indicates that the reaction is sensitive to changes in solvent-ionizing power in a manner similar to that for known ionization reactions.

Secondly, the addition of lithium perchlorate over a range of concentrations up to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

0.80 M gives rise to a normal salt effect. This can be described by a linear relation (10) between the rate constant and the molar concentration of lithium perchlorate:

$$k_r = k_0(1 + b[LiClO_4]),$$

where k_r is the observed rate constant, k_0 represents the rate constant at zero salt concentration, and b is the slope of the linear plot representing the % increase in rate constant over k_0 per 0.01 M increment of lithium perchlorate. Figure 2, from runs 21 to 24, shows the linear plot of rate constant versus lithium perchlorate concentration in 95% ethanol at 50°, with a b value of 1.04. The salt effect is quite small, but is that expected in ionizing solvents such as alcohols.

Finally, runs 21, 26, and 27 indicate that the reaction is sensitive to variation of the leaving group. Changing the leaving group from *p*-toluenesulfonate to *p*-bromobenzenesulfonate increases the rate by a factor of 3.9. A comparison of relative rates of the reactions of isopropyl arenesulfonates and *syn*-*p*-methoxybenzaldoxime arenesulfonates in aqueous ethanol at 50° is tabulated in Table IV. Using the three arenesulfonates as

TABLE IV

Comparison of the rates of isopropyl arenesulfonates (11) and *syn*-*p*-methoxybenzaldoxime arenesulfonates

Arenesulfonate	Isopropyl in 50% EtOH at 50°	*syn*-*p*-Methoxybenzaldoxime in 95% EtOH at 50°
p-Toluene	0.63	0.65
Benzene	1.00	1.00
p-Bromobenzene	2.92	2.72

the leaving group, the reaction of the *syn*-aldoxime arenesulfonates varies in the same direction and by approximately the same magnitude as the ionization of isopropyl arenesulfonates.

An inspection of the rate constants from Table I clearly shows that electron-donating groups accelerate the reaction rate and that electron-withdrawing substituents retard it. The effect of meta- and para-substitution on the rate constant can be correlated by the Hammett equation (12)

$$\log k/k_0 = \rho\sigma,$$

where k is the rate constant of the substituted *syn*-aldoxime *p*-toluenesulfonates, k_0 is the rate constant of the unsubstituted compound, ρ is the reaction constant, and σ is the substituent constant. Figure 3 shows a plot of log k/k_0 versus σ, and a ρ value of -0.77 was obtained when only meta-derivatives (σ^n) were considered, as suggested by van Bekkum *et al.* (13). The *p*-OCH_3 substituent deviates significantly from this line (a Hammett σ value of -0.856 would be required to bring it on the line, which means that the σ^+ value of -0.77 would not fit) and a mesomeric para-interaction energy difference ($\Delta\Delta F_p$) of -0.78 kcal mole^{-1} is obtained from the equation

$$-\Delta\Delta F_p = (\sigma - \sigma^n) \times 2.303RT,$$

where ρ is the value derived from the meta-substituents (-0.77), σ is the -0.856 value required to place the point on the line, and σ^n is the value -0.175 suggested by van Bekkum *et al.* (13) for a para-methoxy substituent from the detailed examination of substituent effects.

For personal use only.

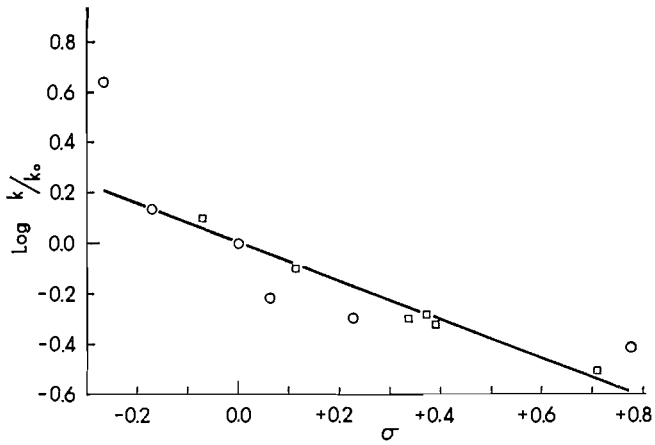

FIG. 3. Plot of log k/k_0 vs. σ for the reaction of meta- (□) and para- (○) substituted *syn*-benzaldoxime *p*-toluenesulfonates in 80% methanol at 50 °C.

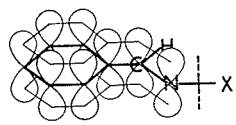
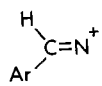
It is difficult to envisage a direct resonance interaction between the substituent and the N—O bond in I that is being broken, as it would be expected to be in the nodal plane of the aromatic π orbitals. Thus, ionization to an imidonium species II would not be expected to give rise to a very negative ρ value, nor could we expect a significant resonance interaction with the ring.



I



II

It should be noted, however, that *p*-methoxybenzonitrile, the product, gains additional stabilization from a resonance structure such as III.

III

If the elimination has progressed to the point that the transition state is beginning to resemble the product, then the *p*-methoxy substituent would be expected to stabilize the transition state and thus react at an enhanced rate.

If, indeed, the transition state does resemble the product nitrile, we would expect a considerable amount of C—H bond breaking. In order that we may ascertain the degree of C—H bond breaking in the reaction, the deuterated aldoxime *p*-toluenesulfonate IV was prepared. A rate constant of 1.36×10^{-5} s^{-1} was obtained in 95% ethanol at 50° for the deuterated compound, as compared with 6.16×10^{-5} s^{-1} for the undeuterated ester under the same conditions. This gives rise to a k_H/k_D value of 4.51 at 50°.

For personal use only.

An approximation of the theoretical isotope effect was calculated by the following expression (14) (this was necessary because of the sp^2 nature of the C—H bond being broken, a type of rupture not commonly observed):

$$k_D/k_H = \exp \frac{hc}{2kT}(\nu_D - \nu_H),$$

where k_D is the rate constant for the labelled compound, k_H is the rate constant for the unlabelled isomer, h is Planck's constant, c is the velocity of light, k is Boltzmann's constant, T is absolute temperature, and ν_D and ν_H represent the vibrational frequencies associated with a C—D and C—H bond, respectively. From the infrared spectra, the measured vibrational frequency of the C—D bond in *p*-chlorobenzaldoxime *p*-toluenesulfonate is 2 240 cm^{-1}, and that for the C—H bond is 3 030 cm^{-1}. Substituting these values into the above equation gives a theoretical k_H/k_D ratio of 5.81. The observed value of k_H/k_D of 4.51 suggests that the rate-determining step must involve the breaking of the C—H bond.

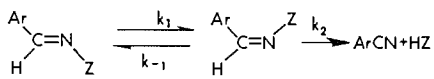
Run 25 in Table III indicates that the reaction is not acid catalyzed. The addition of 0.20 *M* *p*-toluenesulfonic acid had no appreciable effect on the rate. But the rates were observed to be greatly increased by the addition of sodium acetate. The second-order rate constants are calculated by the following equation:

$$k_2 = \frac{k_{obs} - k_1}{[OAc^-]},$$

where k_2 represents the second-order rate constant, k_{obs} is the observed pseudo first-order rate constant, and k_1 is the rate constant in the absence of sodium acetate. The second-order rate constants in the presence of 0.08 *M* sodium acetate are tabulated in Table II. It is interesting to note that the order of reactivity is completely reversed, with a ρ value of +0.44. This is similar to the base-catalyzed dehydrohalogenation of ald-chlorimines (15). A resemblance to this mild base-catalyzed process may also be responsible for the deviation of the *p*-nitro substituent in the uncatalyzed reaction (Fig. 3).

The possibility that the *syn*-aldoxime esters are being isomerized to the corresponding *anti*-ester followed by a *trans*-elimination must also be considered. Thus, in Scheme I,

SCHEME I



the reaction may be represented kinetically by the expression

$$-\frac{d[syn]}{dt} = \frac{k_1 k_2 [syn]}{k_{-1} + k_2}.$$

If k_1 and $k_{-1} > k_2$, then the expression reduces to

$$-\frac{d[syn]}{dt} = k_2 K [syn],$$

where $K = k_1/k_{-1}$, and we would thus obtain the same rate constant for either the *syn*- or the *anti*-ester. As may be seen in Table III, runs 28 to 32, the *anti*-isomer is 65 times faster than the *syn*-isomer. If, however, k_1 is slow and rate determining, we would

not expect to observe a kinetic isotope effect on replacing the oximino hydrogen by deuterium. The intermediate case where $k_{-1} \cong k_2$ reduces the above expression to

$$-\frac{d[syn]}{dt} = \frac{1}{2}k_1[syn]$$

and again no kinetic isotope effect would be observed. The observation of a 65-fold difference in rate between the *syn*- and *anti*-pair, and of a kinetic isotope effect of the magnitude of 4.51, allows us to exclude any possible isomerization mechanism.

A pyrolysis type of mechanism for the arenesulfonate esters may also be ruled out on the basis of the solvent sensitivity and the salt effect. The negative $\Delta S^{\ddagger}$ values in Table V

TABLE V

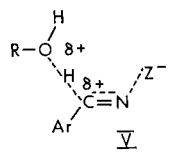
could readily arise from increased solvent constriction in the transition state and is consistent with ionization processes.

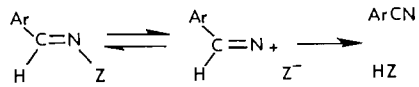
Solvent sensitivity, salt effect, and the dependence of the rate constant upon the leaving group suggest that the reaction is ionic in character. The effect of substituents suggests that a small positive charge may be developed on the conjugated system. The result of isotopic substitution shows that the C—H bond is also considerably stretched. This evidence supports a concerted *cis*-elimination mechanism, and the transition state involving varying degrees of rupture of the N—Z and C—H bonds (V).



V

It is possible that the N—Z bond has been completely broken, and we are measuring the proton loss from species such as II. This suggests the possibility of an ion-pair mechanism (Scheme II) which would involve ionization to the ion pair VI followed by proton abstraction by the gegen ion.

SCHEME II



VI

For personal use only.

This suffers from a possible handicap since, to accommodate the kinetic isotope effect, the last step would have to be rate determining and this would suggest that the stronger the arenesulfonate ion as a base the faster the reaction, which is the reverse of that observed in Table IV. This could be overcome by a large change in the prior equilibrium effectively increasing the steady-state concentration of the ion pair, and cannot be rigorously excluded. We are at this time, however, unable to cite any experiment which can satisfactorily differentiate whether the gegen ion or the solvent molecule is acting as base as in V.

EXPERIMENTAL

Preparation of Materials

p-Chlorobenzaldehyde-d

A solution of 40 g (0.37 mole) of N-methyl aniline in 250 ml of benzene was added slowly, with stirring, to a cooled solution of 60 g (0.34 mole) of *p*-chlorobenzoyl chloride in 250 ml of benzene. The mixture was refluxed for 2 h, cooled, and then washed with 250 ml of water, 250 ml of 5% hydrochloric acid, 250 ml of 5% sodium hydroxide, and 250 ml of water, respectively. The benzene solution was dried, the solvent evaporated, and the residue distilled at reduced pressure. The distillate solidified upon cooling in an ice bath. The yield of the pure N-methyl *p*-chlorobenzanilide was 56 g (60%), m.p. 54–56°.

Anal. Calcd. for $C_{14}H_{12}ClNO$: C, 68.5; H, 4.90; N, 5.71. Found: C, 68.1; H, 5.01; N, 5.58.

N-Methyl *p*-chlorobenzanilide (20 g (0.082 mole)) was dissolved in 200 ml of tetrahydrofuran which was redistilled over sodium just before use. The solution was cooled to 4° and 0.89 g (0.022 mole) of lithium aluminium deuteride was added and the mixture stirred at 4° for 15 h, whereupon 400 ml of 7% hydrochloric acid was added. The tetrahydrofuran was evaporated and the residue steam-distilled. The distillate was extracted with ether. The ethereal solution was dried, the solvent evaporated, and the residue distilled at diminished pressure. The distillate solidified on cooling in an ice bath. The yield of *p*-chlorobenzaldehyde-*d* was 7 g (58%), m.p. 47°. The infrared spectrum in chloroform shows that the vibrational frequency of the C—H bond at 2 837 cm^{-1} has been shifted to 2 112 cm^{-1} in the deuterated compound. The n.m.r. spectrum in deuterochloroform shows no absorption at τ 0.30 attributable to aldehydic C—H.

Oximes

All the *syn*-oximes were prepared by the following general procedure.

A 5-g quantity of hydroxylamine hydrochloride was dissolved in 30 ml of water and 20 ml of 10% sodium hydroxide, and 5 g of the aldehyde was then added. Sufficient 95% ethanol was added to the mixture to obtain a homogeneous solution. The mixture was refluxed for 15 min and cooled, and 100 g of crushed ice was added with shaking. If the oxime separated as a solid, the precipitate was filtered and pressed dry. The crude product was recrystallized from a mixture of skelly B and benzene. If the oxime separated as an oil, the oil was extracted with ether. The ethereal solution was dried, the solvent evaporated, and the residue distilled under reduced pressure. The distillate solidified on standing in the freezer. The yield of the pure oximes was in the range of 75–90%. Infrared spectra of the oximes in chloroform show a strong band at 3 580 cm^{-1} caused by O—H absorption (16). The melting point of the oximes together with the reported value (16) are *syn-p*-methoxybenzaldoxime, m.p. 64, reported 64; *syn-m*-methoxybenzaldoxime, m.p. 40, reported 40; *syn-p*-methylbenzaldoxime, m.p. 79, reported 79; *syn-m*-methylbenzaldoxime, m.p. 60, reported 60; *syn*-benzaldoxime, m.p. 35, reported 35; *syn-p*-fluorobenzaldoxime, m.p. 86, reported 86 (17); *syn-m*-fluorobenzaldoxime, m.p. 68, reported 63 (17); *syn-p*-chlorobenzaldoxime, m.p. 110, reported 106; *syn-m*-chlorobenzaldoxime, m.p. 71, reported 70; *syn-p*-chlorobenzaldoxime-*d*, m.p. 109; *syn-m*-bromobenzaldoxime, m.p. 75, reported 72; *syn-p*-nitrobenzaldoxime, m.p. 131, reported 129; *syn-m*-nitrobenzaldoxime, m.p. 124, reported 120; *anti-p*-methoxybenzaldoxime, m.p. 132–133°, reported 133° (18).

Oxime Acetates

A 0.5-g (3.3 mmoles) quantity of *syn-p*-methoxybenzaldoxime was dissolved in 0.5 ml of acetic anhydride. After 10 min, 5 ml of ether and 5 ml of hexane were added. The mixture was cooled and the precipitate was filtered. The yield of *syn-p*-methoxybenzaldoxime acetate was 0.47 g (74%), m.p. 48–49°, after recrystallization from a 50:50 mixture of ether and hexane. Reported m.p. 48–49° (18). The infrared spectrum in chloroform shows a strong band at 1 755 cm^{-1}.

anti-p-Methoxybenzaldoxime acetate was prepared by the same method as that for the *syn*-isomer. Yield 0.52 g (82%), m.p. 64–65°. Reported m.p. 64–65° (18). The infrared spectrum in chloroform shows a strong band at 1 760 cm^{-1}.

Oxime Arenesulfonates

The following general procedure was used for the preparation of the *syn*-aldoxime arenesulfonates except the nitro-substituted compounds.

To a rapidly stirred solution of 3 mmoles of the oxime in 20 ml of absolute ether, 3.1 mmoles of powdered sodium amide was added and the mixture was stirred for about 5 h. The mixture was filtered and the precipitate washed several times with ether.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

p-Toluenesulfonyl chloride (0.36 g (2.5 mmoles) in 5 ml of ether) was slowly added to a rapidly stirred slurry of the sodium salt of the oxime in 5 ml of ether. The salt produced was removed by filtration and 10 ml of hexane was added to the filtrate. Upon cooling of the mixture, the oxime arenesulfonate crystallized. Recrystallization from a 50:50 mixture of ether and hexane generally gives a pure sample. Yield 50–60%. The infrared spectra in chloroform show strong bands at 1 380 and 1 170 cm^{-1}, characteristic of sulfonate esters (16).

Since the meta- and para-substituted *syn*-nitrobenzaldoximes gave a mixture of the original oxime and the corresponding nitrile when the above method was followed, the procedure was modified. The sodium salt of the oximes was prepared as previously. The salt was dissolved in 5 ml of 50% acetone–water and added slowly with stirring to a cooled solution of *p*-toluenesulfonyl chloride in 2 ml of acetone. The oxime ester separated was collected, washed with 50% acetone, and recrystallized as before. The yield was about 45%.

The relevant data for these *syn*-aldoxime arenesulfonates are summarized in Table VI.

Product Analysis

syn-p-Chlorobenzaldoxime *p*-toluenesulfonate (0.50 g (1.6 mmoles)) was suspended in 10 ml of 95% ethanol at 50°. The suspension dissolved within 12 h, and the mixture was kept at 50° for an additional 24 h, whereupon 20 g of crushed ice was added. The solid separated was filtered and recrystallized from skelly B. The yield of *p*-chlorobenzonitrile was 0.13 g (80%), m.p. 92–93°. Reported m.p. 94–96° (17). The infrared spectrum in chloroform shows a strong band at 2 230 cm^{-1} caused by C≡N absorption (16). *p*-Methoxybenzonitrile, m.p. 61–62°, reported 61–62° (17), was similarly isolated from *syn-p*-methoxybenzaldoxime *p*-toluenesulfonate in 87% yield.

Kinetic Measurements

Absorption curves of the *syn*-aldoxime esters in the ultraviolet region were obtained on a Cary recording spectrophotometer model 14M. Kinetic measurements were taken from a Beckman model DU spectrophotometer at the wavelength of maximum absorption of the corresponding oxime ester. The spectrophotometer is equipped with a double set of thermospacers connected to a circulating constant temperature bath, thermostated within ±0.02° of the particular temperature. All kinetic runs were extrapolated back to zero time, and the small absorption caused by the products of the reaction was corrected in the rate expression. Good first-order curves were observed in every case. As an example, the reaction of the unsubstituted compound is recorded in Table VII, and the results are plotted in Fig. 4.

Reaction of *syn-p*-methoxybenzaldoxime acetate was carried out by the sealed-tube technique. A standard solution of the acetate (2 mg per 100 ml of the solvent) was made up. Samples of approximately 5 ml volume were sealed in ampoules and placed in the temperature bath. The reaction was followed by withdrawing and cooling ampoules at intervals of time, and the optical density was measured.

Infrared Spectra

The infrared spectra of *p*-chlorobenzaldoxime *p*-toluenesulfonate and the deutero-derivative were measured at 1% concentration in carbon tetrachloride solution using the same cells in each case. The spectrum of the deuterated compound has a C—D stretching band at 2 240 cm^{-1} that was not in the spectrum of the undeuterated ester. It also lacked a band at 3 030 cm^{-1}, which is present in the spectrum of the undeuterated aldoxime ester.

ACKNOWLEDGMENTS

The research described herein was supported by the National Research Council of Canada through a grant-in-aid to R. J. C. The n.m.r. and infrared spectra were measured by R. N. Swindlehurst and Mrs. Gail B. Conway; and the microanalyses were performed by Miss Darlene Roberts of this department.

SOME ASPECTS OF THE CHEMISTRY OF CATHARANTHINE AND CLEAVAMINE

JAMES P. KUTNEY, RICHARD T. BROWN, AND EDWARD PIERS
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

Chemical and spectroscopic evidence is presented for an interesting acid-catalyzed rearrangement of the alkaloid catharanthine. Four reaction products (descarbomethoxycatharanthine and cleavamine and its two dihydro derivatives) were isolated, and their formation is rationalized by a mechanism involving ring-opened intermediates. Evidence is presented in support of the proposed mechanism and, in particular, a novel transannular cyclization leading to the *Iboga* alkaloid skeleton is shown in support of the steps postulated for the formation of descarbomethoxycatharanthine.

The X-ray analysis of cleavamine methiodide established the absolute configuration of the lone asymmetric center present in the molecule and, from these results, the absolute configuration of the *Iboga* alkaloids can be derived.

During investigations by the Lilly group (1) on the dimeric *Vinca* alkaloids (vincaleukoblastine (VLB), leurosine, and leurocristine), it was found that each was cleaved by concentrated hydrochloric acid to an indole compound and vindoline derivative. The vindoline derivative of VLB and leurosine was desacetylvindoline (I), whereas leurocristine gave des-$N_{(a)}$-methyl-desacetylvindoline (II). Both VLB and leurocristine afforded the same indole derivative, velbanamine, $C_{19}H_{26}N_2O$, but the corresponding compound with leurosine was called cleavamine, $C_{19}H_{24}N_2$.

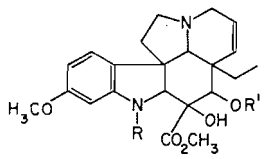
In the same communication it was also reported that the known alkaloid catharanthine (III (2)), when subjected to the same acid treatment, also provided cleavamine as one of the reaction products. The suggestion that cleavamine possessed a tetracyclic structure similar to the known *Aspidosperma* alkaloid quebrachamine (3) stimulated further research in our laboratory to establish conclusively the structure and stereochemistry of this substance. At the outset we felt that this investigation might not only provide indirect evidence for the presence of a catharanthine-like unit in the biologically important VLB molecule, but also illustrate a novel acid-catalyzed rearrangement in the *Iboga* alkaloid series. Furthermore, if the absolute configuration of the asymmetric center in the molecule could be established, it would provide indisputable evidence for the absolute configuration of the *Iboga* alkaloids.

With this view in mind, we initiated a detailed study of the catharanthine–cleavamine transformation and some of our results concerning the structure of cleavamine have already been published (4). Fortunately, the X-ray analysis of cleavamine methiodide established the structure and absolute configuration at C-2[1] as depicted in IV. We now wish to discuss these results in some detail and to present more recent evidence which is relevant to the mechanism of this interesting transformation.

Before considering mechanism, we wish to discuss briefly the stereochemistry of the *Iboga* alkaloids, since, in conjunction with the results of other workers and the evidence presented herein, it is possible to assign the absolute configuration for this series of

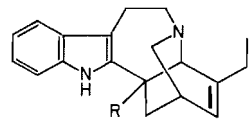
[1]*The numbering system used here is that of the Iboga alkaloids (see ref. 7).*

alkaloids. It is obvious that the absolute configuration of C-2 in IV immediately reveals the absolute configuration of this carbon atom in the catharanthine molecule, since there is little reason to suspect that any configurational change would occur in the catharanthine–cleavamine conversion. However, even this vague possibility has been eliminated in our recent transannular cyclization studies (5) wherein a cleavamine derivative has been converted to dihydrocatharanthine and the *Iboga* alkaloid, coronaridine. These results establish that the same stereochemistry at C-2 prevails in the rigid *Iboga* structure as in the relatively nonrigid cleavamine molecule. Since a previous X-ray study on ibogaine hydrobromide (6) had already established a *cis* relationship between the ethyl group at C-4 and the $\rangle$N—C-19 bridge, it is clear that the absolute configuration at C-4 and, in turn, for the entire *Iboga* alkaloid system is now established as shown in V for ibogamine.



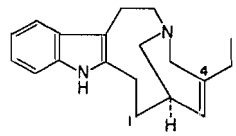
(I) R = CH_3; R' = H

(II) R = H; R' = H

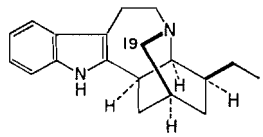


(III) R = $COOCH_3$

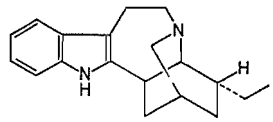
(VI) R = H



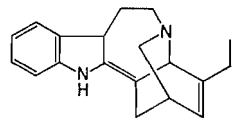
(IV)



(V)



(VII)



(VIII)

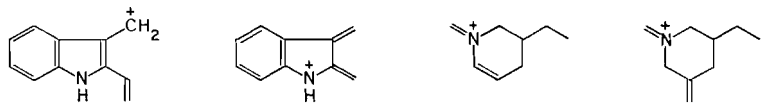
It should be noted that in their elegant work on the alkaloids of *Tabernanthe iboga*, the Ciba group (7) had previously postulated that the ethyl group at C-4 was *trans* to the $\rangle$N—C-19 bridge. Furthermore, these workers had compared the optical rotatory dispersion curve for one of their bicyclic degradation products with a decalin derivative of established configuration and on this basis suggested an absolute stereochemistry for this group of alkaloids. It is pleasing to note that, with the exception of the incorrect assignment at C-4, the remaining stereochemical centers were proposed as in V. Consequently, in this instance, the optical comparison of a piperidone ring with a cyclohexanone system has now been proved as valid, although some reservations about this point were understandably expressed at that time.

Turning to the mechanistic interpretation of the acid-catalyzed rearrangement of catharanthine, we felt that we should carry out a more detailed investigation of this reaction in an attempt to isolate as many products as possible, since these may provide evidence as to the nature of this rearrangement. Apart from the isolation of cleavamine, another product, descarbomethoxycatharanthine (VI), had been previously obtained from this reaction (8) but, since the combined yield of these two products constituted only about 20% of the total reaction mixture, we decided to examine this mixture more closely.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The cleavamine mother liquors and several cleavamine-containing fractions were combined and subjected to several very careful column chromatographic separations. Apart from the many fractions containing intractable gums and resins, one fraction which could be well characterized was obtained. It is appropriate to discuss this in some detail, since additional evidence which was germane to any mechanistic interpretation was furnished.

This fraction, designated as B9, was a mixture of two compounds, as shown by thin-layer chromatography, but numerous attempts to completely separate these compounds by various techniques failed. Consequently, we will discuss the spectral data obtained on B9 and show how the results led to the characterization of these two compounds as the two possible dihydrocleavamines epimeric at C-4. No olefinic protons were apparent in the nuclear magnetic resonance spectrum of B9, and the methyl triplet normally present at 8.96 τ in cleavamine had shifted to 9.13 τ. The mass spectrum showed a molecular ion at *m/e* 282, and other significant peaks at *m/e* 156, 143, 138, and 124 could be attributed to the following fragments, which are given by 4β-dihydrocleavamine (4, 10).[2]



In general, the mass spectrum of B9 was practically superimposable on that of 4β-dihydrocleavamine, and also the infrared spectra were similar. The leading spot of the mixture had the same R_f value as 4β-dihydrocleavamine on thin-layer chromatography, and the second spot was thought to be due to a dihydrocleavamine epimeric at C-4, which we designated as 4α-dihydrocleavamine. Fortunately, from other studies at the Lilly laboratories, a C-4 epimer of 4β-dihydrocleavamine had been isolated and we were able to demonstrate that this compound was identical with our sample of 4α-dihydrocleavamine. A synthetic mixture of the dihydrocleavamines duplicated the behavior of fraction B9 on thin-layer chromatography and gave an identical infrared spectrum.

Two dihydro derivatives epimeric at C-4 could, in theory, arise from an acid-catalyzed rearrangement of dihydrocatharanthine, formed by the reduction of catharanthine during the course of the reaction, or they could arise from the reduction of cleavamine itself. The former possibility is eliminated, since it is well known (8) that dihydrocatharanthine does not yield any tetracyclic products under the reaction conditions utilized above, whereas we have recently shown that cleavamine is not reduced to the dihydro derivatives under these conditions as well. This evidence indicates that these dihydro compounds arise from a ring-opened intermediate which can lead to cleavamine on the one hand and to dihydrocleavamines on the other.

Perhaps the most interesting aspect of the acid reaction on catharanthine comes forth from consideration of the formation of descarbomethoxycatharanthine. Some earlier work by the Lilly group (8) established that, although dihydrocatharanthine, like its relatives in the *Iboga* series (7, 11, 12), decarboxylated readily to yield the corresponding descarbomethoxy base, epi-ibogamine (VII), catharanthine did not undergo an analogous transformation under these conditions. Although this may seem somewhat puzzling,

[2]*In a related investigation to be reported later, we have shown by the X-ray analysis technique that dihydrocleavamine prepared by catalytic reduction of cleavamine has the ethyl group at C-4 in the β-configuration and is therefore referred to as 4β-dihydrocleavamine. The C-4 epimer obtained from decarbomethoxylation of carbomethoxydihydrocleavamine is therefore 4α-dihydrocleavamine.*

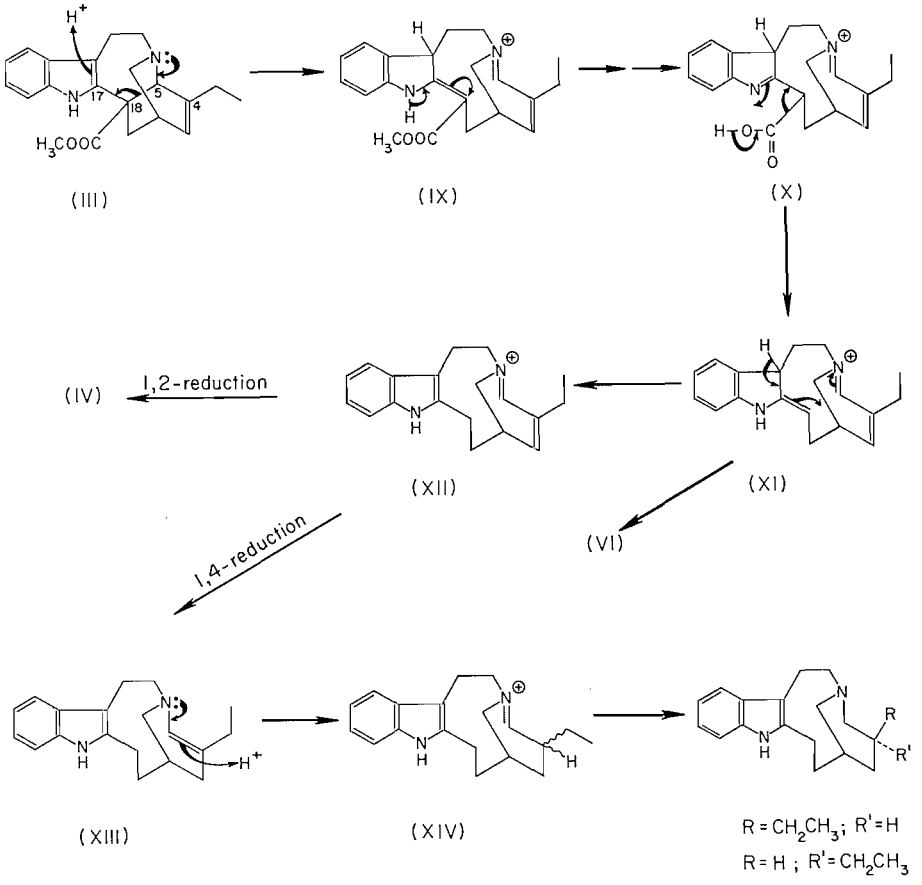
there is a very reasonable rationalization for this difference in reaction. Consideration of the accepted decarboxylation mechanisms (7, 12) for these compounds leads to the realization that in the case of catharanthine an intermediate of type VIII becomes necessary. Molecular models reveal that this intermediate would be very highly strained and there is serious doubt whether it can exist at all. On the other hand, the corresponding intermediate in the reduced series can form easily and it is felt that this accounts for the marked difference in reactivity toward the decarboxylation reaction. Therefore, the formation of descarbomethoxycatharanthine does not involve a simple decarboxylation but must be explained in some other manner.

In relation to some transannular cyclization studies in our laboratory, some of which have been recently published (5, 13, 14), it was extremely attractive to consider that the formation of all the products which have been isolated from the reaction of catharanthine with concentrated hydrochloric acid can be rationalized on the basis of the mechanism shown in Reaction Scheme 1.



REACTION SCHEME 1.

The lone pair of electrons on $N_{(b)}$ in III can participate in a rearrangement to form an iminium ion, with concurrent ring cleavage and protonation at the β-position of the indole. The resulting ring-opened intermediate IX is stabilized by two factors: (i) the

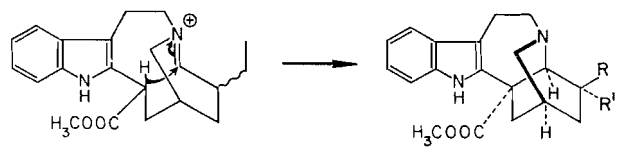
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

conjugated nature of the iminium ion, and (ii) the conjugation of the newly generated double bond between C-17 and C-18 with both the ester and anilino functions. After acid hydrolysis of the ester, decarboxylation may occur via X in a manner analogous to the mechanism proposed for the *Iboga* alkaloids (7, 12). This ring-opened intermediate renders the molecule more flexible and the decarboxylated intermediate XI is obtained, whereas, as already mentioned above, the cyclic intermediate VIII necessary for decarboxylation of the rigid catharanthine molecule is highly strained.

The crucial intermediate XI may follow either of two reaction paths. If the original electron flow is reversed, then the C-5/C-18 bond is regenerated and the product is descarbomethoxycatharanthine (VI). But if the α-methylene indoline system in XI merely rearranges to the indole, the intermediate XII from which the ring-opened tetracyclic compounds must ultimately be formed is obtained. If one assumes that XII is the actual intermediate, 1,2-reduction of the iminium ion will give cleavamine directly. On the other hand, 1,4-reduction can also occur to afford an enamine, XIII, which rearranges in the well-known manner to the iminium compound XIV, with subsequent reduction to provide the two isomeric dihydrocleavamines. A mixture of 4α- and 4β-dihydrocleavamines is obtained, because the approach of the proton to C-4 in XIII can occur from above or below the plane of the ring with equal facility.

A mechanism involving tetracyclic intermediates has also been proposed by the Lilly group to explain some of their results (8), although their detailed mechanistic interpretation still remains to be published.[3]

We wish now to present additional evidence to the results already mentioned above, which we feel provide substantial support for the mechanistic speculations. One of the crucial steps in the mechanism implies a transannular cyclization of intermediate XI to provide a route to descarbomethoxycatharanthine. We have recently demonstrated (5) that this interesting reaction can indeed occur quite easily and does provide the *Iboga* alkaloid skeleton. These results can be summarized by the sequence shown in Reaction Scheme 2.



(XV) R = CH_2CH_3; R' = H

(XVI) R = H; R' = CH_2CH_3

REACTION SCHEME 2.

The isolation of coronaridine (XV) and dihydrocatharanthine (XVI) in this reaction (5) is of considerable interest to the mechanism postulated above. First of all, it provides reasonable evidence for the feasibility of the process XI → VI. Secondly, it also shows that epimerization at C-4, as suggested to explain the isolation of the two dihydrocleavamines, can and does proceed through an iminium–enamine equilibrium. We feel that these results add considerable strength to the postulates mentioned above.

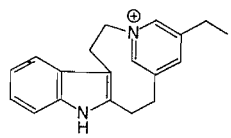
We also wish to point out that it is not possible to ascertain, from the evidence presented herein, exactly when the loss of the ester group occurs, although the sequence

[3]*After our paper had been submitted for publication, a detailed account of this work appeared (9).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

suggested by IX → XI seems most reasonable at this time. It is pertinent to note that the recent isolation of carbomethoxydihydrocleavamine from the reduction of catharanthine with zinc in acetic acid (15) provides evidence that the reduction of the iminium system can occur before the loss of the ester group.

Finally, it is important to emphasize that the last steps of the above mechanism explain the formation of cleavamine and its dihydro derivatives when catharanthine is reacted with acid in the presence of a reducing agent (stannous chloride, mossy tin). Since it has been established (8) that cleavamine is also formed (although in lower yield) by the action of concentrated hydrochloric acid alone, one must account for its formation under these conditions. In the absence of an inorganic reducing agent, the reduction step possibly takes place via an intramolecular redox reaction wherein two molecules of the intermediate XII react to yield one molecule of cleavamine and one of a pyridinium compound XVII. The increase in yield of cleavamine in a reducing medium is thus explicable on the grounds that XII is reduced directly to cleavamine and no pyridinium compound is formed.



(XVII)

The acid-catalyzed rearrangement of catharanthine to the ring-opened intermediates is an interesting conversion both from a mechanistic and a biosynthetic standpoint. Some related aspects of this reaction are under study in our laboratory at present.

EXPERIMENTAL

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet spectra were measured in methanol solution on a Cary 14 spectrophotometer and infrared spectra were taken on a Perkin–Elmer model 21 spectrophotometer. Nuclear magnetic resonance (n.m.r.) spectra were recorded at 60 Mc/s on a Varian A60 instrument. The line positions or centers of multiplets are given in the Tiers τ scale with reference to tetramethylsilane as the internal standard, with the multiplicity, integrated areas, and types of protons being indicated in parentheses. Silica gel G plates were used for thin-layer chromatography (t.l.c.) and were developed by ethyl acetate, or ethyl acetate – chloroform mixtures as given below. The alumina used for column chromatography was Shawinigan reagent, deactivated with 3% of 10% aqueous acetic acid unless otherwise stated. Analyses were performed by the Microanalytical Laboratory, University of British Columbia, and by Dr. A. Bernhardt and his associates, Mulheim (Ruhr), Germany. All molecular weights were determined by mass spectrometry on an Atlas CH4 spectrometer.

Reaction of Catharanthine with Concentrated Hydrochloric Acid

(a) Isolation of Cleavamine and Descarbomethoxycatharanthine

The procedure indicated here is somewhat modified from that originally developed in the Lilly Research Laboratories.

A mixture of catharanthine hydrochloride (40 g), stannous chloride (44 g), and mossy tin (4 g) in concentrated hydrochloric acid (520 ml) was heated under reflux in a nitrogen atmosphere for 75 min. By the end of this time an orange-red gum had formed in the reaction mixture. The acidic solution was decanted from the gum and washed with methylene chloride (3 × 100 ml). The washings were combined with the gum, and then methanol (50 ml) and methylene chloride (100 ml) were added so that a clear solution was obtained. This solution was shaken with 1 *N* aqueous sodium hydroxide (600 ml), separated, and washed with water (200 ml). The sodium hydroxide solution was washed with ether (2 × 100 ml) and the ethereal extract added to the methylene chloride solution. After it was dried over magnesium sulfate, the organic solution was evaporated to leave a reddish oil (32 g), which was taken up in benzene and chromatographed on alumina (1 200 g).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Cleavamine was eluted in the initial benzene – petroleum ether (b.p. 30–60°, 1:1) fractions and recrystallized from methanol to give needles (2.4 g), m.p. 117–119°; one spot of t.l.c. (ethyl acetate); $[\alpha]_D^{26}$ + 73° ($CHCl_3$); λ_{max} (log ϵ): 228 (4.60), 285 (3.87), 292 (3.86) mμ; ν_{max}^{Nujol}: 3 420 (NH), 2 800, 2 740, 2 700 cm^{-1} (Bohlmann bands) (16), no carbonyl absorption; n.m.r. signals (CD_3COCD_3): 0.87 (singlet, 1H, NH), 2.8 (multiplet, 4H, aromatic), 4.72 (doublet, 1H, olefinic), 8.96 τ (triplet, 3H, CH_2CH_3).

Anal. Found: C, 81.30; H, 8.54; N, 10.18; mol. wt. 280. Calcd. for $C_{19}H_{24}N_2$: C, 81.38; H, 8.63; N, 9.99; mol. wt. 280.

Cleavamine methiodide was formed by merely adding an excess of methyl iodide to a methanol solution of cleavamine and allowing the mixture to stand overnight in a refrigerator. The analytical sample was prepared by recrystallizing it from a mixture of methanol – ethyl ether – petroleum ether, m.p. 244–245° (decomp.). This derivative was used for the X-ray analysis (4).

Anal. Found: C, 56.83; H, 6.46; N, 6.63. Calcd. for $C_{20}H_{24}N_2I$: C, 56.87; H, 6.46; N, 6.45.

The sample of cleavamine was identical in every respect with an authentic sample kindly provided by Dr. M. Gorman, Eli Lilly and Company.

Benzene–chloroform (1:1) elution provided unreacted starting material (7 g) in the initial fractions and descarbomethoxycatharanthine (1.0 g) in the later fractions. The latter material was recrystallized twice from ether to yield needles, m.p. 103–104°.

Anal. Found: C, 81.70; H, 8.12; N, 10.10. Calcd. for $C_{19}H_{22}N_2$: C, 81.97; H, 7.97; N, 10.06.

This material was subsequently shown to be identical in every respect with an authentic sample of descarbomethoxycatharanthine kindly provided by Dr. M. Gorman, Eli Lilly and Company.

(b) Isolation of 4α- and 4β-Dihydrocleavamines (Fraction B9)

The later benzene – petroleum ether (1:1) fractions, after the major cleavamine-containing fractions had been removed in the above chromatography, displayed three spots on t.l.c. (ethyl acetate) with R_f values of 0.77, 0.53, and 0.27. The compound with a R_f value of 0.77 was found to correspond to cleavamine. These fractions were combined (5.4 g) and placed on another alumina column (450 g). Elution was begun with benzene – petroleum ether (1:2) and the first four fractions afforded cleavamine (1.4 g) after recrystallization from methanol. The later fractions contained progressively less cleavamine and more of the other two constituents. The last (B9, 55 mg) of the nine fractions obtained with this eluent contained no cleavamine and displayed only two spots on t.l.c. Recrystallization from aqueous ethanol gave light brown prisms, m.p. 127–132°; ν_{max}^{Nujol}: 3 410 (NH), 2 790, 2 740 cm^{-1} (Bohlmann bands); n.m.r. ($CDCl_3$): 2.8 (multiplet, 4H, aromatic), 9.13 τ (broad, 3H, CH_2CH_3), no olefinic proton signals.

Anal. Found: C, 80.56; H, 9.46; N, 10.04; mol. wt. 282. Calcd. for $C_{19}H_{26}N_2$: C, 80.80; H, 9.28; N, 9.92; mol. wt. 282.

Fraction B9 was shown to be a mixture of 4α- and 4β-dihydrocleavamines by comparison (t.l.c. and infrared and mass spectra) with authentic samples as prepared below.

4β-Dihydrocleavamine

Cleavamine (1.5 g) in ethyl acetate (20 ml) was hydrogenated over Adam's catalyst (150 mg). Uptake of hydrogen ceased after 50 min, at which time 1 mole of hydrogen had been absorbed. Filtration and evaporation of the solvent gave 4β-dihydrocleavamine, which recrystallized from methanol as prisms (1.2 g), m.p. 136–138°; one spot on t.l.c. (ethyl acetate); ν_{max}^{Nujol}: 3 410 (NH), 2 790, 2 750 cm^{-1} (Bohlmann bands); n.m.r. (CD_3COCD_3): 0.88 (singlet, 1H, NH), 2.8 (multiplet, 4H, aromatic), 9.17 τ (triplet, 3H, CH_2CH_3).

Anal. Found: C, 81.02; H, 9.59; N, 9.88; mol. wt. 282. Calcd. for $C_{19}H_{26}N_2$: C, 80.80; H, 9.28; N, 9.92; mol. wt. 282.

4α-Dihydrocleavamine

Carbomethoxydihydrocleavamine (15) (500 mg) in 5 *N* hydrochloric acid (30 ml) was heated on the water bath under a nitrogen atmosphere for 8 h. The solution was cooled in ice, made basic with aqueous ammonia, and extracted with methylene chloride (3 × 50 ml). The organic extract was dried, concentrated to a small volume, and filtered through alumina (10g). Evaporation of the solvent gave an amorphous powder (340 mg) which could not be induced to crystallize. In spite of its amorphous nature it showed only one spot on t.l.c. (ethyl acetate); ν_{max}^{Nujol}: 3 350 (NH), 2 750 cm^{-1}, no carbonyl absorption.

This material was subsequently shown to be identical (t.l.c. and infrared spectra) with an authentic sample of a 4-dihydrocleavamine isomer kindly supplied by Dr. M. Gorman, Eli Lilly and Company. We have now shown[2] that this isomer must have the ethyl group in the α-configuration, and therefore carbomethoxydihydrocleavamine is in the 4α series as well.

Mercuric Acetate Oxidation of Carbomethoxydihydrocleavamine

Carbomethoxydihydrocleavamine (4.5 g) and mercuric acetate (10.5 g) in glacial acetic acid (150 ml) were stirred under a nitrogen atmosphere for 40 h. The solution was then filtered from the precipitated mercurous acetate (8.2 g) and heated under reflux for 5 h. The solvent was removed as far as possible under vacuum, and the residue made basic with dilute ammonia (50 ml) and extracted with methylene chloride (3 × 50 ml).

After the solution was dried over sodium sulfate, the methylene chloride was removed, and the dark brown product chromatographed on alumina (200 g, deactivated with 0.6 ml of glacial acetic acid). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

initial benzene fractions afforded a vincadifformine-like product as a white powder (1.15 g). Although the structure of this material has been fully established (14), it bears no direct relevance to the present paper and a more detailed discussion of its chemistry will be presented in a later paper.

The later benzene fractions yielded an amorphous powder (450 mg); one spot on t.l.c. (ethyl acetate – chloroform, 1:9); λ_{max} 226, 285, 293 mμ; $\nu_{max}^{CCl_4}$: 3 400 (NH), 1 705 (C=O) cm^{-1}; n.m.r. ($CDCl_3$): 2.8 (multiplet, 4H, aromatic), 6.30 (singlet, 3H, CH_3O), 9.10 τ (triplet, 3H, CH_2CH_3). This compound was subsequently shown to be coronaridine by comparison with an authentic sample.

The amorphous material was taken up in anhydrous ether and the hydrochloride salt formed by passing in dry hydrogen chloride. Two recrystallizations from acetone–ether afforded the hydrochloride as needles, m.p. 221–223° (decomp.); ν_{max}^{Nujol}: 3 160 (NH), 2 530 (NH), 1 715 cm^{-1} (C=O). An authentic sample of coronaridine hydrochloride, m.p. 221–223° (decomp.), prepared from a sample of coronaridine, completely established the identity (mixed melting point, t.l.c., and infrared spectra).

Benzene–ether (1:1) eluted a compound (440 mg) which was recrystallized from petroleum ether (b.p., 60–80°) to afford prisms, m.p. 143–145.5°; $[\alpha]_D^{23}$ +49° ($CHCl_3$); λ_{max} 225, 286, 293 mμ; ν_{max}^{KBr}: 3 350 (NH), 1 700 cm^{-1} (C=O); n.m.r. ($CDCl_3$): 2.8 (multiplet, 4H, aromatic), 6.38 (singlet, 3H, CH_3O), 9.04 τ (triplet, 3H, CH_2CH_3). This material was identified as dihydrocatharanthine by comparison with an authentic sample which we prepared by hydrogenation of catharanthine.

Reaction of Cleavamine with Concentrated Hydrochloric Acid

A mixture of cleavamine (100 mg), stannous chloride (180 mg), and mossy tin (30 mg) in concentrated hydrochloric acid (3 ml) was heated under reflux in a nitrogen atmosphere for 75 min. The reaction mixture was then treated with dilute aqueous sodium hydroxide and extracted with chloroform. The chloroform extract was washed with water and then dried over anhydrous sodium sulfate. Removal of the solvent *in vacuo* provided 80 mg of a crude reaction product. This product was shown by thin-layer chromatography to consist mainly of cleavamine and a small amount of a very polar component, but *no* dihydrocleavamine. It should be emphasized that t.l.c. can readily detect even very minute amounts of any dihydrocleavamine, and so its absence is conclusively established.

ACKNOWLEDGMENTS

Financial aid from the National Cancer Institute of Canada, the National Research Council of Canada, and Eli Lilly and Company is very gratefully acknowledged. We express our sincere thanks to Drs. M. Gorman and N. Neuss, Eli Lilly and Company, for the generous samples of catharanthine hydrochloride, descarbomethoxycatharanthine, coronaridine, and 4α-dihydrocleavamine, and for their results on the chemistry of catharanthine before publication. We also express our gratitude to Professor Carl Djerassi for the mass spectrometric measurements. One of us (R. T. B.) is indebted to the Canadian Commonwealth Scholarship and Fellowship Committee for a scholarship.

THE ELECTRON-SPIN RESONANCE SPECTRA OF SOME METHYLATED ANTHRASEMIQUINONES

EVIDENCE FOR RESTRICTED ROTATION[1]

R. M. ELOFSON, K. F. SCHULZ, B. E. GALBRAITH, AND R. NEWTON
Research Council of Alberta, Edmonton, Alberta

Received January 7, 1965

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

The hyperfine electron-spin resonance spectra of a number of methyl-substituted 9,10-anthrasemiquinones have been determined. The spectra have been analyzed by computer techniques, and splitting constants have been assigned for all protons. The results indicate that, while the parent quinones are essentially free of steric hindrance, the methyl groups in the α position of the reduced quinones are not free to rotate. The methyl groups in the β position of the semiquinones show normal hyperconjugative behavior. These results are consistent with the different redox potentials of these compounds revealed in a previous study.

In a polarographic study of substituted 9,10-anthraquinones, Crawford *et al.* (1) showed that substitution of a methyl group for a β proton produced little change in the polarographic reduction potential. However, substitution of a methyl group for an α proton caused a considerable increase in the polarographic reduction potential or decrease in the oxidation potential. This was shown to be due to steric factors by judicious choice of suitably substituted anthraquinones. In particular, the steric factor was assumed to operate by causing a resistance to planarity in the reduced quinone compared with the quinone itself, which must be somewhat nonplanar (2). Gill and Stonehill (3) suggested that steric hindrance pushed both the =O and large α substituents out of the ring plane.

In this work an attempt is made to investigate the hyperconjugation (4) and restricted rotation by means of the electron-spin resonance (e.s.r.) hyperfine splitting constants of methylated anthrasemiquinones (5). The results are compared with preliminary observations on the nuclear magnetic resonance (n.m.r.) and infrared spectra of the corresponding quinones.

EXPERIMENTAL

The quinones used in this investigation, except those described below, were provided through the kindness of Dr. R. J. Crawford of the University of Alberta. They were prepared by known procedures and purified by careful recrystallization from isopropyl alcohol. The observed melting points were anthraquinone, 286–288°; 1-methylanthraquinone, 172–173°; 2-methylanthraquinone, 175–177°; 1,2-dimethylanthraquinone, 159–161°; 1,3-dimethylanthraquinone, 163–165°; 2,6-dimethylanthraquinone, 245–247°; 2,7-dimethylanthraquinone, 171–173°; and 1,4-dimethylanthraquinone, 141–142°.

2-CD_3-Anthraquinone

Toluene-CD_3, Merck, was allowed to react with phthalic anhydride in the presence of aluminium chloride. The resulting 4-CD_3-benzoylbenzoic acid was cyclized by treating it with fuming sulfuric acid. The resulting 2-CD_3-anthraquinone had a melting point of 172–174 °C, and no stretching vibration in the infrared caused by aliphatic CH bonds.

1-CD_3-Anthraquinone

Toluene-CD_3, Merck, was brominated in the presence of nitric acid (6). The product contained both *o*- and *p*-bromotoluene-CD_3 which were separated by preparative gas chromatography using a Wilken's Aerograph model 600 gas chromatograph with benzoquinoline on firebrick packing. *o*-Bromotoluene-CD_3

[1]*Research Council of Alberta contribution No. 286.*

was converted to the Grignard by magnesium in ether and treated with phthalic anhydride to produce 2-*o*-tolyl-CD_3 benzoic acid. This was converted by means of fuming sulfuric acid to 1-CD_3-anthraquinone, melting point 170–173°. This material showed no infrared absorption that was due to aliphatic CH bonds but did contain a small amount of 2-CD_3-anthraquinone.

Semiquinone Solution

Solutions of semiquinones were prepared by warming, in the absence of air, 10^{-3} M solutions of the quinones in isopropyl alcohol to which sodium or potassium had been added to produce 0.1 M solutions of the isopropoxide. Some solutions were subjected to irradiation with a mercury lamp instead of heat to produce the semiquinone but the resulting solutions had the same e.s.r. spectra. Solutions for e.s.r. studies were prepared in sealed Pyrex tubes, 0.4 mm o.d. The solutions were frozen, evacuated, and sealed. Occasionally, heating of the sealed solution for some time was required to remove traces of oxygen by oxidation of the semiquinone before a stable semiquinone solution was obtained.

Electron-spin resonance spectra were run on a Varian model 4500 spectrometer fitted with 100 kc modulation. Absolute splitting constants were obtained by using 1,4-benzosemiquinone, $a = 2.37$ oersted, as a standard (7).

Detailed analysis of the e.s.r. spectra was carried out using an IBM model 1620 computer by a technique that will be published elsewhere. This technique involves the numerical manipulations of the recorded spectrum, using only the assumption of symmetry with respect to each splitting constant of the spectrum to eliminate, in turn, each of these splitting constants. In Figs. 1 and 2 some typical spectra together with

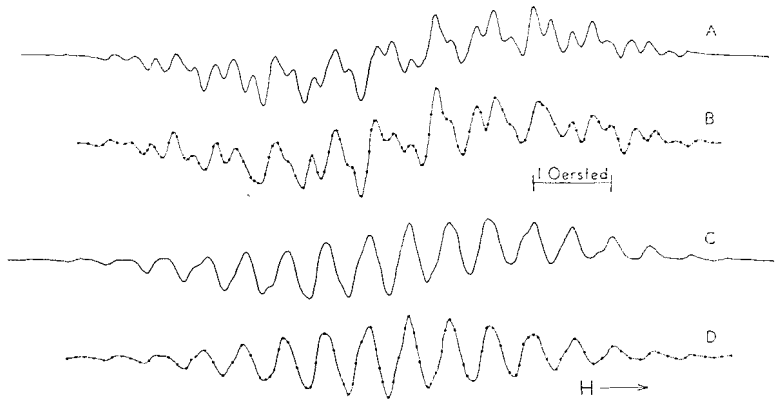

FIG. 1. (A) Experimental e.s.r. spectrum of 1-methylanthrasemiquinone; (B) calculated spectrum of 1-methylanthrasemiquinone; (C) experimental spectrum of 2-methylanthrasemiquinone; (D) calculated spectrum of 2-methylanthrasemiquinone.

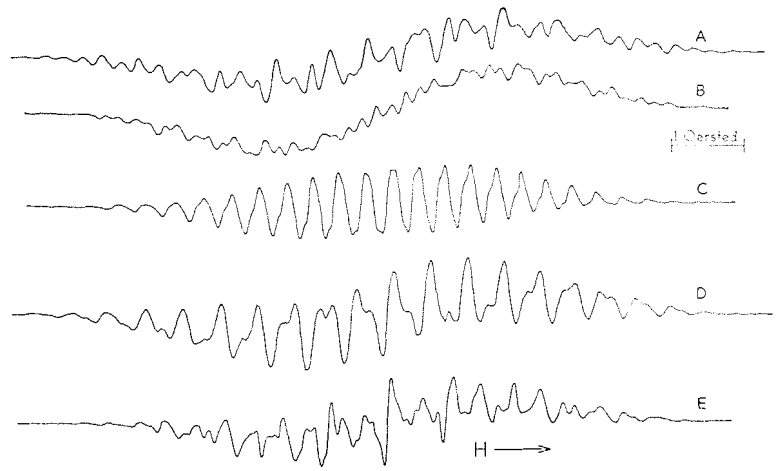

FIG. 2. Experimental e.s.r. spectra of 9,10-anthrasemiquinones: (A) 1,2-dimethyl; (B) 1,3-dimethyl; (C) 1,4-dimethyl; (D) 2,6-dimethyl; (E) 2,7-dimethyl.

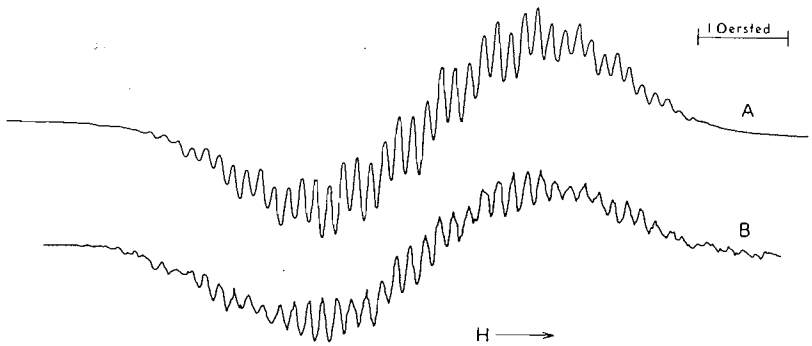

FIG. 3. Experimental e.s.r. spectra of 2-CD_3-anthrasemiquinone: (A) with potassium isopropoxide; (B) with sodium isopropoxide.

spectra reproduced from the numerical analyses are presented. These results are limited by the limitations of the current control to the magnet. However, some of the results might be improved if a Fieldial accessory were added to the present system, since this should improve the stability and linearity of field scan by a factor of 10.

Nuclear magnetic resonance spectra in chloroform solutions containing tetramethylsilane as an internal standard were run on a Varian model 1260 n.m.r. spectrometer.

Infrared spectra were run on a Perkin–Elmer model 221 prism-grating spectrometer.

While splittings due to sodium have not been observed previously in the e.s.r. spectra of alcohol solution of semiquinones, the high resolution obtained in these experiments and the small splitting constants observed in some of the compounds made it necessary to eliminate possible complications that were due to ion pairs (8). In Fig. 3 are shown spectra of 2-CD_3-anthrasemiquinone in sodium isopropoxide and potassium isopropoxide. It is seen that splittings due to the sodium of the order of 0.03 to 0.04 gauss are observed. Since splittings due to potassium are about one-fifth those of sodium, all spectra were finally run in potassium sopro poxide rather than sodium isopropoxide solutions. No splittings due to potassium were observed in his wo rk.

RESULTS

In Table I are summarized the results of the e.s.r. investigation. Since the quality, particularly the symmetry of the spectra, varied, the results have been obtained in differing detail. No attempt has been made to assign specific α or β constants to particular positions.

As previously mentioned, better results may be expected from the computation if spectra of higher symmetry can be obtained. The individual values assigned to splitting constants vary in accuracy but, in general, the smallest assigned splitting constant is known with the greatest accuracy. Since the largest splitting constants limit the width of the spectra, these are also known to a degree of accuracy approaching 10%. The intermediate constants are known with less accuracy. Since the argument developed in this paper is dependent on the value of the smallest and, to a lesser extent, the largest splitting constants, the present results are clearly acceptable even though technical improvements may modify some of the apparent values.

Anthrasemiquinone

In agreement with previous workers (9–11), we found that anthrasemiquinone has a 13-line spectrum which results from a coupling of four β protons with a splitting constant of 0.83 oersted (Oe) and four α protons with a splitting constant of 0.42 Oe, or almost exactly half the β value. The result is in good agreement with that of Adams *et al.* (9) of 0.46 and 0.92 Oe, but is considerably lower than those of Vincow and Fraenkel (10) and Brandon and Lucken (11).

‡Smallest observed splitting constants.

2-Methylanthrasemiquinone

This compound has three groups of splitting constants and shows the normal effect of hyperconjugation of an unhindered methyl group. The four splitting constants of 0.38 Oe are plainly due to the four α protons. The three protons with splittings of 0.91 Oe and the three protons with 0.81 Oe are due to the three methyl protons and the three β protons respectively or vice versa. To distinguish between these two possibilities 2-CD_3-anthrasemiquinone was prepared. Its spectrum, illustrated in Fig. 3, had 46 lines with a spacing of 0.15 gauss arising from a final 7-line splitting that is due to the three deuterium atoms. Venkataraman and Fraenkel (12) found a value of 6.48 for the ratio of a_H/a_D. This strongly suggests that the three splitting constants of 0.91 gauss are due to the three methyl protons in 2-methylanthrasemiquinone.

2,6-Dimethylanthrasemiquinone

Analysis of this spectrum showed that the six methyl protons had large splitting constants, indicating that the electron concentration at the 2- and 6-carbon atoms were somewhat larger than at the 3 and 7 positions. No significant difference could be observed in the individual splitting constants for the α positions, although a more detailed analysis might be expected to yield some difference.

2,7-Dimethylanthrasemiquinone

For this compound the electron concentrations for all the β positions were nearly equal, as indicated by the values for the β positions and the methyl protons, while two distinct pairs were observed for the α positions. In other respects the assigned splitting constants are very close to what might be expected from the results for 2,6-dimethylanthrasemiquinone.

1-Methylanthrasemiquinone

The high degree of reproducibility of the experimental spectrum obtained by calculating back from the assigned values of the splitting constants attests to the uniqueness of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

solution and the interesting conclusions which follow. With high resolution the spectrum has yielded splitting constants that are due to all 10 protons, as shown in Table I. 1-CD_3-Anthrasemiquinone has the smallest detectable splitting constant of 0.17 Oe. This corresponds very closely to the ratio of 1:6.48 for the two large splitting constants at 0.98 Oe for the CH_3 derivative. Therefore, the two splittings of 0.98 Oe must be due to two of the protons on the methyl group. The smallest splitting constant of the 1-CH_3 derivative, 0.21 gauss, is assigned to the third proton of the methyl group, which must therefore occupy a position close to the plane of the ring (5). The rest of the values correspond to expected values for the β protons and the α protons. Under low resolution, i.e. a large modulation, nine protons produce an unevenly spaced spectrum of 12 lines which could arise from two protons with splittings of 0.98 Oe and seven protons with unequal splittings of about 0.60 Oe.

1,4-Anthrasemiquinone

The results for this compound substantiate the assignments made for 1-methylanthrasemiquinone. However, the minimum splitting constant assigned to the two protons of 0.05 gauss indicates that one proton of each methyl group must be still closer to the plane of the ring where the π electron density is nearly zero. The values for the other splitting constants are close to those of 1-methylanthrasemiquinone.

1,2-Dimethylanthrasemiquinone and 1,3-Dimethylanthrasemiquinone

The spectra of these compounds are complex and the precision of measured splitting constants is not high except for the smallest values of 0.20 and 0.22 Oe, each due to a single proton, which helps to confirm the assignment for 1-methylanthrasemiquinone. The differences in the minimum splitting constants are too small to really signify support for the crowding thesis enunciated in ref. 1 and supported by the polarographic data. The data do support the idea that, in 1,2-dimethylanthrasemiquinone, one proton is held closer to the plane of the ring than in the others, but the measured difference is too small to prove the point.

DISCUSSION

The results show clearly that in all compounds the protons on methyl groups in the β position in anthrasemiquinones show normal hyperconjugation behavior with equal splitting constants at least as large as for protons directly attached to the β positions. When a methyl group is in the α position, the splitting constants attributed to the methyl protons are always distributed as two large coupling constants and one small one. These results are best interpreted as occurring because the methyl groups do not rotate, with two protons being symmetrically distributed about the oxygen atom and well out of the ring plane and the third held near or in the plane of the ring.

The equality (near-equality for 1,4-dimethylanthrasemiquinone) of the two large splitting constants indicates that two protons are symmetrically disposed about the oxygen atom and out of the ring plane. If trigonal symmetry of the methyl protons is assumed, this requires the third proton to have an equilibrium position in the ring plane. The small value of the splitting constant assigned to this in-plane proton then becomes a measure of the amplitude of oscillation of the methyl group. This follows if we use the simplified form [1] of the original equation of Heller and McConnell (13) and shown by Stone and Maki (14) to be valid for small oscillations. In this equation, a_H is the splitting

$$a_H = B_2 \cos^2\theta \qquad [1]$$

For personal use only.

constant due to a single proton, θ is the angle between the π orbital of the ring carbon and the CH bond both projected on a plane perpendicular to the CH_3—Ar bond, and B_2 is a constant differing for each compound but proportional to the unpaired electron concentration at the α position. Not unexpectedly, the methyl groups in 1,4-dimethylanthrasemiquinone are held in a much more rigid position than the compounds with only one methyl group in an α position. This pronounced difference was apparent in the polarographic reduction potentials of the quinones where the measured reduction potentials for 1-methyl-, 1,2-dimethyl-, 1,3-dimethyl-, and 1,4-dimethyl-anthrasemiquinone were respectively 0.48, 0.51, 0.50, and 0.53 V vs. S.C.E. compared with a value of 0.43 V vs. S.C.E. for anthraquinone.

Nuclear Magnetic Resonance

The methyl proton shifts of anthraquinones dissolved in chloroform were measured relative to tetramethylsilane. As expected, the methyl protons in the α position were shifted downfield (168 c.p.s.) compared to the shift of 150 c.p.s. for the β methyl protons. This larger shift on the 1-CH_3 is undoubtedly due to the anisotropy of the adjacent carbonyl (15). No evidence for hindered rotation in the form of resolved peaks or even increased line widths could be detected.

Infrared Spectra

In contrast to the n.m.r. results, evidence for some inhibition of rotation can be deduced from the infrared spectra of 1-methylanthraquinone compared with 2-methylanthraquinone. Examination of the symmetrical methyl bending vibration at 1 380 cm^{-1} in CS_2 solutions showed that, while the positions of the two vibrations were the same for both compounds, in 1-methylanthraquinone the shape was distinctly different and is shown in Fig. 4. The band is broader and flatter in 2-methylanthraquinone, suggesting free rotation about the carbon–carbon bond, whereas the band is very narrow, although intense, for 1-methylanthraquinone, suggesting inhibition of rotation (16). The band for 1,4-dimethylanthraquinone is also narrow compared to that of 2-methylanthraquinone.

An explanation is required for the failure to detect restricted rotation by means of n.m.r. in the 1-methylanthraquinone, whereas there can be little doubt of its existence in the corresponding semiquinones as detected in the e.s.r. spectra. As previously suggested (1–3) the quinones may not be quite planar. If the carbonyl oxygens are not in the plane of the rings, the restricted rotation could be expected to be reduced in amount compared with that of the semiquinones, which, because of resonance and other considerations, must be planar. Possibly more important, and supported better by the X-ray data (2), is the fact that in anthraquinone and presumably in the other anthraquinones the C_9—C_{11} bond length is 1.478 Å or nearly that of a normal aliphatic C—C bond. In the completely planar and aromatic semiquinones the C_9—C_{11} bond length should approach that of the other aromatic C—C bonds, viz. 1.38 Å. This would be enough change to produce complete inhibition of rotation in the semiquinone but permit some rotation in the quinone.

Since n.m.r. relaxation times are much longer than those of e.s.r. or light spectroscopy, it is possible that the restriction of rotation observed in the infrared spectroscopy could be real but too small to detect by the longer time constants of n.m.r. spectroscopy. It would appear, therefore, that a small degree of restriction of rotation may occur in the quinone forms of 1-methyl derivatives and that this inhibition becomes complete in the corresponding semiquinones.

Finally, this decrease in entropy associated with the α methyl groups during reduction of the α-substituted quinones is consistent with the greater resistance of these quinones to reduction compared to the β-substituted quinones (1).

ACKNOWLEDGMENTS

Two of us, R. M. E. and B. E. G., acknowledge our great debt to Professor R. B. Sandin as an inspired teacher of chemistry and a true friend and confidant. All of us have worked with him and have been helped and inspired by his intuition. This paper, as previously noted, is a direct outgrowth of the work of R. J. Crawford, while he was a student under Professor Sandin. Thanks are extended to Mrs. F. F. Gadallah for preparation of the 1- and 2-CD_3-anthraquinones, and to Dr. Crawford of the University of Alberta for providing the remaining quinones and for many helpful discussions.

ABSTRACT

The measurement of apparent plate heights resulting from various values of the total sample volume has been carried out for C_5 to C_8 *n*-alkanes on Apiezon L under both isothermal and p.t.g.c. conditions. Plug injection of samples was achieved through the use of a syringe plunger driven at constant speed by a motor. The time for injection of gas samples ranged from 1 to 300 s. All of the results, both isothermal and p.t.g.c., could be correlated to the same plot of H_{app}/H_o against $\sqrt{n}\Delta V_s/V_{T_0}$ where H_{app} is the observed plate height, H_o the limiting plate height at low sample volumes, n the true plate number, ΔV_s the sample volume, and V_{T_0} the isothermal retention volume at the initial temperature. The experimental values lie somewhat above the theoretical curve calculated by van Deemter *et al.* It is confirmed that sample volumes less than $V_{T_0}/2\sqrt{n}$ give negligible excess peak broadening. Applying these concepts to trace analysis, very large samples may be used in p.t.g.c. under such initial temperature conditions that the major component is only weakly retained, while traces of heavier components are concentrated into narrow bands and eluted as sharp peaks with the increased sensitivity provided by the large sample. As an example, chromatograms are presented for the p.t.g.c. analysis of natural gas on deactivated alumina, using sample volumes ranging from 2 to 500 ml.

INTRODUCTION

Early in the development of gas chromatography it was recognized by Glueckauf (1), van Deemter, Zuiderweg, and Klinkenberg (2), and by Porter, Deal, and Stross (3) that the volume occupied by the sample as injected into the gas stream at the column inlet should be maintained below a stipulated value in order to avoid any broadening in the outlet peaks beyond that produced by the chromatographic processes within the column. It has been suggested that the maximum sample size should be kept below a band width of one-quarter of the outlet band (1), or alternatively (2), that the sample volume should be less than $V/2\sqrt{n}$ where V is the retention volume for a component and n is the number of theoretical plates. In programmed temperature gas chromatography, p.t.g.c., Giddings (4) has pointed out that since most components are strongly retained at the initial temperature of the program, relatively large sample volumes in the inlet gas stream are equivalent to only narrow zones in the column. This initial-zone condensation has the effect of reducing the effective sample volume in the gas stream entering the column by the ratio V_{T_r}/V_{T_0} where V_{T_r} and V_{T_0} are the isothermal retention volumes (including column dead space) at the retention temperature and at the initial temperature, respectively. The degree of condensation depends upon the retention of an individual component; since the ratio V_{T_r}/V_{T_0} might easily have a value of 0.01 or less the use of p.t.g.c. would

[1]*RCA contribution No. 287.*
[2]*Permanent address: Southern Alberta Institute of Technology, Calgary, Alberta. Visiting Research Associate, Research Council of Alberta, summer 1964.*

permit sample volumes at least 100 times larger than those used for isothermal gas chromatography without loss of resolution.

The above reasoning assumes that the total amount of the sample components is kept below that which would overload the column. Application to trace analysis where particularly small amounts of material are dispersed through large volumes of sample would be an obvious development. The technique would be suited but not limited to trace components more strongly retained than the bulk of the sample material such as heavy impurities in air or higher hydrocarbons in natural gas. In such a case conditions may be chosen so that the bulk of the sample is only weakly retained and large samples can be used which, although yielding broadened major peaks, produce for the higher boiling trace components sharp narrow peaks. Thus maximum sensitivity and resolution are achieved. It is true that modern detectors have permitted great increases in the sensitivity of detection, but further increases in the detection limits through the use of larger samples are desirable.

The present work was initiated in order to determine the extent of initial-zone condensation in p.t.g.c., and to demonstrate the application to trace analysis of p.t.g.c. with large sample volumes. In addition, measurements have been obtained of the actual increase in isothermal and p.t.g.c. band widths as the result of excessively large samples; these are compared with measurements of van Deemter *et al.*, with a more recent report by Guiochon (5), and with various theoretical predictions.

THEORETICAL

Giddings (4) and Guiochon (5) have treated the sample volume in terms of a Gaussian distribution of the sample in the gas stream. The standard deviation of the sample distribution in the gas stream is converted to an equivalent standard deviation of the sample band on the column. In practice it may be convenient to use the base width of the entering sample peak which is equal to four standard deviations. The additional spreading due to chromatographic processes is then assumed to combine with this initial distribution by addition of variances. Consequently the total variance, σ^2, of the band when it reaches the end of the column is given by

$$\sigma^2 = \sigma_s^2 + \sigma_c^2, \qquad [1]$$

where σ_s^2 is the variance of the initial sample distribution and σ_c^2 that of the normal chromatographic processes in the column. The standard deviation of the band on the column must be converted to a peak standard deviation in the gas stream leaving the column, which may then be conveniently expressed in terms of an apparent plate height. If the sample volume is characterized by the base width of the sample distribution, designated as ΔV_s, then for isothermal chromatography the conclusions of Giddings and of Guiochon may be expressed in the form

$$H_{app} = \frac{L}{16}\left(\frac{W}{V}\right)^2 = \frac{L}{16}\left(\frac{W_c}{V}\right)^2 + \frac{L}{16}\left(\frac{\Delta V_s}{V}\right)^2 = H_c + \frac{L}{16}\left(\frac{\Delta V_s}{V}\right)^2, \qquad [2]$$

where H_{app} is the observed plate height calculated from the observed band width W, W_c is the limiting band width for small samples, and the second term is the contribution to H due to finite sample volume. For p.t.g.c. the effective sample volume becomes $\Delta V_s V_{Tr}/V_{T_0}$ (4) and the plate height relationship (6) takes the form

$$H_{app} = \frac{L}{16}\left(\frac{W}{V_{T_r}}\right)^2 = \frac{L}{16}\left(\frac{W_c}{V_{T_r}}\right)^2 + \frac{L}{16}\left(\frac{\Delta V_s}{V_{T_0}}\right)^2 = H_c + \frac{L}{16}\left(\frac{\Delta V_s}{V_{T_0}}\right)^2. \qquad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

According to this treatment the contribution to H due to finite sample volume is a different and constant value similar to an A term for each component and is added to the various chromatographic contributions.

We frequently are more interested in the relative increase in plate height, which may be expressed in the following forms:

$$[4] \qquad \frac{H_{app}}{H_c} = 1 + \left(\frac{\Delta V_s}{W_c}\frac{V_{Tr}}{V_{T_0}}\right)^2 = 1 + \left(\frac{\Delta V_s}{V_{T_0}}\right)^2 \frac{n}{16},$$

where n is the true plate number corresponding to W_c and V_{Tr} as obtained from small samples. This equation is expressed in general form; for isothermal chromatography V_{T_0} is identical with V_{Tr}.

An alternative treatment of large sample volumes has been presented in slightly different forms by Glueckauf (1, 7) and by van Deemter, Zuiderweg, and Klinkenberg (2). Their treatments are exact and detailed but are not readily amenable to simple theoretical development. They are developed for plug samples, i.e. injection in which the sample concentration is maintained constant over the total duration of the injection as opposed to the Gaussian distribution in concentration mentioned above (4, 5).

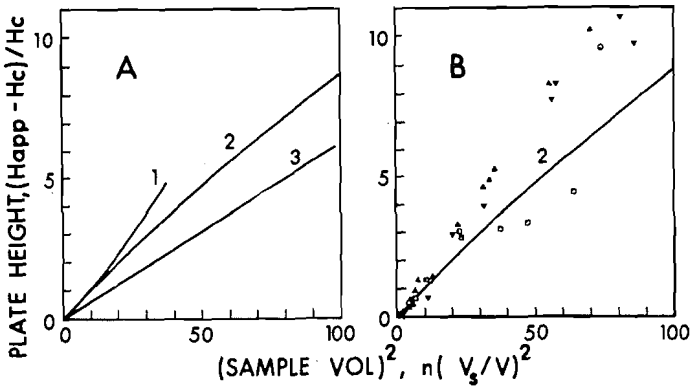

FIG. 1. Relative increase in plate height vs. square of the relative sample volume. A. Theoretical curves. 1. From Glueckauf (1, 7). Plug injection, H_{app} from width at h/e. 2. Derived from van Deemter, Zuiderweg, and Klinkenberg (2). Plug injection, H_{app} from base line intercept. 3. Gaussian injection, ΔV_s = base line intercept of injection. Compare Giddings (4) and Guiochon (5). B. Experimental points for 150 °C for pentane ○, hexane □, heptane ▽, and octane △ compared with curve 2.

The three treatments are compared in Fig. 1A as plots of the relative increase in apparent plate height against the square of the relative sample volume. The differences are largely, and perhaps almost entirely, due to the non-equivalence of the manners in which the plug and Gaussian peaks are described. The sample volume for a Gaussian sample distribution is taken as the base width, and for the plug profiles as the total plug volume. The peak shape of the outlet bands will be Gaussian in all cases for the Gaussian input, and will generally be intermediate between Gaussian and plug for the plug input. The van Deemter treatment is based on an apparent plate height calculated from the base line intercept of the tangents to the outlet peak, while the Glueckauf values are based on peak widths at h/e of the maximum peak height. Although these two widths (in their correct respective expressions) give the same apparent plate height for a Gaussian peak, the h/e width will give a relatively higher value for the flat-topped peaks observed with large plug samples. Thus the Glueckauf curve would be expected to lie above that of van Deemter and both would be expected to lie above that for Gaussian pulses.

EXPERIMENTAL

Systematic measurements of band width for various plug sample injections were made using a 4.3 m by 4 mm inside diameter glass column shaped into a 10 cm coil and packed with 20% Apiezon L on 45 to 60 mesh Chromosorb P. The total weight of stationary phase in the column was 5.6 g and the dead space volume was 41.7 ml. The column was heated in a bath of Dow Corning 550 Silicone oil contained in a 6 in. Dewar flask. A Gow-Mac thermal conductivity cell of pretzel geometry, for which the time constant is given as 1.5 s, was used as detector in conjunction with a Brown recorder of time constant 1 s.

Samples were injected by syringe through a Silicone rubber puncture seal immediately ahead of the column packing. A leak-tight 500 μl Hamilton 1 750 syringe with a Teflon-tipped plunger was used to inject gaseous samples. A special mechanical drive similar to that used by Reilley (8) was constructed to depress the syringe plunger at a controlled uniform rate. This apparatus consisted of a threaded shaft passing through a fixed nut, fitted with a pulley at one end and at the other with a Teflon tip pressing against the syringe plunger. The drive shaft through its fixed nut, a guide sleeve, and the syringe were clamped onto a small frame which could be raised or lowered to take and to inject samples. By using various pulley-belt combinations and a variable speed motor controlled by a GT-21 thyratron rectifier unit (G. K. Heller Co., Las Vegas, Nevada) a range of injection times from approximately one second to several hundred seconds could be obtained. A microswitch pressed by the descending pulley stopped the drive at the end of the injection and prevented damage to the syringe. The drive shaft could be retracted by a motor-reversing switch.

Gas samples included the normal alkanes pentane to octane. Samples were withdrawn from the vapor space above a mixture of the liquid hydrocarbons contained in a 100 ml conical flask closed with a puncture seal. A suitable mixture giving approximately equal amounts of the four components in air was made by injecting into the flask as liquids 5 ml *n*-octane, 1 ml *n*-heptane, 0.05 ml *n*-hexane, and 0.01 ml *n*-pentane. It was necessary to add more pentane when its peak became small. In a 0.5 ml sample convenient concentrations of all components were obtained if the sample flask was heated to about 40°. The syringe with its attached drive was then inserted through the puncture seal into the column. A heat lamp was used to keep the syringe warm during the injection. The column inlet pressure was as much as an atmosphere above atmospheric; this caused helium to flow back into the syringe and a waiting period of 2 min was allowed for the syringe contents to become uniform. The motor was switched on to start the injection and the time measured until the microswitch terminated the injection. By this procedure the earlier peaks from long injection periods were square and symmetrical, indicating uniform plug injection although without the 2 min waiting period the leading edge was distinctly rounded. The total sample appeared to be sufficiently small in all cases so that there was no column overloading.

Peak widths were measured as the base line intercepts of the tangents to the inflection points. Retention volumes were calculated from the midpoint of the injection period to the midpoint of the peak (half-way between the base line intercepts). Retention volumes were expressed at column temperature and mean column pressure; sample volumes at column temperature and inlet pressure. In calculation of the sample volumes, the 0.5 ml volume of the syringe was added to the volume corresponding to the injection time. All measurements were made with a flow rate, at atmospheric pressure and room temperature, of 55 ml per min. This was established in preliminary measurements as being distinctly above the minimum in the plate height – eluent gas velocity curve. For programmed temperature operation the oil bath was heated at $5.0 \pm 0.1°$ per min.

A series of trace analysis experiments was carried out with natural gas samples on a column of deactivated alumina in order to demonstrate the suitability of temperature programming for trace analysis. The column used was 22 g of 80 to 100 mesh alumina deactivated by treatment with 10% lithium chloride solution and packed into a 5 ft by $\frac{1}{4}$ in. copper tube. The copper tubing was wound tightly around an aluminium cylinder containing a cartridge heater and the whole assembly inserted into a Dewar vessel. With this apparatus the column could be cooled to −60° with dry ice and heated to 300° in an approximately linear program by small adjustments to the heater voltage. Gas flow rates and heating rates similar to those used with the gas–liquid column were used here.

For the trace analysis experiments a bypass sample injection system was employed with four different sample volumes ranging from 2.2 to 500 ml. The smaller ones were simply glass U tubes while the larger ones were constructed from round-bottomed flasks. Thus the smaller volumes approached plug injection while the larger ones were close to an exponential decay input pulse (3). The sample in all cases was natural gas from the laboratory supply taken at a pressure only slightly above atmospheric. Since the column inlet pressure was definitely above this, considerable disturbance in the flow occurred when the larger samples were switched in, but the effects of this had disappeared by the time the peaks of main interest emerged. Sample injection was at −60° and the heating was started after the major component, methane, was nearly all eluted. Variability in the minor components of the Edmonton gas supply meant that the samples used were not identical.

RESULTS AND DISCUSSION

Isothermal chromatograms of mixtures of the four hydrocarbons were obtained for a range of sample injection times at temperatures of 30°, 60°, 100°, 150°, and 210°. For

long injection times and wide sample bands mixtures of pentane–heptane and hexane–octane were run successively. Apparent plate heights were calculated from the observed band widths and retention volumes and the best limiting values were estimated by inspection. These are summarized in Table I, and the plate heights show relatively little variation except for the high values observed at 30°. It is assumed that these are due to high mass transfer resistances in the liquid phase resulting from the low liquid diffusivities at this temperature.

TABLE I

*In milliliters at column temperature as measured from injection and corrected for pressure drop (including dead space volume of 41.7 ml).

The relative excess plate height is plotted in Fig. 1B against the square of the relative reduced sample volume as suggested by eq. [4]. The points shown were obtained at 150 °C and the data for other temperatures were in agreement. The experimental conditions correspond to those employed by van Deemter *et al.*; the theoretical line derived from their calculations is included in the figure. Although it is difficult to conclude whether the excess plate height is linear in the square of the sample volume, as would be expected by the simple treatment of the eq. [2], the experimental values lie distinctly above the theoretical curve. Van Deemter, Zuiderweg, and Klinkenberg reported measurements which fell closely on the calculated curve but did not describe their injection procedure nor their method of pressure-drop corrections in sufficient detail to permit a comparison with the methods used here. The present measurements indicate either apparent plate heights higher or relative sample volumes lower than would be expected from the theoretical curve.

Guiochon has reported a few measurements for peak broadening with samples injected by syringe (5). Although his values showed a wide scatter, he concluded that the injection time corresponded to six standard deviations in the sample distribution which would place his results on a curve much lower than ours. In fact they would lie well below curve 3 in Fig. 1A which is calculated for an injection time equal to four standard deviations. Bohemen and Purnell (9) and Purnell and Sawyer (10) have also reported measurements of band broadening with syringe injection of liquid samples. Their apparatus was constructed with one side of the thermal conductivity detector between the injection point and the column so that they were able to obtain a direct measurement of the sample pulse as injected. They did not describe the peak shapes they were working with but found that significant broadening occurred when the width of the sample pulse was more than one-quarter of the width of the eluted peak.

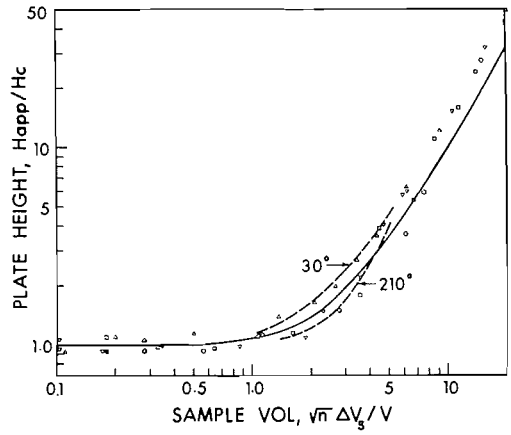

FIG. 2. Relative plate height at various relative sample volumes. Experimental points for 100°, symbols as in Fig. 1B. Best fit lines for measurements at 30° and 210° are also shown. Solid line is theoretical curve derived from van Deemter, Zuiderweg, and Klinkenberg (2).

A somewhat more satisfactory way of presenting the data over wide ranges of sample volume, and at the same time of showing the detailed behavior at the lower values, is by the log–log plot of Fig. 2. Here the relative plate height is plotted against the relative sample volume. The experimental points are given for the isothermal measurements at 100°; measurements at other temperatures showed slight deviations at lower values and the lines for the two extreme temperatures are indicated. Finally the theoretical curve derived from van Deemter, Zuiderweg, and Klinkenberg (2) is also included; the deviations appear to remain in constant proportion at high sample volumes. Glueckauf (1) suggested that the sample band width, considered as a plug, should be less than one-quarter the outlet band width as measured at a height h/e, i.e. $1/4\sqrt{2}$ times the outlet band width as measured by the base line intercept and this limit corresponds to an abscissa value in Fig. 2 of $1/\sqrt{2}$ or 0.7. The more commonly quoted criterion of van Deemter *et al.* that the sample volume should be less than $V/2\sqrt{n}$ corresponds to a feed plug one-eighth of the base width of the emergent band and to an abscissa value of 0.5. Here the increase in apparent plate height is only around 2%. If the sample volume were doubled beyond this point the effect would increase to approximately 10%. To cause a doubling of the apparent plate height the sample volume must be as much as $3V/\sqrt{n}$ or six times the van Deemter limit.

Programmed temperature chromatograms were obtained for the same sample and injection conditions with three different initial temperatures, 30°, 60°, and 100°. Representative chromatograms corresponding to relatively large sample volumes are shown in Fig. 3 for the three starting temperatures. The relative plate heights were plotted against the relative sample volumes as shown in Fig. 4. The points for the 60° initial temperature coincide closely with the line for the isothermal data at 60°. Since 60° was the starting temperature, the isothermal retention volumes at 60° must be used in calculating the relative sample volumes. The value of n, the plate number, is, of course, calculated from the limiting small sample values determined under the program conditions and is an average (11, 12) of the isothermal values over the temperature range of the program. Except for the high isothermal plate heights at 30° the variation of plate height for these conditions was small; even the 30° value contributed very little to the averages so that the variations with temperature in $\sqrt{n}$ were insignificant.

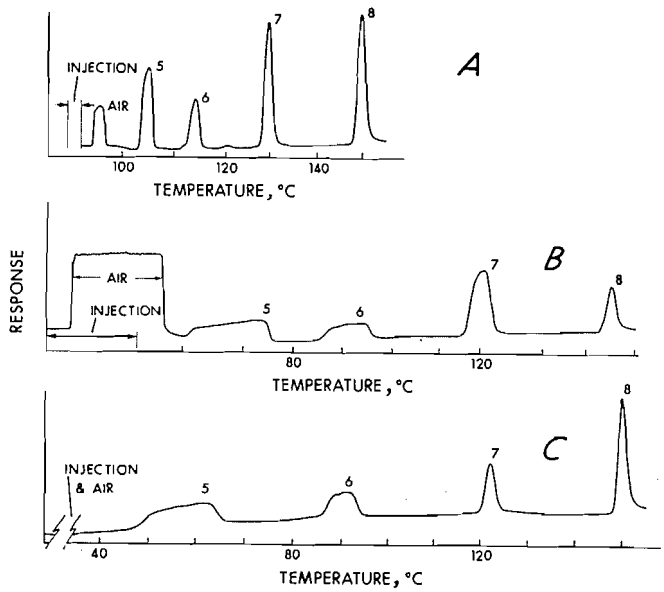

FIG. 3. Programmed temperature gas chromatography chromatograms for pentane, hexane, heptane, and octane. A. Initial temperature 30°, sample injection volume 160 ml. B. Initial temperature 60°, sample injection volume 119 ml. C. Initial temperature 100°, sample injection volume 17 ml.

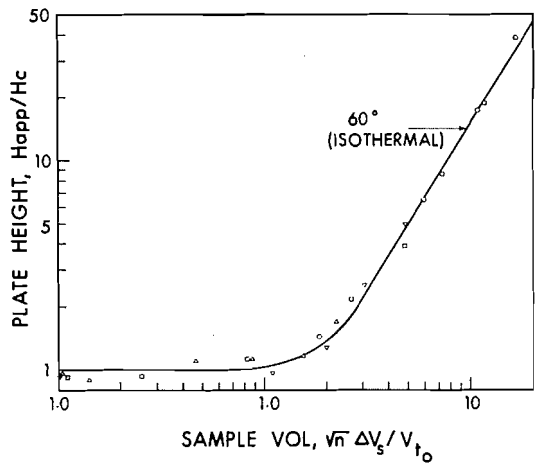

FIG. 4. Relative plate height as a function of relative sample volume for p.t.g.c., starting from an initial temperature of 60°. Symbols as in Fig. 1B, solid line from isothermal measurements at 60°.

The important conclusion from these measurements is that, *apart from differences in* $\sqrt{n}$ *between isothermal and programmed conditions*, the apparent plate height for large samples is the same for p.t.g.c. and for isothermal elution at the initial temperature. The advantage of p.t.g.c. is that it provides elution of all components under optimum or nearly optimum conditions, whereas isothermal elution would lead to such broad bands for the most strongly retained peaks that quantitative measurement or, sometimes, even detection would be impossible. Furthermore, as may be seen by a comparison of the three chromatograms in Fig. 3, larger samples may be accommodated without loss of resolution by simply lowering the initial temperature.

Many problems in trace analysis involve the determination of small amounts of relatively high-boiling impurities in a low-boiling material. The determination of most air pollutants is an example of this situation; another is the analysis of the heavy ends present in natural gas. Frequently these more condensable trace materials are trapped out of a large volume of the parent substance, e.g. air or natural gas, using either direct condensation or adsorption on cooled charcoal or other adsorbent. For example, Mackay, Lang, and Berdick (13) used a low temperature chromatographic precolumn. The concentrated impurities are then transferred to a chromatograph for analysis. The present results indicate that a more satisfactory alternative would be to inject the large volume of material to be analyzed directly onto the chromatographic column at a temperature sufficiently low to condense the trace impurities into narrow bands. Programmed temperature gas chromatography elution, while giving a broad main band, will yield sharp, easily measurable peaks for the trace components.

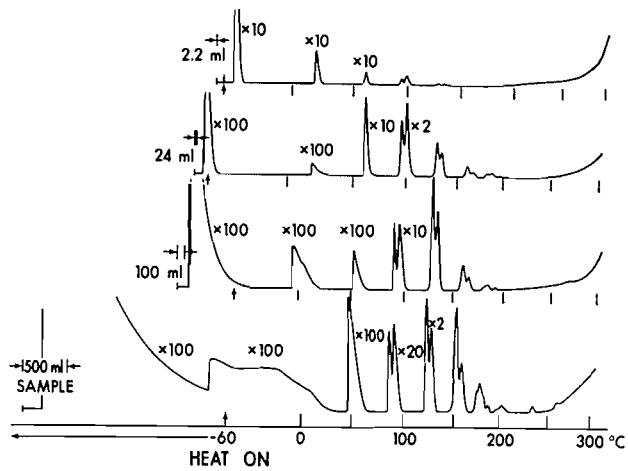

Fig. 5. Programmed temperature gas chromatography chromatograms of natural gas on a column of deactivated alumina using various sample volumes. Initial temperature −60°; heating was started at the time indicated by the arrow.

As an example of this application of p.t.g.c. to trace analysis, a number of experiments were carried out with natural gas from the city supply using a deactivated alumina column as described in the experimental section. Chromatograms obtained with sample volumes ranging from 2 to 500 ml are shown in Fig. 5. The choice of a solid adsorbent permitted lowering the initial temperature to −60°. Under these conditions methane was still only weakly retained, but the hydrocarbons, from butane up, were retained so strongly that even with the 500 ml sample there was no peak broadening. We did not extend this procedure to even higher sample volumes nor use it with a more sensitive detector; both of which would permit a much more comprehensive analysis of the trace components.

A number of advantages may be expected from the use of this technique as compared with the separate trapping out of the trace components. There is a gain in simplicity by the elimination of a separate trapping step. There is no uncertainty about the completeness of trapping, or worry about losses of material in the form of noncondensable fog. Frequently there is interest in compounds of intermediate volatiliy, which may be only partially collected in a conventional trap. In the p.t.g.c. technique, these compounds may give partially broadened bands which still provide useful information. For example, in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Fig. 5 the second peak (ethane) is measurable even though it exhibits pronounced broadening. Furthermore there is a suggestion of a small peak at the trailing edge which indicates the presence of an additional impurity of similar volatility.

These advantages derive from the greater flexibility inherent in programmed temperature as compared with isothermal operation. It is characteristic of p.t.g.c. that each component tends to be eluted under optimum conditions for detection and measurement and these may be further selected by choice of heating and flow rates. This paper has attempted to demonstrate that optimum sample injection conditions may be achieved by proper choice of initial temperature. In other words the operator has independent control of the injection conditions and of the retention characteristics.

ACKNOWLEDGMENTS

We wish to thank G. J. du Cloux for experimental assistance. M. P. Lee participated in preliminary work on trace analysis as did also a group of students under Mr. K. Glen from Victoria Composite High School.

ABSTRACT

The semiempirical SCF–LCAO–MO method of Pariser–Parr–Pople is utilized in the study of the π-electronic structures of thiophene, furan, and pyrrole. The core Hamiltonian expansion contains a U_Z^{++} term, the potential due to the ionized hetero-atom contributing two electrons to the π-system. The γ_{ZZ}, one-center coulomb repulsion integral for the hetero-atom is evaluated from the experimental spectroscopic data only. With the resonance integral β_{CZ}^{c} as the only variable parameter, the calculated π^*–π electronic transitions are in a satisfactory agreement with the experimental data.

INTRODUCTION

The semiempirical MO method of Pariser and Parr (1) has been used in a number of studies of π-electronic structures of the six-membered nitrogen-heterocyclic rings (1, 2) and the hetero-molecules containing carbonyl (3) and thiocarbonyl groups (4), with rather encouraging results. The same holds true for the five-membered heterocyclic rings: furan (5), thiophene (5, 7), and pyrrole (6), where each work has its own modifications to the method.

To further the study of π-electronic structures of the five-membered heterocyclic rings, the present work extends the semiempirical SCF–LCAO–MO method of Pariser–Parr and Pople (1, 8) to thiophene, furan, and pyrrole with several modifications for the treatment of the hetero-atoms. With the thought of making the method more general for such systems and to avoid any separate adjustments for each molecule, this work utilizes only one variable parameter β_{CZ}^{c}, fitted to give the best agreement with the experimental electronic spectra.

The main idea in any SCF calculation (9) is to obtain the best set of SCF–LCAO–π–MO functions from which the properties associated with π-electrons (the π^*–π transitions, the dipole moments, the reaction sites, etc.) can be calculated. The parameters necessary for the SCF calculations, α_i^{c}, β_{ij}^{c}, γ_{ii}, and γ_{ij}, defined by the expressions [1], [2], [3], and [4], are evaluated by recourse to the experimental data (10).

$$[1] \qquad \alpha_i^{c}(1) = \int \chi_i(1) H^{c}(1) \chi_i(1)\, d\nu(1),$$

$$[2] \qquad \beta_{ij}^{c}(1) = \int \chi_i(1) H^{c}(1) \chi_j(1)\, d\nu(1),$$

$$[3] \qquad \gamma_{ii} = \int \chi_i(1)\chi_i(1) 1/r_{12} \chi_i(2)\chi_i(2)\, d\nu(1)\, d\nu(2),$$

$$[4] \qquad \gamma_{ij} = \int \chi_i(1)\chi_i(1) 1/r_{12} \chi_j(2)\chi_j(2)\, d\nu(1)\, d\nu(2),$$

[1]*Part of this work is abstracted from the dissertation submitted by N. S. to the graduate school of Duquesne University in partial fulfillment of the requirement for the Ph.D. degree.*

where H^c stands for the core Hamiltonian (1). The exchange repulsion integrals vanish due to the zero differential overlap approximation. It is assumed that the orbital functions, χ_i, are real.

EVALUATION OF PARAMETERS

The five-membered rings are numbered in the usual manner (22), starting with the hetero-atom Z (Z = S, O, N) as number one. The values of the empirical parameter $\beta_{CZ}{}^c$ are given in Table I. The parameters $\beta_{CC}{}^c$ and the $\gamma_{C_iC_j}$, listed in Tables I and III respectively, are evaluated semiempirically from experimental spectroscopic data (10) following the method of Pariser and Parr (1).

TABLE I

Values of $\beta_{CZ}{}^c$ and $\beta_{CC}{}^c$, for interatomic distances in angstroms (11)

Center	$\beta_{CS}{}^c$ (eV) (thiophene)	$\beta_{CO}{}^c$ (eV) (furan)	$\beta_{CN}{}^c$ (eV) (pyrrole)
1–2, 1–5	−0.900	−1.800	−1.700
2–3, 4–5	−2.665	−2.903	−2.759
3–4	−2.006	−2.006	−1.905

The evaluation of γ_{CZ}, using the uniformly charged sphere approximation (1), requires γ_{ZZ}, the one-center coulomb repulsion integral. For the evaluation of this integral the following considerations are made. Because of the small C—Z—C angle (11), the orbitals on the O and S atoms in furan and thiophene, respectively, are assumed to be non-hybridized. The s orbital contains a lone pair of electrons which is not considered explicitly in this work but rather it is assumed to be included with the other σ and inner electrons in the core parameters.

The p_x and the p_y atomic orbitals (AO's) on the O and S atoms form σ bonds with the C atoms, and the p_z AO, perpendicular to the plane of the ring, contributes two electrons to the π-system.

In the case of pyrrole, the N atom is assumed to be in its sp^2 hybridization state and each sp^2 orbital forms a σ bond with the H and the C atoms, leaving the p_z AO fully occupied and participating in the π-bond formation.

In order to evaluate the integral γ_{ZZ}, it is postulated that on each Z center there exist two singly occupied χ^+ AO's which form an "ion-neutral atom pair".

$$[5] \qquad \underset{(-2W_2)}{2\chi^+(s^2xyz)} \xrightarrow{\Delta E} \underset{(0)}{\chi^{+2}(s^2xy)} + \chi(s^2xyz^2), \qquad (-2W_2 + \gamma_{ZZ} = -W_2 - W_1)$$

where W_2 and W_1 are the second and first ionization potentials, respectively, and $\gamma_{ZZ} = \Delta E = W_2 - W_1$ can be evaluated from the experimental values of W_2 and W_1. Table II gives the spectroscopic data necessary for the evaluation of γ_{ZZ}.

The integrals γ_{CZ} are defined by the expressions* [6], [7], [8], and [9]. Their numerical values are given in Table III.

$$[6] \qquad \gamma_{C_iC_j}\ (\text{eV}) = 11.08 + 0.2668r^2 - 2.9663r,$$

$$[7] \qquad \gamma_{CS}\ (\text{eV}) = 11.49 + 0.3057r^2 - 3.2181r,$$

$$[8] \qquad \gamma_{CO}\ (\text{eV}) = 15.165 + 0.6483r^2 - 5.4727r,$$

**Obtained by the uniformly charged sphere approximation (1) with an effective charge according to Slater (12).*

*Handbook of Chemistry and Physics, The Chemical Rubber Publishing Co., Cleveland, Ohio, 1961. p. 2586.

TABLE III

Values of $\gamma_{C_iC_j}$ in electron volts, for interatomic distances in angstroms (11)

Center	$\gamma_{C_iC_j}$ Thiophene	Furan	Pyrrole
1–2, 1–5	6.857	8.876	8.458
1–3, 1–4	5.248	6.166	6.065
2–3, 4–5	7.518	7.550	7.530
2–4, 3–5	5.651	5.795	5.751
2–5	5.382	5.851	5.754
3–4	7.398	7.406	7.388

[9] $$\gamma_{CN}\ (\text{eV}) = 14.11 + 0.5495r^2 - 4.8272r.$$

The integrals α_i^c, defined by eq. [1], are evaluated by expanding H^c according to Goeppert-Mayer and Sklar (13) with an additional hetero-atom term U_Z^{++}, i.e.,

[10] $$H^c(i) = -\tfrac{1}{2}\nabla^2(i) + U_Z^{++}(i) + \sum_{k=2}^{5} U_k^+(i),$$

where U_k^+ is the potential due to an ionized C atom in its sp^2 valence state, and is defined by

[11] $$U_k^+(i) = U_k^0(i) - \int \chi_k^2(j) 1/r_{12}\, dv(j),$$

U_k^0 being the potential due to a neutral C atom in its sp^2 valence state. The U_Z^{++} is the potential due to a doubly ionized hetero-atom, which has contributed two electrons from its p_Z AO; it is defined by

[12] $$U_Z^{++}(i) = U_Z^+(i) - \int [\chi_Z^+(j)]^2 1/r_{12}\, dv(j) - \int \chi_Z^2(j) 1/r_{12}\, dv(j),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where χ_Z^+ is a singly occupied hetero-atom AO, and U_Z^+ and U_Z^0 are the potentials due to a singly ionized and a neutral hetero-atom, respectively.

The α_2^c integral (for the C_2 atom) can be written as

$$[13]\quad \alpha_2^c(1) = \int \chi_2(1) H^c(1) \chi_2(1)\, dv(1)$$
$$= W_{1C_2} + \int U_1^0(1)\chi_2^2(1)\, dv(1) - \int \chi_2^2(1) 1/r_{12} \chi_1^2(2)\, dv(1)\, dv(2)$$
$$- \int \chi_2^2(1) 1/r_{12} [\chi_1^+(2)]^2\, dv(1)\, dv(2) + \int U_3^0(1)\chi_2^2(1)\, dv(1)$$
$$- \int \chi_2^2(1) 1/r_{12} \chi_3^2(2)\, dv(1)\, dv(2) + \int U_4^0(1)\chi_2^2(1)\, dv(1)$$
$$- \int \chi_2^2(1) 1/r_{12} \chi_4^2(2)\, dv(1)\, dv(2) + \int U_5^0(1)\chi_2^2(1)\, dv(1)$$
$$- \int \chi_2^2(1) 1/r_{12} \chi_5^2(2)\, dv(1)\, dv(2),$$

where W_{1C_2} is the first ionization potential of the C atom in its sp^2 valence state.

Neglecting the penetration integrals, represented by the positive terms in the expression [13], the general expression for a carbon α_i^c can be written as

$$[14]\quad \alpha_i^c = W_{1C} - \sum_{i \neq j} \gamma_{ij} - \sum_{i \neq Z^+} \gamma_{iZ^+}.$$

Similarly, α_Z^c for a hetero-atom can be written as

$$[15]\quad \alpha_Z^c(1) = \int \chi_Z^+(1) \left[-\tfrac{1}{2}\nabla^2(1) - U_Z^{++}(1) - \sum_{k=2}^{5} U_k^+(1) \right] \chi_Z^+(1)\, dv(1)$$
$$= W_{2Z} - \sum_{i \neq Z^+} \gamma_{iZ^+},$$

where W_{2Z} is the second ionization potential of a hetero-atom in its valence state.

TABLE IV

Values of γ_{CZ^+} in electron volts, for interatomic distances in angstroms (11)

Center	γ_{CS^+} (thiophene)	γ_{CO^+} (furan)	γ_{CN^+} (pyrrole)
1–2, 1–5	6.872	8.467	8.885
1–3, 1–4	5.263	6.007	6.175

The integrals γ_{iZ^+}, listed in Table IV, are evaluated from eqs. [16], [17], and [18], obtained using the uniformly charged sphere approximation (1) with effective charges determined by Slater's rules (12) for a particular doubly ionized Z^{++} hetero-atom:

$$[16]\quad \gamma_{CS^+}\ (\text{eV}) = 11.49 + 0.3057r^2 - 3.2181r,$$

$$[17]\quad \gamma_{CO^+}\ (\text{eV}) = 15.165 + 0.6463r^2 - 5.4643r,$$

$$[18]\quad \gamma_{CN^+}\ (\text{eV}) = 14.11 + 0.5488r^2 - 4.8206r.$$

The integrals α_i^c are listed in Table V.

RESULTS AND DISCUSSION

The method proposed above for the evaluation of the parameter γ_{ZZ} and the ionization potential of a hetero-atom utilizes the experimental spectroscopic data for a given molecular state of the hetero-atom, thus specifying the arrangement of the AO's on it

TABLE V

Values of α_i^c in electron volts, for interatomic distances in angstroms (11)

	α_i^c		
Center	Thiophene	Furan	Pyrrole
1	−47.150	−64.060	−58.118
2,5	−43.720	−48.497	−47.500
3,4	−42.618	−44.632	−44.351

and giving a somewhat clearer picture of how the hetero-atom could contribute two electrons to the π-system. This method avoids any further semiempirical adjustments of γ_{zz} (14) and the hetero-atom ionization potential (6).

The method differs in its approach from those previously applied to furan, pyrrole, and thiophene in the work of Pajol and Julg, Sappenfield and Kreevoy (5), and Hahl and Hansen (6). The latter two employ some aspect of the 'self-consistent electronegativity' method to obtain a single configuration function, followed by configuration interaction. Pajol and Julg have used a modified MO method in which the deformation of MO's is taken into account in the calculation of π-electron integrals. The present method is based upon obtaining self-consistency of the MO's, holding all integrals fixed within a single calculation and, between calculations, varying the β_{cz} parameters only. In this it most closely resembles the method due to Julg (5).

The ultraviolet spectra are the most widely used criteria for testing MO-type calculations performed on π-systems. In most cases the low-lying excited states are experimentally known and are assigned. In the case of the three heterocyclics considered in this work, the ultraviolet absorption spectra consists of the unassigned singlet absorption bands (see Table VI). For most of these bands the singlet absorption maxima and their intensities are known. The triplet states have not been reported, although a low-lying very weak band observed in thiophene is speculated to be due to a triplet state (15).

Most of the calculated electronic transitions given in Table VI show a good agreement with the experimentally observed absorption band maxima. The two low-lying overlapping bands in thiophene agree with Milazzo's observation (16). The third band which that author claims is due to the excitation of one electron left on the sulfur AO does not appear in our calculation; our formalism does not account for this situation. The calculated spectrum of thiophene is in better agreement with the work of Price and Walsh (17) who observed two bands from thiophene vapor. Our first two calculated transitions fall in the region of the first band, which extends from 5.16 to 5.90 eV. The third and fourth calculated transitions fall on the second observed band which extends from 6.59 to 8.85 eV.

Most of the transitions calculated agree with the calculations of Pajol and Julg (5), Dahl and Hansen (6), and Sappenfield and Kreevoy (5), although the assignments of Dahl and Hansen are different from ours, which agree with the assignments of Brown and Hefferman (6). The small discrepancies which exist between the observed and the calculated electronic transitions may not necessarily reflect the weakness of the method. It has been observed that the calculated electronic transitions are very sensitive to a relatively small change in the interatomic distances, and the use of rough and approximate dimensions may result in somewhat significant discrepancies between the calculated and the experimental results. For example, using three slightly different sets of interatomic

high, (see Table VIII), follow the usual trend observed in the Pariser–Parr–Pople-type calculations which yield an ionization potential too high by about 1.5 to 2.5 eV (18). It was shown by Hoyland and Goodman (19) that this discrepancy could be removed by applying a correction for the σ-core contraction and the π-orbital deformation in the ionized state. This shows that in order to improve the ionization potential calculation a special treatment of the ionized state is required, and an open shell calculation will therefore be attempted in the near future.

The experimental dipole moments have been reported as 1.8 D↑, 0.7 D↓, and 0.56 D↓ for pyrrole, furan, and thiophene, respectively. The above dipoles lie along the molecular axes and the negative end of the dipole for pyrrole is believed to point up toward the C_3—C_4 bond (20) as indicated by the arrow, and in thiophene and furan to point down toward the hetero-atom (11). The a priori calculation of the total dipole moment cannot be performed due to the uncertainty in the reported σ-moment values (21). The π-moments calculated from the SCF π-electron densities in the ground states (see Table VIII) are 0.87 D↑, 0.95 D↑, and 1.53 D↑ for thiophene, furan, and pyrrole, respectively. The calculated μ_π for thiophene agrees with the value reported by Bak, Christensen, Hansen-Nygard, and Rastrup-Andersen (11) and the μ_π for pyrrole is in agreement with the value given by Pauling (20).

TABLE IX

Ground state SCF π-electron densities q_i, free valency F_i, and π-bond orders P_{ij}

It is known experimentally (22) that all three heterocyclics considered in this work undergo electrophilic substitution at the α-position. Pyrrole and furan exhibit slight basicity, and the oxygen in furan undergoes protonation in acidic media. The above chemical behavior can be best explained qualitatively by the free valency (F_i) distribution (23) shown in Table IX, which also gives the π-electron densities q_i, and the π-bond orders P_{ij}.

ACKNOWLEDGMENTS

MECHANISM OF ACTION OF UDPGal-4-EPIMERASE: ISOTOPE EFFECT STUDIES[1]

RARDON D. BEVILL III,[2] E. ALEXANDER HILL, F. SMITH, AND S. KIRKWOOD

ABSTRACT

The synthesis of uridine diphosphate glucose and uridine diphosphate galactose labeled with tritium in the 4-position permits the observation of the isotope effect associated with the UDPGal-4-epimerase reaction. This isotope effect has been measured for the reaction proceeding in both directions and the values of k_T/k_H fall in the range 1.5 to 3.0. This allows certain conclusions to be drawn concerning the mechanism of this important enzymatic catalysis. The direction and magnitude of the effect indicate that the 4-hydrogen is removed from the hexose in the course of the reaction. They also appear to dispose of several mechanisms that have been proposed for the epimerase. Specifically, mechanisms involving cleavage of the C—O or C—C bonds at carbon-4 of the hexose moiety, such as cleavage of the carbon chain, elimination and readdition of the carbon-4 hydroxyl as water, or ionization to form a carbonium ion, are not supported by the observed data. A mechanism consistent with all observations involves transfer of the hydrogen at carbon-4 to the enzyme in a step that is not rate determining. This is followed immediately by the rate-determining step, which may well be the reorganization of the enzyme–substrate complex to allow return of the hydrogen in the opposite configuration. The larger estimate of the isotope effect indicates a transfer of the carbon-4 hydrogen to a nitrogen atom located in the enzyme's structure; the smaller estimate is consistent with transfer to oxygen or carbon. Transfer to sulfur appears to be definitely eliminated.

During this work a degradative procedure that will permit the location and quantitation of the carbon-bound tritium in any hexose or pentose was developed.

INTRODUCTION

The biological interconversion of D-galactose and D-glucose has been shown to involve the uridine diphosphate hexoses (UDP-hexoses) rather than the free hexoses or hexose phosphates (1). Efforts to elucidate the mechanism of this important enzymatic reaction have shown that there is no incorporation of either hydrogen or oxygen from water during the epimerization (2–4). Purification of the enzyme involved, uridine diphosphate galactose-4-epimerase (UDPGal-4-epimerase), revealed that the coenzyme NAD^+ is required by the enzyme from both calf liver (5) and yeast (6). This suggests that the UDP-hexose is oxidized to the 4-keto derivative which is then reduced to yield the epimeric configuration at C-4 of the hexose moiety, the hydrogen acceptor and donor being NAD^+. However, there was no incorporation of tritium (T) from either NAD^+ or NADH which contained tritium in the 4-position, nor was it possible to detect a 4-keto intermediate (5). In addition, it has been demonstrated that there is no rearrangement of the carbon skeleton of the hexoses during the course of the reaction (7, 8). Bevill *et al.* (9) and Kohn *et al.* (10) have independently demonstrated that the carbon-bound hydrogen in position-4 of the hexoses is retained during the course of the reaction in vivo and in vitro. This establishes that the hydrogen at C-4 is either removed and reintroduced or remains attached to C-4 during the course of reaction.

[1]*Paper No. 5601, Scientific Journal Series, Minnesota Agricultural Experiment Station. This work was supported in part by a grant from the National Institutes of Health.*
[2]*Procter and Gamble Predoctorate Fellow, 1963–1964.*

To investigate this matter further we have studied the kinetic isotope effect observed when tritium is substituted in place of hydrogen at C-4 of the hexose moiety of the UDP-hexoses.

EXPERIMENTAL[3]

Preparation of Methyl α-D-Glucopyranoside-4-T (II)

D-Glucose-4-T (I) (11), 4.20 mg (23.4 μmoles), was dissolved in 100 ml of anhydrous methanol containing 1% HCl generated by the addition of 2.2 ml of acetyl chloride. The solution was refluxed for 3 h, neutralized with Ag_2CO_3, and filtered. To the filtrate was added 0.500 g of carrier methyl α-D-glucopyranoside and the solution concentrated to a sirup. It was taken up in absolute ethanol and crystallized. Yield: 0.3191 g, 63.8%; m.p. 169.0–169.5° (corrected).

Methyl α-D-glucopyranoside-4-T (II) was recrystallized twice from absolute ethanol and then purified through methyl 2,3,4,6-tetra-O-acetyl-α-D-glucopyranoside-4-T to insure chemical and radiochemical purity.

Preparation of Methyl 2,3,4,6-Tetra-O-acetyl-α-D-glucopyranoside-4-T

To a mixture of 3.0 ml of acetic anhydride (32 mmoles) and 3.0 ml of anhydrous pyridine was added 250 mg of methyl α-D-glucopyranoside-4-T (II) (1.30 mmoles). The reaction mixture was heated at 50° for 2 h, then cooled, and evaporated to a small volume (approximately 1 ml). This was dissolved in 15 ml of chloroform, and the solution washed with cold saturated sodium bicarbonate (15 ml) and then with water (15 ml). The chloroform layer was dried over $CaCl_2$ and concentrated *in vacuo* to a sirup which crystallized spontaneously. Recrystallization from absolute ethanol – petroleum ether gave methyl 2,3,4,6-tetra-O-acetyl-α-D-glucoside-4-T. Yield: 364.0 mg, 77%; m.p. 101–102.5° (corrected), mixed m.p. with an authentic sample 101.5–102.5°.

Deacetylation of Methyl 2,3,4,6-Tetra-O-acetyl-α-D-glucopyranoside-4-T

Methyl 2,3,4,6-tetra-O-acetyl-α-D-glucopyranoside-4-T, 360 mg (0.99 mmole), was dissolved in 5.0 ml of freshly prepared sodium methoxide solution (5.0 mg of Na^0 was dissolved in 100 ml of anhydrous methanol). The reaction mixture was allowed to stand overnight at room temperature and then concentrated *in vacuo* to dryness. The solid methyl α-D-glucopyranoside-4-T (II) was dissolved in hot absolute ethanol, filtered, and crystallized. Yield: 154.1 mg, 80%; m.p. 169–169.5°.

Periodic Acid Oxidation of Methyl α-D-Glucopyranoside-4-T (II) and Isolation of D′-Methoxy-D-hydroxymethyldiglycolic Aldehyde (III)

Methyl α-D-glucopyranoside-4-T (II), 0.150 g (0.774 mmole), was dissolved in 15 ml of water, and to this was added a solution containing 0.400 g of H_5IO_6 ((2 moles of periodic acid + 10% excess)/mole of glucoside) in 15 ml of water. This solution was allowed to stand *in the dark* for 4–6 h (it can be left overnight). The excess periodic acid was neutralized with $BaCO_3$ to pH 7.0 The solution was subsequently filtered to remove precipitated barium salts, the precipitate washed with H_2O, and the combined filtrate and washings concentrated to dryness *in vacuo* (bath temperature 40–45°). The white residue obtained was extracted with three 50-ml portions of absolute ethanol which were then filtered. The clear filtrate was evaporated *in vacuo* to yield D′-methoxy-D-hydroxymethyldiglycolic aldehyde (III) as a sirup.

Isolation of Carbon-3 as Ammonium Formate (Va)

The white residue from the ethanol extract, which is crude barium formate, was dissolved in water, filtered to remove any insoluble material, and passed over the cation exchange resin Amberlite IR-120 (H^+ form). The eluate containing formic acid was adjusted to pH 9 with 2 *N* ammonium hydroxide, concentrated to a small volume (3 ml), and transferred to a sublimation flask (5 ml), and the concentration continued to dryness. This solid residue of crude ammonium formate was further dried under vacuum (0.2 mm) for 2 h at room temperature to remove the final traces of moisture. After a cold finger had been inserted, the flask was heated in a water bath (35–40°) to sublime the ammonium formate. When the sublimation was complete, the cold finger was allowed to warm to room temperature and removed from the apparatus, and the sublimed ammonium formate collected. (Ammonium formate is very hydroscopic.) Yield: 47.0 mg, 96.5%; m.p. 112–114°.

Oxidation of the D′-Methoxy-D-hydroxymethyldiglycolic Aldehyde (III) to Strontium D′-Methoxy-D-hydroxymethyldiglycolate (IX)

A solution containing one-half (0.387 mmole) of the total dialdehyde (III) obtained was adjusted to a volume of 50 ml with H_2O. Strontium carbonate, 1.0 g, and Br_2, 0.20 ml, were added and the reaction mixture stirred at room temperature for 30 min, followed by aeration for 30 min. Silver carbonate, 0.50 g, was added and stirring continued for an additional 10 min (it can be left overnight at this point if necessary). The suspension was filtered, and the filtrate treated first with H_2S gas for 1.0 min and then aerated for 30 min.

[3]*The degradation of methyl α-D-glucopyranoside-4-T is given here in detail as an example of the method devised for the location of carbon-bound tritium in any hexose or pentose.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The black solution was filtered through an ultrafine sintered-glass funnel and the clear filtrate was concentrated to a small volume (1–2 ml). Careful addition of warm methanol (6.0 ml) to the warm aqueous solution yielded strontium D′-methoxy-D-hydroxymethyldiglycolate (IX); 88.5 mg, 73.5%; $[\alpha]_D^{20} = -45.0°$, $c = 1.08$. The strontium D′-methoxy-D-hydroxymethyldiglycolate (IX), 80.0 mg (0.254 mmole), was dissolved in 2.0 ml of warm CO_2-free water and filtered while hot, and the funnel rinsed with an additional 1.0 ml of water. To this solution was added 5.0 ml of warm methanol and the clear solution allowed to stand at room temperature overnight. The fine needles of IX which separated were collected by filtration and washed with cold absolute methanol and then with cold anhydrous diethyl ether. Yield: 59.0 mg, 74%; $[\alpha]_D^{25} = -52.1°$, $c = 1.03$ (lit. value, $[\alpha]_D^{20} = -52.9°$, $c = 1$ (12, 13)).

Isolation and Degradation of D-*Glyceric Acid (XI)*

All of the strontium D′-methoxy-D-hydroxymethyldiglycolate from both crystallizations, 65.0 mg (0.206 mmole), was combined and dissolved in 5.0 ml of *N* HCl. The solution was heated on a steam bath for 2 h. Silver carbonate, 10.0 g, was added, the solution stirred for 15 min and filtered. The filtrate was passed over an Amberlite IR-120 exchange resin column (H^+ form) and the acidic effluent concentrated to dryness. Paper chromatography in solvent D for 12 h yielded D-glyceric acid in 91% of the theoretical amount as determined colorimetrically (14). The aqueous solution of D-glyceric acid eluted from the chromatogram was adjusted to pH 9.0 with $Ca(OH)_2$ and the solution evaporated to a small volume (1–2 ml). (A small volume of aqueous solution of calcium glycerate is very critical in the following procedure.) The solution was gently warmed and warm absolute ethanol added to the clouding point. The solution was allowed to crystallize at room temperature overnight, and the crystals of calcium glycerate collected by filtration. Yield: 25.4 mg, 90%; m.p. 137.5–138.0° (lit. m.p. 137–138° (15)). The calcium glycerate, 21.7 mg (0.077 mmole) was dissolved in 5.0 ml of H_2O and 0.077 mmole of H_2SO_4 added to precipitate the calcium ions as $CaSO_4$. The solution was filtered and to the filtrate was added H_5IO_6, 77 mg ((0.336 mmole − 2 moles + 10% excess)/mole of glyceric acid). The reaction mixture was allowed to stand overnight in the dark. It was neutralized to pH 6.6–6.9 with $BaCO_3$ and filtered, and dimedone reagent, 0.043 g (0.306 mmole), was added to the aqueous solution which was warmed gently for 5 min. The formaldehyde methone (XII), which readily crystallized from the reaction mixture, was collected by filtration and the filtrate (F) kept. Yield: 43.2 mg, 96.6%; m.p. 191–191.5°, mixed melting point with an authentic specimen 190–191° (16). The filtrate (F), which contains barium formate, was passed directly over a column of IR-120 (H^+ form) resin and the effluent adjusted with 2 *N* NH_4OH to pH 9.0. The ammonium formate was then sublimed as described previously. Yield: 9.5 mg, 98.1%; m.p. 112–113.5°.

Reduction of D′-*Methoxy-*D-*hydroxymethyldiglycolic Aldehyde (III)*

To a solution of $NaBH_4$ (0.280 g in 10 ml of H_2O) was added an aqueous solution containing one-half (0.387 mmole) of the D′-methoxy-D-hydroxymethyldiglycolic aldehyde (III) obtained. This was shaken to assure thorough mixing, and then allowed to stand 3–5 h. (It may be left overnight without harm.) The solution was neutralized with CO_2 to pH 7.0, and evaporated to dryness *in vacuo* (bath temperature 40–45°). The residue was extracted with absolute ethanol (3 × 50-ml portions) and filtered through an ultrafine sintered-glass funnel. The filtrate was concentrated to dryness, the extraction and filtration processes repeated, and the alcoholic solution concentrated to a clear sirup to give D′-methoxyhydroxymethyldiethylene glycol (IV). Yield: 65.7 mg, 103.0%.

Isolation of Glycolic Aldehyde Methone (VIII)

D′-Methoxyhydroxymethyldiethylene glycol (IV), 65.7 mg (0.387 mmole), was dissolved in 5.0 ml of *N* HCl, allowed to stand for 30 min, and neutralized to pH 6.4 with saturated $NaHCO_3$. To this aqueous solution containing glycolic aldehyde and glycerol was added 110 mg (0.774 mmole) of dimedone reagent and then absolute ethanol dropwise until the dimedone reagent just dissolved. This reaction mixture was allowed to stand overnight and then cooled to 0°, and the crystals of glycolic aldehyde methone (VIII) collected by filtration. The filtrate was concentrated *in vacuo* until a second crop of crystals was well formed and then cooled to 0°, and the crystals collected. This procedure was repeated a third time. The remaining filtrate, which contains glycerol, was evaporated to dryness and extracted first with chloroform (50 ml) to remove the last traces of methone, and then with absolute ethanol (80 ml) to extract the glycerol from the inorganic salts. The chloroform extract was concentrated to dryness and combined with the methone derivative already recovered, and the entire product recrystallized from the minimal amount of 50% ethanol. Yield: 116 mg, 92.8%; m.p. 232–233°, mixed melting point with an authentic specimen 231.5–232.5° (17).

Isolation of Glycerol Tris-O-p-nitrobenzoate (VII)

The ethanol extract containing the glycerol (0.382 mmole) was concentrated to dryness *in vacuo* and then dried under oil pump vacuum (0.2 mm) for 3 h to remove the final traces of ethanol. This dried sirup was dissolved in 5.0 ml of anhydrous pyridine and *p*-nitrobenzoyl chloride, 0.325 g (1.74 mmoles − 4.5 moles/mole of glycerol), was added to the solution. The reaction mixture was heated at 80–90° for 20 min, then cooled rapidly, and poured into 20 ml of saturated $NaHCO_3$ with vigorous stirring. An oil separated and solidified. The solid material was filtered off, washed with H_2O, and dissolved in 100 ml of chloroform. The chloroform

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solution was dried over $CaCl_2$ and then concentrated to a small volume. Petroleum ether (b.p. 35–65°) was added slowly to the point of turbidity and the crystallization of glycerol tris-O-*p*-nitrobenzoate allowed to proceed. Recrystallization from chloroform – petroleum ether yielded 180 mg, 86%; m.p. 195.5–196.5°, mixed melting point 195–196.5° (18).

Preparation of Enzymes

(a) UDPGal-4-epimerase.—*Saccharomyces fragilis* cells, adapted to lactose, were grown as described by Maxwell and de Robichon-Szulmajster (6) with lactose instead of galactose as the carbon source. The cells were collected by centrifugation at 5 000 × *g* for 15 min, washed twice with distilled water, dried for 24 h at room temperature with the aid of a fan, and stored at −20°. All subsequent manipulations were performed at 0–5°. Dried yeast (10 g) was extracted with 24 ml of 2.2% $(NH_4)_2HPO_4$ for 24 h, the slurry being stirred with a magnetic stirrer. The extraction mixture was centrifuged for 20 min at 37 000 × *g*. The supernate (17.5 ml) was dialyzed against two changes, 2 l each, of distilled water containing 6.8×10^{-4} *M* 2-mercaptoethanol for 24 h. The dialyzate (18.0 ml) had 0.90 ml of 1.0 *M* $MnCl_2$ added to it to precipitate the nucleic acids. After it had been allowed to stand for 20 min, the solution was centrifuged at 37 000 × *g* for 15 min. The supernate (16.2 ml) was then fractionated as described by Maxwell and de Robichon-Szulmajster (6).

(b) UDPG dehydrogenase.—This was prepared through step 5 of the procedure of Strominger *et al.* (19).

Deionization, Concentration, Chromatography, and Detection of Sugar Compounds on Paper

All deionization steps used in this study were performed with either single or mixed bed resins in the form of a column. Amberlite IR-120 (H^+ form) was used as the cation exchanger and Amberlite IR-45 (OH^- form) as the anion exchanger. All sugar solutions were concentrated under reduced pressure at 40–45° (bath temperature) by means of a rotary evaporator. Descending chromatography was carried out at room temperature on either Whatman No. 1 or No. 3MM paper with the following solvent systems: (A) pyridine – ethyl acetate – water (2:5:7) using the organic phase (20); (B) isopropyl alcohol – ammonium hydroxide – water (7:1:2) (21); (C) ethyl alcohol – 1.0 *M* ammonium acetate, pH 7.5 (5:2) (22); (D) 1-butanol – acetic acid – water (2:1:1) (23). Free sugars were detected by the alkaline $AgNO_3$ method of Trevelyan *et al.* (24), sugar phosphates by the method of Hanes and Isherwood (25) as modified by Bandurski and Axelrod (26), and nucleotides by ultraviolet absorption.

Radioactivity Determinations

Carbon-14 and tritium were determined in a liquid scintillation counter, Nuclear-Chicago Corporation, model 724. Dual isotope counting (simultaneous determinations of tritium and carbon-14 in the same sample) was accomplished by the channels ratio method (27). Each counting sample contained 0.03 ml water, 2.0 ml of absolute ethanol, and 15.0 ml of scintillator fluid (4.0 g of 2,5-diphenyloxazole (PPO) and 0.050 g of 1,4-bis-2-(5-phenyloxazolyl)-benzene (POPOP) dissolved in 1.0 l of reagent grade toluene).

Preparation of Radioactive Nucleotide Hexoses

Radioactive hexoses (D-glucose-4-T, D-glucose-1-^{14}C, D-galactose-4-T, and D-galactose-1-^{14}C) were acetylated with anhydrous sodium acetate and acetic anhydride as previously described (28). Thus, D-galactose-4-T, 11.3 mg, was dissolved in 2.7 ml of acetic anhydride, and 200 mg of anhydrous sodium acetate was added. The reaction mixture was heated at 95–100° for 2 h and then washed into 50 ml of ice water. The aqueous solution was extracted with 2 × 25-ml portions of chloroform. The chloroform layer was dried over $CaCl_2$ and concentrated *in vacuo* to a sirup which did not crystallize. Yield of pentaacetate: 95% based on radioactivity in the chloroform extract. The β-pentaacetate so formed was phosphorylated by the method of MacDonald (29). Crystalline H_3PO_4, 36 mg, was melted at 50° in a 10-ml conical flask in which the β-pentaacetate above had previously been dried. The flask was tipped to insure mixing and then evacuated by an oil pump (0.2 mm) for 2 h at 50°. The dark brown residue was dissolved in 10 ml of dry tetrahydrofuran and added to 50 ml of ice-cold *N* LiOH. A white precipitate formed immediately and, after 12–16 h, the solution was centrifuged to remove the lithium phosphate. The remaining basic solution was passed over a column of IR-120 (H^+ form) resin, and the eluate neutralized with cyclohexylamine and evaporated to dryness. After it was washed with isopropyl alcohol to dissolve the cyclohexylammonium acetate, the residue was taken up in 50% ethanol and chromatographed in solvent B for 72 h. (The sugar phosphate has an R_{Pi} 1.5 (P_i = orthophosphate).) The D-galactose 1-phosphate-4-T was eluted and the solution concentrated to a sirup which did not crystallize. Yield: 42.1% based on radioactivity. Yields varied from 27% to 42% for the sugar phosphates. The preparation of uridine diphosphate hexoses was accomplished by the procedure of Roseman *et al.* (22). Thus, 12.8 μmoles of D-galactose 1-phosphate dicylcohexylammonium salt (6.0 mg) was converted into the bis-(tri-*n*-octylammonium) salt, and this product reacted with 12.8 μmoles of uridine-5′-phosphoromorpholidate in anhydrous pyridine (5.0 ml) for 5 days. The reaction mixture was treated as described (22) and the UDPGal isolated by paper chromatography in solvent C. Yield: 8.7 μmoles as assayed enzymatically with UDPGal-4-epimerase and UDPG dehydrogenase (5, 19), 68.1%. Average yields were 65–70%. Analytical data for the radioactive uridine diphosphate hexose nucleotides prepared are given in Table I. Reducing power was determined by the method of Park and Johnson (30), acid-labile inorganic phosphate by the procedure of Fiske and Subbarow (31), and total inorganic phosphate by the method of King (32).

*UDPG and UDPGal concentrations were determined by the enzymatic method of Maxwell (5) and Strominger (19).
†Reducing power (30) and acid-labile phosphate (31) were determined after hydrolysis in 0.01 *N* HCl, 100° for 10 min.
‡The concentration was obtained from the absorbance at 262 mμ, using 10 000 as the extinction coefficient. This was set equal to 1.0 for computing the above ratios.
§Total phosphate determined by King's method (32).

Determination of Isotope Effect

UDPGal-1-^{14}C and UDPGal-4-T were mixed together to give a T/^{14}C ratio of 10:1. Each reaction tube contained the following: UDPGal, 35 mμmoles, specific activity 71 500 c.p.m./μmole of T and 7 150 c.p.m./μmole of ^{14}C; glycine buffer, pH 8.7, 40 μmoles; and 36 units of purified yeast epimerase (1.2 μg of protein) in a final volume of 0.50 ml. The reaction mixtures were incubated at 24.8° for times sufficient to obtain 8 to 100% attainment of equilibrium. The reaction was stopped by addition of 10 *N* HCl to adjust the solution to pH 2 and then heated at 100° for 10 min. The hexose mixtures were deionized and chromatographed in solvent A for 36 h on Whatman No. 1 paper. By reference to glucose and galactose markers, the areas corresponding to glucose and galactose were cut out and eluted with water. The hexose solutions were concentrated to a final volume of 0.20 ml and the T/^{14}C ratios determined on suitable aliquots in duplicate.

RESULTS AND DISCUSSION

Degradation of Tritiated Sugars

During this investigation it was important to establish the position of tritium labeling in both glucose and galactose with complete certainty. This was necessary to check the location of T in the starting materials and in the products of enzymatic reaction. Many procedures are described in the literature for the determination of ^{14}C-distribution in sugars (see, for example, Abercrombie and Jones (33)), but only four of these afford a complete determination of the labeling on a millimolar scale (33–35, 12) and none allows the location of label in carbon-bound hydrogen. Consequently, it was necessary to devise a procedure for this purpose. The procedure described here is based on the reactions of Smith and Van Cleave (18) and of Jackson and Hudson (13). Boothroyd *et al.* (12) used the reactions of Jackson and Hudson to locate the position of ^{14}C in D-glucose, while Abercrombie and Jones (33) used the reactions of Smith and Van Cleave for the same purpose. A combination of the two reaction sequences, when properly modified, can be used to locate label in each of the carbon-bound hydrogens of any pentose or hexose. The reaction sequence is unambiguous, produces crystalline derivatives in high yields, and can be applied on a millimolar scale. The results of this degradation on the tritiated D-glucose (9) and the tritiated D-galactose (36) used in these experiments are shown in Table II. In addition, the location of tritium in D-glucose, which was prepared enzymatically from tritiated D-galactose, is presented. This is the first direct proof that 4-hydrogen of galactose remains in the 4-position of the glucose. Although this 4-hydrogen has previously been shown to remain throughout epimerization in vivo and in vitro (9, 10), its precise location in the product had not been determined.

Isotope Effect Studies

The usefulness of isotope effect data in interpreting chemical reaction mechanisms is well known (37–39). In this investigation we have made use of a method described by

Collins (38) for the study of the rates of competing reactions. UDP-hexose samples, labeled either in the 4-position with T or in the 1-position with ^{14}C, were prepared. These were mixed to give a predetermined T/^{14}C ratio and this mixed sample was submitted to the action of the enzyme. It is evident that the rate of appearance of ^{14}C in the product is a measure of the rate of reaction of the species with hydrogen in the 4-position, since any ^{14}C isotope effect should be negligible. The rate of appearance of T in the product is a measure of the rate of reaction of the species with T in the 4-position. At long reaction times, when equilibrium had been attained, the T/^{14}C ratio in the product was identical with that in the starting mixture. Therefore, there is no measurable equilibrium isotope effect. If A_{eq} is defined as the T/^{14}C ratio in the starting and equilibrium UDP-hexoses and A is defined as the ratio at any point in the reaction, the ratio A/A_{eq} can be determined experimentally at any point in the reaction. A plot of A/A_{eq} versus % attainment of equilibrium, when extrapolated to 0% attainment of equilibrium, gives an estimate of the isotope effect k_T/k_H. In view of the rather involved procedures necessary to separate the products and determine T/^{14}C ratios, the reaction was run in both directions over a range of 3–100% of attainment of equilibrium to assure that any systematic errors in the separation and analysis of the products were not affecting the results. The quantity A/A_{eq} was plotted against % attainment of equilibrium and the kinetic isotope effect, k_T/k_H, at 0% of equilibrium was obtained by extrapolation[4] (Fig. 1). It is probable that many systematic errors inherent in the methods used would affect the isotope effects determined for the forward and back reactions in an opposite sense. The reasonable agreement between the two values indicates that the separation procedures do not introduce any serious error. The value of k_T/k_H obtained from a study of the forward reaction (UDPGal → UDPG) was 3.2 and that from the back reaction (UDPG → UDPGal) was 2.9.

Another approach to the determination of the isotope effect requires a relationship between A/A_{eq} and G/G_{eq}, the latter being defined as the fractional approach to equilibrium corresponding to a given value of A/A_{eq}. A treatment somewhat similar to that of Stevens and Attree (41) predicts that a plot of log $(1 - (A/A_{eq} \times G/G_{eq}))$ vs. log $(1 - G/G_{eq})$ should give a straight line which passes through the origin and whose slope is the

[4]*Collins (40) has noted, in comparing the isotopic content of the first 3–6% of the reaction product with that of the initial reactant, that the first few % of reaction product often exhibit anomalous isotope content in comparison to samples removed at intervals during the entire reaction. Thus, there is the possibility of serious error in the evaluation of both the magnitude and direction of isotope effects determined solely on the basis of the isotopic composition of the initial fraction of the reaction product. The extrapolation procedure used here would appear to be greatly preferable.*

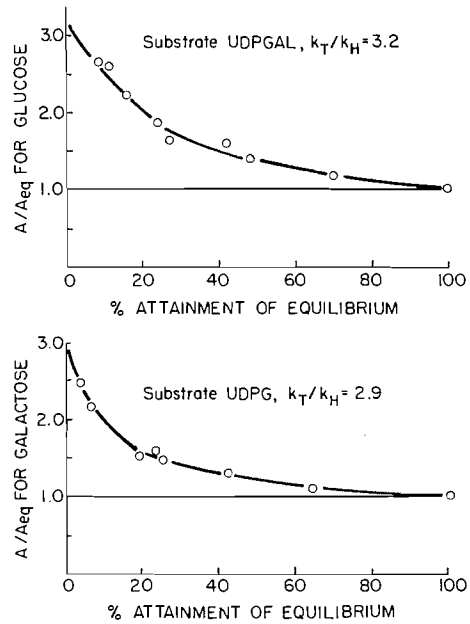

FIG. 1. The kinetic isotope effect: upper curve is A/A_{eq} obtained from glucose with the reaction run in the forward direction (UDPGal → UDPG); lower curve is A/A_{eq} obtained from galactose with the reaction run in the back direction (UDPG → UDPGal).

isotope effect k_T/k_H. The data obtained from reaction in the direction UDPG → UDPGal give a straight line plot at the lower values of log $(1 - G/G_{eq})$ which goes through the origin, but at higher values the plot develops a marked downward curvature. The slope of the straight line portion gives a value for the isotope effect of $k_T/k_H = 1.7$. The data obtained from the reaction in the direction UDPGal → UDPG give a considerable scatter of points, particularly at the higher values of log $(1 - G/G_{eq})$. The isotope effect determined from these points lies between 1.3 and 2.4, depending on the line drawn. It should be pointed out that the extrapolation procedure gives greater weight to the early points while the other procedure gives greater weight to the later points. These two sets of points are subject to a greater experimental error than the intermediate points. A possible explanation for the form of both types of plot would be that two mechanisms of reaction are involved, one of which has a large isotope effect (~3) which becomes unimportant as the reaction proceeds. Despite the element of uncertainty in the value of the isotope effect indicated by the two different methods of plotting, there can be no doubt that there is a "reverse" isotope effect and its magnitude lies somewhere between the values 1.5 and 3.0. Attempts are presently in progress to determine the value with greater precision.

Discussion of the Mechanism

The observations of an inverse isotope effect $k_T/k_H > 1.5$ allows certain conclusions to be drawn concerning the mechanism of the enzyme-catalyzed reaction. The direction and magnitude of the effect make it highly unlikely that this hydrogen is being transferred in the rate-determining step. In numerous cases sizeable normal isotope effects (k_D/k_H or $k_T/k_H < 1$) have been observed and their nature and magnitude have been discussed at length from the standpoint of theory (37–39). Primary deuterium isotope effects in the proton transfer step of the reaction:

$$\text{ethanol} + \text{NAD}^+ = \text{acetaldehyde} + \text{NADH} + \text{H}^+,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

catalyzed by both yeast and liver alcohol dehydrogenase, have been found in the range $k_D/k_H = 0.57$ to 0.32 (42). This reaction is similar to one of the proposed mechanisms for UDPGal-4-epimerase (5). It is possible to obtain small or even inverse primary isotope effects if the hydrogen is bound more tightly in the transition state for its transfer than in the starting state (43, 44). Such a situation can occur in reactions of hydrogen atoms and in very exothermic proton transfers, but the present reaction seems to lack features that would lead to a sizeable inverse primary isotope effect explicable on this basis.

Several of the proposed mechanisms for the epimerase involve cleavage of the C—O or C—C bonds at C-4. Such reactions would involve a trigonal carbon at C-4 in the intermediate or transition state. In such cases it is to be expected that the normal compound would react 12–25% faster than the tritium-substituted compound—the commonly found α-hydrogen isotope effect (45). Specifically, the observed isotope effect would appear to eliminate cleavage of the carbon chain of the hexose as a possible mechanism, as proposed by Leloir (46), since this dictates that C-4 passes through a trigonal intermediate. Elimination and readdition of the carbon-4 hydroxyl as water, or ionization to a carbonium ion, also appear unlikely on the same basis. The assertion that these mechanisms are ruled out by the failure to observe exchange with either hydrogen or oxygen of water (2–4) is based on the assumption that the reaction site is freely available to the water in the reaction medium. If, as may well be the case, the reaction proceeds at a site from which water is excluded, then the exchange data have no bearing on the reaction mechanism. The isotope effect data, on the other hand, rule out these mechanisms regardless of the location of the active site. Small *inverse* secondary α-deuterium isotope effects have been observed for S_N2 reactions of some alkylarylsulfonates and halides (47–49). This reversal of the normal effect has been explained by steric restriction of the out-of-plane bending vibration of the hydrogen attached to the trigonal carbon in the transition state, as a result of repulsion of the entering and leaving groups. It is conceivable that an S_N2-like mechanism could explain a reverse isotope effect as large as 1.5, but a rather complex mechanism would then be required to account for the failure to exchange oxygen with the solvent. Until we have a clearer understanding of the nature of the binding to the enzyme, one cannot rule out this possible mechanism on the basis of the observed isotope effect alone.

The present results should be compared to those of Mahler *et al.* (42) obtained with alcohol dehydrogenase. As has been mentioned previously, the overall isotope effect in this reaction is normal. A more complete analysis of the kinetic data, based on postulated mechanisms, indicated that this isotope effect is not entirely associated with the proton transfer step. In particular, it appears that NADH with deuterium in the so-called α-position is preferentially bound to the enzyme. The isotope effect of the enzyme–coenzyme association is $K_D/K_H = 1.31$ for the liver alcohol dehydrogenase and about 1.4 for yeast alcohol dehydrogenase, indicating a greater constraint in the complex in both cases to the extent of 300–400 cm^{-1} increase in vibrational frequencies. Although the errors in these determinations are probably large, the isotope effects appear real. It is not clear what interactions are responsible for these isotope effects, but it does appear that binding to an enzyme molecule can produce considerable changes in vibrational frequencies.

The type of mechanism which appears to be most nearly consistent with the isotope effect we observe is one in which the carbon-4 hydrogen is transferred to some other atom in a reversible step preceding the rate-determining step. The observed effect is then the equilibrium isotope effect for this reversible step. An isotope effect of 1.6 corresponds to an increase of about 500 cm^{-1} in the total vibrational frequencies of the 4-hydrogen in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

transition state, while an isotope effect of 3.0 corresponds[5] to an increase of about 1 200 cm^{-1}. It is difficult to explain an isotope effect greater than 2.1 in the present reaction if vibrational frequencies of normal molecules are assumed to apply to enzyme-bound molecules.[6] However, the results of Mahler *et al.* suggest that larger isotope effects may be possible in enzymatic reactions. The larger estimate of our observed isotope effect might then be explained by transfer of the 4-hydrogen to a nitrogen. The lower estimate would be consistent with transfer either to oxygen or carbon, but transfer to sulfur seems definitely eliminated.

A mechanism consistent with all of the observations would be as follows:

$$E + SH \overset{K_1}{\rightleftarrows} ESH \overset{K_2}{\rightleftarrows} EH - S \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} EH - S' \overset{K_4}{\rightleftarrows} ES'H \overset{K_5}{\rightleftarrows} E + S'H.$$

Steps 2 and 4 are equilibrium hydrogen transfers to the enzyme; the rate-determining step 3 might be a reorganization of the enzyme–substrate complex which allows the hydrogen to return in the opposite configuration. The results could also be explained if the association of enzyme and substrate (K_1 and K_5) have large equilibrium isotope effects and the other steps occur with small isotope effects. Shiner *et al.* (56) have, however, observed no equilibrium isotope effect in the association of alcohol dehydrogenase with acetaldehyde bearing deuterium on the carbonyl carbon. Therefore, it is highly probable that steps 2 and 4, the equilibrium hydrogen transfers between enzyme and substrate, are associated with the reverse hydrogen isotope effect.

Recently, Wilson and Hogness (57) have reported on the UDPGal-4-epimerase from *E. coli*. This preparation has the highest specific activity yet reported for this enzyme. The difference spectrum between the enzyme plus substrate and the enzyme is very like that of NADH, but is slightly displaced toward the longer wavelengths. The data indicate that 19% of the enzyme-bound NAD is in the reduced form in the presence of the substrate. This provides evidence that, at least in the case of the *E. coli* enzyme, the mechanism involves the oxidation of the hexose to the 4-keto derivative followed by reduction to

[5]*The increase in total vibrational frequencies in the transition state was calculated from the expression (37):*

$$k_H/k_T = \exp 1/RT[(E_0^H - E_0^T) - (E_0^{H\pm} - E_0^{T\pm})],$$

where the E terms are the total zero point energies of the normal and tritiated ground and transition states. If fundamental constants are inserted, and it is assumed that

$$\nu_T \approx \sqrt{\mu_H/\mu_T}, \nu_H = \sqrt{1/2.65}\nu_H$$

for three fundamental frequencies involving the hydrogen in question, we obtain the expression

$$k_H/k_T = \exp 0.276/T\ (\sum\nu_H - \sum\nu_H^{\pm}).$$

Units of ν are cm^{-1}. The pre-exponential part of the isotope effect expression would change these calculations very slightly.

[6]*The sums of three vibrational frequencies associated with various types of hydrogen are tabulated, along with the isotope effect to be expected based on the lower frequency sum for* C—H *(tertiary). These are estimates derived from standard compilations of vibrational frequencies or from spectral analyses (50–53), and must be considered very approximate because of uncertainties resulting from the coupling of* X—H *bending modes with skeletal vibrational modes and of variations resulting from changes in structure or physical state. In particular, the tertiary* C—H *bend is uncertain. Results of this approximate calculation are in accord with available deuterium distribution data (54, 55).*

Bond	*Frequency sum*	k_T/k_H *(max)*

re-form the hydroxyl in the opposite configuration, NAD^+ being the hydrogen carrier involved. All previous attempts to demonstrate this type of function in the calf liver (5), yeast (6), and *L. bulgaricus* enzyme (2) led to negative results.

The higher estimate of k_T/k_H is not consistent with a transfer of the 4-hydrogen to NAD^+ as the first step of the reaction, since the transfer would be to a carbon atom and this would dictate a smaller isotope effect.[6] The lower estimate is still somewhat large for transfer to carbon, but it is possible that enzyme binding might increase the magnitude of the isotope effect. Certainly, the isotope effect data do not in any way preclude a function of NAD^+ in the sense postulated by Wilson and Hogness, since transfer of the 4-hydrogen to a nitrogen within the enzyme structure, with subsequent transfer to NAD^+, would be consistent with even the larger value of k_T/k_H. Since the enzyme catalyzes the reaction at a site on its surface that appears to exclude water, it is possible that it could transfer the equivalent of two hydrogen ions and two electrons from the substrate to form $NADH_2^+$, which would be stable in the absence of water. If the 4-hydrogen were specifically transferred to the nitrogen of NAD^+ by a mechanism of this type, then even the larger value of k_T/k_H could be accounted for by a direct transfer to NAD^+. A final possibility is, of course, that the *E. coli* enzyme utilizes a radically different mechanism than that used by the enzyme from *S. fragilis*.

ABSTRACT

The synthesis of high molecular weight (100 000 to 200 000) polymers and copolymers of L-tryptophan and γ-benzyl-L-glutamate is reported. The optical rotatory dispersion (o.r.d.) of these polypeptides is recorded in the wavelength range 540–320 mμ and the b_0 values of the Moffitt equation, using $\lambda_0 = 212$ mμ, are listed. Poly-L-tryptophan has a b_0 value of +570 in dimethylformamide (DMF). A linear relationship exists between this value, b_0 values of copolymers of various ratios of L-tryptophan and γ-benzyl-L-glutamate, and the value of −670 found for poly-γ-benzyl-L-glutamate. The o.r.d. curve of a poly-L-tryptophan film, in the 330–200 mμ wavelength range, reveals two positive Cotton effects in the 270–290 mμ region and a large negative Cotton effect at 233 mμ. Thus, despite the positive b_0 value, these data prove that poly-L-tryptophan, in DMF, has the right-handed helical conformation. Hypochromicity was found for the tryptophanyl residue in the helical polypeptide. The rotatory contribution of chromophores, such as tryptophan or coenzymes, when bound asymmetrically to a protein, can be very significant, and caution is advised in the interpretation of such o.r.d. curves.

Optical rotatory dispersion (o.r.d.) measurements have become extensively used to determine the conformation of proteins (1, 2, 3). The anomalous rotatory dispersion curves for many synthetic poly-α-amino acids and proteins in the helical conformation have been adequately interpreted by the Moffitt equation (4, 5) $[m']_\lambda = a_0\lambda_0^2/(\lambda^2 - \lambda_0^2) + b_0\lambda_0^4/(\lambda^2 - \lambda_0^2)^2$. Although it is acknowledged that this treatment of o.r.d. data is of a highly empirical nature, the constant b_0 in this equation has been successfully used as a measure of the helical content in polypeptides and proteins. The b_0 value of approximately −630 to −670 ($\lambda_0 = 212$ mμ) has been found for the 100% right-handed helical conformation (5, 6), while the random coil form has a b_0 value of zero (6). The sign of the b_0 has been taken to indicate the sense of helix, and has been corroborated by X-ray studies (7). Estimates of helical content derived from o.r.d. data (8, 9) agree remarkably well with X-ray data for myoglobin (10). More recently a modified Drude equation (11) has been proposed to estimate helical contents in polypeptides based on o.r.d. studies penetrating further into the ultraviolet region. However, this treatment is theoretically inadequate, as a new Cotton effect has since been discovered (Holzwarth and Doty (12) have shown that the 233 mμ Cotton effect is a composite of two such bands and that two circular dichroism bands are responsible for this Cotton effect, one caused by a $n \rightarrow \pi^*$ transition and the other caused by a $\pi \rightarrow \pi^*$ transition), which likewise places

this approach in the empirical category. Consequently, the Moffitt equation will be adhered to in this paper.

Positive b_0 values have been reported for a variety of polymers of D-amino acids and for poly-β-benzyl-L-aspartate (13), poly-L-tyrosine (14), and poly-L-tryptophan (15). Poly-β-benzyl-L-aspartate has been shown to exist as a left-handed helix by two research groups (16). However, poly-L-tyrosine was shown by o.r.d. studies (17, 18) and circular dichroism (19) studies to be a right-handed helix. Consequently, the positive b_0 value must be due to the contribution of the chromophoric side chains on the β-carbon which contributes to the rotation in the visible region of the spectrum.

Sela *et al.* (15) have reported a b_0 value of +410, in dimethylformamide (DMF), for poly-L-tryptophan. The study reported herein was undertaken to establish the sense of the helix of poly-L-tryptophan.

Poly-L-tryptophan was first prepared by Patchornik *et al.* (20). Polymers with average molecular weights of 17 000 (η_{sp}/c = 0.08, 0.2% in DMF) were obtained. As their method for the preparation of N-carboxy-L-tryptophan anhydride (L-tryptophan-NCA) did not readily yield pure anhydride, and since the reported molecular weights were low for definitive conformational studies, a new anhydride preparation is reported. The scheme of preparation is seen in Fig. 1. This method yields polymers with reduced specific vis-

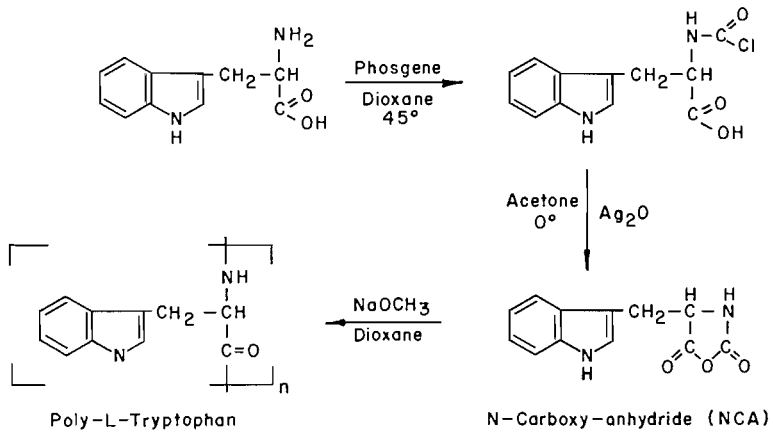

FIG. 1. Synthesis of poly-L-tryptophan.

cosities as high as 1.69 (0.2% in DMF) with weight average molecular weights estimated to be 123 000 (see below). Polymers of even greater molecular weights were completely insoluble in DMF. Poly-L-tryptophan was found to be extremely insoluble in most organic solvents. Dimethyl sulfoxide (DMSO) was found to be a suitable solvent; however, it appears to cause disruption of the secondary structure (see below).

In the following study the synthesis and the o.r.d. behavior of high molecular weight copolymers of various mole ratios of γ-benzyl-L-glutamate and L-tryptophan are reported to evaluate the sense of helix of poly-L-tryptophan, in the manner previously reported by Karlson *et al.* (16).

RESULTS

Poly-L-tryptophan was synthesized by the polymerization of L-tryptophan-NCA in dioxane (4%) by initiation with sodium methoxide (A/I = 50) (21). Poly-γ-benzyl-L-glutamate (PBLG) was prepared by the polymerization of γ-benzyl-L-glutamate-NCA

For personal use only.

(21) in benzene, by initiation with $NaOCH_3$, A/I = 200. Copolymers of various mole ratios were prepared by dissolving each NCA in the solvent used for the synthesis of the homopolymer and mixing the two in the appropriate ratio. In Table I are listed some

physical and optical properties of the polymers and copolymers, the conditions of polymerization, and their estimated weight average molecular weights. The viscosities of poly-L-tryptophan and the copolymers could not be determined with confidence in dichloroacetic acid (DCA) because of the immediate destruction of the indole moiety by this solvent, as indicated by gross discoloration of the solutions. Their viscosities were therefore determined in DMF and these values correlated with values obtained in DCA for a series of PBLG polymers of various molecular weights in both DMF and DCA. The weight average molecular weights of PBLG polymers, determined by viscosities in DCA, has previously been published (22). The molecular weights were estimated to be in the 100 000 to 172 000 range.

The o.r.d. of this set of polymers was determined in DMF, a helix-promoting solvent (1), over the wavelength range 350–540 mμ (Fig. 2). It can be seen that the dispersion changes from the negative curve for helical PBLG to an increasingly more positive one as the tryptophan mole ratio is increased. With these data, b_0 values were calculated using λ_0 = 212 mμ (Table I). The b_0 value for helical PBLG in DMF was found to be −670, agreeing with the value previously reported (5). The b_0 value for poly-L-tryptophan was found to be +570. The discrepancy with the value (+410) previously reported (15) may be due to the much larger molecular weight of the polymer used in this study (120 000 vs. the 18 000 in the previous study). The b_0 values vary linearly from +570 for poly-L-tryptophan to −670 for PBLG (Fig. 3). This indicates that the same helical sense is maintained in these copolymers, namely a right-handed helix. If poly-L-tryptophan and PBLG were helices of the opposite sense of twist, the b_0 value of their copolymers should change markedly over a relatively narrow range of copolymers, representing a region of transition from one helical sense to the other, as found for copolymers of β-benzyl-L-aspartate and γ-benzyl-L-glutamate (16). However, as seen here, this does not

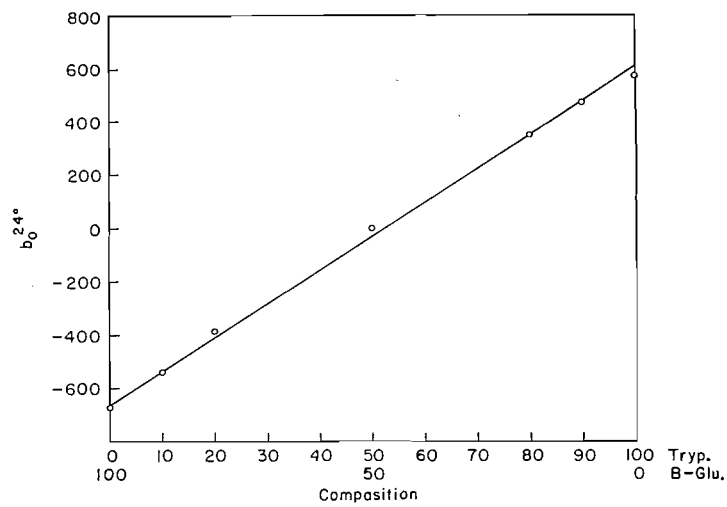

FIG. 3. b_0 values of polymers and copolymers of L-tryptophan and γ-benzyl-L-glutamate in dimethylformamide. Tryp = tryptophan; B-Glu = γ-benzyl-L-glutamate. The b_0 values obtained from the Moffitt equation, using $\lambda_0 = 212$ mμ. See Table I for conditions used.

occur, but rather a gradual b_0 change is seen, at any one point the b_0 being the sum of the mole ratio contribution of the two different b_0 values. Thus, the behavior of the tryptophan copolymers resembles that of the tyrosine copolymers (17). Both of these aromatic amino acids contain a strong chromophoric group on the β-carbon, in close proximity to the peptide bond chromophore, and it is this aromatic chromophore whose rotatory dispersion contribution predominates in the visible and is responsible for the positive b_0 values.

It was hoped that one could investigate the 233 mμ region, where a large negative Cotton effect was found by Simmons *et al.* (23) for the right-handed helical conformation of polypeptides. Such o.r.d. and circular dichroism studies of poly-L-tyrosine (18, 19) in aqueous media revealed this negative Cotton effect and circular dichroic band, further confirming the right-handed sense of the helix of this polymer. The optical rotation of solutions of poly-L-tryptophan in DMF could only be determined down to 300 mμ because of the absorbance of the solvent, and no other transparent helix-promoting solvent for this polymer could be found. In dimethyl sulfoxide, a more transparent solvent, the polymer had a b_0 value of zero, indicating a random conformation. However, films of poly-L-tryptophan could be investigated in the ultraviolet region.

L-Tryptophan was first examined in aqueous media, at pH 6.2, and the o.r.d. curve is seen in Fig. 4. A small positive Cotton effect, $[m'] = +186$, in the 290 mμ region is followed by a larger but yet small negative Cotton effect with its trough at approximately 276 mμ. The molar rotation of the latter trough is $-1\,600$, in comparison with the $-14\,000$ to $-18\,000$ value for a helical polymer at 233 mμ (23, 24). The optical rotation of poly-L-tryptophan at these lower wavelengths was measured on films on the optical face of quartz cells. These films were transparent throughout the whole range of the Bendix spectropolarimeter. The o.r.d. of such a film is seen in Fig. 5. When films were prepared so that at 300 mμ the direction of the rotation was the same as that of the DMF solution, a sharp negative trough was observed at approximately 233 mμ, similar in sign to those observed with solutions of PBLG in the helical conformation. It is significant that the trough in poly-L-tryptophan is at 233 mμ, while the monomer trough was found at 276 mμ. The $[m']_{233}$ is negative in the polymer and the wavelength of this trough is that found for the peptide helical conformation. This trough in the o.r.d. of the helical polymer is probably much larger than that of the monomer, and thus the latter trough is probably obliterated. The small trough at 276 mμ found in the monomer is due to the indole chromophore on the β-carbon atom next to the asymmetric center of the amino acid. Thus, the sign and the position of the Cotton effect in the polymer are what one would expect for a right-handed helix. The observed rotation, rather than the molar rotation, has been shown because the thickness of a film is difficult to calculate accurately. Also seen in Fig. 5 (the broken line) is the absorption spectrum of the film. One other notable feature of the o.r.d. curve is the multiple Cotton effect in the 270–300 mμ region. An expanded view of this region is seen in Fig. 6. The monomer shows only one Cotton effect in this region, with a peak at 296 mμ. The polymer has two peaks, at 296 mμ and 288 mμ. The absorption spectrum in this region shows several shoulders, indicating either more than one electronic transition or vibrational structure. The fact that several Cotton effects are observed in the helical conformation in both poly-L-tryptophan and poly-L-tyrosine may indicate interaction between residues in the helical conformation, thus bringing about either a resonance exciton interaction phenomenon or an enhancement of the contribution of the several vibrational states. Such interactions have been implicated to explain the excimer fluorescence bands found in helical poly-L-tyrosine (25).

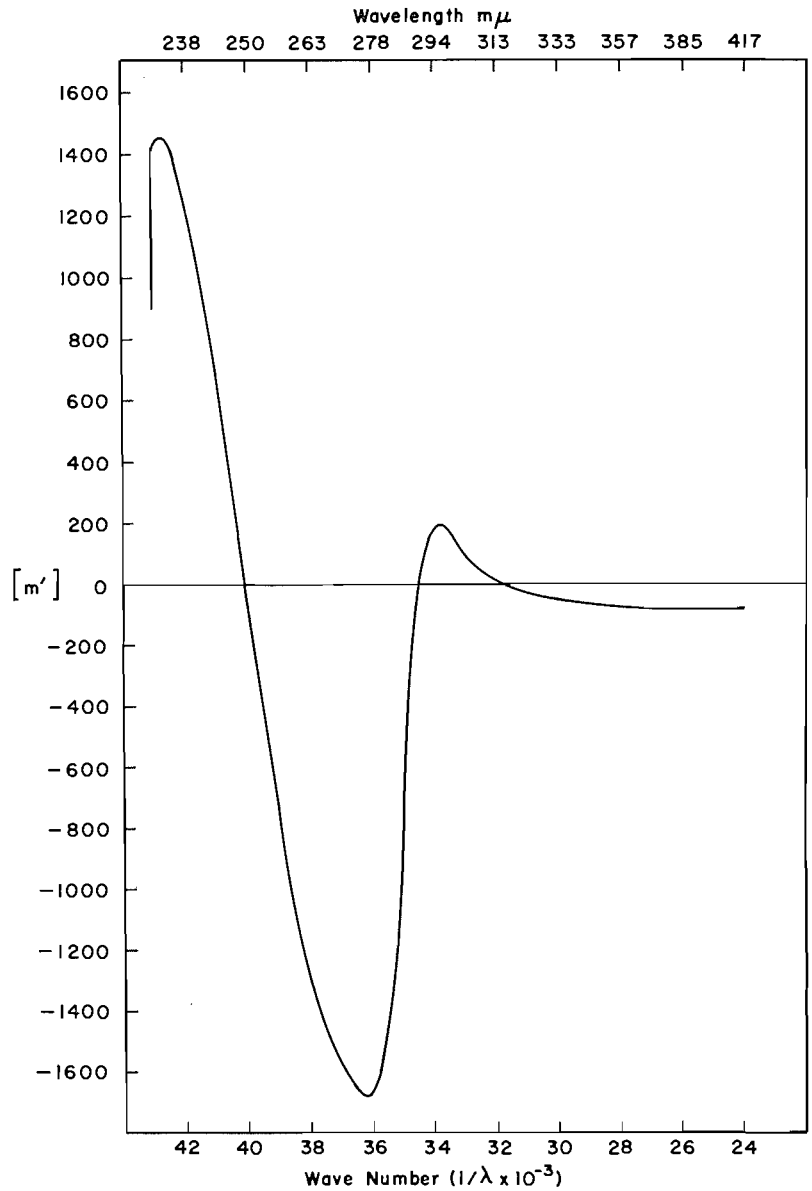

FIG. 4. The optical rotatory dispersion of L-tryptophan in H_2O at pH 6.2. [m'] is mean residue rotation. Concentration, ≃0.04%. Path length: 1 cm in 400–300 mμ range; 1 mm in 300–233 mμ range.

Another optical phenomenon frequently observed in interacting asymmetric systems is hypochromism. Thus, DNA has been found to be hypochromic in the helical conformation compared to the random state (26). In polycytidylic acid, hypochromism was observed in a double-stranded hydrogen-bonded helical structure, as well as in the single-stranded base-stacked helix (27). The extinction coefficient of the peptide absorption band at 190 mμ has also been shown to be conformation dependent (28). Thus, one might anticipate hypochromism in helical poly-L-tryptophan, and such is the case. In DMF the molar

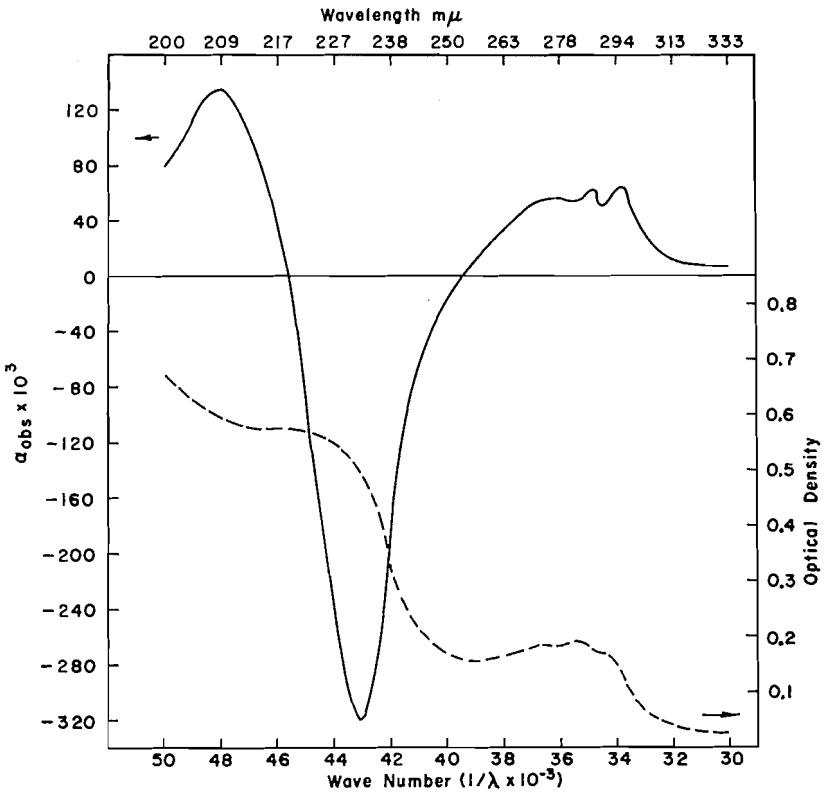

FIG. 5. The optical rotatory dispersion and ultraviolet absorption spectrum of a poly-L-tryptophan film. $\alpha_{observed}$ and optical density vs. wavelength.

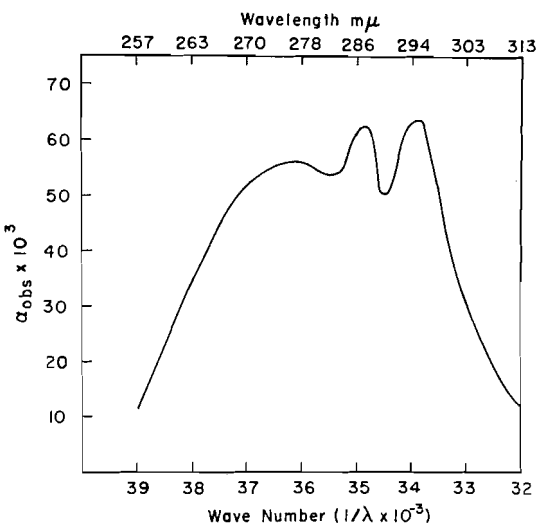

FIG. 6. The optical rotatory dispersion of a poly-L-tryptophan film. An expanded scale of wavelength range 313–257 mμ of film seen in Fig. 5.

extinction coefficient of the helical polymer is $5.58 \pm 0.025 \times 10^3$ at 283 mμ, while that of N-acetyl-L-tryptophan ethyl ester is $6.31 \pm 0.045 \times 10^3$ at 283 mμ. Thus, the hypochromism would further indicate indole–indole interactions. This interaction is also indicated by the low quantum fluorescence yield found for this polypeptide (29). In DMSO, where the polymer was thought to be random, the molar extinction coefficient was found to be 5.9×10^3 (288 mμ), while N-acetyl-L-tryptophan ethyl ester had a molar extinction coefficient of 6.2×10^3 (283 mμ). These values would indicate that the polymer exhibits hypochromicity in DMSO but not quite so large as found in DMF. This would imply that some secondary structure still persists in DMSO. These values for the molar extinction coefficient disagree with those published previously (30). However, as in the case of the b_0 value, the values were obtained with low molecular weight polymers that probably have an insufficient degree of polymerization to maintain a stable secondary structure.

A comment regarding the reported optical titration of poly-L-tryptophan in DMF with DCA (15) is in order. A sharp change in $[\alpha]_{546}^{20}$ occurred between 40–60% (by volume) DCA–DMF. A conformational transition was implied. However, the solvent properties of DMF–DCA (31) mixtures must be evaluated before the above conclusion can be accepted. In DMF–DCA mixtures the viscosity of the solutions increased as DCA was added to DMF until a DCA–DMF (75:25 v/v) composition was reached, and then the viscosity decreased again upon further addition of DCA. This maximum in the viscosity is consistent with the formation of complexes between the two components (32). Similar behavior has been reported for the systems water–dimethylacetamide (33) and DMF–H_2SO_4 (34). Thus, the solvents used in the optical titration are interacting and doubts can be raised concerning the interpretation of the changes in rotation.

SUMMARY

It has been shown that poly-L-tryptophan, despite its positive b_0 value, is a right-handed helix. This is concluded from the linear b_0 relationship of copolymers with γ-benzyl-L-glutamate and the observation of the negative 233 mμ Cotton effect usually found in right-handed helical polypeptides. The additional Cotton effect in the polymer in the 270–300 mμ region, compared to the monomer, and the hypochromism found, probably indicate a conformational-dependent interaction between indole residues, which probably stack in a helical array, or interact with the backbone peptide bonds.

This study also illustrates that great caution should be exercised in the interpretation of an altered b_0 value by the interaction of a chromophore, such as a coenzyme, with an asymmetric molecule, e.g. with an enzyme. A change in b_0 produced by the binding of a chromophore to an asymmetric region does not necessarily imply a conformational change and can be caused by conditions similar to the case studied herein. Such binding produces Cotton effects that may dominate the rotations far from the absorption maximum of the bound moiety and yield misleading b_0 values.

EXPERIMENTAL

Methods

Measurements of the optical rotation of the polymers in DMF* solutions were performed with two polarimeters. For copolymers with less than 20 mole % tryptophan a Rudolf high-precision photoelectric spectropolarimeter, model 800/200AS/759, equipped with a Beckman DU monochromator was used. The light source was a Hanovia (Newark, New Jersey) 150-W d-c. Xenon arc (No. 901C1), cooled by means of a water-jacketed housing. The symmetrical angle used was 3.5° and the wavelength range investigated was

**Reagent grade, Spectro quality, Matheson Coleman and Bell.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

365–589 mμ. Polarimeter tubes of 1 or 2 dm path length were used with concentrations of about 0.5% of the polymer. For copolymers containing more than 20 mole % tryptophan a Bendix–Ericcson Polarimatic-62 automatic spectropolarimeter* with a 150-W d-c. Xenon arc (No. 901C1 Hanovia) was used. The dispersions were performed with a slit of 1 mm. The recorder attachment employed was a Sargent recorder model SR. One-centimeter fused quartz cells were used, having been selected for minimal birefringence.† Concentrations used were in the range 0.10–0.15% and readings were taken in the range 500–300 mμ. Films were made by placing a drop of a dilute DMF polymer solution on the optical face of a 1-mm quartz cell and evaporating the solvent under reduced pressure. All measurements were made at 24°.

Calculation of Rotatory Data

In the spectral region 300–600 mμ, the coefficient, b_0, of the second term in the Moffitt equation (4)

$$[m']_\lambda = \frac{a_0\lambda_0^2}{\lambda^2 - \lambda_0^2} + \frac{b_0\lambda_0^4}{(\lambda^2 - \lambda_0^2)^2}$$

was derived from the slope of the plot $[m'][\lambda^2 - \lambda_0^2]$ vs. $[\lambda^2 - \lambda_0^2]^{-1}$ as suggested by Moffitt and Yang (5). The refractive index dispersion of DMF was obtained from tables (3). The value of $\lambda_0 = 212$ mμ was used. The o.r.d. data in Fig. 4 are expressed in terms of $[m']_\lambda$, the reduced mean residue rotation (1, 3), defined as

$$[m']_\lambda = [\alpha]_\lambda\left(\frac{\text{m.r.w.}}{100}\right)\left\{\frac{3}{n_\lambda^2 + 2}\right\},$$

where $[\alpha]_\lambda$ is the specific rotation at wavelength λ, m.r.w. is the mean residue weight, and n_λ is the refractive index of the solvent at wavelength λ.

Viscometry

Reduced specific viscosities were determined at a concentration of 0.2 g/100 cc in Cannon-Fenske Ostwald viscometers with flow time always exceeding 90 s. All measurements were made at 25 ± 0.1°.

Absorbance Measurements

Optical density measurements were made on a Cary model 14 recording spectrophotometer. For the determination of the molar extinction coefficients, concentrations of $\simeq 1.5 \times 10^{-4}$ *M* were used in a 1-cm cell.

L-*Tryptophan-N-carboxyanhydride*

Nitrogen was passed through dioxane‡ (500 ml) for 90 min in a three-necked 100-ml round-bottomed flask fitted with a thermometer, a gas inlet tube, and a reflux condenser with a gas outlet tube. L-Tryptophan (Calbiochem. grade A) (10 g, 0.049 mole) was added with stirring. Phosgene, first passed through H_2SO_4, was bubbled through the stirred solution, which was kept at 40°, for 90 min. The condenser was removed and dry nitrogen was passed through the clear colored solution (kept at 30 to 35°) until the solution was phosgene free. The solvent was removed on a rotatory evaporator at 40°. The resulting oil was dissolved in dry acetone§ (100 ml) and evaporated to dryness. The oil was dissolved in dry acetone (200 ml) Ag_2O (30 g), celite (15 g), and steel balls (2 doz) were added and the mixture rolled in a 2-l polyethylene bottle for 24 h at 4°. The solution was filtered through celite and the acetone was removed under reduced pressure (temperature maintained at 40°), yielding a thick oil. The oil was dissolved in dry ethyl acetate (400 ml), and *n*-hexane (1 600 ml) was added to the solution, causing heavy opalescence. The solution was then filtered through celite and the filtrate was placed at −20°. When the solution had cooled, *n*-hexane (100 ml) was added, causing crystallization. *n*-Hexane (1 200 ml) was added in several portions. The slightly colored crystals (6 g) were dissolved in ethyl acetate (240 ml), *n*-hexane (660 ml) was added to opalescence, the solution was filtered through celite, and *n*-hexane (2 000 ml) was added to the filtrate in several portions. L-Tryptophan-NCA crystallized out when the solution was allowed to stand at −20°. The crystals were filtered and dried *in vacuo* (1 mm Hg) at −20°, m.p. 145–146° (corrected). Yield: 4 g (35.2%). The supernatants yielded another 2.2 g of crystals. Total yield: 55%.

Anal. Calcd. for $C_{12}H_{10}O_3N_2$: C, 62.61; H, 4.38; N, 12.17. Found: C, 62.3; H, 4.3; N, 12.1.

*Poly-*L*-tryptophan*

L-Tryptophan-NCA (0.202 g, 8.70×10^{-4} mole) was dissolved in a dry dioxane (5 ml) by warming. Sodium methoxide (0.047 ml of 0.373 *N*, A/I = 50) was added with stirring, and the solution allowed to stand for 3 days, after which time the polymer had precipitated out of the viscous solution. The polymer was isolated by pouring the reaction mixture into anhydrous ether (25 ml), washed 3 times with anhydrous ether, and dried at 80° for 2 h *in vacuo* (1 mm Hg). Yield: 0.15 g (93%). $\eta_{sp}/c = 1.69$ ($c = 0.2\%$ in DMF).

Poly-L-tryptophan is insoluble in trifluoroethanol, methanol, acetonitrile, and dioxane. Higher molecular weight polymers were also insoluble in DMF.

Poly-γ-benzyl-L-glutamate

γ-Benzyl-L-glutamate-NCA (36) (0.6 g, 2.28×10^{-3} mole) was dissolved in dry benzene (1%) by warming. Sodium methoxide (0.355 ml, 0.355 *N*, A/I = 200) was added and the solution allowed to stand for 3 days. The polymer was isolated and treated in the same manner as poly-L-tryptophan. $\eta_{sp}/c = 6.3$ ($c = 0.2\%$ in DMF); $\eta_{sp}/c = 1.5$ ($c = 0.2\%$ DCA).

Copolymers of γ-Benzyl-L-glutamate and L-Tryptophan

Example: Copoly (γ-BLGlu:L-Tryp) (90:10). γ-Benzyl-L-glutamate-NCA (0.183 g, 6.95×10^{-4} mole), dissolved by warming in dry benzene (18 ml), was mixed with L-tryptophan-NCA (17.7 mg, 7.73×10^{-5} mole) and dissolved in dry dioxane (1.8 ml). The polymerization was initiated by the addition of sodium methoxide (0.09 ml, 0.345 *N*, A/I = 25) and the reaction mixture was allowed to stand for 2 days. The slightly viscous solution was slowly added to 5 times its volume of *n*-hexane with stirring. The polymer, which separated out as a fibrous material, was lyophilized from dioxane and dried under vacuum (1 mm Hg) at 80° for 2 h. Weight = 0.106 g; yield, 64%. $\eta_{sp}/c = 0.8$ ($c = 0.2\%$ DMF).

The other copolymers of γ-benzyl-L-glutamate and L-tryptophan were prepared in the same manner by varying the mole ratios of the two anhydrides. γ-Benzyl-L-glutamate-NCA (1% in benzene) and tryptophan-NCA (1% in dioxane) were mixed to yield the following compositions: 90:10, 80:20, 50:50, 20:80, 10:90. The copolymers (γ-benzyl-L-glutamate:L-tryptophan, 20:80 and 50:50) (both at A/I = 25) were not soluble in DMF ($c = 0.2\%$); so the A/I was decreased to 10. The conditions of polymerization, the viscosities, the estimated weight average molecular weights, and the optical properties are listed in Table I.

Poly-L-tryptophan Films

A few milligrams of polymer were dissolved in ca. 1 cc of DMF by heating the mixture on a steam bath for several hours. The solution was filtered through a sintered-glass funnel (medium porosity). A drop of the solution was placed on the outside optical surface of a 1-mm fused quartz cell and the cell placed in a vacuum desiccator which was evacuated on a water aspirator. The solution slowly evaporated, leaving a polymer film. The observed rotation varied according to the cell position. This was probably due to the uneven thickness of the film or to orientation of the film as it dried.

ISOBENZOFURANE,[1] A TRANSIENT INTERMEDIATE

LOUIS F. FIESER AND MAKHLUF J. HADDADIN
Chemical Laboratory, Harvard University, Cambridge, Massachusetts
Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

A study of Diels–Alder reactions of tetraphenylcyclopentadienone (II) coupled with development of two improved procedures for the generation of benzyne, one of which affords a practical route to the reactive dienophile 1,4-dihydronaphthalene-1,4-*endo*-oxide (I*a*), led to an investigation of the reaction of I*a* and II. At 80° these reactants combine readily to give the adduct III*a*, which is cleaved on pyrolysis to isobenzofurane VIII*a* and 1,2,3,4-tetraphenylbenzene (IX). The transient existence of isobenzofurane (VIII*a*) was established by trapping it with the 1,4-*endo*-oxide I*a* and isolation of the adducts X and XI. In confirmation of the interpretation, X and XI were obtained by independent synthesis from the adduct V*a* from I*a* and α-pyrone and thermal decomposition of V*a* in the presence of I*a* as trapping agent. Parallel experiments with 1,4-dimethyl-1,4-dihydronaphthalene-1,4-*endo*-oxide, as well as mixed additions, supported the interpretations advanced. Evidence is presented to show that isobenzofurane (VIII*a*) invariably adds *exo* to the bicyclic dienophile.

The background for this work was provided by the development of improved procedures suitable for use as student experiments (1). Diels–Alder reactions pertinent to the present discussion, and procedures for the preparation of intermediates, are recorded in the Experimental part and will be mentioned only briefly here. Tetraphenylcyclopentadienone is a particularly favorable diene for experimentation because termination of a reaction is evident from discharge of the intense purple color. Thus reaction of the dienone with dimethyl acetylenedicarboxylate with evolution of carbon monoxide is complete in 1–2 mins in refluxing *o*-dichlorobenzene, b.p. 179°. Reaction of the dienone with diphenylacetylene to form hexaphenylbenzene can be carried out satisfactorily without solvent (2) only on a small scale because the melting point of the hydrocarbon (455°) is somewhat above the temperature required for its formation. In this case a satisfactory solvent was found in benzophenone (b.p. 306°); the reaction is complete in about 45 min and addition of a little diphenyl ether prevents solidification of the solvent on cooling.

One of two procedures for generation of benzyne proved suitable for preparation of the dienophile required for the present work.

LeGoff (3) introduced diphenyliodonium-2-carboxylate as a benzyne precursor, and we were able to improve both the procedure for preparing the reagent (3, 4) and that for its reaction with tetraphenylcyclopentadienone to such an extent that a student can complete the synthesis of 1,2,3,4-tetraphenylnaphthalene in an afternoon. LeGoff conducted the reaction at a temperature of about 165° and had the task of separating the reaction product from the dienone by chromatography; we ran the reaction in a higher-boiling solvent, used enough benzyne precursor to combine with all the dienone, and so obtained pure 1,2,3,4-tetraphenylnaphthalene by simple crystallization. However, the method proved unsuitable for application to a low-boiling diene such as furane.

[1]*For reasons set forth in L. F. Fieser and M. Fieser, Style Guide for Chemists, L. F. F. strongly advocates this spelling. While he also advocates formula numbers set in boldface arabic type, this practice is inconsistent with the style of this journal. Preliminary communication: J. Am. Chem. Soc. 86, 2081 (1964).*

For personal use only.

A new route to benzyne described by Friedman (5) consists in diazotization of anthranilic acid with isoamyl nitrite in an aprotic solvent in the presence of a diene; the benzenediazonium-2-carboxylate decomposes to benzyne as it is formed. We found that the reaction proceeds particularly well in 1,2-dimethoxyethane as solvent and developed a student preparation of triptycene (1), a second efficient synthesis of 1,2,3,4-tetraphenylnaphthalene, and a simple method for the reaction of benzyne with furane to produce 1,4-dihydronaphthalene-1,4-*endo*-oxide (I*a*, chart below), previously obtained by shaking a solution of *o*-fluorobromobenzene in furane with lithium amalgam for 4 days (6). Generation of benzyne in the presence of 2,5-dimethylfurane similarly afforded 1,4-dimethyl-1,4-dihydronaphthalene-1,4-*endo*-oxide (7).

It is evident that, with this background, we were interested in the report by Wolthuis (7) that 1,4-dihydronaphthalene-1,4-*endo*-oxide (I) is an effective dienophile for simple dienes and decided to investigate its reaction with tetraphenylcyclopentadienone (II). A solution of the reactants in diglyme was refluxed in the expectation that, at this temperature (165°), the adduct III would lose carbon monoxide and afford the tetrahydrotetraphenylanthracene-*endo*-9,10-oxide VI. A vigorous reaction ensued with gas evolution and with discharge of the color in 2 min. Dilution with water precipitated a colorless crystalline product, m.p. 190°, characterized by the n.m.r. spectrum as having only aromatic hydrogens and found by elemental analysis to be a hydrocarbon. The possibility that the product might be 1,2,3,4-tetraphenylanthracene was eliminated by synthesis of the latter (m.p. 295°) by aprotic diazotization of 3-amino-2-naphthoic acid in the presence of tetraphenylcyclopentadienone (II). Other ideas about the nature of the product were dismissed by the finding that 1,4-dimethyl-1,4-dihydronaphthalene-1,4-*endo*-oxide (I*b*) reacts with (II) to give the same aromatic hydrocarbon and this eventually was identified as 1,2,3,4-tetraphenylbenzene (IX) (8). Since this hydrocarbon must result from thermal decomposition of an intermediate, the reaction of I*a* with II was repeated in refluxing benzene. There resulted, in high yield, a colorless product melting at 182–184° (decomp.) and corresponding in analysis to the adduct III*a*. This structure is supported by the ultraviolet spectrum, which contains bands at 275 and 223 mμ (ϵ 11 400 and 35 000) characteristic of a *cis*-stilbene system, by infrared carbonyl absorption at 1 775 – 1 780 cm^{-1}, and by the n.m.r. spectrum: singlet at τ 4.72 (C_9 and C_{10} protons); singlet at τ 7.09 (C_{9a} and C_{10a} protons); multiplet at τ 2.6–2.9 (10 protons of the C_2 and C_3 phenyl groups and 4 protons of the *o*-disubstituted benzene ring); singlet at τ 3.17 (10 protons of the C_1 and C_4 phenyl groups). The fact that the C_9 and C_{9a} protons did not split each other furnishes evidence of an *exo* attack by II at the double bond of I*a* (9, 10).[2] There is no evidence of the configuration at C_1 and C_4, but the high melting point suggests that the carbonyl bridge is in the *exo* orientation to give the symmetrical structure formulated.

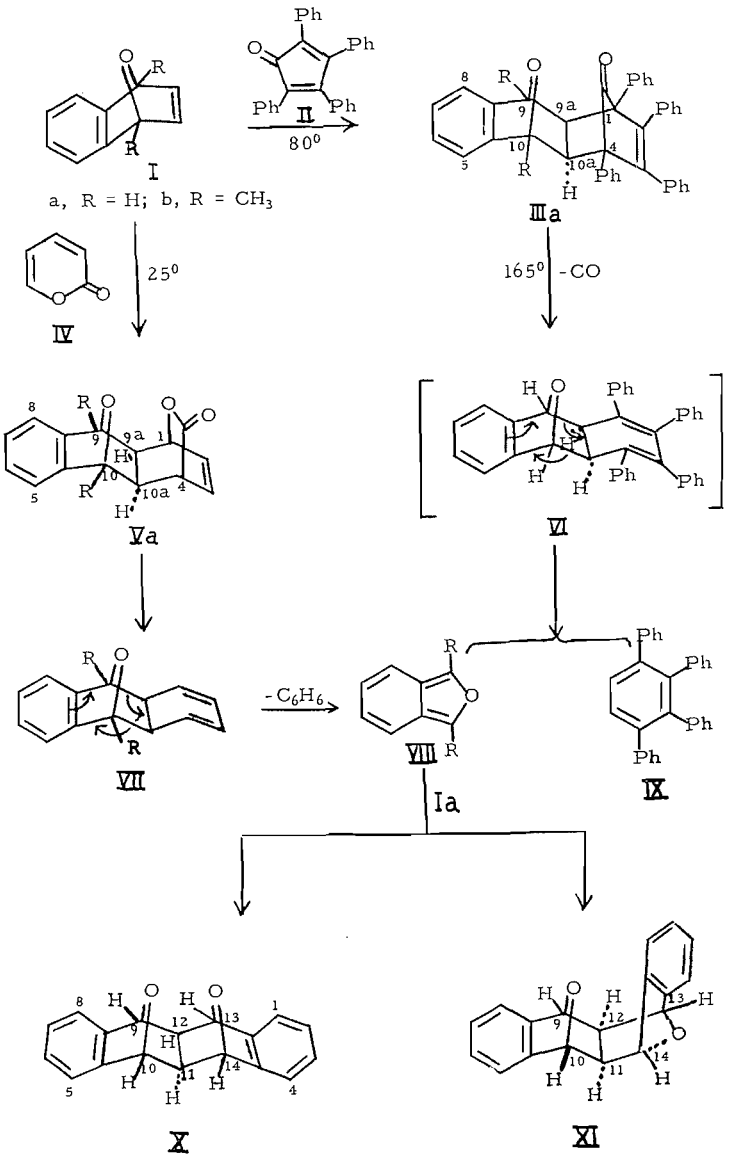
Adduct III*a* decomposed rapidly at the melting point with evolution of carbon monoxide and formation of tetraphenylbenzene (IX) as the only isolated product. We believe that elimination of carbon monoxide gives tetrahydrotetraphenylanthracene-*endo*-9,10-oxide (VI), and that this suffers retrogressive Diels–Alder reaction (11)[3] to isobenzofurane (VIII) and tetraphenylbenzene (IX).

Isobenzofurane (VIII) is unknown and all efforts to isolate it as a product of pyrolysis or to synthesize it thus far have proved fruitless. Nevertheless, its transient existence was

[2]*This conclusion is based on the dependence of the coupling constant for vicinal protons on the dihedral angle (9). For other examples see ref. 10.*

[3]*Comparable reactions are described (11) by Mackenzie and by Wittig and Härle.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



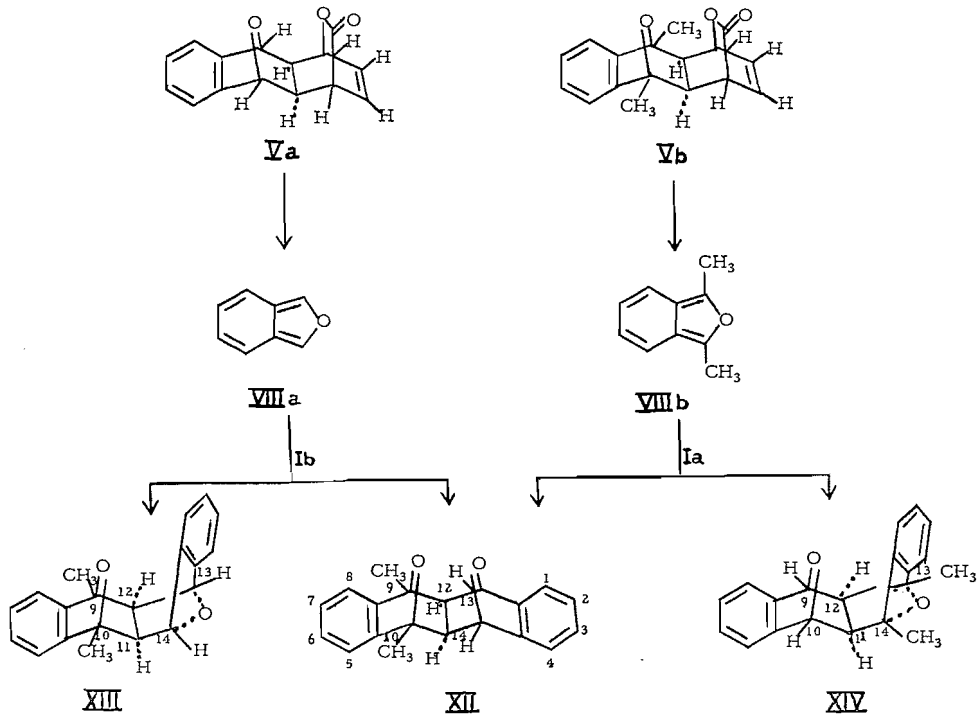
demonstrated by decomposing the adduct III*a* in refluxing diglyme in the presence of the *endo*-1,4-oxide I*a* as trapping agent and isolation of the *exo*, *exo*- and *exo*, *endo*-adducts X and XI, along with tetraphenylbenzene (IX). This hydrocarbon and the *exo*, *endo*-adduct XI are soluble in benzene, in which the *exo*, *exo*-adduct X is practically insoluble; IX and XI are separated easily by chromatography on neutral alumina. The total yield is 91% and the ratio of X to XI is 10:14.

Product X was characterized as follows: m.p. 264–265°; n.m.r.: singlets at τ 2.92 and 2.98 (eight aromatic protons); singlet at 4.59 (four allylic protons adjacent to oxygens); singlet at 8.02 (protons at C_{11} and C_{12}). The high melting point is consistent with the high symmetry of structure X. Product XI, m.p. 175–176°, was characterized as follows: singlets at τ 2.9 and 3.05 (eight aromatic protons); singlet at 5.48 (allylic protons at C_9

and C_{10} next to oxygen); unsymmetrical quartets at 4.85 and 7.35 (J = 2 c.p.s.), two protons each at C_{13}—C_{14} and at C_{11}—C_{12}, probably due to vicinal and long-range coupling (12). The fact that the n.m.r. spectrum of X shows no observable coupling between the protons at C_{10} (or C_{14}) and C_{11} (singlet), whereas that for XI shows coupling between the C_{11} and C_{14} protons but not between the C_{10} and C_{11} protons confirms the assignments *exo, exo* for X and *exo, endo* for XI (9, 10).

The structures assigned were confirmed by an independent synthesis from I and α-pyrone[4] (IV), a diene which is more reactive than II and which combines with I at room temperature to form the adduct V*a* in 95% yield. This adduct, m.p. 105–107°, which decolorizes permanganate and bromine solution, is characterized as follows. Infrared: 1 750 (carbonyl), 1 635 cm^{-1} (C=C); n.m.r.: singlet at τ 3 (four aromatic protons); triplet at 3.6 (two olefinic protons); multiplet at 4.62–5.06 (three allylic protons adjacent to oxygen); multiplet at 6.26–6.44 (C_4-proton); symmetrical quartets at 7.3–7.5 and at 7.73–7.92 (one proton each, probably those at C_{10a} and C_{9a}).

Adduct V*a* decomposes on recrystallization or on long standing at room temperature. When the adduct was added to a hot solution of the *endo*-1,4-oxide I*a* in diglyme and the solution kept at 130° for 2 min, bis-oxides X and XI were isolated in total yield of 81–85%, with carbon dioxide and benzene as by-products. The oxidolactone V*a* on being



heated decomposes with evolution of carbon dioxide and, presumably, the unstable intermediate VII, which rearranges to yield benzene and isobenzofurane (VIII). The fact that X and XI result from two different reactions indicated a common intermediate, namely isobenzofurane (VIII). The n.m.r. data reported above for X show no splitting

[4]*Prepared by a procedure submitted to Org. Syn. by H. E. Zimmerman, G. L. Grunewald, and R. M. Paufler.*

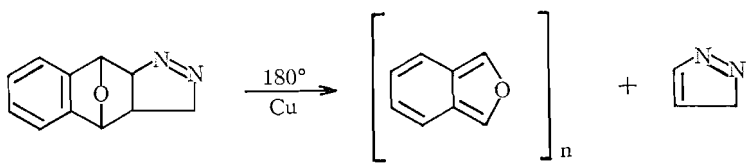
For personal use only.

between C_{11} and C_{10} or (and) C_{14} protons, which means that the addition of isobenzofurane (VIII*a*) must take place from the *exo* side of I*a* (9, 10). This argument does not hold in the case of XI because of the difficulty of identifying the portion of the molecule that belongs to the isobenzofurane substrate.

Analogous reactions starting with 1,4-dimethyl-1,4-dihydronaphthalene-1,4-*endo*-oxide (I*b*) are recorded in the Experimental part. Another set of experiments can be described as involving mixed additions, that is, generation of isobenzofurane (VIII*a*) in the presence of the 1,4-dimethyl-1,4-*endo*-oxide (I*b*), and generation of 1,3-dimethylisobenzofurane (VIII*b*) in the presence of the parent 1,4-*endo*-oxide (I*a*). As expected, each reaction gave a pair of products, one of which was common to both reactions. The product common to both reactions, the dihydrogen–dimethyl derivative XII, has a n.m.r. spectrum showing singlets for the C_{11} and C_{14} protons, which supports the evidence for *exo* attack of the double bond of I*b*. The n.m.r. of adduct XIII shows the same nonsplit pattern of the C_{11} and C_{14} protons as in adduct XI. For the isomeric adduct XIV, the n.m.r. evidence also is consistent with an *exo* addition of VIII*b* to I*a* (see Experimental section) (9, 10).

The substituent methyl groups of 1,3-dimethylisobenzofurane (VIII*a*) exert a control over the addition of this substance to the 1,4-dimethyl-1,4-*endo*-oxide (I*b*), for the sole product is the *exo, endo* adduct (the 13,14-dimethyl derivative of XIII). Inspection of models shows that the methyl groups exert substantial hindrance to an *exo, exo* approach.

This is the first report identifying isobenzofurane and 1,3-dimethylisobenzofurane as unisolated trapping agents. Wittig and Härle (11) reported the formation of polymeric isobenzofurane on heating XV at 180° with copper powder.



XV XVI XVII

EXPERIMENTAL[5]

Tetraphenylcyclopentadienone (L. F. F.)[6]

A mixture of 21 g of benzil, 21 g of dibenzyl ketone, and 100 ml of triethylene glycol was heated over a free flame to dissolve the solid, the temperature was adjusted to 100°, 10 ml of a 40% solution of benzyltrimethylammonium hydroxide was added, and the flask was swirled once for mixing and then let stand. Within 15–20 s the liquid set to a stiff paste of purple crystals and the temperature rose to 115°. When the temperature dropped to 80°, the mixture was cooled and thinned with 50 ml of methanol and the product was collected and washed with methanol; yield 35.5 g (93%), m.p. 219–220°. Recrystallization can be accomplished with 92% recovery by dissolving the ketone in triethylene glycol (10 ml per g) at 220°.

Dimethyl Tetraphenylphthalate (L. F. F.) (2)[7]

A mixture of 2 g of tetraphenylcyclopentadienone, 1 ml of dimethyl acetylenedicarboxylate, and 10 ml of *o*-dichlorobenzene was refluxed gently in a test tube until the color changed from purple to pale tan (about 5 min). The solution was cooled to 100°, 15 ml of 95% ethanol was stirred in, and the solution let stand for crystallization. The yield of colorless crystals, m.p. 257–258°, was 2.2 g (89%).

Hexaphenylbenzene (L. F. F.) (2)

A mixture of 8 g of tetraphenylcyclopentadienone, 8 g of diphenylacetylene, and 40 g of benzophenone was refluxed over a microburner so that it refluxed briskly but without flooding a short air condenser (liquid-phase temperature 301–303°). Carbon monoxide was evolved, the purple color began to fade in 15–20 min and changed to reddish brown in 25–30 min and then lightened slightly. After 45 min the burner was

[5]*Except as noted, the experiments were done by M. J. H. Nuclear magnetic resonance spectra were determined in deuterated chloroform with hexamethyldisiloxane as internal reference set at τ 9.91.*

[6]*Compare Org. Syn., Coll. Vol. 3, 806 (1955).*

[7]*Compare preparation of the anhydride, Org. Syn., Coll. Vol. 3, 807 (1955).*

For personal use only.

removed, 8 ml of diphenyl ether was added, the mixture was reheated to dissolve crystals that separated, and the solution was let stand for crystallization at room temperature. The product, collected and washed free of brown mother liquor with benzene, was obtained as colorless plates, m.p. 454–456° (in a sealed capillary);[8] yield 9.4 g (85%). A satisfactory solvent for recrystallization is diphenyl ether (7 ml per g).

Diphenyliodonium Carboxylate (L. F. F. and M. J. H.) (3, 4)

A three-necked 2-l flask containing 20 g of *o*-iodobenzoic acid and 26 g of potassium persulfate was cooled in an ice bath, 80 ml of ice-cold concentrated sulfuric acid was added, and the mixture was swirled in the ice bath for 4–5 min to check the exothermal reaction and produce an even suspension. The time was noted and the flask removed and mounted in a pan of acetone, a stirrer with a curved Teflon blade was put in place and operated slowly, and a 250-ml dropping funnel was mounted to deliver into a side opening. Three flasks were put into an ice bath to cool: one containing 190 ml of distilled water, another 230 ml of 29% ammonium hydroxide, and another 400 ml of methylene chloride. After the oxidation had proceeded for 20 min, the cooling bath was brought to 10° by addition of crushed dry ice and the solution was stirred for 2–3 min before addition of 20 ml of thiophene-free benzene. Stirring at 10° was continued for 1 h to complete the reaction and the temperature of the cooling bath was kept at −15° while the chilled water was run in under efficient stirring; this precipitates the potassium salt of diphenyliodonium-2-carboxylic acid. The chilled methylene chloride was added for efficient extraction of the product as it is liberated on neutralization, and a 100° thermometer was mounted in a side opening. With efficient cooling (−15°) and stirring, the chilled ammonia solution was run in at an inner temperature of 15–25° in about 10 min. The aqueous layer should be alkaline to test paper (pH 9). The layers were separated and the aqueous layer extracted with two 100-ml portions of methylene chloride. Evaporation of the combined and dried extract afforded 23.3 g of crude material, m.p. 206–208° (decomp.). Crystallization from boiling water (275 ml), after clarification with Norit and cooling at 0°, gave 21.8 g (79%) of colorless prisms of diphenyliodonium-2-carboxylate monohydrate, m.p. 221–222° (decomp.).

Anal. Calcd. for $C_{13}H_9OI \cdot H_2O$ (342.13): C, 45.63; H, 3.24; I, 37.10. Found: C, 45.48; H, 3.19; I, 37.16.

1,2,3,4-Tetraphenylnaphthalene, Method A (L. F. F. and M. J. H.)

A 100-ml round-bottomed flask was charged with 10 g of tetraphenylcyclopentadienone, 11.8 g of diphenyliodonium-2-carboxylate monohydrate, and 60 ml of Eastman's *mp*-diethylbenzene (b.p. 175–181°), and fitted with an 11-cm water-cooled condenser designed as a bearing for a stirrer (Ace Glass 8244 Bearing 24/40). The flask was heated with the free flame of a microburner and the refluxing liquid let rise well into the condenser. When a cloudy zone of condensate appeared at the top, the moisture was removed with an applicator stick wrapped with absorbent cotton; by this technique the water of hydration (which does not appear to react with benzyne) was eliminated in 8–10 min. After 30 min considerable undissolved precursor could still be seen, under illumination, at the bottom of the flask. In another 5 min the color changed to transparent red, and in 1–2 min the solution became pale yellow. Refluxing was continued until the solid was all destroyed (5–10 min), and the flask was connected by means of an Ace Glass 5235 adapter to a condenser and 55 ml of liquid (solvent and iodobenzene) was removed by distillation. After it was cooled, the residue was dissolved in 25 ml of dioxane and the solution rinsed into an Erlenmeyer and diluted with 25 ml of 95% ethanol. The solution was then heated at the boiling point and water was added gradually (6–7 ml) until a few shiny prisms remained undissolved on boiling. Crystallization at room temperature and then for several hours at 0° afforded a product which melts initially in the range 196–199°, solidifies on cooling, and remelts sharply at 203–204°.[9] The yield is 10.3 g (91.6% based on the dienone), which represents 68.7% utilization of the benzyne precursor.

1,2,3,4-Tetraphenylnaphthalene, Method B

Solutions of 1.5 g of anthranilic acid and 2 ml of isoamyl nitrite, each in 15 ml of 1,2-dimethoxyethane, were added simultaneously by drops to a refluxing solution of 3.84 g of tetraphenylcyclopentadienone in 30 ml of 1,2-dimethoxyethane over a period of about 45 min. Evaporation of the solvent on the steam bath with evacuation at the water pump and trituration of the yellowish residue with methanol gave 4.05 g (93%) of white solid, m.p. 196–199°. Crystallization from dioxane–ethanol–water gave prisms of sharp remelt temperature 203–204°.

1,4-Dihydronaphthalene-1,4-endo-oxide

Solutions of 20 ml of isoamyl nitrite in 20 ml of 1,2-dimethoxyethane and of 13.7 g of anthranilic acid in 45 ml of 1,2-dimethoxyethane were added simultaneously by drops to a refluxing mixture of 50 ml of 1,2-dimethoxyethane and 50 ml of furane in a period of 1 hour. Refluxing was continued for 10 min and the brown solution was cooled, made basic with sodium hydroxide, and extracted with petroleum ether. The extract was washed thoroughly with water, clarified with Norit, dried, and evaporated to give an oil which

[8]*Determined with a Mel-Temp apparatus, Laboratory Devices, P. O. Box 68, Cambridge, Mass. 02139. The figure 456° is the average of two determinations of the temperature of melting; 454° is the average of two determinations of the point of solidification.*

[9]*The double melting point was observed also by Herwig, Metlesics, and Zeiss (13). The initial melting point varies with the state of subdivision and is not a reliable index of purity. Several recrystallizations did not change the melting behavior or the remelt temperature.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solidified on cooling to give 7.4 g of crude, yellowish oxide (51% based on anthranilic acid). Crystallization from petroleum ether gave colorless, hard needles, m.p. 56° (53–54.5 (6); 56° (7)).

1,4-Dimethyl-1,4-dihydronaphthalene-1,4-endo-oxide

Diazotization of 13.7 g of anthranilic acid with isoamyl nitrite in 1,2-dimethoxyethane in the presence of 2,5-dimethylfurane was conducted by the same procedure and the product, a yellow liquid, distilled at 120° at 35 mm; yield 10.6 g (67.5%). The n.m.r. spectrum showed singlets at τ 8.66 (six methyl protons), and τ 3.43 (two olefinic protons), and a symmetrical multiplet at τ 3.13 (four aromatic protons).

1,2,3,4-Tetraphenylanthracene

Solutions of 1.9 g of 3-amino-2-naphthoic acid in 20 ml of 1,2-dimethoxyethane and of 3 ml of isoamyl nitrite in 20 ml of the same solvent were added simultaneously by drops to a refluxing solution of 3.84 g of tetraphenylcyclopentadienone in 50 ml of 1,2-dimethoxyethane. The solvent was evaporated at reduced pressure and the red residue was adsorbed from benzene on a column of 90 g of neutral alumina. Elution with 1:1 petroleum ether – benzene afforded 3.7 g of faintly yellow powder, m.p. 292–294° (evacuated capillary); 73% yield based on 3-amino-2-naphthoic acid. Elution with ether afforded 0.55 g of unreacted tetraphenylcyclopentadienone (yield based on the latter, 81.8%). Recrystallization from benzene–methanol gave shiny yellowish prisms, m.p. 293–295° (evacuated capillary), with 95% recovery.

Anal. Calcd. for $C_{38}H_{26}$ (482.58): C, 94.58; H, 5.42. Found: C, 94.51; H, 5.44.

1,2,3,4-Tetraphenyl-1,4-carbonyl-9,10-oxido-1,4,9,9a,10,10a-hexahydroanthracene (IIIa)

A solution of 1.92 g of tetraphenylcyclopentadienone and 1,4-dihydronaphthalene-1,4-*endo*-oxide in benzene was refluxed until the purple color disappeared (1.5 h) and the benzene was evaporated. Trituration of the residue with methanol gave a white solid which, when collected, washed with methanol, and dried, weighed 2.58 g (97.6%), m.p. 182–184° (decomp.). Crystallization from benzene–methanol raise dthe melting point to 184–185° (decomp.) (other physical constants already reported).

Anal. Calcd. for $C_{39}H_{28}O_2$ (528.61): C, 88.61; H, 5.34. Found: C, 88.68; H, 5.53.

Reaction of IIIa with Ia to give IX, X, and XI

A solution of 464 mg of III*a* and 144 mg of I*a* in 4 ml of diglyme was refluxed for 2 min, cooled, and diluted with water. The solid product was collected and dried and on crystallization from benzene afforded 100 mg of needles of X, m.p. 265°. On chromatography of the mother-liquor material on neutral alumina, 1:1 petroleum ether – benzene eluates gave 250 mg of 1,2,3,4-tetraphenylbenzene (IX) and 1:1 benzene–eluates gave 140 mg of XI, m.p. 175–176°. Recrystallization from methanol did not raise the melting point.

1,2,3,4-Tetraphenylbenzene (IX)

The hydrocarbon melted at 190° and corresponded to the known material (8).

Anal. Calcd. for $C_{30}H_{22}$ (382.48): C, 94.20; H, 5.80. Found: C, 94.30; H, 5.77.

Product X (exo, exo, m.p. 265°)

The spectral characteristics of this and other products are recorded in the theoretical part.

Anal. Calcd. for $C_{18}H_{14}O_2$ (262.29): C, 82.41; H, 5.38. Found: C, 82.23; H, 5.44.

Product XI (exo, endo, m.p. 176°)

Anal. Calcd. for $C_{18}H_{14}O_2$ (262.29): C, 82.41; H, 5.38. Found: C, 82.60; H, 5.40.

1,4-Carbonyloxy-9,10-oxido-1,4,9,9a,10,10a-hexahydroanthracene (Va)

1,4-Dihydronaphthalene-1,4-*endo*-oxide (2.88 g) was dissolved in α-pyrone (2 g) and the solution left to stand at room temperature for 4–5 days, during which time the adduct crystallized. Washing with chilled methanol gave 4.5 g (95%) of directly pure material, m.p. 105–107° (decomp.).

Anal. Calcd. for $C_{15}H_{12}O_3$ (240.25): C, 74.99; H, 5.03. Found: C, 74.92; H, 5.12.

Products X and XI from Va and Ia

A solution of 0.6 g of 1,4-dihydronaphthalene-1,4-*endo*-oxide (I*a*) in 10 ml of diglyme was adjusted to 130°, 1 g of V*a* was added in portions, and the solution was kept at 130° for 2 min and then cooled and diluted with water. The white solid which precipitated was collected, washed, and dried and amounted to 0.95 g (87.5%). Crystallization from benzene gave 300 mg of branch-like crystals melting at 264–265°, not depressed on admixture with XII. The mother liquor was poured onto a column of neutral alumina (prepared with benzene), and elution with benzene afforded 400 mg of product XI. Recrystallized from methanol, the substance formed prisms, m.p. 175–176°; a mixture with the product from I*a* and III*a* showed no melting point depression.

The reaction was also carried out by heating the components neat on the steam bath for 30 min; in this case the ratio of products was close to 1:1.

1,4-Carbonyloxy-9,10-oxido-9,10-dimethyl-1,4,9,9a,10,10a-hexahydroanthracene (Vb)

A solution of 1.72 g of 1,4-dimethyl-1,4-*endo*-oxide I*b* in 1 g of α-pyrone was left to stand a few days and when crystallization was delayed, rubbing or scratching was helpful. The yield of V*b*, m.p. 110–112° (decomp.), was 2.4 g (89%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Anal. Calcd. for $C_{17}H_{16}O_3$ (268.30): C, 76.10; H, 6.01. Found: C, 76.31; H, 6.20.

The fluorescent product partially decomposes on recrystallization. It decolorized bromine in carbon tetrachloride and permanganate solution.

Infrared: 1 655 (C=O), 1 635 (C=C), 1 190, 1 170, 1 010, 975, 940, 865, 840, 800, 763 722 cm^{-1}; n.m.r.: singlet at τ 3.10 (four aromatic protons); quartet at 4.97 (allylic proton next to oxygen); multiplet at 6.5 (allylic proton next to carbonyl group); quartet at 7.91 (C_{10a} proton); singlet at 8.42 (six methyl protons).

1,2,3,4-Tetraphenyl-1,4-carbonyl-9,10-oxido-9,10-dimethyl-1,4,9,9a,10,10a-hexahydroanthracene (IIIb)

A solution of 1 g of tetraphenylcyclopentadienone in 4 ml of 1,4-dimethyl-1,4-dihydronaphthalene-1,4-*endo*-oxide was heated on the steam bath for 36 h and chromatographed on neutral alumina. The products isolated and identified were as follows: 1,2,3,4-tetraphenylbenzene (0.9 g), III*b* (100 mg), and the 13,14-dimethyl derivative of XIII (0.38 g).

Compound III*b*, m.p. 248–249° (decomp.), was characterized as follows: infrared, 1 780 cm^{-1} (C=O); ultraviolet, 275–250, 222 mμ (ϵ 6 550, 3 260).

Anal. Calcd. for $C_{41}H_{32}O_2$ (556.67): C, 88.46; H, 5.79. Found: C, 88.53; H, 5.64.

9,10-Dimethyl-9,10-exo-oxido-13,14-exo-oxido-9,10,11α,12α,13,14-hexahydronaphthacene (XII) and 9,10-Dimethyl-9,10-exo-oxido-13,14-endo-oxido-9,10,11α,12α,13,14-hexahydronaphthacene (XIII)

A refluxing solution of 0.6 g of 1,4-dihydronaphthalene-1,4-*endo*-oxide in 12 ml of diglyme was treated with 1.30 g of V*b* in portions; refluxing was continued for 2 min and the solution was cooled. Dilution with water precipitated a white product which was collected, washed with water, and dried (1.05 g, 87%). On chromatography on alumina, elution with petroleum ether gave 380 mg of product XIII, m.p. 157–159°, and 2:8 petroleum ether – benzene gave 420 mg of XII, m.p. 265–267°.

Product XIII crystallized from methanol in short needles, m.p. 159–160°.

Anal. Calcd. for $C_{20}H_{18}O_2$ (290.34): C, 82.73; H, 6.25. Found: C, 82.69; H, 6.38.

The n.m.r. spectrum showed singlets at τ 2.84, 2.9, and 3.09 (eight aromatic protons); unsymmetrical quartets at 4.9 (C_{13} and C_{14} protons) and 7.32 (C_{11} and C_{12} protons); singlet at 8.5 (six methyl protons).

Product XII crystallized from methanol in shiny flakes, m.p. 268–269°.

Anal. Calcd. for $C_{20}H_{18}O_2$ (240.34): C, 82.73; H, 6.25. Found: C, 82.68; H, 6.40.

The n.m.r. spectrum showed singlets at τ 3.07 (eight aromatic protons) and at 4.65 (C_{13} and C_{14} protons); singlets at 8.14–8.15 (six methyl protons and C_{11} and C_{12} protons).

13,14-Dimethyl-9,10-exo-oxido-13,14-endo-oxido-9,10,11α,12α,13,14-hexahydronaphthacene (XIV) and XII

A solution of 1.1 g of the 1,4-dimethyl-1,4-endo-oxide I*b* in 5 ml of diglyme was heated to boiling and treated with 1.8 g of V*a*, added in portions. On cooling, 0.67 g of product XII separated, m.p. 268–269°. Evaporation of the mother liquor and chromatography afforded 100 mg of product XIV, m.p. 144–146°, and 100 mg more of product XII. The n.m.r. spectrum showed singlets at 2.78 and 2.92 (eight aromatic protons), singlets at 5.45 (C_9 and C_{10} protons), at 7.49 (C_{11} and C_{12} protons), and at 8.25 (six methyl protons).

Anal. Calcd. for $C_{20}H_{18}O_2$ (290.34): C, 82.73; H, 6.25. Found: C. 82.62; H, 6.18.

13,14-Dimethyl Derivative of Product XIII

A solution of 80 mg of 1,4-dimethyl-1,4-dihydronaphthalene-1,4-*endo*-oxide in 1 ml of diglyme was heated to 155° and treated with 100 mg of V*b*. Dilution with water afforded 105 mg of product, which on crystallization from methanol, gave 80 mg (71%) of material, m.p. 202–203°.

Anal. Calcd. for $C_{22}H_{22}O_2$ (318.40): C, 82.98; H, 6.96. Found: C, 82.84; H, 6.90.

Infrared spectrum: 1 270, 1 200, 1 130, 1 070, 880, 860, 772, 754, 680 cm^{-1}; n.m.r. spectrum: singlets at τ 2.84, 3.05, 7.46, 8.3, 8.5.

ACKNOWLEDGMENT

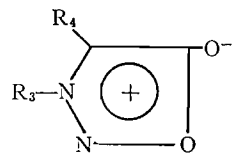
Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

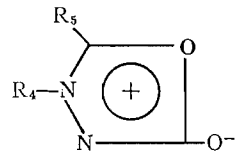
The oxygen–carbonyl isomeric sydnone (V) has been synthesized from 1-benzoyl-1-methylhydrazine hydrochloride (VII) and phosgene. The isosydnone V itself reacts with phosgene to form 2-chloro-5-phenyl-1,3,4-oxadiazole (VI), a new substituted 1,3,4-oxadiazole. Thermal rearrangement of the salt VII takes place at 200° to give 1-benzoyl-2-methylhydrazine, which with phosgene forms the isomer XI. Some mechanistic pathways for these transformations are discussed.

INTRODUCTION

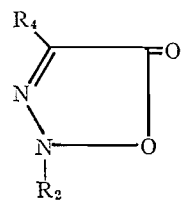
Sydnones I have been investigated extensively (1), but there is only one report (2*a*) on the preparation of the oxygen–carbonyl isomeric system[1] II. The non-mesoionic isomeric system III has not as yet been synthesized.[2] This paper reports the preparation and physical properties of an isosydnone II and an isomer IV.



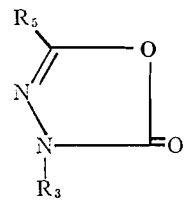
I



II



III



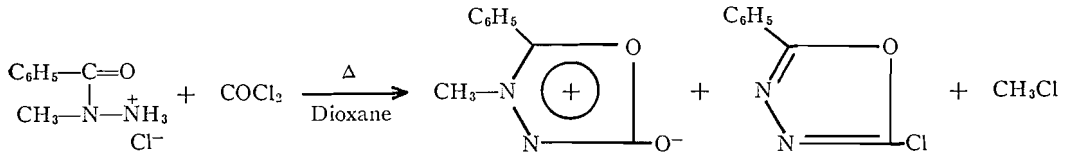
IV

4-Methyl-5-phenylisosydnone (V), together with 2-chloro-5-phenyl-1,3,4-oxadiazole (VI) and methyl chloride, was prepared in about 50% yield from the reaction of 1-benzoyl-1-methylhydrazine[3] hydrochloride (VII) (3) and excess phosgene heated in dioxane for 1 h. The structure of compound V is established by physical measurements and hydrolysis

[1]*Named ψ-2,4-dihydro-4,5-disubstituted 2-keto-1-oxa-3,4-diazole by M. Hashimoto and M. Ohta (2) and indexed in Chem. Abstr. as 5-hydroxy-2,3-disubstituted 1,3,4-oxadiazolium hydroxide, inner salt. For convenience this system will be called isosydnone throughout this paper.*

[2]*G. Sugarman (2b) called this type of compound isosydnone, but we prefer to reserve this name for the mesoionic system II.*

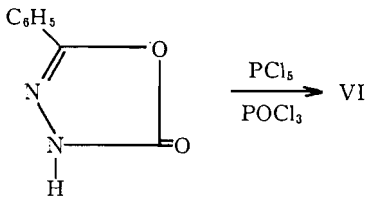
[3]*The n.m.r. spectrum of the free base in 10%* $CDCl_3$ *shows peaks at 2.60, 5.42, and 6.87* τ *in the ratio 5:2:3.*



VII V VI

studies. The nuclear magnetic resonance (n.m.r.) spectrum in 10% deuterochloroform shows peaks at 2.30 and 6.05 τ in the ratio of 5:3. The dipole moment in benzene at 25° is 7.58 ± 0.06 D.[4] Mild hydrolysis of V with sodium hydroxide, followed by hydrochloric acid, gave the starting material VII, showing that no rearrangement had occurred.

Compound VI, isolated from the reaction of VII and phosgene, represents a type of substituted 1,3,4-oxadiazole not previously reported in the literature. The n.m.r. spectrum shows phenyl protons only at 2.0 and 2.4 τ in the ratio of 2:3, and other physical measurements are similar to those of 2-phenyl-1,3,4-oxadiazole (4). Compound VI was prepared by an independent synthesis in very low yield from 2-phenyl-1,3,4-oxadiazolin-5(4H)-one (VIII) and phosphorus pentachloride.



VIII

The following series of experiments (see Experimental) are related to the formation of the products V and VI. (*a*) Compound VII and phosgene heated in dioxane gave a residue that on thin-layer chromatography showed several spots in addition to those of V and VI. (*b*) Compound V and phosgene heated in dioxane gave VI, methyl chloride, and a residue that on thin-layer chromatography showed the same spots as in *a*. (*c*) The free base of VII added to ether containing phosgene very rapidly formed VII and the isosydnone V in high purity. (*d*) Compound VII and phosgene heated in toluene did not dissolve, and starting material only was recovered. (*e*) Reaction of VII and phosgene in dioxane containing pyridine gave the bis compound 1,5-dibenzoyl-1,5-dimethylcarbohydrazide[5] (IX). Compound IX heated in dioxane containing phosgene was recovered

$(C_6H_5CONCH_3NH)_2CO$

IX

unchanged. (*f*) The residue from reaction *a* when allowed to stand in a moist atmosphere gave a small yield of VIII. (*g*) Compound VIII was recovered unchanged when heated with phosgene in dioxane. (*h*) Compound V and hydrogen chloride heated in dioxane did not evolve methyl chloride.

Observations *a*, *b*, *c*, and *d* support the fact that VII in solution and phosgene form V and that V and excess phosgene give rise to the other products formed. Compound VII and phosgene probably form the intermediate X that is rapidly transformed to V. Phosgene may react with V (shown as one of the resonance structures) to form carbon dioxide

[4]*The average value for sydnones is 7–8.8 D (1a).*

[5]*The corresponding 1,5-dibenzoyl-1,5-diphenylcarbohydrazide was obtained by W. Baker et al. (5), by reaction of 1-benzoyl-1-phenylhydrazine hydrochloride and phosgene heated in toluene.*

and the quaternary salt indicated. Such a salt would be expected to lose methyl chloride readily[6] and give VI.

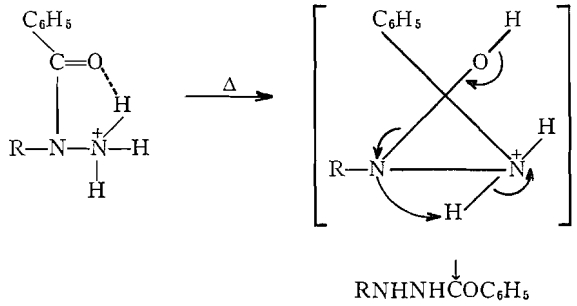
Observation *e* shows that the bis compound IX is not an intermediate in the formation of V from VII. The findings *f*, *g*, and *h* eliminate the idea that V in acidic medium loses methyl chloride to form VIII, and also the possibility that VIII might be intermediate in the formation of VI.

Since the thermal stability of the starting hydrazide salt VII, at an early point in the study, seemed to be of importance, it was investigated. The salt was found to be stable at its melting point of 165°, but heated to 200° it decomposed, forming a clear melt. Nuclear magnetic resonance analysis of the melt showed that VII and its free base were absent, and 1-benzoyl-2-methylhydrazine and its hydrochloride were the products.

$$R{-}N(COC_6H_5)NH_2\cdot HCl \xrightarrow{\Delta} RNHNHCOC_6H_5 + HCl$$

When R is phenyl[7] in the above equation, the N_1 to N_2 rearrangement took place at 210° and gave a quantitative yield of the free base of 1-benzoyl-2-phenylhydrazine.[8]

The reaction would appear to be facilitated by hydrogen bonding in the starting salt and likely passes through the intramolecular intermediate indicated. The product where R is methyl is a base sufficiently strong to retain some of the hydrogen chloride, whereas when R is phenyl none is retained.



[6]*The thermal instability of quaternary pyrazoles is well documented (6).*

[7]*The free base of 1-benzoyl-1-phenylhydrazine is thermally stable to 260°, where it decomposes forming benzanilide and other products (7).*

[8]*Subsequent to our observations, T. Taguchi et al. (8) reported a similar N_1 to N_2 migration.*

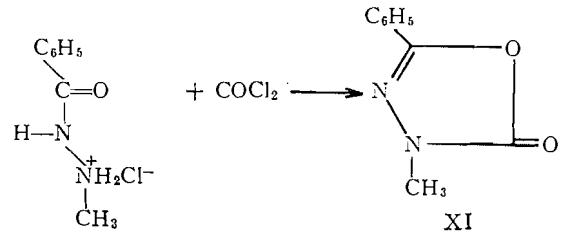
Compound XI, isomeric with the isosydnone V, was prepared from 1-benzoyl-2-methylhydrazine hydrochloride and phosgene and also by alkylation of compound VIII.

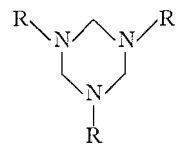


XI

The following reaction sequence was attempted in the hope of obtaining 1-benzoyl-2-methylhydrazine. Benzoic acid hydrazide and formaldehyde gave a product that analyzed for XII,[9] but physical measurements indicated that it was a polymer, most likely the

$$C_6H_5CONHNH_2 + CH_2O \rightarrow C_6H_5CONHN{=}CH_2$$
XII

trimer 1,3,5-tribenzamidohexahydro-*s*-triazine (XIII). The product was reduced catalytically in the presence of acetic acid and formed the desired 1-benzoyl-2-methylhydrazine that was prepared independently from methyl benzoate and methyl hydrazine (3).



(where R is $NHCOC_6H_5$)

XIII

When benzoic acid hydrazide was treated with acetaldehyde, the ethylidene derivative was formed.

$$C_6H_5CONHNH_2 + CH_3CHO \rightarrow C_6H_5CONHN{=}CHCH_3$$

EXPERIMENTAL[10]

1-Benzoyl-1-methylhydrazine Hydrochloride (VII) (3)

Forty-six grams (1.0 mole) of methylhydrazine dissolved in 200 ml of water was held near 40° while 113 g (0.5 mole) of benzoic anhydride was added over a 1-h period. Stirring was continued for 0.5 h and then the solution was concentrated by heating under reduced pressure. Water was removed by adding 200 ml of ethanol and 200 ml of benzene and concentrating under reduced pressure. About 200 ml of ethanol near saturation with hydrogen chloride was added, followed by 1 l of dry ether. The salt that separated was collected and dissolved in 200 ml of water. Solid sodium carbonate was added until the solution was basic and the resulting mixture was extracted twice with 500 ml of ether. The ether extract was dried and then concentrated by heating on a steam bath. The residue was distilled under reduced pressure and 20 g of 1-benzoyl-1-methylhydrazine, b.p. 130° at 1 mm, was obtained. (For the n.m.r. spectrum see footnote 3.)

Anal. Calcd. for $C_8H_{10}N_2O$: C, 63.98; H, 6.71; N, 18.65. Found: C, 64.14; H, 6.91; N, 18.76.

The free base was treated with 100 ml of ethanol saturated with hydrogen chloride followed by about 300 ml of dry ether. The product that separated was recrystallized more slowly from about 100 ml of ethanol and gave approximately 23 g (20% yield) of compound VII, m.p. 165°.

Anal. Calcd. for $C_8H_{10}N_2O{\cdot}HCl$: C, 51.48; H, 5.94; N, 15.01. Found: C, 51.64; H, 6.06; N, 15.01.

A sample of compound VII was heated in an oil bath at 200° for 5 min. The crude product was shown by n.m.r. analysis to be a mixture of 1-benzoyl-2-methylhydrazine and its hydrochloride only. The n.m.r. spectrum of 1-benzoyl-2-methylhydrazine showed peaks at 0.9, 2.2, 2.6, 5.0, and 7.3 τ in the ratio 1:2:3:1:3.

[9]*R. L. Hinman (9) formulated the product as XII, and reported that it failed to reduce to 1-benzoyl-2-methylhydrazine using palladium-on-carbon in ethanol (3).*

[10]*Melting points were determined with a Fisher–Johns apparatus. The infrared spectra were obtained in chloroform unless otherwise indicated and the ultraviolet measurements were taken in ethanol. Nuclear magnetic resonance spectra were measured at 60 Mc with a Varian A60 spectrometer using 10–20% solution in deuterochloroform containing 1% tetramethylsilane as internal standard.*

(a) The Preparation of Compounds V and VI by Reaction of VII with Phosgene

A solution of 1.9 g (0.01 mole) of 1-benzoyl-1-methylhydrazine hydrochloride (VII) and 5 g of phosgene in 100 ml of dry dioxane was heated under reflux for 1 h. The effluent gas was bubbled into ether and methyl chloride was identified by gas chromatography. The mixture was concentrated to dryness by heating on a steam bath under reduced pressure. The residue was dissolved in 100 ml of ethyl acetate, concentrated to about 50 ml, and then allowed to cool. The solid that separated was recrystallized from 10 ml of dioxane and gave 0.8 g (46% yield) of 4-methyl-5-phenylisosydnone (V), m.p. 152° after drying at 100° under reduced pressure.

Anal. Calcd. for $C_9H_8N_2O_2$: C, 61.36; H, 4.58; N, 15.90; mol. wt. 176. Found: C, 61.64; H, 4.71; N, 16.07; mol. wt. Rast 179.

The ultraviolet absorption spectrum of compound V shows λ_{max} 294 mμ, log ϵ 4.05, and the infrared spectrum shows strong bands at 2 994, 1 754 (broad), 1 613, 1 499, 1 453, 1 420, 1 404, 1 284, 1 232 (broad), 1 011, and 688 cm^{-1}. (For other physical data see Introduction.)

The residue obtained after removal of V was dissolved in ethyl acetate and chromatographed using 28–200 mesh silica gel; 100 mg of compound VI (R_f 0.7) was obtained.

A 0.3-g sample of compound V was dissolved in 20 ml of 0.1 *N* sodium hydroxide and then treated with acetic acid. The solution was concentrated to dryness and ethanol – hydrogen chloride mixture was added followed by ether to give 0.1 g of compound VII, as shown by melting point, infrared, and n.m.r. measurements.

(b) The Reaction of Compound V with Phosgene

A solution of 1.5 g of compound V, 25 ml of dioxane, and 1.5 g of phosgene was heated under reflux for 1 h, during which time the effluent gas was collected and shown by comparison using gas chromatography to be methyl chloride. The solvent was removed by heating on a steam bath under reduced pressure and then the residue was extracted with 25 ml of ether. The ether-insoluble material weighed 0.3 g and was identified as V. The ether extract was concentrated and the residue was shown by thin-layer chromatography using a silica plate and ethyl acetate as solvent to be identical with the residue in expt. *a*. The residue was allowed to stand over water and a solid separated. It was recrystallized from water and gave 50 mg of 2-chloro-5-phenyl-1,3,4-oxadiazole (VI), m.p. 75°.

Anal. Calcd. for $C_8H_5ClN_2O$: C, 53.20; H, 2.79; Cl, 19.63; N, 15.51. Found: C, 53.77; H, 3.01; Cl, 19.37; N, 15.29.

The ultraviolet spectrum of compound VI shows λ_{max} 253 mμ, log ϵ 4.28, and the infrared spectrum has bands at 3 000 w, 1 607 w, 1 558 m, 1 526 s, 1 450 m, 1 193 s, 1 076 m, 1 064 s, 1 007 m, 707 m, and 685 cm^{-1} m. (The n.m.r. spectrum is given in the Introduction.)

(c) 1-Benzoyl-1-methylhydrazine and Phosgene

A solution of 2 g of 1-benzoyl-1-methylhydrazine free base was added to 100 ml of dry ether containing dissolved phosgene. A precipitate formed immediately and the mixture was quickly filtered. The filtrate was concentrated by heating at about 30° under reduced pressure. Water was added to the residue and a white solid separated. It was collected, air dried, and recrystallized from dioxane to give 0.3 g of compound V.

(d) Compound VII and Phosgene in Toluene

A mixture of 0.01 mole of compound VII and 100 ml of dry toluene containing 3 g of phosgene was heated under reflux for 1 h. The starting material VII was recovered in almost quantitative yield.

(e) The Preparation of Compound IX by Reaction of Compound VII and Phosgene in Pyridine

A solution of 3.8 g (0.02 mole) of compound VII in 25 ml of pyridine was treated with 1 g (0.01 mole) of phosgene contained in 25 ml of pyridine. After the solution was allowed to stand at room temperature for 1 h, about 100 ml of water was added and the solution was concentrated to dryness by heating under reduced pressure. The solid that formed was recrystallized from ethanol–water mixture and gave 1.5 g of compound IX, m.p. 195°.

Anal. Calcd. for $C_{17}H_{18}N_4O_3$: C, 62.56; H, 5.56; N, 17.17. Found: C, 62.57; H, 5.82; N, 17.05.

A sample of compound IX and phosgene heated in dioxane gave no isosydnone V, and IX was recovered.

(f) The Isolation of Compound VIII

The residue formed in reaction *a* after removal of V initially showed no spot for compound VIII on thin-layer chromatography. After it was allowed to stand in an open vessel for 2 weeks, the residue on recrystallization from benzene gave 50 mg of VIII identical with authentic material.[11]

(g) Compound VIII and Phosgene

A sample of compound VIII and dioxane containing phosgene and hydrogen chloride was heated under reflux for 1 h. The solution was concentrated to dryness by being heated under reduced pressure and compound VIII was recovered in almost quantitative yield.

[11]*Compound VIII was prepared from benzoic acid hydrazide and phosgene according to the method of B. Yasui and H. Uchida (10).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(h) Compound V and Hydrogen Chloride

A sample of compound V dissolved in dioxane containing hydrogen chloride was heated under reflux while a slow stream of nitrogen was added. The effluent gas did not contain methyl chloride as shown by gas chromatography. The residue was placed on a thin-layer silica plate and compound V, but not VIII, was identified.

The Formation of Compound VI from Compound VIII

A mixture of 16.2 g (0.1 mole) of 2-phenyl-1,3,4-oxadiazolin-5(4H)-one[11] (VIII), 21 g of phosphorus pentachloride, and 50 ml of phosphorus oxychloride was heated under reflux for 45 min and then concentrated by being heated on a steam bath under reduced pressure. The residue was extracted with 100 ml of ether. The ether extract was distilled under reduced pressure and gave about 1 g of product, b.p. 140° at 10 mm. The material solidified and was recrystallized from water to give a small yield of compound VI as shown by comparison of the n.m.r. and infrared spectra with those of the material described earlier.

Rearrangement of 1-Benzoyl-1-phenylhydrazine Hydrochloride

A sample of 1-benzoyl-1-phenylhydrazine hydrochloride (11) was heated at 230° for 5 min. A near-quantitative yield of 1-benzoyl-2-phenylhydrazine, m.p. 165° (lit. (12), m.p. 168°), was obtained. The identity of the product was established by comparison of the n.m.r. spectrum with that of authentic material prepared according to the method of Fischer (12).

Preparation of Compound XIII and its Reduction to 1-Benzoyl-2-methylhydrazine

A solution of 21 g (0.15 mole) of benzoic acid hydrazide, 40 ml of ethanol, 12 ml (0.15 mole) of 37% aqueous formaldehyde, and 20 ml of water was heated on a steam bath for 5 min and crystals formed. The product XIII was insoluble in most solvents except dimethylsulfoxide and a sample recrystallized from dimethylsulfoxide–water melted near 170° (footnote 9, m.p. 169°).

Anal. Calcd. for $(C_8H_8N_2O)_3$: C, 64.85; H, 5.44; N, 18.91. Found: C, 64.37; H, 5.45; N, 18.68.

It was not possible to obtain an accurate molecular weight because of solubility problems. The n.m.r. spectrum obtained in dimethylsulfoxide was greatly different from benzoic acid ethylidenehydrazide and in agreement with compound XIII, τ = 2.2, 2.5, and 5.8 in the ratio 2:3:2. The ultraviolet absorption spectrum shows λ_{max} 224 mμ, log ϵ 3.95 (monomer), and the infrared spectrum obtained as a Nujol mull shows absorption peaks at 3 556 w, 3 195 w, 2 900 s, 1 686 s, 1 650 s, 1 481 m, 1 307 m, 939 m, 910 m, and 714 cm^{-1} s.

A mixture of 4.4 g (0.01 mole) of compound XIII, 0.5 g of 5% palladium-on-carbon, 100 ml of acetic acid, and hydrogen was shaken in a Paar apparatus for 2 h, during which time 0.03 mole of hydrogen was absorbed. The catalyst and solvent were removed, and the residue was suspended in 25 ml of 1 *N* sodium hydroxide solution and extracted with ethyl acetate. Evaporation of the dried ethyl acetate solution gave an oil that was dissolved in ethanol and treated with ether containing hydrogen chloride. The 1-benzoyl-2-methylhydrazine hydrochloride, 1.4 g (25% yield), was identical with that prepared from methylhydrazine and ethyl benzoate according to the procedure of Hinman (3).

Benzoic Acid Ethylidenehydrazide

A solution of 4 g of benzoic acid hydrazide, 1 ml of acetaldehyde, and 300 ml of benzene was evaporated on a steam bath and the residue was recrystallized from ether to give benzoic acid ethylidenehydrazide, m.p. 155° (lit. (13), m.p. 157°). The compound is a monomer as shown by physical measurements; mol. wt. calcd. 162, found 164 (micro osmometric); n.m.r. spectrum in $CDCl_3$ shows τ = 8.1 (three protons CH_3, J = 5), τ 2.2 and 2.6 (phenyl, with geminal olefinic proton at approximately same shift as ortho protons obscuring the character of each), τ = −0.9 (amide); infrared spectrum shows peaks at 3 333 vw, 3 215 w, 2 976 m, and 1 658 s, and 1 545, 1 512, 1 280, 1 262, 1 135, 865, 704, and 690 cm^{-1} all m.

3-Methyl-5-phenyl-2,3-dihydro-1,3,4-oxadiazol-2-one (XI)

(*i*) A solution of 1 g of 1-benzoyl-2-methylhydrazine hydrochloride, 1 g of phosgene, and 50 ml of dry dioxane was heated on a steam bath for 1 h and then concentrated at reduced pressure. The solid was recrystallized from ethanol and gave 0.2 g of compound XI, m.p. 105–107°.

Anal. Calcd. for $C_9H_8N_2O_2$: C, 61.36; H, 4.58; N, 15.90. Found: C, 61.29; H, 4.71; N, 15.64.

Compound XI displayed the following physical data: ultraviolet absorption spectrum shows λ_{max} 266 mμ, log ϵ 3.97; infrared spectrum shows strong peaks at 1 785, 1 358, 1 019, and 686 cm^{-1}; n.m.r. spectrum shows τ = 2.1, 2.5, and 6.5 in the ratio 2:3:3.

(*ii*) A solution of 4.8 g (0.03 mole) of 2-phenyl-1,3,4-oxadiazolin-5(4H)-one[11] (VIII), 1.6 g of sodium methylate, 4.3 g of methyl iodide, and 50 ml of methanol was stored at 40° overnight. About half the methanol was removed by evaporation and 100 ml of water was added. The solid that formed was recrystallized from ethanol and gave 2 g (38% yield) of XI identical with the material prepared in procedure *i*.

SYNTHESIS OF ISOTOPICALLY LABELLED OLEFINS VIA THE WITTIG REACTION

J. G. Atkinson, M. H. Fisher, D. Horley, A. T. Morse, R. S. Stuart, and E. Synnes
Isotopic Laboratories of Merck Sharp and Dohme of Canada, Ltd., Montreal, Quebec
Received January 6, 1965

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

A new application of the Wittig reaction to the preparation of olefins of low molecular weight which allows selective labelling in the vinyl or allyl positions with isotopes of hydrogen and carbon has been developed. Using the modification of the Wittig reaction introduced by E. J. Corey, in which a solution of the methylsulfinyl carbanion in dimethyl sulfoxide serves as the base, a series of olefins from C_2 to C_8 were synthesized. The synthesis was applied to the preparation of the following labelled compounds: 5-methylene-^{14}C-bicyclo[2.2.1]hept-2-ene; propene-1-^{14}C; 1-butene-1-^{14}C; propene-1-d_1; 2-methylpropene-1,1-d_2; 2-methyl-d_3-propene-3,3,3-d_3; 2-methyl-2-butene-4,4,4-d_3; 2-methyl-d_3-2-butene-1,1,1-d_3; methylene-d_2-cyclohexane. For the synthesis of carbon-labelled olefins the reaction has few limitations since the intermediates and products are isotopically stable under the reaction conditions. Deuterium-labelled olefins can be obtained from deuterated formaldehyde or β-deuterated phosphonium salts, but α-deuteroketones and aldehydes and α-deuterophosphonium salts lose the isotope to the solvent.

In all the Wittig reactions, benzene was formed as a by-product in 10–15% yield. The mechanism of benzene formation is probably analogous to that proposed by Seyferth involving the decomposition of a pentacovalent phosphorous intermediate.

INTRODUCTION

The use of organic molecules specifically labelled with isotopes of carbon, hydrogen, oxygen, and nitrogen has become a classical method for the study of reaction mechanisms (2, 3). More recently, isotopically labelled molecules have proved to be invaluable sources of information in spectroscopic research. German workers (7) have recently made an extensive study of the infrared (i.r.) and Raman spectra of a number of selectively deuterated olefins. Studies of the dehydration of straight-chain alcohols, specifically labelled with deuterium, during mass spectral fragmentation have been carried out (5). Djerassi (6) has studied extensively the mass spectral cleavage patterns of numerous specifically deuterated steroid species. The mechanism of the retro Diels–Alder reaction of the maleic anhydride adduct of butadiene-1,1,4,4-d_4 has been investigated by Thornton (4). The unusually large H—H coupling constant of formaldehyde was obtained by Shapiro (1) using formaldehyde-d_1.

Carbon-13 labelled molecules have found use in electron-spin resonance (e.s.r.) spectroscopy. Rieker *et al.* (8) have studied the e.s.r. spectrum of the free radical from 2,4,6-tritertiarybutylphenol-1-^{13}C.

These uses have made it necessary to work out unequivocal syntheses for partially but specifically isotope-labelled organic molecules. The purpose of this paper is to report a new general synthesis of deuterated olefins which has been developed in these laboratories (9).

Olefins of low molecular weight, labelled either on the double-bond carbons or in the allylic positions, are widely used in gas-phase kinetics work and the study of hydrogen abstraction reactions. One of the attendant difficulties in the synthesis of such compounds

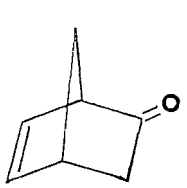
is allylic rearrangement, which leads to scrambling and (or) loss of the label. One approach which seemed particularly attractive was the Wittig reaction (10, 11).

The Wittig reaction has the advantage that, in general, the introduction of the double bond takes place under mild conditions without rearrangement. In addition, there are few side reactions and it seemed that it would be a straightforward matter to separate the volatile products from the main by-product, triphenylphosphine oxide.

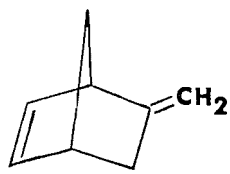
RESULTS

Chemical Syntheses

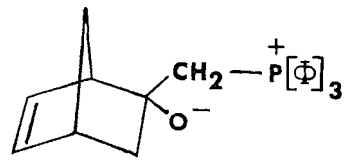
This work began with the synthesis of 5-methylene-bicyclo[2.2.1]hept-2-ene(methylenenorbornene), II, from bicyclo[2.2.1]hept-2-en-5-one(dehydronorcamphor), I, and triphenylmethylphosphonium bromide.



I



II



III

Dehydronorcamphor has been prepared from the Diels–Alder adduct between cyclopentadiene and α-acetoxyacrylonitrile (12) but this approach for introducing a ketone function is relatively unattractive because of the lack of a commercial source of the dienophile. Accordingly, dehydronorborneol was prepared by condensing cyclopentadiene with vinyl acetate followed by hydrolysis (13*a*). Oxidation of the mixture of epimers of dehydronorborneol with chromic acid under various conditions (13, 14) gave, in our hands, poor yields of a hydroxyl-containing ketone fraction. Apparently, under acidic conditions, further oxidation occurs readily and polyoxygenated products result.* The ketone was readily obtained, using Sarett's reagent (16) as described by Cristol and Freeman (17), in yields of 65–70% by modifications of the published procedure (17). A basic medium appears to be necessary for the successful oxidation of such sensitive alcohols to avoid electrophilic attack on the double bond. This is borne out by the successful oxidation of dehydronorborneol to dehydronorcamphor (17, 18) and the preparation of Δ^4-cholesten-3-one (19) by modifications of the Oppenauer oxidation.

Addition of the ketone I to an ethereal solution of triphenylphosphinemethylene and subsequent work-up yielded methylenenorbornene, II, in about 20% crude yield, contaminated with 10–15% of lower boiling impurities. It was not possible to improve the yield by prolonged refluxing of the reaction mixture. The slow decomposition of the initially formed betaine intermediate III (11*c*) is presumably due to the increase in ring strain accompanying the introduction of another trigonal carbon into the already strained bicycloheptene system. Accordingly, methylene-^{14}C-norbornene was prepared from triphenylmethyl-^{14}C-phosphonium iodide and purified by preparative vapor phase chromatography (v.p.c.).†

Because of difficulties encountered when ether was used as a solvent, it was decided to try the dimethyl sulfoxide – sodium hydride system which Corey has introduced as a

See, for example, the chromic acid oxidation of cholesterol (15).

†*The preparation of optically active methylenenorbornene from optically active dehydronorcamphor by the Wittig reaction has been reported (20).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

convenient modification of the Wittig reaction* (21) (eqs. [1] and [2]). Repetition of the preparation of methylenenorbornene using this reagent and examination of the volatile products by vapor phase chromatography showed it to be a mixture of methylenenorbornene, II, and a single lower boiling impurity in a ratio of 30:1; the yield of II was 59%. The lower boiling impurity was proved to be benzene and even careful exclusion of extraneous sources did not prevent its appearance in the product (see Discussion).

[1] $$CH_3{-}\overset{\overset{O}{\|}}{S}{-}CH_3 + NaH \rightarrow CH_3{-}\overset{\overset{O}{\|}}{S}{-}\overset{\ominus}{C}H_2\overset{\oplus}{N}a + H_2$$

IV

[2] $$\Phi_3\overset{\oplus}{P}{-}CH_3\overset{\ominus}{I} + CH_3{-}\overset{\overset{O}{\|}}{S}{-}CH_2Na \rightarrow \Phi_3P{=}CH_2 + CH_3{-}\overset{\overset{O}{\|}}{S}{-}CH_3 + NaI$$

[3] $$\Phi_3P{=}CH_2 + RR'C{=}O \rightarrow RR'C{=}CH_2 + \Phi_3P{=}O$$

A number of other gaseous and volatile hydrocarbons were then synthesized in this system using low molecular weight aldehydes and ketones; the results are shown in Table I.

The general procedure adopted was to prepare a solution of triphenylphosphine ylid in dry dimethyl sulfoxide (21), then to add the carbonyl compound as a solution in the same solvent or, in the case of formaldehyde, as anhydrous polyoxymethylene (eqs. [1–3]). Gaseous products were collected in a trap cooled to the necessary temperature and finally pulled off under vacuum into the trap cooled in liquid nitrogen. Liquid products were distilled into a liquid nitrogen cooled trap under vacuum after completion of the reaction. Purification of gaseous materials was accomplished by bulb-to-bulb distillation on a vacuum line, while liquids were purified by vapor phase chromatography. Identity was established in all cases by comparison of i.r. or n.m.r. spectra with those of authentic samples.

These are the first recorded syntheses of ethylene, propene, 1-butene, isobutene, and butadiene via the Wittig reaction and it is only recently that simple aliphatic aldehydes have been used as the carbonyl component in the Wittig reaction (22).

The last item in Table I records the attempted synthesis of ethyl vinyl ether by the reaction between triphenylphosphinemethylene and ethyl formate. However, the major volatile product was ethyl alcohol, which undoubtedly arises by an alternative decomposition of the betaine intermediate V.

$$\Phi_3P{=}CH_2 + H{-}\overset{\overset{O}{\|}}{C}{-}OC_2H_5 \rightarrow \Phi_3{-}\overset{\oplus}{P}{-}CH_2{-}\overset{\overset{O^{\ominus}}{|}}{\underset{\underset{H}{|}}{C}}{-}OC_2H_5$$

V

$$\Phi_3P{=}CH{-}CHO + C_2H_5OH \leftarrow \Phi_3{-}\overset{\oplus}{P}{-}CH_2{-}\overset{\overset{O}{\|}}{C}{-}H + \overset{\ominus}{O}C_2H_5$$

Isotopic Syntheses

After development of the chemical syntheses, several isotopically labelled compounds were synthesized and analyzed to determine the useful scope of the reaction for labelling with hydrogen and carbon isotopes. The results for deuterium and carbon-14 labelling are shown in Table II and Table III, respectively. Entries 7 to 11 in Table II record unsuccessful attempts to utilize α-deuterated carbonyl compounds and an α-deuterated phosphonium salt.

*We thank Professor L. F. Fieser for pointing out this modification during the early stages of this work.

‡Run in ether using *n*-propyl lithium as the base.

It is apparent that the synthesis has wide application for the preparation of carbon-14 (and carbon-13) labelled olefins, which could, in turn, be converted to a number of other derivatives. Propene-1-^{14}C could conceivably have rearranged to give some propene-3-^{14}C, but the indirect evidence against this possibility is the complete absence of rearrangement in the preparation of 1-butene and methylenecyclohexane, both of which are less stable than their rearrangement products, 2-butene and 1-methylcyclohexene, neither of which was detected in these preparations.

‡Activity 2.01 μc/mole.

The deuterium-labelled compounds were analyzed for isotopic content by mass spectrometry. The high isotopic content of the successful syntheses was also taken as indirect evidence for the position of the label. Had there been double-bond isomerization or equilibration, deuterium would also have been lost or diluted. The position of deuterium labelling was confirmed in the case of the two 2-methyl-2-butenes by a careful n.m.r. analysis (23), which showed that deuterium had completely replaced hydrogen in the positions indicated.

The deuterium-labelled isobutenes and 2-methyl-2-butenes are new compounds, but Italian workers (28) have reported the synthesis of several selectively deuterated propenes. Propene-1,1-d_2 was prepared by the sequence: 2-bromacetyl bromide → 2-bromo-1-propanol-1,1-d_2 → 1,2-dibromopropane-1,1-d_2 → propene-1,1-d_2. Both *cis*- and *trans*-propene-1-d_1 were obtained from the corresponding 1-bromopropene, via the vinyl lithium derivative, which was treated with heavy water, and propene-2-d_1 was synthesized by reduction of acetone with lithium aluminium deuteride and dehydration of the resulting alcohol.

DISCUSSION

The results obtained indicate the general usefulness of the Wittig reaction as a means of preparing a number of volatile hydrocarbons labelled in various positions. The products obtained are stable under the reaction conditions, both chemically and isotopically, which was anticipated on the basis of previous work with the Wittig reaction. Use of the dimethyl sulfoxide – sodium hydride system is particularly advantageous because the high-boiling solvent facilitates isolation of volatile products. The reaction is also very clean in comparison with the use of ether as solvent, the only volatile by-product being benzene.

For carbon labelling the present synthesis would seem to have few restrictions with regard to the structure of either the carbonyl component or the phosphonium salt and for stable products it should be widely applicable. For both carbon and hydrogen isotopes it provides a ready means to obtain allylic labelled compounds which are often difficult to prepare reliably by other means. Such compounds could be obtained by reduction of the appropriate α,β-unsaturated acid or ketone to the alcohol, conversion to the tosylate or bromide, and further reduction. But such intermediates and reactions are well known to lead to allylic rearrangements.

The last entries in Table II show that there are certain limitations to the synthesis of deuterium-labelled compounds. Thus, α-deuterated aldehydes and ketones undergo extensive loss of isotope before condensation with the ylid as evidenced by the low isotopic content of the products from acetaldehyde-d_4, acetone-d_6, and cyclohexanone-2,2,6,6-d_4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The loss or scrambling of deuterium is probably due to enolization of the carbonyl compound with the ylid acting as the base according to the following scheme.

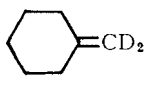
$$CD_3CDO + (C_6H_5)_3P{=}CH_2 \rightleftharpoons \overset{\ominus}{C}D_2CDO + (C_6H_5)_3\overset{\oplus}{P}{-}CH_2D \rightleftharpoons CD_2H{-}CDO + (C_6H_5)_3P{=}CHD$$

$$CD_2H{-}CDO + (C_6H_5)_3P{=}CH_2 \rightarrow CD_2H{-}CD{=}CH_2 \quad \text{(propene-}d_3\text{)}$$

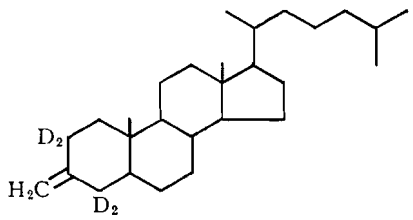
$$CD_3{-}CDO + (C_6H_5)_3P{=}CH_2 \rightarrow CD_3{-}CD{=}CH_2 \quad \text{(propene-}d_4\text{)}$$

$$CD_3{-}CDO + (C_6H_5)_3P{=}CHD \rightarrow CD_3{-}CD{=}CHD \quad \text{(propene-}d_5\text{)}$$

It would seem to be possible to overcome these difficulties by reverting to the ether – alkyl lithium system for the reaction. One run (number 6, Table II) with cyclohexanone and triphenylmethyl-d_3-phosphonium iodide yielded methylene-d_2-cyclohexane, VI, of 94 atom % deuterium content in the methylene group. The slight (5%) loss of isotope is probably due to traces of water or hydroxide ion in the solvent, but the complete absence of any d_3 species in the mass spectrum indicates that there was no enolization of the ketone. Enolization would have produced some α-deuterated ketone, which, in turn, should lead to d_3 or higher species by condensation with doubly labelled ylid.



VI



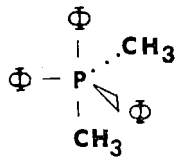
VII

The applicability of the conventional ether system to α-deuterated ketones is confirmed by Cookson's synthesis of 3-methylenecholestane-2,2,4,4-d_4, VII, from the exchanged ketone with good retention of deuterium (24).

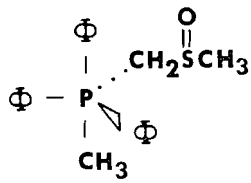
During this work, an interesting side reaction which is worthy of comment was consistently observed. In every Wittig reaction run, whether in ether or dimethyl sulfoxide, benzene was formed as a by-product. In previous work (21), no observation of benzene was made, although Seyferth (25), in a careful investigation of the reactions between methyl lithium and triphenylmethylphosphonium bromide in ether, has shown that benzene is also formed under these conditions in 20–25% yields. In the present work a reaction between triphenylmethylphosphonium iodide and methylsulfinyl carbanion for 16 h yielded 7.5% of benzene by direct isolation. In another reaction, the yield of benzene was determined by isotope dilution using benzene-d_1 and was found to be 13.6%. Seyferth (25) postulated the decomposition of a pentacovalent phosphorous intermediate, VIII, as the source of benzene in his work. Attack of methylsulfinyl carbanion on triphenylmethylphosphonium iodide could lead to a similar structure, IX, which could decompose to yield benzene. Formation of a volatile by-product might be prevented by using a suitably substituted phosphine such as the tri-*p*-methoxyphenyl derivative and such a possibility is under investigation.

Entries 10 and 11 in Table II show that when triphenylmethyl-d_3-phosphonium iodide is used in the dimethyl sulfoxide system extensive loss of deuterium occurs. The most obvious explanation is a fast equilibrium between dimethyl sulfoxide and triphenylphosphinemethylene (eq. [4]). Such an equilibrium would effectively wash out the deuterium and lead to low isotopic content in the product.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



VIII



IX

However, such an equilibrium is made unlikely by the observation that the yield of benzene is unchanged with extended reaction time. If such an equilibrium were as fast as indicated by the loss of deuterium, then longer reaction times would give more opportunity for the formation of the pentacovalent intermediate IX and irreversible formation of benzene. Thus, another mechanism by which deuterium is lost from the phosphonium salt must be operative.

Equations 5 to 8 indicate the currently (11*e*) suggested path for the Wittig reaction. From a consideration of the various intermediates, betaine X is tentatively suggested as the source of deuterium exchange with the solvent (eq. [9]). The conjugate base XI of the betaine should be a stronger base than triphenylphosphinemethylene because it carries a net negative charge and hence should be more likely to remove a proton from a dimethyl sulfoxide molecule.

EXPERIMENTAL

Melting points were taken on a Fisher–Johns melting point block and are uncorrected; boiling points are uncorrected. Infrared spectra were run on a Perkin–Elmer model 21 spectrometer; gas samples were run in a 10-cm cell at about 100 mm pressure. N.m.r. spectra were obtained on a Varian A-60 spectrometer using neat liquids; mass analyses were done on an Associated Electrical Industries instrument, model MS-2.

Materials

The following isotopically labelled starting materials were commercially available (Merck Sharp and Dohme of Canada, Ltd.): methyl-d_3 bromide, methyl-d_3 iodide, 2-propyl-1,1,1,3,3,3-d_6 iodide, ethyl-2,2,2-d_3 bromide, acetaldehyde-d_4, acetone-d_6, cyclohexanone-2,2,6,6-d_4, benzene-d_1, methyl-^{14}C iodide, methyl-^{14}C bromide.

Preparation of Triphenylalkylphosphonium Salts

All the phosphonium salts were prepared by the reaction between triphenylphosphine and the appropriately labelled alkyl halide. Ether was found to be a more convenient solvent than benzene (26) for the preparation of the triphenylmethylphosphonium salts. The preparations are summarized as follows: mole ratio of triphenylphosphine to alkyl halide; concentration of alkyl halide; solvent; temperature and time of reaction; melting point; yield of phosphonium salt.

Triphenylmethyl-d_3-phosphonium bromide: 1.14; 0.5 *M*; ether; 25° for 7 days; 231–233°; 65%.

Triphenylmethyl-d_3-phosphonium iodide: 1.15; 0.4 *M*; ether; 25° for 4 days; 184–186°; 98%.

Triphenylethyl-2,2,2-d_3-phosphonium bromide: 1.05; 0.4 *M*; acetonitrile; reflux for 48 h; 205–208°; 97%.

Triphenyl-2-propyl-1,1,1,3,3,3-d_6-phosphonium iodide: 1.25; 0.4 *M*; acetonitrile; reflux for 4 days; 197–198°; 77%. Isopropyl bromide gave only 10% of phosphonium salt under the same conditions.

Triphenylallylphosphonium bromide: 0.85; 1.2 *M*; acetone; 30° for 24 h; 218–225° with softening at 214°; 92%.

Triphenylmethyl-^{14}C-phosphonium bromide: 1.0; 5 *M*; benzene; 25° for 3 days; 229–231°; 91%. Activity 2 μc/mmole.

Triphenylmethyl-^{14}C-phosphonium iodide: 1.1; 0.8 *M*; ether; 25° for 3 days; 187–189°; 100%. Activity 2 μc/mmole.

Procedure for Wittig Reactions in Dimethyl Sulfoxide

The preparation of butadiene is typical of the procedure used.

A 500-ml three-necked flask was fitted with a condenser and nitrogen inlet, thermometer, and magnetic stirring bar and flushed with nitrogen for 10 min. Reagent grade dimethyl sulfoxide (100 ml) was added to the flask and nitrogen passed over the surface of the vigorously stirred solvent for 30 min. Sodium hydride (50% dispersion, 7.7 g, 0.17 mole) was then added and the mixture heated at 65° under a positive pressure of nitrogen until all the hydride had dissolved (ca. 2 h).

To the cooled reaction mixture triphenylallylphosphonium bromide (57.5 g, 0.15 mole) was added in portions, over 15 min. The reaction was mildly exothermic, the temperature rising briefly to 40°. The dark red solution was stirred at room temperature for 1 h.

To the top of the condenser was attached a bubbler and dry ice cooled trap flushed with nitrogen. Polymeric formaldehyde (3.0 g, 0.1 mole) was added in one portion to the ylid solution stirred in a cold water bath. The temperature rose quickly to 50° and slowly dropped back. Heat was applied gently and the reaction was held at 65° for 1 h and at room temperature for 16 h. After the trap was cooled in liquid nitrogen, vacuum and gentle heating (~60°) were applied to pull volatile materials into the trap.

The volatile material was distilled bulb-to-bulb twice on a vacuum line to remove benzene and traces of dimethyl sulfoxide. It was finally passed slowly through a U-tube of Ascarite and Drierite to remove sulfur impurities and water and condensed into a steel cylinder. Vapor phase chromatography on activated silica gel at 90° showed less than 0.5% gaseous impurities and on polypropylene glycol at 25° it showed about 2.5% of a higher-boiling liquid, probably benzene. A gas phase i.r. spectrum was completely identical with that of an authentic sample of butadiene. Yield = 2.3 g, 0.043 mole (43%).

Conditions for the other syntheses are summarized in Table I and in the text. The product of the reaction between triphenylphosphinemethylene and ethyl formate was found to be a mixture of ethyl formate (1%), ethyl alcohol (85%), and benzene (15%).

Synthesis of isotopically labelled products was accomplished by the same general procedure. Usually the component containing the isotope was used in a slight deficiency unless the excess unlabelled material would have contaminated the product. The labelled compounds were all obtained with a chemical purity greater than 99%.

Benzene Formation

(i) To the reaction mixture of triphenylphosphinemethylene (0.1 mole) and cyclohexanone-2,2,6,6-d_4 (0.1 mole) was added 0.99 g of benzene-d_1 (98% d_1). A sample of the resulting benzene was separated from methylene-2,2,6,6-d_4-cyclohexane by v.p.c. and analyzed by mass spectroscopy. Found: 47.29% -d_1 and 52.70% -d_0, which corresponds to a 13.6% yield of benzene.

(ii) To a solution of 0.1 mole of methylsulfinyl carbanion in 150 ml of dimethyl sulfoxide was added 41 g (0.1 mole) of triphenylmethylphosphonium iodide over 5 min. The reaction was stirred at 25° for 16 h and

heated to 70° for 1 h, and the volatile materials removed under high vacuum. Bulb-to-bulb distillation afforded 0.6 g (0.008 mole, 8%) of pure benzene.

Dehydronorbornyl Acetate (13a)

The compound was prepared in 47% yield from cyclopentadiene and vinyl acetate at 165°; b.p. 85–88° at 19 mm; the infrared spectrum showed a very strong C=O absorption band at 1 725 cm^{-1}. If an excess of vinyl acetate was not used the product was impure and subsequently gave a low yield of dehydronorborneol.

*Dehydronorborneol**

To a cooled magnetically stirred solution of 72 g (1.8 moles) of sodium hydroxide in 1 000 ml of methanol was added 216 g (1.42 moles) of dehydronorbornyl acetate over 20 min. The reaction was protected with an Ascarite tube to exclude carbon dioxide and stirred at room temperature for 3 days. Most of the solvent was removed on a rotary evaporator, 1 500 ml of water added to the residue, and the aqueous phase extracted with 5 × 200 ml of ether. After the solution was dried over calcium chloride and the solvent evaporated, there was obtained 135 g (1.23 moles, 86%) of crude dehydronorborneol, m.p. 94–105°. Further extraction of the aqueous layer with ether yielded an additional 3 g of alcohol, bringing the yield to 88%. Crystallization from 200 ml of petroleum ether (35–60°) and concentration of the mother liquors gave 110 g (70%) of white crystalline product, m.p. 104.5–106°.

Dehydronorcamphor (17)*

A suspension of the chromium trioxide – pyridine complex was prepared by addition of 78.6 g (0.78 mole) of chromium trioxide to 780 ml of pyridine in a 3-l flask, with stirring and cooling to keep the temperature below 25° over 60 min. A further 120 ml of pyridine was then added to increase the fluidity of the reaction mixture. After 30 min of stirring at room temperature, a solution of 30 g (0.27 mole) of dehydronorborneol in 180 ml of pyridine was added over 30 min, the internal temperature being kept below 20°. The reaction mixture was stirred at room temperature for 17 h and filtered through a pad of celite, and the flask and filter pad washed thoroughly with 5 × 250 ml of ether. After dilution with 4 l of cold water, the filtrate was divided into two parts and each part extracted with 8 × 250 ml of ether. Each ether solution was washed with 15% sulfuric acid until the washings remained acidic (5 × 250 ml), 5% sodium bicarbonate (2 × 250 ml), and water (2 × 250 ml). The aqueous solutions were backwashed with ether and the combined ether solutions dried over calcium chloride, filtered, and distilled to yield 18.9 g (0.17 mole, 64% yield) of dehydronorcamphor, b.p. 55° at 15 mm. Analysis by vapor phase chromatography showed that the product had a purity greater than 98%, and the infrared spectrum contained a strong C=O band at 1 740 cm^{-1} and a very weak O—H band at 3 500 cm^{-1}. Several oxidations using 10-g quantities of alcohol gave yields of 65–70% consistently. In one run, half the usual molar amount of chromium trioxide was used but the product was found to contain large amounts of unreacted alcohol.

Methylene-^{14}C-norbornene

A solution of ethyl lithium in 150 ml of ether in a well-dried nitrogen-filled flask was prepared from 1.2 g (0.2 mole) of lithium shot and 13 g (0.12 mole) of ethyl bromide at −13°. To the solution of ethyl lithium, stirred in a bath at −5 to 0°, was added 41 g (0.10 mole) of triphenylmethyl-^{14}C-phosphonium iodide (2 μc per mmole) over 45 min. The ice bath was removed and after 1 h of further stirring a solution of 8 g (0.074 mole) of dehydronorcamphor in 60 ml of ether was added dropwise to the yellow solution of Wittig reagent over 1 h. A white solid formed immediately when each drop of ketone solution reached the solution of triphenylphosphinemethylene-^{14}C, presumably as a result of the rapid formation of the betaine III. The reaction mixture was then stirred and heated under reflux for 2 days, after which the solid was separated by filtration, washed well with ether, and suspended in 100 ml of water. Much of the solid dissolved in the water and the aqueous phase was extracted with 100 ml of ether, which was added to the original filtrate. The combined ether solutions were washed with cold water to neutrality and dried over anhydrous sodium sulfate. After filtration, the ether solution was carefully concentrated and the concentrate distilled through a small helices-packed column under nitrogen. The boiling point rose steadily from 80° to 120° with no sharp break. There was obtained about 3 g of water-white liquid having the characteristic odor of methylenenorbornene. The product was separated from benzene and other contaminants by preparative v.p.c. and finally purified by bulb-to-bulb distillation on a vacuum line. There was obtained 0.900 g (8.5 mmoles) of pure methylene-^{14}C-norbornene; yield, 11.5% based on dehydronorcamphor. Combustion and counting the barium carbonate obtained gave values of 1.90 and 2.12 μc/mmole; calculated: 2.0 μc/mmole.

ACKNOWLEDGMENTS

The infrared and vapor phase chromatographic analyses were performed under the supervision of Mr. Andrew Reich. Mass spectra were obtained through Professor J. Goodings of McGill University and the n.m.r. spectra were performed by Professor J. C. Richer through the cooperation of the Department of Chemistry of the University of Montreal.

**Experimental details are given because it was found that the modifications introduced resulted in higher yields and purer products.*

CHEMISTRY OF NYBOMYCIN

II. SYNTHESIS OF 4,5-DIMETHYL-2,7-DIOXO-1,2,7,8-TETRAHYDRO-1,8-DIAZAANTHRACENE[1]

GRAHAM LEADBETTER AND KENNETH L. RINEHART, JR.
Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois

Received November 13, 1964

Dedicated to Professor R. B. Sandin on the Occasion of his Sixty-Eighth Birthday

ABSTRACT

4,5-Dimethyl-2,7-dioxo-1,2,7,8-tetrahydro-1,8-diazaanthracene, a compound previously obtained from phosphorus – hydrogen iodide reduction of deoxynybomycin, has been synthesized in eight steps from *m*-xylene, in 5% overall yield.

The water-insoluble antibiotic nybomycin (1, 2) was recently assigned (3) structure I (1-formyl-4-hydroxymethyl-5,8-dimethyl-2,7-dioxo-1,2,7,8-tetrahydro-1,8-diazaanthracene). In the assignment of structure I, a key degradation product was compound III (4,5-dimethyl-2,7-dioxo-1,2,7,8-tetrahydro-1,8-diazaanthracene), one of three products isolated from reduction of deoxynybomycin (II) with phosphorus – hydrogen iodide at 240° in a sealed tube.

Compound III was of particular significance in the structural studies on nybomycin, since it alone of the three reduction products (III, IV, and V) retained the basic ring system and fundamental chromophoric unit of nybomycin. Compound III was converted by treatment with dimethyl sulfate in base to its N,N′-dimethyl derivative (VI), which proved of prime importance in deduction of the ring system of nybomycin from nuclear magnetic resonance (n.m.r.) considerations. The present work reports the preparation of the two degradation compounds III and VI, both as confirmation of their structures and as an approach to the development of routes to more complex compounds containing the nybomycin ring system.[2]

In the present preparation *m*-xylene was treated with concentrated nitric and sulfuric acids at room temperature to give 4,6-dinitro-1,3-dimethylbenzene (VIII) (5) in 30% yield, together with the 2,4-dinitro isomer IX in 7% yield. Their previously assigned structures are confirmed by the n.m.r. coupling constants of the two isomers. In the spectrum of VIII, whose two aryl protons are para to one another, the singlets ($J < 1$ c.p.s.) expected (6) are found at τ 1.32 and τ 2.54 (Table I), while the ortho aryl protons of IX, at τ 1.76 and τ 2.36, have the expected (6) large coupling constant ($J = 9$ c.p.s.).

Oxidation of VIII to 4,6-dinitro-1,3-benzenedicarboxylic acid (X) was effected by chromium trioxide in concentrated sulfuric acid at approximately 15° (7). In addition to the dicarboxylic acid X, the monocarboxylic acid XI was always isolated. Chemical shift

[1]*For paper I in this series, see ref. 3.*
[2]*The unsubstituted ring system (VII) of compounds I, II, III, and VI had been prepared previously (4), but unfortunately before the widespread reporting of spectral data.*

For personal use only.

values for the dicarboxylic acid are reported in Table I; the monocarboxylic acid showed only singlets, at τ 1.30 (H-5), τ 2.12 (H-2), and τ 7.20 (aryl methyl).

Two routes were developed for conversion of the diacid X to 1,3-diacetyl-4,6-dinitrobenzene (XIV) via the known (7) diacid chloride XII. Conversion of XII to XIV by treatment of the former compound with diazomethane and subsequent reduction of the bis-diazoketone XIII with hydriodic acid gave XIV in yields as high as 59%. The yield of XIV by the alternative route, treatment of XII with diethyl magnesiomalonate, followed by concurrent hydrolysis and decarboxylation of the dimalonic ester XV, was approximately the same (53%). While the route via XV is somewhat longer and less convenient, it is preferred in view of the potential hazards of explosion and poisoning in working with large quantities of diazomethane and diazoketones.

The diacetyldinitrobenzene (XIV) was reduced by copper in sulfuric acid in 80% yield to 1,3-diacetyl-4,6-diaminobenzene (XVI)[3] and identified by melting point (7) and n.m.r. spectrum (Table I). Acetylation of XVI gave 94% of 1,3-diacetyl-4,6-diacetamidobenzene (XVII), characterized by its amide stretching absorption, elemental analyses, and n.m.r. spectrum (Table I).

Potassium *t*-butoxide catalyzed ring closure of XVII gave compound III in 69% yield. The overall yield of compound III from 4,6-dinitro-1,3-dimethylbenzene (VIII) was thus 15% by the diazomethane route and 14% by the magnesiomalonate route (5% and 4%, respectively, based on *m*-xylene).[4] Like nybomycin and related compounds, synthetic compound III did not melt below 350°. The infrared, ultraviolet, and n.m.r. (Table I) spectra of synthetic compound III matched those reported for the degradation product (8). As further proof of identity, synthetic compound III was converted by methylation to synthetic compound VI. For VI, too, n.m.r., ultraviolet, and infrared spectra (Fig. 1) were identical with those of the methylation product obtained in three steps from nybomycin (I → II → III → VI).

With completion of this synthesis, the heterocyclic skeleton of nybomycin is assured. Future efforts will be directed toward synthesis of derivatives of this ring system.

EXPERIMENTAL

Melting points were determined on a Kofler micro hot stage and are uncorrected. Nuclear magnetic resonance spectra and microanalyses were obtained at the University of Illinois by D. H. Johnson, J. Nemeth, and their associates. Infrared spectra were obtained with a Perkin–Elmer double-beam recording spectrophotometer, model 237, on chloroform solutions or Nujol mulls except as noted in the text. Nuclear magnetic resonance spectra were obtained with a Varian high-resolution n.m.r. spectrometer, model A-60, in the solvents noted in the text. Ultraviolet spectra were obtained with a Beckman recording ultraviolet spectrophotometer, model DB, on ethanolic solutions.

4,6-Dinitro-1,3-dimethylbenzene (VIII)

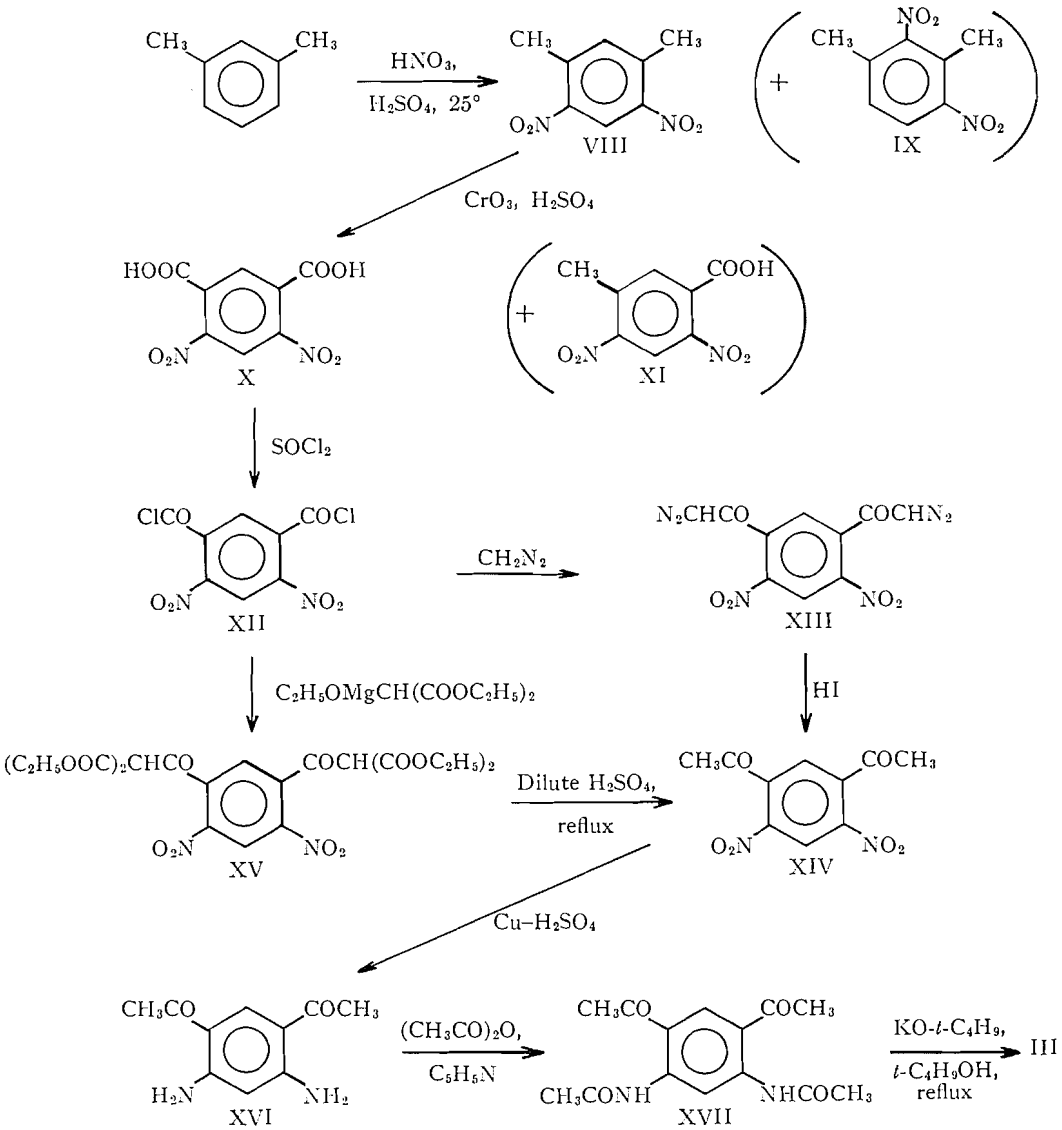
The procedure followed was that of Morgan (9). The crude product obtained from 200 ml of 70% nitric acid, 250 ml of 96% sulfuric acid, and 123 ml (ca. 106 g) of *m*-xylene weighed 150 g (76%). This was recrystallized repeatedly from 95% ethanol (5) until a constant melting product (59.5 g, 30%) was obtained. In five additional runs on a double scale the yields were 30–31%. 4,6-Dinitro-1,3-dimethylbenzene (VIII), m.p. 88–92° (lit. 89–93°) (5), was shown to be free of impurities by thin-layer chromatography over silica gel employing carbon tetrachloride solvent. The structure assigned was in accord with the compound's n.m.r. spectrum (Table I).

In addition to the desired 4,6-dinitro compound (VIII), 2,4-dinitro-1,3-dimethylbenzene (IX) could be isolated from the crude nitration product above by repeated recrystallization from chloroform (10). In

[3]*Ruggli and Reichwein (7) prepared XVI from XII via XIII, 4,6-dinitro-1,3-bischloracetylbenzene, and 4,6-diamino-1,3-bischloroacetylbenzene. Their yield of XVI from XII was approximately 44%, comparable to the present yields, but their route involved isolation of the intermediate bis-diazoketone (XIII) and one step more than either of the present routes.*

[4]*For comparison, the overall yield of compound VII from 4,6-dinitro-1,3-dimethylbenzene was approximately 10% (4).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



another run, from 135 g of mixed dinitroxylenes, the yield of crude 2,4-dinitro isomer (IX), shown to contain a small amount of the 4,6-dinitro isomer (VIII) by thin-layer chromatography, was 1.8 g (7%); the crude compound melted at 73–83° (lit. 82–83°) (10). Its n.m.r. spectrum (in deuterochloroform) contained a singlet at τ 7.54 (six protons, aryl methyl groups) and doublets (J = 9 c.p.s.) at τ 1.76 (one proton, H-5) and τ 2.36 (one proton, H-6).

4,6-Dinitro-1,3-benzenedicarboxylic Acid (X)

This compound was prepared exactly according to the oxidation procedure of Ruggli and Reichwein (7). From 20 g of 4,6-dinitro-1,3-dimethylbenzene (VIII), the yield of 4,6-dinitro-1,3-benzenedicarboxylic acid was 15.9 g (61%), m.p. 230–235° decomp. (lit. 234° decomp.) (7). Nuclear magnetic resonance data for the compound are presented in Table I. In 29 additional runs the yields varied from 29 to 51%.

The water-insoluble side product noted previously (7) was identified as a mixture of 4,6-dinitro-3-methylbenzoic acid (XI) and recovered starting material (VIII). A portion (1.2 g) of the material accumulated from several runs was separated into bicarbonate-soluble and -insoluble fractions. The base-soluble XI weighed 0.9 g and, after recrystallization from water, had m.p. 173–175° (lit. 171–171.5°) (11). Its infrared spectrum (Nujol) had a carbonyl band at 1 720 cm^{-1}; its n.m.r. spectrum (trifluoroacetic acid) contained only singlets, of area ratio 1:1:3 at τ 1.30 (H-5), τ 2.12 (H-2), and τ 7.20 (aryl methyl).

For personal use only.

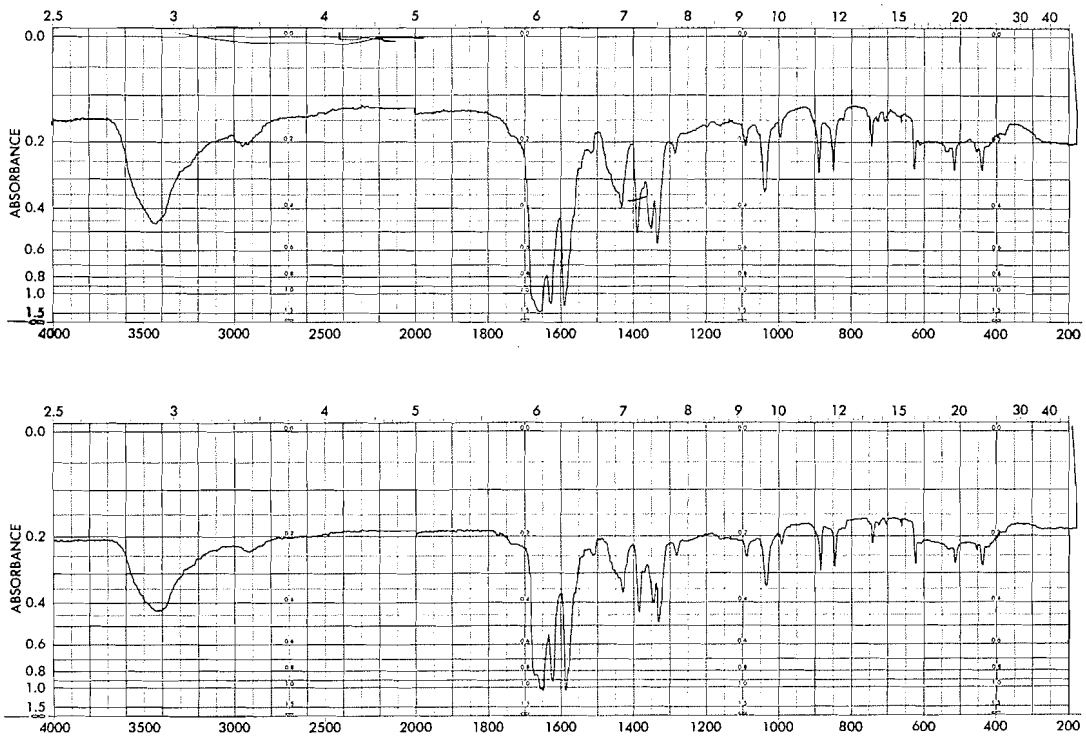

FIG. 1. Infrared spectra of 1,4,5,8-tetramethyl-2,7-dioxo-1,2,7,8-tetrahydro-1,8-diazaanthracene (VI), determined as potassium bromide pellets. Upper curve: sample obtained by methylation of 4,5-dimethyl-2,7-dioxo-1,2,7,8-tetrahydro-1,8-diazaanthracene (III) isolated from phosphorus – hydrogen iodide treatment of deoxynybomycin. Lower curve: sample obtained by methylation of synthetic compound III.

The bicarbonate-insoluble fraction weighed 95 mg and was identified as VIII, m.p. 86–88°.

Enhanced yields in the oxidation could be obtained by re-oxidizing the water-insoluble fraction. From each 20-g batch of material about 13 g of diacid was obtained. This would raise the yield of X by about 13% per run.

4,6-Dinitro-1,3-benzenedicarbonyl Chloride (XII)

The diacid chloride XII, m.p. 104–106° (lit. 106–108°) (7), was prepared in 82% yield by the exact procedure of Ruggli and Reichwein.

Preparation of 4,6-Dinitro-1,3-diacetylbenzene

A. Diethyl Malonate Procedure

The procedure followed was essentially that employed for the preparation of *o*-nitroacetophenone (12). From 27.1 g of magnesium turnings, 180.5 g of diethyl malonate, and 150 g of 4,6-dinitro-1,3-benzenedicarbonyl chloride (XII), the total yield of 4,6-dinitro-1,3-diacetylbenzene (XIV) was 71.2 g (53%). A single recrystallization from 95% ethanol gave the analytical sample, m.p. 137–138°.

Anal. Calcd. for $C_{10}H_8N_2O_6$: C, 47.62; H, 3.17; N, 11.11. Found: C, 47.31; H, 3.15; N, 11.12.

The infrared spectrum (chloroform) of the product contained a carbonyl band at 1 712 cm^{-1}. Its n.m.r. spectral data are found in Table I.

In a second run the yield was 52%.

B. Diazomethane Procedure

The procedure was essentially that of Wolfrom and Brown (11). A solution of 2.39 g (8.13 mmoles) of 4,6-dinitro-1,3-benzenedicarbonyl chloride (XII) in benzene was added dropwise to a stirred solution of 36.45 mmoles of diazomethane in ether (prepared from N-nitrosomethylurea and analyzed by decomposition with benzoic acid and titration with 0.2 *N* sodium hydroxide) (13). The yellow bis-diazoketone (XIII) precipitated and was filtered. It was then suspended in chloroform and stirred while 5 ml of 47% hydriodic acid was added; nitrogen was evolved and the mixture became deep purple. The chloroform solution was washed successively with water, sodium thiosulfate solution, sodium bicarbonate solution, and water; then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dried over magnesium sulfate; and finally evaporated to give 1.22 g (59%) of 4,6-dinitro-1,3-diacetylbenzene (XIV), m.p. 137–138° after two recrystallizations from 95% ethanol. The infrared spectrum and thin-layer chromatographic behavior (silica gel, chloroform solvent) of this sample were identical with those of the sample prepared by method A above. In four additional runs employing the diazomethane procedure, the yields of diacetyl compound (XIV) were 38–40%.

4,6-Diamino-1,3-diacetylbenzene (XVI)

From 948 mg of 4,6-dinitro-1,3-diacetylbenzene (XIV), the procedure of Ruggli and Reichwein gave 639 mg (80%) of 4,6-diamino-1,3-diacetylbenzene (XVI), m.p. 234–235° decomp. (lit. 235° decomp.) (7). An infrared spectrum (Nujol) of the product showed the expected two N—H stretching bands, at 3 500 and 3 320 cm^{-1}. Its n.m.r. values are found in Table I.

In a run on a 10-fold scale the yield was also 80%.

4,6-Diacetamido-1,3-diacetylbenzene (XVII)

The preparation followed a standard procedure (14). From 1.10 g of 4,6-diamino-1,3-diacetylbenzene (XVI) was obtained 1.51 g (94%) of 4,6-diacetamido-1,3-diacetylbenzene (XVII). Two recrystallizations from dimethylformamide gave the analytical sample, which did not melt below 350°.

Anal. Calcd. for $C_{14}H_{16}N_2O_4$: C, 60.86; H, 5.84; N, 10.14. Found: C, 60.78; H, 6.01; N, 10.43.

The infrared spectrum (Nujol) of the product contained amide bands at 3 250 cm^{-1} (N—H stretch) and 1 685 cm^{-1} (C=O stretch). Its n.m.r. spectral data are found in Table I.

4,5-Dimethyl-2,7-dioxo-1,2,7,8-tetrahydro-1,8-diazaanthracene (III)

The procedure was adapted from that of Camps (15). A mixture of potassium *t*-butoxide solution (prepared from 167 mg of potassium and 25 ml of dry *t*-butyl alcohol) and 500 mg of 4,6-diacetamido-1,3-diacetylbenzene (XVII) was heated under nitrogen for 1 h at reflux. Solid matter was filtered; weight, 244 mg. This was heated on the steam bath with 25 ml of 10% sodium hydroxide solution and then filtered hot. The filtrate was acidified with hydrochloric acid, and the resulting precipitate was filtered, washed with water, and dried; weight, 120 mg. Evaporation of the original *t*-butyl alcohol solution yielded further solid material, which was worked up with sodium hydroxide and acid as before to give an additional 179 mg of product. The total yield of compound III was thus 299 mg (69%); it did not melt below 350°. Its infrared (Nujol), ultraviolet, and n.m.r. (trifluoroacetic acid solution, see Table I) spectral data were the same as those of the product obtained from phosphorus – hydrogen iodide treatment of deoxynybomycin (8).

1,4,5,8-Tetramethyl-2,7-dioxo-1,2,7,8-tetrahydro-1,8-diazaanthracene (VI)

The dipyridone III (95 mg) dissolved in 25 ml of refluxing 10% sodium hydroxide solution. After addition of 2 ml of dimethyl sulfate a precipitate appeared; addition was continued until the solution was acidic to litmus. The precipitate was filtered, washed with water and acetone, and dried to give 62 mg (59%) of product (VI).

Anal. Calcd. for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44. Found: C, 71.67; H, 6.13; N, 10.24.

The compound did not melt below 350°, but its infrared (Nujol or potassium bromide, see Fig. 1), ultraviolet, and n.m.r. (trifluoroacetic acid, see Table I) spectra were all identical with those of the material obtained (8) from methylation of the phosphorus – hydrogen iodide product of deoxynybomycin.

ACKNOWLEDGMENT

This investigation was supported by Public Health Research grant No. AI-01278 from the National Institute of Allergy and Infectious Diseases.

ABSTRACT

Results are reported for the photolysis of small, fixed amounts of diazomethane and *cis*-butene-2 in the presence of increasing pressures of the inert gases He, Ar, Xe, N_2, and CF_4. The variation in the percentage yield of the *trans*-dimethylcyclopropane as a function of the inert gas pressure indicates that two basic mechanisms, with opposite dependencies on the inert gas pressure, are responsible for its formation. An initial decrease in the percentage yield of this *trans* isomer with increasing pressure indicates that a source is an isomerization of energized molecules. These excited molecules result from the addition of methylene in a singlet state to *cis*-butene-2. A subsequent rise in the yield of the *trans* isomer with further increases in the pressure indicates that another mechanism, one whose rate is *increased* by an increase in pressure, must be present. This is attributed to a mechanism involving triplet methylene. The pressure regions for the observation of the singlet or triplet behavior of methylene are thus known and the modes of formation of the other C_5 products may be determined.

INTRODUCTION

Skell (1) introduced the idea of relating the stereospecificity (or lack of it) observed in the reaction of methylenes with *cis*-butene-2 to the singlet (or triplet) nature of the methylenic species. The reaction of a methylene molecule in a singlet state with *cis*-butene-2 could conceivably give the complete cyclopropane framework in a single three-center addition step with consequent retention of the *cis* geometry in the 1,2-dimethylcyclopropane product molecule.

[1] 
The addition of a triplet methylene to *cis*-butene-2 must, unless there is a simultaneous triplet to singlet transition, give rise to a triplet intermediate.

[2] 
The triplet intermediate may be pictured as a structure with only two bonds of the ring system present or as some triplet excited state of the cyclopropane sigma bond structure.

[1] *Alfred P. Sloan Research Fellow.*
[2] *Abstracted from the thesis submitted by John I. Generosa in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

Either view leads to the prediction that the reaction need not necessarily lead to stereospecific products due to the weakening of the sigma bond framework. Thus the triplet intermediate can yield either *cis*- or *trans*-dimethylcyclopropane when the triplet to singlet transition does occur.

[3] 
Skell (2) found an example of presumed triplet behavior by this method for diphenylmethylene. Cvetanović (3) also observed that the reaction of oxygen atoms in their ^3P ground state resulted in a mixture of the *cis* and *trans* epoxides. Skell *et al.* (1) have also found that the 1,2-dimethylcyclopropane formed from methylene itself and large excesses of *cis*- or *trans*-butene-2 in the gaseous or liquid phase is almost entirely the *cis* or *trans* isomer respectively. This provides an example of singlet behavior. Ideally, to firmly establish Skell's method of distinguishing singlet and triplet states, one should find a system in which a single species exhibits both kinds of behavior. This evidence has been provided in the case of methylene itself by Anet, Bader, and Van der Auwera (4). This latter experiment was instigated by the spectroscopic findings of Herzberg and Shoosmith (5, 6). Their results indicated that the flash photolysis of diazomethane yields methylene molecules in highly excited singlet states which are subsequently energetically degraded to the ground state, which is a triplet, through collisions with inert gas molecules. The most intense spectrum for the triplet state was obtained when a large excess of nitrogen was present. Thus Anet *et al.* (4) studied the products obtained from the photolysis of small partial pressures of diazomethane and *cis*-butene-2 in the presence of a large excess of nitrogen as the inert gas. They found that the stereospecificity of the reaction was entirely lost. Thus methylene is formed in a singlet state,

$$CH_2N_2 \xrightarrow{h\nu} CH_2(\uparrow\downarrow) + N_2;$$

it may react immediately in its singlet state in a stereospecific manner via eq. [1] as in Skell's original work or, if a large excess of an inert gas is present, it may be degraded to its electronic ground state,

[4] $$CH_2(\uparrow\downarrow) \xrightarrow[\text{frequent collisions}]{N_2} CH_2(\uparrow\uparrow),$$

which then may produce both geometrical isomers via reactions [2] and [3].

The *cis*-dimethylcyclopropane (hereafter referred to as *cis*-DMC) when initially formed by the addition of singlet methylene to an alkene contains a large amount of kinetic energy resulting from the decrease in potential energy on the formation of the two new covalent bonds (7). A large fraction of this energy resides in the vibrational degrees of freedom of the product molecule. The energized *cis*-DMC molecule has been shown to undergo both geometrical isomerization to *trans*-DMC and structural isomerization to *cis*- and *trans*-pentene-2, 2-methylbutene-2, and 2-methylbutene-1 (8, 9).

[6] 
Thus all these C_5 hydrocarbons are obtained as products in the photolysis of diazomethane in the presence of *cis*-butene-2.

Frey (10) has criticized the work of Anet *et al.* on the grounds that the inert gas pressures employed by these workers (~560 mm Hg) were not sufficient to quench the geometrical isomerization of the highly energized *cis*-DMC molecule. Frey argued that Anet *et al.* had not observed triplet methylene and that their observed lack of stereospecificity in the cyclopropanes was due to the geometrical isomerization, reaction [5]. Frey (10) repeated the work of Anet *et al.* with inert gas pressures above 2 000 mm Hg and observed in the reaction the same lack of stereospecificity, which he attributed to the triplet species of methylene. Recently Benson and DeMore (11) have questioned the existence of triplet methylene even in Frey's experiments. They point out that dilution of the reaction mixture with nitrogen or argon in place of *cis*-butene-2 leads to a decreased deactivation efficiency and that the loss of stereospecificity observed by Frey could still be due to the geometrical isomerization reaction.

In this paper we present the results of experiments designed to determine whether or not it is indeed necessary to invoke the participation of triplet methylene in the photolysis of diazomethane, cis-butene-2, and inert gas mixtures, and if the presence of the triplet species is indicated, to determine the minimum pressure of inert gas necessary for the observation of the triplet behavior. The experiments consist of photolyzing mixtures of fixed, small amounts of diazomethane and *cis*-butene-2 held in a constant ratio of 2.5:1 in the presence of an increasing partial pressure of an inert gas.* The gases employed were He, Ar, Xe, N_2, and CF_4 in the pressure ranges of $0 \rightarrow 850$ mm Hg. The yield of *trans*-DMC expressed as a percentage of the total C_5 products is plotted vs. the pressure of the inert gas. This yield should be high at low pressures of the inert gas due to the geometrical isomerization of the energized *cis*-DMC, reaction [5]. As the pressure of inert gas is increased, the percentage yield of *trans*-DMC should decrease as the highly energized *cis*-DMC is deactivated by collision before isomerization can occur. Eventually, at some pressure of inert gas, the percentage yield of *trans*-DMC should begin to *increase* as there are now sufficient collisions with the inert gas molecules to permit the methylene to attain the triplet ground state before reacting with the butene. Only the formation of triplet methylene can cause the curve to rise since there is no other available mechanism for increasing the rate of formation of *trans*-DMC with increasing pressure. The graph of percentage yield of *trans*-DMC vs. inert gas pressure should be U shaped with the minimum in the curve indicating the pressure at which the rate of increase of *trans*-DMC formation from triplet methylene equals the rate of decrease of *trans*-DMC arising from the singlet species. Thus the participation of triplet methylene is proved for any pressure above the value at the minimum even though the absolute rate of formation of the *trans*-DMC from the geometrical isomerization reaction may still be the greater of the two.

**The partial pressures of diazomethane and cis-butene-2 employed in the experiments were 0.9 and 0.35 mm Hg respectively.*

Such a U-shaped curve is to be contrasted with the results obtained by Frey (9) for the photolysis of CH_2N_2 in the presence of increasing pressures of *cis*- or *trans*-butene-2 with no inert gas present. The discussion of these results will be given in terms of the variation in the percentage yields of *cis*-DMC rather than *trans*-DMC since his results for the reaction with *trans*-butene-2 cover a wider range of pressures than those with *cis*-butene-2. A plot of percentage yield of *cis*-DMC vs. increasing pressure showed the initial decrease as predicted due to the deactivation of the energized *trans*-DMC molecules by the *trans*-butene-2. However, the curve continues to decrease with increasing pressure of *trans*-butene-2 as little or no triplet methylene can be formed under these conditions. The rate of addition of methylene to an alkene is very rapid, being approximately 2.4 times smaller than the collision frequency (9). Consequently, with no inert species present, singlet CH_2 reacts before it is degraded to the triplet state. Thus the continued downward slope of the curve in Frey's work indicates a single source of *cis*-DMC, one which has an *inverse* pressure dependence. In the experiments reported here, any change in the sign of the slope must indicate the participation of a new source of *trans*-DMC, one whose rate increases with increasing pressures. The only reaction favoured by an increase in pressure is reaction [4], the conversion of singlet to triplet methylene.

Frey's criticism that pressures greater than 2 000 mm of Hg are necessary to unambiguously detect triplet participation can be checked immediately by noting the values of the pressure at the minima in the curves, and the very existence of a minimum will disprove the criticism of DeMore and Benson. Furthermore, the relative appearance of similar plots for the other C_5 product hydrocarbons will permit one to determine whether the product arises from the reaction of singlet or triplet methylene or both. Other things being equal, the relative efficiencies of the various inert gases in bringing about the singlet to triplet transition may be determined by noting the value of the pressure at which the minimum in the curve occurs and the slope of the line past this point. Also, their relative abilities in deactivating the energized *cis*-DMC molecules will be reflected in the initial slope of the curve before the minimum is reached.

RESULTS AND DISCUSSION

Figure 1 shows the amounts of *trans*-DMC formed at increasing pressures of inert gas expressed as a percentage of the total C_5 product yield. These yields are determined by the relative areas of gas–liquid chromatograms.* The predicted U-shaped curve is exhibited by the experiments with CF_4, N_2, Ar, and Xe while He has only a barely susceptible increase at the highest pressures used. The *relative* behavior of the downward and upward sloping portions of the curves finds a ready explanation in terms of a quenching of a geometrical isomerization and the intervention of triplet methylene respectively. The initial downward slopes should be a reflection of the relative efficiencies of the inert gases at deactivating the excited *cis*-DMC molecules which arise from singlet methylene. Since CF_4 has more internal degrees of freedom than does N_2 which in turn has more than He, one expects the deactivating ability of these species to decrease in the same order. This is precisely what is observed in Fig. 1 where the absolute values of the initial slopes

[FIG. 1. Percentage yield of *trans*-DMC vs. pressure for the inert gases He, N_2, and CF_4.

decrease in the order $CF_4 > N_2 > He$. The gases Xe and Ar have initial slopes experimentally indistinguishable from those for N_2. If the geometrical isomerization were the only source of *trans*-DMC these curves could only continue downwards with increasing pressures of inert gas. Rather, one observes a marked change in the sign of the slope which must be due to the appearance of a new source of the *trans*-DMC. This is ascribed to the reactions of triplet methylene whose relative concentration increases with increasing inert gas pressure. The methylene in this pressure region is energetically degraded to the triplet ground state by collisions with inert gas molecules before a reaction occurs, thus giving rise to the triplet intermediate and to the *trans*-DMC directly. In the highest pressure ranges investigated the gases CF_4, N_2, and Xe are experimentally indistinguishable in their yields of *trans*-DMC. All are superior in this respect to He, and Ar yields an intermediate value of 15% in the 700 mm pressure region. One cannot immediately conclude from this that CF_4, N_2, and Xe are all equally efficient at bringing about the singlet to triplet transition in methylene. There is still a contribution from singlet methylene in this high pressure region. Tetrafluoromethane must in fact be judged superior to the rest. The singlet contribution will be least in this case as CF_4 is the most efficient deactivator. Thus the contribution of the geometrical isomerization reaction at high pressures will be least for CF_4. The minimum in the curve for CF_4, which denotes the pressure at which the decrease in the rate of formation of *trans*-DMC equals the increase in its rate of formation due to triplet methylene, occurs in the region of 100 mm Hg. This is remarkably low. Nitrogen and xenon, both of which have distinct minima in their plots (at approximately 250 mm Hg) must have an almost equal ability at causing the singlet to triplet transition as their initial slopes are almost equal, but must be less efficient than CF_4 in this regard. Argon, which has approximately the same deactivating ability as N_2 and Xe, must be less efficient in causing the spin transition. Helium is the least effective both at deactivating and causing the spin conversion. The contribution of the geometrical isomerization reaction (at high pressures) must be greatest in the case of He but its percentage yield of *trans*-DMC is the smallest of all the gases in this region. This is an important observation as it indicates that at least 50% of the observed *trans*-DMC in this high pressure region for CF_4, Xe, and N_2 must arise from the triplet addition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reaction. This will be a lower estimate as the yield of *trans*-DMC in the He case is probably not due entirely to the geometrical isomerization. (The curve for He does level off, rather than undergo a continual decrease.)

Figure 2 presents other experimental results which further substantiate the above interpretation. These results are given in terms of the *trans*-DMC as a percentage of just the total cyclopropane yield to illustrate clearly the increase in one isomer at the expense of the other. The upper curve is the same set of standard runs for N_2 as presented in Fig. 1. The effect of increasing the *cis*-butene-2 to diazomethane ratio by a factor of 10 is illustrated in the second upper curve. This should result in a smaller fraction of methylene molecules reaching the triplet ground state and in a smaller yield of *trans*-DMC. This is observed. One of the lower curves is for a series of runs with no inert gas and increasing pressures of *cis*-butene-2. There is no U character to this curve within experimental error, the yield of the *trans*-DMC simply decreasing with increasing pressure of the butene as the geometrical isomerization is increasingly quenched. The remaining curve indicates the effect of added oxygen gas in the two pressure regions with the original *cis*-butene-2 : diazomethane ratio. The singlet region is almost unaffected, but the pressure region ascribed to the triplet state is radically changed. The curve never undergoes a change in the sign of its slope indicating that the second, high-pressure source of *trans*-DMC involving the triplet species is effectively quenched.

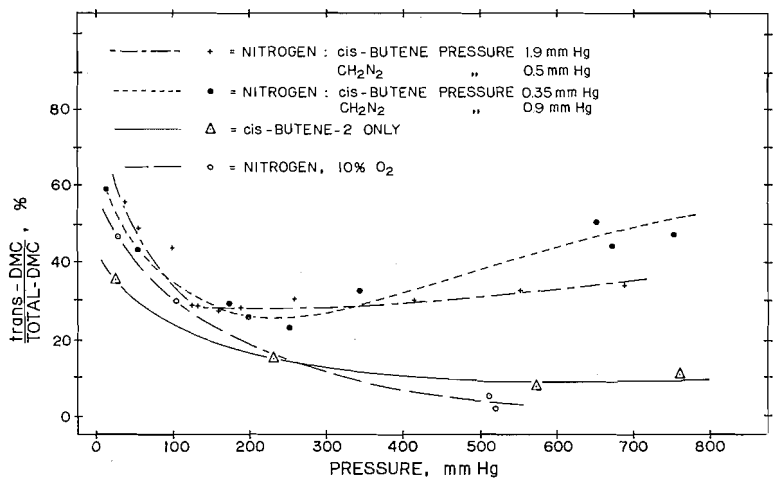

FIG. 2. Percentage yield of *trans*-DMC vs. pressure: ●, N_2 as inert gas; +, N_2 as inert gas with 10 times the *cis*-butene-2: diazomethane ratio; △, no inert gas present; ○, with added oxygen.

All the above data support the conclusion that the reactions observed in the pressure region below 100 mm Hg in the case of CF_4 and below 250 mm in the cases of N_2 and Xe are primarily due to singlet methylene, while for pressures above these values, they are due primarily to the triplet species. Thus whether the precursor of the other C_5 hydrocarbons is triplet or singlet, methylene is now determinable by noting the variation in the percentage yields of these products in the two pressure regions.

The variation in the yield of *cis*-DMC is plotted for CF_4 and He in Fig. 3 as a percentage yield of the total cyclopropanes to emphasize the variation in the *cis*:*trans* isomer ratio. The yield of *cis*-DMC increases initially due to the quenching of the geometrical isomerization to the *trans* isomer, the increase being greater in the case of CF_4

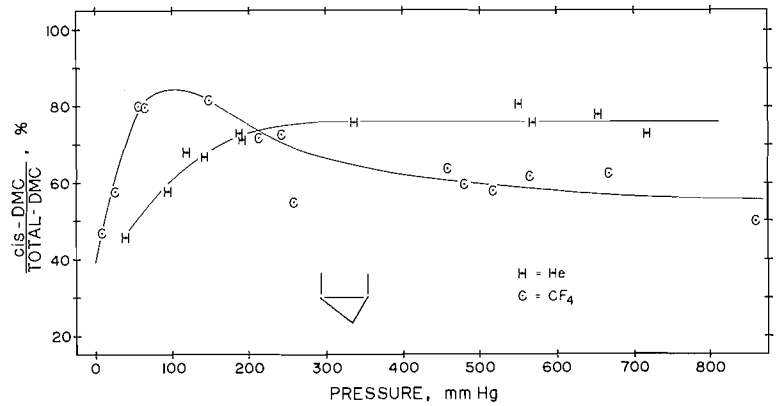

FIG. 3. Percentage yield of *cis*-DMC vs. pressure for the inert gases He and CF_4.

than with He. When the *trans*-DMC yield goes through a minimum, the *cis*-DMC exhibits a maximum, at 100 mm pressure in the case of CF_4. Beyond this point there is a steady decrease to some limiting value between 50 and 60%. This is a reflection of the fact that there are two reactions contributing to the formation of the *cis*-DMC, one which is inhibited by an increase in pressure and one which is made more pronounced. The yield of *cis*-DMC in the high-pressure region is greater for He than for CF_4 as He is less efficient at inducing the spin conversion. The yield with He in the low-pressure region is less since He is not as efficient as CF_4 at deactivation of the energized *cis*-DMC molecules.

Figure 4 shows the variation in the percentage yield of *cis*-pentene-2 with the inert gases CF_4 and He. The yield with CF_4 is seen to undergo a gradual decrease with increasing pressure of the inert gas. There are two modes of formation possible for *cis*-pentene-2. Methylene in its singlet state may insert into a C—H bond of the *cis*-butene-2 molecule to give the product directly, or it may arise from the isomerization of the energized cyclopropanes (12). The *cis*-pentene-2 resulting from the insertion reaction possesses sufficient internal kinetic energy to isomerize to the *trans* isomer. Stabilization of the product by increasing inert gas pressures should lead to an increase in the percentage yield. However, an increase in the inert gas pressure decreases the concentration of the singlet methylene necessary for the insertion reaction and stabilizes the energized DMC molecules. Thus the observed gradual decrease in the percentage yield of *cis*-pentene-2 does not allow one to determine which of the two modes of formation is the major source of this compound. We can obtain some indication of which of these processes is predominant by considering the related question of the variation in the percentage yield of the *trans* isomer. This is shown in Fig. 5. The initial decrease in the yield of *trans*-pentene-2 can be related to the increased collisional stabilization of the *cis* isomer. In the high-pressure region where the average percentage yield is greater, the *trans* isomer may also arise from the isomerization of the energized DMC resulting from the triplet addition reaction. It is reasonable to suppose that the DMC molecules will be more difficult to deactivate than the straight chain species as the structure of the cyclic species is a strained one. Thus the formation of *trans*-pentene-2 from the energized DMC should persist to high inert gas pressures, where its formation from the *cis* isomer is negligible. The addition of oxygen gas in the high-pressure region should reduce the yield of the *trans* isomer to almost zero by quenching the triplet addition reaction and leave as the only source of the *cis* isomer the singlet insertion reaction. The addition of oxygen gas was found to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reduce the percentage yield of the *trans* isomer to only trace amounts while that of the *cis* isomer was almost unchanged or at most slightly increased. These same observations have been reported by Frey (10).

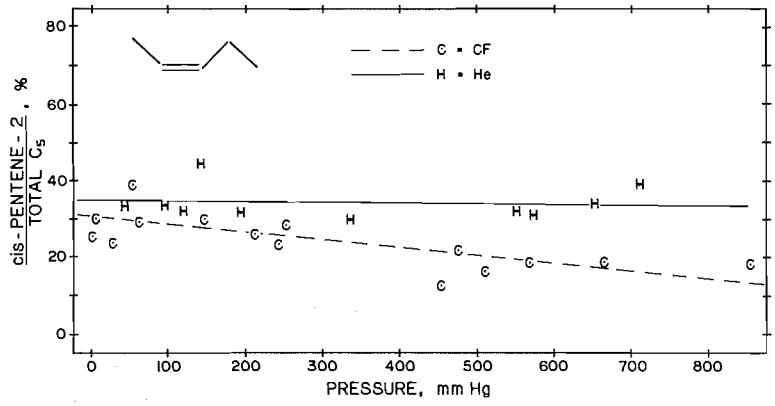

FIG. 4. Percentage yield of *cis*-pentene-2 vs. pressure for the inert gases He and CF_4.

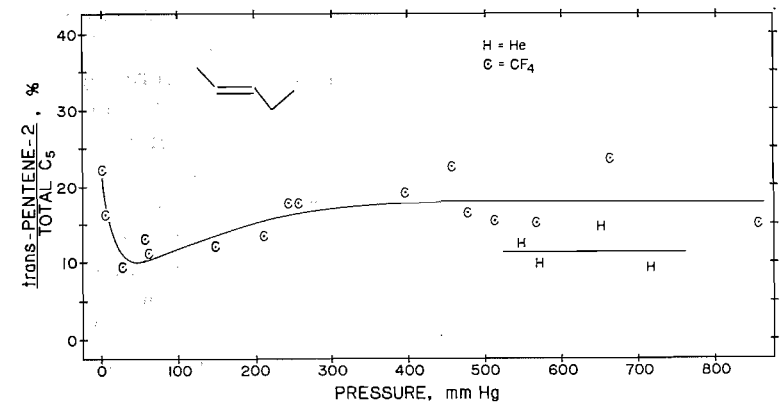

FIG. 5. Percentage yield of *trans*-pentene-2 vs. pressure for the inert gases He and CF_4.

These results are explicable if the principal source of the *trans* isomer is from the energized DMC molecules (or the triplet intermediate itself which should isomerize preferentially to the *trans*-pentene-2) which result from the triplet addition reaction. The *cis*-pentene-2 arises primarily from the singlet insertion reaction. The slight increase in the percentage yield of this isomer can be accounted for by the absolute decrease in the yields of the *trans* isomers on the addition of oxygen gas. The results with He as the inert gas bear out these interpretations. If the primary source of the *cis* isomer at high pressures is from the singlet insertion rather than from the isomerization of the energized DMC, the yield with He should be greater than the yield with CF_4 as the concentration of the singlet species is greater with He. The yield of the *trans* isomer is smaller with He than with CF_4, again reflecting the enhancement of the triplet addition reaction with the latter inert gas. If the major source of the *trans*-pentene-2 was from the isomerization of the energized *cis* isomer just the reverse behavior should have been observed.

Benson and DeMore (11) relate the vanishingly small yields of the *trans* isomers on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

the addition of oxygen gas to an enhanced deactivating ability of this gas over that for N_2 or even *cis*-butene-2. This would explain the formation of the thermodynamically less favored product in a reaction in which the product distribution is determined by the quenching of a final adduct. Indeed, in the present experiments with increasing pressures of *cis*-butene-2 and no inert gas, the yield of *trans*-pentene-2 is again considerably decreased. Thus if one considers only the results with O_2 and *cis*-butene-2, one could conclude that all of the *trans*-pentene-2 arose from an isomerization of the energized *cis* isomers. However, if one compares two gases which may deactivate *without* at the same time reacting with the methylene and thus either prevent the formation of the triplet species, or rapidly remove it, then this argument is seen to be false. This is the case as seen from the results for CF_4 and He where not only does the percentage yield of *trans*-pentene-2 increase with increasing pressures, but does so more in the experiments with CF_4 than those with He. The small yields with O_2 and butene-2 are then explained by the absence of triplet methylene.

The variation in the percentage yield of 2-methylbutene-2 with increasing inert gas pressure is shown in Fig. 6. The form of this variation is readily accounted for by assuming that this isomer may arise either by direct insertion into the vinylic C—H bond of the *cis*-butene-2 or through the isomerization of the energized DMC molecules. The insertion reaction should decrease with increasing inert gas pressures as more of the singlet methylene is converted to the triplet form before reaction with the butene occurs. The deactivation of the energized DMC molecules by increasing concentrations of inert gas molecules should also lead to a decrease in this percentage yield. One would expect the percentage yield of 2-methylbutene-2 to be greater in the case of He than with CF_4 as He is less efficient as a deactivator and is also less efficient at causing the singlet to triplet transition. While singlet insertion must be invoked as the main source of *cis*-pentene-2, one could explain the entire form of the 2-methylbutene-2 curve without the insertion mechanism. That singlet methylene is a precursor of 2-methylbutene-2 is clearly illustrated by the continuous decrease in its percentage yield as the pressure of inert gas is increased.

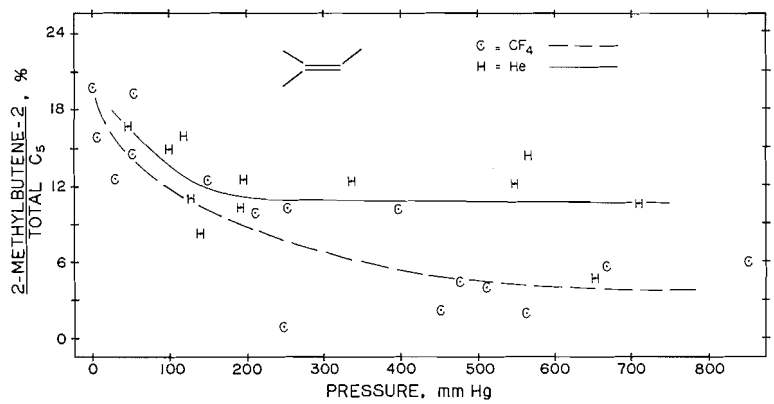

FIG. 6. Percentage yield of 2-methylbutene-2 vs. pressure for the inert gases He and CF_4.

The percentage yield of 3-methylbutene-1, Fig. 7, is seen to increase with increasing pressure of inert gas. This indicates that triplet methylene is a precursor of this isomer. The formation of this compound cannot be explained directly by any insertion mechanism. Nor is the *major source* due to the isomerization of the energized cyclopropanes since

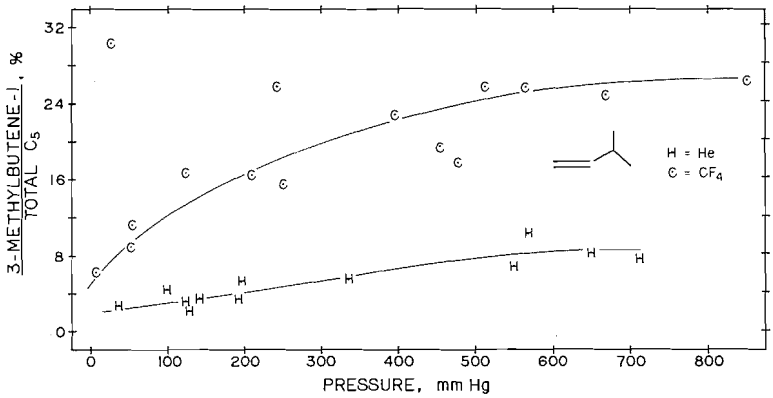

FIG. 7. Percentage yield of 3-methylbutene-1 vs. pressure for the inert gases He and CF_4.

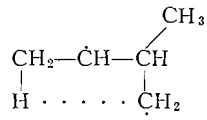
this would decrease with increasing inert gas pressure and the yield with He should then be greater than that observed with CF_4. The opposite behavior is actually observed. The most direct explanation for the appearance of this compound and its dependence on triplet methylene is to propose that the triplet adduct may not only close to give both



cis- and *trans*-DMC but may undergo an internal hydrogen abstraction through a five-membered cyclic intermediate to give the 3-methylbutene-1 directly. This mechanism was previously proposed by Duncan and Cvetanović (13) to account for the formation of this isomer in the photosensitized decomposition of ketene in the presence of *cis*-butene-2. Duncan and Cvetanović conclude, as did Frey (8) from his high-pressure work, that 3-methylbutene-1 can arise from the addition of triplet methylene to *cis*-butene-2. The yield of 3-methylbutene-1 is reduced to almost zero over the whole pressure range by the addition of oxygen gas. This again indicates the participation of triplet methylene. The same result was reported by Frey (8) for a single run in the high-pressure region. In the experiments with CF_4 and Xe, at pressures below 25 mm the yields of 3-methylbutene-1 are found to be high (see Fig. 7 for the CF_4 case) and to drop very rapidly with increasing pressure of inert gas. This effect did not appear in the experiments with N_2 where the lowest pressure employed was 14 mm. Setser and Rabinovitch (14) in studies on the pyrolysis of CH_2N_2 in the presence of *cis*-butene-2 detected a very rapid initial decrease in the percentage yield of 3-methylbutene-1. Thus there may be another mode of formation for the compound which has an inverse pressure dependence, and operates only at very low pressures. This can be explained by a similar type of migration in a highly energized singlet form of the intermediate postulated above, i.e., a bond in the cyclopropane ring structure is broken due to the large excess of vibrational energy giving the singlet form of the intermediate which may again give a 1,4 hydrogen shift to yield 3-methylbutene-1*. This mechanism has been proposed by DeMore and Benson

**There is considerable scatter in the plots for 3-methylbutene-1 in the* CF_4 *and* Xe *runs at these very low pressures, and the present results do not prove unambigously that there is a second mechanism operating at low pressures which gives this isomer. Flowers and Frey (15) in pyrolytic studies on cis-DMC found only minor amounts of 3-methylbutene-1 even at pressures as low as 6.5 mm. However, the cis-DMC molecules will be more efficient than* CF_4 *or* Xe *at cooling highly energized species.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to explain the formation of 3-methylbutene-1 in all cases and they claim that the intervention of triplet methylene is not necessary to explain its appearance as claimed by Frey (10) and Duncan and Cvetanović (13). However, the present results prove that the principal source of 3-methylbutene-1 cannot be due to the rearrangement of a highly energetic species as its percentage yield increases with increasing inert gas pressure and the yield is greater with CF_4 than with He.

THE CONVERSION OF SINGLET TO TRIPLET METHYLENE

Jordan and Longuet-Higgins (16) have determined the relative energies of the lower electronic states of a number of hydride radicals. Their method is semiempirical, making use of observed spectroscopic and heat of formation data rather than attempting to calculate the electronic energies from approximate wave functions. This gives the method a quantitative basis. Their predictions regarding both the geometries and energies for these molecules are in excellent agreement with experiment. We have used their results for CH_2 to estimate the probability of the system crossing from a singlet to a triplet state due to a spin–orbit perturbation. The electronic configuration of the ground state of CH_2 is $(\sigma_g(1s))^2\ \sigma_g^2\ \sigma_u^2\ \pi_u^2$, which gives the following electronic molecular states in order of decreasing stability; $^3\Sigma_g^-$, $^1\Delta_g$, $^1\Sigma_g^+$. Thus if CH_2 is a linear molecule, the ground state should be a triplet. When the molecule is bent the degeneracy of the π_u orbital is lifted and a closed shell configuration can be written for the ground state, giving a singlet,

$$(a_1)^2\ (a_1)^2\ (b_2)^2\ (a_1)^2;\ ^1A_1.$$

Excited states of the bent molecule arise from single or double occupation of the second orbital, b_1, of the linear π_u set, i.e., $^3B_1$, $^1B_1$, and $^1A_1'$ states. Jordan and Longuet-Higgins have determined the relative energies of these states as a function of the bond angle. Their results are shown in Fig. 8. Their calculations predict that the $^3\Sigma_g^-$ state will be the most stable in agreement with the spectroscopic results of Herzberg and Shoosmith (5). The bent state is a singlet and is predicted to have an energy minimum at 107°. (The interaction of the two $^1A_1$ states was taken into account in the calculation.) The interesting feature of these calculations is the crossing of the potential curves for the $^1A_1$ and $^3B_1$ states with change in the bond angle. If the spin quantum numbers were "good" quantum numbers in the sense that the spin angular momentum was a completely independent quantity and always conserved, then no crossover from the singlet to the triplet curve could occur. However, the carbon atom Hamiltonian does have a small but finite spin–orbit interaction component, and thus conservation of spin angular momentum, while almost complete, is not a rigorous requirement in the system. We must ask two questions; will the spin–orbit perturbation indeed "mix" the $^1A_1$ and $^3B_1$ states and will this interaction lead to a kinetically significant rate for the singlet to triplet crossover?

The triplet state spin functions transform as the A_2, B_1, and B_2 irreducible representations of the C_{2v} point group and thus the overall symmetries (space and spin) of the wave function for the $^3B_1$ ground state are B_2, A_1, and A_2 (17). Since the perturbation will "mix" only those states which have identical symmetries, the $^1A_1$ state* may "mix" with the $^3B_1$ ground state. Following the method outlined by Sidman (18) and applying the perturbation at the point of intersection, one finds that the ± 1 spin components of the $^3B_1$ state (^+B and ^-B) mix with the $^1A_1$ state (^0A) giving

$$\psi_1 = \tfrac{1}{2}(^+B + {}^-B + \sqrt{2}\,{}^0A)$$

$$\psi_2 = \tfrac{1}{2}(^+B + {}^-B - \sqrt{2}\,{}^0A)$$

**The singlet spin function transforms as does the A_1 representation.*

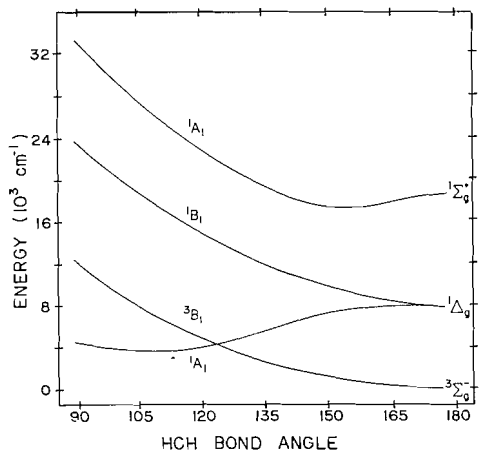

FIG. 8. Variation of the energy with bond angle for the lowest electronic states of methylene after Jordan and Longuet-Higgins (16).

with an energy splitting of $2\sqrt{2}\zeta$, where ζ is the spin–orbit coupling perturbation which we have considered to be determined completely by the carbon 2p orbitals and by an effective potential due to the carbon nucleus only, as suggested by Sidman (18). This yields a value for $\zeta = 14$ cm^{-1} compared to 16.4 cm^{-1} observed for an isolated carbon atom (19). Since these answers differ so little we have employed the value for the isolated carbon atom in our calculations giving $\langle V \rangle = 2\sqrt{2}\zeta = 46.2$ cm^{-1} or 9.18×10^{-15} erg. The probability of a transition from the singlet curve to the triplet curve during a double pass through the point of intersection (as occurs on every complete cycle of the bending vibration) is (20)

$$P_{3\leftarrow 1} = \frac{8\pi^2 \langle V \rangle^2}{h|F_2 - F_1|}\left(\frac{1}{v}\right),$$

where h is Planck's constant, $|F_2 - F_1|$ is the absolute value of the difference in the slopes of the two curves at their point of intersection, and v is the velocity with which the system approaches the crossing point. Dr. Jordan (21) has kindly supplied us with more recent, improved values for $E(^1A_1)$ and $E(^3B_1)$ vs. bond angle and we have used these values to determine a value of 2.80×10^{-12} erg/radian or 2.71×10^{-4} erg/cm for $|F_2 - F_1|$. The velocity of approach v is determined by the number of energy quanta possessed by the bending vibration, by its frequency and reduced mass, and by the C—H bond length. Jordan and Longuet-Higgins estimate the bending frequency ν_2 to be 1 180 cm^{-1}. This value of ν_2 gives a zero point energy which is not quite sufficient to enable the system to reach the point of intersection. (The system could still tunnel through the small remaining barrier of $\sim$175 cm^{-1}.) For the $n = 1$ level of ν_2, the average value of the kinetic energy at the point of intersection will be approximately 1 000 cm^{-1}*. From this value for the kinetic energy we calculate the classical velocity of the reduced mass point through the point of intersection to be 7.28×10^5 cm/s. Substitution of these values gives

$$P^1_{3\leftarrow 1} = 5.08 \times 10^{-3}.$$

**The quantum mechanical virial theorem when applied to a harmonic oscillator states that $\bar{T} = \bar{V} = \frac{1}{2}\bar{E}$, i.e., the average values of the kinetic ($\bar{T}$) and potential ($\bar{V}$) energies are equal for all values of the displacement. When viewed in this manner, rather than in the classical way given above, one calculates a slightly lower value for $\bar{T} = 885$ cm^{-1} for the $n = 1$ state.*

The superscript 1 is added to denote that $P_{3\leftarrow 1}$ depends on the vibrational quantum number through the velocity v. The first-order rate constant for singlet to triplet crossover is

$$k_{3\leftarrow 1} = P^1_{3\leftarrow 1} \times \nu_2 = 1.8 \times 10^{11}\ s^{-1}.$$

This frequency of crossover is approximately ten times greater than the number of collisions per second of an average sized molecule under standard conditions of temperature and pressure. The calculation thus predicts that the formation of triplet methylene from its $^1A_1$ state may compete favorably with the removal of the same singlet species by its reaction with *cis*-butene-2. The addition reaction occurs on almost every collision with the *cis*-butene-2 and if the concentration of the alkene is kept at a low value, as in the present experiments, the reactions of triplet methylene should be observed.

This calculation does not take into account the fact that the methylene molecule is not formed in the lowest of its singlet states (6). It must first, therefore, lose electronic energy either by a radiative process or by collision. Very little is known about the collisional transfer of electronic energy. However, these processes should be rapid compared to the rate of addition of singlet CH_2 to *cis*-butene-2 at the very low ratios of butene/inert gas ($= 5 \times 10^{-4}$) employed in the present experiments. Under these conditions a large percentage of the methylene must reach the $^1A_1$ ground state. Thus the competition will be between the addition reaction and the singlet to triplet crossover for the $^1A_1$ species.

The value of $P^n_{3\leftarrow 1}$ decreases with increasing velocity (large values of the vibrational quantum number n) through the point of intersection. The CH_2 molecule will still be vibrationally excited in the $^1A_1$ state and the rate of triplet formation should increase as the molecule is vibrationally deactivated, reaching a maximum for the $n = 0$ or 1 level. This would account for the enhanced efficiency of CF_4 in generating the triplet species: CF_4 will be the most efficient of the gases investigated here at removing the excess vibrational energy from CH_2. (Recall the very steep initial slope of the curve for CF_4 in Fig. 1 which is again a measure of its ability at removing excess vibrational energy through collisions.)

We have considered the mechanism of the crossover to be an intramolecular one and have not taken into account other magnetic perturbations which may arise through collisions with the inert gas molecules. If the magnetic perturbations induced by the collisions were of greater importance than the vibrational deactivation of the $^1A_1$ state discussed above, one might have expected Xe to be superior to N_2 and CF_4 in causing the singlet to triplet transition. Xenon, since it is the most polarizable of the three gases, should give rise to the greatest change in the electron distribution on collision. If the collision is strong enough to merit the writing of a single wave function for the combined system, CH_2 + inert gas, (i.e., electron exchange is important), one should expect the large spin–orbit forces present in Xe ($\zeta = 8\,250\ cm^{-1}$) to result in considerably higher yields of the triplet species than do N_2 or CF_4. Instead the abilities of Xe and N_2 in this regard are experimentally indistinguishable, and both are less efficient than CF_4. These observations are explicable on the grounds that it is necessary to remove excess vibrational energy in the singlet ground state to achieve appreciable rates of singlet to triplet crossovers. Specifically one wishes to remove vibrational energy from the bending mode of CH_2. Herzfeld and Litovitz (22) have demonstrated that molecules with vibrational frequencies close to the lowest frequency of the vibrationally excited molecule are particularly efficient at quenching, and CF_4 does in fact possess a mode with a frequency of 1 281 cm^{-1} (23), which is close to that predicted for the bending mode in methylene.

EXPERIMENTAL METHODS

A typical high-vacuum system was used for the transferring and purification, by bulb to bulb distillation, of all materials and for their introduction into a "seasoned" 2 l reaction bulb. All pressures were measured by Bourdon gauges (spoon type) to avoid contaminations with mercury vapor. The lamp employed in the photolyses was a medium-pressure mercury vapor lamp (G. E. H-4AB). Care was taken to maintain the reaction flask at 25 ± 5 °C by means of a 7 in. fan. The irradiation times were of 8 h duration.

Diazomethane was prepared by the method of Arndt and Amende (24) modified by extracting the product with decalin rather than diethyl ether. The diazomethane was stored at −196 °C. Before use it was alternately warmed to room temperature, refrozen, and pumped, this procedure being repeated a number of times to remove non-condensibles. The ethylene was removed by pumping for ½ h on the storage bulb, its temperature being maintained at −125 °C. This was followed by a distillation at −70 °C. The *cis*-butene-2 (Matheson, Canada) was degassed by alternate freezing and warming and was subjected to several trap to trap distillations at dry ice – acetone temperature. Nitrogen (Matheson, prepurified grade) specified to have less than 7 p.p.m. oxygen was used. Nitrogen was also treated by passing the gas through a powdered copper – kieselguhr column at 400 °C and then through a spiral trap immersed in liquid nitrogen. No detectable differences were found between runs with the nitrogen purified in this manner and runs with the Matheson lecture bottle grade. Helium, xenon, and argon were all of research grade (99.99% purity) and used without further purification. The carbon tetrafluoride was purified by low-temperature distillations and by passage through a large U tube filled with silica gel and maintained at a temperature of −135 °C. This latter step is to remove hydrocarbon contaminants. Gas – liquid phase chromatographic analysis of the purified CF_4 showed no hydrocarbon impurity.

Analysis of products were performed with g.l.c. The column consisted of an 8 m length of 23% by weight 2,5-hexanedione on 30–60 mesh Columnpax maintained at a temperature of 3 °C, followed by a Perkin-Elmer HX column (2 m, $AgNO_3$ – propylene glycol). Helium was used as the carrier gas. The products were identified by collecting the components as eluted from the g.l.c. in CS_2 cooled in a dry ice – acetone slurry. The solutions were then identified by infrared spectrophotometry. Retention times of the products were also compared with those of known samples.*

ACKNOWLEDGMENTS

We are grateful to Professor F. A. L. Anet, Dr. M. Back, and Mrs. Anne-Marie Van der Auwera for helpful discussions. We wish to thank the Ontario Research Foundation for a grant in aid of research.

COMPLEXES OF BORON TRIFLUORIDE WITH FLUOBORATES[1]

S. BROWNSTEIN AND J. PAASIVIRTA[2]
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received December 23, 1964

ABSTRACT

The occurrence of complexes of boron trifluoride with some fluoborates has been established. Enthalpies of formation were determined for some of these complexes. Infrared and fluorine resonance spectra were obtained in an attempt to elucidate the structures of the complexes.

INTRODUCTION

Complexes of one molecule of boron trifluoride with one molecule of a Lewis base are well established. Only two cases have been reported where 2:1 complexes are stable in solution (1), and these have not been definitely confirmed by another technique (2). It was proposed that the second boron trifluoride in the 2:1 complexes was bound by a fluorine–boron–fluorine bridge. Although there are many examples of other bridging halogen atoms only a few cases have been established for fluorine (3–5). Investigations of Friedel-Crafts catalyzed isomerizations suggest that some reactive intermediates may contain two molecules of boron trifluoride for each molecule of Lewis base (6). It has been found that boron trifluoride at low temperatures forms complexes with alkyl fluorides (7). These results suggest that fluorine-bridged complexes may be of widespread occurrence and could be involved in Friedel-Crafts catalysis using nonmetal fluorides as catalyst. An attempt was made to investigate this phenomenon in extremely simple systems, fluoborate salts and boron trifluoride. Complexes were found but the dependence of stability upon cation shows that the situation is still rather complex.

EXPERIMENTAL

Most of the work was carried out with methylene chloride solutions. The solvent was prepared according to Eastham (8), and all solutions made under vacuum conditions. The $AgBF_4$ was prepared from AgF and BF_3 in nitromethane (9), and purified via its benzene complex (10). Tetra-*n*-butylammonium fluoborate was prepared by the reaction of aqueous alcoholic solutions of silver fluoborate and tetra-*n*-butylammonium iodide. The crude product was recrystallized from methanol–water and vacuum dried, m.p. 161.5 °C, lit. 161.8 °C (11).

Pressure measurements were obtained with a constant volume mercury manometer. The high vacuum system employed was so designed that a minimum quantity of gas was outside the thermostated container. Corrections were made for this volume. Fluorine resonance spectra were obtained at 56.4 and 94.1 Mc with a specially designed variable temperature probe (12). Infrared spectra were obtained with the samples incorporated in KBr pellets and as methylene chloride solutions.

RESULTS AND CONCLUSIONS

A typical plot of pressure vs. total BF_3 in the presence and absence of $AgBF_4$ is shown in Fig. 1. From the dimensions of the apparatus, and assuming gaseous BF_3 to behave idealy, it is possible to calculate the concentration of BF_3 in solution. For a BF_3 partial pressure of 100 mm the variation of solubility with temperature is shown in Fig. 2. If the differential heat of solution of BF_3 in a saturated solution of methylene chloride is constant, a straight line plot should be obtained in Fig. 2. Although there is deviation from

ideal behavior, the average value of the heat of solution was calculated from the Clausius–Clapeyron equation and is listed in Table II.

Once the apparatus had been calibrated for solvent and BF_3, measurements were made with added fluoborate. If it is assumed that the partial pressure of BF_3 is a measure of the free BF_3 concentration in solution, the amount of complexed BF_3 may be calculated. Since the concentration of complex never exceeded 0.04 m this assumption appears

For personal use only.

reasonable. It is then possible to calculate equilibrium constants for complex formation. Results and calculations for tetra-*n*-butylammonium fluoborate at 183 °K are shown in Table I.

TABLE I

Calculation of equilibrium constant for complex formation

BF_3 added*	P (mm Hg)	BF_3 (free)†	BF_3 (gas)‡	BF_3 (liquid)	$B_3F_{10}^-$§	$B_2F_7^-$	K_2‖
2.15	30.5	0.72	0.12	0.60	0.32	0.79	24
2.60	45.8	1.08	0.18	0.90	0.41	0.70	24
3.04	59.0	1.38	0.23	1.15	0.55	0.56	31
3.56	78.5	1.83	0.31	1.52	0.62	0.49	30
4.10	95.7	2.23	0.38	1.85	0.76	0.35	43
4.63	115.0	2.68	0.45	2.23	0.84	0.27	50

*Quantities are in mmoles; 1.11 mmoles of tetra-*n*-butylammonium fluoborate was placed in the apparatus.
†This value is obtained from the relationship between pressure and BF_3 in the absence of fluoborate.
‡This value is calculated from the pressure, temperature, and gas volume.
§Under these conditions there is complete formation of the 1:1 complex and the additional complexed BF_3 is present as the 2:1 complex.
‖This has been multiplied by 36.2 to express K for concentrations in molalities.

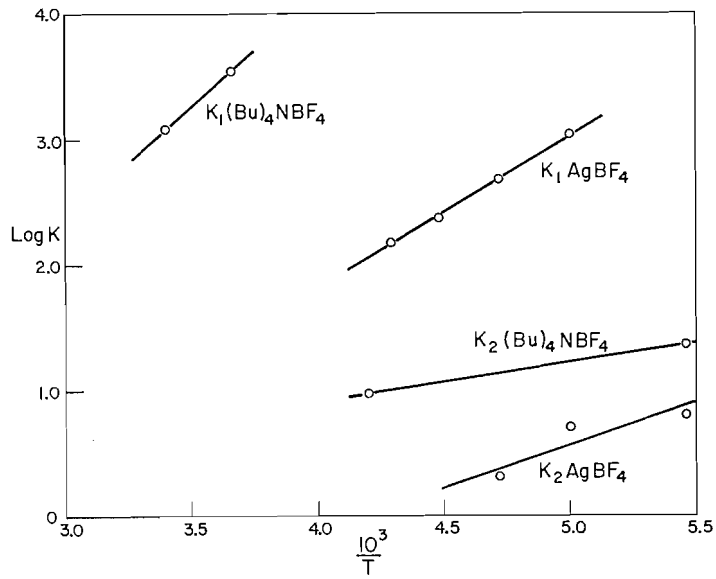

FIG. 3. Temperature dependence of complex formation.

The temperature dependence of the equilibrium constants for complex formation with silver fluoborate and tetra-*n*-butylammonium fluoborate is shown in Fig. 3. The equilibrium constants are given by the following expressions.

$$K_1 = \frac{[MB_2F_7]}{[BF_3][MBF_4]}$$

$$K_2 = \frac{[MB_3F_{10}]}{[BF_3][MB_2F_7]}$$

The nature of the cation has a marked effect on the stability of the complexes. It therefore seems likely that the various fluoborate complexes are present as ion pairs in methylene chloride solution. From the temperature dependence of the equilibrium constant the enthalpy and entropy of formation may be calculated. This is shown in Table II.

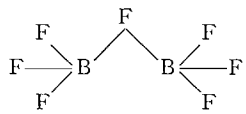
†The differential heat of solution.

Fluorine resonance spectra of the fluoborate salts plus varying amounts of boron trifluoride were obtained from room temperature to the freezing points of the solutions at about 170 °K. Silver fluoborate is not sufficiently soluble to obtain a useful spectrum. However, in the presence of excess boron trifluoride it goes into solution as the complex fluoborate as the temperature is lowered. Under all circumstances only a single line was observed, suggesting rapid exchange between free and complexed boron fluoride and rapid exchange between non-equivalent fluorines within the complex fluoborate. Chemical shifts for the complexes were obtained from samples where composition and temperature were such that the complex was the predominant species in the sample. The fact that these shifts are not merely the average value for the boron fluoride and silver fluoborate is additional confirmation of the existence of complexes in the solution. For a sample with a sixfold excess of BF_3 over tetra-*n*-butylammonium fluoborate the signal from liquid BF_3 was clearly observed after the bulk of the solution had been frozen at 165 °K. This indicates that large amounts of complexes greater than 2:1 could not have been formed under these conditions. The upward drift of K_2 in Table I suggested the possibility of higher complex formation. This cannot be confirmed with these experimental techniques since lower temperatures and higher pressures might produce liquid boron trifluoride.

Infrared spectra of NH_4BF_4, $(Bu)_4NBF_4$, and $(Bu)_4NB_2F_7$ are shown in Fig. 4. The three bands between 1 000 and 1 200 cm^{-1} are characteristic of the fluoborate ion (5). Their replacement by a single very broad band in $(Bu)_4NBF_4$ suggests that there is considerable interaction between cation and anion for this compound. The $B_2F_7^-$ anion is iso-electronic with bis-trifluoromethyl ether, which has a bent structure (13). The infrared spectra of linear and bent molecules of this type have been measured and discussed (14, 15). A linear molecule will have three prominent bands while five are expected for a bent molecule. Since five bands at 8.2, 9.1, 9.5, 9.8, and 12.0 μ are observed for B—F bending and stretching in the spectrum of $(Bu)_4NB_2F_7$ this suggests the possibility that the structure of $B_2F_7^-$ might be as shown.



Other techniques would be required to establish its structure and that of $(Bu)_4NB_3F_{10}$.

LOCALIZATION OF THE C=Se VIBRATION IN THE INFRARED SPECTRA OF SELENOSEMICARBAZONES[1]

B. A. GINGRAS, T. SUPRUNCHUK, AND C. H. BAYLEY
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received January 4, 1965

ABSTRACT

Few organic compounds of selenium are known and, consequently, very little published data are available concerning the various vibrations around the selenium atom. The present paper discusses the C=Se vibration in selenosemicarbazones by comparing their infrared spectra with those of corresponding Se-benzyl derivatives in which the C=Se group has been replaced by a C—Se—Bz. On this basis, it can be seen that a band at 800–780 cm^{-1} in the spectra of selenosemicarbazones is absent in the spectra of the benzyl derivatives. This band is assigned to the C=Se vibration.

In recent years, a few organic compounds of selenium have been investigated with particular emphasis on the localization of the various infrared vibrations around the selenium atom, generally by comparison with infrared spectra of analogous sulfur compounds. For instance, a band at 942 cm^{-1} was attributed to the CSe_2^- ion of diselenocarboxylates by comparison with the spectra of dithiocarboxylates which lacked that band (1). In metal complexes of iso- and seleno-cyanates, the C—Se stretching vibration was found to be in the regions 650 cm^{-1} for $NCSe^-$, and 550 cm^{-1} for $SeCN^-$ (2, 3). In selenoesters of the type Ar—CSeOMe, the region 1 227 – 1 220 cm^{-1} was suggested by Collard-Charon and Renson (4) for the C=Se by comparison with the spectra of the corresponding thio and oxygen compounds, although these workers point out the great similarity between the spectra of sulfur and selenium compounds in this class as well as in all the other compounds of selenium and sulfur they have studied. Thus, in *n*-butyl-4-selenosemicarbazides a band at 1 045 cm^{-1} was assigned to the C=Se vibration while in the corresponding thio compound, a band at 1 055 cm^{-1} was suggested for the C=S, and at 1 070 cm^{-1} (C=Se) and 1 075 cm^{-1} (C=S) in *n*-butyl-4-methyl-2-seleno- and thio-semicarbazides (5). By the same method of comparison, bands at 1 080 cm^{-1} and 1 082 cm^{-1} were assigned to the C=S and C=Se respectively in thio- and seleno-ureas, and at 1 115 cm^{-1} (C=S) and 1 110 cm^{-1} (C=Se) in substituted ureas (6).

In view of the results recently reported from this laboratory on the localization of the C=S in thiosemicarbazones (7), it seemed appropriate to extend this study to selenosemicarbazones. Because of the great similarity between the spectra of thio and seleno compounds already mentioned and because this similarity was found to exist in the case of thio- and seleno-semicarbazones, it was felt that the method of comparison could lead to very misleading conclusions. Indeed, it was found by Jensen (8) that the spectra of thio- and seleno-amides, ureas, and semicarbazides were so much alike that it was impossible to discriminate between the various vibrations. Jensen even argues that all assignments of infrared bands to the C=S group of thioamides may have been erroneous since the same bands appear in spectra of selenoamides.

The present work describes a number of new selenosemicarbazones and their infrared spectra with particular emphasis on the C=Se vibration. Another purpose of this work

[1]*Issued as N.R.C. No. 8362.*

was to study the antifungal properties of selenosemicarbazones and their reaction with metals. Such studies were carried out earlier with thiosemicarbazones (7, 9, 10) and a relationship was found between antifungal activity and complex formation with copper.

The selenosemicarbazones investigated are listed in Table I, together with their melting points and analyses. The preparation of these compounds is complicated by the fact that the required starting material, selenosemicarbazide, is not readily available and cannot be obtained by the procedures used for the oxygen and sulfur analogs. Selenosemicarbazide was obtained accidentally and in low yields during the isomerization of a selenocyanate in the presence of butyraldehyde (11, 12). The possible methods of preparation of selenosemicarbazones were reviewed by Mautner (13) and later by Renson *et al.* (11), who arrived at the conclusion that the best method was one involving an exchange of carbonyl radicals starting from acetone selenosemicarbazone which can be obtained in fair yields. This method was used in the present work.

*Literature m.p. 167–168 (12, 17).

Due to the greater mass of the selenium atom, the C═Se vibration is expected to occur at somewhat lower frequencies than the C═S. The latter does not give rise to as characteristic a band as the C═O group due to the complication of interaction, particularly in the case of thiosemicarbazones where the NH rocking vibrations can interfere; however, the C═S vibration was reviewed recently for several compounds by Colthup (14) and was found to be in the range 1 200 – 1 050 cm^{-1}. Furthermore, in an earlier publication, we assigned a band at around 1 100 cm^{-1} to this vibration in the case of thiosemicarbazones (7). The region between 1 200 and 700 cm^{-1} is, therefore, the logical one for

For personal use only.

the C═Se vibration to occur, at least in the case of selenosemicarbazones. This is substantiated by the value obtained for $\nu_{C=Se}$ using Gordy's rule and the harmonic oscillator equation.[2]

The method used previously (7) for the localization of the C═S vibration by comparing spectra of thiosemicarbazones with those of their copper complexes could not be used with reliability in the present case because of the difficulty in obtaining the copper complexes in sufficient degree of purity. Selenosemicarbazone–copper complexes can be prepared by the method described in a previous publication (10) but purification of the complexes, except in a few cases, resulted in partial decomposition and formation of colloidal selenium. However, benzyl derivatives of selenosemicarbazones, in which the benzyl radical is bonded to the selenium atom, are conveniently prepared and were found suitable for infrared studies, since the required change from C═Se to C—Se—Bz takes place.

Benzyl derivatives were then prepared from the series of selenosemicarbazones listed in Table I, and the new compounds are shown in Table II. Bands between 1 200 and 700 cm^{-1} in the spectra of selenosemicarbazones and their corresponding benzyl derivatives are shown in Table III.

It can be seen from Table III that the bands appear with a striking regularity in the

spectra of seleno- and benzylseleno-semicarbazones. For instance, a band at 1 105 – 1 110 cm^{-1} in the spectra of the seleno compounds is shifted regularly by 15–20 cm^{-1} in the benzyl derivatives while a band at 1 030 – 1 045 cm^{-1} in the former is split into a doublet in the spectra of the latter. This regular pattern can be seen throughout the spectra. The spectra of selenosemicarbazones consistently show a group of two bands, of weak to medium intensity, at 800–780 cm^{-1} and at 775–765 cm^{-1}, while the spectra of benzyl derivatives show only one band at 765 cm^{-1}. The band at 800–780 cm^{-1} is therefore assigned to the C=Se vibration. It is realized that formation of benzyl derivatives not only replaces a C=Se by a C—Se—Bz, but also results in a change of configuration from =N—NH—C(Se)—NH_2 to =N—N=C(SeBz)—NH_2; hence, a loss of a hydrogen atom and replacement of a C—N bond by a C=N bond. The band at 800–780 cm^{-1} (C=Se) in the spectra of selenoisemicarbazones is too low to have resulted from a C—N stretching vibration since this is usually found in the 1 400 cm^{-1} region (15) or between 1 300 and 1 000 cm^{-1} in amines (16). It could be argued that N—H rocking vibration can be found at such a low frequency but there remains in the molecules of benzylselenosemicarbazones free NH_2 groups, so that any N—H rocking should still be detected. The new C=N bond in benzylseleno compounds is likely responsible for an extra band at 1 650 cm^{-1} in the spectra. The new band is at somewhat higher frequency than that normally associated with the aromatic ring. This was examined more closely by comparing the spectra of benzaldehyde selenosemicarbazone with its benzyl derivative. The former has a broad band at 1 600 cm^{-1}, probably due to overlapping of the C=N vibration of the benzilidene grouping with the double bond vibrations of the aromatic ring, while the benzyl derivative shows the same pattern at 1 600 cm^{-1} but has an extra band at 1 650 cm^{-1}. This band is attributed to the C=N of the selenocarbohydrazide residue since it is probable that the vibrations associated with the benzyl radical will overlap with those of the benzene ring in the benzaldehyde portion of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

molecule. The strong absorption at 700 cm^{-1} in the spectra of benzylselenosemicarbazones may be suggestive of a C—Se stretch but no definite assignment can be made since this band may be due to the aromatic ring. Thus, a similar band at 695 cm^{-1} is present in both compounds 8 and 8*a* (Table III) which are aromatic, benzaldehyde seleno- and benzaldehyde benzylseleno-semicarbazone.

In the N—H stretching region, the spectra of selenosemicarbazones are identical with those of corresponding thiosemicarbazones reported earlier (10); they show three bands of medium intensity at 3 420, 3 280, and 3 180 cm^{-1}.

It should be mentioned that, although the preparation of selenosemicarbazone–copper complexes was not generally satisfactory, some were obtained in a fair degree of purity; e.g. dodecanal, *m*-nitrobenzaldehyde, and decanal selenosemicarbazone – copper (I). As with the thiosemicarbazone–copper complexes, the infrared spectra of the seleno–copper complexes are not well resolved but it is interesting to note that the band at 800–780 cm^{-1} (C═Se) disappears while the one at 765 cm^{-1} remains.

The biological properties of selenosemicarbazones will be reported elsewhere but it should be mentioned that the compounds were found to be generally more active than the corresponding thiosemicarbazones against the two organisms studied, *Chaetomium globosum* and *Aspergillus niger*. Furthermore, the activity of thiosemicarbazones was limited to the aliphatic ones, while a number of aromatic selenosemicarbazones (benzaldehyde and *o*-hydroxy-, *o*-chloro-, and *p*-methoxy-benzaldehyde selenosemicarbazones) were found to be active at 10 p.p.m. against *C. globosum*.

EXPERIMENTAL

Selenosemicarbazones

The method used was described by Huls and Renson (17). The new aliphatic compounds are listed in Table I.

Benzylselenosemicarbazones

An alcoholic solution of equivalent amounts of a selenosemicarbazone (from Table I) and sodium was refluxed for 5 min and allowed to cool. An excess (10%) of benzyl chloride was then added and the resulting solution was stirred for 1 h at room temperature, followed by a 5 min refluxing period. After cooling, the sodium chloride was separated out by filtration and the resulting solution was evaporated to a gum which was taken up in benzene–hexane (1:1), and passed through a column of silica gel. Benzene eluted a small amount of a by-product which was found to be benzyl diselenide $(C_6H_5CH_2Se)_2$; m.p. 89, lit. m.p. 92–93 °C (18).

Anal. Calcd. for $C_{14}H_{14}Se_2$: C, 49.41; H, 4.12. Found: C, 50.08; H, 4.94.

The infrared spectrum of this compound supports the diselenide structure instead of the benzyl selenol, since it shows no band in the region where the Se—H vibration is known to occur, at 2 290 – 2 295 cm^{-1} in phenyl selenol and 2 300 – 2 315 cm^{-1} for *n*-butyl selenol (6). Benzene–ether (1:1) eluted the required benzylselenosemicarbazones, listed in Table II.

Selenosemicarbazonato–Copper

Three 1:1 complexes were obtained in a sufficiently pure form for identification: decanal, dodecanal, and *m*-nitrobenzaldehyde selenosemicarbazone–copper (I). They were prepared by adding equimolar amounts of cupric chloride in ethyl alcohol to a warm solution of the selenosemicarbazone in the same solvent. The mixture turned brown and, after cooling, the precipitated complex was collected by filtration. The analyses are given for C, H, N only, since the presence of selenium interferes with the determination of copper.

Decanal selenosemicarbazonato–copper(I), m.p. 104 °C. Required for $C_{11}H_{22}N_3SeCu$: C, 38.98; H, 6.50; N, 12.40%. Found: C, 36.34; H, 5.82; N, 12.11%.

Dodecanal selenosemicarbazonato–copper(I), m.p. 155 °C. Required for $C_{13}H_{26}N_3SeCu$: C, 42.6; H, 7.1; N, 11.45%. Found: C, 42.86; H, 6.5; N, 11.4%.

m-Nitrobenzaldehyde selenosemicarbazonato–copper(I), m.p. 214 °C. Required for $C_8H_7N_4O_2SeCu$: C, 28.8; H, 2.1; N, 16.8%. Found: C, 29.2; H, 2.6; N, 17.0%.

Infrared Spectra

Infrared spectra were taken on a Perkin–Elmer, Model 21, Double-Beam spectrophotometer using KBr pellets.

THE STEREOCHEMISTRY OF HALOGEN DISPLACEMENT BY NITRATE ION

RACEMIZATION AND RETENTION OF CONFIGURATION IN THE SYNTHESIS OF DINITRATE ESTERS

L. D. HAYWARD, M. JACKSON, AND I. G. CSIZMADIA

Department of Chemistry, University of British Columbia, Vancouver, British Columbia, and Institute of Physical Chemistry, Uppsala University, Sweden

Received December 15, 1964

ABSTRACT

The reaction of silver nitrate in dry acetonitrile with 2,5-dideoxy-2,5-diiodo-1,4;3,6-dianhydro-L-iditol resulted in formation of the dinitrate esters of the 1,4;3,6-dianhydrides of D-mannitol, D-glucitol, and L-iditol. Similarly both *endo-* and *exo*-nitrato groups were introduced in displacement of the *endo*-halogen in the 2-deoxy-2-iodo-5-*O*-acetyl and 2-deoxy-2-iodo-5-*O*-*p*-toluenesulfonyl derivatives of 1,4;3,6-dianhydro-L-iditol. Since both types of nitrato groups were stable to silver nitrate, the racemization occurred during the displacement and was attributed to formation of cyclic carbonium ion intermediates. The steric effect of the adjacent ring in the carbonium ions apparently suppressed the termolecular, ion-pair mechanism previously established for the metathesis of acyclic alkyl halides and caused preferential formation of the *exo*-nitrato derivatives.

The heterogeneous reaction of *meso*-dibromostilbene with silver nitrate in acetic acid or acetonitrile gave *meso*-dihydrobenzoin dinitrate with overall retention of configuration. This result could be most readily reconciled with the contrasting sequence of retention and inversion previously reported for *meso-* and *dl*-2,3-dibromobutane if participation of neighboring phenyl groups occurred in the second displacement step.

INTRODUCTION

The metathesis of primary and secondary alkyl halides with silver nitrate is generally more complex than other nucleophilic displacements at saturated carbon atoms (1) since it involves both S_N1 and S_N2 character, third-order kinetics (2), and autocatalysis by silver halide (3). A reaction mechanism [1]–[3] proposed by Hammond and co-workers (2) specified that both silver cation and nitrate ion participated in the rate-determining step [1] to give essentially an ion-pair; collapse of the ion-pair in organic solvents led to formation of nitrate ester [2], or of olefins or alkylated solvent products [3]. Kinetic evidence also indicated formation of a similar intermediate complex in aqueous solution where the organic product was the corresponding alcohol (4).

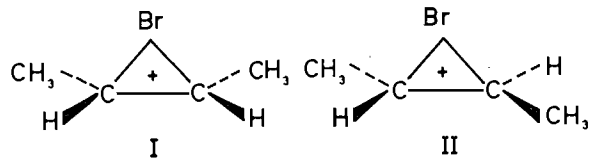
$$[1] \qquad NO_3^- + RHal + Ag^+ \xrightarrow{\text{slow}} NO_3^- R^+HalAg$$

$$[2] \qquad NO_3^- R^+HalAg \xrightarrow{\text{fast}} RONO_2 + AgHal$$

$$[3] \qquad NO_3^- R^+HalAg \xrightarrow{\text{fast}} HNO_3 + AgHal + \text{olefin or solvent alkylates}$$

Inversion of configuration occurred with optically active 2-octyl bromide either in acetonitrile or in suspension in ether (2, 5) and was consistent with formation of an intermediate, rigidly oriented ion-pair. On the other hand, in an ether suspension of silver nitrate optically active α-phenylethyl chloride reacted with *retention* of configuration although inversion occurred in acetonitrile solution (5). With the isomeric 2,3-dibromobutanes Fishbein (6) found that the first halogen was displaced with retention of configuration which was attributed to participation of the neighboring bromine (I and II)

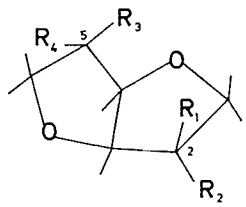
while displacement of the second halogen occurred with inversion with little or no anchimeric assistance from the neighboring nitrato group (6, 7, 8).



In contrast to these results we have observed both racemization and overall retention of configuration in the metathesis of alkyl dihalides during our study of the stereochemistry of nitrate esters (9, 10). Our results and their interpretation in terms of the above mechanisms are described here.

RESULTS AND DISCUSSION

In the three optically active deoxyiodo derivatives of 1,4;3,6-dianhydro-L-iditol (III–V) (11), the iodo groups are in the *exo*-position relative to the two *cis*-fused tetrahydrofuran rings, and, because of the restricted conformations of the V-shaped ring system, the carbon atoms to which they are attached, C-2 and C-5, are sterically hindered from backside attack (11–16). Treatment of the diiodo compound (III) with an excess of silver nitrate in boiling, anhydrous acetonitrile for 8 h gave the three diastereoisomeric



III $R_1 = R_3 = H$; $R_2 = R_4 = I$

IV $R_1 = R_3 = H$; $R_2 = I$; $R_4 = OCOCH_3$

V $R_1 = R_3 = H$; $R_2 = I$; $R_4 = OSO_2C_6H_4CH_3(p)$

VI $R_1 = R_3 = ONO_2$; $R_2 = R_4 = H$

VII $R_1 = R_4 = H$; $R_2 = R_3 = ONO_2$

VIII $R_1 = R_3 = H$; $R_2 = R_4 = ONO_2$

dinitrates (VI–VIII) (9) in yields of 3.7, 6.8, and 14.5% respectively, together with 70% of the theoretical amount of silver iodide (Table I). Compounds IV and V in similar conditions also yielded both *exo*- and *endo*-mononitrato derivatives which were detected chromatographically. The *exo*- and *endo*-nitrato groups were stable to the reaction conditions and hence the racemization occurred during the metathesis in this system thus indicating formation of a carbonium ion intermediate and inhibition of the termolecular S_N mechanism [1]–[3] by the molecular geometry. The slower reaction of compounds III–V (Table I) when compared to those of other alkyl halides (6) supported this conclusion since it indicated the absence of catalysis ("push" (6)) from nitrate ion or neighboring groups. The occurrence of a larger proportion of *exo*- as compared to *endo*-nitrato groups in the products was also consistent with a carbonium ion mechanism

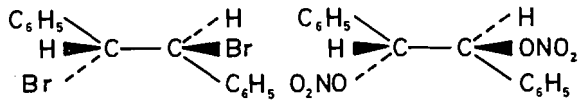
For personal use only.

and product formation under kinetic control, since the attacking anion could approach the carbonium ion with greater facility from the least hindered side resulting in preferential formation of the *exo*-derivative.

It would be of interest to compare the above results with those obtained with the corresponding *endo*-halo derivatives where the molecular geometry suggests that only *exo*-nitrato products would be formed in an S_N2 reaction. Unfortunately a synthetic method for the *endo*-halo derivatives in this series is not available at present.



IX X

We also repeated the metathesis of *meso*-dibromostilbene (IX) first reported by von Walther and Wetzlich (17) in 1900, since the earlier workers had made no stereochemical assignment for their product which melted at 132°. In either 50% acetic acid or acetonitrile suspensions the only dinitrate product we obtained was the *meso*-isomer (X) (53% yield, m.p. 148.5–149.5°). The identity of compound X was confirmed both by catalytic hydrogenation to the parent *meso*-hydrobenzoin and through comparison with the dinitrate esters obtained by direct *O*-nitration of the *meso*- and *dl*-hydrobenzoins.

The result showed that the presence of the phenyl groups in the vicinal dihalide favored displacement of the halogens with *either* retention *or* inversion of configuration at both asymmetric carbons. The present evidence does not permit a final decision between these possibilities but the former appeared to us the more plausible when considered together with the facts reviewed earlier. It is most readily reconciled with the results of Fishbein with 2,3-dibromobutane (6) if it is assumed that the β-phenyl groups participate (18) in the displacement of the second halogen atom in a manner analogous to the participation of the neighboring bromine (I and II) in the displacement of the first halogen as proposed by Fishbein (6). Since β-phenyl participation was not possible in the reactions of α-phenylethyl chloride studied by Kornblum and Hardies (5), the retention of configuration observed in that case was possibly due to participation of the ether solvent in the intermediate complex.

TABLE I

Reaction of silver nitrate with deoxyiodo derivatives of 1,4;3,6-dianhydro-L-iditol

Compound	Temp. (°C)	Time (h)	Product yield (%) AgI	Product yield (%) Nitrate esters*

III	81	6	70	VI, 1.3; VII, 2.9; VIII, 4.4
III	81	8	70	VI, 3.7; VII, 6.8; VIII, 14.5
IV	81	6	94	R_f 0.34, 15,‡ R_f 0.19, 1‡
V	81	6	81	R_f 0.40 to 0.27, 55;‡ R_f 0.15, 2‡

*Products with the highest R_f values were assigned the *exo*-nitrato configuration (cf. ref. 21).
†Starting material (III, 17%) was recovered unchanged.
‡Based on area and intensity of spots on chromatograms (10).

The evidence for β-phenyl group participation in nucleophilic displacements seems clear but the mechanistic pathways apparently remain undecided between formation of a bridged phenonium ion and steric hindrance to attack at one side of a rapidly equili-

brating classical carbonium ion (18). A more detailed study of the dihalostilbene metathesis might help to clarify this picture since the nitrato group exerts little, if any, neighboring group effect in displacements at carbon, a property which has been used to good advantage in synthetic carbohydrate chemistry (19, 20). It should be noted, however, that the presence of a suitably oriented neighboring nitrato group retarded the E_{CO} reaction of nitrate esters, a result which was traced to interaction between the nitrato nitrogen and neighboring alkoxyl oxygen (10).

EXPERIMENTAL

Reaction of Silver Nitrate with Deoxyiodo Derivatives of 1,4;3,6-Dianhydro-L-iditol

The preparation of the crystalline deoxyiodo (III–V) and dinitrate ester (VI–VIII) derivatives of the 1,4;3,6-dianhydrohexitols has been previously described (9, 11). The reaction times, temperatures, and yields of the metathesis products are shown in Table I. A solution of the iodo compound and silver nitrate ("Baker Analyzed" Reagent) in mole proportions 1:2–3 (iodine:silver nitrate) in acetonitrile (dried successively over phosphorus pentoxide and calcium hydride) after being heated for a given time under anhydrous conditions, was cooled and filtered and the silver iodide washed with acetonitrile, dried at 50°, and weighed. The filtrate and washings were concentrated under reduced pressure, then diluted with water, and extracted with chloroform. The combined chloroform extracts were washed with sodium bicarbonate and sodium thiosulfate solutions and water, dried, and evaporated and the residual sirups were chromatographed on alumina columns eluted with ether – ethyl acetate mixtures (9). Eluate fractions were examined for nitrate esters by paper chromatography (21) and the crystalline dinitrates isolated by evaporation of appropriate fractions were weighed and identified by means of mixture melting points with authentic specimens (9). The mono-*O*-acetyl- and mono-*O*-*p*-toluenesulfonyl-nitrate esters of 1,4;3,6-dianhydro-L-iditol were similarly recovered in microgram quantities and identified on paper chromatograms through the photoreaction with diphenylamine (21, 22). The mononitrate isomers with highest R_f values (Table I) were assigned the *exo*-nitrato configuration since the order of the R_f values for the dinitrate esters was VIII > VII > VI (21); relative yields were estimated from the area and intensity of the spots on the chromatogram (10).

1,4;3,6-Dianhydro-D-glucitol-2,5-dinitrate (VII) (0.127 g) and silver nitrate (0.285 g) were dissolved in dry acetonitrile (24 ml) and the solution, after refluxing under a phosphorus pentoxide drying tube for 8 h, was worked up as described above to give 0.114 g (89.7%) of the original dinitrate. Thin layer chromatograms of the product (22) showed no trace of the isomeric dinitrates. Silver nitrate (0.28 g, 99%) was recovered from the aqueous solution on evaporation.

meso-Hydrobenzoin Dinitrate (X)

meso-Hydrobenzoin (21.0 g, m.p. 137.0–139.5°, lit. (23) 138.5°) was nitrated in a nitric acid – acetic acid – acetic anhydride mixture (9) and the crude dinitrate ester (32.3 g, 112%) was purified by chromatography on an alumina column (30 × 500 mm) with benzene – petroleum ether (b.p. 30–60°), followed by recrystallization from the same solvent until the melting point (148.5–149.5°) was not altered on further recrystallization. The infrared spectrum (KBr) showed the characteristic nitrate ester absorptions (10).

Anal. Calcd. for $C_{14}H_{12}N_2O_6$: C, 55.26; H, 3.98; N, 9.21. Found: C, 55.46; H, 3.91; N, 9.11.

Hydrogenation of 47.2 mg of the dinitrate in absolute ethanol (25 ml) over palladium–charcoal (48.6 mg) at 60 p.s.i. for 3.5 h produced *meso*-hydrobenzoin, m.p. 137–140°, with the correct infrared spectrum and R_f values on thin layer chromatograms.

dl-Hydrobenzoin Dinitrate

dl-Hydrobenzoin (24) (21.0 g, m.p. 122.5–124.5°, lit. (23) 119.5–120.5°) was nitrated as above and the crude dinitrate (25.5 g, 86%) after purification as for the *meso*-isomer melted at 105.5–107.5°. The infrared spectrum (KBr) showed the presence of nitrato groups.

Anal. Calcd. for $C_{14}H_{12}N_2O_6$: N, 9.21. Found: 9.17.

Hydrogenation of the dinitrate yielded *dl*-hydrobenzoin, m.p. 99–105°, which judging from the infrared spectrum and chromatograms, contained traces of unidentified impurities.

Reaction of Silver Nitrate with meso-Dibromostilbene

(*a*) *meso*-Dibromostilbene (24) (3.40 g, m.p. 251.0–252.5°, lit. (24) 238°) was suspended in acetic acid (100 ml) at the boiling point and silver nitrate (4.10 g) dissolved in 50% acetic acid (10 ml) was added dropwise with efficient stirring. The initially colorless suspension gradually became pale yellow and after 15 min was filtered and the filtrate was diluted with water (500 ml) and refrigerated. The crude dinitrate which precipitated (1.61 g, 52.6%) was recrystalized from petroleum ether (m.p. 139.5–142.0°) and then chromatographed on a 0.5 mm layer of silicic acid – calcium sulfate (22) with benzene – petroleum ether to give a product melting at 146–148°. The infrared spectrum (KBr) and R_f value agreed with those of authentic *meso*-hydrobenzoin dinitrate.

(*b*) *meso*-Dibromostilbene (3.40 g) suspended in boiling acetonitrile (50 ml) was similarly treated with a solution of silver nitrate (4.10 g) in acetonitrile (5 ml) and the filtrate was evaporated under reduced pressure. Extraction of the brown amorphous residue successively with hot petroleum ether (b.p. 65–110°) and hot methanol, and re-extraction of the residue from the methanol solution with petroleum ether, followed by evaporation of the combined petroleum ether extracts, gave 1.60 g (52.6%) of solid *meso*-hydrobenzoin dinitrate which melted at 145–147° after chromatography and recrystallization from petroleum ether (b.p. 30–60°), and had the correct infrared spectrum. *meso*-Hydrobenzoin, m.p. 137.0–139.5°, was recovered after hydrogenation of this product.

ACKNOWLEDGMENTS

This work was completed during tenure of a Guest Professorship by L. D. H. (1964–1965) at Uppsala University, Sweden. He wishes to thank Uppsala University for this appointment and particularly Professor Stig Claesson for his interest and the excellent facilities and hospitality provided at the Institute of Physical Chemistry. We thank the National Research Council of Canada for scholarships to M. J. and I. G. C. and the Defence Research Board of Canada for financial assistance.

X-RAY POWDER PATTERNS FOR THE IDENTIFICATION OF SOME *n*-ALKANONE SEMICARBAZONES

JACK RADELL, B. W. BRODMAN, AND KIMBALL KRAMER

Research and Development Group, Pitman-Dunn Institute for Research, Frankford Arsenal, Philadelphia, Pennsylvania

Received December 16, 1964

ABSTRACT

The interplanar spacings obtained from the X-ray powder patterns of a series of structurally related semicarbazones were used to unequivocally identify the ketones from which the derivatives were prepared. The advantages of the proposed over the currently used melting points to identify the compounds were cited. The method was found to be applicable to slightly contaminated mixtures of semicarbazones.

INTRODUCTION

The identification of organic compounds by crystalline derivatives is relatively old and well known. Semicarbazones are one of the many such derivatives for ketones. An examination of the literature reveals that different semicarbazones often have reported melting points that are the same or close to one another; e.g., the semicarbazones of 2-hexanone and 2-octanone both have a reported melting point of 122 °C (1).

Semicarbazones are very useful for the isolation of both synthetic and naturally occurring carbonyl compounds. Furthermore, the ease with which the crystalline semicarbazone can be prepared and parent ketone regenerated makes these derivatives especially useful. The value of these derivatives is enhanced by the greater amount of information which can be derived from the X-ray studies presented in this research for a series of similar compounds. This is especially desirable when the amounts of such material are small and insufficient for carrying out classical chemical tests for identification. This problem occurred in our research and led to the presently reported investigation after the use of melting points and mixed melting points were found to be highly unsatisfactory in the identification of the semicarbazones. Considerably smaller samples could be used with such mounting procedures as capillaries. This study was pursued in preference to preparing additional derivatives which would require more time and sample than was used in the X-ray studies. In this way we hoped to identify small quantities of unknown samples and to see how readily the interplanar spacing obtained could be used to distinguish a series of closely related derivatives. In addition, it was hoped that mixtures of derivatives could be used to characterize each of the constituents. An additional problem which makes the melting point identification of semicarbazones difficult is a frequent discrepancy in the reported melting point of a single semicarbazone by different investigators. For example, the melting point of the semicarbazone of 3-heptanone has been reported as 101, 103, and 152 °C (2). In addition the melting points of pure semicarbazones measured in this work differed from reported values (Table I). Although this could result from geometric isomers of the unsymmetrical ketone derivatives, it would not explain the symmetrical cases.

The semicarbazones of ketones studied were not intended to comprise an exhaustive catalogue of these derivatives but rather to show the feasibility of using this method in characterizing a series of closely related compounds. A similar study using 2,4-dinitrophenylhydrazones was reported by Calvert and Przybylska (3).

DISCUSSION

A number of ketones were converted to semicarbazones by a previously reported method (4). These semicarbazones were analyzed for carbon, hydrogen, and nitrogen. The analyses and melting points of the pure materials were determined and reported in Table I. The X-ray powder diffraction patterns were run and the eight most intense peaks are reported for the pure semicarbazones as well as for two sets of mixtures. The major spacings of all semicarbazones occurred between 3.56–13.20 Å. Usually the position of the most intense spacing was enough to identify the semicarbazone of the ketone. Only in four cases was it necessary to use the second most intense spacing for identification. All the semicarbazones could be positively identified by scanning from 6.8° to 25° (2θ) at a goniometer scanning speed of 2° per min. Thus it was possible to make a positive identification in 9 min or less. X-ray patterns of semicarbazide hydrochloride and sodium acetate were run to see if any of their characteristic spacings could be identified in the semicarbazones. None of these spacings appeared in the powder patterns of the semicarbazones reported. This observation was confirmed by the analysis reported in Table I. Since impurities of 2% or less did not effect the X-ray patterns, the unknown semicarbazone could be identified although not scrupulously pure. On the other hand, these impurities did affect the melting point. From runs with a silicon standard we were able to determine our error in measuring 2θ and the corresponding error in interplanar spacing (d) to be ± 0.02 Å at 8° (2θ) and ± 0.001 Å at 40° (2θ).

3.65	100	A† and B‡
9.93	75	B
9.73	62	A
2.83	16	B
5.39	12	B
3.96	9	B
6.91	9	A
3.34	9	B
3.49	9	A
2.74	8	A
5.01	8	B

*Relative intensity, 100 being the strongest.
†Spacings attributed to 2-hexanone.
‡Spacings attributed to 4-decanone.

The intensities and interplanar spacings for each compound in Table I represents the average of four runs as described under Experimental. It was found that the four separate runs differed very little, if at all, in interplanar spacings or intensities.

To determine if components of mixtures could be identified equal weights of 2-hexanone and 4-decanone both with very similar X-ray diffraction patterns were mixed. Both compounds measured separately had a major spacing in common at 3.65 Å and another set in close proximity at 9.82 Å and 9.98 Å respectively. The X-ray diffraction pattern of the mixture showed the most intense spacings at 3.65 Å, 9.93 Å, and 9.73 Å. Although the latter two spacing are slightly shifted all the other spacings previously measured for each compound appeared in the mixture without change (Tables II and III). No spacings were present for the mixture which could not be attributed to one of the components.

EXPERIMENTAL

Semicarbazones

The semicarbazones were prepared by a previously described procedure (4).

Sample Preparation for X-Ray Measurements

Two portions of each semicarbazone were separately ground with a mortar and pestle. Each ground sample was packed into a $\frac{1}{2}$ in. diameter hole in a 1 mm thick microscope slide. The compounds were packed into the hole in the microscope slide by placing an intact microscope slide under the hole and tightly pressing the semicarbazone into the cavity with a spatula. A cover glass was glued over the packed cavity and the whole mount was inverted. The intact slide was slid out to give a finished mount. The mount with exposed sample side up was placed in the sample holder of the goniometer. Two sets of measurements were made for each mounting. After the first measurements were made the mount was rotated 90° for the second set of measurements. Since this procedure was followed for the two portions of each semicarbazone, a total of four runs were made for each sample. This was done in order to reduce the possibility of preferred orientation.

X-Ray Powder Diffraction Measurements

The X-ray measurements were made with a North American Phillips Co. X-Ray Diffractometer (Model 5001) which was equipped with a high angle goniometer. A proportional counter in conjunction with a pulse height analyzer was used for counting. Cu K_α radiation was obtained by operating the copper tube at 40 kV and 18 mA using a nickel filter and passing the radiation through 1° divergent and scattering slits, and a 0.003° receiving slit. The goniometer scanning speed was 2°/min.

CONCLUSIONS

The use of interplanar spacings from X-ray powder diffraction patterns was found to be preferable to the use of melting points for the identification of semicarbazones because (*a*) less sample is ultimately required, (*b*) the information obtained is unambiguous, (*c*) mixtures of semicarbazones can be identified, (*d*) small amounts of impurities do not interfere, and (*e*) the unaltered semicarbazone is recoverable.

ACKNOWLEDGMENT

The authors thank Mr. Dominic Stango of this laboratory for his assistance in the tabulation of the results.

EFFECTS OF THE ELECTRONIC BAND SHAPE OF PALLADIUM METAL ON THE PROTON MODEL FOR HYDROGEN ABSORPTION

J. W. Simons and Ted B. Flanagan
Department of Chemistry, University of Vermont, Burlington, Vermont
Received November 26, 1964

ABSTRACT

The statistical treatment of the proton model for hydrogen absorption by palladium is extended to include a variation of the electron donation energy with hydrogen content, as determined by a density of states function for the combined 4d- and 5s-bands for palladium. This improved model gives better agreement with the high pressure limiting solubility data and the observed critical composition than the original model, when both are fitted to the critical isotherm by the same method. An apparent anomaly in the variation of the isosteric enthalpy of absorption with content is explained by the improved model.

INTRODUCTION

The palladium–hydrogen system has been one of the most extensively studied and well characterized of the metal–hydrogen systems (1). The first statistical model for hydrogen in palladium metal was proposed by Lacher in 1937 (2). More recently, similar models which have a general applicability to interstitial compounds have been proposed by Anderson (3) and by Rees (4). Other quite different models, such as the anion model of Libowitz (5), have also been applied. All of these models have been successful in explaining the main features of the experimental pressure–composition–temperature relationships for hydrogen absorption by palladium.

In Lacher's model hydrogen atoms are considered to be absorbed as protons plus electrons; the electrons enter the lowest energy unfilled states in the electronic bands, primarily the 4d-band, of the palladium metal, and the protons enter a fixed number of energetically equivalent potential energy minima in the palladium lattice. The proton absorption sites have subsequently been shown to be the octahedral interstitial positions in the f.c.c. palladium lattice (6). Approximate theoretical calculations of the state of hydrogen in metals support the idea of hydrogen atoms in palladium existing as protons plus electrons (7, 8). A necessary postulate of the proton model is that nearest-neighbor protons interact attractively via their compensating atmospheres of electrons. This postulate was made, by analogy with Fowler's treatment of critical adsorption on surfaces (9), in order to account for the observed critical phenomenon in the Pd—H system; the P–C–T relationship exhibits a critical point below which two solid phases, α and β, coexist over a range of compositions and above which only a single phase exists. The nature of the attractive interaction between protons was unspecified by Lacher but has recently been discussed somewhat more specifically by Makrides (10).

From the above model Lacher derived the partition function for n absorbed and interacting protons (per Pd atom) distributed in n_s energetically equivalent absorption sites (per Pd atom). Fowler and Smithells (11) had shown previously, for a similar system, that the partition function for absorbed protons alone gives the same chemical potential as that for absorbed hydrogen atoms existing as absorbed protons plus donated electrons, provided that the energy of electron donation to a metal's bands of electronic states is included in the absorption energy for the protons. In Lacher's treatment a constant energy of electron donation is included implicitly in the constant interaction energy of a

proton with its site. The assumption of a constant energy of electron donation is not justified since it is well known that the electronic states in metals form bands and are distributed over a range of energies within each band. It is felt that a realistic proton absorption model, with electron donation to partially empty bands in the metal, must allow for a variable electron donation energy. The present treatment includes specifically the varying energy of electron donation as the unfilled states in the high density 4d-band and the overlapping low density 5s-band of palladium are filled with electrons from absorbed hydrogen atoms. It has been mentioned previously that the distribution of electronic states with energy in the d-band of palladium could affect the absorption of hydrogen (10), but a quantitative investigation has not been made to our knowledge of how this effect enters into a statistical model.

RESULTS AND DISCUSSION

Theory

The expression for the pressure of H_2 gas in equilibrium with absorbed hydrogen in Pd was derived from the above proton model with a variable energy of electron donation and is given by eq. [1].

$$[1] \qquad \ln P_{atm} = 2 \ln \frac{f^{1/2}}{Q(T)} + 2 \ln \frac{n/n_s}{1 - n/n_s} + \frac{2W_H}{RT} + \frac{X_d}{RT} + \frac{4W_{HH}n}{RTn_s} + \frac{2W_e(n)}{RT},$$

where f is the partition function for an H_2 molecule in the gas phase, $Q(T)$ is the partition function for the three degrees of freedom of an absorbed proton, n/n_s is the ratio of the number of absorbed protons to the number of absorption sites, W_H is the sum, relative to hydrogen atoms in the gas phase, of the energies per mole of the first absorbed proton and its donated electron, X_d is the dissociation energy per mole of a hydrogen molecule, W_{HH} is the average value per proton of the total proton–proton interaction energy per mole when all sites are filled, and $W_e(n)$ gives the variation of the energy of electron donation with n. The derivation of eq. [1] is identical to Lacher's derivation in which the effect of the H—H interaction on the distribution of protons among the sites was neglected, i.e., the Bragg–Williams approximation of random distribution was made; the only difference in the final expressions is an additional term, $2W_e(n)/RT$, in eq. [1]. The function, $W_e(n)$, can be evaluated directly from the variation of the density with energy, $N(W_e)$, of vacant electronic states in the combined 5s- and 4d-bands of palladium, assuming that the band shape is not altered appreciably as hydrogen enters interstitial positions in the lattice.

Hoare and co-workers (12) have determined, from the low temperature heat capacities of Ag/Pd alloys, an approximate dependence of $N(W_e)$ upon energy for palladium. This method assumes that each Ag atom donates one electron to the combined 5s- and 4d-bands of Pd which overlap, and the replacement of palladium by silver in the lattice does not alter the band shape of the palladium. Magnetic susceptibility measurements and other evidence support the former assumption but serious objections have arisen as to the validity of the latter, especially for alloys with large Ag contents. In any case, this band shape, as approximated in Fig. 1, can be used to explore the effect of including a variable band energy in the proton model on calculated P–C isotherms and thermodynamic quantities.

Evaluation of Parameters in Eq. [1]

The approximate curve in Fig. 1 for the density of states in the combined 5s- and 4d-bands is represented by the two linear relationships given in eqs. [2*a*], [2*b*].

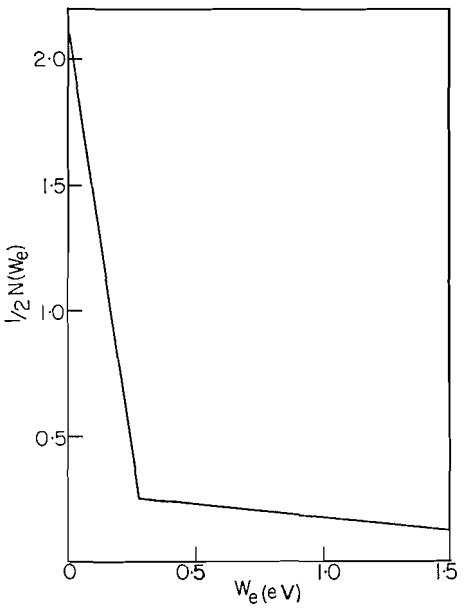

FIG. 1. An approximation to the curve derived by Hoare and co-workers (12) for the density of vacant states in the combined 4d- and 5s-bands of palladium.

[2a] $$N(W_e)_1 = -13.43W_e + 4.26, \qquad W_e \leqslant 0.28 \text{ eV};$$

[2b] $$N(W_e)_2 = -0.207W_e + 0.560, \qquad W_e \geqslant 0.28 \text{ eV}.$$

Since $N(W_e)$ is a decreasing function of W_e, the electrons can be assumed to enter the lowest energy vacant states. Thus the area under the $N(W_e)$ curve between zero and W_e represents the number of donated electrons per Pd atom necessary to increase the electron donation energy by W_e. The integral of $N(W_e)$ solved for W_e gives eqs. [3a], [3b] for the function, $W_e(n)$.

[3a] $$W_e(n)_1 = 7318 - 7318(1.0000 - 1.481n)^{1/2} \text{ cal/mole}, \quad n \leqslant 0.666;$$

[3b] $$W_e(n)_2 = 62404 - 80960(1.0000 - 0.7846n)^{1/2} \text{ cal/mole}, \quad n \geqslant 0.666.$$

The critical point conditions,

$$\left(\frac{\partial \ln P}{\partial n}\right)_T = 0 \text{ and } \left(\frac{\partial^2 \ln P}{\partial n^2}\right)_T = 0,$$

applied to eq. [1], with $W_e(n)$ replaced by $W_e(n)_1$, give eqs. [4] and [5] respectively.

[4] $$\frac{2}{n_c} + \frac{2}{n_s - n_c} + \frac{4W_{HH}}{RT_c n_s} + \frac{7318(1.481)}{RT_c(1.0000 - 1.481n)^{1/2}} = 0,$$

[5] $$-\frac{2}{n_c^2} + \frac{2}{(n_s - n_c)^2} + \frac{7318(1.481)^2}{2RT_c(1.0000 - 1.481n)^{3/2}} = 0.$$

The expression for $W_e(n)_1$ in eq. [3a] was substituted for $W_e(n)$ in eq. [1] since the critical composition, n_c, is known from experiment to be approximately 0.28 (13). An approximate value of $n_s(\sim 0.75)$ was calculated from eq. [5] using the experimental value of the critical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

temperature, $T_c = 573$ °K, and $n_c \sim 0.28$. The critical temperature is accurately known but the value of n_c is uncertain (13). Unique values of the parameters n_c, n_s, and W_{HH} can be obtained which are solutions of both eqs. [4] and [5] and also give a fit of the low hydrogen content α-phase isotherm of Gillespie and Galstaun to eq. [1] at the critical temperature (13). In order to fit the α-phase data, eq. [1] was written in the form given in eq. [6], valid for the case of $n \ll 1$, in which the expression in eq. [3*a*] has been substituted for $W_e(n)$ and the term, $(1 - 1.481n)^{1/2}$, has been approximated by $1 - (1.481n/2)$.

$$[6] \qquad \ln P_{atm}\left(\frac{1 - n/0.75}{n}\right)^2 = 2 \ln \frac{f^{1/2}}{Q(T)} - 2 \ln n_s + \frac{2W_H + X_d}{RT} + \frac{[7318(1.481) + (4W_{HH}/n_s)]n}{RT}$$

The approximate value of $n_s(\sim 0.75)$, discussed above, was used for calculating the difference, $1 - n/n_s$, since for $n \ll 1$ any reasonable uncertainty in n_s will have a negligible effect on the value of this difference. The right-hand-side (r.h.s.) of eq. [6] is a linear function of n at a given temperature. It is seen from Fig. 2 that the α-phase data of

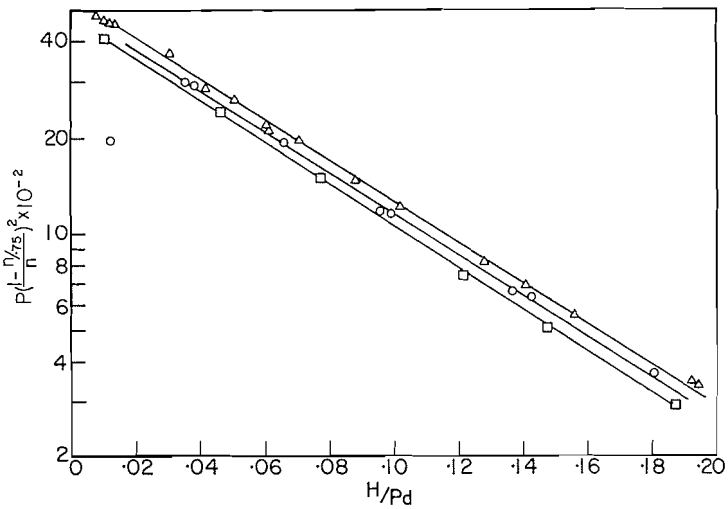

FIG. 2. The α-phase data of Gillespie and Galstaun (13) near the critical temperature plotted according to eq. [6]. (□) 290 °C data; (○) 300 °C data; (△) 310 °C data.

Gillespie and Galstaun at 290, 300, and 310 °C, plotted according to eq. [6], give the expected straight lines. The average slope of these three lines gives the relationship, $4W_{HH}/RT_c = -24.36n_s$. This result together with eqs. [4] and [5] determine the values of n_c, n_s, and W_{HH} given in the first row of Table I. The same treatment using Lacher's

TABLE I

Values of the critical composition, total number of sites, and the H—H interaction energy

	n_c	n_s	W_{HH} (cal/mole)
Equation [1], $W_e(n) = W_e(n)_1$	0.277	0.720	−4995
Equation [1], $W_e(n) = 0$	0.247	0.494	−2278

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

original expression, eq. [1] with $W_e(n) = 0$, gives the values in the second row of Table I. The value of n_c in Table I for $W_e(n) = W_e(n)_1$ is essentially the same as the approximate experimental value mentioned earlier, while the value determined with $W_e(n) = 0$ is probably near the limit of uncertainty in this experimental value. The magnitude of W_{HH} is very sensitive to the particular treatment of the data but, unfortunately, there seem to be no direct estimates of its expected magnitude. Both values of n_s in Table I are less than 1, but the value derived for $W_e(n)_1$ is larger than that for $W_e(n) = 0$, and thus is in better accord with observed maximum solubilities of hydrogen in palladium which approach $n \sim 1$ at high pressures (14). The interpretation of n_s as the number of octahedral positions per Pd atom in the f.c.c. Pd lattice, i.e., $n_s = 1$, is consistent with the model and the known location of H atoms in the lattice.

Enthalpy of Solution

The variation with hydrogen content of the isosteric partial molar enthalpy of solution,

$$\overline{\Delta H} = R\left(\frac{\partial \ln P}{\partial 1/T}\right)_{p,n},$$

of hydrogen in palladium clearly should depend on the electronic band shape for palladium, if this proton absorption model is valid. Lacher has shown that his original theory, in which a delta function band shape is implicitly assumed, predicts a continuous linear increase of $-\overline{\Delta H}$ with increasing n for each of the pure solid Pd—H phases (2). This result reflects the variation of the magnitude of the total H—H interaction energy term with n. The existing α-phase data give qualitative support to this predicted variation, but the paucity and irreproducibility by independent workers of the experimental α-phase results renders a quantitative comparison premature (13, 14*c*, 15, 16). Two recent experimental studies of the high content β-phase, one between 0 and 75 °C (14*c*) and another between 300 and 500 °C (14*b*), are in qualitative agreement with each other in as much as both yield decreasing values of $-\overline{\Delta H}$ with increasing n, which is the opposite behavior to that found in the α-phase and to that predicted by Lacher's original theory.

Equations. [7*a*], [7*b*] give the variation of $\overline{\Delta H}$ with n predicted by eq. [1] for the band shape given by eqs. [3*a*], [3*b*] and the value of n_s in the first row of Table I.

$$[7a] \qquad \Delta\overline{\Delta H}(n) = \frac{4W_{HH}n}{0.720} + 2(7318)[1 - (1.0000 - 1.481n)^{1/2}],\ n \leqslant 0.666,$$

$$[7b] \qquad \Delta\overline{\Delta H}(n) = \frac{4W_{HH}n}{0.720} - 2[62404 - 80960(1.0000 - 0.7846n)^{1/2}],\ n \geqslant 0.666,$$

where

$$\Delta\overline{\Delta H}(n) = \overline{\Delta H}(n) - \overline{\Delta H}(0).$$

A term,

$$\frac{4n}{0.72T}\left(\frac{\partial W_{HH}}{\partial 1/T}\right)_{p,n},$$

has been taken to be zero in eqs. [7*a*], [7*b*]. Although W_{HH} is undoubtedly temperature dependent (14*c*, 16, 17), the α-phase data, required to evaluate W_{HH} at various temperatures, is neither sufficiently extensive nor reproducible enough to unambiguously determine this temperature dependence. A plot of eqs. [7*a*], [7*b*] for the critical value of W_{HH} (first row of Table I), is shown in Fig. 3. It is seen from Fig. 3 that eqs. [7*a*], [7*b*] predict that $-\Delta H$ increases to a maximum value, then decreases as n goes from zero to n_s, which is qualitatively the same behavior exhibited by the experimental results. Any reasonable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

temperature dependence of W_{HH} would probably not affect the qualitative features of Fig. 3.

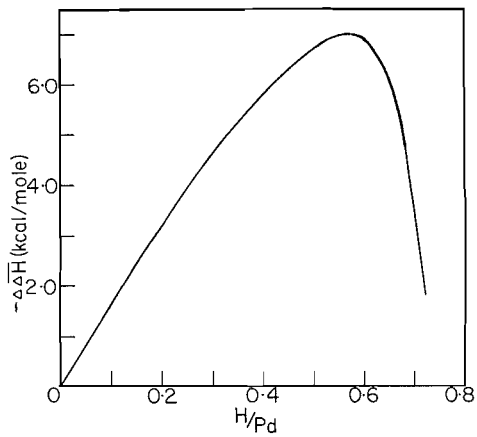

FIG. 3. Predicted variation of the isosteric enthalpy of solution with content.

CONCLUSION

The use of the α-phase data to evaluate theoretical parameters, instead of the two-phase region as in Lacher's original method, was first suggested by Everett and Nordon; they convincingly justify this procedure in a discussion of the hysteresis commonly observed in the two-phase region (16). The similar method employed in the present work uses the critical point in conjunction with the critical temperature α-phase data to determine all of the theoretical parameters shown in Table I. This has the advantages that the magnitude of n_s need not be assumed and the problems of nonequilibrium associated with hysteresis are circumvented. Some confusion exists in the literature as to whether n_s should be identified with the total number of vacancies in the 4d-band of electronic states for palladium, as originally defined, or with the total number of proton absorption sites in the palladium lattice. The high pressure limiting solubilities of hydrogen in palladium and the very nature of the statistical problem are convincing support, in the author's view, of the latter definition.

The results in Table I and Fig. 3 and the accompanying discussions indicate that the experimental band shape derived for Ag/Pd alloys incorporated into the proton statistical model gives generally better agreement with the various experimental observations cited than the original model with a delta function band shape. Quantitative agreement for n_s and the variation of $\overline{\Delta H}$ could probably be improved by using a slightly broader band, but such an attempt seemed unwarranted here in view of the neglected possible effects of lattice expansion during absorption on the band shape and theoretical energy parameters. The effect of lattice expansion on W_H and W_{HH} in Lacher's original theory has been treated by Harasima *et al.* (18). Their treatment leads to asymmetry in the calculated isotherms but does not predict a maximum in $-\overline{\Delta H}$ for values of $n < 1$. The inclusion of lattice expansion effects into the present treatment would be an interesting refinement but would not be expected to alter the above conclusions.

NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY OF SOME SELENIUM COMPOUNDS

T. BIRCHALL,[1] R. J. GILLESPIE, AND S. L. VEKRIS[2]
Department of Chemistry, McMaster University, Hamilton, Ontario
Received December 1, 1964

ABSTRACT

Selenium nuclear magnetic resonance spectra have been observed for a number of selenium compounds. Chemical shifts and coupling constants with hydrogen and fluorine have been obtained. Various systems involving selenium compounds have been studied. It was found that a mixture of $SeOF_2$ and $SeOCl_2$ contains SeOClF and that rapid selenium exchange occurs between $SeOCl_2$ and $SeOBr_2$ presumably via the intermediate SeOClBr. The reactions of selenium tetrahalides with sulfur and selenium trioxides and with boron trifluoride were studied. It was observed that antimony pentachloride, tin tetrachloride, arsenic trichloride, quinoline, and potassium chloride produce considerable shifts in the resonance of selenium oxychloride. These shifts can be interpreted in terms of the acid–base behavior of the solutes.

Although selenium-77 has a nuclear spin of $\frac{1}{2}$ and has a natural abundance of 8.3% there have only been two previous rather limited investigations of the selenium nuclear magnetic resonance and only a very few compounds were studied. Dharmatti and Weaver (1) measured the magnitude and sign of the selenium magnetic moment in a 12 *M* solution of selenous acid by reference to sodium-23. Walchli (2) measured the resonance frequencies of H_2Se, H_2SeO_3, and H_2SeO_4 with reference to D_2O and hence found the chemical shifts between the selenium compounds. The object of the present work was to measure the selenium chemical shifts and coupling constants with other nuclei for a number of selenium compounds and to attempt to use the data to obtain chemical and structural information on selenium compounds in the pure state and in systems with other components.

EXPERIMENTAL

Measurements were made with a Varian Associates DP60 spectrometer operating at 10.276 Mc/s. To make a preliminary observation of the selenium resonance the current control on the magnet power supply was first approximately calibrated by the relatively strong signals of ^{23}Na and ^{127}I. The approximate current required to obtain the selenium resonance was then calculated and the magnet current control adjusted accordingly. Because the selenium signal was expected to be relatively weak, the initial search for a selenium resonance was made using a concentrated aqueous solution of H_2SeO_3 in a non-spinning 15 cm o.d. sample tube and broad-line technique. However, the broad derivative signals obtained by this method were unsuitable for the accurate measurement of chemical shifts and the observation of fine structure due to spin–spin coupling. After a few resonances had been detected in this manner, a method of observing high-resolution spectra was devised. This was an audio side-band method which utilized the Varian V3521 Integrator operating at a modulation frequency of 2 034 c/s and gave a considerably enhanced signal-to-noise ratio (3).

The usual center-band operation employed for proton and fluorine spectra cannot be used for selenium resonance, since it is impossible to obtain the high modulation index ($\beta = 1.8$) required, owing to the much lower magnetogyric ratio of selenium,

$$\beta = \frac{\gamma H_m}{2\pi\nu_m},$$

where γ = magnetogyric ratio of nucleus, H_m = modulating field, and ν_m = frequency of modulating field. The integrator was therefore converted from center-band to side-band operation, the latter being feasible for modulation indices less than unity (3). The conversion was accomplished by inserting a 2 μF capacitor

between the modulation output of the integrator and the sweep coils. This reduces the modulation index somewhat and also provides the 90° audio-phase change necessary for side-band operation (3). By suitable adjustment of both the r.f. phase and audio phase the centre band is eliminated and the signal observed in the first side band only. The spectrum therefore consists of two signals: the upper side band at +2 034 c/s and the lower side band at −2 034 c/s, and it is therefore automatically calibrated.

At normal r.f. power levels, side-band signals would be small, specifically $\beta/2$ times the usual absorption mode signal. However, under the conditions used in side-band operation, the saturation parameter is $\gamma^2(\frac{1}{2}\beta H_1)^2T_1T_2$ and the r.f. power can be increased to a relatively higher level. These conditions give a signal-to-noise ratio comparable to that which would be obtained from the usual absorption mode techniques, but eliminate the long-term noise which makes absorption mode spectra without modulation techniques impossible for selenium.

The field was swept at approximately 1 gauss/min. The modulation index was $\beta = 0.24$ in all cases. The r.f. field was approximately 5 milligauss, but the optimum power level varied from sample to sample. In a few cases adiabatic rapid passage was used. In this case H_1 was adjusted to be as large as possible without unbalancing the probe; approximately 70 milligauss was the maximum H_1 obtainable.

Samples were sealed in 15 mm o.d., 13 mm i.d. tubes except the very volatile SeF_6 and H_2Se, which were sealed in stronger 13 mm o.d., 8 mm i.d. tubes.

Shifts were measured by exchanging samples while sweeping the field. The reference used was either $SeOCl_2$, which gives a strong sharp signal, or 19 mole % aqueous H_2SeO_3. For some samples the spectrum occurred too close to the peaks of either of these reference compounds to enable the shifts to be obtained by the sample-changing technique. In such cases the less satisfactory H_2SeO_4, which gives a rather broad signal, was used as a secondary reference. Spectra were calibrated by the usual side-band technique using a Muirehead–Wigan decade audio oscillator or for large shifts by observing the upper and lower reference side bands, which are separated by twice the modulation frequency of 2 034 c/s.

Proton and fluorine signals were observed by the normal high-resolution technique at 60 Mc/s and at 56.4 Mc/s respectively.

All compounds except those below were the purest available commercial samples and were used without further purification.

Selenium Oxide Dibromide

Bromine (10 ml) was reacted with a mixture of 5 g red selenium and 6 g selenium dioxide in a dry atmosphere. Yellow crystals were obtained on vacuum sublimation at room temperature (4), m.p. 45° (lit. 41.7° (4)).

Selenium Oxide Dichloride

The commercial product was distilled at 1 mm to give a pale-yellow liquid.

Selenium Tetrachloride

Chlorine was passed over 5 g gray selenium and the sublimate was collected (5).

Selenium Oxide Difluoride

This was prepared by the reaction between SeO_2 and SeF_4 (6). Selenium tetrafluoride (20 g) was distilled in vacuum onto a small excess of selenium dioxide and the mixture was refluxed until no more SeO_2 dissolved. The product was vacuum distilled.

Selenium Trioxide

A mixture of phosphoric oxide and a slight excess of selenic acid was heated to 150° under vacuum and the resulting selenium trioxide was condensed onto a cold finger (7), m.p. 120° (lit. 118° (8)).

Anal. Calcd. for SeO_3: Se, 62.2. Found: Se, 63.8.

Selenic Acid

The commercial product was dehydrated by bubbling dry air through a sample of the acid at 2 mm and 150°.

Fluoroselenic Acid

A preparation carried out by the method of Bartels and Class (9), in which the two reactants were condensed together and excess HF was removed under vacuum at room temperature, gave a volatile product which was identified from its infrared spectrum as SeO_2F_2 (10) and a liquid residue which was shown from its Raman and n.m.r. spectra to contain a considerable amount of selenic acid. At 100° the decomposition

$$2HSeO_3F = SeO_2F_2 + H_2SeO_4$$

was found to be essentially complete. A purer product was obtained by carrying out the reaction in liquid SO_2. This gave the selenium resonance reported in Table I.

Chloroselenic Acid

Selenium trioxide was reacted with excess hydrogen chloride in solution in sulfur dioxide (11). After removing most of the excess HCl under vacuum, the mixture was sealed in an n.m.r. tube and kept cold.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It was warmed to room temperature just before the spectrum was run whereupon the mixture separated into two layers. The upper layer gave no selenium resonance, but the lower layer gave a resonance at 475.8 p.p.m. which we have attributed to chloroselenic acid and another very weak signal at 228.2 p.p.m. which was not assigned.

Selenium Dioxide Difluoride

Barium selenate (85 g) was treated with excess fluorosulfuric acid (500 g) at 150° (12). The product was condensed in a liquid air trap. A volatile yellow impurity was separated from the product by repeated vacuum distillation. The fact that the fluorine n.m.r. spectrum of the final product showed only one signal indicated that no fluorine-containing impurities were present in appreciable concentration.

Selenium Hexafluoride

The commercial product was vacuum distilled. The fluorine n.m.r. spectrum showed an extra peak due to an impurity at approximately 20 p.p.m. above, and approximately 5% the intensity of, the signal due to SeF_6.

Selenium Tetrafluoride

Fluorine diluted with nitrogen was passed over freshly sublimed selenium at 0° and the product vacuum distilled (13).

Anal. Calcd. for SeF_4: Se, 51.0. Found: Se, 50.2.

Hydrogen Selenide

Aluminium selenide was prepared by igniting a mixture of 25 g powdered selenium and 15 g powdered aluminium with burning magnesium. The product was treated with water, and the resulting gas was dried by passing it through calcium chloride and phophoric oxide and was finally trapped out in a trap cooled with solid carbon dioxide (14).

Trifluoromethylselenium Compounds

Bis(trifluoromethyl) selenide and bis(trifluoromethyl) diselenide were prepared by the reaction of trifluoromethyl iodide with selenium at 260 °C (15) and also by the reaction of silver trifluoroacetate with selenium at 280 °C (16). Bis(trifluoromethyl) diselenide was removed from the mixture by reaction with mercury; it formed bis(trifluoromethylseleno)mercury, from which it was regenerated with the stoichiometric quantity of iodine (15). Trifluoromethylselenomercuric chloride was obtained by evaporation of an ether solution of stoichiometric quantities of bis(trifluoromethylseleno)mercury and mercuric chloride (15). Bis(trifluoromethyl) selenide and bis(trifluoromethyl) diselenide were purified by vacuum distillation and bis(trifluoromethylseleno)mercury and trifluoromethylselenomercuric chloride were purified by vacuum sublimation at 50 and 70 °C respectively.

RESULTS AND DISCUSSION

Chemical Shifts and Coupling Constants

The selenium chemical shifts that were measured are given in Table I. Spin–spin coupling patterns were observed in a number of fluorine- and hydrogen-containing compounds, and the coupling constants obtained from the selenium, fluorine, and proton spectra are given in Table II. Isotope effects between the signal of fluorine on selenium-80 and fluorine attached to the other selenium isotopes were noted in a number of cases and have been discussed elsewhere (17).

We note that selenium(VI) compounds generally give a resonance to high field of selenium(IV) compounds. The very high-field shift of H_2Se is worthy of comment in view of the fact that PH_3 gives a ^{31}P resonance at very high field, H_2O gives a very high-field ^{17}O resonance, and NH_3 gives a very high-field ^{14}N resonance (18).

For selenium hexafluoride no signal could be detected by the audio side-band slow-passage method but five of the seven components of the spin–spin multiplet were observed by the adiabatic rapid-passage technique.

Selenium Tetrahalide Adducts

A solution of $SeCl_4$ in SO_3 gave a selenium resonance at +88.2 p.p.m., whereas $SeCl_4$ in dimethylformamide gave a resonance at +352 p.p.m. The large down-field shift of the selenium resonance is consistent with the formation of the complex $SeCl_4.SO_3$, which probably has the structure $SeCl_3^+SO_3Cl^-$ (19).

Selenium tetrafluoride forms compounds with SO_3 (6) and BF_3 (20), and the chemical shifts of these compounds in the molten state are given in Table I. The sample tube was heated to about 10° above the melting point of the compound, and the spectrum was observed before solidification occurred. As the shifts for the two compounds are different, one can conclude that both compounds cannot contain an identical SeF_3^+ ion. Other work in this laboratory indicates that $SeF_4.SO_3$ has the essentially covalent structure $SeF_3.SO_3F$ while $SeF_4.BF_3$ has the ionic structure $SeF_3^+.BF_4^-$ (21).

Selenium tetrafluoride was found to react readily with a small excess of selenium trioxide to give at room temperature a clear liquid which slowly deposits a white solid. The liquid gave a selenium spectrum of six peaks, three of which were identical with the three components of the SeO_2F_2 triplet (δ = 528.1 p.p.m. and J = 1 588 c/s); two of the remaining three peaks (δ = 439.7 and 582.3 p.p.m.) could possibly be attributed to the $SeF_4.SeO_3$ adduct, which would be expected to have the structure $SeF_3.SeO_3F$, and the other small peak at 512.4 p.p.m. could be attributed to the small excess of selenium trioxide. The deposition of the white solid and the formation of SeO_2F_2 may indicate that $SeF_4.SeO_3$ is unstable and decomposes slowly, possibly in the following manner:

$$SeF_3.SeO_3F \rightarrow SeOF_2 + SeO_2F_2$$

$$SeOF_2 + SeO_3 \rightarrow SeO_2 + SeO_2F_2.$$

An alternative interpretation of the results would be that the two peaks at 439.7 and 582.3 p.p.m. are a doublet arising from selenium coupled to a single fluorine, possibly in the molecule $Se_2O_5F_2$. The coupling constant J(Se–F) = 1 470 ± 22 c/s and the chemical shift 510.9 ± 4.8 p.p.m. are both consistent with the resonance being due to VI-valent selenium. The diselenyl fluoride could be formed by the reaction

$$SeO_2F_2 + SeO_3 = Se_2O_5F_2.$$

The remaining peaks may be assigned, as before, to excess SeO_3 and to SeO_2F_2.

Reaction occurs between $SeCl_4$ and SeO_3 in $POCl_3$ solution as evidenced by the dissolution of the $SeCl_4$ which only occurs upon the addition of SeO_3. This mixture is unstable at room temperature; a white solid is deposited and chlorine is evolved. An analogous mechanism to that put forward above would fit the experimental observations except that in this case SeO_2Cl_2 decomposes further to give SeO_2 and Cl_2.

Unfortunately, we were unable to obtain solutions of other $SeCl_4$ complexes such as $SeCl_4PCl_5$ and $SeCl_4AlCl_3$ that were concentrated enough to give a selenium signal.

Mixed Halides and Oxyhalides

An equimolecular mixture of $SeOF_2$ and $SeOCl_2$ gave three selenium resonances, a singlet, a doublet, and a triplet indicating the formation of a new compound. From their spin–spin coupling patterns and chemical shifts the singlet and the triplet can be unambiguously assigned to the two original components $SeOCl_2$ and $SeOF_2$. The third doublet peak can clearly be assigned to SeOFCl. As expected, the fluorine spectrum contained a new peak that could be assigned to SeOFCl in addition to the $SeOF_2$ peak. The SeF coupling constant in SeOFCl is appreciably smaller than in $SeOF_2$ (Table II). We note also that the coupling constant in this latter compound is somewhat solvent dependent. The coupling constants obtained from the fluorine spectra agree well with those obtained from the selenium spectra. A mixture of $SeOF_2$ and $SeOBr_2$ gave only two selenium resonances, but a mixture of $SeOBr_2$ and $SeOCl_2$ gave a single peak with a width of approximately 70 c/s lying between the resonances of the pure components. These observations indicate that there is rapid exchange presumably via the formation of the intermediate SeOBrCl.

Se_2Cl_2 is completely miscible with Se_2Br_2. The spectrum of the mixture showed only the two signals of the components except that each was rather broadened. On heating further broadening of the peaks occurred, which indicated that relatively slow exchange occurs between the two species.

Solutions of Selenium

Solutions of red selenium in CS_2, H_2SO_4, SO_3, SeF_4, and $SeOF_2$ were investigated, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in no case could a signal from the dissolved selenium be detected. In most cases the solubility appears to be quite small.

Selenium dissolves readily in selenium oxychloride and it has been shown (22) that Se_2Cl_2 is formed, presumably according to the equation

$$Se + 2SeOCl_2 = SeO_2 + Se_2Cl_2.$$

In agreement with this the n.m.r. spectrum of the solution contained two signals: one at +15 p.p.m., which can reasonably be attributed to a solution of SeO_2 in $SeOCl_2$, and a broad signal at 205 p.p.m., which agrees well with the observed shift for pure liquid Se_2Cl_2 (Table I).

Trifluoromethylselenomercuric Chloride

The chemical shift of a solution trifluoromethylselenomercuric chloride in methanol was found to be 1 214.7 c/s and the coupling constant $J(^{77}Se–^{19}F) = 37.4$ c/s. However, it has been shown that disproportionation occurs, and the equilibrium constant for the reaction

$$(CF_3Se)_2Hg + HgCl_2 \rightleftharpoons 2CF_3SeHgCl$$

has been found to be 20 ± 2 in methanol at room temperature (23). Thus 69.1% of the CF_3Se groups are in the form $CF_3SeHgCl$ under these conditions. Since only one peak was observed in the ^{77}Se spectrum and one, with attendant ^{77}Se and ^{13}C satellites, in the ^{19}F spectrum, there must be rapid exchange of CF_3Se groups between $(CF_3Se)_2Hg$ and $CF_3SeHgCl$. This conclusion is supported by the absence of $^{199}Hg–^{19}F$ coupling in the ^{19}F spectrum, although a very small value for the coupling constant would produce the same result. From the ^{77}Se chemical shift, the $^{19}F–^{77}Se$ coupling constant for a solution of bis(trifluoromethylseleno)mercury, and the calculated composition of the equilibrium mixture formed by $CF_3SeHgCl$, approximate values for the hypothetical solution of pure trifluoromethylselenomercuric chloride were calculated. The values obtained are given in Tables I and II.

Solutions of Acids and Bases in Selenium Oxychloride

Conductivity and e.m.f. measurements (22) indicate that $SeOCl_2$ undergoes the self-ionization

$$SeOCl_2 = SeOCl^+ + Cl^-,$$

so that chloride ion acceptors may be regarded as acids

$$\text{e.g. } SbCl_5 + SeOCl_2 = SbCl_6^- + SeOCl^+,$$

and chloride ion donors or $SeOCl^+$ acceptors may be regarded as bases

$$\text{e.g. } C_5H_5N + SeOCl_2 = C_5H_5NSeOCl^+ + Cl^-.$$

We found that addition of $SbCl_5$ to selenium oxychloride gives a high-field shift that increases linearly with the mole ratio $SbCl_5/SeOCl_2$ (Table III and Fig. 1) which indicates that $SbCl_5$ is a strong acid of the selenium oxychloride solvent system since

$$\frac{\text{moles } SbCl_5}{\text{moles } SeOCl_2} = \frac{\text{moles } SeOCl^+}{\text{total moles } (SeOCl_2 + SeOCl^+)}.$$

Only very few measurements were made on other acids and they are summarized in Table IV. To facilitate comparison of these results it was assumed that the shift is proportional to the mole ratio acid/$SeOCl_2$, and shifts were calculated in each case for the mole ratio 1/3. The small shift for $AsCl_3$ and the apparent dependence of the calculated

Base	**Moles base/moles $SeOCl_2$**	**δ (p.p.m. from $SeOCl_2$)**	**δ calcd. for mole ratio = 1/3**
Quinoline	1:7	10.3	24.0
KCl	1:15	5.1	25.3

shift on the actual concentration used suggests that $AsCl_3$ is a weak acid. The large shift produced by $SnCl_4$ indicates that it is extensively if not completely ionized as a dibasic acid

$$SnCl_4 + 2SeOCl_2 = 2SeOCl^+ + SnCl_6^-.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The two bases quinoline and KCl give high-field shifts of the same order of magnitude as those produced by acids (Table IV). The relatively large shift produced by KCl is of interest as it indicates a strong interaction of the chloride ion with the solvent. This can be most simply expressed in terms of the formation of the complex ion $SeOCl_3^-$ so that the self-ionization of the solvent is perhaps better represented as a chloride ion transfer,

$$2SeOCl_2 = SeOCl^+ + SeOCl_3^-.$$

ACKNOWLEDGMENT

We thank the Directorate of Chemical Sciences of the United States Air Force of Scientific Research and the National Research Council for generous financial aid. We also thank Dr. K. C. Moss and Dr. H. J. Clase for help with the preparation of some of the compounds, Dr. W. A. Whitla for samples of $SeF_4.SO_3$ and $SeF_4.BF_3$, and Mr. J. Bacon for assistance with the development of the audio side-band method for observing the selenium signals.

SURFACE CHEMISTRY AND CATALYTIC PROPERTIES OF BORON PHOSPHATE

1. SURFACE AREA AND ACIDITY

J. B. MOFFAT AND H. L. GOLTZ
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received December 10, 1964

ABSTRACT

Surface properties of the dehydration catalyst, boron phosphate (BP), prepared by the reaction of triethyl borate and phosphoric acid, were investigated by the use of a microbalance system. During evacuation at elevated temperatures, weight changes of the BP were obtained. Nitrogen adsorption isotherms were measured after each treatment. Surface areas appear to increase, and reach a maximum in the range 200–300 °C. Weight changes are initially large but begin to level off as the temperature is increased. Ammonia isotherms were obtained at 25.00 °C on aliquots of the same BP sample after various pretreatments. Amounts of ammonia remaining adsorbed after evacuation overnight were taken as the quantity chemisorbed. An approximate value of 8.9 kcal/mole of ammonia was obtained for the heat of chemisorption of ammonia by measuring the pressure and weight change as the amount of chemisorbed ammonia is decreased on heating the BP to various temperatures in a closed system. Results are interpreted in terms of change of number of active sites with surface area and the deactivation of sites on loss of water.

INTRODUCTION

Much of the work done in an attempt to elucidate the mechanisms by which dehydration catalysts function has involved alumina. However, an examination of patent literature shows that at least one other material, namely boron phsophate, has a high prominence (in terms of numbers of patents devoted to it) as a potential dehydration catalyst. Remarkably little work has been done on the surface chemistry associated with its catalytic properties.

What work has been done on boron phosphate has been largely concerned with its bulk properties as opposed to its surface properties. The first important paper was that of Schulze (1) in 1934 on the crystal structure of boron phosphate. In 1950, Hummel and Kupinskii (2) reported on the vaporization of BPO_4. Cherbuliez and co-workers (3), in a paper published in 1953, worked on the preparation and properties of orthoboric esters. In so doing they experimented with the preparation of boron phosphate from phosphoric acid and triethyl borate. Gerrard and Griffey (4) discussed a novel preparation of boron phosphate from triethyl phosphate and boron trichloride. A number of papers (5, 6, 7) have been concerned with high-pressure forms of boron phosphate. V. F. Ross and co-workers (8) prepared boron phosphate for their n.m.r. studies on this phosphate and several borates.

Recently, several papers devoted exclusively to boron phosphate have appeared. Baccaredda (9) examined the reaction of alcohol and water with boron phosphate prepared by reacting boric acid with phosphoric acid. Friedlin and his co-workers (10) have studied the activity and stability of borophosphate catalysts in the dehydration of a mixture of pyrocatechol and methanol. After the work discussed in the present paper was completed, another paper (11) appeared from the Freidlin group in Russia. In this paper Freidlin discusses the effects of baking temperature and acidity on the dehydration of aliphatic alcohols. Their catalysts were prepared by reacting boric acid with phosphoric acid.

In view of the apparently widespread interest in boron phosphate for industrial use as a dehydration catalyst, it seemed worthwhile to examine the mechanism by which such dehydration takes place. Unfortunately, as has been mentioned, little work has been done on the properties of boron phosphate, especially those of its surface. Hence it appeared necessary and appropriate to initiate studies of the surface chemistry of boron phosphate prior to any attempts to study reactions on the surface.

Presumably the catalytic ability of boron phosphate will be related to (among other things) (1) the surface area, (2) the "acidity" of the sites available, (3) the number of such acid sites, (4) the "surface structure", that is, the inter-site separation on the surface. The surface area is presumably dependent on the prior treatment of the catalyst, such as heat treatment and evacuation. Indeed, the number of active sites may be related to such preliminary treatment, if one argues that the removal of a "sorbed" water molecule from a surface site may alter the activity of the site with respect to dehydration catalysis.

It therefore appeared to be of interest to examine the interdependence of amount of water lost on evacuation, temperature at which evacuation occurred, and surface area of the resulting solid. If one presumes that each acidic site will chemisorb a fixed number of ammonia molecules (most likely one per site) then the amount of ammonia chemisorbed should be directly related to the number of active sites. Further, one might expect that the "acidity" of the sites available will be related to the strength of binding of the ammonia molecules to such sites. Of course, the idea that the number and strength of acid sites might be related to catalytic activity in dehydration reactions is based on analogy with results of studies on silica–alumina catalysts.

Various methods have been suggested for the determination of the number and strength of acid sites on the surface of solids. Hammett indicators (12) have been employed for such purposes. More recently, ammonia chemisorption has found favor for such determinations. Webb (13) was one of the first to use such a method, but interest has been shown by a number of other workers (14–18).

EXPERIMENTAL

Materials

For the present work, samples of boron phosphate were prepared initially by three methods, (1) reaction of boric and phosphoric acids, (2) reaction of triethyl phosphate and boron trichloride, (3) reaction of triethyl borate (TEB) and phosphoric acid (PA). However, for most of the work to be described, samples prepared by method (3) were used. Various ratios of the reactants were tried in an attempt to determine the best method of preparation, and the ratio of 2:1 TEB:PA was ultimately chosen. The middle cut from a distillation of TEB was used for the preparation. Phosphoric acid, C.P. grade, was used without further treatment.

For the adsorption studies, nitrogen gas obtained commercially was passed through a trap filled with magnesium perchlorate and cooled in liquid nitrogen, and then was passed over heated copper filings contained in a copper tube, prior to passage into the vacuum system. Ammonia gas obtained commercially was subjected to a trap-to-trap distillation in the vacuum system before use.

Apparatus

A Cahn RG Electrobalance mounted in a glass bottle which was fitted with hang-down tubes for the sample and weights was employed for all of the present work. For other work, to be reported on later, a volumetric adsorption system fitted with both a manometer and thermistor gauge had been constructed. As a check against the gravimetric system a sample of finely divided titanium dioxide, kindly provided by Dr. R. W. Brickenkamp of National Lead Company, was used in the volumetric system.

The Cahn balance container was attached to a standard adsorption system consisting of a Veeco RG75 ionization gauge, Consolidated Vacuum Corp. triple-scale McLeod gauge, and a wide-bore mercury manometer. Mercury levels were read to ± 0.05 mm with a cathetometer. Appropriate bulbs and stopcocks were available for purifying and dispensing gases. Vacuum was obtained by the use of a Balzers DUO5 oil pump together with two mercury diffusion pumps in series, protected by large liquid nitrogen traps on both sides.

A Hoskin tube furnace, controlled by a de Khotinsky bimetallic strip regulator with a relay, was used to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

heat and control the temperature of the sample contained in a quartz hemi-spherical pan which was suspended from the balance arm by a nichrome wire. The furnace was raised into position around the Pyrex hand-down tube by using two lab jacks. The same length of the hang-down tube was heated in each run. A thermocouple well protruded a distance of 3 cm into the hang-down tube from the bottom. With the quartz pan in weighing position, the bottom of the pan was held approximately $\frac{1}{4}$ in. above the top of the thermocouple well. Temperatures were read to ± 1 °C or better using an uncalibrated Chromel–Alumel thermocouple attached to a Varian G-11 recorder. For the studies of the chemisorption of ammonia, an oil bath outfitted with immersion heater, stirrer, mercury thermoregulator, and relay was used. Temperatures of this bath were checked against a National Bureau of Standards thermometer.

X-ray diffraction patterns were obtained by the capillary tube method using a Philips NRD899 camera. A copper tube and nickel filter were used to obtain diffraction patterns at 30 kV and 20 mA for various exposure times.

Method

The freshly prepared samples of boron phosphate were placed in screw cap bottles for storage. The sample which was used for most of the work was labelled BP6A and had been heated no higher than 100 °C in preparation. A sample of this boron phosphate was placed on the pan of the previously calibrated Cahn balance and pumped overnight at 25 °C. The weight of the sample was followed at the beginning and end of the pumping period on a Leeds and Northrup Speedomax G recorder which was attached to the electronic control of the microbalance. When constant weight (± 1 μg) had been obtained the system was closed from the pump, the sample tube was immersed in liquid nitrogen, and an adsorption isotherm of nitrogen on the sample was obtained. Several desorption points were also obtained for each isotherm. Normally a minimum of 10 points were obtained for each isotherm. On completion of the isotherm, the liquid nitrogen bath was removed and the sample was opened to the pump. At the beginning of the work, difficulties with "popping" of the sample occurred at pumping stages. This was eliminated by first opening the sample to a Cenco Pressovac pump until the weight was approximately constant, then opening the sample to the diffusion pumps, and finally isolating the sample from the Pressovac pump. No evidence of "popping" either visible or from balance readings was obtained with this method.

The furnace was then carefully raised around the sample tube and the sample was pumped at approximately 100 °C overnight. The procedure just described was then repeated. The whole operation was repeated until the previously selected maximum temperature had been obtained. Adsorption isotherms and weight losses were obtained after intervals of heating of approximately 50 deg or in some cases 100 deg.

When the preselected maximum temperature had been attained and the adsorption isotherm completed, pumping was again carried out overnight but this time at room temperature. Following this, the weight of ammonia adsorbed at various pressures was determined with the sample held at 25.00 °C. For each point on the ammonia isotherms times of 12 to 24 h were required to reach equilibrium. When an isotherm pressure of at least 15 to 20 cm Hg had been reached, the system was opened to the pump for a short time and the first desorption point was taken to be that obtained when the weight again became constant. This procedure was contained until four or five desorption points were obtained. Then the sample was opened to the pump and evacuation at 25.00 °C was continued overnight. The weight of the sample was again determined. This weight was taken to be the weight of the sample plus the amount of ammonia chemisorbed.

The sample system was then closed from the pump. The sample tube was heated to various temperatures, at each of which equilibrium was taken to have been reached when the weight of the sample became constant. Equilibrium pressures and sample weights were read for each temperature.

A fresh portion of the sample BP6A was selected for each of the runs previously described. Maximum temperatures from 25 to 450 °C were employed.

Corrections for buoyancy in the microbalance were obtained by employing a 110 mg sample of small diameter quartz rods. The apparent weight was obtained for various pressures up to 700 mm Hg while the quartz sample was held at a constant temperature of 100 $\pm$ 1 °C. This process was repeated for 25 °C and liquid nitrogen temperature.

RESULTS AND DISCUSSION

A Fortran II computer program was prepared for calculations associated with the adsorption isotherms. This program fitted the buoyancy correction data to a polynomial (of 10 terms), and used the equation for the polynomial to make the appropriate corrections to the weights of adsorbate. BET abscissae and BET ordinates were also obtained, together with the surface area by a least squares method. Finally, the number of moles adsorbed, number of molecules adsorbed, number of moles adsorbed per gram, and number of molecules adsorbed per gram were printed out for each pressure recorded. Input data consisted of equilibrium pressures, equilibrium weights adsorbed, buoyancy correction data, and weight of sample.

Figure 1 shows the change in the specific surface area with pretreatment temperature. It is interesting to note that in all cases the surface area initially increases on heating the sample above room temperature. No effort was made to prevent loss of surface area

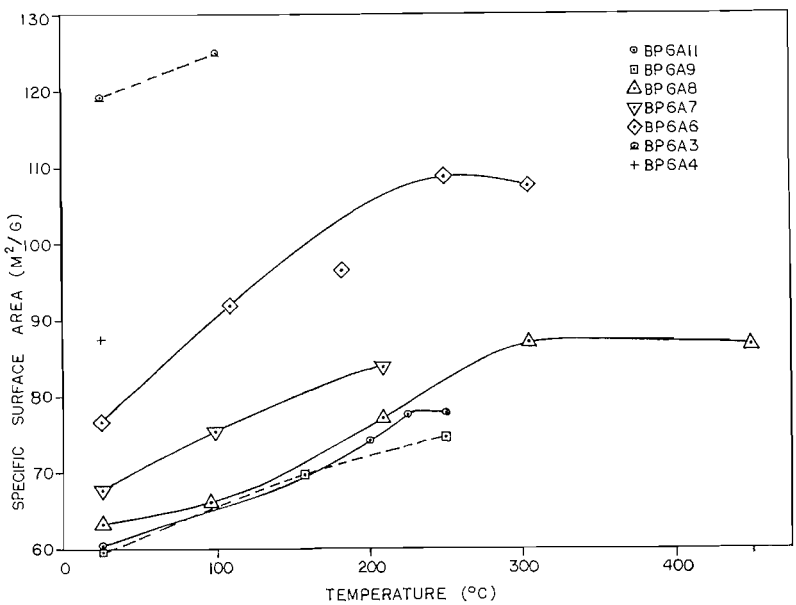

FIG. 1. Change in specific surface area with pretreatment temperature.

by the samples on standing at room temperature in screw cap bottles. Hence, although the initial (25 °C) values of surface area shown in Fig. 1 are all different, nevertheless each represents an aliquot from the same sample, BP6A. One notes that the sample of boron phosphate changed from approximately 120 m^2/g to approximately 55 m^2/g on standing in the sample bottles. Figure 1 also indicates that the surface area apparently reaches a maximum between 200 and 300 °C. It may be significant that many of the patented recipes recommend ultimate heating of the boron phosphate to about 300 °C before use.

It might have been expected that the specific surface area of the solid would decrease on heating, perhaps because of some type of sintering phenomena. However, it seems not unreasonable to presume that the unexpected increase in surface area may be due to the evolution of water from the bulk of the solid during the heating and evacuation process. The transfer of this water from the interior to the surface of the solid could lead to the production of additional porous structure. At some temperature between 200 and 300 °C, it is presumed that all the entrapped water has escaped and on further increase in temperature closing of some of the pores may occur, resulting in a decrease in surface area. This latter effect may become significant at much higher temperatures than were employed in the present work.

In Fig. 2, the weight of the catalyst after evacuation at various temperatures is shown. In general, the shape of the curves for each of the aliquots of BP6A is the same, which is of course to be expected. It should be noted that most of the change in weight (approximately 80% of the total change) has occurred in the temperature range below 250 to

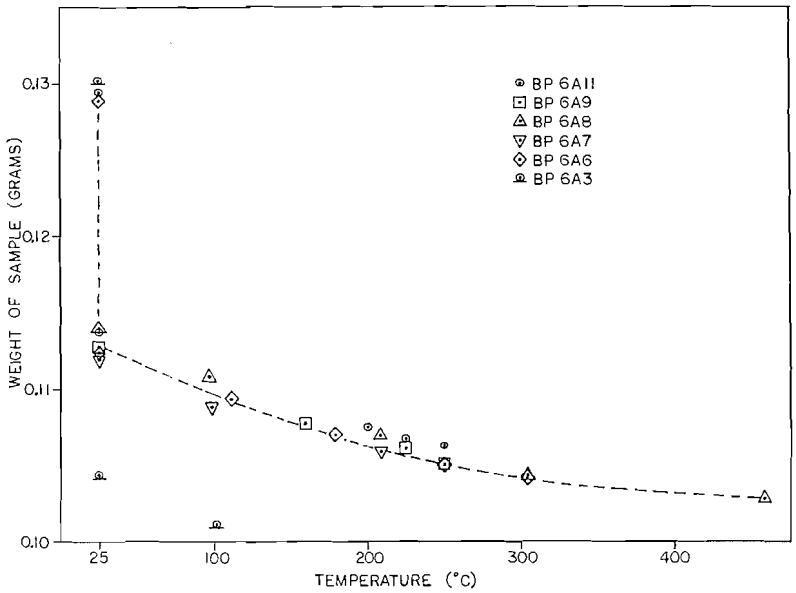

FIG. 2. Weight of catalyst after evacuation overnight at various temperatures.

300 °C. This appears to be consistent with the attainment of approximately constant surface areas in the same temperature region.

Presumably the change of weight which results on evacuation of the phosphate at various temperatures is due largely to loss of water from the surface and interior of the particles. Since, according to Hummel (2), the vaporization temperature is approximately 1 450 °C, it seems unlikely that much of the catalyst in the form of boron phosphate was lost on evacuation at the temperatures used in this experiment. For the same reason it is not expected that much boron or phosphorus in the form of boric oxide or phosphorus pentoxide, respectively, could have been lost from the solid. No attempt was made to determine the composition of the material which had been pumped off the boron phosphate. However, there was no evidence of any deposits on the portion of the vacuum line which was at room temperature, between the heated sample and the pumps.

Figure 3 shows the adsorption isotherms of nitrogen for one of the samples of boron phosphate at various stages in the heating process. No evidence of lack of reversibility was obtained from the desorption points on the isotherms for any of the samples at any of the temperatures employed.

In Fig. 4, isotherms for the adsorption of ammonia at 25.00 ± 0.05 °C are shown for typical samples in terms of milligrams of ammonia adsorbed per square meter of surface area.

The amount of ammonia remaining on the various samples after evacuation under high vacuum at 25 °C overnight is shown in Fig. 5 as a function of maximum pretreatment temperature for each of the aliquots. As has been mentioned previously, this is taken to be the amount of chemisorbed ammonia. The data in Fig. 5 scatter so badly that any positive conclusion may be questionable. However, if the 200 °C point is largely ignored, it then appears that the amount of ammonia chemisorbed is a continuously decreasing function of the temperature, at least up to about 450 °C. Unfortunately, no explanation can be offered for the discrepancy of the point at 200 °C.

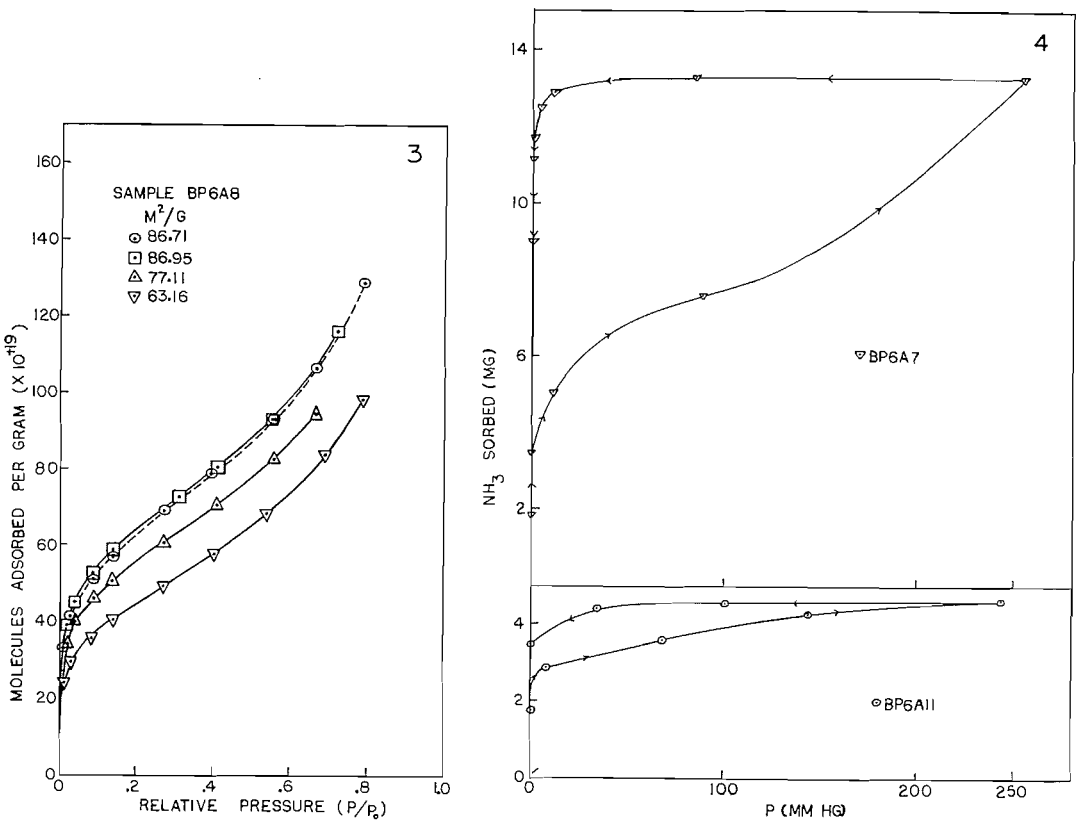

FIG. 3. Adsorption isotherms of nitrogen on a typical sample of boron phosphate at various stages in the pretreatment process.
FIG. 4. Typical adsorption isotherms for the adsorption of ammonia on boron phosphate at 25.00 °C.

To utilize the results obtained from the study of the increase of pressure of ammonia in the closed system with increase of temperature, the following reasoning was employed.

It is not unreasonable to presume that the equilibrium process involved can be represented by

$$BPO_4.NH_3(s) \leftrightarrows BPO_4(s) + NH_3(g)$$

for which an "equilibrium constant" can be defined as

$$K = \frac{N_e P_{NH_3}}{N_o},$$

where N_e = concentration of empty surface sites, N_o = concentration of occupied surface sites, and P_{NH_3} = pressure of ammonia.

It may be presumed that at the start of the run in which the pressure, weight, and temperature data were obtained, all chemisorption sites are occupied and the gas pressure is essentially zero. Hence the concentration of empty surface sites should be proportional to the pressure of ammonia, and the number of occupied surface sites should be given by

$$N_o = W_1 - W_t,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where W_i = initial weight of ammonia chemisorbed and W_t = weight of ammonia desorbed.

Since the pressure of ammonia should be proportional to the weight of ammonia desorbed, then

$$K = \frac{W_t^2}{W_i - W_t}.$$

A plot of the logarithm of this K against the reciprocal of the temperature in °K can then be related to the change in enthalpy or heat content ΔH^0 for the desorption process. It is presumed that this may be taken as a rough measure of the heat of chemisorption.

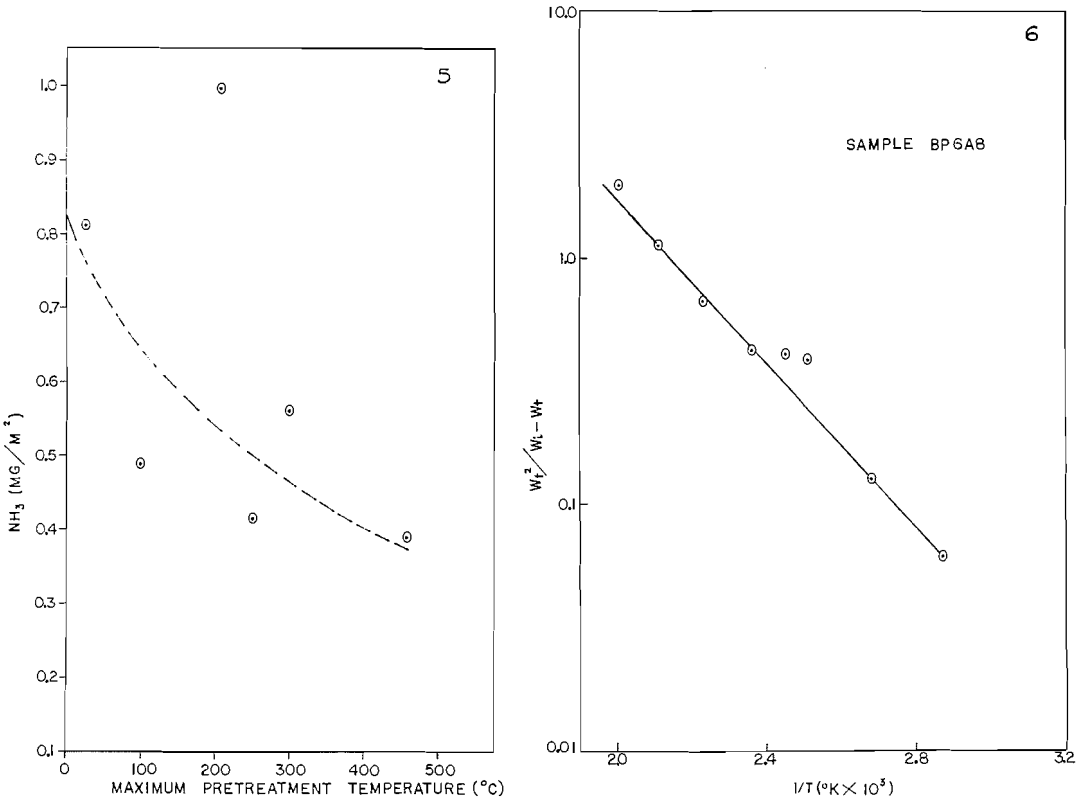

FIG. 5. Amount of chemisorbed ammonia per unit surface area after treatment at various maximum temperatures.

FIG. 6. Heat of chemisorption from the plot of logarithm of K vs. the reciprocal of absolute temperature.

A typical set of data are shown plotted in such fashion in Fig. 6. An average value of 8.9 ± 0.5 kcal/mole was obtained for the heat of chemisorption of ammonia for all the samples studied. This may be compared with the somewhat higher value of 11.5 kcal/mole obtained by Blyholder and Richardson (17) for ammonia on activated iron(III) oxide.

For X-ray powder diffraction measurements, other samples of BP in addition to those prepared in this laboratory were obtained for comparison purposes. Dr. V. Ross very kindly supplied samples from her n.m.r. work at Brown University. Stauffer Chemical Company kindly provided a sample. A sample was also obtained from Alpha Inorganics,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Inc. X-ray diffraction photographs were obtained on these samples and also on samples of BP6A which had been subjected to various pretreatments as mentioned in this paper. Line spacings on these photographs were essentially identical for each sample. However, the lines on those photographs obtained with sample BP6A prior to any kind of treatment were in general quite diffuse. In addition, so-called white radiation effects were apparent. These effects may be attributed to the finely divided nature of the solid.

Samples of BP6A which had been treated at various temperatures up to 450 °C yielded diffraction photographs in which the lines were only slightly sharper. Finally, a sample of BP6A was ignited at a temperature above 1000 °C for about 2 h. The X-ray diffraction pattern resulting from this ignited sample was virtually identical with those of the commercial and Brown samples.

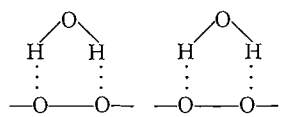
What is perhaps the most disturbing aspect of the present results, at least to the author, is that encountered in a closer examination of the significance of the amounts of chemisorbed ammonia. If it be assumed, as has been done here, that all the ammonia remaining on the solid after pumping overnight is indeed chemisorbed, then one might naively expect that the number of chemisorbed molecules times the area covered per molecule would yield the total surface area.

If the cross-sectional area of the ammonia molecule is taken as 20 Å² (19), the calculated area for the sample containing the least amount of ammonia chemisorbed is approximately three times that obtained from nitrogen adsorption results. For the maximum amount of ammonia chemisorbed (~1 mg/m²), the calculated area corresponds to approximately seven times the measured area.

To calculate an area in agreement with the measured one, it is necessary to use a cross-sectional area for the ammonia molecule of about 3 Å², which corresponds to coverage of a square of approximately 1.4 Å in dimension. It is assumed that complete coverage of the surface occurs. It is interesting to note that Schulze (1) found the P—O distance to be 1.55 Å, and the B—O distance to be 1.44 Å.

The results discussed in this paper appear to indicate that the greater part of the change in surface area, in weight, and in number of acidic sites with change in temperature probably has occurred prior to 300 °C.

There may be some value, at least in terms of suggesting future work, in presenting even an admittedly grossly oversimplified mechanism. It is assumed that the surface of the boron phosphate particles consists in large part of oxygen atoms, so that a simple picture of the chemisorption of water may be as shown below.



Within experimental error, the heat of chemisorption of ammonia is the same for all samples examined. This suggests that the number of sites for chemisorption of ammonia per unit surface area decreases with temperature, but that the strength of the sites remains fixed, at least over the range of temperature studied.

If it is postulated that most of the sites for chemisorption of ammonia are oxygen atoms, then it would appear that the number of sites should increase with pretreatment temperature. However, it may be that only those oxygen atoms which have a hydrogen atom attached are energetically favorable for chemisorption of ammonia. The removal of the water bound to the surface may expose oxygen atoms which are not energetically

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

favored. Further, the evidence that the degree of crystallinity increases with temperature may add support to this suggestion. Presumably, as the crystallinity increases, the forces operative between the species of the solid will increase, as the lattice takes shape. This may then lead to a reduction in the ability of the surface atoms to form chemisorption bonds.

It is tacitly assumed that the sites for chemisorption of ammonia are the same as those taking part in catalytic dehydration. If this is so, then it must be expected, on the basis of the present mechanism, that the catalytic ability of boron phosphate will decrease with the extent of the pretreatment heating and pumping. This has yet to be shown.

While the present results do not of course negate other mechanisms than the one suggested, nevertheless, qualitatively at least, the proposed mechanism appears to fit the experimental information. Further work is obviously necessary to substantiate the hypotheses. In particular, more direct information on the nature of the bond formed between ammonia and boron phosphate would be valuable. This aspect of the work is now being pursued in this laboratory.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge the technical assistance of Mr. H. Goltz, who performed much of the experimental work reported. Translation of a paper from Italian to English was kindly supplied by Dr. M. Z. Cohn of the University of Waterloo. The author is indebted to Eleanor Moffat for preparation of all figures in the paper.

The generous provision of computer time by the Computation Center of the University of Waterloo is gratefully acknowledged. The author is indebted to the National Research Council for financial support, and to the University of Waterloo for the provision of the Cahn Electrobalance.

ALIPHATIC VICINAL FLUOROBROMIDES

SOME PREPARATIONS AND REACTIONS[1]

F. L. M. PATTISON, D. A. V. PETERS, AND F. H. DEAN[2]
Department of Chemistry, University of Western Ontario, London, Ontario
Received November 16, 1964

ABSTRACT

The addition of "BrF", using *N*-bromoamides in anhydrous hydrogen fluoride, to a number of aliphatic alkenes has been studied. As expected, the bromine atom in the resultant vicinal fluorobromides exhibited relatively low reactivity in nucleophilic and hydrogenolytic reactions.

The bromine monofluoride addition reaction, first described by Bowers (2, 3, 4), has been employed mainly in the synthesis of fluorinated steroids. Its application to aliphatic alkenes was undertaken here partly to extend the scope of the reaction and partly to obtain the resultant vicinal fluorobromides as intermediates in other syntheses; of particular interest was their potential use in the synthesis of α-monofluoroalkanoic acids (5). While this work was in progress, parallel studies using perchloryl fluoride were continuing, with α-monofluoroalkanoic acids again as the main goal (5). The two methods are complementary, in that they permit the introduction of the fluorine atom at centers of low electron density (bromonium ion) and high electron density (carbanion) respectively. Prior to this work, the only common aliphatic vicinal fluorohalides were those derived from ethane. Of these, 1-bromo-2-fluoroethane had been reported by Schrader (6) to be formed by the direct addition of "BrF" (using a mixture of bromine and fluorine) to ethylene; the present work may thus be considered as a refinement of this original procedure.

$$RCH{=}CH_2 + CH_3C\overset{+}{O}NH_2Br \rightarrow RCH\underset{\diagdown\,+\,\diagup}{\overset{\diagup\ \ \diagdown}{}}\begin{matrix}Br\\ \\ CH_2\end{matrix} + CH_3CONH_2$$

I

$$RCH\underset{\diagdown\,+\,\diagup}{\overset{\diagup\ \ \diagdown}{}}\begin{matrix}Br\\ \\ CH_2\end{matrix} + HF \rightarrow RCHFCH_2Br + H^+$$

1-Alkenes of medium chain length on treatment with a molar quantity of *N*-bromoacetamide and excess anhydrous hydrogen fluoride in ether gave the expected products in good yield (70–80%), with small amounts of isomeric 2-bromo-1-fluoroalkanes. The structures of the major products were shown to be the 1-bromo-2-fluoroalkanes by nuclear magnetic resonance (n.m.r.) spectroscopy and by their conversion in high yield to the corresponding α-monofluoroalkanoic acids (5). The minor products were isolated in only a few instances (for example, in the addition to allyl bromide); they proved to be the anti-Markovnikov isomers. The minor product was usually not removed from the mixture, because it was destroyed or removed in many of the subsequent reactions. Yields are shown in Table I.

For personal use only.

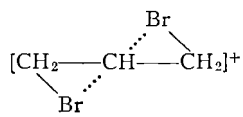
The most satisfactory general technique involved the addition of *N*-bromoacetamide and the alkene, alternately and in small portions, to a cooled (−80°) solution of anhydrous hydrogen fluoride in ether. Some variations were examined briefly. (*a*) *The nature of the bromine source.* Three reagents were tried, *N*-bromoacetamide (NBA), 1,3-dibromo-5,5-dimethylhydantoin (DBH), and 1-bromo-3,5,5-trimethylhydantoin (BTH). All gave approximately the same yields. However, the higher solubility of the hydantoins in the reaction medium permitted a simpler method of adding the reagents. (*b*) *The addition of reagents.* NBA was insoluble in the cold ether solution, but DBH and BTH were sufficiently soluble to be added in one portion prior to the dropwise addition of the alkene. The yields were comparable when the alkene was added in its entirety and the brominating agent was added in portions. Moreover, the yield was only slightly diminished when both the brominating agent and the alkene were added in one portion at the start of the reaction. In short, for maximum yield, alternate portionwise addition is recommended, whereas for maximum simplicity, addition of all reagents to the ether solution is preferred. (*c*) *Solvent.* Ether was found to be satisfactory in most instances. For ethylene, however, methylene dichloride, at a reaction temperature of −30°, proved to be the most effective solvent. 1-Butene gave the fluorobromide in chloroform or in ether–chloroform. In general, a mixture of solvents (such as an ether and a halogenoalkane) is likely to be most generally satisfactory.

The alkene component was varied in order to examine the versatility of the reaction. (*a*) Gases were found to react normally, but in lower yield; ethylene, propylene, and 1-butene thus gave the expected products in 25–50% yield. (*b*) Higher molecular weight alkenes could also be used; 1-decene gave a 78% yield of 1-bromo-2-fluorodecane. 1-Octadecene reacted more slowly, because of its low solubility in the reaction medium; the resultant mixture of product and starting material was used directly in subsequent steps. (*c*) Branched alkenes reacted in lower yield; for example, 2-ethyl-1-butene gave 1-bromo-2-fluoro-2-ethylbutane (56%). (*d*) The highly reactive alkene styrene gave a poor (25%) yield of the adduct by the usual process; much polymeric material was formed. When some pyridine was added to increase the concentration of fluoride ion, the yield of styrene fluorobromide was more than doubled. The designation of the product as 1-bromo-2-fluoro-2-phenylethane is consistent with the observations of Buckles and Knaack (7) on the mode of addition of iodine monochloride to styrene. Stilbene also reacted normally in low yield. (*e*) The presence of other functional groups seemed to have no effect on the addition reaction; for example, methyl 10-undecenoate gave methyl 11-bromo-10-fluoroundecanoate in 71% yield. The addition to acrylates, to allyl esters, and to bridged bicyclic systems (with concomitant Wagner–Meerwein rearrangement) will be described in later communications.

Allyl bromide was expected to form 1,3-dibromo-2-fluoropropane (II) as the predominant product by the usual Markovnikov addition mechanism. It was found, however, that the anti-Markovnikov adduct 1,2-dibromo-3-fluoropropane (III) was formed in 32% yield, while the yield of the Markovnikov adduct II was only 22%.

$BrCH_2CHFCH_2Br$ II

$BrCH_2CHBrCH_2F$ III



IV

Anomalous product ratios have been observed by de la Mare and co-workers in studies of the addition of hypochlorous acid to allyl halides (8, 9, 10). The products in the present

work may be explained by postulating that the reaction proceeds through the symmetrical bromonium ion IV (8). The major product would then arise from nucleophilic attack by fluoride ion on the more plentiful, exposed primary carbon atoms. Simple steric effects may also be involved.

Some side reactions were observed. Ether formation occurred in some reactions. For example, a bromoethoxyheptane was isolated from the addition reaction with 1-heptene; this is probably formed by partial hydrolysis of solvent ether to ethanol, which in turn reacts with the bromonium ion intermediate (I). Other side reactions included the addition of the elements of *N*-bromoacetamide to the double bond and proton elimination from the bromonium ion intermediate; both these reactions were observed principally in the addition to bridged bicyclic systems, and will be described in a later paper.

The aliphatic vicinal fluorobromides are colorless, mobile liquids possessing odors similar to those of the corresponding alkyl bromides. They are nontoxic, indicating that they are not metabolized to fluoroacetic acid; for example, both 1-iodo-2-fluorohexane and 2-fluoro-1-hexanol had $LD_{50} > 107$ mg/kg (intraperitoneal injection into mice). They boil at a higher temperature, have greater densities, and have lower refractive indices than the corresponding alkyl bromides (Table II). They normally exhibit a C—F band in the infrared at 1 010 – 1 016 cm^{-1}. Most of the vicinal fluorobromides are stable when stored in sealed glass ampoules at room temperature, but some, for example styrene fluorobromide and *trans*-1-bromo-2-fluorocyclohexane, showed a marked tendency to decompose; this could be due to autocatalysis by small amounts of hydrogen fluoride formed during the sealing process.

The reactivity of 1-bromo-2-fluoroalkanes towards nucleophilic reagents was expected to be less than that of *n*-alkyl bromides; thus, Hine (11, 12) has found that 1-bromo-2-fluoroethane reacts only one-eighth as rapidly as ethyl bromide with the thiophenoxide ion. In a series of scouting reactions, it was found that the 1-bromo-2-fluoroalkanes underwent nucleophilic substitutions under conditions which were more vigorous than those one might normally use for *n*-alkyl bromides. By this means one or more members (Table II) of the following classes of 2-fluoroalkyl derivatives were prepared (reagents in brackets): acetates (sodium acetate plus sodium iodide in dry dimethylformamide), azides (sodium azide in aqueous dimethylformamide), iodides (sodium iodide in acetone), formates (sodium formate plus sodium iodide in dry dimethylformamide), nitrates (silver nitrate in acetonitrile), thiocyanates (potassium thiocyanate in ethanol), *p*-nitrobenzoates (lithium *p*-nitrobenzoate in dry dimethylformamide), and tosylates (silver tosylate in acetonitrile). When treated with sodium cyanide in dimethyl sulfoxide, 1-bromo-2-fluorohexane gave 1,2-dicyanohexane rather than the expected 3-fluoroheptanonitrile; the analogous reaction of 1-bromo-2-fluoroethane to yield succinodinitrile has been reported by Mirosevic-Sorgo and Saunders (13). 1-Iodo-2-fluorohexane did not alkylate the dimethyl malonate anion. In a study of the reductive elimination of 1,2-dihalides with lithium aluminium hydride, King and Pews (14) have reported that *erythro*-1-bromo-2-fluoro-1,2-diphenylethane formed *trans*-stilbene in 86% yield, whereas *trans*-1-bromo-2-fluorocyclohexane (3) formed fluorocyclohexane in 45% yield.

The acetates (and, to a lesser extent, the nitrates and formates) were important intermediates in a general route to α-monofluoroalkanoic acids; this is probably the most valuable application of the work (5). The nitrates were readily hydrogenolyzed using platinum in ethanol to the corresponding 2-fluoro-1-alkanols, $RCHFCH_2OH$; this affords a convenient route to these hitherto inaccessible fluoroalcohols. (Most common procedures, such as opening of epoxides with hydrogen fluoride (15), yield the isomeric

*The figures shown are for the alkenes; the brominating agent was used in approximately equimolar quantities. *N*-Bromoacetamide was used in all reactions except those of propylene and methyl 10-undecenoate, when 1,3-dibromo-5,5-dimethylhydantoin was the bromine source.
†Ether was the most commonly used solvent, either alone or in combination.
‡The compound listed is the major product.
§The yield represents the total purified mixture of the two fluorobromide isomers; the minor (anti-Markovnikov) isomer amounted to some 3–8% of the total sample (g.l.c. analyses).
‖Yield is based on brominating agent.
¶Crude mixture of unreacted alkene and fluorobromide was used without purification.
**A total of 1.5 moles of pyridine was used (see Experimental).

1-fluoro-2-alkanols, $RCH(OH)CH_2F$.) An even simpler, direct procedure for converting the 1-bromo-2-fluoroalkanes to 2-fluoro-1-alkanols involved the use of sodium formate in hot aqueous dimethylformamide; thus, 2-fluoro-1-hexanol of high purity was obtained in 75% yield.

Because the crude 2-fluorooctadecyl acetate was a greasy, low-melting solid, a more satisfactory crystalline derivative was required for analysis and for conversion to 2-fluorooctadecanoic acid. The *p*-nitrobenzoate was therefore prepared in fair yield. Since nitrobenzoate esters are known to be resistant to acid hydrolysis (16), the *p*-aminobenzoate was prepared in excellent yield using Adams' catalyst.

Vicinal fluorobromides and fluoroiodides were entirely resistant to hydrogenolysis at room temperature and atmospheric pressure using platinum as catalyst; under the same conditions, vicinal dibromides were readily dehalogenated to the corresponding alkanes. For example, *trans*-1-bromo-2-fluorocyclohexane (3) failed to react under conditions that resulted in the ready conversion of *trans*-1,2-dibromocyclohexane to cyclohexane. This difference in reactivity was used to isolate pure 1,3-dibromo-2-fluoropropane (II) from its mixture with 1,2-dibromo-3-fluoropropane (III); the latter, containing a vicinal dibromide grouping, was destroyed by hydrogenation whereas the former was recovered unchanged. The facile hydrogenolysis of benzylic fluorides is well known; even the relatively stable *gem*-difluoro grouping may be reduced if it lies adjacent to a benzene ring (17). Consequently hydrogenolysis of 2-fluoro-2-phenylethyl nitrate yielded only 2-phenylethanol; similarly, styrene fluorobromide gave ethylbenzene. In this latter case, the β-fluorine atom cannot exert its "protecting" action over the bromine atom because, being labile itself, it is easily removed.

EXPERIMENTAL

Physical constants and analytical data for all new compounds are given in Table II. The preparations described below represent typical examples of each procedure; obvious variations for obtaining different members have not been included. Melting points (uncorrected) were determined on a Kofler hot stage, and densities with a Fisher-Davidson gravitometer. The nuclear magnetic resonance spectra were obtained with a Varian DP-60 spectrometer. Infrared spectra were obtained with Beckman IR-7 and IR-5 infrared spectrophotometers. Analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, 77, N.Y. Most of the alkenes were purchased from Humphrey-Wilkinson, Inc., Devine Street, North Haven, Conn. Other reactants were obtained from standard commercial sources. Fractionations were carried out using a 23-plate platinum-plated spinning-band column.

A. Preparation of Vicinal Fluorobromides

1-Bromo-2-fluorohexane

Anhydrous hydrogen fluoride (129.7 g, 6.49 moles) was condensed into a 500 ml polythene bottle cooled in dry ice. Cold (−80°) dry ether (240 ml) was added with magnetic stirring. *N*-Bromoacetamide (69.0 g, 0.50 mole) and 1-hexene (42.5 g, 0.505 mole) were added portionwise and alternately over 27 min, with cooling (−80°) and stirring. The NBA dissolved as it was added. The mixture was stirred for 2 h at −80° and then was allowed to stand overnight at this temperature. The resultant solution was neutralized by being poured slowly into a mixture of sodium carbonate (690 g), water (1 200 ml), ice (500 g), and ether (300 ml). The ether layer was separated and the aqueous layer was extracted with ether. The combined ether extracts were washed with water, treated with nitrous acid to destroy residual acetamide, and then washed with aqueous sodium carbonate and with water until neutral. After drying ($MgSO_4$) and removal of the ether, the resultant amber-colored liquid was fractionated to yield 71.8 g (79%) of 1-bromo-2-fluorohexane. Gas–liquid chromatography (g.l.c.) analysis (DEGS column, 158°) indicated 95 mole % of the main product and 5 mole % of 2-bromo-1-fluorohexane. The infrared spectrum ($CHCl_3$) showed a C—F band at 1 010 and 1 124 cm^{-1}. The n.m.r. spectrum (CCl_4) indicated a $—CH_2Br$ group (doublet of doublets centered at 3.39 p.p.m., J_{HF} 17.4 c/s, J_{HH} 5.6 c/s) and a −CHF group (two widely separated multiplets centered at 4.55 p.p.m., J_{HF} 46.8 c/s).

Variations in Procedure

1,3-Dibromo-5,5-dimethylhydantoin (DBH) and 1-bromo-3,5,5-trimethylhydantoin (BTH) gave results similar to those obtained with NBA. The three following variations in procedure (using DBH as the Br source) were simpler than the above portionwise addition, but gave lower yields.

*Pattison and Howell (20) report b.p. 70–71° at 745 mm, n_D^{25} 1.4236.
†Hoffmann (18) reports n_D^{23} 1.5092.
‡Millington and Pattison (21) report b.p. 116–117.5° at 740 mm, n_D^{25} 1.3784.
§Moderately toxic: LD_{50} 26.6 mg/kg (95% fiducial limits: 19.4–36.6 mg/kg) by intraperitoneal injection into mice.
‖Taylor and Kent (19) report m.p. 109°. The compound was shown to be nontoxic (LD_{50} > 100 mg/kg by intraperitoneal injection into mice).

(a) Alkene added dropwise.—Using 1-hexene (14.7 g, 0.175 mole), DBH (25.0 g, 0.0875 mole), hydrogen fluoride (45.0 g, 2.25 moles) in ether (50 ml), and carbon tetrachloride (50 ml), the alkene was added dropwise to the vigorously stirred mixture of the other components at −30° over 90 min. Yield: 64%.

(b) DBH added portionwise.—Using the same quantities as in (*a*), the DBH was added in 10 portions to the vigorously stirred mixture of the other components at −30° over 90 min. Yield: 66%.

(c) All reactants added together.—All the above reactants were mixed at the start of the reaction and were stirred for 4 h at −30°. Yield: 64%.

Variations in Alkene Component: Representative Procedures

(a) Ethylene.—Ethylene (20.2 g, 0.72 mole) was passed slowly through a stirred mixture of NBA (50.0 g, 0.36 mole), hydrogen fluoride (72.0 g, 3.6 moles), and methylene chloride (200 ml) at −40° to −20° for 5 h. The temperature should not rise above −20° before the neutralization step. Yield of 1-bromo-2-fluoroethane: 23%. Use of ether as solvent or too high a temperature before neutralization results in a negligible yield of product. A reaction using double quantities of reactants gave the same overall yield (23%).

(b) 1-Butene.—1-Butene (25.0 g, 0.45 mole) was passed into a stirred mixture of NBA (48.0 g, 0.35 mole), hydrogen fluoride (50.0 g, 2.5 moles) in chloroform (100 ml) and ether (100 ml) at −60° to −30° for 3.5 h. Yield of 1-bromo-2-fluorobutane: 55%.

(c) 1-Octadecene.—To anhydrous hydrogen fluoride (117 g, 5.85 moles), ether (725 ml), and dioxane (300 ml) in a half-gallon polythene bottle were added 1-octadecene (44 g, 0.174 mole) and NBA (23.1 g, 0.168 mole) alternately and in small portions over 15 min at −80°. The alkene solidified and floated on the surface; even at 0° it had not all dissolved. The tightly capped bottle was placed in a refrigerator for 17 h, at the end of which time the mixture was colorless and homogeneous. The usual isolation procedure gave the crude bromide as a greasy, pale-yellow solid (60.4 g) which was used directly without purification.

(d) 2-Ethyl-1-butene.—1-Bromo-2-fluoro-2-ethylbutane was prepared in the usual way from 2-ethyl-1-butene (34.0 g, 0.40 mole), NBA (57.5 g, 0.42 mole), anhydrous hydrogen fluoride (86.0 g, 4.30 moles) in ether (200 ml). The mixture was neutralized with potassium bicarbonate (208 g) and potassium carbonate (330 g) to minimize the risk of elimination from the tertiary fluoride. Treatment with nitrous acid removed traces of acetamide. Yield of fluorobromide: 56%.

(e) Styrene.—The usual method gave only 25% of the desired product; much polymeric material was formed. The following modified procedure gave a yield of 68%. In a half-gallon polythene bottle were placed anhydrous hydrogen fluoride (113 g, 5.65 moles) and ether (340 ml). With cooling (−80°) and magnetic stirring, a solution of pyridine (120.5 g, 1.5 moles) in ether (300 ml) was slowly added. The resultant pyridine hydrofluoride crystallized at −80° making magnetic stirring impossible. The mixture was stirred vigorously out of the cooling bath, and styrene (44 g, 0.42 mole) and NBA (59.5 g, 0.43 mole) were added alternately over 30 min. The mixture was cooled to −80° for 1 h and refrigerated at 8° overnight. Isolation and purification gave the required product (68%).

(f) trans-Stilbene.—The reaction was carried out in the usual way, using tetrahydrofuran as solvent. The product was isolated from the neutralized mixture by extraction with chloroform. Removal of the solvent and evaporation of the residue at 100° at 0.1 mm gave colorless needles. These were dissolved in benzene and chromatographed on silica gel. The first fraction on evaporation gave an oil which solidified. Recrystallization from 60–80° petroleum ether gave colorless needles of the pure product (25%); no C=C stretching vibration (ca. 1 600 cm^{-1}) or *trans* out-of-plane deformation (960 cm^{-1}) was observed in the infrared.

(g) Allyl bromide.—The reaction was carried out in the usual manner from 30.4 g (0.25 mole) of allyl bromide; reaction did not occur at −80° but was complete in 25 min at −20°. Further cooling and stirring, followed by isolation and fractionation gave 31.5 g of a colorless liquid of b.p. 69–73° at 3 mm. Gas–liquid chromatographic analysis on a Perkin–Elmer Vapor Fractometer (Model 134), using a polypropylene glycol 550 analytical column, showed that this liquid consisted of two major components (94% of total), both of which were shown to be dibromofluoropropanes by elemental analysis and molecular refractivity of the mixture (MR_D 31.38 cc/mole, estimated 31.20 cc/mole). Gas chromatography at 120°, with a flow rate of 80 ml/min of helium, gave retention times of 20 and 26 min and allowed collection of the pure components; to obtain satisfactory resolution, no more than 30 μl of liquid were injected at any one time. The pure components had n_D^{25} 1.5097 and n_D^{25} 1.5026 respectively, corresponding to 1,2-dibromo-3-fluoropropane (III) and 1,3-dibromo-2-fluoropropane (II); Hoffmann (18) reports n_D^{23} 1.5092 for III. Pure II was isolated in larger amounts by hydrogenolytic removal of III from the mixture of II and III, followed by fractionation (see below); the formation of the bis-tosyloxy derivative (q.v.) confirms the presence of II in the original mixture. The overall yields of II and III were 22% and 32% respectively.

(h) Methyl 10-undecenoate.—The ester (69.3 g, 0.35 mole) was added in portions over 10 min to a stirred mixture of DBH (50 g, 0.175 mole), anhydrous hydrogen fluoride (50 g, 2.5 moles), and chloroform (200 ml) at −55°. The mixture was stirred at −40° for a further 3 h. Isolation and fractionation gave the pure saturated ester (72%). An identical yield was obtained using NBA (49 g, 0.35 mole) in chloroform (200 ml) and ether (100 ml).

Side Reactions

The principal side reaction occurring in the addition to simple alkenes involved the formation of ethers (see Discussion). In the preparation of 1-bromo-2-fluoroheptane, a higher boiling fraction was obtained,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

which was purified by preparative gas chromatography (Nester and Faust Prepko at 210° using a 1 in. × 6 ft column of 20% DEGS on 60/80 mesh firebrick with helium (600 ml/min) as carrier); the fraction (ca. 2 g) eluting in 1.7 min was distilled through a spinning-band column to give a bromoethoxyheptane. Its infrared spectrum (CCl_4) was very simple, the main feature being a strong band at 1 106 cm^{-1} (C—O stretch). The n.m.r. spectrum was too complex to permit an assignment of the location of the bromine and ethoxy groups.

B. Reactions of Vicinal Fluorobromides

2-Fluoro-1-hexanol

A mixture of 1-bromo-2-fluorohexane (8.0 g, 43.7 mmoles), sodium formate (5.0 g, 73.5 mmoles), dimethylformamide (50 ml), water (16.6 ml), and tetrahydrofuran (25 ml) was heated under reflux at 130° for 31 h. The cooled mixture was diluted with water (100 ml) and extracted with ether. The extracts were washed with water, with aqueous sodium bicarbonate, and with water again. The dried (Na_2SO_4) solvent-free product gave an infrared spectrum which showed the presence of some formate ester. Hence the product was hydrolyzed by refluxing at 105° for 19 h with water (8 g). Isolation in the usual way gave the pure fluoroalcohol (3.95 g, 75%).

2-Fluorohexyl Acetate

1-Bromo-2-fluorohexane (10.0 g, 54.6 mmoles) was stirred and refluxed with dry sodium acetate (7.0 g, 84.4 mmoles) and sodium iodide (10 g, 66.7 mmoles) in dry dimethylformamide (300 ml) at 130° for 25 h. The cooled mixture was diluted with water and extracted with ether. The extracts were washed, dried, and fractionated to give the pure acetate (6.22 g, 70%).

The following were prepared in essentially the same way (yields in brackets): *2-fluoroethyl acetate* (52%), *2-fluoropropyl acetate* (79%), *2-fluorobutyl acetate* (85%), *2-fluoroheptyl acetate* (78%), *2-fluorooctyl acetate* (71%), and *2-fluorodecyl acetate* (73%). Also prepared by the same method was *methyl 11-acetoxy-10-fluoroundecanoate* (74%) starting from methyl 11-bromo-10-fluoroundecanoate.

2-Fluorohexyl Azide

1-Bromo-2-fluorohexane (14.3 g, 78.2 mmoles) and sodium azide (7.1 g, 109 mmoles) were stirred and heated under reflux in 87% aqueous dimethylformamide (160 ml) for 23 h at 130°. Isolation by ether extraction and purification in the usual way gave the azide (9.52 g, 84%).

2-Fluorohexyl Iodide

1-Bromo-2-fluorohexane (10 g, 54.6 mmoles), sodium iodide (9.5 g, 63.2 mmoles), and acetone (50 ml) were heated under reflux for 22 h. Isolation and purification in the usual manner gave the iodide (10.8 g, 86%). Redistillation from mercury gave a stable liquid, which remained colorless on storing over clean, dry copper turnings in a brown bottle.

2-Fluorodecyl iodide was prepared by the same procedure in 72% yield.

2-Fluorohexyl Formate

1-Bromo-2-fluorohexane (10 g, 54.6 mmoles) was stirred with a suspension of dry sodium formate (6.8 g, 100 mmoles) and sodium iodide (9.0 g, 60 mmoles) in dimethylformamide (300 ml). The mixture, protected from atmospheric moisture, was heated under reflux at 103–105° for 48 h. Isolation and purification in the usual way gave the formate (5.4 g, 67%).

2-Fluoroheptyl formate was prepared in the same way in 77% yield.

Hydrolysis of 2-Fluoroheptyl Formate

2-Fluoroheptyl formate (7.76 g, 52.4 mmoles), 6 *N* hydrochloric acid (35 ml), and dioxane (40 ml) were stirred magnetically at room temperature. The mixture became homogeneous after 40 min, and g.l.c. analysis indicated that only 8% of the formate remained after 4 h. The stirring was continued for 6 h more, and the product was isolated in the usual way. The yield of 2-fluoro-1-heptanol was 5.66 g (81%). The hydrogen n.m.r. spectrum (30.7 w/v % in CCl_4) showed peaks at 0.91 and 1.35 p.p.m. due to the terminal methyl and to the methylene groups respectively; the OH appeared at 3.98 p.p.m. The CH_2OH appeared as a doublet of doublets centered at 3.57 p.p.m. with J_{HF} 24.1, J_{HH} 4.8 c.p.s. The CHF group appeared as a pair of multiplets centered at 4.43 p.p.m. (J_{HF} 51.6 c.p.s.).

2-Fluorohexyl Nitrate

1-Bromo-2-fluorohexane (10 g, 54.6 mmoles) and silver nitrate (12.3 g, 72.4 mmoles) were dissolved in acetonitrile (50 ml), and the solution was heated under reflux at 120° for 27 h. (After 5 h, only 72% of the theoretical amount of silver bromide had been formed.) Isolation and purification gave the pure nitrate (7.54 g, 84%).

2-Fluoro-2-phenylethyl nitrate was prepared in 76% yield from 1-bromo-2-fluoro-2-phenylethane by the same procedure; the first sample for analysis decomposed before reaching its destination, emphasizing its instability.

2-Fluorohexyl Thiocyanate

1-Bromo-2-fluorohexane (7.0 g, 38.2 mmoles), potassium thiocyanate (7.0 g, 72.0 mmoles), and 95% ethanol (25 ml) were heated under reflux at 110° for 20 h. Isolation and purification in the usual way gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the thiocyanate (4.42 g, 72%). This compound is moderately toxic to mice by intraperitoneal injection; LD_{50} 26.63 (19.43–36.57) mg/kg.

2-Fluorooctadecyl p-Nitrobenzoate

Lithium *p*-nitrobenzoate was prepared from a suspension of the acid in methanol by neutralization with aqueous lithium hydroxide. Concentration to small bulk and addition of ether induced the salt to crystallize. Yield: 98%. Crude 1-bromo-2-fluorooctadecane (see above) (15.68 g, 44.7 mmoles), dry lithium *p*-nitrobenzoate (13.4 g, 77.4 mmoles), sodium iodide (8.0 g, 53.4 mmoles), and dimethylformamide (500 ml) were mixed, and *p*-nitrobenzoyl chloride (27.8 g, 149.5 mmoles) was added as a scavenger for water. The solution was refluxed with stirring at 115° for 40 h. A further 7.5 g (43.3 mmoles) of lithium *p*-nitrobenzoate was added, and the heating was continued for a further 31 h. Isolation by ether extraction, washing and drying of the extract, and removal of the solvent gave an oil which crystallized on desiccation at 0.5 mm over P_2O_5. Slow crystallization from ethanol–ligroin (35–60°) followed by recrystallization from 95% ethanol gave 10.6 g (55%) of the ester.

2-Fluorooctadecyl p-Aminobenzoate

2-Fluorooctadecyl *p*-nitrobenzoate (4.6 g, 10.5 mmoles) dissolved in 95% ethanol (100 ml) was hydrogenated at atmospheric pressure using platinum dioxide (200 mg). The theoretical hydrogen uptake was complete after about 5 h. The hydrogenation flask was purged with nitrogen, and conc. hydrochloric acid (20 ml) was added. The catalyst was removed by filtration and water (80 ml) was then added to the filtrate. Yield: 4.02 g (86%) of the hydrochloride salt. The hydrochloride salt was recrystallized three times from ethanol and was then heated at 61° for 4 h at 0.2 mm over P_2O_5 in an Abderhalden pistol, thus giving the free *p*-aminobenzoate (Cl^- negative). The infrared spectrum ($CHCl_3$) showed NH stretch at 3 370 cm^{-1} (w), C=O stretch at 1 711 cm^{-1} (s), and C=C (aromatic) at 1 622 and 1 607 cm^{-1}.

1,3-Bistosyloxy-2-fluoropropane

A mixture of 1,2-dibromo-3-fluoropropane and 1,3-dibromo-2-fluoropropane as prepared above (2.0 g, 9.1 mmoles) and silver *p*-toluenesulfonate (5.0 g, 17.9 mmoles) in acetonitrile (15 ml) was heated under reflux for 112 h, by which time 62% of the theoretical quantity of silver bromide had been formed. The silver salts were removed by filtration and were washed with acetonitrile. Ether was added to the mixture, followed by distilled water to dissolve the unchanged silver tosylate. The ether layer was separated, washed, and dried (Na_2SO_4). Removal of the ether and the acetonitrile at 100 mm gave a syrupy residue, which, on standing overnight in the refrigerator, gave 150 mg of crystals, m.p. 95–105°. Addition of ether to the viscous filtrate gave a further 480 mg, m.p. 108–110°. Total yield: 45%. Recrystallization twice from 95% ethanol gave fine, colorless needles, m.p. 111–112°. An authentic sample, prepared by tosylation of 2-deoxy-2-fluoroglycerol (19) and kindly provided by Dr. P. W. Kent, had m.p. 107–110°, mixed m.p. 108–111°. The toxicity of this fluorotosylate, by intraperitoneal injection into mice, was > 100 mg/kg.

1,2-Dicyanohexane

In an attempt to prepare 3-fluoroheptanonitrile, dried sodium cyanide (3.4 g, 69.5 mmoles) in dry dimethyl sulfoxide (30 ml) was warmed to 88°. 2-Fluorohexyl bromide (10.0 g, 54.7 mmoles) was then added dropwise to this suspension (10 min). The mixture was heated at 90° for a further 40 min. The thick, cooled mixture was diluted with ether (100 ml) and then washed with water. The washings were extracted with ether, and the combined ether extracts were dried (Na_2SO_4). Removal of the ether and distillation of the residue gave 2.63 g (56%) of 1,2-dicyanohexane.

C. Hydrogenations

Attempted Hydrogenolysis of 1-Iodo-2-fluorohexane, 1-Iodo-2-fluorodecane, and trans-1-Bromo-2-fluorocyclohexane

No hydrogenolysis occurred at atmospheric pressure using hydrogen and platinum dioxide in various solvents (methanol, ethanol, and glacial acetic acid). Even ultraviolet irradiation with a Hanovia low-pressure mercury lamp did not appear to promote hydrogenolysis. Under the same conditions (no irradiation), 1,2-dibromocyclohexane readily formed cyclohexane.

Hydrogenolysis of a Mixture of 1,2-Dibromo-3-fluoropropane (III) and 1,3-Dibromo-2-fluoropropane (II)

An approximately equal mixture of the above compounds (6.25 g, 28.4 mmoles) in 95% ethanol (30 ml) was hydrogenated at room temperature and atmospheric pressure, using platinum dioxide (300 mg) as catalyst. Hydrogen (720 ml) was absorbed over a 25 h period. Gas–liquid chromatography showed that the mixture now contained only 11% of III. Removal of the catalyst, isolation of the product, drying (Na_2SO_4), and purification by fractionation gave initially a mixture of the isomeric dibromofluoropropanes, followed by pure II. The latter was at least 98% pure by g.l.c. analysis.

Hydrogenolysis of 1-Bromo-2-fluoro-2-phenylethane

The fluorobromide (10.24 g, 50.5 mmoles) in 95% ethanol (40 ml) was hydrogenated as above, using platinum dioxide (150 mg). Hydrogen uptake (2 440 ml) was complete in about 10 h. Removal of the catalyst, isolation, drying, and purification by fractionation gave a mixture (4.02 g) consisting of 87 mole % of ethylbenzene and 13 mole % of ethylcyclohexane (g.l.c. at 155° on an Apiezon-L column). These two products were identified by comparison of their retention times with authentic samples.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Hydrogenolysis of 2-Fluorohexyl Nitrate

2-Fluorohexyl nitrate (5.05 g, 30.6 mmoles) was hydrogenated at atmospheric pressure using platinum dioxide (60 mg) in ethanol (50 ml) containing acetic acid (1.8 g, 30 mmoles). Hydrogen absorption began at once and was steady at about 10 ml/min. When about 90% had been taken up, absorption ceased. The catalyst was removed by filtration and was washed with methanol. The filtrate was diluted with ether (250 ml) and the solution was washed with water, with brine, and again with water. Drying (Na_2SO_4), removal of the ether, and distillation gave 2-fluoro-1-hexanol (2.47 g, 67%), identical in all respects with the material obtained by the hydrolysis of 1-bromo-2-fluorohexane (see above).

Hydrogenolysis of 2-Fluoro-2-phenylethyl Nitrate

The nitrate (1.12 g, 6.03 mmoles) was dissolved in 95% ethanol (20 ml) containing 6 *N* hydrochloric acid (2 ml). Platinum dioxide (65 mg) was added and the mixture was hydrogenated at room temperature and atmospheric pressure. After 7 h, 510 ml of hydrogen had been absorbed. The catalyst was removed by filtration, ether (100 ml) was added to the filtrate, and the ethereal solution was washed and dried (Na_2SO_4). Removal of the solvent gave a liquid which, by infrared spectroscopy, was shown to be 2-phenylethanol. Further confirmation of the identity of the product was obtained by gas chromatography on two different columns (Apiezon-L and DEGS), and comparison of the retention times with those of an authentic sample.

ACKNOWLEDGMENTS

We wish to express our indebtedness to the National Research Council for financial support, and to Canadian Industries Limited, Montreal, for the award of a Fellowship (F. H. D.). We wish to acknowledge with thanks the gift of a sample of 1,3-bistosyloxy-2-fluoropropane from Dr. P. W. Kent, Department of Biochemistry, University of Oxford, England. We are grateful to Dr. M. K. McPhail and Dr. C. A. deCandole, Suffield Experimental Station, Ralston, Alberta for determining the toxicities, Dr. J. Newton for preparing 1-bromo-2-fluoro-1,2-diphenylethane, and Dr. J. B. Stothers of this department for help with the nuclear magnetic resonance spectra.

THE SYNTHESIS OF α-MONOFLUOROALKANOIC ACIDS[1]

F. L. M. PATTISON, R. L. BUCHANAN,[2] AND F. H. DEAN[3]
Department of Chemistry, University of Western Ontario, London, Ontario
Received November 11, 1964

ABSTRACT

α-Monofluoroalkanoic acids are important intermediates in the synthesis of biologically active fluorine compounds. General methods of preparation have been examined, based on the three following reagents: (*a*) hydrogen fluoride + *N*-bromoacetamide; (*b*) diethyl monofluoromalonate; and (*c*) perchloryl fluoride. The first of these is the recommended procedure for simple unsubstituted α-fluoro acids; however, the fluoromalonate route is less vigorous, and is therefore the method of choice for those α-fluoro acids that contain labile functional groups.

INTRODUCTION

In our program directed towards the synthesis of biologically active fluorine compounds (fluorinated drugs, antimetabolites, amino acids, insecticides, etc.), frequent recourse must be made to α-monofluoroalkanoic acids as intermediates. A general study therefore was undertaken to develop new and improved means of obtaining this class of compound. The work is part of a more general project concerned with new methods of preparing aliphatic fluorine compounds.

A subsidiary motive in preparing these acids concerned their biological degradation. No toxicological data are available for α-monofluoroalkanoic acids higher than 2-fluoropropanoic acid. If acids of this type, containing four or more unbranched carbon atoms, were to undergo β-oxidation, all would be toxic irrespective of the length of the carbon chain, since the toxic fluoroacetyl coenzyme A would be produced in all cases. (The similarity in size of hydrogen and fluorine makes such a suggestion tenable.) However, as will be described later, both odd and even α-monofluoroalkanoic acids were found to be nontoxic, a fact implying inhibition of β-oxidation by the α-fluorine atom.

A survey of the literature indicated that there are no particularly satisfactory methods of preparation which are simple, mild, general, and inexpensive. Of the described procedures, the following are representative.

[*a*] $RCHXCOOR + KF \xrightarrow{\text{autoclave}} RCHFCOOR$ (2, 3)

[*b*] $RCHBrCOOEt + AgF(CaF_2) \rightarrow RCHFCOOEt$ (2, 4)

[*c*] $RBr + CH_2FCOOR \rightarrow RCHFCOOR$ (5)

[*d*] $RCHO + EtOOCCHFCOCOOEt \rightarrow RCH{=}CFCOOH + HOOCCOOEt + EtOH$ (6)

[*e*] $R_2CO + CHFICOOR \xrightarrow{Zn} R_2C(OH)CHFCOOR$ (7)

[*f*] $RCH(OTs)COOEt + KF \rightarrow RCHFCOOEt$ (8, 9)

[*g*] $RCH(OSO_2Ar)CN + KF \rightarrow RCHFCN \rightarrow RCHFCOOH$ (8, 10)

Several of the above methods have disadvantages. Reactions [*a*] and [*b*] require vigorous treatment and usually result in low or nonreproducible yields; moreover, reaction [*a*] is inconvenient in that a pressure autoclave is required. Reaction [*c*] gives rather low

[1]*This paper was presented in part at the Second International Symposium on Fluorine Chemistry, Estes Park, Colorado, July 17–20, 1962 (1).*
[2]*Present address: Department of Organic Chemistry, Bristol Laboratories, Syracuse, 1, N.Y.*
[3]*Present address: Department of Chemistry, University of Delaware, Newark, Delaware.*

yields and promotes undesirable side reactions in the presence of various functional groups. Reactions [*d*], [*e*], and [*f*] are all satisfactory procedures, but the essential intermediates (diethyl fluorooxalacetate, ethyl fluoroiodoacetate, and α-tosyloxyalkanoates respectively) are not easy or convenient to prepare. Reaction [*g*] is also satisfactory for the very low members, but the yields decrease markedly on ascent of the series (e.g. fluoroacetic acid: 60% dropping to 2-fluoropentanoic acid: 16%).

For these and other reasons, we examined a considerable number of procedures, from which the following were selected for more detailed investigation. The classification below is based on the key reagent:

(I) syntheses based on "BrF" addition (HF + $CH_3CONHBr$);

(II) syntheses based on diethyl fluoromalonate; and

(III) syntheses based on perchloryl fluoride.

The first of these permits the introduction of the fluorine atom at centers of low electron density (bromonium ion); the second utilizes a reagent in which the C—F bond has been preformed; and the third favors fluorination at centers of high electron density (carbanion).

RESULTS

I. Syntheses Based on "BrF" Addition

The "BrF" addition, using anhydrous hydrogen fluoride and *N*-bromoacetamide, is based on the work of Bowers (11). The application of the procedure to aliphatic alkenes has been described earlier (12). The vicinal fluorobromides so formed are somewhat resistant to nucleophilic attack (12); hence the routes shown below are time consuming but simple. For example, the formation of the fluoro acetate (12) requires 15 or more hours at 115° using sodium acetate and sodium iodide; the subsequent hydrolysis and oxidation using nitric acid and acetic acid at 50° is complete in about 20–40 h. Until this method had been developed, simple oxidation of the fluoroalcohols $RCHFCH_2OH$ had not been extensively examined, because these compounds are not easily obtained; most common procedures, such as opening of epoxides with hydrogen fluoride, yield the isomeric fluoroalcohols, $RCH(OH)CH_2F$. If these intermediate fluoroalcohols, $RCHFCH_2OH$, are required for other purposes, convenient preparative procedures include hydrogenolysis of the fluoronitrates or hydrolysis of the formates, as described earlier (12).

$$\text{RCH=CH}_2 \xrightarrow[\text{NBA}]{\text{HF}} \text{RCHFCH}_2\text{Br} \begin{cases} \xrightarrow[\text{AgNO}_3]{\text{route 1}} \text{RCHFCH}_2\text{ONO}_2 \xrightarrow[\text{HOAc}]{\text{HNO}_3} [\text{RCHFCH}_2\text{OH}] \rightarrow \text{RCHFCOOH} \\ \xrightarrow[\text{NaOAc}]{\text{route 2}} \text{RCHFCH}_2\text{OAc} \xrightarrow[\text{HOAc}]{\text{HNO}_3} [\text{RCHFCH}_2\text{OH}] \rightarrow \text{RCHFCOOH} \\ \xrightarrow[\text{HCOONa}]{\text{route 3}} \text{RCHFCH}_2\text{OCHO} \xrightarrow[\text{HOAc}]{\text{HNO}_3} [\text{RCHFCH}_2\text{OH}] \rightarrow \text{RCHFCOOH} \end{cases}$$

Some yields are shown in Table I. In the initial work with 1-bromo-2-fluorohexane, the acetate route gave a higher overall yield than that involving the nitrate or the formate; hence route 2 was used for examining the other members.

The above method is satisfactory for relatively low molecular weight unbranched alkenes, but certain variations in structure require special treatment. (*a*) *Styrene* gave the fluorobromide and the corresponding nitrate ($C_6H_5CHFCH_2ONO_2$) (12); attempts

TABLE I

Yields by the "BrF" route to α-monofluoroalkanoic acids

Alkene	Route to acid*	Overall yield of acid (%) based on alkene
$CH_2=CH_2$	2	6
$CH_3CH=CH_2$	2	17
$CH_3CH_2CH=CH_2$	2	27
$CH_3(CH_2)_3CH=CH_2$	1	40
	2	48
	3	36
$CH_3(CH_2)_4CH=CH_2$	2	51
$CH_3(CH_2)_5CH=CH_2$	2	43
$CH_3(CH_2)_7CH=CH_2$	2	47
$MeOOC(CH_2)_8CH=CH_2$	2	43

*The routes correspond to the equations shown above.

to prepare the acetate gave unsaturated products. The subsequent oxidation of the nitrate gave only benzoic and nitrobenzoic acids. This can be explained in terms of homolytic fission of the C—H bond, with resonance stabilization of the intermediate benzylic radical. It is therefore unlikely that α-phenyl-substituted acids can be prepared in good yield by this type of oxidative process. The required product, α-fluorophenylacetic acid, $C_6H_5CHFCOOH$ was accordingly obtained by an alternative procedure (see below). (*b*) *1-Alkenes branched at the 2-position* did not give satisfactory yields of the expected α-fluoroacids. For example, 2-ethyl-1-butene gave the fluorobromide but this was inert to such reagents as sodium iodide and silver nitrate. In an attempt to circumvent this difficulty, the corresponding fluoroiodide (crude) was prepared (12), using hydrogen fluoride and *N*-iodosuccinimide (11), which in turn gave, via the nitrate, an impure sample of 2-fluoro-2-ethylbutanoic acid in insignificant yield. This acid and its methyl ester were therefore obtained by another method (see below). (*c*) *1-Octadecene* gave rise, by the acetate route, to crude 2-fluorooctadecanoic acid; neither 2-fluorooctadecyl *p*-nitrobenzoate nor 2-fluorooctadecyl *p*-aminobenzoate were converted to 2-fluorooctadecanoic acid by the nitric acid treatment. Because of purification difficulties, this acid is more conveniently prepared by the fluoromalonate route, as described below.

When the nitric acid reaction is applied to alkyl acetates which do not contain a vicinal fluorine atom, pronounced chain degradation occurs, even when the concentration of the nitric acid in acetic acid is reduced from 1:1 to 1:3. For example, *n*-heptyl acetate gave heptanoic acid in only 50–60% yield, along with hexanoic and lower acids. Under conditions which favored the conversion of non-fluorinated acetates to acids, 2-fluorodecyl acetate gave 2-fluorodecanoic acid in only 1.3% yield with massive recovery of the starting material. Thus the vicinal fluorine atom, while reducing the reactivity of the acetate, gives rise to much less degradation of the resultant acid. In short, the procedure is mainly of value in the special type of application described in this paper.

II. Syntheses Based on Diethyl Fluoromalonate

$$RBr + CHF(COOEt)_2 \xrightarrow[DMF]{NaH} RCF(COOEt)_2 \rightarrow RCHFCOOH$$

Diethyl fluoromalonate was prepared in 28% yield by Bergmann's procedure (13) but with minor modifications (14). The method involves the reaction of ethyl chloroformate with the enolate of ethyl fluoroacetate in conventional glass apparatus; disadvantages include a low overall yield, a lengthy procedure, and the use of large quantities

of ethyl fluoroacetate (toxic and expensive). Gryszkiewicz-Trochimowski (3) has claimed a 40% yield by treating dimethyl chloromalonate with potassium fluoride in an autoclave. We have not been able to repeat this work, nor has Bergmann (13). The products which have been isolated from the autoclave reaction include dimethyl malonate and dimethyl difluoromalonate, both apparently formed by disproportionation, and tetramethyl ethenetetracarboxylate (see Table IV).

The alkylation step has not previously been reported. Fluoromalonate is more resistant to alkylation than malonate because its anion is a weaker base and therefore a weaker nucleophile. Initial experiments using sodium ethoxide in ethanol gave low yields, as did the more recent modification of first forming the fluoromalonate anion and then replacing the excess ethanol by diethyl carbonate (15). It soon became apparent, however, that the use of sodium hydride in the more polar solvent dimethylformamide gave good yields with no observable side reactions. The conditions for the alkylations varied considerably for the various members. The time of reaction ranged from 2 to 32 h at temperatures from 25 to 100°. The progress of the reactions was followed by pH changes; completion of the reaction was indicated by an acid pH or a levelling off to constant pH. The yields both in the alkylations and in the subsequent hydrolyses could undoubtedly be improved, because the figures shown (Table II) represent the result of one (or occasionally two) small-scale runs.

The hydrolyses were carried out until evolution of carbon dioxide ceased. Times ranged from 5 h (for 2,6-difluorohexanoic acid) to 70 h (for 2-fluorooctadecanoic acid). Dioxane was used as solvent in those cases where the reactants and products were insoluble in the aqueous medium. In some cases there were signs of acid-catalyzed removal of fluorine, as evidenced by etching of the reaction flasks; this is certainly one reason for the rather low yields obtained in many of the hydrolyses. The purity of the liquid acids was determined by preparing the methyl esters, using diazomethane, and examining these by vapor phase chromatography.

TABLE II

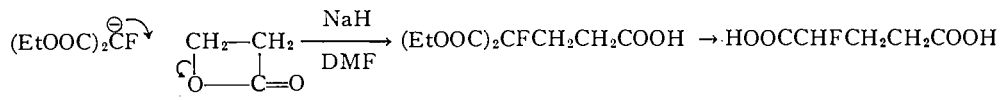
Yields by the fluoromalonate route to α-monofluoroalkanoic acids

Alkyl bromide (RBr)	Yield of $RCF(COOEt)_2$(%)	RCHFCOOH	
		Yield (%), based on $RCF(COOEt)_2$	Overall yield (%), based on $CHF(COOEt)_2$
CH_3CH_2-	77.8*	54.7	42.6
$CH_3(CH_2)_2$-	74.2	80.1	59.4
$(CH_3)_2CH$-	57.0	41.6	23.7
$CH_3(CH_2)_3$-	50.7†	82.8	42.0
$F(CH_2)_4$-‡	78.2	42.1	32.9
$EtOOC(CH_2)_4$-	57.9	39.5	22.9
$CH_3(CH_2)_{15}$-	81.4§	66.4	54.1
$C_6H_5CH_2$-‖	75.2	65.9	49.5

*The sodium ethoxide – diethyl carbonate route gave 53.3% yield.
†The sodium ethoxide – diethyl carbonate route gave 29.0% yield.
‡4-Fluorobutyl iodide was used.
§Crude yield of low-melting solid.
‖Benzyl chloride was used.

Allyl bromide formed diethyl allylfluoromalonate in 79.1% yield, but the hydrolysis and decarboxylation were unsuccessful because of side reactions with the double bond.

In related work, it was found that the fluoromalonate anion can cleave β-propiolactone to give α-fluoroglutaric acid on further treatment.



The less reactive γ-butyrolactone was recovered unchanged under the same conditions.

The application of diethyl fluoromalonate in the preparation of γ-fluoroglutamic acid by the Michael reaction has already been described (14). Its use in other routes to fluorinated amino acids will form the subject of a separate communication.

III. Syntheses Based on Perchloryl Fluoride

The general use of perchloryl fluoride is based on the pioneering work of the Pennsalt group (16). The application of this reagent in the preparation of monofluorosuccinic acid in this laboratory has already been described (17). The following additional reactions have been carried out.

[*a*] $CH_3CH(COOEt)_2 \xrightarrow[NaH/DMF]{ClO_3F} CH_3CF(COOEt)_2 \rightarrow CH_3CHFCOOH$

[*b*] $MeOOCCH_2CH_2CH(COOMe)_2 \xrightarrow[NaH/DMF]{ClO_3F} MeOOCCH_2CH_2CF(COOMe)_2 \rightarrow HOOCCH_2CH_2CHFCOOH$

[*c*] 
[*d*] $C_6H_5CH(COOEt)_2 \xrightarrow[NaH/DMF]{ClO_3F} C_6H_5CF(COOEt)_2 \rightarrow C_6H_5CHFCOOH$

[*e*] $O_2NCH(COOEt)_2 \xrightarrow[KOEt/dioxane]{ClO_3F} O_2NCF(COOEt)_2$

[*f*] $CH_3CH_2CHEtCHO \rightarrow CH_3CH_2CHEtCH(OCH_3)_2 \rightarrow CH_3CH_2CEt{=}CHOCH_3 \xrightarrow[pyridine]{ClO_3F} CH_3CH_2CEtFCOOCH_3 + CH_3CH_2CEtFCOOH$

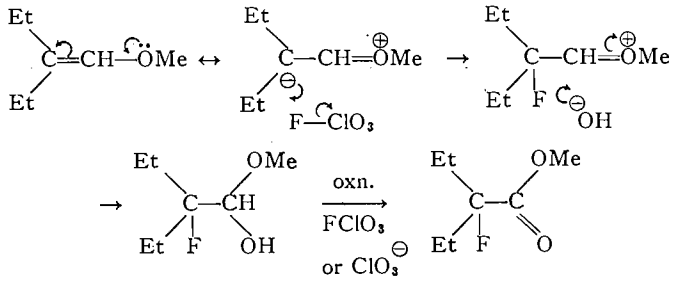
Reactions [*d*] and [*f*] gave rise to two of the acids which could not readily be formed by the "BrF" method above. The chemistry of reactions [*a*], [*b*], [*c*], [*d*], and [*e*] is straightforward. Reaction [*f*] is the most interesting; a plausible mechanism is shown below. A small quantity of the free acid was produced directly, presumably by pyridine-catalyzed loss of methanol from the intermediate hemiacetal followed by oxidation of the resultant aldehyde. The identity of this acid was confirmed by the formation of its *p*-bromophenacyl derivative, using dimethylformamide as solvent. The isomeric 2-fluorohexanoic and 6-fluorohexanoic acids were also converted to their *p*-bromophenacyl derivatives by the same procedure.

DISCUSSION

Of the methods described above, we consider the perchloryl fluoride procedure to be least satisfactory, partly because of difficulties in separating the fluorinated from the non-fluorinated compounds, and partly because the overall yields are often rather low.

The recommended procedure for simple unsubstituted α-monofluoroalkanoic acids is, in our opinion, that utilizing "BrF" addition. Although time consuming, it involves

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



conventional apparatus and readily available intermediates, and is convenient and easy to carry out.

The fluoromalonate route is much milder, and is therefore the method of choice for those α-fluoro acids that contain labile functional groups. The only disadvantage of the method lies in the unsatisfactory preparation of the diethyl fluoromalonate itself as already mentioned; apart from this the alkylations and hydrolyses are very simple, and the procedure is applicable to a wide variety of halides. The fluoromalonate anion is apparently too weak a base appreciably to effect β-elimination from secondary bromides; thus isopropyl bromide alkylates diethyl fluoromalonate in 57% yield. The yields obtained by the fluoromalonate route are considerably better than those reported for the direct alkylation of ethyl fluoroacetate (5).

Many of the compounds described in this paper were submitted for toxicological testing. Results are shown in Table III.

Both fluoromalonic acid and its diethyl ester were found to be toxic. In an independent study, Bergmann and Shahak (19) made the same observation using the sodium salt, and reported that fluoroacetate-type symptoms were produced in mice, rats and guinea pigs with the characteristic accumulation of citrate in the kidneys. In short, the pattern is typical for fluoroacetate, which implies decarboxylation of the original fluoromalonate.

The substituted α-fluoromalonates do not show any particular trend, and are relatively innocuous. Diethyl 4-fluorobutylfluoromalonate was the most toxic member of the class, indicating, perhaps, some type of biochemical degradation to an ω-fluoro fragment containing an even number of carbon atoms. It is significant that alkylmalonic acids up to *n*-heptylmalonic acid are excreted unchanged, whereas *n*-octylmalonic and higher acids are metabolized completely by ω-oxidation (20).

The α-fluoroalkanoic acids are also nontoxic within the limits of biological variation. This can best be explained by inhibition of β-oxidation, as mentioned earlier. The most striking illustration of this is the lack of toxicity of 2,6-difluorohexanoic acid, $F(CH_2)_4CHFCOOH$. The corresponding monofluoro acid, 6-fluorohexanoic acid, $F(CH_2)_5COOH$ is very toxic (LD_{50} 1.35 mg/kg by intraperitoneal injection in mice), the biochemical explanation of which centers around β-oxidation to fluoroacetyl coenzyme A. Hence, the lack of toxicity of the difluoro acid must surely imply inhibition of the β-oxidation process by the α-fluorine atom.

The fluoroacetate-type convulsions observed with α-fluoroglutaric acid suggest that β-oxidation (at the non-fluorinated end of the molecule) has occurred, giving fluoromalonic acid, which in turn apparently decarboxylates to fluoroacetate, as outlined above. It has been reported recently (21) that α-fluoroglutaric acid is a competitive inhibitor of glutamate dehydrogenase, but is inactive against a variety of other enzymes including aconitase and the citrate-condensing enzyme.

The most interesting of the fluorinated unsaturated dibasic acids is monofluorofumaric acid, HOOCCF=CHCOOH (*trans*), in that it is a monofluorinated member of the tricarboxylic acid cycle. Its lack of toxicity indicates that it is not interfering with the normal operation of the cycle.

Infrared measurements on the *alkylated fluoromalonates* show that the α-fluorine atom causes a shift of about 25 cm^{-1} to higher frequency for the ester carbonyl band. The range is 1 754 – 1 757 cm^{-1} as compared with the ester carbonyl frequency of about 1 730 cm^{-1} for the non-fluorinated alkylated malonates. The C—F stretching band lies in the range 1 050 – 1 100 cm^{-1} and is of medium intensity. The fluorine in the *α-fluoroalkanoic acids* causes a similar shift in the acid carbonyl band. The range for the fluoro acids is 1 730 – 1 745 cm^{-1} as compared to 1 700 – 1 725 cm^{-1} for the non-fluorinated acids. The position of the C—F band (1 060 – 1 090 cm^{-1}) is very similar to that observed for the fluoromalonates and again is of medium intensity.

EXPERIMENTAL

Physical constants and analytical data for all new compounds are given in Table IV. The preparations described below represent typical examples of each procedure; obvious variations for obtaining different members have not been included. Purity of acids was checked by gas chromatography of their methyl esters. Melting points (uncorrected) were determined on a Kofler hot stage and densities with a Fisher-Davidson gravitometer. The nuclear magnetic resonance spectra were obtained with a Varian DP-60 spectrometer. Infrared spectra were obtained with Beckman IR-7 and IR-5 infrared spectrophotometers. Analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, 77, N.Y. The perchloryl fluoride was purchased from the Technical Division of Pennsalt Chemicals Corporation, Philadelphia 18, Pa. The sodium hydride dispersion (56.5%) in mineral oil was purchased from Metal Hydrides Incorporated, Beverly, Mass.

A. Syntheses Based on "BrF" Addition

2-Fluorohexanoic Acid

(a) From 2-fluorohexyl nitrate.—A mixture of 2-fluorohexyl nitrate (12) (8.8 g, 53.2 mmoles), glacial acetic acid (21 ml), and concentrated nitric acid (42 ml) was warmed in a 100 ml three-necked flask equipped with a reflux condenser at 40–42° for 52 h. The color changed from pale yellow to green and finally back to pale yellow. The mixture was then cooled, diluted with water (500 ml), and extracted five times with chloroform (50 ml portions). The chloroform extract was extracted with 5% aqueous sodium bicarbonate and the bicarbonate extract was acidified to methyl red with 6 *N* hydrochloric acid. The free acid was then extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. Removal of the ether and distillation yielded the acid (4.40 g, 61.5%). It was subsequently found that the chloroform extraction and bicarbonate wash are unnecessary, as no neutral fraction remains after the oxidation procedure.

(b) From 2-fluorohexyl acetate.—A mixture of 2-fluorohexyl acetate (12) (5.36 g, 33.0 mmoles), glacial acetic acid (35 ml), and concentrated nitric acid (35 ml) was warmed at 48–51° for 20 or more hours. The mixture was cooled, diluted with water, and isolated by ether extraction. The extracts were washed with water and dried over anhydrous sodium sulfate. Removal of the ether, followed by fractionation through a spinning-band column, gave the acid (3.88 g, 87.5%).

(c) From 2-fluorohexyl formate.—A mixture of 2-fluorohexyl formate (12) (5.40 g, 36.4 mmoles), glacial acetic acid (35 ml), and concentrated nitric acid (35 ml) was warmed to 50°. No immediate reaction was apparent, but the mixture slowly turned yellow. After 90 min brown fumes were evolved and a vigorous exothermic reaction occurred. The flask was cooled in cold water, and the mixture was allowed to stand overnight, by which time it had turned green. It was left at room temperature for a further 100 h by which time the color had changed to pale yellow. The acid was isolated as under (*b*) above (3.34 g, 68.3%).

General Comments

(*a*) The color changes acted as a convenient internal indicator. During the reaction, samples were removed from time to time and extracted with chloroform; infrared analysis thereafter gave a measure of nitrate and acetate esters present. It was found that the end of the reaction coincided with the change from green to yellow. This conclusion was confirmed by gas chromatography.

(*b*) By the same procedure the following yields were obtained from the corresponding acetates (reaction times and yields in parentheses): *fluoroacetic acid* (44 h, 51%); *2-fluoropropanoic acid* (64 h, 55.5%); *2-fluorobutanoic acid* (21 h, 58%); *2-fluoroheptanoic acid* (25 h, 84%); *2-fluorooctanoic acid* (31 h, 86%); *2-fluorodecanoic acid* (46 h, 82%) (the last three acids were recrystallized from 35–60° petroleum ether); and *2-fluoroundecanedioic acid* (22 h, 81%), recrystallized from aqueous alcohol.

Special cases are discussed above (see Results).

B. Syntheses Based on Diethyl Fluoromalonate

Diethyl Fluoromalonate

This ester was prepared by the method of Bergmann, Cohen, and Shahak (13), with modifications; some of these have been described previously (14).

Sodium hydride dispersion (56.5%) in mineral oil (85 g, 2.0 moles) was added to anhydrous ether (400 ml) in an ice-cooled 2 l three-necked flask fitted with a stirrer, a reflux condenser with a drying tube, and an addition funnel. Ethyl fluoroacetate (212.2 g, 2.0 moles) in anhydrous ether (200 ml) was added dropwise with stirring over 19 h. No significant amount of hydrogen was evolved for about 4 h; then a slow steady evolution, which became vigorous after about 6 h, began. The mixture was allowed to warm to room temperature gradually over 24 h; it was then refluxed for 2 h to complete the formation of the enolate. Ethyl chloroformate (220.0 g, 2.03 moles) in anhydrous ether (100 ml) was then added over 20 min with stirring and cooling (ice bath). The ice bath was removed and the mixture was allowed to reflux spontaneously for 1.5 h, whereupon it was refluxed in warm water for a further 3 h. After stirring at room temperature for an additional 16 h, ice-cold water was added in sufficient amount to dissolve the sodium chloride present. The ether layer was separated and the aqueous layer was extracted with additional quantities of ether. The combined ether extracts were washed twice with 1% aqueous sodium bicarbonate solution and then with water, and were dried over anhydrous magnesium sulfate. The ether was removed by distillation, using anhydrous calcium sulfate as boiling stones; exclusion of moisture and acid is essential during distillation to avoid severe decomposition. Distillation through a 10 in. Vigreux column yielded recovered ethyl fluoroacetate (57.1 g) followed by crude diethyl fluoromalonate (72.1 g, 27.7%) of b.p. 86–94° at 9 mm, and n_D^{25} 1.4063. Redistillation through a platinum-plated spinning-band column gave the pure fluoroester (61.5 g, 23.6%).

Fluoromalonic Acid

This procedure is modified from that of Bergmann, Cohen, and Shahak (13).

Potassium hydroxide (3.86 g, 68.8 mmoles) was dissolved in absolute ethanol (30 ml) contained in a 50 ml three-necked flask fitted with a stirrer, a reflux condenser, and an addition funnel. Diethyl fluoromalonate (5.0 g, 28 mmoles) was added dropwise with stirring over 10 min. The initial reaction was exothermic; the white salt separated out and the mixture was stirred at room temperature for 7 h. The mixture was cooled and the salt was filtered. It was then dissolved in water and the solution was made distinctly acid

with concentrated hydrochloric acid. After extraction of the aqueous solution five times with ether, drying of the ether extracts over anhydrous magnesium sulfate, and removal the ether by evaporation, the fluoromalonic acid (1.64 g, 48%) was obtained as an off-white solid. Two recrystallizations from ether, the first using decolorizing charcoal, yielded the pure white crystalline acid.

Diethyl n-Propylfluoromalonate

Sodium hydride dispersion (56.5%) in mineral oil (2.38 g, 56 mmoles) was placed in a 100 ml three-necked flask fitted with a stirrer, a reflux condenser with drying tube, and an addition funnel; dry dimethylformamide (40 ml) was added. Diethyl fluoromalonate (10 g, 56 mmoles) was then added dropwise with stirring over 15 min, causing an exothermic reaction and a vigorous evolution of hydrogen. After 4.5 h, enolate formation was complete, as shown by a yellow solution and a lack of hydrogen evolution. *n*-Propyl bromide (6.90 g, 56 mmoles) was then added rapidly with stirring. The mixture was stirred and heated for 13 h at 70°, by which time the pH had levelled off at approximately 6.5; the acid pH indicated completion of the reaction. The reaction mixture was worked up by pouring it into water, extracting twice with ether, and washing the combined ether extracts 3 times with water to ensure removal of dimethylformamide. The ether solution was then dried over anhydrous magnesium sulfate and the ether was removed on a rotatory evaporator. The residual liquid was distilled through a small Vigreux column yielding diethyl *n*-propylfluoromalonate (9.16 g, 74.2%).

Other Alkylated Fluoromalonates

Other alkylated fluoromalonates were prepared in a similar manner (time of heating and temperature given in parentheses). Yields are listed in Table II. *Ethyl* (20 h, 55°), *isopropyl* (32 h, 70–80°), *n-butyl* (18 h, 60°), *4-fluorobutyl* (2 h, 70°), *4-carbethoxybutyl* (4 h, 80°), *hexadecyl* (11 h, 100°), *benzyl* (7 h, 80–85°), and *allyl* (12 h, 25°). Diethyl hexadecylfluoromalonate was not purified; it was hydrolyzed and decarboxylated directly to 2-fluorooctadecanoic acid.

2-Fluoropentanoic Acid

Diethyl *n*-propylfluoromalonate (9.0 g, 40.8 mmoles) and 6 *N* hydrochloric acid (60 ml) were heated under reflux for 23 h, i.e., until carbon dioxide was no longer evolved. The reaction mixture was then poured into water and extracted with ether. The ether extracts in turn were extracted with 5% sodium bicarbonate solution. The aqueous layer was acidified with dilute hydrochloric acid and extracted with ether. After drying of the extracts (anhydrous magnesium sulfate) and evaporation of the ether, vacuum distillation of the residual liquid through a spinning-band column yielded the pure acid (3.93 g, 80.1%). The purity of the acid was checked by vapor phase chromatography of its methyl ester.

Other α-Fluoroalkanoic Acids

Other α-fluoroalkanoic acids were prepared similarly from the corresponding alkylated malonates (time of reflux shown in parentheses): *2-fluorobutanoic* (23 h), *2-fluoro-3-methylbutanoic* (19 h), *2-fluorohexanoic* (17 h), *2,6-difluorohexanoic* (5 h), *α-fluoropimelic* (9 h), and *2-fluoro-3-phenylpropanoic* (8 h). The liquid members were purified by fractionation and the solid members by recrystallization from chloroform, benzene, or petroleum ether. Final purification of 2-fluoro-3-phenylpropanoic acid was achieved by sublimation (55° at 0.075 mm).

2-Fluorooctadecanoic Acid

Crude diethyl hexadecylfluoromalonate (17.3 g, 43.0 mmoles), 6 *N* hydrochloric acid (120 ml), and dioxane (200 ml) were refluxed for 70 h; at the end of this time, negligible evolution of carbon dioxide was observed. The mixture was poured into petroleum ether (b.p. 60–80°) and washed with water to remove the dioxane. An emulsion formed in the petroleum ether extract, and saturated brine solution was added to destroy it. A considerable amount of the sodium salt of the desired acid salted out at the interface and was filtered off. The petroleum ether layer was extracted twice with 10% aqueous potassium hydroxide solution. The sodium salt obtained above was added to the alkaline extract, and the combined mixture was acidified with concentrated hydrochloric acid. The organic acid was extracted with ether. The ether extracts were dried over anhydrous magnesium sulfate and the ether was evaporated on a rotatory evaporator, yielding the crude light-yellow α-fluorostearic acid (8.64 g, 66.4%). Recrystallization from petroleum ether (b.p. 35–60°) gave white crystals of the pure acid.

Diethyl 2-Carboxyethylfluoromalonate

The enolate of diethyl fluoromalonate was formed in the usual manner from diethyl fluoromalonate (5.0 g, 28.1 mmoles), 56.5% sodium hydride dispersion (1.20 g, 28.1 mmoles), and dry dimethylformamide (30 ml). β-Propiolactone (2.16 g, 30 mmoles) was then added rapidly with stirring. The reaction was stirred at room temperature for 1 h, then at 60–65° for 4 h; by this time the pH had levelled off at about 8.5, indicating that no further reaction was taking place. The mixture was poured into water and separated into neutral and acidic fractions in the usual manner. A small quantity of diethyl fluoromalonate (0.22 g) was recovered from the neutral extract. The acid fraction yielded the required product upon distillation (2.82 g, 41.8%).

α-Fluoroglutaric Acid

Crude diethyl 2-carboxyethylfluoromalonate (1.84 g, 7.3 mmole) was refluxed with 6 *N* hydrochloric acid (20 ml) in dioxane (50 ml) for 3.5 days, by which time carbon dioxide evolution had ceased. Most of the hydrochloric acid and solvents were distilled off under reduced pressure through a 10 in. Vigreux column.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The rest of the solvents were removed on a rotatory evaporator, leaving a brown syrup which gave a positive qualitative fluorine test but which would not crystallize. The syrup was thus taken up in ether and extracted with 5% sodium bicarbonate solution to separate the acid from any neutral materials present. The bicarbonate extract was acidified with dilute hydrochloric acid and extracted thoroughly with ether. (α-Fluoroglutaric acid is appreciably soluble in water.) After drying of the ether extracts over anhydrous magnesium sulfate and removal of the ether, 0.5 g of acidic material was obtained. Vapor phase chromatographic analysis of the methyl ester showed it to be only about 67% pure. Thus the yield of the hydrolysis is about 30%. The crude methyl ester was chromatographed through silica gel, the pure ester being eluted with 50:50 petroleum ether (30–60°) – benzene. The purified ester was then hydrolyzed by refluxing in dioxane with 6 *N* hydrochloric acid for 12 h. After removal of solvents the syrupy residue was dissolved in benzene from which white plates of α-fluoroglutaric acid separated, m.p. 105–112°; mixed with authentic sample (prepared by the PF route), m.p. 102–110°.

C. Syntheses Based on Perchloryl Fluoride

2-Fluoropropanoic Acid

Dry dimethylformamide (500 ml) and 56.5% sodium hydride dispersion in mineral oil (12.8 g, 299 mmoles) were placed in a three-necked flask fitted with a dropping funnel, a gas inlet tube, and a condenser. The flask was flushed with nitrogen, and diethyl methylmalonate (50 g, 295 mmoles) was added slowly over 1.5 h with stirring. Stirring was continued until effervescence ceased. The mixture was cooled in ice to 7° and perchloryl fluoride was introduced intermittently until a temperature increase was no longer observed and excess perchloryl fluoride had been added (31.2 g, 305 mmoles). The contents of the flask were flushed with nitrogen, and water (600 ml) was slowly added. The mixture was extracted with ether, and the extracts were washed with water, dried, and evaporated. The residue on fractional distillation gave crude diethyl methylfluoromalonate (30.05 g, 55%), b.p. 80–88° at 13 mm, n_D^{25} 1.4013. The impure ester (27.40 g, 143 mmoles) was heated under reflux with 6 *N* hydrochloric acid (500 ml) for 36 h, by which time a homogeneous solution was obtained. The solution was cooled, diluted with water, and extracted with ether. The extracts were washed with water, dried, and evaporated. The residue on fractional distillation gave impure 2-fluoropropanoic acid (6.74 g, 51%), b.p. 63–66° at 13 mm, n_D^{25} 1.3837. Further fractionation gave the pure acid.

α-Fluoroglutaric Acid

(a) Dimethyl α-carbomethoxyglutarate.—Sodium (2.3 g, 0.1 g-atom) was dissolved in methanol (200 ml) in a three-necked flask fitted with a reflux condenser, a dropping funnel, and a gas inlet tube. An atmosphere of nitrogen was maintained throughout, and the mixture was stirred magnetically. Dimethyl malonate (132.1 g, 1 mole) was added, followed by hydroquinone (200 mg). Methyl acrylate (43.0 g, 0.5 mole) was then added dropwise over a 30 min period to the refluxing solution. The mixture was refluxed for a further 23 h and then allowed to stand at room temperature for 2 days. Acidification (12 ml concentrated hydrochloric acid), filtration, and evaporation gave the crude ester. Chloroform was added, residual traces of sodium chloride were removed by filtration, the solvent was removed, and the residue was fractionated. The pure glutarate ester (83.9 g, 77%) was obtained after the excess dimethyl malonate (42.8% of original quantity) had been recovered.

(b) Dimethyl α-fluoro-α-carbomethoxyglutarate.—In a 500 ml three-necked flask carrying a drying tube, a dropping funnel, and a gas inlet tube was placed redistilled dimethylformamide (75 ml). Dry nitrogen was passed through and a 56.5% dispersion of sodium hydride in mineral oil (10.0 g, 235 mmoles) was introduced. The glutarate ester (50.0 g, 229 mmoles) was added dropwise over 1.5 h with stirring and cooling (ice bath). The dark mixture was stirred for a further 2.75 h at room temperature. Super-dry methanol (20 ml), to destroy the excess sodium hydride, and then dioxane (50 ml) were added. The flask was cooled in an ice bath and, when the temperature had fallen to 3.5°, perchloryl fluoride was introduced intermittently with stirring; the temperature was held in the range 3.5–16°. The addition required about 1.75 h. The end of the reaction was indicated by a fall in temperature on passing in perchloryl fluoride. After standing overnight, the mixture was diluted with water (800 ml) and the product extracted with ether. The extract was washed with water and the ether was removed. Benzene was used to azeotrope any residual water. The resulting residue was heterogeneous because of the presence of mineral oil. The latter (upper layer) was removed with a dropper prior to fractionation on the spinning-band column. After a forerun (6–7 g), the required fluoro ester (23.85 g, 44%) was obtained as a slightly turbid liquid. To obtain a clear, analytical sample, the ester was extracted three times with 60–80° petroleum ether and redistilled through a 23-plate platinum-plated spinning-band column.

(c) α-Fluoroglutaric acid.—The above ester (11.0 g, 46.5 mmoles) was hydrolyzed and decarboxylated by heating under reflux with 6 *N* hydrochloric acid (40 ml) at 115° for 6 h. The cooled hydrolysate was extracted with petroleum ether to remove any residual mineral oil or ester. The hydrochloric acid was distilled off under aspirator pressure. The crude acid was then distilled directly, using a simple distillation head attached to a vacuum adapter; the solid thus obtained (4.64 g, 66.6%), of b.p. 115–155° at 0.1–0.22 mm, was shown by infrared analysis to be the acid and not the anhydride (acetonitrile as solvent). The solid was recrystallized four times from 50:50 benzene–ether and dried at the temperature of refluxing chloroform at 0.5 mm for 3 h. No hydrate formation could be detected.

2-Fluoro-2-carbethoxycyclohexanone

Freshly cut sodium (8.25 g, 0.358 g-atom) was placed in a 1 l, three-necked flask fitted with a mercury-sealed stirrer, a reflux condenser with drying tube, and a dropping funnel. The flask was purged with dry nitrogen. Super-dry ethanol (700 ml) was added with cooling, and the mixture was stirred for 3 h. 2-Carbethoxycyclohexanone (26) (61.1 g, 0.358 mole) and then 0.05% bromthymol blue in alcohol (1 ml) were added. The flask was cooled, and perchloryl fluoride was introduced at such a rate as to maintain the temperature in the range 10–15°; 38.8 g of perchloryl fluoride was thus added over 85 min. The end of the reaction is marked by a color change from green to pale yellow. The flask was flushed with nitrogen, and the mixture was diluted with water (2 l) and extracted with ether. The extracts were washed with water, dried, and fractionated to yield 39.8 g (59%) of the fluoro ester.

The ester was converted to *2-fluorocyclohexanone* in 33.5% yield for other purposes (27) by treatment with aqueous sodium hydroxide at room temperature. Acidification, heating, extraction with ether, drying, and distillation yielded the fluoro ketone, b.p. 71° at 11 mm, n_D^{25} 1.4410, m.p. ca. 7° (lit. (28) b.p. 83–83.5° at 20 mm, n_D^{25} 1.4432); 2,4-dinitrophenylhydrazone, m.p. 138–140° (lit. (28) m.p. 139–140°).

α-Fluorophenylacetic Acid

(a) Diethyl phenylfluoromalonate.—In the usual apparatus and by the usual procedure, 56.5% sodium hydride in mineral oil (6.2 g, 145.6 mmoles) was added to dimethylformamide (250 ml); diethyl phenylmalonate (30 g, 126.8 mmoles) was then added dropwise. Excess sodium hydride was destroyed using dry ethanol (11 ml), and perchloryl fluoride (15.5 g, 151 mmoles) was passed in, the temperature being maintained in the range 7–23°. Bromthymol blue was used as indicator, the color changing from green to reddish brown at the conclusion of the reaction. Isolation in the usual way, followed by fractionation through the spinning-band column, gave the fluoro ester (25.15 g, 78.1%) (16).

(b) α-Fluorophenylacetic acid.—The above ester (5.0 g, 19.6 mmoles) was hydrolyzed and decarboxylated by refluxing at 115–120° with dioxane (30 ml) and 6 *N* hydrochloric acid (20 ml) for 18.5 h, by which time no further evolution of carbon dioxide could be observed. The dark solution was diluted with water (100 ml) and extracted with ether. The extract was washed with water, dried (sodium sulfate), filtered, and evaporated. The residue was placed in a vacuum desiccator (P_2O_5) at 10 mm for 12 h. The partly crystalline mass was then dissolved in benzene, and most of the solvent removed under aspirator pressure. This was repeated several times to ensure that the acid would be dry. Addition of petroleum ether and scratching induced crystallization. The crude material was redissolved by warming and adding a small amount of ether. Upon cooling in ice the acid crystallized as glistening platelets (1.93 g, 63.7%). A small amount was recrystallized from 60–80° petroleum ether – benzene, followed by sublimation at 65–68° at 0.1 mm over a 30 h period. Vapor phase chromatographic analysis (180°, DEGS column) of the methyl ester showed only one peak at 10.5 min (cf. methyl phenylacetate, 7.2 min). The acid is soluble in chloroform, benzene, and ether, but relatively insoluble in carbon tetrachloride and petroleum ether.

(c) Phenylfluoromalonic acid.—To a magnetically stirred solution of reagent grade potassium hydroxide (5.6 g, 100 mmoles) in absolute ethanol (100 ml) was added diethyl phenylfluoromalonate (5.0 g, 19.7 mmoles). Within a minute, the solution set to a white gel. The solid was filtered, washed with ether, and air dried (5.14 g, 95.2%). The salt was dissolved in water (240 ml) and acidified with 6 *N* hydrochloric acid (30 ml). The organic acid was thoroughly extracted with ether. The extracts were washed with water, dried (sodium sulfate), and evaporated under reduced pressure. The acid crystallized spontaneously. Yield: 1.87 g (48%). A small quantity was recrystallized from benzene–ether as the monohydrate; the melting point is unchanged even after standing in a P_2O_5 desiccator at 0.1 mm.

Diethyl Fluoronitromalonate

Diethyl nitromalonate (29) was converted to the fluoro nitro ester by the procedure subsequently described by Freeman (23). The infrared spectrum in carbon tetrachloride showed an ester C=O band at 1 785 cm^{-1} and a very strong C—F band at 1 083 cm^{-1}; also apparent were bands due to the —NO_2 group (1 605(s) and 1 280(s) cm^{-1}).

Methyl 2-Fluoro-2-ethylbutanoate

2-Ethylbutyraldehyde was converted (30) to 1,1-dimethoxy-2-ethylbutane in 82.5% yield using acetone dimethylketal; this in turn was treated with phthalic anhydride (31) to give *1-methoxy-2-ethyl-1-butene* in 80.7% yield. Into a 500 ml three-necked flask carrying a thermometer, a gas outlet tube, a gas inlet tube with a fritted-glass disc, and a stirring magnet was placed 1-methoxy-2-ethyl-1-butene (22.3 g, 195 mmoles), reagent grade pyridine (150 ml), and water (75 ml). Perchloryl fluoride (25.2 g, 246 mmoles) was admitted over 10.25 h with cooling (cold water). The mixture was allowed to stand overnight at room temperature. Five percent sodium bicarbonate (300 ml) was added and the neutral products were extracted with ether. This extract was washed with 6 *N* hydrochloric acid (to remove pyridine), water, sodium bicarbonate, and water. After drying (sodium sulfate) and removal of the ether, the residue was fractionated on the spinning-band column to give the fluoro ester (7.9 g, 34%). The infrared spectrum in $CHCl_3$ showed bands at 1 744 (C=O stretch) and 1 064 (C—F) cm^{-1}. The n.m.r. spectrum (19.3% in CCl_4) showed bands at 0.90 p.p.m. (triplet, J_{HH} 7.1 c.p.s.), at 1.79 p.p.m. (pair of overlapping quartets, J_{HF} 16.5 c.p.s., J_{HH} 7.1 c.p.s.), and at 3.73 p.p.m. (singlet due to OCH_3).

In order to recover the acid fraction, the bicarbonate solution was acidified and extracted with ether.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The extract, after it was washed, dried, and distilled, gave crude 2-fluoro-2-ethylbutanoic acid, b.p. 54–62° at 1 mm. This was converted to its *p-bromophenacyl derivative* by reaction of its dry potassium salt in dry dimethylformamide with *p*-bromophenacyl bromide at 75° for 10 h; removal of the dimethylformamide, addition of ether, filtration, and removal of the ether gave an oil which crystallized at 0°; recrystallization from 60–80° petroleum ether using Norit gave the pure material.

The *p-bromophenacyl derivatives of 2-fluorohexanoic and 6-fluorohexanoic acids* were prepared in the same way. Physical constants are given in Table IV.

ACKNOWLEDGMENTS

We wish to express our indebtedness to the National Research Council for financial support and for a studentship (R. L. B.), and to Canadian Industries Limited, Montreal, for the award of a fellowship (F. H. D.). We wish to acknowledge with thanks the gift of samples of difluoromaleic acid and monofluorofumaric acid from Dr. M. S. Raasch and of monofluoromaleic anhydride from Dr. W. H. Sharkey, Central Research Department, E. I. du Pont de Nemours and Co. Inc., Wilmington 98, Delaware. We are grateful to Dr. M. K. McPhail and Dr. C. A. deCandole, Suffield Experimental Station, Ralston, Alberta and Dr. C. W. Gowdey, University of Western Ontario for determining the toxicities; to Dr. D. A. V. Peters for preparing several of the fluoro acids and intermediates; to Dr. J. Newton for preparing 2-fluoropropanoic acid; to Mr. C. A. Gehrels for preparing diethyl fluoronitromalonate; and to Dr. J. B. Stothers of this department for help with the nuclear magnetic resonance spectra.

CONDITIONS FOR THE PHOTOCHEMICAL NITRATION OF BENZENE

DAVID L. BUNBURY
Department of Chemistry, St. Francis Xavier University, Antigonish, Nova Scotia
Received February 4, 1964

ABSTRACT

The reaction of benzene and nitrogen dioxide to produce nitrobenzene has been studied in the liquid and gas phases, in the dark, and with irradiation by light of 439 mμ and of 366 mμ. The concentration of NO_2 in the liquid was varied from 0.08 to 1.6 moles/l and in the gas from 0.0035 to 0.053 moles/l. No nitrobenzene was produced under any conditions in the liquid phase. Nitrobenzene is produced in the gas phase at high NO_2 concentrations with irradiation by 366 mμ light. The quantum yield is 0.2. At 439 mμ the quantum yield is not more than 0.02. There is a very small dark reaction. As the concentration of NO_2 in the gas is reduced the yield of nitrobenzene falls off very rapidly and is zero at the lowest concentration used, both in dark and light.

INTRODUCTION

It is known that light of wavelength 365 mμ causes decomposition of nitrogen dioxide (1) and that of 436 mμ causes activation (2). It appeared to be interesting, then, to study the different types of reaction which might occur between benzene and NO_2 on using these two wavelengths to initiate the reaction, especially in view of the reported enhancement of the yield of nitrobenzene on irradiating mixtures of benzene and nitrogen dioxide with light (6, 9). The reactions of nitrogen dioxide with organic compounds have been reviewed by Riebsomer (3*a*), Gray and Yoffe (3*b*), Topchiev (3*c*), and Titov (3*d*). Table I summarizes the experimental results of the earlier workers who used conditions comparable to those used in this work.

EXPERIMENTAL

The nitrogen dioxide was obtained from the Matheson Company and purified further by fractional distillation, the middle third being kept. It was stored at dry-ice temperatures in a covered bulb and in all cases was pure white when frozen. It was measured either as a gas at room temperature or as a liquid at 0 °C using calibrated volumes. All calculations for obtaining NO_2 concentration from measured temperature and pressure and for NO_2/N_2O_4 ratios were based on the paper of Verhoek and Daniels (11). The benzene was Fisher certified grade and further purified by freezing. It was gas chromatographically pure on use and measured by pipette or Hamilton microsyringe. The benzene and nitrogen dioxide were handled on a conventional high vacuum system and were dried with P_2O_5 just before use, except where noted. The cells for the liquid phase runs had flat windows and were made of Pyrex glass (greater than 90% transmission in the regions of interest). In run 1 a cell of 30 ml was used, in the other liquid phase runs a cell of 10 ml was used. The gas phase runs were performed in either a liter flask or a 165 ml flask. Both had a small test tube attached with ground joint for freezing the reaction mixtures into the bulb and for removal after reaction. All cells were closed with a ground glass joint and stopcock, and samples degassed prior to use.

The light source was an HBO-109 high pressure mercury vapor lamp with fused quartz envelope, from George W. Gates and Co., Inc. This lamp has an arc of 0.3 mm × 0.3 mm. This arc was placed in the focal plane of a Pyrex lens. The 439 mμ line was isolated using a Farrand Interference Filter, half band width 13 mμ, while the 366 mμ line (actually 350–386) was isolated using a 7-83 filter from Corning Glass Works. Light intensity was measured using the potassium ferrioxalate actinometer of Hatchard and Parker (12). Complete absorption occurred in the liquid phase runs and practically complete absorption in the gas phase runs. After a run samples were usually washed with 10% $KHCO_3$ and then water, dried with Drierite, and analyzed on a Burrell K-1 Kromotog using either Ap-L or silicone columns and usually a thermal conductivity cell as dectector. In runs 23–29 where very small amounts of benzene were used (0.01–0.05 ml) 0.25 ml of benzene was added after the addition of $KHCO_3$. Following each injection of a sample a standard nitrobenzene solution was injected for comparison of retention times and of areas. Identification of the nitrobenzene product was made by trapping it at the exit of the column and comparing its infrared spectrum with that of an authentic sample. Amounts were calculated by the ratio of areas of the unknown and that

produced by the standard solution. To test the possibility of reaction of the nitrobenzene with the base or of adsorption on the drying agent, a 3.45×10^{-4} mole fraction solution of nitrobenzene was washed with 10% NaOH three times and then with water and allowed to stand over Drierite. There was no difference in the size of the nitrobenzene peak given by the washed and unwashed material. Runs 14, 15, 16, 17, and 19 were directly injected onto the column without any treatment.

The basic extract of runs 7 and 8 was acidified with HCl and extracted with 30 ml of benzene, and the benzene evaporated to dryness in a small container. The residue was ground together with a minimum amount of powdered KCl and an infrared spectrum taken of the disc. The only thing found was a small amount of some carboxylic acid which turned out to be in the reagent benzene itself.

RESULTS AND DISCUSSION

The results are summarized in Table II.

The lower limit for the detection of nitrobenzene was 3×10^{-5} mole fraction both for thermal conductivity and hydrogen flame detection. Much smaller samples had to be used with the hydrogen flame detector so the lower limit was no less than that with the thermal conductivity detector.

Reactions in the liquid phase at room temperature will be first considered. Yields in the dark reaction were: the present author 0.00% in 19 days; Wieland 0.00% (5); Gorislavetz 2.27% in 5 h (9); Bass and Johnson 3.8% in 3 months (6); Titov 0.69–6.9% in 4 months (10); and Schaarschmidt and Smolla > 30% in 35 days (7). Longer times with the last authors resulted in a decrease in the yield of nitro products. Ratios of reactants are not the same in any of these cases nor are reaction times, but in several pairs of experiments they are of the same order of magnitude (see Table I). Titov's solution with C_6H_6/NO_2 ratio of 10.8 (most comparable to the results here reported) had 0.0088 mole fraction nitrobenzene after 4 months. Assuming linearity of nitrobenzene production, after 19 days run 4 should have been 0.0014 mole fraction of nitrobenzene. This, however, is 40 to 50 times greater than the lower limit of detection. Also, according to Titov's results the yield of nitrobenzene should go up with an increase in the C_6H_6/NO_2 ratio; therefore, the yield in run 4, if anything, should have been higher. Titov varied the ratio by increasing the benzene, and the fact that the yield increased in almost direct proportion to the amount of benzene even though it was in an excess suggests that it was an impurity which was reacting. In the course of a study of molecular addition compounds of N_2O_4 and aromatic hydrocarbons, Addison and Sheldon (13) found no detectable reaction between benzene and dinitrogen tetroxide during a period of several hours at room temperature. In view of the negative results, the low yields when reaction did occur, and the fact that reaction with even a small amount of impurity would produce some nitric acid, the most probable conclusion is that there is no reaction between pure benzene and NO_2–N_2O_4 at room temperature.

For irradiated mixtures in the liquid phase the present author found no reaction after 3 h with unfiltered mercury light, light of 439 mμ, and light of 366 mμ. After 5 h Gorislavetz (9) found a decrease in yield from 2.27 to 1.49 with unfiltered light and increase to 3.43 (about double) with light of 700–400 mμ, and a small decrease to 2.17 with light of 400–280 mμ. Bass and Johnson (6) found an eightfold increase to 31.4% after irradiation with sunlight for 3 months. The amount of light absorbed in the last two examples is not stated. Under the conditions of the present work the quantum yield for nitrobenzene production is less than 0.01 at 439 mμ and less than 0.011 at 366 mμ. The calculation was based on the lower limit of detection of nitrobenzene and the volume of the sample.

Three runs were made on toluene with amounts and conditions approximately the same as runs 7, 8, and 9. No nitrotoluenes were found. Interestingly, Bass and Johnson (6) found no nitrotoluenes both in the dark and on irradiation with a mercury lamp.

Reaction to produce nitrobenzene does occur in the gas phase. The production of nitrobenzene is very dependent on irradiation, contrary to Schorigin and Toptschiew (8) and to Gorislavetz (9). The production of nitrobenzene is very dependent on the concentration of nitrogen dioxide, in agreement with the authors just mentioned. Comparing runs 23, 24, 25, and 29 and runs 20 and 28 (Table II) it is seen that as the concentration of nitrogen dioxide is reduced, the amount of nitrobenzene falls precipitously even though the nitrogen dioxide is in a large excess except in run 20. Comparing runs 23 and 24 it is seen that increasing the benzene/NO_2 ratio does not decrease the production of nitrobenzene. The fact that it increases is not surprising as about 76% of the benzene was nitrated in run 23. Light of wavelength 366 mμ with a quantum yield of 0.2 is more than 10 times as effective as that of 439 mμ. It may well be that the reaction apparent at 439 mμ is due to a few percent of 404.7 mμ (which can also dissociate NO_2, (14)) getting through the filter.

In a recent paper on the photolysis of NO_2, Pitts, Sharp, and Chan (14) propose a mechanism in which three reactive species are produced by the action of light, activated NO_2, O atoms, and NO_3. Since absorption is practically total at all concentrations here studied the amount of these reactive species produced should at least be of the same order of magnitude at all nitrogen oxide concentrations. Since light of 439 mμ is relatively ineffective, activated NO_2 is most probably not the species involved. Since the concentration of N_2O_4 falls more rapidly than the total oxide concentration (Table III), although not as rapidly as the production of nitrobenzene, it would appear that both N_2O_4 and O atoms or NO_3 are needed for the photochemical nitration of benzene at room temperature. Possibly the oxygen atoms combine with the N_2O_4 to make N_2O_5 which is quoted (3*d*) as being many times more effective than N_2O_4 as a nitrating agent. Titov, however, goes on to suggest that N_2O_5 is so effective because it dissociates to form NO_3 which of course would be present in the photolysis of NO_2 alone.

TABLE III

Actual concentrations of N_2O_4 and NO_2 as total oxide concentration changes calculated at 25°

Total oxide as NO_2 (moles/l $\times 10^2$)	Fraction N_2O_4 dissociated	N_2O_4 (moles/l $\times 10^2$)	NO_2 (moles/l $\times 10^2$)
4.28	0.216	1.68	0.924
0.886	0.421	0.256	0.392
0.62	0.487	0.159	0.302
0.35	0.584	0.073	0.205

No explanation can be offered for the lack of effect of light observed by the other workers. Schorigin and Toptschiew (8) do observe a substantial increase in yield of nitrotoluenes on irridation of toluene and NO_2 (Table I). With benzene and NO_2 they observe a variation in yield with temperature. At 10–12° it is 12.7%, at 25–30° it is 28.5%, at 55–60° it is 31.6%, and at 80–85° it is again 12.7%. Since at 1 atm N_2O_4 is 20% dissociated at 27°, 53% at 60°, and 90% at 100° (15), the variation that they observe might be explained by the requirement that both NO_2 and N_2O_4 be present for nitrobenzene to be formed.

TELLURATE COMPLEXES OF NICKEL, PALLADIUM, AND PLATINUM, AND A PERIODATE COMPOUND OF NICKEL

M. W. LISTER AND P. MCLEOD
Department of Chemistry, University of Toronto, Toronto, Ontario
Received October 19, 1964

ABSTRACT

The periodate or tellurate complexes of nickel, palladium, and platinum have been examined. The preparation of $NaNi_2IO_6.2H_2O$, $NaNi_4(H_3TeO_6)_3.6H_2O$, $Na_6Ni(H_3TeO_6)_3.H_2O$, $Na_9H_5Ni_2(TeO_6)_3$, $Na_5H_3Pd(TeO_6)_2.4H_2O$, and $Na_5H_3Pt(TeO_6)_2.2H_2O$ is described.

Periodate and tellurate ions are known to stabilize relatively high valency states of some transition metals, copper(III) and nickel(IV) in particular (1, 2, 3). Complex periodates and tellurates in general have been reviewed in ref. 4. The present work is concerned with these complexes of nickel, palladium, and platinum. The compounds $NaNiIO_6.H_2O$ and $KNiIO_6.H_2O$ from Ni(IV) have been prepared by Ray and Sarma (3) using somewhat acid conditions, and it was hoped that alkaline oxidation, for instance by hypochlorite ions, might yield different compounds. In fact no very unusual compounds turned up, but the following sections summarize what was found to be the behavior of the above three metals with tellurate or periodate ions.

Nickel

Attempts to prepare a complex periodate of nickel, with the nickel in a valency higher than two, by hypochlorite oxidation, were unsuccessful. Both sodium periodate and nickel hydroxide precipitated so readily that only mixed precipitates were obtained. Periodic acid alone in weakly acid solution did not oxidize divalent nickel ions, and the absorption spectrum of mixtures in solution on a pH from 2 to 4 gave no evidence of any complex ion being formed. When the pH was raised to 4.5 by adding sodium hydroxide, a green solid precipitated. This appeared to be of constant composition, and analyzed as follows: Na, 7.6; Ni, 29.3; I, 31.7; loss in weight at 150 °C (presumably water), 9.5; calcd. for $NaNi_2IO_6.2H_2O$: Na, 5.8; Ni, 29.4; I, 31.8; H_2O, 9.0%. The equivalent weight of the compound as an oxidizing agent (with acidified potassium iodide) agreed with a formula containing divalent nickel, and the green color supports this.

Nickel chloride solution and telluric acid were mixed in a molar ratio of 1 to 3 and addition of alkaline sodium hypochlorite gave a precipitate which was filtered off, washed, and dried. It was green in color, and had no oxidizing properties attributable to a nickel valency higher than two. It analyzed as follows: Na, 22.0; Ni, 11.8; Te, 38.6; calcd. for $Na_9H_5Ni_2(TeO_6)_3$: Na, 20.7; Ni, 11.7; Te, 38.2%. This is probably a genuine compound, since the Ni/Te ratio is quite different from what was put in, but it is so insoluble that no method was found for purifying it. On heating a mixture similar to that above, especially with a larger excess of sodium hypochlorite, a black precipitate resulted, which remained black if very cautiously dried. On heating it turned green. It analyzed as follows: Na, 17.0; Ni, 6.74; Te, 42.44; loss at 150 °C, 4.4; calcd. for $Na_6H_9Ni(TeO_6)_3.H_2O$: Na, 15.4; Ni, 6.56; Te, 42.79; H_2O, 2.0%. The compound turned green at 150 °C, so presumably decomposition as well as water loss had occurred. Its equivalent weight as an oxidizing agent (with excess acidified ferrous ammonium sulfate, and titration of the excess) corresponded to an apparent valency for nickel of 2.78. This is presumably

trivalent nickel, with some decomposition. The formula is probably more correctly written $Na_6Ni(H_3TeO_6)_3.H_2O$.

In acid solution (pH 1.4 to 5.4) nickel(II) perchlorate and telluric acid gave an absorption spectrum virtually the same as that of hydrated Ni^{++}, so there is no evidence of complexing in these solutions. If sodium hydroxide was added when the pH reached 6, an apple-green precipitate formed. A sample prepared from a solution containing equimolar amounts of nickel perchlorate and telluric acid analyzed as follows: Na, 2.1; Ni, 22.3; Te, 37.1; loss in weight at 150 °C, 9.9; calcd. for $NaH_9Ni_4(TeO_6)_3.6H_2O$: Na, 2.2; Ni, 22.45; Te, 36.6; H_2O, 10.3%. This unexpected ratio of ligand to metal is not unprecedented, as $Na_3Co_4(IO_6)_3.11H_2O$, and the corresponding potassium salt, have been prepared (5). The present compound is probably $NaNi_4(H_3TeO_6)_3.6H_2O$.

Palladium

Telluric acid and palladium(II) chloride were dissolved in water in the molar ratio of 3 to 1. The solution was warmed nearly to boiling and sodium hypochlorite (1.5 *M*) containing excess sodium hydroxide was added. An orange-yellow precipitate formed, but this slowly redissolved on continued heating to give a dark-orange solution. On cooling and standing, orange-yellow crystals formed. The compound analyzed as follows: Pd, 13.4; Te, 33.85; Na, 15.2; loss of weight on heating, 9.4; calcd. for $Na_5H_3Pd(TeO_6)_2.4H_2O$: Pd, 14.3; Te, 34.3; Na, 15.45; H_2O, 9.7%. The equivalent weight as an oxidizing agent with ferrous ammonium sulfate was 370; calculated for Pd(IV) to Pd(II), 372. The formula appears to require different numbers of hydrogens attached to the two tellurate groups, in an ion such as $Pd(HTeO_6)(H_2TeO_6)^{-5}$. However, since the compound formed from alkaline solution, it is possible that a hydroxide group is attached to the palladium, in an ion such as $Pd(OH)(H_2O)(H_2TeO_6)_2^{-5}$, differing from the previous ion by two water molecules. It was found that of the four waters formally present in the compound, two were lost easily, and two only at 150 °C. The compound was too insoluble to be investigated by pH titration in aqueous solution.

Platinum

Platinum(IV) chloride and telluric acid were dissolved in water in the molar ratio of 1 to 3. The mixture was made strongly alkaline with sodium hydroxide, and was kept at 95 °C for 2 h. On cooling and standing, bright-yellow crystals formed. The material was difficult to analyze, since reagents which precipitated tellurium also precipitated platinum, and in fact tellurium dust had been used earlier as a precipitant for platinum (6). The method of analysis eventually adopted was to dissolve the compound in 30 ml of concentrated hydrochloric acid, and then to add 50 ml of saturated aqueous sulfur dioxide and 15 ml of 15% aqueous hydrazine hydrochloride. The mixture was kept at 80 °C, and after standing overnight the precipitate of both tellurium and platinum was filtered off. On evaporating the filtrate, more precipitate usually formed, so the process was repeated until no further precipitate was produced. The precipitate was filtered off, transferred to a crucible, and heated in hydrogen at 700 °C for 2 h. This removed the tellurium (presumably as TeH_2) and the crucible was cooled in nitrogen and weighed. The heating in nitrogen was continued until the crucible reached constant weight. This gave the weight of platinum in the sample. The filtrate was evaporated to dryness with sulfuric acid, and the sodium was weighed as sodium sulfate. The tellurium was determined by the method of Gooch and Howland (7). A sample was mixed with 3 g of potassium bromide and 50 ml of 10% sulfuric acid. Bromine was liberated according to the equation

$$H_6TeO_6 + 6HBr \rightarrow TeBr_4 + Br_2 + 6H_2O$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and this was swept out in a stream of nitrogen and caught in potassium iodide solution. The liberated iodine was titrated. The water was determined by the weight loss at 150 °C.

The result of the analysis was Pt, 22.5; Te, 33.9; Na, 13.1; loss on heating, 4.7; calcd. for $Na_5H_3Pt(TeO_6)_2.2H_2O$: Pt, 24.5; Te, 32.1; Na, 14.4; H_2O, 4.5. The compound did not reduce potassium permanganate, which was taken as evidence that it only contained Pt(IV) (see ref. 8). The compound formed rather slowly, even at 95 °C, as shown by progressive change in the spectrum of the solution. With 0.002 *M* platinum, and 0.006 *M* telluric acid, complex formation was half complete in about 1 h. The complex had a strong absorption band which extended just into the visible, but with a maximum at 256 mμ. It only dissolved in water to the extent of 0.05 g/l at 25 °C, though much more concentrated solutions existed briefly during its preparation.

DISCUSSION

Campbell and Nyman (9) have noted that, for similar compounds to those prepared above, the ratio ligand/metal is usually greater than one for complexes prepared from alkaline solution, and one or less from acid solution. The present compounds fit into this generalization: $NaNi_2IO_6.2H_2O$ and $NaNi_4(H_3TeO_6)_3.6H_2O$ were prepared in acid solution; $Na_6Ni(H_3TeO_6)_3H_2O$, $Na_9H_5Ni_2(TeO_6)_3$, $Na_5H_3Pd(TeO_6)_2.4H_2O$, and $Na_5H_3Pt(TeO_6)_2.2H_2O$ were prepared in alkaline solution. Campbell and Nyman suggest that the compounds formed in acid solution are polymers, but there is no evidence on this point for the present compounds.

The compounds $Na_5H_3Pd(TeO_6)_2.4H_2O$ and $Na_5H_3Pt(TeO_6).2H_2O$ are analogous to the compound of silver(III), $Na_6H_3Ag(TeO_6)_2.18H_2O$, prepared by Malatesta (10). This also was prepared from alkaline solution, so its apparently unsymmetrical formula may be due to the presence of a hydroxy group, as was suggested above for the palladium and platinum compounds.

APPLICATION OF DIFFERENTIAL THERMAL ANALYSIS TO THE DISSOCIATION OF MnO_2 AND Mn_2O_3

T. MATSUSHIMA AND W. J. THOBURN
Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario
Received November 4, 1964

ABSTRACT

The method of differential thermal analysis was employed to determine the oxygen pressures produced by the reactions

$$4MnO_2(s) = 2Mn_2O_3(s) + O_2(g)$$

and

$$6Mn_2O_3(s) = 4Mn_3O_4(s) + O_2(g)$$

in the temperature range 250–1 000 °C. The heats of reaction calculated from the slope of the van't Hoff curves are: $\Delta H_{835°K}^0 = 25.8 \pm 1.5$ and $\Delta H_{1200°K}^0 = 25.3 \pm 4.2$ kcal per mole of oxygen. These are in agreement with previously reported values based on equilibrium measurements, but are lower than those determined by calorimetry.

INTRODUCTION

Previous measurements of the oxygen pressures produced by the reactions

[1] $$4MnO_2(s) = 2Mn_2O_3(s) + O_2(g)$$

and

[2] $$6Mn_2O_3(s) = 4Mn_3O_4(s) + O_2(g)$$

present conflicting results, and in addition the corresponding thermodynamic data obtained are not in agreement with those based on calorimetric measurements. Part of the difficulty in static measurements is that the slow reaction rates involved render impractical the approach to equilibrium from both the dissociating and oxidizing sides. Thus, we measured the oxygen pressures by means of a dynamic technique, differential thermal analysis (d.t.a.), which appeared to be particularly suited to study these reactions.

EXPERIMENTAL

Preparation of MnO_2

The oxide was prepared according to the following steps. 1. Approximately 250 ml of Fisher's manganous nitrate solution was heated slowly on a hot plate to eliminate the water of crystallization according to $MnNO_3.6H_2O = Mn(NO_3)_2 + 6H_2O(g)$. 2. The resulting $Mn(NO_3)_2$ crystals were remelted and heated to 200 °C to drive off NO_2 according to $Mn(NO_3)_2 = MnO_2 + 2NO_2(g)$. 3. The resulting MnO_2 was crushed to −100 mesh and the powder was heated for 24 h at 400 °C in a closed alumina vessel and under a substantial flow of oxygen to prevent any dissociation of the MnO_2. 4. The resulting $MnO_2(s)$ was crushed to −200 mesh.

Apparatus

Samples were heated in a horizontal globar resistance furnace, with a 1 in. diameter alumina retort tube. The $MnO_2(s)$ powder and an alumina powder reference material were held in identical platinum crucibles, 1/2 in. in diameter and 1/2 in. deep. The crucibles were embedded symmetrically in alumina powder contained in a porcelain crucible to ensure that most heat absorbed or evolved during a reaction would affect the temperature of the sample.

The temperatures of the sample and alumina reference were measured with platinum – platinum 10% rhodium thermocouples. The diameter of the wires was 0.013 in. and the junctions were filed to a fine point to improve the thermal response of the measurements. Partial pressures of oxygen were maintained constant to within 0.1 mm Hg by means of a Cartesian diver-type manostat.

Experimental Procedure

The thermocouples were carefully centered in the sample and reference, and the boat was placed in the hot zone of the furnace. The furnace and gas system were sealed and evacuated. The temperature was

raised to 250 °C where degassing was allowed to continue for 1 h. Oxygen was then introduced and maintained at a desired pressure by means of the manostat. The temperature of the system was then raised at a uniform rate by increasing in small increments an auto-transformer which controlled the power input. It was found that a heating rate of 3 C°/min was optimum. The temperature of the sample and the temperature difference between the sample and reference, ΔT, were measured with a potentiometer and recorded at intervals from 1 to 2 min.

RESULTS

The differential curves shown in Fig. 1 are typical of these experiments. The components indicated by eqs. [1] and [2] were confirmed by X-ray diffraction analysis. It was assumed that the two sharp breaks in the curve (indicated by the arrows) correspond to the beginning of dissociation of the oxides, and also that the temperatures at these points correspond, within the limits of precision of the experiment, to the equilibrium temperatures for reactions [1] and [2] at the fixed oxygen pressure maintained in the system. These equilibrium temperatures were used to plot the results in the form of van't Hoff curves, as shown in Figs. 2 and 3.

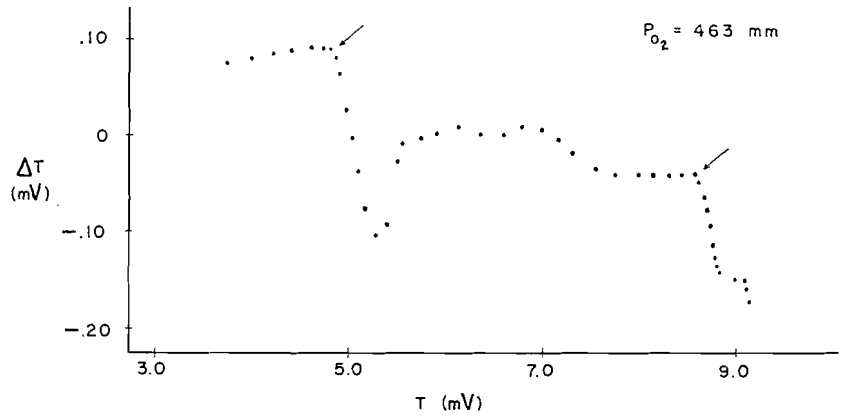

FIG. 1.

The analysis of the van't Hoff plots can be illustrated with reference to Fig. 2. There is first the possibility that the points can be represented by a single straight line. However, the correlation coefficient (r, which equals unity if all points fall on a perfect straight line) was too low (0.67) and the error limits (approximately ±20%) too high to validate such an assumption. A curve could be drawn through the points, indicating that the heat of reaction cannot be considered approximately constant over the temperature range of the experiments. This is not possible, however, as the change in slope over this range is too great to be explained by the effect of heat capacity.

It can be shown that the points fall along two distinct straight lines, the slopes of which were determined by the least squares method. Five pairs of correlation coefficients were determined for each of the two assumed lines by including (i) all of the five middle points with one group, (ii) four of the five middle points with one group, one with the other, etc. The slope and correlation coefficient of the lower temperature portion was affected only by the two higher temperature points of the central five. On the other hand the higher temperature line was appreciably affected only by the lowest temperature point in the central group. Thus, the points plotted in Fig. 2 can best be described as falling along two straight lines, of which the higher temperature part consists of the 10 highest temperature points and the lower temperature point consists of the remaining 7. This combination

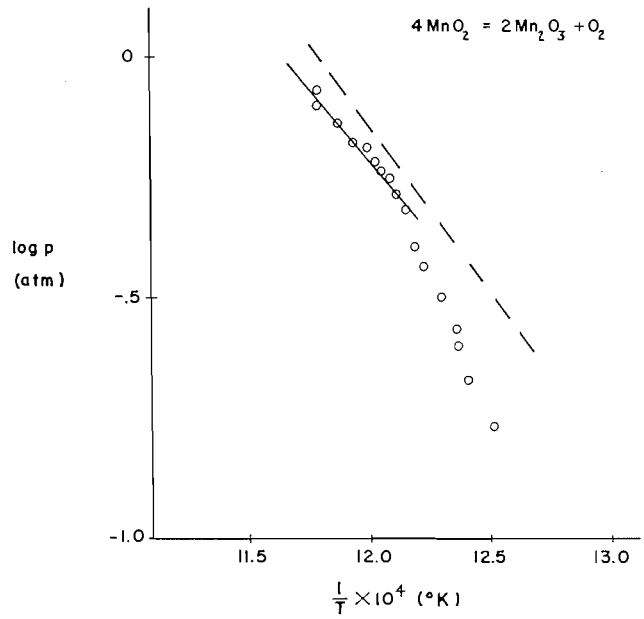

FIG. 2.

results in the maximum correlation coefficients for both lines (0.92 and 0.95 respectively). A similar analysis of the experimental points plotted in Fig. 3 shows that they can best be represented as lying along two straight lines with correlation coefficients of 0.93 and 0.90 respectively.

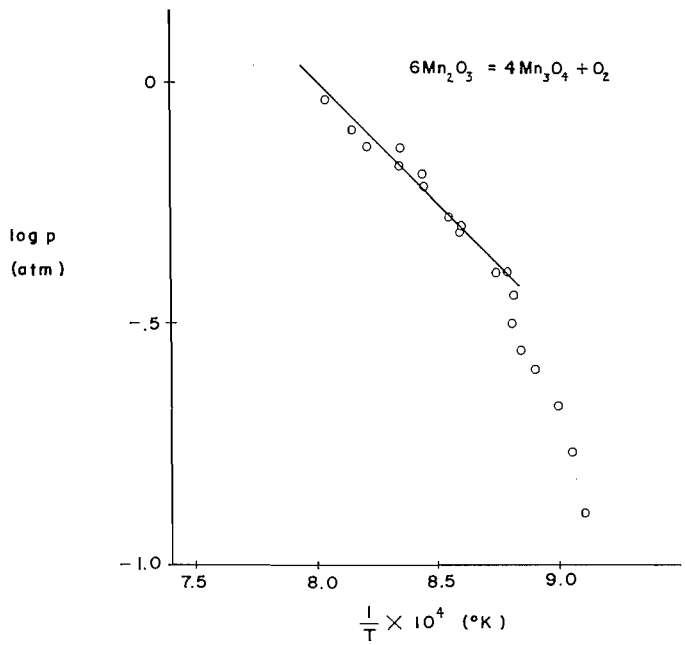

FIG. 3.

Validity of D.T.A. for Equilibrium Measurements

When employing d.t.a. for equilibrium determinations one must be certain that (*a*) the heat effect which causes a sharp break in a differential trace (for example, the break pointed to by the first arrow in Fig. 1) is actually due to the reaction assumed (reaction [1] in this case), and (*b*) at the temperature of this break the reaction is proceeding under reversible conditions within the limits of precision of the experiment.

(*a*) The components of each reaction were confirmed by X-ray analysis which showed, as in Fig. 1 for example, that the sharp breaks from a relatively linear ΔT vs. T trace (indicated by the arrows in Fig. 1) and the resulting peaks were due to the reactions assumed. The procedure consisted of heating MnO_2 under a fixed oxygen pressure to different temperatures and then quenching and analyzing the sample. For example, with respect to the first break at 4.90 mV (568 °C) and peak shown in Fig. 1, two separate runs were carried out heating the sample under identical conditions, with the exception that these runs were halted and the samples quenched when they had reached temperature levels of 4.82 mV (560 °C) and 5.50 mV (627 °C). X-ray analysis produced diffraction lines characteristic in the first case of MnO_2 only and in the latter of Mn_2O_3 only.

(*b*) Known thermodynamic data indicates that reactions [1] and [2] are thermodynamically reversible in the temperature and pressure ranges employed. That is, at a fixed oxygen pressure, MnO_2 is the stable oxide phase at lower temperatures, Mn_2O_3 becoming the stable phase at higher temperatures and Mn_3O_4 becoming the stable oxide phase at still higher temperatures.

The presence of kinetically reversible experimental conditions should also be considered. There is first the possibility that enough initial decomposition to cause a heat effect occurred (due to inhibition of the rate of the reverse reaction) before the equilibrium temperature was reached. This is unlikely as any decomposition substantial enough to cause a measurable heat effect would produce a fresh outer layer of oxide product with which the oxygen could react.

Similarly as the temperature of the sample increases just above the equilibrium temperature for the reaction (at the fixed oxygen pressure in the system) and the reaction begins to proceed, it is possible that at this point the rate of reaction is not high enough to produce a measurable heat effect. Such a slow rate could be due in part to the restriction of the forward reaction by the outer product layer. However, at some temperature significantly above the equilibrium temperature the rate of reaction may increase to such an extent so as to cause a measurable heat effect. For such oxide decomposition reactions as considered here such an increase could be due to either (i) the increase in rate of diffusion of oxygen to the surface of partially decomposed particles, (ii) the rupture of the outer product layer by the force of increased equilibrium oxygen pressure at the reactant–product interface, (iii) the increase in the rate of chemical decomposition as temperature rises, or (iv) a combination of two or all of the above.

With these points in mind reference should be made to the van't Hoff plots of Figs. 2 and 3. The differences in slope between the higher and lower temperature parts are much too large to be attributed to a phase change. Also the possibility that the occurrence of two competing reactions can explain the form of these curves must be discounted because (i) X-ray analysis showed that the heat effects associated with both parts of each van't Hoff curve were due to the same reaction, and (ii) extrapolation of the higher temperature line shows that it should be occurring at the lower temperatures while the lower temperature part should be occurring at the higher temperature.

The appearance of the two straight line portions can best be explained with reference to the rates of the forward reactions, which are sufficiently high to cause a measurable

temperature differential under conditions close to equilibrium only at temperatures above the breaks in the van't Hoff curves. In other words the slopes of the lower temperature lines are a function of the kinetics of the reaction as well as the equilibrium constants (these lines are not vertical indicating that the rates of the reactions are not solely a function of temperature, but also a function of the distance from equilibrium). Thus the points forming the higher temperature portions of the van't Hoff curves represent temperatures from the differential traces (such as those shown in Fig. 1) at which the observed initial decomposition at a fixed pressure (indicated by the arrows in Fig. 1) occurs under conditions close enough to equilibrium to be considered so within the limits of precision of the experiments.

The higher temperature lines in Figs. 2 and 3, representing equilibrium points, can be expressed by

$$\log p_{\text{atm}} = 7.29 - \frac{6250}{T} \quad [3]$$

and

$$\log p_{\text{atm}} = 4.00 - \frac{5000}{T} \quad [4]$$

for reactions [1] and [2] respectively. These lines formed the basis of the thermodynamic calculations outlined in the next section.

Thermodynamic Calculations

(1) MnO_2 Dissociation

The mean standard heat of reaction [1], as calculated from the slope of the van't Hoff curve is $\Delta H_{835^\circ K}^0 = 25.8 \pm 1.5$ kcal per mole of oxygen. The standard free energy change at the same temperature is $\Delta F_{835^\circ K}^0 = 0.763 \pm 0.03$ kcal per mole of oxygen. A third law calculation for the entropy change yields $\Delta S_{835^\circ K}^0 = 30.0 \pm 1.8$ entropy units (e.u.) per mole of oxygen.

(2) Mn_2O_3 Dissociation

The mean standard heat of reaction [2], as calculated from the slope of the van't Hoff curve is $\Delta H_{1200^\circ K}^0 = 25.3 \pm 4.2$ kcal per mole of oxygen. The standard free energy change at the same temperature is $\Delta F_{1200^\circ K}^0 = 0.90 \pm 0.07$ kcal per mole of oxygen. A third law calculation for the entropy change yields $\Delta S_{1200^\circ K}^0 = 20.3 \pm 3.6$ e.u. per mole of oxygen.

TABLE I

$4MnO_2(s) = 2Mn_2O_3(s) + O_2(g)$ (comparison of data)

Source	Method	$\Delta H_{835^\circ K}^0$	$\Delta F_{835^\circ K}^0$
Wicks and Block (3)	Calorimetric	39.2±5	8.8±5
Meyer and Rotgers (1)	Equilibrium	57.8	0
Kapustinsky and Bayushkina (2)	Equilibrium	31.5	0.32
Present work	Differential thermal analysis	25.8±1.5	0.76±.03

Comparison of Results

(1) MnO_2 Dissociation

The most reliable data for reaction [1] are summarized in Table I and are compared to those found by d.t.a. Uncertainty limits for the results of Meyer and Rotgers (1) and Kapustinsky and Bayushkina (2) are not available. For $\Delta H_{835^\circ K}^0$ the present work

is in reasonable agreement with that of the latter authors, while the $\Delta F_{835°K}^0$ values obtained by d.t.a. are in reasonable agreement with both static determinations. The dashed line in Fig. 2 represents the van't Hoff curve determined by Kapustinsky and Bayushkina (2).

TABLE II

$6Mn_2O_3(s) = 4Mn_3O_4(s) + O_2(g)$ (comparison of data)

Source	Method	$\Delta H_{1200°K}^0$	$\Delta F_{1200°K}^0$
Siemonsen (4)	Calorimetric	50.2±2	
Wicks and Block (3)	Calorimetric	—	−24.9±15.8
Meyer and Rotgers (1)	Equilibrium	33.3	3.2
Present work	Differential thermal analysis	25.3±4.2	0.90±.07

(2) Mn_2O_3 Dissociation

Table II indicates that the d.t.a. results are in agreement with the static measurements of Meyer and Rotgers.

For both reactions, thermodynamic values based on vapor pressure measurements are in reasonable agreement (with the exception of $\Delta H_{835°K}^0$ for reaction [1] reported by Meyer and Rotgers) and differ from those produced by calorimetric experiments. Inconsistencies in the data contained in the literature can also be illustrated by considering entropy changes. The value for the entropy change for reaction [1], as calculated from the difference between the entropy values of the components, is $\Delta S_{835°K}^0 = (\Delta H^0 - \Delta F^0)/T = 36.4 \pm 12$ e.u. Similarly, for reaction [2], the corresponding values are $\Delta S_{1200°K}^0 = 11.04 \pm 3$ e.u. and $\Delta S_{1200°K}^0 = 54.7 \pm 24.2$ e.u. The calculations are based on data presented by Wicks and Block (3).

CONCLUSIONS

Thermodynamic values for reactions [1] and [2] based on vapor pressure measurements are not in agreement with those produced by calorimetry. Entropy calculations indicate that some of this difference may be due to inaccurate heat capacity data. The discrepancies illustrate the value of determining thermodynamic functions by employing both equilibrium and calorimetric techniques.

CONDUCTANCES AND SURFACE TENSIONS OF AQUEOUS SOLUTIONS OF SODIUM DECANOATE, SODIUM LAURATE, AND SODIUM MYRISTATE, AT 25° AND 35°

A. N. CAMPBELL AND G. R. LAKSHMINARAYANAN[1]
Chemistry Department, University of Manitoba, Winnipeg, Manitoba
Received December 11, 1964

ABSTRACT

The equivalent conductances of aqueous solutions of sodium decanoate, sodium laurate, and sodium myristate have been determined from the very dilute region up to saturation concentration, at 25° and 35°. The limiting conductances have been obtained from the measurements in the usual way. In addition and for the sake of completeness, the limiting equivalent conductances of sodium formate, sodium acetate, sodium propionate, and sodium butyrate have also been determined at 35°, since they were not known at this temperature.

The effect of increasing chain length on mobility is discussed. From a consideration of the experimental and the theoretical values of the slopes of the plots of equivalent conductance against the square root of the concentration, it is concluded that some sort of interaction, possibly a reversible dimerization of anions, occurs, even in the dilute region, and this could account for the lower experimental values of the slope. This phenomenon has been observed with other long chain electrolytes, however, and the hypothesis of dimerization is not the only possible one.

The critical micelle concentrations have been determined, and recent concepts of micelle formation are applied to interpret their structure. The surface tensions of the aqueous solutions have been measured at 25° and 50°.

The object of this work has been described in a previous publication (1). We have now extended our work to include the decanoate, laurate, and myristate ions (14 carbons, including the carboxyl group) and this is about as far as there is any point in going. In addition, however, to our interest in the limiting conductance of the anion, it was found that the slope of the conductance curve, in the very dilute region, is not that of the Onsager theory, when the number of carbon atoms exceeds six. This phenomenon has been observed by others and it points to peculiarities in the structure of solutions of these salts. Moreover, since the soap-like character of the solutions of these sodium salts is very marked, we were obliged to investigate other physical properties, notably the surface tension.

EXPERIMENTAL

Our method of determining conductances has been described previously (1). Densities were determined with Ostwald–Sprengel pycnometers, cap. 25 ml, and the usual precautions with respect to bouyancy, etc., were taken. The densities are correct to ±0.0001. Viscosities were determined with the Cannon and Fenske modification of the Ostwald viscometer. The stalagmometer method was used to determine surface tension. To obtain a sufficient degree of accuracy, it was necessary to count from 100 to 200 drops but, because these soap-like solutions are sometimes very viscous, this laborious operation could occupy as much as 3 h. An automatic system was therefore desired. Each drop as it fell from the stalagmometer fell into a glass cone, having platinum plates on opposite sides: these plates were connected to an electronic glow counter. The glow counter was enclosed in a Faraday cage to eliminate signal pickup. The apparatus was frequently checked with benzene; the agreement was excellent. Practically any liquid has sufficient conductance to operate the counter when a drop falls into the platinum cone. Because of this high sensitivity, precautions (such as the Faraday cage) against stray currents are necessary. With approximately 200 drops falling in 3 h, the time of formation of a drop is slightly less than 1 min.

[1]*Financed by the National Research Council.*

RESULTS

The limiting equivalent conductances of sodium decanoate, sodium laurate, and sodium myristate were determined by the extrapolation technique of Kohlrausch. Before plotting, the equivalent conductances were corrected for hydrolysis by the method of Campbell and Bock (2). The results are expressed graphically in Figs. 1, 2, and 3. The viscosities are not reproduced, since neither the plot of viscosity nor of fluidity, against either molar or weight concentration, reveals a distinct break at the critical micelle concentration. The surface tensions of aqueous solutions of sodium octanoate, sodium decanoate, sodium laurate, and sodium myristate are reproduced, as functions of the common logarithm of the concentration, in Fig. 4.

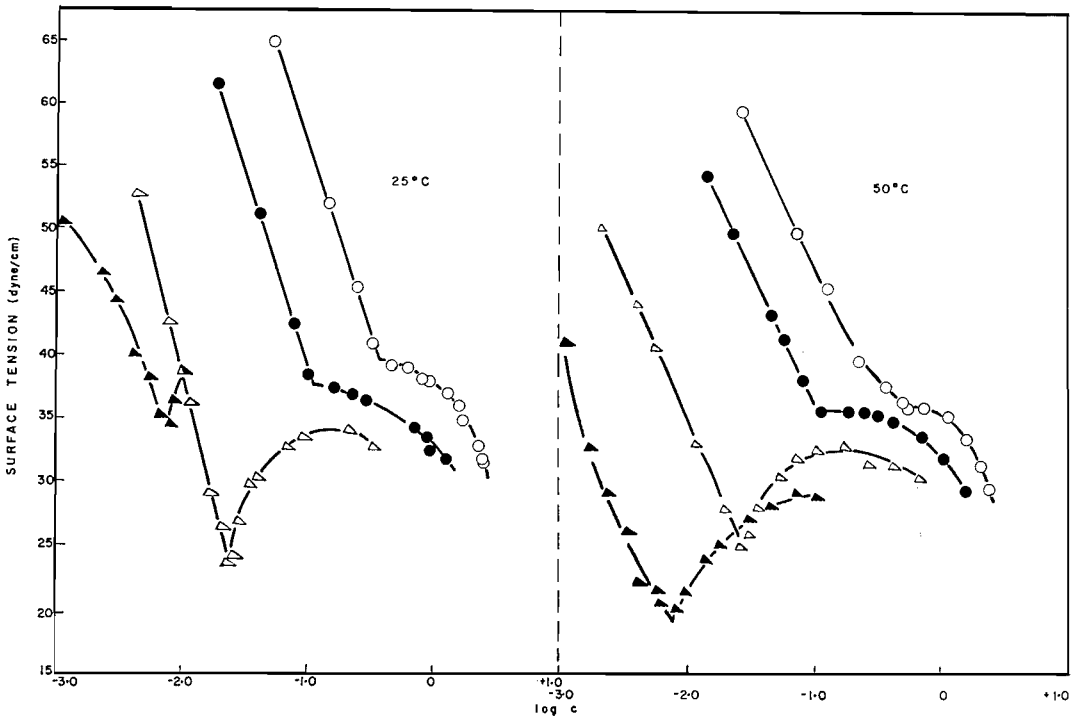

FIG. 4. Surface tension vs. log c: ○ sodium octanoate, ● sodium decanoate, △ sodium laurate, ▲ sodium myristate.

DISCUSSION AND RESULTS

The limiting equivalent conductances, obtained from the plots of equivalent conductance against the square root of the concentration, in the dilute regions, are tabulated in Table I. The limiting equivalent conductances of sodium formate, sodium acetate,

sodium propionate, and sodium butyrate, at 35°, were also determined, since no reliable data were available at this temperature. The limiting ionic conductances of the fatty acid anions, at 25° and at 35°, are summarized in Table II.

TABLE I

Limiting equivalent conductances of sodium salts of fatty acids at 25 and 35 °C

Salt	Temperature (°C)	Λ_0
Hexanoate	25	77.47
Hexanoate	35	96.23
Octanoate	25	73.18
Octanoate	35	90.63
Decanoate	25	72.11
Decanoate	35	89.10
Laurate	25	70.76
Laurate	35	87.86
Myristate	25	70.21
Myristate	35	86.77

Limiting equivalent conductances of fatty acid anions at 25 and 35 °C

		Temperature	
Anion*	Cation	25 °C	35 °C
Formate (C_1)		54.59 (3)	67.69
Acetate (C_2)		40.90 (4)	50.71
Propionate (C_3)		35.80 (5)	44.42
Butyrate (C_4)		32.60 (5)	40.29
Hexanoate (C_6)		27.37 (6)	34.69
Octanoate (C_8)		23.08 (1)	29.09 (1)
Decanoate (C_{10})		22.01	27.56
Laurate (C_{12})		20.66	26.32
Myristate (C_{14})		20.11	25.23
	Na^+	50.10 (7)	61.54 (7)

*C_1, C_2, C_3, etc. indicates the number of carbon atoms in the chain.

When the limiting equivalent conductances are plotted vs. the number of carbon atoms, it becomes obvious that in the lower members of the series the difference in the mobilities of successive anions is fairly high, but from octanoate onwards the decrement becomes smaller and smaller, so that the curve tends to become horizontal. The effect is observed at both temperatures. In other words, after decanoate ion (10 carbon atoms) the mobility of the anion approaches constancy. Similar results for the mobilities of sodium alkyl sulfates, with increasing number of carbon atoms, were obtained by Flockhart (8).

In the state of high dilution the motion of an ion is limited solely by its interaction with the surrounding solvent molecules, there being no other ions within a finite distance. As Edward (9) points out, the carboxyl group binds an inner sheath of water molecules and causes breakdown in the outer zone. Ions of smaller size, such as Na^+, Li^+, F^-, acquire by ion–solvent interaction, a permanent hydration sheath which must be assumed to be larger, the lower the mobility; with carboxylic ions the hydrophobic part increases with increase in number of carbon atoms and hence the hydration effect is correspondingly less. Since, however, the mobility is observed to decrease with increase in the number of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

carbon atoms, this effect must be overbalanced by the absolute increase in ion size. The constant mobility finally attained is not so easily explained. It is probably not justifiable, however, to treat ions of this size as spheres and, if the large fatty acid anions are envisaged as coiled springs with one end oriented in the direction of motion, then it is obvious that the resistance to motion is approximately constant.

The temperature effect on the limiting equivalent conductances of the sodium salts is almost the same for all salts, the ratio varying between 1.236 for decanoate to 1.242 for hexanoate and laurate: the fluidity ratio of water between these temperature limits is 1.237.

It is well known that the equivalent conductances of uni-univalent electrolytes follows Onsager's theoretical equation in the dilute region (concentration $<0.001\ N$), well within the experimental error. In other words, the theoretical slope agrees well with the experimental slope. When, however, the experimental slopes (conductance vs. the square root of the concentration) of sodium octanoate, decanoate, laurate, and myristate are compared with the theoretical slope obtained from Onsager's equations, the experimental slopes are 40–45% lower than the theoretical, except for sodium octanoate, where the deviation is less. The experimental conductivities are higher than the theoretical and hence the slopes are smaller. The higher values can be explained in different ways, e.g., if there are present more ions than the simple uni-univalent sodium and fatty acid anions: i.e., if there is some sort of interaction between the simple ions, even in dilute solution, to form highly conducting ions.

Kraus and co-workers (10, 11, 12) have shown from their study of the conductances of alkyl trimethyl quaternary salts, in dilute solution, that dimerization of cations is responsible for the observed deviations from theory. Recently, Mukerjee and Mysels (13, 14, 15) have suggested that lauryl sulfate ions dimerizes reversibly to a certain extent in dilute solution, to form LS^- ions, thus enhancing the conductance. The same authors observed similar results for some other amphiphilic ions (16). They state that dimerization seems to be a rather general phenomenon with this type of salt and that this makes it possible to explain numerous hitherto unexplained observations.

The explanation of the phenomenon given by Mukerjee is not, however, universally accepted. It can scarcely be accounted for as due to hydrolysis, since our conductances are all corrected for hydrolysis. Parfitt and Smith (17) find that they can account for the deviation from the Onsager slope by using the Fuoss–Onsager equation (18) i.e. with the incorporation of a term representative of ion size. We, however, find that the Fuoss–Onsager equation is insufficient to account for the deviation here. Again, van Voorst Vader (19) using an e.m.f. method, arrives at the same conclusion. To calculate the distance of closest approach, they use the equation of Falkenhagen and Kelbgk (20), and arrive at an $\mathring{a}$ value of 5.6 Å, comparable with the value of $\mathring{a}$ found by Parfitt and Smith. We do not wish to assume a position in this matter, but it seems to us that our deviations are somewhat too great to be accounted for in this way.

Critical Micelle Concentration

The critical micelle concentration (c.m.c.) is obtained by determining the concentration at which normal behavior of any physical property changes sharply, owing to an association or aggregation of ions: this must not be confused with the simple dimerization dealt with in the previous section. When the specific conductance is plotted against concentration, as in Figures 5, 6, 7, and 8, for sodium octanoate, sodium decanoate, sodium laurate, and sodium myristate, respectively, at both temperatures, an abrupt change of slope is

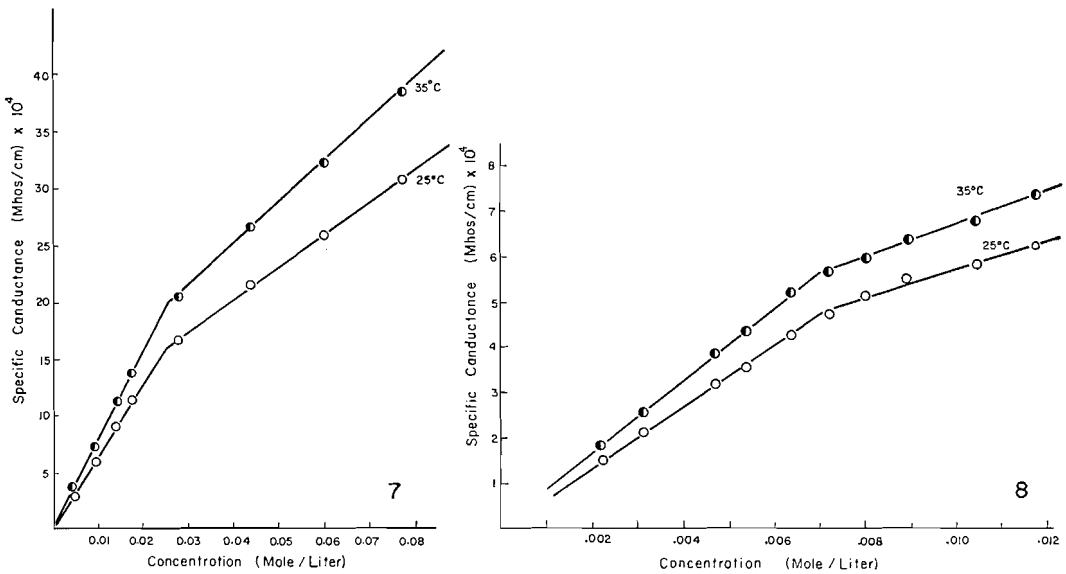

FIG. 7. Specific conductance vs. concentration of sodium laurate.
FIG. 8. Specific conductance vs. concentration of sodium myristate.

observed at the intersection of two curves which are almost straight lines. In a previous publication (1) we reported that sodium octanoate does not form micelles, because we then plotted equivalent conductance against the square root of concentration, a method which is not so sensitive for the detection of the c.m.c. Table III summarizes the critical micelle concentrations, at both temperatures. The value for the critical micelle concentration, at 25°, of sodium laurate agrees closely with that of 0.024 *M*, given by Huff, Brady, and McBain (21).

TABLE III

Comparison of the critical micelle concentrations (m*M*) of sodium salts of fatty acids by different methods at 25, 35, and 50 °C

Sodium salts	Critical concentration at 25 °C by		Critical concentration at 35 °C by conductivity	Critical concentration at 50 °C by surface tension
	Conductivity	Surface tension		
Octanoate	340.0	351.0	360.0	385.0
Decanoate	94.0	95.5	98.0	106.0
Laurate	24.4	23.0	25.0	28.0
Myristate	6.9	6.9	6.95	7.1

Increase of temperature usually raises the c.m.c. In the present case, the effect of temperature is not very great, as shown by Table III. The c.m.c. decreases with increasing chain length, approximately four times from octanoate to decanoate, from decanoate to laurate and so on, both at 25° and at 35°. Similar results were obtained by Harkins (22) and Klevens (23) who found that the c.m.c. increased by a factor of two for the removal of each CH_2 group from the chain.

Evans (24) has proposed an equation for the composition of the micelle in terms of conductance data. If S_1 is the slope of the specific conductivity vs. concentration curve below the c.m.c. and S_2 is the slope above the c.m.c., then according to Evans,

$$1\,000\,S_2 = \frac{(n-m)^2}{n^{4/3}}(1\,000\,S_1 - \Lambda_{Na}) + \frac{n-m}{n}\Lambda_{Na},$$

where n = number of anions in micelle, and m = number of gegenions (cations). An approximate value of n can be calculated, assuming a spherical micelle, from the formula

$$n = \frac{4}{3}\frac{\pi l^3 N d}{10^{24} M},$$

where l = length of hydrocarbon portion attached to the carboxylate group, N = Avogadro number, and d = density.

Using the above equation, from the measured slopes of the specific conductance vs. concentration curves (Figs. 5–8) of all four salts, n and m values have been calculated at both temperatures, and these are summarized in Table IV.

Below the c.m.c. the slope (S_1) increases with increasing chain length and decreasing anion mobility, and above the c.m.c. the gegenion micelle interaction increases, as is seen in the increased value of the ratio of gegenions (m) to single ions (n) with increasing chain length. In fact, the m/n ratio increases linearly with chain length, i.e. the degree of binding of gegenions increases with increase of chain length. The temperature effect upon the ratio m/n is not very great, over the range 25° to 35°.

	35	80.02	36.20	34	24	0.69

*Nearest whole number.
†C_8, C_{10}, etc. refers to number of carbon atoms in the chain.

Viscosity and Fluidity of the Aqueous Solutions of the Salts at 25° and 35°

In the dilute region the changes of viscosity with concentration are not very great, but at higher concentrations an increase of viscosity is observed. The change of slope of the curves, however, is not sufficiently sudden to allow of an exact determination of the c.m.c. Assuming a linear relation to exist both between conductance and temperature and between fluidity and temperature, the temperature coefficients of conductance and of fluidity and the activation energies have been deduced. The similarity in the values of the activation energies of conductance and of fluidity, and the value of practically unity for the ratio of the temperature coefficients, suggest a strong resemblance between the two phenomena (see Table V). Nevertheless, since conductance involves ionic migration through the bulk of the solution and viscosity involves a shearing motion of the whole solution, their mechanisms cannot be identical.

TABLE V

Average values of activation energy of conductance and viscosity (fluidity) and temperature coefficients of conductance and fluidity of sodium salts between 25 and 35 °C

Sodium salt	Activation energy of conductance (kcal/mole)	Activation energy of fluidity (kcal/mole)	Coeffic. of fluidity $\gamma \times 10^2$	Coeffic. of conductance $\beta \times 10^2$	γ/β
Decanoate	4.17	4.38	2.61	2.57	1.02
Laurate	4.29	4.17	2.57	2.64	0.973
Myristate	3.70	3.92	2.39	2.25	1.06

Surface Tensions of Aqueous Solutions of the Salts

If plots are made of surface tension against log concentration, the curves exhibit breaks at the c.m.c. The c.m.c. values for the four salts by the different methods are compared in Table III. Variations of surface tension with concentration follow the same pattern for all four salts. In the dilute region, the addition of salt reduces the surface tension rapidly, sometimes leading to a minimum but in all cases to a pronounced change of slope at the c.m.c. Because of the limited solubility of sodium myristate, the investigation was limited to low concentrations. The minima observed with sodium laurate and sodium myristate are not unusual. Such minima appear to be characteristic of certain colloidal electrolytes (25). In the present case, the minima may be associated with hydrolysis and the formation of mixed monolayers containing undissociated acid and acid anion. Nevertheless, though it may be a coincidence, the concentrations at the minima do correspond with the c.m.c.'s obtained by conductance.

ABSTRACT

A synthetic L-rhamnan containing both rhamnofuranosyl and rhamnopyranosyl units has been used as a model substance in the application of vapor phase chromatography (v.p.c.) to the study of the structure of rhamnose containing polysaccharides. Groups of isomeric methylated sugars obtained from the methylated rhamnan were analyzed by converting them to methylated alditols which had widely different retention times. A Smith periodate degradation of the rhamnan gave 1,2-dihydroxypropane, 1-deoxy-D-erythritol, L-rhamnose, and 5-deoxy-L-arabinose, which were separated by paper chromatography. There were also obtained 1-deoxy-3-*O*-(α-L-rhamnopyranosyl)-D-erythritol and the β-anomer, and 1-deoxy-2-*O*-(L-rhamnopyranosyl)-D-erythritol, separable by v.p.c. as their trimethylsilyl ethers. 1-Deoxy-D-erythritol was synthesized and characterized as the tri-*p*-nitrobenzoate. Of the terminal units in the synthetic rhamnan 35% were furanose and 2,3-di-*O*-methyl-L-rhamnose constituted 75% of the dimethyl fraction indicating that the principal linkage was (1 → 4).

The classical methods for the determination of the structure of polysaccharides have included methylation and periodate oxidation. Separation of the derived methyl ethers has been facilitated by the advent of vapor phase chromatography (v.p.c.), but since the methyl ethers are normally converted to their glycosides prior to separation this introduces an added complication, as most sugars will give two glycosides and may give four (1). The retention times of isomeric glycosides do not always differ greatly, although compounds of varying degrees of methylation are easily separable. The present paper describes a method whereby a group of di-*O*-methylrhamnoses with similar chromatographic behavior may be converted by periodate oxidation and borohydride reduction into a mixture of C_3, C_4, C_5, and C_6 glycitols whose retention times are markedly different and whose separation is thus facilitated. A similar procedure enables the isomeric mono-*O*-methylrhamnoses to be resolved. Each methyl ether gives rise to a characteristic degradation product(s) which enables a mixture of five isomeric ethers to be analyzed rapidly and completely. These separations are described below.

In a similar way the application of the Smith periodate degradation gives isomeric and anomeric glycosides. It has already been shown that in certain cases such mixtures cannot be separated by paper chromatography or paper electrophoresis but may be readily resolved by v.p.c. as their trimethylsilyl ethers (2). These observations are now extended to the separation of anomeric and isomeric rhamnosyl glycosides.

The polysaccharide used in this study was a synthetic rhamnan prepared by the high temperature polymerization of L-rhamnose (3). By analogy with other polysaccharides prepared by this method it was anticipated that the rhamnan would have a highly branched structure and an appreciable proportion of furanosyl units (4). Hydrolysis of the methylated rhamnan would therefore give a mixture of all possible methyl ethers,

[1]*Presented at the 47th Chemical Institute of Canada Meeting, Kingston, Ontario, June 1964.*

furanose and pyranose. Similarly periodate degradation should give several rhamnosyl glycosides. The results obtained have confirmed this general structure of the rhamnan, which is therefore a useful substrate for model studies.

TABLE I

Paper chromatographic separation of L-rhamnose methyl ethers

Fraction	R_f	Color of spot	Weight (mg)	Components
1*a*	0.86	Violet	322	Trimethyl

4	0.1	Yellow-brown	20	Rhamnose

TABLE II

Identification of di-*O*-methyl-L-rhamnoses

Di-*O*-methyl ether	Reaction	Products
2,5-		1-Hydroxy-2-methoxypropane (I) + 2-*O*-methylglycerol (II)
3,5-		5-Deoxy-2,4-di-*O*-methyl-L-arabinitol (III)
	(*i*) BH_4^- (*ii*) IO_4^- (*iii*) BH_4^-	
2,3-		2,3-Di-*O*-methylerythritol (IV)
2,4-		2,4-Di-*O*-methyl-L-rhamnitol (VI)
3,4-		5-Deoxy-2,3-di-*O*-methyl-L-arabinitol (V)

The fully methylated rhamnan was hydrolyzed and the sugars separated by paper chromatography into groups depending on their degree of methylation, as shown in Table I. The 2,3,4- and 2,3,5-tri-*O*-methyl-L-rhamnoses were readily separated as their lactones by v.p.c. and their relative amounts showed that in the polymer 35% of the terminal units were furanose.

Rechromatography of the dimethyl fraction gave three subfractions 2*a*, 2*b* + 2*c*, and 2*d*. Part of fraction 2*d* was obtained pure and identified as 3,4-di-*O*-methyl-L-rhamnose. Electrophoresis of 2*a* indicated the 2,5- and 3,5-di-*O*-methyl ethers while 2*b* and 2*c* did not migrate and were therefore the 2,3- and 2,4-di-*O*-methyl ethers. None of these could be cleanly separated by paper chromatography and since in the past preparative paper electrophoresis had given poor recoveries, and anyhow would not be applicable to the latter pair, the following analytical scheme was adopted (Table II). Fraction 2*a* was reduced with borohydride, oxidized with periodate, and again reduced. The resulting mixture was subjected to v.p.c. Three components were obtained. The products I, II, and III (Table II) were collected separately and identified by the product obtained on demethylation (for I and II) or by the acetaldehyde formed by periodate oxidation of III after demethylation. Fractions 2*b* and 2*c* were similarly reacted and the fragments separated by v.p.c. to give compounds IV, V, and VI (Table II), the identities of which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

were deduced from the nature of the products obtained on demethylation. It was subsequently shown that if the original fraction 2 was reacted without division into subfractions each of the compounds I–VI was separable by v.p.c. (Fig. 1). It is thus clear that all the di-*O*-methylrhamnoses may be uniquely identified by this method. The fact that 2,3-di-*O*-methyl-L-rhamnose was the major component of this fraction indicates that (1 → 4) linkages predominate although all possible linkages occur in the polymer.

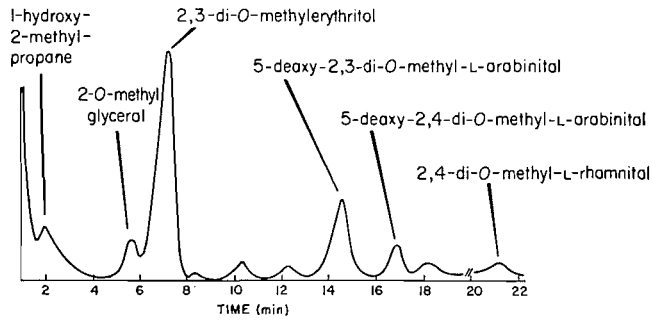

FIG. 1. Vapor phase chromatography of products from di-*O*-methyl-L-rhamnoses.

The mixture of mono-*O*-methylrhamnoses was analyzed by a similar series of reactions except that the free sugars were converted to their methyl glycosides before periodate oxidation. The ether bridge between the two oxidation fragments was cleaved by methanolysis and the products, after hydrolysis, reduced with borohydride. The mixture was then subjected to v.p.c. with the isolation of the products shown in Table III.

TABLE III

Identification of mono-*O*-methyl-L-rhamnoses

Methyl glycoside of mono-*O*-methyl-L-rhamnose		Products	Demethylation product (m.p. of *p*-nitrobenzaote)
2-	(*i*) IO_4^-	2-*O*-Methylglycerol + 1,2-dihydroxypropane	Glycerol (188–192°) + 1,2-dihydroxypropane (125–126°)
3-	(*ii*) MeOH/HCl (*iii*) H^+	3-*O*-Methyl-L-rhamnitol	L-Rhamnitol
4-	(*iv*) BH_4^-	1-Deoxy-3-*O*-methyl-D-erythritol + ethylene glycol	1-Deoxy-D-erythritol (109–110°) + ethylene glycol (148–150°)
5-		1-Deoxy-2-*O*-methyl-D-erythritol + ethylene glycol	

When the rhamnan was subjected to a Smith degradation and the products were analyzed by paper chromatography six distinct fractions were obtained and a seventh which showed considerable trailing. The nature of these fractions, two of which were reducing, is shown in Table IV. The identity of fractions 1, 2, and 4 was readily shown by the preparation of derivatives. Characterization of fraction 3 as a deoxypentose followed from the fact that periodate degradation of its methyl glycoside gave 1,2-ethanediol and 1,2-propanediol. Of greater interest in the present connection were fractions 5 and 6.

Hydrolysis of fraction 5 gave L-rhamnose and 1-deoxy-D-erythritol in equimolecular amounts indicating a glycoside while periodate oxidation and measurement of the formal-

TABLE IV

Paper chromatographic separation of Smith periodate degradation fragments

Fraction	R_g	Weight (mg)	Identity
1	4.48	230	1,2-Dihydroxypropane
2	3.98	257	1-Deoxy-D-erythritol
3	3.14	20	5-Deoxy-L-arabinose
4	2.16	23	L-Rhamnose
5	1.79	134	Rhamnosyl 1-deoxy-erythritols
6	1.30	58	Dirhamnosyl 1-deoxy-erythritols
7	0.90	25	Oligosaccharides

dehyde suggested that the major part of the 1-deoxy-D-erythritol was linked at C-2 and a minor amount at C-3. The remainder of fraction 5 was accordingly converted to its trimethylsilyl derivative and analyzed by v.p.c. (Fig. 2A). Three components were

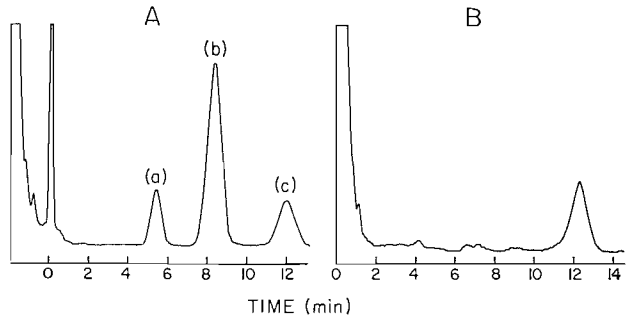

FIG. 2. A. Vapor phase chromatography of trimethylsilyl ethers of (*a*) 1-deoxy-3-*O*-(α-L-rhamnopyranosyl)-D-erythritol, (*b*) the β-anomer, (*c*) 1-deoxy-2-*O*-(β-L-rhamnopyranosyl)-D-erythritol. B. Vapor phase chromatography of trimethylsilyl ethers of L-Rha*p*-(1 → 4)-L-Rha*p*-(1 → 3)-1-deoxy-D-erythritol.

obtained 5*a*, 5*b* (major), and 5*c* and each formed a crystalline *p*-nitrobenzoate. On periodate degradation 5*c* yielded only 1,2-propanediol and hence this component must have been 1-deoxy-2-*O*-(β-L-rhamnopyranosyl)-D-erythritol with the β-linkage inferred from the optical rotation. Both 5*a* and 5*b* gave 1,2-propanediol and 1-deoxy-D-erythritol and on the basis of optical rotation and retention times (5) these components were believed to be 1-deoxy-3-*O*-(α-L-rhamnopyranosyl)-D-erythritol (5*a*) and the corresponding β-anomer (5*b*). The separation of these compounds is further evidence that v.p.c. of trimethyl silyl ethers is capable of separating isomeric and anomeric glycosides. The isolation of these compounds is also evidence that the rhamnan contained 5-*O*-L-rhamnopyranosyl-rhamnose units (5*c*) and 4-*O*-L-rhamnopyranosyl-rhamnose units, both α-linked (5*a*) and β-linked (5*b*).

Investigation of fraction 6 in a similar way showed it to contain L-rhamnose and 1-deoxy-D-erythritol in a 2:1 ratio with not more than 10% of the erythritol residues substituted at C-2. Periodate degradation gave 1,2-propanediol and 1-deoxy-D-erythritol in approximately a 1:2 ratio together with a trace of rhamnose. Conversion to the trimethylsilyl ether and v.p.c. gave only one major component (Fig. 2B) which on desilylation and periodate oxidation gave no formaldehyde. The principal component of this fraction was therefore

L-Rha*p*-(1 → 4)-L-Rha*p*-(1 → 3)-1-deoxy-D-erythritol.

The preparation of 1-deoxy-D-erythritol needed as a standard in these studies does not appear to have been described and it was accordingly synthesized from methyl α,β-L-rhamnofuranosides.

The results reported have demonstrated that periodate degradation of methylated sugars followed by v.p.c. is a quick and convenient method for the analysis and characterization of groups of isomeric sugars. The selective degradation to fragments of varying molecular weight enhances the differences in retention times and by using the glycitols complications of multiple peaks for the same sugar are avoided. The method is capable of extension to other groups of sugars but is particularly convenient with 6-deoxy compounds and will therefore be of use for studies on seaweed and blood-group polysaccharides. If suitable crystalline derivatives of all the cleavage products were known it would be possible to characterize directly each of the v.p.c. fractions. Lack of such derivatives necessitated the demethylation step. As yet there is no data available on the quantitative aspects of this step and hence this method of analysis may only be used qualitatively. As far as the fragments from a Smith degradation are concerned there is an increasing body of evidence to show that the reaction produces a greater number of fragments than can be separated by existing techniques. The combination of trimethylsilyl ethers and v.p.c. is a welcome step forward but methods must be developed for the separation of higher oligomers if full advantage is to be taken of this method of degradation.

EXPERIMENTAL

General and analytical methods have been described previously (2). Chromatograms were run on Whatman 1 paper using ethyl acetate – acetic acid – water (8:2:2) unless otherwise noted. R_g refers to glucose = 1.0.

Analysis of the Rhamnan

Hydrolysis of the polysaccharide gave an almost quantitative yield of L-rhamnose monohydrate, m.p. 92–93° and $[\alpha]_D$ 8.1° (*c*, 2 in water). Partial hydrolysis of the rhamnan with 0.1 *N* HCl at 50° gave 9% rhamnose (1 h), 12% (2 h), 16% (4 h), and 20% (8 h). Estimation of the formaldehyde produced on periodate oxidation of the reduced rhamnan gave a D.P. of 40 on the assumption that each rhamnitol end group gave 1 mole of formaldehyde. Borohydride reduction of the oxidized polysaccharide followed by hydrolysis gave L-rhamnose, 1,2-propanediol (R_g 4.48, di-*p*-nitrobenzoate, m.p. 124–126°), and 1-deoxy-D-erythritol (R_g 3.98, tri-*p*-nitrobenzoate, m.p. 108–109°) in a 1:7:6 molar ratio.

Methylation of Rhamnan

The rhamnan (1.50 g) was dissolved in *N,N*-dimethylformamide and methylated by Kuhn's procedure. The partially methylated product was reacted with Purdie's reagents for 120 h to give a pale-yellow gum (1.55 g) which showed no hydroxyl absorption in the infrared and had $[\alpha]_D$ −24.6° (*c*, 4.2 in acetone). The methylated polysaccharide was so soluble that no fractionation could be achieved with chloroform – petroleum ether mixtures. The methylated polysaccharide was hydrolyzed with sulfuric acid (6) and the brown, water-insoluble substance which separated was subjected to methanolysis and hydrolysis to yield a further quantity of methylated rhamnoses. The ratio of tri:di:monomethyl:free rhamnose was determined by the phenol – sulfuric acid method and was found to be 23:58:19:2. The mixture was resolved on Whatman 3MM paper using butanone–water azeotrope into the four fractions shown in Table I.

Trimethyl Fraction

This fraction (300 mg) was dissolved in water (20 ml) and oxidized with bromine (3 ml) in the presence of lead carbonate (2 g). After 48 h, excess bromine was removed by aeration, insoluble lead salts were removed by filtration, and the filtrate passed through a column of cation exchange resin. The effluent was evaporated and the sirupy product heated at 75–80° *in vacuo* to achieve lactonization. The product was analyzed by gas chromatography (Table V). The 2,3,4-tri-*O*-methyl-L-rhamnonolactone crystallized in the collection tube, remelted at 41°, and had $[\alpha]_D$ −132° → −78° (*c*, 0.3 in water); lit. (7) m.p. 40–41°, $[\alpha]_D$ −138° → −78° (water). The other component did not crystallize and was reacted with phenylhydrazine. A poor yield of 2,3,5-tri-*O*-methyl-L-rhamnonophenylhydrazide, m.p. 156–159°, was obtained; lit. (8) m.p. 160°.

Apparatus: Aerograph A90-P2 and F and M 800.
Column: 3 ft by 0.25 in. i.d., 10% versamide on chromosorb W.
Retention times quoted are relative to the solvent peak.
*Column 150°; helium flow 80 ml/min.
†Column 80–190° at 8°/min; helium flow 95 ml/min.
‡Column 80–200° at 8°/min; raised to 230° after 16 min; helium flow 95 ml/min; using these conditions a mixture of I–VI was successfully separated.
§Column 140–240° at 10°/min; helium flow 95 ml/min.

Dimethyl Fraction

Fraction 2a

Rechromatography of fraction 2 gave the fastest moving material (2*a*) substantially pure and electrophoresis (0.1 *M* sodium borate, 2 h at 450 V) showed approximately equal amounts of two components with M_G values 0.05 and 0.39 corresponding with 2,5- and 3,5-di-*O*-methyl-L-rhamnoses. The mixture (90 mg) was dissolved in water (20 ml) and treated with sodium borohydride (150 mg). The glycitols were oxidized with periodate and the yield of formaldehyde (6.0 mg) indicated about 35 mg of 3,5-di-*O*-methyl-L-rhamnitol. After the removal (barium carbonate) of periodate and iodate sodium borohydride was added and 16 h later the solution was acidified with sulfuric acid and boiled. Barium carbonate was added and the filtrate evaporated to a thin sirup which was extracted with acetone. Removal of the solvent left a sirup which was analyzed by gas chromatography (Tables II and V). Three products were collected and each was characterized after demethylation by heating with hydrobromic acid (45%) for 35 min (9). The product from *compound I* was 1,2-dihydroxypropane (di-*p*-nitrobenzoate, melting point and mixed melting point 125–126°) and that from *compound II* was glycerol (tri-*p*-nitrobenzoate, melting point and mixed melting point 189–192°). The product from *compound III* (32 mg) was oxidized with periodate and gave formaldehyde (7.1 mg). Periodate and iodate were removed with barium carbonate and the solution was saturated with sodium bisulfite. The solution was cooled to 5° and the addition compound was collected and decomposed with aqueous alcoholic hydrochloric acid. This solution was then reacted with semicarbazide hydrochloride and sodium acetate (10). The reaction mixture was extracted with chloroform and evaporation of the solvent gave acetaldehyde semicarbazone, melting point and mixed melting point 160–162°.

Fraction 2d

From the second separation on paper of fraction 2*a* described above part of the slowest moving portion was collected separately to give fraction 2*d* and the intermediate material gave fractions 2*b* and 2*c* (which could not be sharply separated) together with the remainder of 2*d*. Paper electrophoresis of these fractions indicated that 2*b* and 2*c* were non-migrating while fraction 2*d* had an M_G value of 0.36. Quantitative estimation showed that fraction 2*d* constituted 7–8% of fraction 2. A portion of fraction 2*d* (18 mg) was reacted with 2,4-dinitrophenylhydrazine to give 3,4-di-*O*-methyl-L-rhamnose 2,4-dinitrophenylhydrazone, m.p. 166–168° (decomp.), $[\alpha]_D$ 75° (*c*, 0.5 in 1,4-dioxane); lit. (11) m.p. 170° (decomp.), $[\alpha]_D$ 75.6° (*c*, 1 in 1,4-dioxane).

Fractions 2b and 2c

This material (550 mg) was dissolved in water (50 ml) and reduced with sodium borohydride (0.9 g). Periodate oxidation gave a small amount of formaldehyde and the product was again reduced. Gas chromatography of the resulting mixture showed three main components (Tables II and V) of which one (IV) was present as the major constituent. The identity of these components is shown in Table II and is based

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

on the following evidence. *Compound IV* was demethylated and the product (250 mg) gave erythritol tetra-*p*-nitrobenzoate melting point and mixed melting point 250–252°. *Compound V* was demethylated and the product (45 mg) gave formaldehyde (9.9 mg) on oxidation with periodate. Acetaldehyde was recovered from the oxidation mixture and converted to acetaldehyde semicarbazone melting point and mixed melting point 160–162°. *Compound VI* was demethylated and the product (38 mg) was chromatographically identical with L-rhamnitol. Reaction with acetic anhydride in pyridine gave L-rhamnitol pentaacetate, $[\alpha]_D$ ca. 2° (*c*, 2 in chloroform), but which failed to crystallize.

Monomethyl Fraction

A small amount (13 mg) of fraction 3*a* was obtained pure by rechromatographing fraction 3 on Whatman 1 paper. Reaction with phenylhydrazine gave 5-*O*-methyl-L-rhamnose phenylosazone, m.p. 120–123°; lit. (12) m.p. 123–124°.

The remainder of fraction 3 (195 mg) was refluxed for 6 h with methanolic hydrogen chloride (1%) and the glycosides were oxidized with periodate followed by methanolysis, hydrolysis, and borohydride reduction. A portion of the product was examined by gas chromatography (Table V) which indicated five components. The bulk of the product was demethylated and examined by paper chromatography. The compounds found, their derivatives, and their relation to the monomethylrhamnoses are shown in Table III.

Smith Periodate Degradation

To the rhamnan (2.04 g) was added periodic acid (0.5 *M*, 45 ml) and the solution diluted to 100 ml. The oxidation was carried out in the dark at 5° for 100 h (1.1 mole IO_4^- per rhamnose unit) and the solution, freed from inorganic ions, was extracted with ether. The ether extract yielded acetaldehyde characterized as the semicarbazone m.p. 158–160°. The aqueous solution was reduced with borohydride (1.8 g, 24 h) and after removal of borate, hydrolysis (0.1 *N* HCl, 22°, 8 h), and deionization, chromatography on Whatman 3MM paper gave the products listed in Table IV and fractions 1, 2, and 4 were characterized as shown. Fraction 3 was reducing and was believed to be a methyl pentose, presumably 5-deoxy-L-arabinose, on the following evidence. Refluxing with 1% hydrogen chloride in methanol gave a nonreducing product which was oxidized with periodate followed by borohydride reduction. Hydrolysis, deionization, and chromatographic separation gave a 1:1 molar ratio of 1,2-ethanediol (di-*p*-nitrobenzoate, m.p. 142–143°) and 1,2-propanediol (di-*p*-nitrobenzoate, m.p. 125–126°).

Vapor Phase Chromatography of Fractions 5 and 6

Fraction 5 contained some reducing material, presumably L-rhamnose, which was oxidized by aqueous bromine in the presence of lead carbonate. Deionization gave a nonreducing product (126 mg) from a portion (40 mg) of which there was obtained by hydrolysis a 1:1 molar ratio of L-rhamnose (21 mg, phenylhydrazone, melting point and mixed melting point 157–158°, $[\alpha]_D$ 43° (*c*, 2.5 in water)) and 1-deoxy-D-erythritol (13.7 mg, tri-*p*-nitrobenzoate, melting point and mixed melting point 109–110°, $[\alpha]_D$ 2° (*c*, 2 in pyridine)). Oxidation of the rhamnoside with 0.1 *M* periodic acid at 5° for 24 h gave formaldehyde. Hydrolysis of the borohydride-reduced product gave a 5:3 molar ratio of 1,2-propanediol (di-*p*-nitrobenzoate, m.p. 125–126°) and 1-deoxy-D-erythritol (tri-*p*-nitrobenzoate, m.p. 108–110°).

A portion of the rhamnoside (50 mg) was reacted in pyridine (1 ml) with hexamethyldisilazane (0.1 ml) and trimethylchlorosilane (0.2 ml). The product was examined by vapor phase chromatography on a 4 ft column (0.25 in. i.d.) packed with 20% GESF-96 on 60/80 mesh firebrick with a helium flow rate of 90 ml/min at 180°. Three peaks were obtained (Fig. 2A) and the corresponding substances were separately condensed in glass tubing and desilylated by boiling overnight in 80% ethanol to give components 5*a*, *b*, *c*, in the approximate ratio of 1:4:1. Component 5*a* had $[\alpha]_D$ 15° (*c*, 2 in water) and when a portion (1.7 mg) was oxidized with periodic acid (0.1 *M*, 15 ml) no formaldehyde was detected. After reduction and hydrolysis 1,2-propanediol and 1-deoxy-D-erythritol were found in a 1:1 molar ratio. The rest of component 5*a* (11 mg) was reacted in pyridine with *p*-nitrobenzoyl chloride to give 1-deoxy-3-*O*-(α-L-rhamnopyranosyl)-D-erythritol penta-*p*-nitrobenzoate, m.p. 155–158°, $[\alpha]_D$ 12° (*c*, 2 in pyridine).

Anal. Calcd. for $C_{45}H_{35}N_5O_{22}$: N, 7.04. Found: N, 7.07.

Component 5*b* showed no measurable optical activity and was oxidized as described for 5*a*. The two polyols obtained from 5*a* and 5*b* were pooled and characterized as their *p*-nitrobenzoates. Reaction of a portion of 5*b* (10 mg) with *p*-nitrobenzoyl chloride gave 1-deoxy-3-*O*-(β-L-rhamnopyranosyl)-D-erythritol penta-*p*-nitrobenzoate, m.p. 181–183°.

Anal. Calcd. for $C_{45}H_{35}N_5O_{22}$: N, 7.04. Found: N, 7.05.

Component 5*c* (7 mg) was oxidized with periodic acid (0.1 *M*, 20 ml) and gave formaldehyde (0.83 mg). Only 1,2-propanediol was found on reduction and hydrolysis. Reaction of a portion of 5*c* with *p*-nitrobenzoyl chloride gave 2-*O*-(L-rhamnopyranosyl)-1-deoxy-D-erythritol penta-*p*-nitrobenzoate, m.p. 191–193°.

Anal. Calcd. for $C_{45}H_{35}N_5O_{22}$: N, 7.04. Found: N, 7.15.

Fraction 6 gave rhamnose and 1-deoxy-D-erythritol in a 2:1 molar ratio on hydrolysis. Oxidation with periodic acid (0.1 *M*, 15 ml) of a portion (10 mg) gave some formaldehyde (0.075 mg). Barium carbonate was added and the filtrate reduced with sodium borohydride (30 mg). The hydrolysate of the polyalcohol gave 1,2-propanediol and 1-deoxy-D-erythritol in a 1:2 molar ratio. A trace of L-rhamnose was also detected.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The remainder of the glycoside (30 mg) was reacted in pyridine (0.5 ml) with hexamethyldisilizane (0.3 ml) and trimethylchlorosilane (0.6 ml) for 1 h at 40°. Using the same conditions as described for fraction 5 only one peak was obtained. A portion (20 mg) of the desilylated product was oxidized with periodic acid (0.1 *M*, 15 ml) and no formaldehyde was detected. On reduction and hydrolysis 1,2-propanediol and 1-deoxy-D-erythritol were obtained in a 1:2 molar ratio.

Fraction 7 was thought to be heterogeneous because of considerable streaking on chromatograms. Hydrolysis of a portion (10 mg) gave L-rhamnose and 1-deoxy-D-erythritol in a molar ratio of about 4:1. Periodate oxidation of a sample (10 mg) gave formaldehyde (0.21 mg) indicating the presence of some C-2 substituted 1-deoxy-D-erythritol units. Mild hydrolysis of the polyalcohol with hydrochloric acid (0.1 *N*) at room temperature for 8 h gave 1,2-propanediol, 1-deoxy-D-erythritol and a nonreducing substance with R_g 1.80 and hence presumed to be similar to fraction 5. Complete hydrolysis of the polyalcohol gave 1,2-propanediol, 1-deoxy-D-erythritol, and L-rhamnose in a molar ratio of 6:4:1.

Synthesis of 1-deoxy-D-erythritol

L-Rhamnose (2.5 g) was converted to the diethyl dithioacetal, m.p. 133–135°, by a published method (13, 14) and this was converted to the methyl α,β-L-rhamnofuranoside mixture (2.3 g) by the method of Green and Pacsu (15). The furanoside mixture was oxidized with periodic acid at 5°. One mole was consumed. Periodate and iodate were precipitated by the addition of barium carbonate and sodium borohydride (1.5 g) was added to the filtrate. The reduction was allowed to proceed for 16 h at room temperature and then the solution was acidified with hydrochloric acid and refluxed for 6 h. Borate was removed by distillation with methanolic hydrogen chloride and inorganic salts were removed by ion exchange. On evaporation an oily residue was obtained which was homogeneous when examined by paper chromatography and had R_g 3.9.

A portion of the product was further purified by vapor phase chromatography and collected as a clear oily liquid having $[\alpha]_D$ 7.4° (*c*, 2 in methanol). A portion (40 mg) was converted to 1-deoxy-D-erythritol tri-*p*-nitrobenzoate which on recrystallization from acetone had m.p. 109–110° and $[\alpha]_D$ 2° (*c*, 2 in pyridine).

Anal. Calcd. for $C_{25}H_{19}N_3O_{12}$: N, 7.60. Found: N, 7.68.

ACKNOWLEDGMENTS

This investigation was supported by grant number GM 07652 from the Division of General Medical Sciences, Public Health Services, U.S.A. We are grateful to Miss J. Hunter for skillful technical assistance and to Dr. P. Mora for providing the rhamnan.

LE SPECTRE INFRAROUGE DE L'OZONIDE D'AMMONIUM ET LA STRUCTURE DE L'ION O_3^-

KAZIMIERA HERMAN ET PAUL A. GIGUÈRE
Département de Chimie, Université Laval, Québec, Québec

Reçu le 28 decembre 1964

RÉSUMÉ

L'oxydation ménagée de l'ammoniac solide par l'ozone gazeux à basse température donne comme intermédiaire l'ozonide d'ammonium selon l'équation:

$$4NH_3 + 3O_3 \rightarrow 2NH_4O_3 + NH_4NO_3.$$

En élevant la température le solide rouge-orangé apparaît vers -130 °C; il atteint sa concentration maximum vers $-115°$, et à $-90°$ il est complètement décomposé. Les spectres infrarouges montrent, outre les bandes caractéristiques des ions NH_4^+ et NO_3^-, deux fortes bandes d'absorption à 800 et 1 140 cm^{-1} et deux autres assez faibles à 1 260 et 2 053 cm^{-1} qui doivent appartenir aux vibrations ν_2, ν_3, ν_1 et $\nu_1 + \nu_2$ de l'ion O_3^-. Ces fréquences sont nettement plus élevées que les fréquences correspondantes de la molécule d'ozone, ce qui indique des liaisons plus fortes dans l'ion, contrairement aux prévisions. Par analogie avec l'ozone on prévoit pour l'ion O_3^- des longueurs de liaisons de 1.22 Å et un angle au sommet d'environ 100°.

ABSTRACT

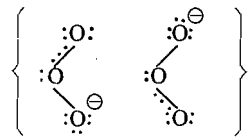
The slow oxidation of solid ammonia by gaseous ozone at low temperature proceeds through an unstable intermediate, ammonium ozonide, after the equation

$$4NH_3 + 3O_3 \rightarrow 2NH_4O_3 + NH_4NO_3.$$

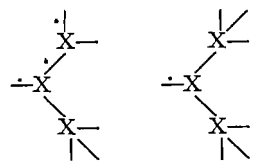
The red solid appears on warming around -130 °C, reaches maximum concentration at about $-115°$, and is all decomposed by $-90°$. The infrared spectra show, besides the characteristic bands of the NH_4^+ and NO_3^- ions, two strong bands at 800 and 1 140 cm^{-1}, and two faint ones at 1 260 and 2 053 cm^{-1} which must belong to the ν_2, ν_3, ν_1 and $\nu_1 + \nu_2$ modes of the O_3^- ion. These frequencies are appreciably higher than the corresponding ones of the ozone molecule, which indicates a stronger bonding in the ozonide ion contrary to most predictions. By analogy with ozone the bond lengths in the ion are estimated to be 1.22 Å and the interbond angle, about 100°.

INTRODUCTION

L'existence des ozonides de métaux alcalins est maintenant bien établie à la suite des résultats tant de l'analyse chimique (1, 2) que de mesures physiques par les méthodes magnétiques (1, 3, 4) et spectroscopiques (4, 5). A cause de l'intérêt qu'elle présente pour les théories électroniques de la valence la structure de l'ion O_3^- a fait l'objet de plusieurs spéculations. Ainsi Kazarnovskii (1) a représenté cette structure comme un hybride de résonance entre deux formules canoniques avec une liaison à trois électrons et peut-être aussi une troisième avec liaisons simples seulement, ce qui l'a conduit à prédire des longueurs approximatives de liaison $r_{O-O} = 1.38$ Å. En tant que molécule triatomique avec 19 électrons de valence, l'ion O_3^- devrait avoir une structure triangulaire (6)—tout comme la molécule ClO_2 (7)—ce qui a été confirmé par le spectre de résonance de spin électronique (3). Par comparaison avec la série des molécules et ions NO_2^+, NO_2, NO_2^- et NO_2^{2-}, et d'après les données bien connues de la molécule d'ozone, Smith (8) a prévu les valeurs suivantes pour l'ion : $r = 1.34 \pm 0.05$ Å et $\theta = 115 \pm 5°$. Pour sa part Pauling (9) entrevoit des valeurs du même ordre ($r = 1.35$ Å et $\theta = 108°$) en se basant sur les deux structures en résonance,



selon la méthode des liaisons de valence, tandis que Green (10) utilise la méthode des orbitales moléculaires et représente ainsi les structures canoniques possibles.



La première, dans laquelle l'ordre de liaison est de $2\frac{1}{2}$, serait la plus importante dans le cas de l'ion ozonide.

Par contre, les données expérimentales sont peu abondantes, sans doute à cause des difficultés de préparation et de l'instabilité chimique des ozonides. Les auteurs russes (1) ont mesuré les premiers le moment magnétique de KO_3 (1.63 magnétons de Bohr, soit très près de la valeur théorique 1.78 pour un électron célibataire), ainsi que la diffraction des rayons X par la méthode des poudres. Ce travail préliminaire a révélé une ressemblance marquée des réseaux cristallins de KO_3 et de KN_3, ce qui semblait indiquer une structure linéaire de l'ion O_3^-. Toutefois une analyse subséquente des figures de diffraction a jeté des doutes sur cette interprétation ; entre autre l'absence des réflexions (121) dans les diagrammes de poudres pouvait selon Zhdanov et Zvonkova (11) être due à une structure triangulaire. Plus récemment encore, alors que le présent travail était en cours, une étude plus poussée de la structure cristalline de KO_3 est parue (12) donnant les coordonnées atomiques suivantes pour l'anion : $r = 1.19$ Å, $\theta = 100°$. Cependant, comme le font remarquer les auteurs, la précision de ces résultats est assez faible à cause de la diffraction excessive par les ions potassium.

Il nous a semblé que la spectroscopie infrarouge était susceptible d'apporter de nouvelles données sur cet intéressant problème. La difficulté, évidemment, résidait dans la préparation d'un échantillon convenable. De nombreuses tentatives pour obtenir un mince film de KO_3 par ozonisation soit de KOH anhydre à 0° (13), soit de KO_2 (14) suivie d'une extraction à l'ammoniac liquide se sont toutes soldées par un échec à cause de la réactivité extrême de ces composés. C'est alors que les récents succès de Solomon et ses collaborateurs (5) dans la préparation de l'ozonide d'ammonium nous ont conduits à étudier ce composé qui offre le grand avantage de pouvoir être synthétisé directement dans la cellule d'absorption à partir des réactifs gazeux à basse pression, et sans manipulation subséquente. Des essais préliminaires ont montré que, malgré son instabilité thermique, il était possible d'obtenir le spectre infrarouge de ce composé en contrôlant rigoureusement la température.

PARTIE EXPÉRIMENTALE

L'ozone a été préparé sur place par dissociation de l'oxygène sous basse pression dans une décharge à micro-ondes. Afin de prévenir toute contamination du premier produit par des oxydes d'azote, nous sommes partis d'oxygène ultra-pur provenant de la décomposition catalytique du peroxyde d'hydrogène (solution à 40% de Becco) soigneusement dégazé sous vide dans le tube A (Fig. 1). Le catalyseur, une fine toile de platine métallique, était suspendu par un fil enroulé sur une tige de verre montée dans l'axe d'un joint rodé B.

Un petit disque de verre fritté supportant des billes de verre dans l'ampoule C servait à arrêter les gouttelettes de liquide entraînées dans le courant gazeux, tandis que deux pièges à azote liquide D et E débarrassaient l'oxygène de toute trace d'humidité, précaution essentielle pour obtenir un bon rendement en ozone (15).

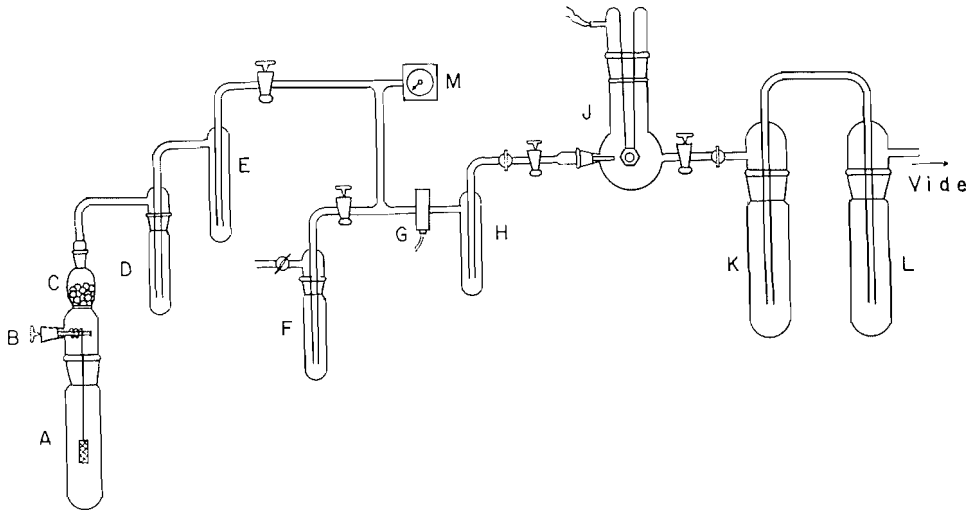

FIG. 1. Schéma de l'appareil utilisé pour préparer l'ozonide d'ammonium.

La pression d'oxygène telle qu'indiquée par le manomètre mécanique M (General Electric, Molecular Vacuum Gage, C-148 388) était amenée à environ 1 mm Hg en ajustant le taux de décomposition du peroxyde d'hydrogène soit en faisant varier la température, soit en manipulant le catalyseur de platine. L'énergie du générateur de micro-ondes ("Raytheon Microtherm"), opérant à 2 400–2 500 Mc, était introduite par le résonateur G placé sur le tube latéral d'un piège à azote liquide H. L'expérience nous a appris qu'il ne se forme pas d'ozone dans le piège quand l'oxygène dissocié est introduit par le tube central, sans doute parce que les atomes se recombinent avant d'atteindre la paroi froide. Cette observation rejoint les conclusions de Schiff (16) et de Ruehrwein et Hashman (17) sur la nécessité d'une température suffisamment basse pour synthétiser l'ozone avec ce genre de décharge électrique. Pour la même raison, il fallait limiter l'énergie (à environ 60 W) afin de prévenir l'échauffement excessif et la désintégration rapide du tube de Pyrex. Une fois allumée (avec une bobine de Tesla) la décharge à micro-ondes était très stable sous une pression voisine de 1 mm Hg. Après quelques minutes l'ozone liquide apparaissait sous forme d'une mince couronne bleue dans le piège au niveau de l'azote liquide. Eventuellement le film liquide glissait jusqu'au fond où il formait une grosse goutte.

L'ammoniac anhydre provenant d'une bouteille (Matheson, 99.99% pur) était liquéfié tel quel dans un piège à carboglace F, d'où il pouvait être distillé au besoin sous basse pression (10^{-2} mm Hg) dans la cellule à absorption J. Celle-ci était en verre, du type courant (18), avec un piège central fermé par un joint verre-métal de Kovar et bloc de cuivre dans lequel était encastré le disque porteur de l'échantillon. Au début ce dernier était en chlorure de sodium comme les fenêtres externes, mais à cause de l'attaque par les réactifs il dut être remplacé par des disques de verres transparents en infrarouge, Eastman Kodak, Irtran-2 (jusqu'à 700 cm^{-1}) ou Irtran-4 (jusqu'à 500 cm^{-1} environ), qui ont l'avantage de résister à la plupart des substances corrosives ainsi qu'aux brusques variations de température. Le seul inconvénient de ces matériaux était leur coloration jaune ; en effet il devenait difficile d'observer la formation ou la disparition de la couleur rouge due à l'ozonide. On pouvait suivre la température de l'échantillon à 1° près au moyen d'un petit thermocouple cuivre–constantan inséré entre le disque porteur et le bloc de cuivre et un potentiomètre de précision (Leeds & Northrup, modèle 8662). La pompe à vide mécanique était protégée par deux pièges à azote liquide K et L montés en série par mesure de précaution contre les explosions (19). Dans le même but toute la verrerie utilisée était soigneusement nettoyée avec de l'acide sulfurique fumant ; les robinets et les rodages étaient lubréfiés avec une graisse de silicone (Dow Corning, High-Vacuum Grease). Nous n'avons jamais observé au cours de ce travail d'explosion ni de décomposition violente des ozonides.

On commençait par déposer un mince film d'ammoniac sur le disque central de la cellule d'absorption en contrôlant la pureté et l'épaisseur par son spectre infrarouge. Après avoir admis l'ozone gazeux, la cellule était détachée du montage, grâce à des joints rodés sphériques, et installée dans le spectromètre à infrarouge (Perkin-Elmer, modèle 12-C). Une fois l'azote liquide évaporé, la température de l'échantillon montait au rythme de 2 °C par minute.

RÉSULTATS

Des essais préliminaires ont montré que les premiers signes de coloration jaune du film d'ammoniac coïncidaient avec l'apparition d'une nouvelle bande d'absorption vers 800 cm^{-1} et la déformation, du côté des hautes fréquences, de la bande de NH_3 solide vers 1 055 cm^{-1} (20). En conséquence ces deux régions furent étudiées soigneusement en fonction de la température. Les écarts de température indiqués dans la Fig. 2 viennent de ce que la vitesse de balayage du spectromètre était assez lente par rapport au taux de réchauffement de l'échantillon. En bref, on observe les phénomènes suivants : au début le spectre ne montre que la forte bande de l'ammoniac cristallin à 1 055 cm^{-1}. La pression partielle de l'ozone gazeux est trop basse et le parcours optique trop court (10 cm environ) pour déceler ses bandes d'absorption. Les deux nouvelles bandes qui apparaissent à 800 et 1 140 cm^{-1} vers -150 °C augmentent d'intensité parallèlement avec le degré de coloration rouge-orangé des produits de la réaction. Peu après on voit poindre l'une des bandes de l'ion NO_3^- à 827 cm^{-1}, l'autre vers 1 085 cm^{-1} (21) étant alors masquée

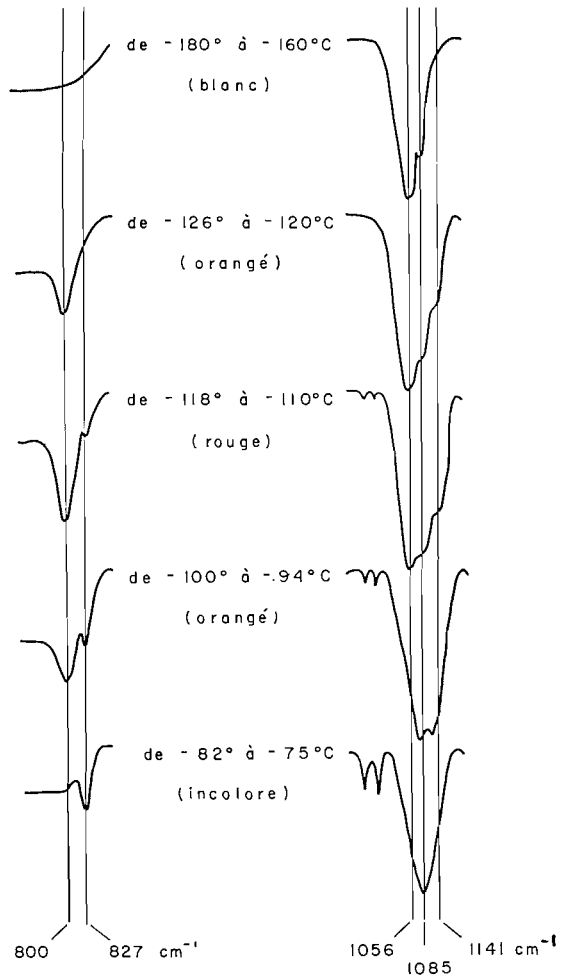

FIG. 2. Evolution des bandes d'absorption en infrarouge vers 9 et 12 μ dans le système $NH_3 + O_3$ entre $-180°$ et -75 °C.

par la forte absorption de NH_3 solide. Au fur et à mesure que celle-ci diminue par suite de la réaction le maximum d'absorption à cet endroit se déplace de 1 055 vers 1 085 cm^{-1}. Concurremment la chaleur de la réaction volatilise une partie de l'ammoniac, d'où le doublet à 932 et 968 cm^{-1}.

Comme il était souhaitable d'observer tout le spectre de vibration (de 3 à 15 μ) du système au moment où la concentration en ozonide d'ammonium a atteint son maximum, nous avons cherché à arrêter la réaction en refroidissant brusquement. Cette opération s'est avérée difficile à cause de l'inertie calorifique de la cellule. En effet si on ajoutait de l'azote liquide dans le piège de la cellule alors que la concentration en ozonide était appréciable, soit vers $-125°$, la réaction continuait et l'ozonide se décomposait presque entièrement avant que l'échantillon ne commence à se refroidir à cause de la mauvaise conductibilité thermique du support (Irtran). Par contre si on refroidissait plus tôt, la réaction s'arrêtait prématurément par suite de la condensation de l'ozone sur la partie supérieure du piège. Pour obvier à cet inconvénient il a fallu entourer ce dernier, de même que le bloc de métal, d'un manchon de Teflon, un bon isolant thermique et, en même temps, parfaitement inerte vis-à-vis de l'ozone et de l'ammoniac. C'est ainsi qu'a pu être obtenu le spectre d'absorption (Fig. 3) du système brusquement refroidi de $-115°$ à $-190°$. En plus des bandes déjà mentionnées on y relève à 1 620 cm^{-1} celle de l'ammoniac

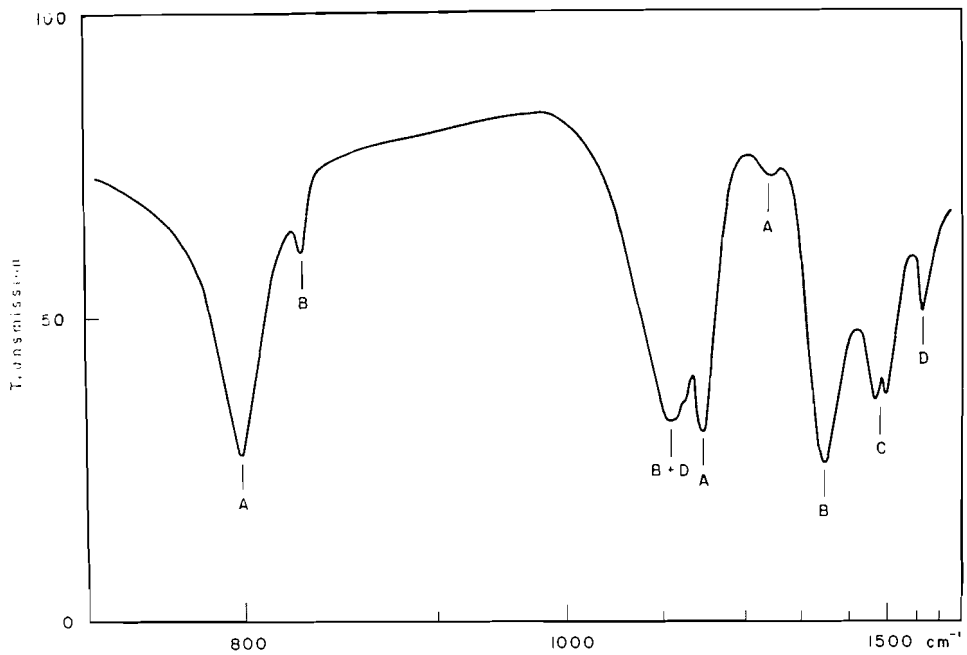

FIG. 3. Spectre infrarouge entre 600 et 1 800 cm^{-1} des produits de la réaction entre l'ozone gazeux et l'ammoniac solide à -115 °C stabilisés à $-190°$: A, O_3^-; B, NO_3^-; C, NH_4^+; D, NH_3.

solide qui n'a pas encore réagi avec l'ozone, ainsi que celles du nitrate d'ammonium à 1 350 et 1 420–1 490 cm^{-1}. Signalons en passant que les maxima d'absorption rapportés ici pour ce composé ne correspondent pas exactement aux données de la littérature (21). Les différences s'expliquent par la nature métastable du produit de la réaction qui ne doit point avoir de structure cristalline régulière; effectivement son apparence est celle d'un verre incoloré.

Enfin un pic assez faible a été noté à 2 053 cm^{-1} qui ne saurait appartenir aux espèces NH_3 ou NH_4NO_3. Comme son intensité varie de la même façon que pour les nouvelles bandes à 800 et 1 140 cm^{-1}, il doit s'agir d'une harmonique ou d'une combinaison. Des diverses possibilités, soit (*a*) le double de la fréquence 1 140 cm^{-1}, (*b*) une combinaison de celle-ci avec une autre de l'ordre de 930 cm^{-1} ou encore, (*c*) une combinaison de la fréquence 800 cm^{-1} avec une autre d'environ 1 260 cm^{-1}, c'est cette dernière qui s'est avérée correcte. En effet une analyse point par point de la courbe d'absorption dans la région de 8 μ a permis de mettre en évidence un pic très faible à cet endroit. Au contraire la région de 11 μ est toujours apparue libre de toute absorption sélective, même dans des films assez épais. L'intensité relative des nouvelles bandes est indiquée entre parenthèses dans le Tableau I.

TABLEAU I

Comparaison des données spectroscopiques et structurales

		Ozone	Ion ozonide
Fréquences (cm^{-1})	ν_1	1 120 (1)*	1 260 (0.2)
	ν_2	704 (5)*	800 (10)
	ν_3	1 050 (10)*	1 140 (5)
Constantes de force de rappel ($\times 10^{-5}$ dynes cm^{-1})	k_1	5.70†	6.5?
	k_{α/l^2}	1.28†	1.5?
Longueur de liaisons (Å)	r_{O-O}	1.278 ± 0.002	1.22
Angle au sommet	α	116°40′ ± 30′	100°?

*Pour l'ozone solide (23).
†D'après le spectre de micro-ondes (29, 30).

DISCUSSION

L'attribution des nouvelles bandes aux vibrations de l'ion O_3^- ne fait pas de doute. En effet, leur comportement en fonction de la température suit rigoureusement l'évolution de la couleur rouge-orangé caractéristique des ozonides (4, 5). Par ailleurs, les seules autres molécules qui pourraient se former dans ce système et montrer des bandes d'absorption dans la même région sont les oxydes d'azote NO_2, N_2O_3, N_2O_4 et N_2O_5. Mais aucune de ces molécules n'a de fréquences fondamentales correspondant exactement aux présentes (22). De plus leurs propriétés physiques, couleur, point de fusion ou de sublimation, etc. ne coïncident aucunement avec celles de l'ozonide d'ammonium. L'ensemble des observations rapportées plus haut peut s'expliquer parfaitement grâce au schéma suivant:

[1] $$4NH_3 + 3O_3 \rightarrow 2NH_4O_3 + NH_4NO_3$$

[2] $$2NH_4O_3 \rightarrow NH_4NO_3 + 2H_2O + \tfrac{1}{2}O_2$$

Il và sans dire que ces équations ne représentent que la réaction globale. On peut imaginer que le premier acte est la décomposition de l'ozone, suivie de l'attaque de l'ammoniac par l'atome d'oxygène avec formation de diverses espèces transitoires ; NH_3O, NH_2OH, HNO_2, HNO_3, etc. La réaction de décomposition [2] avait déjà été démontrée par voie chimique (5).

Par comparaison avec les fréquences fondamentales de l'ozone (Tableau I) la bande à 800 cm^{-1} doit appartenir au mode de déformation ν_2 ; elle est certainement trop basse pour une vibration de valence O—O. Dans H_2O_2, où la liaison est essentiellement simple, cette vibration se trouve à 880 cm^{-1}. D'ailleurs un examen minutieux du spectre de l'ozonide jusqu'à 600 cm^{-1} n'a révélé aucune autre absorption pouvant provenir d'un mode de déformation de basse fréquence. A noter que le spectre des ozonides dans le visible (4) montre un maximum à 4 500 Å et des pics secondaires décalés du premier,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

d'abord de quelque 800 cm^{-1} puis de valeurs décroissantes jusqu'à environ 700 cm^{-1}. La précision de ces mesures n'est cependant pas très grande vu qu'il s'agit de bandes diffuses.

Les deux autres bandes à 1 140 et 1 260 cm^{-1} ont des fréquences et des intensités appropriées pour les vibrations de valence ν_3 et ν_1 de l'ion O_3^-. Ainsi $\nu_3 < \nu_1$, tout comme pour la molécule d'ozone ; de plus les trois fréquences fondamentales de l'ion sont décalées dans le même sens, et à peu près de la même quantité, par rapport à celles de l'ozone. Tel que mentionné au début ces décalages sont de sens opposé à celui prévu par les théories électroniques de la valence. En effet, des fréquences plus élevées impliquent des liaisons plus courtes. Assurément les fréquences caractéristiques de l'ion O_3^- sont affectées par diverses interactions dans l'ozonide d'ammonium solide : forces de Coulomb, de van der Waals, liaisons hydrogène sans doute assez fortes entre NH_4^+ et O_3^-. La dynamique des oscillations internes des ions polyatomiques en est sûrement modifiée. Par exemple, la bande de combinaison $\nu_1 + \nu_2$ de l'ion O_3^- à 2 053 cm^{-1} n'a pas son équivalent dans le spectre de l'ozone solide (23) où c'est plutôt le mode $\nu_1 + \nu_3$ qui est actif en infrarouge. Mais ce ne sont là que des effets de deuxième ordre, comme on peut s'en rendre compte en comparant les fréquences de l'ion NO_3^- des nitrates d'ammonium avec celles des nitrates alcalins (22). Les déplacements observés ici sont donc bien réels, même si leurs valeurs absolues sont un peu incertaines.

A partir des présents résultats on peut évaluer approximativement la longueur des liaisons dans l'ion O_3^- suivant la règle de Badger (24). Pour plus de précision il vaut mieux utiliser cette relation non pas directement mais par comparaison avec les données de l'ozone,

$$\frac{\nu_a}{\nu_b} = \frac{(r_b - C)}{(r_a - C)},$$

où C est la constante empirique 0.68 Å. On obtient ainsi une valeur moyenne de 1.22 Å pour les liaisons O—O dans l'ion, ce qui s'accorde assez bien avec le résultat 1.19 Å de la diffraction des rayons X dans KO_3 (12). Quant à l'angle au sommet α, il est plus difficile à évaluer car les méthodes usuelles de calcul selon l'approximation des forces de valence (25) conduisent à des valeurs imaginaires pour l'ion O_3^- aussi bien que pour la molécule d'ozone. Par exception l'équation utilisée par Bailey et Cassie pour SO_2 (26) donne exactement la même valeur, 100°, que la diffraction des rayons X. La coïncidence est certainement fortuite vu l'imprécision des deux méthodes. C'est néanmoins une bonne indication que l'angle au sommet est plus petit dans l'ion que dans la molécule O_3, en accord cette fois avec les prévisions théoriques.

Signalons enfin que la simplicité des présents spectres confirme les données cristallographiques aussi bien que les conclusions de la théorie (10) à savoir que l'ion O_3^- n'a pas tendance à se dimériser, contrairement à l'ion isoélectronique NO_2^{2-} (27, 28) et à la molécule NO_2.

9,10-DIMETHYL- AND 9,10-DIPHENYL-9,10-DIHYDRO-9,10-ETHANOANTHRACENE BY FRIEDEL–CRAFTS CYCLIALKYLATIONS OF 1,4-DIARYLSUBSTITUTED-1,4-DIOLS

L. R. C. Barclay and Ralph A. Chapman[1]
Department of Chemistry, Mount Allison University, Sackville, New Brunswick
Received November 16, 1964

ABSTRACT

The 1,4-diols, 2,5-diphenylhexane-2,5-diol (I*a*), and 1,1,4,4-tetraphenylbutane-1,4-diol (I*b*) were found to undergo intramolecular cyclodehydrations and dehydration yielding 9,10-disubstituted-9,10-dihydro-9,10-ethanoanthracenes, 2,2,5,5-tetrasubstituted-tetrahydrofurans, and 1,1,4,4-tetrasubstituted-1,3-butadienes when treated with hydrogen fluoride or aluminium chloride. No evidence could be found for intermolecular cyclialkylations of added aromatics such as benzene, anisole, or veratrole. Nuclear magnetic resonance spectra of the products are discussed.

RESULTS AND DISCUSSION

A number of 1,4-diols are readily available from either the action of ketones on acetylenic Grignard reagents or the action of Grignard reagents on appropriate diesters. Bruson (1) reported using two such diols in experiments on the cyclialkylation of various aromatic compounds. The present investigation is concerned with the reactions which take place when the diols 2,5-diphenylhexane-2,5-diol (I*a*) and 1,1,4,4-tetraphenylbutane-1,4-diol (I*b*) are used as alkylating agents in Friedel–Crafts cyclialkylations. In particular it was desirable to determine whether these diols would cyclialkylate an added aromatic or whether they would react intramolecularly. Bruson (1) has reported that the diol (I*b*) cyclialkylated *o*-cresol to yield 5,5,8,8-tetraphenyl-3-methyl-5,6,7,8-tetrahydro-2-naphthol but this structure was based only on a carbon and hydrogen analysis.

The treatment of 2,5-diphenylhexane-2,5-diol (I*a*) with anhydrous hydrogen fluoride in the presence or absence of benzene (Table I, Nos. 1 and 2) yielded a four component mixture. The major component (63%) was found to be the new hydrocarbon, 9,10-dimethyl-9,10-dihydro-9,10-ethanoanthracene (II*a*). The assignment of this structure is based on the following evidence. The ultraviolet spectrum was characteristic of an *o*-disubstituted aromatic with bands at 2 720 Å (ϵ = 1 390), 2 650 Å (ϵ = 1 150) and a slight inflection at 2 580–2 590 Å. The infrared spectrum showed a strong band at 760 cm^{-1} for *o*-disubstitution. The mass spectrum of the compound II*a* showed a parent mass of 234 with a large fragment mass at 206. This fragment mass is attributed to 9,10-dimethylanthracene formed by the loss of the ethano bridge as ethylene from the parent compound. This was further substantiated by the fact that spectral peaks at masses 26, 27, and 28 were in the proper ratio for ethylene and that 9,10-dimethylanthracene was produced when the compound II*a* was heated with selenium at 275°. A similar loss of an ethano bridge has been reported by Campbell and co-workers (2).

The nuclear magnetic resonance (n.m.r.) spectrum of II*a* (see Table II) showed a symmetrical A_2B_2 multiplet centered at 2.73 p.p.m. assigned to the eight aromatic protons of the two ortho-disubstituted rings. It is of interest to note that the methyl protons absorbed on the low field side (8.04) of the methylene protons (8.34). A Stuart-Briegleb model of II*a* showed that the methyls are positioned approximately in the planes of the two aromatic rings. The methyl protons are thus deshielded by the ring current effect and resonate at lower field than normally expected. This effect is similar to that reported by LeGoff (3) for 2,3,6,7-tetraacetoxy-9,10-dimethyl-9,10-dihydro-9,10-ethanoanthracene. The formation of II*a* apparently takes place by a double intramolecular cyclodehydration of the starting diol as shown in the illustration. The remainder of the reaction mixture from hydrogen fluoride treatment of I*a* consisted of a mixture (32%) of *cis*- and *trans*-2,5-dimethyl-2,5-diphenyltetrahydrofuran (III*a*, *b*).

The reaction of the diol (I*a*) with a molar equivalent of aluminium chloride produced a mixture of 59% compound II*a* and 40% of a mixture of the two isomeric furans (III*a*, *b*) mentioned above (Table I, No. 3). On the other hand, reaction of the diol (I*a*) with a catalytic amount of aluminium chloride (Table I, No. 4) produced a mixture of III*a* and *b* (58% and 42%) which were separated by crystallization and repetitive gas–liquid chromatography (g.l.c.) to yield a solid (m.p. 75–76°) and a liquid. Both compounds showed several strong bands in the infrared at 1 000 – 1 100 cm^{-1} characteristic of the furan ethers, as well as strong bands at 705 and 770 cm^{-1} indicating monosubstituted aromatics. On this basis the components were thought to be the isomeric *cis*- and *trans*-2,5-dimethyl-2,5-diphenyltetrahydrofurans. These have been reported previously by Kotlyarevskii and co-workers (4).

The n.m.r. spectra of these compounds (Table II) confirmed their structures to be the *cis*- and *trans*-furan derivatives. The solid isomer showed a singlet at 8.48 p.p.m. assigned to the two methyl groups. The methylene protons absorbed in a well-defined A_2B_2 symmetrical multiplet* centered at 7.83 and the aromatic protons absorbed in a complex multiplet centered near 2.66. The liquid isomer showed a singlet at 8.42 for the methyls, a singlet at 7.77 for the methylenes,* and a complex multiplet centered near 2.75 assigned to the aromatic protons.

The treatment of 1,1,4,4-tetraphenylbutane-1,4-diol (I*b*) with anhydrous hydrogen fluoride in the presence or absence of benzene gave a high yield of the new hydrocarbon,

**This difference in the methylene absorption readily distinguished the two isomers. The determination of the configuration of the isomers by n.m.r. spectroscopy is under investigation and will be reported separately.*

9,10-diphenyl-9,10-dihydro-9,10-ethanoanthracene (II*b*) (Table I, Nos. 5 and 6). The assignment of this structure was based on the following physical and chemical evidence. The ultraviolet spectrum of II*b* gave bands at 2 710 Å (ϵ = 746), 2 642 Å (ϵ = 1 130), and 2 580 – 2 590 Å (ϵ = 1 140). The infrared spectrum showed strong bands at 745 cm^{-1} attributed to *o*-disubstitution and at 707 and 767 cm^{-1} attributed to monosubstitution. The mass spectrum indicated a parent mass at mass 358 with a large fragment mass at 330. This is consistent with the proposed structure. The mass of 330 is due to 9,10-diphenylanthracene produced by the loss of the ethano bridge from the original II*b*. Hydrocarbon II*b* was not soluble in the usual solvents for n.m.r. spectroscopy at room temperature. However, its spectrum was determined at elevated temperatures in tetrachloroethane and this spectrum (see Table II) confirmed the suggested structure.

The singlet at 3.74 (chemical shift from tetrachloroethane) was assigned to the two methylene groups. Under high resolution, the band at −1.07 was resolved into an A_2B_2-type of symmetrical multiplet which could therefore be assigned to the two ortho-disubstituted rings. The two monosubstituted rings absorbed in a complex multiplet in the region near −1.72. Further supporting evidence for this structure was obtained by the thermal decomposition of II*b* yielding 9,10-diphenylanthracene and ethylene which was identified by gas–solid chromatography. The 9,10-diphenylanthracene was identified by its ultraviolet spectrum (see Experimental) and n.m.r. spectrum. The latter showed a symmetrical A_2B_2 multiplet expected of a 9,10-disubstituted anthracene (see Table II). The phenyl protons absorbed as a singlet at 2.37 p.p.m.

The reaction of the diol (I*b*) with a molar equivalent of aluminium chloride (Table I, No. 7) yielded only 14% II*b* with a larger quantity of 1,1,4,4-tetraphenyl-1,3-butadiene (IV). The latter was identified by spectral analyses (see Table II). Reaction of I*b* with a catalytic amount of aluminium chloride yielded what was apparently a mixture of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1,3-butadiene (IV) and 2,2,5,5-tetraphenyltetrahydrofuran (No. 8). This mixture was previously reported by Wasserman and Kloetzel (5) as a mixture with a narrow melting range in the vicinity of 160° which was difficult to separate.

The reaction of the diol (I*b*) with *o*-cresol and aluminium chloride (Table I, No. 9) yielded no phenolic reaction product. The products isolated were 70% crude compound II*b* and the 1,3-butadiene (IV). A similar reaction with veratrole (Table I, No. 10) yielded only the 1,3-butadiene (IV). The report by Bruson (1) that *o*-cresol and the diol I*b* yielded 5,5,8,8-tetraphenyl-3-methyl-5,6,7,8-tetrahydro-2-naphthol is open to question. It is most likely that the compound isolated (m.p. 330–332°) was the ethanoanthracene (II*b*) described in this paper.

It is apparent that 1,4-diaryl-1,4-diols such as I*a* and I*b* undergo intramolecular dehydrations exclusively. They fail to alkylate added aromatics under a variety of conditions. With hydrogen fluoride or molar equivalents of aluminium chloride as catalysts, the predominate reaction was a double aromatic intramolecular cyclodehydration. This provided a synthesis of the 9,10-disubstituted-9,10-dihydro-9,10-ethanoanthracenes. Because of the availability of various diols, the convenience of the cyclodehydration, and high yields obtainable, this reaction will be useful in future syntheses of such bridged hydrocarbons.

EXPERIMENTAL

Apparatus and Methods

The ultraviolet spectra were recorded on a Beckman DK-2 Ratio Recording Spectrophotometer. The infrared spectra were recorded on a Perkin–Elmer Model 137 "Infracord" spectrophotometer. Gas–liquid chromatography analyses were carried out on an F & M Model 500 Programmed Temperature Gas Chromatograph equipped with a dual column attachment. Silicone Gum Rubber on Chromosorb P was used as the column material for all high boiling liquids and solids. The mass spectrometer analyses were determined at an independent laboratory. The n.m.r. spectra were recorded on a Varian A-60 spectrometer equipped with a variable temperature probe. Melting points were determined on a Fisher-Johns melting point apparatus equipped with a microscope or a Thomas Hoover "Unimelt" capillary melting point apparatus. Reactions with anhydrous hydrogen fluoride were carried out in a 12 in. stainless steel MD Test Tube Reactor equipped with stainless steel gaskets made by Autoclave Engineers Inc. Samples of pure components for analyses were obtained by gas–liquid chromatography.

Reagents

The 2,5-diphenylhexane-2,5-diol was a gift of the Air Reduction Chemical Co. It was approximately an equal mixture of the two possible diastereoisomers and was used as such. The 1,1,4,4-tetraphenylbutane-1,4-diol (m.p. 203–205°) was prepared by the procedure of Wasserman and Kloetzel (5).

Reaction of 2,5-Diphenylhexane-2,5-diol (Ia) with Hydrogen Fluoride

(a) With Benzene as Solvent

Benzene (15 ml) and 2,5-diphenylhexane-2,5-diol (2.70 g, 0.010 mole) were placed in the reaction tube and it was cooled below 10° in an ice bath. The hydrogen fluoride (9.5 g) was added from a commercial cylinder and the tube was sealed and stirred for 16 h at room temperature. The tube was then cooled to below 10° and opened. The contents were poured onto crushed ice and the organic material extracted with petroleum ether. After the extract was washed free of acid with sodium carbonate and water, it was dried over sodium sulfate. Distillation of the solvent yielded a solid. Gas–liquid chromatography indicated a four component mixture, the respective components being 63, 18, 14, and 4% of the mixture. Chromatography of this product from petroleum ether on alumina and recrystallization of the solid fractions from ethanol yielded a crystalline solid, m.p. 126–128°. The ultraviolet spectrum gave bands at 2 720 Å (ϵ = 1 390), 2 650 Å (ϵ = 1 150), and an inflection at 2 580 – 2 590 Å. The infrared spectrum showed a strong band at 760 cm^{-1}. The mass spectrum of the compound indicated a parent mass of 234, with a large fragment mass at 206. Peaks were also observed at masses 26, 27, and 28 in the proper ratio for ethylene. The n.m.r. spectrum of this compound (II*a*) is outlined in Table II.

Anal. Calcd. for $C_{18}H_{18}$: C, 92.26 H, 7.74. Found: C, 92.08, 92.18; H, 7.72, 7.80.

(b) With Carbon Tetrachloride as Solvent

The reaction was repeated using 10 ml of carbon tetrachloride as solvent in place of benzene. The petroleum ether extract yielded 2.54 g of product which was found to be a similar mixture to that obtained in (*a*). Chromatography on alumina as above yielded a crystalline solid (68%) which was identical with that obtained above.

For personal use only.

Thermal Decomposition of 9,10-Dimethyl-9,10-dihydro-9,10-ethanoanthracene (IIa)

Selenium (0.50 g) and compound II*a* (0.25 g) were ground together and the mixture was heated in a nitrate bath at 275° for 30 h. Crystals which sublimed were periodically returned to the flask. The cooled mixture was shaken with benzene and decolorizing carbon and then filtered. Distillation of the benzene yielded 0.20 g of solid. Chromatography from benzene on alumina and sublimation of the fractions *in vacuo* yielded a yellow crystalline solid. The ultraviolet spectrum of this gave bands at 3 980 Å (log = ϵ 3.91), 3 780 Å (log ϵ = 3.90), 3 580 Å (log ϵ = 3.64), 3 410 Å (log ϵ = 3.29), 3 260 Å (log ϵ = 2.98), 2 610 Å (log ϵ = 5.21), and 2 530 Å (log ϵ = 4.87). This was identified as 9,10-dimethylanthracene by comparison with the spectrum recorded by Jones (6) and with the tabulation of the main absorption bands which were as follows: 3 980 Å (log ϵ = 3.99), 3 780 Å (log ϵ = 4.00), 3 570 Å (log ϵ = 3.77), 3 410 Å (log ϵ = 3.43), 3 260 Å (log ϵ = 3.03), 2 600 Å (log ϵ = 5.24).

Reactions of 2,5-Diphenylhexane-2,5-diol (Ia) with Aluminium Chloride in the Presence of Benzene

(a) With a Molar Equivalent of Catalyst

Benzene (7.8 g, 0.1 mole) and the diol (I*a*) (2.70 g, 0.01 mole) were mixed and 1.33 g (0.01 mole) of aluminium chloride was added over 10 min. The reaction was vigorous with the evolution of a great deal of hydrogen chloride. Water cooling was used to moderate the reaction. After 1 h at room temperature and 22 h refluxing, the mixture was hydrolyzed on crushed ice. Extraction with ether yielded 2.07 g of a semisolid. Gas–liquid chromatography showed that 59% of the semisolid was compound II*a* while 40% of it was a mixture of the two isomeric substituted tetrahydrofurans (III*a* and *b*).

(b) With a Catalytic Amount of Catalyst. Separation of cis and trans-2,5-Dimethyl-2,5-diphenyltetrahydrofuran (IIIa and b)

Benzene (7.8 g, 0.1 mole), the diol (I*a*) (2.70 g, 0.01 mole), and aluminium chloride (0.10 g, 0.00075 mole) were mixed and refluxed for 12½ h and let stand for 36 h at room temperature. The mixture was then hydrolyzed on ice, extracted with benzene, treated as usual to remove acid, and then freed from benzene by distillation. Gas–liquid chromatography of the residue indicated two components representing 58 and 42% of the mixture respectively and with the same retention time as the minor components obtained in the reaction described above. On standing, part of the liquid crystallized. Filtration of the crystals and recrystallization from ethanol yielded a solid, m.p. 75–76°. The major component of the residual liquid was collected as a liquid by repetitive gas–liquid chromatographic fractionation of small samples of the mixture. Both the crystals and the liquid showed several strong bands in the infrared between 1 000 and 1 100 cm^{-1} characteristic of the furan ethers. Bands at 705 and 770 cm^{-1} indicated monosubstituted aromatics. The n.m.r. spectra of the solid and the liquid are outlined in Table II.

Reactions of 1,1,4,4-Tetraphenylbutane-1,4-diol (Ib) with Hydrogen Fluoride

(a) With Benzene as Solvent

Hydrogen fluoride (10 g) was condensed in the cooled tube. The 1,1,4,4-tetraphenylbutane-1,4-diol (1.97 g, 0.005 mole) was added in small quantities and 5 ml of benzene was added dropwise. The tube was sealed and stirred for 24 h at room temperature. The tube was cooled, then opened, and the contents were poured on ice. A solid was observed that apparently would not dissolve in either benzene or chloroform. It was collected by filtration and a total of approximately 1.8 g of crude solid obtained. Sublimation under high vacuum at 220° yielded a solid, m.p. 312° (II*b*) with decomposition. The ultraviolet spectrum gave bands at 2 710 Å (ϵ = 746), 2 642 Å (ϵ = 1 130), and 2 580 – 2 590 Å (ϵ = 1 140). The infrared spectrum showed strong bands at 767 and 707 cm^{-1} attributed to monosubstitution and 745 cm^{-1} attributed to *o*-disubstitution. Mass spectral analysis indicated a parent mass of 358. There was a strong peak for a fragment mass of 330.

Anal. Calcd. for $C_{28}H_{22}$: C, 93.81; H, 6.19. Found: C, 93.91, 94.07; H, 6.08, 6.14.

(b) In the Absence of Solvent

The reaction was repeated using no solvent. After the reaction mixture had been stirred for 24 h, the tube was opened as usual. The contents of the tube was solid. This solid was added to water to remove adhering acid and was collected by filtration to yield 1.68 g (a 94% yield) of solid, m.p. 309–310° with decomposition. The ultraviolet spectrum was identical to the product from (*a*).

Thermal Decomposition of 9,10-Diphenyl-9,10-dihydro-9,10-ethanoanthracene (IIb)

The compound II*b* (0.25 g) was heated at 315° for 20 min in an atmosphere of nitrogen. Samples of the off-gas from the decomposition were analyzed by gas–solid chromatography on a silica gel column. The major component was found to be ethylene by comparison of retention time with that of an authentic sample. The residual solid was sublimed *in vacuo* to yield a crystalline solid, m.p. 252–254° (lit. (7) 9,10-diphenylanthracene, m.p. 250–252°). The ultraviolet spectrum showed bands at 3 920 Å (log ϵ = 4.14), 3 720 Å (log ϵ = 4.15), 3 540 Å (log ϵ = 3.87), 3 370 Å (log ϵ = 3.73), 2 585 Å (log ϵ = 5.27), and 2 260 Å (log ϵ = 4.48). This was essentially identical with the spectrum of 9,10-diphenylanthracene reported by Jones (6).

Anal. Calcd. for $C_{26}H_{18}$: C, 94.51; H, 5.49. Found: C, 94.51, 94.42; H, 5.67, 5.66.

Reactions of 1,1,4,4-Tetraphenylbutane-1,4-diol (Ib) with Aluminium Chloride in the Presence of Benzene

(a) With a Molar Equivalent of Catalyst

Benzene (7.80 g, 0.1 mole) and the diol (I*b*) (3.94 g, 0.01 mole) were mixed and 1.33 g (0.01 mole) of aluminium chloride was added over 10 min. After 1 h at room temperature and 23 h reflux, the mixture was hydrolyzed on ice and chloroform added. The insoluble solid which formed was collected and after recrystallization from dioxane yielded 0.51 g of II*b*.

From the chloroform-soluble material there was obtained 1.1 g of a solid, m.p. 190–204°. Two recrystallizations from benzene yielded crystals of m.p. 205–207° (hot stage) and 202.5–203.5° (capillary). The infrared spectrum (in Nujol and KBr) showed strong bands near 700 and 770 cm^{-1} attributed to monosubstituted aromatic absorption. There was no hydroxyl absorption. The ultraviolet spectrum had strong broad absorption at 2 480 Å and 3 460 Å consistent with the spectrum of 1,1,4,4-tetraphenylbutadiene (IV) illustrated in the literature (8). The n.m.r. spectrum of IV (see Table II) was also consistent with this structure. The reported melting point for IV was 202.5–203.5° (5).

(b) With a Catalytic Amount of Catalyst

A mixture of benzene (7.8 g, 0.1 mole), the diol (I*b*) (1.82 g, 0.005 mole), and aluminium chloride (0.10 g, 0.00075 mole) were stirred and refluxed for 19 h. The mixture was hydrolyzed on ice and the benzene was allowed to evaporate. The solid which separated was collected by filtration (m.p. 140–165°). Crystallization from ethanol–benzene yielded crystals of m.p. 162–165°. The ultraviolet spectrum of this solid gave broad bands at 3 420 – 3 460 Å and 2 490 – 2 500 Å characteristic of the 1,3-butadiene (IV). The infrared spectrum gave strong bands between 1 000 and 1 100 cm^{-1} indicative of ether absorption. An attempt was made to separate the mixture following the procedure of Wasserman (5) but no pure compounds were obtained.

Reaction of 1,1,4,4-Tetraphenylbutane-1,4-diol (Ib) with Aluminium Chloride

(a) In the Presence of o-Cresol

Following the procedure of Bruson (1), aluminium chloride (8.0 g, 0.06 mole) was suspended in 100 ml of *n*-hexane. The diol (I*b*) (8.0 g, 0.02 mole) and *o*-cresol (10 g, 0.09 mole) were added all at once. After refluxing for 15 h, the mixture was hydrolyzed on 200 ml of 1:4 mixture of hydrochloric acid and water. On treatment with *n*-hexane, there was obtained 5.0 g of insoluble solid which was identified as diphenylethanoanthracene (70%) by its melting point and ultraviolet spectrum. Distillation of the *n*-hexane yielded a mixture of a solid and a liquid. This was found by gas–liquid chromatography to be a mixture of unreacted *o*-cresol and a smaller amount of tetraphenylbutadiene (IV).

(b) In the Presence of Veratrole

A similar reaction was carried out with 3.10 g (0.022 mole) of veratrole, 2.00 g (0.005 mole) of the diol (I*b*), and 2.00 g (0.015 mole) of aluminium chloride. After refluxing for 92 h in 25 ml of low boiling petroleum ether, the mixture was hydrolyzed on ice and extracted with benzene. This product was found to be a mixture of the diene (IV) and veratrole with no compound II*b* or other alkylation product detectable.

ACKNOWLEDGMENTS

The authors thank Dr. A. G. McInnes of the National Research Council, Halifax, Nova Scotia, for recording the n.m.r. spectra of the dimethyl diphenyltetrahydrofurans. Financial assistance from the National Research Council is also gratefully acknowledged. The Varian A-60 n.m.r. spectrometer was purchased with funds from a National Research Council Major Equipment Grant.

THEORETICAL STUDIES ON THE ELECTRONIC SPECTRA OF SUBSTITUTED AROMATIC MOLECULES

PART III. SEMIEMPIRICAL SCF CALCULATIONS FOR POLYCYCLIC ALTERNANT HYDROCARBONS

J. E. BLOOR[1] AND N. BREARLEY

British Columbia Research Council, Vancouver, British Columbia

Received November 30, 1964

ABSTRACT

The effect of changing the method of calculating repulsion integrals within the framework of the semiempirical self-consistent field method is investigated with respect to the transition energies of the alternant hydrocarbons benzene, anthracene, phenanthrene, and pyrene. Of the methods investigated, the one originally suggested by Mataga gave the best agreement with experiment. By statistical analysis of the linear relationship between the internuclear distance r_{pq} and the bond order p_{pq}, the regression line

$$r_{pq} = 1.515 - 0.178p_{pq}$$

was obtained.

The success of the Hückel LCAO procedure in correlating observed p-band transition energies with the Hückel energy number

$$K_i^{\mathrm{H}} = \sum_p^{NP} \sum_q^{NP} C_{ip}^{\mathrm{H}} C_{iq}^{\mathrm{H}}$$

(NP = No. of atoms contributing π electrons) for the highest occupied MO was shown to be due to (1) the relative unimportance of configuration interaction for this transition, (2) the invariance of the electron interaction terms calculated by the SCF method for different hydrocarbons, and (3) the identity of the Hückel energy number K_i^{H} with the corresponding term

$$K_i^{\mathrm{SCF}} = \sum_p^{NP} \sum_q^{NP} C_{ip}^{\mathrm{SCF}} C_{iq}^{\mathrm{SCF}}$$

of SCF theory, the latter value being insensitive to the method of choosing repulsion integrals even though the individual AO coefficients C_{ip}^{SCF} were quite sensitive.

INTRODUCTION

Although a number of calculations have been made of the excited states of polycyclic alternant hydrocarbons using the non-iterative antisymmetric molecular orbital configuration interaction (ASMOCI) method suggested by Pariser and Parr (1–3), very few have been done using the self-consistent field method (SCF) suggested by Pople.

To determine whether the use of SCF molecular orbitals (MOs) rather than Huckel MOs in limited configuration interaction (CI) calculations gives better agreement between experiment and theory, we have computed the transition energies and oscillator strengths of a number of hydrocarbons using as MOs for the CI calculations (*a*) the ground state SCF MOs recently made available by Hoyland and Goodman (5) and (*b*) new SCF MOs calculated using the Mataga and Nishimoto (6) method of calculating repulsion integrals. We have then compared the results with similar calculations carried out by others (1–7, 11–13, 20) and with experiment.

RESULTS

The method of computation has been described in detail in Part II (8) of this series and elsewhere (1, 5). In carrying out CI calculations using SCF MOs and orbital energies, the repulsion integrals were obtained from a curve supplied by Professor L. Goodman constructed as described in (5). The same closed shell MOs were used for both singlets and triplets.

Naphthalene and Anthracene

The spectra of naphthalene and anthracene are fairly well understood, and the polarization of the first two bands of naphthalene has been established experimentally (9). In naphthalene the α band (^1L_b transition) has a 0–0 band at 32 100 cm^{-1}, and the p-band 0–0 band (^1L_a transition) is at 34 700 cm^{-1}. There is an intense band at 44 300 cm^{-1} (^1B_b transition) and a further band in the 50 000 – 60 000 cm^{-1} region.

In anthracene, the ^1L_b transition is not apparent since it is hidden by the intense ^1L_a transition at 26 600 cm^{-1}. The ^1B_b transition is at 39 500 cm^{-1}, and there is a further band around 54 000 cm^{-1} (^1B_a transition). The hidden band in anthracene, whose presence is shown by the behavior of the molecule on substitution of —OH and —NH_2 groups in different positions (10), provides a good means of testing the theory.

A considerable number of SCF CI and ASMO CI calculations have been done on these molecules (3, 4, 6, 11). As can be seen from Table I, there is, for naphthalene, a difference between the results of Gladney (11) and of Pople (4) of 2 200 cm^{-1} in the transition energy for the p band. This is unexpected, since the only difference between these two calculations is that in the former, the repulsion integrals for $r_{pq} > 2.78$ Å are obtained using Pariser and Parr's (2) long-distance formula, whereas in the latter, the inverse distance approximation (4) is used. It is usually assumed (13) that the transition energies are insensitive to repulsion integrals other than those between nearest neighbors. Assuming the absence of numerical error in these two calculations, this implies a very strong sensitivity of the ^1L_a transition energy to the values used for the repulsion integrals between distant atoms. This is a most unexpected conclusion and should be investigated further. In the case of

[c]Ref. 4.
[d]Ref. 11.
[e]Using SCF MOs of Goodman and Hoyland, ref. 5.

anthracene, the difference between Pople's (4) and Gladney's (11) calculations for the p-band transition energy is 1 000 cm^{-1}, all other transition energies being identical. Calculations using the same parameters as Gladney have recently been reported (12). The results were identical for all transitions.

The present CI calculation using Hoyland and Goodman's SCF MOs predicts the order of the first three bands of naphthalene successfully. Whether or not the observed transition in the 46 000 cm^{-1} region consists of two superimposed transitions, as is predicted by Pople's calculation, is at present uncertain. The apparent splitting of this band on substitution by a group such as the amino group could be explained by the appearance of a new charge transfer band in this region (14). A conclusive assignment requires further experimental work.

The quantitative agreement of our calculations with the experimental results, Table I, is not as good for naphthalene as in the case of the Pople (4) and the Mataga (7) calculations. Both the α and p bands are predicted to appear about 3 000 cm^{-1} higher than is observed, even though more configuration interaction (9 configurations) has been used in our calculation than in the previous work. The first triplet is predicted to have $^3B_{2u}$ symmetry by all the SCF calculations. Experimental studies of phosphorescence (15) report a band at 20 900 cm^{-1}, and if we accept this as being due to emission from a $^3B_{2u}$ excited state then the results of Mataga (7) are in very good agreement with experiment. The present results and those of Pople (4) predict considerably higher values for this state (by 2 600 and 4 000 cm^{-1} respectively), while Pariser's (3) calculation gives a value 3 300 cm^{-1} too low.

The results of the calculation on anthracene are given in Table I. The agreement between experimental results and our calculation is poor. In common with the results of Pople (4) and of Gladney (11), the energies of the α and p bands are considerably everestimated, and the present calculation predicts an inversion of these two bands. However, in contrast to the other calculations noted, ours does predict the right order of separation between these two bands.

Phenanthrene

The results on phenanthrene are given in Table II. The only previous SCF calculation on phenanthrene is that of Gladney (11), in which the repulsion integrals are obtained by the method of Pariser and Parr (1, 2).* The agreement with experiment is rather poor: the p-band transition energy is predicted quite well, but the method also predicts an overlap of the α band by the p band. In fact, the two systems are clearly separated (16) with a separation between the two 0–0 bands of 4 850 cm^{-1}, whereas Gladney predicts a separation of 400 cm^{-1}. Our calculation predicts the right order of separation (5 230 cm^{-1}) although the absolute values of the transition energies are about 2 000 cm^{-1} too high.

One of the β systems is clearly seen in phenanthrene, and the fine structure appears to constitute a single progression with a spacing of approximately 1 220 cm^{-1} (16). Our work and Gladney's predict two bands quite close together in this region (see Table II). However, the predicted oscillator strength of one of these is quite low, and the band could be obscured by another one of higher intensity since the observed spectrum is quite broad even at −100 °C.

The present calculation also shows a fourth band of fairly high intensity at around

We do not recommend this widely used approximation for calculations on transition energies of aromatic compounds because of the low value it gives when used to calculate the ^1L_a transition energy of benzene (5.3 eV compared to an experimental value of 5.9–6.2 eV).

46 000 cm^{-1}, which could correspond to the band which has its first peak observed experimentally at 47 500 cm^{-1} (17).

Two recent experimental studies (18, 19) have been made of the triplet states of phenanthrene. McGlynn (18) reports that the first triplet has its origin at 21 730 cm^{-1} and, on the basis of polarization measurements, that it is ^3B in character. Gladney (11) gives the first ^3B at 26 900 cm^{-1}, i.e., rather high. We predict the transition to be at 21 200 cm^{-1}, in exceptionally good agreement with experiment.

Pyrene

There does not seem to be a previous SCF treatment of this molecule, although calculations have been carried out using non-iterative ASMO CI techniques (20, 21, 22). These calculations are in better agreement with the experimental results of Becker (23) than the present SCF results using Hoyland and Goodman's MOs. In particular, we predict (see Table II) that the ^1L_b band ($^1B_{2u}$ symmetry) is at a slightly higher (300 cm^{-1}) frequency than the ^1L_a band, whereas the experimental data show clearly a separation of the 0–0 bands of 3 500 cm^{-1} in the vapor.

THE MATAGA APPROXIMATION

Although the repulsion integrals and resonance integrals used by Hoyland and Goodman (5) were chosen to fit the ionization potentials and transition energies of benzene and ethylene, the use of their MOs to calculate transition energies for the round-field polycyclic hydrocarbons discussed here, and particularly for the long-field molecules styrene, phenyl acetylene, and diphenyl discussed elsewhere (24), has produced very disappointing results. Comparison of the results using SCF MOs and limited CI with those of Pariser using Hückel MOs (Tables I–II) shows that the use of the former MOs gives poorer results than when the latter, supposedly less accurate, MOs are used.

On the other hand, Mataga *et al.* (7) have found that when they used their approximation for the repulsion integrals for naphthalene and anthracene they found very good agreement between theory and experimental data for both the electronic excited states and the bond lengths (calculated from an empirical bond order – bond length relationship). We have therefore used their method for repulsion integrals in SCF calculations on phenanthrene, which was the one molecule which gave quite good agreement with experiment when Hoyland and Goodman MOs and repulsion integrals were used, and on pyrene, for which the Hoyland and Goodman parameters gave quite poor agreement with experiment. The results are compared with the previous results in Table II. It can be seen that for phenanthrene the results for both calculations are in quite good agreement with experiment, and that the transition energies are not greatly altered by the change in repulsion integrals. The results are much better than when Pariser and Parr's (11) method for repulsion integrals was used. For example, use of the latter predicted the ^1L_b and ^3L_a transitions to be over 5 000 cm^{-1} too high compared with the observed values. For pyrene, the results for the ^1L_a, ^1B_b, ^1B_a are in better agreement with experiment than in the case of our previous calculation. However, for the ^1L_b transition, both our calculation and those carried out by Hummel and Ruedemberg (20), by a non-iterative ASMO CI method, predict it to be overlapped by the more intense ^1L_a transition. Recent experimental results (23) clearly assign the 0–0 transition to be at 26 947 cm^{-1} i.e. below the 0–0 for the ^1L_a transition. However, we have not carried out new variational calculations for each excited state but have constructed them from MOs obtained using the ground state Hamiltonian. It is therefore probably more realistic to compare our calculated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

values with the observed Frank–Condon maxima rather than the 0–0 transition, and this would improve the agreement between calculated and experimental values since the ^1L_b transition is partly overlapped by the ^1L_a transition.

BOND LENGTHS

The bond lengths of the polyacene hydrocarbons under discussion in this paper have been determined by X-ray crystallographic methods to a high order of accuracy and should therefore constitute a good means of testing the widely held supposition (25) that a smooth-curve relationship exists between the calculated bond order (p_{pq}) and observed bond lengths (r_{pq}) provided that there are no abnormal non-bonding interactions and that the atoms forming the bonds do not change their states of hybridization. Statistical analysis does give fairly good linear relationship between p_{pq} and r_{pq}. The calculated regression line is given by eq. [1],

$$r_{pq} = 1.515 - 0.178p_{pq}. \qquad [1]$$

The correlation coefficient is 0.81 and the standard deviation is 0.002. The predicted value for the "ideal single bond" between two single sp^2 hybridized carbon atoms is calculated to be 1.515 Å, in good agreement with Mulliken's (25) estimate of 1.51 ± 0.01 Å and that of Bak and Hansen-Nygaard (27) of 1.517 Å.

For ethylene, eq. [1] predicts a bond length of 1.337 Å, in good agreement with recent experimental determinations (28, 29). For benzene, the predicted bond length is 1.398 Å, again in very good agreement with experiment. It can therefore be stated that the SCF method using the Mataga method of calculating repulsion integrals gives bond orders which can be used satisfactorily in estimations of bond distances in alternant hydrocarbons.

DISCUSSION

The most valuable conclusion to be obtained from this study is that excitation energies are very sensitive to the method of calculating repulsion integrals, and that small differences in values of the two-center integrals can result in changes in transition energy of the order of several thousand cm^{-1}.

We have found that, of the three most commonly used methods of obtaining repulsion integrals, the method suggested by Mataga and Nishimoto gives by far the best agreement with experiment for both the round-field molecules discussed here and the long-field molecules discussed elsewhere (24).

We have also found that the agreement with experiment is not as good when the SCF method is used compared to the non-iterative ASMO CI method.

For alternant hydrocarbons, the main difference between the SCF and the Huckel methods is the appearance of small off-diagonal elements between non-nearest neighbors in the former method as shown by eq. [2] for F_{pq}, the off-diagonal elements of the secular determinant. In eq. [2] β_{pq} is the resonance integral between atoms p and q, γ_{pq} is the repulsion integral between atoms p and q, and p_{pq} is the π-bond order between atoms p and q.

$$F_{pq} = \beta_{pq} - \tfrac{1}{2}p_{pq}\gamma_{pq} \qquad p \neq q \qquad [2]$$

These small off-diagonal elements ($\frac{1}{2}p_{pq}\gamma_{pq}$) for non-nearest neighbors are large when either Pariser's or Hoyland and Goodman's method of choosing γ_{pq} is used, and result in a considerable difference in the atomic orbital coefficients of SCF MOs compared to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Hückel MOs used in the ASMOCI method. When the Mataga method is used to calculate the γ_{pq} values, they are found to be smaller in magnitude than in the other methods; consequently the non-nearest neighbor interactions in [2] are smaller and the resulting SCF MOs are much closer to Hückel MOs.

Considerable success has been obtained for the Hückel method in interpreting electronic spectra even though electron repulsion integrals are neglected. For the p bands of alternant hydrocarbons, the success of the simple procedure of equating the p-band transition energy to the difference between the orbital energies in terms of β (25) can be explained by:

(1) the small effect of configuration interaction on the p band making the assumption of a one-configuration wave function for the p band quite accurate;

(2) the correct expression for the transition energy for an excitation of an electron from ψ_i to ψ_k is [3].

$$[3] \qquad E(i \rightarrow k) = E_k - E_i + 2K_{ik} - J_{ik},$$

where for a system of NP atoms, each contributing one π-electron, we have

$$[4] \qquad E_k = \sum_{p}^{NP} \sum_{q}^{NP} C_{kp}C_{kq}F_{pq}$$

$$[5] \qquad = (-I + \tfrac{1}{2}\gamma) + \sum_{p}^{NP} \sum_{q \neq}^{NP} C_{kp}C_{kq}(\beta_{pq} - \tfrac{1}{2}p_{pq}\gamma_{pq})$$

$$[6] \qquad = \alpha + K_k^{SCF}\beta - \tfrac{1}{2} \sum_{p}^{NP} \sum_{q \neq}^{NP} C_{kp}C_{kq}p_{pq}\gamma_{pq}.$$

The symbols in [4] and [5] are quite standard and have been defined elsewhere (8) and in eq. [1]. Equation [6] shows that we can express the SCF orbital energy in a similar way to that of Hückel theory. Thus $(-I + \frac{1}{2}\gamma)$ is equivalent to the Hückel coulomb integral of a carbon atom, β is the standard resonance integral for a C—C bond, and K_i^{SCF} corresponds to the Hückel number K_i^H (25).* The third term of [6] involves electron repulsion terms and has no Hückel counterpart. We have found for the hydrocarbons of Table III the SCF number K_i^{SCF} for the highest occupied MO is very close to the corresponding Hückel number even though the individual SCF AO coefficients are somewhat different from the Hückel ones. This is found to be true for both our SCF calculations for pyrene and phenanthrene, i.e. the number K_i^{SCF} is apparently independent of the choice of repulsion integrals.

We can now write [3] in the form [7].

$$[7] \qquad E_{ik} = (K_k^{SCF} - K_i^{SCF})\beta + \tfrac{1}{2} \sum_{p}^{NP} \sum_{q \neq}^{NP} [(C_{ip}^{SCF}C_{iq}^{SCF} - C_{kp}^{SCF}C_{kq}^{SCF}p_{pq}\gamma_{pq}] + 2K_{ik} - J_{ik}$$

To be able to relate the energy of the p band to a simple difference of K numbers, it is necessary for the last three terms i.e. those involving electron interactions, of [7] to be constant. That this is apparently so, to a first approximation, is shown by the results of column 5 of Table III.

**The Huckel numbers for alternant hydrocarbons are the eigenvalues of the secular determinant when the matrix elements of the determinant are written in units of β, i.e.*

$$E_i^H = \alpha + K_i^H\beta.$$

Key to Symbols in Boxheads of Table III

E_i = Orbital energy of the highest occupied MO.

E_{ik} = Transition energy of the transition $i \rightarrow k$, where k denotes the lowest unoccupied MO.

$E(p)$ = Calculated transition energy of the p band after CI.

$$\Delta = 2K_{ik} - J_{ik} + \tfrac{1}{2} \sum_{p}^{NP} \sum_{q \neq p}^{NP} (C_{ip}C_{iq} - C_{kp}C_{kq})p_{pq}\gamma_{pq}$$

$$= E_{ik} - 2 \sum_{p}^{NP} \sum_{q}^{NP} C_{ip}C_{iq}\beta_{pq}.$$

TABLE III

Transition energies for p bands of alternant hydrocarbons

Molecule	E_i (eV)	E_{ik} (eV)	$E(p)$ (eV)	Electron interaction contribution Δ (eV)
Naphthalene[a]	−10.53	5.16	4.93	2.25
Anthracene[a]	−9.80	4.16	3.96	2.22
Phenanthrene[a]	−10.10	4.63	4.51	1.74
Pyrene[a]	−9.74	4.28	4.10	2.18
Phenanthrene[b]	−9.36	4.4	4.28	1.60
Pyrene[b]	−8.90	3.85	3.75	1.76

[a]Calculated using Goodman and Hoyland's MOs and repulsion integrals, ref. 5.
[b]Calculated using Mataga's method of calculating repulsion integrals, refs. 6–8.

Thus, for energies calculated using Hoyland and Goodman's (5) repulsion integrals, we can write [8] because of the pairing properties of alternant hydrocarbon MOs which make $K_k^{SCF} = -K_i^{SCF}$ for the highest occupied and lowest unoccupied MO respectively,

$$E_{ik} = 4.73K_i^{SCF} + 2.20. \quad [8]$$

For calculations using Mataga integrals (6), we can write [9],

$$E_{ik} = 4.78K_i^{SCF} + 1.70, \quad [9]$$

where K_i^{SCF} refers to the energy of the highest occupied MO.

If we allow a further lowering of 0.2 eV for the effect of configuration interaction on the p state, we arrive at an electron interaction term of 2.0 when Goodman and Hoyland integrals are used and a value of 1.50 eV when Mataga integrals are used. For the relationship between the observed transition energy and the Hückel number K_i^H several authors have arrived at a number of different regression lines which differ depending on the choice of experimental values for the transition energy and on the number and type of hydrocarbon included. Murrell (34) gives the relationship [10], Koutecky (21) gives [11], Slifkin (26) gives [12], and Streitwieser (25) gives [13].

$$E(p) = 4.44K_i^H + 1.016 \quad [10]$$

$$E(p) = 4.76K_i^H + 1.27 \quad [11]$$

$$E(p) = 5.27K_i^H + 1.13 \quad [12]$$

$$E(p) = 4.92K_i^H + 1.30 \quad [13]$$

From this, it is clear that the electron interaction term calculated using Mataga repulsion integrals is more compatible with that derived statistically than that obtained using Hoyland and Goodman's repulsion integrals. The use of the theoretically derived

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

equation [9] to calculate transition energies using K_i^{H} instead of K_i^{SCF} is quite successful, although for some of the larger polyacenes such as pentacene and perylene, the calculated values are somewhat high and it would be preferable to use a constant of 1.3 eV as was used by Koutecky and Streitwieser.* It is, however, clear that the success of simple relationships using Hückel theory is due to (1) the identity between K_i^{H} and K_i^{SCF} and (2) the constancy of the electron interaction terms given in [7]. The magnitude of this electron interaction term as derived from statistical analysis is of the order of 1 eV, and this fact may be used as an extra piece of information in choosing molecular repulsion integrals. It is possible that an alternative method of choosing repulsion integrals can be found which will give a value for the terms in [7] in closer agreement with the statistical regression lines [10–13], but at present, the Mataga method seems to give the best overall results.

ACKNOWLEDGMENTS

We are grateful to the National Research Council of Canada for financial support, and to Professor R. M. Hochstrasser for sponsoring our use of the IBM 1620 computer at the University of British Columbia. We should also like to thank the staffs of the Computing Centres of the University of British Columbia, and of The Franklin Institute for much helpful advice and assistance in the course of this study. The computer programs are available for use at the Franklin Institute Computing Center.

It is possible to justify a lower value of the constant in [9] by making an allowance for the red shift in passing from vapor spectra to hydrocarbon solution. This would be of the order of 0.1–0.2 eV.

ELECTROPHILIC CATALYSIS IN SOLVOLYTIC REACTIONS

VII. SOLVENT EFFECT

R. ANANTARAMAN AND K. SARAMMA[1]
Chemistry Department, University of Kerala, Trivandrum, India

Received October 13, 1964

ABSTRACT

The rates of mercuric chloride catalyzed solvolysis of some alkyl chlorides in aqueous acetone and ethanol solvents have been compared. It is found that the increase in rate on changing from the acetone to the ethanol solvent is less in the catalyzed than in the normal reaction. On the basis that the electrophilic activity of the catalyst is less in aqueous ethanol than in aqueous acetone an explanation for the anomaly has been suggested. The effect, on the rates of solvolysis, of added chloride ions is in accord with the suggested explanation.

The rates of solvolysis of a number of alkyl chlorides, with and without mercuric chloride, in aqueous acetone and aqueous ethanol, together with the values of the heats and entropies of activation, are given in Tables I and II. The Hughes–Ingold theory requires that the rate of solvolysis of an alkyl chloride should increase on changing from aqueous acetone to aqueous ethanol (1). This can be put on a quantitative basis by using the Winstein equation $\log k/k_0 = m\mathbf{Y}$ (2). The data show that, while this is true of the normal solvolysis of all the alkyl chlorides, regarding the catalyzed reaction, *tert*-butyl and *tert*-amyl chloride behave abnormally, the rates in aqueous ethanol being lower. It can also be seen (Table I) that the ratio $k_{\text{ethanol}}/k_{\text{acetone}}$ for the normal solvolysis (k_{I}) is, in all cases, larger than the corresponding ratio for the catalyzed reaction (k_{II}). Since k_{I} varies over a wide range of values, to obtain a proper idea regarding the extent of abnormality in the rates of the catalyzed reaction of the different alkyl chlorides, a factor k_{III}, defined as $k_{\text{II}}/k_{\text{I}}$, has been calculated and included in the last column of Table I. It is evident that completely normal behavior will correspond to a value of 1 for k_{III}.

Since the k_{III} values of all alkyl chlorides are much less than 1, it was thought likely that the abnormal behavior might be due to a lower electrophilic activity of the catalyst in aqueous ethanol, particularly since Foote has shown that mercuric chloride does not form a complex with chloride ions in dry ethanol (3). This has been confirmed by solubility measurements which show that the $HgCl_2$:Cl^- (combined) ratios in 80% aqueous acetone and 80% aqueous ethanol at 31 °C are, respectively, 1:2.86 and 1:2.21, with a mercuric chloride concentration of 0.4 *M* (4). With a mercuric chloride concentration of 0.2 *M* the ratios have the values 1:4.38 and 1:3.0. It is clear that, since the number of chloride ions combining with a molecule of catalyst is less in aqueous ethanol, the electrophilic activity of the catalyst must be smaller in this solvent.* However, two points, namely the lower rates of catalyzed solvolysis in aqueous ethanol shown by *tert*-butyl and *tert*-amyl chloride and the wide variation in the k_{III} values, require explanation.

In Table II, a factor k_{IV} is introduced, which is the ratio of the rate, in aqueous acetone, due to the catalyst alone and the rate of the normal hydrolysis. If 1-chloropropylbenzene, 1-chloroisobutyl benzene, and (1-chloro-2,2-dimethylpropyl)benzene are excluded from consideration, it can be seen that the order of increasing k_{III} values parallels decreasing

[1]*Government of India Research Scholar.*

**This is an amplification of the argument in ref. 5. However, the effects, on the rate, due to a change in the electrophilic activity can be swamped by new kinetic factors introduced by the catalyst.*

*T = 20 °C in all except *p*-$ClPhCH_2Cl$ where it is 68.2 °C. The k_{IV} value for *p*-$ClPhCH_2Cl$ is not likely to be very different at 20 °C since for $PhCH_2Cl$, which shows similar behavior, the k_{IV} value at 82.3 °C is 2.9.

†Reference 27.

k_{IV} values. This means that the abnormality in the rate of the catalyzed reaction in aqueous ethanol increases with the catalytic efficiency of the hydrolytic process. Provided the catalytic activity remains unchanged,* the sensitivity of the rate of solvolysis to the presence of the catalyst should be quantitatively similar in the two solvents. But any change in the catalytic activity will cause abnormal behavior, its extent varying with the alkyl chloride. Thus a substrate like 1-*p*-tolylethyl chloride, whose rate of hydrolysis is especially sensitive to the presence of the catalyst, will be most affected by such a change. On the other hand, the rates of hydrolysis of benzyl and *p*-chlorobenzyl chloride are little affected by the catalyst and so their rates of catalyzed solvolysis in aqueous ethanol will show the least abnormality, in agreement with observation. It may be noted that the two tertiary alkyl chlorides also fit into this pattern. The fact that the rates of their catalyzed solvolysis in aqueous ethanol is lower than the rate in aqueous acetone is accidental, caused by their abnormally low k_I values.†

The exceptional behavior shown by the other three alkyl chlorides has now to be explained. It has been argued that with the other alkyl chlorides, an inverse relationship exists between the extent of abnormal behavior (as shown by the k_{III} values) and the catalytic efficiency for the hydrolysis (as given by the k_{IV} values). These three alkyl chlorides, however, have k_{IV} values which are much larger than those expected on the basis of their k_{III} values. A possible explanation for this is as follows. The catalytic efficiency must increase with the ease with which the C—Cl bond can be heterolyzed (in other words, must increase with the inherent tendency of the substrate to adopt the S_N1 mechanism), and normally this will be the case. But if the catalyst is able to bring into play additional kinetic factors or to change the factors already present in the normal reaction significantly, the above rule may no longer hold. It has been argued on the basis of experimental evidence that the unduly high catalytic efficiency observed in the reactions of these three alkyl chlorides is due to the catalyst calling into play an additional inductomeric effect of substantial magnitude (9). The conclusion, therefore, is that the abnormally high k_{IV} values shown by these three alkyl chlorides are due to this special cause, which has no particular relevance to the argument presented here, so that its validity is not affected.

A closer inspection of the k_{III} values suggests that the explanation given above is not adequate, by itself, to account for the fact they are so much less than unity, even in favorable cases. Thus, according to the argument presented here, benzyl chloride and *p*-chlorobenzyl chloride should show the least abnormality. Yet the k_{III} values are only 0.42 and 0.65 respectively. In our studies of the kinetics of mercuric chloride catalyzed solvolysis of alkyl chlorides, we have found that the sensitivity of the rate to changes in the polarity of the medium is less in the presence of the catalyst than in its absence. Now, although the rates of solvolytic reactions of alkyl chlorides by both the S_N1 and S_N2 mechanisms are considerably accelerated by a change to a more polar solvent, the magnitude of the effect is greater for the S_N1 reaction (10). We believe that the inclusion of the catalyst molecule in the transition state will confer on it some of the properties of the transition state of an S_N2 reaction, in particular the relatively smaller response of the

**A referee has suggested consideration of the viewpoint that in a more ionizing solvent the effect of the catalyst may be expected to be less. We have not considered this possibility because the evidence available does not support it. Thus the value of the catalytic coefficient for the mercuric chloride catalyzed hydrolysis of benzyl chloride is almost constant over the solvent range 45–80% aqueous acetone (6), which involves a greater variation in the ionizing power than a change of solvent from 80% aqueous acetone to 80% aqueous ethanol. A similar situation obtains for the catalyzed solvolysis of p-chlorobenzyl chloride (7).*

†The low k_I values are presumably due to the fact that the tert-alkyl cations have relatively little stability (8).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

rate of substitution to changes in the polarity of the environment, although we recognize that mercuric chloride is here the catalyst and not the substituting agent (11). This is in agreement with the views of Hammond *et al.* (12) that the transition state of the silver ion catalyzed hydrolysis of alkyl halides has a substantial S_N2 character. Other arguments in support of the above conclusion are as follows. (i) A convenient method of distinguishing solvolytic reactions occurring by the S_N1 and S_N2 mechanisms is by determining their *m* values by using the Winstein equation. The *m* values for the normal and catalyzed reactions of some of the alkyl chlorides are respectively (values taken from Fainberg and Winstein (13)): 1-phenethyl chloride, 1.056 (14), 0.40; *tert*-butyl chloride 1.00 (2), 0.50; *tert*-amyl chloride 1.10, 0.50; 1-chloropropyl benzene 0.62, 0.40; benzyl chloride 0.425 (15), 0.43; *p*-chlorobenzyl chloride 0.56, 0.44. Since a high *m* value signifies that the reaction belongs to the S_N1 category, the conclusion from the data is that the *m* values of the catalyzed reaction are more characteristic of S_N2 reactions. (ii) The magnitude of the ionic-strength effect is much less in the catalyzed than in the normal reaction; thus the ionic-strength effect in the hydrolysis of 1-phenethyl chloride is substantial (16), while it is barely detectable in the catalyzed reaction (17). (iii) The "medium effect" which is so characteristic of S_N1 solvolysis is much less marked in the catalyzed reaction; thus the rate of hydrolysis of *tert*-butyl chloride is rather sensitive to its concentration (18), while this is not the case with the catalyzed reaction (19).

With all alkyl chlorides except 1-chloroisobutyl benzene and (1-chloro-2,2-dimethylpropyl)benzene, the heats of activation for the catalyzed reaction in aqueous acetone are markedly lower than in aqueous ethanol, which contrasts with the normal reaction. It is suggested that this is due to the lower electrophilic activity in the ethanolic solvent. For the other two alkyl chlorides, the heats of activation in the two solvents are almost the same, suggesting that steric resistance to solvation is under observation (20). The trend in the entropy values is more difficult to explain. For the catalyzed reaction, the entropy values are more favorable in aqueous ethanol. This is possibly due to the orientational requirement in the transition state being more easily met in the ethanolic solvent consequent on the greater solvation of the catalyst. For 1-chloroisobutyl benzene and (1-chloro-2,2-dimethylpropyl)benzene, however, steric strain due to crowding in the transition state must be dominant, since the entropy values in the two solvents are relatively rather similar.

Addition of chloride ions reduces the rate of the catalyzed reaction because (i) by decreasing the catalyst concentration through formation of complexes like $HgCl_3^-$, $HgCl_4^=$ and (ii) by inducing a mass-law effect (17). An explanation for the latter observation has been given by Ingold (21) and Bunton (22). Of the alkyl chlorides studied (Table III), the mass-law effect is of importance only in the case of 1-phenethyl chloride (9, 17). So, with this exception, the reduction in rate due to added chloride ions must be due to the inactivation of the catalyst. It can be seen that the magnitude of reduction is approximately equal for the hydrolysis of all alkyl chlorides excepting 1-phenethyl chloride, in agreement with the above conclusion. But, the decrease in rate in aqueous ethanol is consistently smaller than in aqueous acetone. This again must be attributed to the greater solvation of the catalyst in this solvent. Further, while the rate decrease in the hydrolytic reaction appears to be little affected by changes in temperature (thus the rate reductions for five alkyl chlorides are about the same although the temperature varies by over 50 °C), this is not the case in aqueous ethanol where the decrease in rate appears to increase with temperature. It is suggested that this may be due to a negative temperature effect on the interaction between the mercuric chloride and the solvent. If this

is the case, the extent of complex formation between mercuric chloride and chloride ions (and hence the rate reduction) should increase with temperature.

EXPERIMENTAL

Materials

1-Phenethyl alcohol, 1-hydroxypropyl benzene, and 1-*p*-tolylethyl alcohol were prepared by the Meerwein-Pondorff reduction of the corresponding ketones. 1-Hydroxyisobutyl benzene and (1-hydroxy-2,2-dimethylpropyl)benzene were prepared by the Grignard reaction with magnesium isopropyl bromide and magnesium *tert*-butyl chloride, respectively. The alcohols were purified through their acid phthalates, prepared in the usual way (23). The alcohols were converted into the chlorides by reaction with thionyl chloride. *tert*-Butyl chloride (24) and *tert*-amyl chloride (25) were prepared by the usual methods.

The physical constants of the alkyl chlorides are given below.

	Boiling point (°C)		n_D^{25}	
Alkyl chlorides	Expt.	Lit.	Expt.	Lit.
CHPhMeCl	78–79/16 mm	81–82/17 mm (26)	1.5250	1.5250 (13)

CH(*p*-MePh)MeCl	134/80 mm; 101/25 mm		1.5220	

A.R.(B.D.H.) mercuric chloride and sodium chloride were used. The latter was dried at 250 °C.
Acetone was purified and dried by the method of Conant and Kirner (30). Lime-dried ethanol was made absolute by refluxing with sodium and diethyl phthalate.

Kinetic Work

The term $x\%$ aqueous acetone or ethanol signifies solvent made up (at room temperature) with x volumes of dry acetone or ethanol and $(100 - x)$ volumes of distilled water. A large stock of solvent was made up to facilitate comparative measurements.

A conventional thermostat (±0.03°) was used for rate measurements at higher temperatures while for work at below room temperature, a Gallenkamp low temperature thermostat fitted with a Jackson thermoregulator was used (±0.02°).

At the higher temperatures, the sealed-bulb technique was used. The appropriate quantity of alkyl chloride was taken in a 100 ml volumetric flask and accurately weighed quantities of mercuric chloride and (or) sodium chloride were transferred to the flask with the aid of the solvent. After dissolution, the solution was made up to the mark. Aliquots (5 ml) were pipetted into neutral glass ampoules (which conformed to the B.P. test for limits of alkalinity (31)), and the ampoules sealed. They were immersed in the thermostat and vigorously shaken for 2 min. Then one ampoule was taken out, immediately chilled to kill the reaction, washed, and broken, under 150 ml of cold, dry acetone/ethanol. The liberated acid was titrated against carbon dioxide free standard NaOH, lacmoid being used as the indicator. At suitable intervals, the other ampoules were removed and the acid estimated similarly. The "infinity" titer (mean of two concordant values) was taken after an interval equal to 8 half-lives. When mercuric chloride was present, a quantity of concentrated potassium iodide solution (neutralized to lacmoid) just sufficient to destroy the mercuric

chloride was added before titration. For work at low temperature, the pipetting was done directly from the volumetric flask which served as the reaction vessel.

The first-order rate coefficients were calculated from the formula $k = (1/t) \ln a/(a - x)$ and the values are expressed in reciprocal second. The values given are the mean from two experiments.

One point deserves mention. It was found for the catalyzed reaction (particularly in aqueous acetone) that the first-order rate coefficients were steady only over an initial limited portion of the reaction. This is illustrated in Table IV. The rate coefficients given are the mean of the values which show constancy derived from duplicate runs. The catalyzed hydrolysis of 1-*p*-tolylethyl chloride did not show even this initial constancy in the rate. To obtain the initial rate, therefore, log k was plotted against log $(a - x)$ a good straight line was obtained. The best straight line was obtained by the method of least squares. Duplicate runs gave good agreement.

REACTIONS OF IMINO RADICALS WITH HYDROCARBON GASES[1]

J. L. BRASH[2] AND R. A. BACK
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received February 19, 1965

ABSTRACT

The photolysis of HNCO vapor has been studied in the presence of ethylene, butene, ethane, propane, and neopentane at 51 °C. Both the olefins and paraffins reduced the yield of CO to about one-third of its value in pure HNCO, which is thought to correspond to the CO formed in the primary photolytic step. Yields of N_2 and H_2 were reduced close to zero in the presence of olefins, and it appears that NH radicals were removed by reaction with olefins. No imines, amines, nor other nitrogenous products could be detected, however, and it is suggested that these were lost by polymerization.

Yields of N_2 were also reduced close to zero in the presence of paraffins, and it appears that NH reacted readily with the hydrocarbons. Once again, no amines could be detected. The yield of H_2, a minor product in pure HNCO, was markedly enhanced, and alkyl radical dimers appeared as products. A mechanism is suggested which involves the decomposition of vibrationally excited amines formed by insertion reactions.

INTRODUCTION

In an earlier paper from this laboratory (1), it was observed that the addition of ethylene reduced the yields of CO, N_2, and H_2 in the photolysis of isocyanic acid vapor; this was attributed to the reaction of NH radicals with ethylene. More recently, in the flash photolysis of HNCO, both ethylene and propane were found to have a similar effect (2). The present paper describes a more detailed study of the reactions of NH radicals, produced in the photolysis of HNCO vapor, with olefin and paraffin gases.

EXPERIMENTAL

The photolysis system, procedure, and the analysis of non-condensable gases were all similar to those used previously (1). All experiments were done at 51 °C using unfiltered radiation from an Hanovia S-500 medium-pressure mercury arc. Gas chromatography, using a variety of columns, was used to examine the products condensable at −196 °C.

Isocyanic acid was prepared and purified as before. A sample of DNCO was prepared by pyrolysis of cyanuric acid-d_3 obtained from Merck, Sharp and Dohme of Canada Ltd. Hydrocarbon gases were all Phillips Research Grade, used after simple degassing. Propane-d_8 was obtained from Merck, Sharp and Dohme of Canada Ltd.

RESULTS AND DISCUSSION

Reactions of NH with Olefins

In agreement with Back and Mui (1), it was observed that the addition of ethylene rapidly reduced the yields of N_2 and H_2 to zero, and that of CO to a constant value, about 1/3 of the yield from the photolysis of HNCO alone. It is reasonable to suggest, as before (1), that the residual CO came from the primary photolysis process,

$$\text{HNCO} + h\nu \rightarrow \text{CO} + \text{NH}, \qquad [1]$$

and that at moderate pressures of ethylene, NH radicals were completely removed by reaction with the olefin, so that formation of N_2, H_2, and two-thirds of the CO, all of which arose from secondary reactions of NH radicals in the pure HNCO system, were suppressed.

[1]*Issued as N.R.C. No. 8421.*
[2]*National Research Council Postdoctorate Fellow, 1961–1963. Present address: Stanford Research Institute, Menlo Park, California, U.S.A.*

By analogy with other biradicals, one might expect NH radicals to add to the double bond of ethylene, forming vibrationally excited ethylenimine which could undergo rearrangement or be stabilized by collision.

[2] $$NH + C_2H_4 \longrightarrow [CH_2{-}CH_2]^* \begin{cases} \longrightarrow CH_2{=}CH{-}NH_2 & [a] \\ \longrightarrow CH_3{-}CH{=}NH & [b] \\ \xrightarrow{+M} CH_2{-}CH_2 \ (NH) & [c] \end{cases}$$

Blank experiments showed that both ethylenimine and vinyl amine could have been readily detected by gas chromatography, using a 3 ft column of polyethylene glycol on firebrick at 50 °C. The unsaturated amine postulated in reaction [2*b*] has apparently not been reported, and probably polymerizes spontaneously.

When HNCO was photolyzed in the presence of ethylene at pressures ranging up to 500 torr, neither ethylenimine nor vinyl amine nor any other nitrogen-bearing products could be detected.[3] It may be concluded that any ethylenimine formed in reaction [2] was not stabilized at these pressures. Failure to find vinyl amine or any other rearrangement product could very probably be due to polymerization, either alone or as copolymers with HNCO, to which these unsaturated amines are notoriously prone. Ethylenimine has recently been observed by Jacox and Milligan (3) as a product of the photolysis of hydrazoic acid in the presence of ethylene in an argon matrix at 4 °K, where it presumably arose via reaction [2*c*]. The low temperature and the solid state thus appear to favour stabilization and prevent polymerization.

A few experiments were done with butene-2 in the hope that butenimine, with more vibrational modes, would be more readily stabilized than ethylenimine. At pressures up to 500 torr of butene-2, however, no stabilized product could be detected.

In summary, the effect of olefins on the yields of CO, N_2, and H_2 in the photolysis of HNCO leaves little doubt that NH reacts readily with olefins. The present observations are compatible with a primary addition to form a cyclic imine, followed by rearrangement and polymerization of the resulting unsaturated products, although they by no means prove such a mechanism.

Reactions of NH with Paraffins

Isocyanic acid vapor was photolyzed in the presence of ethane, propane, and neopentane. The three systems showed the same general behavior. The CO yield fell with increasing pressure of hydrocarbon and became constant at about 1/3 of its original value, while the N_2 yield decreased towards zero; these effects are very similar to those observed with olefins. Hydrogen, however, which was a minor product in pure HNCO (probably arising from combination of NH radicals (1, 2)) and was completely absent in the presence of olefin, increased markedly with increasing pressure of paraffin, becoming constant at higher pressures.

Again by analogy with other biradicals, NH might be expected to undergo insertion into the C—H bonds of the paraffins, forming amines. As with the olefins, however, no amines nor other nitrogenous compounds could be detected by gas chromatography. Hydrocarbon pressures approaching 1 atm were used, and 600 torr pressure of CO_2 was added to the propane–HNCO system; no amines could be detected as products of any of

[3]*Hydrogen cyanide, a possible product by analogy with nitrogen-atom reactions, was also not observed, although it could have been detected if present.*

these experiments. The failure to observe amines indicates either that no insertion reaction occurred, or that the amine formed by insertion decomposed before it could be stabilized by collision.

The only condensable products found from the photolysis of HNCO in the presence of paraffins were *n*-butane and hexane (mostly 2,3-dimethylbutane) from ethane and propane respectively. Decane may have been produced from neopentane but was not analyzed. The dependence of all product yields on hydrocarbon pressure with constant HNCO pressure of 19.6 torr is shown in Fig. 1 and Table I.

159.5	0.099	237.0	0.074
	Av. 0.103		Av. 0.093

The reduction in the yields of CO and N_2, products which were attributed (1) to reactions of NH radicals in the photolysis of pure HNCO, suggests that NH was reacting with alkanes, probably by insertion in a C—H bond followed by decomposition of the excited amine,

[4] $$NH + RH \rightarrow [RNH_2]^* \rightarrow R + NH_2,$$

or alternatively by simple abstraction of hydrogen, which from the present data is indistinguishable. The NH_2 radical would have reacted readily to form ammonia,

[5] $$NH_2 + RH \rightarrow NH_3 + R,$$

and combination of the hydrocarbon radicals formed in reactions [4] and [5] would account for the butane and hexane observed as products from ethane and propane. The possibility of abstraction of hydrogen from HNCO is a complicating factor at low pressure of hydrocarbon, which, lacking knowledge of the H—NCO bond energy, is difficult to assess. In fact, the steady reduction in N_2 and CO evident in Fig. 1, (*a*) and (*b*), could represent a shift in the equilibrium,

[6] $$R + HNCO \rightleftharpoons RH + NCO,$$

to the left, thus inhibiting formation of N_2 and CO by the reaction

[7] $$2NCO \rightarrow N_2 + 2CO,$$

rather than a gradual scavenging of NH radicals via reaction [4]. There is an indication from Fig. 1(*b*), however, that this is not so, as it is seen that neopentane, propane, and ethane, in that order, show a decreasing efficiency in reducing the yield of N_2. This order of efficiency is not compatible with the equilibrium, [6], being a controlling factor, since in that case the efficiency should have followed the C—H bond strengths in the hydrocarbons, i.e., propane > ethane and neopentane. It is compatible with a rather indiscriminate reaction [4], as insertion reactions are known to be, depending approximately on the number of C—H bonds in the molecule. Thus tentatively it appears that abstraction of hydrogen from HNCO by alkyl radicals is not important in the present systems.

Reaction [5] requires NH_3 to be a product. As in the photolysis of pure HNCO (1), however, ammonia, while detectable, was very difficult to measure quantitatively in the presence of HNCO.

The production of hydrogen in the HNCO–alkane systems was surprising and is difficult to explain satisfactorily. To investigate its origin, a small pressure of ethylene (about 1 torr) was added to the propane–HNCO and ethane–HNCO systems, at alkane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

pressures of about 150 torr; the hydrogen yield was reduced to about one-quarter and one-sixth of its former value, respectively, in the two systems. The added ethylene should not have been able to compete effectively with the alkanes for NH radicals (ethylene and propane appear to be about equally efficient in suppressing N_2 and CO production from HNCO photolysis), and the marked reduction in H_2 strongly suggests that the hydrogen was produced via hydrogen atoms, which would have been readily removed by reaction with ethylene.

Further evidence concerning the origin of the hydrogen was obtained by studying HNCO–C_3D_8 and DNCO–C_3H_8 mixtures. The isotopic composition of the hydrogen produced is shown in Table II; it is seen that the hydrogen from both mixtures was largely HD. The H_2 in fact can be reasonably attributed to protium impurity in the DNCO and the C_3D_8, and it appears that to a good approximation each molecule of hydrogen contained one atom of hydrogen from isocyanic acid and one from propane.

TABLE II

Isotopic composition of hydrogen from HNCO–C_3D_8 and DNCO–C_3H_8 mixtures

	Propane pressure (torr)	% H_2	% HD	% D_2
HNCO + C_3D_8	33.8	20.6	77.6	1.8
	36.0	19.8	78.1	2.1
	82.3	14.0	83.9	2.1
	146.9	13.0	85.2	1.8
DNCO + C_3H_8	36.0	9.8	88.7	1.5
	144.0	12.0	87.3	1.6

Two mechanisms may be suggested for the formation of hydrogen. In the first, a second primary process is postulated in the photolysis of HNCO:

[8] $$HNCO + h\nu \rightarrow H + NCO.$$

This would be followed in pure HNCO by

[9] $$H + HNCO \rightarrow [NH_2CO]^* \rightarrow NH_2 + CO,$$

(thus accounting for the absence of hydrogen as a major product in pure HNCO) and in the presence of propane by

[10] $$H + C_3H_8 \rightarrow H_2 + C_3H_7.$$

Hydrogen was a major product in the HNCO–alkane systems and, allowing for some scavenging of hydrogen atoms by olefins arising from disproportionation reactions or present as trace impurities, was approximately equal to the residual CO, so that reaction [8] would have had to occur to about the same extent as reaction [1]. The arguments against the occurrence of reaction [8] to such an extent have been discussed previously (1). Most compelling is the persistence of CO production, about one-third of its value in pure HNCO, in the presence of high pressures of both olefins and paraffins. This and the dependence of N_2 and H_2 yields on HNCO pressure, temperature, and light intensity (1, 2, 4) are difficult to reconcile with occurrence of any major primary process other than reaction [1].

An alternative mechanism for hydrogen formation involves the decomposition of the excited amine, formed by insertion, to yield hydrogen atoms; e.g., with propane,

[11] $$NH + C_3H_8 \rightarrow [CH_3\underset{NH_2}{CH}—CH_3]^* \rightarrow CH_3\dot{\underset{NH_2}{C}}—CH_3 + H.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Reaction [11] must then have been followed exclusively by

[12] $$H + HNCO \rightarrow H_2 + NCO,$$

to meet the requirement of one hydrogen atom coming from HNCO and one from propane.

The crux of this mechanism is the energy of the excited amine formed by insertion. For NH in its ground state, reaction [4] cannot be far from thermoneutral, and reaction [11] must be about 15 or 20 kcal endothermic (5, 6), The NH radical is probably formed by photolysis in an excited singlet state, perhaps the lowest $^1\Delta$ state which has been estimated to be about 27 kcal above the ground state, or possibly in one of several higher singlet states (7, 8). The effective light in the present photolysis was of wavelengths from 2 000 to 2 200 Å, corresponding to quantum energies from 130 to 142 kcal/mole. The dissociation energy of the HN—CO bond is uncertain, but by analogy with ketene should be much less than that of a normal N=C double bond, and could be as weak as 80 or 90 kcal. Thus it is probably energetically possible to form NH in an excited singlet state with sufficient energy to make reaction [11] exothermic. For reaction [11] to compete effectively with reaction [4], the amine intermediate would have to be vibrationally excited well beyond the threshold for C—H bond rupture, and the frequency factor for this mode of decomposition would have to be much larger than that for the C—N split (reaction [4]). The failure to stabilize amines in the present experiments lends some support to their being formed in highly excited states.

The mechanism also requires C—H rather than N—H bond rupture in reaction [11]; this is not unreasonable, being favored statistically and probably energetically (9). The apparent absence of C—C bond rupture is somewhat surprising (no CH_4 or C_2H_6 was observed). Another requirement is that reaction [12] would have had to have been at least 100 times faster than reaction [10] in order to predominate at the highest propane/HNCO ratios used in the isotopic experiments.

Of the two suggested mechanisms, the second is perhaps the less unpalatable. A decision between the two and consideration of other mechanisms that might be suggested must await further investigation of some of the suggested reaction steps.

PERMANGANATE–PERIODATE OXIDATION

VI. THE OXIDATION OF VARIOUS ALIPHATIC COMPOUNDS[1]

E. VON RUDLOFF

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received December 4, 1964

ABSTRACT

A study was made of the reaction of the permanganate–periodate reagent with a wide variety of aliphatic alcohols, polyols, aldehydes, acids, oxy-acids, ketones, ethers, and esters. Saturated monols, ketones, and ethers, as well as acetic, pelargonic, pyruvic, lactic, and oxalic acids reacted only very slowly. Glycols, olefinic alcohols, and unsaturated acids were cleaved to give predictable end products. Activated alcohols and ethyl acetoacetate reacted at relatively high rates. Formic, glyoxylic, lactic, and malonic acids as well as 1,3-propanediol and 2,5-hexane dione reacted extensively and diethyl tartrate consumed as much oxidant as did tartaric acid. The oxidation of tetrahydrofurfuryl alcohol gave succinic acid instead of the expected tetrahydro-2-furoic acid. Saturated mono- and di-carboxylic acids, 3-hydroxy propionic acid, γ-valero lactone, and saturated esters were stable towards the reagent.

INTRODUCTION

Since our initial reports on the permanganate–periodate reagent (1–4) this combined oxidant has found extensive use in the lipid field. Gas–liquid chromatographic (g.l.c.) analysis of the acidic oxidation products obtained from unsaturated fatty acids and esters has confirmed the quasi-quantitative oxidation to predictable end products (5–7). This aspect has made the reagent highly successful in routine analysis of lipids (6–10) as well as in locating the position of double bonds in unknown or isomeric unsaturated fatty acids (6, 7, 11–14).

In order to determine whether the reagent may be applied equally well to other fields of organic chemistry, in particular to terpenes, a systematic study of its mode of reaction at pH 7–8 and room temperature with various oxygenated compounds was carried out. The rate of reaction and amount of oxidant consumed by a variety of alcohols, ketones, aldehydes, ethers, esters, and carboxylic acids was determined by back titration of the unconsumed oxidant (1). In a few pertinent instances the reaction products were isolated and characterized.

Previously it was shown (1) that the reagent hydroxylates an olefinic double bond rapidly to give the isomeric 1,2-ketols (preferentially at pH 7–8) and 1,2-diol (preferentially at pH 9–10) and that these are cleaved by the periodate to give aldehydes and carboxylic acids. Since only catalytic amounts of permanganate are used the aldehydes are oxidized smoothly, though more slowly, to the corresponding carboxylic acids. No side reactions were detected. The mechanism of hydroxylation with permanganate was reviewed in 1958 (15) and has since been studied further by Wolfe and Lemieux (16). It was shown that a cyclic hypomanganate ester intermediate is involved which hydrolyzes either to the ketols or diol depending on the pH of the solution. The periodate cleavage step appears to follow the well-known course (17). Since one of the basic properties of the reagent is the reoxidation of permanganate by the excess periodate, care must be taken with highly reactive compounds that may reduce the permanganate beyond the Mn^{V} stage more quickly than reoxidation takes place, thus bringing the permanganate reaction

[1]*Issued as N.R.C. No. 8372.*

to a stop. Slow addition of such a reactant to the reagent or greater dilution usually prevents this extensive reduction of permanganate. The reverse order of addition (18) cannot be recommended.

EXPERIMENTAL

Most of the compounds used were of commercial origin (reagent grade, if available). When required the compounds were purified by fractional distillation. Aldehydes were taken up in ether and washed with small aliquots of aqueous bicarbonate solution. Ethers were treated with aqueous ferrous sulfate solution to remove peroxides. Formaldehyde, *n*-butanal, *cis*-hex-3-en-1-ol, 2-methyl-hept-2-en-6-ol, and all of the acids were used without prior purification.

Gas–liquid chromatography analyses were carried out with an F & M model 500 chromatograph (F & M Scientific Corp.), using a 180 cm × 6 mm O.D. polyethylene glycol (Carbowax 20M, 15% on Gaschrom P, 60–80 mesh) column which was temperature programmed from 55 °C at 4 °C/min. The helium flow rate was 105 ml/min and the retention time of methyl hexanoate was 7.2 min (measured from the time of injection to initial emergence of the peak). Relative retention times (r.r.t) were measured relative to this standard (r.r.t = 1.00). Since methylation of acids with freshly prepared diazomethane was found to give additional peaks and was incomplete with some dicarboxylic acids, some of the free acids were methylated in methanol containing concentrated sulfuric acid (2–3%). The esters were extracted with ether in the usual manner. Esters of high volatility were not recovered quantitatively.

Oxidation Procedure

The compound to be oxidized (0.25 mmole; 0.5 mmole if little or no uptake of oxidant was expected) was dissolved in water (10–30 ml) and transferred quantitatively to a standard volumetric flask (100.0 ml) containing permanganate–periodate stock solution (20.0 ml), potassium carbonate (69 mg; or more if more than 1 equivalent acidic product was expected), and water (20 ml). The stock solution of oxidant consisted of 97.5 mmoles sodium periodate (20.86 g) and 2.5 mmoles potassium permanganate (25.0 ml of a 0.1 *M* standard solution) per liter. The mixture was shaken, made up to 100.0 ml, and maintained at 20 °C (±2 °C). At the desired intervals, aliquots (10.0 ml) were pipetted into Erlenmeyer flasks containing standard 0.1 *N* sodium arsenite solution (5.0 ml) and sodium bicarbonate (1 g). After standing for at least 10 min the excess arsenite was titrated with standard 0.025 *N* iodine solution, using starch indicator for the end point. Duplicate values for blank determinations agreed within ±0.01 equivalents and aqueous blanks remained constant within this value for 3 to 4 days. If the compound studied was only very slightly soluble in water it was weighed into the volumetric flask. The reagent, potassium carbonate, and water were added to give about 90 ml and this mixture was shaken for 1 to 3 h before it was made up to volume and aliquots were withdrawn. Alternatively, 10 to 50% *tert*-butanol was used as solvent. The values obtained in the back titration were converted to equivalents oxidant consumed per mole of reactant and the results obtained are expressed as atoms of oxygen per mole in Tables I to VI.

Ethanol, *n*-propanol, *n*-butanol, isobutanol, *n*-hexanol, and *n*-octanol consumed 0.10 to 0.18 atoms of oxygen per mole in 24 h and 0.40 to 0.50 in 144 h. Methanol, isopropanol, *sec*- and *tert*-butanol consumed 0 to 0.10 and 0.15 to 0.22 equivalents during the same time. Pyruvic, oxalic, and acetic acid gave corresponding values of 0.02 to 0.05 and 0.06 to 0.10 whereas pelargonic acid used up 0.08 and 0.25 atoms of oxygen per mole. Glutaric, *n*-hexanoic, benzoic, and azelaic acid, methyl acetate, ethyl acetate, and γ-valero lactone, as well as methyl stearate and stearodipalmitin (both in 30% *tert*-butanol solution) did not consume more than 0.01 to 0.05 atoms of oxygen per mole in 3 to 6 days. 3-Hydroxy propionic acid consumed 0.15 equivalents in the first hour and was not oxidized further from then on. The initial uptake appears, therefore, to be due to an impurity. Similarly, succinic acid consumed initially 0.08 equivalents without further oxidation in 5 days.

Benzyl alcohol was also oxidized in the presence of 20% *tert*-butanol. The consumption of oxidant was 0.16, 0.43, 0.80, 2.18, 2.54, and 2.84 atoms oxygen per mole after 1, 3, 6, 24, 48, and 72 h respectively.

Preparative Oxidations

1. Benzyl alcohol (108 mg) was shaken vigorously with standard oxidant (40 ml), potassium carbonate (276 mg), and water (160 ml) for 48 h. The excess oxidant was reduced with sodium bisulfite and the weakly alkaline reaction mixture was evaporated *in vacuo* to a small volume. The mixture was acidified and extracted continuously with ether. The ether extract was dried over anhydrous sodium sulfate and evaporated to give crude acid (85 mg), m.p. 118–121 °C. Recrystallization from water raised the m.p. to 121–122° (undepressed in admixture of authentic benzoic acid).

2. n-Butanol (74 mg) was oxidized as above for 2 weeks. The acidic product (52 mg) was worked up as above. The g.l.c. analysis of the derived methyl esters showed only one major peak (99%) corresponding to methyl butyrate (r.r.t. = 0.32) in addition to the solvent peaks (ether, methanol).

3. Tetrahydrofurfuryl alcohol (102 mg) was oxidized for 24 h in the same manner. After reduction of excess oxidant the alkaline solution was extracted with ether to remove neutral compounds (3.8 mg). The acidic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

fraction (35.2 mg) was worked up as above to give a crystalline product, m.p. 188–191.5 °C (undepressed by admixture of authentic succinic acid). The ethereal mother liquor was methylated and the resulting methyl esters were analyzed by g.l.c. Two peaks were recorded with r.r.t. 2.30 (3%; tetrahydrofuroic acid methyl ester r.r.t. = 2.29) and 2.80 (97%; methyl succinate r.r.t. = 2.80). The purity of the starting material was found to be 90% by g.l.c.

4. 2-Methyl-hept-2-en-6-ol (57 mg) (82% pure) was oxidized as above and gave only traces of neutral product (1.5 mg) and an acidic fraction (31.9 mg). When the latter was taken up in ether and washed with alkali virtually all material (30.5 mg) remained in the ether layer. The g.l.c. analysis gave a single peak with the r.r.t. of γ-valero lactone (r.r.t. = 3.05). In a separate oxidation experiment the reduced solution was evaporated to a small volume and the distillate was treated with iodine in 2 *N* sodium hydroxide solution. A yellow percipitate having m.p. 119–121 °C (undepressed by admixture of iodoform) was obtained.

5. n-Hexanal (100 mg, 92% pure) was oxidized as above for 24 h to give an acid fraction (75.0 mg) which was analyzed by g.l.c. after methylation. Two peaks with r.r.t. 0.93 (10%) and r.r.t. 1.00 (90%) were recorded (methyl hexanoate r.r.t. 1.00, methyl pentanoate r.r.t. = 0.60).

6. Glutardialdehyde. A 25% solution of glutardialdehyde (400 mg) was oxidized as above for 18 h. The acid fraction (82 mg) was obtained crystalline, m.p. 91–95° (undepressed by admixture of authentic glutaric acid). The g.l.c. analysis of the derived methyl esters of the mother liquor gave one main peak (98%) with r.r.t. 3.55 (methyl glutarate r.r.t. = 3.55).

Oxidation of Esters

Methyl stearate, m.p. 37.5–38.8 °C (99.20 mg) was dissolved in *tert*-butanol (30 ml) and added to the standard oxidation mixture (see above). After 24 h the excess oxidant was reduced and the reaction mixture was extracted repeatedly with ether. After evaporation of the solvent, the residue was dried *in vacuo* to constant weight (99.25 mg); m.p. 37.2–38.8 °C.

In a similar experiment oxidation of stearodipalmitin m.p. 67.5–68.3 °C (96.10 mg) gave the unreacted starting material, m.p. 67.5–68.3 °C, in almost quantitative amount (94.55 mg).

RESULTS AND DISCUSSION

The rate of oxidation of saturated aliphatic alcohols was found to be very slow (see Experimental). No significant difference in rate was found between lower and higher homologues or between primary, secondary, and tertiary alcohols. Surprisingly, the rate for methanol was one of the lowest. The oxidation of *n*-butanol gave only *n*-butyric acid as acidic reaction product. Since it is generally accepted that alcohols are attacked only slowly by permanganate in neutral media (19), it follows that at pH 7.5–8 the permanganate–periodate reagent behaves like neutral permanganate towards saturated alcohols. This finding permits the selective oxidation of other functional groups in alcohols provided these are not adjacent to the hydroxyl group. Wall and Serota (20) made use of this property in the selective oxidation of steroidal sapogenins with the permanganate–periodate reagent.

Activated alcohols (see Table I) reacted at much higher rates than the saturated aliphatic alcohols. Thus, benzyl alcohol consumed 1 mole of oxidant in less than 6 h and 2 in just over 2 days. Since benzoic acid was isolated in 70% yield the oxidation was essentially that of the primary alcohol group. When benzyl alcohol was oxidized in the presence of 20% *tert*-butanol the rate of oxidation increased and more than 2 moles of oxidant were consumed in 1 day (see Experimental). The oxidation of tetrahydrofurfurol (see Table I) did not proceed in the expected manner since the main product was succinic acid rather than tetrahydro-2-furoic acid. The reaction with cyclic ethers will have to be studied in more detail to clarify the mechanism by which the ring is opened. Allyl alcohol consumed 4 moles of oxidant very rapidly and another 1 in about an hour; oxidation continued more slowly until nearly 6 moles were consumed. This can be rationalized by assuming that allyl alcohol is hydroxylated very rapidly to glycerol, glyceraldehyde, and dihydroxy acetone and that these are cleaved quickly to give formic acid and formaldehyde. Formic acid appears to be oxidized fairly rapidly (see below); the slow oxidation of formaldehyde at pH 7–8 has been described before (1). Hydroxylation and cleavage may proceed so rapidly that oxidation of the activated hydroxyl group in allyl alcohol may take place only to a very small extent.

144 h	—	—	2.63	0.89	—	—

The oxidation of alcohols with an isolated double bond followed the normal pattern of hydroxylation, cleavage, and subsequent slower oxidation of the oxidizable cleavage products. The overall consumption of 3 moles of oxidant by 2-methyl-hept-2-en-6-ol (see Table I) is in agreement with formation of acetone and 4-hydroxy pentanoic acid. Acetone was characterized by the iodoform reaction and 4-hydroxy pentanoic acid was recovered (as γ-valero lactone) in high yield. It was shown previously (2) that acetone is oxidized only very slowly at pH 7–8 by the reagent. The consumption of almost 4 moles of oxidant by *cis*-hex-3-en-1-ol is in accord with formation of propionic and 3-hydroxy propionic acid. A commercial sample of the latter acid was found to be completely stable towards the reagent (see Experimental).

Simple α-glycols (see Table II) reacted in complete accordance with the concept of periodate cleavage (17, 21, 22) and further oxidation of aldehydic products and formic acid. When the product is formaldehyde, further oxidation is slow (see e.g. ethylene glycol). The rate of oxidation after the initial cleavage of glycerol is somewhat slower than that of formic acid (see Table IV). Similarly, that of 1,2-propanediol is a little slower than the rate of oxidation of acetaldehyde as produced in the oxidation of 2,3-butanediol. This is unexpected since both compounds would also produce formaldehyde, oxidation of which (in addition to either formic acid or acetaldehyde) should lead to a somewhat faster consumption of oxidant. This may be due, at least in part, to a slightly different pH of the respective reaction mixtures. On the other hand, the rate of oxidation of erythritol did approach the expected values closely. The markedly lower rate of cleavage of pinacol is due to steric hindrance (23). Methyl β-L-arabopyranoside consumed slightly more than 3 moles of oxidant rather rapidly without further oxidation. Since cleavage and oxidation of the resulting formic acid require 3 moles of oxidant, the intermediate dialdehyde ether moiety appears to be stable. The formation of cyclic hemialdals (22) in periodate oxidations is well known and it is possible that these are stable towards the permanganate–periodate reagent. Methyl glucoside and free sugars reacted very extensively and their oxidation was not characterized by clearly defined stages.

Water-soluble aldehydes, except formaldehyde, were oxidized smoothly with consumption of 1 mole of oxidant in 6–24 h (see Table III). The oxidation of pelargon aldehyde to pelargonic acid is in agreement with earlier data on the behavior of this aldehyde as part of the oxidation of oleic acid (1). *n*-Octanal also required 3 h shaking to give complete oxidation. *n*-Decanal was too insoluble to give consistent data in the aqueous mixture, but addition of 40% *tert*-butanol resulted in a normal rate of oxidation. The oxidation of *n*-hexanal gave *n*-hexanoic acid in 65% yield. Since no lower homologous acids were

*In 40% *tert*-butanol solution.

found to be present and since some loss of these volatile acids is likely during isolation, the smooth conversion of *n*-aldehydes to the corresponding carboxylic acid is confirmed. The consumption of nearly 2 moles of oxidant by glutardialdehyde and the isolation of glutaric acid from the product indicates that dialdehydes are also oxidized in a predictable manner, except malon dialdehyde which appears to be degraded extensively (see below).

TABLE IV

Aliphatic acids, benzoic, oxalic, glutaric, azelaic, and pyruvic acid were oxidized only very slowly by the reagent (see Experimental). The fact that oxalic acid did not react to any appreciable extent confirms that manganese is not reduced below the Mn^{V} level, thus preventing the well-known autocatalyzed reaction. Formic acid (see Table IV) consumed 1 mole of oxidant in 1 to 2 days. As found earlier (3), malonic acid is also oxidized slowly (see Table IV), the rate being similar to that of 1,3-propanediol. Hence, it is surprising that 3-hydroxy propionic acid was found to be much more stable. Glyoxylic acid (see Table IV) consumed 2 moles of oxidant fairly rapidly, indicating that this acid was cleaved rather than oxidized to oxalic acid. Pyruvic acid was stable towards the reagent and lactic acid was oxidized only slowly. The latter consumed 2 moles of oxidant in 6 days indicating that cleavage has taken place instead of oxidation of pyruvic acid. Tartaric acid reacted very rapidly and the consumption of almost 5 moles in 24 h suggests again that the intermediate glyoxylic acid must be cleaved, which is in agreement with the above conclusions. This is further supported by the data obtained with diethyl tartrate. Cleavage of this ester would yield 2 moles of ethyl glyoxylate. The consumption of a total of 5 moles of oxidant is in agreement with cleavage of this aldehydo ester

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(possibly after hydrolysis to glyoxylic acid). Hydroxylation and cleavage of crotonic acid would yield acetaldehyde and glyoxylic acid. Further oxidation of these two products would require 3 moles of oxidant if the glyoxylic acid moiety is cleaved. Again, the values of oxidant consumed are in good agreement (see Table IV).

TABLE V

Oxidant consumed (atoms oxygen per mole) by some aliphatic ketones

Reaction time (h)	Methyl ethyl ketone	Methyl isobutyl ketone		Methyl *n*-amyl ketone	2,5-Hexane dione	Ethyl aceto-acetate
		(*a*)*	(*b*)†			
1		—	—	—	—	2.09
3	0.01	0.01	0.01	0	0.01	2.54
6	0.01	0.01	0.04	0.02	0.08	2.94

48	0.06	0.05	0.07	0.14	0.40	3.76
120	0.23	0.16	0.20	0.33	0.86	3.90
144	0.30	0.33	0.40	0.55	1.16	3.90

*(*a*) In aqueous solution.
†(*b*) In 20% *tert*-butanol solution.

Ketones were oxidized only very slowly (see Table V). This was anticipated from the very low rate of oxidation of acetone at pH 7–8 (2). The rate of oxidation of methyl isobutyl ketone in the presence of *tert*-butanol was practically the same as in aqueous solution. Noteworthy, again, is the higher rate of oxidation of 2,5-hexanedione, the rate being similar to that of malonic acid and 1,3-propanediol. This would indicate a similar activation of the methylene group in 1,3-diones, although in the ketones it seems more likely that the enol form is the one that reacts. As expected, ethyl acetoacetate reacts rapidly and the consumption of almost 4 moles of oxidant is in agreement with the assumption that the enol form is hydroxylated and cleaved to give acetaldehyde and ethyl glyoxylate as intermediates. The latter two compounds would react further as described above for 2,3-butanediol, crotonic acid, and ethyl tartrate.

As noted previously (3), saturated esters are stable towards the reagent. Methyl and ethyl acetate, as well as methyl stearate and stearodipalmitin, consumed less than 0.05 moles of oxidant in 3 days and the latter two esters were recovered virtually quantitatively (see Experimental). γ-Valero lactone also consumed no oxidant. This confirms that the saturated esters are not hydrolyzed under the ordinary oxidation conditions and this stability accounts in part for the quantitative results obtained in triglyceride analysis (6–9). Some workers have found that in the oxidation of oleic and linoleic acid or their esters a few percent of the next lower homologous monocarboxylic acid (octanoic and pentanoic acid respectively) may be formed in permanganate–periodate oxidation (6, 14, 18). Recent results obtained by Craig and Bhatty (14) indicate that this so-called overoxidation is largely due to the presence of peroxides. However, the very low rate of oxidation of pelargonic acid itself (see Experimental) suggests that a small amount of the next lower homologue may be produced by direct attack on the end products. However, since the reaction time for the oxidation of unsaturated acids and esters is usually less than 24 h, this side reaction cannot amount to more than 3%. In fact, it will normally be smaller since azelaic and hexanoic acids were found to be practically stable towards the reagent. It is also noteworthy that 9,10-epoxy stearic acid was not oxidized by the reagent (1).

TABLE VI

Oxidant consumed (atoms oxygen per mole) by some aliphatic ethers

Reaction time (h)	Diethyl ether	*n*-Dibutyl ether	Bis-(2-methoxy ethyl)-ether	Bis-(2-ethoxy ethyl)-ether
3	0.03	0.11	0.15	0.13
24	0.41	0.40	0.18	0.42
48	0.49	0.48	0.30	0.64
72	0.70	0.58	0.42	0.78
96	0.80	0.67	0.48	1.00
168	1.30	1.11	0.89	1.17

Finally, a few ethers were investigated (Table VI). These were oxidized at a slow rate and the uptake of oxidant did not cease after 7 days. When *p*-dioxane was used as solvent (2) a slow increase in the blank titration was also noted. This confirms that the ethers are not ideal for use as solvent and *tert*-butanol and possibly also pyridine (4) are to be preferred.

ACKNOWLEDGMENTS

The interesting and stimulating discussions with Drs. R. U. Lemieux and A. S. Perlin are gratefully acknowledged. Thanks are also due to Mr. M. Granat for technical assistance.

A PROTON MAGNETIC RESONANCE STUDY OF N-BIS(2-HALOETHYL)AMINES[1]

GEORGE R. PETTIT, JOSEPH A. SETTEPANI, AND RALPH A. HILL
Department of Chemistry, University of Maine, Orono, Maine

Received September 28, 1964

ABSTRACT

The proton magnetic resonance chemical shifts of N-bis(2-haloethyl)amine hydrohalide salts have been found useful for rapidly assessing organohalide composition. An important illustration of nitogen mustard reactivity was obtained by observing the p.m.r. response of N-bis(2-haloethyl)amine hydrohalide salts (in deuterium oxide) following neutralization. In general, the amines rapidly entered a complex series of intra- and inter-molecular reactions. Among the substances studied N-bis(2-fluoroethyl)amine was by far the most stable and remained essentially unchanged during a 7-day period. By contrast N-bis(2-iodoethyl)amine was completely transformed in less than 6 min. The self-condensation reactions of, for example, N-bis(2-chloroethyl)amine appear to be accompanied by transient formation of N-2-chloroethylaziridine (III*b*). The present investigation indicates that p.m.r. spectroscopy is a valuable technique for evaluating the course of nitrogen mustard self-condensation reactions.

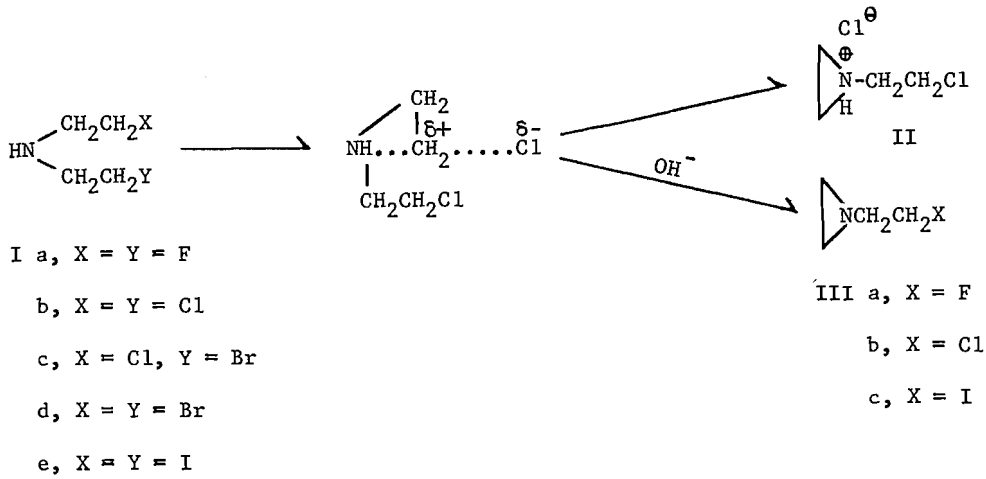
In order to extend both the utility of nitrogen mustards as cancer chemotherapeutic agents and our chemical knowledge of these substances, we have undertaken development of convenient synthetic routes to various symmetrical (with respect to the halogen substituent, e.g., see ref. 2) and unsymmetrical (3) N-bis(2-haloethyl)amines. When it became apparent (2*a*) that even appreciable quantities of incorrectly halogenated impurities accompanying unsymmetrical nitrogen mustards could be difficult to detect, prior to elemental microanalyses, we began to employ proton magnetic resonance (p.m.r.) spectroscopy as a method for rapidly evaluating purity. Prior experience with, and interest in, N-bis(2-chloroethyl)amine (I*b*) self-condensation reactions (4) suggested the potential value of also using p.m.r. measurements to follow and compare the course of such transformations in aqueous solution (at various pH levels) and in other protic and aprotic solvents. The possibility of assessing aziridinium ion (II) formation also appeared attractive. Certain reactions of N-bis(2-chloroethyl)amine are now generally believed to proceed via the corresponding aziridinium salt (5) and additional support for such intermediates[2] in the case of nitrogen mustard reactions would be useful. For example, a meaningful correlation between extent of aziridinium ion formation and antineoplastic activity might then be possible. A summary of initial results obtained in pursuit of these general objectives is presented in the sequel.

Proton magnetic resonance chemical shifts of the four parent N-bis(2-haloethyl)amines (1*a–b* and 1*d–e*), as hydrohalide salts in deuterium oxide solution, allowed each to be readily distinguished from the other members. One unsymmetrically halogenated nitrogen mustard (I*c*) was also studied and as expected the p.m.r. response was again unique. The spectral results summarized in Fig. 1 for the secondary amines and in Fig. 2 for their N-methyl derivatives[3] clearly indicates that proton magnetic resonance spectroscopy provides a very useful means for rapidly distinguishing between the various halogenated

[1]*The present contribution and a previous one (1) may be considered Parts XIV and XIII respectively of our series, Antineoplastic Agents. For Part XII, refer to G. R. Pettit and J. A. Settepani, Chem. Ind. London, 43, 1805 (1964).*

[2]*The structure of 2,2-pentamethylene-1,1-tetramethylene aziridinium perchlorate and related ethylenimonium compounds prepared by Leonard and colleagues (6), however, have been carefully substantiated.*

[3]*Because of insufficient solubility in deuterium oxide (at 20°) a spectrum of N-methyl-N-bis(2-iodoethyl)amine hydrochloride was not included in Fig. 2.*



nitrogen mustards. In Fig. 1 the spectrum of N-bis(2-fluoroethyl)amine hydrobromide provides a classical example of fluorine–proton spin–spin coupling (1). The two lowest field triplets centered at 5.56 and 4.8 δ represent methylene protons adjacent to fluorine and the two high field triplets (at 4.15 and 3.68 δ) reflect methylene protons adjacent to nitrogen (1). Coupling constants for the fluorine derivative and N-bis(2-chloroethyl)-amine hydrochloride were essentially equal (J = 5 c.p.s.) but the triplet assignable to methylene protons adjacent to nitrogen in the latter compound was centered at 3.88 δ and the triplet corresponding to methylene protons adjacent to chlorine was centered at 4.28 δ. With N-bis(2-bromoethyl)amine hydrochloride the partially masked triplet arising at 4.05 δ approximates an A_2B_2 case (7). The principal peak exhibited by N-(2-iodoethyl)amine hydrochloride at 3.84 δ resembled that of the bromine analog. As expected N-2-bromoethyl-N-2-chloroethylamine hydrobromide displayed a near composite of the spectra corresponding to chloroamine I*b* and bromoamine I*d* and the principal peak was positioned at 4.05 δ. Except for the $\oplus$N—CH_3 signal (e.g., see ref. 8) at 3.53 δ each of the tertiary amines noted in Fig. 2 displayed a spectrum qualitatively similar to that of the related secondary amine.

Next, each of the secondary amine (I*a–e*) hydrohalide salts was treated with an equivalent amount of sodium deuteroxide in deuterium oxide. Three minutes later p.m.r. scanning was commenced. Since the scanning time was 4 min a total of 7 min elapsed before the complete spectrum was recorded. The mixtures p.m.r. response was then generally ascertained at 15, 30, 60, and 100 to 120 min intervals. Under the experimental conditions employed, fluoroamine I*a* proved quite stable.[4] Three minutes after neutralizing the fluoroamine (I*a*) hydrobromide salt, a p.m.r. spectrum of the solution showed four new, but nicely resolved, triplets centered at 3.05, 3.55, 4.55, and 5.30 δ (J = 5 c.p.s.). Except for a slight shift (0.05 δ) to lower field and emergence of 2 small split peaks at 1.80 and 2.19 δ by the third day, the spectrum remained otherwise unchanged during a 7-day observation period. Meanwhile, the p.m.r. chemical shifts (Table I) of six representative aziridine derivatives were recorded. On the basis of this

[4]*The* ^{19}F *nuclear magnetic resonance of N-bis(2-fluoroethyl)amine has been studied (9) but proton magnetic resonance chemical shifts were not recorded. Our brief mention of fluoroamine Ia, stability as evidenced by p.m.r. studies, in ref. 2b (footnote 3), represents to our knowledge the only prior report of an N-bis(2-haloethyl)amine p.m.r. investigation.* NOTE ADDED IN PROOF. *An excellent p.m.r. study of 2-chloro- and 2-fluoro-ethylamines has now been summarized by P. L. Levins and Z. B. Papanastassiou. J. Am. Chem. Soc. 87, 826 (1965).*

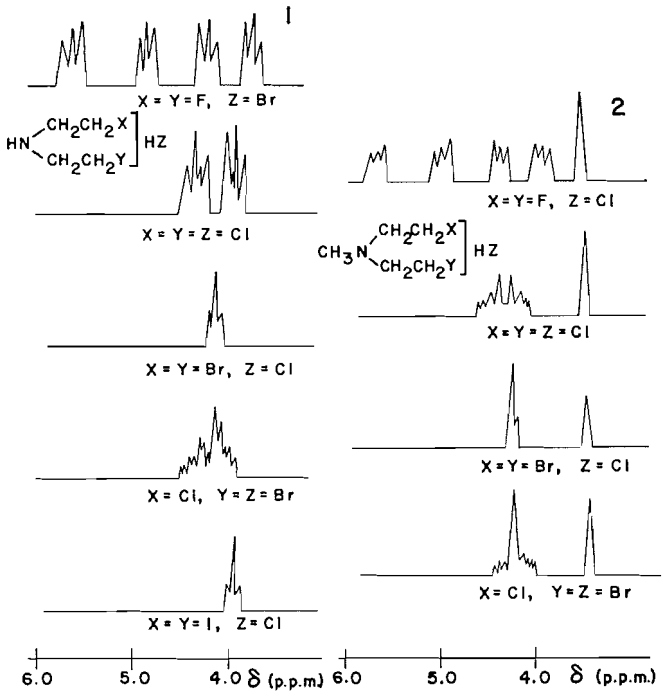

FIG. 1. Proton magnetic resonance spectra of representative N-bis(2-haloethyl)amine hydrohalides in deuterium oxide.

FIG. 2. Proton magnetic resonance spectra of several N-methyl-N-bis(2-haloethyl)amine hydrohalides in deuterium oxide.

study (see also ref. 10) it seemed likely that the aziridinium ion (cf. II) derived from amines such as I*a–e* in deuterium oxide should give rise to a p.m.r. signal at approximately 2.6–3.5 δ and that the parent aziridine (III), in the same solvent, should exhibit a signal at approximately 2.0 δ. Thus, the two small complex signals near 2.0 δ (appearing after 3 days) were tentatively attributed to a small quantity of N-2-fluoroethylaziridine (III*a*).

Repeating the neutralization experiment employing N-bis(2-chloroethyl)amine provided the spectral data illustrated in Fig. 3. Within 7 min after neutralization, 2 triplets centered at 3.35 and 4.05 δ (J = 5 c.p.s.) corresponding to essentially pure amine I*b*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

were recorded. By the time 15 min elapsed two small peaks appeared at 1.90 and 2.25 δ and another at approximately 3.0 δ; the original triplets had shifted downfield 0.05 δ. Accordingly, the two peaks at higher field were tentatively assigned to N-2-chloroethylaziridine (III*b*). During the next 15 min period an increase in hydrogen ion concentration was probably responsible for the overall shift to lower field. The three highest field peaks were relocated at 2.45, 2.65, and 3.36 δ and the triplets became centered at 3.75 and 4.25 δ. With passing of 100 min, the p.m.r. spectrum (Fig. 3) qualitatively resembled that of the original hydrochloride derivative (Fig. 1) although the presence of other substances was apparent. Three days later approximately the same p.m.r. response was elicited.

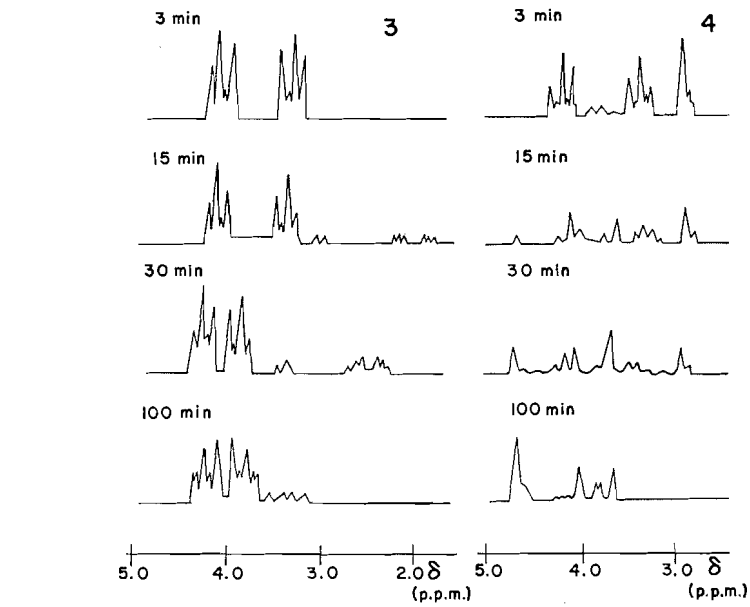

FIG. 3. Proton magnetic resonance spectra of N-bis(2-chloroethyl)amine following neutralization (zero time) of the hydrochloride salt (in deuterium oxide).
FIG. 4. Proton magnetic resonance spectra of N-methyl-N-bis(2-chloroethyl)amine following neutralization (zero time) of the hydrochloride salt (in deuterium oxide).

The two high field partially resolved triplets (centered at 1.85 and 2.20 δ) presented by N-2-bromoethyl-N-2-chloroethylamine hydrobromide 3 min after neutralization were more convincing. The high field signals were assigned to the aziridine ring protons of amine III*b*. Again, the poorly resolved signals in the 3.0 δ region were much less convincing evidence for aziridinium ion ring protons. Fifteen minutes later the spectrum of amine I*c* appeared more complex and the two highest field signals had shifted 0.10 δ to lower field. During the next 15 min a solid began to separate from solution which prohibited further p.m.r. observations.

When the preceding experiment was repeated using N-bis(2-bromoethyl)amine hydrochloride initial reaction of the free base proved quite rapid. The p.m.r. spectrum recorded at time 3 to 7 min displayed two very broad and ill-defined signals centered at 2.5 and 4.0 δ. At a total elapsed time of 16 min a complex multiplet had appeared at 3.39 δ and a partially masked triplet reminiscent of the original hydrobromide salt (of amine I*d*) was positioned at 4.10 δ. Essentially the same p.m.r. spectrum was obtained 2 h later.

In keeping with rapid disappearance of amine I*d* a p.m.r. spectrum of N-bis(2-iodoethyl)amine hydrochloride 3 min after neutralization showed, principally, a weak but broad and unresolved signal centered at approximately 3.8 δ. Interestingly, two small barely discernible peaks were positioned at 1.8 and 2.18 δ and suggested the transient presence of aziridine III*c*. The reactions of amine I*e* culminated at time 6 min with separation of a dark semisolid which precluded further spectral study.

Of the tertiary amines, N-methyl-N-bis(2-fluoroethyl)amine and N-methyl-N-bis(2-chloroethyl)amine were selected for initial examination. A p.m.r. spectrum of the fluorine-containing amine, 3 min after neutralizing the corresponding hydrochloride salt in deuterium oxide solution, was consistent with that expected for the pure base; the methyl peak emerged at 2.80 δ and 4 triplets (J = 5 c.p.s.) were centered at 3.02, 3.52, 4.69, and 5.48 δ. Two hours later an identical spectrum was recorded. Four days later approximately 85% of the original amine had been transformed to a new substance displaying p.m.r. signals at 3.95 and 4.59 δ.[5] After a total time of 7 days the reaction was essentially complete. Analogous reaction of the chloro derivative was considerably faster and nearly complete within 2 h (Fig. 4). Similarly, N-methyl-N-bis(2-bromoethyl)amine disappeared during the first 3 min period and 30 min later reaction seemed terminated. Although the early spectra reproduced in Fig. 4 contain a small peak at 2.78 δ which might correspond to aziridinium ring protons, the present evidence is at best only suggestive. In the tertiary amine experiments just described, the concentration of aziridinium ion, if formed at all, must remain low.[6] In general, firm spectral evidence for terminal piperazine formation was lacking and assignments for the end-products (following neutralization) require a definitive chemical study.

The preceding albeit preliminary experimental results indicate that future p.m.r. investigations of N-bis(2-haloethyl)amines under varying conditions of pH and solvent should lead to a clearer understanding of stability, the course of self-condensation reactions, and important intermediates. Thus, it should now be possible to rapidly determine the optimum time requirements and other experimental conditions for production of selected intermediates and terminal products. By this means, isolation and characterization of, for example, the N-2-haloethylaziridines (III)[7] may become practical. Previous attempts (4, 12) at isolation or preparation of aziridine III*b* have met with failure. Experiments related to these problems are now in progress.

EXPERIMENTAL

The proton magnetic resonance data were recorded using a Varian Associates Model A-60 Spectrometer. Each of the N-bis(2-haloethyl)amines was studied in deuterium oxide (10% solute by weight) using a capillary tube filled with tetramethylsilane as external standard (uncorrected for bulk, diamagnetic susceptibility differences). The chemical shifts reported with deuterium oxide as solvent in Table I were obtained in the same manner. When deuterochloroform was employed as solvent (for the measurements recorded in Table I) the solute also amounted to 10% (wt./vol.) and enough tetramethylsilane was added to standardize the instrument. The chemical shifts (at 20 $\pm$ 1°) are reported using the frequency-independent unit δ (p.p.m.) with respect to tetramethylsilane. In each case the scanning time from low to high field was 4 min (120 c.p.s./min).

After collecting the chemical shift data for each N-bis(2-haloethyl)amine hydrohalide salt, exactly 1 equivalent of sodium deuteroxide (by adding the calculated quantity of sodium to deuterium oxide) in deuterium oxide was added and mixing was achieved by twice inverting the n.m.r. sample tube. At this point the opalescent solution had cleared and 3 min after adding base scanning was commenced. The spectrum was recorded again after 15, 30, 60, and 100 to 120 min intervals. Longer periods were employed

[5]*The composition of this substance (possibly a piperazine) will be ascertained as part of a future investigation.*
[6]*The utility of p.m.r. techniques for mechanism studies depends on relatively high concentrations of important intermediates.*
[7]*In vivo transport of N-bis(2-haloethyl)amine has been postulated to involve aziridine IIIb (11).*

in those cases where reaction appeared incomplete. Scanning was terminated whenever a solid product began to separate from solution.

N-Bis(2-haloethyl)amines

The N-bis(2-haloethyl)amines and their N-methyl derivatives were prepared in this laboratory as part of previous (2, 13) or recently completed (3) investigations. Synthesis of the two new nitrogen mustards, N-2-bromoethyl-N-2-chloroethylamine and its N-methyl derivative, will be described in a separate contribution (3).

Aziridines

The specimen of N-chloroaziridine was supplied (cooled to dry ice temperature) by Aerojet-General Corporation, Azusa, California, and its p.m.r. spectrum was recorded within 2 h of delivery. We are indebted to Drs. Goodman (14) and Leonard (6) for providing the second and sixth compounds entered in Table I. The remaining substances (in Table I) were purchased from Aldrich Chemical Company.

ACKNOWLEDGMENTS

This investigation was aided by Grants No. T-79D and T-79E from the American Cancer Society and by National Science Foundation Research Grant GB-249. We are also grateful to the National Institutes of Health for predoctoral fellowship (to J. A. S., 1963–1964) support.

ANTINEOPLASTIC AGENTS

XV. INTRAMOLECULAR REACTIONS OF N-PHENYL-N′-BIS(2-CHLOROETHYL)UREA[1]

GEORGE R. PETTIT, DAVID S. BLONDA,[2] AND ROGER A. UPHAM
Department of Chemistry, University of Maine, Orono, Maine

Received October 5, 1964

ABSTRACT

Reaction between phenyl isocyanate and N-bis(2-chloroethyl)amine in cold diethyl ether solution yields N-phenyl-N′-bis(2-chloroethyl)urea. The urea was found to rearrange in ethanol solution or upon warming to, respectively, 2-(N-phenylimino)-3-(2′-chloroethyl)-oxazolidine hydrochloride and 1-phenyl-2-oxo-3-(2′-chloroethyl)imidazolidine. Infrared spectral studies, augmented by mass and proton magnetic resonance determinations provided compelling support for the structural formulations. The oxazolidine reaction sequence was also examined employing 4-nitrophenyl isocyanate, 1-naphthyl isocyanate, and N-bis(2-bromoethyl)amine.

Rapid intramolecular rearrangement of N-bis(2-chloroethyl)amides to 2-(2′-chloroethylamino)ethyl esters, in the presence of water, has been well established (for example, see ref. 1). When rearrangement of N-bis(2-chloroethyl)amides to the corresponding ester derivatives was found to be rather general in scope (1*a*), we decided to extend the study to N-substituted-N′-bis(2-chloroethyl)ureas (I). Major impetus for this course resided with the enhanced potential of N-bis(2-chloroethyl)ureas to undergo one of a variety of possible intra- or inter-molecular reactions combined with the possibility of finding a useful antineoplastic agent among substances of this type and (or) their transformation products.

When the present investigation was begun in 1959, one N-phenyl- and one benz(a)anthracene derivative of N-bis(2-chloroethyl)urea had already been described (2, 3). Both urea derivatives were prepared, employing the corresponding isocyanate and N-bis(2-chloroethyl)amine, and purified under mild conditions employing aprotic solvents. No rearrangement reactions of the ureas were reported and the conditions recorded would not have favored transformations of this type. Subsequently, Popp and Swarz (4*a*) reported a series of urea and thiourea[3] derivatives of N-bis(2-chloroethyl)amine which they considered to be the first examples of N-bis(2-chloroethyl)ureas. Here, the crude reaction products were not further purified.[4] Recently, Khedouri, Kim, and Friedman (4*c*) described a series of N-bis(2-chloroethyl)ureas prepared (in benzene solution) from isocyanate derivatives of aspartic acid, glutamic acid, phenylalanine, methionine, and leucine ethyl esters. A reaction employing ethyl L-leucine isocyanate and N-bis(2-chloroethyl)amine was reported to yield (12 and 70% respectively) a crystalline racemate and the optically active urea. The remaining ureas were oils characterized following column chromatography on Florisil. In each case, treating the urea with water, either alone or containing acid or base, provided a hydrochloride salt which was assigned a carbamate structure (e.g. III*b*).

Addition of phenyl isocyanate to a dry ethereal solution of N-bis(2-chloroethyl)amine

[1]*Part XIV. G. R. Pettit, J. A. Settepani, and R. A. Hill. Can. J. Chem. This issue.*
[2]*Present address: E. I. duPont de Nemours and Co., Inc., Wilmington, Delaware.*
[3]*Interestingly, the principal product from reaction between N-bis(2-chloroethyl)amine and phenyl isothiocyanate in diethyl ether solution has been found (in our laboratory) to be N-bis(2-chloroethyl)amine hydrochloride. The same observation has recently been reported by Berlin and Levi (5). A more detailed study of this unexpected reaction is now in progress.*
[4]*Later (4b), a pure specimen of N-(4-fluorophenyl)-N′-bis(2-chloroethyl)urea was reported.*

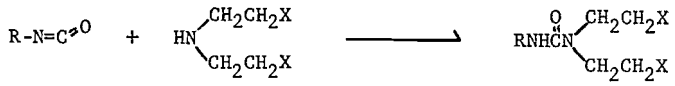
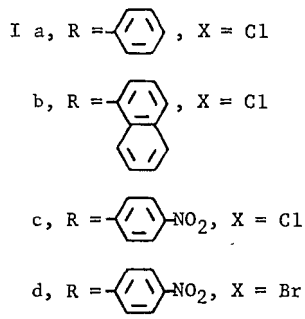
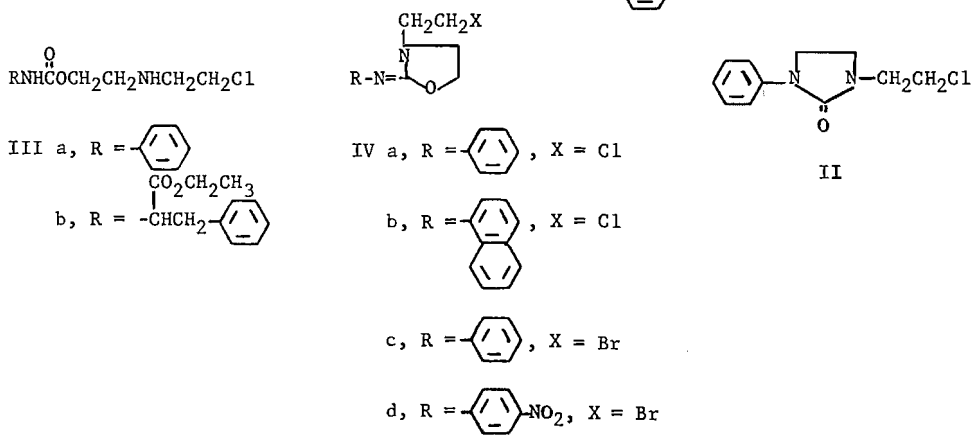
For personal use only.

was selected for initial study. Conversion to urea I*a* proceeded quite rapidly; the reaction product (I*a*) began to separate from solution within a 3 min period. With several examples described below, the reaction began immediately and was essentially complete within a several minute period. Assignment of an N-phenyl urea structure (I*a*) was considered appropriate on the basis of elemental composition and results of infrared spectral and







proton magnetic resonance (p.m.r.) determinations. The infrared spectrum of urea I*a* exhibited N—H absorption at 3 100 cm^{-1} and carbonyl absorption at 1 670 and 1 635 cm^{-1}. Proton magnetic resonance signals were observed at 3.58 δ (approximately 8 methylene-type protons) and in the region 6.82–7.15 δ (phenyl protons). During purification of urea I*a*, certain conditions such as heating or contact with protic solvents led to new products. Warming (steam bath) the urea caused intramolecular cyclization to imidazolidone II with concomitant loss of hydrogen chloride. In addition to molecular weight determination (by mass spectrometry) and elemental composition, assignment of the imidazolidine structure[5] was suggested by its infrared spectrum (no N—H absorption and a single carbonyl band at 1 685 cm^{-1}) and p.m.r. response. The p.m.r. spectrum of imidazolidine II exhibited a band at 3.53 δ (partially masked triplet) attributable to the 8 aliphatic-type protons and a complex response in the 6.8–7.4 δ region assignable to the aromatic protons.

[5]*An analogous reaction sequence was reported by Gabriel in 1895 (6). Warming N-phenyl-N'-(2-chloroethyl)-urea in ethanol-containing base yielded a product assigned the corresponding imidazolidone structure.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Attention was next focused on transformation of urea I*a* in a polar medium. As the amide → ester rearrangement noted earlier (1) was found to proceed satisfactorily in ethanol solution, intramolecular rearrangement of urea I*a* was allowed to proceed in this solvent. Here, two prominent reaction pathways would appear likely: rearrangement to carbamate[6] III*a* or oxazolidine IV*a*. Reaction of urea I*a* in ethanol, at room temperature, was found to proceed quite readily and yield (quantitative) a hydrochloride salt. An infrared spectrum of the product revealed a strong ammonium band at 2 750 cm^{-1} and a broad carbonyl-type band at 1 660–1 680 cm^{-1}. Absence of absorption in the vicinity of 1 720 cm^{-1} (8) eliminated the carbamate structure (III) from further consideration. In addition, relatively strong absorption bands at 1 030 and 1 230 cm^{-1} suggested a vinyl ether-type[7] linkage. In keeping with these observations and elemental microanalytical data, the salt was assigned 2-(N-phenylimino)-3-(2′-chloroethyl)oxazolidine (IV*a*) hydrochloride.[8] Although a p.m.r. spectrum of the salt observed in deuterium oxide solution did not provide definitive support for the structural formulation, the complex signals observed at 4.4–4.6 and 4.95–5.15 δ appeared to involve 8 methylene protons and be consistent with oxazolidine IV*a*.

The reaction sequence leading to phenyl oxazolidine IV*a* was also utilized to prepare the 1-naphthyl derivative (IV*b*) and two oxazolidines (IV*c* and *d*) derived from N-bis(2-bromoethyl)ureas. As might be expected, N-phenyl-N′-bis(2-bromoethyl)urea proved too reactive to be conveniently isolated and was instead converted to oxazolidine IV*c*. While reaction of 4-nitrophenyl isocyanate with N-bis(2-chloroethyl)amine led to the most stable urea (I*c*) examined, analogous reaction with N-bis(2-bromoethyl)amine again led to a relatively unstable urea which was more conveniently characterized as oxazolidine IV*d*.

EXPERIMENTAL[9]

N-Phenyl-N′-bis(2-chloroethyl)urea(Ia)

A 20 g (0.112 mole) sample of N-bis(2-chloroethyl)amine hydrochloride (ref. 11, footnote 23) was neutralized with cold (ice bath) 10% sodium hydroxide solution. The amine was extracted with diethyl ether (3 × 100 ml) and the combined extract was washed with water and dried successively over magnesium sulfate and calcium sulfate. The ethereal solution was cooled (ice bath) and a solution of phenyl isocyanate (13.4 g, 0.112 mole) in dry diethyl ether (75 ml) was added. After approximately 3 min, the colorless crystalline product began to separate from solution. Cooling was continued for 30 min before collecting the product; yield 21.2 g (73%), m.p. 72–74°. Four recrystallizations from ethyl acetate – benzene provided an analytical sample as needles melting at 76–78° (lit. (3) m.p. 74–75°); p.m.r. response ($CDCl_3$ solution) 3.58 (8 methylene protons) and 6.82–7.15 (5 phenyl protons) δ; ν_{max}^{KBr} 3 100, 1 670, 1 635, 1 595, 1 440, 760–755, and 695 cm^{-1}.

Anal. Calcd. for $C_{11}H_{14}Cl_2N_2O$: C, 50.60; H, 5.41; Cl, 27.15; N, 10.72. Found: C, 50.72; H, 5.11; Cl, 27.16; N, 10.92.

1-Phenyl-2-oxo-3-(2′-chloroethyl)imidazolidine(II)

Method A

A 5.0 g specimen of phenyl urea I*a* was heated (steam bath) for approximately 30 h. The remaining pale-yellow residue weighed 4.3 g. Two recrystallizations from ethanol (95%) – methanol yielded a pure specimen

[6]*In this regard, several N-bis(2-chloroethyl)carbamates have been prepared (7), but possible intramolecular rearrangement reactions involving these substances have apparently not been evaluated.*

[7]*For example, see ref. 8, p. 36.*

[8]*Several reactions pertinent to this assignment have been described (6, 9). The products arising from rearrangement of N-phenyl and N-benzyl-N′-(2-chloroethyl)ureas have been assigned oxazoline structures. See also ref. 10.*

[9]*Melting points were observed employing a Kofler melting point apparatus and are corrected. Dr. R. A. Hill of this laboratory provided the infrared and proton magnetic resonance spectra. The p.m.r. spectra were obtained using a Varian Associates Model A-60 NMR Spectrometer. When deuterium oxide was employed as solvent, a sealed capillary tube containing tetramethylsilane (TMS) was added to the sample tube. Otherwise, enough tetramethylsilane was added to the solution (containing approximately 10% by weight of sample) to standardize the instrument. Scanning was performed from low to high field at a rate of 120 c.p.s. per min and measurements are reported in δ (p.p.m.) units with respect to TMS. Elemental compositions were determined in the microanalytical laboratory of Dr. A. Bernhardt, Max-Planck Institute, Müilheim, Germany. Molecular weight determinations (by mass spectrometry) were provided by Dr. R. Ryhage, Karolinska Institutet, Stockholm, Sweden.*

of colorless leaflets melting at 94–94.5°; p.m.r. response ($CDCl_3$ solution) 3.53 (partially masked triplet corresponding to 8 protons) and 6.8–7.4 (5 phenyl protons) δ; ν_{max}^{KBr} 2 900 (weak), 1 685, 1 594, 1 505, 1 490, 1 285, 1 150, and 755 cm^{-1}.

Anal. Calcd. for $C_{11}H_{13}ClN_2O$(225): C, 58.78; H, 5.83; Cl, 15.79; N, 12.47. Found: C, 58.77; H, 5.65; Cl, 15.75; N, 12.61; molecular weight, 225.

Method B

When the urea (I*a*, 0.3 g) was heated at 140° for 24 h in a sublimation tube (at 0.1 mm), 0.1 g, m.p. 92–93°, of the imidazolidone (II) was collected. Found: C, 58.66; H, 5.75; Cl, 16.02; N, 12.23.

2-(N-Phenylimino)-3-(2'-chloroethyl)oxazolidine(IVa) Hydrochloride

A solution of N-phenyl urea I*a* (1.0 g) was prepared in absolute ethanol (10 ml) at room temperature. Before concentration (*in vacuo*, at room temperature) to a viscous oil, the clear solution was allowed to stand approximately 15 h. The oil crystallized during an overnight drying (*in vacuo*) period. An infrared spectrum of the crude product indicated conversion to the oxazolidine was essentially complete, as absorption attributable to N—H or carbonyl was not observed. Three recrystallizations from ethanol – ethyl ether yielded an analytical sample as colorless needles; m.p. 96–97°; p.m.r. response (D_2O solution) 4.25–4.6, 4.95–5.15, and 7.60 δ; ν_{max}^{KBr} 3 400 (weak), 2 750, 1 670 (broad), 1 590, 1 510, 1 275, 1 230, 1 080, 1 030, 980, 900, and 755 cm^{-1}.

Anal. Calcd. for $C_{11}H_{14}Cl_2N_2O$: C, 50.60; H, 5.41; Cl, 27.15; N, 10.72. Found: C, 50.64; H, 5.40; Cl, 26.99; N, 10.70.

N-(1-Naphthyl)-N'-bis(2-chloroethyl)urea(Ib)

Preparation of urea I*b* (14.8 g, 85% yield, m.p. 123–126°) was accomplished using 1-naphthyl isocyanate (9.5 g) and the amine corresponding to 10 g of N-bis(2-chloroethyl)amine hydrochloride in dry diethyl ether (300 ml) as illustrated for synthesis of phenyl urea I*a*. Recrystallization (three times) from acetone afforded an analytical sample as colorless crystals melting at 124–125°; p.m.r. response ($CDCl_3$ solution) 3.64 and 7.02–7.70 (complex) δ; ν_{max}^{KBr} 3 120, 1 670, 1 630, 1 595, 1 515, 1 500, 790, and 770 cm^{-1}.

Anal. Calcd. for $C_{15}H_{16}Cl_2N_2O$: C, 57.90; H, 5.18; Cl, 22.78; N, 9.00. Found: C, 57.75; H, 5.31; Cl, 22.81; N, 8.97.

Naphthyl urea I*b* did not exhibit any change in its infrared spectrum after storage in a sealed container for approximately 1 year.

2-[N-(1'-Naphthyl)imino]-3-(2'-chloroethyl)oxazolidine(IVb) Hydrochloride

A solution of naphthyl urea I*b* (0.5 g) in absolute ethanol (10 ml) was allowed to stand at room temperature 5 h. Addition of dry diethyl ether (100 ml) precipitated 0.28 g of colorless crystals. An infrared spectrum of the crude product exhibited no absorption in the N—H stretching region. Three recrystallizations from ethyl alcohol – ethyl ether led to needles melting at 147–151°. Further recrystallization (using the same solvent) did not improve the melting point. The p.m.r. spectrum (D_2O) displayed a series of complex responses at 4.38–4.55, 4.86–5.15, and 7.70–8.23 δ. The infrared spectrum (ν_{max}^{KBr}) of oxazolidine IV*b* exhibited principal absorption bands at 2 700 (broad), 1 660 (broad), 1 270, 1 105, and 1 030 cm^{-1}.

Anal. Calcd. for $C_{15}H_{16}Cl_2N_2O$: C, 57.90; H, 5.18; Cl, 22.78; N, 9.00. Found: C, 57.53; H, 5.31; Cl, 22.84; N, 8.86.

N-(4-Nitrophenyl)-N'-bis(2-chloroethyl)urea(Ic)

Employing the amine from 5.45 g of N-bis(2-chloroethyl)amine hydrochloride, and *p*-nitrophenyl isocyanate (5.0 g), preparation of *p*-nitrophenyl urea I*c* was accomplished in 79% yield (7.4 g, m.p. 137–140°). In this case, the colorless urea began to separate from solution within a few seconds after initiation of the reaction. On exposure to the atmosphere, the colorless product became pale yellow. Following three recrystallizations from ethyl acetate – hexane a pure specimen melted at 142–144° (cf. ref. 4*a*); p.m.r. response (CH_3CN solution) 3.65 and a quartet (J = 10 c.p.s.) at 7.38, 7.53, 7.85, and 8.0 (4 phenyl protons) δ; ν_{max}^{KBr} 3 100, 1 642, 1 610, 1 590, 1 545, and 1 500 cm^{-1}.

Anal. Calcd. for $C_{11}H_{13}Cl_2N_3O_3$: C, 43.15; H, 4.28; Cl, 23.17; N, 13.73. Found: C, 43.36; H, 4.22; Cl, 23.16; N, 13.63.

The *p*-nitrophenyl urea (I*c*) remained unchanged (as evidenced by its infrared spectrum) during storage in a sealed container for over 2 years.

2-(N-Phenylimino)-3-(2'-bromoethyl)oxazolidine(IVc) Hydrobromide

A dry ethereal solution of N-bis(2-bromoethyl)amine from 15 g of the corresponding hydrobromide derivative (12) was allowed to react at 0–5° with phenyl isocyanate (5.75 g) as described for preparation of urea I*a*. The solid product (12.5 g, 75%) which separated displayed an infrared spectrum consistent with that expected for *N-phenyl-N'-bis(2-bromoethyl)urea*. However, during a 4-day period at room temperature, the urea rearranged to oxazolidine IV*a* hydrobromide. An infrared spectrum (in potassium bromide) of the product indicated conversion to the oxazolidine was complete. Four recrystallizations of the new product from ethanol (95%) – diethyl ether led to a pure sample of colorless needles; m.p. 118–119° and ν_{max}^{KBr} 2 900 (broad), 1 670 (broad), 1 595, 1 512, 1 280, 1 075, 975, 750, and 690 cm^{-1}. The p.m.r. spectrum (in D_2O) exhibited complex responses at 4.0–4.55 and 5.0–5.17 δ, and a sharp band at 7.62 δ.

For personal use only.

Anal. Calcd. for $C_{11}H_{14}Br_2N_2O$: C, 37.74; H, 4.03; Br, 45.65; N, 8.01. Found: C, 37.94; H, 3.87; Br, 45.92; N, 7.95.

2-[N-(4'-Nitrophenylimino)]-3-(2'-bromoethyl)oxazolidine(IVd) Hydrobromide

Reaction between the amine from N-bis(2-bromoethyl)amine hydrobromide (12.0 g) and *p*-nitrophenyl isocyanate (6.32 g) in diethyl ether (150 ml) was conducted as noted in the case of urea I*a*. The colorless solid which began to separate immediately (from the reaction mixture) was collected after 20 min. On exposure to the atmosphere urea I*d* (12.6 g, 83%), m.p. 121–124°, became pale yellow. The infrared spectrum (in potassium bromide) was in complete accord with a N-(4-nitrophenyl)-N'-bis(2-bromoethyl)urea (I*d*) structure. The urea was found to rearrange readily in polar solvents (such as acetone) and was, therefore, more conveniently characterized as the oxazolidine derivative (IV*d*). A 1.0 g specimen of urea I*d* was dissolved in 25 ml of warm ethanol. Immediately after dissolution the crystalline oxazolidine began to separate. Following a 12 h period at room temperature, the product (0.72 g) was collected. Three recrystallizations from ethanol – ethyl ether yielded an analytical sample of yellow platelets melting over the range 134–144° with sintering from 120°; ν_{max}^{KBr} 2 890 (broad), 1 685, 1 590, 1 520, 1 340, 1 250, and 1 075 cm^{-1}.

Anal. Calcd. for $C_{11}H_{13}Br_2N_3O_3$: C, 33.44; H, 3.32; Br, 40.45; N, 10.63. Found: C, 33.52; H, 3.38; Br, 40.42; N, 10.54.

ACKNOWLEDGMENTS

This investigation was aided by Grants No. T-79D and T-79E from the American Cancer Society. We also wish to acknowledge the assistance of R. C. Bansal, K. Parent, and P. A. Whitehouse with several preliminary experiments.

LIGHT SCATTERING OF A CRITICAL BINARY LIQUID MIXTURE: TRIETHYLAMINE–WATER[1]

B. CHU[2] AND W. P. KAO
Chemistry Department, The University of Kansas, Lawrence, Kansas

Received January 22, 1965

ABSTRACT

The coexistence curve and critical opalescence of a binary liquid mixture, triethylamine–water, have been reinvestigated. The measurements showed that the coexistence curve appears to follow a cubic relation to within about 0.003° of the critical solution temperature, and in this range, there is no evidence of a flat region. Furthermore, within the range of the values of s/λ (where $s = 2 \sin(\theta/2)$, λ = wavelength in the medium, and s/λ varied from 1.2×10^{-4} to 7.0×10^{-4} Å^{-1}) and temperatures studied, the light scattering data are in good agreement with the Debye theory (J. Chem. Phys. 31, 680 (1959)). The molecular interaction range of Debye was found to be 5.1 ± 0.3 Å.

The large density fluctuations of any system near its critical point are accompanied by local fluctuations in refractive index. Such a system, being optically inhomogeneous, scatters light very strongly and therefore it looks turbid. This is the so-called "critical opalescence." An equation for light scattering from a critical binary liquid mixture can be formulated as follows (1):

$$[1] \quad I(\theta) = I_d(\theta) + I_c(\theta)$$
$$= I_0 \frac{4\pi^2 V}{\lambda^4 r^2} \frac{1+\cos^2\theta}{2}\left[kT\beta\left(\frac{\rho}{n}\frac{\partial n}{\partial \rho}\right)^2 + \left(\left(\frac{c}{n}\frac{\partial n}{\partial c}\right)^2 \Big/ \left\{\phi_2\left[\frac{\partial}{\partial \phi_2}\left(\frac{P}{kT}\right)\right] + 4\pi^2\phi_2{}^2\left(\frac{H}{kT}\right)\left(\frac{s}{\lambda}\right)^2\right\}\right)\right],$$

where $I(\theta)$ is the intensity of light scattered at an angle θ (between secondary and primary ray) at a large distance r from a scattering volume V, I_d and I_c are scattered intensities due to density and concentration fluctuations, respectively, I_0 is the primary intensity, λ is the wavelength of the light in the medium, k is the Boltzmann constant, T is the absolute temperature, β is the compressibility, ρ is the density, n is the index of refraction, c is the concentration of the second component, P is the osmotic pressure, ϕ_2 is the volume fraction of the second component, and the symbol H represents a factor (2) of the following form.

$$H = \frac{1}{6}\left[\frac{W_{11}}{\omega_1{}^2} l_{11}{}^2 + \frac{W_{22}}{\omega_2{}^2} l_{22}{}^2 - 2\frac{W_{12}}{\omega_1\omega_2} l_{12}{}^2\right],$$

where l_{ij} is the respective range of molecular forces of component 1, component 2, and the mixture. The expressions $W_{ij}/\omega_i\omega_j$ represent the respective cohesive energy densities. Equation [1] is a classical scattering formula corrected for the effect of the energy connected with the existence of local gradients of concentration fluctuations. It is an approximation which breaks down if we extend our measurements over large ranges of s/λ by means of small angle X-ray scattering (3, 4, 5). Furthermore, very long range

[1]*This work was supported by the National Science Foundation (GP 3922).*
[2]*Author to whom requests for reprints should be addressed.*

correlations have not been taken into account. However, it is an adequate representation of experimental facts for critical opalescence of binary liquid mixtures at intermediate temperature distances and in the visible region ($\lambda_0 \cong 365$–600 mμ; $\theta \cong 20$–$145°$). It is also important to note that for a critical binary liquid mixture, the fluctuations are there whether one can observe the opalescence visually or not. The effect may be more pronounced for liquid mixtures with larger refractive index differences in the two components. Therefore, it is somewhat misleading to identify the visibly opalescent region as a separate entity in the one phase region (6). Experimental light scattering data on strongly opalescent critical binary liquid mixtures (7) showed an absence of two kinds of fluctuations as suggested by Hildebrand (8). We chose the system triethylamine–water in order to demonstrate similarities, which may exist in terms of critical opalescence, among systems with upper and lower critical solution points. In fact, triethylamine–water is a relatively troublesome system, partly because it is difficult to make the mixture (water being polar) dust-free and partly because triethylamine seems to attack Pyrex glass.

Reviews of both theory (9, 10) and experiment (7) on critical opalescence have been presented elsewhere. Opalescence of the system, triethylamine–water, near the critical solution temperature has been investigated by Chow (11) and the results on coexistence curves have been summarized (12). Discrepancies in both opalescence (7, 11, 13) and coexistence curve (12, 14) measurements have also prompted us to repeat this system with refined techniques.

EXPERIMENTAL

Materials

Water.—Ion-exchanged water was doubly distilled with an all-Pyrex still fitted with a double vapor bulb (Fisher No. 9-107). Care was taken to exclude CO_2 with a drying tube containing Ascarite.

Triethylamine.—Our triethylamine samples could not be purified by fractional distillation. So, the material was purified by preparative gas chromatography on an Aerograph model A-700 Autoprep vapor fractometer (Wilkens Instrument and Research, Inc.). A 20 ft long × 3/8 in. outside diameter column packed with 30% SE-30 (a General Electric methyl silicone rubber) on 40/60 chromosorb P, operated at 147 °C and 40 p.s.i.g. was used. Flow rates of helium carrier gas were around 200 ml/min. The injection volume was limited to 0.2 ml each time and a short cut in the main peak was collected under helium. Impurities were estimated as being less than 0.01% for the purified triethylamine (purified grade, J. P. Baker Chemical Co.) and less than 0.1% for the purified material purchased from the Matheson, Coleman and Bell Co. The MCB triethylamine had its impurity peak very close to the main peak.

Phase Separation Temperature Measurements

A cleansed 1.3 × 1.3 × 0.1 cm thick flat cell fitted with a 20 cm long and 0.5 cm diameter stem and Teflon stopcock was dried in an oven at 105 °C and stored in a desiccator (or dust-free container) until used. The solutions were prepared from weighed amounts of the purified components. The flat cell was immersed in a large insulated bath fitted with a cooling coil for thermostated circulating cooling fluid and two heaters connected with variable transformers. With vigorous stirring the whole bath could be very slowly heated or cooled from appropriate adjustments of the two heater outputs. This setup was more convenient than a conventional constant temperature bath for phase separation temperature determinations so long as the temperature of the bath could not be changed with the same ease as its controlled precision. With very slow rates of cooling and heating, the phase separation temperature could be determined to 0.001°. In our case, a calibrated Beckman thermometer was used. For concentrations near the critical solution concentration, phase separation temperatures were determined to within 0.002° while for those further away, separation temperatures were determined to within 0.01°. The dead space above the sample in the flat cell was about 4 cc. There should be no appreciable error in composition due to material in the vapor phase.

When measuring the separation temperature of a sample, it was cooled and thoroughly shaken before immersing it in the bath. Then the temperature of the bath was raised (or lowered) slowly and finally at a very slow rate in the vicinity of the phase separation temperature. Two approaches were used: (*a*) slowly heat the homogeneous mixture with shaking until phase separation occurred, and (*b*) slowly cool the separated mixture with shaking until it became homogeneous. Results from (*a*) and (*b*) agreed to within 0.002° for concentrations near the critical solution concentration. Furthermore, phase separation temperatures determined by means of a flat cell agreed, within the limits of error, with those determined in sealed ampuls. It should be noted that the consolute temperature changed with time. At our critical solution concentration, the change amounted to −0.18° over a period of about 105 d for a sample preserved in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Pyrex glass cell which was fitted with a Teflon stopcock and then sealed with paraffin wax. Kohler and Rice (14) attributed this lowering of the consolute temperature to possible attacks of ordinary glass by triethylamine and used quartz cells instead. We always tried to complete our measurements in a few days from freshly prepared samples.

Near-Infrared Spectra

The critical solution mixture was prepared from weighed amounts of purified components. The thermostat block was essentially the same as in previous work (15, 16). Measurements were carried out with a Cary model 14 recording spectrophotometer. All measurements were made in cells with 1 cm optical path length. Carbon tetrachloride was filled in the light path of the cell block to ensure uniform temperature control. The absorbancies ($A_s = -\log I/I_0$) were determined relative to a cell that contained CCl_4, which partially compensated for the CCl_4 in the light path of the sample cell block. Background amounting to $A_s = 0.02$ was not corrected. Temperature of the cell block was controlled to $\pm 0.01°$. However, the near-infrared radiation could heat up the sample rapidly, so only the absorption bands of water and triethylamine at room temperature, and the mixture at a large temperature distance ($\Delta T = T_c - T = 11.3°$) in the 0.9–1.3 μ region were recorded. Those for the critical binary liquid mixture at smaller temperature distances ($T_c - T < 1°$) were measured manually point by point. Then, the sample was exposed to the beam only a few seconds at a time for the recorder to register the absorbancy, which was checked until it could be reproduced. The time interval between each measurement was extended to about 25 min to ensure a uniform temperature distance (ΔT) over the whole absorption bands.

Light Scattering Measurements

Detailed descriptions of the light scattering photometer (1, 7, 17), preparation of solutions, phase separation temperature determinations, and attenuation corrections due to critical opalescence are discussed elsewhere (1, 7). The light scattering photometer was further modified as follows: four 10 × 1 mm slits immersed in the thermostated tank were used to define the incident beam, while a receiver nosepiece with dimensions 10 × 1 mm, and 20 mm apart, was used. Each purified component was further treated by filtration through Millipore filters of 50 mμ average pore size directly into the light scattering cell, which was fitted with a Teflon stopcock. The filter was tested to be inert to both components. The temperature of phase separation, T_p, was again determined directly in the light scattering photometer to 0.01° by slowly heating the homogeneous mixture, at a rate of approximately 0.001° per minute, until phase separation occurred. A filtered fluorescein solution was used as a standard for periodic checks of the performance of the photometer.

Refractive indices of the critical liquid mixture at different wavelengths (λ_0 364, 436, and 575 mμ) were calculated from an empirical mixture rule (16) with the aid of known dispersion curves and densities (18). The calculated corresponding wavelengths in the medium are λ = 268, 321, and 428 mμ respectively.

RESULTS AND DISCUSSION

Coexistence Curve

Values of the critical solution temperature for the system, triethylamine–water, varied from 12.4 to 19.9 °C in the literature (12). Since the separation temperature of a mixture is a sensitive indicator of the state of purity of the components, the variations clearly signify a lack of high-precision measurements of coexistence curves on highly purified systems. Our coexistence curve, as shown in Fig. 1, is not comparable to the work of Rice *et al.* on the system perfluoromethylcyclohexane – carbon tetrachloride (19), but approaches the precision of the work on the system aniline–cyclohexane (20). Cox and Herrington (21) have reported that solubility data may be represented as follows:

$$(T_D - T_c) = \left[A' \log \frac{X'}{1-X'} + B' \right]^3$$

and

$$(T_D - T_c) = \left[A'' \log \frac{X''}{1-X''} + B'' \right]^3,$$

in which $'$ and $''$ refer to the two coexisting phases, T_D is the consolute temperature, and T_c is the critical solution temperature corresponding to the minimum consolute temperature. The constants A' and A'' have also been discussed by Rudd and Widom (22). Figure 2 provides another method for determining the critical solution concentration. The result agrees with the value determined from Fig. 1. Our measurements showed that the coexistence curve appears to follow a cubic relation to within about 0.003° of the critical solution temperature, and in this range, there is no evidence of a flat region.

The data are in qualitative agreement with those of Kohler and Rice (14). In both cases, the cubic equation remains a good representation of the coexistence curve except when $T_p - T_c$ is very small. The discrepancy in the critical solution concentration could possibly be accounted for in terms of impurities in triethylamine. We are, however, unable to prove the possible existence of a small horizontal portion in the coexistence curve. Since the system behaves normally otherwise, we see no compelling reason to hunt for the existence of such a flat top.

Critical Opalescence

The treatment of data according to the Debye theory is described elsewhere (1). Equation (1) may be presented in a simpler form as follows:

$$[2] \qquad \frac{1}{I} = F(T)\left(\frac{T_c}{T}\right)\left[\frac{\Delta T}{T_c} + \frac{8\pi^2}{3} l^2 \frac{\sin^2(\theta/2)}{\lambda^2}\right] = A + B \sin^2(\theta/2).$$

Figure 3 shows a typical set of intensity curves in a plot of reciprocal relative scattered

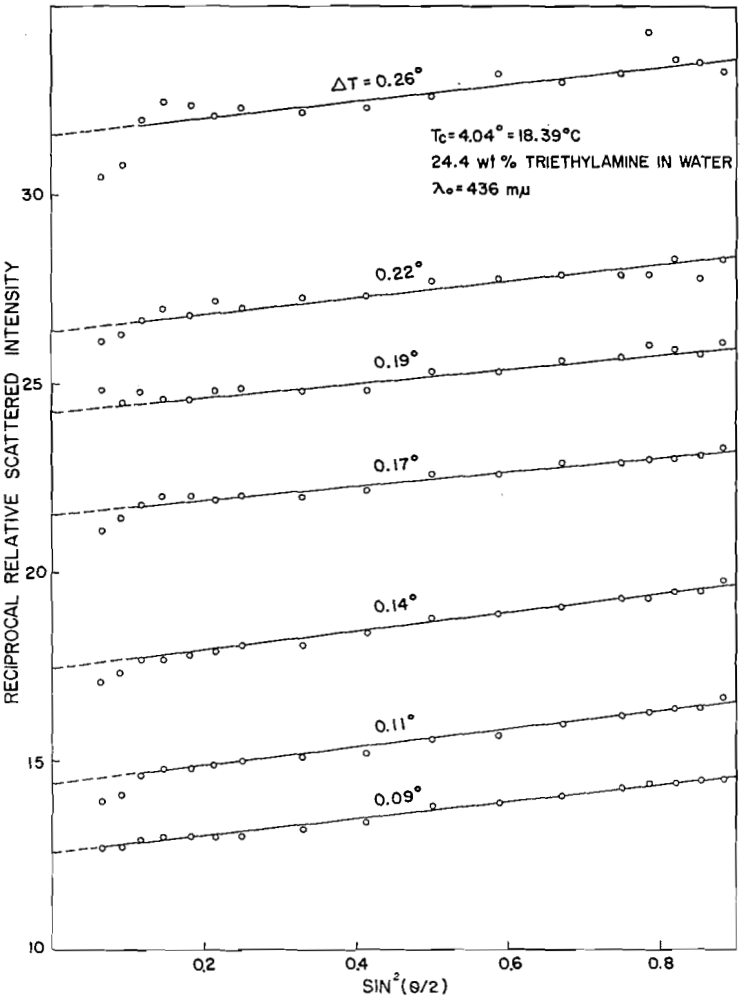

FIG. 3. Plot of reciprocal relative scattered intensity vs. $\sin^2(\theta/2)$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

intensity vs. $\sin^2(\theta/2)$. Such a plot is sometimes referred to as an OZD plot. Only a faint opalescence could be observed at small fixed temperature distances from the critical solution temperature because of low scattered intensity. For the same reason, the presence of dust was detected at small values of the scattering angle (Fig. 3, curve $\Delta T = 0.26°$). Figure 4 shows a plot of A/B vs. T for the three wavelengths we have investigated.

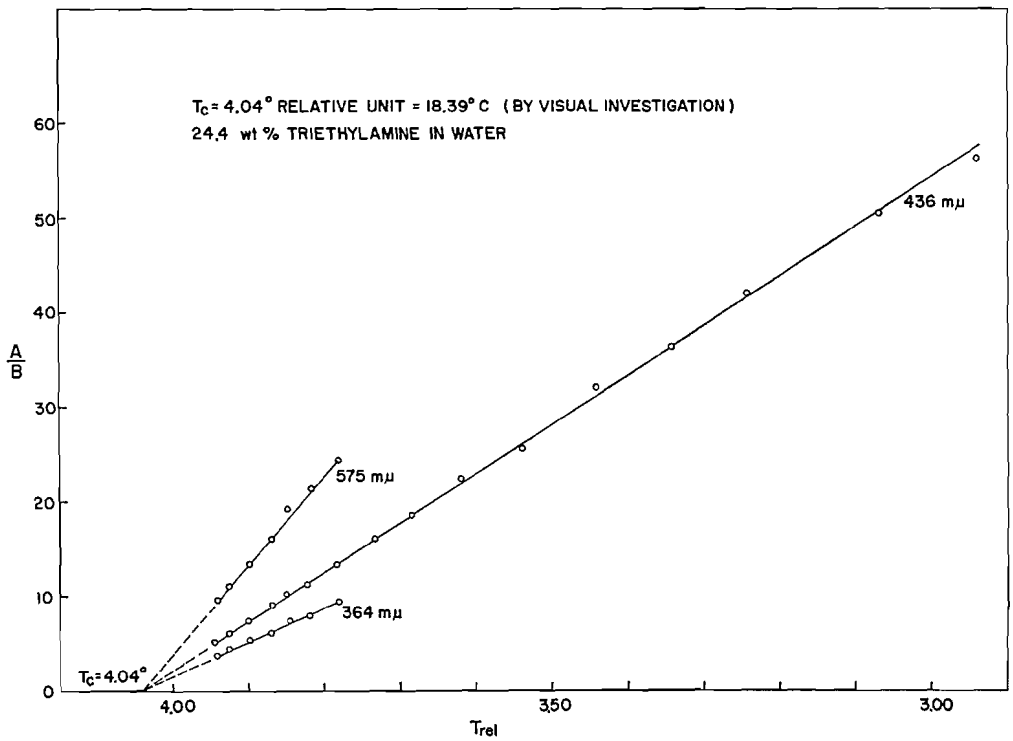

FIG. 4. Plot of A/B vs. temperature.

$$\frac{A}{B} = \left(\frac{3\lambda^2}{8\pi^2 l^2 T_c}\right)(T_c - T),$$

with $T_c = -(\text{intercept/slope})$ of the resulting straight line and $l = 5.1 \pm 0.3$ Å. It should be noted that the molecular interaction range of Debye differs from the short-range correlation length of Fixman (23) by a factor of $(4/15)^{1/2}$ for one component systems. The two lengths do not have exactly the same meaning. According to the (approximate) Debye theory, the interaction range is a property of the averaged intermolecular pair potential and is a constant which should be independent of frequency.

The Critical Region

In the vicinity of the critical point, the equilibrium of the *one* phase system for a binary liquid mixture is near its limit of stability. Appreciable changes in this equilibrium may be induced by outside agencies, such as an applied gravitational field (8) or an electric field (24). In this respect, ultrasonic disturbances may influence the true critical behavior of the system under observation. We question the postulation of two kinds of fluctuations (6, 8): composition variations and fluctuations within such regions; or the system in two phases, yet not distinctly separated phases, but as regions in a type of emulsion when

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

strong visible opalescence is observed. The Debye theory (2) is an excellent representation of experimental facts in the intermediate temperature range. As the critical solution temperature is approached, light scattering is increased because of inhomogeneities produced by concentration fluctuations. "Reflection from the composition gradients between the regions of different composition," as stated by Kruus (6), is but another consequence of critical fluctuations. We see no microscopic phase separation in the opalescent one phase region. No abrupt change in intensity was observed as shown in Fig. 5. The behaviors of the strongly opalescent and the weakly opalescent systems are analogous (compare Fig. 5 and ref. 7, Fig. 2). Furthermore, the concentration fluctuation term (eq. [1]) exists even when ΔT is large. It becomes predominant as T approaches T_c. There is no actual separate region in a type of emulsion that one can distinguish optically.

We have also measured the near-infrared spectra of the critical liquid mixture at different fixed temperature distances from the critical solution temperature. Since the

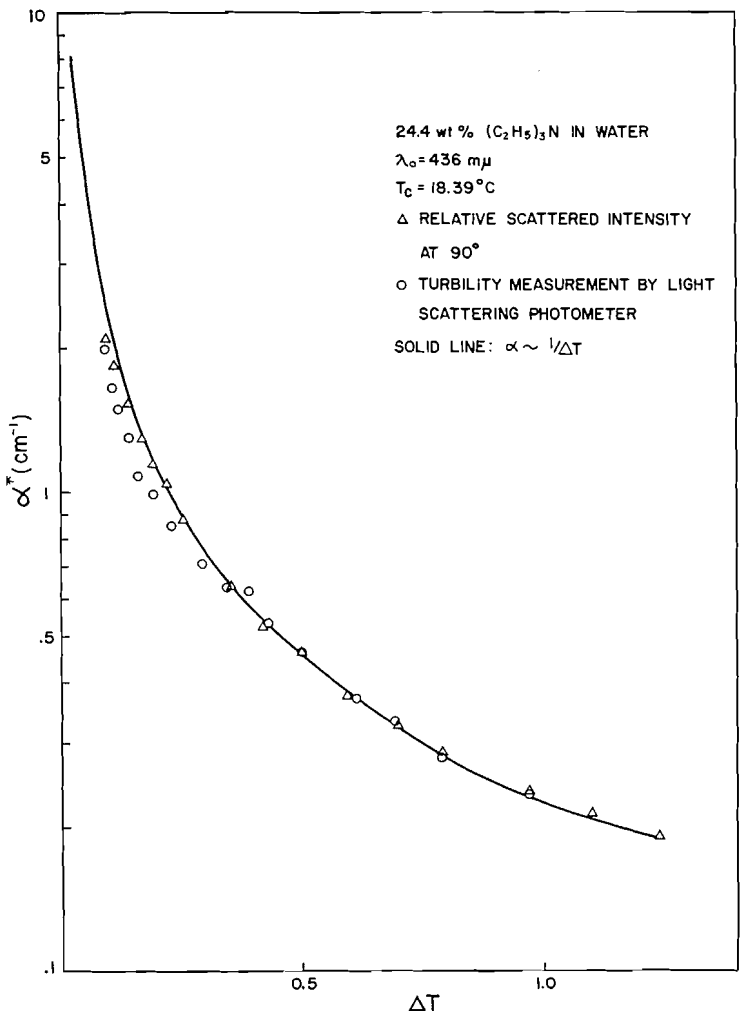

FIG. 5. Plot of extinction coefficient α^* (cm^{-1}) vs. $T_c - T$, where $\alpha^* = 2.303 \log I_0/I$ and I_0 is the transmitted intensity at $T_c - T \sim 5°$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

system has a minimum critical mixing temperature, resulting from sufficiently large negative deviations from Raoult's law which in many instances can be traced to possible complex formation, the vibrational transition bands in the near-infrared region may reveal changes in the intramolecular structure of the two components. The absorption bands of pure water in the 1.1–1.3 μ region have been measured (25). Within the limits of our experiments, we find a lack of frequency shifts and intensity changes between the homogeneous phase at various temperature distances from T_c and the composite phase, as shown in Fig. 6. Such a lack of change appears to signify that the phase separation behavior is essentially intermolecular in nature. On closer examination, the critical mixture contains only 0.054 mole fraction of triethylamine. So, it is not surprising that the absorption spectra remains approximately unchanged from a homogeneous phase to a heterogeneous phase.

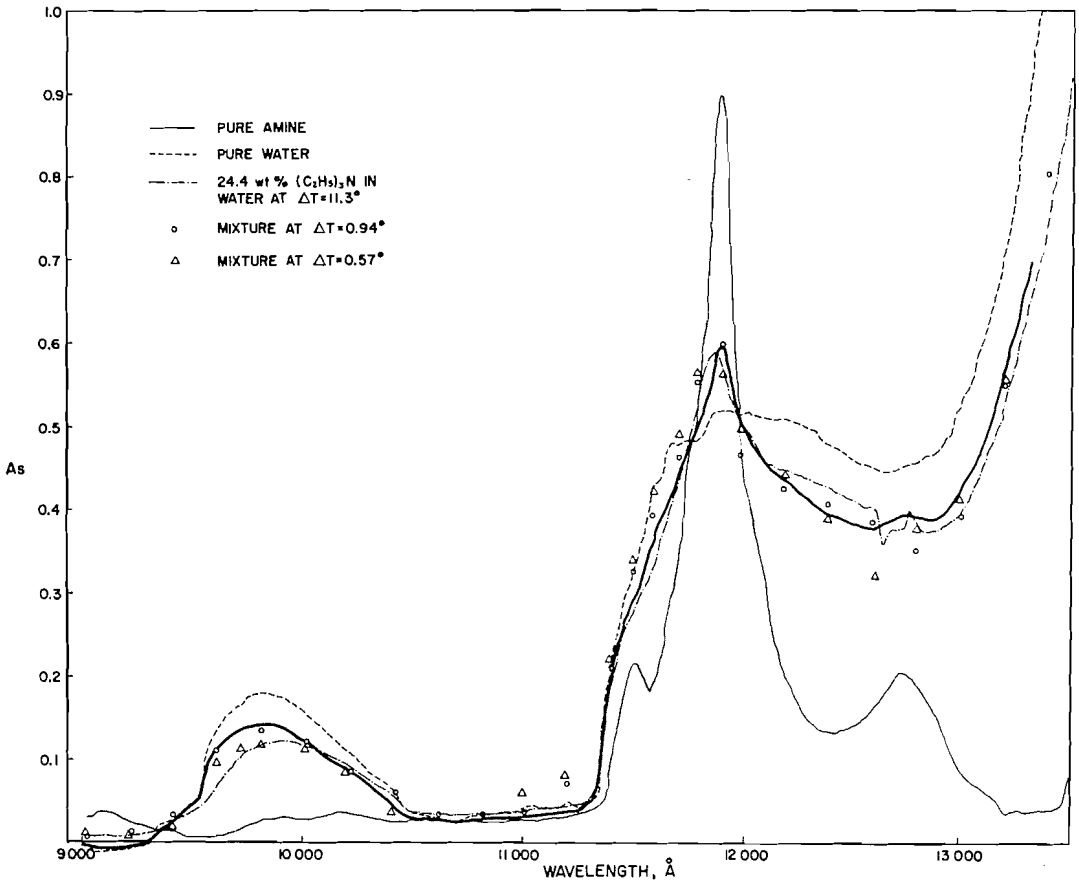

FIG. 6. Absorption bands of water, triethylamine, and the critical binary mixture at different values of $T_c - T$ in the 0.9–1.3 μ region. A_s = log I_0/I. Thick solid line = composite phase;

$$A_s \text{ (composite phase)} = \phi_{H_2O} A_{sH_2O} + \phi_N A_{sN},$$

where ϕ = volume fraction and the subscript N denotes triethylamine.

A QUASI-CRYSTALLINE MODEL OF DIFFUSION IN TERNARY LIQUID SYSTEMS[1]

J. E. LANE[2] AND J. S. KIRKALDY[3]
Department of Metallurgy and Metallurgical Engineering, McMaster University, Hamilton, Ontario
Received December 28, 1964

ABSTRACT

A quasi-crystalline model of a dilute ternary liquid system is proposed in which diffusion occurs by an interchange of species on neighboring lattice sites. Nonelectrolyte molecules are assumed to interchange with any type of diffusing species present in the system. In ternary nonelectrolyte systems relatively large cross-effects are associated with the mutual interchange of the two dilute solute species. The symmetry of the L-matrix arises directly through the application of detailed balance (microscopic reversibility) to this unit process.

In electrolyte solutions, the only significant contribution to the ionic fluxes is expected to arise through interchange of ions with uncharged molecules. For diffusion in an aqueous solution of two strong electrolytes with a common ion, large off-diagonal L-coefficients result from the transformation of the lattice-referred diagonal diffusion matrix, written in terms of ionic fluxes and forces, to a form which relates the two independent salt fluxes and forces. Symmetry of the L-matrix in this case arises indirectly through the application of detailed balance to the ion-solvent interchanges. In aqueous electrolyte solutions the dilute solution ternary L-coefficients can be calculated from the independent individual ionic mobilities at infinite dilution, and these are found to be in excellent agreement with the experimental values for the system NaCl–KCl–H_2O. The application of the model to binary electrolyte solutions at infinite dilution correctly yields the Nernst equation.

The model is extended to solutions of two electrolytes with one or both incompletely ionized and to solutions containing a nonelectrolyte and a strong electrolyte. In all applications of the model the derived L-coefficients satisfy the well-known thermodynamic requirements. When appropriate ancillary data is available, the model yields fair to excellent predictions of the diffusion matrix at low concentrations of the solute species. Possible methods of improving the agreement at higher concentrations are discussed.

INTRODUCTION

In a recent paper (1), hereinafter referred to as I, diffusion in multicomponent substitutional alloys was described in terms of two separate microscopic models, an exchange mechanism and a vacancy mechanism. Both models indicate a similar concentration dependence of the L-coefficients in the number-fixed frame of reference, i.e.,

$$[1] \qquad (L_{ii})_N = K_{ii}N_i,$$

and

$$[2] \qquad (L_{ij})_N = -K_{ij}N_iN_j,$$

where the K's are coefficients expected to vary slowly with concentration. In both models the K_{ii} are positive; the K_{ij} are always positive in the exchange model, but may be negative in the vacancy model for some extreme cases. Both models assume microscopic reversibility and hence the derived phenomenological matrix is symmetric (2). The nonzero off-diagonal coefficients arise in a formal manner through the linear dependence of the fluxes imposed by the specification of the frame of reference in which they are measured, and the form of the conjugate thermodynamic forces associated with this particular frame of reference. Nevertheless, there exists a real microscopic coupling of the

fluxes in both models. This coupling occurs through the interchange of lattice sites by neighboring atoms in the exchange model, and the Kirkendall shift in the vacancy model.

No sufficiently precise diffusion and thermodynamic data is available to test the applicability of eqs. [1] and [2] to substitutional metallic alloys. Data, suitable for computing the L-coefficients, is available in a few ternary liquid systems. It is worthwhile to consider whether either model, with suitable modification, is suitable for the description of diffusion in such systems. The quasi-crystalline model of a liquid has proved useful in interpreting the equilibrium properties of liquid mixtures (3), and it is now extended to include kinetic properties.

THE DIFFUSION MODEL

Experimental evidence of the Kirkendall shift, coupled with theoretical calculations of activation energies, strongly suggests that diffusion in solids occurs by a vacancy mechanism (4). Similar models of diffusion in liquids have been proposed (5) although there is no experimental evidence of a Kirkendall shift in liquids (6). The analysis of I indicated that the concentration dependence of the L-coefficients was similar for both vacancy and exchange models. For this communication the exchange model has been chosen for liquids because it avoids the problem of the vacancy flux, which is observed in substitutional alloys as a Kirkendall shift.

The model is defined as a quasi-crystalline (close-packed) liquid, each lattice point being occupied by one diffusing unit (atom, ion, or molecule) unless otherwise specified. Diffusion occurs by the direct interchange of neighboring units on the lattice. The frame of reference is arbitrarily chosen as one stationary with respect to the quasi-lattice and parallel to one of the principal crystallographic planes. In this model, this frame of reference is coincident with both the number-fixed frame, defined for a system of n diffusing lattice units as

$$\sum_{i=0}^{n-1} (J_i)_N = 0, \qquad [3]$$

where the solvent is component 0, and the volume-fixed frame, defined by

$$\sum_{i=0}^{n-1} \bar{V}_i (J_i)_V = 0, \qquad [4]$$

where $\bar{V}_i$ is the partial molar volume of the i'th of n components.

The phenomenological description of diffusion in the volume-fixed frame of reference is (see I)

$$(J)_V = (L)_V (X)_V, \qquad [5]$$

where $(J)_V$ is a vector consisting of the $(n-1)$ independent fluxes $(J_i)_V$, $i \neq 0$, $(L)_V$ is a unique, symmetric $(n-1) \times (n-1)$ matrix of phenomenological L-coefficients, and $(X)_V$ is the column vector of the $(n-1)$ independent thermodynamic forces $(X_i)_V$, where

$$(X_i)_V = -\left(\frac{\partial \mu_i}{\partial x} - \frac{\bar{V}_i}{\bar{V}_0}\frac{\partial \mu_0}{\partial x}\right). \qquad [6]$$

The transition state formalism of I is used, but the concentrations, c_i, are in moles l^{-1}, to be consistent with common experimental usage. The flux $J_i^{\leftrightarrows j}$ of molecules of type i, resulting from interchanges with species j on the quasi-lattice, is given in I (eq. [20]) as

$$J_i^{\leftrightarrows j} = -k_{ij} c_i c_j \left(\frac{\partial \mu_i}{\partial x} - \frac{\bar{V}_i}{\bar{V}_0}\frac{\partial \mu_0}{\partial x}\right), \qquad [7]$$

For personal use only.

where $\bar{V}_i/\bar{V}_0$ takes the value of unity for the quasi-crystalline model. The k_{ij} are given by

$$[8] \qquad k_{ij} = (RTN)^{-1}10^{-6}\lambda^2\nu_{ij} \exp[-(\Delta G_{ij}^{\neq})_c/kT]y_iy_j/y_{ij}^{\neq},$$

where RT has its usual meaning, N is the total number of moles per cm^3 of the lattice plane normal to the flux, λ is the lattice spacing in the direction of the flux, ν_{ij} is the frequency of forward transitions through the activated state, $(\Delta G_{ij}^{\neq})_c$ is the standard free energy of formation of the activated complex $ij^{\neq}$ on the molar concentration scale, and the y's are the activity coefficients of the various species, also on the molar scale. A liter has been taken as 10^3 cm^3.

The variables in [8] for an isothermal system are λ, the ν_{ij} and the ratio $y_iy_j/y_{ij}^{\neq}$. The lattice spacing is not strongly concentration dependent, and corrections may be included in the model without any difficulty. There is as yet no simple method of determining the concentration dependence of the ν_{ij} and the $y_{ij}^{\neq}$ so that application of this model is made only to systems dilute enough that the k_{ij} are not significantly different from their values, k_{ij}^0, at infinite dilution.

The total flux of i in an n-component system is therefore,

$$[9] \qquad (J_i)_V = \sum_{j=0}^{n-1} J_i^{i \rightleftarrows j}.$$

Using the method described in I for obtaining the phenomenological coefficients from expressions similar to [7], [8], and [9] gives

$$[10] \qquad (L_{ii})_V = \sum_{j=0(\neq i)}^{n-1} k_{ij}c_ic_j,$$

$$[11] \qquad (L_{ij(i\neq j)})_V = -k_{ij}c_ic_j.$$

Equations [10] and [11] are directly applicable to multicomponent nonelectrolyte solutions.

Values of k_{i0}^0 may be obtained from binary diffusion data. In a binary solution the flux of component i is given by [7] as

$$(J_i)_V = -k_{i0}c_ic_0\left(\frac{\partial\mu_i}{\partial x} - \frac{\bar{V}_i}{\bar{V}_0}\frac{\partial\mu_0}{\partial x}\right),$$

which by means of the Gibbs–Duhem equation,

$$c_0\frac{\partial\mu_0}{\partial x} + c_i\frac{\partial\mu_i}{\partial x} = 0,$$

and the relations,

$$c_0\bar{V}_0 + c_i\bar{V}_i = 10^3,$$

and

$$\frac{\partial\mu_i}{\partial x} = \frac{RT}{c_i}\left(1 + \frac{\partial \ln y_i}{\partial \ln c_i}\right)\frac{\partial c_i}{\partial x},$$

yields

$$[12] \qquad (J_i)_V = -k_{i0}(10^3/\bar{V}_0)RT\left(1 + \frac{\partial \ln y_i}{\partial \ln c_i}\right)\frac{\partial c_i}{\partial x}.$$

Fick's first law gives the flux of the i'th component as

$$[13] \qquad (J_i)_V = -[(D_i)_V/10^3]\frac{\partial c_i}{\partial x},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where $(D_i)_V$ is the diffusion coefficient in the volume-fixed frame of reference, in units of $cm^2\ s^{-1}$.

Comparison of [12] with [13] and taking the limit as $c_i \rightarrow 0$ gives k_{i0}^0 as

$$k_{i0}^0 = (D_i^0)_V/c_0^0 RT10^3. \qquad [14]$$

There is no method of obtaining the $k_{ij(j\neq 0)}^0$, but as these only appear in conjunction with the product c_ic_j which, relative to the product c_ic_0, is small in dilute solutions, an estimate may be obtained from the expression

$$k_{ij(i\neq j)}^0 \approx (k_{i0}^0 + k_{j0}^0)/2. \qquad [15]$$

The application of the model to binary nonelectrolyte solutions gives some information on the validity of the approximation

$$k_{i0} = k_{i0}^0 \qquad [16]$$

The direct comparison of eqs. [12] and [13] gives

$$k_{i0} = (D_i)_V \bar{V}_0/10^6 RT\left(1 + \frac{\partial \ln y_i}{\partial \ln c_i}\right),$$

which combined with [14] yields the ratio

$$k_{i0}/k_{i0}^0 = (D_i)_V \bar{V}_0 c_0^0/(D_i^0)_V\left(1 + \frac{\partial \ln y_i}{\partial \ln c_i}\right)10^3. \qquad [17]$$

If $\bar{V}_0$ does not vary significantly in dilute solutions from its value in the pure solvent, the combination of [16] and [17] gives

$$(D_i)_V = (D_i^0)_V\left(1 + \frac{\partial \ln y_i}{\partial \ln c_i}\right). \qquad [18]$$

Equation [18] is equivalent to the statement that the solute mobility $(M_i)_V$ (velocity of the solute in the volume-fixed frame of reference per unit chemical potential gradient) given by

$$(M_i)_V = (D_i)_V \Big/ \left(1 + \frac{\partial \ln y_i}{\partial \ln c_i}\right)RT$$

is independent of concentration. Precise diffusion measurements in several solutions of nonelectrolytes in water (7, 8, 9) show that in the systems studied the D's given by [18] at finite concentrations are larger than the experimental values, the discrepancy increasing with increase in concentration. The disagreement is of the order of a few percent at concentrations near 1.0 M, and increases rapidly with increase in concentration. Therefore, the ternary model may be most usefully applied to solutions of combined concentration below 1.0 M. The information obtained from these experimental results suggests that $k_{i0} < k_{i0}^0$, and hence the moduli of the L-coefficients given by [16], [10], and [11] are expected to be larger than the experimental values.

By the use of [10], [11], [14], [15], and [16], together with the binary diffusion data of Dunlop (10) and Gosting and Akeley (8), the L-coefficients for the ternary solution of raffinose (component 1) – urea (component 2) in water at molar concentrations of $c_1 = 0.0149$ and $c_2 = 0.5$, have been calculated. Using $D_1^0 = 0.4359 \times 10^{-5}$ and $D_2^0 = 1.381 \times 10^{-5}$, the calculated values of $(L_{11})_V$, $(L_{12})_V$, and $(L_{22})_V$ multiplied by $RT \times 10^8$ were found to be 0.00633, −0.00012, and 0.673 which compare favorably with the values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of 0.00618, −0.0013, and 0.657 given by Miller (11). Miller's L-coefficients were obtained from the ternary diffusion data of Dunlop (12) and estimates of the thermodynamic derivatives $\partial \ln y_i/\partial \ln c_j$. This system is not a good test of a quasi-crystalline model because of the large molar volume of the raffinose compared with the urea and water. The only significant comparison that can be made between the result given by this model and that given by Miller is for L_{11} and L_{22}. In both cases the predicted value is larger by approximately 2%.

AQUEOUS SOLUTIONS OF TWO STRONG ELECTROLYTES

The following discussion is restricted to electrolytes of the type A_aB_b, and in general will not be applicable to more complex salts such as those of the class $A_aB_bC_c$. For simplicity, the solvent is considered to be un-ionized.

An aqueous solution containing two electrolytes can only be classified as a ternary diffusion system if one ion is common to both salts (11). The three ionic species are designated 1, 2, and 3, component 3 being the common ion. Although there are four diffusing species, the condition of electrical neutrality,

$$[19] \qquad \sum_{i=1}^{3} z_i c_i = 0,$$

where z_i is the ionic charge (including sign) of the i'th species, imposes the restriction,

$$[20] \qquad \sum_{i=1}^{3} z_i J_i = 0,$$

in every frame of reference. The condition [19] together with the definition of the frame of reference,

$$[21] \qquad \sum_{i=0}^{3} \alpha_i J_i = 0,$$

where α_i is the appropriate weighting factor (partial molar volume in the volume-fixed reference frame), allows only two independent fluxes. Similarly, although there are three ionic species, each with its own chemical potential (sometimes distinguished by the use of the term electrochemical potential) the restriction [19] ensures that only certain combinations of the ionic chemical potentials can exist. The Gibbs–Duhem equation provides an additional dependency between the chemical potentials of the salts and the solvent and therefore only two of the four chemical potential gradients are independent.

The order in the distribution of ionic species in aqueous solutions of electrolytes, resulting from the long range electrostatic forces, allows a simplification in the microscopic model previously used for substitutional metallic alloys and nonelectrolyte solutions. The success of the "principle of specific interaction of ions" (13), indicates that ions of like charge are separated enough to render the mutual interaction negligible in determining the thermodynamic properties in dilute solutions. Ions of like charge are therefore unlikely to occupy adjacent sites on the quasi-lattice, and therefore the probability of forming an activated complex consisting of two ions of like charge is small enough to be neglected as a significant contribution to a diffusion flux. There is a higher probability of finding two ions of unlike charge on two adjacent quasi-lattice sites (but due to the diluteness of the solution the probability is very much lower than for ion–solvent pairs) and hence a small proportion of the activated complexes may consist of two ions of opposite charge. However, if the decomposition of this type of complex results

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in an exchange of the original lattice sites, the two ions are now at the center of an ionic atmosphere with similar sign to their own. This configuration of high local energy cannot decay away in the normal manner by thermal interaction with the new neighbors, but only by two alternate processes, (i) by a reversal of the original interchange, or (ii) by a series of interchanges which reverse the sign of the ionic atmosphere.

The first of these mechanisms would seem most probable, with the net result of zero flux. Although the second mechanism is possible, its small probability, together with the small proportion of activated complexes containing two ions of opposite charge, restricts the net flux arising from this mechanism to insignificant values. Therefore, only the fluxes resulting from ion–solvent exchanges are considered, and these are given by [7] and [9] as

$$[22] \qquad (J_{i(i\neq 0)})_V = J_i^{i\rightleftarrows 0} = -k_{i0}c_i c_j\left(\frac{\partial \mu_i}{\partial x} - \frac{\partial \mu_0}{\partial x}\right).$$

Equation [22] is a complete statement of diffusion in electrolytes for this particular model. It only remains to carry out a mathematical transformation to a form composed only of independent, conjugate fluxes and forces, of which there are a number of alternative choices. The following derivation has been influenced by the fact that the experimental phenomenological coefficients for ternary electrolyte solutions have been given in terms of the two independent salt fluxes and the corresponding thermodynamic forces written in terms of the chemical potential gradients of the salts.

The i'th salt, indicated by the subscript is, contains the i'th ion, where i is not the common ion (component 3). The chemical formula of the i'th salt is always written as $i_{z_3}3_{z_i}$, even if z_i and z_3 have a common factor other than unity. The concentration c_{is} is defined as

$$[23] \qquad c_{is} = c_i/|z_3|,$$

where $|\ \ |$ indicates the modulus. The concentration defined in [23] is directly related to the experimental quantities needed to make a ternary solution and is not to be confused with the thermodynamic mean molar concentration $c_{1s}^{\mp}$ defined as

$$[24] \qquad c_{1s}^{\mp} = (|z_i| + |z_3|)\sqrt{(c_i)^{z_3}(c_3)^{z_i}}\ .$$

The concentration of the common ion is given by

$$c_3 = \sum_{j=1}^{2} c_{js}\,|z_j|,$$

and hence [24] becomes

$$[25] \qquad c_{1s}^{\mp} = (|z_i| + |z_3|)\sqrt{(c_{is}|z_3|)^{z_3}\left(\sum_{j=1}^{2} c_{js}|z_j|\right)^{z_i}},$$

which is only equal to c_{is} for a binary uni-univalent salt solution.

The salt flux J_{is} is given by

$$[26] \qquad J_{is} = J_i/|z_3|.$$

The chemical potentials of the salts are given by

$$[27] \qquad \mu_{is} = |z_3|\mu_i + |z_i|\mu_3.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Each ion is assigned sole occupancy of a quasi-lattice site, so that the ratio of salt to solvent molar volume is

[28] $$\bar{V}_{is}/\bar{V}_0 = |z_3| + |z_i|,$$

and hence the thermodynamic forces are given by [6] and [28] as,

[29] $$X_i = -\left\{\frac{\partial \mu_{is}}{\partial x} - (|z_3| + |z_i|)\frac{\partial \mu_0}{\partial x}\right\},$$

or alternately by means of [27] as

[30] $$X_i = -\left\{|z_3|\left(\frac{\partial \mu_i}{\partial x} - \frac{\partial \mu_0}{\partial x}\right) + |z_i|\left(\frac{\partial \mu_3}{\partial x} - \frac{\partial \mu_0}{\partial x}\right)\right\}.$$

The fluxes of eq. [22] must satisfy the condition [20], hence

[31] $$\sum_{j=1}^{3} -z_j k_{j0} c_j c_0 \left(\frac{\partial \mu_j}{\partial x} - \frac{\partial \mu_0}{\partial x}\right) = 0.$$

As the ionic concentrations and chemical potentials are not all independent, eq. [31] imposes no restrictions on the k_{j0}. The salt fluxes are given by [26], [22], and [31] as

[32] $$(J_{is})_V = -(|z_3|)^{-1}\left\{k_{i0}c_i c_0\left(\frac{\partial \mu_i}{\partial x} - \frac{\partial \mu_0}{\partial x}\right) + \theta_i \sum_{j=1}^{3} k_{j0}c_j c_0\left(\frac{\partial \mu_j}{\partial x} - \frac{\partial \mu_0}{\partial x}\right)\right\},$$

where through [31] we have added a constant θ_i times zero to the right hand side. A value of θ_i is now chosen for which the forces have the form of eqs. [29] or [30] and the fluxes the form of [5]. This yields

$$\theta_i z_3 k_{30} c_3 c_0 = \theta_i \sum_{j=1}^{2} \frac{|z_j|z_j}{|z_3|} k_{j0}c_j c_0 + \frac{|z_i|}{|z_3|} k_{i0}c_i c_0,$$

or

[33] $$\theta_i = |z_i| k_{i0} c_i c_0 \Big/ \left(z_3|z_3|k_{30}c_3 c_0 - \sum_{j=1}^{2} |z_j|z_j k_{j0}c_j c_0\right).$$

Substitution of [33] into [32], with rearrangement of the forces into the form given by eq. [29] results in

[34] $$(J_{is})_V = -k_{i0}c_i c_0 (z_3)^{-2}\left\{1 + |z_i|z_i k_{i0}c_i \Big/ \left(|z_3|z_3 k_{30}c_3 - \sum_{j=1}^{2} |z_j|z_j k_{j0}c_j\right)\right\}$$
$$\times \left\{\frac{\partial \mu_{is}}{\partial x} - (|z_3| + |z_i|)\frac{\partial \mu_0}{\partial x}\right\} - (z_3)^{-2}\left\{k_{10}k_{20}c_1 c_2 c_0 |z_1|z_1 \Big/ \left(|z_3|z_3 k_{30}c_3 - \sum_{j=1}^{2} |z_j|z_j k_{j0}c_j\right)\right\} \times \left\{\frac{\partial \mu_{is(l\neq i)}}{\partial x} - (|z_3| + |z_l|)\frac{\partial \mu_0}{\partial x}\right\}.$$

Noting that z_3 has the opposite sign to z_1 and z_2 and comparing [34] with [5] we find that the L-coefficients for an aqueous solution containing two strong electrolytes with a common ion are given by this model as

[35] $$(L_{il})_V = k_{i0}c_i c_0 (z_3)^{-2}\left\{1 - (z_i)^2 k_{i0}c_i \Big/ \sum_{j=1}^{3} (z_j)^2 k_{j0}c_j\right\}$$

and

[36] $$(L_{12})_V = (L_{21})_V = -k_{10}k_{20}c_1 c_2 c_0 z_1 z_2/(z_3)^2 \sum_{j=1}^{3} (z_j)^2 k_{j0}c_j.$$

If terms involving exchange of ions had been included in eq. [22], and the analysis carried through to eqs. [35] and [36] in an identical manner, then even if

$$k_{ij(j\neq 0)} \approx k_{i0}$$

the dilute solution approximation

$$c_i \ll c_0,$$

would assure that all terms in the k_{ij} could be omitted to give a result identical with [35] and [36]. Indeed, it is expected that the $k_{ij(j\neq 0)}$ are very much smaller than the corresponding k_{i0}, so that their inclusion would be an unnecessary complication.

As the k's must always be positive the L-coefficients of [35] and [36] satisfy all of the thermodynamic requirements (14), i.e.

[37] $$(L_{12})_V = (L_{21})_V;$$

$$(L_{11})_V > 0;\ (L_{22})_V > 0;\ (L_{11})_V(L_{22})_V - (L_{12})_V(L_{21})_V \geqq 0.$$

EVALUATION OF THE k's FOR IONIC SOLUTIONS FROM CONDUCTANCE DATA

The present model, summarized in eq. [22] and without the restriction of electrical neutrality, should describe conductance behavior at infinite dilution where the "time of relaxation effect", normally present in conductance, but not in diffusion, disappears (15). This allows evaluation of the k_{i0} from the corresponding limiting conductance data at infinite dilution. The conductance Ω_i of a solution, due to the presence of the i'th ion is

$$\Omega_i = |z_i| c_i \lambda_i 10^{-3},$$

where λ_i is the equivalent ionic conductance, and hence the flux of ions under an electrical potential gradient $\partial E/\partial x$ is

[38] $$(J_i)_{\text{cell}} = -\frac{|z_i| c_i \lambda_i}{z_i 10^3 F} \frac{\partial E}{\partial x},$$

where the flux is measured with respect to the cell and F is the Faraday. As there is no concentration gradient within the solution the chemical potential gradient of the i'th ion is given by (16),

$$\frac{\partial \mu_i}{\partial x} = z_i F \frac{\partial E}{\partial x}.$$

As the water molecules are assumed to be un-ionized,

$$\frac{\partial \mu_0}{\partial x} = 0.$$

Substitution of the above results into [22] gives

$$(J_i)_V = -k_{10} c_i c_0 z_i F \frac{\partial E}{\partial x},$$

and as the volume-fixed and cell-fixed frames of reference are coincident because the concentration gradient is zero, comparison of this equation with [38] gives

[39] $$k_{i0}^0 = \lambda_i^0 / 10^3 c_0^0 |z_i| F^2$$

at the limit of infinite dilution.

BINARY ELECTROLYTE SOLUTIONS

Before proceeding to check the results of the model against the experimental data for ternary solutions, it is instructive to consider the application of the model to binary solutions. For an aqueous solution of a strong electrolyte dissociating into ions 1 and 3, the flux $(J_{1s})_V$ is given by [34] as

$$(J_{1s})_V = -\frac{k_{10}k_{30}c_1c_0c_3}{(z_1)^2k_{10}c_1 + (z_3)^2k_{30}c_3}\left\{\frac{\partial\mu_{1s}}{\partial x} - (|z_3| + |z_1|)\frac{\partial\mu_0}{\partial x}\right\},$$

which by use of eq. [23], the Gibbs–Duhem equation, the relation

$$\mu_{1s} = \mu_{1s}^0 + (|z_1| + |z_3|)RT \ln y_{1s}^{\mp}c_{1s}^{\mp},$$

where μ_{1s}^0 is the standard chemical potential on the molar scale, $y_{1s}^{\mp}$ is the mean molar activity coefficient, and $c_{1s}^{\mp}$ is given by [24] or [25], can be reduced to

$$[40] \quad (J_{1s})_V = -\frac{k_{10}k_{30}(|z_1| + |z_3|)RT}{|z_3|k_{30} + |z_1|k_{10}}\left\{c_0 + (|z_1| + |z_3|)c_{1s}\right\}\left(1 + \frac{\partial \ln y^{\mp}}{\partial \ln c_{1s}}\right)\frac{\partial c_{1s}}{\partial x}.$$

Comparison of [40] with the flux given by Fick's first law (eq. [13]), which is applicable to any type of solution, yields

$$[41] \quad (D_{1s})_V = \frac{k_{10}k_{30}}{z_3k_{30} + z_1k_{10}}(|z_3| + |z_1|)RT\{c_0 + (|z_3| + |z_1|)c_{1s}\}\left(1 + \frac{\partial \ln y_{1s}^{\mp}}{\partial \ln c_{1s}}\right).$$

By substitution for the k's from eq. [39], the limiting value of the diffusion coefficient at infinite dilution is

$$[42] \quad (D_{1s}^0)_V = \frac{(|z_3| + |z_1|)\lambda_1^0\lambda_3^0RT}{|z_3||z_1|(\lambda_1^0 + \lambda_3^0)F^2}.$$

Equation [42] is the Nernst relation which has been experimentally verified for a large number of electrolyte solutions (17).

Combination of [41] and [42] with the approximation [16] gives

$$[43] \quad (D_{1s})_V = (D_{1s}^0)_V\left(1 + \frac{\partial \ln y_{1s}^{\mp}}{\partial \ln c_{1s}}\right)\{c_0 + (|z_3| + |z_1|)c_{1s}\}/c_0^0.$$

In dilute solutions the term $\{c_0 + (|z_3| + |z_1|)c_{1s}\}/c_0^0$, which allows for variations in the quasi-lattice dimensions, is not significantly different from unity. A number of experimental investigations have shown (17, 18) that eq. [43] is a good approximation for solutions of concentration below 10^{-1} M. At higher concentrations the diffusion coefficients given by eq. [43] are invariably higher than the experimental values. Equation [43] is often corrected by dividing the right hand side by the relative viscosity η_{rel} (17, 18), but this arbitrary procedure will be avoided here.

COMPARISON OF THE MODEL FOR AQUEOUS SOLUTIONS CONTAINING TWO STRONG ELECTROLYTES WITH EXPERIMENTAL OBSERVATIONS

L-coefficients have been calculated by means of eqs. [35] and [36] using the approximation [16] in conjunction with [39], for the system NaCl–KCl–H_2O, and these are compared in Table I, section A, with the experimental values of Dunlop and Gosting (20) and Dunlop (19) at a number of concentrations. The experimental L-coefficients were originally given for the solvent-fixed frame of reference, but these have been transformed to the volume-fixed frame by the method of Hooyman *et al.* (21). The quoted value of the

experimental off-diagonal coefficient is the mean of the experimentally determined $(L_{12})_V$ and $(L_{21})_V$. The agreement is good at low concentrations, and as expected the moduli of the calculated values are higher than the experimental values, the disagreement increasing with the concentration.

Miller (11) has determined from experimental ternary diffusion data and estimated thermodynamic data the L-coefficients for the systems LiCl–KCl–H_2O and LiCl–NaCl–H_2O, each at a single concentration, and these are compared in Table I, section B, with those given by equations [35], [36], [16], and [39]. Again the agreement is good.

AQUEOUS SOLUTION OF TWO ELECTROLYTES WITH ONE, OR BOTH, INCOMPLETELY IONIZED

The general mathematical description of this class of ternary system is cumbersome, and therefore a specific example, Na_2SO_4–H_2SO_4–H_2O, is chosen because experimental values of the L-coefficients have been measured (22). Davies *et al.* (23) have shown that the ionic species Na^+, H^+, SO_4^{--}, $NaSO_4^-$, HSO_4^- exist in detectable quantities, and these species are represented by the subscripts 1–5 respectively. The flux J_{1s} of Na_2SO_4 is given by an extension of [26] as

$$J_{1s} = J_1/2 + J_4/2, \qquad [44]$$

i.e. the flux of Na_2SO_4 is one-half of the combined flux of sodium nuclei, and similarly the flux J_{2s} of sulfuric acid is given by,

$$J_{2s} = J_2/2 + J_5/2. \qquad [45]$$

The ions $NaSO_4^-$ and HSO_4^- are each assumed to occupy two adjacent lattice sites, and hence exchange of either type of ion must occur simultaneously with two water molecules. Equation [22] must be modified for these two ionic species, and by the transition state theory of I,

$$(J_{j(j=4,5)})_V = -k_{j0}c_j(c_0)^2\left(\frac{\partial\mu_j}{\partial x} - 2\frac{\partial\mu_0}{\partial x}\right), \qquad [46]$$

with the k_{j0}^0 given by a modified form of [39] as

$$k_{j0(j=4,5)}^{\ 0} = \lambda_i^{\ 0}/10^3(c_0^{\ 0})^2F^2. \qquad [47]$$

Combination of eqs. [44], [46], [22], and [20] yields,

$$(J_{1s})_V = -\frac{1}{2}\left\{k_{10}c_1c_0\left(\frac{\partial\mu_1}{\partial x} - \frac{\partial\mu_0}{\partial x}\right) + k_{40}c_4(c_0)^2\left(\frac{\partial\mu_4}{\partial x} - 2\frac{\partial\mu_0}{\partial x}\right) + \theta_1\sum_{i=1}^{3} z_ik_{i0}c_ic_0\left(\frac{\partial\mu_i}{\partial x} - \frac{\partial\mu_0}{\partial x}\right) + \theta_1\sum_{j=4}^{5} z_jk_{j0}c_j(c_0)^2\left(\frac{\partial\mu_j}{\partial x} - 2\frac{\partial\mu_0}{\partial x}\right)\right\}. \qquad [48]$$

Assuming local equilibrium of the reactions,

$$NaSO_4^- \rightleftharpoons Na^+ + SO_4^{--},\ HSO_4^- \rightleftharpoons H^+ + SO_4^{--},$$

then,

$$\mu_4 = \mu_1 + \mu_3,\ \mu_5 = \mu_2 + \mu_3,$$

and hence

$$\left(\frac{\partial\mu_4}{\partial x} - 2\frac{\partial\mu_0}{\partial x}\right) = \left(\frac{\partial\mu_1}{\partial x} - \frac{\partial\mu_0}{\partial x}\right) + \left(\frac{\partial\mu_3}{\partial x} - \frac{\partial\mu_0}{\partial x}\right),$$

and

$$\left(\frac{\partial \mu_5}{\partial x} - 2\frac{\partial \mu_0}{\partial x}\right) = \left(\frac{\partial \mu_2}{\partial x} - \frac{\partial \mu_0}{\partial x}\right) + \left(\frac{\partial \mu_3}{\partial x} - \frac{\partial \mu_0}{\partial x}\right).$$

Substitution of these relations into [48], and selection of θ_1 such that the thermodynamic forces are in the form given by [29] results in

$$[49]\quad (J_{1s})_V = -\frac{1}{4}c_0\left[k_{10}c_1 + k_{40}c_4c_0 - \left\{(k_{10}c_1 - k_{40}c_4c_0)^2 \Big/ \left(\sum_{i=1}^{3}(z_i)^2k_{i0}c_i + \sum_{j=4}^{5}(z_j)^2k_{j0}c_jc_0\right)\right\}\right] \times \left(\frac{\partial \mu_{1s}}{\partial x} - 3\frac{\partial \mu_0}{\partial x}\right)$$
$$+ \frac{1}{4}c_0\left[(k_{10}c_1 - k_{40}c_4c_0)(k_{20}c_2 - k_{50}c_5c_0) \Big/ \left(\sum_{i=1}^{3}(z_i)^2k_{i0}c_i + \sum_{j=4}^{5}(z_j)^2k_{j0}c_jc_0\right)\right] \times \left(\frac{\partial \mu_{2s}}{\partial x} - 3\frac{\partial \mu_0}{\partial x}\right).$$

Comparison of eq. [49] with eq. [5] gives

$$[50]\quad (L_{11})_V = \frac{1}{4}c_0\left[k_{10}c_1 + k_{40}c_4c_0 - \left\{(k_{10}c_1 - k_{40}c_4c_0)^2 \Big/ \left(\sum_{i=1}^{3}(z_i)^2k_{i0}c_i + \sum_{j=4}^{5}(z_j)^2k_{j0}c_jc_0\right)\right\}\right],$$

$$[51]\quad (L_{12})_V = -\frac{1}{4}c_0\left[(k_{10}c_1 - k_4c_4c_0)(k_{20}c_2 - k_{50}c_5c_0) \Big/ \left(\sum_{i=1}^{3}(z_j)^2k_{i0}c_i + \sum_{j=4}^{5}(z_j)^2k_{j0}c_jc_0\right)\right].$$

The expressions for $(L_{22})_V$ and $(L_{21})_V$ are given by interchanging in [50] and [51] the subscripts 1 and 4 with 2 and 5 respectively. The coefficients given by the above relations satisfy the thermodynamic requirements [37].

TABLE II

Comparison of experimental L-coefficients for the incompletely ionized system Na_2SO_4–H_2SO_4–H_2O with those calculated from eqs. [29], [38], and [41]. Experimental data from Wendt (22)

		1s = Na_2SO_4, 2s = H_2SO_4; ($\lambda_{H^+}{}^0$ = 349.8, $\lambda_{SO_4^{--}}{}^0$ = 80.0$_2$ (ref. 18, p. 463)); $\lambda_{HSO_4^-}{}^0$ = 51.2 (ref. 28)			
c_{1s}		0.5000	1.000	0.5000	1.000
c_{2s}		0.5000	0.5000	1.0000	1.000
c_0		53.47	52.58	52.29	51.24
$(L_{11})_V \times RT \times 10^8$	Expt.	0.231	0.381	0.226	0.371
	Calcd.	0.273	0.496	0.285	0.526
$(L_{12}=L_{21})_V \times RT \times 10^8$	Expt.	−0.072	−0.084	−0.091	−0.146
	Calcd.	−0.153	−0.206	−0.177	−0.272
$(L_{22})_V \times RT \times 10^8$	Expt.	0.515	0.444	0.802	0.725
	Calcd.	0.834	0.956	1.47	1.66

The concentrations of the various ionic species are not available for salt concentrations as high as those used by Wendt (22). By using the crude approximation that the concentration of $NaSO_4^-$ ions is zero, and that the H_2SO_4 dissociates only as far as the first ionization stage, values of the L's have been calculated from eqs. [50] and [51]. These

are compared in Table II with the experimental values given by Wendt (transforming the published solvent-fixed frame data to the volume-fixed frame of reference). As expected, the agreement is poor due to the crude approximations made in the ionic concentrations, and the very high overall concentration of solute.

AQUEOUS SOLUTIONS CONTAINING A NONELECTROLYTE AND A STRONG ELECTROLYTE

In this class of ternary solution, diffusion proceeds by interchange of nonelectrolyte with water molecules, ions with water molecules, and ions with nonelectrolyte molecules. Nonelectrolyte molecules are represented by the subscript 1 and the ionic species by subscripts 2 and 3. The nonelectrolyte fluxes are therefore given by the expression

$$[52]\qquad (J_1)_V = -k_{10}c_1c_0\left(\frac{\partial\mu_1}{\partial x}-\frac{\partial\mu_0}{\partial x}\right)-\sum_{i=2}^{3}k_{i1}c_ic_1\left(\frac{\partial\mu_1}{\partial x}-\frac{\partial\mu_i}{\partial x}\right),$$

$$= -\left(k_{10}c_1c_0+\sum_{i=2}^{3}k_{i1}c_ic_1\right)\left(\frac{\partial\mu_1}{\partial x}-\frac{\partial\mu_0}{\partial x}\right)+\sum_{i=2}^{3}k_{i1}c_ic_1\left(\frac{\partial\mu_i}{\partial x}-\frac{\partial\mu_0}{\partial x}\right).$$

Similarly the ionic fluxes are given by,

$$[53]\qquad (J_{i(i=2,3)})_V = -(k_{i0}c_ic_0+k_{i1}c_ic_1)\left(\frac{\partial\mu_i}{\partial x}-\frac{\partial\mu_0}{\partial x}\right)+k_{i1}c_ic_1\left(\frac{\partial\mu_1}{\partial x}-\frac{\partial\mu_0}{\partial x}\right),$$

the two ionic fluxes again being subject to the condition of electrical neutrality [20].

Combination of [52] and [53], and the use of the condition [20] to bring the electrolyte forces into the form of eq. [29], results in,

$$[54]\qquad (J_1)_V = -\left\{k_{10}c_1c_0+\sum_{i=2}^{3}k_{i1}c_ic_1-\frac{|z_2||z_3|(k_{21}-k_{31})^2c_{2s}(c_1)^2}{\sum_{i=2,3}|z_i|(k_{i0}c_0+k_{i1}c_1)}\right\}$$

$$\times\left(\frac{\partial\mu_1}{\partial x}-\frac{\partial\mu_0}{\partial x}\right)+c_1c_{2s}\left\{\sum_{i(j=2;\,i\neq j)}^{3}|z_i|(k_{i0}c_0+k_{i1}c_1)k_{j1}\Big/\sum_{i=2}^{3}|z_i|(k_{i0}c_0+k_{i1}c_1)\right\}$$

$$\times\left(\frac{\partial\mu_{2s}}{\partial x}-(|z_3|+|z_2|)\frac{\partial\mu_0}{\partial x}\right),$$

$$[55]\qquad (J_{2s})_V = -\left\{c_{2s}\prod_{i=2,3}(k_{i0}c_0+k_{i1}c_1)\Big/\sum_{i=2}^{3}|z_i|(k_{i0}c_0+k_{i1}c_1)\right\}$$

$$\times\left(\frac{\partial\mu_{2s}}{\partial x}-(|z_2|+|z_3|)\frac{\partial\mu_0}{\partial x}\right)$$

$$+c_1c_{2s}\left\{\sum_{i(j=2;\,i\neq j)}^{3}|z_i|(k_{i0}c_0+k_{i1}c_1)k_{j1}\Big/\sum_{i=2}^{3}|z_i|(k_{i0}c_0+k_{i1}c_1)\right\}\times\left(\frac{\partial\mu_1}{\partial x}-\frac{\partial\mu_0}{\partial x}\right).$$

Comparison of [54] and [55] with [5] gives the L-coefficients as,

$$[56]\qquad (L_{11})_V = c_1\left(k_{10}c_0+\sum_{i=2}^{3}k_{i1}c_i\right),$$

where the third term has been omitted because of its relative smallness,

$$[57]\qquad (L_{12}) = (L_{21})_V = -c_1c_{2s}\left\{\sum_{i(j=2;\,i\neq j)}^{3}|z_i|(k_{i0}c_0+k_{i1}c_1)k_{j1}\Big/\sum_{i=2}^{3}|z_i|(k_{i0}c_0+k_{i1}c_1)\right\},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$[58] \qquad (L_{22})_V = c_{2s} \prod_{i=2,3} (k_{i0}c_0 + k_{i1}c_1) \Big/ \sum_{i=2}^{3} |z_i|(k_{i0}c_0 + k_{i1}c_1),$$

and again the L-coefficients satisfy the requirements [37].

There is no method of obtaining the k_{i1} from binary data, but as the concentration term associated with it is c_1 and not c_0, then any reasonable value assigned to k_{i1} will not seriously influence the calculated L-coefficients for dilute solutions. Accordingly k_{i1} is assigned the same value as k_{i0}.

The approximation [16] was used in conjunction with [14] and [39] to calculate values of the L-coefficients for the system glycine–KCl–H_2O, and these are compared with the experimental values of Woolf *et al.* (24) in Table III, section A. The agreement is good, and as expected, the moduli of the calculated values are greater than the moduli of the experimental values, the discrepancy increasing with concentration.

Table III, section B, contains a similar comparison for the system raffinose–KCl–H_2O. The exchange model is not strictly applicable to this system because of the relatively large partial molar volume of the raffinose. In addition, Miller's L-coefficients (11) have been determined from experimental ternary diffusion data but with estimates of the thermodynamic functions $\partial \ln y_i/\partial \ln c_j$ only. The agreement between the two sets of values is nonetheless good.

DISCUSSION

The simple exchange model provides some insight into the manner in which gross Onsager cross-effects arise in ternary diffusion. In completely nonelectrolyte solutions the off-diagonal coefficients may be directly attributed to interchange of solute molecules. The application of detailed balance (or microscopic reversibility) to the kinetics of this process yields the symmetry property of the diffusion matrix. Direct interchange of solute species (ions) is considered to be negligible in ternary solutions containing two strong electrolytes so diffusion must be attributed to interchange between ions and solvent molecules, each type of exchange being regarded as an independent process. In this case relatively large off-diagonal L-coefficients arise as a result of transforming the lattice referred diagonal diffusion matrix describing the diffusion of the ions to a form which relates the two independent salt fluxes and forces. The fact that one ion must be common to both salts requires a very strong formal "coupling" of the chemical potential gradients of the salts, which ensures that the off-diagonal L-coefficients remain relatively large, even if all of the individual mobilities (or k_{i0}'s in this model) are identical. In an aqueous solution containing a strong electrolyte and a nonelectrolyte, both interchange of ions with nonelectrolyte and the formal requirements of thermodynamics act together to produce a finite off-diagonal coefficient, but by comparison with the case of two strong electrolytes the combined effect is small.

The use of the k's obtained from binary diffusion and conduction data, extrapolated to infinite dilution, places severe restrictions on the use of the model. This approximation, which is equivalent to assuming a constant mobility in the volume-fixed frame of reference, is known to lead to large errors in binary solutions, except at low concentrations. It is therefore not surprising that a similar behavior occurs for ternary solutions. For electrolyte solutions, inclusion of a coupling between interchanges, comparable with the electrophoretic effect (15), would not be sufficient to reduce the error at higher concentrations, and in many cases would increase the discrepancy.

The introduction of a correction based on the relative viscosity of the solution would probably lead to better agreement with real systems. The only models of diffusion in binary

†Experimental L-coefficients obtained by means of estimated thermodynamic data (11).

solutions, which introduce a viscosity factor are those of a quasi-macroscopic nature, based on the application of Stokes' Law. A discussion of this type of model in relation to binary electrolyte diffusion is given by Robinson and Stokes (17). Agreement with experiment is reached only by introducing a parameter in the form of a variable hydration number. Gosting and Akeley (8) and Dunlop and Gosting (7) have shown that the introduction of a viscosity factor does not always lead to agreement, within experimental error, for binary nonelectrolyte solutions. Ellerton *et al.* (25) have used frictional coefficients to describe diffusion in binary aqueous solutions of nonelectrolytes. They show that for the systems studied there is no direct correlation between Stokes' law and the variation of the frictional coefficients with concentration. The exchange model cannot use Stokes' law directly because diffusion is described as a unit rate process, with an overall probability of a flux in a particular direction with a non-zero driving force. Nevertheless, the factors giving rise to a relative viscosity greater than unity must also influence the heat of formation (and hence the activity coefficient), and the frequency of decomposition of the activated complex. It is interesting to note that the system Na_2SO_4–H_2SO_4–H_2O showed the poorest agreement of all the ternary systems considered. The viscosity data of Vinal and Craig (26) for aqueous sulfuric acid solutions, and the more recent discussion of Kaminsky (27) suggests that the SO_4^{--} ions have a very much stronger influence on the relative viscosity of aqueous solutions than any of the ionic species present in the other ternary systems.

It is important to realize that the success of the model in dilute ternary solutions does not prove that diffusion in liquids occurs through a simple exchange mechanism, because the k_{10}'s were obtained from binary diffusion and conductance data, and not from any more fundamental statistical theory. It has been shown in I that both exchange and vacancy models lead to a similar concentration dependence of the L-coefficients in solid solutions. However, the agreement between estimated and experimental L-values in dilute ternary liquid systems lends confidence to the results of the analysis of diffusion in multicomponent alloys given in I, where no experimental data is available to make a direct check of the models.

The exchange model is not restricted to ternary systems. Extension to systems of more than three components is a formal procedure which does not require the introduction of any new principles or assumptions.

REACTIONS OF NITRO SUGARS

I. SOME BENZYLIDENE AND ACYL DERIVATIVES OF METHYL 3-DEOXY-3-NITRO-D-HEXOPYRANOSIDES

HANS HELMUT BAER, FRANK KIENZLE, AND THOMAS NEILSON

ABSTRACT

The 4,6-*O*-benzylidene derivatives VII, VIII, and XVII of methyl 3-deoxy-3-nitro-β-D-mannopyranoside, -β-D-galactopyranoside, and -α-D-glucopyranoside, respectively, were prepared. Acetylation of the β-D-*manno* derivative (VII) led, depending upon the reaction conditions, to its 2-*O*-acetate (IX) and, by way of an unexpected epimerization, to the 2-*O*-acetate (V) of the corresponding β-D-*gluco* isomer. There is evidence that this epimerization proceeds through methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hexopyranos-2-enide (VI). This nitroolefin was obtained by a Schmidt–Rutz reaction from IX (as earlier from V) and was shown to add acetic acid readily giving V. It also added ethanol producing a 2-*O*-ethyl glycoside (XII). Acetylation of the *galacto* derivative (VIII) did not afford an acetate but proceeded with dehydration yielding methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*threo*-hexopyranos-2-enide (X).

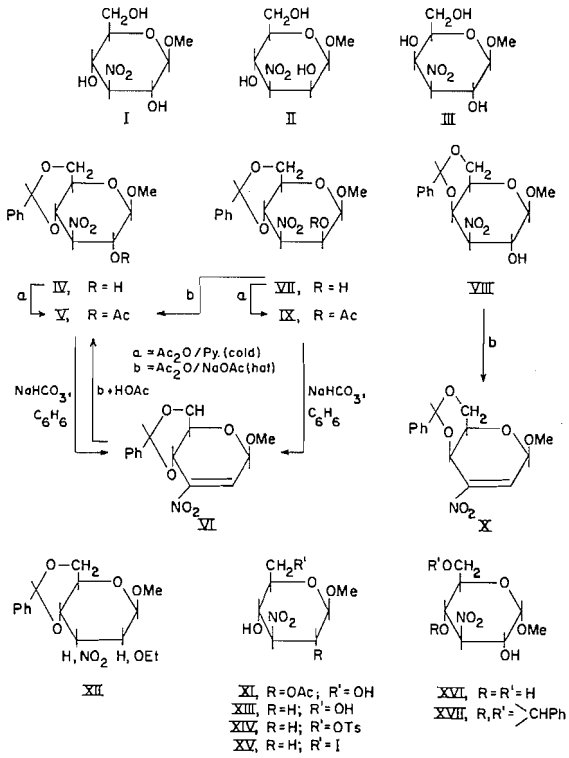
A number of further derivatives of methyl 3-deoxy-3-nitro-β-D-glucopyranoside were prepared, viz., the 2-*O*-acetyl (XI), 2-deoxy-6-*O*-tosyl (XIV), and 2,6-dideoxy-6-iodo (XV) derivatives.

A recent article (1) has described the synthesis of 3-amino-2,3-dideoxy-D-*arabino*-hexose via the corresponding methyl 2,3-dideoxy-3-nitro-β-glycoside (XIII). In view of the potential usefulness of nitro sugar intermediates for similar syntheses which may lead to rare amino sugars, a number of additional 3-deoxy-3-nitro-hexose derivatives have been prepared and some of their reactions have been studied.

Nitromethane cyclization of L′-methoxy-D-hydroxymethyldiglycolic aldehyde (periodate-oxidized methyl β-D-hexopyranosides) had afforded (2, 3, 4) crystalline methyl 3-deoxy-3-nitro-β-D-glucopyranoside (I), -D-mannopyranoside (II), and -D-galactopyranoside (III). The 4,6-*O*-benzylidene derivative (IV) of I had been acetylated (1) to methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (V) which was subsequently converted into a nitroolefin, methyl 2,3-dideoxy-3-nitro-β-D-*erythro*-hexopyranos-2-enide (VI) by treatment with sodium bicarbonate in refluxing benzene (Schmidt–Rutz reaction). We have now prepared the 4,6-*O*-benzylidene derivatives VII and VIII from II and III, respectively, and have studied their behavior in similar reaction sequences.

The benzylidene mannoside (VII) furnished its 2-*O*-acetate (IX) on treatment with acetic anhydride in cold pyridine. Acetylation with hot acetic anhydride and anhydrous sodium acetate, however, did not lead to the same acetate but gave, surprisingly, the 2-*O*-acetyl glucoside (V). This glucoside acetate was also obtained when the nitroolefin (VI) was heated with a mixture of acetic anhydride, acetic acid, and sodium acetate. It appears, therefore, that under the more vigorous acetylation conditions the mannoside (VII) undergoes dehydration followed by addition, to intermediate VI, of a molecule of acetic acid in such a way as to favor equatorial orientation of the nitro and acetoxy substituents (i.e., *gluco* configuration).

The 2-*O*-acetyl-mannoside (IX) furnished *isolable* nitroolefin (VI) by Schmidt–Rutz elimination of acetic acid, as did the glucoside (V). It was noted that the reaction rates were of similar magnitude for V and IX; however, this observation should not be stressed



too much since slightly varying conditions may have prevailed in the heterogeneous reaction media.

When acetylation of the benzylidene galactoside (VIII) was attempted with acetic anhydride and pyridine, decomposition occurred; and acetylation with cold acetic anhydride and sodium acetate led to recovery of starting material. When, however, VIII was *heated* for a few minutes in an acetic anhydride – sodium acetate mixture, a new crystalline product was formed in 96% yield. It was not the expected nor any other *O*-acetate, but proved to be the nitroolefin, methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*threo*-hexopyranos-2-enide (X). Further refluxing of (isolated) X in a glacial acetic acid – acetic anhydride mixture for 2.5 h yielded only starting material. A comparison of these results with those in the *manno* and *gluco* series described above shows that the C-4 configuration influences remarkably the stability of the 2,3-olefinic bond.

Further, it was of interest to study the feasibility of preparing nitroolefins by the Schmidt–Rutz reaction in the absence of a benzylidene blocking group at C-4 – C-6. Compound V was therefore debenzylidenated with a cation exchange resin in aqueous methanol, and crystalline methyl 2-*O*-acetyl-3-deoxy-3-nitro-β-D-glucopyranoside (XI) was obtained. Treatment of XI with sodium bicarbonate in refluxing benzene gave only an intractable mixture, possibly owing to intermolecular addition and (or) polymerization reactions of the nitroalkenediol presumably produced. It is of interest in this connection that the benzylidene nitroolefin (VI) readily added ethanol when refluxed in this solvent.[1]

[1]*This was discovered during an attempt to recrystallize VI from hot ethanol. The addition was probably promoted by the presence of a trace of alkali. Alkali-catalyzed additions of alkoxyl to nitroolefins are well known: cf. (5, 6, 7) and earlier literature cited there.*
