Detection was by ultraviolet light and by DSA. R_f values in the respective solvent systems and detection colors are shown in Table I. The remaining oil from the bisulfite solubles (45 mg) was diluted with acetone and streaked on 9 in. wide Whatman No. 17 paper. After the chromatograms were developed in THF solvent, the compounds were detected with ultraviolet light, cut out, and eluted from the paper with additional THF solvent, yielding ketol I in partially crystalline form (25 mg) and ketol II as an oil (3 mg). Infrared spectra were found to be identical with authentic samples using KBr pellets for ketol I and oil smears for ketol II.

Similar thick-paper chromatography on a portion of the bisulfite-insoluble ether residue (80 mg) yielded crystalline ketol III (10 mg) identical with an authentic sample by infrared spectral comparison. Paper chromatographic comparison of all fractions with an authentic sample of the remaining isomeric ketol 3-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (ω-hydroxypropioguaiacone) indicated that this compound was not among the acidolysis products of western hemlock sapwood.

THE IDENTITY OF OXYJAVANICIN WITH FUSARUBIN[1]

G. P. Arsenault

The antibiotic pigments javanicin and oxyjavanicin were isolated from *Fusarium javanicum* by Arnstein, Cook, and Lacey (1, 2). The structure of javanicin was recently established by synthesis (3) but the structure of oxyjavanicin remains unknown. Ruelius and Gauhe isolated fusarubin from *Fusarium solani*, and suggested that fusarubin and oxyjavanicin were identical (4). However, they were unable to make a direct comparison of the two compounds because of the lack of authentic oxyjavanicin.

(DSA) in paper chromatography. This suggestion has now been shown to be correct. However, he was unable to confirm the presence of ketol I.

EXPERIMENTAL

Air-dried western hemlock sapwood was reduced in a Wiley mill to approximately 40–80 mesh and made extractive-free, native-lignin free by soxhlet treatment with alcohol–benzene (1:2) for 48 h, water for 120 h, and absolute ethanol for 48 h, the wood meal being air-dried between each treatment.

Hemlock wood meal (150 g) in dioxane–water (9:1 v/v) (1 200 ml) containing concentrated HCl (19.95 ml) was refluxed with stirring for 2 h under a nitrogen atmosphere. After filtering of the wood meal residue, the reddish dioxane–water solution was partially neutralized to pH 6.5 with sodium carbonate (10%) and evaporated under reduced pressure to a dark brown oil. The oil was thinned with acetone (20 ml) and sprayed in a fine stream into vigorously stirred water (4 liters). The lignin may also be precipitated by using hexane as solvent, giving a smaller yield of a much lighter colored oil. The flocculent lignin precipitate was filtered and the water extracted with chloroform (6 × 50 ml), the emulsion residues being broken by centrifuging. The chloroform extracts were combined, dried over sodium sulfate, and evaporated to a brownish oil (1.23 g).

The oil was taken up in ether (25 ml), separated from additional lignin precipitate by decanting, and treated as outlined in the preparation of synthetic ketol II (2) using half quantities of solvent. This procedure yielded bisulfite-soluble (48 mg) and bisulfite-insoluble (210 mg) fractions.

Paper chromatography of the bisulfite-soluble oil in tetrahydrofuran – petroleum ether (65–110 °C) – water (3:7:5 v/v) (THF), butanol – ethanol – ammonia – water (40:10:1:49 v/v) (BEAW), and the organic phase of benzene – petroleum ether (80–100 °C) – methanol – water (50:50:1:50 v/v) (Lindstedt) (7) together with synthetic samples showed the two main components to be ketol I and ketol II.

Detection was by ultraviolet light and by DSA. R_f values in the respective solvent systems and detection colors are shown in Table I. The remaining oil from the bisulfite solubles (45 mg) was diluted with acetone and streaked on 9 in. wide Whatman No. 17 paper. After the chromatograms were developed in THF solvent, the compounds were detected with ultraviolet light, cut out, and eluted from the paper with additional THF solvent, yielding ketol I in partially crystalline form (25 mg) and ketol II as an oil (3 mg). Infrared spectra were found to be identical with authentic samples using KBr pellets for ketol I and oil smears for ketol II.

In studies on the chemical nature of pigments from fusaria, we obtained, from the Commonwealth Mycological Institute, a culture of the strain of *F. javanicum* used by Cook and co-workers, and isolated javanicin and oxyjavanicin. Oxyjavanicin was shown to be identical with fusarubin. We suggest that the name fusarubin be retained rather than oxyjavanicin since the structure of the compound was fully elucidated (5) under the name fusarubin.

EXPERIMENTAL

F. javanicum Koorders, IMI 29,817, was grown as described by Arnstein and Cook (2). The pigment mixture was isolated from the culture filtrate as described in method *a* of these workers, in yields of 14 mg per liter. The pigment mixture (301 mg) was separated into two components by ascending thin-layer chromatography on 3 × 2 mm thick plates (200 mm × 200 mm) of silica gel G using three passes of 2% methanol in chloroform as developer. The material in each zone was eluted separately with acetone, and recrystallized from chloroform-*n*-hexane. The upper and lower zones afforded 161 mg of javanicin and 25 mg of fusarubin, respectively. Identification of the two compounds was made by direct comparison (by thin-layer chromatography, infrared spectrum, ultraviolet–visible spectrum, melting point, and mixed melting point) with authentic samples.

ACKNOWLEDGMENTS

The author is indebted to Dr. D. Brewer for the culturing of *F. javanicum*, and to Professor F. F. Nord and Dr. H. W. Ruelius for samples of javanicin and fusarubin, respectively.

THE EFFECT OF ALPHA AND ALPHA′ DEUTERIUM UPON THE P.M.R. OF 2-BUTANONE

O. S. Tee and J. Warkentin

In our work on the relative rates of hydrogen–deuterium exchange at the reactive sites in ketones (1), as followed by n.m.r. spectroscopy, we have observed the effect of α- and α'-deuterium substitution upon the proton resonance of 2-butanone, I. The spectrum of I, in CCl_4 against internal TMS, shows the β-methyl triplet centred at $\tau = 9.00$, the α'-methyl singlet at $\tau = 7.93$, and the α-methylene quartet at $\tau = 7.60$. The coupling constant $J_{H_\alpha H_\beta}$ for the protons of the ethyl group is 7.35 c/s (cf. ref. 2).

If I is exchanged with D_2O in the presence of base,* the α-CH_2 and α'-CH_3 signals decay according to first-order rate laws. As the α-CH_2 is successively deuterated, the β-methyl triplet collapses until at full deuteration it is a close quintet with a splitting $J_{D_\alpha H_\beta} = 1.1$–$1.2$ c/s (Fig. 1), centered about 0.84 c/s upfield from the original β-methyl triplet. It arises

*$OD^\ominus$, $AcO^\ominus$, *and* p-$NO_2PhO^\ominus$ *were employed.*

THE EFFECT OF ALPHA AND ALPHA′ DEUTERIUM UPON THE P.M.R. OF 2-BUTANONE

O. S. Tee and J. Warkentin

In our work on the relative rates of hydrogen–deuterium exchange at the reactive sites in ketones (1), as followed by n.m.r. spectroscopy, we have observed the effect of α- and α'-deuterium substitution upon the proton resonance of 2-butanone, I. The spectrum of I, in CCl_4 against internal TMS, shows the β-methyl triplet centred at $\tau = 9.00$, the α'-methyl singlet at $\tau = 7.93$, and the α-methylene quartet at $\tau = 7.60$. The coupling constant $J_{H_\alpha H_\beta}$ for the protons of the ethyl group is 7.35 c/s (cf. ref. 2).

If I is exchanged with D_2O in the presence of base,* the α-CH_2 and α'-CH_3 signals decay according to first-order rate laws. As the α-CH_2 is successively deuterated, the β-methyl triplet collapses until at full deuteration it is a close quintet with a splitting $J_{D_\alpha H_\beta} = 1.1$–$1.2$ c/s (Fig. 1), centered about 0.84 c/s upfield from the original β-methyl triplet. It arises

*$OD^\ominus$, $AcO^\ominus$, *and* p-$NO_2PhO^\ominus$ *were employed.*

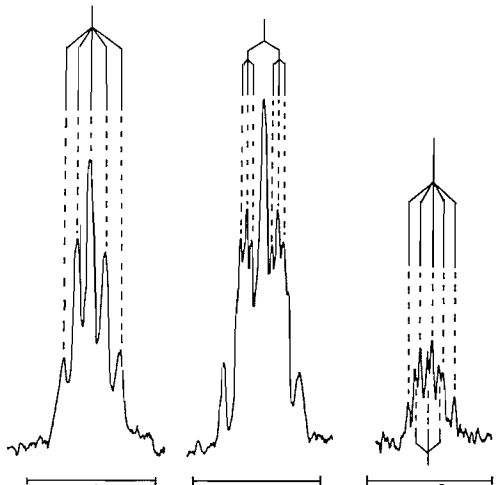

FIG. 1. FIG. 2. FIG. 3.

from the splitting of the β-methyl protons by the two deuterons ($I = 1$) of the CD_2 group, each of which can have $m_s = 1, 0, -1$.

At partial deuteration (ca. 50%), two spectra superimposed can be seen for the β-methyl protons (Fig. 2), viz., the original triplet from molecules still possessing $—CH_2CH_3$, and a pair of triplets arising from β-methyl protons adjacent to a CHD group, their signal first being split into a doublet by the proton ($I = \frac{1}{2}$) and then into triplets by the deuteron ($I = 1$). The splitting $J_{H_\alpha H_\beta}$ due to the proton of the CHD group is 7.25 c/s and the shift associated with the isotopic substitution is about 0.42 c/s upfield. The splitting $J_{D_\alpha H_\beta}$ of the triplets (Fig. 2) is 1.0–1.1 c/s.

As the α'-methyl group is exchanged its signal passes from a singlet (CH_3), through a triplet (CH_2D), to a quintet (CHD_2), which then disappears (CD_3). At approximately 50% exchange the α'-methyl spectrum shows the triplet of CH_2D and the quintet of CHD_2, superimposed (Fig. 3). For both these triplet and quintet spectra $J_{H_\alpha D_\alpha}$ is 2.3–2.4 c/s, and the shift associated with exchange of each proton is about 1.0 c/s upfield.

The results, summarized in Table I, agree with those of Gutowsky for acetone-d_5 (3), and those of Tiers (4, 5), and others (6, 7) on other types of systems. While we have found no previous reference to $J_{D_\alpha H_\beta}$ through saturated bonds, Tiers *et al.* have observed $J_{T_\alpha H_\beta}$ in tritiated ethylbenzene (10).

TABLE I

Group	Shifts relative to signal in undeuterated substrate (p.p.m.)	Shifts relative to signal in undeuterated substrate (c/s)	Coupling constants $J_{H_\alpha H_\beta}$ (c/s)	Coupling constants $J_{D_\alpha H_\beta}$ (c/s)	Coupling constants $J_{H_\alpha D_\alpha}$ (c/s)
CH_2CH_3	0	0	7.35±0.05	—	—
$CHDCH_3$	−.007	−0.42±0.05	7.25±0.05	1.0–1.1	(2.3–2.4)*
CD_2CH_3	−.014	−0.84±0.05	—	1.1–1.2	—
CH_3	0	0	—	—	—
CDH_2	−.017	−1.0±0.05	—	—	2.3–2.4
CD_2H	−.034	−2.0±0.05	—	—	2.3–2.4

*$J_{H_\alpha D_\alpha}$ for the —CHD— group is difficult to measure as the methylene region is complex. However, it is probably 2.3 to 2.4 c/s (cf. α'-CDH_2, CD_2H, and ref. 3).

The shifts upfield associated with the deuterium substitution are consistent with the accepted view (4, 5, 8, 9) that C—D bonds are more electron-releasing than C—H bonds.

All spectra were recorded on a Varian A-60 spectrometer with the probe temperature at ca. 35 °C.

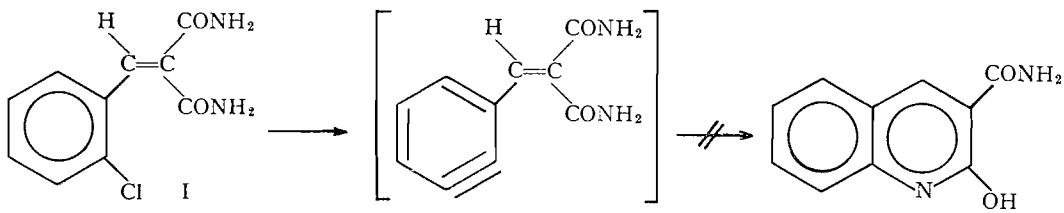
ORTHO-CHLOROBENZALMALONAMIDE AND RELATED COMPOUNDS

RAYMOND P. MARIELLA AND TERRY CONWAY[1]

Recent synthetic techniques (1–11), showing great promise in ring closure reactions, use aryne type intermediates. It was hoped to prepare, for the first time, unsaturated or aromatic type heterocycles directly in one step, via an amide-aryne type intermediate (i.e.):



Since one of the carboxamides was locked in the cisoid position, it was hoped that favorable conditions for the desired reaction would prevail. However, repeated experiments on I using potassium in liquid ammonia were unsuccessful in that the original compound was always isolated. Since I had never been synthesized before, subsequent reactions were performed to confirm its expected chemical behavior.

2-Chlorobenzalmalonamide (I) was synthesized from 2-chlorobenzaldehyde and malonamide. Initial attempts to prepare I using the reagents indicated under basic conditions were not practical. The reaction did proceed successfully under acidic conditions, and it was later found that I did undergo a reverse Knoevenagel reaction under basic conditions. Preliminary attempts to prepare I from II via the acid chloride were not successful, and attempts to hydrolyze III to I by means of concentrated sulfuric acid were also unsuccessful. However, in this latter reaction, 2-chlorobenzalcyanoacetamide (IV) was isolated,

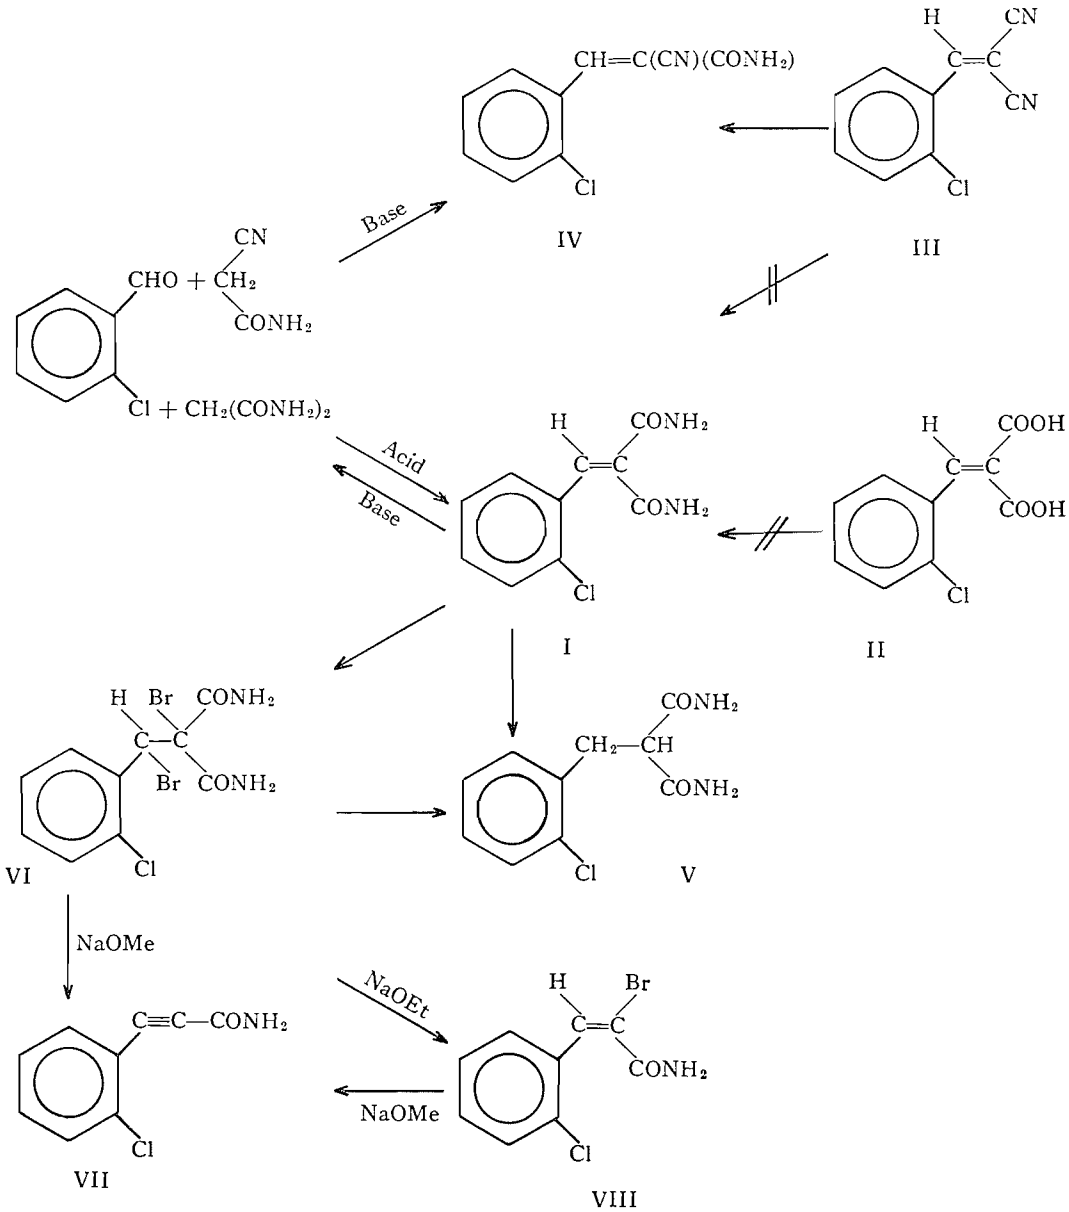
which was identical to the product prepared from cyanoacetamide and 2-chlorobenzaldehyde.

The reduction of I to V was readily accomplished using a platinum catalyst. It is interesting that treatment of VI with zinc metal and zinc chloride in 95% ethanol also gave V. The bromination of I was very slow and was accomplished under heterogeneous conditions in CCl_4 after 20 h. The dibromide (VI) was of variable stability: stable in cold and refluxing 95% ethanol, and unstable in cold absolute methanol. The dibromide (VI) was unstable in refluxing toluene as evidenced by the formation of benzyl bromide (no nuclear bromination was observed). In this regard, VI seems to be a selective solid brominating reagent.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The treatment of VI with sodium methoxide converted VI to VII directly in one step in fairly good yield. The treatment of VI with sodium *ethoxide*, however, gave IX exclusively. To show that the effect was indeed a selective one, the subsequent treatment of IX with sodium *methoxide* also gave VII, which was identical in all respects to the product prepared from VI.

EXPERIMENTAL

All melting points were determined on a Fisher-Johns melting point apparatus and are corrected. Analyses were performed by Micro-Tech Laboratories, Skokie, Illinois. The following chemicals were commercially available and were purchased from the Fisher Scientific Co.: malonamide, malonic acid, malononitrile, cyanoacetamide, and 2-chlorobenzaldehyde. The ultraviolet spectra were determined on a Beckman Spectrophotometer, model DU; infrared spectra were determined on a Perkin–Elmer spectrophotometer, model 21, and the nuclear magnetic resonance (n.m.r.) spectra were determined on a Varian instrument, model A60.

2-Chlorobenzalmalonamide (I)

Malonamide (10 g, 0.1 mole) and 20 ml of glacial acetic acid were refluxed until the malonamide dissolved. 2-Chlorobenzaldehyde (10.7 ml, 0.1 mole) was added, refluxing was continued for 1 h, and the reaction mixture was steam distilled to remove any unreacted aldehyde. The reaction mixture was then cooled and allowed to stand 2 h, and the white solid which formed was filtered off and washed with ether (8.5 g, 37% yield). Repeated crystallizations from 95% ethanol gave fine white crystals, m.p. 196.5–198°.

Anal. Calcd. for $C_{10}H_9ClN_2O_2$: C, 53.46; H, 4.04; N, 12.47. Found: C, 53.52; H, 4.50; N, 12. 34.

The ultraviolet (methanol) showed an absorption maximum (broad band) at 269 mμ, log ϵ = 4.0720. The infrared (KBr disc) showed characteristic strong absorption at 5.9, 6.0, and 6.15 μ indicating an α,β-unsaturated amide. The N—H amide bands at 2.9, 3.0, and 3.1 μ were strong. The n.m.r. (CD_3OD solvent, $(CH_3)_4Si$ standard) showed a sharp singlet at 7.9 p.p.m. for the vinylic proton, the characteristic multiplet for the aromatic protons at 7.1–7.8 p.p.m., and a broad peak at 4.2–5.0 p.p.m. for the amide protons.

2-Chlorobenzalmalonic Acid (II)

2-Chlorobenzaldehyde and malonic acid were allowed to react according to the method of Stuart (12) and the product was obtained in a 63% yield with a melting point identical to that previously reported, m.p. 192°.

2-Chlorobenzalmalononitrile (III)

2-Chlorobenzaldehyde and malononitrile were allowed to react according to the method of Corson (13) and the product was obtained in an 80% yield, m.p. 98 °C (lit. m.p. 95–96 °C (13)).

2-Chlorobenzalcyanoacetamide (IV)

From III

2-Chlorobenzalmalononitrile (III) (35 g, 0.14 mole) was added to 50 ml concentrated sulfuric acid. The mixture was heated with stirring at 100° for 5 min. The warm, dark-orange-colored reaction mixture was then slowly added to 150 ml of ice water. The white precipitate which formed was filtered off and washed with water, giving 20 g of fine white needles (66%). Recrystallization from 95% ethanol gave material, m.p. 171°.

From 2-Chlorobenzaldehyde and Cyanoacetamide

Cyanoacetamide (4.2 g, 0.05 mole), 2-chlorobenzaldehyde (7.0 g, 0.05 mole), 0.3 ml of 2 *M* NaOH, and 150 ml of 95% ethanol were refluxed for 3 h and then allowed to cool. The white precipitate which formed was filtered off and washed well with water (8.1 g, 80%). Recrystallization from 95% ethanol gave a white solid, m.p. 169.5–171°. The mixed melting point with the product formed from III was not depressed, and the infrared spectra of the two products were identical.

Anal. Calcd. for $C_{10}H_7ClN_2O$: C, 58.28; H, 3.52; N, 13.13. Found: C, 58.13; H, 3.42; N, 13.56.

The infrared spectra (KBr) consisted of strong bands at 5.9 and 6.15 μ indicating an unsaturated amide, and strong bands at 2.9 and 3.15 μ indicating N—H vibrations. Also, a very characteristic peak at 4.5 μ showed the presence of the nitrile group.

2-(2-Chlorobenzyl)-malonamide (V)

From I

Into a Parr bomb containing 0.2 g of prehydrogenated platinum oxide and 29 ml of 95% ethanol was added 2.0 g (0.009 mole) of I dissolved in a mixture of 125 ml of 95% ethanol and 1.5 ml of glacial acetic acid. The hydrogenation was completed in 15 min. The reaction mixture was then heated to reflux and the platinum catalyst was filtered from the hot solution. After the filtrate had cooled, the white solid which had separated was filtered off and washed with ether (1.2 g, 51%). Final purification was achieved by sublimation *in vacuo*, m.p. 246.5–247.5°.

For personal use only.

From VI

To a 250 ml three-necked round-bottom flask, equipped with an addition funnel, a mechanical stirrer, and a condenser protected by a drying tube, was added 2.18 g (0.03 mole) of zinc dust, a pinch of zinc chloride, and 25 ml of 95% ethanol. This was heated to reflux with stirring and then 8.57 g (0.02 mole) of 2-chlorobenzalmalonamide dibromide (VI) dissolved in 150 ml of 95% ethanol was slowly added. Refluxing was stopped after 7 h, and the reaction mixture was filtered while hot to remove the zinc dust. The filtrate was then cooled and the precipitate which formed was filtered off and washed with cold 95% ethanol and then ether (1.6 g, 72%) (white shiny flakes from ethanol), m.p. 247–248.5°. The material was identical with the product obtained above from I, the mixed melting point was non-depressed, and the infrared spectra were identical.

Anal. Calcd. for $C_{10}H_{11}ClN_2O_2$: C, 53.00; H, 4.86; N, 12.35. Found: C, 52.84; H, 4.77; N, 12.32.

The ultraviolet spectra indicated no absorption (in methanol) between 230 mμ and 340 mμ. The infrared showed very strong carbonyl amide absorption at 5.95 μ and strong N—H amide bands at 2.9, 2.95, and 3.1 μ. The n.m.r. spectra in trifluoroacetic acid showed a broad multiplet for the amide and aromatic protons from 7.2–8.1 p.p.m., a triplet at 4.15 p.p.m. for the CH group, and a doublet at 3.7 p.p.m. for the methylene group adjacent to the aromatic ring.

2-Chlorobenzalmalonamide Dibromide (VI)

Into a 200 ml three-necked round-bottom flask, equipped with an addition funnel, a mechanical stirrer, and a condenser, were added 50 ml of carbon tetrachloride (which had been dried over calcium chloride) and 5.0 g (0.025 mole) of I. The suspension was brought to reflux and bromine (4.16 g, 0.025 mole) dissolved in 50 ml of carbon tetrachloride was slowly added as the suspension was stirred. The refluxing was continued for approximately 20 h. After the refluxing had been stopped and the mixture cooled, the precipitate was filtered off and washed with carbon tetrachloride and ether. The yield was 7.6 g of shiny, white plates (75%), m.p. 149–150° (decomp.), after several recrystallizations from 95% ethanol. (Decomposition begins at 120°.)

Anal. Calcd. for $C_{10}H_9Br_2ClN_2O_2$: C, 30.84; H, 2.33. Found: C, 31.36, H, 2.26.

The product seemed to be much more stable in 95% ethanol than in absolute methanol. The infrared showed strong amide absorption at 5.95 μ, and medium N—H amide bands at 2.9, 2.95, and 3.15 μ.

2-Chlorophenylpropargylic Acid Amide (VII)

From VI

Into a 50 ml round-bottom flask containing 25 ml of absolute methanol (prepared by the Grignard method) was added 0.5 g of sodium metal. VI (5 g, 0.0125 mole) was added; the mixture was refluxed for 45 min and then cooled and diluted to twice its volume with cold water. The light-yellow precipitate that formed was filtered off and washed with water. The yield was 1.55 g (69%) of light-yellow crystals, m.p. 120.5–121.5° from water.

Anal. Calcd. for C_9H_6ClNO: C, 60.18; H, 3.37; N, 7.80. Found: C, 60.35; H, 3.35; N, 8.28.

The ultraviolet indicated an absorption maximum (broad band) at 250 mμ (log ϵ = 4.158). The infrared showed an amide band at 6.0 μ (strong), triple bond absorption at 4.4 μ (strong), and N=H bands at 2.95, 3.1, and 3.2 (medium). The n.m.r. ($CDCl_3$ solvent against Me_4Si as standard) showed a multiplet for the aromatic protons from 7.0–7.7 p.p.m. and a broad peak for the amide protons from 5.6–6.6 p.p.m. The signal area ratio of the two peaks was 2:1 as expected.

From IX

IX (1.6 g, 0.006 mole) was added to a solution of 0.4 g of sodium in 20 ml of absolute methanol. The reaction mixture was refluxed for 30 min and then diluted to twice its volume with cold water. The precipitate which formed was filtered off and washed with water (0.6 g, 58% of a light-yellow solid), m.p. 120°. This material did not depress the melting point of a sample of VII prepared for VI and the infrared spectra of both samples were identical. When VII was hydrolyzed with 6 *N* NaOH and then acidified, the known 2-chlorophenylpropargylic acid m.p. 131° was obtained (lit. m.p. 132–133° (14)), and our sample did not depress the melting point of an authentic sample.

α-Bromo-β-(2-chlorophenyl)-acrylamide (IX)

VI (20 g, 0.053 mole) was added to a solution of sodium ethoxide (2 g of sodium in 100 ml of absolute ethanol). The mixture was refluxed with stirring for 1 h. The reaction mixture was then cooled, and filtered. The filtrate was evaporated almost to dryness *in vacuo*. The yellow precipitate which formed was heated with 10 ml of water. The solution was allowed to cool, and the precipitate was filtered off and finally washed with ether (4.6 g white needles m.p. 110°, sublimes).

Anal. Calcd. for $C_9H_7ClBrNO$: C, 41.50; H, 2.71; N, 5.38. Found: C, 41.52; H, 2.65; N, 5.45.

The ultraviolet showed a maximum of 264 mμ (broad band) log ϵ = 4.114. The infrared showed strong absorption characteristics of unsaturated amides at 5.9 μ and 6.1 μ. N—H bands (medium) were present at 2.9, 3.0, and 3.15 μ. (KBr disc). The n.m.r. (CD_3OD solvent and Me_4Si standard) showed a multiplet for the aromatic protons from 7.2–8.0 p.p.m., a sharp singlet at 8.25 p.p.m. for the vinylic proton, and a broad peak from 4.4–5.0 p.p.m. for the amide protons.

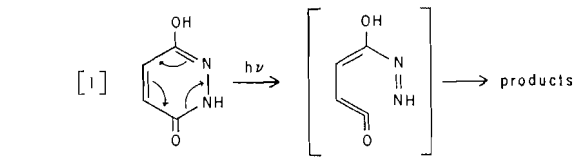
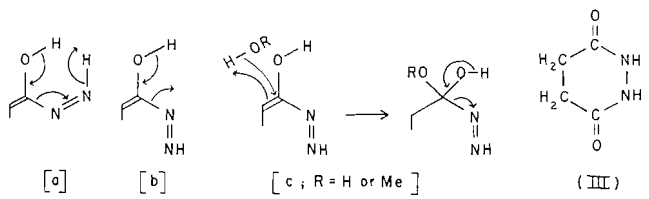
THE PHOTOLYSIS OF MALEIC HYDRAZIDE: EVIDENCE FOR AN INTERMOLECULAR HYDROGEN TRANSFER

A. STOESSL

A previous communication (1) has shown that photolysis of aqueous maleic hydrazide (MH) (I) under nitrogen leads to a complex mixture from which succinic acid was isolated in 26% yield. The structure of MH and the nature of the identified product suggested that a pathway of the photolysis might be analogous to that of six-membered carbocyclic dienes (2). For MH, it would be expressed as in eq. [1]. The intermediate (II) could decompose in a number of ways (for instance, [*a*], [*b*], or [*c*]) in which diimide could, but need not, be involved. The products would be succinic acid (via the ketene) and nitrogen, together with either hydrogen or the products of a hydrogen transfer to one or several acceptors.





The results of some further experiments reported in this communication went only a little way towards providing positive support for these concepts. No further work is planned but the studies uncovered an intermolecular hydrogen transfer which may be of some interest in itself.

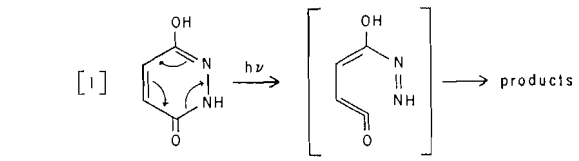
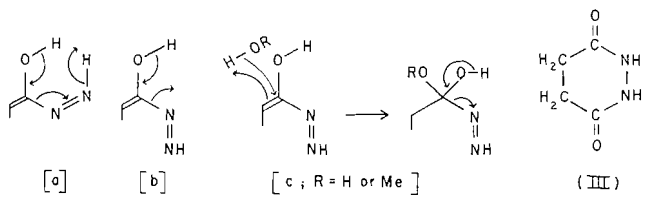
THE PHOTOLYSIS OF MALEIC HYDRAZIDE: EVIDENCE FOR AN INTERMOLECULAR HYDROGEN TRANSFER

A. STOESSL

A previous communication (1) has shown that photolysis of aqueous maleic hydrazide (MH) (I) under nitrogen leads to a complex mixture from which succinic acid was isolated in 26% yield. The structure of MH and the nature of the identified product suggested that a pathway of the photolysis might be analogous to that of six-membered carbocyclic dienes (2). For MH, it would be expressed as in eq. [1]. The intermediate (II) could decompose in a number of ways (for instance, [*a*], [*b*], or [*c*]) in which diimide could, but need not, be involved. The products would be succinic acid (via the ketene) and nitrogen, together with either hydrogen or the products of a hydrogen transfer to one or several acceptors.





The results of some further experiments reported in this communication went only a little way towards providing positive support for these concepts. No further work is planned but the studies uncovered an intermolecular hydrogen transfer which may be of some interest in itself.

Irradiation of aqueous MH in a sealed, evacuated vessel showed that hydrogen was liberated only in traces or, in some runs, not at all. Nitrogen (40%) and carbon dioxide (1.5%) were products of the photolysis from which succinic acid was again isolated in 25% yield. Pathway [*a*] was therefore eliminated from further consideration but the possibility of a hydrogen transfer remained. It occurred to us that MH itself might act as an acceptor in such a step. The expected product, cyclic succinhydrazide (III), was then shown to have the chromatographic properties of one of the components of the irradiation product. This was isolated and found to be identical with the authentic compound in every respect. The yield was estimated as about 3% of photolyzed MH or 13% of the succinic acid formed. Treatment of MH in a dark reaction, with diimide prepared *in situ* from a large excess of azodicarboxylate, did not lead to any reduction. Diimide in a more highly activated state, or an active precursor, would thus be required.

Proof of the intermediacy of ketenes was attempted by the irradiation of MH in dry methanol (2). This produced some of the expected dimethylsuccinate together with cyclic succinhydrazide and nitrogen. No dicarboxylic acids nor the dimethyl esters of fumaric and maleic acids could be detected. The yield of dimethylsuccinate was very low (0.45%) but this was due in part to the high and, in our hands, unavoidable losses during the working-up (more than 67% of the ester was lost in an appropriate control experiment). Further, photolysis in methanol was much more rapid than in water and the product was even more complex. This indicated that competing reactions, which must account for at least some of the photolysis in water, might have been relatively more important in the alcohol. But this is a surmise and the experimental facts give, at the most, only tentative support to scheme [1].

EXPERIMENTAL

General Methods

The reaction vessel was an unsilvered double-walled Dewar flask of Pyrex glass, the annular space A (capacity, ca. 700 ml) of which was provided with an entry B and an outlet C fitted with a break-off seal D. With the solution in A, the flask was evacuated and sealed at B. A Hanovia lamp CH-3 (85W) was placed in the central well of the flask which was cooled by an airstream to 40–44° during the irradiation. The apparatus was then sealed to a Topler pump at C and the gaseous products transferred to the burette via the break-off seal D. Aliquots of the gas were analyzed quantitatively by chromatography on Perkin–Elmer columns I (synthetic zeolite) and J (silica gel, type 15) with helium as carrier and O_2, N_2, H_2, CO_2, and CO as standards.

Fractionation of the aqueous product was followed by paper chromatography in *n*-BuOH–H_2O–HOAc (4:5:1). Melting points were taken on the Kofler stage.

Irradiations in Water

MH (12 millimoles) in water (600 ml) was irradiated for 144 hours; 0.94 millimole had been photolyzed (absorbance at λ_{max} 302 mμ). The gaseous product consisted of N_2 (0.38 millimole) and CO_2 (0.014 millimole). Hydrogen was not detected (traces, 1–2 μl, were found in other runs).

The vacuum distillate from a major portion (91.8%) of the aqueous product was neutral and did not give a precipitate with 2,4-dinitrophenylhydrazine. The distillation residue was extracted with water (several small portions), most of the unchanged MH (m.p. and mixed m.p., 1.12 g) remaining undissolved. The extracts were filtered through a strongly acidic cation exchange resin (Dowex 50W-X8 (4 ml)) with precautions against entry of atmospheric NH_3. Filtrate and washings were distributed by the single withdrawal procedure (3) in *n*-BuOH–H_2O–HOAc (4:5:1; 100 × 25 ml lower, 365 × 25 ml upper phase).

Fractions $\rho = 70$ to $\rho = 169$ (for the terminology, see ref. 3, p. 12) in water, were continuously extracted with ether. Filtration of the extract through silica gel gave crude succinic acid (26 mg). The pure compound (m.p., mixed m.p., infrared spectrum; 20 mg) was obtained on sublimation.

Fractions $\rho = 240$ to $r = 85$ (at least five components) were chromatographed on thin layers of silica gel (*n*-BuOH–H_2O) and the zones containing the desired compound (ultraviolet) extracted with very dilute acetic acid. Re-extraction of the product into ethanol and sublimation furnished cyclic succinhydrazide, m.p. and mixed m.p. 208°, with resetting and decomposition at 275–285°. The infrared (KBr disc) and ultraviolet spectra were identical with those of the authentic compound (4) (λ_{max} 241 mμ, E 7 250).

In another run (0.81 millimole MH photolyzed; 0.19 millimole crude succinic acid isolated), the yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of cyclic succinhydrazide was estimated as 0.025 millimole by semiquantitative paper chromatography (5).

The basic portion of the photolysis product was eluted from the ion exchanger with $N/1$ HCl, to give a small amount of salts. Paper chromatography in three systems showed the presence of ammonia and hydrazine as the main components. The amount of the latter was estimated as 0.0084 millimole by a colorimetric procedure (6) with which the other components did not interfere.

Irradiations in Methanol

MH (5 millimoles) in dry MeOH (250 ml) was irradiated for 96 hours (4 millimoles photolyzed). The solution was evaporated *in vacuo* without warming, the temperature falling to below 0 °C. The residue was extracted with ether and the extracts washed, dried, filtered, evaporated as above, and refiltered in ether into a microtube, most of the solvent being removed in a current of N_2. Quantitative vapor phase chromatography (Perkin–Elmer Carbowax 30%, 6 ft × 0.25 in. at 185°, 70 ml He/min; with the dimethyl esters of succinic, maleic, and fumaric acids as standards) showed the presence of only dimethylsuccinate (2.6 mg). Similar evaporation and ether extraction of dimethylsuccinate (58 mg) in MeOH (250 ml) gave a residue of only 19 mg.

The product from another experiment (12 millimole MH, 600 ml MeOH, 67 hours' irradiation, 2.85 millimoles photolyzed) was shown to contain cyclic succinhydrazide (4.85 mg; 1.5%) by semiquantitative paper chromatography (5). Ammoniacal silver nitrate reagent revealed the presence of at least 10 other distinct spots superimposed on heavy streaking. No succinic, maleic, or fumaric acid was detected (limit < 1 mg).

Attempted Diimide Reduction

MH (0.2 millimole) in water (10 ml) containing acetic acid (1 ml 6 N) was stirred with potassium azodicarboxylate (7) (2 millimoles added in five equal portions). No reduction occurred (ultraviolet and paper chromatography). The same result was obtained with MeOH–HOAc as solvent. Maleic acid in water as above gave succinic acid in 15% yield.

in the case of ketones was the marked preference, in many cases, for *gem* dichlorination with sulfuryl chloride, a reaction which does not occur readily in halogenation with molecular halogens (3). Thus, the major product from the chlorination of acetone with sulfuryl chloride (4) was 1,1-dichloroacetone rather than monochloroacetone. On this basis it was expected *a priori* that the predominant product from the chlorination of monofluoroacetone (I) probably would be 1-fluoro-1-chloroacetone which was desired for other studies.

Contrary to expectations it was found that only very little reaction occurred on the CH_2F group of I and, instead, substitution occurred mainly on the CH_3 group to yield (depending upon conditions) either 1-fluoro-3-chloroacetone (II) or 1-fluoro-3,3-dichloroacetone (III). It was also evident that I was generally less reactive than acetone or monochloroacetone. Thus, whereas 1,1-dichloroacetone was formed very rapidly (and exothermically) during the chlorination of acetone, a similar chlorination of I was much slower and even after several hours (see Experimental) sulfuryl chloride could be recovered and mainly II was formed. On the other hand, after long reaction times (Table I) the major product from a 1:1 (molar) reaction of I with sulfuryl chloride was III. This shows that the CH_2Cl group of II is somewhat more active than the CH_3 group of I but not to the extent that the CH_2Cl group of chloroacetone is more reactive than a CH_3 group of acetone. The fact that relatively short reaction times can lead to a monochlorinated major product is explainable on the basis that under these conditions I is in excess (relative to both the starting material and the monochlorination product) and even acetone can be made to yield mainly monochloroacetone when it is reacted in excess with sulfuryl chloride (1, 4).

TABLE I

Chlorination results

Reactants	[Ketone]:[SO_2Cl_2]*	Products (% based on SO_2Cl_2)†
Monofluoroacetone	1:1	1-Fluoro-3,3-dichloroacetone(60.1) + 1-fluoro-3-chloroacetone(31.3) + 1-fluoro-1-chloroacetone(4.5) + 1-fluoro-1,3,3-trichloroacetone(3.3)
Monofluoroacetone‡	4:1	1-Fluoro-3-chloroacetone‖
Monofluoroacetone + monochloroacetone	1:1:1	1,1-Dichloroacetone(62.5) + 1-fluoro-3,3-dichloroacetone (7.8) + 1-fluoro-3-chloroacetone(9.5)
Monofluoroacetone‡ + monochloroacetone	5:5:1	1,1-Dichloroacetone¶
Monofluoroacetone + acetone	1:1:1	1,1-Dichloroacetone(52) + monochloroacetone(30) + 1-fluoro-3-chloroacetone(15)
Monofluoroacetone§ + acetone	5:5:1	Monochloroacetone(65) + 1,1-dichloroacetone(15) + 1-fluoro-3-chloroacetone(5)

*In each case the last number given is the relative molar ratio of sulfuryl chloride with respect to the relative molar ratio of the ketones.
†Unless otherwise specified, reaction times of 24 h and reaction temperatures of ~25–30° were used.
‡A reaction time of ~1/2 h was used.
§A reaction time of ~2 h was used.
‖Only 50% of SO_2Cl_2 had reacted and this was essentially the only product.
¶About 80% of sulfuryl chloride had reacted and this was essentially the sole product.

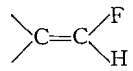
In direct competitions (Table I) both acetone and monochloroacetone reacted much more rapidly with sulfuryl chloride than I. This conclusively establishes that I is generally less active towards sulfuryl chloride than acetone or monochloroacetone.

It is reasonably well established that the acid-catalyzed halogenations of active methylene compounds with molecular halogens proceed through enolic intermediates and that in most (5–8), but not all (9, 10), cases enolization is rate-determining. The same sort of scheme has been suggested for chlorinations with sulfuryl chloride (1, 2)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

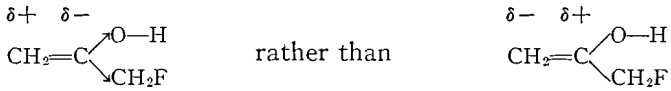
with the exception that chloronium abstraction by the enol often appears to be a slow (rate-determining) step (2) along with enolization.

It has been suggested that the fact that the reactions of fluoro-olefins which lead to saturated derivatives are more exothermic than those of the corresponding fluorine-free olefins (11, 12) might be a result of a decrease in stability of olefins to which are bonded one or more fluorine atoms (13). Obviously, such a tenet fits into the enol mechanism and could explain why the CH_2F group of I is so difficult to substitute, i.e., formation of



is energetically unfavorable. Another factor might also be contributing; if, in the sulfuryl chloride reaction, the base which extracts the carbon-bonded proton in the enol formation step is a halide (8, 14, 15) ion, the approach to a proton in the CH_2F group might be repelled by a direct field effect of the very electronegative fluorine atom.

The decrease in activity of the methyl group in I is not entirely unexpected. Thus, the chlorination of the methyl group in 1,1-dichloroacetone is very slow (16) even in the presence of an excess of sulfuryl chloride. A partial explanation is that the electron-withdrawing substituents polarize the enol intermediates in the "wrong direction", i.e., the electron flow involved in rehybridization during the formation of the carbon–chlorine band is unfavorable.



Thus with sulfuryl chloride, this may be a slow step.

Finally, initial attempts to extend these studies to bromo- and iodoacetone were made and the reactions were found to be very complex. In the case of bromoacetone n.m.r. evidence showed that (1) bromide was considerably displaced by chloride and that (2) much more methyl than methylene substitution occurred, as expected. With iodoacetone, a great deal of molecular iodine was rapidly liberated and a complex mixture of products resulted. These compounds have not been studied further to date.

EXPERIMENTAL

General

Nuclear magnetic resonance, n.m.r., spectra were obtained of the neat liquids using TMS as an internal reference. A Varian A-60 spectrometer (r.f. 60 Mc/s; sample temperature 37 ± 2 °C) was used for these measurements. Gas chromatographic determinations were performed with a column composed of 10% Apiezon-L on 80–90 mesh Anakrom-ABS. Elemental analyses were performed by the Galbraith Laboratories, Inc., Knoxville, Tennessee. Monofluoroacetone was purchased from Mr. David Starr, Department of Chemistry, University of South Carolina, Columbia, South Carolina.

Preparation of 1-Fluoro-1-chloro- and 1-Fluoro-3-chloroacetone

A 500 ml round-bottom flask equipped with a magnetic stirrer, dropping funnel, thermometer, and condenser (protected from atmospheric moisture with a calcium chloride drying tube) was charged with 96 g (1.2 moles) of monofluoroacetone. Sulfuryl chloride (135 g, 1 mole) was added dropwise over a period of 40 min. The temperature of the reaction mixture did not rise above 30 °C during this period. After addition was complete the reaction mixture was stirred 4 h at room temperature after which it was distilled through a large heated and insulated vigreux column (~20 plates) as follows:

Fraction	*B.p. (°C)*	*Pressure (mm Hg)*	*Product (g yield)*
1	15–25	75	SO_2Cl_2(~15) + CH_3—CO—CH_2F(?)
2	26–26.5	78	CH_2F—CO—CH_3(5.3) + CHFCl—CO—CH_3(7.6)
3	82	76	CH_2F—CO—CH_2Cl(30.4) + CH_2F—CO—$CHCl_2$(8.4)
4	82	76	CH_2F—CO—CH_2Cl(23.0) + CH_2F—CO—$CHCl_2$(4.1)
5	69	61	CH_2F—CO—CH_2Cl(13.2) + CH_2F—CO—$CHCl_2$(2.9)

TABLE II

Nuclear magnetic resonance data*

CH_3—CO—$CH_2'F$		$ClCH_2$—CO—$CH_2'F$		CH_3—CO—$CH'ClF$		Cl_2CH—CO—$CH_2'F$	
$\bar{\nu}$† = 471.3	$\bar{\nu}$ = 304.9	$\bar{\nu}$ = 343.0	$\bar{\nu}$ = 300.0	$\bar{\nu}$ = 472	$\bar{\nu}$ = 229.9	$\bar{\nu}$ = 226	$\bar{\nu}$ = 279
τ‡ = 7.81	τ = 5.05	τ = 5.72	τ = 5.0	τ = 7.87	τ = 3.84	τ = 3.78	τ = 4.66
$\lvert J_{HF}\rvert$§ = 4	$\lvert J_{H'F}\rvert$ = 47	$\lvert J_{HF}\rvert$ = 2.5	$\lvert J_{H'F}\rvert$ = 47	$\lvert J_{HF}\rvert$ = 3.5	$\lvert J_{H'F}\rvert$ = 51	$\lvert J_{HF}\rvert$ = 1.8	$\lvert J_{H'F}\rvert$ = 46.7

*The n.m.r. spectra will be discussed in more detail in future publications by B. L. Shapiro and co-workers.
Most of the τ values reported in this table are for neat liquids rather than dilute solutions and, therefore, are only approximate since the chemical shifts and coupling constants (see footnotes* and ‡) of halogenated ketones are quite solvent dependent.
†$\bar{\nu}$ = frequency in c.p.s. The values are probably accurate to ±0.5 c.p.s.
‡The tau scale as defined by G. V. D. Tiers in ref. 17 with τ_{TMS} = 10.0 p.p.m. (= 600 c.p.s.).
§The units of the coupling constants, $|J|$, are c.p.s. and the absolute magnitudes are probably accurate to ±0.3 c.p.s.

The yield of each product listed above was computed from the total weight of the fraction and the percentage, by weight, of each component as determined by gas chromatography. The structures of the products were assigned on the basis of their n.m.r. spectra (Table II). Fraction 4 above, which was mostly 1-fluoro-3-chloroacetone, was subjected to elemental analysis.

Anal. Calcd. for C_3H_4ClFO: C, 32.76; H, 3.62. Found: C, 32.41; H, 3.19.

It is of interest that a significant quantity of sulfuryl chloride was recovered unchanged in this experiment (~5 h reaction time) and that the major product under these conditions was 1-fluoro-3-chloroacetone rather than 1-fluoro-3,3-dichloroacetone which is obtained as a major product under similar conditions when longer (15–24 h) reaction times are used and essentially complete conversion of the sulfuryl chloride occurs (Table I). Complete separations were difficult to obtain via column fractionation under the conditions employed.

Stepwise Chlorination of Monofluoroacetone

To verify the results obtained above, monofluoroacetone was chlorinated by incremental additions of sulfuryl chloride and the products obtained were followed by quantitative n.m.r. This was done by converting the numbers of protons of specific peaks (e.g. Table II) into relative mole ratios. Typically, to 65 mmoles of monofluoroacetone were added 16.3 mmoles of sulfuryl chloride all at once at room temperature. The temperature rose to ~29 °C. After 0.5 h, 12% of the monofluoroacetone had been converted to 1-fluoro-3-chloroacetone (~50% yield based on sulfuryl chloride). An additional 16.3 mmoles of sulfuryl chloride was then added and after 2 h the reaction mixture contained 35% 1-fluoro-3-chloroacetone (70% yield based on sulfuryl chloride) and traces of 1-fluoro-3,3-dichloroacetone. Addition of a further 16.3 mmole portion of sulfuryl chloride resulted, after 2.5 h, in a mixture containing 60% 1-fluoro-3-chloroacetone (80% yield based on sulfuryl chloride), 5% 1-fluoro-3,3-dichloroacetone (10% based on sulfuryl chloride) and 1% of 1-fluoro-1-chloroacetone. About 34% of the original monofluoroacetone was present at this point. A final 16.3 mmole portion of sulfuryl chloride was added and the reaction mixture was stirred at room temperature for 17 h. The reaction mixture now contained 35% 1-fluoro-3,3-dichloroacetone (70% based on sulfuryl chloride), 25% 1-fluoro-3-chloroacetone, and ~1% 1-fluoro-1-chloroacetone. From these results it is apparent that the CH_2Cl group of 1-fluoro-3-chloroacetone is slightly more reactive than the CH_3 group of monofluoroacetone.

Competitive Chlorinations

Equimolar mixtures of acetone with monofluoroacetone and monofluoroacetone with monochloroacetone, as well as monofluoroacetone, alone were treated with sulfuryl chloride as shown in Table I. The reactions were allowed to proceed for ~24 h at room temperature and, in each case, >95% of the sulfuryl chloride reacted. Analyses were done mainly by means of gas chromatography, although estimates were sometimes made by n.m.r.

ACKNOWLEDGMENTS

We are indebted to Mr. Carl Lindemann for the gas chromatographs and to Mr. William Freeman for assistance with some of the experiments.

THE SYNTHESIS OF POTENTIALLY PHYSIOLOGICALLY ACTIVE β-PHENYLETHYLAMINES. PART III. SOME β-ALKOXY-β-(3,4-DIHYDROXYPHENYL)ETHYLAMINES[1,2]

R. A. HEACOCK,[3] O. HUTZINGER,[4] AND B. D. SCOTT

Adrenaline methyl ether (i.e. β-(3,4-dihydroxyphenyl)-β-methoxyethylmethylamine) has recently been reported to produce considerable stimulation of the central nervous system; however, it was much less active than adrenaline peripherally (1, 2). In view of these interesting pharmacological results a number of compounds analogous to adrenaline methyl ether have been prepared.

The methyl and ethyl ethers of both adrenaline and noradrenaline can be obtained by boiling solutions of the catecholamine hydrochlorides in the appropriate alcohols (3, 4, 5, 6). The highly reactive 3,4-dihydroxybenzyl chloride derivative, obtained by treatment of adrenaline with thionyl chloride, is readily converted to the corresponding alkoxy compound by being heated under reflux with an aliphatic alcohol (7, 8); adrenaline methyl, ethyl, and isopropyl ethers have recently been prepared by this procedure (8). This note reports the application of this general procedure to the preparation of the methyl and ethyl ethers of (i) noradrenaline, (ii) 3,4-dihydroxynorephedrine, and (iii) *N*-isopropylnoradrenaline.

Attempts to recrystallize noradrenaline methyl ether hydrochloride from acetone–ethanol mixtures gave an azomethine derivative (i.e. *N*-isopropylidenenoradrenaline methyl ether hydrochloride), from which *N*-isopropylnoradrenaline methyl ether hydrochloride could be obtained by catalytic hydrogenation.

EXPERIMENTAL

Preparation of β-Alkoxy-β-(3,4-dihydroxyphenyl)ethylamines

General Procedure

The catecholamine (2.5 g; free base) was added to thionyl chloride (25 ml) in a dry nitrogen atmosphere and the product maintained under nitrogen at 50°[5] for 30 min.[6] Undissolved solids were removed by filtration of the reaction mixture and dry benzene (15 ml) added to the clear filtrate. The resulting solution was allowed to stand at 5° for several hours and the β-chloro-β-(3,4-dihydroxyphenyl)ethylamine derivative separated out as a colorless crystalline solid. The crude β-chloro derivative, which was obtained by filtration, was washed with a little dry benzene and immediately transferred to a flask containing methanol or ethanol (30 ml). The resulting solution was boiled under reflux for 20 min in a nitrogen atmosphere. The crude semisolid β-alkoxy derivative was obtained by removal of the solvent *in vacuo* and purified by recrystallization from an ethanol – ethyl acetate mixture.

N-isopropylidenenoradrenaline Methyl Ether Hydrochloride

Attempts to recrystallize noradrenaline methyl ether hydrochloride from an ethanol–acetone mixture gave colorless prisms of *N*-isopropylidenenoradrenaline methyl ether hydrochloride, m.p. 188° (with decomposition), which depressed the melting point of the starting material, ν_{max}^{Nujol} 1 680 cm^{-1} ($\rangle C{=}\overset{+}{N}\langle$, cf. ref. 9).

THE ELECTRON SPIN RESONANCE SPECTRUM OF $\overset{+}{N}(CH_3)_3$ IN γ-IRRADIATED BETAINE[1]

R. DREWS, D. CADENA, JR., AND J. ROWLANDS

INTRODUCTION

Electron spin resonance studies of irradiated single crystals of both inorganic and organic compounds have been shown in many studies (1) to lead to detailed knowledge of both the identity and electronic structure of the radicals formed. The present study of the effects of γ irradiation on a single crystal of betaine $[(CH_3)_3\overset{+}{N}CH_2CO_2H]OH^-$ was motivated by the thought that a detailed study of it might help in the further understanding of the radiation chemistry of choline chloride $[(CH_3)_3\overset{+}{N}CH_2CH_2OH]Cl^-$ (2). Unlike choline chloride, however, in which no trace of the species $\overset{+}{N}(CH_3)_3$ was reported, in betaine at room temperature it was the only species observed. Further studies at liquid nitrogen temperature are required to elucidate the radiation chemistry of the system. The radical $\overset{+}{N}(CH_3)_3$ has already been reported in an irradiated single crystal of tetramethyl ammonium chloride (3). In this lattice the radical was shown to be executing restricted rotation at room temperature. In the betaine lattice the radical is seen to exhibit a nitrogen hyperfine tensor whose principal values more closely approximate the cylindrical symmetry to be expected from a planar radical. A comparison of the anisotropic interaction with that found in similar radicals $N(SO_3^-)_2$ (4) and $H_2\overset{+}{N}SO_3^-$ (5) indicates, however, that the restricted rotation of the radical is not completely quenched.

EXPERIMENTAL

Betaine crystals were grown from saturated aqueous solution. The crystals were hexagonal plates. Crystal axes were found by examination of the crystal under a polarizing microscope. The crystal was shown to be

THE ELECTRON SPIN RESONANCE SPECTRUM OF $\overset{+}{N}(CH_3)_3$ IN γ-IRRADIATED BETAINE[1]

R. Drews, D. Cadena, Jr., and J. Rowlands

INTRODUCTION

Electron spin resonance studies of irradiated single crystals of both inorganic and organic compounds have been shown in many studies (1) to lead to detailed knowledge of both the identity and electronic structure of the radicals formed. The present study of the effects of γ irradiation on a single crystal of betaine $[(CH_3)_3\overset{+}{N}CH_2CO_2H]OH^-$ was motivated by the thought that a detailed study of it might help in the further understanding of the radiation chemistry of choline chloride $[(CH_3)_3\overset{+}{N}CH_2CH_2OH]Cl^-$ (2). Unlike choline chloride, however, in which no trace of the species $\overset{+}{N}(CH_3)_3$ was reported, in betaine at room temperature it was the only species observed. Further studies at liquid nitrogen temperature are required to elucidate the radiation chemistry of the system. The radical $\overset{+}{N}(CH_3)_3$ has already been reported in an irradiated single crystal of tetramethyl ammonium chloride (3). In this lattice the radical was shown to be executing restricted rotation at room temperature. In the betaine lattice the radical is seen to exhibit a nitrogen hyperfine tensor whose principal values more closely approximate the cylindrical symmetry to be expected from a planar radical. A comparison of the anisotropic interaction with that found in similar radicals $N(SO_3^-)_2$ (4) and $H_2\overset{+}{N}SO_3^-$ (5) indicates, however, that the restricted rotation of the radical is not completely quenched.

EXPERIMENTAL

Betaine crystals were grown from saturated aqueous solution. The crystals were hexagonal plates. Crystal axes were found by examination of the crystal under a polarizing microscope. The crystal was shown to be

orthorhombic. The extinction directions were parallel and perpendicular to the long diagonal and perpendicular to the surface of the plate. A sketch of the crystal is reproduced in Fig. 1 which also defines the axis system chosen. The crystal was irradiated at room temperature using a ^{60}Co source. An estimated 5 Mrads of irradiation was delivered to the crystal. The crystal was rotated about each of its three orthogonal axes in turn, and spectra were measured at 10° intervals. Measurements were made at room temperature using a Varian V4500 spectrometer using 100 kc/s modulation. The spectra were calibrated by comparison with a solution of Fremy's salt, $(SO_3)_2NO^{2-}$.

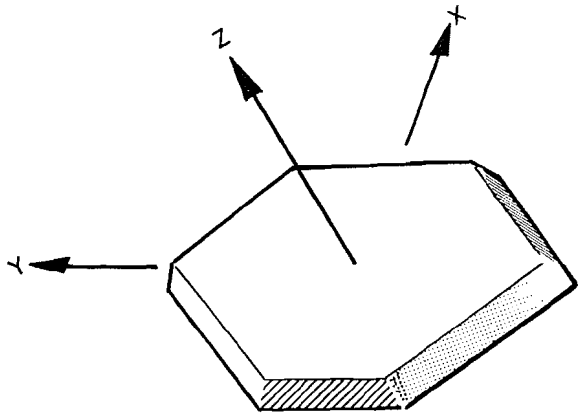

FIG. 1. Sketch of crystal defining crystal axes.

DISCUSSION

The spectra taken along the three crystal axes were consistent with three groups of lines each containing 10 lines of relative intensity 1:9:36:84:126:126:84:36:9:1 required by a radical showing hyperfine interaction to 9 equivalent hydrogens and a nitrogen nucleus. Spectra taken at points between crystal axes were complicated because of the anisotropic nature of the nitrogen coupling, the crystallographic site splitting leading to much overlapping of lines from the two sites. The analysis of these positions was made by assuming the methyl couplings to be isotropic and concentrating on the total spread of the patterns for the two inequivalent sites. The spectrum obtained with the x-axis parallel to the applied field is presented in Fig. 2. Table I gives the direction cosines of principal values of the nitrogen tensor with respect to the crystal axes. The principal values of the nitrogen tensor are all taken to be positive in sign in order to be consistent with values quoted for related species (3, 4, 5), in particular the measured isotropic coupling of the nitrogen nucleus in the radical $\overset{+}{N}H_3$ (6).

TABLE I

Principal values and directions of nitrogen tensor (mc/s with respect to crystal axes)

Nucleus	Tensor (mc/s)²			Principal values (mc/s)	Principal directions
^{14}N	94.0	21.0	41.0	+109	(0.887−0.375−0.267)
	21.0	9.0	5.8	+16	(0.194−0.830−0.523)
	41.0	5.8	28.0	+33	(0.417−0.412−0.809)

In Table II we present the principal values of the nitrogen and methyl couplings. Also included are values obtained for related radicals. From examination of the table it may be seen that the nitrogen principal values in the betaine lattice approximate more closely to

the expected cylindrical symmetry than they do in the corresponding values for the radical in tetramethyl ammonium chloride (3). In fact they are almost identical to the principal values of the nitrogen tensor for the radical $H_2\overset{+}{N}SO_3^-$ in irradiated sulfamic acid. That this radical was exercising restricted rotation was shown by a study of the change in nitrogen coupling with temperature (5). Because of this restricted rotation we are unable to derive a 2p spin population for the unpaired electron (cf. ref. 4). The isotropic nitrogen coupling compares favorably with the value found for $(CH_3)_3\overset{+}{N}$ in tetramethyl ammonium chloride and the radicals $H_2\overset{+}{N}SO_3^-$ (5) and $\overset{+}{N}H_3$ (6). The methyl coupling is, as to be expected, identical within experimental error with that reported for the same radical by Tench (3).

of sulfur atoms. The study included the behavior of the radical concentration (as measured by the signal intensity) upon warming the sample *in situ* (internal warm-up), and by externally warming the samples and repeating the spectra at the lower temperature (external warm-up). The radical species was identified as a polyatomic sulfur chain and a maximum value of its mean chain length was calculated.

RESULTS

The spectrum observed from an irradiated sample of pure COS is shown in Fig. 1. It is characterized by three lines having g-values of 2.042 ± 0.003, 2.028 ± 0.003, and 2.002 ± 0.003. The total spread of the spectrum as measured between the two outer peaks was 65 ± 0.5 G and the central line had a width of 9.2 ± 0.5 G. The intensity of the signal grew steadily with irradiation time until it levelled off after approximately 6 h. The sample turned from colorless to pink when removed from the ultraviolet source for several seconds but this color could be bleached by further irradiation. The radical species were very stable since the intensity did not diminish if the sample was stored for several days at 77 °K.

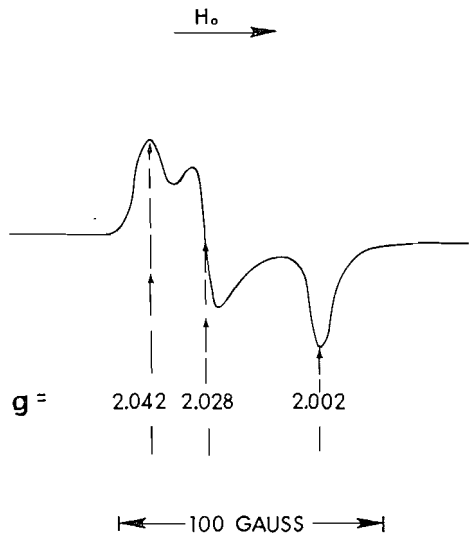

FIG. 1. Electron spin resonance spectrum of ultraviolet photolyzed COS.

Samples containing 1.0 and 0.1 mole % COS in xenon were also irradiated, and gave an identical e.s.r. spectrum to that obtained from pure COS. The intensity increased linearly with time over a period of 12 h, and the same pink aftercolor was observed, although of much weaker intensity. As the sample was warmed the signal intensity began to diminish at −160 °C and continued to do so as the temperature was raised. Because of the low melting points of the substances involved it was not possible to anneal these matrices much above −140 °C, but the e.s.r. spectra recorded after annealing at these temperatures showed the same characteristics as those obtained immediately following irradiation. The samples retained their pink color during warm-up. When each sample was opened to the atmosphere a yellow powder was observed at the bottom of the sample tube.

Further experiments were performed in a cyclodecane matrix (m.p. 10.5 °C) which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

permitted annealing of the samples at higher temperatures. A 0.1 mole % sample of COS in cyclodecane was irradiated at 77 °K and a spectrum was obtained similar to that using a xenon matrix. The intensity of the signal increased linearly with time over a 24 h period but no pink coloration was observed. Although the g-values of the three lines were unchanged, considerable sharpening was evident and the width of the central line decreased to 6.8 ± 0.5 G (see Fig. 2).

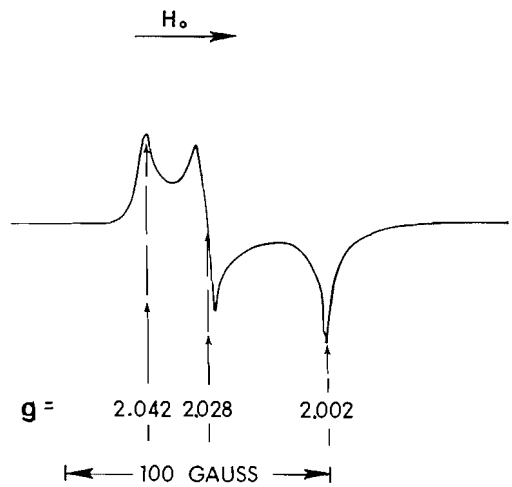

FIG. 2. Electron spin resonance spectrum of ultraviolet photolyzed COS using cyclodecane matrix.

Samples annealed either internally or externally showed similar spectral behavior. The intensity of the signal decreased without change in its basic shape over a warm-up range from −196 °C to −90 °C. The rate of signal decay was most noticeable above −160 °C. This made the recording of spectra of internally warmed samples difficult and it was impossible to make accurate measurements of radical intensity at temperatures above −196 °C. No signal was ever observed after annealing at temperatures higher than −90 °C, nor for values of H_0 corresponding to g-values other than those cited. When the above samples were warmed to room temperature a faint white turbidity was observed.

The numbers of free spins in the different matrices were obtained from the integrated e.s.r. signals by comparison with those from standards of known concentrations.

DISCUSSION

Carbonyl sulfide photolyzes to give carbon monoxide and sulfur atoms (1). The former is diamagnetic and gives no e.s.r. signal while the latter exists in a triplet state and is thus paramagnetic.* It is expected, therefore, that the observed spectrum is due to either sulfur atoms or polyatomic sulfur molecules formed from sulfur atom recombination.

If we assume that the unpaired electrons of a triplet sulfur atom are contained in degenerate 3p orbitals, the Landé g-factor for such a species is calculated at 1.5. The signal observed at $g = 2$ cannot, therefore, be due to free sulfur atoms. A long chain sulfur radical, however, would be expected to have an e.s.r. spectrum centered on a g-value approximately 1% higher than the free spin value (2, 3). The fact that the same characteristic asymmetric spectrum observed for sulfur radicals in the liquid (3) and solid states

**The condensed phase photolysis of* COS *gives* (^3P) *ground state sulfur atoms, while the gas phase photolysis leads to* S(^1D) *atoms.*

(4, 5) has been obtained suggests that the paramagnetic species are polyatomic sulfur chains. The solids formed on sample warm-up support this view.

Annealing characteristics are interesting because they indicate whether chemical or physical changes occur to the spin system as its temperature is raised. For instance, a change in the spectrum of a sample as it was annealed externally would indicate that there was a chemical change taking place in the system. However, if an external warm-up caused no change in the spectrum but an internal warm-up did, it would mean that a physical effect such as the averaging of g-value or hyperfine anisotropy by rotation of the species was taking place. Since the only effect of warming COS samples either inside or outside the cavity was to diminish the intensity of the signal, it is concluded that only one radical species was present and that this decayed at about −90 °C. The failure to observe any sharpening of the spectrum on internal warm-up may be attributed to the fact that the rate of radical decay by bimolecular collisions was rapid compared to the averaging of g-value anisotropy.

Because of the necessity of conserving spin, a sulfur atom chain formed from atoms in a ^3P state must be a biradical and if the chain is sufficiently long there will be no interactions between the unpaired electrons on the terminal sulfur atoms. From a theoretical standpoint the spectrum is consistent with that expected from a polyatomic sulfur biradical. Kneubühl (6) has developed a theory of line shapes for a system in which a single unpaired electron is associated with either axially symmetric or non-axially symmetric molecules. In cases where there is no hyperfine interaction, as would be the case for a polyatomic sulfur chain (^{32}S, $I = 0$), three lines are predicted for non-axially symmetric molecules. This would pertain to a rigid polyatomic sulfur biradical chain since the dihedral sulfur angle in such a chian is 102° (7). On the other hand, if the radical were able to rotate sufficiently rapidly, the anisotropies of the g-factor would be averaged to the isotropic value. It is interesting to note that averaging the three g-values obtained from the spectrum of photolyzed COS gives the same g-factor, within experimental error, as was obtained from the spectrum of liquid sulfur (2).

These results are in broad agreement with those of Buttet and Châtelain (8) although the annealing experiments did not indicate the growth of a second and third radical species at the expense of the first, as were their findings. The fact that lines from different matrices were of different widths, which remained constant during warm-up, suggests that the difference in observations is due to a change in matrix material. Sulfur, a solid at room temperature, would be expected to form a fairly rigid matrix which would allow radicals to recombine in stages. On the other hand, in the photolysis of COS, it is difficult to use a matrix which is solid at room temperature since it must be able to dissolve the substrate. For this reason these matrices do not show the same characteristics of rigidity as sulfur at −90 °C, and allow total annihilation of sulfur biradicals at this temperature.

Although evidence points to the formation of a single radical species, it does not account for the fairly broad central line observed by Radford and Rice (4) and Châtelain and Buttet (5), under certain conditions at 77 °K. It appears that these investigators obtained two radical species and that the broader spectrum was the superposition of a broadened signal from a fairly labile radical, on the asymmetric triplet of the more stable species, which is observed in the photolysis of COS.

From the stoichiometry of the photolytic reaction

$$COS + h\nu \longrightarrow CO + S$$

and from the assumption that the species responsible for the e.s.r. signals are the polysulfur biradicals $\cdot S(S)_nS\cdot$ (2, 3) a maximum value for the mean chain length can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

calculated from the relation

$$(2 \times \text{moles of CO})/(\text{number of free spins}) = \text{mean chain length.}$$

The values found for samples of 100% COS, 0.1 mole % COS in Xe, and 0.1 mole % COS in cyclodecane are given in Table I.

TABLE I

Specimen	Spin intensity in spins/cm of sample measured by: Standard 1	Standard 2	Carbon monoxide content, μmoles	Chain length in terms of sulfur atoms
1. 100% COS	8.5×10^{14}	8.0×10^{14}	2.52	2.5×10^{3}
2. 0.1% COS in Xe	8.5×10^{14}	8.0×10^{14}	1.29	1.3×10^{3}
3. 0.1% COS in cyclodecane	19×10^{14}	17×10^{14}	1.14	0.5×10^{3}

Length of sample is assumed to be 1.5 cm for samples 1 and 2, and was measured as 1.5 for sample 3.

Table I shows a decrease in biradical chain length as the matrix is changed from pure COS to saturated hydrocarbon. Although these figures are not completely consistent they suggest that the radical species is a polymer of length about 1 000 units. The accuracy of the intensity measurements was checked and one of the most serious sources of error was found to occur in measuring the length of a sample in a given tube. It was estimated that this error could be as large as 50% in the cases of COS and COS–xenon samples. An upper limit was taken in these cases, so the average chain length could be as high as 4×10^3.

For the cyclodecane sample the measurement of sample length could be made much more accurately; the main source of error in this calculation was in measuring graphical first moments. Since these were checked against two standards for a number of spectral displays, this measurement of spin intensity is considered to have an error of ±10%.

It is possible to explain the variation in the values of chain length obtained if it is assumed that neither the COS nor the xenon matrices were sufficiently rigid to trap completely the products of photolysis. Although these matrices may be more rigid than that of cyclodecane once photolysis is complete, it is likely that the heat of reaction during irradiation will melt them sufficiently to allow some recombination of radicals. This loss of free spins would cause an apparent increase in the mean chain length. This hypothesis is supported by the formation of the pink color when such samples are removed from the ultraviolet source for a few seconds. The color brings to mind the experiment of Radford and Rice (4) in which sulfur was γ-irradiated without the formation of free radicals.

It is concluded that the stable paramagnetic species formed in the photolysis of COS is a biradical sulfur chain whose average length is no more than several hundred atoms. It is likely that either S atoms or S_2 biradicals are the species responsible for propagation, since it is improbable that entities of higher molecular weight could permeate the matrix.

If the steady-state concentration of these species were high enough, the intensity of the e.s.r. signal would be expected to increase after irradiation had ceased. As no such increase was found, the steady-state concentration of the propagating species was probably too low to permit their detection.

EXPERIMENTAL

Preparation of Samples

Samples were prepared by vacuum distillation of the various constituents into a quartz sample tube attached by a graded seal to a pyrex break seal for product analysis. Each was irradiated at 77 °K in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

quartz Dewar with either a Hanovia medium pressure mercury lamp emitting discontinuously between 2 200 Å and 2 600 Å or an Osram cadmium lamp (λ = 2 288 Å) 3 to 5 cms from the specimen. After irradiation the samples were transferred manually to the spectrometer.

Spectrometer Details

Spectra were recorded as the first derivative of the resonance absorption using a Varian EPR spectrometer, type 4502, fitted with the V-4532 dual cavity and operating at a nominal frequency of 9.5 Gc/s. Normally samples under investigation were kept at 77 °K in the cavity by an insert Dewar filled with liquid nitrogen. For external annealing a Varian type V-4547 variable temperature accessory was set up outside the magnet gap, and specimens were allowed to equilibrate at the desired temperature for about 5 min. When internal annealing was used, the Dewar portion of the variable temperature accessory was placed inside the cavity and the same procedure adopted as for external annealing.

The *g*-values were measured by reference to the parabenzosemiquinone spectrum, which has a central line of $g = 2.0057$ and a spacing of 2.33 G between adjacent hyperfine components (9).

Calibration of Standard

The usual method employs the use of a dual cavity where the standard is placed in one position modulated at 400 c/s, while the unknown is placed in a second position and modulated at 100 kc/s. After the spectra from both samples are recorded under certain gain conditions, the positions of the sample and standard are reversed and the spectra rerecorded using the same modulation amplitudes as before, but the amplifier gains adjusted so that good graphical presentation is still obtained. Comparison of the integrated areas under the absorption curves then determines the number of free spins in the unknown.

A solution of 1,1-diphenyl 2-picryl hydrazyl (DPPH) in benzene was prepared, and the quantity of DPPH dissolved calculated from spectro-photometric data (10). A quantity of solid DPPH was then mixed intimately with powdered potassium chloride and a portion introduced into a sample tube (standard 1). These two samples were used to determine the number of free spins in 'standard 1' using the above procedure.

Although this method was satisfactory in this instance there was sufficient cross talk between the two channels to make the calibration of photolyzed COS samples very difficult to assess quantitatively. Thus an alternative procedure was adopted whereby the sample and standard were run in the same channel consecutively. Intensity measurements on Varian sample 904450-01 (standard 2) containing 3×10^{15} spins per centimeter of length, against standard solutions of DPPH in benzene, showed that this method was at least as accurate as the one discussed previously. By this means 'standard 1' was found to contain 1.8×10^{14} spins per centimeter of length.

Materials

The xenon used was assayed reagent grade, from Airco, and was used without further purification.

The carbonyl sulfide was Matheson reagent grade, which was washed four times with saturated sodium hydroxide, and dried over Drierite. It was then vacuum distilled using *n*-pentane and methanol slushes.

The cyclodecane was a special sample supplied by Columbian Carbon. It was purified by three washings with equal volumes of 1/1 H_2SO_4/HNO_3 and water, and then with concentrated H_2SO_4 until the acid layer remained colorless. After passage through a 20 ft SE30 silicone–rubber gas chromatographic column, it was washed once more with concentrated sulfuric acid, and distilled in a greaseless system at 10 Torr.

THERMODYNAMIC EXCESS FUNCTIONS IN THE SYSTEMS ACETIC ACID – WATER AND ACETIC ACID – CHLOROFORM

J. M. T. M. GIESKES[1]

Campbell and Gieskes (1) recently studied the heats of mixing of the system acetic acid – chloroform – water, and its contiguous binary systems. It was suggested by Scott (2) that these data be combined with the earlier results of Campbell, Kartzmark, and Gieskes (3) on the isothermal vapor–liquid equilibria of this system. In the earlier paper it was shown that the vapor–liquid equilibrium data are in good agreement with the Gibbs–Duhem conditions when a dimerization equilibrium with a single equilibrium constant is taken into account. In the later study of the heats of mixing and the volumes of mixing, the functions $H^E(x)$ and $V^E(x)$ were based on an ideal solution of acetic acid monomers as the most convenient reference state, even though it was recognized that dimerization occurs in both the liquid and vapor phases.

In order to relate the excess free energy of mixing as calculated from the liquid–vapor equilibria to the heats of mixing, it is, of course, necessary to adopt the same reference state. In this case the excess free energy of mixing is defined by the following formulae:

$$\mu_{H_2O}{}^E = RT \ln \frac{P_{H_2O}}{x_{H_2O} P_{H_2O}{}^0}$$

$$\mu_{CHCl_3}{}^E = RT \ln \frac{P_{CHCl_3}}{x_{CHCl_3} P_{CHCl_3}{}^0}$$

$$\mu_{HAc}{}^E = RT \ln \frac{P_1}{x_{HAc} P_1{}^0}$$

and

$$G^E = x_{H_2O}\mu_{H_2O}{}^E + x_{CHCl_3}\mu_{CHCl_3}{}^E + x_{HAc}\mu_{HAc}{}^E$$

where $p_1{}^0$ is the partial pressure of acetic acid monomers above pure acetic acid liquid, and the mole fractions are the formal mole fractions based upon monomeric acetic acid. Corrections for deviations of the vapor from "ideal" behavior will never be more than a few calories, because the second virial coefficients will only be of the order 1 000 cm^3 $mole^{-1}$ at these low pressures. Consequently G^E can be estimated to a very good approximation from the above formulae by postulating that the true species, i.e. water, chloroform, dimeric acetic acid, and monomeric acetic acid behave as an ideal gas mixture.

The System Acetic Acid – Water at 25 °C

From the data of Campbell *et al.* (3) the values of the G^E function were calculated, and plotted. From the smoothed curve through these values a Redlich–Kister (4) equation was calculated having the form

$$G^E = x_1x_2[768 + 472(x_1 - x_2) - 158(x_1 - x_2)^2 - 1060(x_1 - x_2)^3]$$

where x_1 = mole fraction acetic acid and x_2 = mole fraction water.

Campbell and Gieskes (1) reported the heat of mixing at 25 °C to be represented by the equation

$$H^E = x_1x_2[296 + 166(x_1 - x_2) + 19(x_1 - x_2)^2 + 321(x_1 - x_2)^3].$$

The excess entropy of mixing can then be calculated from the relation

$$TS^E = H^E - G^E$$

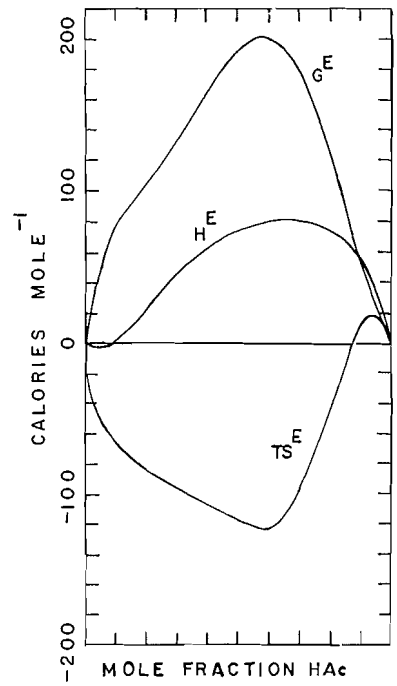

FIG. 1. Thermodynamic excess functions in the system acetic acid – water at 25 °C.

In Fig. 1 the curves for these functions are plotted. It can be seen that the shape of all three thermodynamic functions is very irregular. In view of the complicated interactions (5, 6) which may occur in this system this is not surprising. Of interest is the behavior of the excess entropy of mixing. At high concentrations of acetic acid a positive value occurs. This may well be due to the break up of acetic acid ring dimers as suggested by Cucurezeanu (5) and by Fénéant-Eymard (6). Campbell *et al.* (3) measured the excess volume of mixing for this system, and found it to be negative and quite symmetrical. The Redlich–Kister (4) formula was found to be

$$V^E = x_1x_2[4.58 - 1.25(x_1 - x_2)^2]$$

where V^E is in ml mole^{-1}.

The System Acetic Acid – Chloroform at 25 °C

The excess free energy of mixing was calculated, and the smoothed values fitted the equation

$$G^E = x_1x_2[568 - 291(x_1 - x_2) + 301(x_1 - x_2)^2 + 380(x_1 - x_2)^3]$$

where x_1 = mole fraction acetic acid and x_2 = mole fraction chloroform. Campbell and Gieskes (1) determined the heats of mixing as

$$H^E = x_1x_2[-574 - 71(x_1 - x_2) + 78(x_1 - x_2)^2]$$

and therefore also the excess entropy of mixing can be calculated.

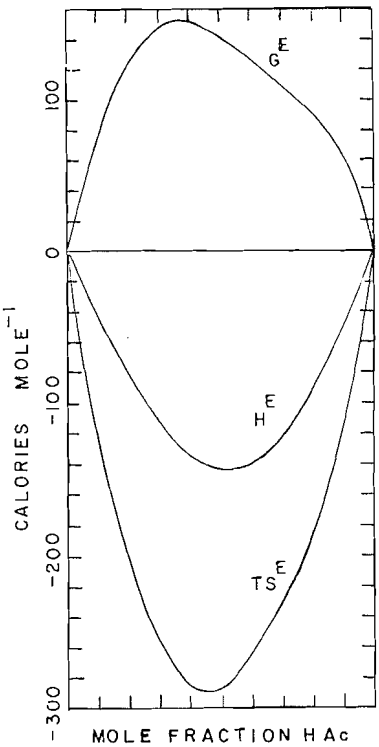

FIG. 2. Thermodynamic excess functions in the system acetic acid – chloroform at 25 °C.

In Fig. 2 the excess functions of mixing are represented. The curves have a fairly regular shape. The excess volume of mixing was determined by Campbell *et al.* (3), and was found to be positive over the entire region of concentration. A Redlich–Kister (4) expression was calculated for this function.

$$V^E = x_1x_2[2.200 + 0.521(x_1 - x_2) - 0.18(x_1 - x_2)^2]$$

where V^E is in ml mole^{-1}.

Haase (7) remarks that in general V^E and S^E have the same sign. This, however, is clearly not the case in the system acetic acid – chloroform. Scott *et al.* (8) found a similar phenomenon in the system $C_7F_{15}H$–acetone. The positive value of V^E and the negative value of S^E seems to the author yet another indication that in this system the antiparallel dipole association of acetic acid ring dimers with chloroform molecules is predominant. This problem was discussed extensively by Campbell and Gieskes (1, 9).

EFFECT OF PRESSURE AND TEMPERATURE ON THE RATE OF THE ACID-CATALYZED HYDRATION OF ETHYLENE[1]

B. T. BALIGA AND E. WHALLEY

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received April 9, 1965

ABSTRACT

The rate of hydration of ethylene in dilute aqueous perchloric acid has been measured in the range 170–190 °C at 100 bars and 100 to 3 000 bars at 180 °C. The energy, entropy, and volume of activation are 33.3 ± ~1 kcal mole^{-1}, −5.7 ± ~2.5 cal deg^{-1} mole^{-1}, and −15.5 ± ~1.5 cm^3 mole^{-1} respectively. The volume of activation shows that at least one molecule of water is strongly bound in the transition state.

The acid-catalyzed hydration of olefins has been much studied in recent years, particularly of relatively highly substituted olefins (see ref. 1 for references). Little has been reported on the hydration of the parent compound ethylene, probably largely because its hydration rate is fast enough for convenient study in dilute aqueous acids only at temperatures above 150 °C. This is well above the boiling point of aqueous acids, and consequently the measurements can be done only under pressure.

The hydration of ethylene is a reaction of considerable importance both theoretically, as the simplest olefin hydration, and technically, as a manufacturing method for both ethanol and (by the reverse reaction) ethylene. The hydration of propylene and isobutylene has recently been studied in this laboratory (1), and the same techniques have now been applied to ethylene. The volume of activation for propylene and isobutylene proved of considerable value in the determination of the mechanism, and consequently the effect of pressure as well as temperature has been studied.

EXPERIMENTAL

Materials

Ethylene was Phillips Petroleum Co. research grade, *n*-heptane was Anachemia Chemicals Ltd. pure grade, and other chemicals were reagent grade.

Analysis of Ethanol

The hydration of ethylene was followed by estimating the alcohol produced. The method of analysis was reported earlier (1).

Kinetic Measurements

The thermostat bath was an aluminum block 14 in. long and 10 in. in diameter, with a hole of 4 in. in diameter and 12 in. long bored centrally to hold the reaction vessel. The outer surface of the block was covered with layers of asbestos paper and wound evenly with two coils of resistance wire, one to serve as the main heater, and one to serve as the intermittent heater. The block was insulated on all sides by transite or vermiculite. The temperature of the block was measured by a platinum resistance thermometer inserted in a hole in the block. It was controlled by a second platinum resistance thermometer connected to a Mueller

[1]*N.R.C. No. 8476.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

bridge whose galvanometer operated a photo-relay and switched the intermittent heater, which usually delivered 15 to 20 W. The temperature of the block was controlled to ±0.02 deg.

The catalyst used for the hydration was perchloric acid. The reaction solution was made by bubbling ethylene through the acid solution at 0 °C until it was nearly saturated. To reduce the loss of ethylene while assembling the vessel and placing it in the thermostat, the same procedure as used for propylene (1) was followed. To compensate for the fall in temperature when the pressure vessel was put into the thermostat block, the block was previously heated to temperatures higher than was desired. Under these conditions, about 60 min was sufficient to reach temperature equilibrium, and the first sample was taken at least 90 min after immersing the vessel. About seven samples were taken during each run and three samples were taken for the infinity reading, which was taken after at least 10 half-lives.

The pressure techniques were the same as those used previously (2, 3). A small cylindrical stainless-steel pressure vessel of about 6 cm^3 capacity was interposed between the valve F and the head (see Fig. 1 of ref. 3). This was to ensure that the oil added to the vessel when a sample was taken was at the same temperature as the vessel.

It was verified by the following experiment that the hydration of ethylene was essentially unidirectional and that no significant amount of olefin was present at equilibrium. An acid solution (0.7 M in perchloric acid) of ethanol of concentration such as to give an optical density about three times that of the infinity reading ($\sim$ 0.26) of the kinetic runs was kept at 180.00 °C and 100 bars for 24 h, which was more than the time taken to complete a run in the hydration experiment. There was no change in concentration of the alcohol within the reproducibility (± ~0.3%) of the measurements. At higher pressures and at this temperature the amount of olefin present would be expected to be even smaller because alcohols dehydrate with an increase of volume.

RESULTS

The hydration of ethylene was first-order in ethylene, and the first-order rate constants k_1 were obtained in the usual way (1). The accuracy of the rate constants was about 3%. The second-order rate constants k_a were obtained by dividing the first-order constants by the concentration of hydrogen-ion at the temperature and pressure of the experiment, assuming the solution compressed as water (4, 5). The results are given in Table I. The runs at 180.00 °C and 100 bars in 0.3145 and 0.6250 M perchloric acid prove that the reaction is first-order in perchloric acid. The effect of temperature on the reaction was also measured in the range 170–190 °C and at a constant pressure of 100 bars.

TABLE I

Rate constants for the acid-catalyzed hydration of ethylene in water

Temp., °C	p/bar	c_{HClO_4}/M^*	$10^6\ k_a$/l mole^{-1} s^{-1}
170.00	100	0.6279	52.4
180.00	100	0.3145	120
		0.6250	119
	400	0.6365	134
	1 000	0.6596	162
	2 000	0.3484	209
	3 000	0.3638	233
190.00	100	0.3071	265

*c_{HClO_4} is the concentration of perchloric acid at the temperature and pressure of the experiment.

The volume of activation $\Delta V^{\neq}$ at zero pressure was obtained graphically by plotting mean volumes of activation $\Delta V_{mean}^{\neq}$ calculated between any two pressures p_1 and p_2 from the formula

$$\ln \frac{k_a(p_2)}{k_a(p_1)} = \frac{-\Delta V_{mean}^{\neq}(p_2 - p_1)}{RT}$$

against $(p_1 + p_2)/2$, where $k_a(p_1)$ and $k_a(p_2)$ are the rate constants at pressures p_1 and p_2, and extrapolating to zero pressure. A graph of this plot for the acid-catalyzed hydration of ethylene is shown in Fig. 1. The advantages of using this method to evaluate $\Delta V^{\neq}$

423612

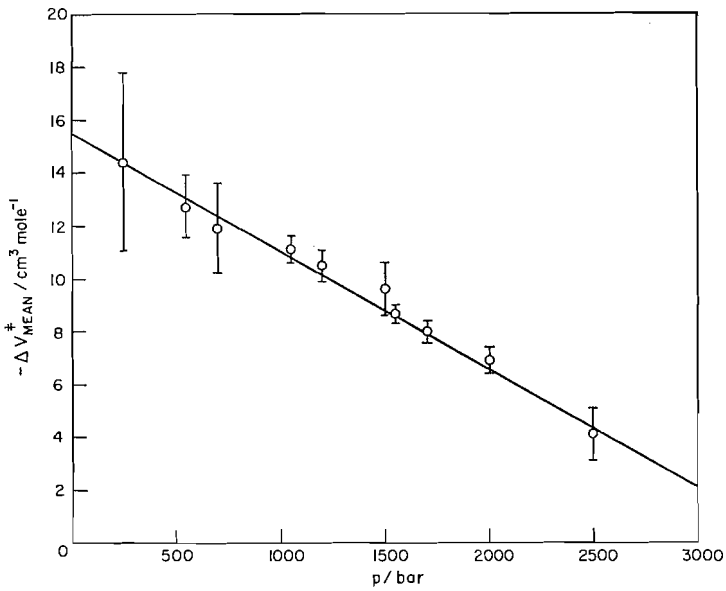

FIG. 1. Effect of pressure on volume of activation for the acid-catalyzed hydration of ethylene in water at 180 °C.

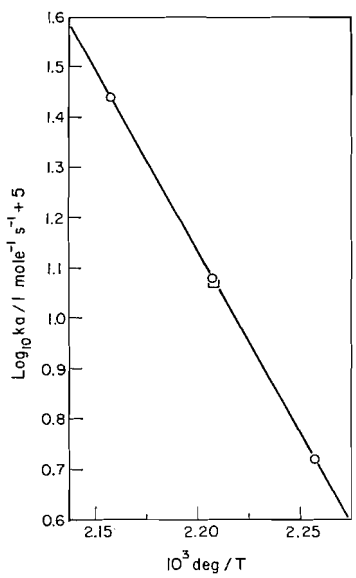

FIG. 2. Effect of temperature on the rate of the acid-catalyzed hydration of ethylene in water at 100 bars.

have been discussed elsewhere (6). The volume of activation $\Delta V^{\ddagger}$ for the acid-catalyzed hydration of ethylene is $-15.5 \pm \sim 1.5$ cm^3 mole^{-1} at 180.00 °C.

The effect of temperature on the reaction is shown by an Arrhenius plot in Fig. 2. The parameters of the Arrhenius equation obtained from this plot are,

$$E_A = 33.3 \pm \sim 1.0 \text{ kcal mole}^{-1},$$

$$\log_{10} A/\text{l mole}^{-1}\text{ s}^{-1} = 12.2,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and the entropy of activation $\Delta S^{\ddagger} = R \ln (A/1 \text{ mole}^{-1})\ (h/ekT)$ is $-5.7 \pm \sim 2.5$ cal deg^{-1} mole^{-1}. The difference between these values and those for zero pressure or 1 bar will be quite inappreciable.

DISCUSSION

The various activation parameters for the acid-catalyzed hydration of ethylene, propylene, and isobutylene are summarized in Table II.

TABLE II

Activation parameters for the acid-catalyzed hydration of olefins in water

Olefin	Ethylene	Propylene (1)	Isobutylene
p/b	100	100	1
Temperature range for $\Delta H_p^{\ddagger}$ and $\Delta S_p^{\ddagger}$, °C	170–190	90–110	25–50
$\Delta H_p^{\ddagger}$/kcal mole^{-1}	32.4±∼1.0	26.4±∼1.0	21.1±∼0.2 (7)
$\Delta S_p^{\ddagger}$/cal deg^{-1} mole^{-1}	−5.7±∼2.5	−5.4±∼2.5	−7.7±∼0.7 (7)
Temperature for $\Delta V^{\ddagger}$, °C	180	100	35
$\Delta V^{\ddagger}$/cm^3 mole^{-1}	−15.5±∼1.5	−9.6±∼1.0	−11.5±∼1.0 (1)

The volume of activation for the acid-catalyzed hydration of ethylene is $-15.5 \pm \sim 1.5$ cm^3 mole^{-1} at 180 °C. Clearly, a loss of volume of this magnitude, which is almost the volume of a water molecule, indicates that the transition state for the hydration of ethylene contains at least one firmly bound molecule of water, and so can be represented as $[\text{ethylene}.H^+.H_2O]^{\ddagger}$. As in the case of propylene and isobutylene, this rules out a mechanism in which a π-protonated ethylene isomerizes unimolecularly to a carbonium ion. The entropy of activation for the hydration of ethylene is $-5.7 \pm \sim 2.5$ cal deg^{-1} mole^{-1}. This is similar to the entropies of activation for the hydration of propylene and isobutylene (see Table II) and confirms the conclusion derived from the volume of activation. It is not in our opinion possible as yet to specify the structure of the transition state in more detail; there are several possibilities which have been discussed in ref. 1 in relation to the hydration of propylene and isobutylene.

The enthalpies of activation show a constant decrease of about 5 kcal mole^{-1} in the series ethylene, propylene, and isobutylene. This is no doubt due largely to the fact that the carbonium ion becomes more stable in the series ethyl, isopropyl, *t*-butyl, and so the olefin can more easily accept the partial positive charge in the transition state.

The volumes of activation for the hydration of propylene and isobutylene are nearly the same, but that of ethylene is nearly 50% more negative. This difference is likely caused at least partly by the higher temperature used for ethylene. The interaction of ethylene with the solvent is small and so its thermal vibrations have relatively large amplitude. They are therefore probably relatively anharmonic, and so cause a large thermal expansivity. The partial expansivity of ethylene is, therefore, probably greater than that of water, of H_3O^+, and of the transition state. This tends to make the volume of activation more negative at higher temperatures.

SURFACE EFFECTS IN THE UNINHIBITED AND THE INHIBITED PYROLYSES OF ISOMERIC HEXANES

PART V. 2,2-DIMETHYL BUTANE (NEOHEXANE)

J. CHRYSOCHOOS[1] AND W. A. BRYCE[2]
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received March 24, 1965

ABSTRACT

The rate of pyrolysis of neohexane decreases slightly with increasing S/V ratio in the pressure range of 15–100 mm at 510–530 °C. The yields of CH_4, C_2H_6, and C_3H_6 increase with increasing hydrocarbon pressure while the yields of i-C_4H_8 and H_2, which increase with increasing hydrocarbon pressure, tend to level off at higher pressures. The rest of the products are pressure independent. The nitric oxide required for maximum inhibition is 12–14 mm for hydrocarbon pressures in the range of 50–120 mm and shifts to slightly higher values for higher S/V ratios. Nitric oxide affects the product distribution slightly. The yields of CH_4 and C_2H_4 increase while the yields of C_2H_6 and 2-methyl butene-2 decrease with increasing NO pressure. Surface-to-volume (S/V) ratio has no effect on the product distribution in the inhibited pyrolysis of neohexane, indicating the role of the inhibitor to be limited to the gas phase for this isomer. The analytical balance does become less complete with increasing NO pressure because of such reactions as

$$R + NO \rightarrow RNO \rightarrow \text{isomerization} \rightarrow \text{further decomposition.}$$

INTRODUCTION

In spite of the great deal of work on the inhibition in the thermal decomposition of gaseous organic compounds the nature of the phenomenon is not yet fully understood. Nitric oxide does reduce the rate of decomposition of many organic compounds to a limiting rate which, although small, is definitely not zero. In earlier attempts to solve this problem, it was contended that the fully inhibited reaction follows a molecular mechanism, with the chain reactions suppressed completely by NO through capture of the chain-propagating radical (1–3). However, some experimental results seem to be imcompatible with the postulate of a molecular mechanism. Hydrogen–deuterium exchange was found to take place in both the uninhibited and the fully inhibited decomposition, indicating that chains exist in both cases (4–6). Recently many attempts have been made to deal with the problem quantitatively. In one of them the inhibitor has been associated with both initiation and termination processes (7–9). A summary of the recent approaches to the phenomenon of inhibition have been given earlier (10–12).

As a part of the comparative study of the decomposition of the isomeric hexanes an investigation has been made of the effect of variation in S/V ratio on both reaction rates and product distribution. Surface effects have been found in the thermal decomposition of isopentane (13).

EXPERIMENTAL

The neohexane used was research grade (99.90%) obtained from the Phillips Petroleum Co., Bartlesville, Okla. The nitric oxide, supplied by the Matheson Co., East Rutherford, N.J., was 99% pure. The methods of purification of the materials and the apparatus used have been described earlier (10, 11).

RESULTS

Initial rates were obtained manometrically throughout the whole investigation, after establishing a 0.95 to 1 correspondence between the initial rates so obtained and those found from the rate of disappearance of neohexane by direct analysis. The initial rates were obtained by taking the slopes of the pressure–time curves at $t = 0$. Fairly complete analytical mass balances were obtained by conventional gas chromatographic techniques supplemented by infrared analyses. However, the mass balance becomes less complete with increasing NO pressure in the inhibited decomposition. Two typical sets of results for the uninhibited and the inhibited decomposition are given in Tables I and II.

TABLE I

Analytical results (mole %) for the decomposition of neohexane (T = 510 °C, $\Delta P/P_i$ = 0.20)

	P_i (mm)		
Product	180	143	120
CH_4	7.2	6.2	6.5
C_2H_6	3.3	2.3	2.5
C_2H_4	3.5	3.0	4.1
C_3H_6	1.1	0.8	0.2
i-C_4H_8	7.9	8.0	8.0
2-Methyl butene-2	3.7	3.2	3.2
H_2	5.0	5.0	4.5
Neohexane	67.0	71.0	70.0
Total	98.7	99.5	99.0

TABLE II

Analytical results (mole %) for various NO pressures in the inhibited decomposition of neohexane (T = 510 °C, $\Delta P/P_i$ = 0.30, P_i = 100 mm)

	NO (mm)			
Product	0	3	10	12
CH_4	10.6	10.6	11.8	12.5
C_2H_6	3.2	3.0	2.6	2.4
C_2H_4	6.5	6.5	6.8	7.5
C_3H_6	0.6	0.6	0.8	0.8
i-C_4H_8	8.0	8.1	8.7	9.0
2-Methyl butene-2	3.5	3.5	3.2	3.0
H_2	4.4	4.4	4.0	3.9
Neohexane	63.0	63.0	60.0	59.0
Total	99.8	99.7	97.9	98.1

The effect of an 11-fold increase in S/V ratio on the rates was investigated for a hydrocarbon pressure range of 15 to 120 mm. The decomposition rates are lower for the packed vessel at lower pressures and become identical for pressures around 110 mm (Fig. 1). However, the reduction in rate due to the packing is less marked than that of the less branched isomeric hexanes (10).

Most of the decomposition products are pressure dependent. Ethane displays a significant increase with increasing neohexane pressure while CH_4 and C_3H_6 are pressure dependent to a less extent. The yields of i-C_4H_8 and H_2 increase with increasing neohexane pressure and tend to level off at higher pressures (Fig. 2).

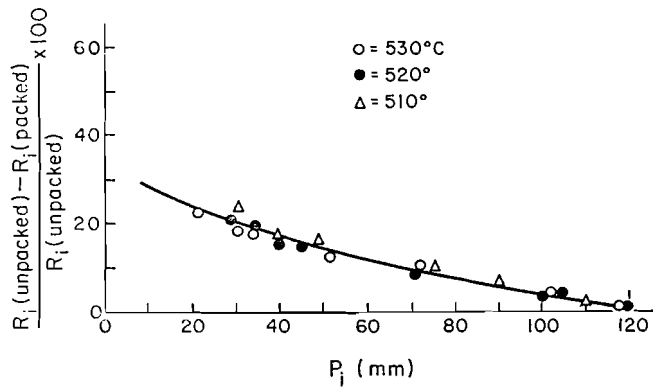

FIG. 1. Percentage reduction in rate due to packing for various initial pressures of neohexane.

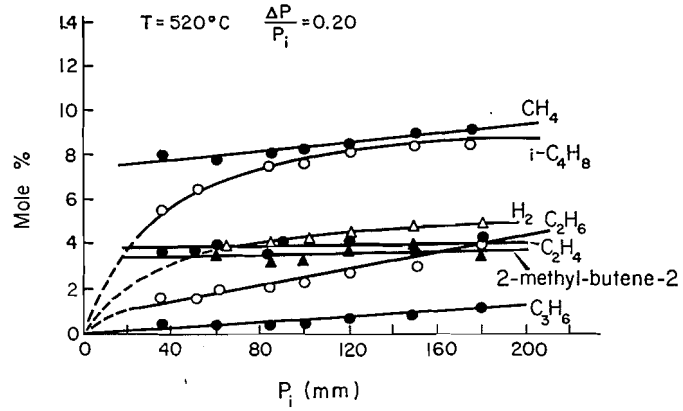

FIG. 2. Variation of product distribution with initial pressure of neohexane.

Nitric oxide reduces the rate of decomposition by about 55%. The reduction in rate is more gradual in comparison to the less branched isomeric hexanes (10). The NO pressure required for maximum inhibition is the same, namely 12–14 mm, for hydrocarbon pressures ranging from 50 to 120 mm (Fig. 3*a*). An increase in S/V ratio from 1 to 5 and 10 cm^{-1} shifts the NO pressure required for maximum inhibition to slightly higher values and reduces the limiting rate (Fig. 3*b*). Nitric oxide does not have a large effect on the product distribution. Methane and C_2H_4 increase slightly while C_2H_6 and 2-methyl butene-2 decrease slightly with increasing NO pressure. The other products appear to be independent of the NO pressure, but there is enough scatter in the results to mask any small changes (Fig. 4). The yield of H_2 is not plotted in Fig. 4 because such a curve would be between the curves for 2-methyl butene-2 and C_2H_6 causing inevitable overlap between them.

An increase in S/V ratio from 1 to 5 and 10 cm^{-1} has no effect on the product distribution. The surface independence of some of the products is illustrated below. The effect of S/V ratio on the C_2H_4/C_2H_6 ratio is shown in Fig. 5. The ratio increases steadily with increasing NO pressure but no effect of S/V ratio on the C_2H_4/C_2H_6 ratio is observed. The independence of the yield of C_3H_6 on both the NO pressure and the S/V ratio is shown in Fig. 6.

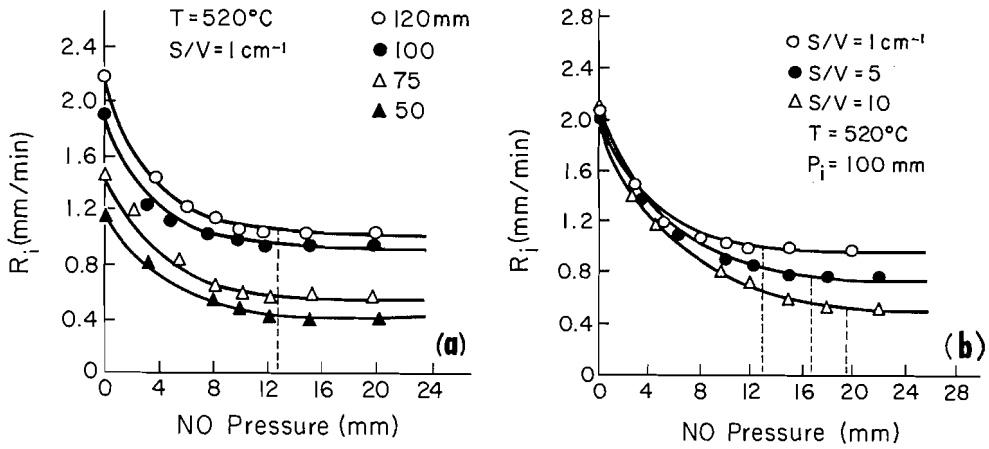

FIG. 6. Variation of the C_3H_6 yield with NO pressure and S/V ratios in the inhibited pyrolysis of neohexane.

TABLE III

Variation of the neohexane/NO ratio with initial pressure of the mixture after adsorption on quartz wool ($(\text{neohexane/NO})_{init} = 3.34$, $T = 310$ °C, contact time = 2 min)

Initial pressure of the mixture (mm)	$(\text{Neohexane/NO})_{final}$
17	2.77
39	3.15
55	3.00
70	3.00
100	3.30

Nitric oxide appears to be less adsorbed on the quartz wool than neohexane. Some results from the relative adsorption of NO and neohexane on quartz wool are given in Table III. Mixtures of neohexane and NO were prepared and after complete mixing their composition was measured by gas chromatography. Change in the composition of the mixture, after adsorption, is observed at low pressures of the mixture. At higher pressure of the mixture no appreciable change is observed in its composition. Certainly results at 310 °C are not necessarily comparable with results at 510 °C. However, it was impossible to obtain results at 510 °C because at temperatures about 400 °C the hydrocarbon was found to decompose rapidly in spite of the small contact time and the amount of NO present. It seems that the large surface of the quartz wool has a significant catalytic effect on the thermal decomposition of neohexane.

DISCUSSION

The products of the uninhibited decomposition can be accounted for by the following mechanism. Addition of more reactions which can be written simply adds to the complexity.

Initiation reactions:

[1*a*] $$(CH_3)_3CCH_2CH_3 \rightarrow CH_3 + (CH_3)_3CCH_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[1*b*] $\rightarrow CH_3 + (CH_3)_2CCH_2CH_3$

[1*c*] $\rightarrow C_2H_5 + (CH_3)_3C.$

Propagation reactions:

[2*a*] $CH_3 + (CH_3)_3CCH_2CH_3 \rightarrow CH_4 + (CH_3)_3CCH_2CH_2$

[2*b*] $\rightarrow CH_4 + (CH_3)_2C(CH_2)CH_2CH_3$

[2*c*] $\rightarrow CH_4 + (CH_3)_3CCHCH_3$

[3*a–c*] $C_2H_5 + (CH_3)_3CCH_2CH_3 \rightarrow C_2H_6 +$ neohexyl radicals

[4*a–c*] $H + (CH_3)_3CCH_2CH_3 \rightarrow H_2 +$ neohexyl radicals

[5*a–c*] neohexyl radicals $\rightarrow CH_3 + (CH_3)_2C{=}CHCH_3$

[6*a–c*] $\rightarrow C_2H_5 + (CH_3)_2C{=}CH_2$

[7*a–c*] $\rightarrow (CH_3)_3C + C_2H_4$

[8] $(CH_3)_3CCH_2 \rightarrow CH_3 + (CH_3)_2C{=}CH_2$

[9] $(CH_3)_2CCH_2CH_3 \rightarrow CH_3 + (CH_3)_2C{=}CH_2$

[10] $\rightarrow C_2H_6 + C_3H_6$

[11] $(CH_3)_3C \rightarrow H + (CH_3)_2C{=}CH_2.$

Recombination reaction:

[12] $CH_3 + CH_3 \rightarrow C_2H_6.$

Propylene appears in very small amount. Therefore reaction [10] participates to a slight extent. Since reaction [10] is directly related to the initiation the yield of C_3H_6 compared to the yields of CH_4, C_2H_6, and H_2 which are formed through the propagation processes, indicates that the chain is not very large. The yield of H_2 is significant. Its main source is assumed to be the $(CH_3)_3C$ radical. Part of this radical is formed through reaction [1*c*] and part through reactions [7*a–c*].

Methane is the major product. This may indicate that reaction [5*a*] was a major mode of decomposition of neohexyl radical. However, the yield of 2-methyl butene-2 is smaller than the yield of CH_4. This might indicate that 2-methyl butene-2 undergoes further decomposition when accumulated in significant amounts.

The initiation processes can take place in both phases (10). The net reduction in rate due to packing is less marked than that for the less branched isomeric hexanes (10). From the relative adsorption of NO and the isomeric hexanes on quartz wool it appears that neohexane is adsorbed more than the less branched isomers. Therefore, a more pronounced effect of the surface on the initiation is expected. The termination involves similar processes in both neohexane and the less branched isomeric hexanes. Therefore, the net reduction in rate should be less marked in neohexane because of the expression

$$\text{net reduction} = \text{effect on initiation} - \text{effect on termination.}$$

Surface-to-volume ratio has no effect on the propagation processes (10, 11).

Nitric oxide reduces the rate up to 55%. However, this reduction is more gradual than it was in the less isomeric hexanes (10). Nitric oxide cannot expell neohexane molecules from the active sites of the wall efficiently and therefore it is expected that NO will suppress the heterogeneous initiation slightly. Even in the fully inhibited decomposition the heterogeneous initiation will participate. This is supported from the observation that the limiting rate is fairly significant in magnitude. Since the heterogeneous function of the inhibitor is more limited in this isomer it is expected that the inhibition phenomenon can be attributed more to homogeneous than heterogeneous processes in this particular case.

For personal use only.

The effect of NO in the gas phase can be revealed through its effect on the product distribution. Simultaneous increase in the yield of C_2H_4 and decrease in the yield of C_2H_6 with increasing NO pressure may be attributed to the competitive set of reactions

[13] $$C_2H_5 + NO \rightarrow C_2H_4 + HNO$$

[3*a*–*c*] $$C_2H_5 + RH \rightarrow C_2H_6 + R$$

which has been discussed earlier (10). The HNO, whose existence has been verified by flash photolysis (14), may participate in such reactions as

[15] $$CH_3 + HNO \rightarrow CH_4 + NO$$

accounting for the slight increase in the yield of CH_4 with increasing NO pressure. Reaction [15] is highly exothermic by about 52 kcal, based on the values

$$D(CH_3—H) = 101 \text{ kcal/mole (15)}$$

and

$$D(H—NO) = 48.6 \text{ kcal/mole (16, 17).}$$

The yield of 2-methyl butene-2 decreases with increasing NO pressure. This decrease can be accounted for as follows: (i) Nitric oxide can abstract hydrogen from the CH_3 groups of $(CH_3)_2C{=}CCH_3$ relatively easier than from neohexane because the double bond weakens the C—H bonds located in β-position to the double bond. Certainly such H-abstraction reactions will be favored as the amounts of NO and 2-methyl butene-2 increase. (ii) 2-methyl butene-2 is formed from the decomposition of neohexyl radicals. Reactions [2*c*], [3*c*], and [4*c*] are related to the yield of 2-methyl butene-2. A possible recombination between NO and neohexyl radicals could form a relatively stable nitroso compound, namely $(CH_3)_3CCH(NO)CH_3$. Whether this compound remains or decomposes further to nitrogen-containing products, it causes a reduction in the yield of 2-methyl butene-2. Similar recombination might take place between NO and $(CH_3)_3C$. Since the latter radical is assumed to be the source of H atoms, a reduction in the yield of H_2 would be expected with increasing NO pressure. Such a reduction has been discussed earlier for all the isomeric hexanes (18).

The possible formation of stable nitroso compounds or of nitrogen-containing products can account for two main observations in the inhibited decomposition of neohexane. First, nitric oxide was recovered for initial NO pressures up to 5 mm, but for NO pressures higher than 5 mm some consumption was observed, increasing with increasing NO pressure. This indicates that NO can be used up through such reactions as

$$R + NO \rightarrow RNO \rightarrow \text{oxime} \rightarrow \text{further decomposition}$$

which, however, gain importance as the NO pressure increases. Nitroso compounds were not detected, perhaps because of the analytical method used. However, in a system containing CH_3 and NO, decomposition products like HCN, H_2O, NH_3, CO, N_2, CO_2, and CH_3CN were found by mass spectrometry (19). Secondly, the analytical mass balance does become less complete as the NO pressure increases, indicating that such nitrogen-containing products may exist but were not detected.

In addition to the above observations another observation can support the argument outlined above. From Table II it is seen that for constant extent of decomposition ($\Delta P/P_i$) the consumption of neohexane increases with increasing NO pressure. If stable nitroso compounds are formed through such reactions as

$$(CH_3)_3C + NO \rightarrow (CH_3)_3CNO$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the pressure of NO will be reduced and at the same time the decomposition of $(CH_3)_3C$ will be suppressed. Therefore one compound would be formed, $(CH_3)_3CNO$, instead of three fragments namely NO, H, and $(CH_3)_2C{=}CH_2$. Under these circumstances to attain the same extent of decomposition in terms of $\Delta P/P_i$ more neohexane must be used up.

STUDIES IN THE WAGNER–MEERWEIN REARRANGEMENT

PART V. RATES OF FORMOLYSIS OF SOME 9-ALKYL-9-FLUORENYLMETHYL TOSYLATES[1]

F. A. L. ANET

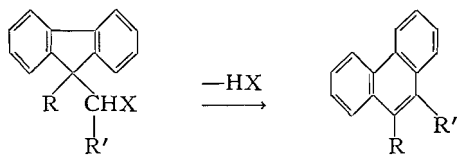
Received March 18, 1965

ABSTRACT

For a series of 9-alkyl-9-fluorenylmethyl *p*-toluenesulfonates, the rates of decomposition in formic acid increase with the size of the alkyl group. Changes in the rate constants are associated with changes in $\Delta S^{\ddagger}$.

When this work was initiated the effect of increasing alkyl substitution at the β-position of neopentyl systems on the rates of rearrangement had not been investigated. The esters (I, X = *p*-toluenesulfonate) appeared well-suited for such a study because the products of solvolysis are known to be completely rearranged and were probably formed by an ionization mechanism, for example, the chlorides (I, X = Cl) and the *p*-toluenesulfonates (I, X = *p*-$CH_3C_6H_4SO_3$) decompose at their melting points and in hot formic acid (1, 2, 3). This method has been found useful for the preparation of a wide range of 9-substituted phenanthrenes (1, 2, 3, 4, 5, 6, and references therein).



I II

The *p*-toluenesulfonates (I, X = *p*-$CH_3C_6H_4SO_3$) decomposed smoothly in 98% formic acid between 30° and 60°. Sodium formate (20 g/l) served as a buffer and had only a small effect on the rates. The rates of appearance of the 9-alkylphenanthrenes (II) were measured spectrophotometrically using the longest wavelength peak of the ultraviolet spectrum (at approximately 345 mμ (7)). This peak is free from end absorption of the fluorene spectrum and gave accurately first-order rate constants reproducible to ±0.2–0.5% having an estimated (8) accuracy of ±0.9–1.6%. Data derived from the third peak (at approximately 330 mμ) were less reliable but provided a useful check. Runs could be followed to greater than 90% completion but rate constants were generally derived from the first two half lives. The yields of 9-alkylphenanthrenes were 98–101% estimated spectrophotometrically and greater than 90% by isolation. As the rates of appearance of the 9-alkylphenanthrenes were accurately first order, they were equated with the rates of decomposition of the *p*-toluenesulfonates. Our results, evaluated by the method of

[1]*Work carried out at The University of Ottawa during the tenure of a National Research Council Postdoctorate Fellowship (1954–56).*

least squares (8), are summarized in Tables I and II. (For the application of spectrophotometric methods to the measurement of rate constants see refs. 9, 10).)

TABLE I

Rate constants for the decomposition of 9-alkyl-9-fluorenylmethyl *p*-toluenesulfonates in 98% formic acid containing 20 g/l sodium formate (min^{-1} multiplied by 10^4)

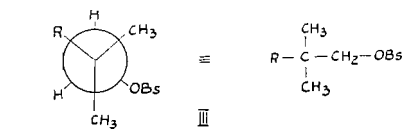
I	38.4°		60.2°
R = CH_3, R′ = H	6.49		86.9
R = C_2H_5, R′ = H	9.68	42.5°	160.7 (60.3°)
		18.6	
R = $(CH_3)_2CH$, R′ = H	22.6_5		317
R = $(CH_3)_3C$, R′ = H	31.6_2*	46.0°	481
		88.2	
R = $C_6H_5CH_2$, R′ = H	6.41		95.9
R = CH_3, R′ = CH_3	425		Not measurable

*33.5 in absence of sodium formate.

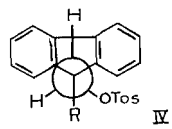
TABLE II

Heats and enthalpies of activation for the rates of decomposition of 9-alkyl-9-fluorenylmethyl *p*-toluenesulfonates (I, R′ = H)

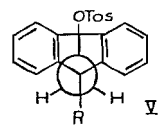
I	$\Delta H^{\ddagger}$, °C	$\Delta S^{\ddagger}$, e.u.
R = CH_3	24.6	+0.5
R = C_2H_5	25.3	+3.5
R = $(CH_3)_2CH$	25.0	+7.1
R = $(CH_3)_3C$	25.7	+13.1
R = $C_6H_5CH_2$	25.6	+6.2



III



IV



V

The rate constants increase with increasing size of the substituent R, as reported (11) for β-substituted neopentyl *p*-bromobenzenesulfonates (III) (see Table III). Of the rotameric forms (12) of I when R_1 = H, shown in IV and V, only IV is likely to be involved in aryl migration leading to ring expansion (11; 13, p. 270 et seq.). Consequently the effect of increasing the size of R can be interpreted as increasing the tendency of the leaving group to ionize and thereby relieve the interaction between R and the toluenesulfonate group (cf. 14, 15 for data confirming this trend). The increase in rate constants is associated with changes in $\Delta S^{\ddagger}$ rather than ΔH (Table II) but unfortunately the data for the *p*-bromobenzene sulfonates (III) (11) show no such consistency.*

Several pieces of information suggest that the *p*-toluenesulfonates (I, X = *p*-$CH_3C_6H_4SO_2$) decompose by a S_N1 process. Thus the secondary *p*-toluenesulfonate

**The accuracy of the rate constants (±1–4%) for the p-bromobenzenesulfonates makes the enthalpies $\Delta S^{\ddagger}$ unreliable (11).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

TABLE III

Comparison of rates of decomposition of *p*-toluenesulfonates (I, R′ = H, X = *p*-$CH_3C_6H_4SO_2$) and *p*-bromobenzenesulfonates (III) (comparisons are in column only and not between series)

R	I at 60.2°	III at 59.7°
CH_3	1.0	1.0
C_2H_5	1.84 (60.3°)	2.4
$(CH_3)_2CH$	3.65	4.1
$(CH_3)_3C$	5.54	34.0

(I, R = R′ = CH_3) decomposes 70 times as fast as the primary ester (I, R = CH_3, R′ = H) (cf. ethyl and isopropyl bromides in 'moist' formic acid which show (16) relative rates of 1 to 26). The effect of increasing the size of R in I parallels that found for a series of complex tertiary chlorides known to decompose by a S_N1 process (for a summary, see ref. 17, p. 664). Conclusions concerning the degree of participation accompanying the decomposition of I are not warranted.

Preliminary experiments showed that the formolysis of 2,2-diphenylpropyl *p*-toluene sulfonate (18) gave a mixture of *cis* and *trans*-α-methylstilbene, the *cis* isomer isomerizing at a lower rate to the *trans* isomer (cf. ref. 19). These experiments will not now be completed.

EXPERIMENTAL

Spectroscopic measurements were made with a Beckmann DK-2 spectrophotometer, using matched quartz cells. Formic acid (98%, Fischer Scientific Co.) containing anhydrous sodium formate (20 g/l) was used as solvent. The *p*-toluenesulfonates have been described elsewhere (1, 18).

Sample concentrations were arranged at the start of each run to provide absorption readings in the range 10–80%. Kinetic data were derived from the first two half-lives. Bath temperatures were kept at ±0.05°. (For quantitative data on the spectra of 9-alkylphenanthrenes see ref. 7.) The general precautions to be observed in determining rate constants spectrophotometrically are described elsewhere (9, pp. 176–181). Data were processed by the method of least squares (8), the constants in Table I being the mean of two independent runs. The reproducibility of the method and the effect of added sodium formate were examined by a large number of runs with the *t*-butyl compound (I, R = $(CH_3)_3C$, R′ = H, X = *p*-$CH_3C_6H_4SO_3$).

CHEMICAL STRUCTURE AND ADSORPTION OF ORGANIC MOLECULES AT THE POLARIZED MERCURY–ELECTROLYTE INTERFACE

R. G. BARRADAS AND P. G. HAMILTON[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received March 9, 1965

ABSTRACT

Previous studies on electrochemical adsorption at mercury of a series of heterocyclic and aromatic nitrogen bases and their respective conjugate ions by electrocapillary measurements are extended to simple saturated heterocyclic compounds containing oxygen and to aliphatic alcohols with different degrees of unsaturation. Adsorption isotherms for various electrode potentials are derived, and standard electrochemical free energies of adsorption are calculated as before, to relate the influence of molecular and electronic structure of the adsorbates on the properties of the electrical double layer. Oxygen as the heteroatom in cyclic compounds and in the hydroxyl group of the alcohols plays a distinct role in the characteristics of metal–adsorbate and adsorbate–solvent interactions through its higher electronegativity as compared with nitrogen. Considerations of the different geometric areas of adsorbed molecules due to isomerism of the saturated heterocyclic compounds, and the varying unsaturation of the alcohols lead to more realistic interpretation of orientation effects, surface coverages, and degrees of adsorbability. Improvement in pressure control in the electrocapillarometer assembly gives better precision in surface tension measurements. Some preliminary results on the adsorption of furfurylamines and related analogues which constitute a newly available class of corrosion inhibitors are briefly discussed.

INTRODUCTION

A comprehensive review of recent work on adsorption of organic substances at solid and liquid electrodes has been published (1). The adsorption of organic compounds as electroinactive additives, or as electroactive reactants, intermediates, or products, plays an important part in the kinetics of electrode reactions, corrosion inhibition, suppression or creation of anomalous polarographic effects, chronopotentiometry, fuel cells, and other electrochemical processes. The advantages of using the mercury electrode for systematic studies of electrochemical adsorption have been discussed (2). The electrocapillary method for investigating adsorption is preferred to differential capacity measurements of greater sensitivity, because the former gives more complete information on the properties of the electrical double layer (3). Electrocapillary measurements of surface excess (Γ_A) are based on unambiguous thermodynamic foundations (4), but the determination of Γ_A from capacitance data is dependent on non-thermodynamic assumptions (5). Despite this fundamental difference the two lines of experimental approach are generally regarded as complementary to one another.

Our principal objectives in the present work on electrochemical adsorption are (i) to examine further the π-orbital interactions on mercury by considering the influence of the triple bond (hitherto uninvestigated) in propargyl alcohol by comparison with the double bond in allyl alcohol and the absence of unsaturation in *n*-propanol; (ii) to study the role of oxygen in the aliphatic alcohols and also as the heteroatom(s) in morpholine and 1,4-dioxane in comparison with pyridine and piperidine, in order to evaluate the contribution of its higher electronegativity and greater availability of lone pair electrons; and (iii) to determine the influence of isomerism in the saturated cyclic compounds (boat and chair conformations). The resolution of these aims will facilitate a clearer interpretation of adsorbate–solvent interactions, surface coverages (Θ), and orientation effects at the

[1]*Holder of Province of Ontario Government Fellowships for 1963–1965.*

polarized mercury–electrolyte interface. The above-mentioned factors are also helpful in the clarification of adsorption behavior of a new class of corrosion inhibitors, namely furfurylamine, its saturated analogue, and their respective derivatives. Some preliminary results of the electrocapillary measurements of these inhibitors will be reported here, but a detailed discussion will be presented elsewhere in conjunction with complementary data from capacitance measurements using a square wave pulse technique (6). Finally, it is hoped that these studies of simple oxygenated compounds may be of some value in elucidating the more complex adsorption behavior of high molecular weight surfactant materials such as the Tritons, polyoxyethylene dodecyl and lauryl ethers, etc. These surfactants form micelles at low bulk phase concentrations, and have practical applications as wetting agents and detergents at the solid/liquid and oil/water interfaces respectively. They are also widely used as maxima suppressors and inhibitory agents in polarographic analysis, but their adsorption mechanism, kinetics, and structure at the mercury electrode are not well understood (7).

EXPERIMENTAL

Apparatus and Method

The method and experimental details employed for obtaining electrocapillary curves are essentially the same as those previously described in detail (2, 8). Since the potentials of the mercury electrode are measured with respect to the calomel electrode immersed in the same electrolyte solution in order to avoid liquid junction potentials, an all-glass cell, having two compartments only, was used for convenience. A third compartment is necessary when potentials of the mercury electrode are also measured with respect to the hydrogen electrode. The capillary was observed by a binocular microscope (Bushnell W × 15 or a Bausch and Lomb SVB-12). The latter model is a stereomicroscope, and is preferred because of the improved viewing of the capillary in "3-dimensions". A significant change in the electrocapillarometer assembly was the use of copper bellows in the nitrogen line. Compression and expansion of the bellows permitted extremely sensitive pressure control which improved the precision and accuracy of surface tension (γ) determinations. The reproducibility of pressure measurements on the anodic side of the potential of zero charge (pzc) for the KCl base electrolyte was ± 0.01 mm. At the pzc variations were less than ± 0.01 mm, but at potentials very cathodic to the pzc (ca. $-1\,200$ mV) the precision of pressure readings was about ± 0.05 mm. The same approximate order of precision in the determination of γ's was experienced for KCl base electrolyte solutions containing organic additives.

Materials Used

Doubly distilled mercury was further purified according to the procedure outlined by Ives and Janz (9). Potassium chloride base electrolyte solution in "equilibrium water" was used as previously described (2). The following substances were investigated in aqueous solutions of 1.0 *N* KCl at 25 ± 1 °C: piperidine, pyridine, morpholine, dioxane, *n*-propanol, allyl alcohol, and propargyl alcohol. The initial organic materials were of the highest purity available commercially and were freshly distilled under nitrogen to avoid atmospheric oxidation prior to use in the electrocapillarometer. The additives are electroinactive within the range of potentials examined of the mercury electrode.

RESULTS

Two sets of electrocapillary curves are shown in Figs. 1 and 2 for pyridine, piperidine, morpholine, and dioxane, and for the three aliphatic alcohols respectively. Electrocapillary curves for piperidine and pyridine have been reported before (2) but they were redetermined here in view of the improved precision due to refinement in the pressure-controlling device. The new results in general compare favorably with the ones reported before, but the new data are used in this paper not only because of the greater precision in γ values, but also because measurements have been made at shorter intervals of 20 mV each over a range of 100 mV in the vicinity of the pzc. This provides more accurate location of the coordinates in the respective shifts of the pzc's (ΔE_{pzc} and $\Delta\gamma_{pzc}$). At other potentials, measurements of γ were taken at 100 mV intervals. As before, all potential measurements were accurate to within 1 mV. At least three pressure readings were taken for each potential step within the range of 0 to $-1\,200$ mV, and in between each reading a

small amount of mercury was expelled from the capillary in order to provide a fresh surface before the subsequent measurement was made.

Surface Excess, Adsorption Isotherms, and Adsorption Coefficients

The amount of organic substance adsorbed at mercury is expressed in terms of the surface excess Γ_A of the organic species as defined in previous papers (2, 10, 11), and obtained from the Gibbs adsorption equation (2, 12) as

$$[1] \qquad -(\partial\gamma/\partial\mu_A)_{E,\mu_{KCl}} = \Gamma_A.$$

Determinations of γ at various activities of the organic substance then give

$$[2] \qquad -(\partial\gamma/RT\partial \ln a_A)_{E,\mu_{KCl}} = \Gamma_A.$$

In neutral KCl solutions, the activities of the organic materials were assumed to be equal to their concentrations. Systematic errors in Γ_A are approximately 10% (2, 8). Figures 3 and 4 give adsorption isotherms for the substances examined, i.e. they show surface coverage in terms of Γ_A as a function of solution concentration of adsorbate c_A at constant potentials. Table I shows Γ_m for calculated planar, perpendicular, and stereoisomeric requirements for a monolayer compared with the highest Γ_m observed experimentally ($\pm 5\%$).

The adsorption coefficient k (cm^3 mole^{-1}) and the net free energy of adsorption $\Delta\overline{G_A^0}$, i.e. the difference between the standard electrochemical free energies of adsorption of an adsorbate and water, has been given by Blomgren *et al.* (13) as

$$[3] \qquad \frac{\Gamma_A}{\Gamma_m - \Gamma_A} = kc_A = \frac{c_A \exp\left(-\Delta\overline{G_A^0}/RT\right)}{0.0555}$$

where c_A is expressed in mole cm^{-3}. This relation is based on the assumption in Langmuir's isotherm that the total number of sites on the electrode available for water and for the organic adsorbate are the same. This model becomes increasingly inapplicable as the size of the organic molecules increases. Our adsorbates are much smaller than those examined by Blomgren *et al.* (13), and we should expect a smaller degree of error in our estimates of k. The values of k, which represent the adsorbability as a function of structure at the pzc, are given in Table II for various Θ's, where Γ_m's are taken as the highest experimentally observed values.

Standard Electrochemical Free Energy of Adsorption as a Function of Potential for Constant Coverage and as a Function of Surface Coverage at Constant Potentials

In a previous paper (2) an equation for the Langmuir isotherm has been presented in

$\Theta = \Gamma_A/(\Gamma_m)_{experimental}$.

terms of the standard electrochemical free energy of adsorption $\Delta\overline{G_A}^0$, analogously to that reported elsewhere for the adsorption of organic ions (5) in the following form:

$$[4] \qquad \ln\left[\frac{55.5}{c_A}\cdot\frac{\Theta}{1-\Theta}\right] = -\Delta\overline{G_A}^0/RT$$

and surface interactions are accounted for by writing [4] as

$$[5] \qquad \ln\left[\frac{55.5}{c_A}\cdot\frac{\Theta}{1-\Theta}\right] = -\frac{\Delta\overline{G_A}^0}{RT} - \frac{P\Theta^{3/2} - Q\Theta^3}{RT}$$

where P and Q are constants depending on the dipole moment, the area occupied by the adsorbed molecules, and on some other characteristics of the particles adsorbed as well as on the dielectric constant of the surface layer. The term $\Theta^{3/2}$ takes account of the electrostatic repulsion between parallel-oriented dipoles, and the term with Θ^3 represents the van der Waals attraction. Hence eq. [5] permits us to evaluate the deviation from eq. [4] as an apparent change of $\Delta\overline{G_A}^0$ with $\Theta^{3/2}$. Figure 5 shows a plot of $\Delta\overline{G_A}^0$ as a function of potential for constant surface coverage of $\Theta = 0.5$ (in terms of experimental Γ_m values) for all the substances examined. Figure 6 shows some typical plots of $\Delta\overline{G_A}^0$ as a function of $\Theta^{3/2}$ at constant potentials.

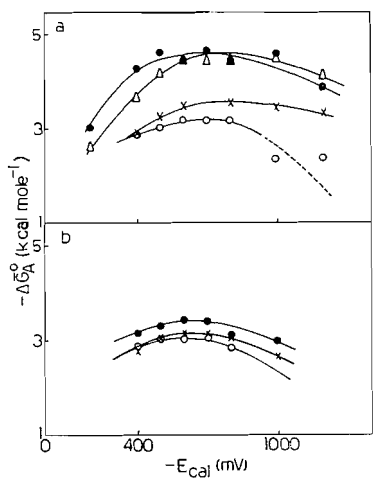

FIG. 5. Values of $\Delta\overline{G_A}^0$ as a function of electrode potential at $\Theta = 0.5$. (*a*) (●) Piperidine, (△) pyridine, (×) morpholine, (○) dioxane. (*b*) (●) n-Propanol, (×) allyl alcohol, (○) propargyl alcohol.

Surface Charge

The surface charge on the metal q_M is obtained from the Gibbs–Lippman equation as

$$-q_M = (\partial\gamma/\partial E)_{\mu_{KCl},\mu_A}. \quad [6]$$

It may be noted that $-q_M = q_S$, where q_S is the net electric charge on the solution side of the double layer. Values of q_M for most of the substances investigated at various electrode potentials and concentrations are shown in Figs. 7 and 8.

DISCUSSION

(a) Morphology of the Electrocapillary Curves

Figures 1 and 2 show the systematic effect of concentration and electrode potentials on the depression of γ. The electrocapillary curves for the heterocyclic compounds indicate that at higher concentrations of additive the order of γ depression is as follows: piperidine > pyridine > dioxane > morpholine. The maximum of these curves is progressively shifted towards positive potentials when concentration of additives is increased. The shifts of the maximum seem to parallel the order of γ depression. On the positive branch with respect to the pzc all the curves diverge without noticeable break except for piperidine at the highest concentrations. Also on the anodic side γ for pyridine is somewhat lower than that of piperidine which indicates some effect due to unsaturation in comparison with its saturated analogue.

On the cathodic side the curves for sufficiently large amounts of additives are at a sharp angle to the base electrolyte curve, and again the most pronounced effect is observed

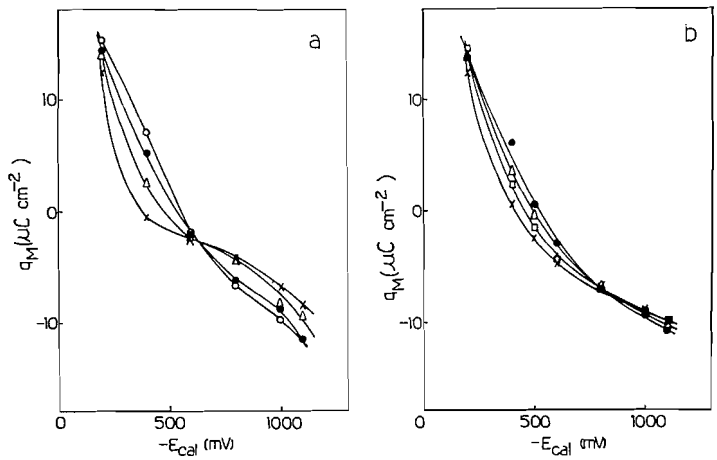

FIG. 7. Charges upon the metal surface as a function of additive concentration in 1.0 N KCl solution and electrode potential. (*a*) Dioxane. (○) 1.0×10^{-2} M, (●) 1.0×10^{-1} M, (△) 3.0×10^{-1} M, (×) 1.0 M. (*b*) Morpholine. (●) 1.0×10^{-1} M, (△) 3.0×10^{-1} M, (□) 5.0×10^{-1} M, (×) 1.0 M.

with piperidine. In general, the electrocapillary curves for the alcohols are less asymmetrical than the cyclic compounds and the order of $\Delta\gamma$ is as follows: n-propanol > allyl alcohol > propargyl alcohol. No break is observed for all three alcohols on both extremes of anodic and cathodic potentials. The least shift of maximum and the attainment of greater symmetry parallels the increasing degree of unsaturation of the three alcohols. $\Delta\gamma$ appears to be the greatest on the anodic branch for propargyl alcohol and relatively smaller for allyl alcohol and n-propanol respectively.

From inspection of Fig. 1, the introduction of oxygen in the cyclic compounds seems to give smaller $\Delta\gamma$ values for morpholine and dioxane in spite of the increased electronegativity of the oxygen atom(s). The unexpected result of dioxane showing greater $\Delta\gamma$ and ΔE_{pzc} than morpholine for correspondingly equal concentrations of additive appears to contradict the trend of increasing electronic density within the ring due to the presence of oxygen. The larger $\Delta\gamma$ for dioxane may perhaps be partly accounted for by the greater field–dipole interaction energy if the molecule can be assumed to adsorb in a boat conformation on mercury (cf. sections *c* and *g* below). Simple considerations of bond moments for C—O and C—N indicate that their respective contributions to the vectorial component of the net dipole moment perpendicular to the mercury surface for both compounds adsorbed in a boat conformation will lead to greater field–dipole interaction energy for dioxane than for morpholine. The shifts in E_{pzc} are not so easily explained as will be seen in section *g*.

(b) Adsorption Isotherms

The adsorption isotherms show in general that the highest values of surface coverage are attained at potentials close to the pzc. Saturation coverage corresponding to a monolayer does not seem to have been reached for all the substances examined (cf. Table I). In general lower values of surface excess were obtained for high negative and positive fields with respect to the pzc.

(c) Maximum Surface Coverage as a Function of Structure

Table I shows the highest Γ_m observed experimentally, and compares with perpendicular, planar, and conformational isomeric space requirements for a monolayer. The molecular

areas have been derived from Leybold space-filling models. The models of the molecules were arranged in the appropriate adsorption positions using a flat surface to represent the metal surface. Photographs of each molecule were taken with a 35 mm camera from a vertical position directly centered over the model. The total area covered by each molecule was calculated by projecting the colored photographic slides outlined on graph paper. Proper allowance in area was made for the molecules to rotate on the surface instead of assuming that they fitted in a close-packed condensed film structure (15). In the cases of morpholine and piperidine the orientation of the N—H bond was taken as perpendicular to the plane of the four central carbon atoms of the ring. If the N—H bond was rotated to a position parallel to the plane of the four central carbon atoms our areas would have to be increased by about 10% for both the chair and boat conformations respectively. Some of our calculated areas are in reasonable agreement with those reported elsewhere (5, 13, 21) but are different from the values given by Hackerman and his co-workers (16, 17, 18). In one paper (16) pyrrolidine and piperidine were given as 45.4 Å^2 and 58.1 Å^2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

respectively from measurements obtained from the maximum radii using atomic models. We have no cause to dispute this choice of area determination except to point out that in a subsequent paper (17) pyrrolidine was retained as 45.5 Å^2 and piperidine was reported as 1.21 × 45.4 Å^2 = 54.9 Å^2. Apart from this inconsistency, it is obvious that an incorrect planar model for piperidine was assumed. In a more recent paper (18) 4-ethylpiperidine was reported as 33 Å^2 in the chair form derived by a method of measurement comparable to ours. In Table I we report 35 Å^2 for piperidine in the chair conformation from a model with the hydrogen atom attached to nitrogen in an axial position. For the hydrogen atom in an equatorial position the value of 38 Å^2 would be obtained. In view of the rapid dynamic situation which may occur between the boat and chair conformations and also between the respective axial and equatorial positions of the hydrogen atom, it is likely that a more realistic value of the molecular area for piperidine (similarly for the other saturated heterocyclic compounds) would be an average one intermediate between 35 and 38 Å^2. Hence, 4-ethylpiperidine may show correspondingly higher areas in view of the size of the ethyl substituent group on the 4-carbon position. For the adsorption of 4-ethylpiperidine on steel powder from cyclohexane solution (18) θ was reported as 0.84 ± 0.28. It was concluded from this finding, in conjunction with a reported "heat of differential adsorption" of 13 kcal per mole, that the molecules are adsorbed in the chair configuration and bonded to the steel surface at nitrogen. In view of the uncertainties in the experimental value of θ and also in the calculated geometrical area of 4-ethylpiperidine it would be difficult to arrive unequivocally at the conclusion regarding the preferred orientation of the adsorbed molecule on steel. The conclusion is not substantiated by any information regarding the dependence of adsorption on potential of the metal in solution.

Our experimental values of Γ_m are generally consistent with the models reported in Table I. The only anomaly is observed with piperidine which could be easily explained if the molecule assumed a perpendicular orientation but this is rather unlikely (cf. section *g*). One may conclude that for piperidine, surface coverage in excess of $\theta = 1$ occurs at the mercury–electrolyte interface, and such behavior could be qualitatively explained in terms of its high basicity ($pK_a = 11.2$), as compared to pyridine $pK_a = 5.2$ and morpholine $pK_a = 8.7$ (14). If piperidine adsorbs on the metal at the nitrogen end of the molecule through lone pair electron interaction, then the effect of withdrawal of the lone pair electrons from nitrogen would tend to affect the attached hydrogen atom by giving this proton an increased "degree of acidity". Such an effect will increase the possibility of intermolecular hydrogen bonding with the lone pair electrons on another piperidine mloecule and thereby drawing the second molecule closer to the interface. The same argument may be applied to morpholine if it adsorbed with the nitrogen atom on the metal but in view of its lower pK_a value there is a corresponding decrease in the "degree of acidity" of the hydrogen atom and a lesser tendency for morpholine to show intermolecular hydrogen bonding. Qualitative support for this argument may be cited from the high resolution n.m.r. spectra of *p*-chloroaniline (19) and 2-methyl piperidine (20). The chemical shifts for the proton on the nitrogen atom are 1.34 and 3.60 p.p.m. for *p*-chloroaniline and 2-methyl piperidine respectively. The latter compound is more basic than the aromatic substance and corresponding withdrawal of the lone pair electrons towards the aromatic ring is greater than that for the saturated heterocyclic compound. This is indicated by the respective effect on the nuclear magnetic resonance (n.m.r.) spectra and it is known that the chemical shift of a proton increases qualitatively with its relative "acidity".

(d) Standard Electrochemical Free Energies

Figure 5 shows that $\Delta\overline{G_A}^0$ has a maximum at slightly negative potentials with respect to the pzc at $\Theta = 0.5$ for all the compounds studied. This behavior is consistent with the trend observed by Blomgren *et al.* (13) for aliphatic neutral compounds. For the alcohols the curves are relatively similar to one another but the lowest $\Delta\overline{G_A}^0$ values are observed for the least saturated compounds. For the heterocyclic compounds the introduction of oxygen into the ring system seems to lower $-\Delta\overline{G_A}^0$ values close to those shown by the alcohols. For constant surface coverage of $\Theta = 0.5$ the variation of $\Delta\overline{G_A}^0$ is less symmetrical over the potential range plotted for the heterocyclic compounds than for the alcohols. The $\Delta\overline{G_A}^0$ values for the alcohols at low anodic potentials have not been plotted because at these high positive fields surface coverages were below 0.5. The values of $\Delta\overline{G_A}^0$ at constant Θ can be regarded as a measure of the inherent strength of the net adsorption forces acting on the organic molecules (13) and this is reflected by comparison of the respective k values computed from eq. [3] and shown in Table II (see section *e*).

Figure 6 shows the linear variation of $\Delta\overline{G_A}^0$ with $\Theta^{3/2}$ calculated according to eq. [5] for dioxane and *n*-propanol. The surface coverage was computed from theoretical values of Γ_m for the boat conformation of dioxane and the planar configuration of *n*-propanol. However, it is to be noted that similar qualitative behavior was observed if experimental values of Γ_m were used for calculating Θ's. The choice of experimental Γ_m values results in systematic displacements of the curves but their *forms* do not change. Pyridine and *n*-propanol show significant breaks in the plots at different potentials, which are comparable to previously reported behavior observed for π-deficient (14) aromatic and heterocyclic bases (2). This has been attributed to sudden orientation effects due to lateral interactions of the adsorbed molecules. There are no sharp inflections in the $\Delta\overline{G_A}^0$ vs. $\Theta^{3/2}$ plots for dioxane, which indicate that any orientation of the adsorbed molecules between upright or inverse positions of either the boat or chair conformations is not detectable in terms of surface coverage because the molecular areas of the four possible configurations are approximately equal to one another. Further support regarding the indecisiveness concerning planar to perpendicular orientation of the adsorbed molecules may also be seen from the zero slopes for most of the plots shown in Fig. 6*a*. The zero slopes mean that there is no net repulsion lateral to the surface so that orientations may possibly be "random" for dioxane. The same general dependence of $\Delta\overline{G_A}^0$ on $\Theta^{3/2}$ was observed for piperidine and morpholine, and can be explained by similar reasons offered for dioxane. There were also no inflections in the plots for allyl and propargyl alcohols since these molecules would probably prefer to adsorb in a planar position on the metal due to π-orbital interaction (2). At high coverages, van der Waals attractive forces dominate between the molecules and this behavior is demonstrated by the typical plot at -600 mV for dioxane where the curve tends to turn upwards at $\Theta = 0.8$. The $\Delta\overline{G_A}^0$ vs. $\Theta^{3/2}$ behavior for all the substances examined confirm the trend of orientation effects presented in Table I.

(e) Degree of Adsorbability

For adsorption on mercury Blomgren *et al.* (13) defined adsorbability at the pzc in terms of the adsorption coefficient k for $\Theta = 0.25$, and Laitinen and Mosier (22) used the adsorption index β for $\Theta = 0.5$ at potentials varying from about -0.6 to -0.8 V saturated calomel electrode (s.c.e.). Both terms have been derived from considerations of

the Langmuir isotherm but it is difficult to make extensive comparisons of the two parameters because of the different adsorbates and base electrolytes used by the respective authors. For the adsorption of β-naphthol in an aqueous phthalate buffer 0.1 M (pH 4.4) with 0.1 M KCl, β was given as 13.0 l mmole^{-1} or 1.3×10^7 cm^3 mole^{-1} for $\Theta = 0.5$ (22). For the adsorption of α-naphthol in 0.1 N aqueous HCl, Blomgren *et al.* (13) reported $k = 5.0 \times 10^7$ cm^3 mole^{-1} for $\Theta = 0.25$, which is possibly based on a theoretical value of Γ_m assuming planar adsorption of the molecule on mercury. From their Γ_A vs. c_A isotherm at -400 mV (with respect to the hydrogen electrode) (13) we calculated $k = 2.0 \times 10^7$ cm^3 mole^{-1} for $\Theta = 0.25$ by using the experimental value of Γ_m. In a similar manner k was estimated as 2.8×10^7 cm^3 mole^{-1} for $\Theta = 0.5$.

The adsorption behavior of quinoline and isoquinoline was found to be quantitatively similar on solid or liquid electrodes (23). Furthermore, it is noted that despite the difference in base electrolytes used, and that β and k values were calculated from capacitance and electrocapillary data respectively, there appears to be some reasonable order of agreement between k and β for the two isomeric naphthols examined. We list in Table II the adsorbability of our organic substances investigated in terms of k at the pzc for different values of Θ. Laitinen and Mosier concluded that higher β values indicate increasing surface activity and decreasing polarity. For some compounds there is also a qualitative parallelism between β and the basicity of the molecule (22). Table II shows a regular trend in the degree of adsorbability which is related to the chemical and physical properties of the respective substances, e.g. piperidine has the highest β and basicity of the compounds investigated. For pyridine Laitinen and Mosier reported $\beta = 0.013$ ($\Theta = 0.5$ at -0.8 V (s.c.e.)) and our value of $k = 1.6 \times 10^4$ cm^3 mole^{-1} is equivalent to $\beta = 0.016$ ($\Theta = 0.5$ at 0.56 V normal calomel electrode (n.c.e.)). The close agreement for the only compound that we have examined in common with Laitinen and Mosier is remarkably coincidental. However, if we calculated $\Theta = 0.5$ on the basis of a theoretical Γ_m corresponding to a planar configuration of the adsorbed molecule, $\beta = 0.032$.

(f) Surface Charge as a Function of Coverage and Electrode Potential

Values of q_M at various concentrations and electrode potentials for dioxane and morpholine are shown in Fig. 7 and for the alcohols in Fig. 8. These plots for piperidine and pyridine are essentially similar to those previously reported (2) and are omitted in this paper for that reason. Morpholine and dioxane are different from those of piperidine and pyridine in that the curves of the oxygen-containing compounds do not show independence of potential at negative potentials with respect to the pzc. Morpholine, pyridine, and piperidine display q_M values which decrease numerically with increasing concentration (cf. ref. 2).

For ease of discussion one can divide the q_M vs. E curves into three sets: (i) pyridine and piperidine (2); (ii) morpholine; (iii) dioxane and the alcohols. The isolation of morpholine is based on the fact that at negative potentials with respect to the pzc, the curves are intermediate in form between sets i and iii. The distinction between i and ii as compared with iii is clearly due to the absence of nitrogen in the latter set of compounds. Dioxane and the alcohols show a common crossing point at about -600 mV for all concentrations, and the numerical value of q_M changes in a reverse order with increasing concentration on the anodic and cathodic sides of the pzc respectively. The general shape of set iii resembles those reported by Blomgren *et al.* (13) for aliphatic substances such as *n*-butanol, *n*-valeric acid, and *n*-valeronitrile, which show a common point of intersection at about -250 mV with respect to the hydrogen electrode. It appears that the nitrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

atom in the nitrilo functional group does not exert such a profound influence on the adsorptive properties of the aliphatic molecule as it does for the cyclic compounds.

It may not be very conventional to equate the structural effects on adsorption of an aliphatic alcohol with that of a cyclic ether, but it is difficult to ignore the resemblance of the q_M vs. E curves for n-propanol and dioxane, which share the common absence of unsaturation. The divergence of q_M values for the alcohols at various comparable concentrations on the anodic and cathodic sides of the pzc, antiparallels the respective degree of unsaturation in the three compounds. The presence of nitrogen and oxygen in the cyclic compounds, and the degree of unsaturation in the aliphatic alcohols seem to contribute distinctive effects on the changes of shape in the q_M vs. E curves, which are again related in a systematic way to the respective adsorbabilities of the different substances.

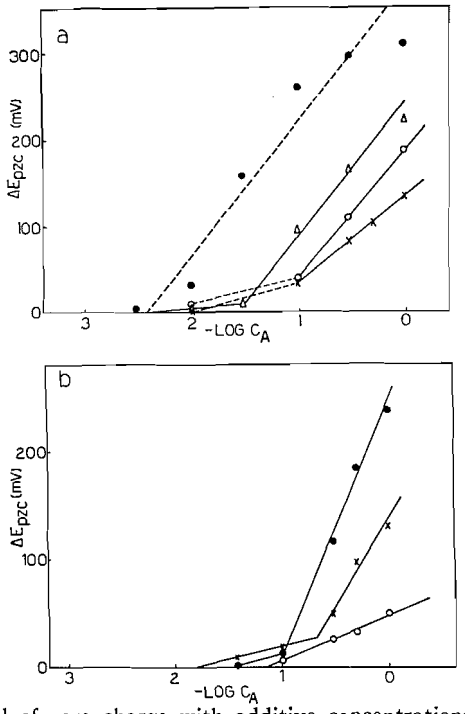

FIG. 9. Shifts of the potential of zero charge with additive concentrations in 1.0 N KCl solution. (*a*) (●) Piperidine, (△) pyridine, (×) morpholine, (○) dioxane. (*b*) (●) n-Propanol, (×) Allyl alcohol, (○) propargyl alcohol.

(g) Variation of ΔE_{pzc} *with log* c_A *and with* $(\Gamma_A)_{pzc}$

Figures 9 and 10 show that $d(\Delta E_{pzc})/d \log c_A$ and $d(\Delta E_{pzc})/d(\Gamma_A)_{pzc}$ change abruptly with increasing c_A and $(\Gamma_A)_{pzc}$ for some of the compounds. Similar behavior was previously shown for several heterocyclic and aromatic amines, and was interpreted as sudden orientations (cf. section *d*) of the adsorbed molecules at critical $(\Gamma_A)_{pzc}$ and c_A values. The sharpest changes of slope at low $(\Gamma_A)_{pzc}$ and c_A values were observed for π-deficient compounds, and conversely, π-excessive compounds showed less pronounced changes of slope at higher $(\Gamma_A)_{pzc}$ and c_A. The relative contributions of π-orbital interaction on mercury for the two classes of cyclic amines were associated with the orientation effects (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

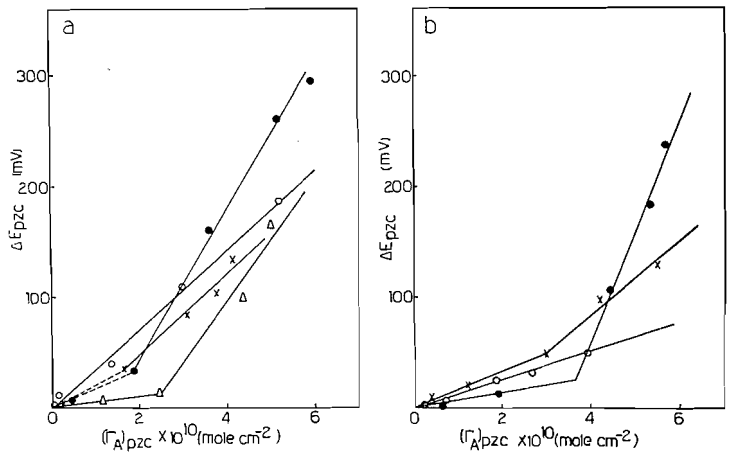

FIG. 10. Shifts of the potential of zero charge against surface excess at the pzc in 1.0 *N* KCl. (*a*) (●) Piperidine, (△) pyridine, (×) morpholine, (○) dioxane. (*b*) (●) *n*-Propanol, (×) allyl alcohol, (○) propargyl alcohol.

In Fig. 9 the repeated results for pyridine and piperidine (both classified as π-deficient (14)) can still be correlated in terms of the respective presence and absence of a partly conjugated π-orbital system. Figures 9*b* and 10*b* present further confirmation of the previously suggested hypothesis of π-orbital effect in relation to orientation (2). At low surface coverage *n*-propanol may adsorb in a planar configuration on the metal but would probably orient to a vertical position with the hydrocarbon end of the molecule attached to mercury at a critical $(\Gamma_A)_{pzc}$ value. This is more consistent with the information in Table I and agrees with the adsorption behavior described for *n*-butanol (13, 21).

Allyl and propargyl alcohols have increasing degrees of unsaturation and these molecules would show greater tendency to adsorb in a planar position on mercury through π-orbital interaction. As surface coverage increases allyl alcohol may orient to a perpendicular position with the hydrophilic end of the molecule pointing towards the solution. The sudden changes in slope for allyl alcohol occur at much higher $(\Gamma_A)_{pzc}$ and c_A values than for *n*-propanol. Propargyl alcohol shows no orientation effects at the respective c_A and $(\Gamma_A)_{pzc}$ values investigated.

The comparative behavior of piperidine, dioxane, and morpholine cannot be explained in terms of π-orbital effects. Moreover, any explanation of sudden orientation from "planar" to "perpendicular" positions on mercury would be erroneous since these compounds exhibit isomeric boat and chair conformations. The areas of the two conformations shown in Table I are approximately identical in magnitude. Furthermore, there is some ambiguity in the choice of models with the hydrogen atom in an axial position when attached to nitrogen in piperidine and morpholine (see Discussion section *c*). There is also an error of about 10% in the computation of Γ_A. Under these circumstances it is not possible to discern any sudden or even gradual orientation of these adsorbed molecules from Fig. 10*a*. The data for piperidine in Fig. 9*a* are so widely scattered that it is difficult to ascertain whether there has been any change in slope at all. It is impossible to draw any valid conclusions from the changes in slope represented by the broken and solid lines shown in Figs. 9*a* and 10*a*.

Cyclohexane has been reported by Selwood (24) to adsorb on nickel in the boat conformation. By analogy it may be possible that the saturated heterocyclic compounds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

could preferentially adsorb in a similar position on mercury. Some support for this suggestion may be obtained by considering their dipole moments. In the gas phase, dioxane $\mu = 0$, but in solution at room temperature a zero moment has also been quoted (26) although a categorical denial of the boat form has not been made. In benzene $\mu = 0.45$ (25) and the apparent dipole moments μ_S are 3.19, 2.21, and 3.56 in nitrobenzene, *t*-butyl chloride, and acetonitrile respectively (27). The latter values suggest that there must be a reasonable predominance of the boat form in certain nonpolar solvents. Adsorption in the chair form for piperidine and morpholine through lone pair electrons of the nitrogen atom interacting on the metal cannot be ruled out but the same situation for either of the symmetrical oxygens in dioxane appears less feasible. Moreover, the greater $\Delta\gamma$, k values at $\Theta = 0.1$ and 0.25, and (Γ_m) experimental observed for dioxane in comparison with morpholine would favor the preferred adsorption of the dioxane molecule in the boat form.

Although Figs. 9 and 10 do not offer any unequivocal experimental evidence for "planar to perpendicular" orientation of the adsorbed molecules of dioxane, morpholine, and piperidine (cf. Discussion section *d*), it is possible that these adsorbates may orient through any of the four upright or inverse positions of the two conformations. If such orientations occur, we suggest that the preferred form will likely be the boat conformation,* and with the heteroatoms pointing outwards to the solution side of the interface. The latter suggestion is in conformity with reported postulates for molecules which do not exhibit conformational isomerism (2, 13, 21, 28). A better test of orientational effects from one isomeric form to another would be to determine the adsorption of substituted derivatives of the saturated heterocyclic compounds, e.g. with a large aliphatic or aromatic group on the 4-carbon position in piperidine. Such a derivative would have less molecular symmetry, and different Γ_m values should result for various preferred orientational positions on the surface. It would also be interesting to examine the effects of *cis–trans* isomerism on adsorption in a way analogous to that described above.

Figures 9 and 10 indicate that an Esin and Markov effect (29) exists for the adsorption of neutral molecules. This effect has been examined for inorganic ions from a general thermodynamic standpoint (30) and will be reported in detail elsewhere (31) for organic ions and for a wide variety of organic molecules including the ones investigated in this paper.

(h) Five-Membered Heterocyclic Compounds

Difficulties were reported in the adsorption studies on solid electrodes for five-membered heterocyclic compounds such as pyrrole (32). The problem is largely resolved by the availability of a new class of corrosion inhibitors (Miles Chemical Co., Elkhart, Indiana), comprising of furfurylamine, tetrahydrafurfurylamine, and their respective derivatives. These compounds contain oxygen as the cyclic heteroatom and are very π-excessive in properties (14). The amino group on the side chain confers high basicity and complete miscibility with water. The adsorptions of these compounds as neutral molecules and ions have been investigated by electrocapillary and capacitance methods, and comparison with their analogous alcohols, e.g. furfuryl alcohol, is presently being carried out.

Furfuryl alcohol is completely miscible with water but the solution decomposes on standing. This has been attributed to gradual change by "resinification" through intermolecular dehydration, which is catalyzed by heat and increasing acidity (33), but the

**The adsorbed molecules are under the influence of the electrode field which may stabilize the conformation with the higher dipole moment (31). This is comparable to a previously published postulate that displacement of the isomeric equilibrium toward the boat form occurs under the influence of coulombic field (35).*

decomposition may be retarded by traces of cyclic or aromatic amines (34). The varying inhibitory action of cyclic amines, e.g. piperidine, furfurylamine, etc., on the decomposition of furfuryl alcohol is currently being examined on a quantitative basis. There appears to be some relation with the varying mitigating effects on corrosion of metals for these organic bases. The electrocapillary curves for the unsaturated furfurylamines in KCl solutions resemble those of allyl and propargyl alcohols. In HCl, the electrocapillary curves are much more symmetrical on both sides of the pzc. The furfurylamines appear to satisfy the most favorable structural requirements for general purpose corrosion inhibition in acidic media since they are adsorbed on the cathodic side of the pzc by virtue of the positive charge on the protonated amino group, and on the anodic side by π-bonding with the metal. Further theoretical and experimental analysis of the Esin and Markov effect (31), and the comparison of electrocapillary and capacitance results (6) for these compounds will be presented in detail later. The descriptions of structural and other effects due to oxygen and nitrogen reported in this paper for the aliphatic alcohols and the six-membered heterocyclic compounds are undoubtedly of value in the interpretation of the adsorptive and (or) corrosion inhibitory properties of these five-membered heterocyclic bases and their analogous alcohols.

ACKNOWLEDGMENTS

We are indebted to the National Research Council and to the University of Toronto for financial support of this work. The pressure-regulation device described in the Experimental section is due to the kind suggestion of Professor B. E. Conway of Ottawa University. The assistance of Mr. F. M. Kimmerle in the determination of the projected molecular areas is gratefully acknowledged. Finally we wish to thank Professor A. G. Brook for helpful discussions on some aspects of organic chemistry of the saturated heterocyclic compounds.

THE PYROLYSIS OF OXIMES OF SOME GAMMA CYANO- AND GAMMA NITRO-KETONES

C. F. H. ALLEN
Rochester Institute of Technology, Rochester, New York
Received January 19, 1965

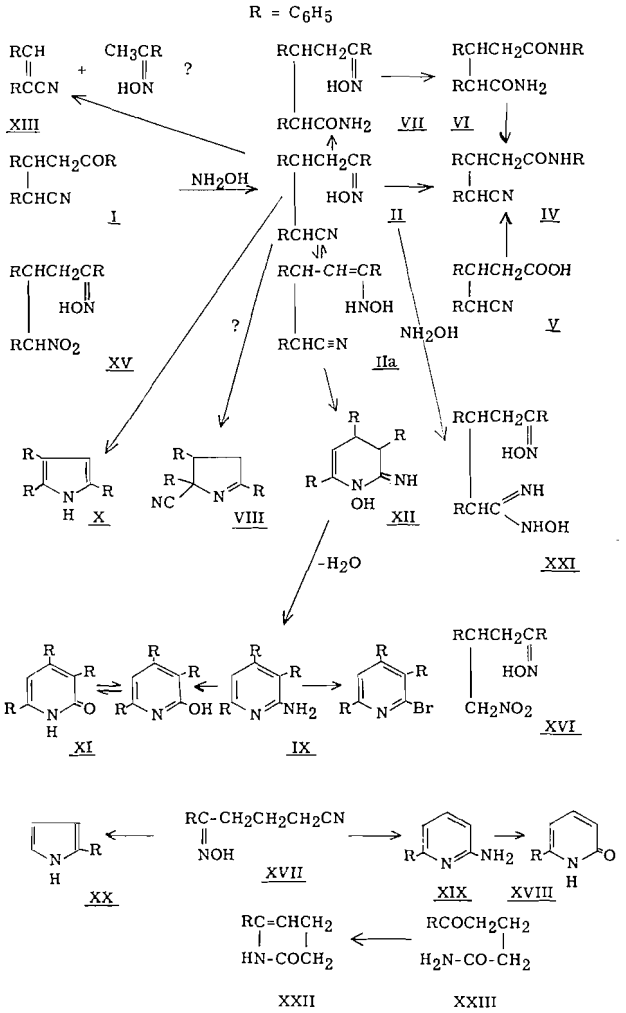
ABSTRACT

Oximes of gamma cyano- and gamma nitro-ketones are decomposed by heat as well as by acids. From the very complex mixtures resulting there have been isolated arylated pyrroles, arylated 2-aminopyridines, and the corresponding pyridones, as well as several minor products. This behavior constitutes a new synthesis of these heterocyclic compounds. In a Beckmann rearrangement γ-benzoyl-α,β-diphenylbutyronitrile gave an anilide, the structure of which was confirmed by an independent synthesis. By physical methods both structures of gamma ketonic amides are confirmed.

The thermal reversal of the Michael addition reaction has recently been shown to proceed in two ways, termed *normal* and *abnormal* (1, 2, 3). To prevent the normal reaction, the use of the cyano-oxime (II), prepared from the parent cyanoketone (I) and hydroxylamine acetate, was selected. Because the reagent can attack both carbonyl and cyano groups, it was important, at the outset, to know the structure of the oxime (II) with certainty. This was demonstrated by an examination of the cyano-anilide formed after its Beckmann rearrangement. The oxime gave an acetate (III) when treated with acetic anhydride or acetyl chloride, from which the parent could be regenerated, but with thionyl chloride it was rearranged to the cyano-anilide (IV). The latter was synthesized independently from the known acid (V)(4) for structure confirmation. Since oxime rearrangement is known to involve groups in the *trans* positions (5), the configuration of II must be the one shown. Concentrated sulfuric acid likewise brought about rearrangement to the anilide, but a by-product was the amide-anilide (VI), formed by addition of water to the cyano group; the nitrile (IV) could be re-formed by treatment of the amide with thionyl chloride (Chart I). The amide-anilide (VI) is isomeric with the amide-oxime (VII), which was isolated in small amount from the residues of the recrystallization of the oxime (II).

In view of the recently established value of the mass spectrometer for predicting the course of degradation reactions (1, 2, 3), most of the new substances described in this paper were so examined, and the presence of possible products noted without resort, at each examination, to isolation by classical procedures. The compounds were given an opportunity to decompose in the all-glass heated inlet (230°) of the mass spectrometer. The resulting mass spectra, therefore, represent the decomposition mixtures. Under these conditions the spectra of the cyano-oxime (II) and its acetate (III) gave several spectral peaks which were considered as probably parent molecule-ions of decomposition products. Of these the large ones at 322 and 295 can be accounted for by assuming a loss of water for the first, and of water plus hydrogen cyanide for the second. The products, formed in approximately equal amounts and actually isolated by classical methods, were the new aminopyridine (IX) and the known (6) pyrrole (X); a secondary product was the already known (7) corresponding pyridone (XI) resulting from hydrolysis of the latter. The structure of the aminopyridine (IX) was clearly demonstrated by its independent conversion to the known pyridone (XI) by the action of nitrous acid, and to the known

CHART I



2-bromo-3,4,6-triphenylpyridine (7) following the procedure used by Case (8) in an analogous instance. The oxime (II) can cyclize in two ways; one is by a direct loss of water to give a pyrroline (mol. wt. 322) (VIII). The other follows a path analogous to that for a modification of the Hantzsch pyridine synthesis from monoximes of 1,5-diketones, as was discovered by Wislicenus (9). In line with this, the aminopyridine is slowly formed by treatment of the parent cyanoketone (I) with hydroxylamine hydrochloride. The reaction path involves the hydrogen atom on the oxime nitrogen in the tautomeric form (II*a*); this adds to the cyano group (XII), with concomitant transannular loss of water, to give the aminopyridine (mol. wt. 322)(IX).

Comparisons of the several mass spectra of the decomposition products of the oxime (II) and those of reference samples of the pyrrole (X) and the aminopyridine (IX) confirmed their presence. In each examination of the oxime (II) there was an excess of peak at *m/e* 322 which varied slightly from one examination to another. It was also noted that a peak at *m/e* 218, not present in mass spectra of the aminopyridine (IX), the pyrrole (X), or 2,4-diphenylpyrrole, appeared to vary slightly in size, correlating with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the amount of excess peak at *m/e* 322. A pyrroline (VIII), if present in the decomposition mixture, would be expected to give a parent peak at *m/e* 322. Although no reference sample of known composition (VIII) was available for comparison, one might expect ring cleavage at the two bonds which are beta to the ring nitrogen, which would be analogous to the fragmentation of pyrrolidines (22). This would leave an ion of *m/e* 218. An alternate process which might also contribute to the *m/e* 218 peak would involve a rearrangement with the loss of a phenyl group and HCN (22).

One of the small ion peaks occurs at *m/e* 205, the molecular weight of α-phenylcinnamonitrile (XIII). This identification not only was supported by comparison with the mass spectrum of an authentic specimen, but also was confirmed in the vapor phase chromatographic estimation of the amount as 2–3% of the thermal products. Its presence suggests that there has been a little abnormal dissociation (1) of the oxime (I), considered as a Michael adduct. The other expected product would be acetophenoneoxime; the latter could not be identified, however.

The cyano-anilide (IV) gave a relatively weak mass spectrum, showing the presence of α-phenylcinnamonitrile (confirmed by reference spectrum). Other components were not completely resolved because of overlapping contributions to peaks in common. It is possible that the peak at 135 may represent some acetanilide (N-methylbenzamide and phenylacetamide were excluded by comparison with reference spectra). The mass spectrum of the products from the cyano-semicarbazone (XIV) showed the presence of small amounts of the same products obtained from the cyano-oxime (I), but there was no evidence for acetophenone semicarbazone.

The formation of the triphenylpyrrole is not limited to the cyano-oxime (II), but is also found with the analogous nitro-oxime (XV). In this instance oxides of nitrogen and water are eliminated. Benzonitrile was present and estimated by gas chromatography in the oily product resulting from a chemical degradation at the bench. The decompositions of both these oximes constitute a new synthesis of triarylpyrroles (10). However, the yields from either oxime are not high enough to make the reaction competitive with that starting with desylacetophenone (6).

In an analogous manner the oxime (XVI) of γ-nitro-β-phenylbutyrophenone decomposed in the heated inlet, yielding 2,4-diphenylpyrrole as the only recognizable product (confirmed by reference mass spectrum), but difficulties in the preparation of the oxime render this approach impractical.

In the case of γ-benzoylbutyronitrile oxime (XVII) there was a mass peak at 188, the molecular weight of the undecomposed parent compound, which decreased with time. There were also peaks at masses 171, 170, and 143, the molecular weights of 2-oxo-6-phenylpyridone (XVIII) (11), 2-amino-6-phenylpyridine (XIX), and 2-phenylpyrrole (XX). These increased with time as would be expected. Identification of the pyrrole was supported by comparison with the complete mass spectrum of an authentic specimen (12). In the laboratory, when this oxime is heated in bulk, it decomposed violently. The only recognizable products were water and the known 2-oxo-6-phenyltetrahydropyridine (XXII) (11).

The hydroximidate (XXI) is a minor product, isolated from the residues in the preparation of the oxime (II). In the heated inlet of the mass spectrometer the hydroximidate gave a very complex spectrum. Peaks were present at *m/e* 322, 321 (characteristic of 2-amino-3,4,6-triphenylpyridine), and at 296 (the molecular weight of 2,3,5-triphenylfuran), but there was none at *m/e* 218. These were confirmed by the identity of their complete mass spectral patterns with those of authentic specimens. The peak at 296 does not occur in the mass spectrum of the pure oxime (II).

EXPERIMENTAL

Preparation of the Oximes

Since the delta ketonic nitriles have two groups that can react with hydroxylamine (13) a mixture of products was to be expected; fortunately, with the adduct I, the major portion of the desired oxime (II) was in the first crystalline portion to separate. The best yield was obtained by 1 h heating, under reflux, of a mixture of 20 g of either diastereomeric nitrile (I) with the hydroxylamine acetate solution resulting from the interaction of 12 g of hydroxylamine hydrochloride in 160 ml of dry methanol, and 33 g of fused potassium acetate in 120 ml of the same solvent, with filtration of the salt; the nitrile slowly went into solution. When the solution had been allowed to stand overnight, most of the oxime separated as clear, hard prisms, containing methanol of crystallization (II*a*). If ethyl alcohol was used, no product separated until the volume was reduced one-half. The oxime was recrystallized first from hot benzene, and then from propyl alcohol. The properties of all new compounds are collected in Table I.

TABLE I

Properties of new substances

No.	Substance	M.p., °C	Empirical formula	Analyses					
				Calcd.			Found		
				C	H	N	C	H	N
II	Cyano-oxime (triphenyl)	137	$C_{23}H_{20}N_2O$	81.2	5.9	8.2	81.6	5.6	8.0
II*a*	II plus CH_3OH	136*	$C_{24}H_{24}N_2O_2$	77.4	6.5	7.5	77.5	6.6	7.6
III	Acetate of II	155	$C_{25}H_{22}N_2O_2$	78.5	5.8	7.3	78.3	6.0	7.4
IV	Cyano-anilide	152	$C_{23}H_{20}N_2O$	81.2	5.9	8.2	81.3	5.6	8.4
VI	Amide-anilide	227–8†	$C_{23}H_{22}N_2O_2$	76.8	6.1	7.9	76.8	6.2	7.9
VII	Amide-oxime	226–7†	$C_{23}H_{22}N_2O_2$	76.8	6.1	7.9	76.9	6.1	7.6

XI	The pyridone	300–1	$C_{23}H_{17}NO$	85.4	5.2	4.3	85.2	5.4	4.3
XIV	Semicarbazone	214 dec.	$C_{24}H_{22}N_4O$	75.4	5.8	14.7	75.3	5.8	14.5
XV	Nitro-oxime (triphenyl)	175	$C_{22}H_{20}N_2O_3$	73.3	5.6	7.8	73.6	5.8	7.6
XVI	Nitro-oxime (biphenyl)	110–11	$C_{16}H_{16}N_2O_3$	67.6	5.6	9.9	67.9	5.8	9.7
XVII	Cyano-oxime (monophenyl)	100–1	$C_{11}H_{12}N_2O$	70.2	6.4	14.9	70.4	6.7	14.9
XXI	The hydroximidate	167–8	$C_{23}H_{23}N_3O_2$	74.0	6.2	11.2	74.0	6.4	11.0

*On block, shrinks at about 85°.
†Mixture shrinks at 210°, melts 219–220°.

The residual solution was treated in two ways: by pouring it into water to precipitate the organic components and get rid of the potassium salts, followed by systematic recrystallization; or (*b*) by direct, tedious fractional crystallization using various solvents. The products identified were a little more of the cyano-oxime (II); 8–10% of unreacted adduct (I) if the reaction time was less than 2 h; the amide-oxime (VII) (5–6%) arising from water, formed in the reaction, and adding to the cyano group; and the hydroximidate (XXI) resulting from the addition of hydroxylamine (13) (13–14%). Doubling the period of heating dropped the yield of oxime to 67–70% and increased those of the amide-oxime and hydroximidates.

The Hydroximidate (XXI)

When a benzene solution of the uncrystallizable, gummy residue was shaken with aqueous copper acetate, very little copper derivative separated. Upon analysis this was found to contain the expected amount of metal for formula XXI, but to have had *one* =NH replaced by =O.

The cyano-oxime (II) dissolves slowly in methanolic sodium methoxide on shaking; it does not give a copper derivative when shaken with aqueous copper acetate. The acetate (III) was obtained by dissolving 1 g of the oxime in 5 ml of hot chloroform, and adding 20 drops of acetyl chloride; when the evolution of hydrogen chloride subsided, an equal volume of acetyl chloride was added and the whole left over night to crystallize. The residual oil, which had a very bright blue fluorescence when illuminated by a source of ultraviolet light,[1] was taken up in methanol, from which 0.4 g of the acetate (II) crystallized. The same acetate was less conveniently obtained by the use of acetic anhydride. If the acetate was boiled for a few minutes with sodium hydroxide in a mixture of water and alcohol, the oxime was quantitatively regenerated.

The oxime (XV) was formed in 95–96% yield by the same general procedure, using the adduct from phenylnitromethane and chalcone (14). As above, both diastereomers gave the same oxime. The preparation of the oxime (XVI) from the nitromethane adduct (15) was erratic, a green oil being formed from which

[1]"*Spectroline*," *Spectronics Corp., Westbury, N.Y. Model SL 3660.*

the oxime separated only after some days. The yields were 0–68%. During manipulative trials a small amount of a blue dye was obtained; this was probably identical with the Knott-Rogers dye (16, 17)—black needles with a bronze reflex, m.p. (on block) 238°.

γ-Butyrophenoneoxime (XVII) was prepared from γ-benzoylbutyronitrile (18) essentially by the procedure employed with II, using methanol. After 80 min, 3 ml of water was added and most of the solvent evaporated. The cooled solution was then inoculated with a little of the previously prepared oxime and left to crystallize overnight (a very slow process); the product separated as very large (up to 5 mm diameter), hard prisms (yield, 27–36%).

The semicarbazone (XIV) corresponding to the oxime (II) was obtained in the usual way, the ethanolic solution being heated under reflux for 80 min. The yield was almost quantitative. Propyl alcohol is preferred for crystallization; acetic acid is unsuitable. The derivative is insoluble in water and in methylene chloride. Both nitriles (I) gave the same semicarbazone.

Rearrangement of Oxime II

To a solution of 1 g of the oxime in 5 ml of hot methylene chloride was slowly added 40 drops of thionyl chloride; gas evolution was rapid. After the oily residual solid was recrystallized from methanol several times, the pure cyanoanilide (IV) was obtained. Its synthesis was accomplished by first converting 1 g of the acid (V) to its chloride by thionyl chloride in hot benzene, evaporating the solution nearly to dryness, and adding more benzene and 1.1 ml of aniline. The white solid formed was worked up by appropriate manipulation, and yielded the same cyano-anilide (mixture melting point, identical infrared and mass spectra).

γ-Carbamoyl-β,γ-diphenylbutyranilide (VI) was obtained when 1 g of the oxime and 10 ml of concentrated sulfuric acid was stirred for 1 h and left overnight at room temperature. The clear solution was poured over ice, and the solid was collected and recrystallized to constant melting point. This amide was dehydrated to the nitrile (IV) by warming its methylene chloride solution with thionyl chloride, removing the excess of reagent by methanol, and recrystallizing the amide from this solvent. There was no depression of melting point on a mixture with an authentic sample of the nitrile.

γ-Benzoylbutyramide

The current availability of γ-benzoylbutyronitrile (18) made mild hydrolysis the preferred route to this amide. The nitrile (6.3 g) was added, in portions, to 20 ml of concentrated sulfuric acid at room temperature. After 3 h the reddish solution was poured into 150 ml of warm water, and the precipitate collected on a filter. It was well-mixed with dilute ammonia to remove γ-benzoylbutyric acid (1.2 g), washed once with water, and, while still wet, dissolved, in 25 ml of 95% ethyl alcohol. Most of the product crystallized on cooling, and a second crop was obtained on concentration. The combined yield was 85–6%. It was used for cyclodehydration to XXII by acetyl chloride (11).

Distillation of the Oximes

The oxime (II) is very sensitive to acidic reagents, to irradiation by ultraviolet light (GE purple X), and to heat, giving uncrystallizable, sticky gums that have a brilliant blue fluorescence when illuminated;[1] this is attributed to the presence of the 2-amino-3,4,6-triphenylpyridine (IX). Numerous small-scale distillations, using 2–5 g of the oxime, were made in miniature apparatus, in vain hope of finding the optimum conditions. Condensing drops of water were visible up to 200°; at this point the pressure was lowered to 1 mm, and the heating was continued as long as any distillate could be observed. The initially thick yellow oil became red and viscous, and a white solid collected in the neck and side of the distilling flask. By gas chromatography it was found that the pyrrole (X) amounted to 19–22%, and the aminopyridine (IX) to 16–20%, with 2–3% of α-phenylcinnamonitrile, b.p., 178–9 at 1 mm. The pyridone was isolated in yields of 12–14%. Larger runs (20–23 g) were than made, using a vacuum throughout (1–0.4 mm) (1.5 h required). Fractions were collected as follows: (A) up to 275–290°, 0.9–1.1 g; (B) 306–315°, 9.5–10.1 g; (C) 365–375°, 2.1–3.5 g; residue. Fraction B set to a thick yellow wax, while C was a red tar. Both were heated under reflux with boiling acetone or ethyl acetate, until a filterable suspension of the pyridone (XI) was formed. Similarly the condensate in the neck and sidearm of the distilling flask was removed. Owing to the large amount of non-crystallizable sticky pitch, yields were not sharply defined. The pyrrole and aminopyridine were separated from each other and from contaminating pyridone by tedious fractional crystallization. The pyridone appeared to have a high vapor pressure for it co-distilled and was found in all fractions collected above 290°, and in the residue; it even persisted through several recrystallization. Metal catalysts (silver solder, stainless steel) had no marked effect, but in the presence of copper only the pyrrole could be isolated; in this instance the aminopyridine appeared to have been hydrolyzed to the pyridone. Added potassium acetate, however, diminished the yield of pyrrole to 6%.

The thermal decomposition were also carried out in various solvents (cumene, dimethylformamide, 1-chloronaphthalene), of which only the latter gave a useful result. After the obvious reaction was over, the solvent was steam distilled, and the residual organic material was treated by appropriate solvents. Column chromatography was not extensively investigated, since preliminary results were not encouraging. A small quantity of the pyrrole was isolated in one sample.

Under similar conditions, the product from decomposition of the nitro-oxime (XV) showed 15–19% of triphenylpyrrole and 0.5–1.5% of benzonitrile by gas chromatography. The 2,3,5-triphenylpyrrole (X) was identified by comparison with an authentic specimen (6), using the melting and mixture melting points of it and its trinitrobenzene complex (19), violet fluorescence, and infrared and mass spectra. It boils at 254–6° at 1 mm.

2-Amino-3,4,6-triphenylpyridine (IX) crystallized from an acetone extract of cut B, and was recrystallized from propyl alcohol. It was also formed, in a 6.5% yield, by the heating of the adduct I and hydroxylamine hydrochloride under reflux for 24 h (Wislicenus' procedure (see ref. 6)). The infrared spectrum (KBr pressing) of the amine is very similar to that of the simpler 2-aminopyridine in the 2–7 micron region. A series of sharp bands are found near 2.9, 3.05, and 3.15 μ, along with a strong sharp band at 6.13 μ.

2-Bromo-3,4,6-triphenylpyridine from the Amino Compound

To a suspension of 0.6 g of the latter in 6 ml of 48% hydrobromic acid was added a solution of 0.2 ml of bromine in 2 ml of hydrobromic acid. After the mixture was cooled to 3°, 2 g of sodium nitrite in 3 ml of water was added. The red tar formed was taken up in ether, and separated from a little of the pyridone; after removal of the ether, the residual tar was taken up in alcohol from which more pyridone separated. After 3 days, most of the bromopyridine had crystallized in rosettes. The yield was 0.3 g (50%) and of pyridone, 0.1 g (16%). Attempts to synthesize the amine from the bromo compound and sodium amide in boiling butyl ethyl ether were unsuccessful.

The pyridone (XI) was easily separated from the various oils and gums by virtue of its relative insolubility in acetone or ethyl acetate. It was also formed by the action of nitrous acid on the aminopyridine. Once dissolved in a solvent it separates slowly, holding traces of the solvent tenaciously; this may result in an apparent low melting point (7). When mixed with the aminopyridine the melting point of the latter is not depressed, but a clear melt is not obtained until 215–230°. Thus, a 2:1 mixture of IX and XI melts at 272–273°. Although acetic acid can be used, dimethylformamide is the preferred solvent; dimethyl sulfoxide is unsatisfactory. The infrared spectrum (KBr pressing) of the pyridone is very similar to that of the simpler compound, 2-pyridone, and includes a broad absorption band in the 6.15–6.4 μ region. The pyridone has a blue fluorescence.

When the oxime (XVII) of γ-benzoylbutyronitrile was heated, there was an extremely rapid decomposition at 190°, with evolution of much steam, but very little hydrogen cyanide. The latter (collected as silver cyanide) corresponded to a 0.2% yield of 2-phenylpyrrole. The residual black pitch was either distilled at a low pressure or extracted with cold benzene (90–95% is left as residue), and the extract examined by thin-layer and column chromatography. Only the 2-oxo-6-phenyltetrahydropyridone (XXII) (yield, 5–10%) was isolated from all fractions of distillate.

Nuclear Magnetic Resonance

The 2-oxo-6-phenyltetrahydropyridine and γ-benzoylbutyramide were examined by n.m.r., and the findings were consistent with the structure written for the first. There was one imino hydrogen (δ = 8.05) (exchangeable by deuterium), one ethylenic hydrogen (δ = 5.48), four methylenic (δ = 2.53, 2.57), and five aromatic hydrogens (δ = 7.43).

Structures of Gamma Ketonic Amides

There has always been some question whether γ-benzoylbutyramides have the open-chain form or are cyclic, as a result of intramolecular addition (11, 20). In the infrared spectrum of the solid (potassium bromide pressing) the two carbonyl groups show up strongly, indicating the open-chain arrangement, but when the amides are dissolved in dimethyl sulfoxide and examined by n.m.r., the cyclic form is favored, since two different kinds of exchangeable hydrogen appear. The presence of the cyclic form of delta ketonic amides in solution was postulated many years ago (21), and has been independently demonstrated by a simple dehydration of such amides by acetyl chloride in the absence of water or hydrogen chloride (11, 20).

Gas Chromatography

The samples were chromatographed on a 6 × 1 200 mm glass column, containing 25% by weight of Dow Corning 200 silicon fluid on acid and base-washed Celite 545. The detector was a Gow-Mac thermal conductivity cell, Model No. 9285, operated at 260°. The column was operated at 250° and the F. H. heater at 280°. The flow rate was 100 ml of helium per minute, the column being thermostatted with boiling *n*-butyl benzoate. The retention times, as related to octadecane, were α-phenylcinnamonitrile, 1.67; for 2,4,5-triphenylpyrrole, 15.5; and for 2-amino-3,4,5-triphenylpyridine, 20.6.

ACKNOWLEDGMENTS

I am greatly indebted to former associates in the Research Laboratories of the Eastman Kodak Company: Mr. John Stenberg for the preparation of γ-benzoylbutyronitrile; Mr. G. P. Happ for the mass spectrometry; Miss Thelma Davis for the infrared spectra; Dr. T. H. Regan for the n.m.r. spectra; Dr. O. E. Schupp for the vapor phase chromatography;

INDEPENDENT YIELDS OF ^{124}Sb AND ^{126}Sb IN THERMAL NEUTRON INDUCED FISSION AND THEIR IMPLICATION ON THE EMPIRICAL Z_p FUNCTION

P. O. STROM,[1] G. R. GRANT,[2] AND A. C. PAPPAS
Department of Chemistry, University of Oslo, Oslo, Norway
Received March 22, 1965

ABSTRACT

The independent fission yields in thermal neutron induced fission of ^{235}U have been measured to be $(9.5 \pm 1.4) \cdot 10^{-6}\%$ and $(1.04 \pm 0.17) \cdot 10^{-3}\%$ for ^{124g}Sb and ^{126g}Sb, respectively. The total independent yields for all isomers of these nuclides are estimated to be $(1.2 \pm 0.2) \cdot 10^{-5}\%$ for ^{124}Sb and $(3.7 \pm 0.6) \cdot 10^{-3}\%$ for ^{126}Sb using a Huizenga–Vandenbosch approach for estimating population of isomeric states.

These data do not seem to support a 50 proton shell effect on the Z_p function, using the "unique" charge distribution curve of Wahl. A revised Wahl plot based on recent information on neutron emission from individual fission fragments is given and discussed in view of shell effects in fission. It is shown that the effect of the Z_p function of the 50 proton shell is very small.

INTRODUCTION

A study of the division of nuclear charge in fission requires determinations of independent yields of individual fission products preferably along single mass chains. Because of inherent difficulties in such measurements (genetic relationships between species concerned and short half-lives) our knowledge of the isobaric charge distributions in fission is quite scanty. However, in thermal neutron induced fission of ^{235}U Wahl *et al.* (1) have shown that in the limited number of cases (six) where more than one independent yield is known for a given mass chain the data indicate that the Gaussian relation

$$[1] \qquad P(Z) = (c\pi)^{-1/2} \exp\left[-(Z - Z_p)^2/c\right]$$

adequately represents isobaric charge distributions. In this equation $P(Z)$ is the fractional chain yield of the fission product Z and Z_p is the most probable primary charge in the chain under consideration.

While these authors have determined a best value 0.94 ± 0.15 for the constant c which allows a reasonable fit to the experimental data from the six mass chains studied (A = 91, 139–143), there may be no unique charge distribution function applicable to all mass chains as suggested by a number of authors (1–5).

A determination of the most probable primary charge for other mass chains is therefore subject to the uncertainties present in the postulates regarding the distribution itself. Despite this indeterminancy the results of measurements of independent and cumulative yields indicate (1) that the charge distribution along any given mass chain can reasonably well be represented by the Gaussian relation in eq. [1] or by a curve approximately Gaussian in character (2, 4).

On the assumption that the charge distribution curve given in eq. [1] is unique and applicable to all mass chains in thermal and low energy fission, Wahl *et al.* (1) were able

[1]*On leave 1963–1964 from the United States Naval Radiological Defense Laboratory, San Francisco, California, U.S.A.*

[2]*Postdoctorate Fellow 1961–1963 under the fellowship program of the Royal Norwegian Council for Scientific and Industrial Research. Present address: Whiteshell Nuclear Research Establishment, Atomic Energy of Canada, Ltd., Pinawa, Manitoba, Canada.*

to fix the most probable primary charge for any mass chain in which an independent yield or cumulative yield early in the chain was available.

To obtain the prompt masses (A') involved corrections for neutron emission from the primary fragments were necessary. These were estimated from experimental data on neutron emission as a function of prompt mass as corrected and correlated by Terrell (6). After a number of unsuccessful attempts to correlate their Z_p values with various charge distribution postulates (2, 4, 7) Wahl *et al.* (1) drew a smooth continuous Z_p function through the "experimental" values in their plot of the distribution of charge given by $[Z_p - A'(Z_f/A_f)]$ versus mass number A' before neutron emission, the fissioning nucleus being characterized by (Z_f, A_f). (Cf. Fig. 3.)

One important feature in their plot is the lack of data in the region $108 < A' < 128$. Thus it is very uncertain how the Z_p function behaves in this region. It seems, however, that the function may enter the region with a sharp rise near the 50 proton shell as indicated by the high independent yield of ^{128}I (8). Such a tendency was previously suggested also by Wahl (5) on the basis of low independent yields of ^{96}Nb and ^{98}Tc. On the other hand the function $[Z_p - A'(Z_f/A_f)]$ may presumably equal zero at the point of symmetry, i.e. $A' = 118$ for ^{235}U(th,f).

The kinetic energy distribution resulting from thermal neutron induced fission has been carefully reinvestigated by Milton and Fraser (9). Two possible ways of explaining the observed dip near symmetric fission in the kinetic energy distribution were discussed by these authors. One of these is based on the assumption that the total excitation energy is nearly constant for all fission fragments and then attribute the decrease in kinetic energy to a decrease in energy release caused by unfavorable splitting of the charge of the fissioning nucleus. Following this idea the kinetic energy measurements would give Z_p values which at no time should fall below the 50 proton shell for the heavy fragment, thus eventually leading to a 50 proton shell effect on Z_p much stronger than anticipated by Wahl *et al.* (1). In view of such ideas and the uncertainty of the "experimental" Z_p function in this region it was desirable to measure independent yields in the mass region 108 to 128. This is rather difficult, however, because of extremely low yields and highly complicated genetic relationships for the nuclides concerned. But, one possibility suggested itself in 1962 when Dropesky and Orth (10) found that ^{126}Sb is "quasi-shielded" by its tin parent, the $\sim 10^5$ y ^{126}Sn.

In a preliminary run using natural uranium and designed to give a measure of the independent yield of the 12.5 d ^{126g}Sb, the 60 d ^{124g}Sb was also observed. Since ^{124}Sb is a shielded nuclide ^{124g}Sb must have been produced either independently in fission or from neutron capture in ^{123}Sb from antimony impurity in the target. The experiments in the present paper were therefore designed to eliminate or to correct, as much as possible, for the contribution to ^{124g}Sb from sources other than fission.

EXPERIMENTAL

Irradiations

Natural uranium (sample no. 1), uranium enriched to 19.9% ^{235}U (sample no. 2), both in the form of UO_3 (respectively 800 mg and 25 mg), uranium enriched to 93.3% ^{235}U[3] (samples nos. 3 and 4) in the form of U_3O_8[4] ($\sim$ 10 mg), together with blank samples (quartz ampoules) were irradiated with thermal neutrons[5] in order to minimize possible adverse effects from fast neutrons on the measurements. The flux (constant within $\pm$10%) was approximately $2 \cdot 10^{12}$ thermal neutrons/cm^2 s and the cadmium ratio was

[3]*The amount of other uranium isotopes in this target was: 1.1% ^{234}U, 0.2% ^{236}U, and 5.4% ^{238}U.*

[4]*The samples enriched in ^{235}U were highly purified and obtained from the U.S. National Bureau of Standards, Washington, D.C.*

[5]*The irradiations were performed in the thermal column of the DR-2 reactor of the Danish Atomic Energy Commission, Risø.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

close to 50. The blank samples were irradiated under the same conditions and subjected to the same chemical treatment as the samples themselves. During the irradiations, which lasted from 1 to 2 weeks, the reactor was operated intermittently. This was taken into consideration as described later. After the irradiation the ampoules were allowed to "cool" for about 1 month prior to radiochemical separations.

Radiochemical Separations

The irradiated target was dissolved in 2 ml of conc. HCl and 1 drop of H_2O_2. The solution was heated to boiling. The quartz ampoule was removed and washed with 7 ml H_2O. A known amount of antimony carrier was added and Sb^{+3} oxidized to Sb^{+5} using several drops of Br_2. After excess Br_2 was expelled by boiling, Sb^{+5} was reduced to Sb^{+3} with $N_2H_4 \cdot HCl$. Saturated oxalic acid (1.5 ml) was added, followed by 1 drop of aerosol solution and 2 ml of 5% thioacetamide to precipitate Sb_2S_3. Heating (water bath) promoted coagulation of the precipitate which was then centrifuged and washed twice with dilute HCl. Two different procedures were then followed:

A. In samples 1 and 2 the Sb_2S_3 was dissolved in 1 ml of conc. H_2SO_4, adding a few drops of HNO_3, and excess HNO_3 removed by fuming. Antimony was further purified as stibine using a procedure similar to that given by Greendale and Love (11).

B. In samples 3 and 4 the Sb_2S_3 was dissolved by boiling with 4 ml of conc. HCl. Antimony was then further purified following essentially the method given by Barnes (12) based on specific sulfide precipitations, alternated with purification steps.

In both procedures antimony was finally converted to metal by reduction with a freshly prepared solution of $CrCl_2$. It was filtered onto a pretreated, weighed filter paper, washed with water and absolute methanol, then dried for $\frac{1}{2}$ h at 100 °C, cooled, and weighed to determine the chemical yield. The samples were then mounted in a standard way. The chemical yield was checked after the decay of the samples through the use of the spectrophotometric determination with rhodamine B given by Greenhalgh and Riley (13).

The 12.80 d ^{140}Ba with a fission yield of 6.35% (14) served as fission monitor. Barium was isolated by following essentially the method described by Minkhinen (15) and mounted as chromate. The chemical yield was determined by weighing.

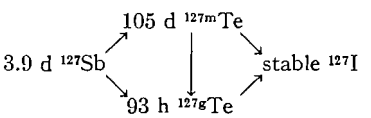
Counting

The final samples were counted using a methane flow β-proportional counter similar to that described by Forsén and Rydberg (16). An Oltronix power supply (type LS 28) was used for the detector high voltage and a Baird-Atomic preamplifier (model 255) fed a Philips electronic counter (model PW 4032). The samples were also studied using an Intertechnique 400 channel γ-pulse height analyzer with a $2\frac{1}{2}$ in. × 3 in. Harshaw thallium-activated sodium iodide crystal.

Nuclides Present

The antimony isotopes (with their decay products) which were present in the samples counted were:

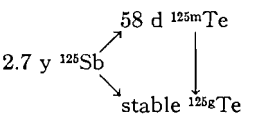
1. ^{127}Sb, which is unshielded and is formed in relatively high yield. It had, however, decayed substantially during the approximate 1 month "cooling" time prior to the isolation of antimony.



2. ^{126}Sb, which at formation consists of two "quasi-shielded" isomers of which only the 12.5 d ^{126g}Sb was present in the counted samples. The decay scheme reported by Dropesky and Orth (10, 17) is given in Fig. 1.

$$12.5 \text{ d } {}^{126g}\text{Sb} \rightarrow \text{stable } {}^{126}\text{Te}$$

3. ^{125}Sb, which is not shielded. Therefore the majority of the mass 125 chain yield was present.



4. ^{124}Sb, which is shielded and formed as three isomers of which only the 60 d ^{124g}Sb was present in the counted samples. The decay scheme reported by Vanhorenbeeck (18) is given in Fig. 2.

$$60 \text{ d } {}^{124g}\text{Sb} \rightarrow \text{stable } {}^{124}\text{Te}$$

The β-counting was done through a 55.3 mg/cm^2 aluminium absorber (total absorption thickness $\sim$ 60 mg/cm^2 including source cover, air, and counter window). This reduced appreciably the weak β-rays from ^{125}Sb, ^{127m}Te, and ^{127g}Te, and absorbed completely the conversion electrons from ^{125m}Te and ^{127m}Te. The hard β-branches from ^{124g}Sb and ^{126g}Sb were relatively unaffected by the absorber.

Gamma spectra taken 50 days after the end of irradiation showed peaks at 0.175, 0.427, and 0.595 MeV almost entirely due to 2.7 y ^{125}Sb. Peaks at 1.15, 1.42, 1.85, and 2.15 MeV were attributed to ^{126g}Sb, as these decayed with a half-life of about 12 days. Herrmann (19) has reported sum peaks at 1.12 and 1.41 MeV for this nuclide and it seems likely that the peaks at 1.85 and 2.15 MeV also are sum peaks; however, this was not explicitly checked. Gamma spectra taken 150 days after the end of irradiation showed besides lines due to 2.7 y ^{125}Sb peaks at 1.37, 1.69, 2.08, and 2.3 MeV in accordance with the γ-spectrum of a pure sample of 60 d ^{124g}Sb.

No contamination could be detected either in the γ-spectra or in the β-decay curves. The half-lives observed are (12.1 $\pm$ 0.3) d for ^{126g}Sb and (3.9 $\pm$ 0.2) d for ^{127}Sb. These are in accordance with the values (12.5 $\pm$ 0.2) d and (3.87 $\pm$ 0.07) d reported by Dropesky and Orth (10).

Determination of Counting Efficiencies

^{124g}Sb.—This nuclide was produced by thermal neutron irradiation of about 15 mg of "specpure" $SbCl_3$. Two months "cooling" time removed the short-lived isomers of ^{122}Sb (3.5 min, 2.8 d), ^{124}Sb (21 min, 93 s), and ^{38}Cl (1 s, 37.3 min). The remaining activity was almost entirely due to ^{124g}Sb as that of ^{36}Cl ($3 \cdot 10^5$ y) could be considered as negligible. From a 250 ml stock solution of ^{124g}Sb, samples for low geometry β-counting were prepared by adding aliquots (25 λ) to known amounts of Sb^{+3} and subsequent quantitative antimony metal precipitation as previously described. These samples were counted in the proportional counter both with and without the 55.3 mg/cm^2 aluminium absorber. In addition aliquots (25 λ) were pipetted onto gold-coated VYNS films, dried, and counted in a $4\pi\beta$ counter and the counting efficiencies obtained. The determinate error was found to be about $\pm 1\%$. Indeterminate errors, however, associated with nonuniform sample thickness in particular, were such that an error of about $\pm 10\%$ is considered more realistic.

The counting efficiency was also determined for the γ-pulse height analyzer using the 1.69 MeV γ-peak with background subtracted. This efficiency was found by comparing the counts under the peak with the number of disintegrations, over the same time period, in the sample when this was counted in the $4\pi\beta$ counter. The estimated error (largely indeterminate due to the background subtraction) is about $\pm 10\%$.

^{126g}Sb.—The counting efficiency for this nuclide was calculated from the relation

$$[2] \qquad \epsilon = \sum_i (f_B)_i (f_M)_i (f_{SA})_i (f_{AB})_i (f_\beta)_i G$$

where G is the geometry used. The correction factors for backscattering f_B, mylar absorption f_M, self-scattering and self-absorption f_{SA}, for absorber, air, and window f_{AB}, were taken from Pappas (3), Rudstam (20), and Buset (21). The fractions of total β-emission f_β were taken from Dropesky and Orth (17) and the summation carried out over all β-branches i. The error estimated in this efficiency is $\pm 10\%$.

^{140}Ba.—Since ^{140}La grows in the ^{140}Ba samples, the counting efficiency of ^{140}La was first measured in a matrix of $BaCO_3$ in a way similar to that described for ^{124g}Sb using a stock solution made up of thermal neutron irradiated "specpure" La_2O_3. With standard parent–daughter equations the counting efficiency for ^{140}Ba could be calculated from the activity of the ^{140}Ba samples measured at different times after separation from lanthanum. The error in the efficiency so obtained is estimated to be $\pm 10\%$. The counting efficiency of ^{140}Ba was also calculated using eq. [2] and data from ref. 3 in good agreement with the results from the more direct determination.

RESULTS

The number of atoms N, of a fission product with essentially no ("quasi-shielded") or entirely no (shielded) growth from parent activities or of one with short-lived precursors, present at the end of an intermittent irradiation is given by

$$[3] \qquad N = \sum_{j=1}^{n} \frac{y\phi N_{235}\sigma}{\lambda} [1 - \exp(-\lambda T_j)] \exp(-\lambda t_j)$$

where y = independent or cumulative yield, ϕ = thermal neutron flux, N_{235} = number of atoms of ^{235}U in the target, σ = thermal neutron fission cross section of ^{235}U, λ = decay constant, T_j = duration of the jth irradiation, and t_j = elapsed time from the end of the jth irradiation to the end of all irradiations.

The summation is carried out over all irradiation periods, n.

The Number of Fissions in the Samples

The decay of the 12.8 d ^{140}Ba – 40 h ^{140}La couple was followed for about 80 days. The number of atoms N_{Ba} of ^{140}Ba present at the end of the irradiation was found from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

observed activity through use of standard parent–daughter equations and the efficiencies determined for ^{140}Ba and ^{140}La. The total number of fissions F

$$[4] \qquad F = \phi N_{235}\sigma \sum_{j=1}^{n} T_j$$

in the sample is obtained by equating N_{Ba} to N in eq. [3] when this refers to ^{140}Ba. One finds

$$[5] \qquad F = N_{Ba}/C$$

where C is a constant characteristic for each irradiation, given by

$$[5a] \qquad C = \sum_{j=1}^{n} y_{Ba}[1 - \exp(-\lambda_{Ba}T_j)] \exp(-\lambda_{Ba}t_j) \Big/ \lambda_{Ba} \sum_{j=1}^{n} T_j.$$

The determinate error in the number of fissions is $\pm 10\%$.

Independent Yield of ^{124g}Sb

Because of the relatively low β-activity of ^{124g}Sb caused by the use of the absorber, the 60 d half-life could not easily be resolved in the long-lived tail of the β-decay curve. The number of atoms of ^{124g}Sb present at the end of irradiation was therefore determined by γ-ray spectroscopy. This was done by measuring the 1.69 MeV γ-ray associated with its decay, using the efficiency determined above and correcting for chemical yield. The atoms present at the end of irradiation are given in Table I for samples 3 and 4, i.e. those from targets with 93.3% ^{235}U in the uranium.

TABLE I

Contribution to ^{124g}Sb from different sources

	Sample	
	3*	4
Atoms at end of irradiation	$8.00 \cdot 10^7$	$3.55 \cdot 10^8$
Atoms due to Sb in target	$<1.6 \cdot 10^5$	$<7.0 \cdot 10^5$
Atoms due to Sb in ampoule	$1.7 \cdot 10^6$	$8.3 \cdot 10^6$
Atoms due to fission in ^{235}U	$7.81 \cdot 10^7$	$3.46 \cdot 10^8$

*Only about 20% of the target was used for this study.

The values given in Table I represent the atoms actually present in the samples, but might not all be due to fission of ^{235}U as the following processes could have influenced the results.

^{124g}Sb$(n,\gamma)^{125}$Sb. According to Murin *et al.* (22) the capture cross section for thermal neutrons in ^{124g}Sb is about 2 000 barns, while Regier (23) reports 16 barns. The conditions of the present experiments were, however, such that the influence of such a high cross section as suggested in ref. 22 would be quite negligible.

^{123}Sb$(n,\gamma)^{124g}$Sb. This reaction will take place in a possible antimony impurity in the target and might therefore significantly influence the results. Sufficiently sensitive equipment was not available to measure the low concentrations of antimony which would cause difficulties. Therefore targets with increasing enrichment in ^{235}U were used as it was expected that the enrichment procedure would remove antimony. This is borne out by the decreasing "apparent" fission yield of ^{124g}Sb with increasing enrichment of ^{235}U in the target as seen from Table II. The maximum amount of antimony impurity in uranium purified in a tributyl phosphate – hexane extraction system is less than 0.01

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

p.p.m. based on uranium according to Nelson and Lang (24). If one makes the very conservative assumption that this limit represents the amount of impurity in the highly purified targets with 93.3% ^{235}U one should be on the safe side. The resulting corrections are given in Table I and amount to only about 0.2%.

^{124}Te(n,p)^{124}Sb and ^{127}I(n,α)^{124}Sb. The average cross sections for these reactions in a fission neutron spectrum have been estimated by Roy and Hawton (25) to be 70 μbarns and 2.6 μbarns, respectively. In the present irradiations, however, where the cadmium ratio was about 50 in the region of exposure the average cross sections should be much smaller. On the basis, however, of the above cross sections the concentrations of tellurium and iodine impurities required to obtain an amount of ^{124g}Sb comparable with that from an antimony impurity of the order discussed above, would be of the order of 10^3 to 10^4 p.p.m. These are orders of magnitude higher than those reported as prominent impurities in uranium purification. Thus, charged particle reactions are considered to be without influence on the results.

Other sources. The quartz ampoules used as target containers were handled as little as possible prior to irradiation. To remove volatile material, they were heated at 500 °C for 3/4 h just before addition of the target material and heat sealing. Blank samples were also irradiated and the number of atoms of ^{124g}Sb produced in the ampoules measured. A correction of about 2% was necessary in the number of atoms of ^{124g}Sb from the highly enriched targets (Table I). Thus all foreseeable corrections amount to only 2 to 3% in the results from the highly enriched targets. Using the corrected values for the number of atoms present at the end of irradiation (Table I) the fission yields obtained are given in Table II for samples 3 and 4.

The results for samples 1 and 2, natural uranium and 19.8% enriched in ^{235}U, are, as seen, seriously influenced by contamination. Only samples 3 and 4 are therefore used in the average value. The error is estimated to be ±15%. The yield given $(9.5 \pm 1.4)\cdot 10^{-6}$% is "apparent" independent yield as it includes parts of the yields of the higher isomeric states (cf. Fig. 2).

TABLE II

Apparent independent fission yields of ^{124g}Sb and ^{126g}Sb

Sample	^{235}U (%)	^{124g}Sb (%)	^{126g}Sb (%)
1	0.72	$1.35\cdot 10^{-4}$	$0.91\cdot 10^{-3}$
2	19.9	$0.55\cdot 10^{-4}$	$0.88\cdot 10^{-3}$
3	93.3	$9.3\cdot 10^{-6}$	$1.11\cdot 10^{-3}$
4	93.3	$9.6\cdot 10^{-6}$	$1.23\cdot 10^{-3}$
Average*		$(9.5\pm 1.4)\cdot 10^{-6}$	$(1.04\pm 0.18)\cdot 10^{-3}$

*For ^{124}Sb see text.

Independent Yield of ^{126g}Sb

The activity of ^{126g}Sb at the end of irradiation was obtained by analytical extrapolation of the β-decay curve observed through the aluminium absorber after subtraction of the long-lived background due to 2.7 y ^{125}Sb and 60 d ^{124g}Sb. The amount of the latter was estimated from the 1.69 MeV γ-peak using the appropriate conversion factor for counting efficiency determined above.

The only non-fission reaction which would influence the number of atoms of ^{126g}Sb present at the end of the irradiation would be:

^{126}Te(n,p)^{126}Sb in tellurium impurity in the target. The average cross section for this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reaction in a fission neutron spectrum is estimated by Roy and Hawton (25) to be 20 μbarns. Thus the same arguments as used in connection with ^{124g}Sb are applicable and result in a negligible influence of charged particle reactions.

The calculated fission yield is given in Table II. The error is estimated to be ±18%. This yield $(1.04 \pm 0.18) \cdot 10^{-3}\%$ is given also as "apparent" yield for the same reasons as stated in connection with ^{124g}Sb (cf. Fig. 1).

The independent yield of ^{126g}Sb has, during the course of the present investigation, also been measured by Lange and Herrmann (26) who found $(0.90 \pm 0.25) \cdot 10^{-3}\%$. Thus the results from the two groups are in excellent agreement.

DISCUSSION

Estimate of Total Independent Yields of ^{124}Sb and ^{126}Sb (All States)

Both ^{124}Sb and ^{126}Sb have isomeric states with branched decay (Figs. 1 and 2). Therefore, to obtain the total independent fission yields of these nuclides from the measured "apparent" yields knowledge of the manner in which the different isomeric states are populated is required. The ground state of ^{124}Sb has a spin 3 (measured) and negative parity (27). On the basis of careful decay scheme studies Vanhorenbeeck (18) assigns spin and parity 8− to the upper (21 min) state and 5+ to the intermediate (93 s) state. These assignments are supported by the second rule given by Brennan and Bernstein (28) for spin coupling in odd–odd nuclei. For ^{126}Sb Dropesky and Orth (17) assign 8− for the ground (12.5 d) state and 5+ for the upper (19 min) state, based on careful decay scheme studies. The Brennan–Bernstein rule (28), however, is not decisive in this case and predicts 3 or 8 for the ground state, but these should form a closely spaced doublet as in ^{124}Sb. According to Dropesky and Orth (17) the 3− state probably exists as an excited level above the 19 min isomer.

The statistical model of Huizenga and Vandenbosch (29, 30) has been used to estimate the population of states in the isomers concerned as follows:

On the basis of correlation studies of fission fragments and prompt γ-rays from thermal neutron induced fission in ^{235}U, Hoffman (31) concludes that the observations indicate an average angular momentum in fission fragments (after neutron emission) of 6 to 8 units. The initial angular momentum distribution required to account for observed isomer ratios in fission has been calculated by Warhanek and Vandenbosch (32) using the Huizenga–Vandenbosch model (29, 30). Basing their calculations on the measured ratio of the ^{134}Cs isomers and assuming that the primary fragments have an angular distribution of the following form

$$[6] \qquad N(J) = (2J + 1) \exp\left[- \frac{J(J + 1)}{2b^2} \right]$$

they obtain a value of about 7.4 for the root mean square angular momentum

$$\sqrt{(\overline{J^2})} = b\sqrt{2}.$$

In connection with the present problem it should be kept in mind that the number of neutrons emitted from the prompt fragments leading to ^{124}Sb, ^{126}Sb, and ^{134}Cs is about the same (6, 9) and that the results of Warhanek and Vandenbosch (32) show very little difference if 1 or 2 neutrons are assumed to be emitted. Furthermore, the nuclides considered are all of the same nuclear type (odd–odd) and the spins involved very similar. Those of ^{134}Cs are measured as 4 and 8 for the ground and excited state, respectively (27).

Hoffman (31) has, however, also shown that one should expect the angular momentum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of prompt fragments to increase with their kinetic energy. The latter is somewhat higher in the 134 mass region than in the region of interest for the present work. Therefore it is probably reasonable to assume that the prompt fragments leading to ^{124}Sb and to ^{126}Sb have an angular distribution characterized by $\sqrt{(\overline{J^2})} = 6.5$. One neutron with energy 1 MeV is assumed to be emitted from these fragments.

The probability of a state with angular momentum J_c to emit a neutron with orbital angular momentum l and energy E leading to a final state J_t is expressed by (30):

$$[7] \qquad P(J_t) \propto \rho(J_t) \sum_{S=|Jt-\frac{1}{2}|}^{J_t+\frac{1}{2}} \sum_{l=|Jc-S|}^{J_c+S} T_l(E).$$

The barrier transmission coefficient $T_l(E)$ for a 1 MeV neutron with angular momentum l is taken from the curves by Feld *et al.* (33). $\rho(J_t)$ is the density of levels with spin J_t, given by

$$[8] \qquad \rho(J_t) = \rho(0)(2J_t + 1) \exp\left[-(J_t + \tfrac{1}{2})^2/2\sigma^2\right]$$

where $\rho(0)$ is the density of levels with zero spin. The parameter σ characterizes the distribution function and the value of $\sigma = 3$ was chosen as this is known to give a reasonable fit to experimental data (30).

In accordance with Warhanek and Vandenbosch (32) it is expected that the fragments decay either to high or low spin states predominantly by dipole radiations and that the number of γ-rays emitted will be between 2 and 3. Therefore, in the present calculations two dipole radiations followed by a third γ-ray are assumed to take place, the latter having the lowest multipolarity necessary to reach the final state concerned. The relative probability for a nucleus with spin J to decay by dipole radiation to states with spin $J - 1$, J, and $J + 1$ is given by the level density factor in eq. [8].

The computer programme given by Hafner, Huizenga, and Vandenbosch (34) for calculating isomer yield ratios was used. The distribution to be expected after emission of one neutron and two γ-rays is given in Table III. The third and final γ-emission is then assumed to populate the states in the final isomers as follows:

TABLE III

Distribution of states after emission of one 1 MeV neutron and two dipole radiations from an initial distribution characterized by $\sqrt{(\overline{J^2})} = 6.5$

	Final spin						
	0–2	3	4	5	6	7	8–13
Probability of state being populated	0.05	0.11	0.25	0.32	0.12	0.08	0.07

A state in Table III *exactly* half-way between two final states is assumed to populate both to the same amount. All other states in Table III are assumed to populate the closest final state. The populations thus obtained are given in Table IV.

If one takes into consideration the branched decays of the isomeric states (Figs. 1 and 2) the amount of ^{124}Sb counted as the long-lived isomer ^{124g}Sb is 0.82. For ^{126}Sb one finds that 0.28 is counted as ^{126g}Sb.

The total independent yields thus obtained are given in Table V. In the values given the uncertainty in branching and population of states is indeterminate for both species.

TABLE IV

Population of isomeric states in ^{124}Sb and ^{126}Sb
(g = ground state, m = metastable state)

State	^{124}Sb	^{126}Sb
3−	0.28 g	
5+	0.57 m_1	0.85 m
8−	0.15 m_2	0.15 g

TABLE V

Total independent fission yields of ^{124}Sb and ^{126}Sb

	Nuclide	
	^{124}Sb	^{126}Sb
Independent yield (%)	$(1.16\pm0.17)\cdot10^{-5}$	$(3.72\pm0.61)\cdot10^{-3}$
Chain yield (%)	$1.7\cdot10^{-2}$	0.10
Fractional independent yield	$(6.8\pm1.0)\cdot10^{-4}$	$(3.7\pm0.6)\cdot10^{-2}$

The Z_p Function

The cumulative yields for mass chains 124 and 126 are respectively $1.7\cdot10^{-2}$% and 0.10% (14). With these values the fractional independent fission yields of ^{124}Sb and ^{126}Sb (all isomers) are obtained and given in Table V. Assuming that the empirical charge distribution curve given by eq. [1] also is valid in this mass region one obtains:

$$Z_p = 48.49 \pm 0.20 \text{ for } A = 124$$

$$Z_p = 49.39 \pm 0.14 \text{ for } A = 126.$$

The limits reflect either the uncertainty in the constant c in eq. [1] or the errors assigned to the independent yields, whatever has the largest effect. The prompt masses A' corresponding to final masses A are obtained by use of the "smoothed" equations given by Wahl *et al.* (1) for the neutron emission from a fission fragment as a function of final mass. This has the following form for the heavy fragments:

[9] $$\nu_h = 0.531\nu + 0.062(A_h - 143).$$

Using $\nu = 2.50$ as the total number of neutrons emitted in thermal neutron fission of ^{235}U, one obtains

$$A_{124}' = 124.2 \text{ and } A_{126}' = 126.3.$$

Recently Troutner, Wahl, and Ferguson (35) have been able to measure the fractional independent yield of the 3.9 d ^{127}Sb and report a value $(5.7 \pm 1.0)\cdot10^{-2}$. The most probable primary charge is therefore $Z_p = 49.5 \pm 0.1$ for $A' = 127.3$.

In Fig. 3 these new data are plotted in the Wahl type of plot. All previously known data (1) are included, but limits given only to the new values. The solid curve represents the empirical Z_p function as given by Wahl *et al.* (1).

The information available in 1962 on the most probable primary charge evaluated from independent and cumulative fission yields indicated that the empirical Z_p function might follow the $Z = 50$ line and thus be strongly influenced by the closed shell of 50 protons (1). A greater preference in fission for isotopes of Sn ($Z = 50$) rather than for low Z elements could be one of two possible explanations to the observed minimum in the total kinetic energy distribution of fission fragments in near symmetric fission (9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

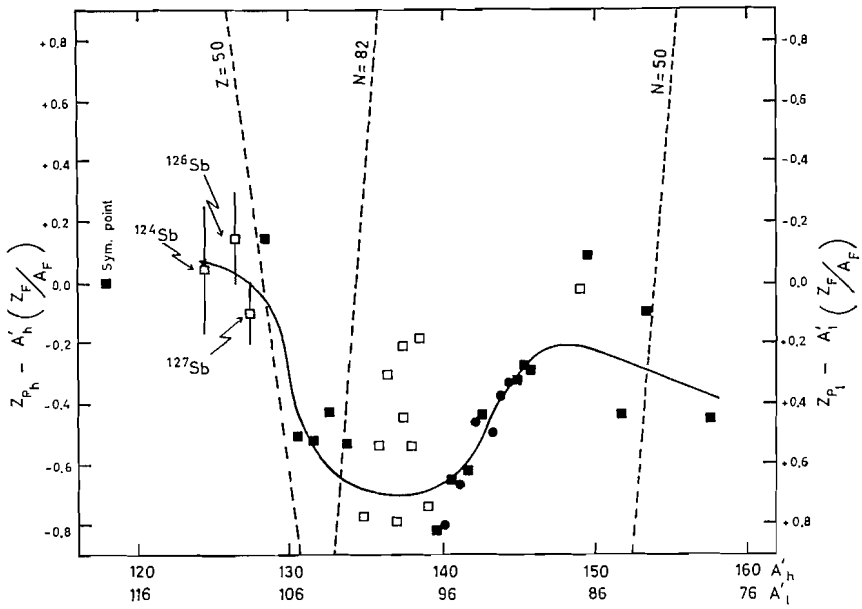

FIG. 3. Wahl plot including data for ^{124}Sb, ^{126}Sb (this work), and ^{127}Sb (35): ● = based on two or more fractional yield values; ■ = based on fractional yield of one fission product not close to a shell edge; □ = based on fractional yield of one fission product within ±1 charge or neutron number of a major closed shell or its complement.

Preference for a 50 proton shell effect might also be drawn from other experimental evidence, as discussed in the paper by Wahl *et al.* (1).

The aim of this investigation was to obtain additional information on this question by "measuring" Z_p values in the region of interest. According to the data plotted in Fig. 3, however, it seems unlikely that the 50 proton shell has as large an effect on the Z_p function as earlier suggested. The Z_p function seems to cross the $Z = 50$ line at a rather high mass number ($A' \sim 128$).

Before proceeding further in the discussion, however, attention should be drawn to an important point in the presentation of the data where our knowledge today is much more detailed than in 1962. This concerns the average number of neutrons emitted from individual fission fragments. As these enter strongly in the $[Z_p - A'(Z_t/A_t)]$ function the results in Fig. 3 might be considerably changed in a more detailed study.

On the basis of the data presented by Terrell (36) and his suggestion that neutron emission is primarily a function of fragment mass and not of mass ratio, Milton and Fraser (9) gave a neutron emission curve applicable to all fissioning nuclei. These authors have quite recently (37) also given further evidence for the general applicability of this curve. The curve is replotted in Fig. 4 for neutron emission as a function of residual mass A. In the same figure are also drawn the functions (linear) used by Wahl *et al.* (1). The latter was based on the overall trend of the neutron emission data, but as can be seen there are in reality large local deviations. The largest deviation is found in the mass region 112 to 130, i.e. just in the region where proton shell effects are discussed. It should, however, be pointed out that the original Milton–Fraser curve was interpolated in this region, but that recent measurements by Apalin *et al.* (38) have proved this proper and heavily supports the curve as drawn in Fig. 4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

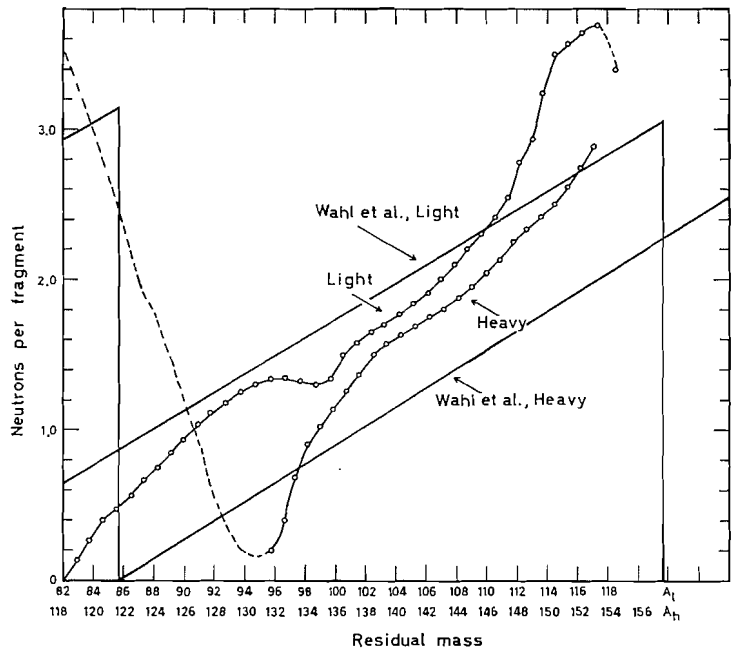

FIG. 4. Neutron emission as function of residual mass, adapted from ref. 9.

The empirical Z_p values from ref. 1 together with the additional values are replotted in Fig. 5, where the solid line A represents the Z_p function from ref. 1 (cf. Fig. 3). The general trend does not seem to have changed at high mass ratios (to the right of the $N = 82$ line). But the new curve rises from its minimum around mass ratio 1.4 more sharply than the old one as if it is "feeling" the approach of the $Z = 50$ shell. This does, however, not last long. At mass ratio 1.3 the curve turns and breaks through the 50 shell (around mass ratio 1.2) whereafter it seems to be heading towards the point of symmetry. Thus it should be concluded that there seems to be a rather limited effect of the 50 proton shell on the Z_p curve.

Therefore the dip in the kinetic energy distribution near symmetric fission should not be explained by a 50 proton shell effect, but should be sought in the large amount of energy going into excitation energy in near symmetric fission fragments, resulting in the emission of a large number of neutrons from these fragments as also observed by Apalin *et al.* (38). This explanation was also given as an alternative by Milton and Fraser (9); however, while this paper was being written (1964), they chose the latter alternative and abandoned the 50 proton shell effect (39).

The conclusions, arrived at in the present study, are supported by the recent determination of the fractional independent yield of ^{121}Sn measured by Wahl and Nethaway (40), 0.07 ± 0.10 or ≤ 0.17. These authors conclude that the value of Z_p is definitely less than 50, thus no proton shell effect seems present at such low masses as $A = 121$.

The discoverers of the double closed shell nuclide $^{132}_{50}Sn_{82}$, Pappas and Wiles (41) and others, expected this nuclide to be especially favored in the fission act due to its special structure. The Z_p value 51.26 reported by Wahl *et al.* (1) for mass number 132 does not seem to support this view. The independent yield, however, used in ref. 1 for estimating Z_p is that for ^{132}Te as reported by Pappas (3), obtained as the difference between measured

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

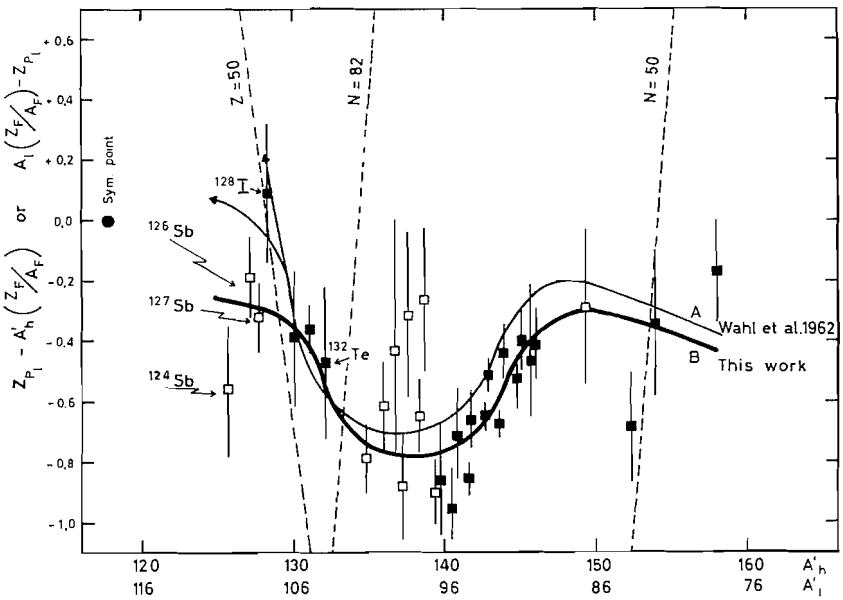

FIG. 5. Revised Wahl plot of empirical Z_p values: ■ = based on fractional yields of fission products not close to a shell edge; □ = based on fractional yield of one fission product within ±1 charge or neutron number of a major closed shell or its complement.

cumulative yields of ^{132}Te and ^{132}Sb. While it was possible in ref. 3 to measure the former to a high degree of accuracy, the latter could only be measured very crudely to ≈ 3%. Improved measurements of the cumulative yield of ^{132}Sb (i.e. cumulative yield of ^{132}Sn and independent yield of ^{132}Sb) are now made available through measurements by Greendale *et al.* (42) who report 3.4 ± 0.4%. With this value together with the chain yield for 132 the corrected fractional independent yield for ^{132}Te is 0.23 ± 0.09. On this basis a value of Z_p = 51.0 ± 0.3 is obtained for mass number 132 (prompt mass 132.2) in agreement with the curve drawn in Fig. 5.

In recent studies Greendale *et al.* (42) have been able to measure the cumulative yield of ^{132}Sn and the independent yields of ^{132}Sb and ^{132}Te. These three values are not inconsistent with the "unique" charge distribution curve of Wahl, but substantially narrower than the empirical curve (2) previously often used in charge distribution studies. As no perturbations are disclosed in the 132 mass chain no effect of double closed shell is indicated.

This leads to the point in Fig. 5 representing ^{128}I, the only nuclide with a strong indication of a 50 proton shell effect. The fact, however, that ^{128}I possesses high independent yield in thermal fission of ^{233}U, ^{235}U, and ^{239}Pu (8) supports an exceptional behavior of this nuclide; a behavior which needs further investigation, as the probability of variations in the width of the charge distribution curve might be especially high in the vicinity of the 50 proton – 82 neutron shell. Conceivably the charge distribution curve may even lack symmetry in this region. In this connection it should be realized that it is just those nuclides that have a nuclear composition within one proton or neutron number removed from a major nuclear closed shell or its complement (indicated by open squares in Fig. 5) that show the greatest scatter in the Wahl type of presentation. This is very likely more than just coincidence.

SYNTHESIS OF 4-*O*-β-D-GALACTOPYRANOSYL-D-GALACTOSE

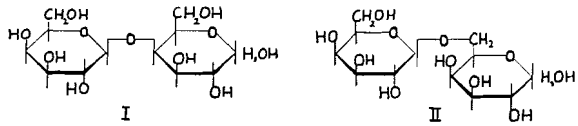
E. J. C. CURTIS AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario
Received May 3, 1965

ABSTRACT

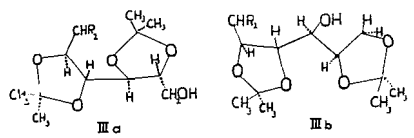
The disaccharide named in the title, 6-*O*-β-D-galactopyranosyl-D-galactose, and the 2(?)-substituted isomer have been synthesized in low yield by the condensation of acetobromo-D-galactose and di-*O*-isopropylidene-aldehydo-D-galactose dimethyl acetal.

INTRODUCTION

The two disaccharides 4-*O*-β-D-galactopyranosyl-D-galactose (I) and 6-*O*-β-D-galactopyranosyl-D-galactose (II) have been isolated from the partial hydrolysis products of



polysaccharides (1, 2). The disaccharide (II) had earlier been synthesized by the condensation of acetobromo-D-galactose with 1,2;3,4-di-*O*-isopropylidene-D-galactose followed by acidic hydrolysis of the isopropylidene residues (3). We now report the synthesis of both II and I. Previous work (4) had shown that acetobromo sugars will readily form glycosides with acyclic sugar derivatives which possess a free hydroxyl group. In the present study aldehydo-D-galactose diethyl dithioacetal (5) was condensed with acetone to yield a mixture containing the 2,3;4,5-(III*a*, R = SEt) and 2,3;5,6-di-*O*-isopropylidene (III*b*, R = SEt) derivatives (cf. the formation of α- and β-di-*O*-isopropylidene-dulcitols



(6)). These thioacetals were readily converted (7) to the mixture of dimethyl acetals (III*a*, III*b*) (R = OMe) which was purified by distillation. Condensation of the dimethyl acetals with acetobromo-D-galactose gave the disaccharide derivatives. After removal of acetyl and isopropylidene residues the mixture of sugars was fractionated first on a charcoal column (8) and then on cellulose (9).

The 1,6-linked disaccharide, the major product, was eluted last in a pure form. It was indistinguishable from an authentic specimen and gave a phenylosazone which was identical with a specimen prepared from the authentic sugar. The fastest-moving fraction on chromatograms was a disaccharide which was provisionally identified as the 1,2-linked isomer since it gave a negative tetrazolium red test (10). The 1,4-linked disaccharide was eluted after this material.

The 1,2(?)-linked isomer was a syrup; it did not give a crystalline phenylosazone; it consumed rapidly 3 moles of periodate and gave rapidly 1.5 moles of formic acid. The sugar underwent overoxidation, the extrapolated values for consumption of periodate and molar yields of formic acid being 4.2 and 3.1 per mole of sugar respectively (Table

I). The disaccharide after reduction with sodium borohydride was oxidized with sodium metaperiodate and then consumed 4.9 moles of periodate and produced 2.8 moles of formic acid per mole of sugar, with no overoxidation (Table II). The values expected from the oxidation of 1 → 2 linked disaccharide are 5 moles and 3 moles respectively.

The 4-*O*-β-D-galactopyranosyl-D-galactose fraction was crystalline and was indistinguishable from an authentic specimen. On oxidation with sodium metaperiodate it yielded 1.7 moles of formic acid and consumed 3.9 moles of metaperiodate per mole. The values expected from a 1 → 4 linked disaccharide are 2 moles and 4 moles respectively (Table III). The yield of formic acid is probably low because of the formation of formyl esters.

EXPERIMENTAL

Paper chromatography was carried out at room temperature on Whatman No. 1 filter paper using the descending method. The following solvent systems were used.

(A) Ethyl acetate:acetic acid:water (9:2:2 v/v)

(B) Butan-1-ol:ethanol:water (3:1:1 v/v)

Sugars were located on chromatograms by spraying either with *p*-anisidine hydrochloride (1% w/v) in butan-1-ol or with silver nitrate in acetone followed by sodium hydroxide in ethanol.

Solutions were concentrated at 40°, under reduced pressure using a water pump. Optical rotations were measured at room temperature either in water or in a specified solvent. All melting points are uncorrected.

*Di-O-isopropylidene-*D*-galactose Diethyl Dithioacetal*

D-Galactose diethyl dithioacetal (71 g) was added to a cold solution of dry acetone (1 l) which contained dry hydrogen chloride (36 g). The mixture was shaken until solution was complete (20 h). After an additional 16 h the solution was neutralized ($PbCO_3$) and filtered, and the filtrate was evaporated to a syrup (92 g).

*Di-O-isopropylidene-*D*-galactose Dimethyl Acetal*

A portion (37 g) of the above dithioacetal derivative plus cadmium carbonate (70 g) was added to dry methanol (250 ml). The resulting mixture was stirred vigorously while a solution of mercuric chloride (80 g) in dry methanol (250 ml) was added portionwise during 22 h. The mixture was then heated under reflux for 6 h. The hot solution was filtered and the solids were washed with hot methanol. The filtrate and washings were concentrated to a small volume and the residue was diluted with chloroform (400 ml). The chloroform solution was extracted with water until it was free of chloride and was then dried over calcium chloride. The solution was passed down a column of activated alumina to remove color and the effluent was evaporated to a syrup. The product was distilled and a fraction (12 g) of b.p. 134–138° at 0.4 mm was collected.

Anal. Calcd. for $C_{14}H_{26}O_7$; C, 54.9; H, 8.5; OMe, 20.2. Found: 54.7; H, 8.5; OMe, 19.8.

*Condensation of Di-O-isopropylidene-*D*-galactose Dimethyl Acetal with Acetobromo-*D*-galactose*

The dimethyl acetal (5.8 g, 0.019 mole) was dissolved in dry, alcohol-free chloroform (40 ml), and silver carbonate (27 g) and Drierite (23 g) were added and the mixture was shaken in the dark at room temperature.

After 3.5 h a solution of acetobromo-D-galactose (11.5 g; 0.028 mole) in dry alcohol-free chloroform (50 ml) plus a few crystals of iodine were added and shaking was then continued. After 23 h a further quantity of acetobromo-D-galactose (7 g, 0.017 mole) in dry chloroform (20 ml) plus Drierite (3.5 g) were added. After 5 days the test for ionizable bromine was negative. The mixture was filtered through a pad of Celite which was washed with chloroform. The filtrate and washings were concentrated and the residual syrup (23 g) was dissolved in dry methanol and the product de-*O*-acetylated by the addition of a catalytic quantity of sodium methoxide in methanol. The solution was evaporated, and the residue was hydrolyzed with warm sulfuric acid (0.1 *N*) until isopropylidene residues had been removed from the sugars. The solution was neutralized ($BaCO_3$) and filtered, and the filtrate was evaporated to a syrup (19 g). Chromatography showed the presence of galactose (mainly) and four components of R_{gal} 3.0, 0.21, 0.32, and 0.64 (solvent A), the last two being present in small amounts only. The fast-moving material presumably still contained isopropylidene or acetate residues.

The syrup was fractionated on a column of charcoal (4.5 × 15 cm). Elution with water removed the bulk of the monosaccharide material, and elution with 5% ethanol:water mixture removed the slower-moving compounds. These were fractionated on a cellulose column (45 × 4.5 cm) using *n*-propanol:ethanol:water (7:1:1 v/v) as solvent.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In this fashion pure *6-O-β-D-galactopyranosyl-D-galactose* (1.09 g) with R_{gal} 0.21 (solvent A) and 0.20 (solvent B) was obtained. Acid hydrolysis (*N* sulfuric acid at 80° for 15 h) of a portion of the sugar gave galactose only. The disaccharide was crystallized from methanol containing a small percentage of butan-1-ol. The product which contained methanol of crystallization melted at 120–121° and had $[\alpha]_D$ +24° (5 min) → +29° (constant value) (*c* 2.37 in H_2O). The sugar gave a phenylosazone m.p. 207° (decomp.) indistinguishable, by infrared analysis, from an authentic specimen.

A fraction (0.8 g) which had preceded 6-*O*-β-D-galactopyranosyl-D-galactose was a mixture. It was refractionated on Whatman 3MM paper to yield *2(?)-O-β-D-galactopyranosyl-D-galactose*, a syrup (0.13 g) which had $[\alpha]_D$ +35° (*c*, 0.285 in water) and R_{gal} 0.64 (solvent A) and 0.48 (solvent B). Hydrolysis of a portion of this disaccharide with acid gave galactose only. The alkaline triphenyltetrazolium red test (10) was negative under conditions which gave a positive test with D-galactose and 6-*O*-β-D-galactopyranosyl-D-galactose.

Periodate Oxidation of the Syrup

A portion (10.2 mg) of the syrup was oxidized with 0.3 *M* sodium metaperiodate (2 ml) in a total volume of 10 ml. Uptake of metaperiodate and production of formic acid were measured in the usual way.

TABLE I

Periodate oxidation of 2(?)-*O*-β-D-galactopyranosyl-D-galactose

Time	Periodate uptake (moles/mole of sugar)	Formic acid (moles/mole of sugar)
10 min	0.97	0.39
30 min	1.73	0.65
1 h 20 min	2.59	0.99
2 h 30 min	3.19	1.21
4 h 40 min	3.63	1.64
18 h 35 min	4.98	3.06
20 h 50 min	5.27	3.25

Periodate Oxidation of 2(?)-O-β-D-galactopyranosyl-D-galactitol

The sugar (24 mg) was dissolved in water (5 ml) and reduced with sodium borohydride (30 mg) added in two portions over 3 h. The excess of sodium borohydride was destroyed (acetic acid), the solution was deionized (Amberlite IR120 resin) and concentrated, and the boric acid was removed from the residue as methyl borate. The residue (21 mg) did not give a color with the *p*-anisidine hydrochloride spray. A portion of the product (8.5 mg) was oxidized as described above.

TABLE II

Periodate oxidation of 2(?)-*O*-β-D-galactopyranosyl-D-galactitol

Time	Periodate uptake (moles/mole of sugar)	Formic acid (moles/mole of sugar)
10 min	3.44	1.82
30 min	3.85	1.96
1 h 0 min	4.40	2.21
2 h 0 min	4.70	2.43
4 h 0 min	4.94	2.61
6 h 0 min		2.71
19 h 0 min	5.05	2.77
22 h 10 min		2.77
24 h 30 min	5.06	2.79

A second fraction (0.29 g) isolated from the 3MM paper was identified as *4-O-β-D-galactopyranosyl-D-galactose*. It crystallized on nucleation with an authentic specimen and was recrystallized from methanol. It had m.p. 200–202°, not depressed with an authentic specimen (m.p. 204°) and had $[\alpha]_D$ +63° → +69° constant value (*c*, 0.32 in water). Its rates of movement on chromatograms were indistinguishable from authentic specimens, R_{gal} 0.32 (solvent A) and 0.21 (solvent B).

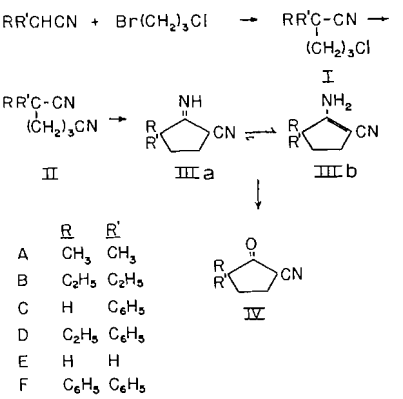
SYNTHESIS OF 2,2-DISUBSTITUTED-5-CYANOCYCLOPENTANONES[1]

STUART S. KULP,[2] VELMER B. FISH, AND NELSON R. EASTON[3]
Wm. H. Chandler Chemistry Laboratory, Lehigh University, Bethlehem, Pennsylvania
Received April 21, 1965

ABSTRACT

The synthesis of a series of 2,2-disubstituted-5-cyanocyclopentanones by hydrolysis of the precursor 3,3-disubstituted-2-amino-1-cyanocyclopentenes (2,2-disubstituted-5-cyanocyclopentanoneimines) is described. The new compounds possess the following substituents: dimethyl, diethyl, phenyl hydrogen, and ethyl phenyl.

The difficulty in hydrolyzing 2,2-diphenyl-5-cyanocyclopentanoneimine to 2,2-diphenyl-5-cyanocyclopentanone (1) led us to the preparation of other compounds of this series and a study of the hydrolyses of these materials. The synthetic approach is outlined in Scheme 1. The new compounds reported here involve the preparation of IV A–D.



SCHEME 1.

The intermediate chloro compounds (I) were obtained by alkylation of the appropriately substituted acetonitrile with 1-bromo-3-chloropropane at −70°. When the dihalide was added at 0°, both halogens were replaced and dicondensation to a substituted pimelonitrile occurred. This is in contrast to the alkylation of diphenylacetonitrile which gave IF in quantitative yield at 0° (1). The dicondensation product from dimethylacetonitrile was 2,2,6,6-tetramethylpimelonitrile which was characterized and hydrolyzed to its corresponding diamide and diacid.

The dinitriles (II) were prepared by treating the chloro nitriles (I) with potassium cyanide. The dinitriles were characterized by hydrolyzing IIA to the amide acid, IIB to its amide acid and diacid, and IIC to its diamide.

Cyclization of the dinitriles (II) was best accomplished with sodium hydride in dioxane. The alicyclics obtained (III A–D) are best represented as enamines (III*b*) rather than iminonitriles (III*a*) as previously found for IIIE (2). These compounds are listed in Table I.

†The 2,4-dinitrophenylhydrazone melted at 204°. Anal. Calcd. for $C_{18}H_{18}N_5O_4$: C, 59.17; H, 4.14; N, 19.17. Found: C, 59.35; H, 4.20; N,19.25.

Hydrolyses of the enamines (III) proceeded readily to the α-cyanocyclopentanones (IV A–D) which is in marked contrast to the findings with the diphenyl analog (IVF) (1). The keto nitriles IV A–D are listed in Table II. Only the dimethyl (IVA) and the monophenyl (IVC) ketones formed 2,4-dinitrophenylhydrazones under the usual conditions.

Additional evidence for the anomalous behaviour of the *gem*-diphenyl enamine (IIIF), previously ascribed to steric hindrance, was sought. The infrared and ultraviolet spectra of compounds III A–F are listed in Table III and show no significant deviation from those reported for the parent compound (IIIE) (2). Likewise, the infrared spectra of IV A–F

about 264 mμ in basic ethanolic solution; however, IVD and IVF have peaks at 270 and 278 mμ under these conditions. Thus, the bathochromic shift of about 29 mμ in changing from neutral to basic solution is comparable to shifts of 36 and 31 mμ as noted for other β-keto nitriles (3).

The enolization of the β-keto nitriles will be reported later.

EXPERIMENTAL

All melting points were determined in an oil bath and are uncorrected. Ultraviolet spectra were determined with a Warren Spectracord in 95% alcohol. Infrared spectra were determined on a Perkin–Elmer model 21 instrument in $CHCl_3$ solution.

5-Chloro-2,2-dimethylpentanenitrile (IA)

An ether solution of 1 mole of the lithium salt of dimethylacetonitrile was prepared from lithium diethylamide as described previously (5). After cooling to −70°, 1 mole of 1-bromo-3-chloropropane was added dropwise over 1 h at a rate to maintain the reaction temperature below −60°. The mixture warmed to room temperature overnight as the acetone – dry ice bath evaporated. After refluxing for 1 h, cooling, and decomposition in the usual manner, the solvent was removed. The remaining liquid was heated to 70° at 20 mm and the crude residue, 136 g (93%), was satisfactory for further synthesis. The following analogs were prepared: IB-diethyl, 70%, b.p. 123° at 10 mm; IC-phenyl, 81%; ID-ethyl-phenyl, 68%, 145–147° at 2 mm.

Addition of the 1-bromo-3-chloropropane to the reaction mixture at 0° gave a quantitative amount of dicondensation product, 2,2,6,6-tetramethylpimelonitrile, m.p. 118–119° from methanol.

Anal. Calcd. for $C_{11}H_{18}N_2$: C, 74.11; H, 10.18. Found: C, 74.20; H, 10.02.

2,2,6,6-Tetramethylpimelamide

Hydrolysis of the pimelonitrile with 80% sulfuric acid on a steam bath for 3 h gave a white solid, m.p. 193–194°.

Anal. Calcd. for $C_{11}H_{22}O_2N_2$: N, 13.05. Found: N, 12.97.

2,2,6,6-Tetramethylpimelic Acid

The above pimelamide gave the diacid by the butyl nitrite procedure (6). The m.p. was 168–169.5° from methanol.

Anal. Calcd. for $C_{11}H_{20}O_4$: C, 61.15; H, 9.32. Found: C, 61.25; H, 9.10.

Attempts to prepare this diacid by basic hydrolysis of either the precursor dinitrile or diamide were unsatisfactory

2,2-Dimethyladiponitrile (IIA)

A mixture of 55 g (1.41 mole) of sodium cyanide in 125 ml of dimethylformamide and 1 ml of water was stirred under reflux. To this was added 125 g (0.86 mole) of crude 5-chloro-2,2-dimethylpentanenitrile over 0.4 h. After refluxing for 2 h the mixture was cooled slightly and 25 ml of water was added. The mixture was refluxed 0.5 h, cooled, poured into a large volume of water, and allowed to stand overnight. The layers were separated, the aqueous layer was extracted with ether, and the combined organic layers were washed with ice-cold 50% sulfuric acid. The ether layer was dried over magnesium sulfate and filtered, and the solvent was distilled and gave a clear distillate, b.p. 145–151° at 14 mm with only a slight forerun and about 8 g of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

residue. The product weighed 93 g (80%). The following analogs were prepared: IIB-diethyl, b.p. 144–146° at 5 mm, 76%; IIC-phenyl, b.p. 170° at 0.5 mm, 60%; IID-ethyl-phenyl, b.p. 180–200° at 3 mm, 52%, after standing several days this oil solidified, m.p. 45.5–47°.

5-Carbamoyl-5,5-dimethylpentanoic Acid

Hydrolysis of IIA with 80% sulfuric acid on a steam bath for 3 h gave a white solid, m.p. 159–161°. Recrystallization from ethyl acetate with a little methanol gave m.p. 160.5–161°.

Anal. Calcd. for $C_8H_{15}O_3N$: N, 8.10. Found: N, 8.19.

5-Carbamoyl-5,5-diethylpentanoic Acid

A mixture of 300 g of IIB and 1 500 ml of 80% sulfuric acid was heated at 110° for 16 h. Sufficient water was cautiously added to decrease the sulfuric acid concentration to about 50%. This mixture was heated at 110° for 24 h, poured on crushed ice, and allowed to stand for 3 days. The solid was collected and dissolved in sodium hydroxide; acidification gave a dark brown solid. Recrystallization from methanol with charcoal did not improve the quality of the product. The solid was distilled, b.p. 190–200° at 0.1 mm. This distillate after two recrystallizations from methanol melted at 152–153.5°.

Anal. Calcd. for $C_{10}H_{19}O_3N$: N, 6.97. Found: N, 6.97.

2,2-Diethyladipic Acid

Obtained from the above amide-acid by the butyl nitrite procedure (6). The crude product, m.p. 99–102°, after three recrystallizations from methanol–water had constant m.p. 102.5–103.5° (reported (7) 90–92°).

Anal. Calcd. for $C_{10}H_{18}O_4$: C, 59.40; H, 8.96. Found: C, 59.40; 59.50; H, 8.83, 8.95.

The infrared spectrum ($CHCl_3$ solution) was in agreement with this structure.

2-Phenyladipamide

A small sample of IIC was treated with 30% hydrogen peroxide and sodium hydroxide (8) and melted at 171–171.5°.

Anal. Calcd. for $C_{12}H_{16}O_2N_2$: C, 65.43; H, 7.32; N, 12.72. Found: C, 65.50; H, 7.63; N, 12.72.

3,3-Dimethyl-2-amino-1-cyanocyclopentene (IIIA)

A suspension of 12 g (0.55 mole) of active sodium hydride (added as 50% dispersion in oil) and 250 ml of dry dioxane was vigorously stirred under reflux in a large 3-neck flask equipped as usual. To this was added 66 g (0.48 mole) of 2,2-dimethyladiponitrile very carefully over 1.5 h. The mixture was refluxed an additional 3 h and then cooled in ice. Water was added cautiously, acetic acid was added to acidify, and the mixture was allowed to stand in ice overnight. The crude brown solid, 60 g (90%), had m.p. 106–108°. Recrystallization raised the melting point to the value reported in Table I. Compounds III B–D were similarly prepared.

5-Cyano-2,2-diethylcyclopentanone (IVB)

A mixture of 30 g (0.18 mole) of IIIB, 15 ml of concentrated HCl (0.18 mole), 85 ml of 8 *N* sulfuric acid, and 100 ml of toluene was heated under reflux for 1 h. The toluene layer was separated, washed with water, and extracted with 10% sodium hydroxide. The aqueous basic solution was cooled and acidified, and the acid solution was extracted with ether. The ether solution was dried (magnesium sulfate), filtered, concentrated, and distilled to give the product reported in Table II. Compounds IVA, IVC, and IVD were similarly prepared.

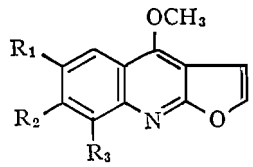
MASS SPECTRA OF SOME FUROQUINOLINE ALKALOIDS

D. M. CLUGSTON AND D. B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ontario
Received May 7, 1965

ABSTRACT

The mass spectra of six furoquinoline alkaloids have been recorded and mechanisms have been proposed for their fragmentation upon electron impact. Strong metastable peaks, present in all spectra, have aided in the interpretation of the fragmentation of these alkaloids. The three alkaloids with a methoxyl group in the 8-position of the quinoline ring may be differentiated from the other three by the presence of relatively intense peaks at M-1 and M-29.

In this investigation we wish to report upon the fragmentation of some furoquinoline alkaloids upon electron impact. The alkaloids which we have examined include dictamnine I and several of its derivatives containing methoxy and methylenedioxy substituents in the benzenoid ring. They are represented in the general formula shown below.



I. Dictamnine	$R_1 = R_2 = R_3 = H$
II. Maculine	$R_1 = R_2 = —OCH_2O—$, $R_3 = H$
III. Kokusaginine	$R_1 = R_2 = OMe$, $R_3 = H$
IV. Skimmianine	$R_2 = R_3 = —OCH_3$, $R_1 = H$
V. Maculosidine	$R_1 = R_3 = —OCH_3$, $R_2 = H$
VI. Flindersiamine	$R_1 = R_2 = —OCH_2O—$, $R_3 = OCH_3$

The spectra of furan and some of its derivatives have been studied (1, 2) but very little has been reported on the spectra of quinoline and its derivatives (3). No studies to our knowledge have been reported on the furoquinoline system itself. Oxygenated benzene systems have, however, been investigated in detail (2, 4, 5) and since all of these alkaloids with the exception of dictamnine carry oxygenated substituents in the benzene ring one might expect to observe fragmentation processes akin to those of the oxygenated benzenes.

The spectra of the six alkaloids are shown in Fig. 1. All show an intense molecular ion peak as one would expect of this aromatic system. In each case they also exhibit a peak at M-15 owing to the loss of a methyl group characteristic of the presence of methoxyl substituents. Of structural interest is the fact that the three alkaloids with an 8-methoxyl substituent show strong peaks at M-1 and M-29. This behavior is also characteristic of 8-methoxy quinolines which we have measured in this laboratory. It seems very likely, therefore, that an 8-methoxyl substituent will give this characteristic pattern in all furoquinoline alkaloids.

In attempting to rationalize the fragmentation of these alkaloids we have first examined the spectrum of dictamnine, the simplest member of the group, and have then examined the spectra of the other alkaloids to ascertain if they undergo similar fragmentation processes.

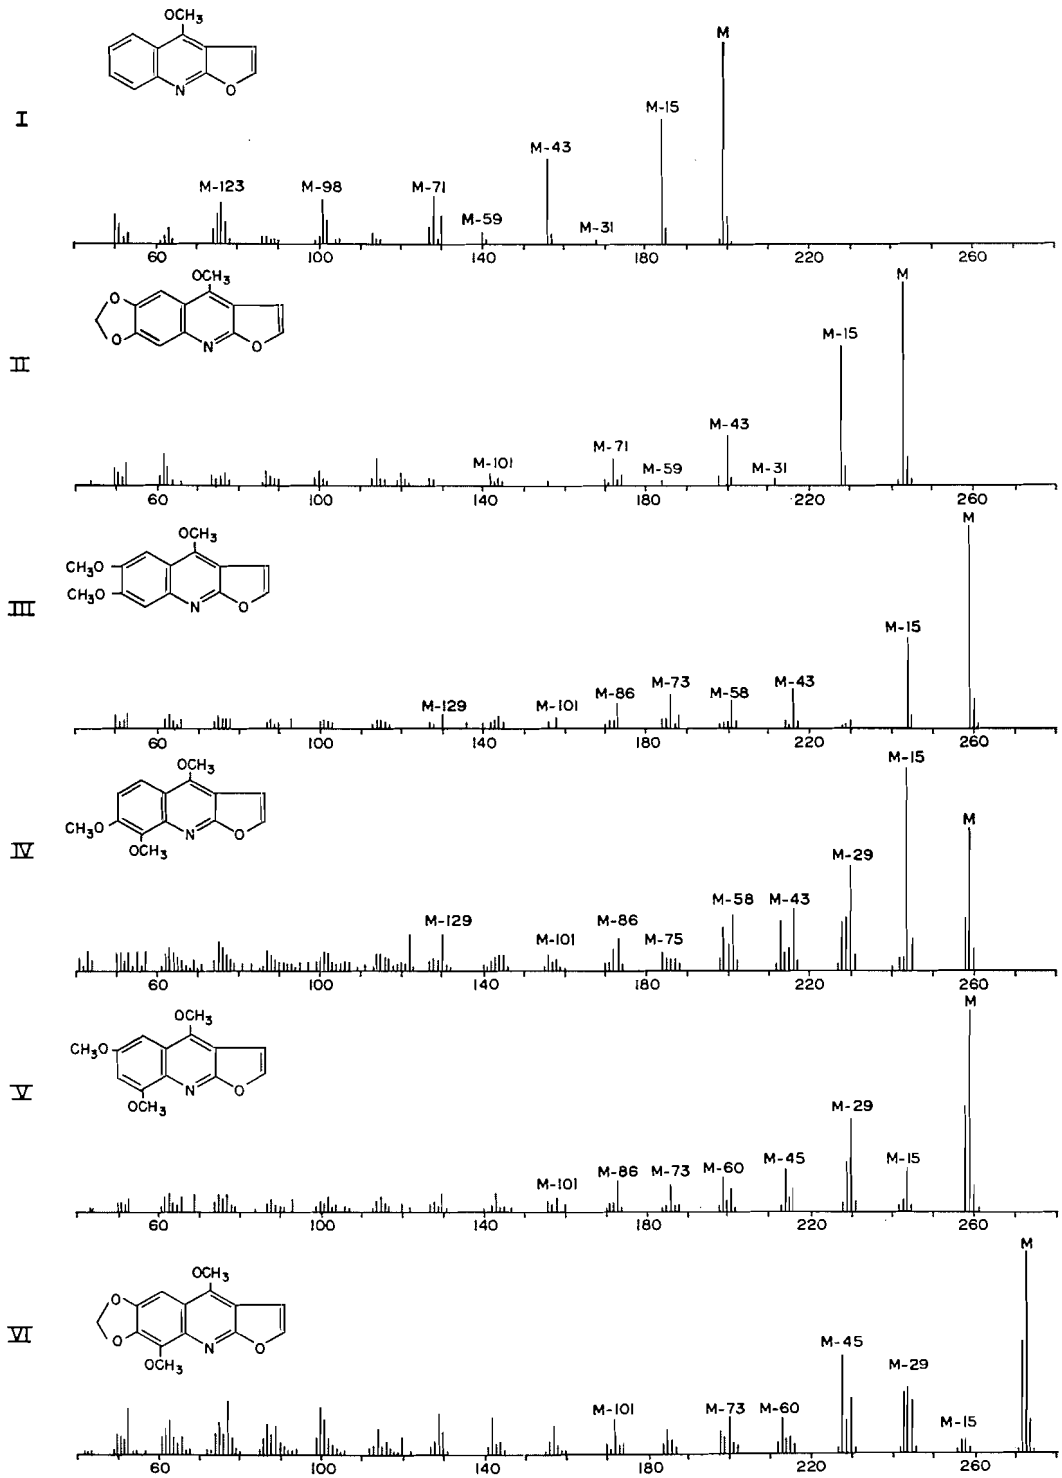

FIG. 1. Mass spectra of I, dictamnine, mol. wt. = 199; II, maculine, mol. wt. = 243; III, kokusaginine, mol. wt. = 259; IV, skimmianine, mol. wt. = 259; V, maculosidine, mol. wt. = 259; and VI, flindersiamine, mol. wt. = 273.

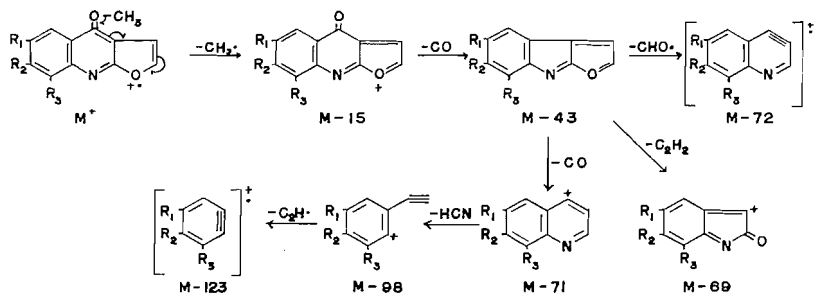
In Scheme 1 a mechanism is advanced to account for the major peaks present in the spectrum of dictamnine. The molecular ion loses a methyl radical leading to the peak at M-15 which then eliminates carbon monoxide leading to the species M-43. This is followed



SCHEME 1.

by a further loss of carbon monoxide yielding the ion at M-71, depicted as a ring-expanded quinoline ion in Scheme 1. We have proposed that initial loss of carbon monoxide involves C_4 of the quinoline ring and that the second CO fragment has its origin in the furan system. It is possible that the order may be the inverse of that above or that no differentiation exists. The problem could be resolved only by synthesis and examination of the fragmentation of suitably labelled compounds. The ion M-43 may also lose a formyl radical ·CH=O leading to the peak at M-72. Loss of CHO is the characteristic behavior of furan (1); however, such a fragmentation seems to be of secondary importance to the loss of CO from benzofuran (2) as well as from the furoquinoline system. We have depicted the M-72 species as a ring-expanded "benzyne" ion-radical. Alternately M-72 may form by loss of H from M-71. Another pathway from the M-43 ion leads to an ion at M-69 which we have attributed to loss of an acetylene molecule. The peak at M-98 is considered to arise from M-71 by loss of HCN and this ion may fragment further to the benzyne ion-radical at M-123.

We have examined the spectra of II–VI inclusive to ascertain if they exhibit analogous behavior. Only in the case of maculine II do we find this scheme in its entirety. For III, IV, V, and VI, however, peaks are observed at M-15, M-43, M-71 and M-72.

The spectra of all of these alkaloids are characterized by strong metastable peaks. In Table I the calculated and observed positions of metastable peaks are recorded corresponding to the transitions outlined in Scheme 1 for the six alkaloids. The presence of these metastable peaks lends support, therefore, to the proposals advanced in Scheme 1.

In the spectrum of dictamnine, peaks of relatively low intensity appear at M-31, M-59, and M-86. These peaks are also present in the other alkaloids (an exception being the

TABLE I

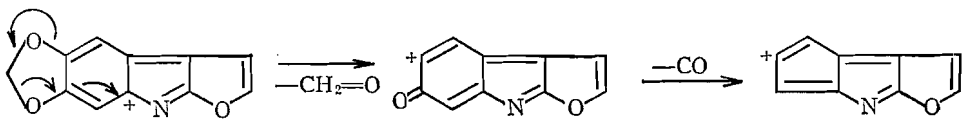
absence of an M-86 peak in maculine). In dictamnine and maculine loss of the 4-methoxyl must account for the formation of the M-31 peak although in the other four alkaloids the loss of another methoxyl is possible. The peak at M-59 may formally be derived from M-31 by loss of CO and that at M-86 by further loss of HCN. Although no attempt is made to formulate a mechanism for these fragmentations, it should be noted that metastable peaks are observed in the spectra of III, IV, and V at 201.0, m^* calcd. M → M-31 = 200.7 and in VI at 214.8, m^* calcd. = 214.5. The transition M-31 → M-59 is supported by metastable peaks in the spectra of IV and V, m^* calcd. 175.4, m^* obsd. 175.9.

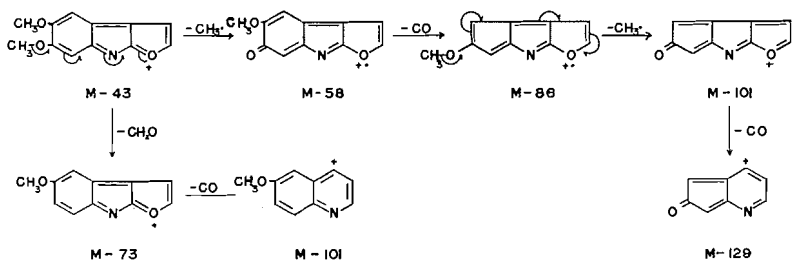
Scheme 1 accounts for the major peaks present in the dictamnine spectrum and for most of those in maculine. In the latter, however, there are peaks at M-73, M-99, and M-101. We consider that the M-73 peak may arise by loss of formaldehyde from the methylenedioxy function and the M-101 peak by subsequent elimination of CO from M-73 as depicted below or by loss of CO from the furan system as in Scheme 1. The M-43 ion is depicted as a resonance hybrid of that shown in Scheme 1 for sake of convenience



M-43 M-73 M-101

in depicting the mechanism. The M-99 peak in maculine might result from a similar loss of a formaldehyde molecule from the ion M-69 of Scheme 1.

Alkaloids III, IV, and V each contain two methoxyl groups in the benzenoid ring. They exhibit peaks at M-73 and M-101 and at M-58, M-86, and M-129. In Scheme 2 a fragmentation mechanism is advanced to account for the formation of these peaks in III.



SCHEME 2.

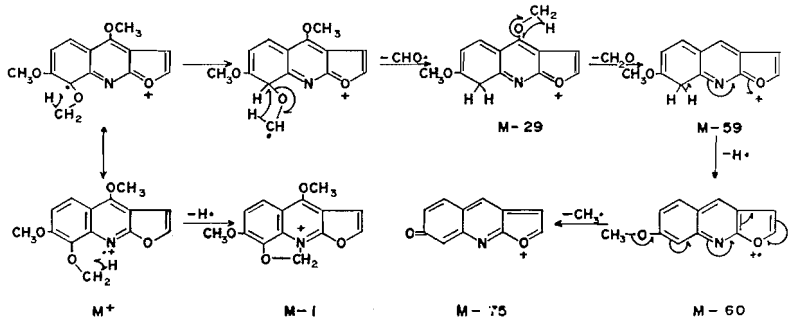
The same mechanism with but slight variation may also be applied to IV and V. In this mechanism the ion of M-43 is considered to lose formaldehyde from one of the two methoxyl groups of the benzenoid ring yielding the M-73 species. Loss of CO from the furan ring leads to an ion of M-101, depicted as a ring-expanded quinoline ion in Scheme 2. The M-43 species may also lose a methyl radical forming the ion-radical of M-58 which by successive loss of CO, CH_3, and CO leads to the ions observed at M-86, M-101, and M-129. Two processes are depicted for the formation of the M-101 ion. A high resolution spectrum would allow one to determine if one or both are operative. In the case of flindersiamine VI the M-43 → M-73 → M-101 sequence is possible through loss of the C_8 methoxyl. Similarly the sequence M-43 → M-58 → M-86 may apply but further fragmentation of flindersiamine via this route is not possible on structural grounds. The transitions M-43 → M-58 are supported by metastable peaks in the spectra of III, IV,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and V where m^* calcd. = 187.0 and the peaks are observed at 187.5, 187.1, and 187.2, respectively. Similarly the transition M-43 → M-73 is supported by the presence of metastable peaks in the spectra of III and V where m^* calcd. = 160.2 and the peaks are observed at 160.2 and 160.5, respectively.

Other schemes may be written which lead to ions of the same composition as those depicted in Scheme 2. Thus the molecular ion might lose a CH_3 radical from one of the methoxyls on the benzenoid ring and this in turn fragment further by loss of CO to an ion of M-43. The M-43 ion formed in this process would then fragment through loss of the same species and in the same order as that depicted in Scheme 2.

In Scheme 3 a mechanism is postulated to account for the formation of the M-1 and



SCHEME 3.

M-29 peaks present in IV, V, and VI. These peaks as noted before differentiate those alkaloids carrying an 8-methoxy substituent from those which lack this structural feature. The formation of the ion M-1 is considered to arise by loss of H from the 8-OMe group and stabilization of the charge by the electron pair on nitrogen, either as shown by formation of a formal C—N bond or alternately by stabilization through space. In each case this transition is supported by a metastable peak at 257.0 in IV and V and at 271.1 in VI.

To account for the loss of 29 mass units (m.u.) in the spectra of IV, V, and VI, an insignificant process in I, II, and III, one must invoke a process involving the 8-OMe group. Loss of 29 m.u. from 1,3-dimethoxy benzene has been reported (4) and a similar fragmentation is shown in Scheme 3 for the generation of the M-29 ion. The loss of 29 m.u. in a concerted fashion is supported by the presence of metastable peaks in the spectra of IV and V, m^* calcd. M → M-29 = 204.2, m^* obsd. = 204.5 in each case. The peak appearing at M-60 in IV, V, and VI may form from M-29 through loss of OCH_3 radical in a single step or in a stepwise fashion by loss of $CH_2{=}O$ and a H radical. Barnes and Occolowitz (4) state that CH_3O is always lost in two steps. However, we have observed one-step loss of CH_3O as discussed previously. In Scheme 3 we have depicted the M-60 radical-ion arising from the M-29 ion by loss of formaldehyde from the C-4 methoxyl followed by loss of H from C_8. In IV and V a peak at M-75 may form by loss of methyl radical from the ion of M-60 but this is not possible in the case of flindersiamine, VI.

Flindersiamine and to a lesser degree skimmianine and maculosidine exhibit peaks at M-28. In the case of flindersiamine the formation of this ion in a concerted elimination is supported by a metastable peak at 220.1 (calcd. 219.9). It is difficult to see how the presence of an 8-methoxyl substituent favors loss of CO involving the furan oxygen. An attractive alternative involves migration of methyl from the 8-OMe group to nitrogen followed by elimination of CO from position 8. Another, but less attractive route, is the loss of HCN from M-1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In the spectra of IV, V, and VI peaks are observed at M-30 and M-45. The M-30 peak may arise by loss of formaldehyde from the molecular ion or alternately by loss of CH_3 from the M-15 species. In the case of IV a metastable peak is present corresponding to the transition M-15 → M-30 (m^* calcd. 214.9) m^* obsd. = 215.1 but no metastable peak corresponding to this transition is present in the spectra of V and VI. It is likely that both processes are operative and the loss of 15 m.u. from M-30 would appear more likely through the sequence M → M-30 → M-45 than the alternate M-15 → M-30 → M-45. In fact the latter is impossible in the case of VI. It is worthwhile to point out that the M-30 ion derived from VI by loss of formaldehyde from C_8 is identical with the molecular ion of II and thus all the peaks observed in the maculine spectrum should be present in VI as in fact they are. Flindersiamine is the only alkaloid of the group which shows a relatively intense peak at M-16. Its formation through the transition M-1 → M-16 is supported by the presence of a metastable peak at 243.0 (m^* calcd. 272 → 257 = 242.8). It is likely that the small M-16 peak observed in the spectra of IV and V may also be attributed to fragmentation via a similar route.

EXPERIMENTAL

The spectra were recorded on a Hitachi Perkin-Elmer RMU-6A mass spectrometer fitted with an all-glass inlet system maintained at 200 °C at an ionizing potential of 80 eV and an ionizing current of 50 μA.

All spectra are plotted in terms of relative abundance with the most intense peak (base peak) being taken as 100%. Only those peaks with an intensity equal to or greater than 2% of the base peak are recorded.

ACKNOWLEDGMENTS

We wish to thank Dr. E. Ritchie, Department of Organic Chemistry, The University of Sydney, Sydney, N.S.W., Australia, for samples of the alkaloids used in this investigation. This work was supported by a grant from the National Research Council of Canada.

EFFECT OF WATER VAPOR ON THE FORMATION OF $CaSO_4 \cdot \frac{1}{2}H_2O$ MODIFICATIONS

R. A. KUNTZE

Cementitious Materials Section, Department of Materials Chemistry, Ontario Research Foundation, Toronto, Ontario

Received April 9, 1965

ABSTRACT

The two recognized forms of calcium sulfate hemihydrate can be identified by the position of a relatively small exothermic peak in their differential thermograms. Hemihydrates prepared at various water vapor pressures up to 760 mm Hg were found to produce this exothermic peak in a position which is characteristic for the β-form. These results indicate that α-hemihydrate cannot be made at atmospheric pressure, as was previously suggested on the basis of heat solution measurements. The typical differential thermogram of α-hemihydrate is only obtained with material made by dehydration in solution or by autoclaving. The effect of ambient water vapor pressure on the position of the three peaks that occur in the differential thermogram of $CaSO_4.2H_2O$ has also been studied. It was found that the incipient temperature of the second endothermic peak, corresponding to the transition of hemihydrate to soluble anhydrite, is displaced independent of the rate of heating from 145 °C to 187 °C with increasing water vapor pressures up to 760 mm Hg. This indicates that, for each temperature, a threshold water vapor pressure exists, above which soluble anhydrite cannot be formed.

Calcium sulfate hemihydrate can be prepared from dihydrate ($CaSO_4.2H_2O$) by three types of dehydration methods, i.e., calcination at atmospheric pressures, digesting in salt solutions, and autoclaving in lump form followed by grinding. The hemihydrates obtained differ in a variety of properties, such as density (1), gauging water requirement (2), heat of solution (3, 4), differential thermal analysis (d.t.a.) exotherms (5, 6), and possibly X-ray diffraction pattern (7). There is general agreement that these differences, which reflect the degree of crystal lattice perfection and surface characteristics, indicate the existence of at least two hemihydrate modifications. This has led to the development of the α- and β-hemihydrate theory (4, 8). Based on limited heat of solution data, the theory states that α-hemihydrate is not only produced by solution processes or autoclaving but also at atmospheric pressure, if the atmosphere is saturated with water vapor. In the absence of water vapor the resulting hemihydrate is of the β-form and at intermediate water vapor pressures the heats of solution indicate mixtures of the two modifications. For example, approximately 75% α-hemihydrate and 25% β-hemihydrate are obtained by dehydration in an atmosphere "nearly saturated with water vapor" (4).

A number of objections have been raised against the part of the theory which deals with dehydrations at atmospheric pressures (9, 10). Hence, a study has been made of the effect of the ambient water vapor pressure present during dehydration on the formation of hemihydrate modifications. For this purpose, differential thermal analysis has been used under controlled atmospheric conditions, such as dry nitrogen, steam, and a number of intermediate partial water vapor pressures. This method has the advantage that it permits the preparation of the hemihydrate and its subsequent identification in one uninterrupted experimental procedure. With the same experiment, it is also possible to study the effect of the ambient water vapor pressure on all dehydration processes occurring within the same temperature range.

EXPERIMENTAL

The differential thermal analysis instrument and the sample holder geometry have been described in detail in an earlier publication (6).

A heating rate of 6 deg min^{-1} was used below 200 °C, since this rate was found to give the best combination of peak definition and resolution. Above 200 °C, a heating rate of 12 deg min^{-1} was necessary to obtain a satisfactory definition of the smaller exothermic peak. The differences between the temperatures of the block and the sample did not exceed 1.5 deg over the entire range of temperatures up to 500 °C. The incipient and peak temperatures reported are those of the block at the time when these points occurred in the thermogram.

The water vapor pressure surrounding the sample was controlled within ±4 mm Hg by passing through the furnace a stream of nitrogen containing known amounts of water vapor. Experiments were carried out at various partial water vapor pressures, in dry nitrogen, and in a steam atmosphere.

The differential thermograms were obtained with −325 mesh samples of a relatively pure form of natural gypsum from San Marcus, Mexico, analyzed to be 99.5% $CaSO_4.2H_2O$. All samples were diluted to 20% with ignited alumina, which was also used as reference material. The results were verified in a number of cases with synthetic gypsum and natural gypsums of different origin.

The gauging water requirement of hemihydrates, obtained at different water vapor pressures, was determined according to ASTM C-472 (11). In order to produce the larger quantities necessary for this determination, each dehydration experiment was repeated with the sample holder being replaced by a ceramic boat, not containing differential thermocouples. In these experiments, heating was discontinued at 200 °C. Additional differential thermal analyses were carried out with these materials to identify the hemihydrate modification, and to establish the absence of residual dihydrate and soluble anhydrite (12).

RESULTS

For the purpose of the present series of experiments, the differential thermograms were considered to consist of two stages (as shown schematically in Fig. 1). During the first stage, hemihydrate is prepared by dehydration of the dihydrate (gypsum) under controlled conditions of partial water vapor pressure. This stage is characterized by one relatively large endothermic peak and is always completed at 150 °C. During the second stage, the hemihydrate formed is further dehydrated to soluble anhydrite, producing an endothermic peak below 200 °C, and this anhydrite is subsequently converted to insoluble anhydrite, as indicated by a smaller exothermic peak. The exact position of the exothermic peak within the differential thermogram can be used for the identification of the hemihydrate form obtained during the first stage.

In Fig. 2, the results are shown in form of actual differential thermograms, obtained

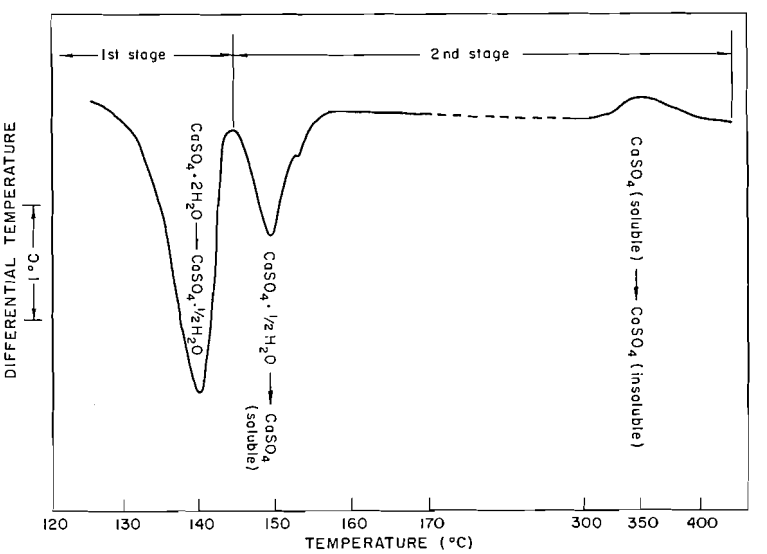

FIG. 1. Formation of $CaSO_4.\frac{1}{2}H_2O$ (1st stage) and subsequent identification (2nd stage) during differential thermal analysis.

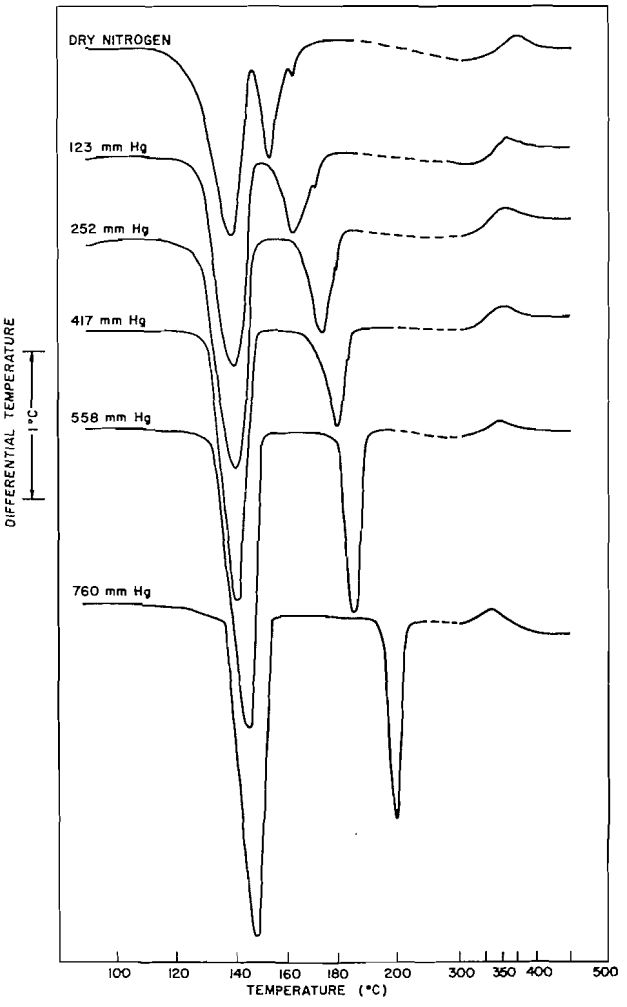

FIG. 2. Differential thermograms of $CaSO_4.2H_2O$ at increasing water vapor pressures.

with increasing ambient water vapor pressures from 0 to 760 mm Hg. The first endothermic peaks, corresponding to the dehydration process

$$CaSO_4.2H_2O_{(s)} = CaSO_4.\tfrac{1}{2}H_2O_{(s)} + 1\tfrac{1}{2}H_2O_{(v)}$$

are affected only to the extent that their incipient temperature increases from 110 °C to 120 °C, while the temperature of the peak does not change. The height of the peaks increases somewhat, indicating a small increase in the rate of dehydration at higher vapor pressures. The first stage of the experimental procedure is completed when these endothermic peaks have appeared, since the hemihydrate present has been prepared under the desired conditions. The second endothermic peaks, representing the continued dehydration

$$CaSO_4.\tfrac{1}{2}H_2O_{(s)} = CaSO_4(\text{soluble})_{(s)} + \tfrac{1}{2}H_2O_{(v)}$$

are effected by the increasing water vapor pressure to a much greater extent than the first endothermic peak. As shown in Fig. 2, the second endothermic peaks become sharper with higher partial water vapor pressures, indicating that hemihydrate is dehydrated at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

faster rates. In Fig. 3, the incipient temperatures of these peaks, which are displaced from 145 °C in dry nitrogen to 187 °C at 760 mm Hg, are plotted against ambient water vapor pressure. These data agree with published calculations for isothermal dehydrations (4, 13), also shown in Fig. 3, except in one case, for which contradicting data are reported (14).

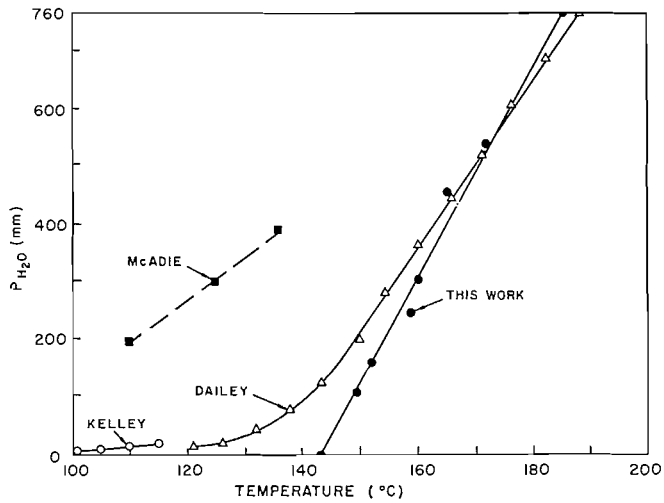

FIG. 3. The incipient temperature of $CaSO_4$ (sol.) formation depending upon water vapor pressure.

The displacement of the incipient temperature of the second endothermic peak, and the shapes of these peaks, suggest that for each temperature a threshold water vapor pressure exists, above which soluble anhydrite cannot be formed. This threshold effect can be demonstrated by producing differential thermograms at different rates of heating. Although the shapes of the second endothermic peaks vary slightly with the rate of heating, because of small differences in the rates of decomposition of hemihydrate, the incipient temperature of these peaks does not change due to the threshold effect of the water vapor pressure.

The third or exothermic peaks are important for the identification of the hemihydrate form produced during the first stage of the experimental procedure (5, 6). In the case of β-hemihydrates, the exothermic peaks occur at approximately 350 °C, whereas with α-hemihydrate, these peaks are observed below 250 °C, immediately following the second endotherms (Fig. 4). All exothermic peaks, obtained in this series of experiments, indicated the presence of the β-modification exclusively, independent of the ambient water vapor pressure present during the dehydration of the dihydrate.

The exclusive production of β-hemihydrate was verified by isothermal dehydration of larger quantities of dihydrate under controlled conditions of water vapor pressure. Subsequent differential thermal analyses at various rates of heating identified the hemihydrate produced in all cases as the β-form. The gauging water requirement of these hemihydrates was above 75 ml per 100 g and decreased to 55 ml per 100 g on exposure to 90% relative humidity at room temperature. The magnitude of the gauging water requirement, and the lack of stability on exposure to 90% relative humidity, is indicative of β-hemihydrate also. The water requirement of α-hemihydrate is approximately 35 ml per 100 g and does not change on exposure to 90% relative humidity.

DISCUSSION

The different physical properties of hemihydrates have been discussed extensively in a number of publications (1–8). In general, it is agreed that the method of dehydration is the most important single factor determining the hemihydrate properties. For example, it is recognized that dehydration in solution or by autoclaving produces the hemihydrate by recrystallization, and the resulting crystals are well developed, dense, and extinguish polarized light uniformly. Hemihydrate, or commercial plaster, made by these processes, has a low gauging water requirement, defined as ml water per 100 g hemihydrate to form a slurry with an arbitrarily established yield point. In contrast, atmospheric dehydration methods do not permit recrystallization and produce poorly defined crystals, or crystalline grains, which are porous and do not uniformly extinguish polarized light. Hemihydrate, or commercial plaster, made by this method, has a high gauging water requirement. The two types of hemihydrate can be prepared reproducibly by the appropriate dehydration methods, and it appears that they are defined adequately by the terms α- and β-hemihydrate, respectively.

It is important to realize that the properties of hemihydrates depend not only on the method of dehydration, but also on a number of other factors, such as particle size distribution and shape, impurities, etc. Therefore, it is obvious that the properties of α- and β-hemihydrates cannot be identical in all cases; instead, they must be expected to cover a range depending on the origin and the past history of the sample. Although these facts are established, an attempt has been made in the case of atmospheric dehydration processes to explain the range of properties obtained by the existence of mixtures of α- and β-hemihydrate. This theory is supported by a single set of heat of solution data (3)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which indicate that hemihydrate obtained at atmospheric pressures is identical to autoclaved hemihydrate or hemihydrate precipitated from acid or salt solutions. Mixtures of the two hemihydrate forms are obtained, therefore, whenever the water vapor pressure falls below 760 mm Hg.

Other experimental observations contradict this theory. For example, the increase in water vapor pressure during dehydration at atmospheric pressures increases the gauging water requirement. Since α-hemihydrate is characterized by a low water requirement, and since artificial mixtures of the two forms show the expected intermediate water requirements (Table I), it is difficult to accept that this modification is formed under conditions of high water vapor pressure. There is also no evidence to show that any other property of the hemihydrate, such as density, appearance under polarized light, rates of hydration or solution, etc., approaches that of α-hemihydrate when the water vapor pressure is increased. Of particular interest is the observation that the water requirements, and some other properties of hemihydrate prepared at atmospheric pressures, change noticeably on exposure to relative humidities above 50%. An increase in the ambient water vapor pressure increases the magnitude of the changes, although α-hemihydrate, prepared by solution processes, etc., does not change in water requirement on exposure.

Differential thermal analysis is the only known alternative method to heats of solution measurement for the identification of hemihydrate modifications. The results of the present work show clearly that α-hemihydrate is not obtained at atmospheric pressures. All differential thermograms of hemihydrates, prepared at atmospheric pressures, have the characteristic shape of β-hemihydrate shown in Fig. 4. The ambient water vapor pressure during dehydration has no effect on the position or the height of the third, i.e., exothermic peak in the differential thermograms. Since artificial mixtures of α- and β-hemihydrate are easily identified by differential thermal analysis (12), it can be concluded that an ambient water vapor pressure between 0 and 760 mm Hg does not produce mixtures of α- and β-hemihydrate.

In the light of the evidence presented in various publications (1–8) and in this paper, it appears that the α- and β-hemihydrate theory must be limited to the following statements.

1. α-Hemihydrate is prepared by dehydration methods, which permit recrystallization, i.e., by solution processes or autoclaving. This hemihydrate form can be identified by its differential thermogram in conjunction with its other properties, such as high density, uniform appearance under polarized light, and low water requirement, which is not affected by exposure to relative humidities above 50%.

2. β-Hemihydrate is prepared by atmospheric dehydrations independent of the ambient water vapor pressure. This hemihydrate form is characterized by its differential thermogram, as well as its low density, heterogeneous appearance under polarized light, and water requirement, which is always considerably higher than that of the α-form, and decreases on exposure to relative humidities above 50%.

Any conclusions based on heat of solution measurements should be treated with caution until additional supporting evidence has been reported.

ACKNOWLEDGMENTS

This work was carried out with a research grant to the Ontario Research Foundation, received from the Department of Economics & Development, Province of Ontario. The author also wishes to thank Mr. D. Renton and Mr. D. Kupke for the preparation of some of the differential thermograms.

^{35}Cl AND ^{37}Cl MAGNETIC RESONANCE OF SIMPLE CHLORINE COMPOUNDS[1]

YASUKAZU SAITO[2]
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received April 27, 1965

ABSTRACT

The nuclear magnetic resonances of ^{35}Cl and ^{37}Cl in a number of simple chlorine compounds were measured. Since both the paramagnetic contribution for chemical shift and the quadrupole coupling constant of the atom are determined by the same radial distribution of the electron, a linear relationship between the chemical shifts and the quadrupole coupling constants may be expected for compounds for which the electronic excitation energies are comparable. This was demonstrated for the series of chloro-substituted methanes. By graphical extrapolation the absolute chemical shift of the reference compound, NaCl aqueous solution, was obtained. The chemical shift of Cl^- aq. ion can be interpreted as the sum of the diamagnetic shift of Cl^- spherical ion and a paramagnetic shift resulting from its hydration. The experimental and theoretical values of the paramagnetic chemical shift of the Cl_2 molecule were -2.06×10^{-3} and -2.17×10^{-3}, respectively. Paramagnetic chemical shifts and line widths of resonance spectra of simple chlorine compounds are discussed, as well as the feasibility of high-resolution chlorine resonances for structural applications.

I. INTRODUCTION

While fluorine resonances have been extensively studied, both experimentally and theoretically, the resonances of other halogen nuclei have remained virtually unexplored. It was the purpose of this work to investigate to what extent chlorine resonances of simple covalently bonded compounds could be measured and what information could be derived therefrom.

All of the halogen nuclei, other than ^{19}F, possess large electric quadrupole moments and accordingly, in most molecular environments, they will have short nuclear relaxation times and greatly broadened resonance lines. The most favorable systems are the simple halide ions (e.g. Cl^-) in aqueous solution, which, because of the more symmetrical electronic environment, have relatively narrow lines (1). In covalently bonded compounds, and since halogens are monovalent, the nucleus is in a highly asymmetric field to which it is strongly coupled. In such cases the resonance lines are often broadened beyond detection. The ^{35}Cl resonance in CCl_4 and in $CHCl_3$ have been previously measured by Diehl (2).

In Table I, nuclear properties of chlorine are shown.

TABLE I

Nuclear properties of chlorine

Isotope	Natural abundance (%)	Magnetic moment μ (in multiples of the nuclear magneton $(eh/4\pi Mc)$)	Spin I (in multiples of $h/2\pi$)	Electric quadrupole moment Q (in multiples of $e \times 10^{-24}$ cm^2)
^{35}Cl	75.4	0.82089	3/2	-7.97×10^{-2}
^{37}Cl	24.6	0.68329	3/2	-6.21×10^{-2}

II. EXPERIMENTAL

The chlorine resonances were measured using a Varian V4210A broad-line spectrometer incorporating a lock-in amplifier with audio phase-sensitive detection at a magnetic field of 14.1 kG (5.89 Mc/s for ^{35}Cl and

[1]*Issued as N.R.C. No. 8545.*
[2]*National Research Council Postdoctorate Fellow, 1963–1964. Present address: Department of Chemistry, Northwestern University, Evanston, Illinois, U.S.A.*

4.90 Mc/s for ^{37}Cl). To avoid modulation broadening the modulation amplitude was progressively reduced until the width of the resonance being observed showed no further narrowing. The radio-frequency power and sweep rate were also optimized. Chemical shifts and line widths were measured for the derivative of the dispersion mode and of the absorption mode, respectively, by keeping H_0 fixed and sweeping the frequency using a Hewlett Packard frequency counter.

All experiments were done at room temperature. Cylindrical sample tubes with about 13 mm inside diameter were employed except for liquid chlorine which was sealed off after distillation in a spherical sample tube with capillary inlet. All compounds were available as commercial products and were measured as the neat liquid except for ionic compounds. Aqueous solutions of NaCl were prepared in various concentrations: 6.14 *M* (saturated solution), 5.00 *M*, 1.00 *M*, 0.50 *M*, and 0.10 *M*. The compounds $NaClO_4$ and $NaClO_3$ were measured as the saturated aqueous solution.

III. RESULTS AND DISCUSSION

Chemical shifts of the chlorine resonance of simple chlorine compounds may be written (3)

[i] $$\delta = \delta_d + K\langle r^{-3}\rangle_{av}\Delta E^{-1}.$$

The first term is the diamagnetic contribution of the chlorine atom and the second term the paramagnetic contribution, in which $\langle r^{-3}\rangle_{av}$ is the average of $1/r^3$ over the radial part of the wave function for the electron, where r is measured with respect to the nucleus, ΔE is an average value of all the electronic excitation energies, and K is a constant. The quadrupole coupling constant e^2qQ is proportional to the same average radial distribution of the electron $\langle r^{-3}\rangle_{av}$ as

[ii] $$e^2qQ = e^2Q\left(\frac{l+1}{2l-1}\right)\left(\frac{2l}{2l+3}\right)\langle r^{-3}\rangle_{av}R',$$

where l is the orbital angular momentum of the electron ($l = 1$ for p electron) and R' is a relativistic correction factor (4). Then eq. [i] may be written

[iii] $$\delta = \delta_d + K'(\Delta E^{-1})(e^2qQ).$$

The chemical shifts of chloro-substituted methanes, CH_3Cl, CH_2Cl_2, $CHCl_3$, and CCl_4, have been measured in p.p.t. (parts per thousand) relative to Cl^- as an aqueous solution of NaCl ($\delta = (H - H_{Cl^-})/H_{Cl^-} \times 10^3$, cf. Table II) and are plotted against the quadrupole coupling constants of these compounds in Fig. 1. This gives an approximately linear relationship, which suggests that the electronic excitation energies of these compounds are almost the same. This is confirmed from the electronic absorption spectra measured by Lacher *et al.* (5) from which ΔE of CCl_4, $CHCl_3$, and CH_2Cl_2 can be estimated as 5.25 eV, 5.42 eV, and 5.77 eV, respectively.

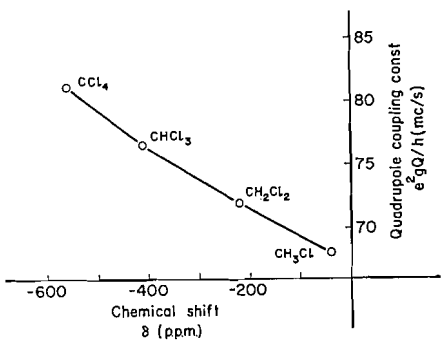

FIG. 1. ^{35}Cl chemical shifts vs. ^{35}Cl quadrupole coupling constants of chloro-substituted methanes. Chemical shifts are relative to chlorine aqueous ion.

The concentration dependence of the chemical shift of Cl^- as an aqueous solution of NaCl was studied from 6.14 M of the saturated solution to 0.10 M and no variation was detected. Therefore, the observed shift cannot be interpreted as the result of ion–ion interaction as in the case of CsBr (6), but rather as the sum of the diamagnetic shift of Cl^- spherical ion and the paramagnetic shift caused by its hydration. Dickinson calculated the diamagnetic shift of Cl^- ion as 1.15 p.p.t., using Hartree-type self-consistent functions for S-state Cl^- ion (7). When we extrapolate the quadrupole coupling constants to zero by using the linear relationship in Fig. 1, we obtain a chemical shift of −2.90 p.p.t., from which the paramagnetic chemical shift of Cl^- caused by hydration can be derived as −1.75 p.p.t. (The reference substance of chemical shifts in Fig. 1 is chlorine aqueous ion.) This value appears reasonable. By comparison the calculated paramagnetic shift of the F_2 molecule is 20×10^{-4} (8), and its observed shift relative to F^- aqueous ion, −548.2 p.p.m. (9), so by difference the paramagnetic chemical shift of hydrated fluorine ion is −1.45 p.p.t. The kind of derivation used for the Cl^- ion is impossible for fluorine aqueous ion, since the fluorine nucleus has no quadrupole moment.

The chemical shift of liquid chlorine has been measured as −0.31 p.p.t. relative to chlorine aqueous ion. Therefore, the true paramagnetic component of the chemical shift of Cl_2 must be −2.06 p.p.t. Applying the theoretical treatment of paramagnetic shifts by Saika and Slichter (8) to the Cl_2 molecule instead of the F_2 molecule yields

$$\text{[iv]} \qquad \delta_p = -\frac{2}{3}\frac{e^2\hbar^2}{m^2c^2}\langle r^{-3}\rangle_{av}\,\Delta E^{-1}.$$

Using 3.67 eV (3380A) for ΔE (10) and 8.24 a_0^{-3} for $\langle r^{-3}\rangle_{av}$ (11), we obtain $\delta_p = -2.17$ p.p.t. from eq. [iv], in good agreement with the observed value.

Chemical shifts of ^{35}Cl resonances and absorption line widths of both ^{35}Cl and ^{37}Cl in several chlorine compounds are listed in Table II. The values of the paramagnetic chemical shifts of these compounds, obtained by adding −1.75 p.p.t. to the observed chemical shifts, are shown in the fourth column. The quadrupole coupling constants as well as viscosity and molecular volume data are also shown in this table.

As shown in Table II, ClO_4^- aqueous ion and ClO_3^- aqueous ion give the largest paramagnetic shift, which may be due to the double bond character in the Cl—O bond. Among carbon-bound chlorine compounds, the paramagnetic shifts are well understood in terms of the electronegativity of the group to which chlorine is bonded. Thus, the more ionic character, the less paramagnetic contribution.

The line widths of ^{35}Cl resonance in Table II could be related to their corresponding quadrupole coupling constants by the equation (12),

$$\text{[v]} \qquad \Delta H = \frac{1}{T_1} = \frac{3}{8}\left(\frac{e^2qQ}{\hbar}\right)^2\left(\frac{4\pi\eta a^3}{3kT}\right),$$

where ΔH is the absorption line width, T_1 the spin lattice relaxation time, η the viscosity of the liquid, and a the effective molecular radius. Accordingly the ratio R, defined by

$$\text{[vi]} \qquad R = (\Delta H)/\left(\frac{e^2qQ}{h}\right)^2(\eta)(a^3),$$

should be a constant. As shown in the eighth column of Table II, this is approximately confirmed. The line widths of chlorine resonances are thus to be understood from the viewpoint of quadrupole interaction.

*Paramagnetic chemical shift was calculated by adding the chemical shift observed relative to chlorine aqueous ion to the paramagnetic chemical shift of chlorine aqueous ion.
†Data of quadrupole coupling constants were taken from ref. 4. The value of CH_3COCl was estimated by extrapolation on the series of CCl_3COCl, $CHCl_2COCl$, and $CH_2ClCOCl$.
‡See eq. [vi]. C_6H_5Cl was taken as basis.

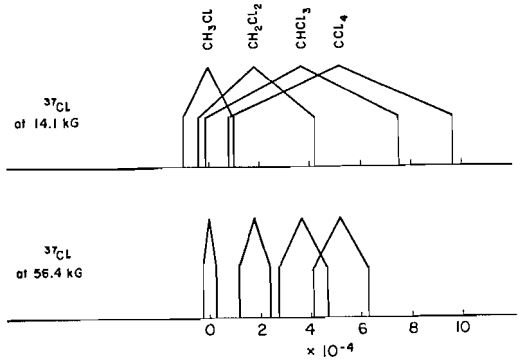

FIG. 2. ^{37}Cl chemical shifts and line widths of chloro-substituted methanes at different magnetic field. Top diagram shows measured resonances at 14.1 kG. Bottom diagram indicates resolution expected at 56.4 kG.

As shown in Table I the ^{37}Cl nucleus has a smaller natural abundance and magnetic moment than ^{35}Cl, which causes weaker signal strengths than the former. But its smaller quadrupole moment favors the resolution of resonance spectra. ^{37}Cl resonance of 1-chloro-2-dichloroethane $CH_2ClCHCl_2$ and chloroacetyl chloride $CH_2ClCOCl$ in which the two non-equivalent Cl's were distinguished by pure quadrupole resonance experiments (13) have been tried, but unfortunately the spectra of these compounds were not resolved at 14.1 kG. However, as illustrated in Fig. 2 where line widths are shown schematically, resolution would be possible if the strength of magnetic field is increased, e.g. four times. The required magnetic field inhomogeneity is of the order to 1×10^{-4}, owing to the large intrinsic line widths. Therefore, chlorine resonances by use of superconducting magnets should be quite favorable for structural applications in chlorine chemistry.

ACKNOWLEDGMENT

The author wishes to express his gratitude to Dr. W. G. Schneider for helpful discussions and encouragement. He is also indebted to Dr. A. D. Buckingham for valuable suggestions and Mr. J. Nicholson and Mr. Y. Lupien for technical help.

THE CHEMISTRY OF THE AMINOCHROMES. PART VIII

THE PREPARATION AND PROPERTIES OF 4- AND 7-METHYLADRENOCHROME[1]

R. A. HEACOCK[2] AND O. HUTZINGER[3]

The Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan

Received April 15, 1965

ABSTRACT

Two new catecholamines, 2- and 5-methyladrenaline, have been prepared from 3-methylcatechol and they gave 4- and 7-methyladrenochrome, respectively, on oxidation. 7-Iodo-4-methyladrenochrome was obtained on oxidation of 2-methyladrenaline with potassium iodate; however, an iodoaminochrome could not be obtained in a similar manner from 5-methyladrenaline. The expected 5,6-dihydroxyindole derivatives were obtained on reduction of these aminochromes.

It has been known for many years that the oxidation of adrenaline with potassium iodate leads to the formation of deep-violet products (1, 2). The compound responsible for the violet color was first isolated in 1937 by Richter and Blaschko who described it as 3-hydroxy-2-iodo-1-methylindoline-5,6-quinone (i.e. 2-iodoadrenochrome) (3). However, it has recently been shown that iodination actually occurs in the 7-position of the adrenochrome nucleus and it was further demonstrated that iodination (and bromination) invariably occurs in the 7-position and not the 2-position in the aminochrome molecule (4).

As part of a research program into the chemistry of the aminochromes, that is being carried out in these laboratories, it was decided to prepare 2- and 5-methyladrenaline (I and II respectively) and to investigate the effects of the methyl substitution of the aromatic ring on the oxidation of these hitherto unknown catecholamines with several different oxidizing agents.

It was possible to prepare I and II by procedures similar to that originally described by Stolz for the preparation of adrenaline (5). ω-Chloro-3,4-dihydroxy-2-methylacetophenone (III) was prepared from 3-methylcatechol (IV) by a Friedel–Crafts condensation with chloracetyl chloride in the presence of aluminium chloride in carbon disulfide solution. Methylation of the phenolic hydroxy groups of III gave ω-chloro-3,4-dimethoxy-2-methylacetophenone (V), a compound that had previously been described in the literature (6), proving that the chloroacetyl residue had entered the aromatic ring of IV in the position ortho to the methyl group. The n.m.r. spectrum of III in hexadeuteroacetone showed two well separated doublets centered at δ 7.38 and δ 6.92 with a coupling constant of ca. 8.5 c.p.s., indicating the presence of two ortho aromatic hydrogens in the molecule and confirming the position of the chloroacetyl residue. ω-Methylamino-3,4-dihydroxy-2-methylacetophenone (VI) was prepared by treating III with methanolic methylamine at room temperature (cf. ref. 7). Treatment of III with sodium iodide in acetone gave 3,4-dihydroxy-ω-iodo-2-methylacetophenone (cf. ref. 6). Preliminary experiments indicated that there was no advantage in using the ω-iodo derivative to prepare VI. 2-Methyladrenaline (I) was obtained in good yield by catalytic hydrogenation of VI. The hydrochloride of I was hygroscopic, but the acid oxalate salt of I was not and was readily purified by recrystallization from aqueous ethanol.

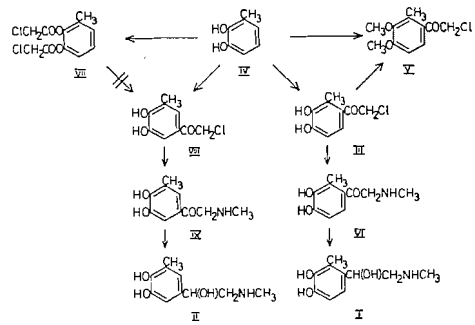


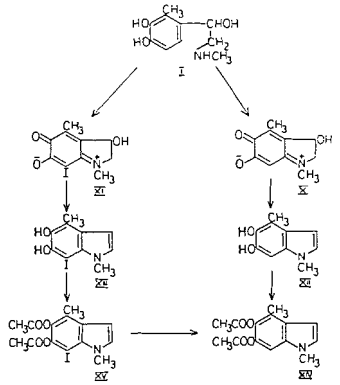
SCHEME 1.

The condensation of 3-methylcatechol (IV) with chloroacetyl chloride in boiling benzene, in the presence of phosphorus oxychloride (i.e. using conditions similar to those originally employed for synthesis of compounds of this type (cf. ref. 5, 8, 9), gave a chloroacetyl derivative of 3-methylcatechol, isomeric with, but different to, ω-chloro-3,4-dihydroxy-2-methylacetophenone (III), obtained by the conventional Friedel–Crafts procedure. This new ω-chloroacetophenone derivative was probably formed by a Fries rearrangement (cf. ref. 10) of an initially formed chloroacetyl ester of IV. In general this type of reaction can be carried out by either isolating a suitable ester of the catechol and subsequently rearranging it with either phosphorus oxychloride (9) or aluminium chloride (11), or by carrying out the entire procedure, without the isolation of the intermediate ester, in the presence of phosphorus oxychloride (9). In the present investigation, the latter procedure was employed. All attempts to bring about a direct Fries-type rearrangement of preformed 2,3-di(chloroacetoxy)toluene (VII) were unsuccessful. The n.m.r. spectrum of the second chloroacetophenone derivative in hexadeuteroacetone showed only a single peak (δ 7.5), corresponding to two hydrogens, in the aromatic proton region, effectively ruling out one of the two alternative structures, i.e., ω-chloro-2,3-dihydroxy-4-methylacetophenone, since the n.m.r. spectrum of this latter compound should indicate the presence of two ortho aromatic protons. Therefore, the only possible structure for this chloroactophenone derivative is ω-chloro-3,4-dihydroxy-5-methylacetophenone (VIII). 3,4-Dihydroxy-ω-methylamino-5-methylacetophenone (IX) was prepared by treatment of VIII with methanolic methylamine, and 5-methyladrenaline (II) was obtained by catalytic reduction of the aminoketone (IX). The hydrochloride, sulfate, and oxalate of 5-methyladrenaline (II) were prepared but were too hygroscopic to purify completely; however, it was possible to prepare a pure nonhygroscopic picrate of II.

4-Methyladrenochrome (X) was obtained as a deep-red crystalline solid on oxidation of 2-methyladrenaline (I) with silver oxide in dry methanol (cf. ref. 12); aqueous solutions of X were readily obtained by oxidizing the base (I) with potassium ferricyanide, buffered with sodium bicarbonate (cf. ref. 13). A crystalline monosemicarbazone of X could be prepared by standard procedures. 7-Iodo-4-methyladrenochrome (XI) was readily obtained as a violet-brown crystalline solid, when an aqueous solution of I was oxidized with potassium iodate.

5,6-Dihydroxy-1,4-dimethylindole (XII) was obtained on reduction of 4-methyladrenochrome (X) with ascorbic acid, and reduction of 7-iodo-4-methyladrenochrome (XI) with sodium borohydride gave 5,6-dihydroxy-7-iodo-1,4-dimethylindole (XIII); all attempts to reduce 7-iodo-4-methyladrenochrome (X I) with ascorbic acid, however, were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 2.

unsuccessful. 5,6-Diacetoxy-1,4-dimethylindole (XIV) and 5,6-diacetoxy-7-iodo-1,4-dimethylindole (XV) were obtained on acetylation of XII and XIII respectively. Deiodination of XV with zinc and acetic acid gave XIV.

The red color of aqueous solutions of 4-methyladrenochrome (X) was discharged by alkali, with the formation of pale-yellow solutions, exhibiting the typical intense yellow green fluorescence associated with 5,6-dihydroxyindoxyls (see ref. 14 for references), indicating that the expected rearrangement of X to 4-methyladrenolutin had occurred. Treatment of an aminochrome with an acetic anhydride – pyridine mixture usually leads to the formation of a 3,5,6-triacetoxyindole derivative (cf. refs. 13, 15). However, solutions of 7-iodo-4-methyladrenochrome (XI) in acetic anhydride – pyridine mixtures did not lose their violet color, even after they had stood for several weeks at room temperature or had been heated at 80° for 2 h, suggesting that no reaction had occurred in this case.

7-Methyladrenochrome (XVI) was obtained as a dark violet, almost black, crystalline solid by the oxidation of 5-methyladrenaline (II) with potassium ferricyanide, in aqueous solution; it could also be prepared, in relatively poor yield, by the oxidation of II by silver oxide in methanol. The properties of the aminochrome (XVI) are unusual in several respects. The low water-solubility of XVI is unusual for non-halogenated aminochromes; aqueous solutions of XVI are violet, and not red in color, showing visible absorption maxima at 534 mμ in water and at 530 mμ in methanol, i.e. at longer wavelengths than are usual for unhalogenated aminochromes (cf. refs. 14, 15, 16). This shift of the visible absorption maxima towards longer wavelengths appears to be associated with 7-substitution. All known 7-halogenoaminochromes absorb in the 530 mμ region (cf. ref. 14). Two other 7-methyl substituted aminochromes have been described; solutions of 7-methyldopachrome and 4,7-dimethylnorepinochrome were prepared by Cromartie and Harley-Mason, and were reported to be deep violet in color (17). It was not possible to prepare an iodo derivative of XVI by the oxidation of II with potassium iodate under a wide variety of conditions; the iodine-free aminochrome (XVI) was invariably obtained. It would appear, therefore, that when the 7-position of the aminochrome nucleus is blocked the iodine atom will not enter any of the alternative free positions in the molecule.

The violet color of aqueous solutions of XVI was also discharged by alkali; yellow fluorescent solutions, presumably containing the corresponding 5,6-dihydroxyindoxyl, were obtained. 5,6-Dihydroxy-1,7-dimethyindole (XVIII: R = H), was obtained on the reduction of 7-methyladrenochrome (XVI) by ascorbic acid; this 5,6-dihydroxyindole

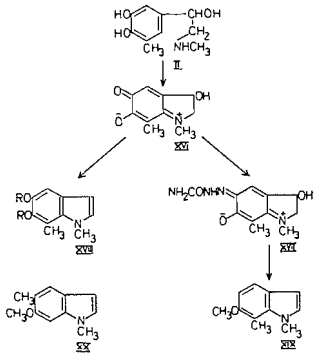

SCHEME 3.

derivative oxidizes readily in air, and was converted to its more stable diacetyl derivative (XVIII: R = CH_3CO).

The n.m.r. spectra of the three 5,6-diacetoxyindole derivatives (in deuterochloroform solution) described above (i.e. XIV, XV, and XVIII: R = CH_3CO) are fully compatible with the structures assigned to them on other grounds. The n.m.r. spectrum of 5,6-diacetoxy-1,4-dimethylindole (XIV) exhibited a singlet peak at δ 6.95, corresponding to the aromatic hydrogen in the 7-position; the hydrogens in the 2- and 3-positions of the indole nucleus in XIV gave rise to two doublets centered at δ 6.96 and δ 6.43 respectively, with a coupling constant of ca. 3 c.p.s. In the case of 5,6-diacetoxy-1,7-dimethylindole (XVIII: R = $COCH_3$), the 4-hydrogen was observed as a singlet at δ 7.19; the 2- and 3-hydrogens gave rise to two doublets centered at δ 6.89 and δ 6.35 respectively with a coupling constant of ca. 3 c.p.s. As would have been expected the n.m.r. spectrum of 5,6-diacetoxy-7-iodo-1,4-dimethylindole (XV) only showed two doublets, due to the 2- and 3-hydrogens, centered at δ 6.96 and δ 6.38 respectively, with a coupling constant of ca. 3 c.p.s. The positions (δ values) of the signals (and the coupling constants) due to the various hydrogen atoms in these substituted indole nuclei are quite compatible with what would have been expected from a consideration of the literature on the n.m.r. spectra of indoles (cf. refs. 4, 18, 19, 20).

5-Methyladrenaline (II) has two positions ortho to the ethanolamine side chain at which intramolecular cyclization might occur during aminochrome formation. However, theoretical considerations and consideration of all reported aminochrome cyclizations suggest that cyclization would occur at the 6-position (after the initial oxidation of the catocholamine to an uncyclized *o*-quinone derivative). If the cyclization occurred in the above manner a normal aminochrome (i.e. 7-methyladrenochrome (XVI)) would result. However, if cyclization had taken place at the 2-position in II, an abnormal aminochrome with the *o*-quinone function in the 6,7-position of the indole ring system would have resulted. To show that abnormal cyclization had not occurred, the monosemicarbazone (XVII) obtained from this aminochrome was treated with hot aqueous alkali, a procedure known to remove the semicarbazide residue from adrenochrome monosemicarbazones (21). The n.m.r. spectrum of the degradation product demonstrated that it was derived from 7-methyladrenochrome (XVI), since the degradation product was clearly 6-methoxy-1,7-dimethylindole (XIX). If abnormal cyclization had occurred during the aminochrome formation from II, the final product would have been 6-methoxy-1,5-dimethylindole (XX). The n.m.r. spectra of the degradation product (i.e. 6-methoxy-1,7-dimethylindole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(XIX)) in carbon tetrachloride and deuterochloroform both clearly show the presence of two aromatic hydrogens in an ortho relationship to each other. These aromatic hydrogen peaks are observed as doublets with a coupling constant of ca. 8.5 c.p.s. In the alternative structure (i.e. XX) the two hydrogens would be in a para relationship to each other and would not be expected to show a coupling constant of this magnitude. The δ values obtained are given in Table I.

TABLE I

Nuclear magnetic resonance spectral data for 6-methoxy-1,7-dimethylindole*

	Values of δ			
Solvent	4-H	5-H	2-H	3-H
CCl_4	7.16	6.62	6.62	6.16
$CDCl_3$	7.35	6.79	6.81	6.33

*All peaks are doublets; the δ values are calculated from the observed doublets.
The coupling constants observed for the 4- and 5-hydrogens are ~8.5 c.p.s. and those for the 2- and 3-hydrogens are ~3.2 c.p.s.

EXPERIMENTAL

Unless otherwise stated the infrared spectra were recorded on a Beckman IR-8 recording spectrophotometer; the ultraviolet and visible absorption spectra were recorded on a Unicam SP.800 recording spectrophotometer and the nuclear magnetic resonance spectra were recorded on either a Varian A-60 or HA-100 instrument. Only the more important peaks in the infrared and nuclear magnetic resonance spectra of certain compounds, which are relevant to the discussion, are reported.

The light petroleum used throughout this investigation was B.D.H. AnalaR grade (b.p. 80–100°). Peroxide-free ether was invariably used to minimize loses of readily oxidizable indole derivatives.

ω-Chloro-3,4-dihydroxy-2-methylacetophenone (III)

Powdered anhydrous aluminium chloride (50 g) was added cautiously, with stirring, to a solution of 3-methylcatechol[4] (25 g) and chloroacetyl chloride (20 g) in carbon disulfide[5] (300 ml), at 10°, with the rigorous exclusion of moisture. The resulting suspension was boiled, under reflux, until the evolution of hydrogen chloride had virtually ceased (ca. 45 min). Ice water (1 000 ml) and concentrated hydrochloric acid (50 ml) were added cautiously to the reaction mixture after it had been allowed to cool to room temperature. The crude product which separated out as an "off-white" solid was removed by filtration, washed with water, and on recrystallisation from water gave ω-chloro-3,4-dihydroxy-2-methylacetophenone (24 g) in colorless needles, m.p. 178°, ν_{max}^{Nujol} 3 480; 3 340; 1 665 cm^{-1}. The n.m.r. spectrum of III in acetone-d_6 showed signals at δ 7.38 (doublet) and δ 6.92 (doublet); J = 8.5 c.p.s.

Anal. Calcd. for $C_9H_9ClO_3$: C, 53.96; H, 4.55; Cl, 17.22. Found: C, 54.16; H, 4.51; Cl, 18.08.

ω-Chloro-3,4-dimethoxy-2-methylacetophenone (V)

A solution of ω-chloro-3,4-dihydroxyacetophenone (1 g) and dimethyl sulfate (1.25 g) in acetone (30 ml) containing anhydrous potassium carbonate (1.4 g) was stirred and boiled under reflux for 8 h. After this time the suspension was poured into water (150 ml), and the aqueous reaction mixture was cooled to 5°. The crude crystalline product was removed by filtration, washed with water, and recrystallized from benzene – light petroleum. It gave ω-chloro-3,4-dimethoxy-2-methylacetophenone in colorless prisms (0.8 g), m.p. 101°, undepressed on admixture with an authentic sample, prepared by the method of Hornbaker and Burger (6). These two samples of this compound also had identical infrared spectra.

3,4-Dihydroxy-ω-iodo-2-methylacetophenone

A solution containing ω-chloro-3,4-dihydroxy-2-methylacetophenone (2 g) and sodium iodide (1.7 g) in acetone (250 ml) was stirred, at room temperature, for 30 min. After this time the solution was filtered, and the filtrate was evaporated to dryness. 3,4-Dihydroxy-ω-iodo-2-methylacetophenone (1.8 g) was obtained in pale-yellow needles, m.p. 171–172°, on recrystallization of the residue from aqueous ethanol.

Anal. Calcd. for $C_9H_9IO_3$: C, 37.01; H, 3.11. Found: C, 37.17; H, 3.11.

[4]*Obtained from the Aldrich Chemical Co.*

[5]*Two other solvents: 1,2-dichloroethane and nitromethane, were tried in place of the carbon disulfide, to reduce the danger of fire, since the carbon disulfide system is very inflammable, but these alternate solvents gave unsatisfactory results.*

3,4-Dihydroxy-2-methyl-ω-methylaminoacetophenone (VI)

ω-Chloro-3,4-dihydroxy-2-methylacetophenone (4 g) was added in portions to a stirred, cooled mixture of methanol (5 ml) and a solution of methylamine (Matheson Co.) in methanol (15 ml, saturated at 5°); stirring was continued until solution was complete (ca. 5 min). The resulting brown solution was allowed to stand at 5° for 2 h, during which time tan-colored prisms of 3,4-dihydroxy-2-methyl-ω-methylaminoacetophenone (2.3 g), m.p. 218–222° (with decomposition) separated out, ν_{max}^{Nujol} 3 200 – 2 600; 1 630 cm^{-1}. It was not possible to purify this product by recrystallization since it does not dissolve in most of the common solvents.

Anal. Calcd. for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71; N, 7.18. Found: C, 60.81; H, 6.72; N, 7.17.

The hydrochloride of 3,4-dihydroxy-2-methyl-ω-methylaminoacetophenone was prepared by stirring a suspension of the base in ethanol with excess concentrated hydrochloric acid; the base dissolved and colorless needles of 3,4-dihydroxy-2-methyl-ω-methylaminoacetophenone hydrochloride, m.p. 256° (with decomposition), separated out after the solution had been stirred at room temperature for a short time (ca. 5–15 min).

Anal. Calcd. for $C_{10}H_{14}ClNO_3$: C, 51.84; H, 6.12; N, 6.08; Cl, 15.30. Found: C, 51.90; H, 5.95; N, 5.76; Cl, 15.20.

Treatment of a solution of ω-chloro-3,4-dihydroxy-2-methylacetophenone (0.5 g) in ether (50 ml) with methanolic methylamine (3 ml) for a few minutes at room temperature gave pale-yellow needles (0.3 g), m.p. 155°. This product, which is readily soluble in water and ethanol, is probably a phenolic methylamine salt of ω-chloro-3,4-dihydroxy-2-methylacetophenone[6] (cf. refs. 5, 22).

Anal. Calcd. for $C_{10}H_{14}ClNO_3$: C, 51.84; H, 6.12; Found: C, 52.04; H, 6.24.

2-Methyladrenaline (I) Hydrogen Oxalate (i.e. 2-Methyl-α-methylaminomethylprotocatechuyl Alcohol Hydrogen Oxalate)

A suspension of 3,4-dihydroxy-2-methyl-ω-methylaminoacetophenone (5 g), oxalic acid dihydrate (3. 25 g), and 5% palladium–charcoal (3 g) in water (300 ml) at 40° was shaken in an atmosphere of hydrogen at atmospheric pressure for 30 h. After this time the reaction mixture was filtered, and the aqueous filtrate concentrated *in vacuo* (nitrogen "leak") to ca. 15 ml; colorless prisms of 2-methyladrenaline hydrogen oxalate (4.2 g) separated out after the concentrate had stood at room temperature overnight. A small sample of the product, purified for microanalysis by recrystallization from water, had m.p. 181° (with decomposition).

Anal. Calcd. for $C_{12}H_{17}NO_7$: C, 50.17; H, 5.97; N, 4.88. Found: C, 50.12; H, 6.11; N, 4.74.

2-Methyladrenaline (I) (Free Base)

A solution of 3,4-dihydroxy-2-methyl-ω-methylaminoacetophenone hydrochloride (3 g) in water (220 ml), containing 5% palladium–charcoal (1 g), was shaken in an atmosphere of hydrogen at atmospheric pressure for 8 h. The catalyst was removed by filtration and the clear filtrate was concentrated *in vacuo* (nitrogen "leak") below 40° to ca. 15 ml. Solid potassium carbonate (2 g) was added to the stirred solution; the crude base (2.6 g), which separated out after the reaction mixture had been allowed to stand at 5° for 1 h, was removed by filtration and was sufficiently pure for the next step in the synthesis of 4-methyladrenochrome. A sample of 2-methyladrenaline, purified for microanalysis by recrystallization from a large volume of methanol, was obtained in colorless prisms (m.p. 190–192° (with decomposition)).

Anal. Calcd. for $C_{10}H_{15}NO_3$: C, 60.89; H, 7.67; N, 7.10. Found: C, 60.85; H, 7.82; N, 6.82.

4-Methyladrenochrome (X) (cf. the Preparation of Adrenochrome by the Method of Heacock et al. (12))

2-Methyladrenaline (1 g) was suspended in absolute methanol (30 ml), and 98% formic acid was added dropwise, with stirring, until a clear solution was obtained. Freshly prepared silver oxide was added in portions to the vigorously stirred solution. After being stirred, at room temperature for 3 min, the reaction mixture was filtered through a Dowex-1 (Cl^-) resin bed (cf. ref. 12). 4-Methyladrenochrome (0.11 g) was obtained in dark-red needles (totally decomposed without melting by 132°)[7] from the deep-red filtrate after it had been allowed to stand at −20° for 4 h. A second crop (0.06 g) of crystalline 4-methyladrenochrome was obtained by adding anhydrous ether (15 ml) to the remaining filtrate and keeping the solution at −20° overnight, $\lambda_{max}^{H_2O}$ 222, 312, 490 mμ; $\lambda_{max}^{CH_3OH}$ 221, 308, 484 mμ.

Anal. Calcd. for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25. Found: C, 62.12; H, 5.82; N, 7.01.

4-Methyladrenochrome Monosemicarbazone

A solution of 2-methyladrenaline hydrochloride, prepared by suspending 2-methyladrenaline (0.2 g) in water (1.5 ml) and cautiously adding 2 *N* hydrochloric acid, with shaking, until all the solid had dissolved, was oxidized with a solution of potassium ferricyanide (1.15 g) and sodium bicarbonate (0.4 g) in water (3 ml). A deep-red solution of 4-methyladrenochrome formed rapidly and considerable frothing occurred (due to the evolution of carbon dioxide). After this solution had been allowed to stand at room temperature for 5 min, a solution containing semicarbazide hydrochloride (0.2 g) and sodium acetate (0.2 g) in water (1.5 ml) was added; the reaction mixture, after being stirred at room temperature for 10 min and standing at 5° for 5 h,

[6]*ω-Chloro-3,4-dihydroxy-2-methylacetophenone could be extracted with ether from aqueous solutions of the yellow product which had been made alkaline with sodium hydroxide.*

[7]*The decomposition points of all the aminochromes and aminochrome semicarbazones described in this paper were measured on a Leitz hot-stage instrument.*

For personal use only.

deposited dark reddish-orange crystals of the crude semicarbazone. 4-Methyladrenochrome monosemicarbazone (0.125 g) was obtained in deep-orange needles (totally decomposed without melting by 248°) on recrystallization of the crude product from a pyridine–water (1.1) mixture.

Anal. Calcd. for $C_{11}H_{14}N_4O_3$: C, 52.79; H, 5.64; N, 22.39. Found: C, 52.95; H, 5.72; N, 22.44.

7-Iodo-4-methyladrenochrome (XI)

Potassium iodate (1.7 g) was added, at room temperature with stirring, to an aqueous solution of 2-methyladrenaline hydrochloride (prepared by cautiously adding 2 *N* hydrochloric acid to a suspension of 2-methyladrenaline (1 g) in water (350 ml) until a clear solution was obtained). The reaction mixture was stirred for 3 h at 5°; during this time deep-violet needles of 7-iodo-4-methyladrenochrome (1.1 g) separated out (totally decomposed without melting by ca. 110°), $\lambda_{max}^{H_2O}$ 234, 314, 534 mμ; $\lambda_{max}^{CH_3OH}$ 234, 309, 530 mμ.

Anal. Calcd. for $C_{10}H_{10}INO_3$: C, 37.64; H, 3.16; I, 39.78; N, 4.38. Found: C, 37.74; H, 3.15; I, 39.85; N, 4.45.

5,6-Dihydroxy-1,4-dimethylindole (XII)

Ascorbic acid was added in portions to a vigorously stirred two-phase system, consisting of an aqueous solution of 4-methyladrenochrome (prepared as described above by the oxidation of 2-methyladrenaline (0.3 g) with potassium ferricyanide) and ether (20 ml), until the red color of the aqueous phase had disappeared. The ether layer was separated and the aqueous phase was extracted with a further quantity of ether. Dry benzene (10 ml) was added to the combined, dried (Na_2SO_4) ether solutions, and the resulting solution was concentrated to ca. 5 ml *in vacuo* (nitrogen "leak"); colorless prisms of 5,6-dihydroxy-1,4-dimethylindole (0.11 g), m.p. 140–141°, were obtained by the addition of a small quantity of *n*-heptane to the warm concentrated benzene solution.

Anal. Calcd. for $C_{10}H_{11}NO_2$: C, 67.78; H, 6.26; N, 7.91. Found: C, 67.56; H, 6.25; N, 7.87.

5,6-Diacetoxy-1,4-dimethylindole (XIV)

A mixture of dry pyridine (2 ml) and acetic anhydride (2 ml) was added to a dried ethereal solution of 5,6-dihydroxy-1,4-dimethylindole (prepared by the method described above). The light-brown solution, obtained after removal of the ether *in vacuo*, was allowed to stand overnight at room temperature and then poured into an ice–water mixture. The crude diacetate, that separated out, afforded colorless needles of 5,6-diacetoxy-1,4-dimethylindole (0.22 g), m.p. 135–136°, on recrystallization from benzene – light petroleum.

Anal. Calcd. for $C_{14}H_{15}NO_4$: C, 64.37; H, 5.79; N, 5.36. Found: C, 64.47; H, 5.82; N, 5.52.

5,6-Dihydroxy-7-iodo-1,4-dimethylindole (XIII)

Sodium borohydride was added cautiously to a vigorously stirred two-phase system, consisting of a suspension of 7-iodo-4-methyladrenochrome (0.5 g) in water (20 ml) and ether (20 ml), until the violet color of the aminochrome had been totally discharged. The ether layer was separated and the aqueous phase was extracted with a further quantity of ether. Dry benzene (10 ml) was added to the combined, dried (Na_2SO_4) ether extracts and the resulting solution was concentrated to ca. 5 ml *in vacuo* (nitrogen "leak"); colorless prisms of 5,6-dihydroxy-7-iodo-1,4-dimethylindole (0.19 g) were obtained by the addition of a small quantity of *n*-heptane to the warm concentrated benzene solution. This substance did not melt, but turned black somewhere between 140 and 180°, depending on the rate of heating.

Anal. Calcd. for $C_{10}H_{10}INO_2$: C, 39.62; H, 3.33; N, 4.62; I, 41.87. Found: C, 39.65; H, 3.24; N, 4.55; I, 42.04.

5,6-Diacetoxy-7-iodo-1,4-dimethylindole (XV)

A mixture of dry pyridine (2 ml) and acetic anhydride (2 ml) was added to a dried ethereal solution of 5,6-dihydroxy-7-iodo-1,4-dimethylindole, and the reaction mixture was worked up as described above. Colorless prisms of 5,6-diacetoxy-7-iodo-1,4-dimethylindole (0.22 g), m.p. 192–193°, were obtained on recrystallization of the crude product from benzene – light petroleum. The n.m.r. spectrum of this substance in deuterochloroform showed two doublets centered at δ 6.96 and δ 6.38 (J = 3.2).

Anal. Calcd. for $C_{14}H_{14}INO_4$: C, 43.43; H, 3.65; I, 32.79; N, 3.62. Found: C, 43.26; H, 3.72; I, 32.37; N, 3.57.

Deiodination of 5,6-Diacetoxy-7-iodo-1,4-dimethylindole (XV)

Zinc powder (0.8 g) was added in portions to a solution of 5,6-diacetoxy-7-iodo-1,4-dimethylindole in glacial acetic acid (5 ml). The suspension was boiled under reflux, with stirring, for 5 min and filtered, and the residual zinc was washed with a small quantity of hot glacial acetic acid. Crushed ice was added to the combined filtrate and washings and the resulting aqueous product was extracted several times with ether. The combined ether extracts were washed with aqueous sodium bicarbonate until free of acetic acid and finally with water. Dry benzene (5 ml) was added to the dried (Na_2SO_4) ether solution and the volume of the solution was reduced to ca. 3 ml. 5,6-Diacetoxy-1,4-dimethylindole (32 mg), identical in all respects with the sample prepared by the method described above, was obtained on the addition of a small quantity of light petroleum to the concentrated benzene solution.

2,3-Di(chloroacetoxy)toluene (VII)

A mixture of 3-methylcatechol (2 g) and chloroacetyl chloride (6 g) was heated in an oil bath at 120–130°, under anhydrous conditions, until hydrogen chloride evolution had ceased (i.e. ca. 90 min). The reaction mixture was poured into water (100 ml) and the product was stirred, at room temperature, for 30 min. The solid which precipitated after the aqueous product had been stored at 5° overnight gave colorless needles of 2,3-di(chloroacetoxy)toluene (3.8 g), m.p. 64°, on repeated recrystallization from aqueous ethanol, ν_{max}^{Nujol} 1 745, 1 770 cm^{-1}.

Anal. Calcd. for $C_{11}H_{10}Cl_2O_4$: C, 47.68; H, 3.63; Cl, 25.59. Found: C, 47.64; H, 3.81; Cl, 25.51.

ω-Chloro-3,4-dihydroxy-5-methylacetophenone (VIII)

A mixture of 3-methylcatechol (54 g), chloroacetic acid (47.3 g), pure phosphorus oxychloride[8] (28 g), and dry benzene was boiled, under reflux, in a nitrogen atmosphere, for 3½ h. Carbon tetrachloride (150 ml) was added and the reaction mixture allowed to stand overnight at 5°. The crude ω-chloro-3,4-dihydroxy-5-methylacetophenone (24 g), m.p. 178°, which separated as a pale-pink solid, was sufficiently pure for use in the next stage of the synthesis and was used directly, after washing with water and carbon tetrachloride. A sample was purified for analysis by recrystallization from water and had m.p. 180°, ν_{max}^{Nujol} 3 490, 3 290, 1 670 cm^{-1}. The n.m.r. spectrum of this substance in acetone-d_6 showed a single singlet peak (δ 7.5) in the aromatic hydrogen region.

Anal. Calcd. for $C_9H_9ClO_3$: C, 53.96; H, 4.55; Cl, 17.72. Found: C, 53.87; H, 4.29; Cl, 17.85.

3,4-Dihydroxy-ω-iodo-5-methylacetophenone

3,4-Dihydroxy-ω-iodo-5-methylacetophenone (pale-yellow needles, m.p. 177°) was prepared from the corresponding chloro compound by a procedure identical to that described above for the preparation of the analogous 2-methylacetophenone derivative.

Anal. Calcd. for $C_9H_9IO_3$: C, 37.01; H, 3.11. Found: C, 37.25; H, 3.38.

3,4-Dihydroxy-5-methyl-ω-methylaminoacetophenene (IX)

A mixture of methanol (5 ml) and a solution of methylamine in methanol (15 ml, saturated at 5°) was added at 0° to solid 3,4-dihydroxy-5-methyl-ω-chloroacetophenone (5 g), and the resulting suspension was shaken in a tightly stoppered flask for 6 min. Excess methylamine and the solvent was then removed *in vacuo*, below 90°; the brownish solid residue was triturated with ethanol (30 ml) and afforded tan prisms of 3,4-dihydroxy-5-methyl-ω-methylaminoacetophenone (2.1 g), m.p. 203–205°. The product, after filtration and washing with ethanol, was sufficiently pure for the next stage in the synthesis. A sample of IX was purified for analysis by recrystallization from a large volume of methanol and was obtained in light tan-colored prisms (m.p. 205–206° (with decomposition)).

Anal. Calcd. for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71; N, 7.18. Found: C, 61.23; H, 6.87; N, 7.09.

3,4-Dihydroxy-5-methyl-ω-methylaminoacetophenone hydrochloride (colorless needles; m.p. 235°, with decomposition) was prepared from the base in an analogous manner to that described above for the preparation of the 2-methyl derivative.

Anal. Calcd. for $C_{10}H_{14}ClNO_3$: C, 51.84; H, 6.12; N, 6.08; Cl, 15.30. Found: C, 51.86; H, 5.87; N, 5.94; Cl, 15.56.

Treatment of ω-chloro-3,4-dihydroxy-5-methylacetophenone with methanolic methylamine in ether, in a manner similar to that described above for the analogous 3-methyl compound, gave pale-yellow needles (m.p. 80°). The microanalytical values for carbon and hydrogen are not incompatible with this substance being a methylamine salt of ω-chloro-3,4-dihydroxy-5-methyl acetophenone (cf. refs. 5, 22).

Anal. Calcd. for $C_{10}H_{14}ClNO_3$: C, 51.84; H, 6.12. Found: C, 52.19, H, 6.30.

5-Methyladrenaline (i.e. 5-Methyl-α-methylaminomethylprotocatechuyl Alcohol (II))

A solution of 3,4-dihydroxy-5-methyl-ω-methylaminoacetophenone hydrochloride (2.4 g) in water (200 ml), containing 5% palladium–charcoal (1 g), was shaken in an atmosphere of hydrogen at atmospheric pressure for 5 h. After this time the catalyst was removed by filtration and the clear filtrate was concentrated *in vacuo* (nitrogen "leak"), below 40°, to ca. 12 ml; solid potassium carbonate (1.5 g) was added, with stirring, and the crude base separated out, after the solution had been allowed to stand at 5° for 1 h. The product obtained in this manner was pure enough for oxidation directly to the corresponding aminochrome. A sample of 5-methyladrenaline was purified for microanalysis by recrystallization from a large volume of methanol and was obtained as colorless prisms, m.p. 195–197° (with decomposition).

Anal. Calcd. for $C_{10}H_{15}NO_3$: C, 60.89; H, 7.67; N, 7.10. Found: C, 60.89; H, 7.84; N, 6.93.

5-Methyladrenaline picrate was prepared by adding a solution of picric acid (0.1 g) in dry benzene (8 ml) to a stirred suspension of the base (0.1 g) in ethanol (1 ml). The solid dissolved and dark-yellow needles of the

[8]*Commercial phosphorus oxychloride was purified by the procedure described by Ott (9), i.e. by washing a solution of the impure product in chloroform with ice water; removing the solvent in vacuo and fractional distillation of the product. The fraction boiling in the range 103–105° was collected and used directly. The direct use of the commercial product, which contains phosphorus pentachloride and phosphorus trichloride, leads to extensive tar formation and low yields of product.*

crude picrate were obtained after the solution had stood at 5° for 3 h. 5-Methyladrenaline picrate (0.12 g) m.p. 183°, was obtained in yellow needles on recrystallization of the crude product from a benzene–alcohol (9:1) mixture.

Anal. Calcd. for $C_{16}H_{18}N_4O_{10}$: C, 45.07; H, 4.26; N, 13.14. Found: C, 45.07; H, 4.32; N, 13.08.

7-Methyladrenochrome (XVI)

5-Methyladrenaline (0.6 g) was suspended in water (5 ml) and 2 *N* hydrochloric acid was added cautiously, with stirring, until a clear solution was obtained. A solution containing potassium ferricyanide (3.5 g) and sodium bicarbonate (1.2 g) in water (10 ml) was added, with stirring; the solution became deep violet in color and vigorous effervescence occurred. 7-Methyladrenochrome (0.18 g) (totally decomposed without melting by 105°) was obtained in deep violet (almost black) needles after the reaction mixture had been allowed to stand at 5° for 1 h, $\lambda_{max}^{H_2O}$ 232, 305, 534 mμ;

Anal. Calcd. for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25. Found: C, 62.60; H, 5.72; N, 6.92.

Attempted Preparation of an Iodo-7-methyladrenochrome

An aqueous solution of 5-methyladrenaline hydrochloride (prepared from 0.3 g of the base) was treated with potassium iodate (0.5 g), at pH 7.2 (the pH of the solution was adjusted to 7.2 by the cautious addition of solid sodium carbonate), in an identical manner to that described above for the preparation of 7-iodo-4-methyladrenochrome. A deep-violet solution, having ultraviolet and visible spectral characteristics identical to those of 7-methyladrenochrome was obtained. The spectrum of the solution was not affected by prolonged reaction time (i.e. ca. 2 h), or by the addition of a further quantity of potassium iodate (0.5 g).

7-Methyladrenochrome monosemicarbazone (0.21 g) (totally decomposed without melting by 245°) was obtained, when a solution of semicarbazide hydrochloride (0.2 g) and sodium acetate (0.2 g) in water (3 ml) was added to a solution of 5-methyladrenaline hydrochloride that had been oxidized with potassium iodate. The sample of 7-methyladrenochrome monosemicarbazone, obtained in this manner, was identical to the product prepared by the method described below.

7-Methyladrenochrome Monosemicarbazone (XVII)

A solution of 7-methyladrenochrome, prepared by the oxidation of an aqueous solution of 5-methyladrenaline hydrochloride (from 1 g of base) with potassium ferricyanide, was treated with a solution of semicarbazide hydrochloride and sodium acetate in the manner described above for the analogous 4-methyl derivative. 7-Methyladrenochrome monosemicarbazone (0.95 g) (totally decomposed without melting by 245°) was obtained in wine-red needles on recrystallization of the crude product from a pyridine–water (1:1) mixture.

Anal. Calcd. for $C_{11}H_{14}N_4O_3$: C, 52.79; H, 5.64; N, 22.39. Found: C, 52.62; H, 5.61; N, 22.22.

5,6-Dihydroxy-1,7-dimethylindole (XVIII: R = H)

Ascorbic acid was added in portions, with stirring, to a two-phase system consisting of ether and an aqueous solution of 7-methyladrenochrome, prepared by the potassium ferricyanide oxidation of 5-methyladrenaline (0.6 g) by the method described above, until the deep-violet color of the solution had disappeared. The ether layer was removed and the aqueous phase was extracted with a further quantity of ether. Dry benzene (10 ml) was added to the combined, dried (Na_2SO_4) ethereal extracts, and the resulting solution concentrated to ca. 5 ml. Colorless prisms of 5,6-dihydroxy-1,7-dimethylindole (0.18 g) were obtained on addition of a small quantity of *n*-heptane to the warm benzene solution. The product could be further purified (m.p. 155°) by high vacuum sublimation at 160° (bath temperature) at 0.2 mm.

Anal. Calcd. for $C_{10}H_{11}NO_2$: C, 67.78; H,6.26; N, 7.91. Found: C, 67.64; H, 6.32; N, 7.87.

5,6-Diacetoxy-1,7-dimethylindole (XVIII: R = $COCH_3$)

A mixture of dry pyridine (3 ml) and acetic anhydride (3 ml) was added to a dry ethereal solution of 5,6-dihydroxy-1,7-dimethylindole, prepared by the method described above. The ether was removed *in vacuo*, and the concentrated reaction mixture was poured into an ice–water mixture, after it had been allowed to stand overnight at room temperature. Recrystallization of the crude product from benzene – light petroleum gave 5,6-diacetoxy-1,7-dimethylindole (0.35 g) in small colorless prisms, m.p. 137–138°.

Anal. Calcd. for $C_{14}H_{15}NO_4$: C, 64.37; H, 5.79; N, 5.36. Found: C, 64.01; H, 5.68; N, 5.21.

6-Methoxy-1,7-dimethylindole (XIX): Prepared by the Alkaline Degradation of 7-Methyladrenochrome Monosemicarbazone and Subsequent O-Methylation (cf. ref. 21)

Solid potassium hydroxide (2 g) was added, with stirring, in a nitrogen atmosphere, to a suspension of 7-methyladrenochrome monosemicarbazone (0.5 g) in water (20 ml) at 90°, the resulting deep red-brown solution was boiled (in an atmosphere of nitrogen) until effervescence had ceased (ca. 2–5 min). The temperature of the solution was then reduced to ca. 50° by the addition of crushed ice; dimethyl sulfate (2.5 ml) was added dropwise and the reaction mixture was cautiously heated to 80°, and maintained at this temperature for 5 minutes. The resulting solution was cooled to room temperature and extracted several times with ether. The combined extracts were washed with *N* potassium hydroxide solution, dried (Na_2SO_4), and evaporated to dryness. The crude product was purified by recrystallization from light petroleum and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

gave 6-methoxy-1,7-dimethylindole in colorless prisms (0.19 g); m.p. 93°: $\lambda_{max}^{C_2H_5OH}$ 224, 275, 292 (sh), 304 (sh) mμ. The significant n.m.r. peaks are given in Table I.

Anal. Calcd. for $C_{11}H_{13}NO$: C, 75.40; H, 7.48; N, 7.99. Found: C, 75.55; H, 7.31; N, 7.98.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Dr. K. McCallum of the University of Saskatchewan for the use of the Varian A-60 nuclear magnetic resonance spectrometer. The authors are also grateful to Dr. R. G. Micetich of R. & L. Molecular Research Ltd., Edmonton, Alberta, and to Dr. R. Greenhalgh and his colleagues in the Defence Chemical, Biological and Radiation Laboratories, Ottawa, Ontario, for assistance in obtaining some of the n.m.r. spectra and to the latter group for some useful comments on the interpretation of the spectra.

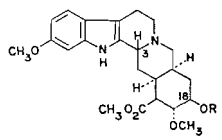
STEREOSPECIFIC SYNTHESIS OF A DIBENZO[*a*,*g*]QUINOLIZINE ANALOG OF 18-HYDROXYALLOYOHIMBANE

B. BELLEAU AND D. DVORNIK[1]
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received April 7, 1965

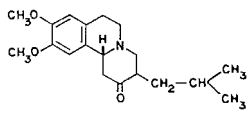
ABSTRACT

Starting from 4-cyclohexene-*cis*-1,2-dicarboxylic acid, the stereospecific synthesis of the dibenzo[*a*,*g*]quinolizine analog IV of epialloyohimbane is described. The synthetic method of approach is outlined in Chart 1. As the trimethoxybenzoic acid ester, the base IV proved to be devoid of significant pharmacological properties.

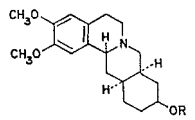
The alkaloid reserpine (I, R = 3,4,5-trimethoxybenzoyl) and several 18-ester analogs possess unique physiological properties, the most striking being their ability to interfere with the storage mechanism of the catecholamine hormones and serotonin (1). Other



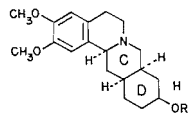
I



II



III



IV

types of analogs such as the 18-ethers (I, R = alkyl) share this property (1) but differ in one important respect: whereas the action of reserpine is protracted, that of the ether derivatives is of shorter duration (1). It seems therefore that an acyl function at position 18 may be essential for prolonged in vivo activity. Quantitatively, reserpine produces effects that are characteristic of irreversible inhibitors such as the alkylating adrenergic blocking agents of the Dibenamine class of drugs (2). It is conceivable that reserpine may be a prototype of selective acylating agents, a hypothesis which readily accounts for the irreversibility characteristics of its action.

Some time ago, it was discovered that a simple benzoquinolizidine derivative (II) known under the name of Tetrabenazine displays reserpine-like activity (3). However, in contrast to reserpine, it is a short-acting compound, a feature which is in accord with the non-acylating properties of the molecule. Evidence is thought to have been produced that Tetrabenazine interacts with the same physiological receptors that serve to bind reserpine (4). This was surprising to us in view of the remote structural analogy between these two drugs. It is apparent that should the same receptors mediate the physiological effects of both reserpine and Tetrabenazine, the formal transformation of the latter to an acylating agent ought to markedly intensify its reserpine-like properties. To this end,

[1]*National Research Council of Canada Postdoctorate Fellow, 1958–1959.*

a close structural analogy to reserpine should be maintained, and accordingly, we elected to synthesize a trimethoxybenzoyl ester of the 3,4-dimethoxyphenyl analog of 18-hydroxy-epialloyohimbane (III). It is the purpose of this communication to report on a stereo-specific approach which led to the synthesis of the isomeric alloyohimbane analog IV (R = 3,4,5-trimethoxybenzoyl). The synthesis of the desired epiallo isomer III was eventually accomplished as described in an accompanying communication (5).

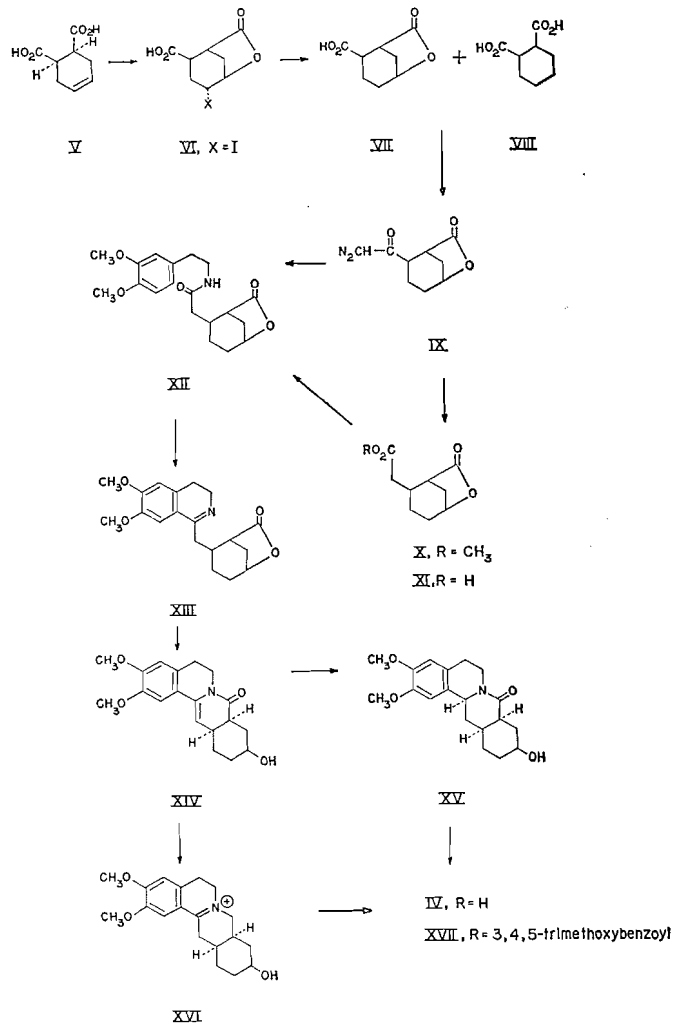


CHART 1.

Our synthetic approach (Chart 1) was based on the readily available starting material *cis*-Δ^4-tetrahydrophthalic acid (V) which provided for the desired *cis* fusion of rings C and D in the end product III. Iodolactonization of V proceeded normally (6) to give iodolactone acid (VI). The lactone VI has recently been described by others (7). Absorption in the infrared at 1 750 cm^{-1} confirmed the exclusive formation of a γ-lactone ring in which the potential 18-hydroxyl function of III assumes the proper configuration.

Catalytic hydrogenolysis of the iodolactone acid afforded the lactone acid VII accompanied in various proportions by *cis*-hexahydrophthalic acid (VIII). On a preparative scale, the separation of the hydrogenolysis mixture presented some difficulty. The formation of *cis*-hexahydrophthalic acid was unexpected; it seems probable on the basis of related experiments (5) that the lactone acid VII is the immediate precursor of the diacid VIII. It has been noted before that γ-lactones with an axial ring oxygen can be susceptible to hydrogenolysis (8). However, this process is slower than reductive dehalogenation. Homologation of the lactone acid VII by way of the intermediate diazoketone IX followed by Wolff rearrangement in the presence of homoveratrylamine offered directly the lactone homoamide XII in good yield. The Wolff rearrangement is known to proceed with retention of configuration (9). Alternatively, the rearrangement was carried out in methanol whereupon the methyl ester X was formed; saponification gave the homoacid lactone XI from which the same oily amide XII could be readily prepared. Bishler–Napieralsky ring closure of the amide led to the dihydroisoquinoline lactone XIII in high yield. It was initially characterized as the picrate but the hydrochloride was later obtained in pure form (5). Cyclization of XIII to the tetracyclic ene-lactone XIV was accomplished in moderate yield by boiling in xylene for several hours. The infrared spectrum of the lactam XIV was in agreement with expectations (see Experimental). Conversion of the ene-lactam XIV to the corresponding reduced base IV involved either catalytic hydrogenation of the double bond to give the reduced lactam XV followed by lithium aluminium hydride reduction to IV or hydride treatment to give the intermediate XVI followed by reduction to IV. Thus, reduction of the iminium ion XVI with lithium aluminium hydride, sodium borohydride, zinc and hydrochloric acid, or with sodium in liquid ammonia – *t*-butanol uniformly produced the same tetracyclic base in a homogeneous state. Surprisingly, zinc – acetic acid reduction, a method which is successful in the yohimbane series (10), led only to unchanged starting material. The reasons for this are not clear. The tetracyclic base IV was readily oxidized to the imine XVI by mercuric acetate (10).

Since it has been shown that the sodium – liquid ammonia – *t*-butanol system leads to the thermodynamically more stable isomer in the analogous yohimbane series (11), it follows that the tetracyclic base obtained by us in this manner must possess the configuration IV in which both the phenyl and 18-hydroxyl substituents are equatorial. In agreement with this conclusion, the tetracyclic base IV gave rise to Bohlmann bands (12) in the region 2 800 – 2 700 cm^{-1} of the infrared spectrum; the stable conformation of IV which places the phenyl and hydroxyl substituents in the equatorial orientation has the electron pair on the nitrogen *trans* to two axial α-hydrogens in accord with the spectroscopic characteristics. Reaction of the base IV with 3,4,5-trimethoxybenzoyl chloride gave the corresponding 18-ester XVII in moderate yield.

It was evident at this point that to obtain the desired isomeric tetracyclic base III (epiallo configuration), an alternative approach had to be sought. More gratifying results are reported in an accompanying paper (5). Since 3-isoreserpine (allo configuration as in the base IV) is devoid of reserpine-like activity (1), the analog XVII would be expected to be also inactive. Dr. M. Pindell of Bristol Laboratories, Syracuse, has confirmed this expectation using a variety of standard tests.

EXPERIMENTAL

Melting points and boiling points are uncorrected. The infrared spectra were determined with an Infracord instrument or a Perkin-Elmer spectrometer model 112G using chloroform as the solvent unless otherwise

noted. The sentence "was worked up in the usual manner" signifies that the reaction mixture was extracted with ether or chloroform and, wherever appropriate, the extract was washed with dilute acid or dilute base followed by drying and evaporation *in vacuo*. Microanalyses by Midwest Microlab, Indianapolis, Indiana.

4-Hydroxy-5-iodo-cis-cyclohexane-1,2-dicarboxylic Acid γ-Lactone (VI)

To a stirred suspension of Δ^4-cyclohexene-*cis*-1,2-dicarboxylic acid in 500 ml of water, 29 g of sodium hydrogen carbonate was added, followed by the addition in portions of a solutions of 29 g of iodine in 200 ml of water containing 112 g of potassium hydroxide. After stirring for 1 h at room temperature some sodium thiosulfate was added until the solution became colorless, and the mixture was acidified with conc. hydrochloric acid. The solution was filtered without delay whereupon a crystalline mass separated from the filtrate. After 1 h at 0°, the solid was collected and recrystallized from ethanol–hexane; m.p. 158–160° (reported (7): 161–162°), yield: 74–80%.

Anal. Calcd. for $C_8H_9IO_4$: C, 32.45; H, 3.06; I, 42.86; Found: C, 32.67; H, 3.30; I, 44.00. Infrared: λ_{max} (Nujol mull) 3 100, 1 750, 1 710 cm^{-1}.

The iodolactone acid VI was further characterized as the crystalline *diethylamine salt*; after recrystallization from methanol – ethyl acetate, the m.p. was 122–124°.

Anal. Calcd. for $C_{12}H_{20}INO_4$: C, 39.04; H, 5.46; I, 34.38; Found: C, 39.02; H, 5.43; I, 35.04.

4-Hydroxy-cis-1,2-cyclohexanedicarboxylic Acid γ-Lactone (VII)

A solution of 25.3 g of the iodolactone acid in 190 ml of methanol containing 12.5 ml of diethylamine was hydrogenated at 85 p.s.i. of hydrogen over 25 g of freshly prepared Raney nickel. After a pressure drop of about 6.5 pounds, the reaction was stopped and the catalyst was removed by filtration. The filtrate was treated with 17.0 g of freshly precipitated silver carbonate, and the suspension was shaken for 20 min and filtered through Florex XXX. The colorless filtrate was evaporated *in vacuo* and the residue was dissolved in 50 ml of 3 *N* aqueous sulfuric acid; some insoluble silver sulfate was removed by filtration and the filtrate was extracted five times with 50 ml portions of ethyl acetate. The combined extracts were dried and evaporated *in vacuo*, and the residue was crystallized from 100 ml of dry ether. This first crop weighed 6.0 g and had m.p. 142–143°. The filtrate was taken to dryness and the residue was partitioned between equal volumes (100 ml) of ether and water. The distribution coefficients of the lactone acid VII and the diacid VIII in this solvent system were 0.1 and 2.0 respectively. After equilibration, the aqueous phase was twice extracted with 100 ml portions of ether. The aqueous phase was saturated with ammonium sulfate and extracted with five 50 ml portions of chloroform. The combined extracts were dried and evaporated, and the residue was crystallized from ethyl acetate – ether to give an additional 0.30 g of lactone acid VII m.p. 140–141°. Total yield: 6.3 g or 47% of the theoretical. After recrystallization from benzene, the m.p. was 143–144°.

Anal. Calcd. for $C_8H_{10}O_4$: C, 56.46; H, 5.92. Found: C, 56.61; H, 5.91. λ_{max}: 1 755, 1 700 cm^{-1}.

From the ether extracts and mother liquors there was isolated from 2 to 4 g of the *cis*-cyclohexane-1,2-dicarboxylic acid (VIII) which was characterized by mixture m.p. determination and comparison of its infrared spectrum with that of an authentic specimen.

Diazoketone IX from Lactone Acid VII

To a cooled solution of 6.78 g of the lactone acid VII in 220 ml of dry benzene containing 6.5 ml of triethylamine was added dropwise 8.6 ml of oxalyl chloride. After standing for 3.5 h, the suspension was filtered and the filtrate was treated with a freshly prepared ethereal solution of diazomethane (from 26 g of *N*-nitrosomethyl urea, 52 ml of 45% aqueous potassium hydroxide, and 370 ml of ether). After standing overnight, the mixture was filtered and the filtrate was evaporated *in vacuo*. The residue (7.4 g or 96% of theory) crystallized spontaneously. It was used as such without further purification.

λ_{max}: 2 140, 1 760, and 1 640 cm^{-1}.

(A) Wolff Rearrangement in Methanol

A quantity of diazoketone equivalent to 0.955 g of lactone acid VII was dissolved in boiling methanol and some freshly precipitated silver oxide was added. The mixture was boiled for 3 h, cooled, and filtered through Celite. The filtrate was evaporated *in vacuo* and the residue was distributed between 6 *N* aqueous sulfuric acid and ether. The ether extract was worked up in the usual manner to give 563 mg of semisolid residue. Repeated extraction of the aqueous layer with chloroform and isolation in the usual manner yielded an additional 110 mg of methyl ester. The total yield of crude ester X was 60%.

λ_{max}: 1 753, 1 725 cm^{-1}.

The *lactone homoacid* XI was obtained through saponification of the preceding crude ester X (542 mg) in boiling 5% methanolic potassium hydroxide. The solution was evaporated to dryness, the residue was taken up in 6 *N* aqueous sulfuric acid, and the resulting solution was saturated with ammonium sulfate and repeatedly extracted with chloroform. The extract was dried and evaporated to give an oil (390 mg or 77% of theory) which was dissolved in benzene and purified by chromatography on silicic acid (6 g). Ether eluted 333 mg of an oil which crystallized from benzene–pentane, m.p. 119–120°. Other crystalline forms of m.p. 111–116° exhibiting changes of crystal form at 100–110° were more frequently observed. These varied forms had superimposable infrared spectra in chloroform.

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.57. Found: C, 59.10; H, 6.53. λ_{max}: 1 750, 1 700 cm^{-1}.

N-(3',4'-dimethoxy-β-phenethyl)-cis-2-carboxy-4-hydroxy-cyclohexane-1-acetamide γ-Lactone (XII)

(A) From the Diazoketone IX

To a solution of 6.87 g of homoveratrylamine in 25 ml of pure dioxane, some freshly precipitated silver oxide was added and the suspension was heated to boiling. Heating was discontinued and a solution of 7.41 g of the crude diazoketone IX in 30 ml of dioxane was added dropwise whereupon a vigorous evolution of nitrogen ensued. At intervals, 13.4 g of silver oxide was added in portions over a period of 1 h. The suspension was then heated under reflux for 3 h, cooled, and filtered through a bed of Florex XXX. The precipitate was washed with acetone, and the washings and filtrate were combined and evaporated. The residue was taken up in chloroform; the solution was washed with dilute aqueous sulfuric acid and then with saturated sodium bicarbonate solution; the chloroform solution was finally filtered through a column of 100 g of aluminium oxide (Woelm, activity II) and the column was thoroughly washed with chloroform. Removal of the solvent *in vacuo* afforded 13.2 g of the crude homoamide lactone XII as an uncrystallizable oil. It was used as such in the next step.

λ_{max}: 2 125, 1 765, 1 640 cm^{-1}.

(B) From the Homoacid Lactone XI

The homoacid lactone acid chloride was prepared by treatment of the acid triethylamine salt in benzene with oxalyl chloride as described above in the case of the preparation of the diazoketone IX. The benzene solution of the acid chloride was treated with excess homoveratrylamine in the cold, and the mixture was worked up in the usual manner to give in high yield the oily homoamide lactone XII identical in the infrared with the amide obtained through the application of method A above.

1-[(cis-2'-Carboxy-4'-hydroxy)-1'-cyclohexylmethyl]-3,4-dihydro-6,7-dimethoxyisoquinoline γ-Lactone (XIII)

The preceeding homoamide lactone XII (13.0 g) was heated under reflux and under an oxygen-free nitrogen atmosphere in 100 ml of dry toluene containing 25 ml of freshly distilled phosphorous oxychloride. After 75 min, the solution was evaporated to dryness *in vacuo*. The residual syrup was taken up in chloroform and the solution was washed twice with saturated sodium bicarbonate, dried, and evaporated to give 12.1 g (97% of theory) of a clear deep-yellow oil.

λ_{max}: 1 750, 1 600, 1 555, 1 500 cm^{-1}.

The *picrate* crystallized from methanol; recrystallization from acetone – ethyl acetate gave yellow crystals m.p. 193–194°; recrystallization from acetone–chloroform gave another form m.p. 175–176°. The two forms are interconvertible.

Anal. Calcd. for $C_{25}H_{26}N_4O_{11}$: C, 53.76; H, 4.69. Found: C, 53.48; H, 4.92.

Ring Closure of XIII to the Tetracyclic Ene-lactam XIV

A solution of 12 g of the preceeding base XIII in 200 ml of dry xylene was heated under reflux for 24 h under an atmosphere of oxygen-free nitrogen. The hot mixture was decanted from some insoluble gum and the solvent was removed *in vacuo*. The residue was dissolved in chloroform and the solution was worked up in the usual manner to give an oil which crystallized from 70 ml of boiling toluene. The yield was 5.1 g (42% of theory). Recrystallization from benzene gave white crystals m.p. 195–196°.

Anal. Calcd. for $C_{19}H_{23}NO_4$: C, 69.28; H, 7.04; N, 4.25. Found: C, 69.83; H, 6.89; N, 4.40. λ_{max}: 3 400, 1 640, 1 500 cm^{-1}.

Catalytic Hydrogenation of XIV to the Decahydrodibenzo[a,g]quinolizinone XV

A solution of 1.41 g of the preceeding ene-lactam XIV in 20 ml of ethanol containing 0.5 ml of 75% aqueous perchloric acid was shaken in a hydrogen atmosphere at atmospheric pressure in the presence of 300 mg of Adam's catalyst. After 6 min, the theoretical amount of hydrogen was adsorbed; the catalyst was removed and the solvent was evaporated. The residue was dissolved in chloroform and the solution was worked up in the usual manner to give a solid which on recrystallization from benzene afforded 1.14 g (80% of theory) of the lactam XV, m.p. 217–219°. Depending on the rate of heating the m.p. varied from 213–216° to 217–219°. Additional recrystallizations did not alter the m.p. The product was homogeneous as ascertained by thin-layer chromatography (silicic acid; chloroform–methanol).

Anal. Calcd. for $C_{19}H_{25}NO_4$: C, 68.86; H, 7.60. Found: C, 68.81; H, 7.72. λ_{max}: 3 400, 1 620, 1 500 cm^{-1}.

Reduction of XV to the Tetracyclic Base IV

To a suspension of 1 g of lithium aluminium hydride in 30 ml of dry ether was added dropwise a solution of 1.44 g of the preceeding lactam XV in 100 ml of dry tetrahydrofuran. After 3 h of heating under reflux, the mixture was cooled and treated successively with 1 ml of water, 0.75 ml of 20% aqueous sodium hydroxide, and 3.5 ml of water. The salts were filtered off, the filtrate was evaporated, and the residue was partitioned between 16 ml of 3 *N* aqueous sulfuric acid and 50 ml of ether. The aqueous phase was made alkaline and extracted with ether. The ether was dried and evaporated and the residue was crystallized from acetone–water to give 1.22 g (89% of theory) of the base IV, m.p. 178–180°. Recrystallization from acetone did not change the m.p.

Anal. Calcd. for $C_{19}H_{27}NO_3$: C, 71.89; H, 8.57. Found: C, 71.92; H, 8.40. λ_{max}: 2 800, 2 760 cm^{-1} (Bohlmann bands); 3 400, 1 500 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Treatment of the base with a 10% excess of mercuric acetate in acetic acid at 60° gave an immediate precipitate of mercurous acetate. After working up the mixture in the usual manner (excess mercuric ions being removed with H_2S), the dehydrobase XVI was isolated as the chloride salt in the form of an uncrystallizable yellow oil identical in the infrared with a sample prepared as described below.

λ_{max}: 3 400, 1 720, 1 500 cm^{-1}.

Reduction of Ene-lactam XIV to the Dehydrobase XVI

The ene-lactam XIV (400 mg) was reduced with lithium aluminium hydride by the same method described above in the case of the reduction of XV to IV. After isolation in the usual manner, the free base (which is sensitive to air) was converted to the oily chloride XVI which was identical in the infrared with a sample obtained by mercuric acetate dehydrogenation of IV (see above).

Attempted reduction of this dehydrobase XVI by zinc in acetic acid led to unchanged starting material. Reduction with boiling hydrochloric acid and zinc gave in good yield the base IV (identity established by mixed m.p. determination and infrared); similar results were obtained using either lithium aluminium hydride or sodium borohydride (in aqueous ethanol). The reduced base was obtained in good yield (75–90%) in each instance.

Reduction with sodium – liquid ammonia – *t*-butanol (using the procedure of Stork and Hill (11)) also gave the base IV in high yield.

3,4,5-Trimethoxybenzoic Acid Ester XVII of the Base IV

The method of Lucas *et al.* (13) was applied. Thus, 317 mg of the base IV was treated in 15 ml of dry pyridine with 920 mg of 3,4,5-trimethoxybenzoyl chloride. After 4 days at room temperature, the mixture was poured onto ice-cold dilute ammonia and the precipitate was collected. After several recrystallizations from methanol, the pure ester XVII (100 mg) had m.p. 149–150°.

Anal. Calcd. for $C_{29}H_{37}NO_7$: C, 68.10; H, 7.24; N, 2.74. Found: C, 67.80; H, 7.24; N, 2.95. λ_{max}: 1 700, 1 590 cm^{-1}.

STEREOSELECTIVE SYNTHESIS OF A DIBENZO[*a*,*g*]QUINOLIZINE ANALOG OF 18-HYDROXYEPIALLOYOHIMBANE

B. BELLEAU AND J. PURANEN
Department of Chemistry, University of Ottawa, Ottawa, Ontario

Received April 7, 1965

ABSTRACT

Starting from *cis*-Δ^4-cyclohexenedicarboxylic acid anhydride, a stereoselective synthesis of *cis*-Δ^4-tetrahydrohomophthalic acid (IX) is described (Chart 1). The synthesis involves selective reduction to Δ^4-tetrahydrophthalide (III) and reaction of the latter with cyanide to give mainly the *cis*-nitrile acid V in good yield. Alkaline hydrolysis leads to the *cis*-homodiacid IX which was characterized as its corresponding anhydride. The nitrile acid intermediate could be transformed to stereoisomeric decahydroisoquinolines (VIII). Bromolactonization of the *cis*-diacid IX afforded the bromo-γ-lactone XIII (R = Br; Chart 2) which underwent hydrogenolysis to the already described γ-lactone homoacid intermediate XV in good yield. Transformation of the latter to the dihydroisoquinoline XVIII was uneventful. Reduction with sodium borohydride gave XIX which on heating gave the two isomeric lactams XX and XXII. The former was identical to a lactam already obtained by a different route (ref. 1). The latter was reduced to the tetracyclic base XXIII which is believed to exist in conformation XXIV*c*. The corresponding trimethoxybenzoic acid ester was prepared and tested for reserpine-like activity. It was found to be inactive. The significance of this result is briefly discussed.

In an accompanying paper (1), a rationale was presented which led to the suggestion that dibenzo[*a*,*g*]quinolizine analogs of certain indole alkaloids may be of physiological interest. In particular, attention was centered on the 18-hydroxyepialloyohimbane analog XXIII (Chart 2), a substance which is related both to the physiologically long-acting molecule of reserpine and the short-acting drug Tetrabenazine (2). If, as suggested by Quinn *et al.* (3), the same receptors are involved in the binding of the two drugs, it may be expected that the analog XXIII should produce protracted effects when interacting at the same level. Our initial attempts to obtain XXIII led instead to a stereospecific synthesis of the "allo"-epimer XXI which, however, is related to the physiologically ineffective 3-isoreserpine. It is the purpose of this communication to describe an alternative approach to the desired epimer XXIII (epiallo configuration). The new approach is based on the use of *cis*-Δ^4-tetrahydrohomophthalic acid (IX) as a key intermediate. The technical procedures provide for large scale preparations and are free of the hazards associated with the handling of large quantities of diazo compounds as was the case in our first approach (1). The ready availability of the *cis*-diacid intermediate IX suggests a number of applications in the field of the synthesis of indole alkaloids.

The preparation of intermediate IX was accomplished as shown in Chart 1. Its use in the synthesis of XXIII is described in Chart 2. A key finding is that 4-cyclohexene-*cis*-1,2-dicarboxylic anhydride (I) can be readily converted in 60–70% yields to Δ^4-*cis*-tetrahydrophthalide (III) by reduction with sodium borohydride in dry dimethyl formamide (DMF). The aldehydo-acid salt II is an obvious candidate as an unisolatable intermediate in this reaction. The phthalide III was characterized by its elemental composition, its equivalent molecular weight and its infrared spectrum. The same structure III was assigned by others (4) to a solid m.p. 100° (hydrazide m.p. 170°) obtained by a different and somewhat ambiguous route. Our preparation is liquid and no well defined crystalline hydrazide could be obtained. The discrepancy may be attributable to *cis–trans* isomerism. That our liquid phthalide III has the *cis* configuration was shown by its stability to potassium *t*-butoxide in *t*-butanol (5).

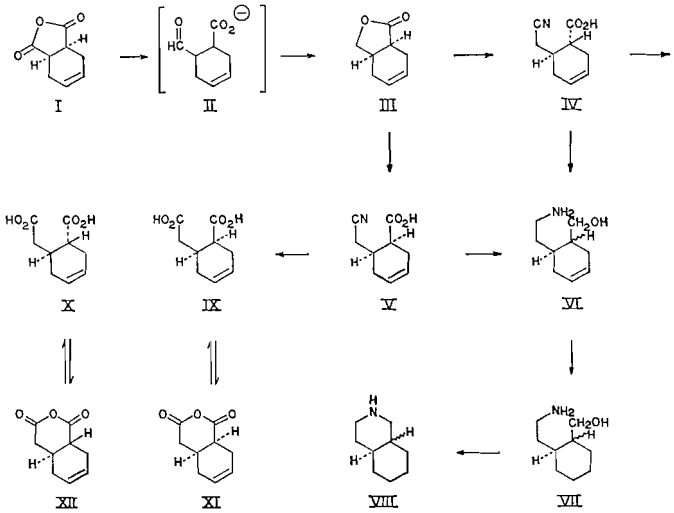

CHART 1.

On the basis of the known reactivity of γ-lactones in nucleophilic carbon–oxygen fission reactions (6), the phthalide III was reacted with cyanide ion using a variety of experimental conditions with a view to obtaining the nitrile-acid V. In the absence of a solvent, only tarry material was produced. In dimethylsulfoxide (DMSO) as the solvent the reaction proceeded smoothly and in good yield but extensive epimerization to the *trans*-nitrile acid IV occurred. Separation of the isomeric nitrile acids IV and V was not feasible on a preparative scale, but the corresponding diacids IX and X resulting from alkaline hydrolysis could be readily separated. In this way it could be established that the *trans*-nitrile acid IV accounted for 40–50% of the mixture when DMSO was used as the solvent. Reduction of the crystalline mixture of isomeric nitrile acids with lithium aluminium hydride gave VI which was converted to VII by catalytic hydrogenation and then to decahydroisoquinoline VIII after treatment with thionyl chloride followed by basification. The melting point behavior of the picrate and hydrochloride salts of VIII was consistent with that expected for a mixture of *cis* and *trans* isomers. Paper chromatography confirmed the presence of the isomeric bases thus pointing to the correctness of the assigned structures for the nitrile acids IV and V. It was eventually found that the proportion of *trans*-nitrile acid IV could be reduced to about 20% of the total yield of nitrile acid product by reacting the lactone III with sodium cyanide in DMF as the solvent. The mixture thus obtained (*cis*:*trans* ratio of 80:20) was hydrolyzed with boiling dilute sodium hydroxide to give a mixture of *cis*- and *trans*-Δ^4-tetrahydrohomophthalic acids (IX and X). The *cis* isomer IX crystallized in pure form from water in 60% yield. From the mother liquors, a mixture of *cis* and *trans* isomers was obtained. Recently, an alternative synthesis of the *cis*- and *trans*-homodiacids IX and X based on the Arndt–Eistert homologation reaction was described (7). The reported melting points for the isomers (7, 8) are in satisfactory agreement with our observations. It was essential at this point to establish the correctness of our configurational assignment to the *cis*-homodiacid IX. The melting points could hardly be relied upon to distinguish between the two isomers because, as was also noted by others (7), they are nearly identical. Recourse was made therefore to the corresponding anhydrides. Using a variety of conditions, Brutcher and Rosenfeld (7) were able to obtain only the *trans*-anhydride XII

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

either from the *cis*-diacid IX or the *trans* isomer X. However, under appropriate conditions, we have been successful in preparing in nearly quantitative yield the *cis*-anhydride XI, m.p. 67–68°. The two isomeric anhydrides exhibit a difference of 100° in their m.p. and have different infrared spectra. Hydrolysis with water regenerated the pure diacid precursor. A mixture of the two anhydrides can be readily separated by crystallization. It is obvious that the conditions applied by Brutcher and Rosenfeld (7) are too vigorous for the *cis*-anhydride to retain its configurational integrity. We found it expedient to isolate and purify the *cis*-diacid IX as its *cis*-anhydride prior to use in subsequent steps. Large scale preparations of this useful intermediate IX have been successfully carried out.

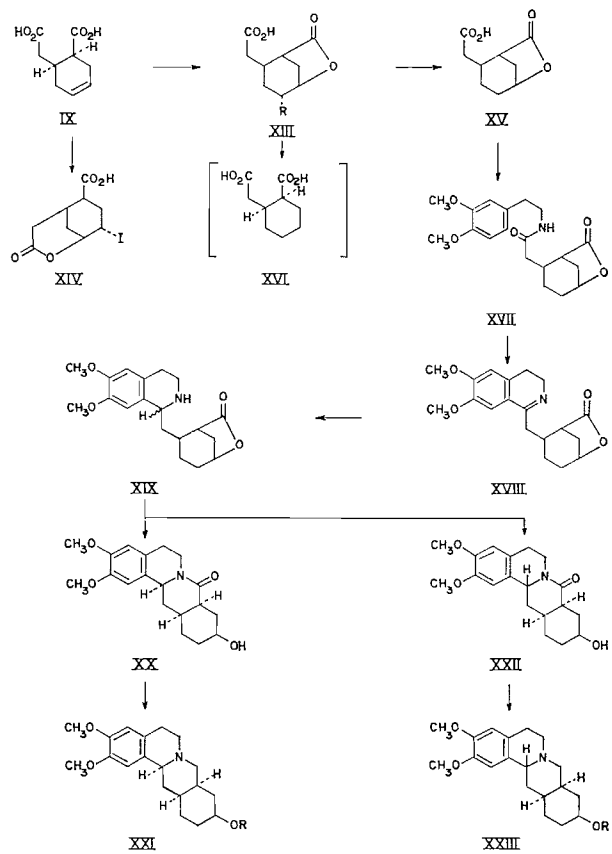

CHART 2.

The synthesis of XXIII from IX is summarized in Chart 2. As a means of introduction of the *cis*-hydroxyl function on ring D of XXIII, we initially submitted the *cis*-homodiacid IX to the Bougault iodolactonization reaction (9). Two likely reaction paths are available, one leading to the desired γ-lactone XIII, the other to the isomeric δ-lactone XIV. In practice, the γ-lactone XIII (R = I) was the major product of the reaction but was uniformly contaminated by small quantities of an isomeric lactone showing strong absorption at 1 720 cm^{-1} in the infrared. Although we have not established the structure of this minor product we suspect that it corresponds to the expected iodo-δ-lactone XIV. The iodo-γ-lactone XIII (R = I) had poor crystallization properties and was somewhat unstable. These difficulties were obviated when it was found that bromolactonization of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

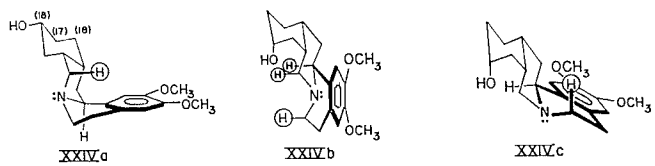
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

IX gave a well crystallized, stable bromo-γ-lactone XIII (R = Br) free of contaminating isomers. If any bromo-δ-lactone isomer was formed, its presence was not detectable by infrared. Hydrogenolysis of the carbon–bromine bond of XIII (R = Br) proceeded best using Raney nickel as the catalyst and afforded the already known lactone homoacid XV (1). A small amount of a by-product lacking the γ-lactone bond but absorbing strongly at 1 700 cm^{-1} was detected. It seems likely on the basis of previous experience (1) that this compound corresponds to *cis*-hexahydrohomophthalic acid (XVI) although no effort was made to characterize it further. The proportion of this contaminant in the hydrogenolysis mixture was found to be a function of the reaction time. Hydrogen uptake was initially very rapid and, if the reaction was stopped as soon as stoichiometry was attained, the amount of by-product (XVI?) was negligible thus suggesting that the homoacid lactone XV can suffer further attack by hydrogen albeit at a slow rate (see preceding paper (1)).

The homoacid lactone XV was next converted in high yield to the previously described (1) oily amide XVII by the mixed anhydride technique. The latter amide was ring closed the the dihydroisoquinoline lactone XVIII (1) which was purified as the crystalline hydrochloride. At this stage, our previous experience (1) suggested that reduction of the double bond of XVIII ought to be accomplished before the formation of ring C to provide for the formation of the two possible isomers at the position 1 of the tetrahydroisoquinoline ring. No stereoselectivity in the reduction of XVIII is to be expected and in agreement with theory, sodium borohydride reduction of XVIII afforded a mixture of epimers (XIX) which was used as such in the next step. Heating in boiling DMF caused smooth cyclization of XIX to two isomeric lactams which could be readily separated by crystallization. From benzene, a lactam m.p. 213–216° (XX) separated whereas a lactam m.p. 161–163° (XXII) was obtained from ethyl acetate. A rapid and quantitiative method of separation of these two isomers consists in digesting the mixture with tetrahydrofuran in which the high-melting isomer is insoluble in contrast to the low-melting one. The lactam m.p. 213–216° proved identical in every respect with the lactam previously obtained by another route (1) and consequently has the configuration XX. Moreover, lithium aluminium hydride reduction of this lactam gave the expected crystalline base (XXI, R = H) already described by Belleau and Dvornik (1). Similar treatment of the low-melting isomer XXII afforded the corresponding tetracyclic base XXIII (R = H) in high yield. In agreement with the configurational assignment, this latter base did not give rise to Bohlmann bands (10) in the infrared (in contrast to its isomer XXI (1)), an observation which might be taken to indicate that the dimethoxyphenyl substituent assumes the axial orientation with respect to ring C (as shown in XXIV*a*). However,



XXIV*a* XXIV*b* XXIV*c*

this is unlikely in view of the fact that the *A* value for a phenyl ring is from 3 to 6 times greater than that of a hydroxyl function (11). Of the alternative conformations XXIV*b* and XXIV*c* only the latter satisfies the criterion of thermodynamic stability (*A* values) and that of the infrared absorption characteristics (absence of Bohlmann bands). Conformation XXIV*b* places more than two axial hydrogens (circled atoms) *trans* to the α-electrons on the nitrogen. It follows that XXIII would not exist in a reserpine-like

conformation because of the absence of the 17 and 16 substituents which in reserpine stabilize conformation XXIV*a*. The possibility must be recognized that ring D of XXIV*c* may exist in a twisted boat conformation which would serve to relieve the 1,3-interactions introduced by the axial hydroxyl. The base XXIII was converted in moderate yield to the corresponding 3,4,5-trimethoxybenzoic acid ester for pharmacological evaluation.

Pharmacological results.—In a variety of standard tests Dr. M. Pindell, Bristol Laboratories, Syracuse, found that the analog XXIII (R = trimethoxybenzoyl) is devoid of reserpine-like activity. It could be argued that the absence in XXIII of the 16 and 17 substituents of reserpine may be responsible for the observed lack of activity either because these substituents participate in the binding of reserpine onto its physiological receptors or because they impose the proper conformation (equivalent to XXIV*a*) to the molecule. However, after our work was completed, we have learned from Dr. G. Muller (Roussel-Uclaf, Romainville, France) that the analog of XXIII in which both the 16 and 17 substituents of reserpine are present (synthesized by the Woodward method for reserpine (12) is also inactive. We are led to the conclusion that the indole ring of reserpine is critical for activity. These observations cast some doubt on the proposed identity of the receptors for Tetrabenazine and reserpine (3).

EXPERIMENTAL

Melting points and boiling points are uncorrected. Infrared spectra were recorded using a Perkin-Elmer Infracord instrument; chloroform solutions were used unless otherwise noted. Microanalyses were by Midwest Microlab, Indianapolis, and by Daessle Organic Microanalyses, Montreal. The sentence "worked up in the usual manner" signifies that the reaction mixture was extracted with ether or chloroform, and that the extract was washed successively with water and dilute base (or dilute acid when appropriate), dried over sodium sulfate, and evaporated to dryness *in vacuo*.

cis-6-Hydroxymethyl-3-cyclohexene-1-carboxylic Acid γ-Lactone (III)

A solution of 152 g of *cis*-Δ^4-tetrahydrophthalic acid anhydride (I) in 475 ml of dry DMF was added dropwise over a period of 1 h to a stirred, ice-cold solution of 30 g sodium borohydride in 475 ml of dry DMF. The temperature of the reaction was kept below 20°. The solvent was removed under reduced pressure and the residue was carefully treated with 2.1 l of 2 *N* aqueous sulfuric acid. After standing for 16 h the turbid solution was extracted with chloroform and the extract was processed in the usual manner. The residue was distilled *in vacuo* to give 71 to 83 g (52–60% yield) of colorless liquid, b.p. 128–130° at 2.8 mm, n^{22} 1.499. Yields as high as 73% were obtained when the starting anhydride I was purified before use. Solvents other than DMF such as diglyme gave inferior yields.

Anal. Calcd. for $C_8H_{10}O_2$: C, 69.54; H, 7.30; Sap. Equiv. 138. Found: C, 68.91; H, 7.27; Sap. Equiv. 140. Infrared: λ_{max} 1 770 cm^{-1}.

Attempts to prepare a crystalline hydrazide were unsuccessful (see ref. 4).

cis- and trans-Δ^4-Tetrahydrohomophthalonitrile (V and IV)

(A) DMF as Solvent

To a boiling suspension of 9.0 g sodium cyanide in 1.3 l of DMF was added in portions a solution of 25 g of the preceding tetrahydrophthalide III in 200 ml of DMF. The mixture was heated under reflux for 18 h, cooled, and filtered, and the filtrate was then evaporated under reduced pressure. The residue was dissolved in water, acidified to pH 3 with dilute sulfuric acid, and thoroughly extracted with chloroform. The extract was washed several times with aqueous sodium bicarbonate, and the combined washings were acidified and cooled in ice whereupon crystals separated. They were collected, the filtrate was extracted with chloroform, and the extract was worked up in the usual manner to give a crystalline mass. The combined solids were recrystallized from water to give 18.7 g (56% yield) of a mixture of *cis*- and *trans*-nitrile acid IV and V, m.p. 72–76°.

Anal. Calcd. for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48. Found: C, 64.90; H, 6.90; N, 8.55. λ_{max} (Nujol mull): 2 240, 1 700 cm^{-1}.

(B) DMSO as Solvent

Using one fifth as much of this solvent as of DMF, the same reaction as described in (A) above was carried out. It was found that in DMSO the optimum reaction time (which minimizes epimerization to IV) is 4 h. The mixture was worked up as described above to give the nitrile acid mixture in 60–65% yield. However, the proportion of *trans* isomer IV in this mixture was increased by a factor of 2–3.

For personal use only.

cis- and trans-Decahydroisoquinoline (VIII) from the cis- and trans-Nitrile Acids IV and V

The sequence of reactions followed conventional lines. Thus, the nitrile acid (IV + V) was reduced in hot tetrahydrofuran (THF) with excess lithium aluminium hydride for 6 h. The mixture was decomposed with water and aqueous sodium hydroxide, and the liberated amino alcohol VI was isolated in crude form in the usual manner. It was purified by a short path distillation (bath temp. 100° under reduced pressure (1.2 mm) to give a colorless oil which was catalytically hydrogenated over Adams' catalyst in ethanol under a pressure of 40 p.s.i. of hydrogen. The reduced base VII was isolated in the usual manner (no olifinic absorption in the infrared, converted to the oily hydrochloride, and treated in dry chloroform with a 10% excess of pure thionyl chloride. After boiling the mixture for 1 h, the solvent was evaporated and the residue was treated at 100° with an excess of 10% aqueous sodium hydroxide. The mixture was cooled and worked up in the usual manner to give a liquid which was purified by distillation to give a colorless liquid, b.p. 80° (bath temp.) at 0.2 mm. It was converted to a crystalline picrate and crystalline hydrochloride which had respective m.p. 151–160° and 165–188° after several recrystallizations from ethanol (reported (13) for the *cis* isomer, 150° and 175–178°). The liquid base gave rise to two distinct spots on paper chromatograms (pyridine–methanol–water).

Anal. Calcd. for the picrate $C_{15}H_{20}N_4O_7$: C, 48.91; H, 5.47. Found: C, 49.22; H, 5.53.

cis-Δ^4-Tetrahydrohomophthalic Acid (IX)

A solution of 33 g of the preceding mixture of nitrile acids IV and V in 600 ml of 1 *N* aqueous sodium hydroxide was heated under reflux until ammonia was no longer evolved (about 66 h). The solution was cooled in ice and acidified to pH 3 whereupon the *cis*-homodiacid IX separated as a white crystalline mass. It was collected, washed, and recrystallized from water to give 22 g (60% yield) of the pure *cis* isomer, m.p. 162–164° (reported (7): 155–157°). Extraction of the combined mother liquors with chloroform yielded 5.3 g of a mixture of *cis* and *trans* isomers (IX and X), m.p. 130–140° (reported for a 50:50 mixture, 130–144° (7). Separation of the *trans* isomer could be more readily accomplished by conversion to the anhydride.

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.57. Found: C, 58.83; H, 6.57. λ_{max} (Nujol): 2 600, 1 700 cm^{-1}.

cis-Δ^4-Tetrahydrohomophthalic Anhydride (XI)

A solution of 400 mg of the preceding *cis*-homodiacid IX in 4 ml of benzene containing 1 ml of acetic anhydride was heated under reflux for 2 h and the solution was taken to dryness *in vacuo*. The residue crystallized from ether–hexane to give 320 mg of crystals, m.p. 67–68° unchanged after recrystallization.

Anal. Calcd. for $C_9H_{10}O_3$: C, 65.05; H, 6.07. Found: C, 65.07; H, 6.15. λ_{max}: 1 795, 1 750, 1 022, 960 cm^{-1}.

Hydrolysis with cold water regenerated the *cis*-homodiacid precursor, m.p. and mixed m.p. 162–164°.

trans-Δ^4-Tetrahydrohomophthalic Anhydride (XII) from a Mixture of cis- and trans-Diacids

When the above mixture of *cis*- and *trans*-homodiacids IX and X (m.p. 130–140°) was treated as described in the preceding experiment, there was obtained a solid which when recrystallized from benzene gave in 50% yield the *trans*-anhydride XII, m.p. 166– 8° (reported (7, 8): 166– 7° and 167– 8°). λ_{max}: 1 798, 1 750, 1 070, 980 cm^{-1}. Hydrolysis of the pure anhydride XII with cold water gave *trans*-Δ^4-tetrahydrohomophthalic acid (X) m.p. 154–155° (reported (7): 154–156°). Mixed m.p. with the *cis* isomer IX, 130–140° (reported (7): 130–144°).

5-Iodo-cis-4-hydroxy-2-carboxy-cyclohexaneacetic Acid γ-Lactone (XIII, R = I)

The *cis*-homodiacid IX was submitted to the conditions of iodolactonization exactly as described for Δ^4-cyclohexene-*cis*-dicarboxylic acid in an accompanying paper (1). After the acidification step, however, the iodolactone did not separate spontaneously. It was extracted with ether and the extract was processed in the usual manner to give a solid which was recrystallized from ethanol–water. Repeated recrystallizations gave crystals of m.p. 133–135° (40% yield.

Anal. Calcd. for $C_9H_{11}IO_4$: C, 34.83; H, 3.54. Found: C, 35.11; H, 3.38. λ_{max}: 1 780, 1 705 cm^{-1}.

On standing, the mother liquors deposited some solid which after repeated recrystallizations from methanol had m.p. 185–188°. This material was tentatively assigned structure XIV on the basis of its infrared spectrum; λ_{max} (Nujol): 1 720, 1 695 cm^{-1}.

Anal. Calcd. for $C_9H_{11}IO_4$: C, 34.83; H, 3.54. Found: C, 34.70; H, 3.44.

5-Bromo-cis-4-hydroxy-2-carboxy-cyclohexaneacetic Acid γ-Lactone (XIII, R = Br)

A solution of 22 g of the *cis*-homodiacid IX in 300 ml of 0.8 *N* aqueous sodium hydroxide was prepared. To this was added a solution of 20.2 g of sodium hydrogen carbonate in 150 ml of water followed by the dropwise addition of 13.2 ml of bromine. Stirring was maintained during the addition and for 1 h at room temperature. Some solid sodium thiosulfate was added to remove some light-yellow color and the solution was acidified to Congo red. After chilling for 2 h, a crystalline mass was collected and recrystallized from methanol–water to give 20.2 g (64% yield) of colorless crystals, m.p. 127–129°, unchanged by further recrystallizations.

Anal. Calcd. $C_9H_{11}BrO_4$: C, 41.08; H, 4.21; Br, 30.37. Found: C, 41.48; H, 4.16; Br, 29.51. λ_{max}: 1 770, 1 700 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

cis-4-Hydroxy-2-carboxy-cyclohexaneacetic Acid γ-Lactone (XV)

A solution of 13.15 g of the preceding bromolactone acid XIII (R = Br) in 150 ml of ethanol containing 3.65 g of pure diethylamine and 2 teaspoonfuls of freshly prepared Raney nickel was shaken in a hydrogen atmosphere under an initial pressure of 80 p.s.i. After a pressure drop of 4.5 p.s.i. the mixture was worked up in the usual manner and the residue was taken up in hot benzene. The diethylamine hydrobromide was filtered off and the filtrate was concentrated and set aside in the cold whereupon 7.5 g (80% yield) of crude lactone homoacid XV, m.p. 95–102°, was obtained. Recrystallization from benzene raised the m.p. to 111–116° (crystal change at 100–110°). Repeated recrystallizations did not alter the m.p. The crude material proved satisfactory for use in the next step. (Reported m.p. (1): 119–120°, 111–116°). This material proved identical as ascertained by mixed m.p. determination and infrared spectroscopy with a sample prepared by another route (1).

From the mother liquors a small amount of chloroform-insoluble material lacking the lactone band at 1 760 cm^{-1} but absorbing strongly at 1 700 cm^{-1} was obtained. It did not decolorize bromine in chloroform and behaved as an acid. It is tentatively assigned the structure XVI. No attempt was made to further characterize this minor component.

Lactone Homoamide XVII by the Mixed Anhydride Technique

A solution of 4.8 g of the preceding lactone homoacid XV in 150 ml of benzene containing 2.6 g triethylamine was cooled in ice and treated dropwise with 2.8 g of freshly distilled ethyl chloroformate. The insoluble salt was filtered; to the ice-cold filtrate 4.7 g of homoveratrylamine was added. After standing for 1 h, the solution was evaporated to dryness to give a viscous yellow oil which proved identical in the infrared with a sample prepared by another method (1). The yield was quantitative.

Cyclization to XVIII

This reaction has been described in an accompanying paper (1). The hydrochloride salt was obtained in crystalline form. It gave yellow crystals from toluene–chloroform, m.p. 175–176°.

Anal. Calcd. for $C_{19}H_{24}ClNO_4$: C, 62.37; H, 6.61; N, 3.83. Found: C, 61.86; H, 6.71; N, 3.69.

Reduction to the Tetrahydroisoquinoline Lactone XIX and Ring Closure to XX and XXII

To a solution of 5.5 g of the preceding hydrochloride salt of XVIII in 66% aqueous ethanol was added in portions 0.75 g of sodium borohydride. After 30 min at room temperature the reaction was complete as ascertained by the disappearance in the ultraviolet of the long-wavelength chromophore at 310 mμ. The solution was concentrated *in vacuo*, and was then saturated with carbon dioxide and thoroughly extracted with chloroform. The extract yielded 3.5 g (70% yield) of a solid absorbing strongly in the infrared at 1 760 cm^{-1} (γ-lactone band). This mixture of epimers (XIX) was used as such in the next step.

The solid thus obtained was heated under reflux in 100 ml of dry DMF for 3 h under an oxygen-free atmosphere of nitrogen. The solvent was removed *in vacuo* and the residue was taken up in benzene whereupon crystals m.p. 191–196° separated. Recrystallization from benzene–methanol raised the mp. to 213–216° (yield: 1.0 g). This lactam XX proved identical in every respect with the lactam previously obtained by Belleau and Dvornik (1).

From the benzene mother liquors there was obtained a crude crop of the isomer XXII which after recrystallization from ethyl acetate had m.p. 161–163°, unchanged after further recrystallizations (yield: 1.10 g).

Anal. Calcd. for $C_{19}H_{25}NO_4$: C, 68.86; H, 7.60; N, 4.23. Found: C, 68.25; H, 7.92; N, 4.25. λ_{max}: 3 400, 1 600 cm^{-1}.

The crude mixture of isomeric lactams XX and XXII could be readily separated by taking advantage of the insolubility in THF of the former isomer.

Reduction of XXII to the Tetracyclic Base XXIII (Epiallo Configuration)

A solution of 900 mg of the lactam XXII in 50 ml of dry THF was added dropwise to a stirred and cooled suspension of 1 g lithium aluminium hydride in 50 ml of dry ether. The mixture was heated under reflux for 20 h and carefully decomposed with 1.1 ml of water followed by the addition of 0.9 ml of 20% aqueous sodium hydroxide and 4.0 ml of water. The solids were filtered, the filtrate was evaporated and the residue was taken up in dilute sulfuric acid. The solution was washed with ether and then made strongly alkaline whereupon a solid separated. It was collected and recrystallized from acetone; m.p. 197–199°, unchanged after additional recrystallizations (yield: 450 mg).

Anal. Calcd. for $C_{19}H_{27}NO_3$: C, 71.89; H, 8.57; N, 4.41. Found: C, 71.97; H, 9.00; N, 4.44. λ_{max}: 3 600, 3 400 cm^{-1}.

In a similar way, the lactam XX gave the isomeric base XXI which proved identical in every respect with a sample prepared as described in an accompanying paper (1).

The *3,4,5-trimethoxybenzoic acid ester* of the epiallo base XXIII was prepared according to the method of Lucas *et al.* (14). After several recrystallizations from methanol it had m.p. 164–165°.

Anal. Calcd. for $C_{29}H_{37}NO_7$: C, 68.08; H, 7.29; N, 2.74. Found: C, 67.76; H, 7.24; N, 2.95. λ_{max}: 1 700, 1 580 cm^{-1}.

NUCLEAR MAGNETIC RESONANCE SPECTRA AND CONDUCTIVITIES OF SOME METAL ACETYLACETONATES

A. J. CARTY, D. G. TUCK

Received March 18, 1965

ABSTRACT

Chemical shift data and conductivities of acetylacetonates of some group IA, IIA, and IIIA metals in dimethylsulfoxide are recorded. It is concluded that nuclear magnetic resonance spectra cannot give definite information on π-bonding in these complexes, though the results for the group III elements are consistent with the presence of such bonds, as is the evidence from related spectroscopic studies.

INTRODUCTION

Nuclear magnetic resonance spectroscopy (n.m.r.) has been used to a considerable extent in the study of inorganic complexes (see, for example, refs. 1 and 2). An early study (3) of diamagnetic acetylacetone complexes of several divalent and trivalent metals has been extended recently (4). Both of these investigations revealed small shifts in the proton spectra of the complexes relative to the enol form of acetylacetone. A much larger effect has been reported for a paramagnetic complex, vanadium (III) trisacetylacetonate (5). In a related study, Hester (6) concluded that the n.m.r. spectrum of silicon trisacetylacetonate chloride hydrochloride indicates the presence of π-orbital 'benzenoid' conjugation involving the ligand and silicon orbitals.

We have reinvestigated the proton n.m.r. spectra of the trisacetylacetonates of aluminium, gallium, and indium as part of a program of work on the coordination complexes of indium (7). We have also recorded the spectra of the salts of lithium, sodium, and potassium, and of the diacetylacetonates of beryllium, magnesium, and calcium in the basic solvent, d_6-dimethylsulfoxide. Conductivities of the compounds in dimethylsulfoxide have also been measured. Although the n.m.r. results agree well with those reported by previous workers (3, 4), our interpretation is somewhat different from that given by them. This is a consequence of our belief that the enol form of acetyl acetone is an unsuitable standard against which to compare the spectra of the complexes.

EXPERIMENTAL

Melting points were determined on a Kofler block.

Materials

The acetylacetone salts were prepared by literature methods.

(a) Group IIIA Metals (8)

Aluminium trisacetylacetonate formed colorless crystals from acetone/ethanol mixtures, m.p. 196°, lit. m.p. 192° (8).

Gallium trisacetylacetonate was crystallized as for the indium salt, m.p. 198°, lit. m.p. 196° (8).

Indium trisacetylacetonate formed colorless crystals from acetone, m.p. 189°, lit. m.p. 186° (8).

(b) Group IIA Metals

Beryllium bisacetylacetonate was crystallized from benzene or chloroform (with large losses, due to high solubility) to white crystals m.p. 108–109°, lit. m.p. 108–109° (9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Magnesium bisacetylacetonate (9) was crystallized from ethanol, m.p. 265–267 °C.
Found: Mg, 11.1; C, 53.2. Calcd. for $C_{10}H_{14}MgO_4$: Mg, 10.9; C, 54.0.
Calcium bisacetylacetonate (10) formed white crystals from ethanol, m.p. 320° (decomp.).
Found: Ca, 15.8; C, 48.7. Calcd. for $C_{10}H_{14}CaO_4$: Ca, 16.8; C, 50.4.

(c) Group IA Metals (11)

Lithium acetylacetonate was prepared by dissolving clean lithium metal in freshly distilled acetylacetone. The product was recrystallized from ethanol/ether mixtures, and dried at $60°/10^{-2}$ mm.
Found: C, 56.8. Calcd. for $C_5H_7LiO_2$: C, 56.7.
Sodium acetylacetonate was crystallized from ethanol/ether mixtures and dried at $70°/10^{-2}$ mm.
Anal. Found: Na, 17.4; C, 46.9. Calcd. for $C_5H_7O_2Na$: Na, 18.9; C, 49.2.
Potassium acetylacetonate was crystallized as for the sodium salt.
Anal. Found: K, 25.0; C, 39.1. Calcd. for $C_5H_7KO_2$: K, 28.3; C, 43.2.

The compounds were analyzed for Na, K, and Ca by flame photometry, and for Mg by EDTA titration. Carbon was analyzed by van Slyke wet oxidation; equally poor results were obtained for some of these compounds by combustion analysis, both by us and by other workers (11). Nuclear magnetic resonance spectra of the sodium and potassium salts showed the presence of small amounts of ethanol, even in samples which had been dried at $70°/10^{-2}$ mm.

Dimethylsulfoxide (d.m.s.o.). Commercial material (B.D.H. laboratory reagent) was refluxed over predried calcium oxide for several hours. The material was fractionated at $10^{-2}-10^{-3}$ mm Hg through a 30 in. column of glass helices. A liberal head and tail fraction was rejected, and refractionation of the middle cut gave material with conductivity not greater than 10^{-7} ohm^{-1} cm^2. d_6-Dimethyl sulfoxide (d_6-d.m.s.o. Merck, Sharpe and Dohme of Canada) was used without further purification.

Conductivity Measurements

The salts were recrystallized immediately before use and dried for several hours *in vacuo*. Measurements were made on a Mullard bridge, type E7591/B using a cell of the type described by Groeneveld and Zuur (12). Exclusion of moisture was essential for reproducible measurements, and as a further precaution the solvents and solutions were kept under nitrogen. The measurements were made at 25 ± 0.2 °C. Nitrogen pressure was used to transfer solvents and to mix solutions during dilution studies (cf. ref. 13 for details of the method).

N.m.r. Measurements

Spectra were obtained on a Varian A-60 analytical spectrometer at a probe temperature of about 36 °C. The d_6-d.m.s.o. was saturated with tetramethylsilane to provide an internal reference. The compounds were examined in approximately 10% solutions and were diluted by volume (as indicated in the table). The results are given on the τ-scale.

RESULTS

Nuclear Magnetic Resonance

Chemical shifts for protons of the various salts in d_6-d.m.s.o. are recorded in the table. Results are also given for deuterochloroform solutions of those salts which were sufficiently soluble in that solvent. Some literature values (CCl_4 solution) are also included to show that the chemical shifts are relatively independent of solvent.

Conductivities

Figure 1 shows the concentration dependence of the conductivities of the Li, Na, and Ca acetylacetonates in dimethylsulfoxide. The curve for the potassium salt (Fig. 2) shows surprising deviations from the monotonic curves for the other salts. Repeat determinations with fresh samples of this salt gave similar curves, although the detailed features of the maxima and minima were not reproducible. This behavior may be related to the apparent instability of dimethylsulfoxide solutions of potassium acetylacetonate, evidenced by the fact that dilute solutions (10^{-2} *M* and below), although initially colorless, become yellowish brown over the course of a few days at room temperature. Fortunately, the more concentrated solutions used in the n.m.r. studies are above the region of apparent instability.

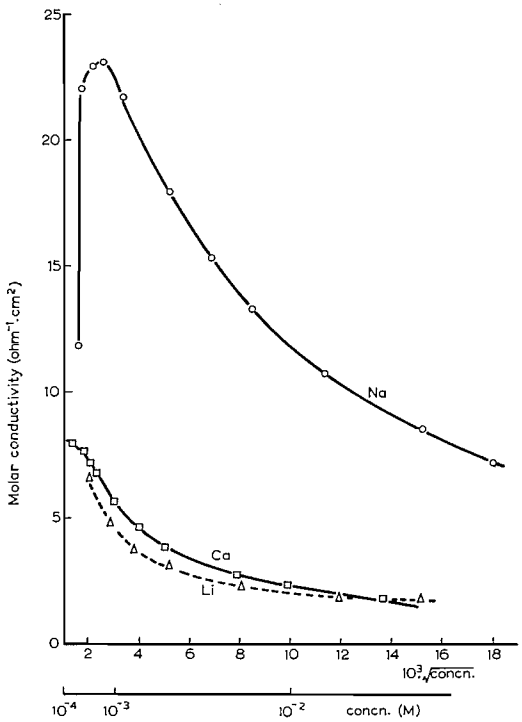

FIG. 1. Molar conductivities of sodium, calcium, and lithium acetylacetonates in dimethylsulfoxide as a function of concentration, and (concn.)$^{\frac{1}{2}}$.

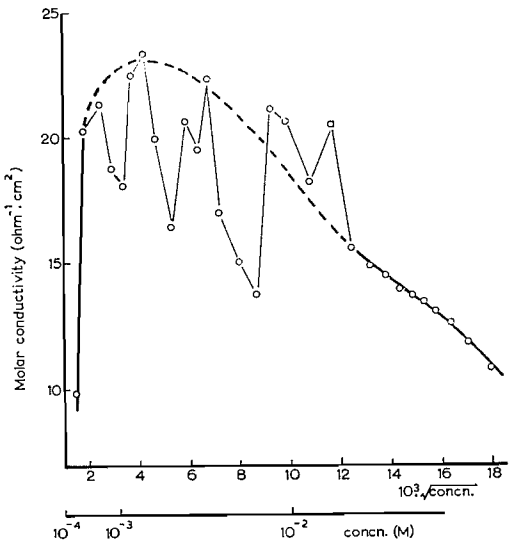

FIG. 2. Molar conductivity of potassium acetylacetonate in dimethylsulfoxide as a function of concentration, and (concn.)$^{\frac{1}{2}}$. The solid line joins the points in the order of measurement (starting with the pure solvent and progressively adding a concentrated solution of the salt); the broken line is drawn by rough analogy with the curves in Fig. 1.

The conductivities at 10^{-3} M of the acetylacetonates of the group IA and IIA salts are as follows.

Element	Li^{I}	Na^{I}	K^{I}	Be^{II}	Mg^{II}	Ca^{II}
Molar conductivity, $ohm^{-1}cm^{2}$	4.46	22.2	23	0.37	0.86	5.3

These show the predictable order K $\geqslant$ Na > Li, Ca > Mg > Be and group I > group II. The conductivities of the group III salts were not determined. The values given can be compared with the molar conductivities of 25–40 found for 1:1 electrolytes at concentrations of $\sim 10^{-3}$ M in dimethylsulfoxide by Sears, Lester, and Dawson (14).

TABLE I

†After fourfold dilution.

DISCUSSION

It is clear from the conductivity measurements that beryllium acetylacetonate is a non-electrolyte in d.m.s.o. and this is in keeping with its high solubility in benzene (9). The solubility evidence (9, 15) suggests that this is also true for the aluminium salt and it is assumed in the following discussion that the group III salts are essentially non-electrolytes.

The acetylacetonates of the remaining elements under study show significant conductivity in 10^{-3} M solution, and this is attributed to the presence, and dissociation, of ion pairs in solution. This dissociation may be aided by the basic nature of the solvent, since, although d.m.s.o. does not appear to form stable salts with group IA and IIA cations (16), it does coordinate to a number of other metal cations to give stable species (17). It is also known to form salts with certain mineral acids (18), presumably by bonding to the acidic proton.

The enol form of acetylacetone shows only one methyl proton peak in the n.m.r. spectrum, and this is ascribed (19) to rapid hydrogen exchange between the two oxygen atoms rather than to any orbital degeneracy in the molecule itself. Previous workers (3, 4, 6) have compared the spectra of acetylacetonate complexes with the enol, and find that the γ-proton signals of most of the complexes occur to high field of the corresponding enol proton. Thus, such comparisons cannot give any information about π-orbital delocalization which, by ring-current effects, would be expected to cause a low-field shift

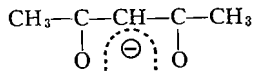
For personal use only.

of the γ-proton (4) in the complex. We considered that a more informative comparison should be possible with the free acetylacetonate anion in which orbital degeneracy of the type



can be assumed to occur. The n.m.r. spectrum of this system can, in principle, be obtained from dilute solutions of the acetylacetonates of group IA metals in an ionizing solvent. The possibility that the *free* anion exists with the oxygen atoms *trans* to one another cannot be ignored, though in ion pairs the *cis* arrangement seems more plausible. Our results (table) show that the spectra of the sodium and potassium salts give concentration-dependent signals for the γ-proton, and that the chemical shifts of the methyl signals are virtually independent of concentration. No concentration dependence was observed for the lithium salt or any of the other compounds examined. The spectra of the highly covalent species (Al, Ga, In, Be, and Li) were characterized by very sharp resonance signals. In the remaining spectra, especially those of the sodium, potassium, and calcium salts, the peaks were rather broad, although the tetramethylsilane resonance suggested that the resolution of the instrument was as good as for the other solutions. This effect may be a function of the expected exchange process between ion pairs and free ions.

The chemical shifts of the methyl groups fall into two distinct groups. Beryllium and the group IIIA metal complexes give signals at τ 8.04 $\pm$ 0.07 whilst the remaining compounds show an absorption within the range τ 8.30 $\pm$ 0.06, but there is no obvious relationship of the detailed shifts to the ionization potential or electron-negativity of the metals. The conductivity and n.m.r. results are consistent with the presence of an equilibrium

$$[\text{ion pair} \rightleftharpoons \text{free anion} + \text{(solvated) cation}]$$

in solutions of the sodium and potassium salts in d.m.s.o. It follows, therefore, that the n.m.r. absorption of the γ-proton of the acetylacetonate anion is to high field of 5.33 τ (the signal of the weakest solution of the potassium salt which we were able to study). It would clearly be valuable to obtain the n.m.r. spectrum of a 10^{-3} M solution of this salt.

In the more concentrated solutions (approx. 0.5 M or above) where the salts of group IA metals would be expected to be essentially undissociated, the γ-protons occur to low field in the order Li < Na < K. Obviously, association of the anion and cation, whether by strong ion-pairing or by formation of metal oxygen bonds (as seems possible for the Li salt), causes some localization of the negative charge at the oxygen atoms of the ligand. This will deshield the γ-proton and cause a low-field shift relative to the free anion. This is important, since in the formation of acetylacetonate coordination complexes, some transfer of negative charge of this type must always occur and hence a low-field shift of the γ-proton relative to the anion is to be expected, irrespective of any other electronic effects which might be present. It may be significant that the order of shifts for the Li, Na, and K salts is that of decreasing ionization potential.

The magnesium and calcium salts are weak electrolytes in 10^{-3} M solution and by the argument above, the n.m.r. spectrum is probably that of the ion pair for each compound. Surprisingly the γ-proton of the Mg complex absorbs 0.06 p.p.m. to high field of the corresponding calcium salt proton. The beryllium bisacetylacetonate shows the largest low-field shift for the γ-proton, of the compounds investigated by us (or by Smith and

Thwaites (4)), implying a strong donation of charge from the anion in bonding to the central metal atom. This result illustrates the difficulty of investigating π-bonding in this type of compound by n.m.r. methods. As noted above, electron localization on the oxygen atom in ion pairs would cause deshielding of the 'olefinic' proton, and the formation of covalent bonds involving electron donation to the metal will have the same effect. There appears to be no quantitative way of estimating the extent of these effects when one is comparing complexes of the same anion with different metals. It follows that there is equally no way of estimating how much (if any) further deshielding of the γ-proton might have occurred through ring currents from 'aromatic' delocalization of π-electrons involving the anion and the central metal atom. In fact, the Be—O bonds in beryllium bisacetylacetonate must be essentially of the pure σ-type, since the only orbitals available for π-overlap with the p_π orbitals on the oxygen are the $3d_\pi$ of the beryllium (assuming a tetrahedral distribution of the oxygens around the metal) and these are probably of too high energy to be utilized. It is notable that the analogous BF_4^- anion, in which the central atom has the isoelectronic rare-gas configuration, is taken by Cotton and Leto (20) to be a pure σ-bonded system against which additional π-contributions to bonding can be compared. The observation of very sharp methyl resonance signals in the beryllium salt and the group III metal complexes suggest a symmetrical (probably planar) configuration for the metal–ligand ring system in agreement with X-ray structural determinations on Fe(III) and Mn(III) trisacetylacetonates (21).

The γ-proton signals of the acetylacetonate complexes of aluminium, gallium, and indium lie well to low field of the corresponding signal in the acetylacetone anion. A quantitative discussion of the origin of this shift is not possible for the reasons outlined above. Further, a precise comparison with the beryllium salt is precluded by the difference in coordination number and orbital hybridization between the group II and group III metals. The n.m.r. results, therefore, serve only to confirm that strong metal–oxygen bonding occurs in the group III complexes. However, the chemical shifts of the signals appear to be virtually independent of the metal (see table; note that the methyl resonances show a larger spread of chemical shifts than the γ-protons). This observation would be consistent with the existence of some effect (e.g. π-orbital delocalization) which effectively masks electronegativity differences of the metals in the various salts, and this is as much as we are able to deduce concerning the existence of π-bonding in these complexes, from this type of evidence.

Results of ultraviolet (3) and Raman (15) spectroscopic measurements are also consistent with a measure of π-bonding in the Al, Ga, and In complexes. Furthermore, the M—O force constant in Al $(acac)_3$ is significantly higher than that for the Cr(III), Co(III), and Fe(III) complexes (22), and the force constants in Al, Ga, and In compounds are very similar to each other (15). These two statements also imply a π-contribution to the M—O bond.

Holm and Cotton (3) have pointed out that since the available p_π orbitals on the oxygen atoms in the acetylacetone anion are filled, the π-donation must be in the sense $\overset{\curvearrowleft}{\underset{\curvearrowright}{M—O}}$, and it is perhaps rather surprising that donation of this type should occur into the nd orbitals of the group IIIA metals (the $(n-1)d^{10}$ shell being filled). It has been suggested (7) that in certain coordination complexes of indium, according to the theory of Craig and Doggett (23) for transition metal elements, strong σ-donation improves the chance of π-overlap with metal d-orbitals by reducing the charge on the metal, allowing the d-orbitals to expand towards the appropriate ligand π-orbitals. It would be very useful

to have some measure of the electronegativities of the oxygen atoms in the acetylacetone anion, to make a comparison of the likelihood of this effect (as against ligands such as H_2O, oxalate, etc.). One factor which might encourage σ-donation is that sp^2 hybridization of the oxygens (implied by the M—O—C bond angles) will place filled non-bonding sp^2 orbitals outside the ring, which may cause repulsion of the M—O bonding electrons towards the metal, with the consequences outlined above.

FATTY ACIDS OF CATALPA BIGNONIOIDES AND OTHER BIGNONIACEAE SEED OILS[1,2]

MARY J. CHISHOLM AND C. Y. HOPKINS
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received May 11, 1965

ABSTRACT

Seed oils of 11 species of Bignoniaceae, representing four of the five tribes of the family, were analyzed by gas–liquid chromatography and other techniques. The fatty acids of *Catalpa bignonioides* oil had the following composition: *trans*-9,*trans*-12-octadecadienoic 5, *trans*-9,*trans*-11,*cis*-13-octadecatrienoic 31, palmitic 5, stearic 1, octadecenoic 8, linoleic 50%. One of the five samples of this species showed evidence of an appreciable amount of conjugated dienoic acid.

Jacaranda semiserrata had 33% of a *cis*,*trans*,*cis* trienoic acid. *Kigelia pinnata* had 57% of a non-conjugated trienoic acid. The other eight species had the ordinary palmitic–oleic–linoleic composition. The total fatty acid composition of the oils is reported.

The tribe Tecomeae yielded both conjugated and non-conjugated seed oils. Single species of each of the other three tribes gave non-conjugated oils.

INTRODUCTION

The seed oils of relatively few species of Bignoniaceae have been studied but it is already evident that very unusual fatty acids occur in this plant family. Recent investigations have disclosed the occurrence of acids with conjugated diene and triene unsaturation (1, 2, 3) and others with non-conjugated unsaturation but with *trans* double bonds (4, 5).

In the present work, the seed oil of *Catalpa bignonioides* and 10 additional species of the family have been examined and their fatty acid composition has been determined. Two of the uncommon acids were identified by orthodox chemical methods. The composition of the mixed acids of each oil was determined by gas–liquid chromatography (g.l.c.) of the methyl esters. In species yielding acids with conjugated double bonds, the content of conjugated acids was determined by ultraviolet absorption analysis and the amount of each non-conjugated acid was calculated as a percentage of the remainder.

RESULTS AND DISCUSSION

Preliminary data are given in Table I. The classification into tribes is that of Engler (6) and the species are named in accordance with Sandwith (7).

The oil content was relatively low in some species, apparently because a large part of the seed is made up of the fibrous wing which contains little or no oil. Most of the oils had refractive indices in the range 1.470–1.476 at 25°, indicating the presence of ordinary unsaturated acids and absence of those with conjugated unsaturation. The exceptions are discussed below.

Catalpa bignonioides

Five lots of seed of this species from different sources were examined. Four of them yielded oils in which the fatty acids contained 31–34% of conjugated triene acid, as shown by the ultraviolet spectra. The acid was concentrated by low-temperature crystallization and identified by means of its adduct with maleic anhydride as *trans*-9,*trans*-11,*cis*-13-octadecatrienoic acid. This acid was found previously in two species of *Catalpa* (2, 8) and in *Chilopsis linearis* (1).

‡Wijs (30 min).

The infrared spectrum of the oil showed stronger absorption in the region 960 cm^{-1} than would be expected from a *trans,trans,cis* conjugated acid, as judged by comparison with the intensity of the main peak at 985 cm^{-1}. Consequently, the presence of non-conjugated *trans* double bonds was suspected.

This was confirmed by fractional crystallization of the mixed acids, which resulted in a concentrate of the *trans* acid along with about 20% of conjugated triene acid. The latter was removed by adduction with maleic anhydride. The remainder of the concentrate yielded *trans*-9,*trans*-12-octadecadienoic acid on recrystallization. Its identity was confirmed by hydroxylation with alkaline permanganate, which gave di-*threo*-9,10,12,13-tetrahydroxystearic acid. *trans*-9,*trans*-12-Octadecadienoic acid was found previously in the seed oil of *Chilopsis linearis* (4).

One sample of seed of *Catalpa bignonioides* gave oil of a different composition. Its ultraviolet spectrum showed a content of only 12% of conjugated triene acid but there was also an absorption peak at 233 mμ, not observed in the oils from the previous seed samples. After allowance was made for the absorption at this wavelength caused by the triene, it was calculated that 7.9% of conjugated diene acid was present.

It appears, therefore, that some samples of this species contain a conjugated diene acid and that other samples do not. Markman and Bodnya (9) reported 4% of conjugated diene acid in their sample, based on ultraviolet absorption analysis, but Earle and coworkers (10) reported no conjugated diene acid. Occurrence of a conjugated diene acid in the oil of *Chilopsis linearis* has been demonstrated (1). It is possible that the diene acid is an intermediate in the formation of the conjugated triene acid in the seed.

In their work, Markman and Bodnya assumed, on the basis of the ultraviolet spectrum, that the conjugated triene acid was eleostearic acid. However, since the spectra of the two isomeric acids (*cis,trans,trans* and *trans,trans,cis*) are almost identical, it seems likely that their triene acid was *trans*-9,*trans*-11,*cis*-13-octadecatrienoic acid, as found in the present work. A comparison of the analyses is given in Table II.

Jacaranda semi-serrata

The small sample of seed (0.1 g) yielded an oil whose ultraviolet spectrum had maxima

Conjugated trienoic	31‡	32.6	28

*Composed of 5% of *trans*-9,*trans*-12-octadecadienoic acid and 50% of linoleic acid.
†Higher in one sample.
‡Identified as *trans*-9,*trans*-11,*cis*-13-octadecatrienoic acid.

at 266, 275, and 286 mμ, characteristic of a *cis*,*trans*,*cis* trienoic acid. This is presumed to be the same acid as the one identified in *J. mimosifolia*, viz. *cis*-8,*trans*-10,*cis*-12-octadecatrienoic acid (3). The absorptivity was equivalent to a content of 33.1% of the acid.

Kigelia pinnata

The seeds yielded a small amount of oil with an iodine value of 185, the highest of any of the oils. The infrared spectrum had maxima at 1 650(w) and 3 000(s) cm^{-1}, indicating ordinary unsaturation. There were no peaks in the region of *trans* and conjugated unsaturation, i.e. 900–1 000 cm^{-1}. Similarly, the ultraviolet spectrum showed no evidence of conjugated double bonds. The g.l.c. curve denoted the presence of 57% of non-conjugated octadecatrienoic acid, judged from its emergence time to be linolenic acid.

TABLE III

Composition of the fatty acids

	Fatty acid, wt. % of total acids

†tr = trace.
‡Also contains 3% of an unidentified acid.

Composition of the Fatty Acids

The total composition of the fatty acids of the oils is given in Table III. *Catalpa* and *Jacaranda*, the only species having appreciable amounts of conjugated trienoic acid,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

contained no non-conjugated trienoic acid. *Kigelia* had a high content of non-conjugated trienoic acid but no other unusual features. The other species had essentially the ordinary palmitate–oleate–linoleate composition with little or no conjugated acid(s). Their content of non-conjugated octadecatrienoic acid (judged to be linolenic) varied from nil to 16%.

The two *Campsis* species were calculated to have a small but measurable amount of conjugated acid on the basis of ultraviolet absorption. *Tabebuia* oil was exceptional in having the highest content of saturated acids, including 12% of stearic acid. The content of hexadecenoic acid was quite low in all of the oils and was estimated to be less than 1%.

Taxonomy and Fatty Acid Composition

Four of the five tribes of Bignoniaceae are represented in the present study. All species found so far to contain conjugated polyenoic acids in the seed oils are from the tribe Tecomeae. They are species of *Catalpa*, *Jacaranda*, and *Chilopsis*. All of the examples of these genera that have been examined, including those in earlier work (1, 2, 3, 8), contain conjugated triene acids. However, it cannot be assumed that conjugated acids occur only in Tecomeae until more species of the other tribes have been studied.

Several species of Tecomeae yield non-conjugated oils (Table III) but, in general, it may be said that this tribe produces oils of unusually varied composition.

EXPERIMENTAL

Samples of some seeds were kindly supplied by the Director, Jardin Botanico, Buenos Aires, and by the Department of Forestry, Republic of South Africa. The remainder were purchased from established commercial suppliers.

Ultraviolet spectra were determined in cyclohexane solution with a Beckman DU spectrophotometer. Infrared spectra were determined in carbon disulfide in a Perkin–Elmer model 21 spectrophotometer with sodium chloride prism. Melting points were determined in capillary tubes and were corrected. The oils were obtained by extracting the finely ground sample with petroleum ether (b.p. 30–60°) at room temperature. Iodine values were determined by the Wijs method (30 min).

The oils were converted to methyl esters by transesterification in methanol with hydrogen chloride catalyst. The esters were examined by g.l.c. and their composition was estimated by measuring the peak areas. The g.l.c. analyses were made using a 1 meter copper column at 185° and a thermal conductivity detector. The liquid phase was a diethyleneglycol – succinic acid polyester (15% on diatomaceous earth).

Catalpa bignonioides

The oil was extracted and the solvent was removed in a current of nitrogen at 25–30°. A typical sample of the oil had infrared absorption maxima at 985(vs) and 958(m) cm^{-1}. Ultraviolet absorption maxima were at 262, 272, 283 mμ and the absorptivity was $E_{1\ cm}^{1\%}$ 556 at 272 mμ, equivalent to 31.4% of conjugated triene acid. There was some absorption but no peak in the 233 mμ region. Three other samples had 32.3, 34.4, and 33.0% of conjugated triene acid.

One sample of the seed gave an oil with absorptivity $E_{1\ cm}^{1\%}$ 211 at 271 mμ, equivalent to 12.0% of conjugated triene acid. The same oil had a peak at 233 mμ and absorptivity $E_{1\ cm}^{1\%}$ 102 at 233 mμ. The absorptivity at 233 mμ due to the content of conjugated triene was calculated to be 15. Hence the net absorptivity due to the diene was 102 − 15 = 87, equivalent to 7.9% of conjugated diene acid, if we employ the factor 0.091 (11). This sample was not investigated further.

The typical oil (35 g) was hydrolyzed by ethanolic 5% potassium hydroxide under nitrogen at 25°. Unsaponifiable matter was removed and the mixed acids were dissolved in acetone and cooled. Crystals were taken off at −5°, −40°, and −62°. The crystals collected at −62° (8.5 g) contained most of the conjugated triene acid. This portion was heated with maleic anhydride in benzene (2), yielding an adduct, m.p. 71–72°. This substance, when mixed with the adduct of maleic anhydride with *trans*-9,*trans*-11,*cis*-13-octadecatrienoic acid (2), did not lower its melting point.

The mixed acids from another portion of the oil (46 g) were crystallized fractionally from acetone by the procedure described previously (4), to concentrate the acid with isolated *trans* bonds. The fractionation was monitored by infrared absorption. The concentrate was treated with maleic anhydride to remove the conjugated triene acid and the rest was crystallized from pentane, giving 1.5 g of *trans*-9,*trans*-12-octadecadienoic acid, m.p. 24–25°. Upon oxidative splitting it gave azelaic and hexanoic acids.

The *trans*,*trans* diene acid (1.0 g) was hydroxylated by alkaline permanganate (12) for 20 min at 10° and the product was crystallized from ethanol. It gave the higher melting racemic form of di-*threo*-9,10,12,13-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tetrahydroxystearic acid, m.p. 147–148°. The melting point was unchanged in admixture with a sample prepared from pure linelaidic acid.

A solution of 0.4 g of the diene acid was treated with 2,4′-dibromoacetophenone by the method of Neish and Lemieux (13). The crude product (0.6 g) was crystallized from ethanol and then from acetone, giving 4-bromophenacyl *trans*-9,*trans*-12-octadecadienoate, m.p. 50.5–51.5°.

Anal. Calcd. for $C_{26}H_{37}O_3Br$: C, 65.39; H, 7.81. Found: C, 65.30; H, 7.80.

Linoleic acid was identified in the final filtrate from the crystallization of the total mixed acids. The acids (2 g) from the filtrate were hydroxylated by alkaline permanganate for 5 min at 10°. The product was crystallized from ethyl acetate and then from ethanol, giving the higher melting form of di-*erythro*-9,10,12,13-tetrahydroxystearic acid, m.p. and mixed m.p. 173–174°.

Other Bignoniaceae Oils

Infrared spectra of the oils of *Bignonia capreolata*, *Pandorea jasminoides*, *Tabebuia rosea*, *Eccremocarpus scaber*, and *Kigelia pinnata* were examined. None showed absorption that would indicate the presence of *trans* double bonds (ca. 960 cm^{-1}), conjugated double bonds (900–1 000 cm^{-1}), or hydroxyl groups (ca. 3 500 cm^{-1}).

All had a fairly strong peak at 3 023 cm^{-1}, denoting considerable unsaturation, except *Tabebuia rosea*, which had lower intensity than the others in agreement with the iodine value. *Kigelia pinnata* showed stronger unsaturation and the peak was at 3 000 cm^{-1}. Its peak of low intensity at 1 650 cm^{-1} also indicated considerable *cis* unsaturation. Absorption at this wave number was very slight for the other species.

Ultraviolet absorption spectra of *Catalpa* and *Jacaranda* oils had maxima attributed to conjugated trienes. The two species of *Campsis* had similar but weak triene absorption at 272 and 282 mμ and *Incarvillea* had a trace amount (Table III). The other oils had no appreciable absorption or maxima in this region.

Evidence of conjugated diene unsaturation was scanty except in the anomalous sample of *Catalpa bignonioides* described above. However, there was a little absorption at 232–233 mμ equivalent to 1.2% of conjugated dienoic acid in *Campsis grandiflora*, less than 1% in *Bignonia* and *Incarvillea*, and none in the other oils. The g.l.c. curve for *Tabebuia* esters included an unidentified peak representing 3% of the total acids.

ACKNOWLEDGMENTS

The authors are indebted to Mr. N. Y. Sandwith for helpful advice in identifying and naming of species, to Mr. R. Lauzon for determination of infrared spectra, and to Mr. H. Seguin for microanalysis.

ALICYCLIC KETYLS

I. ANGULAR DEPENDENCE OF HYPERFINE COUPLING AND CONFORMATIONAL MOBILITY OF CYCLOHEXANONE KETYLS

J. W. LOWN

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 14, 1965

ABSTRACT

The electron paramagnetic resonance (e.p.r.) spectra of ketyls derived from cyclopentanone and 4-*tert*-butyl, 4-methyl, 3-methyl, and unsubstituted cyclohexanone have been recorded in dimethoxymethane at room temperature. The proton hyperfine splittings (a_H) observed with rigid ketyls are consistent with a dihedral angular (θ) dependence of hyperfine coupling of the form, $a_H = 4.8 + 9.6 \cos^2 \theta$. Conformational averaging of the hyperfine coupling is observed with 4-methyl, 3-methyl, and unsubstituted cyclohexanone ketyls. The conformer populations calculated from the e.p.r. spectra are in accordance with A values for the methyl group derived from non-radical cyclohexane compounds.

Ketyls may be generated from ketones by the reducing action of alkali metals in ethereal solvents (1, 2, 3). They display well-resolved electron paramagnetic resonance (e.p.r.) spectra which show the unpaired spin to be concentrated largely on the carbonyl carbon (2), although hyperfine coupling occurs from protons on adjacent carbons. It has been postulated that the efficiency of hyperconjugative coupling to such adjacent protons is dependent on the dihedral angle subtended by the proton and the singly occupied 2p orbital centered on the carbonyl carbon (4). Recently the angular dependence of hyperfine coupling, and conformational mobility, in radicals derived from alicyclic alcohols has been examined (5). The radicals are generated in aqueous solution by hydrogen atom abstraction from the alcohols by primary radicals postulated to be OH·. This system suffers from a number of disadvantages. While hydrogen abstraction occurs mainly alpha to the hydroxyl group, other positions are also attacked leading to complex e.p.r. spectra arising from a mixture of free radicals. Also, many compounds which would provide interesting models are not sufficiently water soluble for the technique.

In view of the relationship of ketyls as conjugate bases of the radicals resulting from the abstraction of an alpha hydrogen in cyclic alcohols, and their specific generation from ketones, it appeared that suitably rigid ketones would serve as good models for testing the angular dependence of hyperfine coupling. The conformational mobility of less rigid ketyls could then be examined. It would then be possible to see if A values (conformational free energy differences) characteristic of substituents in non-radicals had validity when applied to the conformational analysis of nonrigid radicals.

Angular Dependence of Hyperfine Coupling in Ketyls

4-*tert*-Butylcyclohexanone was selected for the preparation of a suitably rigid model ketyl. The ketyl (as in the case of other free radicals discussed) could be generated by the action of potassium on a 5% degassed solution of the ketone in 1,2-dimethoxyethane, producing a yellow solution. The ketyl was quite stable under these conditions and gave a seven line e.p.r. spectrum (see Fig. 1) of overall splitting of 43.2 Oe and having an intensity pattern (1:2:3:4:3:2:1). This was interpreted as arising from coupling with two equivalent (axial) protons, ($a_{H_a} = 14.4$ Oe) and two equivalent (equatorial) protons ($a_{H_e} = 7.2$ Oe). No hyperfine coupling due to the associated potassium ion could be resolved. This is expected since such coupling is small (~ 0.12 Oe) (3). Since the axial

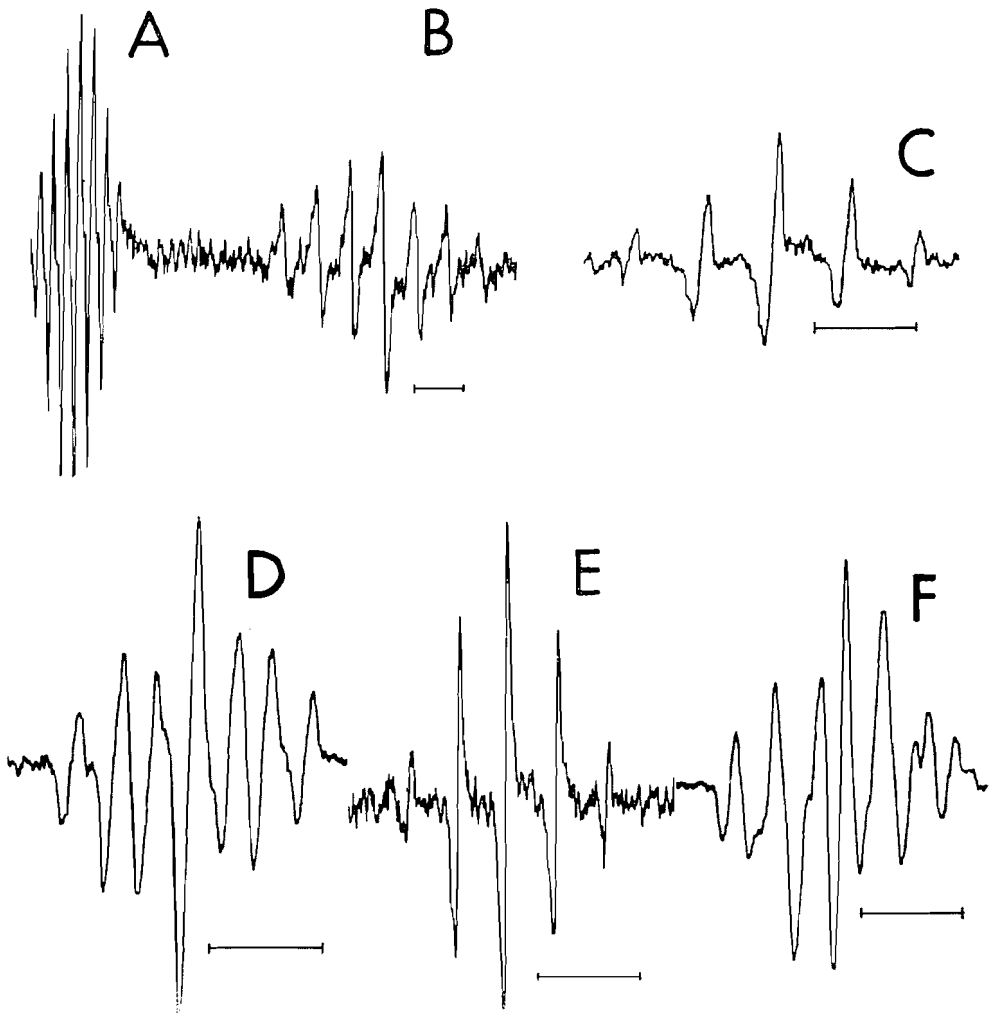

FIG. 1. First derivative e.p.r. spectra. A, 4-*tert*-butylcyclohexyl ketyl at rapid scan; B, 4-*tert*-butylcyclohexyl ketyl at slow scan; C, cyclopentyl ketyl; D, 4-methylcyclohexyl ketyl; E, cyclohexyl ketyl; F, 3-methylcyclohexyl ketyl. The bar in each case represents 20 Oe.

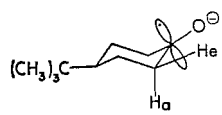
proton is aligned close to the plane of the $C_1 2p$ orbital, it shows more efficient hyperconjugative coupling, reflected in the larger hyperfine constant. Some distortion of the cyclohexane chair is to be expected to accommodate the sp^2 hybridized ketyl carbon, and as a result of the bulky 4-*tert*-butyl group. However, these should not be serious and examination of a Barton model* predicts values for the dihedral angles of $\theta_{a,p} = 0°$,



Scale 1 Å = 10 cm.

$\theta_{e,p} = 120°$ (where a and e subscripts refer to axial and equatorial respectively).

A relationship between dihedral angle and hyperfine coupling a_H of the following form has been proposed (6, 7).

[1] $$a_H = B_0 + B \cos^2 \theta$$

where B_0 and B are constants, characteristic of a given type of radical. In the chair to chair interconversion of the cyclohexyl radical in solid cyclohexane (8, 9), best agreement between theory and practice is obtained with $B_0 = 4.5$ and $B = 40.5$ Oe, while in the case of a radical derived from cyclopentylamine the following constants provide the best agreement, $B_0 = 3.5$ and $B = 45.6$ (5). In the present work substitution of observed hyperfine coupling and measured angles leads to a relationship of the form

[2] $$a_H = 4.8 + 9.6 \cos^2 \theta.$$

To test the application of eq. [2] to five-membered rings the ketyl generated from cyclopentanone was examined. An e.p.r. spectrum consisting of five equally spaced lines ($a_H = 13.8$ Oe) having an intensity pattern of (1:4:6:4:1) was obtained. Thus all four protons at the 2 and 5 positions are equivalent. Examination of a Barton model shows that little conformational freedom exists and that the ring is virtually planar. The dihedral angle is 30° from which eq. [2] predicts a hyperfine coupling of 12.0 Oe. The agreement is fair since no account has been taken of differences of spin density at the ketyl carbon. However, since much better agreement is obtained when eq. [2] is applied to other six-membered rings it is possible that such an equation may not be indiscriminately applied to ketyls of different ring sizes. Such has been the experience with the Karplus relationship when applied to nuclear magnetic resonance spin–spin coupling in five- and six-membered rings (10). Camphor which would have provided a further test of eq. [2] could not be induced to form a ketyl.

Conformational Mobility in Six-Membered Ketyls

Cyclohexyl ketyl afforded an e.p.r. spectrum consisting of five equidistant ($a_H = 10.4$ Oe) lines with an intensity pattern of (1:4:6:4:1). This clearly arises from rapid chair to chair conformational interconversion where two pairs of C_2 and C_6 axial and equatorial protons are expected to show a time-averaged equal hyperfine coupling. Since each conformational form is equally populated a coupling $a_{H_{av}}$ equal to the average of those characteristic of axial and equatorial protons in 4-*tert*-butylcyclohexyl ketyl is anticipated, provided eq. [2] is valid.

$$a_{H_{av}} = \tfrac{1}{2}(a_{Ha} + a_{He}) = \tfrac{1}{2}(14.4 + 7.2) = 10.8 \text{ Oe}.$$

Since the estimated accuracy of the hyperfine coupling constants is ±0.2 Oe and in view of possible distortion of the chair in the rigid ketyl, the agreement is good.

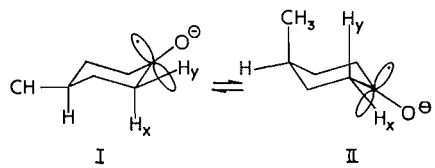
The observation of five equally sharp lines displaying the expected intensity pattern for four equivalent protons is essential to the above argument. This implies that the rate of chair to chair inversion is *not* comparable with the frequency difference of couplings of axial and equatorial protons (11). If such were the case then uncertainty broadening of the lines would result and the simple intensity pattern obtained here would not have been observed. Norman has observed this phenomenon in the case of radicals derived by hydrogen abstraction from piperidine, cyclohexanol, and dioxan (5). In such cases the frequency difference between axial and equatorial couplings corresponded to ~38 Oe, and therefore comparable to the rate of interconversion estimated to be ca. 5×10^8 s^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

That the axial–equatorial frequency difference observed in ketyls is much smaller (corresponding to 7.2 Oe) accounts for the lack of uncertainty broadening, since the rate of conformational inversion might be expected to be comparable with that found by Norman.

Effects of Ring Substitution on the Position of Conformational Equilibrium

4-Methylcyclohexyl ketyl gives a spectrum consisting of a (1:2:1) triplet of (1:2:1) triplets which overlap giving the appearance of seven lines and corresponding to two unequal couplings of 13.5 and 7.5 Oe resulting from conformational averaging between forms I and II.



I II

Provided eq. [2] is valid it is possible to estimate the position of conformational equilibrium from the following relations

$$na_a + (1 - n)a_e = a_{av}(X) \quad [3]$$

$$na_e + (1 - n)a_a = a_{av}(Y) \quad [4]$$

where a_a and a_e are the hyperfine couplings characteristic of axial and equatorially oriented protons in the 4-*tert*-butylcyclohexanone ketyl, n is the proportion of I at equilibrium, and $a_{av}(X)$ and $a_{av}(Y)$ represent the time-averaged couplings observed for protons X and Y respectively. Substitution in eqs. [3] and [4] predicts a value of n between 0.88 and 0.96, representing a great preponderance of I at equilibrium.

Since the ketyl oxygen is held in the sp^2 plane of the ketyl group in both I and II, it will not affect the position of equilibrium. Therefore we may expect the 1,3 interactions of the 4-methyl group and the 2 and 6 axial hydrogens to control the position of equilibrium. The conformational free energy difference of the methyl group in cyclohexyl derivatives is 1.5 to 1.9 kcal/mole (12, 13, 14). Taking a standard free energy difference of 1.74 kcal/mole at 25° predicts an equilibrium constant $K = 19.00$, representing 95% of the more stable conformer at equilibrium (15), or a value for n of 0.95. This good agreement between the observed position of equilibrium and the predicted value gives one confidence in the validity of this approach to the conformational analysis of free radicals, and of the general applicability of A values in this regard. 3-Methylcyclohexyl ketyl similarly gives a basic seven line spectrum with unequal spacing, resolvable into a triplet of overlapping triplets and corresponding to two hyperfine couplings of 13.5 and 7.5 Oe respectively. Therefore in this case also we predict between 88 and 95% of the more stable conformer (placing the 3-methyl group equatorial) at equilibrium. This shows that the A value of the methyl group has equal validity at the 4 and 3 positions of the cyclohexane ring. An examination of ketyls derived from other ring systems and the thermodynamics of their conformational equilibria will be reported in a subsequent publication.

EXPERIMENTAL

Materials

All liquid ketones were fractionated and gave single peaks on gas–liquid chromatographic analysis. 4-*tert*-Butylcyclohexanone was prepared by oxidizing the corresponding alcohol with chromic acid according to

Observed hyperfine couplings in alicyclic ketyls*

Ketone	Intensity pattern	Hyperfine coupling (Oe)
4-*tert*-Butylcyclohexanone	1:2:3:4:3:2:1	$a_{H_a}=14.4$; $a_{H_e}=7.2$
Cyclopentanone	1:4:6:4:1	$a_H=13.8$
Cyclohexanone	1:4:6:4:1	$a_H=10.4$
4-Methylcyclohexanone	1:2:1 triplet of 1:2:1 triplets	$a_{H_1}=13.5$; $a_{H_2}=7.5$
3-Methylcyclohexanone	1:2:1 triplet of 1:2:1 triplets	$a_{H_1}=13.5$; $a_{H_2}=7.5$

*Solvent = 1,2-dimethoxyethane.

the method of Winstein and Holness (16). The ketyls were all generated by the following procedure. Freshly cut potassium was added to degassed 5% solutions of the ketones in dry 1,2-dimethoxyethane. The resulting yellow solutions were allowed to cool to room temperature and transferred to e.p.r. tubes and sealed. First derivative e.p.r. spectra were measured on a Varian V-2503 spectrometer fitted with a V-4532 dual cavity, operating at a nominal frequency of 9.5 Gc.p.s. The microwave power incident on the cavity was attenuated to 10 db below maximum. Hyperfine couplings were measured by comparison with a peroxylamine disulfonate solution in the audio cavity. The triplet spacing of the standard was taken to be 13.0 Oe (17). Reported hyperfine couplings are an average of several determinations with an estimated reproducibility of ±0.2 Oe.

A L.E.T. INDEPENDENT DOSIMETER BASED ON THE CHEMILUMINESCENT DETERMINATION OF H_2O_2[1]

W. A. ARMSTRONG AND W. G. HUMPHREYS

Defence Chemical Biological and Radiation Laboratories, Department of National Defence, Ottawa, Canada

Received April 21, 1965

ABSTRACT

A sensitive method for the determination of H_2O_2 based on the copper-catalyzed chemiluminescent reaction between luminol and H_2O_2 has been developed. The integral luminescence measured with a modified spectrophotofluorometer was found to increase linearly with concentration for 3×10^{-8} to 1.5×10^{-5} M H_2O_2 solutions. This method was applied to the determination of H_2O_2 formed in irradiated water and it was shown that this system may be used as a dosimeter in the range 30 to 3 000 rads. The following values were obtained for the initial H_2O_2 yields: $G(H_2O_2) = 1.22 \pm 0.07$ for ^{60}Co γ-radiation, 1.28 ± 0.09 for 250 kVcp (105 keV effective) X-radiation and 1.31 ± 0.04 for 14 MeV neutrons. These results and those of other workers demonstrate that the initial yield of H_2O_2 in aerated water increases only by about 15% for an increase in radiation l.e.t. of 0.02 to 14 eV/Å.

INTRODUCTION

Very few radiation-induced chemical reactions are independent of the energy and l.e.t. (linear energy transfer) of the incident radiation. Of the chemical dosimeters commonly used, only the ceric sulfate dosimeter has a response nearly independent of l.e.t. The use of it, however, is normally restricted to doses greater than 10 000 rads although a fluorometric method of Ce(III) analysis has extended its range to doses as low as 1 000 rads(1). Since it is the dose range below 1 000 rads that is of particular interest in the field of radiobiology, there is a requirement for a sensitive tissue-equivalent dosimeter whose response is the same for X, γ, and particle radiation.

The initial yield of H_2O_2 in aerated water has been shown to change little for radiations of a wide range of l.e.t. (2) but the method of analysis commonly used by radiation chemists (3, 4) is limited to concentrations produced by doses greater than 4 000 rads. One of the few methods cited in the literature for the determination of H_2O_2 concentrations less than 10^{-6} M is that developed by Andreae (5) and modified by Perschke and Broda (6). It is based on the observation that when H_2O_2 is decomposed by peroxidase in the presence of scopoletin, 1 mole of fluorescent scopoletin is destroyed for each mole of H_2O_2 decomposed. The chief disadvantage of this method is that in order to obtain an accurately measurable decrease in fluorescence, the concentration of H_2O_2 must not be less than 0.33 nor more than 0.84 times the concentration of scopoletin (6). This limits the usefulness of the technique in determining unknown H_2O_2 concentrations over a range of several orders of magnitude. The most sensitive method of analysis which has been applied to irradiated aqueous solutions is based on the chemiluminescent reaction of phthalic cyclic hydrazide with H_2O_2 and was developed by Mayneord (7). By the application of sensitive photomultiplier techniques involving a liquid nitrogen-cooled, nine-stage photomultiplier, he was able to determine H_2O_2 concentrations of the order of 10^{-7} M.

There are available now a number of commercial instruments for the measurement of fluorescence, phosphorescence, and luminescence which, although unable to quantitatively measure the weak luminescence of phthalic hydrazide, might be used to study more intense chemiluminescent reactions. One such reaction reported to be orders of magnitude brighter

[1]*Issued as DCBRL Report No. 461.*

than phthalic hydrazide is the luminol–H_2O_2 reaction (8). Babko has developed a photographic method based on this reaction but only H_2O_2 concentrations in the range 2×10^{-5} to 2×10^{-4} M could be analyzed (9). The investigation reported here was undertaken to develop an analytical technique based on the luminol–H_2O_2 chemiluminescent reaction as followed by either a commercial instrument or one with simple modifications, capable of determining H_2O_2 concentrations of 5×10^{-8} to 10^{-5} M and to apply this technique to the development of a chemical dosimeter with a response nearly independent of l.e.t. for a wide range of energies and capable of measuring doses of 30 to 3 000 rads.

EXPERIMENTAL

Materials

Samples of luminol (5-amino-2,3-dihydro-1,4-phthalazinedione) from Matheson, Coleman and Bell and from Mann Research Laboratories were used without purification after it had been established that recrystallization from dilute aqueous acetic acid did not affect the luminescent properties. All other materials were of reagent grade.

Stock hydrogen peroxide solutions, approximately 10^{-4} M, were prepared by irradiating thrice-distilled water with ^{60}Co γ-radiation to doses of about 100 000 rads. These were analyzed by the Ghormley method (3, 4) which is based on the measurement of the optical absorption of the triiodide ion formed by the reaction of H_2O_2 with KI catalyzed by molybdate ions. The molar extinction coefficient of the triiodide ion at 350 mμ was determined to be 2.44×10^4 by analyzing solutions 10^{-5} to 10^{-4} M in H_2O_2 prepared from a 0.2 M H_2O_2 solution which had been standardized by the standard arsenious acid method. The stock 10^{-4} M H_2O_2 solutions, if kept in the dark, were found to be stable for many weeks.

Water was purified in a manner similar to that described by Dainton (10). Laboratory distilled water was distilled from alkaline permanganate, then from dilute sulfuric acid, then irradiated with ^{60}Co γ-radiation to a dose of about 200 000 rads, and finally refluxed in a quartz still over alkaline permanganate for at least 24 h.

Irradiation vessels made from quartz standard-taper 19/38 joints (o.d. 1.5 cm, i.d. 1.3 cm) were rinsed with chromic acid, washed many times with once-, twice-, and thrice-distilled water, flushed with steam, filled with thrice-distilled water, irradiated to a dose of about 200 000 rads, and finally flushed with steam from the quartz still. Steam from the top of the still column was then condensed directly into the irradiation vessels which were capped immediately after the desired volume (5.0 ml) had been added.

Irradiations

Samples were irradiated with γ-rays from either a 200 curie (dose rate = 14 rad/min) or a 1 000 curie (dose rate = 146 rad/min) ^{60}Co source. A Muller constant-potential machine was used for X-irradiations at a dose rate of 19 rad/min. The beam was filtered with 0.9 g/cm^2 Cu and 0.13 g/cm^2 Al to give an effective energy of 105 keV when the machine was operated at 250 kVcp (kV constant potential). Dose rates were determined with the Fricke ferrous sulfate dosimeter using $G(\mathrm{Fe(III)}) = 15.5$ for ^{60}Co γ-radiation and 14.9 for the X-radiation. The ferric ion yield was determined by its absorption at either 224 mμ or 304 mμ using the extinction coefficients given by Scharf and Lee (11). The appropriate corrections were applied to obtain the dose rates in water.

Monoenergetic 14 MeV neutrons were obtained from a Cockroft–Walton accelerator by means of the $H^3(d,n)He^4$ reaction. Four sample tubes mounted on an aluminium turntable were rotated at 60 r.p.m. as close as possible to the target. The irradiations were monitored with a Tullamore BF_3 counter. The relationship between the output of the monitor and the dose received by the samples was determined by irradiating samples of 10^{-3} M ferrous sulfate – 0.8 M H_2SO_4, calculating the absorbed dose from the ferric ion yield, assuming $G(\mathrm{Fe(III)}) = 10.5$ (1), and comparing this dose with the monitor count. This calibration was repeated each time the tritium target was changed.

Measurement of Chemiluminescence

The chemiluminescence from the copper-catalyzed luminol–H_2O_2 reaction was measured with an Amino–Bowman spectrophotofluorometer (No. 4 8100) equipped with a IP 28 photomultiplier tube. In order to achieve high sensitivity the reaction was carried out in a quartz optical cell placed in the photomultiplier shutter compartment directly in front of the photomultiplier tube.

Preliminary investigations showed that the peak height registered by the microphotometer did not give a reproducible measurement of the luminescent reaction. Thus methods of measuring the total luminescence were investigated. The circuit developed is outlined in Fig. 1. The 50 ohms resistor (R_{14} in ref. 12) across the recorder outlet terminals of the microphotometer was removed and a Texas Instruments rectilinear recorder (coil resistance 1 500 ohms, full scale reading 1 mA) was plugged into the outlet. This put the meter mechanism of the recorder in series with the meter of the microphotometer and permitted the recording of light intensity vs. time curves. The output from the microphotometer was collected on a 33 000 μF capacitor and the voltage across the capacitor measured with a Keithley model 220 vacuum tube voltmeter. To prevent appreciable current leakage back through the microphotometer meter the voltage was limited to less than

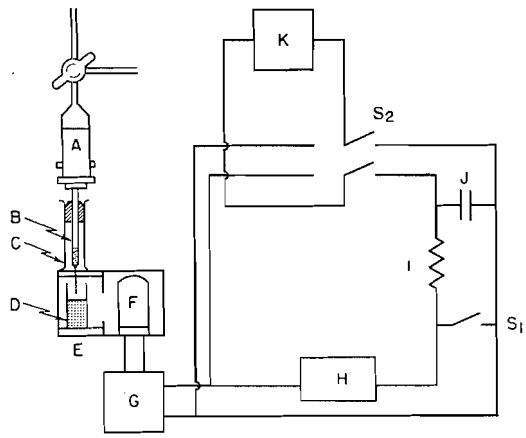

FIG. 1. Apparatus for measuring chemiluminescence. A, plunger activated by compressed air, B, syringe; C, blackened glass tube; D, reaction cell; E, shutter compartment and phototube housing of Aminco–Bowman spectrophotofluorometer; F, photomultiplier tube; G, microphotometer; H, recorder or 1 500 ohms resistor; I, 24 ohms resistor; J, 33 000 μF capacitor; K, vacuum tube voltmeter; S_1 and S_2, switches.

0.1 V. Since voltages as low as 0.01 V could be measured accurately and since the microphotometer was equipped with a seven-position switch to enable changes in sensitivity in fixed steps over the range of 1 000 to 1, accurate measurements could be made over a wide range of light intensities. After it had been demonstrated many times for various reactant concentrations that the voltage across the capacitor after the completion of the chemiluminescent reaction was directly proportional to the area under the light intensity vs. time curve, the integrated luminescence was measured as the voltage multiplied by the microphotometer sensitivity setting. The performance of the system was checked with a low intensity light source of constant output made from a plastic phosphor containing ^{14}C (13). Fluctuations of sensitivity during a day were negligible and over a period of some weeks changes of not more than 5% were observed.

The chemiluminescent reaction was carried out in the following manner. A 2.0 ml sample was pipetted into the optical cell, 0.2 ml of aqueous $CuCl_2$ (10^{-4} to 10^{-2} *M*) added, and the cell placed in position. The reaction was initiated by adding 0.1 ml alkaline luminol, usually 10^{-4} *M* luminol – 0.1 *M* NaOH, and lasted from 10 to 45 s depending upon the reaction conditions. The most satisfactory rate of addition of luminol was obtained when the plunger of the syringe was suddenly subjected to 4 p.s.i. pressure. Under these conditions the reactants were mixed thoroughly by the addition and results were more reproducible than those obtained when the samples were mixed by bubbling through compressed air.

The concentration of H_2O_2 in an irradiated sample was determined from a comparison of its integrated luminescence with the plot of luminescence vs. [H_2O_2] obtained from the analysis of known H_2O_2 solutions freshly prepared by the dilution of the standardized stock solution. Usually known H_2O_2 solutions were analyzed either before or after the irradiated samples although the luminescence vs. [H_2O_2] plot did not change significantly from day to day. Irradiated samples kept in the dark were stable for at least 24 h.

RESULTS

The Chemiluminescent Reaction

An investigation was made of the effects of luminol concentration, Cu^{++} ion concentration and pH on the integrated luminescence from 10^{-7} to 10^{-5} *M* H_2O_2 solutions with a view to finding conditions under which the integrated luminescence would be a linear function of the H_2O_2 concentration.

Preliminary results confirmed Mayneord's observation (7) of a luminescence due to the autooxidation of luminol in alkaline solution but it was found to decrease to a low constant value after the solution had been left to stand for several days in the dark. The solution could then be used for several months with only slight changes occurring in its luminescent properties.

Before each run the luminescence of a thrice-distilled water sample was determined with the same reagent concentrations as were to be used with the H_2O_2 samples. This blank luminescence, never greater than the chemiluminescence from a 3×10^{-8} *M* H_2O_2 sample, was subtracted from the measured luminescence of each H_2O_2 sample.

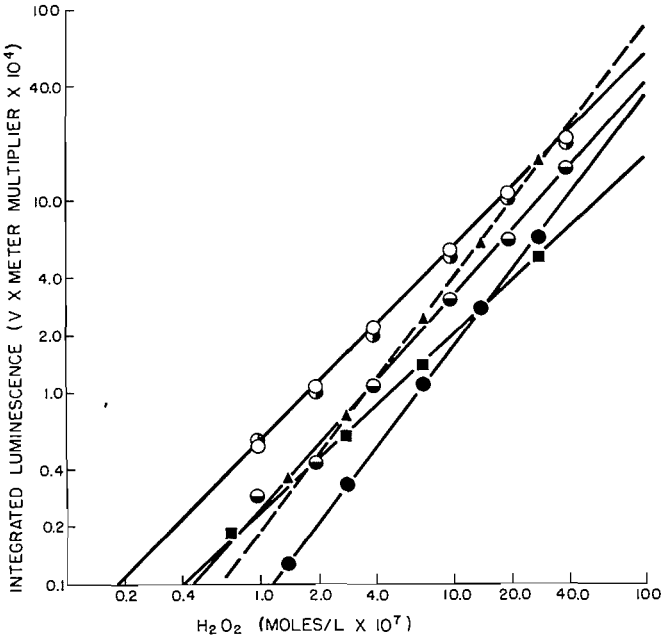

FIG. 2. The effect of luminol and Cu^{++} concentration on luminescence. TABLE I

The effect of luminol and Cu^{++} concentrations on luminescence

[Luminol] (moles/l $\times 10^6$)	[Cu^{++}] (moles/l $\times 10^6$)	[Cu^{++}]/[luminol]	n (Slope of log luminescence vs. log [H_2O_2])
46	46	1	1.33
4.6	4.6	1	1.33
4.6	46	10	1.12
4.6	230	50	1.01
4.6	460	100	1.01
0.46	46	100	0.94

The effects of the concentration of luminol and of $CuCl_2$ on the chemiluminescent reaction are illustrated in Fig. 2. It is evident that

$$\text{integrated luminescence} \propto [H_2O_2]^n$$

where n is the slope of the line obtained when the log of the integrated luminescence is plotted against the log of the H_2O_2 concentration. Values of n for different luminol–Cu^{++} mixtures are listed in Table I. It would appear that n is a function of the ratio [Cu^{++}]/[luminol] and decreases as this ratio increases. For the integrated luminescence to increase linearly with increasing H_2O_2 concentration, n must be 1.0. The reaction mixture which fulfilled this condition and had an acceptably low blank luminescence and high sensitivity was 4.6×10^{-6} M luminol, 4.6×10^{-3} M NaOH, and 4.6×10^{-4} M $CuCl_2$. As shown in Fig. 3 the pH of this system (11.7) was nearly optimal for chemiluminescence efficiency. To obtain these reagent concentrations, 0.1 ml of 10^{-2} M $CuCl_2$ was added to a 2.0 ml sample of H_2O_2 and the reaction initiated with 0.1 ml of 10^{-4} M luminol – 0.1 M NaOH. The

integrated luminescence was found to increase linearly up to H_2O_2 concentrations of about 1.5×10^{-5} M while at higher concentrations there was a decrease from linearity. H_2O_2 concentrations in the range of 3×10^{-8} to 1.5×10^{-5} M could be determined with an accuracy of about $\pm 5\%$.

H_2O_2 in Irradiated Aqueous Solutions

The yields of H_2O_2 were measured in aerated water samples which had been irradiated to doses of 28 to 3 500 rads with ^{60}Co γ-rays, 100 to 1 200 rads with 250 kVcp X-rays, or 100 to 2 200 rads with 14 MeV neutrons. For each type of radiation a plot of $[H_2O_2]$ vs. dose gave a straight line passing through the origin (Fig. 4) and $G(H_2O_2)$ values were determined from the slopes of these lines as calculated by the method of least squares.

The amounts of H_2O_2 formed in irradiated 0.5×10^{-5} M and 1.0×10^{-5} M KBr solutions were also measured for each type of radiation. Results were less reproducible than those obtained with aerated water and plots of $[H_2O_2]$ vs. dose gave small intercepts (0.02 to 0.05×10^{-6} M) on the H_2O_2 axis. For bromide solutions irradiated with γ-rays or X-rays G-values were calculated from the slopes of these plots as determined by the method of least squares while for neutron-irradiated samples they were determined by direct comparison with ferric ion yields in 10^{-3} M ferrous sulfate – 0.4 M H_2SO_4 solutions irradiated simultaneously.

The values of $G(H_2O_2)$ for each set of conditions along with the standard deviations and the number of measurements are listed in Table II. It is felt that for aerated water the G-values of 1.22 ± 0.07 for ^{60}Co γ-rays and 1.28 ± 0.09 for 250 kVcp X-rays are accurate to about $\pm 7\%$. With the neutron irradiated solutions the largest source of error lies in the value of G(Fe(III)). Recently Axtmann and Licari (14) have calculated that G(Fe(III)) for 14 MeV neutrons should be about 10 and have measured a value of 11.5 ± 1.8. We therefore believe that our previously determined value of 10.5 ± 0.2 is valid to about $\pm 10\%$. Hence $G(H_2O_2) = 1.31 \pm 0.04$ for aerated water irradiated with 14 MeV neutrons is accurate to about $\pm 15\%$.

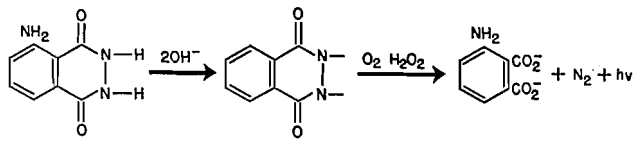
DISCUSSION

The Chemiluminescent Reaction

Although the chemiluminescent reaction of luminol (I) has been investigated since 1928 (15), very few uncontested facts have been put forward and the identity of the emitting species is still in dispute. A number of mechanisms have been proposed and discussed by various authors (8, 15–19). The assumption that some form of luminol is the light emitter is based on the observation that about 70 moles of H_2O_2 are consumed per mole of luminol indicating that luminol may not be consumed in the chemiluminescent reaction (20) and on the similarity of the fluorescence spectrum of luminol in dilute acid solution with the chemiluminescence spectrum in basic solution (15). The opposing view that the 3-aminophthalate ion (III) is the emitter is supported by a close match between the fluorescence spectrum of this compound and the chemiluminescence of luminol and by the fact that the pH – fluorescence efficiency profile is the same as the pH – chemiluminescence efficiency profile (19, 21). The overall reaction based on this assumption is given by eq. [1].

Recently White and co-workers (22) identified nitrogen and sodium 3-aminophthalate as the reaction products of the luminol–O_2 chemiluminescent reaction in alkaline dimethylsulfoxide and also showed that the fluorescence spectrum of the total reaction products

[1]



(I) (II) (III)

from the luminol, NH_3, H_2O_2, and Cu^{++} system was identical with that of the 3-aminophthalate ion (23). Although we did not attempt to identify the reaction products of our luminol, NaOH, H_2O_2, and Cu^{++} system, we did observe that the wavelength of maximum fluorescence of the reaction mixture was identical with that of a sodium 3-aminophthalate solution at the same pH and corresponded as well with the wavelength of the maximum chemiluminescence. A comparison of the increase in fluorescence of the reaction product vs. time with the chemiluminescence vs. time indicated that about one-half of this product was produced during the chemiluminescent reaction, which lasted approximately 10 s, and the rest was formed at a slower rate during the next 2 or 3 min.

This evidence supports the contention that the aminophthalate ion is the light emitter. However, if the chemiluminescence of the parent unsubstituted phthalic cyclic hydrazide is considered, there is no evidence to support hypotheses corresponding to those put forward to explain luminol chemiluminescence. The phthalic hydrazide chemiluminescence spectrum does not resemble its fluorescence spectrum in either acidic or basic solutions and the presumed reaction product, sodium phthalate, does not exhibit detectable fluorescence. Hence there is still some doubt as to the nature of the light emitter.

Our observed dependence of chemiluminescence on pH is similar to that reported by Seliger for the luminol, H_2O_2, and NaOCl system (21). This has been interpreted by White (18) and others as demonstrating that it is the dinegative ion of luminol (II) which takes part in the chemiluminescent reaction.

The effect of copper salts on the luminol reaction has been studied by Babko (24, 25). He explains the increase in the luminescence intensity in the presence of copper salts on the formation of a copper–luminol complex which affects the equilibrium between the neutral, mononegative, and dinegative forms of luminol in favor of the dinegative form and also catalyzes the decomposition of H_2O_2 (25). Under conditions where the concentration of Cu^{++} ions is equal to or greater than the concentration of luminol, the decrease in the slope of log luminescence vs. log $[H_2O_2]$ with increasing Cu^{++} concentration may be due to a quenching effect.

H_2O_2 in Irradiated Solutions

The radiolysis of aerated water may be described by the following equations which are similar to those given by Allen and Schwarz (26) but assume the formation of both hydrated electrons (e_{aq}^-) and H atoms in neutral solutions (27) as well as ionization of the HO_2 radical ($pK \sim 4.4$).

[2] $$H_2O \rightsquigarrow e_{aq}^-, H, OH, HO_2, H_2, H_2O_2$$

[3] $$e_{aq}^- + O_2 \rightarrow O_2^-$$

[4] $$H + O_2 \rightarrow HO_2$$

[5] $$HO_2 \rightarrow H^+ + O_2^-$$

[6] $$O_2^- + O_2^- + 2H_2O \rightarrow H_2O_2 + O_2 + 2OH^-$$

[7] $$OH + H_2O_2 \rightarrow H_2O + HO_2$$

Then for initial yields

[8] $$G(H_2O_2) = G_{H_2O_2} + \tfrac{1}{2}(G_{HO_2} + G_{e_{aq}^-} + G_H - G_{OH}).$$

Although $G_{H_2O_2}$ and G_{HO_2} increase with increasing l.e.t. while $G_{e_{aq}^-}$, G_H, and G_{OH} decrease, the measured initial value of $G(H_2O_2)$ changes very little over a wide range of l.e.t. (2).

As the radiation dose is increased and appreciable concentrations of H_2 and H_2O_2 are built up, reactions [9], [10], and [11] may affect the value of $G(H_2O_2)$.

[9] $$OH + H_2 \rightarrow H_2O + H$$

[10] $$H + H_2O_2 \rightarrow H_2O + OH$$

[11] $$e_{aq}^- + H_2O_2 \rightarrow H_2O + OH + OH^-$$

Sworski (28) and Allen (29) showed that the H_2 could be protected from OH attack by the addition of bromide ion.

[12] $$OH + Br^- \rightarrow Br + OH^-$$

However, with aerated bromide solutions the initial yield of H_2O_2 is dependent on the concentration of the bromide ion (28, 29) and the degree of this dependency is related to the l.e.t. of the radiation (30). The results in Table II are in agreement with this. The value of $G(H_2O_2)$ decreased with increasing bromide ion concentration to a much greater extent for solutions irradiated with ^{60}Co γ-rays than for neutron-irradiated solutions. Therefore the yields of H_2O_2 in irradiated bromide solutions are more dependent on l.e.t. than those in irradiated aerated water.

At high doses the concentration of dissolved oxygen is reduced and reactions [10] and [11] may compete with [3] and [4] resulting in a decrease in the yield of H_2O_2. Usually this falloff is not noticeable with solutions irradiated to doses of less than 10 000 rads. However, in this investigation, water was condensed directly from the still head into the sample tubes which were then immediately capped. The samples were, therefore, not air-saturated and a falloff in the yield of H_2O_2 was noticed at doses greater than 4 000 rads.

The value of $G(H_2O_2) = 1.22 \pm 0.07$ for ^{60}Co γ-radiation (l.e.t. ~ 0.02 eV/Å) is in good agreement with the figure 1.23 by Allen (29). The result with 14 MeV neutrons (l.e.t. ~ 1.2 eV/Å) of 1.31 ± 0.04 also corresponds with the values of 1.31 for 19 Mev deuterons (l.e.t. ~ 0.5 eV/Å) and 1.21 for 32 MeV helium ions (l.e.t. ~ 2.3 eV/Å) given by Schwarz (2). Recently Anta (31) has published $G(H_2O_2) = 1.41$ for aerated 0.4 M H_2SO_4 irradiated with ^{210}Po α-particles (l.e.t. ~ 14 eV/Å) but the value for neutral aerated water is probably somewhat lower since it has been shown that the initial yield of H_2O_2 increases with increasing acidity (2).

It should be emphasized that the values of $G(H_2O_2)$ for aerated water reported here are based on results obtained in a dose range not adequately covered by other workers. Extrapolation of Allen's H_2O_2 yields to zero dose (29) leads to an intercept on the H_2O_2 axis, the exact value of which depends upon the method of water purification. The smallest reported intercept of about 0.3×10^{-6} mole/l is equivalent to a dose of nearly 300 rads and indicates a very high initial yield. The only available results obtained with doses of less than 1 000 rads are those of Mayneord (7). His plot of H_2O_2 concentration vs. dose is linear from 200 to 1 250 rads and extrapolates to the origin but gives $G(H_2O_2) = 1.83$ for 140 kVp X-rays, a value about 50% higher than that obtained in the present investigation with 250 kVcp X-rays. High initial yields are usually attributed to traces of organic impurities (29). Various methods of purification may be used to destroy organic substances in water but it is extremely difficult to protect the purified water from airborne contaminants. In this investigation the problem was avoided by condensing the water directly

into the irradiation vessels and capping them as soon as the desired volume had been added. Reproducible initial H_2O_2 yields could only be obtained through the use of this procedure.

From the results mentioned above it is evident that the initial yield of H_2O_2 in aerated water increases only by about 15% for an increase in radiation l.e.t. of nearly three orders of magnitude. Thus the method of H_2O_2 analysis reported here enables the use of aerated water as a sensitive dosimeter which is nearly independent of the quality of the radiation over a wide range of l.e.t.'s.

SOLVENT EFFECTS IN THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF BENZALMALONONITRILES[1]

M. A. WEINBERGER, R. M. HEGGIE

Received April 15, 1965

ABSTRACT

The nuclear magnetic resonance spectra of a series of substituted benzalmalononitriles were examined in various solvents. The chemical shifts for the olefinic protons are susceptible to large solvent effects which are interpreted as arising from association of a solvent molecule with the olefinic proton (acetone) or a site in its vicinity (benzene). With acetone this leads to a downfield shift from values observed in chloroform. In benzene solution the association produces increased shielding and is present in addition to a second solvation complex, the arrangement of which is governed by the substituent. The difference in behavior of the ethylenic proton in benzalmalononitriles from the formyl proton in benzaldehyde is ascribed to its more highly acidic nature.

INTRODUCTION

In a series of papers (1, 2) Klinck and Stothers reported on studies of the solvent effects in the nuclear magnetic resonance (n.m.r.) spectra of substituted aromatic aldehydes which provided evidence for the occurrence of specific solvent–solute association. In benzene solutions, for example, the observed changes in the chemical shifts of the various protons in the molecule from their values in chloroform solution were interpreted in terms of a molecular complex in which a benzene molecule tends to lie over the electron-deficient portion of the solute, the aromatic rings being parallel to each other. The anisotropy of the benzene then leads to substantially increased shielding of those protons in the vicinity of the center of the solvent ring, and the effect decreases for the more distant protons. Similar "collisional" complexes had been proposed earlier by Hatton and Richards (3) for solutions of amides and other polar compounds in aromatic solvents. These solvents always associate with sites of the solute as far away from an electronegative portion as possible. The observed enhanced shielding by benzene of the formyl and adjacent ring protons in benzaldehydes with electron-withdrawing para-substitutents, and the smaller effect on these protons in the case of electron-donating substituents are thus explained by the association positions of the benzene molecule favored in the respective compounds.

With acetone as solvent the observed differential shifts from chloroform solutions are much smaller and did not allow as definite conclusions for the existence of solute–solvent complexes as with benzene, since part of the shift could be attributed to effects arising from the reaction field of the solvent.

In the present work we have investigated the effect of substituents and solvents on the chemical shift of the protons in benzalmalononitriles which formally resemble the benzaldehydes. The highly electronegative side-chain substituents, however, cause the olefinic protons to be more acidic than the corresponding protons in benzaldehydes. In an interesting synthesis based on this difference in acidity, Bastus (4) obtained acetophone in

[1]*Issued as DCBRL Report No. 462.*

excellent yield by methylation with diazomethane, not directly from benzaldehyde but via benzalmalononitrile and subsequent hydrolysis. It was therefore believed that in the benzalmalononitriles we might encounter more extreme solvent effects with electron-donating solvents. The study of the chemical shifts was simplified by referencing with respect to an internal standard. This eliminated effects due to bulk diamagnetic susceptibility, and the non-specific parts of solvent diamagnetic anisotropy and van der Waals interactions (5).

EXPERIMENTAL

Solutions (10% w/v, about 4–5 mole %) of the compounds in chloroform and acetone were studied at 30°. Deuterated solvents supplied by Merck, Sharp and Dohme of Canada Ltd., Montreal, Que., were used when necessary. In a few examples carbon tetrachloride solutions were also examined, and the spectra of a number of representative compounds were determined in d_6-benzene; 60 Mc/s n.m.r. spectra were recorded with a Varian 4300C spectrometer. The spectra were calibrated by the sideband technique using an electronic counter. The chemical shifts referenced with respect to internal tetramethylsilane are reported as τ values. These are the averages of at least five measurements and have standard deviations of 0.007 p.p.m. or better.

The benzalmalononitriles were obtained by the method of Corson and Stoughton (6) and recrystallized, usually from ethanol. Corrected melting points are given in Table I as well as analytical figures for new compounds.

RESULTS AND DISCUSSION

The chemical shifts of the ethylenic proton in the variously substituted benzalmalononitriles are given as τ values in Table II. This is arranged according to position of the substituent and then in order of increasing values of τ. For reasons to be discussed later the effect of structure on τ will be considered only for chloroform solutions. For the para-substituted compounds there is a qualitative correlation between the expected polarization of the CH bond and the τ value. The latter has a range of 0.45 p.p.m. between the extremes, *p*-nitro- and *p*-dimethylamino-benzalmalononitrile. Quantitatively the correlation between the observed shifts and the Hammett sigma parameters of the substituents as listed by McDaniel and Brown (15) and by Jaffe (16) is, however, not too satisfactory: $\tau = -0.259$ (± 0.035) $\sigma + 2.303$ (± 0.016), correlation coefficient (r) $= -0.93$, $n = 10$. The correlation is no better when the meta- and non-ortho-disubstituted compounds are included ($\tau = -0.244$ (± 0.036) $\sigma + 2.322$ (± 0.015), $r = -0.85$, $n = 20$). As was suggested for the formyl proton in benzaldehydes (1) the exposed nucleus of the ethylenic proton may be more susceptible to perturbing effects than a fluorine for the shift of which much better correlations with substituent constants have been obtained.

In the ortho-substituted benzalmalononitriles the τ values as shown in Table II are, in the main, little affected by the electronic nature of the substituents, and a quantitative correlation with Hammett's σ_r is very poor ($r = -0.22$). The electronic effect of the substituent on the τ values of the ethylenic proton is thus less marked in the ortho- than in the meta- and para-substituted compounds. In addition, the resonance occurs at lower field in each of the ortho-substituted compounds than in the parent compound. The similar behavior in benzaldehydes has been adequately discussed by Klinck and Stothers (1) and explained in terms of reduced side chain – ring conjugation resulting from non-coplanarity because of the presence of an ortho substituent. Since, even with the least bulky substituents, the ethylenic proton in ortho-substituted benzalmalononitriles gives peaks which are 0.3 p.p.m. to lower field than those in benzalmalononitrile or the corresponding para-substituted compounds, it is evident that the effects caused by decreased conjugation completely overshadow the opposite effects due to ring current changes. Calculations based on the model of Johnson and Bovey (17) show that, as the side-chain proton goes out of the plane of the ring, its shielding is increased by, at most, 0.11 p.p.m.

For personal use only.

Further evidence for the isolation of the side chain from the ring in ortho-substituted compounds is afforded by ultraviolet spectra. The K band for 2-methylbenzalmalononitrile occurs at 312 mμ (ϵ = 16 500) and that for 4-methylbenzalmalononitrile at 323 mμ (ϵ = 25 800). Since the substituent in this case is non-functional, Braude's expression (18) for the extinction coefficient ratio in terms of the out-of-plane angle θ of the side chain may be applied with some confidence, giving $\cos^2\theta = 0.64$, and $\theta = 37°$. This may be regarded as a measure of the loss of through-conjugation in the ortho compound.

Solvent Effects

Most of the benzalmalononitriles are not soluble enough in interaction-free solvents such as *n*-hexane and, as a compromise, chloroform or deuterated chloroform was chosen as the standard solvent. Chloroform is an acceptor and very likely associates with the cyano groups. It can be seen from Table II that the τ values in carbon tetrachloride are about 0.1 p.p.m. higher than in chloroform. It is therefore inferred that the effect of association of chloroform with the compounds is relatively small. Use of the chloroform values as reference causes no appreciable error when one is discussing the large changes in benzene and it implies minimum values for the effects observed in acetone.

The dilution shift was checked in a few cases. 2-Nitrobenzalmalononitrile showed no change on fourfold dilution of a 3.5 mole % solution in chloroform and a decrease of 0.02 p.p.m. in acetone. The same change was also found on similar dilution of an acetone solution of the 4-nitro compound. It is therefore considered that "infinite dilution" conditions have been sufficiently approached in these experiments.

Before we consider the shifts in Table II in solvents other than chloroform, the effect of the reaction field of the solvent on the highly polar solute will be calculated in the case of 4-methylbenzalmalononitrile (μ = 4.1 D, by addition of group moments). Using the method of Buckingham (19) based on a spherical cavity model, with a calculated value of 1.93×10^{-23} cc for the polarizability of the solute, the contribution to the shielding of a proton is

$$\sigma_R = -0.104\,[(\epsilon - 1)/(2\epsilon + 2.5)]\,\mu\cos\theta \quad \text{p.p.m.}$$

in which ϵ is the solvent dielectric constant and θ the angle that the proton bond axis makes with the dipole μ (in D). The contribution turns out to be much too small to account for the variation of the shift of the olefinic, ortho, and meta protons[2] with solvent shown in Table III. For the solvent change from chloroform to acetone, for example, the calculated shifts caused by the reaction field are only 0.02 p.p.m. downfield on the ethylenic and meta protons and 0.02 p.p.m. upfield on the ortho proton.

The ellipsoidal cavity model of Diehl and Freeman (20) using ellipsoid semi-axes of 6.25, 3.75, and 1.95 Å, a shape factor of 0.144 as calculated by the method of Ross and Sack (21), and a refractive index of 1.5 leads to a contribution

$$\sigma_R = -0.0323\,[(\epsilon - 1)/(\epsilon + 0.378)]\,\mu\cos\theta \quad \text{p.p.m.}$$

This is even smaller than that calculated with the simpler model. Inspection of Table III indicates that the shift of the olefinic proton in fact depends more on the chemical nature of the solvent. In the relatively non-interacting solvents τ is 2.4, in ethers it is 2.1, and in solvents with carbonyl groups τ drops to 1.8.

To pinpoint the interactions in acetone and benzene solutions it is necessary to determine, as well, the solvent dependence of the shift of the aromatic protons in the benzalmalononitrile molecule. The shifts can be readily deduced only for the para-substituted

[2]*Here and subsequently ortho and meta refer to the ring position relative to the* —CR = $C(CN)_2$ *substituent.*

Methyl acetate	6.68	1.87	2.07	2.57
Acetone	20.7	1.81	2.08	2.57

compounds from the pseudo-AB-like part of the A_2B_2 spectrum (22). Analysis of these spectra also yield values for the sums of the ortho and para coupling constants of 8.5–9.3 c.p.s., which are almost independent of substituent and solvent.

Acetone Solutions

Table IV shows the results for para-substituted benzalmalononitriles and some 1,1-dicyano-2-phenyl-1-propenes. It is apparent that the chemical shift of the aromatic protons of para-substituted benzalmalononitriles is generally decreased in changing from chloroform to acetone solutions and by about the same amount (0.1–0.2 p.p.m.) as for benzaldehydes (2). The propylidene methyl and substituent protons are very little affected by this solvent change, but there is a larger effect on the olefinic proton shift. A large effect on the ethylenic proton shift is also noted in the meta-substituted compounds in Table II. When ortho substituents are present this "solvent shift" is much reduced in most of the examples and is then of the same order as that observed for the formyl proton in benzaldehyde. In the disubstituted benzalmalononitriles without an ortho substituent

the solvent shift is roughly the same, 0.5 p.p.m., as for the derivatives with a single meta or para substituent, whilst if an ortho substituent is present, it appears to govern the solvent effect. A notable exception is 2,6-dichlorobenzalmalononitrile where the solvent shift is more like that of a 3,4-disubstituted compound.

The small solvent effects on aromatic protons in both benzalmalononitriles and benzaldehydes are probably due to a vague solvation of a dipolar nature, but the large changes in τ value of the ethylenic proton are only explicable on the basis of a specific solvent interaction of the acetone carbonyl oxygen with the ethylenic proton. This is quite different from the behavior of the formyl proton in benzaldehydes, but since this ethylenic proton is more acidic, an interaction of the hydrogen bond type with acetone is not unreasonable, and a substantial downfield shift of the field position of the proton results in compounds without ortho substituents. As might be expected, compounds with electron-withdrawing groups in the para position show an enhanced shift, those with electron-donating groups a reduced one compared to the value for the parent compound. With ortho-substituted benzalmalononitriles the situation is complicated by the long-range shielding effects of the substituent and by the possibility of intramolecular hydrogen bonding of it with the olefinic proton. In those compounds where such bonding is unlikely, the "normal" acetone solvent shift of the corresponding para compound would be observed. This is the case with 2-methylbenzalmalononitrile where the solvent shift is nearly as large as that of the 4-methyl analogue and in 2,6-dichlorobenzalmalononitrile where, for steric reasons, intramolecular interaction is not possible. However, those substituents which may show intramolecular association are also most likely to have large magnetic anisotropic effects, and it is impossible at present to separate these factors. The effects can be discussed generally by considering the equilibrium

$$A + \text{acetone} \rightleftharpoons \text{solvent complex (B)},$$

where A is the ortho-substituted benzalmalononitrile, perhaps internally complexed. The solvent shift $\Delta\tau$ is then given by

$$\Delta\tau = \alpha(\tau_B - \tau_A),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where α is the mole fraction of solvent complex and the τ values are those of the extreme forms (A and B). Association with the solvent disrupts the influence of the magnetic anisotropy of the substituent and of any intramolecular hydrogen bond, both of which contribute to the net effect which is measured by $\tau_B - \tau_A$. In 2-nitrobenzalmalononitrile where formation of a six-membered ring would lend some stability to the intramolecular hydrogen bond which is also aided by a favorable electron distribution, one may expect a smaller α than in the 2-alkoxy compounds. The solvent shift for 2-nitrobenzalmalononitrile is, however, much bigger than that for the 2-methoxy analogue. Hence it appears that $(\tau_B - \tau_A)_{NO_2} > (\tau_B - \tau_A)_{OMe}$, i.e. on solvation with acetone the net change in shielding of the ethylenic proton is less in the methoxy than in the nitro compound.

Benzene Solutions

The solvent shifts are shown in Table V as well as their differences from the solvent shifts of the corresponding protons in benzaldehydes observed by Klinck and Stothers (2).

TABLE V

*These differences are $\Delta\tau$(benzalmalononitrile) minus $\Delta\tau$(benzaldehyde) or $\Delta\tau$(1,1-dicyano-2-phenyl-1-propene) minus $\Delta\tau$(acetophenone).

†Solvent shifts of 0.81 and 0.60 p.p.m. were found for the aromatic protons but they could not be assigned.

The results for a few 1,1-dicyano-2-phenyl-1-propenes are also shown and compared differentially with the values for the acetophenones with the same substituent (2). These comparisons yield the striking result that the differences between the solvent shifts of the corresponding protons in benzalmalononitriles and benzaldehydes are quite large but relatively insensitive to substituent, the average values being 0.88 p.p.m. for the olefinic proton, 0.34 p.p.m. for the ortho proton, and 0.22 p.p.m. for the meta proton. To a good approximation therefore the benzene solvent shifts in benzalmalononitriles can be explained in terms of a complex in which two molecules of benzene participate, one whose substituent-dependent position is similar to that in the Klinck and Stothers model for benzaldehydes, and the other whose location over the side chain is independent of the substituent (Fig. 1). The association with the side chain is reminiscent of the complexing of toluene with acetonitrile (23). Ring current effect calculations (17) show that the above differential solvent shifts result for the ethylenic and ortho protons when the second benzene molecule is centered at about 2.5 ring radii over the carbon atom adjacent to the ring, its plane parallel

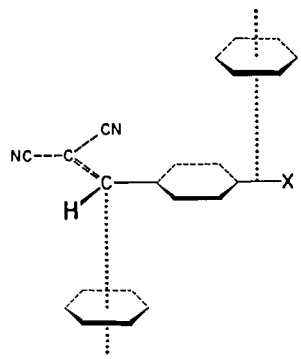

FIG. 1. Association of benzene with a para-substituted benzalmalononitrile. The substituent-dependent position of the benzene molecule at upper right is shown for an electron-donating substituent.

to that of the solute ring. The value calculated for the meta proton is, however, too small by 0.2 p.p.m. A similar model with the second benzene molecule having a position at about 2.5 ring radii over the middle of the bond between the aromatic and olefinic carbons accounts approximately for the observed solvent shifts in the 1,1-dicyano-2-phenyl-1-propenes.

CONCLUSIONS

The strongly electron-attracting cyano groups in benzalmalononitriles cause solvation of the olefinic proton or sites in its vicinity by the donor solvents acetone and benzene, in addition to the solvation normally encountered with these solvents and aromatic molecules. The solvent shifts observed in the n.m.r. spectra are relatively large, but are modified in ortho-substituted compounds.

ACKNOWLEDGMENTS

The authors thank Mr. K. Oikawa and Miss P. M. Lutley for assisting with the n.m.r. spectra. Mr. R. F. Silver, Miss P. D. Frandsen, and Miss S. J. Kelley assisted in the preparation of the compounds.

CEANOTHUS ALKALOIDS

I. ISOLATION, SEPARATION, AND CHARACTERIZATION

E. W. WARNHOFF,[1] S. K. PRADHAN,[2] AND J. C. N. MA[3]
Department of Chemistry, University of Western Ontario, London, Ontario
Received April 13, 1965

ABSTRACT

Five pure alkaloids have been separated from the crude mixture of *Ceanothus americanus* (Rhamnaceae) bases by means of column and thick-layer chromatography. Their molecular formulas have been established as $C_{30}H_{40}O_4N_4$, $C_{29}H_{36}O_4N_4$, $C_{26}H_{38}O_4N_4$, and $C_{28}H_{44}O_3N_4$ (two compounds). One of these may be identical with the previously reported ceanothine. Evidence is presented for the functional groups and other features of the molecules.

Since colonial times various medicinal properties have been ascribed to the plant *Ceanothus americanus* (Rhamnaceae) (1). This shrub is indigenous to eastern and central North America, and other species grow in the western part of the continent (e.g. *Ceanothus velutinus*) and in Mexico (*Ceanothus azurea*) (2). Aside from the non-medical use of the leaves, known as New Jersey or Jersey tea, for a tea substitute during both the American Revolutionary and Civil wars (3), the plant is reputed to have been used for treatment of venereal disease, dysentery, and disorders of the spleen. Its coagulant properties have made it useful as a styptic and oral haemostatic agent (4, 5). Alcoholic extracts of the root bark were found to have hypotensive action (4, 6).

This medical history stimulated chemical investigation of *Ceanothus americanus*. In 1884 Clinch (7) obtained a positive test for alkaloids from the leaves, and shortly thereafter Gerlach (8) isolated alkaloidal material from the root and called it ceanothine. Subsequently Gordin (9) separated the alkaloidal material into two crystalline fractions, and Clark (10) demonstrated that a complex mixture of alkaloids was present. No elemental analytical data were reported in this early work. In 1933 Bertho and Liang (11) described the "first satisfactorily characterized ceanothus alkaloid" and named it ceanothine also. This base, m.p. 227–228°, $[\alpha]_D^{19}$ −309° (chloroform), was assigned the formula $C_{29}H_{36}O_4N_4$. It was found to be monobasic and to contain one N-methyl but no O-methyl group. From a different species, *C. velutinus*, Richards and Lynn (12) isolated a basic material whose analysis fitted the formula $C_{23}H_{26}O_4N_2$. Recently, more systematic, but not very successful, attempts have been made to separate pure alkaloids from the crude mixtures of *Ceanothus* bases by column chromatography monitored by paper chromatography (13, 14).

The foregoing summary emphasizes the difficulty of obtaining pure alkaloids from this plant, and as will become evident below, perhaps none of the compounds reported in the earlier work was completely pure. Indeed, further chemical progress on this problem would have been quite tedious without thin-layer chromatography (t.l.c.) and nuclear magnetic resonance and mass spectroscopy.

Our own interest in *Ceanothus* alkaloids was aroused both by their potential medical applications and by the possibility that they might belong to a new type of plant base. Bertho and Liang's ceanothine had the unusual feature of four nitrogen atoms, only one

of which was basic. Furthermore, at the outset of the present work there were no other Rhamnaceae alkaloids known (15), although recently there has been reported the isolation of two alkaloids from *Zizyphus oenoplia* Mill., an oriental member of the family (16*a*). The structure of one of these bases, zizyphine, has now been determined (16*b*). Originally it was even conceivable that the *Ceanothus* bases might be triterpenoid in origin since the triterpenes ceanothic acid (17) and ceanothenic acid (18) are found in *C. americanus*.

The isolation procedure used in the present work was adapted from previous procedures (13, 14) (see Experimental). Analytical thin-layer chromatography on silica gel developed with chloroform–methanol gave apparently good resolution of the crude alkaloid mixture into 8–10 circular spots. From this observation was developed a separation procedure involving column chromatography on silicic acid followed by further separation of fractions on thick-layer chromatograms. In this way the three least polar constituents, designated I (least polar), II, and III, were isolated in a state of purity according to thin-layer chromatography with chloroform:methanol solutions. Later, however, other t.l.c. solvent systems revealed each of these supposedly pure substances to be in fact mixtures of several components. Therefore, the separation process was further refined to include thick-layer chromatography of appropriate fractions in chloroform–acetone, chloroform–dioxane, chloroform–acetonitrile, and chloroform – ethyl acetate systems. Finally, five of the major alkaloids were obtained pure according to melting point, n.m.r. spectrum, t.l.c. behavior in four solvent systems (see Table IV in Experimental section), and, in the case of IIB, constancy of optical rotation. Their properties are summarized in Table I. The close correspondence in the properties of alkaloid IIB and Bertho and Liang's ceanothine (Table II) suggests that the two compounds are probably identical. Although a direct comparison was not possible,[4] the name ceanothine is now adopted for the II alkaloids since no more of the original German specimen exists.

From what is now known of their chemical and physical properties, the *Ceanothus* compounds are not of terpenoid derivation, but belong to the new class of basic polyamide alkaloids including pandamine (19), zizyphine (16), and the adouétines (20).

The molecular formulas are given with a high degree of confidence since the elemental analyses agree well with the molecular weights determined by mass spectrometer, and checked by titration or thermistor osmometer for some of the compounds. The alkaloids IIIA and IIIB (named ceanothamine-A and -B) are probably stereoisomers rather than structural isomers. All five compounds are monobasic secondary or tertiary amines (Table I). The ceanothines each have one N-methyl group, while the ceanothamines each have two such functions. All of these methylimino groups are attached to the *basic* nitrogen in the molecule as seen from the 0.79–1.05 p.p.m. downfield shift (Table I) of the N-methyl proton magnetic resonance peak in changing from deuterochloroform to perdeuteroacetic acid solution (21). This observation was confirmed in the case of ceanothine-A by the preparation of a neutral N-acetyl derivative with n.m.r. peaks at 2.85 p.p.m. (CH_3—N—C=O) and 2.00 p.p.m. (CH_3—C=O); ceanothine-B and -C did not react with acetic anhydride. Each base contains two to six C-methyl groups (Table I).

Although there are three neutral nitrogen atoms present per molecule, the ultraviolet spectrum (Fig. 1) of each alkaloid (unchanged in acidic or basic medium) is not that of a common neutral nitrogen heterocyclic compound. The infrared spectrum does not allow imide or nitrile functions; hydrogenation experiments exclude oxidized nitrogen functions. From these facts and semiquantitative measurements of the intensity of the

[4]*Professor Bertho has informed us that his ceanothine samples were unfortunately destroyed by fire in 1944, but he is of the opinion that the two compounds are the same.*

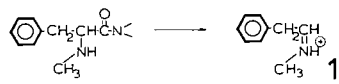
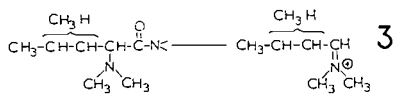
§Microscope hot stage.

carbonyl infrared absorption at 1 580–1 800 cm^{-1}, there are three amide functions per molecule, and two —HNC=O groups can be clearly seen in the n.m.r. spectra of ceanothine-B and -C. Thus, all four nitrogen and three oxygen atoms are accounted for in the alkaloids. The fourth oxygen atom is as yet uncharacterized, but it is evidently not present as another type of carbonyl group (no infrared absorption in 2 000–1 685 cm^{-1} region; no reaction of IIA with sodium borohydride) or as a methoxyl group (negative Zeisel analyses; no n.m.r. peak).





In the mass spectrum of each alkaloid there is one extremely intense peak (even *m/e*). On the reasonable assumption that in the fragmentation of these polyamides the strongest peak will be due to the N-terminal group (there is no C-terminal group) minus the C=O (22, 23, 24), the single nitrogen atom present in this even *m/e* base peak must be the basic nitrogen atom of the alkaloid. For ceanothine-A the base peak is at *m/e* 134 corresponding to $C_9H_{12}N^+$, which, in consideration of another peak at *m/e* 91 ($C_7H_7^+$) and the presence of an N_b-methyl group, must be **1** derived from an N-methylphenylalanyl residue. Ceanothine-B, being a tertiary amine with one N_b-methyl group, therefore contains the N-methylprolyl (hygryl) end group in order to have its base peak at *m/e* 84 ($C_5H_{10}N^+$) corresponding to **2**. For the same reasons ceanothine-C with its base peak at *m/e* 84 must also have the N-methylprolyl end group. Ceanothamine-A and -B both have their base peaks at *m/e* 114 ($C_7H_{16}N^+$), which is presumably due to an N,N-dimethylleucyl or -isoleucyl end group furnishing the ion (**3**).

The ultraviolet spectra of all five alkaloids are very similar (Fig. 1). Hydrogenation of each of the compounds in the presence of palladium results in the uptake of 1 mole equivalent of hydrogen and produces the same change in the ultraviolet absorption of each base (Fig. 1). The chromophore removed by reduction is revealed by the subtraction curve in Fig. 1 to have λ_{max} 250 mμ($\epsilon \sim 4\,000$), which fits very well the system 4 as in the model compounds **5** (25), **6** (26), **7** (27), and **8** (28). The similarities in the ultraviolet spectra and certain features of the n.m.r. spectra strongly suggest that there is a fundamental unit common to all of these alkaloids.

The results of hydrolytic studies and further work in progress will be reported in due course.

EXPERIMENTAL

General

Melting points: Reichert Microscope hotstage, corrected.

Optical rotations: Schmidt-Haensch or Rudolph model 80 polarimeter, chloroform solutions unless otherwise specified, 1-dm tube.

Ultraviolet spectra: Bausch and Lomb Spectronic 505 spectrometer.

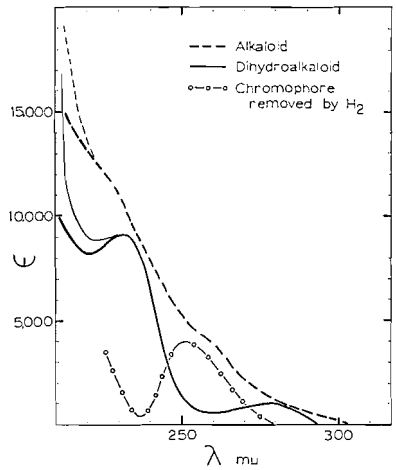

FIG. 1. Ultraviolet spectra of *Ceanothus* alkaloids. Where the curves for the alkaloids and dihydroalkaloids diverge at low wavelength, the lighter line is the absorption of IIA and IIB; the darker line is the absorption of IIC, IIIA, and IIIB.

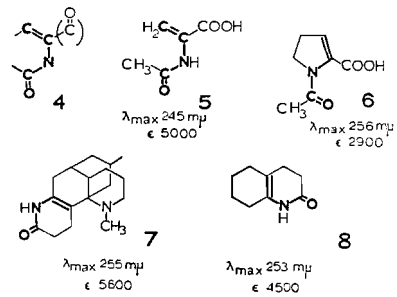

Infrared spectra: Beckman IR-5 or IR-7 spectrometer.

Nuclear magnetic resonance spectra: Varian A-60 spectrometer, cut-and-weigh integrations.

Mass spectra: Consolidated Electrodynamics Corp. model 103, or Associated Electrical Industries model MS-9. Ionization potential 70 V. Samples were introduced directly into the ion source.

Thin-layer chromatography: Camag Kieselgel DF-5 silica gel with calcium sulphate binder and fluorescent indicator. Chloroform refers to the commercial reagent grade containing 0.75% ethanol as a preservative.

Analyses: Dr. A. Bernhardt and associates, Mulheim, Germany; Dr. C. Daesslé and associates, Montreal, Quebec; Dr. J. F. Alicino, Metuchen, New Jersey.

Extraction and Column Chromatography

Ground root bark of *Ceanothus americanus* was supplied by Baxter Laboratories, Morton Grove, Illinois (formerly Flint, Eaton and Co., Decatur, Illinois) and by the S. B. Penick Co., Jersey City, New Jersey. The bark (4 kg) was exhaustively extracted with 60–80° petroleum ether in a Soxhlet type apparatus for 1 week to remove wax and triterpenoids (15.5 g). The defatted bark was dried and then exhaustively extracted with methanol for 2 weeks, the long period being necessitated by the slow solvent cycling rate. The solvent charge was changed after the first, fourth, and ninth days, the color of the extracts changing from a deep red to light tea color.

The methanol extract was diluted, 1 l at a time, with an equal amount of water and acidified with 400 ml of 0.4 *N* sulfuric acid in saturated sodium chloride solution. The acidified mixture was shaken with ether to remove brown neutral material (41 g from the entire methanol extract). The aqueous layer was then basified with 10% sodium hydroxide solution to pH 9–10 and extracted with chloroform. Evaporation of the dried chloroform solution from work up of all the methanol extracts left 9.1 g (0.23%) of crude amorphous alkaloid mixture, the usual yield being between 0.2 and 0.4%. Thin-layer chromatography in methanol:chloroform (7:93) gave 5 major spots: I (R_f 0.65, purplish color on short charring with 30% sulfuric acid), II (0.54, purplish), III (0.46, purplish), IV (0.37, grey), and V (0.33, yellowish); there were other less well-resolved spots closer to the origin. The relative proportions of components II and III varied considerably in different lots.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A 6 × 130-cm column containing chloroform was packed with 1 000 g of silicic acid (Fisher) in layers of gradually decreasing activity, the bottom layer (50 g) having been activated by heating at 120° overnight, the next layer (200 g) being an equal mixture of activated and unactivated silica gel, the next layer (500 g) being unactivated adsorbent, and the top layer (250 g) having been deactivated by addition of 5% by weight of water. The 9.1 g of crude alkaloid in chloroform solution were applied to the column which was then developed with chloroform. The progress of the separation was followed by fluorescence of various bands on the column under ultraviolet light. After 7 l of eluent had been collected, the column was allowed to "run dry". The wet silicic acid was extruded and immediately cut into sections under an ultraviolet lamp. Each section was extracted thoroughly by chloroform–methanol or methanol–ether and filtered. The composition of each fraction was determined by thin-layer chromatography in chloroform:methanol (95.5:4.5). From the figures in Table III and the relative intensities of the charred t.l.c. spots, the crude alkaloid mixture was estimated to consist of ~9% of I, ~25% of II, and ~12% of III. With some batches of crude base the alkaloids were eluted from the column, but extrusion saved time and solvent, and probably gave somewhat sharper separation.

TABLE III

Column chromatogram of alkaloids

Section	Wt., g	Cum. wt., g	Approx. comp.
10	0.258	0.258	(Bottom of column)
11	0.058	0.316	
12	0.063	0.379

25	0.622	7.132	
26	2.130	9.262	(Top of column)

Separation by Thick-Layer Chromatography

Glass plates (20 × 20 cm) coated with 20 g of silica gel were used for thick-layer chromatography. Up to 150 mg of alkaloid mixture from the column chromatogram were applied per plate. Five solvent systems were used for development, some plates being developed two or three times. Chloroform containing 4–10% of methanol was used to separate alkaloid mixtures I, II, III, and IV cleanly from each other. Acetone:chloroform (15:85), dioxane:chloroform (25:75), and acetonitrile:chloroform (15:85) were used for separation of the I and II mixtures into their components. Ethyl acetate:chloroform (50:50) was used for separation of alkaloids III*a* and III*b*. Progress in the thick plate separations was followed by thin-layer chromatograms developed in these solvents and charred with 30% aqueous sulfuric acid at 140° for 10 min to note colors, and then often for a longer time to carbonize the spots. The best means of assessing the purity of the individual alkaloids was a combination of the n.m.r. spectrum (particularly the N-methyl and C-methyl regions), m.p. behavior and t.l.c. behavior in several solvent systems.

Ceanothine-A

The amount of this compound in the II zone is usually less than the ceanothine-B and -C content, and it has so far been obtained pure from only one lot of bark. Material from column chromatographic sections which contained the II spot was purified on thick plates (100 mg/plate) with methanol:chloroform (4:96) to get complete separation from I and then with methanol:chloroform (7:93) to effect complete separation from III. Molecular weight determination of this II by thermistor osmometer gave values of 498 and 511. Subsequent thick-layer chromatography in acetone:chloroform (15:85) gave five zones under ultraviolet light. The lowest zone was separated and further purified by chromatography in dioxane:chloroform (25:75). After several recrystallizations from methylene chloride – ether the colorless matted needles had m.p. 256–259°, $[\alpha]_D$ −256° (*c*, 0.50).

Anal. Calcd. for $C_{30}H_{40}O_4N_4$ (520.65): C, 69.20; H, 7.74; O, 12.29; N, 10.76. Found: C, 69.31, 69.12; H, 7.53, 7.62; O, 12.66; N, 10.78. Mol. wt. (mass spectrum), 520.

When 10 mg of ceanothine-A in 3 ml of *i*-propyl alcohol was treated with a large excess of sodium borohydride and the reaction mixture allowed to stand overnight, 8 mg of basic product was recovered by dilution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with water and extraction. The material was shown to be ceanothine-A by melting point, infrared spectrum, and t.l.c. comparison in methanol:chloroform (3.5:96.5).

Ceanothine-B

In most lots of the root bark this alkaloid was the major component of the II mixture. The II zone was first separated from I and III as described for ceanothine-A. Thick-layer chromatography in acetone:chloroform (15:85) gave a broad purple band under ultraviolet light, the *lower* portion of which band was nearly pure ceanothine-B. Several recrystallizations from chloroform–ether gave colorless matted needles, m.p. 238.5–240.5°, $[\alpha]_D^{25}$ −293° (*c*, 0.68), $[\alpha]_D^{23}$ −292° (*c*, 0.90), pK_a 5.85 [determined in methanol:water (95:5)].[5]

Anal. Calcd. for $C_{29}H_{36}O_4N_4$ (504.61): C, 69.02; H, 7.19; O, 12.68; N, 11.10; 2 (C)CH_3, 5.95; 1 (N)CH_3, 2.97, OCH_3, 6.11. Found: C, 69.33; H, 7.11; O, 13.12; N, 11.51; (C)CH_3, 5.75; (N)CH_3, 3.43, 3.93; OCH_3, 0.00. Neutral equivalent, 505. Mol. wt. (mass spectrum), 504.

The hydriodide salt was prepared from 4 mg of ceanothine-B as described by Bertho and Liang (11) for ceanothine. After two recrystallizations from aqueous acetic acid the white plates had m.p. 195–200°.

Ceanothine-C

This alkaloid was isolated from the *front* edge of the II zone after the thick-layer chromatography in acetone:chloroform (15:85) described for ceanothine-B. Ceanothine-C was further purified by a second thick-layer chromatography in the same solvent system. Several recrystallizations from chloroform:ether gave colorless matted needles, m.p. 223–229°, $[\alpha]_D^{25}$ −368° (*c*, 1.01).

Anal. Calcd. for $C_{28}H_{38}O_4N_4$ (470.60): C, 66.35; H, 8.14; O, 13.60; N, 11.91. Found: C, 66.27, 66.39; H, 8.04, 7.86; O, 13.57; N, 12.43. Neutral equivalent, 485. Mol. wt. (mass spectrum), 470.

Ceanothamine-A and -B

Column chromatogram fractions containing the zone III alkaloids were completely separated from the II and IV zones by thick-layer chromatography in methanol:chloroform (3:97) and (5:95). Zeisel analysis of the total III alkaloids gave 0.00% OCH_3. Thermistor osmometer molecular weight determination on total III gave a value of 492; neutral equivalent titration gave 490. The material from the III band was then chromatographed on thick layers (only 15 mg per plate because of low solubility) in ethyl acetate : chloroform (50:50) to give two main bands.

The upper band of ceanothamine-A crystallized from methylene chloride – ethyl acetate in the form of colorless matted needles, m.p. 276–279°, R_f 0.28 in pure ethyl acetate.

Anal. Calcd. for $C_{28}H_{44}O_4N_4$ (500.66): C, 67.17; H, 8.86; N, 11.19. Found: C, 67.34; H, 8.92; N, 10.94. Mol. wt. (mass spectrum), 500.

The lower band of ceanothamine-B crystallized from methylene chloride – ethyl acetate in colorless matted needles, m.p. 279–280.5°, $[\alpha]_D^{25}$ −370° (*c*, 0.205), R_f 0.16 in pure ethyl acetate on the same plate on which ceanothamine-A gave R_f 0.28. Ceanothamine-B did not noticeably depress the melting point of ceanothamine-A.

Anal. Calcd. for $C_{28}H_{44}O_4N_4$ (500.66): C, 67.17; H, 8.86; O, 12.78; N, 11.19. Found: C, 67.36; 67.43, H, 8.84, 8.97; O, 13.15; N, 11.46. Mol. wt. (mass spectrum), 500.

TABLE IV

R_f values of pure alkaloids in various solvent systems

	$MeOH:CHCl_3$ 4:96	$Me_2CO:CHCl_3$ 15:85	$EtOAc:CHCl_3$ 50:50	$MeCN:CHCl_3$ 15:85
IIA	0.55	0.18	0.10	0.11
IIB	0.55	0.17	0.11	0.09
IIC	0.55	0.21	0.15	0.12
IIIA	0.43	0.12	0.10	0.06
IIIB	0.43	0.10	0.05	0.05

NOTE: The values for a particular system are averages taken from a single t.l.c. plate (250 μ thick layer of silica gel) on which two 10–25 γ spots of each pure compound appeared.

Acetylation of Ceanothines

(*a*) A solution of 27 mg of ceanothine-A in 1 ml of a mixture of chloroform and benzene to which had been added 0.5 ml of acetic anhydride was allowed to stand at room temperature for 24 h. Dilution with sodium bicarbonate solution and extraction with chloroform yielded 27 mg of crude neutral product which was purified by thick-layer chromatography in acetone:chloroform (15:85) to give 19 mg of white crystals of the N-acetate, m.p. 281–282°. The infrared spectrum had no O-acetate carbonyl absorption. The n.m.r. spectrum (deuterochloroform) had unsplit methyl peaks at 2.85 p.p.m. (CH_3—NAc) and 2.00 p.p.m. (CH_3—C=O).

Anal. Calcd. for $C_{32}H_{42}O_5N_4$ (562.68): 1 CH_3C=O, 7.65. Found: CH_3C=O (basic hydrolysis), 7.59.

[5]*The base was not completely soluble in the usual methylcellosolve:water (80:20) system. In the methanol:water (95:5) solvent atropine gave pK_a 8.33, the same value found in methylcellosolve:water (80:20) (29).*

(*b*) A solution of 27 mg of ceanothine-B in 1 ml of chloroform to which had been added 0.2 ml of acetic anhydride was allowed to stand at room temperature for 34 h. Dilution with chloroform–ether and extraction with potassium bicarbonate solution and then with dilute hydrochloric acid left only 4 mg of neutral material (presumably from impurities in the ceanothine-B) in the chloroform–ether solution. Basification of the acid extract yielded 24 mg (90%) of recovered ceanothine-B which after recrystallization from chloroform–ether afforded 17 mg, m.p. 238–240°. T.l.c. comparison also confirmed its identity with starting material.

(*c*) A solution of 10 mg of ceanothine-C in 1 ml of chloroform to which had been added 0.2 ml of acetic anhydride was allowed to stand at room temperature for 62 h. Workup as for ceanothine-B in (*b*) gave no neutral material but 11 mg of basic white solid which after recrystallization from chloroform–ether gave 7.5 mg, m.p. 219–227°. The recovered alkaloid had the same R_f as ceanothine-C.

Hydrogenations

Each alkaloid was hydrogenated over 5% palladium-on-carbon catalyst (Matheson) in a Hösli microhydrogenation apparatus,[6] and the results are collected below. Each dihydrocompound was run on the same t.l.c. plate as the starting material.

Alkaloid	Wt., mg	Mg catalyst	Ml MeOH	Temp.	Atm. pressure, mm	Ml H_2 abs.	Eq of H_2/mole	R_f 2H product	R_f start. material
IIA	14.6	6	5	22°	730	0.85	1.03	0.22	0.43
IIB	48.4	40	20	22°	727	2.71	1.02	0.29	0.44
IIC	5.7	10	3	23°	735	0.34	1.00	0.38 0.27	0.63
IIIA	16.6	7	20	21°	742	0.85	0.90	0.10	0.26
IIIC	15.8	13	20	19°	745	0.90	1.01	0.14	0.28

The crude dihydroceanothine-B had $[\alpha]_D^{25}$ −81° (*c*, 1.01, methanol). Recrystallization from chloroform–ether gave a microcrystalline powder, m.p. 263–273°, $[\alpha]_D^{25}$ −91° (*c*, 0.38, methanol).

Recrystallization of the dihydroceanothamine-A from chloroform–ether gave white crystals, m.p. 305–309°.

Anal. Calcd. for $C_{28}H_{46}O_4N_4$ (502.67): C, 66.90; H, 9.22; O, 12.73; N, 11.15. Found: C, 66.75, 67.01; H, 9.28, 9.38; O, 12.65; N, 10.79.

ACKNOWLEDGMENT

The support of the U.S. National Heart Institute under Grant HE-07394 (formerly H-5762) is gratefully acknowledged. Baxter Laboratories, Morton Grove, Illinois (formerly Flint, Eaton and Company), generously furnished several lots of ground *Ceanothus americanus* root bark. Professors D. B. MacLean and K. Biemann were very helpful in obtaining some of the mass spectra. Dr. W. Simon, Zürich, kindly measured the pK_a values. Mrs. P. Stoessl was responsible for much of the alkaloid isolation.

LIGHT ABSORPTION STUDIES

PART XXI. THE ULTRAVIOLET AND INFRARED ABSORPTION OF *o*-ALKYL- AND *o,o'*-DIALKYL-SUBSTITUTED ANISOLES[1]

Received January 21, 1965

ABSTRACT

Steric effects, previously reported by other workers in *o*- and *o,o'*-alkyl-substituted anisoles, were reinvestigated using compounds carefully purified by vapor phase chromatography. The ultraviolet spectral data indicate that the *o*-alkyl-substituted anisoles exist in one conformation, whereas the investigated *o,o'*-dialkyl-substituted anisoles exist in a different conformation. The conformations appear to be almost independent of the size of the substituent groups. Infrared, dipole moment, and other data are consistent with this interpretation.

INTRODUCTION

It is well known that steric hindrance in a conjugated molecule frequently causes a hypsochromic shift and a hypochromic effect in the ultraviolet absorption *B*-bands ($^1L_a \leftarrow {}^1A$ bands). Related, but by no means identical, effects are observed for *C*-bands ($^1L_b \leftarrow {}^1A$ bands). Generally, the bulkier the hindering group(s), the more pronounced are these steric effects, and particularly so the hypochromic effect; for aromatics, such spectral changes imply an increasing loss of uniplanarity with increasing size of the ortho-substituent(s). Steric effects in the anisoles have previously been investigated by Goodman and co-workers (1, 2). The purpose of the present paper is to extend such work to anisoles containing bulkier *o*-substituents. The spectra were found to be anomalous in that some ultraviolet and infrared spectral effects are observed on *o*-*t*-butyl and *o,o'*-di-*t*-butyl substitution, which are similar to those observed with *o*-methyl and *o,o'*-dimethyl substituents respectively.

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods in 1 cm cells using Beckman model DU and Cary model 14 spectrophotometers calibrated against solutions of potassium chromate and potassium nitrate. Wavelength readings obtained on the two instruments were found to be within 1 mμ of each other. The accuracy of λ_{max} values is estimated to be ± 1 mμ, and the precision of molar absorptivities $\pm 5\%$ or better. Most molar absorptivity values were reproducible to $\pm 2\%$. The oscillator strength, f, was calculated from

$$f = 4.319 \times 10^{-9} \int \epsilon \, d\nu,$$

where ϵ is the molecular extinction coefficient and ν the frequency in cm^{-1}. Each integration was carried out graphically over the entire band envelope.

Generally, our results were in good agreement with recent values reported elsewhere. However, Frolen and Goodman (1) obtained a considerably different spectrum from ours for *o,o'*-dimethylanisole (3); we have therefore redetermined the spectrum of this compound, and have confirmed our original ϵ values. A mass spectrometric analysis showed our compound to be 99.7% pure, the main impurity being 2,4,6-trimethylanisole. See also refs. 4, 5 where spectra similar to ours are reported.

The infrared spectra were determined on Beckman model IR7 and model IR9 spectrophotometers, calibrated against a polystyrene film, using a KBr prism and a diffraction grating. The frequency accuracy

[4]*Present address: Department of Chemistry, Monash University, P.O. Box 92, Clayton, Victoria, Australia.*

in the 1 200 cm^{-1} region is believed to be ± 0.4 cm^{-1} and the frequency reproducibility is ± 0.1 cm^{-1}. Solutions were examined mainly in 0.1 mm and 1 mm cells fitted with sodium chloride or potassium bromide windows. The solute concentration was ca. 0.01–0.06 M (1 mm cells). The integrated absorption intensities (A_{RJ}) were calculated from the equation

$$A_{RJ} = K(1/cl) \times \log_{10}(T_0/T)_{max} \times \Delta\nu_{\frac{1}{2}}^{a} \times 2.303 \times 10^{-4},$$

where c is the molar concentration, l is the cell length in cm, $\log (T_0/T)_{max}$ is the absorbance at the absorption maximum, and $\Delta\nu_{\frac{1}{2}}^{a}$ the band width in cm^{-1} at half maximum intensity (cf. ref. 6 and refs. cited there); K was determined from Ramsay's Tables (7). The intensities were also recorded in terms of the new units, A_{IUPAC} (8). The accuracy of the A values is estimated to be $\pm 5\%$.

Two independent sets of observations were made for all the spectral results. All solvents, except the ethanol, were commercially available spectroanalyzed solvents (Fisher). The ethanol was best-grade undenatured absolute ethanol (Consolidated Alcohol, Toronto).

Most of the compounds were prepared by standard methods as described in the literature or were commercially available samples. The samples were purified by distillation. Final purifications were usually carried out by vapor phase chromatography using the Autoprep model A-700 with fraction collection system on a 10 ft × 3/8 in. column packed with 30% SE-30 silicone rubber on 60/80 mesh Chromosorb W, and sample purity was also checked on 30% Carbowax 20M 10 ft × 3/8 in. and 10% Carbowax 20 MD TPH 10 ft × 3/8 in. columns. For some anisoles, repeated purification using vapor phase chromatography with different columns was necessary before a chromatographically homogeneous sample could be obtained.

DISCUSSION

The ultraviolet spectra are listed in Table I.

Table I shows that the compounds studied fall into two groups, namely anisoles which possess two ortho-alkyl-substituents and anisoles which possess one or no ortho-alkyl-substituent. For the mono-substituted anisoles, not even *o*-*t*-butyl substitution causes

any appreciable wavelength displacement nor is the intensity of the *B*- or *C*-band appreciably reduced. This absence of such typical steric effects may be attributed to the ability of the methoxy group to take up a position in which electronic interaction between the methoxy group and the benzene ring is not reduced appreciably. Considering actual conformations, seven possible forms of *o*-*t*-butylanisole may be obtained by twisting the aryl—O bond, and considering eclipsed and staggered forms in the usual way. These forms are schematically represented in Fig. 1 by structures 1 to 7. The diagrams, it should be noted, are qualitative and idealized since, for example, the bonds and lone-pair hybrids are assumed to make angles of 120° with each other when viewed along the aryl—O bond (cf. ref. 9).

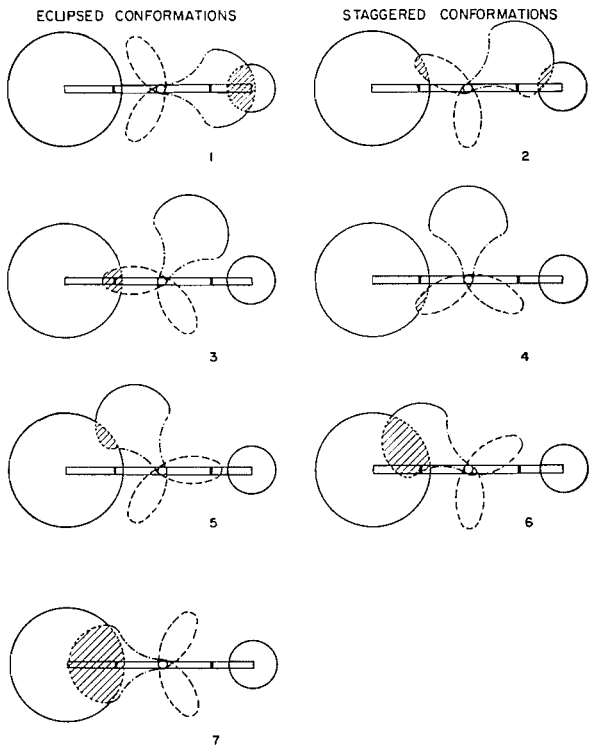

FIG. 1. Schematic diagram of *o*-*t*-butylanisole conformations as the methoxyl group undergoes successive 30° twisting displacements.

In the diagrams, the horizontal bars represent the side-on view of the plane of the benzene ring, attached to which are the ortho-substituents hydrogen and *t*-butyl. The center of each diagram represents the oxygen atom, attached to which are two lone pairs and the oxygen-linked CH_3 group; the former are indicated by dotted lines. Of the seven conformations obtained in this way, four (Nos. 1, 3, 5, and 7) are eclipsed structures in which the repulsive interactions between the bonds and the atomic dipoles are large. These forms will not therefore represent conformations of minimum energy (cf. the fact that ethane has a staggered conformation). Of the remaining three structures, Nos. 2 and 6 have the advantage over structure 4 inasmuch as one of the lone pairs of electrons is able to overlap effectively with the π-electrons of the benzene ring. In *o*-*t*-butylanisole, structure 2 would be preferred to structure 6 since in the latter the repulsive interactions between the *o*-*t*-butyl group and the oxygen-linked methyl group are likely to be considerable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The above considerations suggest that structure 2 is preferred for *o*-alkyl-substituted anisoles. Incidentally, the data for *o*-iodoanisole (3) and for *o*-*t*-butyl-*N*-methylaniline (10) likewise show only slightly modified ultraviolet spectra compared with the spectra of the appropriate reference compounds, indicating that these compounds also may exist in a conformation similar to structure 2. *o*-Nitroanisole shows evidence of steric interactions in the nitrobenzene-type *B*-band of its ultraviolet absorption spectrum (11) but this may be because repulsive interactions between the lone pairs of the oxygen atom of the OCH_3 group and the nitro group displace the latter group from the plane of the benzene ring; the molecule may still exist in form 2.

On the other hand, in *o*,*o*′-dialkyl-substituted anisoles, structures corresponding to form 2 would be appreciably hindered since interactions in that conformation would now be comparable to those existing in form 6. Consequently, it seems probable that in *o*,*o*′-dialkyl-substituted anisoles, conformations analogous to structure 4 are preferred. In structure 4, repulsive interactions are relatively small, but overlap between the unpaired electrons of the oxygen atom and the benzene ring is now more difficult. By assuming this change of conformation, it is possible to explain the drastically reduced oscillator strength of the *C*-band in *o*,*o*′-dialkyl-substituted anisoles, which is approximately independent of the size of the alkyl substituent. A similar behavior, incidentally, is observed for the 2,4,6-trihaloanisoles, where the *C*-band of 2,4,6-triiodoanisole has about the same molar absorptivity as that of 2,4,6-trichloroanisole (12).

Alternative Explanations

The above discussion shows that the spectral data can be rationalized by assuming a different conformation for *o*,*o*′-dialkyl-substituted anisoles, which is preferred because of increased steric interactions in compounds of this type. However, 1,2-disubstituted benzenes may inherently absorb differently from 1,2,3-trisubstituted benzenes, even in the absence of steric interactions (13). There is some evidence for this, since *o*-dimethoxybenzene (veratrole) has an intense *C*-band centered around 275 mμ (ϵ = 2 550), while 1,2,3-trimethoxybenzene (in methanol solution) has a *C*-band centered around 267 mμ (ϵ = 660) (14). Moreover, 1,3,5-trimethoxybenzene has a maximal extinction coefficient of only 480 at λ_{max} 265 mμ (14), although steric interactions in this compound must be relatively small.

However, the present, and other, data cannot readily be rationalized in terms of substituent effects alone. This is well illustrated by the spectrum of 2,3-dimethylanisole, the ϵ value of which is almost as high as for 2-methylanisole, but unlike that for 2,6-dimethylanisole (see Table I).* We conclude therefore that the effect of *o*-alkyl substitution on the *C*-band spectra can best be rationalized in terms of mainly steric interactions affecting the conformations as outlined in this paper.

Infrared Spectra

The frequencies and intensities of the aryl—O stretching absorption of the anisoles, as 0.01–0.06 *M* solutions (1 mm cells) in carbon disulfide, are listed in Table II. Some of the results, are consistent with the conclusion drawn from the ultraviolet spectra, that *o*,*o*′-dialkyl substitution causes a change of conformation, since the results again fall into two groups; those for anisole and monoalkyl-substituted anisoles and those for *o*,*o*′-dialkyl-substituted anisoles. This division is most readily evident for the intensities of the aryl—O stretching band; *o*-alkyl substitution produces some intensity decrease relative to the absorption intensity of anisole, but *o*,*o*-dialkyl substitution produces a

**We are grateful to a referee for suggesting this compound as a test case.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

much greater decrease. Similar changes are observed for the frequency of the aryl—O band, which is lowered slightly by one *o*-alkyl substituent (3.5–10 cm^{-1}), but is lowered more significantly on *o,o'*-dialkyl substitution (28–45 cm^{-1}).

TABLE II

Aryl—O stretching vibrations of alkyl-substituted anisoles in carbon disulfide solution ($\Delta\nu$ = band width, A = integrated absorption intensity)

Substituent		Aryl—O stretching band				
o	*o'*	ν_{max} (cm^{-1})	ϵ_{max}	$\Delta\nu_{\frac{1}{2}}$ (cm^{-1})	A_{RJ} ($mole^{-1}$ l cm^{-2} $\times 10^{-4}$)	A_{IUPAC} practical
H	H	1 246.5	760	5.5	1.5	0.65
CH_3	H	1 243	515	11.6	2.16	0.93
$CH(CH_3)_2$	H	1 241	680	7	1.7	0.75
$C(CH_3)_3$	H	1 236.5	470	10	1.1	0.48
2,3-Dimethylanisole		1 259	655	6.5	1.55	0.67
CH_3	CH_3	1 215	230	8	0.66	0.30
C_2H_5	C_2H_5	1 208	120	10.5	0.45	0.20
$CH(CH_3)_2$	$CH(CH_3)_2$	1 201	100	8.5	0.30	0.13
$C(CH_3)_3$	$C(CH_3)_3$	1 218	285	12	1.24	0.54

Although this band near 1 200 cm^{-1} is clearly not a "pure" C—O stretching band and bands of this type are known to be affected on substitution (for example, by isotopic modification (15)) a possible explanation of the observed spectral changes is in terms of different conformations. That is, in conformation 2 (the preferred form for *o*-alkyl-substituted anisoles), but not in conformation 4 (the preferred form for *o,o'*-dialkyl-substituted anisoles), there may be in addition to the C—O dipole, a dipole caused by the interaction of the lone pair electrons with the π-electrons of the benzene ring which gives rise to a shortening of the aryl—O nuclear bond. This would therefore suggest that compounds which exist in form 2—i.e., compounds in which p–π conjugation occurs —should absorb at higher frequency. It has also been shown that a conjugated carbonyl group affords a more intense band (16), so that it is possible that the lower intensities in *o,o'*-dialkyl-substituted anisoles are due to steric inhibition of this p–π conjugation.

It may next be noted that the infrared stretching bands are generally symmetrical and show no pronounced fine structure, such as might be anticipated if the molecules existed in more than one conformation. A typical spectrum is shown in Fig. 2. The absorption observed at 1 039 cm^{-1} in anisole has been provisionally assigned to the O—methyl stretching vibration (17), although it is probable that this vibration actually occurs at 1 172 cm^{-1} (18). Since there is a closely spaced band at 1 182 cm^{-1} with only slightly lower intensity, the effects of *o*- and *o,o'*-alkyl substitution on this band were not investigated.

Dipole Moments

Additional indications that *o,o'*-dialkyl substitution in anisole can twist the methoxy group from the plane of the benzene ring may be obtained from dipole moment data. The dipole moment in benzene solution of anisole is 1.28 D (19) and that of dimethyl ether is 1.25 D (20). Since the dipoles of an unshared electron pair on an oxygen atom in the sp^3 hydridization state are approximately 1.4 D per electron (9), this indicates that the dipole moments of anisole and of dimethyl ether are caused by the dipole moment of the two lone electron pairs *less* the dipoles of the two bonded groups. The dipole moment of the aryl—O moiety will be made up of a number of components

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

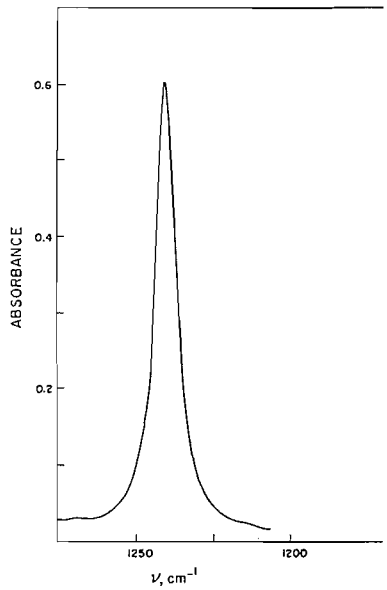

FIG. 2. Infrared aryl—O stretching band of *o*-isopropylanisole.

including an inductive component and a mesomeric component and it is this latter component which is likely to be absent in a substituted anisole existing in form 4. This latter component will tend to shorten the aryl—O nuclear bond, and its removal will therefore cause a reduction in the overall dipole moment. A dipole moment of 1.24 D in benzene solution is, in fact, observed for *o,o'*-dimethylanisole (19) and consequently the data may be regarded as consistent with the interpretation deduced from absorption spectra.

Other Data

Fong and Smyth (21) have recently shown, using microwave absorption techniques, that *o,o'*-dimethylanisole is highly sterically hindered. Le Fèvre *et al.* (22) conclude from a study of molecular polarizabilities that the C_{Ar}—O—C_{Me} plane in this compound is orthogonal with the benzene ring. These data are therefore again consistent with our evidence that *o,o'*-dialkyl-substituted anisoles exist in a different conformation from *o*-alkyl-substituted anisoles or anisole itself.

ACKNOWLEDGMENTS

The authors thank Professor N. Kornblum of Purdue University for a generous sample of *o,o'*-di-*t*-butylanisole. They are indebted to Miss M. A. Shadbolt for competent technical assistance. Financial assistance from the National Research Council of Canada is also gratefully acknowledged.

THE SYNTHESIS OF 2-AMINOBENZENETHIOL HYDROCHLORIDES

RALPH L. DANNLEY AND DIMITRI A. ZAZARIS

Representative 2-aminobenzenethiols were needed to synthesize a series of phosphothiazoles. Surprisingly few of the simple aminothiols are known, the yields are generally poor, and experimental details are often lacking. Much of the difficulty is due to the facile oxidation to disulfides, particularly in alkaline media. It was therefore decided to prepare the hydrochloride salts to obtain greater stability. The salts may be converted to the free aminothiols *in situ* either by treatment with a base or by thermal decomposition in an inert solvent (1). The previously unknown but typical 2-aminobenzenethiols which have been prepared are shown in Table I.

TABLE I

Yields, melting points, and analyses for 2-aminobenzenethiol hydrochlorides

2-Aminobenzenethiol hydrochloride	m.p.*	Yield†	Calcd.			Found‡		
			C	H	N	C	H	N
4-Methyl	189–191§	65	47.85	5.73	8.02	47.83	6.00	7.90

*All melt with decomposition.
†Yields of crude products suitable for most purposes.
‡Analyses performed by Galbraith Laboratories, Knoxville, Tenn.
§From methanol – hydrochloric acid, 1:1.
‖From ethanol – hydrochloric acid (1:1).
¶From methanol saturated with dry hydrogen chloride.
**This hydrochloride salt was too unstable to survive mailing to an analytical laboratory. A Kjeldahl nitrogen analysis was performed on a fresh sample.

The reduction of *o*-nitrophenyl disulfides, a common route to aminothiols, was used in much of the present work. The required sulfides were obtained from *o*-nitrochlorobenzenes and sodium polysulfides. The mixture of di- and tri-sulfides which was thus formed usually was not separated since both yield the thiol on reduction.

Catalytic hydrogenation of the sulfides to the aminothiols was attempted unsuccessfully. Reduction with tin and hydrochloric acid produced the aminothiol hydrochlorides in good yield, however.

4-Carbomethoxy-2-aminobenzenethiol hydrochloride was not prepared directly from the chloro compound through the sulfide, for the ester would be saponified by the strongly alkaline polysulfides. Esterification of the corresponding carboxylic acid proceeded smoothly, however.

The direct replacement of a halogen by the thiol group (or its salt) is generally undesirable because of competitive diaryl sulfide formation. 4-Nitro-2-aminobenzenethiol was prepared in this way, however, to avoid a subsequent reduction of the nitro group.

An alternate route to the aminothiols is by cleavage of benzothiazoles. These hydrolyses

have conventionally been carried out in small quantities in sealed tubes. It has now been found that in a larger scale synthesis of 5-methoxy-2-aminobenzenethiol, hydrolysis of the thiazole in a refluxing aqueous alkaline solution is accomplished in 7 h.

The aminothiol hydrochlorides all exhibited peaks at 3.7 to 4.0 μ in their infrared spectra characteristic of the SH group.

EXPERIMENTAL

bis-(4-Methyl-2-nitrophenyl)trisulfide

Sodium tetrasulfide was obtained by dissolving sulfur (48 g, 1.5 g-atoms) in molten sodium sulfide enneahydrate (120 g, 0.5 mole). This hot liquid was added dropwise to 3-nitro-4-chlorotoluene (171 g, 1.0 mole) in 95% ethanol (700 ml). After the exothermic reaction had ceased, the mixture was refluxed (2 h) and filtered while hot, and the precipitate washed with water (200 ml) and ethanol (100 ml) to give 155 g (84%) of crude product suitable for reduction to the aminobenzenethiol. Recrystallization from glacial acetic acid gave pure bis-(4-methyl-2-nitrophenyl) trisulfide, m.p. 195.5°.

Anal. Calcd. for $C_{14}H_{12}N_2O_4S_3$: C, 45.62; H, 3.28; S, 26.0. Found: C, 45.52; H, 3.31; S, 25.77.

4-Methyl-2-aminobenzenethiol Hydrochloride (a Typical Reduction)

Concentrated hydrochloric acid (730 ml) was slowly added (4 h) at 70° to a well-stirred suspension of the trisulfide (200 g, 0.55 mole) just described, 95% ethanol (1 200 ml), and tin (520 g). After filtration of the hot solution, the filtrate was allowed to stand at room temperature overnight to precipitate a crude product containing tin salts. The precipitate was collected on a filter, washed with ethanol – hydrochloric acid (50:50), and dissolved in hot methanol – hydrochloric acid (50:50). Upon cooling of the methanol solution, tin salts precipitated immediately and were removed by filtration. The filtrate, after several hours, deposited white needles of 4-methyl-2-aminobenzenethiol hydrochloride (125 g, 65%) which were collected and washed with ice-cold methanol – hydrochloric acid. A second recrystallization gave the pure salt (25 g, 13%).

4-Trifluoromethyl-2-aminobenzenethiol Hydrochloride

This compound was obtained by an identical procedure except for the use of 2 000 ml of ethanol per mole of nitro compound.

4-Carboxy-2-aminobenzenethiol Hydrochloride

Sodium disulfide was obtained by adding sulfur (48 g, 1.5 g-atoms) to molten sodium sulfide enneahydrate (360 g, 1.5 moles). This molten mixture was added to a solution of 3-nitro-4-chlorobenzoic acid (300 g, 1.5 moles) in sodium hydroxide (40 g,), water (50 ml), and ethanol (900 ml). After the resultant mixture had been heated under reflux (4 h) and then cooled, the crude disulfide precipitated. The reduction was accomplished as described above.

4-Carbomethoxy-2-aminobenzenethiol Hydrochloride

A mixture of 4-carboxy-2-aminobenzenethiol hydrochloride (40 g, 0.2 mole) and absolute methanol (110 ml) saturated with dry hydrogen chloride was kept overnight at 50–60° and filtered while warm, and the filtrate cooled and saturated again with dry hydrogen chloride. The precipitated 4-carbomethoxy-2-aminobenzenethiol hydrochloride (16 g, 35%) m.p. 198–201°, was collected by filtration and washed with cold methanol saturated with hydrogen chloride. Evaporation of the mother liquor to 25 ml produced more product (10 g, 60% total yield) of m.p. 196–197°.

4-Methoxy-2-aminobenzenethiol Hydrochloride

The sluggish reactivity of the corresponding chloronitro compound in dilute solution necessitated the following procedure to yield the disulfide. A mixture of 3-nitro-4-chloroanisole (183 g, 1.0 mole) and molten sodium disulfide hydrate (272 g, 1.0 mole prepared as described above) was stirred and cooled to maintain a temperature of 105–110°. When the temperature dropped to 40°, the dark mass was extracted with five 200-ml portions of 95% ethanol. The combined ethanol extracts were passed through a column of neutral alumina which adsorbed at least three impurities (distinct bands). To the eluent was added tin (700 g) and hydrochloric acid (1 000 ml). After the spontaneous refluxing ceased, the mixture was heated to 70–80° for 1 h. The mixture was filtered and the filtrate evaporated to 700 ml, hydrochloric acid (500 ml) was added, and the acid solution cooled to precipitate a crude aminothiol hydrochloride contaminated with tin salts. The crude product was dissolved in 200 ml of hot ethanol, filtered to remove tin salts, and the hydrochloride crystallized (67 g, 35% yield) by adding hydrochloric acid (200 ml) and cooling. Recrystallization from methanol saturated with dry hydrogen chloride produced 4-methoxy-2-aminobenzenethiol hydrochloride, m.p. 210–211°.

5-Methoxy-2-aminobenzenethiol Hydrochloride

A mixture of 2-amino-6-methoxybenzothiazole (100 g, 0.55 mole), potassium hydroxide (170 g, 3.0 moles), and water (500 ml) was refluxed until ammonia (70% yield) was no longer evolved (7 h). The solution was cooled, neutralized with acetic acid, and filtered. The precipitate was washed with water, dissolved in hot

For personal use only.

95% ethanol (200 ml), and filtered. The addition of concentrated hydrochloric acid (200 ml) followed by cooling of the solution yielded 5-methoxy-2-aminobenzenethiol hydrochloride (17 g, 20%), m.p. 208–209° (lit. (2) m.p. 210–211 decomp.) after recrystallization from ethanol – hydrochloric acid. A small portion was converted to the free aminothiol, m.p. 102–103° (lit. (3) m.p. 103–105°).

4-Nitro-2-aminobenzenethiol Hydrochloride

A hot solution of sodium sulfide enneahydrate (48 g, 0.20 mole, in a minimum amount of water) was added slowly to a boiling mixture of 5-nitro-2-bromoaniline (4) (54 g, 0.25 mole) and absolute ethanol (150 ml). After the exothermic reaction had subsided, the mixture was refluxed for 1 h and then cooled. The red crystalline precipitate was collected by filtration and treated with three 100-ml portions of water. From this point on the procedure was carried out under a nitrogen atmosphere. The aqueous extracts were acidified to litmus with 10% hydrochloric acid and the precipitated free aminothiol collected on a filter, then immediately dissolved in 95% ethanol (100 ml). The ethanolic solution was clarified by filtration, concentrated hydrochloric acid added (100 ml), and the mixture saturated with dry hydrogen chloride. Upon cooling, 4-nitro-2-aminobenzenethiol hydrochloride precipitated. Recrystallization from ethanol – hydrochloric acid gave crystals (15 g, 30%), m.p. 218–219°.

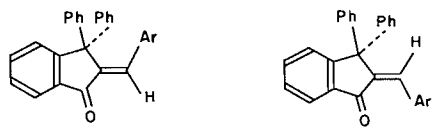
cis–trans ISOMERISM IN 2-ARYLIDENE-3,3-DIPHENYLINDAN-1-ONES[1]

J. A. BEVAN, P. E. GAGNON, AND I. D. RAE

INTRODUCTION

The condensation of aromatic aldehydes with 3,3-diphenylindan-1-one, reported by Gagnon and Charette (1), gave rise to pairs of compounds identified as belonging to the isomeric series I and II. The members of each pair could be separated by crystallization and gave rise to the same substituted indanone on hydrogenation of the benzylidene double bond.



SERIES I — 474 – 496 c/s

SERIES II — 404 – 423 c/s

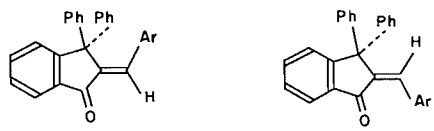
cis–trans ISOMERISM IN 2-ARYLIDENE-3,3-DIPHENYLINDAN-1-ONES[1]

J. A. BEVAN, P. E. GAGNON, AND I. D. RAE

INTRODUCTION

The condensation of aromatic aldehydes with 3,3-diphenylindan-1-one, reported by Gagnon and Charette (1), gave rise to pairs of compounds identified as belonging to the isomeric series I and II. The members of each pair could be separated by crystallization and gave rise to the same substituted indanone on hydrogenation of the benzylidene double bond.



SERIES I — 474 – 496 c/s

SERIES II — 404 – 423 c/s

[1]*Issued as N.R.C. No. 8533.*

Throughout the series the lower melting isomer was also the more soluble and more labile, and was therefore assigned the "*cis*" configuration (I) by analogy with simple *cis–trans* systems (2). The compounds have now been re-examined using nuclear magnetic resonance spectroscopy and some revision of the original assignments has been necessary. It was anticipated that the benzylidene protons of series I would be strongly deshielded by the adjacent carbonyl while those of series II would be relatively unaffected (3). In fact both types of proton gave rise to sharp singlets which were well separated from the complex signals of the aromatic protons, and assignment of configuration presented little difficulty. The results are summarized in Table I.

*Methyl and methylene protons respectively.

DISCUSSION OF SPECTRA

The relatively deshielded benzylidene protons of compounds in series I gave rise to sharp singlets in the narrow range 474–479 c/s except in the two cases where *o*-alkoxy substituents were present in the benzylidene ring, but the positions were more variable in series II. The proton magnetic resonance (p.m.r.) spectrum of the 2-benzylidene-indan-1-one analogous to series I has been reported (4) and a signal at 453 c/s assigned to the benzylidene proton. When bulky substituents are present in the 3-position of the indanone moiety the benzylidene substituent is probably forced closer to the carbonyl, resulting in the greater deshielding of the benzylidene proton (by 25 c/s), which was observed with 2-benzylidene-3,3-diphenylindan-1-ones.

Certain other differences in the spectra of isomeric pairs were attributable to the proximity of 3,3-diphenyl substituents and the benzylidene ring in series I. Thus in this series the protons of the two phenyl groups give rise to multiplets which merge with those of the other aromatic protons in the molecule, whereas in series II they give rise to 10-proton singlets at 435–438 c/s which are clearly distinguishable. Similarly in series I the substituents in the benzylidene ring are shielded by the nearer of the two phenyl groups,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and the chemical shifts of both methyl and methoxyl protons are considerably less than those of toluene (140 c/s) (5*a*) and anisole (226 c/s) (5*b*) respectively. In series II, however, the chemical shifts of protons in such substituents are quite normal, with the exception of those in the *o*-methyl group which are still shielded to the extent of 20 c/s. In this case steric interactions are best reduced by location of the methyl group out of the indanone plane where it could suffer shielding, for example, from the carbonyl group in some conformations.

EXPERIMENTAL

Proton magnetic resonance spectra were recorded on a Varian A-60 spectrometer for dilute solutions (ca. 5%) in deuterochloroform with tetramethylsilane as internal standard.

BASICITIES OF METHYLTHIO- AND PHENYLTHIO-ANILINES[1]

IAN D. RAE[2]

An extensive spectral study of aryl sulfides has led to the conclusion that electron-pair acceptance by the sulfur atom is not an important process in these molecules (1), and it is generally believed that such electron-accepting properties as sulfur does possess will only become prominent when the sulfur atom bears at least a partial positive charge (2). However, a recent study of the dissociation constants of arylthio-phenols has revealed effects which are best explained by proposing that the sulfur atom can accept an electron pair (3).

A bivalent sulfur atom attached to an aromatic ring may interact electronically with the ring in three main ways, by inductive withdrawal of electrons from the ring and by mesomeric donation and acceptance of electrons. In alkylthio- and arylthio-anilines, the inductive effect of the thio-substituent, operating both in the free amine and its conjugate cation, tends to reduce the basicity of the nitrogen atom. This effect falls off as the number of bonds between the sulfur and nitrogen atoms increases and the variation in effect with the position of the substituent should be $o > m > p$. The other electron-withdrawing mechanism available to sulfur, electron-pair acceptance, depends on the

participation of the sulfur *d*-orbitals either in a bonding or non-bonding capacity. Such electron acceptance might lead to conjugation between the nitrogen and sulfur atoms in the free amines (formulae I and II) but such interactions are not possible in *m*-isomers so the substituent effects should be in the order $o, p > m$. Because of the difference in primary quantum number between the sulfur lone-pair electrons (3p) and the aromatic π-electrons (2p) the third process, electron-pair donation to the aromatic ring, is less important for sulfur than it is for oxygen (4, 10).

All the substituted anilines recorded in Table I are less basic than aniline itself since electron-withdrawing effects predominate, and the variation of pK_a values with the position of the substituent relative to nitrogen shows that inductive effects outweigh mesomeric effects.

TABLE I

pK_a values of methylthio- and phenylthio-anilines in water at 25 °C

Substituent	pK_a	Substituent	pK_a
None	4.58 (10)	None	4.58 (10)
o-SCH_3	3.57	*o*-SC_6H_5	2.87, (2.5) (13)
m-SCH_3	4.05 (10)	*m*-SC_6H_5	3.69
p-SCH_3	4.40 (10)	*p*-SC_6H_5	3.91

EXPERIMENTAL

The pK_a values were measured spectrophotometrically using the technique described by Albert and Serjeant (5). The buffers employed had ionic strength 0.01 (6). Pure *o*-methylthioaniline was available commercially and the *o*- and *p*-phenylthioanilines were prepared by the method of Gilman and Broadbent (7). *m*-Phenylthioaniline was prepared by diazotization of *m*-acetamidoaniline and coupling of the diazonium salt with sodium thiophenoxide, followed by hydrolysis of the N-acetyl group; its properties agreed with those recorded in the literature (8).

DISCUSSION

The data presented by Taft (9) support the generalization that, for electron-withdrawing substituents which operate principally by induction, the pK_a values of *o*-, *m*-, and *p*-substituted anilines and aniline itself form a monotonically increasing series. For example, the chloroanilines (2.64, 3.34, 3.98, and 4.58) (10) and the second protonation of phenylenediamines (1.2, 2.8, 3.0, and 4.58).* Clearly the methylthio- and phenylthio-anilines form such series and it may be deduced that the inductive effect of the sulfur atom is the chief base-weakening factor. The greater inductive effect of the phenylthio-substituent is no doubt due to resonance involving structures III and IV which have been proposed to explain spectral (1) and kinetic findings (12). While the effect of both methylthio- and phenylthio-substituents is predominantly inductive, it is possible that the two mesomeric processes also operate, but, in opposite senses, to produce only a small net effect.

SOME COMMENTS ON CRAIG'S RULES

R. A. ABRAMOVITCH AND K. L. MCEWEN

On the basis of valence bond (v.b.) and other calculations, Craig proposed some rules which would permit the prediction of whether or not a certain fully conjugated hydrocarbon would have a totally symmetric v.b. wave function and hence have aromatic character (1–3). The rule was applied to molecules having at least one twofold axis passing through two or more π-centers, an axis that converts one Kékulé structure into itself or into another of the same canonical set. The molecule is labelled with equal numbers of spin symbols α and β, giving different symbols to the two ends of all double bonds in one Kékulé structure such that as few as possible like spins adjoin. Upon performing the symmetry operation, if the sum of p, the number of interchanges of π-electron centers effected by the operation, and q, the number of interchanges of spin symbols required to restore the original labelling scheme from the transformed one, is even, one finds that the molecule will have a totally symmetric v.b. ground state and it should be aromatic. If $p + q$ is odd, the v.b. ground state is non-totally symmetric and the molecule should not have aromatic stability: it would be pseudoaromatic.

A case in which the application of Craig's rules gives ambiguous results has been reported (4). Structure I*a* can be labelled as shown, leading to $p + q = 7$. On the other

From the pK_a values presented here the σ_m and σ_p values for C_6H_5S are calculated to be 0.31 and 0.24 respectively. These should be compared with the values, 0.18 and 0.29, derived by Meyers (3) for the corresponding phenols.

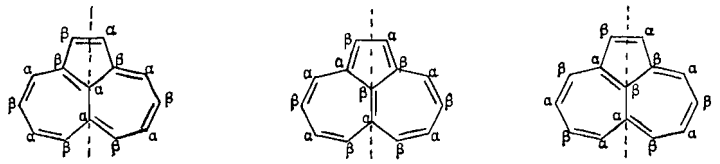
SOME COMMENTS ON CRAIG'S RULES

R. A. ABRAMOVITCH AND K. L. MCEWEN

On the basis of valence bond (v.b.) and other calculations, Craig proposed some rules which would permit the prediction of whether or not a certain fully conjugated hydrocarbon would have a totally symmetric v.b. wave function and hence have aromatic character (1–3). The rule was applied to molecules having at least one twofold axis passing through two or more π-centers, an axis that converts one Kékulé structure into itself or into another of the same canonical set. The molecule is labelled with equal numbers of spin symbols α and β, giving different symbols to the two ends of all double bonds in one Kékulé structure such that as few as possible like spins adjoin. Upon performing the symmetry operation, if the sum of p, the number of interchanges of π-electron centers effected by the operation, and q, the number of interchanges of spin symbols required to restore the original labelling scheme from the transformed one, is even, one finds that the molecule will have a totally symmetric v.b. ground state and it should be aromatic. If $p + q$ is odd, the v.b. ground state is non-totally symmetric and the molecule should not have aromatic stability: it would be pseudoaromatic.

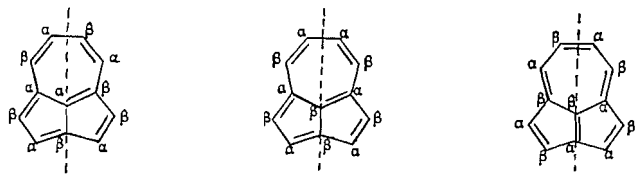
A case in which the application of Craig's rules gives ambiguous results has been reported (4). Structure I*a* can be labelled as shown, leading to $p + q = 7$. On the other

hand, I*b*, in which the axis of symmetry transforms one Kékulé structure into itself, gives rise to $p + q = 8$. I*a* and I*b* are stated to belong to different group representations and may not contribute to the same linear combination v.b. resonance hybrid (4). The



(I*a*) (I*b*) (I*c*)

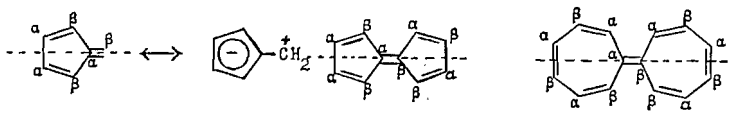
rules are not clear, however, in that structure (I*c*), in which the double bonds are arranged exactly as in I*a*, appears to be labelled in an acceptable manner but gives $p + q = 12$. It has been pointed out (5), however, that this labelling is not acceptable since, upon performing the symmetry operation, one finds that the resulting Kékulé structure has similar spins at the ends of some double bonds (see also II*a*). This aspect of the rules can be made clearer by specifying that the labelling with equal numbers of spin symbols α and β should be carried out in such a way that they give different symbols to the ends of all double bonds in *both* Kékulé structures. In any event, I exhibits aromatic properties (6). A similar situation obtains with the hydrocarbon (II), the dimethyl derivative of which is reported to exhibit polyolefinic character (7).



(II*a*) (II*b*) (II*c*)

$p + q = 8$ $p + q = 5$ $p + q = 10$

The rules were also applied to fulvene (III), and the results would indicate that this molecule should be aromatic (1–3). While (III) does exhibit weak aromatic properties



(III) (IV) (V) (VI)

$p + q = 6$ $p + q = 12$

(a measure of which is indicated by its dipole moment of 1·1D (8) caused by contributing structure IV) the rules do not predict the correct answer at all when they are applied to fulvalene (V), which is quite polyolefinic (9). Neither does it hold for heptafulvalene (VI), which does not behave as an aromatic compound (9). It may or may not be significant that in both of these only one uncharged conjugated structure may be written, in which the symmetry operation transforms the molecule into itself. The rules also indicate that the interesting systems VII and VIII (V and VI, respectively, with one extra C—C bond)

Magnetic Measurements

Magnetic susceptibilities were obtained with a Gouy magnetic balance. The Gouy tubes were calibrated with $Hg[Co(CNS)_4]$. The magnetic data are summarized in Table III. The magnetic moments reported in this table were corrected for diamagnetic contributions by the use of Pascal's constants as indicated by Figgis and Lewis (9).

TABLE III

Magnetic data of N-methyl-γ-butyrolactam complexes

Compound	$\chi_g \times 10^6$	χ_M(corr.) $\times 10^6$	T °K	μ_{eff}, B.M
$[MnL_6](ClO_4)_2$	16.60	14 520	302	5.95
$[FeL_6](ClO_4)_3$	15.56	15 230	303	6.10
$[CoL_6](ClO_4)_2$	13.07	11 570	302	5.31
$[NiL_6](ClO_4)_2$	5.01	4 700	303	3.39

Infrared Spectra

Infrared spectra of the complexes were obtained as chloroform solutions on a Beckman IR-10 recording spectrophotometer.

DISCUSSION

The analytical data of Table I indicate that, except for zinc, the complexes formed are six-coordinate. These might be expected to be octahedral species, a supposition indicated by the magnetic data.

Coordination of the lactam caused no major change in its infrared spectrum except for a shift of the carbonyl stretching vibration. In all cases the frequency of this vibration was lowered on complexation relative to the frequency of the free ligand. Thus the very intense C=O absorption band appearing at 1 680 cm^{-1} in the free lactam gave rise to a strong absorption band shifted of the order of 40 cm^{-1} to lower frequency in the metal ion complexes. Manganese and zinc exhibited the minimum and maximum effects, respectively. In the former case a strong band appeared at 1 645 cm^{-1}; this band appeared at 1 632 cm^{-1} for the latter metal ion. These results are in accord with earlier findings (2), and may be interpreted as evidence for bonding of the ligand to the metal ion through the carbonyl oxygen (3, 5, 10).

From the results of the conductivity measurements appearing in Table II, it can be inferred that the manganese, cobalt, nickel, and zinc complexes are of the 1:2 electrolyte type. These molar conductance values in nitromethane are in reasonable agreement with reference standards determined for this solvent at 20 °C by Gill and Nyholm (11). The iron complex exhibits the expected behavior of a 1:3 electrolyte type.

Finally, the magnetic moments calculated for this series of compounds fall in the range expected for spin-free octahedral complexes (9). The zinc compound, for which data do not appear in Table III, was found to be diamagnetic, as expected.

The above findings are in agreement with the work of Bright and co-workers (6), who found that the electronic spectra of nickel(II) and chromium(III) perchlorate-lactam systems indicated the presence of octahedral species.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the aid of General Aniline and Film Corporation, who supplied the initial sample of lactam, Dr. D. W. Meek and associates of The Ohio State University, who made available a Gouy balance for our use, and the National Research Council of Canada, for financial support. Communication with Drs. D. M. Hart and S. K. Madan is also appreciated.

CONCERNING THE PREPARATION OF *p*-ALLYLPHENOL FROM SAFROLE BY SODIUM – LIQUID AMMONIA REDUCTION

M. J. BALDWIN AND R. K. BROWN

During recent studies (1) of halogen elimination and of halogen and allyl group migration during the rearrangement of allyl 2,6-dichlorophenyl ether (2, 3), some 4-allyl-2-chlorophenol was required as reference material. One possible route for the synthesis of 4-allyl-2-chlorophenol required the precursor *p*-allylphenol. Of the methods available for the preparation of *p*-allylphenol (4–8), that developed by Birch (4), involving the sodium and liquid ammonia reduction of safrole, appeared to be the most convenient and productive.

A repetition of the published procedure with careful attention to Birch's directions, and using anhydrous ethanol with the liquid ammonia, gave a substance whose boiling point agreed with that reported (4, 5) and whose infrared spectrum (neat) supported the structure of *p*-allylphenol.

Gas–liquid chromatography of this substance on a column packing of 20% Apiezon L on Gas-Chrom P (60–80 mesh) with a helium flow rate of 100 ml/min gave only one peak with a shoulder, indicating the presence of two compounds of similar retention times. The ultraviolet spectrum in methanol showed adsorption at 202 μ and 224 μ along with slight absorption at 282 μ. No absorption was found at 244 μ, the region of strong absorption caused by the styrene chromophore (9), thus indicating the absence of *p*-propenylphenol, a product found by Birch (4) when safrole was reduced by sodium in liquid ammonia in the *absence* of alcohol.

The nuclear magnetic resonance (n.m.r.) spectrum of this substance (Fig. 1*a*), in carbon tetrachloride with tetramethylsilane as internal reference, clearly showed it to be a mixture of *p*-allylphenol and *p*-*n*-propylphenol in the molar ratio of 3:1. The boiling points of these two substances are quite similar and are reported to be respectively 236–238° at 760 mm pressure and 232.2–232.5 at 763 mm pressure (5, 10). The allyl group joined to carbon of the benzene ring shows a doublet at 6.75 τ, $J = 7.0$ c.p.s. for the methylene group attached directly to aromatic ring carbon, while the vinyl methylene protons show two characteristic, poorly resolved multiplets centered at 4.90 τ and 5.12 τ.

CONCERNING THE PREPARATION OF *p*-ALLYLPHENOL FROM SAFROLE BY SODIUM – LIQUID AMMONIA REDUCTION

M. J. BALDWIN AND R. K. BROWN

During recent studies (1) of halogen elimination and of halogen and allyl group migration during the rearrangement of allyl 2,6-dichlorophenyl ether (2, 3), some 4-allyl-2-chlorophenol was required as reference material. One possible route for the synthesis of 4-allyl-2-chlorophenol required the precursor *p*-allylphenol. Of the methods available for the preparation of *p*-allylphenol (4–8), that developed by Birch (4), involving the sodium and liquid ammonia reduction of safrole, appeared to be the most convenient and productive.

A repetition of the published procedure with careful attention to Birch's directions, and using anhydrous ethanol with the liquid ammonia, gave a substance whose boiling point agreed with that reported (4, 5) and whose infrared spectrum (neat) supported the structure of *p*-allylphenol.

Gas–liquid chromatography of this substance on a column packing of 20% Apiezon L on Gas-Chrom P (60–80 mesh) with a helium flow rate of 100 ml/min gave only one peak with a shoulder, indicating the presence of two compounds of similar retention times. The ultraviolet spectrum in methanol showed adsorption at 202 μ and 224 μ along with slight absorption at 282 μ. No absorption was found at 244 μ, the region of strong absorption caused by the styrene chromophore (9), thus indicating the absence of *p*-propenylphenol, a product found by Birch (4) when safrole was reduced by sodium in liquid ammonia in the *absence* of alcohol.

The nuclear magnetic resonance (n.m.r.) spectrum of this substance (Fig. 1*a*), in carbon tetrachloride with tetramethylsilane as internal reference, clearly showed it to be a mixture of *p*-allylphenol and *p*-*n*-propylphenol in the molar ratio of 3:1. The boiling points of these two substances are quite similar and are reported to be respectively 236–238° at 760 mm pressure and 232.2–232.5 at 763 mm pressure (5, 10). The allyl group joined to carbon of the benzene ring shows a doublet at 6.75 τ, $J = 7.0$ c.p.s. for the methylene group attached directly to aromatic ring carbon, while the vinyl methylene protons show two characteristic, poorly resolved multiplets centered at 4.90 τ and 5.12 τ.

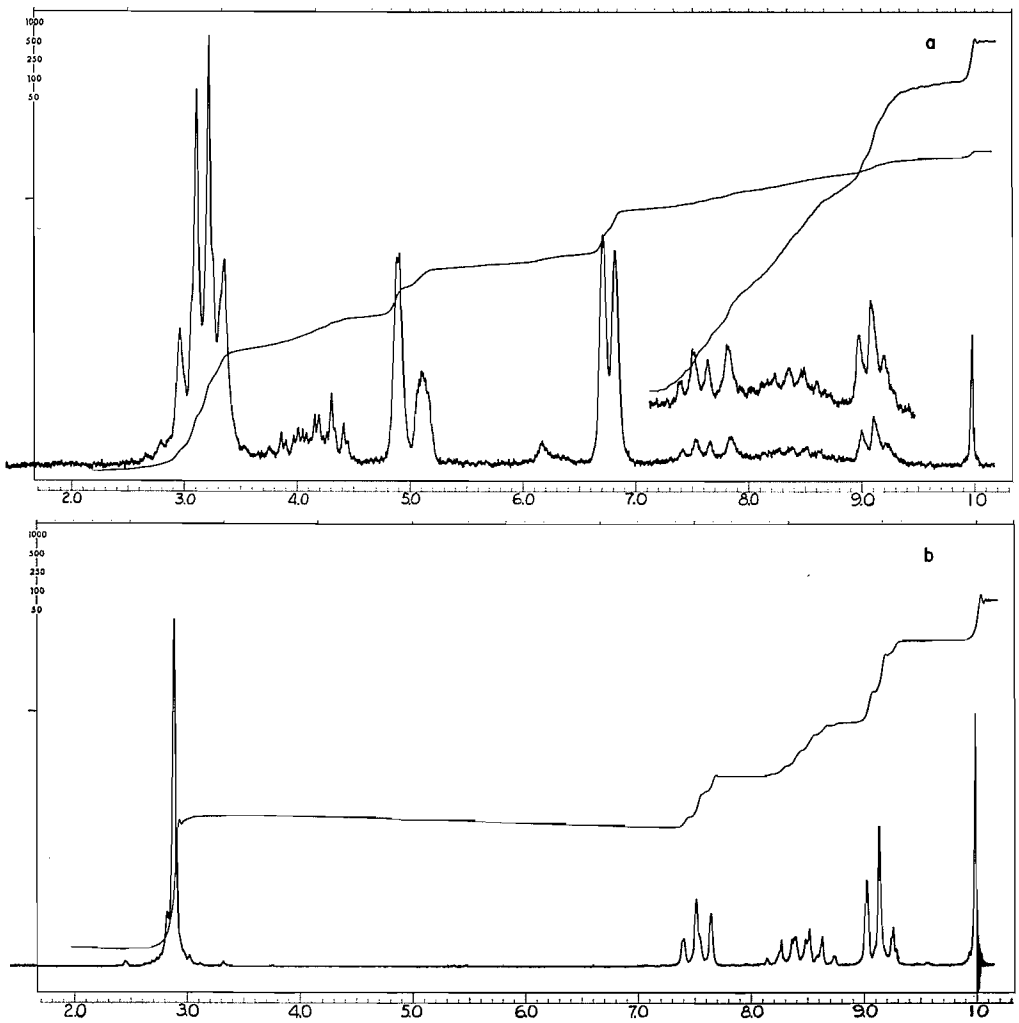

FIG. 1, *a* and *b*.

FIG. 1. Nuclear magnetic resonance spectra in carbon tetrachloride with tetramethylsilane as reference (*a*) product mixture from Birch reduction of safrole in the presence of ethanol, (*b*) *n*-propylbenzene, (*c*) product mixture from Birch reduction of safrole in the absence of ethanol.

The remaining vinyl proton gives a multiplet between 3.8 τ and 4.5 τ. Aromatic proton signals lie between 2.8 τ and 3.5 τ.

The appearance of signals at higher field, above 7.3 τ, characteristic for the *n*-propyl group attached to a benzene ring (ref. 11; see also the n.m.r. spectrum of *n*-propylbenzene in Fig. 1*b*) (triplet at 7.52 τ, $J = 7.0$ c.p.s. for the CH_2 group attached to ring carbon; multiplet between 8.15 τ and 8.75 τ for the other CH_2 group; and a multiplet centered at 9.10 τ for the methyl group) clearly supported the presence of an *n*-propyl group. That no *p*-propenylphenol was present in the mixture was supported also by the absence of a doublet for the methyl group of the propenyl moiety at 8.17 τ and 8.24 τ, $J = 5$ c.p.s. (12) and the sharp olefinic absorption at 4.2 τ. These signals are present in the n.m.r. spectrum (Fig. 1*c*) of the product obtained from the Birch reduction of safrole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

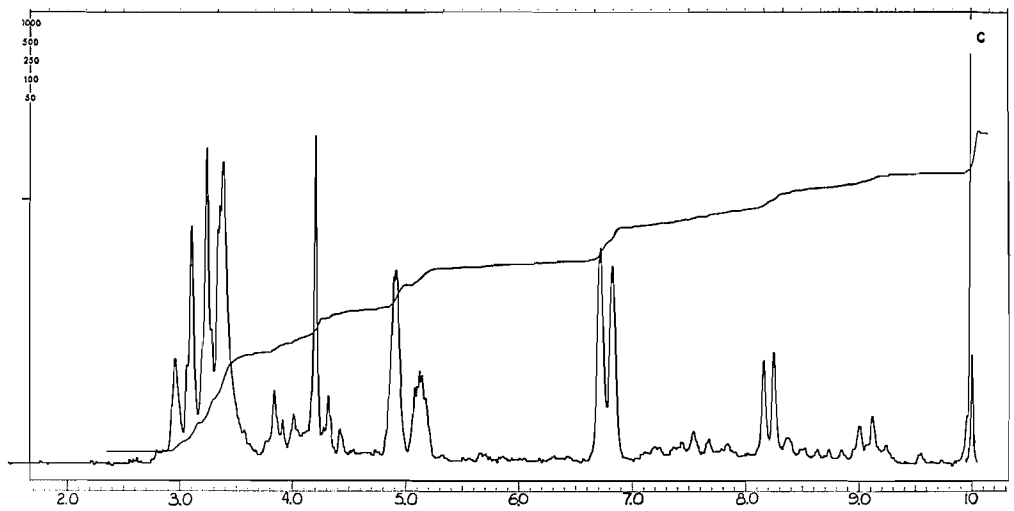

FIG. 1*c*.

in the absence of ethanol (4). The spectrum in Fig. 1*c* indicates that in this case all three of the compounds, *p*-allylphenol, *p*-propenylphenol, and *p*-*n*-propylphenol are present.

A comparison of the integrated areas of the signals for the ring-attached methylene group of both the allyl and *n*-propyl chains (Fig. 1*a*) provided an estimate of the relative amount of the two products. Calculated values for carbon and hydrogen, assuming a 3:1 mixture of *p*-allylphenol and *p*-*n*-propylphenol, are 80.3% and 7.8%, respectively, values quite similar to those calculated for pure *p*-allylphenol (C, 80.6% and H, 7.4%).

It is thus apparent that the reduction of safrole under the conditions employed is somewhat more extensive than originally realized.

KEITH BOWDEN

INTRODUCTION

Recently a number of studies have been made on the application of H_- and $H_=$ acidity functions to a number of strongly basic systems (1–10). The indicators have been nitrogen (1) or carbon acids (2). A number of workers have made H_- measurements in alcoholic alkoxide solutions (4–12). This function measures the ability of a system to ionize an acid, HA, to form the anion, A^-, and is defined as (13)

[i] $$H_- = pK_a - \log([HA]/[A^-]) = -\log(a_{H^+}f_{A^-}/f_{HA}).$$

In dilute aqueous solution H_- becomes identical with pH.

The H_0 acidity function has already been determined in aqueous alcohols, dioxan, and acetone containing hydrochloric acid (13–15). The function is similarly defined as (13)

[ii] $$H_0 = pK_a - \log([BH^+]/[B]) = -\log(a_{H^+}f_B/f_{BH^+}).$$

As the nonaqueous component increases, the acidity of the system, at first, falls to a minimum. The acidity then increases to a value somewhat greater in the case of ethanol and acetone and somewhat smaller in the case of dioxan (containing *very* small quantities of water) than that of the purely aqueous system. These results have been interpreted as a "salting-in" of the uncharged base as the nonaqueous component increases, and this decreases the acidity, H_0 (13). Alternatives to this interpretation are a disturbance in the structure of the water (14, 15) and a change in the relative basicities of the aqueous and nonaqueous components with their concentrations (16–18). This is then followed by an increase in acidity caused by the presence of the strong acid, in the case of an alcohol ROH_2^+, in the more highly nonaqueous solutions.

In aqueous alcohols containing base the equilibrium [iii] exists as

[iii] $$H_2O + OR^- \rightleftharpoons OH^- + ROH$$

and thus the equilibrium constant, K, is given by

[iv] $$K = [OH^-]a_{ROH}f_{OH^-}/[OR^-]a_{H_2O}f_{OR^-}.$$

Caldin and Long have investigated this equilibria in aqueous ethanol using as an indicator, 2,4,6-trinitrotoluene (19). Hine and Hine have also made measurements for isopropyl alcohol containing small quantities of water using the indicator, 4-nitrodiphenylamine (11). Kinetic measurements have been made by Wells (16); Tommila and Murto (20, 21); and by Johnson, Nilawar, and Peters (22). The latter workers, also, have been unable to reproduce the results of Caldin and Long. However, the results on the aqueous ethanol system calculated from the kinetic results of Tommila and Murto (21, 23) do not agree with those of Peters.

The present studies report the extension of the H_- function to aqueous alcohols and aqueous dioxan containing base, using substituted anilines as indicators, to investigate their physicochemical behavior.

EXPERIMENTAL AND RESULTS

The measurements were made as previously described (1–3). A Bausch and Lomb Spectronic 505 spectrophotometer was used. The solvents were purified by standard

THE H_- FUNCTION IN AQUEOUS ALCOHOLS CONTAINING BASE

KEITH BOWDEN

INTRODUCTION

Recently a number of studies have been made on the application of H_- and $H_=$ acidity functions to a number of strongly basic systems (1–10). The indicators have been nitrogen (1) or carbon acids (2). A number of workers have made H_- measurements in alcoholic alkoxide solutions (4–12). This function measures the ability of a system to ionize an acid, HA, to form the anion, A^-, and is defined as (13)

[i] $$H_- = pK_a - \log([HA]/[A^-]) = -\log(a_{H^+}f_{A^-}/f_{HA}).$$

In dilute aqueous solution H_- becomes identical with pH.

The H_0 acidity function has already been determined in aqueous alcohols, dioxan, and acetone containing hydrochloric acid (13–15). The function is similarly defined as (13)

[ii] $$H_0 = pK_a - \log([BH^+]/[B]) = -\log(a_{H^+}f_B/f_{BH^+}).$$

As the nonaqueous component increases, the acidity of the system, at first, falls to a minimum. The acidity then increases to a value somewhat greater in the case of ethanol and acetone and somewhat smaller in the case of dioxan (containing *very* small quantities of water) than that of the purely aqueous system. These results have been interpreted as a "salting-in" of the uncharged base as the nonaqueous component increases, and this decreases the acidity, H_0 (13). Alternatives to this interpretation are a disturbance in the structure of the water (14, 15) and a change in the relative basicities of the aqueous and nonaqueous components with their concentrations (16–18). This is then followed by an increase in acidity caused by the presence of the strong acid, in the case of an alcohol ROH_2^+, in the more highly nonaqueous solutions.

In aqueous alcohols containing base the equilibrium [iii] exists as

[iii] $$H_2O + OR^- \rightleftharpoons OH^- + ROH$$

and thus the equilibrium constant, K, is given by

[iv] $$K = [OH^-]a_{ROH}f_{OH^-}/[OR^-]a_{H_2O}f_{OR^-}.$$

Caldin and Long have investigated this equilibria in aqueous ethanol using as an indicator, 2,4,6-trinitrotoluene (19). Hine and Hine have also made measurements for isopropyl alcohol containing small quantities of water using the indicator, 4-nitrodiphenylamine (11). Kinetic measurements have been made by Wells (16); Tommila and Murto (20, 21); and by Johnson, Nilawar, and Peters (22). The latter workers, also, have been unable to reproduce the results of Caldin and Long. However, the results on the aqueous ethanol system calculated from the kinetic results of Tommila and Murto (21, 23) do not agree with those of Peters.

The present studies report the extension of the H_- function to aqueous alcohols and aqueous dioxan containing base, using substituted anilines as indicators, to investigate their physicochemical behavior.

EXPERIMENTAL AND RESULTS

The measurements were made as previously described (1–3). A Bausch and Lomb Spectronic 505 spectrophotometer was used. The solvents were purified by standard

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

procedures. The alkoxide solutions were made by reaction of sodium and the alcohol under nitrogen, followed by filtration. Freshly prepared solutions were always used. The following indicators (1) were employed: 2,4,4′-trinitrodiphenylamine ($pK_a = 12.35$); 2,4-dinitrodiphenylamine ($pK_a = 13.84$); 2,4-dinitroaniline ($pK_a = 15.00$); 4-nitrodiphenylamine ($pK_a = 15.90$); and 2-nitrodiphenylamine ($pK_a = 17.57$).

The solvent dependence of the spectra over the ionization range was small. The measurements could usually be carried out at a wavelength where the acid did not absorb.

NOTE: (*a*) Containing 0.001 *M* base; (*b*) containing 0.005 *M* base; (*c*) immiscible solutions.
*The averaged H_- values are considered to be accurate to between ±0.05 and ±0.010 unit.

In Table I the H_- values for aqueous alcohol and aqueous dioxan solutions containing base are given. The results are average values and, for the pure alcohols, agree satisfactorily with those published and reviewed elsewhere (4–12, 24). The values obtained from different indicators agreed to within ±0.1 unit and the values, between H_- equal to 13 and 17, were obtained from at least two different indicators.

The variation between the basicity of the aqueous and methanolic systems is small ($\Delta H_- = -0.34$) and the changes were too small for effective measurement. They showed, however, the same regular change as observed for the other alcohols.

DISCUSSION

The discussion will be divided into two sections. First, the relative basicity of the purely alcoholic to the purely aqueous system is considered. For these dilute solutions (e.g. 0.001 *M* sodium alkoxide in the alcohol) there is an order of basicity rising from methanol ($H_- = 10.69$), ethanol ($H_- = 12.62$), isopropyl alcohol ($H_- = 15.00$), *t*-pentyl alcohol ($H_- = 15.98$), to *t*-butyl alcohol ($H_- = 17.16$). The basicity of the methanolic solution is comparable to that of an aqueous solution of the same base concentration. For all of these alcohols there is a direct relation between H_- and dilute base concentrations (up to about 0.1 *M* base) such that (20, 4–12)

$$H_- = B + \log [OR^-], \qquad [v]$$

where B is a constant dependent on the nature of the alcohol. Values are given in Table II. The basicity of an alcoholic solution appears to be a function of both the autoprotolysis constant and the proton affinity of the solvent.

The H_- function, as originally conceived (13), must be firmly anchored in the aqueous pH region. This has recently been effected (1). However, O'Ferrall and Ridd (5) have

set up an acidity scale in methanolic methoxide solutions with methanol as the reference system. They should have, like Schaal (6), termed this a H_m scale. However, these workers clearly recognize the direct relation between their pK_a values obtained from methanolic solution and the aqueous pK_a values for these indicators.

The results can be examined by an adaptation of the ideas of Grunwald (25) and Izmailov (26). The ionization of an acid in an alcohol may be written as

[vi] $$HA + OR^- \rightleftharpoons A^- + HOR.$$

The negative logarithm of the equilibrium constant, pK_e^{HA}, can be defined as

[vii] $$pK_e^{HA} = \log [OR^-] + \log ([HA]/[A^-]).$$

The autoprotolysis constant K_H^{ROH} is related by

[viii] $$pK_H^{ROH} = -\log [OR^-] - \log [ROH_2^+].$$

The above relations and the earlier considerations (eq. [i]), assuming the indicator activity coefficient ratio is unity, gives

[ix] $$pK_a^{HA} - pK_e^{HA} - pK_H^{ROH} = \log [ROH_2^+] - \log a_{H^+}.$$

The degenerate activity coefficient, $\log \gamma^{ROH}$, proportional to the difference in chemical energy of solvation of the protons in water and the alcohol[1] (26), is then given by

[x] $$\log \gamma^{ROH} = \log a_{H^+} - \log [ROH_2^+],$$

or

[xi] $$\log \gamma^{ROH} = pK_e^{HA} + pK_H^{ROH} - pK_a^{HA}.$$

The values so obtained are shown in Table II and are in reasonable agreement with those calculated by other means (26). As the dielectric constant falls, the validity of the assumptions and, therefore, the derived values of $\log \gamma^{ROH}$ become less secure. In the dilute solutions, the acidity of an alcoholic solution is related to that of the same concentration of the base in water by the equation

[xii] $$H_-(\text{alcohol}) - H_-(\text{water}) = pK_H^{ROH} - pK_H^{H_2O} - \log \gamma^{ROH}.$$

[1]*The difference in chemical energy of solvation of the protons in water and the alcohol is equal to 2.303RT log* γ^{ROH} *kcal (26).*

Thus the relative basicity of the alcoholic alkoxide solution is determined by both the change in the autoprotolysis constant and the difference in the energy of the proton in alcohol relative to that in water.

Secondly, the change in basicity from an aqueous, via aqueous alcoholic, to an alcoholic solution will be considered. Irrespective of other effects, there is a gradual change in dielectric constant on progressively changing the medium from water (D = 78.5) to an alcohol (D = 32.6 to 5.8). To assess this factor, aqueous dioxan containing base was examined. Dioxan has a very low dielectric constant. Unfortunately dioxan has a narrow range of miscibility with aqueous sodium hydroxide. The limited results indicate that there is a definite increase in basicity with increasing dioxan content. Unlike the aprotic solvents studied previously (1–3), dioxan is not a strong hydrogen-bond acceptor for water (34). These aprotic solvents, such as dimethyl sulfoxide, compete with the hydroxide ion for the solvating specie, water. This causes very greatly increased activity of the hydroxide ion in these aqueous mixtures (24). The increase in basicity for the aqueous dioxan system could not be caused by the latter effect. Any "salting-in" effect on the uncharged acid, as postulated for the H_0 function, would have the opposite effect and decrease basicity. Thus, a lowering of the dielectric constant appears to increase the activity of the hydroxide ion, in excess of that expected for the simple effect of replacement of water by dioxan (35). A decrease in dielectric constant could also cause an increase in the autoprotolysis constant of water, $pK_H^{H_2O}$, which would cause an increase in the basicity of the system (see eq. [xii] and earlier discussion).

In all the aqueous alcohols studied a regular change in basicity is observed. This is quite unlike the previous data for H_0. Qualitatively a satisfactory explanation of the situation is the gradual change in the *effective* autoprotolysis constant and in the difference in energy of the proton relative to water.

A quantitative estimation of the species actually present has been suggested by Caldin and Long (19). With this method the results for K vary with the composition over quite a wide range and the value increases with increasing water content. The lack of activity corrections (for indicator, base, or solvent), therefore, appear to be important. It is very likely that the activity of the alkoxide and hydroxide vary with the solvent composition. However, the equilibrium constants, K, for any one molar composition are always in the order, t-BuOH > t-PeOH > i-PrOH > EtOH.

THE FEIST SYNTHESIS OF PYRROLE-3-CARBOXYLIC ESTERS

D. M. MCKINNON[1]

In connection with another investigation (1) which required some pyrrole derivatives, their preparation, particularly that of their N-substituted-3-carboxylic esters, was studied. The method of study was that of Feist (2), who condensed benzoin and ethyl β-aminocrotonate in potassium hydrogen sulfate at 170° to produce the N-unsubstituted-pyrrole-3-carboxylic ester (I*a*).

III

crotonic esters, prepared by the reaction of acetoacetic ester with the appropriate amines, with three α-ketols studied, benzoin, α-hydroxyacetophenone, and acetoin, From benzoin and acetoin, the 4,5-diphenyl- (I, *a–e*) and 4,5-dimethyl- (*m–o*) pyrrole-3-carboxylic esters respectively were obtained, while α-hydroxyacetophenone yielded the 4-unsubstituted esters (I, *f–l*) some of which (I, *f–h*, *l*) had been obtained previously (6) by the well-known Paal–Knorr synthesis.

Where it was found impossible to crystallize the pyrrole-3-carboxylic ester, the crude products were either distilled under reduced pressure, or hydrolyzed to the free acid.

Lederer and Paal (6*a*) reported that ethyl α-phenacylacetoacetate condensed with aqueous methylamine to give ethyl 1,2-dimethyl-5-phenylpyrrole-3-carboxylate (I*k*), m.p. 112°. The compound obtained from α-hydroxyacetophenone and ethyl β-aminocrotonate, which gave a satisfactory analysis, had m.p. 75°. Two compounds were obtained from a check of the original experiment. One was identical with that (m.p. 75°) obtained above, while a second, which softened above 85° and melted completely at 112°, was completely converted to the first by being heated at a temperature above its melting point for 5 min. On the basis of its analysis and properties, it is assumed to be an intermediate condensation product (IV), or a tautomer.

$$Ph\cdot CO\cdot CH_2CH(CO_2Et)\cdot C(Me):NMe_2$$

Ethyl β-phenylaminocinnamate also condensed with benzoin under the conditions described above. The tetraphenylpyrrole-3-carboxylic ester (I*p*) was obtained, but the major product was a white crystalline nitrogen-containing material whose infrared spectrum showed no carbonyl absorption. It did not give a satisfactory analysis for any simple product.

The results of the syntheses using α-hydroxyacetophenone show that the groups attached to the carbonyl and hydroxy functions of the α-ketol become pyrrole-5- and pyrrole-4- substituents respectively, and also that the β-aminocrotonic ester must react in that form, and not as its β-iminobutyrate tautomer. They are in contrast to the reactions of α-ketols with β-keto esters (5) where the positions of the substituents in the furans (III) produced are reversed.

These reactions are analogous to the similar Hantzsch (7) and Feist-Benary (8) syntheses of pyrroles and furans where the positions of the group adjacent to the carbonyl function become 5- and 4- substituents respectively.

EXPERIMENTAL

Ethyl β-(o-Dimethylaminophenyl) Aminocrotonate

Equimolar quantities of *o*-aminodimethylaniline and acetoacetic ester, with a trace of acetic acid, were heated under reflux in benzene until the calculated quantity of water, removed by continuous azeotropic distillation, had separated. The solvent was evaporated and the residue distilled under reduced pressure. The pale yellow fraction, b.p. 102° at 0.5 mm was collected (73%).

Found: C, 66.6; H, 7.8; N, 10.3. $C_{14}H_{20}N_2O_2$ requires C, 67.6; H, 8.0; N, 11.3.

2 Methylpyrrole-3-Carboxylic Esters (I, a–o)

Equimolar quantities of the ethyl β-aminocrotonic ester and the α-ketols (acetoin was used as the commercial 85% solution in water) were heated under reflux in ethanol with an approximately equal weight of zinc chloride for times varying between 4 and 24 h. The yellow oils obtained by diluting the ethanol were worked up by trituration under ethanol, distillation under reduced pressure, or hydrolysis to the parent acid. The results are presented in Table I. The products were crystallized from ethanol except where stated.

Reaction of Ethyl α-Phenacylacetoacetate with Methylamine

The reaction, performed as described (7), afforded a solid precipitate, which was recrystallized from ethanol. It softened at 85° and completely melted at 112°.

Found: C, 68.8; H, 7.01; N, 5.74. $C_{15}H_{19}NO_3$ requires C, 68.9; H, 7.28; N, 5.57.

The mother liquors of the reaction, diluted with a large excess of water, gave a precipitate, m.p. 75° (from ethanol), which was identical with the pyrrole (I*k*) obtained above. The compound $C_{15}H_{19}NO_3$ obtained above was heated at 120° for 5 min. The cooled product, recrystallized from ethanol, deposited the pyrrole (I*k*), m.p. 75°.

Reaction of Ethyl β-Phenylaminocinnamate with Benzoin

Benzoin and ethyl β-phenylaminocinanmate were heated under reflux with zinc chloride as described above for the 2-methylpyrrole-3-carboxylic ester for 24 h. The mixture, worked up in the usual manner, gave a white solid which was separated into two components by chromatography on activated alumina in benzene. The course of the elution was followed under ultraviolet light. When the first pale fluorescent band had been eluted, the column was stripped with ether.

The first fraction on evaporation yielded a white solid, m.p. 175–176° from ethanol (17.5%).

Found: C, 83.5; H, 5.51; N, 3.29. $C_{31}H_{25}NO_2$ requires C, 83.8; H, 5.66; N, 3.16.

The second fraction on evaporation yielded a colorless crystalline compound, m.p. 212–220° from benzene.

Found: C, 85.5; H, 5.67; N, 6.13.

STEREOCHEMISTRY OF THE REDUCTION OF CYCLIC KETONES WITH THE PYRIDINE-*n*-BUTYLLITHIUM ADDUCT: STERIC APPROACH AND PRODUCT DEVELOPMENT CONTROLS

R. A. ABRAMOVITCH, W. C. MARSH, AND J. G. SAHA

The dihydropyridyllithium adduct formed from phenyllithium and pyridine has been shown to reduce ketones to the corresponding alcohols (1). While the yield from benzophenone was reasonable (64%), cyclohexanone gave a poor yield (6.5%) of cyclohexanol. It was, nevertheless, thought to be of interest to examine whether or not there was any stereoselectivity in the reduction of cyclic ketones with this reagent. The publication of a study of the stereochemistry of the reduction of cyclic ketones with lithium tri-*t*-butoxyaluminium hydride and the discussion of the factors controlling the geometry of the products formed (2) prompts the reporting of our results.

The reducing agent used here was the adduct (I) formed by the addition of *n*-butyllithium in ether in the cold to an excess of pyridine in dry ether. The ketone in ether was added at room temperature and, after the usual workup (1), the products were analyzed by gas-phase chromatography. In addition to recovered ketone, 2-*n*-butylpyridine was formed, together with the mixture of isomeric alcohols.

Reduction of 4-*t*-butylcyclohexanone in this way gave a mixture of isomeric alcohols of which 91–96% was the *trans*- and 9–4% was the *cis*-isomer. Very similar ratios were obtained when lithium aluminium hydride (3) and lithium tri-*t*-butoxyaluminium hydride (2) were used. It has been proposed (2) that the stereochemical results observed with

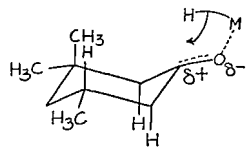
I



II

these two reagents can be accounted for on the basis of steric factors alone ("steric approach control") and not of "product development control" (4). If the attacking reagent is the hydride ion then approach would be easier from the axial side than from the equatorial side; in the latter case, the axial hydrogens at C-2 and C-6 would interfere with a species approaching the carbonyl group. With 3,3,5-trimethylcyclohexanone, however, the axial methyl group at C-3 would lead to a much larger steric hindrance to axial approach, and the main product formed (55–88%) with the complex metal hydrides is the less stable *trans* axial alcohol (2, 5). At first sight the present observation with 4-*t*-butylcyclohexanone would suggest that hydride ion may be the effective reducing agent with (I) as well, and that the direction of attack is governed by the ease of approach of the hydride ion. If this were so, then reduction of 3,3,5-trimethylcyclohexanone should lead to the *trans* alcohol, predominantly. This was not the case, however. Under conditions in which thermodynamic control is highly unlikely (thermodynamic control leads to 100% of the *cis*-isomer (5)) the mixture of alcohols obtained consisted of 79% of the *cis*- and 21% of the *trans*-isomer, i.e. the more stable alcohol predominated, in marked contrast to the complex hydride reductions. This result cannot be rationalized on the basis of ease of attack from the axial side and must indicate that product development control is involved when I is the reducing agent. It is felt that the generalization that it is possible to explain all the stereochemical results of the hydride reduction of cyclic ketones on the basis of steric factors alone is not always justified. The stereochemistry will also depend to a large extent upon how far the geometry of the transition state has progressed towards that of the product: with a powerful hydride ion donor, the geometry of the transition state will resemble that of starting ketone and steric approach control will operate. With a weak hydride donor, as I appears to be, however, the transition state will look more like the product alcohol and, with the oxygen atom probably complexed with the metal (II) so that it will prefer even more to adopt the least hindered configuration, transfer of hydrogen will take place to give mainly the equatorial alcohol. Adduct I may find some use in the reduction of ketones *under non-equilibrating conditions* in which the equatorial isomer is desired but in which axial approach is sterically difficult.

EXPERIMENTAL

The procedure used will be illustrated with the reduction of 3,3,5-trimethylcyclohexanone.

A solution of *n*-butyllithium (0.64 g, 0.01 mole in 4.5 ml of hexane) in dry ether (15 ml) was added slowly with stirring and under oxygen-free nitrogen to a cooled solution of pyridine (4.0 g) in dry ether (25 ml) at such a rate that no rise in temperature occurred. A solution of the ketone (0.7 g, 0.005 mole) in dry ether (25 ml) was now added slowly and the reaction mixture stirred at room temperature for a further 12 h. It was decomposed by the addition of 6 *N* hydrochloric acid (50 ml); the organic layer separated; and the acid layer was extracted with ether. The combined ether layers were dried (Na_2SO_4) and the solvent distilled through a fractionating column. The residue (3–5 ml) was transferred quantitatively to a 10 ml volumetric flask and the volume brought to the mark with acetone. Aliquots of the solution were then analyzed by gas-phase chromatography using a 5 ft × $\frac{1}{4}$ in. column packed with glycerol (20%) on Chromosorb W (80–100 mesh) operated at 100° and a helium inlet pressure of 30 p.s.i. (120 ml/min). Calibration curves using pure *cis* and *trans* alcohols were obtained for the quantitative

For personal use only.

analyses. The response factors for the two alcohols (flame ionization detector) were found to be the same. The average overall yield of alcohols (duplicate runs) was 12.3%. The accuracy of the method was checked by analyzing a synthetic mixture of the two alcohols. The results are correct within ±0.4%.

The mixture of the isomeric 4-*t*-butylcyclohexanols was resolved on a 6 ft × ¼ in. column of 20% Carbowax 20 on Chromosorb W at 130°.

HYDROGEN ATOM ABSTRACTION FROM ETHYLENEIMINE AND ETHYLENEIMINE-d_4[1]

R. F. Klemm

INTRODUCTION

As part of a more extensive investigation into the mercury photosensitized decomposition of ethyleneimine it was necessary to establish the rates at which methyl radicals abstract H attached to both carbon and nitrogen, and thereby subsequently to observe, if possible, the reactions of the ethyleneimino radical. Brinton and Volman (1) using di-*tert*-butyl peroxide as a thermal methyl source reported k_1 for the reaction

[1] $$CH_3 + \overline{CH_2CH_2NH} \rightarrow CH_4 + R\cdot$$

to be $k_1 = 3.2 \times 10^{10} \exp(-4800/RT)$ (mole/cc)$^{-1}$ s^{-1} in the interval 120–160°. Their original value has been adjusted by Shepp's (2) value for

[2] $$CH_3 + CH_3 \rightarrow C_2H_6$$

of $k_2 = 2.2 \times 10^{13}$ (mole/cc)$^{-1}$ s^{-1} independent of temperature. Since the value given by Brinton and Volman (1) is the only determination of k_1 to date, the opportunity was taken to reevaluate k_1 over a wider temperature range (100–260°) using the photolysis of acetone as an alternate methyl source.

EXPERIMENTAL

Ethyleneimine (Fisher reagent) was distilled on a 1 m pyrex helices-packed column with a vapor takeoff. Its purity was ascertained by gas chromatography and mass spectrometry. Acetone (Fisher reagent) was similarly processed. Ethyleneimine-d_4 (Merck, Sharpe & Dohme, Montreal) was 98.5 atom % deuterium, judged from its n.m.r. (nuclear magnetic resonance) spectrum by using known quantities of benzene as internal standard. Acetone-d_6 (Merck, Sharpe & Dohme, Montreal) was 99.5 atom % deuterium and used without additional purification.

The cylindrical quartz photolysis cell was 172 cc in volume and enclosed in a well-lagged, aluminium furnace. Radiation from a Hanovia SH medium pressure lamp was limited to predominantly 3 130 Å

by a Corning 0–54 filter. Acetone and ethyleneimine were individually admitted to the cell and allowed to mix as the lamp equilibrated. No "dark" reaction between reactants was evident. Methane and ethane were resolved by gas chromatography using a temperature-programmed molecular sieve 13X column and a hot wire detector. The various deuterated methanes were determined by mass spectrometry.

RESULTS

With acetone (A) and acetone-d_6 (Ad_6) as methyl sources, data have been obtained according to Methods I and II as employed by Trotman-Dickenson and Steacie (3). Use is made of the relationship

$$[3] \qquad \frac{R(CH_4)}{R^{1/2}(C_2H_6)} = \frac{k_1[E]}{k_2^{1/2}} + \frac{k_4[A]}{k_2^{1/2}}$$

where E = ethyleneimine and k_4 refers to

$$[4] \qquad CH_3 + A \rightarrow CH_4 + CH_2COCH_3.$$

Thus $R(CH_4)/R^{1/2}(C_2H_6)$ should be a linear function of [E] at constant [A] with slope of $k_1/k_2^{1/2}$ and intercept of $k_4[A]/k_2^{1/2}$. Fig. 1 illustrates the validity of such a relationship. Values of $k_1/k_2^{1/2}$ obtained from Fig. 1 are used to obtain the Arrhenius plot, Fig. 2. From the least squares slope of Fig. 2 and Shepp's (2) value of k_2

$$[5] \qquad k_1 = 5.8 \times 10^{10} \exp(-5280/RT) \text{ (mole/cc)}^{-1}\text{ s}^{-1}.$$

The alternate method (Method II) of finding the rate constant for metathetical methyl reactions involves the use of acetone-d_6. Additionally, it circumvents the need for an

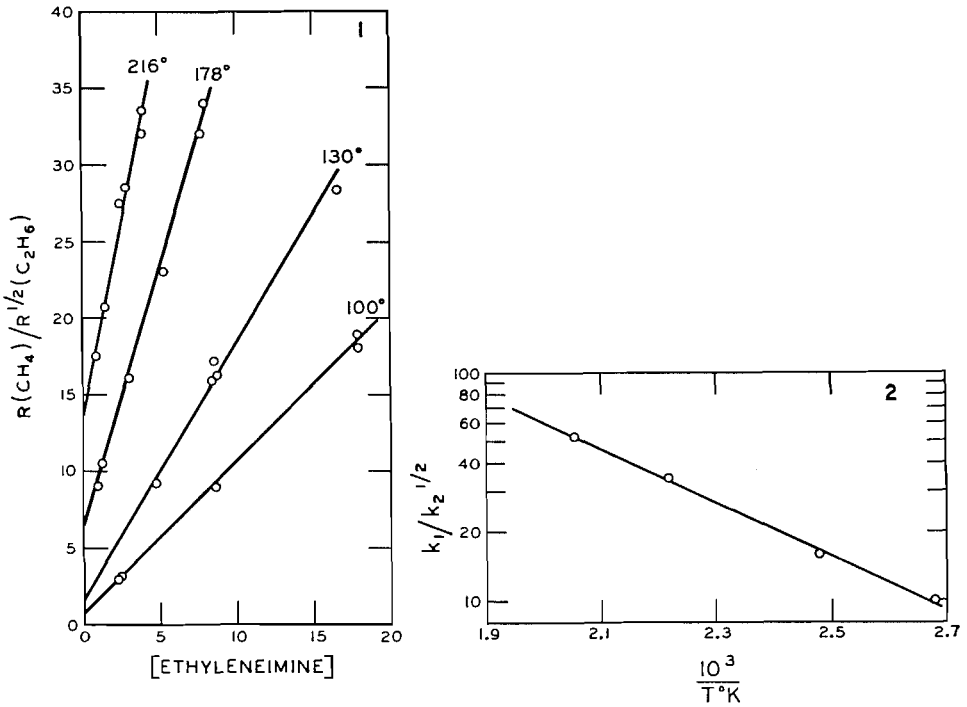

FIG. 1. Ratio of formation rates, $R(CH_4)/R^{1/2}(C_2H_6) \times 10^6$ (mole/cc)$^{1/2}$ s$^{-1/2}$ vs. ethyleneimine concentration $\times 10^7$ mole/cc.
FIG. 2. Ratio of rate constants, $k_1/k_2^{1/2}$ (mole/cc)$^{1/2}$ s$^{-1/2}$ vs. $1/T$ °K $\times 10^3$.

ethane measurement. When Ad_6 is photolyzed, the CD_3 radicals formed yield methane by the reactions

[6] $$CD_3 + Ad_6 \rightarrow CD_4 + \cdot CD_2COCD_3$$

[1] $$CD_3 + E \rightarrow CD_3H + R\cdot .$$

Based upon these reactions, the expression

$$\frac{k_1}{k_6} = \frac{R(CD_3H)}{R(CD_4)} \times \frac{[Ad_6]}{[E]}$$

is obtained. k_1/k_6 is derived from the appropriate pressure measurements and a mass spectrometric determination of CD_3H/CD_4. Figure 3 is a semilog plot of k_1/k_6, so derived, vs. $1/T$ over the range 120–260°; it conforms to the relationship $k_1/k_6 = 0.121 \exp(6000/RT)$. The value

$$k_6 = 7.25 \times 10^{11} \exp(-11400/RT) \text{ (mole/cc)}^{-1}\ \text{s}^{-1}$$

derived from the equations given by Creak, Dainton, and Ivin (4) affords

$$k_1 = 8.8 \times 10^{10} \exp(-5400/RT) \text{ (mole/cc)}^{-1}\ \text{s}^{-1}$$

in fair agreement with k_1 obtained from Method I when allowance is made for the experimental error in (k_1/k_6) and also that in the "best" value of k_6.

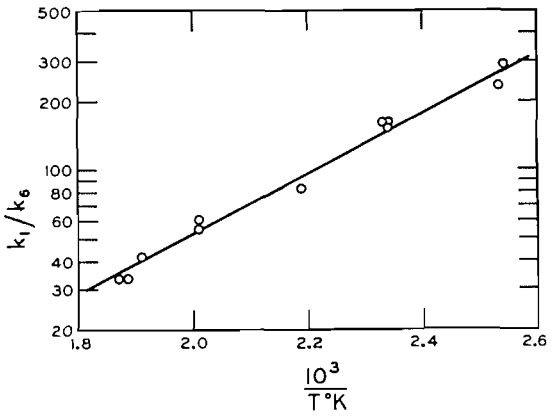

FIG. 3. Ratio of rate constants, k_1/k_6 vs. $1/T$ °K $\times 10^3$.

Up to this point the precise abstractive process to which k_1 refers has not been established (i.e. does k_1 refer to abstraction from nitrogen, carbon, or a combination of both?). To resolve this question acetone was photolyzed in the presence of ethyleneimine-d_4 (Ed_4). The pertinent reactions are

[7] $$CH_3 + Ed_4 \rightarrow CH_4 + \overline{CD_2CD_2N}\cdot$$

[4] $$CH_3 + A \rightarrow CH_4 + \cdot CH_2COCH_3$$

[8] $$CH_3 + Ed_4 \rightarrow CH_3D + \cdot\overline{CDCD_2NH}$$

from which the relationship

$$\frac{R(CH_4)}{R(CH_3D)} = \frac{k_7}{k_8} + \frac{k_4}{k_8}\frac{[A]}{[Ed_4]}$$

is developed. Again $R(CH_4)/R(CH_3D)$ should be a linear function of $[A]/[Ed_4]$. In fact, however, such an expression could not be applied with any reliability because the $m/e = 17$ peak due to CH_3D was less than 0.5% of the CH_4 peak under even the most favorable conditions of high temperature and large $[A]/[Ed_4]$.

The insignificance of reaction [8] compared to reaction [7] even at 200° implies that the only important metathetical process involving methyl radicals is abstraction of an amino hydrogen, thus supporting the assumption of Brinton and Voman (1) in this regard. Furthermore, a ratio $k_7/k_8 > 200$ suggests an activation energy difference between reactions [7] and [8] of roughly 5 kcal/mole, given comparable pre-exponential factors. This would represent an activation energy for reaction [8] of 5.3 + 5.0 = 10.3 kcal/mole. If, following McNesby (5), $E_D - D_H = 1.5$ kcal/mole, then the activation energy for

[9] $$CH_3 + \overline{CH_2CH_2NH} \rightarrow CH_4 + \cdot\overline{CHCH_2NH}$$

would be nearly 9 kcal/mole, in line with the values for similar metathetical processes in the isoelectronic species cyclopropane and ethylene oxide (6).

Since, as a result of the abstraction process, considerable amounts of $\overline{CH_2CH_2N}\cdot$ are formed, it is appropriate to consider reactions which have been proposed to account for their removal. In particular, the possible importance of the following have been investigated

[10] $$2\overline{CH_2CH_2N}\cdot \rightarrow N_2 + 2C_2H_4$$

[11] $$2\overline{CH_2CH_2N} \rightarrow (CH_2)_2NN(CH_2)_2$$

[12] $$\overline{CH_2CH_2N}\cdot \rightarrow CH_3 + HCN$$

Brinton and Volman (1) have proposed [10] on the basis of a mass spectrometric analysis of reactions run to completion, while the occurrence of [11] rests upon the appearance of a peak at $m/e = 84$.

In the present system repeated attempts in the interval 100–250° to observe ethylene by gas chromatographic analysis of the reaction products only established its absence. The unimportance of [10] was additionally confirmed by the absence of any excess N_2 over the small amount associated with residual air in the system. With reaction [11], it was possible to isolate by gas chromatography a sufficient amount of a particular fraction which indicated major responses in its mass spectrum at $m/e = 28, 42, 84$. This is partial evidence that the gas chromatographic peak may be attributed to the dimer, $(CH_2)_2NN(CH_2)_2$, which has been prepared and characterized by Graefe and Mayer (7).

Both HCN and CH_4 have been obtained as principal products of the low pressure reaction of H atoms with ethyleneimine (8). It was proposed that such products arose as a consequence of reaction [12]. Attempts to observe HCN under the present conditions proved futile as might be expected where an excess of amine is present. Evidence for the insignificance of [12] hinges on analyses of the mass spectra obtained in the determination of k_7 according to Method II. By applying experimentally established cracking patterns of CD_4, CD_3H, and CH_4 in the range $m/e = 12$ to $m/e = 21$, it was concluded that less than 0.5% of the methane formed could have arisen via reactions [12] and [7]. A low (0.01) quantum yield for methane production was also observed in the mercury-photosensitized decomposition of ethyleneimine (9).

With regard to the ethyleneimino radical, it can only be concluded that, while it is no doubt a principal product of the abstraction process (reaction [7]) among the reactions previously proposed ([10]–[12]) for this species only reaction [11] is of any consequence in the present system. Therefore it must be stated that the more interesting reactions [10] and [12] are still not definitely established.

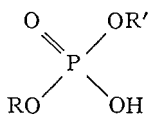
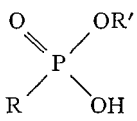
THE PREPARATION AND HYDROLYSIS OF ALKYL HYDROGEN METHYLPHOSPHONATES

Leonard Keay[1]

Although the hydrolysis of secondary phosphate esters (I) has been extensively studied (1–4), the hydrolysis of phosphonate monoesters (II) has received little attention (5, 6), although several esters, mainly those of aromatic phosphonic acids, have been prepared by various means (7–12).



I



II

The phosphonate monoesters are similar to phosphate diesters, being hydrolyzed in strongly acid solution, very stable at neutral pH's, and very slowly hydrolyzed in alkaline solutions (3, 4). Studies on the phosphonate diesters (13, 14) have shown that, just as with the phosphate triesters (15, 16), hydrolysis of one ester group proceeds with P—O fission in alkali and C—O fission in acid solution. It was, therefore, of some interest to study accurately the rates of solvolysis of a series of phosphonate monoesters and see if the results corroborate the mechanisms postulated for dialkyl phosphates (3, 4). Preliminary experiments showed that the hydrolysis of phosphonate monoesters was too slow for accurate measurement in alkaline or neutral solution and detailed measurements were, therefore, only made in acid solution. The pK of ethyl hydrogen methylphosphonate was determined to be 2.00 at 25° and when the hydrolysis rate at 130.5° was determined at several pH's, the observed first-order rate constant increased as the pH decreased, suggesting that, at least over the pH range 1–5, the only substrate involved in hydrolysis

is the neutral species. If this is so, then the specific rate constant is given by $k_N = k_1/$ [neutral ester], where k_1 is the observed rate constant at any pH and the [neutral ester] at that pH is calculated from the pK. The results (Table I) show that in view of the uncertainty of the pH and pK at 130.5°, the k_N is reasonably constant.

TABLE I

The effect of pH on hydrolysis of ethyl hydrogen methylphosphonate; temperature, 130.5°; ester, 0.10 N

Neopentyl hydrogen methylphosphonate	0.10	130.0	0.130

rates of hydrolysis at 130.5° calculated to be methyl, 1.06; ethyl, 1.00; isopropyl, 40; neopentyl, 1.20. The order of reactivity is very close to that observed in the hydrolysis of the diesters (13) and it suggests that the main mechanism involves C—O fission, which has been suggested for the phosphate diesters (3, 4). The acid catalysis also suggests C—O fission since the hydrolysis of phenyl esters which cannot undergo C—O fission is not acid catalyzed (17). The reaction observed is probably a mixture of acid-catalyzed and uncatalyzed reactions. The acid-catalyzed reaction probably proceeds by carbonium ion formation from the protonated hemiester, as has been shown for the 2-ethylhexyl and neopentyl diesters (13, 14). The mechanism of the uncatalyzed reaction of the primary esters could be either C—O fission to form phosphonate anion and carbonium ion, or by an attack by a water molecule on either the carbon or phosphorus atom, although the effect of changing the alkyl group upon the rate makes either mechanism seem unlikely since steric effects are quite marked in substitution reactions at both neopentyl (18, 19) and phosphoryl groups (20, 21, 22).

EXPERIMENTAL

Materials

Phosphonate monoesters were generally prepared by the hydrolysis of the corresponding phosphonochloridate in an aqueous acetone medium. Kinetic studies and neutralization equivalents have shown the reaction to give quantitative yields (20). The same preparation has been carried out with aqueous formic acid and the hemiester demonstrated to have the correct neutralization equivalent (23). The neopentyl hydrogen methylphosphonate was obtained from neopentyl alcohol and methylphosphonic dichloride by mono substitution, followed by hydrolysis of the unisolated neopentyl methylphosphonochloridate.

Methyl hydrogen methylphosphonate.—6.4 g (0.05 mole) methyl methylphosphonochloridate was added slowly with external cooling by ice water. After 24 h, the solvent was removed under reduced pressure and the residual oil dried in a vacuum desiccator containing potassium hydroxide pellets and finally distilled *in vacuo* to yield 5.1 g (90% yield) colorless oil, b.p. 120° at 0.2 mm. Microanalysis: Found P, 28.3; C, 21.5; H, 6.51. $C_2H_7PO_3$ requires P, 27.7; C, 21.4; H, 6.25.

The following other compounds were prepared in a similar manner.

Ethyl hydrogen methylphosphonate.—86% yield, b.p. 120° at 0.3 mm. Microanalysis: Found P, 24.9; C, 29.4; H, 7.32. $C_3H_9PO_3$ requires P, 24.6; C, 28.6; H, 7.14.

Isopropyl hydrogen methylphosphonate.—81% yield, b.p. 123–125° at 0.2 mm. Microanalysis: Found P, 23.1; C, 35.0; H, 7.82. $C_4H_{11}PO_3$ requires P, 22.5; C, 34.8; H, 7.97.

Neopentyl hydrogen methylphosphonate.—44 g neopentyl alcohol and 67.5 triethylamine were dissolved in 200 ml ether and placed in a three-necked flask fitted with stirrer, dropping funnel, and drying tube; 33 g methyl phosphonic dichloride in 100 ml ether was slowly added with stirring and external ice cooling. The mixture was kept at room temperature overnight. The precipitated amine hydrochloride was removed by filtration, but as the filtrate became cloudy on standing, the ether was washed with dilute hydrochloric acid and then with water. The ether layer was dried, the solvent removed, and the residue distilled *in vacuo* to yield a colorless oil, acid to methyl red indicator. Yield 18 g (38%), b.p. 150° at 5 mm, 170° at 9 mm. Microanalysis: Found P, 17.9; C, 43.8; H, 9.07. $C_8H_{15}PO_3$ requires P, 18.7; C, 43.4; H, 9.04.

Evaluation of Rates of Hydrolysis

The hydrolysis of monoalkyl esters was determined by titration of the second acid group liberated upon hydrolysis. A solution of the ester in reaction medium (usually *N*/1 benzene sulfonic acid) was prepared and 5-ml aliquots pipetted into test tubes which were then sealed into vials. The vials were then immersed in a constant-temperature oil bath and at suitable time intervals a vial was removed, cooled, and opened and the contents titrated with standard sodium hydroxide solution using phenolphthalein indicator with a stream of CO_2-free nitrogen to exclude atmospheric CO_2 and prevent end-point fade. CO_2-free water was used for preparing all solutions and at all stages in the work.

The reactions were found to follow a first-order disappearance of reactant.

REACTION OF AMINES WITH DIMETHYLTHIOFORMAMIDE[1,2]

GEORGE R. PETTIT AND LORRIN R. GARSON

Formylation of aromatic amines has been accomplished by the use of dimethylformamide in the presence of sodium methoxide (1). The reaction was found to proceed in a comparable manner with sodium amide or hydride in place of sodium methoxide.[3] However, acylation was not observed employing dimethylformamide alone or in the presence of sodium hydroxide. Subsequently, it became of interest to determine whether substitution of dimethylformamide by a thioamide would provide a route to thioformanilides or follow a different reaction pathway. Thioamides are known (2) to react with amines yielding amidines and in special cases, for example, with 5-thioformamido-6-aminopyrimidines, to produce cyclic formamidines[4] characteristic of the imidazole (in the example cited a purine) ring system. Thus, reaction between an amine and dimethylthioformamide might be expected to yield an N-substituted-N′,N′-dimethylformamidine. The following experiments were undertaken to ascertain the course of reaction between primary amines and dimethylthioformamide in the presence of sodium methoxide.

Dimethylthioformamide, prepared essentially as described by Willstätter (4) in 1909 by treating dimethylformamide with phosphorus pentasulphide,[5] was allowed to react at reflux with 1-aminonaphthalene and sodium methoxide. After 1.5 h, the mixture was cooled, diluted with water, and separated into neutral and basic fractions. When the neutral fraction was found to represent only dimethylthioformamide, thereby eliminating 1-thioformamidonaphthalene from further consideration, the basic fraction was further characterized by conversion to a red crystalline 1,3,5-trinitrobenzene derivative. The base was also found to form bright yellow picrate and styphnate salts. A pure specimen of the basic product (I), m.p. 40–40.5°, was obtained by destroying the trinitrobenzene π-complex with dilute hydrochloric acid. Infrared spectra of both the π-complex and free base (I) displayed a strong absorption band at 1 630 cm^{-1} which was initially assigned and later found to represent a C=N stretching frequency. An infrared band at 1 706 cm^{-1}, reminiscent of carbonyl-type absorption, appeared in infrared spectra of both the picrate and styphnate salts and was eventually attributed to a protonated form of the amidine group.

Employing (7) mass spectral data and results of elemental microanalyses, the base (I) was assigned empirical formula $C_{13}H_{14}N_2$. Considering the composition, chemical properties, and infrared spectra of the base and three derivatives, the substance was readily assumed to be N-(1-naphthyl)-N′,N′-dimethylformamidine (I). Assignments for the positively charged fragments believed to result from simple C–N bond cleavage (8) of the formamidine sidechain have been suggested in structure II. As might be expected,

[1]*The present contribution may be considered Part XVI of our series on Antineoplastic agents. For Part XV, refer to a paper by G. R. Pettit, D. S. Blonda, and R. A. Upham, Can. J. Chem. 43, 1798 (1965).*

[2]*Abstracted in part from the Master of Science thesis submitted by L. R. Garson to the Graduate School, University of Maine, June, 1964.*

[3]*Later the acylation reaction was extended to certain aliphatic amines and to substitution of dimethylacetamide (found to yield acetamides) for dimethylformamide: unpublished experiments by G. R. Pettit and M. V. Kalnins.*

[4]*Cyclization of appropriately substituted 5-thioformamidopyrimidines has been shown (3) to occur readily in hot pyridine or quinoline solution or in methanol containing sodium methoxide. Synthesis of linear formamidines employing an analogous (but intermolecular) reaction between a thioformamide and amine does not appear to have been reported.*

[5]*Recently (5) dimethylthioformamide has been prepared from dimethyl-amine, chloroform, and sodium hydrogen sulfide. Several less convenient methods (6) have also been used in attempts to obtain dimethylthioformamide.*

REACTION OF AMINES WITH DIMETHYLTHIOFORMAMIDE[1,2]

GEORGE R. PETTIT AND LORRIN R. GARSON

Formylation of aromatic amines has been accomplished by the use of dimethylformamide in the presence of sodium methoxide (1). The reaction was found to proceed in a comparable manner with sodium amide or hydride in place of sodium methoxide.[3] However, acylation was not observed employing dimethylformamide alone or in the presence of sodium hydroxide. Subsequently, it became of interest to determine whether substitution of dimethylformamide by a thioamide would provide a route to thioformanilides or follow a different reaction pathway. Thioamides are known (2) to react with amines yielding amidines and in special cases, for example, with 5-thioformamido-6-aminopyrimidines, to produce cyclic formamidines[4] characteristic of the imidazole (in the example cited a purine) ring system. Thus, reaction between an amine and dimethylthioformamide might be expected to yield an N-substituted-N′,N′-dimethylformamidine. The following experiments were undertaken to ascertain the course of reaction between primary amines and dimethylthioformamide in the presence of sodium methoxide.

Dimethylthioformamide, prepared essentially as described by Willstätter (4) in 1909 by treating dimethylformamide with phosphorus pentasulphide,[5] was allowed to react at reflux with 1-aminonaphthalene and sodium methoxide. After 1.5 h, the mixture was cooled, diluted with water, and separated into neutral and basic fractions. When the neutral fraction was found to represent only dimethylthioformamide, thereby eliminating 1-thioformamidonaphthalene from further consideration, the basic fraction was further characterized by conversion to a red crystalline 1,3,5-trinitrobenzene derivative. The base was also found to form bright yellow picrate and styphnate salts. A pure specimen of the basic product (I), m.p. 40–40.5°, was obtained by destroying the trinitrobenzene π-complex with dilute hydrochloric acid. Infrared spectra of both the π-complex and free base (I) displayed a strong absorption band at 1 630 cm^{-1} which was initially assigned and later found to represent a C=N stretching frequency. An infrared band at 1 706 cm^{-1}, reminiscent of carbonyl-type absorption, appeared in infrared spectra of both the picrate and styphnate salts and was eventually attributed to a protonated form of the amidine group.

Employing (7) mass spectral data and results of elemental microanalyses, the base (I) was assigned empirical formula $C_{13}H_{14}N_2$. Considering the composition, chemical properties, and infrared spectra of the base and three derivatives, the substance was readily assumed to be N-(1-naphthyl)-N′,N′-dimethylformamidine (I). Assignments for the positively charged fragments believed to result from simple C–N bond cleavage (8) of the formamidine sidechain have been suggested in structure II. As might be expected,

[1]*The present contribution may be considered Part XVI of our series on Antineoplastic agents. For Part XV, refer to a paper by G. R. Pettit, D. S. Blonda, and R. A. Upham, Can. J. Chem. 43, 1798 (1965).*

[2]*Abstracted in part from the Master of Science thesis submitted by L. R. Garson to the Graduate School, University of Maine, June, 1964.*

[3]*Later the acylation reaction was extended to certain aliphatic amines and to substitution of dimethylacetamide (found to yield acetamides) for dimethylformamide: unpublished experiments by G. R. Pettit and M. V. Kalnins.*

[4]*Cyclization of appropriately substituted 5-thioformamidopyrimidines has been shown (3) to occur readily in hot pyridine or quinoline solution or in methanol containing sodium methoxide. Synthesis of linear formamidines employing an analogous (but intermolecular) reaction between a thioformamide and amine does not appear to have been reported.*

[5]*Recently (5) dimethylthioformamide has been prepared from dimethyl-amine, chloroform, and sodium hydrogen sulfide. Several less convenient methods (6) have also been used in attempts to obtain dimethylthioformamide.*

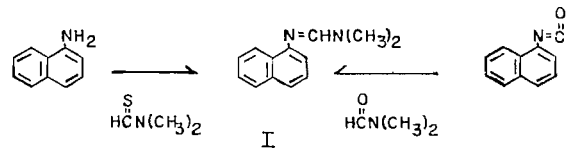
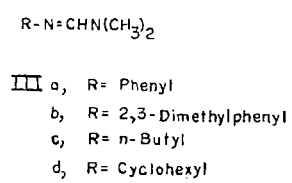
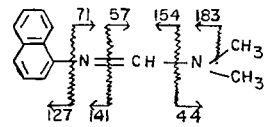
fragments corresponding to *m/e* 57 and 71 were found in relatively small abundance, in fact less than 10%, as a result of further fragmentation. Further support for the formamidine structure (I) was obtained by partially hydrolyzing (9*a*) the base to 1-formamidonaphthalene and the assignment was finally confirmed by direct comparison with an authentic sample (I) prepared (9*b*) from dimethylformamide and naphthyl isocyanate.[6]

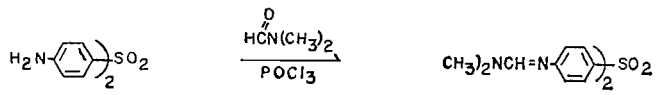


I





II



IV

Meanwhile, the dimethylthioformamide – sodium methoxide reaction sequence was applied to three aromatic and two aliphatic-type amines. Further study of the reaction was terminated when each amine was found to yield a formamidine (III*a*–III*d* and IV). Except for 2,3-dimethylaniline derivative III*b*, the structure of each formamidine was confirmed by comparison with an authentic sample prepared (9*a*, 10, or 11) employing either the dimethylformamide (cf. IV) or isocyanate route. Finally, reaction between dimethylthioformamide and 1-naphthylamine was studied in respect to base requirements. Substituting sodium hydroxide for the alkoxide led to a 90% yield of formamidine I (as the trinitrobenzene derivative). Under similar conditions, 1-aminonaphthalene and dimethylthioformamide alone provided a 97% yield of formamidine (I). At this point the investigation's original objectives had been satisfied and no further attempt was made to extend the scope of the reaction.

In view of the preceding experiments involving 1-aminonaphthalene and dimethylthioformamide, reaction between suitably constituted amines and thioformamides may provide a useful route to certain formamidines.

EXPERIMENTAL

All solvents were redistilled and both dimethylformamide, b.p. 36° (5.5 mm), and dimethylthioformamide were stored over molecular sieve (Fisher type 4A, see reference 1, footnote 9). Dry sodium methoxide was

[6]*Other trisubstituted formamidines have been prepared by this method or by allowing an amine to react with a formamide in the presence of phosphorous oxychloride (10), sulfonyl chloride (11), or phosphorous pentachloride (12). A variety of other methods (13) have been employed for synthesis of the parent system formamidine (14), symmetrically di-substituted formamidines (15), and unsymmetrically disubstituted formamidines (13, 16).*

prepared in this laboratory. The purity of each analytical specimen was assessed by thin-layer chromatography on silica gel G (E. Merck, AG., Darmstadt, Germany) containing calcium sulfate as binder. Thin-layer chromatograms of the 1,3,5-trinitrobenzene complexes and the picrate and styphnate salts were prepared using 15:85 water–tetrahydrofuran as mobile phase (and developed with iodine). Substituting, for example, 1:9 water–tetrahydrofuran or 1:1 chloroform–methanol as eluant led to considerable streaking of the chromatogram.

Melting points were observed employing a Kofler melting point apparatus and are corrected. The infrared spectra were recorded (using potassium bromide) by Dr. R. A. Hill of these laboratories. Microanalytical determinations were provided by Dr. A. Bernhardt, Max-Planck Institut, Mülheim, Germany.

Dimethylthioformamide

Quantities of dimethylformamide amounting to 500 ml (56% yield) were prepared from dimethylformamide (770 ml, 10 moles) and phosphorus pentasulfide (888 g, 4 moles) as described by Willstätter and Wirth (4). The thioformamide was distilled *in vacuo* through a 4-ft vacuum-jacketed column packed with glass helices. The fraction boiling at 77.0–77.6° (3.4 mm) was collected and stored over molecular sieve.

Anal. Calcd. for C_3H_7NS: C, 40.44; H, 7.92; N, 15.72; S, 35.92. Found: C, 40.25; H, 7.67; N, 15.99; S, 35.73.

Several new physical constants including a proton magnetic resonance spectrum of dimethylthioformamide have recently been recorded by Walter and Maerten (5).

N-(1-Naphthyl)-N′,N′-dimethylformamidine (I)

Procedure A

A mixture of dimethylthioformamide (10 ml), 1-aminonaphthalene (0.5 g), and sodium methoxide (0.38 g) was heated at reflux 1.5 h. After it had cooled, the mixture was poured into water (25 ml) and carefully acidified (litmus) with 12 *N* hydrochloric acid. The acidic solution was extracted with diethyl ether and next made basic (litmus) with 6 *N* sodium hydroxide and extracted with diethyl ether. The latter combined and dry (magnesium sulfate) ethereal extract was concentrated (*in vacuo*, steam bath) to a viscous oil. A solution of the product in absolute ethanol (30 ml) was treated with a saturated ethanolic solution of 1,3,5-trinitrobenzene. The solution turned red immediately and approximately 2 minutes later a red crystalline complex began to separate. The *trinitrobenzene complex* weighed 0.89 g (94%) and melted at 142–142.5°. Five recrystallizations from absolute ethanol caused no change in the melting point but produced a pure specimen as fibrous red needles; ν_{max} 1 630, 1 565, and 1 545 cm^{-1}.

Anal. Calcd. for $C_{19}H_{17}N_5O_6$: C, 55.45; H, 4.17; N, 17.02. Found: C, 55.25; H, 4.50; N, 17.09.

A specimen of the 1,3,5-trinitrobenzene complex was treated with 5% hydrochloric acid. The red coloration disappeared at once and the acidic solution was successively extracted with benzene, made basic with potassium hydroxide, and extracted with diethyl ether. The combined ethereal extract was dried (magnesium sulfate) and evaporated (steam bath) to a viscous oil. A specimen of *N-(1-naphthyl)-N′,N′-dimethylformamidine (I)*[7] crystallized from 2-propanol–water as colorless needles melting at 39.5–40.5° (lit. m.p. 40–40.5°, ref. 11); ν_{max} 3 000, 2 900, 1 630 (broad), 1 570, 1 500, 1 460, 1 440, 1 380, 1 270, 1 230, 1 110, 1 080, 1 043, 1 015, 970, 800, and 775 cm^{-1}; mass spectrometry: *m/e* 198 (M^+), 197, 183, 170, 156, 154, 153, 141, 129, 128, 127, 126, 99, 44, 42, 28.[8] Based on an isotope abundance of 15 at M + 1 (199) and 0.8 at M + 2 (200), the product was found consistent with empirical formula $C_{13}H_{14}N_2$.

The *picrate derivative* (prepared in absolute ethanol) of formamidine I recrystallized from absolute ethanol as bright yellow needles melting at 212–213°; ν_{max} 1 705, 1 625, and 1 610 cm^{-1}.

Anal. Calcd. for $C_{19}H_{17}N_5O_7$: C, 53.39; H, 4.00; N, 16.39. Found: C, 52.94; H, 4.04; N, 16.03.

Recrystallizing (3 times) the *styphnate derivative* (prepared in absolute ethanol employing styphnic acid) from absolute ethanol yielded a pure sample of fine yellow needles; m.p. 214–215°; ν_{max} 1 705, 1 635, and 1 565 cm^{-1}.

Anal. Calcd. for $C_{19}H_{17}N_5O_8$: C, 51.47; H, 3.86; N, 15.80. Found: C, 51.82; H, 4.12; N, 15.43.

When reaction between 1-aminonaphthalene and dimethylthioformamide was repeated as described above substituting sodium hydroxide (0.28 g) for sodium methoxide and the basic reaction product treated with 1,3,5-trinitrobenzene, a 1.3 g yield (90%), m.p. 142–143°, of the formamidine (I) complex was isolated. Repeating the same experiment using only 1-aminonaphthalene and dimethylthioformamide led to 1.4 g (97%) of the formamidine (I) 1,3,5-trinitrobenzene complex melting at 142–142.5°. In both cases the trinitrobenzene derivative was found to be identical[7] with the corresponding samples noted above and with that prepared below in Procedure B.

Procedure B

By the general method described by Jovtscheff and Falk (10) formamidine I was prepared (in 82% yield) from 1-naphthyl isocyanate (6.2 g) and dimethylformamide (15 ml). The product (6.4 g) was converted

[7]*Identity was established by mixture melting point determination and infrared spectral comparison with an authentic sample.*

[8]*All values less than 10% of the base peak (198) were omitted.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

to the 1,3,5-trinitrobenzene complex in ethanol solution. Two recrystallizations from ethanol gave a pure specimen melting at 142–142.5°.

N-Phenyl-N',N'-dimethylformamidine (IIIa)

The crude formamidine obtained by allowing aniline (0.65 g) to react with dimethylthioformamide (20 ml) as described in procedure A (for formamidine I) was treated with a saturated solution of styphnic acid in absolute ethanol. The yellow styphnate was collected, washed with ethanol, and dried; the yield was 0.61 g (18%). One recrystallization from ethanol led to bright yellow platelets melting at 169–170°. The same substance (III*a*, styphnate, m.p. 169–170°) was obtained as previously reported (10), using phenyl isocyanate and dimethylformamide. The styphnate salts were found to be mutually identical.[7]

N-(2,3-Dimethylphenyl)-N',N'-dimethylformamidine (IIIb)

Dimethylthioformamide (15 ml) was allowed to react with 2,3-dimethylaniline (5.0 g) as noted for preparation of formamidine I (procedure A). A solution of the crude oily formamidine in absolute ethanol was treated with a saturated ethanolic solution of picrate acid. The yellow solid which separated weighed 1.5 g (16%). Four recrystallizations from absolute ethanol gave bright yellow platelets melting at 177–178°.

Anal. Calcd. for $C_{17}H_{19}N_5O_7$: C, 50.37; H, 4.72; N, 17.28. Found: C, 50.32; H, 5.03; N, 17.54.

4,4-Bis(N',N'-dimethylguanyl)diphenyl Sulfone (IV)

A solution of phosphorous oxychloride (13.0 g) in tetrahydrofuran (30 ml) was added dropwise (during 0.5 h) to a solution composed of dimethylformamide (12.4 g) and tetrahydrofuran (50 ml). Stirring was continued at room temperature for 0.5 h and a solution of 4,4'-diaminodiphenyl sulfone (7.0 g) in tetrahydrofuran (50 ml) was next added dropwise to the reaction mixture. The solid hydrochloride salt which separated was collected and washed with diethyl ether. An aqueous solution of the hydrochloride was treated with potassium hydroxide until the solution became basic (litmus). The mixture was extracted with chloroform and the combined extract was dried and solvent removed *in vacuo*. The crystalline residue weighed 8.1 g. Two recrystallizations from tetrahydrofuran yielded a sample of colorless platelets melting at 146–148°. Additional recrystallization (3 times) from tetrahydrofuran – diethyl ether provided an analytical specimen melting at 149–150°.

Anal. Calcd. for $C_{18}H_{22}N_4O_2S$: C, 60.32; H, 6.19; N, 15.63; O, 8.93; S, 8.93. Found: C, 60.14; H, 6.07; N, 15.67; S, 9.11.

Reaction between dimethylthioformamide and 4,4'-diphenyl sulfone (3.0 g) as illustrated for the preparation of formamidine I proved less satisfactory for preparation of amidine IV. A thin-layer chromatogram (methanol as mobile phase with sulfuric acid development) indicated that less than 30% of the required formamidine (IV) was formed. When the same reaction was repeated in absence of sodium methoxide, only starting amine was isolated.

N-Butyl-N',N'-dimethylformamidine (IIIc)

Applying the general procedure described by Bredereck (11), for reaction between *n*-butylamine (13.2 g) and the dimethylformamide (41.0 g) – phosphorous oxychloride (34.6 g) reagent, afforded 7.1 g (31%) of formamidine III*c* boiling at 61–62° (15 mm). Conversion of 1-butylamine (10.0 g) to formamidine III*c* (2.1 g, 12%) was even less rewarding by use of the dimethylthioformamide (10 ml) route (see I, procedure A). Here, the reaction mixture was heated at reflux 48 h. The identical composition of both products was confirmed by infrared spectral comparison.

N-Cyclohexyl-N',N'-dimethylformamidine (IIId)

Both procedures summarized in the preceding experiment (see III*c*) were repeated with cyclohexylamine (10 g), and essentially analogous yields of oily cyclohexylformamidine III*d* were obtained. Both specimens (III*d*) were converted to styphnate salt derivatives (m.p. 186–187°, ref. 11 reports m.p. 186–187°) and the salts were found to be identical.[7]

ACKNOWLEDGMENTS

This investigation was aided by grant Nos. T-79D and T-79Ef rom the American Cancer Society. We are also grateful to John Occolowitz, Defence Standards Laboratories, Maribyrnong, Victoria, Australia, for determining the mass spectrum of formamidine I and to T. M. Liu for performing a number of introductory experiments.

NUCLEAR MAGNETIC RESONANCE SPECTRAL OBSERVATIONS ON THE GLYCOL-SCISSION OF DEUTERATED D-GLUCOSE[1]

W. MACKIE[2] AND A. S. PERLIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received April 27, 1965

ABSTRACT

The positions of formyl ester groups in products obtained on oxidative glycol-scission of specifically deuterated D-glucose and its 3-*O*-methyl ether have been determined by n.m.r. spectroscopy. These structural assignments are based on the effect of deuteration on the signal given by the proton located α to the formyloxy group in the undeuterated compound. Thus, mono-*O*-formyl-2-*O*-methyl-D-arabinose-4-*d* (IV) produced by lead tetraacetate oxidation of 3-*O*-methyl-D-glucose-5-*d* (I) shows a modified resonance signal for this proton, whereas the signal is absent from the spectrum of the monoformate (III) obtained by periodate oxidation of I. Therefore, IV is a 3-formate and III a 4-formate. According to these findings a furanose form (II) of I is involved in the lead tetraacetate reaction, whereas periodate degrades the pyranose form of the sugar directly.

Oxidation of D-glucose-6,6′-d_2 with lead tetraacetate is shown in similar fashion to yield 2,3-di-*O*-formyl-D-erythrose-4,4′-d_2, evidence that this degradation involves two successive pyranose-to-furanose interconversions.

The preparation of I, and of some other derivatives of D-glucose-5-*d*, is described.

The properties of lead tetraacetate oxidation (1) of D-glucose in acetic acid are consistent with a reaction pathway involving the furanose, rather than pyranose, form of the sugar (2, 3). Most probably a 1,2-lead complex (4) of α-D-glucofuranose is produced and decomposes to 3-*O*-formyl-D-arabinose which, in turn, consumes a second mole of the oxidant and gives 2,3- or 2,4-di-*O*-formyl-D-erythrose. With periodate as oxidant a more complex series of reactions takes place (5–8), but the pyranose form of the sugar undoubtedly plays the dominant role. Probably, therefore, 4-*O*-formyl-D-arabinose is the major initial product, and 2-*O*-formyl-D-glycerose (6) the main end product. Satisfactory information about the structure of these various esters has not been readily accessible in the past because of the general need for reliable means for characterizing partially acylated polyols. With n.m.r. spectroscopy, however, structural problems of this type can now be examined with greater confidence. In the current study, n.m.r. spectral analysis together with the use of specifically deuterated compounds has made it possible to clearly define the structure of some formate esters produced in these glycol-scission oxidations.

The first step in the oxidation of D-glucose by either oxidant has been studied most conveniently with a derivative, i.e., the 3-*O*-methyl ether, that precludes degradation beyond the pentose formate stage (9, 10). Each reaction yields a syrupy product characterized as 2-*O*-methyl-D-arabinose monoformate (ref. 9 and Experimental section). It is pertinent that when the two products were examined at 60 Mc/s, their spectra were so

[1]*Issued as N.R.C. No. 8556.*

[2]*National Research Council Postdoctorate Fellow, 1964–1965.*

closely similar as to suggest that the same product is formed in both reactions. However, when the spectra were recorded at 100 Mc/s several distinct differences became apparent. For the present purpose, attention is restricted to the region at about 530–570 c.p.s. (5.3–5.7 p.p.m.) (Figs. 1*a* and 1*b*) that shows the signal attributable to the proton (A)

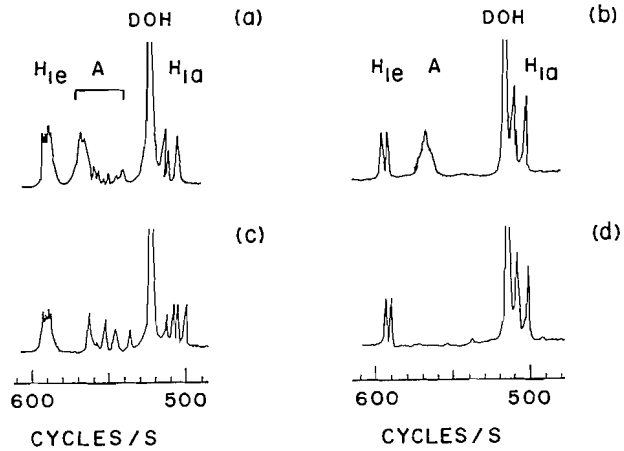

FIG. 1. Partial n.m.r. spectra at 100 Mc/s of oxidation products dissolved in deuterium oxide: (*a*) and (*c*) represent the products obtained by oxidation of 3-*O*-methyl-D-glucose and 3-*O*-methyl-D-glucose-5-*d*, respectively, in acetic acid with one molar proportion of lead tetraacetate; (*b*) and (*d*) represent the products obtained by oxidation of the same two compounds in water with one molar proportion of sodium meta-periodate. A is the signal attributed to the proton located α to the formyloxy group; H_{1e} and H_{1a} are signals attributed to the anomeric protons.

located α to the formyloxy group. This assignment is based on its occurrence at relatively low field and, more important, on the fact that it is displaced toward higher field by about 120 c.p.s. when the ester group is hydrolyzed. There is more splitting of the signal in Fig. 1*a* than in 1*b*, and this greater complexity appears to be reflected also in the signals ascribed to H_{1e} and H_{1a} (11), as well as in other portions of the spectrum that are not shown here. In neither instance, however, was analysis of the spectrum sufficiently complete for a structural assignment to be made.

A more direct approach to the problem was afforded by carrying out the oxidations with 3-*O*-methyl-D-glucose deuteriated at position-5. Degradation of this compound in the pyranose form (I) should give 4-*O*-formyl-2-*O*-methyl-D-arabinose-4-*d* (III), whereas a pathway involving the furanose form (II) should yield 3-*O*-formyl-2-*O*-methyl-D-arabinose-4-*d* (IV). From an inspection of formulae III and IV, it is seen that the resonance signal associated above with proton A can be produced only by the 3-formate, thus making possible a clear choice between the two structures.

It was found, in fact, that the product formed by oxidation with lead tetraacetate gives a signal corresponding in chemical shift to that of proton A (Fig. 1*c*), its intensity being equal to that of the formate proton signal. Also, the structure of this signal is simpler than that of A in Fig. 1*a*, as could be expected upon replacement of an adjacent proton by deuterium. In marked contrast, the periodate oxidation product shows no response in this region of the field (Fig. 1*d*). Therefore, it may be concluded that the lead tetraacetate scission of 3-*O*-methyl-D-glucose yields the 3-formate (IV) and hence that the oxidative attack on D-glucose involves a pyranose $\rightarrow$ furanose interconversion. Periodate oxidation gives the 4-formate (III). In that portion of the overall reaction of D-glucose itself in which the C1–C2 diol is split in the initial step (most evident with the α-anomer (8)) this reagent must oxidize only the pyranose sugar.

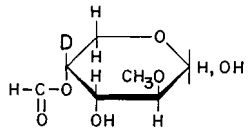
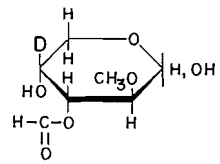
II



III



IV

The possibility that the formyl group of IV could have migrated to position-3 from -4 during lead tetraacetate cleavage (12) cannot be ignored, although such a pathway is at variance with results of recent experiments dealing with this question (3). One must also consider the possibility that the ester group migrates from the 4- to the 5-position of the intermediary *aldehydo*-D-arabinose derivative and that the product isolated is actually 2-*O*-methyl-D-arabinofuranose-5-formate. However, this alternative has been eliminated by examining the product obtained from 3-*O*-methyl-D-glucose-6,6′-d_2. Since its spectrum contains a resonance signal corresponding to that of proton A, the formyloxy group cannot have been located at the di-deuterated 5-position.

An additional point bearing on the n.m.r. spectral data may be noted. The 3-formate gives a more complex overall spectrum than does the 4-formate. This is evident from Fig. 1, and also in other parts of the total spectrum, notably in the signals for methoxy protons. Thus, III contains two nonequivalent methyl groups whereas IV shows two additional, weaker signals attributable to methoxyl protons. Undoubtedly two of these signals represent the two anomeric forms of the product since they are present in the spectra of equilibrated solutions of 2-*O*-methyl-D-arabinose itself and of its 3,4-*O*-isopropylidene derivative, as well as of other 2-*O*-methyl aldoses (unpublished observations). To account for these effects it is suggested that 3-*O*-formyl-2-*O*-methyl-D-arabinose (IV) exists partially in furanose forms.[3] The 4-formate (III) cannot adopt the smaller ring size and its simpler spectrum must be that of the $\alpha\beta$-pyranose mixture only.

Since periodate oxidation of D-glucose gives arabinose esterified at the 4-position, subsequent degradation can proceed to the triose level (6), resulting in an overall uptake of 3 moles of the reagent (5, 7, 8). However, only 2 moles of oxidant are consumed in the lead tetraacetate reaction, the second mole being used to convert arabinose-3-formate to di-*O*-formyl-D-erythrose. Depending upon whether this latter step involves the pyranose or furanose form of the pentose derivative, the final product would be the 2,4- or 2,3-diester. Di-*O*-formyl-D-erythrose obtained from D-glucose (12) gives a spectrum (Fig. 2*a*) that is not readily amenable to analysis. However, this difficulty has been obviated by using D-glucose deuteriated at the 6- and 6′-positions (V). Because of the characteristically large displacement of a proton signal towards lower field when the hydroxyl group α to the proton is formylated (as noted above) it was to be expected that H_2 of the 2,4-derivative (VI) would resonate at relatively low field, and H_3 at a much higher field. By contrast,

[3]*Perhaps this is caused by the same steric influence that leads to a dominance of furanoside in the equilibrium methanolysate of 2,3-di-O-methyl-arabinose (13).*

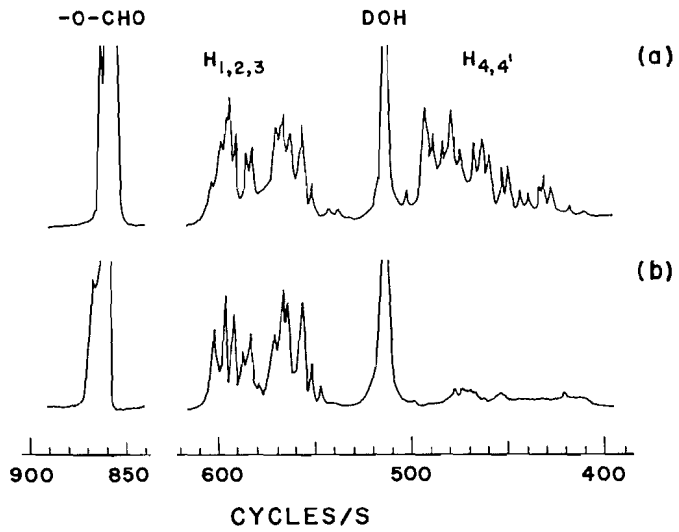

FIG. 2. N.m.r. spectra at 100 Mc/s of oxidation products dissolved in deuterium oxide: (*a*) and (*b*) represent the products obtained by oxidation of D-glucose and D-glucose-6,6′-d_2, respectively, in acetic acid with two molar proportions of lead tetraacetate.

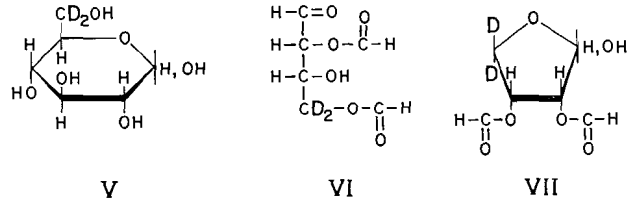
2,3-di-*O*-formyl-D-erythrose-4,4′-d_2 (VII) should exhibit both of these signals at low field. This latter situation was found to apply almost completely for the product of the oxidation of V (Fig. 2*b*), showing that the tetrose formate is esterified predominantly at positions-2 and -3 (as in VII).



V VI VII

Results obtained in the lead tetraacetate oxidation both of 3-*O*-methyl-D-glucose-5-*d* and of D-glucose-6,6′-d_2 are thus consistent in requiring that the initial oxidation step involves D-glucofuranose. The oxidation of D-arabinose-3-formate, in turn, also undoubtedly involves a furanose pathway.

Although lead tetraacetate and periodate are commonly equated as glycol-scission agents, it is clear that they can differ markedly in their mode of attack on reducing sugars. Since tetravalent lead and the iodine atom in periodate have closely analogous properties (14), this difference likely arises mainly from the fact that the sugars can exist in diverse forms and that the two reactions take place in different solvents. Under such circumstances variations in the relative importance of glycol scission and structural change (mutarotation, pyranose–furanose interconversion, etc.) dominate the outcome of the reactions (see also ref. 8). Thus, for example, the rate of oxidation of 3-*O*-methyl-D-glucose by lead tetraacetate in acetic acid is regulated by the intervention of an unusually reactive species, such as a furanose form (3). However, a comparison of acetic acid and benzene as media shows that oxidation of the pyranose form of this sugar itself is sufficiently vigorous in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

benzene to preclude the change in ring size (3). This latter situation appears to apply also for periodate oxidation in water, and since mutarotation can be relatively slow in this solvent some oxidation takes place also at positions other than at the more usually favored *cis*-α-hydroxyhemiacetal group (7, 8).

For the preparation of D-glucose-5-*d*, a compound that does not appear to have been reported previously, D-*xylo*-5-hexulosonic acid (VIII) (15, 16) was utilized as starting material. Hamilton and Smith (17) have reported that VIII is reduced by sodium borohydride to an equimolar mixture of D-gluconic and L-idonic acids. Hence, by using pure borodeuteride the 5-deuterio-hexonic acids were prepared. They were lactonized and a reduction was then carried out with sodium borohydride in the presence of a cation-exchange resin (18), to give a mixture of D-glucose- and L-idose-5-*d*. For as yet undetermined reasons, the overall yield of hexose obtained using these well established procedures was very low. The mixture of sugars was acetonated, and 1,2:5,6-di-*O*-isopropylidene-D-glucofuranose-5-*d* was isolated by fractional crystallization. 3-*O*-Methyl-D-glucose-5-*d* (I) was then prepared by methylation of the diacetone derivative, followed by acid hydrolysis.

D-Glucose-6,6′-d_2 (V) was prepared by reduction of 1,2-*O*-isopropylidene-D-glucofuranurono-6,3-lactone with sodium borodeuteride, followed by acid hydrolysis of the derived 1,2-*O*-isopropylidene-D-glucofuranose-6,6′-d_2, by analogy with the preparation of the di-tritiated sugar (19). 3-*O*-Methyl-D-glucose-6,6′-d_2 was obtained from V via the 1,2:5,6-di-*O*-isopropylidene derivative.

EXPERIMENTAL

Nuclear magnetic resonance spectra were recorded with a Varian HA-100 high resolution spectrometer using deuterium oxide as solvent and tetramethysilane, contained in a coaxial capillary, as reference.

Oxidation of 3-O-Methyl-D-glucose with Lead Tetraacetate or Sodium Periodate

(*a*) 3-*O*-Methyl-α-D-glucose (100 mg) was taken up in water (0.2 ml) and the solution was diluted with acetic acid (6 ml). Lead tetraacetate (220 mg; 0.97 molar equivalents) dissolved in acetic acid (12 ml) was added to the sugar solution, and 10 min later the solvent was evaporated off at 40°. The residue was triturated several times with ethyl acetate, and concentration of the extract afforded a colorless syrup (95 mg). This syrup absorbed strongly in the infrared region at 1 730 cm^{-1}, characteristic of a formate ester group; the intensity of the resonance signal attributable to the proton of this group (at 870 c.p.s.) showed that the product contained 0.94 formate groups.

An alternative isolation procedure, more convenient for oxidations on a smaller scale, was as follows: after removal of the acetic acid by distillation the residue was taken up in deuterium oxide and treated with the equivalent quantity of oxalic acid in deuterium oxide. The lead oxalate was filtered off and the filtrate concentrated *in vacuo* to a volume (about 0.5 ml) appropriate for use directly in the n.m.r. spectrometer sample tube.

(*b*) Sodium metaperiodate (55 mg) was added to a solution of 3-*O*-methyl-α-D-glucose (50 mg; 1 molar equivalent) in deuterium oxide (5 ml). After 10 min reaction time the solution was concentrated *in vacuo* to a volume appropriate for use directly in the n.m.r. spectrometer sample tube. In some experiments, this reaction was carried out in water, the solution was concentrated to dryness, and the oxidation product extracted into ethyl acetate, as described above under (*a*).

3,4-O-Isopropylidene-2-O-methyl-D-arabinopyranose

The syrupy formate ester prepared by lead tetraacetate oxidation[4] (0.35 g) was taken up in cold acetone (10 ml); concentrated hydrochloric acid (0.1 ml) was added, and the solution was stored at 3° for 72 h. Several volumes of acetone were added, and the solution was neutralized with lead carbonate and then concentrated to dryness. The residue (0.30 g) solidified; m.p. 114–117°. Several attempts to recrystallize the material from various solvents were unsuccessful and, as had been found for this same derivative by Barker and Smith (9), the carbon content was considerably lower than the theoretical value (by 1.0% C). However, after a portion of this crude sample had been sublimed it served as seed, thus enabling recrystallization of the pure compound from ether: m.p. 117–118°; $[\alpha]_D$ −108° (*c*, 2.5 in methanol, no mutarotation observed).

Anal. Calcd. for $C_9H_{16}O_5$: C, 52.9; H, 7.9. Found: C, 53.0; H, 8.0.

[4]*3,4-O-Isopropylidene-2-O-methyl-D-arabinose has already been prepared in this connection by Barker and Smith (9), in characterizing the product formed by the oxidation with periodate.*

Reduction of D-*Xylo-5-hexulosonic Acid with Sodium Borodeuteride*

An ice-cold aqueous solution (20 ml) of potassium D-xylo-5-hexulosonate[5] (5.0 g) was added dropwise with stirring to a cooled solution (5 ml) of aqueous sodium borodeuteride[6] (1.0 g). After 1 h at 3° and 18 h at room temperature, the reaction mixture was passed through a column (13 × 2.5 cm) of Amberlite IR-120 (H^+) and the resin was washed thoroughly. The total effluent was concentrated *in vacuo* to dryness, the residue was treated several times with methanol to remove borate, and the syrupy product (4.2 g) was warmed (50–60°) *in vacuo* to aid lactonization of the aldonic acids. Paper chromatographic examination of the syrup (1-butanol:ethanol:water 40:11:19) showed the presence of at least two components ($R_{glucose}$ 0.51 and 1.6) which, together with its infrared absorption characteristics, indicated the presence of a mixture of 1,5-lactone (strong band at 1 730 – 1 740 cm^{-1}), 1,4-lactone (shoulder at 1 775 cm^{-1}), and free acid. Saponification of a portion of the syrup with barium hydroxide caused all of these components to be retained at the starting line of the chromatogram.

Borohydride Reduction of D-*Glucono- and* L-*Idono-lactones in the Presence of Cation-Exchange Resin*

The syrupy mixture of acid and lactone (1.5 g) was dissolved in boric acid (0.05 *M*; 60 ml) and cooled in an ice bath. Excess of Amberlite IR-120 (H^+) was introduced (18), and a solution of potassium borohydride (1.5 g; 60 ml) was then added dropwise with vigorous stirring over a period of 15 min. Stirring was continued for an additional 15 min, the resin was filtered off, the solution was concentrated, and borate was removed from the residue by repeated addition and distillation of methanol. Paper chromatographic examination showed that the syrupy product contained glucose, idose, and probably some sorbitol, as well as the two components of the original syrup. The latter were largely removed by treating a solution of the mixture with Dowex-1 (bicarbonate form) for 1 h, the final yield of product recovered from 3.8 g of the crude reduction product being 0.8 g.

*1,2:5,6-Di-O-isopropylidene-α-*D-*glucofuranose-5-d*

The neutral syrup (0.75 g) was taken up in acetone (50 ml) containing concentrated sulfuric acid (0.4 ml). After 5 h at room temperature the reaction mixture was cooled, saturated with gaseous ammonia, filtered, and concentrated to dryness. The residue (0.95 g) was dissolved in chloroform, the solution was washed with water, and the chloroform-soluble material (0.64 g) was taken up in cyclohexane. An initial crystalline deposit recovered was found to contain a mixture of *gluco-* and *ido-*isomers, which was not separated by repeated recrystallization, but material obtained from the mother liquor consisted only of the *gluco-*isomer; m.p. 109°, its X-ray powder diagram was indistinguishable from that of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose.

*3-O-Methyl-α-*D-*glucose-5-d*

A solution of the deuteriated diacetone-glucose (0.14 g) in methyl iodide (10 ml) containing silver oxide (0.2 g) was heated under reflux for 18 h. The solids were filtered off and washed with chloroform, and the combined filtrate and washings were concentrated to a syrup (0.13 g). Hydrolysis of the latter with 0.1 *N* sulfuric acid furnished 3-*O*-methyl-D-glucose-5-*d*, crystallizing as the α-anomer from ethanol: m.p. 160–161°; identity confirmed by its X-ray powder diagram.

*1,2-O-Isopropylidene-α-*D-*glucofuranose-5-d*

1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranose-5-*d* (15 mg) was dissolved in methanol (1 ml) and 0.1 *N* sulfuric acid (1 ml) (20). After 20 h at room temperature, the solution was neutralized with barium carbonate and then concentrated to dryness.

The n.m.r. spectrum of this product was indistinguishable from that of 1,2-*O*-isopropylidene-D-glucofuranose-5-*d* prepared by a different procedure (21). This fact served to establish that the deuteration procedure had specifically labelled position-5 of the D-glucose moiety in a virtually quantitative manner. Thus the spectrum consists of six well resolved doublets that show coupling between H-1 and H-2, H-3 and H-4, and H-6 and H-6′, respectively. Such data are consistent only with the absence of hydrogen at the 5-position.

*1,2-O-Isopropylidene-α-*D-*glucofuranose-6,6′-d_2*

1,2-*O*-Isopropylidene-α-D-glucofuranurono-6,3-lactone (0.15 g) in water (1 ml) was added to a freshly prepared solution (0.5 ml) of sodium borodeuteride (0.10 g). The reaction mixture was stored overnight in the cold, deionized with a mixture of ion-exchange resins, and concentrated, and borate was then removed from the residue with methanol. The solid product (0.14 g) was recrystallized from methanol–ether: m.p. 156–158°. The n.m.r. spectrum of the product showed that deuteration had been effected only at the 6- and 6′-positions. Thus, signals given by H-6 and H-6′ of the undeuterated compound are absent, H-5 is a doublet (J = 3.5 c.p.s.) that is coupled with the H-4 quartet; the remainder of the spectrum is indistinguishable from that of 1,2-*O*-isopropylidene-D-glucofuranose.

Lead Tetraacetate Oxidation of D-*Glucose-6,6′-d_2*

Crystalline 1,2-*O*-isopropylidene-α-D-glucofuranose-6,6′-d_2 (60 mg) was hydrolyzed on the steam bath for

[5]*Supplied by Miles Chem. Co., Elkhart, Indiana, as the calcium salt; this compound was prepared by double decomposition using potassium oxalate.*

[6]*Supplied by Merck, Sharp and Dohme, Montreal, Quebec.*

3 h with 0.1 *N* sulfuric acid to give the free hexose (35 mg). The latter was taken up in water (0.1 ml) and acetic acid (4 ml), and was then treated with lead tetraacetate (175 mg; 2 molar equivalents) in acetic acid (8 ml). The syrupy product (28 mg) was recovered by extraction into ethyl acetate, as described for the undeuteriated material (12); its n.m.r. spectrum is reproduced in Fig. 2*b*.

*3-O-Methyl-α-*D*-glucose-6,6′-d_2*

The preparation of this compound was analogous to that of the 5-deuterio-3-*O*-methyl ether (above). Crystalline 1,2-*O*-isopropylidene-D-glucofuranose-6,6′-d_2 was acetonated further to give the 1,2:5,6-di-*O*-isopropylidene derivative: m.p. 109°. The latter was methylated with methyl iodide and silver oxide and the product hydrolyzed, giving 3-*O*-methyl-α-D-glucose-6,6′-d_2 by crystallization from ethanol: m.p. 158–160°.

ACKNOWLEDGMENTS

N.m.r. spectra were recorded by M. Mazurek. Microanalyses were performed by W. Haid, who also prepared X-ray powder diagrams.

PROTON MAGNETIC RESONANCE SPECTRA OF D-GLUCOPYRANOSE POLYMERS[1]

C. A. GLASS

Northern Regional Research Laboratory,[2] U.S. Department of Agriculture, Peoria, Illinois

Received March 8, 1965

ABSTRACT

The proton magnetic resonance spectra of carbohydrates in deuterium oxide solution were obtained and considered with respect to probable conformation. The anomeric proton signal occurred at lowest field and was easily recognized. In the various glucose derivatives investigated, this signal occurred from 4.62 to 5.25 τ for equatorial protons and from 5.12 to 5.65 τ for axial protons. Within each of these ranges, the chemical shifts varied inversely with the electronegativity at the C_1 site, as calculated by the technique of Gordy (1). Variable electronegativity at C_1 accounts for the overlap of ranges for equatorial and axial protons, thereby bringing the n.m.r. data into agreement with assignment of the C1 chair form of the pyranose ring to the linear polymers of D-glucopyranose. The orientation of the glucopyranose rings in cyclodextrins is shown to preclude ring current effects, and the up-field chemical shifts of these materials are shown to be consistent with the C1 form.

Some solution properties of amylose, amylopectin, and dextran, such as solubility and changes of optical rotation with pH, may depend on the conformation of the anhydro-D-glucopyranose rings. Reeves (2) investigated the optical rotation of amylose and other carbohydrates in cuprammonium hydroxide solution and interpreted his results in terms of conformational differences between the eight Sachse strainless rings. He was able to show that only the C1 conformation would account for the results on all the substituted D-glucopyranose derivatives examined; although in a few cases the B1 and 3B conformations were not ruled out. Later Reeves (3) interpreted the decrease in rotation for amylose and methyl-β-maltoside with increase in sodium hydroxide concentration as resulting from a conformational change: B1 to 3B. According to Senti and Witnauer (4), X-ray diffraction data favor the C1 conformation for alkali amylose in the solid state. Greenwood and Rossotti (5) investigated the infrared spectra of some carbohydrates and found that their results were compatible with the C1 form for both neutral and alkaline material.

Lemieux, Kullnig, Bernstein, and Schneider (6) showed that in the proton magnetic resonance spectra of five isomeric 1,2,3,4,5,6-hexachlorocyclohexanes, the chemical shift could be correlated with orientation of protons relative to the plane of the ring. A proton equatorially oriented resonated at lower field than an axially oriented proton with the same environment, and this difference was about 0.5 p.p.m. Pople, Schneider, and Bernstein (7) reasoned that the bond-anisotropy contribution would be relatively small and postulated that ring current effects are responsible for the magnitude of the difference in chemical shift between axial and equatorial protons.

From molecular orbital considerations, Karplus (8) has derived this set of equations relating the dihedral angle and the coupling constant.

$$J_{H_1H_2} = A \cos^2\phi - 0.28$$
$$A = 8.5 \text{ when } 0° \leqslant \phi \leqslant 90°$$
$$\text{and } A = 9.5 \text{ when } 90° \leqslant \phi \leqslant 180°$$

[1]*Presented at the 15th Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy, Pittsburgh, Pennsylvania, March 2–6, 1964.*

[2]*A laboratory of the Northern Utilization Research and Development Division, Agricultural Research Service, U.S. Department of Agriculture. Article not copyrighted.*

In a more recent communication (9), he points out that coupling constants depend on factors other than the vicinal dihedral angle and that the relation should be taken only qualitatively. Lenz and Heeschen (10) determined the H_1H_2 dihedral angle of α- and β-D-glucopyranose, α- and β-D-mannopyranose, and some D-glucopyranose derivatives by n.m.r. using a modified Karplus equation. From the dihedral angles, together with the chemical shifts of the anomeric proton signals, they ascribed the C1 or a skewed chair form to these pyranoses. D-Glucose, cellobiose, and maltose were examined by van der Veen (11) and, assuming a C1 form, the alpha and beta configuration of the anomeric proton was correlated with its n.m.r. signal.

Proton magnetic resonance measurements of the anomeric proton signals cannot be completely definitive because conformations C1, B2, and 1B of the alpha anomer have H_1 equatorially oriented and a dihedral angle of 60° between H_1 and H_2. Furthermore, for the beta anomer, three conformations (C1, 1B, and B2) have H_1 axially oriented and at a 180° dihedral angle with H_2. In these ambiguous cases, the possibilities can be narrowed to the C1 conformation with reasonable assurance. The 1B and B2 conformations do not give rotational data consistent with Reeves' observations on cuprammonium complexes (2). Therefore only the C1 conformation appears possible.

Rao and Foster (12) examined methyl D-glucopyranosides, cellobiose, maltose, and the γ-Schardinger dextrin by n.m.r. and considered the pyranose rings to be in the C1 form. We have determined the n.m.r. spectra of some of the compounds studied by Lenz and Heeschen (10) and Rao and Foster (12) and have found good agreement. In addition, nine other carbohydrates were studied to confirm the C1 conformational assignment of pyranose rings in amylose, amylopectin, and dextran.

EXPERIMENTAL

All spectra were obtained on a Varian A-60 n.m.r. spectrometer[3] with a variable temperature probe. Spectra were obtained on solutions of 10 to 20% concentration in D_2O at room temperature with the HOD signal at 5.30 τ as an internal reference. Later the spectra were determined at about 80° and referenced to the prominent signals in the room temperature spectra. Chemical shifts are reported in parts per million (p.p.m.) in τ values with HOD (at room temperature) equal to 5.30 τ. Although the water signal is not the preferred reference, because it is not very sharp and highly subject to shift as a function of temperature, care was exercised to maintain the probe at the same temperature, and frequent checks were made with the addition of materials such as dioxane and acetone. Chemical shifts are reported to the hundredth with a probable uncertainty of ±0.03 p.p.m. Coupling constants are reported in cycles per second (c.p.s.) and are apparent coupling constants determined from the chart. These measured spacings do not give the true value of the coupling constant $J_{H_1H_2}$ since little is known about H_2. They do, however, serve to differentiate between di-axial and axial-equatorial orientations. For brevity these spacings are referred to in the text as J values. Dihedral angles are calculated from the following modified Karplus equation used by Lenz and Heeschen (10):

$$J_{H_1H_2} = F(A \cos^2 \phi - 0.28)$$

where $F = 1.09 \pm 0.05$ and the other constants are as in Karplus' original equation (8).

RESULTS AND DISCUSSION

Nuclear magnetic resonance measurements are given in Table I.

The alpha anomers have calculated dihedral angles between 49° and 58°, and the beta anomers have dihedral angles between 142° and 151°. In the light of Karplus' recommendation (9), since the coupling constants depend on properties other than the dihedral angle, the best interpretation here is that the alpha anomers have an axial-equatorial configuration while the beta anomers have a di-axial configuration.

Data for α- and β-D-glucopyranose, which are obtained simultaneously on the same equilibrated sample, agree well with those of Lenz and Heeschen (10). Any differences

*Methyl signal.
†Signal area ratios.
‡Insufficient resolution but about 3 c.p.s.

are a matter of reference and sensitivity since the coupling constants cannot be determined with great accuracy.

Methyl α- and β-D-glucopyranosides, equilibrated maltose, and the γ-Schardinger dextrin gave results that agree well with those of Rao and Foster (12).

Methyl β-maltoside (methyl *O*-α-D-glucopyranosyl-(1→4)-β-D-glucopyranoside) gives a spectrum that resembles a composite of the corresponding structures in methyl β-D-glucopyranoside and equilibrated maltose. Thus the C_1 proton is axial and, like that of methyl β-D-glucoside, produces a doublet at 5.62 τ with a coupling constant of 7.6 c.p.s. This coupling constant is equivalent to an H_1H_2 dihedral angle of 151°. The anomeric proton of the α-linked nonreducing glucose unit is equatorial and, like the anomeric proton of the nonreducing glucose unit of maltose, has a chemical shift of 4.62 τ, with J = 3.2 c.p.s., corresponding to a dihedral angle of 52° in the nonreducing glucose unit. These findings, together with the cuprammonium work of Reeves (2), show both glucopyranose units to be in the C1 form.

The spectrum of maltotriose (*O*-α-D-glucopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-D-glucopyranose) resembles that of maltose except for the signal area ratios reflecting the two fixed equatorial C_1 protons of the α-pyranosyl rings and the equilibrated mixture of equatorial and axial protons on the reducing end group. The chemical shifts and the coupling constants are about the same as for maltose.

The remaining materials may be considered as two series of glucopyranose carbohydrates: The alpha series consisting of acid-hydrolyzed starch, dextran B1355, dextran B512E, methyl α-isomaltoside (methyl *O*-α-D-glucopyranosyl-(1→6)-α-D-glucopyranoside),

and methyl α-D-glucopyranoside; the beta series consisting of crown gall polysaccharide (poly-*O*-β-(1→2)-D-glucopyranoside), laminarin (poly-*O*-β-(1→3)-D-glucopyranoside), and methyl β-D-glucopyranoside.

Acid-hydrolyzed starch, a commercial preparation from Corn Products Company, has only one signal in the region at 4.62 τ. Resolution was poor, but the coupling constant was about 3.0 c.p.s., indicating a dihedral angle of 53°. The equatorial proton, plus the dihedral angle, indicates the C1 form. Dextran B1355, which is known to contain about 30% α-(1→3)-linkages, in addition to the predominant α-(1→6)-linkages typical of dextrans, gives two signals in this region at 4.73 τ and 5.07 τ. The resolution is less than perfect, but both coupling constants are about 3 c.p.s. Dextran B512E, in which 95% of the linkages are α-(1→6), has a single signal in this region at 5.09 τ. Again, poor resolution precludes highly accurate determination of J, but it is about 2.3 c.p.s., indicating a dihedral angle of 58°. Methyl α-isomaltoside also has two signals in this region: 5.10 τ (J = 3.0 c.p.s.) and 5.17 τ (J = 2.8 c.p.s.).

A comparison of chemical shifts for the anomeric protons within the alpha-anomeric series reveals differences greater than that between the anomeric methyl-D-glucopyranosides. For example, the resonance of the anomeric proton of hydrolyzed starch occurs more than 0.6 p.p.m. downfield of that of methyl α-D-glucopyranoside, whereas that of methyl β-D-glucopyranoside is upfield of methyl α-D-glucopyranoside about 0.4 p.p.m. The occurrence of the signal for hydrolyzed starch so far downfield of that of methyl α-D-glucopyranoside can hardly be ascribed to an axial rather than an equatorial orientation of the anomeric proton of starch. It is reasonable to assume that members of the alpha-anomeric series are all in the same conformation.

A similar comparison of chemical shifts was made in the beta-anomeric series of carbohydrates. In this series, two members were investigated for the first time: Laminarin and crown gall polysaccharide. Crown gall polysaccharide has a signal at 5.12 τ, J = 6.2 c.p.s. An axially oriented H_1 and a dihedral angle of 142° are indicated with C1 as the most probable conformation. Laminarin exhibits a signal at 5.25 τ, J = 6.7 c.p.s. This condition indicates a dihedral angle of 145° and an axial orientation of H_1. Both conditions indicate the C1 conformation.

Also in the beta-anomeric series, there is a range of chemical shifts comparable to that in the alpha series. Crown gall polysaccharide exhibits a signal at 5.12 τ and laminarin at 5.25 τ, whereas methyl β-D-glucopyranoside has one at 5.65 τ. The anomeric protons of these three beta-linked glucopyranoses are certainly axial, and the range of chemical shifts might be related to some property other than pyranose ring conformation.

The variation in chemical shift within each series (Table I) leads to an overlapping of values that reflects either ambiguity in the assignment of axial and equatorial positions to the proton or an influence of other factors in the structure. We believe that differences in electronegativity of the group attached to the glycosidic oxygen (O_1) are the cause of the variations in chemical shift. An experimental relation between n.m.r. chemical shift and the nature of substituents has been developed by Shoolery (13) but without consideration of electronegativity. The property of electronegativity has been utilized, however, to explain differences in molecular dimension, dipole moment, molecular spectra, and reaction rates. Electronegativity of an atom cannot be directly measured so it has been based on various other properties: ionization potential, electron affinities (14), bond-stretching force constants (1), atomic radii (15), and bond energies (16).

In a study of some cyclohexyl derivatives, Neikam and Dailey (17) showed the dependence of chemical shifts of axial and equatorial protons on electronegativity. Eliel,

Gianni, and Williams (18) examined 36 substituted cyclohexanols and found an appreciable overlap of the ranges of chemical shift for axial and equatorial protons. Williamson (19) examined the n.m.r. spectrum of hexachlorobicyclo(2.2.1)heptenes and showed that the differences of internal chemical shift depend on the electronegativity of the substituent. The scale of electronegativities, most applicable in our study, is that of Gordy (1). He relates electronegativity of a nucleus with a bond-stretching constant, the bond length, and the bond order. In a study of a number of compounds, he gives electronegativity values for each element. Kagarise (20) demonstrated a technique of calculating electronegativity at a new site from Gordy values:

$$\chi_{ef} = \frac{\chi_C}{2} + \frac{1}{6}(\chi_x + \chi_y + \chi_z),$$

where χ_C is the electronegativity of the carbon nucleus and where x, y, and z refer to the substituents on the carbon being considered. In this manner, Forsen (21) calculated the infrared frequencies for a number of carbonyl compounds. Electronegativities of some groups are plotted against Pauling's electronegativity values, and a linear relation is obtained.

A typical calculation is this for hydrolyzed starch:

$$\chi_{O_6} = \frac{3.45a}{2} + \frac{2.13a}{2} = 2.79$$

$$\chi_{C_6} = \frac{2.55a}{2} + \frac{1}{6}(2.13a + 2.13a + 2.79\chi_{O_6}) = 2.45$$

$$\chi_{O_{ac}} = \frac{3.45a}{2} + \frac{2.55a}{2} = 3.00$$

$$\chi_{C_5} = \frac{2.55a}{2} + \frac{1}{6}(2.13a + 2.45\chi_{C_6} + 3.00\chi_{O_{ac}}) = 2.54$$

$$\chi_{C_2} = \frac{2.55a}{2} + \frac{1}{6}(2.55a + 2.13a + 2.79\chi_{O_2}) = 2.52$$

$$\chi_{C_3} = \frac{2.55a}{2} + \frac{1}{6}(2.13a + 2.52\chi_{C_2} + 2.79\chi_{O_3}) = 2.52$$

$$\chi_{C_4} = \frac{2.55a}{2} + \frac{1}{6}(2.13a + 2.52\chi_{C_3} + 2.54\chi_{C_5}) = 2.48$$

where a = electronegativity value of nucleus from Gordy (1).

Table II gives the chemical shifts and the electronegativities of the substituents for the materials making up the alpha- and the beta-anomeric series. If it is assumed that the alpha anomers are all C1 in form, then the only difference is in the substituent on O_1. The observed chemical shifts increase from 4.62 τ for hydrolyzed starch to 5.25 τ for methyl α-D-glucopyranoside, whereas the electronegativity of the O_1 substituent decreases from 2.48 for hydrolyzed starch to 2.34 for methyl α-D-glucopyranoside. Intermediate electronegativities produce intermediate chemical shifts. Interestingly, dextran B1355, which contains not only the main-chain α-(1→6)-linkage common to dextrans but also some α-(1→3)-linkage, has two signals: one at 5.07 τ similar to the signal of dextran B512E and one at 4.73 τ. Pasika and Cragg (22) report like signals in the spectrum of dextran B742, which also has some (1→3)-linkages. The O_1 substituent of a (1→3)-linked glucose

TABLE II

Comparison of chemical shift of the anomeric proton with electronegativity of O_1 substituent

Material	O_1 substituent	Chem. shift (τ) H_e	Chem. shift (τ) H_a	Electronegativity
Hydrolyzed starch (α-1→4)		4.62		2.48
Dextran B1355 (α-1→3)		4.73		2.47
Dextran B1355 (α-1→6)		5.07		2.41
Dextran B512 (α-1→6)		5.09		2.41
Methyl α-D-glucopyranoside	$-CH_3$	5.25		2.34
Crown gall polysaccharide (β-1→2)			5.12	2.54
Laminarin (β-1→3)			5.25	2.47
Methyl β-D-glucopyranoside	$-CH_3$		5.65	2.34
α-D-Glucopyranose	—D (?)	4.80		2.13
β-D-Glucopyranose	—D (?)		5.42	2.13

unit is more negative than the substituent of one that is (1→6)-linked, and the chemical shifts for the anomeric protons agree.

Similarly, the beta-anomers exhibit the same relationship. As the chemical shifts increase from 5.12 τ for crown gall polysaccharide to 5.65 τ for methyl β-D-glucopyranoside, the electronegativities decrease from 2.54 to 2.34.

The overlapping ranges of the equatorial and axial protons are explained in terms of the electronegativities of the O_1 substituents. N.m.r. evidence alone would allow either the

For personal use only.

C1 or the 1B conformation for these materials. By using the cuprammonium complexing data of Reeves (2) where available to eliminate 1B, the conformations may be assigned as C1.

The discussion of the alpha- and beta-anomeric series has purposely avoided mention of the two anomers of D-glucose, although they are included in Table II. The relation between chemical shift and electronegativity is not maintained for these conpounds, presumably because we cannot be sure exactly what is being measured. The electronegativity given is that of the nonhydrogen-bonded sugar monomer in each case. Any form of hydrogen or deuterium bonding involving substituents on C_1 will make this site more negative and shift the resonance of the anomeric proton downfield. For example, if the C_1 hydroxyl of one glucose unit is bonded to the acetal oxygen of another, the electronegativity of the O_1 substituent would be 2.54 and the corresponding chemical shift would be about 4.5 τ. Likewise, hydrogen or deuterium bonding involving the D_2O solvent would increase the electronegativity of the substituent and bring about a downfield shift in the resonance of the anomeric proton. Probably hydrogen bonding has influenced the electronegativity of the substituent on O_1 and brought about a downfield shift in the resonance of the anomeric proton from about 5.6 τ to 4.80 τ for the alpha anomer. If the extent and kind of hydrogen bonding were known, the glucose anomers might fit in the proper place in each series. Hence, the chemical shifts of sugar protons might indicate the degree of hydrogen bonding.

In addition to these linear glucopyranose derivatives, two of the Schardinger dextrins were investigated. Although they have the same linkage and conformation as maltose, the anomeric proton signal occurs at a higher field. For the α-Schardinger dextrin, the anomeric proton signal is at 4.95 τ, $J = 2.7$ c.p.s., and for the γ-Schardinger dextrin, at 4.93 τ, $J = 3.5$ c.p.s. The linear counterpart, acid-hydrolyzed starch, which has the same α-(1→4)-linkage, has an anomeric proton signal at 4.62 τ, $J = 3.0$ c.p.s. The dihedral angles obtained from these coupling constants are about the same for all three materials so that the only observed difference is 0.3 p.p.m. chemical shift. Since the linkages in these materials are the same as those in hydrolyzed starch, the electronegativity of the substituents at O_1 is the same. This upfield shift from 4.62 τ for hydrolyzed starch to 4.95 τ for α-Schardinger dextrin is probably related to the ring current effect.

A single D-glucopyranose ring can orient itself with the magnetic field in such a way that ring currents associated with the pyranose ring shift the resonance of axial groups upfield and equatorial groups downfield. This movement is also true for linear materials since free rotation about the glucosidic linkage is possible, and on the average, the rings can orient themselves with the field. The methyl signal of methyl α-D-glucoside (6.64 τ), methyl β-D-glucoside (6.48 τ), methyl β-maltoside (6.44 τ), and methyl α-isomaltoside (6.63 τ) demonstrate this shift (Table I).

Schardinger dextrins, however, are semirigid rings of glucose units and little freedom exists for a glucopyranose ring to move with respect to the other units of the cyclodextrin. Any orientation that might occur must involve some favored orientation of the dextrin as a whole. Construction of cyclodextrins with molecular models, such as Stuart models, shows that the pyranose rings are nearly normal to the plane of the dextrin. As the cyclodextrin is rotated in space, one pyranose ring, favorably oriented, is opposed by another. The orientation that makes the pyranose rings magnetically equivalent is the one with the magnetic field directed normal to the plane of the cyclodextrin ring. Since this orientation places the pyranose rings edgewise to the field vector, no shift would be produced by ring currents.

This theory is supported by the observed chemical shifts for the C_1 proton, about 4.95 τ, which is intermediate between the chemical shifts of hydrolyzed starch (alpha anomer), 4.62 τ, and laminarin (beta anomer), 5.25 τ. The electronegativity of the O_1 substituent for all three materials is about the same, but the laminarin anomeric proton is axial, and that of hydrolyzed starch is equatorial. The resonance in the cyclodextrins occurs at a chemical shift such as would be observed for similar groups in the absence of ring current effects.

At the 1963 Starch Round Table, sponsored by the Corn Industries Research Foundation, Hybil of the University of Maryland described X-ray results that he and his co-workers, Williams and Rundle, has obtained showing glucose units in α-Schardinger dextrin to be C1 in the solid state. We can correlate our n.m.r. results with their X-ray results. The difference in chemical shift for the two Schardinger dextrins might be explainable when probable values for the angles which the glucose rings make with the cyclodextrin ring plane are known.

It has been demonstrated that the C1 pyranose form in solution can be assigned to D-glucose, methyl D-glucopyranosides, methyl β-maltoside, methyl α-isomaltoside, maltose, maltotriose, acid-hydrolyzed starch, α- and γ-Schardinger dextrins, dextrans, laminarin, and crown gall polysaccharide on the basis of n.m.r. data, sometimes combined with rotation data. Future plans call for a continuation of these studies with other carbohydrates and other solvent systems.

ACKNOWLEDGMENTS

We wish to express our sincere gratitude to the following who provided samples: Dr. G. G. Bartless, National Research Council, Saskatoon, Canada, for crown gall polysaccharide; Dr. Dexter French, Iowa State University, Ames, Iowa, for Schardinger dextrins; and co-workers in the Northern Laboratory Dr. C. L. Mehltretter for methyl α- and β-D-glucopyranosides, R. W. Jones for methyl α-isomaltoside, Dr. H. B. Sinclair for methyl β-maltoside, and Dr. A. R. Jeanes for dextrans.

PERMANGANATE–PERIODATE OXIDATION

PART VII. THE OXIDATION OF SOME ACYCLIC MONOTERPENES[1]

E. VON RUDLOFF

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received May 17, 1965

ABSTRACT

The reaction of permanganate–periodate with 1-decene and 1-octadecene in aqueous suspension or media containing *tert*-butanol has been studied. C_{10}-compounds are oxidized almost quantitatively with the aqueous reagent. Myrcene, *cis*-ocimene, citronellol, citronellal, citronellic acid, geraniol, nerol, linalool, and linalyl acetate are all oxidized in high yield to the predicted products. These can serve conveniently for chemical identification of the aliphatic terpenes when isolated from mixtures by gas–liquid chromatography. The reaction may also be useful in locating the ^{14}C-label in tracer studies.

INTRODUCTION

Rapid progress in the analysis of essential oils and other complex mixtures of mono- and sesquiterpenes has been made with the advent of gas–liquid chromatography (g.l.c.). However, the chemical identification of such terpenes in milligram amounts has remained very difficult and usually physical data alone must be relied upon for characterization. Also, even the more efficient liquid phases developed (1–6) do not give complete resolution of all terpenes, and therefore a chemical means of identification for overlapping components is very desirable. Thus, the detection of small amounts of β-pinene in oils containing much sabinene was found to be impossible by physical data (7, 8), and many other such overlaps have been encountered by the author in the analysis of conifer leaf oils and other essential oils.

Since many terpenes have olefinic double bonds it was of interest to determine if these could be oxidized to predictable end products by means of the permanganate–periodate reagent. Earlier, we established that this reagent cleaves olefinic double bonds giving characteristic end products in almost quantitative yields (9–11) and this observation, together with the known behavior of oxygenated functional groups in a wide variety of aliphatic compounds towards the reagent (12), permits a reasonable prediction to be made of the mode of reaction of such groups in terpenes. This communication deals with the oxidation of the common aliphatic monoterpenes.

The permanganate–periodate reagent oxidizes isopropylidene groups almost quantitatively to acetone (11) and isopropenyl groups to varying amounts of formaldehyde (10). When commercial samples of citronellol, citronellal, and geraniol were analyzed by this technique it was confirmed that these exist essentially in the isopropylidene form. Chemical evidence for the predominance of this group in the aliphatic terpenes has been obtained by Caldwell and Jones (13, cf. also 14); Barnes *et al.* (15) have shown by means of infrared spectroscopy that in purified acyclic terpenes the isopropenyl form does not exceed 3%. In the present study the formation of acetone was confirmed by the iodoform reaction and that of formaldehyde by reaction with chromotropic acid.

Souček and Dolejš (16) have oxidized (−)-dihydrolavandulol to L(−)-isopropyl succinic acid by means of the permanganate–periodate reagent which is in full agreement with prediction. The isolation of this acid was useful in establishing the absolute configuration of (−)-lavandulol.

[1]*Issued as N.R.C. No. 8581. Presented in part at the 47th Annual Meeting of the Chemical Institute of Canada, Kingston, June 1–3, 1964.*

Since most terpenes are only very slightly soluble in water, the reaction of permanganate–periodate was first studied with 1-decene and 1-octadecene in the presence of 10 to 50% *tert*-butanol. This solvent was found to give good results in the oxidation of water-insoluble lipids (17). In subsequent experiments with terpenes it was found that the presence of *tert*-butanol is detrimental to the recovery and analysis of neutral oxidation products. Hence, particular attention has been paid to the reaction of 1-decene and 1-octadecene in aqueous suspension. Since this reaction is heterogeneous (at least in the early stages) two procedures were used. In procedure A aliquots of the olefin were shaken with the reagent in separate flasks. This procedure was also used when 30% or more *tert*-butanol was added since it had been found previously (17) that an insoluble periodate salt may be formed. In procedure B the olefin and oxidant were shaken vigorously until solution appeared to be complete and aliquots were withdrawn after various intervals for back-titration of unconsumed oxidant.

EXPERIMENTAL

Melting points were recorded on a Leitz hotstage microscope. Infrared spectra were recorded either as films between sodium chloride plates or as potassium bromide disks, using a Perkin–Elmer model 21 double-beam spectrophotometer. Analytical g.l.c. runs were carried out with an F & M model 500 (F & M Scientific Corp.) chromatograph having a thermal conductivity detector. The purity of starting materials and the composition of oxidation products were determined on 180 × 0.45 cm o.d. polyethylene glycol (Carbowax 20 M, 15% on Gaschrom P, 60–80 mesh) or Apiezon N (10%) columns. In standard runs temperature-programming from 55° to 210° at 4° per min was employed and the helium flow rate was 103–105 ml per min. The percentage composition was determined by measurement of the area under the peaks (triangulation methods) and no correction factor was employed for compounds of different molecular weight. Relative retention times (r.r.t.) were measured with respect to methyl octanoate. Preparative g.l.c. runs were carried out with an Aerograph model A700 instrument (Wilkins Instrument and Research Inc.). Optical rotations were measured either neat or in chloroform solution (3–5%) at room temperature (23–26 °C).

Purification of Starting Materials

All terpenes except linalool contained more than 1% impurities, most of which were removed by preparative g.l.c. on 2.5 to 5 m × 9 mm o.d. polyethylene glycol columns. In a typical experiment citronellol (73.5%) was injected repeatedly in 50 μl aliquots in 24 min cycles, using temperature-programming (non-linear, voltage regulator setting at 50) from 120° to 180°. The trip switch on the recorder was set to collect the upper two-thirds of the recorded citronellol peak. The purity of the collected material was found to be 98.5% and the identity with citronellol was confirmed by comparison of the infrared spectra and physical constants, including relative retention times (r.r.t.).

Several compounds could not be purified to better than 92–95% by preparative g.l.c. Purification by silver nitrate – silicic acid column chromatography (18) was tried, but only citronellol was purified satisfactorily by this method.

Oxidation Procedure

A. Water-Insoluble Compounds

1-Decene (3.55 mg, 0.025 mmoles) was weighed into a glass-stoppered Erlenmeyer flask (50 ml) and to this was added water and *tert*-butanol (8.0 ml), potassium carbonate (6.7 mg), and stock oxidant solution (2.0 ml). The latter consisted of an aqueous solution of sodium metaperiodate (97.5 mmoles/l) and potassium permanganate (2.5 mmoles/l) (12). The mixture was shaken for the required length of time; unconsumed oxidant was determined by addition of excess 0.1 *N* sodium arsenite solution (10.0 ml) and sodium bicarbonate (1 g) followed by back-titration (after 15 min) with standard iodine solution, using starch indicator (2%) for the end point. The values obtained were calculated as atoms of oxygen per mole of olefin (9, 12) (see Tables I and II).

When 30% or more *tert* butanol was used, an insoluble precipitate formed which reacted with arsenite only on heating (17). When more than the above amount of potassium carbonate was added, this precipitate formed more readily. Additional potassium carbonate is required when more than 1 equiv of acid is formed in the reaction.

B-1. Slightly Water-Soluble Compounds

Citronellol (39.06 mg, 0.25 mmole) was weighed into a 100 ml volumetric flask. Water (60–70 ml), potassium carbonate (67 mg), and stock oxidant solution (20.0 ml) were added and the mixture was shaken vigorously until the initial turbidity had disappeared. The solution was made up to volume and aliquots (10.0 ml) were withdrawn at the desired intervals. The amount of residual oxidant was determined as above.

B-2. Water-Soluble or Highly Reactive Compounds

Highly reactive compounds tend to reduce permanganate faster than the latter is reoxidized by periodate. To prevent this extensive reduction of permanganate, the compound to be oxidized was added to the oxidant (same proportions as above) (12). After mixing, the procedure in B-1 was followed.

Preparative Scale Oxidations

The olefin (1–2 mmoles) was added to the required amounts of water, potassium carbonate, and oxidant, and the mixture was shaken for the optimum length of time. The excess oxidant was reduced with a minimum of sodium bisulfite, and the weakly alkaline solution was extracted with ether to remove neutral products. If necessary, potassium carbonate was added to maintain a pH of 7 to 8. The ethereal solution was dried over anhydrous sodium sulfate and evaporated carefully to a small volume. The residue was analyzed by g.l.c. The aqueous portion was evaporated *in vacuo* (rotary evaporator) to a small volume. The aqueous distillate was used for qualitative acetone determination by the iodoform reaction (11) or for qualitative formaldehyde determination with chromotropic acid (10). The precipitated iodoform was filtered off, washed, and dried. The melting point (119–122°) was undepressed in admixture with authentic iodoform. The residue from the evaporation was completely reduced with bisulfite, acidified, and extracted continuously with ether. The ethereal solution was dried and evaporated to give the crude acidic oxidation products. An aliquot (5 to 10 mg) was methylated either with freshly prepared diazomethane or by the methanol – sulfuric acid method (19), and the derived methyl esters were analyzed by g.l.c. The balance of the acidic product was used for crystallization or preparation of crystalline derivatives.

TABLE I

Oxidant consumed (atoms oxygen per mole) by 1-decene and 1-octadecene at 0, 10, 20, 30, and 50% *tert*-butanol in the reaction mixture and using procedure A (continuous shaking) or procedure B-1 (1 h shaking)

1-Decene

The single impurity (5%; possibly 2-decene) could not be removed by preparative g.l.c. or by silver nitrate – silicic acid column chromatography. The rate of oxidation in aqueous suspension and in the presence of 10, 20, 30, and 50% *tert*-butanol was determined by procedure A (see Table I). An aliquot (300 mg) was oxidized in aqueous suspension for 24 h. No neutral product was recovered but the aqueous distillate gave a positive formaldehyde test. The acidic product (328 mg; 96%) showed three peaks on g.l.c. analysis (as methyl esters) with r.r.t. 0.70, 0.99, and 1.69 in 1.5, 5.0, and 93.5% amounts respectively; r.r.t. of methyl heptanoate = 0.71, methyl octanoate = 1.00, and methyl nonoate = 1.69. The derived hydrazide (19) was recrystallized twice from aqueous ethanol; m.p. 92.5–93.5° (undepressed by admixture of authentic *n*-nonanoic hydrazide, m.p. 94–95°).

Anal. Calcd. for $C_9H_{20}N_2O$: C, 62.74; H, 11.70; N, 16.26. Found: C, 62.48; H, 11.51; N, 16.08.

The oxidation was repeated using 20% *tert*-butanol solution. No neutral extract was obtained and the acidic product (96%) contained *n*-heptanoic (2%), *n*-octanoic (8.5%), and *n*-nonanoic (85%) acids as well as several unidentified minor components (g.l.c. analysis of methyl esters).

1-Octadecene

The single impurity (8%, possibly 2-octadecene) could not be removed by g.l.c. or column chromatography. The olefin was oxidized by procedure A and the rate of oxidation in aqueous suspension and media containing *tert*-butanol is shown in Table I. Because of the low solubility, duplicate runs gave values which differed by as much as 0.2 atoms oxygen per mole.

Preparative oxidation (24 h) of 1-octadecene (126.5 mg) in 30% *tert*-butanol gave a neutral extract

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(2.8 mg) and a solid acidic fraction (133 mg, 98.5%); m.p. 54–58°. Recrystallization raised the m.p. to 59.7–61.3°; mixed m.p. with *n*-heptadecanoic acid undepressed.

Anal. Calcd. for $C_{17}H_{34}O_2$: C, 75.50; H, 12.67. Found: C, 75.42; H, 12.34.

Analysis by g.l.c. of the methyl esters derived from the total acidic fraction showed 4 peaks with r.r.t. (methyl octanoate = 1.00) 4.72, 5.10, 5.48, and 5.84 in 0.5, 2, 11.5, and 86% amount respectively. The r.r.t. values corresponded to those of the *n*-C_{14}, C_{15}, C_{16}, and C_{17} methyl esters.

*Mixture containing 10% *tert*-butanol.

Myrcene

Technical grade myrcene was purified by g.l.c. to give a product of 97% purity; n_D^{24} 1.4688, $[\alpha]_D$ +0.25°. The rate of oxidation with the aqueous reagent (procedure B-2) is shown in Table II. Preparative oxidation (150 mg; 48 h) gave acetone (as iodoform), formaldehyde (chromotropic acid color test) and succinic acid (91 mg, 72%); m.p. 185–188.5°. Recrystallization from acetone–chloroform raised the m.p. to 187–189° (undepressed by admixture of authentic succinic acid). Analysis by g.l.c. of the derived methyl esters gave only a single peak with r.r.t. (1.44) of methyl succinate.

cis-Ocimene

The sample, kindly donated by Messrs. International Flavors and Fragrances Inc., Union Beach, N.J., U.S.A., showed four minor impurities (2%) on g.l.c. analysis. The rate of oxidation in water and 10% *tert*-butanol (procedure B-2) is shown in Table II. Preparative oxidation gave acetone and formaldehyde. No ether-soluble acidic product was obtained.

Citronellol

The g.l.c. purified material (see above) had n_D^{23} 1.4552; $[\alpha]_D$ +4.18° (neat) and that obtained by column chromatography n_D^{25} 1.4535; $[\alpha]_D$ +3.52°. The rate of oxidation with the aqueous reagent (procedure B-1) is shown in Table II. Preparative oxidation (156 mg; 6 h) gave a neutral fraction (12 mg), acetone and an acidic extract (142.5 mg, 92.5%), which contained mainly an hydroxy acid (infrared spectrum). Analysis by g.l.c. of the derived methyl esters showed two peaks with r.r.t. 2.03 (4%) (3-methyl adipate = 2.04) and 2.52 (96%). Attempts to purify the expected 6-hydroxy-4-methyl hexanoic acid by distillation or column chromatography failed because of lactone formation and polymerization. The acid was characterized via the methyl ester, $[\alpha]_D$ +4.67° (*c*, 5.0); 3,5-dinitrobenzoate m.p. 145–147°.

Anal. Calcd. for $C_{15}H_{18}N_2O_8$: C, 50.85; H, 5.12; N, 7.91. Found: C, 50.78; H, 5.05; N, 7.75.

When the oxidation was allowed to continue for 4 d the amount of 6-hydroxy-4-methyl hexanoic acid dropped to about 58% and that of 3-methyl adipic acid increased to 28%. In addition at least 9 other acidic oxidation products were recorded in 0.5 to 3% amounts.

Geraniol

The g.l.c. purified material (98%) had n_D^{23} 1.4745 $[\alpha]_D$ −0.20° (neat). The rate of oxidation with the aqueous reagent (procedure B-1) is shown in Table II. Preparative oxidation (160 mg, 24 h) gave no neutral product, acetone and an acidic fraction (106 mg, 88%), n_D^{23} 1.4460, which consisted mainly of levulinic acid (g.l.c. methyl ester r.r.t. = 1.41); phenylhydrazone, m.p. 106.5–108° from benzene and aqueous ethanol (lit. 108° (20)); mixed m.p. undepressed. It is noteworthy that this phenylhydrazone (prepared in ethanolic solution) is in the form of the ethyl ester.

Anal. Calcd. for $C_{13}H_{18}N_2O_2$: C, 66.64; H, 7.74; N, 11.96. Found: C, 66.60; H, 7.76; N, 11.94.

Nerol

The g.l.c. purified material (97%) had n_D^{23} 1.4737, $[\alpha]_D$ −0.1°. The rate of oxidation with the aqueous reagent (procedure B-1) is shown in Table II. Preparative oxidation (152 mg, 24 h) gave acetone and levulinic acid (90%); phenylhydrazone m.p. 105–107°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Linalool

The commercial sample (99%), n_D^{24} 1.4620, $[\alpha]_D$ +0.03° was oxidized as above (see Table II) and acetone and levulinic acid (88%) were identified as the major oxidation products.

Citronellal

The g.l.c. purified compound (96%) n_D^{25} 1.4572 $[\alpha]_D$ +9.39° was oxidized as above (see Table II). Preparative oxidation (308 mg, 48 h) gave acetone and an acidic fraction (270 mg, 90%), but no neutral extract. 3-Methyl adipic acid, m.p. 78–85°, $[\alpha]_D$ +0.1° crystallized from ether–hexane mixture (lit. m.p. 84.5–85° (21)). Purification via the methyl ester did not give a sharp melting compound. Analysis by g.l.c. of the crude methyl esters showed one major peak (95%) with r.r.t. 2.04.

Anal. Calcd. for $C_7H_{12}O_4$: C, 52.49; H, 7.55. Found: C, 52.72; H, 7.74.

Citronellic Acid

The commercial sample was purified via the methyl ester; n_D^{25} 1.4561, $[\alpha]_D$ +3.86°. The free acid was oxidized as above (see Table II). Preparative oxidation (212 mg, 6 h) gave acetone and an acidic fraction (184 mg, 93%) from which 3-methyl adipic acid, m.p. 79–85°, $[\alpha]_D$ +0.2°, was obtained; r.r.t. of derived methyl ester = 2.05.

Linalyl Acetate

The commercial sample (95%) could not be purified further owing to decomposition. The compound was oxidized as above (see Table II). Preparative oxidation (392 mg, 18 h) was carried out with the pH not exceeding 7.5 and yielded a neutral extract (7 mg), acetone, formaldehyde, and an acidic fraction (303.4 mg, 79%). The infrared spectrum of the latter showed it to be an acid containing an acetoxy group (1 250 cm^{-1}, strong).

RESULTS AND DISCUSSION

The rate of reaction of the permanganate–periodate reagent with 1-decene and 1-octadecene in aqueous suspension and media containing 10 to 50% *tert*-butanol is shown in Table I. The oxidation of 1-decene proceeded entirely satisfactorily in aqueous suspension (procedure A) and the assumed product, *n*-nonanoic acid, was isolated in 95% yield.[2] Although the rate of reaction was markedly increased by the addition of *tert*-butanol, no advantage was gained since the yield of *n*-nonanoic acid dropped and measurable amounts of the next lower homologue were formed. With 1-octadecene, at least 20% *tert*-butanol had to be added for a satisfactory rate of oxidation. Under these conditions the yield of the expected acidic oxidation product, *n*-heptadecanoic acid, was 92%.[2] Hence is was concluded that monoterpenes are best oxidized in aqueous suspension but that sesquiterpenes would in all probability require the presence of solvent.

The polyunsaturated monoterpene hydrocarbons myrcene (I) and *cis*-ocimene (IV) were oxidized very rapidly in aqueous suspension (see Table II). Both olefins gave acetone and formaldehyde as neutral products, but only myrcene was oxidized to an isolable acidic product.

Figure 1 shows the various steps of the permanganate–periodate oxidation of myrcene in detail. At pH 7.5 each double bond is hydroxylated by permanganate to a mixture of polyol (II) and isomeric acyloins (e.g. III) (9). These are cleaved by periodate to acetone, succinic semialdehyde, succinic acid, formaldehyde, and formic acid. Acetone and succinic acid are relatively stable towards the reagent (at pH 7.5), but succinic semialdehyde would be oxidized fairly rapidly to succinic acid, formic acid to carbon dioxide, and formaldehyde slowly to formic acid and carbon dioxide (10, 11, 12). Hence the expected products from myrcene would be acetone, formaldehyde, carbon dioxide, and succinic acid, which is in agreement with the experimental results. *cis*-Ocimene (IV) would be expected to yield acetone, formaldehyde, carbon dioxide, and acetic acid, the central fragment (malonic semi- and dialdehyde) being cleaved further (12, 16).

In g.l.c. analysis myrcene overlaps with camphene, sabinene, or β-pinene on non-polar columns, and with 3-carene or α-phellandrene on polar columns (3, 5, 7, 8). Hence the

[2]*Allowing for the impurity being the 2-isomer.*

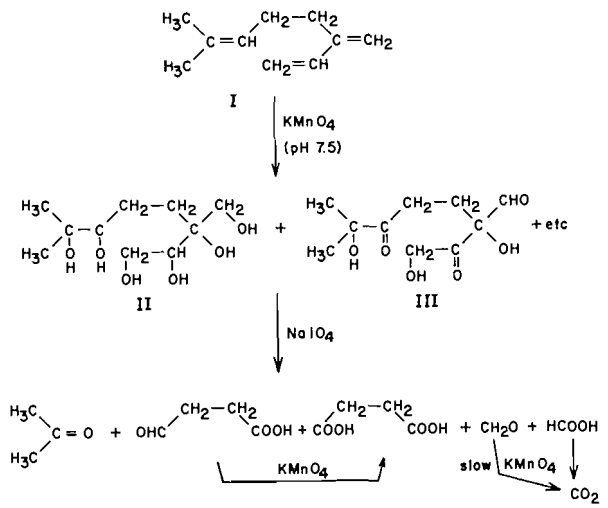

FIG. 1. Permanganate–periodate oxidation of myrcene.

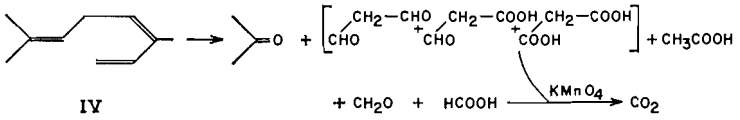
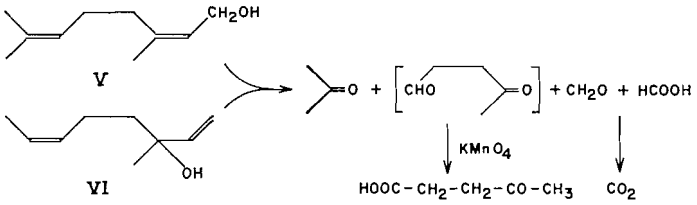
formation of acetone and succinic acid by permanganate–periodate oxidation would confirm the presence of myrcene. Formaldehyde would also be expected from camphene, sabinene, and β-pinene and would have little diagnostic value. *cis*-Ocimene may overlap with limonene, *p*-cymene, 1,8-cineole, and α-terpinene, none of which would be expected to yield acetone in the oxidation. Thus, even qualitative detection of acetone in the oxidation product would have diagnostic value.



The oxygenated aliphatic monoterpenes citronellol, geraniol, nerol, linalool, citronellal, citronellic acid, and linalyl acetate all reacted at a satisfactory rate with the aqueous reagent (see Table II). The rate of reaction of the dienoid compounds was very rapid and precautions against too rapid reduction of permanganate (procedure B-2) was advisable. The amount of oxidant consumed by each of these compounds was in agreement with expected values and in each instance the presumed products were isolated in good yield. Thus geraniol (V*a*), nerol (V*b*) and linalool (VI) gave acetone and levulinic acid as

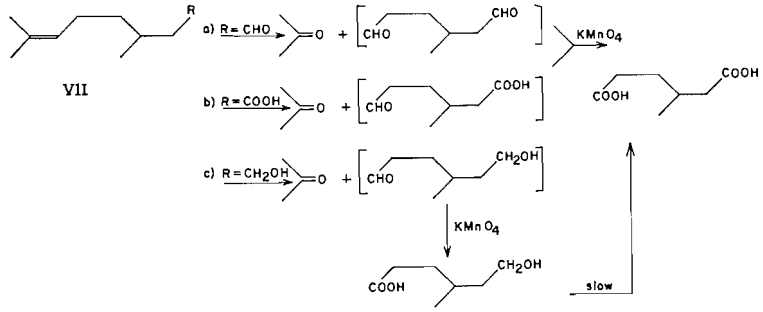


characteristic products. Since methyl ketones are relatively stable towards the oxidant (12), levulinic acid may be presumed to be fairly stable too and the duration of oxidation is not critical. It is noteworthy that the rates of oxidation of geraniol and nerol did not differ significantly. Hence it appears that the reagent does not differentiate between *cis*- and *trans*-isomers, unless steric hindrance is involved (12). In g.l.c. analysis geraniol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

may overlap with bornyl and sabinyl acetate (non-polar columns), neither of which would be expected to yield acetone or an acidic product. Linalool has much lower retention characteristics and tends to overlap with either fenchone or camphor, neither of which is expected to react with the oxidant.

Citronellal (VII*a*) and citronellic acid (VII*b*) were oxidized smoothly to acetone and 3-methyl adipic acid in 6 to 48 h. When citronellol (VII*c*) was oxidized for 4 d, 3-methyl



adipic acid was also obtained, but side reactions became apparent which may detract from the analytical value. Since it was shown previously (12) that primary alcohols reacted only very slowly with the reagent, citronellol was oxidized only for 6 h when 6-hydroxy-4-methyl hexanoic acid and acetone were obtained in excellent yield. 3-Methyl adipic acid was formed only in amounts of 3–5%. 6-Hydroxy-4-methyl hexanoic acid was not obtained previously from citronellol (22), nor does the acid seem to have been prepared by other means. This acid, together with acetone, could serve conveniently for differentiation from borneol, *p*-methan-8-ol, thujyl alcohol, and myrtenol, with which citronellol may overlap.

Finally, linalyl acetate was oxidized to determine if an allylic acetoxy group would be stable. It was already demonstrated that saturated esters were not attacked by the reagent provided the pH was kept at 7.5 or lower (12). The products after 24 h reaction were acetone, formaldehyde, and 2-acetoxy-2-methyl glutaric acid. Hence, this acetoxy group is unaffected by the reagent.

The above results demonstrate clearly that aliphatic terpenes are oxidized by the permanganate–periodate reagent in high yield to predictable end products. These may serve conveniently in the differentiation from the cyclic monoterpenes which may be present in fractions isolated by g.l.c. In this study millimole amounts of the terpenes were oxidized to permit isolation of crystalline derivatives of the characteristic oxidation products. However, the acidic products were also characterized readily by g.l.c. analysis of the methyl esters and acetone and formaldehyde may be detected colorimetrically in very small amounts. Hence for routine analysis of these terpenes milligram amounts will suffice for characterization by permanganate–periodate oxidation. Because of the high yield of characteristic fission products and little, if any, side reaction the method may also be of considerable value in locating the position of ^{14}C-labelled carbon atoms in studies with radioactive compounds. The study is being continued with cyclic terpenes to determine whether equally satisfactory results can be obtained with this group of compounds.

ACKNOWLEDGMENTS

The author wishes to thank Mr. M. Granat for technical assistance and Mr. W. C. Haid for microanalyses and recording of infrared spectra.

THE AMINO PROTON SHIFTS OF SOME SUBSTITUTED ANILINES IN CYCLOHEXANE

T. YONEMOTO,[1] W. F. REYNOLDS,[2] H. M. HUTTON, AND T. SCHAEFER[3]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received May 13, 1965

ABSTRACT

The amino proton shifts of 41 ortho, meta, and para substituted anilines at low concentrations in cyclohexane are reported. The shifts for meta and para substituents correlate with Hammett σ constants and it is shown that they are probably proportional to the π-electron density on the nitrogen atom. These shifts also correlate with the pK_a values of the corresponding anilinium ions in aqueous acid. The amino proton shifts for the ortho substituents, apart from methyl groups, follow a correlation line which lies about 0.5 p.p.m. to low field from that for the meta and para substituents. This negative deviation is discussed in terms of a weak hydrogen bonding interaction with the ortho substituents and the H—N—H bond angles as derived from infrared data.

INTRODUCTION

In recent years, correlations have been noted between Hammett σ constants and the chemical shift of the ring protons in *p*-substituted benzenes (1), formyl protons in *m*- and *p*-substituted benzaldehydes (2), hydroxyl protons in *m*- and *p*-substituted phenols (3), methoxy protons of substituted anisoles (4), and amino protons in *m*- and *p*-substituted anilines (5, 6). The anilines were measured in carbon tetrachloride (5, 6) and acetonitrile (6), where hydrogen bonding between solvent and amino protons is probable (see below).

The ring proton shifts at the para position of substituted benzenes are proportional to the calculated π-electron densities at the carbon atom (7). We report here the amino proton shifts of 41 *o*-, *m*-, and *p*-substituted anilines in cyclohexane solution, where interactions with the solvent are at a minimum, and discuss the results in terms of Hammett σ constants of the substituents, the π-electron density at the nitrogen atom, the pK_a values of the corresponding anilinium ions, and the H—N—H angles derived from high resolution infrared measurements. Low solubility in cyclohexane precluded measurements on a number of compounds, among them the nitroanilines, aminophenols, and *o*- and *p*-phenylenediamines.

EXPERIMENTAL

1. Sample Preparation

Solid anilines were sublimed before use, except for *o*-bromoaniline and *p*-iodoaniline which were recrystallized from cyclohexane. The liquid haloanilines were distilled in vacuum over fresh potassium hydroxide. Spectroscopy-grade cyclohexane was used as a solvent without further purification. As long as solubility allowed, samples of 5, 2, and 1 mole % concentration were prepared by weighing.

2. Spectra

The proton resonance spectrum of the amino group was recorded on a DP60 spectrometer. The solvent resonance peak provided a convenient reference signal, sidebands of which were used to find the shift of the amino proton resonance. The line width of the latter, a broad band due to exchange and relaxation phenomena involving the ^{14}N quadrupole, was usually about 3–5 c/s at 5 mole % and tended to increase with dilution. In some cases the linewidth approached 25 c/s. A dozen recordings were averaged for each solution. The reproducibility of the shifts was about 1 c/s in most cases but for very broad or weak signals it decreased to 3 c/s. The shifts obtained at the three concentrations were extrapolated to infinite dilution. Most of the solutions showed no significant dilution shift in this concentration range. Low solubility in some cases

[1]*National Research Council Postdoctorate Fellow, 1962–1964.*

demanded the use of the shift of the 1 mole % solution only. These are given the superscript *a* in Table I. In other cases large line widths at lower concentrations only allowed the measurement of 2 or 5 mole % solutions. These are given the superscript *b* in Table I.

3. Effect of Purification on Spectra

An investigation of the effect of impurity on the shift was made with aniline solutions. In Fig. 1, line 1 was obtained for aniline distilled in vacuum over potassium hydroxide. Line 2 shows the results for the distilled aniline if the solutions were prepared 1 d after opening the distillation vessel, while line 3 was obtained for undistilled deeply colored aniline. The resonance peaks obtained for the solutions prepared from unpurified aniline were narrower than for purified aniline, probably because of faster proton exchange catalyzed by water or other impurities. For this reason, the error in measurement was larger for the purified aniline solutions. Consequently, although the solutions of unpurified aniline appear to show both a smaller dilution shift and a high-field shift compared to the solutions of purified aniline, the experimental error is such that little was gained by purification.

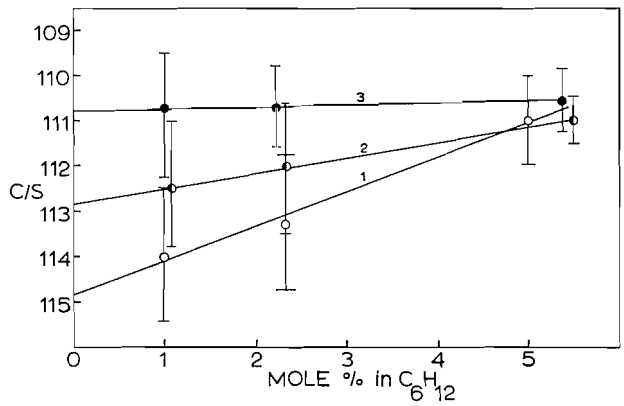

FIG. 1. Line 1 (open circles) shows the chemical shift in c/s to low field from cyclohexane of the amino protons of vacuum-distilled aniline at three concentrations in cyclohexane. Line 2 (half-filled circles) is for aniline which was used one day after vacuum distillation. Line 3 (filled circles) is for unpurified, deeply colored aniline.

RESULTS AND DISCUSSION

In Table I the amino proton shifts, $\Delta\nu$, of 41 *o*-, *m*-, and *p*-substituted anilines are given relative to aniline itself. Prior to the discussion of these shifts in terms of molecular parameters, the state of the aniline molecules in solution must be considered. If our $\Delta\nu$ values represented the true shift at infinite dilution, they would naturally be those of aniline molecules isolated from each other by solvent molecules. Because of signal-to-noise problems, however, the extrapolation to infinite dilution is probably somewhat unreliable.* There may be a substantial, at present undetectable, change in shift between 1 and 0 mole %, especially if self-association through hydrogen bonding occurs.

The intensity of the first overtone of the N—H stretching band of aniline in cyclohexane has been interpreted in terms of hydrogen-bonding association (8). A dimerization model is consistent with the data up to 0.2 *M*. The equilibrium constant for dimer formation is about 0.4 at room temperature (8). For a 0.2 *M* solution, which happens to be about 2 mole %, only about 5% of the aniline molecules are therefore in the form of dimers. On an n.m.r. time scale the dimers will break up and reform rapidly, so that the observed shift represents the weighted average of the monomer and dimer shifts. Unfortunately, the difference in shift between dimer and monomer is not known. However, if we assume

**The viable, if expensive, procedure to follow here would be the use of* ^{15}N *substituted compounds to eliminate quadrupole relaxation broadening and a computer of average transients to allow measurements on very dilute solutions.*

that the substituted anilines have very similar association constants to aniline then the discussions below should still be valid. Certainly, the absortivity–concentration relationships of *m*-methylaniline and *m*-chloroaniline are qualitatively similar to the ones for aniline, although they are somewhat different for *o*-chloroaniline (9). A reasonable expectation is that *o*-substituents would hinder self-association and that self-association through hydrogen bonding leads to low-field shifts. Therefore the observed large low-field shifts for *o*-substituents can also reasonably be discussed in terms of the properties of the isolated molecules, as is done below.

1. Correlation of $\Delta\nu$ with σ Constants

In Fig. 2, $\Delta\nu$ is plotted versus the Hammett σ constants. The effect of more than one substituent is taken as additive (10) and the recent σ values from the analysis of McDaniel and Brown (11) were used when available. For *o*-substituents the σ values derived by Taft (12) were used since these are on the same scale as the Hammett σ values for *m*- and *p*-substituents.

For solubility reasons, the range of σ is only 1.2 units as compared to 1.6 units available in acetonitrile solution (6). Disregarding the *o*-substituents, except for methyl groups, the range of $\Delta\nu$ is very small and we feel there is little to be gained from a least squares treatment. Instead, the dashed line has been drawn as shown in Fig. 2. As expected, the electron-withdrawing substituents (positive σ) lead to a low-field shift. The average deviation for *m*- and *p*-substituents (but including *o*-methyl) is just over 0.03 p.p.m. which is probably within experimental error.

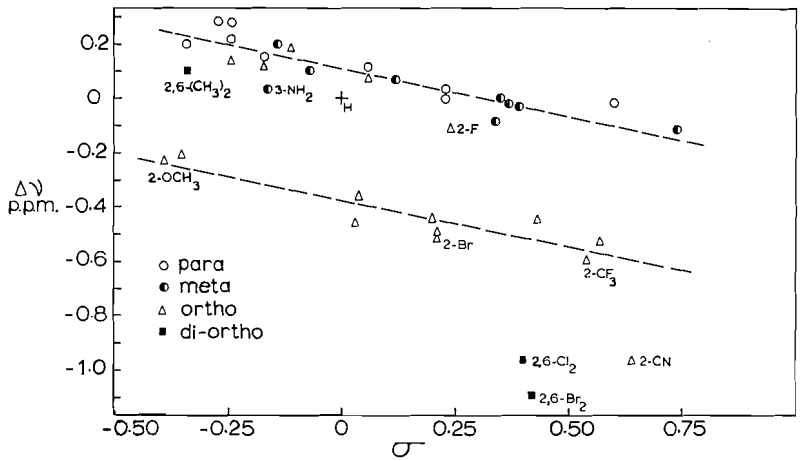

FIG. 2. The chemical shift in p.p.m. relative to aniline of the amino protons in substituted anilines is plotted versus the Hammett σ-constants of the substituents. The unidentified ortho points clustered about the top line are those with methyl groups in the ortho position.

Per unit change in σ, $\Delta\nu$ changes by 0.35 p.p.m. which compares with 0.53 p.p.m. in carbon tetrachloride and 0.97 p.p.m. in acetonitrile solutions (6). The larger values in the latter solutions can be understood in terms of hydrogen bonding to the solvent. As σ increases algebraically the N—H bond increases in acidity, and hydrogen bonding with an acceptor solvent is favored, causing larger shifts. That carbon tetrachloride should hydrogen bond to N—H is perhaps unexpected, yet there is evidence that it does so even to C—H bonds. As an example, proton shifts of many haloalkanes (13) in cyclohexane and carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tetrachloride solution indicate that the latter offers chlorine atoms for hydrogen bonding to the C—H bonds of the solute. Further, it is known that some substituted anilines react rapidly with carbon tetrachloride (14, 15). For the discussion in the next subsection, measurement of amino proton shifts in solvents like cyclohexane is therefore essential.

2. $\Delta\nu$ and π-Electron Density on the Nitrogen Atom

In *p*-substituted benzenes, the *p*-proton shift changes by 1 p.p.m. when the Hammett σ constant changes by 1.4 units (1). For this σ range, the calculated π-electron density on the *p*-carbon atom varies by 0.1 electron (7), indicating a proton shift of about 10 p.p.m./electron. The electron density on the nitrogen atom of substituted anilines is expected to be much less sensitive than the *p*-carbon atom to the influence of a substituent on the ring. Thus, the calculated π-density on the nitrogen atom in *N,N*-dimethylaniline is only 0.007 electrons less than in *N,N*-dimethyl-*p*-anisidine (16). This compares with 0.031 electron more at the *p*-carbon atom in anisole than in benzene (7) (these two calculations used the same bond and core parameters for the oxygen atom in the methoxy group). In this way an approximate estimate may be made of the expected change in $\Delta\nu$ of the amino protons for a change of one unit in σ in the substituted anilines. It is $\Delta\nu \approx 0.007/1.4 \times 0.031 = 0.16$ p.p.m., about half the observed value. However, the N—H bond is much more polarizable than the C—H bond. From chemical shift data, Musher (17) deduces that it is roughly 5/3 more polarizable, leading to a calculated $\Delta\nu$ of 0.27 p.p.m.

The electrostatic field of the excess charge on the nitrogen atom produces a potential difference between the two ends of the N—H bond which drives electrons into the hydrogen 1s orbital. However, the hybridization of the nitrogen atom changes when the ring is substituted (see below) and this will change the excitation energies of the orbitals involved and therefore change any assumed proportionality between π-density and proton shielding.

In view of the approximations and experimental errors involved, it seems reasonable to conclude that the amino proton shift in *m*- and *p*-substituted anilines is primarily dependent on the π-electron density at the nitrogen atom. In this connection, it is interesting to note a shift of the zero point of about 0.08 p.p.m. to high field in Fig. 2. Such a shift also occurs for the proton shifts in *p*-substituted benzenes and is evidence for an additional factor in determining the σ constants. The latter depend on the electronic structure of a reaction intermediate related to the substituted benzoic acids.

3. Correlation of $\Delta\nu$ with pK_a Values

In Fig. 3, $\Delta\nu$ is plotted versus ΔpK_a of the protonated anilines in aqueous acid. The average deviation from the straight line is less than 0.03 p.p.m. However, because of the slight slope of the line a measurement of the amino proton shift in cyclohexane allows the prediction of the pK_a of a substituted aniline with an accuracy of only about ± 0.25 units. For this purpose, it would be better to use a polar solvent like acetonitrile for which the correlation line has a much steeper slope. As in Fig. 2, there is a zero point shift of the correlation line. Also, the point for *m*-aminoaniline shows a rather large negative deviation, a possible result of increased hydrogen bonding for this compound in cyclohexane solution.

The points for *o*-substituted anilines (apart from *o*-fluoro and *o*-methyl anilines) show large negative deviations but they appear to parallel the correlation line for the *m*- and *p*-substituents. The reason for this will become clearer from the discussion below.

4. Ortho-Substituted Anilines

In Fig. 2, the *o*-substituted anilines fall, on an average, about 0.50 p.p.m. below the correlation line for the *m*- and *p*-substituted anilines. Although the scatter is considerable,

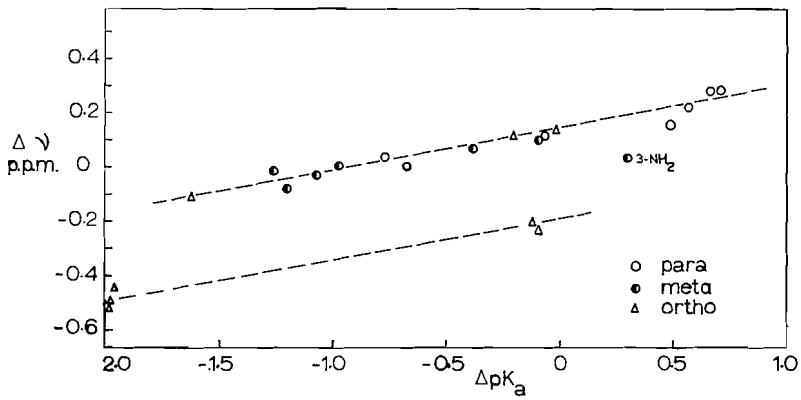

FIG. 3. The chemical shift in p.p.m. relative to aniline of the amino protons in substituted anilines is plotted versus the available ΔpK_a values of the corresponding anilinium ions in aqueous acid; ΔpK_a is relative to the pK_a value of anilinium ion.

we consider that two parallel lines can be drawn, one for *m*- and *p*-substituents and one for the *o*-substituents (with the exceptions of *o*-methyl and *o*-fluoro which are discussed later).

A number of possible reasons for this low-field shift suggest themselves. These are a steric hindrance to π-overlap of the amino group with the ring, the magnetic anisotropy of the substituent (18, 19), the electric field of the substituent dipole (20), and an intramolecular van der Waals or dispersion interaction (21). These will now be discussed in order.

(a) Steric Hindrance to π-Overlap

Electronic absorption spectra (22) and ^{13}C chemical shifts (23) of substituted anilines agree that even bulkier substituents than those under consideration do not cause steric hindrance to π-overlap of the amino group with the ring. In any event, steric hindrance of this nature would lead to high-field shifts of the amino protons since less charge would be delocalized from the amino group into the aromatic nucleus.

(b) Magnetic Anisotropy and Electric Field Effects

We have carried out calculations for both these effects, using the point dipole approximation. The geometry of the system was assumed to be planar with H—N—H angles of 120°, and the mean of the calculated shifts for the two protons was examined. Because of the unfavorable angle between the internuclear vector and the C—X bond, reasonable values of the magnetic anisotropy of the C—X bond lead to quite small shifts (but see the discussion of the cyano group below). In the dipole approximation, the electric field effect of the bond dipole moments (24) dominates. Using the recommended coefficients for the N—H bond (17) in Buckingham's equation (20), low-field shifts are calculated which decrease in the order F > Cl > Br > I, opposite to the observed order of shifts. This is so whether the dipole is placed midway along the C—X bond or on the atom X. We do not reproduce a table of the calculations here since they do not account for the observed shifts.

It is perhaps possible that a judicious choice of anisotropy and bond dipole moments, together with a variation in the location of the dipoles, would lead to agreement with the observed shifts for some of the substituents (see cyano group below). The significance of such an agreement is doubtful. Martin and Dailey (25) point out similar difficulties in accounting for the *o*-proton shifts in substituted benzenes. A further relevant point these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

authors make is that the electric dipole field of the substituent does not contribute significantly to *m*- or *p*-proton chemical shifts in these molecules.

(c) Dispersion Interactions

There is considerable overlap of the van der Waals radii of the amino proton and the heavier halogen substituents. Such an overlap would be expected to lead to low-field shifts of the amino protons because of the fluctuating electric fields arising from the instantaneous dipoles in the halogen atoms (effect proportional to the mean square of these fields (26)). However, the methoxy group causes much the same effect as the heavier halogens and, furthermore, the latter cause nearly the same shift. The similar shielding for bromo and chloro substituents could possibly be rationalized as follows. The hydrogen–iodine distance is so small (about 2.5 Å compared to the sum of the van der Waals radii of $1.2 + 2.15 = 3.35$ Å) that a compensating high-field shift arises from the magnetic anisotropy of the iodine, just as the proton in hydrogen iodide is more shielded than in hydrogen bromide (27). This argument not only serves to show the unreliability of the point dipole approximation in calculating magnetic anisotropy effects at short distances, but also illustrates the tenuousness of any explanation of such low-field shifts in terms of long-range models of electric field and magnetic anisotropy; or dispersion effects. A recent paper from this laboratory (28) concerning the *o*-proton and *o*-fluorine shifts in ethylenes, propylenes, benzenes, and perfluorobenzenes throws some doubt on their explanation in terms of a single one of these effects.

(d) Weak Hydrogen Bonding

It is well known that hydrogen bonding causes a shift to low field of the proton involved. As originally suggested (27) it is probably a combination of the electric field and magnetic anisotropy effects of the proton acceptor. A recent calculation of the shift of the chloroform proton caused by weak hydrogen bonds to nitrogen bases illustrates the difficulties involved in the calculation (27*a*). It turns out that the nitrogen lone pair is responsible for at least 95% of the electric field at the proton in a linear intermolecular hydrogen bond. The point dipole approximation is therefore useless. The calculation also illustrates that the magnetic anisotropy effect is much less than the electric field effect, even for the cyano group.

In our compounds, we consider it most sensible to discuss the ortho shifts qualitatively in terms of an interaction of the N—H bond with the substituent lone pairs, which we prefer to call weak hydrogen bonding as opposed to the strong hydrogen bond found in 2-amino-5-chloro-benzophenone (see below). The plausibility of this approach is supported by the fact that the low-field shift for the *o*-substituents in Fig. 2 increases as σ becomes more positive, i.e., as the N—H bond becomes more acidic its interaction with the substituent increases; as would be expected for hydrogen bonding.

Further support comes from the H—N—H bond angles calculated from the frequencies of the symmetric and antisymmetric stretching bonds of these compounds (14). In Fig. 4, $\Delta\nu$ is plotted versus the H—N—H angle. With the exception of the *o*-trifluoromethyl and *o*-cyano groups (discussed below) there is a roughly parallel change in the expected direction of $\Delta\nu$ with the H—N—H angle. The enhanced H—N—H angle on ortho substitution has been attributed to intramolecular hydrogen bonding (14).

Finally, the splitting of the first overtone of the N—H symmetric stretching band in *o*-substituted anilines has been interpreted in terms of a double-minimum potential for the hydrogen bonded proton (29). This is further support for the above interpretation of the low-field shifts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

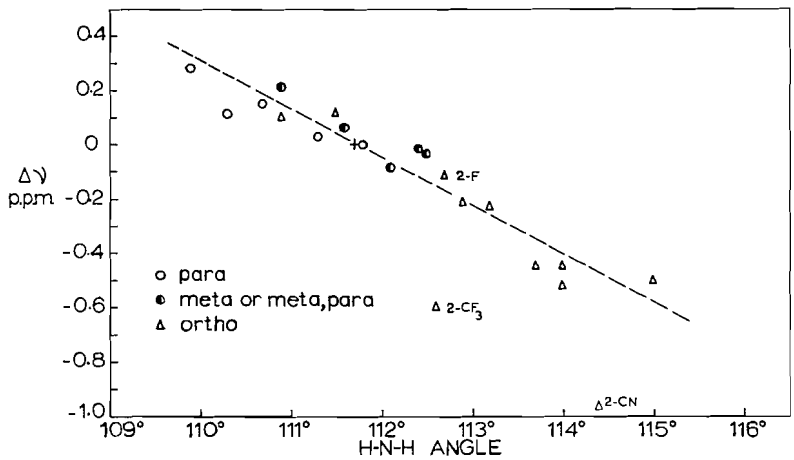

FIG. 4. The chemical shift in p.p.m. relative to aniline of the amino protons in substituted anilines is plotted versus the H—N—H angle derived from the symmetric and antisymmetric stretching frequencies in ref. 14.

From the viewpoint of π-electron density on the nitrogen atom it is important to realize that the range in $\Delta\nu$ of about 1 p.p.m. in Fig. 4 should not be taken as representing a proportionate change in the former. The electron density changes, as discussed above, would be reasonably expected to account only for about 0.3 p.p.m. in $\Delta\nu$. It is true that as the H—N—H angle increases towards 120° the π-overlap between the amino group and the ring will increase but not to the extent that a naive interpretation of the $\Delta\nu$ values would indicate. The *excess* low-field shift for the *o*-substituted anilines is probably caused by the perturbation of the electron density near the proton by the substituent lone pairs.

(e) The o-Fluoro and o-Methyl Substituents

In Fig. 2, the amino proton shift of *o*-fluoroaniline does not deviate far from the straight line. This is to be expected if, as indicated by infrared data (14), the small size of the fluorine atom prevents the close approach of the hydrogen atom to its lone pair orbitals. The amino proton shifts of the compounds containing an *o*-methyl group do not indicate a large anisotropy of the C—C bond (30), unless the anisotropy of the C—H bonds leads to a fortuitous cancellation of the C—C bond anisotropy.

(f) o-Cyanoaniline

In Figs. 2 and 4, the $\Delta\nu$ value deviates strongly to low field from all regular trends. In this particular case, the magnetic anisotropy of the C—X bond is rather large. If an experimental (31) and theoretical value (32) for the triple bond of about 20×10^{-6} cm^3/mole is used, one calculates a low-field shift of about 0.33 p.p.m. for the planar geometry assumed above. This agrees roughly with the excess low-field shifts in Figs. 2 and 4, i.e., from the lines drawn for *o*-substituents in Fig. 2 and the line in Fig. 4.

(g) o-Trifluoromethylaniline

The $\Delta\nu$ value falls roughly on the lower line in Fig. 2. This is not unexpected since the lone pairs of the fluorine atoms are now considerably closer to the hydrogen atom than in *o*-fluoroaniline. In Fig. 4, however, the $\Delta\nu$ value deviates strongly from the expected value. The deviation is easily rationalized in terms of the geometry of the molecule. The interaction of the hydrogen atom and the fluorine atom in the trifluoromethyl group, although stronger than in *o*-fluoroaniline, need not, because of their relative positions lead to an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

enhancement of the H—N—H angle; but the interaction can lead to a considerably increased low-field shift because the lone pairs are now closer to the hydrogen atom.

(h) 2,6-Dichloro- and Dibromoanilines

The low-field shift in these two compounds is roughly twice that of the mono-substituted compounds. This is reasonable in that both amino protons now interact with the substituent, whereas proton exchange leads to an averaging of hydrogen bonded and unbonded shifts for the monosubstituted compounds.

5. Ring Current Shifts

As the H—N—H angle increases the possibility arises of a change in ring current contributions to the amino proton shift (33). To estimate this change we have calculated the ring current contributions to the N—H proton shift for two extreme orientations of the amino group with respect to the plane of the ring: planar, and N—H bonds perpendicular to the ring. Using the procedure recommended by Dailey (34) we find that, at most, the protons in the perpendicular form would be shifted -0.1 p.p.m. relative to protons in the planar form (the adverse angle is more than compensated for by the decrease in ring–proton distance). However, since the H—N—H angle appears to vary between 109° and 115° in our compounds the changes in ring current shifts will amount to less than 0.05 p.p.m., which can be disregarded in our discussion.

6. Strong Hydrogen Bonding

The one compound in Table I expected to form a strong intramolecular hydrogen bond is 2-amino-5-chlorobenzophenone. Here the hydrogen bond to the carbonyl group forms part of a six-membered ring and would be expected to be strong. In agreement, we find a $\Delta\nu$ of -2.65 p.p.m. The H—N—H angle in this compound has not been calculated from the vibrational bands (14), but the splitting of the overtone of the symmetric stretching band has been measured for 2-aminobenzophenone (29). From a plot of this splitting versus H—N—H angle in other compounds we deduce an approximate value of 127° for 2-amino-5-chlorobenzophenone.* From Fig. 4 a predicted shift of 2.50 ± 0.33 p.p.m. follows, assuming the linearity of the plot. It is, however, to be noted that the carbonyl bond and the other ring may contribute to this shift to an unknown extent.

CONCLUSIONS

The small range of the chemical shift of the amino protons of *m*- and *p*-substituted anilines in cyclohexane can be interpreted in terms of small changes in the π-electron density on the nitrogen atom. The much larger shifts in the *o*-substituted anilines are at present best interpreted in terms of weak hydrogen bonding of the amino protons to the substituent. The shifts can be used to predict pK_a values of the anilinium ions but for this purpose it is best to use a polar solvent.

THE PHOTOLYSIS AND THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF HYDROXYLAMINE VAPOR[1]

J. BETTS[2] AND R. A. BACK

Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received April 30, 1965

ABSTRACT

The mercury-photosensitized decomposition (2 537 Å) and the direct photolysis of hydroxylamine vapor have been studied at a pressure of 0.27 Torr, at 25 °C. The mercury-sensitized decomposition followed closely the simple stoichiometry, $3NH_2OH \rightarrow N_2 + NH_3 + 3H_2O$, which strongly suggests an initial decomposition into NH_2 and OH. The direct photolysis was more complex, with N_2, H_2, and H_2O major products, and N_2O and NH_3 minor ones. The mechanism is uncertain, but it seems probable that the major primary process is $NH_2OH + h\nu \rightarrow NH_2O + H$. The absorption spectrum of hydroxylamine vapor was examined, and extinction coefficients determined from 2 250 to 1 600 Å. Absorption was continuous, starting about 2 250 Å, with no structure evident except a broad maximum at about 1 825 Å.

INTRODUCTION

The photolysis of hydroxylamine vapor was studied previously by Smith and Leighton (1) with somewhat inconclusive results, due in part to the accompanying thermal decomposition. The mercury-photosensitized decomposition has apparently never been studied. The present paper describes a re-examination of the photolysis and a first study of the mercury-photosensitized decomposition.

EXPERIMENTAL

Hydroxylamine, prepared by the method of Hurd and Brownstein (2), was stored in the vacuum line at −78 °C and purified as required by repeated sublimation *in vacuo* between traps at 0 and −60 °C until the saturation vapor pressure attained a minimum value. The measurement of the vapor pressure of solid hydroxylamine, and details of the piston pressure gauge used, have been described elsewhere (3).

All experiments were performed in a flow system. Hydroxylamine vapor was supplied from a trap containing the solid held at 0 °C. Flow of reagent and products out of the reaction vessel was controlled by an all-glass needle valve, and was always slow enough that the hydroxylamine vapor reached its saturation pressure at 0°, 0.27 Torr. The reaction vessel was a cylindrical annulus, about 12 cm long, 6 cm o.d. and 4 cm i.d., made of silica. Inside this was sealed another silica tube, forming a thin (5 mm) annular space through which cooling water was circulated, and in the center of this the light source was mounted coaxially. The whole assembly was immersed in a water thermostat at 25 °C. The purpose of this vessel design was to obtain a high light intensity in the reaction vessel so that a reasonable rate of photolysis could be attained even at low pressures of hydroxylamine vapor. Four light sources were used. These were, (*a*) a 200 W Hanovia medium-pressure mercury arc operated normally; (*b*) the same lamp, cooled by a stream of air at 0 °C; (*c*) a 25 W "Spectral" low-pressure zinc lamp (Phillips); and (*d*) a mercury-resonance lamp. Examination of the emission from the cooled medium-pressure arc showed it to consist almost entirely of the 2 537 Å mercury resonance line. The second resonance line at 1 850 Å was effectively removed by absorption by the cooling water. Reaction products were continuously pumped away through the glass needle value. Undecomposed hydroxylamine was trapped at −196 °C and later distilled into a removable trap held at −78 °C. It was estimated spectrophotometrically by oxidation to nitrous acid and formation of an azo dye (4, 5). Occasional attempts were made also to estimate hydrazine using *p*-dimethylaminobenzaldehyde (6) and hydrogen peroxide by complexing with tetravalent titanium (5). The more sensitive oxidation–reduction methods such as iodometry could not be used for hydrogen peroxide because of the large excess of hydroxylamine present (5).

All gaseous products were measured in a gas burette. Hydrogen and nitrogen mixtures were analyzed by combustion of the hydrogen over copper oxide; nitric oxide was isolated at −210°, and nitrous oxide and ammonia, originally trapped at −196°, were separated at −155° in a low-temperature still. It was confirmed by mass spectrometry that there were no other products noncondensable at −78°. No attempt was made to estimate water.

[1]*Issued as N.R.C. No. 8570.*

[2]*National Research Council Postdoctorate Fellow, 1962–1964. Present address: Department of Chemistry, Carleton University, Ottawa, Canada.*

In the mercury-photosensitized decomposition, no special provision was made for introducing mercury, since mercury cutoffs were used in place of greased traps throughout the vacuum system. The mercury-photosensitized reaction between hydrogen and hydroxylamine was also studied in the same apparatus. Hydrogen (Linde, 99.995% pure) was passed through a trap at −196° and allowed to equilibrate to 0° before passage over solid hydroxylamine at 0° and entry into the reaction vessel. Attempts were made to analyze for nitrogen in the large excess of hydrogen present, with rather uncertain results. In most experiments, nitrous oxide and ammonia only were measured.

The ultraviolet absorption spectrum of hydroxylamine vapor had been briefly examined by Smith and Leighton (1) at wavelengths above 2 000 Å; extinction coefficients were not reported. We therefore measured extinction coefficients for the vapor at wavelengths from 1 575 to 2 250 Å, using a silica cell, 22 cm long, attached to a McPherson 0.5 m vacuum grating monochromator equipped with a photomultiplier detector. A continuous flow of vapor through the cell was maintained during the measurement to prevent accumulation of decomposition products.

RESULTS

The Absorption Spectrum

The absorption spectrum of hydroxylamine vapor, measured at pressures of 0.254 and 1.1 Torr, is shown in Fig. 1. Data at the two pressures are in good agreement; the higher-pressure data are the more accurate at longer wavelengths. Absorption in the quartz windows of the cell prevented measurements much below 1 600 Å. No structure was evident at the resolution employed (~10 Å) other than the broad maximum around 1 825 Å, which probably corresponds to dissociative excitation of the lowest excited singlet state. A second dissociative process appears to be setting in at about 1 700 Å. The effective light in the present photolysis experiments was in the long-wavelength shoulder of the broad maximum. The effective emission of the zinc lamp consisted of three lines at 2 139, 2 062, and 2 025 Å, with relative intensities of 9, 1, and 1. These lines should have contributed to the photolysis approximately in the ratio 9/3/5, taking into account the absorption spectrum of the vapor. The effective light from the medium-pressure mercury arc was largely continuous emission with a few lines superimposed, extending from about 2 250 to 1 900 Å.

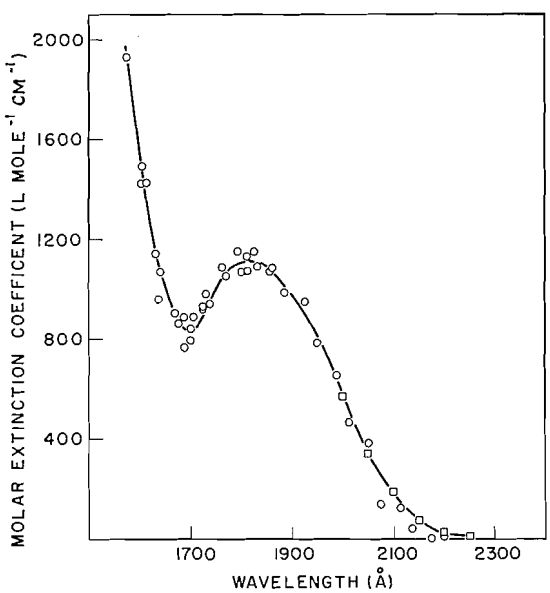

FIG. 1. The absorption spectrum of hydroxylamine vapor: ○ = 0.254 Torr, □ = 1.1 Torr.

The Thermal Decomposition

Some data for the thermal decomposition of hydroxylamine vapor at 0.27 Torr pressure and 25 °C, obtained over a period of 4 months, are shown in Table I. The hydrazine yields are too small to be reliable, and the yields of all products show considerable scatter and no particular trends with flowrate. The addition of nitrogen at atmospheric pressure reduced the combined yields of N_2O and NH_3 about threefold, but lowering the temperature to 5 °C had little effect. At higher hydroxylamine pressures the thermal decomposition was greatly enhanced, as observed previously (1). These observations point to a surface reaction.

‡Average of 3 experiments.
§Average of 2 experiments.

To minimize thermal decomposition, all photochemical experiments were carried out at low pressure, 0.27 Torr, and 25 °C, with the reservoir of solid hydroxylamine held at 0 °C. All photochemical product yields have been corrected for the thermal reaction by simple subtraction of yields from "blank" experiments done shortly before each photolysis. This is a small correction for major products, but a very large and uncertain one for minor ones; this accounts for the negative yields of NO in Table II.

The Direct Photolysis

Product yields and ratios for the direct photolysis are shown in Table II. All experiments were of 1 h duration; the % conversion was varied by varying the flowrate of hydroxylamine and products out of the reaction vessel. Some of the data of Smith and Leighton (1) are also shown for comparison.

The Mercury-Photosensitized Decomposition

Product yields from the mercury-photosensitized decomposition, studied under conditions similar to those of the direct photolysis, are shown in Table III. In both Tables II and III, the varying rates of consumption of NH_2OH (third column) reflect differences in the light intensity, which depended on the light source employed, its age, and its operating conditions.

DISCUSSION

The most notable feature of the present results is the marked difference between the direct photolysis (Table II) and the mercury-photosensitized decomposition (Table III). Hydrogen was a major product in the former, together with lesser amounts of N_2O and NH_3; in the mercury-sensitized decomposition, H_2 and N_2O were very minor products, and NH_3 a major one. From the elemental balance of the products in both systems, water was deduced to be a probable major product.

*Data treated as in Table II.
†All experiments of 1 h duration, at 0.27 Torr pressure and 25 °C.

Rates of decomposition, % conversion, and other conditions were similar in the two systems, and it may be argued rigorously that the different product distributions must reflect different modes of primary dissociation of NH_2OH. The mercury-photosensitized reaction followed to a good approximation the very simple stoichiometry,

[1] $$3NH_2OH \rightarrow N_2 + NH_3 + 3H_2O,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with no significant trends over a 36-fold change in the rate of decomposition and for conversions ranging from 0.7 to 37% (Table III). The following mechanism seems the most probable one.

[2] $$Hg\ 6(^3P_1) + NH_2OH \rightarrow NH_2 + OH + Hg\ 6(^1S_0)$$

[3] $$NH_2 + NH_2OH \rightarrow NH_3 + NHOH$$

[4] $$OH + NH_2OH \rightarrow H_2O + NHOH$$

[5] $$2NHOH \rightarrow N_2 + 2H_2O$$

Smith and Leighton (1) suggested that the direct photolysis proceeded by a primary dissociation into NH_2 and OH, followed by a complex sequence of reactions leading to the observed products. Our mechanism for the mercury-photosensitized decomposition, starting from the same primary dissociation, differs chiefly in the inclusion of the abstraction reactions [3] and [4] which Smith and Leighton apparently considered much too slow to be of importance, probably because they overestimated the strengths of the N—H and O—H bonds in NH_2OH (1). It is well established now that the N—H and O—H bonds in hydrazine, hydrogen peroxide, and probably thus in hydroxylamine, are relatively weak, and abstraction of hydrogen from these compounds is very fast (7, 8, 9). One might still question whether reactions [3] and [4] would have proceeded quantitatively in the present systems with the pressure of NH_2OH of 0.27 Torr. The lack of appreciable yields of N_2H_4 or H_2O_2 over a wide range of intensities and conversions suggests that these reactions were quantitative, although the sensitivity of the analysis for these products was not high.

In reactions [3] and [4], it is suggested that abstraction occurred from the nitrogen rather than from the oxygen atom, partly because the N—H bond is probably weaker, and partly because the resulting NHOH radicals seem more likely to combine simply to N_2 and $2H_2O$ (reaction [5]) as required.

The stoichiometry of the direct photoly : was considerably more complex than that of the mercury-sensitized reaction, with N_2, H_2, and H_2O major products, and appreciable yields of N_2O and NH_3 (Table II). Our results are in fair agreement with those of Smith and Leighton; their % yields of H_2 and N_2O were appreciably higher and that of ammonia lower, although the ammonia analysis was badly scattered, both in the earlier and the present work, reflecting the difficulty in analyzing small amounts of this product (Table II). The conversions attained by Smith and Leighton were much higher than in the present experiments, and it is possible that secondary photolysis of ammonia was occurring and could account for their lower yields of ammonia and higher yields of hydrogen, although there are no significant trends with conversion either in their work or ours. Light intensities employed by Smith and Leighton, reflected in column 2, Table II, were generally much higher than in the present work, although there is some overlap, and this may also have had some effect on the product distribution.

If reactions [2] to [5] represent the mercury photosensitized decomposition, the following mechanism would appear to account for the products observed in the direct photolysis and for the differences between the two systems,

[6] $$NH_2OH + h\nu \rightarrow NHOH + H$$

[7] $$H + NH_2OH \rightarrow NHOH + H_2,$$

followed by reaction [5.] To account for the production of ammonia, and the observation that $N_2 > H_2$, the simplest explanation is the occurrence to the extent of about 40% of a second primary process,

[8] $$NH_2OH + h\nu \rightarrow NH_2 + OH,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

followed by reactions [3], [4], and [5]. The primary process in the photolysis of H_2O_2 vapor is almost certainly a split into 2OH (10, 11) while that of N_2H_4 is probably rupture of an N—H bond (12, 13, 14); it is not unreasonable that NH_2OH might show primary processes analogous to each of these modes of photolysis.

The source of the N_2O observed is not clear. Smith and Leighton suggested that it came from a reaction between H_2O_2 and NH_2OH which they showed to occur readily, with H_2O_2 arising from OH combination or by reaction of OH with NH_2OH. The lack of dependence of % N_2O on light intensity and other considerations indicate that this is not a likely source of N_2O in the photolysis. The reaction,

[9] $$2HNO \rightarrow H_2O + N_2O,$$

has been suggested as a source of N_2O in several systems (15, 16), and it is possible that HNO radicals could have arisen in the present experiments by disproportionation reactions such as

[10] $$2NHOH \rightarrow NH_2OH + HNO$$

Then, however, N_2O should have been formed equally in the direct photolysis and in the mercury-sensitized reaction, which it was not. This suggests that the primary photolysis reaction might have been

[11] $$NH_2OH + h\nu \rightarrow NH_2O + H$$

rather than reaction [6]. The NH_2O radical might be much more prone to disproportionate than NHOH,

[12] $$NH_2O + NH_2O \text{ (or NHOH)} \rightarrow HNO + NH_2OH,$$

and this would explain the production of much more N_2O in the direct photolysis than in the mercury-sensitized reaction. In considering the formation of HNO in a disproportionation reaction, it may be noted that NH_2O is isoelectronic with CH_3O, which disproportionates very readily.

Another possible source of HNO and hydrogen might be the primary process

[13] $$NH_2OH + h\nu \rightarrow HNO \text{ (or NOH)} + H_2$$

by analogy with the photolysis of ethane which yields ethylidene and H_2 (17); there is no proof for or against this possibility.

Evidence against the role of HNO as a precursor of nitrous oxide is the virtual absence of nitric oxide, which one might expect to arise from disproportionation of HNO with other radicals in the system:

[14] $$R + HNO \rightarrow RH + NO.$$

In view of this, direct formation of nitrous oxide from NH_2O radicals is perhaps more probable:

[15] $$NH_2O + NHOH \text{ (or } NH_2O) \rightarrow N_2O + H_2O + H_2.$$

The NH_2O radical would be more likely to undergo this reaction than would NHOH, and if it were formed by reaction [11] in the direct photolysis, the absence of N_2O (and H_2) in the mercury-sensitized reaction would be accounted for.

An alternative possible source of ammonia in the photolysis is the cracking reaction,

[16] $$H + HNOH \rightarrow [NH_2OH]^* \rightarrow NH_2 + OH,$$

followed by reactions [3] and [4]. Such a reaction would be favored at the low pressures used in the present experiments. If it occurred, it would be favored at high intensity at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the expense of reaction [7], so that H_2 would decrease and NH_3 increase with increasing intensity; this was not observed, and reaction [16] may probably be ruled out.

The mercury-photosensitized reaction of hydrogen with hydroxylamine vapor yielded NH_3, N_2O, and N_2 in amounts comparable to the sensitized decomposition of pure NH_2OH, with product ratios roughly independent of hydrogen pressure from 50 to 700 Torr. Nitrogen analysis in the large excess of hydrogen was very uncertain, while the N_2O and NH_3 yields were also considerably scattered. Quenching of Hg $6(^3P_1)$ should have been almost exclusively by hydrogen, generating hydrogen atoms, and the observed decomposition of hydroxylamine confirms that hydrogen atoms reacted rapidly with NH_2OH even at a pressure of the latter of 0.27 Torr. Incomplete and uncertain product analysis (H_2 could not be measured) and uncertainty about the efficiency of quenching of Hg $6(^3P_1)$ in pure hydroxylamine vapor prevent any firm conclusions about the mode of formation of the observed products.

In summary, it appears probable that the mercury-photosensitized decomposition of hydroxylamine vapor proceeds via reactions [2] to [5]. The mechanism of the direct photolysis is less certain, but probably includes primary processes [8] and [11] with secondary reactions [3], [4], [5], [7], and [15]. The thermal instability of the vapor even at low pressure is a formidable obstacle to the more precise kinetic studies that would be needed to confirm or disprove the suggested mechanisms.

PYRIDINE N-OXIDE COMPLEX OF TITANYL PERCHLORATE

V. KRISHNAN AND C. C. PATEL
Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore, India
Received April 13, 1965

ABSTRACT

Pentakispyridine N-oxide oxotitanium(IV) perchlorate, $TiO.5C_5H_5NO.(ClO_4)_2$, has been prepared and its physicochemical properties investigated. The infrared and electronic spectra show that pyridine N-oxide is bonded to the metal ion through oxygen of the N—O. The complex explodes at 215 °C, a temperature slightly above the starting decomposition temperature of titanyl perchlorate, $TiO(ClO_4)_2.3H_2O$.

INTRODUCTION

Recently Ramamurthy and Patel (1, and references therein) prepared pyridine N-oxide complexes of zirconyl, thorium, and uranyl perchlorates and studied their infrared and electronic spectra. But the corresponding titanyl perchlorate complex has not been studied before. Pyridine N-oxide complex of titanyl perchlorate has therefore been prepared and its properties investigated and compared with those of zirconyl complex.

EXPERIMENTAL

Materials Employed

Pyridine N-oxide was prepared by the oxidation of pyridine with hydrogen peroxide in glacial acetic acid medium as described by Ochiai (2). Titanyl perchlorate hexahydrate, $TiO(ClO_4)_2.6H_2O$, was prepared by the reaction of titanium tetrachloride with perchloric acid (3).

Preparation of the Complex

When pyridine N-oxide (3 g) solution in anhydrous ethanol is added to an agitated ethanolic solution of titanyl perchlorate (1 g) at 25 °C a white complex is precipitated. The complex is washed free of pyridine N-oxide with anhydrous ethanol and dried in vacuum over phosphorus pentoxide. The complex was analyzed for titanium by decomposing it by boiling with concentrated nitric acid, precipitating the titanium as hydroxide, and igniting the precipitate to the dioxide. Perchlorate was estimated by the Kurz's method (4) and nitrogen by Duma's semimicro method. The experimental values for titanium, perchlorate, and nitrogen were 6.54, 26.72, and 9.02% while the corresponding values for $TiO.5C_5H_5NO.(ClO_4)_2$ are 6.46, 26.86, and 9.45% respectively.

Properties

The complex is slightly hygroscopic, soluble in water and acetonitrile, and insoluble in nonpolar solvents. The complex is found to explode at 215 °C.

Infrared and Electronic Absorption Spectral Studies

The infrared spectrum of the complex was taken in Nujol mull with a Perkin–Elmer single beam infrared spectrometer, model 112, equipped with sodium chloride optics. The spectrum is given in Fig. 1. The electronic absorption spectrum of the complex in pure dry acetonitrile was taken with a Hilger Uvispeck spectrophotometer, model H 700, using 1 cm matched pair quartz cells. The spectrum is given in Fig. 2.

DISCUSSION

The titanyl complex explodes at 215 °C whereas titanyl perchlorate (5) starts decomposing at 190 °C. This shows that the perchlorate is somewhat thermally stabilized on complex formation. The thermal stabilizing effect on complex formation is also found in pyridine N-oxide complexes of zirconyl and thorium perchlorates (1). Their explosion temperatures are 307 and 350 °C whereas the corresponding perchlorates start decomposing at 275 and 290 °C respectively (6).

The infrared spectrum of $TiO.5C_5H_5NO(ClO_4)_2$ is very similar to that of the zirconyl complex. In these complexes perchlorate retains its T_d symmetry as shown by the ν_3

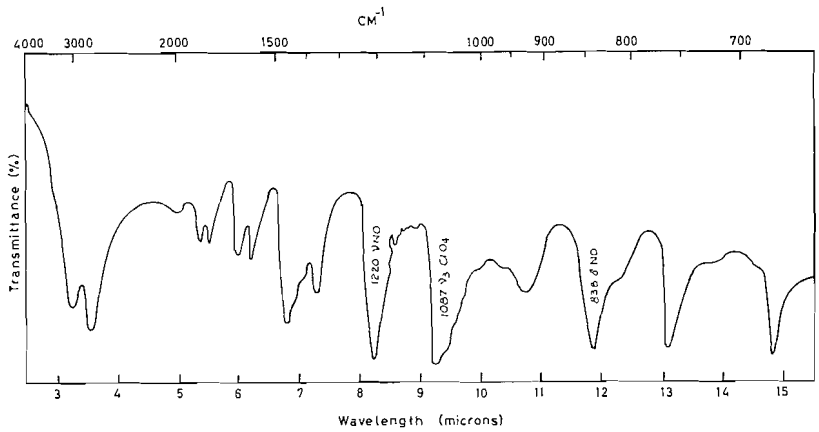

FIG. 1. Infrared absorption spectrum of $TiO.5(C_5H_5NO)(ClO_4)_2$.

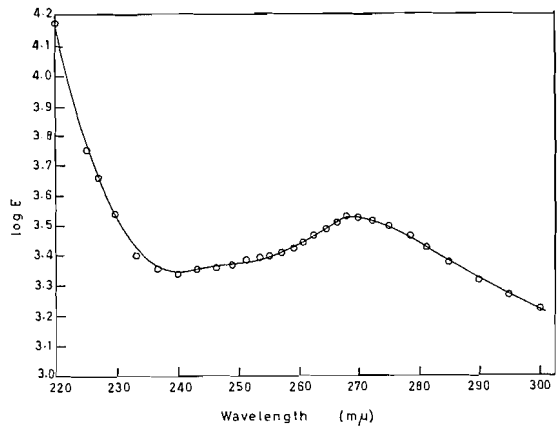

FIG. 2. Electronic absorption spectrum of $TiO.5(C_5H_5NO)(ClO_4)_2$ in acetonitrile.

band at 1 085 cm^{-1} and the nonappearance of the ν_1 band around 930 cm^{-1}. All the pyridine N-oxide vibrations also occur at more or less the same frequencies in the two complexes. The N—O stretching frequency which occurs at 1 265 cm^{-1} in pyridine N-oxide (7) has been lowered to 1 220 cm^{-1} in the titanyl complex. This lowering of the N—O stretching is due to the reduction in π-bond character of N—O as a result of complex formation by the donation of a lone pair of electrons from oxygen of N—O to the metal ion. In the zirconyl complex, the N—O stretching frequency occurs at 1 222 cm^{-1}. The NO frequency difference in these two complexes is so small that it is difficult to draw any conclusion on the bond strength between the metal and pyridine N-oxide in the two complexes. However, the small shift from 1 220 cm^{-1} in the titanyl complex to 1 222 cm^{-1} in the zirconyl complex may be due to the slight decrease in the bond strength of M—ON< from the titanium to the zirconium complex. The N—O bending in the titanyl and zirconyl complexes occurs around 840 cm^{-1}. Thus, practically there is no shift in N—O bending frequency (840 cm^{-1}) (7) on complex formation. This may be due to the two opposing effects: the coordination which raises the N—O bending frequency, and the lowering of the π-bond character which tends to lower the frequency almost to the same extent.

The electronic absorption spectrum of the complex gives a strong band at 268 mμ and also shows another band below 210 mμ, as indicated by the increasing absorption from 220 mμ to the lower wavelength. The electronic absorption spectrum of pyridine N-oxide gives two bands, one intense band at 280 mμ, arising from the $\pi-\pi^*$ transition and a weak band at 320 mμ arising from the $n-\pi^*$ transition of the N—O group (8). The $n-\pi^*$ band has disappeared in the complex due to the stabilization of the non-bonded p-electrons on complex formation. The $\pi-\pi^*$ band of pyridine N-oxide has shifted towards lower wavelength in the complex as a result of the complex formation. The zirconyl complex gives an absorption band at 276 mμ while titanyl complex gives a band at 268 mμ. Thus the hypsochromic shift of the $\pi-\pi^*$ band is greater in the titanyl complex showing stronger bond formation between oxo-titanium and oxygen of $\rangle$NO than that between oxo-zirconium and $\rangle$NO. This is expected considering the smaller cationic size of oxo-titanium ion as compared to the oxo-zirconium ion. This general trend is indicated by a very small shift of N—O stretching frequencies both in the titanyl and zirconyl complexes, where the N—O frequencies occur at 1 220 and 1 222 cm^{-1} respectively.

Titanyl takes five molecules of pyridine N-oxide ligands, thus giving six-coordination to titanium. This suggests d^2sp^3 hybridization with distorted octahedral configuration.

ACKNOWLEDGMENT

The authors' thanks are due to Prof. M. R. A. Rao for his keen interest in the work.

THERMODYNAMIC FUNCTIONS OF THE PARTIALLY DEUTERATED METHYL HALIDES AS ANHARMONIC OSCILLATORS

JOHN R. RITER, JR. AND MARVIN C. GOLDBERG[1]
Department of Chemistry, University of Denver, Denver, Colorado

Received May 4, 1965

ABSTRACT

By determination of the diagonal anharmonic constants x_{ii} in the expression for vibrational terms as a power series in the vibrational quantum numbers, the rigid-rotor anharmonic oscillator thermodynamic functions of the eight partially deuterated methyl halides (CH_2DX and CHD_2X, X = F, Cl, Br, I) have been computed. The effects of omission of the cross terms x_{ij} is discussed. From the computed x_{ii}, the calculated positions of 23 combination bands were found to have a mean deviation of 0.3% above the observed values, and the calculated positions of 11 first overtone bands had a mean deviation of 2.7% below the corresponding observed values. Tables of $-(F^0 - E_0^0)/RT$, $(H^0 - E_0^0)/RT$, S^0/R, and C_p^0/R for the anharmonic case and C_p^0/R for the harmonic case at 100 deg intervals between 100 and 1 500 °K, and thence in 500 deg intervals to 3 000 °K, have been made available. Tables of observed fundamental frequencies, anharmonicity constants x_{ii}, and moments of inertia for all molecules are included. A comparison of differences in each of the four thermodynamic functions for the anharmonic and harmonic cases is given for 1 000 and 3 000 °K. The maximum differences in C_p^0 and S^0 occur for CHD_2Cl and amount to 0.50 and 2.08 (C_p^0), and 0.10 and 0.36 (S^0) cal/mole deg at 1 000 and 3 000 °K respectively, with the anharmonic values always larger.

INTRODUCTION

Departures of real molecules from the rigid-rotor harmonic-oscillator model, used for thermodynamic function calculations, have long been of interest. One of the chief corrections to this model is the anharmonicity of the vibrational motion, i.e. the set of anharmonic constants x_{ij} defined by the equation for vibrational terms as a power series in the quantum numbers v_i

$$[1] \qquad \frac{W}{hc}(v_1, v_2, v_3, \ldots) = \sum_i \omega_i(v_i + \tfrac{1}{2}) + \sum_{i \geqslant j} \sum_j x_{ij}(v_i + \tfrac{1}{2})(v_j + \tfrac{1}{2}) + \ldots$$

with the ω_i the harmonic fundamental frequencies. The evaluation of these anharmonic constants from the vibrational spectra is of course a very formidable task. We have taken the known spectral assignments (1) of each of the partially deuterated methyl halides (PDMH), and from normal coordinate treatments for the series CH_3X, CH_2DX, CHD_2X, CD_3X (1) have deduced a relation for the quadratic constants x_{ii}. The cross term constants x_{ij}, as well as higher terms x_{ijk}, have been assumed to be zero. Using the formulation of Pennington and Kobe (2) we have computed thermodynamic functions for the eight PDMH as rigid-rotor anharmonic oscillators.

ANHARMONIC CONSTANTS x_{ij}

The "single mode" anharmonicity

$$[2] \qquad x_i = 1 - (\nu_i/\omega_i)$$

with ν_i the observed (anharmonic) fundamental, was introduced by Hansen and Dennison in work on the system C_2H_6–C_2D_6 (3). The x_i's for CH_3X and CD_3X were determined by King, Mills, and Crawford (4) and for the PDMH as a part of the above-mentioned normal coordinate analysis (5).

[1]*Present address: U.S. Geological Survey, Denver Federal Center, Denver, Colorado.*

Taking x_{ij} to be zero, which is surely an assumption of convenience (see also the discussion under Conclusions), we find

[3] $$x_{ii} = -\omega_i x_i/2.$$

In this approximation then the combination bands should have frequencies that are the sums of the fundamentals, while the frequency of the nth harmonic ($(n-1)$st overtone) should be given by

[4] $$\nu_i(n) = n\nu_i + (n^2 - n)x_{ii}.$$

That the implication of eq. [3] of strict additivity for sum bands is quite a good one is borne out by comparison of the observed positions of 23 assigned binary sums for the PDMH (1); the mean deviation is 0.3% with three-fourths of the calculated values higher than the observed. For the 11 first overtone bands assigned (1) the mean deviation is 2.7% with the calculated values too low in every case but one. Hence the above expression, eq. [4], overcorrects for overtone anharmonicity. Table I lists the observed fundamentals ν_i and anharmonicity constants x_{ii} for the PDMH.

CALCULATION OF THERMODYNAMIC FUNCTIONS

By the method of ref. 2, the partition function can be written as a product of translational, rigid-rotor, harmonic-oscillator, and anharmonic correction terms. See especially eqs. [1], [9], and [20]. The moments of inertia used are given in Table II. The calculation of the free energy and enthalpy functions, entropies, and heat capacities for both harmonic and anharmonic oscillators was performed on the IBM 709 at the University of Colorado. Thirty temperatures were chosen in the interval from 100 to 3 000 °K, plus 273 and 298 °K. The higher temperatures were not chosen to provide meaningful thermodynamic data, but rather to follow the deviations from the harmonic model caused by the introduction of anharmonicity. Condensed results for the anharmonic case together with C_p^0 for the

CH_2DI	3000	0.26	0.42	0.16	0.97
CHD_2I	3000	0.21	0.33	0.12	0.76

CONCLUSIONS

Table III shows the difference in the dimensionless free energy and enthalpy functions, entropies, and heat capacities for anharmonic and harmonic oscillators at 1 000 and 3 000 °K. The heat capacity, which is essentially the second temperature derivative of the logarithm of the vibrational partition function, is the quantity most sensitive to anharmonic corrections. Note that even at 1 000 °K the anharmonic C_p^0 for CHD_2Cl exceeds the harmonic value by 0.50 cal/mole deg. The maximum deviation in S^0 at 1 000 °K is 0.10 e.u. (entropy units), also for CHD_2Cl.

The neglect of quadratic cross terms x_{ij} is certainly suspect. For example Table IV presents the results of Arakawa and Nielsen (8) for anharmonicity factors in $^{14}NO_2$. Note that x_{11} and x_{12} are about the same size, with x_{13} bigger by a factor of three. Similarly, x_{23} is about five times as big as x_{22}. The consistently low predictions of the first overtone positions in the PDMH is additional evidence there are serious shortcomings in this method.

TABLE IV

Anharmonicity constants in $^{14}NO_2$ (data of ref. 8)

x_{11}	x_{12}	x_{13}	x_{22}	x_{23}	x_{33}
−9.0	−9.7	−28.7	−0.5	−2.7	−16.4

Yet with the number of overtone and sum bands available generally far less than the number required to fix all the x_{ij}, and lacking other information such as transferable constants from isotopic or other related molecules, one feels in general he is on the right track by giving first preference to the diagonal terms.

The method described herein is presented as an attempt to systematically apply meaningful anharmonicity corrections to thermodynamic function calculations for molecules of this size.

ACKNOWLEDGMENT

The authors wish to thank Dr. Walter Macintyre, director of the Computing Center at the University of Colorado, for a grant of computer time.

X-RAY STUDY OF LIQUID $AsBr_3$

R. HOGE AND J. TROTTER
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received May 4, 1965

ABSTRACT

The structure of liquid arsenic tribromide has been investigated by deriving the radial distribution function from X-ray intensity data recorded with monochromatic Cu K_α radiation. The results are consistent with pyramidal molecules with dimensions similar to those in the vapor and solid states. Most of the intermolecular distances in the crystal are preserved in the liquid.

INTRODUCTION

Methods for examining the structures of liquids by X-ray diffraction are well established (1); the object of this investigation was to examine whether significant results could be obtained using counter intensity measurements, with monochromatization of the radiation by pulse height discrimination and balanced filters. Arsenic tribromide was chosen for the study since it has a suitably low melting point, and its structure is known in both solid and vapor states (2, 3).

EXPERIMENTAL

Arsenic tribromide is a colorless crystalline solid at room temperature, it is quite volatile, and is hydrolyzed by water. The molecular weight is 314.7, the melting point is 32.8 °C, and the density of the liquid is 3.54 g cm^{-3}. A sample was sealed in a thin-walled Lindemann glass capillary (diameter 0.5 mm, wall thickness 0.01 mm), and maintained at 75 °C in a stream of warm air.

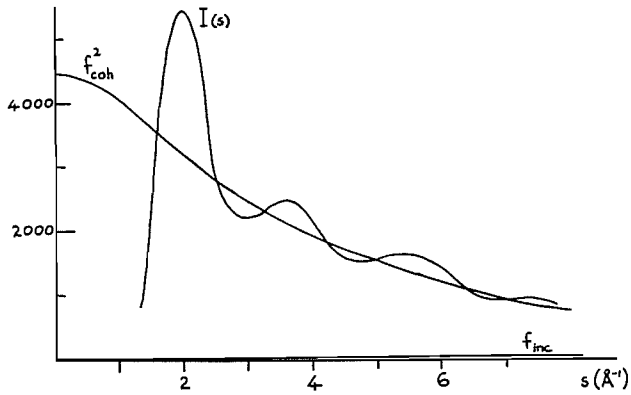

FIG. 1. Corrected and scaled experimental scattering, and independent coherent and incoherent scattering

The diffraction pattern was recorded on a General Electric XRD-5 Spectrogoniometer, with Cu K_α radiation and a scintillation counter. Partial monochromatization was achieved by use of a pulse height analyzer; since the scintillation counter has a rather wide pulse height distribution, further monochromatization was accomplished with Ross balanced filters (0.0100 mm nickel foil and 0.0108 mm cobalt foil (4)). The best experimental arrangement was one with the balanced filters between the X-ray source and the sample (to minimize fluorescence from the cobalt filter reaching the detector) and a nickel filter between the sample and the detector (to absorb fluorescence from the specimen). The pattern was recorded in the range $2° < 2\theta(\text{Cu } K_\alpha) < 148°$, corresponding to a maximum value of $s(= 4\pi \sin\theta/\lambda)$ of 7.8 $Å^{-1}$, with a scan speed of 2° per minute. The scattered intensity was corrected for diffraction by the glass container, for polarization, and for absorption (cylindrical specimen, $\mu R = 8.5$). The corrected experimental scattering, $I(s)$, was then brought to an absolute scale by equating $\sum s^2.I(s)$ and $\sum s^2(\sum f_{coh}^2 + \sum f_{inc})$ in the range $s = 3.0$ to 7.8. $\sum f_{coh}^2$ and $\sum f_{inc}$ are the independent atomic coherent and incoherent scattering

for one $AsBr_3$ molecule. The corrected and scaled experimental scattering is shown in Fig. 1. The function $s.i(s) = (I(s) - \sum f_{coh}^2 - \sum f_{inc})/\sum f_{coh}^2$ was then computed (Fig. 2) and the integral $\int_0^{17.8} s.i(s) \sin rs.ds$ was evaluated for $r = 0.0$ to 10.0 Å in steps of 0.1 Å, the integration being carried out numerically with an interval in s of 0.01 $Å^{-1}$. The resulting radial distribution function $4\pi r^2\rho(r) = 4\pi r^2\rho_o(\sum Z_j) + (\sum Z_j^2)(2r/\pi)$ (integral), is shown in Fig. 3.

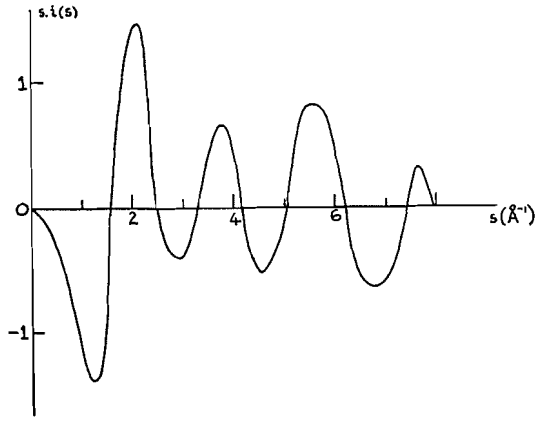

FIG. 2. $s.i(s)$ function.

The diffraction pattern was measured at s values up to 17.0 $Å^{-1}$ using Mo K_α radiation (zirconium/yttrium balanced filter pair). The less favorable peak-to-background of the molybdenum radiation resulted in poorer patterns than for Cu K_α radiation, and no significant fluctuations in the scattered intensity were found at the higher angles.

DISCUSSION

The radial distribution function for liquid arsenic tribromide (Fig. 3) exhibits two very small maxima at about 0.5 Å and 1.5 Å; the small size of these spurious fluctuations gives confidence that the experimental data is reasonably accurate, and the radial distribution function quite reliable. The remainder of the distribution can be interpreted in terms of the presence of pyramidal $AsBr_3$ molecules. The first significant feature is a well-defined maximum at 2.55 Å, corresponding to the As—Br intramolecular distance. A second peak at 3.7 Å probably contains the Br ··· Br intramolecular distances and the shorter intermolecular contacts, and a third peak at 4.4 Å corresponds to further intermolecular separations.

These conclusions can be verified by using the area under the radial distribution curve to calculate the number of distances responsible for each peak. The area under the first peak is 7 100 electrons². One As—Br pair within each molecule contributes $2K_{As}K_{Br}$ to the area, K being the effective number of electrons in an atom (approximately equal to the atomic number). This product is 2 310 electrons², so that the area under the peak at 2.55 Å is caused by 3.1 such pairs in each molecule, that is each arsenic atom is bonded to *three* bromine atoms.

The area under the peak at 3.7 Å (derived by making the maximum symmetrical about 3.7 Å, Fig. 3) is 41 300 electrons². The Br ··· Br intramolecular distances are certainly contained in this peak, and contribute $3 \times 2K_{Br}^2 = 7\,350$ electrons², leaving a further 34 000 electrons² due to intermolecular distances. Each of these intermolecular distances contributes K_mK_n (m, n = As, Br) ≈ 1 200 electrons². The 3.7 Å peak therefore corresponds to 34000/1200 ≈ 28 intermolecular separations. To evaluate the area under the peak at 4.4 Å, the 3.7 Å has to be substracted from the total distribution, giving a peak centered

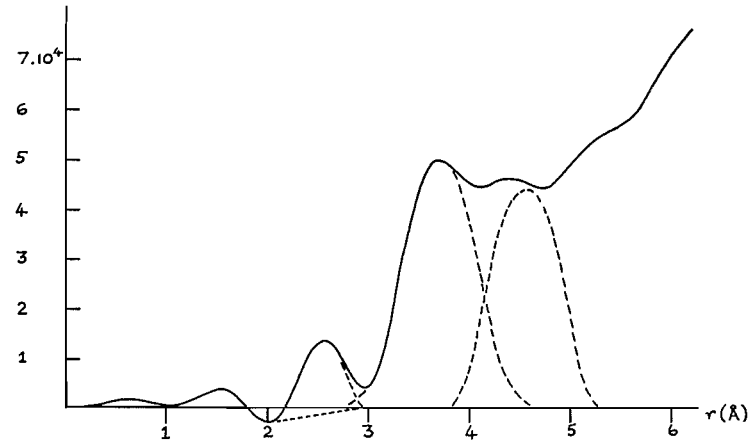

FIG. 3. Radial distribution function for liquid $AsBr_3$($4\pi r^2\rho(r)$, electrons²/Å).

at about 4.5 Å (Fig. 3) with area 34 600 electrons², corresponding to about 28 intermolecular distances.

A single-crystal X-ray study of solid arsenic tribromide (2) has shown that the crystal is built up from discrete pyramidal molecules, which have As—Br = 2.36 ± 0.01 Å, Br—As—Br = 97.7° ± 0.3°, Br ··· Br (intramolecular non-bonded) = 3.55 ± 0.01 Å. The dimensions in the vapor are reported as As—Br = 2.31–2.35 ± 0.02–0.04 Å, Br—As—Br = 100°–101.5° ± 2° (3), not significantly different from the crystal values. The present study of $AsBr_3$ liquid has again indicated pyramidal molecules; the As—Br distance obtained is 2.55 Å, and the difference between this value and those for the solid and vapor is probably not a real difference, but is an indication of the limited accuracy of the liquid study. The intramolecular Br ··· Br distance of 3.55 Å is part of the 3.7 Å peak in the liquid radial distribution function.

In the $AsBr_3$ crystal each molecule has 24 intermolecular As ··· Br and Br ··· Br contacts in the range 3.72–4.00 Å, and 18 distances in the range 4.12–4.33 Å. The number of distances in the shorter range is very similar to the number, 28, of intermolecular distances in the liquid 3.7 Å peak. Although it cannot be claimed that the liquid possesses any periodicity as in a crystal, the agreement between the number of closest contacts in the liquid and in the solid suggests that many of the intermolecular distances of the crystal are preserved over short ranges in the liquid. For the second range of intermolecular contacts, the agreement between number of distances is relatively good (18 in the solid, 28 in the liquid), especially since the liquid value has been determined from a peak which is not clearly resolved. The crystal has no intermolecular distances in the range 4.33–5.0 Å, and this is paralleled to some extent in the liquid, the radial distribution function exhibiting a minimum just below 5 Å, and then rising steeply with an inflection at about 5.2 Å, and no further structure.

The study appears to have been successful in the original purpose of obtaining significant results with the use of balanced filters for monochromatization. The use of only a nickel filter gave poor results, as evidenced by large spurious fluctuations in the radial distribution function at low r; this was a result of radiation other than Cu K_α reaching the counter, particularly fluorescent X-rays from the sample. The balanced filter method seems to compare reasonably well with crystal monochromatization. It has the disadvantage that

the measured intensity curve is a difference between two measurements (one with each filter of the balanced pair), but this is offset by the use of the counter measurements with a high-intensity primary X-ray beam, which are more accurate than the usual film measurements with the weaker monochromatized radiation.

The computations were carried out with our own programs on the IBM 7040 Computer, and we are indebted to the staff of the U.B.C. Computing Centre for assistance, and to the National Research Council of Canada for financial support.

PHOTOCHEMISTRY OF ELECTRONS TRAPPED IN GLASSES OF METHYLTETRAHYDROFURAN AT 77 °K[1]

P. J. Dyne and O. A. Miller
Research Chemistry Branch, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received May 7, 1965

ABSTRACT

In the radiolysis of methyltetrahydrofuran glass at 77 °K electrons are produced with a high yield. These are immobilized in traps in the glass and do not recombine with positive ions. They can be released from their traps by illumination with visible and infrared light and may then diffuse to positive ions and be captured. The quantum efficiencies for bleaching have been measured as a function of wavelength. This quantum efficiency falls as bleaching proceeds and depends on the fraction of the electrons bleached and not on their concentrations. About half the electrons are trapped close to positive ions and, on release, have a high probability of diffusing to the positive ion. The remaining half are trapped homogeneously. On release from their traps, few of these electrons reach positive ions although they diffuse over long distances before being retrapped in the glass. This behavior is compared to that discussed by Samuel and Magee for the thermalization and capture of electrons in liquid water.

The rate of recombination of an electron and positive ion in a condensed phase is an almost unknown quantity and the uncertainties which remain about this process lie at the root of many fundamental problems of radiation chemistry. Important advances, permitting a direct study of the process under special conditions, have, however, recently been made by W. H. Hamill who has extended to radiolytic reactions the techniques of studying the photochemistry of organic glasses which were pioneered by G. N. Lewis (see for instance ref. 1).

In an organic glass at low temperature reactive intermediates formed in radiolytic or photolytic decomposition are held immobile in a rigid solvent cage. They have long lifetimes and can be observed, at leisure, by conventional optical techniques. Ronayne, Guarino, and Hamill (2) (henceforth R. G. and H.) found that, on radiolysis of glasses of 2-methyltetrahydrofuran (MTHF), a strong optical absorption is observed in the near infrared which is due to electrons trapped in the glass. In glasses containing biphenyl as a solute the intensity of the electron band is reduced and a new absorption due to the biphenyl anion ϕ_2^- appears.[3] The electron band is photosensitive, being bleached by visible and near infrared light. If biphenyl is present in a bleaching experiment the intensity of the biphenyl anion band increases as the intensity of the electron band is diminished. Electrons released from their traps in the the glass may be captured by positive ions or by biphenyl molecules.

In a sense this technique allows one to observe, in slow motion, the recombination of electrons and positive ions. This paper describes a study of the photochemistry of the bleaching of trapped electrons in MTHF glasses which shows that thermal electrons have a high mobility in the glass. While few electrons recombine with the positive ion before being trapped, they prefer trapping locations in the vicinity of positive ions.

EXPERIMENTAL

The experimental techniques for purifying MTHF, making optical cells from square drawn glass tubing, and preparing samples follow closely those described by Hamill and his co-workers, and are described in detail in ref. 3. For spectrophotometry a styrofoam optical dewar was used which is based on the design proposed by Nelson (4). Sealed optical cells were irradiated under liquid nitrogen with Co-60 γ-rays at dose

[1]*Issued as AECL No. 2326.*

rates of 3.7×10^{17} eV/min and 1.02×10^{18} eV/min per ml of glass. No effect of dose rate was observed in any of these experiments. After irradiation the cells were transferred to the optical dewar and their absorption recorded using a Beckman D.K.-2 spectrophotometer with an unirradiated cell filled with MTHF in the 'blank' optical path.

Considering that unmatched cells were used which were not optically perfect the precision of the spectrophotometry was good; at an optical density of 0.50 the reproducibility of an absorption peak was ±0.01 (i.e. 2%).

Bleaching was carried out in the optical dewar used for absorption measurements. Two light sources were used, a 500 W slide projector for wavelengths between 4 000 and 7 000 Å and a 100 W microscope illuminator for wavelengths from 8 000 to 18 000 Å. "Monochromatic" light was obtained using Spectracoat "Monopass" interference filters. In the visible region these have a full width at half intensity of ~ 30 Å. More than half the light transmitted by the 5 000 Å filter lies between 4 985 and 5 015 Å. In the near infrared, 10 000 Å or more, the full width at half intensity is ~ 250 Å. For experiments in which complete and rapid bleaching was required, a Corning Glass Filter No. 2600 and interference filters from a Spectracoat Variable band pass set were used.

In the determination of quantum efficiencies absolute light intensities were obtained with a calibrated Eppley 12 junction bismuth–silver thermopile. This was placed in a mock-up of the optical dewar so that the effects of internal reflection in the windows of the dewar were duplicated. Corrections were made for the reflection losses at glass–air interfaces. The thermocouple readings themselves were reproducible to better than 5%.

Two measurements of optical density (o.d.) are required in the calculation of the quantum efficiency: the change in the optical density at the peak of the electron band and the average optical density at the wavelength of the illumination. The measured change in optical density at the peak was about 0.1; the optical density at the wavelength of the illumination would be between 0.1 and 0.3 in many instances. The precision in these two measurements is at best ±10% so that the precision of the quantum efficiency measurements is about ±15%. It would be unrealistic to assume that the accuracy of the absolute intensity measurement was better than ±10% so that the uncertainty in the quantum efficiency must be at least ±25%.

There are further uncertainties in the absolute quantum efficiencies, as well as in the other data reported here, due to possible errors in values for the extinction coefficients of the biphenyl anion and two related quantities, the yield of electrons and the extinction coefficient of the electron band. In this paper we have consistently used the extinction coefficient of 3.7×10^4 l/mole cm at 410 mμ for the biphenyl anion in MTHF glass at 77 °K (2) and 1.6×10^4 l/mole cm for the electron band at 1 200 mμ (5).

Smith and Pieroni (6) have recently measured the yield of trapped electrons in MTHF by electron spin resonance (e.s.r.) methods which are independent of these extinction coefficients. Their yield, 2.6 electrons/100 eV, confirms R. G. and H.'s methods which gave a yield of 3 electrons/100 eV.

RESULTS AND DISCUSSION

Mechanistic Steps in Photobleaching

Before discussing our own data it is convenient to summarize R. G. and H.'s observations in terms of mechanistic steps.

In radiolysis, molecules of MTHF (M) are ionized giving an electron e_k^-, with some kinetic energy greater than thermal and a positive ion P^+.

[1] $$M \rightsquigarrow e_k^- + P^+$$

These free electrons lose energy, become thermalized (e_{th}^-) and may be trapped in the glass (e_{tr}^-).

[2] $$e_k^- \rightarrow e_{th}^- \rightarrow e_{tr}^-$$

In the presence of a solute with high electron affinity (such as biphenyl ϕ_2) a new trapping process may occur.

[3] $$e_{th}^- + \phi_2 \rightarrow \phi_2^-$$

R. G. and H. found that as the concentration of biphenyl solute was increased, the yield of trapped electrons fell to zero and the yield of biphenyl anions reached a plateau. At this concentration they concluded that every electron normally trapped as a result of processes [1] and [2] was now being trapped by [3]. Smith and Pieroni's e.s.r. measurements confirm the validity of this procedure. Since the extinction coefficient of the biphenyl anion is known, its limiting concentration allows one to deduce a value for the yield of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

trapped electrons in steps [1] and [2] and hence to deduce an extinction coefficient for the absorption band of the electrons. The yield of trapped electrons (3 per 100 eV absorbed) is large. By comparison with values of W, the energy/ion pair in gases, which give $G(e^-)$ between 3 and 4, it follows that a greater part, if not all, of the electrons formed in the initial ionization are trapped in the glass and are not captured by the positive ion.

The first step in the bleaching process may be written

[4] $$e_{tr}^- + h\nu \rightarrow e_k^- \rightarrow e_{th}^-.$$

This mobile electron will have one of three fates; it may simply be retrapped in reaction [2], or be recaptured by the positive ion after thermalization

[5] $$e_{th}^- + P^+ \rightarrow \text{not-}e_{tr}^-,$$

or if biphenyl is present, it may be captured by the biphenyl to give ϕ_2^- (reaction [3]).

The Bleaching of the Electron Band

The quantum efficiency for bleaching trapped electrons is not constant but decreases continuously as the bleaching proceeds. This is shown in Fig. 1 for three samples of differing γ-ray dose. The optical density, measured at the peak of the electron band at 1 200 mμ is plotted against the amount of light absorbed. This light absorption is calculated from the product: average % absorption at the wavelength of the illumination $\times$ time of illumination. The slope of these curves at any electron concentration is proportional to the quantum efficiency for bleaching at that concentration. From these curves we see that one can produce samples with identical electron concentrations but which differ markedly in bleaching efficiency. This can be seen by comparing the initial slope of the sample irradiated for 2 min (o.d. 0.64) with the slope for the 4 min sample where bleaching has reduced the optical density to 0.64.

The quantum efficiencies at any electron concentration can be estimated graphically by drawing tangents to the curves shown in Fig. 1. These quantum efficiencies are shown in Fig. 2, where it is seen that they depend on the fraction of electrons bleached and not on their concentration in the sample. We conclude that the electron traps are not all alike. About half of the electrons are easily bleached and the other half has a quantum efficiency for bleaching about 1/20th that of the first group. The spectrum of quantum efficiencies may, of course, be more complex than this, but this simple distribution would give a linear decrease of quantum efficiency to a constant lower value as seen in Fig. 2.

The question then arises: How do these traps differ? What causes this difference in quantum efficiency? One might anticipate that the two (or more) groups of electrons might have different absorption spectra and this would be shown by a change in band shape as the bleaching progresses. R. G. and H. reported that the electron band bleaches as a whole. Our measurements show, however, that this is not exactly true. Fig. 3 compares two spectra, one before bleaching and one after 54% of the original concentration had been removed by illumination at 466 mμ. The partially bleached sample has weaker absorption on the short wavelength side. The electrons forming the more easily bleached fractions must, therefore, absorb more strongly at shorter wavelengths. This effect, however, is small.

The quantum efficiency for bleaching electrons is increased by adding biphenyl, the increase being due to the additional trapping to form ϕ_2^-. Figure 4 shows the quantum efficiency for bleaching electrons and forming biphenyl anions. This could only occur if, in the absence of biphenyl, there was a competition between capture by positive ions and retrapping in the glass (reaction [2]).

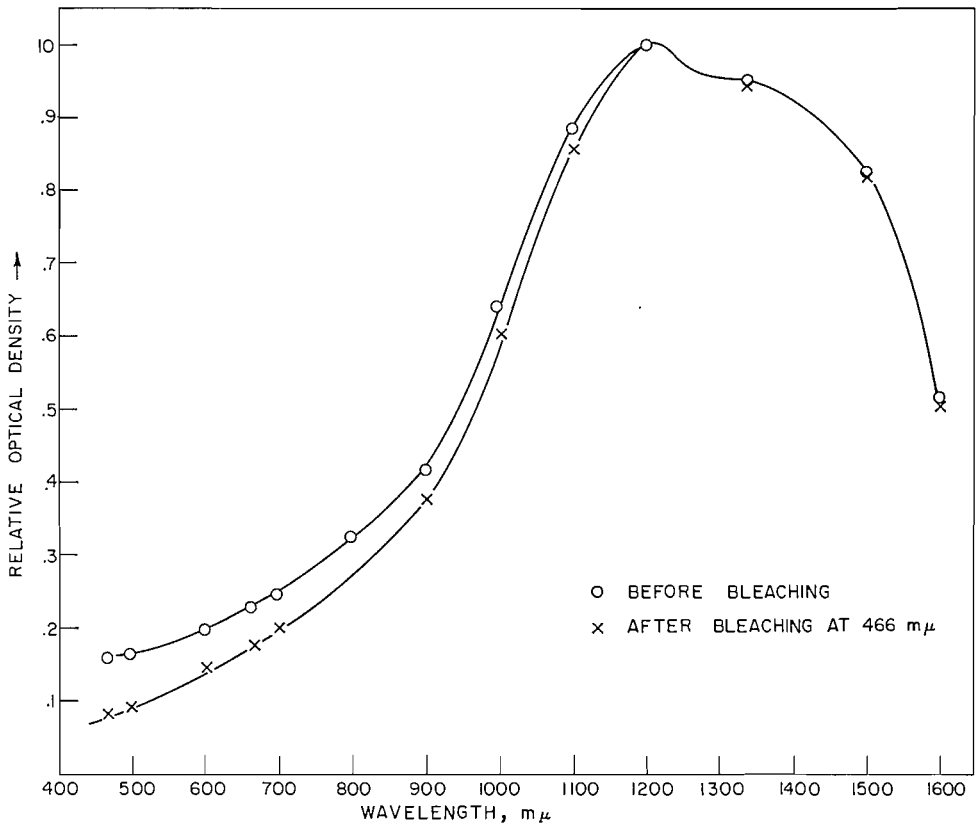

FIG. 3. Optical density of the electron band before bleaching and after bleaching at 466 mμ to 46% of the original optical density. The spectra have been normalized at 1 200 mμ to show the decreased absorption at shorter wavelengths.

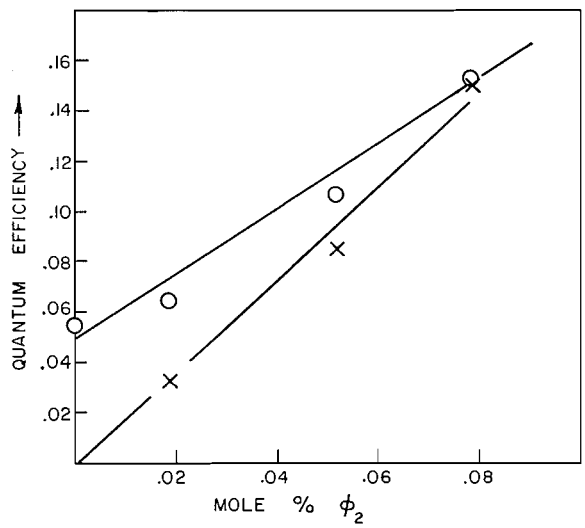

FIG. 4. Quantum efficiency for bleaching electrons (O) and for forming biphenyl anions (×) as a function of the biphenyl concentration. Bleaching carried out at 800 mμ.

If P_N and P_T are the probabilities of neutralizing and trapping, then the measured quantum efficiency for bleaching, Φ_B, is related to Φ_4, the quantum efficiency for initial release from the traps by the relation:

$$[6] \qquad \Phi_B = \Phi_4 \cdot \frac{P_N}{P_N + P_T}.$$

In the presence of biphenyl we have to include P_c, the probability of reaction [3] ($e_{th}^- + \phi_2 \rightarrow \phi_2^-$), and the measured quantum efficiency becomes:

$$[7] \qquad \Phi_B = \Phi_4 \cdot \frac{P_N + P_c}{P_N + P_c + P_T}.$$

Inspection of eq. [6] shows that the quantum efficiency will vary as the probability of recapture by the positive ion (P_N) varies and this provdes an explanation for the variation in the quantum efficiency of bleaching. Suppose that the trapped electrons differed simply in their proximity to a positive ion. Electrons released from traps which are close to positive ions are likely to be recaptured since for these electrons $P_N > P_T$; electrons which are released from traps which are far away from a positive ion are more likely to be retrapped since for these electrons $P_T > P_N$.

This conclusion is consistent with the e.s.r. measurements and the conclusions of Smith and Pieroni (7) on the thermal decay of electrons in MTHF glasses. The kinetics of this decay are complex following neither a first nor second order law. The decay curves for different initial concentrations of electrons can, however, be superimposed. This is analogous to the optical bleaching in that the rate of decay (bleaching for optical measurements) is determined by the fraction of the initial electron concentration which has been removed and that a residue of about half the electrons decay much more slowly than the rest.*

The absolute quantum efficiency of bleaching varies with wavelength as shown in Fig. 5. Two sets of values are shown: the absolute measurements were made using the Eppley thermopile as a standard; the relative measurements were made with a self-balancing bolometer lent to us by Dr. R. Banville. We have adjusted the readings from this instrument to coincide with the absolute measurements at 800 mμ. The agreement between the two measurements is satisfactory.

This variation in quantum efficiency with wavelength suggests that the absorption spectrum consists of two parts, a transition to a bound state giving a strong absorption band peaked at 1 200 mμ which is overlapped on the short wavelength side by the ionization continuum which starts at about 900 mμ and stretches out to the blue. On this interpretation the ionization potential of the trapped electron is $\simeq$ 1.4 eV and the first excited (bound) level is $\simeq$ 1 eV above the ground state.

The trapped electron in MTHF is, consequently, similar in several respects to the solvated electron in liquid ammonia and related solvents. Blades and Hodgins (8) proposed a similar interpretation for the optical absorption of electrons in methylamine. Their Fig. 9 shows a separation of the optical absorption into a band and a continuum identical to that suggested by our quantum efficiency measurements. This observation is supplemented by Jortner's calculation (9) showing that the electron in ammonia is in

Dainton and Salmon (Proc. Roy. Soc. London, Ser. A, 285, 319 (1965)) have recently published studies of the thermal decay of electrons in MTHF, over the temperature range 91 to 97 °K. This decay follows second order kinetics. In these experiments about half of the electrons in the sample, initially irradiated at 77 °K, have decayed before constant temperature is attained and the kinetics observed. This observation is, therefore, not necessarily in disagreement with Smith and Pieroni's observations at 77 °K in which the kinetics of decay of all the electrons was followed.

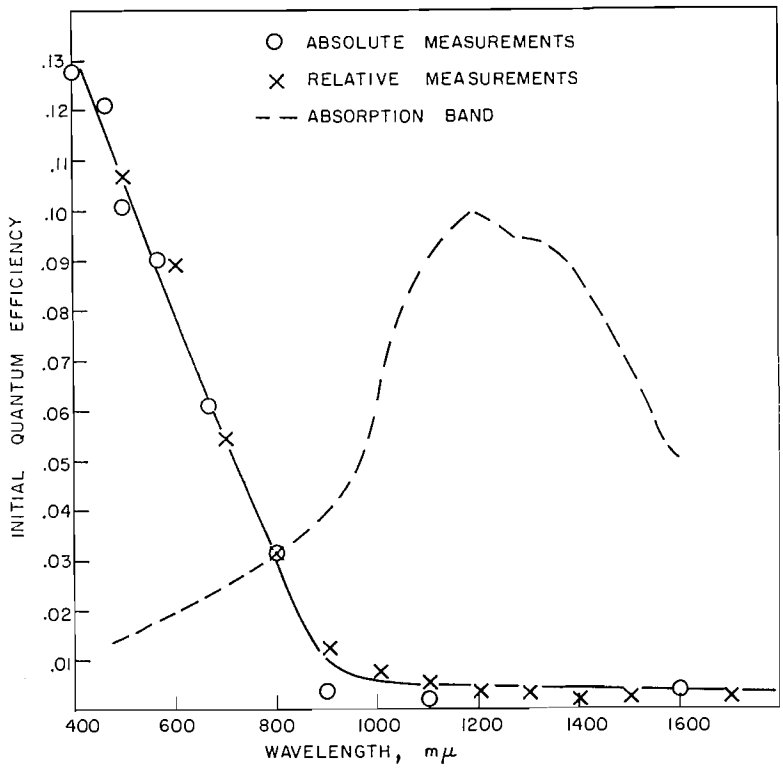

FIG. 5. Quantum efficiency for bleaching as a function of the wavelength of the bleaching light. The envelope of the electron band is shown on the same wavelength scale for comparison.

a trap whose ground state lies $\simeq 2$ eV below the continuum. The trapped electron has an excited bound state ~ 0.8 eV above the ground state.

According to this simple interpretation, the quantum efficiency should fall to zero at long wavelengths. However, while the quantum efficiency is small above 900 mμ, it is not zero. We suggest that some electrons are trapped sufficiently close to a positive ion that, in even the "bound" excited state they also have a finite probability of escape and of being captured by the positive ion. This would require that the quantum efficiency would fall to a very low value after this initial fraction of electrons is bleached out. Qualitatively this is observed: after about 10% of the electrons have been bleached out at longer wavelengths, the quantum efficiency (which is already low) is reduced to 1/10 or less of its initial value. However, bleaching at these wavelengths is so slow that the accurate data on quantum efficiencies required to substantiate this interpretation in detail are not readily obtained.

This conclusion also suggests an interpretation for the change in shape of the electron band. Electrons which are trapped closer to positive ions are moving in a field perturbed by the positive ion. We suggest that this perturbation leads to a stronger absorption in the blue end of the spectrum than is found for isolated, unperturbed, traps.

The Diffusion and Trapping of Electrons in MTHF Glasses

R. G. and H.'s observations on the radiolysis of MTHF glasses lead to two conclusions on the mobility of electrons in this medium:

1. Since the yield of electrons is high, primary recombination of the positive ion and electron is improbable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2. Biphenyl competes with the traps in the glass for electrons at low concentrations (< 0.1 mole %) so that the electron must follow an extended path through the glass before it is trapped by the solvent or captured by solute, as the case may be.

The classical discussion of the motion of an electron in a condensed phase in the vicinity of a positive ion was given by Samuel and Magee (10). Following Onsager (11) they defined a critical escape distance r_c for the electron where its thermal energy (kT) was equal to its coulombic potential energy. The probability of an electron escaping from the field of a positive ion at a distance r is exp $(-r_c/r)$ and is large where $r_c > r$. The critical escape distance for an electron in MTHF with a high frequency dielectric constant of 2.0 (12) is $\sim 1\,200$ Å at 77 °K. These optical experiments were carried out at doses giving final concentrations of ions and electrons of $\sim 5 \times 10^{16}$/cm³. At this concentration the average separation of nearest neighbors of positive ions is ~ 300 Å so that an electron is never free of the coulombic field of a positive ion.

Let the number of trapping sites in the glass be T/cm³, the number of positive ions be P/cm³, and the number of solvent (MTHF) molecules be S/cm³. Let the cross section for electron capture by the trapping sites, positive ions, and biphenyl molecules be σ_T, σ_P, and σ_B (cm²) and the scattering cross section by the solvent molecules be σ_S (cm²).

The macroscopic trapping cross section Σ_T, is equal to $T\sigma_T$ cm^{-1}* and the mean free path for trapping is $1/\Sigma_T$.† We can estimate Σ_T from the experiments in which biphenyl competes with the glass for electrons. From Fig. 6 we see that the yield of electrons is reduced to half its initial value at 0.04 mole % biphenyl. At this concentration $G(e^-) = G(\phi_2^-)$ and, hence, $\Sigma_T = \Sigma_B$ where $\Sigma_B = B\sigma_B$. Since $B = 4 \times 10^{-4}S$ and $S = 7.2 \times 10^{21}$/cm³ we find $\Sigma_T = 2.9 \times 10^{18}\sigma_B$.

The mean square distance (crow's flight) between thermalization and trapping $\overline{r^2}$ is

$$\overline{r^2} = 6(D/\Sigma_T)$$

where Σ_T is the macroscopic trapping cross section and D, the diffusion constant is given by $D = 1/3\Sigma_S = 1/3S\sigma_S$ whence $\overline{r^2} = 2/S\sigma_S\Sigma_T$. This diffusion constant is related to the conventional diffusion constant D' by $D = D'/V$ where V is the velocity of the electron. Using the values of S and Σ_T given above we find

$$\sqrt{(\overline{r^2})} = \frac{10^{-20}}{(\sigma_S\sigma_B)^{1/2}}$$

This is essentially a phenomenological relation. Now σ_S, the scattering cross section, is likely to be of the order of molecular dimensions, i.e. $\sim 10^{-15}$ cm². (The cross section corresponding to the molecular volume of MTHF is 3×10^{-15} cm².) If the electron capture cross section of biphenyl is large it will also be of the same order. Asundi and Craggs (13) found the electron capture cross section at 0.1 eV to be 1.5×10^{-15}/cm² for SF_6. They reported "the highest known electron capture cross section" for perfluoro methylcyclohexane C_7F_{14} to be 7.5×10^{-15} cm².

With $\sigma_S = \sigma_B = 10^{-15}$ cm² we find $\sqrt{(\overline{r^2})} = 10^{-5}$ cm, (1 000 Å). To reduce this crow's flight distance to, say 100 Å, we would have to make both σ_S and σ_B 10 times larger ($\sim 10^{-14}$ cm²) and such values seem improbable. It follows that electrons in MTHF glasses can diffuse over distances which are at least comparable with the separation of positive ions at doses of 1×10^{18} eV/ml.

**The important quantity is Σ_T which can be defined as the reciprocal of the mean free path. The definitions of T and σ_T implying a definite concentration of trapping sites each with a capture cross section are a convenient mathematical formalism.*

†Details of this and other formulae used in this section can be found in "The Elements of Nuclear Reactor Theory" S. Glasstone and M. C. Edlund, D. Van Nostrand Company, New York, 1952.

These estimates can, of course, be criticized because they are based on gas phase data. It might be argued, for instance, that the interaction of thermal electrons with molecules in a condensed phase is very strong and the diffusion of an electron could be described by a very large scattering cross section which bore no real relation to molecular size. This would reduce, $\overline{r^2}$ but does not affect estimates of Σ_T and Σ_B since it simply increases the time which a diffusing electron takes to find a biphenyl molecule or a positive ion. In other words, while we could visualize circumstances in which an electron moves very slowly through the glass, this also means that the trapping process also takes place very slowly since the competition between biphenyl and trapping in the glass is still observed at low biphenyl concentrations.

Smith and Pieroni (7) found that $G(e^-)$ decreased slowly as the total dose increased. From their data $G(e^-)$ is reduced to 90% of its initial value when the final concentration of electrons is $2 \times 10^{17}/cm^3$. If this reduction in yield is due to the recombination of positive ions and electrons then we can say that, at the average positive ion concentration in the irradiation ($10^{17}/cm^3$) the macroscopic capture cross section of positive ions $\Sigma_P = P\sigma_P$ is one tenth Σ_T, i.e. $10^{17}\sigma_P = 1/10(\Sigma_T) = 2.9 \times 10^{17}\sigma_B$ so that $\sigma_P/\sigma_B \sim 3$. The capture cross section of an electron by a positive ion is only three times that for its capture by a neutral biphenyl molecule. This estimate gives an upper limit to σ_P since part of the decrease in yield may be due to the thermally induced recombination of electrons and positive ions which is beginning to occur at a significant rate at these doses.

We can use this estimate of σ_P/σ_B to estimate the bleaching quantum efficiency for electrons homogeneously distributed in the glass. Consider a sample with an average concentration of positive ions during irradiation of $2 \times 10^{16}/cm^3$. Then (putting $\sigma_P = 3\sigma_B$) $\Sigma_P = 6 \times 10^{16}\sigma_B$. If the quantum efficiency of release from the traps is given by equation [6] and P_N and P_T are proportional to Σ_P and Σ_T

$$\Phi_B \approx \Phi_4(\Sigma_P/\Sigma_T) = \phi_4 \left(\frac{6 \times 10^{16}}{2.9 \times 10^{18}}\right) \approx 0.02\ \Phi_4 .$$

If $\Phi_4 = 1$ the maximum value of Φ_B would be 0.02. Referring to the observed quantum efficiencies (Fig. 5) we see that the initial values at wavelengths shorter than 800 mμ are greater than this. It follows, in agreement with our earlier conclusions, that the electrons bleached in the first stages are not homogeneously distributed but are trapped preferentially close to the positive ion.

The quantum efficiencies for bleaching the residual half of the electrons are (Fig. 2) $\sim 1/20$ of the initial value, i.e. they have values of 0.005 or less depending on the wavelength of the light used. These quantum efficiencies are consistent with those to be expected for the diffusion of homogeneously distributed electrons if Φ_4 varies with wavelength, rising linearly from a small value at 900 mμ to a value close to unity at 400 mμ.

The Bleaching of the Biphenyl Anion Band

At wavelengths of 400 and 433 mμ the biphenyl anion band is bleached and the intensity of the electron band increases. We are observing the process

$$\phi_2^- + h\nu \rightarrow \phi_2 + e^-$$

followed by the trapping of the electron in the glass. The longer wavelength band of the biphenyl anion at 660 mμ is not photosensitive in MTHF glasses. A sample containing biphenyl can be bleached alternately with blue (400 mμ) and near infrared (800 mμ) light transferring the electrons from biphenyl molecules to the glass and back again. The results of such an experiment are shown in Fig. 7. The sample containing 0.006 mole %

biphenyl was irradiated giving initial concentrations of $e^- = 6.84 \times 10^{-5}$ moles/l and $\phi_2^- = 1.59 \times 10^{-5}$ moles/l. Prolonged bleaching with red light gave a sample with concentration #2. Irradiations with blue light were carried out in steps 2 to 3, 4 to 5, etc., and irradiations with red light were carried out in steps 3 to 4, 5 to 6, etc.

After the sample has been bleached to point 3 it can be seen that electrons can be transferred to and from the biphenyl molecules with little loss to neutralization of positive ions. In the latter steps (6 to 10) the sum of the electron and biphenyl anion concentration is nearly constant within the precision of the measurements and the accuracy of the extinction coefficients. In the initial bleaching process (1-2-3) more than half of the initial concentration was lost and, according to our interpretation, we have thus, at point 3, eliminated almost all the electrons which are trapped close to positive ions. The high efficiency of transfer of electrons between the glass and biphenyl at this low biphenyl concentration shows again that electrons can diffuse over significant distances in the glass without being strongly affected by the presence of the positive ions.

Electrons in MTHF and the Samuel Magee Model

In conclusion, we compare our observations on the motion of electrons in MTHF glasses with the theoretical conclusions of Samuel and Magee (10) on the motion of electrons in water. They argued that, in liquid water, electrons were thermalized at small distances (12–17 Å) from the positive ion and were, hence, quickly recaptured. The possibility of electron capture by water was regarded, on the basis of information then available (1953), to be improbable.

In MTHF glasses we find evidence that the electron travels considerable distances (100 to 1 000 Å) between thermalization and capture in the glass. The time taken for trapping is long, at least of the order of the dielectric relaxation time (14). Since we find that initial recombination of the positive ion and electron is improbable, it follows that the distance in which the electron is thermalized must be appreciable and certainly greater than the 17 Å distance suggested by Samuel and Magee for liquid water. A distance of at least 100 Å is reasonable. A thermalization distance of 100 Å for electrons in liquid cyclohexane has been suggested by Freeman (15) from conductivity observations. Comparable distances have been estimated by Ffrancon Williams on chemical evidence (16).

In MTHF glasses the effects of coulombic attraction between the positive ion and electron are not dominant. We suggest that instead of providing a compelling driving force for recombination, coulombic attraction produces a weaker effect, concentrating a fraction of the free electrons in traps close to the positive ion. At the end of an irradiation in one of our optical experiments, the average separation of positive ions is $\sim$ 300 Å and so electrons are at most 150 Å from a positive ion. Since we observe a factor of 20 between the bleaching efficiencies for the two groups of electrons, we can make the naive estimate that the closely spaced electron-positive ion pairs are, perhaps, only 1/20 of this distance apart, i.e. $<$ 10 Å. Smith and Pieroni's e.s.r. measurements give an upper limit to this distance. They found an average positive ion – electron separation for all electrons of 50 Å. The separation of the closely spaced group must be less than this and the other electrons must be trapped at greater distances than this from the positive ion. In summary, therefore, we conclude that the "closely spaced" electron-positive ion pairs (which bleach readily) are separated by a distance of 10 to 50 Å and the "homogeneously" trapped electrons lie more than 50 Å from a positive ion.

QUANTITATIVE PREPARATION OF CHLORO- AND BROMOPHTHALAZINES

A. HIRSCH AND D. ORPHANOS
Canadian Technical Tape Ltd., Montreal, Quebec
Received April 27, 1965

ABSTRACT

A new improved synthesis of 1,4-dichloro- and 1,4-dibromophthalazine has been effected by reaction of 1,4-dioxophthalazine with PX_5 (X = Cl, Br) in a sealed reaction flask. Halogenation of the dioxophthalazine has also been accomplished at atmospheric pressure in a halogenated solvent. The synthesis of 1-bromophthalazine is reported.

INTRODUCTION

1,4-Dichlorophthalazine has been synthesized by the reaction of 1,4-dioxophthalazine with either $POCl_3$ (1, 2) or PCl_5 (3–6). Repetition of the $POCl_3$ method gave unsatisfactory results. The use of PCl_5 gave rise to an impure product in 55% yield. The purification of the reaction mixture was quite laborious, and always accompanied by considerable amounts of 1-chloro-4-oxophthalazine, which could only be removed with difficulty.

A modification of this latter method has now been developed in which heating of 1,4-dioxophthalazine with PCl_5 in a sealed reaction vessel results in a quantitative yield of almost pure 1,4-dichlorophthalazine, without the need for further purification.

It has been earlier reported (3) that reaction of 1,4-dioxophthalazine with PBr_5 always affords a mixture of 1,4-dibromophthalazine and 1-oxo-4-bromophthalazine. No yields were mentioned. 1,4-Dibromophthalazine has now been readily obtained in a nearly quantitative yield by applying the modified procedure for the preparation of the analogous dichlorophthalazine.

It was later found that the preparation of 1,4-dibromophthalazine could also be achieved under atmospheric conditions by using CBr_4 as a solvent. In this alternative modification, the obtained yield was 78% and the CBr_4 solvent was easily recovered. No reference to the preparation of 1-bromophthalazine is available.

EXPERIMENTAL

1,4-Dichlorophthalazine

In a closed pressure bottle, a mixture of 1,4-dioxophthalazine (16.2 g, 0.1 mole and an excess of phosphorous pentachloride (85 g) was heated at 140–150° in an oil bath for 4 h. During the heating period the reaction mixture was agitated with the aid of a magnetic stirrer. After cooling to room temperature, the pressure bottle was placed in a refrigerator for a few hours and then carefully opened in a hood. HCl gas escaped vigorously. The solid orange-colored mass was crushed with a spatula and poured into 1 l of ice water. The whole mixture was stirred until all lumps were disintegrated. Then ammonium hydroxide was added to a basic reaction; care being taken to maintain the temperature below 10 °C. The solid was collected on a filter paper, washed with water, and dried. This crude material was redissolved in methylene chloride, shaken with charcoal, and filtered. The colorless filtrate was subjected to partial concentration until a thick paste was obtained. Upon addition of 100 ml diethyl ether, a white crystalline material melting at 161–162° separated. The yield was 19.2 g (96.5%).

1,4-Dichlorophthalazine was recrystallized from tetrahydrofuran in colorless long needles m.p. 164° (lit. m.p. 161–162°, 164°, 164–165°); see Fig. 1.

Infrared spectra were determined on Perkin-Elmer model 337 from Nujol mulls.

1,4-Dibromophthalazine

This compound was prepared in 97% yield by applying the reaction conditions for the preparation of the analogous 1,4-dichlorophthalazine. In this preparation, the halogenating agent was phosphorous pentabromide and a reaction temperature of 140° was more effective.

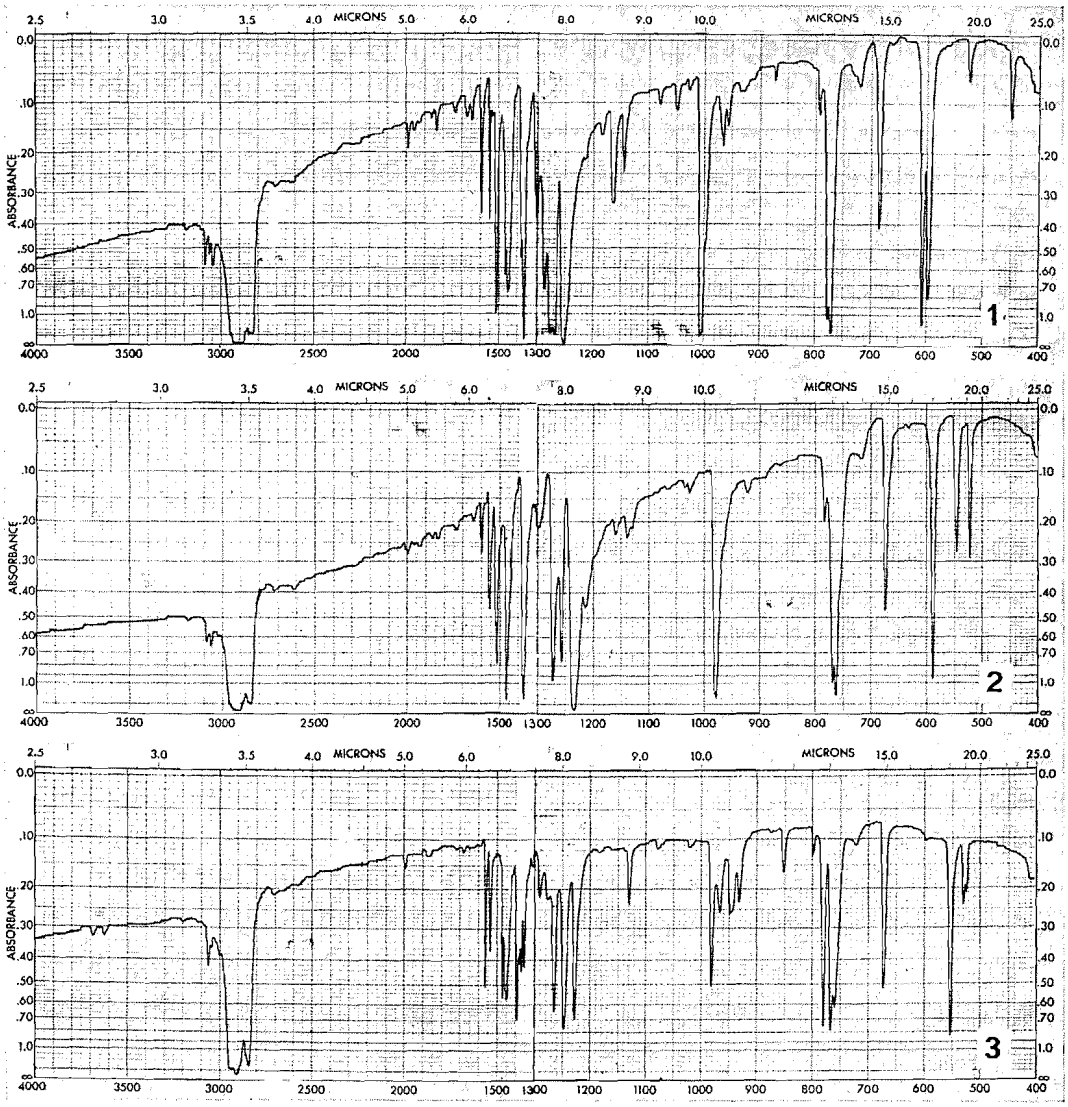

FIG. 1. Absorbance vs. frequency (cm^{-1}) for 1,4-dichlorophthalazine.
FIG. 2. Absorbance vs. frequency (cm^{-1}) for 1,4-dibromophthalazine.
FIG. 3. Absorbance vs. frequency (cm^{-1}) for 1-bromophthalazine.

1,4-Dibromophthalazine was crystallized from tetrahydrofuran in colorless long needles m.p. 160–161° (lit. m.p. 162°); see Fig. 2.

Preparation of 1,4-Dibromophthalazine in an Open Flask

A mixture of 1,4-dioxophthalazine (1.62 g, 0.01 mole), phosphorous pentabromide (9.5 g, 0.02 mole plus 10% excess), and carbon tetrabromide (50 g) were heated at 130° (temperature of oil bath) for 6 h. After cooling, the solid mass was treated with methylene chloride (25 ml) until all lumps had been disintegrated. This mixture, under vigorous stirring, was poured into ice water (100 ml) and stirring was continued for an additional 2 h. The yellow solid material was collected on a filter paper and washed thoroughly with water followed by petroleum ether. 1,4-Dibromophthalazine was crystallized from tetrahydrofuran in long pale-yellow needles melting at 160°, yield 2.2 g (78%).

1-Bromophthalazine

A mixture of phosphorous oxybromide (12 g), diethyl ether (25 ml), 2*H*-1-phthalazinone (2 g), and tetrahydrofuran (80 ml) was stirred at room temperature for 15 min. Then, under vigorous stirring, the mixture was heated for 3 h in an oil bath maintained at a temperature of 55–60°. After cooling, a pale-yellowish solid was collected on a filter paper, washed with diethyl ether, and dried in a vacuum desiccator. The product reacted acidic, and obviously was the hydrobromide salt of 1-bromophthalazine. On heating over 210°, it acquired a grey color and at 245° melted with decomposition, yield 3.5 g. This product was taken in water (no solution was achieved) and under vigorous stirring was carefully neutralized to a weakly basic reaction with ammonium hydroxide. The pale-yellow solid was collected on a filter paper, washed with distilled water until the washings were neutral, and finally washed with petroleum ether. It was dried in the dark in a vacuum desiccator. On heating, it became orange colored at about 100°, and at 175° melted with foaming; yield 2.52 g (88%); see Fig. 3.

PHOTO-ADDITION OF *N*-NITROSODIALKYLAMINES TO CYCLOHEXENE

Y. L. CHOW
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received May 28, 1965

ABSTRACT

Under the simultaneous influence of light and an acid, the nitrosamines derived from four heterocyclic amines readily form 1:1 photo-adducts with cyclohexene giving excellent yields of 2-*tert*-aminocyclohexanone oximes. While *N*-nitrosodi-*n*-butylamine, under similar conditions, gives a fair yield of the 1:1 photo-adduct, *N*-nitrosodicyclohexylamine and *N*-nitrosodi-isopropylamine do not. The conformations of these oximes are discussed in conjunction with the n.m.r. data.

INTRODUCTION

In spite of the stability of neutral *N*-nitrosodialkylamine solutions toward irradiation, these nitrosamines readily undergo photo-decomposition if an acid is present (1). Previous work (1) has shown that such photolysis resulted in rearrangement of the nitrosamines to amidoximes or elimination to give Schiff bases. Though the nature of this photo-decomposition is yet to be elucidated, the behavior of the nitrosamines under an influence of an acid and irradiation is sufficiently intriguing to warrant further scrutiny. In the following we report a novel photo-addition of nitrosamines across a carbon–carbon double bond. Cyclohexene was chosen as the model olefin to demonstrate the photo-addition of various nitrosamines.

RESULTS AND DISCUSSION

The irradiation of *N*-nitrosopiperidine (IA) in methanol containing at least 1 mole equivalent of hydrochloric acid was shown to give a similar result to that in the aqueous hydrochloric acid solution, 2-piperidonoxime and isotripiperidein being the products (1). When the photo-reaction was carried out in a presence of 1 mole equivalent or more of cyclohexene, none of these compounds was detected but instead an excellent yield of 1:1 adduct of the nitrosamine to cyclohexene was isolated. The addition did not take place in the absence of either irradiation or the acid catalysts demonstrating the requirement for both. The adduct is basic and conveniently isolated as the corresponding hydrochloride merely by triturating the residue with cold acetone. Alternatively, the nicely crystalline 1:1 adduct precipitated out on neutralization and was readily purified by recrystallization. The assignment of 2-piperidinocyclohexanone oxime (IIA) to the 1:1 adduct follows from the fact that thermal decomposition gave piperidine and Δ^2-cyclohexenone oxime. Further the adduct was found to be identical (infrared spectra and mixed melting point) with 2-piperidinocyclohexanone oxime synthesized according to the published method (2). Regardless of the mode of preparation only one oxime was obtained. Of the two possible geometric isomers, the *syn* configuration was considered to be more stable due to the probable intramolecular hydrogen bond formation and, therefore, structure III was assigned to the single adduct obtained. It should be mentioned that the crude basic fraction contained a small amount of 2-piperidinocyclohexanone as an impurity as indicated by the weak infrared peak at 1 710 cm^{-1}. Without attempting to isolate the cyclohexanone derivative, the crude basic fraction was oximated to give IIA as the only isolable product. The substituted cyclohexanone was probably formed by the hydrolysis of the oxime IIA during the working up.

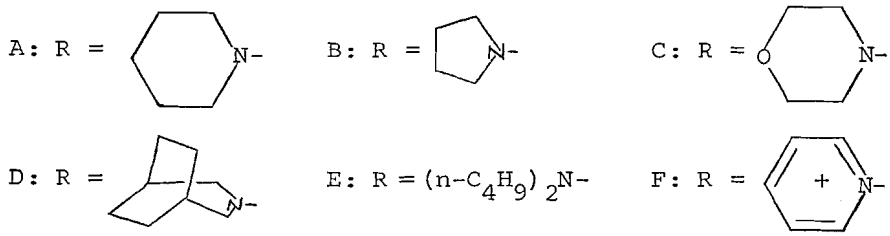
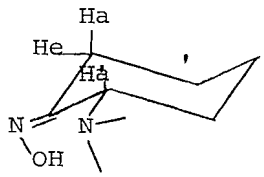
I II





III

The net result of the photo-addition is represented by the addition of a molecule of *N*-nitrosopiperidine as nitroso and piperidino residues across the carbon–carbon double bond. Encouraged by the high yield as well as the simplicity of the photo-addition, several other nitrosamines were subjected to the same photo-addition conditions using cyclohexene as the model olefin in order to examine the scope of the reaction. *N*-Nitrosopyrrolidine (IB) and *N*-nitrosomorpholine (IC) underwent the addition smoothly to give the expected 1:1 photo-adducts, 2-pyrrolidino- and 2-morpholinocyclohexanone oximes (IIB and IIC), in total yield of 82 and 81% respectively. In both cases the presence of small amounts of the corresponding substituted cyclohexanones were detectable spectroscopically (1 710 cm^{-1}). The photo-addition of *N*-nitroso-3-azabicyclo[3,2,2]nonane (ID) to cyclohexene proceeded as expected giving the crystalline hydrochloride (39%) of IID, *N*-(2-oximinocyclohexyl)-3-azabicyclo[3,2,2]nonane, and the corresponding ketone of IID (46%). The ketone was oximated to IID directly. The facile hydrolysis of IID to the ketone was probably due to the steric acceleration associated with bulkiness of the amine group and will be a useful tool if an α-aminoketone is the desired product.

Under similar conditions *N*-nitrosodi-*n*-butylamine (IE) gave the unstable liquid adduct IIE, 2-di-*n*-butylaminocyclohexanone oxime, in only 38% yield and it did not yield a crystalline salt with perchloric, hydrochloric or picric acid. The balance of the starting nitrosamine was transformed to di-*n*-butylamine. On storage IIE decomposed rapidly to a tar but the infrared and n.m.r. spectra of the freshly distilled IIE possessed the absorptions required for the assigned structure. *N*-Nitrosodicyclohexylamine and *N*-nitrosodiisopropylamine did not give the expected adduct under the photolytic conditions. In the former case dicyclohexylamine was the major product and cyclohexylamine, cyclohexanone, and its oxime were the minor products identified in the photolysate. In these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

photolytic reactions the disappearance of the nitroso absorption at 350–360 mμ proceeded much faster than that of the nitrosamine derived from the heterocyclic amines (IA–ID). This observation suggested that another photolytic pathway independent of the photo-addition was operating leading to the different results. Control experiments showed that these acyclic nitrosamines are stable under the conditions without irradiation. Simple hydrolysis is, therefore, not the pathway responsible for the formation of the parent dialkylamines. An investigation is underway presently to locate the end product derived from the nitroso residue of the nitrosamines which should provide a clue to this question.

It is interesting to point out that only those nitrosamines having methylene groups flanking the amino nitrogen undergo photo-addition while those with methine groups do not. Coincident with this observation, it has been shown that the former group of nitrosamines undergo the photo-rearrangement to give amidoximes while the latter undergo the photo-elimination to Schiff bases (1). The course of photo-addition of *N*-nitrosopiperidine is not altered by the presence of air and, therefore, a free radical mechanism is not likely. It is felt that proposal of a mechanism for the photo-addition should not be made until more data are available. The mild conditions required, the simplicity of the reaction, and the excellent yield obtained from heterocyclic nitrosamines all favor application of the photo-addition as a potential tool in the syntheses of α-aminoketoximes.

Discussion of N.m.r. Data

In connection with the conformation of these oximes (II) the spectral data merit a brief discussion. In the infrared region the usual absorptions as expected for an oxime are all present except that each of these oximes shows a complex pattern of several strong absorption peaks in 900 – 1 000 cm^{-1} (3). The bulky α-amino group in II is expected to occupy the equatorial position forcing the oximes to assume the conformation as shown in III. Partial overlap of some of the n.m.r. signals, however, hampered a complete analysis of these spectra. The n.m.r. data of II together with that of 2-pyridiniumcyclohexanone oxime chloride (IIF) are summarized in Table I. All of these oximes show one proton

doublet centered at τ6.8 with a coupling constant of 12–13 c.p.s. Each doublet is further split to a poorly resolved triplet. Decoupling experiments with a Varian HR 100 spectrometer indicated that this proton is coupled to a proton at τ ca. 8.00, part of which is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

submerged under the intense signal due to the other methylene protons. The former is, therefore, assigned to H_e and the latter to H_a in agreement with the large geminal coupling constant and the generally accepted fact that axial protons resonate at higher field than equatorial protons (4). The large chemical shift difference (ca. 1 p.p.m.) between H_e and H_a has its precedence in heterocyclic amines (5). The signal of H_a' appears at or around τ7.2 (except that of IIF) with the width at the half height ($w_{1/2}$) 7–8 c.p.s., which is too narrow for an axial proton signal. It is suggested that C—N bond may have been bent down in order to make intramolecular hydrogen bonding possible and thus to slightly flatten the conformation at this carbon center. Under these circumstances, the coupling pattern of H_a' may depart considerably from the axial character. Pertinent to this assignment is the fact that in the spectrum of IIA hydrochloride (in D_2O) H_a' is now shifted downfield and appears at τ6.05 while the double triplet of H_e remains at τ6.83 which is coupled with H_a at τ8.00. In compound IIF the proton H_a' appears further downfield at τ4.40 as a double doublet (J_{ae} = 4.5 and J_{aa} = 10 c.p.s.) in agreement with the pyridinium ring attached at the same carbon atom.

EXPERIMENTAL

The infrared spectra were recorded in Nujol mull with a Perkin-Elmer model 421 spectrophotometer. All melting points were uncorrected. The analyses were performed by the Microanalytical Laboratory of this Department.

N-Nitrosamines

The nitrosamines were prepared by nitrosation of the respective amines with sodium nitrite in aqueous hydrochloric acid solution. The boiling points are: *N*-nitrosopiperidine (6), 109° at 24 mm; *N*-nitrosopyrrolidine (7), 99–100° at 15 mm; *N*-nitrosodi-*n*-butylamine (8), 112–114° at 13 mm; *N*-nitrosomorpholine (9), 110° at 14 mm. The melting points are: *N*-nitrosodicyclohexylamine (10), 102–104°, and *N*-nitrosodiisopropylamine (11), 42–44°.

N-Nitroso-3-azabicyclo[3,2,2]nonane, prepared by the nitrosation of the parent amine, was recrystallized from methanol–water but turned to a sticky cake on filtration. The analytical sample was prepared by sublimation and has infrared peaks at 3 010, 1 425, 1 340, 1 140, and 912 cm^{-1} and n.m.r. signals at τ5.56 (2H, doublet) and 6.10 (2H, doublet).

Anal. Calcd. for $C_8H_{14}N_2O$: C, 62.30; H, 9.08; N, 18.17. Found: C, 62.38; H, 8.83; N, 18.37.

General Procedure of Photo-addition

In a pyrex photolysis vessel a nitrosamine (0.05 moles), 1 mole equivalent or more of cyclohexene, 1–2 mole equivalents of concentrated hydrochloric acid, and methanol (ca. 300 ml) were placed. The photolysis vessel was cooled with tap water and externally with an ice bath. The solution was agitated with a magnetic stirrer and a slow stream of nitrogen. A Hannovia ultraviolet lamp (type 54A36) situated at the center sleeve was used as the light source. The photolysis was continued until the absorption at 340–360 mμ region disappeared completely. The solvent was evaporated under vacuum. Generally, the hydrochloride of the adduct crystallized on triturating the residue with acetone or isopropanol and was recrystallized from isopropanol. The combined mother liquor was evaporated and the residue was taken up in water. Neutralization with sodium carbonate solution gave the basic fraction which was either ether extracted or filtered. The photo-adduct was then recrystallized or distilled. Each photo-addition was backed with a control experiment. A small portion of the above photolysis solution was kept in a dark icebox. The ultraviolet absorption spectrum was not changed at all over the entire period of photolysis.

Addition of N-Nitrosopiperidine

The nitroso compound (10.5 g) and cyclohexene (50 ml) were photolyzed according to the procedure as described. The residue obtained after evaporation of the solvent was treated with cold acetone to give the hydrochloride (11 g) of 2-piperidinocyclohexanone oxime (IIA). This was recrystallized from isopropanol to give white crystals, m.p. 203–205° (decomposition) and infrared peaks at 3 160, 2 620, 2 550, 1 662 (weak), 1 490, and 1 000 – 900 cm^{-1} (complex).

Anal. Calcd. for $C_{11}H_{21}N_2OCl$: C, 56.76; H, 9.09; N, 12.04; Cl, 15.23. Found: C, 56.73; H, 8.88; N, 12.33; Cl, 15.18.

The combined mother liquor was vacuum evaporated followed by the usual working up to furnish a basic fraction (7.4 g), the infrared spectrum of which showed the carbonyl peak at 1 710 cm^{-1}. The partially crystalline residue was purified by recrystallization from methanol–water and sublimation to give IIA, m.p. 118–120°. Alternatively IIA was synthesized from 2-pyridinium cyclohexanone oxime chloride (IIE)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

according to Birch's method (2). The mixed m.p. of two substance was 118–120°. This substance shows the infrared peaks at 3 240, 2 810, 2 790, 1 665 (weak), 1 490, 890–990 (complex), and 780 cm^{-1}.

Anal. Calcd. for $C_{11}H_{20}N_2O$: C, 67.30; H, 10.27; N, 14.27. Found: C, 67.31; H, 10.24; N, 13.96.

The methanol–water mother liquor obtained from these recrystallizations contained IIA and the corresponding cyclohexanone derivative as shown by the medium intensity carbonyl peak at 1 710 cm^{-1}. Treatment of this mother liquor with hydroxylamine hydrochloride and sodium acetate gave a solid product in which the 1 710 cm^{-1} absorption was no longer present. Recrystallizations from methanol–water gave IIA as the only isolatable product, m.p. 118–120°.

An attempt to distill the partially crystalline residue lead to an extensive decomposition. Distillation of the decomposed products under atmospheric pressure gave piperidine identified as the hydrochloride by the superimposable infrared spectra. Further distillation under vacuum (12 mm) gave a fraction which crystallized and was recrystallized to give Δ^2-cyclohexenone oxime, m.p. and mixed m.p. with an authentic sample prepared from Δ^2-cyclohexenone 87–88°, reported m.p. 89–90° (12).

The photo-addition in the presence of only 20% excess of cyclohexene also gave IIA (36%) and the hydrochloride of IIA (42%). When the photo-addition was carried out under air bubble agitation instead of nitrogen, a yellowish solution was obtained. On working up in the usual manner it gave the hydrochloride (25%) of IIA and a basic fraction which contained mostly IIA and a minor amount of unidentified impurities. Either in the absence of hydrochloric acid or in dark, the intensity of the nitroso peak at 248 mμ did not decrease.

Addition of N-Nitrosopyrrolidine

The nitroso compound (5 g) and cyclohexene (15 ml) were photolyzed as described above. The free base IIB (7.5 g) crystallized immediately upon neutralization and was recrystallized from methanol–water to give white crystals, m.p. 123° and infrared peaks at 3 170, 3 050, 1 650 (weak), 1 490, and 1 000 – 900 (complex) cm^{-1}.

Anal. Calcd. for $C_{10}H_{18}N_2O$: C, 65.89; H, 9.96; N, 15.37. Found: C, 65.80; H, 9.73; N, 15.12.

Addition of N-Nitrosomorpholine

The nitroso compound (8.55 g) and cyclohexene (25 ml) were photolyzed as described above. Following the usual working up procedure, the hydrochloride (5.7 g) of 2-morpholinocyclohexanone oxime IIC and a basic fraction (6.9 g) were obtained. The basic fraction is partially crystalline and the oil and crystals had very similar infrared spectra. Recrystallization of this fraction from benzene – Skellysolve B and sublimation gave IIC, m.p. 113–114°, reported m.p. 118° (2). The same crystals were also obtained when the above hydrochloride was neutrallized with sodium carbonate in aqueous solution and the collected solid sublimed. This has infrared peaks at 3 300, 3 100, 1 650 (weak), 1 490, 1 115, 1 000 – 900 (complex), and 785 cm^{-1}. The n.m.r. spectrum of IIC shows, besides the signals listed in Table I, a triplet at τ6.27 (4H, J = 4.5) due to —CH_2—O—CH_2— protons and a multiplet centered at τ7.50 (4H) due to —CH_2—N—CH_2— protons.

Anal. Calcd. for $C_{10}H_{18}N_2O_2$: C, 60.58; H, 9.15; N, 14.13. Found: C, 60.39; H, 9.23; N, 14.21.

Addition of N-Nitroso-3-azabicyclo[3,2,2]nonane

The nitroso compound (3 g) and cyclohexene (25 ml) were photolyzed as described above. The residue obtained after evaporation of the solvent was treated with cold acetone to give white crystals (2 g) which were recrystallized from isopropanol to give the hydrochloride of *N*-(2-oximinocyclohexyl)-3-azabicyclo[3,2,2]-nonane IID, m.p. 183–185°, infrared peaks at 3 160, 3 085, 2 635, 2 600, 1 660 (weak), 1 485, 900 – 1 000 (complex), and 745 cm^{-1}.

Anal. Calcd. for $C_{14}H_{25}N_2OCl$: N, 10.27. Found: N, 10.13.

A part of the hydrochloride was taken up in water and neutralized to give the free base. Recrystallization of the solid precipitate from Skellysolve B and sublimation gave IID, m.p. 148–151° and infrared peaks at 3 120, 3 070, 2 780, 2 800, 1 180, 940 and 910 cm^{-1}.

Anal. Calcd. for $C_{14}H_{24}N_2O$: C, 71.14; H, 10.24; N, 11.85. Found: C, 71.09; H, 9.93; N, 11.89.

The acetone mother liquor was evaporated and the residue was taken up in water. The aqueous solution was neutralized with sodium carbonate and the precipitate was ether extracted to give the basic fraction. The infrared spectrum of this showed strong absorption at 1 710 cm^{-1} and weak peaks belonging to a small amount of the oxime IID. This fraction was oximated with hydroxylamine hydrochloride and potassium carbonate in methanol–water and purified to give IID exclusively as identified by mixed m.p. 147–150° and by superimposable infrared spectra.

Addition of N-Nitroso-di-n-butylamine

The nitroso compound (8.5 g) and cyclohexene (25 ml) was photolyzed as described and the solvent was vacuum distilled. Trituration of the residue with cold acetone gave a precipitate (3.4 g) which was recrystallized from isopropanol to give di-*n*-butylamine hydrochloride having an infrared spectrum superimposable with that of an authentic sample.

The acetone mother liquor was worked up in the usual manner to give a basic fraction (11.2 g). Distillation of this fraction gave di-*n*-butylamine as the forerun and II as the major fraction, b.p. 100–102° at 0.2 mm (7.6 g). This fraction decomposed gradually changing to a black tar and did not give a satisfactory analysis in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

spite of repeated distillation. Freshly distilled sample of IIE was a faintly yellowish liquid showing infrared peaks at 3 200, 1 640 (medium), 1 180, 945 and 910 cm^{-1}.

Attempted Photo-addition of N-Nitrosodicyclohexylamine

The nitroso compound (3 g) and cyclohexene (25 ml) were photolyzed in ethanol (300 ml) containing concentrated hydrochloric acid (5 ml) under a similar condition as described. The photolysate was vacuum evaporated and the residue was triturated with water to give a precipitate (1.4 g). This precipitate was recrystallized from water to give dicyclohexylamine hydrochloride as shown by the superimposable infrared spectrum.

The aqueous solution was neutrallized with sodium carbonate solution and ether extracted to give a fraction (1.08 g). A portion of this was treated with Brady's reagent to give cyclohexanone 2,4-dinitrophenylhydrazone, m.p. and mixed m.p. 155–158°. The remainder was distilled under atmospheric pressure at a bath temperature 130–140°. This distillate contained cyclohexylamine as identified by a comparison of the infrared spectrum of its hydrochloride with that of an authentic sample. The residue was vacuum distilled at 10 mm. The crystalline distillate was recrystallized from water and sublimed to give cyclohexanone oxime, m.p. and mixed m.p. 85–87°.

Attempted Photo-addition of N-Nitrosodiisopropylamine

The nitroso compound (5.3 g) and cyclohexene (20 ml) were photolyzed as described above. The residue obtained after evaporation of solvent was triturated with cold acetone to give a white precipitate (3 g) which was identified as diisopropylamine hydrochloride. The aqueous mother liquor was neutralized with sodium carbonate followed by the usual work-up to furnish a basic fraction (850 mg). The infrared spectrum of this indicates that the fraction contains diisopropylamine as the major component but no cyclohexanone oxime.

ACKNOWLEDGMENT

The author is much indebted to Messrs. R. Swindlehurst and G. Bigam for recording spectra and Miss D. Roberts for performing analyses. It is a pleasure to acknowledge partial financial support by the National Research Council on this project.

STUDIES IN THE PYRROLINE SERIES

V.[1] 3,3-DIMETHYL-1-PYRROLINE-1-OXIDE

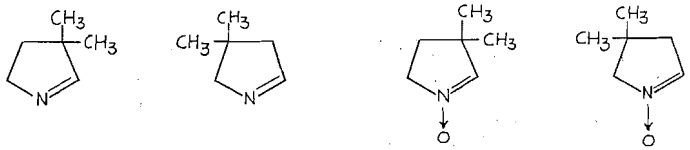
R. BONNETT, S. C. HO, AND J. A. RALEIGH
The Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received March 8, 1965

ABSTRACT

The pyrolysis of 1-ethyl-3,3-dimethylpyrrolidine-1-oxide gives 1-hydroxy-3,3-dimethylpyrrolidine, which, on dehydrogenation, yields 3,3-dimethyl-1-pyrroline-1-oxide. The identification of the nitrone is described. The cyclo-additions of styrene to this nitrone and to 5,5-dimethyl-1-pyrroline-1-oxide were investigated, and the direction of addition was deduced from the n.m.r. spectra of the adducts.

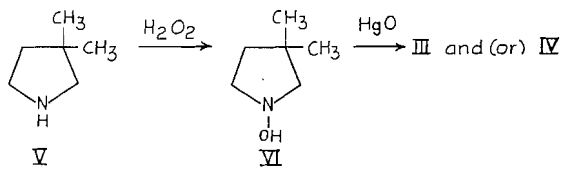
In connection with other work (1) it was desired to prepare pyrroline ring systems with geminal substitution at a β-position, and to this end attempts were made to synthesize one or more of the dimethyl compounds I–IV.



I II III IV

Three approaches were tried. The first followed the nitroalkane synthesis (2) and involved the attempted conjugate addition of nitromethane to senecialdehyde, this being the first step on the route to II and IV. Under a variety of reaction conditions, no absorption due to an unconjugated carbonyl group was found in the infrared spectrum of the product, and it was concluded that 1,4-addition had not occurred to an appreciable extent. This result is presumably due to the steric effect of the substituents at the β-position of the unsaturated aldehyde, and it is pertinent that, whereas nitromethane adds readily across the conjugated system of acrolein (3), in the reaction of crotonaldehyde with nitromethane, conjugate addition is not the main path.

The second approach, which suffered from the disadvantage that it would be expected to yield a mixture of isomers III and IV, was the direct oxidation of the corresponding secondary amine to the cyclic hydroxylamine (ref. 4, cf. 5) followed by dehydrogenation to the nitrone.



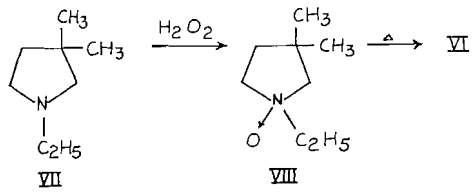
V VI

As others have recently reported (6, 7), some difficulty was experienced with the direct oxidation with hydrogen peroxide, a step which gave erratic and low yields. The best yield

[1]*For Part IV see R. Bonnett. J. Chem. Soc. 2313 (1965).*

of solid 1-hydroxypyrrolidine (from pyrrolidine itself in preliminary experiments) was 8%; and from 3,3-dimethylpyrrolidine the corresponding hydroxylamine could not be isolated, although a trace of the nitrone (III) was obtained.

The third approach did prove successful as a preparative method. 1-Ethyl-3,3-dimethylpyrrolidine (VII) (from the corresponding imide) was converted into the amine oxide (VIII). This, on pyrolysis, eliminated 1-hydroxy-3,3-dimethylpyrrolidine (VI) (cf. ref. 7), which was characterized as the hydrogen oxalate. Oxidation of the cyclic hydroxylamine with yellow mercuric oxide in chloroform or dichloromethane yielded a hygroscopic oil, b.p. 74–76° at 0.55 mm, which solidified on cooling and which was identified as 3,3-dimethyl-1-pyrroline-1-oxide on the basis of the following evidence.



VII VIII

The product gave, not unexpectedly in view of its hygroscopic nature, rather poor analytical values itself, but these figures, and those for the picrate, indicated the molecular formula $C_6H_{11}NO$. Repeated fractionation of the picrate and its mother liquors did not furnish a second derivative. Reduction and hydrogenolysis of the product with lithium aluminium hydride/aluminium chloride gave 3,3-dimethyl pyrrolidine, which indicated that the ring system had remained intact. Both the infrared and ultraviolet spectra of the product were in accord with the nitrone formulation. In the infrared region a strong absorption at 1 580 cm^{-1} was assigned to the —CH=N → O system: 5,5-dimethyl-1-pyrroline-1-oxide shows a similar band at 1 573 cm^{-1} (8). The ultraviolet spectrum had λ_{max} 235 mμ (log ϵ 3.92) in ethanol and λ_{max} 248 mμ (log ϵ 3.98) in hexane. For comparison, 5,5-dimethyl-1-pyrroline-1-oxide has λ_{max} 234 mμ (log ϵ 3.89) in ethanol (8) and λ_{max} 247 mμ (log ϵ 3.94) in hexane. Ultraviolet irradiation produced a considerable decrease in absorption in all cases, presumably as a result of oxaziran formation (9). These results indicated that the base probably had structure III or IV, or could possibly be a mixture of the two. The double bond was located by a combination of chemical and physical methods. Reaction of the base with methyl magnesium iodide, followed by dehydrogenation of the product, furnished a trimethyl-1-pyrroline-1-oxide which (i) had the spectral characteristics of a ketonitrone rather than an aldonitrone (infrared band at ~1 610 cm^{-1} and not at ~1 580 cm^{-1}), (ii) appeared to be a single substance, and (iii) was not identical with 2,4,4-trimethyl-1-pyrroline-1-oxide. Hence it is formulated as IX. Furthermore, reaction of the original dimethyl nitrone with phenyl magnesium bromide, followed by dehydrogenation of the product (X), gave the phenyl nitrone (XI), which, when subjected to the oxygen transfer reaction (10) with triphenylphosphine, gave a volatile base that proved to be identical with an authentic sample (11) of 3,3-dimethyl-2-phenyl-1-pyrroline (XII). Alternatively, the hydroxylamine (X) could be directly converted into the pyrroline (XII) by melting it with potassium hydrogen sulfate. It may be noted that the ultraviolet spectrum of XI shows absorption at somewhat lower wavelength and intensity than that of 2-phenyl-1-pyrroline-1-oxide (12). This is attributed to a certain degree of steric inhibition of conjugation analogous to that which has been observed with a series of phenyl ketones (13).

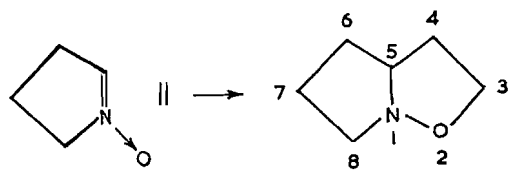
These chemical sequences suggest that the dimethyl nitrone has structure (III), and the proton magnetic resonance spectrum of the base supports this conclusion (1). The absence of the other isomer (IV), in which dehydrogenation has occurred on the least hindered side, is noteworthy. To detect small quantities of this isomer in the product, the sequence (III) → (IX) → trimethylpyrroline was followed, purification at the intermediate and final stages being deliberately avoided. The trimethylpyrroline resulting from this process was examined by vapor phase chromatography, and was shown to consist mainly of a base which had a retention volume different from that of 2,4,4-trimethyl-1-pyrroline, and which was characterized as 2,3,3-trimethyl-1-pyrroline. A small peak which had approximately the same retention volume as 2,4,4-trimethyl-1-pyrroline was indeed present, but amounted to less than 3% of the area of the main peak. It thus appears that dehydrogenation occurs predominantly on the more hindered side of the cyclic hydroxylamine. Two possible interpretations of this result have been considered. Firstly, it is apparent that the nitrone (IV) can undergo self-condensation of the aldol type, whereas III cannot. Hence it might be supposed that both isomers are formed extensively, but that IV is not isolated because it polymerizes. However, it is to be noted that the parent nitrone in this series, 1-pyrroline-1-oxide itself, has been prepared in good yield by this route (7). The second involves the steric effect of the *gem*-dimethyl group, an effect already manifested in certain of the ultraviolet spectra. On the basis of the analogy to the dehydrogenation of N,N-disubstituted hydrazines (14) it is likely that the oxygen function is involved in the initial stages of the reaction: although the process may be further complicated by conformational considerations it would appear reasonable that subsequent reaction proceeds in that direction which will relieve most effectively the non-bonded interactions of C-methyl and C—H bonds, leading to structure III in preference to IV.

The 1-pyrroline-1-oxides are known to undergo cyclo-addition reactions with suitably substituted olefins (15), the adducts possessing the novel 2-oxa-1-azabicyclo[3.3.0]octane ring system (XIII).



XIII

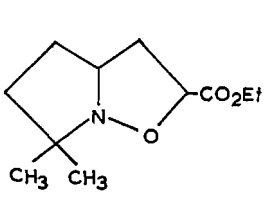
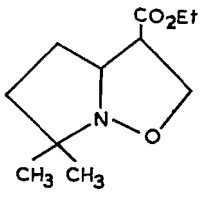
For personal use only.

Thus, for the addition of ethyl acrylate to 5,5-dimethyl-1-pyrroline-1-oxide, evidence has been presented (16) which suggests that the adduct of structure XIV is rapidly formed but that the isomer XV is thermodynamically more stable.

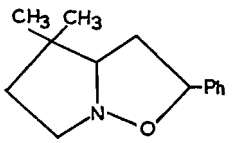


XIV

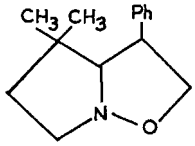


XV

It was of interest to determine whether the nitrone prepared in the present work was subject to this type of addition. Although the yields were only moderate in some instances the cyclo-addition reaction was shown to proceed satisfactorily at temperatures below 100°. The addition of styrene gave a colorless oil which could be satisfactorily purified by distillation under low pressure and which formed a picrate. The infrared and ultraviolet spectra of the adduct were in accord with the bicyclic structure (XVI). A decision between the positional isomers XVI*a* and XVI*b* could be made on the basis of the proton magnetic resonance spectrum, since in XVI*a* the proton at C3 is subject to two deshielding influences and would be expected to be brought into resonance at relatively low field (cf. $PhCH_2OH$ at 5.6 τ (17)), whereas in the isomer there is no similar compounding of deshielding effects. The spectrum of the base did, in fact, show a signal corresponding to one proton at 5.04 τ, and this was assigned to the proton at C3 in structure XVI*a*.



XVIa



XVIb

Since this signal took the form of a triplet, the coupling constants between the C3 proton and the protons at C4 would appear to be fortuitously similar or to be subject to an averaging process (cf. the triplet assigned to the anomeric hydrogen in thymidine (18): the positions of the other signals supported structure XVI*a*, as did the ratios of their areas. That the steric effect of the *gem*-dimethyl group was not primarily responsible for the direction of addition observed to predominate was shown by examining the adduct of styrene and 5,5-dimethyl-1-pyrroline-1-oxide. Again the proton magnetic resonance spectrum showed a signal in the 5 τ region, and it was concluded that addition had occurred in the same sense as in the previous example. The same orientation has been observed in the addition of styrene to benzylidene aniline N-oxide (19).

When it arises the question of configuration at C3 (or C4) has not been settled for any of the 2-oxa-1-azabicyclo[3.3.0]octanes made in this way. Thus in the present examples the two possibilities are indicated in structures XVI*c* and XVI*d*, each being a racemate. The analogous problem in the Diels–Alder reaction has sustained a good deal of attention, and since the *cis* mode of addition has been demonstrated for several examples of 1,3-dipolar addition (19) it remains of particular interest to determine to what extent, if any, considerations analogous to the "rule" of endo-addition (leading to XVI*d*) also apply.

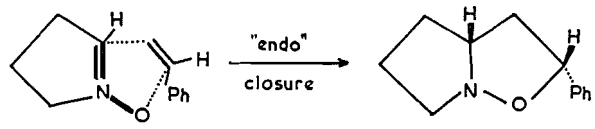
XVIc



XVId

It is pertinent that electron-accommodating substituents at the alkene linkage are not strictly necessary for nitrone addition to proceed in satisfactory yield (15, 19, 20) and that the 1,3-dipolar group, being smaller in extent than the 1,3-diene system, will be less likely to interact directly with such a substituent in the transition state.

EXPERIMENTAL

The following equipment was used. Melting points: Fisher-Johns heated block. Infrared spectra: Perkin–Elmer Infracord or Model 21. Vapor phase chromatography: Aerograph model A-100-C. Proton magnetic resonance spectra: Varian A60; dilute solutions in carbon tetrachloride: tetramethylsilane internal reference. Analyses by Dr. A. Bernhardt, Mulheim.

1-Ethyl-3,3-dimethylpyrrolidine (VII)

$\alpha\alpha$-Dimethylsuccinic acid (257 g) (21) was treated with aqueous ethylamine (50%; 450 ml) and gradually heated to 200° under a short air condenser. After 15 min at this temperature the product, 1-ethyl-3,3-dimethylsuccinimide, was distilled as a colorless liquid, (207 g, 76%), b.p. 110° at 24 mm, η_D^{20} 1.4605.

Found: C, 61.5; H, 8.0; N, 9.4. $C_8H_{13}NO_2$ requires C, 61.9; H, 8.4; N, 9.0.

The imide was reduced in tetrahydrofuran with lithium aluminium hydride in the normal way (21) to give 1-ethyl-3,3-dimethylpyrrolidine (65%) b.p. 127° at 746 mm as a colorless liquid, η_D^{20} 1.4280. Infrared maxima (film) at 2 778, 1 372, and 1 359 cm^{-1}.

Picrate from ethanol, m.p. 165°. Found: C, 47.6; H, 5.7; N, 15.8. $C_{14}H_{20}N_4O_7$ requires C, 47.2; H, 5.7; N, 15.7.

1-Hydroxy-3,3-dimethylpyrrolidine (VI)

1-Ethyl-3,3-dimethylpyrrolidine (63.2 g) was carefully added, with stirring, to hydrogen peroxide (30%; 295 g) cooled in ice so that the internal temperature did not exceed 60°. The mixture was stirred for 24 h. A pinch of platinum black was added and the mixture stirred at room temperature for a further 24 h. Any unchanged amine was extracted with ether, and the resulting aqueous solution was concentrated to an oily liquid, the last traces of water being removed by codistillation with benzene. The picrate, m.p. 135°, of 1-ethyl-3,3-dimethylpyrrolidine-1-oxide was prepared in water and recrystallized from ethanol.

Found: C, 45.1; H, 5.3; N, 15.2. $C_{14}H_{20}N_4O_8$ requires C, 45.15; H, 5.4; N, 15.05.

The amine oxide was pyrolyzed in small portions (7) in an oil bath at 145° and at a pressure of approximately 10 mm. Under these conditions 1-hydroxy-3,3-dimethylpyrrolidine slowly distilled as a pale yellow liquid with an apparent b.p. of 71–74° and in an overall yield of 34–45% based on the tertiary amine. The infrared absorption spectrum (film) showed no band at 2 770 cm^{-1}, a very weak peak at 1 582 cm^{-1}, and a strong band at 3 226 cm^{-1}. The hydrogen oxalate, m.p. 125°, was prepared in acetone and recrystallized from methanol–water.

Found: C, 47.05; H, 7.2; N, 7.1. $C_8H_{15}NO_5$ requires C, 46.8; H, 7.4; N, 6.8.

3,3-Dimethyl-1-pyrroline-1-oxide (III)

The hydroxylamine (3.6 g) in anhydrous chloroform (85 ml) was treated with yellow mercuric oxide (13.5 g) and shaken for 2 h. Another portion of mercuric oxide (3.5 g) was then added, and, after 2 more hours of shaking, the grey-green mixture was filtered (Celite) and the pad washed with a little chloroform. The solvent was removed, and the residual oil was kept in the dark over phosphorus pentoxide for 72 h.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Distillation gave 3,3-dimethyl-1-pyrroline-1-oxide (2.2 g, 62%) as a hygroscopic oil, b.p. 74–76° at 0.55 mm. It solidified, on cooling, to a mass of long needles, m.p. ca. 25°, and was stored at −20°.

Found: C, 62.5; H, 9.4; N, 12.1. $C_6H_{11}NO$ requires C, 63.7; H, 9.8; N, 12.4.

The picrate, m.p. 105° from ethanol. Found: C, 42.2; H, 4.35; N, 16.4. $C_{12}H_{14}N_4O_8$ requires C, 42.1; H, 4.1; N, 16.4.

The infrared spectrum of the nitrone (film) showed peaks at 3 460 (broad) and 1 580 cm^{-1} (strong). The ultraviolet spectrum: in hexane λ_{max} 248 mμ (log ϵ 3.98); in ethanol λ_{max} 235 mμ (log ϵ 3.93). On continued irradiation with ultraviolet light these absorbancies fell sharply.

Methylation Experiments

3,3-Dimethyl-1-pyrroline-1-oxide (1.29 g) in dry ether (15 ml) was added to methyl magnesium iodide (from 0.35 g magnesium) in 25 ml dry ether and then heated under reflux for 1 h. After decomposition with aqueous ammonium chloride, the product was isolated in ether. The ether solution was dried and evaporated to yield 1-hydroxy-2,3,3-trimethylpyrrolidine as an oil. This was dissolved in dry dichloromethane (30 ml) and treated with yellow mercuric oxide (portions of 4.8 g and 1.2 g) as in the previous oxidation experiment. Isolation of the product gave 2,3,3-trimethyl-1-pyrroline-1-oxide (IX) (0.64 g, 44%) as an oil, b.p. 62° at 0.17 mm, which, on cooling, formed very hygroscopic needles. Infrared spectrum (film); 3 436 cm^{-1} (moisture), 1 610 cm^{-1} (C=N → O): ultraviolet spectrum; in methanol λ_{max} 229 mμ, (log ϵ 3.96).

The picrate, m.p. 174°, needles from ethanol.

Found: C, 43.8; H, 4.7; N, 15.6. $C_{13}H_{16}N_4O_8$ requires C, 43.8; H, 4.5; N, 15.7.

Repeated fractional crystallization of the total picrate preparation did not yield an isomeric picrate.

In a second series of experiments, the above steps were repeated starting with 0.4 g of the dimethyl nitrone, but the trimethyl nitrone was not purified by distillation. Instead the crude oily product was heated (free flame) with triphenylphosphine (1 g) for 5 min before the volatile base (0.15 ml) was distilled out. This basic liquid was submitted to purification by vapor phase chromatography (Aerograph instrument, 5 ft Ucon polar column at 95°, helium carrier gas at 100 ml/min). Under these conditions 2,4,4-trimethyl-1-pyrroline exhibited a retention volume of 590 ml. The product from the oxygen-transfer reaction showed a small response at retention volume 580 ml, and a major one at retention volume 750 ml. The ratio of the areas was 1:34. The 2,3,3-trimethyl-1-pyrroline represented by the second peak was collected. Infrared absorption (film) occurred at 1 637 cm^{-1}. The picrate, tiny prisms, m.p. 249–251° (decomp.), from ethanol was analyzed.

Found: C, 46.0; H, 4.5; N, 16.5. $C_{13}H_{16}N_4O_7$ requires C, 45.9; H, 4.7; N, 16.5.

3,3-Dimethyl-2-phenyl-1-pyrroline (XII) from 3,3-Dimethyl-1-pyrroline-1-oxide

(i) Addition of Phenyl Magnesium Bromide

3,3-Dimethyl-1-pyrroline-1-oxide (1 g) in ether (10 ml) was added to phenyl magnesium bromide (from 3 g phenyl bromide) in ether (20 ml), heated under reflux for 1 h and treated with aqueous ammonium chloride. The ether layer was washed with water, dried, and concentrated. Addition of hexane caused 1-hydroxy-3,3-dimethyl-2-phenylpyrrolidine (0.97 g, 57%) to crystallize out as small prisms, m.p. 129°. Recrystallization of a small sample from ether/hexane raised the melting point to 130°.

Found: N, 7.55. $C_{12}H_{17}ON$ requires N, 7.3.

(ii) Dehydrogenation

The hydroxylamine (0.9 g) was stirred in 25 ml dichloromethane with yellow mercuric oxide (5 g) for 3 h. Filtration, drying, and concentration gave an oil which crystallized on cooling (0.71 g, 79%). A small portion of the 3,3-dimethyl-2-phenyl-1-pyrroline-1-oxide was distilled (hot box, 115° at 0.2 mm) and showed a new band in the infrared (film) at 1 534 cm^{-1}. The ultraviolet spectrum (ethanol) had λ_{max} 283 mμ (log ϵ 3.83).

The picrate, m.p. 137°, light-sensitive prisms from ethanol.

Found: C, 51.6; H, 4.5; N, 13.2. $C_{18}H_{18}N_4O_8$ requires C, 51.7; H, 4.3; N, 13.4.

(iii) Oxygen Transfer

3,3-Dimethyl-2-phenyl-1-pyrroline-1-oxide (0.5 g) was heated with 1 g of triphenylphosphine (free flame) for 5 min. A volatile liquid was formed which was distilled off at 125–135° at 15 mm. The infrared spectrum of the liquid was essentially identical with that of authentic 3,3-dimethyl-2-phenyl-1-pyrroline (11). The picrate (0.46 g, 43%) was prepared in ether and recrystallized from ethanol.

M.p. and mixed m.p. 161° (lit. (11) 160°).

Found: C, 53.4; H, 4.5; N, 13.9. $C_{18}H_{18}N_4O_7$ requires C, 53.7; H, 4.5; N, 13.9.

(iv) The Direct Dehydration of the Hydroxylamine (X)

1-Hydroxy-3,3-dimethyl-2-phenylpyrrolidine (0.32 g from (i)) and potassium hydrogen sulfate (0.4 g) were mixed and heated for 1 h in a stoppered tube in an oil bath at 150–155°. Water was added to the warm dark-brown product, which was treated with aqueous sodium hydroxide, and extracted with ether. The ether was washed with water, heated under reflux with charcoal, filtered, and treated with picric acid in moist ether. This gave 0.19 g (28%) of 3,3-dimethyl-2-phenyl-1-pyrroline picrate, m.p. 158–159°, raised to 160–161° on one recrystallization from ethanol. Mixed m.p. 160–161°.

Reduction of 3,3-Dimethyl-1-pyrroline-1-oxide to 3,3-Dimethylpyrrolidine

To lithium aluminium hydride (1 g) in ether (70 ml) was added 3,3-dimethyl-1-pyrroline-1-oxide (0.5 g) in ether (10 ml). The mixture was refluxed for 1 h. Aluminium chloride (anhydrous, 1 g) was then added and the mixture heated under reflux for a further hour. Decomposition with 30% aqueous sodium hydroxide followed by treatment of the separated, washed ether layer with ethereal picric acid gave a precipitate of yellow needles (0.90 g, 62%) m.p. and mixed m.p. 160°.

Analytical sample from ethanol.

Found: C, 43.8; H, 4.8; N, 16.8. $C_{12}H_{16}N_4O_7$ requires C, 43.9; H, 4.9; N, 17.1.

Dipolar Addition Reactions

(i) 6,6-Dimethyl-3-phenyl-2-oxa-1-azabicyclo[3.3.0] octane (XVIa)

3,3-Dimethyl-1-pyrroline-1-oxide (0.5 g) was heated with styrene (2.5 ml) on the steam bath for 20 h. Distillation (hot box; 135° at 0.35 mm) gave the adduct (XVI*a*) as a colorless oil (0.7 g, 73%) with η_D^{20} 1.5345.

Found: C, 77.0; H, 8.6; N, 6.9. $C_{14}H_{19}NO$ requires C, 77.4; H, 8.8; N, 6.45.

λ_{max} (ethanol): 258 mμ, log ϵ 2.45. ν_{max} (film) at 1 595, 1 484, 1 377, 1 359 cm^{-1}. The n.m.r. spectrum (CCl_4 solution, τ values): 2.82 (Ph); 5.04 (Ph—C*H*—O); ~6.81 (NCH); and 7.62–8.57, 8.93 (CH_2 and CH_3) with relative areas of 5.0, 0.95, 3.09, and 10.6 respectively.

The picrate, recrystallized from ethanol, had m.p. 153°.

Found C, 53.9; H, 4.9; N, 12.8. $C_{20}H_{22}N_4O_8$ requires C, 53.8; H, 5.0; N, 12.55.

(ii) 8,8-Dimethyl-3-phenyl-2-oxa-1-azabicyclo[3.3.0] octane

5,5-Dimethyl-1-pyrroline-1-oxide (1 g) in styrene (5 ml) was heated on the steam bath for 8 h. Distillation gave 1.74 g (90%) of the adduct as a colorless liquid, b.p. 98–100° at 0.1 mm., η_D^{20} 1.5335.

Found: C, 77.3; H, 8.7; N, 6.6.

λ_{max} (ethanol): 258 mμ, log ϵ 2.44. ν_{max} (film) 1 603, 1 493, 1 379, 1 364 cm^{-1}. The n.m.r. spectrum (CCl_4 solution, τ values): 2.81 (Ph): 5.13 (Ph—C*H*—O); ~6.20 (NC*H*); and 7.65; 7.86–8.60; 8.69; 8.99 (CH_2 and CH_3) with relative areas of 5.0, 0.97, 1.08, and 12.4 respectively.

The picrate, from ethanol, had m.p. 175°. Found: C, 53.6; H, 4.9; N, 12.8.

ACKNOWLEDGMENTS

Dr. D. E. McGreer is thanked for the n.m.r. spectra, and Mr. K. S. Chan for repeating the preparation of the 3,3-dimethylnitrone. The financial support of the National Research Council of Canada is gratefully acknowledged.

THE KINETICS OF THE INHIBITED AUTOXIDATION OF TETRALIN. II[1]

J. A. HOWARD AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received May 10, 1965

ABSTRACT

The kinetics of the oxidation of tetralin inhibited by a number of phenols have been examined. The chain transfer reaction between phenoxy radicals and hydroperoxides is subject to both polar and steric effects. The rate of this reaction is increased by electron-attracting substituents on the phenol and is decreased both by ortho-alkyl groups on the phenol and by an increase in the size of the substituents on the hydroperoxides.

INTRODUCTION

In Part I (1) it was shown that the overall process for the inhibition of the autoxidation of tetralin by the highly hindered phenol, 2,6-di-*t*-butyl-4-methylphenol (BMP) can be represented by the following simplified reaction scheme

[1] $$I_2 \rightarrow 2I\cdot$$

[2] $$R\cdot(I\cdot) + O_2 \rightarrow RO_2\cdot$$

[3] $$RO_2\cdot + RH \rightarrow ROOH + R\cdot$$

[6] $$RO_2\cdot + AH \rightarrow ROOH + A\cdot$$

[7] $$RO_2\cdot + A\cdot \rightarrow ROOA$$

where I_2 represents α,α'-azo-bis-isobutyronitrile (AIBN) which initiated the oxidation. RH represents tetralin and AH the phenol. The inhibited rate (P) can be represented by

[I] $$P = \frac{ek_1k_3[RH][I_2]}{k_6[AH]}$$

where e is the efficiency with which the AIBN initiates reaction chains.

To represent the inhibition of tetralin oxidation by phenol two additional reactions are required.

[−6] $$A\cdot + ROOH \rightarrow AH + RO_2\cdot$$

[8] $$A\cdot + RH \rightarrow AH + R\cdot$$

The inhibited rate is proportional to the square root of the tetralin hydroperoxide (ROOH) concentration. It is given by

[II] $$P = \frac{ek_1k_3[RH][I_2]\alpha}{2k_6[AH]} + \frac{ek_1k_6k_8[RH][I_2][AH]\alpha}{2k_6[AH](k_{-6}[ROOH] + k_8[RH]) + ek_1k_7[I_2]\alpha}$$

where

$$\alpha = 1 + \left(1 + \frac{4k_6[AH](k_{-6}[ROOH] + k_8[RH])}{ek_1k_7[I_2]}\right)^{1/2}.$$

Inhibition with 4-methoxyphenol requires the additional reaction

[9] $$A\cdot + A\cdot \rightarrow A_2\cdot$$

[1]*Issued as N.R.C. No. 8571.*

The inhibited rate is independent of [AH] at high 4-methoxyphenol concentrations. Neglecting reactions [−6] and [7], it is given by

$$[III] \qquad P = \frac{2ek_1k_3[RH][I_2]}{k_6[AH]}\left(1 + \frac{k_8[RH]}{2(ek_1k_9[I_2])^{1/2}}\right) + k_8[RH]\left(\frac{ek_1[I_2]}{k_9}\right)^{1/2}.$$

The present work describes the inhibition of the oxidation of tetralin by a number of other phenols using the same experimental technique as in Part I (1). Further examples of all three types of kinetics have been found. The accelerating effect of hydroperoxides on inhibited rates has also been examined in detail.

RESULTS AND DISCUSSION

2,6-Di-t-butyl-4-substituted Phenols

Several of these highly hindered phenols were examined. In all cases, they followed the simple first order kinetics described by eq. [I] except that the inhibited rates were very slightly increased by the addition of tetralin hydroperoxide (see below). Values of k_6 at 65 °C calculated from eq. [I] are given in Table I. These results are based on $k_3 = 16.4$ l mole^{-1} s^{-1}, a value which has been calculated from a self-termination rate constant, $k_5 = 4 \times 10^6$ l mole^{-1} s^{-1} (average of some of our unpublished data from 13–50 °C) and a $k_3\sqrt{(2k_5)}$ value of 5.8×10^{-3} l$^{1/2}$ mole$^{-1/2}$ s$^{-1/2}$ at 65 °C. This table also includes values of k_6 for hydrogen abstraction from the same phenols by poly(peroxystyryl) peroxy radicals, these values having been recalculated from our previous data (3) using $k_3 = 178$ l mole^{-1} s^{-1} for styrene at 65 °C (2). The two sets of rate constants are in fair agreement as might be expected for two hydrocarbons which give secondary peroxy radicals since both the steric and the polar effects should be rather similar. The k_6 values in tetralin, like those in styrene (3), can be correlated with the σ^+ constants of the parasubstituents by means of the Hammett equation. The slope of the best straight line, i.e., the ρ factor is −1.36 (standard deviation 0.043*) which is in good agreement with the value of −1.12 found in styrene.

4-CN	1.6	1.7
4-NO_2	0.6	1.0

*Recalculated using k_3(styrene) = 178 l mole^{-1} s^{-1}.

Unhindered and Weakly Hindered Phenols

A thorough study of inhibition kinetics was only attempted for two non-hindered phenols, para-cresol and 4-chlorophenol. Both compounds showed the same kinetic behavior as phenol (1), i.e., they appeared to follow eq. [II]. Our main interest in these simple phenols was to measure the accelerating effect of tetralin hydroperoxide on the

**A better correlation with a smaller ρ factor is obtained if we employ σ values of 0.227 for 4-Cl and the enhanced σ values (4) of 1.00 for 4-CN and 1.27 for 4-NO_2.*

For personal use only.

inhibited rate. For this reason, substituents which were more strongly electron attracting than para-chloro were only cursorily examined since they gave such weak inhibition that the accelerating effect of added hydroperoxide was insignificant. For example, 4-nitro- and 4-cyano-phenol did not measurably inhibit the oxidation of tetralin under the standard conditions used to compare oxidation rates in Table II.

TABLE II

The inhibited oxidation of tetralin at 65 °C

Phenol substituents	Initial rate $\times 10^7$ (moles l^{-1} s^{-1})*	$k_{-6}/k_7 \times 10^7$†

2,6-Bu_2^t-4-CN	1.5	4.9

*With [RH] = 6.61 moles/l, $[I_2] = 1.23 \times 10^{-3}$ mole/l, and [AH] = 6.12×10^{-3} mole/l, unless otherwise noted.
†With added tetralin hydroperoxide.
‡Limiting rate independent of [AH].
§With [AH] = 6.12×10^{-4} mole/l.

The kinetics were also carefully examined for 2,6-dimethylphenol since this compound is known to dimerize very readily in oxidizing hydrocarbons (6, 7, 8). It was expected that this phenol would show the same kinetics as 4-methoxyphenol (eq. [III]), i.e., kinetics which result from the rapid coupling of phenoxy radicals (reaction [9]). This was in fact observed, i.e., as the 2,6-dimethylphenol concentration was increased the rate decreased to a constant limiting value which depended on $[RH] \times [I_2]^{1/2}$ but was unaffected by the further addition of inhibitor. The limit was reached at a dimethylphenol concentration of about 2×10^{-3} mole/l. From this limiting rate, the ratio $k_8/k_9^{1/2}$ was found to be 2.0×10^{-4} $(l/mole\ s)^{1/2}$. This value is very similar to the value of 1.7×10^{-4} $(l/mole\ s)^{1/2}$ which can be calculated from our previous data (1) to be the ratio of $k_8/k_9^{1/2}$ for 4-methoxyphenol. If it is assumed that k_9 is similar to the recently determined value of $\sim 6 \times 10^9$ l $mole^{-1}$ s^{-1} for the dimerization of phenoxy and 4-methylphenoxy radicals in aqueous solution (9), then k_8 will be about 15 l $mole^{-1}$ s^{-1}.

In view of the complex kinetics exhibited by unhindered and weakly hindered phenols in tetralin, "relative inhibiting efficiencies" obtained by comparisons of initial inhibited rates or induction periods are *not* linearly related to the relative rates of reaction [6] (see e.g. ref. 10). Such a correlation only applies to those phenols for which eq. [I] is applicable, i.e., to the highly hindered 2,6-di-*t*-butylphenols.

A plot of the phenol-inhibited rate against the square root of the tetralin hydroperoxide concentration gives a straight line (1, 11). From the first term in eq. [II] the slope of this line is

$$[IV] \qquad \frac{P_1 - P_2}{[ROOH]^{1/2}} = k_3[RH]\left(\frac{ek_1[I_2]}{k_6[AH]}\right)^{1/2}\left(\frac{k_{-6}}{k_7}\right)^{1/2}$$

Since k_6 appears to be virtually the same in styrene and tetralin (Table I) the value obtained previously in styrene (3*) can be used to obtain k_{-6}/k_7 in tetralin. This data is

**Recalculated using k_3 = 178 l $mole^{-1}$ s^{-1} for styrene at 65 °C (2).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

given in Table II for several phenols. In calculating k_{-6}/k_7 the increased rate of chain initiation from the added hydroperoxide has been allowed for in all cases. Table II also includes the initial inhibited rates in the absence of added hydroperoxide under standard conditions ([RH] = 6.61 moles/l (10% by volume *o*-dichlorobenzene as diluent), $[I_2] = 1.23 \times 10^{-3}$ moles/l, and $[AH] = 6.12 \times 10^{-3}$ moles/l).

Equation [IV] was obeyed by phenol over a wide range in $[I_2]$ (10^{-2} to 10^{-4} mole/l), [AH] (5×10^{-2} to 5×10^{-4} mole/l), and [RH] (6.61 to 1.32 moles/l). The values of k_{-6}/k_7 for 4-methoxyphenol and 2,6-dimethylphenol were obtained at low inhibitor concentrations where the kinetics approximate that for phenol itself, i.e., where the inhibited rate is approximately proportional to $[AH]^{-1/2}$. The fact that tetralin hydroperoxide accelerates the inhibited rates for both these phenols implies that reaction [−6] should have been included in the derivation of eq. [III]. When this is done, an extremely complex expression is obtained which, however, still simplifies to $k_8[RH](ek_1[I_2]/k_9)^{1/2}$ at high inhibitor and low hydroperoxide concentrations. The accelerating effect of the hydroperoxide can, for all practical purposes, be neglected from the kinetic treatment when k_{-6}/k_7 is less than about 10^{-5}.

Although the values of k_{-6}/k_7 in Table II cannot be linearly related to the polar effects of the substituents they are significantly larger for electron-attracting than for electron-releasing groups (compare, e.g., 4-methoxyphenol with the other unhindered phenols, or 2,6-dimethylphenol, or 2,6-di-*t*-butylphenol with their 4-cyano derivatives). This polar effect might be due to a change in either rate constant.

Steric effects are both more regular and more pronounced than polar effects. That is, k_{-6}/k_7 decreases along the series phenol, 2,6-dimethylphenol, 2-methyl-6-*t*-butylphenol, and 2,6-di-*t*-butylphenol. The importance of polar effects in this series can be diminished by comparing phenol with 2,6-dimethyl-4-cyanophenol and 2,6-di-*t*-butyl-4-cyanophenol since electron attraction by the 4-cyano group will roughly compensate for electron release by the ortho-alkyl groups. This steric effect is probably due to a change in k_{-6} since the reverse process, i.e., reaction [6], is subject to a very similar steric effect (3). In both reactions [6] and [−6] the steric effect of two ortho-methyl groups is much smaller than the steric effect of two ortho-*t*-butyl groups. This result is in agreement with the conclusions derived from studies of the infrared spectra of ortho-alkyl phenols (12, 13).

TABLE III

Effect of hydroperoxide on $k_{-6}/k_7 \times 10^7$ in tetralin at 65 °C

Phenol substituents	Hydroperoxide			
	Tetralin	$(CH_3)_3C$-	$C_6H_5(CH_3)_2C$-	$(C_6H_5)_3C$-
None	515	225	225	20
2,6-Me_2-4-CN	92	20	20	3.4
2,6-Bu_2^t-4-CN	4.9	1.3	1.5	0.2

The importance of the steric effect in reaction [−6] was confirmed by comparing the acceleration of inhibited rates which was produced by added tetralin, *t*-butyl, cumyl, and triphenylmethyl hydroperoxides. The results in Table III show that increased steric protection of both the hydroperoxide and the phenol reduces k_{-6}/k_7. For each phenol the steric effect of the hydroperoxide can be attributed to reaction [−6] since the peroxy radicals involved in reaction [7] must come mainly from the tetralin, i.e., k_7 is constant for each phenol. The decrease in the rate of reaction [−6] along the series from tetralin to triphenylmethyl hydroperoxide implies that unhindered or partly hindered phenols

For personal use only.

will be more likely to follow the simple kinetics of eq. [I] in a hydrocarbon yielding hindered tertiary peroxy radicals than in one yielding unhindered secondary radicals. Moreover, the inhibition efficiencies of unhindered phenols (relative to highly hindered phenols) should be improved in a hydrocarbon giving tertiary radicals since the unhindered phenoxy radicals will be more likely to end a second chain than to undergo reaction [−6].

Received May 6, 1965

ABSTRACT

Absolute rate constants for the uninhibited oxidation of styrene have been obtained by the rotating sector technique. The rate constants for the propagation (k_p), bimolecular termination (k_t), and a kinetically first order termination (k_x) for 2 M styrene in chlorobenzene can be represented by

$$k_p = (4.7 \pm 0.2) \times 10^7 \exp(-8400 \pm 300/RT) \text{ l mole}^{-1} \text{ s}^{-1}$$

$$k_t = (5.1 \pm 3.4) \times 10^8 \exp(-1800 \pm 1200/RT) \text{ l mole}^{-1} \text{ s}^{-1}$$

$$k_x = (5.8 \pm 1.4) \times 10^7 \exp(-11600 \pm 2800/RT) \text{ s}^{-1}.$$

The rate constant for the reaction of poly(peroxystyryl) peroxy radicals with 2,6-di-*t*-butyl-4-methylphenol can be represented by

$$k_{inh} = 8.4 \times 10^7 \exp(-5600/RT) \text{ l mole}^{-1} \text{ s}^{-1}.$$

Chemically inert solvents can affect the rate of chain initiation and the rate of chain propagation but they do not appear to affect the rate of chain termination.

INTRODUCTION

Although the absolute rate constants for chain propagation and termination in the autoxidation of many hydrocarbons have been determined, these constants are not known for the oxidation of styrene. Our interest in these quantities arose from our studies of the phenolic inhibition process in which styrene was used as the oxidizing substrate (1). This paper reports the measurement of these constants by the rotating sector technique, the theory of which has recently been clearly reviewed by Burnett and Melville (2). The nomenclature of these authors has been generally followed in the brief résumé given below.

The separation of the rate constants for propagation (k_p) and bimolecular termination (k_t)* involves measurement of the lifetime (τ) of the reaction chains. The lifetime is defined by the equation

$$\tau = (2k_tR_i)^{-1/2}$$

where R_i is the rate of the photo-initiation. A sectored disc is rotated between the light and the reaction vessel and oxidation rates are measured at various rotation speeds. At fast speeds the rate is

$$R_f = K[I/(r+1)]^{1/2}$$

where $KI^{1/2}$ is the oxidation rate at a steady light intensity I (i.e., $R_{steady} = KI^{1/2}$), and r is the ratio of dark to light periods. At slow rotation speeds the rate is

$$R_s = KI^{1/2}/(r+1).$$

[1]*Issued as N.R.C. No. 8590.*

**The rate of the reaction*

$$RO_2\cdot + RO_2\cdot \rightarrow \textit{inactive products}$$

is defined as $2k_t[RO_2\cdot]^2$ in this paper rather than $k_t[RO_2\cdot]^2$ as was used by Burnett and Melville.

Rates intermediate between R_f and R_s are denoted by R_λ. They have a complicated dependence on the duration of the light flash (λ) and the lifetime of the chains. Values of the ratio R_λ/R_{steady} have been given in terms of λ/τ for various values of r in Table I of ref. 2. Since λ is known from the rotation speed, τ is readily obtained and this gives k_t once R_i has been measured. Under steady illumination the rate can be represented by

$$R_{steady} = k_p[RH]\left(\frac{R_i}{2k_t}\right)^{1/2}$$

where [RH] is the hydrocarbon concentration. Substitution of R_i and k_t into this expression yields k_p.*

In the oxidation of styrene a first order chain termination process occurs together with the usual second order process (1). Following Burnett and Melville (2), the first order process can be represented as

$$RO_2\cdot \rightarrow \text{inactive products; rate} = k_x[RO_2\cdot].$$

It produces a reduction in the value of R_f/R_{steady}. This ratio is used to obtain a quantity γ by means of the relation

$$\frac{R_f}{R_{steady}} = \frac{((\gamma^2 r + 1)/(r + 1))^{1/2} - \gamma}{1 - \gamma}$$

where γ is defined as $k_x/(k_x^2 + 8k_tR_i)^{1/2}$. Once γ has been determined the value of R_λ/R_{steady} yields a second quantity m defined as

$$(k_x^2 + 8k_tR_i)^{1/2}\lambda/2.\dagger$$

The rate constants k_x and k_t are readily calculated from γ and m. The propagation rate constant, k_p, is obtained from the equation

$$R_{steady} = k_p[RH]\frac{k_x(1 - \gamma)}{4k_t\gamma}.$$

EXPERIMENTAL

The reaction vessel, a 50 ml round-bottomed pyrex flask, was immersed in a water bath and was connected to a standard, constant pressure, oxygen absorption apparatus. It was irradiated through a Corning U.V. transmitting filter (C.S. No. 7-51, maximum transmittance at 365 mμ) with the light from a 200/250 V, 250 W ME/D B.T.H. ultraviolet lamp. The light was collimated by 3.5 in. diameter quartz lenses with a focal length of 6 in. The reaction vessel was shaken along the light beam at 30–120 cycles/min. Oxidation rates did not depend on the shaking speed nor upon the oxygen pressure in the range 50–760 mm.

Two 45° sectors (i.e., $r = 3$) were cut from a disc of blackened aluminium. This disc was driven by a 7.5 W, 10 r.p.m. Bodine synchronous motor through a series of gears which could be changed so as to give rotation speeds varying from 0.4 to 250 r.p.m. The light intensity was monitored by a photocell before and after each oxidation. The transmittance of screens used to decrease the light intensity was measured on a Cary model 14 recording spectrophotometer.

**In this analysis it has been assumed that there was no chain initiation from any thermal (dark) reaction. Such a process leads to a small increase in R_f and to a relatively larger increase in R_s, thereby decreasing the difference between these two rates. Provided the dark rate is less than 5% of the photochemical rate its effect on the estimated lifetimes can generally be neglected (2). Under the experimental conditions employed in this work the thermal rate of oxidation of styrene at 50 °C was only 3.6% of the rate at full light intensity.*

†Values of R_λ/R_{steady} have been tabulated in ref. 2 (Table III) as a function of m for five values of γ at $r = 3$. We have had a more complete table of these ratios calculated at $r = 3$ for values of γ increasing in steps of 0.01 from 0.00 to 0.60. Photocopies of this table may be obtained upon request to:

α,α'-Azo-bis-cyclohexylnitrile (ACHN) was chosen as the photo-initiator because of its high thermal stability. This compound has a maximum absorption at 348 mμ with a molar extinction coefficient of 19.6 in chlorobenzene. For most experiments 10 ml of chlorobenzene was used as a solvent for 3 ml of styrene with an ACHN concentration of 6.68×10^{-3} mole/l. The styrene polyperoxide formed in the oxidation acts as a rather weak photo-initiator.* To some extent, its formation must compensate for the destruction of styrene and ACHN during a reaction since the measured oxidation rates do not vary by more than 2% for a styrene consumption of up to 10%. The transmittance of the reactants at 365 mμ drops by nearly a factor of 3 at this extent of oxidation.

Previous workers have generally determined the chain lifetime by measuring R_λ over the range of flash times which gave rates varying all the way from R_f to R_s. Because R_λ values near R_f and R_s are of little use in estimating τ we found this procedure to be much less accurate than choosing a particular λ which gave a rate midway between R_f and R_s and then repeatedly measuring alternately R_{steady} and R_λ. Even with this procedure rather large errors creep into the calculated values of k_p, k_t, and k_x. That is, oxidation rates are not reproducible to much better than $\pm 2\%$ and there is possibly a variation of $\pm 5\%$ in the rate of chain initiation from one run to another. These relatively small experimental errors can lead to errors of up to 50% in k_p, 20% in k_t, and 30% in k_x. The measured rate of gas adsorption has been taken to equal the rate of oxidation in all calculations. That is, the corrections to the measured rates for nitrogen evolution by the initiator, oxygen absorption by the initiator radicals, and oxygen evolution in bimolecular chain termination were too small to be really significant in any experiment.

RESULTS AND DISCUSSION

When chain termination is bimolecular the oxidation rate must be proportional to $R_i^{1/2}$. Under ideal conditions, the rate should therefore be proportional to the square root of the initiator concentration and to the square root of the light intensity. This ideal, however, is not achieved with styrene. In the first place, at low ACHN concentrations (or in its absence) the oxidation rate is larger than would be expected and, moreover, the reaction is autocatalytic. This is due to photochemical initiation from the styrene polyperoxide formed in the oxidation. The degree of autocatalysis can be correlated with the square root of the polyperoxide concentration. Secondly, at high ACHN concentrations the rate is lower than expected. This is probably due to the absorption of a significant fraction of the light by the initiator so that the rate of chain initiation is no longer uniform throughout the reaction vessel. Under standard conditions with full light intensity the rate was only proportional to $[ACHN]^{1/2}$ in the range 2×10^{-3} to 2×10^{-2} mole/l ACHN. A concentration of 6.7×10^{-3} mole/l, near the middle of this range, was therefore used in most experiments. Finally, upon decreasing the light intensity at this initiator concentration, it was found that the rate was only proportional to the square root of the intensity at, or near, full intensity. At lower intensities the order increased as the intensity decreased, the deviation from a half order relationship becoming more pronounced as the temperature was raised (see Fig. 1). This deviation can be attributed to the occurrence of a first order chain termination process in addition to the normal bimolecular chain termination reaction (see ref. 1). The importance of the first order process naturally increases as the rate of initiation decreases, i.e., as the radical concentration decreases. Furthermore, it is obvious from Fig. 1 that the first order termination has a much higher activation energy than the second order termination.

The rate of chain initiation, R_i, was determined by the induction period method of Boozer *et al.* (ref. 3, see also refs. 1, 4, and 5) using 2,6 di-*t*-butyl-4-methylphenol (BMP), an inhibitor which is known to stop two oxidation chains per molecule (3, 6). The induction periods in equivalent photochemically and thermally initiated oxidations† at 40 °C were

**A concentration of 0.27 mole/l $C_8H_8O_2$ (molecular weight ~ 3 000) increases the rate under the standard conditions by only 15%.*

†The thermal oxidations were initiated with a quantity of α,α'-azo-bis-isobutyronitrile (AIBN) sufficient to give an oxidation rate equal to that produced photochemically. Under these conditions the rates of chain initiation from ACHN and AIBN must be equal (see e.g. refs. 7, 8, 9).

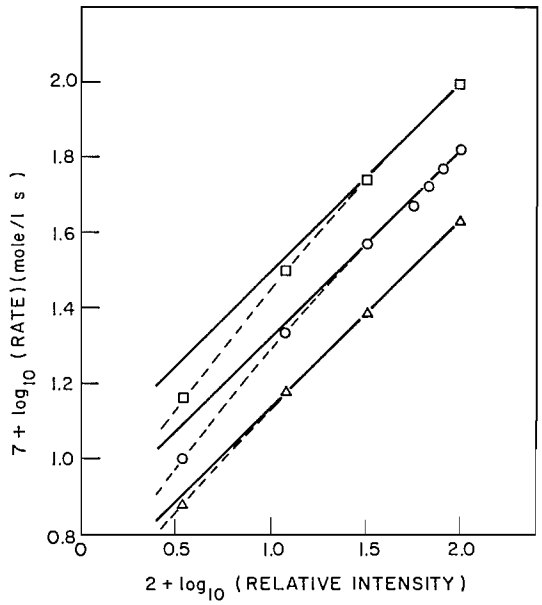

FIG. 1. Rate of oxidation of 2.01 moles/l of styrene in chlorobenzene (with 6.7×10^{-3} mole/l ACHN) as a function of the light intensity at 30° (△), 40° (○), and 50° (□). The solid lines have a slope of 0.5, i.e., only in the region where the experimental points lie on these lines is the oxidation rate proportional to the square root of the light intensity.

compared and were found to be approximately equal.* Similar results were obtained at 40 °C using hydroquinone as the inhibitor.

Our preliminary measurements from 13 to 50 °C suggested that the bimolecular chain termination process had an activation energy (E_t) of about 3 or 4 kcal/mole. This completely unexpected result led us to measure R_i as accurately as was possible over the same temperature range. Cumene was used in place of styrene as the oxidizing substrate in the

TABLE I

Effect of temperature on R_i, k_i, and e for the photochemically initiated oxidation of cumene (cumene 1.66 moles/l in chlorobenzene, ACHN 6.7×10^{-3} mole/l, BMP 5.44×10^{-4} mole/l)

Temp. (°C)	$R_i \times 10^7$ (moles/l s)	$k_i \times 10^5$ (s^{-1})	e
13	2.2	3.5_5	0.46
22	2.4	3.8	0.47
30	2.7	4.4	0.47
40	3.1	4.8	0.48
50	3.5	5.1	0.51

**This comparison was made because the photochemical induction periods might be affected by the photochemically induced decomposition of the BMP-peroxy radical addition product since these cyclohexadienone peroxides have a fairly strong absorption near 365 mμ (6). To check on this point two of these compounds were synthesized by the method of Bickel and Kooyman (6). The t-butyl peroxy and α-tetralyl peroxy derivatives of BMP both had a maximum in their absorption spectra at 370 mμ in chlorobenzene with molar extinction coefficients of 24.9 and 23.9, respectively. Both compounds were about twice as efficient photo-initiators as ACHN. However, in measuring the induction period the BMP concentration was only 0.6% of the ACHN concentration. Chain initiation from the BMP-radical addition products was therefore insignificant compared with initiation from the ACHN.*

chlorobenzene since it gives much sharper induction periods.* The results in Table I show that R_i increases with temperature. It has an apparent activation energy of about 2.4 kcal/mole. Measurements of the rate of nitrogen evolution in pure chlorobenzene (rate constant k_1) suggests that the change in R_i with temperature is due more to a change in the rate of decomposition of the ACHN than to a change in the efficiency (e) with which the cyclohexylnitrile radicals initiate oxidation. This result can be compared with the data of Kodama on the photolysis of azomethane over a wide temperature range in a variety of solvents (10). Kodama found that the rate of nitrogen evolution decreased as the temperature was lowered with an apparent activation energy of about 1 kcal/mole in solvents such as toluene or cyclohexane. This phenomenon was ascribed to the recombination of the initially formed radicals, $CH_3N_2^{\cdot}$ and $CH_3^{\cdot}$, in the solvent cage. Furthermore, Kodama showed that the yield of ethane relative to nitrogen increased as the temperature was decreased with an apparent activation energy of about 1.0–1.7 kcal/mole for the quantity $(1 - [C_2H_6]/[N_2])$. Since the ethane was formed entirely by the geminate recombination of methyl radicals this energy is probably related to the diffusion energy of the methyl radicals. That is, geminate recombination was enhanced by a temperature decrease because of the increase in solvent viscosity. By analogy, therefore, the chain-generating efficiency, e, with ACHN should decrease as the temperature decreases (see also ref. 11). The values of e in Table I show a smaller decrease than would be expected on the basis of Kodama's data, that is, there appears to be little or no geminate recombination between cyclohexylnitrile radicals. However, the overall activation energy for R_i is of about the expected order of magnitude, i.e., it is roughly equal to the sum of the activation energies for nitrogen evolution and for the diffusion of the geminate radical pairs.

TABLE II

Absolute rate constants for styrene oxidation at different light intensities

Temp. (°C)	Light intensity (%)	k_p ($l\,mole^{-1}\,s^{-1}$)	$k_t \times 10^7$ ($l\,mole^{-1}\,s^{-1}$)	k_x (s^{-1})

	32	86 (154)	4.5 (17.8)	0.46

*First order termination could not be detected at full intensity.
†Average of two separate experiments.

The absolute rate constants obtained in this work are given in Tables II–V. Within the limits of experimental accuracy these rate constants do not depend on the light intensity (Table II) although it should be noted that the first order chain termination process cannot be identified at temperatures of 22 °C or less under full light intensity (Tables II and IV). The k_p and k_t values which would be obtained if the first order process were neglected are given in parentheses in Table II. It can be seen that the error introduced by this simplification increases with decreasing light intensity and with increasing temperature. The fact that k_x does not depend on the styrene concentration (Table III) and is not significantly affected by added styrene polyperoxide indicates that the first order process

At 40 °C under the standard conditions with 3 ml of hydrocarbon in 10 ml of chlorobenzene both styrene and cumene give the same induction period. This similarity was assumed to exist at the other temperatures and in the other solvents. That is, it was assumed that the initiation rates measured with cumene as the substrate were also applicable to styrene.

TABLE III

Absolute rate constants at 40 °C for different styrene concentrations in chlorobenzene (R_i assumed to be the same at all styrene concentrations, including pure styrene (see ref. 5))

Styrene (moles l^{-1})	k_p ($l\ mole^{-1}\ s^{-1}$)	$k_t \times 10^{-7}$ ($l\ moles^{-1}\ s^{-1}$)	k_x (s^{-1})

TABLE V

Absolute rate constants for styrene oxidation at 13 °C in different solvents (styrene concentration 2.01 moles/l)

Solvent	$R_i \times 10^7$* ($moles\ l^{-1}\ s^{-1}$)	k_p ($l\ mole^{-1}\ s^{-1}$)	$k_t \times 10^{-7}$ ($l\ mole^{-1}\ s^{-1}$)	Relative rates of oxidation†	
				Photochemical	Thermal (5)‡
n-Decane	1.3	10	3.3	0.38	0.45
t-Butylbenzene	1.6	15	2.2	0.74	0.67
Benzene	1.9	21	3.1	0.99	0.84
Chlorobenzene	2.2	19	2.4	1.00	1.00
Acetonitrile	2.7	23	3.6	1.17	1.58

*R_i measured with cumene as substrate.
†Rates are given relative to the rate in chlorobenzene.
‡Thermal rates are at 65 °C with 0.42 mole/l of styrene.

does not involve a reaction between a peroxy radical and a molecule of styrene or a molecule of styrene polyperoxide.

The data in Table IV can be represented by

$$k_p = (4.7 \pm 0.2) \times 10^7 \exp(-8400 \pm 300/RT)\ l\ mole^{-1}\ s^{-1}$$
$$k_t = (5.1 \pm 3.4) \times 10^8 \exp(-1800 \pm 1200/RT)\ l\ mole^{-1}\ s^{-1}$$
$$k_x = (5.8 \pm 1.4) \times 10^7 \exp(-11600 \pm 2800/RT)\ s^{-1}.$$

The limits of error represent standard deviations calculated by the method of least squares. After correction for the variation in the chain initiation rate with temperature, the overall activation energy is 7.20 ± 0.25 kcal/mole. This value is in fairly good agreement with our

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

previously reported value of 7.7 ± 0.5 kcal/mole which was obtained from the thermally initiated oxidation of styrene (1). The activation energy for propagation is in the range expected for a hydrocarbon which is fairly readily oxidized (7, 8, 9, 12, 13, 14). There is little or no activation energy for bimolecular chain termination (cf. ref. 15). It should perhaps be pointed out that if k_x were neglected the apparent activation energy for bimolecular termination would be about 10 kcal/mole. With regard to the activation energy of the first order process, the oxidation of styrene resembles the polymerization of vinyl chloride which also has a first order chain termination process with a fairly large activation energy, i.e., $k_x = 1.9 \times 10^5 \exp(-7800/RT)$ (16). First order chain termination processes with high activation energies are not confined to liquid phase polymerizations. For example, in the photolysis of acetaldehyde in the gas phase there is a first order termination on the walls with an activation energy of 7 800 kcal/mole (17). The nature of the first order termination in the oxidation of styrene is discussed in the following paper (15).

Under the standard experimental conditions the initial rates of oxidation of styrene inhibited with 1.3×10^{-3} to 1.3×10^{-2} mole/l BMP were measured at four temperatures. Rate constants for the hydrogen atom abstraction reaction from the phenol (i.e., k_{inh}) are included in Table IV. These results can be represented by

$$k_{inh} = 8.4 \times 10^7 \exp(-5600/RT) \text{ l mole}^{-1} \text{ s}^{-1}.$$

Although the absolute rate constants are in fairly good agreement with our previous estimates (1) this activation energy is much larger than the value of 1.7 kcal/mole which we have reported (1). The present value is in fair agreement with the value of about 5 kcal/mole for the reaction of cyclohexyl peroxy radicals with BMP (18) and with values of 6.8 and 7.3 kcal/mole for the reaction of α-phenethyl peroxy radicals with α- and β-naphthol, respectively (14).

In some previous work from this laboratory (5) on the AIBN thermally initiated oxidation of styrene at 65 °C it was shown that solvents affect the rate of chain generation (both k_i and e). After corrections for these changes in R_i were made, it was found that solvents of high dielectric constant increased the rate of oxidation of styrene relative to the rate for pure styrene and those of low dielectric constant decreased the rate. It was suggested that the solvent exerted its main effect on the propagation reaction (see also refs. 19, 20, and 21). This view is supported by the data in Table V since the changes in k_t from one solvent to another are too small to be significant. Similar results at 40 °C indicate that k_x also does not depend on the solvent. It should perhaps be pointed out that the effect of solvents on k_p is not the same as their effect on the polymerization of styrene (22) or on the hydrogen abstraction (23) and addition (24) reactions of chlorine atoms. The influence of the solvents on R_i can probably be mainly attributed to changes in viscosity from one solvent to another (10) since the position of the absorption maximum for ACHN and its extinction coefficient showed little variation with solvent. However, the possibility that the increase in R_i from *n*-decane to acetonitrile is actually an artifact which results from the method by which it is measured cannot be completely ruled out at the present time. That is, even a hindered phenol has a reduced reactivity towards peroxy radicals in polar solvents since the phenolic hydroxyl group forms hydrogen bonds with these solvents. If R_i does not, in fact, vary with the solvent then k_t must increase along the series of solvents from *n*-decane to acetonitrile. In this connection, if increased hydrogen bonding is responsible for an apparent increase in R_i then the measured values of e at the lower temperatures in Table I may be greater than their true values since hydrogen bonding becomes more important as the temperature is decreased. That is, there may, in fact, be a greater increase in e with temperature than the measured values suggest.

ABSOLUTE RATE CONSTANTS FOR HYDROCARBON AUTOXIDATION

II. DEUTERO STYRENES AND RING-SUBSTITUTED STYRENES[1]

J. A. HOWARD AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received May 6, 1965

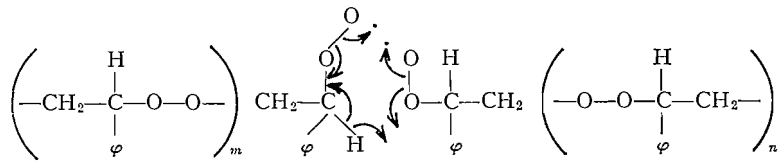
ABSTRACT

The effect of deuterium substitution on the absolute rate constants for the bimolecular chain termination process in the oxidation of styrene indicates that the α-hydrogen is abstracted in this reaction. The first order chain termination process is suppressed both by deuteration of styrene at the α-position and by the addition of heavy water. A possible mechanism for this termination is proposed. There appear to be small secondary deuterium isotope effects in the propagation reaction.

The overall oxidation rates and the propagation rate constants are increased by the addition to the aromatic ring of both electron-attracting and electron-releasing substituents. This is attributed in the former case to the increased stability of the resulting styryl radicals and in the latter case to the increased stability of a dipolar transition state. In hydrogen atom abstraction from 2,6-di-*t*-butyl-4-methylphenol, the peroxy radical from 3-chlorostyrene is more reactive than that from styrene which, in turn, is more reactive than the peroxy radical from 4-methoxystyrene.

INTRODUCTION

A cyclic transition state for the chain-ending interaction of secondary peroxy radicals with one another was first proposed in 1957 by G. A. Russell as a result of his work on the oxidation of ethylbenzene (1). A model of this transition state for two poly(peroxystyryl) peroxy radicals is shown below.



Russell's evidence favoring this mechanism was based on product studies at short kinetic chain lengths and, particularly, on the effects of deuterium substitution on oxidation rates. That is, provided it was assumed that the deuterium isotope effect on the propagation reaction was the same for ethylbenzene as for cumene then it could be calculated from the relative oxidation rates of ethylbenzene and ethylbenzene-α-d_1 that α-phenethyl peroxy radicals interacted to form non-radical products 1.9 times as rapidly as their α-deutero derivatives. This fairly large isotope effect has, so far, not been directly confirmed. We therefore decided to extend our measurements of the absolute rate constants for the autoxidation of styrene by the rotating sector technique (2) to four deuterostyrenes, α-d_1, β-d_2, α,β-d_3, and phenyl-d_5. We have also measured the propagation and termination rate constants for five ring-substituted styrenes (4-CH_3O, 4-CH_3, 4-Cl, 3-Cl, and 4-CN).

EXPERIMENTAL

The experimental conditions were the same as with styrene (2), i.e., 3 ml of hydrocarbon in 10 ml of chlorobenzene with α,α'-azo-bis-cyclohexylnitrile (6.7×10^{-3} mole/l) as the photo-initiator. The deuterostyrenes were obtained from Merck, Sharp and Dohme of Canada, Limited. Their deuterium content was not less than 98% of theory. The isotopic purities were confirmed by mass spectrometry and the positions of labelling were checked by nuclear magnetic resonance (n.m.r.) spectroscopy on the corresponding polystyrenes and polystyrene peroxides. 4-Methoxy-, 4-methyl-, 4-chloro-, and 3-chloro-styrene were obtained from the

[1]*Issued as N.R.C. No. 8591.*

Borden Chemical Company. 3-Nitrostyrene was obtained from the Aldrich Chemical Company. 4-Cyanostyrene was prepared from 4-cyanoacetophenone by the method of Marvel and Overberger (3) and 4-nitrostyrene was prepared from (2-bromoethyl) benzene by the method of Strassburg, Gregg, and Walling (4). All the styrenes were carefully purified before use.

RESULTS AND DISCUSSION

The Deuterostyrenes

Absolute rate constants for styrene and four deuterostyrenes at 40 °C and for styrene and two deuterostyrenes at 13 °C are given in Table I. The values for styrene itself differ somewhat from the values given in the previous paper (2) because they represent particular experiments (rather than the average of several experiments) which were done immediately before or after the deuterostyrene experiments under conditions which were as nearly identical as possible. Although the errors involved in determining k_t are considerable, the results support the occurrence of an α-deuterium isotope effect for bimolecular chain termination. From the data in Table I, the directly measured effect is found to be between 1.8 and 3.0 which is in good agreement with the value of 1.9 obtained indirectly by Russell (1). It provides additional support for the view that the α-hydrogen is abstracted in the bimolecular chain-terminating process for secondary peroxy radicals. This abstraction may occur directly (1) or it may, perhaps, involve the prior elimination of oxygen with the subsequent transfer of a hydrogen atom between the two resulting alkoxy radicals while they are still in the same solvent cage (5).

TABLE I

Absolute rate constants for deuterium-substituted styrenes (3 ml of styrene in 10 ml chlorobenzene)

Styrene	Relative rates of oxidation	k_p (l mole^{-1} s^{-1})	$k_t \times 10^{-7}$ (l mole^{-1} s^{-1})	k_x (s^{-1})
T = 40 °C				
$C_6H_5CH{:}CH_2$	1.00	65	2.7	0.52
$C_6H_5CD{:}CH_2$	1.18	57	1.5	—
$C_6H_5CH{:}CD_2$	1.14	78	2.1	0.50
$C_6H_5CD{:}CD_2$	1.43	55	1.0	—
$C_6D_5CH{:}CH_2$	1.01	69	3.0	0.40
T = 13 °C				
$C_6H_5CH{:}CH_2$	1.00	16	1.9	—
$C_6H_5CD{:}CH_2$	1.14	11	0.7	—
$C_6H_5CD{:}CD_2$	1.39	13	0.6	—

The propagation rate constants in Table I suggest that there are some secondary deuterium isotope effects in chain propagation. The enhanced value of k_p for the styrene-β-d_2 is probably due to the change in the configuration of the β-carbon atom from trigonal to tetrahedral (ref. 6; cf., however, refs. 7 and 8). The low values of k_p for styrene-α-d_1 and the styrene-α,β-d_3 are unexpected and might imply that k_t has been underestimated for these two styrenes, particularly in view of the fact that their actual oxidation rates are greater than for styrene itself. However, the fact that the propagation rate constant for styrene-α-d_1 is probably smaller than for styrene has been confirmed by n.m.r. analysis of the polymer produced by co-oxidizing equal concentrations of these two compounds at 40 °C. The polymer was prepared in a thermally initiated oxidation under conditions where the chain length was fairly long. It was purified by precipitation from a benzene solution with petroleum ether and n.m.r. analysis gave $(k_p)_{C_6H_5CHCH_2}/(k_p)_{C_6H_5CDCH_2} \approx 1.27$ with good agreement between the isotope effect calculated from the C_6H_5/CH ratio and from the CH_2/CH ratio. This value adds some support to the idea that there is a small positive secondary α-deuterium isotope effect in the propagation reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

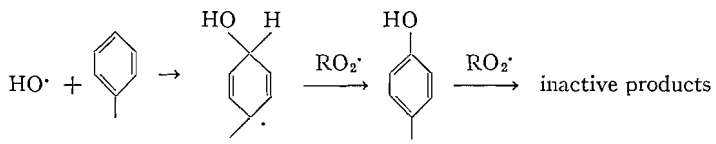
The absolute rate constants for α-deuterostyrene were measured at four temperatures from 13 to 50 °C. They can be represented by

$$(k_p)_{C_6H_5CDCH_2} = (2.3 \pm 0.3) \times 10^8 \exp(-9500 \pm 1300/RT) \text{ l mole}^{-1} \text{ s}^{-1}$$

$$(k_t)_{C_6H_5CDCH_2} = (4.8 \pm 1.5) \times 10^9 \exp(-3700 \pm 1200/RT) \text{ l mole}^{-1} \text{ s}^{-1}.$$

The propagation activation energy is in fairly good agreement with the value found for styrene (2). The small activation energy for bimolecular termination is probably significant. However, if it is ignored an average value for k_t of $(1.2 \pm 0.3) \times 10^7$ l mole^{-1} s^{-1} is obtained. After correction for the variation in the chain initiation rate with temperature the overall activation energies for the oxidation of styrene (2), $C_6H_5CDCH_2$, $C_6H_5CHCD_2$, and $C_6D_5CHCH_2$ are all close to 7.2 kcal/mole.

Probably the most noticeable feature about Table I is that no first order termination could be detected under full illumination at 40 °C when the styrene contained a deuterium in the α-position. This was also true at 50 °C. These results indicate that k_x for styrene-α-d_1 is less than one-quarter of the value for styrene (2) and suggest that the α-hydrogen atom is abstracted in the rate-determining step of the first order termination process. Since this hydrogen is not abstracted from either monomer or polyperoxide (2) it must come either from a minor oxidation product or there must be an intramolecular abstraction in which the peroxy radical abstracts from one of the styrene units in its own chain. In the latter case, if abstraction occurred from the middle of the chain a benzyl radical would be produced and this radical should be able to continue the chain unless it was very deeply buried in the coiled up polymer. However, we were unable to detect any radicals by electron spin resonance (e.s.r.) in a sample of the polyperoxide polymer formed under conditions where first order termination was an important process. This suggests that if the first order process involves an intramolecular abstraction the hydrogen must come from the growing end of the polymer. This would give an unstable alkyl radical which should immediately decompose to a ketone and a hydroxyl radical. Alternatively, the benzyl radical formed by α-hydrogen atom abstraction from the middle of the chain may depolymerize to give formaldehyde, benzaldehyde, and, eventually, a hydroxyl radical (9). This radical could either initiate a new chain or add to an aromatic ring to give a cyclohexadienyl radical.



These radicals would not be expected to continue the chain but they could terminate additional chains by loss of hydrogen to give a phenol. The phenol would then react with more peroxy radicals in the usual way. This last reaction could perhaps be the actual process which shows the first order kinetics for chain termination.

The connection between compounds such as phenols, which contain readily exchangeable and abstractable hydrogen atoms, and the first order termination process is indicated by some experiments on the effect of H_2O and D_2O on the oxidation of styrene. That is, we have shown previously (10) that the addition of 10–20% by volume of H_2O increases the rate of oxidation of styrene by 12–15% and D_2O increases the rate by 30–50%. Some experiments on the rotating sector apparatus have now shown that the effect of H_2O can be entirely attributed to an increase in k_p, probably by a simple inert solvent effect (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In contrast, although D_2O has no effect on k_t and little effect on k_p, it entirely eliminates all measurable first order termination even at 50 °C (i.e., at 50 °C, k_x in the presence of D_2O is less than 0.2 s^{-1}). No deuterium could be detected by infrared spectroscopy in samples of styrene polyperoxide prepared in the presence of D_2O and therefore this isotope effect is not due to exchange of the α-hydrogen atom in the polymer. A possible explanation for these results is that the addition of D_2O causes those labile hydrogen atoms which are suitable for abstraction (e.g., phenolic hydrogens) to be replaced by much less readily abstractable deuterium atoms. These labile hydrogen atoms must therefore play an important role in the first order chain termination process just as does the α-hydrogen atom.

*At 2.01 moles/l. That is, these relative rates were calculated after correcting the measured rates to the values they would have at a concentration equal to that obtained with 3 ml of styrene in 10 ml of solvent. This correction produces the largest change with 4-methoxystyrene, the ratios obtained with the measured rates being 1.68 and 1.77, respectively.

†Rate constant for hydrogen abstraction from 2,6-di-*t*-butyl-4-methylphenol.

‡These oxidations were initiated thermally with 0.31 mole/l azo-bis-isobutyronitrile and were then compared with the rate obtained with styrene under these conditions.

§Average value from preceding paper (2).

The Substituted Styrenes

The absolute rate constants and thermal and photochemical rates of oxidation (relative to styrene at the same concentration) for five ring-substituted styrenes at 40 °C are given in Table II, the substituents being arranged in order of decreasing electron-donating power. This table also includes relative thermal rates of oxidation for meta- and para-nitrostyrene. Both these compounds are oxidized extremely slowly when the reaction is initiated photochemically. The slow photooxidations are not due to the low intrinsic oxidizability of the nitrostyrenes but, instead, result from their strong absorption of light at the initiating wavelength of 365 mμ. The rates of oxidation of all these styrenes were unaffected by decreasing the oxygen pressure from 760 mm to 50 mm.

The relative rates for 4-methoxystyrene and 4-nitrostyrene are in fairly good agreement with the values 1.56 and 0.99, respectively, obtained by Russell and Williamson (11) for the thermally initiated oxidations of 1.0 *M* styrene solutions in benzene at 60 °C.

Although the strongly electron-donating 4-methoxy group does produce a fairly large increase in the oxidation rate, there is no obvious correlation between the relative rates and the polar properties of the substituents. This result contrasts with the results obtained for the oxidation of substituted cumenes (11, 12) and toluenes (12) and for many other reactions involving hydrogen atom abstraction by radicals from substituted aromatic compounds (11, 13).

The absolute rate constants for first order termination do not vary appreciably from one substituent to another, but for second order termination there would appear to be an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

increase in k_t as the substituents become more strongly electron attracting. However, it should be pointed out that Russell and Williamson's measurements of oxidation rates for mixtures of styrene with 4-methoxystyrene and with 4-nitrostyrene suggest that the rate constants for chain termination (k_t and k_x) are the same for all three styrenes (11).

The propagation rate constants cannot be correlated with the polar effects of the substituents. In this respect, therefore, the reactivity of substituted styrenes towards peroxy radicals differs from their reactivity towards the polystyryl radical (14) and the polystyrene anion (15). In these cases the reactivities can be approximately correlated with the σ constants of the substituents (see, however, ref. 16). The present results resemble instead those obtained for the reactivities of substituted styrenes towards methyl methacrylate and maleic anhydride, both of which give rise to strongly alternating systems as does styrene and oxygen (14). That is, with both these monomers electron-releasing groups enhance reactivity but electron-withdrawing groups either have little effect (maleic anhydride) or also enhance reactivity (methyl methacrylate) (14).

The results in Table II can be compared with the relative propagation rate constants obtained by Russell and Williamson by the competitive co-oxidation of styrene, 4-methoxystyrene, and 4-nitrostyrene with analysis for the unreacted styrenes (11). Solution of the "copolymerization" equation gave $(k_p)_{4MeO}/(k_p)_{styrene} = 1.2–1.8$ and $(k_p)_{4NO_2}/(k_p)_{styrene} = 0.2–0.6$. In a similar way, except that the styrene polyperoxide was analyzed, Dulog *et al.* (17) have obtained relative propagation rate constants for para-F, Cl, Br, I, and CH_3 styrenes at 50 °C. The relevant rate constants are $(k_p)_{4Me}/(k_p)_{styrene} = 1.4–1.5$ and $(k_p)_{4Cl}/(k_p)_{styrene} = 0.98–1.12$. The results obtained by both groups of workers suggest that the reactivity towards addition to styrene of para-substituted styryl peroxy radicals may depend on the para-substituent. It was, therefore, conceivable that a regular change in k_p with the polar properties of the substituents was disguised by a change in the reactivity of the attacking peroxy radicals. That is, the relatively large k_p's for electron-attracting substituents might be due to the greater reactivity of the corresponding peroxy radicals rather than to the enhanced reactivity of the substituted styrenes themselves.

With this point in mind, we measured the oxidation rates at 40 °C of 4-methoxy- and 3-chloro-styrene in the presence of several different concentrations of the inhibitor, 2,6-di-*t*-butyl-4-methylphenol. These inhibited rates yield k_p/k_{inh} where k_{inh} is the rate constant for abstraction of the phenolic hydrogen by peroxy radicals. The k_{inh} values obtained are compared with the value given previously for styrene at 40 °C (2) in Table II. The differences in k_{inh} are surprisingly large considering the distance separating the reaction site and the substituent. However, the changes in k_{inh} are in the expected direction. That is, hydrogen atom abstraction from phenols by peroxy radicals is known to involve a significant separation of charge in the transition state (13, 18). The radical with an electron-attracting substituent will tend to have a higher electron affinity than an unsubstituted radical or a radical with an electron-donating substituent. The transition state for this radical will therefore tend to be stabilized relative to the transition states for the other radicals and the rate constant for its reaction with the phenol will therefore be larger. However, the effect of substituents on the reactivity of peroxy radicals in hyrogen atom abstraction from phenols will be very much greater than their effect on reactivity for addition to styrene since the former reaction is so very much more sensitive to polar factors (e.g., 4-methoxyphenol is more than 80 times as reactive towards styryl peroxy radicals as is 3-chlorophenol (13)). Therefore, although the increased reactivity of styryl peroxy radicals containing electron-attracting substituents will tend to disguise the decreased reactivity of the substituted styrene itself, this effect should be relatively small.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The k_p values in Table II should therefore reflect mainly changes in the reactivity of the styrene molecule rather than its peroxy radical.* This means that polar effects are small in chain propagation and although they probably account for the small accelerating effect of the 4-methoxy and 4-methyl substituents their influence with electron-attracting substituents is more than outweighed by the effect these substituents have in increasing the stability of the resulting styryl radical. That is, electron-donating groups contribute little to radical stability, but radical stabilization by electron-attracting groups roughly parallels their electron-attracting ability in the para-position (14, 19). If we consider the transition state for propagation to consist of the three resonance forms

$$\underset{\text{I}}{XC_6H_4CH{=}CH_2\cdot OOR} \leftrightarrow \underset{\text{II}}{XC_6H_4\overset{\delta+}{C}H\text{---}\overset{\delta-}{C}H_2{:}OOR} \leftrightarrow \underset{\text{III}}{XC_6\dot{H}_4CH{-}CH_2{:}OOR}$$

then the present results suggest that structure III (which resembles the products) plays a more important role than structure II in stabilizing the transition state. This conclusion differs from the suggestion we made previously that structure II must make an important contribution to the transition state because of the fairly good correlation between the dielectric constant of a solvent and its effect on the rate of oxidation of styrene (20). That is, solvents with high dielectric constants increased the oxidation rate and this was attributed to their stabilizing influence on the dipolar structure II. The present results imply that in free radical reactions, solvent effects provide a more sensitive test than substituent effects for the occurrence of a contribution from structure II to the transition state.

TABLE III

Absolute rate constants for 4-methoxystyrene at different temperatures

Temp. (°C)	k_p (l mole^{-1} s^{-1})	$k_t \times 10^{-7}$ (l mole^{-1} s^{-1})	k_x (s^{-1})
22	55	1.7	0.20
30	81	1.8	0.30
40	123	2.2	0.45
50	159	1.7	0.77

The absolute rate constants for 4-methoxystyrene (Table III) give

$$k_p = (1.3 \pm 0.1) \times 10^7 \exp(-7200 \pm 500/RT) \text{ l mole}^{-1}\text{ s}^{-1}$$
$$k_t = (1.9 \pm 0.2) \times 10^7 \text{ l mole}^{-1}\text{ s}^{-1}$$
$$k_x = (8.5 \pm 0.4) \times 10^5 \exp(-8900 \pm 500/RT) \text{ s}^{-1}.$$

The propagation and first order termination activation energies are rather lower than the values found for styrene (2). The overall activation energy is 6.2 ± 0.4 kcal/mole.

ACKNOWLEDGMENT

We wish to thank Mr. M. Lesage for measuring the n.m.r. spectra of the styrene polyperoxide samples.

In calculating the absolute rate constants R_i was assumed to be the same for the substituted styrenes as for styrene itself. However, the referee has pointed out that the polar substituents (chloro, cyano, nitro) may have some effect on R_i at the substrate concentrations employed. If this is indeed the case, it might account for some of the "discrepancies" in k_p, e.g., it is hard to imagine the 3-chloro substituent having much stabilizing ability on a benzyl-type radical.

THE PREPARATION OF A TRIVINYL CARBONIUM ION

T. S. SORENSEN
Department of Chemistry, University of Alberta at Calgary, Calgary, Alberta
Received April 13, 1965

ABSTRACT

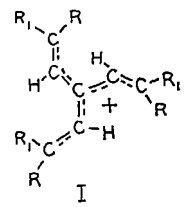
The preparation of a stable trivinyl carbonium ion is described. A detailed evaluation and comparison of the n.m.r. spectrum of this ion with other stable carbonium ions, coupled with the use of ultraviolet spectroscopy, is used for the structure proof. The synthesis of the necessary tetraene precurser and the cyclization reactions of the above ion are also described. Comparisons of the cyclization rate of various stable carbonium ions are given and an attempt is made to evaluate the resonance stability of the trivinyl carbonium ion.

INTRODUCTION

Triphenyl carbonium ion is the classic of stable carbonium ions but examples of what might be called aliphatic analogs, trivinyl carbonium ions, have not been observed. In the last few years, however, many "enylic" carbonium ion solutions have been prepared, chiefly by Deno and his students; the structural confirmation of these ions being obtained mainly from the use of n.m.r. spectroscopy in quantitatively accounting for the hydrogen atoms. Sufficient results have now been obtained on carbonium ion proton positions in n.m.r. spectroscopy and the position of their maxima in ultraviolet spectroscopy that an analysis of the more complex behavior of trivinyl carbonium ions can be attempted.

Tricyclopropyl carbonium ion has been observed (1) and is a remarkably stable compound compared to the *t*-butyl cation, the obvious, though not so easily visualized, explanation being some sort of orbital overlap which delocalizes the positive charge. On this basis, a trivinyl carbonium ion might be expected to be even more stable. It is also of theoretical interest to observe to what extent the extra cross-conjugated —CH=C< group will stabilize this system over a divinyl carbonium ion.

Evidence is now presented to show that a trivinyl carbonium ion, I (R = R′ = CH_3), can be prepared at low temperatures, as a solution in neat fluorosulfonic acid. Attempts



I

to prepare the analogs R = CH_3, R′ = H, and R = R′ = H have not been successful because the necessary carbonium ion precursors could not be obtained. Fluorosulfonic acid is even stronger than sulfuric acid and has a conveniently low melting point and viscosity. It has been previously used (2) as a protonating acid solvent in several instances as has the related chlorosulfonic acid (3).

One of the cyclized ions has been recovered from sulfuric acid solution by Deno and Pittman (4) and we believe that sufficient verification of the recoverability of these dienylic ions has been obtained in other similar systems (4, 9).

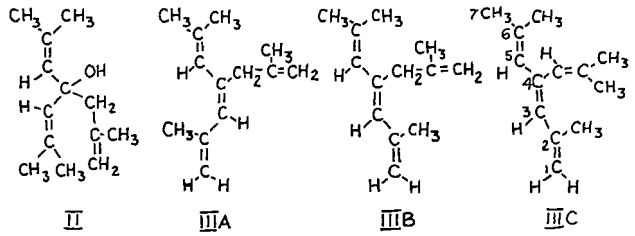
RESULTS

Synthesis of the Polyenes

Methallyl magnesium chloride can be added to phorone to yield the alcohol II which was obtained only in an impure form because of its very ready dehydration. The alcohol



II IIIA IIIB IIIC

was easily dehydrated to yield a mixture containing principally (>95%) three compounds (labelled A, B, and C in the order of elution from a g.l.c. column). Compound A (52% of the total) could be separated in nearly pure form by careful fractional distillation at reduced pressure. Final purification was accomplished by preparative g.l.c. Compounds B (23%) and C (25%) could not be separated by distillation but could be separated in small amounts by the laborious application of preparative g.l.c. There are three possible unrearranged products of this simple dehydration III A and B, which are *cis* and *trans* isomers and a fully conjugated tetraene III C, for which there are no geometric isomers. Compound C is the fully conjugated tetraene as is quickly seen by the absence of $—CH_2—$ signals in the n.m.r. spectrum (Fig. 1C). The *cis* structure III A is assigned to the compound A and the *trans* to B based on experience obtained in the structural assignments of *cis*- and *trans*-2,4,6-trimethyl-1,3,5-heptatriene (5) which are similar to III A and III B (a methyl group instead of a methallyl group at C4). The significant feature in the n.m.r. spectrum of A (Fig. 1A) is a methyl group resonance at 8.44 τ which is absent in tetraene B (Fig. 1B). The presence of this same feature, at 8.40 τ, was in part used to assign the structures of the heptatrienes and a corresponding assignment is made in the case of the tetraenes. Also, the ultraviolet spectrum of tetraene A is similar to that of the *cis*-triene and that of tetraene B to the *trans*-triene (see Table I). The ultimate correctness of the geometry assigned to these two tetraenes rests therefore mainly on the validity of the original triene assignments.

Attempts to prepare III C by use of the Wittig reaction on phorone led to a mixture of two products (g.l.c.) neither of which had the correct retention time for III C. These compounds decomposed on attempted preparative separation at 150 °C and could not be characterized.

Attempts were made to prepare tripropenyl carbinol, as reported (6), from ethyl crotonate and 2 moles of propenyl magnesium bromide, with a view to dehydrating this to the corresponding conjugated tetraene. In our hands, the reaction leads mainly to ketonic material, presumably due to 1,4-addition. In another attempt, allyl magnesium chloride was added to hepta-2,5-dien-4-one. A small yield of a polyene mixture was obtained but the individual components could not be obtained pure. The material was very unstable and it should be noted that the system is favorable for Cope cyclizations (7). By adding allyl magnesium chloride to ethyl crotonate, there was obtained in 60% yield, 4-allylhepta-1,5-dien-4-ol. This was easily dehydrated to the corresponding tetraene IV which is a mixture of two isomers in about equal amount (the g.l.c. traces overlap

VI	396‡	45 000	96% H_2SO_4
XII	396	50 000	96% H_2SO_4
	395	—	FSO_3H

* Shoulder.
†Based on the ϵ_{max} of the VII and VIII mixture which was determined in 96% H_2SO_4 as 40 000 and which is assumed for these ions in FSO_3H. This value is likely low in view of the extraneous material appearing in the n.m.r. spectrum of I.
‡A similar result has been found by Deno and Pittman (4).

strongly). These are likely *cis* and *trans* isomers about the 3,4-double bond. Attempts to cause the isolated double bond to move into conjugation failed.

Attempts to prepare trivinyl carbinol by adding vinyl magnesium bromide to ethyl carbonate or ethyl acrylate yielded only polymeric material in both cases.

The Carbonium Ions

The chemical shifts of the carbonium ion protons in fluorosulfonic acid are consistently at 0.2–0.3 p.p.m. higher field than in 96% sulfuric acid, with reference to external tetramethylsilane. The trivinyl carbonium ion cannot be prepared in sulfuric acid solvent because of the high freezing point of the latter. However, one would still like to compare the τ values for the protons in this ion with those of similar ions, almost all of which have been obtained in sulfuric acid. This comparison is obtained by recording curves where the ion I (R = R′ = CH_3) has only partially cyclized and one can directly compare the proton positions of the original trivinyl ion relative to those of the cyclized ions. Since the cyclized ion positions are well known in 96% sulfuric acid, one can easily calculate theoretical τ values for the trivinyl carbonium ion protons in this solvent. All τ values referred to in the text are for (hypothetical) 96% sulfuric acid solution. It should be emphasized that this involved procedure is only valid because all the protons appear to be shifted a constant amount in the two solvents and is done only because direct comparisons are needed.

Fig. 2A shows the spectrum of III C obtained in fluorosulfonic acid at −55 °C. The two main peaks in their respective regions are at 3.11 τ and 7.65 τ with relative areas about 1:6 (depending to some extent on how one extends the line for the peak at 7.65 τ). These positions are at higher fields than those in divinyl carbonium ions (see Table II) and, coupled with the immediate disappearance of only these two peaks on warming, lead to the conclusion that one is observing the trivinyl carbonium ion I (R = R′ = CH_3). The ultraviolet spectrum shows a similar phenomena, a peak disappearing at 402 mμ and the resulting appearance of one at 373 mμ. The other n.m.r. peaks in the spectrum fit to some extent with those obtained by the protonation of the *cis* and *trans* unconjugated tetraenes III A and B. The conjugated tetraene sample used for this work contains no

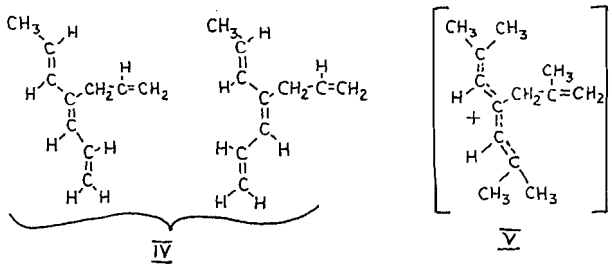
TABLE II
Comparison of n.m.r. proton positions

Ion	Protons	Resonance position (τ)
	12 Methyl protons 1 Alkene proton	7.04* 2.26
	2 Methyl protons 12 Alkene protons	7.33 and 7.38 (av. 7.35) 2.79 and 3.01 (av. 2.90)
	18 Methyl protons 3 Alkene protons	7.65 3.11

*Reported in ref. 8.

III A and no more than 1–2% of III B. There may be somewhat more than 1% of a higher retention product but the tetraene has approximately 97% purity and the bulk of the extraneous peaks are not due to impurities. There are two reasonable positions for the protonation of III C, at C1 or C3. Protonation at C3 leads to the same intermediate ion (V) that is presumed to be formed on protonation of III A or B.



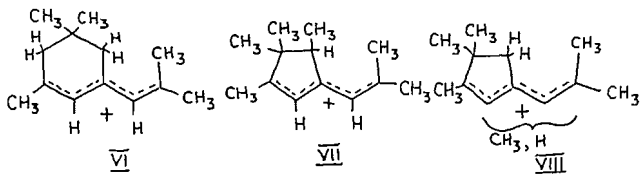
IV V

The relative affinity of C1 or C3 for a proton will ordinarily depend on the stability of the resulting ions. In the above case, however, the tetraene was added dropwise (a rapid addition) to the fluorosulfonic acid and the position of the addition might be kinetically controlled to some extent. Considering the method of addition, there is surprisingly little polymeric material (absorption background about 9 τ). Addition of the tetraene from the gas phase was not very satisfactory since fluorosulfonic acid is reasonably volatile and trace amounts will polymerize the incoming tetraene on the walls of the vacuum line.

Fig. 2B shows the spectrum of the sulfuric acid solution of either III A or B, for comparison purposes, in order to show the similar peak positions of this ion with the extraneous absorption discussed above. The structure of this ion (VI) has been previously proven by Deno and Pittman (4) who have prepared it from the alcohol II and independently by first synthesizing the corresponding cyclized triene. Fig. 2C shows the

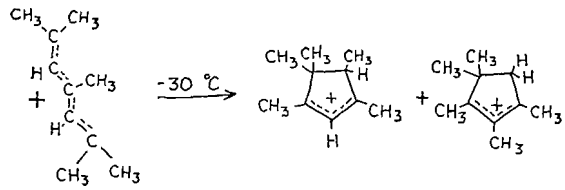
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

spectrum resulting from the warming of the solution of Fig. 2A (Half-life of ion I ca. 1 h at −55 °C). This is compared with Fig. 2D which was obtained by adding the conjugated tetraene to 96% sulfuric acid. Even at −30 °C, this same spectrum was obtained. In general, there is reasonable agreement for the peaks which have appeared from warming the solution in Fig. 2A with those obtained in sulfuric acid solution, the former being somewhat sharper in the less viscous solvent. The spectrum shown in Fig. 3 D is assigned to a mixture of ion VII (ca. 60%) and ion VIII (ca. 40%), the relative amounts not changing on standing at 25 °C.



VI VII VIII

This assignment is based on (*a*) the presence of $^{+}C—CH_3$ methyl groups at 7.44 τ, in the region found for dienylic ions; (*b*) the presence of a sharp peak at 7.92 τ, very characteristic of a methyl group attached to carbon atoms between carbonium ion centers, but of an intensity indicating only 40% of the area expected if the solution contained pure VIII; (*c*) the presence of three peaks in the region where protons attached to carbon atoms between carbonium ion centers are found, two for ion VII and one for ion VIII; and (*d*) the *gem*-dimethyl protons found at 8.68 τ, indicating that they are one carbon removed from a carbonium ion center, i.e., compare with the higher signals found in ion VI and also with the extensive table of proton positions elaborated by Deno *et al.* (8). There is also a precedent for the formation of these two compounds. The cyclization of the ion IX at −30 °C leads to ions X and XI except that, in this case, the ion X quickly rearranges to ion XI (9).



IX X XI

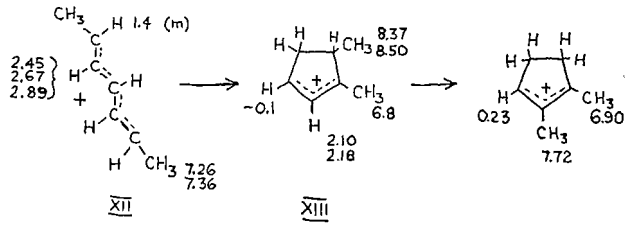
As additional evidence, the ultraviolet spectra of these ions have been determined (Table I). Ion VI has a λ_{max} 396 mμ, similar to acyclic dienylic ions (4, 9) while the mixture of ions VII and VIII have λ_{max} 378 mμ, at considerably shorter wavelengths but certainly still due to a dienylic ion. Cyclopentenyl ions are known (10) to absorb at appreciably shorter wavelengths than cyclohexenyl ions or acyclic analogs so that the ultraviolet evidence also supports the assignment of the structures VII and VIII.

Attempts to add the compound IV to sulfuric acid resulted only in polymer formation, but in very dilute solutions an ultraviolet spectrum was obtained, λ_{max} 356 mμ, ϵ_{max} 43 000. This ion would be expected to be analogous to ion VI without methyl groups at C3, C5, or C2′.

For comparisons of the rates of various cyclizations, ions IX and XII were prepared in fluorosulfonic acid. Ion IX has a half-life of only a few minutes at −55 °C; an n.m.r.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

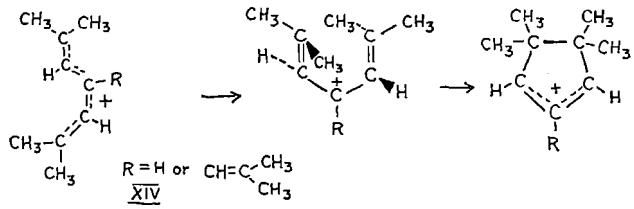
spectrum of the pure ion, uncontaminated with cyclized ion, was not obtained. Ion XII is more stable and, interestingly, one can observe the fleeting appearance of the intermediate ion XIII during the warming-up process.



XII XIII

DISCUSSION

The trivinyl carbonium ion, I (R = R′ = CH_3), undergoes a cyclization reaction at least 10^5 times faster than the corresponding divinyl carbonium ion XIV, even allowing for a statistical factor favoring the cyclization in I, but its cyclization is slower than that of the ion IX. The rapidity of the cyclization of IX compared to XIV has been suggested (9) to be due to steric repulsion of methyl groups resulting in a non-planar ion and a lower transition state energy for IX. Molecular model studies of I, where R = R′ = CH_3, indicate that it is likewise prevented by steric repulsion from being completely planar. The above steric argument may be used to explain its fast cyclization reaction but an alternative rationalization can be envisaged. For cyclization to take place, the molecule must have two double bonds in an s-*cis*, s-*cis* arrangement. It is clearly impossible for these to be coplanar with the middle carbon and, in fact, molecular model studies indicate that at least one of the double bonds (and probably both) must be nearly orthogonal to this carbon. One is therefore comparing intermediates where the positive charge is localized on a secondary carbon or delocalized by an allylic system with resulting reduction in energy. This process is represented below.



XIV

By analogy to the triphenyl carbonium ion, ion I might be expected to have a propeller shape. The actual position of the n.m.r. signals may be taken as evidence that the delocalization involves all three rings simultaneously (propeller shape), with concomitant reduction in the charge density at the individual positions and higher τ values. Alternatively, there may be a rapid interchange of non-equivalent groups leading to averaged τ values which could be higher than in divinyl carbonium ions.

There was some vague indication in the n.m.r. spectral results that the stability of ion I might not differ greatly from that of V. In comparing the stability of these two ions we can ignore the fact that ion V can cyclize readily since this process probably occurs subsequently. Hückel simple M.O. calculations (11) lead to values of 2 β for the stabilization energy of I and 1.464 β for V. The corresponding polyenes, III C and III A or B,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

have stabilization energies of 1.441 and 0.988 β respectively. These calculations are, however, of limited value because of the steric effects involved, and it is not unreasonable to expect that because of deviations from maximum overlap in the trivinyl carbonium ion, its stabilization energy could be lowered to nearly that of the divinyl carbonium ion. An analogy for this can be found. Triphenyl carbonium ion has a pK_R^+ of -6.63 while the corresponding diphenyl carbonium ion value is -13.3 (12). However, this difference is attributed mainly to a steric effect favoring ionization in the triphenyl case and the resonance energy of these two ions is postulated to be nearly the same.

The ion I (R = H, R′ = CH_3) will not have any steric repulsions preventing coplanarity, but results with the corresponding divinyl carbonium ion XII lead us to believe that ion I will not be much more stable toward cyclization than is XII.

Ultraviolet Spectra

The trivinyl carbonium ion has a λ_{max} 402 mμ, ϵ_{max} ca. 45 000 in fluorosulfonic acid. This is not greatly different from that of divinyl carbonium ions and is in agreement with the results of Hückel simple LCAO calculations which predict a transition energy of β in both cases. The curve for the trivinyl carbonium ion, is however, somewhat broader than that of the divinyl carbonium ion.

EXPERIMENTAL

Ultraviolet spectra were measured using a Beckman DK-1 or DU with 0.1 cm cells and are listed in Table I. Infrared spectra have been obtained on all new compounds using a Perkin–Elmer model 337 spectrophotometer. The n.m.r. spectra were recorded using a Varian Assoc. A-60 spectrometer equipped with a variable temperature probe, using ca. 10% solutions in carbon tetrachloride and tetramethylsilane internal reference. For the carbonium ion spectra in FSO_3H or H_2SO_4, tetramethylammonium cation (8) or external tetramethylsilane was used as a reference. Areas were obtained by integration or by weighing the peaks. Gas chromatography separations were made using an Aerograph "Autoprep" model A-700 with a 12 ft × 3/8 in. column packed with 30% Carbowax 20M on 60/80 Chromosorb W, HMDS treated. Analytical results were obtained on an Aerograph "Hy-Fi" model 600 using a 6 ft × 1/8 in. column of 5% SE-30 on Chromosorb W.

The gas-phase addition of polyenes to sulfuric acid has been described previously (9). Addition of the polyenes to FSO_3H was made dropwise from a capillary tip at -80 °C. The fluorosulfonic acid was redistilled in the absence of moisture. The preparation of several of the trienes used in this work has been described previously (5).

4-Methallyl-2,6-dimethylhepta-2,5-dien-4-ol (II)

Methallyl magnesium chloride was prepared by adding 45.2 g (0.5 moles) of methallyl chloride in 100 ml of ether over a 3 h period to 182.4 g (7.5 moles) of magnesium suspended in 1 l of dry ether. Magnesium chloride precipitates out and the ether solution becomes very syrupy. Phorone, recrystallized from ether, m.p. 28 °C, 35 g (0.25 moles) in 100 ml of ether, was added over a 30 min period to this solution. After letting the mixture stand for several hours, most of the ether solution was decanted from the excess magnesium and then decomposed by adding 500 cc of water to it. The two layers were separated, and the aqueous layer was extracted with a further 200 ml of ether. The magnesium turnings were also washed with water and portions of ether; the combined ether layers were then dried over magnesium sulfate. The ether was removed under reduced pressure and the residue was distilled through a spinning band column, b.p. ~60 °C at 0.25 mm. Slight cloudiness in the product indicated that some dehydration had occurred. Yield 40.2 g (82%).

Dehydration of 4-Methallyl-2,6-dimethylhepta-2,5-dien-4-ol

The title alcohol (46.5 g, 0.24 moles) in 100 ml of benzene was treated with 100 mg of *p*-toluenesulfonic acid. The solution was then heated to reflux temperature and the water formed by azeotropic distillation was collected in a Dean–Stark trap. The residual benzene solution was washed with aqueous potassium hydroxide and several times with water before drying over anhydrous magnesium sulfate. Rapid distillation of the residue after removal of the benzene yielded 32.5 g (77%) of crude mixed tetraenes, b.p. 25–35 °C at 0.05–0.2 mm. This mixture was analyzed by g.l.c. and showed three main peaks (>95% of the total area). The remaining 5% consists of several longer retention peaks, one of which overlaps to some extent with the third of the three main peaks. The approximate amounts of each compound were determined by measuring the area under the peaks and are 52%, 23%, and 25% in the order of increasing retention time.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

This mixture was fractionally distilled at 5–6 mm through a 1 m spinning band column, 12 fractions of nearly equal size being collected.

Fraction No.	Boiling range, °C	Refractive index, $n_D^{21.5}$
1.	57–68.5	1.4821
2.	68.5–69.5	1.4878
3.	69.5–70.5	1.4885
4.	70.5–71.0	1.4892
5.	71.0–72.0	1.4907
6.	72–75.0	1.4951
7.	75.0–76.0	1.4994
8.	76.0–76.5	1.5016
9.	76.5–77.0	1.5044
10.	77.0–78.0	1.5091
11.	78.0–78.5	1.5115
12.	78.5	1.5070

A significant amount of material polymerizes in the distillation pot during the course of the distillation (about 12 h). Each of the above fractions was analyzed by g.l.c. Fractions 2–5 were 98% compound A but the other fractions were mixtures. By using the best fractions for g.l.c. preparative separations, it proved possible to isolate each compound. For this purpose, fractions 2–5 were used to obtain A, 8 to obtain B, and 10–11 to obtain C. The column operating temperature was 125 °C, the helium flow rate was ca. 200 ml/min, and the size of the injection sample was 50 μl. The retention times were 11, 18, and 20.25 min respectively. The g.l.c. trace for compound A is completely separated but those for compounds B and C overlap to some extent. These could be obtained in about 98 and 97% purity respectively; the main impurity in C is not B but a higher retention product which could not be completely removed. Attempts to use longer columns necessitated higher temperatures, and 12 ft was picked as the maximum length possible without causing decomposition of the sample. The n.m.r. and ultraviolet spectra of these tetraenes are reported in Fig. 1 and Table I. The purity of the compounds separated by g.l.c. was checked by analytical g.l.c. These tetraenes were stored under nitrogen in the freezing compartment of a refrigerator. Before use, they were evaporated under high vacuum to remove any polymeric material.

Compound A. cis-2,6-dimethyl-4-(2-methyl-2-propenyl)-1,3,5-heptatriene (III A).—$n_D^{23.5}$ = 1.486. Anal. Calcd. for $C_{13}H_{20}$: C, 88.56; H, 11.44. Found: C, 88.31; H, 11.47.

Compound B. trans-2,6-dimethyl-4-(2-methyl-2-propenyl)-1,3,5-heptatriene (IIIB).—n_D^{25} = 1.496. Anal. Calcd. for $C_{13}H_{20}$: C, 88.56; H, 11.44. Found: C, 88.18; H, 11.44.

Compound C. 2,6-dimethyl-4-(2-methyl-1-propenyl)-1,3,5-heptatriene (III C).—$n_D^{22.5}$ = 1.516. Anal. Calcd. for $C_{13}H_{20}$: C, 88.56; H, 11.44. Found: C, 88.46; H, 11.73.

4-Allylhepta-2,5-dien-4-ol

Magnesium (60 g, 2.47 moles) and 500 ml of ether were placed in a 2 l three-neck flask. A solution of 20 g (0.26 moles) of allyl chloride in 100 ml of ether was added at such a rate that the solution maintained a gentle reflux. Then a solution of 55.5 g (0.49 moles) of ethyl crotonate and 133 g (1.74 moles) of allyl chloride in 400 ml of ether was added over a 2 h period. The solution was refluxed for 1 h and then decomposed with cold saturated ammonium chloride (500 ml). The two layers were separated, the aqueous layer was extracted with a further 250 ml of ether, and the combined ether fractions were dried over anhydrous potassium carbonate. Distillation of the residue after removal of the ether yielded 50 g (59%) of clear liquid, b.p. 63–63.2 °C at 5–6 mm, n_D^{22} = 1.4687. Reported (13) b.p. 93.5° at 35 mm, n_D^{20} = 1.4707. Anal. Calcd. for $C_{10}H_{16}0$: C, 78.89; H, 10.59. Found: C, 78.39; H, 10.02.

The n.m.r. spectrum is in good agreement with the expected structure. The spectrum also indicates the presence of only one (presumably *trans*) isomer.

Dehydration of 4-Allylhepta-2,5-dien-4-ol

A solution consisting of the above alcohol (20 g, 0.132 moles), dry benzene (100 ml), and *p*-toluenesulfonic acid dihydrate (100 mg) was heated under reflux (~1 h), about 2 ml. of water being collected in a Dean–Stark trap. The solution was then washed with potassium hydroxide solution and several times with water before being dried over potassium carbonate. Rapid distillation of the residue, after careful removal of the benzene, gave 11.8 g of product (67%), b.p. 53 °C at 5–6 mm. This was redistilled through a spinning band column to yield a constant refractive index product, b.p. 54.3–54.5 °C at 5–6 mm, n_D^{21} = 1.5365. This material shows two, nearly equal size, very strongly overlapping peaks on g.l.c. analysis. This result is also consistent with the n.m.r. spectrum of the material which shows two overlapping doublets for the split methyl protons. The integrated areas for the alkene, methylene, and methyl protons are in the expected ratio of 9:2:3. This product is therefore a mixture of *3,4-trans and 3,4-cis-4(2-propenyl)-1,3,5-heptatriene* (IV).

Anal. Calcd. for $C_{10}H_{14}$: C, 89.49; H, 10.51. Found: C, 89.79; H, 10.47.

Attempts to isomerize the double bond with acetic acid – sulfuric acid resulted in much polymerization and the recovery of only unchanged starting material.

Reaction of Phorone and 2-Methyl-2-propenylidenetriphenylphosphorane

A suspension of 19.39 g (0.055 moles) of methallyltriphenylphosphonium chloride in 150 ml of ether was treated with 1 equiv of butyl lithium (20 ml of a 2.83 *M* heptane solution). The resulting red solution was stirred an additional 30 min, and then 6.21 g of phorone (0.045 moles) in 100 ml of dry ether was added over a 30 min period. The resulting solution was refluxed in a N_2 atmosphere for 18 h. Water (200 ml) was added, the two layers were separated, and the aqueous layer was extracted with a further 100 ml of ether. The combined ether layers were dried over potassium carbonate. Removal of the ether left a residual paste from which 5.4 g (68% assuming $C_{13}H_{20}$) was distilled at about 0.1 mm. Analysis by g.l.c. indicates two main components in the ratio 3:5. Both have retention times slightly longer than that expected for III C. Spectral studies of the mixed material by n.m.r. and infrared tend to confirm the absence of the desired product. These two components appear to decompose on attempted preparative g.l.c. at 150 °C using the previously described column.

ACKNOWLEDGMENTS

The author wishes to thank the National Research Council of Canada for financial support. Acknowledgments are also due to Dr. Frank Adam for many helpful discussions, Mr. Kam. T. Wong for help in the low-temperature ultraviolet spectral measurements, and Miss V. Knutsen for the n.m.r. spectra.

THE MONO-OXALATO COMPLEXES OF IRON(III)

PART I. EQUILIBRIA

R. F. Bauer and W. MacF. Smith
Department of Chemistry, Queen's University, Kingston, Ontario

Received October 1, 1964

ABSTRACT

The formation of the mono-oxalato complexes of iron(III) has been examined spectrophotometrically at ionic strength 0.50, between 5 and 25 °C and hydrogen ion concentrations 0.2 to 0.5 *M*. Evidence is presented that the protonated complex $FeHC_2O_4^{++}$ is present in significant concentration in these solutions. The formation quotients of the species $FeC_2O_4^{+}$ and $FeHC_2O_4^{++}$ for temperatures 5, 15, and 25 °C have been determined and the extinction coefficients at 310 mμ have been estimated.

INTRODUCTION

The formation of the oxalato complexes of iron(III) has been studied by Badoz-Lambling (1, 2) and Babko and Dubovenko (3). Lambling established the existence of the complexes $Fe(C_2O_4)^+$, $Fe(C_2O_4)_2^-$, and $Fe(C_2O_4)_3^{3-}$ on the basis of neutralization curves and estimated values for the formation constants of these complexes. Using the method of continuous variation with solutions 5×10^{-4} *M* in iron(III) perchlorate and in oxalic acid Babko and Dubovenko found that at pH 1 the complex $Fe(C_2O_4)^+$ is the predominant species in aqueous solution. This is consistent with Lambling's values for the formation constants which indicate that the concentration of $Fe(C_2O_4)_2^-$ should be less than 0.5% of that of $Fe(C_2O_4)^+$ under these conditions.

There appears to be no published data indicating that the protonated mono-complex $Fe(HC_2O_4)^{++}$ is formed. However, in view of the fact that at pH 1 the ratio $[HC_2O_4^-]/[C_2O_4^=]$ is of the order of 1000/1, a relatively small formation constant could lead to such a complex being a significant species in solution. Before a study of the kinetics of the oxalate complexes of iron(III) was undertaken we obtained information about the formation constants of mono-oxalato iron(III) and the corresponding protonated complex at ionic strength 0.5.

EXPERIMENTAL

Apparatus

The formation of the complexes was examined spectrophotometrically using thermostated quartz cells of 10 mm and 1 mm path length and a Beckman DK1 extended range spectrophotometer. Optical densities at λ 310 mμ were used in assessing the formation quotients. At this wavelength the species $C_2O_4^=$, $HC_2O_4^-$, and $H_2C_2O_4$ are substantially transparent and the difference in the extinction coefficients of the oxalato complexes of iron(III) and the iron(III) not so complexed approaches a maximum. pH measurements were made with a Radiometer Number 4 pH meter.

Solutions

Solutions were prepared from triply distilled water, the second distillation being from alkaline permanganate solution. Solutions involving iron(III) perchlorate, perchloric acid, and sodium perchlorate were prepared and analyzed as previously described (4). Oxalic acid was reagent grade from Nichols Chemical Company.

DISCUSSION

Preliminary Considerations

The predominant reactions to consider are

$$Fe^{+++} + C_2O_4^= \rightleftharpoons Fe(C_2O_4)^+$$

$$Fe^{+++} + HC_2O_4^- \rightleftharpoons Fe(HC_2O_4)^{++}.$$

For personal use only.

Other pertinent reactions which may occur are (*a*) the hydrolysis of Fe^{+++} to $Fe(OH)^{++}$, (*b*) the formation of polynuclear iron(III) species, (*c*) the photochemical oxidation of oxalic acid sensitized by ferric ion.

Reactions *a* and *b* have been studied by Mulay and Selwood (5), Milburn and Vosburgh (6), and Turner and Miles (7). Turner and Miles consider that the absorption spectrum of iron(III) solutions is interpretable in terms of $FeOH^{++}$ having absorption peaks at 205 mμ and 300 mμ and Fe^{+++} having one at 240 mμ. The dimer $Fe_2(OH)_2^{4+}$ is believed to absorb fairly markedly at 335 mμ and Milburn and Vosburgh suggest that this polynuclear iron(III) species contributes significantly to optical density at hydrogen ion concentrations of 0.2 *M* if the ferric ion concentration exceeds 10^{-3} *M*. Since the method described below of treating the experimental data is based on the assumption that the effective extinction coefficient of Fe(III), $\epsilon_{Fe\ eff}$ is constant at a given acidity it was necessary to determine the dependence of $\epsilon_{Fe\ eff}$ on the concentration of Fe(III). The values of $\epsilon_{Fe\ eff}$ will depend on the relative concentrations of Fe^{+++}, $FeOH^{++}$, and $Fe_2(OH)_2^{++}$. The ratio $[FeOH^{++}]/[Fe^{+++}]$ should remain constant but the ratio $[Fe_2(OH)_2^{4+}]/[FeOH^{++}]$ should rise with increase in concentration of total iron(III). This could lead to a significant dependence of extinction coefficient of iron(III) on its total concentration. To assess the magnitude of such an effect we have measured at λ 310 mμ the effective extinction coefficient of iron(III) in solutions containing ferric perchlorate (2×10^{-4} to 20×10^{-4} *M*) and perchloric acid (0.1 to 0.4 *M*) with ionic strength adjusted to 0.5 with sodium perchlorate. The results are given in Table I. Rabinowitch and Stockmayer (8) point out that in the absence of significant contribution from the dimer

$$\epsilon_{Fe\ eff} = \epsilon_{Fe^{+++}} + \epsilon_{FeOH^{++}} K_h/[H^+]$$

where $\epsilon_{Fe\ eff}$ is the effective extinction coefficient of iron(III) ion. $\epsilon_{Fe^{+++}}$ and $\epsilon_{FeOH^{++}}$ are the extinction coefficients of ferric ion and its first hydrolysis product, and K_h is the first hydrolysis quotient for ferric ion. Plots of $\epsilon_{Fe\ eff}$ against $1/[H^+]$ involving our data are linear but the data in Table I do indicate a significant dependence of $\epsilon_{Fe\ eff}$ on the iron(III) concentration at a given acidity. Our measurements (outlined below) relating to the formation of the protonated complexes were made in solutions with iron(III) concentrations in the range 2×10^{-4} to 6×10^{-4} *M* and over this range the variation in the value of $\epsilon_{Fe\ eff}$ is less than 11%. The quantity which is pertinent in assessing data bearing on complex formation is the change in optical density due to complex formation on the addition of oxalate. The contribution to the observed change in optical density (ΔD_{obs}) which is due to a change in $\epsilon_{Fe\ eff}$ will be $\Delta c'\ \Delta\epsilon_{eff}$ where $\Delta c'$ is the decrease in the concentration of iron(III) due to oxalate complexing and $\Delta\epsilon_{Fe\ eff}$ is the corresponding change in the effective extinction coefficient which must be substantially less than

TABLE I

The effective extinction coefficient ϵ of iron(III) in acidified aqueous solutions of ferric perchlorate at 25 °C and wavelength 310 mμ. All values for ϵ are in $mole^{-1}\ l\ cm^{-1}$

	Concentration of iron(III) perchlorate (moles l^{-1})		
$[H^+]$	2×10^{-4}	6×10^{-4}	20×10^{-4}
0.10	82.5	91.3	139
0.20	66.2	72.6	104
0.40	59.6	63.0	77.4

(91.3 − 82.5 =) 8.8 mole^{-1} l cm^{-1}. The overall observed change in optical density will be approximately $\Delta c'$ ($\bar{\epsilon}_{Fe\ ox} - \bar{\epsilon}_{Fe\ eff}$) where $\bar{\epsilon}_{Fe\ ox}$ is the effective extinction coefficient of the iron oxalate complexes and $\bar{\epsilon}_{Fe\ eff}$ that for the iron(III) not complexed with oxalate. As shown below ($\bar{\epsilon}_{Fe\ ox} - \bar{\epsilon}_{Fe\ eff}$) is greater than 1.1×10^3. Consequently the correction to be applied to the observed optical density will be less than $8.8/(1.1 \times 10^3)$ (= 0.008) of its value and we have neglected it.

Livingston (9) and Allmand and Webb (10) showed that carbon dioxide is formed when ferric oxalate solutions are irradiated in the presence of oxygen. Our experiments in which solutions were irradiated in the spectrophotometer with λ 310 mμ and the spectrophotometric character examined at intervals indicate that photochemical changes during our measurements were negligible.

Interpretation of Spectrophotometric Data

For λ 310 mμ the species $C_2O_4^=$, $HC_2O_4^-$, and $H_2C_2O_4$ do not contribute significantly to optical density and the difference in the optical densities of two solutions differing only in that one (s) contains oxalate and the other (ref.) does not is

$$[1] \qquad D_s - D_{ref} = \Delta D = \sum X_i(\epsilon_i - \epsilon_{Fe\ eff}) = \sum X_i \Delta\epsilon_i$$

where X_i is the concentration of a particular oxalate-iron complex and ϵ_i its extinction coefficient. It is assumed that any change in $\epsilon_{Fe\ eff}$ following upon the decrease in concentration of uncomplexed iron does not lead to significant change in $\Delta\epsilon_i$.

The data subjected to examination below were obtained with solutions where [H$^+$] was equal to or greater than 0.2 *M*. Connick and co-workers' (11) values for the hydrolysis constant for ferric ion indicate that under these conditions $FeOH^{++}$ constitutes less than 1% of the uncomplexed iron(III). Consequently

$$[2] \qquad a = [Fe^{+++}] + [FeC_2O_4^+] + [FeHC_2O_4^{++}]$$

where "*a*" represents the total concentration of iron(III).
Also

$$[3] \qquad b = [C_2O_4^=] + [HC_2O_4^-] + [H_2C_2O_4] + [FeC_2O_4^+] + [FeHC_2O_4^{++}]$$

where "*b*" is the total concentration of oxalate.
The concentrations of these species are interrelated by the formation quotients Q_1 and Q_2 for the complexes and the acid ionization quotients Q_{a_1} and Q_{a_2} for oxalic acid.

$$Q_1 = \frac{[FeC_2O_4^+]}{[Fe^{+++}][C_2O_4^=]} \qquad Q_2 = \frac{[FeHC_2O_4^{++}]}{[Fe^{+++}][HC_2O_4^-]}$$

$$Q_{a_1} = \frac{[H^+][HC_2O_4^-]}{[H_2C_2O_4]} \qquad Q_{a_2} = \frac{[H^+][C_2O_4^=]}{[HC_2O_4^-]}$$

It follows from these relations and eqs. [2] and [3] that

$$[4] \qquad b = [C_2O_4^=]\left(1 + \frac{[H^+]}{Q_{a_2}} + Q_1[Fe^{+++}] + \frac{Q_2[H^+][Fe^{+++}]}{Q_{a_2}} + \frac{[H^+]^2}{Q_{a_1}Q_{a_2}}\right).$$

If both $FeC_2O_4^+$ and $FeHC_2O_4^{++}$ are present eq. [1] becomes

$$[5] \qquad \Delta D = \Delta\epsilon_1[FeC_2O_4^+] + \Delta\epsilon_2[FeHC_2O_4^{++}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

which in terms of equilibrium quotients becomes

$$\Delta D = [Fe^{+++}][C_2O_4^{=}]\left(\Delta\epsilon_1 Q_1 + \frac{\Delta\epsilon_2 Q_2[H^+]}{Q_{a2}}\right)$$

and this with [4] yields

$$\frac{\Delta D}{[Fe^{+++}]}\left(1 + \frac{[H^+]}{Q_{a2}} + \frac{[H^+]^2}{Q_{a1}Q_{a2}}\right) = -\Delta D\left(Q_1 + \frac{Q_2[H^+]}{Q_{a2}}\right) + b\left(\Delta\epsilon_1 Q_1 + \frac{\Delta\epsilon_2 Q_2[H^+]}{Q_{a2}}\right).$$

In our experiments iron(III) was in substantial (from 5- to 30-fold) excess over total oxalate and complexing was incomplete. The values for the association constants derived from our data below indicate that more than 80% of total iron remains uncomplexed under conditions most favorable for its removal as oxalate complexes and that over 95% remains free for 90% of the measurements. Also, as indicated above, hydrolysis and dimer formation have negligible effects at the acidity and iron(III) concentrations of this work. We have consequently equated the concentration of ferric ion to "a". A plot of $\Delta D/a$ against ΔD for constant b and $[H^+]$ should yield a straight line with the negative slope S given by

[7] $$S = \frac{Q_1 + \frac{Q_2[H^+]}{Q_{a2}}}{1 + \frac{[H^+]}{Q_{a2}} + \frac{[H^+]^2}{Q_{a1}Q_{a2}}}.$$

[7] may be written

[8] $$S\left(\frac{Q_{a2}}{[H^+]} + \frac{[H^+]}{Q_{a1}} + 1\right) = \frac{Q_{a2}}{[H^+]}Q_1 + Q_2$$

If it be assumed that $FeHC_2O_4^{++}$ is not formed to an appreciable extent then eq. [8] becomes

[9] $$S\left(\frac{Q_{a2}}{[H^+]} + \frac{[H^+]}{Q_{a2}} + 1\right) = \frac{Q_{a2}}{[H^+]}Q_1$$

where S is still the negative slope of the plot of $\Delta D/a$ against ΔD.*

If the left side of eqs. [8] and [9] is plotted against $Q_{a2}/[H^+]$, a straight line should be obtained with slope Q_1, the formation quotient for $FeC_2O_4^+$. A significant magnitude for the intercept indicative of Q_2 would suggest formation of $FeHC_2O_4^{++}$.

Dissociation Quotients for Oxalic Acid

The first and second dissociation quotients of oxalic acid at ionic strength 0.50 and temperatures 5 to 25 °C were needed in the interpretation of our data. Two series of buffered solutions corresponding to mixtures of $H_2C_2O_4$ with $NaHC_2O_4$ and $NaHC_2O_4$ with $Na_2C_2O_4$ were prepared from solutions of sodium hydroxide and oxalic acid, and perchloric acid and sodium oxalate. The ionic strength was adjusted with sodium perchlorate. pH readings were made using Radiometer saturated calomel and G202B glass

As $[Fe^{+++}]$ is less than "a" our approximation will lead to estimates of $\Delta D/[Fe^{+++}]$ and of S which are somewhat low. However, variation in the value of $[Fe^{+++}]/a$ (and in the percentage error in S) with acidity should be slight. For example at the highest oxalate concentration used and an iron concentration of 4×10^{-4} M, calculations based on our values for Q_1 and Q_2 (obtained directly from plots based on [9]) indicate that the percentage of iron(III) in the uncomplexed form changes from 91.8 to 93.0 as the hydrogen ion concentration changes from 0.2 to 0.4 M. Consequently, while our estimate for Q_2 may be slightly high, the error in Q_1 associated with our approximation should be negligible compared with experimental errors.

electrodes. The hydrogen ion concentration in the oxalate solutions were estimated using the relationship

$$[H^+] = \frac{\text{antilog } (-\text{pH})}{\gamma_{H^+}'}$$

where γ_{H^+}' was determined empirically from pH readings on solutions containing known concentrations of perchloric acid and adjusted to ionic strength 0.5 with sodium perchlorate.* Concentrations of the various species in the oxalate solutions could be readily calculated from the known overall composition of the solutions and the hydrogen ion concentrations. The values for the ionization quotients Q_{a_1} and Q_{a_2} caculated from the data interpreted in this way are given in Table II. These vaues are fairly consistent with those of Dutt and Sur (12) of 7.586×10^{-2} for K_{a_1} and 2.089×10^{-4} for K_{a_2} for ionic strength of about 1.1 and temperature 32 °C.

TABLE II

The ionization quotients of oxalic acid at ionic strength 0.50

Temp. (°C)	Q_{a_1} (mole l^{-1})	Q_{a_2} (mole l^{-1})
5.0	$(4.77 \pm 0.06) \times 10^{-2}$	$(2.32 \pm 0.05) \times 10^{-4}$
15.0	$(5.90 \pm 0.07) \times 10^{-2}$	$(2.23 \pm 0.05) \times 10^{-4}$
25.0	$(6.25 \pm 0.08) \times 10^{-2}$	$(2.16 \pm 0.06) \times 10^{-4}$

Measurements Relating Directly to the Association Constants

The data bearing directly on the association constants were obtained with solutions containing oxalic acid concentrations of either 2×10^{-5} or 4×10^{-5} M, total iron(III) concentrations from 2×10^{-4} to 6×10^{-4} M, and perchloric acid concentrations between 0.2 and 0.5 M. All solutions were of ionic strength 0.5 and runs were made at 5, 15, and 25 °C with temperature control better than ±0.1 deg. Spectrophotometric absorption curves were obtained covering a wavelength range which included λ 310 mμ with the solution in the reference beam of the double beam spectrophotometer differing from the "sample" solutions only in that it did not contain oxalic acid. In consequence with 1 cm absorption cells the optical density corresponded to ΔD of the above equations. All solutions were prepared from available stock solutions and examined spectrophotometrically within 10 h of the time of preparation.

The plots of $\Delta D/a$ against ΔD for constant oxalate concentration yielded straight lines with negative slopes whose values (S) are given in Table III. Figure 1 shows plots of

$$S\left\{\frac{Q_{a_2}}{[H^+]} + \frac{[H^+]}{Q_{a_1}} + 1\right\} \text{ against } \frac{Q_{a_2}}{[H^+]}$$

suggested by eq. [8]. The data for 25 and 15 °C imply lines with positive intercepts and consequently the presence of significant concentrations of protonated complexes, although the uncertainties associated with the values of the slopes and intercepts and of Q_1 and Q_2 are considerable. The plot for the data for 5 °C shows two points (the lowest) falling markedly below an approximate linear grouping of the other six points. The figure shows lines of regression with that for the lowest temperature drawn ignoring the two lowest

γ_{H^+}' showed a significant dependence on acidity over the range of perchloric acid concentrations 5×10^{-5} to 3×10^{-1} M when estimated from data obtained with a glass electrode but was constant to within ±2% when a quinhydrone electrode was used. It should be noted that γ_{H^+}' is only a parameter for relating pH reading and hydrogen ion concentrations and is not to be identified necessarily with the activity coefficient of hydrogen ion.

TABLE IV

The formation quotients of $FeC_2O_4^+$ (Q_1) and of $FeHC_2O_4^{++}$ (Q_2) at ionic strength 0.50

Temp. (°C)	Q_1 (mole^{-1} l)	Q_2 (mole^{-1} l)
5.0	5.6×10^7	1.27×10^4
15.0	5.06×10^7	2.17×10^4
25.0	2.45×10^7	2.22×10^4

points. Table IV contains the values of Q_1 and Q_2 obtained from the slopes and intercepts of these lines. The 95% confidence limit determined by standard methods and assigning equal weight to each point are better (less) than ±17% of the value given for Q_1 and ±30% of the value given for Q_2 for 25 and 15 °C.

We have obtained approximate values for $\Delta\epsilon_1$ and $\Delta\epsilon_2$ by solving eq. [6] simultaneously using a number of sets of experimental values at 25 °C. The arithmetic means are 1.22×10^3 mole^{-1} l cm^{-1} for $\Delta\epsilon_1$ and 1.41×10^3 mole^{-1} l cm^{-1} for $\Delta\epsilon_2$. Since the values for $\epsilon_{Fe\ eff}$ at wavelength 310 mμ are about 2% of these, $\Delta\epsilon_1$ and $\Delta\epsilon_2$ may be considered as approximate values for the extinction coefficients of the complexes $FeC_2O_4^+$ and $FeHC_2O_4^{++}$.

In Fig. 2 are shown the absorption curves of two solutions at 25 °C differing considerably in acidity and, on the basis of our values for ionization and formation quotients Q_{a_1}, Q_{a_2}, Q_1 and Q_2, in the relative concentrations of the protonated and unprotonated species. We estimate that in the solution indicated by the filled circles the concentrations of $FeC_2O_4^+$ and $FeHC_2O_4^{++}$ are 1.43×10^{-4} and 2.2×10^{-5} respectively while in that

indicated by the open circles the corresponding concentrations are 1.43×10^{-4} and 5.52×10^{-5}. It is apparent that there are no marked differences in the forms of the absorption curves. The observed difference in the optical densities of these solutions agrees with that calculated on the basis of our quotients and extinction coefficients at λ 310 mμ to within 1%.

There is the possibility that the protonated monocomplex is monodentate or bidentate. It does not appear to be possible to assess definitely the alternatives on the basis of our data.

THE MONO-OXALATO COMPLEXES OF IRON(III)

PART II. KINETICS OF FORMATION

R. F. Bauer and W. MacF. Smith
Department of Chemistry, Queen's University, Kingston, Ontario

Received October 1, 1964

ABSTRACT

The kinetics of the formation of the mono-oxalato complexes of iron(III) have been examined spectrophotometrically over the range of temperatures 5 to 25 °C in an aqueous medium of ionic strength 0.50 and the range of hydrogen ion concentrations 0.03 to 0.45 *M*. The kinetically significant paths under the conditions studied involve reactions first order in iron(III) and in bioxalate but there appears to be some decrease in the second order rate constant with increase in hydrogen ion concentration at the highest acidities and at the highest temperatures. Although there is no significant contribution to the rate by an acid-independent path first order in free oxalate under the experimental conditions, the possibility of the rate constant for such a path being greater than that first order in bioxalate is not precluded.

INTRODUCTION

The kinetics of the anation reaction of iron(III) ion with fluoride (1), chloride (2), bromide (3), thiocyanate (4), and sulfate (5) have been examined by techniques ranging from relaxation methods to stopwatch timing and show a fairly marked dependence of the second order rate constant on ligand type. Such behavior is in contrast to that exhibited by certain bivalent metal ions such as nickel(II) whose rate constants for corresponding anation reactions show little dependence on ligand type (6) and are presumably controlled by the rate of water loss from the metal ion.

This paper presents more information bearing on the influence of ligand type on the anation reactions of iron(III). The reaction studied, that of iron(III) with oxalate ion and its protonated forms, is convenient to examine because of its relative slowness in acid solution. It differs from the anation reaction of iron(III) with singly charged ligands which have been previously examined in that the principal complex formed is probably bidentate rather than monodentate.

EXPERIMENTAL

Materials

Solutions were prepared from triply distilled water, the second distillation being from alkaline permanganate. Ferric perchlorate (non-yellow), perchloric acid (double vacuum distilled 70%), sodium perchlorate (anhydrous), and oxalic acid were all reagent grade. The sodium perchlorate was dried at 110° for 2 h before weighing. Stock solutions ferric perchlorate and perchloric acid were analyzed for acid and iron content by the method previously discussed (1).

Method and Apparatus

The reaction was followed spectrophotometrically with a Beckman DK-1 spectrophotometer at λ 310 mμ using thermostated standard 1 cm silica cells as reaction vessels. Two solutions, one containing iron(III) perchlorate, the other oxalic acid, and both adjusted for ionic strength and acidity, were simultaneously injected into the reaction cell from thermostated 2 ml syringes fitted with polythene tips to ensure mixing. The solution in the cell in the reference beam had a composition identical with the reacting solution except that it contained no oxalic acid. At λ 310 mμ the uncomplexed oxalic acid and its ions do not contribute significantly to optical density and the difference in optical densities (ΔD) of reference and sample solutions is

$$[1] \qquad \Delta D = \{r\epsilon_{FeHC_2O_4} + (1 - r)\epsilon_{FeC_2O_4}\}x$$

where x is the total concentration of the complexes, r is the fraction of the complexes which is $FeHC_2O_4^{++}$, and ϵ is the extinction coefficient in $mole^{-1}\ l\ cm^{-1}$ of the species indicated by the subscript. If it is assumed that at a given acidity the ratio $[FeC_2O_4^{+}]/[FeHC_2O_4^{++}]$ remains at the equilibrium value, the change of

optical density is proportional to x, the concentration of complexed iron. Since as indicated in the preceding paper the extinction coefficients of the two complexed species differ by less than 20%, ΔD would remain nearly proportioned to x even if there were moderate deviations from the equilibrium value.

INTERPRETATION OF THE KINETIC DATA

In interpreting the experimental rate data we have used the integrated form of the relation

$$\frac{dx}{dt} = k_f''(a - x)(b - x) - k_b x \qquad [2]$$

where a is the total concentration of iron(III) in all species, b is the total concentration of oxalate, and x is the total concentration of iron(III) complexed as $FeC_2O_4^+$ and $FeHC_2O_4^{++}$.

k_f'' is a composite rate constant for the formation of the complexes and will depend on the rate constants of the various paths. It will involve factors for the fractions of uncomplexed oxalate in the protonated and unprotonated forms and will consequently depend on the concentration of hydrogen ions. k_b is a corresponding composite constant for the reactions involving breakup or aquation of the complexes and like k_f'' will be acid dependent.

The relation [2] will be valid for a variety of possible mechanisms, e.g. three parallel forward reactions opposed by back reactions if the ratio of the concentrations of the protonated and unprotonated complexes is maintained close to the equilibrium value.

$$Fe^{+++} + HC_2O_4^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} FeC_2O_4^+ + H^+$$

$$Fe^{+++} + C_2O_4^{=} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} FeC_2O_4^+$$

$$Fe^{+++} + HC_2O_4^- \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} FeHC_2O_4^{++}$$

$$FeC_2O_4^+ + H^+ \rightleftharpoons FeHC_2O_4^{++} \text{ (equilibrium)}*$$

In this case eq. [2] takes the form

$$\frac{dx}{dt} = (k_1 + k_3)[Fe^{+++}][HC_2O_4^-] + k_2[Fe^{+++}][C_2O_4^{=}] - (k_{-1}[H^+] + k_{-2})[FeC_2O_4^+] - k_{-3}[FeHC_2O_4^{++}]$$

which may be written

$$\frac{dx}{dt} = \left(\frac{k_1 + k_3}{Q_{a2}}[H^+] + k_2\right)s(a - x)(b - x) - ((k_{-1}[H^+] + k_{-2})(1 - r) + k_{-3}r)x$$

or

$$\frac{dx}{dt} = k_f s(a - x)(b - x) - k_b x \qquad [3]$$

*The transition state for this reaction would of course be different from that for reaction [1].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where Q_{a2} is the acid ionization quotient for $HC_2O_4^-$,

$$s = [C_2O_4^{=}]/([HC_2O_4^-] + [C_2O_4^{=}]),$$

$$r = [FeHC_2O_4^{++}]/([FeHC_2O_4^{++}] + FeC_2O_4^{+}]),$$

$$[4] \qquad k_f = \frac{k_1 + k_3}{Q_{a2}}[H^+] + k_2.$$

Equation [2] would of course also apply if the protonated complex were formed solely by protonation of $FeC_2O_4^+$ if the rates of protonation and deprotonation of the complexes were rapid compared to the rate of complex formation. In this event k_f would equal

$$\frac{k_1}{Q_{a2}}[H^+] + k_2$$

instead of

$$\frac{k_1 + k_3}{Q_{a2}}[H^+] + k_2.$$

There is the marked possibility that the protonated and unprotonated complexes are formed from a common intermediate. The rate expression [2] would then apply only if the rate-controlling steps involved solely the transformation of the initial reactants to the intermediate or if the intermediate occurred in the relatively small concentrations consistent with applicability of the stationary state approximations.

If x_e represents the total concentration of complexes at equilibrium

$$[5] \qquad \frac{k_b}{k_f} = \frac{(a - x_e)s(b - x_e)}{x_e}$$

Substitution of [5] into [3] with rearrangement yields

$$\frac{dx}{(ab - x_e x)(x_e - x)} = \frac{k_f s}{x_e}\,dt$$

which on integration and introduction of the condition that $x = 0$ when $t = 0$ yields

$$[6] \qquad \log\left(\frac{x_e - x}{x_e}\right) + \log\left(\frac{ab}{ab - x_e x}\right) = \frac{k_f s}{2.303 x_e}(x_e^2 - ab)t.$$

The second term on the left of [6] is negligible relative to the first. a is much greater than b under our experimental conditions and even when x approaches x_e the product $x_e x$ is rarely as great as 1% of ab.

It follows from [1] that

$$[7] \qquad \frac{x_e - x}{x_e} = 1 - \frac{\Delta D_t}{\Delta D_\infty}$$

where x_e and ΔD_∞ are corresponding values for equilibrium.

Substituting [7] into [6] and dropping the second term on the left of [6] yields

$$[8] \qquad \log\left(1 - \frac{\Delta D_t}{\Delta D_\infty}\right) = \frac{k_f s}{2.303 x_e}(x_e^2 - ab)t.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The slope S' of the plot of log $(1 - (\Delta D_t/\Delta D_\infty))$ against t should then be related to k by the relation

$$[9] \qquad k_f = \frac{2.303 x_e S'}{s(x_e^2 - ab)}.$$

x_e and s can be calculated from the values of the association quotients of the mono-oxalate complexes and the ionization quotients for oxalic acid given in the previous paper.

RESULTS OF THE KINETIC MEASUREMENTS AND DISCUSSION

The data from kinetic runs for all conditions investigated yielded linear plots for log $(1 - (\Delta D_t/\Delta D_\infty))$ against time. Rate constants k_f were calculated from the slopes of these plots using eq. [9] and showed no significant dependence on total concentration of iron(III) or oxalate at a given acidity over the range of concentrations investigated, i.e. 2×10^{-4} to 8×10^{-4} for iron(III), 2×10^{-5} to 12×10^{-5} for oxalate. Mean values for k_f for each acidity and temperature along with the standard deviations are given in Table I and plotted in Fig. 1 against the concentration of hydrogen ions.

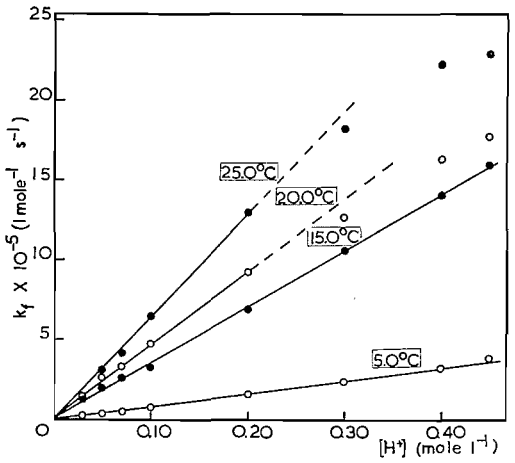

FIG. 1. Plots of observed forward rate constant k_f against hydrogen ion concentration.

As indicated above

$$k_f = \frac{k_1 + k_3}{Q_{a2}}[H^+] + k_2$$

if there are three parallel paths, one first order in oxalate and the other two first order in bioxalate.

Figure 1 indicates a linear relationship between k_f and $[H^+]$ (i.e. proportionality between rate and bioxalate ion concentration) over the range of acidities investigated for the two lowest temperatures and a significant falloff from first order dependence on hydrogen ion concentration for the highest acidities at the two highest temperatures. Lines of regression through the points at each temperature, ignoring those for concentrations of hydrogen ion in excess of 0.2 M at 20 and 25 °C, have slopes implying, through eq. [4], values for $k_1 + k_3$ listed in Table II. Cursory examination of Fig. 1 suggests that k_f approaches zero at zero hydrogen ion concentration and consequently that k_2 equals zero. However,

statistical treatment of the data, implies values for k_2 of $(19 \pm 20^*) \times 10^3$ at 15 °C and $(30 \pm 32) \times 10^3$ mole^{-1} l s^{-1} at 25 °C. It is apparent that there is the possibility that k_2 is larger than $k_1 + k_3$. However, under all conditions investigated $k_2[C_2O_4^{=}]$ must be negligible compared with $(k_1 + k_3)[HC_2O_4^{-}]$ because of the very large value of the ratio $[HC_2O_4^{-}]/[C_2O_4^{=}]$ and consequently there will be negligible contributions to the overall rate by the path with first order dependance of rate on free oxalate ion concentration.

The plot of log $(k_1 + k_3)$ against $1/T$ implies effective values for $\Delta H^{\neq}$ and $\Delta S^{\neq}$ of 18 ± 4 kcal mole^{-1} and 16 ± 10 cal deg^{-1} mole^{-1} respectively. In the subsequent argument we tentatively identify the experimental $(k_1 + k_3)$ with k_1 and consequently imply that the values for $\Delta H^{\neq}$ and $\Delta S^{\neq}$ apply to the path with rate constant k_1. It is of interest that $\Delta H^{\neq}$ for other anation reactions of iron(III) range from 13 kcal (thiocyanate) to 22.8 kcal (fluoride) and $\Delta S^{\neq}$ from −5 cal deg^{-1} (thiocyanate) to +35 cal deg^{-1} (fluoride). However, the points in the plot of log k against $1/T$ for oxalate show considerable dispersion and do not rule out curvature. We do not therefore consider our values for $\Delta H^{\neq}$ and $\Delta S^{\neq}$ suitable for critical comparison with those for other anation reactions. It is possible that an extensive group of measurements obtained with a technique such as "stop flow" which would remove complications due to back reaction and permit an extension of the

*95% confidence limit.

20	9.8±3.2
25	14.4±1.0

temperature range might help elucidate through the shape of the log k against $1/T$ plot whether $(k_1 + k_3)$ is indeed composite.

It is apparent that an acceptable mechanism for the reaction between iron(III) and oxalate must be in accord with a second order rate law, first order in iron(III) ion and first order in bioxalate for all conditions except the highest acidities at the two highest temperatures where there is some decrease in the magnitude of the second order rate constant with increase in acidity.

k_1 (and also k_3) could conceivably be composite and involve rate constants for steps in a series reaction leading to the formation of the final complex. For example, if the protonated complex could be ignored the reaction path might be

$$Fe^{+++} + HC_2O_4^- \underset{k_b}{\overset{k_a}{\rightleftharpoons}} FeC_2O_4^{+}\cdot + H^+$$

$$FeC_2O_4^{+}\cdot \xrightarrow{k_d} FeC_2O_4^{+} \qquad [10]$$

where $FeC_2O_4^{+}\cdot$ represents a monodentate intermediate. That the formation of a monodentate intermediate is rate controlling in the formation of the multidentate complexes of nickel(II) is suggested by the findings of Wilkins and co-workers (7) and of Margerum and co-workers (8).

If the stationary state approach is applicable, the following relation should apply for the forward rate of formation of the bidentate complex.

$$\frac{k_d k_a}{k_b[H^+] + k_d}[Fe^{+++}][HC_2O_4^-]$$

At any one hydrogen ion concentration the rate should be first order in iron(III) and in bioxalate with an effective rate constant k_1 equal to $k_d k_a/(k_b[H^+] + k_d$. If $k_b[H^+]$ is much less than k_d then the rate constant k_1 equals k_a (i.e. the first step is rate controlling) and the rate constant is independent of acidity. If $[H^+]$ is such that $k_b[H^+]$ becomes significant relative to k_d there will be a decrease in k_1. A corresponding mechanism involving a protonated monodentate intermediate would imply that k_1 should be independent of hydrogen ion concentration. In fact, in the range of higher acidities where there appears to be a falloff in the observed rate constant, the protonated complex is a significant species at equilibrium and should not be ignored. Identification of a protonated intermediate with the final protonated complex would imply a series reaction which in general would show a dependence of rate on concentration more involved than the second order dependence which is actually observed. The possibility of there being a reaction path parallel to that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

summarized by eq. [10] and involving a protonated intermediate different from the final product cannot be definitely ruled out but we shall ignore this possibility and assume that the essential reaction path is that summarized by eq. [10] and that the final protonated and unprotonated species are in labile equilibrium. Such an assumption is in accord with our data and our method of interpreting them and implies values quoted for $k_1 + k_3$ above are those for k_1.

The work of Eigen and co-workers (6, 9, 10) and of Wendt and Strehlow (11) has led to general acceptance of a mechanism of ion association which emphasizes that there is a rate-determining exchange between ligand and the water of the first coordination shell of the metal ion within ion pairs where the partners are separated by one water molecule. The rate of water loss may be independent of or dependent on the nature of the potential ligand of the ion pair. In the latter case the reaction could approach in character that often designated by S_N2. Ion pair formation should be a labile process and an equilibrium concentration of ion pairs relative to reactant species may be expected. On this basis the concentration of ion pairs between iron(III) and bioxalate would be $K_{10}[Fe^{+++}][HC_2O_4^-]$ where K_{10} is an equilibrium quotient whose magnitude may be roughly estimated by the method of Hammes and Steinfeld (12, 13). For ions of opposite charge and valences three and one the value of the association quotient is about 14 $mole^{-1}$ l if the separation of centers is assumed to be 5 Å. The values for ion pairs between iron(III) and various singly charged anions may be expected to vary somewhat but not markedly and the value 14 may be considered to represent the order of magnitude of association quotients.

The rate constant k_1 for complex formation should on this picture be $K_{10}k_1^*$ where k_1^* is a first order rate constant. Also, if our value for $k_1(+ k_3)$ is indeed that for formation of the monodentate intermediate, $k_1(+ k_3)/K_{10}$ will represent the effective first order rate constant for transformation of the ion pairs into the intermediate and at 25 °C will be of the order of 1 440 $mole^{-1}$ l s^{-1}/14 $mole^{-1}$ l $\approx$ 100 s^{-1}. The rate constants at 25 °C for the anation reactions of iron(III) in aqueous solution are listed in Table III along with values for the reciprocal of the ionization constants (K_a) for the acids conjugate to the associating ligand. The ionic strengths to which the rate constants apply vary from 0.1 to 1.0 but the effect of such variation on the constants should be small. On the basis of the theory outlined above, the first order rate constants k_1^* for transformation of ion pair to complex should be roughly parallel to the rate constants listed for all singly charged ligands. The values listed for the ionization constants apply to zero ionic strengths but their reciprocals should give fair measure of the ability of the ligand in the ion pair to accept protons from water in the inner hydration sphere of the metal ion. It is apparent that there is a fairly marked increase in rate constant with increase in ligand basicity and that the value which we have determined for bioxalate is roughly in accord with there being a correlation between rate constant and ligand basicity for singly charged anions and monodentate complex formation.

Wendt and Strehlow (11) have suggested that the dependence of rate on ligand type is related to the ability of the potential ligand in an ion pair to accept a proton from one of the waters coordinated with the metal ion. In this picture such an inner hydrolysis leads to an increase in the rate of loss of one of the other water molecules coordinated with the metal ion. If it is assumed that the partially desolvated metal ion is the precursor to the complex, such an increase in the rate of water loss could lead to an increase in the first order rate constant for complex formation from the ion pair and in the second order rate constant with regard to the primary reactants.

Superficial assessment of the data of Table III suggests that they are in accord with such

*Obtained by extrapolation.

a view. However, we doubt the direct applicability of Wendt and Strehlow's hypothesis to the reactions of iron(III) mainly because the rate constant for water exchange from iron(III) is markedly in excess of the value of the rate constant for complex formation. The rate constant for the exchange of a water molecule from the first coordination sphere of hexahydrated iron(III) ion has been estimated by Connick and co-workers on the basis of nuclear magnetic resonance (n.m.r.) measurements to be in the range 2.4×10^4 to 1.1×10^6 s^{-1} (21, 22). The presence of a ligand in the ion pair could conceivably raise the value for water exchange of the hydrated metal ion through inner hydrolysis in the ion pair above this. We have implied that the first order rate constant for formation of the oxalate complex from the ion pair is approximately 100 s^{-1}, a value substantially less than that for water exchange. If it is assumed that the rate of water exchange measures the rate of formation of the pentahydrated iron(III) and that this is the precursor to complex formation it is apparent that very few of the partially desolvated ion pairs complete reaction to form the complex and that the reaction

$$(Fe(H_2O)_5^{+++} \ldots HC_2O_4^-)_{\text{ion pair}} \rightleftharpoons (Fe(H_2O)_5^{+++} \ldots HC_2O_4^-)_{\text{ion pair}}$$

is essentially in equilibrium. If the equilibrium constant for this reaction is represented by K^1 and the rate constant for transformation of the partially desolvated ion pair into mono-complex (presumably with proton transfer from the bioxalate ion to the water of the solvent) by k^1 then

$$k^* = K^1k^1$$
$$\text{or } k_1 = K_{10}K^1k^1$$

The associating ligand will then be influential via its effect on K^1 and k^1. Presumably there will be partial proton transfer from water coordinated with the metal to the associating ligand in both types of ion pairs and although such inner hydrolysis may well affect the lability of loss and gain of water it is difficult to see how there could be much influence on the equilibrium constant K^1. On the other hand the rate constant k^1 for the relatively slow nucleophilic attack by the ligand would doubtlessly be dependent on the nucleophilicity of the ligand. We suggest that the influence of ligand is through its nuc'eophilicity towards the metal ion rather than its basicity with regards to proton acceptance, and that the apparent parallelism of rate constant on the basicity is a reflection of the parallelism between basicity and nucleophilicity.

The behavior of iron(III) and nickel(II) in anation reactions seems to be in marked contrast. For nickel the rate of reaction is close to the rate of water loss and in terms of the above picture this implies that the probability of nucleophilic attack by ligand within the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

partially desolvated ion pair is much greater than that for attack by water, whereas for iron(III) the converse applies. As the relative nucleophilicities of water and a given ligand (e.g. oxalate) should not be greatly different for the reactions involving nickel(II) and iron(III) perhaps the differences in behavior are to be explained in terms of availability of water for nucleophilic attack within the ion pairs.

RADIATION-INDUCED CHANGES IN THE UNSATURATION OF POLYISOPRENE[1]

MORTON A. GOLUB AND JEANNE DANON[2]
Stanford Research Institute, Menlo Park, California
Received March 12, 1965

ABSTRACT

Polyisoprene in the solid state and in benzene solution undergoes radiation-induced *cis–trans* isomerization and loss of unsaturation. Starting with various *cis* or *trans* polymers, the isomerization approaches an equilibrium in which the *cis/trans* ratio is around 50/50 for polyisoprenes irradiated in solution or in the solid state. The *G*(isom.) values for either *cis* → *trans* or *trans* → *cis* isomerization, i.e., the number of *cis* (or *trans*) units isomerized initially per 100 eV absorbed by *both* polymer and solvent, in 1% solution, and by polymer alone, in the solid state, are about 1.0 and 10, respectively. The energy transfer mechanism proposed previously for polybutadiene and squalene isomerization is assumed to hold for polyisoprene as well. The loss of unsaturation in films irradiated with electrons under nitrogen is twice as rapid as in films γ-irradiated *in vacuo*, the *G*(-d.b.) (d.b. = double bond) values being 13.4 and 6.7, respectively. Correspondingly, *G*(-d.b.) for a γ-irradiated solution is 27, calculated in terms of energy absorbed directly by the polymer; intermolecular energy transfer is again indicated, although phenylation may also contribute to the loss of double bonds in solution. The large drop in unsaturation in solution and in the solid state is attributed to a chain process involving cyclization and some cross-linking, with the participation of both free radicals and carbonium ions. Work with polyisoprene-3-*d* confirmed the importance of isomerization and loss of unsaturation and gave an activation energy of 1.1 kcal/mole for the latter reaction.

INTRODUCTION

Considerable theoretical as well as practical interest has been shown in recent years in the radiation chemistry of polyisoprene, and a number of fundamental papers (1–8) and reviews (9–13) have appeared dealing with various microstructural changes produced in this polymer and with possible mechanisms to account for these changes. The principal change noted for polyisoprene, apart from cross-linking and evolution of hydrogen, is a more or less important decrease in the original isoprenic unsaturation (—$C(CH_3)$=CH— double bonds). Most of the published data on this latter effect are based on changes in the infrared absorption bands of irradiated polyisoprenes at 12 μ (C—H out-of-plane deformation vibration of the —$C(CH_3)$=CH— unit) and (or) at 6 μ (C=C stretching vibration of this same unit), but some unsaturation data have also been obtained by various chemical means.

The question of the loss of unsaturation in irradiated polyisoprene has met with much controversy, some workers taking the position that the effect is small but real, and others contending that the effect is very large. According to Turner and co-workers (3), the infrared spectrum of a degassed sample of natural rubber, irradiated *in vacuo* to a dose of 326 Mrads, showed only small changes in the 12 and 6 μ bands, while squalene, a hexaisoprene which can serve as an intermediate molecular weight model for polyisoprene, showed (4) about a 10% drop in chemical unsaturation when irradiated to a dose of 242 Mrads. A comparable result was obtained by Hayden (6) who reported a 10% decrease in the 6 μ band for a rubber film irradiated *in vacuo* to 410 Mrads. On the other hand, Heinze *et al.* (7) have observed as much as 25% reduction in the 12 μ band for carefully purified, but not degassed, samples of natural rubber irradiated with electrons under nitrogen to

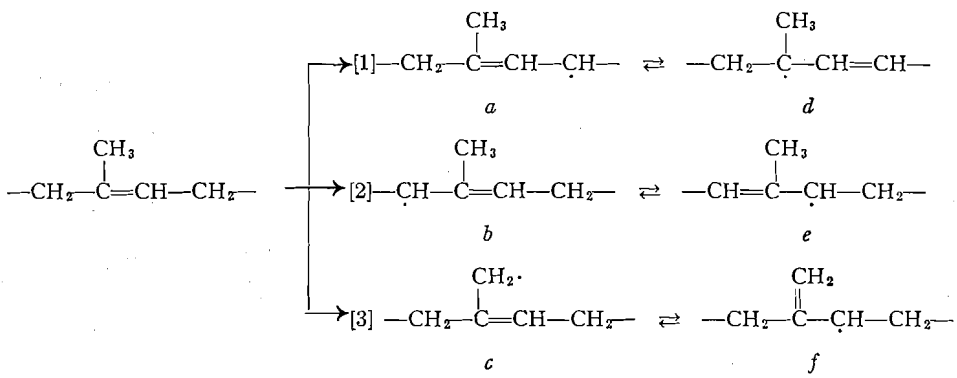
[1]*Presented at the IUPAC Meeting, Moscow, USSR, July 1965.*
[2]*NATO Fellow, 1962–1963, from Laboratoire de Chimie Physique, Faculté des Sciences, Orsay (S. et O.), France.*

250 Mrads; after a dose of 1 400 Mrads the unsaturation was reduced to below 20% of the original value. Moreover, Kuzminsky *et al.* (14) claimed a decrease in unsaturation, determined by chemical titration and infrared analysis, of 50% after about 220 Mrads, and as much as 70% after 500 Mrads for unpurified natural rubber exposed to X-rays in air.

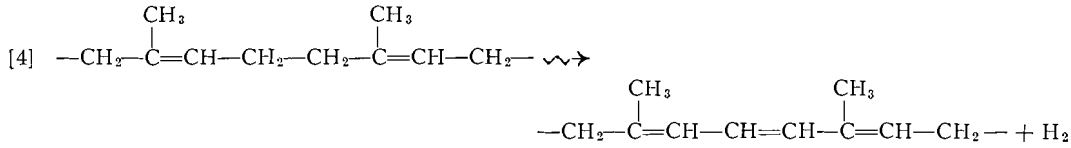
In sharp contrast to Heinze's rapid loss of unsaturation and even Turner's and Hayden's moderate reduction in unsaturation is the observation by Loughborough *et al.* (15) that a sulfur-based vulcanizate of natural rubber on irradiation in nitrogen showed a decrease of only about 2% after 100 Mrads and approximately 15% after about 1 000 Mrads.

However, it is not obvious how the different results obtained by these workers can be reconciled, and one of the aims of this research is to resolve the question of the actual consumption of double bonds in the irradiation of polyisoprene. In this connection, it is important to point out that a diminution of the 12 μ band (associated with the —C(CH_3)=CH— units, whether *cis* or *trans*) in the spectrum of *cis*-polyisoprene can represent not only a loss of the original double bonds but also some *cis* → *trans* isomerization, inasmuch as the absorption of the *trans* unit at 12 μ is approximately 70% of that of the corresponding *cis* unit (16). Since polybutadiene undergoes radiation-induced *cis–trans* isomerization in the solid state with a high $G(c \rightarrow t) \sim 8.0$ (17), and liquid squalene likewise undergoes this same type of reaction, although with a much lower yield ($G(t \rightarrow c) = 0.83$) (18), it is reasonable to expect polyisoprene to show this reaction too. Such a reaction had been suggested by Turner (3, 13), but there is no unambiguous evidence for it. Accordingly, a further aim of this study was to explore the possibility of a radiation-induced *cis–trans* isomerization of polyisoprene in the solid state. Moreover, since polybutadiene and squalene were found to isomerize with much greater yields in benzene than in the pure state, a related aim was to carry out complementary irradiations of polyisoprene solutions in order to seek an analogous benzene-sensitized isomerization of this polymer.

Apart from the observed decrease in original unsaturation, evidence was obtained for the radiation-induced formation of new double bonds in solid polyisoprene. Thus, a small increase in vinylidene units (>C=CH_2) was indicated (3) by a growth of the 11.3 μ infrared band coupled with the appearance of a shoulder near the 6 μ band. Also, the formation of *trans* —CH=CH— units was suggested by the development of a band at 10.4 μ, as noted by Hayden and as may be seen in the published spectra of Heinze *et al.* and of Turner and co-workers (3). Moreover the last-named workers, on the basis of ultraviolet spectroscopic analysis, concluded that a very small amount of conjugated diene groups and an even smaller amount of conjugated triene groups were also formed. The following processes were postulated to account for the new unsaturation.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



The diene groups were considered to arise through disproportionation reactions involving the mesomeric radicals *d*, *e*, and *f*, while the trienes were assumed to arise through disproportionation reactions involving the radicals *a* and *b* and to a negligible extent through reaction [4] (3). It should be noted that isoprenic double bonds formed according to reaction [2] cannot be distinguished from the original double bonds, except for possible *cis–trans* effects, so that this reaction can neither be proved nor disproved on the basis of ordinary polyisoprene. However, the use of a suitably deuterated polyisoprene, such as $(—CH_2—C(CH_3)=CD—CH_2—)_n$, should afford a direct test for this and other double bond shift reactions. Since, as demonstrated by Turner *et al.* and by Hayden, reactions [1] to [4] were not very important, it was not one of our main aims to study these reactions in detail, but rather to focus attention on the decrease in original unsaturation and the phenomenon of *cis–trans* isomerization both in the solid state and in solution. Nevertheless, the availability of the above deuterated polyisoprene prompted us to carry out some irradiation experiments with it and to examine briefly the various reactions mentioned above.

EXPERIMENTAL

Materials

Five different polyisoprenes were used in this work: naturally occurring all-*cis* (Hevea) and all-*trans* (Balata) polyisoprenes, obtained through the courtesy of the B. F. Goodrich Research Center, Brecksville, Ohio; two synthetic polyisoprenes with very high *cis*-1,4 structure but different 3,4 content (Ameripol SN, obtained from Goodrich-Gulf Chemicals, Inc., Cleveland, Ohio, and Shell isoprene rubber, obtained from Shell Chemical Company, Torrance, California); and a sample of *cis*-polyisoprene-3-*d*, specially prepared by the late Dr. David Craig and Mr. Harold Tucker of the Goodrich Research Center and kindly donated to us.

As analyzed by nuclear magnetic resonance (n.m.r.) methods (19, 20) and supported by infrared (see below), the microstructure of Ameripol SN consists of 97.3% *cis*-1,4, 2.0% *trans*-1,4, and 0.7% 3,4 units while that of the Shell rubber consists of 89.4% *cis*-1,4, 6.2% *trans*-1,4, and 4.4% 3,4 units. Since the 3,4 units are not involved in *cis–trans* isomerization, for purposes of following this reaction only the percentage of the total 1,4 polymerization units having the *cis* (or *trans*) configuration in the polymer before and after irradiation was significant. Accordingly, the initial *cis*-1,4 contents of Ameripol SN and Shell rubber were taken as 98 and 94% respectively, while those for Hevea and Balata were assumed (20) to be 100 and 0%, respectively. The detailed microstructure of the deuterated polyisoprene was not determined but its high *cis* —C(CH$_3$)=CD— content was confirmed by n.m.r. analysis.

Irradiations

For the solid state work, thin films were cast from dilute benzene solutions of the purified polymers onto rock salt plates and irradiated *in vacuo* to various doses at room temperature, using a 1 500 curie ^{60}Co γ-ray source. Some polyisoprene films were irradiated under a stream of cooled nitrogen, using 1 MeV electrons from a G.E. resonant transformer. Because of the heat generated in the course of the high intensity electron irradiation, the polymer films were kept close to room temperature during irradiation by placing them in contact with a surface cooled by a suitable coolant. In addition, some films of polyisoprene-3-*d* were irradiated with electrons at −15 and −50 °C as well as at room temperature. The various films were analyzed before and after irradiation by infrared spectroscopy.

For solution work, portions of the polyisoprene solutions, with and without antioxidant, were sealed in conventional n.m.r. tubes *in vacuo* or in air and then γ-irradiated. The isomerization and loss of unsaturation in the polymers were followed by analysis of the n.m.r. spectra obtained directly on the irradiated tubes. In several of the low dose runs, complementary infrared analysis was conducted on samples of polyisoprene recovered from the irradiated solutions; the results were in good accord with those obtained from n.m.r. Since the polyisoprene solutions became completely gelled invariably when irradiated *in vacuo*, and frequently even when irradiated in air, especially at high doses, it was not feasible to recover the polymers from those runs for purposes of infrared analysis; however, the gelation did not interfere with obtaining fully satisfactory n.m.r. spectra of highly irradiated solutions.

Infrared Analysis

As noted above, changes in the 12 μ band of polyisoprene can arise from either *cis–trans* isomerization or loss of original unsaturation, or both. Consequently, for a film irradiated to a dose D, the absorbance of the 12 μ band, relative to that of the 7.25 μ band (due to CH_3 groups) as an internal standard, designated $(R_{12})_D$, can be expressed by the relation

$$[5] \qquad (R_{12})_D = [R_{12}^{H} - (R_{12}^{H} - R_{12}^{B})(t_0 + x)](1 - y).$$

R_{12}^{H} and R_{12}^{B} are the corresponding relative absorbances of the 12 μ bands for pure *cis* (Hevea) and pure *trans* (Balata) polyisoprenes, respectively, t_0 is the initial *trans*-1,4 content in the polymer, x is the fraction of double bonds isomerized from *cis* → *trans* (or *trans* → *cis*, in which case x is negative, by definition), and y is the fraction of the original —C(CH_3)=CH— units destroyed. Dividing relation [5] by the corresponding expression for the relative absorbance of the 12 μ band in the unirradiated polyisoprene, we obtain the more convenient relation

$$[6] \qquad R_1 = (R_{12})_D/(R_{12})_0 = \frac{M - Nx}{M}(1 - y)$$

where R_1 can be measured directly, and the constants M and N are given by

$$[7] \qquad M = 1 - (1 - R_{12}^{B}/R_{12}^{H})t_0$$

$$[8] \qquad N = (1 - R_{12}^{B}/R_{12}^{H}).$$

Making the reasonable assumption that the extinction coefficient of the 7.25 μ band is the same in both Hevea and Balata, we further obtain[3]

$$R_{12}^{B}/R_{12}^{H} = \epsilon_{12}^{B}/\epsilon_{12}^{H} = 0.625$$

and hence the particular values for M and N given in Table I for various polyisoprenes studied. Thus by determining the extent of isomerization x, we can calculate directly from relation [6] the loss of unsaturation y.

TABLE I

Radiation-induced isomerization and decrease of unsaturation in various polyisoprenes in the solid state

To obtain x, the method of Cunneen *et al.* (22), developed for polyisoprene solutions, was adapted for polymer films. The Cunneen method is based on the fact that Hevea and Balata possess characteristic bands at 8.89 and 8.74 μ, respectively,[4] and that at 9.18 μ the absorption of both polymers is identical. Our method thus consists of deriving an expression for the *trans* content of isomerized polyisoprene as a function of the ratio of absorbances (relative to that of the 9.18 μ band as an internal standard) of the 8.89 and 8.74 μ bands. It may be seen that the method gives results which are independent of the loss of unsaturation. Expressions analogous to relation [5] can be written for these bands

$$[9] \qquad (R_{8.89})_D = [R_{8.89}{}^{H} - (R_{8.89}{}^{H} - R_{8.89}{}^{B})t](1 - y)$$

$$[10] \qquad (R_{8.74})_D = [R_{8.74}{}^{H} - (R_{8.74}{}^{H} - R_{8.74}{}^{B})t](1 - y)$$

where $R_{8.89}{}^{H}$ (or $_{8.74}$) and $R_{8.89}{}^{B}$ (or $_{8.74}$) are corresponding relative absorbances at the wavelengths indicated for Hevea and Balata, respectively, and $t = (t_0 + x)$ is the total *trans* content of the polymer. Dividing [9] by [10], and substituting for the empirical values of the various R^{H} and R^{B} terms, we obtain, finally

$$[11] \qquad t = \frac{2.53 - 1.05R_2}{R_2 + 2.16}$$

where $R_2 = (R_{8.89})_D/(R_{8.74})_D = A_{8.89}/A_{8.74}$, the A's being the measured absorbances at the given wavelengths. The validity of relation [11] was verified by measurements on the spectra of synthetic mixtures of these two polymers.

The infrared analysis employed here to follow *cis–trans* isomerization and loss of unsaturation thus consisted of determining x by means of relation [11] and then substituting its value in relation [6], from which y was obtained. The spectra of irradiated polyisoprene films as well as films cast from irradiated solutions were obtained from 2 to 15 μ with a Perkin–Elmer Model 221 infrared spectrophotometer.

Nuclear Magnetic Resonance Analysis

The n.m.r. spectra of irradiated polyisoprene solutions ($\sim$ 1% concentration in benzene) were obtained at room temperature with a Varian HR-60 spectrometer operated at both normal and slow magnetic field sweep rates; the procedure was essentially the same as that described for squalene solutions (18). The assignment of the significant peaks in the spectra of irradiated polyisoprene solutions (which contained no internal standard) was based on examination of the spectra of unirradiated solutions containing tetramethylsilane. The slow sweep spectra ($\sim$ 0.5 c.p.s./s) were employed to give the best possible resolution of the *cis* and *trans* methyl proton resonance peaks at 8.21 and 8.32 τ, according to the technique of Chen (19), while the normal magnetic sweep spectra ($\sim$ 2 c.p.s./s) were used to determine the olefinic proton content (—CH=$\dot{C}$—, at 4.90 τ). The combination of slow and normal sweep spectra, and planimetric integration of the appropriate peaks, thus provided data for estimating the extent of isomerization and loss of original double bonds in irradiated polyisoprene solutions.

RESULTS AND DISCUSSION

Solid State Irradiations

The infrared spectra of the various *cis*-polyisoprenes after γ-irradiation *in vacuo* to doses of 400-500 Mrads were similar to that published by Turner *et al.* (3), while those obtained for films irradiated to comparable doses with electrons in a nitrogen atmosphere were similar to those published by Heinze *et al.* (7). Hence, there was no need to present them here.

Typical data, based on infrared analysis, for the radiation-induced *cis–trans* isomerization and decrease of original unsaturation in the *cis*-polyisoprenes in the solid state are presented in Table I. These and other data were used to construct the kinetic plots shown in Figs. 1 and 2 from which G-values for these two important processes were obtained (see Table II). Because films of Balata (*trans*-polyisoprene) tend to undergo rapid post-irradiation oxidation, especially when heated for the purpose of obtaining spectra characteristics of the amorphous polymer, very little solid state work was done with this material.

The shapes of the kinetic plots presented in Fig. 1 for the radiation-induced isomerization of polyisoprene in the solid state conform to the known first order reversible character of such a process (17). Although these particular irradiations have not been carried to the

[4]*The 8.89 and 8.74 μ bands, as suggested by Sutherland and Jones (23) and recently demonstrated by Binder (24), are associated with the methyl vibration of the cis and trans* —C(CH_3)=CH— *units, respectively.*

point of equilibrium, in view of some measurements on γ-irradiated Balata films which reveal definite *trans* → *cis* isomerization, there is no doubt that an equilibrium does exist. Moreover, the radio-stationary *cis*/*trans* ratio for the solid state irradiations appears to be nearly the same as that obtained (~ 50/50) in the solution irradiations of *cis*- and *trans*-polyisoprenes (see Fig. 6). In this connection, it should be noted that the equilibrium *cis* content of the internal double bonds of squalene when isomerized in benzene is around 45–50% (as with Balata in solution), but the corresponding equilibrium in pure squalene was not determined (18). It is also noteworthy that the isomerization of natural rubber and Balata catalyzed by sulfur dioxide at 140 °C (22) leads to a similar equilibrium *cis* content (~ 55%).

TABLE II

G-values for changes in unsaturation of various irradiated polyisoprenes

Polymer	Irradiation temp., °C	*G*(-d.b.)	G_p(isom.)	G_s(isom.)
	γ-Irradiations			
Shell polyisoprene	25–30	6.7	9.0	1.0
Ameripol SN	25–30		10.9	
Hevea	25–30		14.1	0.5
Balata	25–30		10	1.1
	Electron irradiations			
Shell polyisoprene	25–30	13.4	14.4	
Polyisoprene-3-*d*	15	15.0		
	−15	10.7		
	−50	8.6		

Because of the nonlinearity of the isomerization plots in Fig. 1, the G_p(isom.) values given in Table II correspond to the number of *cis* or *trans* double bonds *initially* isomerized per 100 eV absorbed by the *pure* polymer. The value indicated for γ-irradiated Balata is only an estimate based on limited data. Partially reflecting the different initial *cis* contents of Hevea, Ameripol SN, and Shell polyisoprene, the G_p(isom.) values for the γ-irradiation of these polymers fall in the decreasing order, 14.1, 10.9, and 9.0, respectively. A somewhat higher G_p(isom.) of 14.4 is noted for the electron-irradiated Shell polymer. Undoubtedly the microstructural differences between these high *cis*-polyisoprenes involving, for example, 0, 0.7, and 4.4% 3,4 units, respectively, and their likely participation in competing intramolecular energy transfer processes, must be responsible for the larger spread in *G*-values than is expected solely on the basis of different initial *cis* contents in these polymers. Considering G_p(isom.) ~ 10 as representative for the solid state γ-ray-induced isomerization of either *cis*- or *trans*-polyisoprene, we note that it is of the same order of magnitude as that for the corresponding reaction in *cis*- and *trans*-polybutadienes (8.0 and 4.0 respectively) (17, 25). Thus the mechanism advanced to explain the isomerization in the latter polymers—involving direct as well as indirect excitation of the double bonds to a state where free rotation and hence geometric interconversion can take place—probably holds for the polyisoprenes as well. The comparative isomerizability of various small, medium, and high molecular weight olefinic compounds has been discussed recently (25) and treated more fully in our previous paper (18), so that there is no need to expand further on this topic here.

It can be seen from the straight line plots of Fig. 2 that polyisoprene undergoes also an important radiation-induced consumption of the original double bonds. This reaction proceeds twice as fast in the films irradiated with electrons under nitrogen as in those

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

irradiated with γ-rays *in vacuo*, the G(-d.b.) values being 13.4 and 6.7[5] respectively. From the G(-d.b.) values given in Table II for polyisoprene-3-*d* irradiated with electrons at several temperatures (based on the plots in Fig. 4), an activation energy of 1.1 kcal/mole was calculated for the loss of double bonds in that polymer. This value, which probably holds for ordinary polyisoprene too, compares very well with the activation energy of 0.53 kcal/mole reported previously for the same process in the model compound squalene (18). This additional result further emphasizes the similarities in the radiation chemistry of the various isoprenic compounds.

Apart from the decrease in relative intensities of the 12 and 6 μ bands (associated with consumption of the —C(CH_3)=CH— units), which was more pronounced in the case of electron irradiations than in the case of γ-irradiations, the infrared spectra of irradiated polyisoprenes also revealed subtle changes in both the 8.5–9.5 μ and 7.5–7.7 μ regions which were related to the *cis–trans* isomerization.

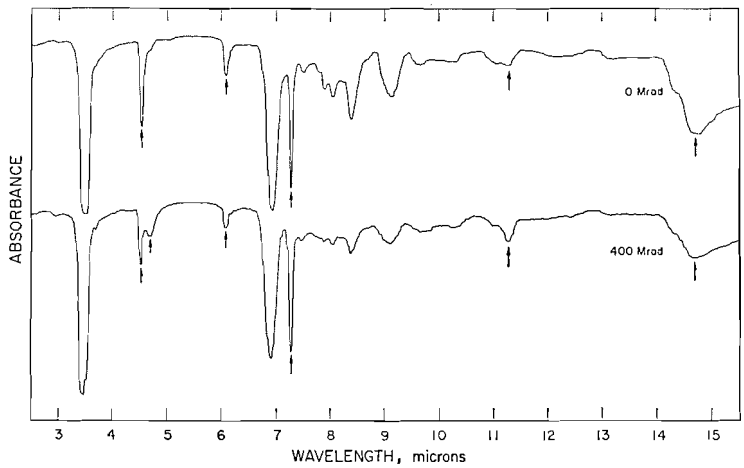

FIG. 3. Infrared spectra of *cis*-polyisoprene-3-*d* before and after irradiation with electrons.

Confirmation of the important loss of original unsaturation and occurrence of *cis–trans* isomerization in irradiated polyisoprene films is afforded by an examination of the infrared spectra of *cis*-polyisoprene-3-*d* before and after irradiation (Fig. 3). Thus the decrease in the 4.5 μ band (C—D stretching vibration for an olefinic carbon atom) and the growth of a band at 4.65 μ (C—D stretching vibration associated with a saturated carbon atom) provide unambiguous evidence for the transformation of the original —C(CH_3)=CD— units in the monodeuterio polyisoprene into the saturated structures $\rangle$C(CH_3)—CDH— and (or) $\rangle$C(CH_3)—CD$\langle$. Accompanying these spectral changes is a marked decrease in relative intensity of the 14.7 μ band (C—D out-of-plane deformation of the *cis* and *trans* —C(CH_3)=CD— units), analogous to the situation with the 12 μ band in ordinary polyisoprene. As shown in Fig. 4, the intensity of the 14.7 μ band diminishes faster than that of the 4.5 μ band, the intensities of both bands having been expressed relative to that of the 7.25 μ band as an internal standard. If, now, the ratio of absorption coefficients for the

[5]*Due to additional data acquired since the previous paper (18) was submitted, as well as to a re-examination of the earlier results, it was necessary to revise the G(-d.b.) for polyisoprene announced in that paper from 5.3 to the new value of 6.7. This change does not affect the earlier arguments, however.*

For personal use only.

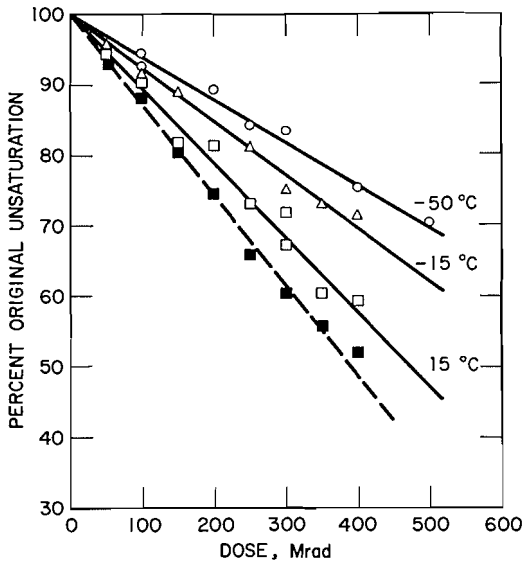

FIG. 4. Decrease of original unsaturation in *cis*-polyisoprene-3-*d* (based on changes in the 4.5 μ band) on irradiation of films with electrons under nitrogen at different temperatures. The dashed line (with closed squares) represents the decrease in relative intensity of the 14.7 μ band for the films irradiated at 15 °C.

cis and *trans* —C(CH$_3$)=CD— units is assumed to be comparable to that for the corresponding —C(CH$_3$)=CH— units, as is quite reasonable, it follows from Fig. 4 that *cis–trans* isomerization definitely occurs in polyisoprene-3-*d*. In fact, it may be calculated[3] that a film of this polymer irradiated to a dose of 400 Mrads with electrons at 15 °C has a *cis* content of 57% (of the remaining 58% original double bonds), which agrees rather well with the 63% *cis* content noted in Fig. 1 for the Shell polyisoprene which was similarly irradiated. This result clearly substantiates the infrared method used to assess the *cis–trans* isomerization and loss of unsaturation in the ordinary polyisoprenes.

The rates at which the double bonds are consumed in both ordinary and monodeuterio polyisoprenes when irradiated with electrons under nitrogen at around 15–25 °C (compare appropriate plots of Figs. 2 and 4) are not only approximately equal to each other but are also comparable to that observed by Heinze *et al.* (7) for electron-irradiated Hevea films. Thus, for example, after a dose of about 400 Mrads the unsaturation decreased by about 38% in Shell polyisoprene and by about 42% in polyisoprene-3-*d*, whereas the corresponding decrease in the Hevea studied by Heinze *et al.* can be estimated (from their Fig. 11) as around 30–35%.[6] The γ-irradiated polyisoprenes, on the other hand, showed a decrease in unsaturation of only about 9–10% after a dose of 200 Mrads. This rate of consumption of original double bonds, although somewhat higher than that reported by Hayden (6) for polyisoprene ($\sim$ 10% after 410 Mrads, based on the 6 μ band), is of the same order of magnitude as that in squalene observed by Turner (4) ($\sim$ 10% at 242 Mrads) and by ourselves (18) (7% at 200 Mrads, corresponding to a G(-d.b.) of 4.6).

On the basis of the detailed discussion presented in the previous paper (18), we are led to consider that cyclization and cross-linking involving some double bonds are responsible

[6]*For a more exact comparison of these two studies, it should be noted that the Hevea sample of Heinze et al., which was exposed to electrons for a dose of 400 Mrads, showed a diminution of about 40% in the intensity of the 12 μ band compared to a diminution of 46% in our simliarly irradiated Shell polyisoprene (see Table I).*

for the radiation-induced loss of unsaturation in polyisoprene, just as in squalene.[7] Both free radical and ionic mechanisms were invoked for these two processes. Such an interpretation, however, does not account for the surprising fact that the loss of double bonds occurs more rapidly with electrons than with γ-rays. It might be thought, of course, that the films irradiated under nitrogen, which were not outgassed in contrast to the films irradiated *in vacuo*, encountered sufficient residual oxygen to undergo an additional loss of double bonds through some radiation-induced oxidation. Certainly the drastic drop in unsaturation observed by Kuzminsky *et al.* (14) for polyisoprene irradiated in air can be explained in this way. But this argument probably does not apply to our electron-irradiated films since there was no infrared evidence to suggest that they were at all oxidized.

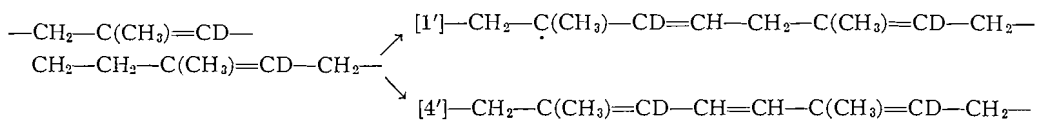
Whatever the particular mechanism(s) may be, the very high G(-d.b.) values of 7–13 obtained in the present work, combined with the very low activation energy for the loss of double bonds, are compatible with a carbonium ion chain mechanism for this process occurring in polyisoprene. On the other hand, a free radical chain mechanism is consistent with the fact, noted above, that sulfur, which apparently can act as a free radical scavenger (12, 13), lowers considerably the rate of disappearance of double bonds in a natural rubber vulcanizate exposed to γ-rays (15). At the present time, we cannot say for certain which of the two mechanisms is the dominant one, and future work involving other additives which act either as radical acceptors or electron sinks should help settle this point. But the evidence so far obtained prompts the view that the loss of double bonds consists of chain cyclization and cross-linking involving the participation of both free radicals and carbonium ions.

To conclude the discussion of the solid state work, we may comment on some other aspects of the spectra of irradiated polyisoprene and polyisoprene-3-*d*. In common with the spectra published by Turner *et al.* and by Heinze *et al.*, and as also reported by Hayden (6), our spectra for undeuterated polyisoprenes showed the development of a very small blip at 10.4 μ and in the case of Hevea and Ameripol SN, a slight increase in the 11.3 μ band indicative of new vinylidene unsaturation. With Shell polyisoprene, on the other hand, the latter band actually showed a small decrease in intensity. The changes in the 11.3 μ band thus observed for the various irradiated polyisoprenes are reminiscent of the growth or decay of this same band encountered incidentally in the course of the $TiCl_4$-catalyzed cyclization of these polymers (Fig. 8, ref. 21), and presumably has the same type of explanation: formation of vinylidene units through a process such as reaction [3] which is in equilibrium with the radiation-induced consumption of such double bonds.

Although the appearance of the 10.4 μ band in the spectra of irradiated polyisoprenes has been attributed by other workers (3, 6, 7) to the production of *trans* —CH=CH— units, it is more likely that this band is due to the presence of cyclic structures in the polymer backbone. Such an interpretation was invoked for the 10.4 μ band in the spectra of cyclized polyisoprenes, and it is significant that the relative intensity of this band in these polymers (see Figs. 1 and 2, ref. 21) is quite comparable to that of an extensively electron-irradiated polyisoprene (see Fig. 9, ref. 7, for example). Since both the CH_2 deformation vibrations of cyclohexyl rings and *trans* —CH=CH— units absorb fortuitously at around 10.3 μ, we require additional evidence to decide which of these structures is responsible for the observed absorption. If the —CH=CH— units were actually formed in polyisoprene, say, through reaction [1] or reaction [4], analogous reactions [1′] and (or) [4′] should take

[7]*The zero order consumption of double bonds observed in these two isoprenic compounds is difficult to explain on mechanistic grounds, unless the energy absorption is the only limiting factor here.*

place in polyisoprene-3-*d* to yield —CD=CH— units, which absorb at 11.2 μ (26), and new —CH=CH— units, respectively:



As may be seen from Fig. 3, there is no development of absorption at 10.3 μ to suggest that reaction [4′] occurs to any significant extent. On the other hand, although the figure does show an increase in absorption at 11.3 μ, in view of a similar increase at this wavelength in the spectra of irradiated Hevea and Ameripol SN (but not in Shell polyisoprene, which actually shows a decrease), this growth at 11.3 μ might simply be due to the formation of $\rangle C{=}CH_2$ units in monodeuterio polyisoprene (reaction [3′]) just as with ordinary polyisoprene, and not at all to —CD=CH— units through reaction [1′]. In addition, Fig. 3 shows no development of a band at 12 μ to support the occurrence of the "deuterio" analog of the other double bond shift reaction (2).[8] These observations with respect to reactions [1], [2], and [4] thus agree qualitatively with the findings of Turner *et al.* (3) based on ultraviolet spectra of irradiated Hevea, that diene and triene structures are formed in very low yields, the *G*-values being around 0.09 and 0.02, respectively.

Solution Irradiations

As in the solid state, polyisoprene in dilute benzene solution undergoes pronounced radiation-induced *cis–trans* isomerization and loss of original unsaturation. Unambiguous evidence for the former reaction is clearly indicated in Fig. 5 which shows representative

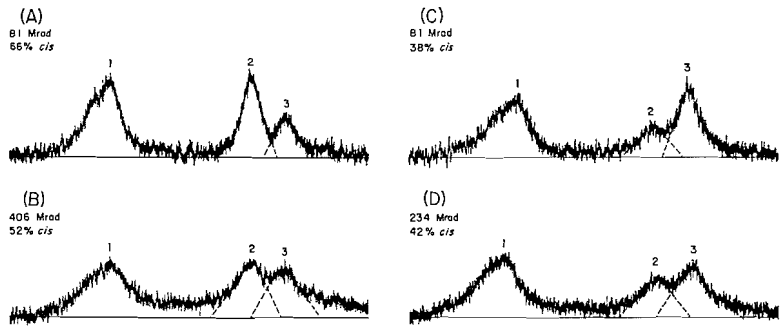


FIG. 5. Nuclear magnetic resonance spectra obtained at slow magnetic field sweep rate of Shell polyisoprene (A, B) and Balata (C, D) in benzene solution after γ-irradiation to various doses. Peak 1, $—CH_2—\dot{C}=$; peak 2, *cis* $—C(CH_3)=$; peak 3, *trans* $—C(CH_3)=$.

slow sweep n.m.r. spectra of solutions of both *cis*- and *trans*-polyisoprenes exposed to various γ-ray doses. Thus, the *cis* methyl proton resonance peak becomes progressively smaller and the *trans* peak progressively larger as the *cis* polymer (Shell polyisoprene) is irradiated to higher doses, while the reverse is the case with the *trans* polymer (Balata). Eventually, an equilibrium is attained in which the *cis/trans* ratio is about 50/50 (Fig. 6). To appreciate the important changes in these slow sweep spectra, it should be noted that peak 2 is completely absent in the spectrum of unirradiated Balata, whereas peak 3 is

[8]*It is worth noting also that the absence of a 12μ band in the spectrum of irradiated polyisoprene-3-d demonstrates that no discernible radiation-induced isotopic substitution occurs in this polymer.*

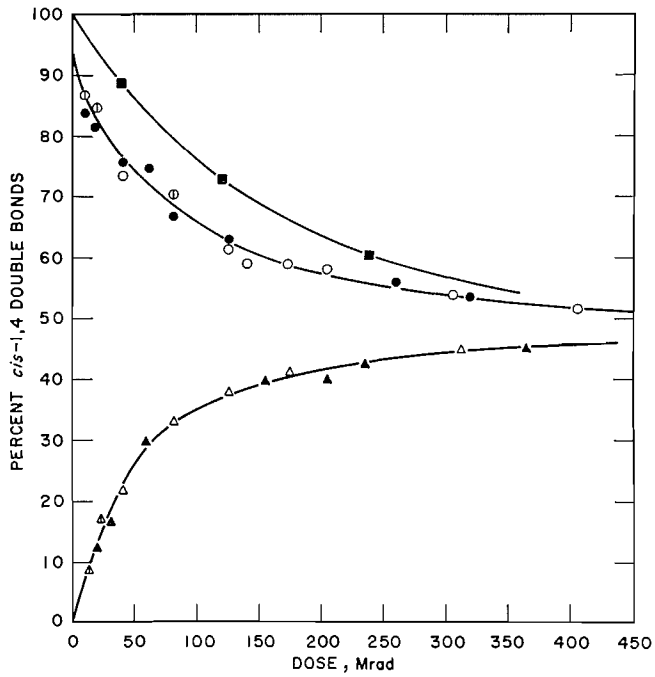

FIG. 6. Radiation-induced *cis–trans* isomerization of various polyisoprenes in benzene. Samples γ-irradiated *in vacuo*: Hevea with natural antioxidants (a.o.) (■); Shell polyiosprene with (●) and without (○) a.o.; Balata with (▲) and without (△) a.o. Samples γ-irradiated in air, with a.o.: Shell polyisoprene, ⊕; Balata, ⧋.

barely present in the spectrum of unirradiated Shell polyisoprene (corresponding to a *trans* content of about 6% of the 1,4 units).

The signal-to-noise ratio of these spectra is poor, owing to the high dilution of the polymer solution (~ 1% polyisoprene in benzene), but this offered no real difficulty in determining the *cis/trans* ratio in the irradiated polymers. In fact, in some related experiments carried out at the higher polymer concentrations, the signal-to-noise ratio improved to the point where the slow sweep spectra of polyisoprene were as well defined as the corresponding squalene spectra shown in the previous paper (18); except for yielding somewhat different kinetic data for the *cis* → *trans* and *trans* → *cis* isomerization, the spectra for the more concentrated solutions presented the same separation of *cis* and *trans* methyl peaks and the same equilibrium *cis/trans* ratio. We chose to concentrate on the 1% polyisoprene solutions in this study so as to have isomerization data which could be compared directly with corresponding data reported for polybutadiene (in 1% benzene solution) (17).

A more serious problem than the signal-to-noise situation in the spectra typified by Fig. 5 is the fact that the loss of unsaturation in polyisoprene, as in irradiated squalene, involving processes such as

$$-CH_2-C(CH_3)=CH-CH_2- \rightarrow -CH_2-\underset{|}{C}(CH_3)-\underset{|}{CH}-CH_2-$$

gives rise to "saturated" methylene groups which appear at higher field than the corresponding "unsaturated" methylene groups. The protons of the former groups, along with new tertiary protons, show up fortuitously in the *cis* and *trans* methyl proton region. This perturbation of the n.m.r. spectrum in the range of interest becomes more serious as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the dose and hence the loss of unsaturation increases, so that the determination of the *cis/trans* ratio in the highly irradiated solutions can be regarded as somewhat uncertain.

In Fig. 6 are plotted kinetically the isomerization data obtained from n.m.r. spectra for various polyisoprenes irradiated in benzene solution under different conditions. As may be seen, the presence or absence of oxygen or antioxidant has no perceptible effect on the rate of isomerization of Shell polyisoprene or of Balata. These two polymers isomerize in solution at roughly comparable rates and approach, at high doses, a common equilibrium structure with a *cis/trans* ratio of $\sim 50/50$. Surprisingly, Hevea in solution with antioxidant isomerizes at a lower rate than does Shell polyisoprene, which is just the reverse of the situation in the solid state case where the polymers are free of antioxidant. Evidently the natural antioxidants left in Hevea in the solution case exert some inhibiting effect on the isomerization reaction, which nevertheless approaches the same equilibrium as with the Shell polyisoprene or Balata.

From the initial slopes of the curved plots of Fig. 6, the G_s(isom.) values given in Table II were obtained. These values represent the number of *cis* or *trans* double bonds isomerized initially per 100 eV absorbed by both polymer and solvent. Taking a G_s(isom.) of ~ 1.0 as typical for *cis*- and *trans*-polyisoprenes in 1% solution in benzene, we see that, if no energy transfer occurred between solvent and polymer molecules, the effective isomerization yield would be ~ 100 double bonds per 100 eV absorbed by the polymer alone. Since, as we have seen, the pure polyisoprene isomerizes with a yield of about 10 double bonds per 100 eV, it follows that the polymer must receive some nine times as much energy from the solvent as it does directly. This efficiency of intermolecular energy transfer is practically the same as that encountered with polybutadiene (17). Since the topic of intermolecular energy transfer in benzene solutions of various *cis* and *trans* olefinic compounds has been discussed in detail in the previous paper (18) and elsewhere (25, 27), we shall not pursue the matter here. Suffice to say, we have shown definitely that *cis*- and *trans*-polyisoprenes, in common with polybutadiene, squalene, and butene-2, undergo radiation-induced *cis–trans* isomerization both in the pure (solid) state and in benzene solution. In the latter case, it has been assumed that much of the energy transfer from solvent to solute proceeds from the benzene triplet (3.6 eV) to the low-lying triplet state of the polymer double bond (3.2 eV).

Turning now to the radiation-induced loss of original unsaturation in polyisoprene in benzene, we note that this reaction was studied by following the sharp decrease in relative area of the olefinic proton peak in the normal sweep n.m.r. spectra with dose; since these spectra were substantially the same as the corresponding ones for irradiated squalenes (18), there was no need to present them here. From the straight line kinetic plots obtained for the loss of unsaturation, the G-value for this process was found to be 0.27 double bonds consumed per 100 eV of energy absorbed by the whole solution. This corresponds to a hypothetical yield of 27 double bonds per 100 eV absorbed by the polymer alone, as though there were no energy transfer between excited benzene and polyisoprene molecules. Since this yield is some four times that in the pure polymer (G(-d.b.) = 6.7), we again see the participation of intermolecular energy transfer, although some of the enhanced loss of double bonds in the solution case compared to that in the solid state may be due to phenylation of polyisoprene, just as in squalene (18). Interestingly, the latter compound, in a 10% solution in benzene, showed a loss of unsaturation (hypothetical yield of 9.8 double bonds consumed per 100 eV absorbed by solute alone) which is comparable to that of polyisoprene, taking into account the fact that the solutions of these two compounds were irradiated at different concentrations.

STRUCTURES OF MERCURY MERCAPTIDES

PART II. X-RAY STRUCTURAL ANALYSIS OF MERCURY ETHYLMERCAPTIDE

D. C. BRADLEY[1] AND N. R. KUNCHUR[2]

Department of Chemistry, University of Western Ontario, London, Ontario

Received November 16, 1964

ABSTRACT

The unit cell parameters for $Hg(SC_2H_5)_2$ were determined by X-ray diffraction: $a = 7.54 \pm 0.02$; $b = 4.87 \pm 0.01$; $c = 23.80 \pm 0.04$ Å; $\beta = 85°$. The unit cell contains four formula units, and a complete structural analysis revealed a molecular lattice with insignificant intermolecular bonding involving mercury and sulfur. Interatomic distances (excluding C—H) were determined.

INTRODUCTION

This work forms a part of the programme of studying the coordination compounds of mercaptans with mercury. Recent work (1) showed that mercury methylmercaptide had an unusual structure and it seemed worthwhile to investigate the structure of mercury ethylmercaptide. The crystal structure $Hg(S \cdot C_2H_5)_2$ was partially solved by Wells (2) but his results were qualitative. The work described in the present paper was carried out to locate all atoms (except hydrogens) in order to establish the stereochemistry of mercury in this compound and to obtain reliable values for the dimensions of the molecule.

EXPERIMENTAL

Mercury ethylmercaptide $Hg(S \cdot C_2H_5)_2$ was prepared by Wertheim's method (3) and purified by crystallization from ethanol. It forms thin plates on (001) outlined by (110) faces. With Cu K_α radiation ($\lambda = 1.542$ Å) the compound had a high absorption coefficient of 421 cm^{-1}. Unfortunately the thinness and fragility of the crystals prevented them from being ground into spheres or cylinders to facilitate the absorption correction. The thin plates were cut into needles with square cross-section of 0.1 mm. Absorption corrections were applied assuming that the needles were cylinders of diameter 0.1 mm.

The cell parameters were $a = 7.54 \pm 0.02$ Å; $b = 4.87 \pm 0.01$ Å; $c = 23.80 \pm 0.04$ Å; $\beta = 85°$; $Z = 4$; $d_{calcd} = 2.45$ g cm^{-1}; $d_{obs} = 2.47$ g cm^{-1}; space group = Cc.

The intensity data on $h0l$ and $0kl$ reflections were collected using the multifilm technique and a range of exposure times on a Stoe Weissenberg camera. Intensities were estimated visually and corrected for Lorentz and polarization factors. The relative F_0 values were scaled by Wilson's method, and in the final stages the scaling was improved by comparison with the calculated structure amplitudes.

Structure Determination

Although the systematic absences correspond to the space groups Cc and $C2/c$, the latter space group was discarded on the basis of the intensities of the reflections hkl with l odd. The space group Cc has no special positions and so all atoms have to be placed in general positions. $h0l$ and $0kl$, being the best resolved projections, were considered for structure determination. Patterson syntheses computed for these projections gave the following coordinates for the mercury atom.

	x/a	y/b	z/c
Hg	0.000	0.218	0.000

The contribution of mercury to the structure amplitude is such that it has only a real component for hkl with l even and only an imaginary component for hkl with l odd. A mercury-phased Fourier has, therefore, a higher symmetry than the real symmetry with the result that for every peak in a $h0l$ Fourier map, another peak related to the first by a center of symmetry (which is at origin where mercury is placed) would be produced. So if the distribution of two sulfur atoms and four carbon atoms around mercury is acentric, four peaks for two sulfur atoms and eight peaks for four carbon atoms would be produced. Since the stereochemistry of the mercury mercaptide molecule was not known, the problem of locating the light sulfur and carbon atoms was solved by the following procedure.

The values for atomic scattering factors for all atoms were taken from ref. 4. A mean isotropic temperature factor $B = 2.8$ Å^2 was applied to the scattering curves of all atoms. F_{obs} were brought on the absolute scale by Wilson's method.

Both the $h0l$ and $0kl$ Patterson projections showed clearly peaks corresponding to mercury–sulfur interactions. Since the coordinates of mercury were known, the coordinates of sulfur were derived. Structure factors were calculated for mercury and one sulfur atom only. For the reflections hkl with l even, both mercury and sulfur contributed to the real part of the structure amplitude and only sulfur contributed to the imaginary part. Contribution of mercury was subtracted from the real part while the imaginary part was not changed since it did not have any contribution from mercury. Phase angles were calculated using the modified real component and the unmodified imaginary component. These phase angles were used for computing a mercury difference Fourier. The coefficients used in this Fourier were obtained by subtracting the contribution of mercury from the F_{obs} which were brought on an absolute scale. A similar procedure was carried out for reflection hkl with l odd. Only sulfur contributed to the real part and both sulfur and mercury contributed to the imaginary part of these reflections. The $h0l$ and $0kl$ mercury difference Fourier done in this manner revealed the positions of all sulfur and carbon atoms. New phase angles were calculated considering all light atoms in the structure factor calculations, and a second cycle of mercury difference Fourier syntheses was carried out. A third cycle was repeated so that the atomic coordinates of all atoms were further refined. The 'y' coordinate of mercury was also refined during these successive Fourier syntheses. The final agreement index for various groups of reflections is shown in Table I. The final mercury difference Fourier projections upon (010) and (001) are shown in Figs. 1 and 3.

The final coordinates are listed in Table II while the observed and calculated structure factors including the phase angles are listed in Table IV. The lowest value of F_0 which could be observed was 8, and hence unobserved reflections are indicated as < 8. The agreement index stated in Table I takes into account observed reflections as well as observed and unobserved reflections.

TABLE I

Type of reflections	No. of observed reflections	No. of observed and unobserved reflections	Agreement index for observed reflections only	Agreement index for observed and unobserved reflections

Diffraction Effects and the Accuracy of Coordinates

The diffraction effects due to the presence of heavy mercury atom were eliminated by doing mercury difference Fourier syntheses. A rough estimate regarding the accuracy of the coordinates was obtained by comparing the common 'Z' coordinates of the atoms in the two projections. The deviations in the coordinates of mercury and sulfur are found to be 0.01 Å and 0.05 Å respectively. All carbon atoms excepting carbon C_4 correspond to reasonable bond lengths and bond angles within the molecule. The bond length C_3—C_4 of 1.84 Å is much longer than one would expect. On the whole one can state that all carbon atoms have been located and thus the stereochemistry of the mercury mercaptide molecule was defined.

RESULTS AND DISCUSSION

The various bond lengths and bond angles obtained from the final coordinates are shown in Table III. The arrangement of the molecules in the (*h*0*l*) and (0*kl*) projections can be seen in Figs. 2 and 4 respectively. In the crystal structure a simple molecule C_2H_5S—Hg—SC_2H_5 contains two Hg—S bonds which are linear within the experimental errors, the Hg—S distance being 2.45 Å for both these bonds. There are four more sulfur atoms arranged at a distance of 3.54 Å from each mercury arranged in a square planar configuration. The short Hg—S bonds are perpendicular to this plane so that a mercury atom is surrounded by six sulfur atoms in a distorted octahedral arrangement. The low melting point of this compound (76 °C) suggests that the sulfur atoms at 3.53 Å and 3.56 Å from mercury do not give rise to strong intermolecular bonds. A comparison of this compound with mercury methylmercaptide (1) shows that the next longer Hg—S bond lengths of 3.25 Å in the latter are slightly shorter than in the former. The higher melting point of $Hg(SCH_3)_2$ (175°) suggests that the secondary interactions are of greater significance in this compound. Also the larger size of the ethylmercaptide group leads to a looser packing of the mercury ethylmercaptide molecules and hence the crystal structure is essentially molecular in type. It is noteworthy that the estimated sum of the Van der

Waal's radii of mercury sulfur of 3.35 Å is greater than the secondary Hg . . . S bond lengths in $Hg(SCH_3)_2$ but less than those in $Hg(SC_2H_5)_2$.

ACKNOWLEDGMENTS

We are indebted to the U.S. Office of Naval Research for supporting this research. We thank Mr. W. Wilson of the Computation Center for much help in writing the programs in Fortran IV for IBM 7040 computer and Dr. J. Hart for providing the computing facilities.

THE STEREOCHEMISTRY OF THE TETRAHYDROPIMARIC ACIDS[1]

J. W. ApSimon, P. V. Demarco, and J. Lemke
Department of Chemistry, Carleton University, Ottawa, Canada
Received June 3, 1965

ABSTRACT

Evidence is presented that the fully reduced derivatives of pimaric acid (I), sandaracopimaric acid (II), and isopimaric acid (III) have *trans–anti–trans* fused skeletons. The implications of this observation are discussed.

Extensive chemical evidence both degradative and synthetic has confirmed the structures of pimaric acid I (1), sandaracopimaric acid II (2), and isopimaric acid III (3). The vinyl groups in these acids readily absorb 1 mole of hydrogen using a palladium catalyst in ethanol yielding the corresponding dihydro-derivatives I, II, or III (ethyl group in place of vinyl at C-13); however, the nuclear double bonds require more vigorous conditions for reduction, hydrogenation occurring with Adams' catalyst in acetic acid for 24 h to give the tetrahydropimaric acids (IV*a* is tetrahydropimaric acid and IV*b* is tetrahydrosandaracopimaric or isopimaric acid).[2]

Edwards and Howe (1*a*) showed that, in the case of the hydrogenation of dihydropimaric acid, the nuclear double bond underwent migration to the $\Delta^{8,9}$ position giving V which was then reduced. This isomerization could be carried out by the action of acid on dihydropimaric acid I (Et for vinyl at C-13) giving V which, on hydrogenation, gave the fully reduced acid IV*a*. On the basis of the commonly accepted concept that the addition of hydrogen occurs from the less hindered side of an unsaturated molecule in a *cis* fashion (for reviews on the stereochemistry of hydrogenation see ref. 4) one would predict that the

tetrahydropimaric acids IV*a* and IV*b* would have the *trans–anti–cis* fused backbones IV*a* or IV*b* (H-8 is α). We have shown that this is not the case and describe the work here. During the course of our studies Asselineau (5) described two tetrahydro derivatives from pimaric acid; one was identical to that obtained by earlier workers with m.p. 240°; however, if the hydrogenation was carried out under pressure at 60° another tetrahydro acid m.p. 168° was obtained. On the basis that this latter acid was formed very readily (4 h) Madame Asselineau applying the above generalization (4) assigned to it the *trans–anti–cis* configuration IV*a* (H-8 is α). She was unable to assign a configuration to the acid m.p. 240° which we show in the sequel to have the *trans–anti–trans* configuration.

The dihydro acids I, II, and III (Et for C-13 vinyl) were hydrogenated using Adams' catalyst in acetic acid using the conditions of Edwards and Howe (1*a*). Reduction proceeded slowly (up to 24 h) with uptake of 1 mole of hydrogen, and the tetrahydro acids IV*a* and IV*b* were isolated. The first crops from the crystallization of these products were pure compounds as shown by vapor phase chromatography (v.p.c.) of their methyl esters; however, the mother liquors contained up to 15% of another compound which had a longer retention time than the unreduced species or the major products. In the case of the reduction of dihydropimaric acid I (Et for vinyl at C-13), the methyl ester of this minor product had the same retention time on two columns as the methyl ester of the acid m.p. 168° kindly supplied by Madame Asselineau (5). We have been unable to isolate this compound in a pure state from the hydrogenation reaction mixture. If the French workers are correct in their assignment of configuration to the acid m.p. 168°, then the configuration of the tetrahydropimaric acid m.p. 240° is unknown, a fact which encouraged us in our studies.

The following sequence of reactions was performed in all three series starting from the dihydro acids I, II, or III (Et for C-13 vinyl). Reaction with excess diborane in tetrahydrofuran followed by alkaline peroxide work-up gave the corresponding diols VI*a*, VI*b*, and VII as major products.[3] The stereochemistries shown for these diols are assigned on the basis of the preferred mode of attack of diborane from the less hindered side of the double bond giving products resulting from *cis* addition of reagent (6). Our intention was to oxidize these alcohols to the corresponding keto aldehydes VIII*a*, VIII*b*, and IX, but even though Jones' reagent (7) has been reported to oxidize alcohols without affecting

	R_1	R_2

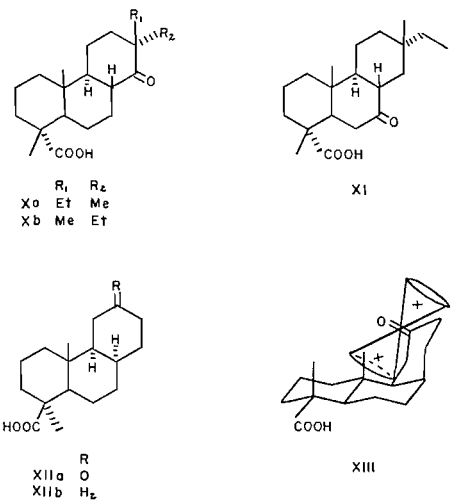
[3]*The other products from this reaction are a complex mixture which we have not as yet made any attempt to separate.*

the stereochemistry at α-carbons (1*c*, 8), we were unable to realize this aim and such oxidation of the diols VI*a*, VI*b*, and VII gave mixtures which could not be separated. On oxidation with an excess of Jones' reagent high yields of the keto acids X*a*, X*b*, and XI were obtained, which were unaffected by treatment with base and hence must have the most stable *trans–anti–trans* configuration (9). The n.m.r. spectra of the acids X*a* and X*b* supported this assignment; their C-10 methyl signals both appeared at 59 c.p.s. below tetramethylsilane, compared to 48 c.p.s. for dihydropimaric acid I (Et for C-13 vinyl and 49 c.p.s. for II (Et for C-13 vinyl). Thus in going from the corresponding dihydro acid to the keto acids X*a* and X*b* the C-10 methyl groups are deshielded.[4] If the configuration of X*a* and X*b* had been *trans–anti–cis*, then the C-10 methyl groups in the two keto acids would have been in the shielding cones of the carbonyl groups (10) and thus might have been expected to resonate at higher field than in the parent compounds. Such a prediction is supported by our earlier work on the perhydrophenanthrene acids derived from podo-



carpic acid (11). The acids XII*a* and XII*b* were synthesized from the natural product for model studies. The keto acid XII*a* showed C-10 methyl resonance at 40 c.p.s. below tetramethylsilane compared to 58 c.p.s. for the reduced acid XII*b*, the methyl group clearly lying in the shielding cone of the carbonyl group at C-11 as illustrated in XIII.

The keto acids X*a*, X*b*, and XI were next reduced, using the Wolff–Kishner technique, to the fully reduced acids IV*a* and IV*b* (H-8 is β). These two products were identical to the tetrahydropimaric acids obtained by hydrogenation. Although the ketoacids had the most stable configuration, there was a possibility that hydrazone formation in the Wolff–Kishner procedure was faster with the less stable epimer which could be present in low concentration at equilibrium (12). Decomposition of such a hydrazone would then give the less stable *trans–anti–cis* isomer. To test this possibility, we reduced ketopimaric acid X*a* by reduction of the dithioketal with Raney nickel, a method which has been demonstrated to proceed without affecting the stereochemistry at α-carbon atoms to carbonyl groups (13). The dithioketal was prepared by the method of Fieser (14) and was obtained as a high melting crystalline solid which, on refluxing with Raney nickel in ethanol overnight, yielded the same tetrahydropimaric acid IV*a* (H-8 is β) as obtained by the Wolff–Kishner reduction of X*a* or by hydrogenation of dihydropimaric acid I (Et for C-13 vinyl).

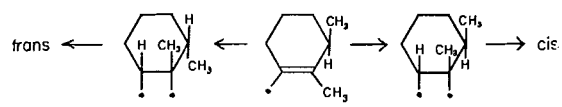
[4]*It may be argued that the double bond has a large effect in these spectra. This is not the case as the fully reduced acids show the same C-10 methyl resonance positions.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

We therefore assume that in all three cases Wolff–Kishner reduction proceeds in the expected manner to give the *trans–anti–trans* tetrahydro acids IV*a* and IV*b* (H-8 is β) and thus hydrogenation of the dihydroacids I, II, and III (Et for C-13 vinyl) also yields these compounds. It now remains to rationalize the formation of these *trans* products on catalytic hydrogenation.

The early work of Linstead (15) on the hydrogenation of phenanthrene and diphenic acids over platinum led to the postulate that reduction occurs from the less hindered side of an unsaturated molecule with simultaneous transfer of two or more hydrogen atoms from the catalyst to the adsorbed molecule. This concept has led to the commonly accepted generalization that catalytic hydrogenation of double bonds results in *cis* addition of hydrogen from the less hindered side of the unsaturated linkage. There are, however, many cases documented of *trans* products from hydrogenation, as illustrated by the studies of Siegel (16) and Hussey (17). These workers have used dialkyl cycloolefins as substrates to study the stereochemistry of catalytic hydrogenation over various catalysts. In all their cases mixtures of products have been observed, the amounts of each isomer depending on the reaction conditions: for instance, in the case of 1,2-dimethylcyclohexene about 80% of *cis* reduction product is obtained at atmospheric pressure over platinum, rising to over 95% at very high hydrogen pressures. To account for these observations Siegel and his co-workers (16) have suggested that *trans* isomers arise from an isomerization to 2,3-dimethylcyclohexene on the catalyst surface followed by desorption and readsorption on both sides of the new double bond in a random manner giving mixtures resulting from the formal *cis* and *trans* addition of hydrogen to the original double bond. Objections to this postulate have been advanced on two counts (18); firstly, the necessary isomerization is in a thermodynamically unfavorable direction (i.e. tetrasubstituted to trisubstituted double bond) and, secondly, if the isomerization did occur the olefin would be unlikely to desorb to the required extent. Regarding the first of these objections it may also be argued that the trisubstituted double bond isomer is the more reactive entity present in low concentration at equilibrium and hence reduces first displacing the equilibrium further in that direction (16*b*).

Hussey and his associates (17) believe that a "stereochemically symmetrical intermediate" is involved (XIV for the case in question) and the objection to this suggestion (18) is that it is difficult to account for the observed pressure dependences. The present



XIV

situation is thus somewhat unsettled. In our cases, we are dealing with cyclic olefins in a conformationally more rigid system which may therefore yield further information on this problem.

For the purpose of discussion we will consider $\Delta^{8,9}$-dihydropimaric acid V which appears to be the species which is reduced.[5,6] Why does one observe large yields of *trans* hydrogenation product in this case? The first explanation that comes to mind is an acid catalyzed

[5]*We assume that the species being reduced in the cases of dihydrosandaracopimaric acid and dihydroisopimaric acid is the* $\Delta^{8,9}$ *isomer also, though for reasons which will be developed later, it does not matter which double bond isomer is reduced.*

[6]*The same product ratios were observed by v.p.c. for the hydrogenation of both dihydropimaric acid and* $\Delta^{8,9}$*-dihydropimaric acid methyl esters.*

For personal use only.

double bond isomerization prior to reduction so that the reactant is in fact the $\Delta^{7,8}$, $\Delta^{8,14}$, or $\Delta^{9,11}$ species. Our objection to this possibility is that, as in the case of 1,2-dimethylcyclohexane, it is thermodynamically unfavorable though the same counterargument may also be applied. We must, however, consider what would happen if such an isomerization did take place (16*b*) and was followed by transfer of hydrogen.[7] Double bond migration on catalyst surface is well known. It has been suggested that isomerization is accelerated by an allylic rearrangement (19, 20), the allylic hydrogen that is removed being available to the catalyst surface (Fig. 1) and, in the case of subsequent reduction, hydrogen transfer then being able to proceed without desorption. If this is the case then we would expect transfer of hydrogen to the same side of the molecule as the allylic hydrogen being

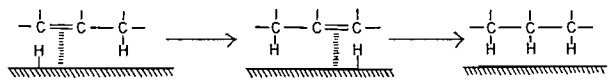

FIG. 1.

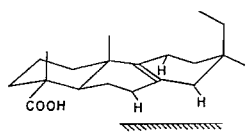
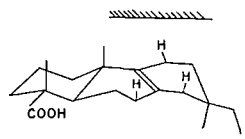
removed, and thus the product of hydrogenation would be expected to have a *cis* B–C ring junction. This is illustrated in XV and the allylic hydrogen atoms are shown in their approximate orientation to the catalyst surface. Formula XVI shows the situation if one considers that the dihydropimaric acid derivative with an 8,9-double bond could exist in the conformation XVI and here again, although it is difficult to see from models which side of the molecule is more available to the catalyst surface, either mode of adsorption on catalyst followed by allylic migration and reduction would still give a product with a *cis* B–C ring fusion. It is of course conceivable that desorption occurs after double bond migration as suggested by Siegel (16) and subsequent readsorption could occur from the other side of the molecule; however, we do not feel this would be a major pathway with such a large molecule where such a process would involve approach of catalyst from the highly hindered β-face. Likewise the "dissociatively adsorbed olefin" pathway (17) leads to a similar conclusion.



XV



XVI

Our observations suggest the possibility of an alternative mechanism of catalytic hydrogenation in the case of inaccessible double bonds. It is well known that if a double bond is difficult to reduce then the use of acetic acid as solvent and a relatively large amount of catalyst is often advantageous, and in several cases traces of stronger acid have been used for the reduction of extremely unreactive double bonds (21). In our case, we have noted that reduction of $\Delta^{8,9}$-dihydropimaric acid is accelerated fivefold by the addition of a few drops of perchloric acid to the reaction mixture. This, plus observations that reduction in acid solution changes the steric course of reduction of steroidal olefins (22) and of

[7]*There are conflicting reports on such isomerizations. Siegel (16b) has shown that 1,2-dimethylcyclohexane is isomerized rapidly to 2,3-dimethylcyclohexane yet Burwell (28) was unable to detect any isomerization of* $\Delta^{1,9}$- *or* $\Delta^{9,10}$-*octalins. We are attempting to detect small amounts of double bond isomers by v.p.c. techniques but at the present time have been unsuccessful.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cyclic ketones (23), suggests that hydrogen transfer from solvent as protons is a vital step in the reaction sequence[8] (24). To account for the observed products it is suggested that the first step of the reduction is protonation of the nuclear double bond, possibly whilst the olefin is associated with the catalyst surface, to yield a tertiary carbonium ion which then adds hydrogen as hydride ion from the catalyst surface (a similar proposal has been advanced by Augustine, ref. 26). Thus if the olefin is close to catalyst surface,

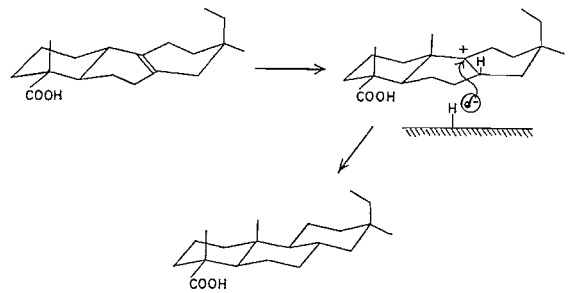


FIG. 2.

then the α-face of the molecule is effectively shielded giving an intermediate protonated from the β-side. That hydrogen adsorbed on catalyst can function as hydride ion receives support from the work of Pliskin and Eischens (27) who have examined the infrared spectrum of hydrogen adsorbed on platinum and observed bands associated with platinum hydrides. Such a mechanism needs to be tested and we have further work in progress to this end. An obvious approach would seem to be by catalytic deuteration studies (28), which we have started, but extensive deuterium exchange was encountered in our compounds (29); further studies are in progress.[9]

EXPERIMENTAL

Nuclear magnetic resonance spectra were determined on a Varian A-60 spectrometer, and chemical shifts are given in c.p.s. below tetramethylsilane used as an internal standard. Sample concentrations were approximately 10% (w/v) in deuterochloroform as solvent. All optical rotations were taken using absolute ethanol as solvent, and compound concentrations ranged from 1.0–1.5 g per 100 ml. Melting points are uncorrected and were determined on a Kofler hot stage. Infrared spectra were determined on a Perkin-Elmer 137 or 237 "Infracord" spectrophotometer in Nujol mulls. Hydrogen uptake is expressed as percentage of theory for one double bond.

Partial Hydrogenation of the Pimaric Acids

(i) Pimaric acid I (2.0 g), m.p. 216–218 °C, $[\alpha]_D$ +62.4°, and ν_{max} 1 698^{-1} (—COOH), 825 cm^{-1} (trisubstituted double bond), 913 and 994 cm^{-1} (vinyl group), was hydrogenated by the method of Edwards and Howe (1*a*). Hydrogen (98%) was absorbed yielding small needle-like crystals of dihydropimaric acid I (Et for C-13 vinyl) (1.8 g), m.p. 239–244 °C, $[\alpha]_D$ +23.0°, and ν_{max} 1 698 cm^{-1}, (—COOH), 825 cm^{-1} (trisubstituted double bond).

(ii) Sandaracopimaric acid II (1.9 g), m.p. 169–170 °C, $[\alpha]_D$ −20.1°, ν_{max} 1 698 cm^{-1}, 825 cm^{-1}, 913 and 994 cm^{-1} was hydrogenated as above. Hydrogen (100%) was absorbed yielding dihydrosandaracopimaric acid II (Et for C-13 vinyl) (1.75 g), m.p. 170–174 °C, $[\alpha]_D$ +20.8°, ν_{max} 1 698 cm^{-1}, 825 cm^{-1}.

(iii) Isopimaric acid III (950 mg), m.p. 160–161 °C, $[\alpha]_D$ 0°, ν_{max} 1 698 cm^{-1}, 825 cm^{-1}, 913 and 994 cm^{-1} was hydrogenated as above. Hydrogen (101%) was absorbed yielding dihydroisopimaric acid III (Et for C-13 vinyl) (910 mg), m.p. 172–175 °C, $[\alpha]_D$ −7.2°, ν_{max} 1 698 cm^{-1}, 825 cm^{-1}.

[8]*A referee has suggested that the acid may affect the properties of the catalyst (25); however, even if this is the case, it is still difficult to account for the observed stereochemistry of the hydrogenation products. We thank this referee for this and other suggestions.*

[9]*Dr. O. E. Edwards and his associates have concurrently observed large percentages of trans products in the catalytic hydrogenation of an acid derived from podocarpic acid, XIIb ($\Delta^{8,9}$). This work will be published independently, and we thank Dr. Edwards for keeping us informed of the progress of his studies.*

Hydrogenation of Dihydropimaric Acids

(i) Dihydropimaric acid (100 mg) was hydrogenated with Adams' catalyst by the method of Edwards and Howe (1*a*). Hydrogen (97.5%) was absorbed over a period of 24 h yielding tetrahydropimaric acid IV*a* (85 mg), m.p. 240–241 °C, $[\alpha]_D$ +18.4°, and ν_{max} 1 695 cm^{-1} (—COOH).

(ii) Dihydrosandaracopimaric acid (100 mg) was hydrogenated with Adams' catalyst as above. Hydrogen (99%) was absorbed over a period of 24 h, and crystallization from aqueous methanol gave tetrahydrosandaracopimaric acid IV*b* (90 mg), m.p. 172–174 °C, $[\alpha]_D$ +19.1°, and ν_{max} 1 695 cm^{-1}.

(iii) Dihydroisopimaric acid (100 mg) was hydrogenated as above. Hydrogen (97.5%) was absorbed over a period of 24 h. Crystallization from aqueous methanol yielded tetrahydroisopimaric acid IV*b* (85 mg), m.p. 173–174 °C, $[\alpha]_D$ +19.4°, and ν_{max} 1 695 cm^{-1}. Mixed melting point with tetrahydrosandaracopimaric acid was undepressed, and their infrared spectra were superimposable.

Hydroboration Procedure (ref. 9a)

Diborane (1.0 mole per mole of reactant) was added every 3 h for three consecutive additions to a stirring solution of the reactant in dry tetrahydrofuran maintained at room temperature over nitrogen. On the fourth addition, diborane (3.0 moles per mole of reactant) was added, and the solution was allowed to stir for a further 8 h before the destruction of the excess diborane by the addition of water. Sodium hydroxide (30 ml 3 *N*) and hydrogen peroxide (5 ml 30%) were then added to the resulting suspension and the mixture was refluxed for 2 h, after which time the mixture was concentrated on a rotary evaporator and ether-extracted to yield the crude product.

Hydroboration of Dihydropimaric Acids

(i) Dihydropimaric acid (4.23 g) was subjected to these conditions. Thin-layer chromatography of the reaction mixture, using benzene – ethyl acetate (4:1) on silical gel, illustrated the presence of six compounds. The product was then chromatographed on neutral alumina (90 g Woelm Gr. 1). Elution with ether produced a pale-yellow oil (1.59 g) which was shown by thin-layer chromatography to be a mixture of four compounds. Further elution with ether – ethyl acetate (4:1) yielded colorless needles (2.63 g). Recrystallization from ether–benzene gave fluffy needles (2.2 g, 50%) which proved to be the required diol V*a*. Sublimation at 130° and 10^{-4} mm yielded the diol, m.p. 174–175°, $[\alpha]_D$ −17.6°, ν_{max} 1 025 and 3 400 cm^{-1} (—OH).

Anal. Calcd. for $C_{20}H_{36}O_2$: C, 77.86; H, 11.76. Found: C, 77.80; H, 11.70.

(ii) Dihydrosandaracopimaric acid (2.1 g) was hydroborated as described above. Thin-layer chromatography of a sample of the reaction mixture indicated the presence of six compounds. The viscous semisolid reaction product was then washed twice with *n*-hexane leaving insoluble material (1.5 g), which was crystallized twice from aqueous methanol to yield stout prisms (1.1 g, 41%) which showed only one spot on thin-layer chromatography and proved to be the required diol V*b*. Sublimation at 130° at 10^{-4} mm yielded colorless plates of the diol, m.p. 183–184°, $[\alpha]_D$ −17°, ν_{max} 1 025 and 3 410 cm^{-1}.

Anal. Calcd. for $C_{20}H_{36}O_2$: C, 77.86; H, 11.76. Found: C, 78.66; H, 11.56.

(iii) Dihydroisopimaric acid (900 mg) was reduced as described. Thin-layer chromatography of a sample of the crude reaction mixture (910 mg) indicated the presence of two compounds. The semicrystalline product was then separated on thin-layer plates giving two fractions. The bottom fraction, on elution with ether, gave colorless needles (740 mg, 87%) which crystallized from aqueous methanol. They were sublimed at 130° at 10^{-4} mm to give the required diol VII, m.p. 183–184°, $[\alpha]_D$ +31.9°, ν_{max} 1 025 and 3 410 cm^{-1}.

Anal. Calcd. for $C_{20}H_{36}O_2$: C, 77.86; H, 11.76. Found: C, 77.33; H, 11.67.

*Oxidation of the Dihydropimaric Diols VI*a*, VI*b*, and VII*

(i) Dihydropimaric acid diol VI*a* (475 mg) was dissolved in acetone (50 ml), and Jones' reagent (7) was added dropwise with stirring until the reaction mixture no longer changed color (3 min). The mixture was allowed to stir for 10 min, after which time excess oxidant was decomposed with methanol, and the reaction mixture was concentrated on a rotary evaporator to a green oil which was shaken with water and ether-extracted. Drying and evaporation gave an oil (430 mg) with ν_{max} at 2 750 and 1 740 cm^{-1} (aldehyde) and 1 700 cm^{-1} (carbonyl). This product resisted all attempts at purification so was oxidized again with Jones' reagent for a further 10 min. Ether extraction after decomposition of excess oxidant gave ketoacid X*a* which crystallized as prisms from aqueous methanol (410 mg), m.p. 244–245°, $[\alpha]_D$ −48.7°. Infrared spectrum, ν_{max} at 3 400 – 3 000 cm^{-1} and 1 695 cm^{-1} (—COOH), 1 695 cm^{-1} (carbonyl).

Anal. Calcd. for $C_{20}H_{32}O_3$: C, 74.96; H, 10.06. Found: C, 75.10; H, 10.02.

In later oxidations the reaction mixture was stirred for 15 min without attempts at isolation of the ketoaldehyde.

(ii) Dihydrosandaracopimaric diol VI*b* (230 mg) was oxidized as described above without attempting to isolate the intermediate keto aldehyde. Isolation after 20 min reaction time gave the ketoacid X*b* (195 mg) as plates from aqueous methanol, m.p. 205–207°, $[\alpha]_D$ −30.6°. Infrared spectrum, ν_{max} 3 500 – 3 000 cm^{-1} and 1 695 cm^{-1}.

Anal. Calcd. for $C_{20}H_{32}O_3$: C, 74.96; H, 10.06. Found: C, 75.04; H, 9.86.

(iii) Diol VII (400 mg) was oxidized as described giving the keto acid XI (350 mg), m.p. 239°, $[\alpha]_D$ +2°, identical in all respects to a sample prepared by hydrolysis of the corresponding methyl ester (3).

Equilibrium Procedures

The keto acid was dissolved in aqueous methanol (20 ml) to which was added potassium hydroxide (100 mg), and the mixture was refluxed for 3 h. The mixture was then acidified with 2 *N* hydrochloric acid, and ether-extracted to yield the equilibrated keto acid.

(i) The keto acid X*a* (12 mg) was subjected to these conditions, and recovery of the equilibrated acid (10 mg) gave crystalline material with m.p. 242–245° and $[\alpha]_D$ −47.2°, identical in all respects (mixed m.p., infrared, n.m.r., and thin-layer chromatography) to starting material X*a*.

(ii) Ketodihydrosandaracopimaric acid X*b* (15 mg) was equilibrated to yield a white crystalline product (13 mg) with m.p. 207–208° and $[\alpha]_D$ −30.8°, identical to starting material X*b*.

(iii) Ketodihydroisopimaric acid XI (10 mg) was equilibrated and gave crystals (9 mg) with m.p. 238–240°, identical to XI.

Wolf–Kishner Reduction Procedure

The keto acid under consideration (100 mg), 95% hydrazine (2 ml which had stood for several days over molecular sieve), and triethylene glycol (7 ml freshly distilled over anhydrous magnesium sulfate), were refluxed at 140° overnight. Potassium hydroxide (1.2 g) was then added, and the temperature was gently raised to 200° ± 5° for a further 6 h, with distillation of hydrazine out of the reaction flask. The reaction mixture was cooled, acidified with 2 *N* sulfuric acid, and ether-extracted. The ether extract was washed well with water, dried, and evaporated to yield the crude reaction products.

(i) The keto acid X*a* (120 mg) was subjected to the conditions described above to yield a crude crystalline product (101 mg) which when crystallized twice from aqueous methanol and sublimed at 120° at 10^{-4} mm gave short needle-like crystals, m.p. 240–241°, $[\alpha]_D$ +19°, ν_{max} 3 300 – 3 000 cm^{-1} and 1 695 cm^{-1} (—COOH). Mixed melting with tetrahydropimaric acid IV*a* gave no depression of melting point, and their infrared spectra were superimposable.

(ii) The keto acid X*b* (110 mg) was reduced as described above, giving crystals (96 mg) which when recrystallized twice from aqueous methanol and sublimed at 130° and 10^{-4} mm gave needles (89 mg) with m.p. 174–175°, $[\alpha]_D$ +19.5°; ν_{max} 3 300 – 3 000 cm^{-1} and 1 695 cm^{-1}. Mixed melting point with tetrahydrosandaracopimaric acid IV*b* gave no depression, and their infrared spectra were superimposable.

(iii) Upon reduction of the keto acid XI (90 mg), crude tetrahydro acid (80 mg) was obtained which when recrystallized from aqueous methanol and sublimed at 130° and 10^{-4} mm gave long, white needles, m.p. 171–172°, $[\alpha]_D$ +19.0°, ν_{max} 3 300 – 3 000 cm^{-1} and 1 695 cm^{-1}. Mixed melting point with tetrahydrosandaracopimaric acid IV*b* gave no depression of melting point, and their infrared spectra were superimposable.

Reduction of the Dithioketal of Ketodihydropimaric Acid Xa

The keto acid X*a* (128 mg) in acetic acid (5 ml) was mixed with boron trifluoride etherate (0.5 ml) and ethanedithiol (0.5 ml) (14) and allowed to stand for 2 d at room temperature when a crystalline solid was precipitated. Filtration and washing with cold methanol gave the dithioketal as small needles, m.p. above 275° (110 mg); thin-layer chromatography demonstrated the absence of starting material in this product. The dithioketal (110 mg) was refluxed with W-2 Raney nickel (30) in ethanol for 15 h. Filtration and evaporation gave tetrahydropimaric acid (96 mg). After recrystallization from methanol, this was identical in all respects to the Wolff–Kishner or hydrogenation product IV*a* (H-8 is β).

ACKNOWLEDGMENTS

We wish to thank the National Research Council of Canada for financial aid and the Government of Ontario for a fellowship (to P. V. D.). We are indebted to Dr. O. E. Edwards for his encouragement and helpful discussions.

SULFUR ISOTOPE EFFECTS IN THE HYDROGEN ION DECOMPOSITION OF THIOSULFATE

U. AGARWALA, C. E. REES, AND H. G. THODE
McMaster University, Hamilton, Ontario
Received April 15, 1965

ABSTRACT

Sulfur isotope effects in the decomposition of thiosulfate have been studied. There are two distinct intermolecular isotope effects and these have been used to examine various mechanisms for the reaction. By use of the theory of competing isotope reactions the thiosulfate decomposition mechanisms of La Mer and Davis have been shown to predict isotope effects not in accord with experiment, while a simple bimolecular three-centered reaction has been shown to predict sulfur and sulfite isotope effects in good agreement with the experimentally determined values of 1.9% and 0.9%.

INTRODUCTION

The study of kinetic isotope effects in the course of a chemical reaction can give information regarding the mechanism by which the reaction proceeds and the nature of the activated complexes associated with rate-controlling steps in the reaction. The information derived from such experiments forms a valuable addition to that obtained in more conventional kinetic studies.

The hydrogen ion decomposition of thiosulfate has been extensively studied (1–11). Various kinetic investigations have been made (2, 3, 4, 9, 10, 11) but the results remain difficult to interpret on the basis of a reaction mechanism. Because of this, a study of the intermolecular isotope effects involving ^{32}S and ^{34}S in thiosulfate decomposition is likely to be of value. In addition, the thiosulfate ion is of special interest since it contains two non-equivalent sulfurs, so that the products of the decomposition, sulfite and sulfur, each show distinct intermolecular isotope effects. Thus the study of sulfur isotope fractionations provides a more than usually strong diagnostic tool for the determination of the reaction mechanism.

THEORETICAL

The theory of isotope fractionation in the course of chemical reactions is considered in terms of the theory of absolute rates and was first formulated by Bigeleisen (12). For the competing isotope reactions

$$A_1 + B + \ldots \rightarrow P_1 + \ldots .$$

$$A_2 + B + \ldots \rightarrow P_2 + \ldots .$$

the ratio of rate constants is given by:

$$\frac{k_1}{k_2} = \left(\frac{Q_2}{Q_1} \Big/ \frac{Q_2^{\ddagger}}{Q_1^{\ddagger}}\right) \frac{\nu_{1L}^{\ddagger}}{\nu_{2L}^{\ddagger}}.$$

This expression omits the transmission coefficient and Wigner tunnelling correction of absolute rate theory, the assumption being made that for heavy elements these terms will remain invariant under isotopic substitution. The terms Q_2/Q_1 and $Q_2^{\ddagger}/Q_1^{\ddagger}$ are ratios of

partition functions for the reactants and activated complexes respectively and each may be evaluated as

$$\prod_i^N \frac{u_{2i}}{u_{1i}} \left(\frac{e^{-u_{2i}/2}}{e^{-u_{1i}/2}} \right) \frac{1 - e^{-u_{1i}}}{1 - e^{-u_{2i}}}$$

where $u_i = h\nu_i/kT$ and ν_i is the ith fundamental vibrational frequency of the molecule. If n is the number of atoms in the molecule, then for the reactants N is $(3n - 6)$, and for the activated complexes it is $(3n - 7)$ since in an activated complex one of the vibrational degrees of freedom (ν_L) is non-genuine, corresponding to the cleavage of a bond, and is equivalent to a translation along the reaction coordinate.

According to Slater (13) the term $\nu_{1L}^{\ddagger}/\nu_{2L}^{\ddagger}$, the ratio of the two frequencies which become imaginary in the activated complexes, may be evaluated in terms of the effective masses of the activated complexes as they traverse the critical region of the reaction coordinate. So that:

$$\nu_{1L}^{\ddagger}/\nu_{2L}^{\ddagger} = \sqrt{(\mu_2^{\ddagger}/\mu_1^{\ddagger})}.$$

Bigeleisen and Wolfsberg (14) have considered the more complicated case where in the activated complex there is not merely a bond breaking but there is simultaneous bond rupture and formation, the case of the three center reaction.

If we consider the case of the tri-polar group ABC with a bond between B and C breaking while one between A and B forms, the mass term in the expression for rate constant ratios may be written:

$$\left(\frac{\frac{1}{M_{B1}} + \frac{1}{M_{C1}} + p\left(\frac{1}{M_{B1}} + \frac{1}{M_{A1}}\right) + 2p^{1/2}\frac{1}{M_{B1}}}{\frac{1}{M_{B2}} + \frac{1}{M_{C2}} + p\left(\frac{1}{M_{B2}} + \frac{1}{M_{A2}}\right) + 2p^{1/2}\frac{1}{M_{B2}}} \right)^{1/2}.$$

Here the parameter p represents the relative amounts of bond formation and bond extension. For $p = 0$, 1, and ∞ the formula represents pure bond rupture, equal rupture and formation, and pure bond formation respectively.

TABLE I

Fundamental vibrational frequencies for the three main isotopic species of thiosulfate ion

Molecule	Frequencies, cm^{-1}					
$^{32}S^{32}SO_3^=$	1 123 (2)*	541 (2)	335 (2)	995 (1)	435 (1)	669 (1)
$^{34}S^{32}SO_3^=$	1 123	541	333	995	423	666
$^{32}S^{34}SO_3^=$	1 107	538	335	983	430	664

*Figures in parentheses indicate degeneracy.

Calculations

To calculate partition function ratios it is necessary to know the fundamental frequencies of the three isotopic species of thiosulfate. The ion has the form XYZ_3 and is a tetrahedral molecule belonging to the point group C_{3v}. The method of Slawsky and Dennison (15) was used to determine the force constants for this molecule using the fundamental frequencies for $^{32}S^{32}SO_3^=$ reported by Siebert (16) and the crystal structure data of Taylor and Beevers (17). Five of the six distinct fundamental frequencies were used to calculate the five unknown force constants which were then used to calculate the sixth fundamental

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

frequency for a check of the method. The calculated values of force constants are: $k_1 = 6.64$, $k_2 = 0.88$, $k_3 = 0.53$, $k_4 = 0.013$, and $C = 3.95$ dyn/cm. These values were used to calculate the fundamental frequencies of $^{32}S^{34}SO_3^=$ and $^{34}S^{32}SO_3^=$ which values are shown in Table I.

EXPERIMENTAL

Partial decomposition of thiosulfate ($\sim 10\%$) was carried out by the following method: To 1 500 ml of 0.01 *M* sodium thiosulfate pentahydrate solution, 10 ml of 5.0 *N* HCl was added, followed by 250 ml of thiophene-free benzene at 25 °C. The whole mixture was stirred for 15–20 min. When the experiments were performed at 47 °C, the stirring was continued for 3–4 min only. To quench the reaction 0.1 *M* iodine solution was added, an amount slightly in excess of that required to convert $S_2O_3^=$ to $S_4O_6^=$ and sulfite to sulfate. The whole mixture was vigorously shaken for 20–30 more minutes and kept for some time so that the benzene and aqueous phases were separated. From the aqueous layer $SO_4^=$ was precipitated as $BaSO_4$. From the benzene layer sulfur was separated, by evaporating benzene on a water bath, and was then oxidized to sulfate and precipitated as $BaSO_4$. The sulfur from the benzene layer represents the outer sulfur of thiosulfate ion (the thio sulfur), whereas $BaSO_4$ precipitated from the aqueous layer represents the central sulfur (the sulfite sulfur). The weight of barium sulfate from sulfur was usually lower ($\sim 20\%$) than that precipitated from the aqueous layer.

Thiosulfate used in the above reactions was also decomposed completely by silver nitrate at 25 °C, according to the following equation:

$$S - SO_3^= + 2AgNO_3 + H_2O \rightarrow Ag_2S + SO_4^= + 2HNO_3.$$

The silver sulfide and the sulfate formed by this reaction contain respectively all the thio and sulfite sulfurs of the thiosulfate (18). These were converted to SO_2 and their isotopic ratios were measured. These isotopic ratios were compared separately with those of the corresponding sulfurs obtained by partial decomposition of thiosulfate.

All the samples were analyzed as sulfur dioxide (19) on a 90° simultaneous collection mass spectrometer whose design and operation have been described previously (20).

Under the experimental conditions there is the possibility of a side reaction, especially at 47 °C (21), which may be written:

$$10H_2O + S_4O_6^= + 7I_2 \rightarrow 4SO_4^= + 14I^- + 20H^+.$$

The isotopic ratio of sulfate formed in this reaction might produce an error in the isotopic ratio of the sulfate formed by the decomposition of thiosulfate. However, the rate of this reaction is dependent on the concentration of iodine and iodide (21). Excess of iodide will suppress the reaction. Under our experimental conditions, there is a very slight excess of iodine and a large excess of iodide. Therefore, the formation of the sulfate by this method should be very small. In one experiment a dilute solution of iodine was added to the tetrathionate solution and kept overnight. A small amount of sulfate formed due to the above reaction was precipitated as $BaSO_4$ and the isotopic ratio of sulfur was measured by the usual method. Sulfate sulfur was found to be depleted in ^{34}S by 10 parts per thousand (p.p.t.). As will be seen later in this paper, this value of depletion is approximately the same as was found in sulfite sulfur formed by the decomposition of thiosulfate into sulfur and sulfite. Thus, this very slow side reaction should not produce any serious error in the experimental results.

Many investigations (6) have reported the simultaneous production of various polythionates, the most likely of which is pentathionate formed by reaction [2] which competes with the main reaction [1]:

[1] $$H^+ + S_2O_3^= \rightarrow HSO_3^- + S$$

[2] $$6H^+ + 5S_2O_3^= \rightarrow 2S_5O_6^= + 3H_2O.$$

The extent of each of the two reactions may be evaluated separately, at any time, by titration. The method described by Zaiser and La Mer (6) uses simultaneous iodine and base titration. It was found that reaction [2] goes to the extent of 1–1.8%, while reaction [1] goes to the extent of 14% in about 30 min. This indicates that reaction [1] under our experimental conditions is predominant.

Willard (22) has shown that there is no possibility of isotope exchange between the thiosulfate and sulfite produced in reaction [1]. This exchange becomes appreciable only at temperatures in excess of 60 °C.

RESULTS

The experimental results are given in Tables II, III, and IV which represent thiosulfate decompositions using hydrochloric acid at 25 °C, hydrochloric acid at 47 °C, and acetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

acid at 47 °C respectively. In each table column 2 represents the $^{34}S:^{32}S$ ratios in the starting material, measured relative to a laboratory standard.

$$\delta = \frac{\left(\frac{^{34}S}{^{32}S}\right)_{sample} - \left(\frac{^{34}S}{^{32}S}\right)_{standard}}{\left(\frac{^{34}S}{^{32}S}\right)_{standard}} \times 1000 \text{ p.p.t.}$$

Column 3 represents the $^{34}S:^{32}S$ ratios in the products of the reaction, measured relative to the same standard, and column 4 is the net isotope effect between reactants and products. The isotope effects for sulfite sulfur and thio sulfur are designated $\delta(^{34}SO_3^{=})$ and $\delta(^{34}S)$ respectively.

TABLE II

Isotope effects in the decomposition of thiosulfate (temperature 25 °C, acid used HCl)

Products	$\delta^{34}S$ in 100% decomposition of thiosulfate, p.p.t.	$\delta^{34}S$ in 10% decomposition of thiosulfate, p.p.t.	Isotope effect, p.p.t.
Sulfur	−2.30	−21.50	−19.20
Sulfite	−0.81	−9.54	−8.73
Sulfur	−2.30	−21.80	−19.50
Sulfite	−0.81	−9.88	−9.07
Sulfur	+1.33	−16.20	−17.53
Sulfite	−0.65	−8.30	−7.65
Sulfur	+1.33	−17.43	−18.76
Sulfite	−0.65	−7.75	−7.10
Average $\delta(^{34}S)$			−18.8
Average $\delta(^{34}SO_3^{=})$			−8.1

TABLE III

Isotope effects in the decomposition of thiosulfate (temperature 47 °C, acid used HCl)

Products	$\delta^{34}S$ in 100% decomposition of thiosulfate, p.p.t.	$\delta^{34}S$ in 10% decomposition of thiosulfate, p.p.t.	Isotope effect, p.p.t.
Sulfur	+1.33	−17.60	−18.93
Sulfite	−0.65	—	—
Sulfur	+1.37	−18.99	−20.32
Sulfite	−0.65	−8.79	−8.14
Sulfur	+1.33	−19.20	−20.54

Average $\delta(^{34}S)$			−17.0
Average $\delta(^{34}SO_3^{=})$			−8.9

NOTE: From Tables II, III, IV; average $\delta(^{34}S) = -18.6$ p.p.t., average $\delta(^{34}SO_3^{=}) = -8.5$ p.p.t.

DISCUSSION

Two mechanisms due to La Mer and his co-workers (9) and to Davis (11) have been suggested for the decomposition of thiosulfate.

The La Mer mechanism may be written

$$[3] \qquad H^+ + S_2O_3^{=} \overset{K}{\rightleftharpoons} HS_2O_3^-$$

$$[4] \qquad S_2O_3^{=} + HS_2O_3^- \overset{k_1}{\rightarrow} (HS_2O_3 \cdot S_2O_3)^{3-}$$

$$[5] \qquad (HS_2O_3 \cdot S_2O_3)^{3-} \overset{k_2}{\rightarrow} HSO_3^- + SO_3^{=} + S_2$$

where $k_1 \sim 2k_2$.

This reaction scheme shows the formation of bithiosulfate by a protonation process followed by bithiosulfate and thiosulfate ions coming together to form an addition compound. The addition compound then decomposes to form bisulfite, sulfite, and sulfur.

The mechanism proposed by Davis is as follows

$$H^+ + S_2O_3^{=} \overset{K}{\rightleftharpoons} HS_2O_3^-$$

$$HS_2O_3^- + S_2O_3^{=} \overset{k_1}{\rightarrow} HS_3O_3^- + SO_3^{=}$$

$$HS_3O_3^- + S_2O_3^{=} \overset{k_2}{\rightarrow} HS_4O_3^- + SO_3^{=}$$

$$\vdots \qquad\qquad \vdots \qquad\qquad \vdots$$

$$HS_8O_3^- + S_2O_3^{=} \overset{k_7}{\rightarrow} HS_9O_3^- + SO_3^{=}$$

$$HS_9O_3^- \overset{k}{\rightarrow} S_8 + HSO_3^-$$

After the initial protonation of thiosulfate, a series of unstable addition compounds are formed, each of which reacts with thiosulfate to form the next member of the series, until finally eight sulfurs break off the last member forming sulfur and bisulfite.

Calculations have been made, and are presented below, of the isotope effects to be expected in the decomposition of thiosulfate, the following models being considered: (i) Simple unimolecular mechanism, (ii) simple one step bimolecular mechanism, (iii) Davis mechanism, (iv) La Mer mechanism.

Calculations are made without taking into account any possible isotope effect in protonation of the reacting species. It is not to be expected that there will be any sulfur isotope effect in the process of protonation and the simple models considered for activated complexes will not be affected by the presence or absence of protons.

Simple Unimolecular Mechanism

If the decomposition of thiosulfate is unimolecular, with respect to sulfur isotope effects, then the three distinct isotopic cases may be written

$$S_2O_3^{=} \xrightarrow{k_1} SO_3^{=} + S$$

$$S^*SO_3^{=} \xrightarrow{k_2} SO_3^{=} + S^*$$

$$SS^*O_3^{=} \xrightarrow{k_3} S^*O_3^{=} + S$$

where S refers to ^{32}S and S* to ^{34}S.

For small fractions of reaction the sulfur and sulfite isotope effects, referred to the starting material, are given by:

$$-\delta(^{34}SO_3^{=}) = (k_1/k_3) - 1$$

$$-\delta(^{34}S) = (k_1/k_2) - 1.$$

For the unimolecular reaction, the activated complex is assumed to be the same as the starting material, except that the vibrational mode corresponding to the S—S bond extension has taken on an imaginary frequency. This frequency in the ion $S_2O_3^{=}$ is ~ 430 cm^{-1} and in the evaluation of partition functions for the activated complexes its contribution is omitted. The mass term is taken as the reduced mass of the dipolar species S—SO_3 and may be evaluated using either mass or atom fragments. The results of rate ratio calculations are shown in Table V.

TABLE V

Predicted isotope effects in the decomposition of thiosulfate: simple unimolecular model

	Mass fragments		Atom fragments	
Rate ratio	$T = 25$ °C	$T = \infty$	$T = 25$ °C	$T = \infty$
k_1/k_2	1.031	1.022	1.025	1.015
k_1/k_3	1.008	1.004	1.019	1.015

NOTE: Experimentally, $k_1/k_2 = 1.019$, $k_1/k_3 = 1.009$, assuming the above model (see Table IV).

It may be seen that the simple unimolecular model does not give rise to predicted isotope effects that are in accord with experiment either from the point of view of their absolute or their relative magnitudes.

Simple One Step Bimolecular Mechanism

If the decomposition of thiosulfate is bimolecular, there are three distinct isotopic cases each of which has two possible modes of reaction.

$$S_2O_3^{=} + S_2O_3^{=}\left[\rightleftharpoons O_3^{=}S\underset{b}{\cdots}S\underset{f}{\cdots}SSO_3^{=}\right] \xrightarrow{k_1} SO_3^{=} + SO_3^{=} + SS$$

$$S_2O_3^{=} + S_2O_3^{=}\left[\rightleftharpoons O_3^{=}SS\underset{f}{\cdots}S\underset{b}{\cdots}SO_3^{=}\right]\xrightarrow{k_1} SO_3^{=} + SO_3^{=} + SS$$

$$S_2O_3^{=} + S^*SO_3^{=}\left[\rightleftharpoons O_3^{=}S\underset{b}{\cdots}S\underset{f}{\cdots}S^*SO_3^{=}\right]\xrightarrow{k_2'} SO_3^{=} + SO_3^{=} + SS^*$$

$$S_2O_3^{=} + S^*SO_3^{=}\left[\rightleftharpoons O_3^{=}SS\underset{f}{\cdots}S^*\underset{b}{\cdots}SO_3^{=}\right]\xrightarrow{k_2''} SO_3^{=} + SO_3^{=} + SS^*$$

$$S_2O_3^{=} + SS^*O_3^{=}\left[\rightleftharpoons O_3^{=}S\underset{b}{\cdots}S\underset{f}{\cdots}SS^*O_3^{=}\right]\xrightarrow{k_3'} SO_3^{=} + S^*O_3^{=} + SS$$

$$S_2O_3^{=} + SS^*O_3^{=}\left[\rightleftharpoons O_3^{=}SS\underset{f}{\cdots}S\underset{b}{\cdots}S^*O_3^{=}\right]\xrightarrow{k_3''} SO_3^{=} + S^*O_3^{=} + SS$$

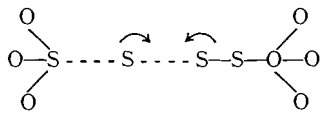
The equations above represent in each case the equilibrium between the reactants and the activated complex followed by the unidirectional steps to form the reaction products. The "b" and "f" in the activated complexes indicate the breaking and formation of bonds.

For small fractions of reaction the thio sulfur and sulfite sulfur isotope effects, referred to the starting material, are given by:

$$-\delta(^{34}SO_3^{=}) = \frac{2k_1}{k_3' + k_3''} - 1$$

$$-\delta(^{34}S) = \frac{2k_1}{k_2' + k_2''} - 1.$$

For the bimolecular three-centered reaction, the activated complex is assumed to be the same as the starting material, except that the S—S bond stretching frequency in each thiosulfate is imaginary. In physical terms this means that as the two thiosulfates come together, the thio sulfur breaks off one and becomes attached to the other thiosulfate group while at the same time the sulfite of this group is beginning to separate from the sulfur.



The partition function terms appropriate to k_1/k_2', k_1/k_2'', k_1/k_3', and k_1/k_3'' are 1.0094, 1.0094, 1.0040, and 1.0040 respectively. The results of calculations using this model are presented in Table VI.

The calculations indicate that this model gives good agreement with experiment, both from the point of view of the magnitude and of the isotope effects and their relative values, for atom fragments and a p value of about 0.1.

The Davis Mechanism

The Davis mechanism proceeds in seven distinct steps with isotope fractionation in each, the net sulfur and sulfite fractionations being the means of the fractionation in these steps.

Let us consider the nth step of the reaction: the reaction is three centered, and the activated complex may be schematized as:

$$O_3^{=}S\underset{b}{\cdots}S\underset{f}{\cdots}S_{n+1}O_3^{=}$$

TABLE VI

Predicted isotope effects in the decomposition of thiosulfate: simple bimolecular model

	p term							
	0	10^{-3}	10^{-2}	10^{-1}	1	10	10^{2}	10^{3}
	(A) Mass fragments (T = 25 °C)							
k_1/k_2'	1.0094	1.0094	1.0094	1.0095	1.0099	1.0106	1.0111	1.0113
k_1/k_2''	1.0313	1.0317	1.0324	1.0341	1.0357	1.0354	1.0342	1.0336
k_1/k_3'	1.0040	1.0040	1.0040	1.0041	1.0045	1.0052	1.0057	1.0059
k_1/k_3''	1.0075	1.0074	1.0071	1.0063	1.0050	1.0042	1.0040	1.0040
$2k_1/(k_2' + k_2'')$	1.0202	1.0204	1.0208	1.0216	1.0227	1.0228	1.0225	1.0223
$2k_1/(k_3' + k_3'')$	1.0058	1.0057	1.0055	1.0052	1.0048	1.0047	1.0049	1.0049
	(B) Atom fragments (T = 25 °C)							
k_1/k_2'	1.0094	1.0094	1.0095	1.0104	1.0144	1.0200	1.0230	1.0241
k_1/k_2''	1.0246	1.0251	1.0260	1.0281	1.0298	1.0281	1.0260	1.0251
k_1/k_3'	1.0040	1.0040	1.0040	1.0040	1.0040	1.0040	1.0040	1.0040
k_1/k_3''	1.0191	1.0186	1.0176	1.0146	1.0090	1.0050	1.0041	1.0040
$2k_1/(k_2' + k_2'')$	1.0169	1.0172	1.0177	1.0192	1.0220	1.0240	1.0245	1.0246
$2k_1/(k_3' + k_3'')$	1.0115	1.0113	1.0107	1.0093	1.0065	1.0045	1.0041	1.0040

NOTE: Experimentally, $2k_1/(k_2' + k_2'') = 1.0186$, $2k_1/(k_3' + k_3'') = 1.0085$, assuming the above model (see Table IV).

The isotopically distinct cases, with their corresponding rate constants are:

$$O_3S - - - S - - - S_{n+1}O_3 \quad (k_{1n})$$

$$O_3S - - - S^* - - - S_{n+1}O_3 \quad (k_{2n})$$

$$O_3S^* - - - S - - - S_{n+1}O_3 \quad (k_{3n})$$

$$O_3S - - - S - - - S..S^*..SO_3 \quad (k_{4n}).$$

The last of these may be neglected for small fractions of reaction, so that the overall thio sulfur and sulfite sulfur isotope fractionations are given by:

$$-\delta(^{34}S) = \frac{1}{7}\sum_{n=1}^{7}\left(\frac{k_{1n}}{k_{2n}} - 1\right)$$

$$-\delta(^{34}SO_3^{=}) = \frac{1}{7}\sum_{n=1}^{7}\left(\frac{k_{1n}}{k_{3n}} - 1\right).$$

If we consider the activated complex to be the same as the starting material except that the S—S stretching frequency in the thiosulfate becomes imaginary, the partition function ratios appropriate to k_{1n}/k_{2n} and k_{1n}/k_{3n} are 1.0094 and 1.0040 respectively. Table VII shows the results of calculations based on this model.

TABLE VII

Predicted isotope effects in the decomposition of thiosulfate: Davis mechanism

	p term							
	0	10^{-3}	10^{-2}	10^{-1}	1	10	10^{2}	10^{3}
	(A) Mass fragments (T = 25 °C)							
k_1/k_2 (average)	1.0313	1.0317	1.0325	1.0342	1.0365	1.0370	1.0364	1.0360
k_1/k_3 (average)	1.0076	1.0074	1.0071	1.0063	1.0051	1.0043	1.0040	1.0040
	(B) Atom fragments (T = 25 °C)							
k_1/k_2 (average)	1.0246	1.0251	1.0250	1.0281	1.0298	1.0281	1.0260	1.0251
k_1/k_3 (average)	1.0191	1.0186	1.0176	1.0146	1.0090	1.0050	1.0041	1.0040

NOTE: Experimentally, k_1/k_2 (average) = 1.0186, k_1/k_3 (average) = 1.0085, assuming the above mechanism (see Table IV).

It may be seen that the model chosen on the basis of the Davis mechanism does not give rise to predicted isotope effects that are in accord with experiment, either for mass or atom fragments or over the entire range of p values.

The La Mer Mechanism

It is assumed that there is no isotope fractionation in the initial protonation equilibrium between thiosulfate and bithiosulfate [3] and that further there will be no isotope effect in the formation of the addition compound [4]. Such isotope effects as are observed experimentally will then be the result of fractionation in the third stage of the reaction sequence in which the addition compound decomposes. Since the second and third stages of the sequence have rate constants of the same order of magnitude, the third stage is not completely rate controlling, so the experimentally observed fractionations should be lower than those predicted for the third stage alone.

From the point of view of isotope effect calculations the La Mer addition compound is very similar to the tetrathionate ion, so that the isotope fractionations to be expected in the third stage of the La Mer mechanism should be similar to those obtained in the decomposition of tetrathionate. From the experimental results on this decomposition (23) the thio sulfur and sulfite sulfur isotope effects in the decomposition of the La Mer addition compound should be ~ -8 p.p.t. and ~ -7 p.p.t. respectively.

Calculations may be made, assuming the rate-controlling step in the La Mer addition compound decomposition to be the breaking off of an $SO_3^=$ group. These are not presented here since they are formally the same as calculations made for the decomposition of tetrathionate (23). However, the results of such calculations confirm the arguments of the above paragraph in that they predict isotope effects which are smaller than those observed experimentally.

Thus the isotope effects are too small and do not have the correct relative magnitudes, also the dilution effect, caused by the preceding stage of the La Mer mechanism being partially rate controlling, will further reduce the net isotope effects.

CONCLUSIONS

The calculations and arguments in the preceding section show that it is difficult to explain the isotope effects observed experimentally in the decomposition of thiosulfate in terms of a unimolecular model or in terms of the Davis or La Mer mechanisms.

However, the second model considered, in which the decomposition of thiosulfate is considered to be a one step bimolecular process, can lead to predictions in accord with experiment. When the isotope effects for this model are calculated, using atomic masses rather than mass fragments and a p factor of 0.1, then good agreement is obtained, both for the absolute magnitude of the effects and their relative values. Considering the physical nature of the model chosen, it seems reasonable that atom rather than mass fragments should be significant and that the p value for the reaction should indicate that bond cleavage is somewhat more advanced than bond formation.

Received April 21, 1965

ABSTRACT

The crystal structure of erbium titanate, $Er_2Ti_2O_7$, has been shown by X-ray and neutron powder diffraction to be of the cubic pyrochlore type, with $a_o = 10.0762 \pm 6$ Å. Least-squares isotropic refinement based on resolved single reflections gave $x(O_2) = 0.4200 \pm 10$ and $R = 2.25\%$. Ionic and neutral X-ray scattering factors gave practically identical results. The six equal Ti—O_2 distances in the distorted coordination octahedron of the Ti atom are 1.955 ± 5 Å. The two short (apparent) Er—O distances are 2.1815 ± 5 Å (Er—O_1) and 2.471 ± 8 Å (Er—O_2). The infrared spectrum of the titanate in the region 1 600 to 250 cm^{-1} shows features similar to those encountered in the spectra of other simple oxygen compounds of titanium.

INTRODUCTION

Previously we had occasion to examine compounds of the type $Ln_2Ti_2O_7$ (La = La, Pr, Nd, Sm, Gd, Dy, Ho, Er, and Y) prepared by firing intimate mixtures of the corresponding sesquioxide (or Pr_6O_{11}) and rutile in air (1). Some of these compounds (La, Nd, Sm, Gd, Dy, Yb, and Y) had been investigated by Roth (2), who stated that the crystal structures of the Sm, Gd, Dy, Yb, and Y titanates were similar to that of pyrochlore, $NaCaNbTaO_6F$ (3–6), while the X-ray powder patterns of the La and Nd compounds strongly suggested distorted structures of the pyrochlore type. Our results confirmed this finding to the extent that the titanates of Sm, Gd, Dy, Ho, Er, and Y gave very similar patterns, indexable on a cubic unit cell of the pyrochlore symmetry, whereas the powder patterns of the La, Pr, and Nd compounds were different and much more complex. Very recently Brixner (7) prepared the complete series of these lanthanon titanates and reported the unit-cell dimensions of the cubic members, again in agreement with Roth's results.

To demonstrate the similarity of the cubic titanates with pyrochlore Roth calculated the intensities of the reflections 111, 222, 400, 331, and 333 + 511 for $Sm_2Ti_2O_7$. The atoms were assumed to be distributed in a unit cell of symmetry *Fd3m* as follows (origin taken at center (8)):

16 Sm in 16(*c*): 000 etc.
16 Ti in 16(*d*): $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ etc.
8 O_1 in 8(*a*): $\pm$(1/8, 1/8, 1/8) etc.
48 O_2 in 48(*f*): *x*, 1/8, 1/8 etc.

Two values of *x*, 0.375 and 0.414, were used in the calculation. The latter value was reported by Byström (6) for the cubic pyrochlore $Cd_2Ta_2O_7$, while $x = 0.375 = 6/16$ applies to a double cell of the fluorite type, with eight oxygen atoms missing from the equipoint 8(*b*): $\pm$(3/8, 3/8, 3/8) etc.

The agreement between the diffractometer peak heights and the calculated intensities was poor for both parameter values, but similar calculations for $Nd_2Zr_2O_7$, $Y_2Zr_2O_7$, and

$Nd_2Sn_2O_7$ in the same paper gave a fair fit. The higher value gave better agreement in all four cases. Roth concluded that the parameter of the oxygen atom in $Sm_2Ti_2O_7$ was slightly different from that in $Cd_2Ta_2O_7$.

The evidence presented by Roth seems to indicate that it is reasonable to assume a pyrochlore-type structure for the four compounds, and that x is greater than 0.414. However, since the shape of the coordination figure of the Ti atom in the pyrochlore structure depends on x (for $x = 7/16 = 0.4375$ it is a regular octahedron of oxygen atoms), in the absence of an accurately determined value of the parameter an important feature of the structure remains unknown. Furthermore, the contribution of O_1 to the structure factor of $Sm_2Ti_2O_7$ is relatively small, and it is even less significant in the two zirconates and the stannate. Thus the possibility that the eight O_1 atoms are distributed statistically over 8(*a*) and 8(*b*), or that they are entirely in 8(*b*), may not be great, but it cannot be ruled out unless the observed intensities are shown beyond doubt to fit the pyrochlore structure better than any other reasonable model.

For this reason we carried out a more detailed investigation of the crystal structure of one of the cubic titanates. $Er_2Ti_2O_7$ seemed the best choice. It gave powder patterns of very good quality, and it was well suited for a neutron diffraction study, since the absorption cross-section of erbium is lower than that of Sm, Gd, or Dy, and at the same time the large quantities of material needed for neutron powder diffraction were more readily procurable.

EXPERIMENTAL

Erbium oxide of 99.9% purity (Lindsay Chemical Division, American Potash & Chemical Corporation, Code No. 1305; main impurities, Ho and Tm), which had been calcined at 600 °C, was thoroughly mixed with rutile (TiO_2, Fisher certified reagent) by grinding the fine powders together and brushing the resulting mixture repeatedly through a 200 mesh screen. Disks 1 in. diameter were then pressed at 10 000 p.s.i. without binder.

Two batches of $Er_2Ti_2O_7$ were prepared, one for exploratory and X-ray work, and another, totalling about 40 g, for neutron diffraction experiments. Green disks of the first batch were fired, on recrystallized alumina support in open air, for 1 h at 1 300 °C, cooled in furnace, transferred to another furnace, fired at 1 400 °C for 2 h, and again cooled in furnace. The first firing cycle took 1 day, the second, 2 days. Powder photographs of the titanate taken before and after the second firing were practically identical.

The second batch was fired, in a 2 day cycle, at 1 400 °C for 2 h and cooled in furnace. The fired disks were crushed and ground to pass a 325 mesh screen. The powder was pressed again and refired in a similar manner with a 4 h soaking. The final product obtained by crushing and grinding the sintered material was a pale-pink powder which passed easily a 325 mesh screen.

A thermogravimetric analysis (t.g.a.) run on a green pellet of about 2.6 g in a carefully adjusted Stanton HT-SM thermobalance, which was sensitive to ±1 mg (heating rate, 6 deg/min; Pt crucible in stagnant air), indicated no change in weight on heating from room temperature to 1 400 °C.

Well-exposed powder photographs of both batches still contained what appeared to be the residual 110 reflection of the rutile pattern, of an estimated intensity of about 0.4 (relative to the strongest line of intensity 100).

Integrated X-ray intensities were obtained by 2θ counting scans of the peaks at 1/8° (2θ) / min and subtracting appropriate background counts. Generous allowance was made for background on both sides of a peak. Three complete rounds, and additional counts wherever they appeared desirable, were taken. The shape of the $\sigma(\Delta N)$ vs. N curve followed reasonably closely $N^{-\frac{1}{2}}$ vs. N, the precision σ being 0.8–2% for I_o between 20 and 100, 0.2–3.3% for I_o between 5 and 20, and 1–25% for I_o less than 5. A Norelco diffractometer with a proportional counter, pulse-height analyzer, and rotating specimen holder were used both for counting and for survey charts. The generator was a Philips PW 1010 unit with additional external stabilization. Cu K_α radiation ($\lambda\alpha_1 = 1.54051$ Å) filtered with nickel, and 1° slits were employed throughout, except for the 111 and the correlation peaks, where ½° slits had to be substituted to obtain the correct intensities.

Special attention was paid to the preparation of the specimen. After preliminary experiments powder of batch 2 (325 mesh) was slightly moistened with a solution of polyvinyl alcohol in acetone and pressed to a circular disk 1 in. diameter and 3/16 in. thick. The disk had a completely smooth surface and could be inserted directly into the rotating specimen holder. Comparison with smear mounts showed good agreement between specimens prepared by the two methods, but the intensities from the pressed disk were much higher and more reproducible, especially in the low-angle range. There was no indication of preferential orientation, presumably because of the great fineness of the powder and the high crystal symmetry.

The lattice parameters were obtained from powder photographs taken with a 114.6 mm diameter camera of the Straumanis type. Nelson-Riley extrapolation and least-squares refinement gave final values of a_o with very small spreads. The correction for refraction fell within the limits of uncertainty of the determination.

The neutron diffraction experiments were performed at the NRX reactor of the Atomic Energy of Canada Ltd. at Chalk River, Ont. The erbium titanate powder was enclosed in a flat circular container 4 in. diameter and 1/8 in. thick, formed by 0.01 in. thick vanadium foil held in an aluminium ring mount. The neutron beam was monochromatized by reflection from the 111 plane of a germanium crystal (λ = 2.234 Å). The third-order content of the monochromatized beam was reduced to about 2% with a 5 in. thick quartz single-crystal filter, whose absorption had been calibrated in dependence on neutron energy, and by differential absorption in the specimen. A straight-through count was used to obtain the absorption correction. The 2θ transmission scan covered the angular range of 2θ from 20 to 91° in ¼° (2θ) increments. The counting time per point was 5–6 min. There was some contamination of the recorded pattern from the aluminium mount.

Because of accidental circumstances at the time the neutron diffraction patterns were not of a quality sufficient for a refinement of the oxygen parameter, but they were adequate for a confirmation of the results of the X-ray study.

Infrared spectra of $Er_2Ti_2O_7$ and of comparison compounds were recorded using KBr pellets on a Perkin–Elmer Model 521 spectrophotometer from 4 000 to 250 cm^{-1}.

Computations were performed on Royal McBee LGP-30 and IBM 1620 (40K) computers. The final refinement of the structure from X-ray data was carried out by Dr. F. R. Ahmed using programs described in ref. 9.

RESULTS OF THE X-RAY STUDY

The lattice parameter of the second batch of erbium titanate, a_o = 10.0762 ± 6 Å, differed remarkably little from that of the first batch, 10.0759 ± 10 Å. The high degree of compatibility of both a_o values with those of other $Ln_2Ti_2O_7$ phases will be discussed elsewhere, but it should be noted that they are higher than the value reported for $Er_2Ti_2O_7$ by Brixner (7), 10.069 ± 1 Å.

Preliminary intensity calculations based on the pyrochlore model (case I, Table III) and using neutral atomic scattering factors* corrected for dispersion (10) indicated that $x(O_2)$ was in the vicinity of 0.425. This value, together with assumed values of the individual isotropic temperature factors, $B(Å^2)$, was used as the initial value in a block diagonal least-squares refinement based on 20 $|F_o|$ from single, fully resolved reflections (Table II). A weighting scheme defined by $1/w = 1 + [(K|F_o| - b)/a]^2$ (a = 300, b = 400, K, scaling factor) was adopted (9). The refinement was repeated till the slowly converging unweighted R(neutral) was brought down to 2.42%; this was accomplished in 9 cycles (Table I). The initial values for the 5th cycle were estimated from the averages of the parameters obtained in the preceding cycles, and for cycles 6 to 8 the shifts were multiplied by 0.5 to avoid oscillation.†

For comparison, the pyrochlore structure was refined using the tabulated scattering factor for Ti^{3+} and graphically estimated factors for Er^{3+} and O^{2-}, all corrected for dispersion (10).‡ To prevent oscillation of the parameters the shifts were multiplied by 0.5 from the beginning. This procedure resulted in a substantial measure of agreement already in the 2nd cycle (Table I). The slowly converging R(ionic) was reduced after 7 cycles to 2.25%, which is a value only slightly lower than R_9(neutral).

Inspection of the differences between F_o and F_c suggested that the refinement might be improved further if the very weak reflections 931 and 953 were disregarded altogether, as with 931 and 953 omitted R_9(neutral) decreased to 1.88% and R_7(ionic), to 1.63%. This

*Er, *Thomas-Fermi-Dirac; oxygen and* Ti, *self-consistent field.*

†*At the beginning of the refinement* $|F_o|$ *(311) was by mistake taken to be 368.3 instead of 212.6. Although* $x(O_2)$ *refined, after 4 cycles, to 0.4188, and* B(Er), B(Ti), *and* $B(O_2)$ *to 0.644, 1.568, and 0.667 respectively, with R decreasing from 7.67 to 6.57%, the single wrong* $|F_o|$ *caused* $B(O_1)$ *to increase steadily to 18.90. A similar situation resulted with the ionic scattering factors. Considering that all atoms contribute to the intensity of 311, it is interesting to note the selectivity of the effect.*

‡Er^{3+}, *extrapolated, Thomas-Fermi-Dirac;* Ti^{3+}, *self-consistent field;* O^{2-}, *extrapolated, self-consistent field.*

*All 20 $|F_o|$ of Table II were used in the refinement. With $F_o(931)$ and $F_o(953)$ omitted the standard deviations for the last cycle were 0.385 for the neutral and 0.338 for the ionic scattering factors.

would leave 18 $|F_o|$, of which 14 contain contributions from both the metal and the oxygen atoms, and 4 (222, 622, 662, and 10.6.2) from the metal atoms only.*

Further refinement on this basis, using as initial parameter values those from cycles 9(neutral) and 7(ionic), did not improve R(neutral) and R(ionic) but made them progressively worse. At the same time the scale factor and $x(O_2)$ remained practically unchanged, while B(Er) increased somewhat, B(Ti) varied slightly, and $B(O_2)$ increased, after 3 cycles, by some 40%. However, $B(O_1)$ decreased and eventually assumed negative values. A somewhat worse but otherwise much the same result was obtained by omitting, in addition to 931 and 953, the "metal only" reflections 222, 622, 662, and 10.6.2.

Although in the first refinement, which included all 20 $|F_o|$, the final values of $B(O_2)$ were practically identical with B(Ti), and $B(O_1)$, compared with B(Er) and B(Ti), seemed far too low, the still smaller, and eventually negative, values of $B(O_1)$ resulting from the second refinement were clearly unreasonable. Since the scale factor and $x(O_2)$ remained practically constant further refinement using a reduced number of $|F_o|$ was considered unprofitable. In fact, it was felt that at this stage the uncertainties in the scattering factors and the dispersion corrections set a far more serious limit to further improvement of the accuracy. Moreover, the slow convergence of R seemed to indicate that the disparity of f(Er) and f(O), and the location of Er and Ti in special positions, were not favorable to further progress of the refinement.

The final values of the parameters are then those of cycle 9 for the neutral atoms and cycle 7 for the ionic atoms (Table I). In particular, $x(O_2)$ = 0.4202 and 0.4200 for the

The intensities of the reflections originating in the oxygen atoms only (cf. Table II) were too low to be measured with confidence.

*Scaled to I_c(case I). The I_c values are normalized to I_c(222). Reflections with zero contribution from the oxygen atoms have been omitted.
†Zero contribution from the metal atoms.
‡Includes all observed intensities up to 844.
§Includes 111, 311, 331, 511 + 333, 531, 533, 711 + 551, 731 + 553, 733, 751 + 555, 911 + 753, and 931.

neutral and ionic case respectively. These values were used to calculate the intensities of the observable reflections. The calculated intensities, I_c, were normalized to $I_c(222)$ and the absolute $|F_o|$ were converted to the I_o values listed in Table II. The agreement indices, $\Sigma|I_c - I_o|/\Sigma I_o$ and $\Sigma I_c/\Sigma I_o$, were 3.55% and 1.014 for the neutral and 3.67% and 1.014 for the ionic scattering factors. When intensities lower than 2 were rejected the corresponding values were 3.16%, 1.006, 3.03%, and 1.007 respectively.

The standard deviation $\sigma(x)$ was ± 0.0010 for the neutral and ± 0.0009 for the ionic model. These uncertainties are greater than the difference between x(neutral) and x(ionic). This circumstance, together with the consistently lower values of $\sigma(B)$ for the ionic scattering factors, seems to justify taking 0.4200 ± 10 as the final value of $x(O_2)$. No attempt has been made to attribute special significance to the low thermal parameters of both oxygen atoms.

ALTERNATIVE STRUCTURES

In view of the relatively small contribution of O_1 to the diffraction intensities the possibility of existence of alternative structures was examined. Intensities were calculated from the final parameter values (ionic) for the following distributions:

case II: 8 O_1 in 8(b), 8(a) unoccupied;

case III: 8 O_1 distributed at random over 8(a) and 8(b).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

As a check of the sensitivity of the intensities to the location of O_1 a fourth alternative, case IV, was considered, in which the 8 O_1 atoms were omitted. The possibility of a statistical distribution of the Er and Ti atoms over 16(*c*) and 16(*d*) was disregarded because of the low *R* values for case I.

The alternative distributions did not give as good an agreement as case I for those reflections that involve both the metal and oxygen atoms (Table III). The differences between I_o and I_c were particularly noticeable for 111, 311, 331, and 511 + 333. At higher Bragg angles the differences were of the order of the experimental error for case I and could no longer be used to distinguish between the four alternatives.

Since the intensities of Table III have been normalized to $I_c(222)$, to which the oxygens do not contribute, the calculated intensities for cases I–IV can be compared directly. However, the temperature factors and $x(O_2)$ used in calculating I_c were in all four cases those of cycle 7(ionic), and the I_o were scaled with respect to case I. It may be objected that if case II or case III had been taken as models for the least-squares refinement, case I might have emerged less favorably in the comparison.

Calculation shows that $I_c(111)$ for case I changes, for small variations in x, by about $5.6\,\Delta x.I$, so that for $\Delta x = \pm 0.03$ the change in the intensity would be ca. ± 4.4. At the same time $I_c(840)$, $I_c(844)$, and $I_c(880)$, which change with x but not with the location of O_1 and for which the indices are sufficiently high to magnify the effect of Δx considerably, would change in the following manner:

	$I_c - I_c/I_o - F_c/\lvert F_o\rvert$		
hkl	$\Delta x = -0.03$	$\Delta x = 0$	$\Delta x = 0.03$
840	7.84 − 0.79 − 0.88	10.06 − 1.01 − 1.00	11.32 − 1.14 − 1.06
844	12.56 − 1.22 − 1.12	9.91 − 0.96 − 1.00	8.20 − 0.79 − 0.91
880	5.53 − 1.23 − 1.14	4.25 − 0.95 − 1.00	4.14 − 0.94 − 0.99

It is thus seen that in order for the ratios $I_c(840):I_c(844):I_c(880)$ and $F_c(840):F_c(844):F_c(880)$ to remain reasonably close to the observed ratios the value of Δx must be quite close to zero; and the same holds for other reflections of this type, and a fortiori for the "metal only" reflections.

Consequently the Δx-induced variation in $I(111)$ will be insignificant and the differences between $I_o(111)$ and $I_c(111)$ for cases I, II, and III will be produced almost entirely by the location of O_1; and similarly for the intensities of the other critical reflections. Inspection of the index $\sum|\Delta I|/\sum I_o$ (Table III) for the three physically meaningful cases then leaves no doubt that case I is the correct choice. This argument can of course be strengthened by taking into consideration other suitable reflections, such as 12.4.0, and by calling to attention the necessity of matching the observed and the calculated intensities of the "metal only" reflections 222, 622, 662, and 666 + 10.2.2, all of which are strong.

A more obvious demonstration of the correctness of the pyrochlore model was provided by the neutron diffraction pattern. With $b(O) = 0.577$, $b(Ti) = -0.34$, and $b(Er) = 0.79 \times 10^{-12}$ cm (natural isotopic contents) (10), the neutron scattering amplitudes are particularly favorable for locating the O_1 atom, since the non-zero contributions of Ti and Er to structure factors with h, k, l all even will now have opposite signs and thus counteract each other, and the oxygen contributions will be appreciable.

Neutron diffraction intensities were calculated from the final parameter values for the neutral atoms for first-order reflections up to 620 and for third-order reflections up to 19.1.1. Although third-order reflections with very high $h^2 + k^2 + l^2$ had to be taken into

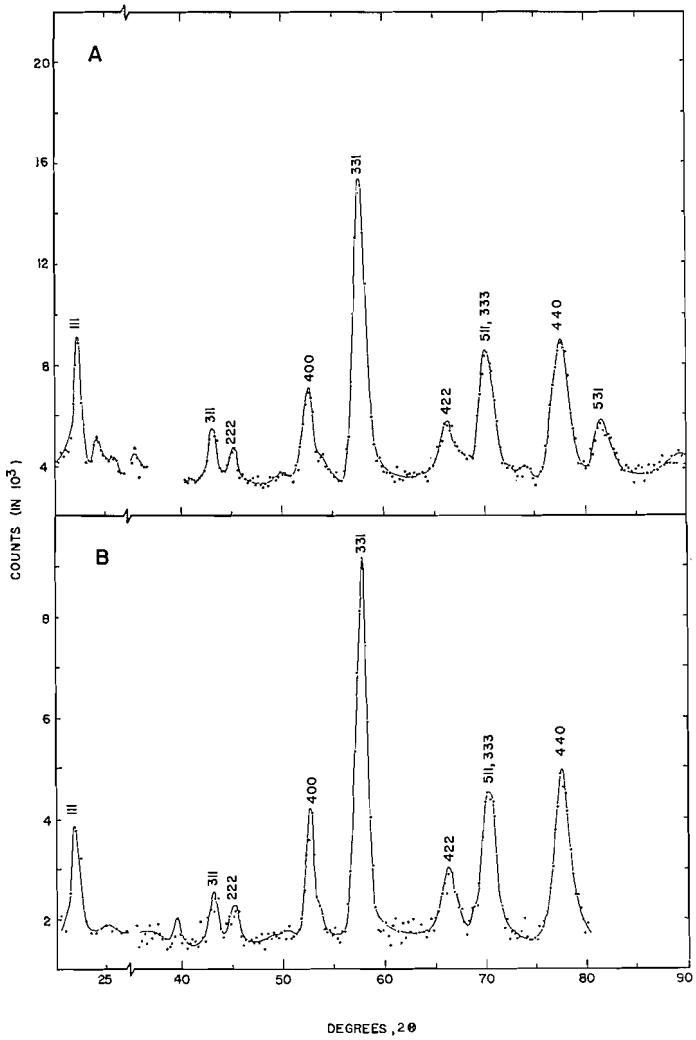

FIG. 1. Neutron powder diffraction patterns of erbium titanate. A, unfiltered beam; B, quartz filter in the beam.

account, it was found that the third-order contamination in the quartz-filtered spectrum amounted to only about 2% of the first-order intensity, so that only the strongest third-order reflections had a noticeable effect on the diffraction pattern.

The extent of agreement between the observed patterns and the intensities calculated for cases I–IV can be judged by comparing Fig. 1 and 2. In spite of the uncertainty in the amount of the third-order contamination there can be little doubt that the pyrochlore model is the only one that fits the observed patterns.

DESCRIPTION OF THE STRUCTURE

The principal features of the structure may be seen in Figs. 3–5. Figure 5 in particular shows the arrangement of the distorted TiO_6 octahedra (with the six O_2 atoms equidistant) about the erbium atoms, and the coordination scalenohedron of the six O_2 atoms (in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

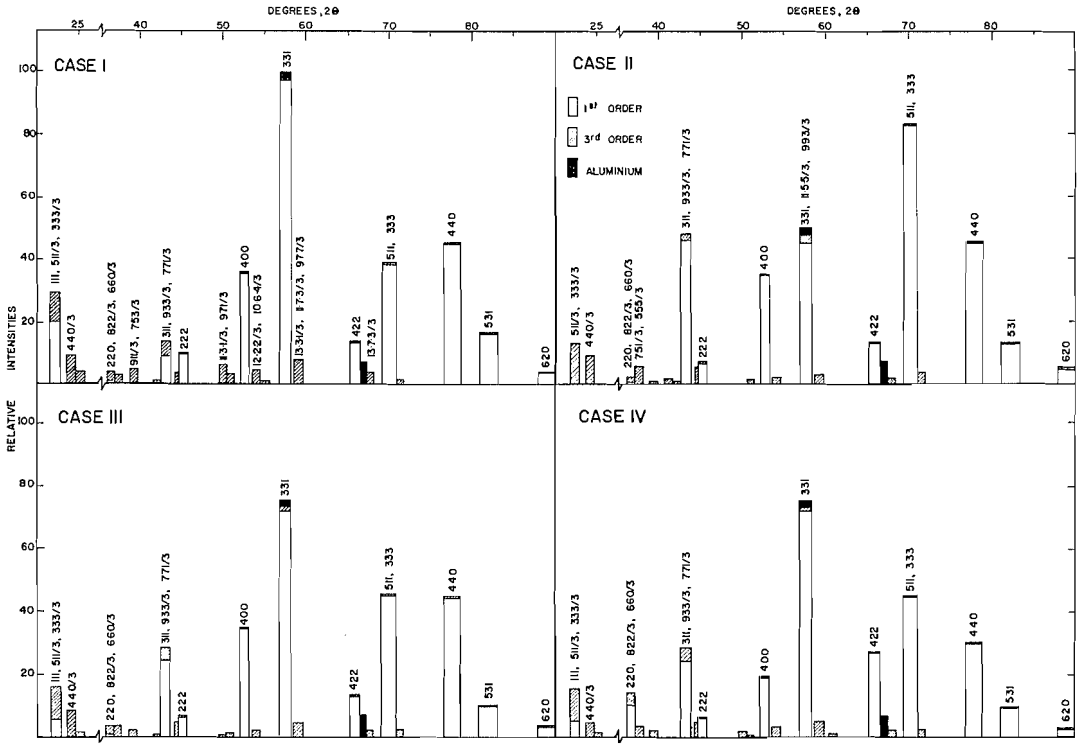

FIG. 2. Representation of the neutron diffraction intensities calculated for cases I–IV, with 2% of third-order contamination. The column heights for case I have been adjusted relative to the observed peak heights. The column heights for cases II–IV are on the same scale as those for case I. The two Al peaks are spurious first-order reflections from 111 and 200. Note the break in the angular range between 27 and 35° (2θ).

equatorial positions) and the two O_1 atoms (in polar positions) about each erbium atom. This scalenohedron is related, via a rhombohedron, to the coordination cube of a metal atom in the fluorite structure, the latter being, geometrically, the limiting case of the pyrochlore structure for $x = 3/8$.

Each O_1 atom is completely enclosed in a cage of four erbium atoms at the corners of a regular tetrahedron. This isolation from the TiO_6 framework may be expected to affect the vibrational freedom of the O_1 atoms. It might account for the low value of $B(O_1)$ if the temperature factor could be considered a physically meaningful quantity rather than an arithmetical parameter of the refinement process; and it might be helpful in the interpretation of the infrared spectrum.

Apparent interatomic distances and selected bond angles are listed in Table IV. The figures indicating precision refer to the last decimal. They are conservative estimates of σ obtained from the uncertainties in a_0 and x. In the absence of an anisotropic refinement of the thermal parameters no attempt has been made to take into account thermal motion in computing the distances. Obviously those distances that involve O_2 depend ultimately on the reliability of the scattering factors and dispersion corrections used in the refinement. That apparent interatomic distances in simple compounds should be viewed with caution even when based on single-crystal data and a large number of observed reflections has been demonstrated for $CaWO_4$ in a recent paper by Burbank (11), in which a set of 828 $|F_o|$'s obtained by a conventional single-crystal method, and a set of 54 $|F_o|$'s derived from

neutron diffraction intensities, are compared with 104 $|F_o|$'s based on the author's absolute intensity measurements.

The only Er—O distances that were found in the literature were those for Er_2O_3 obtained from neutron diffraction (12). The shorter of the two Er—O distances in erbium titanate, Er—O_1, compares well with the shortest distance in the oxide, but the Er—O_2 separation is appreciably greater than any of the Er—O distances in Er_2O_3.

The shortest Ti—O distance, 1.955 Å, is seen to be very close to the average of the Ti—O distances in a variety of simple oxygen compounds of titanium (Table V), almost all of which contain Ti atoms in octahedral environment.

Each O_2 atom is surrounded by two Ti atoms at 1.955 Å, two Er atoms at 2.471 Å, four O_2 atoms at 2.599 Å, and another four O_2 atoms at 2.921 Å (Fig. 3). The symmetry of this coordination is *mm* (Fig. 5).

INFRARED SPECTRUM

The transmission spectra of erbium titanate and of Er_2O_3 (calcined at 600 °C; C type), rutile (calcined at 950 °C), and tetragonal $BaTiO_3$ of high purity (prepared by the double-oxalate method and calcined at 950 °C; loose unpoled powder) are shown in Fig. 6. The portions of the spectra between 4 000 and 1 600 cm^{-1} show no characteristic features and have been omitted.

The spectrum of Er_2O_3 (A, 563; B, 505; C, 469; D, 414; E, 377; F, 332; G, 318; and H, 291 cm^{-1}) is better defined than the Nujol-mull spectrum published previously by Baun and McDevitt (27), for which the positions of the band maxima were reported as 563, 500–345 (broad band), 325, and 285 cm^{-1}.

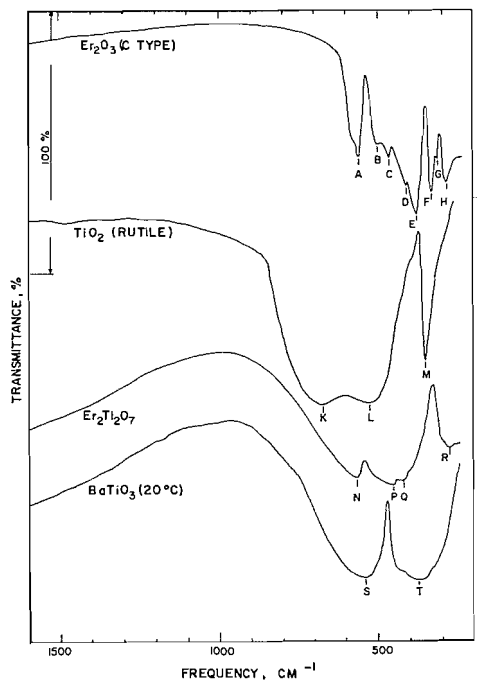

FIG. 6. Infrared spectra of erbium titanate and comparison substances. For positions of the absorption maxima see text.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The absorption maxima were at 675 (K), 515 (L), and 350 (M) cm^{-1} in the rutile spectrum, and at 535 (S) and 370 (T) cm^{-1} in the spectrum of $BaTiO_3$. Although standard KBr-pellet technique was used, the peak maxima were not in complete agreement with the band centers reported for $BaTiO_3$ in pressed KBr disks by Last (28), 540 (or 545?) and 400 cm^{-1}, and the bands were broader. This discrepancy may be real and may have originated in the physical state of the $BaTiO_3$ powder. Last powdered a small section of a single crystal to a particle size of about 1 micron, whereas we used polycrystalline powder obtained by calcining barium titanyl oxalate. The fine powder passed 325 mesh with ease and was subsequently ground with KBr. It is possible that a higher calcining temperature and a more careful reduction of the particle size may have produced a spectrum more closely similar to Last's, though the absorption maxima reported in Last's paper for transmission spectra obtained with a thin single crystal of $BaTiO_3$ and with polarized radiation were appreciably lower, 495 and 517 cm^{-1} for the electric vector parallel to the *a* axis and to the *c* axis respectively. They would be lowered further by correcting for surface reflectivity of the thin crystal plate.

The positions of the absorption maxima in the spectrum of erbium titanate were 560 (N), 450 (P), 425 (Q), and 280 (R) cm^{-1}. The gross features of the spectrum resemble those of rutile and, allowing for a shift towards higher frequencies, also those of $BaTiO_3$.

It seems to be generally agreed that Last's assignment of the highest-frequency band in $BaTiO_3$ to a Ti—O stretching vibration, ν_1, is correct. His assignemnt of the lower-frequency (T) band to a Ti—O—Ti bending mode, ν_2, has been the subject of some discussion (29, 30, 31), but recent detailed studies and *K–K* analyses of the spectra of titanate perovskites (32), and comparison of the spectra of $BaTiO_3$ and rutile with the spectra of the corresponding model structures $KMgF_3$ and MgF_2 (33, 34), indicate that neither ν_1 nor ν_2 are affected by the nature of the heavy cation and that ν_2 indeed is a bending mode of the TiO_6 octahedron. A similar situation exists in rutile.

It is tentatively suggested that while the main, broad absorption bands of the erbium titanate spectrum arise from Ti—O modes, the minor features of the spectrum (shoulders and subsidiary maxima in the PQ band) are probably associated with the oxygen environment of the erbium atoms. In view of the greater complexity of the erbium titanate structure and the different arrangement of the TiO_6 octahedra a more satisfactory interpretation of the spectrum will have to await a detailed comparative study of the spectra and dielectric characteristics of $Ln_2Ti_2O_7$ and related compounds.

CONCLUSION

The above results have established that $Er_2Ti_2O_7$ has the pyrochlore structure, with some distortion in the TiO_6 coordination octahedra. From the similarity of the diffraction patterns of erbium titanate with those of the other $Ln_2Ti_2O_7$ preparations it may be concluded that the titanates of the elements from Sm to Lu belong to the same structure type, as suggested previously (2, 1, 7).

For a more direct confirmation, and to determine if the parameters of the O_2 atom differ significantly from one lanthanon to another, the crystal structures of two other titanates are now being refined in similar manner. At the same time the examination of the infrared spectra is being extended to the other titanates.

ACKNOWLEDGMENTS

We are indebted to Dr. F. R. Ahmed of the Division of Pure Physics, National Research Council, Ottawa, for the refinement of the structure. We should also like to express

CORRELATION OF ETHYLENIC PROTON COUPLING CONSTANTS WITH THE ELECTRONEGATIVITY OF SUBSTITUENTS

INTERPRETATION OF THE DEVIATIONS OF BROMO AND IODO SUBSTITUENTS

F. HRUSKA,[1] G. KOTOWYCZ,[1] AND T. SCHAEFER[2]

ABSTRACT

It is shown that for the geminal, *cis* and *trans* proton coupling constants in vinyl bromide and vinyl iodide there exist significant deviations from an inverse linear relationship between coupling constants and the electronegativity of the substituent in monosubstituted ethylenes. By an adaptation of the box model of Juan and Gutowsky to the ^{13}C—H coupling constants in the system $CH_2{=}{=}^{13}CHX$, it is shown that there are related anomalies in the ^{13}C—H coupling constants in vinyl bromide and vinyl iodide. A comparison of the three types of ^{13}C—H coupling constants in some vinyl compounds suggests that there may be an interaction between the substituent and the C—H bond which affects the coupling constant but not the s-character of the carbon orbital in the bond.

INTRODUCTION

Following the suggestion of Banwell and Sheppard (1), an inverse proportionality between the three proton coupling constants in monosubstituted ethylenes ($J_g \equiv J_{gem}$, $J_c \equiv J_{cis}$, $J_t \equiv J_{trans}$) and the electronegativity, E_X, of the substituent, X, has been accepted (2–4). Theoretical support for such a relationship was provided by Karplus (5), who showed that substituent-induced changes in the hybridization of the carbon atoms in the fragment HCCH are the primary cause, as opposed to a direct inductive effect on the polarity of the C—H bonds (6, 7).

Some time ago, one of us noted that the coupling constants in vinyl bromide deviated consistently from the straight line relationship (3). Banwell and Sheppard indicated a similar, if smaller, deviation for vinyl chloride (1). In this paper we point out the extent of these deviations and discuss them in the light of present knowledge of spin–spin coupling in vinyl compounds.

Two papers by Goldstein *et al.* appeared on the proton spectra of the vinyl halides (8, 9). While they did not discuss electronegativity correlations, the very accurate values of the proton coupling constants given there will be used in our discussion.

Preferred Values of Coupling Constants and Electronegativity

The geminal proton coupling, J_g, in ethylenic compounds is often strongly solvent dependent (9, 10). According to Watts and Goldstein (9), it depends on the dielectric constant of the medium. They extrapolate the values of J_g for the vinyl halides and vinyl cyanide to a "zero-field" value, i.e., to a medium with unit dielectric constant. Since the error in this extrapolation is somewhat uncertain, we prefer to use the values of J_g, J_c, and J_t in cyclohexane at infinite dilution. In any case, our conclusions would not be changed by the use of the "zero-field" values of J_g. The solvent dependence of J_c and J_t is relatively small and certainly not large enough to cause ambiguities even if values in different solvents are used.

In addition to the vinyl halides and vinyl cyanide, Table I lists J values for other compounds. These were chosen for one or more of the following reasons: The J values

were accurately determined, preferably in solvents of low dielectric constant (e.g. the vinyl ethers were measured in tetramethylsilane); the J values were needed to cover the range 1 to 4 of E_X; the E_X values of the substituents were fairly reliable, i.e., the E_X values from different scales agreed fairly well.

E_X values from Pauling (11), Huggins (12), Gordy (13), Pritchard and Skinner (14), and

from Cavanaugh and Dailey (15) were considered in arriving at the values in Table I. For substituent groups the E_X values of Cavanaugh and Dailey were favored since these derive from chemical shift measurements and have been used in a variety of coupling constant correlations (16, 17). In any case, the various E_X values do not deviate by more than about 0.1 unit from the set in Table I.

Linearity of the Correlation of J with E_X

In Figs. 1 to 4, the individual J_g, J_c, and J_t values and their sum are plotted versus E_X. The following features of these plots are noted. Within experimental error, with the *consistent* exception of I and Br, a change in E_X of 0.1 unit is sufficient to bring the J values on to the solid straight line. Two other exceptions are S, which deviates from the lines except for its J_c value, and Al where only J_g deviates outside of $\Delta E_X = 0.1$ limit.* A third exception is J_c for X = H. If I and Br are disregarded, 5 points out of 44 in Figs. 1 to 4 deviate outside the $\Delta E_X = 0.1$ limit. Out of these 5, S accounts for 3.

The points for I and Br, 8 in all, deviate negatively from the solid line. The extent of these deviations can best be measured from Fig. 4. The average deviation, including S but excluding I and Br, is 0.8 c/s in a range of about 36 c/s in $J_g + J_c + J_t$. The deviations of I and Br are −6.4 and −5.4 c/s, respectively; an average of −5.9 c/s. On the other hand, if S is excluded together with I and Br, an average deviation of 0.5 is found in 36 c/s and the average deviation of S, Br, and I is now −4.5 c/s.

It is suggested, therefore, that I and Br (and perhaps S) deviate significantly from the assumed straight line relationship. In other words, I and Br appear to be much more electronegative than the E_X values in Table I suggest. In fact, Br would appear to be more electronegative than Cl (see Fig. 4) and I about as electronegative as Cl. This anomaly is discussed below.

From the solid lines in Figs. 1 to 4, the dependence of the J values on E_X can be written

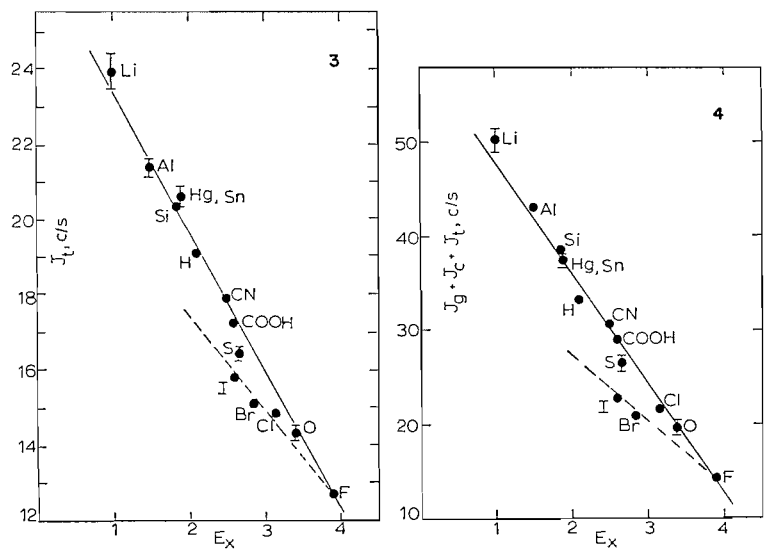

FIG. 3. A plot of the *trans* proton coupling constant versus E_X in some vinyl compounds.
FIG. 4. The sum of the geminal, *cis* and *trans* proton coupling constants plotted versus E_X in some vinyl compounds.

**The proton resonance spectrum is that of the etherate of trivinylaluminium and therefore there is an additional uncertainty in either J or E_X.*

as $\Delta J_c = -4.7\Delta E$, $\Delta J_t = -3.2\Delta E$, $\Delta J_g = -3.3\Delta E$, $\Delta(J_g + J_c + J_t) = -3.9\Delta E$. Karplus (5) predicts $\Delta J_c > \Delta J_t$. A recent review suggests $\Delta J_c = -4\Delta E$ and $\Delta J_t = -3.3\Delta E$ (4).

Discussion of the Deviations for I and Br

(a) J Dependence on Other Molecular Parameters

In addition to the E_X dependence, other factors which may affect the proton coupling constants in these compounds are changes in bond angle, C=C bond length, exchange integrals, bond excitation energies, π-bonding, and molecular vibrations (5). From the available structural data on the vinyl halides and ethylene (18–24) and from the estimates given by Karplus (5), it appears unlikely that changes in bond angle or C=C bond length are responsible for these deviations. Thus, the C=C bond length appears to vary by less than 0.01 Å and any bond angle changes are also too small. Theory predicts +1.5 c/s as the π-electron contribution to J_c and J_t in ethylene (25). Hence, any reasonable change in π-bonding in vinyl bromide and iodide is too small to account for the observed deviations. Whether the other three factors would account for them is not known.

(b) Relation of Deviations to a Hybridization Model

However, it is interesting to note that I and Br cause anomalies in other coupling constants as well. In their discussion of $J(^{13}C—H)$ in methane derivatives, Juan and Gutowsky (26, 27) define a quantity Δ_X. It is derived from the $J(^{13}C—H)$ values and expresses the affinity for s-character of the substituent X and is expected to follow E_X. For the halogens Δ_X is virtually the same in spite of the large range of E_X. More precisely, on the box model in which changes in $J(^{13}C—H)$ are caused solely by rehybridization of the C—H bond, the experimental $J(^{13}C—H)$ values lead to Δ_X values which follow the order Br > I > Cl > F. Br and I appear to be more electronegative than Cl or F.

Juan and Gutowsky extend their treatment to substituted ethylenes and calculate the s-character in the carbon orbital of the C—H bond in the system $=^{13}CHX$ by using the Δ_X values for the substituted methanes. By a variation of their procedure, we have calculated Δ_X values for the halogens, the cyano group, and silicon from the experimental $J(^{13}C—H)$ values in the system $=^{13}CHX$ as follows.* For substituted methanes Juan and Gutowsky (27) write

$$0.25\Delta_X J_0 = J_{CH}(CH_3X) - J_{CH}(CH_4) \quad [1]$$

$$J_{CH} = J_0\alpha_H^2 \quad [2]$$

where $J_0 = 500$ c/s and α_H^2 is the s-character of the carbon orbital in the C—H bond. For ethylene we write†

$$0.316\Delta_X J_0 = J_{CH}(CH_2{=}{}^{13}CHX) - J_{CH}(CH_2{=}CH_2) \quad [3]$$

$$J_{CH} = 156.4 \text{ c/s} = J_0\alpha_H^2 = (495 \text{ c/s})(0.316). \quad [4]$$

In these equations, account is taken of the actual structure of ethylene (22, 23) which has an HCH angle of 117.5°. Hence we use $\alpha_H^2 = 0.316$ for a C—H bond in ethylene and from the experimental $J(^{13}C—H)$ value in ethylene (28) the value $J_0 = 495$ c/s follows. This procedure normalizes to $\Delta_X = 0$ for H. From the available data (Table I) eq. [3] yields Δ_X values of F = 0.280, Cl = 0.240, Br = 0.257, I = 0.220, CN = 0.130, and Si = −0.097.

In Fig. 5 these Δ_X values are plotted versus E_X since they are expected to follow E_X,

*$J(^{13}C—H)$ values are not available for the other compounds in Table I.

†Contributions by π-electrons to $J(^{13}C—H)$ are expected to be ≈ 2 c/s (26, 31) and to vary little for the various substituents.

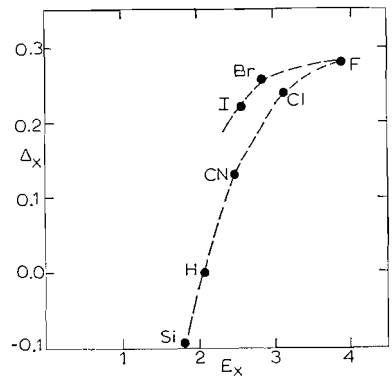

FIG. 5. The quantity Δ_X as defined and derived in the text for vinyl compounds plotted versus E_X.

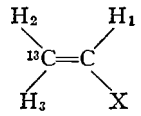
although not necessarily linearly. F, Cl, H, CN, and Si appear to fall on a smooth curve, from which I and Br deviate considerably. Effective E_X values of I = 3.0 and Br = 3.4 bring them on to the curve. In Fig. 4, effective E_X values of I = 3.1 and Br = 3.3 bring them on to the straight line relating $J_g + J_c + J_t$ to E_X. In their effect both on $J(^{13}C—H)$ and on $J_g + J_c + J_t$, I and Br appear to be much more electronegative than is normally accepted.

It seems reasonable to conclude that the anomalies in $J(^{13}C—H)$ and $J_c + J_g + J_t$ have a common origin. This behavior is expected if rehybridization is the reason for the change in $J(^{13}C—H)$ on substitution, since Karplus (5) finds the reason for the decrease in J_c and J_t as E_X increases in the rehybridization of the carbon atoms in the fragment HCCH.

(c) Rehybridization at the β-Carbon

J_c and J_t will depend also on the rehybridization of the β-carbon in CH_2=CHX. From the available data (8, 29, 30) it appears, however, that this is much smaller at the β-carbon. In structure I the $J(^{13}C—H_2)$ and $J(^{13}C—H_3)$ values are given in c/s. Juan and Gutowsky

X	$^{13}C—H_2$	$^{13}C—H_3$		X	$^{13}C—H_2$	$^{13}C—H_3$
CN	165.42	163.20		Br	160.26	163.63
F	162.16	159.18		I	159.20	164.09
Cl	160.89	162.64		Si	156.45	156.13



I

(27) suggest possible interactions between lone pairs on the substituent and the C—H bonds which affect $J(^{13}C—H)$ but not the s-character of the C—H bond. In that case, $J(^{13}C—H_2)$ would be least affected by such interactions. According to these authors, changes in the polarity of the C—H bond (ionic terms in the bond wave function) do not make an important contribution to $J(^{13}C—H)$.* Nevertheless, we note that $J(^{13}C—H_2)$ for H, I, Br, Cl, F, CN vary smoothly in the expected direction with the parameter μ/r, where μ is the substituent dipole moment and r is the C—X bond length. Thus, CN with $\mu \simeq 4$ D causes the largest change in $J(^{13}C—H_2)$, as would be expected if the C—H_2 bond is being polarized by electric fields to favor a contributing structure C^-H^+.

**The small deviations from addivity in polysubstituted halomethanes are in the wrong direction to be explained by polarity effects.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The $J(^{13}C—H_3)$ values do not vary in this way, the largest values occurring for I and Br. An interaction between the lone pairs on I and Br and the C—H_3 bond is again possible here. How such interactions would affect J_c and J_t is not obvious but a detailed theory will have to account for the parallel deviations of J_c, J_t, and $J(^{13}C—H)$. J_g behaves like J_c and J_t (Figs. 1 to 4) but the HCCH fragment calculations (5) do not make any predictions on this matter.

(d) Objections to the Rehybridization Model

Ranft (31) accepts the rehybridization model and rationalizes the anomalies in $J(^{13}C—H)$ for the methyl halides by writing

$$[5] \qquad J(^{13}C—H) = 64 + 15.4r(C—X)E_X.$$

In this way the calculated E_X values for the halogens agree well with their normally accepted values. Support for eq. [5] comes from the work of Bent (32). The p-character of the carbon orbitals concentrates in the direction of the more electronegative substituent (hence the E_X dependence of $J(^{13}C—H)$); while increasing p-character in the carbon bond to a more distant substituent increases overlap and therefore the C—X bond energy (hence the dependence of $J(^{13}C—H)$ on $r(C—X)$).

A necessary consequence is the concept of bent bonds as pointed out originally by Muller and Pritchard (33). This is because the "interorbital" angles corresponding to the hybridization parameters obtained from $J(^{13}C—H)$ data are consistently smaller than the observed bond angles (26). There is conflicting evidence as to whether the maximum electron density of a σ-bond always lies along the internuclear line or not (34, 35). In view of the behavior of the three $^{13}C—H$ couplings discussed above, it may be best not to treat $J(^{13}C—H)$ data as support for the concept of bent bonds.

CONCLUSIONS

The geminal, *cis* and *trans* proton coupling constants in vinyl bromide and vinyl iodide (and perhaps vinyl sulfide) show significant deviations from the linear inverse relationship between coupling constants and the electronegativity of the substitutent in vinyl compounds. An adaptation of the box model to the $J(^{13}C—H)$ values in vinyl compounds suggests that these anomalies in proton coupling constants are closely related to anomalies in $J(^{13}C—H)$ in vinyl bromide and vinyl iodide.

ABSTRACT

The screening effect of the diffuse layer on the self-atmosphere (or discrete-ion) potential of a counter-ion adsorbed from aqueous electrolyte on to a plane charged interface is investigated. A theory based on Fourier–Bessel integrals and the approximate method of Loeb and Williams for treating the potential distribution in the diffuse layer is presented. The distribution of counter-ions in the adsorption plane surrounding a specified ion adsorbed in the plane is expressed in terms of a two-dimensional grand canonical ensemble and this is approximated by a 'revised cut-off model'. The 'Grahame cut-off model' is an approximation to the adsorbed counter-ion distribution based on a canonical ensemble and we present arguments to show that this interpretation is incorrect. We also show that the radius of the revised disc is, in general, smaller than that of the Grahame disc but approaches it at large charge densities (σ_β) of counter-ions in the Stern inner region. Comparison is made with an alternative approach to this discrete-ion effect by Buff and Stillinger, who also applied a Fourier–Bessel technique to the mercury – aqueous electrolyte system. Their results provide a lower estimate to the magnitude of the self-atmosphere potential, whereas our revised cut-off model gives an upper estimate. A third method, which assumes the adsorbed ions to be situated on a hexagonal lattice, is also discussed and is found to give a potential larger than the upper estimate of the revised cut-off approach.

It is shown that the effect of the diffuse layer is to diminish the discrete-ion potential at the adsorbed ion. When the electrolyte concentration tends to zero the results with the Grahame model reduce to those derived in an earlier paper from the method of multiple electrostatic images. Calculations on the discrete-ion potential at an adsorbed counter-ion are given for metallic and dielectric surfaces in contact with an aqueous 1–1 electrolyte solution and the parameters of the inner region are chosen to be consistent with known data on mercury and silver iodide systems. It is shown in both cases that on dilute salt solutions ($\lesssim M/100$) the diffuse layer screening is small compared to the unscreened term except at small charge densities of counter-ions in the inner region.

1. INTRODUCTION

The theory of the discrete-ion (or discreteness-of-charge) effect for adsorbed ions has recently been applied to a variety of charged interfaces in aqueous electrolyte systems and though still in its initial stages, it has explained, certainly in a qualitative manner, several phenomena quite inconsistent with the classical Gouy–Chapman–Stern double layer theory. The adequacy and applicability of the theory to the experimental situation has been the topic of a number of papers (1–12) and here we need only mention some results of the comparison with experiment. The discrete-ion effect was originally introduced to explain the Esin–Markov effect, which is concerned with the dependence on electrolyte concentration of the potential of the electrocapillary maximum for the mercury–electrolyte interface. Evidence has been obtained for the mercury–electrolyte interface (13), silver halide – electrolyte interfaces (see refs. 6, 7, 8, 14, 15), and fully ionized monolayers (11) that the potential at the inner boundary of the diffuse layer (the outer Helmholtz plane or O.H.P.) passes through a maximum when the primary charge at the interface

is increased at fixed ionic strength in the electrolyte medium. This behavior is accompanied by an apparent strong dependence of the Stern specific (chemical) adsorption energy of counter-ions on the electrical conditions at the interface (see ref. 11). Two anomalous stability properties found for example with silver halide sols are (i) a decrease in concentration of coagulating electrolyte (i.e. a decrease in stability) with increase in the surface density of potential-determining ions (6, 7, 8, 16), particularly with polyvalent coagulating ions and (ii) the phenomenon of mutual antagonism in the presence of mixed coagulating electrolytes (17). All these properties find a common explanation in the discrete-ion effect.

Three different approaches to the discrete-ion effect have been proposed. The earliest one is that of Soviet authors (1–4) who account for the discrete nature of the adsorbed ions by representing the distribution of these ions in the Stern layer (inner Helmholtz plane or I.H.P.) by a regular hexagonal array and this model has very recently been examined by Barlow and Macdonald (18) (see also Stigter (38)). In the second method, which has been developed by the present authors (6–12), the discrete-ion effect for the adsorbed counter-ions is described in terms of a lateral repulsion between neighboring counter-ions in the case where these are all of the same sign. Consequently in the adsorption plane each counter-ion is surrounded by an area in which the mean surface charge distribution is strongly depleted. This depletion causes a change in the potential at the adsorbed ion, and this change may be called the self-atmosphere or fluctuation potential. The resultant mean potential at the center of an adsorbed ion due to its Coulomb interaction with all the surrounding ions (minus the 'self-image' potential) has been called the micropotential, and the basis of the discrete-ion effect is that this potential differs from the mean electrostatic potential at the adsorption plane, which is called the macropotential. Following Grahame (19) we imagine that each (fully charged) adsorbed ion is situated at the center of a disc which is free of adsorbed charge and has an area equal to the average area per adsorbed counter-ion. This method, which we shall call the 'Grahame cut-off' approximation, has been used in the earlier papers by us (6–12). In this paper, investigations of this model by statistical mechanics show that the radius of the Grahame disc, which is to be free of adsorbed charge, is too large, particularly at small densities of adsorbed ions; we shall refer to the model of the appropriate smaller disc as the 'revised cut-off' approximation. The third method is that of Buff and Stillinger (20) who have recently applied cluster theory to the discrete-ion effect for adsorbed ions in the mercury–electrolyte system. Their key assumption is that the electrostatic forces between adsorbed ions are weak because of the proximity of the conducting mercury surface and they conclude that the pair distribution function of the adsorbed ions is mainly governed by the short-range forces between them. For the hard-sphere model this is equivalent to choosing a cut-off disc having as radius the distance of nearest approach between two adsorbed ions and thus their approach bears some resemblance to that used by us.

Buff and Stillinger criticize (at least for the mercury surface) the model of the plane hexagonal lattice of surface ions which has been used to account for the discrete-ion effect (1–5). The hexagonal lattice is the configuration minimizing the electrostatic interaction energy of the adsorbed ions and it might appear that this should be a reasonable model for the distribution of ions around a given ion in the adsorption plane, provided the electrostatic energy of the ion with its neighbors and their images in the planes of dielectric discontinuities at the interface is appreciably greater than $\mathbf{k}T$, where $\mathbf{k}$ is Boltzmann's constant and T the absolute temperature. However, the validity of a highly ordered two-dimensional structure is not only governed by the magnitude of this energy. A better criterion is probably the steepness of the potential well which characterizes the cell in

which the adsorbed ion is subjected to thermal motion. We have therefore recently investigated the effect of temperature on a hexagonal array of point charges at the mercury surface (21). Making use of the equipartition theorem in statistical mechanics the root mean square displacement $(\overline{r^2})^{1/2}$ of an adsorbed ion in the field of the surrounding lattice ions, which are all fixed in their lattice positions, is calculated. This displacement can be regarded as the mean radius of the 'blur' in the ion's position due to its thermal motion. When the radius of the blur exceeds half of the nearest neighbor distance ($s/2$) then the central ion has left its oxn hexagonal cell and this must mean that the lattice structure is breaking down. In the absence of diffuse layer screening at the mercury surface and for the double layer parameters given in Fig. 2, $(\overline{r^2})^{1/2} = s/2$ at an area per univalent surface ion of 85 Å^2, corresponding to a surface charge density of 19 μC/cm^2. If the effect of the diffuse layer is included, the repulsive forces between the adsorbed ions are reduced, so that the lattice would become unstable at lower areas. In the limiting case where the O.H.P. is assumed to be a perfect conductor, $(\overline{r^2})^{1/2} = s/2$ at an area of 70 Å^2 per adsorbed ion. In recent unpublished work we have found that the lattice structure breaks down at similar charge densities for the silver halide – water interface. This seems to bear out Buff and Stillinger's objection to the lattice model since the results indicate that the hexagonal lattice is not a good description of the relative positions of adsorbed ions except at high densities of adsorbed (univalent) ions. As a result of the breakdown of the hexagonal lattice at $\sigma_\beta < 15$–20 μC/cm^2, the probability of ions approaching to within distances appreciably closer than the nearest neighbor distance s in the hexagonal lattice is quite large. In our opinion, the adsorbed layer of counter-ions should behave more like a two-dimensional dense gas than like a solid, for such σ_β. Nevertheless, we shall show that all three methods of treating the discrete-ion effect give similar results for the self-atmosphere potential at an adsorbed ion at the mercury–water interface.

The hexagonal lattice and Grahame cut-off models may be regarded as similar approaches to the problem. The hexagonal lattice around a specified ion can be replaced by a smoothed-out charge having the mean surface charge density and giving the same potential as the lattice at the center of the ion. We find that this ion is now at the center of a circular 'hole' free of charge, which corresponds to the disc in the Grahame model, but has a different (larger) radius. Whereas the rigid lattice structure takes no account of thermal motion the Grahame model is superior in that it does allow for such motion, although to a rather arbitrary extent which is independent of temperature. If we assume no oscillations in the two-dimensional pair distribution function of adsorbed ions (i.e. we exclude high charge densities exceeding ~ 20 μC/cm^2), then we are able to show that, quite independently of the nature of the planes bounding the 'Stern' inner region, both the revised and Grahame cut-off approximations overestimate the absolute magnitude of the self-atmosphere potential. But it follows from the comparisons by Krylov (5) and Barlow and Macdonald (18) of the hexagonal lattice and Grahame models that the latter gives a smaller absolute value for the self-atmosphere potential and is therefore the more accurate. We shall show that the revised cut-off model is more accurate than the Grahame one, but the differences are small in the mercury case. Krylov (5) has applied the results of the hexagonal lattice and Grahame models to the experimental adsorption isotherms of HCl and HBr at the air–water interface and finds that the Grahame model gives the closer agreement between the calculated and experimental so-called Esin–Markov coefficients. One point in favor of the lattice model is that if the thermal motion is approximated by small (harmonic) oscillations about the lattice sites, then a term $\mathbf{k}T/z_\beta e_0$ is added to the micropotential (21) where e_0 is the proton charge and z_β the valency of the adsorbed ion.

Since this term is independent of the density of adsorbed ions it can be ignored in the discrete-ion theory and can be treated as part of the true specific adsorption energy.

We shall also show that again in the absence of oscillations in the pair distribution function the Buff–Stillinger hard-sphere model provides a lower estimate in the magnitude of the self-atmosphere potential. However, when the O.H.P. in the mercury system is assumed to be a perfect conductor, and is separated from the mercury wall by a distance less than the distance of nearest approach of two adsorbed ions, then this lower estimate from the hard-sphere model differs at the most by 10% from the upper estimate that can be obtained with the cut-off model. The reason for this good agreement is essentially the short-range character of the electrostatic interaction of two adsorbed ions situated between two metallic walls, as stressed by Buff and Stillinger. When the O.H.P. is replaced by an aqueous diffuse layer the short-range character is less marked but the above results are not greatly altered; since the exact value of the radius of the equivalent circular hole for the lattice model, as mentioned above, is likewise of secondary importance we can understand why all three models agree. Because of the short-range character of the electrostatic interaction between the surface ions at the mercury surface the self-atmosphere potentials calculated from both the hexagonal lattice and Grahame models may be quite good approximations even when neither model gives an accurate picture of the surface ion-pair distribution function. In the case of a dielectric – aqueous electrolyte interface, the interaction of two adsorbed ions is no longer of such short-range nature and hence we must expect a greater difference between Buff and Stillinger's theory and our two cut-off models.

Two problems which have so far been largely ignored are the effect of the thermal motion of the adsorbed ions and the screening effect of the diffuse layer on the self-atmosphere potential. The first, a more difficult problem will be considered in a later paper and here we shall only investigate the diffuse layer screening for the cut-off approximation. In their treatment of the discrete-ion effect for the head-group ions of an ionized monolayer, Bell, Levine, and Pethica (10) allowed for the diffuse layer by placing in the bulk solution at a depth equal to the Debye–Hückel thickness of the diffuse layer, an imaginary charged disc, similar to the one used in the cut-off approximation but oppositely charged. On 0.1 M 1–1 electrolyte solution this screening term amounted to a significant factor whose magnitude depended on the surface concentration of head-group ions, but on 0.001 M the effect was negligible compared with the unscreened term except at high areas per head-group ion. The diffuse layer correction tended to reduce the magnitude of the self-atmosphere potential and, as to be expected, assumed a greater proportion of this potential with increase in area per head-group ion. In the present paper we shall develop a more rigorous method of calculating the screening effect of the diffuse layer on the self-atmosphere potential at an adsorbed counter-ion. The method of multiple imaging used in previous papers (9, 11) to determine the self-atmosphere potential is replaced here by a more general technique involving the use of Fourier–Bessel integrals. (Throughout this paper ref. 9 will be designated I.) This approach was used over 30 years ago by Oka (22) and at a later date by Schmutzer (23) in the related problem of the surface tension of electrolyte solutions. The technique has been introduced recently into the double layer problem by Buff and Stillinger (20) but we had independently worked out the main details in the present paper prior to the publication of their work, and are indebted to Prof. F. J. Ursell for suggesting the general method. Fourier transforms have also been introduced by Hurst and Jordine (36) in the problem of the electrostatic interaction of montmorillonite plates. Recently Krylov and Levich (24) investigated the potential distribution in the diffuse layer in the presence of a discrete layer of adsorbed ions in the Stern layer.

However, their emphasis and method of treating the diffuse layer, which resembles that of Stillinger and Kirkwood (25), are different from those used in this paper.

2. THE CUT-OFF DISC MODEL AND THE CONDITION OF ELECTRICAL NEUTRALITY

We shall adopt the model of Grahame (13, 19) and Devanathan (26) for the electric double layer as shown in Fig. 1. The mean charge densities on the wall, the inner Helmholtz plane, and the diffuse layer are σ_0, σ_β, and σ_d respectively. The I.H.P. and O.H.P. are situated at distances β and $d(>\beta)$ from the wall. We assume that the inner region of thickness d is a uniform medium of dielectric constant ϵ_1 and take the dielectric constants of the diffuse layer (ϵ) and the wall-medium (ϵ_2) as equal to the bulk value of the aqueous and nonaqueous phases respectively. More elaborate models of the inner region have been introduced by Devanathan (26), Mott, Parsons, and Watts-Tobin (27), and more recently by Bockris, Devanathan, and Müller (28). Our analysis could be extended, for example, to the case where the two zones of the inner region separated by the I.H.P. have different dielectric constants but for simplicity we shall confine ourselves to a single dielectric constant which may be regarded as an appropriate mean. The mean electrostatic potentials at the wall, the I.H.P., and the O.H.P. are ψ_0, ψ_β, and ψ_d respectively. We wish to determine the mean electrostatic potential or micropotential at the center of an ion of charge $z_\beta e_0$ adsorbed on the I.H.P. This potential can be written as $\psi_\beta + \phi_\beta$, where ϕ_β is the self-atmosphere or fluctuation potential associated with the discrete character of the ionic charge. In order to calculate ϕ_β, the mean surface charge density surrounding the specified ion $z_\beta e_0$ is required.

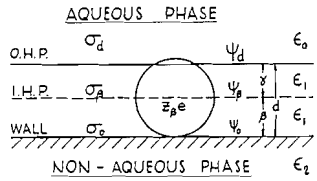

FIG. 1. Model of the electric double layer.

The use of an adsorption isotherm for counter-ions in electric double layer theory is meaningful provided the adsorbed layer is treated as a separate phase. In applying the methods of statistical mechanics we can choose a canonical ensemble (closed system) for the adsorbed phase so that the total number of adsorbed ions N is fixed. Thus we are working with a subspace of the entire configurational part of the phase space available to the ions and this is permissible for large enough N. The electrochemical potential of the adsorbed ions must be a function of their number N which is a thermodynamic variable, and hence, by definition, the fluctuation potential ϕ_β is calculated for specified N. If $g(\rho)$ is the two-dimensional pair distribution function for adsorbed ions at separation ρ in the I.H.P. and the adsorbed phase is treated as a two-dimensional fluid, then from statistical mechanics (see Hill, p. 185 (29)), we have the 'canonical normalization' condition,

$$[2.1] \qquad \frac{N}{A}\int_A g(\rho)\,\mathrm{d}A = N - 1,$$

where we integrate over the area A of the I.H.P. This relation amounts to the statement that the integral of the fluctuation surface density of ions is -1 and it is applicable to any

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

type of intermolecular force. The mean surface charge density in the I.H.P. at distance ρ from a specified ion $z_\beta e_0$ may be written as

$$z_\beta e_0 q(\rho) = \sigma_\beta + S(\rho), \qquad [2.2]$$

where $S(\rho)$ is the (canonical ensemble) fluctuation surface charge density due to the presence of this ion at position $\rho = 0$. By substitution of $\sigma_\beta = Nz_\beta e_0/A$, [2.1] becomes the electrical neutrality condition

$$\int_A S(\rho)\, dA = -z_\beta e_0. \qquad [2.3]$$

An important but difficult problem relevant to the accuracy of the cut-off approximation is the asymptotic behavior of $S(\rho)$ at large ρ. If the adsorbed phase is treated as open, i.e. we use a grand canonical ensemble for the adsorbed ions, then the fluctuation surface charge density becomes $S^*(\rho)$, such that $S^*(\rho) \to 0$ as $\rho \to \infty$ and

$$S(\rho) = S^*(\rho) - z_\beta e_0 k_A(\sigma_\beta)/A, \qquad [2.4]$$

where the form of $k_A(\sigma_\beta)$, which is a positive proper fraction, is discussed in Appendix A. Substituting [2.4] into [2.3], we may allow A to become infinite when integrating $S^*(\rho)$ and so

$$2\pi \int_0^\infty \rho S^*(\rho)\, d\rho = -z_\beta e_0[1 - k_A(\sigma_\beta)]. \qquad [2.5]$$

If $V(\rho)$ is the potential of the mean force between two adsorbed ions at separation ρ, averaged over all configurations of the other ions, in a grand canonical ensemble for the adsorbed phase, then $V(\rho) \to 0$ as $\rho \to \infty$ and

$$S^*(\rho) = \sigma_\beta[\exp(-V(\rho)/\mathbf{k}T) - 1]. \qquad [2.6]$$

We shall show below how [2.5] can be used to obtain qualitative information concerning $V(\rho)$ and the self-atmosphere potential ϕ_β.

It is convenient to introduce r_β defined by

$$\pi r_\beta^2 \sigma_\beta = z_\beta e_0[1 - k_A(\sigma_\beta)]. \qquad [2.7]$$

Then [2.5] and [2.6] will be satisfied by the hypothetical distribution function

$$V(\rho) = \infty,\ \rho < r_\beta; \qquad V(\rho) = 0,\ \rho > r_\beta, \qquad [2.8]$$

which describes the revised cut-off approximation. If $|k_A(\sigma_\beta)| \ll 1$, then r_β becomes the radius r_0 of the disc whose area is equal to the average area available to an adsorbed ion, and so

$$\pi r_0^2 \sigma_\beta = z_\beta e_0. \qquad [2.9]$$

This is the Grahame cut-off approximation, used in the previous papers by the authors (6–12). The following interpretation of $k_A(\sigma_\beta)$, which is proved in Appendix A, suggests that $k_A(\sigma_\beta)$ is small at large σ_β. Consider a grand canonical ensemble for the phase of adsorbed counter-ions and suppose that $z_\beta e_0$ is fixed in position at $\rho = 0$. This ion now becomes the center of an external force field and the total number of mobile adsorbed ions has been reduced by 1. To restore thermodynamic equilibrium, counter-ions will tend to cross the O.H.P. from the diffuse layer into the inner region. Since the charge density σ_β is unaltered at large ρ in a grand canonical ensemble, such a movement of ions can only

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

occur in the vicinity of the fixed ion at $\rho = 0$. The quantity $k_A(\sigma_\beta)$ is the 'mean fraction' of one ion that enters the adsorbed phase. Clearly, for high densities, the I.H.P. cannot accommodate this ion under the necessary condition of fixed σ_β at large ρ and so $k_A(\sigma_\beta)$ is small. From [2.7] and [2.9]

$$[2.10] \qquad r_\beta/r_0 = [1 - k_A(\sigma_\beta)]^{1/2} < 1.$$

By [2.5]–[2.7], we can also write

$$[2.11] \qquad r_\beta^2 = 2\int_0^\infty \rho[1 - \exp(-V(\rho)/\mathbf{k}T)]\,d\rho = a^2 + 2\int_a^\infty \rho[1 - \exp(-V(\rho)/\mathbf{k}T)]\,d\rho$$

and this is equivalent to

$$[2.12] \qquad k_A(\sigma_\beta) = 1 - \frac{a^2}{r_0^2} - \frac{2}{r_0^2}\int_a^\infty \rho[1 - \exp(-V(\rho)/\mathbf{k}T)]\,d\rho.$$

As $\sigma_\beta \to 0$, $r_0 \to \infty$, but provided the integral in [2.11] or [2.12] converges, $k_A(\sigma_\beta) \to 1$ and r_β tends to a finite upper limit. The more short-range the function $V(\rho)$, the larger is $k_A(\sigma_\beta)$ and the smaller is this limiting value of r_β.

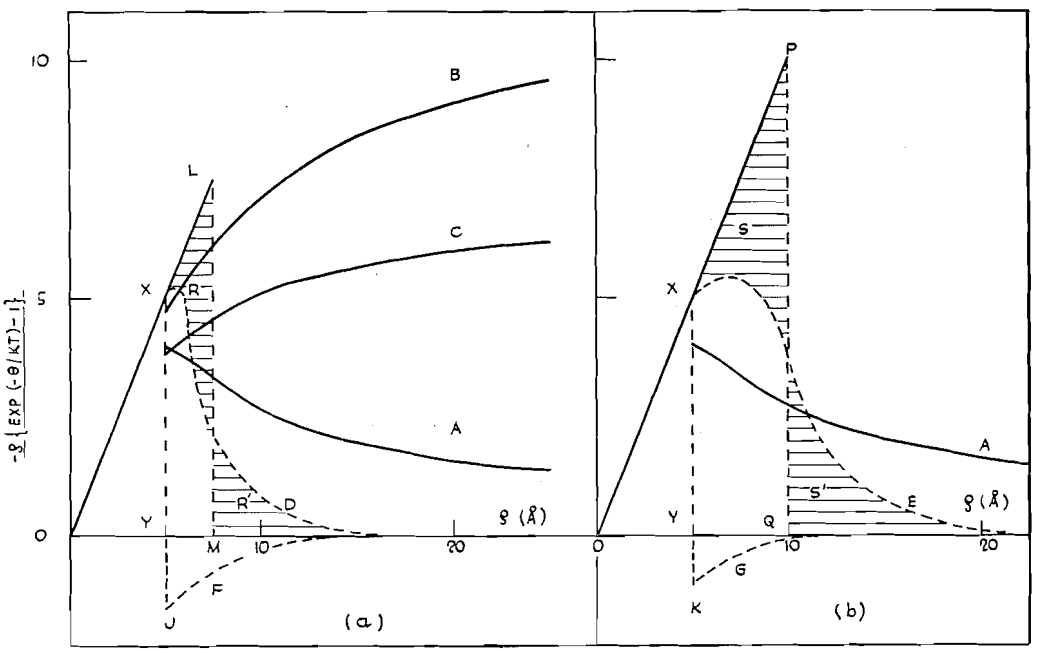

FIG. 2. Behavior of the pair distribution function $\exp(-\theta/\mathbf{k}T)$ where θ is $V(\rho)$ or $U(\rho)$. The quantity $2\pi\sigma_\beta \exp(-U(\rho)/\mathbf{k}T)$ is the mean charge in the I.H.P. lying between ρ and $\rho + d\rho$ when an adsorbed ion is situated at $\rho = 0$. The corresponding charge that would be present in the same area $(\rho, \rho + d\rho)$ in the absence of the adsorbed ion is $2\pi\sigma_\beta\rho\,d\rho$ and the function plotted in curves A, B, and C is proportional to the difference between these charges. Curves A, B, and C describe respectively mercury, silver iodide, and bulk electrolyte with the following parameters at 20°. A. Hg. $\epsilon = 80.1$, $\epsilon_1 = 10$, $\epsilon_2 = \infty$, $\beta = 3$, $\gamma = 2$. B. AgI. $\epsilon = 80.1$, $\epsilon_1 = 10$, $\epsilon_2 = 15$, $\beta = 3$, $\gamma = 1$. C. Bulk electrolyte. $\epsilon = 80.1$. Triangle OXY represents the Buff–Stillinger hard-sphere model, $a = 5$ Å.

The dashed curves D and E describe the hypothetical behavior of the pair distribution function $\exp(-V(\rho)/\mathbf{k}T)$ for the mercury–electrolyte system at ordinary values of σ_β. The radius r_β equals 7.5 Å in *a* and 10 Å in *b*. Curves D and E are so chosen that area $R = R'$ and $S = S'$ as required by the electrical neutrality condition. Curves F and G depict the general trend of the pair distribution function from the Helfand, Frisch, and Lebowitz model. The points J and K are calculated from [2.13] with $a = 5$ Å.

In Figs. 2*a* and 2*b*, which depict $\rho[1 - \exp(-V(\rho)/\mathbf{k}T)]$ as a function of ρ, the form [2.8] is represented by the triangles OLM and OPQ where $r_\beta = 7.5$ and 10 Å respectively. The two broken curves D and E illustrate possible forms of the true distribution function $V(\rho)$ satisfying [2.5]–[2.7] for the above values of r_β and these curves are obtained as follows. If a, the distance of nearest approach between two ions, equals 5 Å, then the condition [2.7] requires that the respective shaded areas be equal (i.e. $R = R'$ and $S = S'$). From our knowledge of the Debye–Hückel theory, we suggest that because of diffuse layer screening, $V(\rho)$ dies off exponentially with ρ at large ρ. The curves D and E are known for $\rho < a$ (the hard-sphere part where $V(\rho) = \infty$) and we have joined the two parts at large and small ρ by a continuously turning curve. Now according to Stillinger and Kirkwood (25), Krylov and Levich (24), and Martynov and Derjaguin (30) oscillations occur in the potential distribution in the diffuse layer at large electrolyte concentrations (> 0.6 M for the 1–1 valency type) because of ion size, although apparently these oscillations are weak. At low σ_β, similar oscillations in $S^*(\rho)$ are unlikely and we exclude their possibility or assume them unimportant in Fig. 2, i.e. we regard the adsorbed layer of counter-ions as a two-dimensional gas.

For the Buff–Stillinger hard-sphere model with small σ_β, $V(\rho) = \infty$, $\rho < a$, and $V(\rho) = 0$, $\rho > a$ and in Fig. 2, this model is represented by the triangular form OXY. At larger σ_β, one could use the theory of a two-dimensional fluid given by Helfand, Frisch, and Lebowitz (31). When two spheres of such a fluid are in contact (at separation a) their (canonical ensemble) distribution function reads in our notation

$$q(a) = \frac{1}{2}\left[\left\{1 - \left(\frac{a}{2r_0}\right)^2\right\}^{-1} + \left\{1 - \left(\frac{a}{2r_0}\right)^2\right\}^{-2}\right]. \qquad [2.13]$$

At $a = 5$ Å and $r_0 = 7.5$ and 10 Å, $q(a) = 1.20$ and 1.10 respectively. Curves F and G in Figs. 2*a* and 2*b* respectively show the expected form of $\rho(1 - q(\rho))$ for $r_0 = 7.5$ and 10 Å with this model. It might appear that the normalization condition [2.1] is not satisfied by the models of Buff and Stillinger and Helfand, Frisch, and Lebowitz. However, their hard-sphere models strictly apply to uncharged species in a canonical ensemble and this means that at large ρ, their function $q(\rho) = -k_A/A$, where the fraction k_A is of the order of 1. Hence, in Figs. 2*a* and 2*b*, the functions $\rho(1 - q(\rho))$ for hard-spheres have very long 'tails' (which are not shown in the diagrams) extending to the very edge of the interface and lying just above the ρ-axis at large ρ. These ensure that the condition [2.1] is satisfied. For example, in Fig. 2*a*, the area under this tail beyond the distance $\rho = r_0$ must compensate exactly the area bounded by the two ordinates $\rho = a$ and $\rho = r_0$, the line OL, and either the ρ-axis in the Buff–Stillinger theory or the curve JF in the Helfand–Frisch–Lebowitz theory. The contribution to the self-atmosphere potential from the distant parts of these tails is negligible and thus it would seem that since both r_0 and r_β differ from the hard-sphere a, there could be a considerable discrepancy between our value of the self-atmosphere potential and that of Buff and Stillinger. However, we show below that for the case where the inner region is bounded by two infinitely conducting walls, their expression for ϕ_β differs only slightly from that obtained with the cut-off models. At the same time, we believe that the curves JF and KG are on the wrong side of the ρ-axis, because the electrostatic repulsion between adsorbed ions is ignored.

The Grahame cut-off approximation, in which r_β is identified with r_0, may be described as follows. In the usual double layer theory we imagine a uniform sheet of charge density σ_β on the I.H.P. An area equal to $z_\beta e_0/\sigma_\beta$ is then available to each ion and if this charge is spread out uniformly over a disc, its radius r_0 is given by [2.9]. We suppose now that this

disc of charge is contracted to a point which becomes the center of the discrete ion $z_\beta e_0$. This is equivalent to choosing the potential distribution $V(\rho) = \infty$, $\rho < r_0$; $V(\rho) = 0$, $\rho > r_0$. In the corresponding description of the revised cut-off approximation [2.8], we contract a disc of radius r_β and charge density σ_β to a point. It is then necessary to augment the resulting charge $z_\beta e_0[1 - k_A(\sigma_\beta)]$ at the center of the disc by an amount $z_\beta e_0 k_A(\sigma_\beta)$, thereby attaining the charge $z_\beta e_0$ of a single ion at this center. The difference between the two approximations can be understood from the relation between the pair distribution functions in grand canonical and canonical ensembles. The two ensembles for the adsorbed phase should give the same thermodynamic properties of our system, such as the electrochemical potential of an adsorbed ion and therefore the micropotential and self-atmosphere potential. However, the eqs. [2.3] and [2.5], being essentially fluctuation relations, take different forms (cf. Hill, p. 236 (29)). In the grand canonical ensemble it follows from the discussion given above that the effect of fixing an ion $z_\beta e_0$ at $\rho = 0$ is to remove a fraction $1 - k_A(\sigma_\beta)$ of one ionic charge from the uniform charge distribution σ_β on the I.H.P. in the vicinity of $\rho = 0$; hence the eq. [2.5]. In the canonical ensemble, a whole unit $z_\beta e_0$ of ionic charge is removed from the I.H.P. and so we have eq. [2.3]. However, a fraction $k_A(\sigma_\beta)$ of this unit represents a diminution of amount $k_A(\sigma_\beta)/N$ in the surface density of counter-ions at large ρ. This is responsible for a 'long tail' similar to that described above for the hard-sphere model and again the contribution to the self-atmosphere of the fixed ion at $\rho = 0$ from the minute decrease in density is found to be negligible. This illustrates a characteristic of strong electrolyte theory that ionic atmospheres are governed by the pair distribution function of the grand canonical ensemble. It should be clearly understood that the term 'contraction' used here is simply a graphic way of representing the difference between the average ion density (or absolute probability distribution) on the plane and the ion density (or conditional probability distribution) when it is known that one surface ion has its center in a given position on the plane.

It is convenient to examine the limiting case of small σ_β and low electrolyte concentrations. If ρ is small compared to both the mean separation of two adjacent adsorbed ions and the thickness of the diffuse layer, then a good approximation to $V(\rho)$ is given by the interaction energy $U(\rho)$ of an isolated pair of adsorbed ions at separation ρ, in the absence of diffuse layer screening. We now introduce the functions

$$y(u) = (1 + 4u^2)^{-1/2} \qquad [2.14]$$

and

$$Y(t, w) = f_1 y(t) + \sum_{n=1}^{\infty} \sum_{m=n, n\pm 1} f_1^m f_2^n \{2 - (m - n)^2\} y(mt + nw), \qquad [2.15]$$

where

$$f_1 = (\epsilon_1 - \epsilon_2)/(\epsilon_1 + \epsilon_2), f_2 = (\epsilon_1 - \epsilon)/(\epsilon_1 + \epsilon). \qquad [2.16]$$

For the general case of different dielectric constants ϵ, ϵ_1, ϵ_2 the energy $U(\rho)$ may be expressed in the form

$$U(\rho) = \frac{(z_\beta e_0)^2}{\epsilon_1 \rho} [1 + Y(\beta/\rho, \gamma/\rho)], \qquad [2.17]$$

where $\gamma = d - \beta$. In the particular case where $\epsilon_1 = \epsilon_2$, this simplifies to

$$U(\rho) = \frac{(z_\beta e_0)^2}{\epsilon_1 \rho} [1 + f_2 y(\gamma/\rho)]. \qquad [2.18]$$

The series [2.15] represents the sum of an infinite array of electrostatic images due to multiple reflections in the plane of the wall and in the O.H.P. of the isolated pair of ions. In describing the discrete-ion effect the general sum [2.15] will appear again with different 'basic' functions $y(u)$. A closed expression in the form of a Fourier–Bessel integral, which is equivalent to [2.15] can also be used (2, 3, 4, 20).

For a perfectly conducting wall (e.g. mercury) where $\epsilon_2 = \infty$ and $f_1 = -1$ (and with $f_2 \neq -1$), $U(\rho)$ dies off as $1/\rho^3$ at large ρ. In Fig. 2*a*, this case is illustrated by curve A, which is a plot of the function $\rho\{1 - \exp(-U(\rho)/\mathbf{k}T)\}$ (see legend for double layer parameters). The electrical neutrality condition [2.3] or [2.5] is not satisfied by curve A. For the above double layer parameters, $U(\rho) = 1.6$, 0.6, and 0.3 $\mathbf{k}T$ at $\rho = 5$, 7.5, and 10 Å respectively at $T = 20°$, illustrating the short-range character of the Coulomb forces at the metallic wall. In the hexagonal lattice model the interaction energy of an adsorbed ion with its neighbors in the inner region exceeds $6U(s)$ and therefore at $s < 10$ Å (corresponding to an area per adsorbed ion $\lesssim 100$ Å^2) this energy is greater than 1.8 $\mathbf{k}T$ at the above mercury surface. However, we have already indicated that this is not a sufficient criterion for a stable hexagonal lattice. For a dielectric wall $U(\rho)$ decreases as $1/\rho$ at large ρ and so the integral in [2.11] or [2.12] diverges if $V(\rho)$ is replaced by $U(\rho)$. In Fig. 2*a*, curve B is a plot of $\rho\{1 - \exp(-U(\rho)/\mathbf{k}T)\}$ for a wall of low dielectric constant (see legend) and, for comparison, curve C depicts the case of two ions in bulk water of dielectric constant $\epsilon = 80$. The values of $U(\rho)$ at $\rho = 5$, 7.5, and 10 Å are respectively 2.8, 1.7, and 1.2 $\mathbf{k}T$ at $T = 20°$. However, diffuse layer screening will force convergence of the above integral.

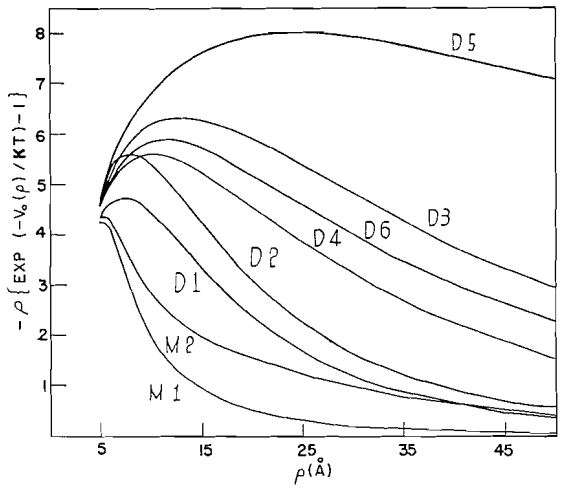

FIG. 3. Behavior of the pair distribution function exp $(-V_0(\rho)/\mathbf{k}T)$ for metallic and dielectric walls. $\epsilon = 80.1$, $T = 20°$.

At small enough σ_β, $V(\rho)$ can be approximated by $V_0(\rho)$, the interaction energy of an isolated pair of adsorbed ions at separation ρ in the presence of a diffuse layer, provided ρ is small compared to the mean distance between two neighboring adsorbed ions. In the limiting case of zero electrolyte concentration, $V_0(\rho)$ reduces to $U(\rho)$. In Appendix D, we have obtained an expression for $V_0(\rho)$ in the form of a Fourier–Bessel integral and in Fig. 3 we have plotted $\rho\{1 - \exp(-V_0(\rho)/\mathbf{k}T)\}$ as a function of ρ for both metallic and dielectric walls with various parameters describing the double layer. In these curves we have chosen $a = 5$ Å and thus $V_0(\rho) = \infty$ for $\rho < 5$ Å; hence there is a discontinuity in the ordinate at $\rho = 5$ Å. Our results show that the higher the electrolyte concentration c or the potential ψ_d at the O.H.P., the smaller is $V_0(\rho)$, as is to be expected. For general σ_β, $V(\rho)$ should decay more rapidly than $V_0(\rho)$ with increase in ρ and hence substitution of $V_0(\rho)$ for $V(\rho)$ into [2.11] yields an upper limit to the value of r_β. In Table I we estimate this upper limit to r_β by numerical integration of [2.11]. In view of the long computing time required, only a limited number of cases have been considered.

TABLE I

In describing the discrete-ion effect it is convenient to introduce the following convention into our notation. As explained in Section 3, the 'self-image' contribution to ϕ_β will be ignored and therefore in Section 4 only the part of ϕ_β which depends directly on σ_β is determined. For both metallic and dielectric walls and for the general diffuse layer screening, we shall denote this part by $\phi_1(0, 0)$ and introduce the function $g_\phi(r_\beta)$ by writing

$$\phi_1(0, 0) = -\frac{4\pi\beta\gamma}{\epsilon_1 d}\sigma_\beta g_\phi(r_\beta). \qquad [2.19]$$

In the revised cut-off model used here, $\phi_1(0, 0)$ is the potential at the center of a disc of radius r_β on the I.H.P. due to a surface charge density $-\sigma_\beta$ uniformly distributed on this disc and screened by the diffuse layer.

A limiting case which has received considerable attention in the past is that of two conducting walls bounding the inner region and in this section we shall proceed to examine the form of $g_\phi(r_\beta)$ for this limiting case. In an earlier paper (ref. 7, eq. [7]) it was shown that $g_\phi(r_\beta) - 1$ is a measure of the deviation from Grahame's linear relation between the micropotential ψ_1 and the mean potential in the inner region for two such walls. This relation reads

$$\psi_1 - \psi_d = \frac{\gamma}{d}(\psi_0 - \psi_d) \qquad [2.20]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and is obtained when $g_\phi(r_\beta) = 1$. (The fact that we previously identified r_β with r_0 does not affect the present discussion.) Also, Calvert (32) has shown that for two conducting walls, the cut-off model yields

$$[2.21] \qquad g_\phi(r_\beta) = 1 - \frac{d^2}{\beta\gamma}\left[\tfrac{1}{4}f(\tau) + s_0^2 I_2(\tau) + s_0^4 I_4(\tau) + \ldots\right],$$

where $\tau = r_\beta/d$, $s_0 = (\beta - \gamma)/2d$ and if K_1 is the Bessel function of the second kind with imaginary argument and order 1,

$$[2.22] \qquad f(\tau) = \frac{8\tau}{\pi}\sum_{m=1}^{\infty}\frac{1}{(2m-1)}K_1(\overline{2m-1}\,\pi\tau)$$

and

$$[2.23] \qquad I_2(\tau) = 2\tau^2\sum_{m=1}^{\infty}\frac{1}{(\tau^2 + (2m-1)^2)^{3/2}} - 1,$$

$$[2.24] \qquad I_4(\tau) = 2\tau^2\sum_{m=1}^{\infty}\frac{\{4(2m-1)^2 + \tau^2\}}{\{\tau^2 + (2m-1)^2\}^{7/2}}.$$

The expansion [2.21], which reduces to the form derived in I when $\gamma = \beta$ ($s_0 = 0$), is valid for $|s_0| < 0.5$ if $\tau > \sqrt{2}$ and for $|s_0| < 0.36$ if $\tau > 1$. Some values of the coefficient in [2.20] for various τ and also of $1 - g_\phi(r_\beta)$ when $\gamma = 1$ or 2 Å and $\beta = 3$ Å are shown in Table II.

TABLE II

Two conducting walls bounding inner region with $\beta = 3$

r_β/d	1.0	1.2	1.4	1.6	1.8	2.0
$10f(\tau)/4$	0.2160	0.1242	0.0708	0.0400	0.0225	0.0126

I_4	0.5553	0.3559	0.2148	0.1253	0.0716	0.0404
$1 - g_\phi$ $\gamma = 1$	0.0597	0.0340	0.0193	0.0109	0.0061	0.0034
$1 - g_\phi$ $\gamma = 2$	0.0818	0.0470	0.0267	0.0151	0.0085	0.0047

It is apparent from Fig. 2 that the cut-off approximation [2.8] overestimates the magnitude of $\phi_1(0, 0)$, since the net charge defined by the fluctuation charge density $S^*(\rho)$ in the shaded area R (or S) must equal the corresponding charge in R' (or S') and in the cut-off approximation the charge in R (or S) which replaces that in R' (or S') is now closer to the center of the adsorbed ion, $z_\beta e_0$. On the other hand an underestimate of $|\phi_1(0, 0)|$ is given by the formula

$$[2.25] \qquad \phi_1(0, 0) = -\frac{4\pi\beta\gamma}{\epsilon_1 d}\sigma_\beta g_\phi(a),$$

which follows from the Buff–Stillinger model. Now the analysis in the Appendix of I shows that if the restriction of [2.5] is removed then σ_β and r_β can be varied independently in the formula [2.19]. If we put $g_\phi = 1$, $\phi_1(0, 0)$ is proportional to σ_β and is independent of the radius r_β of the disc; this is the limiting form at $r_\beta = \infty$. On the other hand if we choose $r_\beta = d$ and assume $\gamma = \beta$, then $g_\phi = 1 - f(1)$, where from Table I, $f(1) \approx 0.09$. The function $f(r_\beta/d)$ rapidly diminishes with increase in r_β having, for example, a value 0.005 at $r_\beta/d = 2$. Thus for the model of an inner region sandwiched between two metallic walls the over- and under-estimates given above for $\phi_1(0, 0)$ differ at most by 9% for $r_\beta \geqslant d$. But from [2.11], $r_\beta > a$ and for simple inorganic ions a and d are of the same order. We

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

conclude that the error in $\phi_1(0, 0)$ at $\beta = \gamma$ with either the Grahame cut-off model (radius of disc $r_0 > r_\beta$) or the revised cut-off model (radius of disc r_β), should be less than 9%. When $\beta \neq \gamma$ these conclusions are still valid and indeed from Table I, the error is smaller because $I_2(\tau) < 0$. A cut-off radius r_c giving the correct $\phi_1(0, 0)$ lies between the distance of nearest approach a of two adsorbed ions and the cut-off radius r_β defined by [2.11]. Furthermore a simple way of obtaining the correct $\phi_1(0, 0)$ if r_c were known, whilst satisfying [2.5], would be to approximate to the true fluctuation charge density $S^*(\rho)$ beyond $\rho = r_c$ by placing an annulus of uniform charge density and total charge $z_\beta e_0[1 - k_A(\sigma_\beta)] - \pi\sigma_\beta r_c^2$ between $\rho = r_c$ and some $\rho \gg r_c$. The annulus makes a negligible contribution to $\phi_1(0, 0)$.

It follows from the above analysis that even though Buff and Stillinger's a is apparently fixed and practically independent of σ_β and our disc radius r_β exceeds a and increases somewhat with decrease of σ_β, the two approaches are in good agreement on the value of the self-atmosphere potential for two metallic walls. A more striking result is that although r_0 increases indefinitely with decrease in σ_β, the Grahame cut-off model yields values for $|\phi_1(0, 0)|$ which exceed only slightly those obtained with the revised cut-off model. Because of the short-range character of the electrostatic interaction of two adsorbed ions situated between two metallic walls, the contribution to $\phi_1(0, 0)$ from the distribution function $S^*(\rho)$ beyond a distance $\rho = d$ is small, so that when $\rho > d$ the exact form of $S^*(\rho)$ is not needed in a first order theory. In other words, the function $g_\phi(r_\beta)$ in [2.19] changes only slightly with r_β for $r_\beta > d$ and hence the radius of the disc carrying a specified σ_β is unimportant.

In their comparison of the hexagonal lattice and the Grahame cut-off model ($r_\beta = r_0$), Barlow and Macdonald (18) discuss the case where the wall and O.H.P. are perfect conductors and also assume $\psi_d = 0$. It can be shown from an earlier paper (7) that if the 'self-image' part of ϕ_β is again ignored, the micropotential then takes the form

$$[2.26] \qquad \psi_1 = \psi_\beta + \phi_1(0, 0) = \frac{\gamma}{d}\psi_0\left[1 + \frac{4\pi}{\epsilon_1}\{1 - g_\phi(r_0)\}\frac{\beta\sigma_\beta}{\psi_0}\right].$$

If $\sigma_0 = 0$, the electrostatic relations pertaining to the inner region yield $\psi_0 = \psi_\beta = 4\pi\gamma\sigma_\beta/\epsilon_1$ and, using the notation of Barlow and Macdonald, [2.20] becomes $\psi_1 = (\gamma/d)\psi_0(1 + \Delta_0)$, where

$$[2.27] \qquad \Delta_0 = \frac{\beta}{\gamma}[1 - g_\phi(r_0)].$$

The expansion [2.21] for $g_\phi(r_0)$ is valid when $r_0 > d$ (i.e. $\sigma_\beta < 16\ \mu C/cm^2$ for $d = 5$ Å) and then $\Delta_0 > 0$ in [2.27]. The following discussion is restricted therefore to this range of σ_β. To compare the micropotential ψ_1 derived from the hexagonal lattice and cut-off disc theories, it is sufficient to consider the self-atmosphere potential $\phi_1(0, 0)$ since the determination of ψ_β is identical in the two theories. Also, for two perfectly conducting walls $\phi_1(0, 0)$ is determined only by σ_β (and the dimensions and dielectric constant ϵ_1 of the inner region) and so is independent of σ_0 at constant ϵ_1. Barlow and Macdonald evaluate Δ_0 on the basis of the hexagonal model and for $\gamma = \beta$ and $\sigma_\beta < 10\ \mu C/cm^2$ (when $\Delta_0 > 0$), find Δ_0 to be considerably smaller than that given by [2.22] with the Grahame cut-off model (for example, by a factor of 12 at $\sigma_\beta = 10\ \mu C/cm^2$). This feature is also obtained by Krylov (5) and comparison of [2.21] with Barlow and Macdonald's values of Δ_0 for $\gamma \neq \beta$ again yields this difference. However, we have argued that the Grahame cut-off approximation to the magnitude of the self-atmosphere potential [2.19] is an overestimate and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

this means that [2.27] is an underestimate. It follows that the Grahame cut-off model provides a lower estimate of $|\phi_1(0, 0)|$ than does the hexagonal model and is therefore the more accurate, contrary to comments by Barlow and Macdonald; the revised cut-off model in turn gives a somewhat better value than the Grahame model. It should be stressed that Δ_0 is a correction to the linear relation between ψ_1 and ψ_0 which is small except at large σ_β and so the discrepancy between the two values of Δ_0 quoted by Barlow and Macdonald does not affect the good agreement on $\phi_1(0, 0)$ for the two models. When $\sigma_\beta > 20$ μC/cm^2 we can no longer apply the argument developed above to predict which of the two theories is the more accurate, since the existence of a lattice structure can no longer be ruled out. It is significant that the hexagonal lattice model implies that σ_β is unchanged at large ρ, so that $k_A(\sigma_\beta) = 0$ and therefore $r_\beta = r_0$; this is consistent with our contention that the lattice model is justifiable only at large σ_β.

3. AN INTEGRAL FORM OF THE SELF-ATMOSPHERE POTENTIAL

Let the mean potential $\Psi(x)$ at distance x from the wall satisfy Laplace's equation both in the wall-medium, $x < -\beta$, and in the inner region $-\beta < x < \gamma$, where $\gamma = d - \beta$ is the distance between the I.H.P. and the O.H.P. In the diffuse layer $x > \gamma$, we assume the Poisson–Boltzmann (P.B.) equation to hold, and for a 1–1 electrolyte this reads

$$[3.1] \qquad d^2\Psi(x)/dx^2 = (8\pi n e_0/\epsilon) \sinh (e_0\Psi(x)/\mathbf{k}T),$$

where n is the number per unit volume of univalent ions of either type in the electrolyte interior. This has the solution

$$[3.2] \qquad \Psi(x) = 4\mathbf{k}T/e_0 \tanh^{-1}[\exp -(\kappa x') \tanh(\eta_d/4)],$$

where $x' = x - \gamma$ and $\eta_d = e_0\psi_d/\mathbf{k}T$ and κ is the characteristic Debye–Hückel parameter of the electrolyte defined by

$$[3.3] \qquad \kappa^2 = 8\pi n e_0^2/\epsilon\mathbf{k}T.$$

Many authors have investigated the limitations of the P.B. equation and have dealt, in particular, with the volume (ion size), dielectric, and self-atmosphere effects; the latter corrects for the correlation between ion positions in the diffuse layer. One important aspect of ion size, first considered by Buff and Stillinger (20) and more recently by us (33) is the correction to the potential at an ion from the diffuse layer 'cavity charge' that would be present inside the exclusion volume of the hydrated ion if the ion were absent. This 'cavity effect' has been ignored by previous authors and a more rigorous statistical approach (24, 25, 30) shows that it becomes important in 1–1 electrolytes at concentrations above 0.1 M. The uncorrected P.B. equation, however, should be a reasonable approximation for 1–1 electrolyte concentrations $\lesssim 0.01$ M if $\psi_d \lesssim 100$ mV and $\lesssim 0.1$ M if $\psi_d \lesssim 50$ mV. In this paper we shall be applying the discrete-ion theory to systems in electrolyte concentrations of 0.1 M or less and because we are concerned with the self-atmosphere potential of an adsorbed ion in the *inner region* and are *correcting* for diffuse layer screening, we feel justified in using the P.B. equation at the present stage of our first-order theory.

In Section 2 we explained how the (revised) cut-off model can be described in terms of a removal of charge $z_\beta e_0[1 - k_A(\sigma_\beta)]$, distributed uniformly with charge density σ_β over a disc of radius r_β, and also the placing of a point charge $z_\beta e_0$ at the center of the disc (for brevity, we shall refer to this as the contraction process). Our task is to calculate the change in potential (ϕ_β) at the center of the disc due to the contraction process and in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

particular, to determine its dependence on σ_β. The uniform charge distribution σ_β outside the radius r_β is unchanged and therefore makes no contribution to ϕ_β. Prior to the contraction process the mean potential distribution was $\Psi(x)$, whereas after the contraction this distribution may be written as

$$\psi(x, \rho) = \Psi(x) + \phi(x, \rho), \qquad [3.4]$$

where $\phi(x, \rho)$ is the fluctuation potential distribution and x and ρ are the usual cylindrical polar coordinates with origin at the center of the disc in the I.H.P. It follows that $\phi_1(0, 0) = \phi_\beta$. Again $\psi(x, \rho)$ satisfies Laplace's equation in the two regions $x < -\beta$ and $-\beta < x < \gamma$ and the P.B. equation in the diffuse layer $x > \gamma$ namely

$$\nabla^2\psi(x, \rho) = (8\pi n e_0/\epsilon) \sinh (e_0\psi(x, \rho)/\mathbf{k}T). \qquad [3.5]$$

Adopting the method of Loeb (34) and Williams (35) we assume ϕ small and subtract [3.1] from [3.5] to obtain the approximate relation

$$\nabla^2\phi(x, \rho) = \kappa^2 \cosh (e_0\Psi(x)/\mathbf{k}T).\, \phi(x, \rho). \qquad [3.6]$$

The coefficient of $\phi(x, \rho)$ on the right can be interpreted as a local diffuse-layer κ^2 (or electrolyte concentration) which is a function of x. The solution of [3.6] is

$$\phi(x, \rho) = \int_0^\infty X(x, k) J_0(k\rho)\, \mathrm{d}k, \qquad [3.7]$$

where $J_n(k\rho)$ is the Bessel function of the first kind of order n and the function $X(x, k)$ is obtained in Appendix B.

The fluctuation potential $\phi(x, \rho)$ can be written as

$$\phi(x, \rho) = \phi_1(x, \rho) + \phi_2(x, \rho). \qquad [3.8]$$

Here $\phi_1(x, \rho)$ is *defined* as the potential change due only to the removal of the charge $z_\beta e_0(1 - k_A(\sigma_\beta))$ spread over the disc of radius r_β on the I.H.P. Then $\phi_2(x, \rho)$ is due to the creation of a point charge $z_\beta e_0$ at the center of the disc for fixed uniform σ_β on the I.H.P. beyond the radius r_β. Since $\phi(x, \rho)$ satisfies Laplace's equation when $x < \gamma$ and the linear eq. [3.6] is assumed when $x > \gamma$, the two potentials $\phi_1(x, \rho)$ and $\phi_2(x, \rho)$ can satisfy [3.6] separately and hence can be treated independently. As a result of the contraction process the uniform charge density σ_0 (e.g. of stabilizing or potential-determining ions) on the wall is replaced by a charge distribution $\sigma_0(\rho)$, the exact form of which is known in two limiting cases. One is that of a perfectly conducting wall, when the condition that the potential at this wall be constant implies that we can choose

$$\phi_1(-\beta, \rho) = \phi_2(-\beta, \rho) = 0 \qquad [3.9]$$

and these conditions automatically account for the change in charge distribution, $(\sigma_0(\rho) - \sigma_0)$ which accompanies the contraction process. The other is that of a perfect dielectric wall on which the charge density remains fixed i.e. $\sigma_0(\rho) = \sigma_0$, when we may assume continuity of the normal component of the 'perturbed' dielectric displacement across the wall. This yields the boundary condition

$$\epsilon_2(\partial\phi_1(x, \rho)/\partial x)_{x=-\beta-0} = \epsilon_1(\partial\phi(x, \rho)/\partial x)_{x=-\beta+0} \qquad [3.10]$$

and an identical relation for $\phi_2(x, \rho)$. In the classical case of AgI particles, the wall potential ψ_0 is assumed constant, implying complete mobility of the stabilizing ions on the wall, even though AgI is a dielectric medium. A distinction should be made, however, between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the potential of the mean force at the center of a stabilizing ion and the mean potential at the wall and it is the former potential which presumably is constant. We need to add to the right-hand side of [3.10] a term $4\pi(\sigma_0'(\rho) - \sigma_0)$, where $\sigma_0'(\rho)$ is the part of $\sigma_0(\rho)$ due to the removal of the charged disc. However, in the present paper we shall not pursue the difficult problem of the true form for $\sigma_0(\rho)$, but shall confine ourselves to the two limiting cases described by [3.9] and [3.10].

We denote the potentials $\phi_1(0, 0)$ and $\phi_2(0, 0)$ at the center of the disc by ϕ_1 and ϕ_2. The potential ϕ_1 depends directly on σ_β and, because we are interested in that part of the discrete-ion effect which varies with σ_β, we shall be concerned with ϕ_1. The 'self-image' potential ϕ_2 has been treated by other authors (2, 3, 20) and will only be briefly discussed here. It is convenient to write $\phi_2 = \phi_2' + \phi_2''$, where the main term ϕ_2' is obtained when $\sigma_\beta = 0$ for a specified electrolyte concentration. The term ϕ_2'' arises from the change in the diffuse layer local electrolyte concentration, due to the presence of a uniform σ_β at $\rho > r_\beta$. It will depend approximately on the sum $\Delta\sigma_0 + \sigma_\beta$ where $\Delta\sigma_0$ is the increment in σ_0 resulting from a change in σ_β at fixed electrolyte concentration. For a conducting wall at constant potential, $\Delta\sigma_0 + \sigma_\beta$ and therefore ϕ_2'' will be small. For the case $\sigma_0 =$ constant, $|\phi_2''|$ will increase with $|\sigma_\beta|$ but $|\phi_1|$ does likewise. Because ϕ_2 is the potential at the center of an empty circle of radius r_β due to placing an ion there, it seems unlikely that even in this case ϕ_2'' will be a significant fraction of ϕ_2. Thus in the light of the above discussion we attribute the dependence of the discrete-ion effect on σ_β mainly to ϕ_1, and shall not determine ϕ_2 in the present paper.

A limitation of our basic eq. [3.6] is that $\phi(x, \rho)$ is assumed small in the diffuse layer though it must be stressed that we used a linear theory only for $\phi(x, \rho)$ and not for the average potential $\Psi(x)$. However, the largest values of $\phi(x, \rho)$ and $\phi_2(x, \rho)$ will in fact occur near the central ion charge in the region $x < \gamma$ which is outside the diffuse layer and where $\phi(x, \rho)$ accurately satisfies Laplace's equation. (The remarks below about the magnitude of γ have some bearing here.) Also the two terms $\phi_1(x, \rho)$ and $\phi_2(x, \rho)$ in [3.8] have opposite signs which tend to reduce the magnitude of $\phi(x, \rho)$.

For some systems (e.g. AgI – electrolyte solution interface (7, 8, 21)) it seems possible that γ is very small and in our model this would have the effect of making ϕ_2' very large. However, it must be pointed out that in defining γ we have identified several different quantities to make mathematical treatment possible. As Buff and Stillinger (20) have remarked the plane of dielectric discontinuity and the mean (outer Helmholtz) plane of nearest approach of diffuse layer ions to the interface are not identical in principle and we may denote their distances from the adsorption plane ($x = 0$) by γ_1 and γ_2 respectively. For cations and anions of comparable size in the diffuse layer, one would certainly expect the counter-ions to be adsorbed closer to the wall than the distance of nearest approach of co-ions and therefore γ_2 will remain appreciable. If $\gamma_2 > \gamma_1$, the mean potential at the wall is given by

$$\psi_0 = \frac{4\pi\sigma_0\beta}{\epsilon_1} + 4\pi(\sigma_0 + \sigma_\beta)\left(\frac{\gamma_1}{\epsilon_1} + \frac{\gamma_2 - \gamma_1}{\epsilon}\right) + \psi_d, \qquad [3.11]$$

where ψ_d is the mean potential at $x = \gamma_2$. This is equivalent to an inner region of dielectric constant ϵ_1, with the plane of dielectric discontinuity and the diffuse layer boundary coincident, and of thickness γ_m for its 'outer zone' given by

$$\gamma_m = \gamma_1 + \epsilon_1/\epsilon(\gamma_2 - \gamma_1). \qquad [3.12]$$

Since $\epsilon_1/\epsilon \ll 1$, γ_m may appear small when γ_1 is small even if γ_2 is appreciable. In addition

to these 'mean γ's' there may also be a 'local γ' to consider as suggested by Barlow and Macdonald [18]. If the adsorbed ions retain the part of their hydration shell of radius b lying on the solution side, then each absorbed ion has its own local region of dielectric saturation and in general the potentials of different adsorbed ions are no longer additive. If, to avoid great mathematical difficulties, we retain the concept of a plane of dielectric discontinuity, then the appropriate values of γ for calculating ϕ_1 and ϕ_2 will both lie between γ_1 and b and it is interesting to note that if the major contribution to ϕ_1 comes from a portion of the disc of radius a then the γ's for ϕ_1 and ϕ_2 should be close together. Barlow and Macdonald (18) have suggested a value of b as much as 7 Å for the mercury – KI electrolyte solution interface, but this seems excessive and values of 2–3 Å for the local γ are perhaps more reasonable.

4. EVALUATION OF THE SELF-ATMOSPHERE POTENTIAL $\phi_1(x, \rho)$

We shall first consider the limiting case where the wall is a perfect dielectric. The function $\phi_1(x, \rho)$ satisfies Laplace's equation in the region of space $x < \gamma$ and the linear eq. [3.6] in the diffuse layer where $x > \gamma$. Also, $\phi_1(x, \rho)$ and the corresponding normal component of the dielectric displacement must be continuous at the wall and at the O.H.P. Thus in addition to [3.10] we have the boundary conditions

[4.1] $$\phi_1(x, \rho) \text{ continuous at } x = -\beta \text{ and } x = \gamma,$$

[4.2] $$\epsilon_1(\partial\phi_1(x, \rho)/\partial x)_{x=\gamma-0} = \epsilon(\partial\phi_1(x, \rho)/\partial x)_{x=\gamma+0}.$$

Since $\phi_1(x, \rho)$ is due to the removal of a disc of charge density σ_β and radius r_β, where r_β is defined by [2.7], $\phi_1(x, \rho)$ at $x = 0$ on the I.H.P. must satisfy the conditions

[4.3] $$\phi_1(x, \rho) \text{ continuous}$$

and

[4.4] $$\epsilon_1\left[\left(\frac{\partial\phi_1(x, \rho)}{\partial x}\right)_{x=-0} - \left(\frac{\partial\phi_1(x, \rho)}{\partial x}\right)_{x=+0}\right] = \begin{cases} 0 & , r > r_\beta \\ -4\pi\sigma_\beta & , r < r_\beta \end{cases}.$$

The solutions of Laplace's equation for $\phi_1(x, \rho)$ in the inner region and in the wall medium are given in Appendix C.

Case of Small Potential at the O.H.P.

In this particular case, the value of $\phi_1(x, \rho)$ at the center of the disc is expressed in integral form as

[4.5] $$\phi_1(x, \rho) = \frac{-2\pi\sigma_\beta r_\beta}{\epsilon_1} \int_0^\infty \frac{N(k)}{D(k)} \cdot J_1(kr_\beta) \frac{dk}{k},$$

where, introducing the notation

[4.6] $$f = \epsilon/\epsilon_1, f_p = \epsilon_2/\epsilon_1, f' = f(1 + \kappa^2/k^2)^{1/2}, f_2' = (1 - f')/(1 + f')$$

with f_1 defined in [2.16], then

[4.7] $$N(k) = (1 + f_1 e^{-2k\beta})(1 + f_2' e^{-2k\gamma}),$$

[4.8] $$D(k) = (1 - f_1 f_2' e^{-2k(\beta+\gamma)}).$$

When the electrolyte concentration is so small that we can put $\kappa = 0$ then f_2' tends to f_2 (also defined in [2.16]) and $\phi_1(0, 0)$ will be denoted by $\phi_1^*(0, 0)$. In Section 2 we found eq.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[2.19] to be a convenient way of expressing $\phi_1(0, 0)$ for the case of two conducting walls and we can write $\phi_1^*(0, 0)$ in a corresponding form with the appropriate $g_\phi(r_\beta)$ now denoted by $g_\phi^*(r_\beta)$, namely

$$[4.9] \qquad \phi_1^*(0, 0) = \frac{-2\pi\sigma_\beta}{(z_\beta e_0)^2} \int_0^{r_\beta} \rho U(\rho)\, d\rho = -\frac{4\pi\beta\gamma}{\epsilon_1 d}\, \sigma_\beta g_\phi^*(r_\beta),$$

where $g_\phi^*(r_\beta)$ is derived in Appendix C and is expressed as an infinite series having a form similar to [2.17] which represents multiple image reflection in the two boundaries of the inner region. The first relation of [4.9] is a direct consequence of the cut-off model, if [2.17] is substituted for $U(\rho)$ in the integral. In the second relation in [4.9], both $g_\phi^*(r_\beta)$ and $U(\rho)$ depend on distance only and therefore r_β and σ_β may be treated as independent variables. Differentiating [4.9] with respect to r_β we obtain

$$[4.10] \qquad U(r_\beta) = \frac{2\beta\gamma}{\epsilon_1 dr_\beta} (z_\beta e_0)^2 g_\phi^{*\prime}(r_\beta),$$

where the prime denotes differentiation with respect to r_β. The formulae [4.9] and [4.10] apply not only to the limiting case of zero electrolyte concentration ($\kappa = 0$) but also to the opposite limit of infinite concentration, when the conducting O.H.P. may be treated as a perfect conductor and $f_2 = -1$. The wall may be either a dielectric or a conductor ($f_1 = -1$). Thus the case of two conducting walls bounding the inner region as described by [2.19] and [2.21] is also included in the above relations.

Case of General Potential at the O.H.P.

For general η_d, the potential at the center of the disc $\phi_1(0, 0)$ can be expressed as

$$[4.11] \qquad \phi_1(0, 0) = \phi_1^*(0, 0) + \Delta\phi_1(0, 0),$$

where

$$[4.12] \qquad \Delta\phi_1(0, 0) = (2\pi\sigma_\beta r_\beta/\epsilon_1) I_1,$$

with I_1 given by [C.20].

If instead of a perfect dielectric, the wall is a perfect conductor, then [3.9] holds and we need only put $f_p = \infty$ and hence $f_1 = -1$ in the above formulae for $\phi_1^*(0, 0)$ and $\Delta\phi_1(0, 0)$.

In the limiting case where $r_\beta \gg d$ a simple expression is obtained for $\phi_1(0, 0)$. Let

$$[4.13] \qquad C_1 = \epsilon_1/4\pi d,\ C_1 = \epsilon_1/4\pi\beta,\ C_2 = \epsilon_1/4\pi\gamma$$

be the capacitances per unit area of the molecular condensers consisting of (i) the inner region, (ii) the part of this region of thickness β lying between the I.H.P. and the wall, and (iii) the part of thickness γ lying between I.H.P. and O.H.P., respectively. Suppose also that the diffuse layer can be regarded as a molecular condenser of capacitance per unit area

$$[4.14] \qquad C_d = \epsilon_1/4\pi(\kappa \cosh \tfrac{1}{2}\eta_d)^{-1}$$

in series with the condensers of the inner region. This means that the diffuse layer can be replaced by a conducting wall at a distance $(\kappa \cosh \frac{1}{2}\eta_d)^{-1}$ from the O.H.P. This distance is the Debye–Hückel length defined by an effective electrolyte concentration which would be found at a point in the diffuse layer where the potential is $\psi_d/2$. For a perfect dielectric wall, we show in Appendix C that for large r_β the discrete ion potential at the center of the disc is the potential drop across a molecular condenser of unit area which consists of C_2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and C_d in series and has the charge $-\sigma_\beta$ on the I.H.P. This potential is given by

$$\phi_1(0, 0) = -\sigma_\beta\left(\frac{1}{C_2} + \frac{1}{C_d}\right) \qquad [4.15]$$

which is independent of β and ϵ_2. For a perfectly conducting wall, the corresponding formula reads (Appendix C)

$$\phi_1(0, 0) = -\frac{\sigma_\beta}{C_1}\cdot\left(\frac{1}{C_2} + \frac{1}{C_d}\right)\Big/\left(\frac{1}{C_1} + \frac{1}{C_d}\right). \qquad [4.16]$$

Although the condition $r_\beta \gg d$ strictly applies only to a dielectric wall at low electrolyte concentration (see Table I) the formulae [4.15] and [4.16] are useful because they give simple upper bounds to $\phi_1(0, 0)$.

For a general interface with a diffuse layer beyond the O.H.P. and an arbitrary r_β it is again possible to write $\phi_1(0, 0)$ in the form [2.19] but now $g_\phi(r_\beta)$ will depend on η_d as well as on r_β. Since η_d will vary with σ_β we should really write $g_\phi(r_\beta, \eta_d(\sigma_\beta))$ but the explicit dependence of g_ϕ on η_d will be omitted. Comparison of [4.15] or [4.16] with [2.19] yields the limiting form $g_\phi(\infty)$. For a perfectly conducting O.H.P. ($\epsilon = \infty$), again adopting the convention $g_\phi(r_\beta) = g_\phi^*(r_\beta)$, we find that [4.15] yields $g_\phi^*(\infty) = d/\beta$ when the wall is a dielectric and either [2.21] or [4.16] gives $g_\phi^*((\infty) = 1$ when the wall is metallic. Simplified versions of the electrostatic arguments in I justifying these results are outlined in Appendix C.

For a dielectric wall in the limiting case of zero electrolyte concentration ($\kappa = 0$), $U(\rho)$ behaves as $1/\rho$ when $\rho \to \infty$ and it follows from [4.9] that at large r_β, $g_\phi^*(r_\beta)$ increases as r_β. In order that $g_\phi^*(r_\beta)$ remain finite, the screening by the diffuse layer is essential when applying the cut-off model at a dielectric wall and it should be remarked that the hexagonal lattice behaves similarly. This infinite limit to $g_\phi^*(r_\beta)$ is due to the model of an infinite sheet of like charges in the absence of equal and opposite charges which would produce screening; such a model is, of course, physically impossible. For either a conducting wall or a conducting O.H.P., $U(\rho)$ behaves as $1/\rho^3$ at large ρ and hence $g_\phi^*(\infty)$ is finite. The derivative on the right of [4.10] behaves as $1/r_\beta^2$ for large r_β and so $g_\phi^*(r_\beta) = g_\phi^*(\infty) - w/r_\beta$ where it will be seen that the constant $w > 0$. When $\gamma = \beta$, $s_0 = 0$ in the formula [2.21] for two infinitely conducting boundaries of the inner region and since $K_1(x)$ behaves as $\exp(-x)/\sqrt{x}$ at large x, we see that in this case $U(\rho)$ behaves as $\exp(-\pi\, d\rho)/\sqrt{\rho}$ at large ρ. We have not succeeded in transforming the more general case $\gamma \neq \beta$ ($s_0 \neq 0$) into a corresponding form but it seems likely that $U(\rho)$ displays a similar asymptotic behavior. This limiting case describes the most extreme form of screening, since it corresponds to infinite electrolyte concentration at a conducting wall.

5. NUMERICAL RESULTS AND DISCUSSION

In this paper we shall only consider the mean potential energy $z_\beta e_0 \phi_1(0, 0)$ and shall postpone the more difficult problem of the discrete-ion contribution to the electrochemical potential of an adsorbed ion to a future paper. If the function $g_\phi(r_\beta)$ (denoted g_ϕ in this section) could be assumed independent of the charge $z_\beta e_0$ on an adsorbed ion, then $z_\beta e_0 \phi_1(0, 0)$ would be identical with the discrete-ion part of the electrochemical potential. In calculating this energy it is necessary to assume some relation between r_β and σ_β and for simplicity we have chosen the Grahame relation [2.9] which overestimates $|\phi_1(0, 0)|$. We have calculated the unscreened term $e_0\phi_1^*(0, 0)/\mathbf{k}T$ from [4.9], (assuming $z_\beta = 1$) and in Fig. 4 have plotted this quantity as a function of r_β for both the metallic medium –

water and dielectric medium – water interfaces. [We are particularly interested in both mercury and silver iodide – water interfaces and in this section we have chosen values for the double layer parameters which are consistent with known data on these systems.] The parameters are given in the figure legend and, as to be expected, the curves show that the discrete-ion potential increases with an increase in γ or a decrease in ϵ_1. For the same values of the relevant parameters of the inner region the discrete-ion potential at the silver halide wall is greater than at the mercury wall and this is compatible with the greater screening by the image terms in the latter case. The effect of screening of the Grahame cut-off model by the diffuse layer of a 1–1 electrolyte is shown in Fig. 5 and Table III. In Fig. 5 we have plotted $e_0\Delta\phi_1(0, 0)/\mathbf{k}T$ for the silver iodide – water interface as a function of r_β over a range of $|\eta_d|$ and salt concentration. For the mercury surface it is more convenient to show this dependence as in Table III. These results confirm the conclusion drawn from the much simpler model introduced by Bell, Levine, and Pethica (10) that on dilute solutions ($< M/100$) the diffuse layer screening is small compared to the unscreened term except at large r_β. An increase in $|\eta_d|$ or salt concentration c increases $\Delta\phi_1(0, 0)$ but since $|\eta_d|$ decreases with c, the explicit dependence of $\phi_1(0, 0)$ on c is not immediately accessible unless σ_β and η_d are known. The plots in Figs. 4 and 5 and the results in Table III can only indicate qualitative trends in the behavior of $\phi_1(0, 0)$, because the distribution function $S^*(\rho)$ is not determined. We should expect that these results become more reliable the smaller r_β, i.e. the higher the surface charge density σ_β. The results in Table I show that

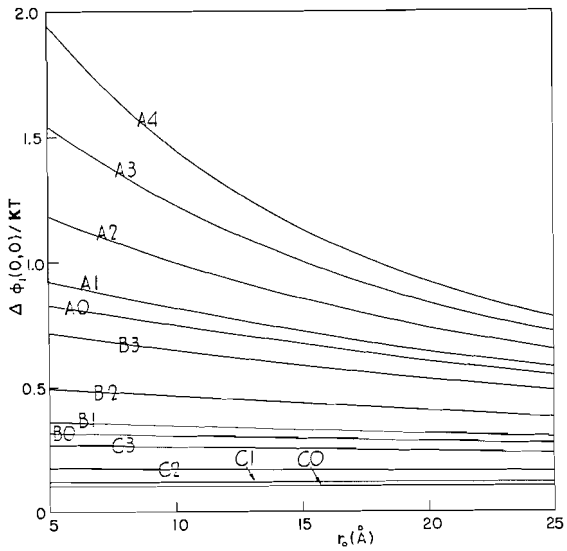

FIG. 5. Diffuse layer correction $(\Delta\phi_1\ (0, 0)/\mathbf{k}T)$ to the discrete-ion potential at a dielectric wall. $\epsilon = 80.1$, $T = 20°$, $\epsilon_2 = 15$, $\epsilon_1 = 10$, $\beta = 3$ Å, $\gamma = 1$ Å. A. $M/10$. B. $M/100$. C. $M/1000$. The numbers 4, 3, 2, 1, and 0 refer to the value of $|\eta_d|$.

the larger values of r_β plotted in the above curves (> 15 Å say) may be somewhat unrealistic in the case of strong screening e.g. at a mercury wall or in high electrolyte concentrations.

It was shown in Section 2 that for the idealized model of two conducting planes bounding the inner region, we were able to impose fairly narrow limits on the value $\phi_1(0, 0)$ even though the distribution function was unknown. To arrive at this result it was found convenient to express $\phi_1(0, 0)$ in the form [2.19] and then to examine the factor g_ϕ as a function of r_β. We found that g_ϕ varies only slightly with r_β, and this suggests that g_ϕ is a very useful quantity in describing the discrete-ion potential. In Figs. 6 and 7, we have plotted the term g_ϕ as a function of r_β with varying $|\eta_d|$ and c for the silver iodide – water interface. As expected, there is a much greater variation in g_ϕ at this interface than for the model of two conducting walls. It can be seen from Fig. 6 that $g_\phi(a)$, the smallest value of g_ϕ, lies in the range 1.25 to 1.54 when $\gamma = 1$ and $\beta = 3$, the actual value depending on $|\eta_d|$ and c; the corresponding range in $g_\phi(a)$ from Fig. 7 when $\gamma = 2$ and $\beta = 3$ is 1.13 to 1.26. We observe that $g_\phi(a)$ diminishes with increase in $|\eta_d|$ or c. From Table I, it appears that for a silver iodide wall the maximum value of r_β at low σ_β is of the order 15 Å in 0.1 M salt solution, about 20–25 Å in 0.01 M and in the range 25–50 Å in 0.001 M, depending on the value of $|\eta_d|$. Electrophoretic measurements indicate that the value of $|\eta_d|$ at coagulation is of the order of 2 for a number of common hydrophobic sols in 1–1 valent electrolyte. Thus assuming a maximum $r_\beta = 15$ Å and $|\eta_d| = 2$ in a 0.1 M solution g_ϕ will therefore lie between 1.36 and 1.92 when $\gamma = 1$. This is to be compared with the constant value of $g_\phi = d/\beta = 1.33$ assumed by the authors in earlier papers (7, 8, 17). For $\gamma = 2$, the corresponding increase in g_ϕ is from 1.17 to 1.75 whereas d/β is now 1.67. Thus for 1–1 electrolytes, the value $g_\phi = d/\beta$ was apparently an underestimate for $\gamma = 1$ and could possibly have been an overestimate for $\gamma = 2$. If we assume a maximum in r_β of 20 Å for the concentration 0.01 M and $|\eta_d| = 2$, then g_ϕ lies between 1.46 and 2.81 for $\gamma = 1$ and between 1.22 and 2.29 for $\gamma = 2$. In Table IV, we give g_ϕ for the mercury–water interface with

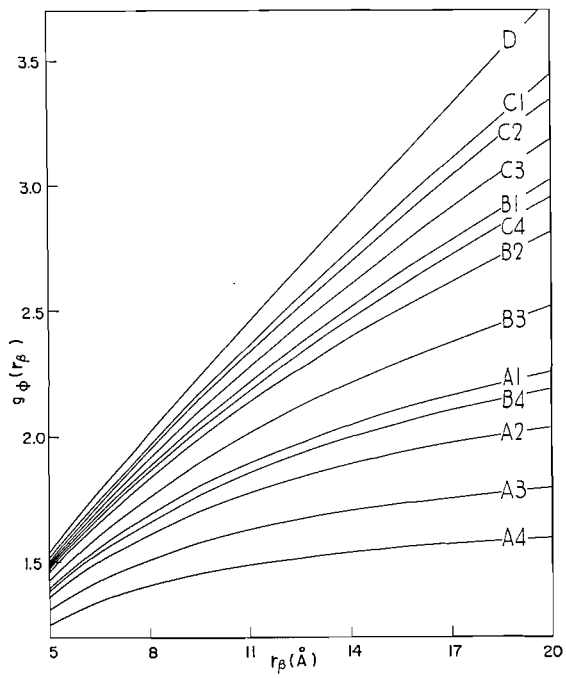

FIG. 6. The function $g_\phi(r_\beta)$ for a dielectric wall with $\gamma = 1$ Å, $\epsilon = 80.1$, $\epsilon_1 = 10$, $\epsilon_2 = 15$, $\beta = 3$ Å. A. $M/10$. B. $M/100$. C. $M/1000$. The numbers 4, 3, 2, and 1 refer to the value of $|\eta_d|$. D is the unscreened case.

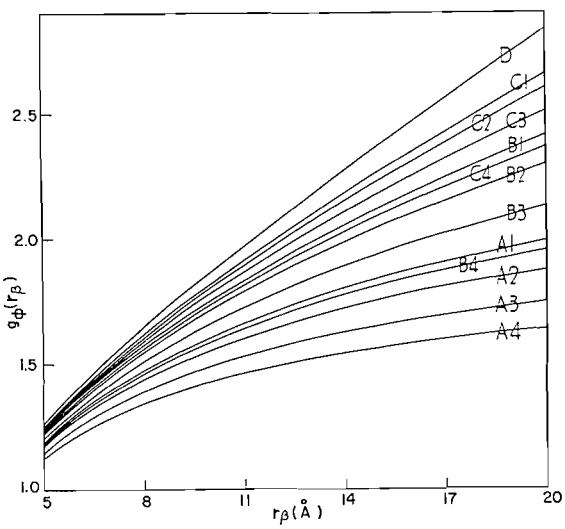

FIG. 7. The function $g_\phi(r_\beta)$ for a dielectric wall with $\gamma = 2$ Å, $\epsilon = 80.1$, $\epsilon_1 = 10$, $\epsilon_2 = 15$, $\beta = 3$ Å. A. $M/10$. B. $M/100$. C. $M/1000$. The numbers 4, 3, 2, and 1 refer to the value of $|\eta_d|$. D is the unscreened case.

various η_d, c, and r_β. These values should be compared with the underestimate $g_\phi = 1$ which was suggested in an earlier paper (9). The greater screening at this interface restricts the range of r_β (5 to 15 Å) over which g_ϕ can be applied. The explanation of the various phenomena described in the Introduction in terms of the discrete-ion effect requires that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$\phi_1(0, 0)$ be fairly large. This, in turn, requires that γ should not vanish and that g_ϕ should be of the order of 1. When the parameters of the inner region are chosen to be consistent with experimental data, values of g_ϕ result which lie in the range 1 to 2 for most experimental conditions at charged interfaces as shown by Table IV and Figs. 6 and 7. The earlier estimates of g_ϕ, namely $g_\phi = d/\beta$ for a silver iodide wall and $g_\phi = 1$ for a metallic wall, were thus not too greatly in error. The discussion in Section 3 would indicate that γ can hardly vanish.

To understand the significance of the above results in the stability theory of silver iodide sols we first point out that our calculations on a 1–1 electrolyte can be applied to a binary symmetrical electrolyte of valency type Z–Z. We need only replace e_0, κ, and η_d respectively by Ze_0, $Z\kappa$, and $Z\eta_d$ and also the Grahame relation [2.9] by

$$\pi r_\beta^2 \sigma_\beta = -Z z_\beta e_0, \qquad [5.1]$$

provided z_β is redefined as ± 1, according as the adsorbed counter-ion is positive or negative. In the previous papers (6–8) on the relation between the discrete-ion effect and colloid stability, we compared the coagulating powers of 1–1, 2–2, and 3–3 electrolytes and assume $g_\phi = d/\beta$ for all three valency types. Choosing the same value of g_ϕ we also treated a mixture of 1–1 and 2–2 electrolytes and showed that the phenomenon of mutual antagonism can be obtained on the basis of the discrete-ion effect. Because present-day electric double layer theory, for a variety of reasons (for example neglect of image terms in the diffuse layer (37)), is likely to be inadequate to give a quantitative account of the coagulating properties of trivalent ions, we shall confine our discussion to a comparison of 1–1 and 2–2 electrolytes.

The concentrations $c = 0.1$ and 0.01 M of 1–1 electrolyte correspond to $c/Z^2 = 0.1$ and 0.0025 M of 1–1 and 2–2 valency types respectively and these are typical flocculating concentrations for silver halide sols. The discrete-ion correction has a significant effect on stability when $|\sigma_\beta| > |\sigma_\beta^m|$, where $|\sigma_\beta^m|$ is the value of σ_β at the maximum in $|\psi_d|$ which is obtained when the wall potential is varied at fixed electrolyte concentration. In the examples given in earlier papers (6–8) σ_β^m was in the range 2 to 4 $\mu C/cm^2$ for the 1–1 case and 1 to 2 $\mu C/cm^2$ in the 2–2 case. According to [5.1] which gives an upper bound to r_β for a specified σ_β, $r_\beta = 13$ Å at $\sigma_\beta = 3$ $\mu C/cm^2$ in 1–1 electrolyte and $r_\beta = 26$ Å at $\sigma_\beta = 1.5$ $\mu C/cm^2$ in 2–2 electrolyte. It is shown elsewhere (17) that, in the case of 2–2 electrolyte in the range $|\sigma_\beta| > |\sigma_\beta^m|$, values of g_ϕ significantly greater than 1 are required to explain mutual antagonism for a 1–1 plus 2–2 electrolyte mixture in terms of the discrete-ion effect. If we assume $|\eta_d| = 2$ and a value of r_β as low as 10 Å for the case of 0.0025 M of 2–2 electrolyte, Figs. 6 and 7 show that such values of g_ϕ are readily attainable.

Some of the manifestations of the discrete-ion effect (such as those in colloid stability) should strictly be described in terms of a function, which we may call $g_\mu(r_\beta)$. This is the factor in the discrete-ion contribution to the electrochemical potential which corresponds to $g_\phi(r_\beta)$ in the potential $\phi_1(0, 0)$. It can be shown that $g_\mu(\infty) = g_\phi(\infty)$ and it is likely that for finite r_β, $g_\phi(a) < g_\mu(r_\beta) < g_\phi(r_\beta)$. Table IV and Figs. 6 and 7 show that $g_\phi(a)$ is nearly always greater than 1.

APPENDIX A

For a canonical ensemble the pair distribution function $g_{ij}(r)$ between two ions of types i and j, charges $z_i e_0$ and $z_j e_0$, at separation r in a volume V of a 1–1 electrolyte solution may be written as

$$\frac{N_t}{V}[g_{ij}(r) - 1] = f_{ij}^*(r) + k_{ij}/V = f_{ij}(r). \qquad [A.1]$$

Here N_t is the total number of ions of either type, k_{ij} is a constant, and $f_{ij}^*(r) \to 0$ as $r \to \infty$ in the sense that it becomes negligible outside the 'sphere of influence' or the 'region of the ionic atmosphere' of the fixed ion i. For a grand canonical ensemble, the term k_{ij}/V is absent. Assuming the limiting Debye–Hückel theory of electrolytes, we postulate that

$$[A.2] \qquad f_{ij}^*(r) \approx \frac{N_t}{V} z_j \frac{e_0 \varphi_i(r)}{\mathbf{k}T} \approx \frac{-N_t}{V} \cdot \frac{z_i z_j e_0^2}{\epsilon \mathbf{k} T} \frac{e^{-\kappa r}}{r},$$

where $\varphi_i(r)$ is the potential in the ionic atmosphere of ion i and κ is given by [3.3] if $N_t = nV$. Integrating over a large enough sphere with center at ion i (which can be taken equal to V)

$$[A.3] \qquad \int_V f_{ij}^*(r)\, dv = \frac{-4\pi N_t z_i z_j e_0^2}{\epsilon \mathbf{k} T V \kappa^2}.$$

Summing over the two ion types, we obtain the conditions of electrical neutrality

$$[A.4] \qquad e_0 \int_V (z_i f_{i1}^* + z_2 f_{i2}^*)\, dV = -z_i e_0,\ i = 1, 2.$$

For a canonical ensemble we have the 'normalization' condition

$$[A.5] \qquad \int_V f_{ij}(r)\, dv = -1,\ i = j;\ 0,\ i \neq j,$$

which leads to conditions identical in form to [A.4]. Integrating the second relation in [A.1] over V and making use of [A.3] and [A.5] the linear Debye–Hückel theory yields $k_{11} = k_{22} = k_{12} = -1/2$ and so we arrive at the important result

$$[A.6] \qquad e_0(z_1 k_{i1} + z_2 k_{i2}) = 0,\ i = 1, 2.$$

It follows that although the individual pair distribution functions $f_{ij}(r)$ do not tend to zero at large r, the charge density distribution functions for the canonical ensemble $e_0(z_1 f_{i1}(r) + z_2 f_{i2}(r))$, $i = 1, 2$ tend to zero, as in the case of the grand canonical ensemble. This is equivalent to the condition of 'local electrical neutrality' which is obeyed throughout the system for both canonical and grand canonical ensembles. A clearer picture of the physical significance of the term k_{ij}/V is obtained by writing [A.1] as

$$[A.7] \qquad f_{ij}(r) = \frac{(N_t - \frac{1}{2})}{V} [\bar{g}_{ij}(r) - 1] = f_{ij}^*(r) - \frac{1}{2V},\ \bar{g}_{ij}(r) = g_{ij}(r) + \frac{1}{2N_t},$$

where $\bar{g}_{ij}(r) \to 1$ as $r \to \infty$. By fixing an ion i we have prevented this ion from participating in the thermal motion, thereby reducing by 1 the total number of ions free to move in the volume. This causes an adjustment of the ion concentration at large r from $2N_t/V$ to $(2N_t - 1)/V$. Because of the condition of local electrical neutrality this can only be achieved by reducing the concentration of positive and negative ions by the same amount, which explains the factor $(N_t - 1/2)$ in [A.7].

Consider now the problem of an adsorbed ion $z_\beta e_0$ fixed at $x = \rho = 0$ on the I.H.P. Suppose that a grand canonical ensemble is chosen for the adsorbed layer of counter-ions in this plane and the electrolyte in the aqueous phase is again a 1–1 type. In the diffuse layer, the function $f_{ij}(r)$ of [A.1] is replaced by $f_{\beta j}(x, \rho)$, the fluctuation density distribution of ions of type j due to the presence of the fixed absorbed ion $z_\beta e_0$. We may expect $f_{\beta j}(x, \rho)$ to take the form

$$[A.8] \qquad f_{\beta j}(x, \rho) = f_{\beta j}^*(x, \rho) + k_{\beta j}/V,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where $f_{\beta j}^*(x, \rho)$ is zero outside the hemisphere of influence of the absorbed ion. As a result of the extremely small change in electrolyte concentration at large x when $z_\beta e_0$ is fixed in position, $k_{\beta j}$ varies very slightly with x in the region of the diffuse layer, but this may be ignored. Since no ions oppositely charged to $z_\beta e_0$, which we shall call type 1, are allowed to cross the O.H.P.,

$$\int_V f_{\beta 1}(x, \rho)\, \mathrm{d}V = 0, \qquad [A.9]$$

where V is the volume of the electrolyte phase. Substituting [A.8] with $j = 1$

$$k_{\beta 1} = -\int_V f_{\beta 1}^*(x, \rho)\, \mathrm{d}V. \qquad [A.10]$$

The grand canonical, two-dimensional, fluctuation distribution function for adsorbed ions $f_\beta^*(\rho)$ due to the fixed ion $z_\beta e_0$, is confined to the 'circle of influence', and thus $f_\beta^*(\rho) \to 0$ as $\rho \to \infty$. Since the system as a whole is treated as a canonical ensemble, the 'normalization condition' replacing the first equation in [A.5] is

$$\int_V f_{\beta 2}(x, \rho)\, \mathrm{d}V + \int_A f_\beta^*(\rho)\, \mathrm{d}A = 1, \qquad [A.11]$$

where ion type 2 has the charge $z_\beta e_0$. Local electrical neutrality in the electrolyte interior requires that $k_{\beta 1} = k_{\beta 2}$ and so, by [A.8] and [A.10], [A.11] yields

$$\int_A f_\beta^*(\rho)\, \mathrm{d}A + \int_V [f_{\beta 2}^*(x, \rho) - f_{\beta 1}^*(x, \rho)]\, \mathrm{d}V = -1. \qquad [A.12]$$

The eq. [3.8] for $\phi(x, \rho)$ should be interpreted as yielding the grand canonical functions $f_{\beta j}^*(x, \rho)$ in the diffuse layer in the same way as the Debye–Hückel theory gives $f_{ij}(r)$ in [A.2]. Because $z_2 = -z_1 = z_\beta$ we can write

$$f_{\beta j}^*(x, \rho) = n\mathrm{e}^{\pm z_\beta e_0 \Psi(x)/\mathbf{k}T}[\mathrm{e}^{\pm z_\beta e_0 \phi(x,\rho)/\mathbf{k}T} - 1] \approx \frac{\pm n z_\beta e_0 \phi(x, \rho)\mathrm{e}^{\pm z_\beta e_0 \Psi(x)/\mathbf{k}T}}{\mathbf{k}T}, \qquad [A.13]$$

where $j = 1$ or 2, according as the sign is plus or minus. The volume integral in [A.12] therefore reads

$$\int_V [f_{\beta 2}^*(x, \rho) - f_{\beta 1}^*(x, \rho)]\, \mathrm{d}V = \frac{-2nz_\beta e_0}{\mathbf{k}T} \int_V \phi(x, \rho) \cosh \frac{z_\beta e_0 \Psi(x)}{\mathbf{k}T}\, \mathrm{d}V \qquad [A.14]$$

$$= \frac{-2nz_\beta e_0}{\mathbf{k}T\kappa^2} \int_V \nabla^2 \phi\, \mathrm{d}V = \frac{2nz_\beta e_0}{\mathbf{k}T\kappa^2} \int_A \frac{\partial \phi}{\partial n} \cdot \mathrm{d}A = -q^*(\sigma_\beta)/z_\beta e_0,$$

where we denote differentiation along the normal to the O.H.P. drawn outward into the diffuse layer by $\partial/\partial n$. We have substituted [3.6] and then applied Green's theorem and Gauss's theorem in turn. Because $\phi(x, \rho)$ is the potential change in the hemisphere of influence as a result of fixing the adsorbed ion $z_\beta e_0$ on the O.H.P., $q^*(\sigma_\beta)$ is the total amount of charge that crosses the O.H.P. into the inner region during this process. Since a grand canonical ensemble is being used for the adsorbed phase (i.e. V is large) the surface charge density σ_β is unaltered at large ρ when $z_\beta e_0$ is fixed in position and consequently the movement of ions of type 2 across the O.H.P., which gives $q^*\sigma_\beta$ can only take place in the circle of influence. Substituting [A.14] into [A.12],

$$q^*(\sigma_\beta)/z_\beta e_0 = 1 + \int_A f_\beta^*(\rho)\, \mathrm{d}A. \qquad [A.15]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The quantity $z_\beta e_0 f_\beta^*(\rho)$ is identical with the fluctuation charge density $S^*(\rho)$ which is given by [2.6]. Substituting [2.6] into [A.15] and expressing σ_β in terms of r_0 by means of [2.9], we have

$$[A.16] \qquad q^*(\sigma_\beta)/z_\beta e_0 = 1 - \frac{2}{r_0^2}\int_0^\infty \rho[1 - \exp(-V(\rho)/\mathbf{k}T)]\,\mathrm{d}\rho.$$

Suppose we choose a canonical ensemble for the phase of adsorbed ions. When one ion $z_\beta e_0$ is fixed at $x = \rho = 0$ and thereby becomes the source of an external force field, no ions are permitted to cross the O.H.P. Corresponding to [A.7], the fluctuation distribution function for adsorbed ions $f_\beta(\rho)$ can be written as

$$[A.17] \qquad f_\beta(\rho) = \frac{N}{A}[q(\rho) - 1] = f_\beta^*(\rho) - k_A(\sigma_\beta)/A$$

and the condition of constant total number of adsorbed ions [2.1] yields

$$[A.18] \qquad \int_A f_\beta(\rho)\,\mathrm{d}A = -1.$$

It follows from [A.15], [A.17], and [A.18] that

$$[A.19] \qquad k_A(\sigma_\beta) = q^*(\sigma_\beta)/z_\beta e_0$$

and so [A.16] is identical with [2.12]. In place of [A.8] we postulate for the fluctuation density distribution in the electrolyte phase

$$[A.20] \qquad f_{\beta j}(x, \rho) = f_{\beta j}^*(x, \rho) + \bar{k}_{\beta j}(x)/V,$$

where certain properties of the function $\bar{k}_{\beta j}(x)$ can be obtained as follows. If we assume that $\phi(x, \rho)$ does not change sign in the hemisphere of influence then by [A.13], $f_{\beta 1}^*(x, \rho)$ and $f_{\beta 2}^*(x, \rho)$ are opposite in sign. Since a normalization condition of the type [A.9] will hold for $\bar{f}_{\beta 1}(x, \rho)$ and $\bar{f}_{\beta 2}(x, \rho)$, it follows from [A.20] that the integrals

$$\int_V \bar{k}_{\beta 1}(x)\,\mathrm{d}V \text{ and } \int_V \bar{k}_{\beta 2}(x)\,\mathrm{d}V$$

are also of opposite sign. Beyond the diffuse layer ($x \gg \kappa^{-1}$), however, the condition of local electrical neutrality requires that $\bar{k}_{\beta 1}(x) = \bar{k}_{\beta 2}(x)$ and since V is much larger than the volume occupied by the diffuse layer, these two integrals would have the same sign, unless $\bar{k}_{\beta 1}(x)$ and $\bar{k}_{\beta 2}(x)$ are both virtually zero for $x \gg \kappa^{-1}$. This means that the process of fixing ion $z_\beta e_0$ at $x = \rho = 0$ does not alter the concentration in the electrolyte interior for the canonical ensemble. From the normalization conditions for $\bar{f}_{\beta j}(x, \rho)$

$$[A.21] \qquad \int_V f_{\beta j}^*(\rho)\,\mathrm{d}V = \frac{-1}{V}\int_V \bar{k}_{\beta j}(x)\,\mathrm{d}V = \frac{-A}{V}\int_\gamma^\infty \bar{k}_{\beta j}(x)\,\mathrm{d}x,\ j = 1, 2,$$

since $\bar{k}_{\beta j}(x)$ differs from zero only near the O.H.P. in the range of x defined by the diffuse layer. Making use of [A.14] and [A.19], we therefore derive

$$[A.22] \qquad \frac{z_\beta e_0 k_A(\sigma_\beta)}{A} + \frac{e_0}{V}\int_\gamma^\infty [z_1\bar{k}_{\beta 1}(x) + z_2\bar{k}_{\beta 2}(x)]\,\mathrm{d}x = 0,$$

which may be interpreted as follows. Consider a prism of unit area in cross section, normal to the interface and including the I.H.P. and diffuse layer, at large distance ρ from the fixed ion $z_\beta e_0$. When the canonical ensemble is used, the process of fixing $z_\beta e_0$ at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$x = \rho = 0$ produces a change in charge equal to $z_\beta e_0 k_A(\sigma_\beta)/A$ on the part of the I.H.P. contained in the prism. The condition of local electrical neutrality requires an equal and opposite change in net charge in the diffuse layer part of the prism and this change is given by the integral term in [A.22]. We have chosen here the simplified model of fixed σ_0 on the wall. The analysis could be extended to allow for the presence in the electrolyte of the 'potential-determining' ion type which may constitute the charge σ_0, but this would involve additional normalization conditions and a more complicated form of the local electrical neutrality.

We need to comment on the use of the same 'local' functions $f_{\beta j}^*(x, \rho)$ and $f_\beta^*(\rho)$ in the grand canonical and canonical ensembles. The terms $k_{\beta j}/V$, $k_A(\sigma_\beta)/A$ and $\bar{k}_{\beta j}(x)/V$ contribute a negligible amount to the self-atmosphere potential $\phi_1(0, 0)$ and so common local distribution functions lead to the same expression for $\phi_1(0, 0)$ with the two ensembles. The differential equation satisfied by $\phi(x, \rho)$ in the two ensembles differ because of changes $k_{\beta 1}/V$ in the bulk concentration of electrolyte and $k_A(\sigma_\beta)/A$ in the surface concentration of adsorbed ions at points distant from the fixed ion. These differences are negligible at large enough V and A and hence $\phi(x, \rho)$ is virtually the same potential function in the two ensembles.

APPENDIX B

On substituting [3.2] into [3.6], we can write [3.6] in the form given by Williams (35)

$$[B.1] \qquad \frac{1}{\rho}\frac{\partial}{\partial \rho}\left(\frac{\rho \partial \phi(x, \rho)}{\partial \rho}\right) + \frac{\partial^2 \phi(x, \rho)}{\partial x^2} = \kappa^2\left[1 + \frac{8 \exp(-2\kappa x')\xi}{(1 - \exp(-2\kappa x')\xi)^2}\right]\phi(x, \rho)$$

where $\xi = \tanh^2 \frac{1}{4}\eta_d$. Separation of variables gives as the solution of [B.1] the integral

$$[B.2] \qquad \phi(x, \rho) = \int_0^\infty X(x, k) J_0(k\rho) k \, dk,$$

where $X(x, k)$ satisfies the equation

$$[B.3] \qquad \frac{d^2X}{dx^2} = \left[\kappa^2\left\{1 + \frac{8 \exp(-2\kappa x')\xi}{(1 - \exp(-2\kappa x')\xi)^2}\right\} + k^2\right]X.$$

If the substitution $y = \exp(-2\kappa x')$ is made then [B.3] becomes

$$[B.4] \qquad \frac{d^2X}{dy^2} + \frac{1}{y}\frac{dX}{dy} = \left[\frac{\alpha^2}{y^2} + \frac{2\xi}{y(1 - y\xi)^2}\right]X,$$

where $\alpha = (1 + k^2/\kappa^2)^{1/2}/2$. The solution of this equation which tends to zero as $x \to \infty$, can be expressed as

$$[B.5] \qquad X(x, k) = F(k) y^\alpha (1 - y\xi)^{-1}\left[1 - \left(\frac{2\alpha - 1}{2\alpha + 1}\right) y\xi\right] \exp(-\gamma \sqrt{(\kappa^2 + k^2)}),$$

where $F(k)$ is an arbitrary function of k. In the case where $\eta_d \to 0$, [3.6] reads $\nabla^2 \phi(x, \rho) = \kappa^2 \phi(x, \rho)$ and [B.3] simplifies to

$$[B.6] \qquad \frac{d^2X}{dx^2} = (\kappa^2 + k^2)X.$$

This equation has the solution

$$[B.7] \qquad X(x, k) = F(k) \exp(-x\sqrt{(\kappa^2 + k^2)}),$$

to which [B.5] reduces on putting $\eta_d = 0$.

APPENDIX C

The solution of Laplace's equation for $\phi_1(x, \rho)$ in the inner region and in the wall-medium can be expressed in the forms

$$[C.1] \qquad \phi_1(x, \rho) = \int_0^\infty kJ_0(k\rho)[A(k)e^{kx} + B(k)e^{-kx}]\,dk + \int_0^\infty kJ_0(k\rho)C(k)e^{-k|x|}\,dk, \; -\beta < x < \gamma,$$

$$[C.2] \qquad \phi_1(x, \rho) = \int_0^\infty kJ_0(k\rho)E(k)e^{kx}\,dk, \; x < -\beta.$$

On differentiating [C.1] and substituting into [4.4] we find that

$$[C.3] \qquad 2\int_0^\infty k^2C(k)J_0(k\rho)\,dk = \begin{cases} 0 & , \rho > r_\beta \\ -4\pi\sigma_\beta/\epsilon_1, & \rho < r_\beta \end{cases}.$$

The Fourier–Bessel inversion of [C.3] yields

$$[C.4] \qquad kC(k) = \frac{-2\pi\sigma_\beta}{\epsilon_1}\int_0^{r_\beta} \rho J_0(k\rho)\,d\rho = \frac{-2\pi\sigma_\beta}{\epsilon_1}\frac{r_\beta}{k}J_1(kr_\beta).$$

From [C.1], the value of $\phi_1(x, \rho)$ at the center of the disc reads

$$[C.5] \qquad \phi_1(0, 0) = \int_0^\infty [A(k) + B(k) + C(k)]k\,dk = \frac{-2\pi\sigma_\beta}{\epsilon_1}\int_0^\infty \frac{J_1(kr_\beta)}{k}[1 + a(k) + b(k)]\,dk$$

after having made use of [C.4] and introducing

$$[C.6] \qquad a(k) = A(k)/C(k), \; b(k) = B(k)/C(k).$$

In the case of small potentials (small η_d) at the O.H.P., the solution [B.7] applies in the diffuse layer region ($x > \gamma$) and $\phi_1(x, \rho)$ is given by the form [3.7] namely

$$[C.7] \qquad \phi_1(x, \rho) = \int_0^\infty F_1(k)e^{-x\sqrt{(\kappa^2+k^2)}}\,J_0(k\rho)\cdot k\,dk, \; x > \gamma.$$

The boundary conditions [3.10], [4.1], and [4.2] yield the four simultaneous equations

$$[C.8] \qquad a(k) + b(k)\,e^{-2k\gamma} - d(k) = -e^{-2k\gamma},$$

$$[C.9] \qquad a(k) + b(k)\,e^{2k\beta} - e(k) = -1,$$

$$[C.10] \qquad a(k) - b(k)\,e^{-2k\gamma} + f'd(k) = e^{-2k\gamma},$$

$$[C.11] \qquad a(k) - b(k)\,e^{2k\beta} - f_p e(k) = -1,$$

where

$$[C.12] \qquad d(k) = \frac{F_1(k)\,e^{-\gamma(\sqrt{(\kappa^2+k^2)}-k)}}{C(k)}, \; e(k) = E(k)/C(k).$$

Hence, solving for $a(k)$ and $b(k)$ and substituting into [C.5], we derive the expression [4.5] for the potential at the center of the disc $\phi_1(0, 0)$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

When $\kappa = 0$, we may expand in the form used by us (11)

$$[C.13] \qquad \frac{N(k)}{D(k)} = 1 + f_1 e^{-2k\beta} + \sum_{n=1}^{\infty} \sum_{m=n-1,n,n+1} f_1^m f_2^n \{2 - (m-n)^2\} e^{-2k(m\beta+n\gamma)},$$

which can be substituted into [4.5]. Introducing

$$[C.14] \qquad g\left(\frac{u}{v}\right) = \int_0^\infty \frac{1}{k} J_1(kv) e^{-2ku} dk = \left[1 + \left(\frac{2u}{v}\right)^2\right]^{1/2} - \frac{2u}{v},$$

the expression [4.5] for $\phi_1(0, 0)$ simplifies to the $\phi_1^*(0, 0)$ introduced in [4.9], where if G is the infinite series which is derived from the function g in the same way as Y is derived from y in [2.15], then

$$[C.15] \qquad g_\phi^*(r_\beta) = \frac{dr_\beta}{2\beta\gamma}[1 + G(\beta/r_\beta, \gamma/r_\beta)].$$

In the case of a general potential at the O.H.P., it is convenient to introduce the function

$$[C.16] \qquad Q(x) = \left[1 - \left(\frac{2\alpha - 1}{2\alpha + 1}\right) \cdot \xi e^{-2\kappa x}\right] \Big/ [1 - \xi e^{-2\kappa x}].$$

In place of [C.7], the potential in the diffuse layer is given by

$$[C.17] \qquad \phi_1(x, \rho) = \int_0^\infty F_1(k) e^{-x\sqrt{(\kappa^2+k^2)}} Q(x - \gamma) \cdot J_0(k\rho) k \, dk, \; x > \gamma.$$

The coefficients of $d(k)$ in eq. [C.8] and [C.10] become $-Q(0)$ and $hf'(dQ/dx)_{x=0}$ respectively, where

$$[C.18] \qquad h = 1 - \frac{1}{\sqrt{(\kappa^2 + k^2)}} \cdot \frac{(dQ/dx)_{x=0}}{Q(0)} = 1 + \frac{4\xi\kappa}{(1-\xi)(2\alpha + 1 - (2\alpha - 1)\xi)\sqrt{(\kappa^2 + k^2)}}.$$

Introducing

$$[C.19] \qquad f_2'' = (1 - hf')/(1 + hf'),$$

it can be verified that the effects of the diffuse layer is to add on to [4.9] the positive quantity $\Delta\phi_1(0, 0)$ in [4.12], where

$$[C.20] \qquad I_1 = \int_0^\infty \frac{J_1(kr_\beta)}{k} H(k) \, dk,$$

with

$$[C.21] \qquad H(k) = \frac{(f_2 - f_2'') e^{-2k\gamma}(1 + f_1 e^{-2k\beta})^2}{(1 - f_1 f_2 e^{-2k(\beta+\gamma)})(1 - f_1 f_2'' e^{-2k(\beta+\gamma)})}.$$

In the limiting case of $\eta_d = 0, h = 1$ and so f_2'' is replaced by f_2' in [C.21].

When $r_\beta \gg d$ we can neglect "edge effects" and assume $\partial\phi_1/\partial\rho = 0$. Thus $\phi_1(x, \rho)$ depends only on x and will be denoted by $\Phi_1(x)$. The equation [B.1], which is satisfied by $\phi_1(x, \rho)$ becomes an ordinary differential equation in $\Phi_1(x)$ which is identical with [B.3], provided $k = 0$. Since $\alpha = 1/2$ the eq. [B.5] yields

$$[C.22] \qquad \Phi_1(x) = A e^{-\kappa x}/(1 - \xi e^{-2\kappa(x-\gamma)}),$$

where A is a constant of integration. In determining $\Phi_1(x)$ for a perfect dielectric wall, the condition [3.10] implies that the wall is uncharged. For $x < 0$, $\Phi_1(x)$ is a constant which is zero since $\Phi_1(x) \to 0$ as $x \to \infty$. In the region $0 < x < \gamma$, $d\Phi_1/dx$ is constant and from [4.2] and [4.4]

$$[C.23] \qquad \epsilon_1(d\Phi_1/dx)_{x=+0} = -4\pi\sigma_\beta = \epsilon(d\Phi_1/dx)_{x=\gamma+0}.$$

Hence, applying [C.22]

$$[C.24] \qquad \Phi_1(x) = -\frac{4\pi\sigma_\beta}{\epsilon\kappa}\,\mathrm{sech}\,\tfrac{1}{2}\eta_d,$$

and at large r_β the potential at the center of the disc is given by

$$[C.25] \qquad \Phi_1(0, 0) = \Phi_1(0) = \Phi_1(\gamma) - \frac{4\pi\gamma}{\epsilon_1}\sigma_\beta,$$

which leads to [4.13].

For a perfectly conducting wall at $x = -\beta$, [3.9] applies and the constant A in [C.22] is different. If the potential drops from the I.H.P. to the wall and O.H.P. are $E_B\beta$ and $E_C\gamma$ where E_B and E_C are the corresponding field strengths, then

$$[C.26] \qquad \phi_1(0, 0) = \Phi_1(0) = E_B\beta = E_C\gamma + \psi(\gamma).$$

From [4.4]

$$[C.27] \qquad \frac{\epsilon_1}{4\pi}(E_B + E_C) = -\sigma_\beta,$$

and from [4.2] and [C.22]

$$[C.28] \qquad E_C = \frac{-\epsilon}{\epsilon_1}\left(\frac{d\Phi_1}{dx}\right)_{x=\gamma+0} = \frac{\epsilon\kappa}{\epsilon_1}\psi(\gamma)\cosh\tfrac{1}{2}\eta_d.$$

Eliminating E_B, E_C, and $\psi(\gamma)$ from the equations above we obtain $\phi_1(0, 0) = \Phi_1(0)$, which is given in [4.14]

To justify the results that $g_\phi^*(\infty) = 1$ or d/β according as the wall is metallic or dielectric we suppose that a sheet of charge density $-\sigma_\beta$ is situated in the I.H.P., which lies between two equipotential planes B and C at distances β and γ respectively. If the planes are metallic, their potentials are zero, the potential drops from the I.H.P. to B and C must be equal and so $E_B\beta = E_C\gamma$. By use of the electrostatic condition [C.27] if follows that

$$[C.29] \qquad E_B = \frac{4\pi\gamma}{\epsilon_1 d}\sigma_\beta,\ E_C = \frac{4\pi\beta}{\epsilon_1 d}\sigma_\beta.$$

The potential at the I.H.P. is now

$$[C.30] \qquad \phi_1(0, 0) = \Phi_1(0) = -E_B\beta = -E_C\gamma = \frac{-4\pi\sigma_\beta}{\epsilon_1}\frac{\beta\gamma}{d},$$

and thus $g_\phi^*(\infty) = 1$. For a dielectric wall at B and an infinitely conducting O.H.P. at C, we remove the boundary B and put $E_B = 0$ so that $\epsilon_1 E_C = 4\pi\sigma_B$. The potential at the I.H.P. is therefore

$$[C.31] \qquad \phi_1(0, 0) = -E_C\gamma = \frac{-4\pi\sigma_\beta}{\epsilon_1}\gamma,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

which is independent of ϵ_2 and gives $g_\phi^*(\infty) = d/\beta$. If the electrolyte concentration is assumed so large that κ is virtually infinite, then [4.13] and [4.14] reduce respectively to [C.31] and [C.30].

APPENDIX D

It is a simple matter to determine $V_0(\rho)$ from the analysis in Appendix C. We need to find the potential, $\phi_0(0, \rho)$ say, due to a point charge $z_\beta e_0$, situated at the origin $x = \rho = 0$, at any point in the I.H.P. at distance ρ from the origin. Since the second integral in the right-hand member of [C.1] represents the potential distribution in an infinite medium of dielectric constant and

$$\int_0^\infty J_0(k\rho)\, e^{-k|x|}\, dx = (x^2 + \rho^2)^{-1/2}$$

it follows that the formula (C.4) for $kC(k)$ is replaced by

$$[D.1] \qquad kC_0(k) = \frac{z_\beta e_0}{\epsilon_1} J_0(k\rho).$$

The determination of the functions $A(k)$ and $B(k)$ in [C.1] proceeds exactly as before. In the case of small potentials at the O.H.P. we obtain

$$[D.2] \qquad V_0(\rho) = z_\beta e_0 \phi_0(0, \rho) = -\frac{(z_\beta e_0)^2}{\epsilon_1} \int_0^\infty \frac{N(k)}{D(k)} J_0(k\rho)\, dk.$$

When the electrolyte concentration (or κ) tends to zero, this reduces to the interaction energy in the absence of screening $U(\rho)$, defined by [2.17]. For arbitrary potential at the O.H.P., we obtain

$$[D.3] \qquad V_0(\rho) = U(\rho) - \frac{(z_\beta e_0)^2}{\epsilon_1} \int_0^\infty J_0(k\rho) H(k)\, dk.$$

ULTRAVIOLET STUDY OF THE IONIZATION OF BISULFATE ION

J. T. EDWARD AND I. C. WANG
Department of Chemistry, McGill University, Montreal, Quebec
Received August 24, 1964, and, as revised, June 15, 1965

ABSTRACT

Studies of the ultraviolet absorption of dilute aqueous solutions of lithium, sodium, potassium, and ammonium sulfates show that the concentration of sulfate ion in the presence of univalent cations can be determined from the optical density of the solution at 190 mμ. The concentrations of sulfate ion thus determined in dilute solutions of sulfuric acid are in agreement with values reported previously from Raman spectral, conductivity, and other studies, which indicate a dissociation constant $K_2 = 0.01$ for the second stage in the ionization of sulfuric acid.

Sulfuric acid ionizes in water in two stages.

[1]* $$H_2SO_4 \rightleftarrows H^+ + HSO_4^-$$

[2]* $$HSO_4^- \rightleftarrows H^+ + SO_4^=$$

Estimates of the dissociation constant for the first stage vary, but it is known to be very large, so that dissociation to hydrogen ion and bisulfate ion is essentially complete in acid solutions more dilute than about 80% (3). The dissociation constant for the second stage has been estimated by several different methods to be about 0.01 (4 (p. 383), 5, 6), so that even in relatively dilute solution ionization of bisulfate ion is incomplete. In the present study we have shown that the ultraviolet absorption of dilute solutions of sulfuric acid confirms this value for the second dissociation constant. Ultraviolet absorption was used long ago to determine the dissociation constant of nitric acid (7).

EXPERIMENTAL

Solutions of reagent grade lithium, sodium, potassium, ammonium, and magnesium sulfates and of sulfuric acid were made up in distilled water free from carbon dioxide. The absorption of these solutions over the range 185–200 mμ was measured in quartz cells of 1.0 or 0.1 cm light path with a Unicam SP 500 spectrophotometer at 27.0 ± 1.5 °C against water as a blank. No attempt was made to purge this apparatus of oxygen, although it is known that absorption by oxygen becomes increasingly important at lower wavelengths (8) and can result in spurious absorption peaks because of scattered light (9). Spurious peaks of this nature at 186–188 mμ were observed in several cases, as exemplified in Fig. 1 (curve *a*) for sodium sulfate. These peaks were not observed when measurements were made down to 186 mμ with cells of 1.0 mm light path in a Perkin–Elmer 350 spectrophotometer purged with nitrogen (Fig. 1, curve *b*). No attempt was made to observe the spectrum at shorter wavelengths; recently Halmann and Platzner (10) have reported a peak at 185 mμ (ε, 200) for this solution. Our results with the Perkin–Elmer spectrophotometer are in fair agreement with those obtained in 1932 by Ley and Arends (11) (cf. Fig. 1).

Further evidence of scattered light in the unpurged Unicam spectrophotometer came from the failure to obtain linear Beer's law plots at wavelengths below 190 mμ; on the other hand, linear plots at these wavelengths were obtained with the purged Perkin–Elmer spectrophotometer. However, at 190 mμ scattering has become relatively unimportant in the Unicam, as shown by the linearity of Beer's law plots in Fig. 2 for low concentrations of salts. Consequently, all measurements were made at this wavelength with the Unicam spectrophotometer.

RESULTS AND DISCUSSION

Spectra of lithium, sodium, potassium, and ammonium sulfates down to 190 mμ were found to be essentially the same, and must be due to sulfate ion, since alkali and alkaline earth metals are transparent in this region of the spectrum (12). Recently Halmann and

**No account is taken in these equations of the degree of hydration of the ions, which varies with the concentration of acid (1, 2); this is discussed later in the paper.*

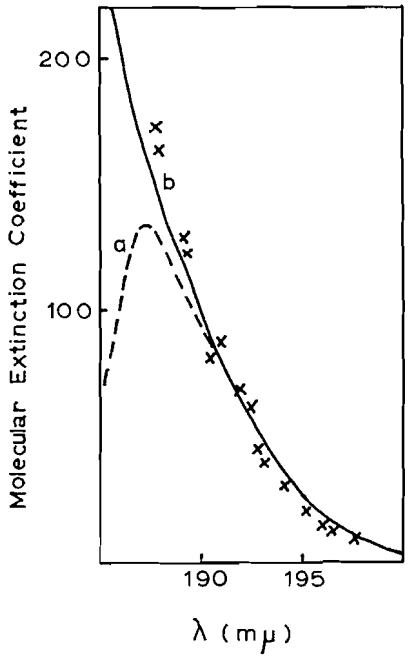

FIG. 1. Measurements of ultraviolet absorption of sodium sulfate: (*a*) 0.00998 *M* solution in Unicam SP 500 spectrophotometer; (*b*) 0.0277 *M* solution in Perkin–Elmer 350 spectrophotometer. (×) Values reported by Ley and Arends (11).

Platzner (10) have attributed a peak at 185 mμ in the spectrum of sodium sulfate in water to a "change-transfer-to-solvent" (c.t.t.s.) transition. Peaks due to these transitions are sensitive to the nature of the solvent, and are shifted to shorter wavelengths with increasing concentration of counterion (13), presumably because of ion association. This may explain the deviation from Beer's law for 1:1 electrolytes (curve *a*, Fig. 2) at concentrations above 0.1 M, and the lower absorbance for magnesium sulfate (curve *b*, Fig. 2) at all molar concentrations, since ion association is extensive at much lower concentrations for 1:2 electrolytes (4 (p. 416), 14).

The absorption of sulfuric acid (curve *c*, Fig. 2) is always much less than that of the sulfate salts and Beer's law is not obeyed even at low concentrations. This indicates that dissociation of bisulfate ion to hydrogen ion and sulfate ion is incomplete.

It seems likely that, as a first approximation, the effect of H_3O^+ and of NH_4^+ as counterions should be similar, so that curve *a* would give the absorbance of sulfuric acid at different molar concentrations if it were (like the salts) completely ionized to sulfate ion. The difference between curves *a* and *c* may accordingly be taken as a measure of the extent to which bisulfate ion is not ionized to sulfate ion.* The fraction α of bisulfate dissociated in different stoichiometric concentrations of sulfuric acid has been calculated from the equation

$$[3] \qquad \alpha = A_{H_2SO_4}/A_{M_2SO_4}$$

**This argument ignores the fact that at a given stoichiometric concentration, the ionic strength of a solution of alkali metal sulfate will be greater than that of a solution of sulfuric acid. This effect will become less important at lower concentrations, where effects of ionic strength become less important and curve a is linear.*

TABLE I

Fraction (α) of bisulfate ion dissociated in different molar concentrations of sulfuric acid

Concentration (M)	α	Concentration (M)	α
0.010	0.566	0.100	0.269
0.020	0.458	0.150	0.242
0.040	0.379	0.200	0.230
0.060	0.324	0.250	0.219
0.080	0.291	0.300	0.212

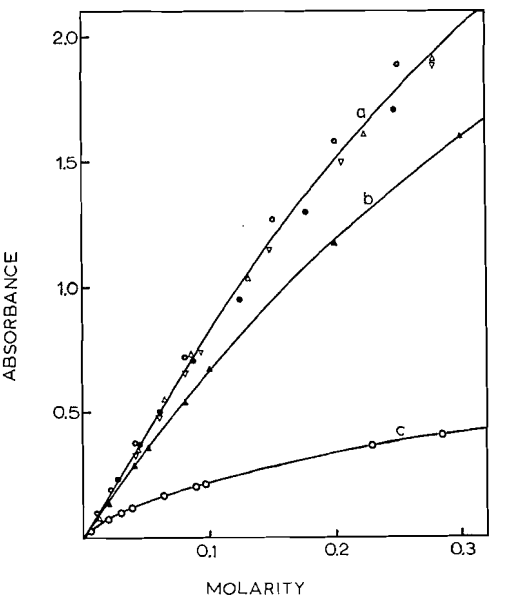

FIG. 2. Absorbance of 1 mm thickness of sulfate solutions at different concentrations: (*a*) lithium sulfate (○), sodium sulfate (△), potassium sulfate (▽), ammonium sulfate (●); (*b*) magnesium sulfate; (*c*) sulfuric acid.

where $A_{H_2SO_4}$ is the absorbance of the sulfuric acid solution (obtained from curve *c*) and $A_{M_2SO_4}$ is the absorbance of the same concentration of univalent cation sulfate (obtained from curve *a*). The results are given in Table I.

The concentration quotient K_2' for the equilibrium represented by eq. [2] may be calculated from the relation

$$K_2' = c\alpha(1 + \alpha)/(1 - \alpha) \qquad [4]$$

where c is the stoichiometric (molar) concentration of acid. In Fig. 3 $pK_2'(= -\log K_2')$ has been plotted against the square root of the ionic strength, μ, of solutions ranging in concentration from 0.01 to 0.30 M. Also shown in this figure are the values of pK_2' at 25° obtained from conductivity (5) and Raman spectral studies (3). The extrapolation to zero ionic strength shown in Fig. 3 gives the thermodynamic pK_2 of 1.99 ($K_2 = 0.0102$) already reported. It is evident that the pK_2' values obtained in the present study are in reasonable agreement with the earlier values, particularly at lower ionic strengths, where (for the reasons given above) they are likely to be more reliable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

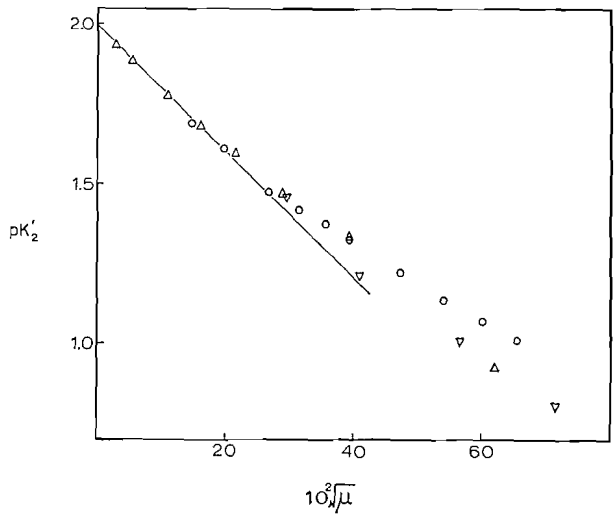

FIG. 3. Plot of pK_2' against the square root of the ionic strength (μ) of aqueous sulfuric acid. Experimental points: this paper (○); Sherrill and Noyes (given in ref. 5) (△); Smith (given in ref. 3) (▽).

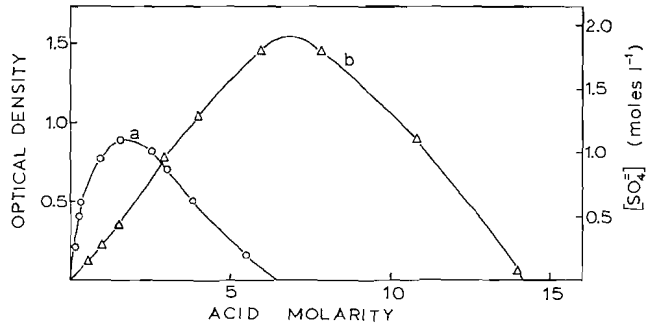

FIG. 4. Variation in absorbance at 190 mμ (curve *a*; left-hand scale) and in concentration of sulfate ion (curve *b*; right-hand scale) with concentration of aqueous sulfuric acid.

With cells of 1 mm light path, absorbance measurements at 190 mμ cannot be made with the Unicam SP 500 spectrophotometer on solutions of inorganic sulfates more concentrated than about 0.3 *M* (the absorbance then exceeding 2.0) (Fig. 2). However, absorbance measurements can be made for all concentrations of sulfuric acid. The results are shown in Fig. 4 (curve *a*). The absorbance of the acid solution increases with concentration up to a maximum in 1.75 *M* acid and thereafter decreases. However, the concentration of sulfate ion (as measured by Raman spectra (3)) increases with acid concentration up to a maximum in 7 *M* acid (Fig. 4, curve *b*) and thereafter decreases.* Evidently sulfate ion becomes progressively more transparent to radiation of 190 mμ wavelength as the acid concentration is increased. This may possibly be explained by the

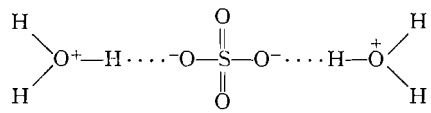
**Equations [1] and [2] both ignore hydration of ions; the latter should be replaced by*

[2*a*] $$HSO_4^-(aq.) + nH_2O \rightleftarrows H^+(aq.) + SO_4^=(aq.),$$

the formulae of the equation now representing the hydrated ions. The activity of water in aqueous solutions of sulfuric acid decreases drastically with increase of molarity of acid (1); at acid strengths above 7 M this effect outweighs the increase in concentration of bisulfate ion with increasing acid concentration, so that the concentration of sulfate ion decreases.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

formation of stable sulfate-oxonium ion-pairs or ion-triplets (such as I). In 7 *M* sulfuric acid there are approximately 1.9 moles of SO_4^-, 5.1 moles of HSO_4^-, 8.9 moles of H_3O^+, and 29.6 moles of H_2O (3). If each H_3O^+ binds 3 water molecules (1), very little water is left to hydrate the other ions, and ion association (e.g. to form I) should be strong. Such a drastic alteration in the environment of the sulfate ion from that found in water would be expected to lead to a corresponding alteration in the energy of the c.t.t.s. transition (13).



I

The results given in Fig. 4 are of some practical importance because they show that aqueous sulfuric acid at concentrations greater than about 6 *M* is reasonably transparent at 190 mμ, and hence this region of the spectrum may be used to study protonation phenomena in sulfuric acid.

ACKNOWLEDGMENTS

We are indebted to Professor G. C. B. Cave and Professor C. Sandorfy for the loan of equipment, and to Mr. K. C. Liu for experimental assistance. Grateful acknowledgment is made to the Petroleum Research Fund, administered by the American Chemical Society, and to the National Research Council for financial support.

STEROIDS AND RELATED NATURAL PRODUCTS. XXV

PHOTOCHEMICAL TRANSFORMATION OF 3β-NITRITO-5α-LANOSTANE[1]

GEORGE R. PETTIT,[2] RAYMOND E. KADUNCE,[3] PAUL SUNDER-PLASSMANN, AND JOHN OCCOLOWITZ[4]

Department of Chemistry, University of Maine, Orono, Maine

Received April 6, 1965

ABSTRACT

Ultraviolet irradiation of 3β-nitrito-5α-lanostane was found to follow an unusual reaction pathway and yield 2-oximo-3-oxo-3,4-seco-5α-lanostane (IV). The new aldehyde was easily converted to oxime and phenylhydrazone derivatives. Acetylating the photolysis product led to an oxime acetate (IX) which readily rearranged to 1-cyano-3,4-seco-5α-lanostane (III). Confirmation for the structural assignments was obtained from a series of proton magnetic resonance and mass spectral studies. Application of the new photochemical reaction was suggested to preparation of certain aldehydes otherwise accessible only with difficulty.

Chemical degradation of lanosterol to both 14α-methyl progesterone and 14α-methyl testosterone was previously accomplished, as part of an investigation concerned with evaluating the biological importance of 14α-methyl steroids (1). Reconstituting the triterpene-type ring A of lanosterol to one typical of the steroid hormones requires, at present, a somewhat lengthy series of synthetic steps. With eventual view to providing a greater selection of methods for reconstructing or otherwise transforming the 3β-hydroxy-4,4-dimethyl system of lanosterol, we decided to study photolytic decomposition[5] of 3β-nitrito-5α-lanostane (I*b*).

Preparation of 3β-hydroxy-5α-lanostane (I*a*) was performed essentially as previously reported (1*c*), and the required nitrite ester (I*b*) was prepared in good yield using nitrosyl chloride (5*a*) in pyridine. Although the ester proved relatively unstable (5*b*, 5*c*) rapid chromatographic purification on a Florisil column was found suitable for preparing a pure specimen. Irradiation (high-pressure mercury vapor arc lamp) of nitrite I*b* in benzene solution was performed under conditions commonly employed for the Barton reaction.[5] After approximately 40 min at 15°, spot tests (diphenylamine in concentrated hydrochloric acid) for the nitrite ester became negative. When a total of 45 min had elapsed, irradiation was terminated and the crude product was isolated. A thin-layer chromatogram of the product indicated that at least six substances were present. Partial separation of the viscous yellow oil on a column of basic alumina led to two readily predictable products in small yield: the substance expected from alkoxy radical decomposition with α-hydrogen fission (3-oxo-5α-lanostane, II) and the substance resulting from intermolecular hydrogen abstraction (alcohol I*a*). The ketone (II) was finally separated from an oily impurity (later assumed to be nitrile III) by preparative thin-layer chromatography. However, the

[5]*Stereoselective intramolecular hydrogen abstraction by alkoxy radicals formed during photolysis of nitrites and recombination of the resulting carbon radicals with nitric oxide to form nitroso monomers, dimers, or oximes has been designated the Barton reaction (2). An interesting review of the reaction has been prepared by Nussbaum and Robinson (2) and valuable extensions have recently been described by Barton and colleagues (3). A non-cage free-radical mechanism for the transformation has been proposed (4a) and other studies (4b, 4c) related in a general way to the mechanism of photochemical reactions have recently been summarized.*

major photolysis product (1.3 g from 3.6 g of I*b*) was eventually assigned structure IV. The vitreous-like aldehyde (IV) resisted attempts at crystallization, and was further purified by successive column and preparative thin-layer chromatography on silica gel. Aldehyde IV appears to have arisen by alkoxy radical decomposition with carbon–carbon bond cleavage followed by a novel series (I*b* → IV) of transformations. While the mechanistic pathway leading to aldehyde IV is only a tentative suggestion, experiments described below provide definitive support for the structural formulation.

At the outset, photolytic transformation of nitrite I*b* was not expected to follow a predictable reaction pathway and any firm assumption concerning composition of the product(s) seemed premature. Shortly after the photolysis product was found consistent with empirical formula $C_{30}H_{53}NO_2$, Robinson and colleagues (6) reported conversion of certain nitrite esters (adjacent to a tertiary-carbon atom) to the corresponding hydroxamic acids. Thus, it appeared that an initially formed alkoxy radical underwent ring fission to give a tertiary-carbon radical which then combined with nitric oxide yielding a tertiary-nitroso aldehyde (such as V) with eventual formation of hydroxamic acid VI (2). An infrared (neat) study of the photolysis product showed stretching absorption at 3 395, 1 710, and 1 670 cm^{-1} and on this basis hydroxamic acid structure VI did not appear likely[6]. Also, the product gave a negative iron(III) chloride test, and attempts to prepare a crystalline lactam derivative by reduction with a variety of reagents including zinc – acetic acid[7] and Raney nickel (9) were unsuccessful. Furthermore, an infrared examination of substance IV in chloroform solution revealed free hydroxyl stretching at 3 630 cm^{-1} and bonded hydroxyl absorption at 3 330 cm^{-1} characteristic of an oxime grouping (10). Absence[8] of infrared absorption in the 2 700 cm^{-1} region typical of aldehyde carbon–hydrogen stretching delayed recognition of this functional group until detection by a proton magnetic resonance (p.m.r.) investigation.

In carbon tetrachloride solution a p.m.r. spectrum of oxime IV exhibited, in addition to high-field skeletal responses, signals at 2.50 (two protons), 9.05 (one proton) and 9.63 (one proton) δ. The low-field response at 9.05 δ was undiminished by treating the solution with deuterium oxide (12*a*); however, the signal at 9.63 δ was absent. The oxime proton of androstane derivative VII*a* (prepared for comparison purposes), in the same solvent, emerged at 8.75 δ and also disappeared on exposure to deuterium oxide. Similar observations were noted in both cases using deuterochloroform as solvent. The signals at 9.05 and 9.63 δ were, therefore, assigned to aldehyde (12*b*) and oxime (12*c*) protons, respectively.

Presence of the aldehyde group was further substantiated by conversion of substance IV to dioxime VIII*a* using hydroxylamine in pyridine solution (13). Infrared carbonyl absorption was absent in the product and a p.m.r. signal for the oxime proton appeared at 7.54 δ. Treating the dioxime with nickel(II) chloride in ethanol gave a deep orange precipitate indicative of a vicinal *anti* dioxime (13*a*).

An attempt at confirming respective assignment of positions C-2 and C-3 for the oxime and aldehyde groups was next undertaken. Aldehyde IV was allowed to react with excess phenylhydrazine in ethanol (14) as the first step in a sequence directed at obtaining the corresponding osotriazole (15). The crystalline phenylhydrazone derivative, which separated from solution as the reaction progressed, was assigned structure VIII*b*. Results of elemental and mass spectral analyses were consistent with a monophenylhydrazone structure (VIII*b*). Interestingly, a p.m.r. spectrum of the hydrazone suggested two different

[6]*An infrared and ultraviolet study of hydroxamic acids has recently been reported (7).*

[7]*We are grateful to Dr. C. H. Robinson (6b) for providing us with unpublished details of his experience with the cyclic hydroxamic acid → lactam reduction reaction (8).*

[8]*The mono-2,4-dinitrophenylhydrazone derivative of glyoxal also lacks absorption in the aldehyde region (11).*

For personal use only.

environments for the C-1 methylene group protons as two distinct signals corresponding to one proton each were evident[9] at 2.58 and 2.78 δ. The five aromatic-type protons emerged at 6.67–7.15 δ and signals corresponding to one proton each appeared at 7.61 (oxime or amino proton) and 7.78 (C-3 proton) δ. The signal at 7.61 δ disappeared in the presence of deuterium oxide. No further attempt at preparing a diphenylhydrazone derivative was made when a series of experiments (IV $\rightarrow$ III) beginning with acetylation of oxime IV were shown to reflect 2,3-positioning of the oxime and aldehyde groups.

Allowing oxime IV to react with acetic anhydride – pyridine at room temperature led to a crystalline monoacetyl derivative corresponding to empirical formula $C_{32}H_{55}NO_3$. An infrared spectrum of the acetate (IX) displayed carbonyl absorption at 1 790 (acetate) and 1 715 (aldehyde) cm^{-1}. Confirmation for assignment IX was obtained by evaluating the acetate's p.m.r. spectrum. In addition to responses expected for the hydrocarbon skeleton, three significant peaks were observed: three acetyl protons at 2.15, two methylene protons at 2.54, and one aldehyde proton at 9.31 δ. No change in the p.m.r. response occurred when the solution was treated with deuterium oxide. Nearly identical infrared and p.m.r. spectra were observed in the acetyl regions employing an authentic sample of oxime acetate VII*b*.[10]

Oxime acetate IX derived from photolysis product IV proved quite labile and purification required mild procedures. Recognition of the unusual stability properties of acetate IX opened a path to the most compelling structural evidence for aldehyde IV and its transformation products. When the acetate was chromatographed in hexane–benzene solution on silica gel and elution delayed until the following day, the product was nitrile III. The distinctive nitrile infrared stretching frequency at 2 350 cm^{-1} and absence of carbonyl-type absorption provided the first indication that oxime IX had been converted to a nitrile. In accordance with structure III the lowest-field signal in the nitriles p.m.r. spectrum appeared at 2.25 δ. Elemental analytical data for the nitrile corresponded to empirical formulas $C_{30}H_{53}N$ or $C_{29}H_{51}N$. Definite selection of the formula (III) representing loss of one carbon atom was possible when mass spectral examination of the nitrile yielded a molecular ion at m/e 413. Formation of the nitrile with loss of one carbon atom indicated a type of "second-order Beckmann" rearrangement (16) arising from an α-oximino aldehyde structure, thereby eliminating a ketone formulation for the photolysis product. In addition, facile formation of the nitrile[11] by simply absorbing oxime acetate IX on silica gel suggested an *anti* configuration for the photolysis product (IV). Basic hydrolysis of *syn* oxime acetates having an adjacent oxygen substituent results in saponification with relatively little rearrangement (17).

In summary, photochemical transformation of 3β-nitrito-5α-lanostane (I*b*) was found to follow a novel reaction pathway leading to aldehyde IV.[12] The preceding experiments suggest that the new photochemical reaction may provide a useful synthetic avenue to certain α-oximino aldehydes and derivatives, e.g. α-amino acids, otherwise accessible only with difficulty.

[9]*Appearance of a partially resolved or distinct C-1 methylene doublet in p.m.r. spectra of the photolysis product and derivatives may be due, in part, to asymmetry of the adjacent C-10 position (see e.g. ref. 12d).*

[10]*The oxime acetate signal of substance VII*b *appeared with a shoulder at approximately one-half height which may indicate a mixture of anti and syn isomers.*

[11]*Significant amounts of nitrile-containing products have been obtained by Beckmann rearrangement of unconjugated oximes using p-toluenesulfonyl chloride in pyridine (18).*

[12]*Although several examples of irradiation-induced cleavage of a triterpene ring A have been recorded (19), the presently described reaction appears to follow a unique course. The experimental results used in support of structure IV, however, do not necessarily exclude a reaction sequence involving ring B (cf. 20, p. 584). Final support for the structural assignments must now await correlation with a substance of established structure.*

EXPERIMENTAL

Melting points were determined employing a Kofler melting point apparatus. Introduction to the experimental section of a previous contribution (1*c*) concerned with oxidation of 3β-acetoxy-5α-lanostane provides a brief description of several reagents and techniques (e.g. silica gel t.l.c.) employed below. The acetic anhydride, pyridine (from potassium hydroxide), and all solvents were redistilled. In addition, diethyl ether was further purified by filtration through a column of activated alumina. Acid-washed alumina (Merck, Rahway), neutral alumina (E. Merck, AG., Darmstadt, Germany), basic alumina (Aluminum Company of America F-20), silica gel (0.05–0.20 mm, E. Merck), and Florisil (100 mesh) were employed as column chromatographic adsorbents. Fluorescent silica gel (HF 254, average particle size 5–25 μ, E. Merck) was employed for one preparative thin-layer chromatogram, which contained a substance fluorescent under ultraviolet light. The photolysis experiments were performed using a Hanovia high-pressure mercury arc lamp (Englehard Hanovia, Inc., 200 W) with a Pyrex filter sleeve (E. H., Inc., No. 516-27-116). All new substances are colorless unless otherwise noted.

The p.m.r. spectra were obtained using a Varian Associates Model A-60 n.m.r. spectrometer. Each solvent contained approximately 10% w/v of sample and enough tetramethylsilane was added to standardize the instrument. The scanning rate (from low to high field) was 120 c.p.s./min and measurements are reported in

δ (p.p.m.) units with respect to TMS. The optical rotation (chloroform solution) and infrared measurements and elemental analyses were provided by Drs. Hill, Janssen, and Bernhardt (1*c*). Mass spectral determinations were performed using a direct inlet technique.

3β-Hydroxy-5α-lanostane (Ia).

A specimen (45 g) of 3β-acetoxy-7,11-dioxo-5α-lanostane was converted to 3β-hydroxy-5α-lanostane as previously described (1*c*). The crude product (37.4 g) was dissolved in 1:1 benzene–hexane and absorbed on 750 g of acid-washed alumina. Elution with the same solvent gave a sample (8.5 g) of alcohol I*a* melting at 172–175°. Further elution with benzene gave a pure sample (12.5 g) which after recrystallization from chloroform–methanol melted at 173–175°; $[\alpha]_D^{20}$ +34.8 (*c*, 1.1); reported (21) m.p. 171–172°, $[\alpha]_D$ +35°.

3β-Nitrito-5α-lanostane (Ib)

Method A

A solution of nitrosyl chloride (2 ml) in pyridine (20 ml) was added dropwise (over 1 h) to a solution of alcohol I*a* (4.0 g) in dry benzene (50 ml) and pyridine (25 ml). After stirring the mixture one additional hour, the brown solution was diluted with water and extracted with benzene. The combined benzene extract was washed with cold dilute hydrochloric acid, washed with water, dried, and concentrated *in vacuo*. A thin-layer chromatogram (3:17 ethyl ether – hexane mobile phase) indicated that the product contained a small quantity (less than 10%) of starting alcohol. A solution of the residue in petroleum ether was chromatographed on Florisil (90 g) and eluted with the same solvent to yield 3.6 g of nitrite ester I*b* melting at 122–126°. Two recrystallizations from hexane afforded an analytical sample melting at 123.5–126.5°; $[\alpha]_D^{20}$ +28.9° (*c*, 2.35); ν_{max}^{KBr} 1 640, 1 595, and 800 cm^{-1}.

Anal. Calcd. for $C_{30}H_{52}NO_2$: C, 78.40; H, 11.62; N, 3.05. Found: C, 78.02; H, 11.45; N, 3.16.

In later experiments, a 5-min addition period for the nitrosyl chloride (at ice-bath temperature) and a 1/2 h period at room temperature was found satisfactory. In general, the nitrite ester proved sensitive and rapid isolation and purification proved desirable.

Method B

Samples of the nitrite ester suitable for the photolysis reaction were prepared as follows. Nitrosyl chloride was passed into a pyridine (40 ml) solution of alcohol I*a* (4.0 g) at −10°. Stirring and addition of gaseous nitrosyl chloride was continued until the reaction mixture retained a pale-brown color. The solution was allowed to warm to room temperature and after 1/2 h was poured into ice water (200 ml) .The solid product was collected, washed with cold water, and dissolved in hexane, and the resulting solution was washed with cold dilute hydrochloric acid and water. Removal of solvent (*in vacuo* at room temperature) gave 3.7 g (87%) of the nitrite ester.

2-Oximo-3-oxo-3,4-seco-5α-lanostane (IV)

A solution of the nitrite ester (I*b*, 3.6 g) in dry benzene (250 ml under nitrogen) was cooled (10–15°) and irradiated for 45 min. Spot tests (diphenylamine in concentrated hydrochloric acid) for the nitrite group became negative after 40 min. The fluorescent green solution was concentrated *in vacuo* at room temperature to a viscous yellow oil. A hexane solution of the residue was chromatographed on basic alumina (70 g). One fraction eluted with hexane–benzene (1:1) afforded a viscous yellow oil (0.6 g). A 0.09-g sample of the oil was further purified using preparative thin-layer chromatography (8:1 hexane – ethyl ether mobile phase). By this means a 0.04-g specimen of *3-oxo-5α-lanostane* (II), m.p. 130–134°, was isolated.[13] The next most abundant component (0.02 g) was an oily nitrile (λ_{max}^{Nujol} 4.44 μ) later assumed to correspond with degradation product III. The fractions eluted with 3:2 to 1:4 hexane–benzene corresponded to the principal photolysis product. A thin-layer chromatogram (5:1 hexane – ethyl ether mobile phase) indicated that these fractions (IV, 1.3 g) represented a nearly pure substance. Continued elution with benzene gave an oily fraction (0.04 g) which was not investigated further, while the fractions eluted with benzene – ethyl ether and with ethyl ether afforded another 2.7 g of viscous oil. The latter fractions were combined and rechromatographed on acid-washed alumina (60 g). The fraction (0.64 g, m.p. 160–170°) eluted with hexane–benzene (3:1) was recrystallized from chloroform–methanol and identified[13] as *3β-hydroxy-5α-lanostane (21).*

When attempts to crystallize the principal photolysis product (1.3 g) proved unsuccessful, the photolysis reaction was repeated. As with the example noted above, a thin-layer chromatogram (9:1 hexane – ethyl acetate mobile phase) indicated that the crude product was composed of at least six components. Chromatographic separation of the viscous yellow oil was repeated employing neutral alumina with hexane, benzene, and chloroform solvent systems. Essentially the same observations were made. The following procedure, however, was used to obtain a pure specimen of oxime IV.

The reaction was again repeated and the product was chromatographed on 100 g of neutral alumina. Elution with 99:1 to 9:1 hexane – ethyl acetate yielded 1.6 g corresponding principally to 3-ketone II, lesser quantities of 3β-alcohol I*a*, and a small quantity of the nitrile (III) accompanied by a trace of nitrite ester (I*b*). Continued elution with 9:1 hexane – ethyl acetate to ethyl acetate gave 1.5 g of oxime IV. The oxime was rechromatographed on silica gel (45 g) and elution with 99:1 to 19:1 hexane – ethyl acetate removed

[13] *Identity was established by mixture melting point determination and infrared spectral comparison (in potassium bromide) with an authentic sample.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

approximately 0.1 g of less polar impurities. The next fraction eluted with 19:1 hexane – ethyl acetate weighed 1.15 g and was found by thin-layer chromatography (9:1 hexane – ethyl acetate mobile phase) to represent pure product (IV, 31% yield). However, attempts to crystallize the vitreous solid were unsuccessful. An analytical specimen was prepared by preparative thin-layer chromatography on silica gel HF 254 (4:1 cyclohexane – ethyl ether mobile phase), and the desired zone was identified using an ultraviolet lamp. In this case, the plate was first eluted with methanol (and reactivated at 110°) to remove some impurities. The oxime was eluted from the silica gel with chloroform, and the solution was filtered, concentrated to dryness *in vacuo*, treated with pentane, and finally evaporated in high vacuum to yield a colorless foam. Purity was reconfirmed by a thin-layer chromatogram but attempts to crystallize the product were again unsuccessful. A p.m.r. spectrum of the oxime in CCl_4 exhibited responses at 0.11, 0.74, 0.80, 0.84, 0.89, 1.15–1.47 (complex and broad), 2.50 (two methylene protons), 9.05 (one aldehyde proton) and 9.63 (one oxime proton) δ. After shaking the carbon tetrachloride solution with deuterium oxide for 15 min, the peak at 9.63 δ disappeared. The infrared spectrum displayed absorption at: ν_{max}^{KBr} 3 300 (broad), 1 700 (broad), 1 470, 1 450, 1 392, 1 370, and 1 200 cm^{-1}. Results of elemental analyses were consistent with the oxime structure.

Anal. Calcd. for $C_{30}H_{53}NO_2$: C, 78.37; H, 11.62; N, 3.05; O, 6.96. Found: C, 77.95; H, 11.48; N, 3.16; O, 7.35.

3-Oxo-5α-lanostane (II)

To a solution of 3β-hydroxy-5α-lanostane (2.0 g) in acetone (150 ml) at room temperature was added excess 8 *N* chromium trioxide reagent (22). When oxidation appeared complete, the remaining chromium trioxide was reduced with methyl alcohol and the mixture was filtered through Celite and concentrated to approximately 10 ml. After dilution with water, the product was collected and recrystallized from hexane to yield 1.43 g melting at 132–133°, $[\alpha]_D^{20}$ +25.4° (*c*, 7.29); reported (21) m.p. 127–128° and $[\alpha]_D$ +27°.

P.m.r. Chemical Shifts of 3β-Acetoxy-17-oximo-5α-androstane (VIIa) and 3β-Acetoxy-17-acetoximino-5α-androstane (VIIb)

Oxime VII*a* (23): p.m.r. in CCl_4 solution 0.80, 0.84, 1.19, 1.61, 1.88 (three acetate protons), 2.34 (broad, C-3 proton), and 8.75 (one oxime proton which disappears in the presence of deuterium oxide); in $CDCl_3$ solution 0.84, 0.88, 1.23–1.82 (complex), 1.97, 2.11 (three acetate protons), 2.44 (broad, C-3 proton), and 8.64 (one oxime proton which disappears in the presence of deuterium oxide). Oxime acetate VII*b* (16, 23): in CCl_4 solution 0.84, 0.94, 1.22–1.72 (broad and complex), 1.88 (3-acetate), 2.0–2.02 (oxime acetate), and 2.42 (broad, C-3 proton).

2,3-Dioximo-3,4-seco-5α-lanostane (VIIIa)

The dioxime derivative (VIII*a*, 0.06 g) obtained (0.08 g hydroxylamine hydrochloride, 1 ml pyridine, for 12 h at room temperature) from 0.08 g of the mono-oxime IV was purified by preparative thin-layer chromatography (3:1 hexane – ethyl ether mobile phase). Recrystallization from chloroform–hexane gave a pure sample melting at 168–171°: p.m.r. in $CDCl_3$ solution gave responses at 0.46, 0.78, 0.89, 0.99, 1.15–1.50 (complex and broad), 2.58 (two methylene protons) and 7.54 (broad, oxime proton, disappears in the presence of deuterium oxide) δ; ν_{max}^{Nujol} 3 570, 959, 935, and 885 cm^{-1}.

Anal. Calcd. for $C_{30}H_{54}N_2O_2$: C, 75.89; H, 11.47; N, 5.90. Found: C, 75.73; H, 11.49; N, 6.26.

2-Oximo-3-phenylhydrazono-3,4-seco-5α-lanostane (VIIIb)

Phenylhydrazine hydrochloride (0.53 g) in water (8 ml) was added to a stirred solution of oxime IV (0.75 g) in ethanol (30 ml). After approximately 3 h at room temperature, a crystalline product began to separate. Eighteen hours later, the mixture was cooled and the solid was collected and washed with methanol: yield 0.62 g (62%), m.p. 158–160°. An analytical specimen (pure as evidenced by thin-layer chromatography using 7:3 hexane – ethyl acetate as mobile phase) recrystallized from acetone–methanol as pale-yellow crystals, m.p. 169–170°; p.m.r. spectrum in $CDCl_3$ solution 0.65, 0.80, 0.90, 0.99, 1.18, 1.52, 2.58 (one proton), 2.78 (one proton), 6.67–7.15 (five aromatic protons), 7.61 (one proton which disappears in the presence of deuterium oxide) and 7.78 (one C-3 proton); ν_{max}^{KBr} 3 200, 1 600, 1 560, 1 510, 1 490, 1 470, 1 380, 1 250, 1 230, 1 160, 970, and 930 cm^{-1}. The mass spectral data (M^+ at 549 with a calculated mass of 549) and elemental analyses were also consistent with structure VIII*b*.

Anal. Calcd. for $C_{36}H_{59}N_3O$: C, 78.63; H, 10.82; N, 7.64; O, 2.91. Found: C, 78.74; H, 10.70; N, 7.78; O, 2.79.

2-[O-Acetyloximo]-3-oxo-3,4-seco-5α-lanostane (IX)

A solution of oxime IV (0.60 g) in acetic anhydride (4 ml) and pyridine (8 ml) was allowed to stand at room temperature 15 h. The mixture was poured into ice water containing excess sodium bicarbonate and allowed to stand 1 h. A hexane extract of the aqueous mixture was washed with water and concentrated *in vacuo* (after drying) at room temperature to a viscous yellow oil (0.52 g) which melted at 104–115°, following crystallization from hexane. Three recrystallizations from hexane – ethyl ether yielded a pure sample melting at 117–119°; $[\alpha]_D^{20}$ +37.5° (*c*, 0.48); p.m.r. spectrum in CCl_4 solution 0.71, 0.75, 0.80, 0.84, 1.14–1.45 (complex and broad), 2.15 (three acetyl protons), 2.54 (two methylene protons), and 9.31 (one aldehyde proton which remains unchanged in the presence of deuterium oxide) δ; ν_{max}^{KBr} 1 790, 1 715, 1 470, 1 370, 1 220, and 1 160 cm^{-1}.

Anal. Calcd. for $C_{32}H_{55}NO_3$: C, 76.59; H, 11.05; N, 2.79; O, 9.57. Found: C, 77.08; H, 11.18; N, 2.70; O, 9.12.

The oxime acetate was found sensitive and purification was achieved more easily by avoiding heat, light, and the atmosphere. In earlier experiments, an analytical sample prepared following four recrystallizations from hexane melted at 120–123° and exhibited $[\alpha]_D^{20}$ +35.8° (*c*, 0.36). Found: C, 76.74; H, 11.24; N, 2.33; O, 9.88.

1-Cyano-3,4-seco-5α-lanostane (III)

A solution of oxime acetate IX (0.14 g) in 4:1 hexane–benzene was added to a column of silica gel. After approximately 20 h the column was eluted with the same solvent. Removal of solvent *in vacuo* yielded an oil (0.09 g) which solidified, m.p. 83–87°, upon trituration with methanol. Recrystallization from methanol afforded pure needles melting at 85–87°; $[\alpha]_D^{20}$ +42.4° (*c*, 0.24); p.m.r. in CCl_4 solution gave signals at 0.15, 0.69, 0.72, 0.83, 1.05–1.55 (complex and broad) and 2.25 (partially masked doublet) δ; ν_{max}^{Nujol} 2 350 and 1 400 cm^{-1}.

Anal. Calcd. for $C_{29}H_{51}N$: C, 84.26; H, 12.35; N, 3.39. Found: C, 84.52; H, 12.21; N, 3.40.

A mass spectrum of the nitrile exhibited a molecular ion at 413 (calcd. mol. wt. 413).

ACKNOWLEDGMENTS

ON A PLATINUM–RHODIUM – OXYGEN ELECTRODE IN SILICATE MELTS

R. E. RANFORD[1] AND S. N. FLENGAS
Department of Metallurgy and Material Science, University of Toronto, Toronto, Ontario

Received March 22, 1965

ABSTRACT

The potential of the formation cell

$$\begin{array}{l} \text{Pt} - 10\%\ \text{Rh} \\ \quad\quad\quad\ \ \text{O}_2 \end{array} \Big| \begin{array}{c} \text{NiO} \\ \text{(silicate solvent)} \end{array} \Big| \ \text{Ni}$$

was studied in the temperature range 900 °C to 1 100 °C. The platinum–rhodium – oxygen electrode was found to behave reversibly in the pressure range 5×10^{-3} atm to 1 atm oxygen. The effects on the cell potential of oxygen pressure, nickelous oxide concentration, and temperature, were all found to follow an exact Nernst relationship.

INTRODUCTION

In spite of the established ionic nature of molten silicates (1–4), very few precise electrochemical measurements in these systems can be found in the literature. The concentration of oxygen anions in silicates has been shown (5) to be governed by an acid–base relationship of the type:

$$[O^{2-}] + [—O—] = 2[O—]$$

for which,

$$K_{eq} = \frac{[O—]^2}{[O^{2-}][—O—]}$$

The equilibrium constant represents the reaction between free oxygen anions O^{2-} in the slag and double-bonded oxygen —O— to form single-bonded oxygen O— species. The O— species are found at the end of a broken silicate chain as —Si—O, while the species —O— indicate oxygen shared between two silicon atoms as —Si—O—Si— in the inner structure of the silicate network. The concentration of the free oxygen anions in an oxide system of the type $MO—SiO_2$ is determined by the overall composition of the mixture, the basicity of the metal oxide component, and temperature.

Potentiometric determination of oxygen ion activities, or metal oxide activities, should therefore be possible by potential measurements using a suitable formation cell. The cell should include an oxygen electrode representing the reaction

$$O^{2-} = \tfrac{1}{2}O_2 + 2e^-$$

as well as a metal – metal ion electrode.

Didtschenko and Rochov (6) were the first to operate a platinum–oxygen concentration cell in solutions of various metal oxides in lead silicate. The results indicated a dependence of the potential on the type of metal oxide present. However, no attempt was made to investigate the quantitative response of this electrode to either oxygen pressure, temperature, or concentration of the metal oxide in the electrolyte. Flood, Forland, and Motzfeldt (7) carefully investigated the behavior of a platinum–oxygen electrode in molten carbonate and sulfate melts. Two oxygen electrodes were used in each cell, and the results indicated an exact Nernst relationship with respect to the mole % carbonate in these mixtures.

[1]*Present address: Dominion Foundries and Steel Co. Limited, Hamilton, Ontario, Canada.*

The reversibility of the oxygen electrode in silicate melts, and its exact response to either oxygen anion concentration in the melt, or to the oxygen pressure over the electrode, has not been shown in any previous work. In the present investigation, a systematic study was made using a simple formation cell of the type

Ni	NiO (X)	Pt – 10% Rh
(–)	(K_2O—Na_2O—SiO_2)	O_2 (+)

The experimental technique for operating oxygen electrodes in silicate melts has been developed. The potentials of the cell were measured as a function of oxygen pressure, of NiO concentration in the electrolyte, and temperature.

The Ni–NiO electrode was chosen because of the stability of the divalent oxide at high temperatures. Bogatskii (8) has shown that the higher oxide Ni_2O_3 totally decomposes at temperatures higher than 800 °C.

EXPERIMENTAL

The cell design is shown in Fig. 1.

The electrode assembly consisted of the oxygen and nickel electrodes. The nickel electrode was made by welding a spectrographically pure nickel rod of 1/8 in. diameter to a stainless steel wire. The oxygen electrode consisted of two concentric platinum – 10% rhodium alloy tubes of a total length of 20 in. To economize on this alloy, the upper halves of these tubes were made of silver welded to the alloy. The melt was contained in a platinum crucible.

Preliminary experiments indicated that stirring the melt made the measured potentials unstable. Therefore all measurements were made under absolutely static conditions. For this purpose, the oxygen–argon mixtures were introduced through the inner tube and then allowed to escape into the outer tube through an exit hole drilled at approximately 1/2 in. higher than the melt level. The inner tube was approximately 1/4 in. O.D., and was immersed in the melt to about 1/2 in. The outer tube of 1/2 in. diameter with a flared end was also immersed into the melt and simply separated the nickel electrode compartment from the oxygen in the inner tube. The nickel electrode was at all times under a slight positive pressure of purified argon.

To eliminate short circuits as well as electrode movements, the oxygen electrode assembly, the nickel electrode, and the slag containing crucible, were all firmly positioned by a boron nitride disc machined to hold both the electrodes and the crucible. A Pt – Pt, 13% Rh thermocouple was also led through this insulator with the bead placed about 1/4 in. above the melt.

The cell was carefully assembled outside the furnace, including the positioning of the electrodes, and the addition of the slag to the crucible. The assembled cell was then introduced into the furnace and was evacuated at about 300 °C for 12 h to remove any absorbed water from the slag. The temperature was then raised to that required for the experiment, and purified argon was fed into the nickel electrode compartment.

The furnace consisted of a single, tubular, silicon carbide element (Crusalite), connected in series to a power-stabilized variac. With this type of power source, and a fairly constant room temperature, the cell temperature could be controlled to ±2 deg, up to 1 400 °C.

The silicate solvent chosen for this work had the composition 54 mole % SiO_2, 28 mole % K_2O, and 18 mole % Na_2O, corresponding to a weight % of 46, 37, 16, respectively. The melting point of this slag is 750 °C. The melt was prepared by mixing stoichiometric amounts of reagent-grade potassium and sodium carbonates with silica at 900 °C. To control the rapid carbon dioxide evolution, silica was added gradually into the molten carbonates as quartz glass. The melt was finally evacuated to remove any residual carbon dioxide. A solute slag containing 0.75 weight % nickelous oxide was prepared by dissolving into the solvent melt the desired amount of nickelous oxide. This slag was then used for adding the solute to the cell to make the desired concentrations. Solute additions were made by removing the inner electrode and dropping weighed amounts of solute slag into the crucible.

At each concentration level, the equilibrium potentials were measured as a function of temperature on heating and cooling the cell in the temperature range 900 °C to 1 100 °C. The duration of a temperature cycle was about 12 h. At the end of every cycle run, the melt was sampled and analyzed for the nickel content.

The oxygen electrode was operated under a total pressure of 1 atm. Various mixtures of argon and oxygen were employed. The gas mixtures were made by metering known volumes of the two gases into the oxygen electrode. Calibrated rotameter type flowmeters were used, and the compositions of the mixtures at the higher oxygen concentrations were also verified by Orsat gas analysis.

The partial pressure of oxygen was varied stepwise from 5×10^{-3} atm to 1 atm. Potentials were measured at each oxygen-to-argon ratio, with the temperature and the metal ion concentration kept constant.

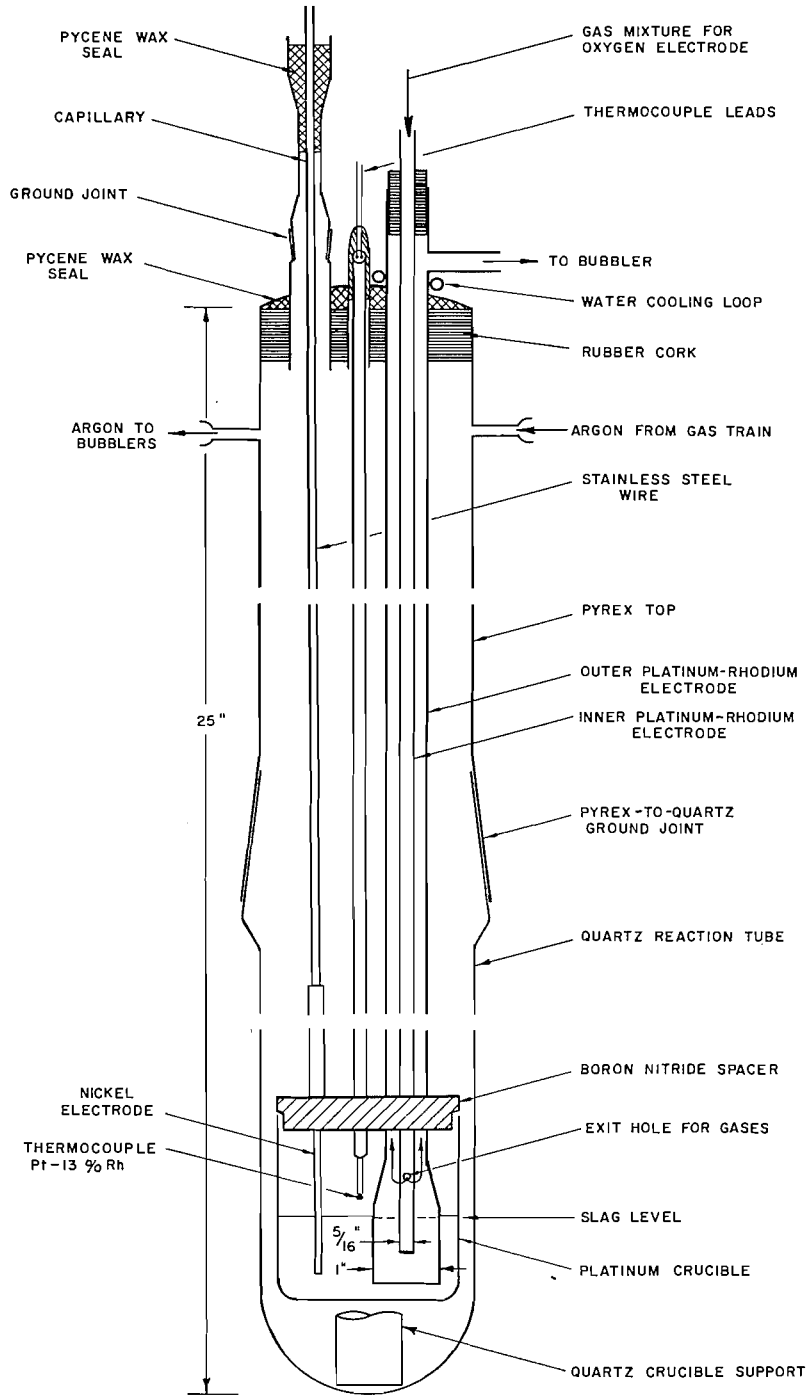

FIG. 1. Cell design.

One early difficulty experienced in this work was the uncontrollable oxidation of the nickel electrode, and the subsequent increase of the nickelous oxide concentration in the melt. This resulted in a continuous decrease in the cell potential with time at a given temperature. This effect was particularly evident when the oxygen electrode was operated at an oxygen pressure of 1 atm. Over a period of 24 h, the cell potential would decrease by as much as 20 mV. However, using a low oxygen pressure i.e., 5×10^{-2} atm, at the oxygen electrode, it was found that the potential decreased by about only 1 mV. Accordingly, in all experimental work reported here, the low oxygen pressure of 5×10^{-2} atm was used. In the investigation of the effect of pressure on the potential, the entire run lasted approximately 6 h, and the time spent at the high oxygen pressures was kept to a minimum.

The potentials were measured with a type K-2, Leeds and Northrup potentiometer.

Thermoelectric potentials were also measured at temperatures from 800 °C to 1 200 °C by short circuiting the Pt–Rh and nickel electrodes. In the temperature range of the experiments, these amounted to only 2 to 4 mV and were neglected in the calculations as negligibly small.

RESULTS

For the cell

Ni	NiO (X)	Pt – 10% Rh
(−)	K_2O:Na_2O:SiO_2	O_2 (+)
	28 18 54	(at P_{O_2} atm)

the corresponding cell reaction is given as:

$$Ni_{(s)} + \tfrac{1}{2}O_{2(\text{at } P_{O_2})} = NiO_{(\text{in solution})}$$

The relationship between the cell potential, the activity of NiO in the melt, and the oxygen pressure at the oxygen electrode, can be readily derived as:

$$[1] \qquad E_{\text{cell}} = E_{\text{NiO}}{}^{0} - \frac{2.303RT}{2F} \log \frac{a_{\text{NiO}}}{P_{O_2}{}^{1/2}}$$

where, $E_{\text{NiO}}{}^{0}$ is the standard formation potential of pure solid NiO at that temperature. This may be calculated from the standard free energy of formation of solid nickelous oxide (9) at that temperature, following the relationship: $\Delta G_f{}^{0} = -2E^{0}F$. Accordingly, the nickelous oxide activity, a_{NiO}, refers to pure solid NiO as the standard state.

For the study of the effect of pressure, the cell potential was measured as a function of the oxygen pressure at the platinum–rhodium electrode, at constant nickelous oxide content and constant temperature.

The results of two pressure runs are shown in Fig. 2.

The plot of the measured potential versus the log $P_{O_2}{}^{1/2}$ is linear, as expected from eq. [2]. The slopes of the straight lines are in good agreement with the theoretical slopes for a two-electron electrode process. These runs were done at two different temperatures and concentrations of nickelous oxide.

In Fig. 2, the two potential curves differ by 31 mV on the high oxygen pressure side and by 23 mV on the low pressure side. Assuming that the activity coefficient of NiO remains constant in the temperature and concentration range considered, the calculated difference from eq. [1] is only 20 mV.

The results shown in Fig. 2 were obtained over the pressure range from pure oxygen to 5×10^{-3} atm pressure. At the high oxygen pressures ($0.75 \sim 1$ atm), steady potentials were established within 10 min, while more time was required when changing the gas composition to lower pressures. This slower response of the electrode at the lower pressures may be explained by the time required to purge the preceding atmosphere in the apparatus and replace it with the new mixture.

During a run, the potentials were reproducible over a complete pressure cycle, indicating the reversibility of the oxygen electrode in these melts.

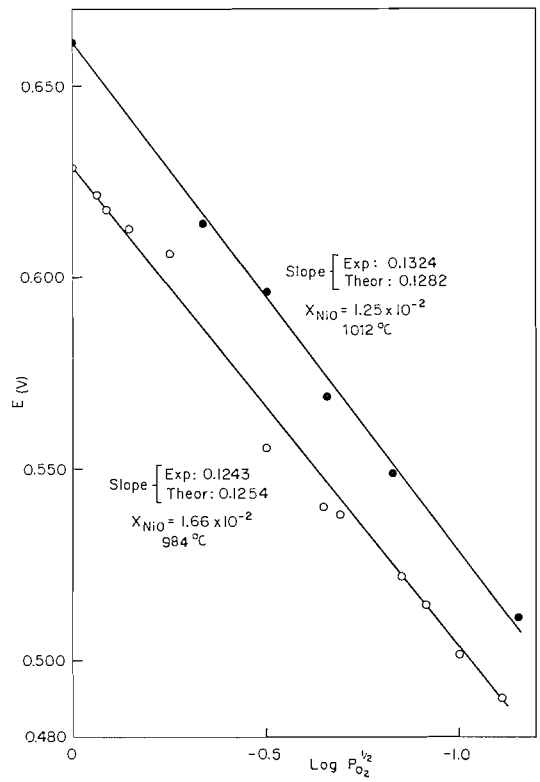

FIG. 2. Electromotive force of the cell

Ni	NiO (X)	Pt – 10% Rh
(–)	(K_2O:Na_2O:SiO_2)	O_2 (+)

as a function of log $P_{O_2}^{1/2}$.

Cell potentials were also measured as a function of temperature, at concentration levels from 7.5×10^{-4} to 1.5×10^{-2} mole fraction of NiO.

For these measurements, the oxygen pressure at the oxygen electrode was maintained at the low pressure of 5×10^{-2} atm.

The results are shown in Fig. 3.

Although scatter of the order of ± 5 mV is present, all curves are almost parallel, indicating the consistency of the results. From the data on Fig. 3, the cell potentials were obtained at the three selected temperatures of 900 °C, 1 000 °C, and 1 100 °C, and are plotted versus log X_{NiO} in Fig. 4.

By eq. [1], and on the assumption that the activity coefficients are constant at each of the temperatures, the theoretical slopes were calculated, and are shown by the dotted straight lines drawn through the experimental points. Since these lines closely approximate the data, it may be concluded that the activity coefficients are constant and therefore the system obeys Henry's law.

The arithmetic means of the activity coefficients, calculated from all the available experimental points, are given in Table I.

The plot of log γ_{NiO} versus the reciprocal of the absolute temperature is also linear. From the slope, the partial molar heat of mixing of solid nickelous oxide is found to be

DISCUSSION

The partial molar properties of nickelous oxide, calculated with respect to pure solid NiO as the state of reference, do not provide any information concerning the nickelous oxide species in solution.

In the partial molar properties shown in Table I, the experimental values include the thermal data for the fusion of nickelous oxide at these temperatures. Accordingly, the activity coefficients and the partial molar heats of mixing of nickelous oxide must be recalculated to represent the liquid state of reference.

The relationship between the heats of mixing of solid, $(\overline{\Delta H_m})_{S,NiO}$, and liquid nickelous oxide, $(\overline{\Delta H_m})_{L,NiO}$, is given by the expression:

$$[2] \qquad (\overline{\Delta H_m})_{S,NiO} = (\overline{\Delta H_m})_{L,NiO} + \Delta H_F$$

where, ΔH_F corresponds to the heat of fusion at the mixing temperature.

Similarly, the activity coefficients are related by the expression

$$[3] \qquad \Delta G_F = RT \ln \frac{(\gamma_{NiO})_S}{(\gamma_{NiO})_L}$$

where, ΔG_F is the free energy of fusion of nickelous oxide at the mixing temperature. $(\gamma_{NiO})_S$ and $(\gamma_{NiO})_L$ are activity coefficients referring to pure solid and pure liquid nickelous oxide, respectively, as the states of reference.

From eqs. [2] and [3], and the thermodynamic data for fusion given in the literature (10), the partial molar properties of liquid nickelous oxide were calculated and are also shown in Table I. These calculations are given without any limits of accuracy, as the heat of fusion of NiO, as well as the heat capacities are only approximate (10).

The activity coefficients of liquid nickelous oxide indicate positive deviations from ideality, increasing with increasing temperature. The partial molar heat of mixing is exothermic, and the excess entropy of mixing is also negative, indicating the formation of complex nicelo-silicate species in solution.

The calculation of activity coefficients in terms of an "ionic" model does not affect the positive deviations from ideality found in this system. Thus, the activity in the "molecular" model is given as

$$[4] \qquad a_{NiO} = \gamma_{NiO} X_{NiO} = \gamma_{NiO} \times \frac{n_{NiO}}{n_{NiO} + n_{K_2O} + n_{Na_2O} + n_{SiO_2}} = \gamma_{NiO} n_{NiO}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where n_{NiO} is the number of moles of NiO per gram-mole of solution. In the "ionic" model,

$$a_{NiO} = \gamma_{NiO}'(N_{Ni^{++}}N_{O^{--}}) = \gamma_{NiO}' \frac{n_{Ni^{++}}}{n_{K^+} + n_{Na^+} + n_{Ni^+}} \cdot N_{O^{--}}$$

$$= \gamma_{NiO}' \frac{n_{NiO}}{2n_{K_2O} + 2n_{Na_2O} + n_{NiO}} N_{O^{--}}$$

where $N_{Ni^{++}}$ and $N_{O^{--}}$ represent the ionic fractions of nickel and oxygen, and γ_{NiO}' is the "ionic" activity coefficient.

For the dilute solutions of nickelous oxide in a slag having the specified composition, this equation reduces to

[5] $$a_{NiO} = \gamma_{NiO}' \frac{n_{NiO}}{0.92} N_{O^{--}}.$$

The comparison of the two expressions [4] and [5] for the activity gives the following relationship between the "molecular" and the "ionic" activity coefficients.

[6] $$\frac{\gamma_{NiO(molecular)}}{\gamma_{NiO}'_{(ionic)}} = \frac{N_{O^{--}}}{0.92}$$

As the oxygen anion fraction $N_{O^{--}}$ is always less than unity, it is evident that the "ionic" activity coefficients show deviations from ideality, which are even more positive than those indicated by the "molecular" model. It should be noted that large positive deviations from ideality have also been found by Chipman *et al.* (11) in solutions of ferrous oxide in a basic slag containing calcium and magnesium oxides.

The properties of silicates are understood at present by the gradual breakdown of the silicate network upon the addition of oxygen ions from a more basic oxide. The simple ionic theory, however, is inadequate to account for the existence of free oxygen anions in any slag in which the MO/SiO_2 ratio is less than 2. To resolve this problem, several models have been proposed (12, 13) in which other ionic species besides the orthosilicate have been considered. Such calculations, however, are rather arbitrary and do not necessarily represent the true structure of the silicate. Furthermore, the various models cannot account for Henry's law behavior, as found in this work. The positive deviations from ideality in an acidic slag of this type indicate that the concentration of the free oxygen anions is relatively high. Their activity is expected to be governed by the more basic components K_2O and Na_2O that constitute the solvent slag. The positive temperature dependence of the activity coefficient is then indicative of the dissociation of the complex silicate network at the higher temperatures.

If these assumptions are correct, it may be predicted that for a given weak basic oxide, like nickelous oxide, the positive deviations from ideality should become more pronounced as the basicity, or the proportion of the more basic components in the solvent slag, is increased.

ACKNOWLEDGMENT

The authors are indebted to the National Research Council of Canada for a research grant in support of this work. The assistance of the Mines Branch of the Department of Mines and Technical Surveys, Ottawa, in the analysis of the silicate samples, is also gratefully acknowledged.

SPECTROSCOPIC STUDIES OF ALCOHOLS

V. INTRAMOLECULAR HYDROGEN BONDS IN 2-CYANOETHANOL AND IN SOME NITROALCOHOLS[1]

P. J. KRUEGER AND H. D. METTEE
Department of Chemistry, University of Alberta, Calgary, Alberta
Received May 19, 1965

ABSTRACT

The enthalpy difference between the *trans* and the intramolecularly hydrogen bonded *gauche* conformation of 2-cyanoethanol in dilute CCl_4 solution is shown to be -0.14 ± 0.03 kcal/mole from the temperature dependence of the fundamental OH stretching bands. At higher concentrations cyclic dimers with double OH...O bonds form. The enthalpy change on dimerization is -6.1 ± 0.3 kcal/mole. A small percentage of dimers with acylic OH...O bonds are also present, but these are thermodynamically less stable than the cyclic dimers.

Intramolecular hydrogen bonds are found between OH and NO_2 groups in some 2-nitroalcohols, leading to stabilization of the *gauche* form with respect to the *trans* form. For 2-nitroethanol the *trans* conformer is in equilibrium with two intramolecularly hydrogen bonded conformers ($\Delta H = -0.40 \pm 0.10$ and -0.71 ± 0.09 kcal/mole respectively). 2,2-Dinitropropanol and 2-methyl-2-nitro-1,3-propanediol show complex ν_{OH} bands due to *trans* and intramolecularly hydrogen bonded *gauche* conformers. 2,2,2-Trinitroethanol has a relatively narrow symmetrical OH peak at temperatures up to 55 °C which is assigned to the exclusively populated intramolecularly hydrogen bonded conformation.

INTRODUCTION

High-resolution infrared spectra of 2-substituted ethanols in the 3 μ region give valuable information about the factors affecting intramolecular hydrogen bond strengths (particularly geometry), and about those governing frequency displacements of hydrogen bonded OH groups. As a continuation of previous studies on 2-mono-, 2,2-di-, and 2,2,2-trihalosubstituted ethanols (3), hydrogen bonding in 2-cyanoethanol (hydracrylonitrile) and in some nitroalcohols in dilute CCl_4 solution has been investigated.

Cyano Groups as Proton Acceptors

The cyano group is well known to be a moderately strong proton acceptor because of the directed lone pair orbital on the nitrogen atom (4). The linearity of the group prevents steric complications in intermolecular hydrogen bonding studies. Hydrogen bond strengths between nitriles and phenol ($\Delta H = -4$ kcal/mole) and methanol ($\Delta H = -2$ kcal/mole) have been measured (5)

In the formation of intramolecular hydrogen bonds to the cyano group in 2-cyanoethanol the geometry of the system plays a major role, prohibiting access of the proton donating group to the nitrogen lone pair orbital. The weaker hydrogen bonds which form involve the π-electrons of the triple bond. The OH stretching frequencies of representative hydroxynitriles and their acetylene analogues have been studied by Allerhand and Schleyer (4), and intramolecular NH...CN interaction has been noted in *o*-cyanoaniline (6). No thermodynamic investigation of the strength of intramolecular hydrogen bonds to nitrile groups appears to have been reported.

The gas phase electron diffraction results of Yamaha (7) on 2-cyanoethanol itself showed

[1]*While this work was in progress the authors were informed of other studies then in press on nitro groups as proton acceptors in hydrogen bonds by Schleyer et al. (1). Their work did not, however, include quantitative thermodynamic measurements on which this paper is based. Since this work was completed, H. E. Ungnade, E. M. Roberts, and L. W. Kissinger have also confirmed the existence of weak hydrogen bonds between nitro groups and alcoholic* OH *groups (2).*

no evidence of an intramolecularly hydrogen bonded *gauche* conformation, and the conclusion was reached that the molecule was exclusively in the *trans* form.

Nitro Groups as Proton Acceptors

Although chelation in *o*-nitrophenol is a well established fact (1, 8*a*) based on numerous investigations using a wide variety of techniques, intramolecular $OH\cdots O_2N$ hydrogen bonding in systems which do not involve direct resonance interaction of the OH and NO_2 groups (which is responsible for the unusual strength of the intramolecular hydrogen bond in *o*-nitrophenol and the large OH spectral shift) is subject to conflicting reports. In connection with other studies of intramolecular hydrogen bonds in simple systems (3), 2-nitroethanol is of particular interest since no quantitative thermodynamic data on the conformational mobility of this compound appear to be available.

Flett (9) found only a broad band at 3 588 cm^{-1} for 2-nitroethanol in CCl_4 solution, significantly lower than the OH stretching frequency of 3 636 cm^{-1} usually found for monomeric normal primary alcohols under the same conditions. Kuhn, Luettke, and Mecke (10) report a *trans* band at 3 623 cm^{-1} and a *gauche* band at 3 608 cm^{-1} for 2-nitroethanol, and conclude that the latter is more stable because of a weak intramolecular $OH\ldots O_2N$ hydrogen bond. For nitroalcohols with two β-hydroxyl groups Urbanski and co-workers (11) have interpreted shifts in both ultraviolet and infrared peaks associated with the NO_2 group in terms of intramolecular hydrogen bonding.

Recently intramolecular hydrogen bonding in 2-nitroalcohols, including 2-nitroethanol, has been refuted on the basis of infrared studies in the 3 μ region using a NaCl prism spectrophotometer of low resolution (12, 13).

Studies of intermolecular hydrogen bonding of various hydroxylic proton donors and nitro compounds as proton acceptors show that nitro groups uniformly form weak hydrogen bonds as reflected in very small spectral shifts of the OH vibrational band (1). Spectra obtained with high resolution are therefore essential for the complete interpretation of the role these weak hydrogen bonds play in conformational equilibria, and the investigation of the temperature dependence of such spectra is advisable since frequency displacements do not necessarily measure the strength of weak intramolecular hydrogen bonds.

EXPERIMENTAL

Spectroscopic measurements were made with a Beckman IR-7 infrared spectrophotometer operating at a calculated nominal slit width of about 1 cm^{-1}. Matched fused quartz absorption cells of 2 and 10 cm path length were used. Cell temperatures were controlled with a Lauda UK-70 DW Ultrakryostat. Other details concerning technique have been described previously (3). Carbon tetrachloride (reagent grade) was dried over P_2O_5 and fractionally distilled through a 50 theoretical plate spinning band column. Other solvents used were commercial products of spectroscopic quality.

Hydracrylonitrile (Eastman) was dried over anhydrous sodium sulfate and fractionally distilled through a 23 plate spinning band column, collecting colorless material with a b.p. 82.5 °C at 4 mm, n_D^{23} 1.4257 (lit. b.p. 82 °C at 4 mm, n_D^{25} 1.4374 (14)). 2-Nitroethanol was a commercial product (K & K Laboratories, Inc.) which was dried over anhydrous Na_2SO_4 and distilled under reduced pressure (n_D^{25} 1.4497; lit. 1.4383^{25} (15), 1.4403^{20} (16)). 2-Methyl-2-nitro-1,3-propanediol and 2,2-dinitropropanol were given by Dr. H. E. Ungnade, Los Alamos Scientific Laboratory, University of California. A small sample of 2,2,2-trinitroethanol (as an anhydrous CCl_4 solution) was obtained from Dr. T. N. Hall, U.S. Naval Ordnance Laboratory, White Oak, Silver Springs, Maryland, U.S.A. This was diluted further with dry CCl_4 and used directly.

RESULTS AND DISCUSSION

2-Cyanoethanol

Concentrations of the order of 10^{-4} *M* in CCl_4 were necessary to eliminate a broad concentration and temperature dependent absorption band centered at 3 500 cm^{-1}. At these low concentrations a concentration independent but temperature dependent doublet

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

remained in the 3 μ region. The more intense high frequency component (3 633.$_8$ cm^{-1}) must be due to the *trans* conformation, with the low frequency component (3 619.$_0$ cm^{-1}) due to the intramolecularly hydrogen bonded *gauche* conformation.[2] Figure 1(*a*) shows some typical spectra.

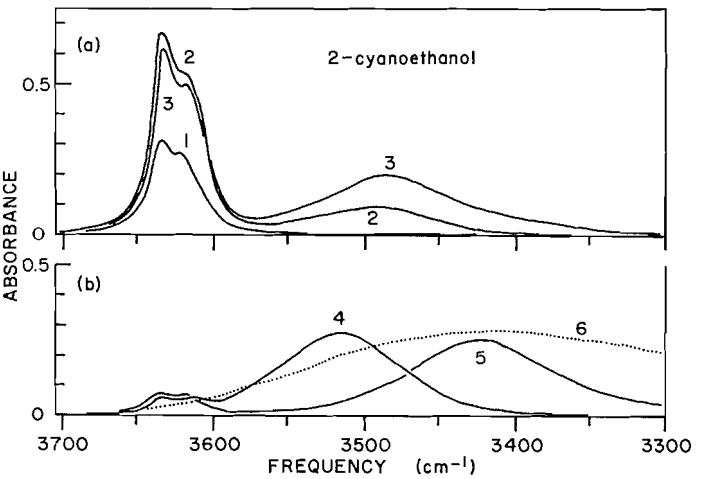

FIG. 1. Fundamental OH stretching bands of 2-cyanoethanol in dilute CCl_4 solution: (1) concentration 4×10^{-4} *M*, path length 10.0 cm, temperature 20 °C; (2) concentration 2.5×10^{-3} *M*, path length 2.00 cm, temperature 20 °C; (3) same as (2) but at 0 °C; (4) concentration 2.5×10^{-3} *M*, and 0.65 *M* with respect to acetonitrile in both sample and reference cell; (5) concentration 2.5×10^{-3} *M*, and 0.5 *M* with respect to diethyl ether in both sample and reference cell; (6) capillary film of pure 2-cyanoethanol.

The relative intensity of the *trans/gauche* doublet is increased slightly by intermolecular association which sets in at the higher concentrations ($\sim 10^{-3}$ *M*). The first associated species to appear with increasing concentration would be expected to be the dimer (*vide supra*) which could conceivably have one of the following structures.

$$N{\equiv}CCH_2CH_2OH\cdots OCH_2CH_2C{\equiv}N \quad (H)$$

I

$$N{\equiv}CCH_2CH_2O \quad (H) \quad OCH_2CH_2C{\equiv}N \quad (H)$$

II

$$N{\equiv}CCH_2CH_2OH\cdots N{\equiv}CCH_2CH_2OH$$

III

In I and III the proton acceptor molecule could also be in the intramolecularly hydrogen bonded gauche form.

Figure 1(*b*) shows comparative spectra of the 2-cyanoethanol–acetonitrile and the 2-cyanoethanol – diethyl ether complexes respectively in dilute CCl_4 solution, as well as a spectrum of a thin film of pure 2-cyanoethanol. It is known that the frequencies of bonded OH groups can show a marked dependence on the proton acceptor concentration (17) so that these band positions do not represent values extrapolated to infinite dilution, but they are useful in identifying the nature of the 2-cyanoethanol dimer. Since the *G* value (17) of diethyl ether ($G = 64$) is very close to that of CCl_4 ($G = 69$) little change

[2]*These bands have been reported at 3 625 and 3 610 cm*$^{-1}$ *(9) and at 3 632 and 3 617 cm*$^{-1}$ *(4) in very dilute* CCl_4 *solution.*

For personal use only.

in the 2-cyanoethanol–Et_2O complex band is expected as the Et_2O concentration is altered, but the 2-cyanoethanol–acetonitrile complex band is expected to shift to somewhat higher frequency on extrapolation to infinite dilution (*G* for CH_3CN is 93). The basicity of the N atom in 2-cyanoethanol is expected to be less than that of the N atom in acetonitrile,[3] so that the frequency shift on intermolecular hydrogen bond formation as in III should be *less* than that in $N{\equiv}CCH_2CH_2OH\cdots N{\equiv}CCH_3$ hydrogen bond formation. This is not the case. On the other hand the electron-withdrawing nature of the $C{\equiv}N$ group would increase the acidity[3] of the OH but decrease the basicity of the hydroxyl oxygen atom in 2-cyanoethanol,[4] making it a poorer proton acceptor than the oxygen atom in diethyl ether. Therefore the frequency shift on intermolecular hydrogen bond formation as in I is expected to be *less* than that on $N{\equiv}CCH_2CH_2OH\ldots OEt_2$ hydrogen bond formation, and this is observed experimentally. A dimer like II is expected to have a bonded OH frequency like that of I, or perhaps a little higher.

The hydrogen bond strength of 6.1 kcal/mole in the 2-cyanoethanol dimer as determined in this work rules out III and favors II over I. Strengths of $OH\ldots N{\equiv}C$ hydrogen bonds involving phenol and methanol have been found to be only 4 and 2 kcal/mole respectively (5) whereas the ΔH values for dimerization of simple alcohols are 6–7 kcal/mole (20), in line with the 2-cyanoethanol value. There is considerable evidence favouring cyclic dimers with two non-linear $OH\cdots O$ hydrogen bonds for simple alcohols (*8b*), and this may also apply to the 2-cyanoethanol dimers. The capillary film shows extremely broad OH absorption, presumably due to a variety of molecular aggregates.

Figure 2(*b*) shows the temperature dependence of the *trans/gauche* absorbance ratio

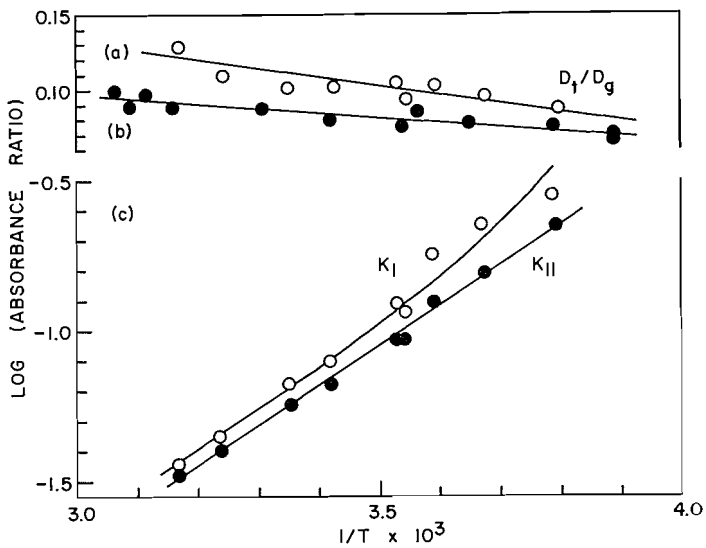

FIG. 2. (*a*) Temperature dependence of *trans/gauche* absorbance ratio of monomeric 2-cyanoethanol at concentrations where some dimerization occurs. (*b*) Temperature dependence of *trans/gauche* absorbance ratio in monomeric 2-cyanoethanol in very dilute CCl_4 solution ($\leqslant 4 \times 10^{-4}$ *M*). (*c*) Temperature dependence of dimerization constant for 2-cyanoethanol at higher concentrations in CCl_4 ($4 \times 10^{-4} <$ concentration $\leqslant 2.5 \times 10^{-3}$ *M*). Apparent equilibrium constants K_I and K_{II} calculated on the basis of open and cyclic dimers respectively. For convenience the factor 2 in the K_{II} expression is omitted.

[3]*The Taft* σ^* *values (18) for* $HOCH_2CH_2$— *and* $N{\equiv}CCH_2CH_2$— *groups are estimated to be +0.20 and +0.46 respectively relative to a value of zero for the* CH_3— *group. Electron-withdrawing groups on a nitrile decrease the frequency shift observed on intermolecular hydrogen bond formation with a given proton donor (4).*

[4]*It has been demonstrated that this is the case in 2,2,2-trifluoroethanol (19).*

at concentrations in CCl_4 where intermolecular association is absent. Evaluation of the slope of the $\log_{10}(D_t/D_g)$ vs. $1/T$ plot by the least squares method gives $\Delta H = -0.14 \pm 0.03$ kcal/mole for the process in which the hydrogen bond forms. Considering the interactions between non-bonded atoms on the adjacent carbon atoms in the *trans* and *gauche* forms (21), it follows that the *trans* → *gauche* process is accompanied by the gain of one weak repulsive interaction (H—H) and the loss of two stronger repulsive interactions (H—CN and H—OH) as well as the gain of the attractive OH—CN interaction. The observed $-\Delta H$ is therefore probably greater than would be expected on the basis of the intramolecular hydrogen bond alone because of the lost repulsive interactions, i.e. the hydrogen bond strength itself is less than 0.14 kcal/mole. The very weak nature of this interaction accounts for the fact that no bonded OH peak is observed for compounds of the type $HO—(CH_2)_n—CN$ when $n = 3$ or 4 (4).

From measurements at higher concentrations the enthalpy change on intermolecular association can be determined. Using absorbances at the maxima of the intermolecularly bonded peak (D_d), the *trans* peak (D_t) and the *gauche* peak (D_g) as estimates of the respective relative concentrations, the following approximate equilibrium expressions apply for the formation of I and II respectively.

$$K_{\mathrm{I}} = D_d/(D_t + D_g - D_d)^2$$

$$K_{\mathrm{II}} = D_d/2(D_t + D_g)^2$$

In the first expression the total monomer absorbance $(D_t + D_g)$ is corrected for the absorbance of "terminal" OH groups of open dimers, which probably contribute to the *trans* band (8*c*). Extinction coefficient differences for the bands are ignored since the behavior of K vs. $1/T$ will be affected little if $E_t \approx E_g$, which is reasonable for such a weak intramolecular hydrogen bond. Furthermore, the dimer concentration was always relatively small. Figure 2(*c*) shows the temperature dependence of K_{I} and K_{II}. The linearity of K_{II} vs. $1/T$ implies that cyclic dimerization is the dominant type of association in this concentration range, with $\Delta H = -6.1 \pm 0.3$ kcal/mole (least squares method, 90% confidence limits), which reflects the intermolecular hydrogen bond strength of the two angular OH···O bonds in the cyclic dimer. The plot of K_{I} vs. $1/T$ is linear at high temperatures where the dimer concentration is small, but curves upward at lower temperatures where dimer concentration is larger.

Figure 2(*a*) also shows the increase in D_t/D_g in solutions where dimerization occurs. This increase indicates the contribution of some 'terminal" OH absorption from a small amount of the acyclic dimer I to the *trans* band. At these low concentrations the monomeric conformational equilibrium should not be affected by the presence of a minute amount of dimer. Because the measurements were made at several concentrations these points are spread over a narrow belt, the edges of which can be extrapolated to meet line (*b*) in Fig. 2 at −35 °C, where all I would have reverted to the more stable II.

Acetone Cyanohydrin

Weak intramolecular OH interaction with a nitrile group leading to a formal four-membered ring also seems possible. Thus, for acetaldehyde cyanohydrin, only one OH band has been reported at 3 607 cm^{-1} (ref. 4, interpreted as "bonded" ν_{OH}) and 3 604 cm^{-1} (ref. 9, interpreted as "free" ν_{OH}). For acetone cyanohydrin we have found a single sharp symmetrical band at 3 600.$_4$ cm^{-1}, $\Delta\nu_{1/2}{}^a = 16.{}_6$ cm^{-1} at 28 °C, shifting to 3 602.$_6$ cm^{-1} with $\Delta\nu_{1/2}{}^a = 17.{}_3$ cm^{-1} at 55 °C, and becoming slightly asymmetric on the high frequency side. The low value of this OH frequency indicates that it belongs to a hydrogen bonded

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

group. Rotation about the C—O bond to move the hydroxyl proton from the *gauche* to the *trans* position with respect to the CN group would bring repulsive forces between the oxygen lone pair orbitals and the CN π-electrons into play, and this may help to stabilize the *gauche* form. Intramolecular hydrogen bonding involving OH···O=C interaction in four-membered rings is well known in carboxylic acids (22), and similar NH···O=C interaction in partially deuterated primary acid amides leads to *cis–trans* isomerism of the —NHD groups (23).

Nitroalcohols

Figure 3(*a*) shows the fundamental OH stretching bands of 2-nitroethanol (0.0038 *M* in CCl_4) obtained at room temperature. The maximum at 3 630 cm^{-1} is assigned to the *trans* conformer, and maxima at 3 620 and 3 612 cm^{-1} are assigned to two intramolecularly hydrogen bonded *gauche* conformers. These measurements agree well with those of Schleyer *et al.* (1).

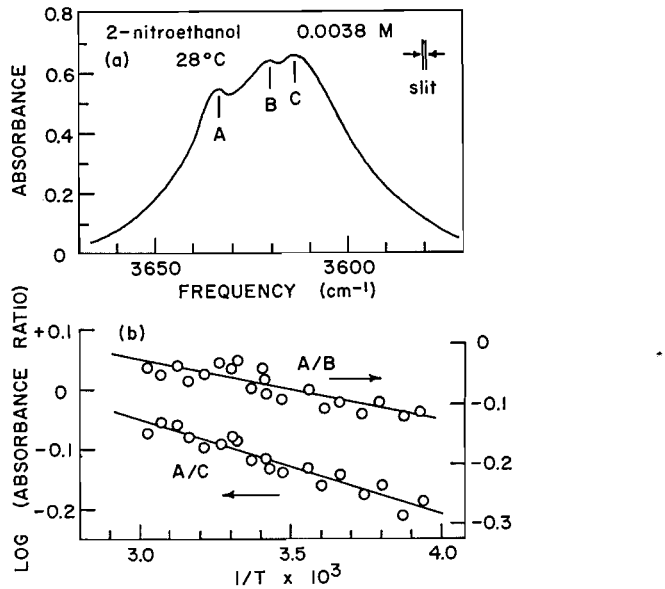

FIG. 3. (*a*) Fundamental OH stretching bands of 2-nitroethanol, 0.0038 *M* in CCl_4, path length 2.00 cm, temperature 28 °C. (*b*) Temperature dependence of OH absorbance ratios for 2-nitroethanol.

The temperature dependence of the spectra, shown in Fig. 3(b), indicates that bands B and C arise from conformers which are thermodynamically more stable than the *trans* conformer (band A) by -0.40 ± 0.10 and -0.71 ± 0.09 kcal/mole respectively (least squares method, 90% confidence limits). Since the barrier to rotation about a C—NO_2 bond is known to be insignificantly small (6 cal/mole, ref. 24), hydrogen bonded conformations involving one or both oxygen atoms of the nitro group have been suggested (1). In the conformer where the OH group bonds to one of the nitro group oxygen atoms, the proton may be imbedded in an oxygen p-orbital, forming a six-membered ring. It is doubtful whether more specific assignments of bands B and C can be made at the present time. The $-\Delta H$ values observed are probably larger than the hydrogen bond strengths themselves because of the loss of repulsive non-bonded interactions on going from the *trans* to the *gauche* form.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The present measurements on 2-methyl-2-nitro-1,3-propanediol (Fig. 4(*a*)) are in agreement with those of Schleyer *et al.* (1). The main maximum at 3 608.$_1$ cm^{-1} and the shoulder at ~3 591 cm^{-1} are attributed to OH intramolecularly bonded to NO_2 in two different ways, the pronounced high frequency shoulder at 3 633 cm^{-1} is due to "free" OH groups, whereas the very weak low frequency shoulder at ~3 553 cm^{-1} must be due to intramolecular OH...O bonding in a seven-membered ring. Although OH...O_2N interaction is weaker than OH...O interaction the former is favored because of the proximity of the two groups in the molecule.

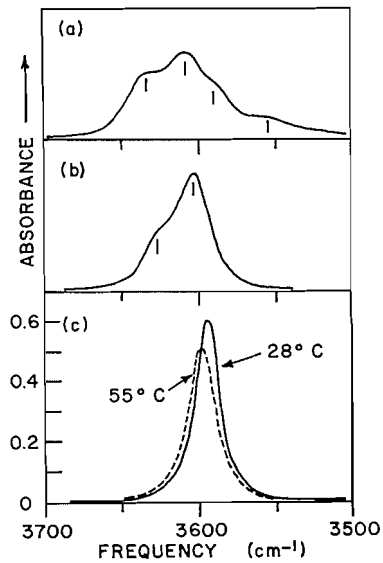

FIG. 4. Fundamental OH stretching bands of several nitroalcohols in dilute CCl_4 solution, path length 2.00 cm, temperature ambient unless indicated: (*a*) 2-methyl-2-nitro-1,3-propanediol (1.8×10^{-3} *M*); (*b*) 2,2-dinitropropanol (3.1×10^{-3} *M*); (*c*) 2,2,2-trinitroethanol (~6×10^{-3} *M*).

In 2,2-dinitropropanol (Fig. 4(*b*)) the relative intensity of the "free" OH shoulder (3 628 cm^{-1}) has diminished with respect to the intramolecularly hydrogen bonded band (3 602.$_7$ cm^{-1}) because of the enhanced acidity of the OH group due to the electron-withdrawing effect of two NO_2 groups, and the possibility of hydrogen bonding to two NO_2 groups. In the extreme case of 2,2,2-trinitroethanol a narrow ($\Delta\nu_{1/2}^{a} = 20$ cm^{-1}) symmetrical OH band is observed at 3 593.$_2$ cm^{-1} at room temperature (Fig. 4(*c*)). At 55 °C the peak has moved to 3 596.$_6$ cm^{-1}, but it is still symmetrical. The low frequency and narrow symmetrical nature of this band imply a single intramolecularly hydrogen bonded conformation. The acidity of the OH group would be enhanced by the electron-withdrawing effect of three NO_2 groups. Further, "free" OH groups can only arise by rotation about the C—O bond, bringing strong repulsive forces between the lone pair orbitals on the hydroxyl oxygen atom and the nitro groups into play. Thus even a weak OH...O_2N bond would be sufficient to keep all the OH groups hydrogen bonded.

Nitro groups are therefore capable of acting as proton acceptors in intramolecular hydrogen bond formation in aliphatic systems.

COORDINATION COMPOUNDS OF OLEFINS WITH ANHYDROUS SILVER SALTS

II. AN INFRARED AND NUCLEAR MAGNETIC RESONANCE INVESTIGATION OF SILVER TETRAFLUOROBORATE – OLEFIN COMPLEXES[1]

H. W. QUINN, J. S. MCINTYRE, AND D. J. PETERSON
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received May 18, 1965

ABSTRACT

A determination has been made of the changes which occur in the infrared and proton magnetic resonance spectra of a number of olefins when they form $AgBF_4$.2 olefinates. The data obtained indicate that: (i) asymmetric substitution at a double bond results in nonsymmetric orientation of the silver ion relative to the trigonal carbon atoms and to the plane of the pi orbital; (ii) complexing may affect the rotation about the bond between a secondary or tertiary tetrahedral carbon and a trigonal carbon in order to reduce interaction between the two olefin molecules; (iii) in the solid state, lattice restrictions can result in interaction between the two olefin molecules.

INTRODUCTION

Numerous investigations of the nature of the interaction of aliphatic monoolefins with silver(I), palladium(II), and platinum(II) by study of the infrared (1–4), Raman (5), and nuclear magnetic resonance (n.m.r.) (2, 6, 7, 8) spectra have been reported.

These studies have established that, upon complexing, the olefinic character of the hydrocarbon molecule is retained although it is perturbed by withdrawal of pi electrons, presumably effected, as Dewar has suggested (9), by overlap of the pi molecular orbitals with the atomic orbitals of the metal ion. In the infrared, the perturbation results in a shift of the double bond stretch vibration to a lower frequency from that in the uncomplexed olefin by 50–70 cm^{-1} for Ag(I) and about 150 cm^{-1} for Pt(II) while in the n.m.r. the olefinic protons are somewhat deshielded producing a change in chemical shift of less than 1 p.p.m. The reported data, relating particularly to Ag(I) complexes, do not, however permit speculation regarding the positioning of the silver ion with respect to the double bond.

Some structural determinations of platinum(II) and palladium(II)–olefin complexes have revealed that, whereas the symmetric ethylene molecule is symmetrically oriented about the bond joining it to the metal atom (10–12), the styrene molecule, exhibiting nonsymmetric substitution at the double bond, is not symmetrically oriented, the bond to the metal atom making an angle of 74° with the double bond axis at a point closer to the β- than to the α-carbon of the vinyl group (13). No similar structural data exist for mono-olefin – silver ion complexes.

The present investigation of the infrared and n.m.r. spectra of a number of anhydrous silver tetrafluoroborate – olefin complexes deals primarily with the changes which occur in the olefin spectra when complex formation is effected and the dependence of the magnitude of the change upon the substitution at the double bond. The unsaturated hydrocarbons employed have included the methyl-substituted ethylenes from ethylene through 2,3-dimethyl-2-butene, some straight chain 1-olefins from C_3 to C_{18}, and several branched-chain olefins.

EXPERIMENTAL

Anhydrous silver tetrafluoroborate was prepared from silver fluoride and boron trifluoride according to the method of Olah and Quinn (14).

Ethylene and *cis*- and *trans*-2-butene were Matheson C.P. grade with a 99.5% minimum purity.

Propylene, 2-methylpropene, 1-butene, 1-pentene, 2-methyl-2-butene, 4-methyl-1-pentene, and 2,4,4-trimethyl-1-pentene were Phillips pure grade materials of 99% minimum purity.

The straight chain 1-olefins from C_6 to C_{18} with the exception of C_{13} were obtained from Humphrey-Wilkinson, Inc. and were purified by fractional distillation.

All of the remaining olefins employed were obtained in 95% minimum purity from Columbia Organic Chemicals.

The n.m.r. solvents were Merck reagent grade chloroform and 99.5% isotopically pure deuterochloroform purchased from Merck, Sharp and Dohme.

Preparation of Complexes

Earlier investigations (4) have established that, with the exception of ethylene, the most stable complexes exhibit a 1:2 silver tetrafluoroborate : olefin stoichiometry. Preparation of the solid complexes was accomplished by exposure of anhydrous $AgBF_4$ to gaseous olefin until the weight increase corresponded essentially to the 1:2 stoichiometry or contact of $AgBF_4$ with liquid olefin in a 1:2 mole ratio. With the straight-chain 1-olefins above C_3, and branched-chain 1-olefins above C_4 the complex has a melting point above 35 °C. The complexes of lower molecular weight olefins dissociate without melting at higher temperatures. The complexes with the lower olefins demonstrated a marked hygroscopicity which tends to decrease with increasing olefin molecular weight.

Chloroform or deuterochloroform solutions of the complexes were prepared by contact of a 10% solution of the olefin with anhydrous $AgBF_4$ in an amount slightly less than that necessary for preparation of the $AgBF_4$.2-olefinate. Although $AgBF_4$ was relatively insoluble in chloroform, the complex was readily soluble and a clear, colorless solution was obtained. A slow reaction between chloroform and $AgBF_4$ was observed resulting in precipitation of AgCl, upon standing at 25 °C for some time. This reaction appeared to proceed more rapidly in the presence of excess uncomplexed $AgBF_4$ and less rapidly in the presence of excess olefin, suggesting that uncomplexed silver salt was involved. At 0 °C, the reaction was much retarded and, at −80 °C, the complex could be kept frozen indefinitely without evidence of silver chloride precipitation. Precipitation of a small amount of AgCl during recording of the n.m.r. spectrum did not appear to affect at all the spectrum of the complex.

Infrared Spectra

The infrared spectra were recorded at 25 °C with a Perkin–Elmer 421 grating spectrophotometer. Nujol and fluorolube mulls of the crystalline complexes were prepared in a dry box and placed in cells with KBr windows. Chloroform solutions of the complexes were compensated by samples of the solvent in identical 0.1 mm cells with KBr windows.

Nuclear Magnetic Resonance Spectra

The n.m.r. spectra of chloroform or deuterochloroform solutions of the complexes were recorded with a Varian A60 proton resonance spectrometer. By a first-order treatment of the spectra, the chemical shifts were measured relative to internal tetramethylsilane (TMS) and the chemical shifts and coupling constants for the $AgBF_4$ complexes compared with those of the uncomplexed olefins at identical concentrations in the same solvent.

RESULTS

Stoichiometry of Complexes

From the infrared and n.m.r. spectra it was possible, except with ethylene, to establish that all olefins employed formed $AgBF_4$.2 olefinates as the most stable complexes, both in the crystalline form and in chloroform solution. Earlier investigations (4) have shown that, with ethylene, complexes of lower stoichiometry are formed and it is considered that the ethylene complex employed in this study has the stoichiometry, $AgBF_4.C_2H_4$. With other olefins, infrared bands of uncomplexed olefin were observed only after a 2:1 mole ratio of olefin : silver salt had been exceeded. Similarly, identical n.m.r. shifts were observed for systems of 1:1 and 2:1 olefin : silver salt stoichiometry but further addition of olefin resulted in decreasing shifts. With the chloroform solutions, a stoichiometry of less than 2:1 resulted also in incomplete solution of $AgBF_4$ while at the 2:1 mole ratio all of the salt was dissolved.

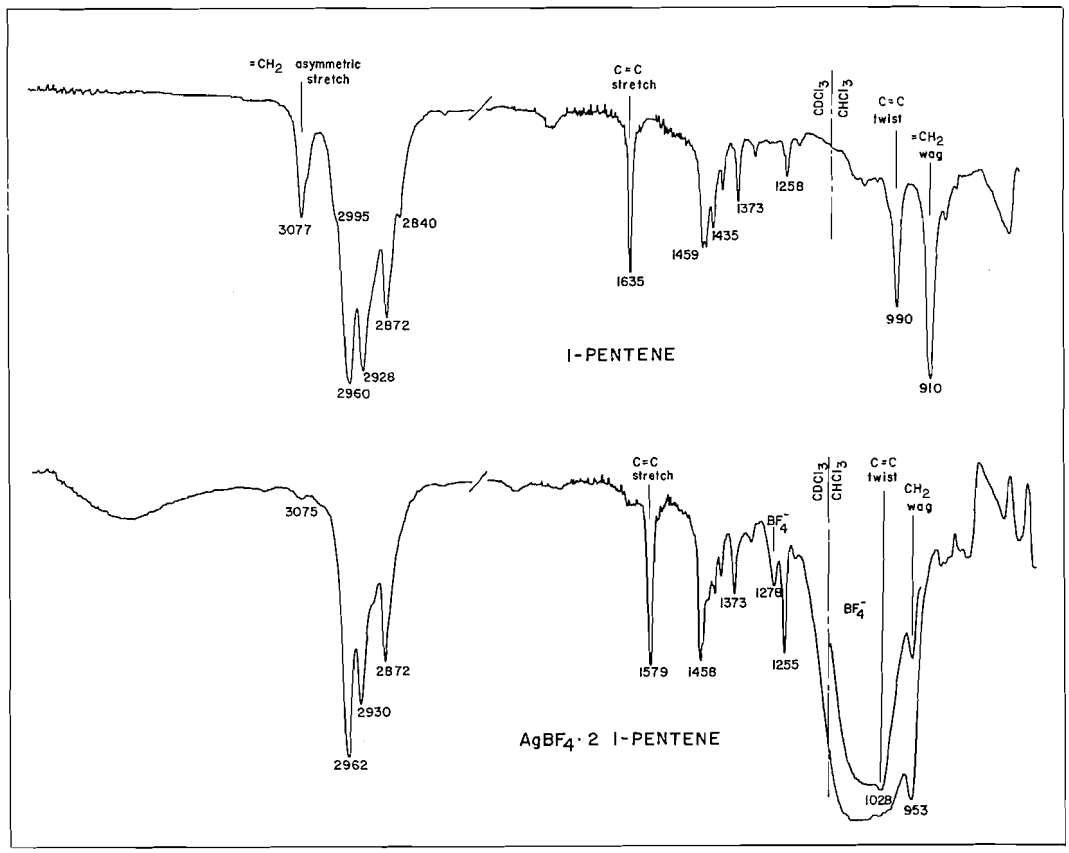

FIG. 1. Infrared spectra of 1-pentene and $AgBF_4$.2 1-pentene (10% in $CDCl_3$ and $CHCl_3$).

Infrared Spectra

Formation of the $AgBF_4$.2 olefinates results in some significant changes in the olefin spectrum. As may be seen from the comparison of the spectrum of $AgBF_4$.2 1-pentene with that of 1-pentene depicted in Fig. 1, complex formation results in a shift of the C=C stretch vibration frequency from 1 635 cm^{-1} to 1 579 cm^{-1}, a shift of the C=C twist out-of-plane deformation from 990 cm^{-1} to 1 028 cm^{-1}, and a shift of the CH_2 wag deformation from 910 cm^{-1} to 953 cm^{-1}. Similar shifts as observed with a variety of olefins are recorded in Table I.

With *trans*-2-butene and 2,3-dimethyl-2-butene, in which the C=C stretch vibration is infrared inactive, the shifts were obtained from the Raman spectra of nitromethane solutions. Chloroform solutions of the complexes were unsatisfactory for Raman because of the slow reaction of the solvent with $AgBF_4$ (*vide* Experimental, Preparation of Complexes). Complex formation does, however, introduce sufficient asymmetry to give an infrared active C=C stretch with these olefins.

In general, the magnitude of the shift to lower frequencies of the C=C stretch vibration is dependent upon substitution at the double bond, being about 55 cm^{-1}, 63 cm^{-1}, and 70 cm^{-1} for mono-, di-, and tri-alkyl substitution, respectively. These values reflect increasing interaction of the silver ion with the double bond, i.e. more extensive overlap

For personal use only.

of the olefinic pi orbital with the Ag^+ orbitals, as a result of increasing pi basicity due to the $-I$ effect of the alkyl substituents. The shift is not, however, very dependent upon the extent of branching of the alkyl substituent being, for example, 56 cm^{-1} for 1-pentene, 57 cm^{-1} for 3-methyl-1-butene, and 56 cm^{-1} for 4,4-dimethyl-1-pentene.

†Fluorolube and Nujol mulls compared with 10% CCl_4 and CS_2 solution of olefin.
‡Raman spectrum of nitromethane solution.
§Chloroform or deuterochloroform solutions (10% olefin by volume).
‖Accuracy doubtful because of strong solvent absorption in this region.
¶Probably an out-of-plane bending mode, e.g. $C(CH_3)_2$ wag which is shifted to lesser extent than is th CH_2 wag.

In the crystalline complexes of straight-chain 1-olefins with 13 or more carbon atoms, the band representing the C=C stretch vibration appears as a doublet with a splitting of about 9 cm^{-1}, one member being at higher and one at lower frequency than the corresponding single band observed with the shorter chain 1-olefins. In solution or in the melt this splitting disappears, however (Fig. 2). No similar splitting is observed in solid 1-octadecene.

Only with $AgBF_4$.2 3,3-dimethyl-1-butene (*t*-butylethylene) has a splitting of the C=C stretch band been observed in chloroform solution, (Fig. 3). In this instance, the splitting amounts to 20 cm^{-1}, one member of the doublet being about 10 cm^{-1} lower and the other 10 cm^{-1} higher than the frequency of the corresponding single band observed for $AgBF_4$.2 3-methyl-1-butene (isopropylethylene). This same splitting is observed in the crystalline complex of 3,3-dimethyl-1-butene but not in that of crystalline $AgBF_4$.2 3-methyl-1-butene.

In addition, the spectrum of $AgBF_4$.2 3,3-trimethyl-1-butene shows a splitting, but no significant frequency shifts, of the bands attributed to a symmetric CH_3 scissors at $\sim$ 1 360 cm^{-1} and an in-plane CH_3 rock at about 1 200 cm^{-1}.

Accurate determination of the shifts to higher frequency of the C=C twist and CH_2 wag deformations effected by complexing was difficult because of superposition of these bands upon the very intense BF_4^- absorption band at about 1 065 cm^{-1}. With some of the complex spectra it was possible, however, to identify the bands and determine the shifts. Those olefins having vinyl substitution exhibit, upon complexing, a somewhat greater shift of the CH_2 wag frequency ($\sim$ 45 cm^{-1}) than of the C=C twist frequency ($\sim$ 35 cm^{-1}). No splitting of these bands was observed in complexes which demonstrated splitting of the C=C stretch vibration band. With *cis*-2-butene and 2-methyl-2-butene, the out-of-plane hydrogen deformation does not constitute a C=C twisting mode, occurring at lower frequencies than does the C=C twist band in *trans*-2-butene and undergoing a somewhat greater shift to higher frequencies upon formation of the silver salt complex. With propylene, the C=C twist deformation frequency is shifted to a lesser extent than with the other monoalkyl olefins. Similarly, the CH_2 wag deformation is shifted somewhat less for propylene, 39 cm^{-1}, than for the other monoalkyl olefins, $\sim$ 45 cm^{-1}. This shift is also lower for vinylidene, e.g. 2-methylpropene or 2,4,4-trimethyl-1-pentene, than for vinyl substitution.

An interesting feature of the $AgBF_4$.2 1-pentene spectrum (Fig. 1) and of all the complex spectra is the very marked decrease in intensity of the bands at about 3 075 cm^{-1} and 2 995 cm^{-1} which are attributed to the asymmetric CH_2 stretching and CH stretching modes respectively. Although the band at 2 995 cm^{-1} (which appears as a shoulder in the olefin spectrum) was not detectable in the complex, a very small band was always observed at 3 075 cm^{-1}. The absence of any evidence of these bands having been shifted to lower frequencies and superimposed upon the other CH stretch absorption bands (requiring a shift of more than 80 cm^{-1} for $=CH_2$) supports the suggestion that for these vibrations an intensity change only is involved.

Nuclear Magnetic Resonance Spectra

A comparison of the proton resonance spectrum of the $AgBF_4$.2 olefinate with that of the parent olefin has established that, although, in general, the pattern is the same for both, there is an increase in the downfield chemical shift of the protons relative to tetramethylsilane when the olefin is complexed. The magnitude of the increase in chemical shift is dependent upon the nature and extent of substitution at the double bond and is quite similar to that previously reported (2, 8).

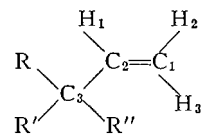
In Table II are reported the chemical shifts for the olefins and $AgBF_4$.2 olefinates from ethylene, through the various methyl-substituted ethylenes, to 2,3-dimethyl-2-butene (tetramethylethylene). With the exception of those for the *trans*-2-butene system, all spectra were obtained at room temperature; the lower stability of the $AgBF_4$.2 *trans*-2-butene complex (4) required that the spectrum be obtained at reduced temperature (−40 °C) in order that the maximum chemical shifts could be observed. Lowering the temperature did not affect, however, the shifts observed with the other olefins. The presence of a single pattern (even at −40 °C) when uncomplexed olefin is known to be present in a system, indicates a rapid exchange between complexed and uncomplexed species.

While the chemical shifts of the olefinic protons are essentially identical in ethylene and *cis*- and *trans*-2-butene, upon complexing the change in the shift is twice as great for the butenes (45 c.p.s.) as for ethylene (21 c.p.s.). While the change in chemical shift of the methyl protons in propene (17 c.p.s.) is essentially the same as for those in *cis*- and *trans*-2-butene and 2,3-dimethyl-2-butene and in the methyl group (R_3) at the mono-substituted carbon atom of 2-methyl-2-butene, it is greater for the methyl protons in 2-methyl-propene (25 c.p.s.) and in the methyl groups (R_1 and R_4) at the disubstituted carbon of 2-methyl-2-butene (25 c.p.s.).

Approximate chemical shift and coupling constant data for a number of 1-alkenes of configuration



and their $AgBF_4$ complexes are reported in Tables III and IV and the chemical shift changes obtained therefrom are found in Table V. The data were obtained by a first-order treatment of the spectra and in the case of the olefins agree very well with literature data (15, 16). Since the object of this investigation was to establish the general dependence of spectral changes when the complex is formed upon the alkyl substitutent at the double bond rather than to obtain highly accurate n.m.r. data for the complexes, the first-order treatment was considered to be satisfactory.

The effect of complex formation upon the chemical shifts is a downfield change of order $\Delta\nu_1 > \Delta\nu_2 > \Delta\nu_3$ (where ν is the chemical shift of the proton in c.p.s. from TMS). Although the magnitude of the change of chemical shift is not markedly dependent upon the alkyl substitutent, there appears to be some increase in $\Delta\nu_1$ when there is a single proton in the 3-position.

From Table III it is apparent that, in the uncomplexed olefin, H_2 is slightly more shielded than H_3 but that, in the complex, H_3 is more shielded. The change of chemical shift of H_2 relative to H_3 which tends to increase as the alkyl substitutent becomes bulkier near the double bond is given in column 6 of Table V and is illustrated for 3,3-dimethyl-1-butene in Fig. 4.

Complex formation appears to result in a small decrease in the magnitude of $J_{1,2} + J_{1,3}$. While the change in the coupling constant $J_{2,3}$ is as small as to approach the experimental error, there is a suggestion of an increase in its magnitude upon complexing of the olefin.

With many of the olefins, complex formation results in very little change in the coupling constant, $J_{1,4}$, between the protons on C_2 and C_3. There is, however, a noticeable decrease (except with vinylcyclohexane) when there are two alkyl substituents on C_3. As one of those substituents becomes bulkier, there is a greater decrease in $J_{1,4}$, e.g. from 0.9 c.p.s. for methyl to 1.5 c.p.s. for neopentyl.

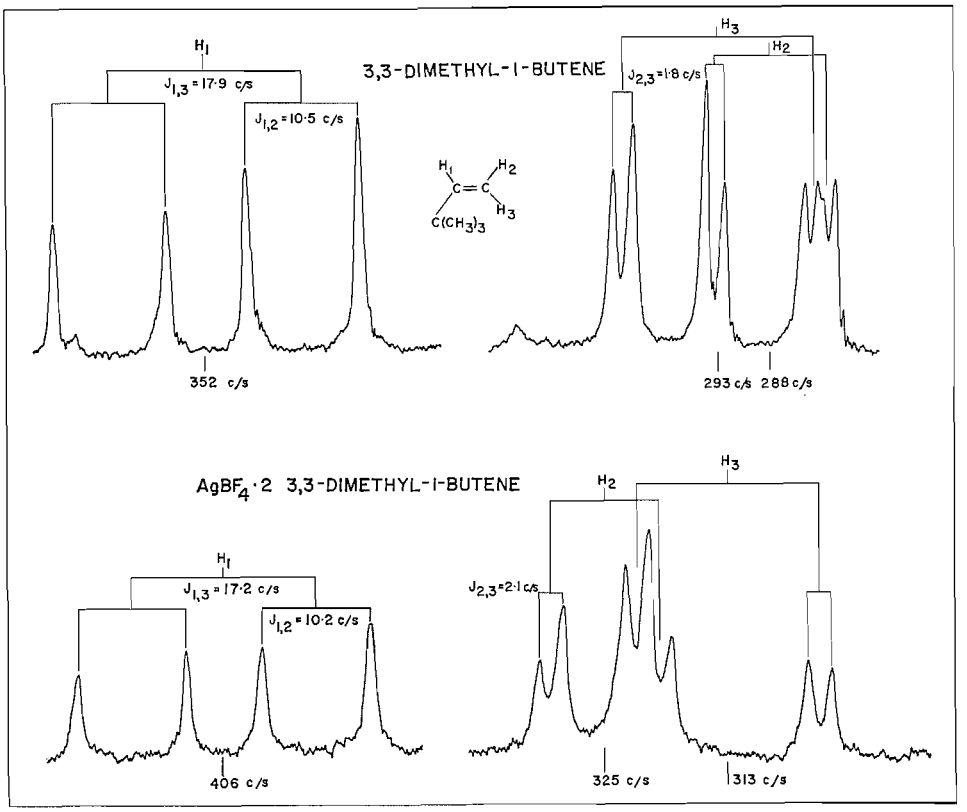

FIG. 4. Proton resonance spectra for the vinyl protons in 3,3-dimethyl-1-butene and $AgBF_4$.2 3,3-dimethyl-1-butene (10% in $CDCl_3$).

DISCUSSION

The splitting observed in the C=C stretch band for crystalline complexes of long chain 1-olefins which disappears upon melting or dissolving the complex is probably attributable to crystal lattice restrictions which require that the long alkyl chain assume a position resulting in interaction between the olefin molecules in the $AgBF_4$.2 olefinate. Such intermolecular interaction is known (17) to produce splitting of infrared bands, particularly those assigned to deformation modes in long chain paraffins and polymers. While it is tempting to interpret the splitting of the C=C stretch band as indicative of non-equivalent complexing of the two olefin molecules at the silver ion because of intermolecular interactions, this does not appear at present to be possible since one would expect to observe as well a splitting of the CH_2 wag and C=C twist deformation bands.

Similarly, the splitting observed in the C=C stretch band, as well as in some of the methyl deformation bands, for the complex of 3,3-dimethyl-1-butene in solution may arise from interaction between the olefin molecules introduced by the *t*-butyl group adjacent to the double bond. The observation (Table I) that removal of one of the methyl groups in the 3-position, as in 3-methyl-1-butene eliminates the splitting suggests that in this case there is a possibility of reduction of intermolecular interaction by rotation about the C_2C_3 bond.

This suggestion is further substantiated by the dependence of the change in the coupling

constant $J_{1,4}$, between the protons on C_2 and C_3, upon the substituents in the 3-position. The magnitude of $J_{1,4}$ in olefins has been related (16) to the population of the rotational conformers about C_2C_3, being greater when there is substitution at C_3 which tends to increase the population of the *trans* conformer, since $J_{1,4}$ *trans* is greater than $J_{1,4}$ *gauche*, while maintaining the staggered conformations. In general when there are two protons at C_3 and the alkyl substituent is linear, there appears to be no hindered rotation about C_2C_3 and $J_{1,4}$ has a value that is representative of one *trans* and two *gauche* conformers, i.e. 6–6.5 c.p.s. When, however, the alkyl group is branched near C_3 or if there is a single proton at C_3, there may be rotational hindrance, the population of *trans* conformer will be greater and $J_{1,4}$ will increase to about 7.5 c.p.s. if there are equivalent numbers of *trans* and *gauche* conformers and to about 11 c.p.s. if the *trans* conformer predominates.

If the observation that complexing of olefins having two protons at C_3 results in no significant change in $J_{1,4}$ can be interpreted to indicate that complex formation does not affect the rotation about C_2C_3 in those olefins, the decrease in $J_{1,4}$ upon complexing of olefins with only one proton at C_3 can then be interpreted to indicate that in the complex the proton is less frequently in the *trans* position. This situation could arise if, in order to reduce interaction between the two olefin molecules complexed at the silver ion, the favored rotational conformations have the proton closer to the silver ion (i.e. less often in the *trans* position) and the interfering alkyl groups directed away.

Such a change in populations of rotational conformers would also decrease the shielding at H_1 due to the contribution of the magnetic anisotropy in the bond C_3C_4 (18) and may explain the larger $\Delta\nu_1$ values observed when there is a single proton at C_3. When, however, there are no protons at C_3, the interaction cannot be eliminated by changing the rotation about C_2C_3 and the splittings in the spectrum of $AgBF_4$.2 3,3-dimethyl-1-butene result.

Since it is known that electron-withdrawing functional groups in a molecule markedly decrease the intensities of CH stretching bands (19) the observed very marked decrease in intensities of the  and $=C \rightarrow H$ stretch absorption bands when the olefin is complexed may be due to the decrease of pi electron density at the trigonal carbon atoms. There is also a possibility that the reduced intensities are indicative of smaller changes of dipole moment for these vibrations when the olefin is complexed.

The shifts observed in the out-of-plane hydrogen deformation frequencies upon complex formation are quite analogous to the frequency rise observed when the alkyl group is replaced by a more electropositive group (containing a metal atom), 20 cm^{-1} for the C=C twist and 50–65 cm^{-1} for the CH_2 wag deformation (20, 21) which has been explained in terms of electron inductive and mesomeric effects for the twist and wag respectively. While silver ion complexing is not equivalent to substitution of a metal atom for the α-carbon of an alkyl substituent, it does result in decrease of pi electron density at the trigonal carbon atoms and might be expected to produce shifts similar to those observed when the substituent metal atom can effect a similar decrease. A comparison of some of the infrared frequencies for trimethylvinylsilane and the $AgBF_4$ complex of the structurally similar olefin, 3,3-dimethyl-1-butene is given in Table V. It is observed in particular that the C=C stretch and CH_2 wag frequencies are very similar for these two compounds. The difference between the frequencies for the CH_2 wag in the silane and 3,3-dimethyl-1-butene has been attributed to decrease of pi electron density at the terminal carbon by d_π–P_π overlap with the silicon atom (21).

If an increase in the CH_2 wag frequency can be explained in terms of decreased electron

density at that carbon atom, the lesser shift observed upon complexing for vinylidene than for vinyl substitution would indicate a lesser decrease of electron density in the vinylidene compounds.

The small apparent decrease of $J_{1,2} + J_{1,3}$ upon complexing may result from a reduced contribution of the pi electrons to the coupling constants. Karplus (22) has calculated the pi electron contribution to approximate +1.5 c.p.s. for *cis* and *trans* coupling in olefins.

Since it is known that the magnetic shielding of protons at trigonal carbon atoms in aromatic and olefinic compounds increases with increasing pi electron density at the carbon (23–25), it is to be expected that decrease in pi density by overlap of the pi orbital with an atomic orbital of the silver ion might well result in a proton deshielding. It has been suggested (26) that if there is a paramagnetic contribution by the pi electrons to the proton shielding, pi bonding to a metal atom could result in increased shielding of olefinic protons. To date, however, no such increased shielding has been observed upon formation of complexes resulting in only slight perturbation of the olefin molecule (2, 8). Schug and Martin (8) have suggested that the proton deshielding observed upon complexing of unsaturated compounds with aqueous silver ion might be largely accounted for by polarization effects. This argument is not too convincing, however, since the observed deshielding changes much more markedly with increasing distance from the silver ion than would be calculated. While there may be then shielding effects attributable to factors other than change of pi electron density at the trigonal carbons, the latter effect may, in these complexes, predominate and the observed shifts will be discussed in the light of this possibility.

TABLE VI

Comparison of infrared data for trimethylvinylsilane with those for $AgBF_4$.2 3,3-dimethyl-1-butene

	Infrared (cm^{-1})		
	C=C	CH_2 wag	C=C twist
$(CH_3)_3CCH{=}CH_2$	1 636	908	995
$AgBF_4.2(CH_3)_3CCH{=}CH_2$	1 570 1 590	953	1 030
$(CH_3)_3SiCH{=}CH_2$	1 590	949	1 005

Employing the premise that the extent of perturbation of the olefin molecule when complexed is dependent upon the pi basicity of the olefin (as suggested by the infrared shifts), one might expect a continuously increasing pi electron withdrawal from the double bond with increasing methyl substitution resulting in increasingly greater olefinic proton deshielding. On this basis the observation that the methyl protons of 2,3-dimethyl-2-butene are not more deshielded than are those of the 2-butenes is rather surprising. If, however, the model of the silver ion – olefin complex postulated by Dewar (9) applies, one must consider not only the effect on proton shielding of electron withdrawal by overlap of the bonding pi orbital of the olefin with the vacant s or sp hybrid orbital of the ion (σ-bonding) but also of the electron donation effected by the overlap of an occupied d-orbital of the ion with the antibonding pi orbital (π-bonding). The result of stronger complexing will be then both more pi electron withdrawal from and more d-electron donation to the olefin and the change of proton shielding may not be markedly dependent upon the pi basicity of the olefin. The observed net deshielding, however, establishes that the pi electron density decrease at the trigonal carbons is not fully compensated by d-electron donation (i.e. the σ-bond is stronger than the π-bond).

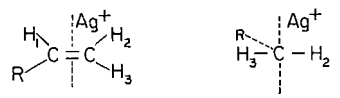
The greater deshielding of the methyl protons in 2-methylpropene and of those at the disubstituted carbon of 2-methyl-2-butene may suggest non-equivalent d-orbital overlapping, i.e. non-equivalent reshielding by d-electrons, at the two trigonal carbon atoms, that at the disubstituted carbon being less. A similar suggestion derives from a consideration of the greater deshielding of the proton at the substituted than at the terminal trigonal carbon atom of monoalkyl substituted 1-alkenes (Table V) which in turn suggests that the silver ion is not symmetrically positioned with respect to the trigonal carbon atoms but is closer to the terminal carbon. Such a positioning is consistent with that observed for the palladium atom relative to the double bond of styrene in the palladium chloride – styrene dimer (13) and may also follow from the suggestion that Markownikoff double-bond additions (which perhaps involve π-complex intermediates (27)) indicate a higher electron density at the less-highly substituted carbon atom in asymmetrically substituted olefins.



Electronic effect Steric effect

FIG. 5. Schematic representation of the effect of the alkyl substituent upon positioning of the silver ion at the double bond of a monoalkyl substituted 1-alkene.

Bothner-By and Naar-Colin have suggested (15) that the greater shielding of H_2 than of H_3 in a 1-alkene might be attributable to a field effect of the dipole which is directed somewhat toward H_2. A similar approach to explain the greater shielding of H_3 in the complex would require a field or electronic effect directed more toward H_3 than H_2. It appears reasonable to suggest that, if, as a result of a steric effect introduced by the alkyl substituent, the silver ion is somewhat displaced from the plane of the pi orbital away from the substituent, the direction of overlap of the occupied d-orbital with the antibonding pi orbital will be at an angle to that plane and any field effect due to the d-electrons will be directed more toward H_3 than H_2 resulting in a greater reshielding of H_3. With increasing steric effect of the alkyl substituent the silver ion would be located further out of the plane of the pi orbital and a greater difference in the reshielding of H_3 relative to H_2 would be expected (as observed in Table V, column 6). Increasing steric effect seemingly is introduced by increasing the extent of substitution at the tetrahedral carbon atom, C_3, and by branching of the substituent groups.

The positioning of the silver ion at the olefinic double bond might then be considered to be determined by a combination of an electronic effect and a steric effect of the alkyl substituent which position it with respect to the trigonal carbon atoms and the plane of the pi orbital respectively. This is schematically illustrated in Fig. 5.

The observation that in general the most stable complexes exhibit a 1:2 silver ion : olefin stoichiometry suggests that in order to achieve maximum orbital overlap, complexing probably involves sp digonal hybrid orbitals, e.g. sp_x, and the two associated d-orbitals, d_{xy} and d_{xz}, resulting in an orientation of the olefin molecules with their double bonds in perpendicular planes with the silver ion between them.

ACKNOWLEDGMENT

The authors wish to thank J. C. Evans (The Dow Chemical Company, Midland, Michigan) for providing Raman data and E. B. Baker and J. P. Heeschen (The Dow Chemical Company, Midland, Michigan) for helpful discussion relating to the n.m.r. study.

CHLORIDE AND SULFATE ION ASSOCIATION WITH SOME LANTHANIDE AND ACTINIDE IONS

P. G. MANNING

A stepwise stability constant (b) for a metal (M) – ligand (L) ion association reaction in solution is defined as

$$[1] \qquad b_n = [ML_n][ML_{n-1}]/[L].$$

Bjerrum (1) proposed that the ratios of stepwise stability constants for two stages of ion association may be given by the equation

$$[2] \qquad P = b_1{:}b_2 = S \times T,$$

where S is a statistical factor readily calculable from a knowledge of the number of cation bonding sites and ligand groups, and T is a measure of the work done in bringing a second ligand from infinity to its equilibrium position in the ML_2 species against the repulsive force exerted by the already bound ligand. Thus, if the cation has N available sites and the anion is monodentate then $S = 2 \times N(N - 1)$. The factor 2 arises because the probability of a ligand's leaving the ML_2 species is twice that of leaving the ML. The T factor is electrostatic in nature and is independent of the ability of the metal ion to bind ligands (1). For the chloride complexes of Sn^{2+} and Hg^{2+} (cations of similar size to rare earths) $T = 2.0$ (1), and for the Zn–mandelate system (2) $T = 1.5$.

Bjerrum (3) has shown that

$$[3] \qquad \log T = \frac{1}{2.303} \times \frac{e^2}{Dr} \times \frac{1}{kK}$$

where e is the electronic charge, D the dielectric constant, r the separation of the charged ligands in the ML_2 species, k the Boltzmann constant, and K the absolute temperature. In an earlier work (4) it was shown that acetate hydrogen-bonded to the protons of the cation hydration sheath and that $T = 1.1$. It was also shown that if acetate ion binds to a proton of a given water molecule then the second proton of that same water becomes relatively unattractive to a second acetate. The ligand–ligand separation is greater in an ion pair than in a complex, and using simple Coulombic theory and $T = 1.1$ for an ion pair, then $T \simeq 1.4$ for rare-earth complexing with a singly charged ligand. Moreover, this T value ($= 1.4$) is likely to be a lower limit because $D \sim 78$ for an ion pair and $D \ll 78$ for a complex (5). A reasonable T value for rare-earth–chloride complexing would seem to be 1.5.

Table I presents P values determined experimentally for rare-earth chlorides, and Table II presents calculated S, T, and P values for 6- and 8-hydrated cations and for chloride complexing and ion pairing. The ion pair calculations were performed assuming that chloride binds at the octahedral (oct.) edge of a 6-hydrated cation (Brady's model, ref. 9) and at the corresponding dodecahedral (dodec.) edge of an 8-hydrated cation. Should chloride ion hydrogen-bond to the protons of the cation primary hydration

NUCLEOPHILIC CATALYSIS IN THE HYDROLYSIS OF DICHROMATE[1]

BERTA PERLMUTTER-HAYMAN AND MICHAEL A. WOLFF

The hydrolysis of the dichromate ion, viz.

[1] $$Cr_2O_7^{2-} + H_2O \rightarrow 2HCrO_4^-,$$

has been found to be catalyzed by bases (1, 2, 3), the results suggesting a correlation between the base strength and the catalytic constant. The special case where the catalyzing base is CrO_4^{2-} has recently been investigated (4) by measuring the influence of the ratio $[CrO_4^{2-}]/[Cr_2O_7^{2-}]$ on the rate of exchange of ^{17}O between the bridging and terminal positions in $Cr_2O_7^{2-}$. The catalytic constant was found to be much higher than that of the strongest base, OH^-. It was concluded (4) that not only basic strength but other properties characteristic of good nucleophilic reagents play a role in the catalysis. Following Edwards (5), the authors used polarizability as the additional criterion for nucleophilic character, and obtained a reasonable correlation between the catalytic constants, basic strengths, and polarizabilities of OH^-, CO_3^{2-}, NH_3, and CrO_4^{2-}. Some of the catalytic constants employed are only approximate (1); in particular, those of negatively charged ions contain a certain arbitrariness (2), because they refer to different ionic environments. However, this does not seriously affect the correlation, and in any case CrO_4^{2-} has an abnormally high rate constant in comparison with its basic strength. This fact becomes even more striking when we consider the charge-type of the reaction.

Now, if this high reactivity of CrO_4^{2-} is indeed due to its nucleophilic character (as expressed by its high polarizability), and not to its special role in the reaction scheme, other typical nucleophiles should also accelerate the hydrolysis. In this note we wish to illustrate this point by two examples: thiourea and urea. Both these substances are very weak bases (the pK of the conjugate acid being 0.96 for thiourea and 0.18 for urea (6)); thiourea, however, is a good nucleophile in many substitution reactions (5).

NUCLEOPHILIC CATALYSIS IN THE HYDROLYSIS OF DICHROMATE[1]

BERTA PERLMUTTER-HAYMAN AND MICHAEL A. WOLFF

The hydrolysis of the dichromate ion, viz.

[1] $$Cr_2O_7^{2-} + H_2O \rightarrow 2HCrO_4^-,$$

has been found to be catalyzed by bases (1, 2, 3), the results suggesting a correlation between the base strength and the catalytic constant. The special case where the catalyzing base is CrO_4^{2-} has recently been investigated (4) by measuring the influence of the ratio $[CrO_4^{2-}]/[Cr_2O_7^{2-}]$ on the rate of exchange of ^{17}O between the bridging and terminal positions in $Cr_2O_7^{2-}$. The catalytic constant was found to be much higher than that of the strongest base, OH^-. It was concluded (4) that not only basic strength but other properties characteristic of good nucleophilic reagents play a role in the catalysis. Following Edwards (5), the authors used polarizability as the additional criterion for nucleophilic character, and obtained a reasonable correlation between the catalytic constants, basic strengths, and polarizabilities of OH^-, CO_3^{2-}, NH_3, and CrO_4^{2-}. Some of the catalytic constants employed are only approximate (1); in particular, those of negatively charged ions contain a certain arbitrariness (2), because they refer to different ionic environments. However, this does not seriously affect the correlation, and in any case CrO_4^{2-} has an abnormally high rate constant in comparison with its basic strength. This fact becomes even more striking when we consider the charge-type of the reaction.

Now, if this high reactivity of CrO_4^{2-} is indeed due to its nucleophilic character (as expressed by its high polarizability), and not to its special role in the reaction scheme, other typical nucleophiles should also accelerate the hydrolysis. In this note we wish to illustrate this point by two examples: thiourea and urea. Both these substances are very weak bases (the pK of the conjugate acid being 0.96 for thiourea and 0.18 for urea (6)); thiourea, however, is a good nucleophile in many substitution reactions (5).

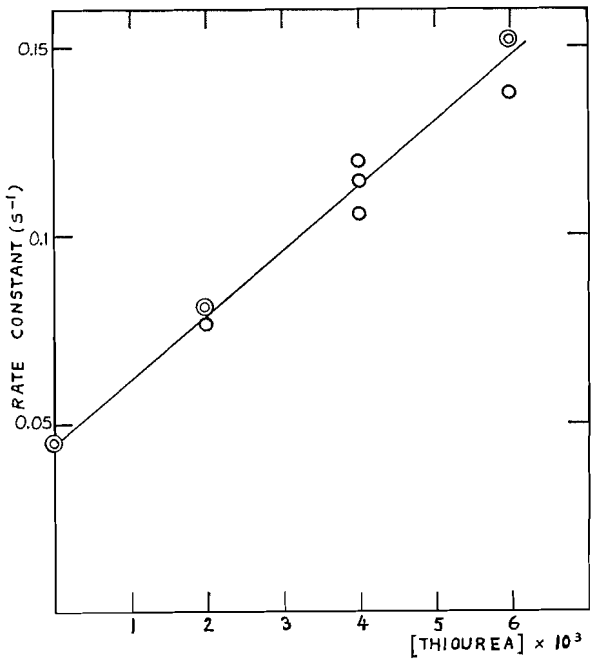

FIG. 1. The pseudo-first-order rate-constant as a function of thiourea concentration. (Coinciding results are designated by double circles.)

Our reaction mixtures contained 0.016 M sodium acetate and a trace of acetic acid in order to ensure a pH of ~ 7, where the contributions of both H^+ and OH^- to the observed rate are negligible (2). The measuring technique was the same as that described previously (2). Thiourea was employed in concentrations between (2 to 6) $\times 10^{-3}$ M. Figure 1 shows the pseudo-first-order rate-constant as a function of thiourea concentration. From the slope we calculate

$$k_{\text{thiourea}} = 17.2 \text{ mole}^{-1} \text{ l s}^{-1}.$$

The intercept represents a residual rate which is due to the solvent and the acetate (2).

On the other hand urea, up to a concentration of ~ 1 M, causes only a slight increase above this residual rate, which leads to $k_{\text{urea}} \sim 0.012$ mole^{-1} l s^{-1}. The catalytic effect of thiourea is therefore due almost entirely to nucleophilic properties other than basic strength. Further experiments are in progress, aiming at the determination of the factors governing the catalytic activity in this reaction (3).

We should like to thank S. de Groot for technical assistance.

THE YIELD OF SINGLET OXYGEN IN THE REACTION OF CHLORINE WITH HYDROGEN PEROXIDE

R. J. Browne and E. A. Ogryzlo

In a recent communication (1) it was shown that all the chemiluminescence from the reaction of chlorine with aqueous hydrogen peroxide could be attributed to the two singlet states of oxygen $a^1\Delta_g$ and $b^1\Sigma_g^+$. Emission from these two states has also been studied in the products of an electrical discharge (2, 3). In these gas phase studies it was shown that the visible emission at 6 340 Å arises from a simultaneous electronic transition in two colliding O_2 ($^1\Delta_g$) molecules and that the emission intensity in this band is proportional to the square of the O_2 ($^1\Delta_g$) concentration.

[1] $$\text{i.e. } I_{6340} = k' [O_2 (^1\Delta_g)]^2$$

Since the band at 12 700 Å is due to the emission from one O_2 ($^1\Delta_g$) molecule we can write

[2] $$I_{12700} = k''[O_2 (^1\Delta_g)]$$

the ratio of the emission intensities in these two bands is given by

[3] $$R = \frac{I_{6340}}{I_{12700}} = k[O_2 (^1\Delta_g)].$$

When O_2 ($^1\Delta_g$) is obtained from an electrical discharge both R and the absolute concentration of O_2 ($^1\Delta_g$) can be measured (see ref. 2). Hence the proportionality constant k in eq. [3] can be evaluated (for a particular detecting system). With this value of k it is possible to estimate the O_2 ($^1\Delta_g$) concentration in any system simply by measuring the ratio R for that system. In contrast to other methods of determining chemiluminescence yields, geometric factors and collisional quenching rates are of no consequence when eq. [3] is used.

Using an $f/4.5$ Hilger-Watts glass-prism spectrometer with a slit of 500 microns combined with an R.C.A. 7102 photomultiplier the following results were obtained when O_2 ($^1\Delta_g$) was measured in the products of an electrical discharge:

$$[O_2 (^1\Delta_g)] = 1.5 \times 10^{-5} \text{ mole/l}; R = 36; k = 2.4 \times 10^6 \text{ l/mole}.$$

When the emission from the chlorine – hydrogen peroxide reaction was observed with the same optical system, the maximum ratio R measured was 1.8×10^3. From eq. [3] it follows that the concentration of O_2 ($^1\Delta_g$) is 7.5×10^{-4} mole/l. If we assume the bubble temperature is 300 °K this corresponds to a partial pressure of 14 mm Hg. Since the total oxygen pressure in the bubbles is about 750 mm Hg, this corresponds to a minimum yield of 2% O_2 ($^1\Delta_g$) in the reaction.

There are a number of reasons for believing that the yield of O_2 ($^1\Delta_g$) is actually larger than this. Firstly, the temperature of the gas in the bubbles is probably somewhat above room temperature since the reaction is about 62 kcal exothermic. We have not found it possible to estimate the bubble temperature directly; however, the "vibrational temperature" of the emitting gas can be estimated from the relative intensity of the emission from vibrationally excited states. From the intensity of the O_2 ($^1\Delta_g$, $v = 1$ to $^3\Sigma g^-$, $v = 0$) transition at 10 670 Å we estimate a vibrational temperature somewhat less than 600 °K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It is quite likely that the true temperature of the gas is less than this so that the yield reported is low by a factor of two at most.

Secondly, insofar as the reaction is not infinitely fast, dilution of the O_2 ($^1\Delta_g$) by Cl_2 and by H_2O vapor will give low values for the yield. We have attempted to minimize these effects by working with a cooled and very basic solution where the reaction is rapid, the vapor pressure of water is low, and the bubble temperature is nearer to 25 °C.

The question of the yield of O_2 ($^1\Sigma g^+$) will prove much more difficult to answer, because not only is it quenched on almost every collision by water molecules, but it is also rapidly formed from the reaction of two O_2 ($^1\Delta_g$) molecules (4). We have studied the reaction in nonaqueous solvents, but even less emission from O_2 ($^1\Sigma g^+$) was observed in these systems.

NOTE ADDED IN PROOF: Some recent work by R. M. Badger, A. C. Wright, and R. F. Whitlock (to be published) indicates that at a pressure of 1 atm only 1/5 of the 12 700 Å band intensity is due to the spontaneous emission process (the remaining portion being due to a pressure-induced transition). This means that the ratio R for the aqueous reaction is actually 5 times as great and therefore the yield of O_2 ($^1\Delta_g$) is at least 10% in this reaction.

$J_{^{13}C-H}$ FOR SUBSTITUTED ALDEHYDES

R. M. HAMMAKER

Malinowski *et al.* (1) have proposed an empirical equation predicting $J_{^{13}C-H}$ for a substituted aldehyde XCHO from $J_{^{13}C-H}$ for CH_4 and CH_3X. The valence bond approach of Juan and Gutowsky (2) for an sp^2 carbon atom yields the following theoretical equation for $J_{^{13}C-H}$ for a substituted aldehyde:

$$[1] \qquad J_{^{13}C-H}(XCHO) = J_{^{13}C-H}(HCHO) + 4/3[J_{^{13}C-H}(CH_3X) - J_{^{13}C-H}(CH_4)].$$

Values of $J_{^{13}C-H}(XCHO)$ calculated from eq. [1] using the $J_{^{13}C-H}(CH_3X)$ data (3–10) listed in Table I deviate significantly from the experimental values listed in Table I. Plots of Δ, defined as observed $J_{^{13}C-H}(XCHO)$ less the value calculated from eq. [1], versus the observed $J_{^{13}C-H}$ value are linear. Least squares analysis for all the data in Table I except X = o-C_6H_4OH and OH gives the result:

$$[2] \qquad \Delta = 0.658\, J_{^{13}C-H}(XCHO); \text{ obs. } -113.3.$$

It is quite likely that the true temperature of the gas is less than this so that the yield reported is low by a factor of two at most.

Secondly, insofar as the reaction is not infinitely fast, dilution of the O_2 ($^1\Delta_g$) by Cl_2 and by H_2O vapor will give low values for the yield. We have attempted to minimize these effects by working with a cooled and very basic solution where the reaction is rapid, the vapor pressure of water is low, and the bubble temperature is nearer to 25 °C.

The question of the yield of O_2 ($^1\Sigma g^+$) will prove much more difficult to answer, because not only is it quenched on almost every collision by water molecules, but it is also rapidly formed from the reaction of two O_2 ($^1\Delta_g$) molecules (4). $J_{^{13}C-H}$ FOR SUBSTITUTED ALDEHYDES

R. M. HAMMAKER

Malinowski *et al.* (1) have proposed an empirical equation predicting $J_{^{13}C-H}$ for a substituted aldehyde XCHO from $J_{^{13}C-H}$ for CH_4 and CH_3X. The valence bond approach of Juan and Gutowsky (2) for an sp^2 carbon atom yields the following theoretical equation for $J_{^{13}C-H}$ for a substituted aldehyde:

$$[1] \qquad J_{^{13}C-H}(XCHO) = J_{^{13}C-H}(HCHO) + 4/3[J_{^{13}C-H}(CH_3X) - J_{^{13}C-H}(CH_4)].$$

Values of $J_{^{13}C-H}(XCHO)$ calculated from eq. [1] using the $J_{^{13}C-H}(CH_3X)$ data (3–10) listed in Table I deviate significantly from the experimental values listed in Table I. Plots of Δ, defined as observed $J_{^{13}C-H}(XCHO)$ less the value calculated from eq. [1], versus the observed $J_{^{13}C-H}$ value are linear. Least squares analysis for all the data in Table I except X = o-C_6H_4OH and OH gives the result:

$$[2] \qquad \Delta = 0.658\, J_{^{13}C-H}(XCHO);\ \text{obs.} -113.3.$$

TABLE I

Calculated and observed ^{13}C—H coupling constants of substituted aldehydes (XCHO)

	$J_{^{13}C-H}$, c.p.s.			
	Experimental		Calcd. from eqs.	
Substituent (X)	CH_3X	XCHO	[1] and [2]	[4]
—H	125 (3)	172 (6)	172	172.0
—$C(CH_3)_3$	124 (3)	168.6	168.3	168.1
—CH_2CH_3	124 (4)	170.6	169.7	168.1
—CH_3	124.9 (7)	172.4	172.0	171.6
—C_6H_5	126 (3)	173.7	174.3	175.8
—o-C_6H_4OH	124 (5)	177 (8)	173.9	168.1
—$N(CH_3)_2$	131 (3)	191.2	192.5	195.2
—O^-	130.8 (9)	194.8 (9)	194.6	194.4
—CCl_3	134 (3)	207.2	207.0	206.8
—OH	141.5 (9)	222 (8)	225.5	235.8
—OCH_3	139.6 (10)	226.2	227.0	228.5
—F	149.1 (10)	267 (8)	266.5	265.2

NOTE: Numbers in parentheses are references; data without such numbers are from ref. 1.

Addition of Δ calculated from eq. [2] to $J_{^{13}C-H}$(XCHO) calculated from eq. [1] yields $J_{^{13}C-H}$(XCHO) values in good agreement with observed values.

A plot of Δ versus $J_{^{13}C-H}$(XCHO) calculated from eq. [1] is also linear and least squares analysis for all data in Table I except X = o-C_6H_5OH and OH gives:

$$\Delta = 1.902\, J_{^{13}C-H}(\mathrm{XCHO}); \text{ calcd. } -327.7. \quad [3]$$

The addition of eqs. [1] and [3] and use of observed $J_{^{13}C-H}(CH_4)$ and $J_{^{13}C-H}$(HCHO) from Table I give the following Malinowski-type equation*

$$J_{^{13}C-H}(\mathrm{XCHO}) = 10.7 + 3.87\,[J_{^{13}C-H}(CH_3X) - 2/3\, J_{^{13}C-H}(CH_4)]. \quad [4]$$

This equation may also be obtained by least squares analysis of all data in Table I except X = o-C_6H_4OH and OH. The constants in eq. [4] are different from those in eq. [2] of ref. 1 because of the use of different data in the least squares analysis.

Table I lists $J_{^{13}C-H}$(XCHO) values calculated from the combination of eqs. [1] and [2] and from eq. [4] where the standard errors of estimate are 1.5 c.p.s. and 5.3 c.p.s., respectively. The fit of eq. [4] to the data in Table I is a mild improvement over the fit in ref. 1 for the nine data common to both. The calculation using the combination of eqs. [1] and [2] gives better overall fit as anticipated; however, this approach is not useful for predicting a value of $J_{^{13}C-H}$(XCHO) which has not been measured. In cases where $J_{^{13}C-H}$(XCHO) has been measured (1, 8, 11) but $J_{^{13}C-H}(CH_3X)$ is not known, the latter may be predicted from the combination of eqs. [1] and [2]. $J_{^{13}C-H}$ values for seven methane derivatives predicted in this way are listed in Table II.

An alternate way of writing eq. [4] is

$$J_{^{13}C-H}(\mathrm{XCHO}) = J_{^{13}C-H}(\mathrm{HCHO}) + 4/3\,[(2.902\, J_{^{13}C-H}(CH_3X) - 238.1) - J_{^{13}C-H}(CH_4)], \quad [5]$$

which is eq. [1] with $J_{^{13}C-H}(CH_3X)$ replaced by (2.902 $J_{^{13}C-H}(CH_3X)$ − 238.1). Thus, for eq. [1] to give a correct prediction, the term in $J_{^{13}C-H}(CH_3X)$ must be increased above

The quantity in parentheses in eq. [4] is φ_X in eq. [2] of ref. 1.

—$CHCl_2$	196.5 (*b*)	131.4
—OCH_2CH_3	225.6	138.9

NOTE: All data from ref. 1 except as noted: (*a*) ref. 8; (*b*) ref. 11.

the observed $J_{^{13}C-H}(CH_3X)$ and the required increase is larger the greater the electronegativity of X. The Δ values from eq. [2] whose addition to eq. [1] is required for correct prediction increase linearly (within 0.1 electronegativity unit or better) with the electronegativity of the first atom of X (12) and with the group electronegativity of X (13).

The cause of this required correction to eq. [1], which appears to vary linearly with substituent electronegativity, remains uncertain. Eq. [1] assumes no π electron contribution to $J_{^{13}C-H}$. Juan and Gutowsky interpreted the fact that their equation for ethylene derivatives gave $J_{^{13}C-H}$ values consistently higher than observed values as a consequence of a negative π electron contribution to $J_{^{13}C-H}$ of 5–10 c.p.s. However, this effect showed no dependence on substituent. It seems reasonable that a π electron correction must be applied to eq. [1]; however, such a correction seems unlikely to show the observed dependence on substituent electronegativity. The sources in addition to π electron contributions to $J_{^{13}C-H}$ that determine the parameters for eq. [4] and its equivalent expressions may include significant spin-dipole and (or) electron orbital contributions to $J_{^{13}C-H}$ as suggested by Karabatsos and Orzech (14), who maintain that the Fermi contact term alone is not adequate to account for $J_{^{13}C-H}$ values for substituted aldehydes and that s characters calculated from $J_{^{13}C-H}$ are unreliable and misleading. On the other hand, observed $J_{^{13}C-H}$ values for substituted aldehydes appear (15) to vary linearly with the group orbital electronegativities (13), which themselves are linearly related to the amount of s character in the hybrid orbitals.

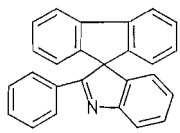
ALIPHATIC CHEMISTRY OF FLUORENE
PART X. 2-PHENYLINDOLENINE-3-SPIRO-9′-FLUORENE

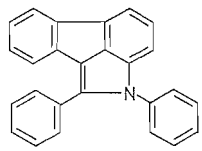
P. M. G. Bavin

Wislicenus and Fehrle in 1915 (1) reported that 9-benzoylfluorene reacted rapidly with phenylhydrazine in hot acetic acid to give a substance $C_{26}H_{17}N$. The absence of an α-methylene group precludes formation of an indole, and it was of interest to establish the structure of this product. In addition to the structures I and II proposed earlier (1), we have considered III and eliminated it by synthesis. Physical methods have established that the unknown is the spiroindolenine (I).

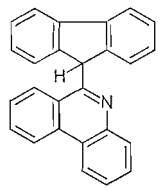
The empirical formula $C_{26}H_{17}N$ has been confirmed. The ultraviolet spectrum is typical of 9-substituted fluorenes (e.g. 9,9-dimethylfluorene (2)), although less well resolved, and eliminates both II (9-benzylidenefluorene) and III (phenanthridine). The mass



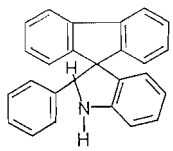
I



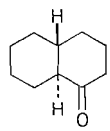
II



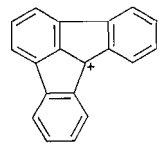
III



IV



V



VI

spectrum confirms the molecular weight (343). Chemical confirmation of structure I has been difficult to obtain. The indolenine is resistant to alkalis, to oxidizing agents, and to dimethyl sulfate in boiling nitrobenzene (3, 4). Its stability towards strong acids is noteworthy and in marked contrast to the lability of 3,3-dimethylindolenines (5). The presence of the 2,3,3-trisubstituted indolenine system prevents acid-catalyzed rearrangement. However, hydrogenation gave the expected indoline (IV, cf. ref. 6) characterized by its infrared (very sharp N—H stretching band at 3 400 cm^{-1}), ultraviolet (typical fluorene spectrum), and mass spectra (parent ion at m/e 345).

Indolenines have only rarely been reported as the major products of the reaction of phenylhydrazine with ketones (methyl isopropyl ketone (7, 8); iosbutyraldehyde (9, 10); the decalone (V) (11); and methylated cyclohexanones (12)). Their formation as by-products of the Fischer indole synthesis is known to be favored by use of acetic acid as solvent (13). 9-Acetylfluorene forms a rather unstable phenylhydrazone and both 9-acetyl and 9-benzoylfluorene form 2,4-dinitrophenylhydrazones. Benzhydryl phenyl ketone was recovered unchanged after it was boiled with phenylhydrazine in acetic acid. This ketone does not enolize (13) and it may be the facile enolization (14, 15) of 9-benzoylfluorene which is responsible for the rapid formation of I (cf. the mechanism of the Fischer indole synthesis, generally held to involve initial tautomerism of the hydrazone (16)).

For comparison purposes 6-(9-fluorenyl)-phenanthridine (III) was synthesized by a general method (17). The ultraviolet spectrum closely resembled that of phenenthridine (18), confirming its structure.

EXPERIMENTAL

Melting points were recorded using a gas-heated block and thermometer calibrated for stem exposure. Microanalyses were carried out by Mr. M. Graham.

2-Phenylindolenine-3-spiro-9'-fluorene (I)

The crude product (1) was recrystallized several times from chloroform–cyclohexane to give pale yellow prisms, obtained colorless only after the impurities were oxidized with permanganate in acetone. As a result of solvation, the melting point was variable, in the range 219–229°. (Lit. m.p. 217–218° (1).) Analytical samples, prepared by drying at 120° and 0.01 mm, had m.p. 229–230°.

Found: C, 91.08; H, 5.02; N, 4.28; $C_{26}H_{17}N$ requires C, 90.93; H, 4.99; N, 4.08.

The ultraviolet spectrum in 95% ethanol showed the following peaks (λ (mμ)/log ϵ): 306/3.98; 295/3.72; 282/3.94; 267/4.19.

The indolenine was recovered unchanged from the following reaction conditions: alcohol – sulfuric acid (50–98%), alcohol – hydrochloric acid; potassium hydroxide and boiling ethanol or diethylene glycol; sodium borohydride (large excess) in methanol; dimethyl sulfate in boiling nitrobenzene; potassium permanganate in boiling aqueous acetone; sodium dichromate or chromium trioxide in hot acetic acid.

2-Phenylindoline-3-spiro-9'-fluorene, IV

A solution of the indolenine (1.4 g) in ethyl acetate (50 ml) containing 10% palladium-on-charcoal (0.1 g) was shaken in a hydrogen atmosphere. The uptake of hydrogen (115 ml at N.T.P., theory 91.5 ml) was complete in 1 h. The product separated from cyclohexane as colorless needles, m.p. 199°–200°, depressed to 155° by I.

Found: C, 90.23; H, 5.43; N, 3.86. $C_{26}H_{19}N$ requires C, 90.40; H, 5.54; N, 4.06.

The infrared spectrum of a Nujol mull showed a very sharp band at 3 400 cm^{-1}, attributed to the NH stretching mode.

9-Acetylfluorene Phenylhydrazone

This was prepared in hot acetic acid, crystallized from methanol as colorless slender needles, m.p. 140–142° with decomposition.

Found: C, 84.27; H, 6.19; N, 9.13; $C_{21}H_{18}N$ requires C, 84.53; H, 6.08; N, 9.39.

9-Acetylfluorene 2,4-Dinitrophenylhydrazone

This crystallized from heptane as orange needles, m.p. 202–203°.

Found C, 65.36; 65.47; H, 4.41, 4.31; N, 14.61. $C_{21}H_{16}N_4O_4$ requires C, 64.94; H, 4.15; N, 14.43.

9-Benzoylfluorene 2,4-Dinitrophenylhydrazone

This crystallized from benzene as orange blades, m.p. 207–209° with decomposition.

Found: C, 69.32; H, 3.98; N, 12.35. $C_{26}H_{18}N_4O_4$ requires C, 69.32; H, 4.03; N, 12.44.

Benzhydryl phenyl ketone was recovered unchanged after it was boiled under reflux for up to 12 h with an excess of phenylhydrazine in acetic acid.

6-(9-Fluorenyl)-phenanthridine (III)

9-(9-Fluorenyl)-9-fluorenol (0.8 g) was converted to the phenanthridine in the usual way (17). The basic product separated from heptane as small colorless prisms (0.07 g), m.p. 204–205°.

Found: N, 3.87. $C_{26}H_{17}N$ requires N, 4.09.

A solution in sulfuric acid was colorless, the starting alcohol giving an orange solution. The ultraviolet spectrum of a hexane solution showed the following peaks (μ/log ϵ_{max}): 344.7/3.49; 338.0/2.98; 322.7/3.13; 314.3/3.42; 301.2/4.05; 290/4.03; 279.4;* 273.3;* 267;* 261;* 255/4.70; 250.* (* Denotes shoulder.)

Mass Spectra

The main features of the spectra are as follows (*m/e* values).

For 2-phenylindolenine-3-spiro-9-fluorene, the parent ion is at 343, doubly charged ion at 171.5; the small number of fragmentations indicates a relatively stable molecule. The main fragmentations are 343 → 266, loss of 77, i.e. C_6H_5; 343 → 239, loss of 104, i.e. $C_6H_5 \cdot CH{=}\overset{\oplus}{N}$ or equivalent, easily the most important fragmentation.

For *2-phenylindoline-3-spiro-9'-fluorene*, the parent ion is at 345, doubly charged ion at 172.5; the larger number of ions indicates a less stable molecule. The three main fragmentations, of comparable importance, are 345 → 268, shown to occur directly by the presence of a metastable ion at 208.2 i.e. loss of 77, C_6H_5; 345 → 267, loss of 78, i.e. C_6H_6 (indications of a second metastable ion at 206.6 masked by 208.2 suggest

that 345 → 267 also occur directly); 345 → 239, loss of 106, i.e. $C_6H_5CH_2$—$\overset{\oplus}{N}H$ or equivalent; of lesser importance are ions at 329, loss of 16, i.e. NH_2 or equivalent, and 213, loss of 132.

The ion at 239 is common to both spectra. It probably represents a stable ion, for which structure VI is not unreasonable (cf. fluoradene).

1,2-*O*-ISOPROPYLIDENE-α-D-GLUCOFURANOSE-5-*d* AND -5,6,6′-d_3[1]

W. Mackie[2] and A. S. Perlin

D-Glucose-5-*d* (I), required in a recent study on oxidative glycol-scission, has been prepared in low isotope yield via a series of reactions that involve initially the reduction of D-*xylo*-5-hexulosonic acid with sodium borodeuteride (1). Other means for preparing this labelled sugar have also been examined and one, which is more satisfactory for the purpose and, in addition, provides a ready route to D-glucose-5,6,6′-d_3 (II), is reported here.

The current method is based on the conversion of 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone (III) to the 5-keto derivative (IV). This oxidation step was carried out with chromium trioxide in acetic acid, ketone IV being isolated as a crystalline monohydrate. Coincidentally, the same compound was very recently prepared by oxidation of III with activated manganese dioxide (2), although details of this procedure have yet to be communicated. In accord with the structure ascribed to IV (2) the nuclear magnetic resonance (n.m.r.) spectrum of the compound consists of four doublets (Fig. 1*a*) (in addition to the *O*-isopropylidene methyl group signals), showing coupling between H_1 and H_2, H_3 and H_4. The latter two protons resonate at much lower frequencies than do their counterparts in the original D-glucurone derivative (III). One of these (probably H_4)

1,2-*O*-ISOPROPYLIDENE-α-D-GLUCOFURANOSE-5-*d* AND -5,6,6′-d_3[1]

W. Mackie[2] and A. S. Perlin

D-Glucose-5-*d* (I), required in a recent study on oxidative glycol-scission, has been prepared in low isotope yield via a series of reactions that involve initially the reduction of D-*xylo*-5-hexulosonic acid with sodium borodeuteride (1). Other means for preparing this labelled sugar have also been examined and one, which is more satisfactory for the purpose and, in addition, provides a ready route to D-glucose-5,6,6′-d_3 (II), is reported here.

The current method is based on the conversion of 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone (III) to the 5-keto derivative (IV). This oxidation step was carried out with chromium trioxide in acetic acid, ketone IV being isolated as a crystalline monohydrate. Coincidentally, the same compound was very recently prepared by oxidation of III with activated manganese dioxide (2), although details of this procedure have yet to be communicated. In accord with the structure ascribed to IV (2) the nuclear magnetic resonance (n.m.r.) spectrum of the compound consists of four doublets (Fig. 1*a*) (in addition to the *O*-isopropylidene methyl group signals), showing coupling between H_1 and H_2, H_3 and H_4. The latter two protons resonate at much lower frequencies than do their counterparts in the original D-glucurone derivative (III). One of these (probably H_4)

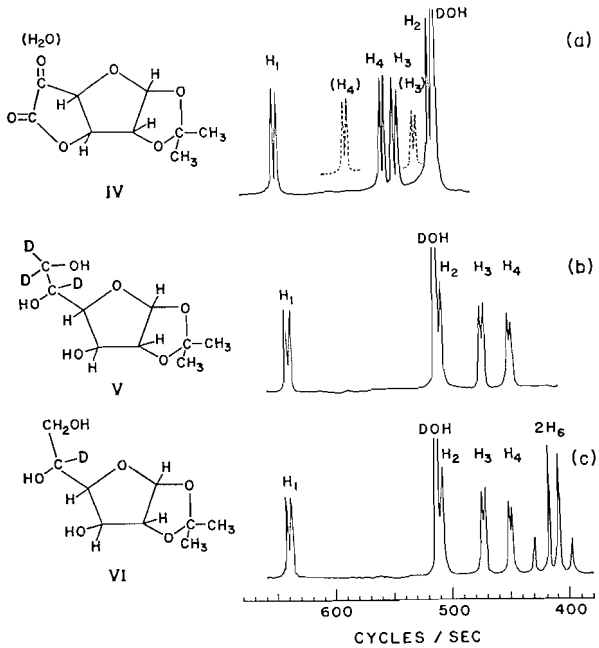

FIG. 1. Nuclear magnetic resonance spectra at 100 Mc/s in deuterium oxide of (*a*) 1,2-*O*-isopropylidene-α-D-xylohexofuranurono-6,3-lactone-5-ulose (IV); the broken line tracings show the location of the H_3 and H_4 signals after excess of potassium carbonate has been added to the solution; (*b*) 1,2-*O*-isopropylidene-α-D-glucofuranose-5,6,6′-d_3; (*c*) 1,2-*O*-isopropylidene-α-D-glucofuranose-5-*d*. Signals at relatively high field for protons of the isopropylidene groups are omitted.

gives its signal even further downfield (broken line) when the lactone structure is opened, whereas the other is affected slightly in the reverse fashion. The probability that the ketone group of IV is hydrated to give the *gem*-diol has already been pointed out (2). More direct evidence of this effect has been obtained by examining the resonance characteristics of the protons associated with the water of hydration, dimethyl sulfoxide being the solvent of choice for this purpose (3). Thus, the spectrum showed two singlets 149 and 133 c.p.s., respectively, downfield from the H_1 signal, both of which disappeared when deuterium oxide was added to the solution (3).[3] The non-equivalence of these signals, as well as their chemical shift (3), shows clearly that the protons responsible cannot be those of water itself but, rather, must be structural elements of the compound in solution.

Borohydride reduction of IV was found to yield 1,2-*O*-isopropylidene-α-D-glucofuranose and only a minor amount of the isomer having the L-ido configuration. Hence by using sodium borodeuteride, 1,2-*O*-isopropylidene-α-D-glucofuranose-5,6,6′-d_3 (V) was obtained in almost quantitative yield. Alternatively, the ketone (IV) was first converted to the sodium salt, and then reduced with the borodeuteride to produce a uronic acid deuteriated at position 5. The latter product was lactonized, and reduced with borohydride, giving a 2:1 mixture of 1,2-*O*-isopropylidene-α-D-glucofuranose-5-*d* (VI) and the corresponding L-ido derivative, from which VI was readily isolated by fractional crystallization.

The n.m.r. spectra of V and VI (Fig. 1) show clearly that the deuteriation steps were fully specific for the positions designated. Thus, in Fig. 1*b* signals attributable only to

[3]*The known gem-diol, chloral hydrate, gives a signal intermediate in chemical shift between those of the two singlets noted above. Because of the α-proton this signal is in the form of a doublet (J = 6.0 c.p.s.), and it has an intensity twice that of the α-proton triplet; on addition of deuterium oxide, the latter signal collapses to a singlet and the signals for the gem-diol protons disappear.*

protons 1 to 4 are found, and 1*c* contains the two extra doublets expected for the isolated 6- and 6′-protons. The high stereoselectivity of the reductions in yielding D-gluco isomers is particularly fortunate for the present purpose. However, this would not necessarily have been anticipated since borohydride reduction of 1,2-*O*-isopropylidene-α-D-xylo-hexofuranose-5-ulose gives the L-idose derivative predominantly (4), and with D-xylo-5-hexulosonic acid about equal proportions of the two isomeric aldonic acids are obtained (5).

EXPERIMENTAL

1,2-O-Isopropylidene-α-D-xylohexofuranurono-6,3-lactone-5-ulose (IV)

Chromium trioxide (1.25 g) was added to a stirred solution of 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone (III) (1.40 g) in acetic acid (25 ml). After 20 h, when a negative test with lead acetate showed that all of the oxidant had been consumed, the acetic acid was removed by lyophilization. Examination of the reaction mixture by thin-layer chromatography (benzene–methanol (9:1)) indicated the presence of a trace of unreacted III and two major products, one travelling faster than III (and later found to be IV), and the other being retained at the origin (as yet unidentified). The dark green residue was extracted with chloroform and the extract concentrated to a syrup (0.92 g), hot water was added, and, on cooling, the green aqueous solution deposited white needles. Two crops of the crystalline material were collected (total yield, 0.25 g) and, after recrystallization from water, the product had m.p. 128–130° (on a microscope melting block; dehydration appeared to take place at 115–125°); m.p. 145–148° (in a capillary tube). $[\alpha]_D$ +73° (*c*, 1.2 water) (ref. 2 gives m.p. 146–149°; $[\alpha]_D$ +76°).

Anal. Calcd. for $C_9H_{10}O_6.H_2O$: C, 46.5; H, 5.2. Found: C, 46.3; H, 5.3.

The compound absorbed strongly at 1 785 cm^{-1} (γ-lactone). A chromatographically pure, syrupy sample of IV obtained by countercurrent extraction (chloroform–water) of the crude oxidation product, showed absorption at 1 620 cm^{-1} (ascribed to the ketone group) and also at 1 780 cm^{-1} (γ-lactone).

The n.m.r. spectrum of the crystalline product is recorded in Fig. 1*a*. Presence of water of hydration was readily detected as an increase in the intensity of the DOH signal when the compound was dissolved in the deuterium oxide.

1,2-O-Isopropylidene-α-D-glucofuranose-5,6,6′-d_3 (V)

To a solution of sodium borodeuteride[4] (75 mg) in water (1 ml) was added an aqueous solution (2 ml) of the ketolactone (IV) (150 mg). The solution was stored at 3° overnight, treated with Amberlite-IR 120 (H^+), and concentrated to dryness, the residue being treated several times with methanol to remove borate. The product (142 mg) was crystalline, and acid hydrolysis followed by paper chromatographic examination ((ethyl acetate – pyridine – water (10:4:3)) showed that it was a derivative mainly of glucose, with idose ($R_{glucose}$ 1.4) present in low proportion. After several recrystallizations from ethyl acetate the product (103 mg) had m.p. 158–160°; its X-ray powder diagram was indistinguishable from that of 1,2-*O*-isopropylidene-α-D-glucofuranose. The n.m.r. spectrum is recorded in Fig. 1*b*.

1,2-O-Isopropylidene-α-D-glucofuranose-5-d (VI)

Sodium bicarbonate (95 mg) was added to a cold solution of the ketolactone (IV) (225 mg) in water (3 ml) and the solution left overnight at 3°. To this cooled solution sodium borodeuteride (170 mg) in water (1 ml) was added, and after 30 min the reaction mixture was allowed to warm to room temperature. One hour later the solution was deionized with mixed-bed ion exchange resins and concentrated to a syrup (237 mg). This product was dissolved in toluene (6) and heated under reflux for 3 h to promote lactonization, and the solvent was then evaporated off. Thin-layer chromatography of the residue showed the presence of two components having mobility close to that of III, with additional material at the origin. The residue (228 mg) was extracted with acetone, and the soluble material was taken up in water (2 ml) and treated at 3° overnight with potassium borohydride (120 mg in 1 ml of water). The final product (140 mg) was found by acid hydrolysis, followed by paper chromatographic examination, to consist of a mixture of gluco and ido-isomers in a ratio of about 2:1. Material obtained after several recrystallizations from ethyl acetate had m.p. 156–158°; its X-ray diffraction diagram was indistinguishable from that of 1,2-*O*-isopropylidene-α-D-glucofuranose. Its n.m.r. spectrum is recorded in Fig. 1*c*.

ACKNOWLEDGMENT

Nuclear magnetic resonance spectra were recorded by M. Mazurek. Microanalyses were performed by W. Haid, who also prepared X-ray powder diagrams and infrared spectra.

THE ACTION OF FENTON'S REAGENT ON CYCLOPROPYLCARBINOL

C. C. LEE, A. J. CESSNA, AND MOIRA K. FROST

Fenton's reagent is well known as a source of OH radicals (1–3). In connection with some exploratory studies on the possibility of inducing rearrangements by γ-irradiation of cyclopropylcarbinol (I) in aqueous solution, which may involve OH radicals, the action of Fenton's reagent on I was investigated.

In the initial experiments, 2.0 *M* solutions of ferrous sulphate and hydrogen peroxide were added simultaneously to a dilute aqueous solution of I, and the resulting mixture was heated under reflux for 3 h. The products, identified by nuclear magnetic resonance and vapor phase chromatography analyses, were unchanged I, cyclobutanol (II), allylcarbinol (III), and cyclopropanecarboxaldehyde (IV). These results show the occurrence of rearrangements besides the expected oxidation of a primary alcohol to an aldehyde (4, 5). Facile interconversions among the cyclopropylcarbinyl, cyclobutyl, and allylcarbinyl systems are well known in carbonium ion types of reactions (6 and references given therein), whereas the free radical photochlorination of methyl-^{13}C-cyclopropane showed quite different results (7). It is thus of interest to ascertain whether the rearrangements accompanying the oxidation of I by Fenton's reagent is ionic or free radical in nature. To this end, compound I was subjected to treatment under various conditions, and the results are summarized in Table I.

From Table I, it may be noted that expts. 1–6 showed that oxidation of I to IV occurred within 2 minutes and that the observed rearrangements of I to II and III took place during the subsequent heating of the reaction mixture under reflux. This was further confirmed by expts. 7–10 when the two components on Fenton's reagent were first heated under reflux for 1 h before being added to I. The remaining expts. 11–20 showed that neither hydrogen peroxide nor ferrous sulfate alone could cause any reaction, and that the species responsible for the rearrangements was the ferric ion. These results demonstrated conclusively that the rearrangements observed under the present reaction conditions arose from a polar rather than a free radical mechanism. The findings are very similar to the aluminium alkoxide induced rearrangements found to accompany the Oppenauer oxidation of I (8). By analogy with the mechanism suggested by Kolthoff and Medalia (5), the oxidation of I by Fenton's reagent may be formulated as follows.

[1] $$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + HO\cdot$$

[2] $$Fe^{2+} + HO\cdot \rightarrow Fe^{3+} + OH^-$$

It is thus of interest to ascertain whether the rearrangements accompanying the oxidation of I by Fenton's reagent is ionic or free radical in nature. To this end, compound I was subjected to treatment under various conditions, and the results are summarized in Table I.

From Table I, it may be noted that expts. 1–6 showed that oxidation of I to IV occurred within 2 minutes and that the observed rearrangements of I to II and III took place during the subsequent heating of the reaction mixture under reflux. This was further confirmed by expts. 7–10 when the two components on Fenton's reagent were first heated under reflux for 1 h before being added to I. The remaining expts. 11–20 showed that neither hydrogen peroxide nor ferrous sulfate alone could cause any reaction, and that the species responsible for the rearrangements was the ferric ion. These results demonstrated conclusively that the rearrangements observed under the present reaction conditions arose from a polar rather than a free radical mechanism. The findings are very similar to the aluminium alkoxide induced rearrangements found to accompany the Oppenauer oxidation of I (8). By analogy with the mechanism suggested by Kolthoff and Medalia (5), the oxidation of I by Fenton's reagent may be formulated as follows.

[1] $$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + HO\cdot$$

[2] $$Fe^{2+} + HO\cdot \rightarrow Fe^{3+} + OH^-$$

[3] $$HO\cdot + \triangleright\!\!-CH_2OH \rightarrow \triangleright\!\!-\dot{C}HOH + H_2O$$

[4] $$\triangleright\!\!-\dot{C}HOH + Fe^{3+} \rightarrow \triangleright\!\!-CHO + H^+ + Fe^{2+}$$

The ferric ions produced according to eqs. [1] and [2], besides reacting as in eq. [4], could act as a Lewis acid to induce rearrangements typical of carbonium ion reactions involving the cyclopropylcarbinyl system.

*Assayed by v.p.c. Compounds I, II, III, and IV are, respectively, cyclopropylcarbinol, cyclobutanol, allylcarbinol, and cyclopropanecarboxaldehyde.

†In expts. 15–18, the ratio of g-ions of Fe^{3+} to moles of I was 2:1; in expts. 19 and 20, this ratio was 1:1.

EXPERIMENTAL

Cyclopropylcarbinol (I), cyclobutanol (II), and cyclopropanecarboxaldehyde (IV) were obtained by methods mentioned previously (8). Allylcarbinol (III) was prepared by the lithium aluminium hydride reduction of vinylacetic acid (6). All of these compounds, I, II, III, and IV, were purified by preparative v.p.c. before their use either as reactant or as standards in v.p.c. calibrations.

For expts. 1–6, a typical run is as follows. In a three-necked flask fitted with reflux condenser and two dropping funnels was placed a solution of 0.25 g (3.5 mmole) of I in 12.5 ml of water. The vessel and its content were heated in an oil bath to maintain a gentle reflux. The Fenton's reagent, consisting of 2.0 *M* solutions of ferrous sulphate and hydrogen peroxide (9), were added simultaneously through the two dropping funnels, 3.5 ml (7.0 mmole) of each solution being used. The mixture was heated under reflux for the desired length of time, cooled in an ice bath, and extracted three times with 3-ml portions of absolute ether. After the extract was dried over anhydrous magnesium sulphate, it was analyzed by v.p.c., using a column packed with 30% β,β'-oxydipropionitrile on 30–60 mesh fire brick.

In a larger scale experiment with 3 h of refluxing time, the products, I, II, III, and IV, were recovered by preparative v.p.c. and identified by comparisons of their n.m.r. spectra and v.p.c. retention times with those of authentic samples.

For expts. 7–10, the two components (3.5 ml each) of Fenton's reagent were heated under reflux together for 1 h and then the mixture was added to the solution of I in the reaction vessel. In expts. 11–20, instead of Fenton's reagent, 3.5 ml of a solution containing the appropriate compound and 3.5 ml of water were used. The reaction mixtures from expts. 7–20 were worked up exactly as described for expts. 1–6.

ADDENDUM: EVIDENCE FOR $ZnF_2.2H_2O$

E. A. SECCO AND O. K. SRIVASTAVA

(Ref. Can. J. Chem. 43, 175 (1965))

More detailed data from weight loss, X-ray diffraction, and solubility studies on an unknown fluoride hydrate reveal that the earlier interpretation in terms of zinc fluoride dihydrate (1) is not valid. It is necessary, therefore, to present a reinterpretation of the previously reported data along with more recent results.

EXPERIMENTAL

Five grams of the unidentified fluoride hydrate supplied by A. D. MacKay Inc. were stirred in 200 ml of distilled water for 1 h and filtered. The filtrate, on slow evaporation at room temperature, produced crystals of zinc fluoride tetrahydrate. The insoluble residue was washed several times with distilled water and dried in air.

Weight loss studies were carried out and X-ray diffraction patterns obtained on three samples, viz., I the stock sample, II zinc fluoride tetrahydrate crystals obtained from the filtrate, and III the insoluble residue.

RESULTS AND DISCUSSION

The results of the weight loss studies are summarized in Table I.

TABLE I

1.98	11	1.99	30
—	—	1.90	23
1.87	11	1.87	28
1.84	9	—	—
1.76	50	1.78	82
1.73	19	1.73	20
1.64	9	1.62	60
1.60	27	—	—
1.56	23	1.56	54
—	—	1.51	60
1.49	22	1.48	42

It is now concluded that the weight loss and solubility data along with the X-ray diffraction pattern of the unknown fluoride hydrate are compatible with an equimolar mixture of zinc fluoride tetrahydrate and zinc hydroxyfluoride. Unfortunately, the stoichiometric weight losses expected from the dehydration of a fluoride dihydrate via a hemihydrate is fortuitously quasi-identical to the equimolar mixture.

STRUCTURAL FEATURES OF TWO EXTRACELLULAR POLYSACCHARIDES FROM SERRATIA MARCESCENS[1]

ROBERT YOUNG[2] AND G. A. ADAMS

Division of Biosciences, National Research Council, Ottawa, Canada

Received June 2, 1965

ABSTRACT

A polysaccharide insoluble in acidified ethanol solution has been isolated from a culture filtrate of *Serratia marcescens*. Fractionation by cetyltrimethylammonium bromide ("Cetavlon") and by diethylaminoethyl (DEAE) cellulose yielded a polysaccharide which was electrophoretically homogeneous and contained D-glucose, L-rhamnose, D-galactose, L-*glycero*-D-*manno*-heptose, D-*glycero*-D-*manno*-heptose, glucosamine, and galactosamine in an approximate molar ratio of 6.5:3.5:0.5:1.0:0.5:1.0:0.2. However, following methylation it was found that the fully methylated polysaccharide could be fractionated by organic solvents into a rhamnoglucan and a heptoglucan. Both polysaccharides contained lipid material consisting mainly of hydroxy myristic acid and hydroxy lauric acid. The main chain of the rhamnoglucan was composed of (1 → 3) linked L-rhamnopyranose units and (1 → 4) linked D-glucose units with the non reducing end groups being D-glucose; some branching occurred through D-glucose units. The heptoglucan was composed mainly of chains of (1 → 4) linked D-glucose units with smaller amounts of (1 → 6) linked D-glucose and (1 → 2) linked D-*glycero*-D-*manno*-heptose units; these chains were terminated by D-glucopyranose and L-*glycero*-D-*manno*-heptose end groups.

Although previous work (1, 2, 3) has indicated the presence of polysaccharides in the culture filtrates of *Serratia marcescens*, no attempt has been made to isolate them in homogeneous form and to examine their structural features. The preparation, fractionation, and preliminary examination of the extracellular polysaccharides produced by *Serratia marcescens*, grown on a sucrose medium, has been carried out in this laboratory and described in a previous communication (4). The crude polysaccharides were fractionated primarily on the basis of their solubility in acidic ethanol solution. In the present study, the acid–alcohol insoluble polysaccharides have been fractionated further and information on their main structural features has been obtained. The constitution of an acidic glucomannan isolated from the acid–alcohol soluble material will be reported in a later communication.

The acid–alcohol insoluble polysaccharide preparation, on examination by moving boundary electrophoresis (5) in borate buffer, was found to comprise one main component together with several other minor polysaccharide fractions. Cetavlon (6) precipitated a small amount of polysaccharide from aqueous solution, leaving a fraction in the supernatant which showed fewer minor fractions on electrophoresis. Further purification of this latter fraction was achieved by chromatography on diethylaminoethyl (DEAE) cellulose (7). Elution was effected with a gradient (0–0.5 *M*) phosphate buffer at pH 6,

[1]*Issued as N.R.C. No. 8632.*

[2]*National Research Council Postdoctorate Fellow 1963–1965.*

followed by a gradient (0–0.3 *M*) sodium hydroxide. The major polysaccharide component was eluted with the phosphate buffer. It contained 0.98% nitrogen, 7% ash, had $[\alpha]_D$ +62° (*c*, 1.0 in H_2O) and gave a sharp symmetrical peak ($\mu = -2.38 \times 10^{-5}$ cm^2 s^{-1} V^{-1}), on free boundary electrophoresis in borate buffer with only a trace of a faster moving component. This polysaccharide was considered pure enough to warrant structural studies.

The constituent neutral monosaccharides of the polysaccharide were determined quantitatively after acid hydrolysis by gas–liquid partition chromatography (g.l.p.c.) of the derived acetylated polyols (8). This procedure provided identification of the various sugars, which were D-glucose, L-rhamnose, D-*glycero*-D-*manno*-heptose, L-*glycero*-D-*manno*-heptose, and a trace of D-galactose. Configuration of the sugars was assigned by later determination of the specific rotation of crystalline derviatives. The presence of heptose was first indicated by positive color reactions with *p*-anisidine hydrochloride (9) and the specific periodate – acetyl acetone spray reagent (10). The acetylated polyols on g.l.p.c. gave two peaks in the heptitol region. These could have arisen from reduction of one heptulose or from reduction of two heptoses. However, authentic heptuloses were found to give a different color when sprayed with the orcinol reagent and do not give a positive reaction with the periodate – acetyl acetone reagent (10). Partition chromatographic procedures could not be employed to isolate the two heptoses as they had similar chromatographic mobility to glucose which was present in large excess. The polysaccharide hydrolysate was treated with glucose oxidase and the resulting gluconic acid removed with basic ion-exchange resin. The residual mixture of neutral monosaccharides was fractionated by cellulose column chromatography. A fraction was obtained containing both heptoses, mixed with a small amount of galactose. The latter was removed by conversion to the 1,6-dialdehyde with galactose oxidase (11) and subsequent preparative paper chromatography. A portion of the material containing the two heptoses was treated with 1 mole equivalent of periodate. This selectively cleaved the exocyclic C_6—C_7 bond and reduction of the resulting aldehyde gave the parent hexose (12). Paper and gas–liquid partition chromatographic evidence showed mannose to be the only hexose produced. The remainder of the heptose mixture was reduced and acetylated. The resulting heptitol acetates were separated by preparative g.l.p.c. and identified as D-*glycero*-D-*manno*-heptitol heptaacetate and L-*glycero*-D-*manno*-heptitol heptaacetate.

In a separate experiment, using cellulose column chromatography with a different eluant, the major heptose component L-*glycero*-D-*manno*-heptose was isolated and identified by its specific rotation and preparation of a crystalline derivative.

The presence of hexosamine in the polysaccharide was indicated initially by paper chromatography. This was confirmed by g.l.p.c. (13) of the trimethyl silyl derivatives of the polysaccharide hydrolysate; 8.1% glucosamine and 2.3% galactosamine were found to be present.

The polysaccharide was found to consume 0.58 moles of periodate per anhydro hexose unit. Most of the glucose residues were oxidized and all the rhamnose residues remained intact. Utilization of the Smith procedure (14) indicated no contiguous rhamnose residues in the molecule. The products were glycerol, erythritol, rhamnose, and glucose in a molecular ratio of 1.1:1.05:1.0:0.13.

Exhaustive methylation of the polysaccharide with dimethyl sulfate and sodium hydroxide, with methyl iodide and silver oxide, and also by Kuhn's procedure (15) did not raise the methoxyl content above 35.5%. Examination by infrared spectroscopy showed only a small amount of absorption in the hydroxyl region. The methylated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

product was fractionally precipitated from chloroform solution with light petroleum to give an insoluble fraction (polysaccharide A) and a soluble fraction (polysaccharide B).

Methylated polysaccharide A was hydrolyzed, and demethylation of a sample of the products indicated glucose and rhamnose were the only constituent sugars. The mixture of *O*-methyl ethers was analyzed by a combination of gas–liquid, paper, and thin-layer chromatography. The relative amounts of *O*-methyl sugars in the mixtures were determined by g.l.p.c. using three different liquid phases. The quantitative results for methylated polysaccharide A are given in Table I; each of the methylated sugars was characterized by isolation of a crystalline derivative. Also present in the hydrolysate was an appreciable amount of lipid material, which was identified by chromatographic techniques as α-hydroxy fatty acids.

TABLE I

Hydrolysis products* from methylated polysaccharide A from *Serratia marcescens*

O-Methyl ether	Composition (mole %)
2,3,4,6-Tetra-*O*-methyl-D-glucose	7.4
2,4-Di-*O*-methyl-L-rhamnose	29.0
2,3,6-Tri-*O*-methyl-D-glucose	63.6

*Also found was a small amount of dimethyl- and monomethyl-glucoses.

Methylated polysaccharide B was found to contain a large proportion of free lipid material. This was separated from the methylated polysaccharide by column chromatography on silicic acid, and found to contain methoxy myristic acid, methoxy lauric acid, and two unidentified fatty acids. A methylated polysaccharide was obtained which appeared homogeneous on thin-layer chromatography, but infrared spectroscopic examination indicated the presence of some lipid moieties. Hydrolysis followed by demethylation of a small portion of the sugar ethers indicated the constituent monosacchrides to be glucose, L-*glycero*-D-*manno*-heptose, and D-*glycero*-D-*manno*-heptose. Insufficient material was available for separation and characterization of the *O*-methyl ethers, but gas–liquid and paper chromatography identified the main components as shown in Table II. Also obtained from the hydrolysis products of the methylated polysaccharide was a lipid component. This was not further investigated, as a comprehensive study of the bound lipids from *Serratia marcescens* polysaccharides is at present underway in this laboratory.

TABLE II

Hydrolysis products of the methylated heptoglucan

Component sugar	Molar ratio
2,3,4,6-Tetra-*O*-methyl-glucose	3.7
2,3,6-Tri-*O*-methyl-glucose	3.5
2,3,4-Tri-*O*-methyl-glucose	1.0
3,4,6,7-Tetra-*O*-methyl-D-*glycero*-D-*manno*-heptose	1.05
Fully methylated D-*glycero*-D-*manno*-heptose	0.3
Fully methylated L-*glycero*-D-*manno*-heptose	2.2

From the above results it is apparent that the polysaccharide product, which resulted from various fractionation procedures and appeared homogeneous on electrophoresis, contained two entirely different polysaccharides, a rhamnoglucan and a heptoglucan.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The possibility cannot be dismissed, however, that since the polysaccharide preparation before methylation appeared homogeneous on free boundary electrophoresis, the two polysaccharides may have been joined by some alkali-labile bond. The failure to find any galactose or hexosamine in the methylation products, both of which were present in the hydrolysis products of the original polysaccharide, indicates that other polymeric species may exist. This failure could also be attributed to the destruction of the hexosamine during the prolonged methylation with strong alkali.

A significant feature of the polysaccharide is the presence of an appreciable amount of lipid. The latter must have been firmly bound since any 'free' lipid would not have survived the purification procedures used and would almost certainly not have been precipitated with ethanol. During the Haworth methylation, treatment with 30% sodium hydroxide for a long period of time would have cleaved any amide or ester bound fatty acids. This explains why these substances were found in the light-petroleum soluble fraction which was obtained after methylation. However, infrared spectroscopy has indicated that a significant proportion of the lipids survived the alkali treatment and so it is possible that these were glycosidically linked. This is substantiated by the fact that the lipids found in the hydrolysate of methylated polysaccharide A have unmethylated hydroxyl groups which suggests that the lipids were bound to the polysaccharide through these groups. The indication supplied by infrared spectroscopy was confirmed by the finding of lipids in the acid hydrolysates of both methylated polysaccharides. The dilution effect introduced by these non-carbohydrate moieties in the polysaccharide accounts for the low methoxyl values of the methylated polysaccharide. The gradual increase in methoxyl content during prolonged Haworth methylation may be explained by slow cleavage of ester and amide bound fatty acids which would make additional hydroxyl groups available for methylation.

Although no unique structure can be postulated for the rhamnoglucan, from the methylation results the following deductions can be made. The main chain of the polysaccharide comprises (1 → 3) linked L-rhamnopyranose units and (1 → 4) linked D-glucopyranose units, the chain being terminated by D-glucopyranose residues. If the chain is unbranched, the amount of tetra-*O*-methyl-glucose indicates a chain length of 14. The molecular weight, however, gives a degree of polymerization of 35, and while this value represents the average for the mixture of polysaccharides the discrepancy is too great to be explained in this way. Consequently a certain amount of branching must occur, and this possibility is supported by the presence of small quantities of partially methylated glucose residues in the hydrolysis products of the methylated polysaccharide. On the other hand, some of the latter residues may have hydroxyl groups unsubstituted during methylation because of the presence of fatty acids, which were later cleaved off by acid hydrolysis. To establish unequivocally the sequence of glucose and rhamnose units in the chain, oligosaccharides formed by partial hydrolysis of the molecule would have to be isolated. Evidence accrued by periodate oxidation, however, shows that there are no contiguous rhamnose residues. Consequently since there are approximately twice as many (1 → 4) linked glucose residues as (1 → 3) linked rhamnose residues, it is possible that the following partial structure may be present.

$$\rightarrow 3)\text{L-Rha}p(1 \rightarrow 4)\text{D-G}p(1 \rightarrow 4)\text{D-G}p(1 \rightarrow 3)\text{L-Rha}p(1 \rightarrow 4)\text{D-G}p(1 \rightarrow 4)\text{D-G}p(1 \ldots$$

Definite conclusions from the results of periodate oxidation are limited since a significant proportion of hydroxyl groups in the polysaccharide are substituted by fatty acids and since the results were obtained on what is now known to have been a mixture of polysaccharides. The glycerol formed must have arisen from end groups of glucose and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

L-*glycero*-D-*manno*-heptose together with any other residues which were chain-ending. Theoretically the ratio of erythritol to rhamnose in the oxidation products should be the same as the ratio of 2,3,6-tri-*O*-methyl-D-glucose to 2,4-di-*O*-methyl-L-rhamnose. The relatively low yield of erythritol can be attributed in part to the substitution of some glucose residues at positions C_2 and C_3 by fatty acids. This substitution would explain the presence of some unoxidized glucose residues in the products of periodate oxidation.

The results of the methylation study indicate that the heptoglucan is composed of main chains of $(1 \rightarrow 4)$ linked glucose residues with smaller amounts of $(1 \rightarrow 6)$ linked glucose and $(1 \rightarrow 2)$ linked D-*glycero*-D-*manno*-heptose moieties. These chains are terminated by D-glucopyranose and L-glycero-D-*manno*-heptose units. No prediction can be made as to whether or not branching occurs.

The occurrence of heptoses in polysaccharides of gram-negative bacteria is well known (16). L-*Glycero*-D-*manno*-heptose and D-*glycero*-D-*manno*-heptose have both been found in cell wall polysaccharides. As far as the authors are aware, however, this is the first report of two different heptoses occurring in the same molecule. Parikh and Jones (17) found D-*glycero*-D-*manno*-heptose linked $(1 \rightarrow 2)$ in an extracellular polysaccharide of *Azobacter indicum*. This heptose is linked in the same way in the heptoglucan described above. No other attempts have been made to find the mode of linkage of heptoses in polysaccharides.

It is obvious that the culture filtrate of *Serratia marcescens* contains several distinct polysaccharide entities, two of which, a rhamnoglucan and a heptoglucan, have been studied in some detail. The pattern of occurrence is very similar to that already found in the capsular polysaccharides from this bacteria (18). The conclusion, therefore, is that these extracellular polysaccharides have their origin in the capsular layer. From the cells of *Serratia marcescens* an entirely different polysaccharide containing glucose, mannose, and mannuronic acid has been isolated and its structure determined (19).

EXPERIMENTAL

All evaporations were carried out under diminished pressure below 40°.

Paper chromatograms were run by the descending method on Whatman No. 1 filter paper, using the following solvent systems (v/v).

(*a*) Ethyl acetate:pyridine:water (10:4:3).

(*b*) Butan-1-ol:ethanol:water (4:1:5, upper phase).

(*c*) Ethyl acetate:acetic acid:formic acid:water (18:3:1:4).

Sugars were detected on chromatograms by *p*-anisidine hydrochloride (9) or alkaline silver nitrate (20) spray reagents. Paper electrophoresis was done on Whatman 3 MM paper in 0.1 *M* sodium tetraborate at a potential gradient of 25 V/cm for 2 h. The rates of movement of the glycoses on the paper chromatograms are relative to that of D-glucose (R_{glu}) or 2,3,4,6-tetra-*O*-methyl-D-glucose (R_g), and relative to D-glucose (M_g) on the paper elctrophoretograms.

Gas–liquid partition chromatography (21) was done with a Pye argon chromatograph fitted with an ionization detector using straight glass columns (120 × 0.5 cm inside diameter) with the following packings:

(*a*) 10% (w/w) Carbowax 6,000 on 80–100 acid-washed Chromosorb W (Johns-Manville),

(*b*) 10% (w/w) neopentyl glycol succinate (Applied Science Laboratories) on 80–100 mesh non-acid-washed Chromosorb W (Johns-Manville),

(*c*) 15% (w/w) polyphenyl ether on Gas Chrom A, 100–200 mesh.

The retention times of the methylated glycoses are quoted relative to methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucoside (T_g) and the polyols to hexa-*O*-acetyl-D-galactitol (T_{gal}). Preparative g.l.p.c. was carried out on an F and M model 500 chromatograph.

Thin-layer chromatography was carried out with silica gel G using benzene:acetone (1:1) as developing solvent (22) and the sugars were detected by spraying with 70% sulfuric acid. Preparative thin-layer chromatography was effected on 0.66 mm thicknesses of silica gel G on glass plates (20 × 20 cm). Sugar regions on the plates were detected by the following method.

After removal of solvent, the plates were sprayed heavily with methanol and guide strips (1 cm wide) of Whatman No. 1 filter paper, thoroughly soaked with water, were pressed against the plate and left for 10 min. The strips were removed and sprayed with *p*-anisidine hydrochloride, thus indicating the position of the sugar zones on the plate. These were marked and scraped from the plate, and the products were obtained by extraction with boiling butan-1-one.

For personal use only.

A Tiselius-type, Spinco model H apparatus was used for moving boundary electrophoresis in 0.05 *M* borate buffer (5).

Melting points were determined on a Fisher-Johns apparatus and are corrected.

Isolation of the Acid–Alcohol Insoluble Polysaccharide from the Crude Extracellular Polysaccharide Material

Batches of the desired polysaccharide were obtained according to the following typical experiment. Crude extracellular polysaccharide (4) (200 g) containing 3.5% nitrogen and 42% ash was taken up in water (6 l); an insoluble residue was washed twice with water and the washings were added to the solubles. The aqueous solution (6 520 ml) was poured with vigorous stirring into ethanol (32.5 l) containing conc. hydrochloric acid (140 ml). The precipitate which formed was filtered off, washed twice with 80% aqueous ethanol, and freeze-dried to yield a polysaccharide (15 g) containing 5.8% nitrogen and 19% ash. Moving boundary electrophoresis showed at least three peaks, with one main one.

Fractionation and Purification of the Polysaccharide

(a) Fractionation by Cetavlon (6)

Polysaccharide material (35 g.) was slurried in water (1 500 ml), and a portion which remained insoluble was removed by centrifugation. To the combined supernatant and washings (2 300 ml), was added a 1% aqueous solution of cetyltrimethylammonium hydroxide (Cetavlon) (500 ml) and 0.5 *N* sodium hydroxide (40 ml). The precipitate obtained was dissolved in 10% acetic acid and dialyzed, and the solution was poured into ethanol (4 volumes). This gave fraction (i) (1.4 g), which had 4.4% nitrogen and 21% ash. Acid hydrolysis of fraction (i) afforded glucose, mannose, and uronic acid, in the ratio of 3:1:1 as assessed by visual examination of paper chromatograms. Subsequent additions of Cetavlon followed by boric acid (23) gave no further precipitates.

The supernatant (3 850 ml) was acidified to pH 4.5 with acetic acid, dialyzed overnight, and poured into ethanol (5 volumes) giving fraction (ii) (8.8 g). This polysaccharide had 1.7% nitrogen and 7% ash. Visual inspection of paper chromatograms of the acid hydrolysis products indicated glucose, rhamnose, heptose, hexosamine, and uronic acid in a ratio of 5:2:1:1:1. Moving boundary electrophoresis showed the presence of one major component with traces of two faster moving components.

(b) DEAE–Cellulose Chromatography (7)

Fraction (ii) (8.8 g) from the above Cetavlon fractionation was dissolved in water (100 ml), and the solution was poured onto a column (7.5 × 36 cm) of diethylaminoethyl cellulose (phosphate form) as described by Neukom *et al.* (7). The column was eluted with a gradient of sodium dihydrogen phosphate (pH 6) (0–0.5 *M*; 4 l) followed by a gradient of sodium hydroxide (0–0.3 *M*; 2 l). Fractions (ca. 20 ml) were collected and analyzed for sugars by the phenol – sulfuric acid method (24). Two polysaccharide fractions were eluted; one by the phosphate buffer (fraction A) and the other by alkali (fraction B). The polysaccharides were recovered by dialyzing for 48 h, stirring with mixed ion exchange resins, evaporating the eluate to a small volume, and pouring into ethanol (5 volumes).

Fraction A (6.9 g) had 0.98% nitrogen and 7% ash and on acid hydrolysis gave glucose, rhamnose, heptose, hexosamine, and a trace of fucose. Fraction B (0.54 g) gave glucose, uronic acid, and a trace of mannose on hydrolysis.

Fraction A was used for structural investigations and henceforth will be referred to as 'the polysaccharide'.

Properties of the Polysaccharide

The polysaccharide had $[\alpha]_D^{25}$ 62° (*c*, 1.0 in water). A portion (50 mg) was dissolved in formamide (2 ml) and acetylated with acetic anhydride (0.8 ml) after addition of pyridine (6 ml). Vapor pressure osmometry of the acetylated derivative using the Mechrolab osmometer indicated a minimum degree of polymerization of 35. Moving boundary electrophoresis gave a large symmetrical peak having $\mu = -2.38 \times 10^{-5}\ cm^2\ s^{-1}\ V^{-1}$, plus one small fast moving impurity.

Samples (10 mg) of the polysaccharide were hydrolyzed with *N* sulfuric acid for 12 h. Quantitative analysis by g.l.p.c. of reduced acetylated products of the hydrolysate, using the procedure of Gunner *et al.* (8) indicated the following neutral sugars: D-glucose, L-rhamnose, D-galactose, L-*glycero*-D-*manno*-heptose, and D-*glycero*-D-*manno*-heptose in a molar ratio of 6.5:3.5:0.5:1.0:0.5. (The configurations of glucose, rhamnose, and the heptoses was established later by the determination of the specific rotation of their derivatives. Since galactose oxidase is specific for the D enantiomorph, the above assigned configuration for galactose is correct).

The presence of heptose in the polysaccharide hydrolysate was indicated by the brown-black color of a spot, R_{glu} 0.91 in solvent A, on a chromatogram sprayed with *p*-anisidine hydrochloride. Orcinol reagent (25) gave a red spot, R_{glu} 0.91; all the available authentic heptoses gave a similar red color, while heptuloses gave a blue-green color. Periodate – acetyl acetone spray reagent (10) gave the characteristic yellow color of formaldehyde, providing further evidence that heptose was present. Examination by g.l.p.c. on column B of the alcohol acetates (8) derived from the hydrolyzed polysaccharide gave two peaks in the heptitol region, having T_{gal} 2.32 and 1.98.

Since the two heptoses had the same chromatographic mobility on paper and cellulose columns as galactose and also moved close to a large amount of glucose, it was impossible to isolate the heptoses by normal partition chromatographic procedures. Crude extracellular polysaccharide (10 g) was hydrolyzed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with N H_2SO_4 for 12 h. The recovered mixture of sugars was dissolved in water (250 ml) and stirred overnight, at room temperature, in an atmosphere of oxygen with glucose oxidase (1 g). The gluconic acid formed was removed by basic ion exchange resin and the aqueous eluate evaporated to a syrup (1.29 g). Investigation by g.l.p.c. of the alcohol acetates (8) prepared from a portion of the syrup showed the latter to contain 27% heptose. A partial separation of the sugars was obtained by fractionating the syrup on a cellulose column with *n*-propanol:ethyl acetate:water (7:2:1). The fraction (600 mg) containing the heptoses was further fractionated on filter paper sheets in solvent A. The recovered syrup (165 mg) was shown by g.l.p.c. (8) to contain galactose in addition to the two heptoses. The syrup was dissolved in 0.1 M phosphate buffer pH 7.0 (10 ml) and ethanol (5 ml). Galactose oxidase (11.5 mg) with a small amount of catalase was added, and the solution was stirred and aerated with oxygen at room temperature for 24 h. A further addition of galactose oxidase (2.2 mg) and catalase was then made and the digestion was continued for a further 24 h. The solution was evaporated to small volume and the components were separated on filter sheets. The galactose was quantitatively converted to *meso-galacto*-hexodialdose, R_{glu} 0.43 in solvent A. The heptose mixture (57 mg) could not be resolved by paper chromatography using the following solvent systems and gave a spot with R_{glu} 0.97 in solvent B, 0.96 in solvent C, and 0.94 in solvent A. Paper electrophoresis in borate buffer did not separate the sugars which both had M_g 0.8. The heptose mixture had $[\alpha]_D$ −4° (*c*, 1.0 in H_2O).

A portion (22 mg) of the syrupy material was selectively periodate oxidized according to the method of Perry (12). After treating with 2% methanolic hydrogen chloride to form the methyl glycosides, 1 mole equivalent of periodate was added to the syrup. The resulting aldehyde was reduced with sodium borohydride and the free sugar was obtained by acid hydrolysis. Paper chromatography and g.l.p.c. (8) showed the products to consist mainly of mannose with traces of unreacted heptoses and a trace of unknown pentose, R_{glu} 1.29.

The remainder (30 mg) of the fraction containing the two heptoses was reduced with sodium borohydride and acetylated with acetic anhydride and sulfuric acid. The resulting acetylated heptitols were isolated by preparative g.l.p.c.

D-*Glycero*-D-*manno*-heptitol heptaacetate had the same retention time, T_{gal} = 1.98, on column B at 210° as the same derivative of the authentic sugar. The acetylated heptitol had $[\alpha]_D$ +34° (*c*, 0.38 in $CHCl_3$). The reported value for D-*glycero*-D-*manno*-heptitol heptaacetate is +36.1° (in $CHCl_3$) (26). L-*Glycero*-D-*manno*-heptitol heptaacetate had the same T_{gal} = 2.32 as the corresponding derivative of the authentic sugar, using the same conditions as above. The crystals had $[\alpha]_D$ −11° (*c*, 1.1 in $CHCl_3$) and m.p. 116° compared with $[\alpha]_D$ −13.3° (*c*, 2 in $CHCl_3$) and m.p. 119° reported in the literature (26).

Isolation of L-*Glycero*-D-*manno*-*heptose*

Crude extracellular polysaccharide (14.2 g) was hydrolyzed with 2 N sulfuric acid for 12 h. The resulting monosaccharides were treated with glucose oxidase as described earlier. The gluconic acid was removed with basic ion-exchange resin, Duolite A4. The eluate was concentrated to a syrup and fractionated on a cellulose column, using butan-1-ol, 1/2 saturated with water as eluant to give two fractions (A and B).

Fraction A (100 mg) was shown by paper chromatography and by g.l.p.c. (8) to contain L-*glycero*-D-*manno*-heptose, together with traces of glucose and gluconic acid. Preparative paper chromatography in solvent A yielded the pure heptose (52 mg). The sugar had $[\alpha]_D$ +14° (*c*, 0.85 in H_2O); attempts to crystallize it failed. The literature value (27) for D-*glycero*-L-*manno*-heptose is $[\alpha]_D$ −15.3° (equil.). A portion of the heptose (20 mg) was treated with benzoyl chloride (200 mg) in pyridine (2.0 ml), and the resulting compound was recrystallised from ethanol – light petroleum, b.p. 30–60°. Hexa-*O*-benzoyl-L-*glycero*-D-*manno*-heptose had m.p. 100° and $[\alpha]_D$ −32° (*c*, 1.0 in $CHCl_3$). The reported values (28) of hexa-*O*-benzoyl-D-*glycero*-L-*manno*-heptose are m.p. 99° and $[\alpha]_D$ +30.8°.

Chromatographic procedures indicated that Fraction B (250 mg) comprised a mixture of both heptoses together with mannose, galactose, glucose, and a trace of gluconic acid. Preparative paper chromatography yielded a mixture (118 mg) of the two heptoses but these could not be further resolved by chromatographic procedures.

Hexosamine Determination

Paper chromatography of the hydrolysis products of the polysaccharide in solvent B, indicated a spot with the same R_{glu} 0.66 as glucosamine or galactosamine, which gave a blue spot with ninhydrin. The polysaccharide contained 0.98% nitrogen which was consistent with the presence of hexosamine in the polymer. This was confirmed as follows by using the method described by Perry (13).

An aliquot (52 mg) from the hydrolysis products of the polysaccharide was N-acetylated and converted to the trimethylsilyl ethers. Examination of the latter by g.l.p.c. on column B at 191° showed peaks with the same retention times as the trimethylsilyl derivatives of 2-acetamido-2-deoxy-D-glucose and 2-acetamido-2-deoxy-D-galactose, in the ratio 1:0.28. By incorporating an internal standard of galactosamine hydrochloride (4.80 mg) in a second aliquot (52 mg), the hexosamine content of the polysaccharide was calculated to be 10.4%, comprising 8.1% glucosamine and 2.3% galactosamine.

Periodate Oxidation of the Polysaccharide

A sample (101 mg) of the polysaccharide was dissolved in water (30 ml), 0.0375 M sodium metaperiodate (50 ml) was added, and the solution was made up to 100 ml with water. The flask was stored in the dark

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

at 15°, together with solutions of periodate and iodate of the same molarity. At intervals, aliquots (1.0 ml) were removed and diluted to 250 ml with water and periodate was determined spectrophotometrically (29). Periodate consumption reached a constant value of 0.58 moles per mole of anhydrohexose unit after 24 h.

After the oxidation was complete, excess periodate was destroyed by ethylene glycol and the solution was dialyzed. The non-dialyzable material was reduced with potassium borohydride. The resulting polyalcohol (92.5 mg) was hydrolyzed with N H_2SO_4 for 4 h at room temperature (14), and the products were examined by paper chromatography. No oligosaccharides could be detected. Total hydrolysis was then effected with N H_2SO_4 at 100° for 6 h. Paper chromatographic examination of the products indicated the presence of rhamnose, erythritol, glycerol, and a small amount of glucose. A portion of the hydrolysate was reduced with sodium borohydride, and the products were acetylated and examined by g.l.p.c. (8) on the three different columns (A, B, and C). Four peaks were obtained, corresponding to glycerol triacetate, erythritol tetraacetate, rhamnitol pentaacetate, and glucitol hexaacetate. By estimating the areas under the peaks given by the individual components, the following molecular ratio of the polyols was obtained: glycerol, erythritol, rhamnitol, glucitol (1.10:1.05:1.0:0.13).

Methylation of the Polysaccharide

The polysaccharide (5.0 g) was dissolved in water (100 ml) and treated with sodium borohydride (100 mg) for 2 h. Methylation was carried out by additions of dimethyl sulfate and 30% sodium hydroxide (30) on seven successive days. Extraction with chloroform furnished partly methylated polysaccharide (2.68 g). From the residual aqueous solution the remaining polysaccharide material (2.25 g) was recovered and methylated five times more with dimethyl sulfate and sodium hydroxide yielding chloroform soluble methylated polysaccharide (1.32 g).

The combined chloroform soluble material (4.00 g) was methylated four times with Purdie's reagents (31). The syrup obtained was dissolved in a minimum of chloroform and poured into a large excess of petroleum ether to yield a precipitated methylated polysaccharide having methoxyl 32.3%. Two more Purdie methylations did not increase this value. The syrup was dissolved in dimethyl formamide (40 ml) and methyl iodide (20 ml); silver oxide (10 g) was added at intervals, and methylation was conducted according to the method of Kuhn *et al.* (15). An additional Kuhn methylation did not increase the methoxyl content (35.5%) of the petroleum ether insoluble material. Examination by infrared spectroscopy indicated only a very small amount of hydroxyl absorption.

The syrup (3.59 g) obtained from methylation of the polysaccharide was fractionated by dissolving in chloroform and pouring into petroleum ether. The precipitate obtained was designated polysaccharide A (1.127 g). Evaporation of the supernatant gave a syrupy methylated polysaccharide B (1.25 g).

Hydrolysis of Methylated Polysaccharide A

Methylated polysaccharide A (1.127 g), $[\alpha]_D$ +97° (c, 0.49 in $CHCl_3$), OCH_3 35.5%, was hydrolyzed with 72% sulfuric acid (w/w) (30 ml) for 30 min at room temperature and with 12.5% (w/w) sulfuric acid at 100° for 4 h (32). The solution was neutralized and carefully evaporated to a syrup (892 mg). Paper chromatography of the syrup and g.l.p.c. of the derived methyl glycosides indicated 2,3,4,6-tetra-*O*-methyl-glucose, a dimethyl-rhamnose, and 2,3,6-tri-*O*-methyl-glucose as the major components. The methylated sugars were fractionated on cellulose (45 × 3 cm), (i) light petroleum (b.p. 85–100) – butan-1-ol (7:3), saturated with water, (ii) light petroleum – butan-1-ol (4:6) saturated with water, and (iii) butan-1-ol, half saturated with water, being used as eluants to give fractions I–VI. Table III shows the composition of fractions I–III. Composition of the individual fractions was calculated from g.l.p.c. data obtained from their methanolysis products. Since some of the peaks overlapped on certain columns, it was necessary to use mean values from all three columns to determine the molar ratio of each component; these are as follows: 2,3,4,6-tetra-*O*-methyl-D-glucose, 2,4-di-*O*-methyl-L-rhamnose, 2,3,6-tri-*O*-methyl-D-glucose (0.27:1.0:2.2). Almost identical values, 0.24:1.0:2.2, were obtained by g.l.p.c. of the methanolysis products of methylated polysaccharide A.

Isolation and Identification of the Methylated Sugars

Fraction I (123.4 mg) gave on demethylation with boron trichloride (33), glucose and rhamnose. The mixture was separated on thin-layer plates and three fractions were obtained. The fastest moving fraction (50 mg), gave only glucose on demethylation. It had R_g = 1.00 in solvent B and had $[\alpha]_D$ +82° (c, 0.71 in H_2O). The sugar was converted to its anilide which, on recrystallization from ethyl ether – light petroleum, gave white needles m.p. 136°; reported value 137° (34). The m.p. was not depressed on mixing with an authentic sample of *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-glucosylamine. The remainder of fraction I was combined with fraction II.

Fraction II (499.0 mg) on demethylation gave glucose and rhamnose and on paper chromatography gave two unresolved spots in solvent B, R_g 0.89 and R_g 0.84. Fractionation by preparative thin-layer chromatography gave two pure fractions. The faster moving component gave only rhamnose on demethylation. The sugar had R_g 0.89 in solvent B and had 30.0% methoxyl groups compared with a theoretical value of 32.3% for dimethyl-6-deoxy hexose. In borate buffer it had M_g 0.00 and it had $[\alpha]_D$ +12° (c 0.9 in H_2O). Spraying with *p*-anisidine hydrochloride gave a yellow-brown spot. A portion of the syrupy material was

TABLE III

Hydrolysis products from methylated polysaccharide A

Fraction No.	Yield (mg)	Components identified	G.l.p.c. retention times (T_g), sugars examined as methyl glycosides			Composition (mole %)	Relative amount (mg)
			Column A	Column B	Column C		
1	123.4	2,3,4,6-Tetra-*O*-methyl-D-glucose	0.71, 1.00*	0.73, 1.00	0.73, 1.00	45.1	59.4
		2,4-Di-*O*-methyl-L-rhamnose	0.84	0.73	0.50	25.4	27.5
		2,3,6-Tri-*O*-methyl-D-glucose	2.69, 3.64	1.96, 2.49	1.29, 1.68	24.4	30.3
2	499.0	2,4-Di-*O*-methyl-L-rhamnose	0.84	0.73	0.50	32.9	150
		2,3,6-Tri-*O*-methyl-D-glucose	2.69, 3.64	1.96, 2.49	1.29, 1.68	67.1	349
3	74.0	2,3,6-Tri-*O*-methyl-D-glucose	2.69, 3.64	1.96, 2.49	1.29, 1.68	98.0	72.5

*Where two values are given, they refer to the β and α anomers respectively.

converted to the anilide. After recrystallization from light petroleum (b.p. 30–60°), the crystals of *N*-phenyl-2,4-di-*O*-methyl-L-rhamnosylamine had m.p. 138–139° and $[\alpha]_D$ +134° → +4° (equil.) (*c*, 1.00 in ethanol), reported values (35) m.p. 141° and $[\alpha]_D$ +136° → +4° (equil.). The remainder of fraction II was combined with fraction III.

Fraction III weighed 72.5 mg. The syrupy product showed a single spot on paper chromatography, R_g 0.84 in solvent B. Demethylation gave only glucose. The sugar, $[\alpha]_D$ +70° (*c*, 2.28 in H_2O), gave a reddish-brown color with *p*-anisidine hydrochloride. On slow evaporation from ethanol, crystals of 2,3,6-tri-*O*-methyl-D-glucose were obtained, which on recrystallization from absolute ether had m.p. 119–121°, $[\alpha]_D$ +70°; reported values m.p. 121–123° and $[\alpha]_D$ +70° (36). Preparation of the 1,4-di-*p*-nitrobenzoate (36) yielded the crystalline derivative, m.p. 189° (after recrystallization from methanol) and $[\alpha]_D$ −31° (*c*, 1.0 in $CHCl_3$). Reported values are m.p. 189–190° and $[\alpha]_D$ −33° (36).

Fraction IV (54.2 mg) gave a single spot, R_g 0.74 on paper chromatographic examination in solvent B. Demethylation gave only glucose. A small portion was treated with 3% methanolic hydrogen chloride and the products were examined by g.l.p.c. on column B. A number of peaks indicative of lipids were observed; this finding was inconsistent with the paper chromatographic homogeneity of this fraction. The remainder of the fraction was extracted with 50% aqueous methanol, to remove methylated sugars from lipid material. The supernatant gave on evaporation a syrup (15.9 mg), which was shown by g.l.p.c. to contain only one component. From its paper chromatographic mobility and from the retention time of its methyl glycoside on g.l.p.c. this sugar was tentatively identified as 2,3-di-*O*-methyl-glucose.

Fraction V (33.6 mg) was extracted with 50% aqueous methanol giving a component (4.1 mg) which had R_g 0.58 in solvent B and gave a yellowish-brown color with *p*-anisidine hydrochloride (9). Demethylation yielded glucose.

Fraction VI (54.3 mg) after similar treatment gave a methylated sugar (3.4 mg) with chromatographic mobility R_g = 0.47, which yielded only glucose on demethylation.

Lipids from Methylated Polysaccharide A

The aqueous-methanol insoluble residues from fractions IV–VI were combined and found to be readily soluble in chloroform. From infrared spectroscopy and thin-layer chromatographic characteristics, the material was found to comprise a mixture of long-chain, methoxy carboxylic acids. Examination, as methyl esters, by g.l.p.c. (37) showed two isomeric C_{12} hydroxy fatty acids, together with a small amount of hydroxy myristic acid.

Purification of Methylated Polysaccharide B

Methylated polysaccharide B (1.25 g) was found to have a low methoxyl content (ca. 10%) and yet had little OH absorption in the infrared. The syrup was refluxed with methanol overnight, and on cooling an insoluble residue (340 mg) remained. The thin-layer chromatographic behavior of this latter material showed it to be non-polar, and since infrared spectroscopy indicated a mixture of hydrocarbons, it was concluded that it had originated from the light petroleum.

The methanol soluble material was fractionated on a column of silicic acid, using the following elution sequence; hexane, benzene, benzene:ether (1:1), and chloroform:methanol (1:1). The fractions obtained were shown by thin-layer chromatography to consist of two main groups of substances: (*a*) lipid material (325 g) and (*b*) methylated polysaccharide. Infrared spectroscopy of the lipid material indicated a long hydrocarbon chain (bands around 3 000, 1 450, 1 380, and 750 cm^{-1}) with carbalkoxy (1 725 and 1 280 cm^{-1}) and alkoxy (1 120 cm^{-1}) substituents. Examination by g.l.p.c. (37) indicated the presence of the following fatty acids: methoxy myristic, methoxy lauric, and two unidentified acids.

Constitution of Methylated Polysaccharide B

The methylated polysaccharide (326 mg) obtained from the silica column had methoxyl content of 37.25% and $[\alpha]_D$ +37° (*c*, 2.12 in $CHCl_3$). The molecular weight was 1 660 as assessed by vapor phase osmometry using the Mechrolab osmometer. The material moved as a single homogeneous spot on thin-layer chromatography in chloroform:methanol:water (80:20:2). Infrared spectroscopy showed only a small amount of free hydroxyl groups but showed a relatively large peak at 1 640 cm^{-1} and at 1 730 cm^{-1}. The latter are not consistent with a methylated neutral polysaccharide and appear to be due to non-carbohydrate moieties firmly bound to the molecule.

Methylated polysaccharide B (310 mg) was hydrolyzed with 72% sulfuric acid (8.7 ml) for 30 min at room temperature and with 12% acid at 100° for 4 h (32). During the hydrolysis, lipid material was precipitated. The supernatant aqueous solution was neutralized and carefully evaporated to a syrup (178 mg) of partially methylated monosaccharides. Demethylation gave glucose, L-*glycero*-D-*manno*-heptose, and D-*glycero*-D-*manno*-heptose. No rhamnose could be detected in the demethylation products. The methylated sugars were examined by paper chromatography in solvent B. Spots corresponding to 2,3,4,6-tetra-*O*-methyl-glucose (R_g 1.00), 3,4,6,7-tetra-*O*-methyl-D-*glycero*-D-*manno*-heptose (R_g 0.86), 2,3,6-tri-*O*-methyl-glucose (R_g 0.80), and unknown spots with R_g 0.91, 0.70, and 0.35 were obtained. The latter were brownish yellow with *p*-anisidine hydrochloride (9). The spot corresponding to 3,4,6,7-tetra-*O*-methyl-D-*glycero*-D-*manno*-heptose gave a red color with triphenyl tetrazolium spray reagent (38). This spray is specific for sugars with the C_2 position unsubstituted. The same component also moved (M_g 0.28) on paper electrophoresis

in borate buffer. Examination by g.l.p.c. (21) on columns A, B, and C of the methanolysis products from a small sample gave results shown in Table II. (The molar ratios were obtained from the mean values of the areas of the peaks.) Authentic samples of the fully methylated heptoses were obtained by treating a small portion of the heptose with methyl iodide and barium oxide in dimethyl formamide (39). After shaking at room temperature for 24 h, the mixture was extracted with light petroleum and the products were examined by g.l.p.c. in both instances only one peak was observed.

ACKNOWLEDGMENTS

CONSTITUTION OF AN EXTRACELLULAR ACIDIC GLUCOMANNAN FROM SERRATIA MARCESCENS[1]

G. A. ADAMS AND ROBERT YOUNG[2]
Division of Biosciences, National Research Council, Ottawa, Canada
Received June 25, 1965

ABSTRACT

An acidic glucomannan isolated from culture filtrate of *Serratia marcescens* contained D-glucose and D-mannose (3.5:1), D-glucuronic acid (5.5%), and "bound" fatty acids (7.4%). The polysaccharide, on examination by moving boundary electrophoresis and by sedimentation in the ultracentrifuge, was homogeneous. Degree of polymerization was estimated to be ca. 20 by vapor pressure osmometry. Isolation of nigerose (3-*O*-α-D-glucopyranosyl-D-glucopyranose) established the glycosidic linkage between the D-glucose units as α (1 → 3). Methylation and periodate oxidation data showed that the D-glucose and D-mannose units were joined by (1 → 3) linkages in a straight chain structure terminated at the non-reducing end by a unit of D-glucuronic acid which was attached to C_3 of a D-mannose residue. The reducing end of the molecule was terminated by a D-glucose unit. The fatty acids, consisting mainly of hydroxymyristic acid and myristic acid, were attached to the molecule mainly by ester linkages.

Polysaccharides have been isolated from culture filtrates of *Serratia marcescens* and some preliminary studies have been made on their fractionation and composition (1, 2). In a previous study made in this laboratory, the crude polysaccharides were separated primarily on the basis of their solubility in acidified 80% aqueous ethanol solution (3). From the soluble portion, an acidic glucomannan was isolated and an investigation of its chemical structure is reported in this paper.

The acidic glucomannan was homogeneous on moving boundary electrophoresis and on ultracentrifugation. It was isolated in 3.1% yield from the crude extracellular polysaccharides of the culture filtrate and contained D-glucose and D-mannose (3.5:1), and D-glucuronic acid (5.5%). The composition and properties of the polysaccharide are given in Table I.

TABLE I
Composition and properties of polysaccharide

Electrophoretic mobility, u ($cm^2\ s^{-1}\ V^{-1}$)	-8.4×10^{-5}
$[\alpha]_D^{25}$	+60° (c, 1 in H_2O)
Degree of polymerization	20 ± 1
Monosaccharides*	D-Glucose 77.8% D-Mannose 22.2%
Uronic acid	5.5%
Glucosamine	Nil
Lipid	Bound 7.44% Free nil
Nitrogen	1.55%
Nitrogen (protein)	1.55%
Phosphate	Inorganic 0.10% Organic 0.09%

*Calculated as a percentage of the neutral sugar content.

Graded hydrolysis of the polysaccharide yielded three uronic acid components (A, B, and C) which were separated from the neutral sugars by ion-exchange chromatography

For personal use only.

and from each other by paper chromatography. Component A was identified as D-glucuronic acid by gas–liquid partition chromatography (g.l.p.c.) of the derived 2,3,5,6-tetra-*O*-trimethylsilyl-gulono-1,4-lactone (4) and by reduction to glucose. Component B was an aldobiouronic acid composed of D-glucuronic acid and D-mannose, as shown by the finding of equimolar amounts of D-glucose and D-mannose after reduction and hydrolysis of the methyl ester methyl glycoside of the aldobiouronic acid. Component C was an aldotriouronic acid comprising a glucuronic acid residue attached to two mannose units.

Methylation of the disaccharide glucoside derived from the aldobiouronic acid (component B) followed by methanolysis yielded methyl 2,3,4,6-tetra-*O*-methyl-α,β-D-glucosides and methyl 2,4,6-tri-*O*-methyl-α-D-mannoside. Therefore, component B was 3-*O*-(D-glucuronosyl)-D-mannose.

The polysaccharide proved highly refractory to methylation by the Haworth procedure; other methylation procedures were inapplicable because of lack of solubility of the partly methylated polysaccharide in the appropriate solvents. Gradual saponification of fatty acids attached to the polysaccharide by ester linkages may account in part for the slow methylation of the polysaccharide (5). Some fatty acids were found in the acid hydrolysate of the methylated polysaccharide, having apparently survived alkaline hydrolysis during the methylation procedures. Although repeated methylations could not raise the methoxyl content of the polysaccharide to theoretical value, no hydroxyl absorption was present in the infrared spectrum.

The methylated polysaccharide was hydrolyzed and the *O*-methyl sugars and *O*-methyluronic acid were separated by solvent extraction. The methylated sugars were separated quantitatively from each other by paper chromatography and the results are given in Table II. Identification of the individual *O*-methyl sugars was made by preparation of

TABLE II

Methylated sugars from methylated polysaccharide

Methylated sugar	Composition (mole %)
2,4,6-Tri-*O*-methyl-D-glucose	13.5
2,4,6-Tri-*O*-methyl-D-mannose	4.1
2,4-Di-*O*-methyl-D-glucose	1.0

crystalline derivatives and by comparison of retention times of their glycosides on g.l.p.c. with those of authentic samples. Isolation of 2,4,6-tri-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-mannose showed that the polysaccharide had a main chain of D-glucose and D-mannose units joined by $(1 \rightarrow 3)$ glycosidic bonds. The relatively high specific optical rotation of the polysaccharide (+60°) as well as that of its methyl ether (+57°) indicated that most of the glycosidic bonds were in the α configuration. Identification of nigerose, 3-*O*(α-D-glucopyranosyl)-D-glucopyranose, as the main product of partial acid hydrolysis proved the existence of an $\alpha(1 \rightarrow 3)$ linkage between the D-glucose units.

The hydrolysis products from the reduced aldobiouronic acid portion of the methylated polysaccharide were 2,4,6-tri-*O*-methyl-D-mannose and 2,3,4-tri-*O*-methyl-D-glucose. This finding confirmed the earlier conclusion that the D-glucuronic acid was linked to C_3 of a mannose residue in the main chain and also was in a terminal position.

The consumption of periodate (0.24 mole) per anhydrohexose unit showed that most of the hexose residues were resistant to periodate oxidation confirming the existence of

mainly (1 → 3) linkages in the molecule; only the reducing end groups and the D-glucuronic acid would be oxidized.

From the methylation data it is apparent that the polysaccharide consisted of D-glucose and D-mannose units joined in a straight chain to form a glucomannan. The acidic component was a unit of D-glucuronic acid constituting the non-reducing end group and attached to a D-mannose residue. The absence of any tetra-*O*-methyl sugars showed that there were no hexose units in non-reducing terminal positions. The reducing end of the molecule was a D-glucose unit as established by its reduction to sorbitol. The presence of 2,4-di-*O*-methyl-D-glucose in the hydrolysate of the methylated polysaccharide may have been due to incomplete methylation. It did not represent a branch point in the molecule as no corresponding methylated sugars forming end groups were found. The most likely explanation, however, was that some of the fatty acids were attached to the glucose units in the molecule through C_6 and were only removed by acid hydrolysis of the methylated polysaccharide.

Earlier data indicated that the polysaccharide had a degree of polymerization of ca. 20 units (3). Such a molecule, having the structure as described above, would consume 0.23 moles of periodate and yield 0.13 mole of formic acid per sugar unit if no hydrolysis of intermediary esters occurred; experimental values of 0.24 moles of periodate consumed and a yield of 0.11 moles of formic acid are in reasonable agreement with the theoretical values.

Previous studies of the polysaccharides in culture filtrates of *Serratia marcescens* have reported only the sugars found after acid hydrolysis, and little or no fractionation of polysaccharides was attempted (1, 2). Current studies in this laboratory have established the presence of a rhamnoglucan and a heptoglucan, in addition to the described acid glucomannan as extracellular polysaccharides of *Serratia marcescens* (5). Similar, but not identical polysaccharides have also been found as components of the capsular polysaccharides of *Serratia marcescens* (6).

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated, melting points are corrected, and all evaporations were done at 35 °C or less.

Chromatography

Paper chromatograms were run by the descending method on either Whatman No. 1 or No. 3 MM filter paper in the following solvent systems (v/v ratio).

(A) Butan-1-ol:ethanol:water (40:11:19)
(B) Pyridine:ethyl acetate:water (1:2.5:2.5)
(C) Pyridine:ethyl acetate:water (10:4:3)
(D) Ethanol:benzene:water:ammonia (47:200:14:1)
(E) Ethyl acetate:acetic acid:formic acid:water (18:3:1:4)

Neutral sugars were detected on papers by *p*-anisidine hydrochloride (7) or alkaline silver nitrate (8) spray reagents; amino sugars were detected by the Morgan–Elson reagent (9) and by ninhydrin (0.1% in chloroform) and the heptoses by detection of formaldehyde after periodate oxidation (10).

Gas–liquid partition chromatography (g.l.p.c.) was carried out with a Pye argon chromatograph fitted with an ionization detector (^{90}Sr 80 μc) using straight glass columns (120 × 0.5 cm inside diameter) containing the following packings:

(A) 10% w/w Carbowax 6000 on 80–100 mesh acid-washed Chromosorb W (Johns-Manville); operating temperature 155 °C,

(B) 10% w/w neopentyl-glycol sebacate polyester (Applied Science Laboratories) on 80–100 mesh non-acid-washed Chromosorb W (Johns Manville); operating temperature 175 °C,

(C) 15% polyphenyl ether on Gas Chrom A, 100–120 mesh; operating temperature 200 °C,

(D) Apiezon L, 10% on Gas Chrom P; operating temperature 190 °C,

Thin-layer chromatography (t.l.c.) was done on glass plates coated with silica gel G (0.25 mm thickness).

For personal use only.

Developing solvents (v/v) were:
(A) benzene:acetone (1:1),
(B) benzene:methanol (96:4).

Electrophoresis

An aqueous solution of the polysaccharide (1%) was dialyzed against sodium borate solution, 0.05 *M*, pH 9.2 for 48 h at 5 °C. The solution was analyzed in a free boundary apparatus (Spinco model H). Paper electrophoreses were done on Whatman 3MM paper in 0.1 *M* sodium borate solution at a potential gradient of 25 V/cm for 2 h.

Sedimentation

The polysaccharide solutions used in the foregoing free boundary electrophoresis measurements were centrifuged in a Spinco model E ultracentrifuge at 58 780 r.p.m., and the sedimentation pattern was photographed at appropriate time intervals.

Isolation and Properties of Polysaccharides

The isolation procedure was essentially that previously described (3) with some minor refinements added. The starting material was culture filtrate solids (114.5 g ash-free basis), nitrogen 6.04%. The polysaccharide fraction which was soluble in acidified 80% aqueous ethanol solution was recovered by evaporation and dialyzed (28 h, tap water), weight 7.1 g, N 2.18%, and $[\alpha]_D^{25}$ +57° (*c*, 1.0 in water). Purification by a modified Cetavlon – boric acid procedure (11) yielded a main insoluble fraction 3.44 g, N 1.55%. On electrophoresis a single symmetrical peak was observed. Ultracentrifugation showed a main peak with a small faster moving peak ahead of it; the latter had sedimented in 2 h 15 min. The composition and properties of the polysaccharide are given in Table I. Analytical procedures were described in an earlier paper (3), except that for uronic acids which were determined as their 2,3,5,6-tetra-*O*-trimethylsilyl-aldono-1,4-lactone derivatives by gas–liquid chromatography on column B (4).

Isolation of Neutral Sugars and Uronic Acid Components

Polysaccharide (10 g) was heated in *N* sulfuric acid (200 ml) in a boiling water bath for 10 h. After neutralization, barium ions were removed by Amberlite IR-120 and the acidic components were adsorbed on a column of Dowex I (OH^- form). After the neutral sugars were washed off with water, the acids were eluted with *N* sodium hydroxide solution; passage over Amberlite IR-120 removed the sodium ions and the acid fraction (wt. 846 mg) was recovered. Chromatographic examination on paper in solvent E showed three spots: A had the same mobility as glucuronolactone, and the other two spots, B and C, had $R_{glucurone}$ values of 0.35 and 0.14 respectively. The acids were separated on Whatman No. 3 MM paper with solvent E to yield A 46 mg, B 362 mg, and C 15 mg. Component A had $[\alpha]_D^{25}$ +18.5° (*c*, 1 in water), and the sugar obtained by lithium aluminium hydride reduction (12) and acid hydrolysis of its methyl glycoside methyl ester was identified chromatographically (solvent B) as glucose. A portion of the reduced methyl ester methyl glycoside (3 mg) was methylated by the Kuhn procedure (13) and examined by g.l.p.c. on columns A and B. The only peaks observed corresponded to those of authentic methyl 2,3,4,6-tetra-*O*-methyl-α-D-glycoside and 2,3,4,6-tetra-*O*-methyl-β-D-glucoside. The methylated glycosides were subjected to methanolysis (5% methanolic hydrogen chloride, reflux for 6 h) and re-examined by g.l.p.c.; no change was observed, establishing the absence of any aldobiouronic acid in component A.

Component B, 20 mg, $[\alpha]_D^{25}$ +39° (*c*, 1% in water), was let stand in 2% methanolic hydrogen chloride (5 ml) for 48 h at room temperature. The methyl ester methyl glycoside was dissolved in tetrahydrofuran:ethyl ether (4:1) and reduced with lithium aluminium hydride (50 mg) (12). The recovered disaccharide glycoside (13 mg) was hydrolyzed with *N* sulfuric acid, and chromatographic examinations of the hydrolysate in solvents B and C showed glucose and mannose. An additional amount of the disaccharide glycoside (28 mg) was fully methylated (13) and the methylated product was extracted into chloroform. The solvent was removed and the syrup was heated with 4% metholic hydrogen chloride (3 ml) for 7 h at 100 °C. The glycosides were examined by g.l.p.c. on columns A and B. Three peaks were obtained corresponding to authentic samples of methyl 2,3,4,6-tetra-*O*-methyl-β-D-glucoside, methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucoside, and methyl 2,4,6-tri-*O*-methyl-α-D-mannoside. Hence the original methylated disaccharide was 3-*O*-(2,3,4,6-tetra-*O*-methyl-D-glucosyl)-2,4,6-tri-*O*-methyl mannose. Component C (15 mg) was converted to its neutral glycoside as described above and the acid hydrolysate on chromatographic examination (solvents B and C) showed glucose and mannose in a ratio of approximately 1:2.

Methylation

The polysaccharide (5.02 g, N 1.55%) was methylated with dimethyl sulfate and 45% sodium hydroxide (14). After 12 methylations, the methoxyl content was only 17.6% and only 886 mg of the product were soluble in chloroform. Five additional methylations increased the methoxyl content to 21.4%. The methylated product was partly soluble in dimethyl sulfoxide and was methylated by Srivastava's procedure (15) without any appreciable gain in methoxyl content. Insolubility in dimethyl formamide precluded application of the Kuhn methylation method (13). Repeated methylations by the Haworth procedure (14) gave a product (2.72 g) whose methoxyl content could not be increased beyond 34.8%, $[\alpha]_D^{25}$ +53° (*c*, 0.6

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in chloroform). There was no hydroxyl adsorption at 3 500 cm^{-1}. The methylated polysaccharide was dissolved in chloroform (50 ml) and precipitated by the addition of petroleum ether (b.p. 30–60°). One main fraction was recovered, 2.39 g, methoxyl 38.4%, $[\alpha]_D^{25}$ +58.2° (*c*, 1 in chloroform). Methylation by Purdie's procedure (16) did not increase the methoxyl content of this product.

Methanolysis of Methylated Polysaccharide

For preliminary examination of the constituent methyl glycosides by g.l.p.c. a small sample of the methylated polysaccharide was methanolyzed as follows: methylated polysaccharide (19 mg) was heated in a sealed tube with 7% methanolic hydrogen chloride for 12 h at 100 °C. After neutralization (Ag_2CO_3) the recovered glycosides were examined on columns A and B. The peaks were tentatively identified as (1) methyl 2,4,6-tri-*O*-methyl-β-D-glucoside, (2) methyl 2,4,6-tri-*O*-methyl-α-D-mannoside, (3) methyl 2,4,6-tri-*O*-methyl-α-D-glucoside, and (4) methyl di-*O*-methyl glucoside.

Acid Hydrolysis of Methylated Polysaccharide

The methylated polysaccharide (2.3 g) was dissolved by stirring for 60 min in 72% sulfuric acid at room temperature (17). The acid solution was then diluted with water to 12.5% and refluxed for 4 h. The solution was neutralized with barium carbonate and barium hydroxide and heated at 65 °C for 1 h. After filtration, the clear solution was extracted with ethyl acetate for 96 h to remove neutral methylated sugars (fraction I 0.5940 g). The aqueous solution was acidified with *N* sulfuric acid to pH 2.0, and extraction with ethyl acetate was continued for a further 96 h to give fraction II (0.5506 g). The aqueous solution was neutralized with barium hydroxide and filtered, and the solids were recovered by freeze-drying (fraction III 0.2667 g). Chromatographic examination (solvent D) showed that fraction I contained only methylated sugars; fraction II contained methylated sugars and methylated uronic acid components and fraction III contained methylated uronic acids and a trace of a dimethyl glucose. The components of fraction II and III were completely separated on sheets of Whatman 3 MM paper using solvent D into neutral methylated sugars and methylated uronic acids. Purified materials were combined to yield methylated sugars (912 mg) and methylated uronic acids (305 mg).

Separation of Neutral Sugars

The mixture (900 mg) was separated on Whatman No. 1 paper using solvent D. Three fractions were obtained (1) trimethyl glucose, (2) trimethyl mannose, and (3) dimethyl glucose. Since fractions 1 and 2 were not completely free of each other and also of debris from the filter paper they were further purified by t.l.c. using solvent A and three 40 min development periods. The appropriate pure sugars were combined to yield (1) trimethyl-glucose (390 mg), (2) trimethyl-mannose (121 mg), and dimethyl-glucose (28 mg).

Identification of Methylated Sugars

2,4,6-Tri-O-methyl-D-glucose

This sugar yielded only glucose on demethylation with boron trichloride (18). On paper chromatograms it gave the same bright red color with *p*-anisidine spray and the same R_g values (0.47 in solvent C and 0.86 in solvent A) as 2,4,6-tri-*O*-methyl-D-glucose. The syrup crystallized readily and after recrystallization from ethyl ether had m.p. and mixed m.p. 123–125 °C, $[\alpha]_D^{25}$ +71° (*c*, 1.0 in water). Anilide formation yielded *N*-phenyl-2,4,6-tri-*O*-methyl-D-glucosylamine, m.p. 162–165° C (19). Examination of the methyl glycoside of this sugar by g.l.p.c. on column B gave 2 peaks which had the same retention times as authentic samples of methyl 2,4,6-tri-*O*-methyl-β-D-glucoside and methyl 2,4,6-tri-*O*-methyl-α-D-glucoside.

2,4,6-Tri-O-methyl-D-mannose

On demethylation with boron trichloride this sugar gave only mannose. Its R_g 0.61 (solvent D) and M_g 0.0 in borate buffer were in agreement with those of an authentic sample of 2,4,6-tri-*O*-methyl-D-mannose. On seeding, the syrup crystallized and after recrystallization from ethyl ether had m.p. 62–65° and $[\alpha]_D^{25}$ +17° (*c*, 1 in water) (20). The anilide, after recrystallization from ethyl ether had m.p. and mixed m.p. 132 °C and $[\alpha]_D^{25}$ +7.6° (*c*, 0.5 in methanol) in good agreement with the reported values (21). Gas liquid chromatography of the methyl glycoside on column B and column C gave one peak corresponding to that of authentic methyl 2,4,6-tri-*O*-methyl-α-D-mannoside.

2,4-Di-O-methyl-D-glucose

This sugar (28 mg) gave only glucose on demethylation. On paper chromatograms it had the same R_g values in solvents A and D as 2,4-di-*O*-methyl-D-glucose. It had no mobility in borate buffer on electrophoresis and gave a negative reaction with triphenyltetrazolium chloride (22, 23) and periodate–benzidene spray (24). The sample was converted to its methyl glucoside by refluxing with 2% methanolic hydrogen chloride for 5 h. The glycosides were separated by g.l.p.c. on column C into 2 peaks which had the same retention times as authentic methyl 2,4-di-*O*-methyl-α-D-glucoside and methyl 2,4-di-*O*-methyl-β-D-glucoside.

Identification of Methylated Uronic Acids

A sample of the methylated uronic acid fraction (Ba salt) was examined on paper chromatograms using solvent E and showed four components having R_g values of 0.87, 0.67, 0.50, and 0.25 respectively. These were separated by filter paper chromatography using solvent E to yield fractions I (34 mg), II (28 mg), III (103 mg), and IV (80 mg). Small samples (10 mg) of each fraction were converted to their methyl ester

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

methyl glycosides by heating with 2% methanolic hydrogen chloride (1 ml) at 100 °C in a sealed tube for 6 h. Reduction with lithium aluminium hydride (25 mg) in tetrahydrofuran (30 ml) yielded methyl glycosides, portions of which were hydrolyzed by heating for 12 h at 100 °C with *N* sulfuric acid. Chromatographic examination of the sugars in solvent D showed one spot R_g 0.64 from fraction IV, and 2 spots R_g 0.64 and 0.61 respectively from fractions I, II, and III. These R_g values corresponded to those for 2,4,6-tri-*O*-methyl-D-mannose (R_g 0.61) and 2,3,4-tri-*O*-methyl-D-glucose (R_g 0.64). Portions of the methyl glycosides of these sugars were examined by g.l.p.c. on column B and column C. Methyl 2,4,6-tri-*O*-methyl-α-D-mannoside, methyl 2,3,4-tri-*O*-methyl-β-D-glucoside, and methyl 2,3,4-tri-*O*-methyl-α-D-glucoside were found and their identity confirmed by chromatography of authentic samples of these glycosides under the same conditions.

The remaining quantities of fractions III and IV were converted to their methyl ester methyl glycosides and reduced with lithium aluminium hydride to the corresponding disaccharide methyl glycoside and methyl glycoside respectively. The glycosides were hydrolyzed to their free sugars with *N* sulfuric acid. Fraction IV yielded only 2,3,4-tri-*O*-methyl-D-glucose and fraction III a mixture of 2,3,4-tri-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-mannose. The mixture was separated on paper sheets using solvent D and the sugar was identified as follows.

2,4,6-Tri-O-methyl-D-mannose

On paper chromatograms using solvents A and D, this sugar had the same R_g values as an authentic sample of 2,4,6-tri-*O*-methyl-D-mannose. Refluxing an ethanolic solution of the sugar with aniline yielded the crystalline anilide which on recrystallization from ethyl ether gave *N*-phenyl-2,4,6-tri-*O*-methyl-D-mannosylamine, m.p. 132 °C and $[\alpha]_D^{25}$ +7.3° (*c*, 0.4 in methanol) in good agreement with reported values (21).

2,3,4-Tri-O-methyl-D-glucose

This syrup gave the same color with *p*-anisidine hydrochloride and had the same mobility on paper chromatograms in solvents A and D as an authentic sample of 2,3,4-tri-*O*-methyl-D-glucose. The crystalline anilide, *N*-phenyl-2,3,4-tri-*O*-methyl-D-glucosylamine, had m.p. 145° C and $[\alpha]_D^{25}$ +72° (*c*, 1.0 in ethanol (25).

Partial Hydrolysis of Polysaccharide

The optimal conditions for maximum production of di- and tri-saccharides were found to be as follows: polysaccharide (1.0 g) was dissolved in *N* sulfuric acid and heated in a glass pressure bottle for 15 h at 70 °C. After neutralization with barium hydroxide and filtration of the solution, a syrup (674 mg) was recovered. Chromatographic examination on paper (solvent B and C) showed glucose, mannose, a spot having the same mobility as nigerose ($R_{maltose}$ 1.13) and several unidentified spots. Impure nigerose (80 mg) was recovered by preparative chromatography on sheets of Whatman No. 1 paper and after extraction with methanol yielded 69 mg of chromatographically pure product. Complete acid hydrolysis yielded only glucose.

Nigerose Octaacetate

A portion of the syrup (50 mg) was acetylated with acetic anhydride (2 ml) containing sodium acetate (30 mg) by refluxing for 1 h. The cooled solution was poured into ice water (100 ml) and extracted with chloroform (4 × 30 ml). The chloroform extract was washed with saturated sodium bicarbonate solution, dried with anhydrous sodium sulfate and concentrated to a syrup (28.1 mg). Preparative thin-layer chromatography (solvent B) yielded a pure sample of β-nigerose octaacetate (18 mg). Recrystallization from ethanol yielded β-nigerose octaacetate, m.p. 150–151 °C, $[\alpha]_D^{25}$ +77° (*c*, 0.9 in chloroform) in good agreement with reported values (26).

Periodate Oxidation

The polysaccharide (100.2, 100.1 mg) was dissolved in water (50 ml) and oxidized by 0.1 *M* sodium periodate at 5 °C in the dark; at intervals, aliquots were removed for estimation of periodate consumption (27) and formic acid production (28). The results expressed in moles per mole of anhydroglucose were as follows:

Time (hours)	Formic acid produced	Periodate consumed
48	0.07	0.22
69	0.07	0.24
92	0.09	0.24
121	0.10	0.245
144	0.11	0.26
168	0.12	0.28

Lipid Determination

"Free" lipids in the polysaccharide were extracted with water:chloroform:methanol as previously described (29). "Bound" lipids were determined in the residue by hydrolyzing for 2 h at 100 °C with 6 *N* hydrochloric acid followed by extraction of the released fatty acids with petroleum ether (b.p. 30–60):ethyl ether (1:1). The fatty acids were dried *in vacuo* to constant weight, converted to their methyl esters (16),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and identified by g.l.p.c. on column D. The fatty acids (7.44%) were identified as hydroxy myristic acid, myristic acid, lauric acid, hydroxy lauric acid, palmitic acid, palmitoleic acid, oleic acid, and stearic acid (in approximate order of amounts found).

Identity of Sugar Forming Reducing End of the Polysaccharide

Polysaccharide (10 mg) was dissolved in water (1 ml) and reduced with sodium borohydride (20 mg) over a period of 2 h. The solution was neutralized with acetic acid and passed over a column of Amberlite IR-120, and the borate was removed by repeated distillation with methanol. The reduced polysaccharide was hydrolyzed with *N* sulfuric acid for 12 h at 100 °C. After neutralization of the acid with barium carbonate, the sugars were oxidized by *N* iodine (4 ml) and *N* sodium hydroxide (6 ml) for 24 h at room temperature. The acidic components were removed with Amberlite IR-4B and the hexitol was recovered as a syrup. Chromatographic examination of the hexitol in solvent C with mannitol (R_{glu} 0.97) and sorbitol (R_{glu} 0.92) as references showed that it was sorbitol.

ON THE RELATIONSHIP BETWEEN EQUILIBRIUM PRESSURES AND THE PHASE DIAGRAM OF A REACTIVE SYSTEM

THE SYSTEMS: $NaCl–Na_2ZrCl_6$, $KCl–K_2ZrCl_6$, $NaCl–KCl–ZrCl_4$

R. L. LISTER[1] AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario

Received February 5, 1965

ABSTRACT

The binary equilibrium phase diagrams for the systems $NaCl–Na_2ZrCl_6$ and $KCl–K_2ZrCl$ were established from the combined results of cooling curve and vapor pressure measurements. A portion of the ternary $NaCl–KCl–ZrCl_4$ has also been determined. Vapor pressure measurements on the two pure compounds, Na_2ZrCl_6 and K_2ZrCl_6, as well as on mixtures with the respective alkali metal chlorides, were taken. The vapor-producing reaction is given as

$$M_2ZrCl_6 = 2MCl + ZrCl_{4(v)}$$

where M represents, respectively, sodium and potassium.

Thermodynamic relationships relating the phase diagram to the measured equilibrium pressures have been developed. The classical shape of the pressure–temperature curves, even for the pure compound, as well as mixtures of the two components, indicates a dependency on liquidus and eutectic melting. Vapor pressure measurements were also carried out over that composition of the ternary which could be of interest for the recovery of zirconium metal by fused salt electrolysis. From these data, the activities and the other partial molar properties of the components in solution were calculated for both the M_2ZrCl_6 and $ZrCl_4$ species.

INTRODUCTION

Zirconium tetrachloride vapor has been found (1) to react directly with solid alkali metal chlorides and to form complex compounds of the general formula M_2ZrCl_6. These compounds represent stabilized forms of the highly volatile zirconium tetrachloride, and could be considered as potential electrolytes for the recovery of zirconium metal by fused salt electrolysis. The problem of solubility of $ZrCl_4$ in alkali chloride melts may be explained in terms of compound formation, and the thermal stability of these solutions may be directly related to the decomposition pressures of $ZrCl_4$ vapor. The complexes of the type M_2ZrCl_6 have also been shown to exist as congruently melting compounds in phase diagram studies by both Howell *et al.* (2) and Morozov and In'Chzhu (3). The former have determined the phase diagram between NaCl and Na_2ZrCl_6, while the latter have investigated the system $KCl–K_2ZrCl_6$. Morozov and In'Chzu (4) have also investigated the thermal stability of the pure compounds Na_2ZrCl_6, K_2ZrCl_6, and Cs_2ZrCl_6 by transportation vapor pressure measurements.

In the present study, the binary equilibrium phase diagrams for the systems $NaCl–Na_2ZrCl_6$ and $KCl–K_2ZrCl_6$ have been determined with accuracy by the cooling curve technique, as well as from vapor pressure measurements (1). The vapor pressures of $ZrCl_4$ in equilibrium with various compositions across the systems $NaCl–Na_2ZrCl_6$ and $KCl–K_2ZrCl_6$ were also investigated at various temperatures. A portion of the ternary diagram of the system $NaCl–KCl–ZrCl_4$ has been defined, and vapor pressure measurements over the low melting region, i.e., that concentration range which would be considered for electrodeposition of zirconium metal, have been made.

From the results, activities and other partial molar properties of the component salts in their molten solutions have been calculated. It is shown that the thermodynamic

[1]*Present address: National Lead Company, Research Laboratory, P.O. Box 58, South Amboy, New Jersey 08879, U.S.A.*

information obtained from reaction pressure measurements is severely restricted by eutectic and liquidus melting. Accordingly, such measurements can be interpreted only in relation to the phase diagram of the system.

THERMODYNAMIC RELATIONSHIPS

In a simple phase diagram representing the binary system MCl–M_2ZrCl_6, there are four temperature–composition zones of interest (shown in Fig. 1).

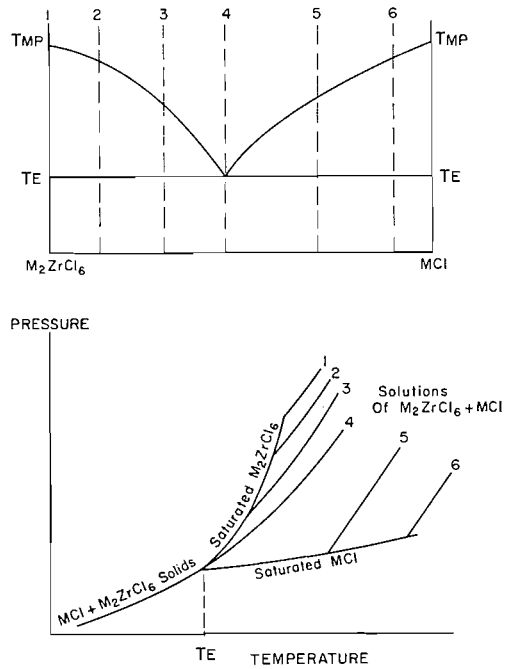

FIG. 1. Predicted pressure versus temperatures curves.

The first includes all compositions and temperatures below the eutectic tieline. In this area, the phases present are: pure solids M_2ZrCl_6 and MCl, and a vapor phase of $ZrCl_4$.

The decomposition reaction may be represented as

$$M_2ZrCl_{6(s)} = 2MCl_{(s)} + ZrCl_{4(v)}$$

and the equilibrium constant for this reaction is

[1] $$K_{eq} = \frac{a_{MCl}^2 f_{ZrCl_4}}{a_{M_2ZrCl_6}}$$

where a_{MCl} and $a_{M_2ZrCl_6}$ are the activities of MCl and M_2ZrCl_6, respectively, and f is the fugacity of $ZrCl_4$ vapor. For all practical purposes, the vapor may be considered as an ideal gas at low pressures, and therefore its fugacity may be taken equal to its pressure. The state of unit activity for the condensed phases shall be defined as the pure solid compounds at all temperatures. For the vapor phase, the standard state is chosen as zirconium tetrachloride vapor at 1 atm. Therefore, in this range,

[2] $$K_{eq} = P_{ZrCl_4}$$

since $a_{MCl} = 1$, and $a_{M_2ZrCl_6} = 1$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The variation of the equilibrium constant with temperature is given by the well-known van't Hoff relationship

$$[3] \qquad \frac{\mathrm{d} \ln K_{eq}}{\mathrm{d}\left(\frac{1}{T}\right)} = \frac{-\Delta H_r^0}{R}$$

or by its equivalent

$$[4] \qquad \frac{\mathrm{d} \ln P_{ZrCl_4}}{\mathrm{d}\left(\frac{1}{T}\right)} = \frac{-\Delta H_r^0}{R}$$

where P_{ZrCl_4} is the measured reaction pressure of $ZrCl_4$ in equilibrium with the pure solids M_2ZrCl_6 and MCl at any temperature below the eutectic, and ΔH_r^0 is the standard heat of the decomposition reaction.

From eqs. [2] and [4] it can be seen that the pressure exerted over the system corresponds to the decomposition of pure solid M_2ZrCl_6 and will be equal to the thermodynamic equilibrium constant K_{eq}. Over a limited temperature range, the plot of log P (mm) vs. $1/T$ (°K) should therefore exist as a straight line relationship. Pressure measurements in this range are independent of the composition of the mixtures, and therefore all mixtures should be represented by a single vapor pressure curve. Equation [2] is valid only in the case of negligible or no solid-solubility of the pure materials. If, however, a degree of solid-solubility exists, the equilibrium constant would then include the activities of the solid components in their solutions.

The second zone of interest includes all compositions of the M_2ZrCl_6 side of the eutectic, defined by the corresponding eutectic and liquidus tielines. In this range, the solutions of MCl and M_2ZrCl_6 are saturated with respect to M_2ZrCl_6. The phases present are a solution of the liquidus composition, pure solid M_2ZrCl_6, and a vapor phase of $ZrCl_4$ in equilibrium, according to the reaction

$$M_2ZrCl_{6(s)} = 2MCl_{(sol)} + ZrCl_{4(v)}.$$

In this range, $M_2ZrCl_{6(s)} \rightleftharpoons M_2ZrCl_{6(\text{in sol})}$, and accordingly, $a_{M_2ZrCl_6} = 1$. Therefore,

$$[5] \qquad K_{eq} = P_{ZrCl_4} a_{MCl}^2$$

or,

$$[6] \qquad P_{ZrCl_4} = \frac{K_{eq}}{a_{MCl}^2}$$

where K_{eq} represents the equilibrium constant at that temperature. For calculations, the equilibrium constant obtained from measurements below the eutectic may be expressed as a function of temperature, and then extrapolated to the desired temperature.

From eq. [6], it may be seen that the temperature–pressure curve will change slope at the eutectic temperature because of the introduction of the activity of MCl, which is less than unit in these solutions. The predicted shape of the pressure–temperature curves is shown in Fig. 1. As the temperature is further increased beyond the eutectic temperature, the composition of the solution in equilibrium with the pure solid changes, following the liquid solubility line, and, therefore, the activity of MCl will be changing continuously. The activity of the MCl does not depend upon the composition of the mixture, but rather

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

on the composition of the saturated solution, which is temperature dependent. At any specific temperature in this composition range, the pressure of zirconium tetrachloride exerted by any two different compositions will be identical, and there should be one common pressure curve for all compositions.

This brings to light a rather important conclusion which has been neglected in the interpretation of reaction pressure measurements done in the past. Free energies of formation of pure compounds can be obtained only at temperatures below the corresponding eutectic temperature, as this is the only range where the thermodynamic equilibrium constant may be equated to a reaction pressure. For example: when measuring the reaction pressures of *pure* M_2ZrCl_6, some free alkali metal chloride will always be produced because of its decomposition. Measurements taken at temperatures higher than the corresponding eutectic of the MCl–M_2ZrCl_6 binary system would therefore represent saturated solutions of liquidus composition. It is evident that the thermodynamic properties of the *pure* compound cannot be obtained in this range; instead, the data may be used to calculate the partial molar properties of the solutions.

Differentiation of the logarithm of eq. [7] with respect to $1/T$ gives

$$[7] \qquad \frac{\mathrm{d} \ln P_{ZrCl_4}}{\mathrm{d}\left(\frac{1}{T}\right)} = \frac{\mathrm{d} \ln K_{eq}}{\mathrm{d}\left(\frac{1}{T}\right)} - \frac{2\,\mathrm{d} \ln a_{MCl}}{d\left(\frac{1}{T}\right)}$$

where the temperature dependence of the activity is given by

$$\frac{\mathrm{d} \ln a_{MCl}}{\mathrm{d}\left(\frac{1}{T}\right)} = \frac{(\overline{\Delta H}_m)_{MCl}}{R}.$$

Equation [7] may now be expressed as

$$[8] \qquad \frac{\mathrm{d} \ln P_{ZrCl_4}}{\mathrm{d}\left(\frac{1}{T}\right)} = -\frac{\Delta H_r^0 + 2(\overline{\Delta H}_m)_{MCl}}{R} = -\frac{\Delta H_r'}{R}, \text{ or}$$

$$[9] \qquad \Delta H_r' = \Delta H_r^0 + 2(\overline{\Delta H}_m)_{MCl}.$$

The latter represents the heat term obtained from the log P_{ZrCl_4} vs. $1/T$ plot and, therefore, the temperature dependence of the pressures in the temperature range previously defined. The heat term $\Delta H_r'$ shown in this equation depends upon the heat of the standard reaction at the given temperature, and the partial molar heat of mixing of the MCl in a solution of the liquidus composition. The ΔH_r^0 term is expected to be temperature dependent, while the partial molar heat of mixing is, in the general case, both temperature and composition dependent. If the temperature dependency over a small temperature range is neglected, then the slope of the log P_{ZrCl_4} vs. $1/T$ curve will change only as the $(\overline{\Delta H}_m)_{MCl}$ changes with composition.

If the solution is ideal, then the heat of mixing with respect to the solid standard state would be only the heat of fusion. Therefore, it would be expected that the log P_{ZrCl_4} vs. $1/T$ curve should change slope at the eutectic temperature, even when the solutions are ideal.

The third zone of interest is represented by the MCl-rich side of the eutectic, and all temperatures below the liquidus but above the eutectic. The equilibrium in this involves

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the $ZrCl_4$ vapor phase and a solution of MCl and M_2ZrCl_6 saturated with respect to MCl. The equation governing the decomposition reaction in this range is

$$M_2ZrCl_{6(sol)} = 2MCl_{(s)} + ZrCl_{4(v)}$$

for which

$$K_{eq} = \frac{P_{ZrCl_4}}{a_{M_2ZrCl_6}}$$

and

$$[10] \qquad \frac{d \ln P_{ZrCl_4}}{d\left(\frac{1}{T}\right)} = -\frac{\Delta H_r^0 - (\overline{\Delta H}_m)_{M_2ZrCl_6}}{R} = -\frac{\Delta H_r'''}{R}$$

$$[11] \qquad \Delta H_r''' = \Delta H_r^0 - (\overline{\Delta H}_m)_{M_2ZrCl_6}.$$

For a given mixture of this composition, increasing the temperature to that above the eutectic would cause a change in slope of the log P vs. $1/T$ plot because of the introduction of the activity of the M_2ZrCl_6 component in solution. Again the predicted shape of the curves on this side of the phase diagram may be seen in Fig. 1. All compositions of this range are represented by a common vapor pressure curve, the curvature of which would depend upon the deviations of the solutions from ideality.

Finally, the fourth zone of interest includes all compositions at temperatures above the liquidus solubility lines. In this area, the system is described by homogeneous solutions of MCl and M_2ZrCl_6 and a vapor phase of $ZrCl_4$. The decomposition reaction is

$$M_2ZrCl_{6(sol)} = 2MCl_{(sol)} + ZrCl_{4(v)}$$

for which the equilibrium constant is given by

$$[12] \qquad K_{eq} = \frac{P_{ZrCl_4} a_{MCl}^2}{a_{M_2ZrCl_6}}$$

Following the same treatment as before, we obtain

$$[13] \qquad \frac{d \ln P_{ZrCl_4}}{d\left(\frac{1}{T}\right)} = -\frac{\Delta H_r^0 - (\overline{\Delta H}_m)_{M_2ZrCl_6} + 2(\overline{\Delta H}_m)_{MCl}}{R}$$

where

$$[14] \qquad \Delta H_r'' = \Delta H_r^0 + 2(\overline{\Delta H}_m)_{MCl} - (\overline{\Delta H}_m)_{M_2ZrCl_6}.$$

In the liquid region, the partial molar heat of mixing terms correspond to solutions of fixed composition, and their temperature dependence will be due only to a change of the heat capacities, which are either very small or give a negligible contribution over a limited temperature range. Therefore, the plot of log P vs. $1/T$ will again become linear, and the slope of the curve should give a heat term that includes all the heats in this equation. When crossing the liquid solubility line upon increasing temperature, the pressure curve will again undergo a change in slope because of the introduction of the activity of the other component, as may be seen in Fig. 1. It is seen that the pressure temperature curve should change slope at the eutectic and the liquidus temperatures; accordingly, it should be possible to construct the phase of the system from vapor pressure measurements.

EXPERIMENTAL

The sodium and potassium hexachlorozirconates were prepared by the direct reaction of the solid alkali metal chlorides with zirconium tetrachloride vapor at 1 atm (1). The sodium and potassium chlorides were of reagent grade and were vacuum degassed at about 400 °C to remove any traces of water. The zirconium tetrachloride was of reactor grade, purified by triple distillation in the presence of copper filings. A quantitative analysis on the hexachlorozirconates produced indicated a mole ratio of $MCl/ZrCl_4 = 2.00 \pm 0.01$ and further identification was made by the X-ray diffraction patterns (1).

The apparatus used for the phase diagram study consisted of a closed-end tube furnace, powered by a voltage-stabilized variac. The variac could be turned down by a variable speed eccentric drive, thus allowing for various uniform linear cooling rates. The furnace was wound noninductively to eliminate the possibility of induced currents in the thermocouples.

The temperature measurements were made using 22-gauge chromel–alumel thermocouples, calibrated against a platinum – platinum rhodium standard. The thermocouple tips were cut as small as possible to increase their response to the temperature fluctuations. When the furnace was at thermal equilibrium, the temperature was recorded with the current both on and off to determine if the net currents induced by the windings affected the thermocouple readings; no difference was observed. Temperature measurements were recorded continuously on a 1 mV full scale deflection recorder, and were intermittently checked by a potentiometer.

The mixture to be studied was introduced into a heart-shaped ampoule, and evacuated while being heated to 160 °C. The cell was then vacuum sealed, loaded into the furnace, and heated to the desired temperature. The initial cooling rate was rapid, usually about 2 deg per minute, and was of importance only to obtain the approximate positions of the inflections and plateaux which occurred for the material. This was followed by a series of cooling curves taken using rates of cooling of between 3/4 to $1\frac{1}{4}$ deg per minute. During the cooling cycle, the cells were periodically shaken to assure a uniform temperature in the melt and minimize supercooling.

A static method was used for the vapor pressure measurements, the apparatus for which is shown in Fig. 2. It consists of the following major sections: the furnace heating the reaction cell, the vacuum system, and the heated air bath. To obtain a constant temperature zone, a heavily insulated tubular furnace, 25 in. long with a 10 in. internal diameter, was used. The wiring consisted of one continuous coil over the whole length of the inner tube, and three equal resistance coils superimposed on this, each independently controlled by a variac. The power was supplied through a voltage stabilizer and with a fairly constant room temperature, a steady state heat flow gave an excellent temperature control of ±0.50 deg for long periods of time over the middle 6 in. of the furnace.

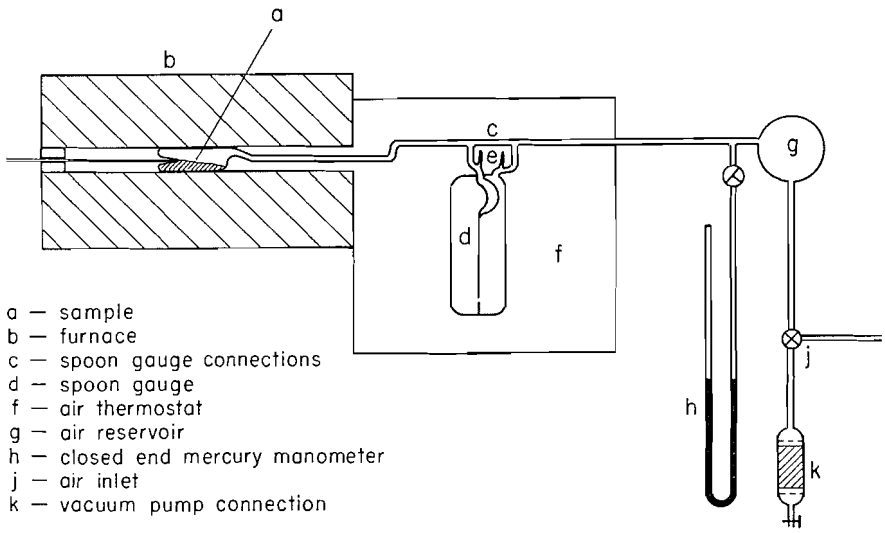

FIG. 2. Pressure measurements apparatus.

The reaction cell was constructed of quartz and was connected to a quartz spoon gauge. The external part of the gauge was connected to a manometer and two-way stopcock. To allow for evacuation of the system, a bypass of the spoon gauge was made which was later sealed under vacuum. The spoon gauge

was made totally of quartz and acted as a null point detector, while keeping the corrosive zirconium tetrachloride vapor separated from the mercury in the closed-end manometer. The sensitivity of the spoon gauge was such that pressure differences of better than $\frac{1}{2}$ mm could be easily detected.

To prevent condensation of zirconium tetrachloride vapor, the spoon gauge and cell connections were heated in an air furnace to a temperature above the dew point of zirconium tetrachloride. The air furnace was heavily insulated and thermally controlled at 390 ± 15 °C.

The approximate volume of the reaction cell, spoon, and connecting glass tubing was determined, and at all times this volume was maintained at a low level, so that with a large amount of material in the cell, only a small amount of $ZrCl_4$ vapor would be required to fill the cell volume. To determine the true compositions of the mixtures in the cell, approximate corrections were made to allow for the amount of $ZrCl_4$ in the vapor phase at the various temperatures.

Various compositions of alkali metal chlorides and hexachlorozirconates were transferred to the quartz cell in a dry box, and the cell was then flame sealed to the system. The system was evacuated while increasing the temperature to between 160 and 180 °C, and evacuation continued at this temperature for at least 3 h, so that all traces of water vapor in the apparatus could be removed.

The hot box was then cooled, the bypass constriction sealed, the hot box heated to the required temperature, and the vapor pressure measurements initiated. After the temperature had remained constant for the desired length of time, e.g. 5 h for vapor pressure readings of less than 400 mm and 3 h for readings above 400 mm, the spoon gauge pointer was adjusted to null by alternately evacuating and introducing air into the external part of the spoon gauge. To prevent breakage of the gauge, the pointer was kept at about the null position at all times. To determine the equilibrium pressure versus temperature curve, readings were taken on both increasing and decreasing temperature cycles.

Initially, the pressure runs were made on the pure hexachlorozirconates. This was followed by a series of runs using mixtures of the pure hexachlorozirconates and their respective alkali metal chlorides, so that the effect on the pressure curves due to the change of composition over the entire range from pure hexachlorozirconate to alkali metal chloride could be observed. These mixtures were made by weighing the reaction cell before and after the addition of each of the two components in a dry box. Similarly, a few runs were made in the ternary $NaCl–KCl–ZrCl_4$ system, for the purpose of determining the pressure at temperatures and compositions suitable for fused salt electrolysis.

Zirconium tetrachloride vapor has been shown to be unimolecular in the vapor phase by the work of Fisher and Rahlfs (5), and Spiridonov *et al.* (6). Therefore, the pressures measured represent the thermodynamic pressure of the $ZrCl_4$ species over the systems.

RESULTS

Phase Diagram Determination

Figure 3 represents the binary equilibrium phase diagram for the system $NaCl–Na_2ZrCl_6$. This diagram was compiled with the information obtained from cryoscopic measurements and supplemented by liquidus points obtained from the vapor pressure curves. It can be seen that the results for the liquidus obtained from the vapor pressure measurements agree quite well with those obtained by the cooling curve technique. In Fig. 3, the results obtained by Howell *et al.* (2) were recalculated to correspond to the $NaCl–Na_2ZrCl_6$ scale, and are included for comparison.

No accurate data for the NaCl side of the eutectic were given. The present work indicates the same eutectic temperature of 548 °C, but the liquid solubility lines are shifted slightly. The melting point of the Na_2ZrCl_6 in both cases was found to be 646 ± 1 °C. This work has shown the eutectic to be at 61.50 mole % Na_2ZrCl_6.

Figure 4 represents the binary equilibrium phase diagram for the system $KCl–K_2ZrCl_6$ obtained in the same manner. The results of Morozov and In'Chzhu (3) are also included for comparative purposes, and indicate a large discrepancy in the position of the liquid solubility lines. The latter found a eutectic which occurred at 47 mole % K_2ZrCl_6, and 594 °C. This work has shown the eutectic to be at the same temperature, but at 40.00 mole % K_2ZrCl_6. The melting point of K_2ZrCl_6 was determined at 799 ± 2 °C.

X-ray diffractometer measurements made on dilute solutions rapidly quenched from above the eutectic temperatures indicated no evidence of solid solubility in either system: $NaCl–Na_2ZrCl_6$ or $KCl-K_2ZrCl_6$.

Figure 5 represents the 600 °C and 540 °C isotherms for the system $NaCl–KCl–ZrCl_4$

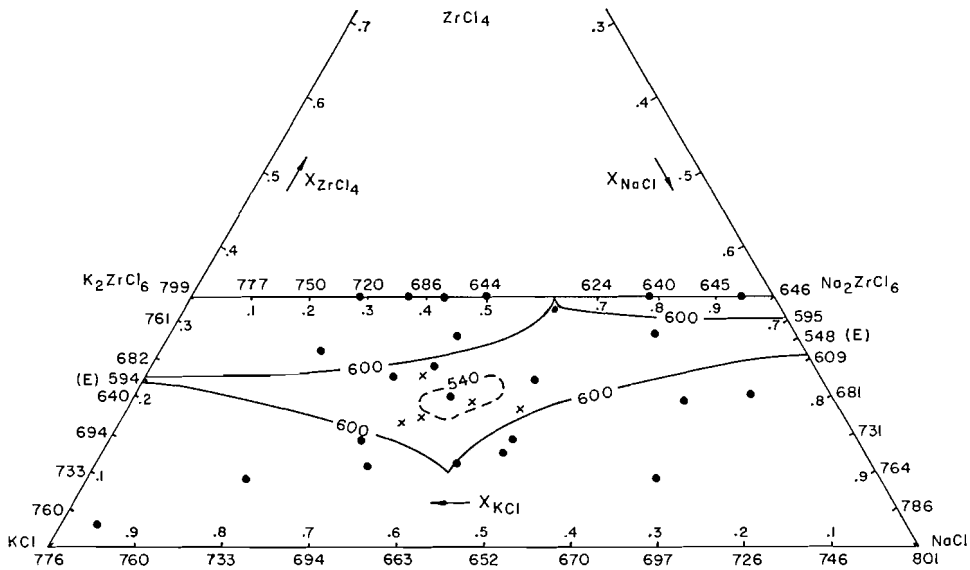

FIG. 5. The 540 °C and 600 °C isothermal surfaces in the KCl–NaCl–$ZrCl_4$ ternary system.

in the dilute $ZrCl_4$ range. It appears that the ternary eutectic occurs at 513 ± 3 °C, with the approximate composition 36 mole % NaCl, 20 mole % $ZrCl_4$, and 44 mole % KCl. The solid circles represent the points obtained, by cooling curves, while the ×'s represent the compositions where vapor pressure measurements have been made.

Vapor Pressure Measurements

The equilibrium vapor pressures of zirconium tetrachloride over the two pure components Na_2ZrCl_6 and K_2ZrCl_6, respectively, were measured. Various compositions of MCl and M_2ZrCl_6 were also investigated according to the decomposition reaction

$$M_2ZrCl_{6(s,l,sol)} = 2MCl_{(s,l,sol)} + ZrCl_{4(v)}$$

where the M_2ZrCl_6 and MCl are in the solid, liquid, or solution states, depending upon the composition and temperature at which the investigation was carried out.

Figure 6 represents the $\log P$ vs. $1/T$ plots for the various compositions over the system NaCl–Na_2ZrCl_6. Curve 1 represents the vapor pressure curve of solutions of NaCl and Na_2ZrCl_6 saturated with respect to Na_2ZrCl_6. The pressure curves for all systems follow curve 1, up to the liquidus temperature and then change slope; therefore, the intersections of curve 1 with the curves 2, 3, 4, and 5 occur at the liquid temperatures for the respective compositions, as shown in Fig. 6. These points have also been included in Fig. 3, as liquidus temperatures determined by vapor pressure measurements. Curves 2, 3, 4, and 5 represent the pressures of $ZrCl_4$ vapor in equilibrium with solutions of NaCl and Na_2ZrCl_6 on the Na_2ZrCl_6 side of the eutectic. Curve 6 represents the equilibrium pressures of $ZrCl_4$ vapor over solutions of NaCl and Na_2ZrCl_6 saturated with respect to NaCl. The curve is common for all compositions up to the corresponding liquidus temperatures, after which a change in slope occurs at the liquidus composition and temperature. Curves 7 to 12 inclusive represent the equilibrium pressures of $ZrCl_4$ vapor over the liquid solutions on the NaCl side of the eutectic. The vapor pressure measurements corresponding to all curves, with the exception of curve 6, were fully reproducible

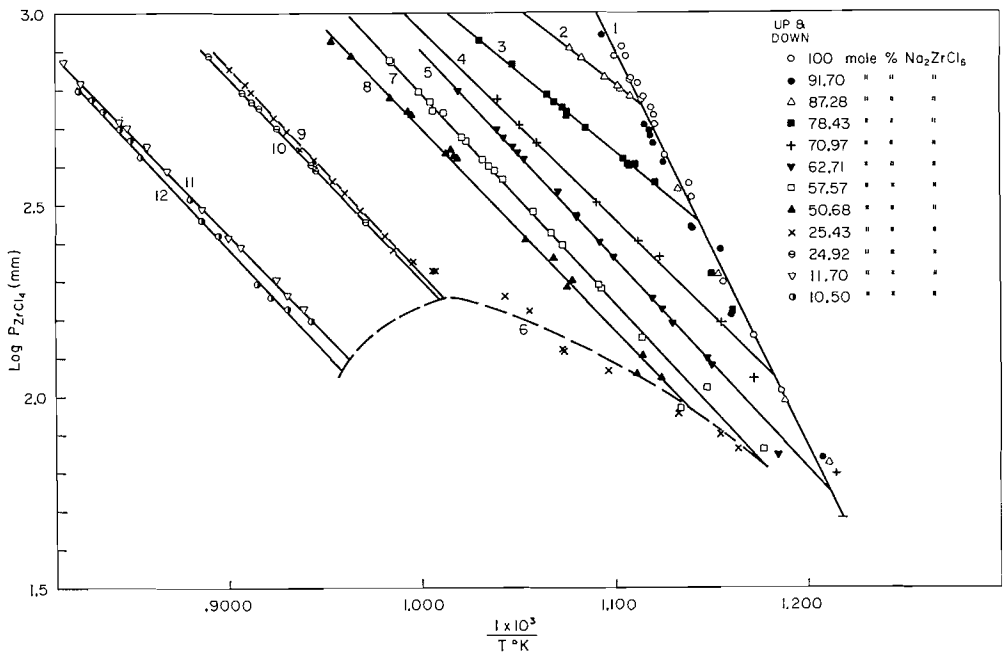

FIG. 6. Zirconium tetrachloride pressures in the Na_2ZrCl_6–NaCl system as a function of temperature at various compositions.

on both an increasing and decreasing temperature cycle. The pressures corresponding to solutions saturated with respect to sodium chloride (curve 6) are only approximate, and the curve was established by extrapolating the high temperature curves to the liquidus temperature indicated from the phase diagram for the specified composition. It may be seen that the experimentally obtained points approximate this curve. The magnitude of the pressures measured, as well as the observed irreversibility of the system at low pressures, did not permit vapor pressure measurements at temperatures below the eutectic. Accordingly, the effect of eutectic melting could not be observed in this system.

Figure 7 represents the log P vs. $1/T$ plots for the equilibrium pressures corresponding to various compositions of the binary system KCl–K_2ZrCl_6. Curve 1 represents the pressures of $ZrCl_4$ vapor in equilibrium with solutions of KCl and K_2ZrCl_6 saturated with respect to K_2ZrCl_6, and is common for all compositions up to the corresponding liquidus temperature. Liquidus melting is similarly shown by the change in slope at the liquidus temperature, and these temperatures have also been included in the corresponding phase diagram in Fig. 3. Curves 2, 3, 4, and 5 correspond to the completely liquid phase. Curves 6, 7, and 8 represent measurements on the potassium chloride side of the eutectic and could be obtained only at temperatures above the liquidus, as at lower temperatures, the system was too stable to produce a measurable vapor pressure. A detailed summary of the vapor pressure data is given in Table I for the system NaCl–Na_2ZrCl_4, and Table II for the system KCl–K_2ZrCl_6.

Vapor pressure measurements were also taken on selected compositions lying in the eutectic valley of the ternary NaCl–KCl–$ZrCl_4$ system, as shown in Fig. 5. The log P vs. $1/T$ curves for these specified compositions are given in Fig. 8, and the data for these curves may be found in Table III. The pressures correspond to the molten range only, as the pressures exerted over the saturated solution were again too small to be measured.

Tables I to III inclusive show the log P relationships determined by the least squares method over the temperature range specified, as well as the liquidus temperature, and the heats of reactions calculated from the slopes of the log P vs. $1/T$ curves, according to the previously derived relationships [9] and [14]. The partial molar heats of mixing of the M_2ZrCl_6 at various compositions may be determined from the difference

$$[15] \qquad \Delta H_r' - \Delta H_r'' = (\overline{\Delta H}_m)_{M_2ZrCl_6}$$

where the quantities $\Delta H_r'$, and $\Delta H_r''$ have been defined previously. These calculations are also shown in Tables I and II. The error limits applied to the heat terms were obtained from the standard deviations.

The partial molar properties correspond to the liquid compositions denoted as "corrected at the liquidus." This correction was found necessary because at higher pressures a small amount of zirconium tetrachloride was depleted from the initial mixture in order to fill the free volume of the pressure-measuring apparatus.

DISCUSSION OF RESULTS

The partial molar heats of mixing of K_2ZrCl_6 and Na_2ZrCl_6 for various compositions of the MCl–M_2ZrCl_6 mixtures are included in Tables I and II, and indicate that the solution processes are highly endothermic.

The linearity of the pressure curves shown in Figs. 6 and 7 indicates that the heats of mixing may be considered as constant in the temperature range of the pressure measurements. Heats of mixing calculated in this manner refer to the pure solids M_2ZrCl_6 as the state of reference, and include by definition the heats of fusion of the complex compounds. The relationship between the heat of fusion and the partial molar heats of mixing, referred to either pure solid or pure liquid M_2ZrCl_6, is given as

$$[16] \qquad (\overline{\Delta H}_m)_{s,M_2ZrCl_6} = (\overline{\Delta H}_m)_{l,M_2ZrCl_6} + \Delta H_f$$

where $(\overline{\Delta H}_m)_{s,M_2ZrCl_6}$ and $(\overline{\Delta H}_m)_{l,M_2ZrCl_6}$ are the heats of mixing of pure solid and liquid M_2ZrCl_6, respectively, and ΔH_f is the corresponding heat of fusion.

An estimate of the heat of fusion may be made only for the K_2ZrCl_6 compound, where pressure data could be obtained at temperatures higher than its melting temperature. From curve 1 in Fig. 7, it is seen that the pressure curve changes slope at about 798 °C, which corresponds to the liquidus temperature for the 99 mole % M_2ZrCl_6 mixture on the phase diagram. Such a concentrated solution is expected to obey Raoult's law and behave ideally. Accordingly,

$$(\overline{\Delta H}_m)_{l,K_2ZrCl_6} = 0$$

and

$$(\overline{\Delta H}_m)_{s,K_2ZrCl_6} = (\Delta H_f)_{K_2ZrCl_6} = 62.4 \text{ kcal/mole.}$$

This is an unusually high heat of fusion, indicative of a dissociating complex compound. From the results in Table II, it is seen that the heats of mixing of solid K_2ZrCl_6 become less endothermic as the solution becomes more concentrated in KCl, indicating that the dissociation of the $ZrCl_6^{--}$ anion in solution decreases with increasing chloride ion concentration.

If the dissociation reaction is represented by the general equation

$$ZrCl_6^{2-} \rightarrow ZrCl_{6-n}^{n-2} + nCl^-$$

then the decrease in dissociation may be accounted for by a common ion effect.

Activity Calculation in the Binary Systems

The activity of the M_2ZrCl_6 in the totally liquid range may be calculated at any temperature, T, from the van't Hoff relationship

$$[17] \qquad \ln \frac{a_T}{a_{T_L}} = \frac{(\overline{\Delta H}_m)_{M_2ZrCl_6}}{R}\left[\frac{1}{T} - \frac{1}{T_L}\right]$$

where a_T is the activity of the M_2ZrCl_6 species at any temperature T; a_{T_L} is the activity at the liquidus temperature; and $(\overline{\Delta H}_m)_{M_2ZrCl_6}$ is the partial molar heat of mixing of M_2ZrCl_6 of the MCl–M_2ZrCl_6 solutions given in Tables I and II. For the calculation, the activity along a liquidus tieline is taken as equal to unity, thus defining the standard state as being that of the pure solids at all temperatures. Activity isotherms, calculated at selected temperatures by this method, are shown in Figs. 9 and 10 for the systems $NaCl$–Na_2ZrCl_6 and KCl–K_2ZrCl_6, respectively.

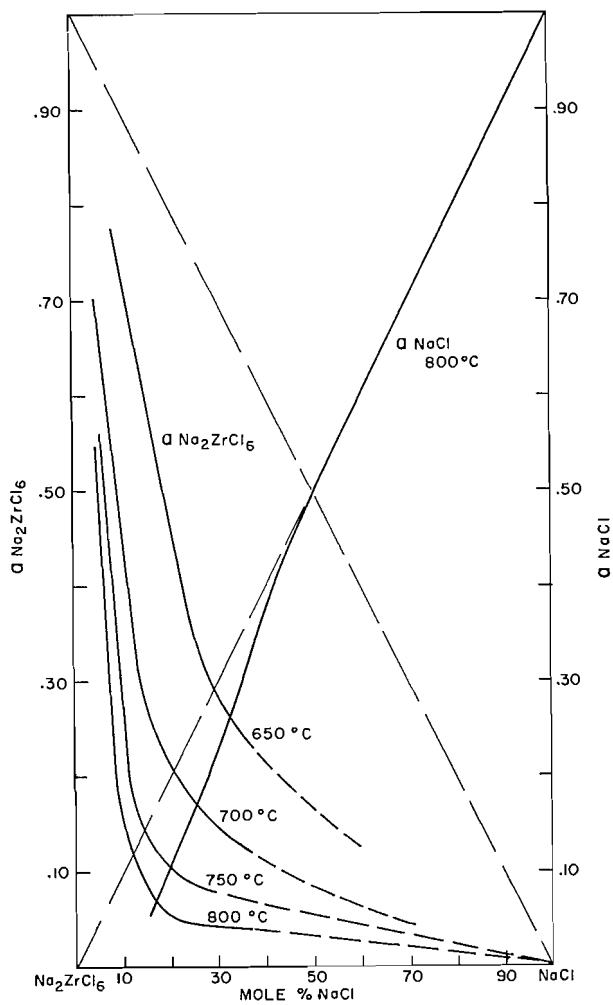

FIG. 9. Activity isotherms of Na_2ZrCl_6 and NaCl, in the Na_2ZrCl_6–NaCl binary system.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

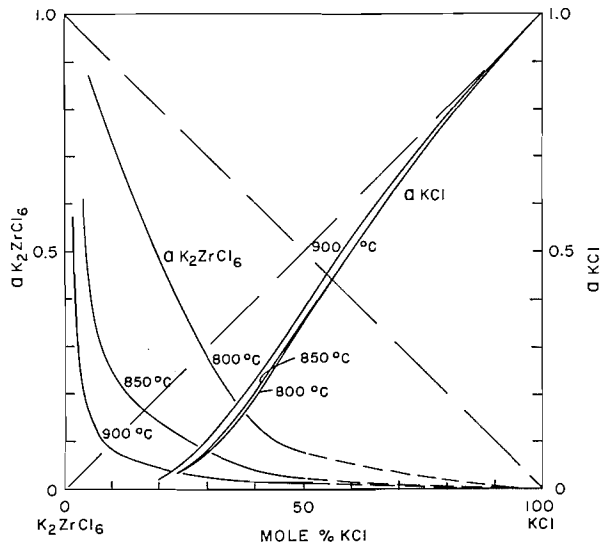

FIG. 10. Activity isotherms of K_2ZrCl_6 and KCl, in the K_2ZrCl_6–KCl binary system.

These data were obtained in the range of pure M_2ZrCl_6 to the eutectic composition and were then extrapolated to the infinite dilution range (indicated by the dotted lines). The activity coefficients of the MCl component have been determined by the Gibbs–Duhem equation in the form

$$[18] \qquad \log \gamma_1 = -\int_{N_1=1}^{N_1=N_1} \frac{N_2}{N_1} \, \mathrm{d} \ln \gamma_2.$$

Activities of MCl calculated from these results are also shown in Figs. 9 and 10. The activity isotherms indicate negative deviations from ideality for the two components. The activities of the M_2ZrCl_6 decrease with increasing temperature, indicating dissociation of the complex species at higher temperatures. This dissociation is also indicated by the large positive values of the partial molar heats of mixing shown in Tables I and II and discussed previously. With reference to the MCl component, the activities approach ideality in the concentrated MCl side, and are, for all practical purposes, temperature independent.

A solution containing m moles of MCl and n moles of M_2ZrCl_6 may be thought to be equivalent to one containing $m + 2n$ moles MCl, and n moles of $ZrCl_4$. Accordingly the activities of zirconium tetrachloride in the system MCl–$ZrCl_4$ have also been calculated with respect to the pure solid $ZrCl_4$ as the standard state. For the calculation the vapor pressure exerted by pure solid $ZrCl_4$ has been obtained from the relationship (7)

$$[19] \qquad \log_{10} P_{ZrCl}{}^{0} \text{ (mm)} = \frac{-5400}{T} + 11.766$$

and the activities were calculated as

$$[20] \qquad a_{ZrCl_4} = \frac{P_{ZrCl_4}}{P_{ZrCl_4}{}^{0}}$$

where P_{ZrCl_4} is the experimentally obtained pressure over the solutions in the liquid range.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The results of these calculations for the systems NaCl–$ZrCl_4$ and KCl–$ZrCl_4$ are given in Figs. 11 and 12. The activity isotherms show pronounced negative deviations from ideality, indicating the effect of the formation of the complex $ZrCl_6^{2-}$ species in solution.

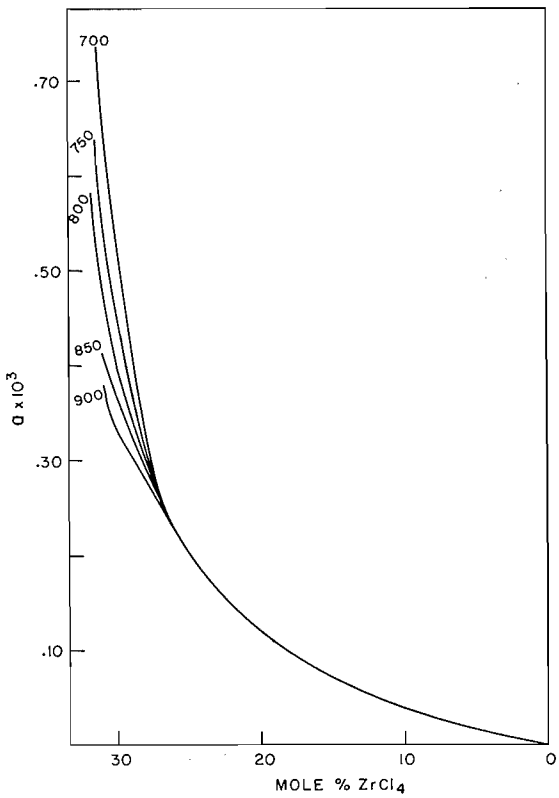

FIG. 11. Activity isotherms of $ZrCl_4$ in the NaCl–$ZrCl_4$ system.

The partial molar heats of mixing of zirconium tetrachloride have also been calculated from the temperature dependence of the activities, and are shown in Table IV.

The partial molar properties, calculated with respect to either M_2ZrCl_6 or $ZrCl_4$ solids as the states of reference, are related by the following thermodynamic cycle:

[a] $$2MCl_{(s)} + 2[(MCl)_{m+2n}\cdot(ZrCl_4)_n] = 2[(MCl)_{m+2n+i}\cdot(ZrCl_4)_n] \ldots . 2(\overline{\Delta H}_m)_{MCl}$$

[b] $$M_2ZrCl_{6(s)} = 2MCl_{(s)} + ZrCl_{4(v,\ 1\ atm)} \ldots . \Delta H_r^0$$

[c] $$M_2ZrCl_{6(s)} + [(MCl)_{m+2n}\cdot(ZrCl_4)_n] = [(MCl)_{m+2n+2}\cdot(ZrCl_4)_{n+1}] \ldots . (\overline{\Delta H}_m)_{M_2ZrCl_6}$$

[d] $$ZrCl_{4(s)} = ZrCl_{4(v,\ 1\ atm)} \ldots . \Delta H_s.$$

Reactions [a] and [c] represent the mixing of pure solids M_2ZrCl_6 and MCl, respectively, while reactions [b] and [d] correspond to the processes of the decomposition of solid M_2ZrCl_6 and to the sublimation of zirconium tetrachloride.

When these equations are added in the sequence [c] + [d] − [a] − [b], it is found that

[e] $$ZrCl_{4(s)} + [(MCl)_{m+2n}\cdot(ZrCl_4)_{n-1}] = [(MCl)_{m+2n}\cdot(\overline{ZrCl_4})_n] \ldots . (\Delta H_m)_{ZrCl_4}.$$

Reaction [e] is the process of mixing solid zirconium tetrachloride. Therefore, the various heat terms are related by the following expression:

[21] $$(\overline{\Delta H}_m)_{ZrCl_4} = (\overline{\Delta H}_m)_{M_2ZrCl_6} + \Delta H_s - \Delta H_r^0 - 2(\overline{\Delta H}_m)_{MCl}.$$

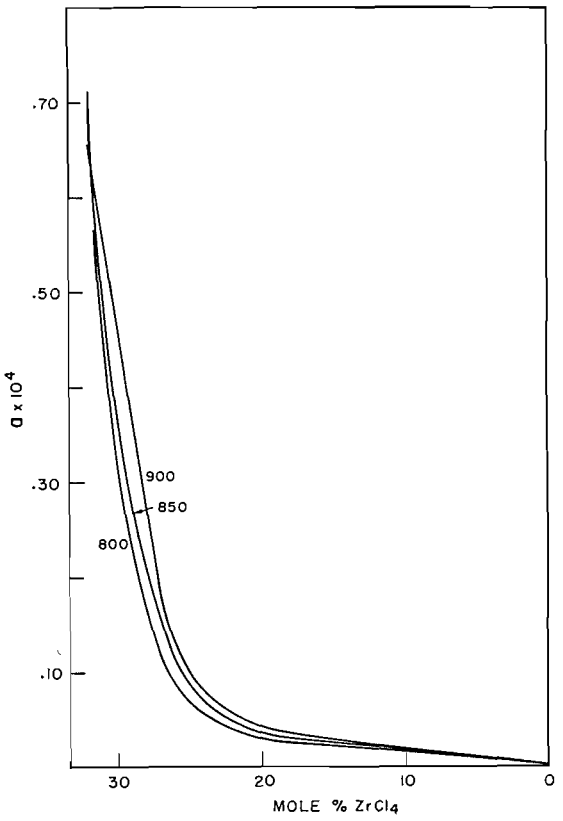

FIG. 12. Activity isotherms of $ZrCl_4$ in the KCl–$ZrCl_4$ system.

TABLE IV

The partial molar heats of mixing of $ZrCl_4$ in the systems NaCl–$ZrCl_4$ and KCl–$ZrCl_4$

NaCl–$ZrCl_4$ system		KCl–$ZrCl_4$ system	
Mole % $ZrCl_4$ corrected at liquidus	$(\overline{\Delta H}_m)_{ZrCl_4}$ (kcal)	Mole % $ZrCl_4$ corrected at liquidus	$(\overline{\Delta H}_m)_{ZrCl_4}$ (kcal)
31.41	6.27±0.1	33.21	2.60±0.1
30.37	5.74±0.1	31.84	0.73±0.1
29.23	1.89±0.1	30.99	−3.19±0.1
27.78	−0.22±0.1	27.02	−10.67±0.1
26.72	−0.50±0.1	23.52	−9.35±0.1
25.16	0.78±0.1	18.54	−9.80±0.1
16.79	0.00±0.1	12.56	−8.30±0.1
16.56	0.40±0.1	8.92	−10.18±0.1
9.41	0.24±0.1		
8.62	−0.18±0.1		

Equation [21] may also be used for the calculation of the heat of decomposition ΔH_r^0 of pure solid K_2ZrCl_6. Thus, from equation [19] the heat of sublimation of zirconium tetrachloride is calculated as 24 850 cal/mole; the partial molar heats of mixing of K_2ZrCl_6 and $ZrCl_4$, respectively, are given in Tables II and IV. The slight temperature dependence of the activities of potassium chloride indicates that the partial molar heat of mixing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of KCl should be negligibly small. For the 32.2 mole % $ZrCl_4$ composition, corresponding to almost pure K_2ZrCl_6, the approximate heat of decomposition is calculated as

$$\Delta H_r^0 = 84.7 \text{ kcal/mole.}$$

It is evident that the thermodynamic analysis of a system of the type $ZrCl_4$–MCl depends upon the choice of components. When choosing M_2ZrCl_6 as a component, the behavior of the pressure–temperature curves may be understood and predicted. Furthermore, some knowledge of the properties and structure of these liquids may be gained. Thus, it has been indicated that the $ZrCl_6^{--}$ anion dissociates in these solutions, and that the dissociation is promoted by higher temperatures and is suppressed by a higher chloride ion concentration. As the formation of the $ZrCl_6^{--}$ complex anion has already satisfied most of the bonding requirements of zirconium tetrachloride, the activities of M_2ZrCl_6 in solution indicate rather moderate deviations from ideality.

On the contrary, activities calculated with respect to zirconium tetrachloride as the component indicate pronounced negative deviations from ideality. Such deviations could be accounted for only by the tendency of zirconium tetrachloride to react with the alkali metal chlorides and form complex species in solution. From these results, however, the nature of the complexes could not be specified and the dissociation effect was not too apparent. Furthermore, the behavior of the pressure–temperature curves could not be predicted.

It is evident that the choice of M_2ZrCl_6 as a component is more useful in indicating the properties of these liquids. On the other hand, activities calculated with respect to zirconium tetrachloride are of practical value in indicating the thermal stability of the solutions.

Ternary System NaCl–KCl–$ZrCl_4$

As indicated previously, the vapor pressure measurements taken at compositions in the area of the ternary eutectic valley were of interest from the point of view of determining a low vapor pressure area over this system, which might be used in an electrodeposition process. The decomposition temperatures given in Table II correspond to the temperature at which the equilibrium pressure exerted by the system becomes 1 atm. These decomposition temperatures are all quite high, indicating a high degree of thermal stability of the system.

In the concentration range of the liquid corresponding to the 600 °C isothermal surface, the pressures of zirconium tetrachloride are less than 6 mm. The decomposition pressures over the binary systems, NaCl–$ZrCl_4$ and KCl–$ZrCl_4$, have also been calculated from the data as a function of composition, and the pressure isotherms are given in Figs. 13 and 14 for comparison.

It is seen that the decomposition pressures increase rapidly with increasing zirconium tetrachloride content, thus diminishing the usefulness of the more concentrated $ZrCl_4$ solutions for purposes of electrolysis.

A given solution of zirconium tetrachloride in the liquid range may be stablilized when subjected to an external pressure equal to the corresponding decomposition pressure indicated on the isotherms. Thus, the problem of solubility may be understood in terms of the thermal stability of the solutions.

In Table V, a comparison between the pressures measured over the ternary compositions and the pressures exerted over the corresponding MCl–$ZrCl_4$ binary systems, having the same $ZrCl_4$, is given. It may be seen that the pressures of the ternary are of the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

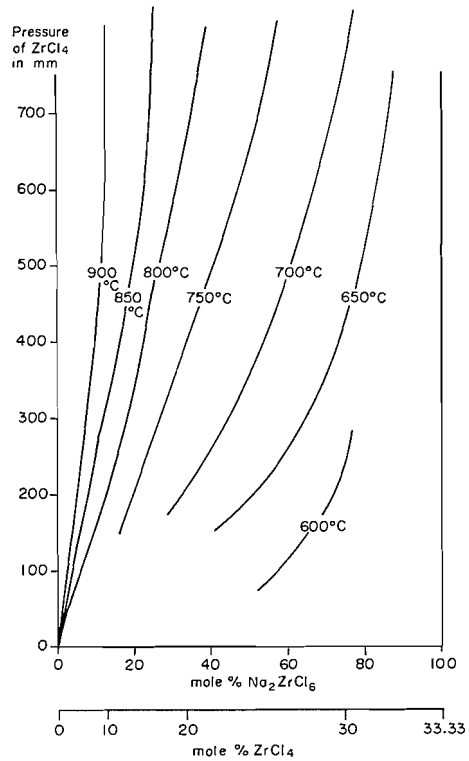

FIG. 13. Pressure isotherms of $ZrCl_4$ in the NaCl–$ZrCl_4$ system.

order of magnitude as for the corresponding binary solutions of the KCl–$ZrCl_4$ system; however, the NaCl–$ZrCl_4$ solutions exhibit pressures which are greater by one to two orders of magnitude. This may be understood by the following equilibria:

$$\begin{array}{ccc} K_2ZrCl_{6(sol)} + 2NaCl_{(sol)} & \overset{[1]}{\rightleftharpoons} & NaZrCl_{6(sol)} + 2KCl_{(sol)} \\ \downarrow\uparrow [2] & & \downarrow\uparrow [3] \\ 2KCl_{(sol)} + ZrCl_{4(v)} & & 2NaCl_{(sol)} + ZrCl_{4(v)} \end{array}$$

Reaction [1] represents an exchange reaction, while [2] and [3] represent the vapor-producing reactions. The equilibrium vapor over the solution can represent only one of the two possible decomposition reactions, the other being totally suppressed. The similarity between the pressures exerted by the ternary and by the binary KCl–$ZrCl_4$ systems appears to indicate that the latter is the vapor-producing reaction; accordingly, the equilibrium represented by reaction [1] is shifted to the left. If the Na_2ZrCl_6 complex exists in solution, it should be present in such small quantities that its equilibrium pressure should be very small and decomposition reaction [3] would be totally suppressed.

For the electrodeposition of zirconium in a fused salt bath containing NaCl–KCl–$ZrCl_4$, it may be said that the K_2ZrCl_6 is the prominent zirconium bearing species, while only a small amount of Na_2ZrCl_6 is present in the solution. The ternary offers the advantage of operating in a totally liquid phase at low temperatures ($\sim$ 600 °C) and pressures. Although a correspondingly low pressure could be achieved in the KCl–$ZrCl_4$ system at

such low temperatures, the phases present would always be solid and liquid according to the phase diagram. It appears, therefore, that the use of a ternary solution should be beneficial for electrolytic purposes.

CONCLUSIONS

It has been shown that the solubilities of zirconium tetrachloride in alkali chloride melts may be explained by formation of compounds of the general formula M_2ZrCl_6. The thermal stability of the solutions increases with increasing ionic size of the alkali metal cation.

The possibility of using the ternary NaCl–KCl–$ZrCl_4$ as a fused salt medium for the electrodeposition of zirconium metal appears quite promising. If we consider the 600 °C isotherm as a reasonable working temperature, it has been shown that the pressure exerted over the ternary system in this temperature and concentration range is less than 6 mm. The K_2ZrCl_6 complex appears to be present in the ternary in preference to the Na_2ZrCl_6 species and imposes its equilibrium pressure. The dissociation of this complex to smaller ionic species indicates that the solution could possess favorable ionic mobilities.

Equilibrium vapor pressures of zirconium tetrachloride have been obtained over the entire composition range for the binary systems NaCl–Na_2ZrCl_6 and KCl–K_2ZrCl_6. The pressure data have been used to calculate activities and to support the phase diagram determinations. The thermodynamic properties of the *pure* solid compounds M_2ZrCl_6 may be obtained from equilibrium pressure measurements at temperatures up to only the eutectic of the binary system M_2ZrCl_6 and MCl and not, as is commonly assumed,

For personal use only.

to the melting point of the pure compound. The vapor pressure curves for the decomposition of the compound undergo a change in slope at the eutectic and the liquidus temperatures, and from these, the phase diagram for any system of this type can be predicted. Thus, the interpretation of thermodynamic data derived from reaction pressure measurements is restricted by eutectic and liquidus melting in the system. When these two effects are accounted for, a far more complete thermodynamic analysis of the system may be derived, and the partial molar properties of the components in the solutions may be calculated.

It should be emphasized that the conclusions drawn from this treatment would be equally applicable to any reactive system, such as sulfates, carbides, silicides, etc., where a congruently melting compound exists, which will decompose upon heating, producing a vapor phase.

SPECTROSCOPIC STUDIES OF ALCOHOLS

VI. INTRAMOLECULAR HYDROGEN BONDS IN ETHANOLAMINE AND ITS *O*- AND *N*-METHYL DERIVATIVES

P. J. KRUEGER AND H. D. METTEE
Department of Chemistry, University of Alberta, Calgary, Alberta
Received May 19, 1965

ABSTRACT

The competitive intramolecular OH · · · N and NH · · · O hydrogen bonding in ethanolamine and *N*-methylethanolamine has been studied in dilute C_2Cl_4 solution by means of the temperature dependence of the fundamental OH and NH stretching bands. Of the three conformers identified for each of these compounds, the least stable shows a distinct band which is assigned to a "terminal" OH group involved in an intramolecular NH · · · OH hydrogen bond. Enthalpy differences between conformers are reported and discussed, and compared with those found for the conformational equilibria in 2-methoxyethylamine and *N*,*N*-dimethylethanolamine.

INTRODUCTION

Hydrogen bonding studies involving both NH groups and OH groups as proton donors and both N atoms and O atoms as proton acceptors are of interest since such multiplicity of proton donor and acceptor sites is prevalent in many biological systems. Both intra- and intermolecular OH · · · N and NH · · · O bonds may form, leading to a number of complexes in simultaneous equilibrium. This paper reports some infrared absorption studies of a simple model compound ethanolamine in a relatively inert solvent under conditions where only intramolecular hydrogen bonds can form.

Bergmann, Gil-Av, and Pinchas (1) first reported a downward shift of the OH stretching frequency on intramolecular OH · · · N hydrogen bond formation in *N*-mono- and *N*,*N*-disubstituted 2-aminoethanols in dilute CCl_4 solution. More recently Flett (2) has compared OH stretching frequencies in a number of substituted alcohols in dilute CCl_4 solution. The downward frequency displacements from the normal monomeric "free" OH position on intramolecular hydrogen bonding are much greater in *N*,*N*-dialkyl-2-aminoethanols than in 2-alkoxyethanols. Freedman (3) has reviewed the frequency shift data pertaining to inter- and intramolecular OH · · · O and OH · · · N hydrogen bonds, concluding that in simple compounds (or binary systems) containing similar OH · · · O and OH · · · N bonds the latter are stronger. Mean energies of intermolecular OH · · · N, OH · · · O, and NH · · · O hydrogen bonds have been estimated to be about 7, 6, and 2–3 kcal/mole respectively (4*a*).

Kanzawa (5) have investigated OH · · · N bonding in the diasteroisomeric ephedrines and related compounds, but the interpretation of these spectra is complicated by the presence of the phenyl and methyl groups on the 2-*N*-methylaminoethanol skeleton.* The conclusion that the —$NHCH_3$ group in ephedrine plays almost no role as a proton donor in intramolecular hydrogen bond formation is probably not justified in the light of the results on alkanolamines reported in this paper.

Kuhn, Luettke, and Mecke (8) concluded that strong intramolecular OH · · · N hydrogen bonds form in ethanolamine and its *N*-methyl derivatives, but no thermodynamic

**Intramolecular OH · · · π-electron hydrogen bonding occurs in benzyl alcohol (6) and in 2-phenylethanol ($\Delta H = -1.04 \pm 0.02$ kcal/mole for the trans–gauche equilibrium (7)). The methyl group exerts its steric influence in the conformational equilibrium.*

investigation of these compounds appears to have been reported to date. Although the magnitude of OH (or NH) frequency shifts on hydrogen bond formation are conventionally considered to be measures of the hydrogen bond strength, following the work of Badger and Bauer (9), caution must be exercised in the application of this rule if (*a*) experimental measurements of frequency shifts are not made at very low base concentration (10), (*b*) small enthalpy differences (small frequency displacements) are involved, (*c*) comparisons are made between systems involving radical changes in the nature of the base (11), and (*d*) intramolecular hydrogen bonds are formed (where the AH···B distance and geometry are largely dictated by the system). In such cases ΔH reflects a change in molecular conformation in which all the nonbonded interactions in the two conformations are balanced against each other. The attractive force between two groups which engage in hydrogen bonding is just one of these interactions. The hydrogen bond also involves a repulsive interaction between A and B which ultimately decides the minimum A···B distance.

EXPERIMENTAL

A Beckman IR-7 infrared spectrophotometer was employed under the conditions described previously (12). Matched fused quartz absorption cells with a path length of 2.0 cm were used. Cell temperatures were regulated with a Lauda UK70D Ultrakryostat. All the aminoalcohols and their *O*- and *N*-methyl derivatives were commercial products which were dried and fractionally distilled through a 23-theoretical-plate spinning band column. Boiling points and refractive indices of the fractions collected for use agreed well with literature values. Reagent grade tetrachloroethylene was dried over P_2O_5 and distilled through a 50-theoretical-plate spinning band column. This was used as a solvent instead of carbon tetrachloride, which is known to be a poor solvent for aminoalcohols and alkyl amines (13, 14, 15). Alkanolamine concentrations were of the order of 0.01 *M* or less, while amine concentrations were about 0.02 *M*. No concentration dependent bands due to intermolecular association were found. For ethanolamine in CCl_4 (concentration range 0.11–1.00%) such a band has been reported at 3 340 cm^{-1} (16).

RESULTS AND DISCUSSION

The high resolution infrared spectra in the 3 μ region obtained at room temperature for dilute C_2Cl_4 solutions of ethanolamine and 3-aminopropanol and some of their *O*- and *N*-methyl derivatives are shown in Fig. 1. The OH and NH frequencies are recorded in Table I, which also includes some comparative values from the literature.

The spectra of *N*,*N*-dimethylethanolamine and 2-methoxyethylamine are simply interpreted in terms of an equilibrium between "free" and "bonded" OH and NH_2 groups respectively, arising from *trans* and *gauche* conformers.* In *N*,*N*-dimethylethanolamine the ν_{OH} shift on intramolecular OH···N hydrogen bond formation is 132 cm^{-1}. For 2-methoxyethylamine, where weaker intramolecular NH···O hydrogen bonds form, "free" and "bonded" NH_2 groups exhibit the antisymmetric vibrational mode at 3 398 and 3 387.$_5$ cm^{-1} respectively (ν_{NH} shift = 10.$_5$ cm^{-1}). The *trans* population greatly exceeds the *gauche* population. Since the symmetric vibrational mode in aliphatic amines in C_2Cl_4 solution has a low intensity (14), the two components due to "free" and "bonded" NH_2 groups were only observed as a broad weak band at about 3 331 cm^{-1}, with asymmetry on the low frequency side.

The spectra of ethanolamine and *N*-methylethanolamine are similarly composed of "free" OH and NH bands as well as the characteristically broad OH···N band and the "bonded" NH bands which have undergone only a small displacement. A broad very weak absorption is found in the region where the symmetric NH_2 stretching vibration of "free" and "bonded" NH_2 groups is expected. In addition, a distinct band is found

**The gauche form may deviate from the perfectly staggered conformation, according to n.m.r. data on the ephedrines (19).*

FIG. 2. Temperature dependence of peak absorbance ratios in ethanolamine spectra in dilute C_2Cl_4 solution. Letters refer to bands in Fig. 1.

about 15 cm^{-1} below the "free" OH band in each of these spectra (bands B and E, Fig. 1). The identification of this band follows from the observed temperature dependence of these spectra.

Figure 2 shows some of the changes in relative band intensities as a function of temperature (log absorbance ratios vs. $1/T$). From the slopes the enthalpy differences (ΔH) between conformers involved in the equilibria may be determined, fitting lines to the experimental points by the least-squares method. For ethanolamine and *N*-methylethanolamine there is a competition between intramolecular OH···N and NH···O hydrogen bonds. The experimentally determined ΔH values are fitted to postulated

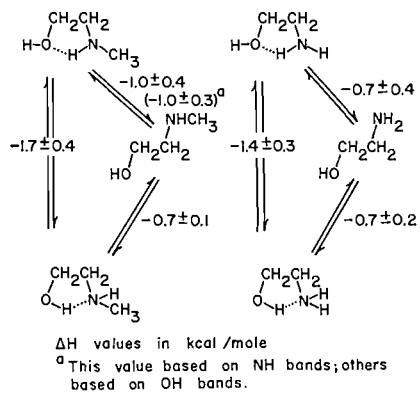

FIG. 3. Conformational equilibria for ethanolamine and *N*-methylethanolamine in dilute C_2Cl_4 solution, together with experimental ΔH values (with calculated 90% confidence limits). For each system, stability increases in the downward direction.

equilibria in Fig. 3. The intramolecularly hydrogen bonded species would presumably take up quasi-*gauche* conformations in which the proton donor and acceptor groups are in relative positions consistent with the strongest hydrogen bond permitted by the restrictive geometry of the system and the other nonbonded forces involved.

Bands B and E in the spectra of ethanolamine and *N*-methylethanolamine are assigned to the "terminal" OH group of conformers with angular NH···OH hydrogen bonds. On lowering the temperature of the *N*-methylethanolamine solution band E ("terminal" OH in NH···OH bond) decreases with respect to the "free" OH band ($\Delta H = -1.0 \pm 0.4$ kcal/mole) and more rapidly with respect to the OH···N band ($\Delta H = -1.7 \pm 0.4$ kcal/mole), while the "free" NH band increases with respect to the "bonded" NH band ($\Delta H = 1.0 \pm 0.3$ kcal/mole), and the "free" OH band decreases with respect to the OH···N band ($\Delta H = -0.7 \pm 0.1$ kcal/mole). These ΔH values are self-consistent and fit the scheme outlined in Fig. 3 if the conformer with the NH···O bond has the lowest stability, and if the "terminal" NH group (in the conformer bonded OH···NH) absorbs at the same frequency as the "free" NH and with about the same extinction coefficient. The data for ethanolamine can be interpreted in a similar way.

The temperature dependence of the "free" and "bonded" antisymmetric NH_2 bands of 2-methoxyethylamine shows that here too the *trans* conformer appears to be more stable than the *gauche* conformer with the NH···O bond, in this case by 1.6 ± 0.9 kcal/mole (Fig. 2). These two bands are badly overlapped and since the *trans* conformer predominates, the high frequency side of this band was reflected across the ordinate at the band maximum and the resulting symmetrical band subtracted from the experimental envelope to obtain the "bonded" band. The electron-donating methyl group in 2-methoxyethylamine would be expected to increase the NH···O hydrogen bond strength over what it is in ethanolamine, but it would at the same time increase the repulsion between the O and N atoms in the *gauche* conformation. The latter factor, which dominates over the weak NH···O bond in ethanolamine, becomes even more important in 2-methoxyethylamine. The angular nature of the NH···O bond removes the screening effect of the H atom between the N and O atoms and also weakens the attractive interaction.

Although the early work of Smith and Creitz (20) on association of simple alcohols in CCl_4 solution gave some evidence for a characteristic "terminal" OH group frequency of an acyclic dimer at 3 636 cm^{-1} for a monomeric "free" OH group (21), an analysis of all the more recent work suggests that the terminal OH group of the open dimer absorbs at the same frequency as the monomer (22). This is also considered to be the case in intramolecular OH···OH hydrogen bonds in various diols (23, 24, 25).

The question as to why a terminal OH in an intramolecular NH···OH system absorbs at a slightly lower frequency than a "free" OH, whereas a terminal OH in an intramolecular OH···OH system with similar geometry does not, remains to be answered. A possible explanation lies in the relative polarizabilities of the proton donating group and the proton accepting group. For the NH···OH system, the OH dipole fluctuation during vibration would be accompanied by changes in the oxygen lone pair dipole, which may induce charge fluctuation in the more mobile N lone pair orbital and thus exercise a damping effect on the vibration of the terminal OH, thereby lowering its frequency. Non-linearity of the hydrogen bond would augment interactions of this nature.

Following this argument further, the terminal NH frequency in an intramolecular OH···NH system would not be expected to differ from the corresponding "free" NH frequency because dipole oscillations during an NH vibration are smaller than in an OH vibration, and because the polarizability of the O atom is not as great as that of the N atom.

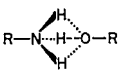
Previous infrared investigations of 1,2-aminoalcohols do not deal with the 3 625 cm^{-1} "terminal" OH band. Sicher, Horak, and Svoboda (13) obtained spectra of some 2-aminocyclanols using a LiF prism spectrophotometer but note only one NH_2 band (presumably a composite of the antisymmetric vibrations of "free" and "bonded" NH_2 groups) without discussing NH···O bonding. It is not possible to draw any conclusions concerning the "terminal" OH band from the spectra of *cis*- and *trans*-2-aminocycloundecanol published in their paper. Drefahl and Heublein (26) show shoulders on the low frequency side of the "free" OH bands in *trans*-2-aminocyclohexanol, *cis*-2-aminocyclohexanol, and 1-amino-2-hydroxytetraline, but do not comment on them. Burford, Hewgill, and Jeffries (27) report low resolution data for some 2- and 3-aminocyclohexanols. Kuhn, Luettke, and Mecke (8) do not discuss intramolecular NH···OH hydrogen bonding and its effect on the OH group which is acting as a base.

In 3-aminopropanol the OH···N interaction is much greater than it is in ethanolamine, as measured by comparison of the bonded/free intensity ratios and the ν_{OH} shifts which are 243 and 115 cm^{-1} respectively. This can be accounted for by more favourable geometry for intramolecular hydrogen bonding in the six-membered ring. The large ν_{OH} shift in 3-aminopropanol masks the NH bands completely, but the "terminal" OH band is present 12 cm^{-1} lower than the "free" OH band. In 3-methoxypropylamine the antisymmetric NH_2 stretching band is wide ($\Delta\nu_{\frac{1}{2}}^{a} \sim 25.5$ cm^{-1} compared to 20.5 cm^{-1} in 2-methoxyethylamine) and has a flattened maximum, suggesting that it is composed of two closely spaced bands of equal intensity. On going from a five- to a six-membered ring the net NH···O attraction has also been increased.

The enthalpy difference between *trans* and OH···N hydrogen bonded *gauche* forms of *N*,*N*-dimethylethanolamine ($\Delta H = -2.8 \pm 0.2$ kcal/mole) is much greater than the corresponding difference for ethanolamine itself and for *N*-methylethanolamine ($\Delta H = -0.7 \pm 0.1$ and -0.7 ± 0.2 kcal/mole respectively). Within the uncertainty of these measurements there is no detectable increase in the relative stability of the *gauche* conformer in going from ethanolamine to the *N*-methyl derivative, although there is a large increase in the relative stability of the *gauche* conformer for *N*,*N*-dimethylethanolamine. This can be ascribed to the change in basicity of the N atom which is in the order $RNH_2 < R_2NH \ll R_3N$ for the base strengths of *n*-alkyl amines towards protonic acids in non-aqueous solvents (*4b*). The usual pK_b values determined in aqueous solution are altered by solvation effects to lead to an apparent basicity order $R_2NH > RNH_2 > R_3N$ towards a small acid (where F- and B-strain are absent). These values therefore do not measure the nitrogen lone pair electron density, which is increased by the substitution of methyl groups. Another factor which may contribute to the large increase in $-\Delta H$ on going from $HOCH_2CH_2NHCH_3$ to $HOCH_2CH_2N(CH_3)_2$ is the "Thorpe–Ingold effect" (28). Crowding of the two methyl groups on the nitrogen may increase the $H_3C—N—CH_3$ angle, with an accompanying decrease in the angle the N lone pair orbital makes with the C—N bond. This would favor OH···N interaction in the five-membered ring.

Using infrared techniques, Zeegers-Huyskens, Lamberts, and Huyskens (29) have investigated intermolecular OH···N hydrogen bonding in alcohol–amine systems in CCl_4 using low ($\sim$0.015 *M*) alcohol concentrations and amine concentrations 3–30 times as high. No competitive intermolecular OH···N and NH···O hydrogen bonding studies have been reported, and such investigations would be difficult because of the large ν_{OH} shift which would mask the NH bands. The high rate of proton exchange in alcohol–amine solutions as deduced from n.m.r. measurements has been attributed to coordinated migration of the protons in complexes involving two non-linear hydrogen bonds of the following type (30).

It is not known whether such hydrogen bonding interaction is possible if the N and O atoms are tied together by a two carbon chain as in ethanolamine. A cyclic complex involving three non-linear hydrogen bonds has been suggested (31) for primary amine – alcohol mixtures in an inert solvent.



The hydrogen bond enthalpies determined calorimetrically (32) for the systems ROH + n-$BuNH_2$ = −7.48 kcal/mole, ROH + Et_2NH = −5.28 kcal/mole, and ROH + Et_3N = −4.89 kcal/mole have been interpreted in terms of triply, doubly, and singly hydrogen bonded complexes respectively.

The main contributions of this paper are (*a*) the characterization of a "terminal" OH vibration in intramolecular NH···OH hydrogen bonds, and (*b*) the presentation of spectral data which indicate that in ethanolamine, N-methylethanolamine, and 2-methoxyethylamine the *gauche* conformer with an intramolecular NH···O hydrogen bond appears to be thermodynamically less stable than the corresponding *trans* conformer. This focuses attention on the delicate balance between the exothermic contributions (electrostatic, delocalization, and dispersion forces) and the endothermic contribution (repulsive force between O and N) to the overall NH···O interaction energy (33) in these systems.

FORMATION OF CYCLIC *O*-2′-HYDROXYETHYLIDENE ACETALS FROM POLYALCOHOLS OF 4-*O*-LINKED POLYSACCHARIDES[1]

P. A. J. GORIN AND J. F. T. SPENCER
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received June 3, 1965

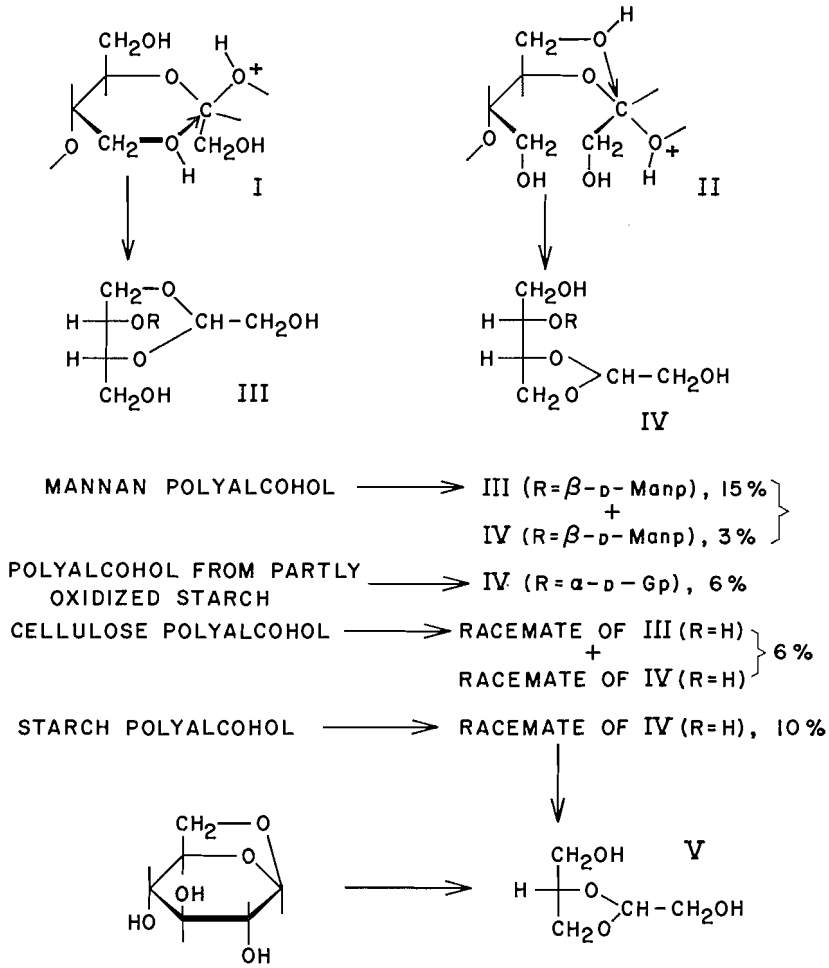
ABSTRACT

Partial acid hydrolysis of polyalcohols derived from some 1,4-*O*-linked polysaccharides gave cyclic *O*-2′-hydroxyethylidene derivatives as by-products in yields of 6–18%. Polysaccharides containing β-links such as *Rhodotorula glutinis* mannan and cellulose gave rise to 6-membered ring acetals with lesser amounts of the 5-membered ring form. On the other hand, two α-linked polyalcohols, obtained following partial and complete oxidation of starch with sodium periodate, were converted to 5-membered *O*-2′-hydroxyethylidene acetals.

In a previous publication oxidation of the exocellular mannan from *Rhodotorula glutinis* with periodic acid and reduction with sodium borohydride to a polyalcohol was described (1). Partial hydrolysis of the polyalcohol gave as the main product 2-*O*-β-D-mannopyranosyl-D-erythritol which arose from alternate 3-*O*- and 4-*O*-β-D-mannopyranosyl units in the mannan. Paper chromatographic examination showed two minor products running at 1.7 (A) and 2.1 (B) times the rate of 2-*O*-β-D-mannopyranosyl-D-erythritol (1). To obtain good yields of A and B for characterization purposes, various hydrolysis conditions have now been investigated and the most suitable appeared to be hydrolysis for 1 h at 100° in an aqueous solution adjusted to pH 2 with hydrochloric acid. Coincidentally, these experimental conditions gave an optimum yield of 2-*O*-β-D-mannopyranosyl-D-erythritol. More prolonged heating caused further hydrolysis to mannose and erythritol. These hydrolysis conditions differ from those of Smith and co-workers (2) who used 0.5 *N* hydrochloric acid at room temperature for 8 h to degrade oat glucan polyalcohol to 2-*O*-β-D-glucopyranosyl-D-erythritol, its 1,3-*O*-(2′-hydroxyethylidene) derivative (3) and other related products. Oat glucan is similar to the above mannan in that it has 1,3-β- and 1,4-β-pyranosyl units distributed along a polymer chain.

In a larger scale experiment the mannan polyalcohol hydrolysate was fractionated on cellulose, and A and B were isolated in yields of 15% and 3% respectively based on polyalcohol. Compound A was crystalline and, based on the observed molecular weight of 316, consumed 2 moles of sodium periodate with concomitant release of 1 mole of acid. Methylation gave a crystalline hexa-*O*-methyl ether which was hydrolyzed to two products detectable on a paper chromatogram. One of these was obtained by extraction of the aqueous hydrolysate with chloroform and was tentatively identified as 2,3,4,6-tetra-*O*-methyl-D-mannose. The other remained in the aqueous phase and was shown to be 4-*O*-methyl-D-erythritol which was characterized as its crystalline tris-*p*-nitrobenzoate. Partial hydrolysis of A gave 2-*O*-β-D-mannopyranosyl-D-erythritol which was isolable only in low yield since the stability of the *O*-2′-hydroxyethylidene group was close to that of the glycosidic link. The above information indicates that A is 1,3-*O*-(2′-hydroxyethylidene)-2-*O*-β-D-mannopyranosyl-D-erythritol (III; R = β-D-Manp), similar to 1,3-*O*-(2′-hydroxyethylidene)-2-*O*-β-D-glucopyranosyl-D-erythritol obtained from oat glucan polyalcohol (3), via an acid-catalyzed acetal migration reaction.

[1]*Issued as N.R.C. No. 8628.*



The amorphous minor product B consumed 1.8 moles of periodate with formation of 0.9 moles of acid, and on partial hydrolysis gave 2-*O*-β-D-mannopyranosyl-D-erythritol and a compound corresponding to glycolaldehyde on thin-layer chromatography (t.l.c.) using silica gel plates. Methylation of B followed by hydrolysis provided 1-*O*-methyl-D-erythritol characterized as its tris-*p*-nitrobenzoate and a sugar corresponding to 2,3,4,6-tetra-*O*-methyl mannose on a paper chromatogram. Compound B is therefore in all likelihood 3,4-*O*-(2′-hydroxyethylidene)-2-*O*-β-D-mannopyranosyl-D-erythritol (IV; R = β-D-Manp).

To obtain further information on the acetal migration reaction, a polysaccharide containing 1,4-α-hexopyranosyl units was used as starting material. Accordingly starch was oxidized with 0.4 moles of sodium periodate per anhydroglucose unit, and the product was isolated and reduced with sodium borohydride. Partial hydrolysis of the polyalcohol gave a complex mixture including compound C which ran at 1.6 times the rate of 2-*O*-α-D-glucopyranosyl-D-erythritol on a paper chromatogram. Chromatography of the mixture on cellulose provided compound C in 6% yield. Partial hydrolysis of this product gave 2-*O*-α-D-glucopyranosyl-D-erythritol and glycolaldehyde, the latter being characterized by conversion to glyoxal bis-2,4-dinitrophenylhydrazone. Methylation of C followed by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydrolysis of the resulting hexa-*O*-methyl ether provided 2,3,4,6-tetra-*O*-methyl-D-glucose and sirupy 1-*O*-methyl-D-erythritol, which was converted to its tribenzoate. These data show that C has the 3,4-*O*-(2′-hydroxyethylidene)-2-*O*-α-D-glucopyranosyl-D-erythritol (IV; R = α-D-Gp) structure.

Other polyalcohols from polysaccharides containing 1,4-α- and 1,4-β-glucopyranosyl units were partially hydrolyzed and gave rise to 5- and 6-membered *O*-2′-hydroxyethylidene acetal rings, respectively.

Cellulose was oxidized in the presence of excess sodium periodate and the product was reduced with sodium borohydride. The resulting cellulose polyalcohol was partially hydrolyzed and resulting glycolaldehyde was destroyed with hot aqueous barium hydroxide. The reaction product was examined on paper chromatograms, and erythritol and two faster moving minor components were detected. These by-products (racemates of III (R = H) and IV (R = H)) were isolated as a mixture by cellulose chromatography in 6% yield and converted to their *p*-nitrobenzoates which were separated by fractional crystallization. The minor product crystallized initially and was identical with 3,4-*O*-(2′-hydroxyethylidene)-DL-erythritol tris-*p*-nitrobenzoate, described later. The mother liquors provided a tris-*p*-nitrobenzoate which was deesterified to the racemate of III (R = H). This was hydrolyzable to erythritol and since it was not oxidized with sodium periodate the erythritol residue was substituted in the 1,3 or 2,3 positions. The n.m.r. (nuclear magnetic resonance) spectrum of the derivative was indistinguishable from that of 1,3-*O*-(2′-hydroxyethylidene)-L-erythritol tris-*p*-nitrobenzoate and differed from that of the 2,3-*O*-isomer. The derivative had zero specific rotation and was therefore racemic. Authentic specimens, kindly supplied by Dr. N. K. Richtmyer, were obtained by oxidation of anhydroheptosans with sodium periodate and subsequent hydrogenation (4, 5).

Fully oxidized starch, on treatment in the above manner, was converted to the polyalcohol which was partially hydrolyzed to give sirupy 3,4-*O*-(2′-hydroxyethylidene)-DL-erythritol (racemate of IV (R = H)) in 10% yield. On periodate oxidation followed by sodium borohydride reduction and hydrolysis, this was converted to glycerol, which contained a trace of erythritol. Compound IV (R = H) was purified via its crystalline tris-*p*-nitrobenzoate which was characterized as follows. Deesterification and oxidation of the product with periodic acid followed by sodium borohydride reduction of the resulting glyceraldehyde derivative yielded 2,3-*O*-(2′-hydroxyethylidene)-DL-glyceritol (racemate of V), which was converted to its optically inactive bis-*p*-nitrobenzoate. The n.m.r. spectrum of this compound was identical with the bis-*p*-nitrobenzoate of the D-isomer (V), obtained following oxidation of levoglucosan with periodic acid and reduction of the product by sodium borohydride. Although inversion at C-2′ of the D-isomer during its preparation seems likely, by analogy with the acid-catalyzed conversion of the thermodynamically unstable methyl 4,6-*O*-benzylidene 2,3-di-*O*-methyl α-D-glucoside to the stable form (6), definite proof of this is lacking.

Formation of 5-membered *O*-2′-hydroxyethylidene acetal rings from a polysaccharide containing 1,4-α-hexopyranosyl units occurs. This contrasts with preferential formation of 6-membered acetal rings from the polysaccharides with 1,4-β-hexopyranosyl units. Simultaneous protonation of the oxygen originally involved in the glycosidic link (before periodate oxidation) and nucleophilic attack at C-1 by a primary hydroxyl group of the erythritol moiety appears to take place (as in I and II) resulting in formation of cyclic acetals (III and IV). Since the acetal migration reaction appears to be controlled by kinetic factors the size of the resulting ring should depend on the relative proximity to C-1 of the two available primary hydroxyl groups in the erythritol residue(s).

For personal use only.

Formation of small amounts of *O*-2′-hydroxyethylidene acetals from a variety of polyalcohols shows that care should be exercised in using the Smith degradation for structural analysis of polysaccharides. Conclusions drawn from paper chromatographic evidence should be checked by isolation and characterization of the reaction products.

EXPERIMENTAL

Specific rotations were measured at 25°. Nuclear magnetic resonance measurements were carried out with a Varian HA 100 n.m.r. spectrometer with tetramethyl silane as standard. *n*-Butanol–ethanol–water (40:11:19 v/v) was used as solvent for paper chromatography and chloroform–methanol–water (90:10:1 v/v) for t.l.c.

Formation of 1,3-O- and 3,4-O-(2′-Hydroxyethylidene)-2-O-β-D-mannopyranosyl-D-erythritol (A and B respectively) from Rhodotorula glutinis Mannan Polyalcohol

A 1% aqueous solution of mannan polyalcohol was adjusted to pH 2 with hydrochloric acid and then heated at 100°. Aliquots were taken out at intervals and neutralized (Ag_2CO_3), and the products were examined on paper chromatograms (spray: ammoniacal silver nitrate). 2-*O*-β-D-Mannopyranosyl-D-erythritol and spots running at 1.7 (A) and 2.1 (B) times the rate of the above polyol were detected. (No spots were detected initially using the *p*-anisidine hydrochloride spray). During the first 3 h only these three components were detected, but thereafter mannose and erythritol were formed, in trace amounts at first, but in high proportion after 24 h. The spot intensities of A and B decreased after 1–3 h, the latter more rapidly.

Characterization of A (III; R = β-D-Manp)

The mannan polyalcohol (3.5 g) was hydrolyzed at 100° for 1 h in water (250 ml) adjusted to pH 2 with hydrochloric acid. After neutralization (Ag_2CO_3), the mixture was fractionated on a cellulose column using *n*-butanol one-half saturated with water as solvent, and A (0.42 g), B (0.09 g), and 2-*O*-β-D-mannopyranosyl-D-erythritol (1.67 g) were eluted. Two recrystallizations from ethanol gave compound A with m.p. 168–170° and $[\alpha]_D$ −3° (*c*, 1.0 MeOH). It consumed 2 moles of sodium periodate with concomitant release of 1 mole of acid.

Anal. Calcd. for $C_{12}H_{22}O_{10}$: C, 44.17; H, 6.80; mol. wt., 326. Found: C, 44.3; H, 6.8; mol. wt. in H_2O, 316.

Its n.m.r. spectrum in D_2O precluded a methyl orthoformate group which is possible from the analytical figures.

Hydrolysis of A for 20 h at 100° with 0.01 *N* hydrochloric acid gave 2-*O*-β-D-mannopyranosyl-D-erythritol, which was isolated in 30% yield by cellulose chromatography (solvent: *n*-butanol one-half saturated with water). It was crystallized from methanol–ethanol and had m.p. 82–86° and $[\alpha]_D$ −36° (*c*, 0.9 MeOH) and its X-ray diffraction pattern was identical with that of an authentic specimen. Gorin and Spencer (1) reported m.p. 87–90° (from EtOH) and $[\alpha]_D$ −36° (*c*, 1.1 H_2O). Another hydrolysis product, glycolaldehyde, was detected with Bredig's reagent as a yellow spot R_f 0.4, on an orange background, or as a brown spot with the 50% sulfuric acid spray.

Compound A (0.30 g) was methylated at room temperature using the sodium hydroxide – dimethyl sulfate procedure of Haworth (7). Dimethyl sulfate was destroyed by heating the solution at 100°, and following neutralization the product was isolated by continuous chloroform extraction. The extract was methylated to completion with silver oxide in refluxing methyl iodide (8). The resulting hexa-*O*-methyl ether was recrystallized twice from *n*-hexane to give material (0.20 g) with m.p. 63–64° and $[\alpha]_D$ −8° (*c*, 1.0 EtOH).

Anal. Calcd. for $C_{18}H_{34}O_{10}$: C, 52.67; H, 8.35; mol. wt., 410. Found: C, 52.4; H, 8.2; mol. wt. in Me_2CO, 418.

A portion (0.10 g) of the ether was hydrolyzed with *N* sulfuric acid (5 ml) at 100° for 18 h. Neutralization ($BaCO_3$), filtration, and five extractions with chloroform removed tetra-*O*-methyl mannose (63 mg) which gave a red spot on a paper chromatogram with the *p*-anisidine hydrochloride spray. The remaining sirupy 4-*O*-methyl-D-erythritol (32 mg) ran at 1.2 times the rate of glycerol on a paper chromatogram (ammoniacal silver nitrate spray), had $[\alpha]_D$ +13° (*c*, 2.0 EtOH), and was characterized by conversion to its tris-*p*-nitrobenzoate; m.p. 154–157° (from EtOAc) and $[\alpha]_D$ −72° (*c*, 0.9 $CHCl_3$).

Anal. Calcd. for $C_{26}H_{21}O_{13}N_3$: C, 53.52; H, 3.63. Found: C, 53.4; H, 3.65.

This material gave an X-ray diffraction pattern identical with authentic material prepared in the following manner.

Charlson and Perlin (9) have shown that in acetic acid 6-*O*-methyl-D-glucose consumes 2 moles of lead tetraacetate in forming di-*O*-formyl-4-*O*-methyl-D-erythrose. Accordingly, a solution of 6-*O*-methyl-D-glucose (0.18 g) in acetic acid (50 ml) containing water (2 ml) was treated with 2.0 moles of 1% lead tetraacetate in acetic acid. After 30 min 1.85 moles of oxalic acid in acetic acid was added, the precipitate of lead oxalate was filtered off, and the filtrate was evaporated to dryness. To the residue sodium borohydride (0.20 g) in water (20 ml) was added, and after 1 h excess reagent was destroyed with acetic acid. The solution was evaporated and boric acid was removed by repeated evaporation from methanol. Extraction of the residue

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with ethyl acetate gave 4-*O*-methyl-D-erythritol with $[\alpha]_D$ +9° (*c*, 2.5 EtOH). Its tris-*p*-nitrobenzoate had m.p. 151–154° and $[\alpha]_D$ −72° (*c*, 1 $CHCl_3$).

Anal. Calcd. for $C_{26}H_{21}O_{13}N_3$: C, 53.52; H, 3.63. Found: C, 53.6; H, 3.35.

Smith *et al.* (10) reported m.p. 162.5–164° (from Me_2CO–EtOH) and $[\alpha]_D^{22}$ +80° (*c*, 1 $CHCl_3$) for the tris-*p*-nitrobenzoate of the enantiomer.

Characterization of B (IV; R = β-D-Manp)

Using the same procedure as in the partial hydrolysis of A, a sample of B (30 mg) was converted to 2-*O*-β-D-mannopyranosyl-D-erythritol, which after crystallization from methanol–ethanol had m.p. and mixed m.p. 81–84° and gave an X-ray diffraction pattern identical with that of authentic material. Glycolaldehyde appeared to be formed also, as shown by t.l.c. Periodate oxidation of B for 24 h resulted in consumption of 1.8 moles of oxidant with release of 0.9 moles of acid.

Methylation of B (93 mg) gave a derivative (87 mg) which was shown to be fully methylated since it gave after hydrolysis two spots on t.l.c. (spray: 50% sulfuric acid) which corresponded to 2,3,4,6-tetra-*O*-methyl-D-mannose and 4-*O*-methyl-D-erythritol (or its enantiomer). The mobilities and color reactions of the products on paper chromatograms with *p*-anisidine hydrochloride and ammoniacal silver nitrate sprays were identical with authentic specimens. 1-*O*-Methyl-D-erythritol was isolated by the previously described procedure and converted to its tris-*p*-nitrobenzoate which had m.p. 150–153° (from EtOAc) and $[\alpha]_D$ +75° (*c*, 1.0 $CHCl_3$).

Anal. Calcd. for $C_{26}H_{21}O_{13}N_3$: C, 53.52; H, 3.63. Found: C, 53.5; H, 3.4.

Its X-ray diffraction pattern was identical with that of 4-*O*-methyl-D-erythritol tris-*p*-nitrobenzoate. Since the compound derived from B had a specific rotation which was equal and opposite to the 4-*O*-methyl derivative, the 1-*O*-methyl-D-erythritol tris-*p*-nitrobenzoate structure is indicated.

3,4-O-(2′-Hydroxyethylidene)-2-O-α-D-glucopyranosyl-D-erythritol (C or IV (R = α-D-Gp)) from Starch Modified with Sodium Periodate (0.4 Mole) and Sodium Borohydride

Soluble starch (22.8 g) was oxidized with aqueous sodium periodate (12.2 g in 500 ml) for 10 d. The resulting dialdehyde starch was precipitated by addition of acetic acid (2.5 l), filtered off, and washed with acetic acid. The dried isolated product was added with stirring to a solution of sodium borohydride (5.0 g) in water (1 l). After 24 h the solution was adjusted to pH 7 and evaporated to dryness and boric acid was removed by repeated evaporation from methanol. The product was dissolved in water (500 ml) and isolated after precipitation with 4 volumes of methanol. Yield, 16.0 g.

The resulting starch polyalcohol (9.5 g) was partially hydrolyzed in a similar manner to the mannan polyalcohol. The product was refluxed in methanol and 6.7 g of soluble material was isolated. On a paper chromatogram the mixture gave spots corresponding to erythritol, 2-*O*-α-D-glucopyranosyl-D-erythritol, and many slower moving materials. In addition compound C running at 1.6 times the rate of 2-*O*-α-D-glucopyranosyl-D-erythritol was detected. Chromatography of the hydrolysate on cellulose using *n*-butanol one-half saturated with water as solvent gave compound C as a sirup (0.54 g) with $[\alpha]_D$ +107° (*c*, 1.0 MeOH).

Compound C (200 mg) was methylated by the previously described procedure to give its hexa-*O*-methyl ether (236 mg). Hydrolysis of a portion (200 mg) gave two detectable products corresponding to tetra-*O*-methyl-glucose and 1-*O*-methyl-erythritol when examined by paper chromatography and t.l.c. Fractionation of the hydrolysate by the previously described method (methylation of A) gave 2,3,4,6-tetra-*O*-methyl-D-glucose (109 mg) which was recrystallized twice from *n*-hexane to give material with m.p. and mixed m.p. 81°. The other component, 1-*O*-methyl-D-erythritol (46 mg), was converted to its tribenzoate which had m.p. 99–100° (from ethyl acetate – *n*-hexane) and $[\alpha]_D$ +44° (*c*, 1.0 $CHCl_3$).

Anal. Calcd. for $C_{26}H_{24}O_{17}$: C, 69.63; H, 5.39. Found: C, 69.4; H, 5.5.

The derivative gave an X-ray diffraction pattern identical with that of 4-*O*-methyl-D-erythritol tribenzoate (m.p. 98–100°, $[\alpha]_D$ −38° (*c*, 0.8 $CHCl_3$). Found: C, 70.0; H, 5.3). The specific rotations therefore show that the two tribenzoates were enantiomers.

Compound C (76 mg) was partially hydrolyzed with 0.01 *N* sulfuric acid (10 ml) at 100° for 24 h. The solution was neutralized ($BaCO_3$), filtered, and evaporated to a mixture which was examined by t.l.c. (sprays: 50% sulfuric acid and Bredig's reagent). One of the spots co-chromatographed with glycolaldehyde. Chromatography of the remainder on cellulose (solvent: *n*-butanol one-half saturated with water) gave 2-*O*-α-D-glucopyranosyl-D-erythritol (43 mg) which was recrystallized three times from methanol–ethanol. It had m.p. 134–135° and $[\alpha]_D$ +136° (*c*, 0.6 H_2O) and gave an X-ray diffraction pattern identical with that of an authentic specimen. Charlson and Perlin (9) report a higher melting point of 147–148° and $[\alpha]_D$ +130° (*c*, 1.8 H_2O) for this material.

Compound C (100 mg) was partially hydrolyzed as described above and extraction of the hydrolysate with refluxing ethyl acetate gave a product (7 mg) containing glycolaldehyde (t.l.c.). This was treated with an ethanolic solution (5 ml) of 2,4-dinitrophenylhydrazine (45 mg) and acetic acid (1 ml) for 24 h under reflux. The solution was seeded with the expected product and left in the refrigerator for 1 week. A few crystals of glyoxal bis-2,4-dinitrophenylhydrazone were formed which had m.p. and mixed m.p. 308–312° and gave an X-ray diffraction pattern identical with that of an authentic specimen.

3,4-O-(2′-Hydroxyethylidene)-DL-erythritol (Racemate of IV (R = H)) from Starch Polyalcohol

Starch polyalcohol (7.5 g) prepared from completely oxidized soluble starch was partially hydrolyzed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

according to the previously described conditions. Erythritol (2.35 g), m.p. and mixed m.p. 107–109°, was isolated by crystallization from ethanol (30 ml) and the mother liquors were evaporated to a syrup (4.32 g). One-half of the sirup was heated at 100° for 1 h in aqueous barium hydroxide (5.0 g in 100 ml) to destroy glycolaldehyde. Carbon dioxide was then bubbled through to remove alkali and the precipitate of barium carbonate was removed. Fractionation of the product on a cellulose column using benzene–ethanol–water (300:50:1 v/v) as solvent gave a fraction (0.76 g), which moved at 1.2 times the speed of glycerol on a paper chromatogram. It consumed 1.0 mole of sodium periodate after 24 h, and reduction of the product with sodium borohydride and acid hydrolysis gave glycerol and a trace of erythritol (paper chromatogram).

A portion (90 mg) of IV (R = H) was converted to 3,4-*O*-(2′-hydroxyethylidene)-DL-erythritol tris-*p*-nitrobenzoate (0.31 g) with m.p. 125–127° (from EtOAc) and $[\alpha]_D$ 0° (*c*, 1.2 $CHCl_3$).

Anal. Calcd. for $C_{27}H_{21}O_{14}N_3$: C, 53.03; H, 3.46. Found: C, 53.15; H, 3.6.

3,4-*O*-(2′-Hydroxyethylidene)-DL-erythritol (200 mg), obtained on deesterification of the tris-*p*-nitrobenzoate with 0.1 *N* sodium methoxide (0.3 mole) in methanol, was oxidized overnight by periodic acid (0.40 g) in water (10 ml). The solution was neutralized ($BaCO_3$) and filtered, and the filtrate was treated with sodium borohydride (0.20 g). After 24 h the solution was neutralized with acetic acid and evaporated to dryness, and boric acid was removed from the residue by repeated evaporation from methanol. Dissolution in water followed by continuous extraction with chloroform gave the racemate of V (0.12 g) which had $[\alpha]_D$ 0° (*c*, 3.2 EtOH) and gave glycerol (paper chromatogram) on acid hydrolysis. It was converted to 2,3-*O*-(2′-hydroxyethylidene)-DL-glyceritol bis-*p*-nitrobenzoate with m.p. 90–92° (from EtOAc–*n*-hexane) and $[\alpha]_D$ 0° (*c*, 2 $CHCl_3$).

Anal. Calcd. for $C_{19}H_{16}O_{10}N_2$: C, 52.78; H, 3.73. Found: C, 52.4; H, 3.68.

The derivative gave a complex n.m.r. spectrum in chloroform which was identical with that of 2,3-*O*-(2′-hydroxyethylidene)-D-glyceritol tris-*p*-nitrobenzoate, obtained from levoglucosan following successive periodic acid and sodium borohydride treatments. The polyol V obtained in this way had $[\alpha]_D$ +8.5° (*c*, 3.6 EtOH), and its derived bis-*p*-nitrobenzoate (from EtOAc) had m.p. 100–101° and $[\alpha]_D$ −17° (*c*, 1.1 $CHCl_3$).

Anal. Calcd. for $C_{19}H_{16}O_{10}N_2$: C, 52.78; H, 3.73. Found: C, 52.6; H, 3.8.

2,3-*O*-(2′-Hydroxyethylidene)-D-glyceritol prepared by periodic acid and sodium borohydride treatment of levoglucosan gave an n.m.r. spectrum in D_2O which was identical with that of a specimen prepared using sodium periodate and sodium borohydride as reagents. In the latter experiment the pH of the reaction solutions was kept above 7.

O-(2′-Hydroxyethylidene)-erythritols (Racemates of III (R = H) and IV (R = H)) from Cellulose Polyalcohol

Cellulose polyalcohol (11.0 g) prepared from fully oxidized cellulose, according to the previously described method, was partially hydrolyzed. The solution was neutralized (Ag_2CO_3), filtered, and evaporated to a sirup which was dissolved in hot ethanol (50 ml). On cooling, crystallization of erythritol (4.68 g), m.p. and mixed m.p. 108–111° took place and after filtration the mother liquor was evaporated to a sirup (5.0 g). Half of the sirup was treated with barium hydroxide as described previously and then fractionated on a cellulose column (solvent: benzene–ethanol–water 300:50:1 v/v) to give a mixture of *O*-(2′-hydroxyethylidene)-erythritols (0.70 g) which gave rise on acid hydrolysis to erythritol. On paper chromatography two spots were detected moving at 1.2 and 1.4 times the rate of glycerol (spray: ammoniacal silver nitrate) and corresponded to the 3,4-*O*- and 1,3-*O*-isomers, respectively. The latter was the major component since successive treatments of the fraction with sodium periodate, sodium borohydride, and acid gave erythritol and a small proportion of glycerol.

A portion (0.14 g) was converted to mixed tris-*p*-nitrobenzoates which were fractionally crystallized from ethyl acetate (10 ml) to give 3,4-*O*-(2′-hydroxyethylidene)-DL-erythritol tris-*p*-nitrobenzoate (37 mg) with m.p. and mixed m.p. 125–126° and $[\alpha]_D$ 0° (*c*, 2 $CHCl_3$).

Anal. Calcd. for $C_{27}H_{21}O_{14}N_3$: C, 53.03; H, 3.46. Found: C, 52.8; H, 3.7.

Its X-ray diffraction pattern was identical with that of authentic material isolated from starch polyalcohol. Addition of a little *n*-hexane to the mother liquor gave 1,3-*O*-(2′-hydroxyethylidene)-DL-erythritol tris-*p*-nitrobenzoate (170 mg) with m.p. 131–133° and $[\alpha]_D$ 0° (*c*, 2 $CHCl_3$).

Anal. Calcd. for $C_{27}H_{21}O_{14}N_3$: C, 53.03; H, 3.46. Found: C, 53.0; H, 3.5.

The product obtained on deesterification of this tris-*p*-nitrobenzoate was not oxidized by aqueous sodium periodate. The complex n.m.r. spectrum of the tris-*p*-nitrobenzoate in chloroform was identical with the spectrum of authentic 1,3-*O*-(2′-hydroxyethylidene)-DL-erythritol (4). It differed from that of 2,3-*O*-(2′-hydroxyethylidene)-erythritol (5).

ACKNOWLEDGMENTS

The authors would like to thank Dr. N. K. Richtmyer for samples of 1,3-*O*- and 2,3-*O*-(2′-hydroxyethylidene)-erythritols. Preparation of X-ray diffraction patterns and microanalytical determinations were carried out by Mr. W. Haid, and n.m.r. spectra were obtained by Mr. M. Mazurek.

THERMAL STABILITY OF AN ADSORBED ARRAY OF CHARGES IN THE EINSTEIN APPROXIMATION

J. Ross Macdonald and C. A. Barlow, Jr.
Texas Instruments Incorporated, Dallas, Texas
Received December 28, 1964

ABSTRACT

For an infinite hexagonal array of ions adsorbed on a conducting plane of infinite extent, the thermal fluctuation from strict lattice ordering in the neighborhood of a given adion is considered. The ions are imaged in the uniform, conducting adsorbent and are assumed to move freely in the plane; they thus arrange themselves in a perfect hexagonal array at absolute zero temperature. By use of the accurate planar potential seen by one adion moving in the field arising from an infinite number of fixed hexagonally arrayed surrounding ions, the root-mean-square (r.m.s.) amplitude of planar vibration of the ion relative to its neighbors is approximately determined for several values of nearest neighbor distances between ions, r_1. On the basis of these results, we find, for example, that for a distance, β, between the center of charge of an ion and the imaging plane of 3 Å, an ionic valence z_v of unity, and an effective dielectric constant of ϵ, a hexagonal array with $r_1 = 15$ Å is stable up to a temperature, T_0, of approximately $1760/\epsilon$ °K while one with $r_1 = 21$ Å is stable up to about $760/\epsilon$ °K. Results apply to adsorption from either a gas or liquid phase and, as well, to an array of real dipoles adsorbed on a non-conducting surface. The appropriate values for ϵ are of the order of 2 and 6, respectively, for adsorption from gas or from aqueous electrolytes. For various r_1's, explicit expressions for T_0 are obtained which depend on ϵ, β, and z_v.

INTRODUCTION

In many treatments (1–7) of the adsorption of ions from a gas phase onto a conducting plane adsorbent, it is assumed that the adions are strongly bound to the surface by physical or chemisorption forces but are free to move in the plane. If the adsorbent surface is relatively uniform and without many discrete, strongly preferred adsorption sites, then the mutual repulsion between adions will tend to make each such ion move as far away from every other ion as possible, leading, at absolute zero temperature and for surface coverage of a monolayer or less, to the establishment of a fixed hexagonal array of discrete charges, the configuration that minimizes the electrostatic energy of interaction in the plane. As the concentration of adions is quasi-statically increased, a hexagonal array will be maintained but with decreasing nearest-neighbor distance, r_1. Finally, a full hexagonally arranged monolayer of adsorbed ions will be reached when steric forces prohibit the addition of further adions in the first adsorbed layer.

At non-zero temperature, planar thermal vibrations of adsorbed ions will tend to destroy the long range order of the fixed hexagonal array. As the coverage is decreased, mutual repulsion between adions weakens because r_1 increases and, at a given non-zero temperature, a coverage will be reached where thermal energy and interaction energy are comparable and the order represented by the hexagonal array substantially disappears. Alternatively, at fixed coverage, increasing temperature will eventually lead to "melting" of the two-dimensional adsorbed structure and again the order will degrade.

This paper is concerned with establishing approximate but reasonably quantitative conditions for the loss of quasi long range order (defined later), primarily in the case of ions electrically imaged in a conducting adsorbent surface. Such imaging leads to the formation of nonideal discrete dipoles which can again form ordered hexagonal arrays at low temperatures or sufficiently high coverages. This situation of ordered dipolar arrays

has received much attention in treatments of adsorption from a gas phase, although the dipoles are usually approximated as ideal (1–6). Elsewhere, we (see ref. 8, hereafter referred to as II) have treated the situation of hexagonally arrayed, nonideal dipoles in considerable detail and have also discussed the error to be expected from using the classical electrostatic image potential. For most cases of interest, the error is small, and the classical imaging formula was used there and will also be employed herein since we shall make use here of planar potentials calculated by the methods of II.

The question of thermal stability of a hexagonal array of adions is also of importance in adsorption of ions from a liquid phase. In a number of treatments of the electrolyte double layer (9–13), it has again been assumed that at least above some minimum surface coverage, the ions adsorbed on the electrode (usually a mercury drop) arrange themselves in a fixed hexagonal array. In this situation, there is the possibility of imaging of adions in the diffuse double layer as well as in the electrode (10–13). Such imaging leads to an infinite array of image charges perpendicular to the adsorbent surface and has been termed infinite imaging (13). When the imaging in the diffuse layer is assumed to be incomplete, the situation is termed partial imaging, whose limit is the present single-imaging situation (8) when imaging in the diffuse layer (if it exists) is absent or negligible. Bell, Levine, and Mingins (14) have considered the thermal stability problem for a partial-imaging situation nearly approximating infinite imaging. Their results and method, which is based on more approximate planar potentials and calculations than those used herein, will be discussed later.

The results of the present treatment, which apply to adsorption from a gas phase and, perhaps to a somewhat lesser extent, to adsorption from an electrolyte, may be used to show under what conditions the single-imaging, hexagonal-array treatment of nonideal dipoles referred to earlier (8) is a good representation of the actual situation for an adsorbed layer of ions. Buff and Stillinger (15) have constructed a cluster integral theory of the double layer in which in treating the adsorbed ionic layer they properly account for short range forces. Hence, in their treatment the tendency of the adsorbed ions to form a lattice under conditions approaching close packing, as a result of the steric effects arising from such short range forces, is a natural consequence of the theory. It is important to recognize that the long range forces between the ions will also play a part in creating array structures. These arrays have nothing to do with steric effects and so are quite different from any arrays consistent with the Buff and Stillinger treatment. In the present work, we are concerned with the long range interaction type of array and ignore short range forces entirely. Our interest is to determine under what conditions such arrays are essentially undestroyed by thermal motion and therefore under what conditions arrays are adequate as models for the adsorbed layer. It should be pointed out that in those circumstances where the long range forces lead to array structures, the Buff and Stillinger theory loses validity: The reason for this is that in their theory (eqs. [33] *et seq.*) the long range forces are treated as a small perturbation—all Mayer f-bonds are linearized in the long range interaction and, consistent with this, contributions from the long range forces to clusters higher than first order are ignored. It is precisely in the regime where long range forces lead to array structures that such approximations become poor, however. Clearly, the treatments of Buff and Stillinger and those which assume an array model *ab initio* are complementary, but one should know where the crossover occurs, and this question, while not considered by Buff and Stillinger, is approximately answered by this paper. As we shall see, even for infinite imaging (13), where adsorbed concentrations must be somewhat

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

higher than for single-imaging situations in order that a hexagonal array will be formed and maintained at the usual experimental temperatures, there is an appreciable range of surface concentration less than the maximum experimentally observed concentration over which the hexagonal array seems to be a good model. The Buff and Stillinger approach seems more appropriate only at rather small adsorbed concentrations where quasi long range order has completely disappeared and where the effect of adsorption itself on measured quantities such as double-layer differential capacitance is still small.

THERMAL AVERAGING CALCULATION

Before actually attempting to estimate the degree of thermal disorder present in a lattice, it is desirable to present a physical picture of the system as the temperature is raised from absolute zero. Consider the surroundings of a given particle: At any finite temperature, the correlation between the position of that particle, taken to define the origin, and the position of any other particle is a steadily decreasing function of distance. In fact, for sufficiently large arrays there will be a distance beyond which the fluctuations of particle positions relative to the particle at the origin will be comparable to or greater than the zero-temperature lattice separation between nearest neighbors. It is consequently only within such distances that the lattice structure is a good concept. Within this distance, the environment of a particle is that of a two-dimensional "microcrystal"; beyond this distance are other particles in motion, essentially uncorrelated with the given particle and belonging to their own microcrystals. As a particle moves over the surface, some particles remote from the given one gradually leave this microcrystal and are replaced by other particles. Thus, after a sufficiently long time the original microcrystal will disappear and new microcrystals will have formed. In this respect, our two-dimensional system is different from the usual concept of a solid, three-dimensional lattice and resembles more the case of liquid crystals. Nonetheless, it is important to recognize that at any time the environment of any particle may be considered as a crystal of possibly very many lattice spacings in size. Now as the temperature is increased, the correlations between particle positions decrease and accordingly the sizes of the microcrystals decrease. Of course, provided the interaction potential between particles asymptotically falls off faster than the inverse square of the distance, all particles sufficiently remote from a given one will play an arbitrarily minor role in influencing that particle or its immediate surroundings. Accordingly, we shall say that quasi long range order exists provided the size of the microcrystals is sufficient that negligible change would result in the neighborhood of a given particle by taking the size of the microcrystals as infinite. In the present work, we shall, in fact, use the potential appropriate for an infinite array in carrying out thermal averaging.

As the temperature is raised further, quasi long range order begins to deteriorate and the particles become so agitated that eventually even the short range order, correlations between the positions of near neighbors, has dropped to a point where fluctuations play a significant role in determining even the local environment of a given particle. When the microcrystals have become only a few lattice spacings in linear dimension, a further raising of the temperature will finally destroy the obvious lattice structure and the n-body correlations remaining will become sufficiently small to be considered as mere perturbations upon a highly randomized system, as in Buff and Stillinger's (15) treatment of long range forces.

As has already been pointed out, the transition between the phase possessing indefinitely long range order and that described by microcrystals takes place at absolute zero. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

transition which concerns us here, however, is the one wherein the neighborhood of a particle ceases to resemble a lattice at all, that is, the melting of the microcrystals. It is this melting which truly affects the appropriateness of a lattice model of a particle array for practical purposes. We shall be concerned, therefore, with the regime in which this gradual phase transition takes place and shall use the term "quasi long range order" to indicate the order of a microcrystal having a minimum linear dimension sufficiently greater than r_1. Note that our treatment involves a gradual diminution of order and is not relevant to first order phase transitions which may possibly occur.

In describing melting phenomena of three-dimensional crystals, two types of criteria have been used: One of these involves macroscopic thermodynamic quantities such as chemical potentials and pressures of the two phases; the other approach (which should lead to the same results, of course) is the microscopic statistical method exemplified by the melting criterion of Lindemann. This criterion which provides that melting takes place when the root-mean-square (r.m.s.) displacement of a particle relative to its neighbors is of the order of the lattice spacing or thereabouts seems appropriate for the type of gradual loss-of-ordering transition considered here. In applying such a criterion to the present situation, the "critical" r.m.s. displacement is determined by the maximum amount of disorder deemed consistent with an array model. Thus, the value actually used amounts to a choice for which the ions fluctuate so strongly as to be somewhat weakly associated with their lattice sites but not so strongly as to destroy the appropriateness of such sites as estimates of particle positions, and hence of local potentials. Finally, some discussion is necessary regarding the basis for calculating the r.m.s. thermal motion of a given particle relative to its neighbors.

Let us consider a fixed hexagonal array of ions of charge e and their images in the plane, conducting adsorbent. Let β be the distance between the center of charge of an adion and the conducting plane and r_1 the nearest-neighbor distance for adsorbed ions. Take the origin of a rectangular coordinate system on the adsorbent surface between a given adion and its image, let x and y be in the plane, and take z positive along the outward perpendicular to the plane. For convenience define the normalized quantities $R_1 \equiv r_1/\beta$, $X \equiv x/\beta$, $Y \equiv y/\beta$, and $Z \equiv z/\beta$. Then $Z = 1$ will define the plane in which the centers of charge of the adions lie. There will be a charge at $(X, Y, Z) = (0, 0, 1)$, $(R_1, 0, 1)$, $(R_1/2, \sqrt{(3)}R_1/2, 1)$, etc.

An accurate treatment of thermal averaging should involve averaging in the plane with all adions subject to thermal motion. Since even the problem of determining the accurate potential at a given point in the $Z = 1$ plane arising from an infinite number of fixed, hexagonally arranged surrounding ions is itself quite difficult (8, 13), we shall consider the simpler problem in which the ion originally at (0, 0, 1) is allowed to move, under thermal perturbation, in the potential arising from all other ions and their images, taken to be substantially at the regular lattice sites. The solution of this problem will approximate closer and closer to the full vibration problem above as the planar r.m.s. distance of vibration from the equilibrium position at (0, 0, 1) decreases. For consistency as well as stability, of course, we demand that this r.m.s. vibration distance be sufficiently small. Since the criterion we shall use for melting of two-dimensional quasi long range order is not very precise, the accuracy and applicability of the solution of the simplified problem will be adequate for our purpose. This simplification was also made by Bell, Levine, and Mingins (14). In further support of the reasonableness of this approximation, we remark that the very same replacement of coupled particles by a system of individual particles, each

For personal use only.

vibrating in the constant potential well representing the average interaction (calculated here as though at absolute zero) with its neighbors, was introduced by Einstein to calculate the vibrational energy of a solid (16) (see ref. 17 for an application of the Einstein model to adsorption). When Debye subsequently removed this approximation, it was seen that in spite of the introduction of coupled vibrations the Einstein and Debye theories predicted almost identical behavior except at temperatures very close to absolute zero. When we realize that except for a multiplicative constant these thermal energies predicted so accurately by the Einstein model are identical to the mean-square-displacement of the particles relative to their neighbors, we gain some optimism regarding the usefulness of our approach.

To carry out two-dimensional averaging conveniently, we need an analytic expression for the potential $\psi_a(X, Y, 1) \equiv \psi_a$ at the point $(X, Y, 1)$ arising from all charges but that originally at (0, 0, 1). Although such an expression was obtained in II, it is too complicated to lend itself readily to the weighted double integration needed in two-dimensional averaging. Thus, here we shall initially consider one-dimensional averaging along certain selected lines in the plane, then apply these results to consideration of two-dimensional motion.

Bell, Levine, and Mingins (14) have carried out their thermal stability, partial-imaging treatment using a fixed-array planar potential arrived at by two distinct types of approximation. First, only terms in the potential quadratic in x and y have been kept. Second, the doubly infinite sums remaining in the expression for the potential have been approximated by finite sums: only contributions from ions and their images lying relatively near the origin have been included. The quadratic approximation allows the integrals arising in the averaging problem to be carried out analytically. Another consequence of retaining only terms through quadratic is that to this order of approximation the potential becomes circularly symmetric. This is very convenient in determining the r.m.s. thermal displacement from the origin in the two dimensions of the planar array inasmuch as each degree of freedom contributes equally, reducing the complexity of the problem to that of one dimension. In the present calculation, however, higher order terms destroy the circular symmetry and present us with an essentially two-dimensional problem which is not so easily reduced to one dimension. Thus, we have been led to the method of studying motion along selected lines. As it turns out, the potential for single imaging in the neighborhood of the origin ($r \equiv (x^2 + y^2)^{1/2} \lesssim 0.3r_1$) is fairly well approximated by the circularly symmetric form when a hexagonal array itself is a good approximation. We shall later see in the present single-imaging case how much difference is obtained between results calculated with the quadratic approximation and the results obtained when this approximation is not made.

Figure 1 shows the potential difference $\xi \equiv \psi_a(X, Y, 1) - \psi_a(0, 0, 1)$ plotted versus the normalized distance l for several values of R_1 and several specific lines in the plane indicated by the heavy lines and arrows in the diagrams. These curves were calculated by the method described in II using $\beta = 3$ Å, $\epsilon = 1$, and positive adions of unit valence. Here ϵ is the dielectric constant in the neighborhood of adsorbed charges and l is the distance from an assumed center of one-dimensional vibration normalized by the basic triangle height $h \equiv (\sqrt{(3)}/2)r_1$. Thus for the line to which the solid curves apply, $l \equiv 2r/\sqrt{(3)}r_1 \equiv 2R/\sqrt{(3)}R_1 \equiv 4x/3r_1$, where $R \equiv r/\beta$. This particular line, a binary axis (and its five other half-line equivalents under the symmetry of the hexagonal lattice), is that along which vibration can occur most readily because the potential increases most slowly along

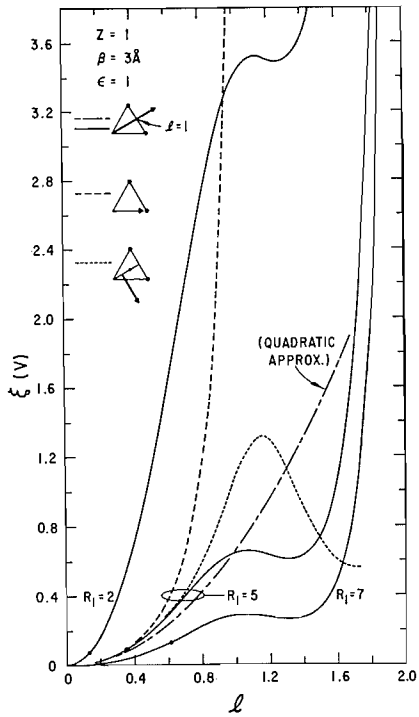

FIG. 1. The quantity $\xi \equiv \psi_a(X, Y, 1) - \psi_a(0, 0, 1)$ versus normalized distance: $l = |4X/3R_1|$, $l = (\sqrt{(3)}/2)|X/R_1|$, and $l = (1/\sqrt{3})|(4X/R_1) - 1|$, respectively, for the three directions indicated. The distance l is measured along the heavy directed lines in the diagrams.

this line. Thus, it is of the most immediate interest to obtain the r.m.s. distance, $\overline{(r^2)}^{\frac{1}{2}}$, of vibration along this line. It will be termed line 1.

Let us define $L \equiv \overline{(r^2)}^{\frac{1}{2}}/h$ as the normalized r.m.s. vibration amplitude. Then

[1]
$$L^2 = \frac{\int_0^\infty l^2 \rho(\xi) \exp(-e\xi/\epsilon kT)\, d\xi}{\int_0^\infty \rho(\xi) \exp(-e\xi/\epsilon kT)\, d\xi} = \frac{\int_0^{l\max} l^2 \exp(-e\xi/\epsilon kT)\, dl}{\int_0^{l\max} \exp(-e\xi/\epsilon kT)\, dl}.$$

The second form follows because the weighting factor $\rho(\xi) \propto (d\xi/dl)^{-1}$. The quantity l_{max} is the value of l for which $\xi = \infty$ provided such an l exists, and is infinite otherwise; $l_{max} = 2$ for line 1. The dielectric constant enters (1) because ξ was calculated with $\epsilon = 1$.

The introduction of ϵ is itself an approximation; it has been discussed at length elsewhere (6, 8, 13). For adsorption from a gas phase, there will be no material between adions and ϵ can arise only from adion polarizability itself. Therefore, in this case ϵ will vary with coverage and will lie between approximately 1 and 3 or 4 at most. In the single-imaging

electrolyte case, it has been found (8) that there is a very high field in the inner region of the double layer where ions are adsorbed and this field (for constant ϵ) varies only slightly with adsorbed ion concentration (itself a function of electrode charge). The field is large enough to produce almost entire dielectric saturation of the dipolar contribution of water molecules between adions. Thus, in this case the appropriate dielectric constant is probably 6 or less (8, 18) and will not vary much with coverage until the contribution from ionic polarizability outweighs that from water-molecule polarizability when the coverage approaches that of a monolayer. There is a feedback mechanism at work here which tends to ensure complete saturation. If the field is large enough to produce some dielectric saturation, the consequent reduction in ϵ will increase the effective field, reducing ϵ further and so on. The final self-consistent value of field and dielectric constant may not be that for complete saturation—this depends on the details of the dielectric constant-field dependence—but in the electrolyte single-imaging case, saturation is apparently virtually complete (8). In the present calculations, we shall use $\epsilon = 6$; remember, however, that ϵ and T enter the equations together. Thus, the lower ϵ appropriate for gas phase adsorption can be associated with a higher temperature than the 20 °C we shall use in the electrolyte situation.

Since the potential is an even function of l, it must involve l^{2n}, $n = 1, 2, 3 \ldots$, not l^n. To carry out the integrations in [1] numerically, we found it convenient to fit $\xi(l^2)$ by rational approximations of the form

$$[2] \qquad \xi \cong [l^2/f(l^2)] \sum_{i=0}^{3} \alpha_i l^{2i} \Big/ \sum_{i=0}^{3} \beta_i l^{2i},$$

where $f(l^2)$ varies in form with the line considered. For line 1, $f(l^2) = l^2 - 4$; for line 2, a bisectrix axis (associated with the dashed curve in Fig. 1), $f(l^2) = l^2 - 4/3$, $l_{max} = \sqrt{(4/3)}$; and for line 3 (associated with the dotted curve in Fig. 1), $f(l^2) = 1$, $l_{max} = \infty$. The constants α_i and β_i were determined for given β and R_1 from numerical values of $\xi(l^2)$ calculated by the methods of II. A Chebyshev type of rational fitting* was used in finding best values for α_i and β_i. This is an equi-ripple method which minimizes the absolute error between the original (or transformed) data and the approximation. Typical values obtained for $\beta = 3$ Å and $R_1 = 5$ were, for line 1, $\alpha_0 = 121.2885$, $\alpha_1 = -29.07516$, $\alpha_2 = -25.75952$, $\alpha_3 = 12.05564$, $\beta_0 = -45.52907$, $\beta_1 = 33.67155$, $\beta_2 = -29.53773$, and $\beta_3 = 1$. With ξ available to very high accuracy in the form of eq. [2], the integrals of [1] could be readily evaluated numerically.

It is of interest to note that when $\xi(l^2) \cong \chi l^2$, where χ is a constant, the integrals can be evaluated analytically and yield

$$[3] \qquad L_0 = (\epsilon kT/2e\chi)^{1/2} \equiv (\phi_1/\chi)^{1/2},$$

where $\phi_1 \equiv \epsilon kT/2e$. This quadratic approximation has been evaluated in several cases using χ values obtained from an accurate fit of $\xi(l^2)$ near the origin. The dash–dot curve of Fig. 1 is the result for $R_1 = 5$ and line 1. For the quadratic approximation, as pointed out by Bell, Levine, and Mingins (14), who used only this approximation with $2\phi_1$ rather than ϕ_1 since two-dimensional vibrations were envisaged, the average value $\bar{\xi} = \epsilon kT/2e = \phi_1$. Since the original ξ was defined with $\epsilon = 1$, we must divide the above result by ϵ to obtain the average potential difference appropriate to a non-unity value of ϵ.

RESULTS OF CALCULATIONS

The single-imaging curves of Fig. 2 were calculated for line 1 using eqs. [1] and [3]. Clearly, terms in ξ higher than l^2 cause L to be less than L_0 provided the peak and valley parts of the ξ curves have negligible effect in the averaging. When they do become important, for $R_1 > 4.5$, the moving ion can vibrate further, on the average, and $L > L_0$. The dotted curve in Fig. 2 has been derived from the results of Levine, Mingins, and Bell (14) by transforming from the value $\epsilon = 10$ they used to $\epsilon = 6$, more appropriate for the electrolyte situation, by changing the normalization to agree with our convention, and by dividing their results by $\sqrt{2}$ to change (within the framework of the quadratic approximation) from two-dimensional to one-dimensional motion and averaging. It is evident that the ion can vibrate considerably more freely in the nearly infinite-imaging case than in the single-imaging case. For $\epsilon = 2$, more appropriate for adsorption from a gas phase, the curves of Fig. 2 apply to a temperature of about 790 °K.

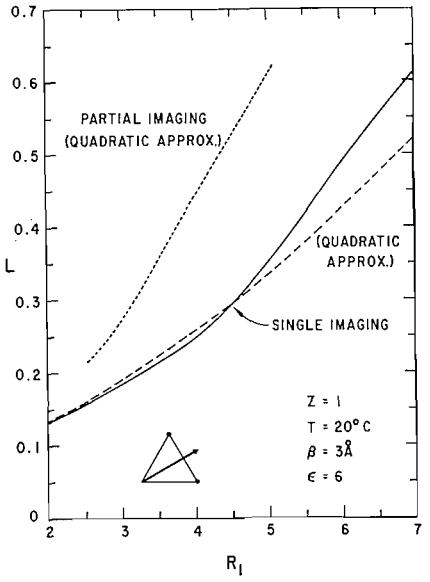

FIG. 2. The normalized r.m.s. vibration amplitude $L \equiv [3(\overline{X^2 + Y^2})/4R_1^2]^{1/2}$ versus normalized nearest-neighbor distance $R_1 \equiv r_1/\beta$.

The superiority of two-dimensional over one-dimensional averaging depends on the ratio of the normalized distance l_0, over which circular symmetry is a good approximation, to L. If both these numbers are small enough that a hexagonal array is well maintained, two-dimensional averaging using the quadratic approximation will be the more appropriate provided $l_0/L \lesssim 1$. When vibration along a particular line, such as line 1, is greatly favored over all other directions of vibration, l_0/L will be much less than unity and the assumption of circular symmetry will be very poor.

Figures 1 and 2 show that $l_0/L \approx 1$ for $R_1 = 5$. The ratio will be even larger for smaller R_1. Thus, for the input parameters shown in Fig. 2, two-dimensional averaging will be a somewhat better approximation than one dimensional for $R_1 \gtrsim 5$. If a criterion is established for the maximum one-dimensional L for which we may expect maintenance of a hexagonal array, then the criterion is divided by $\sqrt{2}$ to obtain that appropriate for

For personal use only.

circular symmetry and two-dimensional averaging. It seems to us reasonable to pick $L \lesssim 0.5$ as a rough criterion for hexagonal array (microcrystal) stability. This is somewhat more stringent than that used by Bell, Levine, and Mingins (14) when transformed to the same basis for comparison. The two-dimensional criterion is thus $L_2 \lesssim 0.35$. It is of interest to compare this figure with the corresponding one for the melting of single-crystal solids: In the latter case the value ~ 0.1 has been found to be appropriate (19); however, it is important to realize that the case considered here is actually quite different from that of solids insofar as first order phase transitions are not treated and the forces are the long range repulsions of the similarly charged adions and their images rather than the crystal-binding fields of an ionic crystal or the short range forces found in metals and covalent crystals. We should accordingly not expect the analogous values to carry over from one situation to the other. Although we have here used the stability criterion $L_2 \lesssim 0.35$, Fig. 2 may be used in conjunction with any other reasonable value to obtain the limiting value of R_1 appropriate to the new criterion.

Since $L \simeq 0.35$ from Fig. 2 for $R_1 = 5$, this value of R_1 seems, according to the above criterion, to be at or near the limit of hexagonal stability for the choices $\beta = 3$ Å, $z_v = 1$, $\epsilon = 6$, and 20 °C. Further, Fig. 1 shows that for $l \lesssim 0.35$, circular symmetry is a fair approximation for $R_1 = 5$. In fact, the values of L obtained for lines 1, 2, and 3 were 0.351, 0.268, and 0.344, respectively, for $R_1 = 5$. The fair correspondence of these figures indicates the approximate validity of the circular symmetry assumption for $R_1 \lesssim 5$ under the conditions of Fig. 2. The quadratic approximation for $R_1 = 5$ leads to $L_0 \simeq 0.336$, again showing that this further approximation is also not too bad for this value of R_1. Note that the heavy solid circles on the curves of Fig. 1 indicate the calculated values of L for the conditions of Fig. 2. It is worth noting that these conditions lead for $R_1 = 5$ to an adsorbed charge density, q_1, of 8.22 μC/cm^2, a nearest-neighbor distance of 15 Å, and an area per adsorbed ion of about 195 Å^2.

When the present two-dimensional averaging stability criterion is applied to the partial-imaging curve of Fig. 2, one obtains a limiting R_1 of about 3.5. In turn, this leads to a limiting area per ion of about 106 Å^2, almost exactly the criterion for loss of hexagonal order derived by Bell, Levine, and Mingins for the partial-imaging case. This agreement is somewhat fortuitous since the effect of our more stringent criteria for loss of quasi long range order is offset by the present use of $\epsilon = 6$ rather than 10. Comparison of the present results for partial and single imaging shows that the hexagonal array is appreciably more rigid for single imaging, and quasi long range order is not lost until ionic nearest-neighbor distance is appreciably greater in the single-imaging case than for partial imaging. Note especially that since the circular symmetry assumption is not very well met for $R_1 = 5$, the criteria for melting should actually lie between the two values 0.35 and 0.5, leading to a larger limiting R_1 than 5 (and accordingly even poorer applicability of the assumption of circular symmetry) for stability calculations at 20 °C.

Finally, Fig. 3 shows how L depends on ϕ_1 for several values of R_1. The temperature scale shown at the top is appropriate for $\epsilon = 6$; its values should be multiplied by 3 for the choice $\epsilon = 2$ more appropriate in the gas adsorption situation. In this case, we see that even the array with $R_1 = 7$ will be stable at room temperature. For $\epsilon = 3$, it will be stable only below about −20 °C. We may write the temperature at which stability tends to disappear according to the present two-dimensional criterion as $T_0 \sim 1760/\epsilon$ or $760/\epsilon$ °K for $r_1 = 15$ Å or 21 Å, respectively, when $\beta = 3$ Å. Note that since the $R_1 = 2$ curve is exactly proportional to $\sqrt{\phi_1}$, the circular symmetry and quadratic approximations are completely valid for this curve.

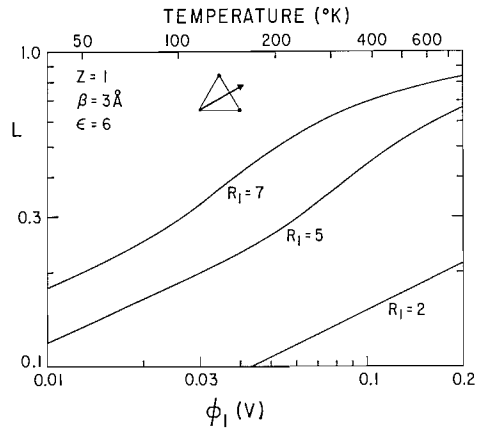

FIG. 3. The normalized r.m.s. amplitude L versus $\phi_1 \equiv \epsilon kT/2e$. The temperature scale at the top applies for $\epsilon = 6$.

Thus far, we have considered only adions of valence $z_v = 1$. When z_v is different from unity, our ϕ_1 becomes ϕ_1/z_v^2. Thus, for adions of valence 2, for example, the instability temperature is four times greater than that for $z_v = 1$. Further, when $R_1 \gtrsim 5$, it turns out (8) that $\psi_a(0, 0, 1)$, for example, may be well approximated by β times the field at (0, 0, 1) derived by replacing all nonideal dipoles by ideal dipoles (6). In this case, ξ will be proportional to β^2, and our present L curves, derived with $\beta = 3$ Å, may be transformed to apply to arbitrary β by replacing a given ϕ_1 by ϕ_1/β^2. In the present work we have used $\beta = 3$ Å since this value seems most appropriate for most electrolyte double layer situations of interest. In adsorption from a gas phase, β may frequently be somewhat smaller even when the imaging plane is taken ≈ 0.5 Å behind the "physical" surface of the conducting adsorbent (8, 16). When $R_1 \gtrsim 5$, the effective ϵ appropriate for adsorption from a gas phase is probably (6) appreciably less than 2. For $r_1 = 15$ Å, we may finally write $T_0 \sim 1760(z_v\beta/3\text{ Å})^2/\epsilon$ °K. A similar expression for $r_1 = 21$ Å is $T_0 \sim 760(z_v\beta/3\text{ Å})^2/\epsilon$ °K.

No information seems currently available concerning the sharpness of melting of two-dimensional order with temperature increase or increase in nearest-neighbor distance. It is clear, however, that if quasi long range order has disappeared by the time R_1 has reached a certain value, say R_{10}, R_1 must be somewhat smaller than R_{10} before the order will reestablish itself. Further, R_1 must be larger than R_{10} before the cluster theory of Buff and Stillinger (15) is a good approximation. If $R_{10} = 5$, for example, corresponding to a q_1 of 8.22 μC/cm², a q_1 of 10 or 12 μC/cm² might be required before hexagonal order were regained, and a value of q_1 as small as 5 or 6 μC/cm² might be required before the Buff–Stillinger approach would be applicable. As an example, for 1.0 N KI ($z_v = -1$), the results of Grahame (20) indicate that the charge on the electrode, q, might have to be less than ~ -9 μC/cm² for the Buff–Stillinger approach to apply and greater than ~ -6 μC/cm² for the hexagonal lattice model to apply. Between -9 and -6 μC/cm² neither model would theoretically apply well but the gap might be bridged reasonably accurately by extrapolation between the results of the two approaches. Grahame's data extends to $q_{max} = 18$ μC/cm² and $|q_{1(max)}| \cong 42.61$ μC/cm², indicating that the hexagonal model applies, at 20 °C, $\epsilon = 6$, and $z_v = \pm 1$, over a much greater and more important part of the $|q_1|$ range than does the Buff–Stillinger approach.

TERPENOIDS

XII. THE STRUCTURE OF CHAPARRIN[1]

T. A. DAVIDSON, T. R. HOLLANDS, P. DE MAYO, AND M. NISBET
Department of Chemistry, University of Western Ontario, London, Ontario

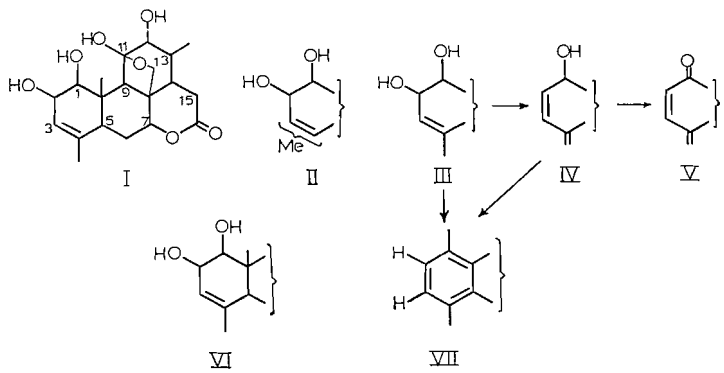
Received June 23, 1965

ABSTRACT

Chaparrin, the bitter principle from *Castela nicholsonii* may be dehydrated in two stages to give the partially aromatized substance chaparrol. By further stepwise degradation the latter has been converted to the dihydrophenanthrene (XIII) which allows the assignment of structures XVII and I to chaparrol and chaparrin respectively.

In 1922 Bosman (2) reported the isolation, from *Castela nicholsonii* Hook (Chaparro amargosa), of two bitter substances, castelin and castelamarin. In view of the improbable nature of the structure (the lactone of 2-hydroxy-3-methoxycyclohexaneacetic acid) proposed for one of these, a reinvestigation seemed called for. However, an attempt to isolate either of these substances failed. Instead, a new and apparently unrelated compound was obtained and characterized. While it was under investigation the isolation of the same substance was reported by Geissman and Chandorkar (3). Although there were originally minor differences in the characterization, essentially similar conclusions had been reached. Further degradative work was then continued with exchanges of information between the two groups resulting, by different means, in the same gross structural conclusions (1, 4).

It is the purpose of this report to present our results leading to the selection of formula I as the representation of the constitution of chaparrin. Our results leading to the elucidation of the stereochemistry and absolute stereochemistry of this substance together with those of chaparrol and its isomers neochaparrol and isochaparrol will be presented in the following paper in this series.



Chaparrin, best isolated (see Experimental) as the acetate mixture, forms a tri- and a tetraacetate from which chaparrin can be recovered on alkaline hydrolysis. Since chaparrin has the formula $C_{20}H_{28}O_7$ three oxygen atoms remain to be accounted for.

Of these, two must be present in a lactone. Thus, although chaparrin will dissolve in aqueous alkali and is precipitated from the alkaline solution on acidification it shows, itself,

[1]*Part of the material here described was first presented in preliminary form (1).*

For personal use only.

no acidic properties: it is, for instance, recovered unchanged on brief diazomethane treatment. Since the infrared spectrum of the acetate shows no absorption higher than 1740 cm^{-1}, and the lack of strong maximal absorption in the ultraviolet precludes the possibility of α,β-unsaturation, the presence of γ-lactone could be excluded. The ready re-lactonization on acidification rendered a large ring lactone improbable, leaving only a δ-lactone for serious consideration.

The remaining oxygen atom is assigned to a carbonyl function (masked in chaparrin itself) for the following reasons. Chaparrin triacetate-A and chaparrin tetraacetate both show the low intensity $n \rightarrow \pi^*$ absorption in the ultraviolet associated with saturated ketones and aldehydes. Chaparrin does not, however, have absorption here nor does it show a Cotton effect in its optical rotatory dispersion (o.r.d.) curve. The sodium salt, on the other hand, shows carbonyl absorption near 1 730 cm^{-1} (Nujol mull). These facts, and others to be described below and in the following paper establish that chaparrin is a hemi-ketal. Since this is so, the absorption at 1 720 cm^{-1} shown by chaparrin must be attributed to the δ-lactone alone and supports the assignment of ring size.

Chaparrin shows only end-absorption in the ultraviolet (ϵ_{203} = 5 600) and so is devoid of conjugation. On bromination of the tetraacetate a crystalline tetraacetate dibromide was obtained. Since chaparrin and its acetates showed no indication of further unsaturation, with the functional groups already enumerated, chaparrin must be tricarbocyclic.

Chaparrin tetraacetate contains three methyl groups. One (at τ 8.57, singlet) is attached to quaternary carbon while a singlet at τ 8.32 indicated the presence of a vinylic methyl group. The third methyl group appeared as a doublet centred at τ 9.00 ($J \sim 6.6$ c.p.s.) (see also Table I) and was assigned to a methyl group attached to carbon bearing one hydrogen atom.

Some indication as to the environment of the ethylenic linkage was obtained by periodic acid titration of chaparrin. There was a rapid consumption of 1 mole of oxidant, and the crude product showed maximal absorption at 244 mμ ($\epsilon \sim 4\,500$). Since there is both a single ethylenic linkage and vinyl methyl group, this suggested the presence in chaparrin of the system indicated in II. This was more clearly shown by the following sequence of transformations.

On heating in 0.1 *N* hydrochloric acid chaparrin loses one molecule of water to give, amongst other products, a diene, characterized as the triacetate. This diene shows maximal absorption of 228 mμ (ϵ = 13 400) and so is heteroannular and very lightly substituted. In the n.m.r. spectrum it could be observed that the vinyl methyl absorption was now absent, and that absorption (two protons) had appeared at τ ca. 5.00 (multiplet in the triacetate) which could be attributed to an exocyclic methylene group. This compound, anhydrochaparrin-A, on hydrogenation, absorbed two molecules of hydrogen giving a crystalline tetrahydroanhydro derivative which was optically transparent in the ultraviolet. These observations are compatible with the conversion of the part-structure shown in III to that shown in IV.

Oxidation of anhydrochaparrin-A with 2,3-dichloro-4,5-dicyanobenzoquinone (DDQ) gave, by conversion of an alcohol to a ketone, a dienone with maximal absorption at 276 mμ (ϵ = 10 000). This is compatible with expectation for a substance with structure V.

On prolonged treatment with dilute mineral acid chaparrin may be induced to lose a second molecule of water (4). This may also be achieved by passage of anhydrochaparrin-A in ether–benzene solution through a column of alumina or, better, by dissolution of chaparrin in cold concentrated hydrochloric acid. The product, chaparrol, $C_{20}H_{24}O_5$, is aromatic. It shows benzenoid absorption in the ultraviolet (ϵ_{268} = 400) and inspection of the n.m.r.

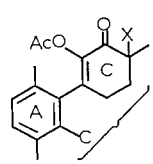
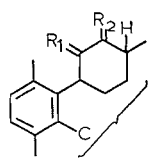
spectrum confirmed this conclusion since the presence of two aromatic protons, as a singlet (at τ 3.02), could be observed. Two aromatic methyl groups at τ 7.74 and 7.79 were also present, the chaparrin singlet near τ 8.57 now being absent. Taking into consideration the requirements expressed in the part-formula III, the part-structures VII and VI for chaparrol and chaparrin follow, the conversion of IV to VII being, essentially, a dienol–benzene rearrangement (5). Chaparrol proved a useful starting point for further structural investigation into the remaining rings of the chaparrin framework.

Under a variety of conditions chaparrol could be oxidized by hexavalent bismuth to give enolic material. In acetic acid a monoacetate was obtained which on methylation with diazomethane gave a methyl ether monoacetate. The methyl ether itself was obtained with bismuth triacetate in ethylene glycol again followed by treatment with diazomethane. Oxidation in acetic acid followed by acetylation gave the enol acetate monoacetate. The ultraviolet absorption of these compounds clearly indicated the conjugation of the enolic system with the aromatic ring.

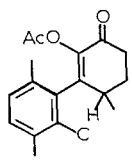
Bromination of the enol acetate gave a monobromo derivative in which this extended chromophore was untouched. The position of entrance of the bromine atom was revealed by changes in the signal for the remaining non-aromatic methyl group. This absorption, originally present (Table I) as a doublet near τ 9.0 was now displaced to 7.73 and had become a singlet. This permitted the part-structure VIII, X = Br to be written for the bromoenol acetate and VIII, X = H for the enol acetate itself. At this point the alternative IX for the enol acetate could not be strictly excluded, but was unlikely in view of the tetracyclic nature of the substance and the restrictions implied by Bredt's Rule. The size of ring C (VIII, X = H) was suggested by the position of absorption (at 1 697 cm^{-1}) of the ketonic carbonyl group.



VIII



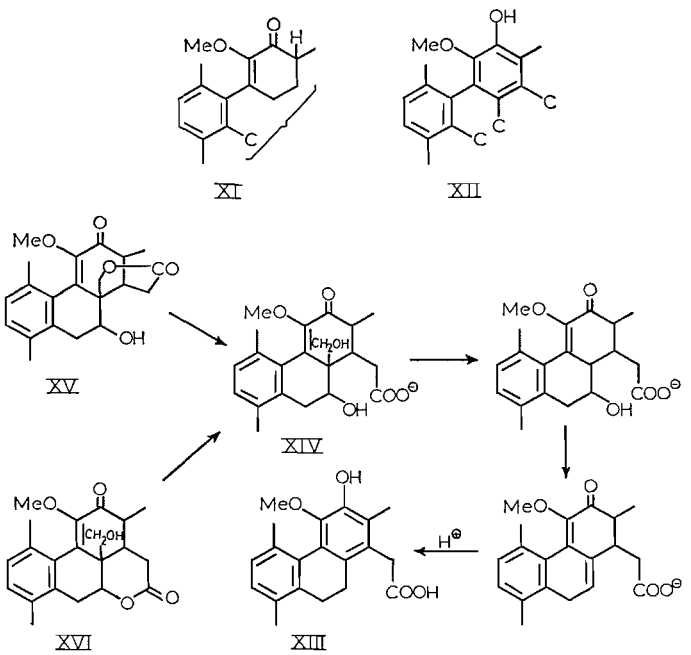
X a R_1 = O
R_2 = H,OH
b R_1 = H,OH
R_2 = O



IX

These facts required that the part-structure VII for chaparrol be expanded to X*a* or X*b*.

In the n.m.r. spectrum of a number of chaparrin and chaparrol derivatives there appeared a two-proton nonequivalence quartet. Chaparrin tetraacetate, for instance, shows these signals at τ 5.75 (2H, AB; J_{AB} = 12.6; $\delta_B - \delta_A$ = 44.2 c.p.s.). The presence of these signals was suggestive of a $-CH_2OR$ (R = H or Ac) grouping in these compounds, where the point of attachment was a quaternary carbon. The correctness of this view is shown by the following sequence of reactions which also revealed the disposition of the atoms constituting rings B and D.



The enol methyl ether (XI) was treated with dilute alcoholic alkali: conditions suitable for the induction of dealdolisation. After standing, the solution was acidified and a crystalline product obtained. Its analysis indicated that in the overall process the elements of formaldehyde had been lost. This substance evidently contained an enolic acidic function because of the spectral shift observed in the ultraviolet in neutral and alkaline solution. Further information was contained in the n.m.r. spectrum (Fig. 1). In this spectrum signals for three aromatic or vinylic methyl groups were apparent. Since two were necessarily to be attributed to ring A the previously secondary methyl group in ring C (in XI) must now be attached to a double bond. The methyl ether remained intact, and there were still only two aromatic protons. The original nonmethylated oxygen adjacent to the ether must, therefore, still be present, and must be the new enolic (and therefore phenolic since the enol required stabilisation) function. Part-structure XII may then be written in which two carbon atoms are lacking. One of these is the carbonyl group of the original lactone, while the other was represented in chaparrin and chaparrol by the $—CH_2OH$ grouping. In a supposed reverse aldol reaction this would be eliminated as formaldehyde (6). That this was so was confirmed by treatment of VIII (X = H) with sulfuric acid and estimation of the formaldehyde (15%) by the chromotropic acid procedure (10).

A singlet (2H) at τ 6.20 in the n.m.r. spectrum of the phenol remained to be attributed. This is in the position expected of a phenylacetic acid, and so permitted the final representation of the structure of the dihydrophenanthrene derivative as XIII. The ultraviolet absorption spectrum may be compared with those of certain diphenyls (Fig. 2): more exact models are not available.

Its genesis from the anion XIV allows of two structures for the ether itself (and therefore of chaparrol), depending on the position of lactonization (XV and XVI). The n.m.r. spectrum of chaparrol shows a multiplet (1H) near τ 5.5 which moves very slightly (to 5.2) in a monoacetate prepared from chaparrol by heating in acetic anhydride in the absence of base. However, in this derivative a nonequivalence quartet (2H) is visible at τ 6.01

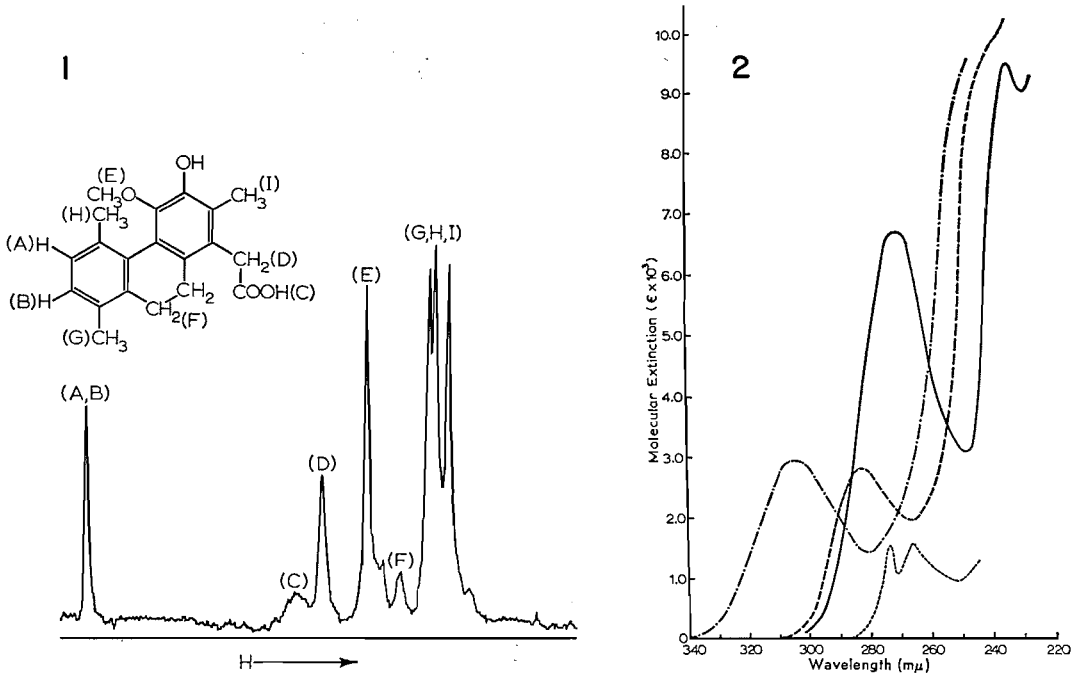

FIG. 1. Nuclear magnetic resonance spectrum of dihydrophenanthrene (XIII).
FIG. 2. Ultraviolet spectra of – – – neutral and —·—·— alkaline dihydrophenanthrene (XIII); of —— 2-hydroxy-2′-methoxybiphenyl (ref. 12, λ_{max} corrected for solvent); and of – – – – 2,2′,5,5′-tetramethyl biphenyl (ref. 13, λ_{max} corrected for solvent).

(2H, AB; J_{AB} = 12.0; $\delta_B - \delta_A$ = 22.8 c.p.s.) in an area quite clear of absorption in chaparrol, itself requiring that the primary hydroxyl group be that function acetylated. The single hydrogen must accordingly be attributed to the lactonic methine hydrogen, both facts requiring that the primary hydroxyl group not be involved in lactone formation: structure XV for the ether must therefore be excluded.

With the main structure of chaparrol completed only the specific positions of the oxygen in the masked ketol in ring C remained to be ascertained. In a large number of derivatives of chaparrin and chaparrol there appears a singlet (1H) whose position fluctuates about τ 7.0. In chaparrin tetraacetate and chaparrol monoacetate it is at 6.71 and 6.93 respectively. Deuterium exchange studies (to be reported later) indicate that this proton is adjacent to a (masked or potential) carbonyl. Since, in all compounds (including those derivatives where C_9 is inverted) the band, attributed to the proton at C_9, remains a singlet, then there are no protons on carbon atoms adjacent to C_9. Hence C_{11} must be the location of the (masked) carbonyl. The singularity of the absorption also provides confirmatory evidence for the position of the —CH_2OH grouping. The correctness of XVII as the representation of chaparrol was demonstrated by the nature of an acetate obtained from chaparrol by acetylation with acetic anhydride and pyridine. This substance (XVIII) was a triacetate, as shown by analysis and by the presence of three singlets in the n.m.r. spectrum to be attributed to acetyl groups. It was thus an enol acetate. This was confirmed by the ultraviolet spectrum which exhibited intense maximal absorption at 244 mμ. In this substance the absorption attributed to the proton at C_9 is lacking.

A combination of the part-structure VI with that part of XVII which is relevant to chaparrin leads to two possible formulations for the latter, XIX and I. That represented by XIX may be rejected because the proton at C_9, as already mentioned, is a singlet.

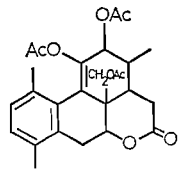
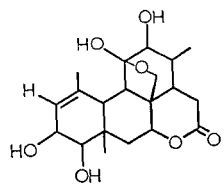
XVII



XVIII

With the structure of chaparrin and chaparrol established it is possible to discuss the nature of some reduction products of these compounds.

Reduction of chaparrol with sodium borohydride gave a dihydro compound showing no carbonyl absorption in the infrared spectrum. Oxidation with chromium trioxide in pyridine gave back some chaparrol. That reduction of the (masked) carbonyl had not taken



XIX

place was shown by the ultraviolet spectrum of the triacetate obtained by acetylation (acetic anhydride – pyridine) of this dihydrochaparrol. This showed the same maximal absorption (at 244 mμ) in the ultraviolet as did chaparrol triacetate. Furthermore acetylation of the dihydrochaparrol gave a triacetate which could be oxidized with manganese dioxide overnight to regenerate chaparrol triacetate.

It is, therefore, the lactone which has been reduced by the sodium borohydride treatment. The initially observed formation of only a triacetate under the acetylation conditions was not surprising since the hydrolysis of a labile hemiacetal acetate could be expected during the working up. Under modified conditions the tetraacetate could be isolated. The sequence of reactions can be represented as in XVII $\rightarrow$ XXI.

Reduction of chaparrin tetraacetate in a similar manner gave an acetal triacetate in which one of the four original acetoxyl functions had also been hydrogenolyzed. Under acetylation conditions the relevant hydroxyl group was reacetylated with the formation of the hemiacetal tetraacetate. Oxidation of this with chromic acid in acetic acid regenerated chaparrin tetraacetate. Oxidation of the hemiacetal in the hemiacetal triacetate with sodium dichromate in acetic acid or with manganese dioxide, gave a triacetate of chaparrin (chaparrin triacetate B) different from that previously obtained by the acetylation of chaparrin. The resistance to further oxidation with manganese dioxide probably excludes C_2 as the site of hydrogenolysis and the position of the free hydroxyl group, while the presence of the nonequivalence quartet at τ 6.17 (2H, A.B; $J_{AB} = 9.0$; $\delta_B - \delta_A = 20.9$ c.p.s.) implies that the primary hydroxyl group is not acetylated. Hydrogenolysis must therefore have occurred at this position.

More prolonged exposure of chaparrin tetraacetate to the action of sodium borohydride gave a substance lacking carbonyl absorption in the infrared spectrum. This substance, which had the empirical formula $C_{20}H_{30}O_7$, most probably has the structure XXII corresponding to a dihydrochaparrin.

The structure of chaparrin so arrived at has many features in common with that of quassin (7, 8) the bitter from *Quassia amara*. Since the first presentation of this work in preliminary form, Polonsky and her collaborators, in the course of an impressive and detailed study of Simaroubacea constituents, have elucidated the structure and stereochemistry of glaucarubol (9) the bitter from *Simaruba glauca* and their deductions have been confirmed by X-ray analysis (11). This substance they showed, stereochemistry aside, to be a 15-hydroxychaparrin. Further comment on this relationship will be made in the following paper.

EXPERIMENTAL

Infrared spectra and rotations were determined in chloroform solution, ultraviolet spectra in 95% ethanol and "light petroleum" refers to the fraction of b.p. 60–80°. Melting points were determined on the Köfler hot stage.

Thin-layer chromatography (t.l.c.) was done using Camag silica gel DF-5 with fluorescent indicator. Elution of fractions from preparative t.l.c. was done with ethyl acetate.

The n.m.r. spectra were determined in deuteriochloroform using 1% tetramethylsilane as internal standard using a Varian D.P. 60 spectrometer. The peak positions were determined using an audio oscillator calibrated with a Hewlett Packard 522-B frequency counter. Band positions are in tau (τ) units.

Isolation of Chaparrin Tri- and Tetraacetates

The ground branches (3 kg) supplied by S. B. Penick and Co. were soaked in ethanol (95%, 8 l) for 24 h. After draining, fresh alcohol was replaced and the procedure repeated a total of five times. Evaporation of the combined extracts to 4 l under reduced pressure led to the separation of a green greasy solid which was collected and defatted by extraction in a soxhlet with benzene. The resultant powdery solid (40 g) was acetylated (acetic anhydride – pyridine, room temperature overnight) and the acetylated material was evaporated to dryness under reduced pressure.

The residue in benzene was added to a column of alumina (Brockmann Grade III, 530 g). Elution with ether–benzene (1:19) gave chaparrin tetraacetate (3.7 g) which after recrystallization from ethyl acetate – light petroleum had m.p. 229–231°, $[\alpha]_D$ +33° (*c*, 1.29 in pyridine), $\lambda_{max}^{CHCl_3}$ 308 mμ (ϵ = 38).

Anal. Calcd. for $C_{28}H_{36}O_{11}$: C, 61.22; H, 6.64. Found: C, 61.19; H, 6.46.

Further elution with ether–benzene (1:9) gave chaparrin triacetate-A (8.5 g) which after recrystallization from ethyl acetate – light petroleum had m.p. 125–135° (solvated), $[\alpha]_D$ −4° (*c*, 0.91 in pyridine) and +70° (*c*, 1.01), $\lambda_{max}^{CHCl_3}$ 315 mμ (ϵ = 25). The analytical specimen was dried at 140° (0.1 mm).

Anal. Calcd. for $C_{26}H_{34}O_{10}$: C, 61.65; H, 6.77. Found: C, 61.94; H, 6.82.

Preparation of Chaparrin

The hydrolysis of either acetate, or a mixture of the two as isolated by partial chromatographic separation may be performed as follows: The acetate (~40 mg) in alcoholic potassium hydroxide (1 *N*; 3 ml) was heated on the steam bath for 90 min. The alcohol was removed under reduced pressure, water (5 ml) was added, and the mixture was acidified. The resultant precipitate was collected, washed with water, and dried (m.p. 299–301°). Recrystallization from methanol gave material of m.p. 306–308°, $[\alpha]_D$ +14° (*c*, 0.81 in pyridine). The material showed no maximum in the ultraviolet between 300–320 mμ in methanol or in dimethylformamide λ_{max} 203 (ϵ = 5 600).

Anal. Calcd. for $C_{20}H_{28}O_7$: C, 63.14; H, 7.42. Found: C, 62.84; H, 7.22.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Chaparrin (18.3 mg) in aqueous methanol was treated with excess periodic acid. The consumption was 1.01 atoms of oxygen. After 100 h this had increased to 1.55 atoms. Extraction of the residue gave material having absorption at 244 mμ ($\epsilon \sim 4\,500$).

Acetylation of Chaparrin Triacetate-A

The triacetate (54 mg) in pyridine (4 ml) and acetic anhydride (2 ml) was heated at 110° for 4 h. The reagents were removed *in vacuo* and the residue crystallized from ethyl acetate – light petroleum to give the tetraacetate, m.p. 218–232°. Recrystallization gave material (44 mg) m.p. 228–230°, $[\alpha]_D$ +35° (*c*, 0.99 in pyridine).

Bromination of Chaparrin Tetraacetate

The tetraacetate (50 mg) in chloroform (1 ml) was added to a solution of bromine in chloroform (0.2%, 10 ml). The mixture was allowed to stand for 8 h, excess bromine was removed with aqueous sodium thiosulfate, and the product separated by t.l.c. (solvent: diethyl ether). After crystallization from methanol at low temperature the dibromide was obtained, m.p. 158–160°, $[\alpha]_D$ +119° (*c*, 0.6).

Anal. Calcd. for $C_{28}H_{36}O_{11}Br_2$: C, 47.45; H, 5.08. Found: C, 47.92; H, 5.14.

Anhydrochaparrin-A

Chaparrin (92 mg) was dissolved in methanol (100 ml); water (80 ml) and hydrochloric acid (*N*, 20 ml) were then added, and the solution was heated for 4 h (until there was little further change in the absorption near 225 mμ). After isolation with chloroform the product was crystallized from ethanol to give anhydrochaparrin-A, m.p. 258–260°, $[\alpha]_D$ +40° (*c*, 0.77 in ethanol), λ_{max} 230 mμ (ϵ = 17 500).

Anal. Calcd. for $C_{20}H_{26}O_6$: C, 66.28; H, 7.23. Found: C, 66.05; H, 6.99.

Anhydrochaparrin-A Triacetate

(*a*) Anhydrochaparrin-A (35 mg) in pyridine (4 ml) and acetic anhydride (2 ml) was allowed to stand overnight. Evaporation and crystallization from ethyl acetate – light petroleum gave the triacetate, m.p. 178–180°, $[\alpha]_D$ +61° (*c*, 1.5). The compound showed no absorption in the hydroxyl region (3 600 – 3 400 cm^{-1}) of the infrared spectrum.

Anal. Calcd. for $C_{26}H_{32}O_9$: C, 63.92; H, 6.60. Found: C, 64.36; H, 6.75.

(*b*) Chaparrin tetraacetate (50 mg) was refluxed in acetic acid (2 ml) for 6 h. Evaporation and crystallization of the residue from ethanol gave the triacetate (23 mg), m.p. 178–180°, $[\alpha]_D$ +58° (*c*, 0.51), λ_{max} 223, 230, 239 (ϵ = 16 300, 17 700, and 11 000) respectively.

Hydrogenation of Anhydrochaparrin-A

The compound (42 mg) was hydrogenated in ethanol over palladized charcoal (5%, 60 mg). The uptake was 2 mole equivalents. After 100 min the solution was filtered and evaporated, and the product was crystallized from ethyl acetate – diethyl ether and from chloroform – diethyl ether to give the tetrahydro compound, m.p. 140–142°. There was no absorption in the ultraviolet above 200 mμ.

Anal. Calcd. for $C_{20}H_{30}O_6.H_2O$: C, 62.48; H, 8.39. Found: C, 62.41; 62.40; H, 8.43, 8.08.

Dehydroanhydrochaparrin

Anhydrochaparrin-A (45 mg) and 2,3-dichloro-4,5-dicyanobenzoquinone (39 mg) were dissolved in dry dioxan (3 ml) and heated in a sealed tube at 85° for 15 h. A precipitate of quinol formed slowly. Chloroform was added to the cooled solution and the organic phase was washed with water until the washings were colorless. Evaporation and crystallization from ethanol gave the dienone, m.p. 245–247°, $[\alpha]_D$ +278° (*c*, 0.97 in ethanol), λ_{max} 276 mμ (ϵ = 10 000 in dioxan).

Anal. Calcd. for $C_{20}H_{24}O_6$: C, 66.65; H, 6.71. Found: C, 66.75; H, 6.90.

Chaparrol

(a) From Chaparrin

Chaparrin (1.5 g) was added to hydrochloric acid (conc., 15 ml) and the mixture was allowed to stand at room temperature for 45 min. After dilution with water the product was isolated with chloroform. After evaporation the residue was crystallized from ethyl acetate to give chaparrol, m.p. 220–223°, $[\alpha]_D$+107° (*c*, 1.22 in pyridine), λ_{max} 268 mμ (ϵ = 400).

Anal. Calcd. for $C_{20}H_{24}O_5$: C, 69.75; H, 7.02. Found: C, 69.35; H, 6.69.

(b) Through Anhydrochaparrin-A

Chaparrin (437 mg) as a slurry in hydrochloric acid (0.1 *N*, 50 ml) was refluxed for 2 h. The product (containing crude anhydrochaparrin-A) was then filtered in chloroform through a column of alumina (11 g, Grade III). The chloroform eluate gave, from ethyl acetate, chaparrol m.p. 199–205° (177 mg).

Hydrogenation of chaparrol in acetic acid over platinum oxide catalyst resulted in the uptake of 1 mole equivalent of hydrogen.

Chaparrol from Anhydrochaparrin-A

Anhydrochaparrin-A (40 mg) was chromatogramed on alumina (Woelm neutral Grade III, 1 g). The crystals were dissolved into ethanol and evaporated to dryness, and the gum was put on the column with benzene. The material (25 mg) eluted with 10% ether–benzene was crystallized from ethyl acetate – light petroleum, UV_{max} 268 mμ (ϵ = 400), m.p. 211–215°, and so it is chaparrol.

For personal use only.

Chaparrol Monoacetate

A solution of chaparrol (160 mg) in acetic anhydride (10 ml) containing acetic acid (ca. 0.5 ml) was heated on the steam bath for 4 h. After dilution with methanol the product was evaporated to dryness (165 mg). The product containing some chaparrol was separated by thin-layer chromatography by development with ether when the monoacetate had an R_f of ca. 0.7. Elution of the band with chloroform and crystallization from ethyl acetate – light petroleum gave the pure monoacetate, m.p. 194–196°, $[\alpha]_D$ +116° (*c*, 0.42), λ_{max} 270, 278 mμ (ϵ = 460, 410).

Anal. Calcd. for $C_{22}H_{26}O_6$: C, 68.38; H, 6.78. Found: C, 68.55; H, 7.15.

Chaparrol Triacetate

Chaparrol (110 mg) was added to a mixture of acetic anhydride (3 ml) and pyridine (6 ml) and the solution was allowed to stand for 72 h at room temperature. After evaporation of the reagents under reduced pressure the product was filtered, in benzene solution, through a short column of alumina. After five crystallizations from ethyl acetate – light petroleum the triacetate (25 mg) was obtained, m.p. 176–178°, $[\alpha]_D$ +120° (*c*, 1.15 in chloroform), λ_{max} 244, 276 mμ (ϵ = 12 500 and 1 025 respectively).

Anal. Calcd. for $C_{26}H_{30}O_8$: C, 66.37; H, 6.43. Found: C, 66.09; H, 6.34.

Bismuth Trioxide Oxidation of Chaparrol

(*a*) Bismuth trioxide (250 mg) was added to a solution of chaparrol (200 mg) in acetic acid (15 ml) and the mixture was heated under reflux for 5 h. The cooled supernatant was poured into chloroform, and the organic medium was washed with water. Evaporation afforded a gum giving a dark green coloration with alcoholic ferric chloride solution and which showed λ_{max} 247, 300 mμ (ϵ = 5 200 and 11 700 respectively) in neutral and λ_{max} 350 mμ (ϵ = 7 200) in alkaline solution.

Methylation of the gum (diazomethane) afforded, after crystallization from ethanol, the methyl ether acetate (XVI; —CH_2OH becomes —CH_2OAc) m.p. 189–199° (65 mg). Recrystallization from chloroform–ether raised the m.p. to 198–202°, $[\alpha]_D$ +144° (*c*, 0.46), λ_{max} 247, 302 mμ (ϵ = 3 200 and 10 400 respectively).

Anal. Calcd. for $C_{23}H_{26}O_6$: C, 69.33; H, 6.78; OMe, 7.79. Found: C, 69.06; H, 6.78; OMe, 7.89.

(*b*) Bismuth triacetate (44 mg) and chaparrol (30 mg) were added to ethylene glycol (60 ml) and heated to 150°. After 3 h the absorption at 298 (neutral) and 350 (alkaline) mμ reached maxima ($\epsilon \sim$ 8 000 and 6 000 respectively). The mixture was then cooled, diluted with water, and extracted with chloroform. After evaporation the residual gum was methylated (diazomethane) and chromatographed on silica gel. Elution with ether–benzene (1:19) gave the methyl ether (XVI), m.p. 273–275°, $[\alpha]_D$ +203° (*c*, 0.77 in pyridine), λ_{max} 244, 300 mμ (ϵ = 3 400 and 10 200 respectively).

Anal. Calcd. for $C_{21}H_{24}O_5$: C, 70.76; H, 6.79. Found: C, 70.50; H, 6.82.

(*c*) Chaparrol (500 mg) in refluxing acetic acid (40 ml) was treated with bismuth trioxide (500 mg) and heated for 5 h. The product was isolated in the usual way and acetylated (acetic anhydride – pyridine at room temperature for 16 h). The resulting material, isolated with chloroform, after crystallization from ethanol and from chloroform – diethyl ether gave the enol acetate acetate (part structure VIII; X = H), m.p. 183–185°, $[\alpha]_D$ +111° (*c*, 1.28), λ_{max} 288 mμ (ϵ = 9 800), ν_{max} 1 750, 1 697 cm^{-1}.

Anal. Calcd. for $C_{24}H_{26}O_7$: C, 67.59; H, 6.15. Found: C, 67.38; H, 5.87.

Bromination of Chaparrol Enol Acetate Acetate

The enol acetate (100 mg) in acetic acid (50 ml) containing bromine ($\sim$75 mg) and a drop of hydrobromic acid in acetic acid was allowed to stand. After 22 h, uptake had ceased at 1.14 atoms of bromine. Dilution of the remainder, isolation with chloroform, washing of the organic phase with sodium bisulphite, and evaporation gave crystals (98 mg) m.p. 209–211°, $[\alpha]_D$ +108° (*c*, 0.95), λ_{max} 304 mμ (ϵ = 9 000).

Anal. Calcd. for $C_{24}H_{25}BrO_7$: C, 57.03; H, 4.99. Found: C, 57.10; H, 4.99.

Dihydrophenanthrene (XIII) Formation

The enol ether alcohol (XVI) (46 mg) was dissolved in ethanol (20 ml) and aqueous potassium hydroxide (1 *N*, 20 ml) was added. After standing overnight the now yellow solution was acidified, and the product was isolated with chloroform and crystallized from ethyl acetate – light petroleum, m.p. 200–202°, $[\alpha]_D$ +79° (*c*, 0.98), λ_{max} 250, 294 mμ (ϵ = 9 600 and 2 800 respectively), λ_{max} (alkaline) 250, 310 mμ (ϵ = 12 100 and 3 000 respectively).

Formaldehyde Estimation

The enol acetate (part structure VIII; X = H) of chaparrol (2.79 mg) was dissolved in sulfuric acid (conc., 0.5 ml), and chromotropic acid (10 mg) and water (0.1 ml) were added. The mixture was heated at 100° for 20 min and diluted to 10 ml, and the optical density was measured at 570 mμ. Comparison with a standard and controls gave 15% as the amount of formaldehyde liberated.

Reduction of Chaparrin Tetraacetate

(*a*) Chaparrin tetraacetate (1 g) and sodium borohydride (5 g) were dissolved in ethanol (100 ml) and the solution was left for 30 min. After dilution with water the hemiacetal triacetate (XXIII; OAc's C_1, C_2, and C_{12}) was isolated with chloroform and crystallized from ethyl acetate – light petroleum (530 mg) m.p. 223–224°, $[\alpha]_D$ +56° (*c*, 0.68).

Anal. Calcd. for $C_{26}H_{36}O_{10}$: C, 61.40; H, 7.14. Found: C, 61.49; H, 7.15.

Acetylation of the reduction product (75 mg) (pyridine – acetic anhydride at room temperature, 16 h) followed by decomposition of the acylating medium with ice water and hydrochloric acid gave, after isolation with ethyl acetate and crystallization from light petroleum, the hemiacetal tetraacetate (XXIII; OAc's at C_1, C_2, C_{12}, and $—CH_2O$), m.p. 189–191°, $[\alpha]_D$ +95° (*c*, 0.78).

Anal. Calcd. for $C_{28}H_{38}O_{11}$: C, 61.10; H, 6.91. Found: C, 61.41; H, 6.66.

(*b*) Chaparrin tetraacetate (160 mg) in ethanol (5 ml) was treated with a solution of sodium borohydride (160 mg) in water (2 ml), and the mixture was set aside for 30 h. After the addition of excess hydrochloric acid the ethanol was removed by evaporation, water (20 ml) was added, and the product was isolated with chloroform. Crystallization from acetone gave the product, m.p. 250–252°, $[\alpha]_D$ 67° (*c*, 0.6 in methanol).

Anal. Calcd. for $C_{20}H_{30}O_7$: C, 62.81; H, 7.91. Found: C, 62.62; H, 7.78.

Oxidation of the Acetal Tetraacetate

The tetraacetate (XXIII; OAc's at C_1, C_2, C_{12}, and $—CH_2O$) (15.7 mg) was dissolved in chromic acid – acetic acid (0.02 *N*, 10 ml). After 4 h oxidation had ceased with the consumption of 1.1 atoms of oxygen. Isolation of the product with chloroform, and crystallization from ethyl acetate – light petroleum gave chaparrin tetraacetate, m.p. and mixed m.p. 231–233°, $[\alpha]_D$ +34° (*c*, 0.46 in pyridine).

Oxidation of the Acetal Triacetate

(*a*) The triacetate (XXIII; OAc's at C_1, C_2, and C_{12}) (155 mg) in chloroform (5 ml) was shaken with active manganese dioxide for 3 d. Filtration gave a gum. This was separated by thin-layer chromatography (solvent: diethyl ether). Material with R_f near 0.35 was eluted with ethyl acetate (30 mg) and the triacetate-B (XIX; OAc's at C_1, C_2, and C_{12}) crystallized from ethyl acetate – light petroleum, m.p. 245–247°, $[\alpha]_D$ +18° (*c*, 0.87).

Anal. Calcd. for $C_{20}H_{34}O_{10}$: C, 61.65; H, 6.77. Found: C, 61.85; H, 6.72.

Chaparrin triacetate was unaffected by this reagent.

(*b*) The triacetate (25.9 mg) was dissolved in sodium dichromate – acetic acid solution (0.02 *N*, 10 ml). After 6 h, uptake of oxygen had ceased at 1.15 atoms. Isolation of the product with chloroform and crystallization from benzene gave the same triacetate obtained as described in (*a*), m.p. 248–250°, $[\alpha]_D$ +17° (*c*, 0.65).

This same compound was obtained by hydrolysis of chaparrin tetraacetate using a mole per mole ratio of potassium hydroxide in ethanol at room temperature for 2 h.

Dihydrochaparrol

Sodium borohydride (ca. 100 mg) was added to a solution of chaparrol (265 mg) in ethanol (8 ml). After 3 h the solution was diluted with water and extracted with chloroform. The product (140 mg) crystallized from ethyl acetate – light petroleum, m.p. 198–200° and 228–232°, $[\alpha]_D$ +63° (*c*, 0.71 in methanol), λ_{max} 270 (ϵ = 440).

Anal. Calcd. for $C_{20}H_{26}O_5.H_2O$: C, 65.91; H, 7.74. Found: C, 65.57; H, 7.66.

Oxidation of Dihydrochaparrol

Dihydrochaparrol (31 mg) was added to a mixture of chromium trioxide (35 mg) and pyridine (0.5 ml) and shaken for 2.5 h. Dilution of the mixture with aqueous acid and isolation with chloroform gave a gum which on t.l.c. gave a fraction having the same R_f as chaparrol. The eluted product had m.p. 215–220° undepressed on admixture with chaparrol of m.p. 218–222°, $[\alpha]_D$ +104° (*c*, 0.62 in pyridine).

Acetylation of Dihydrochaparrol

Dihydrochaparrol (25 mg) in pyridine (2 ml) and acetic anhydride (1 ml) was heated overnight on the steam bath. After removal of the solvents under reduced pressure the residue was filtered through a short column of Woelm acid alumina. Separation by t.l.c. gave the triacetate XXII which crystallized from ether – light petroleum (15 mg) (m.p. 152–156°) and which on further crystallization from the same solvent melted at 153–156, $[\alpha]_D$ +184° (*c*, 0.63), λ_{max} 244 mμ (ϵ = 13 400).

Anal. Calcd. for $C_{26}H_{32}O_8$: C, 66.08; H, 6.83. Found: C, 66.12; H, 6.82.

Dihydrochaparrol Tetraacetate

Dihydrochaparrol (96 mg) was heated on the steam bath for 17 h in acetic anhydride (5 ml) and pyridine (0.5 ml). It was then diluted with water and neutralized with sodium bicarbonate. The solution was extracted with chloroform to yield 140 mg crude product, separated by thin-layer chromatography (solvent: diethyl ether). The fraction (100 mg R_f near 0.7) was again separated (solvent: diethyl ether – benzene (1:3). The tetraacetate had m.p. 138–189°, $[\alpha]_D$ +218° (*c*, 0.76), λ_{max} 244, 276 (ϵ = 13 000 and 1 030 respectively).

Anal. Calcd. for $C_{28}H_{32}O_9$: C, 65.61; H, 6.29. Found: C, 65.33; H, 6.73.

Oxidation of the Triacetate (XXI)

The triacetate (XXI) (22 mg) in acetone (10 ml) was stirred with active manganese dioxide (200 mg) overnight. After filtration the solvent was evaporated separation by preparative thin-layer chromatography (solvent: diethyl ether) gave material which after crystallization from ethyl acetate – light petroleum (7 mg) had m.p. 176–178°, $[\alpha]_D$ +121° (*c*, 0.44). The melting point was undepressed on admixture with chaparrol triacetate (XVIII).

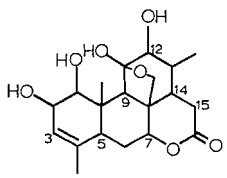
ABSTRACT

Evidence is presented which leads to the absolute stereostructures XX, X, XI, and XII for chaparrin, chaparrol, isochaparrol, and neochaparrol respectively. The absolute configuration is arrived at by conversion to an optically active biphenyl (dihydrophenanthrene).

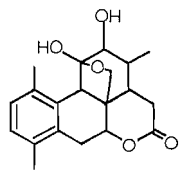
In our preceding papers (1, 2) we showed that the gross structures I and II were to be attributed to chaparrin, the bitter principle extracted from *Castela nicholsonii* (chaparro amargosa) and to chaparrol, its degradation product, respectively. Similar conclusions were simultaneously reached by Geissman and Ellestad (3). It is the purpose of this paper to discuss the stereochemistry of these and related compounds.

On the assumption that the absolute stereochemistry of the molecule requires that the primary hydroxyl be β, nine asymmetric centers remain in chaparrin giving a total of 512 possible isomers. Although a tenth center at C_{11} is introduced by the hemiketal formation, the stereochemistry of this center is rigidly defined with respect to the primary hydroxyl group and so does not increase the total number of isomers.

Chaparrol (II), derived from chaparrin by the acid-catalyzed loss of two molecules of water, has, aside from C_8 and C_{11}, five centers of asymmetry (32 isomers) and appeared a suitable starting point for investigations.



I



II

Whereas chaparrin (I) is stable to the action of mild alkali, and may be recovered from its acetate by alkaline hydrolysis, chaparrol (II) is not stable. Merely its solution in aqueous ethanolic alkali at room temperature for 30 min is sufficient to isomerize it to a new compound, isochaparrol. However, the transformation is not instantaneous because after 7 min some chaparrol can be recovered from a solution in which it has been present as an anion. Some slow step, other than lactone opening, is therefore involved.

The formation of isochaparrol could in principle involve isomerization at C_9, C_{12}, C_{13} (the last, through ketol equilibration), with, in addition, a possible change in the position of lactonization; or a combination of these. The substance is still a hemiketal since it shows no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

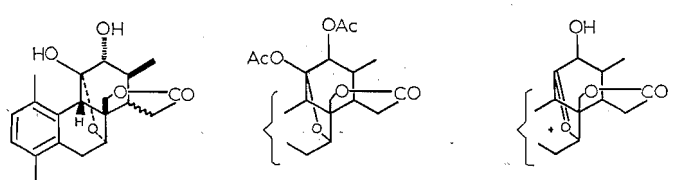
Cotton effect in the 300 mμ region. Reduction with sodium borohydride gives a dihydroisochaparrol which, having no carbonyl absorption in the infrared, is evidently a hemiacetal hemiketal analogous to that formed from chaparrol (1).

Acetylation of isochaparrol gives a monoacetate, which also shows a plain optical rotatory dispersion curve above 280 mμ, and in which a secondary alcoholic function (with methine proton at τ 5.00; $J \sim 8.4$ c.p.s.) has been acetylated. Acetylation under forcing conditions (acetic anhydride – perchloric acid) results in further acetylation to give a diacetate. The second function to be acetylated is also a secondary alcohol (methine proton at τ 4.43), but the product, isochaparrol diacetate, now exhibits a positive Cotton effect curve.* A secondary hydroxyl group is therefore involved in ketal formation in isochaparrol, and in the formation of this substance hydrolysis and relactonization on to the primary hydroxyl group must have occurred since it is now no longer available for acetylation. This could not be the only change, however, since formation of the carboxylate anion had been shown, as stated, to be a necessary but insufficient requirement for isochaparrol formation. At least one slower process, presumably an epimerization, was hence required.

Acetylation of isochaparrol under different conditions, analogous to those used by Polonsky and her collaborators in the acetylation of isoglaucanol A (4), that is, with sodium acetate and acetic anhydride, gave a different product. This is most probably to be represented as in (IV).† The difference in behavior may be attributed to the high energy of the strained oxonium ion (V) which would be an intermediate in the acid-catalyzed formation of IV. The alternative acetylation at C_7 therefore occurs. Base-catalyzed acetylation, on the other hand, might well be expected to occur under these conditions at the more acidic (though more hindered) 11-hydroxyl group (17).

The proton at C_{12} in isochaparrol is a doublet (τ 6.56; $J \sim 8.4$ c.p.s.) whose large spin–spin coupling with the adjacent C_{13} methine proton indicates a *trans* diaxial relationship of these protons. Because of the requirements of the hemiketal system, isochaparrol must thus be represented as in the *cis*-fused B/C system (III) where only C_{14} remains undefined.

The stereochemical assignments in III are not all, however, transferable to the equivalent centers in chaparrol. Isomerization of chaparrol to isochaparrol under deuterating conditions and comparison of n.m.r. spectra of deuterated and non-deuterated material clearly indicated that, by their disappearance from the deuterated proton spectrum, the protons at C_9 and C_{12} had been exchanged. In addition, the C_{13} methyl group, which was a clear doublet in chaparrol and a broad singlet in isochaparrol (18), was distinctly narrower and taller in deuterated isochaparrol. The proton at C_{13} must, through ketol equilibration, have exchanged. Since such exchange at these centers implies the opportunity of epimerization, only the configuration at C_7 must necessarily be the same in chaparrol as in isochaparrol.



III IV V

We are indebted to Dr. W. A. Ayer for these determinations.

†*We understand from Mme. Polonsky that she has now reached a similar conclusion, and that isoglaucanol A is attributed the structure 15-hydroxyisochaparrol.*

The stereochemistry at C_{12} in chaparrol may be deduced as follows. In chaparrin the C_{12} hydroxyl is axial, firstly because the low intensity $n \rightarrow \pi^*$ absorption in chaparrin triacetate-A ($\lambda_{max}^{CHCl_3}$ 315 mμ, $\epsilon = 25$) moves to shorter wavelength ($\lambda_{max}^{CHCl_3}$ 308 mμ, $\epsilon = 38$) on acetylation to give the tetraacetate. This parallels the equivalent acetylation of methyl 3α,12α-dihydroxy-11-oxocholanoate (λ_{max} 313 $\rightarrow$ λ_{max} 308 mμ, ref. 19). Secondly, the difficulty of acetylation of this function is in keeping with an axial disposition. Because chaparrin is a hemiketal, ring C may be represented as in VI and so, with the previously made assumption that the primary hydroxyl group is β, the axial 12-hydroxyl group is then necessarily α.

The transference of this conclusion to the equivalent center in chaparrol is only permissable if, in the conversion of chaparrin to this substance, no inversion takes place at C_9; that is, that no conformational change in ring C has occurred. This was demonstrated by conducting the acid-catalyzed dehydration in deuterium chloride: the proton at C_9 was not exchanged.

Treatment of chaparrol with boiling pyridine—conditions under which the lactone is not opened—isomerizes it to a new substance termed neochaparrol. This differs from chaparrol in the configuration at C_9. Thus, preparation in pyridine containing 2% D_2O gives neochaparrol in which the C_9 proton, as judged from the relevant n.m.r. spectra, (see Table I) has been exchanged. In addition, acetylation of neochaparrol under conditions suitable for converting chaparrol into its triacetate (VII) gives, in fact, the same substance.

TABLE I

N.m.r. data from neochaparrol and some isochaparrol derivatives

Compound	C_7 H τ	C_9 H τ	C_{12} H τ (J)	C_{13} Me τ (J)	—CH_2—OR τ	Aromatic H, τ	Aromatic Me, τ	Acetate Me, τ

*Spectrum done in pyridine.

One significant feature readily observed was the fact that neochaparrol did not form a hemiketal. The infrared spectrum showed clearly resolved peaks at 1 715 and 1 750 cm^{-1} (KBr) for the ketonic and lactonic carbonyl functions respectively, and the optical rotatory dispersion curve showed a strongly positive Cotton effect ($a = +250$), in agreement with the stereochemistry proposed for this homoconjugated π-system (21).

It may be presumed that since the B/C ring junction in chaparrin is stable, that it is *trans* fused. From a consideration of models, this was probable, and since there is no inversion in the conversion to chaparrol, this is required to have a *trans* fusion also. The same conclusion may be reached by an alternative route.

Clearly, since stereochemically chaparrol and neochaparrol differ only at C_9 it is this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

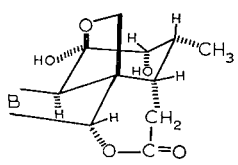
inversion at this point which has discouraged hemiketal formation. Since no assumption with regard to the stereochemistry at C_{14} has been made, four possibilities [9α,14α; 9β,14α; 9α,14β; 9β,14β] exist for the B/C/D ring systems in these two substances.

Inspection of models makes it evident that the two cases wherein the C_9 proton is β, hemiketal formation will not occur. In this pair the model with 14β proton the distance is, in the most favorable arrangement, too great to be spanned by the ethereal oxygen, and in this and the model with 14α proton hemiketal formation increases severely the non-bonded interaction between the oxygen function at C_{11} and the C_1 methyl group. On the other hand the two models with the C_9 proton in the α configuration are well oriented for hemiketal formation, and such formation rather decreases the interaction of the C_{11} oxygen function with the C_1 methyl group. This, with the favorable bond energy changes, rationalizes the hemiketal formation.

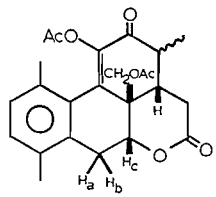
Hence, irrespective of the configuration at C_{14}, it can be concluded that in chaparrol (and hence chaparrin) the C_9 proton is α, and that in neochaparrol it is β. This conclusion is supported by the optical rotatory dispersion curve of chaparrol. A Cotton effect appears in the 270–280 mμ region and is due to an optically active aromatic B-band: its sign (positive) is in agreement with the 9αH-stereochemistry in chaparrol (see ref. 21, p. 293).

With the configuration at C_9 established in chaparrin, since chaparrin prefers to lactonize at C_7 rather than at the primary hydroxyl, it follows that the side chain at C_{14} is α. Were it β, inspection of models clearly indicates that, the occasion provided, the carboxyl group should prefer the less strained closure on to the primary hydroxyl group.

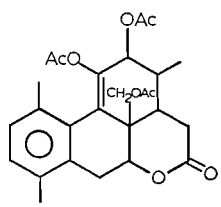
The following observations are compatible with this conclusion. The enol acetate previously described (1, 2), prepared by the bismuth oxide oxidation of chaparrol followed by acetylation, may, with the stereochemistry now assigned, be represented as in VIII, or



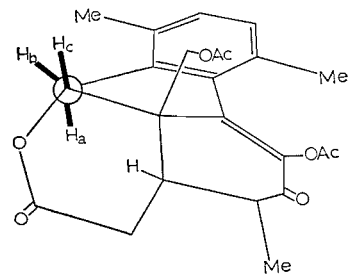
VI



VIII



VII



IX

as IX in the most favorable conformation. H_a and H_c are then coplanar and *trans*, and a large spin–spin coupling constant between them would be expected. There is, in addition, a smaller coupling to be expected between H_b and H_c. The proton H_c is partly overlain by the methylene protons of the primary acetate (Fig. 1), but a doublet of doublets may be observed, one of the coupling constants of which is large (near 10 c.p.s.).

All the asymmetric centres of chaparrol have therefore been defined with the exception of C_{13}. The coupling between the protons at C_{12} and C_{13} is small ($J \sim 3$ c.p.s.) but since

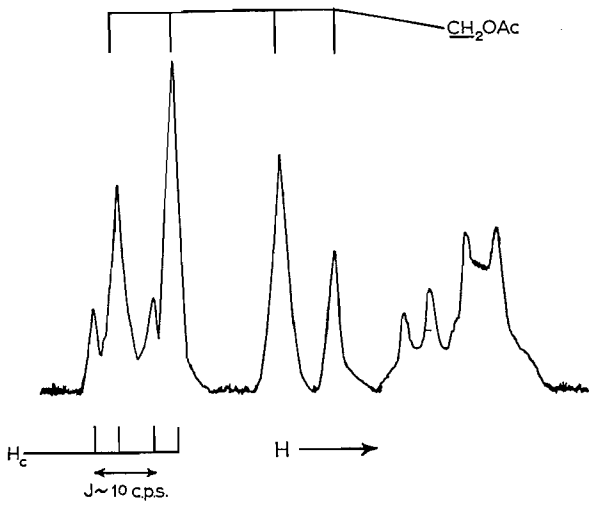


FIG. 1. Nuclear magnetic resonance spectrum of IX in region showing H_c and —CH_2OAc.

the C_{12} proton is equatorial* this is not informative since axial–equatorial and equatorial–equatorial couplings are comparable. Although compelling evidence is not available the following argument suggests that the methyl group is α (equatorial), and that it is therefore inverted in isochaparrol formation. That this was a possibility has already been demonstrated by the deuteration experiments reported.

Chaparrol shows no Cotton effect above 290 mμ, but as already mentioned, presents a peak at 283 mμ. In contrast the corresponding monoacetate (2) exhibits a negative Cotton effect around 300 mμ ($a = -56$). No change in structure occurs during acetylation since acid hydrolysis regenerates chaparrol. It is therefore the primary hydroxyl which has been acetylated. (See Table I, ref. 1.)

In such a configuration (and with the previously made assumption that the absolute configuration at C_8 is as shown) the 13-methyl group of chaparrol monoacetate, irrespective of configuration, falls into a positive octant (22). Ring A roughly lies in a nodal plane. The positive effect of the 13-methyl group is counterbalanced by carbon atoms 6 and 7, the 8,14-lactone and the 12α-hydroxyl group all falling into negative octants. Moreover, the negative Cotton effect is still enhanced, and probably largely attributable to the 8β-CH_2OAc function also in a negative octant. If the 13-methyl group were axial, it would be expected that the strong non-bonded diaxial interactions, occuring between the 8β-acetoxy-methyl and the 13β-methyl groupings, would lead to conformational changes, with ring C becoming a boat or twisted. A stronger negative Cotton effect might then be expected.

Accepting these conclusions the stereostructures of chaparrol, isochaparrol, and neochaparrol may be represented as in X, XI, and XII, respectively.

Five of the asymmetric centers in chaparrin are thus defined.

The configurations of the two hydroxyl groups in ring A of chaparrin follow from the study of the n.m.r. spectra of certain derivatives. Chaparrin triacetate-A shows a doublet ($J \sim 8$ c.p.s.) at τ 5.0. This doublet, which is due to the methine proton at C_1, is obscured

**The configuration at C_{12} does not change in the conversion of chaparrol to isochaparrol but the ring conformation does, and hence the C_{12} proton becomes axial, as already noted.*

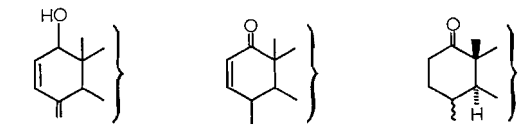
X XI XII

in the tetraacetate by the C_{12} methine proton which moves from ca. 6.18 to 4.92. This same doublet may be discerned in the isomeric triacetate-B (1) of chaparrin in which the primary hydroxyl group is unacetylated.

The magnitude of the coupling between the C_1 and C_2 protons requires, in the fused system, that these protons be coplanar and diaxial.

The manganese dioxide treatment of chaparrin gives chaparrinone, an α,β-unsaturated ketone, by oxidation at C_2. Hydrogenation then gives, with the uptake of one molecule of hydrogen, the saturated ketone dihydrochaparrinone. Aside from the stereochemistry at C_4 the complete molecule may be represented in four ways. In two of these, indicated by the partial structures XIII and XIV, a positive Cotton effect would be predicted, irrespective of the configuration at C_4 while in the other two a negative Cotton effect would very probably be expected. The observation of a weak positive Cotton effect ($a = +16$) restricts the possibilities to XIII and XIV. Usually 2-oxo-steroids exhibit rather strong positive rotatory dispersion curves ($a \approx +120$), but in the present substance this positive effect is counterbalanced by the 1-hydroxyl group (5, 6) and the 4-(probably β)-methyl group; moreover, this grouping seems to have induced a conformational change of ring A in XIII in order to release 1,3-diaxial interactions with the 10-methyl substituent. From this it is reasonable to conclude that the methyl group at C_{10} is β in chaparrin.

XIII XIV



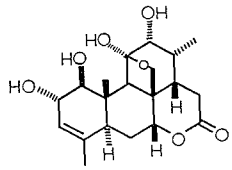
XV XVI XVII

The acid-catalyzed dehydration of chaparrin gives, aside from anhydrochaparrin-A (XV) (2), an isomeric substance which is an unsaturated ketone (XVI) (3). This compound, anhydrochaparrin-B, may be hydrogenated to the saturated ketone hemiketal (XVII), or which three other stereochemical representations are possible, depending on the nature of the A/B ring fusion.

The rotatory dispersion curve of this substance shows a rather strong positive Cotton effect ($a = +94$). An examination of the four molecular models of this ketone permits an interpretation of the positive Cotton effect which is observed, in terms of XVII. The angular methyl at C_{10}, ring C and its substituents, the hemi-ketal bridge between the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

8-hydroxymethylene and C_{11}, all fall into positive octants. This strong positive contribution effect is only partly counterbalanced by carbon atoms C_6 and C_7 of ring B and very slightly by the δ-lactone grouping (far away from the carbonyl) falling into negative octants. With this evidence the stereochemistry of chaparrin may be represented in its entirety as shown in XX.



XX

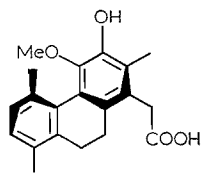
These arguments have been based on the assumption that the absolute configuration of the C_8 center has the primary hydroxyl group β. This may be justified in the following way.

The Cotton effects exhibited by several of the above mentioned compounds have been related to those shown by corresponding compounds from the steroid series. Since the absolute configuration of natural steroids has been established, the absolute configuration of chaparrin may be ascertained. A further, and independent, argument also leads to the same conclusion.

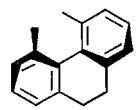
A degradation product of chaparrol, instrumental in arriving at the gross structure of this substance, was attributed the structure represented in XXI. This substance has, of course, no asymmetric centre and accordingly might be expected to have no optical activity. However, the considerable amount of steric interference between the methoxyl group and the aromatic methyl group at C_1 could prohibit their mutual crossing, despite the aromatization of ring C, under the mild condition for the genesis of XXI.

The dihydrophenanthrene is in fact optically active. Its optical rotatory dispersion curve exhibited three successive Cotton effects of increasing amplitudes towards shorter wavelengths, in agreement with the inherently dissymmetric nature of the chromophore (see Experimental). The shape of the dispersion curve from 600 mμ to about 300 mμ appeared to be very similar to, and of the same sign as, that of the 2,2′-dimethyl dihydrophenanthrene (XXII) reported by Mislow and Hopps (7) which has been attributed the (R)-configuration. The change of —OMe for —CH_3 in an unchanged stereochemical situation gives the (S)-configuration for the absolute stereochemistry of the dihydrophenanthrene from chaparrol which is that represented in XXI.

If it be assumed that in the aromatization of chaparrin the angular methyl group migrates and retains its position relative to the substituent at C_{11} in going from I to II then, if the angular methyl group be β, the dihydrophenanthrene CXXI) will have the (S)-configuration, as observed. Since it has been demonstrated that the angular methyl group and the hydroxyl methyl group at C_8 are on the same side of the molecule the absolute stereochemistry of chaparrin is as represented in XX.



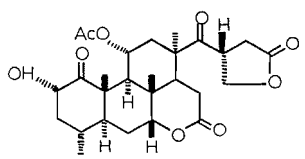
XXI



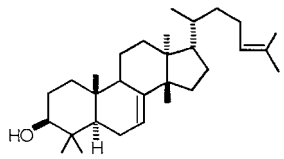
XXII

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

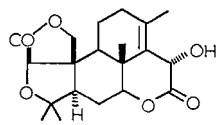
Subsequent to the description of the gross structure of the chaparrin and that of the earlier reported quassin (8, 9) a number of other members of this chemical family have been investigated, largely because of the efforts of Polonsky and her school (ref. 10 and earlier papers in this series). The structure of simarolide (XXIII) (11) confirmed by X-ray studies (12) is of special relevance. It has the absolute configuration shown, which is that of the triterpenoids, and its relationship to butyrospermol (XXIV), as has been pointed out (13–15), is obvious. The loss of the side chain has clear association in the chemistry of limonin with the conversion of limonol to merolimonol (XXV) (20). Since this has been amply discussed elsewhere (13–16) further elaborations, in the absence of additional evidence, would be supererogatory. It is sufficient to note that the structure and stereochemistry deduced for chaparrin conforms with the general pattern.



XXIII



XXIV



XXV

EXPERIMENTAL*

Neochaparrol (XII)

A solution of chaparrol (60 mg) in pyridine (4 ml) was refluxed for 2 h. The pyridine was removed under reduced pressure and the gummy residue was dissolved in chloroform. The solution was washed with dilute hydrochloric acid and water. Removal of the solvent afforded a glass which was crystallized from ethyl acetate (37 mg) m.p. 225–230 °C. Further recrystallization from ethanol raised the melting point to 233–237 °C, $[\alpha]_D$ +150° (*c*, 0.6, methanol); o.r.d. (*c*, 0.1, dioxane): $[\Phi]_{600}$ +385°, $[\Phi]_{500}$ +771°; $[\Phi]_{400}$ +1 768°; $[\Phi]_{318}$ +11 252°; $[\Phi]_{279}$ −13 739°; $[\Phi]_{246}$ −6 622°; $[\Phi]_{228}$ −17 217°.

Anal. Calcd. for $C_{20}H_{24}O_5$: C, 69.75; H, 7.02. Found: C, 69.70; H, 6.77.

The deuterated material was prepared as follows: chaparrol (88 mg) was refluxed in pyridine containing 2% D_2O for 2 h. After evaporation to dryness the product was crystallized from ethyl acetate – light petroleum and from ethanol – light petroleum.

Preparation of Chaparrol with Deuterium Chloride

Chaparrin (113 mg) was dissolved in deuteriochloric acid (1.5 ml) and allowed to stand for 45 min. The reaction mixture was poured into heavy water (5 ml) and the product isolated with chloroform. Crystallization from ethyl acetate – light petroleum gave chaparrol, m.p. 215–216°. Chaparrol (X) o.r.d. (*c*, 0.1, dioxane): $[\Phi]_{600}$ +502°; $[\Phi]_{500}$ +626°; $[\Phi]_{400}$ +1 128°; $[\Phi]_{300}$ +2 821°; $[\Phi]_{283}$ +4 792°; $[\Phi]_{278}$ +3 196°; $[\Phi]_{276}$ +3 385°; $[\Phi]_{270}$ +2 442°; $[\Phi]_{232}$ +20 977°; $[\Phi]_{226}$ +3 550°; $[\Phi]_{222}$ +16 457. Chaparrol monoacetate o.r.d. (*c*, 0.13, dioxane): $[\Phi]_{600}$ +216°; $[\Phi]_{500}$ +397°; $[\Phi]_{400}$ +995°; $[\Phi]_{348}$ +1 070°; $[\Phi]_{324}$ +408°; $[\Phi]_{288}$ +6 080°; $[\Phi]_{274}$ +5 130°; $[\Phi]_{256}$ +3 880°.

Isochaparrol

A solution of chaparrol (93 mg) in methanol (10 ml) containing potassium hydroxide (0.5 g) was refluxed under nitrogen for 4 h. After evaporation of the methanol, water was added and the mixture was acidified and extracted with chloroform. The product was crystallized from ethyl acetate – light petroleum and was

**For general indications, see Part XII (1). The optical rotatory dispersion (o.r.d.) curves, obtained through the courtesy of Dr. L. Throop, were measured with an automatic spectropolarimeter of the Japan Spectroscopic Co. Ltd. (JASCO), model ORD-UV-5.*

For personal use only.

homogeneous on thin-layer chromatography (solvent: diethyl ether, R_f 0.24) and had constant rotation $[\alpha]_D$ −48° (*c*, 0.7). The m.p. varied with the rate of heating in the region 135–138° to 156–158°.

Anal. Calcd. for $C_{20}H_{24}O_5$: C, 69.75; H, 7.02. Found: C, 69.35; H, 7.12.

The deuterated material was prepared as follows: potassium deuteroxide (from potassium hydroxide and heavy water, evaporation, re-dissolution in heavy water and evaporation) (0.5 g) was added to heavy water (10 ml) and chaparrol (92 mg). The mixture was refluxed for 6 h under nitrogen. Acidification with deuteriochloric acid, extraction with chloroform, and crystallization from ethyl acetate – light petroleum then gave deuterated isochaparrol. Deuterated isochaparrol was obtained in a similar manner from neochaparrol.

Isochaparrol was also obtained under the following conditions.

(*a*) Solution of chaparrol in 5% (w/v) aqueous ethanolic potassium hydroxide at room temperature for 30 min. After 7 min, crystallization yielded chaparrol.

(*b*) Solution of neochaparrol in ~1% (w/v) aqueous ethanolic potassium hydroxide at room temperature for 6 min.

Equilibration of isochaparrol in alkali gave no detectable amount of neochaparrol as indicated by thin-layer chromatography (t.l.c.).

Isochaparrol Monoacetate

Isochaparrol (40 mg) in pyridine (1 ml) and acetic anhydride (0.5 ml) was heated for 4 h on a steam bath, then set aside overnight. Evaporation of the reagents and filtration of the residue through a short column of alumina gave material which was crystallized from ethyl acetate – light petroleum to give the monoacetate, m.p. 237–239°, $[\alpha]_D$ +17° (*c*, 0.58).

Anal. Calcd. for $C_{22}H_{26}O_6$: C, 68.38; H, 6.78. Found: C, 67.91; H, 6.94.

Isochaparrol Diacetate

(*a*) Isochaparrol (20 mg) was dissolved in a mixture of acetic acid (1 ml) and acetic anhydride (0.5 ml). Perchloric acid (5 *N* in acetic acid, 5 drops) was added, care being taken to keep the temperature below 35 °C. After 35 min the mixture was diluted with diethyl ether (30 ml) and the ethereal solution was washed with 3% aqueous sodium bicarbonate. Removal of the ether afforded a solid which was crystallized from chloroform – light petroleum to m.p. 308–310°.

Anal. Calcd. for $C_{24}H_{28}O_7.\frac{1}{2}H_2O$: C, 65.87; H, 6.60. Found: C, 65.99; H, 6.48.

(*b*) Isochaparrol (9 mg) and sodium acetate (16 mg) were refluxed in acetic anhydride (1.5 ml) for 2 h. The solution was evaporated to dryness with methanol. A mixture ca. 1:1 was obtained of two compounds, as shown by t.l.c. (solvent: diethyl ether).

The second spot was the same as obtained in part (*a*) m.p. 308–310° and mixed m.p. 308–310°, $[\alpha]_D$ −20° (*c*, 0.71).

Anal. Found: C, 66.27; H, 6.45.

The first spot was a new diacetate crystallized from ethyl acetate – light petroleum m.p. 188–191°.

Anal. Calcd. for $C_{24}H_{28}O_7$: C, 67.27; H, 6.59. Found: C, 66.89; H, 6.60.

Acid Hydrolysis of Chaparrol Triacetate

The triacetate (48 mg) was added to a mixture of dioxane (3 ml) and hydrochloric acid (3 ml, 3 *N*) and the mixture allowed to stand at room temperature for 5 days. The product after isolation was complex, but thin-layer chromatography (solvent: ether) gave material which after crystallization from ethyl acetate – light petroleum was identified by melting point and rotation as neochaparrol.

Chaparrinone

A mixture of chaparrin (80 mg), manganese dioxide (800 mg), and dioxane (100 ml) was stirred overnight at room temperature for 13 h. The product remaining after filtration and evaporation was separated by thin-layer chromatography (solvent: 5% methanol in chloroform). The fraction of R_f 0.18 was crystallized from ethanol – ethyl acetate to give chaparrinone, m.p. 230–232°, $[\alpha]_D$ −47° (*c*, 0.88, pyridine), λ_{max} 241 mμ (ϵ = 5 700).

Anal. Calcd. for $C_{20}H_{26}O_7$: C, 63.48; H, 6.93. Found: C, 63.16; H, 6.57.

Dihydrochaparrinone

Chaparrinone (45 mg) in ethanol (10 ml) was hydrogenated over palladized charcoal (5%, 10 mg). The product (uptake 0.9 mole) was crystallized from ethanol – ethyl acetate to give the saturated ketone, m.p. 258–260°, $[\alpha]_D$ −3° (*c*, 0.78, EtOH).

Dihydrochaparrinone (XIII) o.r.d. (*c*, 0.1, dioxane): $[\Phi]_{600}$ +180°; $[\Phi]_{500}$ +340°; $[\Phi]_{400}$ +520°; $[\Phi]_{313}$ +2 000°; $[\Phi]_{307}$ +1 900°; $[\Phi]_{302}$ +1 950°; $[\Phi]_{267}$ +860°; $[\Phi]_{250}$ +980°.

Anal. Calcd. for $C_{20}H_{28}O_7$: C, 63.14; H, 7.42. Found: C, 63.10; H, 6.96.

Anhydrochaparrin-B (XVI)

Chaparrin (700 mg) was added to hydrochloric acid (*N*, 50 ml) and the mixture refluxed for $1\frac{3}{4}$ h in an oil bath (ca. 120°). The isolated material was separated by thin-layer chromatography (solvent: 5% MeOH in $CHCl_3$). Chaparrol and anhydrochaparrin-B ran close together ($R_f \sim 0.4$). Anhydrochaparrin-A (XV) runs more slowly in this system. The mixture of chaparrol and anhydrochaparrin-B was applied to thin-layer

For personal use only.

plates again (solvent: diethyl ether) in which chaparrol had R_f 0.38 (152 mg) and anhydrochaparrin-B R_f 0.12 (158 mg).

Crystallization from ethanol – ethyl acetate gave the ketone, m.p. 258–260°, $[\alpha]_D$ +38° (*c*, 1.98, EtOH), λ_{max} 232 mμ (ϵ = 10 100).

Anal. Calcd. for $C_{20}H_{26}O_6$: C, 66.28; H, 7.23. Found: C, 66.22; H, 7.16.

Dihydroanhydrochaparrin-B

Anhydrochaparrin-B (34 mg) was hydrogenated in ethanol solution (10 ml) over palladized charcoal. The uptake of hydrogen ceased at 1 mole equivalent, and the product, after crystallization from ethanol – ethyl acetate – light petroleum, had m.p. 228–230°, $[\alpha]_D$ +54° (*c*, 1.02).

Dihydroanhydrochaparrin-B (XVII) o.r.d. (*c*, 0.12, dioxane): $[\Phi]_{600}$ +210°; $[\Phi]_{500}$ +255°; $[\Phi]_{400}$ +470°; $[\Phi]_{303}$ +4 400°; $[\Phi]_{260}$ −5 020°; $[\Phi]_{246}$ −4 450°.

Anal. Calcd. for $C_{20}H_{28}O_6$: C, 65.91; H, 7.74. Found: C, 65.56; H, 7.4.

Acetylation of Neochaparrol

Neochaparrol (20 mg) in pyridine (3 ml) containing acetic anhydride (1.5 ml) was heated overnight on the steam bath. After removal of the reagents under reduced pressure, filtration of the residue in benzene solution through a short column of alumina and crystallization from ethyl acetate – light petroleum gave chaparrol triacetate identified by m.p. and mixed m.p., $[\alpha]_D$ +121° (*c*, 0.53).

Dihydroisochaparrol

Sodium borohydride (20 mg) in aqueous ethanol (2 ml, 1:1) was added to a solution of isochaparrol (29 mg) in ethanol (0.5 ml). After 1 h the excess reagent was decomposed with acid, water was added, and the product was isolated with chloroform. After crystallization it had m.p. 254–256°, $[\alpha]_D$ −65° (*c*, 0.65, MeOH).

Anal. Calcd. for $C_{20}H_{26}O_5$: C, 69.34; H, 7.57. Found: C, 68.88; H, 7.86.

Hydrolysis of Chaparrol Monoacetate

The monoacetate (9 mg) was dissolved in dioxane (0.8 ml) containing hydrochloric acid (3 *N*, 0.8 ml) and the mixture was allowed to stand at room temperature for 25 h. After dilution and isolation with chloroform the product was crystallized from ethyl acetate – light petroleum. It had m.p. 210–215° undepressed on admixture with an authentic specimen of chaparrol.

Dihydrophenanthrene (XXI) o.r.d. (*c*, 0.08, dioxane): $[\Phi]_{600}$ 0°; $[\Phi]_{500}$ +236°; $[\Phi]_{400}$ +945°; $[\Phi]_{304}$ +19 162°; $[\Phi]_{286}$ −15 915°; $[\Phi]_{265}$ +46 977°; $[\Phi]_{241}$ −48 597°; $[\Phi]_{224}$ +132 829°; $[\Phi]_{222}$ +105 291°; $[\Phi]_{217}$ +140 930°.

REACTIONS OF SUGAR CHLOROSULFATES

PART VI. THE STRUCTURE OF UNSATURATED CHLORODEOXY SUGARS

H. J. JENNINGS[1] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario and The University of Bristol, England

Received May 20, 1965

ABSTRACT

Methyl α- and β-L-arabinopyranosides when treated with sulfuryl chloride yielded methyl 4-chloro-4-deoxy-α-D-xylopyranoside 2,3-dichlorosulfate and methyl 3,4-dichloro-3,4-dideoxy-β-D-ribopyranoside 2-chlorosulfate respectively. L-Arabinose gave, in addition to 4-chloro-4-deoxy-D-xylosyl chloride 2,3-dichlorosulfate, an unsaturated tetrachloro–tetradeoxy dimer. The structure and mode of formation of these compounds is discussed.

DISCUSSION

L-Arabinose when treated with sulfuryl chloride gave a syrupy mixture of chloroform-soluble products, one of which was shown to be 4-chloro-4-deoxy-D-xylosyl chloride 2,3-dichlorosulfate.* Methanolysis of the syrupy mixture yielded crystalline methyl 4-chloro-4-deoxy-α-D-xylopyranoside 2,3-dichlorosulfate (I) the structure of which was proved by the following series of reactions. An identical crystalline compound was obtained by the reaction of methyl β-L-arabinopyranoside with sulfuryl chloride thus establishing the configuration of the methyl glycosidic group and the pyranose ring structure of I. When treated with pyridine I gave a crystalline cyclic sulfate ester derivative, thus indicating the presence of vicinal chlorosulfate ester groups in I (1), and dechlorosulfation of I with sodium iodide (1)† gave a crystalline methyl chlorodeoxypentopyranoside. Hydrolysis of the methyl chlorodeoxypentopyranoside required drastic conditions (25% sulfuric acid) and gave a crystalline chlorodeoxypentose the periodate oxidation of which (2 moles periodate uptake, 1 mole formic acid liberated) was consistent with presence of the chlorodeoxy group on position C-4. The chlorodeoxypentose was proved to be of the D-*xylo*-configuration because the less likely alternative structure (the result of 4-chloro-substitution with retention of configuration) 4-chloro-4-deoxy-L-arabinose had been synthesised previously and was shown to have different physical constants (2).‡

The reaction of L-arabinose with sulfuryl chloride gave in addition to the chloroform-soluble products another highly crystalline compound (II) which separated from the acid wash of the reaction mixture. Compound II originated from the carbohydrate component of the reactants because the corresponding reaction with D-arabinose yielded the crystalline L-enantiomer of II. In comparison with similar reactions of other reducing sugars with sulfuryl chloride (2, 3) this appears to be a unique property of arabinose. A tentative structure (II) was proposed (2) based on elemental analysis, infrared spectroscopy (unconjugated ethylenic bond, 1 655 cm^{-1}) and approximate molecular weight determination (ca. 300). It was a trehalo-type dimer because it was non-reducing and the presence of vinylic chlorine was inferred because II was stable when subjected to ozonolysis (4)

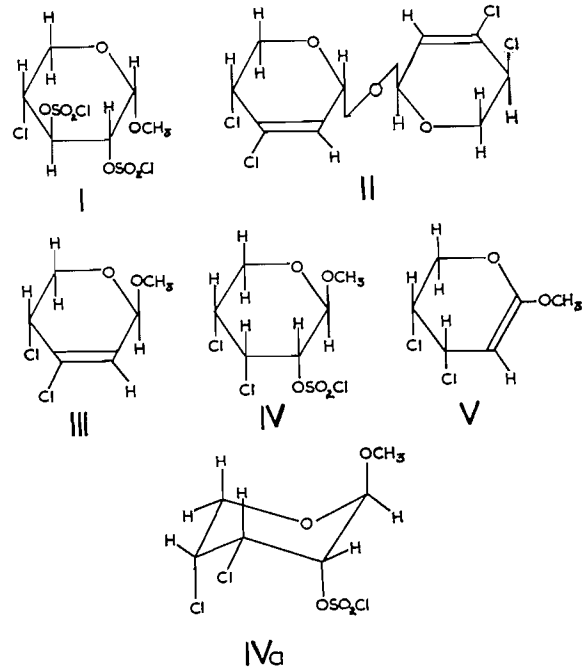
[1]*Present address: Department of Chemistry, The University of Bristol, England.*

**In one reaction a crystalline compound was obtained the elemental analysis of which was consistent with this structure. However, the structure could not be proved as the crystals decomposed and could not be isolated from subsequent reactions.*

†*Part IV in this series.*

‡*Part III in this series.*

and lead tetraacetate oxidation (5). The structure of II, 4-deoxy-3,4-dichloro-α-D-*glycero*-pent-2-enopyranosyl 4′-deoxy-3′,4′-dichloro-α-D-*glycero*-pent-2′-enopyranoside, was finally confirmed by methanolysis of the dimer (II) to give III, methyl 4-deoxy-3,4-dichloro-β-D-*glycero*-pent-2-enopyranoside, which was also obtained from methyl α-L-arabinopyranoside by an independent synthesis.



Methyl α-L-arabinopyranoside was treated with sulfuryl chloride to give a syrupy product, which was further heated with pyridine hydrochloride in chloroform solution to ensure chlorodeoxy-substitution and replacement of as many chlorosulfate groups as possible. A crystalline compound (IV) was isolated from the reaction mixture which was shown to be methyl 3,4-dichloro-3,4-dideoxy-β-D-ribopyranoside 2-chlorosulfate in the following way. Dechlorosulfation of IV with sodium iodide (1) gave a syrupy methyl dichlorodideoxypentopyranoside which was shown to be homogeneous by thin layer chromatography (t.l.c.) and which gave an elemental analysis consistent with this formulation. Prolonged hydrolysis of the syrupy methyl glycoside afforded a crystalline dichlorodideoxypentose in small yield. The presence of hydroxyl groups on adjacent carbon atoms and thus of chlorodeoxy groups on C-3 and C-4 of the dichlorodideoxypentose was proved by its considerable electrophoretic mobility in borate buffer (M_g = 0.68). This precludes the possibility of C-5 chlorodeoxy-substitution (3). Also a crystalline dichlorodideoxy-1,2-*O*-isopropylidene derivative was obtained from the mother liquors of the above hydrolysis products which were shown to contain only the 3,4-dichlorodideoxypentose and the unhydrolyzed methyl 3,4-dichlorodideoxypentopyranoside (t.l.c.). It was argued that 3,4-dichloro-3,4-dideoxy groups were both formed with inversion of configuration to give the D-*ribo* derivative on the following evidence. Inversion of configuration at C-4 would be expected as both methyl β-L-arabinopyranoside and L-arabinose gave 4-chloro-4-deoxy-D-*xylo* derivatives when treated with sulfuryl chloride. Methyl β-L-arabinopyranoside on treatment with sulfuryl chloride gave only a 4-chloro-4-deoxy-*xylo* derivative

(I) (axial anomeric methoxyl groups in the *CI* conformation) resistant to further chloro-substitution whereas methyl α-L-arabinopyranoside (equatorial anomeric methoxyl group in the *CI* conformation) gave a 3,4-dichloro-substituted derivative (IV). This observation is consistent with a mechanism of chloro-substitution with inversion of configuration at C-3 in the latter case. This has been demonstrated previously, when it was found that only the β-D-anomer (equatorial anomeric methoxyl group in the *CI* conformation) of the analogous methyl α- and β-D-galactopyranosides gave a 3,4,6-trichloro-D-*allo* derivative using similar reaction conditions. Chloro-substitution at C-3 in this case was shown to be dependent on the removal of the 1:3-diaxial interaction to the approach of chloride ion (3). A further example of a similar effect has also been reported (6).

Treatment of IV with pyridine gave compound III previously obtained by the methanolysis of the unsaturated dimer (II), and the structure of III was ascertained as follows. The elemental analysis and infrared spectrum (unconjugated ethylenic bond 1 657 cm^{-1}) of III indicated that it (III) was a product of elimination from IV and that it still contained two chlorodeoxy groups. Although structure III is the preferred elimination product as it involves a 2,3-*trans* elimination from IV, structure V is the alternative possibility the formation of which would involve a 1,2-*cis* elimination from IV. The n.m.r. spectrum of the elimination product (in carbon tetrachloride) contained two doublets (1 proton each) at 5.88 and 4.87 p.p.m. which could be assigned unambiguously to the vinylic and the anomeric proton of III respectively. Although the alternative structure V also has a vinylic proton it is unlikely that the C-3 proton of V would give a simple doublet. The remaining signals in the spectrum were a singlet assigned to the anomeric methoxyl group (3 protons, 3.34 p.p.m.) and a complex group of signals (3 protons) which were assigned to the remaining protons on C-4 and C-5 of III. A comparison of the n.m.r. spectra of II with III (in hot pyridine solution because of the insolubility of II in most solvents) was made and the spectra are shown in Fig. 1. Except for the anomeric methoxyl protons (3 protons, 2.59 p.p.m.) of III the remaining three groups of peaks in the spectra of II and III were similar in appearance and had the same proton ratios. The principal difference in the remaining groups of peaks was the difference in chemical shift of the signal assigned to the anomeric protons of II (two protons, 4.88 p.p.m.) and III (one proton, 4.33 p.p.m.). This could be attributed to the difference of configuration of the anomeric protons of II and III (α and β respectively) and provides tentative evidence that II is a symmetrical α,α′-linked dimer. Some support for this is also found in the high positive rotation of II.

In the formation of III from IV it is likely that 2,3-*trans*-diaxial elimination from the *1C* conformation of IV (IV*a*) had taken place, as this has previously been demonstrated to be the preferred mode of elimination of chlorosulfate groups under these conditions (1). This supports the fact that chloro-substitution had taken place on C-3 of IV with inversion of configuration as the alternative product (C-3-chlorodeoxy-substitution with retention of configuration) would require a 2,3-*cis* elimination to give III. Also this *trans*-diaxial elimination process provides a possible explanation of the formation of the monomeric unit of the dimer (II). It might be expected that 4-chloro-4-deoxy-D-xylosyl chloride, previously obtained in the reaction of sulfuryl chloride with L-arabinose, would be further substituted at C-3 to give 3,4-dichloro-3,4-dideoxy-D-ribosyl chloride 2-chlorosulfate (VI) which could undergo an analogous elimination to give compound VIII. Thus VI and VIII would be the precursors of the dimer II although it is difficult to see how either of these highly substituted compounds is extracted from chloroform solution by aqueous sulfuric acid to become the water-soluble precursor. Perhaps this is achieved

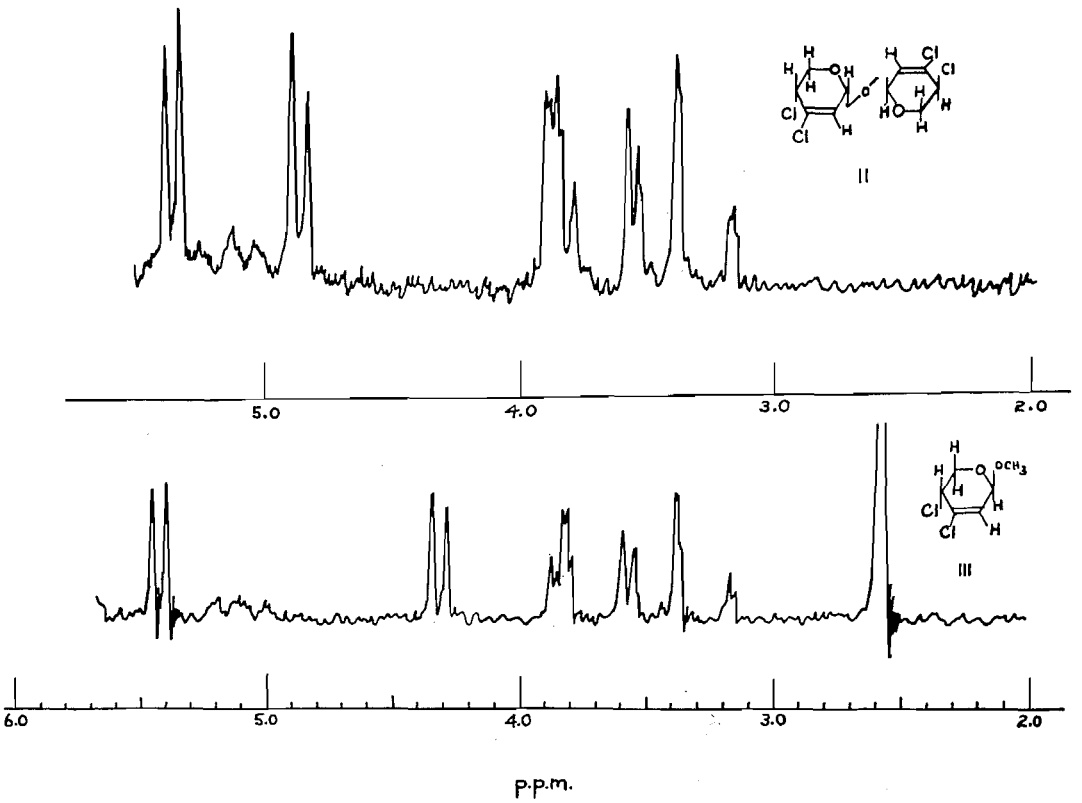

FIG. 1. Spectra of II and III both run in pyridine.

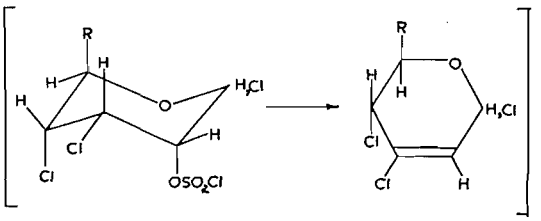

VI R=H
VII R=CH_2Cl

VIII R=H
IX R=CH_2Cl

through the agency of C-1 quaternary pyridinium salts which are known to form from acetohalo sugars (7). This still leaves the basic problem of the mechanism of the aqueous dimerization process which at present is not understood.

It is interesting to note that although reaction of sulfuryl chloride with D-galactose gave a fairly good yield of 3,4,6-trichloro-3,4,6-trideoxy-D-allosyl chloride 2-chlorosulfate (configurational analogue of VI) it does not appear to yield any analogous aqueous insoluble dimeric product from the acid wash of the reaction mixture (3). This might be explained by the inability of the allosyl chloride derivative to attain its *1C* conformation (VII) under these conditions, thus preventing the attainment of the favored *trans*-diaxial arrangement of the groups on C-2 and C-3 for elimination to give intermediate IX. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

could be attributed to the higher energy state of the *1C* conformation of the allosyl chloride derivative (VII) in comparison with VI due to the larger —CH_2Cl group at C-5 of VII. Some corroborating evidence for this is that methyl 3,4,6-trichloro-3,4,6-trideoxy-α-D-allopyranoside 2-chlorosulfate when treated with pyridine gave only the product of hydrolysis of the 2-chlorosulfate ester whereas the analogous compound IV (minus the large —CH_2Cl group at C-5) gave the 2,3-*trans* elimination product III. 3,4,6-Trichloro-3,4,6-trideoxy-D-allose gave a syrupy 1,2-*O*-isopropylidene derivative after a prolonged reaction time using the same vigorous conditions as applied in the formation of the corresponding 3,4-dichloro-3,4-dideoxy-D-ribose derivative. A previous attempt to make this 1,2-*O*-isopropylidene derivative had been unsuccessful (3).

EXPERIMENTAL

Optical rotations were measured at 21 ± 3°. Melting points were determined on a Kofler hot stage and are uncorrected. All solutions were concentrated under reduced pressure below 50°. Thin layer chromatographic analysis was carried out on prepared silica gel G plates. Infrared spectra were determined using a Perkin-Elmer model 21 instrument on samples dissolved in chloroform (6% w/v) unless otherwise stated. The n.m.r. spectra were determined at 60 Mc/s using a Varian M.60 n.m.r. spectrometer and trimethyl silane was used as an internal indicator.

4-Chloro-4-deoxy-D-xylosyl Chloride 2,3-Dichlorosulfate

L-Arabinose (10 g) was treated with sulfuryl chloride (21 ml) and pyridine (40 ml) in chloroform solution (2), and the reaction mixture was allowed to stand at room temperature for 4 h. The chloroform solution was then filtered and washed with 10% sulfuric acid, saturated sodium bicarbonate solution, and distilled water. Concentration of the chloroform extract afforded a syrup (7 g) which was shown to be a mixture containing at least 2 components (t.l.c.). The syrup partially crystallized on standing and the crystals (1 g) were removed from the syrup by washing them with chloroform–petrol (b.p. 40–60°). They had m.p. 84° and $[\alpha]_D$ +80° (*c*, 0.6 in chloroform).

Anal. Calcd. for $C_5H_6Cl_4O_7S_2$: C, 15.7; H, 1.6; Cl, 37.0; S, 16.7. Found: C, 16.0; H, 1.7; Cl, 36.4; S, 16.0.

This crystalline product could not be isolated again in subsequent reactions, and as it decomposed on standing, further reactions were carried out on the syrupy mixture of products.

Methyl 4-Chloro-4-deoxy-α-D-xylopyranoside 2,3-Dichlorosulfate

The syrupy mixture of products from above (7 g) was refluxed with anhydrous methanol for 8 h. Concentration of the methanol solution to a small volume produced a crystalline compound which was removed from the solution by filtration. Successive recrystallizations from methanol–water and chloroform–petrol (b.p. 40–60°) gave colorless needles (1 g) of $[\alpha]_D$ +49° (*c*, 1.0 in chloroform) and m.p. 89° undepressed on admixture with an authentic sample synthesised by another route (see below).

4-Deoxy-3,4-dichloro-α-D-glycero-pent-2-enopyranosyl 4′-Deoxy-3,4-dichloro-α-D-glycero-pent-2′-enopyranoside (II)

The 10% sulfuric acid wash from the above described reaction was left to stand in a beaker open to the atmosphere, and after 24 h fine colorless needles began to appear, the yield of which increased on further standing. The acid wash was allowed to stand for a further 48 h before the crystals were removed by filtration. Recrystallization from acetone–water gave colorless needles (0.8 g) of m.p. 223° and $[\alpha]_D$ +190° (*c*, 1.1 in doxane).

Anal. Calcd. for $C_{10}H_{10}Cl_4O_3$: C, 37.4; H, 3.1; Cl, 44.3. Found: C, 37.3; H, 3.5; Cl, 43.3.

The infrared spectrum of the crystals (0.8% in KBr) indicated no hydroxyl absorption and the presence of an unconjugated ethylenic bond (1 655 cm^{-1}). The crystals did not reduce Fehlings' solution and had an approximate molecular weight of 300 as determined by the Rast method (8). It was found that the yield of this crystalline product could be improved considerably (1.5 g) by allowing the L-arabinose–sulfuryl chloride reaction mixture to stand for 24 h before working up the products. The yield of chloroform-soluble product decreased correspondingly. The crystals were unaffected by ozonolysis (4) and by lead tetraacetate oxidation (5) of the chloroform solution.

The acid wash from the reaction between D-arabinose and sulfuryl chloride also gave a similar non-reducing crystalline product which when recrystallized from acetone–water gave needles of m.p. 223° and $[\alpha]_D$ −186° (*c*, 0.7 in dioxane).

Methyl 4-Deoxy-3,4-dichloro-β-D-glycero-pent-2-enopyranoside (III)

The crystals of the D-enantiomer above (0.6 g) were refluxed with 100 ml of anhydrous methanol and 0.6 ml of concentrated sulfuric acid for 24 h. The solution was concentrated to a small volume and partitioned between chloroform and water. The chloroform solution was washed with saturated sodium bicarbonate

solution, dried (anhydrous sodium sulfate), and concentrated to a syrup which crystallized. Recrystallization from methanol–water gave colorless plates (0.4 g, 58%) of $[\alpha]_D$ +53° (*c*, 0.8 in methanol) and m.p. 72–73° undepressed on admixture with the authentic compound synthesised by another route (see below). The crystals also gave an infrared spectrum indistinguishable from that of the authentic compound.

Methyl 4-Chloro-4-deoxy-α-D-xylopyranoside 2,3-Dichlorosulfate

Methyl β-L-arabinopyranoside (5 g) was treated with sulfuryl chloride (11 ml) and pyridine (20 ml) in chloroform solution (2). The washed chloroform extracts gave on concentration a syrup which crystallized. Recrystallization from methanol–water gave colorless needles (4 g, 29%) of m.p. 88–90° and $[\alpha]_D$ +49° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_6H_9Cl_3O_8S_2$: C, 19.0; H, 2.4; Cl, 28.1; S, 16.9. Found: C, 19.0; H, 2.3; Cl, 28.3; S, 16.6.

No further chloro-substitution was obtained when the crystals were heated with pyridine hydrochloride in chloroform solution (3) and the original crystalline compound was obtained in good yield (80%).

Methyl 4-Chloro-4-deoxy-α-D-xylopyranoside 2,3-Cyclic Sulfate

The above crystals (2 g) were dissolved in anhydrous pyridine and the solution was left at room temperature for 16 h. The solution was poured into ice water and the aqueous solution was extracted with chloroform. The chloroform solution was washed with 5% sulfuric acid, saturated sodium bicarbonate solution, and distilled water. The chloroform solution was dried (anhydrous sodium sulfate), filtered, and concentrated to a syrup which rapidly crystallized (0.6 g, 56%). Recrystallization from ether–petrol (b.p. 40–60°) gave colorless crystals of m.p. 106–107° and $[\alpha]_D$ +100° (*c*, 1.0 in methanol).

Anal. Calcd. for $C_6H_9ClO_6S$: C, 29.5; H, 3.7; Cl, 14.5; S, 13.1. Found: C, 29.7; H, 3.6; Cl, 14.2; S, 12.8.

Methyl 4-Chloro-4-deoxy-α-D-xylopyranoside

The crystals of the dichlorosulfate ester derivative described above (5 g) were dechlorosulfated in methanol solution by sodium iodide in the presence of barium carbonate (1). The solution was filtered and the filtrate was concentrated to a small volume. Water was added and the aqueous solution was continuously extracted with chloroform. Concentration of the chloroform solution gave a syrup which crystallized, and recrystallization of the product from ethyl acetate gave colorless needles (0.8 g, 37%) of m.p. 102–103° and $[\alpha]_D$ +135° (*c*, 0.9 in methanol).

Anal. Calcd. for $C_6H_{10}ClO_4$: C, 39.4; H, 6.1; Cl, 19.5. Found: C, 39.8; H, 6.1; Cl, 19.2.

4-Chloro-4-deoxy-D-xylopyranose

The crystals of the methyl glycoside above were unaffected by boiling *N* sulfuric acid; therefore, more drastic conditions were tried.

The methyl glycoside (0.6 g) was dissolved in 25% sulfuric acid and the solution was heated at 100° for 5 h. The solution was diluted with water, neutralized with barium carbonate, filtered, deionized by passage through Amberlite IR120 (H form) and Duolite A4 (OH form) ion exchange resins, and concentrated to a syrup which crystallized. Recrystallizations from acetone–ether gave colorless crystals (0.3 g, 55%) of m.p. 145° and $[\alpha]_D$ −45.5° (5 min) → +9° (equilibrium, 24 h) (*c*, 1.1 in methanol).

Anal. Calcd. for $C_5H_9ClO_4$: C, 35.6; H, 5.4; Cl, 21.1. Found: C, 36.1; H, 5.3; Cl, 21.3.

Periodate Oxidation of 4-Chloro-4-deoxy-D-xylopyranose

The oxidation was carried out in the dark at 25° using a small sample (10 mg) of the compound in distilled water (25 ml) containing 0.3 *M* sodium metaperiodate (1 ml). Aliquots (2 ml) were removed at intervals and the consumption of periodate (9) and the production of formic acid (10) were measured and were respectively as follows: 1.66, 0.77 (1.30 h); 1.88, 0.89 (6.30 h); 2.00, 1.02 (24 h); 2.14, 1.18 (48 h).
