Ethyl radicals were generated in the presence of monomer molecules by the illumination of a gaseous mixture of diethyl ketone and the monomer with 3 130 Å radiation. To obtain more comprehensive information we have measured the rate constant for the addition of the ethyl radical to the various monomer molecules over a range of about 100 deg; values of the energy of activation and the pre-exponential factor can then be compared for the different monomers and the reactivity considered upon a more detailed basis.

EXPERIMENTAL PROCEDURE

The apparatus and method have been described in two earlier papers (1, 12). The kinetic analysis requires that the ethyl radical shall always be present in great excess over all other radicals. Acrylonitrile and styrene are far more reactive than the olefins towards the ethyl radical, and it was therefore necessary to use much lower initial concentrations than previously for these monomers, and to correct for consumption during the experiment. With these precautions the calculated rate constants were insensitive to variation of composition or intensity, and polymer was not formed in the reacting system.

The analysis followed the initial pattern of separation into CO, ($C_2H_6 + C_2H_4$), and C_4H_{10} fractions, each of which was estimated by the gas burette. The kinetic analysis requires a knowledge of the composition of the C_2 fraction, and this was obtained using the value of the ratio $\Delta = R(C_2H_4)/R(C_4H_{10})$ appropriate to the system, where $R(Z)$ denotes the rate of formation of the product Z. Many values of Δ have been measured for the photolysis of diethyl ketone in the presence of a wide variety of substrates; for all such systems under our prescribed conditions Δ is independent of temperature and has a mean value lying within the range 0.13 ± 0.01. The application of the appropriate value of Δ to the calculation of the rate constants is discussed in the next section.

THE KINETIC ANALYSIS

The mechanism proposed for the photolysis of a gaseous mixture of diethyl ketone and the vinyl monomers $CH_2{=}CHX$ by 3 130 Å radiation and under the conditions given above is analogous to that adopted for the olefinic systems (1, 12).

[1] $$CH_3CH_2COCH_2CH_3 + h\nu \rightarrow 2CH_3CH_2\cdot + CO$$

[2] $$2CH_3CH_2^{\cdot} \rightarrow C_4H_{10}$$

[3] $$2CH_3CH_2^{\cdot} \rightarrow C_2H_6 + C_2H_4$$

[4] $$CH_3CH_2^{\cdot} + CH_3CH_2COCH_2CH_3 \rightarrow CH_3CH_3 + CH_3\dot{C}HCOCH_2CH_3$$

[5] $$CH_3CH_2^{\cdot} + CH_3\dot{C}HCOCH_2CH_3 \rightarrow CH_3CH(CH_2CH_3)COCH_2CH_3$$

[6] $$CH_3CH_2^{\cdot} + CH_2{=}CHX \rightarrow CH_3CH_3 + V^{\cdot}$$

[6a] $$CH_3CH_2^{\cdot} + V^{\cdot} \rightarrow CH_3CH_2V$$

[7] $$CH_3CH_2^{\cdot} + CH_2{=}CHX \rightarrow CH_3CH_2CH_2\dot{C}HX$$

[7a] $$CH_3CH_2^{\cdot} + CH_3CH_2CH_2\dot{C}HX \rightarrow CH_3CH_2CH_2CH(CH_2CH_3)X$$

The symbol V$^{\cdot}$ indicates a radical formed by the abstraction of one hydrogen atom from the molecule of the vinyl monomer. The rate constants for metathesis (k_6) and addition (k_7) between the ethyl radical and the monomer molecule may be calculated from the equations:

$$\frac{k_6}{k_2^{1/2}} = \left(\frac{R(C_2H_6) - R(C_2H_4)}{R(C_4H_{10})^{1/2}}\right)\frac{1}{[B]} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}} = \left(\frac{R(C_2)}{R(C_4)} - 2\Delta\right)\frac{R(C_4)^{1/2}}{[B]} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}},$$

$$\frac{k_7}{k_2^{1/2}} = \frac{R(CO) - R(C_2H_6) - R(C_4H_{10})}{[B]R(C_4H_{10})^{1/2}} = \frac{R(CO) - R(C_2) - (1 - \Delta)R(C_4)}{[B]R(C_4)^{1/2}},$$

where [D] and [B] represent the concentration of diethyl ketone and the vinyl monomer respectively in molecules/cm^3; $R(Z)$ is the rate of formation of product Z in molecules/cm^3 s; C_2 and C_4 denote the product fractions with the specified carbon number; $\Delta = R(C_2H_4)/R(C_4H_{10})$; and $k_4/k_2^{1/2}$ has been previously determined (12).

The C_2 fractions were not normally analyzed for C_2H_4 and C_2H_6 content in this investigation, and so the right-hand form of each equation was used. A value of Δ is therefore required for each monomer system investigated. For the octene-1 system the value of 0.136 was used previously (12); this system has recently been reinvestigated using analytical gas chromatography and yielded the result: $\Delta = 0.137 \pm 0.010$, independent of temperature (13). The value of 0.136 was retained for heptene-1 and also used for the closely related monomer vinyl *n*-butyl ether. The acrylonitrile system has also been independently investigated using gas chromatography (14) yielding the value $\Delta = 0.127 \pm 0.014$, independent of temperature, and so the value of 0.127 was uniformly applied to the results of this study. No independent values of Δ exist for either the styrene or the vinyl acetate systems. The value of 0.136 was employed in the preliminary communication (15) and the results have since been recalculated using $\Delta = 0.127$. For neither monomer was the change in the value of $E_7 - \frac{1}{2}E_2$ or of $\log A_7/A_2^{1/2}$ greater than 0.1 unit, which is much less than the uncertainty in each case. The negligible effect of a 7% change in the value of Δ is not accidental, as all the experiments were planned to make the results insensitive to the value of Δ.

The results given for acrylonitrile in Fig. 1 belong to two distinct sets. The filled circles represent results of this investigation, and were calculated using a uniform value of 0.127 for Δ. The open circles are results of James and Ogawa (14); in each of these experiments the C_2 fraction was analyzed by gas chromatography for C_2H_4 and C_2H_6 and the result calculated directly from the analysis. The two sets form a single statistical population, and the Arrhenius parameters were calculated on this basis.

The molecules of acrylonitrile and styrene contain the formally unsaturated nitrile and phenyl groups respectively. The analytical method does not distinguish addition to the vinyl group from addition to an unsaturated group in the same molecule, but

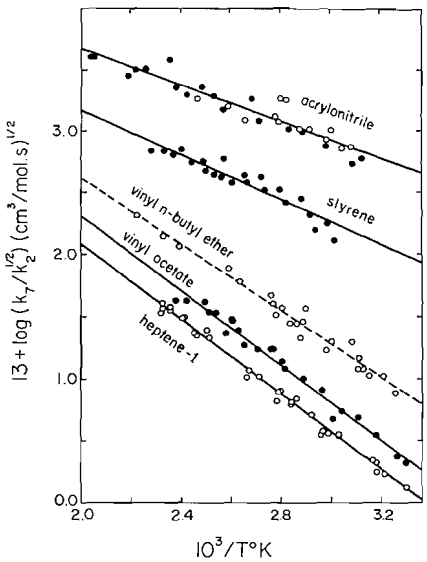

FIG. 1. Addition of the ethyl radical to vinyl monomers. The points and the line for vinyl *n*-butyl ether have been moved uniformly upwards by 0.5 units to avoid confusion.

independent attempts have been made to detect addition to the nitrile group of acetonitrile (14) and to the phenyl group of benzene (13). No addition could be detected to either substance, and it was estimated that $k_7(CH_3CN)/k_7(CH_2{=}CHCN) < 0.001$ and $k_7(C_6H_6)/k_7(C_6H_5CH{=}CH_2) < 0.001$ over the whole temperature range of this study. Appreciable addition of the ethyl radical to the substituent groups of acrylonitrile or styrene therefore appears to be unlikely.

The metathetical reaction [6] does not occur rapidly enough to be measured for any of the vinyl monomers by the method of this investigation.

RESULTS AND DISCUSSION

The Arrhenius plots for the addition of the ethyl radical to the four vinyl monomers $CH_2{=}CHX$ and the reference olefin heptene-1 are given in Fig. 1, and the Arrhenius parameters are listed in Table I.

TABLE I

Addition of the ethyl radical to vinyl monomers

Monomer	Number of expts.	Δ	C	B	$13 + \log A_7/A_2^{1/2}$	$E_7 - \frac{1}{2}E_2$ (kcal/mole)	$10^{13}k_7/k_2^{1/2}$ (at 100 °C)
Acrylonitrile	31	0.127	5.162	0.743	5.2±0.3	3.4±0.4	1 480
Styrene	22	0.127	4.980	0.905	5.0±0.3	4.1±0.6	360
Vinyl *n*-butyl ether	23	0.136	4.787	1.336	4.8±0.3	6.1±0.5	16
Vinyl acetate	23	0.127	5.341	1.512	5.3±0.3	6.9±0.5	19
Heptene-1 (ref. 1)	34	0.136	5.156	1.530	5.2±0.1	7.0±0.2	11

The constants B and C are the coefficients of the straight lines $13 + \log (k_7/k_2^{1/2}) = C - 10^3B/T$ fitted to the experimental results. The rate constants are expressed in units of cm³/molecule s; the limits of error are calculated at the 5% probability level.

None of the values of $13 + \log A_7/A_2^{1/2}$ deviates significantly from 5.1; this value is apparently insensitive to the substituent group X, and is probably characteristic of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

structural unit $CH_2{=}CH{-}$ which is common to all the molecules. In contrast, the energy of activation $E_7 - \frac{1}{2}E_2$ varies widely with the nature of the substituent group, and therefore the wide range of values of k_7 at a given temperature is almost entirely due to the variation in E_7. Reactivity is conferred upon the vinyl group by the substituent in the order $CN > C_6H_5 > OR > OCOR > R$, where R denotes an alkyl group.

The rate constants for the addition of the ethyl radical to a series of monomers in the gas phase may be compared with the corresponding rate constants for the addition of other free radicals. The wide range of values makes a log–log plot necessary, but the degree of linear correlation between the sets of rate constants may be judged by the closeness of the points to a reference line of unit gradient. Figure 2 shows such an attempt with the polyethylene radical, and is discussed in detail below. It is not truly representative of this kind of test because most of the values of Q_0 had to be calculated from the results of other copolymerizing systems and are therefore subject to more than the usual degree of error. Similar diagrams have been drawn for both the polystyrene radical (14) and the methyl radical (13) using directly determined results only. These show a reasonable degree of linear correlation in each case and indicate that radicals of widely differing intrinsic reactivity are capable of revealing a consistent pattern of reactivity among monomers if the polar effects are similar.

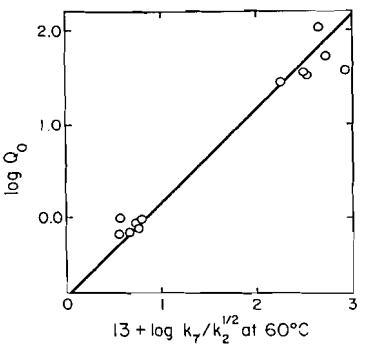

FIG. 2. Correlation of the rate constant k_7 with the parameter Q_0; the reference line has unit gradient.

Vinyl *n*-butyl ether seems to be more selective than the other monomers in its reactivity towards free radicals. The degree of reactivity shown by acrylonitrile, styrene, and vinyl acetate is consistent with the response of these monomers towards free radical polymerization (4). Vinyl *n*-butyl ether fails to yield high polymer under free radical conditions although the ether is nearly as reactive as vinyl acetate towards the ethyl radical, and this failure cannot be explained by an easy chain transfer process of the type that prevents the polymerization of heptene-1. On the other hand, the ready addition of the ethyl radical to vinyl *n*-butyl ether is paralleled by numerous examples of the addition of the rather electrophilic perhaloalkyl radicals to vinyl alkyl ethers (16). These observations indicate a higher electron density at the β-carbon atom of the vinyl group in vinyl *n*-butyl ether than in vinyl acetate, a conclusion which is supported by recent spectroscopic studies.

The nuclear magnetic resonance spectra of certain vinyl alkyl ethers have recently been discussed (17), and the most striking feature of the results is the extreme high-field position of the β-protons of the ethers, at about 80 c.p.s. above ethylene. This indicates conjugation between the lone pair of the oxygen atom and the π-electrons of the vinyl group, resulting in an increased charge density at the β-position. Certain doublets in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

vibrational spectra of the vinyl alkyl ethers reveal the presence of two rotational isomers, and a recent detailed study of vinyl methyl ether shows that the *cis* form lies 1.15 ± 0.25 kcal/mole below the *trans* form (18). Non-bonded interaction between the oxygen lone pair and the vinyl group is again indicated in the unsubstituted vinyl alkyl ethers. However this characteristic doublet is replaced by a singlet in the spectra of vinyl α,α-difluoroalkyl ethers (19); the fluorine atoms appear to inhibit the flow of charge from the oxygen atom to the vinyl group by virtue of their electronegativity. By the same reasoning we should expect the interaction between the non-carbonyl oxygen atom and the vinyl group to be much less in vinyl acetate than in vinyl *n*-butyl ether, giving to the latter the greater electron density at the β-carbon atom of the vinyl group. This would be consistent with the observations that vinyl *n*-butyl ether responds more readily to cationic polymerization and has the lower energy of activation for the addition of the ethyl radical.

In the introduction we have suggested that the addition rate constant k_7 may be an acceptable alternative to the copolymerization parameter Q_0 as an index of the intrinsic reactivity of a monomer at a given temperature. To find whether Q_0 and k_7 are linearly related, we have calculated values of Q_{0B} for each substrate from the Q_B and e_B values based upon styrene, using the equation:

$$\log Q_{0B} = -\log r_A = \log (Q_B/Q_A) + e_A(e_A - e_B)/2.303,$$

and the values $Q_A = 0.03$ and $e_A = -0.43$ for ethylene (10). The results are listed in Table II. For two of the substrates the Q and e values were not available, so those for a closely related monomer were used instead. Values of Q_0 have been directly determined for vinyl acetate at 90 °C and for *n*-butyl acrylate at 70 °C (10) and are included in Table II for comparison. Values of Q_0 may also be estimated for methyl acrylate and methyl methacrylate from the corresponding reactivity ratios for the copolymerization of these monomers with ethylene at 150 °C (11); they have not been included in this correlation as the reaction temperature was 90 deg higher than our standard of 60 °C, and the kinetic behavior of these systems was rather unusual.

TABLE II

vinyl *n*-butyl ether and acrylonitrile showing the greatest deviation; otherwise the correlation is reasonably satisfactory for a range of values of k_7 of over 100-fold. In particular there is no systematic connection between the deviation and the value of e. Some of the values of Q and e may be subject to appreciable error, and indeed those for ethylene are average values obtained from three somewhat divergent sets; it is therefore difficult to judge the reliability of the derived Q_0 values of Table II. It seems reasonable to conclude that the directly determined values of k_7 offer an alternative index of intrinsic reactivity which is no less reliable than the set of derived values of Q_0.

REACTIONS OF THE ETHYL RADICAL

V. ADDITION TO THE MONOMETHYL ACRYLONITRILES

D. G. L. James and Takeshi Ogawa[1]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received October 19, 1964

ABSTRACT

The Arrhenius parameters have been measured for the addition of the ethyl radical to methacrylonitrile and to the *cis* and *trans* isomers of crotononitrile. The energy of activation for each of these derivatives is significantly greater than for acrylonitrile. There is no significant variation among the values of the energy of activation for the monomethyl acrylonitriles, so that the introduction of a methyl group into the acrylonitrile molecule appears to raise the energy of activation by an amount which is insensitive to the position of the group. The pre-exponential factor is significantly smaller for each of the crotononitrile isomers than for methacrylonitrile; the partial shielding of the β-carbon atom of crotononitrile is thus expressed by a steric factor rather than by an energy term. The *cis–trans* isomerization of crotononitrile is photosensitized by diethyl ketone illuminated by 3 130 Å radiation in both the liquid and gaseous phases; a mechanism of triplet state energy transfer is proposed for the process.

INTRODUCTION

In Part IV of this series we have considered the effect of the substituent group upon the reactivity of a vinyl monomer CH_2=CHX towards the addition of the ethyl radical (1). A wide range of reactivity was discovered; thus acrylonitrile proved to be 80 times as reactive as vinyl acetate at 100 °C. The energy of activation varied greatly among the monomers, and this variation determined the differences in reactivity almost exclusively. No significant variation was found among the values of the pre-exponential factors, suggesting uniformity of steric conditions at the site of radical attack.

In this paper we consider the effect upon the reactivity of the molecule CH_2=CHX of the introduction of a second substituent group. We have chosen to examine this phenomenon with the three monomethyl derivatives of acrylonitrile. Acrylonitrile owes its low energy of activation to the influence of the electrophilic nitrile group upon the reactivity of the vinyl group. In the monomethyl acrylonitriles the electrostatic influence of the nitrile group is partially offset by the electron-donating capacity of the methyl group, and the corresponding change in the reactivity of the vinyl group towards addition should be observable as an increase in the energy of activation. Moreover, the steric factor for the addition reaction should be different for the geminal and vicinal patterns of substitution of methacrylonitrile and the crotononitriles respectively, and the effect should be observable as a difference in the pre-exponential factors. Finally, the easy separation of crotononitrile into *cis* and *trans* forms offers the possibility of finding a difference of reactivity between the isomers and of detecting the photosensitization of isomerization by diethyl ketone.

EXPERIMENTAL PROCEDURE

Ethyl radicals were formed in the presence of monomer molecules by the illumination of a gaseous mixture of diethyl ketone and the monomer with 3 130 Å radiation. The apparatus and general method have been described previously (2). The diethyl ketone and the monomers were purified by passage through the 2 m "Ucon polar" column of the Beckman Megachrom preparative gas chromatograph at 110 °C. Crotononitrile

[1]*Present address: Department of Chemistry, Birkbeck College (University of London), Malet Street, London W.C.1. England.*

For personal use only.

was separated quantitatively into *cis* and *trans* isomers in this way. The isomers were identified by their nuclear magnetic resonance spectra (3).

Acrylonitrile and methacrylonitrile are very reactive towards the ethyl radical, and it was therefore necessary to use a low initial concentration for these reactants, and to correct for consumption during each experiment. With these precautions the calculated rate constants were insensitive to variation of composition or intensity, and no polymer was formed. The analysis followed the initial pattern of separation into CO, ($C_2H_4 + C_2H_6$), and C_4H_{10} fractions, each of which was estimated by the gas burette. The fractions were examined on a Perkin–Elmer Model 154 C gas chromatograph using helium as a carrier gas and a 2 m column J at 80 °C. No impurities were found in the fractions and the composition of each C_2 fraction was determined from the peak areas, using an appropriate sensitivity factor (2).

The products of the gas-phase reaction were also analyzed to determine whether the geometrical isomerization of the crotononitriles was photosensitized by diethyl ketone under the action of 3 130 Å radiation. After photolysis and removal of the CO, C_2, and C_4 fractions, the residue was condensed and analyzed on the Perkin–Elmer Model 154 C gas chromatograph, using the 2 m column R.

The photosensitized isomerization of the crotononitriles in the liquid phase was examined by illuminating a deaerated liquid mixture of diethyl ketone and the *cis* or the *trans* isomer with 3 130 Å radiation at constant intensity for different periods at 85 °C. A small sample of the product was analyzed using the 4 m column R. Control experiments were performed on the thermal isomerization of deaerated samples of the pure isomers at 85, 190, and 260 °C; these indicated that no correction for a thermal reaction was necessary in the evaluation of the photosensitized isomerization at 85 °C.

THE KINETIC ANALYSIS

The mechanism proposed for the photolysis of a gaseous mixture of diethyl ketone and a monomethyl acrylonitrile by 3 130 Å radiation under the specified conditions is given below for the case of methacrylonitrile; the crotononitriles will show analogous reactions.

[1] $$CH_3CH_2COCH_2CH_3 + h\nu \rightarrow 2CH_3CH_2\cdot + CO$$

[2] $$2CH_3CH_2\cdot \rightarrow C_4H_{10}$$

[3] $$2CH_3CH_2\cdot \rightarrow C_2H_6 + C_2H_4$$

[4] $$CH_3CH_2\cdot + CH_3CH_2COCH_2CH_3 \rightarrow CH_3CH_3 + CH_3\dot{C}HCOCH_2CH_3$$

[5] $$CH_3CH_2\cdot + CH_3\dot{C}HCOCH_2CH_3 \rightarrow CH_3CH(CH_2CH_3)COCH_2CH_3$$

[6] $$CH_3CH_2\cdot + CH_2{=}C(CN)CH_3 \rightarrow CH_3CH_3 + CH_2{=}C(CN)CH_2\cdot$$

[6a] $$CH_3CH_2\cdot + CH_2{=}C(CN)CH_2\cdot \rightarrow CH_2{=}C(CN)CH_2CH_2CH_3$$

[7] $$CH_3CH_2\cdot + CH_2{=}C(CN)CH_3 \rightarrow CH_3CH_2CH_2\dot{C}(CN)CH_3$$

[7a] $$CH_3CH_2\cdot + CH_3CH_2CH_2\dot{C}(CN)CH_3 \rightarrow CH_3CH_2CH_2C(CH_2CH_3)(CN)CH_3$$

The rate constants for metathesis (k_6) and addition (k_7) between the ethyl radical and the monomer molecule may be calculated from the equations:

[I] $$\frac{k_6}{k_2^{1/2}} = \left(\frac{R(C_2H_6) - R(C_2H_4)}{R(C_4H_{10})^{1/2}}\right)\frac{1}{[B]} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}}$$

[II] $$\frac{k_7}{k_2^{1/2}} = \frac{R(CO) - R(C_2H_6) - R(C_4H_{10})}{[B]R(C_4H_{10})^{1/2}} = \frac{(1 - M)R(CO)}{[B]R(C_4H_{10})^{1/2}},$$

where [D] and [B] represent respectively the concentration of diethyl ketone and the monomer in molecules/cm^3; R(Z) is the rate of formation of the product Z in molecules/cm^3 s; $k_4/k_2^{1/2}$ has been previously determined (4); and $M = [R(C_2H_6) + R(C_4H_{10})]/R(CO)$.

The addition of the ethyl radical to the carbon–carbon triple bond of heptyne-1 proceeds at an easily measurable rate (5). To complete this study we have attempted to detect the addition of the ethyl radical to the carbon–nitrogen triple bond of acetonitrile. Experiments were performed between 90 and 203 °C at relatively low ethyl radical

concentrations, but yielded no evidence for the addition reaction. The values of M fluctuated unsystematically about unity between limits of 0.95 and 1.03, which are unusually widely spaced for this type of study. Accordingly the lower limit of 0.95 was adopted as the critical value of M at which addition would become perceptible. For each experiment $M = 0.95$ corresponds to a certain value of $10^{13}k_7/k_2^{1/2}$; this is taken as the maximum value that $10^{13}k_7/k_2^{1/2}$ may attain under the conditions of that experiment without addition becoming perceptible. In this way we can show that

$$k_7(\text{acetonitrile})/k_7(\text{heptyne-1}) < 0.05 \text{ at } 108°, \text{ and } < 0.04 \text{ at } 142°; \text{ also that}$$

$$k_7(\text{acetonitrile})/k_7(\text{acrylonitrile}) < 0.0003 \text{ at } 108° \text{ and } < 0.0004 \text{ at } 142°.$$

Clearly the nitrile group has a low reactivity towards the addition of the ethyl radical, and is unlikely to contribute appreciably to the reactivity of acrylonitrile or its methyl derivatives in this respect.

The low reactivity of the hydrogen atoms of acetonitrile towards metathesis may be inferred from the same series of experiments. Values of $10^{13}k_6/k_2^{1/2}$ calculated from these results were small in magnitude even in comparison with those for *n*-heptane (5), and variable in sign, indicating a very small rate constant for abstraction. An upper limit for $k_6/k_2^{1/2}$ was obtained from the results of each experiment by assuming that metathesis would be just perceptible if

$$\frac{k_6}{k_2^{1/2}} = \frac{1}{10}\frac{[\text{D}]}{[\text{B}]}\frac{k_4}{k_2^{1/2}}.$$

This assumption was tested by comparing the calculated and limiting values for $k_6/k_2^{1/2}$ for each experiment; with one exception the calculated value was considerably smaller. By this method we can show that

$$k_6(\text{acetonitrile})/k_6(\text{heptyne-1}) < 0.03 \text{ at } 108° \text{ and } < 0.02 \text{ at } 142°; \text{ whereas}$$

$$k_6(\text{acetonitrile})/k_6(n\text{-heptane}) < 0.23 \text{ at } 108° \text{ and } < 0.15 \text{ at } 142°.$$

Clearly the nitrile group does not share with the ethynyl group the property of activating the hydrogen atoms of an adjacent methylene group. Wijnen found that metathesis between the $CD_3\cdot$ radical and acetonitrile was also slow, but still measurable (6), probably by virtue of the greater reactivity of the $CD_3\cdot$ radical. The metathetical reaction [6] does not occur rapidly enough to be measured for any of the unsaturated nitriles by the method of this investigation.

RESULTS AND DISCUSSION

The Arrhenius plots for the addition of the ethyl radical to the unsaturated nitriles are given in Figs. 1 and 2. The two vinyl compounds are compared in Fig. 1; as the reactivities of acrylonitrile and methacrylonitrile are similar one set of results has been uniformly displaced 0.2 units with respect to the other, as shown by the vertical scales. The results for acrylonitrile were obtained in two independent investigations; the open circles represent the results of this study, whereas black circles denote those of James and MacCallum (1). All the results for acrylonitrile were treated as a single set for the statistical analysis. Figure 2 shows the results for the *cis* and *trans* isomers of crotononitrile; the points for the reactive monomer vinyl acetate were added for comparison (7).

Statistical analysis of these data yields the values listed in Table I. Similar data for octene-1 (8) and 2-methyl pentene-1 (9) have been included to assist the interpretation.

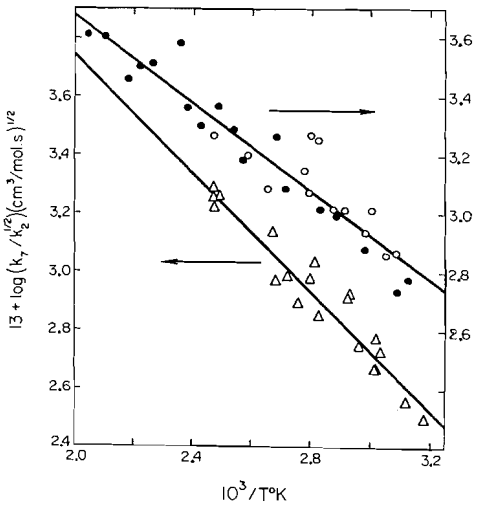

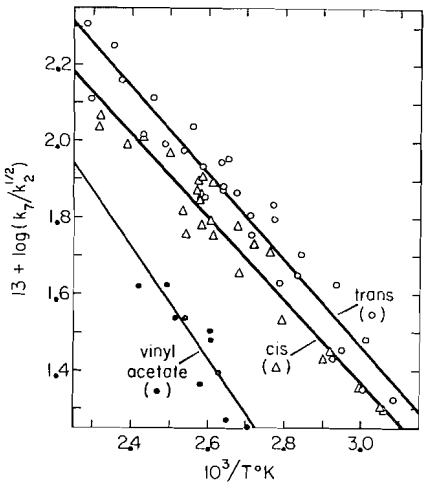

FIG. 1. Addition of the ethyl radical to vinyl compounds. Circles, acrylonitrile; $E_7 - \frac{1}{2}E_2 = 3.4 \pm 0.4$ kcal/mole; triangles, methacrylonitrile; $E_7 - \frac{1}{2}E_2 = 4.6 \pm 0.7$ kcal/mole.

FIG. 2. Addition of the ethyl radical to the crotononitrile isomers; the values of $E_7 - \frac{1}{2}E_2$ are *cis*, 5.0 ± 0.5; *trans*, 5.2 ± 0.6 kcal/mole.

All the values of Table I are based consistently upon the direct analysis of the C_2 fraction of each experiment, rather than upon an indirect estimate as used previously (5). The Arrhenius parameters for octene-1 are therefore revised values, and differ from the original parameters; this deviation will be discussed in Part VI of this series (8).

Acrylonitrile is reduced at the dropping mercury electrode, whereas the 1-alkenes are not reduced. The nitrile group activates the double bond towards reduction by its capacity to withdraw electron density, but in the crotonitrile isomers this tendency is partially offset by the capacity of the substituent methyl groups to increase the electron density at the double bond. These ideas are confirmed by the polarographic half-wave potentials measured for 1.0 mM solutions of these nitriles in acetonitrile containing 0.1 M tetrabutyl ammonium iodide (8). The half-wave potentials were -1.67, -1.94, and -1.95 V for acrylonitrile, *cis*-crotononitrile, and *trans*-crotononitrile, respectively, relative to the mercury pool at 25 °C. The influence of the methyl group as an electron density donor is clearly significant, and we shall suggest below that it has a significant influence upon the comparative reactivity of the nitriles towards the addition of the ethyl radical.

THE ARRHENIUS PARAMETERS AND REACTIVITY

The monomethyl acrylonitriles are distinguished as a class from acrylonitrile by the values of the energy of activation, $E_7 - \frac{1}{2}E_2$. The substitution of a methyl group for one of the hydrogen atoms of acrylonitrile increases the energy of activation for the addition reaction by an amount which is significant for each of the monomethyl acrylonitriles. There is no significant variation among the values of $E_7 - \frac{1}{2}E_2$ for the three monomethyl acrylonitriles, so that the introduction of the methyl group appears to raise the energy of activation by an amount which is independent of its position. The values of $E_7 - \frac{1}{2}E_2$ for the monomethyl acrylonitriles are still low in comparison with the value for octene-1; it is clear that the activation of the double bond by the nitrile group remains the dominant factor, whereas the deactivating effect of the methyl group is significant, uniform but

minor. The degree of activation conferred upon the double bond by the substituent alkyl and nitrile groups when present singly may be inferred from the values of $E_7 - \frac{1}{2}E_2$: ethylene, 8.6 kcal/mole (10); octene-1, 7.6 kcal/mole; and acrylonitrile, 3.4 kcal/mole. A single alkyl group activates the double bond by increasing the stability of the adduct radical by hyperconjugation, and two geminal alkyl groups cooperate to give a still greater reactivity, as in 2-methyl pentene-1. A single nitrile group activates the double bond by increasing the stability of the adduct radical by conjugation, and two geminal nitrile groups cooperate so effectively that methylene malononitrile polymerizes spontaneously. However, a comparison of the values of $E_7 - \frac{1}{2}E_2$ for styrene (4.1 kcal/mole (1)), methacrylonitrile (4.6 kcal/mole), and acrylonitrile (3.4 kcal/mole) indicates that the reactivity conferred upon the double bond of acrylonitrile by the highly electrophilic nitrile group may be due in part to a favorable polar effect. Polar effects are normally negligible in the addition reactions of the ethyl radical (1), but its ionization potential of 8.78 V is probably not high enough to prevent an appreciable contribution from ionic forms to the stability of the transition state in such a favorable case as acrylonitrile (7). The adverse polar effect introduced by the methyl group of methacrylonitrile appears from the value of the energy of activation to be much greater than the favorable effect of hyperconjugation. The β-carbon atom of the double bond is the preferred site for addition for each of the monomethyl acrylonitriles. Hyperconjugation should favor this addition for methacrylonitrile, but have no effect in the case of the crotononitrile isomers. The lack of any significant variation among the values of the energy of activation for these three nitriles indicates that hyperconjugation does not make a significant contribution to their reactivity.

The monomethyl acrylonitriles may form a single set in respect to the energy of activation, but they are split into two distinct sets when the pre-exponential factor is considered: the crotononitriles and methacrylonitrile, with vicinal and geminal patterns of substitution respectively. Table I shows that the values of $13 + \log A_7/A_2^{1/2}$ for methacrylonitrile are significantly higher than those for each of the crotononitriles, whereas the values for the *cis* and *trans* isomers are indistinguishable from each other. Such results may be interpreted in terms of steric effects at the carbon atom in the β-position with respect to the nitrile group, which is the most probable site for addition. This carbon atom is relatively unobstructed in methacrylonitrile, but it is partially shielded by the methyl group in crotononitrile, and to a similar degree in each of its isomers. A parallel difference in steric factors appears to govern the reactivity of 2-methyl pentene-1 and *trans*-octene-4 towards the ethyl radical; addition to the geminal compound 2-methyl pentene-1 is easily measured (9), but addition to the vicinal compound *trans*-octene-4 proceeds too slowly to be detected (5). The whole pattern of reactivity shown by acrylonitrile and its monomethyl derivatives is paralleled by the methyl esters of acrylic acid and its monomethyl derivatives (9).

COPOLYMERIZATION PARAMETERS AND REACTIVITY

One purpose of this investigation was to detect any difference between the reactivities of the *cis* and *trans* isomers of crotononitrile towards the addition of free radicals. It would appear from Fig. 2 that the *trans* isomer is the more reactive towards the addition of the ethyl radical. However statistical analysis reveals no significant differences for the two isomers between the respective values for the energy of activation, pre-exponential factor, or rate constant at 100 °C, as is clear from Table I. On the other hand, Fig. 2 reveals that the crotononitriles are much more reactive towards the addition of the ethyl

radical than the well-known monomer vinyl acetate (5). This suggested that the crotononitrile isomers (B) might copolymerize with styrene (A) under free radical conditions, offering an opportunity to detect a difference in reactivity from the values of the reactivity ratio r_A. Preliminary results show that the copolymerization is governed by the penultimate unit effect, and that the reactivity ratios to be compared are: $r_{AA}(trans) = 20$ and $r_{AA}(cis) = 18$; these values suggest that the *cis* isomer is the more reactive in homogeneous radical copolymerization (11).

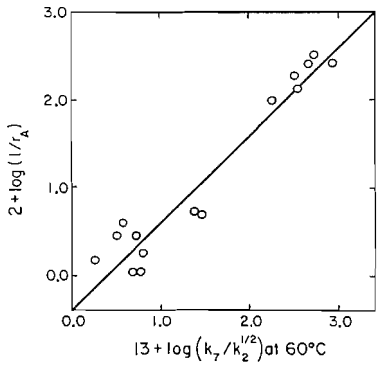

FIG. 3. Correlation of the rate constants for the addition of the polystyrene radical and the ethyl radical to various monomers at 60 °C. A line of unit gradient has been drawn for reference.

The rate constants for the addition of the ethyl radical to a series of monomers in the gas phase at 60 °C have been compared with the corresponding rate constants for the addition of the polystyrene radical in solution in Fig. 3; a line of unit slope has been drawn for reference. The wide range of values makes a plot of log $(1/r_A)$ against log $(k_7/k_2^{1/2})$ necessary; r_A is the reactivity ratio for the copolymerization of styrene (A) with a monomer (B) either identical with, or closely allied to, the substrate of the ethyl radical addition. The values used in the correlation are listed in Table II. The scatter of the points from the reference line is small, and not systematically related to the *e* value of the monomer. We conclude that there is reasonably good linear correlation between the rate constants for the addition of the ethyl radical in the gas phase and of the polystyrene radical in solution. A similar degree of correlation has been found between the rate constants for the addition of the ethyl radical in the gas phase and of the methyl radical in solution (8).

THE PHOTOSENSITIZED *cis–trans* ISOMERIZATION OF CROTONONITRILE

Photosensitization of the *cis–trans* isomerization of crotononitrile is observed when diethyl ketone is added to one of the isomers and the mixture is illuminated with 3 130 Å radiation. The isomerization occurs in both liquid and gaseous systems. No isomerization occurs in the absence of either diethyl ketone or the sensitizing radiation at the temperatures of this study, although thermal isomerization occurs at much higher temperatures (17).

The liquid phase experiments were conducted at 85 °C and constant intensity upon a deaerated binary mixture of diethyl ketone and one of the pure isomers of crotononitrile at an initial molar ratio of 1:1.3. The results are shown in Fig. 4, and indicate that the concentration c of the chosen isomer at time t is related to its initial value c_0 by the equation:

$$\ln ((2c/c_0) - 1) = -k^*t, \qquad [III]$$

where the constant k^* has the same value for both the *cis* and the *trans* isomer.

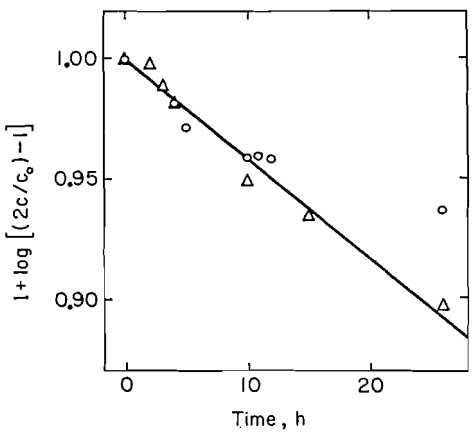

FIG. 4. Photosensitized isomerization of crotononitrile by diethyl ketone in the liquid phase with 3 130 Å radiation: triangles, the *cis* isomer; circles, the *trans* isomer.

Illumination of a gaseous mixture of diethyl ketone and one of the isomers of crotononitrile by 3 130 Å radiation also causes a slow isomerization to occur in addition to the normal range of reactions [1] to [7*a*]. The rate of isomerization is approximately equal to the rate of the addition reaction [7].

We propose that the photosensitized isomerization of crotononitrile proceeds by the transfer of triplet state energy from an excited molecule of diethyl ketone to a molecule of either isomer of crotononitrile. Molecules of crotononitrile in the triplet state will undergo rapid geometrical isomerization before deactivation stabilizes them in the *cis* or *trans* form. The literature of photosensitization provides comparable examples of systems where *cis–trans* isomerization proceeds through promotion to the triplet state, and where the triplet state of diethyl ketone is the effective donor in a photosensitization process.

The *cis–trans* isomerization of butene-2 in the gas phase can be effected with a variety of photosensitizers, including mercury atoms (18, 19) and benzene and pyridine molecules (18, 20, 21, 22). The essential step in the mechanism of photosensitization is the transfer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of triplet state energy from the excited sensitizer to the olefin molecule. This transfer of energy occurs at almost every collision between the donor and acceptor species. The molecules of the olefin in the triplet state may undergo repeated geometrical isomerization by internal rotation before their configuration is stabilized by deactivation to the ground state (22).

Diethyl ketone has been shown to photosensitize the conversion of *cis*-piperylene to the *trans* form in solution (23). The capacity of excited molecules of diethyl ketone to act as donors in a triplet–triplet energy interchange in the gas phase has been established in a study of the fluorescence of biacetyl photosensitized by diethyl ketone illuminated by 3 130 Å radiation (24).

The mechanism proposed for the *cis–trans* isomerization of crotononitrile (B) photosensitized by diethyl ketone (D) is given in outline below; a molecule in the triplet state is distinguished by an asterisk.

$$D^* + B(cis) \rightarrow D + B^* \qquad (k_c)$$
$$D^* + B(trans) \rightarrow D + B^* \qquad (k_t).$$

Configurations of the triplet state are not distinguished as many cycles of internal rotation are expected during the lifetime of B*. Deactivation of the triplet state regenerates the isomers:

$$B^* \rightarrow B(cis) \qquad (k_c')$$
$$B^* \rightarrow B(trans) \qquad (k_t').$$

At constant intensity of illumination [D*] may be taken as constant. The kinetics are particularly simple if $k_c = k_t = k$ and $k_c' = k_t'$; these assumptions are paralleled in the kinetic analysis of the *cis–trans* isomerization of butene-2 photosensitized by benzene and pyridine (22). The rate equation then becomes

$$\ln ((2c/c_0) - 1) = -k[D^*]t, \qquad [IV]$$

which is identical with eq. [III] if $k^* = k[D^*]$. The experimental results of Fig. 4 are therefore consistent with the simple form of the mechanism given above.

An alternative mechanism for the photosensitized isomerization of crotononitrile would exist if the addition of the ethyl radical to the crotononitrile molecule were reversible. Certainly the *cis–trans* isomerization of butene-2 can be sensitized by the reversible addition of iodine atoms (25, 26) or of thiyl radicals (27) and the *cis-trans* isomerization of crotononitrile can be sensitized by the reversible addition of bromine atoms (28). The kinetic study of the *cis–trans* isomerization of methyl crotonate photosensitized by diethyl ketone under 3 130 Å illumination yields evidence that the reversible addition mechanism becomes predominant above 200 °C (9). However, over the temperature range of the present study (51 to 165 °C) the methyl crotonate system appears to isomerize by the triplet state energy transfer mechanism. The kinetic behavior of both the methyl crotonate and the crotononitrile systems is very similar in this temperature range; indeed for none of the four substrates does the value of $E_7 - \frac{1}{2}E_2$ deviate significantly from 4.7 kcal/mole, or the value of $13 + \log A_7/A_2^{1/2}$ from 4.6. We should therefore expect the crotononitrile system to resemble the methyl crotonate system in isomerizing by the triplet energy transfer mechanism in the temperature range of this study, but possibly by the reversible addition mechanism at much higher temperatures.

ENTHALPIES OF INTRAMOLECULAR HALOGEN–HYDROXYL INTERACTIONS

A. W. BAKER AND A. T. SHULGIN
Dow Chemical Company, Walnut Creek, California
Received August 28, 1964

ABSTRACT

Enthalpies of halogen–hydroxyl interactions have been evaluated for the 2-halophenols in carbon tetrachloride. These values, in −kcal/mole, corrected for the temperature dependence of absorptivity coefficients, are Cl = 1.44, Br = 1.21, and I = 1.08. From enthalpy differences measured in unsymmetrical 2,6-dihalophenols, it is shown that the interaction in 2-fluorophenol lies between those in 2-bromophenol and 2-iodophenol, thus reaffirming the order Cl > Br > F > I.

The nature of halogen–hydroxy interactions is still open to conjecture despite intensive investigations (1–21) during the past several years. The investigations have been pursued by the use of several different techniques and have encompassed both intra- and intermolecular interactions of various phenols and alcohols. However, despite this attention, many aspects of the interactions are inadequately understood. For example, there has been no general agreement as to accepted values of these energies of interaction, nor has the relative order of energies within the halogen series been unambiguously determined.

For both 2-haloethanols and 2-halophenols, it is generally agreed that in "inert" solvents, 1, the difference ($\Delta\nu_{OH}$) between the frequencies of the free and bonded O—H configurations increases in the order F < Cl < Br < I, and 2, the proportion of the compound existing in the free (or *trans*) form increases in the same order. In addition, for the 2-halophenols, it is accepted that the O—H group is constrained to two coplanar positions by resonance interaction with the aromatic π-system and that it spends negligible time in residence between them. On the other hand, there is disagreement over the following points concerning these interactions. 1. Can these interactions be considered to be hydrogen bonds in the usual sense? 2. If we consider that these interactions embrace all contributions, such as from orbital basicity, atomic diameter, polarizability, and dipole moment, which halogen admits of the largest energy of interaction? 3. What is the relative order within the halogen series of the energies of interaction? 4. Does the Badger–Bauer rule (3), which states that the enthalpy of interaction (ΔH) is proportional to $\Delta\nu_{OH}$, apply to this interaction in which the O—H $\cdots$ X is highly bent away from the preferred rectilinear orientation?

Disagreement on question 1 stems from the fact that half-band widths and absorptivities of the O—H bands of 2-halophenols are only slightly larger than those of phenol- and alkyl-substituted phenols. In analogy with intermolecular hydrogen bonding, it would have been expected that both should show marked increases (9, 22). Explanations for this unexpected behavior have been offered previously (13, 15) and shall be the subject of subsequent discussions. However, this paper will deal only with the remaining three questions by the critical evaluation of enthalpies of these interactions, specifically, in the 2-halophenols in the single solvent, carbon tetrachloride.

Since 2-fluorophenol and 2-fluoroethanol each exhibit but a single O—H band, the enthalpy of interaction cannot be evaluated directly by these spectroscopic techniques. These bands are grossly unsymmetric, indicating that the two components occur so close

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

together that they contribute to a single band envelope. It has been observed previously (13), however, that unsymmetrical 2,4,6-trihalophenols exhibit two bands, each displaying a frequency characteristically assignable to the appropriate ortho-halide, regardless of the combination specifically represented. In the three possible unsymmetric 2-fluoro-6-halophenols (with or without a 4-halogen substituent), the O—H · · · · F band has the higher frequency in each case and is much broader than any of those involving the other halogens. Enthalpy differences can be measured accurately, thus allowing the relative strengths of the interactions to be determined. These data, combined with the measured enthalpies for 2-chloro-, 2-bromo-, and 2-iodo-phenol, determine the enthalpy of the fluorine–hydroxyl interaction to within perhaps a tenth of a kcal per mole. Obviously, the solvent is participating in these interactions and the *cis* and *trans* forms might be solvated or stabilized by different amounts. Therefore, enthalpies determined for one solvent system need not necessarily apply to a second, nor need the relative order established in one solvent system be the same as in a second. This is a moot question and will be investigated later in detail.

EXPERIMENTAL

The enthalpy calculations in this study required that the experimental data be obtained from compounds of high purity. If an ortho-halophenol displaying a *cis* to *trans* absorbance ratio[1] of 40 were contaminated by as little as 2½% of non-ortho-halogenated phenol (which would absorb at approximately the same frequency as the *trans*-isomer) the apparent ratio would be halved. Consequently, an undetermined but relatively large error would be embodied in any calculation involving that ratio. The same problem exists in the corresponding unsymmetrical dihalophenols but to a smaller degree since the absorbance ratios are more nearly unity. To meet the demands of purity, frequent use was made of gas–liquid chromatography (g.l.c.) in the course of synthesis, isolation, and purification of all compounds.

The separations were performed on a Wilkins Aerograph A-700 Autoprep, using helium as a carrier gas. Three 5 ft, 3/8 in. diameter columns were necessary: Apiezon L (7% on 50–60 mesh Anakrom), ethylene glycol succinate (5% on 60–80 mesh acid-washed Chromosorb W), and 20 *M* Carbowax (10% on the Chromosorb support). These columns are abbreviated in the following discussion as A-L, EGS, and 20 *M*, respectively.

The four monohalophenols were obtained from commercial sources. 2-Fluoro-(Aldrich Chemical Company), 2-chloro-, and 2-iodo-phenols (Eastman Kodak) were purified by preparative separation on the 20 *M* column. Analyses by reinjection verified the absence of both free phenol and the para-isomer. 2-Bromophenol (Dow Chemical Company) required the Apiezon L column. A small phenolic contaminant, although well separated at 112 °C and 300 ml/min gas flow (phenol at 2.3 min, 2-bromophenol at 5.0 min, and air at 0.5 min) was still present in the purified sample. The residual impurity (0.05%) was undoubtedly due to unsuspected tailing either from the column or from the collection technique. A second pass reduced this to an acceptable level. For the other monohalophenols, a single separation achieved adequate purity.

None of the unsymmetrical 2,6-dihalophenols have heretofore been described in the literature. They were synthesized by the halogenation of an appropriate, purified monohalo compound, and separated from the congeneric para- and di-substitution products as described in Table I. The corresponding trihalophenols also investigated have been described earlier (13). (See below.)

The solvent employed in these studies, carbon tetrachloride, was dried by suspended P_2O_5, and filtered directly into the sample cell in which the desired phenol had previously been captured from the Autoprep. This technique was employed when weighed samples were not required, as it effectively precluded the absorption of water. It has been observed here, as previously (23), that when small amounts of liquid phenols are weighed for dissolution, water pickup appears severe despite the employment of an acceptably dry solvent and an inert atmosphere. It must be concluded that the initial absorption of water by certain phenols, when dry, is extremely rapid.

The spectra were recorded directly in absorbance on a Beckman IR-7 prism-grating spectrophotometer at an effective resolution of 1.8 cm^{-1}. The absorbance potentiometer was calibrated by a set of linearity discs over the optical density (o.d.) range of 0.05 to 0.91, and found, after a zero adjustment, to be linear to within ±0.005 o.d. units. The temperature runs were obtained in 1 cm cells at phenol concentrations of approximately 5×10^{-3} *M*. The temperature of both sample and reference cells was controlled and measured by thermistors. The read-out thermistor was in contact with the solution inside the cell; we believe the temperature to be accurate to within 0.1 °C, described previously (23).

[1]*The cis and trans names apply to the two coplanar conformers in which the hydroxyl group is directed toward, and away from, respectively, the halide.*

2-Fluoro-6-bromophenol	3 578.6	3 524.9	28.5	20.0
2-Fluoro-6-iodophenol	3 578.7	3 501.9	32.0	25.1
2-Chloro-6-bromophenol	3 535.1	3 521.6	—	—
2-Chloro-6-iodophenol	3 532.9	3 494.8	19.1	—
2-Bromo-6-iodophenol	3 513.4	~3 490	—	—

The ν_{OH} band referred to as 1 is the band due to the O—H group oriented *trans* or, for the dihalophenols, toward the 2-position substituent. The half-band widths lined out could not be determined accurately because of inadequate band separation.

The spectra were obtained at temperatures ranging from 25 to 75 °C; in order to assure the necessary accuracy, a minimum of three repeat runs at the temperature extremes and two at intermediate points were taken. Band areas were measured repeatedly with a rolling disc planimeter until it was felt that the areas of these somewhat arbitrarily divided bands had been established to within 0.3%. The spectral data are given in Table II.

DISCUSSION

The energy of intramolecular halogen–hydroxyl interactions has always been considered to be less than that of intermolecular hydrogen bonds. Early attempts to evaluate this energy employed qualitative arguments (24), based either on measured free energies (2) and estimated entropies (25) or on relative peak heights of competitive halogens (13). The former arguments indicated that the bond strengths increased parallel to the increase in frequency shift in going from fluorine to iodine. This established the order I > Br > Cl > F. In contrast, the latter arguments (13), employing peak heights, indicated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

that the order was Cl > Br > F > I. The early direct measurements of enthalpies of halophenols in the vapor state (6, 26) tended to support the latter order although the quantitative results were questioned (26) because of impure samples. More recent quantitative work is in general agreement that iodine forms the weakest bond of any halogen, but there is yet uncertainty concerning the strengths of interactions to the remaining halogens. Regarding intermolecular effects, there is now apparent agreement that the order of decreasing strength is F > Cl > Br > I. All of these data are summarized in Table III.

TABLE III

Literature enthalpies of halogen–hydroxyl interaction

Molecular environment	Compound	Technique	Halide F	Cl	Br	I	Ref.
Vapor state	2-Chlorophenol	Infrared		3.9			6
	2-Iodophenol	Infrared				3.2	26
Intramolecular, liquid	2-Halophenols	Infrared		1.27	1.86	1.00	27
	2-Halophenols	Nuclear magnetic resonance		2.3	2.0	1.5	28
	2-Haloethanols	Infrared	2.1	1.2	1.2	0.8	17
Intermolecular, liquid	Phenol vs. aliphatic halides	Infrared	3.1	2.2	2.0	1.7	20
	Phenol vs. cyclohexyl halides	Infrared	2.6	2.4	1.8	2.0	19

Other techniques have also been used but, unfortunately, have added further disagreement over the relative order of the halogens. The nuclear magnetic resonance (n.m.r.) values quoted in Table III are larger than those obtained from infrared, but nonetheless, maintain the order most generally accepted for the three heavier halogens, namely, Cl > Br > I. However, no interaction at all involving fluorine could be detected and it was assumed to be zero. This assumption was modified in a subsequent paper wherein the authors inferred that there was indeed interaction, but weaker than that involving iodine. Qualitative arguments employing dipole moment measurements of these phenols have led to conflicting assignments for fluorine. One report (29) attributes to fluorine the strongest interaction of any halogen; another (14) places it between bromine and iodine as suggested in the work below. Finally a qualitative infrared investigation of competitive hydrogen bonding (16) concluded that fluorine does indeed enter into an interaction in 2-fluorophenol but that its energy of interaction is the smallest of any halogen.

Enthalpies of 2-Halophenols

The enthalpies reported in this study have been obtained from area measurements of the two competitive hydroxyl bands displayed by each halophenol. These bands are shown in Fig. 1 for the 2-halophenols and in Fig. 2 for the unsymmetrical 2,6-dihalophenols. Enthalpy values derived in this way are based upon the assumption that the ratio of the band absorptivity coefficients is temperature independent. This assumption is inherent in all of the infrared data quoted above. We have examined this premise in a previous publication (30) and have found that corrections amounting to several percent of the measured enthalpies must be applied to obtain more accurate values.

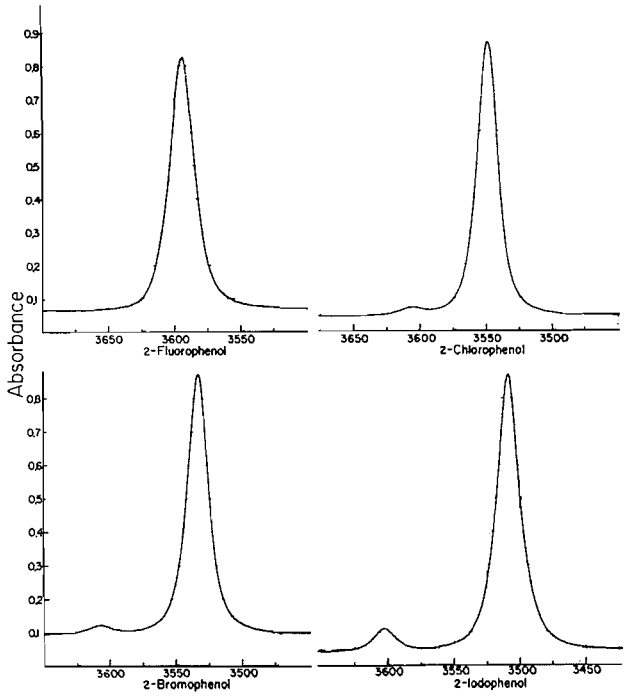

FIG. 1. ν_{OH} bands of the 2-halophenols. Solvent CCl_4.

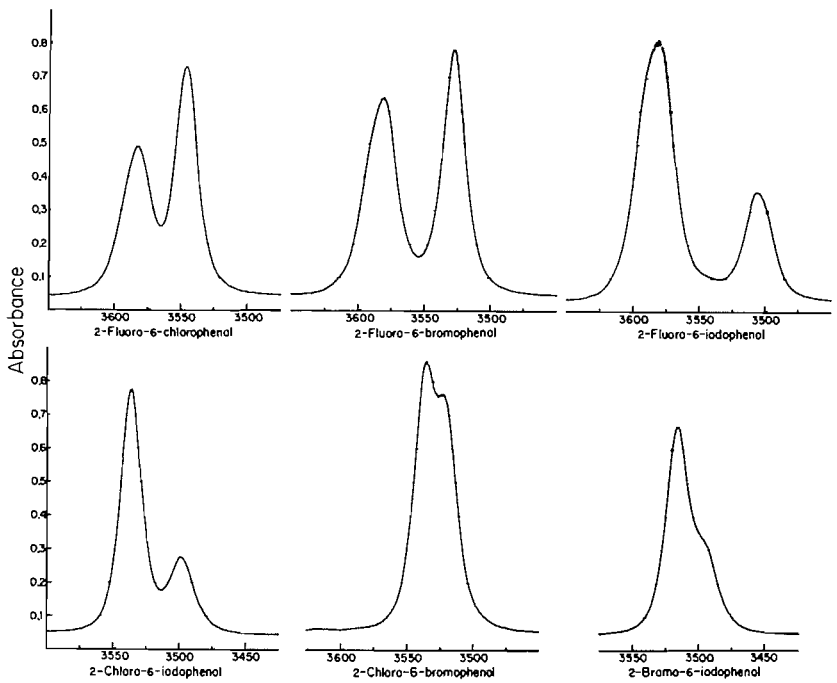

FIG. 2. ν_{OH} bands of the unsymmetrical 2,6-dihalophenols. Solvent CCl_4.

These corrections are obtained from the absorptivities of phenol and of symmetrical 2,6-dihalophenols measured at 25 and 75 °C. For these compounds, only a single O—H band exists; the temperature dependency of phenol should parallel that of the *trans*-component of the 2-halophenols and the temperature dependency of the dihalophenols that of the *cis*-component. This assumption appears to be reasonable and it is consistent with the behavior of the other band parameters such as the temperature shifts of frequencies and of half-band widths. The temperature corrections were calculated by the relationship

$$\Delta H_c = -4.571 \frac{\partial \log \frac{\alpha_1}{\alpha_2}}{\partial 1/T},$$

where α_1 and α_2 are the absorptivity coefficients of the two bands in each compound. As shown previously (30), this can be put into the form

$$\Delta H_c = -4.571 \left[\frac{\log \frac{\alpha_1^{25}}{\alpha_1^{75}} - \log \frac{\alpha_2^{25}}{\alpha_2^{75}}}{0.483 \times 10^{-3}} \right] \text{cal/mole}$$

for temperature limits of 25 and 75 °C. The ratios, α^{25}/α^{75} for phenol, dichloro-, dibromo-, and diiodo-phenols were found (30) to be 1.075, 1.056, 1.055, and 1.053, respectively. The value of this ratio for the fluoro group, measured here from 2,6-difluorophenol, is 1.066. Since the enthalpy for *o*-fluorophenol must be derived indirectly, this ratio can be utilized only in obtaining corrections for the enthalpy differences in the mixed fluoro–halophenols. The corrections for the other 2-halophenols are, in kcal/mole, −0.07, Cl; −0.08, Br; and −0.09, I. The addition of these corrections to the measured enthalpies of the 2-halophenols results in an increase of absolute magnitude in each case.

TABLE IV

Enthalpy values of halophenols, kcal/mole (solutions in carbon tetrachloride)

			Area			Peak height

A summary of these corrections, together with the measured and corrected enthalpies, is given in Table IV. Also listed are the corresponding values for the unsymmetrical di- and tri-halophenols. Results obtained by the use of optical densities are included for comparison. It can be seen that these values are much less consistent than those from band areas and that the corrections are so large as to have little meaning. This behavior indicates that temperature dependencies of optical densities cannot be transferred from one molecular system to another and that enthalpies based upon peak heights are not as reliable as those from band areas. Therefore, only the latter values will be considered in the following discussion. The enthalpies and ranking of the 2-halophenols that admit of direct measurement are, from Table IV, Cl (1.44) > Br (1.21) > I (1.08). A value can now be obtained for 2-fluorophenol by considering the following data from the mixed dihalophenols.

Unsymmetrical Di- and Tri-halophenols

All of the 2-halophenols except 2-fluorophenol have two well-resolved bands, thereby permitting enthalpies to be determined directly. However, due to the occurrence of only a single band in 2-fluorophenol, the enthalpy of interaction must be evaluated indirectly, i.e., by use of the unsymmetrical 2-fluoro-6-halophenols. The two bands in each of these three compounds are resolved adequately to permit the determination of relative band areas.

The bands were separated into the respective areas by arbitrary graphical techniques. Fortunately, as shown previously (31), the calculated enthalpy is virtually insensitive to the way the bands are separated (within reasonable limits) as long as any assumptions are applied consistently throughout a temperature run. Results corresponding to those discussed above for 2-halophenols are also listed in Table IV. Since the absorptivity temperature ratios are in the order F > Cl > Br > I, the pairing of the halogens acts to increase the enthalpy correction of the heavier with respect to the lighter. In the case of F ↔ Cl and F ↔ Br, the numerical value of the observed enthalpy difference is increased in each case because the interaction energy is larger for the heavier two halogens. However, in the remaining four comparisons (F ↔ I, Cl ↔ Br, Cl ↔ I, and Br ↔ I), the reverse occurs because the lighter atom dominates the interaction.

These relationships are diagrammed for clarity in Fig. 3 and are shown for both area and optical density measurements. The arrows point to the halogen forming the stronger

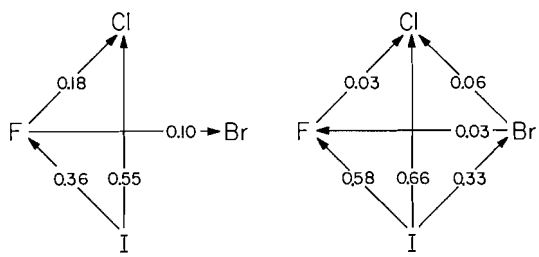

FIG. 3. Enthalpy differences, in kcal/mole, of the halogen–hydroxyl interaction as determined (A) from corrected area measurements, and (B) from uncorrected optical density values. Arrow points in direction of stronger association. Compounds examined

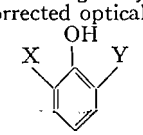

X, Y = F, Cl, B, I; X ≠ Y.

interaction (with the O—H group), and the enthalpy differences in kcal/mole are recorded on each arrow. The values missing from the diagram, for 2-bromo-6-iodophenol and for 2-bromo-6-chlorophenol, were not obtained due to inadequate band separation. This prevented accurate assignment of areas to the appropriate bands.

For the area diagram (Fig. 3) there is remarkable good internal agreement in the ΔH difference between chlorine and iodine by the two different routes. The direct value is 0.55 kcal/mole, and the value obtained by adding I → F and F → Cl is 0.54 kcal/mole. For the trihalophenols, the corresponding direct value is 0.56 kcal/mole. The two-step value is not available since the F → Cl compound was not run; however, the I → F value is 0.33 kcal/mole compared to 0.36 kcal/mole found for the dihalophenol. Due to the internal consistency of these results and to the reproducibility of the values obtained in duplicate runs, we believe the accuracy of these data to be better than ±0.05 kcal/mole.

Direct comparisons of energies obtained from the mixed dihalophenols give the following order for the decreasing enthalpy of the halogen–hydroxyl interaction: Cl > Br > F > I. Fluorine is definitely placed to the right of bromine by area measurements, although by only a small amount. It is placed to the left of bromine by use of peak height calculations, but not when the corrections are added. Such values that are obtained through the employment of peak heights become yet less reliable as the band separations become very small. Under these conditions, the temperature dependence of each band is diluted by the temperature dependence of the other, and as $\Delta\nu$ approaches zero, the enthalpy measured by peak heights will also approach zero. This effect is observed in the optical density diagram for the compounds 2-bromo-6-iodophenol and 2-bromo-6-chlorophenol, the two specific compounds not amenable to area measurement. The band separations are approximately 17 cm^{-1} and 14 cm^{-1}, respectively; in the former case, the band shows only an inflection point but no double maximum. The sum I → Br and Br → Cl is 0.39 kcal/mole, only two-thirds of the well-resolved I → Cl value of 0.66 kcal/mole.

From the excellent agreement in the enthalpy differences between the di- and trihalphenols, one must conclude that the presence of the additional halogen in the 4-position has no effect on these values. However, as correctly pointed out by the referee, there could conceivably be an appreciable difference in solvent effects for the 2-halo- and 2,6-dihalo-phenols. In the former compounds, the *trans*-conformer affords greater opportunity for solvent interaction, whereas in the latter compounds, the hydroxyl group in either conformer should be shielded from the solvent by approximately equal amounts. This could result in an internal inconsistency in transferring data between the mono- and di-substituted phenols. For this reason, the direct comparison of the interaction to fluorine and to bromine in 2-bromo-6-fluorophenol is given first preference. Thus, since this comparison shows that the ΔH to bromine is unequivocally larger than to fluorine, the enthalpy value for the fluorine–hydroxyl interaction is taken as 1.19 kcal/mole, slightly lower than that of O—H · · · Br.

Analogous Interactions in the 2-Haloethanols

Some intersting comparisons can be made between the data given here for the 2-halophenols and those recently published for the 2-haloethanols (17). Although these families are chemically dissimilar, the many spectral features they display in common strongly suggest that the actual physical interactions between the —OH and halo groups are qualitatively similar in both. Since band separations are small in these latter compounds, the use of peak heights for enthalpy evaluations was mandatory; therefore, it was necessary for the previous authors to accept the concomitant inaccuracies discussed above.

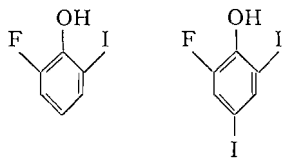
The enthalpies found (Table III) for the O—H · · · I and O—H · · · Br interactions were −0.8 and −1.2 kcal/mole, values surprisingly close to those given here for the 2-halophenols. The value for the O—H · · · Cl interaction was considered to be equal to, or slightly less than, that of the O—H · · · Br interaction. This is at variance with the increase found in the 2-halophenols and can readily be explained by the inherent decrease in measured ΔH as $\Delta\nu$ approaches zero. More disturbing is the placement of the O—H · · · F interaction as the largest of the four. This is based on the premise that the very unsymmetrical band shown by 2-fluoroethanol can be graphically resolved into two separate components and that the individual temperature dependency of each band can be determined. The procedure is, at best, questionable since many infrared bands are unsymmetric in compounds where only a single conformer can exist.

Compounds demonstrating this type of band dissymmetry are the unsymmetrical 2,6-dihalophenols. As discussed above, two ν_{OH} bands occur due to interactions with the two proximal halogens. Each band can be produced by only a single conformer; rotation around the C—O bond is restricted by at least 4 kcal/mole so that the O—H group is constrained to an in-plane residence. In the two compounds 2-fluoro-6-iodophenol and 2-fluoro-4,6-diiodophenol, the band due to the O—H · · · F interaction is grossly unsymmetric, as is readily observed for the former compound in Fig. 2. In order to assess the extent of this dissymmetry, two parameters are evaluated. These are defined as follows: the band is divided left and right by a vertical line drawn through the band maximum. The high-frequency part of the half-band width lying to the left of this line is divided by that to the right. This ratio is a measure of band dissymmetry and is unity for a symmetric band.

Values of this ratio found at 25 and 75° for the above two compounds are



25° 1.42	1.32
75° 1.12	1.37.

In the first compound, the symmetry of the band increases with temperature. In the second, however, the dissymmetry increases in a manner similar to that observed in the single band in 2-fluoroethanol, and from which an apparent ΔH had been calculated (17). Despite this difference in temperature behavior of band shape, the ΔH's (F ↔ I) measured in the two phenols are identical. This supports the obvious conclusions that the O—H · · · F bands in these phenols consist of only one conformer and that the dissymmetry is due to other factors. Calculated ΔH values predicated upon assumed symmetry must therefore be discounted.

ACKNOWLEDGMENT

We thank Dr. Finger of Illinois State Geological Survey for a generous sample of the 2,6-difluorophenol employed in this study.

THE REACTIVITY OF THE CYCLIC POLYENES TOWARDS FREE RADICALS

II. METATHESIS WITH THE ETHYL RADICAL

A. C. R. BROWN[1] AND D. G. L. JAMES

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received August 27, 1964

ABSTRACT

Arrhenius parameters have been measured for metathesis between the ethyl radical and certain cyclic polyenes, chosen to reveal the extent to which particular structural features in a cyclic molecule may influence its reactivity towards metathesis. The highest reactivity was observed in cyclohexadiene-1,4 and is associated with the greatest increase in the delocalization of the π-electron system, which is only slightly offset by a minor change in the conformation of the carbon ring. Intermediate reactivity was displayed by the conjugated molecules cyclohexadiene-1,3 and cycloheptatriene, whereas cyclooctatetraene, which possesses no methylenic hydrogen atoms, was much less reactive. Very low reactivity was found in bicyclo[2.2.1]heptadiene-2,5; this molecule possesses the carbon ring structure of cyclohexadiene-1,4 symmetrically bridged by a methylene group, and the constraint imposed by this bridge upon the geometry of the ring appears to limit the reactivity of the molecule decisively.

The ratio of the rate constants for disproportionation and combination between the cyclohexadienyl radical and the ethyl radical is $k_d/k_c = 0.38 \pm 0.03$. The nature of the interaction between these two radicals is discussed, and the significance of this ratio is considered.

INTRODUCTION

The kinetic study of metathesis between the ethyl radical and certain hydrocarbons of simple structure was discussed in an earlier paper (1). Arrhenius parameters were measured with sufficient precision to reveal significant differences in reactivity due to bond order (*n*-heptane, heptene-1, and heptyne-1). A comparison of corresponding rate constants for cyclohexene and for *trans*-octene-4 indicated that a cyclic structure may significantly increase the reactivity per active hydrogen atom.

This study has now been extended to include cyclic polyenes of various classes chosen to investigate effects peculiar to cyclic systems. Firstly the class: cyclohexadiene-1,3, cyclohexadiene-1,4, and cyclooctadiene-1,5, chosen to reveal any cumulative enhancement of reactivity due to two double bonds present in $\Delta^{1,3}$, $\Delta^{1,4}$, or $\Delta^{1,5}$ relationship in a cyclic molecule. Secondly the class: bicyclo[2.2.1]heptadiene-2,5 and cyclohexadiene-1,4, which should show the effect of geometrical constraint imposed by a methylene bridge upon the reactivity of a cyclic $\Delta^{1,4}$ system. Finally the diverse class: cycloheptatriene, cyclooctatetraene, and benzene, which were included to study reactivity in systems characterized by multiple conjugation, an absence of methylene groups, or aromaticity.

The rates of metathesis between the polyacrylonitrile radical and certain cyclic polyenes appear to be very sensitive to the detailed structure of the latter. Metathesis with cycloheptatriene is so rapid that this substance completely inhibits the free radical polymerization of acrylonitrile, whereas under equivalent conditions cyclohexadiene-1,3 forms high copolymer with acrylonitrile (2). The factors which determine the reactivity of a molecule towards metathesis with a radical have been discussed in recent review articles (3–8). Polar effects are potentially important in metathesis between the electrophilic polyacrylonitrile radical and the cyclic polyenes, but the wide variation in electrical nature of these polyenes (2) renders the corresponding rate constants an uncertain measure of their

[1]*Present address: Petrochemical and Polymer Laboratory, Imperial Chemical Industries Ltd., Runcorn, Cheshire, England.*

intrinsic reactivity. Polar effects are seldom large in the reactions of the ethyl radical, and so the results of this study should give a better measure of the intrinsic reactivity of the cyclic polyenes. The cyclohexadienyl radical is generated by metathesis between the ethyl radical and either of the cyclohexadienes, and so the interaction of the cyclohexadienyl and ethyl radicals can be conveniently studied. The particular interest of this system arises from the formation of benzene as a product of one of the disproportionation reactions, and therefore allows us to see to what extent the peculiar stability of this product may influence the ratio of disproportionation to combination.

EXPERIMENTAL PROCEDURE

The apparatus and general method were described in two earlier papers (1, 9). The techniques of purification of reactants and analysis of products were later improved by the use of the Beckman Megachrom preparative gas chromatograph and the Perkin–Elmer Vapour Fractometer model 154C respectively (10), and the application of gas chromatography has been extended in this study. The reagents were of the purest grade commonly obtainable commercially. Each was further purified by the preparative chromatograph and the purity of the selected fraction was then examined by the analytical chromatograph. The only evidence of residual impurities was found for cyclooctatetraene (0.2% styrene) and for the cyclohexadienes (0.1% benzene). Such a concentration of styrene in cyclooctatetraene would have a negligible effect upon the observed rates of addition or metathesis with the ethyl radical (11), but benzene is an important product of the interaction of the ethyl radical with the cyclohexadienes, and a small correction of the apparent rate of formation of benzene was necessary.

The analysis followed the pattern of separation and measurement of CO, C_2, and C_4 fractions, supplemented by analysis by gas chromatography (10). The CO fraction was pure and free from traces of hydrogen and methane. The C_2 fraction consisted entirely of C_2H_4 and C_2H_6, except for systems containing cyclooctatetraene, when C_2H_2 was also present. Each component of the C_2 fraction of every run was estimated, following the calibration of the instrument by standard mixtures. The C_4 fraction was pure butane.

Special Procedure for Cyclohexadiene-1,4

The photolysis of diethyl ketone in the presence of cyclohexadiene-1,4 gave benzene and a less volatile hydrocarbon, both in significant quantity. No cyclohexadiene-1,3 was found among the products of this system. After the removal of the CO, C_2, and C_4 fractions the residue was normally analyzed for benzene on the Perkin–Elmer 6-ft column R at 50 °C in a stream of helium. If a column temperature of 100° was used, and the benzene, cyclohexadiene-1,4, and diethyl ketone were allowed to pass through, then two further peaks were observed. One of these peaks was also found when the products of the photolysis of pure diethyl ketone were examined, but the other was observed only when cyclohexadiene-1,4 was also present in the reacting system. The substance of the latter peak was accumulated in a series of experiments, separated by the chromatograph, and trapped by passing the effluent gas at the appropriate time through a hypodermic needle into 5 ml of 100% ethanol. The ultraviolet absorption spectrum of the resulting solution was obtained with the Cary model 11 spectrophotometer. The spectrum was very closely similar to that of cyclohexadiene-1,3 but of course could not be this substance. We shall suggest in the discussion that the cyclohexadienyl radical is generated in this system, and that the absorption band is due to 1-ethylcyclohexadiene-2,4 from the combination of cyclohexadienyl and ethyl radicals. This combination should also form 1-ethylcyclohexadiene-2,5, but the column failed to separate the isomers. Benzene is also formed during the photolysis of diethyl ketone in the presence of cyclohexadiene-1,3, but cyclohexadiene-1,4 was not found among the products. The failure of each cyclohexadiene to isomerize to the other under the reaction conditions indicates that mutual interaction of cyclohexadienyl radicals is negligible in these systems.

THE KINETICS OF METATHESIS WITH THE ETHYL RADICAL

Under the experimental conditions of this investigation, the photolysis of diethyl ketone conforms to the simple mechanism (12–15):

[1] $$CH_3CH_2COCH_2CH_3 + h\nu \rightarrow 2CH_3CH_2\cdot + CO,$$

[2] $$2CH_3CH_2\cdot \rightarrow C_4H_{10},$$

[3] $$2CH_3CH_2\cdot \rightarrow C_2H_6 + C_2H_4,$$

[4] $$CH_3CH_2\cdot + CH_3CH_2COCH_2CH_3 \rightarrow CH_3CH_3 + CH_3\dot{C}HCOCH_2CH_3,$$

[5] $$CH_3CH_2\cdot + CH_3\dot{C}HCOCH_2CH_3 \rightarrow CH_3CH(CH_2CH_3)COCH_2CH_3.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

One molecule of carbon monoxide is equivalent to two ethyl radicals and hence to one molecule of either ethane or butane. If reactions [1–5] account for all the products, then

$$[I] \qquad M = [R(C_2H_6) + R(C_4H_{10})]/R(CO) = 1,$$

where $R(X)$ is the rate of formation of the product X in units molecules/cm^3 s. A new series of photolyses of pure gaseous diethyl ketone gave the result:

$$M = 1.005 \pm 0.005;$$

the values of $k_4/k_2^{1/2}$ calculated from the equation:

$$[II] \qquad k_4/k_2^{1/2} = [R(C_2H_6) - R(C_2H_4)]/[D]R(C_4H_{10})^{1/2},$$

where [D] is the concentration of diethyl ketone in molecules/cm^3, support the previous result (1):

$$k_4/k_2^{1/2} = 10^{(-7.5\pm0.1)} \exp(-7\,800 \pm 200)/RT \text{ (cm}^3\text{/molecule s)}^{1/2}.$$

These experiments also gave the result:

$$k_3/k_2 = R(C_2H_4)/R(C_4H_{10}) = 0.123 \pm 0.008$$

which, although somewhat lower than the previous value of 0.136 (1), is supported by the values obtained from the photolyses of diethyl ketone in the presence of cyclic polyenes (Table I).

The ethyl radicals formed by the photolysis of diethyl ketone may be expected to abstract hydrogen atoms from any hydrocarbon species present in the reacting system. Representing the cyclic polyene by RH_2, the initial metathetical reaction forms ethane:

$$[6] \qquad CH_3CH_2\cdot + RH_2 \rightarrow CH_3CH_3 + RH\cdot.$$

Mutual interaction of RH· radicals can be neglected in this study, as the light intensity was always high enough to ensure that the ethyl radical was present at a much higher concentration than the RH· radical. The RH· radical is therefore removed by interaction with the ethyl radical, and both combination and disproportionation must be considered:

$$[c] \qquad RH\cdot + \cdot CH_2CH_3 \rightarrow RHCH_2CH_3,$$

$$[d] \qquad \rightarrow R + CH_3CH_3,$$

$$[e] \qquad \rightarrow RH_2 + CH_2{:}CH_2.$$

The kinetics are particularly simple if we can neglect the disproportionation reactions [*d*] and [*e*], and if addition of the ethyl radical to the double bond of the polyene RH_2 is also negligible. Then the quantities k_3/k_2 and M should have the same values in the presence of the polyene as they have for the photolysis of pure diethyl ketone. This agreement is observed when RH_2 is cyclooctadiene-1,5. In this study the photolysis of pure diethyl ketone vapor was characterized by the values: $k_3/k_2 = 0.123 \pm 0.008$ and $M = 1.005 \pm 0.005$; when cyclooctadiene-1,5 vapor was also present the values were: $k_3/k_2 = 0.122 \pm 0.007$ and $M = 0.997 \pm 0.012$. Significant participation of reaction [*d*] would yield an excess of ethane and raise the value of M above unity; whereas reaction [*e*] would yield an excess of ethylene and raise the value of $R(C_2H_4)/R(C_4H_{10})$, which is assumed to measure k_3/k_2. Clearly both reaction [*d*] and reaction [*e*] can be neglected in the case of cyclooctadiene-1,5. Reaction [*d*] would yield the conjugated product cyclooctatriene-1,3,5, and therefore the suppression of this reaction in favor of the combination process [*c*] is perhaps rather surprising. It will be apparent later that the product R must

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

possess a very high delocalization energy in order that reaction [*d*] may compete significantly with reaction [*c*]; indeed in this investigation the only examples of such competition occurred with the cyclohexadienes, which yielded benzene by the sequence of reactions [6] and [*d*]. We can dismiss the possibility that the value of M for the cyclooctadiene-1,5 system is due to a fortuitous cancelling of opposed effects due to simultaneous participation of reaction [*d*] and addition of the ethyl radical to the double bond; this would cause M to vary with the temperature and the relative concentration of the reactants, and such variation is not observed. Moreover the reactivity of an isolated double bond in a cyclic hydrocarbon towards addition of the ethyl radical has been shown to be very low in the case of cyclohexene (9). We have assumed that reaction [*d*] may also be neglected both for cycloheptatriene and for cyclooctatetraene. In each case the nature of the product R renders the significant participation of reaction [*d*] far less probable than in the case of cyclooctadiene-1,5. The diagnostic use of the value of M is invalidated by the addition of the ethyl radical to both cycloheptatriene and cyclooctatetraene (9).

The ethylene-forming reaction [*e*] normally regenerates the original substrate RH_2 and can be detected only by observation of the ratio $R(C_2H_4)/R(C_4H_{10})$. The value of this ratio for pure diethyl ketone is 0.123 ± 0.008, and is not significantly altered in the presence of cyclic polyenes, as is apparent from Table I. Clearly reaction [*e*] is negligible for each of these cyclic polyenes, all the ethylene being formed by the disproportionation of ethyl radicals. We conclude that both reactions [*d*] and [*e*] can be neglected for each of the substrates, cyclooctadiene-1,5, cycloheptatriene, and cyclooctatetraene. The rate constant for reaction [6] is then given by the simple relationship (1):

$$\text{[III]} \qquad \frac{k_6}{k_2^{1/2}} = \frac{R(C_2H_6) - R(C_2H_4)}{[B]R(C_4H_{10})^{1/2}} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}},$$

where [D] and [B] represent the concentrations of diethyl ketone and the hydrocarbon respectively.

Benzene is formed during the illumination of a gaseous mixture of diethyl ketone with either of the cyclohexadienes, indicating the reaction sequence:

$$\text{[6]} \qquad CH_3CH_2\cdot + C_6H_8 \rightarrow CH_3CH_3 + C_6H_7\cdot,$$

$$\text{[}d\text{]} \qquad CH_3CH_2\cdot + C_6H_7\cdot \rightarrow CH_3CH_3 + C_6H_6.$$

Kinetic analysis shows that less than 30% of the cyclohexadienyl radicals react as [*d*], the remainder combining with ethyl radicals:

$$\text{[}c\text{]} \qquad CH_3CH_2\cdot + C_6H_7\cdot \rightarrow C_6H_7CH_2CH_3.$$

The adduct was detected by gas chromatography, but the column used failed to separate the adduct into the two isomers expected: 1-ethylcyclohexadiene-2,4 and 1-ethylcyclohexadiene-2,5. It was shown above that the values of $R(C_2H_4)/R(C_4H_{10})$ eliminate the significant participation of the ethylene-forming reaction:

$$\text{[}e\text{]} \qquad CH_3CH_2\cdot + C_6H_7\cdot \rightarrow CH_2{=}CH_2 + C_6H_8.$$

This was confirmed by a more sensitive test. Any cyclohexadiene formed by the disproportionation reaction [*e*] is almost certain to be a mixture of the two isomers. The same cyclohexadienyl radical is formed by abstraction of hydrogen from either cyclohexadiene-1,3 or cyclohexadiene-1,4, and it has been established (16) that the mutual disproportionation of cyclohexadienyl radicals gives cyclohexadiene-1,3 and cyclohexadiene-1,4 in the ratio of 1:2.7. Thus a reacting system that initially contained only one of the cyclohexadiene isomers would continuously form the other isomer if reaction [*e*] were appreciable,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and the detection of a trace of the second isomer in the presence of major amounts of the first is readily accomplished by gas chromatography. No such trace was found in either system, and we conclude that reaction [*e*] is negligible.

Each molecule of benzene formed in reaction [*d*] is accompanied by a molecule of ethane. Addition of the ethyl radical to either of the isolated double bonds of cyclohexadiene-1,4 is inappreciable, and so we expect, and find, that

$$M = [R(C_2H_6) + R(C_4H_{10})]/R(CO) > 1.$$

However, if ethane is formed solely by reactions [3], [4], [6], and [*d*], it follows that

$$M^* = [R(C_2H_6) + R(C_4H_{10}) - R(C_6H_6)]/R(CO) = 1, \qquad [IV]$$

and the observed value of M^* is 1.015 ± 0.021, independent of temperature, confirming the mechanism. The rate constant of reaction [6] for cyclohexadiene-1,4 is given by the appropriate modification of eq. [III]:

$$\frac{k_6}{k_2^{1/2}} = \frac{R(C_2H_6) - R(C_2H_4) - R(C_6H_6)}{[B]R(C_4H_{10})^{1/2}} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}}. \qquad [V]$$

The same equation may be used for cyclohexadiene-1,3, as the generation and consumption of the cyclohexadienyl radical is common to the two cyclohexadienes.

DISCUSSION

The results of this investigation are relevant to two aspects of chemical kinetics: the general problem of the relationship between reactivity and molecular structure, and the particular topic of the relative importance of combination and disproportionation in the reactions of the cyclohexadienyl radical. Each of these subjects will be discussed separately under an appropriate heading.

I. Structure and Reactivity

The principal aim of this section is to enquire whether the kinetic results reveal any general pattern of reactivity. The cyclic olefins fall naturally into three classes.

(1) The first class contains cyclic olefins which possess one or more reactive methylene groups. Reactivity in this class follows the order: cyclohexadiene-1,4 > cyclohexadiene-1,3 > cycloheptatriene > cyclooctadiene-1,5 > cyclohexene.

(2) The second class consists of cyclooctatetraene, which has no methylene groups, but shows moderate reactivity.

(3) In the third class are the unreactive polyenes: bicycloheptadiene and benzene.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The reactivity of a particular cyclic olefin may be strongly influenced by one or more of several factors.

(*a*) The extent of delocalization of the π-electron systems may differ in the molecule and in its derived radical, as in the sequence: cyclohexadiene-1,4 > cyclohexene > benzene.

(*b*) There may be a difference in strain energy in the molecule and its derived radical. Such strain may originate in the limitations imposed by the cyclic structure upon the conformation of the ring, and appears to govern the difference in reactivity: cyclohexadiene-1,4 $\gg$ bicyclo[2.2.1]heptadiene-2,5.

(*c*) Another factor may be the number and relative position of equivalent reactive hydrogen atoms.

Delocalization and Reactivity

The order of reactivity towards metathesis: cyclohexene < cycloheptatriene < cyclohexadiene-1,3 < cyclohexadiene-1,4, is shown by the Arrhenius plots of Figs. 1 and 2. We propose that the principal cause of this order of reactivity is that the gain in the delocalization energy attending metathesis increases in the same order. Certainly the most reactive olefin, cyclohexadiene-1,4, shows the greatest formal increase in delocalization in the change from the two isolated double bonds of the molecule to the π-electron system delocalized over five carbon atoms in the cyclohexadienyl radical. A much smaller change in delocalization attends the formation of the cyclohexenyl radical from cyclohexene, and the reactivity of cyclohexene is correspondingly low.

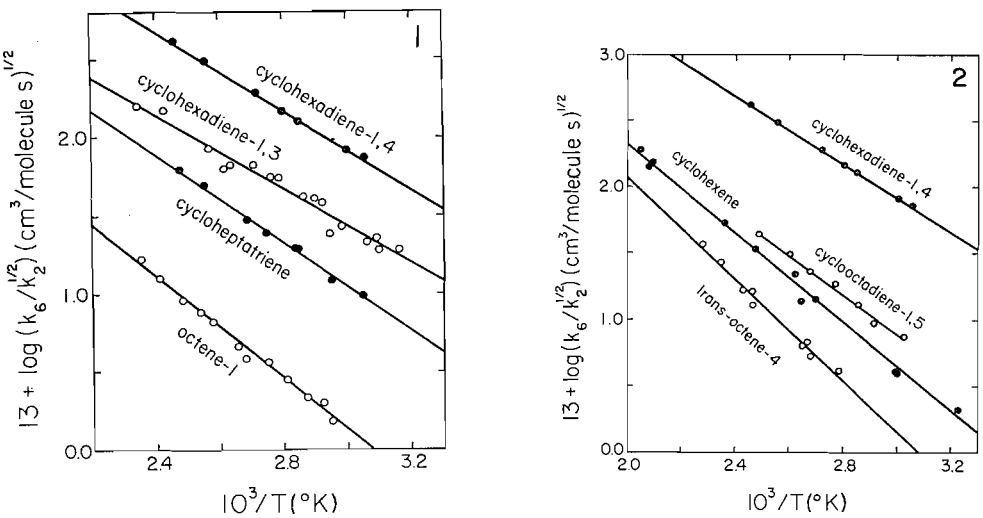

FIG. 1. Metathesis between the ethyl radical and cyclic polyenes, showing how the reactivity of the polyene may be influenced by the increase in the delocalization of the π-electron system attending metathesis. Octene-1 is included for reference.

FIG. 2. Metathesis between the ethyl radical and unconjugated cyclic olefins; *trans*-octene-4 is included for reference.

Cyclohexadiene-1,4 and cyclohexadiene-1,3 each yield the cyclohexadienyl radical as a product of metathesis, and thereby offer a special opportunity to test the proposition that the reactivity of such compounds is dominated by the increase in delocalization attending metathesis. Formally, the proposition is valid for this pair; the less reactive

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

polyene cyclohexadiene-1,3 suffers the smaller increase in delocalization from a four-carbon to a five-carbon system. However, this argument is inconclusive unless the change in the geometry of the carbon ring accompanying the formation of the cyclohexadienyl radical from the parent molecule is minimal, or at least equivalent, for each of the cyclohexadienes. Recent structural studies indicate that the change in geometry is indeed minimal, and are discussed below.

The electron spin resonance spectrum of the cyclohexadienyl radical shows that the six carbon atoms are coplanar and that the unpaired electron is delocalized over five carbon atoms (17). The pure rotational Raman spectrum of cyclohexadiene-1,4 vapor reveals that the molecule behaves as a very nearly symmetric top rotor; the small deviation of the carbon atoms from coplanarity is towards C_{2v} symmetry (18). The four carbon atoms of the conjugated system of cyclohexadiene-1,3 are probably coplanar; the other two carbon atoms may be expected to oscillate symmetrically through this plane in opposite phase.

We conclude that the geometry of the carbon ring of each of the cyclohexadienes departs only slightly from the planar form of the cyclohexadienyl ring, and therefore that the greater reactivity of cyclohexadiene-1,4 may properly be linked with the greater increase in the delocalization of the π-electron system attending metathesis.

Cycloheptatriene lies between cyclohexene and cyclohexadiene-1,3 in its reactivity towards metathesis. The reactivity of the hydrogen atoms of the methylene group of cycloheptatriene is associated with a change in delocalization from a slightly non-planar six-carbon system to a planar seven-carbon system. The pure rotational Raman spectrum of cycloheptatriene vapor shows that the molecule behaves as a nearly symmetric top rotor (18). The low-temperature proton magnetic resonance spectrum of cycloheptatriene in trifluorobromomethane reveals that the deviation of the ring from coplanarity is towards the boat form, and that cycloheptatriene is a mixture of two such rapidly equilibrating non-planar conformers (19). The geometry of the carbon ring of the cycloheptatriene molecule therefore departs only slightly from the planar, regular heptagonal structure of the tropyl radical. The structure of the tropyl radical has been deduced from the electron resonance spectrum of solid cycloheptatriene bombarded by electrons at -196 °C (20) and of a dilute solid solution of cycloheptatriene in a single crystal of naphthalene irradiated by X-rays at room temperature (21), and also from the ultraviolet absorption spectrum of the radical formed by the flash photolysis of ditropyl vapor at low pressure (22). The results indicate that the unpaired electron of the tropyl radical occupies a largely antibonding degenerate orbital and confers a uniform time-average spin distribution upon the radical (21). The tropyl radical therefore possesses an unusually high degree of symmetry, which may explain why cycloheptatriene is so much more reactive than cyclohexene, although metathesis extends delocalization over only one additional carbon atom in each case.

The molecule of benzene possesses a high delocalization energy associated with the six π-electron system delocalized over a planar, symmetrical six-carbon ring. A much smaller degree of delocalization is associated with the π-electron systems of either the phenyl radical (23) or the cyclohexadienyl radical (17); so that a considerable loss in delocalization energy will attend both the metathetical and the addition reactions of the ethyl radical with benzene. Benzene should therefore be much less reactive than cyclohexene towards the ethyl radical, and indeed neither metathesis nor addition could be detected for benzene in this study. The rate constant for metathesis was estimated as no more than 2% of the value for octene-1 between 100 and 120 °C, and ethyl benzene could not be

found among the products. A recent study of the interaction of toluene with the methyl radical at 60 °C is largely concerned with the reactivity of the aromatic ring (24). The products of addition of the methyl radical to the ring are easily found after reaction in the liquid phase, but cannot be detected after reaction in the gas phase. Metathesis with toluene is observed in the gas phase, and 15% of the hydrogen is abstracted from the aromatic ring. It was suggested that the transition state for interaction between the methyl group and the aromatic ring is a loose addition complex which may yield the products either of addition or of metathesis according to its environment. The reactivity of the aromatic ring towards the alkyl radicals seems to be marginal, and the reactivity of the methyl radical may well be only just sufficient to form the loose addition complex at a kinetically appreciable concentration in the gas phase; it is perhaps not surprising that the rather less reactive ethyl radical fails to perturb the stable aromatic system appreciably in the gas phase.

Ring Conformation and Reactivity

The high reactivity of cyclohexadiene-1,4 towards metathesis is associated with the $\Delta^{1,4}$ double bond distribution of its six-membered carbon ring. Bicyclo[2.2.1]heptadiene-2,5 possesses a similar structural unit in its molecule, but it is so unreactive towards metathesis that no reaction could be detected in our systems. The reactivities of cyclohexadiene-1,4 and bicycloheptadiene may be compared as follows. An estimate can be made, for each experiment performed, of the maximum value (U) that the abstraction rate constant could have while remaining undetectable. It was assumed that the rate of abstraction should be detectable if:

$$[VI] \qquad \frac{k_6}{k_2^{1/2}} > \frac{1}{10}\frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}} = U.$$

Each value of U was compared with the value (A) of $k_6/k_2^{1/2}$ for cyclohexadiene-1,4 at the same temperature, obtained from the observed results by interpolation. Table II shows that the ratio U/A may be as low as 0.003.

TABLE II

Comparison of the reactivity of bicycloheptadiene (C_7H_8) and cyclohexadiene-1,4 (C_6H_8) towards metathesis with the ethyl radical*

Temp. (°K)	U (C_7H_8)	A (C_6H_8)	U/A
323	0.20	63	0.0031
336	0.35	90	0.0039
341	0.61	102	0.0060
360	1.10	160	0.0069
366	1.39	183	0.0076
382	4.53	255	0.018
398	5.72	347	0.016
404	8.02	388	0.021

*The variables U and A represent respectively an estimated upper limit and an actual value of $k_6/k_2^{1/2}$ for the species named, in units $(cm^3/molecule\ s)^{1/2}$.

The low reactivity of bicycloheptadiene may be ascribed to restrictions imposed by the methylene bridge upon the geometry of the $C_7H_7^{\cdot}$ radical formed by the removal of a hydrogen atom from one of the bridgehead carbon atoms. Firstly, the six-carbon ring cannot become planar as in the cyclohexadienyl radical, and so the associated gain in delocalization is no longer available to facilitate metathesis. Secondly, the carbon atom

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

with the free valence cannot easily even approach coplanarity with the three other carbon atoms to which it is bonded, and therefore the bridgehead carbon–hydrogen bond should be much stronger than the normal tertiary carbon–hydrogen bond. Nuclear magnetic resonance studies have shown that this bridgehead bond has a much higher degree of s-character than is found in a normal sp^3 bond (25). All other hydrogen atoms of the bicycloheptadiene molecule are likely to show low reactivity towards metathesis, but the double bonds are reactive towards the addition of free radicals in general, and the ethyl radical in particular. The same series of experiments yielded both a satisfactory Arrhenius plot for the addition of the ethyl radical (26), and the evidence that bicycloheptadiene is unreactive towards metathesis, thereby affirming the validity of this evidence.

Cyclooctadiene-1,5 was chosen as a cyclic polyene likely to conform closely to the ideal of a strainless system of non-interacting double bonds which are unreactive towards the addition of the ethyl radical. The last assumption is confirmed by the value $M = 0.997 \pm 0.012$, and the values of M and $R(C_2H_4)/R(C_4H_{10})$ indicate that reactions [6] and [*c*] are the only significant reactions of the cyclooctadiene-1,5 system. Figure 2 shows the Arrhenius plots for abstraction of a hydrogen atom from cyclooctadiene-1,5 and certain structurally related molecules. These were chosen as likely to reveal, by comparison with cyclooctadiene-1,5, any effects upon the reactivity of the molecule which might be endued by:

(*a*) an unstrained ring structure (*trans*-octene-4),
(*b*) a strained ring structure (cyclohexene),
(*c*) cumulative interaction of double bonds in a $\Delta^{1,4}$ system (cyclohexadiene-1,4).

Results for abstraction of a hydrogen atom from *trans*-octene-4 and from cyclohexene have been published previously (1), and were calculated from the equation:

$$[\text{VII}] \qquad \frac{k_6}{k_2^{1/2}} = \left(\frac{R(C_2H_6) + R(C_2H_4)}{R(C_4H_{10})} - \frac{2k_3}{k_2}\right)\frac{R(C_4H_{10})^{1/2}}{[B]} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}},$$

using $k_3/k_2 = 0.136$ throughout. In the present study we have reinvestigated the reactions of the ethyl radical with octene-1, and have obtained a value of k_3/k_2 for each run from the ratio $R(C_2H_4)/R(C_4H_{10})$, measured by gas chromatographic analysis. The original results have been confirmed in general, and in particular the new value of k_3/k_2 is 0.137 ± 0.010; but a slight systematic change in the values of $k_6/k_2^{1/2}$ leads to small changes in A_6 and E_6 giving the values listed in Table I. Accordingly we have retained 0.136 for the calculation of $k_6/k_2^{1/2}$ for the closely related olefin *trans*-octene-4. However, inspection of Table I reveals that the value $k_3/k_2 = 0.12$ is appropriate to systems containing cyclic olefins, and of these cyclooctadiene-1,5 seems to be most closely related to cyclohexene. Accordingly we have used the value of 0.122 uniformly for k_3/k_2 in eq. [VII] for the recalculation of the results obtained earlier with cyclohexene; this change has little effect upon the individual values of the rate constants, but reduces the energy of activation slightly to $E_6 - \frac{1}{2}E_2 = 7.5 \pm 0.4$ kcal/mole.

Inspection of Table I shows that the precision of the values of the Arrhenius parameters is insufficient to reveal systematically the separate effects of ring structure and ring strain upon the reactivity of cyclooctadiene-1,5, cyclohexene, and *trans*-octene-4, although Fig. 2 reveals an enhanced reactivity for the cyclic olefins. On the other hand, the very high reactivity of cyclohexadiene-1,4 is apparent both from Table I and from Fig. 2; this is associated with the large increase in delocalization that attends the formation of the

For personal use only.

cyclohexadienyl radical from the molecule of cyclohexadiene-1,4, and is discussed elsewhere in this paper.

The Equivalence of Hydrogen Atoms in Metathesis

If n denotes the number of equivalent reactive α-methylenic hydrogen atoms present in each molecule, then the values of $13 + \log (A_7/A_2^{1/2}n)$ are: cycloheptatriene, 5.0 ± 0.3; cyclohexene, 5.0 ± 0.2; cyclohexadiene-1,4, 5.1 ± 0.1; cyclohexadiene-1,3, 4.4 ± 0.2; and cyclooctadiene-1,5, 4.4 ± 0.4. There is no characteristic value for this quantity if the cyclic olefins are regarded as members of a single set. However, the set seems to divide naturally into two subsets: those with isolated activated methylene groups (cycloheptatriene, cyclohexene, and cyclohexadiene-1,4) having a characteristic value of 5.0, and those with two adjacent activated methylene groups (cyclohexadiene-1,3 and cyclooctadiene-1,5) having a characteristic value of 4.4. The higher value is associated with the subset of molecules which offer the more favorable steric conditions for metathesis. In the other subset we might expect mutual crowding of the four hydrogen atoms in the two adjacent activated methylene groups to create less favorable steric conditions and thereby to depress the value of $13 + \log (A_7/A_2^{1/2}n)$. However, the average values of the pre-exponential factor per reactive hydrogen atom for the two subsets stand in the ratio 4:1, which is far too great to be explained by mutual crowding. Delocalization and ring strain are more likely sources of reactivity differences of this order, and indeed delocalization appears to govern the difference in reactivity of the cyclohexadienes. Further experiments are being carried out to determine whether the harmony observed within the subsets is fortuitous or part of a general pattern of reactivity.

Cyclooctatetraene

Cyclooctatetraene is the only hydrocarbon of this study to be decomposed directly by the 3 130 Å light used to generate the ethyl radicals from diethyl ketone. The direct photolysis of cyclooctatetraene vapor by 2 537 Å light has been reported to yield equimolar amounts of acetylene and benzene with a quantum yield of 0.10 for a pressure of 6 mm cyclooctatetraene (27). These products were also obtained in equimolar ratio in this study with 3 130 Å light. As cyclooctatetraene absorbs fairly strongly at 3 130 Å, with $\log \epsilon = 2.4$ (27), it was not practicable to reduce its concentration to a level at which direct photolysis would be negligible, and indeed the ratio $R(C_2H_2)/R(CO)$ varied between the limits 0.025 and 0.095. The kinetic analysis of this system is based upon the assumption that the direct photolysis proceeds independently of the other reactions of cyclooctatetraene.

The kinetic evidence indicates that the ethyl radical undergoes both metathetical and addition reactions with cyclooctatetraene. In our kinetic analysis we have assumed that the only significant reactions involving cyclooctatetraene are:

[6] $$CH_3CH_2^{\cdot} + C_8H_8 \rightarrow CH_3CH_3 + C_8H_7^{\cdot},$$

[c] $$CH_3CH_2^{\cdot} + C_8H_7^{\cdot} \rightarrow C_{10}H_{12},$$

[7] $$CH_3CH_2^{\cdot} + C_8H_8 \rightarrow C_{10}H_{13}^{\cdot},$$

[7c] $$CH_3CH_2^{\cdot} + C_{10}H_{13}^{\cdot} \rightarrow C_{12}H_{18},$$

[8] $$C_8H_8 + h\nu \rightarrow C_6H_6 + C_2H_2.$$

Partial support for this simple scheme is provided by the ratio $R(C_2H_4)/R(C_4H_{10}) = 0.123 \pm 0.006$ which is typical for the photolysis of diethyl ketone in the presence of a cyclic polyene (Table I). Further support was provided by the self-consistency of the results obtained. Thirteen experiments were performed, and each experiment yielded a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

result for both the rate of metathesis and the rate of addition. Rate constants for metathesis were calculated from eq. [III] and those for addition (9) from the equation:

$$[\text{VIII}] \qquad \frac{k_7}{k_2^{1/2}} = \frac{R(\text{CO}) - [R(\text{C}_2\text{H}_6) + R(\text{C}_4\text{H}_{10})]}{[\text{B}]R(\text{C}_4\text{H}_{10})^{1/2}}.$$

The Arrhenius plots for addition and metathesis are given in Fig. 3. Addition occurs

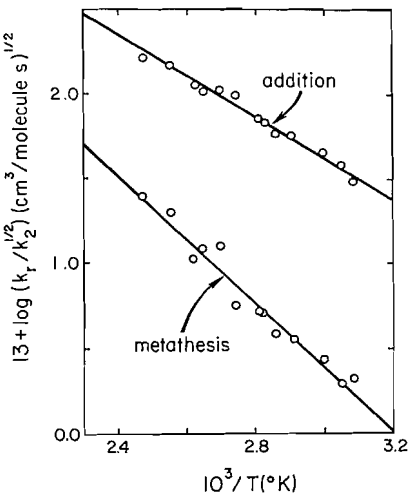

FIG. 3. Reactions of the ethyl radical with cyclooctatetraene; metathesis, $k_r = k_6$, $E_6 - \frac{1}{2}E_2 = 8.6 \pm 1.2$ kcal/mole; addition, $k_r = k_7$, $E_7 - \frac{1}{2}E_2 = 5.6 \pm 0.6$ kcal/mole.

much more rapidly by virtue of a much lower energy of activation; thus $E_7 - \frac{1}{2}E_2 = 5.6 \pm 0.6$ kcal/mole, which is significantly lower than $E_6 - \frac{1}{2}E_2 = 8.6 \pm 1.2$ kcal/mole. The latter value is the highest found for a metathetical reaction in this study, but cyclooctatetraene is the only molecule to give evidence of metathesis and yet to possess no methylene group. We should consider whether the independent sequences of reactions: [6], [*c*] and [7], [7*c*] ought to be replaced by the competitive scheme:

$$[7] \qquad \text{CH}_3\text{CH}_2\cdot + \text{C}_8\text{H}_8 \rightarrow \text{C}_{10}\text{H}_{13}\cdot,$$

$$[7c] \qquad \text{CH}_3\text{CH}_2\cdot + \text{C}_{10}\text{H}_{13}\cdot \rightarrow \text{C}_{12}\text{H}_{18},$$

$$[7d] \qquad \text{CH}_3\text{CH}_2\cdot + \text{C}_{10}\text{H}_{13}\cdot \rightarrow \text{CH}_3\text{CH}_3 + \text{C}_{10}\text{H}_{12},$$

where reaction [7*d*] gives the additional ethane originally attributed to reaction [6] and also forms the partially conjugated 1-ethylcyclooctatetraene-1,3,5,7. This alternative scheme is paralleled by a mechanism which has been proposed to explain the formation of CF_3H by the interaction of trifluoromethyl radicals with benzene (28, 29, 30):

$$[7'] \qquad \text{CF}_3\cdot + \text{C}_6\text{H}_6 \rightarrow \text{CF}_3\text{C}_6\text{H}_6\cdot,$$

$$[7d'] \qquad \text{CF}_3\cdot + \text{CF}_3\text{C}_6\text{H}_6\cdot \rightarrow \text{CF}_3\text{H} + \text{CF}_3\text{C}_6\text{H}_5.$$

However, reaction [7*d*'] is much more strongly favored energetically than reaction [7*d*], since the resonance energy of a benzene system is about five times as great as for a cyclooctatetraene system (31).

The strongest evidence against the alternative scheme rests upon the reasonable assumption that the energy of activation for the disproportionation reaction [7*d*] is unlikely to be appreciably larger than for the combination reaction [7*c*], and therefore the apparent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

difference $E_6 - E_7$ should lie near zero. The observed value $E_6 - E_7 = 3.0 \pm 1.8$ kcal/mole indicates clearly that most of the additional ethane must be formed by a route other than the sequence of [7] and [7*d*].

We conclude that reactions [6] and [7] are independent. The value of $13 + \log (A_6/A_2^{1/2}) = 6.0 \pm 0.7$ is the highest observed in this study, but no other molecule possesses the steric advantages of having eight equivalent reactive hydrogen atoms singly bonded to the carbon atoms of the ring.

Finally, the internal self-consistency of the results indicates that they do reflect the reactivity of the ground electronic state of cyclooctatetraene rather than that of the metastable triplet state, which has been suggested as the precursor of the decomposition products (32). The observed rate constants for addition and metathesis are not abnormal for the ground state configuration, so that the contribution of the ground state to the observed reactivity can scarcely be negligible. The energies of activation appropriate to the triplet and ground states would be quite different, so that the Arrhenius plots for an effectively composite reaction would show curvature. The observed linearity indicates that the corresponding parameters represent the reactivity of the ground state of cyclooctatetraene.

II. The Cyclohexadienyl Radical

The generation and consumption of the cyclohexadienyl radical in the cyclohexadiene-1,4 system is adequately described by the mechanism:

[6] $$CH_3CH_2^{\cdot} + C_6H_8 \rightarrow CH_3CH_3 + C_6H_7,$$

[*c*] $$CH_3CH_2^{\cdot} + C_6H_7^{\cdot} \rightarrow C_8H_{12},$$

[*d*] $$CH_3CH_2^{\cdot} + C_6H_7^{\cdot} \rightarrow CH_3CH_3 + C_6H_6.$$

In this system ethane is formed only in reactions [3], [4], [6], and [*d*], and so the rate of reaction [6] is given by:

[IX] $$R_6 = R(C_2H_6) - R(C_2H_4) - R(C_6H_6) - k_4[D]R(C_4H_{10})^{1/2}/k_2^{1/2}.$$

Measurement of the ratio k_d/k_c is therefore possible, and yielded the result:

[X] $$k_d/k_c = R(C_6H_6)/[R_6 - R(C_6H_6)] = 0.38 \pm 0.03,$$

independent of temperature in the range 50 to 120 °C. Adopting the symbol Δ for the ratio of the rate constant for disproportionation to that for combination, we can express the results of this study in the form:

[XI] $$\Delta(C_6H_7^{\cdot} + {}^{\cdot}CH_2CH_3) = 0.38 \pm 0.03$$

[XII] $$\Delta(CH_3CH_2^{\cdot} + {}^{\cdot}CH_2CH_3) = 0.123 \pm 0.008.$$

A meaningful comparison of these values is possible only if the mechanism of the disproportionation and combination reactions is understood. Bradley (33) and Kerr and Trotman-Dickenson (7) have suggested that the paths of these two reactions pass through a common transition state. Thus two ethyl radicals will interact to form a highly activated molecule of butane, and this molecule is the common activated complex for both combination and disproportionation. Considerable bending of the carbon–carbon bond will occur and will lead to the type of interaction suggested in Fig. 4*a*, which represents the activated complex in terms of a four center model. Disproportionation can arise from the transfer of the newly-bonded hydrogen atom and the simultaneous cleavage of the central carbon–carbon bond, whereas combination results from the deactivation of the entire

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

complex. As each hydrogen atom in the two methyl groups is equivalent, it follows that the number of hydrogen atoms available for disproportionation is given by $n_d = 6$, whereas the number of modes of association leading to combination is $n_c = 1$. The significant quotient for the interaction of two ethyl radicals is $(n_c\Delta/n_d) = 0.020 \pm 0.001$. The validity of the theory of a common activated complex has been discussed recently by Dixon, Stefani, and Szwarc in the light of new experimental evidence (34). We shall discuss how this treatment may be applied to the interaction of the cyclohexadienyl radical with the ethyl radical.

The structure of the cyclohexadienyl radical has been inferred from the electron spin resonance spectrum of liquid (17) and solid (35) cyclohexadiene-1,4 during irradiation with 2.8 MeV electrons. The six carbon atoms are coplanar; the electron spin density at the methylene group is close to zero, and at the other positions is given by: ortho, 0.35; meta, −0.10; para, 0.50. Clearly, the ortho and para positions are the only sites in the cyclohexadienyl radical at which the initial interaction with the ethyl radical is probable, and the configuration of the corresponding activated complexes are represented in Figs. 4*b* and 4*c*. As the reaction

[*e*] $$C_6H_7\cdot + \cdot CH_2CH_3 \rightarrow C_6H_8 + CH_2{=}CH_2$$

has been shown to be negligible, only the two methylene hydrogen atoms of the cyclohexadienyl radical may be transferred during disproportionation. From Fig. 4*b* we assign $n_d^o = 4$ and $n_c^o = 2$ since the two ortho positions are equivalent; but from Fig. 4*c* it appears that the appropriate carbon–hydrogen distance is so great that $n_d^p = 0$, and clearly $n_c^p = 1$. The actual mechanism of interaction is probably related to the separate configurations of Figs. 4*b* and 4*c*, but the problem of superposition remains. The two extreme models for the overall interaction would represent the three configurations as either independent or indistinguishable. In the former case the ethyl radical would become specifically associated with one of the three sites in the cyclohexadienyl radical at an early stage; the activated complex would be quite strongly bonded and resemble the resultants rather than the reactants. If each configuration were to contribute independently and with equal weight, summation would give the effective values: $n_d = 4$, $n_c = 3$, and $(n_c\Delta/n_d) = 0.29 \pm 0.02$.

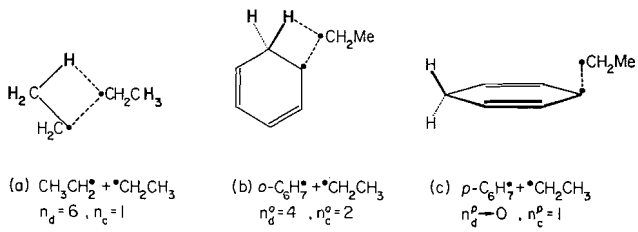

FIG. 4. Models for the transition state for disproportionation and combination of the cyclohexadienyl and ethyl radicals.

On the other hand, the three separate configurations of the activated complex may be kinetically indistinguishable, possibly by the operation of the uncertainty principle (36). The ethyl radical may become associated with the cyclohexadienyl radical as a whole, without causing much perturbation of its electronic structure; such an activated complex would be rather loosely bonded and resemble the reactants fairly closely. The assignment of an effective value to n_c is more difficult in this case; it may well be 3, but clearly cannot

be less than 1. Accordingly the minimum possible value of $(n_c\Delta/n_d)$ is 0.19 ± 0.02, with $n_c = 1$ and $n_d = 2$.

The behavior of the system may lie between these extreme models; however, this minimum value is substantially greater than the corresponding value of 0.020 ± 0.001 for the interaction of two ethyl radicals. The marked tendency of the cyclohexadienyl radical towards disproportionation presumably arises from the large delocalization energy of the product, benzene.

FAST REARRANGEMENT OF *exo*-NORBORNANOL IN STRONG ACID SOLUTIONS

GIDEON FRAENKEL, PHILLIP D. RALPH,[1] AND JOHN P. KIM
Evans Chemical Laboratory, The Ohio State University, Columbus, Ohio
Received September 23, 1964

ABSTRACT

Nuclear magnetic resonance spectra have been obtained at several temperatures for solutions of 2-*exo*-norbornanol in strong acids. The spectra change with temperature reversibly. It is concluded that the 2-*exo*-norbornanol undergoes very rapid rearrangement, the fast steps being 2,6 and 3,2 hydride shifts, respectively.

INTRODUCTION

There is a vast literature which concerns carbonium ion rearrangements of bicyclic compounds (1–3). Of the many systems studied none has been the subject of such intensive investigation as the reactions of 2-substituted norbornanes. These detailed kinetic (4) and isotopic (5) studies of solvolysis and deamination reactions reveal the operation of 3,2 and 6,2 hydride shifts, respectively, and Wagner–Meerwein rearrangements and imply the intermediacy of several different carbonium ions. Hitherto these rearrangements have been observed in irreversible systems. In this work it will be shown by the methods of nuclear magnetic resonance (n.m.r.) spectroscopy that 2-*exo*-norbornanol is stable in strong acid solutions and at the same time undergoes fast skeletal rearrangements.

RESULTS AND DISCUSSION

The n.m.r. spectrum of 2-*exo*-norbornanol in methylene chloride is shown in Fig. 1. The absorptions at 6.19 tau and 7.87 tau arise from C*H*OH and the bridgehead hydrogens respectively. The remaining hydrogens on C_3, C_5, C_6, and C_7 give the multiplets in the region of 8.8 tau; the line for OH appears at 8.21 tau. The same spectrum is obtained using dimethyl sulfate and methanol as solvents with the exception that the chemical shift of the OH proton changes with solvents due to differences in hydrogen bonding. The chemical shifts of the solvent protons are as listed in the literature (6). In all these solutions the n.m.r. absorption for the OH hydrogen consisted of a single line. Thus O—H exchange was too fast to permit observation of C_2H, OH coupling. However, using trifluoroacetic acid as solvent, the line for C_2H appears at 5.40 tau and the rest of the spectrum (Fig. 2A) has a slightly different appearance from those obtained with the other solvents. Furthermore, due to fast proton exchange, the OH resonances in the acid and alcohol are merged. Since 2-*exo*-norbornanol was quantitatively recovered from trifluoroacetic solution, these changes must be due to a specific solvent effect.

When 2-*exo*-norbornanol is dissolved in 97% sulfuric acid or mixtures of trifluoroacetic acid and sulfuric acid the peak due to C*H*OH disappears and the remaining spectrum consists of two broad lines at 7.8 tau and 8.8 tau (Fig. 2E). The starting material was quantitatively recovered from these solutions also. Hence the effects found here do not arise from unusual chemical reactions. On heating the solutions of 2-*exo*-norbornanol in H_2SO_4–CF_3CO_2H between 0 and 60° the resonance due to C*H*OH broadens and disappears

[1]*Present address: Chemistry Department, Imperial College of Science and Technology, London, S.W.1, England.*

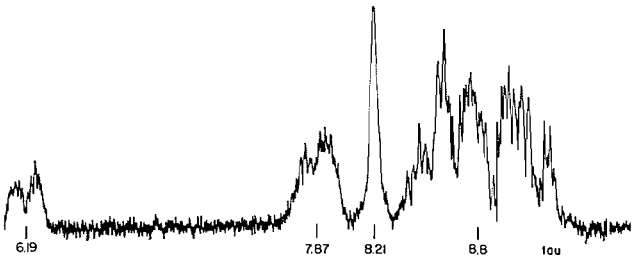

FIG. 1. Nuclear magnetic resonance spectrum, 60 Mc, 35°, of 2-*exo*-norbornanol 5% in CH_2Cl_2.

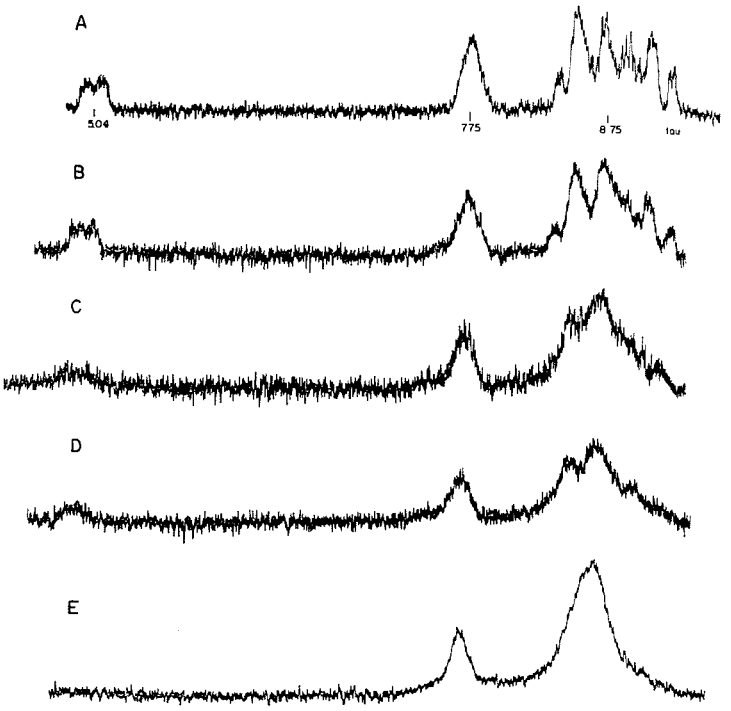

FIG. 2. Nuclear magnetic resonance spectra of 2-*exo*-norbornanol 5% in mixtures of H_2SO_4–CF_3CO_2H, 35°: (A) pure CF_3CO_2H; (B) 15% H_2SO_4; (C) 20% H_2SO_4; (D) 30% H_2SO_4; (E) 60% H_2SO_4. Acid concentrations are in volume %.

whilst the multiplets at 7.8 tau and 8.8 tau coalesce to single lines (Fig. 3), the effect being reversible with temperature. The same results were obtained at 40° with increasing sulfuric acid concentration (Fig. 2). The similarity of the low temperature spectra of the acid solutions to the spectrum of 2-*exo*-norbornanol in trifluoroacetic acid together with the quantitative recovery of the norbornanol from all these solutions strongly implies that the alcohol was the predominant species in solution. Furthermore, it is unlikely that norbornene was involved in these systems since similar experiments with norbornene yielded only tars.

These results do not originate from solvent effects or unusual chemical transformations. However, the disappearance of the peak at 5.04 tau together with the coalescence of the two multiplets at 7.8 tau and 8.8 tau to broad lines observed in these n.m.r. spectra of

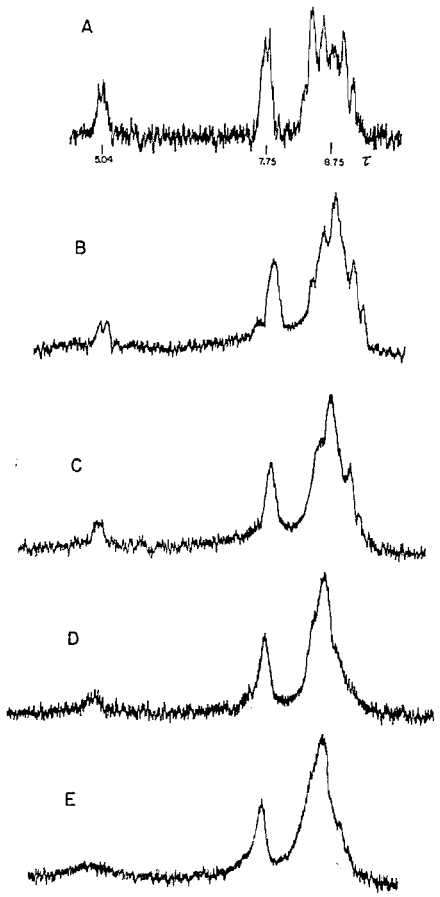

FIG. 3. Nuclear magnetic resonance spectra of 2-*exo*-norbornanol 5% in H_2SO_4–CF_3CO_2H at different temperatures: (A) 100% CF_3CO_2H, 35°; (B) 40% H_2SO_4, 0°; (C) 40% H_2SO_4, 10°; (D) 40% H_2SO_4, 30°; (E) 40% H_2SO_4, 40°.

acidified 2-*exo*-norbornanol solutions is most satisfactorily accounted for by fast hydrogen exchanges between magnetically non-equivalent sites (7).* Such processes occur in the well-known carbonium ion rearrangements which 2-*exo* derivatives of norbornane undergo, see steps [1], [2], and [3] below.

Fast skeletal rearrangement would have the effect of averaging several chemical shifts and coupling constants, the details depending on the nature of the fast steps in the reaction. At the higher acidities and temperatures employed in this work, the ratio of the integrals of the two peaks at 7.8 tau and 8.8 tau was 2/9. From the positions of these peaks and the way the line shapes changed with acidity at different temperatures, it is evident that the peak at 7.8 tau corresponds to both bridgehead hydrogens whilst that at 8.8 represents all the remaining *hydrogens* including C_2H.

It is now worthwhile to attempt to identify the fast rearrangement steps responsible for changing the n.m.r. spectrum of norbornanol in strong acid solution. If only one step were responsible for fast rearrangement, [1], [2], or [3], the final chemical shift of C_2H

**Solutions of 2-exo-norbornanol in 100% H_2SO_4 allowed to stand several hours yield derivatives of cyclohexene (8).*

should lie in the region 4.5 to 7.0 tau and thus be resolvable from the other structure. Average shifts, δH_2 at the limit of fast rearrangement for different steps are:

step [1] $$\delta_{H_2} = \frac{\delta_{H_1}^{0} + \delta_{H_2}^{0}}{2}$$

step [2] $$\delta_{H_2} = \frac{\delta_{H_2}^{0} + \delta_{H_3 exo}^{0} + \delta_{H_3 endo}^{0}}{3}$$

step [3] $$\delta_{H_2} = \frac{\delta_{H_2}^{0} + \delta_{H_6 exo}^{0} + \delta_{H_6 endo}^{0}}{3}.$$

Zero superscripts indicate chemical shifts of hydrogens at slow exchange. However, the final shift of H_2 lies in the region 8.8 tau. Thus the shift of H_2 must be averaged with those of more than 3 other hydrogens, and more than one fast step is involved in the rearrangement. The fact that the n.m.r. absorption due to the bridgehead hydrogens in 2-*exo*-norbornanol changes relatively little as the rate of rearrangement increases strongly suggests that the bridgehead hydrogens are not *rapidly* undergoing exchange with other positions and implies that the Wagner–Meerwein shift is not one of the fast steps.

The operation of steps [2] and [3], a Namenkin rearrangement and a 6,2 hydride shift respectively would cause averaging of the chemical shifts of the hydrogens on C_2, C_3, C_5, and C_6. The resultant averaged shift would not be expected to differ greatly from that for the hydrogens on C_7, the peak at 8.8 tau would correspond to 9 hydrogens, that at 7.8 tau to 2. Such a mechanism qualitatively accounts for the results reported here.* It is not possible to describe the order in which these rearrangements occur or to determine the rates themselves. To do so would require a complete analysis of the n.m.r. spectrum of 2-*exo*-norbornanol.

In view of the results from previous work (2) it is surprising that the Wagner–Meerwein rearrangement in the present system is so much slower than the 3,2 and 6,2 hydride shifts. However, among all the rearrangements reported for derivatives of 2-*exo*-norbornanol only the present example represents a system in equilibrium. Schleyer and Olah (9) have found that the norbornyl cation in SbF_5 gives rise to resolvable absorption which integrates 1:4:6 at low temperatures and a single broad line at higher temperatures. Under

The absence of net chemical change in the system precludes the detection of intermolecular hydride exchange steps.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

these conditions the Wagner–Meerwein and 6,2 hydride shift are fast throughout whilst changes in the n.m.r. spectra with temperature must be ascribed to different rates of the 3,2 hydride shift. That the relative rates of these rearrangement steps in the present work and other researches cited above should be so different can only be ascribed to the effects of solvents.

EXPERIMENTAL

Nuclear Magnetic Resonance Spectra

All spectra were determined with the Varian A60 NMR spectrometer equipped with a variable temperature probe. The resolution of the instrument always exceeded 0.15 c.p.s.

Chemicals

The 2-*exo*-norbornanol was kindly supplied by Professor Paul G. Gassman of this department. The material was sublimed immediately before use. The trifluoroacetic acid came from Eastman Kodak and sulfuric acid 100% was prepared by mixing the appropriate amounts of Dupont 97% sulfuric acid with stabilized sulfur trioxide from Baker and Adams.

Isolation of Norbornanol from Acid Solutions

The acid solution of norbornanol was slowly added by means of a Teflon syringe to aqueous sodium bicarbonate at 0°. The mixture was extracted with ether, the ether layer dried with magnesium sulfate, and the solvent removed. Norbornanol was identified by its n.m.r. spectrum.

ACKNOWLEDGMENTS

This work was supported by the National Institutes of Health and the Petroleum Research Fund of the American Chemical Society.

Received October 26, 1964

ABSTRACT

The *Bocconia latisepala* Wats., has been chemically studied. Each part was extracted separately with petroleum ether and with ethanol. The extracts were crystallized and purified by chromatographic methods. Cerylic alcohol was isolated from petroleum ether extracts of the bark, stems, and leaves. The bark and stems, leaves, roots, and seeds afforded the alkaloids chelerythrine, sanguinarine, protopine, α-allocryptopine, and oxysanguinarine, identified by their physical and chemical properties.

The *Bocconia* genera of the alkaloid-rich Papaveraceae family contains nine species most of which are native to Mexico. They were used by the Indians as dyes and, of more interest, in a variety of medicinal preparations (1, 2).[1]

Armendariz (3) and later Manske (4, 5) in chemical studies on *B. arborea* reported the presence of chelerythrine (3–6), sanguinarine (3, 6), protopine (3, 4, 6), and allocryptopine (4) as well as other unidentified substances. Studies of *B. cordata* Wild (formerly *Macleya cordata*) (7, 8, 9), *B. frutescens* L. (10), and *B. parcei* Hecht (11) have also been reported. No chemical studies of *B. latisepala* Wats., a common medicinal plant of northeastern Mexico, have been made so it was selected for study. Pulverized samples of the roots, bark and stems, leaves, and seeds were each extracted with petroleum ether and then ethanol. The course of the extraction and later fractionations were followed by thin-layer chromatography (t.l.c.) (12).

The petroleum ether extracts of the bark and stems and the leaves afforded a precipitate shown to be cerylic alcohol. The filtrate from the extract of the bark and stems on alumina chromatography afforded more cerylic alcohol, chelerythrine (yellow, m.p. 205° decomp.), and sanguinarine (orange, m.p. 255–258° decomp.) identified by their infrared spectra, pseudocyanides, and t.l.c. R_f values. A white compound, m.p. 360–363°, was not further investigated since it gave negative results in the usual alkaloid tests. In addition to these two alkaloids, the alcoholic extract of the leaves and the roots afforded oxysanguinarine, protopine, and α-allocryptopine.

The petroleum ether extract of the seeds afforded a reddish, fluorescent oil (33.5%) shown upon saponification to contain principally stearic and palmitic acids and smaller amounts of oleic and lauric acids. From the non-saponifiable fraction was isolated a small amount of chelerythrine and sanguinarine. Thin-layer chromatography indicated that α-allocryptopine and oxysanguinarine were also present.

EXPERIMENTAL

Melting points (uncorr.) were determined on a Kofler hot stage. Ultraviolet spectra were determined on a Beckman DU spectrophotometer and infrared spectra on a Beckman IR-5 spectrophotometer or a Perkin–Elmer Infracord. Micronalyses were by Dr. A. Bernhardt, Mülheim/Ruhr, Germany. Identification methods and reactions were those of Cheronis (13), Feigl (14), and Cromwell (15).

[1]*These plants known locally as "llora sangre" (weeping blood), "tlacoxihuitl" "palo del diablo" (devil's stick), and "cocoxihuitl" were used by early Indians as healing agents (1). Hernández (2) mentioned that the stems were used to dissipate films and ulcers of the eyes. The "juices", fruits, and crushed leaves were applied as cataplasms to heal old wounds and dissolve warts.*

Plant Materials

Samples of *Bocconia latisepala* Wats. (16) were collected in Chipinque, Nuevo León, México at an altitude of 1 500 meters in July 1960, November 1961, and August 1963.

Thin-Layer Chromatography

Glass plates (20 × 20 × 0.3 cm) were used to support films of silica gel G (Merck) or aluminium oxide G coated with a DESAGA applicator. Plates were developed with *n*-butanol – acetic acid – water (75:15:10 v/v).

Extraction of Bark and Stems

General Procedure

The powdered, dry bark and stems of *B. latisepala* (800 g) were extracted first with petroleum ether (b.p. 30–60°) and then with ethanol. The marc was discarded. After t.l.c. examination, each extract was concentrated at 40–50° under reduced pressure to 250 ml, a quarter of its original volume. After cooling, any precipitate present was collected and the filtrate evaporated to dryness and worked up separately.

Petroleum Ether Extract

On concentration of the petroleum ether extract 2.5 g (0.31%) of a greenish precipitate *ITP* (m.p. 72–76°) was obtained. Crystallization from petroleum ether raised the m.p. to 79–80°. Evaporation of the filtrate (five fluorescent spots on t.l.c.) afforded 0.99 g (0.12%) of a greenish, resinous material. This was dissolved in 20 ml of petroleum ether, placed on chromatographic column of 80 g of neutral alumina (Merck), and eluted with solvents of increasing polarity. Fractions with similar t.l.c. characteristics were combined for attempts to separate their components. From fractions 1–12 an orange precipitate, principally of chelerythrine and sanguinarine (t.l.c.), was obtained. From fractions 13–20, there was obtained 140 mg of a white precipitate (*ITC*), m.p. 79–80°, later identified as cerylic alcohol. The second crop, a brown precipitate (32 mg) on fractional crystallization from cyclohexane gave 8 mg of yellowish needles (*2TC*, m.p. 205–207°, decomp.) and a second crop of 20 mg of orange crystals (*3TC*, m.p. 255–258°, decomp.). On treatment with acids *2TC* acquired a golden-yellow color and *3TC* an orange–red color. They were subsequently identified as chelerythrine and sanguinarine. From fractions 21–25, the same yellow and orange precipitates (58 mg) were obtained. A white precipitate (10 mg, *4TC* m.p. 330–333°) was isolated from fractions 26–31. It was subsequently identified as oxysanguinarine by its color reactions and R_f value on t.l.c.

ITP, on crystallization from chloroform or methanol (Norite), afforded white crystals, m.p. 79–80°. The infrared spectrum exhibited bands at 2.83 μ (OH), 3.45 μ (C—H), and 6.85 μ (CH_2). *ITP* was optical inactive (chloroform or methanol), contained one C-methyl group (Kuhn-Roth), no double bands (tetranitromethane), and one active hydrogen (Zerewitinoff). The reduction test with chromic acid was positive and the molecular weight (Rast, in camphor) was 346 (calcd. 382). *ITP* was identified as cerylic alcohol.

Anal. Calcd. for $C_{26}H_{54}O$: C, 81.60; H, 14.2; O, 4.18. Found: C, 81.49; H, 13.91; O, 4.01.

ITP, when treated with acetyl chloride in pyridine and worked up in the usual way, afforded an acetyl derivative, m.p. 64–65° (lit. (17) 65°), infrared 5.77 and 8.05 μ.

Anal. Calcd. for $C_{28}H_{56}O_2$: C, 79.18; H, 13.29; O, 7.53. Found: C, 79.12; H, 13.36; O, 7.65.

Similarly *ITP* afforded a benzoate when treated with benzoyl chloride in the presence of petroleum ether and sodium hydroxide. Crystallization from petroleum ether afforded white crystals, m.p. 47–49°. The infrared spectrum indicated absence of hydroxyl groups and the presence of an ester function (5.80 μ and 7.92 μ).

Anal. Calcd. for $C_{33}H_{58}O_2$: C, 71.42; H, 12.01. Found: C, 81.36; H, 11.95.

Compound *2TC*, m.p. 205–207°, gave a yellow color with acids or with potassium persulfate. The ultraviolet spectrum of *2TC* in ethanol (violet solution) shows absorption with λ_{max} (log ϵ) = 255 mμ (4.6), 298 (4.68). Its infrared spectrum (KBr) shows λ_{max} = 3.30, 3.35, 6.25, 6.40, 6.60, 6.90, 7.10, 7.50, 7.90, 8.30, 9.40, 9.65, and 10.60 μ.

Anal. Calcd. for $C_{21}H_{19}NO_5$: C, 69.03; H, 5.24; N, 3.83. Found: C, 69.12; H, 5.28; N, 3.71.

A mixed melting point with an authentic sample of chelerythrine was undepressed. The R_f of *2TC* and chelerythrine on t.l.c. were similar as were their fluorescence under ultraviolet light and their behavior with modified Dragendorff's reagent.

Compound *3TC*, m.p. 255–258°, exhibits ultraviolet absorption in ethanol at λ_{max} (log ϵ) = 259 (4.34), 312 (4.61), and 338 (4.18). Its infrared spectrum (KBr) shows bands at λ_{max} = 3.32, 6.15, 6.20, 6.44, 6.75, 8.45, 9.30, and 9.42 μ.

Anal. Calcd. for $C_{20}H_{15}NO_5$: C, 68.76; H, 4.33; N, 4.01. Found: C, 68.75; H, 4.25; N, 4.15.

A mixed melting point with sanguinarine was undepressed. The R_f of *3TC* and sanguinarine were identical as was their behavior under ultraviolet light and with modified Dragendorff's reagent.

Compound *4TC*, was identified by a mixed melting point with oxysanguinarine and by comparison of their R_f's on t.l.c.

The concentrated petroleum ether extract of 759 g of dried leaves afforded 5 g (0.66%) of impure cerylic alcohol. The greenish filtrate (negative tests for alkaloids) was discarded. The marc from the leaves yielded an ethanol extract which gave a positive alkaloid test. On concentration to a quarter of its volume, a precipitate (*11-HP-1*, 10.0 g, 1.33%) was obtained which gave a strong positive test for alkaloids. The filtrate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(positive test for alkaloids) was evaporated to dryness and the residue (*11-HR*, 8.32 g, 1.1%) was dissolved in chloroform and chromatographed on 400 g of alumina. The fractions containing the two components with the lowest R_f values on t.l.c. (*2HC* and *3HC*), were combined for separation by the pseudocyanide procedure (4, 18, 19, 20). Fractional crystallization from acetone gave 40 mg of white crystals (*A*), m.p. 256–257° (reported (4, 20) for the pseudocyanide of chelerythrine, m.p. 258°), which was not changed after three recrystallizations from acetone. Concentration of the filtrate gave 70 mg of white crystals (*B*) m.p. 234–236° (reported (4, 18) for the pseudocyanide of sanguinarine, m.p. 237–238°). On hydrolysis of *A* with diluted hydrochloric acid, the hydrochloride of chelerythrine, m.p. 256–258° (reported (6) 254–256°, yellow needles), was obtained. Thin-layer chromatography showed only one component which had the same R_f value as a simultaneously run sample of the authentic alkaloid. (*B*) was recrystallized twice from acetone, to give a product, m.p. 225–226°, identical with that reported (20) for sanguinarine pseudocyanide. On hydrolysis with dilute hydrochloric acid, sanguinarine hydrochloride was obtained as dark-red crystals, m.p. 204–206° (reported (17) 203–205°). Thin-layer chromatography showed only one orange spot having the same R_f value as an authentic specimen of sanguinarine. A methanol solution of 100 mg of a mixture of *2HC* and *3HC* was chromatographed on 60 g of silica gel. On development with chloroform there was observed an upper red band and a lower yellow band which after elution with chloroform was shown to be chelerythrine. Ethyl acetate eluted the red band (sanguinarine). Thin-layer chromatography of each fraction showed a single spot and comparison with authentic samples of the alkaloids established their identity.

The precipitate (*11-HP-1*) showed four fluorescent spots on t.l.c. It was dissolved in chloroform and chromatographed on 300 g of alumina. Fractions 6–12 afforded two different alkaloids, 65 mg of white crystals (*11-HP-2*), m.p. 160°, subsequently identified as α-allocryptopine and 459 mg of a tan precipitate (*11-HP-3*), m.p. 330°, later identified as oxysanguinarine. From fractions 13–34, after fractional crystallization, compounds *11-P-4*, m.p. 75–78° (identified as impure cerylic alcohol), *11-HP-5*, m.p. 155–159°, and *11-HP-6*, m.p. 171–174°, weighing 184 mg, compound *11-HP-7*, m.p. 206–207°, were obtained. Compound *11-HP-7* was identified as protopine, on the basis of t.l.c. and mixed melting point determination. Compounds *11-HP-5* and *11-HP-6* did not give positive alkaloid tests and so it was not further examined.

Compound *11-HP-2* (α-allocryptopine), m.p. 160°, showed a single violet spot on t.l.c. when observed under ultraviolet light. The color of the spot slowly changed to yellow on standing. *11-HP-2* in ethanol exhibit λ_{max} mμ (log ε) 236 (4.2) and 288 (3.6). The infrared spectrum (KBr) showed bands max. = 3.0, 3.5, 5.83, 6.25, 6.8, 7.9, and 9.7 μ.

Anal. Calcd. for $C_{21}H_{23}O_5N$: C, 68.24; H, 6.28; O, 21.66; N, 3.79. Found: C, 68.48; H, 5.95; O, 21.90; N, 3.77.

Compound *11-HP-3* (oxysanguinarine), m.p. 330°, gave a salmon or brownish spot on t.l.c. when observed under ultraviolet light. Its ultraviolet spectrum in ethanol exhibited λ_{max} mμ (log ε) = 256 (4.33) 286 (3.82), 310 (4.0), and 330 (3.8). Its infrared spectrum exhibited bands λ_{max}^{KBr} at 2.96, 3.45, 6.05, 6.75, 7.6, and 7.9 μ.

Anal. Calcd. for $C_{20}H_{13}O_5N$: C, 69.16; H, 3.77; O, 23.03; N, 4.03. Found: C, 70.57; H, 3.54; O, 23.23; N, 3.66.

The dried, powdered roots (500 g) were extracted and worked up by the general isolation procedure. The reddish petroleum ether solution left, on evaporation, 5.5 g (1.1%) of a reddish residue (*IRP*). A 5 g sample of *IRB* was chromatographed on alumina; from the eluates 150 mg of chelerythrine was obtained, besides two other non-alkaloidal fractions, *IRB* (brownish-red precipitate), m.p. 140–145°, and *IRC* (light-brown precipitate) m.p. 165–175°. They were not further investigated.

From the ethanolic extracts of the roots 40 g (8%) of a dark resin (*11-RR*) was obtained. This residue gave positive alkaloid tests. A chloroform solution of the residue was chromatographed on alumina and from the eluate; α-allocryptopine, chelerythrine, sanguinarine, protopine, and oxysanguinarine were isolated and identified.

Petroleum Ether Extract of the Seeds

From 906 g of ground, dried seeds a reddish ethereal extract was obtained. It gave weakly positive alkaloid tests. Evaporation to a quarter of its volume gave 0.85 g of a reddish, greasy precipitate (0.94%). On evaporation of the filtrate there remained 305 g (33.5%) of a reddish fluorescent oil, specific gravity, 0.935 at 31°; $n_D^{37°}$ 1.4326; iodine index 69.02; saponification index 176. A t.l.c. of a sample of the oil showed the presence of chelerythrine and sanguinarine. The oil was saponified and by chromatography of the liberated fatty acids, principally stearic and palmitic acids were isolated with smaller amounts of oleic and lauric acids.

The marc was extracted, first with acetone and then with ethanol. Both extracts were chromatographed on alumina yielding sanguinarine, chelerythrine, and oxysanguinarine.

ACKNOWLEDGMENTS

This research was made possible by a grant (GM 11332-01) from the U.S. Public Health Service, National Institutes of Health. We thank Dr. R. H. Manske, Dominion Rubber Company Ltd. (Canada) and Dr. J. Slavick, Prague, Czechoslovakia, who furnished several reference alkaloids.

A SIMPLIFIED PROCEDURE FOR THE ANALYSIS OF COMPLEX NUCLEAR MAGNETIC RESONANCE SPECTRA

II. THE ANALYSIS OF SYMMETRICAL TRIFLUOROBENZENE, THE AA'A''XX'X'' SYSTEM[1]

R. G. JONES,[2] R. C. HIRST,[3] AND H. J. BERNSTEIN
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received October 8, 1964

ABSTRACT

The analysis of the six spin AA'A''XX'X'' system consisting of two sets of three chemically equivalent nuclei with spin $\frac{1}{2}$ and four coupling constants J_{AA}, J_{XX}, J_{AX}, and J_{AX}' has been developed with the use of group theory and the appropriate Hamiltonian. It is found that there will be differences in the A and X spectra if $J_{AX} \neq J_{AX}'$ and simultaneously $J_{AA} \neq J_{XX}$. If $J_{AA} = J_{HH}$ the A and X spectra become identical. If $J_{AX} = J_{AX}'$ each spectrum of course becomes trivial.

The complex n.m.r. spectrum of the AA'A''XX'X'' can be decomposed into subspectra, and the analysis of the nuclear magnetic resonance spectra of symmetrical trifluorobenzene has been carried out in this manner. The experimental proton and fluorine spectra of this molecule exhibit marked differences. Calculated spectra have been fitted to the experimental spectra and the following values of the coupling constants have been found:

$|J_{HH}| = 2.30 \pm 0.03$ c.p.s., $\quad |J_{FF}| = 5.83 \pm 0.03$ c.p.s.,
$|J_{HF}| = 8.96 \pm 0.03$ c.p.s., $\quad |J_{HF'}| = 1.68 \pm 0.03$ c.p.s.

The sign of J_{HH} is the same as the sign of J_{FF}. J_{HF} and J_{HF}' have opposite signs. It is not possible to relate the signs of J_{HH} and J_{FF} to the signs of J_{HF} and J_{HF}' in this type of spectrum. However, comparison of the signs of couplings in related molecules suggest that J_{HF}, J_{HH}, and J_{FF} have the same sign.

INTRODUCTION

The high-resolution n.m.r. spectrum of the A_2X_2 system with four distinct coupling constants, i.e., AA'XX', has been studied and a number of experimental spectra of this type have been analyzed (1–4). This problem presents no difficulties in the construction of the basic symmetry wave functions and the matrix elements of the Hamiltonian can be derived without much labor.

The next higher homologue in the A_nX_n series is the AA'A''XX'X'' system, symmetrical trifluorobenzene for example, consisting of two sets of three chemically equivalent nuclei with spin $\frac{1}{2}$ and having four distinct coupling constants J_{AA}, J_{XX}, J_{AX}, and J_{AX}' as in the AA'XX' system. By analogy with the AA'XX' system we might expect the AA'A'' and XX'X'' parts of the spectrum to be identical, but it will be shown that this is not so in general.

Wilson (5) illustrated the group theoretical procedures for utilizing molecular symmetry in setting up the equations for calculating the n.m.r. spectra resulting from spin–spin coupling in such molecules. The basic symmetry wave functions and the corresponding matrix elements of the Hamiltonian, essential to the analysis of the spectrum of symmetrical trifluorobenzene, were derived (5). The emphasis was, however, placed on the formulation of the problem rather than the detailed analysis.

It is intended in this paper that the emphasis shall be on the analysis of spectra of AA'A''XX'X'' systems in general and the symmetrical trifluorobenzene problem in

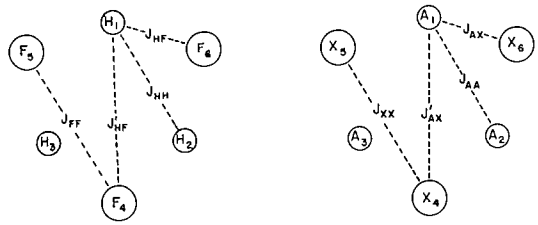
particular. The systematic simplifications that arise from direct application of the procedures outlined by Diehl, Jones, and Bernstein (6) (hereafter referred to as Part I) or from inspection of the tables of matrix elements, will be used as an aid in the interpretation of the spectra.

The AA′A″XX′X″ system with a fixed configuration can belong to one of the two symmetry classifications denoted by D_{3h} and C_{3v}. The geometry of the C_{3v} point group is either two staggered or two eclipsed equilateral triangles of different size and out of plane. The point group D_{3h} corresponds to two staggered equilateral triangles in a plane (e.g. symmetrical trifluorobenzene). All configurations with either D_{3h} or C_{3v} symmetry can be treated, however, under the C_{3v} classification. For symmetrical trifluorobenzene one may also use D_3 symmetry. The four coupling constants which arise in symmetrical trifluorobenzene are indicated below where A = ^{1}H and X = ^{19}F.



All of the 64 basic symmetry wave functions are presented here, together with the corresponding diagonal elements of the Hamiltonian and the off-diagonal elements between functions which mix.

THE METHOD OF ANALYSIS OF THE AA′A″XX′X″ SYSTEM

The procedures outlined in Part I will be used to sort out, where possible, the transition patterns of the A and X nuclear species of the AA′A″XX′X″ system. Information concerning coupling between the groups AA′A″ and XX′X″ will first be derived from examination of the subspectra corresponding to the maximum values of $|F_z(\mathrm{AA'A''})|$ and $|F_z(\mathrm{XX'X''})|$. Then any other simple patterns which can be recognized will be investigated in detail.

THE BASIC SYMMETRY WAVE FUNCTION DIAGRAM AND THE ENERGY LEVEL DIAGRAM FOR THE AA′A″XX′X″ SYSTEM

The eight basic symmetry wave functions of three equivalent nuclei are well known (2). The 64 molecular basic symmetry functions of the AA′A″XX′X″ system can be constructed from the 64 product wave functions obtained by taking the product of each of the AA′A″ functions with the eight XX′X″ functions, in turn, as indicated by Wilson (5).

However, following the procedure of Part I, it is not necessary at this stage to write out the 64 molecular symmetry wave functions in their entirety. It is of more importance to know at this stage the relevant quantum numbers characterizing the wave functions, i.e., $F_z(\mathrm{AA'A''})$ and $F_z(\mathrm{XX'X''})$, and the molecular symmetry species to which they belong. It has been shown (5) that there are 20 molecular wave functions belonging to the A_1 symmetry species. Sixteen are formed from ($A_1 \times A_1$) type products and four from ($E \times E$) products. There are four ($E \times E$) type wave functions belonging to the A_2 symmetry species. The 20 degenerate pairs of wave functions belonging to the E symmetry species are made up from eight ($A_1 \times E$) type, eight ($E \times A_1$) type and four ($E \times E$) type

product functions. The basic group symmetry wave functions and the molecular product functions are given in Table I. In this table $\underline{F_z(\mathrm{AA'A''})}$ is used to represent the eight basic symmetry wave functions of the three A nuclei, for example, $\underline{F_z(\tfrac{1}{2})}$ in the A_1 symmetry species represents $(\alpha\alpha\beta + \alpha\beta\alpha + \beta\alpha\alpha)/3^{-1/2}$ (and similarly for the X nuclei). The molecular product functions formed from products, $\underline{F_z(\mathrm{AA'A''})} \times \underline{F_z(\mathrm{XX'X''})}$, are represented by $\underline{F_z(\mathrm{AA'A''}),F_z(\mathrm{XX'X''})}$.

It should be noted here that, since for the purpose of deriving an energy level diagram we require only the overall symmetry of the wave functions and not intimate details of their construction, we need consider only one wave function of each of the degenerate pairs of (AA'A'') and (XX'X'') wave functions.

The procedure as set out in Part I then allows us to write down an energy level diagram picking out the A nuclear species and X nuclear species transitions from Table I. The energy level diagram is schematically represented in Fig. 1.

It is apparent from Fig. 1 that the energy levels for $F_z(\mathrm{XX'X''}) = \frac{3}{2}$ in the A_1 symmetry species together with the levels for $F_z(\mathrm{XX'X''}) = \frac{3}{4}$ in the E symmetry species constitute an energy level diagram similar to that for three, isolated, equivalent nuclei (2). The same can be said for the energy levels corresponding to $F_z(\mathrm{XX'X''}) = -\frac{3}{2}$. These diagrams give rise to subspectra which we denote a_3. In the AA'A'' part of the spectrum these a_3 subspectra appear as two intense lines, symmetrically spaced about ν_H and separated by the sum of coupling constants $2J_{AX} + J_{AX}'$ (see Part I). Each line has one eighth of the total AA'A'' intensity. The XX'X'' spectrum has equivalent features arising from two x_3 subspectra.

In Fig. 1 the $F_z(\mathrm{XX'X''}) = +\frac{1}{2}$ pattern in the A_1 and A_2 symmetry species is identical with that for an AB_2 system. This is true also for the corresponding $F_z(\mathrm{XX'X''}) = -\frac{1}{2}$ pattern. The corresponding subspectra will each have one eighth of the intensity of the relevant part of the spectrum (AA'A'' or XX'X''). They are designated as ab_2 in the AA'A'' part and xy_2 in the XX'X'' part.

Each of the $F_z(\mathrm{XX'X''}) = \pm\frac{1}{2}$ patterns (one for $+\frac{1}{2}$ and one for $-\frac{1}{2}$) of the E symmetry species (Fig. 1) is identical with the energy level diagram characteristic of an ABC system. and its spectrum is denoted by *abc*. The energy levels within the E symmetry species are doubly degenerate and hence the intensity of each transition between E symmetry species energy levels must be counted twice. As a result each of the *abc* subspectra will acount for a quarter of the intensity of either the AA'A'' or XX'X'' spectrum.

We expect therefore to be able to identify in the AA'A'' part of the spectrum of AA'A''XX'X'', subspectra of the types a_3, ab_2, and *abc*, and in the XX'X'' part, subspectra of the types x_3, xy_2, and *xyz*. Therefore, the solution to the six spin AA'A''XX'X'' system has been reduced in complexity to a problem involving the solution of three spin systems with spectra of the types a_3, ab_2, and *abc*.

The remarks made so far apply equally well to both the AA'A'' and XX'X'' parts of the AA'A''XX'X'' system and therefore as yet there is no indication that the spectra of the two parts will be different.

BASIC SYMMETRY WAVE FUNCTIONS, ENERGY LEVELS, TRANSITION ENERGIES, AND INTENSITIES FOR THE AA'A''XX'X'' SYSTEM

The AA'A''XX'X'' problem is, in general, characterized by four spin coupling constants J_{AA}, J_{XX}, J_{AX}, and J_{AX}' and two parameters H_A and H_X which represent the magetic fields at the two types of nuclei. It will be convenient to define new quantities,

[a]The degeneracy of the molecular wave functions in the E species is not shown.

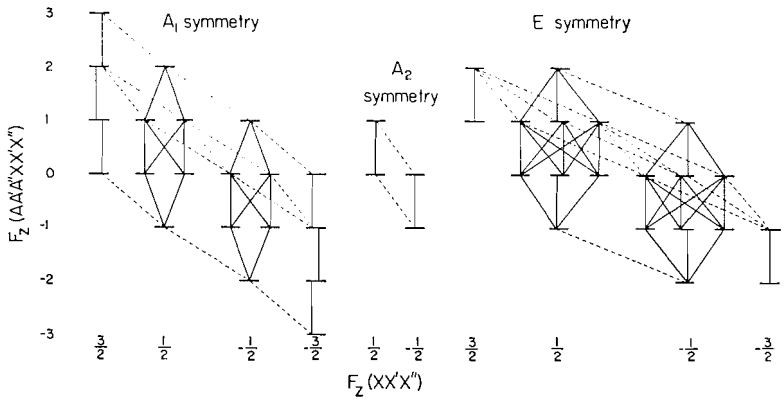

FIG. 1. Energy level diagram for the AA'A''XX'X'' system. The solid tie lines indicate AA'A'' transitions i.e., transitions permitted by the selection rule $\Delta F_z(\mathrm{AA'A''}) = \pm 1$, $\Delta F_z(\mathrm{XX'X''}) = 0$. The broken tie lines indicate XX'X'' transitions, i.e., transitions permitted by the selection rule $\Delta F_z(\mathrm{AA'A''}) = 0$, $\Delta F_z(\mathrm{XX'X''}) = \pm 1$. For clarity, only some of the X transitions have been sketched in. If $F_z(\mathrm{AA'A''})$ were plotted as abscissa instead of $F_z(\mathrm{XX'X''})$, the solid tie lines would represent X transitions and the dotted tie lines A transitions.

$$K = J_{\mathrm{AA}} + J_{\mathrm{XX}}, \qquad L = 2J_{\mathrm{AX}} - J_{\mathrm{AX}}',$$
$$M = J_{\mathrm{AA}} - J_{\mathrm{XX}}, \qquad N = 2J_{\mathrm{AX}} + J_{\mathrm{AX}}',$$

and

$$\nu_{\mathrm{A}} = \frac{\gamma_{\mathrm{A}} H_{\mathrm{A}}}{2\pi}, \qquad \nu_{\mathrm{X}} = \frac{\gamma_{\mathrm{X}} H_{\mathrm{X}}}{2\pi},$$

where γ_{A} and γ_{X} are the magnetogryric ratios of the two types of nuclei.

The basic symmetry wave functions for the AA'A''XX'X'' system have been discussed qualitatively above. The product functions of the type $(\mathrm{A_1} \times \mathrm{A_1}) = \mathrm{A_1}$, $(\mathrm{A_1} \times \mathrm{E}) = \mathrm{E}$, and $(\mathrm{E} \times \mathrm{A_1}) = \mathrm{E}$ give rise directly to basic symmetry wave functions, but the $\mathrm{E} \times \mathrm{E}$ products have to be combined to give linear combinations of species $\mathrm{A_1}$, $\mathrm{A_2}$, and E. There are four $\mathrm{E} \times \mathrm{E}$ products characterized by $F_z(\mathrm{AA'A''}) = F_z(\mathrm{XX'X''}) = \frac{1}{2}$ which can be combined to give linear combinations, using a group theoretical formula (5) of the type

$$\psi(\mathrm{A_1}) = (\mathrm{E}_{1/2}(\mathrm{A})\mathrm{E}_{1/2}(\mathrm{X}) + \mathrm{E}_{1/2}'(\mathrm{A})\mathrm{E}_{1/2}'(\mathrm{X}))2^{-1/2}$$
$$\psi(\mathrm{A_2}) = (\mathrm{E}_{1/2}(\mathrm{A})\mathrm{E}_{1/2}'(\mathrm{X}) - \mathrm{E}_{1/2}'(\mathrm{A})\mathrm{E}_{1/2}(\mathrm{X}))2^{-1/2}$$
$$\psi(\mathrm{E}) = (\mathrm{E}_{1/2}(\mathrm{A})\mathrm{E}_{1/2}(\mathrm{X}) - \mathrm{E}_{1/2}'(\mathrm{A})\mathrm{E}_{1/2}'(\mathrm{X}))2^{-1/2}$$
$$\psi(\mathrm{E}') = (\mathrm{E}_{1/2}(\mathrm{A})\mathrm{E}_{1/2}'(\mathrm{X}) + \mathrm{E}_{1/2}'(\mathrm{A})\mathrm{E}_{1/2}(\mathrm{X}))2^{-1/2},$$

where E and E' are a degenerate pair in the E symmetry species.

The matrix elements of the Hamiltonian,

$$= \frac{\gamma_{\mathrm{A}} H_{\mathrm{A}}}{2\pi} F_z(\mathrm{A}) + \frac{\gamma_{\mathrm{X}} H_{\mathrm{X}}}{2\pi} F_z(X) + \sum_{i<j}^{\mathrm{A}} J_{ij} I_i \cdot I_j$$
$$+ \sum_{i<j}^{\mathrm{X}} J_{ij} I_i \cdot I_j + \sum_{i}^{\mathrm{A}} \sum_{j}^{\mathrm{X}} J_{ij} I_i \cdot I_j,$$

have been derived and are presented in Table II together with the molecular basic symmetry wave functions.

There are no off-diagonal matrix elements between functions of different symmetry or between functions of different total spin. This divides the total matrix into submatrices as indicated by the solid horizontal lines. Further simplification follows if we neglect off-diagonal matrix elements between functions whose diagonal elements differ by an amount involving the large chemical shift between the A and X nuclei. This is the simplification which follows when we proceed from AA'A''BB'B'' to AA'A''XX'X''. Further subdivision of the matrix is indicated by broken lines, the largest order of the secular equation to be solved now being two in the A_1 symmetry species and three in the E symmetry species. Explicit energies for the interacting A_1 states can be derived by defining two positive quantities C, D and angles θ, ϕ $[0 < \theta, \phi < \pi]$ by,

$$C \cos 2\theta = \tfrac{3}{4}K + \tfrac{1}{24}(3L - N)$$

$$C \sin 2\theta = -\frac{\sqrt{2}}{12}(3L - N)$$

$$D \cos 2\phi = \tfrac{3}{4}K - \tfrac{1}{24}(3L - N)$$

$$D \sin 2\phi = \frac{\sqrt{2}}{12}(3L - N)$$

The corresponding wave functions and energies are given in Table III.

The stationary state wave functions for the E states that interact are given in Table IV. The elements of the $[a]$, $[b]$ eigenvector matrices are evaluated from the corresponding energy matrix and the matrix of the elements of the Hamiltonian.

TABLE IV

Stationary state wave functions for the E species, $\pm\frac{1}{2},\pm\frac{1}{2}$ blocks

State	Wave function
$3E_1^*$	$a_{11}(3E_1) + a_{12}(4E_1) + a_{13}(5E_1)$
$4E_1^*$	$a_{21}(3E_1) + a_{22}(4E_1) + a_{23}(5E_1)$
$5E_1^*$	$a_{31}(3E_1) + a_{32}(4E_1) + a_{33}(5E_1)$
$1E_0^*$	$b_{11}(1E_0) + b_{12}(2E_0) + b_{13}(3E_0)$
$2E_0^*$	$b_{21}(1E_0) + b_{22}(2E_0) + b_{23}(3E_0)$
$3E_0^*$	$b_{31}(1E_0) + b_{32}(2E_0) + b_{33}(3E_0)$
$4E_0^*$	$b_{11}(4E_0) + b_{12}(5E_0) + b_{13}(6E_2)$
$5E_0^*$	$b_{21}(4E_0) + b_{22}(5E_0) + b_{23}(6E_0)$
$6E_0^*$	$b_{31}(4E_0) + b_{32}(5E_0) + b_{33}(6E_0)$
$3E_{-1}^*$	$a_{11}(3E_{-1}) + a_{12}(4E_{-1}) + a_{13}(5E_{-1})$
$4E_{-1}^*$	$a_{21}(3E_{-1}) + a_{22}(4E_{-1}) + a_{23}(5E_{-1})$
$5E_{-1}^*$	$a_{31}(3E_{-1}) + a_{32}(4E_{-1}) + a_{33}(5E_{-1})$

The transition patterns derived from Table I and shown in Fig. 1 can now be picked out from Table II using the symmetry selection rule and,

$$\Delta F_z(\mathrm{AA'A''}) = \pm 1, \quad \Delta F_z(\mathrm{XX'X''}) = 0 \qquad \text{for A transitions,}$$

$$\Delta F_z(\mathrm{XX'X''}) = \pm 1, \quad \Delta F_z(\mathrm{AA'A''}) = 0 \qquad \text{for X transitions.}$$

The results are shown in Fig. 2. For the AA'A'' portion of the spectrum there are 22 transitions between A_1 symmetry species energy levels, 2 transitions between A_2 symmetry species energy levels and 32 doubly degenerate transitions between E symmetry species energy levels. This gives a total of 56 transitions. The breakdown is the same for the 56 XX'X'' transitions.

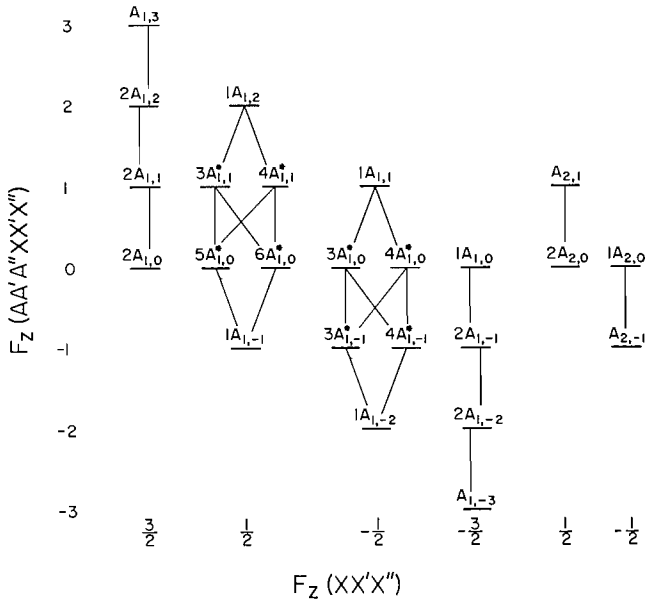

FIG. 2*a*. A schematic representation of the AA'A'' transitions within the A_1 and A_2 symmetry species. A similar schematic diagram can be constructed for XX'X'' transitions.

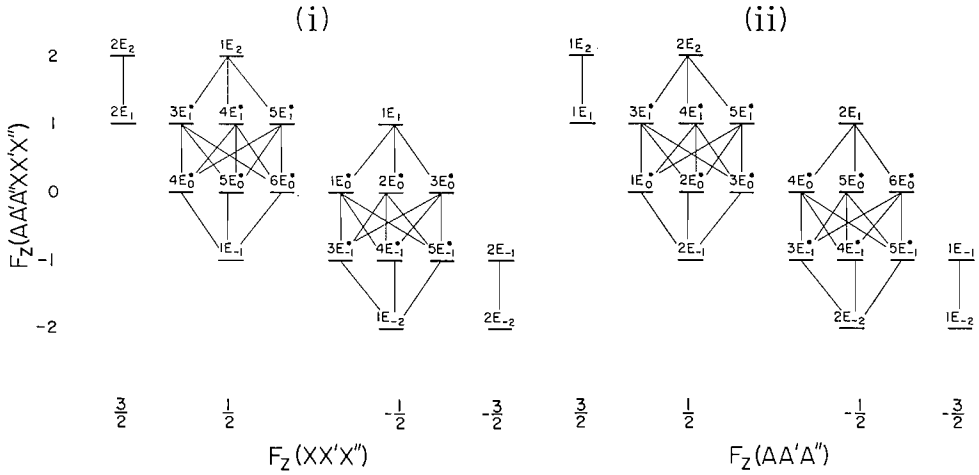

FIG. 2*b*. A schematic representation of (i) the AA'A'' transitions and (ii) the XX'X'' transitions within the E symmetry species. In order to simplify the appearance, not all of the transitions between the energy levels of the 3 × 3 determinants have been shown.

The energies and relative intensities of one half of the AA'A'' transitions belonging to the A_1 and A_2 symmetry species are given in Table V. For each of the 1 to 12 transitions given in Table V there is an exactly similar line reflected across ν_A (transitions 13–24). An exactly similar set of transitions (centered about ν_X) is obtained for the 22 A_1 and 2 A_2 transitions of the XX'X'' group.

Explicit expressions for the transition energies can be written for only two AA'A'' and two XX'X'' transitions occurring in the E symmetry species (49 to 52). These are given in Table VI.

TABLE V

Transition energies and relative intensities of the A_1 and A_2 symmetry species A transitions[a]

No.	Transition	Energy relative to ν_A	Relative intensity
1	$4A_{1,1}-1A_{1,2}$	$\frac{3}{4}K+\frac{1}{6}[N+L]+C$	$3\sin^2\theta$
2	$6A_{1,0}-3A_{1,1}$	$\frac{1}{4}[N-L]+C+D$	$[2\cos\theta\sin\phi+\sin\theta\cos\phi]^2$
3	$2A_{2,0}-A_{2,1}$	$\frac{1}{2}L$	1
4	$1A_{1,-1}-6A_{1,0}$	$-\frac{3}{4}K+\frac{1}{6}[N+L]+D$	$3\cos^2\phi$
5	$5A_{1,0}-3A_{1,1}$	$\frac{1}{4}[N-L]+C-D$	$[2\cos\theta\cos\phi-\sin\theta\sin\phi]^2$
6	$3A_{1,1}-1A_{1,2}$	$+\frac{3}{4}K+\frac{1}{6}[N+L]-C$	$3\cos^2\theta$
7	$6A_{1,0}-4A_{1,1}$	$\frac{1}{4}[N-L]-C+D$	$[2\sin\theta\sin\phi-\cos\theta\cos\phi]^2$
8	$1A_{1,-1}-5A_{1,0}$	$-\frac{3}{4}K+\frac{1}{6}[N+L]-D$	$3\sin^2\phi$
9	$5A_{1,0}-4A_{1,1}$	$\frac{1}{4}[N-L]-C-D$	$[2\sin\theta\cos\phi+\cos\theta\sin\phi]^2$
10	$2A_{1,2}-A_{1,3}$	$\frac{1}{2}N$	3
11	$2A_{1,1}-2A_{1,2}$	$\frac{1}{2}N$	4
12	$2A_{1,0}-2A_{1,1}$	$\frac{1}{2}N$	3

[a]Transitions 13 to 24 are mirror reflections of 1 to 12 respectively, about ν_A, the center of the spectrum. The 24 XX'X''transitions, 25–48, have similar energies relative to ν_X (see text).

TABLE VI

Explicit E symmetry species transition energies and relative intensities

No.	Transition	Energy	Rel. intensity
49	$2E_1-2E_2$	$\nu_A+\frac{1}{2}N$	2
50	$2E_{-2}-2E_{-1}$	$\nu_A-\frac{1}{2}N$	2
51	$1E_1-1E_2$	$\nu_X+\frac{1}{2}N$	2
52	$1E_{-2}-1E_{-1}$	$\nu_X-\frac{1}{2}N$	2

For the AA'A'' spectrum inspection of Fig. 2 and Tables V and VI indicates that the transitions numbered 10, 11, 12, 49 (one a_3 subspectrum) and 22, 23, 24, 50 (the other a_3 subspectrum) give rise to two strong lines with 12 units of relative intensity each and separated by $|2J_{AX}+J_{AX}'|=|N|$ as was predicted using the principles of Part I. An identical set of lines is found in the XX'X'' spectrum.

In the AA'A'' spectrum transitions numbered 1 to 9 give rise to one ab_2 subspectrum and transitions 13 to 21 give rise to the second ab_2 subspectrum. Comparison of the transition energies and intensities of either ab_2 subspectrum, as given in Table V, with those of the well known AB_2 system (2) gives the following relations between the parameters of either ab_2 subspectrum and the parameters of the AA'A''XX'X'' problem:

$$|J_{ab}|=|J_{AA}+J_{XX}|=|K| \quad \text{and} \quad |\nu_0\delta_{ab}|=|J_{AX}-J_{AX}'|.$$

The separation of lines 3 and 15 (i.e., the separation of the a chemical shifts in the ab_2 subspectra) is $|L|=2J_{AX}-J_{AX}'$. Also the separation of the mean of lines 5 and 7 and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mean of lines 17 and 19 (i.e., the separation of the b chemical shifts in the two ab_2 subspectra) is $|N - L|/2 = |J_{AX}'|$.*

The remaining parameter to be determined, $|M| = |J_{AA} - J_{XX}|$, appears only in the E symmetry species matrices, and only the transitions within the *abc* energy level diagrams are affected by M. The parameter M cannot be obtained explicitly from the *abc* subspectra because of the third-order determinants that appear. However, a closer examination of these E symmetry transitions is worthwhile since it is here that any differences between the AA'A'' and XX'X'' spectra must arise.

It is possible to detect the differences between AA'A'' and XX'X'' by using Fig. 2*b*, (i) and (ii), as a guide and the corresponding diagonal matrix elements (see Table II). We are concerned with the $F_z(XX'X'') = \pm\frac{1}{2}$ and $F_z(AA'A'') = \pm\frac{1}{2}$ patterns respectively. We may write the energies, E_i, of a given third-order determinant as $E_i = H_i + P_i$, where H_i is the diagonal element and P_i is a diagonalization constant. The property of trace invariance requires that $\sum_i P_i = 0$. When these energies are defined for each third-order determinant in Fig. 2*b*, (i) and (ii), and the transition energies are written down for both the AA'A'' and XX'X'' parts, it is found that J_{AA} appears independently of J_{XX} in some transition energies of the AA'A'' part. Correspondingly J_{XX} appears independently of J_{AA} in some of the XX'X'' transition energies. From inspection of the transition energies, the differences in positions of the lines arise in transitions between the solutions of the third-order determinants and the stationary state energy levels ($1E_2$, $1E_1$, $1E_{-1}$, $1E_{-2}$ in (i) and $2E_2$, $2E_1$, $2E_{-1}$, $2E_{-2}$ in (ii)). Even so, these differences cannot arise unless $J_{AA} \neq J_{XX}$ and $J_{AX} \neq J_{AX}'$. The nine lines arising from transitions between the third-order determinants in the *abc* subspectra will have the same positions relative to ν_A and ν_X in the AA'A'' and XX'X'' spectra, respectively.

The intensities must next be considered in order to account for all the differences between the A and X spectra. It is possible to express the intensities of the transitions within the E symmetry species in terms of the first-order breakdown ($J_{AX} = J_{AX}'$) relative intensity distribution and the eigenvector matrix elements which determine mixing within the 3×3 determinants (see Table IV). The results are given in Table VII for the AA'A'' transitions of E symmetry species and in Table VIII for the XX'X'' transitions of E symmetry species. The six lines which have different positions in corresponding *abc* subspectra also have different intensities. The nine lines which have the same positions in corresponding subspectra can also have different intensities. Therefore the AA'A'' and XX'X'' spectra appear quite different.

In the special case that $J_{AA} = J_{XX}$, i.e., $M = 0$, the *abc* transitions in the AA'A'' group are identical to the *abc* transitions in the XX'X'' group.

THE ANALYSIS OF THE N.M.R. SPECTRUM OF SYMMETRICAL TRIFLUOROBENZENE

Symmetrical trifluorobenzene is a good example of the AA'A''XX'X'' system in which the differences between the two parts of the spectrum A (^{1}H) and X (^{19}F) are quite clear.

EXPERIMENTAL

The sample of symmetrical trifluorobenzene [n_D^{25}, 1.4110; b.p. 76 °C at 744 mm] was kindly supplied by Dr. G. C. Finger. It was used without further purification and the n.m.r. spectra showed no unexplained

**Inspection of Figs. 1 or 2 shows that the energy level diagrams of the two ab_2 subspectra taken together are identical in form to the energy level diagram of an AB_2X system (7, 8). Thus these two ab_2 subspectra could be designated as an ab_2x subspectrum, and relationships between the two ab_2 subspectra could be defined in terms of the coupling constants J_{ax} and J_{bx} ($\nu_0\delta_{AB} = 0$ here). When this is done the formulae for the transitions and intensities for AB_2X give all the ab_2 transition frequencies and intensities and the x transition frequencies. However, some of the x transition intensities are not given correctly, and for this reason the ab_2x analogy has not been used here.*

The two abc energy level diagrams may be considered together to form an abcx subspectrum, but because of the non-analytical character of abc systems, the abcx analogy was not helpful in this work.

97	$2E_{-1}-3E_0^*$	$3b_{32}^2$

[a]One half of the transitions are presented in this table. For each transition given there is a corresponding transition (transitions 98 to 112) with identical intensity reflected about ν_X.
[b]These intensities are to be multiplied by 2 to account for the degeneracy.

lines. A 30% by volume solution in carbon disulfide, with tetramethylsilane (TMS) internal standard, was degassed and sealed under vacuum into a 5 mm O.D. sample tube.

Preliminary ^1H and ^{19}F spectra were run on a standard Varian 60 Mc/s high resolution n.m.r. spectrometer. Final spectra were obtained using the Varian unit and an RSI "spin decoupler". The field was locked to the TMS internal standard using the method of Freeman and Whiffen (9). The positions of each of the reported peaks in the ^1H spectrum were measured with a reproducibility of ± 0.02 c.p.s., or better, by manually sweeping the scanning audio oscillator across each peak and noting the frequency for maximum recorder deflection. This frequency as well as the frequency of the 1 000 c.p.s. tuning fork oscillator locking frequency was accurately monitored with a Hewlett-Packard 522B electronic counter using a 526C multiperiod average plug-in unit.

In the ^{19}F spectrum the field was locked to one of the two "tall" peaks in the spectrum. The positions of about two thirds of the lines were measured directly as above, and the positions of the remaining lines were obtained by interpolation on recorded spectra. The lower field half of the ^{19}F spectrum was obtained by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

locking onto the upfield "tall" peak, and the upfield half of the spectrum was obtained by locking onto the low field peak. These two halves were joined to give the complete experimental ^{19}F spectrum.

The experimental ^{1}H and ^{19}F spectra are given in Figs. 3 (*a*) and 4 (*a*), respectively, and the corresponding experimental line positions are in Tables IX, X, and XI. The similarities and differences between the two spectra can be seen quite clearly from these experimental results. Observed intensities are not given because of the difficulty of accurately measuring intensities when so many lines overlap. However, Figs. 3 and 4 show good agreement of calculated intensities and experimental peak heights.

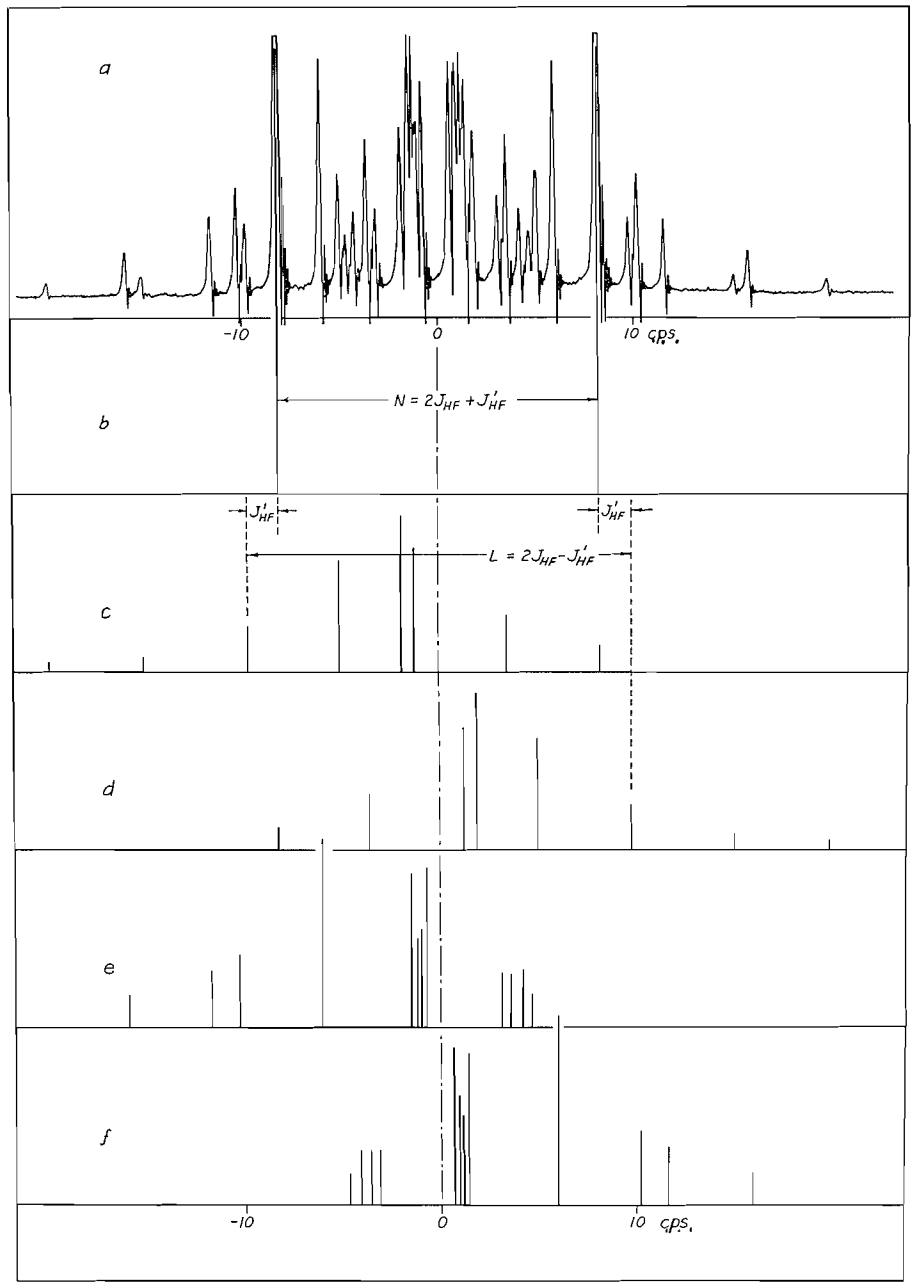

FIG. 3. Experimental and calculated 60 Mc/s ^{1}H n.m.r. spectra of *sym*-trifluorobenzene, 30% by volume in carbon disulfide: (*a*) experimental, (*b*) two calculated a_3 subspectra, (*c*) and (*d*) calculated ab_2 subspectra, (*e*) and (*f*) calculated *abc* subspectra.

For personal use only.

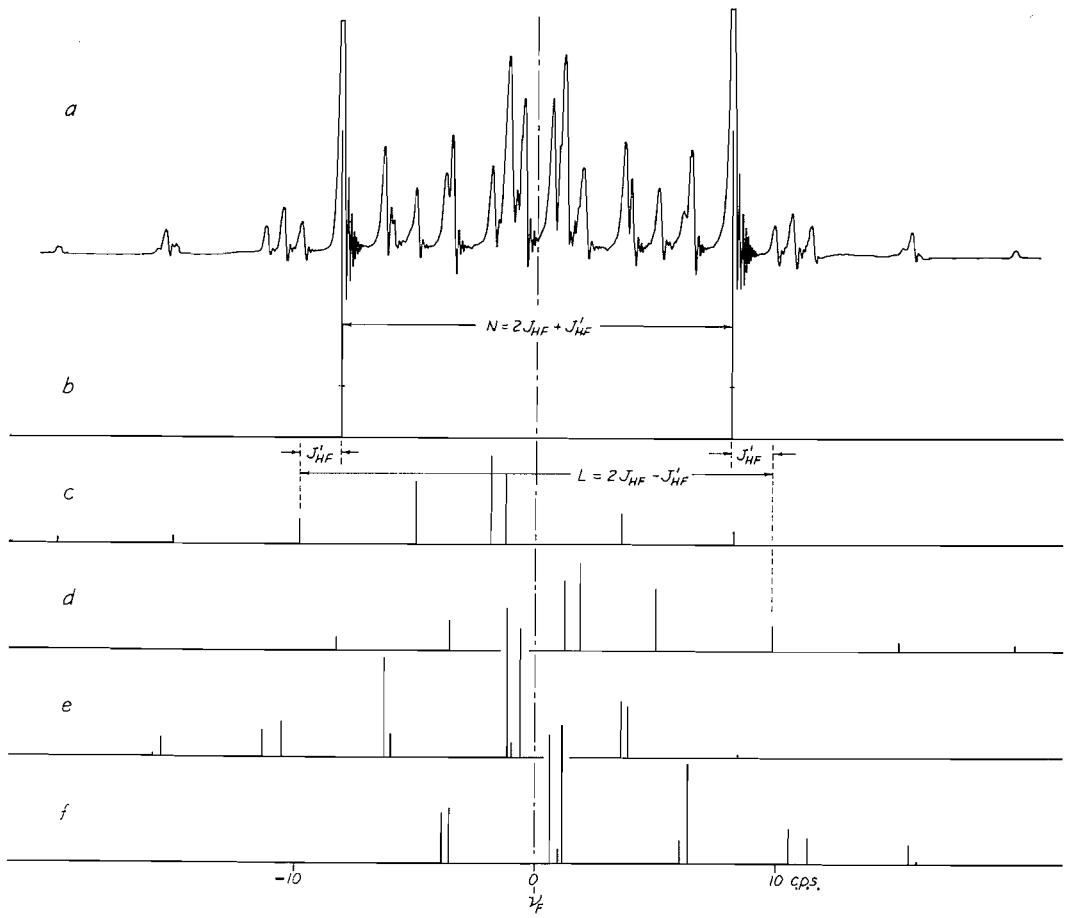

FIG. 4. Experimental and calculated 56.4 Mc/s ^{19}F n.m.r. spectra of *sym*-trifluorobenzene, 30% by volume in carbon disulfide: (*a*) experimental, (*b*) two calculated a_3 spectra, (*c*) and (*d*) calculated ab_2 subspectra, (*e*) and (*f*) calculated *abc* subspectra. Fig. 4 (*b*), (*c*), (*d*) is identical with Fig. 3 (*b*), (*c*), (*d*). The differences between the ^1H and ^{19}F spectra result from differences between Fig. 3 (*e*) and (*f*) and Fig. 4 (*e*) and (*f*).

METHOD OF ANALYSIS

The method of analysis follows from the arguments and results set out above. Therefore we have looked for the a_3 (and x_3) and ab_2 (and xy_2) subspectra in both parts of the spectrum and verified that for this case they are identical. The a_3 lines, with 12 units of intensity each, are the most distinctive features of both spectra. They appear as very intense lines 16.24 c.p.s. apart and symmetrical about the center of each spectrum. They are given in Figs. 3 (*b*) and 4 (*b*) where the A lines are numbered 10, 11, 12, 49 and 22, 23, 24, 50 and the X lines are numbered 34, 35, 36, 51 and 46, 47, 48, 52 in accordance with Tables V, VI, VII, and VIII. Hence we know that $N = 2J_{HF} + J_{HF}' = 16.24$ c.p.s.

The ab_2 subspectra were not picked out quite as easily. However, inspection of the observed line positions given in Tables IX–XI, together with the consideration of the relative intensity distribution and the knowledge that the two ab_2 subspectra in each part, taken together, must form a pattern of lines symmetrical about the center, led us to the assignment of the transitions 1 to 7 and 13 to 19 in the proton spectrum as indicated in Fig. 3 (*c* and *d*). Transitions 8 and 20 were hidden by the a_3 lines, and transitions 9 and 21

[a]Line positions are in c.p.s. from center of spectrum, ν_F. Negative sign indicates downfield displacement from ν_F. The line positions 83–97 are the 15 lines of one of the *abc* subspectra. The line positions of the second fluorine *abc* subspectrum, 98 to 112, are mirror reflections about ν_F.

described above. The values are as follows: $|N| = 2J_{HF} + J_{HF}' = 16.24$ c.p.s., $|L| = 2J_{HF} - J_{HF}' = 19.60$ c.p.s., and $|K| = J_{HH} + J_{FF} = 8.13$ c.p.s. The ortho H–F coupling constant, J_{HF}(ortho), is identified as J_{HF}, and J_{HF}' is identified as the para H–F coupling constant by observing the statistical weights with which these two couplings appear. Hence $J_{HF} = J_{HF}$(ortho) $= 8.96 \pm 0.02$ c.p.s. and $J_{HF}' = J_{HF}$(para) $= -1.68 \pm 0.02$ c.p.s. It is assumed that J_{HF}(ortho) is positive on the basis of the absolute sign determination of Buckingham and McLaughlan (10) that J_{HH}(ortho) is positive in aromatic compounds and the fact that J_{HH}(ortho) is the same sign as J_{HF}(ortho) in fluorobenzene (11). Actually the magnitudes and relative signs of J_{HF} and J_{HF}' can be obtained directly from the spectrum, once the ab_2 spectra are assigned, as shown in Fig. 3 (*c*, *d*) and Fig. 4 (*c*, *d*) (see Table V also).

The only transitions that are affected by the remaining parameter, $M = |J_{AA} - J_{XX}|$, are those involving the E symmetry 3 × 3 determinants. The value of M is obtained by guessing various values of M, solving the 3 × 3 determinants numerically, and calculating the transition frequencies and intensities. Since in the case of symmetrical trifluorobenzene, variation of the single parameter M must give a satisfactory fit in position and intensity of 12 *abc* type ^{1}H transitions and 8 resolvable *abc* type ^{19}F transitions, a unique fit seems assured. The calculated proton transition frequencies and intensities of E symmetry are given in Table X along with the experimental line positions. The corresponding fluorine data are in Table XI. Figure 3 (*e* and *f*) shows a plot of the ^{1}H lines, and Fig. 4 (*e* and *f*) shows the ^{19}F lines. The best value of $|M|$ is 3.53 ± 0.02 c.p.s. Since $|K| > |M|$, J_{HH} and J_{FF} have the same sign and their magnitudes are 2.30 ± 0.02 c.p.s. and 5.83 ± 0.02 c.p.s., but no information is obtained from the spectrum as to which value corresponds to which coupling. Also the spectra are independent of the signs of J_{HF}(ortho) and J_{HF}'(para) relative to J_{HH} and J_{FF}. However, in the present case, these last two couplings can be assigned and the signs related to J_{HF}(ortho) and J_{HF}'(para) by comparison with the coupling constants in similar molecules.

In a large number of aromatic compounds the proton–proton couplings lie in the ranges 7–9 c.p.s. and 1–3 c.p.s. for ortho and meta protons (2), respectively. Other workers (4, 12) have shown ortho and meta aromatic couplings to be of the same sign. Meta fluorine–fluorine couplings have been found in the few cases studied to have values in the range 2–4 c.p.s. (2) with no signs known. These data, combined with that in Table XII of the couplings in some 1,3,5-trisubstituted benzenes, strongly suggest that J_{HH} and J_{FF} are positive and should be assigned the values 2.30 c.p.s. and 5.83 c.p.s., respectively.

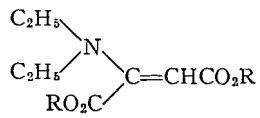
NOTES

NUCLEOPHILIC ADDITION OF TRIETHYLAMINE TO DIMETHYL ACETYLENEDICARBOXYLATE

ROBERT J. ALAIMO[1] AND DONALD G. FARNUM[2]

During our studies concerning 1,3-dipolar additions involving dimethyl acetylenedicarboxylate as the dipolarophile and triethylamine as the base used to generate the 1,3-dipole, an interesting side reaction was observed.

In all cases, a dark-red polymeric material and a viscous, pale-yellow oil were obtained in addition to the product of 1,3-dipolar cycloaddition. The pale-yellow oil analyzed for a composition $C_{10}H_{17}NO_4$, and its infrared, ultraviolet, and nuclear magnetic resonance (n.m.r.) spectra were consistent with structure I, dimethyl α-diethylaminomaleate (or fumarate).



I, R = CH_3.
II, R = CH_3CH_2.

The infrared spectrum showed two non-equivalent carbonyl functions at 1 750 and 1 700 cm^{-1} and a very intense double bond peak at 1 575 cm^{-1}. The ultraviolet spectrum had a maximum at 287 mμ (extinction coefficient 35 400) which compares favorably with the model compound ethyl β-dimethylaminocrotonate with an ultraviolet maximum at 275 mμ (extinction coefficient 22 400) (1).

The n.m.r. spectrum showed two sharp singlets at τ 6.2 and 6.5 p.p.m. which were assigned to the protons of the non-equivalent methyl ester groups; a triplet centered at τ 8.9 assigned to the methyl protons of the ethyl group; a quartet centered at τ 6.8 assigned to the methylene protons of the ethyl group; and a sharp singlet at τ 5.5 assigned to the vinyl proton, the relative areas being consistent with these assignments.

This amino ester was prepared in quantitative yield when equimolar quantities of dimethyl acetylenedicarboxylate, triethylamine, and triethylamine hydrobromide were heated together for 4 h in refluxing methylene chloride, the same conditions as those used in the 1,3-dipolar additions. Triethylamine hydrobromide alone also reacts with dimethyl acetylenedicarboxylate to give an 80% yield of the same product, but triethylamine alone with dimethyl acetylenedicarboxylate gave none of the desired amino ester I. Thus a proton source seems to be necessary. The structure of the product was also confirmed by reaction of diethylamine with dimethyl acetylenedicarboxylate to give the same amino ester in 85% yield.

Reppe (2) reported that tertiary amines or their salts reacted with acetylene or its monosubstituted derivatives in the presence of water to yield quaternary vinyl-ammonium

[1]*Dow Chemical Company Summer Research Fellow, 1962–1963.*
[2]*Fellow of the Alfred P. Sloan Foundation.*

bases. Ruhemann and Cunnington (3) studied the reaction of diethyl acetylenedicarboxylate with diethylamine in ethereal solution at room temperature. They identified the amino ester formed as "Ethylic diethylamidomaleate" II. Vassiliades and Capatos (4), on the other hand, reported that diethylamine and dimethyl acetylenedicarboxylate reacted in alcohol solution at −10° to yield a mixture of the ester amide III and the diamide IV. In our work, no indication of ester-amide or diamide was found in any of the reactions.

$C_2H_5O_2C—C\equiv C—CON(C_2H_5)_2$ III

$(C_2H_5)_2NOC—C\equiv C—CON(C_2H_5)_2$ IV

EXPERIMENTAL

Dimethyl α-Diethylaminomaleate (I)

(a) With Triethylamine Hydrobromide

To a solution of 2.0 g (0.014 mole) of dimethyl acetylenedicarboxylate (Eastman 7235) in 15 ml of methylene chloride heated to reflux was added dropwise a suspension of 2.7 g (0.014 mole) of triethylamine hydrobromide* in 45 ml of methylene chloride. The addition took about 30 min, but the rate of addition did not appear to be critical. The mixture was refluxed for 4 h after addition and the clear solution changed to pale yellow. The solution was then cooled, washed once with 50 ml of water, and dried over anhydrous sodium sulfate.

The reaction mixture was then filtered and the solvent removed *in vacuo*, yielding 2.95 g of yellow–red oil (98%). The amino-ester was purified by molecular distillation at 70° and 5 mm to give a pale-yellow viscous oil (80% recovery). λ_{max} 287 mμ (ϵ = 35 400) (ethanol). ν_{max} 1 750, 1 700, 1 575 cm^{-1} (neat). τ 5.5 (relative area 1.1) singlet; 6.2 (3.2) singlet; 6.5 (2.9) singlet; 6.8 (3.9) quartet; 8.9 (6.0) triplet (carbon tetrachloride).

Anal. Calcd. for $C_{10}H_{17}NO_4$: C, 55.80; H, 7.96; N, 6.51. Found: C, 55.63; H, 7.93; N, 6.41.

Gas chromatographic analysis showed two peaks of areas 987 to 13. The retention time of the smaller peak corresponded to that of dimethyl acetylenedicarboxylate.

(b) With Diethylamine

To a stirred solution of 3.0 g (0.021 mole) of dimethyl acetylenedicarboxylate in 50 ml of methylene chloride chilled in an ice bath was added dropwise a solution of 1.6 g (0.021 mole) of diethylamine in 20 ml of CH_2Cl_2. The stirring in the ice bath was continued for 3 h after addition. The solvent was removed *in vacuo*, yielding 4.5 g (100%) of a pale-yellow oil whose infrared spectrum was identical with that of I. Gas chromatography of this sample under the same conditions as in (*a*) again gave two peaks with the same retention times as those in (*a*). The peak corresponding to the amino-ester accounted for 85% of the total area.

(c) With Triethylamine

With the procedure used in (*a*) but using 3.0 g (0.021 mole) of dimethyl acetylenedicarboxylate in 35 ml of methylene chloride and 2.1 g (0.021 mole) of triethylamine in place of triethylamine hydrobromide in 15 ml of methylene chloride, only starting materials and non-volatile red polymeric material were obtained.

(d) With Triethylamine and Triethylamine Hydrobromide

With the procedure used in (*a*) but using 3.0 g (0.021 mole) of dimethyl acetylenedicarboxylate in 30 ml of methylene chloride and a suspension of 2.1 g (0.021 mole) triethylamine and 3.7 g (0.021 mole) triethylamine hydrobromide in 75 ml of methylene chloride a quantitative yield (4.5 g) of the amino-ester I was obtained.

PYROLYSIS STUDIES. XIV.[1] THE PYROLYSIS OF *t*-BUTYL BENZOATES

GRANT GILL SMITH AND BRIAN L. YATES

In an attempt to determine accurate σ^0 values we have studied the intramolecular gas-phase elimination of benzoic acids from ethyl (1) and isopropyl (2) benzoates. Meta- and para-substituent effects in these reactions follow a Hammett σ^0 relationship and it is believed that proximity effects are a minimum for this intramolecular vapor-phase reaction. The values of ρ obtained for the ethyl and *i*-propyl benzoate (0.20 and 0.33 respectively) were rather small and it was thought that a study of the thermal elimination of the acid from *t*-butyl benzoate esters would prove to follow the upward trend and be larger than 0.33 and therefore more suitable for a determination of σ^0 values. Because of the larger *t*-butyl group there was also the possibility that interesting steric effects may alter the rates for certain ortho-substituents.

From the results reported in this paper, it is clear that the thermal decomposition of *t*-butyl benzoates is not a simple intramolecular homogeneous reaction but rather the reaction is subject to occurring also on the walls which activate the reactor and cause an increasing amount of heterogeneous reaction. Since all efforts failed to avoid the heterogeneous reaction, it is apparent that pyrolyzing of *t*-butyl benzoate is not suitable for studying linear free energy relationships.

EXPERIMENTAL

Preparation of the t-Butyl Benzoates

The esters were prepared by refluxing the benzoyl chloride with *t*-butyl alcohol in the presence of pyridine. The benzoyl chlorides were either purchased or prepared by refluxing the benzoic acid with thionyl chloride. The physical constants of the esters are given in Table I.

TABLE I

The physical constants of substituted *t*-butyl benzoates

*Lit. n_D^{25} 1.4896 (S. G. Cohen and A. Schneider. J. Am. Chem. Soc. 63, 3382 (1941)).
†Lit. b.p. 158.5 at 3 mm, n_D^{25} 1.5041 (R. Altschul. J. Am. Chem. Soc. 70, 2569 (1948)).

Method of Pyrolysis

All of the esters were pyrolyzed at 271.7° in a stainless steel reactor of constant volume (200 ml), whose design and operation have been described (2*b*). The reaction was followed automatically by measuring the increase in pressure inside the reactor by using a stainless steel diaphragm closing one end of the reactor as a null gauge, and a pressure transducer connected to a strip chart recorder. The temperature was maintained to within 0.02° with a large glass wool lagged aluminium block which was electrically heated. Before each ester was introduced care was taken that the surface of the reactor was completely deactivated (3); this was done by leaving the products of pyrolysis of 3-butenoic acid inside the reactor at 400° for at least 1 day, and verifying that the rate constant obtained for the pyrolysis of 1-phenylethyl methyl carbonate in the reactor was 1.85×10^{-3} at 307.2 °C, the value obtained in a reactor with a completely deactivated surface (see Part XIII of this series). Since all esters could be injected into the evacuated reactor as liquids it was

[1]*Part XIII. J. Org. Chem. To be published.*

For personal use only.

not necessary to dissolve them in an inert solvent, although the effects of such radical-inhibiting solvents as cyclohexene and toluene were also determined.

Product Analyses

The pyrolysis products from the pyrolysis of the *p*-methoxy and unsubstituted *t*-butyl benzoates were collected in a liquid nitrogen trap. Vapor-phase chromatographic analysis of the products on a silica gel column at 150 °C revealed only the presence of nitrogen and *i*-butylene, while the acids were reclaimed from the trap as solids.

RESULTS AND DISCUSSION

It would be expected on the basis of the results for the *i*-propyl benzoates that good first-order kinetics would be obtained in the pyrolysis of the *t*-butyl benzoates, and that substituent effects would follow a σ^0 relationship. The results actually obtained for the pyrolysis of the *t*-butyl benzoates are given in Table II; the four rate constants given for each ester was the result of four consecutive runs on that ester, the reactor having a completely deactivated surface before the start of the measurements on that ester. The results given are those for just one set of runs; on *three* completely separate occasions the same four esters were pyrolyzed with the same care to make sure that the surface of the reactor was completely deactivated before the start of the pyrolyses and the same results were obtained as those given in Table II.

TABLE II

Rates of pyrolysis of *t*-butyl benzoates at 271.7 °C

Substituent	$k \times 10^{-3}$, s^{-1}
p-MeO	3.0, 4.0, 6.9
H	3.08, 3.15, 3.25, 3.37
m-F	4.85, 4.89, 4.80, 4.86
p-Cl	5.40, 5.48, 5.52, 5.65

The degree of adherence to the expected first-order kinetics and the reproducibility of the results were found to depend on the ester being studied. Thus, for the *m*-fluoro ester, good first-order plots of $(P_\infty - P_t)$ against time were obtained, and the results were reproducible to the extent of $\pm 2\%$. This is the usual reproducibility obtained for pyrolyses in this apparatus. However, this reproducibility was not shown in the rates of pyrolysis of the other *t*-butyl esters, for each succeeding run of the ester the first-order plots became increasingly curved, and as can be seen from Table II, the rate constants obtained from the plots became greater in magnitude.This behavior was shown to the greatest extent by the *p*-methoxy ester, and only to a small extent by the *p*-chloro ester.

A comparison of the rates of pyrolysis of the *t*-butyl esters also reveals an anomaly, namely that the rate of pyrolysis of the *m*-fluoro ester is slower than that of the *p*-chloro, whereas if substituent effects in the pyrolysis of the *t*-butyl benzoates followed a σ^0 relationship, as was found for the ethyl and *i*-propyl benzoates, the rates should be in the opposite order. On this account and because of the unreproducibility of the data for the pyrolysis of some of the *t*-butyl benzoates it is obvious that this reaction is not very suitable for a determination of substituent constants, but it is of interest as to why this behavior is shown in the pyrolysis of the *t*-butyl benzoates.

It is well recognized (4) that in studying homogeneous gas-phase reactions it is necessary to deactivate the surface of the reactor before reproducible results can be obtained. This may be done either by pyrolyzing the compound to be studied many times or by leaving the products of pyrolysis of allyl bromide (4) or 3-butenoic acid for some time in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reactor. This deactivation process seems to involve covering the surface of the reactor with an inert carbon layer which prevents surface catalysis. Under these conditions the gas-phase intramolecular decomposition of carboxylic esters and other types of compounds have been studied and reproducible data obtained. The presence of oxygen or free radicals, however, leads to reactivation of the surface of the reactor, giving fast rates and, generally, curved first-order plots.

The behavior shown by some of the *t*-butyl benzoates, namely that with each succeeding run the first-order plots became more curved and the magnitude of the rate constants became greater, is characteristic of that which would be shown if the previously deactivated surface of the reactor was becoming increasingly activated with each succeeding run. The most likely way in which this could occur would be if the ester was decomposing partially by a surface-catalyzed reaction leaving the surface more and more active. It would appear then, on the basis of this evidence, that some *t*-butyl benzoates under the present conditions can pyrolyze in two ways, one by the normal cyclic elimination reaction that is well known in ester pyrolysis (5), and the other by a surface-catalyzed reaction. It is doubtful that the wall reaction goes by way of a chain mechanism because the products of pyrolysis of *t*-butyl *p*-methoxy benzoate were shown to be exclusively *i*-butylene and *p*-methoxybenzoic acid, and also no effect on the rate of pyrolysis of any of the *t*-butyl benzoates was noted when the pyrolyses were carried out in a threefold excess of such radical inhibitors as toluene and cyclohexene. Because reproducible data were obtained for the pyrolysis of the *m*-fluoro ester it must be concluded that there is very little wall reaction in the pyrolysis of this ester. It would appear then that the relative importance of the normal *cis*-elimination reaction and the wall reaction depends on the substituent, i.e. the wall reaction becomes more important the more electron releasing the substituent in the benzene ring, hence it is greatest for the *p*-methoxy ester and least or non-existent for the *m*-fluoro ester. The *t*-butyl group is also more electron releasing than the *i*-propyl group. Further, if the *t*-butyl *p*-chlorobenzoate partially decomposes by a wall reaction while the *m*-fluoro ester does not, this is probably the reason why the *m*-fluoro ester decomposes more slowly than the *p*-chloro ester, when as stated earlier it would be expected that the reverse would be true. On the basis of this work it would seem then that in the pyrolysis of the carboxylic ester RCO_2R' if the groups R and R′ are too electron releasing, the ester will decompose by a wall reaction as well as the normal *cis*-elimination reaction.

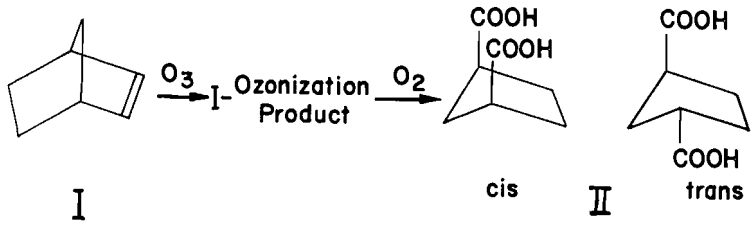
ISOMERIC 1,3-CYCLOPENTANEDICARBOXYLIC ACIDS FROM THE OXIDATIVE OZONIZATION OF NORBORNENE[1]

SAMUEL C. TEMIN AND MELVIN E. BAUM

We wish to report an unexpected *cis–trans* isomerization which occurs when the ozonization product of bicyclo[2.2.1]heptene-2(norbornene), (I), is oxidized to 1,3-cyclopentanedicarboxylic acid, (II).



Several oxidative procedures have been reported to convert norbornene to pure *cis*-1,3-cyclopentanedicarboxylic acid (norcamphoric acid). These include oxidation of norbornene with permanganate (1) as well as the action of chlorine (2) and hydrogen peroxide (3) on I-ozonization products prepared in methanol. By use of a newly developed chromatographic technique (4) for the quantitative estimation of *cis* II and *trans* II in mixtures of the isomers, it was discovered (Table I) that the procedures involving oxidation of I-ozonization product yielded small amounts of *trans* II, previously undetected. Isomer distribution was not influenced by ageing the ozonization product (Table I, expt. 3) or preparing it at either −70 or 25 °C (Table I, expts. 2 and 4).

TABLE I
cis/trans Acid ratios

¶Duplication of ref. 1.

As much as 10% of *trans* II was obtained, however, when norbornene ozonization product prepared in water or an alcohol as solvent was oxidized with air (5) (Table I, expts. 5 and 6). The ratio of *cis* to *trans* obtained by this procedure was essentially the

[1]*Contribution No. RD-63-13.*

same over a temperature range of −70 to 25 °C during ozonization. Norcamphoric acid (*cis* II) is known to isomerize to the *trans* isomer under acidic conditions (6, 7, 8). However, extended treatment of pure norcamphoric acid under the conditions used for oxidation of the ozonization product—bubbling air through a hot formic acid solution— caused no isomerization. This experiment serves to substantiate that the *trans* acid observed in these experiments did not result from isomerization of already formed norcamphoric acid.

The isomeric ratios were determined by a liquid–liquid chromatographic technique (4) utilizing a silicic acid column. It was demonstrated that interconversion of the isomers does not occur on the column, and that elution of both acids is essentially quantitative. The chromatographic technique permitted high purity *trans* II to be obtained free from *cis* isomer. The chromatographically purified *trans* acid had a melting point of 98–99 °C, several degrees higher than previous reported values. Pospischill (6) reported m.p. 87–88.5° for *trans* II, Ingold and Mohrhenn (9) reported m.p. 89°, and Birch and Dean (8) reported m.p. 95.5–96.5°. Chromatographically pure *cis* II melted at 121.5–122.5 °C.

The equilibrium isomer composition of II under acidic conditions was also determined. In previous HCl-catalyzed isomerizations (6, 8) the crude product obtained was estimated to consist of about equal parts of the two isomers. In all cases, however, the separation of isomers was incomplete and only impure *trans* II was isolated. In this work quantitative analysis of the isomers in the product mixtures permitted determination of a definite value, for the equilibrium isomer composition of II, of 1.0:1.0 at 110 °C. The equilibrium was approached from both sides, i.e., both mixtures rich in *cis* and *trans* II were isomerized by refluxing in concentrated HCl. The rate of isomerization was slow since equilibrium was not reached in 48 h.

EXPERIMENTAL

Norbornene Ozonization

The low temperature ozonization products were prepared as described by Perry (3). During ozonization at room temperature, if conducted by passing the ozone–oxygen stream through a solution of norbornene (I) in a solvent, there were rapid losses of the highly volatile olefin by entrainment in the gas stream. To minimize the loss of I during ozonization at 25°, norbornene dissolved in the appropriate solvent (15% solution) and ozone (2.3% in oxygen) were simultaneously added, at equimolar rates, to the reactor containing the same amount of solvent as used for the norbornene solution. The norbornene solution was metered to the reactor by means of a small pump. When water was employed as the reaction medium, an emulsion of norbornene in water was used. A solution of 66 g of norbornene in 14 ml of *n*-heptane was added slowly to 630 ml of water, containing 3.5 ml of Tergitol NP-14 and 1.5 ml of Triton X-405, with rapid stirring in a home blender. Stirring was continued for several minutes. The emulsion, which was stable for about 24 h, was added simultaneously with ozone to water in the reactor. The ozonization product formed was soluble in water.

Oxidations

The hydrogen peroxide oxidations of norbornene ozonization products were carried out as described by Perry (3). The air oxidations were performed by adding 85% formic acid (100 ml per 0.1 mole norbornene) to the ozonization solution, and then bubbling air (0.5 l/min) through the well-stirred, heated mixture (70–80° water bath) for 10 to 14 h. During this time the alcohol, if used as ozonization medium, was allowed to slowly evaporate. To maintain constant volume, the solvent loss was replenished by adding additional 85% formic acid. Finally, the solvents were removed *in vacuo* at 70 to 80° to give a residue suitable for chromatographic analysis.

Infrared Spectra of Acids

Characteristic absorption bands for *cis*-1,3-cyclopentanedicarboxylic acid (Nujol mull) were found at 7.76 (s), 8.01 (m), 8.25 (m), 9.78 (w), and 10.32 (w) microns. The *trans* acid has characteristic absorption bands at 8.17 (s) and 8.79 (w) microns. The absorption spectra of the *trans* acid in a Nujol mull containing water changed, particularly in the 10.3 to 11.3 micron region associated with the acid OH groups. Under these conditions, the *cis*-acid spectrum was unchanged. Apparently hydrogen bonding occurred with the *trans* acid but not with the *cis* acid which is internally bonded (4).

Equilibration of Acids

A solution of 3.0 g of *cis*-1,3-cyclopentanedicarboxylic acid in 60 ml of 20.2% hydrochloric acid was refluxed for 112 h at 110°. The solvent was removed *in vacuo* at room temperature, and the residue was analyzed by chromatography. The *cis/trans* ratio was 1.00:1.00. Similarly, a mixture of 2.7 g of the *trans* acid and 0.5 g of the *cis* acid was refluxed with 60 ml of 20.2% hydrochloric acid for 112 h. The *cis/trans* ratio in the product was 1.04:1.00 according to chromatographic analysis. A solution of 10 g of the *cis* acid in 85% formic acid was heated at 85° for 28 h while air was bubbled through at about 0.5 l/min. Solvent was removed *in vacuo* at 80°. The residue, analyzed chromatographically, showed the presence of less than 1% *trans* isomer.

Chromatographic Analysis

A detailed description of the chromatographic procedure has been published (4).

THE CHEMICAL SHIFT OF THE HYDROXYL PROTON OF PHENOLS IN DIMETHYL SULFOXIDE

Robert J. Ouellette

The effect of ring substituents on the spectral properties of phenols has been examined by several groups of workers (1). The infrared stretching frequency of the phenolic hydroxyl group has been shown to vary linearly with σ^- values for 4-substituents in both the simple series and the 2,6-di-*t*-butyl series (2). The identical ρ has been found for both series. The effect of substituents on the nuclear magnetic resonance (n.m.r.) signal of the phenolic proton might also be expected to correlate with σ^- if the chemical shift is dependent on both inductive and resonance factors. However, the observed resonance signal represents a time average of all possible phenolic aggregates at the concentration under consideration. Therefore, it is necessary to extrapolate to infinite dilution in order to obtain the chemical shift of a definable species: that of the monomeric phenol. Dilution studies on phenols have led to inconclusive results as the extrapolated values of the chemical shifts are closely similar and only a trend with σ is noted (3). The reason for this lack of a correlation is unknown at present. The introduction of bulky substituents

in the ortho positions, such as exists in 2,6-di-*t*-butyl-*p*-cresol, leads to a stabilized resonance signal which is independent of concentration (4). It has been shown that the effect of substituents in the 4-position on the hydroxyl resonance signal of 4-substituted 2,6-di-*t*-butyl phenols is proportional to σ^{-1}. The necessity of utilizing bulky groups to stabilize the hydroxyl resonance signal can be avoided by employing a solvent which serves as a good hydrogen acceptor. Phenolic aggregates can be eliminated with a hydrogen acceptor, and the resultant resonance signal will reflect the effect of substituents on the phenol ring. Dimethyl sulfoxide is utilized in this study to stabilize the hydroxyl resonance (5).

EXPERIMENTAL

Dimethyl sulfoxide (Crown Zellerbach) was distilled from calcium hydride under reduced pressure and stored over Linde molecular sieves. Uptake of atmospheric moisture was reduced by working under a nitrogen atmosphere in the preparation of samples. All phenols utilized in this study were available in this laboratory.

The solutions were approximately 1 mole % in phenol. The hydroxyl resonance signal was independent of concentration in the 0.005 to 0.02 mole fraction range. All spectra were obtained on a Varian A-60 spectrometer. The probe temperature was maintained at 40°. All resonances appeared at lower field than the 221 c.p.s. low field C_{13}—H satellite of dimethyl sulfoxide. The satellite was utilized as the internal standard and the τ values for the hydroxyl resonances were calculated in the standard manner.

*The τ values were calculated utilizing the 221 c.p.s. low field C_{13}—H satellite of dimethyl sulfoxide as the internal standard.

RESULTS AND DISCUSSION

The positions of the hydroxyl resonance signals of 22 phenols, expressed in τ values, are given in Table I. The correlation between the observed resonance signals and σ^- values (6) is represented in Graph 1. The range of hydroxyl resonances is much larger than that observed from dilution work (3). The calculated ρ is 1.29. This value is higher than that of 0.73 which was obtained for the 4-substituted 2,6-di-*t*-butylphenols.* The sensitivity of the infrared stretching frequencies (2) of both the simple and the hindered series of 4-substituted phenols indicates that the hydroxyl group is coplanar with the aromatic nucleus. Furthermore, the use of σ^- in the correlation of the hydroxyl resonance signals of the hindered phenols also suggests that the hydroxyl group is coplanar with the

**The ρ was calculated from the data in ref. 1.*

aromatic nucleus. The enhanced sensitivity of substituents on the hydroxyl resonance signals in this study, therefore, must be a reflection of the effect of solvent. The phenolic hydrogen must be effectively bonded to dimethyl sulfoxide. That a specific hydrogen bonded species is present in solution is supported by the absence of a concentration dependence of the resonance signal. Therefore, phenols in dimethyl sulfoxide more closely resemble an ionizing process in which the effect of substituents on the developing charge is reflected.

I

and methionine-methyl-^{14}C (1, 2) have shown that the ring structure is not derived from acetate and, in particular, that the tropolone ring is not synthesized in a similar manner to stipitatic acid (3). Acetate-1-^{14}C was incorporated into the N-acetyl group while methionine-methyl-^{14}C was incorporated into the O-methyl positions only. Further experiments have ascertained that the A ring and carbon atoms 5 and 6 of the B ring are derived from phenylalanine (4, 5) but not tyrosine (2). The non-equivalence of phenylalanine and tyrosine suggested that ring A and carbons 5, 6, and 7 were derived from a C_6—C_3 fragment via the cinnamic acid pathway. The results of Battersby and co-workers (6) with phenylalanine-1-^{14}C and cinnamate-3-^{14}C have shown this hypothesis to be correct. In the same paper, the incorporation of tyrosine-3-^{14}C into the tropolone ring of colchicine is reported. Additional experiments with tyrosine-3-^{14}C (7) indicated that colchicine elaborated under these conditions was specifically labelled at position 12.

The present investigations using ornithine-2-^{14}C and methanol-^{14}C were an attempt to ascertain whether the tropolone ring of colchicine might possibly be derived from ornithine, as in the tropane alkaloids (8, 9), and a three-carbon fragment not derived directly from acetate. Ornithine was considered as a remote possibility in the ring-C synthesis since at the time these experiments were conducted no positive results had been reported regarding the biosynthetic pathway for the elaboration of the tropolone ring in colchicine. The feeding experiments with cinnamate-3-^{14}C were performed prior to the publication of Battersby and co-workers (6) and substantiate their results. Table I is a summary of the incorporation data for the administered tracers. The low incorporation of label from ornithine-2-^{14}C conclusively indicates that this amino acid is not a precursor of colchicine. Table II presents the specific activities of the degradation products of colchicine derived from the cinnamate-3-^{14}C and methanol-^{14}C feeding experiments. Colchicine was labelled only in the O-methyl groups by methanol-^{14}C and in the case of cinnamate-3-^{14}C, the label appeared at C_5 as was found by Battersby and co-workers (6). The specific incorporation of methanol-^{14}C was high and is presumed to be mediated by the established one-carbon metabolic pathway involving L-methionine and S-adenosylmethionine (10).

EXPERIMENTAL

Aqueous solutions of the tracers were administered via wicks to *Colchicum autumnale* corms during the vegetative stage of the plants. Ten plants each were used for the cinnamate and ornithine feedings while two plants were used for the methanol experiment. The plants were fed over a 10 day period and stored at −20 °C after 14 days. Colchicine was isolated from the plant tissue using a method described by Leete (5). Radioactive samples were counted in duplicate using either a Nuclear Chicago Model 725 liquid scintillation spectrometer or a Tracerlab Mylar window continuous gas flow counter. Allowance was made for a counting error of 5% or less in each determination.

The radioactive colchicine was diluted with cold material to the specific activities indicated in Table II before degradation. Degradation of the colchicine was performed using previously described methods (1, 4).

									No carbonyl compounds	

*Commercial carbon monoxide contained about 1% hydrogen.
†Melting point 158–159°; mixed melting point with authentic sample (3) was 157–159°.
‡Melting point 218–220°; mixed melting point with authentic sample (9) was 218–220°.

might be expected to undergo ring closure to afford six- and seven-membered heterocyclic substances.

Reaction of 1,3-diphenyl-2-propanone oxime with commercial carbon monoxide (containing about 1% hydrogen) under conditions similar to those used in the synthesis of 3-phenylphthalimidine from benzophenone oxime (1) gave 2-formamido-1,3-diphenylpropane (15% yield) and N,N^1-di(1,3-diphenylisopropyl) urea (20%), identified by direct comparison with authentic samples. These products were accompanied by traces of three different crystalline substances exhibiting carbonyl stretching frequencies in their infrared spectra, possibly indicating that some cyclization had occurred. When the mole ratio of hydrogen to substrate was increased to 3:1, as shown in experiment 2, then the yield of the formamide was doubled and in addition, di(1,3-diphenylisopropyl) amine was produced in 39% yield (no primary amine (2) was produced). Application of the same reaction to 4-phenyl-2-butanone oxime (experiment 3) gave 2-formamido-4-phenylbutane (identified by direct comparison with an unambiguously synthesized authentic sample (4)) and di(4-phenyl-2-butyl) amine.

It is probable, as shown in reaction sequences [1] and [2], that the primary amine (II) was the precursor of the formamide (III), and the former compound also condensed with the imine intermediate (I) to yield the intermediate imine (IV) which subsequently was reduced to yield the secondary amine (V). Evidence for these reactions exists in the recent literature (5, 6).

[1] $$(PhCH_2)_2C{=}N{-}OH \xrightarrow[-H_2O]{H_2} \underset{I}{\left[(PhCH_2)_2C{=}NH\right]} \xrightarrow{H_2} \underset{II}{(PhCH_2)_2CHNH_2}$$

$$\downarrow CO$$

$$\underset{III}{(PhCH_2)_2CHNHCHO}$$

[2] $$I + II \xrightarrow[-NH_3]{} \underset{IV}{\left[(PhCH_2)_2C{=}NCH(CH_2Ph)_2\right]} \xrightarrow{H_2} \left[\underset{V}{(PhCH_2)_2CH}\right]_2NH$$

Since the products from the aralkyl ketone oximes were markedly dependent on the mole ratio of hydrogen to substrate, we re-investigated the direct cyclization of benzophenone oxime with carbon monoxide containing various quantities of hydrogen. Treatment of 1 mole of benzophenone oxime with 1.5 moles of hydrogen and 30 moles of carbon monoxide yielded mainly diphenylmethane and about 5% of 3-phenylphthalimidine. Further increase in the mole ratio of hydrogen caused complete elimination of 3-phenylphthalimidine.

In the reaction of 2-ethoxy-1-naphthaldehyde oxime with commercial carbon monoxide, ring closure to the 8-position was expected since the 2-position was blocked. However, no cyclization occurred. From these results, as well as those of other workers (7), evidently only five-membered heterocycles can be formed in significant yields from aromatic compounds containing the C=N group.

EXPERIMENTAL

General Considerations

These have been described previously (1, 8).

Reaction of 1,3-Diphenyl-2-propanone Oxime with Commercial Carbon Monoxide

Chromatographic separation of the product on alumina afforded the compounds shown in experiment 1, Table I, and compounds A, B, and C.

Compound A (1% yield) was recrystallized from ethanol, m.p. 197–198°.

Anal. Calcd. for $C_{16}H_{13}NO$: C, 81.62; H, 5.57; N, 5.95. Found: C, 81.63; H, 5.84; N, 6.01.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Infrared spectrum of compound A (KBr): 1 665(S), 1 640(S). Nuclear magnetic resonance (given in δ units; spectrum obtained in deuterated chloroform): 3.09 (singlet, area = 2H), 6.25 (singlet, area = 1H), 7.4 (multiplet, area = 8H), and 8.4 (doublet, area = 1H). A possible structure for compound (A) is 3-benzyl-1-isoquinolone.*

Compound B (about 2% yield) was recrystallized from ethanol, m.p. 275–276°. Anal. Found: C, 81.28; H, 5.73; N, 8.58; O, 4.90. The infrared spectrum of compound B showed a strong carbonyl peak at 1 675 cm^{-1}; its ultraviolet spectrum exhibited a peak at 270 mμ. A possible molecular formula for compound (B) is $C_{22}H_{18}N_2O$.

Compound C (2% yield) was recrystallized from chloroform, m.p. 233–234°. Anal. Found: C, 71.12, H, 5.17; N, 8.94. The infrared spectrum showed a strong peak at 1 720 cm^{-1}. A possible molecular formula for compound (C) is $C_{19}H_{16}N_2O_3$.

Reaction of 1,3-Diphenyl-2-propanone Oxime with Carbon Monoxide and Hydrogen to Yield Di(1,3-diphenyl-isopropyl) amine and 2-Formamido-1,3-diphenylpropane

The following compounds were obtained:

(1) Di(1,3-diphenylisopropyl) amine (isolated as the hydrochloride and recrystallized from ethanol), m.p. 245–246°.

Anal. Calcd. for $C_{30}H_{32}NCl$; C, 81.60; H, 7.25; N, 3.17. Found: C, 81.58; H, 7.48; N, 3.01.

(2) 2-Formamido-1,3-diphenylpropane, m.p. 88–89°; mixed melting point with authentic sample (2) m.p. 88–89°, 88–89°; n.m.r. (in $CDCl_3$): 7.8 (CHO, area = 1H), 7.28 (aromatic H, area = 10H), 6.28 (NH, area = 1H), 4.38 (N—CH, area = 1H), 2.88 (CH_2, area = 4H).

Reaction of 4-phenyl-2-butanone Oxime with Carbon Monoxide and Hydrogen to Yield 2-Formamido-4-phenyl-butane and Di(4-phenyl-2-butyl) amine

Work-up of the product by alumina chromatography afforded compounds (A) and (B). Treatment of compound (A) with anhydrous hydrogen chloride in ether yielded 1.7 g of di(4-phenyl-2-butyl) amine hydrochloride which was recrystallized from ethanol, m.p. 198–199°.

Anal. Calcd. for $C_{20}H_{28}NCl$: C, 75.53; H, 8.88; N, 4.42. Found: C, 75.13; H, 8.68; N, 4.37.

Compound (B) was directly compared with an unambiguously synthesized authentic sample of 2-formamido-4-phenylbutane (4) and shown to be the same. Infrared spectrum of compound (B): 3 250(S), 3 020(m), 2 900(S), 2 840 (m), 1 655(s), 1 600(W). Nuclear magnetic resonance (in $CDCl_3$): 8.8 (CHO, area = 1H), 7.5 (NH, area = 1H), 7.1 (aromatic H, area = 5H), 4.8 (C—C—H, area = 1H), 2.68 (CH_2, area = 2H), 1.88 (CH_2, area = 2H), 1.18 (CH_3, area = 3H).

Reaction of 2-Ethoxy-1-naphthaldehyde Oxime with Carbon Monoxide and Hydrogen

2-Ethoxy-1-naphthaldehyde oxime (5 g) was allowed to react with 2 000 p.s.i. of commercial carbon monoxide in the presence of dicobalt octacarbonyl (1.2 g) at a temperature of 235° for 2.5 h. The product (freed of catalyst) contained no cyclic carbonyl group.

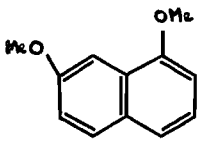
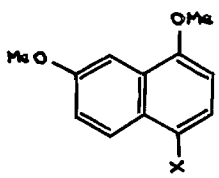
SUR LES PRODUITS DE SUBSTITUTION DU DIMÉTHOXY-1,7 NAPHTALÈNE

JEAN-CLAUDE RICHER ET CLAUDE LAMARRE

Au cours d'une étude récente, Bell et Buck (1) ont rapporté que la nitration du diméthoxy-1,7 naphtalène (I) conduit au diméthoxy-1,7 dinitro-4,8 naphtalène (III*a*) alors que la bromuration de I conduit à un mélange de dibromo-2(?),4(?) et de dibromo-4,8 diméthoxy-1,7 naphtalènes (IV et III*b*). Ces travaux ont été repris; des produits de disubstitution dont les propriétés physiques correspondent à celles rapportées ont été obtenus. De plus les produits de monosubstitution II*a* et II*b* ont pu être isolés en utilisant des conditions expérimentales ménagées.

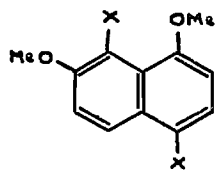


I



II a) X = NO_2

b) X = Br



III a) X = NO_2

b) X = Br

Les spectres de résonance magnétique nucléaire (r.m.n.) de ces divers dérivés ont été examinés et les caractéristiques spectrales résumées au Tableau I ont permis d'en établir la structure.

TABLEAU I

Déplacements chimiques des protons aromatiques*

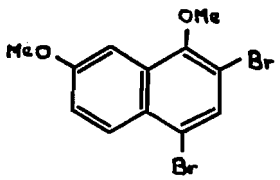
Diméthoxy-1,7 naphtalènes	H_2	H_3	H_5	H_6	H_8
Nitro-4[b] (II*a*)	7.11 (8.7)	8.26 (8.7)	8.57 (9.3)	7.63	7.44 (1.7)
Dinitro-4,8[b] (III*a*)	7.37 (8.5)	8.38 (8.5)	8.82 (9.5)	8.08 (9.5)	—
Bromo-4[a] (II*b*)	6.62 (8.3)	7.53 (8.3)	8.06 (9.3)	7.26	7.56 (2.8)
Dibromo-2,4[a] (IV)	—	7.72 (singulet)	8.04 (9.2)	7.16	7.34 (2.6)
Dibromo-3,4[a] (V)	6.95 (singulet)	—	8.10 (9.4)	7.17	7.47 (2.7)

*Les spectres r.m.n. ont été déterminés à l'aide d'un appareil Varian A-60 pour des solutions dans le chloroforme deutéré (produits marqués *a*) ou la diméthylacétamide (produits marqués *b*) suivant la technique décrite par Wells (4). Les déplacements chimiques ont été mesurés par rapport au benzène utilisé comme standard interne et sont rapportés en p.p.m. (échelle δ et tétraméthylsilane utilisé comme zéro). Les valeurs entre parenthèses indiquent les constantes de couplage entre protons ortho (H_2 vs. H_3, H_5 vs. H_6) ou les protons méta (H_6 vs. H_8). Ces constantes sont exprimées en c.p.s.

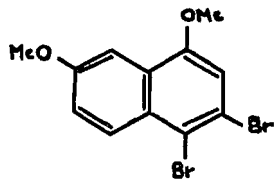
1. Les spectres r.m.n. des produits de monosubstitution correspondent à la superposition des éléments d'un système AB sur un système ABX et sont cohérents avec les structures II*a* et II*b* attendues.
2. Le spectre r.m.n. du dérivé dinitré comporte deux paires de doublets (J = 8.5 et J = 9.5 c.p.s.) et confirme la structure III*a* proposée (1) pour ce dérivé.
3. La structure IV proposée mais non prouvée (1) pour le dérivé dibromé de point de fusion 67.5° est confirmée par r.m.n. Le spectre comporte en effet un singulet (H_3) superposé aux éléments d'un système ABX (H_5, H_6 et H_8).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

4. Pour le dérivé dibromé p.f. 124–126°, la r.m.n. suggère la structure V au lieu de la structure III*b* proposée (1). Le spectre de ce dérivé montre en effet *un* et *un seul* singulet (H_2) superposé aux éléments d'un système ABX. A cause de la proximité du groupe méthoxy, la position du singulet correspondant à l'hydrogène (H_2) est déplacée vers les champs magnétiques plus élevés par rapport au singulet (H_3) du dérivé IV.



IV



V

La formation des dérivés dibromés IV et V n'était pas prévue considérant que l'introduction d'un atome de brome sur un cycle devrait avoir tendance à désactiver ce cycle et prévenir l'introduction d'un substituant sur le même cycle. La formation prépondérante de IV indique que la désactivation du cycle A par l'introduction d'un atome de brome en position 4 n'est pas grande; la formation de V en quantités mineures n'est plus alors aussi surprenante si l'on considère les effets combinés du méthoxy en position 7 qui active légèrement les réactions en position *amphi* (position 3) et du brome en position 4 qui "oriente" les substitutions vers la position 3.

PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés en tubes capillaires ouverts au moyen d'un thermomètre étalonné avec des substances pures de points fusion connus. Les chromatographies ont été réalisées selon la méthode de Stahl (2) à l'aide de couches de 250 microns de Silcia gel G. Les chromatogrammes ont été développés à l'aide de benzène ou d'éther de pétrole 60–110. La présence des taches est révélée à l'aide d'une lampe ultraviolette. Les analyses sont de C. Daesslé, Organic Microanalysis, Montréal.

Diméthoxy-1,7 nitro-4 naphtalène (IIa)

L'action de l'acide nitrique sur I selon le processus expérimental de Thomson *et al.* (3) conduit avec un rendement de 69% au dérivé II*a*, p.f. 127–128°; R_f 0.75 (benzène).

Anal. Calc. pour $C_{12}H_{11}NO_4$: C, 61.80; H, 4.75; N, 6.01. Trouvé: C, 61.84; H, 4.96; N, 6.02.

Diméthoxy-1,7 dinitro-4,8 naphtalène (IIIa)

La dinitration de I selon les indications de Bell et Buck (1) ou de Thomson *et al.* (3) conduit toujours au même dérivé III*a*, p.f. 213° (litt. (1) 209°); R_f 0.49 (benzène).

Bromo-4 diméthoxy-1,7 naphtalène (IIb)

L'action de 1 mole de brome en solution dans le chloroforme sur 1 mole de I fournit avec un rendement de 71% le dérivé monobromé II*b*, p.f. 71°; R_f 0.44 (éther de pétrole).

Anal. Calc. pour $C_{12}H_{11}O_2Br$: C, 53.93; H, 4.15; Br, 29.93. Trouvé: C, 53.84; H, 4.15; Br, 29.57.

Dibromo-2,4 et dibromo-3,4 diméthoxy-1,7 naphtalènes IV et V

La méthode de Bell et Buck (1) est fidèlement suivie et les deux dérivés attendus (IV et V) sont obtenus. Le dibromo-2,4 diméthoxy-1,7 naphtalène (IV) fond à 67.5° (litt. (1) 65–67°); R_f 0.45 (éther de pétrole). Le dibromo-3,4 diméthoxy-1,7 naphtalène (V) fond à 127° (litt. (1) 124–126°); R_f 0.48 (éther de pétrole).

PHOTOCHEMICAL SYNTHESIS OF VINYLTHIOLS

O. P. Strausz, T. Hikida, and H. E. Gunning

Vinyl mercaptan and its simple derivatives, like the vinyl alcohols, were assumed to be unstable until quite recently, although occasional references in the patent literature (1) can be found to their alleged preparation. It was only last year that Stacey and Harris (2) reported the first successful synthesis through the X-ray-induced chain addition of H_2S to various substituted acetylenes. These authors described the preparation of five compounds: 1-propene-1-thiol, 2-butene-2-thiol, 3,3,3-trifluoropropene-1-thiol, hexafluoro-2-butene-2-thiol, and 2-phenylethene-1-thiol. Vinyl mercaptan itself, however, was not mentioned.

Our interest in vinylic mercaptans arose from the fact that we have found them to be a major product of the reaction of singlet D sulfur atoms with olefins (3). Thus with ethylene, vinyl fluoride, 1,1-difluoro ethylene, propylene, and isobutylene as substrates the corresponding vinylic mercaptan comprises ca. 10–45% of the condensable fraction of the reaction products.

In the present communication, however, we would like to report the synthesis of vinyl mercaptan and 1-propene-1-thiol by another photochemical route, namely the ultraviolet light induced chain addition of H_2S to the corresponding acetylene. Thus when H_2S admixed with acetylene or methyl acetylene, in the liquid phase at −78 °C, in a quartz or Vycor 7910 reaction cell, was exposed to the unfiltered radiation of a medium pressure mercury arc, CH_2:CHSH and CH_3CH:CHSH were respectively formed in good yields. Minor products were H_2, polymer, CS_2, the saturated mercaptan, and possibly some olefins and dithiols. The reaction proceeds in the gas phase as well at room temperature, but with a much smaller yield. In addition secondary processes set in at an earlier stage in the gas-phase reactions.

The reaction mechanism is represented by the familiar scheme:

$$[1] \quad H_2S + h\nu \rightarrow H + SH,$$

$$[2] \quad RC{\equiv}CH + SH \rightarrow R\dot{C}{=}CHSH,$$

$$[3] \quad R\dot{C}{=}CHSH + H_2S \rightarrow RHC{=}CHSH + SH,$$

$$[4] \quad R\dot{C}{=}CHSH + SH \rightarrow RCSH{=}CHSH,$$

$$[5] \quad 2SH \rightarrow H_2S_2,$$

$$[6] \quad 2R\dot{C}{=}CHSH \rightarrow (RC{=}CHSH)_2,$$

$$[7] \quad H + H_2S \rightarrow H_2 + SH,$$

$$[8] \quad H + RC{\equiv}CH \rightarrow RH_2\dot{C}_2,$$

$$[9] \quad RH_2\dot{C}_2 + H_2S \rightarrow RH_3C_2 + SH.$$

The competition between steps [2] and [3] on one hand and [4], [5], and [6] on the other is largely responsible for the observed difference in yield in the gas and liquid phase reactions.

Product identifications were performed by infrared, nuclear magnetic resonance (n.m.r.), and mass spectrometric analyses on the gas chromatographically refined products.

TABLE I

The mass spectra of 1-propen-1-thiol and vinyl mercaptan compared to those for the isomeric episulfides*

	Relative intensity			Relative intensity	
m/e	Propenethiol	Propylene sulfide	*m/e*	Vinyl mercaptan	Ethylene sulfide

27	11.8	12.6			
26	4.9	5.7			
15	3.0	3.8			

*The spectra were obtained on a Metropolitan-Vickers Model MS-2 spectrometer at 70 eV.

The mass spectra of the two mercaptans in comparison with the isomeric episulfides are given in Table I. It can be seen from the data that while the cracking patterns for the two types of compounds are quite similar, the mercaptans show a greater tendency for the vinylic split, $(RHC{=}CH)^+ + SH$, as evidenced by their higher mass ratios 27/60 and 41/74 for the C_2 and C_3 compounds respectively.

The infrared spectrum (in CCl_4) of the vinyl mercaptan showed strong absorption at 1 580 cm^{-1} (—C=C—) and the characteristic SH absorption at 2 580 cm^{-1}. The corresponding absorption bands for the propene-1-thiol appeared at 1 620 and 2 590 cm^{-1} respectively.

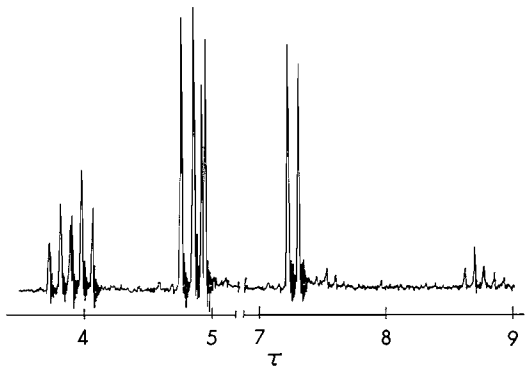

FIG. 1. The n.m.r. spectrum of vinylmercaptan in a CCl_4 solution. The weak resonances at τ = 8.6–9 are probably due to the trimer of the tautomeric thio-acetaldehyde.

The n.m.r. spectrum of vinyl mercaptan, shown in Fig. 1, as obtained in a CCl_4 solution using TMS as a standard gave a doublet in the SH resonance region at τ-values of 7.2 and 7.3, a quartet in the terminal $=CH_2$ region at τ-values of 4.72, 4.82, 4.90, and 4.84. A multiple $=CH_2$ resonance centered on a τ-value of 3.90 also appeared.

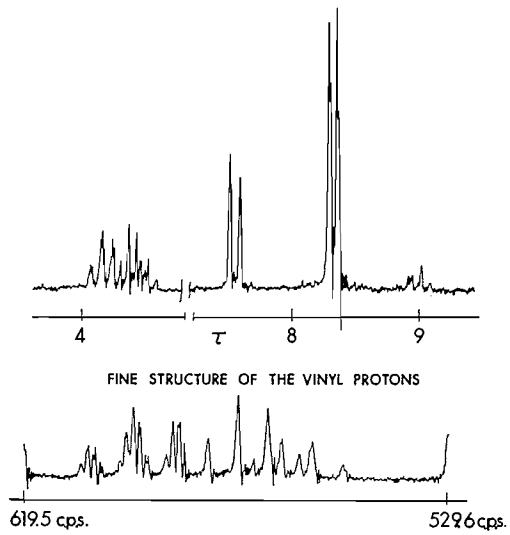

FIG. 2. The n.m.r. spectrum of 1-propene-1-thiol in CCl_4 solution. The weak signals centered at τ-value of 9 are probably due to the trimer of the tautomeric thio-propionaldehyde.

Similarly the n.m.r. spectrum of the propene-1-thiol, given in Fig. 2, showed a poorly resolved double doublet in the CH_3 resonance region at τ-values of 8.34 and 8.28, while the SH resonances appeared at τ-values of 7.59 and 7.51. The multiplet for vinyl protons was found centered at a τ-value of 4.3. The spin–spin coupling between the two vinylic protons is 9.1 c.p.s., an order of magnitude larger than would be expected for terminal vinyl protons. Consequently the structure must be 1-propene-1-thiol. Furthermore, the fine structure of the vinylic proton multiplet at τ = 4.3 indicates that of the two possible geometrical isomers only one is present; that is, one of the two vinyl doublets is split to

For personal use only.

a quadruplet–quintuplet–quadruplet configuration through coupling to the SH and CH_3 protons, while the other gives two overlapping quadruplets through coupling to the methyl protons. The integrated peak areas were in the right proportion in each spectrum.

Both the infrared and n.m.r. spectra of the propene-1-thiol agree in the main with those reported by Stacey and Harris. One significant difference, however, is that according to the n.m.r. data the 1-propene-1-thiol obtained here consists of only one geometrical isomer, while Stacey and Harris (2) obtained a mixture of the *cis* and *trans* isomers. Now, Skell and Allen (4) have shown that the radical-chain addition of HBr to methyl acetylene is a stereospecific process. At higher conversions, however, the Br atom catalyzed *cis* → *trans* isomerization of the 1-bromo-1-propene product occurs readily, leading to equilibrium mixtures. In our experiment the conversion of methyl acetylene was 11%, while in Stacey and Harris' experiment it was 22% or greater and therefore it would appear that similar considerations apply to the H_2S—C_2H_2 system as was found for the HBr addition reaction (4).*

Both thiols synthesized here are colorless liquids with the characteristic mercaptan odor. They readily undergo polymerization on standing at room temperature to colorless oils and (or) white solids. There is no evidence for isomerization to the episulfide structure but a slow tautomeric conversion to the corresponding thio-aldehydes is probable (5).

EXPERIMENTAL

A cylindrical quartz reaction vessel, 5 cm in diameter and 2 cm in length was used for the liquid phase reactions. It was immersed in a dry ice–acetone bath with the liquid level in the cell below that of the coolant. Irradiation was effected through the flat window of the cell above the bath by a Hanovia, model 30620, medium-pressure mercury arc, positioned ca. 10 in. above the cell. To prevent warming of the cell by infrared emission from the lamp, a quartz plate was interposed between the cell and lamp.

Several runs were done on both systems under slightly different conditions, a representative example of which will be given below.

$CH_3C{\equiv}CH + H_2S$

Liquid methyl acetylene (5 ml) and 15 ml of liquid H_2S was introduced to the above cell and irradiated for 20 min. The noncondensable product, hydrogen, which amounted to 0.065 mmoles was removed at −196 °C. After distilling off the excess reactants at −98 °C, 0.6 ml of liquid remained. This could be distilled at −64 °C, with only a small amount of oily residue remaining. The volatile fraction was then transferred to the sample tube of a gas chromatographic unit by *in vacuo* distillation and analyzed on an 8 ft tricresylphosphate-on-firebrick column at 35 °C. The separated components were trapped from the gas chromatographic effluents and collected for identification. In addition to traces of substrates dissolved in the product three components appeared on the chromatogram. The first peak, a C_4H_6 hydrocarbon, which was an impurity in the methylacetylene, eluted in 5.2 min from the column, the second, CS_2, in 8.0 min, and the third peak, the propene-1-thiol, in 12.3 min. The composition for the whole sample in peak area percentage was: C_4H_6 (12%), CS_2 (1%), and $CH_3CH{=}CHSH$ (87%).

Thus, the total yield of the propenethiol, assuming a density of 0.8 g ml^{-1}, is about 0.4 g or 5×10^{-3} mole. From the lamp characteristics (140 W input, max 2 W output in the H_2S-absorbing region, i.e. $\lambda < 3\,000$ Å) and the geometrical arrangement of the cell-lamp assembly, the quantum yield may be estimated to be in the order of 100.

$C_2H_2 + H_2S$

The experiments with acetylene were carried out as with methyl acetylene, but here the whole cell was immersed in the cooling bath to minimize the danger of explosion. Since acetone absorbs strongly below $\lambda = 3\,000$ Å the yields were generally lower than with methyl acetylene. Also the acetylene to hydrogen sulfide ratio had to be kept low, $\leqslant$ 1:10 by liquid volume, although no explosion occurred in one run with a volume ratio of 1:5. On the other hand with 1:1 mixtures, explosion resulted on irradiation.

In a 1.5 h irradiation of a 1:5 $C_2H_2H_2S$ mixture with a total volume of 18 ml, 1.0 ml of liquid remained after the excess reactants were distilled off at −130 °C. This was distilled at −64 °C and analyzed by gas

**Note added in proof: Drs. F. W. Steacey and J. F. Harris of DuPont (ref. 2) have kindly informed us that further n.m.r. studies of their propene-1-thiol have shown the compound to be a single isomer, probably the trans, rather than a mixture of cis and trans as originally reported (2). Thus the apparent discrepancy between the two studies has been resolved.*

chromatography on the above column. Three peaks appeared on the chromatogram which were identified as C_2H_5SH (retention time 7.5 min), C_2H_3SH (9.2 min), and acetone (14.2 min). The acetone was an impurity in the acetylene. The vinyl mercaptan fraction was rerun on a 16 ft silicone-550 with 2% stearic acid on Kromat CE column which allowed the separation of the small amount of CS_2 present from the vinyl mercaptan. The percentage peak area composition of the 1 ml of liquid was: 62% acetone, 33% vinyl mercaptan, 4.5% C_2H_5SH, and 0.5% CS_2. A very small amount of nonvolatile oil was also formed.

The n.m.r. spectra were obtained on a Varian 100 Mc instrument.

ACKNOWLEDGMENT

We thank Mr. G. Bigam for the n.m.r. spectra. This work was supported by a grant from Imperial Oil Limited and the National Research Council of Canada.

DECOMPOSITION OF THE ETHYL RADICAL AND THE MECHANISM OF THE PYROLYSIS OF *n*-BUTANE

J. H. Purnell and C. P. Quinn

As a result of a detailed analytical study of the kinetics of formation of the products in the initial stages of the pyrolysis of *n*-butane we have offered support (1) for the homogeneous mechanism:

[1] $$\left.\begin{array}{l} C_4H_{10} \rightarrow C_2H_5\cdot + C_2H_5\cdot \\ C_4H_{10} \rightarrow CH_3\cdot + C_3H_7\cdot \end{array}\right\},$$

[2] $$C_4H_9\cdot \rightarrow C_2H_4 + C_2H_5\cdot,$$

[3] $$C_4H_9\cdot \rightarrow C_3H_6 + CH_3\cdot,$$

[4] $$C_2H_5\cdot + C_4H_{10} \rightarrow C_2H_6 + C_4H_9\cdot,$$

[5] $$CH_3\cdot + C_4H_{10} \rightarrow CH_4 + C_4H_9\cdot,$$

[6] $$H\cdot + C_4H_{10} \rightarrow H_2 + C_4H_9\cdot,$$

[7] $$C_2H_5\cdot \rightarrow C_2H_4 + H\cdot,$$

[8] $$\left.\begin{array}{l} C_2H_5\cdot + C_2H_5\cdot \rightarrow C_4H_{10} \\ C_2H_5\cdot + C_2H_5\cdot \rightarrow C_2H_4 + C_2H_6 \end{array}\right\}.$$

In order to explain several unusual features of the results, we proposed that the unimolecular decomposition of the ethyl radical [7] was in its pressure-dependent region under the conditions of our experiments. It has now been suggested (2) that an alternative interpretation of our results is possible. This alternative involves the assumption that the decomposition of the ethyl radical, [7], is strictly first order for the conditions of our study, and that a molecular process,

[M] $$C_4H_{10} \rightarrow C_2H_4 + C_2H_6,$$

DECOMPOSITION OF THE ETHYL RADICAL AND THE MECHANISM OF THE PYROLYSIS OF *n*-BUTANE

J. H. Purnell and C. P. Quinn

As a result of a detailed analytical study of the kinetics of formation of the products in the initial stages of the pyrolysis of *n*-butane we have offered support (1) for the homogeneous mechanism:

[1] $$\left.\begin{array}{l} C_4H_{10} \rightarrow C_2H_5\cdot + C_2H_5\cdot \\ C_4H_{10} \rightarrow CH_3\cdot + C_3H_7\cdot \end{array}\right\},$$

[2] $$C_4H_9\cdot \rightarrow C_2H_4 + C_2H_5\cdot,$$

[3] $$C_4H_9\cdot \rightarrow C_3H_6 + CH_3\cdot,$$

[4] $$C_2H_5\cdot + C_4H_{10} \rightarrow C_2H_6 + C_4H_9\cdot,$$

[5] $$CH_3\cdot + C_4H_{10} \rightarrow CH_4 + C_4H_9\cdot,$$

[6] $$H\cdot + C_4H_{10} \rightarrow H_2 + C_4H_9\cdot,$$

[7] $$C_2H_5\cdot \rightarrow C_2H_4 + H\cdot,$$

[8] $$\left.\begin{array}{l} C_2H_5\cdot + C_2H_5\cdot \rightarrow C_4H_{10} \\ C_2H_5\cdot + C_2H_5\cdot \rightarrow C_2H_4 + C_2H_6 \end{array}\right\}.$$

In order to explain several unusual features of the results, we proposed that the unimolecular decomposition of the ethyl radical [7] was in its pressure-dependent region under the conditions of our experiments. It has now been suggested (2) that an alternative interpretation of our results is possible. This alternative involves the assumption that the decomposition of the ethyl radical, [7], is strictly first order for the conditions of our study, and that a molecular process,

[M] $$C_4H_{10} \rightarrow C_2H_4 + C_2H_6,$$

plays a significant role in *n*-butane pyrolysis. Because reaction [7] seems likely to be involved in many organic pyrolyses, it is clearly essential to establish whether or not this recently proposed alternative mechanism is compatible with the experimental results we have already published. Three tests may be applied.

First, it may be observed that, unlike our original mechanism, the alternative does *not* predict that an inert gas would increase the production of ethylene at the expense of ethane. In our earlier paper, we included a diagram clearly demonstrating the occurrence of this effect.

A second test of the alternative mechanism lies in a study of the product ratio,

$$\beta = \frac{[C_2H_4] + [C_2H_6]}{[CH_4]}.$$

From the results already presented (1) it can be deduced that, at constant temperature, over the pressure range 12.5 to 151 mm Hg of *n*-butane, β is constant to $\pm 6\%$ at the 96% confidence limit. This result is entirely compatible with our original explanation but only compatible with the alternative mechanism if the molecular process [M] contributes less than 19% of the total C_2 products under these conditions. This maximum value is almost half the 33% contribution envisaged by Laidler *et al.* (2) in proposing the alternative mechanism.

Finally, a steady state treatment of the alternative mechanism composed of reactions [1]–[8] and [M], yields

$$\frac{1}{(\alpha - 1)[C_4H_{10}]} = \frac{k_4}{2k_7} + \frac{k_M}{2k_7}\sqrt{\frac{k_8}{k_1[C_4H_{10}]}}$$

where

$$\alpha = \frac{[C_2H_4]}{[C_2H_6]}.$$

If k_7 were independent of pressure, this result would demand linearity of a plot of $\{(\alpha - 1)[C_4H_{10}]\}^{-1}$ against $[C_4H_{10}]^{-1/2}$, with a finite and positive *y*-intercept and positive slope. Figure 1 illustrates such a plot formed from the experimental results presented in our earlier paper. It is clear that the data may be taken either to fall on a line of positive curvature passing through the origin or on a straight line of *negative* *y*-intercept. The first possibility is incompatible with the alternative mechanism while the latter, absurdly, implies a negative rate constant. In contrast, our original interpretation (1) gives an excellent quantitative description of these same results.

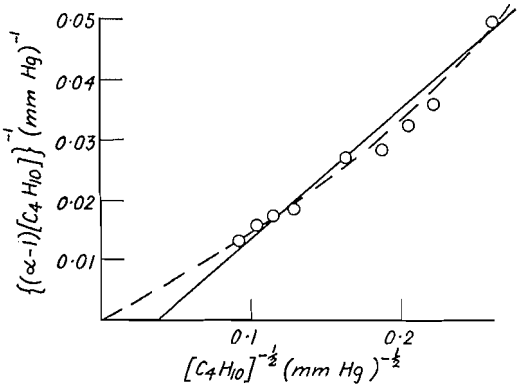

FIG. 1. Experimental values of $\{(\alpha - 1)[C_4H_{10}]\}^{-1}$ as a function of $[C_4H_{10}]^{-1/2}$ for *n*-butane pyrolysis at 518 °C.

These considerations confirm us in the view, which we have already expressed (3), that no molecular processes are important in *n*-butane pyrolysis. The suggested alternative mechanism does *not*, therefore, describe our experimental results, and we are forced, again, to the conclusion that the unimolecular decomposition of the ethyl radical is pressure dependent in the conditions of many organic pyrolyses. Confirmation of this view comes from recent work on ethane pyrolysis (4, 5), and from preliminary studies of hydrogen atom addition to ethylene in titration flow experiments (6).

AROMATIC SUBSTITUTION

PART VIII.[1] SOME ASPECTS OF THE MECHANISM OF THE TSCHITSCHIBABIN REACTION[2]

R. A. ABRAMOVITCH, F. HELMER, AND J. G. SAHA

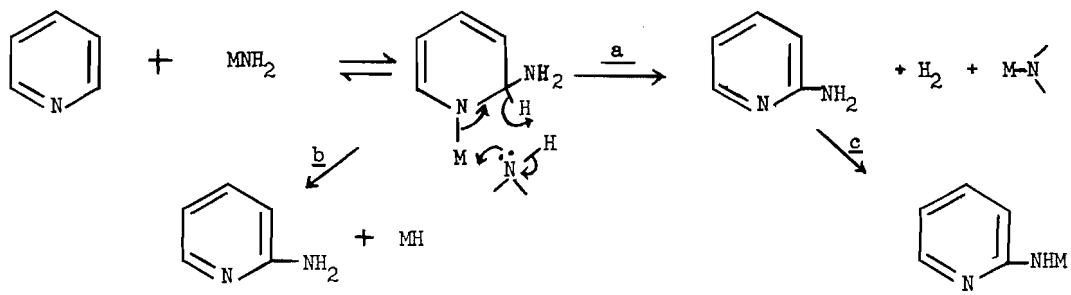
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received October 16, 1964

ABSTRACT

The mechanism of the direct amination of pyridines is discussed in terms of both addition–elimination and elimination–addition pathways. The absence of deuterium kinetic isotope effects as well as the orientations observed in such reactions rule out the intervention of 2,3- or 2,6-dehydropyridines. The effect of a 3-methyl group upon the reactivities towards the amide ion of the various nuclear positions in pyridine has been determined. Predictions based on molecular orbital (m.o.) calculations are discussed in terms of the detailed mechanism of this reaction and of the orientations observed.

The direct amination of pyridine and its derivatives by means of alkali metal amides—the Tschitschibabin reaction—was, until recently, thought to involve a two-step addition–elimination process with the formation of a σ-complex (1–3). The mechanism proposed which accounts for the evolution of hydrogen (path *a*) is illustrated in Scheme 1 (4). An alternative, and probably competing, pathway is the thermal decomposition mode *b*, which would be rendered more facile [as is observed (2)] by the presence of



SCHEME 1.

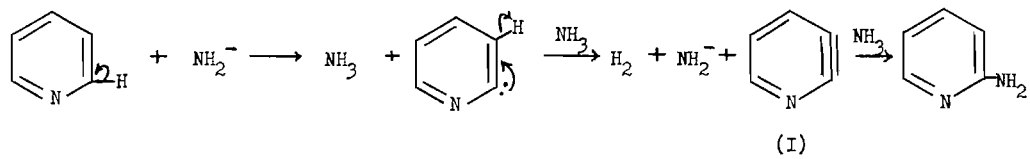
oxidizing agents such as potassium nitrate (elimination of MOH instead of MH). Ammonia could be formed in step *c* which would also lead to the pyridyl-substituted alkali metal amide which, in turn, could attack pyridine to give the 2,2′-dipyridylamines sometimes observed in such reactions (2).

[1]*Part VII. R. A. Abramovitch and Choo-Seng Giam. Can. J. Chem. 42, 1627 (1964).*

[2]*Part of this work has been published in preliminary form (R. A. Abramovitch, F. Helmer, and J. G. Saha, Chem. Ind. London, 659 (1964)).*

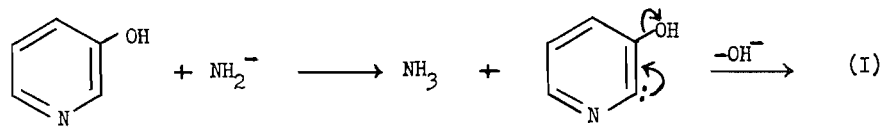
In general, attack at C_2 of the pyridine nucleus is usually observed if this position is vacant. If substituents are present at both C_2 and C_6 then the amide ion enters at the 4-position. Some attack at C_4 leading to 4-aminopyridine was also observed with pyridine itself under forcing conditions (1, 2). When pyridine is heated at 80–130° with sodium in toluene in the presence of ammonia, a mixture of 2-amino- and 4-amino-pyridine is said to be formed together with some 4,4′-dipyridyl (5). Formation of the latter from pyridine and sodium metal is unexceptional (4).

On the other hand, Levitt and Levitt (6) suggested that the observations could be better accommodated by an elimination–addition mechanism which would involve the



SCHEME 2.

formation of a 2,3-pyridyne (I) (or, in some cases, of a 3,4-pyridyne) (Scheme 2). In support of this, it was stated that amination of 5-ethyl-2-methylpyridine gave the 4-amino derivative instead of the expected 2-amino-3-ethyl-6-methylpyridine. Also, the formation of 2,6-diaminopyridine from the reaction of 3-hydroxypyridine with an excess of sodamide at 210° (7), and attributed (7) to the reduction of the phenolic function by nascent hydrogen, was said (6) to provide instead evidence for the intermediacy of (I) in this reaction:



This proposed general mechanism has been attacked strongly (8, 9). In the first place, a number of reports in the literature indicate that many 3-substituted pyridines undergo direct amination predominantly, if not exclusively, at C_2. Examples include 3-picoline (10), 3-*n*-butylpyridine (11), nicotine (12), 3-ethylpyridine (13), 3-aminopyridine (14), nicotinamide (15), nicotyrine (16), anabasine and *N*-methylanabasine (17), and 5,6,7,8-tetrahydroisoquinoline (18). Secondly, the amination of 5-ethyl-2-methylpyridine does, in fact, give the expected 2- and not the 4-amino derivative (19) as claimed (6), and this has been confirmed recently both for 5-ethyl-2-methyl- as well as for 2-methyl-5-*n*-propyl-pyridine (20). The intervention of (I) in the reaction with 3-hydroxypyridine is rendered less probable by the report that 3,4-dihydroxypyridine gave 2-amino-3,4-dihydroxypyridine in the Tschitschibabin reaction (21). Again, if a 2,3-dehydropyridine intermediate were really involved one would have expected addition of a nucleophile to give a 3-substituted pyridine mainly, due to the electron-attracting character of the ring-nitrogen atom (22). Hence, some 3-aminopyridine would be expected in the amination of 3-hydroxypyridine, but was not obtained.

Confirmation of previous data as well as the obtention of new evidence concerning the mechanism of this reaction made the object of the work described here. No *quantitative* data on the effect of substituents upon the orientation of the entering amide ion and the reactivity of the pyridine nucleus have been published. The reaction of 3-picoline with

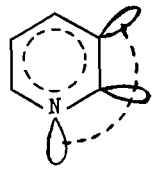
sodamide in boiling toluene has now been studied quantitatively. It was first established once again that 2-amino-3-picoline is the main product formed, the 2,3-/2,5-isomer ratio being 91:9. It was also shown that under the reaction conditions used no 4-amino-3-picoline was detectable by gas chromatography in the product. In fact, in none of the experiments carried out in our laboratory was this compound found to be present. Clearly, these results cannot be interpreted in terms of a 2,3-pyridyne intermediate mechanism, at least not as a major pathway for the reaction.

In the reaction of phenyllithium with 3-picoline, in which once again the 2-phenyl isomer is formed predominantly, it has been shown that the 3-methyl group activates the 2-position towards nucleophilic attack compared with the same position in pyridine itself (23). It was of interest to find out whether a similar situation prevailed in the sodamide reaction and competitive runs were carried out in which an excess of a mixture of 3-picoline and pyridine in boiling toluene was allowed to react with sodamide. Gas-chromatographic analysis of the reaction products gave a value of ${}^{CH_3}{}_HK = 0.22$ for the total rate ratio and values of ${}^{CH_3}{}_HF_2 = 0.40$ and ${}^{CH_3}{}_HF_6 = 0.039$ for the partial rate factors for attack at C_2 and C_6, respectively, compared with attack at C_2 in pyridine itself. Thus, in this case, the 3-alkyl substituent deactivates the nucleus quite unexceptionally towards nucleophilic attack, though the reasons for the predominant attack at C_2 are not clear yet (for a discussion of the similar orientation observed in the reaction of 3-alkylpyridines with phenyllithium see ref. 23).

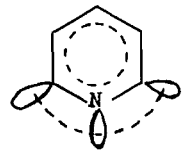
The intervention of a pyridyne intermediate mechanism was tested for by a study of the reaction of sodamide with an excess of a mixture of pyridine and pyridine-3*d*. Unreacted pyridine was recovered and analyzed for its deuterium content by mass spectroscopy. If, as it would appear likely to be, the hydride-ion elimination step in Scheme 2 were the rate-determining one then, assuming a minimum deuterium isotope effect of 1.5 (24), one would have expected an increase in the pyridine-3*d* content of the recovered starting material of at least 1%, an increase which would be quite easily measured by the analytical method used. In actual practice the isotopic content of the recovered pyridine – pyridine-3*d* from the reaction mixture was identical within experimental error with that recovered from the blank. This eliminates a mechanism in which elimination of the hydrogen atom at C_3 is rate determining.

A way which might possibly circumvent the above experimental objections to a pyridyne intermediate mechanism was proposed in the form of the very interesting concept of lone-pair interaction in a dehydropyridine intermediate, a concept which was bolstered by molecular orbital calculations (25). According to this theory a 2,3-dehydropyridine may be stabilized by interaction of the vacant sp^2 carbon orbitals with the sp^2 hybrid orbital containing the nitrogen lone pair of electrons (II). This, it is calculated, would explain the lack of formation of any 3-aminopyridine derivatives (expected from the reaction of amide ion with a 2,3-pyridyne not stabilized by lone-pair interaction) and the absence of 4-aminopyridine (the latter is obtained, however, under more vigorous conditions as has been pointed out above). To account for substitutions at C_2 in 3-substituted pyridines it was postulated that a 2,6-dehydropyridine intermediate (III) could be formed readily. (It was pointed out, however, that in the amination of pyridine a 2,3-pyridyne was more likely to form than a 2,6-dehydropyridine since the 3-position is more favorable for the hydride-ion elimination (26)—a possibility negated by our results unless one assumes that it is the proton-elimination step in Scheme 2 that is rate determining.)

Unfortunately, this interesting proposal also goes contrary to a number of already published observations and to the present results. Thus, the well-established amination



(II)



(III)

of 5-ethyl-2-methyl- and 2-methyl-5-*n*-propyl-pyridine at C_6 (20) cannot be accounted for by either a 2,3- or by a 2,6-dehydropyridine intermediate. The possibility that it was the proton-elimination stage in an elimination–addition mechanism which was the rate-determing step was tested very readily by repeating the experiment using 3-picoline and sodamide but with 3-picoline-2*d* and determining the 2,3-/2,5-isomer ratio quantitatively. This ratio was unchanged within experimental error, namely 92:8, and hence a 2,6-dehydropyridine intermediate was again discounted. It was ruled out completely by carrying out the amination on a mixture of pyridine – pyridine-2*d* and analyzing for the isotopic composition of the recovered starting material. If a 2,6-dehydropyridine were formed by a mechanism in which either the proton or the hydride-ion elimination step is rate determining a deuterium kinetic isotope effect would have been expected. With the concentrations used here and assuming a minimum isotope effect of 1.5 the pyridine-2*d* percentage in the recovered starting material should have increased from 26.6% to about 30.5% of the total. In actual practice, the *maximum* value of k_H/k_D observed was 1.05, ruling out the formation of dehydropyridine intermediates as a general mechanism for the Tschitschibabin reaction. It is also of interest to note that when a 3-halopyridine unsubstituted at C_4 is treated with potassium amide in liquid ammonia only the 3,4-pyridyne appears to be generated (26), whereas the m.o. calculations including lone-pair interaction predict that the 2,3-pyridyne would be the more stable intermediate (25). A reaction described in the literature which undoubtedly needs confirmation but which may actually involve a 3,4-pyridyne intermediate is that of 2-picoline with sodamide at a relatively high temperature. Under these conditions it was reported (27) that 3,6-diamino-2-picoline was one of the products isolated, together with 4,6-diamino-2-picoline. These could arise by the addition of ammonia to a 6-amino-2-methyl-3,4-pyridyne intermediate formed from 6-amino-2-picoline, the normal product of reaction under milder conditions. Alternatively, this may be another example of the type of orientation recently observed in the phenylation of pyridine with phenylcalcium iodide, which gave rise to some 2,5-diphenylpyridine (28).

The reactions with 3-picoline-2*d* and with pyridine-2*d* also throw some light upon another aspect of the mechanism of this reaction as well as upon a fundamental concept in the theory of nucleophilic substitution in the pyridine series in general. The absence of a primary deuterium isotope effect in the reactions illustrated in a simplified manner in Scheme 3 can be explained in one of two ways: (i) the addition steps leading to (V) and (VI) are the rate-determining ones, while the second, hydride-ion elimination step is relatively fast. This would seem to be rather unlikely since the amide ion should be more stable than a hydride ion; (ii) the hydride-ion elimination steps (V → VII and VI → VIII) are rate determining and *the addition stages are virtually irreversible*[3] *or the equilibria lie far on the product side and are not rapidly reversible.* Such a situation was found to obtain in the related reaction of phenyllithium with pyridine derivatives (29). Further work

[3]*This might be due to the formation of an N-sodio-derivative.*

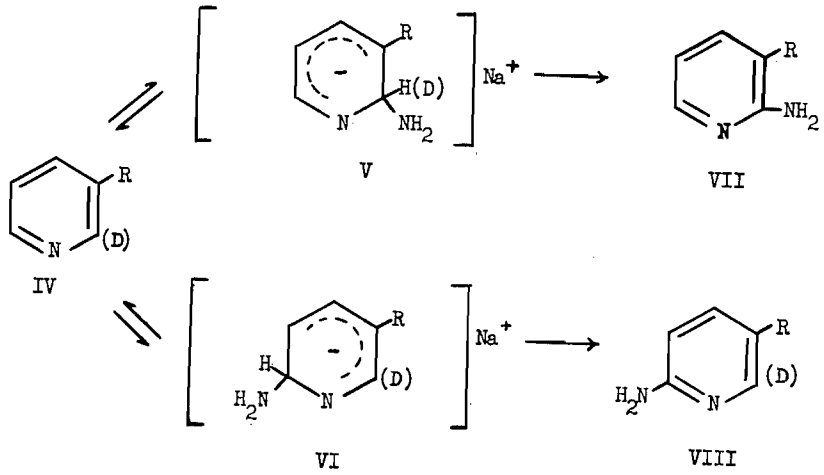

SCHEME 3.

is in progress to determine which of these two alternatives is, indeed, the correct one in the present case. In either case, the first i.e., *the addition step would be product determining* and the orientation would be governed by the effect of the substituent upon the ease of attack by the amide ion, and *not* by its effect upon the relative ease of elimination of a hydride ion from C_2, C_4, or C_6. On the basis of certain molecular orbital calculations of nucleophilic localization energies (30) and ground state π-electron densities (31, 32) it has been suggested (32) that the addition of the amide ion to pyridine should give predominantly the 4-amino σ-complex rather than the 2-amino derivative. The fact that 2-aminopyridine is formed mainly (if not exclusively) was attributed to a rate-determining elimination of hydride ion (presumably following a rapidly reversible addition step); the orientation would then depend on the relative ease of elimination of H^- from C_2 and C_4, respectively, and not upon the relative ease of attack at the two positions (32). The present results rule out this suggestion. Alternative possibilities are that the ground state π-electron densities for the various nuclear positions are actually in the order $2 < 4 < 3$ (4, 33) and that the non-crossing rule does not hold (33), or that the pyridine molecule that undergoes attack is actually complexed at nitrogen so that the values of the localization energies for the pyridinium ion (4, 33) should be employed for predictive purposes. One weak aspect of predictions based on calculations for the isolated molecule is that they do not take into account the fact that the reactions are actually being carried out in solution, where solvation effects may be very marked. There is, indeed, some evidence that solvation of the lone pair of electrons on nitrogen plays a fundamental, if not dominant, role in the determination of the relative reactivities of various nuclear positions in pyridine (34) as well as in the preferential orientation imposed by a 3-substituent upon an attacking nucleophile (35). This aspect is being explored further.

EXPERIMENTAL

Commercial 2° pyridine (Reilly Tar and Chemical Co.) was dried (KOH) and fractionally distilled; the fraction b.p. 110–112° at 720 mm was used. Commercial synthetic 3-picoline was similarly treated; the fraction b.p. 138–140° at 720 mm was used.

The preparation of pyridine-2*d* and 3-picoline-2*d* has already been described (36). Pyridine-3*d* was prepared similarly from 3-bromopyridine and *n*-butyllithium (15% solution in *n*-hexane). Commercial

2-amino-3-picoline and 2-amino-5-methylpyridine (Reilly Tar and Chemical Co.) were purified, the first to constant boiling point (100–103° at 11 mm), the second to constant melting point (77–78°). 2-Aminopyridine, purified by repeated recrystallization from light petroleum (b.p. 40–60°), had m.p. 55–56°.

Amination of 3-Picoline

3-Picoline (0.968 g, 0.01 mole) and sodamide (0.44 g, 0.011 mole) in toluene (0.4 ml) were boiled gently under reflux for 20 h, the reaction mixture was cooled in ice, and 5% aqueous sodium hydroxide (25 ml) followed by water (10 ml) carefully added. Sodium hydroxide pellets were now added so as to saturate the aqueous solution which was then extracted with benzene. The combined organic layers were dried ($MgSO_4$), the solvent removed under vacuum, and the oily residue analyzed quantitatively by gas chromatography using the following conditions: a column of 10 ft × ¼ in. silicone nitrile on Gas-Chrom P (1:6 w/w), column temperature 132°, injector temperature 190°, and helium inlet pressure 40 p.s.i., resulting in a flow-rate of 60 ml/min. Under these conditions 2-amino-3-picoline had a retention time of 36 min 30 s, and the 2-amino-5-methylpyridine 43 min 45 s. Duplicate runs were carried out in all cases. Identical conditions were used in the experiments with 3-picoline-2*d*. The average value of the 2,3-/2,5-isomer ratio was 91:11 in the case of 3-picoline and 92:8 with 3-picoline-2*d*.

Reaction of Pyridine and 3-Picoline with Sodamide under Competitive Conditions

Pyridine (1.439 g, 0.018 mole), 3-picoline (1.534 g, 0.016 mole), and sodamide (0.144 g, 0.0037 mole) in toluene (3 ml) were placed in a three-necked flask in a thermostat at 103° and the suspension stirred under reflux for 24 h. The reaction mixture was cooled in ice, treated with 5% sodium hydroxide solution and worked up as above. After drying over magnesium sulfate, the solvent and excess pyridines were distilled up to 130° at atmospheric pressure and the residue was transferred quantitatively to a volumetric flask which was filled up to the mark with toluene. Aliquots of this solution were then analyzed quantitatively by gas chromatography on a 9 ft × ¼ in. silicone nitrile on Gas-Chrom P (1:6 w/w) column operated at 163° and a helium inlet pressure of 20 p.s.i. Under these conditions 2-aminopyridine had a retention time of 24 min 15 s, 2-amino-3-picoline a retention time of 29 min 10 s, and 2-amino-5-methylpyridine a retention time of 35 min 45 s. Calibration curves (concentration vs. area of peak) were prepared for all three compounds. Runs were carried out using different relative amounts of pyridine and 3-picoline and the total rate ratios calculated by making the necessary corrections.

Reaction of Sodamide with Pyridine – Pyridine-3d Mixture

A mixture of pyridine and pyridine-3*d* (10.0 g, 0.127 mole) was dissolved in purified *N,N*-dimethylaniline (10.0 g), sodamide (0.247 g, 0.0063 mole; sodamide : pyridine ratio = 1:20) was added and the suspension was heated at 105–110° for 24 h. Some ammonia was evolved during the early part of the reaction. The yellow reaction mixture was treated with 10% aqueous sodium hydroxide with cooling, and then with concentrated sodium hydroxide solution. It was then extracted with ether and the ether layer dried (KOH) and distilled. The fraction b.p. 90–120° was collected and redistilled through a Vigreux column, the pure pyridine fraction, b.p. 114–115° (7.85 g), being collected. This was now treated again as above with a fresh batch of sodamide (0.195 g) and the reaction mixture heated and worked up. The recovered purified pyridine – pyridine-3*d* mixture (6.13 g) was reacted once again with fresh sodamide (0.148 g) as above and the unreacted pyridine recovered (3.85 g). A sample of this material was used for the mass spectroscopic analysis.

A blank run was carried out with a portion of the same pyridine – pyridine-3*d* mixture as was originally used above. This mixture (3.0 g) in *N,N*-dimethylaniline (3 g) was heated at 105–110° for 72 h and the pyridine recovered. A sample of this was used to obtain a value for the isotopic composition of the starting material and analyzed mass spectroscopically. A sample of ordinary purified pyridine, as was used in making up the original mixture with pyridine-3*d*, was analyzed as well to determine the contribution due to ^{13}C and ^{15}N in this material. The percentage of C_5H_4DN in the recovered pyridine used as the blank was 37.05%. The percentage of C_5H_4DN in the recovered pyridine from the reaction mixture was 37.15%. A duplicate run gave % C_5H_4DN = 37.12%.

Reaction of Sodamide with Pyridine – Pyridine-2d Mixture

A mixture of pyridine – pyridine-2*d* (2.513 g) and sodamide (0.413 g) in dimethylaniline (5 ml) was reacted and worked up as described in the pyridine-3*d* experiment. The recovered pyridine – pyridine-2*d* mixture was purified by preparative gas chromatography on a 5 ft × ¼ in. column packed with GE-SF-96 silicone on Gas-Chrom P (60-80 mesh) (20% by weight) operated at 100° with a helium inlet pressure of 40 p.s.i. The collected material (retention time 7 min 50 s) was distilled and analyzed by mass spectroscopy. Duplicate runs were carried out. A blank run using the same mixture as above but omitting the sodamide gave a value for the isotopic composition of the starting pyridine (26.6% C_5H_4DN). The pyridine recovered from reaction mixture No. 1 had a C_5H_4DN content of 26.4%, that from reaction mixture No. 2 a C_5H_4DN content of 27.0%. On the basis of this second figure k_H/k_D could be calculated to be 1.05. Assuming a kinetic deuterium isotope effect of 1.5 one would have expected the recovered pyridine from the two reaction mixtures to contain 30.80 and 30.19% of C_5H_4DN, respectively.

THE ORTON REARRANGEMENT IN APROTIC SOLVENTS

PART II.[1] THE ACID-CATALYZED BROMINATION OF ANISOLE BY A SERIES OF 4-SUBSTITUTED N-BROMOACYLANILIDES

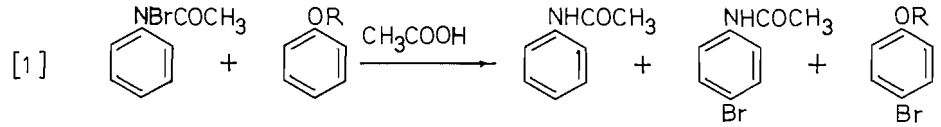
JOHN M. W. SCOTT AND JUNE G. MARTIN
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received October 28, 1964

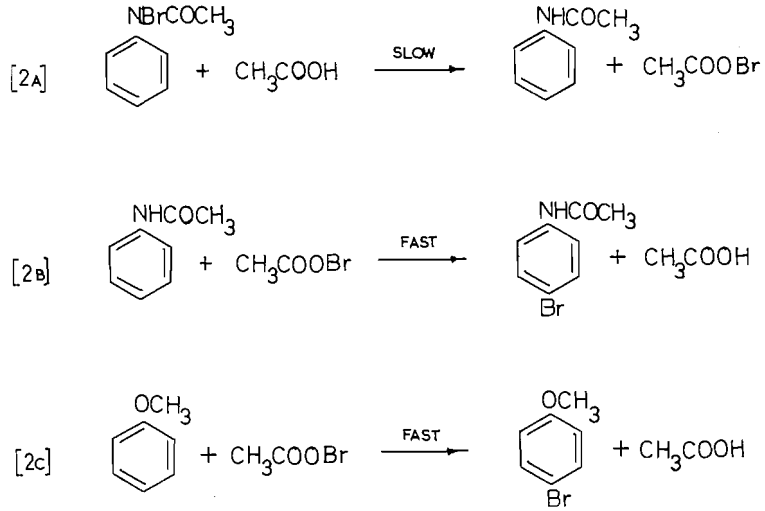
ABSTRACT

Anisole has been brominated using a sequence of brominating reagents generated by the reaction of a series of 4-substituted N-bromoacylanilides 4-RC_6H_4NBrAc (R = Ph, H, Cl, and NO_2) with a series of carboxylic acids R'COOH (R' = CF_3, CCl_3, CH_2Cl, and CH_3). The isomer distributions of the bromoanisoles produced have been measured for each N-bromoacylanilide–carboxylic acid pair and their variation with both the structure of the N-bromoacylanilide and the carboxylic acid provides a useful basis for a discussion of the mechanism of the bromine migration.

Israel, Tuck, and Soper (2) have demonstrated the acid-catalyzed intermolecular transfer of bromine from N-bromoacetanilide to anisole (R = Me) and phenetole (R = Et):



From the observation that the above reaction was zero order with respect to the aromatic ether they concluded that both the bromine transfer reaction and the concurrent rearrangement proceeded via the intermediate production of acetyl hypobromite according to the following scheme:



Dewar and Scott (3) and Scott (1) have observed similar transfers of bromine to chlorobenzene when N-bromo-2-nitroacetanilide or N-bromo-4-nitroacetanilide are treated with

[1]*The communication ref. 1 is to be considered as Part I of the present series.*

For personal use only.

trichloroacetic acid in chlorobenzene. These particular experiments indicate that the bromine transfer reaction is not confined to situations in which the solvent is activated towards electrophilic attack.

In a more detailed investigation of the bromine transfer reaction Dewar and Couzens (4, 5) were able to demonstrate that such processes are not always zero order with respect to the aromatic ether. This important observation led Dewar and Couzens to reject the Soper mechanism (eqs. 2*a*, 2*b*, and 2*c*) but, in an alternative scheme which was offered, the acid hypobromites were retained as "complexed" rather than kinetically free intermediates. Dewar (4) has described intermolecular bromine transfer as an 'intra-complex reaction' but the nature of the complexes involved was not definitely established. The present communication is primarily concerned with the nature of these complexes as revealed by a detailed examination of the products obtained in a series of bromine transfer reactions. Soper and his co-workers (2) were only able to detect 4-bromoanisole when they treated N-bromoacetanilide with acetic acid and anisole dissolved in chloroform. By treating N-bromoacetanilide with a series of carboxylic acids in anisole and analyzing the products of these reactions by vapor-phase chromatography we have been able to detect both 2- and 4-bromoanisole in the reaction products. Isomer distributions in aromatic substitutions are well known to be sensitive to the structure of the attacking electrophile (6); consequently an examination of the variation of the isomer distribution in the bromine transfer reaction with the structure of both the N-bromoacylanilide (NBAA) and acid catalyst might be expected to provide some insight into the mechanism of this reaction. The results of such an investigation in which 16 unique NBAA – carboxylic acid pairs were used to brominate anisole are described below.

EXPERIMENTAL

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The thermostat used was of conventional design and experiments were carried out at 25 ± 0.02 °C.

The product analyses were determined by vapor-phase chromatography using an Aerograph AP-90 instrument equipped with a 10 ft × ¼ in. stainless steel column packed with 5% fluorinated silicone (QF 1) on Chromosorb W/HMDS 60–80. For the isomer distribution analyses the operating conditions were: injection oven 193 °C, detector oven 163 °C, and column oven 100 °C. The inlet pressure was 20 p.s.i. and the flow rate 25 ml He min^{-1}. Under these conditions the following retention times were observed: 2-bromoanisole 14.9 min, 3-bromoanisole 11.86 min, 4-bromoanisole 13.14 min, and 2,4-dibromoanisole 68.2 min. For the analysis of the yield of bromoanisoles biphenyl was used as an internal standard and the column oven was raised to 133 °C, whilst the other instrument parameters were identical to those given above. Under these conditions 4-bromoanisole had a retention time of 4.01 min and biphenyl a retention time of 8.73 min. Both yield and isomer distribution estimations were carried out using calibration curves constructed by correlating chromatograph peak areas determined by triangulation with the composition of synthetic mixtures.

The concentrations of the acid solutions were determined by titration with standard sodium hydroxide solution and the purity of the NBAA's determined by active bromine analysis in the usual way.

Materials

Acetanilides

Acetanilide and 4-nitroacetanilide were commercial samples and were used without further purification. 4-Aminobiphenyl and 4-chloroaniline were acylated with acetic anhydride. The melting points of all the anilides were in satisfactory agreement with those previously reported.

N-Bromoacylanilides

N-Bromo-4-nitroacetanilide, N-bromo-4-phenylacetanilide, and N-bromoacetanilide were all prepared by the route previously described for N-bromo-4-phenylacetanilide (1). Provided that the sodium hypobromite – bicarbonate solution used to effect the N-bromination was maintained in the vicinity of 0 °C during the addition of anilide, we were able to isolate relatively pure samples of each of the above substances. The routine preparation of N-bromoacetanilide by an alternative procedure (7) proved very erratic (see also ref. 5). N-Bromo-4-chloroacetanilide was prepared as before (1).

Acid Solutions

A purified sample of anisole was distilled with liberal rejection of initial and tail fractions, b.p. 152°. Trifluoroacetic acid was distilled, b.p. 73°, and A. R. grade acetic acid was fractionally frozen twice. A. R. grade trichloroacetic acid and monochloroacetic acids were used without further purification. The acid solutions were prepared from pure anisole and the appropriate acid as rapidly as possible to avoid contamination with atmospheric moisture and were stored in ruby-red glass flasks placed in a desiccator containing calcium chloride.

Miscellaneous Compounds

The 2- and 4-isomeric bromoanisoles were commercial samples which were distilled prior to their use; 2-bromoanisole had b.p. 217° and 4-bromoanisole had b.p. 215°. The 3-isomer was prepared from 3-anisidine in the usual way and distilled, b.p. 110° at 25 mm. 2,4-Dibromoanisole was prepared by brominating 2-bromoanisole in acetic acid. Recrystallization of the product from ethanol and then light petroleum gave prisms, m.p. 59–59.5° (lit. 61°). Biphenyl was recrystallized from light petroleum (b.p. 30–60°); m.p. 66° (lit. 69°).

Method

In a typical run the N-bromoacylanilide (ca. 0.01 mole) was dissolved in a 10 ml aliquot of the acid solution in a conical flask (50 ml) equipped with a ground-glass stopper. The flask was then wrapped in foil to exclude light and placed in the thermostat until the reaction was complete, as indicated by either the reaction of a portion of the reaction mixture with acid potassium iodide solution or the appearance of crystals of the parent anilide. Reaction times varied from a few hours to a maximum of 2 days. If the parent anilide separated during the course of reaction it was collected by filtration, the filtrate removed to avoid dilution prior to washing the solid with light petroleum (b.p. 40–60). The crystals were then dried and weighed and their melting point determined. The ratio of 2-bromoanisole to 4-bromoanisole (R) was determined as described above, the results recorded in Tables I–IV being the mean from at least three injections. It was observed that the brominations became more selective with decrease in acid strength as well as with decrease in the basic strength of the amine related to the NBAA. As the selectivity of the brominations increased there was a paralleled decrease in the accuracy with which the isomer distributions could be measured. The results for N-bromo-4-nitroacetanilide represent the limit of usefulness of the present method of analysis and this is reflected in the relatively large standard deviations in the measured isomer distributions for this compound. The results are, however, sufficiently accurate to establish definite trends in the isomer distribution with the structure of the acid and the NBAA in all cases. Three acid concentrations were used in the experiments employing trifluoroacetic acid as a catalyst to ascertain if the R parameter was dependent on the catalyst concentration. With N-bromo-4-chloroacetanilide and N-bromo-4-phenylacetanilide the R values showed a small increase with decrease in the acid concentration, but with the other two NBAA's of interest the results were random. It was concluded that until a more sensitive method of analysis could be developed for measuring small R values the small variation of this parameter with acid concentration was of little importance and would not alter any conclusions which we wish to draw at the present time. For the analysis of the total bromoanisoles present in the reaction mixture two 4 ml aliquots of the filtrate were added to two separate conical flasks (5 ml) containing known weights of biphenyl. At least three injections of the resulting solutions were made and the percentage yield of bromoanisoles was based on the active bromine analysis of the N-bromoacylanilide and is expressed with a standard deviation. The recovery of nitrogen bound bromine as 2- and 4-bromoanisoles averaged in the region of 80–90% (see Tables I–IV). The fate of the remaining bromine was not established, but the possibility of some rearrangement accompanying the bromine transfer reaction cannot be ruled out (cf. ref. 2).

Free Radical Reactions

The possibility that the observed isomer distributions might be derived from simultaneous acid-catalyzed and free radical reactions was considered and investigated. N-Bromoacetanilide, N-bromo-4-phenylacetanilide, and N-bromo-4-nitroacetanilide (ca. 0.01 mole) were allowed to react with anisole (10 ml) in daylight and the products examined as previously. The R values were found to be very small (ca. 0.01) being very close to the acid-catalyzed R values for N-bromo-2-nitroacetanilide; consequently this compound was selected for some further experiments. Suitable weights of this substance were added to three flasks A, B, and C, two of which contained anisole (50 ml) whilst the third (C) contained anisole and acetic acid (50 ml, 0.377 N). Flasks B and C were protected from the light with metal foil and the three flasks were then placed in the thermostat and active bromine analyses carried out on the contents of each flask at suitable time intervals. Within 4 h the flask exposed to the light contained no active bromine but flask B displayed only a 2.5% loss of active bromine over a period of ca. 100 h. On the other hand, the active bromine content of flask C demonstrated a steady reduction with time and a first-order plot gave an excellent straight line up to 70% of the reaction; ($k = 6.2 \times 10^{-5}$ s^{-1}) which corresponds to a half-life of 3.1 h and a complete reaction time (10 half-lives) of 31 h. These experiments, combined with the fact that any reasonable free radical mechanism would predict the isomer distributions to be independent of both the nature of the acid catalyst and NBAA, strongly suggest that results in Tables I–IV correspond to acid-catalyzed reactions with no important free radical component.

DISCUSSION

The present series of experiments show that the isomer distributions obtained in the acid-catalyzed bromination of anisole by a series of NBAA's depend on the structure of both the catalyst and the brominating reagent. The Soper mechanism requires that these isomer distributions should be independent of the NBAA and consequently our results are not compatible with this mechanism. They are, however, consistent with the idea that transition states leading to the formation of 2- and 4-bromoanisole contain an anisole molecule together with an acid and NBAA molecule, i.e. the bromine transfer reaction has at least a termolecular transition state at the product-determining stage. The manner in which these species are linked or reorganized in the transition state is uncertain but structures I and II represent useful working hypotheses.

The relative stabilities of structures I and II will reasonably depend on the nature of the alkyl and aryl groups (R′ and Ar) leading to different isomer distributions as the nature of these groups is varied. Structures I and II also represent favorable reaction paths in a medium of poor ionizing power such as anisole in that they involve no extensive charge separation. The results reported here are also consistent with the composition of complex given by Dewar and Couzens (ref. 4, p. 190).

The rate constants for the electrophilic attack of anisole at the 2- and 4-positions, (respectively k_o and k_p) are related to the R parameter by the equation:

$$R = 2k_o/k_p \qquad [4]$$

The logarithm of the R parameter demonstrates rough correlations with the pK_a's* of the catalyzing acids, separate curves being obtained for each NBAA as shown in Figs. 1 and 2. The scatter of the individual points in the case of N-bromoacetanilide is con-

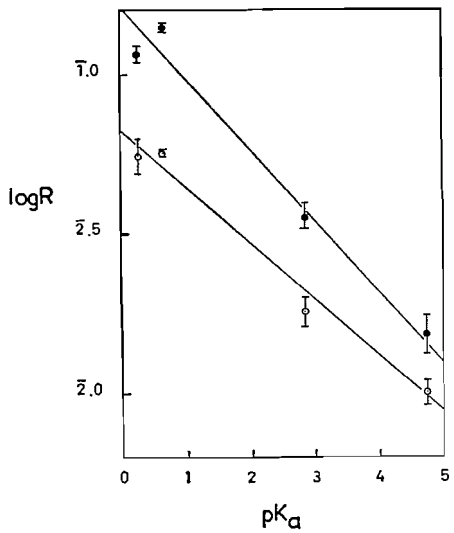

FIG. 1. Correlation between the isomer distribution parameter (R) and the pK_a of the catalyzing acid. ○, N-Bromo-4-phenylacetanilide; ●, N-bromo-4-chloroacetanilide.

siderable and the standard deviations of the individual points are large in the case of N-bromo-4-nitroacetanilide, reflecting the difficulty of measuring small R values accurately. The least-squares slopes of these lines, which are a kind of Brönsted exponent, vary with the nature of the substituent attached to the 4-position of the NBAA and they correlate with the Brown and Okamoto σ^+ parameter (Fig. 3 and Table V). In view of the large probable error (10) in the slopes (see Table V) the choice of the σ^+ parameter, rather than the Hammett σ or the pK_b's of the amines related to the NBAA's is rather arbitrary and will not be considered further.

To a first approximation the relationships between R and pK_a can be expressed in the form:

$$\log R = \alpha_s \mathrm{p}K_a + C, \qquad [5]$$

The use of pK_a values appropriate to water for linear free energy correlations in aprotic solvents such as anisole has ample precedent (see ref. 11, Chap. VI and also refs. 12, 13, and 14).

where α_s and C are constants. Using eq. [4] it is possible to resolve eq. [5] into two separate Brönsted equations of the form:

[6] $$k_o = G_o K_a^{\alpha o}$$

and

[7] $$k_p = G_p K_a^{\alpha p}.$$

The meaning of the symbols in eqs. [6] and [7] follows the usual convention (11) and the subscripts o and p refer respectively to ortho and para attack. Combining eqs. [4], [6], and [7] gives

[8] $$\log 2k_o/k_p = \log R = (\alpha_p - \alpha_o)\mathrm{p}K_a + \log 2G_o/G_p,$$

which on comparison with eq. [5] gives

[9] $$\alpha_s = \alpha_p - \alpha_o$$

and

[10] $$C = \log 2G_o/G_p.$$

The experimental slopes are all negative which means that $\alpha_o > \alpha_p$. The enhanced value of α_o as compared to α_p implies a steeper intersection of the substrate–electrophile potential energy curves for attack at the 2-position of anisole. This might result from either a higher localization energy at the 2-position or steric repulsion between the attacking electrophile and the methoxy group. Both of these factors acting together probably contribute to the higher value of α_o.

ABSTRACT

The infrared spectra of complexes of 1-methyl-2-pyridone and 1-methyl-2-quinolone with Lewis acids are consistent with interaction at the carbonyl group. The stretching frequency of this group, ν_{CO}, is lowered on complex formation, the change being proportional to the Lewis acidity. Two other bands, at 1 670 and 1 380 cm^{-1} move to lower frequency in much smaller steps and are associated with ring modes.

INTRODUCTION

The spectroscopic consequences of forming complexes between electron-deficient species and molecules containing carbonyl groups are well known (1–5). The size of the downward displacement of ν_{CO} is governed by many factors and can vary from 21 cm^{-1} in *m*-nitrobenzaldehyde:$HgCl_2$ (1) to 263 cm^{-1} in xanthone:BI_3 (6). The properties of the organic molecule which determine the size of $\Delta\nu_{CO}$ have to do with the polarity (and polarizability) of the C═O group but these have not, as yet, been put on a quantitative basis. With an understanding of these facts it is possible to make certain deductions about assignments of bands to carbonyl-stretching vibrations. This has been done in the case of γ-pyrones (4) and γ-pyridones (7) and resulted in a reversal of previous assignments for ν_{CO} and ν_{CC}, confirming suggestions to this effect by Bellamy and Rogasch (8), after measuring solvent shifts in absorption bands in γ-pyridones.

A study of complex formation in α-pyridones was undertaken to see if the above behavior was consistent; to find out whether the method might be applicable to tautomeric dihydroxypyridines; and to help in the understanding of some of the features in the spectra of α-pyridone salts (9).

RESULTS

The bands in the spectra of 1-methyl-2-pyridone complexes are shown in Table I and those of 1-methyl-2-quinolone complexes in Table II. Table III lists some bands due to the coordinate bond stretching vibration.

DISCUSSION

Vibration ν_{8a} and the Carbonyl-Stretching Vibration

Assignments in 1-methyl-2-pyridone have been considered by Katritzky and Jones (10), who along with Bellamy and Rogasch (8) attribute the 1 670 cm^{-1} band to the carbonyl-stretching frequency. Neither comment on the fact that there is a shoulder to this band at slightly lower frequency (in $CHCl_3$ solution) but its absence may be due to instrumental limitations. In the solvent shift studies (8) no separation took place even in the most perturbing solvent which suggests that both bands move together. The two bands are distinguished much more clearly of course when complex formation occurs. The carbonyl

frequency in the $HgCl_2$ complex of 1-methyl-2-pyridone is displaced to 1 558 cm^{-1} and a slightly less intense doublet at 1 645 cm^{-1} and 1 650 cm^{-1} remains. One or both of the latter must clearly be the highest frequency ring mode (ν_{8a}) and not the 1 590 cm^{-1} band so designated by Katritzky and Jones (10).* The situation is entirely analogous in 1-methyl-2-quinolone and its $HgCl_2$ complex. Here the 1 650 and 1 640 cm^{-1} bands are assigned to the ring mode and carbonyl frequency in the free base, which move to 1 622 and 1 543 cm^{-1} in the $HgCl_2$ complex. The changes in ν_{CO} on complex formation with $HgCl_2$, both about 100 cm^{-1}, are somewhat larger than previously recorded for heterocyclic carbonyl compounds (4, 6, 7), but of the right order.

The doublet at 1 645 and 1 650 cm^{-1} in the $HgCl_2$ complex of 1-methyl-2-pyridone is also present in the $CdCl_2$ complex, but in the other complexes the higher frequency component slowly becomes less intense and subsides to a weaker shoulder. The assignment of this band to an overtone or combination tone in Fermi resonance with the ring-stretching mode (ν_{8a}) seems quite reasonable therefore. Since ν_{8a} belongs to the a' species, Fermi resonance is permitted between this mode and the combination tone of the two out-of-plane hydrogen-deformation modes ν_{11} and ν_{10b}. Equally probable would be a combination tone of an in-plane hydrogen-deformation mode in the 1 150 cm^{-1} region and a planar skeletal deformation mode, ν_{6a} or ν_{6b}. Inaccessibility of the region below 650 cm^{-1} prevents speculation about the skeletal modes.

Consideration of alternative assignments does not yield any improvement but the reverse. For example, assignment of the 1 585 cm^{-1} band to ν_{CO} is not only inconsistent with our experience of carbonyl-stretching frequencies but would mean a drop of only 23 cm^{-1} between free base and $SbCl_5$ complex, which is far too small. Reversal of the 1 664 and 1 660 cm^{-1} bands in the free base is trivial since they are so close.

Vibration ν_{8b}

The doublet near 1 606 and 1 590 cm^{-1} in CCl_4 solution referred to by Bellamy and Rogasch (8) as of variable intensity seems to be chiefly at 1 580 cm^{-1} in $CHCl_3$ solution with indeterminate high and low frequency shoulders and is assigned to ν_{8b}. Katritzky and Jones (10) with prism resolution find only one band at 1 590 cm^{-1}. The solid state spectrum is similar to the $CHCl_3$ solution spectrum in this region. Again it seems plausible to invoke Fermi resonance to explain the two bands of variable intensity. The fact that

**The nomenclature for ring vibrations is derived from that used originally for benzene (11) and by subsequent authors for other six-membered rings, e.g. pyridine (12), diazines (13). Very approximate normal coordinate displacements are shown in the accompanying figures. (The drawings become similar to those published by Katritzky and Jones if the (10) z-axis is changed from 1,4 to 3,6.)*

Lewis acids bands. BF_3: 1 130, 1 116, 904, 880 cm^{-1}. BCl_3: 720, 702, 695, 675 cm^{-1}.

in the complexes there is only one strong band (ν_{8b}) which appears between 1 555 and 1 570 cm^{-1} depending on the Lewis acid supports this assumption. ν_{11}, at about 766 cm^{-1} to 784 cm^{-1} in the complexes, is most probably the band whose first overtone interacts with ν_{8b}. The species of $2\nu_{11}$ is a', the same as the planar vibration ν_{8b}, and therefore the resonance condition is satisfied. In the free base though 755 (ν_{11}) + 837 (?) = 1592 would give a value more in keeping with the 1 606 / 1 590 cm^{-1} doublet. The assignment and species of the 837 cm^{-1} band are not known.

Vibration ν_{19a}

The third skeletal mode is found at 1 529 cm^{-1} in the free base with little shift on complex formation, and with quite a constant frequency in the different complexes. It is not a strong band except when in proximity to other strong bands.

For personal use only.

Vibration ν_{19b}

In the 1 460 cm^{-1} region two medium intensity bands can be found in the free base and in the complexes. A ring-stretching mode (ν_{19b}) and an asymmetric CH_3 deformation mode would be expected in this region, and the higher frequency band at $\sim$ 1 455 cm^{-1} is assigned to the ring mode and the $\sim$ 1 435 cm^{-1} band to the CH_3 asymmetric deformation. A band at 1 416 cm^{-1} is assigned to the symmetric CH_3 deformation. The interpretation given here differs from that of Katritzky and Jones (10). One of the ring modes was overlooked by not observing ν_{8a} in coincidence with ν_{CO} (10); and the weak shoulder at 1 500 cm^{-1} was attributed to a ring mode. A more probable explanation for the 1 500 cm^{-1} band in the free base is as the first overtone of the CH out-of-plane deformation (ν_{11}) at 758 cm^{-1} (CS_2).

Vibration ν_{14}

The absorption at 1 389 cm^{-1} in the free base moving to progressively lower frequency as the Lewis acid gets stronger presents an aspect of complex formation not seen before. Previous observations of progressive shifts with increasing Lewis acidity have been either a gentle rise ($\sim$ 20 cm^{-1}) in some bands (ν_1) in complexes formed by coordination at a heterocyclic nitrogen atom (14, 15) or a large decrease in ν_{CO} ($\sim$ 100–250 cm^{-1}) on complex formation at a C=O group in a heterocyclic molecule (4, 6, 7) (plus a small relaxation ($\sim$ 35 cm^{-1}) in an interacting ring vibration of similar frequency, generally ν_{8a}) (4). Since the lowering in frequency in the 1 389 cm^{-1} band parallels that in the 1 664 and 1 660 cm^{-1} band thus following the order of relative Lewis acidity, and since there is no trend in the mass of the Lewis acid, it follows that the change in frequency must reflect a change in force constant in the bonds whose motion results in this vibration. This change in force constant must be induced by the alteration in the C=O bond structure on complex formation. The absorption at 1 389 cm^{-1} must therefore belong to a ring mode of some description, and the only one in this region is the vibration ν_{14}. For many years there was much confusion over the assignment of ν_{14} in benzene, but a recent decision in favor of the 1 309 cm^{-1} band seems to be acceptable (16). In pyridine the 1 375 cm^{-1} band assignment to ν_{14} is supported by normal coordinate calculation (17), and so is the 1 346 cm^{-1} band in pyrazine (18). The vibration is inactive in the infrared spectrum of benzene but is permitted in pyridine and the diazines; it also increases in intensity as more polar atoms are introduced into the ring. It should produce a bond with more intense absorption in 1-methyl-2-pyridone as the vibration involves stretching the polar CH_3N—CO bond. The problem of its bathochromic shift cannot be solved by an appeal to various valence bond structures, but is probably connected with electron depletion from the ring as a whole.

Vibrations ν_{12} *and* ν_1

The ring-breathing modes, ν_{12} and ν_1, are rarely of appreciable intensity in infrared spectra, though usually intense in Raman spectra. Two weak bands occur in the proper region of the spectra. These are at 1 000 cm^{-1} and 978 cm^{-1} in the free base, and about 1 020 and 1 000 cm^{-1} in the complexes.

Vibrations ν_3, ν_{9a}, ν_{15}, *and* ν_{18a}

There should be four in-plane hydrogen-bending vibrations associated with the ring hydrogens. Katritzky and Jones (10) have these at 1 318, 1 154, 1 138, and unassigned, respectively. The 1 154 cm^{-1} band has a more plausible assignment (*vide infra*) so the preferred assignments are 1 318, 1 240, 1 151, and 1 050 cm^{-1} respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Vibrations ν_5, ν_{10b}, ν_{11}, *and* ν_{17b}

The in-phase out-of-plane hydrogen-bending mode gives rise to a strong infrared-active band and the 755 cm^{-1} band is thus assigned to ν_{11}. Three other bands occur in this region which could be assigned to these vibrations, and are at 873, 837, and 720 cm^{-1}. It is unlikely that the carbon out-of-plane modes could give rise to bands of such high frequency. The precise assignment of the 873, 837, and 720 cm^{-1} bands cannot at the moment be attempted.

Methyl Group Vibrations

The deformation vibrations have already been discussed. Authority for higher than usual methyl group symmetric deformation frequencies in NCH_3 groups comes from normal coordinate analyses of N-methyl amides (19, 20). The rocking modes are also at higher frequencies in NCH_3 groups (19, 20) compared with CCH_3 groups (21). Accordingly the bands at 1 180 and 1 134 cm^{-1} are assigned to the a' and a'' rocking modes.

Miscellaneous Vibrations

A weak band is observed in 1-methyl-2-quinolone at 1 492 cm^{-1}. This band also appears at 1 493 cm^{-1} in the $HgCl_2$ complex but is still of only moderate intensity. As the Lewis acidity increases, and the absorption of the carbonyl-stretching vibration moves to lower frequency this band becomes steadily more intense and also retreats to lower frequency. This could be explained as a case of Fermi resonance between the 1 492 cm^{-1} band, assigned to 2×750 cm^{-1} or the first overtone of an in-phase out-of-plane hydrogen deformation and the perturbed carbonyl group.

Ligand Group Vibrations

Most of the MX stretching bands due to the Lewis acid are below the rock salt region. Exceptions are the BF_3 and BCl_3 complexes. In the BF_3 complex of 1-methyl-2-pyridone bands at 1 118 and 1 095 are identified with a' and a'' asymmetric stretching modes of the $^{11}BF_3$ group, respectively. The shoulder at 1 150 cm^{-1} has been assigned to the a'' $^{10}BF_3$ asymmetric stretching vibration. The symmetric $^{11}BF_3$ stretching vibration probably gives rise to the strong absorption at 932 cm^{-1}. These frequencies are consistent with other values in BF_3 complexes, and are a measure of the very good donor characteristics of the α-pyridone molecule (22). Vibrations involving B—Cl bond stretching are observed in the 650–840 cm^{-1} region (23–25) and several appropriate frequencies are listed in the table.

TABLE III

B—O stretching vibrations

	1-Methyl-2-pyridone		1-Methyl-2-quinolone	
	^{11}B	^{10}B	^{11}B	^{10}B
BF_3	955	970	973	990
BCl_3	967	980	988	1 002
BBr_3	982	995	999	1 025

A strong band occurring only in the boron halide complexes near 980 cm^{-1} should be appropriate for the BO stretching vibration (see Table III). Although higher frequencies have been assigned to such bands (23, 24) for nitrogen–boron bonds these have not been without criticism (26), and values near 785 cm^{-1} (in $H_3N{:}BH_3$) suggested. One anomaly with the higher frequency assignments (24) was the absence of a component due to the ^{10}B isotope which should give a band of one fourth the intensity of the ^{11}B component

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

displaced some 20–40 cm^{-1} to higher frequency. The assignments in the α-pyridone:BX_3 series are all made more plausible by the presence of a shoulder some 13–26 cm^{-1} higher than the main component. Overlapping prevents an estimate of the relative intensities. The shift to higher frequency in the series $BF_3 \rightarrow BCl_3 \rightarrow BBr_3$ parallels the increasing order of Lewis acidity. The α-pyridone:BF_3 assignments are not perhaps quite as clear as the other complexes in this area because of overlapping bands.

EXPERIMENTAL

1-Methyl-2-pyridone and 1-methyl-2-quinolone were obtained as crystalline solids from The Aldrich Chemical Company.

1-Methyl-2-pyridone Complexes

$HgCl_2$ complex.—1-Methyl-2-pyridone (1.09 g, 0.01 mole) in 5 ml acetone was mixed with 2.72 g (0.01 mole) $HgCl_2$ in 5 ml acetone giving an immediate white solid, m.p. 130–133 °C.

Anal. Calcd. for $C_6H_7NO.HgCl_2$: C, 18.93; H, 1.85; N, 3.68. Found: C, 19.04; H, 2.24; N, 3.38.

$CdCl_2$ complex.—1-Methyl-2-pyridone (1.09 g, 0.01 mole) in 5 ml absolute ethanol on mixing with 1.83 g (0.01 mole) $CdCl_2$ in 150 ml absolute ethanol gave a white precipitate, m.p. > 290°.

Anal. Calcd. for $C_6H_7NO.CdCl_2$: Cl, 24.3. Found: Cl, 24.5.

$ZnCl_2$ complex.—$ZnCl_2$ (1.36 g, 0.01 mole) in 60 ml acetone and 1.09 g (0.01 mole) 1-methyl-2-pyridone in 5 ml acetone gave, on mixing and evaporation of the solvent, a white solid, m.p. 124–127°.

Anal. Calcd. for $(C_6H_7NO)_2.ZnCl_2$: Cl, 20.0. Found: Cl, 20.4.

$SnBr_4$ complex.—1-Methyl-2-pyridone (1.143 g, 0.011 mole) in 150 ml CCl_4 was treated with 0.69 ml $SnBr_4$ (0.005 mole). The resulting white solid was not hygroscopic; m.p. 225–227°.

Anal. Calcd. for $(C_6H_7NO)_2.SnBr_4$: Br, 48.7. Found: Br, 46.2.

BF_3 complex.—This has been previously described (27); m.p. 124–126°.

Anal. Calcd. for $C_6H_7NO.BF_3$: C, 40.72; H, 3.99; N, 7.92. Found: C, 40.46; H, 4.11; N, 7.67.

BCl_3 complex.—Gaseous BCl_3 passed into a CCl_4 solution of 1-methyl-2-pyridone resulted in a white hygroscopic solid, m.p. 115–123°. Due to their hygroscopic nature there are no analytical data for this and subsequent complexes. They are assumed to have 1:1 stoichiometry. They were also handled in a dry box.

BBr_3 complex.—Liquid BBr_3 was dropped into a CCl_4 solution of 1-methyl-2-pyridone giving a slightly viscous solid which soon hardened; m.p. 106–109°.

$SbCl_5$ complex.—Same procedure gave a white hygroscopic solid, m.p. 85–87°.

1-Methyl-2-quinolone Complexes

$HgCl_2$ complex.—1-Methyl-2-quinolone (1.59 g, 0.01 mole) in 30 ml acetone and 2.72 g (0.01 mole) $HgCl_2$ in 5 ml acetone were mixed, and after 30 s white platelets separated; m.p. 197–198°.

Anal. Calcd. for $C_{10}H_9NO.HgCl_2$: C, 27.88; H, 2.11; N, 3.25. Found: C, 27.80; H, 2.19; N, 2.95.

$ZnCl_2$ complex.—$ZnCl_2$ (0.68 g, 0.005 mole) in 50 ml acetone (filtered) added to 1.59 g (0.01 mole) 1-methyl-2-quinolone in 30 ml acetone. A solid slowly formed after standing a short while; m.p. 228–229°.

Anal. Calcd. for $(C_{10}H_9NO)_2.ZnCl_2$: C, 52.83; H, 3.99; N, 6.16. Found: C, 52.70; H, 4.10; N, 5.86.

$SnCl_4$ complex.—A stable non-hygroscopic solid was formed when $SnCl_4$ was dropped onto a solution of the base in CCl_4; m.p. > 290°.

Anal. Calcd. for $(C_{10}H_9NO)_2.SnCl_4$: Cl, 24.5. Found: Cl, 24.5.

BF_3 complex.— BF_3 gas when passed into a CCl_4 solution of 1-methyl-2-quinolone gave a white solid; m.p. 197–200°. This and subsequent BX_3 complexes were too hygroscopic to permit analytical determination. They are assumed to have 1:1 stoichiometry.

BCl_3 complex.—A white solid formed on passing BCl_3 gas into the base in CCl_4; m.p. 254–256°.

BBr_3 complex.—BBr_3 (0.78 ml, 0.08 mole) dropped onto CCl_4 solution of the base (1.298 g, 0.08 mole) gave a pale-yellow solid; m.p. 254–257°.

$SbCl_5$ complex.—1-Methyl-2-quinolone (0.786 g, 0.005 mole) in CCl_4 treated with 0.63 ml (0.005 mole) $SbCl_5$ gave a white solid; m.p. 220–222°.

Anal. Calcd. for $C_{10}H_9NO.SbCl_5$: Cl, 38.7. Found: Cl, 39.9.

Microanalyses were by Mr. L. E. Swim (Dow Chemical Company, Midland, Michigan, U.S.A.). Zn, Cd, and Hg halide complexes were estimated by argentimetric titration; Sn and Sb halides by acid–base titration. Melting points (in sealed tubes) are uncorrected. Spectra were obtained as described previously (7).

ACKNOWLEDGMENTS

The assistance of Mrs. R. H. Veach in preparing many of the complexes and recording their spectra is gratefully acknowledged. Mr. L. E. Swim and his associates (Dow Chemical Company, Midland, Michigan, U.S.A.) are thanked for the microanalyses.

PROTONATED CARBONYL GROUPS

V. α-PYRIDONE SALTS[1]

DENYS COOK[2]
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received October 28, 1964

ABSTRACT

Salts of 1-methyl-2-pyridone and 1-methyl-2-quinolone with strong acids have been prepared and their infrared spectra recorded between 4 000 and 650 cm^{-1}. Protonation of the carbonyl group occurs giving rise to OH stretching, in-plane and out-of-plane bending vibrations which absorb in characteristic regions of the spectrum, namely 1 900 – 3 300 cm^{-1} (depending on the anion), $\sim$ 1 250 cm^{-1}, and $\sim$ 800 cm^{-1} respectively, with appropriate shifts on deuteration. Other tentative assignments are made.

INTRODUCTION

The first article in this series gave an interpretation of the infrared spectra of protonated γ-pyrones (1). The simplicity of the spectra, in particular the absence of deuteration shifts in bands other than those due to the OH group, made the assignments relatively straightforward. Subsequent articles have dealt with increasingly complex systems (2, 3, 4) and the consistent behavior of the vibrational aspects of the protonated carbonyl group has justified attempts to deal with even more complicated systems.

1-Alkyl-2-pyridones fall into this category, and an initial survey of several salts of 1-methyl-2-pyridone seemed to show several inconsistencies, some of which, however, were removed when 1-methyl-2-quinolone salts were examined. It has been previously claimed, after an examination of the vibrational spectrum of the hydrochloride (5), that 2-pyridone protonates at the nitrogen atom but proton magnetic resonance spectra of 2-pyridone cations and deuterated analogues indicated O protonation (6). A more recent study of the infrared spectrum of the solid hexachloroantimonate was also put forward as supporting this concept (7).

RESULTS AND DISCUSSION

The bands in the spectra of salts of 1-methyl-2-pyridone and 1-methyl-2-quinolone are shown in Table I and II respectively. Those due to OH vibrations are summarized in Table III.

Vibrations of the OH Group

Strong absorptions at 2 272 and 1 902 cm^{-1} in the HCl salts of the pyridone (I) and quinolone (II) respectively, moving to progressively higher frequency with increasing anionic complexity, are associated with the OH-stretching vibration of the protonated carbonyl group. The band is very broad and strong and has not been found too useful in giving information on protonation sites. Deuteration shifts and half bandwidths are similar to previous observations (Table III). The very low value of ν_{OH} in 1-methyl-2-quinolone.HCl is noteworthy.

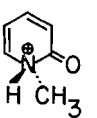
I II

In-plane deformation modes (δ_{OH}) of the OH group have previously been located near 1 260 cm^{-1} (1–4). Occasionally splitting into two components is observed (correlation field splitting) which can sometimes be ascribed to unit cell coupling (8, 9) when crystal data are available (1). In 1-methyl-2-pyridone salts there are four bands which seem to disappear, or decrease in intensity, on deuteration, and this effect is more marked in the HCl salt. These bands are at 1 468, 1 380, 1 260, and 1 112 cm^{-1}. Correlation field splitting into four components seems unlikely even though the average value, 1 305 cm^{-1}, is reasonably close to the average value of δ_{OH}, 1 260 cm^{-1} (4). On the other hand perturbation of ring vibrations on deuteration substitution is not observed in γ-pyrone or γ-pyridone salts, though it does occur quite markedly in pyridinium salts (10), and other protonated heterocyclic bases (11).

It was assumed, and the study of 1-methyl-2-quinolone salts later confirmed, that the 1 468, 1 380, and 1 112 cm^{-1} bands were not associated with the in-plane hydrogen-bending mode. This mode thus gives rise to one single absorption band at 1 260 cm^{-1} which is equivalent to a medium intensity band present in the deuterated salt at 992 cm^{-1}, the isotopic ratio being 1.27. Furthermore this is the only new band to occur in this region of the spectrum. Thus α-pyridone salts turn out to be consistent with other protonated carbonyl groups in having δ_{OH} near 1 260 cm^{-1}. In the 1-methyl-2-pyridone hydrohalides there is a trend towards higher values of δ_{OH} with decreasing anionic size. In the 1-methyl-2-quinolone salts this trend is not noticeable. The α-pyridone salts are not consistent though in having a single band for δ_{OH}, for most salts studied previously have two components (3).

The position of δ_{XH} has been used diagnostically to indicate protonation site, and tertiary amine groups have been found to have δ_{NH} near 1 402 cm^{-1} (12). The presence of the two bands near 1 468 and 1 380 cm^{-1} could have indicated a split band (average 1 424 cm^{-1}) due to correlation field effects, in quite a realistic position for a protonated N atom as in III.



III

This possibility must be discounted since no split ND deformations are found in the appropriate region i.e. 1 468 / 1.35 = 1 087 and 1 380 / 1.35 = 1 022 cm^{-1}. In addition the effect of a positive charge on the N atom would have a large inductive effect on the carbonyl group significantly raising its stretching frequency to near 1 780 – 1 800 cm^{-1}, as has been described for N-aroyltrialkylammonium halides (13), 2,2-dimethyl-6-quinuclidone salts (14), and N-acyltrialkylammonium and N-acylpyridinium halides (15). Alternative explanations must be sought for the 1 468, 1 380, and 1 112 cm^{-1} bands as will be described below.

Vibrations of the Ring and Carbonyl Group

The six-membered conjugated ring in 1-methyl-2-pyridone should be capable of analysis in principle in terms of the vibrational characteristics of a perturbed benzene molecule,

*Very approximate half bandwidth.

with the addition of carbonyl group and N-methyl group vibrations. 2-Pyridone itself is known to have alternate double (3,4 and 5,6) and single bonds (2,3 and 4,5) plus the lactam grouping mesomeric bonds (16). The changes these differences from hexagonal symmetry make in the vibrational characteristics, symmetry questions apart, are not known.

Seven planar vibrations of the ring are permitted, the approximate normal coordinate displacements being shown in the previous paper (17). The bands in the 1-methyl-2-pyridone salts at 1 632, 1 588, 1 535, 1 468, 1 380, 1 065, and 1 032 cm^{-1} are assigned to the vibrations ν_{8a}, ν_{8b}, ν_{19a}, ν_{19b}, ν_{14}, ν_{12}, and ν_1 respectively and a little arbitrarily. They are, however, in keeping with values in other six-membered heterocyclic rings.

The changes that take place on deuteration of the salts seem to be more pronounced than those in γ-pyrones (1) for example, where hardly any changes in ring vibrations were noticed, but less pronounced than in pyridine (10) or 1,4-diazines (11) where large changes in several bands take place. Part of the reason for the large change in the pyridine salts must be because protonation takes place directly on a ring atom and alters the ring bond force constants. In the γ-pyrone salts the ring is insulated from such effects by the carbonyl group. In α-pyridones too one would expect this insulating effect, but either for reasons of symmetry or π-electron interaction, it does not occur.

The assignments become a little clearer on consideration of the bands in 1-methyl-2-quinolone salts. In these salts the 1 460 cm^{-1} band moves only very slightly in position and changes little in intensity, and the 1 390 cm^{-1} band shifts only about 30 cm^{-1} to lower frequency instead of the 60–70 cm^{-1} in the 1-methyl-2-pyridone salts. It is thus possible to relate the bands in the two isotopic series in 1-methyl-2-quinolone salts with

greater assurance, and to extrapolate them to the 1-methyl-2-pyridone salts. The intensity changes on deuteration in the 1 460 cm^{-1} bands may also be due in part to their slight shift away from the strong 1 490 to 1 500 cm^{-1} band, from which they derive some of their intensity in the H salts.

No clear explanation for the larger than usual change in frequency on deuteration of the 1 390 cm^{-1} band seems possible. Because of the slow drift in this band as the Lewis acid in the complexes changes (17), a real alteration in the force constant of the bonds involved would be supposed, since mass or mechanical effects clearly could not be responsible with such a wide variety of Lewis acids. However a change in frequency associated with an isotopic change in the protonated base could only be due to a mass effect. Further work to clear up this anomaly is obviously desirable.

The assignment of the 1 112 cm^{-1} band which decreases in intensity on deuteration is also the subject of some uncertainty. No new band in the region near 1 112 / 1.37 = 812 cm^{-1} in the deuterated salts is apparent apart from the 980 cm^{-1} band due to δ_{OD}. It seems therefore likely that, as was assumed earlier, it is not connected with δ_{OH}. Whenever splitting of the OH in-plane deformation modes has been noted, both components have always been quite prominent in both isotopic species (1, 2, 3). The most probable assignment of the 1 112 cm^{-1} band, and one consistent with its intensity, would be to an overtone or combination tone. If it is due to a first overtone the fundamental would be near 556 cm^{-1}, beyond the range of the instrument used to record these spectra, but in the spectral region where the ring in-plane (ν_{6a} and ν_{6b}) and out-of-plane (ν_{16a} and ν_{16b}) bending modes would occur. If it is due to a combination tone then one probable participant would be the out-of-plane hydrogen-bending mode γ_{CH}, near 760 cm^{-1}. The other partner should then be near 352 cm^{-1}, which may be ascribed to a ring out-of-plane bending mode, or to $2\nu_L$ where ν_L is a lattice mode associated with the hydrogen bond.

Previous experience has indicated that the carbonyl-stretching frequency should be in the 1 500 cm^{-1} region (see Table III of ref. 3). Two exceptions are the salts of N,N-dimethylacetamide (4) and N,N-dicyclohexylacetamide (15) which have ν_{CO} at 1 386 and 1 400 cm^{-1} respectively, and it is believed that vibrational coupling, well known to occur in the free bases, is responsible for these low values. The situation in antipyrine, a cyclic amide, is not definite either, for though an assignment of a band at 1 496 cm^{-1} to the carbonyl-stretching vibration was made, it was noted that coupling very probably took place (3).

In the α-pyridones studied here the same conditions apply, for not only are the amide group vibrations coupled, but there may be interactions between these and the higher frequency ring modes. Identification of the carbonyl frequency is therefore not a simple matter. Some information may be obtained, however, from an examination of several complexes of α-pyridones with Lewis acids (17). In accordance with previous experience the carbonyl frequency would be expected to decrease on complex formation with a weak Lewis acid (18) and go to progressively lower values as the Lewis acidity increased (19, 20). The only band that fits this description in 1-alkyl-2-pyridone is at 1 662 cm^{-1} in the free base, at 1 561 cm^{-1} in the $HgCl_2$ complex, moving progressively to 1 492 cm^{-1} in the $SbCl_5$ complex. Two other bands which move gently to lower frequency as ν_{CO} decreases are at 1 670 cm^{-1} moving to 1 622 cm^{-1} in steps of $\sim$ 5–10 cm^{-1}, thus recalling the behavior of γ-pyrone complexes (20), and at 1 374 cm^{-1} moving to 1 328 cm^{-1}. In the α-pyridone salts therefore the 1 500 cm^{-1} band is most satisfactorily assigned to the

protonated carbonyl group stretching mode. It is not accidental either that this value is close to the carbonyl-stretching frequency in a complex of 1-methyl-2-pyridone with a strong Lewis acid, as both the proton and the strong Lewis acid seem to offer the same degree of perturbation to the carbonyl group (20, 21).

The symmetry of 1-methyl-2-pyridone is so low that all vibrational modes [$(3 \times 15) - 6 = 39$] are infrared active. This situation does not alter in the salts and the cation has 42 active modes. As only about 30 bands are listed in Table I it is obvious that many fundamentals are missing. Notwithstanding this it is suggested that part of the complexity of the 1 300 to 1 600 cm^{-1} region is due to the effect of mechanical interactions and Fermi resonances, and that many of the assignments must remain tentative till further data can substantiate them.

2 Base : 1 Acid Salts

The acids $HAsF_6$, HPF_6, and $HSbF_6$ gave only the 2:1 salts whose spectra show no absorption near 3 300 cm^{-1}, but broad strong absorption reaching a maximum in intensity near 900 cm^{-1}, with characteristic transmission windows (22). These salts are thought to contain short, possibly symmetrical hydrogen bonds (23, 24). Usually the anion is a large complex polyatomic molecule but sometimes the iodide ion seems to fit the required lattice conditions. The hemihydrochloride dihydrate of 1-methyl-2-quinolone, prepared by allowing the 1:1 salts to hydrate in air, seems to belong to this class. The water molecules probably form hydrogen-bonded bridges between successive Cl^- ions.

EXPERIMENTAL

1-Methyl-2-pyridone Salts

Hydrohalides were made by passing the appropriate gas through an ether solution of the base. Ethereal HI (from aqueous solution) gave the 2:1 salt, but the 1:1 salt was subsequently made from excess aqueous HI and the base giving the monohydrate, which was then dehydrated by gentle heating *in vacuo*. Salts of complex acids were made by dissolving the base in $CHCl_3$, saturating with the appropriate HX, then adding the Lewis acid SnX_4 or $SbCl_n$. Most of the salts were then handled in a dry box.

All salts were analyzed by titrimetric methods and gave satisfactory figures for 1:1 salts for monobasic acids, and 2:1 for dibasic acids. Melting points:* HCl, 170–172°; HBr, 175–176°; HI, monohydrate, 73–75°; anhydrous, 116–119°; $HSbCl_4$, 128–131°; H_2SnBr_6, 132–135°; H_2SnCl_6, 167–169°; $HSbCl_6$, 186–189°.

1-Methyl-2-quinolone Salts

The same procedures as for the 1-methyl-2-pyridone salts were used with the same results. Melting points: HCl, 151–153°; HBr, 198–200°; HI, 159–162°; $HSbCl_4$, 169–171°; H_2SnBr_6, 223–225°; H_2SnCl_6, > 290.

Replacement of the protonating hydrogen atom with deuterium was achieved with D_2O or DBr. Attempts to prepare the DI salts, however, yielded the 2:1 salt. All deuterated salts were prepared using vacuum line techniques and were subsequently handled in a dry box. Spectra were recorded as described previously (4).

ACKNOWLEDGMENT

The assistance of Mrs. R. H. Veach in preparing some of the compounds and recording their spectra is gratefully acknowledged.

A STUDY OF THE PECTIN PRESENT IN THE BARK OF AMABILIS FIR (ABIES AMABILIS)

S. S. BHATTACHARJEE[1] AND T. E. TIMELL[2]

Department of Chemistry, McGill University, and the Pulp and Paper Research Institute of Canada, Montreal, Quebec

Received November 9, 1964

ABSTRACT

A pectic material has been isolated from the bark of *Abies amabilis* (Dougl.) Forbes in a yield of 2%. On hydrolysis it yielded D-galacturonic acid, D-galactose, and L-arabinose in a ratio of 85:4:11, and also traces of rhamnose. The product, when submitted to several conventional fractionation methods, appeared homogeneous. Further resolution could be effected by acidification of an aqueous solution of the pectin, followed by ultracentrifugation. The insoluble portion (50%) was an electrophoretically homogeneous *galacturonan* with $[\alpha]_D$ +246°. The material remaining in solution (30%), here referred to as a *pectic acid*, had $[\alpha]_D$ +225° and on hydrolysis gave D-galacturonic acid, D-galactose, and L-arbabinose in a ratio of 74:7:19, as well as traces of rhamnose.

The structure of the galacturonan was established by partial hydrolysis and methylation. It consisted of α-D-galacturonic acid residues linked together by (1 → 4)-glycosidic bonds to a linear macromolecule. The same techniques were applied to the pectic acid. While a unique structural formula could not be assigned in this case, one probable alternative involved a framework of (1 → 4)-linked α-D-galacturonic acid residues together with a few residues of 1,2,4-linked L-rhamnose. Some of the galacturonic acid units carried at C-2 and C-3 side chains which were terminated by D-galactopyranose and L-arabinofuranose residues. A few of the latter also occurred as inner units, probably in the side chains. This appears to be the first time a pectic material has been resolved into a galacturonan and a pectic acid containing the four sugar residues usually found in pectins. It is probable that the pectin occurring to a limited extent in wood has a similar composition.

In previous investigations several polysaccharides were isolated from the bark of amabilis fir (*Abies amabilis*) (1), namely a cellulose (2), a galactoglucomannan (3), a glucomannan (4), and a xylan (5). The present study is concerned with the pectic substances also present in this bark. Pectin has previously been isolated from both wood and bark by Anderson and his co-workers (6–9). Painter and Purves (10) obtained pectin in a yield of 7% from white spruce inner bark. Similarly, inner bark of white birch has yielded a pectin in a yield of 3–4% (11). During the early stages of cell differentiation, the primary wall and the middle lamella consist largely of pectin. The pectic substances of cell walls in the phloem, cambial, sapwood, and heartwood regions have recently been studied by Thornber and Northcote (12).

The pectic group of polysaccharides is based on residues of D-galacturonic acid, D-galactose, L-arabinose, and L-rhamnose, with the galacturonic acid usually, albeit not always, predominating. A polymer containing only D-galacturonic acid residues (a galacturonan) seems to have been isolated only on one occasion, namely from sunflower heads (13). Lately, it has become evident that most of the so-called pectic acids probably also contain neutral sugar residues, such as D-galactose, L-arabinose, L-rhamnose, and L-fucose (14–18). The exact constitution of these heteropolymers is still unknown although the main features of one pectic acid have recently been established (17).

RESULTS AND DISCUSSION

When extractive-free fir bark was treated with chlorous acid for complete removal of polyphenolic material, a holocellulose was obtained in a yield of 50%. A mixture of

For personal use only.

polysaccharides, including a galactoglucomannan (3) and pectic material, was removed by extraction with hot water, the amount corresponding to a yield of 1.8% of the bark. The extract on hydrolysis gave galacturonic acid, galactose, glucose, mannose, arabinose, and xylose in a ratio of 10:8:20:44:10:8. Free boundary electrophoresis indicated that it consisted of at least three components. The solid residue was treated with hot 0.5% ammonium oxalate in water to give a crude ammonium pectate with $[\alpha]_D$ +120° in water and in a yield of 6.0% of the bark. On hydrolysis the product gave the same sugars as above, the ratio being 38:8:10:22:12:10. Boundary electrophoresis showed that it consisted of one major, fast-moving and three or four slower components.

Anderson and co-workers (19) have recently claimed that decarboxylation can easily occur on isolation of pectin by techniques such as those used here. Using different times of treatment with both water and ammonium oxalate, 16 samples were isolated. Yields, specific rotations, and sugar compositions remained practically constant throughout, showing that in the present case the pectic material underwent no chemical change during its isolation. When the crude ammonium pectate was subjected to chromatography on diethylaminoethylcellulose (20), three fractions were obtained. Water eluted a galactoglucomannan (52%), phosphate buffer an acidic arabinoxylan (7%), and sodium hydroxide a pectic acid (28%), containing galacturonic acid, galactose, and arabinose residues. Obviously, the crude ammonium pectate was a mixture of at least three different components.

The pectic acid was separated from the other polysaccharides by forming the insoluble calcium pectate which was washed with alkali and water. The purified product, obtained in a yield of 30%, had $[\alpha]_D$ +230° in water and on hydrolysis gave galacturonic acid, galactose, and arabinose in a ratio of 85:4:11, and also traces of rhamnose. Boundary electrophoresis indicated that the product was not homogeneous. Several attempts were made to effect further resolution by renewed treatment with calcium chloride, precipitation with cetyltrimethylammonium hydroxide, fractional precipitation with ethanol from an aqueous solution, and ion exchange chromatography on diethylaminoethylcellulose. In each case, the fractions obtained were unchanged in composition and optical rotation.

Yean and Goring (21) have recently shown that sodium lignosulfonate can be conveniently separated from neutral polysaccharides by an electrophoresis–convection technique. When the crude ammonium pectate was subjected to this procedure, the upper layers in the electrolyte vessel contained the galactoglucomannan, while the pectic acid was located at the bottom. Very little resolution could be achieved, however, with the purified product.The repeated failure to resolve the purified ammonium pectate any further made it tempting to conclude that the product must be chemically homogeneous in spite of the electrophoretic evidence. At this stage, however, it was discovered that the product could actually be resolved into two fractions. While several procedures were found to be applicable, they were all based on the different solubility in water of the two components. When an aqueous solution of the purified ammonium pectate was passed through a column with a cation exchange resin in the acid form, a slightly cloudy, colloidal solution was obtained. Ultracentrifugation at 40 000 g gave in 50% yield a precipitate, the sodium salt of which had $[\alpha]_D$ +246° in water and which on hydrolysis gave only galacturonic acid. The portion remaining in solution amounted to 30%, had $[\alpha]_D$ +225°, and contained, in addition to traces of rhamnose, residues of galacturonic acid, galactose, and arabinose in a ratio of 74:7:19. The first polysaccharide was obviously a *galacturonan*. The second will, somewhat arbitrarily, be referred to here as a *pectic acid*.

The same fractionation was attained when a solution in water of the purified ammonium pectate was treated with dilute sulfuric acid or aqueous sodium chloride, respectively, followed by ultracentrifugation. On electrophoresis–convection of the ammonium pectate, a colloidal, viscous layer formed at the bottom of the vessel. When this layer was diluted with water and subjected to ultracentrifugation, the same two fractions were again obtained. Boundary electrophoresis showed that the galacturonan was homogeneous, while the pectic acid was probably still somewhat heterogeneous. Application of the four fractionation methods referred to above failed to effect any further resolution, showing that no separate galactan or araban was present. Gel filtration, using Sephadex G-200 was also of no avail, indicating the absence of low molecular weight material. The pectic acid was probably a mixture of closely related acidic polysaccharides, differing slightly in their content of galacturonic acid residues. Both polysaccharides were accordingly subjected to structural analysis.

When the galacturonan was hydrolyzed with a commercial pectinase enzyme, a series of four polymer-homologous oligomers of galacturonic acid were obtained, ranging from the di- to the penta-saccharide. The propylene glycol ester of the acidic polymer was reduced in water with sodium borohydride to the corresponding galactan (14). Reduction of the acetylated galacturonan with diborane in diglyme (22) proved less efficient. The reduced product, which still contained a few galacturonic acid residues, was methylated and hydrolyzed, giving, in a molar ratio of 1:350:1, 2,3-di-*O*-methyl-D-galacturonic acid, 2,3,6-tri-*O*-methyl-D-galactose, and 2,3,4,6-tetra-*O*-methyl-D-galactose, which were identified through crystalline derivatives. The number-average degree of polymerization of the *O*-methylgalactan was 450, as determined from osmotic pressure measurements. Only one nonreducing end group was thus present per average molecule.

These results show that the galacturonan was a linear polysaccharide containing at least 450 (1 → 4)-linked α-D-galacturonic acid residues. The unbranched nature of the galacturonan and its relatively high degree of polymerization are probably the reasons for its insolubility in water. When the pectic acid was subjected to a mild, partial acid hydrolysis, arabinose appeared immediately in the hydrolysate, soon followed by galactose. On prolonged hydrolysis, the four galacturonic acid oligomers, previously obtained from the galacturonan, were formed. In order to make available more of these compounds, the purified, but unfractionated, ammonium pectate was partially hydrolyzed. A combination of ion exchange and paper chromatography gave four pure oligomers. 4-*O*-(α-D-Galactopyranosyluronic acid)-D-galacturonic acid was tentatively identified by conversion to the known α-(1 → 4)-linked galactobiose (23). The corresponding galacturonotriose, on reduction, methylation, and hydrolysis, gave 1 mole of 2,3,4,6-tetra-*O*-methyl-D-galactose and 2 moles of 2,3,6-tri-*O*-methyl-D-galactose.

2-*O*-(α-D-Galactopyranosyluronic acid)-L-rhamnose was identified through its crystalline, fully methylated methyl glycoside dihydrate (17) and from the *O*-methyl sugars obtained on hydrolysis of the latter. The fourth oligosaccharide was a galacturonosyl rhamnosyl rhamnose. The nature of the linkage between the two rhamnose residues could not be determined with certainty. A similar trisaccharide has been isolated from alfalfa pectic acid (17). The nature of the first two oligosaccharides shows the presence of (1 → 4)-linked α-D-galacturonic acid residues. The isolation of the last two oligomers indicates that rhamnose was probably an integral part of the pectic acid.

A reduction of the pectic acid prior to its methylation would obviously make it impossible to distinguish between the galacturonic acid and the galactose residues. The polysaccharide was therefore methylated directly by the Haworth and the Purdie

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

methods, but under mild conditions in view of its lability towards alkali (24, 25). The mixture of *O*-methyl glycosides obtained on methanolysis was resolved into an acid and a neutral portion with the aid of exchange resin. The acid fraction was esterified, reduced with lithium aluminium hydride, and hydrolyzed. The neutral portion, finally, was also hydrolyzed. The neutral *O*-methyl sugars present in each fraction were separated by preparative paper chromatography. Seven of the compounds obtained were crystalline or were identified through crystalline derivatives. The remaining three were tentatively identified by other means. The methylation data are summarized in Table I.

TABLE I

Sugar constituents of the methylated pectic acid

Component	Mole %	Component	Mole %
Unknown sugars	1.8	D-Galacturonic acid	4.3
3-*O*-Methyl-L-rhamnose	2.6	2-*O*-Methyl-D-galacturonic acid	10.5
Di-*O*-methyl-L-arabinose	2.4	3-*O*-Methyl-D-galacturonic acid	9.7
2,3,5-Tri-*O*-methyl-L-arabinose	13.3	Di-*O*-methyl-D-galacturonic acid	0.3
2,3,4-Tri-*O*-methyl-D-galactose	1.2	2,3-Di-*O*-methyl-D-galacturonic acid	45.3
2,3,4,6-Tetra-*O*-methyl-D-galactose	7.2	2,3,4-Tri-*O*-methyl-D-galacturonic acid	1.4

The large amount of 2,3-di-*O*-methyl-D-galacturonic acid shows that the pectic acid contained a framework of (1 → 4)-linked D-galacturonic acid residues, probably, in view of the high specific rotation of the polysaccharide, in the α-D-modification. The presence of 2-*O*- and 3-*O*-methyl-D-galacturonic acid and of D-galacturonic acid indicates that the framework was partly branched through C-2 or C-3 or both, respectively. The 2,3,4-tri-*O*-methyl-D-galactose evidently originated from nonreducing end groups. The majority of the D-galactose and L-arabinose residues were present as nonreducing end groups, precluding the presence of a separate galactan or araban. Their number was only slightly less than that of galacturonic acid residues carrying branches. A small amount of inner arabinose and (1 → 6)-linked galactose residues were also present. The nature of the galacturonosyl rhamnose obtained on partial hydrolysis in conjunction with the presence of 3-*O*-methyl-L-rhamnose among the *O*-methyl sugars strongly indicate that a few rhamnose residues were an integral part of the galacturonan framework, with at least some of them serving as branching points through their 4-position. No evidence was obtained for the presence of (1 → 4)-linked galactose residues, such as those constituting the galactan occurring in seeds from *Lupinus albus* (26, 27).

It is not possible to assign a unique structural formula to the pectic acid on the basis of the present experimental evidence. One of several possibilities is a molecule consisting of a framework of (1 → 4)-linked α-D-galacturonic acid residues, carrying numerous branches containing D-galactopyranose and L-arabinofuranose residues, most of them present as end groups. Since partial acid hydrolysis produced no galacturonic acid oligomers containing (1 → 2)- or (1 → 3)-linkages, a direct attachment of side chain galacturonic acid residues to the backbone is not likely. The presence of (1 → 4)-linked galacturonic acid residues elsewhere in the side chains is, of course, not excluded.

The experimental evidence presented for the structure of the present pectic acid from fir bark is quite similar to that reported by Aspinall and Fanshawe (17) for their alfalfa pectic acid, and it is clear that these two polysaccharides are closely related. No other pectic acid has so far been studied in similar detail.

CONCLUSIONS

To the best of the authors' knowledge, the present investigation represents the first successful resolution of a pectic material into a galacturonan and a pectic acid. There is little reason to doubt that in the future pectins from other sources will also prove amenable to this treatment. The earlier conclusion of Aspinall and Cañas-Rodriguez (14) that pectin might consist of "a mixture of acidic polysaccharides, one composed solely of D-galacturonic acid residues and the other or others containing both neutral sugar and D-galacturonic acid residues" appears eminently justified in view of the present results.

Bark obviously contains much more pectin than wood. No wood pectin has so far been subjected to a structural analysis, mostly, no doubt, because of the small quantities present. It is known, however, that the primary wall and middle lamella in wood cells are rich in galacturonic acid, galactose, and arabinose residues (12, 28–30). An α-(1 $\rightarrow$ 2)-linked-D-galacturonosyl rhamnose has been isolated from pine (31, 32) and beech (33) woods. The presence in wood of pectic material similar to that found in the fir bark is therefore quite likely.

EXPERIMENTAL

General experimental conditions were the same as in a previous paper (34). The following solvent systems were used for paper chromatography: (A) ethyl acetate, acetic acid, water (9:2:2 v/v), (B) ethyl acetate, acetic acid, water (18:7:8), (C) ethyl acetate, acetic acid, formic acid, water (18:3:1:4), (D) ethyl acetate, pyridine, water (8:2:1), and (E) 2-butanone, water, ammonia (90:8:2). For preparative purposes, Whatman No. 3MM filter paper with a wick of No. 50 paper was used. R_{GalA} values refer to the rate of movement of the sugars relative to galacturonic acid. M_G values refer to the rate of movement of a sugar relative to glucose on paper electrophoresis in 0.05 M borate solution. Specific rotations were determined in water (c, 1.0), unless otherwise stated.

Isolation of Crude Pectin

For isolation of crude pectin, the bark was first treated with chlorous acid as described elsewhere (1). The average yield of holocelluloses in several experiments was 50 $\pm$ 2%.

Batches of holocellulose (50 g) were stirred at 75° with water (1 l) containing 6% of potassium acetate for 3, 6, 9, and 12 h, respectively. Each of the four residues was extracted at the same temperature with 0.5% aqueous ammonium oxalate, aliquots being withdrawn after 3, 6, 9, and 12 h. Each of the 16 fractions thus obtained was purified by washing the insoluble calcium pectate with water. The purified ammonium pectates were all essentially similar, with average yield from the holocellulose 3.5%, $[\alpha]_D$ +195°, and the ratio of galacturonic acid, galactose, and arabinose 77:6:17.

For large-scale recovery of pectin, holocellulose (1 200 g) was stirred in water (18 l) containing 6% potassium acetate at 75° for 12 h. The residue was recovered by filtration and washed with hot water (20 l). After concentration to 3 l, the extract was added to ethanol (15 l). The precipitate formed was recovered by filtration, washed successively with 70% aqueous ethanol, ethanol, and petroleum ether, and finally dried *in vacuo* to give a white powder (42 g, 3.5% of holocellulose). The solid residue was extracted with 0.5% aqueous ammonium oxalate at 75° for 12 h. The extract was recovered in the usual way to give a white product (145 g, 12% yield) with $[\alpha]_D$ +120°.

Purification of Crude Ammonium Pectate

Crude ammonium pectate (113 g) was dissolved in water (2 l) and a 10% aqueous solution of calcium chloride (1.5 l) was added. The precipitate formed was washed with water and then suspended in water (4 l) to which 8% aqueous sodium hydroxide (2 l) was added. The suspension was stirred, and the solids were recovered by filtration, and washed with dilute acetic acid and water. The calcium pectate was treated with ammonium oxalate, insoluble calcium oxalate was removed by centrifugation, and the supernatant solution was concentrated and added to ethanol. The precipitate was recovered as described above to give 37 g of material (33% of crude product); $[\alpha]_D$ +230°; OCH_3, 0.9%; ash, 2.3%.

Chromatography on Diethylaminoethylcellulose (16, 20)

Purified ammonium pectate (400 mg) in aqueous solution was added to the top of a column containing diethylaminoethylcellulose in the phosphate form. The column was eluted in succession with 500 ml each of water, 0.025 M, 0.05 M, 0.10 M, and 0.25 M sodium dihydrogen phosphate, and, finally, using gradient elution, with water – 0.3 M sodium hydroxide (2 l). The fractions (15 ml each) were analyzed polarimetrically and by the phenol – sulfuric acid method (35). After deionization with exchange resins, the pectic material was recovered in the usual way.

Electrophoresis–Convection

The apparatus used has been described elsewhere (21). Ammonium pectate (500 mg) was dissolved in water (400 ml) and subjected to electrophoresis. After 5 h, a turbid, viscous layer was observed at the bottom of the vessel used. The experiment was terminated after 8 h, and fractions were carefully removed with a syringe, starting with the top layer.

Resolution of Purified Ammonium Pectate

Acidification.—Purified ammonium pectate (500 mg) was dissolved in water, and the solution was passed through a column containing Amberlite IR-120 exchange resin (acid form). The turbid eluate was concentrated and subjected to ultracentrifugation at 40 000 g. The supernatant, clear solution was treated with more exchange resin until no more turbidity was observed. The final, clear solution was concentrated and added to ethanol. The precipitate formed was recovered in the usual way to give a water-soluble *pectic acid* (160 mg); $[\alpha]_D$ +225°; OCH_3, 2.7%; ash, 0.35%. The solid residue was washed with water and subjected to the same ultracentrifugation, a process which was repeated six times, after which the material was washed with acetone and petroleum ether and dried *in vacuo*, yielding 250 mg of the water-insoluble *galacturonan*; $[\alpha]_D$ +246°; OCH_3, 0.6%; ash, 0.16%.

Alternatively, *N* sulfuric acid was added slowly to an aqueous solution of the ammonium pectate until a pH of 4.0 had been reached. The precipitate and solution were recovered as described.

Addition of aqueous sodium chloride.—A saturated solution in water of sodium chloride (10 ml) was added slowly to an aqueous, 1% solution of ammonium pectate (100 ml). The precipitate formed and the solution were treated as above.

Electrophoresis–convection.—The turbid, viscous solution obtained at the bottom after electrophoresis was diluted with water and subjected to ultracentrifugation. The precipitate and solution gave the same products as the other two methods.

Partial Acid Hydrolysis of the Purified Ammonium Pectate

Purified ammonium pectate (40 g) was dissolved in water (972 ml) to which 28 ml of concentrated sulfuric acid was added. The solution was heated on a steam bath for 3.5 h. After cooling, an equal volume of acetone was added. The precipitate formed was recovered by filtration and washed with aqueous acetone. The degraded product (18 g) gave only galacturonic acid on complete hydrolysis.

The filtrate and washings were neutralized with barium carbonate, treated with a cation exchange resin, and added to the top of a column containing Amberlite CG-45 (formate form) anion exchange resin. After washing with water until a Molisch test was negative, elution was continued with increasing concentrations of formic acid (0.001 *N* to 2 *N*). Eight fractions were collected and examined by paper chromatography (solvents A to D). Further resolution was effected with solvent B, using preparative paper chromatography.

Identification of Oligosaccharides

Galacturonotriose.—This trisaccharide (60 mg) had $[\alpha]_D$ +187°, R_{GalA} 0.04, 0.39, and 0.05 in solvents A, B, and C, respectively, and melted with decomposition at 135–142°. Partial hydrolysis gave galacturonic acid, galacturonobiose, and some galacturonotriose. The methyl ester methyl glycoside was reduced with sodium borohydride, methylated, and hydrolyzed, giving two sugars which were separated by paper chromatography (solvent E). One of the components (35 mg) was identified as 2,3,6-tri-*O*-methyl-D-galactose by conversion to the corresponding galactonolactone, which had melting point and mixed melting point 97–98°. The second compound (20 mg) was shown to be 2,3,4,6-tetra-*O*-methyl-D-galactose through its aniline derivative which had melting point and mixed melting point 192–194°.

Galacturonosyl rhamnosyl rhamnose.—This trisaccharide (90 mg) had $[\alpha]_D$ +118°, had R_{GalA} 0.10 in solvent C, and gave 1 mole of galacturonic acid and 2 moles of rhamnose on prolonged hydrolysis. Partial hydrolysis yielded rhamnose, galacturonic acid, and galacturonosyl rhamnose. After prior reduction with borohydride, only galacturonosyl rhamnose and a trace of galacturonic acid were obtained on hydrolysis.

Galacturonobiose.—This disaccharide (700 mg) had $[\alpha]_D$ +154° and R_{GalA} 0.23, 0.60, and 0.20 in solvents A, B, and C, respectively. It melted with decomposition at 125–135°. After treatment with trimethylorthoformate, esterification with diazomethane, and reduction with lithium aluminium hydride (23), a neutral disaccharide was obtained which gave only galactose on hydrolysis and had $[\alpha]_D$ +175°. The compound could not be induced to crystallize but was chromatographically and ionophoretically identical with an authentic sample of 4-*O*-(α-D-galactopyranosyl)-D-galactose (36).

2-O-(α-D-Galactopyranosyluronic acid)-L-rhamnose.—This oligosaccharide (300 mg) had $[\alpha]_D$ +108° and gave equimolar amounts of galacturonic acid and rhamnose on prolonged hydrolysis. The methyl ester methyl glycoside, after reduction with sodium borohydride, on hydrolysis gave galactose and rhamnose. When the disaccharide was directly reduced, galacturonic acid was the only reducing sugar obtained on hydrolysis. The fully methylated aldobiouronic acid, after recrystallization from chloroform – ethyl ether, gave methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-galactopyranosyluronic acid)-3,4-di-*O*-methyl-L-rhamnopyranoside dihydrate which had m.p. 66–68° and $[\alpha]_D$ +98° (*c*, 0.5 in chloroform) (17). The compound (50 mg) was reduced with diborane in diglyme and hydrolyzed, giving equimolar amounts of two compounds which on demethylation gave galactose and rhamnose, respectively. They were tentatively identified from their rates of movement in solvent E as 2,3,4-tri-*O*-methyl-D-galactose and 3,4-di-*O*-methyl-L-rhamnose.

Partial Enzymic Hydrolysis of the Galacturonan

An aqueous solution of the sodium salt of the galacturonan was treated with a commercial pectinase preparation (Nutritional Biochemical Corporation, Cleveland, Ohio) using the technique of Painter (37). The hydrolysate was resolved into five fractions using paper chromatography (solvent B). A plot of the degree of polymerization of each oligomer versus $R_{GalA}/(1 - R_{GalA})$ was linear.

Esterification and Reduction of the Galacturonan

The galacturonan (20 g) was esterified with propylene oxide and reduced with sodium borohydride as described earlier (11). After four such treatments, a product (13 g) was obtained which on hydrolysis gave galactose and galacturonic acid in a ratio of 94:6. When the fully acetylated galacturonan was reduced with diborane in diglyme (22) a product was obtained in 50% yield containing galacturonic acid and galactose residues in a ratio of 3:2. This method accordingly appeared to have no advantage in this case.

Methylation of the Galacturonan and Identification of Methylated Sugars

The reduced galacturonan (10 g) was methylated four times with dimethyl sulfate and alkali. The partly methylated product (8 g) was further methylated by the procedure of Kuhn and co-workers (38), yielding a product (3.5 g), which was further reduced with lithium aluminium hydride in tetrahydrofuran. After two further methylations with methyl iodide and silver oxide, the *O*-methylgalactan (2.0 g) had $[\alpha]_D$ +128° (*c*, 1.0 in chloroform) and OCH_3 42.7%. Methanolysis and hydrolysis gave a mixture containing one major and two minor constituents.

*2,3,6-Tri-O-methyl-*D*-galactose.*—The sirupy sugar (980 mg) had $[\alpha]_D$ +84°. The derived 2,3,6-tri-*O*-methyl-α-D-galactonolactone, on recrystallization from ethyl ether, had melting point and mixed melting point 97–98°.

*2,3,4,6-Tetra-O-methyl-*D*-galactose.*—This sirup (3 mg) had $[\alpha]_D$ +102°. It was converted to its aniline derivative which had melting point and mixed melting point 196–198°.

*2,3-Di-O-methyl-*D*-galacturonic acid.*—This compound (4 mg) was converted to its methyl ether methyl glycoside, reduced with lithium aluminium hydride, and hydrolyzed. The aniline derivative of the 2,3-di-*O*-methyl-D-galactose thus obtained had melting point and mixed melting point 130–132°.

Determination of the Molecular Weight of the Methylated Galactan

Osmotic pressure measurements were carried out with the *O*-methylgalactan dissolved in chloroform–ethanol (9:1 v/v) as described previously (39). Extrapolation to zero concentration gave a value of 0.28 for $(h/w)_{w\to 0}$, corresponding to a number-average molecular weight of 91 800 and a degree of polymerization of 450.

Methylation of the Pectic Acid

The pectic acid (8 g) was methylated for 20 h at 10° with dimethyl sulfate and alkali. Treatment with methyl iodide and silver oxide gave a product (1.5 g) which had $[\alpha]_D$ +118° (*c*, 1.0 in chloroform) and OCH_3 39.2%, not raised on further methylations. The methylated pectic acid (1.2 g) was directly hydrolyzed by refluxing with *N* sulfuric acid for 12 h. The neutralized (barium carbonate) and deionized solution was added to the top of a column containing Dowex 1-X4 (acetate form) anion exchange resin. Neutral sugars were removed with water. The eluate on concentration gave a sirup (270 mg) which was resolved by paper chromatography using solvent E. Acid sugars were eluted with 30% aqueous acetic acid, yielding a sirup (645 mg) which was treated with methanolic hydrogen chloride, reduced with lithium aluminuim hydride, and hydrolyzed. The mixture of neutral *O*-methyl sugars thus obtained was resolved as above.

Identification of Methylated Sugars

Neutral Series

*3-O-Methyl-*L*-rhamnose.*—This sugar (11 mg) had $[\alpha]_D$ +40° and gave rhamnose on demethylation. Crystals obtained from the sirup had m.p. 106–108°.

*Di-O-methyl-*L*-arabinose.*—This sugar (10 mg) had $[\alpha]_D$ +65° and gave arabinose on demethylation. The aniline derivative could not be induced to crystallize.

*2,3,5-Tri-O-methyl-*L*-arabinose.*—This sugar (60 mg) had $[\alpha]_D$ −36° and gave arabinose on demethylation. The 2,3,5-tri-*O*-methyl-L-arabonamide had melting point and mixed melting point 134–135°.

*2,3,4,6-Tetra-O-methyl-*D*-galactose.*—This sirupy compound (40 mg) had $[\alpha]_D$ +106°. The aniline derivative had melting point and mixed melting point 193–195°.

Acid Series

*2-O-Methyl-*D*-galactose.*—This compound (73 mg) gave no color reaction with triphenyltetrazolium hydroxide (40) and had $[\alpha]_D$ +80°. Crystals produced from the sirup had m.p. 145–146°. The aniline derivative had m.p. 159–161°.

Anal. Calcd. for $C_7H_{14}O_6$: OCH_3, 16.0. Found: OCH_3, 15.2.

*3-O-Methyl-*D*-galactose.*—This sugar (67 mg) had $[\alpha]_D$ +101° and gave a color reaction with triphenyltetrazolium hydroxide. Its M_G value was higher than that of 2-*O*-methylgalactose.

Anal. Calcd. for $C_7H_{14}O_6$: OCH_3, 16.0. Found: OCH_3, 15.2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

*2,3-Di-O-methyl-*D*-galactose.*—The sirupy sugar (336 mg) had $[\alpha]_D$ +78°. The aniline derivative had m.p. 130–131°.

Anal. Calcd. for $C_8H_{16}O_6$: OCH_3, 29.8. Found: OCH_3, 28.9.

*2,3,4-Tri-O-methyl-*D*-galactose.*—This compound (11 mg) had $[\alpha]_D$ +107° and gave a crystalline aniline derivative with melting point and mixed melting point 164–166°.

ACKNOWLEDGMENT

The authors wish to express their gratitude to Dr. C. T. Bishop and to Dr. R. L. Whistler for generous gifts of sugar samples. They are also thankful to Dr. H. I. Bolker and Dr. C. B. Purves for help and advice.

ENTROPY DIFFERENCES FOR SOME RELATED PAIRS OF COMPLEX IONS[1]

J. LIN[2] AND W. G. BRECK
Department of Chemistry, Queen's University, Kingston, Ontario
Received November 3, 1964

ABSTRACT

The temperature coefficient of e.m.f. of a cell consisting of a saturated calomel electrode and a redox electrode of $K_4Fe(CN)_6$ and $K_3Fe(CN)_6$ has been determined by e.m.f. measurements at a series of equimolal concentrations of the above salts and at temperatures of 20, 25, 30, 35 °C. The results for this calomel–redox cell are expressed by the equation $E_{CR}^0 = 0.1200 - 0.00214(t - 25)$, or for the redox electrode against a hydrogen gas electrode, $E_{HR}^0 = 0.3644 - 0.00280(t - 25)$, with E in V and t in °C. Analogous results are available in the literature for other such pairs of complex ions; an examination of these data leads to the hypothesis that the following trichelated pairs: Fe $dip_3^{2+/3+}$, Fe $phen_3^{2+/3+}$, Ru $dip_3^{2+/3+}$, are respectively nearly isentropic.

To know the difference in entropy between a pair of complex ions such as $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$, which have the same chemical composition but different charge, is equivalent to the evaluation of a single-ion entropy as can be seen by writing for the reaction,

$$[1] \qquad Fe(CN)_6^{3-} + \tfrac{1}{2}H_2 = Fe(CN)_6^{4-} + H^+;\ \Delta S^0 = S_1^0 - S_2^0 + S_{H^+}{}^0 - \tfrac{1}{2}S_{H_2}{}^0,$$

where the subscripts 1 and 2 on the S^0 terms refer respectively to the reduced and oxidized forms of the complex ion. The quantities ΔS^0, $\frac{1}{2}S_{H_2}{}^0$ and $S_1^0 - S_2^0 + S_{H^+}{}^0$ are in principle determinable by experiment. Thus the evaluation of $S_1^0 - S_2^0$ is equivalent to that of $S_{H^+}{}^0$; however, it is not at present clear how the absolute entropy of a single ion can be measured directly.

For the purpose of *assigning* entropies to single ions it is often assumed conventionally that $S_{H^+}{}^0 = 0$ at all temperatures. On the other hand the absolute evaluation of $S_{H^+}{}^0$ has been attempted according to various arguments (1); of these one of the most convincing, by Gurney (2), is based on effecting a coincidence for cations and anions of the correlation between entropies and viscosity B-coefficients, yielding the absolute result, $S_{H^+}{}^0 = -5.5$ e.u. Representation of ionic entropies by the use of equations both fundamental and empirical has had limited success. If the ion in solution is regarded in an approximate way as a charged sphere in a continuous dielectric medium, then the Born equation (3) may be applied to assess the free energy of solvation and differentiation with respect to temperature gives the electrostatic entropy of solvation, ΔS_S, which, for water at 25 °C as the medium, becomes (3)

$$[2] \qquad \Delta S_S = -9.4z^2/r,$$

where z is the valence of the particular ion and r the radius of the spherical boundary between ion and dielectric medium. Laidler (4) has shown that it is possible to fit the observed entropies of hydration of simple ions to the Born relation by adjustment of the coefficient of z^2/r to give the partially empirical relations:

$$[3] \qquad S_{abs}{}^0 = \tfrac{3}{2}R \ln M + 10.2 - 11.6z^2/r_u;$$

[1]*From part of the Ph.D. thesis of J. L.*
[2]*Holder of a Province of Ontario Fellowship. Present address: Institute for the Study of Metals, The University of Chicago, Chicago, Illinois.*

[4] $$S_{conv}^0 = 5.5z + \tfrac{3}{2}R \ln M + 10.2 - 11.6z^2/r_u.$$

In the above the term $\frac{3}{2}R \ln M$ is the usual contribution to the entropy by an uncharged atom of mass M/N_0; r_u is Pauling's univalent radius (5); the term z^2/r_u represents the electrostatic contribution according to the approximate Born model; and the term $5.5z$ adjusts the ion entropies from an absolute scale (based on $S_{H^+}^0 = -5.5$ e.u.) to the conventional scale (based on $S_{H^+}^0 = 0$).

Powell and Latimer (6) have obtained good agreement with experiment by use of the equation for simple ions,

[5] $$S_{conv}^0 = \tfrac{3}{2}R \ln M + 37 - 270z/r_e^2,$$

where r_e is an adjusted radius in a term which is notably not of the Born form. While this equation calculates values on the conventional scale it is absolute in the sense that in order to put values for cations and anions on the same line it is required to assume that $S_{H^+}^0$ is, in fact, close to zero. More recently Noyes (7) by a matching technique, and Glueckauf (8) by treating in more detail the nature of the dielectric, have refined the Born approach to the electrostatic entropy of hydration to obtain more complicated terms in z^2/r.

Equations have also been presented to represent entropies of complex ions, particularly oxy-anions. That of Couture and Laidler (9) contains the usual electrostatic term in z^2/r while others (10) do not. King (11) observes that for monatomic ions S^0 depends on z while for complex ions it depends on z^2. Of immediate interest is an empirical equation by George, Hanania, and Irvine (12),

[6] $$S^0 = A - B|z| + Cn,$$

where z is the numerical value of the valence, n the number of ligands; A is a function of the size of the ion and its effect on solvent structure; the coefficient B depends on the identity of the ligand and C is a contribution per ligand. For cyanide as the ligand, $A = 45$, $B = 43$, and $C = 18.5$ e.u. Accordingly, the entropy difference for the pair $Fe(CN)_6^{4-/3-}$ is given by B, viz. 43 e.u. (presumably on the conventional basis that $S_{H^+}^0 = 0$ although such is not stated). For dipyridyl (dip) as the ligand B is quite small at 3 ± 4 e.u., being the entropy difference for the pair $Fe\,dip_3^{2+/3+}$.

It is the intention here to compare values of the quantity $S_1^0 - S_2^0 + S_{H^+}^0$, which are experimentally determinable as, for example, in eq. [1], for related pairs of complex ions such as $Fe(CN)_6^{4-/3-}$, $Fe\,dip_3^{2+/3+}$, $Fe(CN)_4\,dip^{2-/1-}$, and others in the hope that some conclusions might be reached concerning the values of $S_1^0 - S_2^0$ (and of $S_{H^+}^0$) as well as their dependence on valence. Some such results have been obtained and are reported along with others by George, Hanania, and Irvine (12). However, since specific experimental data for the reaction in eq. [1] involving the pair $Fe(CN)_6^{4-/3-}$ were lacking, it was decided to determine these data by measurement of the temperature coefficient of e.m.f. of an appropriate cell.

EXPERIMENTAL

For the measurement of the temperature coefficient of e.m.f. of the cell,

Hg	Hg_2Cl_2, KCl sat'd.	KCl sat'd.	$K_4Fe(CN)_6$ m $K_3Fe(CN)_6$ m	Pt,

H cells were used with the saturated calomel electrode in one limb and the redox electrode in the other, separated by a 2% agar plug saturated with KCl. The calomel electrodes were prepared (13) 2 weeks before

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

use and allowed to stand in a thermostat regulated at the required temperature for at least 2 days before measurements were taken. The other half-cell containing the equimolal redox solutions at various concentrations (m) equillibrated much more rapidly in the bath. The bath temperatures of 20, 25, 30, 35 °C were controlled to within a few hundredths °C and for all except the two most dilute solutions the reproducibility was within 0.1 mV over a period of more than a day; for the most dilute, 0.2 mV over a period of 6 h.

RESULTS

The e.m.f. values, E, obtained at 20, 25, 30, 35 °C for the cell at various equimolal concentrations of $K_4Fe(CN)_6$ and $K_3Fe(CN)_6$ are shown in Fig. 1 plotted against the function $\mu^{1/2}/(1 + \mu^{1/2})$, where μ is the ionic strength. Extrapolating to zero ionic strength for each temperature and representing the results in an equation by least-squares yields for the calomel–redox cell (CR), with t in °C and E in V,

$$E_{CR}^0 = 0.1200 - 0.00214(t - 25), \quad [7]$$

and since in this temperature range the potential of the calomel electrode against the hydrogen gas electrode (HC) is given by (14)

$$E_{HC}^0 = 0.2444 - 0.00066(t - 25), \quad [8]$$

there is obtained for the cell reaction, $Fe(CN)_6^{3-} + \frac{1}{2}H_2 = Fe(CN)_6^{4-} + H^+$,

$$E_{HR}^0 = 0.3644 - 0.00280(t - 25); \ \Delta S^0 = -64.6 \text{ e.u.} \quad [9]$$

Taking $\frac{1}{2}S_{H_2}^0$ as 15.6 e.u. (15), $S_1^0 - S_2^0 + S_{H^+}^0 = -49.0$ e.u.

Data are available in the paper of George, Hanania, and Irvine (12) for calculation of the value of the same function for analogous reactions involving other related pairs

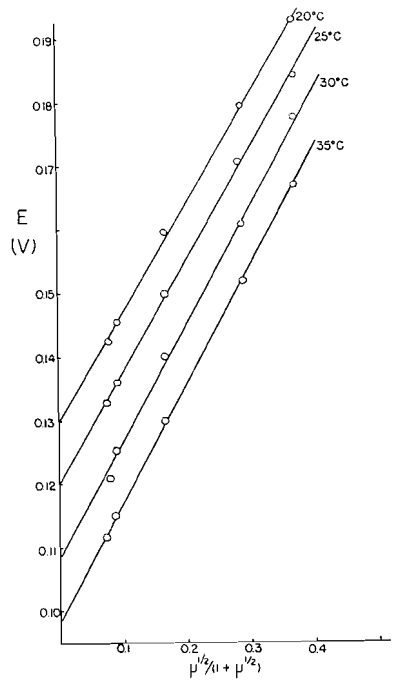

FIG. 1. Plot of e.m.f. (E) in V for calomel redox cell against the function $\mu^{1/2}/(1 + \mu^{1/2})$ at temperatures 20, 25, 30, 35 °C.

of complex ions. The results are in Table I where the subscripts 1 and 2 on the S^0 terms refer to the reduced and oxidized forms respectively; "dip" signifies a dipyridyl and "phen" an O-phenanthroline ligand.

TABLE I

Values of $S_1^0 - S_2^0 + S_{H^+}{}^0$ in e.u. for related pairs of complex ions

Pair 1/2	$S_1^0 - S_2^0 + S_{H^+}{}^0$	Reference
$Fe(CN)_6^{4-/3-}$	−49.0	This work
$Fe(CN)_4\,dip^{2-/1-}$	−34.6	12
$Fe\,dip_3^{2+/3+}$	−6.9*	12
$Fe\,phen_3^{2+/3+}$	−5.2	12
$Ru\,dip_3^{2+/3+}$	−5.1	12
$Os\,dip_3^{2+/3+}$	+0.8	12
$Fe(H_2O)_6^{2+/3+}$	+43.0	15

*This value recalculated. The value given (12) is 8.2 e.u.

DISCUSSION

In Table I the difference in values for $Fe(H_2O)^{2+/3+}$ and $Fe(CN)_6^{4-/3-}$ amounts to the enormous figure of 92 e.u. There is a good chance of accounting for much of this on the basis of valences and radii. But the difference in values for $Fe(H_2O)_6^{2+/3+}$ and, say, $Fe\,phen_3^{2+/3+}$ of 48.2 e.u. is also impressive and here the charges are the same. It appears that large, neutral ligands such as dipyridyl or O-phenanthroline are extremely effective in insulating the surrounding water structure from the effect of the charge on the central ions. On the assumption that $S_{H^+}{}^0$ is not very large, the difference in entropy, $S_1^0 - S_2^0$, for $Fe(H_2O)_6^{2+/3+}$ is notably large and positive. As large, neutral ligands such as O-phenanthroline are substituted the radii of the ions increase, becoming more nearly equal, and the surrounding water structure becomes shielded from the effect of charge on the central ions. If this shielding is completely effective, the entropy difference $S_1^0 - S_2^0$ should drop to zero; if the shielding is incomplete, $S_1^0 - S_2^0$ should become less positive, but not negative. This argument requires that $S_{H^+}{}^0$ must be somewhat negative. For example, in the case of $Fe\,phen_3^{2+/3+}$, if the shielding is complete, $S_1^0 - S_2^0 = 0$, and $S_{H^+}{}^0 = -5.2$ e.u. On the other hand, if the shielding is incomplete, $S_1^0 - S_2^0 > 0$, and $S_{H^+}{}^0$ is more negative than −5.2 e.u. If the argument is applied to the case of $Fe\,dip_3^{2+/3+}$, $S_{H^+}{}^0 \leqslant -6.9$ e.u.

When full coordination with negative ligands occurs, as for the pair $Fe(CN)_6^{4-/3-}$, the difference in entropy is considerably negative owing to the change in total charges on the complex ions. As dipyridyl ligands are substituted for cyanide the value of $S_1^0 - S_2^0 + S_{H^+}{}^0$ increases almost linearly to −6.9 e.u., or in the case of $Fe\,phen_3^{2+/3+}$, to −5.2 e.u. This substitution process differs from that in the previous paragraph in that changes in charge are involved. It is thus seen that the substitution of large, neutral ligands in the one case for water molecules reduces the large positive difference for $Fe(H_2O)_6^{2+/3+}$, in the other case for negative cyanide ligands reduces the large, negative entropy difference for $Fe(CN)_6^{4-/3-}$. At some point these different substitution processes must cause the entropy difference, $S_1^0 - S_2^0$, to pass through zero and the most likely point is where the shielding of central positive charge and replacement of negative ligands are at the same maximum, namely for the trichelated species.

It seems more than coincidental that the values −6.9, −5.2, −5.1 e.u. are so close

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

for the trichelated pairs. This should be the case, of course, if the shielding were completely effective so that in all three cases $S_1^0 - S_2^0 = 0$. As a matter of fact the above values of -6.9 for Fe $dip_3^{2+/3+}$ and -5.2 for Fe $phen_3^{2+/3+}$ have hardly been distinguished experimentally. George, Hanania, and Irvine (12) give $\Delta H^0 = -32.7$ kcal mole^{-1} for both cell reactions analogous to [1] and for the E_{cell}^0 values 1.141 and 1.120 V respectively; Dwyer and McKenzie (see ref. 12) obtained 1.120 and 1.096 V; Hume and Kolthoff (see ref. 12) measured the same e.m.f. for both cell reactions in 1 M sulfuric acid solution. The values of ΔS^0 are sensitive to such small differences in e.m.f., and George, Hanania, and Irvine estimate the error in ΔS^0 at ± 2 e.u., which covers the above deviations for the trichelated pairs.

TABLE II

Standard entropy differences, $S_1^0 - S_2^0$ in e.u.

Pair 1/2	$S_1^0 - S_2^0$	$-(z_1 - z_2)$	$-(z_1^2 - z_2^2)$
$Fe(CN)_6^{4-/3-}$	-43.3	1	-7
$Fe(CN)_4dip^{2-/1-}$	-28.9	1	-3
$Fe(CN)_2dip_2^{0/1+}$	-14.8*	1	$+1$
$Fe\,dip_3^{2+/3+}$	-1.0	1	$+5$
$Fe(H_2O)_6^{2+/3+}$	$+48.7$	1	$+5$

*By interpolation.

According to the arguments above, it is postulated that the related pairs, Fe $dip_3^{2+/3+}$, Fe $phen_3^{2+/3+}$, and Ru $dip_3^{2+/3+}$ are respectively isentropic, or very nearly so, and the values averaged to obtain the result, $S_{H^+}{}^0 = -5.7$ e.u. The value for Os $dip_3^{2+/3+}$ of 0.8 has been omitted as being too far off; if the data are accurate then the shielding is presumably incomplete for this largest element of the series. Taking $S_{H^+}{}^0 = -5.7$ e.u., values of $S_1^0 - S_2^0$ have been calculated and entered in Table II along with differences in z and z^2 for certain pairs.

It is difficult to see how the pattern of the various entropy differences can be explained in terms of differences in z whereas they are in good accord with differences in z^2 as shown in Table II or in Fig. 2 by the plot of values of $S_1^0 - S_2^0$ against $-(z_1^2 - z_2^2)$ for the complex ion species (for this purpose the aqueous ions are not considered as one of the series of complex ions). Little has been said in the foregoing about radii of ions,

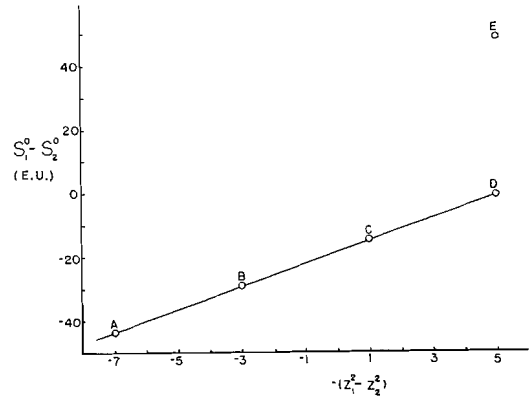

FIG. 2. Plot of $S_1^0 - S_2^0$ in e.u. against $-(z_1^2 - z_2^2)$ for complex ion pairs: (A) $Fe(CN)_6^{4-/3-}$; (B) $Fe(CN)_4\,dip^{2-/3-}$; (C) $Fe(CN)_2\,dip_2^{0/1+}$; (D) $Fe\,dip_3^{2+/3+}$; (E) $Fe(H_2O)_6^{2+/3+}$.

which also affect the electrostatic entropy term. However for the complex ion pairs considered this contribution cannot be important as the differences in radii involved must be relatively small.

If the present arguments are valid, they lend support to Gurney's result that $S_{H^+}{}^0 = -5.5$ e.u. On the other hand, if Gurney's result is accepted a priori, then it must be concluded that certain trichelated pairs are nearly isentropic. Apart from any theoretical importance attached to the evaluation of absolute ion entropies, it is of considerable experimental significance to have available well-behaved redox electrode systems with zero or very small temperature dependence of potential.

SOME BASE-CATALYZED CONDENSATIONS OF SYSTEMS OF THE FORM $R_1R_2C{=}C(CN)_2$

MARY R. S. WEIR AND J. B. HYNE
Department of Chemistry, University of Alberta at Calgary, Calgary, Alberta
Received November 2, 1964

ABSTRACT

We have investigated the condensations of the systems $\phi CH_3C{=}C(CN)_2$, $\phi HC{=}C(CN)_2$, and $CH_3HC{=}C(CN)_2$ in the presence of organic bases. Proton nuclear magnetic resonance (n.m.r.) spectral evidence is presented in support of the suggested structures of the condensation products, and an attempt has been made to present diagrammatically the interrelation between these condensations and other known reaction pathways for condensations of this type.

INTRODUCTION

The reactive nature of methylenemalononitrile systems of the type $R_1R_2C{=}C(CN)_2$ in the presence of base has been known for some time (1, 2). In particular the tendency of such compounds to undergo condensations and dimerizations in the presence of base has been the subject of several recent investigations (3–7). The general mechanism of the base-catalyzed dimerizations of several alkylidenemalononitriles of the type $R_1R_2C{=}C(CN)_2$ has been described previously (6). We have now extended this study to some other methylenemalononitriles whose behavior under the basic reaction conditions appears to be somewhat more complex. Table I represents an attempt to show the interrelationships between the different reaction pathways, which we believe to be possible under various basic reaction conditions, leading to both carbocyclic and heterocyclic products.

Path A (Table I). Cyclodimerization of Alkylidenemalononitriles in the Presence of Organic Bases

When both R_1 and R_2 are alkyl groups, the critical first step is base abstraction of a proton from one of these groups. This is followed by attack of the anion so formed on a second monomer molecule, and then ring closure (4, 6). The same pathway is followed when $R_1 = \phi$ and $R_2 = CH_3$, the base abstracting a proton from the CH_3 group in the initial step.

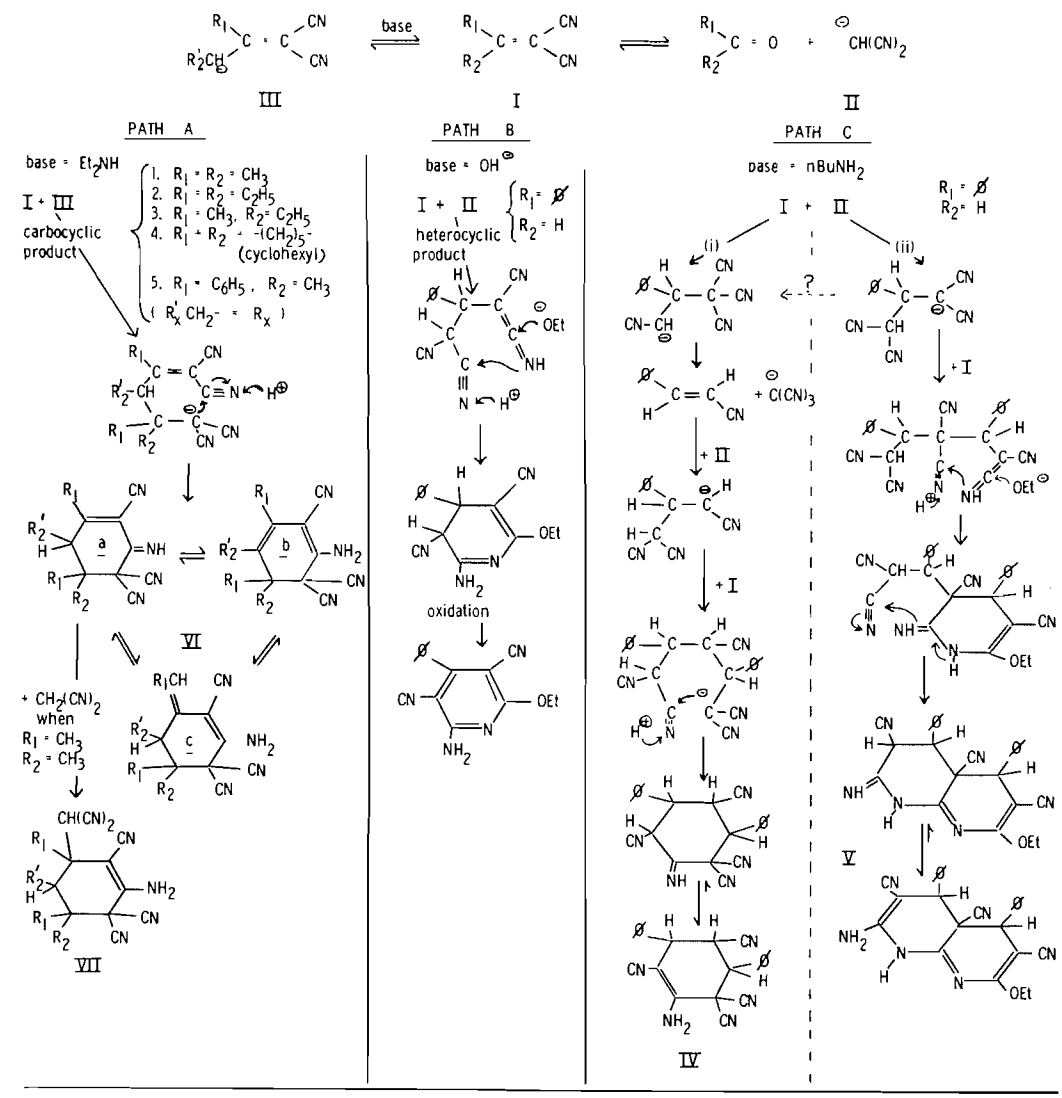
Path B (Table I). Condensation of Benzalmalononitrile in Ethanolic Potassium Hydroxide Solution

The formation of substituted pyridines by the action of ethanolic potassium hydroxide solution on benzalmalononitrile has been reported previously (7). The reaction was shown to proceed via a reverse aldol cleavage of the diene to benzaldehyde and malononitrile anion, followed by attack on the β-carbon atom of a second diene molecule by the $^{(-)}CH(CN)_2$ anion, and subsequent ring closure.

Path C (Table I). Condensation of Benzalmalononitrile in the Presence of Organic Bases

In contrast to its behavior in ethanolic potassium hydroxide solution benzalmalononitrile appears to undergo more complex condensations in the presence of *n*-butyl amine in aqueous ethanol. The initial step here again seems to be cleavage to benzaldehyde, or the corresponding anil with the organic base, and malononitrile anion, followed by attack of the latter on a molecule of monomer. In this case, however, there is further

TABLE I



incorporation of a second monomer molecule into the products. Also, under conditions which are as nearly identical as possible, *two* products of m.p.'s 210–213 °C, IV, and 155–158 °C, V, are obtained, IV being produced in some cases and V in others. Suggested structures for these products and possible pathways leading to them are outlined in Table I.

It may be noted that pathways A and B represent mechanistically the two simplest modes of condensation available to the alkylidene- and arylidene-malononitrile systems respectively. Thus, if the β-carbon carries a group (e.g. $C_2H_5CH_3C{=}C(CN)_2$) from which a proton may be readily extracted by base, then this abstraction is in fact the first step: if the system (e.g. $\phi HC{=}C(CN)_2$) does not contain such a group, then the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

condensation is forced to proceed via attack on the β-carbon by a $^{(-)}CH(CN)_2$ anion, i.e., via a Michael condensation.

Special Case (Table II). Condensation of Ethylidenemalononitrile in the Presence of Organic Bases

Although ethylidenemalononitrile might have been expected to follow path A and give the dimeric product VI on treatment with base, we found no evidence for this material being formed. The spectral data strongly suggested that the product isolated was in fact VIII (although in the absence of solvent a second condensation product was also formed —see structure proof section).

STRUCTURE PROOFS

1. β-Methylbenzalmalononitrile Dimer

Of the compounds listed as reacting according to path A, the condensation products of 1–4 have been discussed (4, 6). β-Methylbenzalmalononitrile, (III, 5), appears to undergo dimerization in the presence of base by a similar pathway (Table I, Path A) leading to compound IX (special case of VI*a*). This reaction has been studied previously by Anderson, Bell, and Duncan (3) who isolated the bright-yellow crystalline dimer from the condensation of acetophenone and malononitrile in the presence of base. They reported its infrared spectrum and noted that it "did not agree with the expected 4-amino-1,1,5-tricyano-2,6-diphenylhepta-1,3,5 triene" (3), but they did not suggest an alternative structure. The n.m.r. spectrum (Fig. 1.1) of the dimer is consistent with the cyclic imino structure shown, IX. The AB quartet at 6.8 τ rules out the possibility of the previously proposed (3) triene structure $\phi(CH_3)C{=}C(CN){-}C(NH_2){=}CH{-}C(\phi){=}C(CN)_2$, and its tautomer $\phi(CH_3)C{=}C(CN){-}C(=NH){-}CH_2{-}C(\phi){=}C(CN)_2$. The CH_2 group in the latter would be expected to give rise to a singlet signal rather than to an AB quartet. The large coupling constant (17 c.p.s.) of this quartet is similar to that noted by Calvin and co-workers (8) for the geminal coupling in the cyclic system XIII when the conformation of the molecule was fixed by cooling to −65 °C. The amino form of the cyclic dimer, X, is also inconsistent with the observed spectrum, since it again would not give rise to an AB quartet. The position of the CH_3 signal at 8.2 τ seemed somewhat low for a CH_3 on a saturated carbon. However, comparison of the two systems $CH_3CH{=}C(CN)_2$ and $\phi(CH_3)C{=}C(CN)_2$ indicated that the presence of a phenyl group on the carbon carrying the CH_3 significantly lowered the position of the CH_3 signal, the one in ethylidenemalononitrile appearing at 7.9 τ and that in β-methylbenzylmalononitrile at 7.5 τ.

XIII

Apart from the apparently exclusive formation of the imino form here the dimerization of β-methylbenzalmalononitrile fits the pattern recently described (4, 6) for several alkylidenemalononitriles where both R_1 and R_2 are alkyl groups. In the present case the imino structure is presumably favored over the amino since straight conjugation from the phenyl group through to the imino group is possible only in the former, IX, the amino form, X, involving a cross-conjugated system. Also an examination of molecular models indicates that the ring strain in the cyclic amino form with two endocyclic

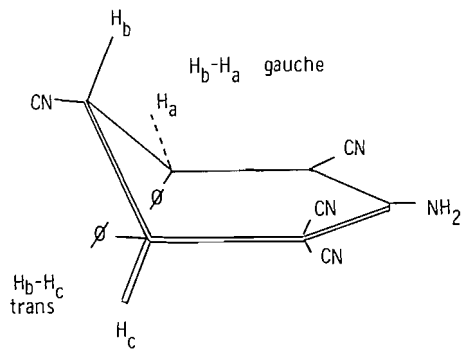
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

double bonds is greater than that in the imino form in which one double bond is outside of the ring.

2. Products from Benzalmalononitrile

Benzalmalononitrile, on treatment with *n*-butyl amine in ethanolic solution gave two crystalline products, of m.p.'s 210–213 °C and 155–158 °C respectively.

A. The structure which seems to best fit the n.m.r., infrared, and analytical data on the 210–213° compound is IV, Table I. The outstanding structural feature in the n.m.r. spectrum (Fig. 1.2) of this material is the partially split AB quartet with the superimposed split singlet centered around 5.8 τ. We have interpreted this as an ABC system (9), in which the A and B hydrogens are involved in mutual splitting while the C hydrogen is not split by A. Such a system is present in the structure proposed, hydrogens A and B being on adjacent carbons and the angle between the two C—H bonds being about 60°, while hydrogens B and C, also on adjacent carbons, are *trans* to each other, and the C—H bonds are at approximately 180°. (See diagram of model.) Consideration of the



Projection drawing IV

Karplus curve (10, 11, 12) indicates that the expected coupling constants for such a system would be small in the case of the A and B hydrogens and large for the B and C hydrogens: the observed J values are in fact as follows: $J_{AB} = 2$ c.p.s.; $J_{BC} = 13$ c.p.s.; $J_{AC} = 0$ c.p.s.

The other compelling piece of evidence in favor of this structure was obtained from deuterium-labelling experiments. When benzalmalononitrile was replaced by $C_6H_5CD{=}C(CN)_2$ as starting material in the base-catalyzed condensation the 210–213° compound which was isolated had only 1 singlet at 5.1 τ (Fig. 1.2*b*) in the n.m.r., instead of the quartet with superimposed singlet. The rest of the spectrum was unchanged. This would fit the proposed structure if both carbons carrying phenyl groups were deuterated, the structure being XI: the 5.1 τ peak now lies *between* the two peaks in the quartet assigned to hydrogen B. On the other hand, if the reaction were run with unlabelled benzalmalononitrile but in C_2H_5OD as solvent we should expect to see two singlets (those due to hydrogens A and C) remaining in the quartet region of the spectrum. These in fact appear (Fig. 1.2*a*) at 5.5 τ (the position of the split singlet due to hydrogen A (Fig. 1.2)) and at 5.9 τ (between the two peaks in the AB quartet assigned to hydrogen C in Fig. 1.2). The nonexchangeability of the benzylic hydrogen of benzalmalononitrile under basic conditions was checked (see experimental section).

A possible mechanistic pathway leading to this product is outlined in Table I, Path C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(i). Here, instead of the "normal" Michael addition of malononitrile to benzalmalononitrile, we suggest that an "abnormal" Michael addition (13) takes place, involving the intramolecular shift of a CN group; the system then undergoes a reverse Michael reaction to give cinnamonitrile plus $^{(-)}C(CN)_3$. Such rearrangement retrogression products are not unknown in the literature (14, 15). The subsequent steps in the mechanism, addition of a malononitrile anion, and then of a second molecule of benzalmalononitrile and final ring closure, are indicated in Table I. The compound appears to contain one molecule of ethanol of crystallization, readily removed by heating under vacuum to 90°, or by heating at atmospheric pressure to 160°. Ethanol, or methanol, of crystallization could be reintroduced into the compound by crystallization of the de-ethanolated material from the appropriate solvent. The n.m.r. spectra of the ethanolate and of the de-ethanolated material were identical, except for the signals due to ethanol. Alkaline permanganate oxidation of IV gave benzoic acid in a yield which suggested the presence of two phenyl groups per molecule. Hydrolysis of IV in 30% sulfuric acid gave a ketone.

B. Consideration of the analytical and spectral data have lead us to suggest V as a likely structure for the 155–158° compound. The infrared spectrum of the material shows C=C, C=N, N—H and a strong conjugated CN band. The n.m.r. spectrum includes two single peaks at 5.2 τ and 5.4 τ, each of area 1 (the hydrogens on the carbons carrying phenyl groups), a signal at 3.6 τ of area 1.8 (the amino hydrogens), and a signal at 1.5 τ of area 0.8 (the hydrogen on the ring nitrogen), as well as the phenyl and the ethanolic CH_3CH_2 hydrogen signals (Fig. 1.3). The mechanism is outlined in Table I, Path C (ii). Hydrolysis of V in 30% aqueous sulfuric acid gave a ketone. Oxidation of the 155–158° compound with alkaline permanganate solution, or with dichromate, gave benzoic acid in a yield which suggested that each molecule of starting material contained two phenyl groups.

As isolated from the reaction medium this material contains one molecule of ethanol of crystallization, in addition to the bonded EtO, removable by heating under vacuum to 90° for several hours. This ethanol is reincorporated into the molecule by recrystallization of the de-ethanolated material from 95% ethanol (or it may be replaced by methanol by a similar procedure). The n.m.r. spectra of the ethanolate and the de-ethanolated material are identical, except for the signals due to ethanol. Both of these products from the condensation of benzalmalononitrile using *n*-butyl amine as catalyst, appear to be quite different from the cyclobutane dimers of the type XII, described recently by Patai and Rappoport (16), who stated that these can be produced by treatment of alkylidenemalononitriles with malononitrile under conditions similar to those used in some of the experiments here. The cyclobutane dimer of benzalmalononitrile was readily prepared by irradiation of the solid monomer for a few days with a sun lamp according to the method of Baker and Howes (17), but we were not able to produce this compound in solution media, either by using malononitrile, or malononitrile plus base, as catalyst. However, as Patai and Rappoport also state (16), these condensations are extremely sensitive to experimental conditions, so that even when the procedures given in the experimental part are followed closely the results are irreproducible. In many cases we isolated only tars or starting materials.

3. Products from Ethylidenemalononitrile

The extreme sensitivity of ethylidenemalononitrile to base is evident from the special precautions (20, 21) necessary in the preparation of the pure liquid. Contact with even the small amounts of alkali present in Pyrex glassware is sufficient to cause the liquid monomer to condense to a pale-yellow solid over a period of 1 or 2 days at room temperature. To determine whether this condensation of ethylidenemalononitrile followed

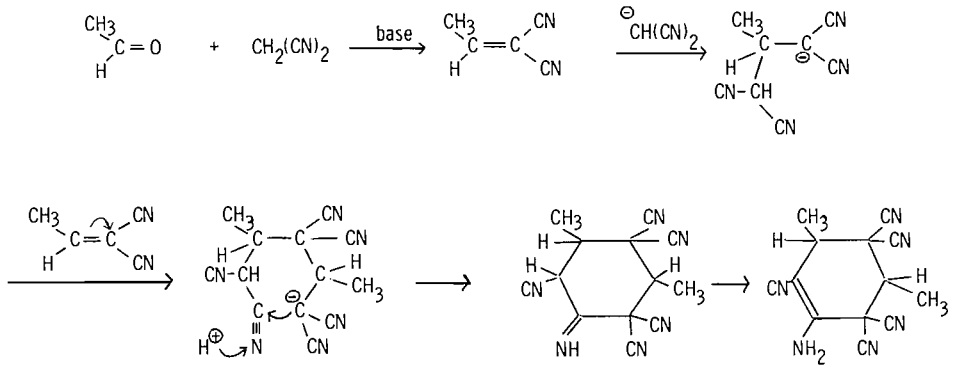
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the general pattern recently described (4, 6) for the base-catalyzed condensation of alkylidenemalononitriles (Table I, Path A), we have now investigated the reaction under more controlled conditions in dilute solution, in the presence of added base. By analogy to the base-catalyzed dimerization of isopropylidenemalononitrile (4) ethylidenemalononitrile might have been expected to form the dimeric product VI. Also by analogy to the isopropylidene system (4) the other expected product here would have been of type VII, formed by 1,4 addition of malononitrile to the imino form of the dimer (VI) (see Table I).

However, all of the spectral and analytical evidence we have obtained strongly suggests that the product isolated from the treatment of ethylidenemalononitrile with base in solution, or from acetaldehyde plus malononitrile (the precursors of ethylidenemalononitrile) and base in solution, was in fact VIII. Furthermore, this material (15) was not the same as the yellow solid formed by the action of base on the pure liquid ethylidenemalononitrile.

The reaction mechanism leading to VIII is outlined in Table II, and the n.m.r. spectrum is given in Fig. 1.4.

TABLE II



VIII

The area of the methyl doublets around 8.4 τ is in agreement with structure VIII and clearly indicates that the material is neither the simple dimer nor the dimer plus, malononitrile which might have been predicted by analogy to the isopropylidenemalononitrile system (4). Both the n.m.r. and the infrared spectra suggest that VIII is present almost exclusively in the amino form. Thus the infrared spectrum has a strong conjugated CN absorption which could not be accommodated in the imino structure; likewise the NH_2 signal of area 2 in the n.m.r. spectrum at 3.9 τ favors the amino form. The two sets of doublets centered around 8.4 τ and the overlapping quartets at 6.8 τ suggest that the compound exists as a mixture of two conformers.

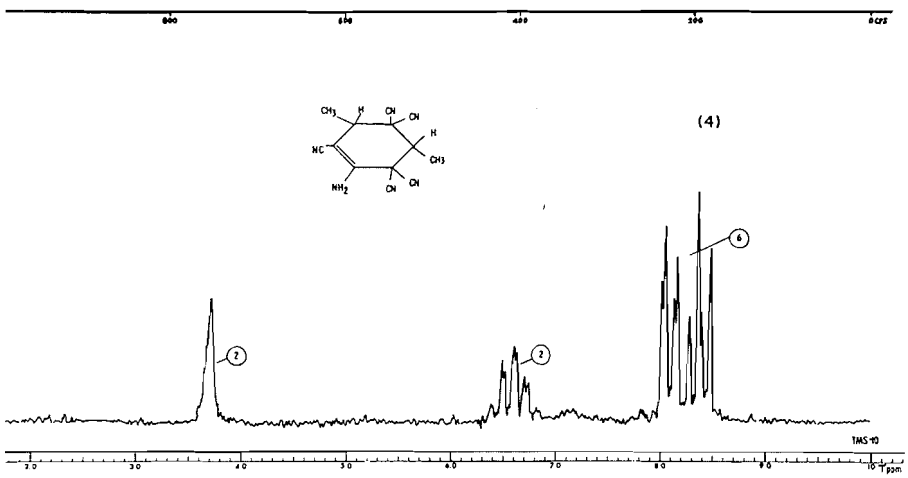

FIG. 1. (i) The spectra were run in the following solvents: (1) and (2) in acetonitrile and in benzonitrile; (3) in acetone and in benzonitrile; (4) in acetonitrile. All solutions approximately 10%. (ii) Relative peak areas are shown in the circled numbers. (iii) Tetramethylsilane internal standard.

The tendency of ethylidenemalononitrile to undergo condensation via attack on the β-carbon by a malononitrile anion in contrast to the pathway involving abstraction of a proton from a methyl in $(CH_3)_2C{=}C(CN)_2$ is possibly best explained on the basis of the inductive effects of the two methyl groups which reduce the effective polarization of the molecule and hence the net positive charge on the β-carbon, thereby making it less susceptible to attack by a malononitrile anion. Replacement of one of the CH_3 groups by a proton appears to diminish this effect sufficiently to favor condensation via initial attack on the β-carbon.

The other material isolated, the yellow solid formed by the action of base on liquid ethylidenemalononitrile, appears from the elemental analysis to be a simple polymer without any additional malononitrile incorporated into the structure. The infrared spectrum indicated that it did not contain any NH or conjugated CN. The n.m.r. spectrum showed two doublets around 8 τ and two shattered quartets between 6.5 and 7.5 τ. However, the low solubility of the material made good spectral determinations difficult. It seems possible that the yellow solid might be a mixture of cyclobutane dimers of the kind XII recently described by Patai and Rappoport (16) as being formed from systems of the type $ArCH{=}C(CN)_2$. However, molecular weight determinations were conflicting and failed to give clear evidence in favor of a dimeric structure.

General Remarks

Attempted base-catalyzed condensations of β-ethylbenzalmalononitrile, β-phenylbenzalmalononitrile, and β-naphthylmethylenemalononitrile, as well as of several ring-substituted benzalmalononitriles, have in our hands yielded only tarry products so far. It would appear that base-catalyzed condensations of arylmethylenemalononitriles are much more sensitive to reaction conditions than are those of the alkylidenemalononitriles studied here (with the exception of ethylidenemalononitrile). As we have already indicated, these condensations are not always reproducible even when the experimental procedures are followed closely. Also, when, as in the case of the arylmethylenemalononitriles, the first step in the reaction involves a Michael addition, in contrast to abstraction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of a proton from an alkyl group as in the alkylidenemalononitrile cases, the number of subsequent mechanistic pathways available to the system is greatly increased; hence the greater variety of products obtained from benzalmalononitrile under basic conditions.

EXPERIMENTAL

Preparation of β-Methylbenzalmalononitrile (18)

Acetophenone (60 g, 0.50 mole) and malononitrile (33 g, 0.50 mole) were added to 4 g (0.057 mole) of ammonium acetate plus 12 ml of glacial acetic acid in 200 ml of benzene. The mixture was heated to reflux with stirring and the water evolved was collected in a Dean-Stark trap. Refluxing overnight produced 14 ml of water. The benzene was then removed under vacuum leaving a yellow solid, which was crystallized from 50% ethanol. The product was obtained in the form of pale-yellow prisms of m.p. 93–94°. (Lit. (18) 94 °C.) Yield 75 g, 90%.

Preparation of Ethylidenemalononitrile

Two recent patent references (19, 20) are available for the preparation of this material. We found, however, that the following method worked for the preparation of the quantities we required.

Malononitrile (3.3 g, 0.05 mole) and acetaldehyde (3.0 g, 0.07 mole) were dissolved in 50 ml of benzene, and a few drops of diethylamine were added. The solution was left at room temperature for 2 h, and then washed with dilute hydrochloric acid and water, and dried over "Drierite". Removal of the solvent gave a clear liquid, which was vacuum distilled from glassware previously well washed with dilute hydrochloric acid. $n_D^{20} = 1.4571$; infrared (smear) 3.2, 3.3, 4.4, 6.2, 6.95, 7.25, 7.50, 8.35, 9.20, 9.50, 10.20, 11.50, in μ; n.m.r. in CCl_4, doublet, relative area 3, centered on 7.75 τ, quartet, relative area 1, centered on 2.25 τ.

Base-catalyzed Condensation of β-Methylbenzalmalononitrile

β-Methylbenzalmalononitrile (4 g) was dissolved in 95% ethanol with slight warming, and a few drops of diethylamine added. On standing overnight a solid was deposited from the mixture. On crystallization from ethanol this gave 2.9 g of bright-yellow needles of m.p. 206–207 °C. (Yield 72%.)

Anal. Calcd. for $C_{22}N_{10}N_4$: C, 78.57; H, 4.76; N, 16.65; molecular weight, 336. Found: C, 78.42; H, 5.02; N, 16.50; molecular weight, 330.

The main infrared peaks (in KBr) are 2.92, 4.43, 6.23, 6.32 (shoulder), 6.45, 6.70, 6.90, 7.00, 7.95, 13.10, 13.50, 14.40, in μ. λ_{max} values in the ultraviolet: 324 mμ and 250 mμ. This compound may also be prepared from acetophenone and malononitrile plus base by the method of Anderson, Bell, and Duncan (3).

Base-catalyzed Condensation of Benzalmalononitrile

Benzalmalononitrile (1 g, 0.0065 mole) was dissolved in 50 ml of 95% ethanol, and 0.2 g (0.0033 mole) of malononitrile added. The flask was then swept with nitrogen, and 0.4 g (0.0055 mole) of *n*-butylamine was added. After stirring in a stream of nitrogen gas for about 24 h the solid product was collected, washed with 95% ethanol, and recrystallized from ethanol. This reaction was not reproducible, an intractable tar being the only product on many occasions. Also the crystalline product formed was sometimes the material of m.p. 155–158 °C, and sometimes that of m.p. 210–213 °C. Average yields were 0.10 g for the 210–213° compound, and 0.1–0.2 g for the 155–158° material. The difficulty of drying the samples thoroughly without removal of some of the ethanol of crystallization complicated the analyses in both the 210–213° and the 155–158° compounds.

210–213° Melting Compound

Analyses: (a) ethanolate.—Calcd. for $C_{24}H_{19}N_5O$: C, 73.40; H, 4.84; N, 17.80; molecular weight, 393. Found: C, 73.25; H, 5.26; N, 17.52; molecular weight, 406.

(b) De-ethanolated sample.—Calcd. for $C_{22}H_{13}N_5$: C, 76.02; H, 3.75; N, 20.06. Found: C, 76.08; H, 3.69; N, 19.63.

Main bands in the infrared spectrum of the de-ethanolated compound (KBr): 2.80, 2.89, 3.00, 3.20, 3.24 (weak), 4.50, 6.08, 6.20 μ. There was also a broad absorption between 13.7 and 14.4 with peaks at 13.72, 13.99, and 14.32, in μ.

Permanganate Oxidation of Solid, M.P. 210–213°

The material (0.1 g) was refluxed overnight in a mixture of 0.3 g of potassium permanganate, 1 small pellet of sodium hydroxide, and 10 ml of water. After cooling, the mixture was acidified with dilute sulfuric acid and refluxed for a further 30 min. The manganese dioxide was then taken up with sodium bisulfite, and the aqueous solution cooled and extracted with ether; 0.05 g of benzoic acid was obtained from the ether extracts; m.p. 121–122 °C, mixed melting point with an authentic sample of benzoic acid, 122–124 °C.

Hydrolysis of Solid, M.P. 210–213°

The solid (0.1 g) was heated with 20 ml of 30% aqueous sulfuric acid overnight. The resulting white powder was washed with distilled water till free from acid and dried. Attempted recrystallization led to discoloration. A strong ketone absorption was now present in the infrared spectrum, whose main peaks (KBr) were at 3.35, 5.68, 6.69, 6.82, 13.73 (shoulder at 13.9), and 14.28 μ.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

155–158° Melting Compound

Analyses: (a) ethanolate.—Calcd. for $C_{27}H_{26}N_6O_2$: C, 69.50; H, 5.58; N, 18.00; molecular weight, 466. Found: C, 69.81; H, 5.54; N, 18.54; molecular weight, 419.

(b) De-ethanolated sample.—Calcd. for $C_{25}H_{20}N_6O$: C, 71.50; H, 4.76; N, 20.00. Found: C, 71.18; H, 4.79; N, 20.13.

Main absorptions in the infrared spectrum of de-ethanolated compound (KBr): 2.90 (shoulder at 2.80 and 3.00), 3.30–3.40 (weak), 4.50, 6.10, 6.25 (shoulders at 6.00 and 6.32), 6.70, 6.90, 14.00, and 14.30 (shoulders at 3.76), in μ. The permanaganate oxidation and the sulfuric acid hydrolysis were carried out in the same manner as for the other compound described above. The main infrared peaks (KBr) in the hydrolysis product were at 2.90 (shoulder at 2.85), 3.20–3.40 (broad and weak), 4.50, 5.70, 6.15, 6.25, 7.73, 6.90, 13.80 (shoulder at 13.95), and 14.30 μ.

Base-catalyzed Condensation of Ethylidenemalononitrile in Solution

Ethylidenemalononitrile (1 g) was dissolved in 25 ml of benzene and a small amount of malononitrile and 3 drops of diethylamine were added. The mixture was left at room temperature for 2 h, washed with dilute hydrochloric acid and then with water, and dried over Drierite. Removal of the benzene left a glass which crystallized to a white solid overnight. On recrystallization from chloroform this yielded a finely crystalline white powder of m.p. 173–174 °C. The main absorptions in the infrared were at 2.79, 2.86, 2.98, 3.25, 4.47, 6.04, 6.16, and 6.83, in μ.

Anal. Calcd. for $C_{13}H_{10}N_6$: C, 62.40; H, 4.00; N, 33.60; molecular weight, 250. Found: C, 62.50; H, 4.33; N, 33.40; molecular weight, 229.

This compound could also be prepared by the following method: 2.4 g (0.055 mole) of acetaldehyde and 6.6 g (0.050 mole) of malononitrile were dissolved in 100 ml of benzene and 6 drops of diethylamine were added to the mixture. After standing at room temperature for 2 h the benzene solution was washed with dilute hydrochloric acid, and then with water. Removal of the solvent and crystallization from chloroform as above gave the white crystalline product.

Base-catalyzed Condensation of Ethylidenemalononitrile in Absence of Solvent

Ethylidenemalononitrile on standing in contact with glass for 1 or 2 days condensed to a yellow solid, which on crystallization from 95% ethanol gave a pale-yellow powder of m.p. 166–168°.

Anal. Calcd. for $C_{10}H_8N_4$: C, 65.30; H, 4.35; N, 30.41; molecular weight, 184. Found: C, 64.95; H, 4.53; N, 30.72; molecular weight, 180, 270 (on two separately prepared samples of material).

Preparation of Benzalmalononitrile-d_1

Ethyl benzoate was reduced with lithium aluminium deuteride to $C_6H_5CD_2OH$ (21) which was then oxidized with activated manganese dioxide to C_6H_5CDO (22). The benzaldehyde-d_1 was condensed with malononitrile following the method already described for the preparation of benzalmalononitrile.

1. To 1.7 g (0.041 mole) of lithium aluminium deuteride in 500 ml of dry ether was added, dropwise, 10 g (0.067 mole) of ethyl benzoate. After addition of the ester the mixture was refluxed for a further hour, the excess deuteride destroyed with wet ether, and the mixture poured into ice-cold 10% sulfuric acid. Extraction with ether and removal of the solvent gave 6.5 g (88%) yield of alcohol. The infrared spectrum of the product showed strong C—D absorptions at 4.5 and 4.7 μ. No ester absorption was apparent at this stage.

2. Activated manganese dioxide (22 g, 0.26 mole) was added to 250 ml of benzene and the mixture refluxed till no more water appeared to be coming off. The water evolved was collected in a Dean-Stark trap. $C_6H_5CD_2OH$ (6.5 g, 0.059 mole) was then added, and the refluxing continued till a further 1 ml (approximately) of water was collected. The mixture was then cooled and filtered and the solvent removed under vacuum. Benzaldehyde-d_1 (3.8 g, 67% yield) was isolated. This was distilled through a Nester/Faust micro spinning band column. The final product showed a strong carbonyl absorption in the infrared at 5.9 μ, and C—D absorptions at 4.5 and 4.7 μ. No alcohol or ester absorptions were apparent.

Control Experiment on Base-catalyzed Exchange of the Benzylic Hydrogen in Benzalmalononitrile

Benzalmalononitrile was dissolved in methanol-d_1 and the n.m.r. spectrum recorded. The benzylic hydrogen, appearing downfield from the aromatic hydrogens, is readily distinguishable from the latter. The addition of a drop of *n*-butyl amine or of ethanolic potassium hydroxide to the solution caused no appreciable change in the relative areas of the benzylic and aromatic hydrogens. Addition of several drops of base eventually caused the benzylic hydrogen peak to almost disappear, but not before the aromatic hydrogen absorptions had also decreased in intensity and sharpness, and the solution had turned brown, the latter presumably being due to condensation and tar formation.

Notes

Molecular weights were determined osmometrically. Melting points are uncorrected.

COMPLEX FORMATION BETWEEN PROPARGYL CHLORIDE AND BENZENE

JAMES TYRRELL
Department of Chemistry, McMaster University, Hamilton, Ontario
Received November 5, 1964

ABSTRACT

The proton resonance signals of the methylene and ethynyl hydrogens in propargyl chloride shift upfield in going from cyclohexane to benzene as solvent. This is interpreted as being due to complex formation between propargyl chloride and benzene. Though the methylene proton resonance signal shifts farther upfield than does the ethynyl proton resonance signal, it is found that only a 1:1 complex exists between the two molecules. The complex is considered to be one in which the methylene protons "bond" to the π-electron system of the benzene ring. The ethynyl proton of the propargyl chloride is thought to lie close enough to the ring to interact with the "ring current", but not close enough to be a prime agent in complex formation.

INTRODUCTION

Nuclear magnetic resonance can be used to study the phenomenon of hydrogen bonding in solution and can allow very accurate determination of the extent of association between the complexing agents. Where the hydrogen involved is bonding to an oxygen or nitrogen the proton resonance signal moves downfield relative to that of the uncomplexed proton signal. Where the solvent is benzene or some other aromatic compound, the proton resonance signal is found to move upfield: this being explained by the large anisotropy in the magnetic susceptibility of aromatic molecules, commonly referred to as the "ring current" effect (1). In propargyl chloride, however, it was shown by Hatton and Richards (2) that both the methylene and the ethynyl proton resonance signals moved upfield in going from cyclohexane to benzene as solvent. In fact, the shift upfield of the proton resonance signal of the methylene group (27 c.p.s.) was greater than that of the ethynyl proton (18.6 c.p.s.). Though this difference was not commented on by the above authors, it was considered significant enough to be studied more closely.

EXPERIMENTAL

The propargyl chloride used was obtained commercially and fractionally distilled, the main fraction having a boiling point of 56 °C. The benzene and cyclohexane used were AnalaR reagents and were used without further purification. The investigation was carried out with a concentration of 0.2 mole/l of propargyl chloride, the solvent ranging from pure cyclohexane through various mole fractions of benzene in cyclohexane. As cyclohexane was used both as an inert solvent and as an internal reference from which to measure the chemical shift, it was impossible to obtain results in pure benzene.

The instrument used in these investigations was an Associated Electrical Industries R.S.2 nuclear magnetic resonator, the samples being studied at room temperature (25 °C) using a 60 Mc probe. To detect the proton resonance signal at the low concentrations used, it was necessary to operate at high power and at a fairly high filter setting. Calibration was obtained using an audio frequency unit in the spectrometer and side bands were taken from the internal reference to encompass the region being studied.

If the chemical shift in cycles per second from cyclohexane of the proton resonance signal in pure cyclohexane is denoted by δ_A, and the chemical shift in the mixed solvent by δ_1, then the chemical shift due to complex formation can be taken as $\delta = \delta_1 - \delta_A$. In addition, if x_B is taken as the mole fraction of the active solvent in cyclohexane, and δ_{AB} is taken to be the chemical shift if complex formation is complete, then it is possible to use the following equation to determine the association constant K_n:

$$[1] \qquad x_B/\delta = x_B/\delta_{AB} + 1/K_n\delta_{AB}.$$

The above formula assumes a 1:1 complex and was derived in the same manner as that given by Brand, Eglinton, and Morman (3). The position of the proton resonance signals were obtained with considerable accuracy by placing side bands of known frequency on either side of the proton signal. In the case of the methylene proton resonance signal where there are two peaks, the mid-point of these was taken.

To investigate the activating power of substituents on neighboring methylene groups, a number of compounds were studied in carbon tetrachloride and in benzene, with tetramethylsilane as the reference standard. The chemical shift of the methylene proton resonance signal on going from carbon tetrachloride to benzene as solvent was noted. Of the compounds studied propargyl chloride, methylene chloride, and chloroacetonitrile were commercial products which were dried and distilled before use. The 1,4-dichlorobut-2-yne was supplied by Dr. G. Eglinton. The concentration of solute in all cases was taken to be 0.2 mole/l of solvent.

RESULTS AND DISCUSSION

When x_B/δ was plotted against x_B for propargyl chloride in benzene–cyclohexane, a straight line graph was obtained from whose slope and intercept it was possible to obtain the values for K_n and δ_{AB}. The method of least squares was employed to obtain the limiting errors in the results. Tables I*a* and I*b* give the results obtained for the methylene

protons and for the ethynyl proton respectively. These results led to the following constants.

(*a*) From the methylene protons: $K_n = 1.01 \pm 0.02$ (mole fraction)$^{-1}$; $\delta_{AB} = 63.8 \pm 1.3$ c.p.s.; degree of association ($x_B = 1$) $= 0.50 \pm 0.01$.

(*b*) From the ethynyl proton: $K_n = 0.96 \pm 0.06$ (mole fraction)$^{-1}$; $\delta_{AB} = 37.0 \pm 2.4$ c.p.s.; degree of association ($x_B = 1$) $= 0.49 \pm 0.04$.

The effect of different neighboring groups on the chemical shift of the methylene proton in going from carbon tetrachloride to benzene as solvent is shown in Table II. The results tended to suggest that the activating power of the neighboring groups followed the order: C≡C < Cl < C≡N.

The results obtained for propargyl chloride indicated that the δ_{AB} for the methylene protons was nearly twice that obtained for the ethynyl proton. This indicated that the

methylene protons were interacting to a greater extent with the ring current of the benzene than was the ethynyl proton. The results obtained from studying the chemical shift of the methylene protons gave a straight line graph indicating the presence of a 1:1 complex. However, the graph obtained from the ethynyl proton results was slightly curved at lower values of x_B. This curvature was not pronounced and was probably due to the increasing importance of experimental error when measuring small differences. However, within their stated errors all points lay on a straight line. The association constants obtained for both types of protons were identical within the limits of experimental error, indicating that the results obtained from the methylene and ethynyl protons referred to the same 1:1 complex. In this complex it would appear that the methylene protons were closer to the ring than the ethynyl proton, the axis of the molecule lying at an angle above the plane of the ring.

The work of Buckingham, Schaefer, and Schneider (4) provided the theoretical basis for interpreting the results obtained as being due to complex formation. The contributions to the chemical shift from the Van der Waals forces, the reaction field, and the bulk diamagnetic susceptibility were effectively eliminated by using cyclohexane both as an inert solvent and as the internal reference. This left only two contributions to the chemical shift arising from the presence of the solute in the solvent. These were the shift due to the solvent magnetic anisotropy and the shift arising from complex formation. Now Schneider (5) has shown that the latter contribution is usually negative while the former contribution, particularly in aromatic solvents, is large and positive. For propargyl chloride in benzene the ethynyl and methylene proton resonance signals were shifted upfield, which suggested that the small chemical shifts of the solute proton signal, arising from complex formation in aromatic solvents, were effectively amplified because of the large magnetic anisotropy of the active solvent. It was therefore assumed that the chemical shifts observed were the result of complex formation between propargyl chloride and benzene.

Though the foregoing allows one to assume complex formation between propargyl chloride and benzene it does not help to decide whether the association is due to a form of hydrogen bonding between the methylene protons and the π-electron system of benzene, or whether it is due to dipole-induced dipole effects produced by the solute dipole. Both forms of association would be strongly influenced by temperature. While it is now generally accepted that hydrogen bonding can occur between the C—H group of a molecule such as chloroform and the π-electrons of benzene (6), there is still considerable controversy as to whether hydrogen bonding can occur in a situation in which a CH_3 group or a CH_2 group is the hydrogen donor. Abrahams (7), for instance, has concluded that association between methyl halides and aromatic solvents is caused by

For personal use only.

hydrogen bonding; whereas Schneider (5) attributes the complex formation to a dipole-induced dipole form of attraction. The present state of knowledge only allows one to conclude that propargyl chloride forms a 1:1 complex with benzene, in which the methyllene protons are closer to the plane of the ring than is the ethynyl proton.

COORDINATION COMPLEXES OF GROUP (IV) HALIDES

PREPARATION OF THE COMPLEXES OF TITANIUM TETRACHLORIDE, TITANIUM TETRABROMIDE, AND TIN TETRACHLORIDE WITH SOME THIO-, ISOTHIO-, AND ISO-CYANATE LIGANDS[1]

SUMER CHAND JAIN[2] AND ROLAND RIVEST
Department of Chemistry, University of Montreal, Montreal, Quebec

Received September 21, 1964

ABSTRACT

Coordination complexes between ethyl thiocyanate, ethyl isothiocyanate, ethylene dithiocyanate, ethyl isocyanate, and tetrachlorides of titanium and tin and titanium tetrabromide have been prepared. The analytical results indicate that under different experimental conditions one can obtain compounds of the following type:

$MX_4.L$	$2MX_4.L—L$	$MX_4.2L$	$MX_4.L—L$
a	*b*	*c*	*d*

where MX_4 is a Lewis acid and L, L—L are mono- and bi-dentate ligands respectively. The complexes obtained are compared with the dinitrile complexes prepared by us previously (1).

INTRODUCTION

After our study on the nitrile and dinitrile complexes of group (IV) halides (1) where coordination was reported to take place through the nitrogen atom of the CN group, it was considered interesting to study the thiocyanate, isothiocyanate, and isocyanate molecules as ligands having the sulfur and oxygen atoms respectively in addition to nitrogen atoms as donor atoms. Since these functional groups are linear, the two donor atoms present in the ligand molecule cannot coordinate to the same metal atom but can, without putting too great a strain on the ligand molecule, coordinate to two different metal atoms and form a bridge between them.

Some work has been reported on the inorganic thiocyanate complexes of Co, Ni, Cu, Cr, Pt, etc. (2), by Mitchell and Williams. In their article the authors had intended to use inorganic thiocyanates to diagnose the type of binding in terminal thiocyanate complexes. Taking into account all the factors influencing the vibration frequency of the CN group, they could not reach their original goal but could, however, make correlations between infrared band frequencies and structure. These correlations were: (*a*) the frequency was at higher wave numbers in the order M—NCS $\leqslant$ M—SCN $<$ B—SCN—M, where M was the central metal ion and B the cation used to neutralize the charge on anionic thiocyanate; (*b*) for a given arrangement of the thiocyanate ion, the more polarizing the cation the greater the frequency of the CN vibrations; (*c*) bridged thiocyanates could also be obtained.

Lewis and co-workers (3) using infrared together with X-ray and ultraviolet spectral studies have found that the bonding in the $[Mo(NCS)_6]^{3-}$ ion occurs through the nitrogen; inorganic thiocyanate and isothiocyanate have thus largely been studied as ligands, but very little is reported on the organic thiocyanates and isothiocyanates as ligands with group (IV) halides.

[1]*Paper presented at the 47th Chemical Institute of Canada Conference, Kingston, June 1, 1964.*
[2]*Present address: Postdoctorate Fellow, Chemistry Department, University of Western Ontario, London, Ontario, Canada.*

The purpose of this work was to investigate: (*a*) how the coordination of thiocyanates compares with nitriles in the complexes with group (IV) halides; (*b*) which of the two possible donor atoms, sulfur or nitrogen, are involved in coordination; and (*c*) how the coordination of thiocyanates compares with the coordination of isocyanates and isothiocyanates.

EXPERIMENTAL

The experimental setup and the method of preparation of the complexes were quite similar to the ones used previously (1, 4). The Lewis acids used were purified by appropriate methods as mentioned in a previous publication (1). The ligands were obtained from the Fisher Scientific Co. and were dried on molecular sieves before use. The reactions were performed in solutions in methylene chloride or hexane (Table I). The ethyl isothiocyanate complex with titanium tetrachloride was a liquid at room temperature and all the other complexes reported were solid, powdery products which were filtered, washed, and dried under vacuum at room temperature.

The analysis of chlorine and of the metals have been described previously (5, 6). The results are included in Table I. The infrared spectral measurements were carried out on a Perkin–Elmer spectrophotometer Model 21, using a sodium chloride prism. The results obtained for the stretching frequency of the functional group are included in Table II.

TABLE II

Infrared spectra results (in Nujol mulls)

Complex	Stretching frequency of the functional group (cm^{-1})		Shift in stretching frequency (cm^{-1})
	Pure ligand	Compound

INFRARED SPECTRA AND STRUCTURAL DISCUSSION

From the work of Lieber and Rao (7) organic thiocyanates exhibit a band at 2 140 cm^{-1} probably due to the C≡N frequency and another one in the 683–722 cm^{-1} region mostly due to C—S stretching. For our complexes of ethyl thiocyanate as monodentate

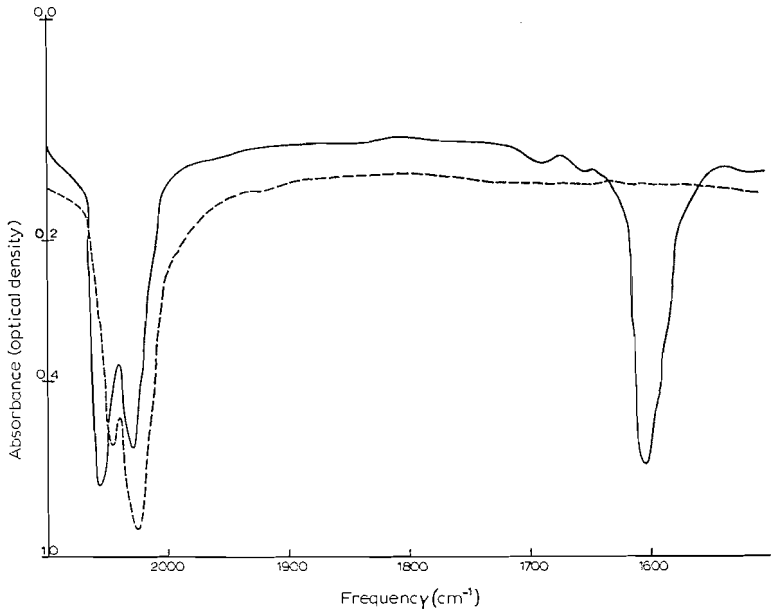

FIG. 1. Infrared spectra of pure C_2H_5NCS (- - -), complex $TiCl_4.C_2H_5NCS$ (—). (Both taken in Nujol mulls.)

and ethylene dithiocyanate as bidentate ligand, the infrared spectra indicate a positive shift of the CN-stretching frequency similar to the shift observed for dinitrile complexes. However, in the dinitrile series (1) the values of the frequency shifts in similar compounds were always lower for the $SnCl_4$ than for the $TiCl_4$ complexes. In our thiocyanate complexes they are about the same. Moreover, in the dinitrile series the frequency shifts were identical for the complexes of $TiCl_4$ and of $TiBr_4$ and in the thiocyanate series they are much smaller for the $TiBr_4$ complexes.

Since one would not expect any steric effect on the bonding to titanium when passing from R—SCN to R—CN if the bonding is done through nitrogen, one would then explain this effect by assuming that coordination is done through sulfur and thus explain the steric hindrance of the bromine compared to that of the chlorine in the titanium complexes. In the comparison between the complexes of dinitriles with the complexes of dithiocyanates, one point worth mentioning is that the thiocyanate complexes had relatively low true melting points and that they could be purified by sublimation. This was not the case for the dinitrile complexes which decomposed before melting.

The complex of $TiCl_4$ with ethyl isothiocyanate is quite different from the analogous complex with ethyl thiocyanate. 1. The color of the complex with ethyl isothiocyanate is dark orange whereas the color of the other one is yellow. 2. One is a liquid at room temperature, the other has a melting point of 90 °C. 3. The infrared spectrum of the thiocyanate complex is quite similar to the spectrum of the pure thiocyanate ligand except for the band assigned to the SCN group observed at 2 160 cm^{-1} in the pure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ligand and shifted to 2 195 cm^{-1} in the complex, whereas the infrared spectrum of the complex isothiocyanate is very different from the spectrum of the pure isothiocyanate ligand. According to Lieber (7) the infrared spectra of isothiocyanates exhibit a strong band in the region of 2 100 cm^{-1} due to the isothiocyanate group. This band shows its fine structure at smaller layer thickness and leads to two bands as we observed for the pure ligand. As one would expect on coordination these bands are increased by about 40 cm^{-1}. A new band at 1 605 cm^{-1} is particularly surprising. It indicates a great change of the electron distribution of the ligand in the complex and could be explained only by assuming that it is due to N=C bonding.

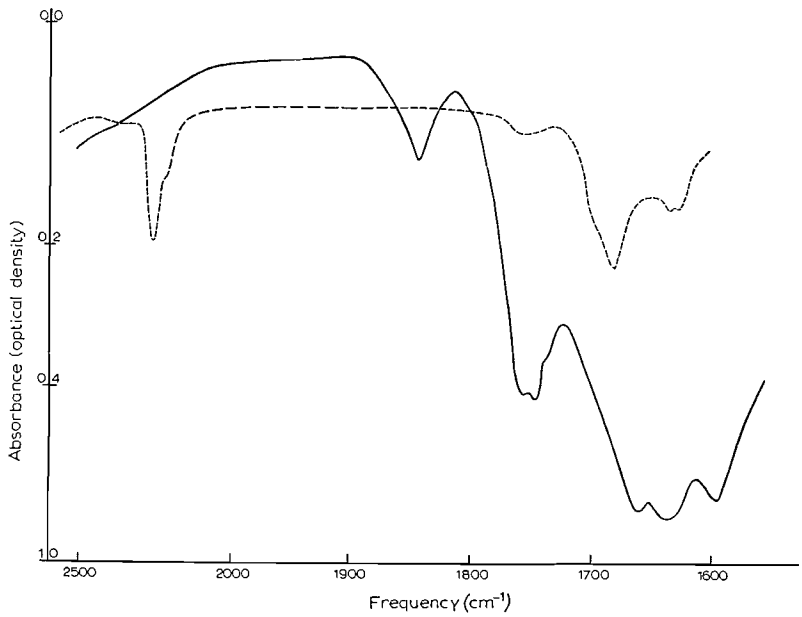

FIG. 2. Infrared spectra of pure C_2H_5NCO (- - -), complex $TiCl_4.2C_2H_5NCO$ (—). (Both taken in Nujol mulls.)

It is interesting to note that a similar effect has been observed in the case of isocyanate, Fig. 2. In the pure state isocyanate has a band at 2 272 cm^{-1}; this band vanishes in the $TiCl_4$ complex and a new band appears at 1 845 cm^{-1}, and a doublet at 1 700 cm^{-1} in the pure ligand is shifted to 1 750 cm^{-1} and intensified. The explanation of so many important changes in the spectrum of the ligand when coordinated can be qualitatively explained by assuming that coordination favors the following form C_2H_5—N=C=O over the other form C_2H_5—N—C≡O. Although this last form would contribute to a good description of the free ligand, it would not be favored in the adduct because it has a positive formal charge on oxygen.

The infrared spectrum of this compound in CH_2Cl_2 solutions shows both the original peaks and the new peaks indicating that the compound is considerably dissociated in solution. This is quite interesting since it indicates that through dissociation the original ligand is regenerated and may indicate that in the complex the molecular changes happening to the ligand are reversible if the ligand is liberated.

STEROIDS

IX.[1] THE SOLVOLYSIS OF 4,4-DIETHYLCHOLESTERYL METHANESULFONATE

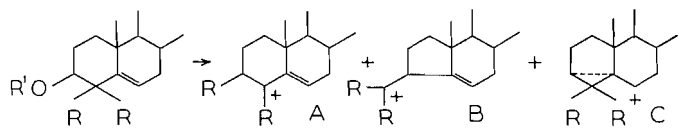
D. N. GUPTA,[2] G. SCHILLING, AND G. JUST
Departments of Chemistry, McGill University and Ayerst, McKenna and Harrison

Received October 16, 1964

ABSTRACT

The acetolysis of 4,4-diethylcholesteryl mesylate gave 11% 3,4-dialkyl (A), 39% 3α,5-cyclo (C), and 50% A-norcholestene (B) derivatives. The corresponding yield for the 4-4,dimethyl series is 25, < 11.6, and > 61.4%.

Knowledge of the mechanism of solvolysis of cholesteryl derivatives does not permit one to predict with reasonable accuracy the solvolytic reactions of 4-monomethyl (2, 3) or 4,4-dimethyl (4, 5, 6) cholesteryl derivatives. Since small changes in structure seem to have a fairly large effect on the reactions, we undertook a study of the reactions of 4,4-diethylcholesteryl mesylate, expecting to obtain a product distribution similar to that observed in the solvolysis of 4,4-dimethylcholesteryl tosylate. In that reaction (6), one isolates products formally derived from carbonium ions A, B, and C in the yields indicated.



I, R=CH_3	25%	> 61.4%	< 11.6%
III, R=C_2H_5	11%	50%	39%

Since the results obtained are somewhat unexpected, we would like to report on them.

Cholest-4-en-3-one (7) was converted to 4,4-diethylcholest-5-en-3-one (II) by appropriately modifying the procedure described by Woodward, Barton, and co-workers (8). Lithium aluminium hydride reduction (8) of ketone II gave 4,4-diethylcholesterol (III) in quantitative yield. When ketone II was reduced with sodium borohydride in N,N-dimethylformamide (9) and the resulting mixture separated on alumina, there was obtained the starting material, 3α-alcohol IV, and 3β-alcohol III in 63.5, 1.2, and 15.1% yields respectively. The stereochemical assignment of the two epimeric alcohols was based on the relative yield of products obtained and the relative ease of elution on alumina (10).

Solvolysis of 4,4-Diethylcholesteryl Mesylate (IIIa)

Mesylate III*a* was prepared by treatment of 3β-alcohol III with methanesulfonyl chloride in pyridine for 2 h at 0°. Because of its instability, it could not be purified by crystallization. However, reasonably satisfactory analytical data could be obtained for it. Mesylate III*a* was solvolyzed in buffered aqueous acetone for 16 h at reflux temperature (4–6). Ether extraction and chromatography on silica gel gave a hydrocarbon fraction (56.2%) and an alcohol fraction (36.3%). The latter was roughly separated into three sub-fractions during elution with hexane–benzene mixtures.

Hydrocarbons

From the hydrocarbon fraction, the olefins IX, VIII, and XI were separated by preparative thin-layer chromatography (t.l.c.).

Hydrocarbon IX, $[M]_D$ −21.2°, did not absorb in the ultraviolet above 220 mμ. Its nuclear magnetic resonance (n.m.r.) spectrum showed a poorly resolved two-proton signal around 5 p.p.m. and a one-proton signal at 3 p.p.m. which could be assigned to the doubly allylic proton at C_3. A similar signal was observed in the n.m.r. spectrum of 3-isopropenyl-A-norcholest-5-ene (IX*a*), $[M]_D$ −31° (6). Gas–liquid chromatography (g.l.c.) (see Table I) showed one peak at 7.05 min and a 1.8% contamination of VIII at 8.6 min. When alcohol VI, the structure of which is proved below, was submitted to g.l.c., the major portion (65%) was pyrolyzed and gave a hydrocarbon having a retention time identical to that of IX. Hydrocarbon IX was also obtained from alcohol VI by treatment with phosphorus oxychloride – pyridine, thus confirming the structure assigned.

Diene VIII absorbed in the ultraviolet at 238, 245, and 253.5 mμ, a pattern characteristic for dienes of this type (6). Gas–liquid chromatography showed one single peak at 8.6 min. Its structure was established by comparison with an authentic sample prepared by reacting 4-ethylcholest-4-en-3-one with an ethyl Grignard reagent (11).

Hydrocarbon XI, $[M]_D$ −580°, did not absorb in the ultraviolet above 220 mμ, thus excluding the possibility of a conjugated diene structure. The purity of the compound was established by g.l.c., which showed one peak at 6.7 min and a 1% impurity at 5.9 min (probably dienes XII or XIII). The n.m.r. spectrum showed a poorly resolved quartet at 5.18 p.p.m. (2H, $HC_6{=}C_7H$) and signal at 2.5 p.p.m. (1H, $HC_8{-}C_7{=}$). A one-proton signal due to cyclopropyl methine proton in conjugation with $\Delta^{6,7}$ could not be detected. These protons were reported to absorb around 1.1 p.p.m. (12, 13). In the case of hydrocarbon XI, methylene and methyl absorption obscured this region and prevented identification of cyclopropyl proton resonance peaks. A band at 780 cm^{-1} in the infrared spectrum of XI confirmed the presence of a *cis*-disubstituted double bond. The shift to the higher region indicated some conjugation with the cyclopropane ring (14, 15). The molecular rotational change[3] of alcohol VII and hydrocarbon XI was compared with that of the analogous compounds in the cholesteryl series (16). The changes were in the same direction but quite different in magnitude, reflecting some unusual deformation which is probably steric in origin (17, 18). Hydrocarbon XI was also obtained by the acid-catalyzed demethoxylation (19) of 4,4-diethyl-6β-methoxy-3α,5-cyclocholestane (VII*a*). The only other hydrocarbon which could possibly fit some of the spectroscopic data is 3-(pent-2′-en-3′-yl)-A-norcholest-5-ene (IX). Its structure, however, has been proved conclusively and can therefore be excluded as an alternative.

No other hydrocarbons could be isolated by t.l.c., although g.l.c. of the crude solvolysis

[3] *3α,5-Cyclocholestane derivatives (16): alcohol, $[M]_D$ +98°; hydrocarbon, $[M]_D$ −173°; $\Delta[M]_D$, +271°. 4,4-Diethyl-3α,5-cyclocholestane derivatives: alcohol XI, $[M]_D$ +246°; hydrocarbon, $[M]_D$ −580°; $\Delta[M]_D$ +826°.*

FLOWSHEET 1.

mixture indicated the presence of hydrocarbons having retention times of 7.5 (X) and 5.9 (XII, XIII) min. Hydrocarbons of identical retention time were also obtained when alcohol VI was submitted to g.l.c. It was noted that when the retention times of the structurally analogous hydrocarbons from the solvolyses of 4,4-dimethyl- (6) and 4,4-diethylcholesteryl sulfonates were plotted against each other, a straight line was obtained (except for hydrocarbons IX and IX*a*). This was taken as additional evidence for the presence of hydrocarbon X, and possibly XII and XIII.

Alcohols

Column chromatography and further purification by t.l.c. and crystallization gave alcohols V, VI, and VII.

The structure of alcohol VI was established as follows. The n.m.r. spectrum of the alcohol showed signals at 5.33 p.p.m. (1H, HC_6=) and 2.61 p.p.m. (1H, HC_3—C=C) (6). The alcohol was tertiary since it resisted acetylation at room or reflux temperature. Dehydration with phosphorus oxychloride – pyridine (6) gave a mixture of dienes. Separation on t.l.c. gave as major hydrocarbon olefin IX, and as minor product diene X, which absorbed in the ultrvaiolet at 251 mμ. Gas–liquid chromatography of X showed a major peak (70%) at 7.5 min in addition to minor peaks, which are either impurities or due to decomposition. A conjugated diene, 3-isopropylidene-A-norcholest-5-ene (X*a*), having identical ultraviolet spectrum and similar g.l.c. pattern, was also obtained in the 4,4-dimethyl series (6). It had been obtained directly from solvolysis of 4,4-dimethylcholesteryl tosylate or by treatment of 3-isopropanol-A-norcholest-5-ene (VI*a*) with phosphorous oxychloride in pyridine. There is therefore very little doubt about the structure of diene X.

Alcohol VII, $[M]_D$ +246°, was the major constituent of the alcohol fraction. Its infrared spectrum exhibited bands at 3 050 (inflection), 1 005 – 1 035, and 850 cm^{-1} and showed no absorption for C=C stretch around 1 600 – 1 650 cm^{-1}. Two vibrations at

For personal use only.

1 000 – 1 020 and 860 cm^{-1} in the cyclopropane ring have been frequently used to indicate an *i*-steroidal structure (20–22). Slabey (23) found that the presence of two substituents on a cyclopropane ring raised the characteristic frequencies at 1 000 – 1 020 cm^{-1}. These findings and the observed frequencies in the infrared spectrum of alcohol VII indicated the *i*-steroidal structure for it. The n.m.r. spectrum showed no signal for olefinic protons and a one-proton signal at 4.76 p.p.m. was assigned to the proton α to the oxygen function.

Chemical evidence supporting the structural assignment of VII came from the oxidation of VII with chromium trioxide – pyridine (24) to ketone XIV, $[M]_D$ +472°, ν_{CCl_4} 1 690 cm^{-1} (cyclopropyl ketone). The ketone did not absorb in the ultraviolet above 220 mμ. Comparison of molecular rotational change[4] (XIV → VII) with that observed in the 3α,5-cyclocholestane series showed that the changes were in the same direction but quite different in magnitude.

The alcohol VII appeared quite stable to base but very labile to acid. It was transformed quantitatively to 6β-methyl ether VII*a* by simple crystallization from methanol (compare ref. 6).[5] Ether VII*a*, $[M]_D$ +433°, absorbed in the infrared at 3 040 (inflection) and 1 095 cm^{-1} and showed no absorption around 3 600 cm^{-1}. Josien and co-workers (25) had reported a band at 1 095 cm^{-1} for a number of *i*-steroid ethers which distinguished them from normal methyl ethers of steroids. The n.m.r. spectrum showed a sharp three-proton peak at 3.13 p.p.m. (OCH_3) and a one-proton signal at 4.18 p.p.m. characteristic of a proton α to an oxygen function. Treatment of VII*a* with 0.001 *M* *p*-toluenesulfonic acid in absolute ethanol (19) gave a mixture of dienes. Separation by t.l.c. gave 4,4-diethyl-3α,5-cyclocholest-6-ene (XI) and 3,4-diethylcholesta-3,5-diene (VIII) in 27% and 9% yields respectively.[6]

Alcohol V was isolated in lowest yield from the solvolysis of 4,4-diethylcholesteryl tosylate. Some doubts persisted about its purity. The structural assignment was based on the following observation. Alcohol V resisted acetylation with acetic anhydride – pyridine at room temperature. At reflux temperature, a small amount of 3,4-diethylcholesta-3,5-diene (VIII) was obtained. The n.m.r. spectrum of alcohol V showed a one-proton signal at 5.5 p.p.m. (=C_6H).

Quantitative Study of Hydrocarbon Mixtures by G.L.C.

Preparative t.l.c. was used to isolate the individual compounds from the solvolysis of 4,4-diethylcholest-5-en-3β-yl mesylate (III*a*) in a pure form. However, a quantitative product distribution could not be obtained since some of the compounds, in particular diene X, were not isolated. The losses of the products due to desorption difficulties and during crystallization also did not permit a quantitative estimation of various components of the mixture. The purity of some of the compounds was by no means certain since the compounds of this nature frequently co-crystallize.

In order to ascertain the purity of the isolated compounds and the percentage composition of the solvolysis products, the hydrocarbon fractions from acetolysis of 4,4-diethylcholesteryl mesylate (III*a*) were subjected to gas–liquid chromatography (5% DC 710 on silanized gaschrom P, 6 ft column at 265.3° ± 2). Wherever possible the retention times were correlated with the retention times of the authentic samples.

[4]*3α,5-Cyclocholestane derivatives (16): ketone, $[M]_D$ +157°; alcohol, $[M]_D$ +98°; $\Delta[M]_D$ +59°.*

For personal use only.

Alcohols were excluded from the g.l.c. analyses when it was desired to determine the percentage composition of the solvolysis products, since they led to dehydration products.[7] All hydrocarbons were shown to be stable to the g.l.c. conditions used except for 3-(3′-isopentylidene)-A-norcholest-5-ene (X). The percentage yield for this diene hence represented a minimum value. No appropriate correction could be applied to compensate for its transformation during g.l.c. because the peaks due to the rearranged products were poorly resolved. The structural assignment of X was based completely on analogy with 3-isopropylidene-A-norcholest-5-ene (X*a*) (ultraviolet, g.l.c. retention times correlation and decomposition pattern, optical rotations). The g.l.c. results are summarized in Table I.

TABLE I

Hydrocarbon	Retention time* (min)	% yield acetolysis	Evidence

IX	7.05	30.5	Isolated
X	7.50	14.6	Gas–liquid chromatography
VIII	8.70	11.3	Isolated

*5% DC 710 on silanized gaschrom P, 6 ft column at 265.3°.

DISCUSSION

The yields of the major types of products obtained are summarized on Flowsheet I and contrasted with the results from the 4,4-dimethyl series. It can be seen that substitution of ethyl for methyl groups resulted in the decrease of products of alkylshift (A) and an increase of cyclosteroids (C).

Since it has been demonstrated (6) that the products of alkylshift arise from a boat-like intermediate and that 4β-methylcholesteryl tosylate (2, 3) gave mainly products of type A due to hydride shift, it may be concluded that the conformation of the starting material or intermediate is not only governed by the 4β,10β-dialkyl interaction, but also by the presence of the 4α-alkyl groups, which tends to restore the boat into the chair form.

The difference in product distribution in the 4,4-dimethyl and 4,4-diethyl series is perhaps not significant, in particular since the solvolyses were performed on the tosylate in one case and on a noncrystalline mesylate in the other case. However, taken together with the results of the solvolysis of 4β-methylcholesteryl tosylate, the product yield reported might reflect the conformation of the intermediate(s).

Further work to determine the exact nature of the intermediate is in progress.

EXPERIMENTAL[8]

4,4-Diethylcholest-5-en-3-one (II)

A stirred solution of 25 g of cholest-4-en-3-one in 250 ml of dry *tert*-butanol was treated with a solution of 28 g of potassium metal in 750 ml of the same solvent at 40°. Ethyl iodide (10 ml) in 25 ml of *tert*-butanol was then added over a period of 5 min. The reaction mixture was refluxed for 2 h with constant stirring and was further stirred for 6 h at 60°. The bulk of the solvent was removed *in vacuo*. Ether extraction and washing with 2 *N* hydrochloric acid gave a yellow amorphous residue (27 g), which showed in the infrared bands at 1 710 cm^{-1} (saturated ketone), 1 675 (inflection), and 1 610 cm^{-1}. The ultraviolet, λ_{max}^{ETOH} 241 mμ (ε 1 000), showed the presence of nearly 10% of the starting material.

Chromatography on alumina (activity II–III) and elution with hexane gave 16 g (56%) of ketone II, m.p. 92–94°. Crystallization from chloroform–methanol raised the melting point to 95–96° (26).

[7]*The results for the acetolysis of IIIa were recorded since acetolysis gave mainly hydrocarbons and since the product composition of the acetolysis of 4,4-dimethylcholesteryl tosylate (6) had been recorded.*

[8]*For details in instrumentation and general procedures, see ref. 27.*

Reduction of Ketone II with Lithium Aluminium Hydride

A solution of 13.5 g of II in 1 l of anhydrous ether was reduced with lithium aluminium hydride (8). After extraction, the ethereal solution was concentrated to 100 ml, and diluted with methanol. A colorless crystalline product (13 g), m.p. 126–129°, was obtained. Crystallization from ether–methanol gave 10 g (73.7%) of 4,4-diethylcholest-5-en-3β-ol (III), m.p. 129–130°, $[\alpha]_D^{22}$ −55.9° (*c* 1.52). The alcohol gave a single spot on t.l.c., using benzene–ether (95:5) as the solvent system.

Anal. Calcd. for $C_{31}H_{54}O$: C, 84.09; H, 12.29. Found: C, 83.98; H, 12.09.

3,4-Diethylcholesta-3,5-diene (VIII)

A solution of 515 mg of 4-ethylcholest-4-en-3-one was added dropwise at 0° to a solution of ethyl magnesium iodide formed from 1.52 g of magnesium and 10 ml of ethyl iodide in 75 ml of anhydrous ether. The reaction mixture was refluxed for 24 h and cooled and the excess Grignard reagent destroyed by adding cold saturated solution of ammonium chloride. Ether extraction gave 635 mg of colorless residue. Two crystallizations from ether–acetone gave 250 mg (50%) of pure 3,4-diethylcholestadiene (VIII), m.p. 123–123.5°, $[\alpha]_D^{23}$ −63°, λ_{max}^{ETOH} 238 mμ (ϵ 13 800), 245 (14 900), 253.5 (9 600).

Anal. Calcd. for $C_{31}H_{52}$: C, 87.66; H, 12.34. Found: C, 87.74; H, 12.11.

4,4-Diethylcholesteryl Mesylate (IIIa)

A solution of 9.6 g of 4,4-diethylcholesterol (III) in 24 ml of freshly distilled pyridine was reacted with 12 ml of methanesulfonyl chloride for 2 h at 0° with continuous stirring. The reaction mixture was poured on crushed ice and extracted with cold ether. The ethereal solution was washed with cold dilute hydrochloric acid and with ice-cold water. It was dried over magnesium sulfate and the solvent removed *in vacuo* at room temperature. A colorless crystalline residue (14 g) was obtained. The crude mesylate III*a* absorbed in the infrared at 1 415, 1 380, 1 340, 1 175, 960, and 900 cm^{-1}. No absorption maxima were shown in the ultraviolet above 220 mμ. Further crystallization of mesylate III*a* could not be effected due to extreme instability.

Anal. Calcd. for $C_{32}H_{56}O_3S$: C, 71.15; H, 11.09; S, 6.29. Found: C, 71.14; H, 10.28; S, 6.49.

Solvolysis of Methanesulfonate IIIa

Methanesulfonate III*a* (14 g) was solvolyzed in 2.55 l of 90% acetone containing 14 g of anhydrous sodium acetate for 16 h at reflux temperature. Part of the solvent was distilled off and the remainder diluted with 2 l of water and extracted with ether. The ethereal solution was washed with 5% sodium bicarbonate and water and dried over magnesium sulfate and the solvent removed *in vacuo*. A colorless oily residue (8.9 g) was obtained. The product did not show absorption for the mesyl group in the infrared. Chromatography on silica gel and elution with hexane gave 5.01 g (56.2%) of hydrocarbon mixture. Further elution with hexane–benzene (1:1) gave 3 g (36.2%) of alcohol fraction which was roughly separated into three sub-fractions.

A. Purification of Hydrocarbon Fraction

Preparative t.l.c. was used to separate hydrocarbons VIII, IX, and XI from the mixture as described below.

The glass plates (8 in. × 8 in.) were covered with 3 mm thick silica gel G and air dried overnight. They were then sprayed with a 5% solution of silver nitrate and activated by heating at 120°; 200 mg of hydrocarbon mixture was applied on each plate and the chromatogram developed with hexane–ether (95:5). Two ultraviolet-active bands were detected with the ultraviolet lamp and gave, after desorption from silica gel by extraction with ether, hydrocarbons XI (R_f 1) and VIII (R_f 0.77) in 20 and 6.8% yields respectively. A third band (R_f 0.67) appeared when the plates were exposed to the atmosphere for 10–12 h and gave, after desorption with ether, hydrocarbon IX in 18% yield.

4,4-Diethyl-3α,5-cyclocholest-6-ene (XI)

Crystallization of 340 mg of hydrocarbon XI (R_f 1) from ether–acetone gave 128 mg of crystals, m.p. 90–90.5°, $[\alpha]_D^{23}$ −137° (*c*, 1.36), νKBr 1 020, 780 cm^{-1}.

Anal. Calcd. for $C_{31}H_{52}$: C, 87.64; H, 12.37. Found: C, 87.64; H, 12.70.

3,4-Diethylcholesta-3,5-diene (VIII)

The residue (110 mg) from the middle band, R_f 0.77, gave, after crystallization from ether–acetone, 60 mg of hydrocarbon VIII, m.p. 124°, $[\alpha]_D^{23}$ −63° (*c*, 2.16), $\lambda_{max}^{C_6H_{12}}$ 238 mμ (14 000), 245 (14 900), 253.5 (9 600). Gas liquid chromatography showed one peak at 8.6 min. The melting point was not depressed upon admixture of an authentic sample.

3-(Pent-2′-en-3′-yl)-A-norcholest-5-ene (IX)

The residue (300 mg), R_f 0.67, was crystallized from ether–acetone to give 170 mg of IX; m.p. 69–70°, $[\alpha]_D^{23}$ −5.03° (*c*, 1.53). Gas–liquid chromatography showed a peak at 7.0 min, and a 1.8% impurity at 8.7 min (VIII).

Anal. Calcd. for $C_{31}H_{52}$: C, 87.64; H, 12.37. Found: C, 87.64; H, 12.12.

B. Purification of Alcohols on T.L.C.

The plates (8 in. × 8 in.) coated with silica gel G (3 mm thick) were used for the separation of alcohols

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

V, VI, and VII. An ethereal solution containing 150–200 mg of the alcohol mixture was applied on each plate and the chromatogram developed with hexane–ether (85:15). The bands of identical R_f values were collected and desorbed from silica gel with ether. Filtration and removal of the solvent gave alcohols V, VI, and VII in 1.5, 7.5, and 13.7% yields respectively.

3-(3'-Hydroxypent-3-yl)-A-norcholest-5-ene (VI)

Crystallization of 600 mg of the residue from ether–acetone gave 170 mg of alcohol VI, m.p. 104–105°, $[\alpha]_D^{23}$ −8.1° (*c* 1.76).

Anal. Calcd. for $C_{31}H_{54}O$: C, 84.09; H, 12.39. Found: C, 84.17; H, 12.16.

Treatment of Alcohol VI with Phosphorus Oxychloride – Pyridine

A solution of 60 mg of alcohol VI in 0.6 ml of pyridine was heated under reflux with 0.6 ml of phosphorus oxychloride for 1 h. The excess reagent was destroyed by careful addition of iced water. The reaction mixture was extracted with ether and the ethereal solution washed neutral. It was dried over magnesium sulfate and the solvent removed *in vacuo* to give a brown oily residue. Thin-layer chromatographic separation, using hexane as solvent system, gave two hydrocarbons IX and X in 55 and 16% yields respectively. Crystallization of 32 mg of hydrocarbon IX from ether–acetone gave 9 mg of substance, m.p. 68–69.5°, $[\alpha]_D^{23}$ −5° (*c*, 0.7). The hydrocarbon did not absorb in the ultraviolet. Gas–liquid chromatography showed a single peak at 7.05 min. The n.m.r. spectrum showed signals at 5 p.p.m. (1H, HC_6) and 3 p.p.m. (1H, HC_3—C=). The identity of the compound was established by comparison of the physcial and spectral characteristics with a sample obtained in the solvolysis. The second, minor fraction (9 mg) from the fast-moving band gave, after crystallization from ether–acetone, 3 mg of X, m.p. 92–93°, $\lambda_{max}^{C_6H_{12}}$ 252 mμ (ε 10 400). Gas–liquid chromatography showed a complex pattern with peaks at 5 min (20%), 5.75 min (69.7%), and 7.05 min (10.4%).

Attempted Acetylation of Alcohol VI

Alcohol VI was recovered unchanged when treated with acetic anhydride and pyridine at room temperature. At reflux temperature, the product which was formed did not absorb in the infrared in the hydroxyl or carbonyl region. Too small a quantity of the product did not permit further purification and characterization.

4,4-Diethyl-3α,5-cyclocholestan-6β-ol (VII)

The alcohol residue (400 mg) from the silica gel gave, after crystallization from ether–acetone at 4–5°, 300 mg of VII, m.p. 89–90°, $[\alpha]_D^{22}$ +55.5° (*c*, 2.23).

Anal. Calcd. for $C_{31}H_{54}O$: C, 84.09; H, 12.29. Found: C, 84.33; H, 12.21.

Treatment of VII with Chromium Trioxide

To a solution of 92 mg of VII in 0.9 ml of pyridine was added 91 mg of chromium trioxide in 0.9 ml of pyridine (24). The reaction mixture was swirled and left overnight. The mixture was poured into water, extracted twice with ether–benzene (1:1) and filtered through supergel to break the emulsion. The combined organic solution was washed neutral and dried over magnesium sulfate and the solvent removed *in vacuo*. A brown oily residue (84 mg) was obtained. Thin-layer chromatographic separation and two crystallizations from ether–acetone gave ketone XIV, m.p. 99–100°, $[\alpha]_D$ +116.5° (*c*, 1.19).

Anal. Calcd. for $C_{31}H_{52}O$: C, 84.48; H, 11.87. Found: C, 84.20; H, 11.85.

4,4-Diethyl-6β-methoxy-3α,5-cyclocholestane (VIIa)

A part of the residue which gave alcohol VII was crystallized from ether–methanol to give crystalline ether VII*a*, m.p. 68°, $[\alpha]_D^{23}$ +94.85° (*c*, 1.77).

Anal. Calcd. for $C_{32}H_{56}O$: C, 84.14; H, 12.36; OCH_3, 6.80. Found: C, 84.33; H, 12.17; OCH_3, 5.82.

Treatment of Ether VIIa with Absolute Ethanol – p-Toluenesulfonic Acid

To a solution of 200 mg of ether VII*a* in 2 ml of absolute ethanol was added 1.8 ml of an ethanolic solution of *p*-toluenesulfonic acid (0.001 *M*) and the mixture refluxed for 30 min (19). It was neutralized with a few drops of 5% sodium bicarbonate and diluted with water and the organic material extracted with hexane. The crude product (190 mg) did not absorb around 1 100 cm^{-1}. Preparative t.l.c. (silica gel impregnated with 5% silver nitrate) using hexane as solvent system, gave hydrocarbons VIII and XI in 9 and 27% yields respectively.

3,4-Diethylcholest-5-en-4-ol (V)

Alcohol, m.p. 125–129°, $[\alpha]_D^{23}$ −36.3° (*c*, 1.256), was obtained in small quantity only. Repeated crystallizations from ether–acetone did not alter the melting point. The n.m.r. spectrum of the compound showed a one-proton signal at 5.5 p.p.m. (1H, C_6H).

Anal. Calcd. for $C_{31}H_{54}O$: C, 84.09; H, 12.29. Found: C, 84.38; H, 12.05.

Acetylation of V

Acetylation at room temperature gave starting material. When a mixture of 60 mg of alcohol V, 1 ml of acetic anhydride, and 1 ml of pyridine was refluxed, the product obtained showed no absorption for a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

carbonyl group. Thin-layer chromatographic purification and crystallization from ether–methanol gave 10 mg of VIII, m.p. 121–122.5° $[\alpha]_D^{23}$ −62.5° (*c* 0.7), $\lambda_{max}^{C_6H_{12}}$ 238, 245, 253 mμ. The identity of the diene was established by melting point, mixed melting point, and by the comparison of ultraviolet absorption with a synthetic sample.

ACKNOWLEDGMENTS

We wish to thank Dr. Stammer for taking the n.m.r. spectra, and the National Research Council of Canada and Bristol Laboratories for financial support.

DETERMINATION OF THE FIELD DEPENDENCE OF THE TAFEL SLOPE FOR THE STEADY-STATE ANODIC OXIDATION OF ALUMINIUM

M. J. DIGNAM, D. GOAD, AND M. SOLE
Department of Chemistry, University of Toronto, Toronto, Ontario
Received September 4, 1964

ABSTRACT

A novel and sensitive experimental technique has been developed and employed to measure the field variation of the Tafel slope at 25 °C for the steady-state anodic oxidation of aluminium. The data have been fitted to an equation of the form $I = \alpha \exp[\gamma E - \delta E^2]$ where I and E are the current density and field strength in the anodic film and α, γ, and δ are positive constants for isothermal conditions. Some information concerning the field variation of the interfacial potentials has also been obtained.

1. INTRODUCTION

In a recent publication (1) by one of us (M. J. D.) a theory was presented to explain the field and anomalous temperature dependence of Tafel slopes for processes occurring at high electrostatic fields. In this paper Tafel slope results for Ta, Nb, and Al were compared with the theory. The Al results were preliminary ones obtained during the investigation reported herein. The purpose of the present publication, in addition to presenting a novel experimental method, is to provide the experimental details, the data, and the calculations from which the Al results were obtained. In addition, some further information regarding interfacial potentials is presented.

The principle of the method is elementary; experimental complications arise, however, as a result of transient conduction phenomena (2), interfacial potentials, and space charge effects (3). If these phenomena did not exist, one can imagine carrying out an experiment in which the film was formed at a known field strength, E_1, to a potential V_1, following which the potential was suddenly changed to V_2 and held constant. The field strength immediately after switching, E_2, will then be $(V_2/V_1)E_1$. Since the cell currents can be measured, sufficient information is available to determine the Tafel slope ($\simeq \Delta E/\Delta \log I$, where I is the anodic current density). Because of the existence of transients, even pseudo steady-state conditions[1] would not be established for some time after changing the voltage, by which time the film would be thicker and hence E_2 would no longer be given by $(V_2/V_1)E_1$. To get around this difficulty, V_2 must be increased proportionally to the charge passed in order to compensate for film growth. This can be accomplished with the aid of electronic analogue computer equipment. This does not, however, overcome the difficulty introduced by the presence of unknown and most likely current-dependent interfacial potentials. One can overcome this problem, however, by in effect extrapolating the data to infinite film thickness for which the interfacial potentials become infinitesimal compared to the applied potential. The details of the equipment and procedure are given in the following sections. It is worth mentioning here, however, that the method is applicable only if film formation takes place with close to 100% current efficiency (strictly speaking, the current efficiency need only be independent of current density and film thickness). In addition, it is not absolute, in that it requires an independent determination of the field strength in the film for one set of conditions. Within

[1]*Under potentiostatic conditions, true steady-state conditions (i.e. $dE/dt = 0 = dI/dt$) can not be achieved since the field is changing as the film grows.*

these limitations, however, the method is very sensitive, allowing for example the Tafel slope to be determined with a precision of better than 2% for a change in field strength of only 3%. It is therefore ideally suited for obtaining the variation of Tafel slope with field strength. It is to this end that the method has been applied herein, the data being fitted to the following equation (cf. ref. 1, eq. [28])

$$I = i_0 \exp\{-[\phi - \mu^* E(1 - \mu^* E/C\phi)]/kT\}. \qquad [1.1]$$

For the purposes of the present paper, i_0, ϕ, μ^*, and C can simply be regarded as empirical constants to be determined from the data. A full discussion of the equation can be found in the original paper. A glossary of symbols used in Section 2 *et seq.* is given in the Appendix.

2. EXPERIMENTAL

Apparatus

The circuit, depicted in Fig. 1, was designed to satisfy the following equations:

$$\mathrm{d}V/\mathrm{d}t = Y, \qquad \text{for } t \leqslant t_0 \qquad [2.1]$$

$$(V + A) = y(V_0 + A) + y(Y/I_r)\int_{t_0}^{t} I \, \mathrm{d}t, \qquad \text{for } t > t_0. \qquad [2.2]$$

In these equations Y is a constant given by $e_1/100$ V/s, e_1 is a constant potential (cf. Fig. 1), V is the potential of the Al electrode with respect to the reference electrode, t is the time, t_0 is the specific time at which switches S_1 and S_2 are moved from positions 1 to positions 2, A is a constant voltage which may be altered from one experiment to the next, y is a constant factor, which may also be altered, and is equal to $1/(1 + R_y)$, where R_y is expressed in megohms, and I_r and V_0 are the values of I and V at time t_0, just before switching to circuit 2.

The triangular symbols represent high-gain, d-c., inverting, operational amplifiers, No. 3101 made by Donner Scientific Co.; the square symbol, a Keithley Instruments Inc. No. 610A electrometer-amplifier. The resistors are all 0.1% wire-wound; the capacitor, high quality polystyrene.

Referring all circuit potentials to ground and identifying the output of amplifier 2, say, as $V(2)$, etc., the circuit analysis proceeds as follows. With the switches in positions 1, the following equations can be written down immediately from a knowledge of conventional electronic analogue computer circuits:

$$-\mathrm{d}V(1)/\mathrm{d}t = e_1/100 = Y \qquad \text{for } t \leqslant t_0 \qquad [2.3]$$

$$-V(2) = V_{\mathrm{ref}} \qquad [2.4]$$

$$V(3) = -V(1) - V(2) - A \qquad \text{for } t \leqslant t_0 \qquad [2.5]$$

$$V = V(3) - V_{\mathrm{ref}} \qquad [2.6]$$

where V_{ref} is the potential of the reference electrode with respect to ground. From eqs. [2.3] to [2.6], eq. [2.1] is obtained.

At time t_0, just before the switches are connected to circuit 2, $V = V_0$, and hence, using eqs. [2.4] to [2.6] we obtain:

$$-V(1) = V_0 + A \qquad \text{at } t = t_0. \qquad [2.7]$$

Again, just before the switches are connected to circuit 2, the potentiometer, P, is adjusted so that:

$$V(\mathrm{P}) = e_1 \qquad \text{at } t = t_0, \qquad [2.8]$$

where $V(\mathrm{P})$ is the potential at the wiper arm of the potentiometer. Noting that $V(\mathrm{P})$ is proportional to the cell current, we may write:

$$V(\mathrm{P}) = \beta I_r \qquad \text{at } t = t_0 \qquad [2.9]$$

$$V(\mathrm{P}) = \beta I \qquad \text{at } t > t_0, \qquad [2.10]$$

where β is a constant for a given oxidation run. After the switches are connected to circuit 2 (i.e. for $t > t_0$) eqs. [2.4] and [2.6] are still valid. Equations [2.3] and [2.5], however, become

$$-\mathrm{d}V(1)/\mathrm{d}t = V(\mathrm{P})/100 \qquad \text{for } t > t_0 \qquad [2.11]$$

$$V(3) = -yV(1) - V(2) - A \qquad \text{for } t > t_0, \qquad [2.12]$$

where $y = [1 + R_y \text{ (in megohms)}]^{-1}$ as before. From eqs. [2.3] and [2.8]–[2.11], we obtain $-\mathrm{d}V(1)/\mathrm{d}t = RI/I_r$ which on integration using the boundary condition [2.7] gives:

$$-V(1) = V_0 + A + (Y/I_r)\int_{t_0}^{t} I\,\mathrm{d}t. \qquad [2.13]$$

From eqs. [2.4], [2.6], [2.12], and [2.13], eq. [2.2] is obtained.

The electrolysis cell, constructed of lucite, is shown diagramatically in Fig. 1. The electrolyte used was a 30% solution of ammonium pentaborate in ethylene glycol (4), as it has been shown by Bernard and Cook to lead to 100% current efficiencies for the formation of Al_2O_3. The reference electrode was a glass electrode, $E^0 = -0.657$ V (with respect to the reversible hydrogen electrode), which was positioned in a tube connected to the cell through a capillary-tipped sidearm adjacent to the anode.

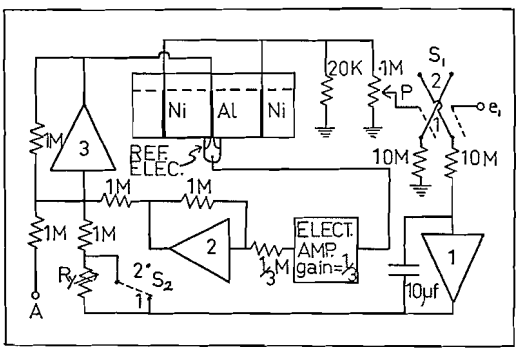

FIG. 1. Electronic circuit used to obtain steady-state conduction data.

Experimental Procedure

Aluminium sheet (99.996% Al, 0.04 in. thick) was formed into paddle-shaped electrodes of dimensions 1 in. × 0.25 in. for the paddle, 1 in. × 0.06 in. for the tab. Following routine cleaning procedures, the electrodes were electropolished at about 0.2 A/cm² and 25 °C in 5 parts ethyl alcohol to 1 part 70% perchloric acid by volume (5). The electrodes were rinsed briefly in ethyl alcohol, rinsed for 1 min in running distilled water, dried in a clean air jet, and stored in a desiccator over activated alumina.

A typical experimental run was carried out as follows. The cell was filled to just above the shoulders of the paddle-shaped aluminium electrode and was then connected into the circuit with S_1 and S_2 in positions 1, and e_1 set to zero. A value of e_1 of about 10 V was then applied to give a value of y of precisely 0.1 V/s. The cell current was then monitored (by measuring V(P) with a digital voltmeter) until no change in cell current with time could be detected. The cell current usually became constant by the time the cell potential reached about 20 V. No evidence of interference from electrolyte creeping up the electrode tab was found, in accord with a previous investigation (3). Following the attainment of a constant current, V(P) was adjusted to equal e_1, as mentioned previously, and then S_1 and S_2 (in that order) were switched to positions 2. The current, as measured by V(P), was then followed until it became constant. This current reading, the current reading before switching, and the potential $V(3)$ at the time of each of the current readings were then recorded.

In fact, the recording of $V(3)$ was an error in procedure, $V(1)$ being the required potential. Subsequent determinations of the potential V_{ref} at the current densities in question enabled the value of $V(1)$ to be deduced from the measured values of $V(3)$ with an uncertainty no greater than 2 V. This uncertainty is of no consequence, its effect on the intercepts in Fig. 2 and hence on μ^*, C, and ϕ being negligible. Its effect on the slopes of the lines in Fig. 1, and therefore on Z (see Section 3), is perhaps as great as 6%, which is likewise of little consequence.

After the second current reading, the switches were returned to positions 1 and the entire procedure was repeated from this point on. This procedure was continued until $V(3)$ exceeded 100 V, the limit of the capability of the amplifiers. In a typical run, 8 to 10 sets of readings would be obtained in this way, the value of A and y being held constant for any given run, but varied from run to run. From a single set of readings I_r/I and $V' = -V(1) - A$ were obtained, where $V(1)$ is determined at the time I is measured. Graphs of $\log I_r/I$ versus $1/V'$ were then constructed for each run. Figure 2 shows the data for one series of runs, each for the same value of y but different values of A, plotted in this way. The current ratios were measured with an accuracy of 1% or better, the value of $1 - y$ being known to 0.1%, and A to better than 1%. Similar sets of data to that presented in Fig. 2 were obtained for five different values of y. The pertinent results obtained from these sets are presented in Section 4 of this paper along with the discussion of the results. All of the data pertain to 25 °C.

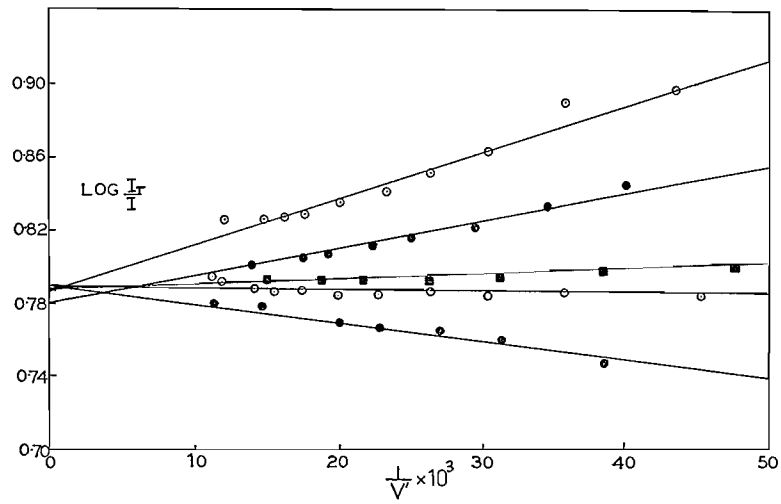

FIG. 2. Typical experimental data: dependence of log I_r/I on V' (in volts) for $y = 0.9524$ and various values of A.

3. THEORY OF METHOD

In analyzing the data obtained using the circuit illustrated in Fig. 1, we shall assume that all of the films on which measurements were performed were sufficiently thick so that there exists in the film a region which is essentially devoid of space charge. An essentially space charge free region will exist in a sufficiently thick film provided that both positively and negatively charged defects are present in the film, or alternatively for any thickness provided that the charged defect concentration is very low. Experimentally, the existence of a space charge free region is demonstrated by the lack of dependence of the differential field strength, dV/dX, on the film thickness, X, for films thicker than about 100 Å on Ta, Nb, and Al (2, 3). Since for Al the differential field strength does vary with film thickness below about 100 Å (3), the first alternative appears to be the correct one at least for this system, although such need not be assumed for the following argument.

We may now write

$$V = E_\infty X + \psi, \tag{3.1}$$

where V is the potential of the anode with respect to a reference electrode, X is the thickness of the oxide film, E_∞ is the field in the space charge free region of the film, and

$$\psi = \int_0^x (E_x - E_\infty)\, dx + \psi',$$

where ψ' is the sum of the electrostatic potential differences across the metal–oxide interface, the oxide–solution interface, and the solution – reference electrode interface. Since we are interested only in variations in ψ, the fact that it is indeterminate will not concern us. Accepting the condition that a space charge free region exists in the film, under steady-state oxide formation conditions ψ will be independent of X, the total film thickness. In general, however, it will be a function of electrolyte composition, temperature, and current density.

Assuming 100% current efficiency for film formation, the film thickness, X, is related

to the ion current density in the space charge free region of the film, I_∞, and the thickness at time t_1, X_1, by the equation:

$$X = X_1 + f\int_{t_1}^{t} I_\infty \, dt, \qquad [3.2]$$

where $f = W_e/\rho F$, W_e and ρ are the electrochemical equivalent weight and density of the oxide, and F is Faraday's constant. The external, observed current density, I, is made up of two terms, I_∞ and the current associated with the alteration of the space charge density in the oxide and of surface charge densities.

In rationalized units, the relevant Maxwell equation and the equation of continuity lead to the following equation for the one dimensional case:

$$(\partial^2 E_x/\partial t \partial x) = (-1/K\epsilon_0)\partial I_x/\partial x,$$

where K is the dielectric constant of the oxide and ϵ_0 is the permittivity of free space. Integration within the oxide from the metal–oxide interface to the space charge free region in the film, assuming K constant, gives:

$$\partial E_\infty/\partial t - \partial E_0/\partial t = (-1/K\epsilon_0)(I_\infty - I_0),$$

where E_0 and I_0 are the field strength and current density in the oxide at the metal–oxide interface. However, from Gauss's theorem, $E_0 = \sigma'/\epsilon_0 K$, and hence $\partial E_0/\partial t = (1/\epsilon_0 K)\partial\sigma'/\partial t$, where σ' is the surface charge density on the metal, so that we may write:

$$\partial E_\infty/\partial t = (1/K\epsilon_0)(I - I_\infty), \qquad [3.3]$$

where I, which equals $I_0 + \partial\sigma'/\partial t$, is the current in the metal per unit electrode area. From eqs. [3.1] to [3.3] we may now write:

$$V = E_\infty\left[X_1 + f\int_{t_1}^{t} I \, dt - fK\epsilon_0\Delta E_\infty\right] + \psi, \qquad [3.4]$$

where $\Delta E_\infty = E_\infty(t) - E_\infty(t_1)$, the change in E_∞ from time t_1 to time t. For Al_2O_3, $f \simeq 5 \times 10^{-5}$ cm^3/C, $K \simeq 10$, and $E_\infty \simeq 8 \times 10^6$ V/cm, so that for a change in field, ΔE_∞, as large as 20% of E_∞, $fK\epsilon_0\Delta E \simeq 0.0035$ Å, which may be neglected compared with X_1.

From eq. [3.4] we have that $dV/dt = fE_\infty I$ for I and hence E_∞ held constant. The circuit eqs. [2.1] and [2.2] can therefore be written:

$$dV/dt = Y = fE_r I_r \qquad \text{for } t \leqslant t_0 \qquad [3.5]$$

$$(V + A) = y(V_0 + A) + yfE_r\int_{t_0}^{t} I \, dt \text{ for } t > t_0. \qquad [3.6]$$

Applying eq. [3.4] to the conditions prevailing at time t_0 and $t > t_0$ respectively, we obtain (neglecting the charging term, $fK\epsilon_0\Delta E_\infty$)

$$V_0 = E_r X_0 + \psi_r \qquad [3.7]$$

$$V = E_\infty\left[X_0 + f\int_{t_0}^{t} I \, dt\right] + \psi, \qquad [3.8]$$

where ψ_r is the value of ψ for $E = E_r$, and X_0 is the value of X at $t = t_0$. Eliminating V_0 and X_0 from eqs. [3.6] to [3.8] we obtain:

$$(E_r - E_\infty)/E_r = (1 - y) + [(\psi_r + A)(1 - y) - (\psi_r - \psi)]/(V' - \psi_r), \qquad [3.9]$$

where $V' = (V + A)/y - A$. That this definition of V' is equivalent to that given in Section 2 (i.e. $V' = -V(1) - A$) follows from eqs. [2.4], [2.6], and [2.12]. Accepting the conduction equation, eq. [1.1], as applying to the space charge free region of the film, we may write:

$$[3.10] \qquad (E_r - E_\infty)/E_r = 2.303kT(\mu^* E_r)[1 - (\mu^*/C\phi)(E_r + E_\infty)]^{-1} \log (I_r/I).$$

Elimination of E_∞ from eqs. [3.9] and [3.10] leads to the desired equation:

$$[3.11] \qquad \log (I_r/I) = W[1 + Z/(V' - \psi_r)] + S/(V' - \psi_r)^2,$$

where

$$[3.12] \qquad W = (\mu^* E_r/2.303kT)[1 - (\mu^* E_r/C\phi)(1 + y)]\,(1 - y),$$

$$[3.13] \qquad Z = \left[\psi_r + A - \frac{\psi_r - \psi}{1 - y}\right]\left[\frac{1 - 2y\mu^* E_r/C\phi}{1 - (1 + y)\mu^* E_r/C\phi}\right],$$

and

$$S = \left(\frac{\mu^* E_r}{2.303kT}\right)\cdot\left(\frac{\mu^* E_r}{C\phi}\right)[(\psi_r + A)(1 - y) - (\psi_r - \psi)]^2.$$

For $V' \gg \psi, \psi_r$, and $A(1 - y)$, a condition readily satisfied, eq. [3.11] reduces to

$$[3.14] \qquad \log (I_r/I) \simeq W(1 + Z/V'),$$

where terms of the order of $(\psi/V')^2$ or smaller have been neglected compared with unity. A plot of $\log (I_r/I)$ versus $1/V'$ for fixed y and A should therefore be linear, yielding values of W and Z. Again, $W/(1 - y)$ should be linear in y, yielding values of $\mu^* E_r/2.303kT$ and $\mu^* E_r/C\phi$.

Finally, for fixed y, A should vary linearly with Z with a slope close to unity (since $2y \simeq 1 + y$) and have an intercept $A_0 = (\psi_r - \psi)/(1 - y) - \psi_r$, which will in turn be a function of y if ψ is a function of field strength.

4. DISCUSSION OF RESULTS

In Fig. 2, the data for a series of runs for fixed y and varying A have been plotted according to eq. [3.14]. As predicted, the data for a given run fall on a straight line with the intercepts, W, for the different runs the same within experimental error (since W is not a function of A). Two runs whose points gave poor linear plots were rejected. The cause of this anomalous behavior is not known, but is likely due to a faulty film, giving localized oxygen evolution. This effect was observed directly in a few runs.

From similar sets of runs, as shown in Fig. 2, mean values of W as a function of y were obtained and have been plotted in Fig. 3 according to eq. [3.12]. The lines through the points are equal in length to 4 times the standard deviation of the mean for each set of W values, representing therefore 95% confidence limits. The abscissa, $W/(1 - y)$, is proportional to the reciprocal Tafel slope, being in fact $E_r[\log (I_r/I)/(E_r - E_\infty)]$, with the ordinate, y, equal to E_∞/E_r. This follows from eq. [3.9] where it can be seen that as $V' \to \infty$, $E_\infty/E_r \to y$. Figure 3 represents, therefore, the variation of Tafel slope with field strength. It is worth noting that the direction of change of the Tafel slope is opposite to that which would occur if the effect arose from a decrease in current efficiency with decreasing current density. It is also a much larger variation than could be attributed to possible variation of current efficiency (4). The total range of field strength over which these measurements could be made was limited at the low end by the electronic equipment and at the high end by heating effects which occur at high current densities.

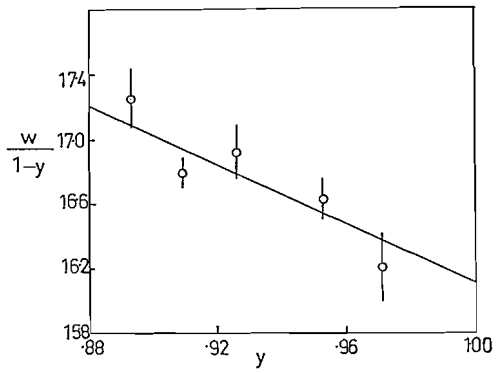

FIG. 3. Results plotted according to eq. [3.12], illustrating the variation of Tafel slope (related to $W/[1 - y]$) with field strength (related to y).

From the slope and intercept of Fig. 3, the following values were calculated:

$$E_r\mu^* = 2.04 \text{ eV}, \qquad \sigma = 14\%$$

$$C\phi = 7.65 \text{ eV}, \qquad \sigma = 3\%.$$

To obtain a value for μ^*, E_r must be known. By interpolation from the data of Bernard and Cook (4) the field in the oxide corresponding to a rate of voltage rise for formation of 0.1000 V/s (i.e. E_r) was calculated. Four values of E_r were obtained corresponding to the four different methods used by Bernard and Cook to determine the film thickness. These methods were measurements of total charge passed, weight of stripped oxide, anode weight gain, and optical interference. The values of E_r were, respectively, 0.086_6, 0.085_8, 0.085_4, and 0.083_7 V/Å. Weighting the final value 1/2, because of the lower precision of this measurement, we obtain $E_r = 0.085_6$ V/Å with a standard deviation of 1.3%. The corresponding current density was determined to be $I_r = 2.09_5 \times 10^{-4}$ A/cm² with a standard deviation of 0.7%. The actual uncertainty in E_r and I_r is probably around 5% because of interfacial potential effects and electrode surface roughness. Using these values in conjunction with the present values of $E_r\mu^*$ and $C\phi$ and eq. [1.1], we obtain:

$$\mu^* = 23.8\ e\text{Å}, \ C\phi = 7.65 \text{ eV}, \ i_0 \exp[-\phi/kT] = 10^{-29.0} \text{ A/cm}^2.$$

Numbers differing slightly from these have been reported earlier (1), as previously mentioned. The significance of these results is discussed in the earlier paper and will not be repeated here.

To test the validity of eq. [3.13], and also to obtain values of $A_0 = (\psi_r - \psi)/(1 - y) - \psi_r$, A has been plotted against Z for the various sets of runs (see Fig. 4), and the best straight line with unit slope has been drawn through each set. (The theoretical slope differs from unity by at most 4.5%.) Although there is considerable scatter, the results confirm eq. [3.13] well within experimental error.

The values of A_0 obtained from Fig. 4 have been plotted against $1/(1 - y)$ in Fig. 5, the lines through the points representing 95% confidence limits. Within experimental error, the points lie on a straight line with a non-zero slope. Actually the relation cannot be rigorously linear since it may be shown that the linearity condition, $dA_0/d(1 - y)^{-1} = \text{constant}$, can only be satisfied for A_0 independent of y. It might be hoped that considerable information concerning the variation of ψ with current density (or field strength) could be extracted from the results of Fig. 5. Unfortunately, this is not the case. One can

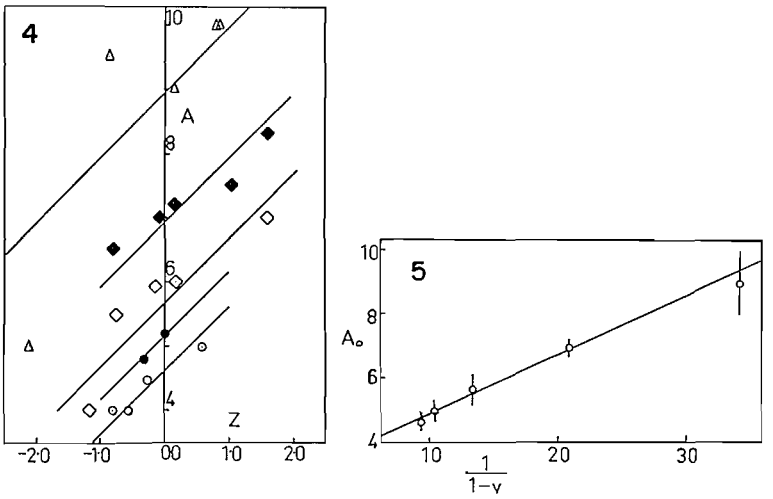

FIG. 4. Results plotted according to eq. [3.13] for various values of y (from top to bottom y = 0.9709, 0.9524, 0.9259, 0.9091, and 0.8929 respectively). The lines represent least square regression lines of unit slope (A and Z in volts).
FIG. 5. Variation of A_0 (volts) with y.

say, however, that ψ does not vary according to a Tafel equation, i.e. $\psi \neq a + b \log I$, since if this were so, A_0 would be independent of y to a very good approximation. This follows from the fact that $\psi_r - \psi$ would then be given by $b \log I_r/I$, which in turn is very nearly proportional to $1 - y$, the deviation from proportionality arising from the field dependence of the Tafel slope for ionic conduction. Provided that ψ contains a component which changes sufficiently rapidly with I (i.e. more rapidly than $\log I_r/I$) then an approximately linear relation between A_0 and $1/(1 - y)$ is predicted in accord with the results. For example, we might assume ψ to be made up of a constant term, Tafel terms, and resistive terms. Accordingly,

$$\psi = a + b \log I + dI, \qquad [3.15]$$

where a, b, and d are constants.

Substituting for ψ and ψ_r in the equation for A_0, we obtain:

$$A_0 = d(I_r - I)/(1 - y) + \text{constant} \qquad [3.16]$$

and since for all the experimental points, $I_r \gg I$, we predict a linear relation between A_0 and $1/(1 - y)$. Clearly, however, eq. [3.15] is not unique in giving rise to this prediction. More extensive data would be required in order to gain further information concerning the current dependence of the interfacial potentials.

CHARGE TRANSFER IN THE RADIOLYSIS OF DILUTE SOLUTIONS OF HYDROCARBONS IN KRYPTON MATRICES AT 77 °K[1]

J. A. STONE

Research Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received November 20, 1964

ABSTRACT

The radiolysis of dilute solutions (0.3 to 10 electron %) of saturated hydrocarbons in krypton matrices at 77 °K results in the production of much more hydrogen than that obtained in the absence of krypton. This enhanced hydrogen yield is independent of hydrocarbon concentration over the range studied. The cyclohexane–krypton system was studied in detail. The energy transferred from the krypton to the cyclohexane results in a large first-order yield of hydrogen with a corresponding large yield of cyclohexene. Cyclohexane-d_{12} irradiated at the same concentration in a krypton matrix has the same product yields. However, when mixtures of cyclohexane and cyclohexane-d_{12} are irradiated in a krypton matrix the hydrogen evolved has a high H_2 content which must be the result of an isotope effect in the energy transfer process. This isotope effect and the enhancement of product yields is consistent with a charge transfer mechanism.

INTRODUCTION

The chemical effects of energy transfer in the radiolysis of mixtures of hydrocarbons have been observed in both the liquid and solid phases (1, 2). In these experiments, the isotopic composition and deuterium atom content of the hydrogen evolved in the radiolysis of dilute solutions of a deuterated hydrocarbon (usually cyclohexane-d_{12}) in saturated hydrocarbons were measured. The method is limited to isotopically substituted molecules. When products other than hydrogen are examined complications arise due to secondary reactions, e.g. a change in identity of the initially formed radicals by hydrogen atom abstraction from the solvent (3). The use of a noble gas as the solvent was considered to be attractive since stable products can arise only from the solute. Energy transfer will therefore show up as a difference in the overall decomposition of the hydrocarbon solute from that which would be expected for the same amount of hydrocarbon in the absence of the noble gas.

Homogeneous mixtures of hydrocarbon and krypton were irradiated in the solid state since difficulties due to limited solubility could then be avoided. Krypton was chosen in the first series of experiments because of its ready availability and the fact that it is a solid at liquid nitrogen temperatures. The first ionization potential is 13.999 eV, well above that of any hydrocarbon molecule and the metastable level is 9.915 eV (4). By studying hydrocarbons with ionization potentials either above or below 9.9 eV a clear distinction can therefore be made between excitation transfer due to induced ionization by metastable atoms (Penning Effect) and other forms of transfer.

We have found that the amount of radiolytic decomposition observed when a saturated hydrocarbon is dispersed in a krypton matrix is far greater than that for the pure hydrocarbon alone.

EXPERIMENTAL PROCEDURE

Materials

The krypton (Matheson Research Grade) was distilled several times from trap to trap. Mass spectrometric analysis showed that some xenon ($\sim 0.02\%$) was present but oxygen was absent ($< 0.001\%$).

[1]*Issued as A.E.C.L. No. 2161.*

Cyclohexane-d_{12} and butane-d_{10} (Merck) were used as received. Cyclohexane was Fisher Spectro Grade and contained no cyclohexene. All other hydrocarbons were Philips' Research Grade and were used without further purification.

Sample Preparation and Irradiation

The krypton and appropriate hydrocarbon were degassed separately, mixed in the gas phase, and then condensed at 77 °K to give a homogeneous solid sample. Hoke valves with Teflon seats were used throughout the vacuum line to eliminate the use of greased stopcocks. Since the liquid hydrocarbon samples required were so small (0.005 to 0.100 ml in each experiment) a special degassing technique was used. A clean, dry micropipette containing the required volume of liquid hydrocarbon was placed in a narrow tube, closed at one end, which was attached to the vacuum line using a Teflon O-ring seal. The lower part of the tube was immersed in liquid nitrogen while the upper part was heated. After all the hydrocarbon was frozen in the bottom of the tube, degassing was by the usual freeze-pump-thaw technique. Gas–liquid chromatographic analysis after sample irradiation showed that this degassing technique led to no loss of sample. For isotopic experiments with mixtures of cyclohexane and cyclohexane-d_{12} the two liquids were degassed separately. Butane and butane-d_{10} were measured out separately in the gas phase before degassing.

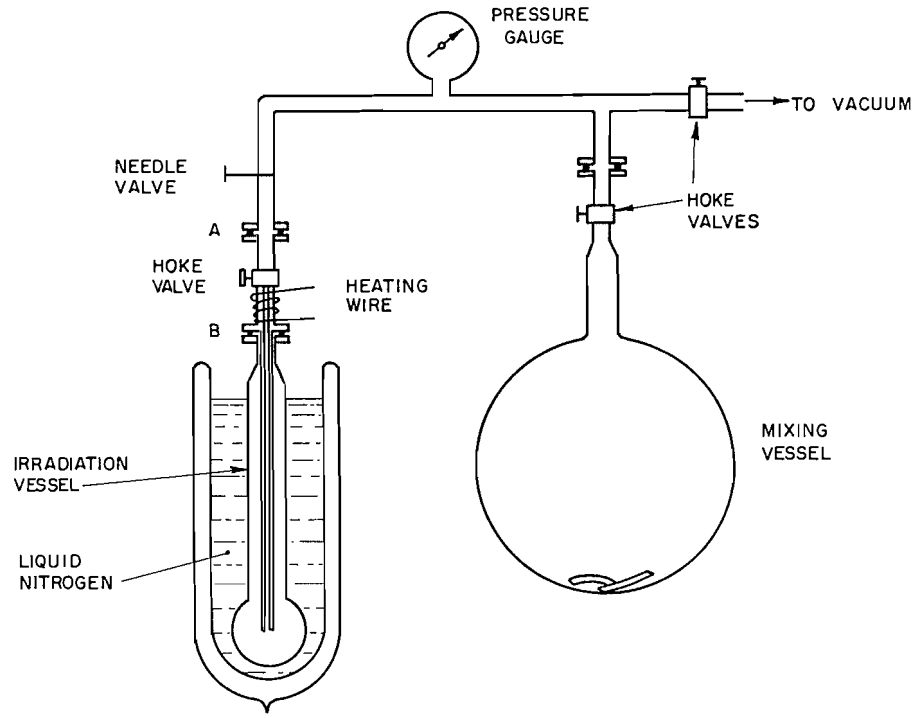

FIG. 1. Apparatus for preparing homogeneous mixtures of hydrocarbons and krypton in the solid phase at 77 °K.

A liter bulb containing a few, small Teflon chips was evacuated and flamed out. The degassed hydrocarbon was passed into the vessel and frozen in the bottom together with a measured volume of krypton (typically from 300 to 500 ml at N.T.P.). The flask was warmed to room temperature and shaken to ensure thorough mixing of hydrocarbon and noble gas. The gaseous mixture was then leaked slowly through a needle valve and condensed in the bottom of the irradiation vessel at 77 °K as shown in Fig. 1. The irradiation vessel was a tube with a bulb of $\sim$ 30 ml capacity blown at the lower end. To the upper end was attached, by means of an Edwards vacuum union, B, a Hoke valve with an extended brass tube. This tube was electrically heated during sample deposition to prevent hydrocarbon condensing in it. The pressure in the mixing flask was read with an all metal, aneroid pressure gauge and the needle valve was adjusted to ensure a constant sample flow of $\sim$ 6 ml/min. With this flow rate reasonably reproducible results could be obtained while the time for sample deposition was not excessively long. At higher flow rates lower product yields were obtained probably due to local melting and hence segregation of the sample during deposition. When all the sample had been condensed the valve was sealed and the vacuum was broken at A. The sample was irradiated at 77 °K

in a Co-60 γ source at a dose rate of 2.33×10^{22} eV/l h in cyclohexane as determined by Fricke dosimetry. All samples, unless otherwise stated, were irradiated to a total dose of 4.66×10^{22} eV/l. Energy absorption in the krypton was found by interpolation from the tables of Grodstein (5).

Analysis

After irradiation only $\sim 1\%$ of the hydrogen produced was in the gas phase, the remainder being trapped in the matrix. The sample was melted to release the hydrogen and was frozen again at 77 °K. An evacuated 250 ml bulb was attached to the sample tube at union A and the hydrogen, together with krypton at its vapor pressure at 77 °K, was equilibrated through the two vessels. The gas in the bulb was then analyzed mass spectrometrically for H_2 and ^{86}Kr, it being assumed that the amount of ^{86}Kr present in the gas phase did not vary from experiment to experiment. The method was calibrated by irradiating a known amount of cyclohexane (which yielded a known amount of hydrogen) then adding some krypton gas and repeating the above procedure. The reproducibility of this calibration procedure was better than 3%. The relative amounts of H_2, HD, and D_2 in experiments with deuterated hydrocarbons were also measured mass spectrometrically.

Samples for liquid product analysis were obtained by cooling the sample tube to 193 °K, releasing the krypton, and diluting the small amount of hydrocarbon left at the bottom of the sample vessel with 0.5 ml of a suitable solvent. The determination of cyclohexene and bicyclohexyl by gas–liquid chromatography has been described previously (3).

RESULTS

(1) Irradiation of Pure Cyclohexane in the Solid Phase at 77 °K

The yields of the major products in the radiolysis of solid cyclohexane were determined using large samples (5 ml) irradiated at the same dose rate as in all the other experiments. These yields, which were independent of dose over the range $1.1–2.8 \times 10^{22}$ eV/l, were $G(H_2) = 4.65$, G(cyclohexene) = 2.35, and G(bicyclohexyl) = 1.55.

The isotopic composition of the hydrogen evolved from two mixtures of cyclohexane and cyclohexane-d_{12} in the solid phase and one in the liquid phase was measured. These results are shown in Table I. Comparative figures for mixtures with 5.6 electron % total hydrocarbon concentration in krypton matrices are also included.

TABLE I

The isotopic composition of the hydrogen evolved from mixtures of cyclohexane and cyclohexane-d_{12} irradiated under various conditions

Phase	Mole % C_6D_{12}	% H_2	% HD	% D_2
Solid (77 °K)	50	54.5	32.3	13.2
Krypton matrix (77 °K)	50	66.0	17.0	17.0
Solid (77 °K)	75	28.7	38.2	33.1
Krypton matrix	75	42.0	24.0	34.0
Liquid (293 °K)	75	27.8	42.4	29.8

(2) Irradiation of Hydrocarbons in Krypton Matrices at 77 °K

All G values quoted in this paper have been calculated using the total energy absorbed in the samples.

(a) Hydrogen Yields

A blank run showed that no hydrogen was formed ($G < 0.02$) when pure krypton was irradiated in the absence of any hydrocarbon. If water was present as an impurity some hydrogen was produced. The mixing vessel and irradiation vessel were therefore always thoroughly flamed out between runs.

At 5.6 electron % cyclohexane in krypton $G(H_2)$ was, within experimental error, constant with dose up to at least 6×10^{22} eV/l. $G(H_2)$ had an almost constant value of ~ 2.4 for dilute solutions (0.3 to 12 electron %) of cyclohexane in krypton. Over a smaller hydrocarbon concentration range $G(H_2)$ for n-hexane was ~ 1.8 and for methylcyclohexane was ~ 1.3. These results are shown in Fig. 2. $G(D_2)$ values from cyclohexane-d_{12}

at concentrations from 3 to 8 electron % in krypton were as scattered as those for $G(H_2)$ from cyclohexane. $G(D_2)$ was independent of hydrocarbon concentration and had an average experimental value of 2.1. $G(H_2)$ from 4.8 electron % butane in krypton was determined in a single experiment to be 1.8.

(b) Isotopic Experiments

Mixtures of cyclohexane and cyclohexane-d_{12} at a constant hydrocarbon concentration of 5.6 electron % in krypton were irradiated. The isotopic composition of the hydrogen evolved is shown in Fig. 3 for the full range of hydrocarbon mixtures. Figure 2 shows that the reproducibility of $G(H_2)$ from cyclohexane–krypton mixtures is poor but since in Fig. 3 only % composition is given these variations in total yield have been ignored. It was found, however, that although the total hydrogen yield was not very reproducible the relative yields of H_2, HD, and D_2 in these mixed samples could be reproduced to better than 5%. It is to be noted that even from 99% isotopically pure cyclohexane-d_{12} irradiated in a krypton matrix 4.4% HD and 1.9% H_2 were produced.

Similar isotopic experiments were performed with mixtures of butane and butane-d_{10} in krypton at a constant hydrocarbon concentration of 4.8 electron %. These results are presented in Table II with results for cyclohexane taken from the smoothed curves of Fig. 3 for comparison.

TABLE II

The isotopic composition of hydrogen evolved from mixtures of butane and butane-d_{10} compared with that from mixtures of cyclohexane and cyclohexane-d_{12} all irradiated in krypton matrices

Mole % deuterated species	Butane			Cyclohexane		
	% H_2	% HD	% D_2	% H_2	% HD	% D_2
86.6	29.3	24.3	46.3	26.0	22.3	51.2
49.6	70.4	15.0	14.6	68.0	16.4	15.6
29.2	82.2	11.3	6.5	84.0	10.2	6.8

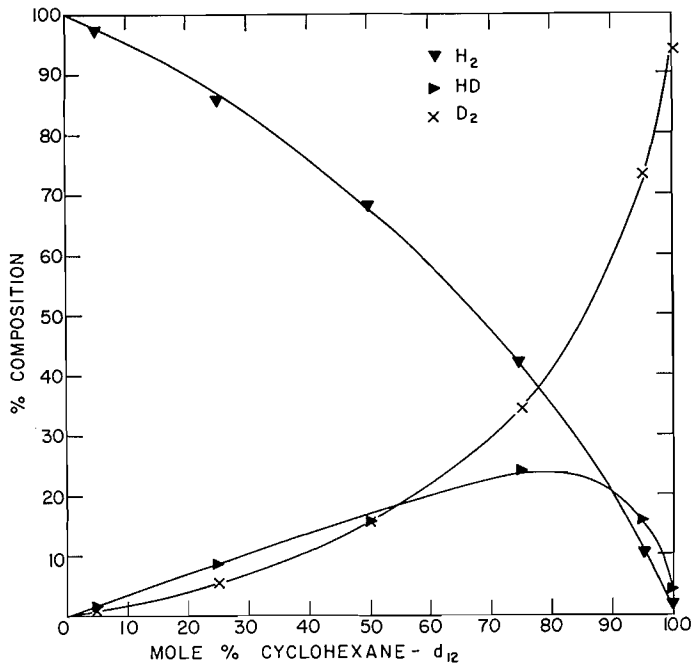

FIG. 3. The isotopic composition of the hydrogen evolved from mixtures of cyclohexane and cyclohexane-d_{12} irradiated in krypton matrices at 77 °K.

(c) Effect of Solutes

The effects of the solutes carbon tetrachloride and benzene on the yields of hydrogen, cyclohexene, and bicyclohexyl from 5.6 electron % cyclohexane in krypton were determined. The results are shown in Table III.

TABLE III

The effect of solutes on the yields of products from cyclohexane irradiated in a krypton matrix

Additive	$G(H_2)$	G(cyclohexene)	G(bicyclohexyl)
0	2.4	1.7	0.29
0.37 electron % CCl_4	0.9	0.6	0.055
0.30 electron % C_6H_6	1.6	1.10	0.070

G(cyclohexene-d_{10}) and G(bicyclohexyl-d_{22}) from 5.6 electron % cyclohexane-d_{12} in krypton mixtures were 1.56 and 0.36, respectively.

A mixture of 2.6 electron % cyclohexane, 2.6 electron % cyclohexane-d_{12}, and 0.37 electron % carbon tetrachloride irradiated in a krypton matrix yielded 68.6% H_2, 13.8% HD, and 17.5% D_2.

DISCUSSION

Energy transfer experiments of the chemical type described here can detect only that part of the energy absorbed from the incident radiation which is (*a*) transferable and (*b*) can then lead to chemical change. Since, presumably, energy can be transferred from the donor to the acceptor molecules only by certain specific paths not all the energy which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

causes chemical decomposition in the donor (in the case of hydrocarbons) is available for transfer. Also, in the radiolysis of hydrocarbons, some of the energy is dissipated without leading to chemical decomposition. It will therefore be impossible to say absolutely how much of the energy, which is initially absorbed in the inert gas, causes decomposition in the hydrocarbon solute. The relative amounts of energy transferred in different systems may, however, be determined by comparing the observed product yields with those expected for the same amount of hydrocarbon in the absence of krypton.

The major portion of this work has been a study of the enhancement of product yields when dilute solutions of cyclohexane and cyclohexane-d_{12} are irradiated in krypton matrices at 77 °K. The main features of the energy transfer process will be established from four experimental observations: 1, the invariance of the chemical yields with hydrocarbon concentrations, 2, the nature of the hydrocarbon decomposition as shown by experiments with mixtures of light and deuterated hydrocarbons, 3, the effect of solutes on the product yields, and 4, the isotope effect in the energy transfer process. Finally, we will show that these experimental results are compatible with a charge transfer mechanism.

(1) Energy Transfer as a Function of Hydrocarbon Concentration

$G(H_2)$ from solid cyclohexane at 77 °K is 4.65. In a hydrocarbon–noble gas mixture if no energy transfer occurs $G(H_2)$ will be a linear function of the electron fraction of hydrocarbon, e.g. at 5 electron % the value will be 0.23 whereas the experimental value is 2.4. Figure 2 shows that energy transfer does occur in hydrocarbon–krypton matrices and is (*a*) considerable, (*b*) almost independent of hydrocarbon concentration over a 40-fold range, and (*c*) results in different hydrogen yields from different hydrocarbons.

As shown above $G(H_2)$ from 5 electron % cyclohexane in a krypton matrix is 10 times greater than expected in the absence of energy transfer. As the cyclohexane concentration decreases, the ratio of the actual hydrogen yield to the expected yield increases rapidly. The constancy of the hydrogen yield with hydrocarbon concentration leads us to conclude that over the range studied all available energy is transferred. At 12 electron % hydrocarbon there are 10 krypton atoms for each hydrocarbon molecule. Assuming a close-packed structure each krypton atom is adjacent to at least one hydrocarbon molecule. At the lowest concentration used (0.3 electron %) there are $\sim$ 400 krypton atoms for every cyclohexane molecule. Each krypton atom, although it may not be in contact with a hydrocarbon molecule will not be far removed (closer than 20 Å). Dyne and Denhartog (6) have shown that in hydrocarbons the range of energy transfer is $\sim$ 50 Å. In the present case complete transfer, independent of the hydrocarbon concentration over the limited range used, is not unreasonable since the range of transfer does not have to be large.

Figure 2 shows that different hydrocarbons produce different amounts of hydrogen as a result of energy transfer. This may seem surprising since in the liquid phase the $G(H_2)$ values for the pure hydrocarbons do not show such large differences (cyclohexane 5.55, *n*-hexane 5.0, and methylcyclohexane 4.4). However, hydrogen is formed in the radiolysis of hydrocarbons in more than one process (7). The relative efficiencies of energy utilization in these processes may be different for different molecules so that if energy transfer enhances only one mode of hydrogen formation large differences in $G(H_2)$ are possible.

(2) The Nature of the Hydrogen Yield

The isotopic composition of the hydrogen evolved from mixtures of cyclohexane and cyclohexane-d_{12} dispersed uniformly in a krypton matrix is markedly different from that observed in the radiolysis of mixtures of the two hydrocarbons in either the solid or liquid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

phases (see Table I and Fig. 3). In particular the yield of HD is reduced by about a factor of two in the krypton matrix while the D_2 and in particular the H_2 yields are increased. This suggests that much of the hydrogen is formed in a reaction involving the elimination of two hydrogen atoms from the same molecule. This is supported by the fact that the yield of olefin is large, and the yield of bicyclohexyl is small (Table III). In a krypton matrix G(cyclohexene)/G(bicyclohexyl) $\simeq 6$ whereas in the radiolysis of solid or liquid cyclohexane the ratio is ~ 1.5. In summary, these isotopic results show that the transfer of energy from krypton to cyclohexane leads mainly to products (hydrogen and cyclohexene) characteristic of a first-order decomposition of cyclohexane. Energy transfer also leads to smaller concentrations of other products which must be formed in reactions involving the participation of more than one cyclohexane molecule. These products are bicyclohexyl and some of the hydrogen (demonstrated by a yield of HD from mixtures of cyclohexane and cyclohexane-d_{12} in krypton).

The transfer of energy from krypton to a hydrocarbon has also been reported by Bouldin and Gordy (8). Using electron spin resonance techniques they have observed the formation of both deuterium atoms and methyl-d_3 radicals in an irradiated krypton matrix containing methane-d_4. The experiments were performed at 4.2 °K. In agreement with the present work they found that above 0.3 electron % methane-d_4 the amount of energy transferred [in their case measured by G(D atoms)] did not show a great variation with hydrocarbon concentration. At 0.3 electron % CD_4 G(D) was 1 whereas in pure methane-d_4 G(D) was 1.9. In the present work at 0.3 electron % cyclohexane $G(H_2)$ is ~ 2.4 while for pure cyclohexane at 77 °K $G(H_2) = 4.65$. In both cases therefore the irradiated systems at 0.3 electron % hydrocarbon behave as if they were composed of $\sim 50\%$ hydrocarbon. Using electron spin resonance Bouldin and Gordy could only measure decomposition to atoms and radicals. By measuring $G(H_2)$ we believe that we have a more complete picture of the overall decomposition. $G(H_2)$ for the radiolysis of methane in the solid phase is not known and the value of 1.9 for G(D) given by Bouldin and Gordy would imply $G(D_2) < 1$ (since at these low temperatures D atoms can form D_2 only by combination which will be in competition with the recombination of D and CD_3 to yield CD_4 again). We think that this value is too low to represent the total hydrogen yield and that energy transfer must also lead to molecular hydrogen formed by the decomposition of single hydrocarbon molecules.

(3) The Effect of Solutes

$G(H_2)$ from cyclohexane krypton mixtures is decreased by the addition of small quantities of carbon tetrachloride and benzene, the former being the more effective (see Table III). These results have been compared in Table IV with the corresponding reductions in hydrogen yield obtained when the same concentrations of the two solutes are added to liquid cyclohexane (9, 10).

TABLE IV

The effect of solutes on hydrogen yields from cyclohexane in the presence and absence of a krypton matrix

	$\Delta G(H_2)$	
Solute	Liquid cyclohexane	5.6 electron % cyclohexane in krypton
0.37 electron % CCl_4	1.3	1.5
0.30 electron % C_6H_6	0.75	0.80

We have suggested earlier in this discussion that energy transfer from krypton to cyclohexane results in hydrogen formation by one method of decomposition which in the liquid phase accounts for only part of the hydrogen yield. From Table IV we see that values of $\Delta G(H_2)$ in the two systems are remarkably alike, i.e. the same small solute concentration depresses $G(H_2)$ by the same amount whether the environment is krypton or cyclohexane (it is to be noted however that the % decrease in $G(H_2)$ is very different in the two cases). This suggests that the same mechanism of inhibition of hydrogen formation occurs in both cases, i.e. that that part of the hydrogen yield which can be most easily inhibited in the liquid phase radiolysis of hydrocarbons is formed by the same mechanism as the whole yield produced by energy transfer in a krypton matrix. We have shown previously that energy transfer which occurs in mixtures of saturated hydrocarbons can be suppressed by the addition of small amounts of carbon tetrachloride (3). This energy transfer process has been interpreted in terms of charge transfer (11) while the action of carbon tetrachloride has been shown to be consistent with an electron capture mechanism (12). We will show later that a combination of charge transfer and electron capture is consistent with the results of radiolyses in krypton matrices.

Table III shows that G(cyclohexene) is reduced to the same extent as $G(H_2)$ by the addition of carbon tetrachloride or benzene but G(bicyclohexyl) is reduced to a much greater extent. Since the cyclohexane molecules are isolated in the matrix, bicyclohexyl must be formed on warming up the sample, i.e. by combination of two cyclohexyl radicals. Szwarc (13) has shown that cyclohexyl radicals are stable in solid cyclohexane at 77 °K and the same should hold for cyclohexyl radicals trapped in a krypton matrix at the same temperature. If solute is present on melting, radical scavenging will occur. In fact cyclohexyl chloride was detected among the products from the matrix containing carbon tetrachloride. Cyclohexene is not reduced in yield to the same extent as bicyclohexyl and therefore much of it must be produced in a reaction not involving the disproportionation of cyclohexyl radicals.*

(4) The Isotope Effect in the Energy Transfer Process

$G(H_2)$ from cyclohexane in krypton is ~ 2.4 while $G(D_2)$ from cyclohexane-d_{12} in krypton is ~ 2.1. The corresponding olefin yields are 1.70 and 1.56. With the assumption made earlier that all available energy is transferred this means that the efficiency of utilizing this energy to produce chemical decomposition is slightly greater for cyclohexane than for cyclohexane-d_{12}. The effect of isotopic substitution is not large. When, however, the two species are dispersed in the same krypton matrix a large isotope effect is observed, e.g. a 50/50 mixture of the two yields hydrogen containing 75 atom % H and 25 atom % D. The hydrogen present as H_2 accounts for 66% of the total. This means that the isotope effect occurs mainly in the energy transfer reaction since a kinetic isotope effect could not yield more than 50% H_2. This means that cyclohexane and cyclohexane-d_{12} are in competition for the available energy, the light hydrocarbon being favored. Exactly the same conclusion applies to the butane/butane-d_{10}/krypton system which yields hydrogen with almost the same isotopic composition as in the cyclohexane experiments (Table II).

(5) The Mechanism of Energy Transfer

The four main experimental conclusions that must be satisfied by any proposed mechanism are: 1, energy transfer over distances up to 20 Å is very efficient; 2, the

**Klots and Johnsen (14) have shown that k(disproportionation)/k(combination) for cyclohexyl radicals in the liquid phase is 1.3 so that for the radiolysis of pure cyclohexane in a krypton matrix only $\sim$ 22% of the cyclohexene yield could be accounted for by radical disproportionation.*

major products of the transfer of energy from krypton to cyclohexane are hydrogen and cyclohexene; 3, small concentrations of carbon tetrachloride or benzene reduce the yields of the products of energy transfer; 4, when mixtures of light and deuterated hydrocarbons are irradiated in a krypton matrix preferential energy transfer to the light hydrocarbon occurs.

Examples of the enhancement of the radiolytic decomposition of hydrocarbons in the gas phase upon addition of noble gases are well known (15, 16, 17). Explanations for this phenomenon in terms of charge transfer and ion molecule reactions have been advanced. It is of interest to see whether such mechanisms are consistent with the results obtained in the present study.

The action of γ-rays is to produce ions, electrons, and excited molecules. The ionization process is non-selective so that in the case of a krypton matrix containing a low concentration of hydrocarbon most of the energy will be deposited in the krypton and initially krypton ions will predominate. Magee (18) has discussed theoretically the mechanism of transfer of a positive charge from an ion to a neutral molecule or atom. He considers that the resonance charge transfer process, e.g.

[1] $$Kr^+ + Kr \rightarrow Kr + Kr^+,$$

involving the same atomic species may have a very large cross section "since the momenta of the heavy pair (ion and molecule) do not have to change as the electron jump occurs and a close collision is thus not necessary." In the case of a lattice where the krypton atoms are in close contact the movement of the electron hole should be facile and hence migration from the initial place of ionization is rapid. Transfer of charge by this mechanism to the proximity of a hydrocarbon molecule should proceed with high efficiency.

Mass spectrometric observation of charge transfer reactions from Kr^+ to methane has been reported by Melton (19) and Field, Head, and Franklin (20). The reactions involved both simple charge transfer and also dissociative charge transfer. The analogous, energetically allowed reactions for Kr^+ and C_6H_{12} are:

[2] $$Kr^+ + C_6H_{12} \rightarrow Kr + C_6H_{12}^+$$

[3] $$\rightarrow Kr + C_6H_{11}^+ + H$$

[4] $$\rightarrow Kr + C_6H_{10}^+ + H_2.$$

Hydrogen is produced directly in reactions [3] and [4] and could be produced from $C_6H_{12}^+$ upon charge neutralization.

[5] $$C_6H_{12}^+ + e \rightarrow C_6H_{12}^* \rightarrow \cdot C_6H_{11} + H$$

[6] $$\searrow C_6H_{10} + H_2.$$

The isotopic experiments showed that much of the energy transfer leads to hydrogen and olefin formed by the decomposition of a single molecule. This suggests that either reactions [4] or [2] and [6] predominate. However, reactions [3] and [5] need not necessarily be ruled out since Klein, Scheer, and Kelley (21) have shown that H atoms can take part in disproportionation reactions with radicals to yield H_2 and an olefin. In the present case for no isotopic mixing this would imply the reaction between an H atom and its geminate radical.

[7] $$H + \cdot C_6H_{11} \rightarrow H_2 + C_6H_{10}.$$

However, the same authors showed that diffusion of hydrogen atoms is very rapid at 77 °K so that in these cyclohexane–krypton experiments much more isotopic mixing of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the hydrogen isotopes should occur than that experimentally determined. Reactions [4] and [6] are therefore the most probable.

It has been shown that low concentrations of carbon tetrachloride in irradiated organic glasses can capture electrons with high efficiency (22).

$$[8] \qquad e + CCl_4 \rightarrow CCl_4^- \overset{?}{\rightarrow} CCl_3 + Cl^-.$$

The negative ion formed, CCl_4^- (or Cl^-), is very stable and is held rigidly until charge neutralization occurs upon melting. Since carbon tetrachloride reduces the hydrogen yield in the cyclohexane–krypton system much of the hydrogen cannot be formed before charge neutralization, i.e. major contributions from reactions [3] and [4] can be ruled out.

A charge transfer mechanism is therefore consistent with the experimental results that energy transfer is both rapid, practically independent of hydrocarbon concentration over the range studied, and that hydrogen is produced in a large part by a unimolecular decomposition of the hydrocarbon molecule. Assuming $G(Kr^+)$ is ~ 4.0 as in the gas phase (23) then for cyclohexane a $G(H_2)$ value of 2.4 corresponds to an efficiency of utilizing the transferred charge (assumed to be complete) of 60%. For other hydrocarbons, the calculated efficiencies are *n*-hexane 44%, methylcyclohexane 32.5%. These efficiencies are in the same order as the $G(H_2)$ yields in the liquid phase at ambient temperature. Since in the latter case hydrogen is formed by other processes as well, this could mean that the production of hydrogen upon charge neutralization is not 100% efficient and that the efficiency is different for different molecules. Since both cyclohexane and methylcyclohexane have ionization potentials equal to or lower than the metastable level of krypton (9.915 eV) a contribution to the hydrogen yield from the Penning effect might be possible:

$$[9] \qquad Kr^* + C_6H_{12} \rightarrow C_6H_{12}^+ + e + Kr.$$

However, both butane and hexane have ionization potentials above the krypton metastable level so that reactions analogous to [9] are not possible for these compounds. A major contribution of [9] to the observed phenomenon is most improbable.

The outstanding experimental result to be explained by this charge transfer hypothesis is the isotope effect, i.e. the fact that there is no isotope effect on total yields when deuterated and light hydrocarbons are irradiated separately in a krypton matrix but when mixtures of the two are used a large one does appear. Magee (18) has suggested that exothermic reactions of the type

$$[10] \qquad A^+ + B \rightarrow A + B^+$$

occur readily by passage through an excited electronic state $(A + B)^+$ to a lower state, the process being formally equivalent to a quenching process in photochemistry. The charge transfer complex may last for periods of many vibrations before either separating again or passing over to the form $B^+ + A$ with liberation of energy. It is during the lifetime of the collision complex that the possibility of an isotope effect exists. Bellas, Rousseau, Strausz, and Gunning (24) have shown that cyclohexane is much more effective than cyclohexane-d_{12} in competing with nitrous oxide to quench Hg $6(^3P_1)$ atoms. A similar observation was made for butane and butane-d_7. This was explained on the assumption that the transfer reaction proceeds through the formation of a well-defined transition complex involving both hydrocarbon molecule and excited mercury atom (25). For the radiolysis of the single hydrocarbons in a krypton matrix very little difference between $G(D_2)$ and $G(H_2)$ is to be expected since the frequency factor for the transition state will

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

not affect the final yield. However, when the light and deuterated hydrocarbons are in competition the higher frequency factor for the light hydrocarbon means that more of these molecules will produce H_2 at the expense of D_2 production from the deuterated hydrocarbon.

ACKNOWLEDGMENTS

The author wishes to thank Dr. P. J. Dyne for many helpful discussions during the preparation of this paper. Dr. R. H. Betts is thanked for his critical comments on the final draft of the paper.

INTRAMOLECULAR HYDROGEN TRANSFER IN MERCURY PHOTOSENSITIZATION OF PENTENE-1[1]

D. W. PLACZEK[2] AND B. S. RABINOVITCH
Chemistry Department, University of Washington, Seattle, Washington

Received November 27, 1964

ABSTRACT

Upon photosensitization with Hg 6 ($^3P_1$), pentene-1 undergoes several reactions: the well-known C—C and C—H ruptures and the recently found isomerization consisting of an H-atom transfer and subsequent bond formation. We report two additional products formed by an H-transfer mechanism, 1,2-dimethylcyclopropane and cyclopentane, the former being a major product.

INTRODUCTION

Evidence for the existence of a hydrogen migration mechanism amongst the reactions of mercury photosensitized (Hg 6 ($^3P_1$)) olefin was first given by Callear and Cvetanović (1). They noted that photosensitization of *cis*-ethylene-d_2 yielded the *asymmetric* product as well as the expected *trans* species. A later study (2) of butene-1 again provided strong evidence that this mode of reaction is operative; methylcyclopropane was found to be a major product within an intermediate pressure range. The nature of the H-atom shift, whether 1,2 or 1,4, was, however, not established.[3] Further evidence for 1,2-migrations came from studies by Srinivasan of a trio of compounds: he reported that photosensitized 1,5-hexadiene yielded primarily allylcyclopropane (3), 1,4-pentadiene yielded vinylcyclopropane (4), and one of the products of photosensitized 1,5-cyclooctadiene was bicyclo-[5.1.0]octene-3 (4). A 1,2 migration process in ethylene-d_2 has also been verified in quantitative detail (5).

That possible products of 1,2 H-atom translocations occur to a negligible extent in the propylene (6), isobutene (2), and butene-2 (7) systems and that 1,3 shifts are minimal, if at all extant, in the butene-1 system (2, 8) evoked from Kebarle and Avrahami (7*b*) the suggestion that H-atom transfers are favored in the order 1,4 > 1,3 > 1,2.

To further clarify the situation, Majer, Pinkard, and Robb (9) have just published a restudy (10) of the reactions of photosensitized pentene-1. Possible migration processes and products of electronically excited triplet pentene-1 may be represented as follows:

$$H_3CCH_2CH_2\dot{C}H\dot{C}H_2\dagger \xrightarrow{1,3(1,3)} H_3CCH_2\dot{C}H\dot{C}HCH_3\dagger \rightarrow \textit{cis}\text{- and }\textit{trans}\text{-pentene-2}$$

$$\xrightarrow{1,4(1,4)} H_3C\dot{C}HCH_2\dot{C}HCH_3\dagger \rightarrow \textit{cis}\text{- and }\textit{trans}\text{-dimethylcyclopropane}$$

$$\xrightarrow{1,5(1,5)} H_2\dot{C}CH_2CH_2\dot{C}HCH_3\dagger \rightarrow \text{methylcyclobutane}$$

$$\xrightarrow{1,2(2,3)} H_3CCH_2\dot{C}HCH_2\dot{C}H_2\dagger \rightarrow \text{ethylcyclopropane}$$

$$\xrightarrow{1,3(2,4)} H_3C\dot{C}HCH_2CH_2\dot{C}H_2\dagger \rightarrow \text{methylcyclobutane}$$

$$\xrightarrow{1,4(2,5)} H_2\dot{C}CH_2CH_2CH_2\dot{C}H_2\dagger \rightarrow \text{cyclopentane}$$

[1]*Supported in part by the National Science Foundation.*
[2]*Abstracted from the Ph.D. thesis of D. W. Placzek, 1965.*
[3]*The 1,2 and 1,4 shift correspond, respectively, to the reverse processes for methylcyclopropane isomerization by H-atom migration within the ring or by H-atom migration from the methyl to the ring; see D. W. Setser and B. S. Rabinovitch. Can. J. Chem. 40, 1425 (1962).*

Here the first number pair refers to the nature of the shift and the second pair in parentheses refers to the particular carbon atoms involved. Majer *et al.* looked especially for ethyl cyclopropane and methyl cyclobutane, the products of 1,2(2,3) and 1,5(1,5) translocations; a 1,3(2,4) shift also gives rise to methylcyclobutane, but this mechanism was excluded by these authors. The 1,2(2,3) process is the analogue of the 1,2(2,3) shift in butene-1, but the mechanism most closely related to 1,4(1,4) migration in butene-1 is here the 1,4(1,4) process which would give rise to dimethylcyclopropane. Ethylcyclopropane was not found by Majer *et al.*, and dimethylcyclopropane was not reported; however, methylcyclobutane was a major product. The complete absence of ethylcyclopropane does indeed verify that, in this case, a 1,2 migration is not a preferred path. Some pentene-2 that was found was attributed by these workers to a radical mechanism, namely, the disproportionation of pentyl radicals formed by the addition of H atoms to the reactant pentene-1, rather than to a 1,3(1,3) H-atom migration.

At the time of publication of the work of Majer *et al.* (9) we had already in progress an investigation of the pentene-1 system. The products they looked for do not exhaust the list of possible products of migration mechanisms; cyclopentane and 1,2-dimethylcyclopropane are missing. The presence or absence of these products, some formed by singular reaction paths, can shed light on the validity of the empirical rule of Kebarle and Avrahami. This rule had a somewhat tenuous foundation at the time of its formulation in that several results forming its basis came from studies performed at a single, low pressure; this is an experimental condition not conducive to the formation of ring species. Indeed, a major contribution by Cvetanović and Doyle (2) was the re-emphasis of the important role of pressure effects in these systems and the concomitant correlation of possibly "conflicting" data so provided. Thus cyclopropane, which is an intermediate that must decline in amount at lower pressure, is actually formed (11) to the extent of 1.4% at the optimal pressure of 7 cm. This value is sevenfold larger than the 0.2% found by Avrahami and Kebarle (6) (although this does not substantially affect their conclusion that cyclopropane is a minor product).

EXPERIMENTAL

Pentene-1 was obtained from Phillips Petroleum Company. It was purified chromatographically until free of impurity peaks. Runs were carried out statically in a 5.3 cc Vycor tube, of diameter 0.9 cm, which was irradiated with a low pressure Hanovia quartz helical resonance lamp. Reactants were saturated with mercury, and reactions were run at the ambient temperature, 22 °C. Reaction times varied from 0.5 to 5.0 min.

Analyses were made with a 300 ft squalane-coated capillary column maintained at 0 °C, with an argon ionization detector. Peak height calibrations were known from various pure samples. Under these conditions, the *trans*-dimethylcyclopropane peak was submerged by the reactant pentene-1 peak. The amounts of *cis*- and *trans*-pentene-2 formed were the same within experiental error. The *trans*- and *cis*-cyclopropanes can undoubtedly be assumed to be produced in comparable, although not necessarily equal, amounts. Retention times and identities were calibrated by use of the pure compounds.

RESULTS AND DISCUSSION

The results (Table I) are in partial agreement with those of Majer *et al.*: methylcyclobutane is certainly a major product, and no ethylcyclopropane was found. But, by contrast, we find that both 1,2-dimethylcyclopropane and cyclopentane are formed, and the former in quantities comparable to the methylcyclobutane. The cyclopentane is produced in minor amounts; at 2 cm pressure, the lowest pressure used, the percentage of cyclopentane relative to methylcyclobutane is 2.6%; at higher pressures, the percentage seems reduced to ~1.0%. The corresponding relative values for *cis*-1,2-dimethylcyclopropane are identical, i.e. 40%, within experimental error at the two pressure extremes.

20	1.9	1.8	40.9	0.9

[a]Expressed in %, relative to methylcyclobutane product; the pentenes are not necessarily products of an H-migration process (10).
[b]The *trans* product was also formed, see text.
[c]Data retrieval precluded by small extent of reaction or loss of sample.

Majer *et al.* showed that methylcyclobutane product passed through a maximum at 3.5 cm total pressure, as does therefore dimethylcyclopropane; a cyclopentane maximum presumably occurs at a little lower pressure.

Noteworthy is the fact that both of these products are produced by single reaction paths and that both result from 1,4 shifts; but the cyclopentane is formed via a *primary* → *secondary* H transfer and the dimethylcyclopropane by a *secondary* → *primary* H migration. These data illustrate that any empirical rule used to predict the aptitude of a positional shift must be properly, and perhaps extensively, modified by the nature of the processes involved; and, in this, the diradical systems apparently behave much like monoradical systems as to relative ease of H-atom translocations (12). The modification is attributable to conventional interpretation in terms of relative stability of various types of radicals. Apart from these cautionary remarks, the data seem to substantiate the predictions of Kebarle and Avrahami.

In view of the above, it can be seen that methylcyclobutane is not produced in quantities which greatly exceed the amount of 1,2-dimethylcyclopropane for two reasons: on the one hand, one mode of production, 1,3(2,4) transfer, is not highly favored, and on the other, a *primary* → *primary* transfer is required for the preferred 1,5(1,5) mode, as opposed to the *secondary* → *primary* H shift which leads to the production of the dimethylcyclopropane. The total lack of ethylcyclopropane and the relatively minute yield of the pentene-2, some or all of which is undoubtedly due to disproportionation of pentyl radicals, demonstrates that 1,2 and 1,3 translocations are unlikely.

Srinivasan's findings (3, 4) remain a hindrance to the formulation of a complete mechanistic rationale for reactions of this genre. That some ordinarily favorable transfers are hindered in his system due to the presence of vinylic hydrogens fails to account for the fact that of the other possible, albeit less favorable, cases, the least preferred according to the prior considerations is the one that does indeed occur.

It appears desirable to reiterate (5) the relationship between reactions of mercury photosensitized electronically excited compounds† and the reactions of highly vibrationally excited ground singlet state cyclopropanes*:

[1*a*] $$\nabla\text{—C=C}^* \rightarrow \text{C=C—C—C=C} \qquad (13)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[1*b*]	$C{=}C{-}C{-}C{=}C\dagger \rightarrow \triangledown{-}C{=}C$	(4)
[2*a*]	$\triangledown{-}C^* \rightarrow C{-}C{-}C{=}C$	(15)
[2*b*]	$C{-}C{-}C{=}C\dagger \rightarrow \triangledown{-}C$	(2)
[3*a*]	$\triangledown^* \rightarrow C{-}C{=}C$	(16)
[3*b*]	$C{-}C{=}C\dagger \rightarrow \triangledown$	(6, 11)
[4*a*]	$CH_3CH^* \rightarrow C{=}C$	(17)
[4*b*]	$C{=}C\dagger \rightarrow CH_3CH.$	(5)

The last is the 2-carbon analogue of the preceding cyclopropane examples. The asterisk signifies the excited singlet state. In these examples, the rearrangements of vibrationally excited singlet cyclopropanes readily reverse (but not microscopically) the reactions of electronically excited triplet olefins. The reactions of triplet cyclopropanes differ from those of the singlet species. For example, triplet state cyclopropane undergoes polymerization (18, 19) and geometric isomerization (19) but not structural isomerization (in significant amount) to propylene. Similarly, Duncan and Cvetanović (20) have studied the reaction of presumably triplet state 1,2-dimethylcyclopropane and have obtained a product distribution which deviates considerably from that of vibrationally excited singlet dimethylcyclopropane (21).[4] The reactions of the two electronic states take place on distinctly different surfaces. The activated complex for reactions of the type (singlet cyclopropane) → (singlet propene) involves ring rupture and 1,2 H-atom transfer (22) in an α,γ-diradical. The triplet state cyclopropane, on the other hand, evidently leads to an α,β-diradical, which is presumably a relatively long-lived species; it can go through an activated complex characteristic of alkyl radicals, for which the non-adjacent H transfer, with a multi-membered ring intermediate, seems favored. The failure of triplet state cyclopropane to yield propylene readily is in this sense the microscopic concomitant of the low yield of cyclopropane which arises from triplet diradical propylene.

ACKNOWLEDGMENT

We wish to thank Dr. W. D. Walters for the gift of a sample of methylcyclobutane.

[4] *That the "pressure independent" production of certain olefins from triplet dimethylcyclopropane (ref. 20 and report by R. J. Cvetanović. Photochemistry Symposium, Rochester, 1963) takes place on a triplet surface, rather than via a very rapid internal conversion to a singlet cyclopropane surface, follows from the quasi-pressure independent character of this process and from the difference between these olefin products and those formed from hot singlet dimethylcyclopropane. It is further supported by the failure of analogous triplet cyclopropane to yield propylene at pressures at which vibrationally excited singlet cyclopropane, if formed by internal conversion, would do so readily (19).*

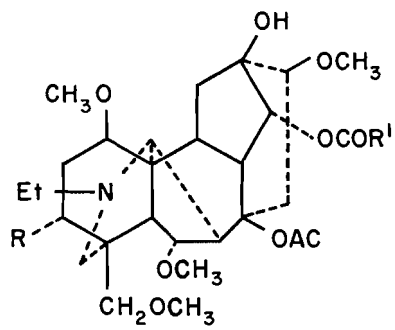
ABSTRACT

The alkaloid chasmanine, $C_{25}H_{41}O_6N$, isolated from *A. chasmanthum* contains four methoxyl and two hydroxyl groups as well as an imino-ethyl. It undergoes the usual pyrolytic reaction and the unsaturated product, pyrochasmanine, $C_{25}H_{39}O_5N$, gives rise to an acid-catalyzed allylic rearrangement product, isopyrochasmanine. Pyrochasmanine, on treatment with lithium aluminium hydride, is demethoxylated. It can be concluded that the base, like bikhaconine, contains the sequence $\rangle C(OH)—CH_2—CH(OCH_3)—$. Chasmanine can be oxidized to a compound containing a cyclopentanone ring so that its second hydroxyl must be secondary and located on a five-membered ring. It is possible to benzoylate the secondary hydroxyl and acetylate the tertiary hydroxyl. The n.m.r. characteristics of the resulting double ester determine the location of these two groups and their stereochemistry. The relative position of two of the remaining methoxyl groups is established via a demethylation reaction resulting in the formation of a cyclic ether. All the chemical reactions studied are in agreement with structure IV (R = R′ = H) for chasmanine. There is, however, no positive proof for the location of the fourth methoxyl and it has been placed in ring A by analogy. An attempted correlation with bikhaconine is described.

Recently the isolation of five alkaloids from the roots of *Aconitum chasmanthum* Stapf has been reported (1). One of these, indaconitine I, the structure of which has already been established (2), had been isolated long ago from this source by Dunstan and Andrews (3). Two others, designated chasmaconitine and chasmanthinine, have been shown to have structures II and III respectively (1).



I, R = OH, R′ = C_6H_5

II, R = H, R′ = C_6H_5

III, R = H, R′ = -CH=CH-C_6H_5

We now wish to report on the fourth alkaloid, previously identified as base B (1), for which the name chasmanine is now suggested. Whereas chasmaconitine and chasmanthinine were isolated from the weak bases, chasmanine was obtained from the fraction containing the strong bases, of which it formed the main component.

Chasmanine (base B), $C_{25}H_{41}O_6N$, was earlier reported to melt at 84–88°. By further purification this has been raised to 90–91°. The base was optically active, $[\alpha]_D^{25}$ +23.6°.

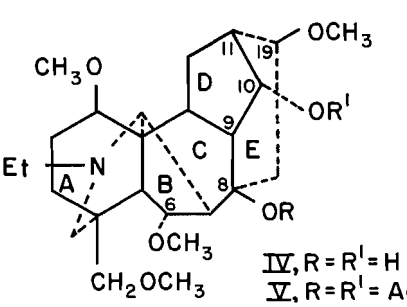
Although it crystallized readily, all attempts to prepare crystalline salts failed. Its infrared spectrum contained a broad absorption band with a small peak at 3 475 and two well-defined peaks at 3 365 and 3 263 cm^{-1} indicative of hydroxyl groups, but contained no carbonyl absorption, so that no ester group is present. The nuclear magnetic resonance (n.m.r.) spectrum revealed the presence of four methoxyl groups (δ 3.31, 3.21 corresponding to three protons each and δ 3.28 corresponding to six protons) and an N-ethyl group (triplet centered at δ 1.03). Acetylation of the base with acetic anhydride and *p*-toluenesulfonic acid produced a readily crystallized diacetate, the n.m.r. spectrum of which confirmed the introduction of two acetyl groups (δ 2.02, 1.97). Oxidation of chasmanine with chromium trioxide in acetone (3) gave rise to a gummy ketone characterized as its crystalline monoacetate. In the infrared the latter showed a band at 1 752 cm^{-1} attributable to a five-membered cyclic ketone, and one at 1 727 cm^{-1} indicative of an acetate carbonyl. In the n.m.r. spectrum only one acetyl group was indicated (δ 1.99). Both the ketone and its acetyl derivative were converted back to chasmanine by reduction with sodium borohydride and lithium aluminium hydride respectively.

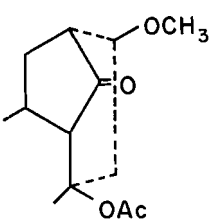
Oxidation of chasmanine with chromium trioxide – pyridine complex (Sarett's reagent) went further than chromium trioxide in acetone and gave two products, one, m.p. 196°, $C_{23}H_{33}O_6N$, that contained a cyclopentanone ring, but had lost the imino-ethyl group and had the properties of an azomethine. It formed an ethiodide convertible into chasmanine by reduction with sodium borohydride. In the n.m.r. spectrum the azomethine showed a singlet at δ 3.72 attributable to the protons of a methylene adjacent to an oxygen (—CH_2—O—), and a singlet at δ 7.51 that can be ascribed to —CH=N—. The infrared spectrum contained bands at 1 655 cm^{-1} attributable to the latter function, and at 1 761 cm^{-1} indicative of a five-membered cyclic ketone. The second oxidation product is neutral, m.p. 206–207° ($C_{25}H_{37}O_7N$). It also contains a cyclopentanone ring, but its imino-ethyl group has been oxidized to an acetyl group. It is converted back into chasmanine by the action of lithium aluminium hydride.

Consequently, of the six oxygens in chasmanine, four are present in methoxyl groups, one is in a tertiary hydroxyl, and the sixth is in a secondary hydroxyl located on a five-membered ring.

Just as with lycoctonine ($C_{25}H_{41}O_7N$) and aconitine ($C_{34}H_{47}O_{11}N$), if all the oxygen-containing substituents in chasmanine are replaced by hydrogen, there is obtained the common empirical formula $C_{21}H_{33}N$. As a working hypothesis, therefore, we have assumed that chasmanine possessed the same carbon–nitrogen skeleton common to lycoctonine and aconitine, and that it could be represented by structure IV. Hence the diacetate would be V and the keto-monoacetate or 10-dehydrochasmanine VI. The oxidation products obtained by the action of Sarett's reagent would be N-deethyl-10-dehydrochasmanine-azomethine and N-acetyl-N-deethyl-10-dehydrochasmanine.



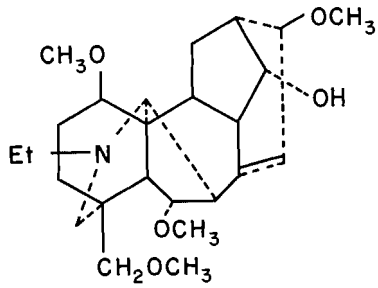
IV, R = R' = H
V, R = R' = Ac



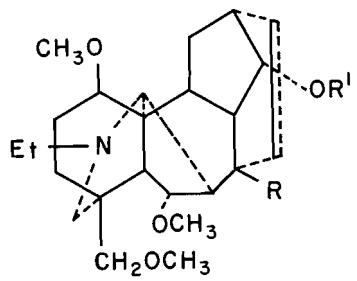
VI

The stereospecific course of the reduction of the ketone and the keto-monoacetate VI indicates the position of the secondary hydroxyl in the five-membered ring. There are two possible positions for a secondary hydroxyl in this ring. Whereas there is free access to the C-12 position, the C-10 position is hindered on one side and would thus account for a stereospecific reduction.

Diacetylchasmanine V when heated *in vacuo* gave rise to three products showing distinct spots in thin layer chromatography. The relative yield of each component varied with the condition of pyrolysis. The combined product was not crystalline and could not be separated by chromatography on alumina, although after saponification it separated readily into three crystalline components that proved to be pyrochasmanine VII, isopyrochasmanine VIII, and demethylisopyrochasmanine IX.



VII



VIII, R = OCH_3, R' = H
IX, R = OH, R' = H
X, R = OAC, R' = AC
XIV, R = R' = H

Pyrochasmanine VII, the compound of intermediate mobility showed in the infrared an absorption band at 3 430 cm^{-1} attributable to a hydroxyl and one at 1 634 cm^{-1} characteristic of a double bond. Its n.m.r. spectrum contained signals for one olefinic proton (δ 5.43, J = 6 c.p.s.), for four methoxyl groups (δ 3.14, 3.28, 3.24, 3.21) and an imino-ethyl (triplet at δ 1.04). When pyrochasmanine was heated with methanolic perchloric acid, it was converted quantitatively to isopyrochasmanine VIII identical with the most mobile component of the hydrolyzed pyrolytic product. Isopyrochasmanine in its n.m.r. spectrum still showed the presence of four methoxyl groups and an imino-ethyl, but in the olefinic region the spectrum contained the signals of two protons (multiplet at δ 5.75–6.12). The acid-catalyzed allylic rearrangement involved in the conversion of pyrochasmanine to isopyrochasmanine has been observed in several highly oxygenated diterpenoid alkaloids (4–7).

The structure of the third compound, demethylisopyrochasmanine IX isolated from the hydrolyzed product of pyrolysis was verified as follows. The n.m.r. spectrum of the compound revealed the presence of three methoxyls only (δ 3.21, 3.30, 3.32), an imino-ethyl (triplet centered at δ 1.02), and two olefinic protons (multiplet at δ 5.67–5.91). The two olefinic protons indicate that the allylic shift has taken place and therefore that the new hydroxyl is at C-8. The presence of a double bond was confirmed by the formation of a dihydro derivative on catalytic hydrogenation. The low chromatographic mobility of IX suggested the presence of an additional hydroxyl, and this was confirmed by the preparation of a diacetyl derivative X (n.m.r. δ 1.93, 1.99) that could be hydrogenated

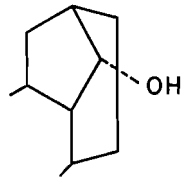
XII



XIII

to a dihydrodiacetyl derivative XI also obtainable by acetylation of the dihydro derivative obtained from IX.

The dihydrodiacetyldemethylisopyrochasmanine XI was pyrolyzed *in vacuo* at 180–190° for 5 min. The crude pyrolytic product (single spot in thin layer chromatography) showed in the n.m.r. spectrum a single acetyl group (δ 2.02) and one olefinic proton (multiplet at δ 4.98–5.28). It could not be crystallized, but after hydrolysis was characterized as its crystalline perchlorate XII; catalytic hydrogenation of this salt produced a dihydro derivative XIII also characterized as its crystalline perchlorate. Since compound XI undergoes pyrolytic elimination of an *O*-acetyl group, it follows that the additional hydroxyl in IX must be located at C-8 as mentioned above.

Pyrochasmanine VII treated with lithium aluminium hydride in tetrahydrofurane at room temperature underwent the allylic shift and demethoxylation, giving rise to demethoxyisopyrochasmanine XIV ($C_{24}H_{37}O_4N$). The n.m.r. spectrum of XIV contained signals characteristic of an imino-ethyl (triplet centered at δ 1.02), of two olefinic protons (multiplet at δ 6.03–5.78), and of three methoxyl groups (δ 3.29, 3.28, 3.22), thus confirming the loss of one methoxyl as well as the shift in double bond in the course of the reaction. Catalytic hydrogenation of the perchlorate of XIV gave the corresponding dihydro derivative, isolated as the perchlorate. This salt was identical in every respect (melting point, that of the mixture, infrared spectra, X-ray powder patterns) with the perchlorate of the dihydro derivative XIII.

The above described formation of pyrochasmanine and its transformation products are characteristic of diterpenoid alkaloids containing the sequence $\rangle C(OH)—CH_2—CH(OCH_3)—$ in ring E as was well established in connection with delphinine (8), pseudaconitine (5), and bikhaconitine (7). What is unusual with these reactions in chasmanine is the formation of isopyrochasmanine and its demethyl derivative in the initial pyrolytic reaction. For instance, the pyrolysis of pseudaconitine produced pyropseudaconitine as the only identified base, while isopyropseudaconine was produced by an acid-catalyzed rearrangement of pyropseudaconine (5). As mentioned already, the relative proportions of the three compounds produced by the pyrolysis of chasmanine were dependent on the conditions of the experiment. Heating for less than 5 min at 170–180° favored the formation of pyrochasmanine VII while heating for a longer time (10 min) at higher temperatures (190–200°) produced mainly isopyrochasmanine VIII and demethylisopyrochasmanine IX. The production of a demethylisopyro compound as a direct product of pyrolysis had not been observed before in other diterpenoid alkaloids.

The product of the already described pyrolysis of diacetylchasmanine can also be worked up in a different way. When the crude pyrolyzed product was treated with lithium aluminium hydride in tetrahydrofurane, three compounds were obtained, i.e., isopyrochasmanine VIII, demethylisopyrochasmanine IX, and demethoxyisopyrochasmanine XIV. These compounds were separated readily by chromatography on alumina. In this

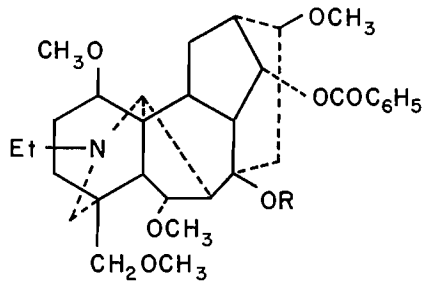
For personal use only.

experiment, the yield of demethylisopyrochasmanine was higher than when the isolation was carried out after hydrolysis of the product. Surprisingly it was found that demethylisopyrochasmanine could be obtained in 30% yield by treatment of isopyrochasmanine with lithium aluminium hydride in tetrahydrofurane.

Treatment of chasmanine with benzoyl chloride in pyridine at room temperature gave a high yield of monobenzoylchasmanine XV; it was amorphous, but formed a crystalline hydrochloride. The benzoylated product in turn, when acetylated gave rise to crystalline acetylbenzoylchasmanine XVI. The n.m.r. spectrum of this diester showed, in addition



XV, R = H

XVI, R = Ac

to the main features already present in the spectrum of chasmanine, five aromatic protons (multiplet at δ 8.23–7.20) and a triplet centered at δ 5.07 that may be attributed to the C-10 hydrogen. That this signal is not a doublet as in the case of the other esterified aconite-type alkaloids examined (9) indicates that the C-10 proton must be flanked not by one but by two other protons. Consequently, the substituent at the bridgehead position C-11 must be a hydrogen and not a hydroxyl as in aconitine, pseudaconitine, etc. The signal for the acetyl group protons was at quite high field (δ 1.36). As pointed out previously (9) this shift to high field in esterified oxygenated diterpenoid alkaloids is due to the anisotropic effect of the benzene ring of the aromatic acid, and indicates the location and orientation of the benzoyl ester group. Hence the secondary hydroxyl present on a five-membered ring in chasmanine is the one that was esterified by the action of benzoyl chloride and must be located at C-10. Consequently, the substituents on rings D and E are located as required by structure IV and the stereochemistry of the hydroxyl at C-10 must be the same as that of the benzoyloxy group in aconitine.

Isopyrochasmanine VIII when heated for 40 min on the steam bath with 50% sulfuric acid gave a mixture of three products: a component that could not be purified completely (but appeared from its n.m.r. spectrum to contain two methoxyls only), some demethylisopyrochasmanine IX, and tridemethylanhydroisopyrochasmanine XVII, $C_{22}H_{31}O_4N$. If, however, the reaction was carried out for $2\frac{1}{4}$ h, two products only were obtained, i.e., IX and XVII. Jacobs and Sato (10) had found that isopyrooxodelphinine when heated at 40° with zinc chloride and 5% hydrochloric acid underwent a similar demethylation and gave rise to a didemethyl and a tridemethyl cyclic ether. Wiesner *et al.* (11) in a later interpretation of this result provided evidence that the two methyl groups that were removed with the resulting formation of a cyclic ether were located at C-6 and C-17. Consequently, the most probable structure of tridemethylanhydroisopyrochasmanine which contains only one methoxyl—n.m.r. δ 2.50 (3 H)—is XVII and affords strong evidence for the presence of a methoxyl at both C-6 and C-17 positions in the alkaloid (IV). The latter was already indicated by the n.m.r. spectrum of N-deethyl-10-dehydrochasmanine-azomethine (δ 3.72).

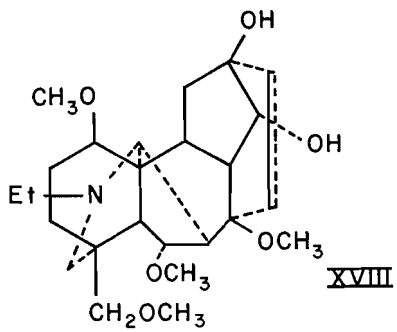
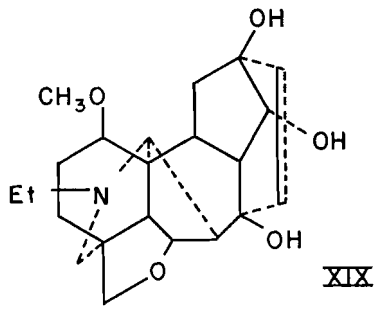
XVII

Neoline undergoes a similar demethylation (6). The structure suggested for neoline (6) differs from that suggested for chasmanine only in that it contains an α-hydroxyl at C-1 in ring A while chasmanine contains a C-1 β-methoxyl. In order to correlate the two through their cyclic ether derivatives, it is necessary to demethylate chasmanine at C-1. Jacobs and Sato (10) in their demethylation experiments had used neutral oxo-derivatives and had observed that by carrying out the reaction at 60° they could obtain a completely demethylated compound. Isopyrochasmanine was therefore oxidized with permanganate in aqueous acetone to remove the imino-ethyl group (12) and the resulting secondary base was acetylated to N-acetyl-N-deethylisopyrochasmanine. This N-acetyl derivative was heated with zinc chloride in 5% hydrochloric acid for 1 h at 70–75° and the crude product (single spot in thin layer chromatography) was reduced with lithium aluminium hydride in tetrahydrofurane. This series of reactions yielded exclusively the tridemethyl cyclic ether XVII already described. The failure of the reaction to remove the last remaining methoxyl, i.e., that in ring A, cannot be considered as militating against the presence of a C-1 methoxyl since an exactly parallel series of reactions carried out with isopyrobikhaconine XVIII gave rise to a product XIX still carrying a methoxyl.



XVIII



XIX

The location of the C-6 methoxyl has been derived from the formation of the cyclic ether. Not only is this position confirmed, but the orientation of the group is also determined by the course of the oxidation of chasmanine with potassium permanganate. It has been established that in the aconite type of diterpenoid alkaloids, in which the C-6 methoxyl is α, potassium permanganate oxidation under neutral (or basic) condition leads mainly to N-deethylation whereas in the lycoctonine type, in which the C-6 methoxyl is β, the same oxidizing agent leads to a lactam (12). The oxidation of chasmanine with permanganate, under these conditions, gives an excellent yield of N-deethylchasmanine, so that the alkaloid must contain a C-6 methoxyl in the α-configuration.

N-Deethylchasmanine when treated with ethyl iodide is converted back to chasmanine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

When treated with methyl iodide instead, it is converted to N-methyl-N-deethyl-chasmanine, $C_{24}H_{39}O_6N$, m.p. 90–92°. This new base, like the acetylated and benzoylated chasmanine described above, has not yet been reported to occur in nature.

Because of the ease with which the allylic rearrangement takes place in pyrochasmanine, it is highly probable that the configuration of the C-19 methoxyl is the same as in the other aconite alkaloids already investigated.

The location of all the substituents in the proposed chasmanine structure IV has been confirmed chemically except for the ring A methoxyl. Concerning the carbon skeleton, it is known that pyrodelphonine shows unexpected absorption in the ultraviolet (λ_{max} 245 mμ, log ϵ 3.8) and that this disappears on acidification. Wiesner *et al.* (6) noticed similar spectroscopic properties in pyroneoline and considered that this similarity indicated an analogy between the neoline and the delphonine structures. The ultraviolet spectra of pyrochasmanine and of pyrobikhaconine show absorption at λ_{max} 244 mμ, log ϵ 3.74 and λ_{max} 249 mμ, log ϵ 3.71 respectively. In both cases the peak disappeared on acidification. This parallel spectroscopic behavior of chasmanine and bikhaconine as well as delphonine and neoline supports the assumption of the same carbon skeleton in all four compounds.

There is a close relation between structure IV suggested for chasmanine and the structure of bikhaconine, the hydrolytic alkamine derived from bikhaconitine (7). The only difference is that bikhaconine contains a C-11 bridgehead hydroxyl that is absent in chasmanine. In an attempt to find a rigorous confirmation of the structure of chasmanine, we sought to correlate the base with bikhaconine. Such a correlation involved removing the C-11 hydroxyl from the latter, either by first opening ring E or by direct attack on the hydroxyl.

Although the initial opening of ring E prior to removal of the hydroxyl appeared to be the more promising, three different methods of achieving this proved unsuccessful and failed to yield the ultimate expected product.

After several fruitless attempts to remove the C-11 hydroxyl directly it was decided to try a recently described method. Okamoto *et al.* (13) have reported that a bridgehead *O*-mesylate group in a pseudokobusine derivative could be hydrogenolyzed by high pressure hydrogenation over Raney nickel. Although in pseudokobusine the hydroxyl thus removed is a carbinolamine the reaction might work with bikhaconine if it proceeded through radical formation.

Methanesulfonation of bikhaconitine gave the desired mesylate $C_{37}H_{53}O_{13}NS$ (XX) in a good yield. Deoxyindaconitine and deoxyaconitine were similarly smoothly mesylated to XXI and XXII respectively. The last compound was a monomesylate and it was the bridgehead hydroxyl that reacted; even forced conditions could not mesylate the second ring E hydroxyl. The hydrogenation of bikhaconitine mesylate at 41 atm and 120–130° for 15 h gave two products. The main product separated by chromatography represented a 60% yield; it still contained the mesylate and the veratroyl groups, but lacked the acetoxy group. Its structure has been confirmed by an alternative synthesis. Pyrobikhaconitine was hydrogenated over platinum to the dihydro derivative and this when mesylated gave the same mesylate XXIII previously obtained from XX.

The minor product of the hydrogenation over Raney nickel was obtained in 5% yield only. Although it could not be crystallized, its infrared and n.m.r. spectra revealed that it no longer contained the mesylate and acetoxy groups, but still contained an imino-ethyl, four methoxyl, and the veratroyl groups. It was assumed to possess structure XXIV, and was hydrolyzed into the corresponding hydroxy base XXV.

Pyrochasmanine VII prepared as described above was hydrogenated catalytically to

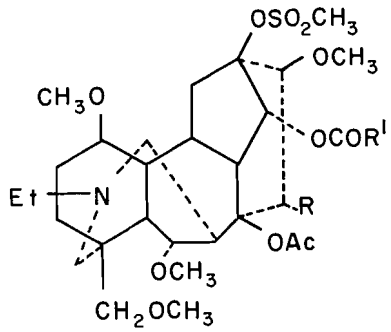
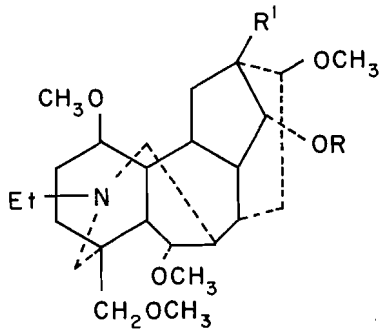
For personal use only.



XX, R = H, R' = $C_6H_3(OCH_3)_2$
XXI, R = H, R' = C_6H_5
XXII, R = OH, R' = C_6H_5



XXIII, R = $COC_6H_3(OCH_3)_2$, R' = OSO_2CH_3
XXIV, R = $COC_6H_3(OCH_3)_2$, R' = H
XXV, R = R' = H

its amorphous dihydro derivative. This derivative had exactly the same R_f value as the hydroxy base XXV in thin layer chromatography, thus suggesting their identity. All attempts to crystallize the two products or their salts failed, and the quantities available were too small for further comparison. The correlation work will be repeated but the present results are now reported as they do support the structure of chasmanine although they do not constitute a rigorous proof.

Ochiai, Okamoto, and Sakai (14) have reported the isolation from *Aconitum subcuneatum* Nakai and *Aconitum yesoensis* Nakai (both plants collected in the northern part of Japan) of an alkaloid designated Toroko-base II, m.p. 85–88°, $C_{24}H_{39}O_6N$, $[\alpha_D]$ +43°, containing an imino-methyl. Further purification and investigation by these authors has shown that the base had m.p. 90–91°, $[\alpha]_D$ +25.0° and contained an imino-ethyl instead of an imino-methyl, so that the empirical formula was corrected to $C_{25}H_{41}O_6N$. A direct comparison of chasmanine with Toroko-base II has shown the two to be identical in every respect (melting point, that of the mixture, infrared spectra, and X-ray powder patterns).

Undoubtedly the discovery of the occurrence of the base in *A. subcuneatum* antedates the report of its occurrence in *A. chasmanthum*. Since, however, the designation Toroko-base, meant to be tentative, refers to the place where the plant was collected, it is proposed to abandon it and retain the name chasmanine[3] derived from the specific name of one of the plants in which the base occurs.

EXPERIMENTAL

The infrared spectra were taken in Nujol mulls (unless otherwise mentioned) on a Perkin–Elmer double beam Model 21B spectrometer. The n.m.r. spectra were measured in chloroform solution containing

[3]*Professor E. Ochiai is in agreement with this proposal.*

tetramethylsilane as an internal reference, on a Varian A-60 instrument, and the chemical shifts are given in p.p.m. The ultraviolet spectra were measured on a Cary recording spectrometer Model 11.

The melting points were taken on a Kofler hot stage and were not corrected. For column chromatography Woelm grade IV neutral alumina was used, unless otherwise mentioned, and for thin layer chromatography the adsorbent was Merck silica gel G, and the developing solvent employed was cyclohexane – chloroform – diethyl amine. All extracts were dried and subsequently evaporated under reduced pressure.

Chasmanine

The alkaloid was isolated from the plant extract as previously described (1). After several recrystallizations from *n*-hexane it consisted of fine colorless needles, m.p. 90–91°, $[\alpha]_D^{25}$ +23.6° (*c*, 2.5 in EtOH), pK_a 6.3 (in 80% ethanol).

Anal. Calcd. for $C_{25}H_{41}O_6N$: C, 66.49; H, 9.15; N, 3.10. Found: C, 66.31; H, 9.09; N, 3.14.

ν_{max} 3 460, 3 365, 3 260 cm^{-1} (OH); 1 113, 1 095 cm^{-1} (OCH_3). In the n.m.r. spectrum: singlets at δ 3.31 (3H), 3.28 (6H), 3.21 (3H), triplet centered at δ 1.03 (3H). Chasmanine may be distilled at 150° and 5×10^{-5} mm without decomposition, but the pure crystalline base is somewhat unstable and after several months it contains a considerable amount of impurities (~10%).

Diacetyl Chasmanine

A mixture of chasmanine (109 mg) and *p*-toluenesulfonic acid (100 mg) in acetic anhydride (3 ml) was heated on a steam bath for 1 h. After cooling, the mixture was poured on ice and made basic with sodium carbonate, and the solution extracted with chloroform. Evaporation of the extract left a gum (128 mg) which was dissolved in *n*-hexane – benzene (1:1) and chromatographed on alumina. The column was eluted with the same solvent mixture and the eluate evaporated to dryness. There was left a residue (93 mg) which crystallized when triturated with *n*-hexane. After several recrystallizations from the same solvent, the diacetyl chasmanine produced consisted of colorless needles, m.p. 139–141°.

Anal. Calcd. for $C_{29}H_{45}O_8N \cdot \frac{1}{2}H_2O$: C, 63.96; H, 8.45; N, 2.57. Found: C, 63.76; H, 8.46; N, 2.79.

ν_{max} 1 725, 1 242 cm^{-1} (acetate). In the n.m.r. spectrum: singlets at δ 2.02 (3H), 1.97 (3H), 3.30 (3H), 3.28 (3H), 3.22 (6H), triplet centered at δ 1.05 (3H), poorly resolved triplet at δ 4.76 (1H).

Oxidation of Chasmanine with Chromic Oxide

(*a*) To a solution of chasmanine (640 mg) in acetone (15 ml) cooled in ice, a solution of chromic oxide (650 mg) in acetone (10 ml) also cooled in ice was added all at once. After having been left 48 h at room temperature, the acetone was evaporated, the residue was suspended in 2 *N* sulfuric acid (60 ml), and sodium sulfite was added until the green color persisted. The liquor was made basic with sodium carbonate and extracted with chloroform. Evaporation of the extract yielded the crude oxidation product (585 mg) which in thin layer chromatography was found to contain minor contaminating substances and some starting material as well. The crude product was therefore acetylated by the usual method. The resulting product was dissolved in benzene, chromatographed on alumina, and eluted with benzene. Fractions 2–7 of the eluate on evaporation left a crystalline acetyl ketone (480 mg), m.p. 151–159°. After several recrystallizations from acetone – *n*-hexane, it consisted of colorless needles, m.p. 158–160°.

Anal. Calcd. for $C_{27}H_{41}O_7N$: C, 65.96; H, 8.41. Found: C, 65.79; H, 8.83.

ν_{max} 1 751, 1 727, 1 242 cm^{-1}. In the n.m.r. spectrum: singlets at δ 1.99 (3H), 3.28 (9H), 3.19 (3H), triplet centered at δ 1.08 (3H).

Hydrolysis of the pure acetyl ketone (V) gave a colorless glass that failed to crystallize. ν_{max} 3 350 cm^{-1} (OH), 1 750 cm^{-1} (cyclic five-membered ketone). An attempt to prepare a crystalline salt also failed.

To a small quantity of the amorphous ketone in methanol, sodium borohydride was added. The reduction product, worked up as usual, was identical in every respect with chasmanine. Reduction of the crystalline monoacetyl ketone with lithium aluminium hydride also produced chasmanine shown by X-ray powder patterns to be identical with the original alkaloid.

(*b*) To a solution of chasmanine (243 mg) in pyridine (1 ml) was added chromium trioxide – pyridine complex, prepared from chromium trioxide (600 mg) and pyridine (9 ml), and the reaction mixture allowed to stand at room temperature for 90 h. The mixture was made basic with dilute ammonia and extracted thoroughly with chloroform. Evaporation of the extract left a brown syrup which was suspended in 5% hydrochloric acid and extracted with chloroform to remove the neutral product (extract A). The aqueous solution was rendered alkaline with sodium carbonate and extracted with chloroform. Evaporation of this previously dried extract left a syrup (112 mg); it was dissolved in chloroform, chromatographed over Florisil, and eluted with the same solvent, the eluate being collected in 10 ml fractions. Evaporation of the eluant left a number of crystalline fractions that were combined and recrystallized in ether from which N-deethyl-10-dehydrochasmanine-azomethine separated as colorless needles, m.p. 196°, wt. 20 mg. ν_{max}^{KBr} 1 761 cm^{-1} CO), 1 655 cm^{-1} (—CH=N—); $\nu_{max}^{CHCl_3}$ 1 756, 1 634 cm^{-1}. In the n.m.r. spectrum: singlet at δ 7.51 (1H, —CH=N—), δ 3.72 (2H, $\rangle$C—CH_2—OCH_3), δ 6.68, 6.74, 6.76 ($4OCH_3$).

Anal. Calcd. for $C_{23}H_{33}O_6N$: C, 65.85; H, 7.93; N, 3.34. Found: C, 65.86; H, 7.93; N, 3.37.

The extract A from the acid separation was washed with water, dried, and evaporated. The residual syrup (156 mg) was chromatographed over Florisil exactly as above. The crystalline fractions obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

from the eluate were combined and recrystallized from *n*-hexane – acetone from which N-acetyl-N-deethyl-10-dehydrochasmanine separated as colorless scales, m.p. 206–207°, wt. 54 mg. ν_{max}^{KBr} 1 755 cm^{-1} (CO), 1 660 cm^{-1} (N—Ac). In the n.m.r. spectrum: signals at δ 6.68, 6.72, 6.75 ($4OCH_3$), singlet at δ 2.19 (N—Ac).

Anal. Calcd. for $C_{25}H_{37}O_7N \cdot H_2O$: C, 62.35; H, 8.16; N, 2.91. Found: C, 62.06; H, 7.89; N, 2.90.

Conversion of N-Deethyl-10-dehydrochasmanine-azomethine to Chasmanine

N-Deethyl-10-dehydrochasmanine-azomethine (23 mg) was dissolved in ethyl iodide (1 ml), the solution kept for 3 h at room temperature and evaporated to dryness under reduced pressure. The residue was crystallized twice from ethanol, m.p. 250–251° (decomp.), wt. 20 mg. ν_{max}^{KBr} 1 762, 1 672 cm^{-1}.

Anal. Calcd. for $C_{23}H_{33}O_6N—C_2H_5I$: C, 52.17; H, 6.66; N, 2.44. Found: C, 52.38; H, 6.71; N, 2.42.

To a solution of the ethiodide (18 mg) in methanol sodium borohydride (18 mg) was added and the solution was allowed to stand at room temperature for 16 h. The reduction product, worked up as usual, was a crystalline mass which after recrystallization from *n*-hexane consisted of colorless needles, m.p. 88–89°, wt. 4 mg. A further crop (8 mg) was obtained from the mother liquor. In admixture with chasmanine the melting point was unaltered, and the infrared spectra of both were superimposable.

Reduction of N-Acetyl-N-deethyl-10-dehydrochasmanine

This product (10 mg) was refluxed for 20 min with lithium aluminium hydride (40 mg) in tetrahydrofurane (5 ml). The reaction mixture, worked up as usual, yielded a crystalline substance (9 mg) which after recrystallization from *n*-hexane had m.p. 85°, wt. 5 mg. It was identical in every respect with chasmanine.

Benzoylchasmanine (XV)

A mixture of chasmanine (47 mg), freshly distilled benzoyl chloride (0.15 ml), and pyridine (1 ml) was kept at room temperature for 1 h. The reaction mixture was poured onto ice and made basic by the addition of potassium carbonate and the solution extracted with chloroform. Evaporation of the extract left the crude product (79 mg) which after chromatography in benzene on alumina afforded benzoylchasmanine (48 mg) which gave only one spot in thin layer chromatography. The product could not be induced to crystallize. It was distilled at 145° and 5×10^{-5} mm, but gave somewhat unsatisfactory analytical figures. ν_{max} 3 350 (OH), 1 710 cm^{-1} (CO). In the n.m.r. spectrum: multiplet at δ 8.10–7.30 (5H), triplets centered at δ 5.17 (1H) and 1.08 (3H), singlets at δ 3.30 (6H), 3.26 (3H), 3.17 (3H). It formed a hydrochloride that crystallized from acetone as colorless prisms, m.p. 248–249°, and gave good analytical results.

Anal. Calcd. for $C_{32}H_{45}O_7N \cdot HCl$: C, 64.86; H, 7.67. Found: C, 64.60; H, 7.76.

Acetylbenzoylchasmanine (XVI)

Benzoylchasmanine (264 mg) was heated on a steam bath for 1 h with *p*-toluenesulfonic acid (150 mg) and acetic anhydride (5 ml). The reaction mixture, worked up as usual, yielded acetylbenzoylchasmanine (260 mg) which solidified when triturated with *n*-hexane. After several crystallizations from the same solvent, it consisted of a microcrystalline solid, m.p. 148–156°.

Anal. Calcd. for $C_{34}H_{47}O_8N$: C, 68.32; H, 7.93. Found: C, 68.34; H, 7.84.

In the n.m.r. spectrum: singlets at δ 3.37 (3H), 3.27 (3H), 3.24 (3H), 3.16 (3H) (OCH_3 groups), 1.36 (OAc), triplets centered at δ 1.07 (3H), 5.07 (1H).

Acetylbenzoylchasmanine readily formed a perchlorate which after two crystallizations from ethanol consisted of colorless needles, m.p. 231–234°. ν_{max} 1 718, 1 600, 1 583 (weak), 719 cm^{-1} (strong).

Anal. Calcd. for $C_{34}H_{47}O_8N \cdot HClO_4$: C, 58.45; H, 6.88. Found: C, 58.24; H, 7.02.

Pyrolysis of Diacetylchasmanine

Diacetylchasmanine (264 mg) was heated under reduced pressure (10 mm) during 6 min at 185–190° (air bath). The product was dissolved in ether, chromatographed on a short column of alumina, and eluted with ether. Evaporation of the elutate left a gum (234 mg) which showed three spots in thin layer chromatography. The mixture could not be separated by column chromatography. It was dissolved in 2% methanolic potassium hydroxide (20 ml) and the solution refluxed for 1 h. The methanolic solution was evaporated to dryness, the residue dissolved in ice-cold water, and the aqueous solution extracted with chloroform. Evaporation of the extract left a gum (219 mg) which was dissolved in *n*-hexane and chromatographed on alumina. It was eluted with *n*-hexane, with benzene, with 50% chloroform–benzene and finally with chloroform, the eluate being collected in 10 ml fractions.

The *n*-hexane eluate (fractions 2–5) yielded isopyrochasmanine VIII (62 mg) which, after several crystallizations from *n*-hexane, was obtained as colorless elongated prisms, m.p. 177–179°. ν_{max} 3 450 (OH), 1 106, 1 087 cm^{-1} (OCH_3). In the n.m.r. spectrum: singlets at δ 3.31 (6H), 3.25 (3H), 3.21 (3H), triplet centered at δ 1.02, multiplet at δ 6.12–5.75.

Anal. Calcd. for $C_{25}H_{39}O_5N$: C, 69.25; H, 9.07. Found: C, 68.98; H, 9.28.

Fractions 6–10 made up the benzene eluate. Fractions 6 and 7 contained mainly pyrochasmanine VII but was contaminated with isopyrochasmanine. Fractions 8 and 9 yielded pure pyrochasmanine (74 mg) while fraction 10 contained mainly pyrochasmanine with an impurity of lower mobility in thin layer chromatography. Fractions 6, 7, and 10 were combined and rechromatographed thus affording a second crop of pure pyrochasmanine (35 mg). Pyrochasmanine, after crystallization from *n*-hexane, consisted of colorless prisms, m.p. 126–129°. ν_{max} 3 430 (OH), 1 634 cm^{-1} (double bond). In the n.m.r. spectrum: singlets at δ 3.14

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(3H), 3.28 (3H), 3.24 (3H), 3.21 (3H), doublet at δ 5.43 (1H) (J = 6 c.p.s.), triplet centered at δ 1.04 (3H).

Anal. Calcd. for $C_{25}H_{39}O_5N$: C, 69.25; H, 9.07. Found: C, 69.16; H, 8.78.

The chloroform–benzene and chloroform eluates gave fractions 11–13. They contained demethylisopyrochasmanine IX (36 mg), homogeneous in thin layer chromatography. After several crystallizations from *n*-hexane – acetone, it consisted of colorless needles, m.p. 163–165°. ν_{max} 3 420, 3 418 cm^{-1} (OH), 743 cm^{-1} (double bond). In the n.m.r. spectrum: singlets at δ 3.32 (3H), 3.30 (3H), 3.21 (3H), triplet centered at 1.02 (3H), multiplet at δ 5.91–5.67 (2H). For analysis a sample was sublimed at 150° and 9×10^{-5} mm.

Anal. Calcd. for $C_{24}H_{37}O_5N$: C, 68.70; H, 8.89. Found: C, 68.56; H, 8.86.

Isopyrochasmanine VIII

Pyrochasmanine (20 mg) dissolved in methanol (5 ml) containing 1 drop of 70% perchloric acid was heated under reflux for 30 min. The reaction mixture was evaporated, the residue dissolved in water, and the solution made basic with sodium carbonate and extracted with chloroform. Evaporation of the extract left a residue of isopyrochasmanine that crystallized spontaneously. Recrystallized from *n*-hexane it separated as colorless elongated prisms, m.p. 177–179°, This product was identical with the sample obtained directly from the pyrolysis mixture (melting point, that of the mixture, infrared spectra, mobility in thin layer chromatography).

Demethoxyisopyrochasmanine XIV

A mixture of pyrochasmanine (32 mg) and lithium aluminium hydride (50 mg) in tetrahydrofurane (5 ml) was stirred for 15 h at room temperature. After decomposition of the excess hydride by the addition of wet ether, the mixture was diluted with methylene chloride and filtered. The inorganic material was washed with methylene chloride and the combined filtrate and washings were evaporated to dryness. The residue was dissolved in *n*-hexane and passed through a short column of alumina, and the solution evaporated to dryness. The residue was demethoxyisopyrochasmanine (29 mg) which crystallized when triturated with *n*-pentane. Recrystallized from *n*-hexane, it consisted of colorless fine needles, m.p. 84–88°. ν_{max} 3 410 (OH), 710, 690 cm^{-1} (double bond). In the n.m.r. spectrum: singlets at δ 3.29 (3H), 3.28 (3H), 3.22 (3H), a triplet at δ 1.02 (3H), a multiplet at δ 6.03–5.78.

Anal. Calcd. for $C_{24}H_{37}O_4N$: C, 71.43; H, 9.24. Found: C, 71.41; H, 9.37.

Demethoxyisopyrochasmanine formed a perchlorate which after several crystallizations from isopropanol gave colorless prisms, m.p. 207–210°.

Anal. Calcd. for $C_{24}H_{37}O_4N.HClO_4$: C, 57.14; H, 7.54. Found: C, 56.98; H, 7.66.

Dihydrodemethoxyisopyrochasmanine

The perchlorate of demethoxyisopyrochasmanine (55 mg) was dissolved in ethanol (10 ml) and hydrogenated in the presence of platinum oxide (22 mg). When the absorption of hydrogen had ceased, the catalyst was removed by filtration and the filtrate evaporated to dryness. The residue was dissolved in water and the solution was made basic with sodium carbonate and extracted with chloroform. Evaporation of the extract left a foam (54 mg) which was dissolved in benzene, chromatographed on alumina, and eluted with benzene. The eluate on evaporation yielded pure dihydrodemethoxyisopyrochasmanine (52 mg) which could not be induced to crystallize. Its n.m.r. spectrum contained no signal attributable to double bond protons. The base was converted to the perchlorate which crystallized from ethanol. After two recrystallizations from the same solvent, it consisted of colorless prisms, m.p. 173–174°.

Anal. Calcd. for $C_{24}H_{39}O_4N.HClO_4$: C, 56.92; H, 7.91. Found: C, 57.32; H, 7.68.

Demethylisopyrochasmanine IX

Isopyrochasmanine (48 mg) and lithium aluminium hydride (50 mg) were stirred overnight in tetrahydrofurane (5 ml) at room temperature. The reaction mixture was worked up as in the similar experiment with pyrochasmanine. Thin layer chromatography showed the presence in the product of starting material and several other substances of lower mobility. The product was dissolved in benzene, chromatographed on alumina, and eluted with benzene. Fractions 3–5 of the benzene eluate contained demethylisopyrochasmanine. The total yield obtained (20 mg) was crystallized twice from *n*-hexane – acetone from which the compound separated as colorless needles, m.p. 158–164°. After sublimation at 145° and 5×10^{-5} mm, it melted at 163–165°, and was identical in melting point, that of the mixture, infrared spectra, and behavior in thin layer chromatography with demethylisopyrochasmanine isolated in the pyrolysis reaction described above.

Reduction of Pyrolysis Product with Lithium Aluminium Hydride

Diacetylchasmanine (1.880 g) was pyrolyzed at 190° (air bath) for 8 min. The crude reaction mixture was dissolved in ether, chromatographed on alumina, and eluted with ether. Evaporation of the eluate left a foam (1.765 g) which was dissolved in tetrahydrofurane (25 ml) and stirred overnight at room temperature with lithium aluminium hydride ($\sim$ 0.5 g). The excess hydride was decomposed by the addition of wet ether and the product was worked up exactly as described above for the reduction of pyrochasmanine. The product (1.532 g) was found by thin layer chromatography to contain three compounds. It was dissolved in benzene and chromatographed on alumina. The column was eluted first with benzene, then with chloroform–benzene (1:4) and chloroform–benzene (1:1), and finally with chloroform and with chloroform containing 3% methanol, the eluate being collected in 50 ml fractions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Fractions 2–6 (benzene eluate) contained isopyrochasmanine (658 mg) which after two crystallizations from *n*-hexane consisted of colorless needles, m.p. 177–179°.

Fractions 7–9 (chloroform–benzene (1:4)) and fractions 10–13 (chloroform–benzene (1:1)) both yielded demethoxyisopyrochasmanine (439 mg) which was slightly impure and was rechromatographed. The eluted material consisted of the homogeneous compound (407 mg) which crystallized from *n*-hexane as fine needles, m.p. 84–88°. It formed a perchlorate separating from isopropanol as colorless prisms, m.p. 207–210°.

The remaining fractions (14–17) eluted with chloroform and methanol–chloroform, yielded a residue (436 mg) which in thin layer chromatography showed one main spot and a few weaker, less mobile spots. Repeated chromatography in benzene on short alumina columns gave homogeneous demethylisopyrochasmanine (427 mg) which after crystallization from *n*-hexane – acetone melted at 163–165°.

All three products, isopyrochasmanine, demethoxyisopyrochasmanine, and demethylisopyrochasmanine, were identical in every respect with samples obtained in previous experiments described above.

Diacetyldemethylisopyrochasmanine X

Demethylisopyrochasmanine (60 mg) was heated on a steam bath with acetic anhydride (2 ml) and *p*-toluenesulfonic acid (50 mg). The reaction mixture, worked up as usual, yielded the product which was chromatographed on alumina in benzene solution and eluted with the same solvent. On evaporation, the eluate left the diacetyl compound (53 mg) which crystallized from *n*-hexane as colorless plates, m.p. 121–123°.

Anal. Calcd. for $C_{28}H_{41}O_7N$: C, 66.77; H, 8.21. Found: C, 66.57; H, 8.19.

ν_{max} 1728, 1716 (CO), 705 cm^{-1} (double bond). In the n.m.r. spectrum: triplet centered at δ 1.02 (3H), singlets at δ 1.93 (3H), 1.99 (3H), 3.29 (3H), 3.21 (6H), multiplet, at δ 6.60–5.83 (2H). Hydrogenation under the usual conditions gave the dihydrodiacetyl derivative (see below).

Dihydrodemethylisopyrochasmanine

Demethylisopyrochasmanine (213 mg) dissolved in ethanol (20 ml) containing a few drops of 70% perchloric acid was hydrogenated in contact with platinum oxide (57 mg). The reaction product, worked up as usual (see above hydrogenation of demethoxy compound), consisted of a gum (212 mg) which crystallized on contact with ether. After several recrystallizations from ether – *n*-hexane, dihydrodemethylisopyrochasmanine formed colorless prisms, m.p. 124–127°.

Anal. Calcd. for $C_{24}H_{39}O_5N.\frac{1}{2}H_2O$: C, 66.97; H, 9.37. Found: C, 67.34; H, 9.66.

Diacetyldihydrodemethylisopyrochasmanine XI

A mixture of dihydrodemethylisopyrochasmanine (200 mg) and *p*-toluenesulfonic acid (100 mg) was heated with acetic anhydride (5 ml) for 1 h on the steam bath. The diacetyl product (188 mg), isolated as usual from the reaction mixture, was crystallized from *n*-hexane from which it separated as colorless prisms, m.p. 123–125°.

Anal. Calcd. for $C_{28}H_{43}O_7N$: C, 66.51; H, 8.57. Found: C, 66.68, H, 8.73.

ν_{max} 1 730, 1 720 cm^{-1} (CO). The product was identical with that obtained by the catalytic hydrogenation of diacetyldemethylisopyrochasmanine.

Demethoxypyrochasmanine

Diacetyldihydrodemethylisopyrochasmanine (109 mg) was heated under reduced pressure (15 mm) for 5 min at 190° (air bath). The product was dissolved in benzene, chromatographed on alumina, and eluted with the same solvent. Evaporation of the eluate left a gum (80 mg) which gave a single spot in thin layer chromatography. ν_{max} 1 727 cm^{-1} (CO).

The gummy product (80 mg) thus obtained was refluxed with 3% methanolic potassium hydroxide (5 ml) for 30 min. The solvent was evaporated, water and ice were added, and the solution extracted with chloroform. Evaporation of the extract left a residue which was dissolved in *n*-hexane – benzene (1:1), chromatographed on alumina, and eluted with the same solvent. The eluate yielded homogeneous demethoxypyrochasmanine (61 mg) which failed to crystallize. It was converted to the perchlorate which crystallized from isopropanol as prisms with a slight yellowish cast, m.p. 198–202°. ν_{max} 3 475 cm^{-1} (OH).

Anal. Calcd. for $C_{24}H_{37}O_4N.HClO_4.\frac{1}{2}H_2O$: C, 56.21; H, 7.60. Found: C, 56.22; H, 7.60.

Dihydrodemethoxypyrochasmanine

Demethoxypyrochasmanine perchlorate (39 mg) was dissolved in ethanol (10 ml) and hydrogenated in contact with platinum oxide (25 mg). When hydrogen absorption had ceased, the catalyst was filtered off and the filtrate evaporated to dryness. The residue was dissolved in water, and the solution made basic with sodium carbonate and extracted with chloroform. Evaporation of the extract left a gum which was converted into the perchlorate. The salt crystallized from ethanol as colorless prisms, m.p. 173–174°. It was identical in melting point, that of the mixture, mobility in thin layer chromatography, infrared spectra, and X-ray powder patterns with the salt derived earlier from pyrochasmanine and designated dihydrodemethoxyisopyrochasmanine perchlorate (see above).

Demethylation of Isopyrochasmanine

Experiment 1

Isopyrochasmanine (141 mg) was dissolved in 50% sulfuric acid (5 ml) and heated on the steam bath for 40 min. The cooled solution was diluted by the addition of ice and alkalized with sodium carbonate. It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was extracted six times with chloroform and the combined extract evaporated to dryness. There was left a residue (121 mg) which gave three spots in thin layer chromatography. The residue was dissolved in benzene, chromatographed on alumina, and eluted first with benzene, then with benzene–chloroform (1:1), with chloroform, and finally with chloroform containing 2% methanol, the eluate being collected in fractions of 30 ml.

Fractions 1–3 (benzene eluate) afforded a compound (32 mg) which after crystallization from ether consisted of colorless needles, m.p. 164–167°. In the n.m.r. spectrum: singlet at δ 3.29 (6H), triplet centered at δ 1.02 (3H), multiplet at δ 5.90–5.62 (2H). For analysis a sample was sublimed at 145° and 10^{-4} mm.

Anal. Calcd. for $C_{23}H_{33}O_4N$: C, 71.29; H, 8.58. Found: C, 74.22; 9.18.

The analytical figures are unsatisfactory and indicate either the presence of an impurity or partial solvation with benzene even after sublimation (calcd. for $C_{23}H_{33}O_4N.C_6H_6$: C, 74.80; H, 8.44).

Fractions 4–6 eluted with benzene–chloroform (1:1) gave demethylisopyrochasmanine (35 mg) which, after crystallization from ether and sublimation, melted at 163–165°, undepressed by admixture with the product obtained in the pyrolysis. The infrared spectra of the two compounds were identical and so was their behavior in thin layer chromatography.

Fractions 7–10 eluted with chloroform and with chloroform containing 2% methanol yielded tridemethylanhydroisopyrochasmanine XVII (45 mg) which formed colorless prismatic crystals from methanol, m.p. 245–248° (decomp.). For analysis a sample was sublimed at 170° and 5×10^{-5} mm.

Anal. Calcd. for $C_{22}H_{31}O_4N$: C, 70.75; H, 8.27; N, 3.75. Found: C, 70.66; H, 8.27; N, 3.81.

Because of the low solubility of the product, its n.m.r. spectrum was obtained in pyridine solution, and for comparison the spectrum of isopyrochasmanine was taken in the same solvent. Compound XVII: singlet at δ 2.50 (3H), triplet centered at 0.25 (3H). Isopyrochasmanine: singlets at δ 2.63 (3H), 2.59 (3H), 2.49 (3H), 2.31 (3H), triplet centered at δ 0.30 (3H).

Experiment 2

Isopyrochasmanine (41 mg) dissolved in 50% sulfuric acid (2 ml) was heated on the steam bath for 2¼ h. The reaction mixture worked up as in Experiment 1 gave a product (27 mg) which crystallized spontaneously and in thin layer chromatography showed two spots: a more mobile one (weak) corresponding to demethylisopyrochasmanine, and a less mobile one (strong) corresponding to tridemethylanhydroisopyrochasmanine (XVII). The last compound was obtained in a pure condition by crystallization of the crude product from methanol, m.p. 245–248°.

Experiment 3

Tridemethylanhydroisopyrochasmanine was treated under the conditions described in Experiment 2. It was recovered unchanged in 70% yield.

Experiment 4

Isopyrochasmanine (210 mg) was dissolved in acetone (40 ml) and potassium permanganate (150 mg) in 50% acetone–water (40 ml) was added all at once. The mixture was stirred for 5 min at room temperature and the excess permanganate decomposed with sulfurous acid (sodium sulfite and dilute sulfuric acid). After evaporation of the acetone the remaining aqueous solution was made basic by the addition of aqueous sodium carbonate and extracted with chloroform. The extract was evaporated to dryness and the residue, which was homogeneous in thin layer chromatography, was heated on the steam bath for 90 min with acetic anhydride (2.5 ml) and pyridine (2.5 ml). The reaction mixture, worked up as usual, was dissolved in benzene, chromatographed on alumina, and eluted with benzene. Evaporation of the eluate left the residual gummy N,O-diacetyl-N-deethylisopyrochasmanine (250 mg) which gave a single spot in thin layer chromatography. Its infrared absorption spectrum indicated the presence of an N—Ac group (1 610 cm^{-1}) and an O—Ac group (1 715, 1 245 cm^{-1}). The compound was heated in a water bath (60–65°) for 1 h with zinc chloride (10 g) in 5% hydrochloric acid (3.5 ml). The solution, after cooling, was diluted with water (25 ml) and extracted continuously with chloroform for 50 h. The chloroform extract, on evaporation to dryness, left a gum (167 mg) which was dissolved in tetrahydrofurane (10 ml) and heated with lithium aluminium hydride under reflux for 2 h. The excess hydride was decomposed with wet ether and the solution diluted with chloroform and filtered. The inorganic filtered salt was washed with chloroform and the combined filtrate and washings were evaporated to dryness. There was left a residue (142 mg) which in thin layer chromatography produced only one spot identical in mobility with that produced by tridemethylanhydroisopyrochasmanine XVII. The product was dissolved in chloroform, chromatographed on alumina, and eluted with chloroform. The residue left after evaporation of the eluate was crystallized twice from methanol from which it separated as colorless prisms, m.p. 244–247° (decomp.). Its n.m.r. spectrum in pyridine solution showed a signal at δ 2.50 corresponding to three protons, identical with that of compound XVII.

Demethylanhydroisopyrobikhaconine

Isopyrobikhaconine (XVIII) (130 mg) after the same sequence of reactions as described in Experiment 4 above, yielded demethylanhydroisopyrobikhaconine (XIX) (112 mg) which after crystallization from ethanol was obtained as colorless prisms, m.p. 242–243°. For analysis it was sublimed at 190° and 6×10^{-5} mm. In the n.m.r. spectrum in pyridine solution it showed signals at δ 2.50 (3H) and a triplet centered at δ 0.25 (3H).

Anal. Calcd. for $C_{22}H_{31}O_5N$: C, 68.01; H, 7.96. Found: C, 68.24, H, 8.26.

N-Deethylchasmanine

To chasmanine (243 mg) in acetone (40 ml) potassium permanganate (152 mg) in 50% acetone–water (40 ml) was added all at once. After the mixture had been stored for 5 min at room temperature, the excess permanganate was reduced by the addition of sodium sulfite and dilute sulfuric acid. The liquor was concentrated until the acetone had evaporated, was made basic with sodium carbonate, and extracted with chloroform. The extract was evaporated to dryness, the residue dissolved in benzene, chromatographed on alumina, and eluted with the same solvent. Evaporation of the eluate left a residue which solidified when triturated with ether, and crystallized from benzene (152 mg). The mother liquor, when chromatographed on alumina, yielded a further crop of N-deethylchasmanine (60 mg). The product after two crystallizations from benzene, consisted of colorless needles, m.p. 232–234°. Its n.m.r. spectrum did not contain a triplet at $\delta \sim 1.0$.

Anal. Calcd. for $C_{23}H_{37}O_6N$: C, 65.22; H, 8.81. Found: C, 65.02; H, 8.82.

N-Methyl-N-deethylchasmanine

N-Deethylchasmanine (83 mg) in 50% ether–methanol (6 ml) was heated under reflux for 30 min with methyl iodide (1 ml) and powdered potassium carbonate (100 mg). The solvent was evaporated and the residue dissolved in water and extracted with methylene chloride. The extract was evaporated and the residue dissolved in *n*-hexane – benzene (1:1), chromatographed on alumina, and eluted with the same solvent. Evaporation of the eluate left a residue (78 mg) which crystallized spontaneously. After several crystallizations from *n*-hexane, N-methyl-N-deethylchasmanine formed fine colorless needles, m.p. 90–92°. In the n.m.r. spectrum: singlets at δ 3.31 (3H), 3.28 (6H), 3.23 (3H), and 2.29 (3H).

Anal. Calcd. for $C_{24}H_{39}O_6N$: C, 65.87; H, 8.98; N, 3.20. Found: C, 65.64; H, 9.10; N, 3.19.

When N-deethylchasmanine was treated similarly with ethyl iodide, it was converted back to chasmanine.

Bikhaconitine Methanesulfonate (XX)

Bikhaconitine perchlorate (1.2 g) with pyridine (10 ml) and methanesulfonyl chloride (2 ml) was kept at room temperature overnight. The resulting brown mixture was poured into ice water, made basic with potassium carbonate, and extracted with chloroform. The extract, after drying over magnesium sulfate, was evaporated to dryness. It left a brown gum that was dissolved in benzene, chromatographed on alumina, and eluted with benzene. Evaporation of the eluate left a residue that crystallized when triturated in the presence of ether. Recrystallized from methanol, it consisted of colorless prisms, m.p. 188–190°, yield, 0.9 g.

Anal. Calcd. for $C_{37}H_{53}O_{13}NS$: C, 59.10; H, 7.11. Found: C, 59.01; H, 7.16.

Deoxyaconitine methanesulfonate was also prepared exactly as above. It formed colorless prisms from methanol, m.p. 194–195°.

Anal. Calcd. for $C_{35}H_{49}O_{12}NS$: C, 59.39; H, 6.98. Found: C, 59.22; H, 7.00.

Further treatment with methanesulfonyl chloride failed to introduce a second group.

Hydrogenolysis of Bikhaconitine Mesylate

Bikhaconitine mesylate (900 mg) dissolved in dioxane (100 ml) was hydrogenated over Raney nickel at 120–130° and 41 atm for 15 h. The product, isolated as usual, was dissolved in benzene and extracted with 5% hydrochloric acid. The aqueous solution was alkalized with potassium carbonate and extracted with chloroform. The gummy residue (500 mg) left after evaporation of the extract showed two spots in thin layer chromatography; it was dissolved in benzene–hexane (1:1) and chromatographed on grade III alumina. Elution was done first with the same solvent mixture, then with benzene, with benzene–chloroform, and finally with chloroform. The first eluate yielded 290 mg of a mixture of components A and B while the benzene and benzene–chloroform eluates yielded pure B. Rechromatography of the first eluate gave pure A and pure B. Component B, recrystallized from ether, consisted of colorless prisms, m.p. 190–193°.

Anal. Calcd. for $C_{35}H_{51}O_{11}NS$: C, 60.60; 7.36. Found: C, 61.11; H, 7.45.

That this component is correctly designated by formula XXIII has been shown by its alternative preparation from pyrobikhaconitine (7). This compound was hydrogenated catalytically by the usual procedure over platinum oxide to dihydropyrobikhaconitine, colorless needles from ether, m.p. 181–183°.

Anal. Calcd. for $C_{34}H_{47}O_9N \cdot \frac{1}{2}H_2O$: C, 65.57; H, 7.47. Found: C, 65.71; H, 7.98.

Treatment with methanesulfonyl chloride as described above gave the *O*-mesylate, m.p. 191–194°, identical in every respect (mixture melting point, infrared, thin layer chromatography) with the hydrogenolysis component.

The minor component A separated by chromatography from the product of hydrogenolysis could not be obtained very pure because of paucity of material, and because it failed to crystallize. The infrared and n.m.r. spectra showed that it no longer contained the mesylate nor the acetoxy groups, but still contained an imino-ethyl, four methoxyls, and the two veratroyl methoxyls. It was assumed to have structure XXIV and it was hydrolyzed to the corresponding alkamine XXV.

Pyrochasmanine was hydrogenated catalytically to dihydrochasmanine. The product could not be induced to crystallize; it had the same behavior in thin layer chromatography as compound XXV. All attempts to prepare crystalline salts from the two products failed. It is probable that the two compounds were identical but there was insufficient material for further comparison.

A NOVEL SYNTHESIS FOR AMINODIDEOXY SUGARS

3-AMINO-2,3-DIDEOXY-D-ARABINO-HEXOSE

HANS HELMUT BAER AND THOMAS NEILSON
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received August 20, 1964

ABSTRACT

The 4,6-*O*-benzylidene derivative II of methyl 3-nitro-3-deoxy-β-D-glucopyranoside (I) was prepared. Its 2-*O*-acetate (III) was converted by a Schmidt–Rutz reaction into methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hexos-2-enide (IV). Selective hydrogenation of the olefinic double bond in IV afforded methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*arabino*-hexopyranoside (V). The debenzylidenated derivative of V (VI) was reduced to methyl 3-amino-2,3-dideoxy-β-D-*arabino*-hexopyranoside hydrochloride (VII), from which the free reducing sugar (VIII), the *N*-acetyl glycoside (IX), the *N*-acetyl glycoside 4,6-di-*O*-acetate (X), and the *N*-acetyl glycoside 4,6-di-*O*-mesylate (XI) were obtained. The solvolysis of XI proceeded with neighboring group participation to give a product of either aziridine (XII) or pyrrolidine (XIII) structure.

More than a dozen amino sugars of unusual structures have been characterized as components of antibiotics (1). In the present paper is described the synthesis of a new amino dideoxy hexose, 3-amino-2,3-dideoxy-D-*arabino*-hexose (VIII). Although this particular sugar has not as yet been discovered in nature, it may well prove to become significant in further analytical and synthetic investigations in the field of carbohydrate antibiotics.

Methyl 3-nitro-3-deoxy-β-D-glucopyranoside (I), which is readily available (2, 3) by nitromethane cyclization from methyl β-D-glucopyranoside, was converted into its 4,6-*O*-benzylidene derivative II in 74% yield. Acetylation of II with acetic anhydride in pyridine gave methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-nitro-3-deoxy-β-D-glucopyranoside (III) in 90% yield. This is noteworthy because acetylations, in the presence of pyridine, of other cyclic nitro alcohols have been known (4) to lead to dehydration. Treatment of acetate III with solid sodium bicarbonate in refluxing benzene smoothly afforded nitroolefin IV, methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hexos-2-enide (Schmidt–Rutz reaction (5, 6)). This compound is the first sugar derivative possessing a nitroolefin grouping as part of a glycosidic ring; it is very reactive as far as addition reactions are concerned. Thus, it easily adds ammonia or ethanol. Catalytic hydrogenation of IV using 10% palladium on charcoal readily furnished methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*arabino*-hexopyranoside (V).[1] Proof of the configuration at C-3 is established below. Since V was obtained in 87% yield after recrystallization, this hydrogen addition appeared to be remarkably stereoselective. Gentle hydrolytic removal of the benzylidene blocking group in V produced methyl 2,3-dideoxy-3-nitro-β-D-*arabino*-hexopyranoside (VI). For preparative purposes, VI may be obtained from II in 50% overall yield without purification of the intermediates III, IV, and V. Catalytic reduction, with platinum in the presence of 1 molar equivalent of hydrochloric acid, converted VI into methyl 3-amino-2,3-dideoxy-β-D-*arabino*-hexopyranoside hydrochloride (VII) which, on acid hydrolysis, gave the corresponding free sugar, 3-amino-2,3-dideoxy-D-*arabino*-hexose hydrochloride (VIII).

[1]*The hydrogenation, which was carried out in ethyl acetate, showed a sharp decrease in rate after 1 mole of hydrogen had been consumed and therefore did not affect the nitro and benzylidene groups. Similar selective hydrogenations using palladium black in absolute ethanol have been reported, although with the latter catalyst in ethyl acetate the selectivity has been said to be less marked (cf. ref. 6, pp. 315–316).*

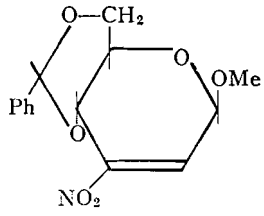
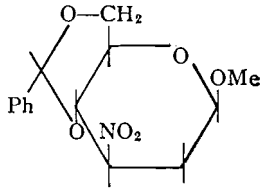
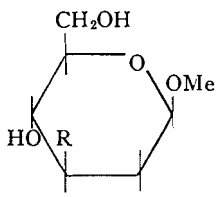
II, R = H.
III, R = Ac.



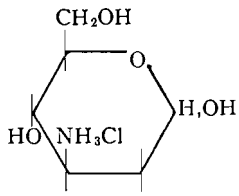
IV



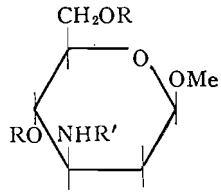
V



VI, R = NO_2.
VII, R = NH_3Cl.



VIII



IX, R = H, R′ = Ac.
X, R = R′ = Ac.
XI, R = Ms, R′ = Ac.

The configuration at C-3, where the asymmetry had been relinquished and then regenerated in the course of the above synthetic pathway, was established by nuclear magnetic resonance (n.m.r.) spectroscopy and by experiments involving solvolysis with neighboring group participation. For these purposes the *N*-acetyl-4,6-di-*O*-acetyl derivative X, *N*-acetate IX, and *N*-acetyl-4,6-di-*O*-mesylate XI were prepared by standard procedures in crystalline condition and high yields from the amino glycoside hydrochloride VII.

The n.m.r. spectrum[2] of triacetate X showed methyl proton signals at 8.09, 7.95, and 6.50 τ in an intensity ratio 1:2:1. The signals were assigned to the *N*-acetyl, *O*-acetyl, and methoxy groups, respectively. In accord with the known stereochemistry at C-4 and C-5 the chemical shift of the *O*-acetyl signal indicated equatorial arrangement of the substituents at these carbons. (Cf. the ranges recorded (7, 8, 9) for equatorial (7.91–8.03 τ) and axial (7.78–7.88 τ) acetoxy groups in pyranose and inositol derivatives.) The τ-value of the signal attributed to the acetamido group agreed well with the values reported (7, 8, 9) for equatorial disposition (8.02–8.11 τ) but differed from those found (7) in cases of axial disposition (7.92, 7.94 τ). The spectrum, therefore, implied a configuration as shown in formulas X and X*a*.

An independent proof of configuration was provided by solvolysis of the dimesylate XI. When the dimesylate was solvolyzed in refluxing 95% ethanol in the presence of sodium acetate, a quantitative yield (2 moles) of sodium mesylate was produced. Since the solvolyzed glycoside could not be obtained in crystalline form, it was directly acetylated under two sets of conditions, viz., acetic anhydride – pyridine and acetic anhydride – sodium acetate. On both occasions a crystalline acetate (m.p. 110°, $[\alpha]_D$ −231° in ethanol) was isolated in 85–90% yield. Complete elemental analysis (C, H, N, O, and molecular weight) established the molecular formula $C_{11}H_{17}NO_5$ for this acetate. The infrared spectrum in carbon tetrachloride exhibited peaks at 1 740 cm^{-1} (ester carbonyl) and 1 660 cm^{-1}

[2]*Obtained with a Varian V-4302 High Resolution Spectrometer operating at 60 Mc/s. The solvent was deuterochloroform, and the spectra were calibrated by the side-band technique with tetramethylsilane as internal standard.*

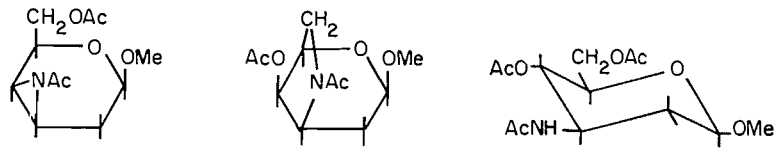
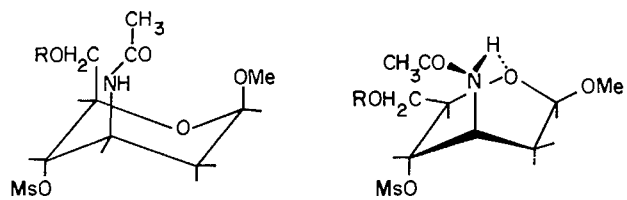
(amide I[3]), but there were no amide II and N—H bands. The integrated n.m.r. spectrum[2] revealed the presence of *two* acetyl groups (8.02 and 7.95 τ) and one methoxy group (6.68 τ).

The analytical and spectral data of the acetylated solvolysis product are compatible only with structures XII and XIII. A decision between these two structures cannot be made as yet. However, the formation of either structure requires internal displacement of one mesyloxy group through attack by the acetamido nitrogen. An obvious steric condition that must be met in both cases is the orientation of the acetamido group as depicted in XI. The acetamido group in XI is *trans* to the C-4 mesyloxy group and thus suitably arranged for rearward attack leading to the aziridine XII; and it is *cis* to C-6 rendering possible a cyclization to the pyrrolidine XIII. The nitrogen ring that was engendered furnished proof, therefore, of the configuration at C-3, regardless of whether the acetylated solvolysis product was XII or XIII.[4]





The formation in neighboring group reactions of sugar aziridines in competition with (thermodynamically favored) oxazolines or other five-membered heterocycles has been observed on several occasions (10–14); of particular relevance to the present work are instances involving benzamido (11, 12) and acetamido (13) sugar derivatives. There were no exceptions to the generally accepted mode of reaction which requires *trans* vicinal reactive groups. In the cases cited the three-membered rings arose under conditions of anionic displacement, however, and not by solvolysis with an acid acceptor. Aziridine formation under the latter conditions might nevertheless be possible if for any reason the formation of an oxazolidine intermediate[5] were impeded. Thus, in the case of XI, in conformations such as XI*a* or XI*b* which place the 3,4-substituents in the diaxial arrangement conducive to participation, the acetamido group might be prevented by steric hindrance or proton bonding from aligning suitably for *carbonyl* attack at C-4. Formation of the less strained structure XIII would perhaps seem more likely. However, one would then have to assume that the acetamido group would be able to assist anchimerically in the removal

[3]*In a solid state spectrum this peak occurred at a very similar frequency (1 643 cm^{-1}) suggesting absence of association.*

[4]*The substantially higher τ-value of the methoxyl signal given by the acetylated solvolysis product as compared to that of X may be interpreted (9a) in terms of an axial* OCH_3 *group in the former; conformational models taking this into account can be constructed for both XII and XIII.*

[5]*Solvolyses of trans vicinal acylamido–sulfonyloxy systems normally lead to cis acylamido alcohols via an oxazolidine which opens in the presence of water (cf. ref. 15).*

of the C-4 sulfonyloxy group; for in view of the general resistance to solvolysis, even under more drastic conditions, of isolated, secondary sulfonyloxy groups in sugars (16) the observed, facile displacement would be difficult to explain without invoking neighboring group participation.

It is anticipated that the new principle of synthesis involving nitroolefinic glycosides can be used to prepare further aminodideoxy sugars. Work along these lines is in progress.

EXPERIMENTAL

Methyl 4,6-O-Benzylidene-3-nitro-3-deoxy-β-D-glucopyranoside (II)

Methyl 3-nitro-3-deoxy-β-D-glucopyranoside (2) (7.8 g), zinc chloride (7.8 g), and benzaldehyde (50 ml) were stirred together at room temperature for 24 h. Water (400 ml) was added and the heterogeneous mixture was stirred for 15 min. Upon addition of petroleum ether (400 ml, b.p. 80–100°) a semi-crystalline mass separated, which was collected and washed twice with 100 ml of petroleum ether. Crystallization from aqueous ethanol gave the benzylidene derivative II (8.0 g, 74%) as needles of m.p. 181–182° and $[\alpha]_D^{23}$ −72.5° (*c*, 1 in ethanol).

Anal. Calcd. for $C_{14}H_{17}NO_7$ (311.3): C, 54.01; H, 5.51; N, 4.50. Found: C, 54.07; H, 5.57; N, 4.65.

Methyl 2-O-Acetyl-4,6-O-benzylidene-3-nitro-3-deoxy-β-D-glucopyranoside (III)

Benzylidene derivative II (7 g) was dissolved in pyridine (70 ml), and acetic anhydride (20 ml) was added with ice cooling. The reaction mixture was left overnight at room temperature and then poured into 500 ml of ice water. The crude acetate which separated was washed thoroughly with water to remove all traces of pyridine, and dried (yield 8 g). Crystallization from aqueous ethanol furnished the acetate III (7.2 g, 90%) as plates melting at 193–194° and showing $[\alpha]_D^{23}$ −77.7° (*c*, 0.99 in chloroform).

Anal. Calcd. for $C_{16}H_{19}NO_8$ (353.2): C, 54.40; H, 5.42; N, 3.97. Found: C, 54.41; H, 5.60; N, 4.15.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-β-D-erythro-hexos-2-enide (IV)

The nitroolefin IV was obtained from the *O*-acetyl compound III by Schmidt–Rutz elimination of acetic acid, i.e., by refluxing in benzene in the presence of solid sodium hydrogen carbonate. In order to follow this heterogeneous phase reaction and to determine its point of completion, small test samples were withdrawn occasionally, cleared from suspended bicarbonate, allowed to evaporate, and inspected by infrared spectroscopy. A gradual decrease in the intensities of the acetyl and nitroalkane frequencies at 5.72 and 6.44 mμ, respectively, and a concomitant appearance of a nitroolefin peak at 6.55 mμ indicated proceeding of the reaction. Completion as shown by the absence of the former frequencies was usually attained within 2 days but sometimes required up to 4 days; difficultly controllable conditions such as stirring efficiency or traces of moisture may have been responsible for these variations which did not, however, seem to affect the yields.

For practical purposes acetate III (5 g) was refluxed, with magnetic stirring, with 25 g of dry sodium bicarbonate in 125 ml of reagent grade benzene. After completion of the reaction (see above) the mixture was allowed to cool, filtered, and the filtrate was evaporated leaving a near-colorless crystalline residue of IV (4.1 g). This material was suitable without further purification for the next synthetic step. An analytical sample of IV was obtained in a small-scale run (200 mg of III), the crude product of which was recrystallized from ethyl acetate – petroleum ether (30–60°) giving 110 mg (66%) of needles with m.p. 144–145° and $[\alpha]_D^{23}$ −192.5° (*c*, 1.2 in chloroform).

Anal. Calcd. for $C_{14}H_{15}NO_6$ (293.3): C, 57.33; H, 5.16; N, 4.78. Found: C, 57.19; H, 5.32; N, 4.91.

Attempted recrystallization of the compound from *ethanol* resulted in the formation of an ethoxy derivative (m.p. 122–123°), presumably arising from the addition of solvent across the double bond. Further work on this and similar addition reactions is currently being undertaken.

Methyl 4,6-Benzylidene-2,3-dideoxy-3-nitro-β-D-arabino-hexopyranoside (V)

Crude nitroolefin IV (4.1 g) from the previous experiment was dissolved in ethyl acetate (200 ml) and shaken under hydrogen (S.T.P.) with 500 mg of 10% palladium on charcoal (Matheson, Coleman & Bell) for 15 min. Gas uptake was rapid and showed a sharp decrease in rate after 300 ml had been consumed. The filtrate from the catalyst was evaporated to give a crystalline residue (4 g). Recrystallization from aqueous ethanol afforded compound V (3.6 g, 87%) as needles of m.p. 148–149° and $[\alpha]_D^{23}$ −95.5° (*c*, 1.1 in chloroform).

Anal. Calcd. for $C_{14}H_{17}NO_6$ (295.3): C, 56.94; H, 5.83; N, 4.74. Found: C, 57.19; H, 5.87; N, 4.80.

Methyl 2,3-Dideoxy-3-nitro-β-D-arabino-hexopyranoside (VI)

Benzylidene derivative V (1.5 g) in 200 ml of methanol–water (4:1, v/v) was refluxed and magnetically stirred with 6 g of Dowex 50 W – X8 (H^+) for 4 h. The resin was removed, and the filtrate on evaporation gave a crystalline residue which was freed from the last traces of water by two co-evaporations with 50 ml of ethanol. Recrystallization from ethyl acetate – petroleum ether (30–60°) afforded 610 mg (58%) of the debenzylidenated derivative VI; needles, m.p. 177–179°; $[\alpha]_D^{23}$ −33.3° (*c*, 0.96 in water).

Anal. Calcd. for $C_7H_{13}NO_6$ (207.2): C, 40.58; H, 6.33; N, 6.76. Found: C, 40.48; H, 6.39; N, 6.58.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Omitting the recrystallizations described above for compounds III, IV, and V it was possible to obtain 1.1 g of pure VI starting from 3.3 g of II (overall yield 50%).

In several later experiments debenzylidenation was effected by heating V in acetic acid – water (7:3, v/v) on a steam bath for precisely 30 min. This quicker procedure was at least as satisfactory, the yields in pure VI being 60–62%.

*Methyl 3-Amino-2,3-dideoxy-β-*D*-arabino-hexopyranoside Hydrochloride (VII)*

Nitroglycoside VI (1 g) was shaken under hydrogen (S.T.P.) with prereduced platinum oxide (200 mg) in water containing 1 molar equivalent of hydrogen chloride (48 ml of *N*/10 HCl added to excess water). Uptake of 3 moles of hydrogen (324 ml, corrected volume) was complete within approximately 2 h. Evaporation of the filtrate yielded a gum that could be crystallized from ethanol – ethyl acetate. The aminoglycoside hydrochloride VII thus obtained (640 mg, 62%) formed needles melting with decomposition at 145–150° and exhibiting $[\alpha]_D^{23}$ −41.0° (*c*, 0.83 in water).

Anal. Calcd. for $C_7H_{16}NO_4Cl$ (213.7): C, 39.35; H, 7.56; N, 6.56; Cl, 16.60. Found: C, 39.33; H, 7.46; N, 6.47; Cl, 16.5.

*3-Amino-2,3-dideoxy-*D*-arabino-hexose Hydrochloride (VIII)*

Aminoglycoside hydrochloride VII (500 mg) was refluxed overnight with 10 ml of *N* hydrochloric acid. The hydrolysate was decolorized with activated charcoal and evaporated with 10 consecutive additions of water (10 ml) to ensure removal of all excess hydrogen chloride. The amino sugar hydrochloride was finally obtained as a froth that was dried in a high vacuum; yield, 450 mg (96%). $[\alpha]_D^{23}$ +54° (*c*, 0.9 in water). A sample was found to reduce Fehling solution.

Anal. Calcd. for $C_6H_{14}NO_4Cl$ (199.6): C, 36.09, H, 7.06; Cl, 17.76. Found: C, 36.29; H, 7.31; Cl, 18.03.

Similar material was produced in good yield in the hydrolysis of compound IX, below.

*Methyl 3-Acetamido-2,3-dideoxy-β-*D*-arabino-hexopyranoside (IX)*

Nitroglycoside VI (1 g) was hydrogenated as described in a previous paragraph to give an aqueous solution of aminoglycoside hydrochloride VII. This was used for *N*-acetylation (17) without prior isolation of VII. After removal of the platinum catalyst, the filtrate (60 ml) was stirred with 25 ml of Dowex-1, carbonate form, and methanol (3 ml) and acetic anhydride (0.5 ml) were added. After 90 min the anion exchange resin was removed and the solution stirred briefly with 10 ml of Dowex-50W (H^+). The filtrate therefrom was evaporated giving a sirup which crystallized when treated with ethanol. The acetamide IX formed needles with m.p. 191–192° (from ethanol–ethyl acetate) and $[\alpha]_D^{23}$ −37.2° (*c*, 1.04 in ethanol). The yield was 950 mg (91%).

Anal. Calcd. for $C_9H_{17}NO_5$ (219.2): C, 49.30; H, 7.82; N, 6.39. Found: C, 49.27; H, 7.99; N, 6.49.

*Methyl 3-Acetamido-4,6-di-O-acetyl-2,3-dideoxy-β-*D*-arabino-hexopyranoside (X)*

Acetamide IX (150 mg) was dissolved in pyridine (5 ml) and acetic anhydride (0.5 ml) was added. The reaction mixture was left at room temperature for 24 h, then poured onto ice (25 g), and extracted three times with 20 ml of chloroform. The combined chloroform extracts were washed with water (2 × 20 ml), dried over anhydrous sodium sulfate, and evaporated, the last traces of pyridine being azeotropically removed with toluene (2 × 10 ml). Crystallization of the residue from ethyl acetate – petroleum ether (30–60°) gave the triacetate X (160 mg, 77%) as needles of m.p. 157.5–158° and $[\alpha]_D^{23}$ +9.9° (*c*, 0.61 in ethanol).

Anal. Calcd. for $C_{13}H_{21}NO_7$ (303.3): C, 51.47; H, 6.98; N, 4.62. Found: C, 51.56; H, 6.99; N, 4.80.

*Methyl 3-Acetamido-2,3-dideoxy-4,6-di-O-mesyl-β-*D*-arabino-hexopyranoside (XI)*

A solution of acetamide IX (500 mg) in pyridine (5 ml) was chilled to 0°, and methanesulfonyl chloride (0.70 ml, 4 molar equivalents) was added dropwise with stirring. The mixture was stirred a further 30 min and then left overnight at 0°. Upon addition of ice (25 g) dimesylate XI (350 mg) separated in the course of 2 h. Concentration and removal of pyridine from the filtrate by evaporation *in vacuo* produced a second crop (400 mg) of crude dimesylate. The combined crops were recrystallized from ethanol yielding 650 mg (75%) of XI as needles with m.p. 155–156° and $[\alpha]_D^{23}$ −5.5° (*c*, 0.9 in dimethylformamide).

Anal. Calcd. for $C_{11}H_{21}NO_9S_2$ (375.4): C, 35.19; H, 5.64; N, 3.73; S, 17.08. Found: C, 35.31; H, 5.60; N, 3.81; S, 17.05.

Solvolysis of the Dimesyl Derivative XI

Dimesyl derivative XI (275 mg) and anhydrous sodium acetate (300 mg) were refluxed in 95% ethanol (25 ml) for 48 h. The cooled solution was concentrated *in vacuo* and filtered from a crystalline solid which was identified by its infrared spectrum as sodium mesylate. The yield was 171.5 mg (calcd. for 2 molar equivalents, 173.5 mg). The filtrate was freed from ethanol *in vacuo*. As the nearly colorless residue could not be obtained in crystalline condition it was dissolved in pyridine (2 ml), and acetic anhydride (0.5 ml) was added. The reaction mixture was left overnight at room temperature. Ice (25 ml) was added and the mixture was extracted three times with 25 ml of chloroform. The combined extracts were washed twice with 10 ml of water, dried over magnesium sulfate, and evaporated to dryness to give gum, the last traces of pyridine being azeotropically removed by co-distillation with toluene (2 × 10 ml) *in vacuo*. Crystallization from ethyl acetate / petroleum ether (30–60°) gave prismatic needles (160 mg) melting at 102–104°. After recrystalliza-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tion from the same solvents the product melted at 105–107°, and after a further recrystallization from ethyl acetate – cyclohexane it showed m.p. 106–107°. (Slow crystallization by evaporation of solvent in the air afforded large prisms with m.p. 110°). $[\alpha]_D$ −231° (*c*, 0.7 in ethanol). The compound is to be assigned either structure XII or (isomeric) structure XIII; its yield based on XI was 90%. The analytical sample was dried at 56° and 0.1 mm.

Anal. Calcd. for $C_{11}H_{17}NO_5$ (243.3): C, 54.31; H, 7.04; N, 5.76; O, 32.89. Found: C, 54.27; H, 7.14; N, 5.70; O, 32.87; molecular weight, 236 (Rast method with camphor).

An analogous acetylation of the solvolyzed material using 2.5 ml of acetic anhydride in the absence of pyridine (the sodium acetate left over from the solvolysis being sufficient to serve as a catalyst) gave the same product in similar yield.

In some of the runs a few milligrams of a by-product was isolated which crystallized out as needles when the crude gum obtained in the acetylation was dissolved in ethanol (from which XII (or XIII) did not crystallize). The by-product (m.p. 171–172°) differed from the main product in that it exhibited infrared bands associated with a —NH—$COCH_3$ structure. The spectrum also differed from that of triacetate X. A mixture melting point with X was depressed (ca. 145°). No analytical or rotation data were obtained owing to lack of material.

Infrared Absorption Data

Unless otherwise stated the infrared spectra of the compounds listed were taken using the Nujol mull technique and a Perkin–Elmer Infracord instrument. Only the most characteristic absorption bands are given.

REACTION MECHANISM STUDIES

3. SOLVENT EFFECTS AND THE NATURE OF THE TRANSITION STATE IN THE DIAXIAL → DIEQUATORIAL REARRANGEMENT

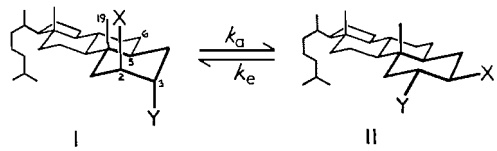
J. F. KING AND R. G. PEWS
Department of Chemistry, University of Western Ontario, London, Ontario

Received November 6, 1964

ABSTRACT

The rates of the diaxial → diequatorial rearrangement of 2β,3α-dibromocholestane (I*a*), and the analogous bromohydrin *p*-toluenesulfonates (I*d* and I*e*) and anisates (I*f* and I*g*) have been measured in various solvents. The change in rate with variation in solvent was found to correlate with the change in the ionizing power of the solvents. The sensitivity of the rate of rearrangement to changes in solvent ionizing power, as measured by the ratio of the rate of rearrangement in nitromethane to that in decalin, was found to be smaller for the dibromide (I*a*) than for the esters (I*d* to I*g*). A detailed discussion of the mechanism of the reaction is presented. It is proposed that the following factors (either singly or simultaneously) could lead to the smaller sensitivity to solvent change shown by the dibromide (I*a*) as compared with the esters (I*d* to I*g*): (*1*) a difference in a postulated change of the axial:equatorial opening ratio with change in solvent, and (*2*) the development of a smaller charge in the transition state for the rearrangement of the dibromide (I*a*) as compared with that in the rearrangement of the esters, when the reactions are carried out in the less polar solvents. It is argued that the operation of the latter factor would be most simply interpreted in terms of a merged ion-pair, cyclic-concerted mechanism, as initially suggested by Grob and Winstein.

A merged ion-pair, cyclic-concerted mechanism for the diaxial → diequatorial rearrangement of 5α,6β-dibromocholestane was suggested in 1952 by Grob and Winstein (1). Their proposal, which was a significant modification of an earlier mechanism put forward by Barton and Miller (2), stated, in effect, that the reaction takes place in solvents of high ionizing power via an ion pair, in solvents of lowest ionizing power through a cyclic nonpolar transition state, and in solvents of intermediate polarity through a transition state intermediate in character between these two extremes. The specific basis for



I II

a X, Y = Br

b X = Br, Y = OH

c X = OH, Y = Br

d X = Br, Y = CH_3–C$_6$H$_4$–SO_2O

e X = CH_3–C$_6$H$_4$–SO_2O, Y = Br

f X = Br, Y = CH_3O–C$_6$H$_4$–COO

g X = CH_3O–C$_6$H$_4$–COO, Y = Br

this suggestion was their observation that the change in the rate of rearrangement accompanying a change in the ionizing power of the solvent was larger than that expected of a cyclic, concerted process (typified by the Claisen or Cope rearrangements) and smaller than that expected of an ionic reaction, e.g. unimolecular solvolysis. Winstein has reiterated this proposal (3), and other discussions of the diaxial → diequatorial rearrangement have been in terms of this mechanism (4, 5, 6). Though the basic idea has gained credence through the presentation of evidence supporting a merged ion-pair, cyclic-concerted process in certain other reactions,* no additional data specifically concerned with the nature of the diaxial → diequatorial rearrangement have been reported. Some of our experiments connected with work reported in Part 1 of this series (6) suggested that further information on this reaction might be obtained by comparing the effect of solvents on the rate of rearrangement of a vicinal dibromide with the corresponding effect on the rate of rearrangement of the analogous bromohydrin sulfonate and carboxylate esters. It was hoped that by thereby comparing the solvent sensitivity of very closely related reactions that a more detailed analysis of the experimental results might be applied in order to assess the validity of the proposed merged ion-pair, cyclic-concerted mechanism.

RESULTS

2β,3α-Disubstituted 5α-cholestanes (I) were chosen for this investigation because these compounds had been subjected to considerable study already, and the amount of necessary preliminary work was correspondingly less than it would have been with another system. Whereas there is only one diaxial dibromide (I*a*) corresponding to structure I, there are two diaxial bromohydrins, I*b* and I*c*. For a meaningful comparison of the dibromide with the bromohydrin esters it was necessary to include the esters of both bromohydrins. The characterization and rearrangement of both of the tosylates (I*d* and I*e*) (6) and one of the anisates (I*f*) (5), as well as the dibromide (12), had been previously described. The other anisate (I*g*) was accordingly prepared and found to rearrange on heating in nitromethane at 99° to a mixture containing 95 ± 5% of the diequatorial isomer (II*g*), identified by comparison with an authentic specimen prepared from the bromohydrin (II*c*) (13, 14).

TABLE I

Rate constants ($\times 10^4$ s^{-1}) for the diaxial → diequatorial rearrangement under various conditions*

	CF_3COOH: $CHCl_3$ (1:1) at 25°	Triglyme at 135°	TMS–phenetole† at 135°	Decalin at 99°	Phenetole at 99°	Triglyme at 99°	Nitrobenzene at 99°	Nitromethane at 99°	$\frac{k_{CH_3NO_2}}{k_{decalin}}$

*Values without parentheses give k_{equil}, the rate of formation of the equilibrium mixture. Values in parentheses give k_a the rate of the reaction I → II, obtained from the relation $k_a = k_{equil}K/(K+1)$ where K is the equilibrium constant of the reaction I ⇌ II. The following mean values of K (derived from data in Table II) were used: I*a* ⇌ II*a*, $K \sim 19$; I*d* ⇌ II*d*, $K \sim 12$; I*e* ⇌ II*e*, $K \sim 7$. I*f* ⇌ II*f*, $K \sim 19$; I*g* ⇌ II*g*, $K \sim 19$.

The rate constant for the formation of the equilibrium mixture, k_{equil}, was measured polarimetrically as previously described (5, 6). The variation of k_{equil} with change of solvent is summarized in Table I (the numbers without parentheses). The choice of solvent in these experiments was limited by (*a*) the solubility of the compounds, and (*b*) the tendency of some of the compounds (especially the tosylates) to undergo solvolysis; the greater ease of handling at elevated temperatures was also a factor leading to the use of comparatively high boiling solvents.

For the purposes of the discussion in the next section it is pertinent to consider the evaluation of k_a, the rate constant for the reaction I $\rightarrow$ II. If k_e is the rate constant for the reverse process II $\rightarrow$ I, and K the equilibrium constant for the reaction I $\rightleftharpoons$ II, then from simple kinetic theory $k_{equil} = k_a + k_e = k_a(K + 1)/K$; i.e. knowing K, one may obtain k_a from k_{equil} simply by multiplying by $K/(K + 1)$. The values of K listed in the footnote in Table I are only approximate, and since the variation in K with change in solvent for any single compound appears to be small in comparison with the uncertainty in the values (see Table II), a single approximate mean value of K for each compound was used to calculate the values of k_a listed in parentheses in Table I. Because of the uncertainty in the measurement of K, the values of k_a are less precise than those of k_{equil}; in fact it is by no means certain that this procedure is any more meaningful than merely assuming $k_a \sim k_{equil}$. In any event nothing in the Discussion of the Mechanism (in which the term "rate of rearrangement" will refer, in principle, to k_a) depends on any *experimental* distinction between k_a and k_{equil}.

To obtain the data in Table I it was necessary to know the specific rotations of the various equilibrium mixtures. The values used for these quantities are summarized in Table II. Some of these values are from previous work, the others were obtained by heating the diaxial isomer for five half-lives (or in most instances, longer) and determining the composition of the product polarimetrically. Though a reaction time of more than five half-lives would have been desirable in order to approximate the true equilibrium value more closely, the polarimetric analysis of products of longer heating was often rendered impracticable by slow side reactions and general decomposition. As a result some of the values in Table II for the percentage of the diequatorial isomer (II) in the equilibrium mixture may be low; it can be shown that the *maximum* error in the rate constants listed in Table I that is introduced by incomplete equilibration is less than 10% and in all probability is much less.

Notably absent from Table II are data for the rearrangements of the esters in decalin. These reactions are so slow that side reactions seriously hamper the analysis of mixtures from runs carried beyond 25% reaction; direct determination of the equilibrium mixture (which would have involved heating some of the specimens for many months) was deemed impracticable. In view of the negligible variation of the equilibrium composition with solvent (as manifest in Table II), it is believed that no important error is introduced by assuming that the equilibrium composition in decalin is much the same as in the other solvents. The use of decalin as solvent also presented some difficulties in preliminary experiments to obtain the data in Table I. Consistent results were obtained only after the solvent had been subjected to thorough treatment to remove aromatic impurities (presumably mostly tetralin). Addition of glass beads to the reaction vessel in the decalin experiments had no effect on the rate, indicating that surface reactions are not significant with this solvent, and hence presumably not with the more polar solvents either.

The ionizing powers of the solvents used in the experiments at 99° have been estimated according to various procedures; the values are summarized in Table III. The dielectric

For personal use only.

determined directly; the value for nitromethane is that estimated by Berson *et al.* (17), the value agreeing well with an approximate value obtainable by direct measurement. Direct determination of **Z** values for decalin and nitrobenzene is not possible because of insolubility in the former case and solvent absorption in the latter; solvent absorption also interferes with an accurate determination of the **Z** value for nitromethane. Kosower indirectly estimated a **Z** value of 60.1 kcal/mole for isoöctane from a combination of the long wavelength absorption of pyridine N-oxide and a roughly linear plot of **Z** versus this band for other solvents (19). Our observation of a lower value for phenetole (58.9 kcal/mole) and also for tetrahydrofuran (58.8 kcal/mole), raises serious doubts about the accuracy of such a manoeuvre, since by any other mode of estimating solvent ionizing power saturated hydrocarbons are distinctly less polar than ethers. The values for $\Omega_{25°}$ are derived by interpolation from those given by Berson (17) for other temperatures; the *G* values (20) were obtained from the position of the carbonyl-stretching frequency of benzophenone (only). Included in Table III are values given by Brownstein (18) for his composite *S* values for nitrobenzene and nitromethane, together with those for compounds closely related to decalin and phenetole.

The agreement among the different ways of measuring solvent ionizing power is only approximate but does suffice to indicate the following order: decalin < phenetole $\leqslant$ triglyme < nitrobenzene $\leqslant$ nitromethane. For the rearrangement of I*a* and I*d* the rates (Table I) follow the same order with only the minor exception that the rearrangement of I*d* is slightly faster in phenetole than in triglyme (though the reverse order is found with I*a*). It would appear then that the rates of rearrangement qualitatively follow the ionizing power of the solvent, the agreement being about as good as that between the various methods of estimating ionizing power themselves. As it appeared extremely likely that the rates of rearrangement of the other esters (I*e*, I*f*, and I*g*) would show the same trend with change in solvent, the study of the rates of these reactions was limited to the solvents of highest and lowest ionizing power.

If we take the ratio of the rate constants (either k_{equil} or k_a) in nitromethane and decalin, i.e. $k_{CH_3NO_2}/k_{decalin}$, as an indicator of the sensitivity of the reaction to change in solvent ionizing power, it is apparent from Table I that the rearrangement of 2β,3α-dibromocholestane is distinctly less sensitive to such changes than the rearrangements of the esters. It should be noted that the rate constants for the rearrangements are sufficiently similar in magnitude that this difference in sensitivity to solvent results in the rearrangement of I*d*, I*e*, and I*f* being *slower* than that of I*a* in decalin, but *faster* in nitromethane.

Most of the solvents in this work have not been used extensively (if at all) in other studies of the effect of solvent on reactivity, but some sort of comparison between the present reactions and various others may be obtained by plotting log k_a vs. **Z** for the reactions in phenetole, triglyme, and nitromethane (the solvents for which the **Z** values in Table III are believed to be most meaningful). The slope of the best straight line for each of these plots may be converted by the equation $\mathbf{Z} = 104.2 + 8.11 \log k_1$ into Winstein's *a* parameter (21), which has been used to describe the solvent sensitivity of a number of reactions (10, 21). For the rearrangement of 2β,3α-dibromocholestane (I*a*) $a \sim 0.5$ and for that of 2β-bromocholestan-3α-yl tosylate (I*d*) $a \sim 1$. Approximate though the *a* values from this procedure are, they would indicate that the rearrangement of I*d* is about as sensitive to change in the ionizing power of the solvent as the solvolysis of *p*-methoxyneophyl tosylate itself (for which $a = 1$, by definition (21)).

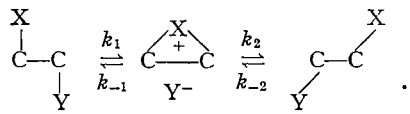
The rearrangement of I*d*, and in smaller measure I*a*, when carried out in a 1:1 mixture of trifluoroacetic acid and chloroform is notably faster than in any of the other solvents.

Within 5 min of adding the solid tosylate I*d* to pure trifluoroacetic acid at room temperature, it is essentially completely converted to a mixture consisting of about 80% II*d* and less than 20% solvolysis products. Since I*d* does not dissolve instantaneously in trifluoroacetic acid, the actual time for complete reaction is even less. Just how much of this effect is due to enhanced solvent ionizing power and how much to the acidity of the medium is not clear. As indicated in Table I, the rearrangement of I*f*, in which protonation of either of the ester oxygen atoms would strongly retard the rearrangement by the usual mechanism (5), proceeds very slowly if at all in trifluoroacetic acid.

DISCUSSION OF THE MECHANISM

The mechanism of the diaxial → diequatorial rearrangement (at least in polar solvents) as proposed by Barton and Miller (2), and Grob and Winstein (1), may be generalized as in eq. [1], formula III representing the diaxial isomer and V the diequatorial isomer. From the known properties of the reactions of substituted cyclohexane derivatives, this description may be expanded further as in Scheme 1. If one takes each of the divisions of the ordinate in the energy diagram in Scheme 1 as equal to 10 kcal/mole then the diagram

[1]



III IV V

may be taken as an approximate representation of the free energy changes in the rearrangement of the 2,3-dibromocholestanes (I*a* ⇌ II*a*) at 99°. There is no basis for assigning any quantity to ΔG_{VII} (except that it be less than ΔG_{TS1} or ΔG_{TS2}) and that portion of the diagram is indicated by a broken line. The diaxial opening rule (22, 23) requires that ΔG_{TS1} be less than ΔG_{TS2}, as drawn. This rule is commonly rationalized (see, for example, Valls and Toromanoff (24)) in terms of a reaction scheme in which attack at one carbon of the three-membered ring species gives a diaxial chair isomer, and attack at the other yields a diaxial twist-boat which in a subsequent rapid conformational inversion leads to the diequatorial chair isomer (cf. Scheme 1). With such a mechanism the difference between the free energies of activation for the formation of the diaxial (chair) and diequatorial (chair) isomers is governed by the free energy difference between a partly formed diaxial chair and a partly formed diaxial twist-boat. The free energy values for VIII and "TS3" indicated on the diagram for Scheme 1 are simply rough estimates based on the corresponding quantities measured in simpler systems (cf. Eliel (25) pp. 206 and 211); the value for $\Delta G_{\text{VI}} - \Delta G_{\text{IX}}$ is derived from the equilibrium constant, K (see footnote, Table I), and $\Delta G_{\text{TS2}} - \Delta G_{\text{VI}}$ from the rate constants in Table I.

The energy diagrams for the rearrangements of the bromohydrin tosylates (I*d* ⇌ II*d* and I*e* ⇌ II*e*) are in all likelihood qualitatively similar to that for the reaction I*a* ⇌ II*a*, but the rearrangement of the anisates may very well be distinctly different. It has been shown (5) that the transition state in the rearrangement of the carboxylic esters is polarized so that there is a negative charge on the halogen and a positive charge on the ester group, i.e. that if the reaction were to proceed through an ion pair it would be an acyloxonium bromide and not the alternative, a bromonium acylate. In this case the "onium" ion is part of a five-membered ring and the diaxial opening rule may no longer apply. Examination of molecular models indicates that there is considerable angle strain accompanying a *cis* fusion of an acyloxonium ion with a cyclohexane ring, and that attack on the carbon

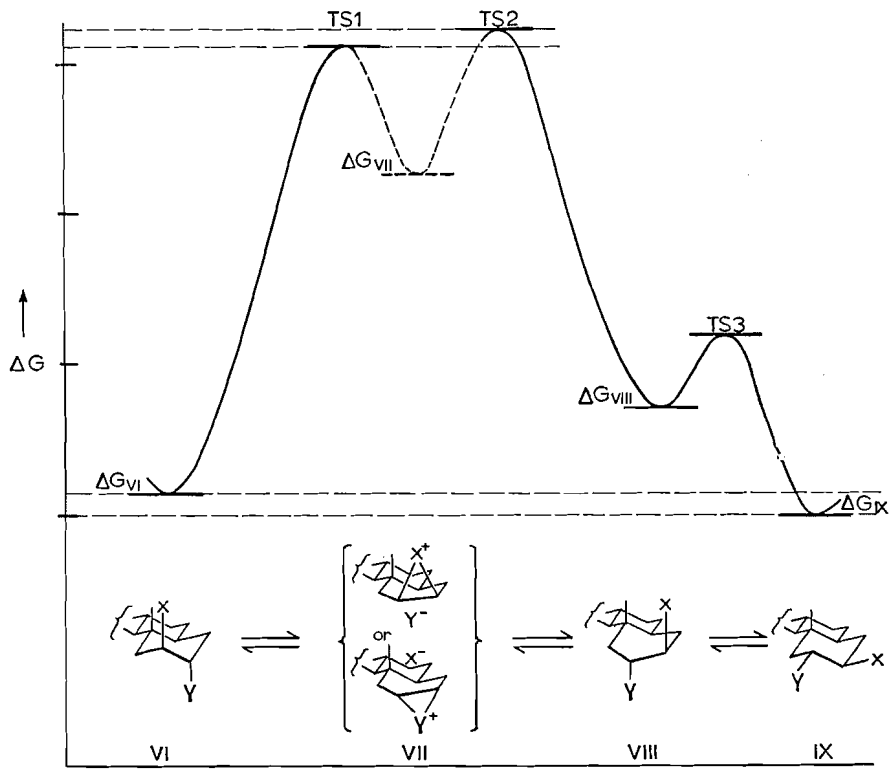
For personal use only.



SCHEME 1.

bearing the equatorial oxygen (diaxial opening) would give a transition state in which this strain is somewhat relieved, while attack at the carbon bearing the axial oxygen (direct diequatorial opening) would lead to a transition state in which the angle strain is apparently increased. On the other hand substitution of an *axial* function in a simple cyclohexane system is normally faster* than that of the analogous equatorial function (cf. Eliel (25), pp. 223ff.). The two effects oppose each other and it is not evident which is stronger. But it would seem likely that the axial : equatorial opening ratio is much smaller with the acyloxonium ion than with a three-membered ring intermediate, and may well be < 1. Such is probably the case in the rearrangement I*f* $\rightleftharpoons$ II*f*, in which in addition to the above factors, any reagent attacking at C-2 (which would give diaxial opening) would be subjected to considerable steric compression with the hydrogens of the nearby axial methyl group (C-19).

In terms of the rate constants defined in eq. [1], we may (assuming steady-state conditions) express the measured rate for the reaction I $\rightarrow$ II (also III $\rightarrow$ V, and VI $\rightarrow$ IX) by $k_a = k_1/(1 + k_{-1}/k_2)$. From the discussion just given, for the reaction of I*a*, I*d*, or I*e*, $k_{-1} > k_2$ and hence $k_a < k_1$, and for the rearrangement of I*f* or I*g*, k_a is probably only slightly less than k_1. The question that now arises is how the observed solvent dependence of k_a may be rationalized in terms of k_1 and the ratio k_{-1}/k_2. Most of the remainder of this section will be devoted to this problem, beginning with the possible role of the axial : equatorial opening ratio, k_{-1}/k_2. To simplify matters the following treatment is

**Except for a bimolecular displacement in which the attacking group is significantly smaller than the leaving group, which would not appear to be the case here.*

based initially on an ionization mechanism; any conclusion derived in this way may be readily adapted to a "merged mechanism," which is examined later in the discussion.

Variation in the Axial: Equatorial Opening Ratio

Consider a hypothetical reaction $X \rightarrow Y \rightarrow Z$, in which the positions in the reaction coordinate of all three species and the free energies of X and Z are fixed (so that $\Delta G_Z > \Delta G_X$), and ΔG_Y (the free energy of Y) is variable (see Fig. 1). Let $\Delta\Delta G^{\ddagger}$ be defined as the difference between the free energies of the transition states, specifically, the free energy of the transition state in the reaction $Y \rightleftharpoons Z$ minus that for the transition state in the reaction $X \rightleftharpoons Y$. The question is what effect will variation of ΔG_Y have on $\Delta\Delta G^{\ddagger}$.

In the degenerate case in which Y is a transition state (curve *a* in Fig. 1), $\Delta\Delta G^{\ddagger}$ is obviously zero. As ΔG_Y is diminished, at some point Y will cease to be a transition state and will become a true intermediate so that there will be a transition state between X and Y and another between Y and Z. According to the Hammond postulate (26),* as

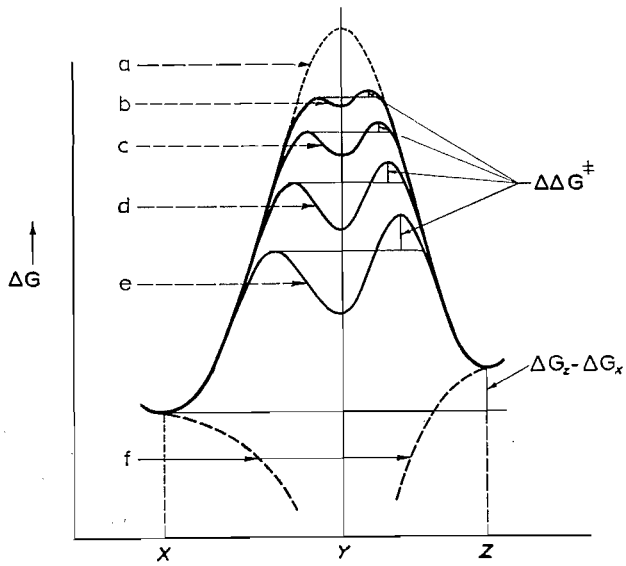

FIG. 1.

ΔG_Y is lowered still further an increasingly extensive atomic reorganization will be required on going from Y to either of the transition states. That is to say, as ΔG_Y decreases, the transition states move away from Y to resemble increasingly X and Z, respectively (cf. curves *b* to *e*, Fig. 1). If the lowering of the free energy of Y is continued to the extreme case (cf. curve *f*, Fig. 1), $\Delta\Delta G^{\ddagger}$ will become identical to the difference in free energy between X and Z, i.e. $\Delta G_Z - \Delta G_X$, this value presumably being approached asymptotically as ΔG_Y diminishes. Without attempting to describe the relation between $\Delta\Delta G^{\ddagger}$ and ΔG_Y exactly, we can see that $\Delta\Delta G^{\ddagger}$ is a non-linear function of ΔG_Y such that $\Delta\Delta G^{\ddagger}$ equals zero when ΔG_Y is large, and tends to increase to the value $\Delta G_Z - \Delta G_X$ as ΔG_Y becomes very small.

**Strictly speaking the Hammond postulate deals with potential energies rather than free energies. The discussion given here is essentially qualitative and is presented in terms of free energies in order to keep the argument and symbolism as simple as possible. For the species corresponding to potential energy maxima and minima, it is simply assumed that the potential energies and free energies will show sufficient correspondence for the conclusions drawn to be qualitatively valid.*

The conclusion of this general treatment may now be applied specifically to the diaxial → diequatorial rearrangement. If the discussion be restricted for the moment to an ion-pair mechanism, then since the ion pair has the greatest dipole moment of any species in the reaction, an increase in the ionizing power of the solvent would be expected to operate most significantly by lowering the free energy of the ion pair. To the extent that the effect of solvent on the completely covalent species of the reaction may be neglected, the diaxial → diequatorial rearrangement corresponds to the reaction X → Y → Z just discussed; thus VI corresponds to X, VII to Y, and VIII to Z, and the lowering of ΔG_Y is effected by solvation of the ion pair (VII) as the ionizing power of the solvent is increased. In terms of the rate constants defined in eq. [1], $\Delta\Delta G^{\ddagger} = RT \ln k_{-1}/k_2$. Therefore, increasing the ionizing power of the medium lowers the free energy of the ion pair (which corresponds to ΔG_Y), and this in turn is accompanied by a trend to an increase in $\Delta\Delta G^{\ddagger}$ and hence in k_{-1}/k_2, the axial : equatorial opening ratio. To summarize, on the assumption that the chief effect of a change in solvent polarity is on the free energy of the intermediate ion pair, *an increase in the solvent ionizing power would be expected to be accompanied by an increase in the axial : equatorial opening ratio* (k_{-1}/k_2).

As has been pointed out previously, k_a, the rate constant for the reaction I → II, is given by $k_a = k_1/(1 + k_{-1}/k_2)$. If the ionization is normal, k_1 will increase rapidly with an increase in solvent ionizing power. But from the above argument k_{-1}/k_2 is also expected to increase with solvent polarity and therefore any increase in rate constant accompanying an increase in the solvent ionizing power will be *smaller* for k_a than for k_1, i.e. the increase in k_{-1}/k_2 tends to damp the effect on k_a of the simultaneous increase in k_1. Such an effect may account for part—or, conceivably, even all—of the rather low sensitivity of k_a to a change in solvent in the rearrangement of 5α,6β-dibromocholestane (1). This rationalization, then, represents a possible supplementary, or even alternative, explanation for the data on which Grob and Winstein based their suggestion of a "merged mechanism" for the diaxial → diequatorial rearrangement of 5α,6β-dibromocholestane.

If the experimental observations reported in the *present* study are to be rationalized in terms of changes in the ratio k_{-1}/k_2, a further point must be considered. For a variation in the axial : equatorial opening ratio to account for the differences in solvent sensitivity of the rearrangement of the dibromide (I*a* ⇌ II*a*) as compared with that of the bromohydrin tosylate (I*d* ⇌ II*d*), it is necessary not only for k_{-1}/k_2 to vary with solvent but also for the variation in the case of the dibromide (I*a*) to be different from that with the tosylate (I*d*). It will be recalled that the greater the change in k_{-1}/k_2 with change in solvent polarity, the smaller the change in k_a (assuming the change in k_1 to be the same). Therefore it is necessary on this basis to devise a reason why the hypothetical variation in k_{-1}/k_2 might be greater for the dibromide than for the tosylate. The argument in the next paragraph indicates a way in which this might conceivably occur, though owing to current ignorance of the details of the energy diagrams in such complex reactions, this rationale can only be regarded as a plausible suggestion.

In the discussion of the generalized scheme X → Y → Z, it was concluded that as ΔG_Y becomes very small $\Delta\Delta G^{\ddagger}$ probably tends gradually to the value $\Delta G_Z - \Delta G_X$. Such an asymptotic approach to a limiting value bespeaks a non-linear relationship in which $\Delta\Delta G^{\ddagger}$ is more sensitive to a change in ΔG_Y at some region where ΔG_Y is comparatively large than at a region where it is comparatively small. This would suggest that in two *different* reactions a greater sensitivity to change in ΔG_Y would be more likely to be found when Y is in a comparatively shallow "energy well" (e.g. curve *b*, Fig. 1) rather than in a deep "energy well". Translating the symbolism of the general case to that of the diaxial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$\rightarrow$ diequatorial rearrangement, it would appear that the sensitivity of the ratio k_{-1}/k_2 to a change in solvent ionizing power might be expected to be greater in the case of an ion pair which is rapidly converted to the diaxial or the diequatorial isomer, than in that in which the formation of the nonionic compounds from the ion pair is slow. Since the bromide ion is found to exhibit greater nucleophilic activity than the tosylate anion (27), it is almost certain that the bromonium bromide ion pair would, in fact, more readily recombine to form the diaxial or the diequatorial compound, than would the bromonium tosylate. Hence, if the above argument holds, the ratio k_{-1}/k_2 in the case of the dibromide (I*a*) would be expected to increase more rapidly with an increase in solvent polarity than it would in the case of the bromohydrin tosylate (I*d*). This in turn would lead to what is observed experimentally, that is to say, to a greater sensitivity to a change in solvent ionizing power on the part of k_a for the rearrangement of the tosylate (I*d*), than that of k_a for the dibromide (I*a*). It is perhaps worth repeating at this point that it has been necessary to make some fairly extensive assumptions in order to derive an explanation for the variations in rate with change in solvent in terms of variations in the axial:equatorial opening ratio. The discussion is included, nonetheless, in order to show that *without invoking any differences in the behavior of* k_1 (the rate constant for the ionization step), it is possible to conceive of a set of circumstances which might possibly lead to a smaller sensitivity to solvent change in the rearrangement of the dibromide (I*a*) than in the case of the bromohydrin tosylate (I*d*).

Difference in the Sensitivity of the Rate of the First Step

As the possible sources and effects of a variation in the axial : equatorial opening ratio have been examined at some length, it is appropriate now to consider the significance of factors connected with k_1, the ionization rate constant. Again, making some drastic simplifications about the importance and nature of the solvation of the transition state, k_1 may be expressed by the following well-known equation (28) in terms of k_0, the rate of ionization of I in a vacuum, and a term dealing with the effect of solvent.

$$\ln k_1 = \ln k_0 + \frac{\mu_{\pm}^2}{kTr_{\pm}^3}\left(\frac{\epsilon - 1}{2\epsilon + 1}\right) = \ln k_0 + \frac{e_{\pm}^2 d_{\pm}^2}{kTr_{\pm}^3}\left(\frac{\epsilon - 1}{2\epsilon + 1}\right).$$

In the latter term $\mu_{\pm}$ is the dipole moment of the transition state and $r_{\pm}$ the radius of the solvent cavity (assumed to be spherical) occupied by the transition state; this term may be expanded by expressing the dipole moment in terms of the magnitude of the charge ($e_{\pm}$), and the distance ($d_{\pm}$) between the positive and negative centers of charge in the transition state. The factor $e_{\pm}^2 d_{\pm}^2/kTr_{\pm}^3$ defines the slope of the straight line obtained from a plot of ln k_1 vs. $(\epsilon - 1)/(2\epsilon + 1)$. For the rearrangements of I*a* and I*d* the ratio of the slopes is given by:

$$[2] \qquad \frac{\text{slope Ia}}{\text{slope Id}} = \frac{(e_{\pm})_{Ia}^2 (d_{\pm})_{Ia}^2 (r_{\pm})_{Id}^3}{(e_{\pm})_{Id}^2 (d_{\pm})_{Id}^2 (r_{\pm})_{Ia}^3}.$$

Since the tosylate (I*d*) is more bulky than the dibromide (I*a*), and the same relation presumably holds for analogous transition states, then $(r_{\pm})_{Id}^3/(r_{\pm})_{Ia}^3 > 1$. Temporarily assuming an ion-pair mechanism, we estimate the distance between the centers of the two bromine atoms in the ion pair from I*a* to be ~ 5.0 Å, and the distance from the positively charged bromine to the approximate center of charge for the tosylate anion in the ion pair from I*d* to be ~ 4.5 Å. From the Hammond postulate one would expect that the transition state would resemble the ion pair to the extent that the distances between the

charges in the transition state follow the same order, and therefore $(d_{\mp})_{Ia}^2/(d_{\mp})_{Id}^2 > 1$. But the rearrangement of I*a* has in fact been found to be *less* sensitive to solvent change than that of I*d*, viz., slope I*a* / slope I*d* $\sim$ 0.5 to 0.6. If any of this is due to differences in sensitivity of k_1, and if eq. [2] is even qualitatively valid, then *slope Ia / slope Id can be less than one only if there is a distinctly smaller value for the magnitude of the charge* ($e_{\mp}$) *in the transition state of the dibromide rearrangement* as compared with that of the bromohydrin tosylates. It remains now to see what the smaller value of $e_{\mp}$ means in terms of the mechanism of these reactions.

In contrast to the diaxial → diequatorial rearrangement, the solvolysis of primary and secondary bromides has been found by Winstein, Grunwald, and Jones (29) to be slightly more sensitive to solvent ionizing power than that of the corresponding tosylates or brosylates (*p*-bromobenzenesulfonates). These authors' investigations were carried out using a more polar range of solvents than that used in our study and it is conceivable that their results are not directly applicable to this discussion. They would suggest, however, that there is no reason to expect that the magnitude of the charge ($e_{\mp}$) in the transition state of a *true ionization* of an aliphatic bromide is less than that in the ionization of a corresponding sulfonate ester. But it was concluded in the above paragraph that $e_{\mp}$ for the *rearrangement* of the dibromide (I*a*) is less than that for the rearrangement of the tosylate (I*d*). It follows, therefore, that if the rearrangement of the tosylate (I*d*) is proceeding via an ion pair, the rearrangement of the dibromide (I*a*) cannot also be taking place through an ion pair but rather must be going through a species with a smaller development of charge. In other words if the observed differences in the effect of solvent stem to any degree from the behavior of k_1, the reaction of I*a* must proceed in some solvents at least, via a merged ion-pair, cyclic-concerted mechanism as suggested initially by Grob and Winstein (1) for the rearrangement of 5β,6α-dibromocholestane. There is nothing in this discussion which demands that the rearrangement of the tosylates (I*d* and I*e*) be taking place via fully formed ion pairs; it does require, however, that if the tosylates are also rearranging through a "merged mechanism" that the magnitude of the charge in the transition state be greater than that in the corresponding stage of the rearrangement of the dibromide, i.e. that the rearrangement of the tosylates be more like an ionic reaction than that of the dibromide.

It is perhaps of interest to take note of a curious feature of "merged-mechanism" reactions. With reference to Fig. 1 again, it would appear that as the energies of the transition states become higher accompanying a decrease in solvent ionizing power, the transition state comes to resemble the intermediate Y more closely. Hence $e_{\mp}$, the magnitude of the charge at either end of the dipole of the transition state, becomes *greater* as the solvent ionizing power is diminished. If the merged mechanism be defined as above, then this indicates the interesting possibility that a merged mechanism may show an increased, constant, or decreased value for $e_{\mp}$ with decrease in solvent ionizing power, though presumably the increase in $e_{\mp}$ must be less than that for the ion-pair extreme case.

Specific Solvation Effects

Much of the above discussion of mechanism has sought to find an explanation for our observations in terms of general phenomena. In any limited study the possibility exists that comparatively specific factors may actually be responsible. It might be suggested, for example, that in the rearrangement of the dibromide the two bromine atoms and the two attached carbon atoms (C-2 and C-3) form a four-membered ring in the transition state, whereas in the rearrangement of the esters the corresponding atoms may form a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

six-membered ring; such a geometrical difference might conceivably (by an unspecified mechanism) be responsible for the lower solvent sensitivity of the rearrangement of the dibromide. Recent observations in this laboratory (30) indicate that a four-membered ring transition state does not have to be solvent insensitive. It has been found that the rearrangement of 2β-chloro-3α-thiophenoxycholestane, in which the chlorine, the two carbons, and the sulfur atom presumably form a four-membered ring in the transition state, is at least as sensitive to solvent change as the esters in the present investigation.

Though as mentioned already the effect of solvents in this study correlates acceptably with the ionizing power of the solvents, there might still remain the possibility that either the greater sensitivity to solvent change shown by the esters, or the smaller effect of the medium in the dibromide rearrangement, might be due to some sort of special interaction with some of the solvents. If there were a specific interaction with the incipient tosylate anion in I*d* and I*e*, there would also have to be an interaction of similar effect with the developing acyloxonium cation in I*f* and I*g* (and also with the sulfur or the chlorine of 2β-chloro-3α-thiophenoxycholestane), since these compounds show a sensitivity to the same solvents of the same order of magnitude. On the other hand any specific interaction of either the positively or the negatively charged bromine atoms in the rearrangement of I*a* would have to be manifest also in the rearrangement of either the tosylates or the anisates, since a positively charged bromine atom is formed in the former case and a negatively charged bromine in the latter. To devise a consistent system with the above data on such a basis would seem complicated; at this juncture we much prefer the alternative view that the observed phenomena reflect the operation of a few general effects rather than a number of specific interactions.

Concluding Summary

The aim of this study was to elucidate the detailed mechanism of the diaxial → diequatorial rearrangement, particularly with a view to establishing whether or not it belongs to the proposed class of merged ion-pair, cyclic-concerted reactions. It was found that the rates of the diaxial → diequatorial rearrangement of compounds I*a* and I*d* increase with increasing polarity of the solvent. The rate of rearrangement of the dibromide (I*a*) does not show as great an increase as that of the tosylate I*d* (or those of the other esters I*e* to I*g*). Because the dibromide (I*a*) and the esters (I*d* to I*g*) have similar structures, it is believed that the difference in solvent sensitivity shown by the rates is significant and warrants close analysis.

On the basis of a two-step mechanism, involving the formation of either an ion pair or of an intermediate with smaller charge separation than an ion pair, it is argued that the difference in behavior shown by the dibromide (I*a*) may be due either to a difference connected with the rate of the first step (k_1), or to a difference in the behavior of the intermediate, specifically in the variability of the ratio of axial to equatorial opening (k_{-1}/k_2). The assumptions required to make the latter factor workable are such as to suggest that it is probably the less important of the two, but it cannot be dismissed with the evidence at hand. If the different behavior of the dibromide should derive mainly from the first step, it is shown that this would most likely be due to a smaller magnitude of charge in the transition state ($e_{\pm}$) of the dibromide reaction, and that this in turn would indicate a "merged mechanism". The possibility that the observed differences reflect the operation of specific solvent effects is considered to be unlikely.

Though the avowed goal of clarifying the detailed mechanism of the diaxial → diequatorial rearrangement has not yet been reached, it is felt that the results and discussion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

presented here give increased insight into the reaction and point the way to further experiments, which, it is hoped, will remove the remaining uncertainties. Such experiments are now being carried out.

EXPERIMENTAL

Melting points were determined using a Kofler block and are uncorrected. Optical rotations given in the characterization of compounds refer to solutions in chloroform ($c \sim 1.0$). Infrared spectra were obtained using Beckman IR-5 or IR-7 spectrophotometers equipped with sodium chloride optics. Thin-layer chromatography was carried out using Camag Kieselgel D5 or DF5. Petroleum ether refers to the fraction of boiling range 35–60°.

Phenetole and triglyme were purified as previously described (6). Commercial tetramethylene sulfone (supplied under the trade name "Sulfolane" by the Phillips Petroleum Company, Bartlesville, Oklahoma) was distilled under reduced pressure, first from potassium hydroxide and then from potassium permanganate; the distillate solidified on standing, m.p. 18–22°. Anhydrous chloroform free from alcohol was prepared by the method described by Vogel (31). Eastman Kodak white label trifluoroacetic acid was distilled before use. Fisher Certified Reagent grade nitrobenzene was twice partially frozen and separated from the unfrozen material; it was then fractionally distilled twice and the middle fraction from the second distillation redistilled under reduced pressure from calcium hydride. Commerical reagent grade nitromethane was washed three times each with (*a*) 20% of its volume of a solution containing sodium bicarbonate (25 g/l) and sodium bisulfite (25 g/l), (*b*) 5% sulfuric acid, and (*c*) water; the nitromethane was then dried over phosphorus pentoxide and distilled under reduced pressure from calcium hydride. BDH Laboratory Reagent grade decalin (mixed *cis* and *trans* isomers) was stirred vigorously with concentrated sulfuric acid at 90–100° for 24 h and then stirred with an alkaline 5% potassium permanganate solution at room temperature for 24 h; this was followed by drying with phosphorus pentoxide and distillation in an inert atmosphere under reduced pressure from lithium aluminium hydride. The preparation and properties of the dibromocholestanes (I*a* and II*a*) and the bromohydrin tosylates (I*d*, I*e*, II*d*, and II*e*) were as previously described (6, 32).

2β-Bromocholestan-3α-yl Anisate (If)

This compound was prepared as described by Barton and King (5); m.p. 136–138°, $[\alpha]_D$ +83°; reported m.p. 136–138°, $[\alpha]_D$ +83°.

3β-Bromocholestan-2α-yl Anisate (IIf)

This compound was isolated from the pyrolytic equilibrium experiments as previously described (5); m.p. 110–114°, $[\alpha]_D$ −34°; reported m.p. 114–115°, $[\alpha]_D$ −37°.

3α-Bromocholestan-2β-yl Anisate (Ig)

A slight excess of redistilled anisyl chloride was added to a solution of 3α-bromocholestan-2β-ol (12), and the mixture allowed to stand overnight at room temperature. After work-up the compound was recrystallized twice from 2-ethoxyethanol (ethyl cellosolve) and three times from a mixture of ether and methanol; m.p. 115–118°, $[\alpha]_D$ +36°.

Anal. Calcd. for $C_{35}H_{53}O_3Br$: C, 69.86; H, 8.88. Found: C, 70.29; H, 8.61.

2α-Bromocholestan-3β-yl Anisate (IIg)

2α-Bromocholestan-3β-ol (13, 14) was treated with anisyl chloride in pyridine as above. After four recrystallizations from ether–methanol the compound melted at 174–176°, $[\alpha]_D$ −44°.

Anal. Calcd. for $C_{35}H_{53}O_3Br$: C, 69.86; H, 8.88. Found: C, 69.98; H, 8.75.

Rate Measurements and Determination of the Composition of the Pyrolytic Equilibrium Mixtures

The rate measurements and the determination of the equilibrium composition of the reactions run above room temperature were carried out as before (6), except that the rate constants were calculated from the slope of the best straight line for the plot of $\log \alpha_o - \alpha/\alpha_o - \alpha_{eq}$ vs. time, as determined by the method of least squares. The following procedure was used for the experiments in trifluoroacetic acid – chloroform (1:1). The compound (20–30 mg) was weighed into a flask and dissolved in chloroform (0.5 ml); trifluoroacetic acid (0.5 ml) was added, the solution transferred to a polarimeter tube, and the rotation measured at intervals. Most of the data from these experiments are summarized in Tables I and II.

The rate of rearrangement of 2β-bromocholestan-3α-yl tosylate (I*d*) in decalin was obtained from the following data: initial $[\alpha]_D$ +52°; $[\alpha]_D$ after 137 h at 99°, +35°, +41°, +36°; $[\alpha]_D$ after 336 h at 99°, +24°, +22°, +21°; average $k_{equil} = 4 \times 10^{-7}$ s^{-1}.

On heating at 99° for 357 h in decalin the rotation of 3α-bromocholestan-2β-yl tosylate (I*e*) changed from +50° to +33° (average of three runs). Absorption at 995 cm^{-1} in the infrared spectrum and the presence of a spot corresponding to the diequatorial isomer (II*e*) in a thin-layer chromatogram established that rearrangement was occurring; the chromatogram, however, also indicated that some decomposition was taking place. Three further runs heated for 708 h showed much the same change in rotation as those run for 357 h; thin-layer chromatography of the mixtures from the longer reaction time indicated considerable decomposition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Comparison of the relative intensities of the spots due to the diaxial and diequatorial isomers in the latter reaction mixture, with those obtained from mixtures of known composition indicated that the reaction mixture contained less than 30% but more than 20% rearranged product (II*e*). Based on the polarimetric reading at 357 h, $k_{equil} = 2 \times 10^{-7}$ s^{-1}. Taking the maximum value of 30%, as estimated by thin-layer chromatography of the mixture after heating for 708 h, $k_{equil} = 1.4 \times 10^{-7}$ s^{-1}.

Rearrangement of 2β-Bromocholestan-3α-yl Tosylate (Id) in Trifluoroacetic Acid

2β-Bromocholestan-3α-yl tosylate (I*d*) (22 mg) was added to trifluoroacetic acid (3 ml) at room temperature and the mixture shaken to dissolve the substrate. After 5 min the reaction mixture was poured into water and the aqueous mixture extracted with ether. The ether extract was washed with dilute sodium bicarbonate and water, dried over sodium sulfate, and the solvent evaporated. Examination of the infrared spectrum showed the product to be principally the diequatorial isomer (II*d*), with less than 20% solvolysis product (estimated from the intensity of the band at 1 786 cm^{-1}) and no starting material (I*d*). The above experiment was repeated with the addition of lithium trifluoroacetate (250 mg). (The salt was prepared from trifluoroacetic acid and lithium carbonate and was purified by recrystallization from anhydrous tetrahydrofuran.) The infrared spectrum of the crude product showed a large increase in the proportion of the solvolysis product, judged again by the band at 1 786 cm^{-1}.

Attempted Rearrangement of 2β-Bromocholestan-3α-yl Anisate (If) in Trifluoroacetic Acid

2β-Bromocholestan-3α-yl anisate (23 mg) was dissolved in trifluoroacetic acid (2 ml), the solution let stand at room temperature for 18 h, and then worked up in the same way as with the tosylate (I*d*), above. The infrared spectrum and specific rotation of the product were identical to those of the starting material. In another experiment, the anisate (I*f*) (31 mg) was heated in trifluoroacetic acid (1 ml) in a sealed ampoule at 99° for ½ h. The specific rotation of the product, isolated as described above, was found to be +33°, as compared with +85° for the pure starting material. Examination of the infrared spectrum indicated, in addition to starting material, some solvolysis product absorbing at 1 786 cm^{-1}. An attempt to detect the rearranged isomer (II*f*) by thin-layer chromatography was inconclusive because of the difficulty in finding a solvent system capable of resolving the diaxial and diequatorial isomers.

Solvent Polarity Measurements

At least three traces of the infrared spectrum in the carbonyl region of a solution of benzophenone (4–7 mg) in the solvent (0.2 ml) vs. the solvent, were run on a Beckman IR-7 spectrophotometer calibrated using the water vapor peak at 1 662.82 cm^{-1} (33). The following values for the carbonyl maxima (ν^s) were obtained: decalin 1 667.$_6$ cm^{-1}, phenetole 1 662.$_3$ cm^{-1}, triglyme 1 662.$_0$ cm^{-1}, nitromethane 1 660.$_5$ cm^{-1}, nitrobenzene 1 660.$_0$ cm^{-1}. The *G* values (20) were calculated from the relation $G = 7.90 \times 10^3 (1\,681 - \nu^s)/\nu^s$, and are listed in Table III.

The ultraviolet and visible spectra of solutions of 4-carbomethoxy-N-ethylpyridinium iodide (prepared by the method of Kosower (19)) in the solvents studied were determined on a Bausch and Lomb Spectronic 505 spectrophotometer calibrated with at least two Hg emission bands flanking the absorption maximum. The composition of the solutions, λ_{max} values, and the apparent extinction coefficients are as follows: 4-carbomethoxy-N-ethylpyridinium iodide (0.3 mg) in phenetole (5 ml) containing chloroform (41.3 mg), λ_{max} 486 mμ (ϵ_{app} 1 400); 4-carbomethoxy-N-ethylpyridinium iodide (0.3 mg) in phenetole (5 ml) containing chloroform (97.5 mg), λ_{max} 486 mμ (ϵ_{app} 1 100); 4-carbomethoxy-N-ethylpyridinium iodide (1.6 mg) in triglyme (10 ml) (*freshly* distilled from lithium aluminium hydride), λ_{max} 466 mμ (ϵ_{app} 1 030); 4-carbomethoxy-N-ethylpyridinium iodide (0.2 mg) in tetrahydrofuran (5 ml) containing chloroform (24.4 mg), λ_{max} 486.5 mμ (ϵ_{app} 2 200). The **Z** values (19) in Table III were obtained from the relation $\mathbf{Z} = 2.859 \times 10^4/\lambda_{max}$ (where λ_{max} is in mμ).

ACKNOWLEDGMENTS

This work was made possible by grants-in-aid and a scholarship from the National Research Council, by a Frederick Gardner Cottrell grant-in-aid from the Research Corporation, and a scholarship from Dow Chemical of Canada Limited. We thank Dr. R. K. Chan of this department for determining the dielectric constant of triglyme and Professor Jerome A. Berson (University of Wisconsin) for a stimulating discussion of the results described in this paper.

THE WALLACH REARRANGEMENT

PART II.[1] KINETICS AND MECHANISM OF THE ACID-CATALYZED REARRANGEMENT OF AZOXYBENZENE

E. BUNCEL AND B. T. LAWTON

Department of Chemistry, Queen's University, Kingston, Ontario

Received September 21, 1964

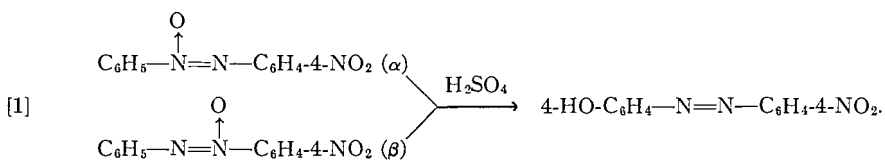
ABSTRACT

The rate of rearrangement of azoxybenzene to *p*-hydroxyazobenzene has been measured in 75.3–96.4% sulfuric acid at 25° and in 65.0–90.4% sulfuric acid at 75.5° by spectrophotometric methods. The pK_a of azoxybenzene in aqueous sulfuric acid has also been determined. It is found that although azoxybenzene is almost completely protonated over the entire range of acid concentration studied, the rate increases by more than 1 000-fold. A two-proton process is therefore indicated and mechanisms are proposed involving a dication (II) as the key intermediate. The rate data do not allow differentiation between two proposed mechanisms, one involving two equilibrium protonations, and the other a single equilibrium protonation followed by rate-determining proton transfer. Past mechanisms of the Wallach rearrangement are discussed.

INTRODUCTION

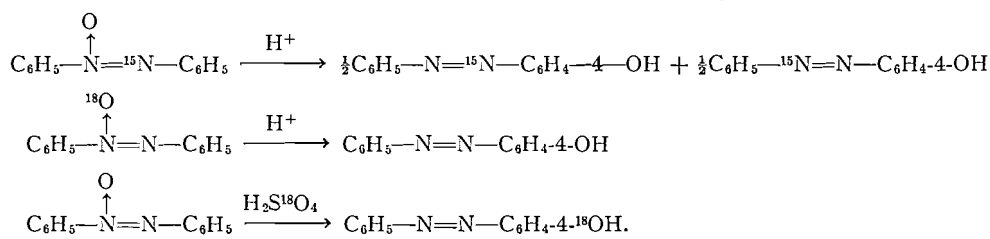
In 1880, Wallach and Belli (2) discovered that azoxybenzene on treatment with concentrated sulfuric acid isomerized to *p*-hydroxyazobenzene. This reaction is known as the Wallach rearrangement. Since then numerous studies have been made to elucidate the nature of this reaction but up to the present time (1) no kinetic study of the Wallach rearrangement has been reported. As an introduction to the present work the more recent studies on this topic will be reviewed.

Of particular interest to the early investigators was to determine whether the rearrangement is intramolecular or intermolecular, and the direction of migration of the oxygen function in the case of substituted azoxybenzenes. Angelli (3), who was the first to isolate two position isomers of a mono-substituted azoxybenzene, observed that both isomers of 4-nitroazoxybenzene gave the same rearranged product, 4-nitro-4′-hydroxyazobenzene (eq. 1). When both para positions are substituted, the oxygen enters one of the ortho positions (4*b*).



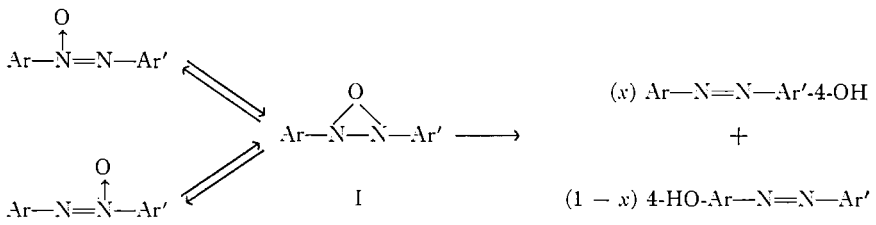
[1]

The most revealing studies on the mechanism of the acid-catalyzed para rearrangement have been the N-15 and O-18 tracer investigations of Shemyakin *et al.* (5, 6). Their main observations can be summarized by the following equations:



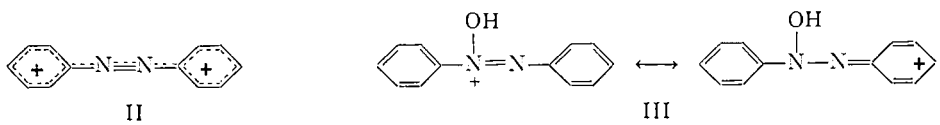
[1]*A preliminary communication on part of this work has appeared (ref. 1).*

In addition, azoxybenzene recovered from partial reaction in all three types of experiments contained the original label undisturbed. On the basis of the equalization of the nitrogen label during the rearrangement but not prior to it, Shemyakin *et al.* deduced that a symmetrical intermediate must be formed. They proposed that the symmetrical intermediate was the N,N-oxide (I) and suggested Scheme 1 for the mechanism of the Wallach rearrangement.



SCHEME 1.

The α and β isomerization was included in the scheme for the following reasons. Although azoxybenzene itself does not undergo this isomerization under the conditions of the rearrangement, as shown by the N-15 tracer experiments, Gore (7) found that β-4-nitroazoxybenzene underwent extensive conversion to the more stable α-isomer under rearrangement conditions.[2] Now the isomerization of β-4-nitroazoxybenzene in $H_2S^{18}O_4$ resulted in no O-18 enrichment in the recovered α-isomer (6). Shemyakin hence concluded that the N,N-oxide was a common intermediate in isomerization and rearrangement. Gore (7) suggested that the dicationic species (II) is also a possible intermediate in the Wallach rearrangement. He considered that II represents the major reaction route, with a minor route proceeding via the monocationic species (III).



Oxygen-18 tracer studies on the azoxybenzene rearrangement have also been carried out, independently, by Oae *et al.* (9); the results are very similar to those of the Russian workers. The mechanism proposed by Oae *et al.* is shown in Scheme 2.

The value of kinetic data in the interpretation of the mechanism of acid-catalyzed reactions is well known (10). It was with the expectation that kinetic data would shed further light on the mechanism of the Wallach rearrangement that the present study was initiated.

RESULTS

Kinetic Data

Before a kinetic study of the acid-catalyzed rearrangement of azoxybenzene could be undertaken it was important to determine to what extent the reaction was quantitative and what was the nature of side products, if any, under the kinetic conditions. Previous work had shown that azobenzene, an azo-sulfonic acid, aniline, and polymer may all be formed as side products of reaction (4*a*). However, in the single reported study (11*a*) where the conditions were comparable to those planned for the kinetic work, i.e. low azoxybenzene concentrations (ca. 10^{-3} *M*), the yield of *p*-hydroxyazobenzene was found

[2]*The only other report of α–β isomerization under rearrangement conditions is due to Angelli (8) who found that a bisazoxybenzene isomerized as well as rearranged in cold sulfuric acid.*

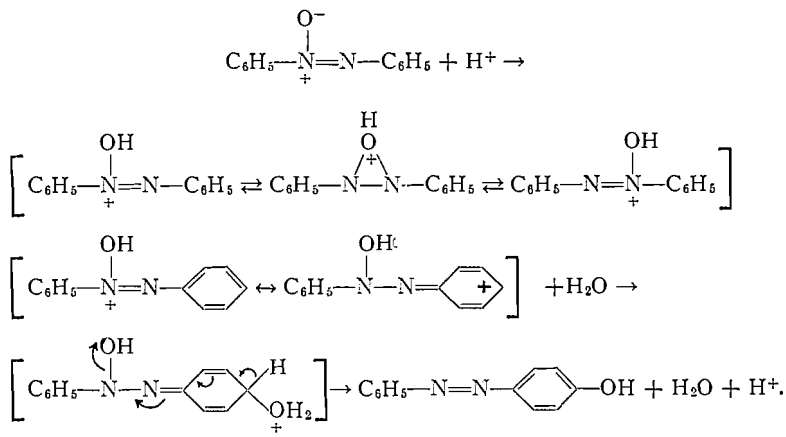

SCHEME 2.

to be quantitative by spectrophotometry and no side products were apparent. In contrast, the earlier work was carried out at much higher azoxybenzene concentrations, from 0.5 *M* to 3 *M*, and often at high temperatures and for long reaction times. Since it thus appeared that the formation of side products may be connected with the reactant concentration and the vigor of the reaction conditions, it was decided to carry out a trial run under favorable reaction conditions.

The data for the run ($1.87 \times 10^{-3}M$ azoxybenzene in 88.22% H_2SO_4 at 25° C) are shown in Table I. The rate of reaction was followed spectrophotometrically (12). Aliquots were removed periodically and quenched in ethanolic aqueous alkali, thus taking advantage of the long-wavelength absorption of the anion of *p*-hydroxyazobenzene (λ_{max} = 435 mμ) compared with azoxybenzene (λ_{max} = 323 mμ), as shown in Fig. 1 and Fig. 2. The spectra of the quenched solutions were both qualitatively and quantitatively identical with that of *p*-hydroxyazobenzene. After eight half-lives the spectra remained constant for several more half-lives. The pseudo-first-order rate constant, calculated from the linear plot of log (O.D.$_\infty$ − O.D.$_t$) at 435 mμ against time, is 5.20×10^{-5} s^{-1}. These results showed that under the kinetic conditions *p*-hydroxyazobenzene is produced quantitatively. However, as the acid concentration was increased it was observed that the absorbance of the "infinity solutions" was greater by a few percent than the calculated value and the absorption maximum was shifted slightly. This result was shown to be due to decomposition of *p*-hydroxyazobenzene. In 96.4% sulfuric acid this decomposition amounted to about 1.5% per half-life of the azoxybenzene reaction. Runs in over 92% sulfuric acid were corrected for this decomposition of *p*-hydroxyazobenzene.

In order to confirm the soundness of the rate data a check was made by another method. Instead of following the rate by a sampling procedure and spectrophotometric measurement of the quenched alkaline solutions, the rate was followed by direct spectrophotometric measurement of the acid solutions in a thermostatted cell of a spectrophotometer. Spectral sweeps were taken at various time intervals over the regions of protonated azoxybenzene (λ_{max} = 390 mμ) and protonated *p*-hydroxyazobenzene (λ_{max} = 463 mμ). The curves exhibited a regular decrease of the 390 mμ absorption and corresponding increase of the 463 mμ absorption, with a single well-defined isosbestic point. Rate constants were calculated both from the disappearance of the azoxybenzene absorption and the development of the *p*-hydroxyazobenzene absorption. The rate constants so obtained

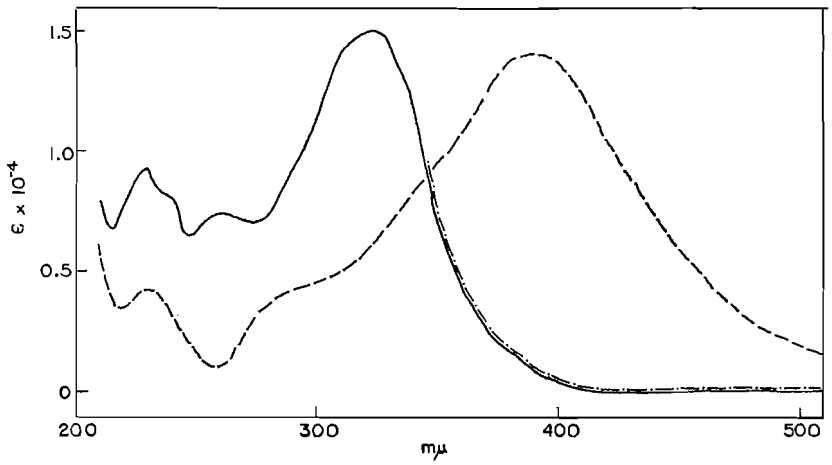

FIG. 1. Spectrum of azoxybenzene in 95% ethanol (—); 90% sulfuric acid (---); aqueous ethanolic alkali (1 *M*) (-·-·).

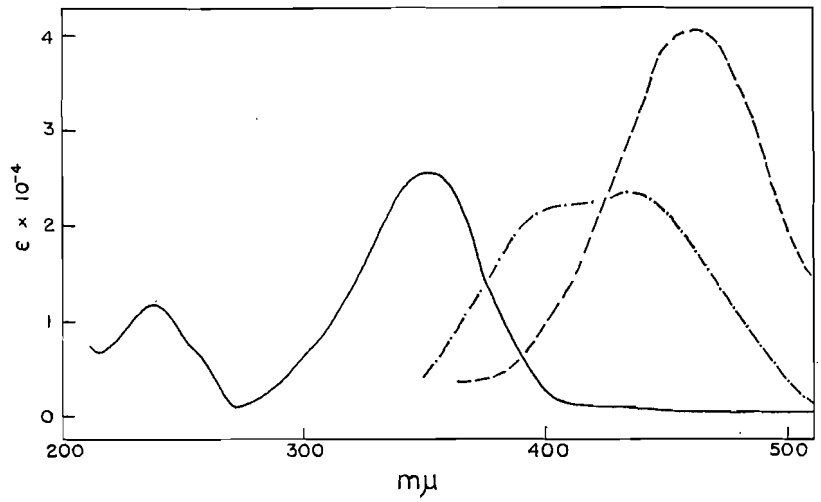

FIG. 2. Spectrum of *p*-hydroxyazobenzene in 95% ethanol (—); 90% sulfuric acid (---); aqueous ethanolic alkali (1 *M*) (-·-·).

were equal within experimental error and also agreed with the value obtained by the quenching method. These results are shown in Fig. 3.

The rate data at 25° and 75° and at various acid concentrations are recorded in Table II. The usual method of measurement was the dilution method. At 75°, some of the rates were determined by a sealed-tube method. The reproducibility of the rate data was about 2% when the same stock solution of sulfuric acid was used and about 10% between two different stock solutions of acid. The larger error in the latter case is evidently caused by the very steep rise in rate constant with acid concentration and the difficulty of reproducing exactly a given acid concentration by ordinary analytical techniques; thus at 95% H_2SO_4 the rate increases by 9% for an increment of 0.1% H_2SO_4 while at 80% H_2SO_4 the corresponding increase in rate constant is 30%.

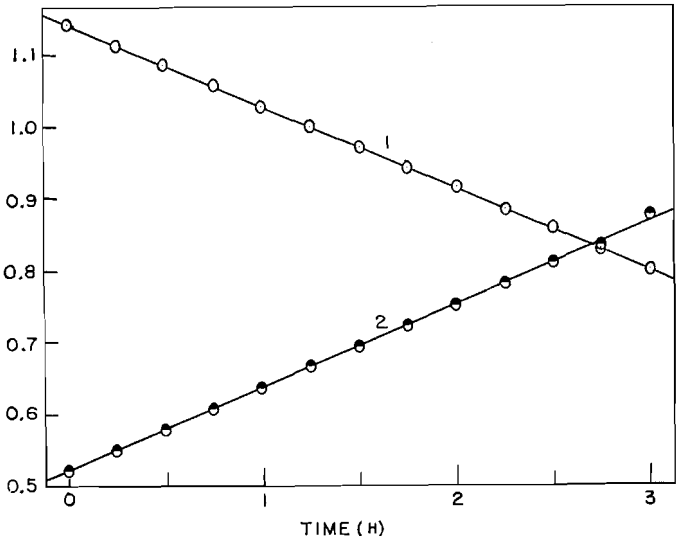

FIG. 3. First-order plots for rearrangement of $3.93 \times 10^{-5} M$ azoxybenzene in 90.37% H_2SO_4 by the "direct" method: (1) $1 + \log (O.D._\infty - O.D._t)$ vs. time, absorbances at 463mμ; (2) $-\log (O.D._t - O.D._\infty)$ vs. time, absorbances at 390 mμ. Rate constant from plot (1), 7.24×10^{-5} s^{-1}, from plot (2), 7.35×10^{-5} s^{-1}.

Product analysis was also carried out, at two acid concentrations, 90.4% H_2SO_4 and 77.5% H_2SO_4, in order to cover most of the range of the kinetic study. The azoxybenzene concentration was about $3 \times 10^{-2} M$. Unexpectedly it was found that the quantity of side products, mainly azobenzene, depended not only on the reaction time, as anticipated from the kinetic work, but also on the manner of isolation of products. The most satisfactory method was slow addition of the acidic reaction mixture to cooled aqueous sodium hydroxide, keeping the temperature below 0°. If during the neutralization the temperature was allowed to reach 50°, the side products increased by several percent. Also the exclusion of light was found to be necessary, both during reaction and work-up.

*Data were obtained by the dilution method unless otherwise stated.
†Direct method.
‡Sealed tube method.

When this precaution was not taken, small amounts of *o*-hydroxyazobenzene were obtained. The reaction at 90.4% H_2SO_4 after 5 half-lives yielded 3% of unchanged azoxybenzene, 1.5% of other neutral material, and 95% of *p*-hydroxyazobenzene. At 77.5% H_2SO_4 after 2.5 half-lives, the corresponding values were 17, 2, and 81% respectively. The product analyses were hence in full agreement with the kinetic data.

pK Determinations

Knowledge of the pK_a of azoxybenzene is essential for the interpretation of the kinetic data, since azoxybenzene is expected to be appreciably protonated in the acid concentrations employed. The pK_a of azoxybenzene in 20% ethanol and 80% sulfuric acid – water mixture was found to be −6.45 by Jaffé and Hahn (11*b*), based on the H_0 scale appropriate for this ethanolic aqueous acid medium (13*a*). Since the present study was carried out in aqueous medium, in which interpretation of rate data is less ambiguous than in mixed solvents (14*a*), determination of the pK_a of azoxybenzene in aqueous sulfuric acid was deemed necessary.

Spectra of azoxybenzene solutions of various sulfuric acid concentrations, covering the complete range of protonation, were recorded. The data, shown in Table III, were treated by the methods of Davis and Geissman (15) and Katritzky, Waring and Yates (16). The two methods gave pK_a values of −5.15 and -5.14 ± 0.05, respectively, rounded off to −5.15.

The Katritzky–Yates procedure also allows one to test whether or not a given substrate undergoes equilibrium protonation in the manner of a true Hammett base (understood to mean a primary aromatic amine (17)). Thus, since $H_0 = pK_a - \log [BH^+]/[B]$, a plot of log $[BH^+]/[B]$ against H_0 should be linear of unit slope, if in fact protonation of the base is governed by H_0. For azoxybenzene the value of this slope, calculated from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ϵ_{383} and ϵ_{323} plots is 0.92 ± 0.10 and 1.01 ± 0.05 respectively. (The error depends directly on the gradient at the inflection point of the sigmoid curves.) It is therefore concluded that, within the error of the present measurements, the protonation of azoxybenzene is in fact governed by the Hammett acidity function H_0.

DISCUSSION

Proposed Mechanism for Wallach Rearrangement

The kinetic data coupled with the pK measurement allow an interpretation of the mechanism of the rearrangement of azoxybenzene. The first deduction, that the reaction is acid catalyzed, is evident from the rapid increase in rate with acid concentration. Further insight on the manner of the acid catalysis is obtained by calculating the extent of monoprotonation of azoxybenzene ($C_{SH^+}/C_S + C_{SH^+}$) in the acid solutions used, from the relationship $\log C_{SH^+}/C_S = pK_a - H_0$. The unexpected result then becomes apparent that azoxybenzene is present almost entirely in the protonated form even in

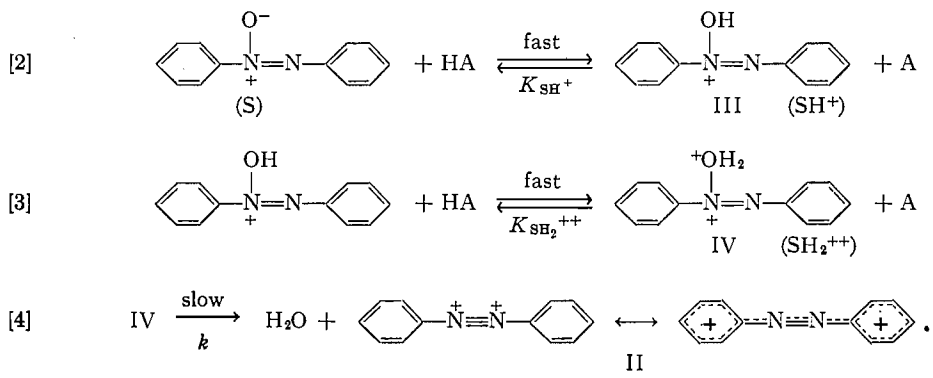
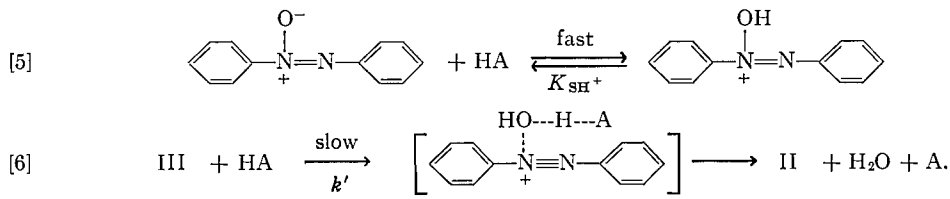
the lowest acid concentrations used, and yet there is a great increase in the rate of reaction with increasing concentration. Thus the data of Table IV show that on increasing the sulfuric acid concentration from 75.3% to 85.6% the protonation changes only from 96.7% to 99.9%, yet the rate constant increases by 140-fold. From 85.6% to 96.4% sulfuric acid the extent of protonation remains virtually constant, but the rate constant increases by another 12-fold over this range.[3] This striking increase in rate constant with acidity while the amount of monoprotonated species remains virtually unchanged can only be explained on the basis that a second proton transfer is involved at some stage of the reaction.

With the knowledge that the transfer of two protons is a necessary feature in the reaction path of the conversion of azoxybenzene to *p*-hydroxyazobenzene (VIII), it is possible to formulate mechanisms which may then be tested by the experimental data. The proposed reaction paths are given in Schemes 3 and 4.

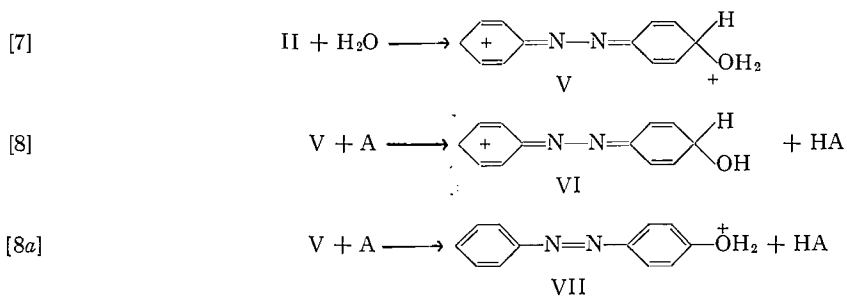


SCHEME 3.



SCHEME 4.

Steps [4] and [6] are followed by [7], [8] or [8*a*], and [9] or [9*a*].



[3] *The degrees of protonation given in Table IV are slightly different from those reported in (1) due to the replacement of the H_0 values compiled by Paul and Long (14a) by the recently measured Jorgenson–Hartter H_0 scale (17). Use of the new H_0 scale has also changed the pK_a of azoxybenzene from −5.10 to −5.15.*

[9] $$VI + A \longrightarrow VIII + HA$$

[9a] $$VII + A \longrightarrow VIII + HA.$$

Scheme 3 begins with a rapid equilibrium protonation of azoxybenzene; the site for the proton has been shown to be the coordinated oxygen (11*b*). (The acid is depicted as HA in order to include all possible species present in the relatively concentrated acid, viz. H_3O^+, H_2SO_4; A is then the conjugate base of HA, which is also depicted without charge.) Next follows a second fast equilibrium protonation, again on the oxygen. The rate-determining step is the loss of a water molecule from the oxonium ion to give the dication (II). Steps [3] and [4] are analogous to the formation of a carbonium ion from an alcohol. Scheme 4 also begins with a rapid equilibrium protonation, but is followed directly by a rate-determining proton transfer to oxygen with simultaneous heterolysis of the nitrogen–oxygen bond. Thus step [6] of Scheme 4 combines step [3] and [4] of Scheme 3. The dication (II), formed by either of the two schemes, would then undergo further reactions as outlined in eq. [7]–[9], which for the present are assumed to be fast steps. According to the classical interpretation of acid-catalyzed reactions, Scheme 3 is the two-proton analogue of the A-1 case while Scheme 4 is similar to the A-S_E2 mechanistic case (14*b*). The following discussion on the correlation of the kinetic data with theoretical derivations will consider both these schemes.

Rate Expressions for Scheme 3

The rate of reaction is given by the Brönsted eq. [10], in which the symbols have their usual significance. Substitution for a_{H^+} is made in terms of h_+ since the second equilibrium protonation is governed by the h_+ acidity function ($h_+ = a_{H^+}f_{C^+}/f_{CH^{++}}$ where C^+ is the reference charged base and CH^{++} its conjugate acid), the resulting expression [11] can then be equated with $k_{obs}\cdot(C_S + C_{SH^+})$ where k_{obs} is the pseudo-first-order rate constant, assuming that there is negligible diprotonation ($C_{SH_2^{++}} \ll C_{SH^+}$) and yields the final rate expression [12].

[10] $$\text{Rate} = \frac{ka_{SH_2^{++}}}{f_{\neq}} = \frac{kC_{SH^+}f_{SH^+}a_{H^+}}{K_{SH_2^{++}}f_{\neq}}$$

[11] $$= \frac{kC_{SH^+}h_+f_{SH^+}f_{CH^{++}}}{K_{SH_2^{++}}f_{\neq}f_{C^+}}$$

[12] $$\log k_{obs} - \log \frac{C_{SH^+}}{C_S + C_{SH^+}} = -H_+ + \log \frac{k}{K_{SH_2^{++}}} + \log \frac{f_{SH^+}f_{CH^{++}}}{f_{\neq}f_{C^+}}.$$

An alternative rate expression can be derived by substitution for a_{H^+} in the expressions for K_{SH^+} and $K_{SH_2^{++}}$ in terms of h_0 and h_+, respectively, followed, as previously, by equating the Brönsted equation with $k_{obs}(C_S + C_{SH^+})$:

$$a_{SH^+} = \frac{a_S h_0 f_{BH^+}}{K_{SH^+}f_B}; \quad a_{SH_2^{++}} = \frac{a_{SH^+}h_+f_{CH^{++}}}{K_{SH_2^{++}}f_{C^+}}$$

$$\text{rate} = \frac{ka_{SH_2^{++}}}{f_{\neq}} = \frac{kC_S h_0 h_+ f_S f_{BH^+} f_{CH^{++}}}{K_{SH^+}K_{SH_2^{++}}f_{\neq}f_B f_{C^+}}$$

[13] $$\log k_{obs} - \log \frac{C_S}{C_S + C_{SH^+}} = -H_0 - H_+ + \log \frac{k}{K_{SH^+}K_{SH_2^{++}}} + \log \frac{f_S f_{BH^+} f_{CH^{++}}}{f_{\neq}f_B f_{C^+}}.$$

In order to test the experimental rate and equilibrium data according to eqs. [12] and [13], knowledge of the acidity function H_+ is required. The presently available measurements show that for the indicator 4-aminoacetophenone over the acid range 75–95%

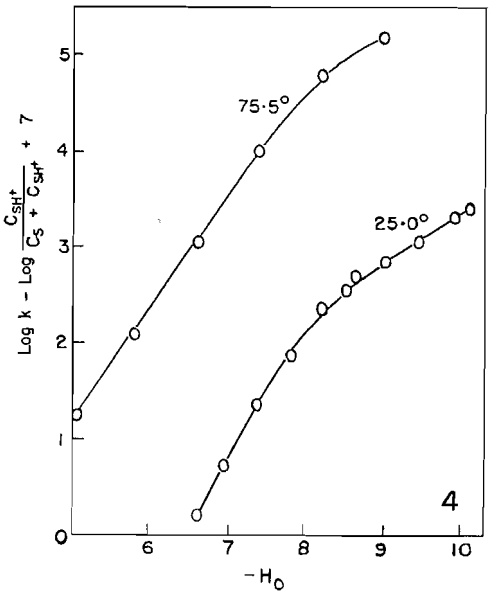

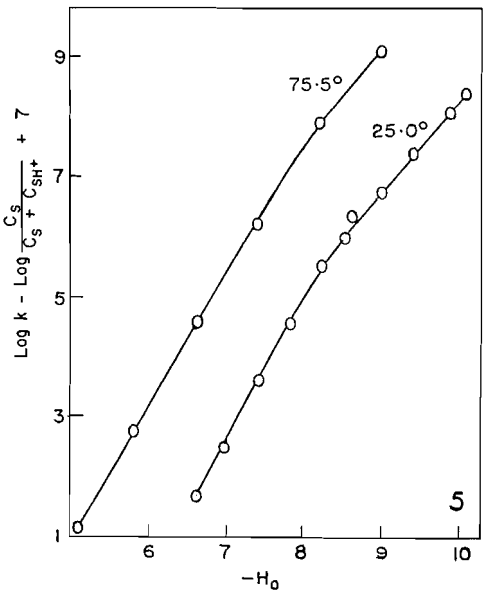

FIG. 4. Plot showing rate dependence based on rate expression [12].
FIG. 5. Plot showing rate dependence based on rate expression [13].

H_2SO_4 H_+ is a parallel function of H_0 (18). Although the generality of this relationship has not been proved, as has not the applicability to this particular system, it has, however, been found to hold in some other studies (19), and hence H_0 will be substituted for H_+ in these tests.[4] Hence the plots of the left sides of eqs. [12] and [13] against H_0 should be linear with slopes of 1 and 2 respectively if the activity coefficient terms are zero or constant. The plots are shown in Figs. 4 and 5 and the appropriate data are contained in Table IV. All the plots are curved downwards and the initial slopes are slightly in excess of the predicted values. Thus the 25° and 75° curves of Fig. 4 have initial slopes of 1.30 and 1.19, while the corresponding curves of Fig. 5 have slopes of 2.32 and 2.17.[5] The assumptions behind these plots must be critically examined. The pairs $C^+ - CH^{++}$ and $SH^+ - T.S.$ have the same charge characteristics and both differ by one proton. The ratios of the activity coefficients should then vary in a parallel manner with acid concentration, i.e. $f_{C^+}/f_{CH^{++}} = f_{SH^+}/f_{\pm}$. In the case of eq. [13], however, the argument concerning cancellation of activity coefficients cannot be made, so that this term would not be expected to cancel, unless fortuitously. Therefore the plot of Fig. 4 according to eq. [12] is considered to be the more sound one theoretically. A possible reason for the deviation from linearity at the higher acid concentrations will be considered later.

Rate Expressions for Scheme 4

Since all acid species present can fulfill the function of HA one should have general acid catalysis. In practice this is difficult to demonstrate in strongly acid solutions (14*b*)

[4]*The parallelism of H_+ and H_0 refers to H_0 values compiled by Long and Paul (14a) and will not be strictly correct when the recently measured Jorgenson–Hartter (17) values are used. However, in view of the scarcity of data on the H_+ function it seems to be desirable to continue assuming this parallelism with the new H_0 function (17) also, even though an error may be introduced. It is also noteworthy that for the medium 20% ethanol – 80% aqueous sulfuric acid H_0 and H_+ are equivalent functions (13b).*

[5]*If the H_0 values at 25° (17) are corrected to 75° using the data of Gelbstein et al. (20) then the 75° slopes become 1.25 and 2.44 respectively. Similarly, if the other plots involving H_0 are so corrected, the slopes of the 75° plots assume values closer to the 25° plots. This would indicate that there is no change in mechanism over this temperature range.*

and hence acidity function correlations are sought. The problem now arises whether to assign the H_2O of H_3O^+ a structural role in the transition state (14*b*). If a transition state free of H_2O is considered then the rate expressions [14] and [15] may be derived.

$$[14] \qquad \log k_{obs} - \log \frac{C_{SH^+}}{C_S + C_{SH^+}} = -H_0 + \log k' + \log \frac{f_{SH^+} f_{BH^+}}{f_{\neq}' f_B}$$

$$[15] \qquad \log k_{obs} - \log \frac{C_S}{C_S + C_{SH^+}} = -2H_0 + \log \frac{k'}{K_{SH^+}} + \log \frac{f_S f_{BH^+}^2}{f_{\neq}' f_B^2}.$$

Except for the activity coefficient terms, these equations are similar to [12] and [13], derived for Scheme 3, and in practice cannot be differentiated from them.

When water is considered to be present in the transition state one may derive eq. [16] and [17] for consideration.

$$[16] \qquad \log k_{obs} - \log \frac{C_{SH^+}}{C_S + C_{SH^+}} = \log C_{HA} + \log k' + \log \frac{f_{SH^+} f_{HA}}{f_{\neq}''}$$

$$[17] \qquad \log k_{obs} - \log \frac{C_S}{C_S + C_{SH^+}} = -H_0 + \log C_{HA} + \log \frac{k'}{K_{SH^+}} + \log \frac{f_S f_{HA} f_{BH^+}}{f_{\neq}'' f_B}.$$

The activity coefficient term in [16] is likely to change uniformly with acid concentration. In fact the $\log k_{obs} - \log (C_{SH^+}/C_S + C_{SH^+})$ vs. $\log C_{H^+}$ plots at 25° and 75° are curved with initial slopes of 27 and 25! No obvious assumption can be made concerning the activity coefficient term in [17]. A plot of $\log k_{obs} - \log (C_S/C_S + C_{SH^+})$ vs. $\log C_{H^+} - H_0$ is closely similar to that in Fig. 5, with initial slopes at 25° and 75° of 2.30 and 2.13 respectively.

In evaluation of the above tests of Schemes 3 and 4 it is apparent that the rate data do not fit exactly any of the derived rate expressions. Hence differentiation between the proposed schemes cannot be made. Also, yet other mechanisms cannot be excluded. In this regard the curvature of the plots provides a clue, since the break in most of the curves occurs very close to the monohydrate composition. A plausible explanation would appear to be that step [7] of the proposed scheme may become rate determining as the water activity decreases, which will become particularly crucial above the monohydrate composition. Alternatively, the curvature could be considered to lend support to Scheme 3. If, as is likely, catalysis by H_2SO_4 is less effective than by H_3O^+, then this decreasing dependence of rate on acidity would be expected, particularly above the monohydrate composition.

The Bunnett Criteria

According to the proposals of Bunnett (21, 22) $\log k_{obs} - \log (C_{SH^+}/C_S + C_{SH^+})$ was plotted (*i*) against $\log a_{H_2O}$ and (*ii*) against $\log C_{H^+} + H_0$. Plot (*i*) is curved; at 25° the initial slope is −2.1 decreasing to −0.5 while at 75° the slopes are −2.8 and −0.8. Plot (*ii*) is also curved; the corresponding slopes at 25° are −1.8 and −0.4 and at 75°, −1.5 and −0.5. Negative slopes in the Bunnett-type plots indicate that water is not involved in the rate-determining transition state, either as nucleophile or as proton-transfer agent. The Bunnett criteria are thus in accord with Scheme 3 but are subject to the qualification that they have not been extensively tested in the high acid regions used in this study and neither is it known whether they would apply to two proton processes. It has also been suggested (22) that curvature in these plots is indicative of more than one competing mechanism.

Activation Parameters

The activation parameters calculated from the rate data at 25° and 75° for the common acid concentrations from 75% to 90% H_2SO_4 are given in Table V. Long *et al.* (23) have proposed that entropies of activation may be used as criteria of mechanism in acid-catalyzed hydrolyses; thus reactions proceeding by the A-1 mechanism have in general $\Delta S^{\ddagger}$ values between 0 and +20, while A-2 reactions have $\Delta S^{\ddagger}$ values between −10 and −30. The $\Delta S^{\ddagger}$ values for azoxybenzene rearrangement fall somewhere in between the two ranges. However, most of the literature data refer to very dilute acid solutions, in contrast to the present work. The data (Table V) show a trend, that $\Delta S^{\ddagger}$ becomes more positive as the acid concentration decreases, so that a positive $\Delta S^{\ddagger}$ might well result in dilute acid solution. This would then be in accord with the A-1 mechanism of Scheme 3, though it is not known whether the entropy criterion would apply to two-proton processes.

TABLE V

Activation parameters for azoxybenzene rearrangement

% H_2SO_4	90.37	85.61	80.15	75.30
E_a(kcal)	22.1±0.2	22.7±0.2	24.7±0.3	26.8±0.5
Log A	12.08	12.03	12.47	12.86
$\Delta S^{\ddagger}$ (e.u.)	−5.3±0.5	−5.5±0.5	−3.5±0.9	−1.7±1.5

It was also hoped that the high temperature data might provide an indication of a competing mechanism proposed in the past (7, 9). The close similarity of the various curves at the two temperatures suggest that there is no change in reaction mechanism on increasing the temperature from 25° to 75°.[5]

Discussion of Previous Mechanisms of the Wallach Rearrangement

Shemyakin *et al.* (5) proposed that the Wallach rearrangement proceeds by way of the N,N-oxide intermediate as a means of explaining the equalization of the nitrogen label on rearrangement. As evidence of this intermediate, the Russian workers cited the formation of 50%–60% azobenzene when the rearrangement was carried out in chlorosulfonic acid in presence of potassium iodide (6). However, that chlorosulfonic acid may act in an anomalous manner is indicated by the finding that 4,4′-dichloro- and 4,4′-dibromoazoxybenzene in chlorosulfonic acid yielded only the corresponding azobenzenes (24), whereas in sulfuric acid the former yielded some 2-hydroxy-4,4′-dichloroazobenzene in addition to the azobenzene (4*b*). In view of the complex situation with respect to side products (4) under usual preparative conditions, a more extensive study of the effect of added iodide on the rearrangement of a number of azoxybenzenes, both in sulfuric acid and in chlorosulfonic acid, is required for such evidence to be decisive. It is doubtful that the role of the α-β isomerization in the scheme of the Wallach rearrangement can be considered as known in the absence of further tracer as well as kinetic studies.

The interpretation of Shemyakin *et al.* (5, 6) suffers from the disadvantage that it does not consider the participation of acid, even though the reaction is clearly acid catalyzed. The basic difficulty with the N,N-oxide intermediate is that it appears not to provide a path for further reaction on the basis of the theories of acid catalysis. Oae *et al.* (9) consider the protonated N,N-oxide to be intermediate in the interconversion of α- and β-isomers but not in the Wallach rearrangement. The difficulty now becomes that in order to explain the lack of equalization of label in the recovered azoxybenzene one has to postulate that protonation of azoxybenzene is not reversible, as shown in Scheme 2,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

a situation which is not likely to obtain in view of the present equilibrium (pK) studies. Further, our data show that monoprotonated azoxybenzene is not the rate-limiting species, as is suggested by Scheme 2.

In conclusion it should be stated that the present work has not provided proof of the dication intermediate (II), although it is fully in accord with this intermediate. Definitive evidence may perhaps be found through kinetic and other physical studies, now in progress, in anhydrous acids where it is possible that (II) might become stabilized.

EXPERIMENTAL

Materials

Recrystallizations were carried out in the dark to exclude the possibility of *cis–trans* isomerization, and in the case of azoxybenzene the occurrence of the ortho-Wallach rearrangement. Ultraviolet and visible spectra were determined on a Beckmann DK1 recording spectrophotometer using 1 cm quartz cells. Commercial 95% ethanol was fractionally distilled using a Dufton column and the fraction boiling at 78.2 °C was collected. The following compounds were recrystallized at least twice from aqueous ethanol and their ultraviolet and visible spectra in 95% ethanol determined: *trans*-azoxybenzene, m.p. 35–36° (lit. (11*a*) m.p. 35°), log ϵ_{max} 4.17 (322 mμ), 3.87 (260 mμ), 3.95 (232 mμ) (lit. (25) log ϵ_{max} 4.16 (323 mμ), 3.85 (260 mμ), 3.92 (231 mμ)); *p*-hydroxyazobenzene; m p. 153–154° (lit. (26) m.p. 155–156°) log ϵ_{max} 4.40 (349 mμ) (lit. (27) log ϵ_{max} 4.39 (348 mμ)); *trans*-azobenzene; m.p. 67.5–68.5° (lit. (28) m.p. 68–69.5°); *o*-Hydroxyazobenzene was prepared by irradiating a 4% solution of azoxybenzene in 95% ethanol for 3 h using a Hanovia high pressure mercury lamp with a quartz insert. The product had m.p. 83–84° (lit. (29*a*) m.p. 82.5–83.5°), log ϵ_{max} 4.26 (323 mμ) (lit. (29*b*) log ϵ_{max} 4.26 (323 mμ).

Fisher C.P. Reagent grade sulfuric acid was used throughout this study. Concentrations were determined by titrating weighed samples with standard sodium hydroxide. The aqueous sulfuric acid solutions used for both the kinetic measurements and the pK studies were prepared by dilution by weight of a stock solution of known concentration. All concentrations of sulfuric acid are percent by weight.

Product Analysis

Azoxybenzene (1.2 g) was dissolved in 200 ml of 77.5% sulfuric acid contained in a stoppered, aluminium foil covered flask. The reaction was carried out for 1 000 h at room temperature, equivalent to 2.5–3.0 half-lives. The reaction mixture was then added slowly to a solution of 250 g of sodium hydroxide in 250 g of water cooled in ice–methanol. The temperature of the neutralization process was never allowed to rise above 0 °C. By a series of ether extractions from acidic and basic solutions, the products of the rearrangement and unreacted azoxybenzene were separated into neutral, basic, and acidic fractions which were then analyzed qualitatively by thin-layer chromatography, using 35–60° petroleum ether and benzene–methanol (10:1) as developers, and quantitatively by ultraviolet and visible spectroscopy.

A second rearrangement was similarly carried out by dissolving 1 g of azoxybenzene in 200 ml of 90.4% sulfuric acid. After 12.5 h at 25 °C, equivalent to 5 half-lives the reaction mixture was worked up as previously.

Kinetic Procedures

Dilution Method

The reaction solution was prepared by adding a 0.01 g accurately weighed sample of azoxybenzene to 25 ml of aqueous sulfuric acid of known concentration in a 50 ml round bottom glass stoppered flask wrapped in aluminium foil and immersed in the thermostatted bath. Samples were removed at regular intervals using a 1 ml fast delivery calibrated pipette and run into 40 ml of quenching solution, which had been precooled in ice–water, in a 50 ml graduated flask. The flasks were stored in the dark and after attaining room temperature were made up to mark with quenching solution and analyzed spectrophotometrically. Rate constants were calculated from absorbances at 435 mμ, the wavelength corresponding to maximum absorption of *p*-hydroxyazobenzene in the quenching solution, 1 M NaOH in 80% aqueous ethanol (ϵ = 22 830).

Sealed Tube Method at 75.5°

The reaction solution was prepared as for the dilution method except that 0.005 g of azoxybenzene was used. Two milliliter samples were pipetted into small tubes which were sealed, wrapped in foil, and placed in the thermostatted oil bath at 75.5 °C. The tubes were removed at intervals, cooled, and stored in a refrigerator. On completion of the run the contents were added to quenching solution, made up to 50 ml, and analyzed as previously. Studies on the decomposition of *p*-hydroxyazobenzene in aqueous sulfuric acid, where required, were carried out under the same conditions as the kinetic measurements.

Direct Method at 25 °C

The reaction solution was prepared by successive dilution: a 1 ml portion of a solution of 0.01 g azoxybenzene in 50 ml sulfuric acid was further diluted to 50 ml using sulfuric acid of the same concentration. This solution was placed in the thermostatted sample cell. Aqueous sulfuric acid of the same concentration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

as the reaction solution was used in the reference cell. The spectrum of the reaction solution was recorded at regular time intervals from 500 mμ to 375 mμ.

pK Determination

A 1 ml sample of a 2×10^{-3} *M* solution of azoxybenzene in 95% ethanol was pipetted into a 50 ml flask and the solvent evaporated with a slow stream of dry nitrogen. Aqueous sulfuric acid (25 ml) of known concentration was added and the flask was agitated vigorously to ensure dissolution of the azoxybenzene. The spectrum of each solution was recorded over the range 300–500 mμ. For the 85, 90, and 95% sulfuric acid solutions, in which the rearrangement is relatively fast, the spectra were recorded at regular time intervals and extrapolated to zero time. In the case of the 85 and 90% sulfuric acid solutions, the extrapolated values did not differ by more than 5% from the first recorded values. In the case of the 95% sulfuric acid the difference was 12%. The results are shown in Table III.

AN ELECTRON SPIN RESONANCE STUDY OF TRAPPED ELECTRONS FORMED AT 77.5 °K BY GAMMA IRRADIATION OF AN ORGANIC GLASS[1]

D. R. SMITH AND J. J. PIERONI

Research Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received November 26, 1964

ABSTRACT

2-Methyltetrahydrofuran (MTHF) traps electrons and free radicals or radical-ions when irradiated with ^{60}Co gamma rays at 77.5 °K. The e.s.r. difference spectrum technique has been used to determine the microwave saturation properties and line shape parameters of the absorption due to "trapped" electrons. These measurements support the postulate that physically trapped electrons are present and indicate that trapped electrons and free radicals or radical-ions exist in local concentrations which are considerably greater than their average concentration in the sample. It is concluded that they are trapped in clusters. A study of the thermal decay of the trapped electrons supports the cluster model.

INTRODUCTION

Hamill and co-workers (1) have irradiated 2-methyltetrahydrofuran (MTHF) at 77 °K and observed a broad optical absorption band with a maximum at about 13 000 Å. This absorption band could be removed by photobleaching. Salmon (2) observed that both the near infrared optical absorption band and an electron spin resonance (e.s.r.) singlet could be photobleached with visible light and each disappeared fairly rapidly at 90 °K, suggesting that both are due to the same species.

When certain aromatic solutes are dissolved in MTHF, gamma radiolysis yields the optical absorption spectrum of the solute anion and the 13 000 Å band is diminished or eliminated depending on the solute concentration. If the solute concentration is such that both the solute anion spectrum and the 13 000 Å are observed, photochemical bleaching with light of wavelength greater than 6 000 Å removes the 13 000 Å band and enhances the intensity of the anion optical spectrum (1). These results suggest that solute anions are formed during bleaching by the capture of electrons and that the 13 000 Å band is due to solvated or trapped electrons. This identification is supported by the fact that in solutions of alkali metals in ammonia or amines, the "solvated electron" has a strong optical absorption band in the near infrared wavelength region (3).

The work of Hamill *et al.* provides strong evidence for the possibility that after ionization of a molecule, an electron and its parent ion can remain apart and can make significant contributions to the chemical reactions which occur as a result of subjecting solid organic material to ionizing radiation. In view of this, it was decided to attempt a closer examination of the nature of the solvated or trapped electron. With such a purpose in mind a study of microwave saturation properties and e.s.r. line shape parameters of paramagnetic species can be profitable. Such a study can yield information concerning magnetic interactions with other magnetic moments such as those due to hydrogen nuclei, or unpaired electrons, and can also lead to values for T_1 and T_2. A knowledge of T_1 enables one to ensure that a spectrum is being observed under slow passage conditions. This is a prerequisite for measurement of a true saturation curve. For convenience we shall henceforth refer to the solvated or trapped electron in MTHF as the trapped electron without implying anything regarding its nature.

A study of the kinetics of the thermal disappearance of trapped electrons in MTHF has also been carried out in an effort to gain more information concerning their spatial distribution.

THEORY

The reader is referred to Ingram's book (4) for a basic discussion of microwave saturation, T_1, T_2, etc.

Portis (5) and Castner (6) have provided a thorough description of line broadening associated with saturation phenomena. Saturation behavior depends on the mechanism of line broadening. Portis describes various phenomena which give rise to "homogeneous" and "inhomogeneous" line broadening. We shall only refer to those which concern this work. The homogeneous case can arise from dipolar interaction between unpaired electrons. The energy absorbed from the microwave field is distributed to all the electron spins and thermal equilibrium of the spin system is maintained. The inhomogeneous case occurs when the line width arises from variations (slow compared to the time for a spin transition) in the local magnetic field. Energy is transferred only to those spins whose local fields satisfy the conditions for resonance. Portis introduces the concept of "spin packets" which have very little interaction with each other and whose width is determined by the electron–electron spin–spin interaction. The observed response of the spin system will be a superposition of the spin packet absorptions. In other words a spin packet is a group of magnetically interacting unpaired electrons which see similar local fields due to nuclear magnetic moments. Each spin packet sees a slightly different local field and hence each absorbs at a slightly different value of H_z. The observed spectrum is the envelope of the spin packet absorptions and the shape of the envelope is the intensity distribution of the magnetic fields due to the magnetic moments of nearby nuclei (assuming no significant inhomogeneity in the external d-c. field H_z). To summarize, when pure homogeneous broadening occurs one observes the absorption due to a spin packet; when inhomogeneous broadening occurs one observes a line envelope due to superimposed spin packets. In the former case a plot of absorption intensity (V_R) vs. microwave field intensity (H_1) rises to a maximum and then decreases fairly rapidly. At the same time the absorption line appears to become wider (this is called "saturation broadening"). In the latter case, V_R increases to a maximum and then decreases so slowly that it often appears to have levelled off. The line width remains unchanged (i.e. no "saturation broadening" occurs). There are of course intermediate cases which reflect the ratio of the spin packet width to the envelope width.

The theory which Portis (5) has derived for saturation of an inhomogeneously broadened line assumes that the spin packet width is negligible compared to the line envelope width. Castner (6) has extended this theory to yield a general expression for the absorption component of the magnetic susceptibility χ'' without assuming that the spin packet width is small compared to the line envelope width. Two frequency distributions are used to describe a line; $g(\omega - \omega')$ is the assumed Lorentzian line shape function of the individual homogeneously broadened spin packet, $h(\omega - \omega_0)$ is the observed Gaussian distribution of static fields describing the envelope of the distribution of spin packets. Castner defines $A = \Delta\omega_L/\Delta\omega_G$ where $\Delta\omega_L$ is one half the frequency width for half maximum of $g(\omega - \omega')$ and $\Delta\omega_G$ is the width of the inhomogeneously broadened envelope $h(\omega - \omega_0)$. The line envelope width (ΔH_{pp}) between derivative maxima, in gauss (G), is given by $\sqrt{2}\Delta\omega_G/\gamma$. γ is the gyromagnetic ratio and has a value of 1.76×10^7 s^{-1} G^{-1}.

A saturation curve is a plot of V_R (height of absorption signal at ω_0) vs. microwave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

field (H_1) or (microwave power)$^{1/2}$. Castner has plotted calculated saturation curves for various values of A. The value of A applicable to the experimental curve is determined by a curve-fitting procedure which Castner has outlined. $\Delta\omega_L$ is then calculated from $\Delta\omega_G$ and A. The equation $\Delta\omega_L T_2 = 1$ is used to obtained T_2.

$\Delta\omega_L$ is the spin packet half width at half maximum due to spin–spin dipolar interaction between unpaired electrons. In MTHF this would include both trapped electrons and unpaired electrons on free radicals. ΔH, the spin packet full width at half maximum in G, has been related to the molarity, M, of unpaired electrons by Smith and Wyard (7) who determined eq. [1] experimentally. After determining ΔH_{pp} and A, ΔH is obtained from eq. [2*a*] or [2*b*].

$$\Delta H = (60 \pm 30)M \qquad [1]$$

$$\Delta H = 2\Delta\omega_L/\gamma \qquad [2a]$$

$$\Delta H = \sqrt{2}A\Delta H_{pp}. \qquad [2b]$$

Again using curve-fitting techniques, Castner shows how to find the value of the microwave field H_1 at which eq. [3] applies.

$$H_1 = (1/\gamma)(T_1T_2)^{1/2}. \qquad [3]$$

Hence T_1 is calculated from H_1 and T_2.

EXPERIMENTAL

Samples were irradiated at liquid nitrogen temperature by gamma rays from ^{60}Co. The irradiation dose rate, obtained by ferrous sulfate dosimetry (11), was calculated to be 6.2×10^{18} eV l^{-1} s^{-1} in MTHF using a measured density of 1.06 g ml^{-1} for MTHF at 77.5 °K.

Spectra were obtained using the e.s.r. difference spectrum technique. This technique and the procedure for the preparation and handling of MTHF samples have been described previously (8). The scan rate was calibrated using the major hyperfine splitting of the tetracene positive ion (9). The total concentration of radicals and trapped electrons was determined by comparison of their doubly integrated e.s.r. spectrum with that of a free radical reference. Both samples were present in the dual cavity at the same time and both were at 77.5 °K. Their spectra were obtained consecutively without retuning the spectrometer. The reference was the stable free radical in nuclear reactor irradiated terphenyl coolant which had been stored at room temperature for 3 years. This was calibrated by the same procedure at room temperature by comparison with a solution of DPPH in CCl_4. The DPPH solution was calibrated by its optical absorption using an extinction coefficient $\epsilon = 1.31 \times 10^4$ l mole^{-1} cm^{-2} at 5 200 Å (10). The methods for cavity Q and cavity input power measurements were the same as those used by Castner (6).

It was found that 20 cycle modulation frequency and 2.0 G modulation amplitude ($\omega_m H_m = 250$) satisfied the slow passage requirement. To compensate for the lower spectrometer sensitivity at 20 cycle modulation frequency, the signal to noise ratio was increased by using the less "noisy" sample-cooling method of passing a flow of gaseous nitrogen through a coil at 77.5 °K and then over the sample tubes. The silica vacuum-jacketed cavity insert used for this purpose is shown in Fig. 1. The cooled nitrogen is passed through two vacuum-jacketed arms which are inserted into the two cavity sample positions. The unbleached sample is placed inside one arm and the bleached sample in the other. A copper–constantan thermocouple, calibrated against a N.B.S. Standard platinum resistance thermometer was placed in one arm at the top of the resonant cavity volume, i.e. about 0.25 in. above that part of the sample volume which generates most of the e.s.r. signal. If any error in determining the sample temperature occurs by this procedure, the temperature measured should be too high. Since our liquid nitrogen was at 77.5 °K (slightly contaminated by oxygen) and the temperature indicated by the thermocouple was 81 °K, the error must be less than 3.5 deg. The e.s.r. singlet, attributed to trapped electrons, was found to be stable for the duration of the experiment at this temperature. When results were obtained at 77.5 °K, the apparatus previously described (8) was used.

The spectroscopic g-values were measured by placing solid DPPH whose $g = 2.0036$ (4) in one cavity position and the unknown in the other cavity position. The magnetic field at which resonance for both DPPH and the unknown occurred was measured with a proton resonance gaussmeter.

RESULTS

(1) Difference Spectra

Figure 2*a* is the e.s.r. spectrum of unbleached MTHF which had been gamma irradiated for 90 min. Figure 2*b* is the spectrum of another sample of matched dimensions which

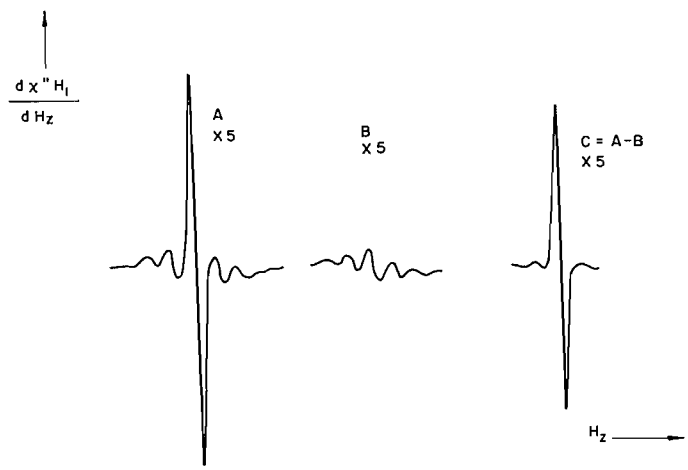

FIG. 2. First derivative e.s.r. spectra of gamma-irradiated MTHF. (A) unbleached, (B) photochemically bleached, (C) difference between A and B.

had also been gamma irradiated for 90 min, and bleached by visible light and was present in the dual cavity at the same time as the unbleached sample. Figure 2*c* is the difference between 2*a* and 2*b* obtained by the technique of measuring e.s.r. difference spectra described earlier (8). Figure 3 is the same as Fig. 2 but the spectra were measured at 10 times greater sensitivity. A, B, and C in Figs. 2 and 3 were obtained by consecutive scans, without retuning the spectrometer, at 77.5 °K. Figures 2*c* and 3*c* demonstrate that the singlet and about one-third of the intensity of the septet disappear during photobleaching. Consequently, to obtain the pure e.s.r. singlet due to trapped electrons, using the e.s.r. difference spectrum technique, the sample to be bleached was irradiated for 90 min and compared to a sample irradiated for 60 min, which remained unbleached (Results, section 2*a* and Fig. 4).

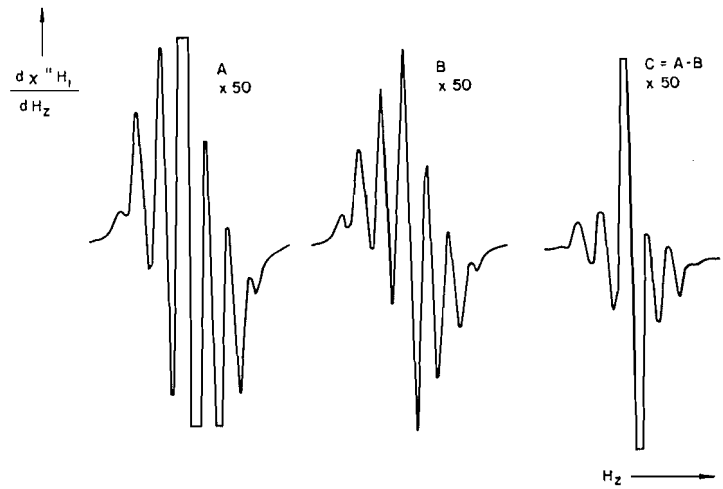

FIG. 3. Same as Fig. 2 but these spectra were obtained using a 10 times greater sensitivity.

The septet spectrum has a 20.5 G average hyperfine splitting and linewidths of about 10 G between derivative maxima. The integrated lines have relative intensities roughly equal to 1:3.9:6.7:8.2:6.7:3.9:1.

(2a) Line Shape and Width

The first derivative difference spectrum due to trapped electrons is shown in Fig. 4. The points represent calculated Gaussian and Lorentzian line shapes normalized to the maximum of the experimental line. The experimental line appears to be nearly Gaussian with a width between derivative maxima of 4.5 G. This spectrum was obtained at 77.5 °K using 100 kc/s modulation frequency and 1 G modulation amplitude. No fast passage distortion occurred because at the low value of H_1 (4.8×10^{-3} G) used no detectable saturation was occurring. Fast passage effects only occur when the signal is at least partly saturated.

(2b) g-Values

To obtain g for the trapped or solvated electron an unbleached sample was examined using $H_1 = 2.9 \times 10^{-3}$ G. At this low microwave intensity, the difference in saturation behavior between the radical or radical-ion and the electron (see Results, section 3) enabled observation of the electron singlet with little interference from the septet. Values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

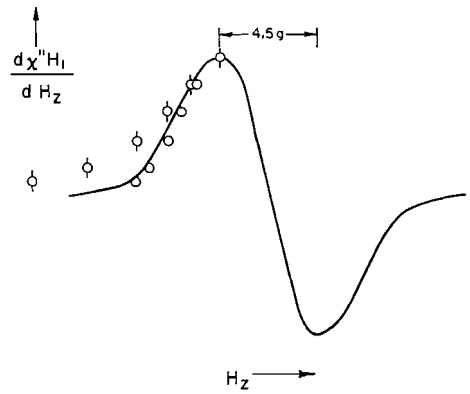

FIG. 4. The line is the first derivative e.s.r. spectrum of trapped electrons in MTHF. The points are calculated Gaussian (O) and Lorentzian (-O-) line shapes normalized to the observed derivative maximum.

of g for the radical or radical-ion were determined with a photochemically bleached sample. Both g-values were found to equal 2.003 ± 0.001 relative to $g = 2.0036$ for DPPH.

(3) Saturation Curve

Figure 5 is a plot of V_R vs. H_1 at 81 °K for trapped electrons and free radicals in MTHF. Both plots have been normalized to the maximum signal height. The line shape and width did not change in the range of H_1 used so V_R was taken to be proportional to the amplitude of the first derivative absorption signal. For the free radical, the central line intensity was measured.

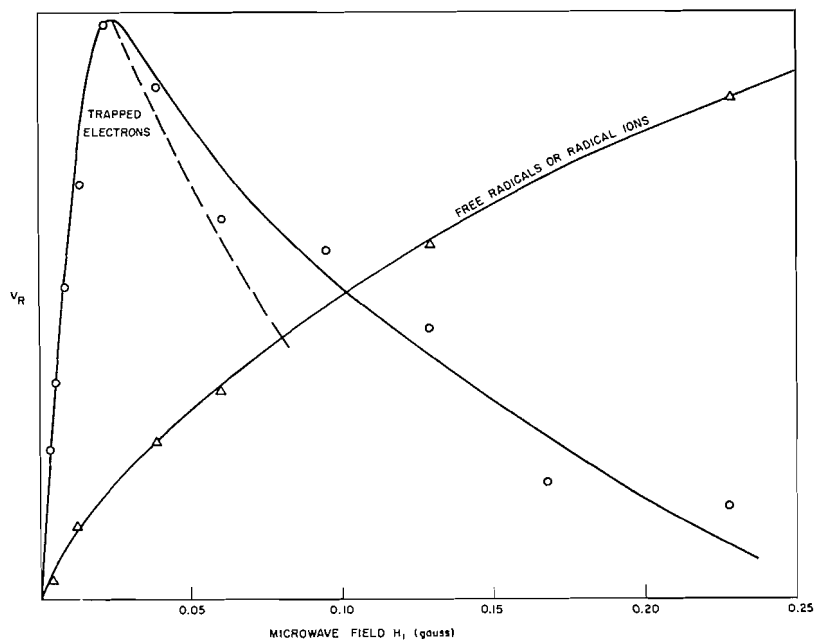

FIG. 5. Microwave saturation curves; O electrons and △ radicals or radical ions trapped in MTHF at 81 °K. ---- Theoretical for pure homogeneous broadening. Irradiation dose equals 2.25×10^{19} eV ml^{-1}.

For personal use only.

(4) Thermal Decay Curves at 77.5 °K

At 77.5 °K using 100 kc modulation frequency and $H_1 = 4.8 \times 10^{-3}$ G, the signal intensity was followed as a function of time after irradiation. Since, at the low value of H_1 used, the septet intensity was negligible, accuracy was improved by observing an unbleached MTHF sample in one cavity position and a stable reference free radical sample in the other cavity position. The reference was used to monitor fluctuations in the spectrometer sensitivity. The septet intensity decreases somewhat during the thermal disppearance of trapped electrons, in fact, the observations seem analogous to those obtained by photobleaching. In this experiment, the small contribution by the septet to the intensity of the trapped electron singlet was graphically estimated and subtracted. Three radiation doses were used and the resulting decay curves are shown in Fig. 6. The normalized curves are fairly well superimposed as shown in Fig. 7. After an initially more rapid decay for about 50 h, the trapped electron concentration decayed more slowly and linearly. The data did not fit either first or second order kinetic plots.

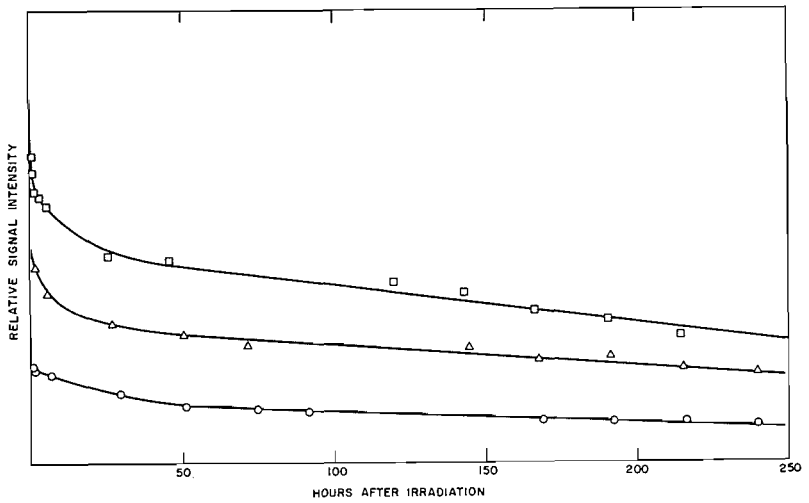

FIG. 6. Thermal decay of electrons trapped in MTHF at 77.5 °K. Irradiation dose equals ○ 9.8×10^{18} eV ml^{-1}, △ 1.74×10^{19} eV ml^{-1}, □ 3.43×10^{19} eV ml^{-1}.

(5) Thermal Decay at Temperatures Greater than 77.5 °K

These data suffice only to demonstrate the temperature at which trapped electrons or free radicals disappear rapidly, i.e. in 10–20 min. Small temperature increments were used but the sample was only kept for about 5 min at each temperature. The data were obtained as a graph of concentration vs. time. Figure 8 is a plot of the slope of this graph vs. the temperature at the point of measurement. It is seen that 92 to 95 °K is a very critical temperature range for the disappearance of trapped electrons. At the same time, the intensity of the septet decreased by roughly one-third. The remaining septet intensity remained stable up to 100 °K and disappeared in 5 min at 101 °K. In another sample, from which the trapped electrons had been bleached, the remaining free radicals or radical-ions did not disappear rapidly until 101 °K.

DISCUSSION AND CONCLUSIONS

(1) The Nature of the "Trapped Electron"

As discussed in the introduction, the e.s.r. singlet has been attributed to trapped

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

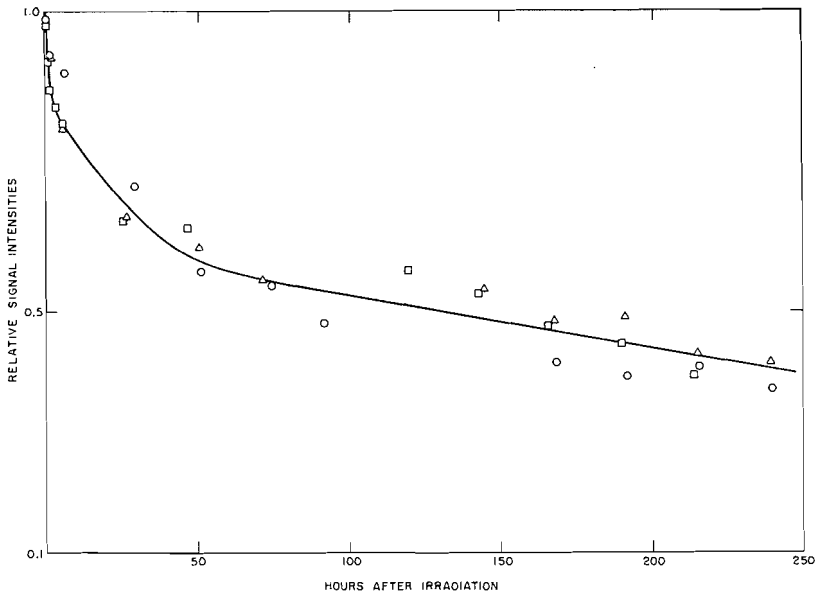

FIG. 7. The data of Fig. 6 normalized to unity. The symbols refer to the same irradiation doses as in Fig. 6.

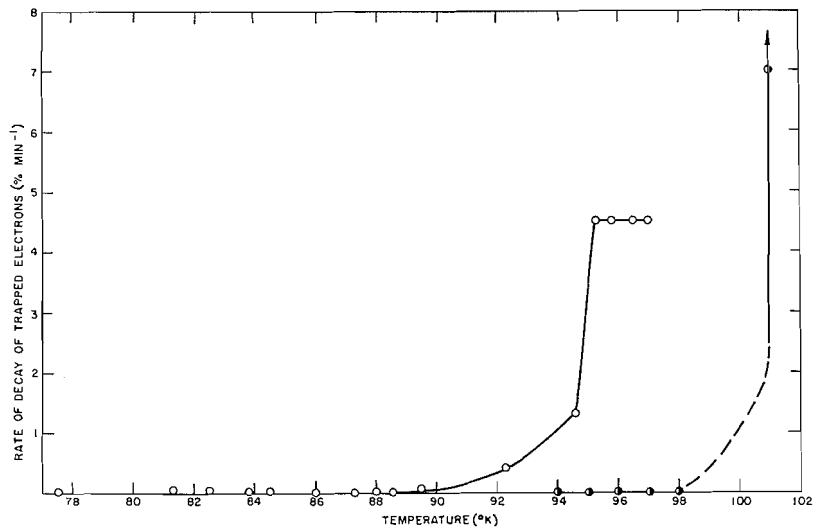

FIG. 8. MTHF irradiated to a dose of 4.5×10^{19} eV ml^{-1}. Approximate rate of thermal decay vs. temperature. ○ Trapped electrons, ◑ free radicals or radical-ions remaining after thermal or photochemical reaction of the trapped electrons.

electrons. This identification is supported by the e.s.r. line width and the microwave saturation measurements.

The e.s.r. singlet due to trapped electrons is essentially gaussian in shape and no saturation broadening occurs (the line width is independent of H_1) in the range of H_1 studied. This agrees with the theoretical picture of a line which is inhomogeneously broadened by either isotropic or anisotropic proton hyperfine interaction. The magnetic

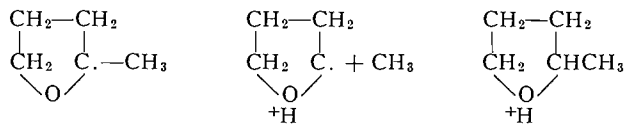
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

interaction by protons has an intensity distribution which is approximately gaussian. The 4.5 G line width is unusually narrow compared to that observed in a hydrocarbon radical under the same conditions. In organic radicals trapped in a glassy or polycrystalline matrix at low temperature, an isotropic proton interaction of 20–40 G and a proton dipolar broadening interaction of 10 G are common. This shows that the trapped electron is experiencing weaker magnetic interactions due to protons than does an electron on a free radical.

The observed saturation curve for the septet absorption is a typical example (15) of a saturation curve for a hydrocarbon radical in a solid matrix whose e.s.r. lines exhibit considerable inhomogeneous broadening due to anisotropic proton hyperfine interaction, i.e. $\Delta\omega_L/\Delta\omega_G$ is fairly small. Comparison of the trapped electron saturation curve with that for the septet absorption confirms that the absorption due to trapped electrons is experiencing less inhomogeneous broadening than does the absorption due to an electron on a free radical. It is concluded that in MTHF the spin density of a trapped electron at any proton is less and its distance from any proton is greater than are the same parameters for an unpaired electron on a free radical. In other words the trapped electron orbital is relatively independent of molecular orbitals and it may be expected to behave as an independent chemical species. This is support, from physical measurements, of the conclusions reached by Hamill and co-workers (1) on the basis of chemical and optical absorption measurements.

(2) The Location of the Postitive Charge

The septet e.s.r. spectrum is interpreted as being due to one or both of the species I and II.



I II III

The three methyl protons and one of the beta CH_2 protons give a 20.5 G hyperfine splitting while the other beta CH_2 proton gives a 41 G hyperfine splitting. This would yield a septet with the observed splittings and with relative intensities of 1:4:7:8:7:4:1. Species I agrees with the interpretation of Dainton and co-workers (12).

The septet line splitting of 20.5 G is typical of the isotropic hyperfine splittings observed in saturated aliphatic radicals. The 10 G line width is typical of the e.s.r. spectra of saturated aliphatic radicals (at liquid nitrogen temperature) whose isotropic hyperfine structure is partly due to a rotating methyl group. This rotation somewhat reduces, by averaging, the anisotropic line broadening due to the methyl protons (14).

The ratio of the yield of trapped electrons to that of the species giving the septet absorption is 0.88 ± 0.04 (13). Therefore there is a positively charged species in the sample whose yield is nearly equivalent to that of the species represented by the septet. Dainton and co-workers suggest that the positive charge resides on a nearby solvent molecule (species III) but species II cannot be excluded because, by analogy with the $CH_3\dot{C}HOH$ radical, its e.s.r. spectrum should be the same as that of I. We found the spectra of $CH_3\dot{C}HOH$ and $CH_3\dot{C}HOD$ to be the same in C_2H_5OH and C_2H_5OD which had been gamma irradiated at liquid nitrogen temperature. Thus the hydroxyl hydrogen in the $CH_3\dot{C}HOH$ radical has little effect on its e.s.r. spectrum. Furthermore, formation of II compared to III involves less motion of a proton. There must be a limit to proton mobility, above which reaction with trapped electrons occurs. This should enhance the yield of I relative to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the yield of trapped electrons. Our yield ratio suggests that this occurs to a small extent.

The average energy absorbed per ion pair formed in organic gases is usually 25–30 eV and should be similar in solids. Consequently, assuming the absence of energy transfer effects the maximum possible yield of positive or negative species is about three per 100 eV compared to the observed yields, measured by e.s.r., $G(e) = 2.6$ and $G(I \text{ or } II) = 3.0$ (13).* Thus the magnitude and near equivalence of $G(e)$ and $G(I \text{ or } II)$ indicate nearly total efficiency of charge separation after the initial ionization of an MTHF molecule. This suggests little or no proton motion and favors species II as the site of the positive charge.

The yields and reactions of the species formed in irradiated MTHF will be discussed in a later paper.

(3) The Nature of the Electron Trap

The results indicate that the electrons are trapped as a separate chemical entity and should not be considered similar to an unpaired electron on a free radical. There are two clues regarding the nature of the trap. The first is that in the radiolysis of hydrocarbons, trapped electrons have only been observed in systems which form a glass at low temperatures. The second clue comes from some results in ethanol and methanol where broadening of the trapped electron e.s.r. line (identified by Chachaty and Hayon (16)) by electron–proton dipolar interaction is about three times as great as in MTHF. Zeldes and Livingston (17) have shown by deuterium substitution that the major interaction is with the hydroxyl hydrogen nucleus. In other words the trapped electrons are primarily surrounded by alcohol molecules which are oriented so that their hydroxyl group points at the electron. By analogy the electron in MTHF may be trapped in a field of oriented molecular electric dipoles. In a glass there may be some groups of molecules properly oriented to do this but it is far more likely that a thermalized electron's electric field induces its trap by causing a rotation of solvent molecules to a favorable orientation. Forces inhibiting molecular rotation must be weaker in a glassy hydrocarbon matrix than in a crystalline one, favoring this type of trapping.

Trapped electrons in MTHF disappear at 92–95 °K, apparently via reaction with free radicals or radical-ions, while the remaining free radicals or ions persist to 101 °K. If the sudden enhancement of reactivity were due to a phase change, both species should totally disappear at the same temperature. It is possible that 93–96 °K is the temperature above which the oriented solvent dipoles relax, releasing the electrons from their traps.

Since we cannot determine whether the inhomogeneous broadening of the trapped electron e.s.r. singlet arises from a weak isotropic interaction or from dipolar proton hyperfine interaction it is difficult to draw any conclusions regarding the delocalization of a trapped electron orbital. It is probably due to a mixture of the two types of interaction. In other words the trapped electron must be experiencing dipolar interaction with neighboring protons but its wave function probably has a low value on the nearest neighbor protons in the wall of the solvent "cage". Qualitatively, this is similar to the picture of an *F*-center in KCl interacting with nearest neighbor potassium nuclei (5, 18). Even though the magnetic moment of a proton is greater than that of a potassium nucleus, a trapped electron in MTHF experiences less inhomogeneous broadening than does an *F*-center in KCl as shown by the difference in their saturation curves and by the 10 times smaller width of the envelope of the e.s.r. line due to trapped electrons in MTHF compared to that due to *F*-centers in KCl (5). Presumably this means that the orbital motion of a trapped electron in MTHF is more localized than that of an *F*-center. In

G = number of species formed per 100 eV energy absorbed in the sample.

support of this proposal, the g-value for an electron in MTHF (2.003 ± 0.001) is close to the free spin value $g = 2.0023$. The g-value shift for an F-center in KCl compared to that of a free spin electron is -0.007 (19), suggesting a greater spin orbital coupling for the F-center.

T_1 (calculated in Discussion, section 4) seems to be rather short compared to what one might expect. T_1 is increased by decreasing temperature since this reduces the efficiency of spin lattice processes. However, $T_1 = 7.5 \times 10^{-5}$ s for trapped electrons in MTHF at 77.5 °K is similar to T_1 for amino acid radicals (15) and for KCl F-centers (5) at room temperature but is 75 times longer than T_1 for solvated electrons in liquid ammonia (20). Without a knowledge of the relaxation mechanism it is difficult to draw any conclusions from the value of T_1.

(4) Spatial Distribution of Trapped Electrons and Free Radicals or Radical Ions

The saturation curve for trapped electrons in MTHF reveals that this is a case where $\Delta\omega_L$ has a value of significant magnitude compared to $\Delta\omega_G$ in contrast to F-centers in which case $\Delta\omega_L$ is negligible compared to $\Delta\omega_G$. Using Castner's graphical techniques (6) it is found that the experimental saturation curve for trapped electrons corresponds to that obtained theoretically when $A = \Delta\omega_L/\Delta\omega_G = 0.2$. Since $\Delta\omega_G = 4.5\ \gamma/\sqrt{2}$ or $56. \times 10^7$, $\Delta\omega_L = 1.12 \times 10^7$ and $T_2 = 8.9 \times 10^{-8}$ s. The value of H_1 at which eq. [3] holds is 0.022 G so $T_1T_2 = 6.7 \times 10^{-12}$ and $T_1 = 7.5 \times 10^{-5}$ s. From eq. [2*a*] or [2*b*], $\Delta H = 1.27$ G and from eq. [1] the average local concentration of trapped electrons and free radicals surrounding a trapped electron is 0.02 ± 0.01 M. The overall total of the free radical and trapped electron concentrations in the sample has been measured and equals 0.0018 M. Thus the local concentrations of these species are 11 ± 5 times higher than the bulk concentration. It is concluded that electrons and free radicals are trapped in clusters. This agrees with the cluster model of the initial distribution of primary species along the track of a Compton electron. The electrons and free radicals are trapped before the volume which they occupy has expanded sufficiently to overlap with neighboring clusters. The 0.02 M cluster concentration indicates an average minimum separation of 44 ± 7 Å between a trapped electron and a neighboring trapped electron or free radical. If they were distributed homogeneously at 0.0018 M concentration the average minimum separation between neighboring unpaired spins would be 93 Å.

The fact that the normalized thermal decay curves of the trapped electrons are independent of total radiation dose (i.e. initial concentration) at 77.5 °K suggests that a trapped electron reacts with a primary species in the same cluster and this result therefore supports our postulate. At first one might predict first order decay kinetics based on this model but this would assume that the reaction rate within a cluster is the same for all clusters. If the "cluster reactivity" is assumed to vary then the results are as expected. Neither first nor second order kinetics are obeyed but the normalized decay curves (for different initial concentrations) are superimposed. In other words, varying the radiation dose varies the concentration of clusters and not the average concentration within a cluster.

Salmon (2) found second order decay kinetics at 90 °K. From this and other evidence, Dainton and co-workers (12) postulate that on warming or photochemical bleaching the trapped electron in MTHF reacts with a primary species from another track. This disagrees with our conclusions drawn from results obtained at 77.5 and 81 °K.

(5) Consequences of the Cluster Model

The average distance between neighboring unpaired electron spins suggests that an electron becomes trapped when separated by 40–50 Å from its parent ion. Hence when

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

trapped it may still experience a significant coulombic force of attraction from the parent ion. The dielectric constant of liquid MTHF is 4.6 (21) and it may be lower in the solid (22). If it equals 4.6, the parent ion's coulomb field at a point 50 Å distant would be 0.07 eV or 10 kT. It is possible that photochemical bleaching merely serves to free an electron from its trap and it is subsequently attracted back to the parent ion where charge neutralization must occur. We suggest the possibility that photochemical bleaching results in the electron reacting with a primary species in the same cluster rather than with one in another cluster as postulated by Dainton *et al.* (12).

We have concluded in section 4 (Discussion) that thermal disappearance of a trapped electron at 77.5 °K involves reaction within the same cluster. The mechanism of thermal escape from a trap is not known, but once this occurs, the coulombic field of the parent ion presumably draws the electron to it.

Our picture of clusters containing trapped electrons and free radicals or positive ion radicals with an average separation between neighboring species of about 50 Å merits examination in terms of solute competition for electrons before they become trapped. We have suggested that electrons induce their own trap via orientation of solvent molecule electric dipoles. The yield of trapped electrons in the absence of solute indicates that the probability of trapping is about unity. Addition of a solute which reacts at every encounter would require a concentration equal to or greater than the local (cluster) concentration of electrons to capture all the electrons before they become trapped. Since the ratio of the concentration of electrons and free radicals or radical ions is 0.88 ± 0.04 (12) this corresponds roughly to 0.009 M or 0.076 mole % of solute. Hamill *et al.* observe that at 0.08 mole % of biphenyl in MTHF, 60% of the limiting yield of anion is formed and that 0.15–0.2 mole % of solute is required to reach the limiting yield of anion (1). We regard this as good qualitative agreement with the proposed model.

INFRARED SPECTRA OF TRIS-ETHYLENEDIAMINE COMPLEXES OF RUTHENIUM(II)

A. D. ALLEN AND C. V. SENOFF
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario

Received October 14, 1964

ABSTRACT

A number of complexes $[Ru(en)_3]X_2$, where X = I^-, Br^-, $PtCl_4^{2-}$, ClO_4^-, and PF_6^-, have been prepared and their infrared spectra measured in the solid state between 4 000–600 cm^{-1}. The effect of the various anions on the spectra and assignments for the observed fundamental vibrations are discussed.

The infrared spectra of ethylenediamine complexes have recently been reviewed (1). The available infrared data suggest that ethylenediamine coordinates to a metal with the *gauche* configuration (2). This has been substantiated by X-ray structural data for a number of ethylenediamine complexes (3, 4, 5). In this paper we report the preparation of a series of ruthenium(II) complexes, $[Ru(en)_3]X_2$, where en = ethylenediamine and X = I^-, Br^-, $PtCl_4^{2-}$, ClO_4^-, and PF_6^-. The infrared data for these complexes are given in Table I. Data for the N-deuterated complexes are found in Tables II and III.

RESULTS AND DISCUSSION

Band Assignments for the Complexes $Ru(en)_3X_2$

(a) NH_2 Vibrations

There are six fundamental modes of vibration associated with the NH_2 group, viz., asymmetrical stretching, symmetrical stretching, bending, wagging, twisting, and rocking. Deuteration of the amino hydrogens confirmed the assignment of the absorption bands to NH_2 vibrations.

The NH_2 stretching vibrations were observed in the frequency range, 3 400–3 000 cm^{-1} shifted to 2 500–2 325 cm^{-1} in the spectra of the N-deuterated complexes (Tables II and III). The average value for the ratio, $\nu(NH)/\nu(ND)$ was 1.35, in reasonable agreement with the value of 1.37 calculated using the simple harmonic oscillator approximation. Most of the ruthenium(II) complexes exhibited four NH_2 stretching vibrations. In general, the absorption bands were broad for the simple halide salts (Figs. 1 and 2) but were much sharper in the salts of the complex anions (Figs. 3, 4, 5).

Two NH_2 bending motions were observed between 1 600–1 570 cm^{-1}. The corresponding bands in the N-deuterated complexes appeared at about 1 180–1 170 cm^{-1}, in agreement with published data for other ethylenediamine metal complexes (6, 7).

The strong band observed in all the spectra of the undeuterated complexes at about 1 330 cm^{-1} which disappeared in the spectra of the N-deuterated complexes has been assigned to the NH_2 wagging mode. Another NH_2 wagging vibration has been assigned to the weak to strong band occurring between 1 145–1 120 cm^{-1} depending upon the anion involved.

The NH_2 twisting modes have been shown to occur at lower frequency than the wagging modes when an NH_2 group is bound to two other atoms (8). Hence, the bands between 1 030–1 010 cm^{-1} and 980–960 cm^{-1} have been assigned to the twisting motions of the NH_2 groups.

The final NH_2 angle deformation mode to be observed is the NH_2 rocking mode which appears as a strong absorption band at about 630 cm^{-1}. The isotope ratio, $\nu(NH)/\nu(ND)$ has the smallest value for this vibration (about 1.20), indicating that there is probably a large amount of coupling with the metal–nitrogen motions occuring at lower frequencies.

(b) CH_2 Vibrations

The pattern of the CH_2 vibrations should closely parallel the NH_2 vibrations. The CH_2 stretching modes were observed between 3 000–2 750 cm^{-1} as medium to strong absorption bands and were not very much affected by N-deuteration (Table III). In general, three such absorption bands were observed in the spectra of most of the ruthenium(II) complexes.

The four types of CH_2 angle deformation modes should decrease in frequency in the order: bending > wagging > twisting > rocking (9). It was possible to observe only one CH_2 bending vibration, at about 1 465–1 450 cm^{-1}, but it is interesting to note that two such bands were detected in the spectra of the N-deuterated complexes at about 1 450–1 430 cm^{-1}. These vibrational modes were apparently not significantly shifted upon N-deuteration, indicating very little coupling with the corresponding NH_2 motions.

Two weak bands that appear in the spectra at about 1 390 and 1 370 cm^{-1} and which showed appreciable frequency shifts in the N-deuterated complexes have been assigned to the CH_2 wagging motions, which are apparently coupled with the corresponding NH_2 vibrations.

The CH_2 twisting vibration appears as a medium to strong band at about 1 275 cm^{-1}

except for the hexafluorophosphate salt which has two bands at 1 284 and 1 258 cm^{-1} assigned to this deformation mode. The spectra of the N-deuterated salts indicate very little coupling with the NH_2 vibrations.

Finally, two weak bands at about 870–860 cm^{-1} have been assigned to the CH_2 rocking motions, but could not be detected in the spectra of the N-deuterated specimans since they were obscured by strong N—D absorptions that appeared in this region.

(c) C—C and C—N Vibrations

There are three possible types of motion associated mainly with the N—C—C—N chain of the ligand, viz., the C—C stretch, the C—N stretch, and the bending of the N—C—C—N chain (in plane bending and torsional motion). For the *cis* conformation, the C—N stretching vibrations for uncoordinated ethylenediamine have been observed at 1 104 and 1 065 cm^{-1} (10). It has been shown that the C—N frequency will probably be shifted in going from the *cis* to the *gauche* configuration, while the C—C stretching vibration should not be affected (11). It seems reasonable to assume that ethylenediamine coordinated to ruthenium(II) has the *gauche* configuration in view of the available X-ray structural data for other similar metal complexes (3, 4, 5). Hence, the medium to strong bands appearing at about 1 106 and 1 040 cm^{-1} have been assigned to the C—N stretching modes. The spectra of the N-deuterated complexes do not show these bands since they are apparently hidden under the N—D bands occurring in the same region. The C—C stretching mode has been assigned to the strong band at about 1 000 cm^{-1}, which is only slightly shifted upon N-deuteration. The C—C stretch for ethylenediamine occurs at 980 cm^{-1} (10). The bending vibrations of the N—C—C—N chain were not observed in the rock salt region of the spectra reported in this paper.

The Effect of Various Anions on the Spectra of the Complexes $[Ru(en)_3]X_2$

In the absence of X-ray structural data, it is difficult to arrive at any specific conclusions regarding the effect of a given anion on the infrared spectrum of the cation, $[Ru(en)_3]^{++}$. The data in Table I indicate that the NH_2 stretching region is quite sensitive to a change in the anion. Powell and Sheppard have stated that the observed spectral differences for the complexes $[M(en)_2]X_2$, where M = Pd or Pt and X = Cl^- or $PtCl_4^{2-}$, can be attributed to hydrogen bonding between the amino hydrogen atoms and a given anion (7). This explanation has recently been questioned by Klett, who has reinvestigated the infrared spectra of these salts (12). Klett has attributed the spectral differences to changes in crystal structure rather than hydrogen bonding. Examination of the data presented in Table I indicates that there is a gradual increase in frequency for the NH_2 stretching vibrations as the anion is varied in the order: I^-, Br^-, $PtCl_4^{2-}$, ClO_4^-, PF_6^-. If hydrogen bonding were the only factor causing the change in frequency of these vibrations, then the NH_2 stretching vibrations should occur at higher frequency for the iodide than the bromide salt. Clearly, this is not the case. There is also a change in the shapes of the NH_2 stretching bands (Figs. 1 to 5), which cannot be attributed solely to hydrogen bonding. The perchlorate and hexafluorophosphate salts each exhibit two very strong bands and one or two poorly resolved, weak, broad bands, while the other salts show four bands of comparable intensity. It seems quite probable that the bromide and iodide salts have similar crystal structures which are different from those salts with a relatively large anion. The similarity of the spectra for the perchlorate and hexafluorophosphate salts suggests that these two also have similar structures.

The assignments for the absorption bands in the infrared spectra of the complexes reported in this study agree very well with assignments made for a series of bis-ethylenediamine complexes of palladium(II) and platinum(II) by Klett (12). Analogous

osmium complexes are being prepared and their infrared spectra will be compared with those of the ruthenium complexes.

EXPERIMENTAL

(1) Infrared Spectra

All spectra were recorded on a Perkin-Elmer 521 grating spectrophotometer which was calibrated with polystyrene film in the NaCl region. The normal instrument settings were used: slit schedule 1 000, attenuator speed 11.00, amplifier gain 4.5, and scan suppression 5–6. The sharp bands were scanned at approximately 1 cm^{-1} per 5 s and at about 1 cm^{-1} per s for all other bands. Solid samples were prepared as Nujol and hexachlorobutadiene-1,3 mulls between NaCl or KBr plates. For comparison, the spectra of several complexes were determined with the KBr wafer technique and it was found that they did not substantially differ from those obtained with the mull technique. Reproducibility was ± 1 cm^{-1} and the precision of the band maxima is believed to be within ± 2 cm^{-1}.

*(2) The Complexes $[Ru(en)_3]X_2$**

The following general procedure was used to prepare these complexes. Commercial ruthenium trichloride (0.5 g) was dissolved in water (5 ml), and an excess of zinc powder and ethylenediamine (5 ml) were simultaneously added with mechanical stirring. The resulting mixture was warmed for 20 min and then filtered by gravity to remove the excess zinc and ruthenium metals. The appropriate anion (via the potassium, sodium, or ammonium salt) was then added to the filtrate at room temperature or at 0 °C to effect the precipitation of the desired complex. The yields were in the range 40–60%. The iodide, bromide, perchlorate, and hexafluorophosphate salts were recrystallized from hot water containing a small amount of their respective anions. All compounds were thoroughly dried *in vacuo* at 78 °C in the presence of P_2O_5. Analytical data are presented in Table IV.

TABLE IV

Analytical data for the complexes $[Ru(en)_3]X_2$[a]

	Calculated			Found		
X^-	% C	% H	% X	% C	% H	% X
I^-	13.46	4.49	47.47	14.02	4.88	47.4
Br^-	16.33	5.44	36.28	16.17	6.05	36.1
$PtCl_4^{2-}$ [b]	11.32	4.09	—	12.10	4.22	—
ClO_4	17.31	5.77	—	16.21	5.49	—
PF_6^-	12.61	4.20	—	12.70	4.27	—

[a]Microanalyses were carried out by Dr. A. Bernhardt, Mulheim, West Germany.
[b]Taken to be $[Ru(en)_3]PtCl_4 \cdot H_2O$.

(3) N-Deuterated Complexes

The N-deuterated iodide and bromide salts were prepared by dissolving the undeuterated samples in D_2O (99.78%) and allowing the exchange of the NH_2 hydrogen atoms to occur, followed by evaporation to dryness *in vacuo* in the presence of P_2O_5. The procedure was repeated until the infrared spectrum showed no NH_2 absorption bands. The chloroplatinate(II) salt was precipitated by the addition of a concentrated D_2O solution of K_2PtCl_4 to the N-deuterated iodide salt in D_2O. The N-deuterated salts were not further analyzed.

SLIP FLOW IN LONG, SINGLE CAPILLARIES

PART II.[1] STEADY-STATE FLOW AND SPECULAR REFLECTION

R. M. BARRER AND D. NICHOLSON

Physical Chemistry Laboratories, Chemistry Department, Imperial College, London, England

Received October 16, 1964

ABSTRACT

The steady-state slip flow of the rare gases (He, Ne, Ar, Kr, and Xe) and of propane, CO_2, and SO_2 has been studied at different temperatures in long, single glass capillaries. The results give values of viscosity which are in agreement with literature values when Ar is used as a calibrating gas. The results can be expressed as a linear plot of the non-dimensional permeability ratio K/K_0 against reciprocal Knudsen number; the intercept on the K/K_0 axis is a. The value of this intercept depends on both gas and temperature being higher for light gases and high temperatures than for more condensable gases and low temperatures. The parameter a is therefore replaced by $((2 - \beta)/\beta)a_1$ where $(1 - \beta)$ is the so-called specular reflection coefficient and a_1 is a constant. The factors affecting $(1 - \beta)$ have been discussed. It is suggested that contributions to $(1 - \beta)$ will arise both from elastically and from inelastically scattered molecules, and the magnitude of these contributions is assessed in terms of the properties of the gas and the surface. The expression finally obtained is compared with experimental values of $(1 - \beta)$.

1. INTRODUCTION

The flow of gases in single capillaries has received considerable attention since the classical work of Knudsen (1), but the nature of the gas–wall interactions which influence the steady state, and of the transition from molecular to streamline flow, are not yet fully understood. It was therefore thought of interest to use long, glass capillaries of uniform bore to study steady and transient flow outside the molecular flow regime. In this paper we report the steady-state measurements and consider specular reflection. An early study of gas flow in metal capillaries by Adzumi (2) showed that the material of the capillary influenced the flow rate in the slip flow regime. He also found (3) that the differences between flow rates for hydrogen and ethylene could not be accounted for by kinetic theory considerations alone. Recently Huggill (4) and Berman and Lund (5) have shown that such differences between gases can also be observed in the transition and molecular flow regimes.

The equations governing gas flow are conveniently expressed in terms of the permeability K. For a single capillary this can be related to the flow rate, G, by

$$K = \frac{Gl}{\pi r^2 (p_1 - p_2)},$$

where $G = \partial(p_2 V)/\partial t$. p_1 is the pressure at the ingoing side, p_2 that at the outgoing side, r is the radius of the capillary of length l, and V is the volume of the outgoing side.

The permeability equation for slip flow is

$$K = \frac{r^2(p_1 + p_2)}{16\eta} + \delta D_K, \qquad [1]$$

where $D_K = \frac{4}{3}r(2RT/\pi M)^{\frac{1}{2}}$; T, M, and η are the gas temperature molecular weight and viscosity respectively, and δ is a coefficient. It is one of the purposes of this paper to investigate the nature of δ.

Equation [1] in dimensionless form (6) is

$$K/K_0 = (u + a), \qquad [2]$$

where $K_0 = 3\pi D_K/64$, and $u = r(p_1 + p_2)/\pi\eta\bar{v}$. u is equal to $r/\bar{\lambda}$ when $\eta = \frac{1}{2}\rho\lambda\bar{v}$, so that the value of u is an indication of the relative importance of different modes of transport (here $\bar{v}$ is $2(2RT/\pi M)^{\frac{1}{2}}$ and $\bar{\lambda}$ is a mean free path corresponding to the mean pressure). When $u \gg 1$, Poiseuille flow occurs and eq. [2] is valid; as u approaches unity, however, [2] no longer holds and for capillaries in which $l \gg r$ Knudsen was the first to show (1) that K passes through a minimum at $u \simeq 0.3$, and that $K = D_K$ for the limit when $u \to 0$.

An equation based on the work of Weber (7) should be applicable to the transition regime in long capillaries (6):

$$K = K_0\left\{u + a + \frac{a'}{u}\ln(1 + bu)\right\} \qquad [3]$$

Equation [3] differs appreciably from [2] only when u is less than 5; the difference is 2% when $u = 5$.

According to Weber the constants a, a', and b should have the values 5.33, 0.366, and 4.0, respectively; on the other hand Maxwell's slip theory for diffusely reflected molecules leads to a value of 4.0 for a in eq. [2]. The measurements discussed here mostly fall in the region $5 < u < 100$ which means that a contributes between 5 and 50% of the total permeability.

2. EXPERIMENTAL

(a) Apparatus and Flow Measurements

The capillaries were supplied by the British Petroleum Company as coils of helix radius about 5 cm, and in lengths of up to 50 m. They were mounted by sealing each end with 'Araldite' into a previously dried and etched tube which had been drawn out at its end. These seals were then surrounded by mercury cups, but even protected in this way they would not withstand cooling below about −80 °C, and had a limited lifetime when subjected to repeated cooling to this temperature. The capillaries used are listed in Table I. Series A refers to capillaries intended mainly to study transient flow, whilst series B were rather shorter and were used to augment the steady-state data. Mounted capillaries were protected from mercury vapor by traps cooled to 195 °K, and an appropriate correction was made to the outgoing volume for each gas used.

TABLE I

Ref. No.	Length (cm)	Radius from Ar flow (cm × 10^3)	Mean radius by microscope (cm × 10^3)	No. of readings	Maximum radius recorded (cm)	Minimum radius recorded (cm)
1A	1 587	5.25_3	5.56±0.3	44	6.35×10^{-3}	5.40×10^{-3}

2B	$452._4$	5.59				

*Using CO_2 viscosity data of Johnston *et al.* (12).
†Using Ar at 25 °C.

Temperature control was achieved in a conventional thermostat near room temperatures, and with a stirred ice bath at 273 °K. For low temperature measurements an alcohol and 'Cardice' bath was used. It was found to be possible to maintain the temperature constant to within 0.3 °C with regular additions of crushed solid carbon dioxide although the mean temperature could be chosen between 195.5 and 196.5 °K. Temperatures were measured either by thermometer or with a thermocouple calibrated against a carbon dioxide vapor pressure thermometer at 195.5 °K (8).

When first mounted, a capillary was pumped out for several days at room temperature with a dynamic vacuum lower than 10^{-6} mm of mercury. Between each run the capillary system was outgassed for at least 4 h, and in most cases for a longer time, at room temperature. For series B measurements, in which transient state flow was not studied, degassing between runs required only a short time.

Flow rates were measured by noting the rate of change of p_2. p_2 was never allowed to rise to more than 0.1% of p_1 which was kept constant. Details of this type of measurement have been given elsewhere (9).

Gases used were either spectroscopically pure (He, Ne, Ar, Kr, Xe + 1% Kr, C_3H_8) or were prepared and purified in the laboratory (SO_2, CO_2). The length of the capillary was determined by making a large number of measurements of helix diameter on single turns. No regular deviation from circular could be detected in any of the capillaries and it is estimated that the absolute error in length was less than 0.2% for the long capillaries and less than 1% for the short capillaries.

(b) Internal Radius Measurement

Desty *et al.* (10) found that there was less than ±1% fluctuation from the mean radius for a capillary of 0.007 in. internal bore prepared by drawing from 'Veridia' tubing. Measurements on our capillaries indicated that the bore may be rather less consistent than this. The values obtained for 4 capillaries, cut into sections after use, are reported in Table I. Each reading had a reliability of ±2% and readings were made at regular intervals along the length of the capillary (capillary 1A had a slight taper). The third column of Table I gives values of the mean radius calculated from Poiseuille flow of argon (i.e. from the slope $\pi r^4/8\eta l$ of a plot of $G/(p_1 - p_2)$ against $\bar{p}$) and taking its viscosity (11) at 0 °C as $2.1001.10^{-4}$ P. The slight discrepancy between microscope and flow radii in capillaries 1A and 2A is probably due to geometrical factors discussed briefly below.

3. RESULTS

(a) Slopes of Slip Flow Lines

A value for the viscosity of any other flowing gas can be calculated from the slopes of K/K_0 plotted against p_1, using the radius obtained from the calibration with argon. For this purpose points with $u < 5$ were ignored and the best straight line, determined by a least mean square procedure, was used. Viscosity coefficients obtained in this way are compared with literature values in Table II. Typical data obtained at 0 °C for helium are illustrated in Fig. 1 as a plot of K/K_0 against u. At this temperature the viscosities agreed with Johnston's data (12) to within 2% or better. Low temperature results (Fig. 2) were rather more scattered, and viscosities may be reliable only to within 3%. Good independent viscosity data are not available in this region except for CO_2.

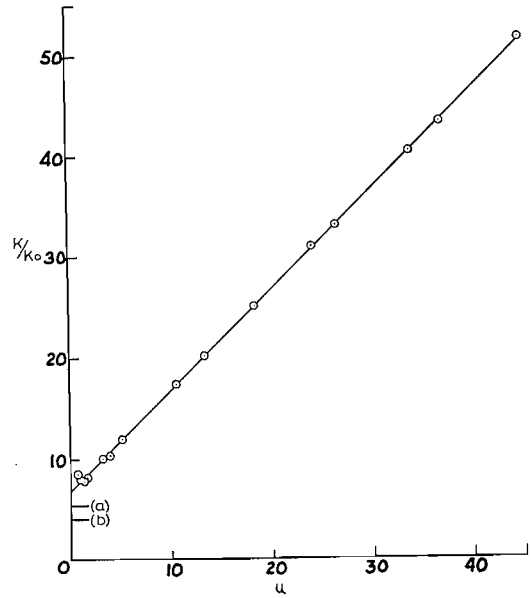

FIG. 1. Permeability ratio, K/K_0, for helium in capillary 1A as a function of $u = r/\bar{\lambda}$, and hence of mean pressure: (*a*) locates the theoretical intercept according to Weber; (*b*) locates this intercept according to Maxwell.

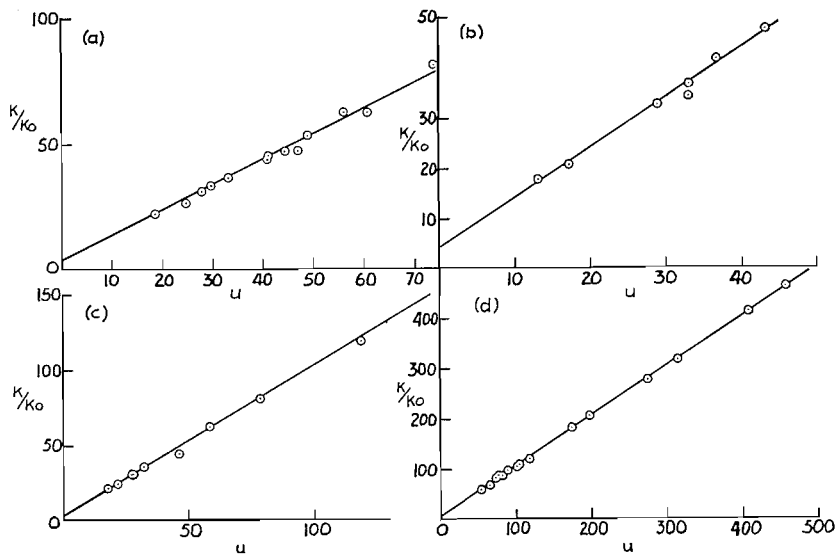

FIG. 2. Some permeability ratios, K/K_0, as functions of u at low temperatures: (*a*) CO_2 at 195.7 °K, in capillary 2A; (*b*) SO_2 at 239.8 °K, in capillary 4A; (*c*) C_3H_8 at 196.3 °K, in capillary 4A; (*d*) CO_2 at 196.3 °K, in capillary 5A.

The discrepancies between radii determined with the microscope and by flow, and between experimental viscosities and the literature values, led us to consider whether any correction of the Poiseuille term in eq. [1] was necessary.

(i) A reappraisal was made of the solution of the Navier Stokes equation (15) which gives the Poiseuille equation. The effect was considered of including first and second order derivatives of the mass velocity with respect to x (which may be important when $x \rightarrow l$). Secondly, the influence of helical curvature was examined by transforming the equation to suitable orthogonal coordinates (16) and solving it to obtain a corrected Poiseuille equation. In each instance the corrections were negligible.

(ii) Fluctuations in radius along the length of the capillary could also modify the flow. Thus if the mean fluctuation in radius found in capillary 1A (Table I) was repeated regularly along its length the measured flow rate would be $\sim 0.6\%$ less than that predicted from the 'flow' radius. In this estimate it was assumed that fluctuations in radius have no marked effect on the form of the pressure gradient. A consequence of this simplification is that the frequency of these fluctuations does not affect the final result. Under the microscope a slight departure from a circular cross section of the capillaries was also noted but it was estimated that this could change the flow rate by no more than 0.05%.

(b) Slip Flow Intercepts

Slip flow measurements allow the parameter a of eq. [2] to be calculated which, according to simple kinetic theory, should be a constant independent of gas and temperature. Results for capillaries of series A and B showed that this was not the case (Table III, column 4). The values of a were calculated for each point as $((K/K_0) - u)$, and their averages are quoted together with the mean standard deviations σ. In some cases, particularly for the series B capillaries, the deviation of a single point was more than 3σ and such data were discarded in order to calculate the final value. The values for helium are the most consistent and those for the heavy gases the least; in particular, the value of 0.8 for xenon at 0 °C in capillary 1A must be disregarded as in this case the results were widely scattered. From Table III it can be seen that values of a, among a similar series of molecules (He, Ne, Ar, Kr, Xe), tend to decrease with increasing molecular mass or boiling point. Values of a are also smaller for other molecules of higher boiling point

(CO_2, SO_2, and C_3H_8) than for the gases He, Ne, and Ar. It is further seen that a decreases with falling temperature for the two gases for which the relevant data were obtained (He and Ar).

Such differences of intercept were anticipated by Maxwell in his theory of slip (17) and have been observed by Millikan (18). Maxwell equated the viscous drag across any plane in the flowing gas with momentum transferred to the walls. This results in the following expression for slip velocity, v_{os}:

$$[4] \qquad v_{os} = \frac{2 - \beta}{\beta} \frac{2\eta}{\rho\bar{v}} \frac{dv_{ox}}{dr},$$

where β is the fraction of diffusely reflected molecules, and therefore $(1 - \beta)$ is the fraction specularly reflected. If v_{os} is substituted as a boundary condition in the derivation of the Poiseuille equation, we obtain eqs. [1] and [2] with

$$[5] \qquad a = 4.00 \frac{2 - \beta}{\beta}.$$

β can be regarded as an indication of the extent to which momentum is exchanged with the surface. Complete exchange results in reflection according to the cosine law ($\beta = 1$) whereas no exchange results in a reversal of the perpendicular velocity component and a retention of the horizontal components ($\beta = 0$). In intermediate cases Nocilla (19) postulated two interaction parameters:

$$[6] \qquad \beta_T = \frac{\pi_i - \pi_r}{\pi_i}$$

$$[7] \qquad \beta_N = \frac{P_i - P_r}{P_i - P_w},$$

where the subscripts i, r, and w refer to 'incident', 'reflected', and 'wall' respectively, and π and P represent tangential and normal momenta. For gas flow in the x-direction along a tube only the first of these need be considered, so that $\beta = \beta_T$.

TABLE IV

a_1	Authors
4.80	Kramers (21) (1949)
4.0–5.1	Payne (22) (1953)
4.48	Mott-Smith (23) (1954)
4.54	Wang Chang and Uhlenbeck (24) (1956)
4.49	Willis (25) (1962)
4.68	Cercignani *et al.* (26) (1964)

It is clear from eqs. [4] and [5] that the values of β obtained from gas flow measurements depend on the value of the slip flow term. It has been pointed out by many authors that Maxwell's derivation cannot be considered rigorous because it assumes that the velocity distribution function at several mean free path lengths from the wall will be the same as that at the wall. Several attempts have been made to calculate a more realistic slip term than that of Maxwell by a solution of the Maxwell Boltzmann equation (20). Two unsatisfactory features of these treatments are, first, the division of molecules into two groups (those which undergo perfectly diffuse reflection and those which undergo perfectly specular reflection), and secondly, the use of unrealistic force laws between molecules (usually 'Maxwell molecules' are considered, which repel each other according to an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

inverse fifth power law). The values of a_1 in the expression $a = a_1((2 - \beta)/\beta)$ which replaces Maxwell's value of $a_1 = 4.00$ are listed in Table IV for some recent treatments. However, no final verdict can yet be given concerning the best value of a_1.

4. SPECULAR REFLECTION

In the final columns of Table III values of β are given, calculated on the basis of $a_1 = 4.00$ and $a_1 = 4.50$. The so-called specular reflection coefficient, $1 - \beta$, has received some attention experimentally (2, 18), but little has been said regarding factors which may influence it. In the following section we have attempted to make an analysis of these factors. In doing so we have considered contributions from elastically and inelastically scattered molecules and the effect which surface forces and surface roughness will have on these: the final result is summarized in eq. [18]. The analysis has been set in quantitative terms as far as is possible in order that an assessment of the magnitudes of the factors involved can be made, but it must be emphasized at the outset that the complexities of gas–surface interactions do not allow a rigorous treatment of the problem.

The related problem of the accommodation coefficient, α, has received considerable attention (27, 28, 31). A classical treatment in which a single impinging atom exchanges energy with a three-dimensional lattice initially at 0 °K gave results for α quantitatively in agreement with experimental results (28). Two important assumptions are made in these theories of energy accommodation. The first is that atoms are incident normally on the surface; the second, that atoms are not trapped at the surface.* The first of these is clearly inadequate when dealing with the parameter β which, when it is less than unity, may indicate the persistence of a mass velocity component parallel to the surface.

De Boer (30) pointed out two factors which influence specular reflection. The first is the effect of surface roughness in scattering the molecules treated as de Broglie waves, and the second is adsorption. The following discussion is an expansion of these ideas.

(a) Elastic Scattering

An approximate treatment of scattering of de Broglie waves is given in Appendix 1. The result can be expressed in terms of the temperature, the molecular mass of the gas, and the height $\mu/2$ of an average surface serration, as

$$[8] \qquad 1 - \beta_1 = 1 - \exp\left[\frac{-h^2}{\mu^2 2mkT}\right],$$

where β_1 is the randomly scattered fraction of the molecules making elastic collisions with the surface. If one chooses μ in this expression to be about 10^{-5} cm, which is the order of magnitude of the irregularities on a polished surface, then eq. [8] becomes

$$\beta_1 = \exp\left[\frac{-9.58.10^{-4}}{MT}\right].$$

Thus $(1 - \beta_1)$ is approximately 1.10^{-6} for helium at 200 °K, which has the smallest value of MT encountered in these experiments.

It is probable, however, that elastic collisions with the surface will involve the impinging atom with a few surface atoms only, and from the viewpoint of collisions that the surface may be regarded as being composed of identical facets each having the area of a few atoms.

**Goodman (29) has developed a model which does not include this second restriction but he could find only qualitative agreement with experiment.*

For personal use only.

In Appendix 2 we consider the effects of facets such as these on the net flow of molecules specularly reflected at the surface. An extra factor $(1 - \beta_2)$ multiplies the expression for the number of molecules which interact elastically with the surface and are specularly reflected:

$$[9] \qquad 1 - \beta_2 = \left\{1 - \frac{2\int_0^{\pi/2} \sin^2 \Psi\, h(\Psi)\, d\Psi}{\int_0^{\pi/2} h(\Psi)\, d\Psi}\right\},$$

where Ψ is the angle of inclination of a facet towards the direction of flow, and $h(\Psi)$ is a distribution function such that $h(\Psi)\, d\Psi$ gives the number of facets with Ψ between Ψ and $\Psi + d\Psi$.

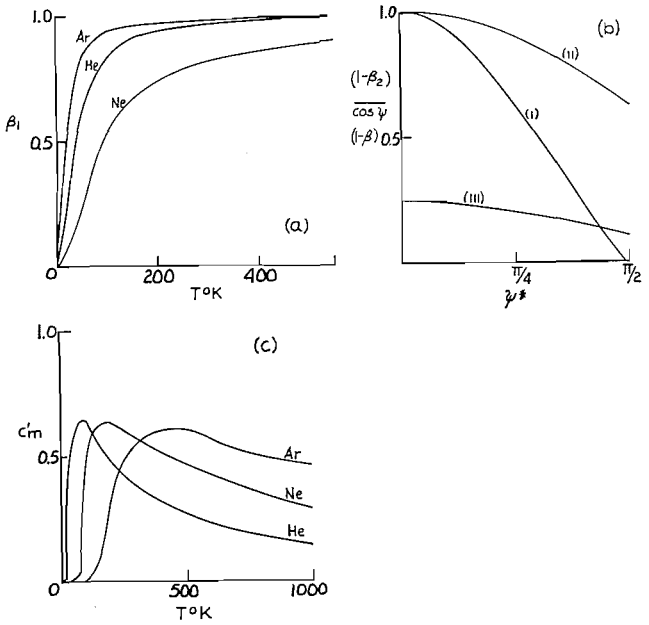

FIG. 3. (*a*) β_1 calculated from eq. [8] plotted against the absolute temperature for Ar, Ne, and He. (*b*) Curve *i*, $(1 - \beta_2)$ plotted against Ψ^* from eq. [19]; curve *ii*, $\overline{\cos \Psi}$ plotted against Ψ^* from eq. [19]; curve *iii*, $(1 - \beta)$ plotted against Ψ^* for He at 300 °K. (*c*) Values of c_m' calculated from eq. [14] plotted against the absolute temperature for Ar, Ne, and He.

On the basis of the foregoing argument we take μ in eq. [8] as being of the order of angstroms. The effect of T on β_1 calculated from this equation is illustrated in Fig. 3*a*, in which He, Ne, and Ar have been chosen as examples and μ taken as 2 Å.

It has been assumed that μ is not a function of temperature, but the increase in lattice vibration frequency with temperature could modify μ, particularly when the reflecting surface consists largely of adsorbed molecules with liquid-like properties, or is a liquid surface.

(b) Inelastic Gas–Surface Collisions

The division of molecules into those which, respectively, interact inelastically and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

elastically with the surface necessitates choosing a rather arbitrary criterion for distinguishing these two groups. Such a criterion is a condensation coefficient

$$[10] \qquad c_\alpha = \left(1 - \exp -\frac{E}{RT}\right),$$

where E is the least energy required for an adsorbed atom to evaporate from the lowest adsorbed energy level and is equal to the exothermal adsorption energy but opposite in sign. This criterion is approximate because atoms with energies greater than E may well exchange energy quanta with the surface so that they are not undergoing elastic scattering. A quantitative study of condensation has been made by Lennard-Jones and Devonshire (32) but the perturbation method used makes values of c_α higher than 0.3 unreliable. In summary it may be said that $(1 - \exp -E/RT)$ is probably a rather low estimate for c_α.

If n molecules impinge on unit area in unit time and the mean time of adsorption is τ then the surface population for a very sparse coverage is $n\tau c_\alpha$. This population consists of $n\tau c_m$ molecules in energy levels where surface translation occurs and $n\tau c_1$ molecules in energy levels in which translational motion is not possible. When E_s is the height of the energy barrier to surface diffusion, we have

$$[11] \qquad \begin{aligned} n\tau c_\alpha &= n\tau c_m + n\tau c_1 \\ &= n\tau[\exp -E_s/RT - \exp -E/RT] + n\tau[1 - \exp -E_s/RT]. \end{aligned}$$

The population $n\tau c_1$ does not contain any molecules which retain a 'memory' of the mass flow velocity existing in the gas phase.

Of the molecules in the mobile level at any time, a fraction will have come from the immobile group; the remainder are molecules whose velocities still include the influence of the mass flow velocity existing in the gas phase.

In order to compute these fractions we consider the rate of entry, n_g, of molecules into the mobile population from the gas phase and their rate of entry, n_s, from the immobile level, and assume that there is detailed balancing for the reverse passage of molecules in the mobile levels into gas phase and immobile levels respectively. Then the fraction of molecules in the mobile population which may be considered as having a decaying drift velocity is $n_g/(n_g + n_s)$. If we designate k_a as the probability per second that a molecule in the immobile population will enter the mobile population then the number which undergo this transition is $n_s = n\tau c_1 \cdot k_a$ while from the gas phase $n_g = Nc_m$. The fraction of all molecules leaving the surface which retain a 'memory' of their original gas phase drift velocity is then

$$[12] \qquad c_m^{\,1} = \frac{c_m^{\,2}}{c_m + c_1\tau k_a}.$$

The quantities τ and k_a in this equation may be expressed in terms of E and E_s. The adsorption time is $\tau = \tau_0 e^{E/RT}$ where τ_0 is approximately the reciprocal of the vibration time of an adsorbed molecule and is $\sim 10^{-12}$ s. An expression for the transition probability k_a has been obtained by Lennard-Jones and Strachan (35) using a perturbation technique to solve the appropriate Schrödinger equation. The final expression was of the form

$$[13] \qquad k_a = A(\exp E_s/RT - 1)^{-1}.$$

A depends in a complex way on the parameters in the Morse equation used to express

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the molecule–surface interaction, and on the number of energy levels below E_s. For Ar on KCl, A was found to be 10^{10}. Using this value, and the Morse parameters and combination rules given by Goodman (28), we find that A for He is about 2.5×10^{10}, and for Ne about 1.3×10^{10}. Inserting τ and k_a from [12] and [11], we obtain

$$[14] \qquad c_m^{\,1} = \frac{[e^{-E_s/RT} - e^{-E/RT}]^2[e^{E_s/RT} - 1]}{[e^{E_s/RT} - 1][e^{-E_s/RT} - e^{-E/RT}] + [1 - e^{-E_s/RT}]\, e^{E/RT}10^{-2}}$$

where it has been assumed that $A\tau_0 \sim 10^{-2}$ in all cases.

In Appendix 3 we derive an expression for the probability $(1 - \beta_3)\,\overline{\cos \Psi}$ that a molecule from the population $n\tau c_m^{\,1}$ will be specularly reflected. The mean time τ_s in eq. [3.6] is given by

$$[15] \qquad \tau_s = \tau_0 \exp \frac{E - E_s}{RT},$$

and k_b defined in Appendix 3 is given (35) by an expression similar to eq. [13] but with a different temperature dependence:

$$[16] \qquad k_b = B[1 - e^{-(E-E_s)/RT}]^{-1}$$

so that

$$[17] \qquad (1 - \beta_3) = \exp - \frac{B\tau_s}{1 - \exp -(E - E_s)/RT}$$

(c) Comparison of Theory with Experiment

We can now write the specular reflection coefficient as

$$[18] \qquad (1 - \beta) = (1 - \beta_1)(1 - \beta_2)(1 - c_a) + c_m^{\,1}(1 - \beta_3)\ \overline{\cos \Psi},$$

in which $c_m^{\,1}$, c_a, β_1, β_2, β_3, and $\overline{\cos \Psi}$, are given in eqs. [8], [9], [10], [14], [17], and [3.5]. Of these terms β_2 and $\overline{\cos \Psi}$ depend on the distribution and inclination of facets. Unfortunately it would be very difficult to obtain a reliable experimental measure of these quantities. However, their inclusion in eq. [18] indicates how surface roughening will affect $(1 - \beta)$. Thus $h(\Psi)$ would be expected to have a semi-Gaussian form exp $(-\text{const.}\ \Psi^2)$ in which the constant decreases as the surface becomes roughened. An approximation to this function is a step function with a sharp cut off at a value of $\Psi = \Psi^*$. This greatly simplifies the integrations in eqs. [2.8] and [3.6], and gives

$$[19] \qquad 1 - \beta_2 = \frac{\sin 2\Psi^*}{2\Psi^*} \quad \text{and} \quad \overline{\cos \Psi} = \frac{\sin \Psi^*}{\Psi^*}.$$

The variation of $(1 - \beta_2)$ and $\overline{\cos \Psi}$ with Ψ^* is illustrated in Fig. 3*b*, together with a graph of $(1 - \beta)$ against Ψ^* for He at 300 °K. The values used for the other quantities in this case are discussed below.

In the following calculations we have considered a surface rough on an atomic scale only, and have therefore taken both $(1 - \beta_2)$ and $\overline{\cos \Psi}$ as unity in all cases. The remaining parameters depend on the physical properties of the gas and surface. Possible values of E and E_s have been chosen (34) for Ar, Ne, and He in order to make the calculations (Table V). The values for Ar are those used by Lennard-Jones and Strachan (35) whilst E_s for He and Ne was chosen to be $E/10$, in keeping with these values, although this is probably a low estimate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

TABLE V

Gas	E (cal mole^{-1})	E_s (cal mole^{-1})	$a = 4.00$ ($B\tau_0$)	$a = 4.50$ ($B\tau_0$)
He	360	36	1.30	1.75
Ne	800	80	0.21	0.25
Ar	1 800	200	0.09	0.12

Calculations of the contribution of elastic scattering to $(1 - \beta)$ at 300 °K for Ar shows that even with $\mu = 1$ Å this is only 2×10^{-4} and therefore negligible. Hence the second term in [18], $c_m^1(1 - \beta_3)$, can be compared with the mean experimental value at 300 °K of $(1 - \beta)$ of 0.15 ($a_1 = 4.0$) or 0.09 ($a_1 = 4.5$), and $B\tau_0$ calculated. The values of $B\tau_0$ obtained suggest that B is about 10^{11} for Ar (if $\tau_0 \sim 10^{-12}$), which is the order of magnitude to be expected (35). In the case of He elastic scattering is quite important. For example, if $\beta_2 = 0.1$, and $\mu = 1$ Å, the contribution to $(1 - \beta)$ from the first term in [17] is larger than the experimental value of $(1 - \beta)$. A choice of $\mu = 2$ Å was therefore made and comparison of theory with experiment at 300 °K led to the values of $B\tau_0$ recorded in Table V. A increases with molecular weight so it might be expected that B will also: on the other hand τ_0 for He will be about the same or less than for Ar and the tenfold increase in B is unexpectedly large.†

$(1 - \beta)$ at other temperatures was calculated using these values of $B\tau_0$, and the theoretical and experimental points as well as the form of c_m^1 are shown in Figs. 3*c* and 4*a*, *b*, and *c*. For Kr and Xe only very slight variation of $(1 - \beta)$ with temperature is predicted.

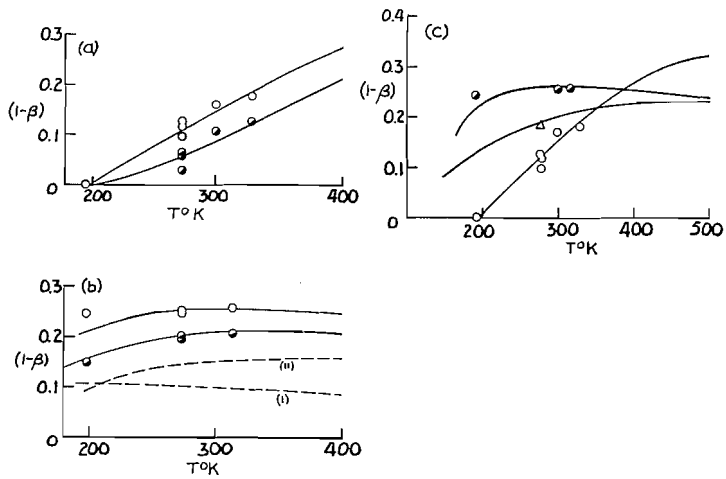

FIG. 4. In Figs. 4*a*, *b*, and *c*, the assumed values of E and E_s are those given in Table V. $\overline{\text{Cos}\,\Psi}$ and $(1 - \beta_2)$ are both taken to be unity. In Fig. 4*b* the roughness, μ, is taken as 2 Å. (*a*) Curves of $(1 - \beta)$ against T °K for Ar: ⊙ = experimental points for $a = 4.00$, ◑ = experimental points for $a = 4.50$. The full lines are theoretical curves taking $B\tau_0 = 0.09$ (upper line) and 0.12 (lower line). (*b*) Curves of $(1 - \beta)$ against T °K for He: ⊙ = experimental points for $a = 4.00$, ◑ = experimental points for $a = 4.50$. The full lines are theoretical curves taking $B\tau_0 = 1.30$ (upper line) and 1.75 (lower line). The curve (*i*) gives contributions from elastic and curve (*ii*) from inelastic scattering, both for $B\tau_0 = 1.30$. (*c*) $(1 - \beta)$ as a function of T °K for Ar (⊙), Ne (△), and He (◑). The full curves are theoretical and cover a wider temperature range, to show the crossing of the curves.

†*This suggests that A might also increase above the value of 10^{-2} adopted in [14]. However, an order of magnitude of 10 in this term has little effect on C_m^1 for He.*

5. DISCUSSION

Although the dependence of $(1 - \beta)$ on temperature is quite well reproduced, firm conclusions cannot be drawn at this stage. A more rigorous test of the views advanced here would require some means of assessing Ψ and $h(\Psi)$ and well-defined values of E, E_s, A, and B for the surface–gas pair.

In spite of these reservations the following points may be mentioned.

(i) Elastic scattering is apparently only important for light gases. Thus, even for Ne, $(1 - \beta_1)(1 - c_\alpha)$ is about 0.008 in the region 200–400 °K. This is because $(1 - c_\alpha)$ rapidly tends to zero for heavier gases and also because at constant temperature β_1 varies as $\exp(-\text{const.}/M^{1/2})$. On the other hand these terms do not depend on a mass flow velocity and so they are applicable to Knudsen flow as well as to slip flow.

(ii) Apparent specular reflection of heavier (easily condensed) gases indicates imperfect momentum exchange. A major factor is the time of stay on the surface although this is not related to $(1 - \beta)$ in any simple way. An interesting feature which appears from this analysis is that c_m^1 at high temperatures is bigger for heavy than for light gases because there is less interchange between mobile and immobile energy levels when E and E_s become large.

(iii) Surface roughness tends to increase the spread of $h(\Psi)$ towards higher values of Ψ but may also affect E by increasing the number of surface sites of high affinity.

It is notable that $(1 - \beta_2)$ (which depends on Ψ alone) can become negative and in principle it should be possible to reduce the flow rate of very light gases below the value for perfectly diffuse reflection by severe surface roughening.

ACKNOWLEDGMENTS

We would like to thank Mr. Ash of the Department for his interest in this work, and also Mr. L. E. Fraenkel of the Department of Mathematics for discussion of the Navier–Stokes equations. One of us (D. N.) is indebted to British Petroleum Limited for a postdoctoral fellowship.

APPENDIX 1

The number of molecules impinging on unit area in unit time from a Maxwellian population is, in terms of spherical polar coordinates, θ, ϕ, and v (Fig. 1.1),

$$[1.1] \qquad n = \int_0^{\pi/2} \int_0^{2\pi} \int_0^{\infty} C_g' \frac{v_r^3}{\pi^{3/2}} e^{-v_r^2} \cos\theta \sin\theta \, d\theta \, d\phi \, dv,$$

where C_g' is the number of molecules in unit volume, v the molecular speed, and $v_r = v(m/2kT)^{1/2}$.

For specular reflection the path difference between incident and reflected wave must

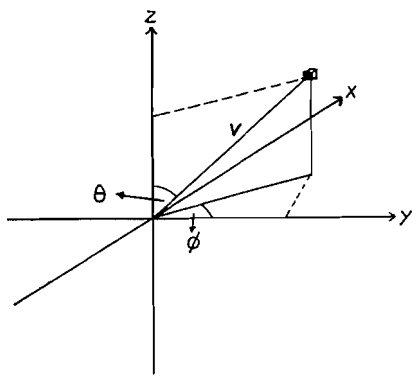

FIG. 1.1.

be such that $\Lambda \geqslant \mu \sin\theta$ where μ is twice the height of a surface discontinuity (30), and Λ is the de Broglie wavelength. For molecules we have $\Lambda = h/mv$. Hence for specular reflection

$$[1.2] \qquad v^* \leqslant \frac{h}{m\mu \cos\theta}.$$

Equation 1.2 defines a velocity v^* above which specular reflection of elastically scattered molecules will not occur. The number diffusely reflected is given by

$$[1.3] \qquad n_t = C_g' \frac{2}{\pi^{1/2}} \int_0^{\pi/2} \int_0^{v^*} v_r^3 e^{-v_r^2} \cos\theta \sin\theta \, d\theta \, dv,$$

where the integration over ϕ from 0 to 2π has been taken.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Because θ is the independent variable in [1.2] the integral over v can be taken and

$$[1.4] \qquad n_t = C_g' \left(\frac{2kT}{\pi m}\right)^{1/2} \int_0^{\pi/2} (1 + \delta^2 \sec^2\theta) \exp(-\delta^2 \sec^2\theta) \cos\theta \sin\theta \, d\theta$$

where $\delta = h/\mu\sqrt{2mkT}$.

The probability of specular reflection is thus

$$[1.5] \qquad (1 - \beta_1) = 1 - \frac{n_t}{\frac{1}{4}C_g'\bar{v}} = 1 - 2\delta^2 \int_\delta^\infty \frac{1 + x^2}{x^3} e^{-x^2} dx$$

$$= 1 - 2\delta^2 \int_\delta^\infty \frac{e^{-x^2}}{x^3} dx - 2\delta^2 \int_\delta^\infty \frac{e^{-x^2}}{x} dx$$

in which the substitution $x = \delta \sec\theta$ has been made. If we integrate the first integral by parts, eq. [1.5] leads to

$$[1.6] \qquad (1 - \beta_1) = 1 - e^{-\delta^2}.$$

APPENDIX 2

We consider the specular reflection of molecules from the elementary facets which are inclined at an angle Ψ to the direction of flow. WW' in Fig. 2.1*a* represents the cross section of a facet which is parallel to the direction of flow as indicated by the arrow. The net flow across plane A in the x-direction is

$$[2.1] \qquad n_0 = n_1 - n_r,$$

where n_1 is the number of molecules coming from the left and striking unit area in unit time, and n_r is the same number coming from the right.

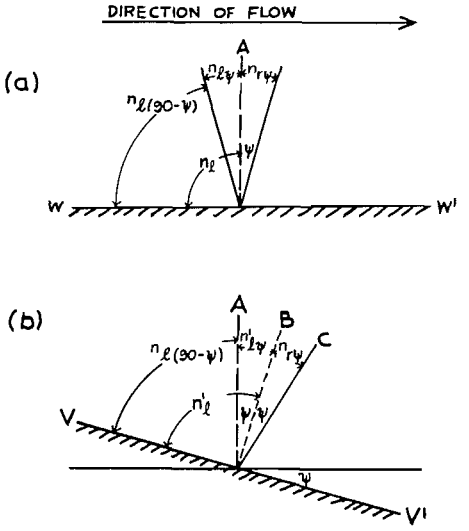

FIG. 2.1.

Figure 2.1*b* shows the cross section of a facet VV' inclined at angle Ψ towards the local direction of flow and B is a plane perpendicular to it. As in Fig. 2.1*a*, A is perpendicular to the flow direction. The molecules coming from the left of B are (*a*) $n_{1(90-\Psi)}$ in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

segment VA which is identical with the same number in Fig. 2.1*a*; (*b*) $n_{l\Psi}'$ in the segment AB which actually came from the right of A but are transferred in the direction of flow. As there are fewer molecules arriving from this side of A than from the left $n_{l\Psi}' < n_{l\Psi}$. The number of molecules transferred in the direction of flow is augmented by the number $n_{r\Psi}$ coming from the segment BC which will now be reflected to the right of plane A.

Hence the total number of molecules transferred to the left after reflection from VV' is

$$n_l' = n_{l(90-\Psi)} + n_{l\Psi}' + n_{r\Psi} = n_l - n_{l\Psi} + n_{l\Psi}' + n_{r\Psi}. \qquad [2.2]$$

By a similar argument we can also write

$$n_r' = n_r - n_{r\Psi} \qquad [2.3]$$

and the net flow across plane A is now

$$n_l' - n_r' = n_l - n_r - n_{l\Psi}' + 2n_{r\Psi}. \qquad [2.4]$$

The difference $n_{l\Psi} - n_{l\Psi}'$ is the number of molecules transferred across A which arrive from the segment of angle Ψ. We will denote this number by $n_{0\Psi}$ so that [2.4] is

$$n_l' - n_r' = n_0 - n_{0\Psi} + 2n_{r\Psi}. \qquad [2.4a]$$

We now postulate that for each facet of inclination Ψ to be found at a given cross section there is an identical facet of inclination $(180 - \Psi)$ at the same cross section. The flow across plane A through this facet is

$$n_l'' - n_r'' = n_0 - n_{0\Psi} - 2n_{l\Psi} \qquad [2.5]$$

and for the pair we have on summing [2.4*a*] and [2.5]

$$\begin{aligned} 2n_0{}^{\Psi} &= 2n_0 - 2n_{0\Psi} + 2n_{r\Psi} - 2n_{l\Psi} \qquad [2.6] \\ &= 2n_0 - 4n_{0\Psi}, \\ \text{i.e.} \quad n_0{}^{\Psi} &= n_0 - 2n_{0\Psi}, \end{aligned}$$

where $2n_0{}^{\Psi}$ is the total number of molecules transferred across the two planes which are inclined at angle Ψ.

From [1.1] the number of molecules striking unit area per second coming from segment 0 to Ψ in a Maxwellian gas at rest is

$$\begin{aligned} n_\Psi &= C_g' \int_0^\infty \frac{v_r^3}{\pi^{3/2}} e^{-v_r^2}\, dv \int_0^{2\pi} d\phi \int_0^\Psi \sin\theta \cos\theta\, d\theta \\ &= \frac{C_g'}{4} \bar{v} \cdot \sin^2 \Psi \\ &= n_0 \sin^2 \Psi, \end{aligned}$$

which is $\sin^2 \Psi$ times the number of molecules impinging on unit area in unit time. If we assume that this treatment will apply approximately to the flowing gas we can substitute in [2.6] to give

$$n_0{}^{\Psi} = n_0(1 - 2\sin^2 \Psi). \qquad [2.7]$$

Equation [2.7] predicts that $n_0{}^{\pi/2} = -n_0$ and that $n_0{}^{\pi/4} = 0$, as would be expected. When Ψ ranges from 0 to $\pi/2$, we must assume that the facets are distributed according to a function $h(\Psi)\, d\Psi$ and the modified flow is

$$[2.8] \qquad n_0^{\Psi} = n_0\left[1 - \frac{2\int_0^{\pi/2} \sin^2\Psi h(\Psi)\,d\Psi}{\int_0^{\pi/2} h(\Psi)\,d\Psi}\right] = n_0(1-\beta_2).$$

APPENDIX 3

We consider here those molecules which are adsorbed at a level in which they remain mobile, which exchange energy during their movements on the surface, and which finally evaporate again without becoming immobilized. On adsorption these molecules possess a component of mass velocity v_{0_x} in the direction of flow, the remaining components of $\mathbf{v}_0$ are zero (i.e. there is no net mass flow to the walls). We assume that collision between adsorbed molecules and substrate is the only mechanism which reduces mass velocity (i.e. that changes of direction in traversing facets do not affect this quantity).

On the surface molecules move across the facets with two-dimensional molecular velocities $\mathbf{v}_2$, which are distributed according to a (non-Maxwellian) distribution function $f_2(\mathbf{v}_2,t)$. It is assumed that f_2 does not change appreciably with position over the region of surface which a molecule can cover during its time of stay, and we designate the mean surface population (molecules cm^{-2}) over this region as C_s'.

If the probability per molecule that energy exchange, which is not large enough to bring about evaporation or condensation to the immobile level, occurs in unit time is k_b, and the surface population is so dilute that intermolecular collisions are not important, then we can apply a relaxation time approximation (33) to the Boltzmann equation (20) and write

$$[3.1] \qquad \frac{\partial f_2}{\partial t} = -k_b(f_2 - f_2^{0}),$$

where f_2^0 is the Maxwellian distribution which would be achieved at infinite time.

If k_b is independent of $\mathbf{v}_2$ and t then eq. [3.1] becomes

$$[3.2] \qquad \int \mathbf{v}_2 \frac{\partial f_2}{\partial t}\,d\mathbf{v}_2 = -k_b\int \mathbf{v}_2 f_2\,d\mathbf{v}_2 + k_b\int \mathbf{v}_2 f_2^{0}\,d\mathbf{v}_2.$$

Applying the customary transformation (20) to the left-hand side of [3.2] we have

$$[3.3] \qquad \int \mathbf{v}_2 \frac{\partial f_2}{\partial t}\,d\mathbf{v}_2 = \frac{\partial}{\partial t}\int \mathbf{v}_2 f_2\,d\mathbf{v}_2 - \int f_2 \frac{\partial \mathbf{v}_2}{\partial t}\,d\mathbf{v}_2$$

and as $\mathbf{v}_2$ is not a function of t the second integral on the right-hand side of [3.3] is zero.

Substituting [3.3] in [3.2] we have

$$\frac{\partial}{\partial t}\int \mathbf{v}_2 f_2\,d\mathbf{v}_2 = -k_b\int \mathbf{v}_2 f_2\,d\mathbf{v}_2 + k_b\int \mathbf{v}_2 f_2^{0}\,d\mathbf{v}_2.$$

Now $\int \mathbf{v}_2 f_2^0\,d\mathbf{v}_2 = 0$ and $\int \mathbf{v}_2 f_2\,d\mathbf{v}_2 = C_s'\mathbf{v}_{0_2}$ where $\mathbf{v}_{0_2}$ is the mass velocity of the molecules on the surface after a time t, hence

$$[3.4] \qquad \int \frac{d\mathbf{v}_{0_2}}{\mathbf{v}_{0_2}} = \int -k_b\,dt.$$

The boundary conditions in the integration of [3.4] are found as follows in order to obtain the mean drift momentum per molecule of the gas before (π_1) and after interaction (π_r). The ratio of these quantities is equated in [6] with the specular reflection coefficient.

Let τ_s be the mean lifetime of molecules adsorbed in the mobile levels. We consider a representative group of molecules which are desorbed in a short time interval about τ_s from the facets. The facets involved are also taken to be a representative group. We assume that all molecules leaving at $t = \tau_s$ arrived on the surface at $t = 0$ whence the value of π_1 is that appropriate to the flowing gas close to the surface which is mv_{0_x}. At τ_s, $\pi_r = mv_{0_x}(\tau_s)$ where $v_{0_x}(\tau_s)$ is the component of mass velocity in the plane of the facets, resolved in the x-direction, i.e. $v_{0_x}(\tau_s) = \mathbf{v}_{0_2}\,\overline{\cos\Psi}$. $\overline{\cos\Psi}$ is a mean value of the cosine of the angle of inclination of the facets, given by:

$$[3.5] \qquad \overline{\cos\Psi} = \frac{\int_0^{\pi/2} \cos\Psi\, h(\Psi)\, d\Psi}{\int_0^{\pi/2} h(\Psi)\, d\Psi}.$$

Using these boundary conditions in the integration of [3.4] we obtain

$$[3.6] \qquad (1 - \beta_3)\ \overline{\cos\Psi} = \frac{\mathbf{v}_{0_2}\,\overline{\cos\Psi}}{v_{0_x}} = \overline{\cos\Psi}\,.\,e^{-k_b\tau_s}.$$

SLIP FLOW IN LONG, SINGLE CAPILLARIES

PART III. THE TRANSIENT STATE OF FLOW

R. M. Barrer and D. Nicholson

Physical Chemistry Laboratories, Chemistry Department, Imperial College, London, England

Received October 16, 1964

ABSTRACT

The time lag in establishing steady-state slip flow in long, single capillaries has been measured for the rare gases at 0 °C, for CO_2, Xe, and propane at 196 °K, and for SO_2 at 240 °K. The results are presented as non-dimensional time-lag quotients and as the reciprocals of this quotient plotted against u the reciprocal Knudsen number. Attention is drawn to some properties of reciprocal time lags, in particular the fact that they often have the same form as the permeability function when plotted against concentration. When adsorption is not appreciable, agreement between experiment and theory is very good in the slip flow regime but becomes less so as the transition regime is approached. Experiments at the lower temperatures showed that the effect of adsorption could be detected for CO_2, Xe, and propane but not for SO_2. These results can be interpreted in terms of a Freundlich isotherm but it seems probable that the time lag is particularly sensitive to the presence of sites of high adsorption potential.

1. INTRODUCTION

In this paper measurements of time lag in single capillaries are reported and discussed. The measurements, made in the slip flow regime, were carried out in the series A capillaries described in Part II (1). The method of measuring time lags by extrapolating to zero pressure the linear part of the plot of outgoing pressure, P_2, against time, t, has been described elsewhere (2). In these experiments P_2 was always less than 0.05% P_1, and so $P_1 - P_2 \simeq P_1$.

The equation for non-steady-state slip flow can be formulated in a manner analogous to Fick's law as

$$\frac{\partial C_g'}{\partial t} = \frac{\partial}{\partial x}\left[D(C_g')\,\frac{\partial C_g'}{\partial x}\right],$$

where $D(C_g')$ is the concentration-dependent diffusion coefficient and C_g' is the gas phase concentration in molecules cm^{-3}. $D(C_g')$ is related to the integral diffusion coefficient or permeability K by

$$K = 1/C_0 \int_0^{C_0} D(C_g')\,dC_g',$$

where C_0 and O are the ingoing and outgoing concentrations.

When D depends on concentration a direct solution of the Fick's law equation can only be found in an approximate form (3). A general procedure due to Frisch is, however, available (4) for obtaining the time lag, and expressions have been developed for this parameter for cases when slip flow is occurring in single capillaries (Ash, Barrer, and Nicholson (5)). The physical conditions considered in this publication were slip flow and transition flow without adsorption, for which the permeability is given by eqs. [2] and [3] of Part I; and slip flow, with immobile adsorption, described by various isotherm equations, at the surface of the capillary. The results were expressed in dimensionless form, the quotient involving the time lag, which can be found from experimental data, being

$$\mathscr{L} = \frac{LK_0}{l^2},$$

where L is the measured time lag in seconds in a capillary of length l and radius r, and $K_0 = (\pi r/16)(2RT/\pi M)^{1/2}$, M and T being the molecular weight and absolute temperature of the gas. If the time-lag quotient with immobile adsorption is indicated by subscript 2 then it is found that $\mathscr{L}_2 = \mathscr{L} + (2u_m/r)\mathscr{L}_1$ where $\mathscr{L}$ here is the time-lag quotient without adsorption, and u_m is defined in terms of the monolayer capacity C_m as $u_m = (rC_m/2\eta)(2RTM/\pi)^{1/2}$. The form of $\mathscr{L}_1$ depends on the adsorption isotherm. The results of the earlier paper are summarized in Table I, in which non-dimensional time-lag quotients are expressed as functions of the dimensionless parameter u. As explained in Part II u can be identified approximately with $r/\bar{\lambda}$ where $\bar{\lambda}$ is the mean free path associated with $P_1/2$, and a is the slip flow intercept which is constant for a given gas and temperature.

One general feature of these equations is that $\mathscr{L}$ decreases as u increases, its value at the beginning of the slip flow regime being about 1/3 of that for Knudsen diffusion in the same capillary. This means that l must be large if suitable time lags are to be obtained. For example, in capillary 1A (l = 1 500 cm, $r = 5.10^{-3}$ cm) L was about 10 min for He with an ingoing pressure of 2 cm Hg at 273 °C and about 35 min for Kr under the same conditions; time lags below 5 min are difficult to measure accurately.

2. THEORY

Ash, Barrer, and Nicholson (5) have discussed ways in which the expressions of Table I might be compared with experimental results. An interesting property of these equations which was not discussed in that publication is the behavior of the reciprocal time lags. These have proved useful in assessing experimental data, and accordingly will be mentioned here.

The form of the curve of the time lag against u for slip flow with no adsorption is reminiscent of a rectangular hyperbola and suggests that reciprocal functions might be of interest. We can write for the slip flow regime

$$[1] \qquad \frac{1}{\mathscr{L}_2} = \frac{u^3(u+a)^3}{Q_0 + \nu Q_1},$$

where $\nu = 2u_m/r$. The denominator of [1] may be written in the form

$$[2] \qquad Q_0 + \nu Q_1 = \sum a_n u^n = a_5 u^5 + \text{----} + a_0 + \sum_1,$$

where a_n are coefficients and $\sum_1$ is the sum of terms with powers of u greater than 5, and will be negligible when $1/\mathscr{L}_2$ is a linear function of u.

(a) $Q_1 = 0$. No Adsorption

We find,

$$[3] \qquad 1/\mathscr{L} = 3.750u + 5.3906a\gamma = s_0 u + i_0,$$

where $\gamma = 1 + 0.0897(a/u) - 0.0696(a/u)^2 + \text{- - - - -}$ which converges when $u > a$; some values of γ are given in Table II which show that γ is not very variable over quite wide ranges of a/u. The function $u^3(u+a)^3/Q_0$ is plotted in Fig. 1 where it can be seen that there is no appreciable departure from linearity when $u > 10$.

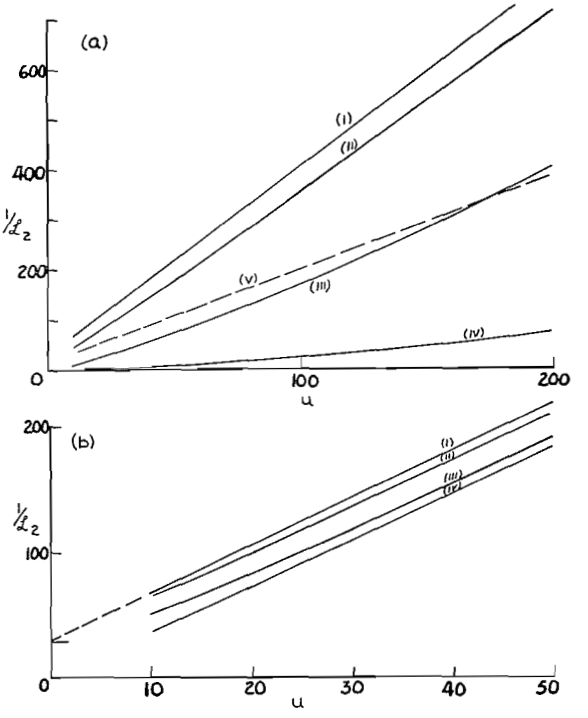

FIG. 1. Reciprocal time-lag quotients as functions of u. (*a*) Slip flow with Freundlich isotherm. (*i*) No adsorption ($a = 5.0$); (*ii*), (*iii*), (*iv*) Freundlich isotherm with $n = 2$ and $\nu k_f = 1.0$, 10.0, and 100 respectively; (*v*) Henry's law ($n = 1.0$) with $2k_s/r = 1.0$. (*b*) Slip flow with Langmuir isotherm. (*i*) No adsorption ($a = 5.3$); (*ii*), (*iii*), (*iv*) $k_1 = 0.01$, 0.10, and 1.00 respectively.

In the transition regime a much more complicated expression is obtained for the time lag (5) (see Table I). Its reciprocal and K/K_0 are both illustrated in Fig. 2 in which a value of $a = 6.0$ has been taken. It would be much more difficult to obtain an equation such as

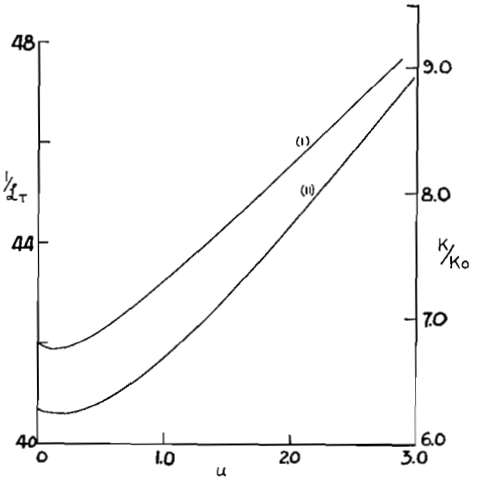

FIG. 2. Reciprocal time-lag quotients and relative permeabilities in the transition flow regime, as functions of u. (*i*) $1/\mathscr{L}_T$ vs. u; (*ii*) K/K_0 vs. u. $1/\mathscr{L}_T$ is calculated from eq. 1*f* from Table I; K/K_0 is obtained from the corresponding integrated form of Weber's equation (Part II); $a = 6.0$, $a' = 0.198$, $b' = 4.0$.

[3], in this case. Similarly no proof of this correspondence between reciprocal time lag and K/K_0, in the general case when K/K_0 is represented by a series, has yet been found.

(b) Q_1 Is Not Zero

b.1.—The simplest example is for Henry's law adsorption. Here,

$$[4] \qquad i_0/i_H = s_0/s_H = 1 + 2k_s/r,$$

where s_H and i_H are the slope and intercept of $1/\mathscr{L}_2$. The Freundlich isotherm (which reduces to Henry's law when $n = 1$) gives rise to curved plots of $1/\mathscr{L}_2$ against u (Fig. 1*a*).

b.2.—With Langmuir adsorption we can consider two extremes. (*i*) $uk_1 \gg 1.0$. The logarithmic term in Q_1 becomes negligibly small compared with the other terms and an equation similar to [3] is obtained in which γ is replaced by γ_1, a series which, like γ, does not depend markedly on u. Thus, as the monolayer is approached $1/\mathscr{L}_2$ against u tends to the same slope as $1/\mathscr{L}$ against u. It can also be shown that if this line is extrapolated back to $u = 0$ the intercept is

$$[5] \qquad i = i_0 - 7.031\nu.$$

(*ii*) $uk_1 < 1$. The logarithmic part of the expression for Q_1 can be expanded as a series of uk_1, and when uk_1 is sufficiently small the terms in $\sum_1$ (eq. [2]) become negligible. The ratio of the slopes is then

$$[6] \qquad \frac{s_0}{s_1} = \left[1 + \frac{\nu k_1}{16}(3ak_1 - 8)(ak_1 - 2)\right].$$

By definition $u_m k_1 = k_s$ so that [6] can also be written

$$[6a] \qquad \frac{s_0}{s_1} = \left[1 + \frac{2k_s}{r}\frac{(3ak_1 - 8)(ak_1 - 2)}{16}\right],$$

which reduces to [4] when k_1 is small. For intermediate values of uk_1 the terms in $\sum_1$ will no longer be negligible and no algebraic expression has been found for $1/\mathscr{L}_2$. The behavior of $1/\mathscr{L}_2$ with different values of k_1 is illustrated in Fig. 1*b*.

b.3.—When adsorption proceeds beyond the monolayer the expansion of the logarithmic term in u/q, where u is always less than q, must also be included in Q_1.

(i) $uk_1 < 1.0$. The expansion in terms of u/q for the B.E.T. and Huttig models are different only in powers of u/q greater than the fifth (5). Thus, if u/q is not very close to 1, eq. [6] can be replaced by the same expression in both cases, viz:

$$[7] \qquad \frac{s_0}{s_B} = \left[1 + \frac{\nu k_1}{16}(3ak_1 - 8)(ak_1 - 2) + \frac{\nu}{16q}((3a/q) - 8)((a/q) - 2)\right]$$

in which the term containing q tends to 0 when $a/q \to 0$.

(ii) $uk_1 > 1.0$. The ratio of slopes is

$$[8] \qquad \frac{s_0}{s_B} = \left[1 + \frac{\nu}{q} + \frac{1}{16q}\left(\frac{3a}{8q} + 3\left(\frac{a}{q}\right)^2\right)\right]$$

and the intercept can be written

$$i_B \simeq \frac{35a}{3(1 + \nu/q)} + \frac{\nu}{2}.$$

Calculations made previously (5) showed that ν would be about 5, and as q represents an upper limit to u this will usually be about 100 for the slip flow approximation to apply.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Thus the lines in Fig. 1*b* for Langmuir adsorption will have only slightly different slopes if the effect of multilayer adsorption is taken into account. Furthermore as $a \simeq \nu$ the terms in a/q in [8] are quite negligible compared with ν/q and so eq. [8] can be written

$$[8a] \qquad \frac{s_0}{s_B} = (1 + \nu/q).$$

3. RESULTS

(a) Adsorption Effects Negligible

The steady-state measurements discussed in Part I enable one to find a value of a, and also to calculate u for a particular value of the pressure. Hence a comparison of experimental values of $\mathscr{L}$ with those predicted from the steady state can be made. Such comparisons show good or very good agreement and provide a test of the Frisch method. Plots of $1/\mathscr{L}$ and of $\mathscr{L}$ against u for Ne at 0 °C in capillary 1A are shown in Fig. 3.

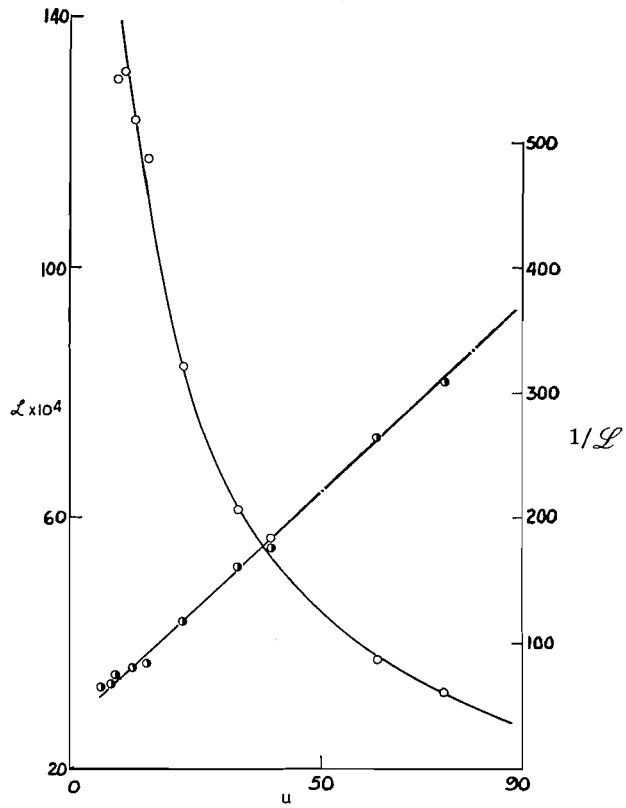

FIG. 3. Time-lag and reciprocal time-lag quotients in the slip flow regime for Ne at 0 °C, as functions of u. (*i*) Theoretical line and experimental points for $\mathscr{L}$ against u; (*ii*) theoretical line and experimental points for $1/\mathscr{L}$ against u; $a = 6.2$.

An alternative procedure is to assume that the expression for $\mathscr{L}$ is correct and to solve equation I*a* (Table I) for each experimental value of u and $\mathscr{L}$. This was done using an iterative method, on the London Mercury computer, and the results for steady state and transient state mean a values are given in Table III. The standard deviations quoted here

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

indicate that time-lag results are more scattered than steady state K values and reflect the fact that the time lag is more difficult to measure accurately.

TABLE III

Values of a in capillary 1A at 273 °K

Gas	Steady state	Transient state
He	$6.7_2 \pm 0.2$	$6.6_8 \pm 0.5$
Ne	$5.7_3 \pm 0.1$	6.2 ± 1.0
Ar	5.1 ± 0.3	5.8 ± 1.2
Kr	4.2 ± 0.5	4.1 ± 1.5

When u is < 5, $\mathscr{L}_T$ is lower than $\mathscr{L}$ by more than 5% of $\mathscr{L}$ (see ref. 5) and the equation for the transition regime should be more appropriate. This region is examined in detail in Fig. 4 where helium and neon results are compared with $\mathscr{L}_T$ which has been calculated using the a values already established for the slip flow regime. There is a considerable

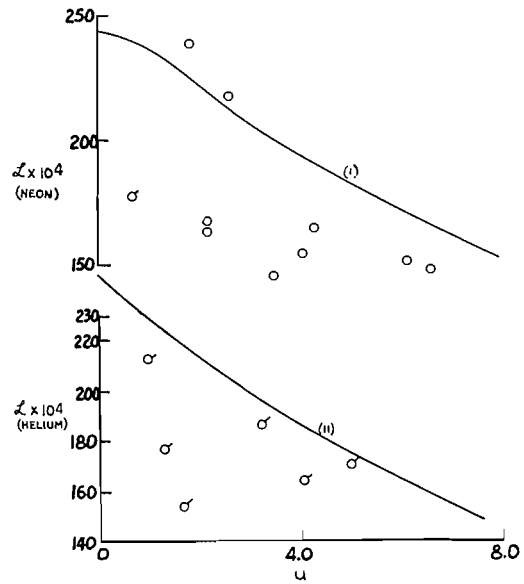

FIG. 4. Time-lag quotient in the transition regime as a function of u. ○ = Ne at 0 °C; ♂ = He at 0 °C. (*i*) Calculated with $a = 6.2$, from eq. 1*f* of Table I; (*ii*) calculated with $a = 6.7$, from eq. 1*f* of Table I.

scatter in time-lag points as this region is approached; in part this is because there is a lower limit to the pressure measurements which can be reliably made with the existing apparatus. Nevertheless it is clear that there is a definite tendency for experimental time lags to be low. One reason might be that a true steady state was not achieved when the time lag was large. However K/K_0 does not show the same marked deviation from Weber's equation (5) in the steady state. The absolute value of the time lag for He was quite low (about 10 min) and the runs were continued for more than 10 times L which should be ample time to establish the steady state.

(b) Systems with Adsorption

Because of experimental difficulties which arise at low temperature (1) most measure-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ments were made at 'cardice' temperature. This excludes measurements involving adsorption for a number of potentially interesting gases; e.g., Ar and Kr would not be expected to exhibit detectable differences in time lag in capillaries such as these, with radii of the order of 5×10^{-3} cm, until liquid oxygen or nitrogen temperature are reached. Four measurements on Kr at 'cardice' temperature confirmed that this was the case. A further restriction arises because otherwise suitable gases often condense at quite low u values.

In Fig. 5 the results obtained for adsorbable gases are illustrated as $\mathscr{L}_2$ and $1/\mathscr{L}_2$ plotted against u. For SO_2 at $\sim$ 240 °K adsorption is scarcely detectable but for all other cases time lags are definitely longer than would be expected if no adsorption occurred.

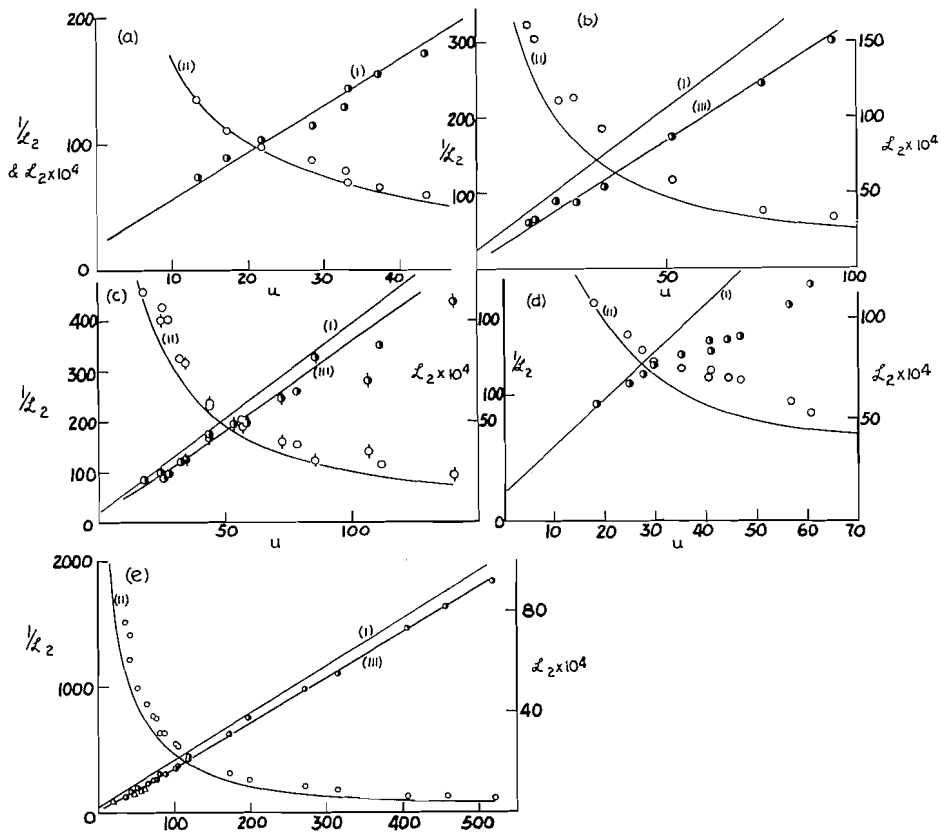

FIG. 5. Time-lag and reciprocal time-lag quotients for slip flow with adsorption, as functions of u. (*a*) SO_2 at 239.8 °K in capillary 4A; (*b*) Xe at 195.7 °K in capillary 2A; (*c*) Propane at 196.3 °K in capillaries 3A and 4A; (*d*) CO_2 at 195.7 °K in capillary 2A; (*e*) CO_2 at 196.3 °K in capillary 5A. Lines (*i*) and (*ii*) refer to $1/\mathscr{L}$ and $\mathscr{L}$ respectively, and line (*iii*) to $1/\mathscr{L}_2$ (calculated below). In Figs. 5 (*a*), (*b*), (*d*), and (*e*), ○ = $\mathscr{L}_2 \times 10^4$, ◑ = $1/\mathscr{L}_2$, while in Fig. 5 (*c*), ○ = $\mathscr{L}_2 \times 10^4$ and ◑ = $1/\mathscr{L}_2$, in capillary 4A; ⊖ = $\mathscr{L}_2 \times 10^4$ and ◐ = $1/\mathscr{L}_2$, in capillary 3A; △ = $1/\mathscr{L}_2$ for CO_2 in capillary 2A.

Although there was considerable experimental scatter, one feature emerged clearly from the results obtained in capillaries 1A, 2A, and 3A; this was that behavior characteristic of Langmuir adsorption (Fig. 1*b* and ref. 5) was not observed. To confirm this a series of experiments was performed with CO_2 in capillary 5A. This capillary was the longest one used (2 000 cm) and it was possible to obtain time lags of about 4 min at $u \simeq 500$. The value of u corresponding to saturation vapor pressure was $q = 1\ 260$ (Table IV) so that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

adsorption beyond a completed monolayer would certainly be expected for points with u greater than about 150. Standard deviations for the three highest points calculated from the P_2 against t lines were about 1% of the time lag in each case.

TABLE IV

	q	$1 + \nu/q$	n	$k_t\nu$*	k_s (cm)
CO_2	1 260	1.004	1.1_1	0.13	
Propane	340	1.014	1.1_0	0.15	
Xe	5 600	1.0009	1.0	0.18	4.9×10^{-4}

*$k_t\nu = 2k_s/r$ when $n = 1.0$.

The theory discussed earlier (5) and the lines illustrated in Fig. 1*b* indicate that the behavior observed might be expected when uk_1 is less than 1.0. However, this criterion requires that the k_1 should be about 10^{-2} and it is unlikely that such low k_1 values would exist for the systems studied here, or that adsorption would be detectable in such instances (5). Again, it is possible that post-monolayer adsorption might be responsible for the divergence of $1/\mathscr{L}$ and $1/\mathscr{L}_2$. For CO_2, Xe, and propane values of q are given in Table IV; thus for propane $(1 + (\nu/q)) \simeq 1.014$, i.e. a 1% divergence in slope might be expected, but this is not sufficient to explain the results obtained. For propane $\mathscr{L}_2$ values were corrected by subtracting $\mathscr{L}/q$ (ref. 5) to account for post-monolayer adsorption.

It may be concluded that of the isotherms so far considered the Freundlich equation (Fig. 1*a*) would be expected to provide the best fit to the experimental results. To a good first approximation the time-lag quotient for this isotherm can be written

$$\mathscr{L}_2 = \mathscr{L}\left\{1 + \frac{15n^2\nu k_t u^{(1/n)-1}}{(4n+1)(2n+1)}\right\}$$

from which

$$[9] \qquad \log\left[\frac{\mathscr{L}_2}{\mathscr{L}} - 1\right] = \left(\frac{1}{n} - 1\right)\log u + \log\left[\frac{15n^2\nu k_t}{(4n+1)(2n+1)}\right].$$

From the plots of $\log(\mathscr{L}_2/\mathscr{L} - 1))$ against $\log u$ shown in Fig. 6, values of n and νk_t were calculated for Xe, propane, and CO_2. These results are summarized in Table IV and the reciprocal time-lag quotients calculated from them using eq. 1*b* of Table I are shown in Fig. 5 (curves *iii*).

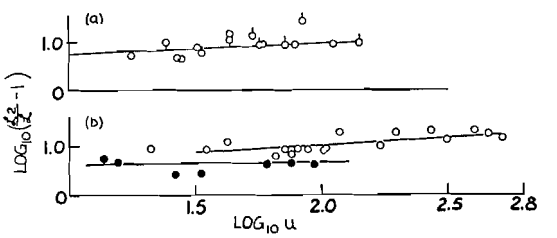

FIG. 6. Log $(\mathscr{L}_2/\mathscr{L} - 1)$ vs. log u. (*a*) ○ = propane in capillary 4A at 196.3 °K, ♂ = propane in capillary 3A at 196.3 °K; (*b*) ○ = CO_2 in 5A at 196.3 °K, ● = Xe in 2A at 195.7 °K.

In all these instances n does not differ significantly from the 'Henry's law' value of 1.0, and for Xe it would even appear that Henry's law is obeyed. On the other hand a calculation based on the value of k_s quoted in Table IV and taking the specific area of Xe at

196 °K to be 20 Å shows that monolayer coverage should have been achieved for the highest values of u. The reason for this behavior most probably originates in the nature of the time lag. Thus the theoretical consideration of the time lag (5) shows that processes involving large energies (adsorption of the first layer) are very much emphasized in comparison with those involving smaller energies (subsequent condensation of second, etc., layers). Similarly the part played by the most energetically sorbing sites in the adsorption process would be exaggerated in time-lag measurements.*

The Freundlich isotherm can be derived on the assumption that site energies are randomly distributed (7), and can therefore be taken as being associated with adsorption on an energetically heterogeneous surface. However, one of the weaknesses of this isotherm is that it does not reduce to Henry's law at low surface coverages. This suggests that n should actually be an increasing function of concentration, having a value of 1 at low concentrations (Henry's law), and therefore that the values of n we have obtained from the time-lag measurements are suitably weighted means for the surface concentration ranges studied. But, as explained above, the theory of the time lag shows that the mean value obtained for n will be weighted towards its value for lower concentrations and must thus give low values for n.

4. CONCLUSION

The experimental results for slip flow without adsorption are in excellent agreement with the theory based on Frisch's method and indicate that this procedure can be applied with confidence. The prediction that adsorption on the walls of single capillaries should be detectable from time-lag measurements in the slip flow regime has proved to be correct, although the interpretation of these results is less certain. One factor which cannot be fully accounted for at present is the possibility of surface flow. Although previous calculations have shown that this is unlikely to be important (5) there is some uncertainty in the estimation of surface diffusion coefficients. In most of the systems studied the surface flow is probably insignificant because time lags tend to be longer not shorter than would be expected; however, SO_2 is an exception and it may be that appreciable surface fluxes exist in this system.

One of the major difficulties of time-lag measurements is that they cannot yet be made with the degree of accuracy of permeability measurements. When more precise experimental results can be obtained time-lag measurements of the type discussed here and in ref. 5 may provide a means of investigating surface heterogeneity.

ACKNOWLEDGMENTS

We would like to thank Mr. R. Ash of this department for helpful discussions. One of us (D. N.) is indebted to the British Petroleum Company for a postdoctoral fellowship.

THE STRUCTURE OF A SYNTHETIC ARABINAN

G. G. S. DUTTON

Received April 27, 1964

ABSTRACT

Hydrolysis of the fully methylated synthetic arabinan showed it to have a highly branched structure in which about 16% of the terminal units were furanose and 2,3-di-*O*-methyl-L-arabinose was the principal di-*O*-methyl ether. A method has been developed whereby mixtures of isomeric di- or mono-*O*-methyl arabinoses may be qualitatively analyzed by successive borohydride reduction, periodate oxidation, and borohydride reduction. The resulting fragments may be separated directly by vapor phase chromatography or by paper chromatography after demethylation.

A variety of monosaccharides has been polymerized by Mora and his associates (1) and in previous papers we have reported on the structure of a synthetic glucan (2) and of a xylan (3). The present paper reports on the nature of an arabinan prepared by the polymerization of L-arabinose. The polysaccharide used in this study was prepared by Dr. Mora and was part of the same sample whose physical properties have already been reported (1). It has only been possible to carry out a methylation study owing to the small amount of polymer available. A novel method of qualitatively analyzing a mixture of isomeric methylated sugars has been developed and although the quantitative accuracy is not known some indication of the principal components, and hence linkages, may be obtained.

The arabinan was methylated three times by the method of Kuhn (4) and six times by Purdie's method (5) to give eventually a fully methylated product which was hydrolyzed with sulfuric acid (6). The methylated sugars were separated by paper chromatography into the fractions shown in Table I and indirect evidence for the presence of the majority of compounds was obtained by application of periodate degradation schemes similar to that shown in Table II.

Fraction 1, the fastest moving material, was characterized as 2,3,5-tri-*O*-methyl-L-arabinose by formation of the crystalline amide. The possible components of fraction 2

were the 2,3,4-tri-*O*-methyl-, 2,5- and 3,5-di-*O*-methyl-L-arabinoses. Of these only the last would migrate on electrophoresis and examination in this way showed that 7–10% of fraction 2 was the 3,5-di-*O*-methyl ether. The overall composition of this fraction may be approximately determined by successive borohydride reduction, periodate oxidation, and borohydride reduction. The fragments produced may be demethylated with hydrobromic acid (7), the products separated by chromatography and estimated quantitatively. Under these conditions the 2,3,4-isomer will give arabinitol, the 3,5-isomer will give erythritol while the 2,5-ether will give an equimolecular mixture of ethylene glycol and glycerol as shown in Table II. Application of this method to fraction 2 gave arabinitol, erythritol, glycerol, and ethylene glycol in a molar ratio of 16:2:1:1. Although the quantitative nature of the demethylation step has not been examined in detail it should be noted that the sum of the weights of the demethylated glycitols recovered was almost quantitative for a mixture containing about 7% of 3,5-di-*O*-methyl-L-arabinose. Furthermore glycerol and ethylene glycol were obtained in equimolecular amounts which suggested that no selective decomposition had taken place. These results indicated that 2,3,4-tri-*O*-methyl-L-arabinose was the main component of fraction 2 and taken in conjunction with the weight of the 2,3,5-isomer isolated in fraction 1 showed that approximately 16% of the non-reducing end groups in the polysaccharide were furanose.

TABLE II

Periodate analysis of fraction 2

Components (L-arabinose ethers)	Reactions	Product	Demethylation product
2,3,4-Tri-*O*-methyl	(*i*) BH_4^-	2,3,4-Tri-*O*-methyl-L-arabinitol	L-Arabinitol
3,5-Di-*O*-methyl	(*ii*) IO_4^-	2,4-Di-*O*-methyl-L-erythritol	Erythritol
	(*iii*) BH_4^-	2-*O*-Methylglycerol	Glycerol
2,5-Di-*O*-methyl		+	+
		mono-*O*-methylethylene glycol	ethylene glycol

Fraction 3 was believed to consist of the 2,3-, 2,4-, and 3,4-di-*O*-methyl ethers. Electrophoretic examination showed one migrating component which amounted to about 15% of the fraction and corresponded to the 3,4-isomer. Periodate oxidation of fraction 3 gave a small amount of a sugar with a significantly higher R_f value than the bulk of the fraction which was unchanged. This fast moving material was isolated and was assumed to be 2,3-di-*O*-methylerythrose since reduction and demethylation gave erythritol according to the following scheme.

3,4-Di-*O*-methyl-L-arabinose $\xrightarrow{IO_4^-}$ 2,3-di-*O*-methyl-L-erythrose $\xrightarrow{BH_4^-}$ 2,3-di-*O*-methyl erythritol $\xrightarrow{HBr}$ erythritol.

Of the three possible isomers 2,4-di-*O*-methyl-L-arabinose cannot undergo cleavage with periodate, the 2,3-ether will undergo slow oxidation while the 3,4-isomer will be rapidly oxidized (8). Furthermore only the 3,4-isomer can give rise to erythritol and therefore the isolation of this glycitol confirms the electrophoretic assignment. The remaining material was reduced, oxidized, and reduced as shown,

2,3-di-*O*-methyl-L-arabinose, 2,4-di-*O*-methyl-L-arabinose $\xrightarrow[(ii)\ IO_4^-]{(i)\ BH_4^-}$ 2,3-di-*O*-methyl-L-threose, 2,4-di-*O*-methyl-L-arabinitol $\xrightarrow[(ii)\ HBr]{(i)\ BH_4^-}$ threitol, arabinitol,

and the glycitols obtained by demethylation were characterized thus proving the presence of the 2,3- and 2,4-di-*O*-methyl ethers in fraction 3. The ratio of threitol to arabinitol was 16:1 showing that 2,3-di-*O*-methyl-L-arabinose was the major constituent of fraction 3.

Fraction 4 contained the mono-*O*-methyl-L-arabinoses and reference to Table III shows that each monomethyl ether will form a characteristic glycitol when submitted to periodate degradation. Vapor phase chromatography showed the presence of each glycitol which, after demethylation, was characterized as its *p*-nitrobenzoate.

TABLE III

Periodate analysis of fraction 4

1 Mono-*O*-methyl ether of L-arabinose	2 Product formed by (*i*) IO_4^-, (*ii*) BH_4^-	3 Demethylation product	4 Melting point of *p*-nitrobenzoate of 3 (°C)

	ethylene glycol (III)	ethylene glycol	143–144
3-	2-*O*-Methyl-L-erythritol(IV)	Erythritol	251–252
4-	2-*O*-Methylglycerol (II)	Glycerol	190–192
5-	1-*O*-Methyl-D-glycerol (I)	Glycerol	190–192

*The Roman numeral refers to the order of appearance on vapor phase chromatography.

The results presented here show that the arabinan was a highly branched polysaccharide in which there was a high proportion of furanosyl units. In these respects this polymer closely resembled the others examined.

Some of the analytical methods used to identify the components of a complex mixture of isomeric sugars represent a useful application of vapor phase chromatography where the original sugars, or their derivatives, themselves lack sufficient volatility. It is hoped that the application of the methods outlined here will be of general use in the study of other arabinose-containing polysaccharides especially those of natural origin.

EXPERIMENTAL

General methods have been described previously (2).

Methylation and Hydrolysis

The arabinan (1.60 g) was dissolved in dimethylformamide (25 ml) by warming to 55–60°. The solution was cooled and methyl iodide (5 ml) and silver oxide (5 g) were added. The mixture was shaken mechanically at room temperature for 3 days and the product recovered by extraction with chloroform. The Kuhn methylation was repeated twice more but a fully methylated arabinan (1.36 g, OMe, 39.8%, no hydroxyl band in the infrared) was only obtained after six treatments with Purdie's reagents. The final product was a yellow glass which could not be purified by fractional precipitation owing to its solubility in 95% petroleum ether (30–60°) and 5% chloroform. This probably explains the slightly high methoxyl value.

The fully methylated arabinan (1.25 g) was dissolved in 72% sulfuric acid (6) and after 1 h the thick solution was diluted with water to an acid concentration of 2 *N* and was boiled for 8 h. The solution was neutralized with barium carbonate and evaporated to give a mixture of methylated sugars (1.15 g). The mixture was resolved on Whatman 3MM paper using butanone–water azeotrope and gave the fractions shown in Table I.

Identification of Components

Fraction 1, 65 mg, $[\alpha]_D$ −38° (*c*, 1.5 in water) was oxidized with bromine and the acid lactonized. The lactone had $[\alpha]_D$ −24° (*c*, 1.5 in water) and vapor phase chromatography indicated only minor amounts of impurities. Reaction with methanolic ammonia gave the amide as a sirup $[\alpha]_D$ 20° (*c*, 1.5 in ethanol) from which a small quantity of 2,3,5-tri-*O*-methyl-L-arabonamide, melting point and mixed melting point 135–137°, was obtained.

Fraction 2 was subjected to the reactions shown in Table II. The sirup (410 mg) was dissolved in water (50 ml) and reduced for 24 h with sodium borohydride (1 g). Excess hydride was destroyed by the addition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of acetic acid and the solution made 0.1 *M* with respect to periodic acid. Periodate and iodate ions were removed 16 h later by the addition of barium carbonate and the filtrate again reduced overnight with borohydride (1 g). The solution was acidified with acetic acid and evaporated to dryness. The residue was dissolved in hydrobromic acid (45%, 10 ml) and refluxed for 35 min. The solution was deionized by passage through Amberlite IR-120 and Duolite A-4 resins and the components were resolved on Whatman 3MM paper in ethyl acetate – pyridine – water (9:2:2). Analysis showed arabinitol, erythritol, glycerol, and ethylene glycol in the molar ratio of 16:2:1:1. The individual compounds were characterized as follows: L-*arabinitol* (285 mg), pentaacetate melting point and mixed melting point 74–75°; *erythritol* (26 mg), tetra-*p*-nitrobenzoate melting point and mixed melting point 251–253°; *glycerol* (10 mg), tri-*p*-nitrobenzoate melting point and mixed melting point 190–192°; and *ethylene glycol* (7 mg), di-*p*-nitrobenzoate melting point and mixed melting point 143–145°. Paper electrophoresis of a sample of fraction 2 in borate buffer (0.07 *M*) showed non-migrating components and material with an M_G of 0.3. Using the phenol – sulfuric acid method the ratio of non-migrating to migrating material was 16:1.

Fraction 3, 280 mg, when subjected to electrophoresis indicated a component with M_G of 0.0 and a minor component with M_G of 0.40, the latter constituting 15% of the total. The mixture was subjected to the following series of reactions. The sirup was dissolved in cold periodic acid (0.1 *M*, 50 ml) and the solution stored at 5°. Excess periodate and iodate were precipitated (barium carbonate), the solution was evaporated, and the product was examined by paper chromatography using butanone–water azeotrope. A new component with R_f of about 0.7 was observed. The mixture was resolved, the new sugar (presumably 2,3-di-*O*-methyl-L-erythrose) was reduced, and the alcohol demethylated. The product (22 mg) was identified as erythritol by paper chromatography and by conversion to the tetra-*p*-nitrobenzoate, melting point and mixed melting point 251–253°. The non-degraded dimethyl sugar fraction was subjected to borohydride reduction, periodate oxidation, and a second borohydride reduction followed by demethylation with hydrobromic acid. The residue (165 mg), composed of threitol and arabinitol, molar ratio 16:1, was resolved by paper chromatography. Threitol (122 mg) was converted to the tetra-*p*-nitrobenzoate, melting point and mixed melting point 220–222°. Arabinitol (9.8 mg) was not further characterized.

Fraction 4, 150 mg, was subjected to periodate oxidation and borohydride reduction. The *O*-methyl glycitols and ethylene glycol were separated by vapor phase chromatography using an Aerograph instrument, model A90-P2, and a 3 ft column ($\frac{1}{4}$ in. I.D.) of 13% Versamid on Diatoport. The individual *O*-methyl glycitols were demethylated with hydrobromic acid and the products were characterized as their *p*-nitrobenzoates. These results are shown in Table III.

Fraction 5, 15 mg, $[\alpha]_D$ 102° (*c*, 0.5 in water) was identified as L-arabinose on conversion to the phenylosazone, melting point and mixed melting point 161–163°, by reaction with phenylhydrazine hydrochloride and sodium acetate in 80% ethanol.

ACKNOWLEDGMENTS

We gratefully acknowledge the financial support of the Public Health Service (GM 07652) and the skilful assistance of Miss J. Hunter. We are also indebted to Dr. M. C. Keith for some initial experiments on the arabinan and for the preparation of the fully methylated polysaccharide.

STUDIES ON STOBBE CONDENSATION

REACTIONS OF ALDEHYDES AND KETONES WITH DIMETHYL METHYLSUCCINATE

A. M. EL-ABBADY AND H. H. MOUSA

Department of Chemistry, University College for Girls, Ain Shams University and National Research Centre, U.A.R.

Received August 7, 1964

ABSTRACT

Benzaldehyde, *o*-methoxybenzaldehyde, *p*-chlorobenzaldehyde, benzophenone, and acetophenone are condensed with dimethyl methylsuccinate in the presence of potassium *tert*-butoxide to give the corresponding β-half-esters. In the case of *o*-methoxybenzaldehyde the lactonic acid (IX) is also obtained. The β-half-esters are cyclized by sodium acetate and acetic anhydride to the corresponding acetoxynaphthoates which are converted into their methoxynaphthoates. Alkaline hydrolysis of the β-half-esters yields the corresponding itaconic acids, the anhydrides of which are converted to their α-half-esters.

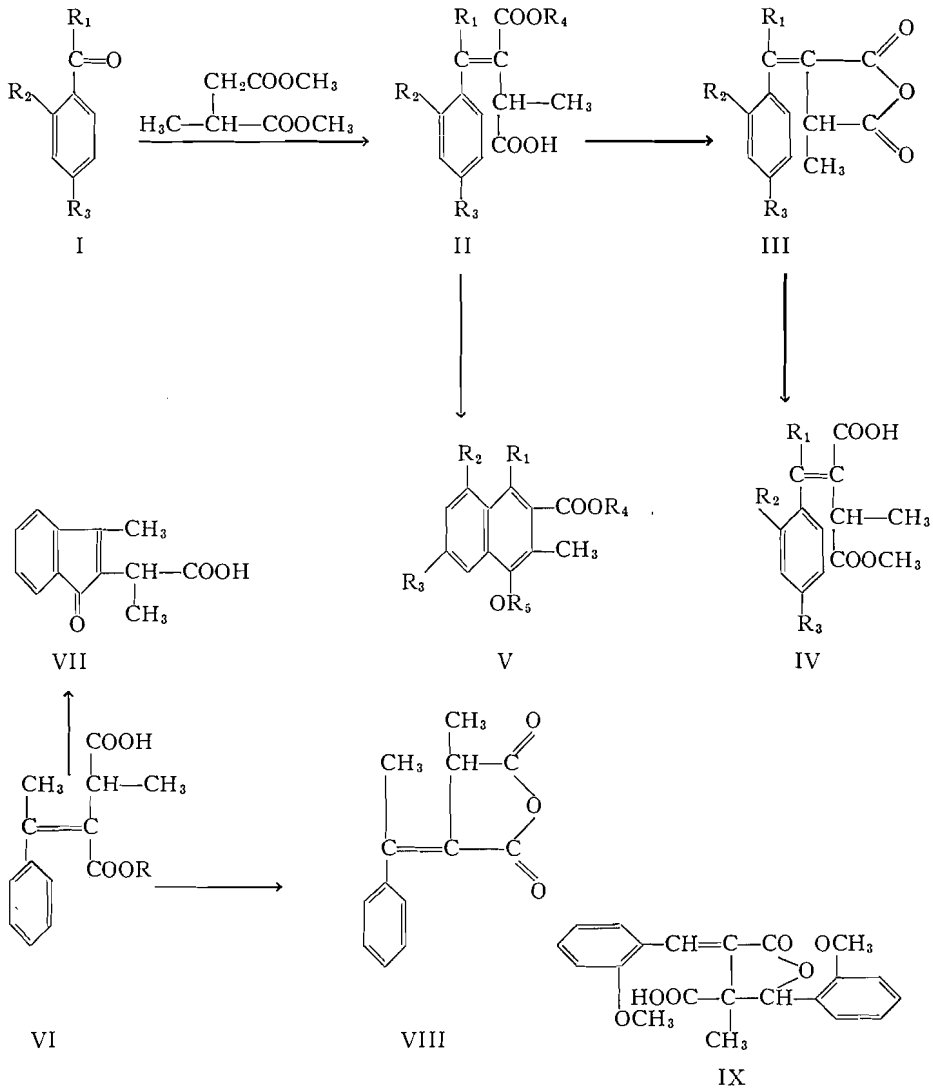
In a preliminary communication (1, 2) the reaction of two representative ketones, benzophenone and fluorenone, with diethyl methylsuccinate in the presence of sodium ethoxide was shown to proceed by a Stobbe condensation giving the expected half-esters in good yields. In the present work we are reporting an extension of this study on both aldehydes and ketones. Benzaldehyde, *o*-methoxybenzaldehyde, *p*-chlorobenzaldehyde, benzophenone, and acetophenone were condensed with dimethyl methylsuccinate in the presence of potassium *tert*-butoxide (3); from the products were formed anhydrides, half-esters, indones, and naphthalene derivatives. In all these reactions, exact parallels were found with the corresponding products previously obtained from ethyl succinate itself (3).

Good yields (60–72%) of the β-half-esters (II) were obtained from the condensation of benzaldehyde, *o*-methoxybenzaldehyde, benzophenone, and acetophenone. However, the yield was only poor, as expected, with *p*-chlorobenzaldehyde, but a shorter period of reflux was found to increase this yield slightly and minimize resinification. In the case of acetophenone, the isomeric β-half-ester (VI; R = CH_3) was also obtained and separated.

The condensation of the aldehydes in general afforded, in addition to the expected half-esters, varying amounts of the corresponding itaconic acids.

o-Methoxybenzaldehyde gave also a small amount of an acidic non-ketonic substance, m.p. 217°, which was found to be the lactonic acid (IX). The constitution of (IX) as 2-*o*-anisyl-3-carboxy-4-*o*-methoxybenzylidene-3-methyl-5-oxotetrahydrofuran follows from the following observations: (*a*) the infrared spectrum (KBr) showed a strong band at 1 750 cm^{-1}, characteristic of the stretching frequencies of carbonyl groups of α,β-unsaturated-γ-lactones (4) and (*b*) alkaline hydrolysis of the substance gave the itaconic acid (II; $R_1 = R_3 = R_4 = H$, $R_2 = CH_3O$) and *o*-methoxybenzaldehyde which was characterized as the 2,4-dinitrophenylhydrazone. Analogs of (IX) have frequently been observed in the condensations of ethyl succinate with aromatic aldehydes. The formation of this lactonic acid at high temperature is evidence for (*a*) the relative stability of the intermediate paraconic ester (3) towards the *tert*-butoxide ions; and (*b*) the comparative reactivity of *o*-methoxybenzaldehyde. When *o*-methoxybenzaldehyde was condensed with dimethyl methylsuccinate in the presence of sodium ethoxide at −15°, the lactonic acid (IX) was obtained as the main product.

Benzaldehyde and *p*-chlorobenzaldehyde also gave different amounts of benzoic acid and *p*-chlorobenzoic acid arising from a Cannizzaro reaction, a common side reaction in Stobbe condensations (3). The difference in the yields of this side reaction, was confirmed by treating *p*-chlorobenzaldehyde, benzaldehyde, and *o*-methoxybenzaldehyde with potassium *tert*-butoxide under the same conditions of the Stobbe experiment but in the absence of the succinic ester, where the yields of the resulting benzoic acids, as expected, were found to be 45, 22, and 5% respectively. This is in agreement with the electronic structures of these aldehydes where the −I effect of the Cl atom in *p*-chlorobenzaldehyde favors the side reaction (by the transfer of a hydranion) while the +T effect of the methoxyl group in *o*-methoxybenzaldehyde opposes it.



Hydrolysis of the half-esters using 10% sodium hydroxide solution gave very good yields of the corresponding itaconic acids except that from *p*-chlorobenzaldehyde which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

gave a poor yield of the corresponding itaconic acid. This was improved by lowering the temperature of reflux (130°, oil bath) and by decreasing the concentration of the alkali (5%). The half-ester of benzaldehyde gave a purer product in higher yield when barium hydroxide was used. The two isomeric half-esters of acetophenone (II; $R_1 = R_4 = CH_3$, $R_2 = R_3 = H$ and VI; $R = CH_3$), separated by fractional crystallization after distillation, gave the corresponding itaconic acids which were found to be identical with those obtained from the hydrolysis of the crude undistilled mixture of the half-esters. This indicates that the two forms of the half-ester are stable to heat. The constitutions of the two isomeric itaconic acids of acetophenone as *cis*- and *trans*-α,γ-dimethyl-γ-phenylitaconic acid (II; $R_1 = CH_3$, $R_2 = R_3 = R_4 = H$ and VI; $R = H$ respectively) were demonstrated in the usual way (3); (*a*) the two acids gave acetophenone on oxidation with alkaline permanganate, showing the absence of double bond migration and (*b*) cyclization of both itaconic acids (m.p.'s 139° and 178–180°) with concentrated sulfuric acid (5) at room temperature was successful only in the case of the acid of m.p. 178–180°, yielding the indoneacetic acid (VII) as a yellow, crystalline solid, m.p. 127° (2,4-dinitrophenylhydrazone, m.p. 186–187°).

The structures and the *cis* configuration of the β-half-esters from the three aldehydes and benzophenone were confirmed in the usual way (3) by their cyclization with fused sodium acetate in acetic anhydride (6) to the corresponding methyl acetoxymethylnaphthoates (V) in good yields. Alkaline hydrolysis of the acetoxy esters gave the corresponding phenolic acids. Methyl 4-acetoxy-3-methyl-1-phenyl-2-naphthoate (V; $R_1 = C_6H_5$, $R_2 = R_3 = H$, $R_4 = CH_3$, $R_5 = CH_3CO$) afforded in addition to the expected phenolic acid (V; $R_1 = C_6H_5$, $R_2 = R_3 = R_4 = R_5 = H$) a phenolic solid which was found to be the phenolic ester (V; $R_1 = C_6H_5$, $R_2 = R_3 = R_5 = H$, $R_4 = CH_3$), as it showed bands in the infrared region (Nujol mull) at 3 500 (hydroxyl) and 1 715 cm^{-1} (aryl esters). The phenolic ester and acids when treated with dimethyl sulfate and anhydrous potassium carbonate in acetone afforded the corresponding methoxy esters. Methyl 4-methoxy-3-methyl-2-naphthoate (V; $R_1 = R_2 = R_3 = H$, $R_4 = R_5 = CH_3$) was obtained as a liquid and identified in the form of its solid methoxy acid (V; $R_1 = R_2 = R_3 = R_4 = H$, $R_5 = CH_3$). The itaconic acids were converted by acetyl chloride (7) into their anhydrides (III and VIII) in very good yields, except the itaconic acid from benzaldehyde (II; $R_1 = R_2 = R_3 = R_4 = H$) which failed completely to dehydrate and was recovered unchanged. The anhydrides on boiling with methanol (8) gave the corresponding α-half-esters (IV) in excellent yields. Thus in the formation of the α- and β-half-esters, and in the reactions of the latter, exact parallels are found with the analogous compounds from ethyl succinate in which the positions of the ester groups have been rigorously proved (3).

EXPERIMENTAL*

Condensation of Aldehydes or Ketones with Dimethyl Methylsuccinate (General Procedure)

A solution of the aldehyde or ketone (0.1 mole) and dimethyl methylsuccinate (0.1 mole) in dry *tert*-butanol (25 ml) was added under nitrogen atmosphere to a boiling solution of potassium *tert*-butoxide (from metallic potassium (0.12 mole) and *tert*-butanol (85 ml)). The addition took place in a period of 20 min, and the whole mixture was then refluxed under nitrogen for a further 45 min (the time of reflux was reduced to half an hour in case of *p*-chlorobenzaldehyde). The ice-cold mixture was acidified (litmus) with cold dilute hydrochloric acid. Distillation of alcohol under reduced pressure left a residue, which was diluted

**All melting points and boiling points are uncorrected, unless otherwise stated, the melting range of analytical samples was less than 1°. All yields refer to the yields of crude material. Infrared spectra were recorded on a Perkin–Elmer Infracord 137 spectrophotometer with a sodium chloride prism. Microanalyses are carried out by A. Bernhardt, Max-Plank-Institute, Mulheim (Ruhr).*

with water and extracted with ether. The ethereal solution was washed with water and repeatedly extracted with sodium bicarbonate solution which was then acidified with cold dilute hydrochloric acid to give the reaction product.

Benzaldehyde (10.6 g) gave a brown viscous oil (15.5 g), which failed to solidify. This when subjected to distillation under reduced pressure (140–150° at 0.3 mm, oil bath) gave a trace of benzoic acid (0.5 g) and most of the residue started to resinify. Saponification of the product (1 g) with a saturated solution of barium hydroxide (15 ml, 4 h heating at 100°) gave a barium salt which after filtration, washing with ethanol, and acidification with dilute hydrochloric acid yielded *cis*-α-methyl-γ-phenylitaconic acid (II; $R_1 = R_2 = R_3 = R_4 = H$) as colorless solid (0.8 g, 85% yield), m.p. 194° (from methanol).

Anal. Calcd. for $C_{12}H_{12}O_4$: C, 65.44; H, 5.49. Found: C, 65.44; H, 5.66.

When the above experiment was repeated but without the substituted succinic ester; benzoic acid, m.p. 122°, was obtained in about 22% yield.

o-Methoxybenzaldehyde (13.6 g) gave a viscous brown oil (25 g). Treatment of this oil with benzene in the cold, precipitated a solid (22 g) on standing. This solid after filtration was treated with boiling benzene in which it partly dissolved. The insoluble fraction (3.7 g) was found to be the itaconic acid (II; $R_1 = R_3 = R_4 = H$, $R_2 = CH_3O$), m.p. 198–199° (from water). This melting point was undepressed on admixture with a specimen of *cis*-γ-*o*-methoxyphenyl-α-methylitaconic acid obtained from the alkaline hydrolysis of the half-ester (II; $R_1 = R_3 = H$, $R_2 = CH_3O$, $R_4 = CH_3$) as shown later. Evaporation of the benzene solution gave the soluble fraction as a solid (17.6 g, 66% yield) which was crystallized from benzene, m.p. 168–170°. This was identified as β-methyl-α-hydrogen *cis*-γ-*o*-methoxyphenyl-α-methylitaconate (II; $R_1 = R_3 = H$; $R_2 = CH_3O$, $R_4 = CH_3$).

Anal. Calcd. for $C_{14}H_{16}O_5$: C, 63.62; H, 6.10. Found: C, 63.80; H, 6.28.

The original benzene mother liquor on long keeping gave a small amount of a solid acid (2.5 g), m.p. 217° (from methanol), which failed to give a 2,4-dinitrophenylhydrazone. This substance was found to be 2-*o*-anisyl-3-carboxy-4-*o*-methoxybenzylidene-3-methyl-5-oxo-tetrahydrofuran (IX). Infrared spectrum (KBr): 1 750 cm^{-1}.

Anal. Calcd. for $C_{21}H_{20}O_6$: C, 68.47; H, 5.4; CH_3O, 16.84; mol. wt. and equiv. wt., 368). Found: C, 68.59; H, 5.60; CH_3O, 17.08; mol. wt., 346; equiv. wt., 360.

Alkaline hydrolysis of this substance (0.4 g, 2 h refluxing with 10% sodium hydroxide solution) gave acid and neutral products. The acid (0.25 g), m.p. 196–198 (from water), on admixing with the previous specimen of *cis*-γ-*o*-methoxyphenyl-α-methylitaconic acid (II; $R_1 = R_3 = R_4 = H$, $R_2 = CH_3O$) gave no depression. The neutral semisolid (0.1 g) gave an orange 2,4-dinitrophenylhydrazone, m.p. 238° (from ethanol). This on admixing with an authentic specimen of *o*-methoxybenzaldehyde 2,4-dinitrophenylhydrazone (from B.D.H. *o*-methoxybenzaldehyde), m.p. 243–244° (from ethanol), gave no depression.

No *o*-methoxybenzoic acid was detected accompanying the Stobbe product. When the experiment was carried out under the same conditions, but in the absence of the methylsuccinic ester, *o*-methoxybenzoic acid (5% yield), m.p. 100°, was obtained and identified by its melting point and mixed melting point with a specimen of *o*-methoxybenzoic acid (B.D.H.).

Saponification of the half-ester (II; $R_1 = R_3 = H$, $R_2 = CH_3O$, $R = CH_3$) (1 g) with 10% sodium hydroxide solution (15 ml, 2 h refluxing), gave a colorless solid (0.8, 84.5% yield), m.p. 198–199° (from water). This was identified as *cis*-γ-*o*-methoxyphenyl-α-methylitaconic acid (II; $R_1 = R_3 = R_4 = H$, $R_2 = CH_3O$).

Anal. Calcd. for $C_{13}H_{14}O_6$: C, 62.39; H, 5.64. Found: C, 62.41; H, 5.66.

Alternative Preparation of 2-o-Anisyl-3-carboxy-4-o-methoxybenzylidene-3-methyl-5-oxotetrahydrofuran (IX)

A solution of *o*-methoxybenzaldehyde (12.1 g, 2 mole) and dimethyl methylsuccinate (4.4 g, 1 mole) in anhydrous ether (100 ml) was added dropwise with cooling (−15°) and shaking to a suspension of finally powdered alcohol-free sodium ethoxide (2 mole, from 1.12 g sodium in 50 ml dry ether). A precipitate rapidly separated. The mixture was kept for 2 days at −15° and then at 0 for another 2 days. The ice-cold mixture was acidified (litmus) with cold dilute hydrochloric acid. The ethereal layer was separated and the aqueous layer was extracted with ether. The ethereal layer and extracts were washed with water then repeatedly extracted with sodium carbonate solution. This was acidified to give an oil which was taken into ether and dried (Na_2SO_4). Evaporation of the solvent gave a semisolid (9.5 g) which solidified completely under benzene, m.p. 215–220°. This was crystallized from methanol as colorless crystals, m.p. 219–221°, and on admixing with a sample of the lactonic acid (IX, m.p. 217°) gave no depression.

p-Chlorobenzaldehyde (14 g) gave a deep-brown resinified oil (15 g). This was partly solidified after the addition of a little amount of benzene and standing. The solid fraction (about 2 g) melted over a wide range indicating that it was a mixture. Treatment of this mixture with boiling water gave two substances. The soluble one (1.4 g), m.p. 240° (from benzene), was found to be *p*-chlorobenzoic acid, and identified by its melting point and mixed melting point with an authentic specimen of *p*-chlorobenzoic acid (B.D.H.). The insoluble colorless substance (0.5 g), m.p. 206° (from methanol), was found to be *cis*-γ-*p*-chlorophenyl-α-methylitaconic acid (II; $R_1 = R_2 = R_4 = H$, $R_3 = Cl$)

Anal. Calcd. for $C_{12}H_{11}O_4Cl$: C, 56.27; H, 4.32; Cl, 13.95. Found: C, 56.22; H, 4.17; Cl, 14.56.

The benzene solution gave, after evaporation, an oily residue (about 13 g). A part of this oil (4 g) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

refluxed with 5% sodium hydroxide solution at 130° (oil bath) for 4 h. The solid product obtained after acidification, was treated repeatedly with boiling water. The insoluble part (1.1 g, m.p. 206° from methanol) was identified as *cis*-γ-*p*-chlorophenyl-α-methylitaconic acid (II; $R_1 = R_2 = R_4 = H$, $R_3 = Cl$) by its melting point and mixed melting point with the acid obtained directly from Stobbe reaction. The hot water washings gave after cooling a colorless solid (0.4 g, m p. 240°) which was found to be *p*-chlorobenzoic acid. When the Stobbe experiment was carried out normally but with no methylsuccinic ester; a solid acid, m.p. 240°, was obtained in about 45% yield and was identified as *p*-chlorobenzoic acid.

Benzophenone (18 g) gave a solid product (22 g, 72% yield). This was crystallized from benzene as colorless crystals, m.p. 152°, and identified as β-methyl-α-hydrogen-γ,γ-diphenyl-α-methylitaconate (II; $R_1 = C_6H_5$, $R_2 = R_3 = H$, $R_4 = CH_3$).

Anal. Calcd. for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85. Found: C, 73.64; H, 5.73.

Saponification of this half-ester (1 g) resulted in the known γ,γ-diphenyl-α-methylitaconic acid (2) (II; $R_1 = C_6H_5$, $R_2 = R_3 = R_4 = H$) as colorless crystals, m.p. 178° (from water).

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44. Found: C, 73.29, H, 5.41.

Acetophenone (12 g) gave a brown viscous oil (19 g, 76.6% yield). On distillation a heavy, pale-yellow oil, b.p. 158° at 0.7 mm, was obtained (12.2 g, 64.5% yield) which was partially solidified. The solid was separated by decantation, washed with little cold benzene, and crystallized from methanol as colorless needles (4.5 g), m.p. 106–108°. This was found to be β-methyl α-hydrogen *cis*-α,γ-dimethyl-γ-phenylitaconate (II; $R_1 = R_4 = CH_3$, $R_2 = R_3 = H$).

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50. Found: C, 68.07; H, 6.11.

Saponification of this crystalline half-ester (1 g) gave a colorless solid (0.7 g) crystallizable from benzene, m.p. 139°, and was identified as *cis*-α,γ-dimethyl-γ-phenylitaconic acid (II; $R_1 = CH_3$, $R_2 = R_3 = R_4 = H$).

Anal. Calcd. for $C_{15}H_{14}O_4$: C, 66.65; H, 6.02. Found: C, 66.99; H, 6.42.

Alkaline hydrolysis of the oil fraction (1 g from about 7.5 g) gave a colorless solid (0.65 g), m.p. 178–180° (from water). This was identified later as *trans*-α,γ-dimethyl-γ-phenylitaconic acid (VI; R = H).

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.65; H, 6.02. Found: C, 66.72; H, 6.16.

Saponification of the crude undistilled Stobbe product of acetophenone yielded a semisolid acid. This after treatment with charcoal gave colorless droplets of oil which solidified after cooling (42% yield), m.p. 124–157°, and was partly soluble in hot benzene. The insoluble fraction was found to be the acid (VI; R = H) of m.p. 178–180°, and the soluble fraction to be the acid (II; $R_1 = CH_3$, $R_2 = R_3 = R_4 = H$) of m.p. 139°.

Oxidation of α,γ-Dimethyl-γ-phenylitaconic Acids

α,γ-Dimethyl-γ-phenylitaconic acid (m.p. 139°, 0.5 g) was dissolved in 20% sodium carbonate solution (5 ml). Potassium permanganate solution (0.8 g in 45 ml water) was added dropwise with stirring until the color of permanganate persisted. The mixture was left for 2 h at room temperature, then extracted with ether. The ethereal layer after washing with water and drying (Na_2SO_4) was evaporated to give an oily residue (0.2 g). This oil gave a 2,4-dinitrophenylhydrazone, m.p. 229–230° (from ethanol), which on admixing with an authentic specimen of acetophenone 2,4-dinitrophenylhydrazone (from B.D.H. acetophenone) gave no depression. Repeating the above oxidation on the acid isomer (m.p. 178–180°) gave the same product.

Action of Concentrated Sulfuric Acid on the α,γ-Dimethylitaconic Acids

α,γ-Dimethyl-γ-phenylitaconic acid, m.p. 178–180°, (0.5 g) was treated with concentrated sulfuric acid (15 ml) at room temperature. The mixture was allowed to stand for 30 min, then poured on ice. 2-Methyl-2-(3-methyl-1-indone)-acetic acid (VII) was precipitated after cooling and crystallized from ether – petroleum ether (b.p. 40–60°) as long yellow needles (0.25 g), m.p. 127°. Infrared spectrum (Nujol mull): 1 790 and 1 740 cm^{-1}.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59. Found: C, 71.64; H, 5.52.

It gave a 2,4-dinitrophenylhydrazone as orange crystals, m.p. 186–187° (from ethanol).

Anal. Calcd. for $C_{19}H_{16}O_6N_4$: C, 57.57; H, 4.07; N, 14.14. Found: C, 57.73; H, 4.15; N, 13.89.

When the experiment was repeated on the acid isomer, m.p. 139°, a colorless solid was obtained which was found to be the starting material.

Cyclization of the β-Half-esters (General Procedure)

The β-half-ester (except that of *p*-chlorobenzaldehyde) (5 g) and anhydrous sodium acetate (2 g) in acetic anhydride (40 ml) were refluxed for 6 h, then worked up by removing the acetic anhydride under reduced pressure, adding water, then extracting the product with ether. The ethereal solution was washed with sodium bicarbonate solution and then water and dried (Na_2SO_4). Evaporation of the solvent left a neutral product.

The cis-β-half-ester from benzaldehyde (II; $R_1 = R_2 = R_3 = H$, $R_4 = CH_3$) gave a solid, crystallizable from benzene as colorless crystals, m.p. 120°, (69% yield) and was found to be methyl 4-acetoxy-3-methyl-2-naphthoate (V; $R_1 = R_2 = R_3 = H$, $R_4 = CH_3$, $R_5 = CH_3CO$).

Anal. Calcd. for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46. Found: C, 70.33; H, 5.63.

Alkaline hydrolysis of this product (2 g, 2 h reflux in 10% sodium hydroxide solution, 50 ml) gave 4-hydroxy-3-methyl-2-naphthoic acid (V; $R_1 = R_2 = R_3 = R_4 = R_5 = H$; 90% yield) as dirty needles, m.p. 237–238° (from methanol).

Anal. Calcd. for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99. Found: C, 71.27; H, 5.26.

The cis-β-half-ester from o-methoxybenzaldehyde (II; $R_1 = R_3 = H$, $R_2 = CH_3O$, $R_4 = CH_3$) afforded a neutral solid (61% yield), crystallizable from methanol as colorless needles, m.p. 123–125°, and was identified as methyl 4-acetoxy-8-methoxy-3-methyl-2-naphthoate (V; $R_1 = R_3 = H$, $R_2 = CH_3O$, $R_4 = CH_3$, $R_5 = CH_3CO$).

Anal. Calcd. for $C_{16}H_{16}O_5$: C, 66.66; H, 5.59; CH_3O, 21.52; CH_3CO, 14.93. Found; C, 67.03; H, 5.70; CH_3O, 20.98; CH_3CO, 15.52.

Saponification of this acetoxyester as usual gave a quantitative yield of 4-hydroxy-8-methoxy-3-methyl-2-naphthoic acid (V; $R_1 = R_3 = R_4 = R_5 = H$, $R_2 = CH_3O$) as dirty crystals, m.p. 243–245° (from methanol).

Anal. Calcd. for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21. Found: C, 67.40; H, 5.27.

The cis-β-half-ester from p-chlorobenzaldehyde (II; $R_1 = R_2 = H$, $R_3 = Cl$, $R_4 = CH_3$) (4 g) and anhydrous sodium acetate (1.5 g) in a mixture of acetic anhydride (25 ml) and glacial acetic acid (25 ml) were heated at 130° (oil bath) for 3 h. The reaction mixture was then worked up as in the general procedure. The neutral product (3.8 g) as a brown viscous oil was saponified to give a semisolid product from which dirty crystals (20% yield) of 6-chloro-4-hydroxy-3-methyl-2-naphthoic acid (V; $R_1 = R_2 = R_4 = R_5 = H$, $R_3 = Cl$) were isolated, m.p. 275–276° (from aqueous methanol).

Anal. Calcd. for $C_{12}H_9O_3Cl$: C, 60.88; H, 3.80, Cl; 15.01. Found: C, 60.78; H, 3.88; Cl, 15.1.

The β-half-ester from benzophenone (II; $R = C_6H_5$, $R_2 = R_3 = H$, $R_4 = CH_3$) proceeded normally with a quantitative yield of methyl 4-acetoxy-3-methyl-1-phenyl-2-naphthoate (V; $R_1 = C_6H_5$, $R_2 = R_3 = H$, $R_4 = CH_3$, $R_5 = CH_3CO$) which was obtained as a colorless solid crystallizable from methanol, m.p. 137°.

Anal. Calcd. for $C_{21}H_{18}O_4$: C, 75.43; H, 5.43. Found: C, 75.28; H, 5.53.

This gave on alkaline hydrolysis a solid mixture which was dissolved in ether and the ethereal solution was extracted with sodium carbonate solution. The alkaline extract afforded a solid acid (40% yield) and the ethereal layer gave a phenolic solid (58% yield). The acid was crystallized from benzene as colorless light crystals, m.p. 232°, and identified as 4-hydroxy-3-methyl-1-phenyl-2-naphthoic acid (V; $R_1 = C_6H_5$, $R_2 = R_3 = R_4 = R_5 = H$).

Anal. Calcd. for $C_{18}H_{14}O_3$: C, 77.68; H, 5.07. Found: C, 77.94; H, 5.48.

The phenolic solid was crystallizable from benzene as colorless needles, m.p. 155°, and its infrared spectrum and analysis fitted for methyl 4-hydroxy-3-methyl-1-phenyl-2-naphthoate (V; $R_1 = C_6H_5$, $R_2 = R_3 = R_5 = H$, $R_4 = CH_3$). Infrared spectrum (Nujol mull): 3 500 and 1 710 cm^{-1}.

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 78.06; H, 5.52. Found: C, 78.15; H, 5.43.

Methylation of Phenolic Acids (General Procedure)

The phenolic acid (1 g), dimethyl sulfate (3 g), and anhydrous potassium carbonate (4 g) in acetone (30 ml) were refluxed for 12 h on a water bath. Removal of acetone afforded a solid residue to which water was added to dissolve any inorganic material. The organic product was then filtered or extracted with ether.

4-Hydroxy-3-methyl-2-naphthoic acid (V; $R_1 = R_2 = R_3 = R_4 = R_5 = H$) gave a colorless oil (87.5% yield). This when refluxed with 10% sodium hydroxide solution (15 ml) for 2 h, afforded, after washing with ether and acidification with cold hydrochloric acid, 4-methoxy-3-methyl-2-naphthoic acid (V; $R_1 = R_2 = R_3 = R_4 = H$, $R_5 = CH_3$) (92% yield) as colorless crystals, m.p. 207° (from benzene).

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59; CH_3O, 14.35. Found: C, 72.29; H, 6.20; CH_3O, 14.36.

4-Hydroxy-8-methoxy-3-methyl-2-naphthoic acid (V; $R_1 = R_3 = R_4 = R_5 = H$, $R_2 = CH_3O$) required a bigger amount of acetone (50 ml), and absolute methanol (20 ml) was added for its dissolution. The produced methyl 4,8-dimethoxy-3-methyl-2-naphthoate (V; $R_1 = R_3 = H$, $R_2 = CH_3O$, $R_4 = R_5 = CH_3$) was separated as colorless needles (95% yield), m.p. 108–110° (from methanol).

Anal. Calcd. for $C_{15}H_{16}O_4$: C, 69.21; H, 6.20. Found: C, 69.56; H, 6.25.

This after saponification as usual gave 4,8-dimethoxy-3-methyl-2-naphthoic acid (V; $R_1 = R_3 = R_4 = H$, $R_2 = CH_3O$, $R_5 = CH_3$) (87.7% yield) as a colorless solid, m.p. 209–211° (from acetic acid).

Anal. Calcd. for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73; CH_3O, 25.16. Found: C, 67.73; H, 5.74; CH_3O, 24.22.

6-Chloro-4-hydroxy-3-methyl-2-naphthoic acid (V; $R_1 = R_2 = R_4 = R_5 = H$, $R_3 = Cl$) gave the corresponding methoxy ester (V; $R_1 = R_2 = H$, $R_3 = Cl$, $R_4 = R_5 = CH_3$) as colorless needles (99% yield), m.p. 100–102° (from methanol).

Anal. Calcd. for $C_{14}H_{13}O_3Cl$: C, 63.51; H, 4.9; Cl, 13.42. Found: C, 63.52; H, 4.89; Cl, 12.55.

4-Hydroxy-3-methyl-1-phenyl-2-naphthoic acid (V; $R_1 = C_6H_5$, $R_2 = R_3 = R_4 = R_5 = H$) gave methyl 4-methoxy-3-methyl-1-phenyl-2-naphthoate (V; $R_1 = C_6H_5$, $R_2 = R_3 = H$, $R_4 = R_5 = CH_3$) (88% yield) as colorless crystals, m.p. 113–115° (from methanol).

Anal. Calcd. for $C_{20}H_{18}O_3$: C, 78.41; H, 5.92. Found: C, 78.82; H, 5.99.

Methyl 4-hydroxy-3-methyl-1-phenyl-2-naphthoate (V; $R_1 = C_6H_5$, $R_2 = R_3 = R_5 = H$, $R_4 = CH_3$) gave a neutral solid, m.p. 113–115 (from methanol). This on admixing with a specimen of the above methoxy ester (V; $R_1 = C_6H_5$, $R_2 = R_3 = H$, $R_4 = R_5 = CH_3$) gave no depression.

Preparation of α-Half-esters (General Procedure)

The itaconic acid (1 g) was dissolved in the least amount of hot acetyl chloride (in case of the itaconic acid from *p*-chlorobenzaldehyde, a mixture of acetic anhydride and acetyl chloride was required). The mixture was refluxed for 2 h on a water bath and the excess acetyl chloride was then removed under reduced pressure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to give a solid itaconic anhydride. This anhydride (0.5 g) was then refluxed in dry methanol (10 ml) for 3 h. After the removal of excess methanol under reduced pressure, a solid residue was obtained.

The itaconic acid from o-methoxybenzaldehyde (II; $R_1 = R_3 = R_4 = H$, $R_2 = CH_3O$) proceeded normally to give the anhydride (III; $R_1 = R_3 = H$, $R_2 = CH_3O$) (0.8 g, 75% yield) as colorless needles, m.p. 149–150° (from benzene).

Anal. Calcd. for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21. Found: C, 66.66; H, 5.29.

Treatment of this anhydride with methanol gave the α-half-ester (IV; $R_1 = R_3 = H$; $R_2 = CH_3O$) (70% yield) as colorless crystals, m.p. 162–163° (from methanol).

Anal. Calcd. for $C_{14}H_{16}O_5$: C, 63.62; H, 6.10. Found: C, 63.38; H, 6.22.

The itaconic acid from p-chlorobenzaldehyde (II; $R_1 = R_2 = R_4 = H$, $R_3 = Cl$) (1 g) was dissolved in acetic anhydride (10 ml). Acetyl chloride (15 ml) was then added to the solution, and the experiment was carried out as usual to give the anhydride (III; $R_1 = R_2 = H$, $R_3 = Cl$) (0.9 g, 89% yield). This was separated in yellow crystals from acetic anhydride, m.p. 175–177°.

Anal. Calcd. for $C_{12}H_9O_3Cl$: C, 60.88; H, 3.8; Cl, 15.01. Found: C, 60.34; H, 3.41; Cl, 16.15.

Treatment of this anhydride with methanol gave α-methyl β-hydrogen *cis*-γ-*p*-chlorophenyl-α-methyl-itaconate (IV; $R_1 = R_2 = H$, $R_3 = Cl$) (80% yield) as pale-yellow crystals, m.p. 143–144° (from benzene–benzine, b.p. 40–60°).

Anal. Calcd. for $C_{13}H_{13}O_4Cl$: C, 58.1; H, 4.42; Cl, 13.2. Found: C, 58.23; H, 4.75; Cl, 13.68.

The itaconic acid from benzophenone (III; $R_1 = C_6H_5$, $R_2 = R_3 = R_4 = H$), on dehydration, gave the known anhydride (1) (III; $R_1 = C_6H_5$, $R_2 = R_3 = H$) (0.7 g, 78% yield) as colorless crystals, m.p. 148° (from benzene).

Anal. Calcd. for $C_{18}H_{14}O_3$: C, 77.68; H, 5.07. Found: C, 78.17; H, 5.07.

This anhydride when treated with methanol yielded the α-half-ester (IV; $R_1 = C_6H_5$, $R_2 = R_3 = H$) (78% yield) as colorless solid crystallizable from ether – petroleum ether (b.p. 40–60°), m.p. 154–155°.

Anal. Calcd. for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85. Found: C, 74.11; H, 5.81.

cis-α,γ-Dimethyl-γ-phenylitaconic acid (II; $R_1 = CH_3$, $R_2 = R_3 = R_4 = H$) gave on dehydration, *cis*-α,γ-dimethyl-γ-phenylitaconic anhydride (III; $R_1 = CH_3$, $R_2 = R_3 = H$) (0.8 g, 92% yield) as colorless needles, m.p. 94–95° (from benzene).

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.21, H; 5.59. Found: C, 72.32; H, 5.68.

Treatment of this anhydride with methanol gave the α-half-ester (IV; $R_1 = CH_3$, $R_2 = R_3 = H$) as a colorless solid (85.5% yield) crystallizable from methanol, m.p. 121–123°.

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50. Found: C, 67.79; H, 6.70.

trans-α,γ-Dimethyl-γ-phenylitaconic acid (VI; R = H) afforded, on dehydration, *trans*-α,γ-dimethyl-γ-phenylitaconic anhydride (VIII) (0.7 g, i.e. 84% yield) as colorless crystals, m.p. 89–90° (from benzene, petroleum ether, b.p. 40–60°).

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59. Found: C, 72.60; H, 5.58.

THE REACTION OF ACTIVE NITROGEN WITH ETHANOL[1]

P. A. GARTAGANIS[2]

Physical Chemistry Department, Ontario Research Foundation, Toronto, Ontario

Received May 31, 1963

ABSTRACT

The reaction of active nitrogen with ethanol has been investigated in the range 300 to 593 °K using a modified condensed-discharge Wood–Bonhoeffer fast-flow system. The only condensable products found in appreciable amounts were hydrogen cyanide and water. Hydrogen was the main noncondensable product. A very small amount of acetaldehyde was also formed along with traces of ethane, ethylene, methane, acetonitrile, cyanogen, and probably carbon monoxide. The overall activation energy is 3.4 kcal/mole. It is postulated that the mechanism consists of the formation of two fragments NC_2H_5 and OH, from which the condensable products result as follows:

$$N + C_2H_5OH \rightarrow NC_2H_5 + OH,$$

$$NC_2H_5 \rightarrow CH_3 + HCN + H,$$

$$CH_3 + N \rightarrow HCN + 2H,$$

$$H + OH \rightarrow H_2O,$$

$$2H \rightarrow H_2.$$

A number of products found in trace quantities are produced by concomitant reactions of the hydrogen atoms with methyl radicals, and with ethanol as well as by disproportionation of ethyl radicals to produce ethane and ethylene. A preliminary study of the reaction of active nitrogen with isopropanol indicated that the energy of activation is in line with the energies of activation of methanol and ethanol.

INTRODUCTION

The reaction of active nitrogen with methanol has been discussed in a previous paper (*1*). The present investigation was initiated as a further step towards the study of the kinetics of the reactions between active nitrogen and various oxygen-containing organic compounds. The reaction with ethanol appeared to be of interest because of the opportunity for comparing the reactivity of the two lower members of the series. Some preliminary experiments were also performed with isopropanol to assess the trend of the reaction of active nitrogen with a higher alcohol.

EXPERIMENTAL

The apparatus and procedure used in carrying out the reactions were similar to those described by Gartaganis and Winkler (*2*), except that the spherical reaction vessel was replaced by a 100 cm reaction tube of 16 mm i.d. Thermocouple wells and observation windows were placed at regular intervals along the reaction tube. The products were identified by mass spectrometry and gas phase chromatography (Vapor Fractometer, Model 154, Perkin Elmer Corp. polyethylene glycol on Teflon powder; helium; 80 °C). Hydrogen cyanide was measured with silver nitrate and the water with Karl-Fischer reagent. The ratio of water to hydrogen cyanide was determined by the following method. The reaction products were trapped in methanol and titrated with Karl-Fischer reagent added to the trap through a septum from a microburette ending to a hypodermic needle. Ten milliliters 1 *N* potassium hydroxide were introduced with a syringe, the trap was then opened, 3 *N* ammonium hydroxide added, and the hydrogen cyanide determined with silver nitrate as usual.

RESULTS

The reaction was accompanied by a bright peach-colored flame, similar to those observed with hydrocarbons or methanol. As in the case of the latter compound the reaction of

[1]*Presented at the 46th Annual Conference of the Chemical Institute of Canada, Toronto, June 1963.*
[2]*Present address: Dominion Tar & Chemical Co. Ltd., Central Research Laboratories, Senneville, P.Q.*

active nitrogen with ethanol was found to be relatively simple inasmuch as very few products were produced and there seemed to be no extensive side reactions to complicate the kinetic considerations. Of course, intermediate steps of this type of reaction may be kinetically very complex. Hydrogen cyanide and water in approx. 2 to 1 ratio were the only condensable products found in appreciable amounts. Hydrogen was the main non-condensable product. A very small amount of acetaldehyde was formed along with small amounts (less than 2%) of ethane, ethylene, methane, acetonitrile, cyanogen, and probably carbon monoxide.

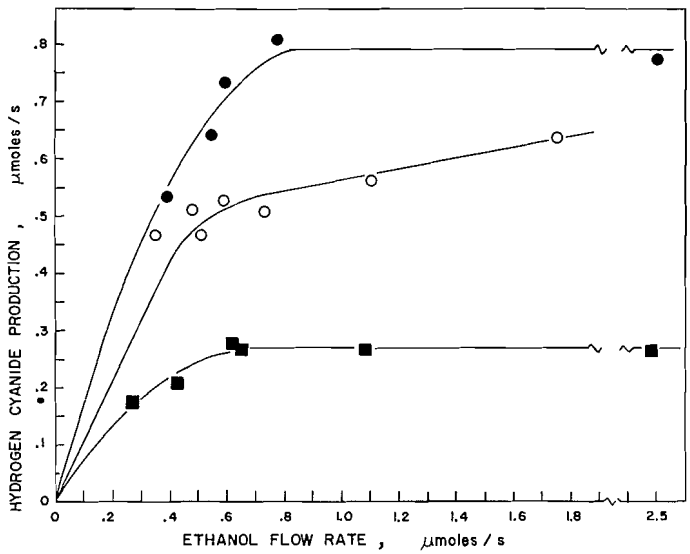

FIG. 1. Hydrogen cyanide production as a function of alcohol flowrate in the reaction of active nitrogen with ethanol. ●, 593 °K; ○, 428 °K; ■, 300 °K.

The yield of hydrogen cyanide, the only nitrogen-containing major product recovered at 300, 428, and 593 °K at various flow rates, is shown in Fig. 1. Since it is now recognized that the principal chemically reactive constituent present in active nitrogen is the nitrogen atom in the ^4S ground state (3), second-order rate constants for the nitrogen atom – ethanol reaction were calculated in a manner similar to that previously outlined for the methanol reaction (1).

A Reynolds-number calculation (4) showed that streamline flow prevailed in the reaction vessel and, therefore, the following integrated second-order expression was used for the calculation of the rate constants, assuming that one molecule of ethanol yields two molecules of hydrogen cyanide, i.e. assuming $n = 1/2$.

$$k_2 = \frac{(b + c)^2 R^2 T^2}{n(a - b/n) VP^2} \ln \frac{b(a - x)}{a(b - nx)}.$$

The pertinent kinetic data are shown in Table I. Another series of experiments with a different atomic nitrogen concentration was done earlier and the results agree with the information reported above.

A number of exploratory experiments were performed using the same apparatus and experimental conditions to study the general characteristics of the reaction of active nitrogen with isopropanol. The results are presented in Fig. 2 and Table I (in this case

n in the reaction rate formula is 1/3). The molecular nitrogen flow rate was 16.3 μmoles/s, and the atomic nitrogen flow rate, determined from the reaction with ethylene at 590 °K, was 1.06 μmoles/s.

DISCUSSION

From the results of the present investigation, it is apparent that ethanol resembles methanol closely in its primary reaction with nitrogen atoms. The following steps account for the formation of hydrogen cyanide.

[1] $$N + C_2H_5OH \rightarrow NC_2H_5 + OH,$$

[2] $$NC_2H_5 \rightarrow HCN + CH_3 + H,$$

[3] $$CH_3 + N \rightarrow HCN + 2H.$$

It appears from spin considerations referred to earlier (1) that atomic rather than molecular hydrogen is produced by reactions [2] and [3]. Combination of the hydroxyl fragment of reaction [1] with this atomic hydrogen in the presence of a third body produces water:

[4] $$OH + H \rightarrow H_2O.$$

On the other hand the reaction $OH + N \rightarrow HNO$ does not seem to occur to any appreciable extent.

Recombination of hydrogen atoms by three-body collisions with ethanol molecules and with nitrogen (5) provide the only noncondensable product found in large amounts:

[5] $$H + H + N_2 \rightarrow H_2 + N_2.$$

It was again noticed that the limiting value of the rate of hydrogen cyanide formation does not correspond to the maximum nitrogen atom concentration indicated from the ethylene reaction and the same phenomenon was observed with isopropanol. It is probable that, in addition to the above reactions, homogeneous catalyzed recombination takes place with no product formation.

[6] $$N + N + C_2H_5OH \rightarrow N_2 + C_2H_5OH,$$

[7] $$N + NC_2H_5OH \rightarrow N_2 + C_2H_5OH.$$

It should be noted, however, that while reactions [6] and [7] are possible, catalytic recombination has fallen somewhat into disrepute in active nitrogen reactions. The earlier temperature dependence of hydrogen cyanide in the ethylene reaction, for example, now appears to have been an experimental artifact characteristic of the spherical reaction vessels used (7).

A reaction similar to eq. [7] has been postulated for ethylene by Kelly and Winkler (6). The formation of the small amounts of secondary hydrocarbon by-products probably resulted from reactions of various fragments with atomic hydrogen or with themselves, viz.

[8] $$CH_3 + H \rightarrow CH_4,$$

[9] $$C_2H_5 + H \rightarrow C_2H_6,$$

[10] $$2CH_3 \rightarrow C_2H_6,$$

[11] $$2C_2H_5 \rightarrow C_2H_4 + C_2H_6.$$

Conceivably ethyl radicals could be produced from the NC_2H_5 fragment directly or as a result of further attack by atomic nitrogen.

[12] $$NC_2H_5 \rightarrow N + C_2H_5,$$

[13] $$N + NC_2H_5 \rightarrow N_2 + C_2H_5.$$

Reaction [13] seems most unlikely, as there is no reason to expect the NC_2H_5 complex to have an appreciable existence before decomposing into hydrogen cyanide plus fragments.

Finally, hydrogen abstraction by hydrogen atoms or methyl radicals could account for the production of traces of acetaldehyde from ethanol.

CONCLUSION

As a result of the present investigation it can be concluded that ethanol molecules react with atomic nitrogen by C—O bond scission to form radicals that produce in a few simple steps hydrogen cyanide, water, and hydrogen, the principal products of this reaction. Some "wastage" of nitrogen atoms takes place and is probably due to homogeneous catalyzed recombinations, the alcohol and molecular nitrogen acting as the third body. The energy of activation for methanol, ethanol, and isopropanol reactions was calculated between 3.2 and 3.5 kcal/mole.

AROMATIC SUBSTITUTION

PART IX.[1] ON THE MECHANISM OF THE PSCHORR CYCLIZATION

R. A. ABRAMOVITCH AND G. TERTZAKIAN
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

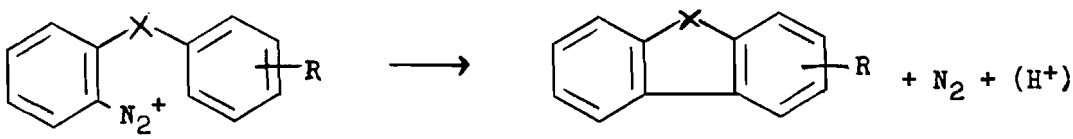
Received November 19, 1964

ABSTRACT

The decomposition of the diazonium salt from 3-(*o*-aminobenzoyl)pyridine has been studied under various conditions. A competitive-type cyclization of an equimolar mixture of the diazonium salts of 2-aminobenzophenone and 2-amino-3′-nitrobenzophenone has also been carried out. The results are interpreted in terms of a radical process in the copper-catalyzed reactions. It is suggested that the uncatalyzed thermal decompositions in aqueous acid solution give rise to a diradical cation intermediate in equilibrium with the aryl cation.

INTRODUCTION

The mechanism of the Pschorr and related cyclizations I → II has been the subject of much debate, without any definite conclusions being reached. Most of the arguments put forward have been based on analogies with the well-known intermolecular reactions



(I) (II)

of diazonium salts and on the effects (or lack of effects) of substituents present in the nucleus being attacked upon the yields of cyclized products. The reaction has been carried out under a variety of conditions ranging from the copper-catalyzed decomposition of the solid diazonium salts or of diazonium salt solutions in aqueous acid, through base-catalyzed decompositions and cyclizations to thermal decomposition in aqueous acid in the absence of a catalyst. Two recent reviews (1, 2) have summarized the conditions under which cyclization has been achieved and the various factors which affect the nature and yield of products obtained.

In general, two alternative mechanistic pathways have been proposed. The first of these is based essentially on the analogy between the Pschorr cyclization and the various intermolecular arylations which are known to involve the intermediacy of aryl radicals e.g. the Gomberg–Hey reaction, the decomposition of *N*-nitrosoacetanilides and of dimethyltriazens, and the Sandmeyer, Gattermann, and Waters (3) reactions, and on the fact that when conditions such as those used in the above reactions are employed to effect cyclization substituents seem to exert a minor influence upon the yield of cyclized products, unlike the situation which exists in the usual electrophilic substitution reactions. Such are the base-catalyzed reactions (see, however, (2)), the copper-catalyzed decompositions, and the thermal decomposition of *N*-nitrosoacetanilides. The second, involving mainly the uncatalyzed thermal decomposition in aqueous acid and analogous in many

[1]*Part VIII. R. A. Abramovitch, F. Helmer, and J. G. Saha. Can. J. Chem. This issue.*

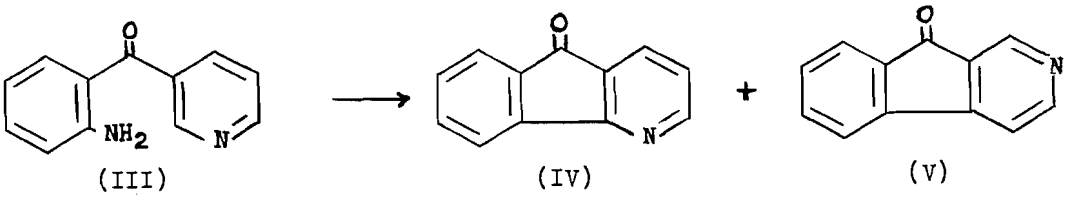
For personal use only.

ways to the decomposition of simple diazonium salts in aqueous acid (4), has been thought to involve a heterolytic process (1, 2).

A large number of observations are left unexplained, however. The copper-catalyzed reaction may involve the formation of radicals (probably not "free" but adsorbed at the surface of the catalyst) or a mechanism in which both aryl cations and radicals are participating may be operative (5). In the uncatalyzed decomposition, the absence of a marked substituent effect is perplexing if the reactions go through the formation of a phenyl cation intermediate. For example, the diazonium salt from *o*-aminobenzophenone gives a 65% yield of fluorenone, while cyclization of the corresponding 3′-nitro derivative gives a 33% yield of the mixed nitrofluorenones (6). This has been attributed (6) to the intermediacy of a highly reactive "hot" phenyl cation for, had an aryl radical been formed, the nitro group, it is argued, should have favored homolytic attack. On the other hand, one must assume that such a highly reactive cation is also selective to explain the ratio of angular to linear products formed in similar cyclizations onto a naphthalene ring (5). Unfortunately, no kinetic data are available to date on the effect of substituents upon the *rates of the cyclization step*, and most of the conclusions drawn have been based upon yields of products. DeTar and Relyea (6) have measured the effect of substituents upon the relative yields of cyclized products and phenols formed in the fluorenone synthesis. According to the heterolytic mechanism the aromatic nucleus and water would compete for the aryl cation, and the presence of a nitro substituent, which decreases considerably the nucleophilicity of the aromatic nucleus, should lead to a large increase in phenol formation relative to cyclization. Though such an effect was actually observed its magnitude was very small. Thus, with (I; X = CO, R = H) the ratio of fluorenone to phenol was 1.85, while with (I; X = CO, R = *m*-NO_2) this ratio was 0.5. This may be compared with the decrease by one nitro group of the reactivity of benzene towards nitration of the order of 10^6 (7), and with the fact that whereas the isopropyl cation is very reactive and non-discriminating in its attack upon toluene (8), nitrobenzene may be used as a solvent in Friedel–Crafts alkylations. The kinetics of the thermal decomposition of (I; X = CO) in aqueous acid solution have established that the rate-determining step is the S_N1 decomposition of the diazonium salt and that the substituent R has a small, predictable effect upon this step (6). But, contrary to what was implied (6), no information was available from these studies concerning the rates of cyclization of the intermediates once they are formed.

In the present study, two approaches were used to attempt to distinguish between a homolytic and a heterolytic mechanism for the cyclization. In the first approach, it was hoped to take advantage of the fact that the pyridine (and even more so the pyridinium) nucleus is highly resistant to electrophilic attack e.g. the Friedel–Crafts reaction does not take place with pyridine; the substitution of a $=N^+H-$ group for a ring $=CH-$ in benzene decreases the reactivity towards hydrogen exchange by a factor of ca. 10^{-18} (9). The copper-catalyzed decomposition of the diazonium salt of 2-amino-*N*-methyl-*N*-3′-pyridylaniline gave a mixture of carbolines (72%) while the thermal decomposition yielded 47% of cyclized products (10). The total yield of cyclized products in the copper-catalyzed reaction was comparable to that obtained (78%) (11) when *N*-(3-amino-2-pyridyl)-*N*-methylaniline was ring-closed to the α-carboline, i.e. a similar cyclization (with similar internuclear separation (12)) but onto a benzene ring. This showed that the pyridine ring in the above case was not deactivated towards nuclear attack and that the attacking species was probably a radical, bound in some way with the copper catalyst. The extent of attack upon the pyridine ring in the uncatalyzed thermal decomposition

was surprisingly high for a reaction involving a cationic intermediate. This *might* be accounted for by an activation of the pyridine nucleus by the 3-amino substituent. The argument is weakened by the fact that a positively charged aryl residue (produced in the S_N1 decomposition) attached to the 3-amino group would reduce considerably the latter's electron-donating capacity to the pyridine ring. In addition, in the acid medium used the pyridine ring would undoubtedly be protonated and be even less susceptible to electrophilic attack. To eliminate this possible source of ambiguity, however, the cyclization under a variety of conditions of the diazonium salt from 3-(*o*-aminobenzoyl)pyridine (III) was studied. Here an electron-attracting carbonyl group is present at C_3 rendering the pyridine ring even less susceptible than before to electrophilic attack.



The reaction of 3-pyridyllithium with *o*-nitrobenzaldehyde at −70° gave the expected alcohol (VIII) in 45–55% yield, but since the latter exhibited a marked tendency to undergo aerial oxidation it was not purified but was oxidized directly to the ketone (IX). The results of the cyclization studies are summarized in Table I. The azafluorenones (IV)

and (V) were known compounds as was (VII). The structure of the phenol (VI) was confirmed by its physical and chemical properties and by its analysis and infrared spectrum.

The second approach attempted to gain a quantitative measure of the effects of substituents upon the actual *rate* of cyclization. Since the rate-determining step in these reactions is the S_N1 elimination of nitrogen, straightforward kinetic runs would not provide the information needed (13) and a "competitive-like" technique was used to

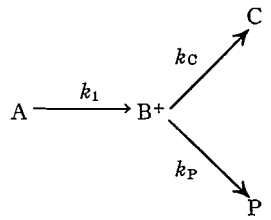
obtain semiquantitative estimates of relative rates of cyclization. For two consecutive first order reactions of the type



in which the formation of the carbonium ion B^+ is rate-determining it can be shown that

$$[1] \qquad \frac{k_{CS}}{k_{CH}} = \frac{C_S}{P_S} \cdot \frac{P_H}{C_H} \cdot \frac{k_{PS}}{k_{PH}},$$

where k_{CH} and k_{CS} are the rate constants for the cyclization of the intermediate carbonium ion onto unsubstituted and substituted aryl rings, respectively, k_{PH} and k_{PS} are the corresponding rate constants for the formation of the two phenols, C_H, C_S, P_H, and P_S are the concentrations of unsubstituted cyclized product, substituted cyclized product, unsubstituted phenol, and substituted phenol at any moment during the reaction (provided cyclized product and phenol are the only products formed and that the overall yields are almost quantitative). Whereas the concentrations of all the products can be determined at any time during the reaction the relative rates of cyclization k_{CS}/k_{CH} can only be obtained as a function of the relative rates of phenol formation k_{PS}/k_{PH}. While a substituent R in (I) has a small effect upon k_1 (6) its distance from the cationic site is relatively large and it should, therefore, not exert any appreciable inductive effect (and no direct mesomeric effect) upon it. Consequently, once the cation is formed in dilute aqueous acid solution, R should have a negligeable effect upon the hydroxylation reaction i.e. k_{PS}/k_{PH} may be assumed to be approximately one.

Preliminary attempts to effect the simultaneous decomposition of equimolar mixtures of the diazonium sulfates of 2-aminobenzophenone and 3-(*o*-aminobenzoyl)pyridine (III) followed by analysis of the reaction products failed. To isolate the azafluorenones from the acidic reaction medium it was necessary to basify it with ammonia (after chilling it); this led to the precipitation of undecomposed diazonium hydroxides which were extracted by chloroform or benzene together with the required products. When an excess

For personal use only.

of cold alkaline β-naphthol solution was added to the cooled aliquot from the reaction mixture to destroy unreacted diazonium salts azo-dyes were formed immediately; but when the reaction mixture was extracted and the extract subjected to gas-chromatographic analysis none of the expected cyclized products could be detected. It would appear as though either the β-naphthol or the dyes are binding the products in such a way as to prevent their detection. These experiments were not pursued further. Instead, the "competitive" cyclization of mixtures of diazotized 2-aminobenzophenone and 2-amino-3′-nitrobenzophenone was studied since these compounds give almost quantitative yields of mixtures of cyclized products and phenols (6), and the gas-chromatographic analysis of the reaction products presented no difficulties.

EXPERIMENTAL

3-(2′-Nitrobenzoyl)pyridine

A solution of 3-bromopyridine (15 g) in dry ether (45 ml) was added under a nitrogen atmosphere over a period of 15 min to a stirred solution of *n*-butyllithium (7.6 g) in hexane (50 ml) and anhydrous ether (50 ml) at −70 to −80°. The mixture was stirred at that temperature for a further 15 min and then *o*-nitrobenzaldehyde (14.5 g) in dry ether (100 ml) was added dropwise during 25 min. Stirring was continued at −70° for 2 h and then at room temperature for a further 1¼ h. The light brown reaction mixture was poured into ice and water (2 l) saturated with salt, the ether layer was separated, and the aqueous phase was extracted with ether (6 × 200 ml). The combined extracts were evaporated and the residue steam distilled. The residue was salted out and extracted with ether (6 × 50 ml) and the combined extracts were dried (Na_2SO_4) and evaporated to yield crude 2′-nitrophenyl-3-pyridylmethanol (11 g, 48%) as a viscous brown oil. Infrared spectrum (liquid film): 3 180 (m)(br), 1 590(w), 1 535(s), 1 487(w), 1 435(m), 1 355(s), 1 030(m), 845(w), 785(m), and 705 cm^{-1}(s).

A solution of 2′-nitrophenyl-3-pyridylmethanol (11 g) in pyridine (80 ml) was added with shaking to a suspension of chromium trioxide (9 g) in pyridine (85 ml) and the mixture allowed to stand at room temperature overnight. It was then poured into water (1 l) saturated with salt. The black mixture was extracted with ether (6 × 100 ml), the ether evaporated, and the residue steam distilled until free of pyridine. The residue was salted out and extracted with ether (6 × 50 ml) and the extracts dried (Na_2SO_4) and evaporated to yield a viscous brown oil (7.8 g, 86%). A portion (1.2 g) of this product was chromatographed on alumina (50 g). A mixture of benzene – light petroleum (b.p. 36–48°) (2:1 v/v) eluted *3-(2′-nitrobenzoyl)pyridine* (0.612 g) as yellow crystals, m.p. 56–58°, which on recrystallization from aqueous ethanol had m.p. 60–60.5°. (Found: C, 63.52; H, 3.84. $C_{12}H_{18}N_2O_3$ requires C, 63.16; H, 3.53.) Infrared spectrum (Nujol mull): 1 670(s), 1 525(s), 1 420(m), 1 357(s), 1 290(s), 930 (m), 785(m), 722(m), and 693 cm^{-1}(w).

3-(2′-Aminobenzoyl)pyridine

3-(2′-Nitrobenzoyl)pyridine (7.8 g) was dissolved in ethanol (70 ml), 10% palladium–charcoal (1 g) was added, and the suspension boiled under reflux. Hydrazine hydrate (99%, 15 ml) was added and boiling continued for 1 h. The mixture was filtered and evaporated, eventually under reduced pressure. The residual viscous orange oil (7.2 g) was dissolved in benzene and chromatographed on a column of alumina (350 g). Benzene eluted *3-(2′-aminobenzoyl)pyridine* (2.5 g) as an orange oil which crystallized. This product proved difficult to purify but recrystallization from ethanol eventually gave analytically pure amine, m.p. 247–249°. (Found: C, 72.73; H, 5.06. $C_{12}H_{10}N_2O$ requires C, 72.71; H, 5.09.)

2- and 4-Azafluorenone

2-(3′-Aminobenzoyl)pyridine (1.3 g) in sulfuric acid (4 ml) and water (50 ml) was diazotized at 4° with sodium nitrite (0.52 g) in water (4 ml) with vigorous stirring. The solution was stirred for 15 min and the excess nitrous acid destroyed by the addition of solid urea. Gattermann copper (1 g) was added and stirring continued for 1 h. The mixture was filtered and the filtrate basified with concentrated ammonia solution and extracted with chloroform (6 × 40 ml). The organic layer was extracted with 5% aqueous sodium hydroxide (7 × 40 ml), dried (Na_2SO_4), and evaporated to yield a nearly black tar (0.96 g) which crystallized on cooling. This was dissolved in benzene and chromatographed on a column of alumina (100 g). Elution with a mixture of benzene and light petroleum (b.p. 36–48°) (2:1) yielded 4-azafluorenone (0.32 g, 27%) as a yellow solid, m.p. 140–141° from ethanol. The melting point was undepressed on admixture with an authentic sample (14). Kruber (15) reports m.p. 139–140° for this compound. Elution with benzene gave 3-benzoylpyridine (0.095 g, 8%) as an almost colorless oil, the retention time on gas chromatography and the infrared spectrum of which were identical with those of an authentic sample. Infrared spectrum (liquid film): 1 660(s), 1 585(s), 1 450(m), 1 418(m), 1 315(m), 1 280(s), 1 195(w), 1 055(w), 1 025(m), 935(m), 920(s), 780(m), 710(s), and 648 cm^{-1}(m). Further elution with benzene gave 2-azafluorenone (0.224

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

g, 20%) as a yellow solid, m.p. 155–158°. Sublimation at 110° and 0.3 mm and recrystallization from ethanol raised the melting point to 158.5°. Courts and Petrow give m.p. 156–158° for this compound (16). (Found: C, 79.49; H, 4.11. Calcd. for $C_{12}H_7NO_2$: C, 79.55, H, 3.89.)

Samples of the above three compounds were used to obtain calibration curves plotting weight of compound vs. area under peak to permit the quantitative analysis of mixtures using gas chromatography. A 2 ft × ¼ in. 15% Apiezon N on Fluoropak column operated at 200° and at a helium inlet pressure of 50 p.s.i. was used for the analysis.

Decomposition of Diazotized 3-(2′-Aminobenzoyl)pyridine

3-(2′-Aminobenzoyl)pyridine (0.100 g) in water (10 ml) containing sulfuric acid (0.4 ml) was cooled to 5° and diazotized with sodium nitrite (0.040 g) in water (2 ml). After 10 min the excess nitrous acid was decomposed with urea (starch–iodide paper) and the solution decomposed by one of the methods described below. Unless otherwise specified, the mixture was basified with concentrated ammonium hydroxide (2 ml) at the end of the reaction and extracted with chloroform (3 × 15 ml); the chloroform solution was extracted with 10% aqueous sodium hydroxide (3 × 15 ml), dried (Na_2SO_4), and evaporated down to a small volume. This was transferred to a 1 ml volumetric tube and made up to 1 ml with chloroform. Accurately measured aliquots were then analyzed by gas chromatography.

(i) Thermal Decomposition at 80°

The above diazotized solution was stirred at 80 ± 1° for 2 h. The average yields of cyclized products on two runs were: 4-azafluorenone, 3.5%; 2-azafluorenone, 2.85%. No 3-benzoylpyridine could be detected. The basic aqueous phase was brought to pH 7 with 50% aqueous acetic acid and the turbid solution extracted with chloroform; the extracts were dried (Na_2SO_4) and evaporated to give *3-(2′-hydroxybenzoyl) pyridine* as a pale-yellow oil which crystallized. On recrystallization from light petroleum it had m.p. 63–64°. (Found: C, 72.36; H, 4.63. $C_{10}H_9NO_2$ requires: C, 72.35; H, 4.55.) Infrared spectrum (CCl_4 solution): 3 100(w)(br), 3 050(w), 1 630(s), 1 487(m), 1 450(m), 1 416(m), 1 337(s), 1 310(s), 1 146(m), and 930 cm^{-1}(m). The average yield obtained in two runs was 67%.

(ii) With Ultraviolet Light at 30°

The solution of diazotized amine was placed in a Vitreosil beaker which was cooled by a current of air. The stirred solution was illuminated with a Hanovia type 30 600 ultraviolet lamp with a violet filter and the temperature maintained at 30°. Brisk effervescence set in after 10 min but began to subside after another 10 min. Stirring was continued for 1 h after which the solution was worked up and analyzed gas chromatographically as described above. Only two peaks, corresponding to 4- and 2-azafluorenone, were detected. The average yields obtained were: 4-azafluorenone, 36.8%; 2-azafluorenone, 26.2%. No phenol could be isolated from the aqueous phase.

(iii) With Gattermann Copper

The stirred diazonium salt solution (from 0.92 g of amine) was treated with Gattermann copper at 4°. Stirring was continued for 1 h and the suspension filtered and worked up. The average yields obtained were as follows: 4-azafluorenone, 30.3%; 2-azafluorenone, 19.5%; 3-benzoylpyridine, 13.0%; 2-(3′-hydroxybenzoyl)pyridine, 10%.

(iv) With Precipitated Silver

Freshly precipitated silver (0.10 g) was added to the stirred diazonium salt solution (from 0.092 g of amine) at 4° and stirring continued at this temperature for 6 h. As the decomposition was still incomplete the mixture was stirred at room temperature for 48 h, worked up, and analyzed. The average yields were: 4-azafluorenone, 2.2%; 2-azafluorenone, 1.6%; 3-benzoylpyridine, 1.1%. A large peak with a retention time of 21 min was also observed in the gas chromatogram and may be due to the dimer, but was not characterized further. Six minor peaks with retention times between 1 and 6 min were also detected.

(v) With Iron Filings

The diazonium salt solution was treated with iron filings (0.10 g, previously washed with glacial acetic acid, water, alcohol, and ether) at 4°, stirring continued at that temperature for 6 h and then at room temperature for 42 h. The solution obtained after filtration of the iron was deep red. The average yields were: 4-azafluorenone, 4.8%; 2-azafluorenone, 2.5%; 3-benzoylpyridine, 22%. Two other peaks with retention times of 1 and 19.5 min, respectively, were also observed in the chromatogram but were not identified.

(vi) With Zinc Dust

The use of reagent grade zinc dust (0.10 g) at 4° for 6 h gave 4-azafluorenone (16.3%), 2-azafluorenone (9.3%), and 3-benzoylpyridine (15.4%).

(vii) With Alkali at 40°

20% Aqueous sodium hydroxide (4 ml) was added to the diazotized amine solution, and the mixture stirred for 4 h with the temperature maintained at 40°. The mixture was extracted with chloroform and worked up to give 4-azafluorenone (9.4%), 2-azafluorenone (4.0%), and 3-benzoylpyridine (3.2%). Another peak with retention time 21 min (cf. decomposition with silver) was also observed but no phenol could be isolated from the basic solution.

Thermal Decomposition of Aqueous Acid Solutions of Equimolar Mixtures of the Diazonium Sulfates of 2-Aminobenzophenone and 2-Amino-3′-nitrobenzophenone

The preparations of 2- and 4-nitrofluorenones and of 2-hydroxy-3′-nitrobenzophenone have already been described (6). Standard solutions of these compounds as well as of fluorenone and 2-hydroxybenzophenone were prepared and calibration curves of weight of compound vs. area under chromatogram peak obtained independently for each one of them using a 2 ft × 1/4in. 15 % Apiezon N on Fluoropak column operated at 200° and a helium inlet pressure of 40 p.s.i. Under such conditions, 2- and 4-nitrofluorenone were not resolved from each other and the mixture of these two isomers, as obtained from a model Pschorr cyclization using 2-amino-3′-nitrobenzophenone, was used in preparing the calibration curve. The retention times were as follows: 2-hydroxybenzophenone, 7.5 min; fluorenone, 10 min; 2-hydroxy-3′-nitrobenzophenone, 33 min; 2- and 4-nitrofluorenone, 53 min.

A mixture of 2-aminobenzophenone (0.049 g) and 2-amino-3′-nitrobenzophenone (0.061 g) was placed in a 100 ml tall lipless beaker and dissolved in concentrated sulfuric acid (2 ml) and water (12 ml). The solution was cooled to 5° and solid sodium nitrite (0.040 g) slowly added with stirring while the temperature was maintained at 5°. As soon as the solution gave a positive starch–iodide test no more nitrite was added, the solution was stirred for a further 10 min and the excess nitrous acid decomposed by the addition of urea. The beaker was then transferred quickly to a thermostated water bath kept at 45° and vigorous stirring maintained for the required length of time (5, 10, or 18 min); the beaker and contents were then quickly chilled to 0° and the mixture transferred to a cold separatory funnel and quickly extracted with cold chloroform (2 × 15 ml). The extracts were dried (Na_2SO_4) and evaporated to a small volume (ca. 50 μl). The whole of the solution was then injected as quantitatively as possible into the gas chromatograph and the relative molar ratios of the products determined.

DISCUSSION

The relatively high proportion of cyclized product resulting from attack onto a pyridinium nucleus in the copper-catalyzed cyclization of the diazonium salt of (III), as well as the amount (13%) of deaminated product formed, suggests very strongly the intervention of a homolytic pathway under these conditions. It has been suggested (5) that the copper-catalyzed cyclization involves the formation of both aryl radicals and cations at the surface of the metal. This suggestion was based on a comparison of the ratios of angular to linear benzofluorenones formed on cyclization of the diazonium salt of 2-(*o*-aminobenzoyl)naphthalene under various reaction conditions. The thermal decomposition (presumed to proceed via a cationic intermediate) gave an angular:linear ratio of 2.2, the copper-catalyzed decomposition *and the thermal decomposition of the alkaline solution* gave a ratio of 4.4, while the alkaline decomposition in the presence of benzene and the decomposition of the *N*-nitrosoacylarylamine gave a ratio of 9.0–10. The high ratios in the last cases may well be due, however, to steric hindrance to the formation of the σ-complex with benzene on the α-side but not on the β-side: this could lead to one conformation cyclizing at the α-position of the naphthalene ring while the other could either cyclize at the β-position or react with benzene to give the phenylated product. This last alternative is not available when the alkaline decomposition is carried out in the absence of benzene. A similar argument may be used to explain the results obtained in the decomposition of benzophenone *o*-diazohydroxide in benzene (17). A good deal of evidence has accumulated in support of a radical mechanism for the alkaline decomposition of diazonium salts (1, 6). It must also be noted that the steric requirements of the copper-catalyzed reactions—where the reacting species is undoubtedly close to the surface of the metal—and those carried out in the absence of metal catalysts could well be different so that comparisons of examples of reactions in which one of the alternative modes of reaction involves steric crowding have to be viewed with caution. The formation of 10% of the phenol in our case may be a measure of the extent that the reaction goes via a cationic intermediate; however, a radical pathway for the formation of this product, though less likely, is not eliminated.

The photochemical decomposition of the acidic diazonium salt solution gave rise to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

the highest yield of cyclized product, the 4- to 2-azafluorenone ratio being 1.4 as compared with 1.55 in the copper-catalyzed reaction. Neither 3-benzoylpyridine nor the phenol could be detected among the products under these conditions. The relatively high yield is consistent with a homolytic pathway in this case. The photo-catalyzed Pschorr-type reactions have also been investigated by Huisgen and Zahler (18). While these authors were able to obtain reasonably good yields of fluorenone and *N*-methylcarbazoles from the corresponding diazonium salts, the yields of dibenzofuran and of benzofluorenes starting with the appropriate amines were very poor. Decomposition of the aqueous acid solution of diazotized *o*-aminodiphenylether gave a 44% yield of the phenol and only a 1% yield of cyclized product. The conclusion reached by Boudreaux and Boulet (19), based on magnetic susceptibility measurements, that aryl radicals are formed by the photolysis of solutions of diazonium salts, has been questioned (20). It has been shown that when an aqueous solution of *p*-dimethylaminobenzenediazonium chloride at pH 5 is photolyzed in the presence of air or oxygen the *p*-dimethylaminophenoxy radical is formed and it has been suggested that the latter probably arises from a secondary reaction of the photolysis product, namely the phenol (20). The results do not necessarily extrapolate to pH values below 5 such as were used in the present work in which no phenol was apparently formed.

No phenol was obtained in the thermal decomposition of the diazonium salt of (III) under alkaline conditions and the overall yield of cyclized products was low (13.4%), probably due to the formation of "diazo-tars". The results are consistent with the intermediacy of radical but not of cationic intermediates. Silver, iron, and zinc metals were much less effective catalysts than was copper in the cyclization reaction and azo and dimeric products appeared to be formed though this was not confirmed. The formation of azo-compounds and of dimers has already been observed in Pschorr-type reactions (12). The main product obtained on thermal decomposition of the diazonium salt in aqueous acid solution was the phenol. In addition, however, a 6.4% yield of cyclized products was obtained. This result would be very surprising for a substitution involving an aryl cation, since the nucleophilicity of a pyridinium nucleus towards protons is about 10^{-18} smaller than that of a benzene ring and a 3-carbonyl group would be expected to decrease this nucleophilicity further still. Thus, in spite of the large increase in reactivity due to the intramolecular character of the reaction and, even assuming the formation of a "hot", unselective aryl cation, the pyridinium nucleus would hardly be expected to compete effectively with the surrounding water molecules for the positive center. In any event, the intermediate formed by the thermal decomposition of diazonium salts in organic solvents has been shown to be highly reactive *but selective* (21). It seems more probable, therefore, that most of the cyclized product results from the intervention of some type of homolytic mechanism. This is discussed further below.

The results of the "competitive" thermal decompositions of diazotized 2-aminobenzophenone and 2-amino-3′-nitrobenzophenone in aqueous acid solution are given in Table II. On the assumption that $k_{PS} = k_{PH}$, substitution of the experimentally found values for C_S/P_S and P_H/C_H into eq. [1] gives $k_{CS}/k_{CH} = 0.45$. Thus, if the rates of hydroxylation of the two reactive intermediates are presumed equal, cyclization onto the nitro-substituted benzene ring takes place only half as fast as that onto a ring not bearing the highly deactivating (towards electrophilic attack) nitro-group. If, on the other hand, the nitro-group has any effect upon the cationic center it should, if anything, slightly enhance the hydroxylation process by withdrawing electrons inductively. A twofold enhancement of the rate of hydroxylation in the nitro-compound would result in the

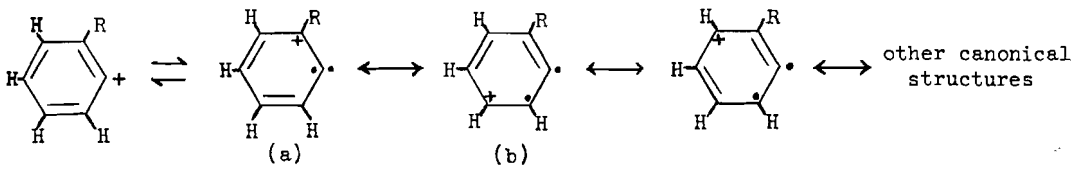
TABLE II

Relative yields of products from the simultaneous decomposition of diazotized 2-aminobenzophenone and 2-amino-3′-nitrobenzophenone

Reaction time (min)	Molar ratio of fluorenone to 2-hydroxybenzophenone	Molar ratio of nitrofluorenones to 2-hydroxy-3′-nitrobenzophenone
5	2.24	1.08
10	2.54	0.91
10	2.44	1.18
10	2.82	1.34
10	2.72	1.06
18	2.66	1.35
Average	2.58	1.15

relative rates of cyclization being about equal on the basis of our results. The above value for k_{CS}/k_{CH} is, therefore, a minimum one.

While there is no reason to doubt that the rate-determining step in the thermal decomposition is the S_N1 heterolysis with elimination of nitrogen, the above results are difficult to reconcile with the properties expected of a cationic intermediate, even of a "hot" one. A possible solution to this dilemma has been suggested on the basis of the results obtained in the thermal decomposition of dry benzenediazonium borofluoride in organic solvents (21). From both isomer ratio and total rate ratio as well as electron spin resonance (e.s.r.) studies it was proposed, following Taft (22), that the aryl cation initially formed isomerized to the diradical cation (X) and that it is this that attacks the



(X)

adjacent aromatic nucleus giving rise to cyclized product. The phenol could then arise from the aryl cation form. The diradical cation (X) (canonical structure (*a*) would give the species some of the properties of a triplet carbene) would be expected to behave as a strongly electrophilic free radical in substitution reactions, and this would account for both the low yield of azafluorenones in the cyclization of 3-(2′-aminobenzoyl)pyridine and for the slight deactivation observed in the cyclizations onto a nitro-substituted nucleus. While the pyridine ring is slightly more reactive than is benzene towards phenyl radicals, $^{C_5H_5N}_{C_6H_6}K$ is only 0.47 when the attacking reagent is the more electrophilic *o*-nitrophenyl radical (23) and this is even more marked when nitrobenzene is the substrate (24). Species (X) would be even more electrophilic than the nitrophenyl radical, but this should be compensated somewhat by the intramolecular character of the reactions. The participation of such an intermediate in the decomposition might rationalize many observations that have been made on the Pschorr reaction over the years. For example, the demethylation and deamination observed in suitable cases (25) may well be consistent with a hydrogen abstraction by the triplet carbene form (X*a*).

AN EXOCELLULAR MANNAN, ALTERNATELY LINKED 1,3-β AND 1,4-β FROM RHODOTORULA GLUTINIS[1]

P. A. J. GORIN, K. HORITSU,[2] AND J. F. T. SPENCER
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received October 15, 1964

ABSTRACT

The yeast, *Rhodotorula glutinis*, gives an exocellular mannan containing 1,3-β- and 1,4-β-D-mannopyranose residues arranged in a straight chain of at least 90 units. Consecutive 1,3-β links are absent and although consecutive 1,4-β links may exist they are present at most in only a very small proportion. The 1,3-β- and 1,4-β-D-mannopyranose residues are therefore arranged alternately in the chain.

Mannans from *R. mucilaginosa*, *R. minuta*, and an unidentified *Rhodotorula* spp. 62-506 appear to have similar structures.

Rhodotorula glutinis, when grown on a 5% glucose – yeast nitrogen base medium, produced exocellular polysaccharides consisting mainly of mannan, in yields of up to 2.2 g per liter. Initially, the crude polysaccharide was oxidized with sodium periodate and the product then reduced with sodium borohydride. Hydrolysis gave mannose, erythritol, and glycerol, suggesting 1,3 and 1,4 links in the polysaccharide. It differed, therefore, from the mannans containing 1,2-α- and 1,6-α-pyranosyl links (with 1,3-α links in some cases) associated with certain yeasts (1, 2, 3), fungi (4), and bacteria (5, 6).

Hydrolysis of the crude polysaccharide gave another hexose and a methyl pentose in addition to mannose. Purification of the mannan was effected via its water-insoluble copper complex formed with Fehling's solution. The pure mannan had a specific rotation of −78° indicating β-linkages and on periodate oxidation it consumed oxidant rapidly, eventually after 2 days consuming 0.61 mole with the release of 0.07 mole of acid. These data suggest approximately equal amounts of 1,3-β and 1,4-β links in a straight chain structure, perhaps similar to the polysaccharide isolated by Smith and co-workers (7) from the uredospores of wheat stem rust. The latter polymer originally described as a glucomannan was fractionated later to yield a mannan (8).

Further structural data were obtained by methylation of the mannan. The *O*-methyl mannoses formed on acid hydrolysis of the methylated mannan were converted to their methyl glycosides which were separated by gas phase chromatography (g.l.c.). Methyl 2,3,6- and 2,4,6-tri-*O*-methyl mannosides were identified and occurred in almost equal amounts. These compounds had higher retention times than the 2,3,4- and 3,4,6-isomers. Some dimethyl methyl mannoside, probably formed because of undermethylation or demethylation (9), and methyl 2,3,4,6-tetra-*O*-methyl mannoside (1.1% of total signal) were also detected. The low proportion of nonreducing end groups should arise (barring cyclic polysaccharide structures) either from a slightly branched polymer or from the end unit of a straight chain polysaccharide containing approximately 90 mannose residues.

The sequence of 1,3 and 1,4 links in the mannan was elucidated by the Smith technique (10). The periodate-oxidized mannan was reduced with sodium borohydride and the modified polymer partially hydrolyzed with acid. Paper chromatography showed the presence

[1]*Issued as N.R.C. No. 8312.*
[2]*National Research Council of Canada Postdoctorate Fellow, 1963–1964.*

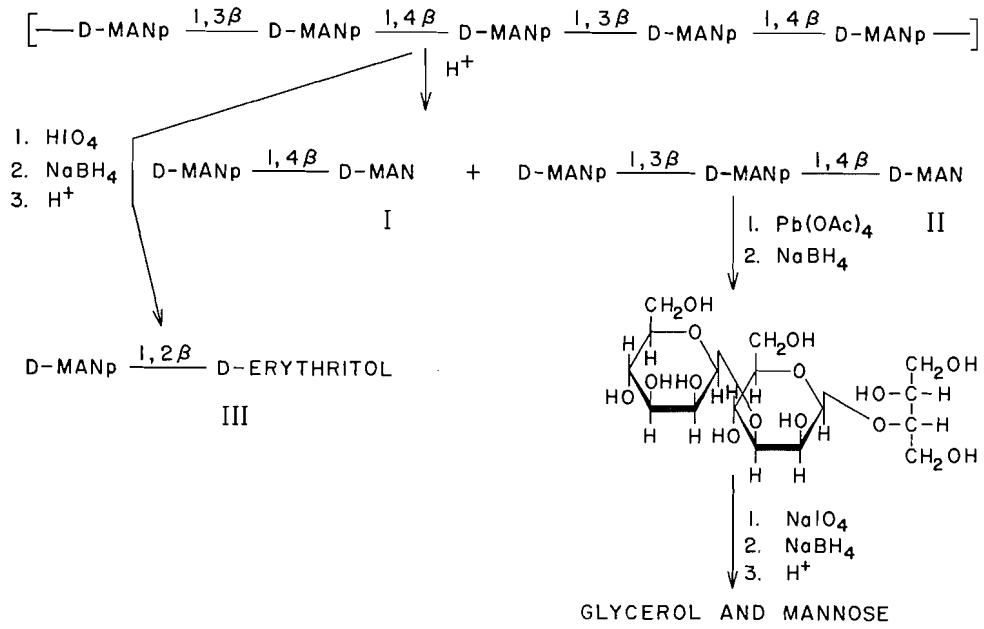

FIG. 1. Degradation products of *R. glutinis* mannan.

of 2-*O*-β-D-mannopyranosyl-D-erythritol (III), which should arise from D-mannopyranosyl residues alternately linked 1,3-β and 1,4-β. The absence of fragments of higher molecular weight negated the possibility of two or more consecutive 1,3 links. Periodate and methylation experiments pointed to approximately equal proportions of 1,3 and 1,4 linkages in the mannan. Exact determination of the amounts of 1,3 and 1,4 linkages was precluded by possible periodate overoxidation and lack of accurate conversion factors for the methylated methyl mannosides in the g.l.c. experiment. Evidence against the possibility of two or more consecutive 4-*O*-linked mannosyl units in the mannan was obtained by examination of the mannotriose fraction formed on partial hydrolysis.

A series of oligosaccharides from the mannan was isolated after treatment with *N* hydrochloric acid at 75 °C for 4 h. The disaccharide fraction, isolated chromatographically, consumed 1.76 moles of lead tetraacetate rapidly (11) and therefore contained at least 76% of 4-*O*-β-D-mannopyranosyl-D-mannose (I). This disaccharide was isolable as crystals in 67% yield. Since the mannosidic linkage attached to a 4-position is thus more stable than that attached to the 3-position, the presence of two or more consecutive 1,4 links should be reflected by occurrence of appreciable amounts of *O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 4)-D-mannose in the trisaccharide fraction. Lead tetraacetate oxidation kinetics of this fraction showed a high proportion of 4-*O*-linked reducing end and reduction of the oxidation product gave an amorphous mannobiosyl erythritol fraction which consumed 2.8 moles of periodate with concomitant formation of 1.0 moles of acid in accord with a predominating O-β-D-mannopyranosyl-(1 → 3)-*O*-β-D-mannopyranosyl-(1 → 2)-D-erythritol structure (IV). This material arose from *O*-β-D-mannopyranosyl-(1 → 3)-*O*-β-D-mannopyranosyl-(1 → 4)-D-mannose (II). The oxidation product after reduction with sodium borohydride followed by hydrolysis gave mannose and glycerol. The presence also of a barely detectable amount of erythritol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

showed that only a very small proportion of consecutive 1,4 links could be present. Alternately, the erythritol could have arisen from a trace amount of *O*-β-D-mannopyranosyl-(1 → 4)-*O*-β-D-mannopyranosyl-(1 → 2)-D-arabitol. The mannan can therefore be regarded as having alternate 1,3-β and 1,4-β pyranose links.

TABLE I

Specific rotations and periodate oxidation characteristics of mannans

Parent organism	$[\alpha]_D^{25}$ in water	Molar uptake of sodium periodate after 5 h	23 h	48 h
R. glutinis	−78° (*c*, 0.6)	0.52	0.55 (0.07)*	0.61 (0.07)
R. mucilaginosa	−79° (*c*, 0.1)	0.54	0.54 (0.07)	0.60 (0.07)
R. minuta	−88° (*c*, 0.1)	0.53	0.54 (0.04)	0.58 (0.06)
62-506	−80° (*c*, 0.1)	0.54	0.56 (0.07)	0.62 (0.07)

*Figures in parentheses refer to acid production in moles/mole.

Other *Rhodotorula* spp. gave rise to similar mannans, although in lesser yield than *Rhodotorula glutinis*. Mannans from *R. minuta*, *R. mucilaginosa*, and an unnamed species designated 62-506 were purified via their copper complexes. The products and specific rotations close to −80° and their periodate oxidation characteristics were similar to those obtained on purified *R. glutinis* polysaccharide (Table I). Reduction of the oxidized polysaccharides, followed by hydrolysis yielded mannose, erythritol, and a trace of glycerol. These polymers also appear to be 1,3-β;1,4-β-mannans and are quite different from the main exocellular polysaccharides of the related *Cryptococcus* genus. Those arising exocellularly from *C. laurentii* (12) and the capsule of *C. neoformans* (13) consist of glucuronic acid, mannose, and xylose.

EXPERIMENTAL

Culture Methods

Cultures of *Rhodotorula glutinis*, *R. mucilaginosa*, *R. minuta*, and an as yet unclassified species (62-506) isolated from fish gut contents obtained in Northern California, were grown in shaken flasks or in stirred fermentors. The medium contained Wickerham's chemically defined yeast nitrogen base (Difco) (14) and 5% glucose (this medium does not contain mannan). The shaken cultures were grown in 500 ml Erlenmeyer flasks containing 100 ml medium and incubated either on a New Brunswick rotary shaker, eccentricity 1/2 in., at a speed of about 250 r.p.m. at 20 °C or on a Gump shaker, eccentricity 1 in., a speed of 230 r.p.m. at 24 °C. When stirred fermentors were used, they were 5 l New Brunswick glass jar type fermentors, operated at 400 r.p.m. at a temperature of 24 °C, with an air flow rate of about 1 l/min/fermentor, or, for larger batches, they were 30 l stainless steel fermentors similar in design to the New Brunswick equipment. The progress of the fermentation was followed by determining the increase in drainage time of the culture from a 10 ml pipette. When the maximum drainage time was reached, the cells were removed by centrifugation and the polysaccharides were precipitated from the supernatant by the addition of 2 volumes of ethanol. The product from *R. glutinis* contained C, 39.7; H, 6.5; N, 1.2; ash, 3.7, and gave mannose and traces of another hexose and a methyl pentose on hydrolysis.

The yields, per liter of medium, of mannan were as follows: *R. glutinis*, 2.2 g; *R. mucilaginosa*, 0.8 g; *R. minuta*, 0.3 g; 62-506, 0.7 g.

Purification of Polysaccharides

The mannan could be precipitated from solution by Fehling's solution as its copper complex, either directly from the fermentation liquor or subsequent to ethanol precipitation. In a typical experiment mannan from *R. glutinis* (3.5 g) was dissolved in water (500 ml) and Fehling's solution added (200 ml). The precipitate was filtered off and washed with water and methanol. The product (2.6 g) was then decomposed by gradual addition of *N* hydrochloric acid to a stirred aqueous suspension (150 ml). When dissolution was complete and the light-blue color eliminated by a slight excess of acid 4 volumes of methanol were added to the slightly acidic solution. Yield, 2.1 g.

A sample (100 mg) of purified mannan was hydrolyzed in *N* sulfuric acid (10 ml) at 100 °C. The specific rotation of the solution after 18 h was +15° (based on hexose) and on further heating this value remained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

unchanged. After 42 h the solution was neutralized ($BaCO_3$), filtered, and evaporated. Crystallization from ethanol provided α-D-mannose (52 mg) with m.p. 129–131 °C, undepressed on admixture with an authentic specimen, and $[\alpha]_D$ +26° → +14° (constant value; *c*, 1.05 H_2O).

The specific rotations and periodate oxidation characteristics of four purified mannans are listed in Table I.

Reduction of periodate oxidation products from the four polysaccharides with sodium borohydride followed by acid hydrolysis for 2 h with *N* HCl at 100 °C yielded mannose, erythritol, and a small amount of glycerol.

Methylation of R. glutinis Mannan

Purified mannan (1.00 g) was methylated at room temperature with dimethyl sulfate and sodium hydroxide by the Haworth procedure (15). Destruction of reagent followed by neutralization gave an insoluble partially methylated mannan (0.86 g) with —OCH_3, 42.4%. The mother liquor was continuously extracted with chloroform and a further 0.23 g of methylated mannan obtained. The two fractions were combined and methylated further using the Kuhn method (16) of silver oxide in dimethyl formamide – iodomethane.

The methylated mannan (1.08 g) was refluxed overnight in 5% methanolic hydrogen chloride (50 ml), neutralized (Ag_2CO_3), filtered, and evaporated. The product (1.13 g), now water soluble, was hydrolyzed with 2 *N* hydrochloric acid (10 ml) for 24 h at 100 °C. Removal of acid yielded the free methyl sugars. These were shown on paper chromatograms using the *p*-anisidine hydrochloride spray (17) to consist of tri-*O*-methyl mannoses and traces of di-*O*- and tetra-*O*-methyl mannoses. A portion (20 mg) was converted to a mixture of methyl mannosides by refluxing for 3 h in 5% methanolic hydrogen chloride (5 ml). The product was examined by g.l.c. using 2% neopentyl glycol succinate on HMDS Chromosorb W (80–100 mesh) in a 5 ft × 1/4 in. o.d. copper tube at 143 °C with helium (29 p.s.i.) as carrier gas (18). The g.l.c. unit was of conventional design using thermal conductivity detectors. The following glycosides were detected, their proportion being expressed as percentages of the total area under the peaks; the other figures in parentheses are the emergence times. Methyl 2,3,4,6-tetra-*O*-methyl mannoside (1.1%, 3.7 min); 2,4,6- (46.7%, 8.7 min); 2,3,6- (48.7%, 11.3 min);d i-*O*-methyl mannosides (2.4%, 16.7and 19.0 min; 0.5%, 22.7 and 26.3 min). 3,4,6-*O*- and 2,3,4-*O*-substituted mannosides had retention times of 6.9 and 7.0 min, respectively.

Partial Hydrolysis of R. glutinis Mannan

(i) Isolation of 2-O-β-D-Mannopyranosyl-D-erythritol Monohydrate

Purified mannan (4.0 g) was dissolved by stirring in water (500 ml) at 100 °C overnight. After cooling periodic acid (12.0 g) was added and oxidation allowed to proceed for 20 h. Excess oxidant was removed by addition of barium carbonate and after filtration the filtrate was treated with sodium borohydride (2.0 g). Two hours later acetic acid was added and the solution shaken with Amberlite IR120. The filtered solution was evaporated to dryness and residual boric acid removed by repeated evaporations of methanol. The modified polysaccharide was hydrolyzed with 0.01 *N* hydrochloric acid (100 ml) at 100 °C for 1 h. The methanol-soluble product, after removal of acid, gave spots on a paper chromatogram corresponding to mannosyl erythritol, smaller amounts of mannose and erythritol, and a trace of glycerol (solvents: acetone–water 4:1 (v/v) and butanol–ethanol–water, 40:11:19 (v/v); detector: silver nitrate – sodium hydroxide dip (19)). No oligosaccharides running more slowly than mannosyl erythritol were detected. Two faint spots were detectable in the butanol–ethanol–water solvent with rates compared with mannosyl erythritol (R_{ME}) of 1.7 and 2.1.

The 2-*O*-β-D-Mannopyranosyl-D-erythritol (0.83 g) was isolated by chromatography on cellulose using butanol saturated with water as eluant. The product after two crystallizations from ethanol had m.p. 87–90 °C and $[\alpha]_D$ −36° (*c*, 1.1 H_2O), and gave mannose and erythritol on hydrolysis. It consumed after 12 h 3.05 moles of sodium periodate with concomitant formation of 0.87 mole of acid.

Anal. Calcd. for $C_{10}H_{20}O_9 \cdot H_2O$: C, 39.7; H, 7.3. Found: C, 40.0; H, 7.3.

The specific rotation is close to −36° recorded for the syrupy 2-*O*-β-D-mannopyranosyl-D-erythritol in methanol (20).

The materials with R_{ME} 1.7 and 2.1 were obtained in yields of 0.80 g and 0.47 g and appeared to be side-products formed by molecular rearrangement of the modified polymer under the influence of acid. This conclusion was reached since treatment of each compound with 0.01 *N* hydrochloric acid at 100 °C for 3 h caused partial hydrolysis to mannosyl erythritol, as indicated on paper chromatograms.

Partial hydrolysis of the modified polymer with 0.1 *N* sulfuric acid at 100 °C for 1 h gave rise to mannosyl erythritol and trace spots with R_{ME} 1.7 and 2.1. Spots corresponding to mannobiosyl or mannotriosyl erythritol were not detected.

(ii) Isolation and Characterization of Mannobiose and Mannotriose Fractions

Preliminary experiments showed that the optimum yields of oligosaccharide from mannan were obtained using *N* hydrochloric acid at 75 °C for 4 h. Thus on partial hydrolysis of mannan (5.0 g) with acid (70 ml) the oligosaccharide products were fractionated on a cellulose column, after neutralization, using various solvents. Mannose (1.13 g) was obtained initially by use of *n*-butanol half saturated with water. Mannobiose (0.68 g) was eluted with acetone–water (6:1 (v/v)) and mannotriose (0.50 g) with acetone–water (3:1 (v/v)). Finally mannotetraose (0.44 g) and mannopentaose (53 mg) were eluted with acetone–water ((2:1 (v/v)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The di-, tri- and tetra-saccharides moved on a paper chromatogram in ethyl acetate – acetic acid – water (9:2:2 (v/v)) at rates of 1.3, 0.5, and 0.3 respectively, compared with lactose.

The mannobiose fraction was oxidized with lead tetraacetate and consumed 1.42, 1.69, 1.71, and 1.76 moles of oxidant after 2, 5, 10, and 15 min respectively. Crystallization from methanol–ethanol yielded 4-*O*-β-D-mannopyranosyl-D-mannose (458 mg). The disaccharide had m.p. 195–199 °C, undepressed on admixture with an authentic specimen and $[\alpha]_D$ −11° (*c*, 1.8 H_2O). Its X-ray diffraction diagram was identical with that of an authentic specimen.

The mannotriose fraction had $[\alpha]_D$ −35° (*c*, 0.9 H_2O) and consisted mainly of material with a 4-*O*-linked reducing end. In this instance 1.47, 1.78, 1.74, and 1.98 moles of lead tetraacetate were consumed after 2, 5, 10, and 15 min respectively. Mannotriose (153 mg) was dissolved in water (0.5 ml) and acetic acid (25 ml) and treated with a 1% solution of 2 moles of lead tetraacetate in acetic acid. After 30 min oxalic acid (2 moles) in acetic acid was added, the precipitate of lead oxalate filtered off, and the solution evaporated. The residue was reduced with sodium borohydride (100 mg) in water (20 ml). After 2 h the solution was worked up as described previously in this section. Paper chromatographic examination showed mainly mannobiosyl erythritol and a smaller proportion of mannobiosyl arabitol. These were separated by cellulose column chromatography using acetone–water (6:1 (v/v)) as eluant. The mannobiosyl erythritol (49 mg) gave mannose and erythritol on hydrolysis and had $[\alpha]_D$ −50° (*c*, 1.1 H_2O). It consumed 2.6, 2.8, and 2.8 moles of sodium periodate after 4, 23, and 48 h respectively, and after 23 and 48 h, 1.0 mole of acid was formed. A portion was oxidized with excess sodium periodate for 24 h and the solution then deionized and reduced with sodium borohydride for 2 h. Hydrolysis of the product gave on a paper chromatogram mannose and glycerol with a barely detectable amount of erythritol.

ACKNOWLEDGMENTS

The authors thank Mr. N. Gardner for technical assistance, Mr. M. Mazurek for carrying out microanalyses, and Mr. W. C. Haid for preparation of X-ray diffraction patterns.

Received November 18, 1964

ABSTRACT

The oxidation by *Acetobacter suboxydans* of several aldose dimethylacetals and diethyldithioacetals has been achieved. Isolation and characterization of the ketose products showed that the oxidations had followed the Bertrand–Hudson rules.

Previous workers (1, 2, 3) have reported unsuccessful attempts to adapt *A. suboxydans* to the oxidation of aldose dithioacetals and dimethylacetals. Bollenback and Underkofler (4) reported reducing values for aldose dithioacetals during an attempted oxidation, but Mitchell (3) has shown that these were most likely due to the oxidation of the sulfur atoms by the copper reagent used in the determination of the reducing values. We have now succeeded in oxidizing several aldose acetals and thioacetals (Table I) and have isolated the ketose products which were characterized as their 2,5-dichlorophenylhydrazones (except for compound C).

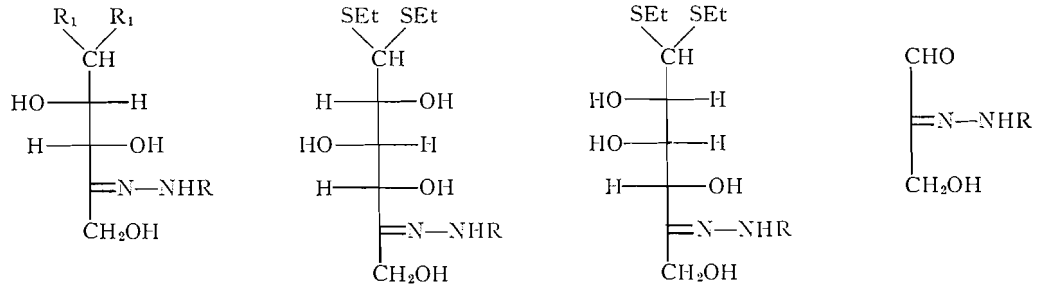
TABLE I

Substrate	Product	% yield	Time of oxidation (days)
D-Arabinose dimethylacetal	4-*keto*-D-Arabinose dimethylacetal	(A) 80	8
D-Arabinose diethyldithioacetal	4-*keto*-D-Arabinose diethyldithioacetal	(B) 70	19
D-Glucose dimethylacetal	5-*keto*-D-Glucose dimethylacetal	(C) 60	18
D-Glucose diethyldithioacetal	5-*keto*-D-Glucose diethyldithioacetal	(D) 60	15
D-Mannose diethyldithioacetal	5-*keto*-D-Mannose diethyldithioacetal	(E) 45	44
D-Galactose diethyldithioacetal	(3?)-*keto*-D-Galactose diethyldithioacetal	60	54

The usual technique used, when sugars are to be oxidized by *A. suboxydans*, is to inoculate the substrate broth with one drop of a culture of *A. suboxydans* grown on D-sorbitol. It was felt that this was insufficient inoculation, for the growth of the organism on unfavorable substrates, and in our work we have used 1–2 ml of the inoculation culture to promote the growth of the organism and thus to achieve oxidation. The oxidation of the sugar acetals and thioacetals followed the well-known Bertrand–Hudson rules (1, 5), although in the case of the *keto*-D-galactose diethyldithioacetal the position of the keto group has not yet been fully established and discussion of the structure of this compound will be left to a later publication.

Borohydride reduction of A followed by acid hydrolysis gave xylose and arabinose, indicating that the keto group was on C_4 of the parent compound. Periodate oxidation of the 2,5-dichlorophenylhydrazone (II*a*) of A showed a rapid uptake of 1 mole of periodate with neither liberation of formaldehyde or production of acid, and within a short

while a precipitate of hydroxypyruvaldehyde 2-(2,5-dichlorophenylhydrazone) (V) had formed. The 2,5-dichlorophenylhydrazone (II*b*, III, and IV) of B, D, and E, also gave V on treatment with periodate, thus confirming that the keto group in the parent compound had been formed adjacent to the primary hydroxyl group.



II III IV V

(*a*) $R_1 = OCH_3$
(*b*) $R_1 = SEt$

$R = C_6H_4Cl_2$

A crystalline hydrazone of C could not be obtained. However, borohydride reduction of C followed by acid hydrolysis gave idose and glucose, identified by gas chromatography, after reduction and acetylation, as iditol and sorbitol hexaacetates respectively. The extension of this work to the oxidation of other sugar acetals and the use of ketose products in the preparation of amino and branched chain sugars is being further nvestigated.

EXPERIMENTAL

All evaporations were carried out under reduced pressure and below 50°. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured at 23 ± 3° with a Hilger Standard Polarimeter. Paper chromatography was carried out by the descending method at room temperature on Whatman No. 1 filter paper. The solvent system was butan-1-ol:ethanol:water, 3:1:1 (w/v). Sugars were detected on paper chromatograms by the following spray reagents: (i) alkaline silver nitrate (6), (ii) *p*-anisidine hydrochloride (7).

Preparation of Substrates

Diethyldithioacetals

The aldose (10 g) was dissolved in ice-cold concentrated hydrochloric acid (10 ml) and shaken with ethanethiol (10 ml). The temperature was maintained at 0° by immersion in ice water and by the addition of ice chips to the reaction mixture. Within 15 min the reaction mixture had usually solidified and the crystals were washed with ice-cold water until acid free and then recrystallized from ethanol or aqueous ethanol.

D-*Arabinose Dimethylacetal*

This was prepared by the general method of Wolfrom and Thompson (8).

D-*Glucose Dimethylacetal*

This was prepared by the method of Wolfrom and Thompson (8).

Acetobacter suboxydans (N.R.C. 471) was kindly supplied by the culture division of the National Research Council. The acetals to be oxidized were made up as a broth, containing the acetal (2.5%), yeast extract (0.5% w/v), potassium dihydrogen phosphate (0.05% w/v), and D-glucose (0.05% w/v) dissolved in tap water. After sterilization the solutions (25 ml), in 250 ml conical flasks, were inoculated with a vigorously growing culture of *A. suboxydans* (1–2 ml) grown on D-sorbitol. The flasks were stored in the dark, without agitation, at room temperature and the course of the oxidations was followed by paper chromatography. At a convenient time the oxidations were terminated by the addition of ethanol (2 vols.). After filtration and deionization the solutions were concentrated and the oxidation products separated by paper, column chromatography, or by continuous extraction from aqueous solutions by chloroform.

For personal use only.

Preparation of 2,5-Dichlorophenylhydrazones

Molar ratios of the ketose and 2,5-dichlorophenylhydrazine were dissolved in a small volume of ethanol and left at room temperature overnight. Addition of water usually caused immediate crystallization and the product was recrystallized from ethanol by dropwise addition of water.

*4-keto-*D*-Arabinose Dimethylacetal*

D-Arabinose dimethylacetal was oxidized and gave a syrupy product with $[\alpha]_D = -41.3$ (*c*, 0.8, methanol). This ketose gave a crystalline 2,5 dichlorophenylhydrazone, m.p. 133° and $[\alpha]_D = -34.4$ (*c*, 0.44, methanol).

Anal. Calcd. for $C_{13}H_{18}O_5N_2Cl_2$: C, 44.19; H, 5.14; N, 7.93. Found: C, 43.93; H, 5.22; N, 8.20.

*4-keto-*D*-Arabinose Diethyldithioacetal*

D-Arabinose diethyldithioacetal gave on oxidation a crystalline ketose, m.p. 120–121° and $[\alpha]_D = -17.3°$ (*c*, 0.52, methanol).

Anal. Calcd. for $C_9H_{18}O_4S_2$: C, 42.54; H, 7.09; S, 25.19. Found: C, 42.35; H, 6.89; S, 25.36.

This ketose gave a crystalline 2,5-dichlorophenylhydrazone with m.p. 90–91° and $[\alpha]_D = -7°$ (*c*, 0.2, methanol).

Anal. Calcd. for $C_{15}H_{22}O_3S_2N_2Cl_2$: C, 43.60; H, 5.33; S, 15.49; N, 6.78. Found: C, 43.41; H, 5.33; S, 15.39; N, 6.86.

*5-keto-*D*-Glucose Dimethylacetal*

D-Glucose dimethylacetal gave on oxidation a syrupy ketose with $[\alpha]_D = +3.2°$ (*c*, 3.5, water), which did not give a crystalline hydrazone.

*5-keto-*D*-Glucose Diethyldithioacetal*

D-Glucose diethyldithioacetal gave on oxidation a syrupy ketose, $[\alpha]_D = -30°$ (*c*, 1.4, water), which yielded a crystalline 2,5-dichlorophenylhydrazone, m.p. 97° $[\alpha]_D = -24°$ (*c*, 0.5, methanol).

Anal. Calcd. for $C_{16}H_{24}O_4S_2N_2Cl_2$: C, 43.37; H, 5.42; N, 6.32; S, 14.44. Found: C, 43.53; H, 5.40; N, 6.48; S, 14.48.

*5-keto-*D*-Mannose Diethyldithioacetal*

D-Mannose diethyldithioacetal gave on oxidation a syrupy ketose, $[\alpha]_D = +28°$ (*c*, 1.67, water), which yielded a crystalline 2,5-dichlorophenylhydrazone, m.p. 129–130°, $[\alpha]_D = +40°$ (*c*, 0.25, methanol).

Anal. Calcd. for $C_{16}H_{24}O_4S_2N_2Cl_2$: C, 43.37; H, 5.42; N, 6.32; S, 14.44. Found: C, 43.24; H, 5.49; N, 6.50; S, 14.29.

Periodate Oxidations

Oxidations were carried out in the dark at room temperature in 50% aqueous ethanol containing excess sodium metaperiodate.

Hydroxy Pyruvaldehyde 2-(2,5-Dichlorophenylhydrazone)

The 2,5-dichlorophenylhydrazone of the ketose, when treated with periodate, gave an orange precipitate after a very short time. This precipitate was filtered off and after recrystallization from ethanol–water had m.p. 190–195° (decomp.).

Anal. Calcd. for $C_9H_8O_2N_2Cl_2$: C, 43.72; H, 3.24; N, 11.34. Found: C, 43.36; H, 2.95; N, 11.78.

*Sodium Borohydride Reduction of 4-keto-*D*-Arabinose Dimethylacetal*

4-*keto*-D-Arabinose dimethylacetal (100 mg) was reduced with sodium borohydride (100 mg) at 0° for 3 h. Excess sodium borohydride was converted to sodium borate which was removed as methyl borate after passage through Amberlite I.R. 120 (H^+) resin. The resultant syrup (90 mg) was hydrolyzed for 3 h at 80° with sulfuric acid (1 *N*, 1 ml). After neutralization of the acid, and concentration of the solution, paper chromatograms showed two components which co-chromatogrammed with xylose and arabinose and which were easily distinguished from lyxose and ribose.

*Sodium Borohydride Reduction of 5-keto-*D*-Glucose Dimethylacetal*

5-*keto*-D-Glucose dimethylacetal when subjected to the above procedure gave two components with $R_f = R_{glucose}$ and $R_f = 1.67\ R_{glucose}$. Borohydride reduction of this mixture followed by acetylation with acetic anhydride and pyridine gave a mixture of two hexaacetates identified by gas chromatography as sorbitol and iditol hexaacetates.

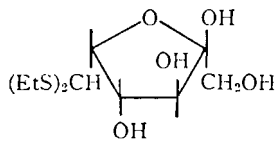
APPENDIX

In continuation of studies of methods for the synthesis of branched chain sugars (9) we are assessing a possible route in which one stage is the oxidation of aldose dithioacetals by the specific dehydrogenase system of *Acetobacter suboxydans*. To date our results are less complete than those of Williams and Jones (previous section) but some differences have been noted. Under the conditions of our experiments, a crystalline ketose derivative was obtained from the oxidation of D-glucose diethyldithioacetal, but the diethyldithioacetals of D-mannose, D-arabinose, and D-ribose were not oxidized by *A. suboxydans*. Very recent results indicate however that a bacterial suspension prepared under modified conditions will effect oxidation of these thioacetals.

The organism was grown on a medium containing D-glucose as the carbon source (10); the cells were washed from the agar surface and collected by centrifugation for 1 h at 2 000 *g*. D-Glucose diethyldithioacetal (5 g) was dissolved in a suspension of the bacterium (250 ml containing 15 ml wet-packed cells), the pH was adjusted to 6.8 by the addition of aqueous sodium hydrogen carbonate, and the suspension was shaken under an atmosphere of oxygen in a 1 l flask bearing a sidearm attached to a manometer. The oxygen was replenished at 24 h intervals and the uptake ceased after 4 days (total consumption 0.45 mole, 90%). After centrifugation, the solvent was removed at 40° and finally by azeotropic distillation with benzene, and the resultant syrup was extracted with warm methylene dichloride (100 ml). The extract was filtered and reduced in volume; addition of light petroleum (b.p. 40–60°) gave a crystalline product. Recrystallization from methylene dichloride / light petroleum (b.p. 40–60°) gave D-*xylo-hexos-5-ulose diethyldithioacetal* (3.1 g, 62%) m.p. 66–67°, $[\alpha]_D$ −30.5° (*c*, 2.1, in H_2O). (Found: C, 42.1; H, 7.2; S, 22.0. $C_{10}H_{20}O_5S_2$ requires C, 42.2; H, 7.1; S, 22.5.) The nuclear magnetic resonance (n.m.r.) spectrum was consistent with this structure. The derived 2,5-dichlorophenylhydrazone had m.p. 102–103°, $[\alpha]_D$ −15° → −58° (constant after 6 days) (*c*, 1.6, in MeOH). On periodate oxidation it yielded hydroxypyruvaldehyde 2-(2,5-dichlorophenylhydrazone), melting point and mixed melting point 190–191° (decomp.). The infrared spectrum of this derivative was identical with that of an authentic sample prepared from D-fructose 2,5-dichlorophenylhydrazone (11).



The ketose showed no carbonyl absorption in the infrared region, thereby suggesting that it exists in the crystalline form as a cyclic modification. Mutarotation was difficult to observe directly, but through the kindness of Dr. T. R. Emerson of Westfield College (University of London) and by the use of the Bellingham and Stanley / Bendix–Ericsson automatic recording spectropolarimeter, it was found that a rapid mutarotation did occur, $[\alpha]_{322}$ −57.5° (30 s) → −47° (2 min, const.) (*c*, 0.8, in H_2O). The compound therefore has structure I. On reduction with sodium borohydride D-glucose diethyldithioacetal was recovered together with a small amount of a second diethyldithioacetal which, on acidic hydrolysis, gave two products having the chromatographic mobilities of idose and its 1,6-anhydride.

REARRANGEMENT REACTIONS FOLLOWING ELECTRON IMPACT ON ETHYL AND ISOPROPYL ESTERS

A. G. HARRISON[1] AND E. G. JONES
Department of Chemistry, University of Toronto, Toronto, Ontario

Received November 5, 1964

ABSTRACT

The mass spectra of ethyl and isopropyl propionate and butyrate show rearrangement ions R_1COOH^+ and $R_1C(OH)_2^+$ formed by reactions [*a*] and [*b*]:

[*a*] $$R_1COOR_2^+ \rightarrow R_1COOH^+ + (R_2 - H),$$

[*b*] $$R_1COOR_2^+ \rightarrow R_1C(OH)_2^+ + (R_2 - 2H).$$

The mass spectra of ethyl-d_2 propionate and butyrate show that both [*a*] and [*b*] occur with essentially complete scrambling of the alkoxy hydrogens. For the isopropyl esters the mass spectra of the isopropyl-d_6 molecules show that reaction [*a*] occurs by transfer of one of the methyl hydrogens to the acid moiety while reaction [*b*] occurs predominately by transfer of two methyl hydrogens.

INTRODUCTION

The mass spectra of aliphatic esters of formula R_1COOR_2 show a number of characteristic rearrangement processes the general features of which have been elucidated (1, 2). When R_1 is three carbons or greater in length and contains hydrogen in the γ-position a rearrangement occurs to form the enol ion of the corresponding acetate (reaction [1]).

[1] $$RCH_2CH_2CH_2COOR_2^+ \rightarrow RCH{=}CH_2 + CH_2{=}C(OH)OR_2^+.$$

Deuterium labelling (3–6) has shown that reaction [1] involves a specific transfer of the γ-hydrogen to the oxygen, presumably through a cyclic intermediate (7).

When R_2 is ethyl or higher, further rearrangements may occur which lead not only to formation of the acid ion R_1COOH^+ (reaction [2]) but also to formation of the protonated acid ion $R_1C(OH)_2^+$ (reaction [3]). The formation of the latter ion has permitted estimation of the proton affinity of acids (8, 9). For the smaller R_1 groups reaction [2] occurs almost exclusively to give the charge on the $(R_2 - H)$ fragment.

[2] $$R_1COOR_2^+ \rightarrow R_1COOH^+ + (R_2 - H),$$

[3] $$R_1COOR_2^+ \rightarrow R_1C(OH)_2^+ + (R_2 - 2H).$$

The evidence concerning the hydrogens transferred in reactions [2] and [3] is neither as extensive nor as conclusive as the evidence for reaction [1]. From the mass spectra of *sec*-butyl acetates mono-deuterated in the C_2 and C_3 positions, McLafferty and Hamming (10) concluded that the hydrogens of C_1, C_3, and C_4 of the butyl group were involved in reaction [3]. While the present work was in progress two papers (11, 12) have appeared concerning rearrangement reaction [3] in butyl and pentyl acetates. From the mass spectra of selectively deuterated *n*-butyl acetates it was suggested (11) that the rearrangement occurred by a selective transfer of one hydrogen from the C_3 position of the alcohol followed by a random selection of the second hydrogen. On the other hand, the results for the *n*-pentyl acetates indicated (12) that the first hydrogen was selected practically equally from the C_3 and C_4 positions, followed by random selection of the second from the remaining hydrogens. Godbole and Kebarle (8) concluded from the

[1]*Alfred P. Sloan Fellow 1962–1964.*

mass spectra of labelled ethyl acetates and formates that the hydrogen transfer reactions to the acid portion of the molecule involved essentially complete scrambling of the ethyl hydrogens. On the other hand, their results for isopropyl acetate show a pronounced preference for transfer of the hydrogens from the 1 and 3 positions of the propyl group.

To obtain further information on the hydrogens transferred in reactions [2] and [3] and to obtain information on the relative importance of reactions [1] and [2] we have prepared ethyl-1,1-d_2 propionate and butyrate and 2-propyl-1,1,1,3,3,3-d_6 propionate and butyrate and compared the spectra of the labelled and unlabelled molecules. The results obtained not only provide information on the rearrangement reactions discussed above but also provide information on a number of other fragmentation processes in these esters.

EXPERIMENTAL

Mass spectra were obtained with an A.E.I. MS-2 mass spectrometer at 50 V electron energy and 10 V cm^{-1} repeller field strength. Appearance potentials were determined in the usual manner (13) using xenon or krypton to calibrate the voltage scale.

The ethyl esters, both labelled and unlabelled, were prepared by the acid-catalyzed esterification of the free acid by the appropriate alcohol following the procedure given by Vogel (14). For the isopropyl esters this procedure gave poor yields. Much better yields were obtained by reaction of the appropriate acid anhydride with the labelled or unlabelled alcohol using zinc chloride catalyst (15). Final purification in all cases was by gas–liquid chromatography (g.l.c.) using a diisodecylphthalate column.

The ethyl-d_2 alcohol and isopropyl-d_6 alcohol were obtained from Merck, Sharp and Dohme, Montreal and were of better than 98% isotopic purity (16).

RESULTS AND DISCUSSION

Partial mass spectra of ethyl-1,1-d_2 propionate and 2-propyl-1,1,1,3,3,3-d_6 propionate are compared with the spectra of the unlabelled esters in Table I, while the spectra of the

Of particular interest in the present context are the rearrangement ions formed by reactions [2] and [3] which occur at masses[3] 74 and 75 for the unlabelled propionates and masses 88 and 89 for the butyrates, although, as will be shown below, a large fraction of the mass 88 ion current in the ethyl butyrate spectrum corresponds to the $CH_2{=}C(OH)OC_2H_5^+$ ion formed by reaction [1]. The ion current at mass 102 in the spectrum of isopropyl butyrate moves to mass 108 in the d_6 compound and obviously corresponds to the $CH_2{=}C(OH)OC_3H_7^+$ ion formed by reaction [1].

The mass spectra of the labelled and unlabelled propionates in the mass 70–80 region are compared in Table III and the ionic contributions for the various masses presented in detail. For the isopropyl esters little confusion can arise. The mass 75 of the unlabelled ester moves to mass 76 and 77 in the labelled ester corresponding to transfer of HD and 2D to the acid moiety, while the mass 74 moves to mass 75 corresponding to transfer of D in reaction [2]. The small mass 73 moves to mass 74 and therefore cannot be the

[3]*Since only singly charged ions will be discussed the m/e ratio will be referred to as the mass throughout.*

For personal use only.

$C_2H_5COO^+$ ion formed by loss of the isopropyl group but is probably the $C_2H_4COOH^+$ ion formed by loss of H from $C_2H_5COOH^+$. Such a decomposition is known (17) to proceed with retention of the acid hydrogen.

73	0.36	$C_2H_4COOH^+$		

The calculations for the ethyl esters are more complex since the total intensities for the labelled and unlabelled spectra differ slightly and, in addition, a number of the masses in the deuterated spectrum may have more than one contributor. To make the calculations possible we have multiplied all intensities in the labelled spectrum by 1.10 to make total intensities equal and we have further assumed that the ion at mass 73 in the unlabelled ester is formed by loss of C_2H_5 and is therefore either the $COOC_2H_5^+$ or the $C_2H_5COO^+$ ion. Undoubtedly a small amount may arise by loss of H from $C_2H_5COOH^+$, however, comparison with the spectrum of the isopropyl ester suggests that this contribution will be small. With these assumptions the ionic contributions detailed in the final column are calculated for the ethyl-d_2 propionate spectrum.

Similar calculations carried out for the mass 87–91 region of the labelled and unlabelled butyrates are presented in Table IV. Again the calculations for the isopropyl case are straightforward, however, the calculations for the ethyl esters are complex and it is not possible by equating intensities in the labelled and unlabelled spectra to solve directly for the ionic contributors at all masses. We have therefore made the logical assumption that the mass 88 intensity of the ethyl-d_2 spectrum corresponds entirely to $C_3H_7COOH^+$ formed by reaction [2] and that this reaction occurs by complete scrambling of the ethyl hydrogens as was found for the ethyl propionate. On this basis the contributions detailed in the last column of Table IV are obtained. The calculations show that approximately 92% of the mass 88 of the unlabelled ester has moved to mass 90 in the labelled spectrum and therefore must retain the two deuteriums. The major portion of the mass 88 therefore corresponds to the $CH_2{=}C(OH)OC_2H_5^+$ ion formed by reaction [1], while the remaining 8% corresponds to the $C_3H_7COOH^+$ ion formed by reaction [2]. This is in contrast to the results for isopropyl butyrate where reaction [1] produces an ion (mass 102) only 0.63 the intensity of the ion (mass 88) formed by reaction [2]. The presence of the isopropyl group appears to facilitate the rearrangement reaction [2].

From the calculations of Tables III and IV for the deuterated esters one obtains the following results for the transfer of H and D to form the R_1COOH^+ and $R_1C(OH)_2^+$ ions by reactions [2] and [3].

Ethyl-d_2 propionate:

$$C_2H_5COOD^+ : C_2H_5COOH^+ = 1.59:2.59 = 0.41:0.59;$$
$$C_2H_5C(OD)_2^+ : C_2H_5C(OD)(OH)^+ : C_2H_5C(OH)_2^+ = 0.19:2.10:1.81 = 0.05:0.51:0.43.$$

Ethyl-d_2 butyrate:

$$C_3H_7COOD^+ : C_3H_7COOH^+ = 0.61:0.92 = 0.40:0.60 \text{ (assumed)};$$
$$C_3H_7C(OD)_2^+ : C_3H_7C(OD)(OH)^+ : C_3H_7C(OH)_2^+ = 0.16:1.44:0.94 = 0.06:0.57:0.37.$$

Isopropyl-d_6 propionate:

$$C_2H_5COOD^+ : C_2H_5COOH^+ = 2.34:0;$$
$$C_2H_5C(OD)_2^+ : C_2H_5C(OD)(OH)^+ = 8.72:1.14 = 0.88:0.12.$$

Isopropyl-d_6 butyrate:

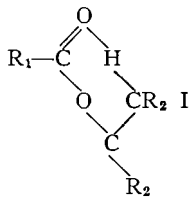
$$C_3H_7COOD^+ : C_2H_5COOH^+ = 4.67:0;$$
$$C_3H_7C(OD)_2^+ : C_3H_7C(OD)(OH)^+ = 6.57:0.82 = 0.89:0.11.$$

These results clearly show that the transfer of one H in reaction [2] involves complete scrambling of the ethyl hydrogens, while transfer of two hydrogens in reaction [3] for the ethyl esters proceeds with extensive scrambling of the the ethyl hydrogens, the experimentally observed ratio for transfer of D_2:HD:H_2 being close to the ratio 0.10:0.60:0.30 calculated for complete equivalence of the two D and three H. The results for the ethyl esters are in agreement with the results obtained by Godbole and Kebarle (8) for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

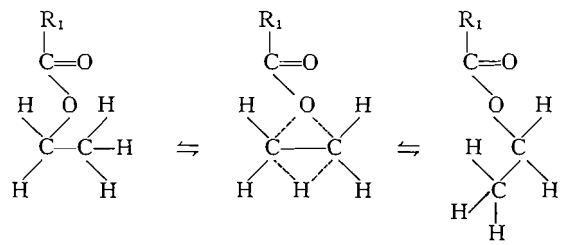
similar rearrangements in ethyl acetate. The results for the isopropyl esters, on the other hand, show that transfer of one hydrogen in reaction [2] proceeds, within experimental error, exclusively by transfer of the methyl hydrogen. Reaction [3] for the isopropyl esters occurs predominately by transfer of two of the methyl hydrogens as shown by the ratios for transfer of D_2:DH = 0.88:0.12. Complete scrambling of the isopropyl hydrogens would lead to D_2:HD = 0.72:0.28 while transfer of one of the methyl hydrogens followed by random selection of the second hydrogen would lead to the ratio D_2:HD = 0.83:0.17. The present results are in agreement with the results obtained for reaction [3] in $CD_3COOCD(CH_3)_2$ which showed transfer of H_2 : transfer of HD = 0.88:0.12 (8). It has been noted (12, 18) that rearrangement reaction [2] in the acetates leads almost exclusively to formation of the $(R_2 - H)^+$ ion rather than the R_1COOH^+ ion since the ionization potential of the olefin fragment is lower. For the esters studied in the present work the ionization potentials of the R_1COOH fragments are comparable to the ionization potentials of the olefin fragments with the result that appreciable intensities are noted corresponding to the acid ion.

It has been suggested (7, 18) that reaction [2] may occur through formation of a cyclic intermediate (I) involving transfer of the β-hydrogen of the alcohol moiety.



The results obtained in the present work for the isopropyl esters are clearly consistent with this interpretation since only the methyl (β) hydrogens are involved in reaction [2]. However, for the ethyl esters both the present results and previous work (8) show that the β-hydrogens are not transferred exclusively but that complete randomization of the ethyl hydrogens has occurred in the transfer process. This may be taken to indicate either that such a cyclic transition state is not applicable or that randomization of the ethyl hydrogens has occurred prior to formation of the intermediate. With regard to the latter possibility, it might be noted that for the ethyl esters a rather simple rearrangement of the parent ion (reaction [4]) could lead to essentially complete randomization of the hydrogens in reaction [2].

[4]



Such a rearrangement would be less likely for the isopropyl esters since it would involve shifting of the oxygen linkage from a secondary to a primary carbon rather than the symmetrical shift shown above. The above suggestion is clearly speculative since no other evidence can be found in the spectra of the ethyl esters to support such a rearrangement.

For reaction [3] it has been suggested (7) that the first hydrogen transfer also may occur by the cyclic intermediate I. It is not surprising therefore that the ethyl esters show extensive randomization of the ethyl hydrogens in reaction [3] as well as in reaction [2]. The results for the isopropyl esters are in accord with this suggestion while the results for the butyl (11) and pentyl (12) acetates suggest a selective transfer of the first hydrogen but through an intermediate of larger ring size. The major difference in the results for the isopropyl esters as compared to the butyl and pentyl esters is that transfer of the second hydrogen in the isopropyl esters appears to be specifically one of the terminal methyl hydrogens while for the other esters randomization of all the hydrogen has occurred.

A possible reason for this selectivity in the isopropyl case may be surmised from an examination of the energetics of formation of $R_1C(OH)_2^+$. The relevant data are summarized in Table V. The heats of formation of the neutral esters necessary for the thermochemical calculations were taken from Brion and Dunning (19) while the heats of formation of other neutral species were taken from the compilation of Bernecker and Long (20).

‖Reference 19.

The average $A(CH_3C(OH)_2^+)$ from ethyl acetate leads to $\Delta H_f(CH_3C(OH)_2^+) = 3.42$ eV assuming C_2H_3 (vinyl) as the neutral fragment. On the other hand, $A(CH_3C(OH)_2^+)$ from isopropyl acetate leads to $\Delta H_f(CH_3C(OH)_2^+) = 4.24$ eV assuming C_3H_5 (allyl) as the neutral fragment. This higher heat of formation is also obtained from the appearance potential of $CH_3C(OH)_2^+$ in *n*-propyl acetate. This difference in the calculated heats of formation for $R_1C(OH)_2^+$ from the ethyl and isopropyl esters is also found in the propionates and it is clear that the neutral fragment (or fragments) for the isopropyl esters cannot be the allyl radical.

One may reverse the calculations and use $\Delta H_f(R_1C(OH)_2^+)$ derived from the ethyl esters in the thermochemical cycle for the isopropyl esters to calculate $\Delta H_f(C_3H_5) = 2.15 \pm 0.2$ eV. Although the heat of formation of the cyclopropyl radical is not known accurately it is probably about 2.4 eV and it is therefore possible that the C_3H_5 formed from the isopropyl esters in reaction [3] has the cyclopropyl structure. For the isopropyl esters transfer of one hydrogen from each methyl group in reaction [3] would permit the formation of the cyclopropyl radical without further hydrogen rearrangement and would also explain the selective transfer of the hydrogens in the rearrangement reaction.

The mass spectra obtained for the deuterium-labelled molecules provide information on some of the other fragmentation processes, particularly for the butyrate esters, and deserve some comment.

Formation of Mass 73 in Butyrate Esters

Both the ethyl and isopropyl butyrates show a significant ion current at mass 73. For the isopropyl ester a metastable at 60.6 indicates the decomposition

[5] $$C_3H_7COOH^+ \rightarrow CH_2CH_2COOH^+ + CH_3.$$

This is supported by the observation that the fragment ion moves to mass 74 and the metastable to 61.5 in the labelled ester since the precursor ion has become $C_3H_7COOD^+$. A similar fragmentation is observed in the spectrum of butyric acid.

For the ethyl-d_2 butyrate the major contribution remains at mass 73 with smaller contributions at masses 74 and 75. The contributions at 73 and 74 presumably arise by reaction [5] although no metastable was observed. That portion occurring at mass 75 must incorporate both deuteriums and probably originates by loss of methyl from the $CH_2{=}C(OH)OCD_2CH_3^+$ ion.

Formation of Mass 70 in Ethyl Butyrate

The ion current at mass 70 in ethyl butyrate has the empirical formula $C_4H_6O^+$ (2). In the d_2 compound approximately one-half of this intensity moves to mass 72 indicating retention of both deuteriums. The most probable reaction is the loss of H_2O from the mass 90 intermediate.

[6] $$CH_2{=}C(OH)OCD_2CH_3^+ \rightarrow CH{\equiv}COCD_2CH_3^+ + H_2O.$$

The remainder of the ion current is found at masses 70 and 71 and the mechanism of formation is not clear.

Formation of Masses 60 and 61 in Butyrate Esters

The mass spectrum of ethyl butyrate shows a mass 61 ion current which is considerably more intense than that observed for isopropyl butyrate. The precursor ion is undoubtedly the $CH_2{=}C(OH)OCH_2CH_3^+$ ion and the rearrangement is therefore similar to that occurring in the spectrum of ethyl acetate. The relative intensities at masses 63, 62, and 61 in the d_2 compound are in agreement with complete scrambling of the ethoxy hydrogens in the rearrangement process. A similar rearrangement might be expected from the enol form of the isopropyl acetate ion (mass 102), however, the intensity of the precursor ion is much lower.

Both the ethyl and isopropyl esters show large ion currents at mass 60. In the isopropyl-d_6 butyrate this peak moves to mass 61 indicating retention of one deuterium and suggesting reaction [7] similar to that observed in butyric acid, although one cannot eliminate a concerted mechanism proceeding from the parent ester ion.

[7] $$C_3H_7COOH^+ \rightarrow CH_2{=}C(OH)_2^+ + C_2H_4.$$

A similar reaction in ethyl butyrate will account for the observed results.

Formation of R_1^+ and R_2^+ from R_1COOR_2

For ethyl propionate and isopropyl butyrate R_1^+ and R_2^+ occur at the same mass for the unlabelled esters. The spectra of the labelled esters allows an estimate of the relative contributions. For ethyl-d_2 propionate approximately 50% of the mass 29 moves to mass 31 indicating that $C_2H_5^+$ is formed equally from both ends of the ester molecule. For the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

isopropyl-d_6 butyrate approximately 66% of the mass 43 of the unlabelled ester is found at mass 49 in the labelled ester indicating the relative contributions $R_1^+:R_2^+ = 1:2$.

ACKNOWLEDGMENTS

We are indebted to Mr. D. Van Raalte for measurement of some of the appearance potentials. The financial support of the National Research Council of Canada and the Alfred P. Sloan Foundation is gratefully acknowledged.

THE USE OF POLYACRYLAMIDE GELS FOR CHROMATOGRAPHY OF PROTEINS

K. SUN[1] AND A. H. SEHON
Department of Chemistry, McGill University, Montreal, Quebec
Received October 29, 1964

ABSTRACT

Sixteen copolymers of acrylamide and N,N′-methylene bisacrylamide were synthesized using ammonium persulfate and dimethylaminopropionitrile as initiators. The water regain values of these gels were found to increase with decreasing total monomer concentration and with decreasing N,N′-methylene bisacrylamide / acrylamide ratio. The partition coefficients (K_d) of a variety of compounds of molecular weights between 104 and 580 000 were determined by normal elution column chromatography for three gels. The K_d values for a given solute using different gels were found to increase with decreasing total monomer concentration of the gel and with decreasing N,N′-methylene bisacrylamide / acrylamide ratio. For various solutes through the same column, the K_d values varied linearly with the logarithms of the corresponding molecular weights over the K_d range of 0.1 to 0.6. However, a number of compounds showed deviations from this relationship.

INTRODUCTION

In recent years, the use of cross-linked natural and synthetic polymers for column chromatography has proved to be a very versatile tool for the fractionation of macromolecules according to molecular size. Starch (1), dextran (2), polystyrene (3, 4), agar (5), polyacrylamide (6, 7), and agarose (8, 9) gels have all been used. Of these compounds, polystyrene is hydrophobic and, therefore, not suitable for the fractionation of most biological materials, which are hydrophilic. The use of starch columns for the chromatographic separation of proteins from polypeptides, or from other small molecules was shown to be effective (1). However, starch is not too useful for the separation of macromolecules.

Commercially available cross-linked dextrans (known as Sephadex and supplied by A. B. Pharmacia, Uppsala, Sweden) have been widely and successfully used. Similarly, polyacrylamide gels have been shown to be effective in the separation of proteins (6, 7, 10, 11) and agarose gels have been used for the fractionation of large aggregates, such as cells, mitochondria, and microsomes (8). The R_f values of solutes on polyacrylamide gels were found to increase with their molecular weights (10), and there was a linear relationship between the R_f values for a given macromolecule and the total concentrations of the monomers used in the polymerization procedure. From a recent abstract (12), it appears that the partition coefficients of 17 test substances with molecular weights ranging from 193 to 3 500 000 have been determined by upward elution chromatography on polyacrylamide gels.

The present study constitutes an extension of the work done in this laboratory on the preparation of a number of synthetic gels from well-defined vinyl and divinyl water-soluble monomers (6). A series of gels was synthesized from acrylamide and N,N′-methylene bisacrylamide by varying the concentration of the reagents. The water regain for each of these gels was determined and the partition coefficients of a group of 18 compounds with molecular weights ranging from 104 to 580 000 were established. As

[1]*This work will be incorporated into a thesis to be submitted to McGill University in partial fulfillment for the requirements of the Ph.D. degree.*

will be illustrated for two gels, the partition coefficients (in the range of 0.1 to 0.6) were shown to be directly proportional to the logarithms of the molecular weights of the solutes.

MATERIALS AND METHODS

Acrylamide, N,N′-methylene bisacrylamide, ammonium persulfate, and β-dimethylaminopropionitrile were generously supplied by Cyanamid Co. of Canada Ltd. Chlorogenic acid and caffeic acid were purchased from Aldrich Chemical Co. Inc., Milwaukee, Wisconsin. Histamine, 5-hydroxyindole-3-acetic acid and sodium chloride were Fisher Scientific Co. (Montreal) reagent grade chemicals. Bovine gamma globulin and lysozyme were purchased from Pentex Inc., Kankakee, Illinois. Bovine fibrinogen, bovine haemoglobin, bovine serum albumin, pepsin, ovomucoid, trypsin, and ribonuclease were purchased from Nutritional Biochemicals Corp., Cleveland, Ohio. Conjugates of bovine serum albumin with chlorogenic acid,[2] caffeic acid,[2] 5-hydroxyindole-3-acetic acid[3], and histamine[3] were prepared in this laboratory.

(i) Preparation of Polymers

Sixteen different cross-linked polymers were prepared by varying the relative and absolute concentrations of acrylamide and N,N′-methylene bisacrylamide. For the sake of brevity, the different polymers will be identified by a code consisting of two numbers; the first number denotes the number of grams of acrylamide in 100 ml of the reacting solution and the second number denotes the number of grams of the cross-linking agent, N,N′-methylene bisacrylamide, used with every 100 g of acrylamide. Below is given a detailed description of the preparation of polymer "5-5".

Acrylamide (25.0 g) and N,N′-methylene bisacrylamide (1.25 g) were dissolved at room temperature in boiled distilled water. The solution was filtered, diluted to 500 ml with boiled distilled water, and deareated by a water pump for approximately 5 min, and then β-dimethylaminopropionitrile (0.5 ml) and ammonium persulfate (0.5 g) were cautiously added with gentle stirring. The reaction vessel was then placed into a thermostated water bath at 50 °C. Polymerization started in a few minutes and was practically complete in 2 h. The gel formed was cut into small pieces and washed exhaustively with distilled water to remove any unreacted monomers. It was then freeze dried, pulverized in a mortar, and separated into batches of uniform granular size by passage through a series of standard sieves. The fraction of 100 to 200 mesh was used for packing the chromatography columns.

(ii) Determination of Water Regain Values

A method similar to that of Pepper *et al.* was used (13). The polymer granules were allowed to swell in water for at least 24 h. About 15 ml of the gel was then transferred into a weighed Lusteroid tube (100 × 16 mm), the bottom of which was perforated and covered with glass wool. The tube was suspended inside a glass centrifuge tube (120 × 35 mm), which was provided with a constriction (at about 30 mm from the bottom) so that the lower part acted as a reservoir for the filtered liquid. The water in the interstitial space of the gel was removed by centrifugation at 300 – 1 000 g for about 20 min at 5 °C. The Lusteroid tube containing the gel was weighed and then dried to constant weight in a vacuum desiccator at room temperature. From the difference of the two weights,[4] the water regain (denoted as W_r) was calculated as grams of water imbibed per gram of dry gel.

(iii) Chromatography and Analyses

Packing of the columns and sample application were performed according to the method described by Flodin (14). Usually a column of 425 × 25 mm was used and the eluant was 0.9% saline (w/v). In general, 1 ml samples, consisting of artificial mixtures of 2–4 components of the substances listed in Table I, were applied. Experiments were usually performed at 5 °C in a cold room.

Effluent fractions of 3 or 5 ml were collected with an LKB Radi Rac fraction collector[5] and their optical densities recorded with an LKB Uvicord Spectrophotometer[5] or with a Beckman DU Spectrophotometer. In addition, bovine gamma globulin, bovine serum albumin, and lysozyme were qualitatively identified by the "ring" test with the appropriate homologous rabbit antisera, by paper electrophoresis, and by sedimentation velocity experiments. The identities of haemoglobin and of the various protein–hapten conjugates were established by comparing their spectra over the range of 200–600 mμ with those of the pure compounds. The concentrations of these substances were determined spectrophotometrically at 490 and 280 mμ, respectively. Trypsin, ovomucoid, and pepsin were identified by their mobility on paper electrophoresis. Chlorogenic acid, caffeic acid, 5-hydroxyindole-3-acetic acid, histamine, and tryptophane were measured spectrophotometrically at 280 mμ and compared with the spectra of the pure compounds in the ultraviolet spectral region.

The peak volume, V_e, of each compound was estimated to the nearest ml from the recordings of the Uvicord. The void volume for a given gel, V_0, was determined by the elution of a sample of dilute India ink.

The imbibed volume of a given column, V_i, was calculated by multiplying the number of grams of the gel used for packing (denoted by a) by the water regain of that particular gel, i.e. $V_i = aW_r$. For calibration purposes, the elution volume of each compound was established by passing the compound on its own through the chromatographic column. The partition coefficients of the various compounds eluted were calculated for each gel using the expression (15)

$$K_d = \frac{V_e - V_0}{V_i} = \frac{V_e - V_0}{aW_r}.$$

RESULTS AND DISCUSSION

The rigidity of the gels was found to increase with increasing concentrations of both mono- and di-vinyl monomers used in the copolymerization process and to depend particularly markedly on the degree of cross-linking. In experiments with the relatively more rigid gels (20-20, 20-15, 20-10, 20-5, 15-20, 15-15, 15-10, 15-5, 10-20, 10-15, and 10-10), flow rates were regulated to ca. 20 ml/h by adjusting the hydrostatic head or with the use of an adjustable screw clamp at the outlet of the column. In the case of the softer gels (10-5, 5-20, 5-15, 5-10, and 5-5), only much slower flow rates of the order of 2–7 ml/h could be obtained and often the columns were clogged and needed repacking. Uniformity of the size and shape of the granules is another important factor controlling flow rates and affecting the void volume of a given gel; it is obvious that for a better characterization of the gels, it would be advantageous to use granules prepared by the bead-polymerization procedure.[6]

The water regain may be taken as a good indication of the degree of porosity of a gel. In Fig. 1 are given the water regain values of 16 gels prepared at different concentrations of monomers. It is evident that the amount of water accommodated within the gels depends on the concentration of both mono- and di-vinyl monomers; it increases with the decreasing concentrations of reagents, this effect being enhanced by a decrease of the concentration of the cross-linking divinyl monomer at a constant concentration of

[6]*During preparation of this paper, the availability of different grades of bead-polymerized polyacrylamide gels was announced by Calbiochem., Los Angeles, California.*

acrylamide. As would be expected, these results demonstrate that on decreasing the ratio of methylene bisacrylamide to acrylamide, the resulting three-dimensional network becomes more loosely bound and more easily accessible to water clusters. One arrives at a similar conclusion from a consideration of the peak elution volumes for compounds of different molecular weights (see Table I). Thus, from the partition coefficients (K_d) for gels 15-15, 5-20, and 5-5 listed in Table I, for a series of compounds of molecular weights varying from 104 to 580 000, it can be inferred that the more cross-linked gel 5-20 is less easily permeable than gel 5-5 to all solutes except those that show adsorption properties to the gel bed, i.e. lysozyme and tryptophane.

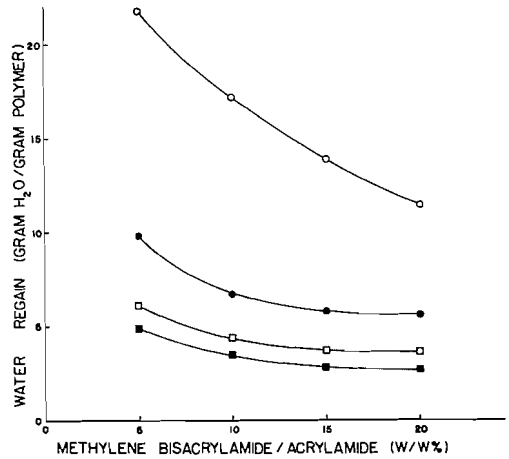

FIG. 1. Water regain values of polyacrylamide gels as a function of acrylamide concentration (○ 5%, ● 10%, □ 15%, ■ 20%) and of the relative concentrations of methylene bisacrylamide and acrylamide.

Although the values of the partition coefficients of many solutes listed in Table I are distinctly different, in practice, perfect separation could not be accomplished unless the partition coefficients of the two solutes differed by 0.3 or more. The reason is that the solutes were eluted in rather diffuse peaks, often spreading through 20–70 ml, increasing with increasing elution volume. A possible remedy for this situation is to employ an upward elution technique which may provide sharper elution zones. To illustrate the degree of separation, a chromatogram of the fractionation of bovine gamma globulin, bovine haemoglobin, ovomucoid, and tryptophane with a 5-5 column is shown in Fig. 2. As can be seen from Table I and Fig. 2, these gels were found useful for the separation of protein–hapten conjugates from the haptens themselves (e.g. BSA – chlorogenic acid conjugate from chlorogenic acid with a 15-15 column) and of high molecular weight proteins from smaller ones (e.g. bovine gamma globulin from lysozyme with a 15-15 column and bovine gamma globulin from ovomucoid, trypsin, or lysozyme with a 5-5 column). According to experimental data, the recovery in all cases is almost 100%. If a low yield of a pure component can be tolerated, even compounds of close molecular weights (e.g. bovine gamma globulin and bovine serum albumin, or bovine gamma globulin and bovine haemoglobin) can be separated with one or two repeated runs, each time recovering only the peak eluate.

The peak volumes in Table I were obtained from single component runs. In a multi-component system, interaction of the solutes may alter the degree of separation and the elution volume, which would be reflected in a change in the partition coefficients. However,

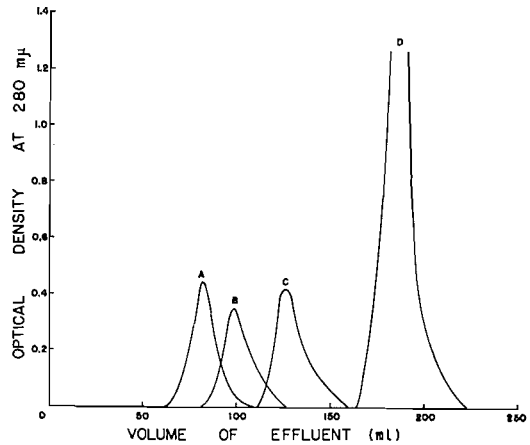

FIG. 2. Fractionation of bovine gamma globulin (A) mol. wt. 150 000, bovine haemoglobin (B) mol. wt. 68 000, ovomucoid (C) mol. wt. 29 000, and tryptophane (D) mol. wt. 203; with a 25 × 425 mm column of gel 5-5 and 0.9% saline (w/v) as eluant.

for the systems used, interaction between solutes was not too serious and peak volumes in single and multiple component runs were quite close (±3 ml) and reproducible. In Figs. 3 and 4 are given the chromatograms for the separation of bovine serum albumin from lysozyme and from ribonuclease, respectively and for the pure components.

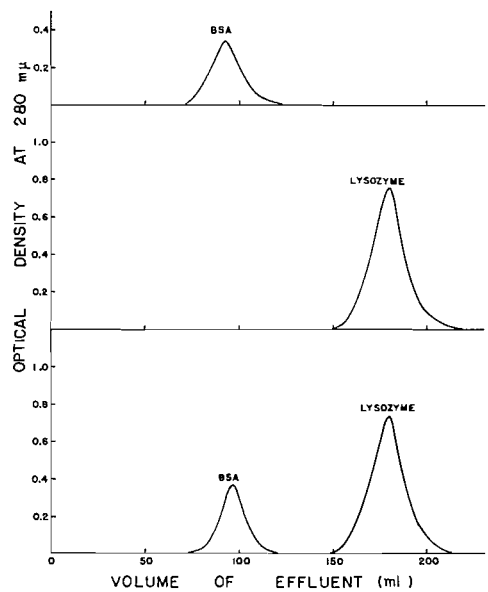

FIG. 3. Chromatograms of single and multiple component runs of bovine serum albumin and lysozyme through a 25 × 425 mm column of gel 15-15 using 0.9% saline (w/v) as eluant.

It should be noted that the gel was under different stress in experiments designed to determine the water regain and during chromatography. In the former case, it was under a strong centrifugal force, whereas in the latter it was only subjected to 1 or 2 ft of hydrostatic pressure, the effect of which is conceivably much smaller. The calculated imbibed

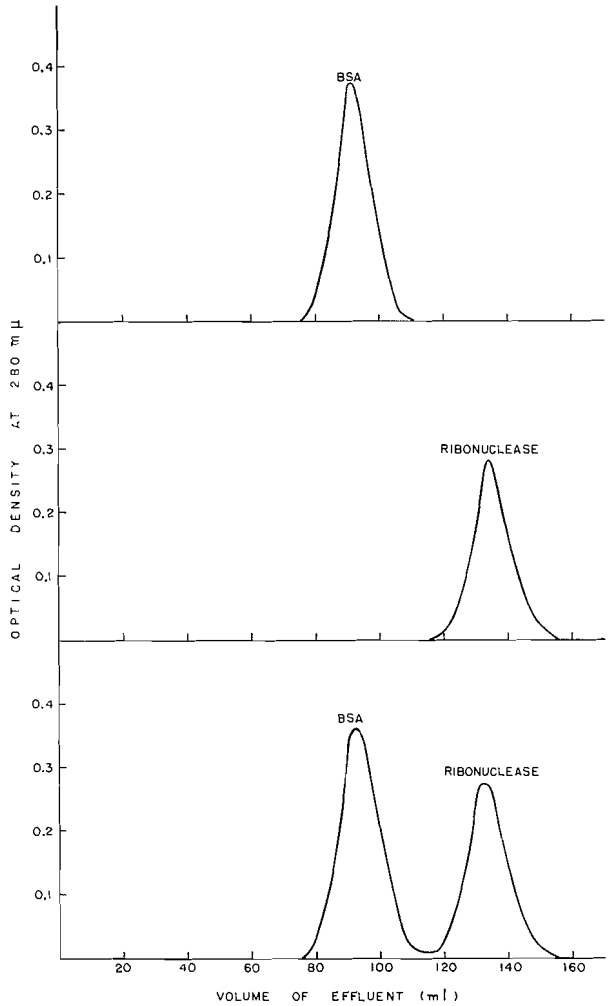

FIG. 4. Chromatogram of single and multiple component runs of bovine serum albumin and ribonuclease through a 25 × 425 mm column of gel 15-15 using 0.9% saline as eluant.

volumes can, therefore, be slightly lower and the calculated partition coefficients consequently slightly higher than the real values, but probably by a constant factor and hence still correct on a relative scale. An additional error may have been introduced by neglecting the effect of ionic strength on the water regain values. In retrospect, it would seem advisable to establish the water regain for a given gel with each eluant.

From the plot of the partition coefficients of eight proteins (bovine gamma globulin, bovine serum albumin, bovine haemoglobin, pepsin, ovomucoid, trypsin, lysozyme, and ribonuclease) in gel 5-20 and gel 5-5 versus the corresponding logarithms of molecular weights (Fig. 5), it is evident that a simple linear relationship exists between these two parameters. A similar relationship was observed with Sephadex (16) and agar gels (17). Further, as can be seen in Fig. 5, bovine haemoglobin and lysozyme have much bigger K_d values than those expected from their molecular weights. These discrepancies may be due to the molecular weight dependence of haemoglobin on concentration (17, 18) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

on the known adsorptive properties of lysozyme on polyacrylamide (12) and other columns. Also in Fig. 5, one can see that the K_d value of bovine gamma globulin is slightly larger for gel 5-20 than for gel 5-5. However, this difference of 0.014 would correspond to an error of approximately 1 ml in the elution volume and this is considered to be within the limit of accuracy obtainable with the present method.

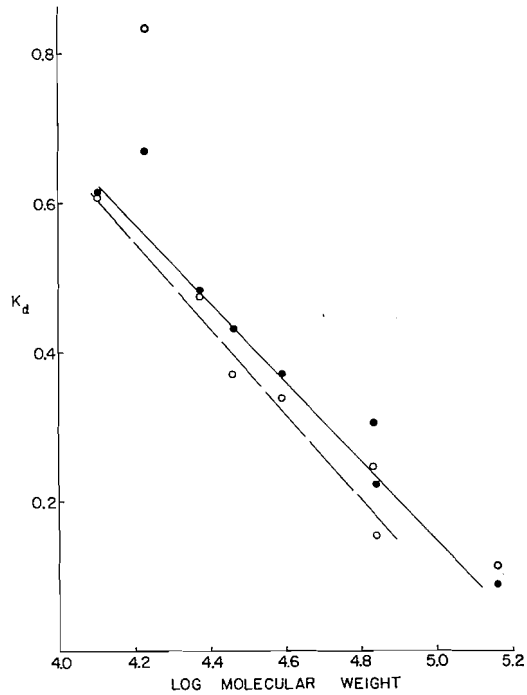

FIG. 5. Plot of the partition coefficients of the solutes versus the logarithms of their molecular weights in gels (●) 5-5 and (○) 5-20.

The relationship between the partition coefficients and molecular weights outside the K_d range of 0.1 to 0.6 are not shown. In the case when $K_d < 0.1$, the molecules are only partially admitted or completely excluded by the gel matrix. When $K_d > 0.6$, the molecules are so small that their molecular dimensions are not appreciably different to be separated by the molecular sieve mechanism alone. The fact that some of the K_d values exceed 1.0 clearly indicates that other mechanisms, e.g. adsorption, are also present. The small molecules used all contained an aromatic ring and it was shown that such substances exhibit adsorptive properties to beds of Sephadex (19). Perhaps this is also the case with polyacrylamide gel.

Although the various commercially available Sephadex grades have proved to be very useful in the fractionation of biopolymers, polyacrylamide gels seem to offer some advantages which make them worthy of further consideration: 1, the starting materials are cheaper and more readily available; 2, the lack of ionizable groups in the polymer chain minimizes possible complications due to adsorption and ion-exchange properties; 3, the stability of this gel network in the presence of acids is expected to be higher than that of the dextrans since the former contains only carbon–carbon bonds and no glycosidic linkages as in the case of the latter (15); 4, the similarity in chemical structure between

For personal use only.

acrylamide and N,N′-methylene bisacrylamide and the well-defined nature of these monomers make these gels more amenable to a systematic study of their physical properties.

SYNTHESIS OF 4-ACETAMIDO-4-DEOXY-SUGARS

A. J. DICK[1] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario
Received October 26, 1964

ABSTRACT

The tri-*O*-methanesulfonate derivative (I) of methyl α-D-xylopyranoside has been prepared. This compound when heated with sodium azide in *N*,*N*-dimethylformamide yielded a 4-azido derivative with inversion at C_4. It (I) was thus converted to a methyl 4-azido-4-deoxy-β-L-arabinopyranoside (II) and thence by removal of methanesulfonate residues to a 2,3-anhydro-L-ribopyranoside derivative and further to methyl 4-amino-4-deoxy-β-L-xylopyranoside (V); 4-acetamido-4-deoxy-1,2;3,5-di-*O*-isopropylidene-L-xylose (IX), a sugar with nitrogen in the ring, was prepared from 4-acetamido-4-deoxy-L-xylose. Acetolysis of methyl 4-acetamido-4-deoxy-L-xylopyranoside yielded a pentacetate of unknown ring size (X or XI).

The synthesis of sugar derivatives containing nitrogen as the hetero atom in pyranose rings has been a subject of recent investigation (1). The first synthesis of a sugar derivative with nitrogen as the hetero atom in a five-membered ring, methyl 4-acetamido-4-deoxy-L-erythrofuranoside, was also achieved recently (2). These syntheses all involve replacement of the ring oxygen atom of sugars by the nitrogen atom of an *N*-acetyl group on a primary carbon atom.

The synthesis of derivatives of 4-amino-sugars with the nitrogen function on a secondary carbon atom is of interest in order to investigate the possible formation of a five-membered furanose ring containing nitrogen as the hetero atom. Methyl 4-amino-4-deoxy-α-D-glucopyranoside has been synthesized (3) via an S_N2 displacement of the 4-*O*-methanesulfonyl group of methyl 2,3,6-tri-*O*-benzoyl-4-*O*-methanesulfonyl-α-D-galactopyranoside by azide. Overend *et al.* (4) have synthesized methyl 4-amino-4-deoxy-α-D-lyxoside by the preferential cleavage of the epoxide ring of methyl 3,4-anhydro-β-L-riboside by ammonia.

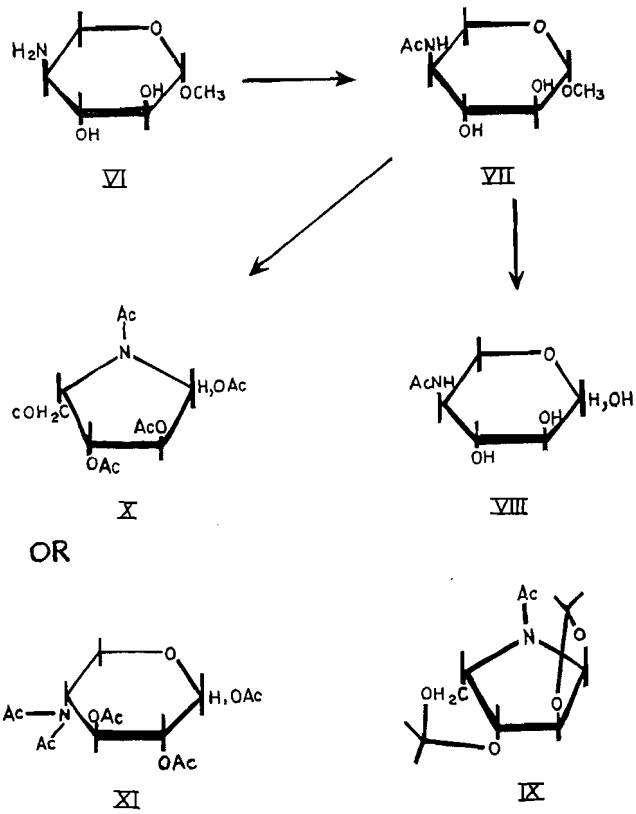
The present communication reports a facile route to the synthesis of derivatives of 4-amino-4-deoxy-pentoses (5). The reaction of sodium azide with the 2,3,4-tri-*O*-methylsulfonyl derivative of methyl α-(I)D-xylopyranoside in dimethylformamide solution gave an azido-deoxy-di-*O*-methylsulfonyl derivative. The azide ion is considered to attack selectively at C-4 in an S_N2 displacement reaction to yield, methyl 2,3-di-*O*-methylsulfonyl-4-azido-4-deoxy-β-L-arabinopyranoside (II). Goodman *et al.* (6) have observed the selective replacement of the 4-*p*-tolysulfonyl group of methyl 2-*O*-benzoyl-3,4-di-*O*-*p*-tolysulfonyl-β-L-arabinopyranoside by azide which led to the synthesis of 4-acetamido-4-deoxy-D-ribose. An analogous situation exists for the reaction of the chlorosulfate ester derivatives of methyl α-D-glucopyranoside, methyl β-D-glucopyranoside, methyl α-D-galactopyranoside, and methyl β-D-galactopyranoside with pyridine hydrochloride. With an excess of pyridine hydrochloride, Jennings and Jones (7) have obtained 4,6-dichloro-dideoxy-substituted derivatives, with inversion of configuration occurring at C-4, in each of these cases, except with methyl 2,3,4,6-tetra-*O*-chlorosulfonyl-β-D-galactopyranoside, which gave a 3,4,6-trichloro-substituted compound as well as other products. It may be noted that reaction of methyl 2,3,4,6-tetra-*O*-methylsulfonyl-α-D-glucopyranoside (V) with an excess of sodium azide in *N*,*N*-dimethylformamide has been shown (8) to give a di-azido-deoxy derivative which is methyl 2,3-di-*O*-methylsulfonyl-4,6-di-azido-4,6-dideoxy-α-D-galactopyranoside.

Reduction of methyl 2,3-di-*O*-methylsulfonyl-4-azido-4-deoxy-β-L-arabinopyranoside (II) with Raney nickel in methanol followed by *N*-acetylation with acetic anhydride in *tert*-butyl alcohol – water gave methyl 2,3-di-*O*-methylsulfonyl-4-acetamido-4-deoxy-β-L-arabinopyranoside (III).

Reaction of methyl 2,3-di-*O*-methylsulfonyl-4-azido-4-deoxy-β-L-arabinopyranoside (II) with methanolic potassium hydroxide gave the 2,3-anhydro derivative (IV). Sorkin and Reichstein (9) report that the reaction of methyl 2,3-di-*O*-*p*-tolysulfonyl-4,6-*O*-benzylidene-α-D-galactopyranoside with sodium methoxide in methanol yields methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-gulopyranoside. By analogy, the anhydro sugar, (XII), is probably methyl 2,3-anhydro-4-azido-4-deoxy-β-L-lyxopyranoside* and (IV) not the corresponding ribopyranoside. Cleavage of this epoxide with aqueous potassium hydroxide gave a mixture containing predominantly methyl 4-azido-4-deoxy-β-L-xylopyranoside (V) with a low positive optical rotation, and in smaller yield methyl 4-azido-4-deoxy-β-L-arabinopyranoside (XII) with a high optical rotation. The mixture could be separated by fractional crystallization from chloroform–petrol.

Reduction of methyl 4-azido-4-deoxy-β-L-xylopyranoside (V) gave methyl 4-amino-4-deoxy-β-L-xylopyranoside (VI), isolated as the crystalline hydrochloride salt, which consumed 2 moles of periodate and liberated 1 mole of formic acid in unbuffered periodate. *N*-Acetylation of VI gave methyl 4-acetamido-4-deoxy-β-L-xylopyranoside (VII) which consumed 1 mole of periodate per mole. Hydrolysis of VII with Amberlite IR 120 cation

**Nuclear magnetic resonance studies and further chemical work have now shown XII to be the* L-*ribopyranoside derivative. Details will be given in a later publication.*



exchange resin (H^+ form) yielded a clear colorless syrup which was strongly reducing to Fehling's solution and which gave absorptions in the infrared corresponding to *OH*, *N—H*, and *N—Ac*. Paper chromatography of the syrup and the purified crystalline material showed only one component. The compound, on periodate oxidation in unbuffered aqueous solution consumed 2 moles of periodate and liberated 1 mole of formic acid; no overoxidation occurred and no formaldehyde was produced. Had the *N*-acetyl group been on C_2, overoxidation would have occurred. These results are consistent with the structure proposed for 4-acetamido-4-deoxy-L-xylopyranose and indicate that the six-membered oxygen ring is the highly favored ring form for the free sugar. The isopropylidene derivative of VIII was a colorless syrup, which crystallized after vacuum distillation. Its infrared spectrum showed absorptions corresponding to *N*—Ac and the isopropylidene group but no absorption attributable to *—OH* or *—NH*. The elemental analysis supports these results and is consistent with the structure 1,2;3,5-di-*O*-isopropylidine-4-acetamido-α-L-xylofuranose (IX). Molecular models indicate that a pyranose type structure is most unlikely.

Acetolysis of methyl 4-acetamido-4-deoxy-β-L-xylopyranoside (VII), gave a syrupy acetate which showed absorptions in the infrared corresponding to *—O—*Ac and *N—*Ac, but no absorption attributable to *—NH*. This compound is thus either 1,2,3,5-tetra-*O*-acetyl-4-acetamido-4-deoxy-L-xylofuranose (X) or 1,2,3-tri-*O*-acetyl-4-diacetamido-4-deoxy-L-xylopyranose (XI). Acetolysis of methyl 4-acetamido-4-deoxy-α-D-ribopyranoside was claimed to give 1,2,3,4-tetra-*O*-acetyl-4-acetamido-4-deoxy-D-ribofuranose (6) but no proof was given.

The investigation of the other monoazido-di-*O*-methylsulfonyl derivatives is being continued.

EXPERIMENTAL

Solutions were concentrated under reduced pressure below 40° with a rotating vacuum-type evaporator. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Optical rotations were measured at 23 ± 3° with a Hilger Standard Polarimeter. Infrared spectra were measured with a Perkin–Elmer Model 21 spectrophotometer. Paper chromatography was carried out by the descending method at room temperature on Whatman No. 1 filter paper for qualitative purposes or on Whatman 3MM filter paper for preparative purposes in butan-1-ol : ethanol : water, 3:1:1. Sugars were detected on paper chromatograms by the following spray reagents: (i) alkaline silver nitrate (10); (ii) *p*-anisidine hydrochloride (11); (iii) sodium metaperiodate – potassium permanganate (12); (iv) sodium iodide and methyl red (epoxide spray (13)). Rates of movement of the sugars on paper chromatograms are given relative to that of rhamnose (R_{rh}).

Methyl 2,3,4-Tri-O-methylsulfonyl-α-D-xylopyranoside (I)

D-Xylose (technical) (100 g) was treated with methanolic hydrogen chloride according to the method of Hudson (14) and yielded crystalline methyl β-D-xylopyranoside (23 g). The residual syrups (75 g), $[\alpha]_D = +98°$ (*c*, 6.60 in water) containing approximately 50 g methyl α-D-xylopyranoside (calculated from the specific rotation) was dried thoroughly, dissolved in dry pyridine (400 ml), and treated with methanesulfonyl chloride (180 g) in the usual manner. The syrupy product was dissolved in hot ethyl acetate and the solution allowed to cool. Methyl 2,3,4-tri-*O*-methylsulfonyl-α-D-xylopyranoside crystallized slowly from this solution; 60 g were obtained from several crops. Three crystallizations from ethyl acetate gave colorless plates which melted at 130.5–131.5° and had $[\alpha]_D = +80°$ (*c*, 2.54 in chloroform).

Anal. Calcd. for $C_9H_{18}O_{11}S_3$: C, 27.1; H, 4.5; S, 24.1. Found: C, 27.0; H, 4.3; S, 24.3.

Reaction of Methanesulfonyl Derivatives with Sodium Azide

(*a*) Methyl 2,3,4-tri-*O*-methylsulfonyl-α-D-xylopyranoside (I) (12.0 g) was dissolved in *N*,*N*-dimethylformamide (150 ml) and a solution of sodium azide (2.35 g, 1.2 mole) and urea (0.4 g) in water (15 ml) was added. This solution was heated at 115° under a stream of nitrogen for 36 h. The black reaction mixture, containing precipitated sodium methanesulfonate, was cooled and poured into ice water (200 ml). The crystalline precipitate which formed was filtered off and the filtrate partitioned between chloroform and water. The chloroform layer was dried (Na_2SO_4), decolorized with charcoal, and filtered, and the filtrate evaporated to dryness. The residue crystallized on standing and was recrystallized from methanol to give methyl 2,3-di-*O*-methylsulfonyl-4-azido-4-deoxy-β-L-arabinopyranoside (II) as large, colorless needles (9.6 g, 92%) which melted at 128–128.5° and had $[\alpha]_D = +140°$ (*c*, 1.96 in chloroform).

Anal. Calcd. for $C_8H_{15}N_3O_8S_2$: C, 27.8; H, 4.35; N, 12.2; S, 18.5. Found: C, 27.6; H, 4.2; N, 12.2; S, 18.8.

When this reaction was carried out with I (4.0 g) dissolved in *N*,*N*-dimethylformamide (100 ml) containing excess sodium azide (2.3 g, 3.5 mole) and urea (0.15 g) in water (5 ml), under the same conditions as described above, the monoazido-deoxy-derivative (II) was again isolated in 50% yield. No other products were isolable.

The infrared spectrum of II in chloroform showed strong absorption at 2 140 cm^{-1} attributable to azide, and strong absorption at 1 370 cm^{-1} and 1 182 cm^{-1} attributable to sulfonate.

Methyl 2,3-Di-O-methylsulfonyl-4-acetamido-4-deoxy-β-L-arabinopyranoside (III)

Methyl 2,3-di-*O*-methanesulfonyl-4-azido-4-deoxy-β-L-arabinopyranoside (4.0 g) was reduced with Raney nickel in methanol. The Raney nickel was filtered off, the filtrate was evaporated to a pale-yellow syrup which was *N*-acetylated in *tert*-butyl alcohol – water (10.1) solution (100 ml) with acetic anhydride (2.0 ml). Evaporation of the solvent gave a glass which on crystallization from methanol gave XI (3.4 g, 81%) as colorless crystals which melted at 158–159° and had $[\alpha]_D = +117°$ (*c*, 2.06 in methanol). The infrared spectrum in chloroform showed absorption at 3 450 cm^{-1} and 1 513 cm^{-1} attributable to *N*—H, strong absorption at 1 683 cm^{-1} attributable to *N*—Ac, and strong absorption owing to the sulfonate groups.

Anal. Calcd. for $C_{10}H_{19}NO_9S_2$: C, 33.2; H, 5.3; N, 3.9; S, 17.7. Found: C, 33.0; H, 5.0; N, 4.2; S, 18.0.

Reaction of Methyl 2,3-Di-O-methylsulfonyl-4-azido-4-deoxy-β-L-arabinopyranoside (II) with Methanolic Potassium Hydroxide

To a solution of potassium hydroxide (10 g) in methanol–water (4:1) (200 ml) (II) (10.0 g) was added. This mixture was heated to boiling point which caused II to dissolve. The solution was refluxed for 2 h. The dark-brown reaction solution was diluted to 400 ml with water, concentrated to 200 ml, and extracted with ether (200 ml). The ether extract was washed with water, dried (Na_2SO_4), and filtered, and the filtrate was concentrated to a clear syrup (4.5 g) which crystallized on standing. Recrystallization of this material from petrol (35–60°) gave long, fine needles which melted at 54–55° and had $R_{rh} = 2.2$ (spray iv) and $[\alpha]_D = -14°$ (*c*, 1.54 in chloroform). This substance analyzed for the anhydro sugar, methyl 2,3-anhydro-4-azido-4-deoxy-β-L-ribopyranoside.

Anal. Calcd. for $C_6H_9O_3N_3$: C, 42.1; H, 5.3; N, 24.6. Found: C, 41.8; H, 5.5; N, 24.2.

The infrared spectrum in chloroform showed absorption at 2 120 cm^{-1} attributable to the azido groups and absorption at 1 270 cm^{-1} attributable to the epoxide ring.

Reaction of Methyl 2,3-Anhydro-4-azido-4-deoxy-β-L-ribopyranoside with Aqueous Potassium Hydroxide

To an aqueous solution (150 ml) of potassium hydroxide (5 g) IV (4.5 g) was added and the mixture was heated under reflux for 4 h. The dark-brown reaction solution was cooled and de-ionized by passing it through Amberlite IR 120 cation exchange resin (H^+ form). The elute was evaporated to a mobile syrup (3.8 g) which crystallized on standing. This material was dissolved in chloroform, and petrol (b.p. 60–80°) was added to incipient turbidity. Fine needles (0.55 g) were obtained which, after two recrystallizations from chloroform–petrol, melted at 108–108.5° and had R_{rh} = 2.2 (spray iii) and $[\alpha]_D$ = 141° (*c*, 0.56 in chloroform).

Anal. Calcd. for methyl 4-azido-4-deoxy-β-L-arabinopyranoside (XII), $C_6H_{11}O_4N_3$: C, 38.1; H, 5.8; N, 22.2. Found: C, 38.1; H, 6.1; N, 21.9.

The mother liquors were concentrated to a syrup which crystallized on standing. Recrystallization from chloroform–petrol (35–60°) gave fine needles (2.7 g) which melted at 81–83° and had R_{rh} = 1.7 (spray iii) and $[\alpha]_D$ = +31.3° (*c*, 1.64 in chloroform).

Anal. Calcd. for methyl 4-azido-4-deoxy-β-L-xylopyranoside (V), $C_6H_{11}O_4N_3$: C, 38.1; H, 5.8; N, 22.2. Found: C, 38.4; H, 6.0; N, 22.4.

Reduction of Methyl 4-Azido-4-deoxy-β-L-xylopyranoside (V)

The above compound V (1.1 g) was reduced with Raney nickel in methanol to yield a clear colorless syrup (0.84 g). The crystalline hydrochloride salt of VI was prepared by dissolving the crude amino sugar in acetone and adding concentrated hydrochloric acid. The hydrochloride salt was recrystallized from methanol–acetone and melted at 136–137° (decomp.) and had R_{rh} = 0.94 and $[\alpha]_D$ = +53° (*c*, 0.225 in water). Periodate oxidation of VI in unbuffered aqueous solution resulted in the consumption of 2 moles of periodate and the liberation of 1 mole of acid.

Anal. Calcd. for $C_6H_{14}O_4NCl$: C, 36.1; H, 7.0; N, 7.0; Cl, 17.8. Found: C, 36.0; H, 7.0; N, 7.2; Cl, 18.1.

Methyl 4-Acetamido-4-deoxy-β-L-xylopyranoside (VII)

Syrupy 4-amino-4-deoxy-β-L-xylopyranoside (VI, 0.84 g) was dissolved in water (20 ml) and acetic anhydride (2 ml) was added. This mixture was allowed to stand at room temperature with occasional shaking for 20 min. The solution was concentrated to a clear colorless syrup (1.05 g) which crystallized on standing. This material was crystallized from chloroform–petrol (60–80°) to give white needles of VII which melted at 157–158° and had R_{rh} = 1.48 (spray iii) and $[\alpha]_D$ = +52.7° (*c*, 2.22 in methanol). When oxidized in unbuffered aqueous solution, VII consumed 1 mole of periodate.

Anal. Calcd. for $C_8H_{15}O_5N$: C, 46.8; H, 7.3; N, 6.8. Found: C, 46.3; H, 7.7; N, 6.9.

Hydrolysis of Methyl 4-Acetamido-4-deoxy-β-L-xylopyranoside (VII)

Amberlite IR cation exchange resin (H^+ form) (2 g) was added to a solution of VII (0.65 g) in water (50 ml). This mixture was heated at a bath temperature of 90° with stirring for 4 h. The mixture was then cooled, the resin filtered off, and the filtrate concentrated to a colorless syrup (0.48 g) which was strongly reducing to Fehling's solution and which showed one spot on a paper chromatogram at R_{rh} = 0.81 (sprays i, ii, iii). The infrared spectrum (smear on NaCl) showed a broad absorption band at 3 550 – 3 220 cm^{-1} attributable to *OH* and *NH*, absorption at 1 640 cm^{-1} attributable to *N*—Ac, and strong absorption at 1 560 cm^{-1} attributable to *NH*. The syrup was caused to crystallize by treatment with ethyl acetate and was recrystallized from methanol–ether to give 4-acetamido-4-deoxy-L-xylopyranose (VIII), which melted at 157–158° and had $[\alpha]_D$ = −22°, mutarotating to −16° (*c*, 1.00 in water). When oxidized in unbuffered aqueous solution, VIII consumed 2 moles of periodate and liberated 1 mole of acid. No overoxidation occurred and no formaldehyde was produced.

Anal. Calcd. for $C_7H_{13}O_5N$: C, 43.93; H, 6.8; N, 7.3. Found: C, 44.0; H, 7.0; N, 7.2.

1,2;3,5-Di-O-isopropylidene-4-acetamido-4-deoxy-α-L-xylofuranose (IX)

Dry acetone (50 ml), anhydrous $CuSO_4$ (0.5 g), and a drop of concentrated sulfuric acid was added to syrupy VII (0.12 g). The mixture was shaken at room temperature for 40 h and was then filtered, the filtrate was neutralized with barium hydroxide and filtered, and the filtrate was concentrated. The syrupy residue was partitioned between ether and water and the ether layer dried (Na_2SO_4) and filtered, and the filtrate concentrated to a colorless syrup (0.055 g). The syrup was distilled under reduced pressure and the resultant syrup crystallized to give IX, m.p. 66–80°; $[\alpha]_D$ = +131 ± 3° (*c*, 2.30 in chloroform) and R_{rh} = 2.47 (spray ii). The infrared spectrum (smears on NaCl) showed strong absorption at 1 677 cm^{-1} attributable to *N*—Ac and a doublet at 1 392, 1 384 cm^{-1} attributable to the ispropylidene group but no absorption attributable to *OH* or *NH*.

Anal. Calcd. for $C_{13}H_{21}O_5N$: C, 57.6; H, 7.8; N, 5.2. Found: C, 57.8; H, 7.9; N, 5.33.

Acetolysis of Methyl 4-Acetamido-4-deoxy-β-L-xylopyranoside (VII)

The above compound VII (0.18 g) was acetolyzed according to the method of Hudson (14) in 10 ml

acetolysis solution. The reaction was followed polarimetrically and the optical rotation had become constant after 24 h. The solution was then poured into an excess of sodium bicarbonate in water and this solution was extracted with carbon tetrachloride. The carbon tetrachloride extract was washed with water and concentrated to a colorless syrup (0.065 g) which was distilled under vacuum. This material was homogeneous on thin-layer chromatography. The infrared spectrum (smear on NaCl) showed strong absorption at 1 755 cm^{-1} for *O*—Ac and at 1 686 cm^{-1} for *N*—Ac but no absorption owing to *N*—*H*. 1,2,3-Tri-*O*-acetyl-4-diacetamido-4-deoxy-L-xylopyranose (XI) (1,2,3,5-tetra-*O*-acetyl-4-acetamido-4-deoxy-L-xylofuranose (X)) had $[\alpha]_D = -23°$ (*c*, 0.95 in chloroform).

Anal. Calcd. for $C_{16}H_{21}O_9N$: C, 50.1; H, 5.9; N, 3.9; *O*-acetyl, 47.9; total acetyl (*O* + *N*), 59.9. Found: C, 48.8; H, 5.9; N, 4.0; *O*-acetyl, 54.4, 57.2; total acetyl (*O* + *N*), 61.1.

NOTES

THE REACTION OF GALACTOSE WITH HYDRAZINE AT ELEVATED TEMPERATURE[1]

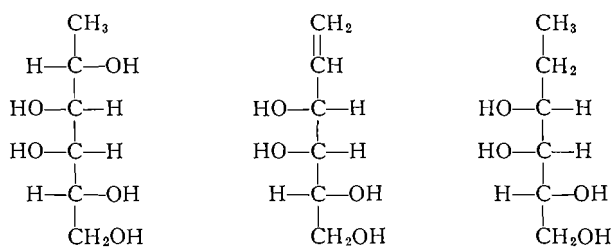
J. K. N. JONES, P. REID,[2] AND J. R. TURVEY[3]

An investigation (1) of the hydrazinolysis of the α_1-acid glycoprotein of human plasma is in progress in this laboratory. We wished to study the effects of hydrazine on the carbohydrate moiety of the glycoprotein and therefore investigated the effect of hydrazine on some model compounds. It has already been shown (1) that the optimum results are obtained with α_1-glycoprotein using a reaction time of 48 h and this time therefore was adopted for the present study of the effect of hydrazine on galactose. Yosizawa and Sato (2) treated reducing sugars in 10% (w/v) solution in anhydrous hydrazine at 100° for 10 h (in sealed tubes). Under these conditions they reported that 20.9% of galactose was destroyed with production of a pentose, a 2,5-anhydro-hexose, and other unidentified products. In contrast, Kaverzneva and Tsi De-Fan (3) concluded that mannose was not decomposed (appreciably) when treated with anhydrous hydrazine for 4 h at 100°. The results obtained by us with D-galactose are reported here.

When a 2% (w/v) solution of galactose in 95+% hydrazine was boiled under reflux for 48 h, the products contained little unchanged galactose. Paper chromatography of the products and use of the silver nitrate spray (4) indicated the presence of three major components and traces of others. One of these major products, compound A, was obtained crystalline from the crude reaction mixture after removal of excess hydrazine. Paper chromatographic separation of the residual syrup yielded the other major products, B and C.

Compound A, which was obtained in 33% yield, was identified as L-fucitol (*syn*-1-deoxy-D-galactitol) on the basis of its optical rotation, and that of the derived pentabenzoate and on the basis of the melting point and mixed melting point with authentic specimens of the alcohol and its pentabenzoate.

Compound B was obtained as a syrup contaminated with traces of a pentose and compound C. It was chromatographically identical with 3,4,5,6-tetrahydroxy-L-*lyxo*-hex-1-ene, prepared by the acid hydrolysis and subsequent reduction with sodium borohydride of methyl 5,6-didehydroxy-α-L-*arabino*-hexoside (5). Ozonolysis of compound B yielded D-lyxose, whereas ozonolysis of the synthetic tetrahydroxy-L-*lyxo*-hex-1-ene yielded L-lyxose. Compound B is thus probably 3,4,5,6-tetrahydroxy-D-*lyxo*-hex-1-ene.



Compound A Compound B Compound C

[1]*Part of a paper presented at the Meeting of the American Chemical Society, Philadelphia, 1964.*
[2]*Present address: Chemistry Department, University of British Columbia, Vancouver 8, British Columbia.*
[3]*Present address: Chemistry Department, University College of North Wales, Bangor, Wales.*

Catalytic hydrogenation of 3,4,5,6-tetrahydroxy-L-*lyxo*-hex-1-ene and of compound B gave products which were chromatographically identical with compound C. This is, therefore, tentatively identified as 1,2-dideoxy-D-*lyxo*-hexose (*syn* 5,6-dideoxy-D-*arabino*-hexose).

The reaction of hydrazine with galactose to give these three products is complex. Initial hydrazone formation and subsequent Wolff–Kishner reduction of the hydrazone under the slightly basic conditions of the reaction would account for compound A. Similarly, compound C could arise from a reduction of the osazone but compound B must arise from an elimination reaction, the mechanism of which is obscure.

EXPERIMENTAL

For paper chromatography the solvent systems were (*a*) 1-butanol, ethanol, water (3:1:1, v/v), (*b*) ethyl acetate, acetic acid, water (6:3:2, v/v). Rates of migration on paper chromatograms are quoted relative to the rate of movements of the solvent front (R_F), to that of fucose (R_{Fucose}), and to that of galactose (R_{Gal}). All solutions were concentrated under diminished pressure.

Optical rotations were measured at 20 ± 2° in water unless otherwise stated.

Hydrazinolysis of Galactose

D-Galactose (2.057 g) in 95+% hydrazine (Eastman; 100 ml) was boiled under reflux for 48 h using a "Drierite" guard tube. Excess of hydrazine was removed by distillation and the last traces removed by drying *in vacuo* over concentrated sulfuric acid. Chromatographic examination of the residual syrup in solvent (*a*) (silver nitrate spray) indicated the presence of three major components with R_{Gal} values of 2.62, 3.82, and 4.6, together with minor components, R_{Gal} 4.73, and a component streaking behind R_{Gal} 2.62. The *p*-anisidine hydrochloride spray reagent (6) showed only traces of material resembling a pentose.

Isolation and Characterization of Compound A

The hydrazine-free syrup crystallized on being moistened with methanol and cooled. The crystals were filtered, washed with methanol at −15°, and dried (0.559 g), m.p. 153–156°. After two recrystallizations from methanol and one from acetone the melting point was 155–157°, mixed melting point with authentic L-fucitol 156–157; $[\alpha]_D$ +185° (*c*, 0.216 in a 4:1 (v/v) mixture of 5% ammonium molybdate and 1 *N* sulfuric acid). Richtmyer and Hudson (7) give $[\alpha]_D$ +196 for this compound and $[\alpha]_D$ −195° for D-fucitol in acidified ammonium molybdate solution. The benzoate of compound A was prepared and, after recrystallization had m.p. 150–151°; mixed melting point with authentic L-fucitol benzoate (m.p. 148–150°) was 148–150°; $[\alpha]_D$ −4.1 (*c*, 4.42 in chloroform); lit. values (8), m.p. 149–150°; $[\alpha]_D$ −5.96° (in chloroform).

Anal. Calcd. for $C_{41}H_{34}O_{10}$: C, 71.7; H, 4.95; molecular weight, 686. Found: C, 71.68, 71.49; H, 5.12, 5.2; molecular weight, 657 (determined on a 0.5% solution in chloroform using a Mechtrolab osmometer).

Isolation and Characterization of Compounds B and C

The syrup (0.96 g) remaining after crystallization of compound A was separated on sheets of Whatman 3 MM paper using multiple development in solvent (*b*). The compounds were located by spraying guide strips with the silver nitrate spray (4) and three compounds recovered by extraction of the appropriate zones with water. Compound A (0.12 g) yielded a benzoate with melting point and mixed melting point with authentic L-fucitol benzoate of 147–149°.

Compound B (0.193 g) was a syrup with R_F 0.50, R_{Fucose} 1.82 in solvent (*a*) and was contaminated with traces of a pentose and compound C. It reduced neutral permanganate solution and decolorized bromine water. Subsequently, it was shown to be chromatographically indistinguishable from 3,4,5,6-tetrahydroxy-L-*lyxo*-hex-1-ene, in the two solvent systems.

Compound C (0.293 g) was a syrup with R_F 0.57, R_{Fucose} 2.08 in solvent (*a*). It had $[\alpha]_D$ +2.6°. It was chromatographically indistinguishable from the products obtained by catalytic reduction of compound B and of 3,4,5,6-tetrahydroxy-L-*lyxo*-hex-1-ene in the two solvent systems.

Synthesis of 3,4,5,6-Tetrahydroxy-L-lyxo-hex-1-ene

Methyl 5,6-didehydroxy-α-L-*arabino*-hexoside (0.8 g), prepared by the method of Ball, Flood, and Jones (5), was hydrolyzed with *N* sulfuric acid at 100° for 1 h. The solution was cooled, neutralized with barium hydroxide, filtered, and then concentrated to 10 ml. Sodium borohydride (1 g) was then added and the solution left for 16 h. Acetic acid was added to pH 6 and the solution passed through a column of Amberlite IR 120 (H^+ form). After concentration of the eluate to dryness, boric acid was removed as methyl borate by distilling off portions (10 ml) of methanol. The product was then purified by chromatography on sheets of Whatman 3 MM paper as described previously (yield, 0.18 g).

Ozonolysis of 3,4,5,6-Tetrahydroxy-L-lyxo-hex-1-ene

The above compound (0.15 g) in methanol (25 ml) was ozonolyzed for 15 min with external cooling. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solution was then boiled under reflux for a few minutes with zinc powder and filtered, and the filtrate concentrated to a syrup. Chromatographic examination in solvents (*a*) and (*b*) indicated that the main product was lyxose. This product was separated from impurities by chromatography on filter paper as described above and yielded syrupy L-lyxose, $[\alpha]_D$ +7.0°. The *p*-tolylsulfonylhydrazone derivative had m.p. 141–142° (lit. 141° (9)).

Ozonolysis of Compound B

Compound B (0.15 g) was ozonolyzed and the product separated as described above to yield D-lyxose (89 mg), $(\alpha)_D$ −10.0°. The *p*-tolylsulfonylhydrazine derivative had m.p. 141–142°, mixed melting point with the *p*-tolylsulfonylhydrazine derivative of authentic D-lyxose (m.p. 142–143°) 142–143°.

Reduction of 3,4,5,6-Tetrahydroxy-L-lyxo-hex-1-ene

This compound (0.405 g) in ethanol (100 ml) was reduced with hydrogen (5 atm) over 5% palladium on charcoal for 10 h. After being filtered, the solution was evaporated to a syrup (0.400 g). Paper chromatography showed the absence of starting material and production of a compound identical in R_F value with compound C.

Reduction of Compound B

Compound B (5 mg) was reduced as above to give a compound identical in chromatographic mobility with compound C.

For personal use only.

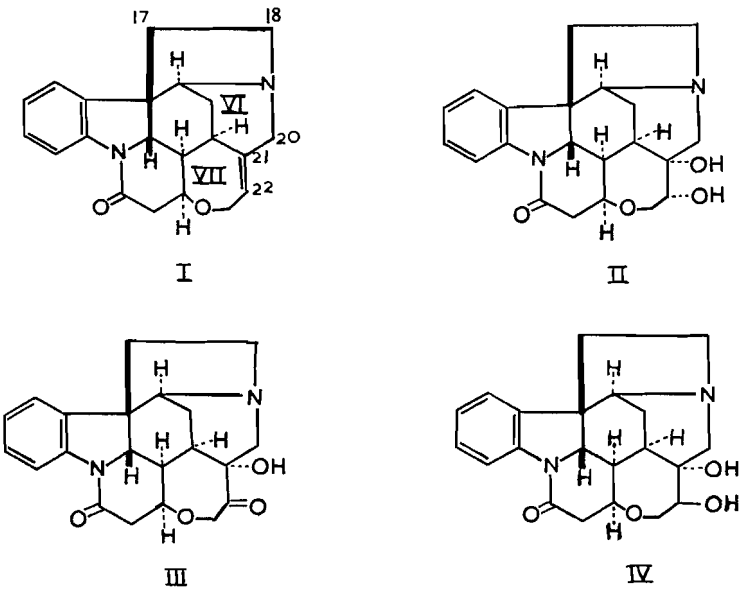
of a dihydroxystrychnine by catalytic hydrogenation of the ketol III, which had been obtained from I by oxidation with weakly acidic permanganate. Prelog, apparently on the basis of the similarity in melting points, concluded that his dihydroxy compound was identical with Kotake's, and thus had structure II. This assignment is generally accepted (6).



I II III IV

Consideration of models shows that the structure of Prelog's product depends on the conformation of ring VII in the ketol III. If this ring exists in a boat conformation (similar to the one which it is forced to adopt by the double bond in I), the hydrogen would be delivered from the convex face of the molecule, and the reduction product would have structure IV. If ring VII in III is a chair, the carbonyl group is turned in such a way that the delivery of hydrogen should lead to structure II. It is difficult to decide from models which of the conformations is favored. In the boat one, ring VI also exists as a boat and there is an interaction between the carbonyl group and two of the hydrogens on C_{17} and C_{18}; if ring VII exists in a chair conformation, ring VI is a chair and the main interactions would involve a hydrogen attached at C_{20}. Probably the chair conformation is the more stable one.

In the present work (started in connection with another problem) we prepared III (5). The spectra of this compound are in accord with the structure previously assigned. Catalytic reduction of III gave after crystallization of the crude product a compound which from physical properties and the tenacious way it held solvent was clearly the same as Prelog's material. This compound was (as Prelog had suggested (5)) identical with II prepared directly from I (4). In the later crops from the crystallizations of the hydrogenation product, we obtained a second material. A study of the mass spectra of II and the new compound shows that they are isomers, probably stereoisomers. On the basis of spectra and analysis, the new compound is assigned structure IV, and is therefore the previously unknown *trans* dihydroxy compound. These results indicate that ring VII in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

III exists in both of the possible conformations; the relative yields of II and IV suggest that the chair conformation is favored.

EXPERIMENTAL

21-Hydroxy-22-ketodihydrostrychnine (III)

The ketol III, which was prepared by the method of Prelog and Kathriner (5), had m.p. 235–237° (from ethanol) (lit. 239–241°). $\nu_{max}^{CH_2Cl_2}$ 3 450, 2 870, 1 702, 1 673, 1 604, 1 484, 1 397, 1 332, 1 204, 1 135, 1 107, 1 089, 1 053, 1 020, 980, and 960 cm^{-1}; the nuclear magnetic resonnace (n.m.r.) spectrum does not have the vinyl absorption at 5.87 δ, which is present in strychnine.

cis-21,22-Dihydroxydihydrostrychnine (II)

The dihydroxy compound II was prepared by the method of Kogure and Kotake (4) except that dioxane with a trace of pyridine was used as a solvent for the reaction. The product after drying in vacuum for several days at 140° had m.p. 228° (lit. 228–230° (4), 240° (3), and 243–245° (5)). ν_{max}^{KBr} 3 350, 3 050, 2 905, 2 850, 1 665, 1 604, 1 490, 1 467, 1 425, 1 406, 1 370, 1 339, 1 292, 1 209, 1 157, 1 142, 1 095, 1 047, 1 030, 1 017, 992, 967, 942, 884, and 772 cm^{-1}; R_F (on Camag DF5 alumina using 1:1 acetone–water) = 0.57.

Reduction of the Ketol (III)

The ketol III (2.3 g) was hydrogenated following the method of Prelog and Kathriner (5). The crude product was purified by crystallization from ethanol – ethyl acetate mixtures. The earlier crops of crystals (1.1 g) had m.p. 97–99° and 144–145°. A portion of these on drying in high vacuum had m.p. 226–228° not depressed by addition of II; identity was confirmed by infrared and n.m.r. (in deuteropyridine) spectra and by thin-layer chromatography.

Later crops of crystals (350 mg) had m.p. (without vacuum drying) 248°, depressed by addition of II. ν_{max}^{KBr} 3 440, 2 920, 2 860, 1 643, 1 598, 1 488, 1 468, 1 416, 1 333, 1 318, 1 290, 1 280, 1 257, 1 226, 1 193, 1 168, 1 150, 1 136, 1 108, 1 088, 1 065, 1 028, 988, 968, 938, 818, and 765 cm^{-1}; R_F (on Camag DF5 alumina using 1:1 acetone–water) = 0.81. The n.m.r. spectrum of this compound in deuteropyridine differs from that of II. The compound is assigned structure IV.

Anal. Calcd. for $C_{21}H_{24}N_2O_4$: C, 68.46; H, 6.57; N, 7.60; O, 17.37. Found: C, 68.31; H, 6.72; N, 7.38; O, 17.40.

The mass spectra of II and IV were determined on a Hitachi RMU-6D single focussing mass spectrometer using a Micro-Tek inlet system and an ionizing voltage of 80 eV. The spectra were similar but showed some differences. Neither spectrum showed a molecular ion at m/e 368; both have peaks at 350, 332, and 303. They also show peaks at 130, 143, 167, and 220, which appear in the spectrum of strychnine (7).

11α,12α-EPOXY-3,20-DIOXOPREGNANE

P. ZIEGLER

In the course of work on the preparation of steroids with a ruptured C-ring, 3,20-dioxo-Δ^{11}-pregnene was oxidized with chromic acid. The reaction was carried out at room temperature in aqueous acetic acid – sulfuric acid, using equimolar proportions of steroid and oxidizing agent to provide 60–70% of a crude, crystalline product. Spectrophotometric examination in the infrared region showed the absence of hydroxyl, acetoxyl, carboxyl, and aldehyde groups; there was, however, an indication of the presence of epoxide absorption as evidenced by two medium-sized bands at 805 cm^{-1} and 878 cm^{-1}. Elemental analyses of the purified compound agreed with the formula for 11,12-epoxy-3,20-dioxopregnane. The n.m.r. spectrum showed the presence of an AB type pattern in the region of 3 p.p.m., characteristic of steroidal 11,12-epoxides; the chemical shifts (δ, 2.98 and 3.14 p.p.m.) and coupling constants ($J_{11,12} = 4$, and $J_{9,11} = 0$ c.p.s.) are in excellent agreement with values reported (1) for 11α,12α-epoxides, but not for the corresponding β-epoxides. Reduction of the unknown with lithium aluminium hydride and subsequent oxidation of the product with chromic acid provided 70% of 3,12,20-trioxopregnane (2). This evidence gives further support for the α-configuration of the epoxide; it is known (3, 4) that the lithium aluminium hydride reduction of a steroidal 11α,12α-epoxide, such as 3β-acetoxy-11α,12α-epoxy-5α,22a-spirostane, yields the corresponding 12α-hydroxy compound, while 11β,12β-epoxides provide (5, 6) 11β-hydroxy steroids. These results agree with the concept (7) of axial attack on an epoxide by aluminiohydride ions via an S_N2 mechanism, the product having the hydroxyl group in the axial position. An exception to this rule seems to have been observed (5, 8) in the lithium aluminium hydride reduction of methyl 3α-acetoxy-11α,12α-epoxycholanate to 3α,11α,24-trihydroxycholane.*

The reaction of isolated double bonds with chromic acid is a complex one, but there are many indications that epoxides are formed as final or intermediary products. Chromic acid oxidations of 2,4,4-trimethylpent-1-ene (9), 2,4-dimethylpent-2-ene (10), and 1,1-diphenyl-2-methyl-prop-1-ene (11) gave good yields of the corresponding epoxides. In the steroid field, chromic acid oxidation of 5α-hydroxy-6β,16α-dimethyl-$\Delta^{6,7}$-pregnenolone 3-acetate yielded (12) the corresponding 6α,7α-epoxide, and $\Delta^{8,14}$-cholestenyl acetate (13) as well as $\Delta^{8,14}$-ergostenyl acetate (14) afforded a mixture of products including the 7-oxo- and 15-oxo-8α,14α-epoxides.

EXPERIMENTAL

11α,12α-Epoxy-3,20-dioxopregnane

A solution of chromic acid (1 g) in water (2 ml), acetic acid (25 ml), and sulfuric acid (1 ml) was added within 10 min to a solution of 3,20-dioxo-Δ^{11}-pregnene (3.15 g) in acetic acid (25 ml). During this addition, the mixture first turned cloudy, and then a green–black, gummy precipitate formed. As soon as all of the oxidizing solution had been added, the mixture was diluted with water (100 ml). This addition of water was made in several portions over a period of 10–15 minutes, and the gummy precipitate gradually dissolved to give a clear, green solution. A precipitate settled out shortly after the addition of water had been completed; after ½ h, the precipitate was filtered off, washed with water, and vacuum dried at 70° to provide 1.28 g of material, m.p. 142–152°. Dilution of the filtrate with more water (35 ml) yielded an additional

**A personal communication from Ciba Ltd., received since acceptance of this manuscript, states that an error was made in U.S. patent 2,599,481 and in corresponding patents issued in other countries, and that the lithium aluminium hydride reduction of methyl 3α-acetoxy-11α,12α-epoxycholanate actually yields 3α,12α,24-trihydroxycholane.*

0.82 g of solid, m.p. 147–153°. The two crops were combined and charcoal added. Recrystallization from ethyl acetate gave 1.47 g of crystals, m.p. 170–178°. Two further recrystallizations from this solvent raised the melting point to 182–185°; $[\alpha]_D^{25}$ +78.1° (*c*, 0.598, dioxane).

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15; O, 14.53. Found: C, 76.50, 76.29; H, 9.18, 9.18; O, 14.68, 14.59.

3,12,20-Trioxopregnane

Lithium aluminium hydride (0.57 g) and 11α,12α-epoxy-3,20-dioxopregnane (1 g) were refluxed in ether (100 ml) for 4 h. An additional 0.75 g of reducing agent was then added, and refluxing was continued for 4 more hours. The cooled mixture was decomposed by dilute acetic acid and then poured into dilute hydrochloric acid, and the products were extracted with ether. After washing and evaporation of the solvent extract, the residue (0.9 g) was dissolved in acetic acid (20 ml) and water (2 ml). This solution was then treated dropwise, over a period of 15 min, with a solution of chromic acid (0.8 g) in water (10 ml), acetic acid (40 ml), and sulfuric acid (1 ml). After 15 h the mixture was poured into water, the products were extracted with ether – methylene chloride, and the solvent extract was worked up in the usual way. The residue (0.85 g) was crystallized from ether to give 0.67 g of material, m.p. 190–192°. Two further recrystallizations from ether and acetone gave pure 3,12,20-trioxopregnane, m.p. 198–201°, giving no depression on admixture melting point, and exhibiting an infrared spectrum which was superimposable on that of an authentic sample of this compound.

THE ALKALOIDS OF FUMARIACEOUS PLANTS. LII. A NEW ALKALOID, CULARICINE, AND ITS STRUCTURE

Richard H. F. Manske

The author (1) has described an investigation of the alkaloids of *Corydalis claviculata* (L.) DC. in which an amorphous phenolic fraction was obtained. At the time of publication it had not been possible to isolate pure individual bases from this fraction although it was shown to consist, to a large extent, of a base or bases which on O-methylation generated cularine. It has now been possible to isolate two phenolic bases and to determine the structure of one of these, namely that of cularicine. The other base proved to be identical with cularidine which had already been obtained from *Dicentra cucullaria* (L.) Bernh. (2).

The empirical formula of cularicine, $C_{18}H_{17}O_4N$, suggests that it might be cularidine or an isomer in which two methoxyls have been replaced by a methylenedioxy group and

THE ALKALOIDS OF FUMARIACEOUS PLANTS. LII. A NEW ALKALOID, CULARICINE, AND ITS STRUCTURE

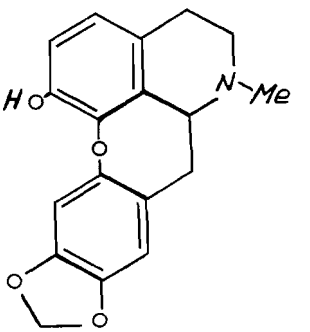
Richard H. F. Manske

The author (1) has described an investigation of the alkaloids of *Corydalis claviculata* (L.) DC. in which an amorphous phenolic fraction was obtained. At the time of publication it had not been possible to isolate pure individual bases from this fraction although it was shown to consist, to a large extent, of a base or bases which on O-methylation generated cularine. It has now been possible to isolate two phenolic bases and to determine the structure of one of these, namely that of cularicine. The other base proved to be identical with cularidine which had already been obtained from *Dicentra cucullaria* (L.) Bernh. (2).

The empirical formula of cularicine, $C_{18}H_{17}O_4N$, suggests that it might be cularidine or an isomer in which two methoxyls have been replaced by a methylenedioxy group and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the absence of methoxyl (Zeisel) lends further support to such a hypothesis. It has been possible to convert cularicine to cularine by well-known reactions. Its O-methyl ether when heated with phloroglucinol and sulfuric acid (3) generated a vicinal dihydroxy compound and this on reacting with diazomethane yielded cularine. The structure of cularicine is therefore that shown below.



EXPERIMENTAL

Though it was possible to achieve a fair degree of separation by passing a chloroform solution of the total phenolic alkaloids through a column of neutral alumina it was later discovered that cularidine formed a very sparingly soluble perchlorate whereas that of cularicine was readily soluble.

Cularidine

A hot methanolic solution of the phenolic bases was treated with perchloric acid until the mixture was just acid to Congo test paper. Even while hot the sparingly soluble perchlorate of cularidine separated in virtually colorless prisms. It was separated from the cooled mixture, washed with methanol, and recrystallized from a large volume of boiling methanol. It then melted at 297°* with slight gas evolution but little darkening. Cularidine was liberated from this salt by shaking with chloroform and aqueous ammonia. The washed chloroform extract was evaporated to a resin and the latter dissolved in a small volume of methanol. Seeding with a crystal of cularidine induced immediate crystallization. When recrystallized from methanol the cularidine thus obtained melted at 156° either alone or in admixture with a specimen from *D. cucullaria*. The ultraviolet and infrared spectra of the bases from the two sources were superimposable respectively; $[\alpha]_D^{22}$ +292° and +295° (c = 0.99, $CHCl_3$). Five kilograms of dried plant material yielded 10 g of cularidine perchlorate.

Cularicine

The methanolic filtrate from the cularidine perchlorate was concentrated somewhat, diluted with aqueous ammonia to incipient turbidity, and shaken with a large volume of ether. The ether extract was washed with water and the solvent removed. The residue from the latter was dried, dissolved in dry chloroform, and passed through a long column of neutral alumina. The eluate consisted of a small amount of cularidine isolated as its perchlorate. The column was then eluated with chloroform–methanol (100–4) and the eluate evaporated to a resin. The latter when dissolved in a small volume of methanol readily yielded a crop of colorless stout prisms of cularicine melting at 183–184° which when recrystallized from methanol melted at 185°; $[\alpha]_D^{22}$ +295° (c = 0.96, $CHCl_3$). The yield was ca. 2.0 g from 5 kg of plant material.

Anal. Calcd. for $C_{18}H_{17}O_4N$: C, 69.45; H, 5.47; N, 4.50. Found: C, 69.92, 69.87; H, 5.42, 5.48; N, 4.70.

Conversion of Cularicine to Cularine

A solution of 0.25 g of cularicine in methanol was left overnight with an excess of an ethereal solution of diazomethane. The resulting non-phenolic base isolated in the usual way was obtained only as a colorless non-crystalline resin. It yielded a hydrochloride which crystallized readily from methanol and then melted with only slight decomposition at 267° when placed in the bath at 250°.

Anal. Calcd. for $C_{19}H_{19}O_4N.HCl$: C, 63.08; H, 5.53; N, 3.87; 1OMe, 6.97. Found: C, 63.06; H, 6.04; N, 3.60; OMe, 8.69.

The high methoxyl value could be still further increased by further digestion in the Zeisel apparatus and is undoubtedly due in part at least to the elimination of methyl iodide from the N-methyl group.

**All melting points are corrected.*

For personal use only.

The above O-methylcularicine (0.22 g) was brought to the boiling point in a solution containing 0.5 g phloroglucinol in 8 cc of a solution of sulfuric acid prepared from 21 cc of concentrated acid and 25 cc water. Boiling was continued for 2 min and the mixture was then heated on a steam bath for 4 h. The diluted and cooled mixture was filtered to remove the phloroglucide and then extracted with three successive portions (200 cc) of ether. The aqueous solution was then rendered just alkaline with ammonia and extracted with three successive portions (150 cc) of ether. The combined ether extract was evaporated to dryness and the brittle colorless resin (0.09 g) dissolved in methanol, treated with an ethereal solution of diazomethane, and allowed to remain overnight.

The non-phenolic base (0.075 g) isolated in the usual way from the above reaction mixture was dissolved in hexane containing a small amount of dry ether. Seeding of this solution with a crystal of cularine caused immediate crystallization and the base thus obtained melted sharply at 115° either alone or in admixture with cularine. The acid oxalate prepared from this in methanol was washed with the same solvent and then melted at 245° either alone or in admixture with an authentic specimen of cularine oxalate.

Cularicine O-Ethyl Ether

The O-ethylation of cularicine with diazoethane in methanol–ether proceeded readily and the resulting non-phenolic base yielded a hydrochloride which was virtually insoluble in acetone but could be crystallized from hot methanol. It was obtained in colorless prisms which melted with only little decomposition at 275°.

Anal. Calcd. for $C_{20}H_{21}O_4N.HCl$: C, 63.91; H, 5.86; 1OEt, 11.98. Found: C, 64.17; H, 5.99; OEt, 12.58.

The free base, O-ethylcularicine, regenerated from this hydrochloride was crystallized from ether–hexane and consisted of stout prisms melting at 114°.

Anal. Calcd. for $C_{20}H_{21}O_4N$: C, 70.80; H, 6.20; N, 4.13. Found: C, 70.83, 70.87; H, 6.19, 6.21; N, 4.20.

AN IMPROVED SYNTHESIS OF ε-*N*-ACETYL-L-LYSINE AND SIMILAR COMPOUNDS

Leo Benoiton and Jean Leclerc

Enzymic experiments in our laboratory have required us to prepare large amounts of ε-*N*-acetyl-L-lysine. We have found that use of the original procedure (1), or a modification of it (2), for its synthesis, leads to material which is free of lysine only after several recrystallizations which are accompanied by a considerable loss of material. Final yields were usually in the 20–35% range. To overcome this, various ion-exchange resin systems have been used to purify the compound (3, 4). These are adequate but their use renders the procedure laborious. We have sought and found a procedure which is simpler and which gives better yields of pure ε-*N*-acetyl-L-lysine.

The usual synthesis consists in the acylation of the copper salt of the amino acid with acetic anhydride (1, 2). However, the reaction is far from being complete; and since the solubility of the unreacted starting material is similar to that of the product, purification by recrystallization is not efficient. We have overcome the difficulty by using a different acylating agent, namely, *p*-nitrophenyl acetate. Nitrophenyl esters are used routinely as acylating or peptide bond forming agents in peptide chemistry (5). In the presence of an excess of *p*-nitrophenyl acetate, no unsubstituted amino acid remained in a solution of the copper salt of lysine after 12 h. Moreover, most of the product had precipitated out of

ϵ-*N*-Acetyl-L-lysine*	65–75	51.0	8.6	14.9	51.0	8.6	14.9
δ-*N*-Acetyl-L-ornithine	60	—	—	16.1	—	—	16.0
γ-*N*-Acetyl-L-diaminobutyric acid†	65	45.0	7.6	17.5	44.8	7.6	17.5

*$[\alpha]_D^{23}$ +22.1 (1 in 5 *N* HCl).
†New compound, $[\alpha]_D^{23}$ +42.8 (0.6 in 5 *N* HCl).

The results of the experiments are summarized in Table I. Optical rotation measurements indicated that no racemization had occurred. Assay of a sample of ϵ-*N*-acetyl-L-lysine for its L-lysine content using lysine decarboxylase from *Bacterium cadaveris* (6) indicated a contamination not exceeding 0.2%.

The copper salt of γ-*N*-acetyl-L-diaminobutyric acid did not precipitate out of the reaction mixture. Consequently, the product was isolated using an ion-exchange resin. In two preparations, ϵ-*N*-acetyl-L-lysine was also isolated in this manner without previously filtering off the copper salt. Material of the same purity with no increase in yield was obtained.

EXPERIMENTAL

p-Nitrophenyl acetate, crystallized from 95% ethanol, m.p. 78°, was prepared from acetyl chloride and the sodium salt of *p*-nitrophenol as described for the chloracetyl ester (7). It has been prepared using acetic anhydride (8), and is commercially available (Eastman Co., Rochester, N.Y.).

General Procedure

Excess cupric carbonate was added to a boiling solution of the amino acid (0.01 mole) and the mixture was filtered. To the filtrate, at room temperature, was added sodium bicarbonate (0.03 mole), *p*-nitrophenyl acetate (0.02 mole), and a few milliliters of ethyl acetate to keep the ester in solution. The mixture was stirred vigorously for 15 h after which time the precipitated copper salt was filtered off and washed with cold water and ethyl acetate. The material was suspended in warm water, freed of copper with H_2S followed by charcoal treatment, and the resulting solution evaporated to dryness. The residue was recrystallized from water-ethanol.

Isolation Using Dowex 50

After the reaction had been completed, the mixture was acidified to litmus with HCl (enough to dissolve the precipitate if one was present), and extracted twice with ether. The mixture was freed of copper with H_2S, and stirred in the presence of 80 ml of Dowex 50 (H^+ form) for 1 h. The resin was filtered off, washed with copious amounts of water, and then stirred in 3 *N* ammonium hydroxide for $\frac{1}{4}$ h. The resin was removed by filtration, the filtrate evaporated to dryness, and the residue crystallized from water.

II. NUCLEAR MAGNETIC RESONANCE INVESTIGATION OF ADDUCTS OF *N*-METHYLFORMAMIDE WITH HCl AND HBr AND *N,N*-DIMETHYLFORMAMIDE WITH PROTONATING ACIDS AND SILVER SALTS[1]

STEPHEN J. KUHN AND JOHN S. MCINTYRE

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received October 1, 1964

ABSTRACT

The proton magnetic resonance spectra of dimethylformamide – proton acid and dimethylformamide – silver salt complexes in 2-nitropropane solution as well as *N*-methylformamide·HCl and HBr adducts in tetramethylene sulfone solution have been investigated. The results indicate that the protonation takes place on the carbonyl oxygen. For most of the acids investigated, the acid strength correlates with shifts of both the methyl proton and the proton complexed at the carbonyl oxygen. The dimethylformamide – silver salt complexes have a structure similar to the DMF – Lewis acid or protonating acid adducts.

INTRODUCTION

The structure of the adducts formed when amides are dissolved in protonating acids has been the subject of many investigations during recent years. A geat deal of the previous work has been discussed by Jones and Katritzky (1) and the present authors (2) who conclude that amides predominantly interact with protonating acids, Lewis acids, and alkylhalides at the oxygen atom.

In the n.m.r. spectra of liquid dimethylformamide two peaks of equal area have been found for the *N*-methyl groups. Fraenkel and Niemann (3) have shown that these two peaks remain unchanged in aqueous strong acid solution and in 100% H_2SO_4 and D_2SO_4. They point out that in the *O*-protonated form, restricted rotation around the C—N bond would still exist, while in *N*-protonated amides this restriction would be eliminated. No definite peak could be assigned to the O—H proton because of the fast exchange of protons. Gillespie and Birchall (4) recorded the proton resonance spectra of acetamide, formamide, dimethylacetamide, and dimethylformamide in fluorosulfonic acid at low temperature and were able to observe for the first time the signal from the captured proton and determine with certainty the site of protonation.

We have reported an n.m.r. study of the Lewis acid adducts of dimethylformamide and concluded that the interaction is on the carbonyl oxygen of the molecule (2). In the present investigation, salts of dimethylformamide from different protonating acids have been prepared and the proton resonance spectra of these compounds have been recorded. The *N*-methylformamide·HCl and HBr salts, DMF·$AgBF_4$, and DMF·$AgClO_4$ are also

[1]*Contribution No. 117.*

For personal use only.

included. All of our investigations have been carried out at room temperature with the exception of the DMF·HCl salt which was also studied at −57 °C.

EXPERIMENTAL

(1) Preparation of DMF – Proton Acid Adducts

(*a*) DMF (0.2 mole) was dissolved in 100 ml of ether and the solution was saturated with HCl or HBr. The precipitated solid was filtered, washed three times with 25 ml of ether, and pumped dry, and 0.1 mole of product was dissolved in 80 g of 2-nitropropane.

(*b*) The $ClSO_3H$, CH_3SO_3H, CCl_3COOH, CF_3COOH, $CHCl_2COOH$, $CH_2ClCOOH$, picric acid, benzoic acid, and CH_3COOH adducts were made by carefully measuring 0.1 mole of DMF and 0.1 mole of acid into 80 g of 2-nitropropane. The n.m.r. spectra of these solutions were recorded without isolating the compounds.

(2) Preparation of N-Methylformamide·HCl and HBr Salts

N-Methylformamide (0.2 mole) was dissolved in 100 ml of ether and the solution was saturated with either HCl or HBr gas at 0 °C. The solid product was filtered, washed with ether, and pumped dry. The salts were dissolved in tetramethylene sulfone and their n.m.r. spectra were recorded at room temperature.

(3) Preparation of DMF·$AgBF_4$ and DMF·$AgClO_4$ Salts

Anhydrous silver salt (0.1 mole) was dissolved in 80 g of 2-nitropropane, and 0.1 mole of DMF was added dropwise to the solution which was kept around 0 °C during the addition.

Nuclear Magnetic Resoance

The nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer. All spectra were obtained at room temperature; the DMF·HCl complex was also measured at −57 °C.

Chemical shifts of the methyl protons were measured relative to the second band of the 2-nitropropane septuplet on a 100 cycle sweep width. The aldehyde, the amine, and the protonated oxygen peaks were measured relative to internal tetramethylsilane. For the *N*-methylformamide·HCl and HBr adducts, the peaks are relative to external tetramethylsilane.

RESULTS AND DISCUSSION

N-Methylformamide·HCl and HBr Salts

The n.m.r. spectra of solutions of *N*-methylformamide·HCl and HBr adducts in tetramethylene sulfone contain three signals below the methyl region; assignments were made as in Table I. The presence of three peaks at low field immediately shows that the protonation takes place on the carbonyl oxygen. The relative areas of the peaks are approximately 1:1:1. If the *N*-atom of the molecule is protonated, one less proton signal should be present and the ratio of areas should be 2:1. The spectra for *N*-methylformamide and the *N*-methylformamide·HBr complex are shown in Fig. 1 and Fig. 2 respectively. The adducts were recovered unchanged by diluting the solution with ether.

TABLE I

Proton shifts of *N*-methylformamide·HCl and HBr complexes in tetramethylene sulfone*

Adduct	Formyl	NH	OH
N-Methylformamide	512(1.1)	438(0.9)	
N-Methylformamide·HCl	528(1.1)	581(1.0)	953(0.9)
N-Methylformamide·HBr	538(1.1)	612(0.9)	890(1.0)

*Shifts are in c.p.s. downfield from tetramethylsilane; areas of the peaks are shown in parentheses.

N,N-Dimethylformamide Salts

The results in Table II show that there are considerable shifts in the proton peaks of DMF – proton acid adducts. In all of the spectra a new peak appears which is assigned to the proton captured by the carbonyl oxygen. The presence of two methyl peaks

indicates the retention of the conjugated structure of DMF in these complexes. The two methyl proton signals are doublets for most of the compounds and in the others appear as broad peaks. In all cases including a solution of DMF·HCl in chloroform at −57° only a singlet was observed for the OH and CH proton.

TABLE II

Proton shifts of DMF – protonating acid and silver salt adducts in 2-nitropropane

Adduct	*cis* Methyl*	*trans* Methyl*	Aldehyde†	OH†
DMF	102	94	474	—

DMF·$CH_2ClCOOH$	96	87	484	667
DMF·Benzoic acid	96	89	—	635
DMF·CH_3COOH	98	90	481	591
DMF·$AgBF_4$	94	87	488	—
DMF·$AgClO_4$	96	90	490	—

*Shifts in c.p.s. upfield from second peak in nitropropane septuplet. The *cis* or *trans* is with respect to the aldehyde proton.
†Shifts in c.p.s. downfield from internal tetramethylsilane.

In an earlier study a correlation between the Lewis acid strength and the methyl proton shift has been found (2). It was expected that a similar correlation between the proton shifts of the DMF – proton acid adduct and the acid strength would be obtained. The relative order of acid strength of protonating acids measured by the ionization constant in water solution at 25 °C (5) is compared below with the relative order of acid strength obtained by comparing the n.m.r. spectra of DMF – protonating acid adducts.

$-\log k$	Methyl proton shifts in DMF·HX adducts	Position of OH-proton in DMF·HX adducts
Trifluoroacetic acid	Trifluoroacetic acid	Trifluoroacetic acid
Picric acid (0.38)	Trichloroacetic acid	Trichloroacetic acid
Trichloroacetic acid (0.89)	Dichloroacetic acid	Dichloroacetic acid
Dichloroacetic acid (1.30)	Picric acid	Picric acid
Chloroacetic acid (2.86)	Chloroacetic acid	Chloroacetic acid
Benzoic acid (4.20)	Benzoic acid	Benzoic acid
Acetic acid (4.76)	Acetic acid	Acetic acid

It can be seen that the results obtained by the two methods agree well with the exception of picric acid.

DMF·AgX Adducts

Adducts (1:1) of DMF with $AgBF_4$ and $AgClO_4$ have also been prepared in solution and the proton resonance spectra of these compounds have been recorded. Their spectra show close similarity to those of the DMF – Lewis acid and DMF – protonating acid complexes (Table II). The coordination has taken place again on the carbonyl oxygen as indicated by the preservation of the conjugated structure of the DMF. The proton shifts in these salts are comparable to those of DMF – weak Lewis acid or protonating acid complexes.

CADMIUM SPECIES IN BASIC SOLUTION

D. E. RYAN, J. R. DEAN, AND R. M. CASSIDY
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received October 30, 1964

ABSTRACT

The principal cadmium-containing species in basic solutions varies with the concentration of hydroxide ion such that the solubility of cadmium hydroxide can be satisfactorily expressed, in solutions of high ionic strength, in terms of $[Cd(OH)^+] = 3.0 \times 10^{-9}[OH^-]^{-1}$, $[Cd(OH)_2]_{soln} = 1.0 \times 10^{-6}$, $[Cd(OH)_3^-] = 1.2 \times 10^{-6}[OH^-]$, and $[Cd(OH)_4^{2-}] = 3.1 \times 10^{-6}[OH^-]^2$. Since the solubility varies from 10^{-4} to 10^{-6} *M*, the predominant species at high concentrations of hydroxide ion is $Cd(OH)_4^{2-}$; at low concentrations of hydroxide ion $Cd(OH)^+$ is the principal cadmium-containing ion in solution. There is little free cadmium ion in solutions whose hydroxide ion concentration is greater than 10^{-4} *M*.

Cadmium hydroxide is precipitated as stable β-$Cd(OH)_2$ on the addition of an excess amount of alkali to a solution of a cadmium salt (1). Unlike zinc hydroxide, its solubility is not greatly increased by the presence of excess hydroxide ion. Nevertheless, the existence of hydroxo complexes is indisputable. Casey (2), in discussing the cadmium electrode of the nickel:cadmium battery, stated that the conversion of cadmium to cadmium hydroxide involves an intermediate complex that must be considered. Lake and Goodings (3) concluded from polarographic studies that the cadmium, in concentrated hydroxide solutions, exists in finite concentrations as the tetrahydroxocadmate ion, $Cd(OH)_4^{2-}$. In dilute solutions no appreciable amounts of cadmate ion are formed (4) but solid compounds corresponding to $Na_2Cd(OH)_4$ have been prepared in saturated sodium hydroxide (5). Marcus (6) found no evidence for the existence of polynuclear species and stated that slight hydrolysis, corresponding to the reaction $Cd^{2+} + H_2O \rightleftarrows Cd(OH)^+ + H^+$, was observed. Dryssen (7) has recently shown, through solvent extraction studies using long-chained amines in benzene, that Cd^{2+} forms four mononuclear hydroxo complexes in the rather narrow pH range 9–13 and reported a pK_4 value, at an ionic strength = 3, of 12.0.

Other workers (8, 9, 10) have reported results on solubility and complex formation but failure to consider ionic strength variations makes it difficult, in practical work, to use the values reported. Since a knowledge of the cadmium-containing species in 7 *N* alkali was required, this paper records the results of an investigation into the change in solubility of cadmium hydroxide with changing hydroxide ion concentration; from the data obtained the amounts of Cd^{2+}, $CdOH^+$, $Cd(OH)_2$, $Cd(OH)_3^-$ and $Cd(OH)_4^{2-}$ present in basic solution can be calculated.

METHOD

The overall method involved the equilibration of freshly prepared cadmium hydroxide with solutions containing various concentrations of hydroxide ion and determination of the total cadmium content in the equilibrated solution. A colorimetric method using cadion (11) was first used to determine the cadmium at an ionic strength of 1; however, at higher ionic strengths potassium perchlorate was precipitated through reaction of the reagent solution (cadion in potassium hydroxide) with the perchlorate used to maintain constant ionic strength, and development of another procedure for the determination of small differences in cadmium concentration was necessary. A method, based on measurement of the fluorescence developed when 8-hydroxyquinoline-5-sulfonic acid reacts with cadmium ion (12), proved satisfactory for determining 0.1 p.p.m. cadmium with a precision better than 5%; a detailed account of the factors influencing the method will be published shortly.

Cadmium hydroxide preparation.—The white precipitate of cadmium hydroxide was prepared by the dropwise addition, with stirring, of 1.5 *N* carbonate-free sodium hydroxide to 0.64 *N* cadmium nitrate solution. The base was added at a rate of about 60 drops/min and the entire precipitation process was carried out under a nitrogen gas atmosphere. The precipitate was washed with doubly distilled water and tested to ensure complete removal of excess hydroxide ions. Since aging could have a marked effect on the solubility, the precipitation process was the same for each run and the precipitate was allowed to stand in water for approximately 12 h before filtration.

Equilibrium procedure.—Sodium perchlorate was used to maintain a constant ionic strength and the freshly prepared cadmium hydroxide was agitated, in contact with sodium hydroxide solutions, in a constant temperature bath and shaker. The agitation period was from 10 to 14 d at a bath temperature of 24.5 ± 0.5 °C. All precautions were taken to avoid contact of the solutions with the air. The Nalgene tubes and contents were flushed with nitrogen, capped, and then sealed with wax to ensure tightness. After the agitation period the tubes were centrifuged and the supernatant liquid was decanted through a sintered glass funnel; an aliquot of this solution was made up to a volume to be analyzed.

RESULTS

The solubility of cadmium hydroxide at various equilibrium hydroxide concentrations is given in Table I; at least three replicate samples were studied. Initial concentrations of hydroxide ion are recorded for $[OH^-]$ greater than 10^{-3} *M*; here the differences between beginning and equilibrium concentrations are negligible. Lower concentrations of hydroxide ion at ionic strength = 1 were calculated from measured pH_a values made with a combination glass electrode; we assumed an activity coefficient of 0.809 for hydrogen ion and a K_w of 1.69×10^{-14} (13). The solubilities are uncertain by about $\pm 1 \times 10^{-6}$ *M*.

TABLE I

Solubility of cadmium hydroxide

Ionic strength = 7		Ionic strength = 1	
$[OH^-]$, *M*	Solubility × 10^5, *M*	$[OH^-]$, *M*	Solubility × 10^5, *M*
7.0	16.0	0.93	0.4_8
6.0	11.0	0.54	0.2
5.0	7.6	0.47	0.1
4.0	4.9	0.26	0.2
3.0	2.5	0.047	0.2
2.0	1.2	6.3×10^{-4}	0.6
1.0	0.5_3	4.1×10^{-4}	0.8
0.75	0.3	1.7×10^{-4}	2.2
0.10	0.2	0.68×10^{-4}	4.8
0.05	0.2	0.55×10^{-4}	5.5
0.01	0.3		
0.005	0.4		

INTERPRETATION OF RESULTS

Solid cadmium hydroxide can go into solution through the following processes.

(*a*) $$Cd(OH)_2\downarrow \rightleftarrows Cd(OH)_{2\ soln}$$

(*b*) $$Cd(OH)_2\downarrow \rightleftarrows CdOH^+ + OH^- \quad \Updownarrow \quad Cd^{2+} + OH^-$$

(*c*) $$Cd(OH)_2\downarrow + OH^- \rightleftarrows Cd(OH)_3^- \quad \uparrow\downarrow \ OH^- \quad Cd(OH)_4^{2-}$$

As the concentration of hydroxide increases from 0.55×10^{-4} *M*, the solubility decreases until a minimum solubility of 0.1×10^{-5} is approached. The only reaction which will give a decreasing cadmium concentration with increasing hydroxide concentration is reaction (*b*); as the concentration of hydroxide ion increases, the amount of cadmium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydroxide dissolving by reaction (*b*) must decrease (the $[Cd^{2+}]$ and $[Cd(OH)^+]$ in solution decreases) and the solubility becomes smaller. At the minimum solubility it seems reasonable to assume that the cadmium concentration in solution is the result of reaction (*a*) and that the undissociated species, $Cd(OH)_2$, predominates. Beyond this minimum, since the solubility now begins to increase with increasing hydroxide concentration, reaction (*c*) becomes significant and higher hydroxo complexes $Cd(OH)_3^-$ and $Cd(OH)_4^{2-}$ are formed.

If the following reactions are assumed,

$$Cd^{2+} + OH^- \rightleftarrows CdOH^+$$
$$CdOH^+ + OH^- \rightleftarrows Cd(OH)_{2\ soln}$$
$$Cd(OH)_{2\ soln} + OH^- \rightleftarrows Cd(OH)_3^-$$
$$Cd(OH)_3^- + OH^- \rightleftarrows Cd(OH)_4^{2-},$$

and since $[Cd^{2+}][OH^-]^2 = K_{sp}$, the amounts of cadmium-containing species in solution are given by the following expressions,

$$[CdOH^+] = K_1K_{sp}[OH^-]^{-1}$$
$$[Cd(OH)_2]_{soln} = K_2K_{sp}$$
$$[Cd(OH)_3^-] = K_3K_{sp}[OH^-]$$
$$[Cd(OH)_4^{2-}] = K_4K_{sp}[OH^-]^2,$$

where K_1, K_2, K_3, and K_4 are the overall formation constants for $Cd(OH)^+$, $Cd(OH)_2$, $Cd(OH)_3^-$, and $Cd(OH)_4^{2-}$ respectively.

If the possibility of the presence of all entities Cd^{2+}, $CdOH^+$, $Cd(OH)_{2\ soln}$, $Cd(OH)_3^-$, and $Cd(OH)_4^{2-}$ is assumed, it follows that the measured cadmium concentration is composed of a fraction of each. Therefore:

$$[Cd]_{tot} = \text{solubility}$$
$$= [Cd^{2+}] + [CdOH^+] + [Cd(OH)_2]_{soln} + [Cd(OH)_3^-] + [Cd(OH)_4^{2-}]$$
$$= K_{sp}[OH^-]^{-2} + K_1K_{sp}[OH^-]^{-1} + K_2K_{sp} + K_3K_{sp}[OH^-] + K_4K_{sp}[OH^-]^2.$$

At low concentrations of hydroxide ion, where cadmate complexes are not present, the $[Cd]_{tot}$ can be expressed in terms of K_{sp}, K_1, K_2, and the $[OH^-]$; similarly at high hydroxide ion concentrations the solubility is dependent upon the formation of cadmate complexes and the $[Cd]_{tot}$ is correctly expressed in terms of K_{sp}, K_3, K_4, and $[OH^-]$. For example, if it is assumed that only the tetrahydroxo species is present at high concentrations of hydroxide ion, the calculated value for K_4K_{sp} is $(3.1 \pm 0.1) \times 10^{-6}$ in 2–7 *N* base; the constancy of the calculated value shows the assumption to be a valid one and the concentration of $Cd(OH)_4^{2-}$ in solution at any hydroxide ion concentration is given by $3.1 \times 10^{-6}[OH^-]^2$. A similar calculation for solutions 1 *M* in hydroxide ion gives 5.3×10^{-6} for K_4K_{sp} and lower complexes must make a significant contribution to the solubility here. Since a minimum solubility of 1.0×10^{-6} is approached, the intrinsic solubility of cadmium hydroxide may be taken as equal to this value and K_2K_{sp} would be 1.0×10^{-6}. The calculated value for K_3K_{sp}, therefore, from the solubility determined in 1 *M* hydroxide solution, is 1.2×10^{-6} when the contributions of $Cd(OH)_4^{2-}$ and $Cd(OH)_2$ are considered.

Calculated solubilities, using the equation

$$[Cd]_{tot} = 1.0 \times 10^{-6} + 1.2 \times 10^{-6}[OH^-] + 3.1 \times 10^{-6}[OH^-]^2,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

agree satisfactorily with the experimental results at hydroxide ion concentrations greater than the minimum solubility value. The minimum solubility occurs experimentally between 0.5 and 0.05 M OH^- where measured solubilities were (0.1–0.2) $\times 10^{-5}$ M; all calculations for constants were made outside these limits for cases where significant solubility changes were observed. The results show that the predominant species at high basicities is the tetrahydroxo complex and that significant solubility changes with increasing hydroxide ion concentration are due to the formation of $Cd(OH)_4^{2-}$.

From solubility measurements at lower concentrations of hydroxide ion K_1K_{sp} can be calculated. Because of the high sodium ion content meaningful measurements of low concentrations of hydroxide ion were not obtained at an ionic strength of 7; however, cadmium hydroxide showed the same solubility at an ionic strength of 1 for similar concentrations of hydroxide ion (Table I), and the calculated constants should apply equally well at high ionic strengths. Since at low concentrations of hydroxide ion

$$[Cd]_{tot} = K_{sp}[OH^-]^2 + K_1K_{sp}[OH^-]^{-1} + K_2K_{sp},$$

the calculated value for K_1K_{sp} is $(3.0 \pm 0.1) \times 10^{-9}$ from hydroxide ion concentrations 6.3×10^{-4} and 4.1×10^{-4} M. (The recorded values of K_{sp} are between 10^{-14} and 10^{-15} (1) and $K_{sp}[OH^-]^{-2}$ makes a negligible contribution here.) The amount of $CdOH^+$ in solution is therefore given by $3.0 \times 10^{-9}[OH^-]$; calculated solubilities at lower hydroxide ion concentrations are within 10% of the experimentally determined solubilities. The value $10^{-14}[OH^-]^{-2}$ calculated for the concentration of free cadmium ion in solution, although unreliable since it varied by $\pm 10^{-1}$, shows that there is little free cadmium ion in solutions with hydroxide ion concentrations greater than 10^{-4} M.

A comparison of the results calculated from

$$[Cd]_{tot} = 3.0 \times 10^{-9}[OH^-]^{-1} + 1 \times 10^{-6} + 1.2 \times 10^{-6}[OH^-] + 3.1 \times 10^{-6}[OH^-]^2$$

with the experimentally determined solubilities is shown in Table II.

The results show that, at the ionic strengths considered, a satisfactory estimate of the solubility of cadmium hydroxide in hydroxide solutions can be calculated from the above equation. The equilibration procedure used to obtain these results is an attractive one in its simplicity and its general applicability to complex formation involving a common ion of a slightly soluble substance; however, accurate measurements of small changes in solubility are necessary and are often difficult experimentally.

HEATS OF MIXING AND HEAT CAPACITIES IN THE SYSTEM: ACETIC ACID – CHLOROFORM – WATER, AT 25°

A. N. CAMPBELL AND J. M. T. M. GIESKES[1]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received November 19, 1964

ABSTRACT

The heats of mixing, H^E, and heat capacities, at 25 °C, have been determined both for the ternary system: acetic acid – chloroform – water, and for the component binary systems: acetic acid – chloroform and acetic acid – water. The results are discussed in their bearing on the equilibria existing in these systems.

This paper is a continuation of previous work on the thermodynamic properties of the system: acetic acid – chloroform – water (1). The heat of mixing can be readily obtained from direct calorimetric measurements and is, therefore, not subject to the inaccuracies which are involved when the quantity is obtained from the temperature variation of the excess free energy.

The heat of mixing is a direct measure of non-ideality. It can be represented, for a binary solution, by equations such as those suggested by Redlich and Kister (2) of the form

$$H^E = x(1 - x)[A + B(2x - 1) + C(2x - 1)^2 + \ldots],$$

whence the partial molal enthalpies of mixing can be calculated from the following equations:

$$H_1^E = (1 - x)^2[A + B(4x - 1) + C(2x - 1)(6x - 1) + D(2x - 1)^2(8x - 1)],$$

$$H_2^E = x^2[A + B(4x - 3) + C(2x - 1)(6x - 5) + D(2x - 1)^2(8x - 7)],$$

where x is the mole fraction of component 1. The variation of H^E with temperature or the excess heat capacity at constant pressure is another important quantity in the theory of solutions.

The International Critical Tables report some values for the heats of solution of chloroform and of acetic acid in water, but there is some doubt about their reliability: no recent data could be found in the literature. Timofeev (3) gives the heats of solution of acetic acid in chloroform and of chloroform in acetic acid, presumably at infinite dilution, as −502 and −581 cal per mole of solute, respectively. Faucon (4) studied the heats of mixing of acetic acid and water, over the complete range of concentration, at 7°. Pickering (5) studied dilute solutions of acetic acid at 18.6°.

The specific heat of chloroform has been obtained with a reasonable degree of accuracy by a number of authors and their values are reported in the International Critical Tables. The most recent values are those obtained by Staveley, Tupman, and Hart (6) who report the value of C_p over the temperature range 10–56 °C. The specific heats of acetic acid and acetic acid – water mixtures have been investigated by Neumann (7) who reports data for 23.9, 42.0, 59.5, and 80.5 °C. No work has been done on mixtures of acetic acid and chloroform, or on the ternary mixtures of acetic acid, chloroform, and water.

EXPERIMENTAL

Purification of the Materials

Acetic acid.—The water content of acetic acid obtained from Canadian Industries Limited was determined from the observed freezing point. After addition of a calculated amount of acetic anhydride, the acetic acid was boiled under reflux for about 12 h. After distillation the acetic acid was further purified by means of fractional crystallization until a freezing point of 16.58 °C was obtained.

Chloroform.—Fisher Certified chloroform (A.C.S.) was treated with concentrated sulfuric acid to remove possible traces of alcohol. After extraction of the sulfuric acid with water, the chloroform was dried over anhydrous calcium chloride and finally distilled from anhydrous phosphorus pentoxide. Chloroform had to be purified every 2 weeks because of decomposition of chloroform after several weeks.

Water.—Distilled water was obtained by means of the distillation of water in a Barnstead still, yielding water with a specific conductivity of 5×10^{-6} mho/cm at 25 °C.

1. Heats of Mixing

The calorimeter was similar to that used by Campbell, Kartzmark, and Friesen (8). As a check of the reliability of the apparatus, we determined the heats of mixing of the system: methanol–benzene; this system has been studied by Scatchard *et al.* (9), who give a Redlich and Kister type of equation to reproduce the heat of mixing for any given mole fraction. For five mixtures extending over the complete range of concentration, our results differed by +2 to −4.5 cal from the calculated values, on a total of from 62 to 159 cal. We estimate the overall accuracy of the measured heats of mixing to be of the order of ±3%.

2. Heat Capacities

These were determined by a method essentially the same as that of Campbell and Nagarajan (10). The accuracy of the measurements is ±0.5%.

RESULTS

1. Heats of Mixing

(a) The system: acetic acid – water.—The results are given in Table I. These results when plotted on a smoothed curve gave values which were used for the establishment of an equation of the Redlich and Kister form (2), where $A = 296$, $B = 166$, $C = 19$, $D = 321$, and x is the mole fraction of acetic acid.

(c) The system: acetic acid – chloroform – water.—The results of heat of mixing are reproduced in Table III and graphically in Fig. 1, where lines of equal heat of mixing, deduced from binary and ternary data, are drawn, including that of zero heat of mixing. Campbell and Kartzmark (8) have proposed to call these lines "idemcals".

We have been able to calculate, using four measured points, a slightly modified Redlich–Kister equation for the ternary heats of mixing data. This equation has the form:

$$H^E = x_1x_2[296 + 166(x_1 - x_2) + 19(x_1 - x_2)^2 + 321(x_1 - x_2)^3] + x_1x_3[-574 - 71(x_1 - x_3) + 78(x_1 - x_3)^2] + x_2x_3[395 - 730(x_2 - x_3) + 2\,138(x_2 - x_3)^2] + 1\,507x_1x_2x_3,$$

where x_1 = mole fraction HAc, x_2 = mole fraction H_2O, x_3 = mole fraction $CHCl_3$, and the units of H^E are cal per mole of mixture. Heats of mixing calculated by this equation are also shown in Table III.

The first three parts of the equation are due to the binary systems HAc–H_2O, HAc–$CHCl_3$, and H_2O–$CHCl_3$, respectively. In other words, this equation yields, for the

For personal use only.

binary system H_2O–$CHCl_3$ at 25 °C, an equation which could not be obtained experimentally because of the immiscibility. The last part of the equation is a ternary correction term.

The heat of mixing for the system H_2O–$CHCl_3$ can therefore be represented by the equation:

$$H^E = x_2x_3[395 - 730(x_2 - x_3) + 2\,138(x_2 - x_3)^2],$$

where x_2 = mole fraction H_2O and x_3 = mole fraction $CHCl_3$. Hence the heat of mixing is positive over the entire region of concentration for which miscibility is possible.

2. Heat Capacities

The results obtained for the binary system: acetic acid – chloroform and for the ternary system: acetic acid – chloroform – water are reported in Table IV. In Fig. 2 the excess heat capacity, calculated from the heat capacities of the pure components, is represented as a function of concentration for the binary system: acetic acid – chloroform. In Fig. 3 some lines of equal excess heat capacity for the ternary system, deduced from the data of Table IV, are represented.

DISCUSSION OF RESULTS

1. Heats of Mixing

(a) The System: Acetic Acid – Water

In this system there occurs a change of sign in the heat of mixing. The heat of mixing is negative only in the concentration range 0–0.1 mole fraction acetic acid. The fact that the heat of mixing is positive over a large range of concentration (heat absorbed) can be explained in accordance with the ideas of Joerges and Nikuradse (11). In the pure state both water and acetic acid are strongly associated. On mixing, the acetic acid dimer forms an open chain dimer and acetic acid monomers, both of which associate with water molecules. Energy is required for the dissociation of the associated complexes, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

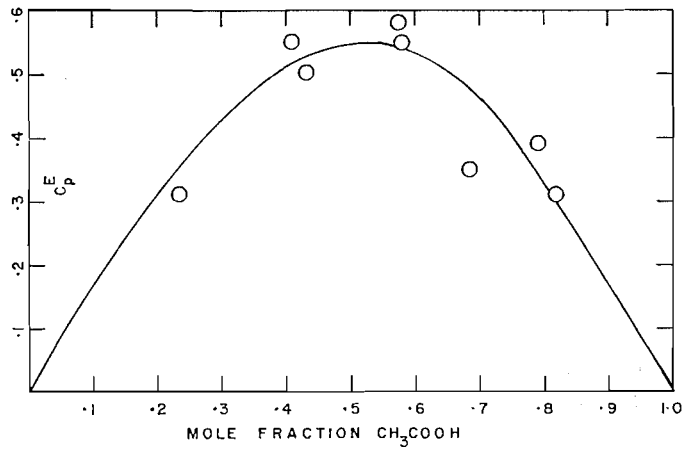

FIG. 2. Excess heat capacity for the system acetic acid – chloroform.

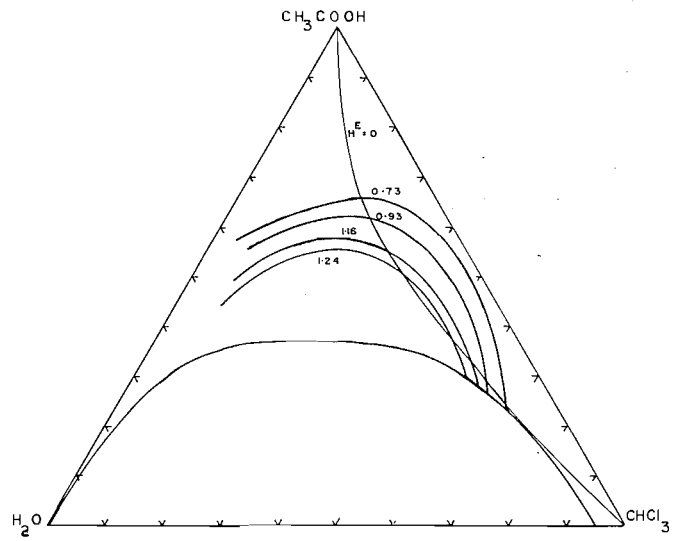

FIG. 3. Lines of equal excess heat capacity for the system acetic acid – chloroform – water.

energy is liberated by the formation of the mixed complexes. The number of mixed associated complexes cannot be larger, and is usually smaller, than the total number of dissociation products. This means that, even if

$$H_{\text{diss}}(\text{I}) + H_{\text{diss}}(\text{II}) < H_{\text{ass}}$$

where the H's represent the heats of dissociation or association per mole of acetic acid, of water, and of mixed complexes, respectively, a positive ΔH of mixing can result; in other words, the energy required to break up the individual associates may be larger than the energy set free by the formation of the mixed complexes. This is clearly what happens with mixtures of water and acetic acid. In the dilute region, ionic hydration energies will play an increasingly important role and this may be one of the factors leading to a negative value of the heat of mixing.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The Redlich and Kister equation represents the data within the limits of accuracy, as can be seen from Table I.

(b) The System: Acetic Acid – Chloroform

In this system the heat of mixing is negative over the complete range of concentration, i.e. heat is set free on mixing.

The Redlich and Kister formula can be applied successfully, and from Table II it follows that this formula represents the results within limits of accuracy.

In this system, only acetic acid is associated in the pure state. On mixing with chloroform, two processes can occur. The acetic acid dimers can break up to give monomers which in turn will associate with chloroform molecules. The ring dimer may also persist and associate with chloroform in an antiparallel dipole arrangement, and this latter process will be accompanied by a negative heat effect. The negative value of H^E and also the evidence reported in our paper on the dielectric behavior of this system (12) (in particular, the extrapolated value of 216 for the Debye polarization) suggest that both processes may occur but that the latter process is dominant.

(c) The System: Acetic Acid – Chloroform – Water

In this system (disregarding the solutions with very high concentration of water) there are two distinct regions, one of positive heat of mixing and one of negative heat of mixing. The region of negative heat of mixing is relatively small, which indicates that the interaction between water and acetic acid and between water and chloroform is more important than that between chloroform and acetic acid. Furthermore, the interaction between chloroform and water also leads to a positive heat of mixing. From Fig. 1 it can be seen that in the ternary system there occurs a maximum heat of mixing, which is larger than any in the contiguous binary systems. This maximum is mainly due to the chloroform–water interaction.

Of particular interest is the line of zero heat of mixing. This line coincides with the line of zero volume of mixing, as found by Campbell, Kartzmark, and Gieskes (13). In the ternary system, therefore, there appears to be a series of solutions where pseudo-ideality exists, i.e., the opposing interactions are such that the effects of these interactions on the values of the excess functions are balanced to give ideal values of the excess functions. Nevertheless, we consider that the coincidence of the $H^E = 0$ and $V^E = 0$ line is purely accidental. It does not mean that $G^E = 0$ and $C_p{}^E = 0$ for these concentrations, and all the evidence seems to point to $G^E > 0$ over the entire region of concentration. Hence, the pseudoideality is at best partial.

2. Heat Capacities

From the measurements by Neumann (7) and by ourselves, it seems that the value of the excess heat capacity is positive over the entire region of concentration of the ternary system. The error involved in the determination of specific heat is usually less than 0.5% but this has a large effect on the calculated value of the excess heat capacity. Nevertheless, from Fig. 2 it can be seen that the curve of the excess heat capacity ($C_p{}^E[x]$) is approximately symmetrical. The lines of equal excess heat capacity, as represented in Fig. 3, are of an approximate nature. There is no doubt, however, that the lines will follow the pattern of those in Fig. 3. The consequence of the positive value of $C_p{}^E$ is that both H^E and S^E will increase in value with increasing temperature over the entire range of concentration. The line of zero heat of mixing will shift to the side of the binary system: acetic acid – chloroform, with increasing temperature.

ELECTRON SPIN RESONANCE SPECTRA OF ^{15}N-CENTERED RADICALS AT LOW TEMPERATURES

I. THE RADICAL NH_3^+ TRAPPED IN NH_4ClO_4[1]

M. FUJIMOTO[2] AND J. R. MORTON

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received October 8, 1964

ABSTRACT

The electron spin resonance spectrum of NH_3^+ trapped in ammonium perchlorate (95% ^{15}N) was examined at 300 °K, 77 °K, and 4 °K. The spectra are interpreted in terms of π-radical theory, and demonstrate the different stages in the freezing-out of the rotational motion of the ion.

INTRODUCTION

Interesting changes (1, 2) in the electron spin resonance (e.s.r.) spectra of the trapped radicals $NH_2^+SO_3^-$ and $NHSO_3^-$ on cooling the host crystals to 77 °K prompted this reexamination of the spectra (3, 4) of NH_3^+ trapped in NH_4ClO_4. It was anticipated that changes in the hyperfine interactions of the protons and the nitrogen nucleus on cooling to 77 °K and 4 °K would elucidate the different stages (4) in the freezing-out of the rotational motion of the ion.

EXPERIMENTAL

In order to obtain improved resolution ammonium perchlorate enriched in $^{15}NH_4ClO_4$ to 95% was purchased from Merck, Sharp, and Dohme Co. Ltd., Montreal. Single crystals of this material, grown by slow evaporation of aqueous solutions, were irradiated with 1.3 MeV ^{60}Co γ-rays in order to generate in them the $^{15}NH_3^+$ radicals. The latter are stable indefinitely at room temperature (4), but before taking low-temperature spectra it was necessary to monitor the decay (3) of the ClO_3 radicals, also formed on irradiation.

Crystals of ammonium perchlorate are orthorhombic (5), and the unit cell, which contains four molecules of NH_4ClO_4, has dimensions $a = 9.20$ Å, $b = 5.82$ Å, $c = 7.45$ Å in the space-group *Pnma*. The unit-cell directions of the crystals were identified with a polarizing microscope, and correlated with the above axes by means of X-ray diffraction photographs. The crystals usually formed hexagonal tablets on {001}, and were elongated along [010].

Electron spin resonance spectra of the irradiated crystals were obtained with a Varian V-4502 spectrometer and V-4012A magnet system. Magnetic field measurements were carried out with the aid of a Varian F-8A proton fluxmeter and a Computer Measurements Company model 707B frequency counter. Low temperature spectra were obtained with Dewar vessels fitting into the V-4532 cavity. The liquid nitrogen Dewar was a quartz vessel of conventional design; the liquid helium Dewar was similar to that described (6) by Hornig and Hyde.

RESULTS

The spectra of NH_3^+ trapped in NH_4ClO_4 crystals at 300 °K have already been described by Cole (3), who advances convincing evidence for the planarity of the radical. The three protons are equivalent for all orientations of the crystal in the magnetic field, and their hyperfine tensors are diagonal in the crystallographic *abc* axis system, as is that of the nitrogen nucleus. The spectrum for the orientation H_0 parallel to the *a*-axis is shown in Fig. 1*a*. The ^{15}N nucleus has spin 1/2 and a higher magnetogyric ratio ($\gamma_{15} = 4.315$) than the normal isotope (^{14}N, spin 1, $\gamma_{14} = 3.076$) and so the spectra of $^{15}NH_3^+$ are somewhat simpler than those of $^{14}NH_3^+$. The principal values of the proton and ^{15}N tensors are given in Table I.

[2]*Visiting scientist, on leave from Department of Physics, University of Manitoba, Winnipeg, Manitoba.*

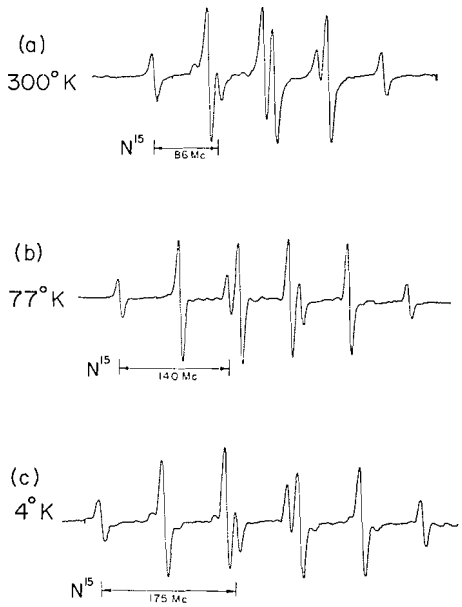

FIG. 1. First derivative electron spin resonance spectra of $^{15}NH_3^+$ in γ-irradiated ammonium perchlorate, H_0 parallel to a-axis, at (*a*) 300 °K, (*b*) 77 °K, and (*c*) 4 °K.

As will be apparent from Fig. 1*b* the spectra obtained at 77 °K differed in some respects from those obtained at room temperature. A large increase in the ^{15}N hyperfine interaction for H_0 parallel to the a-axis was accompanied by a decrease in its value for H_0 parallel to b or c. Moreover, two magnetically distinguishable sites for the radical were apparent when H_0 explored the ac plane. The three protons in the radical remained equivalent at all orientations, however.

TABLE I

Hyperfine tensors for $^{15}NH_3^+$ at 300 °K

Nucleus	Tensor	Principal values*	Principal directions†
Protons	73.3 0.0 0.0 0.0 73.2 0.0 0.0 0.0 69.6	73.3 73.2 69.6	(1.000, 0.000, 0.000) (0.000, 1.000, 0.000) (0.000, 0.000, 1.000)
^{15}N	85.7 0.0 0.0 0.0 73.2 0.0 0.0 0.0 69.6	85.7 73.2 69.6	(1.000, 0.000, 0.000) (0.000, 1.000, 0.000) (0.000, 0.000, 1.000)

*Units of all tensors are Mc/s.
†Direction cosines refer to the *abc* axis system.

At 4 °K the spectra were much more difficult to interpret, because the $^{15}NH_3^+$ radical was no longer rapidly rotating in the crystal. Hyperfine interactions with four non-equivalent spin 1/2 nuclei were apparent, and, in addition, two sites could be distinguished as H_0 explored the ac and bc planes. The spectrum for H_0 parallel to the a-axis is shown in Fig. 1*c*, and it will be seen that ^{15}N hyperfine interaction has increased still further, to 175 Mc/s. At this orientation, which is almost (Fig. 2) perpendicular to the radical plane,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the inequivalence of the three protons is not resolvable. It was quite impossible to determine the off-diagonal elements α_{ac} and α_{bc} ($\alpha_{ab} = 0$) for the three proton and the ^{15}N hyperfine tensors. Instead, Table III shows the diagonal elements only, that is, the parameters obtained for the orientations H_0 parallel to a, b, and c. Even here some difficulty was experienced, particularly for the orientation H_0 parallel to b. An ^{15}N interaction of approximately 15 Mc/s, together with the normal line-width of 10 Mc/s, led to an ill-resolved spectrum and errors of ± 5 Mc/s in the hyperfine constants. In assigning to the various nuclei the eight hyperfine constants obtained for the orientations H_0 parallel to b and c, use was made of the assumption that the three proton interactions should have the same diagonal sum (within experimental error).

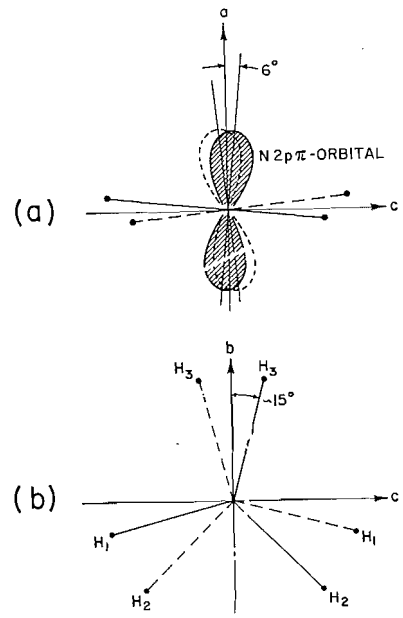

FIG. 2. Orientation of NH_3^+ radical in ammonium perchlorate crystal, projection along (*a*) *b*-axis, (*b*) *a*-axis.

DISCUSSION

Interest in the radical NH_3^+ arises from the fact that NH_3^+ and the isoelectronic methyl radical are the prototypes of a large number of π-electron radicals. The methyl radical has been found to be "planar or very nearly planar" (7), although this had not been anticipated theoretically (8, 9). Radicals derived from methyl, including (10, 11) $CH_2(CO_2H)$ and $CH(CO_2H)_2$ and many others (12), have been trapped in single crystal matrices and studied by e.s.r. The proton and ^{13}C hyperfine interactions are consistent (13, 14) with a planar configuration for these radicals. The radical NH_3^+ was first studied in 1961 (3), and since then detailed calculations (15) of the *isotropic* nitrogen and proton hyperfine interactions have confirmed its planar configuration. It will be shown that the present determination of the *anisotropic* proton interaction in NH_3^+ at 4 °K is consistent with theoretical predictions (2, 13).

It was clear from the results of previous workers (3, 4) that the NH_3^+ radical in NH_4ClO_4 was "tumbling" in the lattice at room temperature, there being only a slight preference for the crystallographic *a*-axis as an axis of rotation. At 77 °K the present

TABLE III

Hyperfine tensor components for $^{15}NH_3^+$ at 4 °K

Nucleus	Magnetic field parallel to: *a*	*b*	*c*
H_1	81.5±0.5	120±5	25±2
H_2	81.5±0.5	70±5	71±2
H_3	81.5±0.5	20±5	129±2
^{15}N	175.0±0.5	15±5	41±2

results indicate that the motion is largely restricted to rotation about an axis perpendicular to the proton plane (in *ac*, ±6° from *a*), the rotation rate being rapid compared to anisotropic electron–proton hyperfine interactions of about 10^8 s^{-1}. The spectra obtained at 4 °K clearly demonstrated that at this temperature the rotation rate about the axis perpendicular to the proton plane had slowed to very much less than 10^8 s^{-1}.

The principal values of the proton tensors cannot be obtained from Table III. However, it will be seen that the proton interaction parameters for H_0 parallel to *b* are almost equal to those for H_0 parallel to *c*. This must mean that, within the overall experimental error, the radical is symmetrically oriented with respect to the *b* and *c* axes, as, for example, in Fig. 2*b*. The smallest (numerically) principal value of an α-proton tensor in a π-electron radical is (11) parallel to the X—H bond, and the largest (numerically) is perpendicular to the X—H bond but in the radical plane. Neglecting the fact that the perpendicular to the radical plane is 6° from *a*, and assuming that the radical is planar, the largest and smallest principal values of the H_1 and H_3 tensors can be estimated from the data of Table III by a 15° rotation of axes about the *a*-axis. The "principal values" so obtained were 127 and 18 Mc/s for H_1, 137 and 12 Mc/s for H_3. The reasonable agreement obtained suggests the following principal values for the proton tensors in NH_3^+: (−)15 ± 5 Mc/s parallel to the N—H bond; (−)83 ± 2 Mc/s perpendicular to the radical plane; and (−)132 ± 5 Mc/s perpendicular to the N—H bond in the radical plane. The negative sign given these parameters was not determined experimentally but is required theoretically (11, 13). The isotropic proton interaction is therefore (−)77 ± 7 Mc/s and the anisotropic (traceless) tensor has principal values +61, −6, and −55 Mc/s, corresponding to the above principal directions. The anisotropic proton interactions in NH_3^+ are thus considerably larger than those expected (12) from protons attached to a carbon-centered π-radical. However, this has been predicted theoretically (2, 13) and, for example, with a bond length of 1.0 Å, and effective nuclear charge 3.7, the calculated (2) principal values for the corresponding principal directions are +63, −11, and −53 Mc/s.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The ^{15}N hyperfine interaction in $^{15}NH_3^+$ is similar to that reported (2) for other nitrogen-centered π-radicals, when the conversion factor $\gamma_{15}/\gamma_{14} = 1.403$ is applied. The very large principal value for H_0 perpendicular to the radical plane is typical (2), and the apparent deviation from axial symmetry is due, in part, to this large principal value, which has a component along c but not along b.

ACKNOWLEDGMENT

The authors are grateful to Dr. L. D. Calvert for checking the unit-cell dimensions of the crystals by means of X-ray diffraction photographs.

GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART XIII. THE VOLATILE OIL OF THE LEAVES OF JUNIPERUS HORIZONTALIS MOENCH[1]

F. M. COUCHMAN[2] AND E. VON RUDLOFF

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received November 25, 1964

ABSTRACT

The neutral leaf oil of the creeping juniper from the Prairies was analyzed by gas–liquid chromatography. *d*-Sabinene (36.5%) was found to be the major constituent, and smaller amounts of *d*-limonene (17.5%), *p*-cymene (3.0%), *d*-α-pinene (1.6%), γ-terpinene (0.4%), *d*-terpinen-4-ol (4.6%), linalool (0.8%), citronellol (0.8%), γ-cadinene (1.3%), *l*-elemol (3.8%), α-cadinol or γ-eudesmol (1.6%), and impure α-cyperone (3.9%) were isolated. α-Thujene (3.0%), camphene (0.2%), β-pinene (0.3%), myrcene (3.0%), β-phellandrene (0.2%), terpinolene (0.1%), 2,4-(8)-*p*-menthadiene (0.1%), methyl citronellate (0.4%), and geraniol (0.2%) were tentatively identified. The composition of this oil closely resembles that of Rocky Mountain juniper leaves. A small amount of the oil from a hybrid of these two species was analyzed and the possibility of detecting hybridization by analysis of the leaf oil is discussed.

The creeping juniper (*Juniperus horizontalis* Moench) is widely distributed in Canada, being found from coast to coast. It is ordinarily distinguished by its low creeping habit of growth and radiating branches. Like the Rocky Mountain juniper, it has no commercial value except for ornamental planting and numerous forms have been developed. In Parts IX and XI of this series (1, 2) the analysis of the volatile oils of the leaves of savin juniper (*J. sabina* L.) and Rocky Mountain juniper (*J. scopulorum* Sarg.), respectively, were described. This publication deals with a similar analysis of the leaf oil of the creeping juniper. No reference in the chemical literature dealing with this oil could be found.

A large batch of leaves of mature plants found near Saskatoon, Saskatchewan, was steam distilled to give a pale-yellow oil (0.89% yield) having n_D^{30} 1.4763 and $[\alpha]_D^{30}$ +36.76°. The oil was prefractionated into hydrocarbons and oxygenated compounds by elution chromatography on modified silicic acid as described previously (2). These fractions were subdivided into mono- and sesqui-terpenes, by preparative gas–liquid chromatography (g.l.c.) on short columns. The four fractions thus obtained were fractionated further into single components by preparative g.l.c. All major and some minor constituents were isolated and characterized by their physical properties. Several trace components were tentatively identified by their relative retention times (r.r.t.). The percentage composition (Table I, column A) was determined by measurement of the area under the peaks (triangulation method, average of duplicate) as recorded in linear temperature-programmed runs (Fig. 1A). The components identified by r.r.t. only are shown in parentheses. The error of the method was discussed before (2). The numbering of peaks is the same as used for the oil from Rocky Mountain juniper (2).

Whereas it is accepted that some of the chemical components of conifer wood can be used for taxonomic correlations (3–7), it has only recently been demonstrated that the same may hold for the components of conifer leaf oils (1, 8). Comparison of the composition of the leaf oils from Savin (1), Rocky Mountain (2), and creeping juniper shows that all three contain *d*-sabinene as a major component. Also, common to all three junipers

are nearly all monoterpene hydrocarbons and methyl citronellate, terpinen-4-ol, citronellol, geraniol, the isomeric cadinenes, elemol, and α-cadinol or γ-eudesmol. However, the oil of creeping juniper has a noticeably higher content of limonene and *p*-cymene and contains α-cyperone which was not found in the other two oils. The many similarities confirm a close correlation between chemical composition (qualitative) and botanical relationship, all three junipers belonging to the subgenus Sabina (9). Furthermore, the lack of sabinyl acetate (the major constituent of the oil of Savin) in the leaf oils of creeping and Rocky Mountain junipers indicates a close genetic relationship between these two species. The absence of safrole from the oil of creeping juniper in contrast to the presence of 1.5 to 4% in that of the Savin juniper is noteworthy.

The creeping juniper is known to hybridize extensively with Rocky Mountain juniper in the Banff area (10). Since it was found that the oil of Rocky Mountain juniper plants from different localities (2) did not differ qualitatively nor to any marked extent quantitatively, it was of interest to determine if the oil from a hybrid would show any specific chemical differences. A small amount of the oil from a creeping juniper with considerable Rocky Mountain juniper character (the plant selected was a 2 ft high mature female) was analyzed by linear temperature-programmed runs (see Fig. 1B and Table I, column B). Comparison shows that the oil from the hybrid contains all components except the trace peaks *A*, 15, 24*b*, and 32. Also, peaks *B*, 12, 24, and 25 were recorded in trace amounts only, whereas these were present in somewhat larger amounts in the oil of creeping juniper

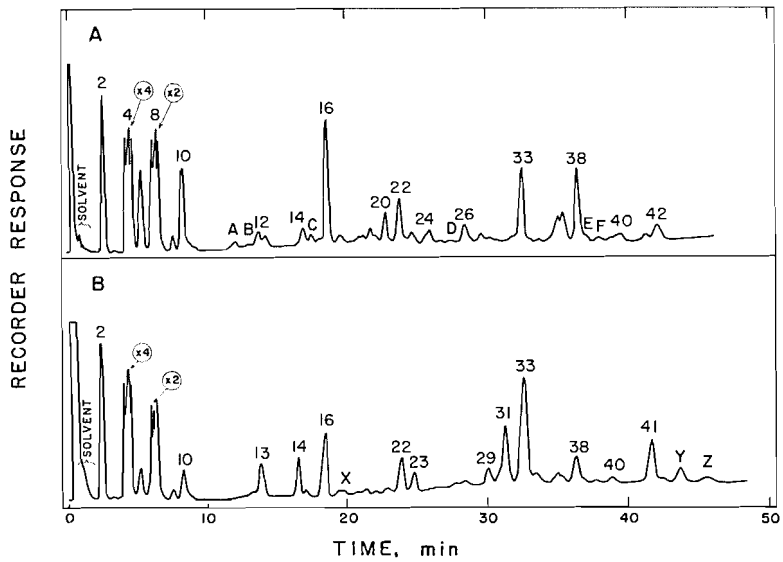

FIG. 1. Gas chromatogram of the volatile oil of (A) creeping juniper and (B) hybrid leaves (6 ft × 3/16 in. o.d. polyethylene glycol 20M column, temperature programmed from 65 to 210 °C at 4° per min).

and peak 25 was recorded in 1.8 to 4.3% amount in the oil of Rocky Mountain juniper. Three new components, *X*, *Y*, and *Z*, were recorded and components 13 (isothujone), 14 (linalool), 23 (unidentified C_{15} hydrocarbon), 29 (unidentified), and especially 31 (unidentified) and 41 (acetate II) were present in considerably larger amounts. The reversal of the relative amounts of components 41 and 42 may be significant since Rocky Mountain juniper leaves contained about 5% of component 41 and only about 1% of component 42. These differences indicate that a direct comparison of chromatograms of the leaf oils of junipers, and perhaps also other conifers, may be helpful in taxonomic classifications. However, many individual hybrids as well as parent plants will have to be investigated to substantiate this observation.

EXPERIMENTAL

The g.l.c. techniques used have already been described in detail (1, 5). An F & M model 500 chromatograph (F & M Scientific Corp.) was used for analytical runs using linear temperature-programming (2), and preparative runs were carried out with an Aerograph "Autoprep" model 700. Optical rotations were measured on solutions in chloroform (1 to 5%) at room temperature. Infrared spectra were recorded on a Perkin–Elmer model 21 double-beam spectrophotometer as liquid films between sodium chloride plates. Individual components were identified by comparison of their infrared spectra and relative retention times.

Materials

The foliage of the creeping juniper was obtained from mature plants growing near the South Saskatchewan River approximately 10 miles south of Saskatoon. Woody branches and berries were removed and the residual leaves (6.56 kg) were steam distilled for 3 h. The distillate was taken up in ether, washed with saturated $NaHCO_3$ solution and water, and dried (Na_2SO_4), and the ether evaporated. The residual oil (58.5 g, 0.89%) had n_D^{30} 1.4763, $[\alpha]_D^{30}$ +36.76° (*c*, 2.57). Reference compounds were those obtained previously (1, 5). The liquid phases used in g.l.c. columns were commercial products. The foliage (32 g) of the hydrid juniper was obtained on the south slope of the eastern portion of Tunnel Mountain, Banff, Alberta. Steam distillation gave a light-yellow oil (0.35 g), n_D^{25} 1.4775, $[\alpha]_D^{25}$ +38.2°.

Analytical Chromatograms

Linear temperature-programmed chromatograms were obtained with 2–3 μl aliquots of oil using 6 ft × 3/16 in. o.d. polyethylene glycol (PEG 20M) (Fig. 1) or Apiezon N (A-N) columns. The percentage composition was determined by measurement of the area under each peak (triangulation method) on duplicate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

chromatograms obtained on the PEG 20M column (see Table I). The values for those components which were unresolved on this column (e.g. α-thujene and α-pinene) were obtained from runs on other columns (1, 2).

The r.r.t. values and purity of isolated components were determined on PEG 20M, A-N, polyethylene glycol adipate polyester (APEG), rapeseed oil (RO), and ethylene glycol bis-(propionitrile) (EGPN) columns under the conditions (isothermal) described previously (1, 11). The r.r.t. values of monoterpenes were measured relative to limonene, oxygenated monoterpenes and sesquiterpenes relative to camphor, and oxygenated sesquiterpenes relative to cedrol (see Table I).

Prefractionation

Silicic acid was impregnated with polyethylene glycol (Carbowax 20M) as described by Kugler and Kovats (12).

Creeping juniper leaf oil (22.02 g) was dissolved in petrol (Skellysolve B, b.p. 60–80 °C) (50 ml) and poured onto a previously prepared column of deactivated silicic acid (200 g). Elution with Skellysolve B (1 000 ml) gave a hydrocarbon fraction (14.61 g), while elution with methanol (1 000 ml) yielded oxygenated terpenes (9.85 g). Aliquots (500 μl) of the hydrocarbon mixture were injected onto a 3 ft $\times$ 3/8 in. o.d. SE-30 silicone polymer (25% on Chromosorb W, 40–60 mesh) column, which was nonlinearly programmed from 80 to 150 °C in 20 min. The monoterpenes were eluted within 11 min and collected as a single fraction in an ice-cooled collection flask. The sesquiterpenes were collected similarly as a second, unresolved fraction. Aliquots (100 μl) of the oxygenated terpenes were fractionated in the same manner into mono- and sesqui-terpenes, programming the same column from 120 to 200 °C in 20 min.

Monoterpene Hydrocarbons

Preparative g.l.c. of the monoterpene hydrocarbon fraction (repeated injections of 100 μl aliquots) on a 20 ft $\times$ 3/8 in. PEG 20M column programmed from 100 to 170 °C in 40 min resulted in the isolation of components 2, 4, 8, 9, and 10. Component 2 was found to be a mixture of α-pinene and tentatively identified α-thujene (r.r.t. 0.35 and 0.31 on the A-N and EGPN columns respectively). Component 4 was found to be sabinene, n_D^{26} 1.4656, $[\alpha]_D^{26}$ +90.84° (*c*, 2.6), containing a small amount of β-pinene (r.r.t. = 0.57 on EGPN column). The r.r.t. values and spectral properties showed component 8*a* to be *d*-limonene, n_D^{26} 1.4698, $[\alpha]_D^{26}$ +95.59° (*c*, 2.4); component 9 to be γ-terpinene, n_D^{26} 1.4713; and component 10 to be *p*-cymene, n_D^{26} 1.4820. Components 6, 8*b*, 11*a*, and 11*b* were obtained only impure, but the r.r.t. values showed them to correspond to myrcene, β-phellandrene, terpinolene, and 2,4-(8)-*p*-menthadiene respectively.

Oxygenated Monoterpenes

Aliquots (100 μl) of the mixture of oxygenated monoterpenes were chromatographed on a 6 ft $\times$ 3/8 in. PEG 20M column (100 to 210 °C in 35 min). Components 16*a* and 22*b* were isolated almost pure and were found to correspond to terpinen-4-ol, n_D^{27} 1.4747, $[\alpha]_D^{28}$ +14.81° (*c*, 4.57), and citronellol, n_D^{27} 1.4593, $[\alpha]_D^{28}$ +11.47° (*c*, 1.57), respectively. Component 14, n_D^{27} 1.4588, $[\alpha]_D^{27}$ +44.09° (*c*, 0.98), corresponded to linalool with a carbonyl impurity. The remaining oxygenated monoterpenes could not be identified.

Sesquiterpene Hydrocarbons

Preparative g.l.c. on the 20 ft $\times$ 3/8 in. o.d. PEG 20M column (30 μl aliquots, 150 to 205 °C in 50 min) gave component 22*a* in a fairly pure state. The infrared spectrum of this component corresponded to γ-cadinene; n_D^{26} 1.5068. Components 18*b*, 19*a*, 23, and 24 were not obtained in sufficient amount to permit characterization. Component 20 had an infrared spectrum similar to cadinene I of the oil of *J. scopulorum*.

Oxygenated Sesquiterpenes

Aliquots (50 μl) of the last fraction were chromatographed on the 6 ft $\times$ 3/8 in. o.d. PEG 20M column (160 to 220 °C in 30 min) and components 33, 36, and 38 were isolated in a fairly pure state. Component 33 corresponded to *l*-elemol, n_D^{28} 1.4955, $[\alpha]_D^{24}$ −14.00° (*c*, 0.60). Component 36 had the r.r.t. of α-cadinol and γ-eudesmol, but since these two alcohols cannot be distinguished by their infrared spectra (13), the identification is uncertain. Component 38 had n_D^{26} 1.5109, $[\alpha]_D^{24}$ +36.66° (*c*, 0.06) and its infrared spectrum was very similar to that of α-cyperone, although it contained an alcoholic impurity. Since δ-cadinol has the same r.r.t. on the PEG 20M column it could be the contaminant. Component 41 appeared to be the same as acetate II from the oil of Rocky Mountain juniper, but the presence of relatively large amounts of component 42, which may be an isomer, prevented isolation in the pure state.

ACKNOWLEDGMENTS

We wish to thank Mr. M. Granat for technical assistance and Mr. W. C. Haid for recording the infrared spectra.

THE Hg 6($^3P_1$) PHOTOSENSITIZATION OF CHLORODIFLUOROMETHANE

M. G. Bellas, O. P. Strausz, and H. E. Gunning
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received December 7, 1964

ABSTRACT

The reaction was studied in a circulatory apparatus under a variety of conditions. The sole primary process occurring is C—Cl bond scission. The Cl atoms formed in the primary step, through an abstractive attack on the substrate, generate chlorodifluoromethyl radicals ($CF_2Cl\cdot$). All principal reaction products, CF_2H_2, CF_2Cl_2, CF_2ClCF_2Cl, CF_2HCF_2H, and CF_2HCF_2Cl, can be accounted for by the combination–disproportionation reactions of the $CF_2H\cdot$ and $CF_2Cl\cdot$ radicals. The observed strong dependence of the primary quantum yields on the incident light intensities has been ascribed to a rapid substrate-reforming step.

INTRODUCTION

In mercury photosensitization only methyl chloride has been investigated (1, 2) in detail among the alkyl chlorides. With the higher homologs, only the primary processes have been examined by the monoisotopic sensitization technique (2). At room temperature the sole primary step occurring with methyl chloride, and probably with the higher homologs as well, is the scission of the C—Cl bond with a quantum efficiency of unity.

Our interest in the present study was to establish the mode of primary decomposition of the chlorodifluoromethane molecule. Probable primary routes are: (*a*) C—Cl bond rupture, as with the alkyl chlorides, giving rise to difluoromethyl radicals and (*b*) a molecular split, to form difluorocarbene and HCl. In either case the system could serve as a useful source of the corresponding radicals, and in addition provide information on the effect of fluorine substitution on the primary alkyl chloride reactions.

EXPERIMENTAL

Because of the difficulties associated with calomel formation in the reactions of Hg 6($^3P_1$) atoms with chlorinated hydrocarbons, this reaction was studied in a circulating system, described elsewhere (3), at cell temperatures of 120° and above. Since, under these conditions, calomel does not deposit on the cell face, a constant light intensity was ensured during the entire illumination period.

Two mercury resonance lamps were utilized in all experiments described in the present study. The first source of Hg 2 537 Å resonance radiation was a Hanovia SC-2537 quartz discharge tube of helical shape, and the second was a Hanovia No. 87A45 U-shaped discharge tube, fashioned of Vycor 7910. A Vycor 7910 filter for the first source, and the envelope of the lamp itself for the second, served to remove the 1 849 Å resonance line. The lamps were thermostated at 25.1 ± 0.1 °C. The warm-up period was always at least 90 min. Lamp intensities were determined using propane actinometry, and the nitrous oxide – paraffin system. The values obtained by the two different actinometers agreed within 1%.

The reactant was circulated for 5 min prior to irradiation to allow mercury vapor–liquid equilibration. At the conclusion of the irradiation the fractions volatile at −183 °C were analyzed by gas chromatography (g.c.) on a 28 ft di-*n*-butyl maleate column (I). The following compounds could be resolved: difluoromethane, dichlorodifluoromethane, 1,2-dichlorotetrafluoroethane, *sym*-tetrafluoroethane, 1-chloro-1,1,2,2-tetrafluoroethane, 1,3-dichlorohexafluoropropane, 1,1,2,2,3,3-hexafluoropropane, and 1-chloro-1,1,2,2,3,3-hexafluoropropane, as well as the substrate, chlorodifluoromethane. In the experiments with added HCl, the procedure was similar to that described above.

In the experiments with added methanethiol products noncondensable at −138.7 °C were removed by means of a Toepler pump and analyzed on column I. This fraction consisted of CF_2H_2, CF_2HCl, CF_2Cl_2, CF_2HCF_2H, CF_2HCF_2Cl, and CF_2ClCF_2Cl. The material condensed at −138.7 °C was analyzed by g.c. using an 8 ft tri-*o*-tolyl phosphate column at room temperature. CH_3SH, CF_2HSCH_3, and CH_3SSCH_3 could be resolved. In the flow experiments with added nitric oxide, carried out in a single-pass system (4), the fraction condensable at −117.0 °C was trapped and analyzed by g.c. using a 10 ft polyethylene glycol column with temperature programming. It consisted of nitrosodifluoromethane and difluoroformaldeoxime.

The products were identified by their g.c. retention times, as well as by mass spectrometric analysis of the isolated peaks. In the case of CF_2HNO and $CF_2{=}NOH$ infrared absorption spectra were also obtained. The gas chromatograph was calibrated using pure samples.

The gases were obtained from Matheson of Canada. The chlorodifluoromethane, with a stated purity of 99.9% minimum, was further purified by preparative g.c. on two different columns, a 22 ft dimethyl sulfolane column, and column I, both operated at 0 °C, after which no impurities could be detected. The nitric oxide, 99.0% minimum purity, was triply distilled through liquid oxygen prior to use. Mass spectrometric analysis showed it to be at least 99.9% pure. The methanethiol and the hydrogen chloride, both with a stated purity of 99.0% minimum were purified by low temperature distillation. Mass spectrometric analysis revealed no detectable impurities.

RESULTS AND DISCUSSION

CF_2HNO and $CF_2{=}NOH$ were the only products found in single-pass flow experiments, carried out at room temperature, using 12 Torr substrate pressure with 2 mole % added nitric oxide. These results, coupled with the fact that hydrogen and hydrogen chloride were not detected as products in the uninhibited runs, indicate that C—Cl bond scission is the only primary process occurring in the reaction. Only two modes involving a C—Cl split can be written.

[1*a*] $$Hg^* + CF_2HCl \rightarrow CF_2H + Cl + Hg$$

[1*b*] $$Hg^* + CF_2HCl \rightarrow CF_2H + HgCl.$$

The quantum yield of [1*b*] has been shown to be $\leqslant 0.13$ mole/einstein (5), while the combined quantum yield for [1*a*] and [1*b*] will be shown later in this paper to have a value $\geqslant 0.94$.

The main products of the uninhibited reaction were CF_2H_2, CF_2Cl_2, CF_2ClCF_2Cl, CF_2HCF_2H, CF_2HCF_2Cl, and calomel which could not be measured under the experimental arrangements. Consequently, to account for the CF_2Cl-containing products, reactions must be considered which lead to CF_2Cl radicals since these species are not formed in the primary process. The only possibilities are

[2] $$CF_2H + CF_2HCl \rightarrow CF_2H_2 + CF_2Cl$$

[3] $$Cl + CF_2HCl \rightarrow HCl + CF_2Cl,$$

the latter being the more important since abstraction by Cl atoms have been shown to be more rapid than abstraction by radicals (6). Thus the E_a for H-atom abstraction from CH_3Cl by Cl atoms is 3.1 kcal/mole (6, 7), whereas for abstraction by CH_3 radicals it is 9.4 kcal/mole (8). The observation that $\Phi(CF_2H_2) \ll \Phi(CF_2Cl)$ (cf. Table II) indicates that reaction [3] rather than [2] is the predominant source of CF_2Cl radicals. The C_2 products can be accounted for by the following combinations:

[4] $$CF_2H + CF_2H \rightarrow CF_2HCF_2H$$

[5] $$CF_2Cl + CF_2Cl \rightarrow CF_2ClCF_2Cl$$

[6] $$CF_2H + CF_2Cl \rightarrow CF_2HCF_2Cl.$$

Although arguments have been presented for the occurrence of reaction [3], no measurable amount of HCl could be found. It appears that if HCl is formed it is consumed rapidly in the system. This is expected since methyl radicals are known to react rapidly with HCl (9), with $E_a = 5$ kcal/mole and $\log A = 9.0$ (l mole s) (7). The rate for difluoromethyl radicals should not be greatly different.

The data appearing in Fig. 1 support this conclusion. The increase in $\Phi(CF_2H_2)$ with time indicates that some of the CF_2H_2 product is formed in a secondary reaction such as

[7] $$CF_2H + HCl \rightarrow CF_2H_2 + Cl.$$

**Small quantities of* HCl *are extremely difficult to detect; consequently they could have been lost in the analysis.*

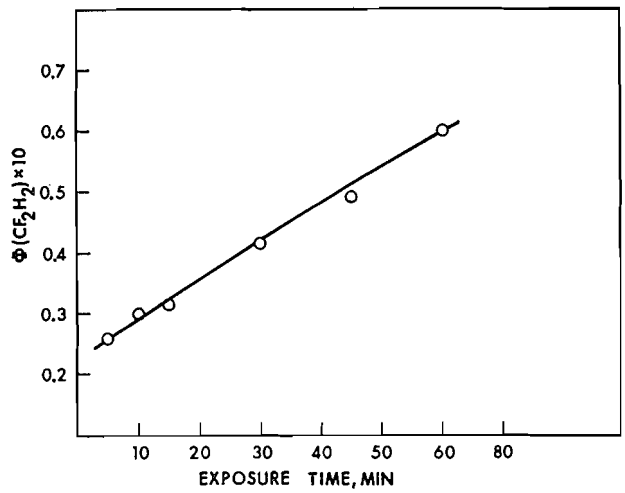

FIG. 1. Quantum yield of difluoromethane as a function of exposure time $P(CF_2HCl) = 25$ Torr. $T = 120$ °C.

Further support for this argument comes from experiments performed with added HCl, for which the data are summarized in Table I. It is seen that with increasing amounts of added HCl, $\Phi(CF_2H_2)$ increases and $\Phi(C_2F_4H_2)$ simultaneously decreases, owing to the more efficient competition of [7] with the recombination step [4].

TABLE I

Quantum yields* of products as a function of mole % added HCl in the decomposition of chlorodifluoromethane

	Φ,† mole/einstein		
Product	0 mole % HCl	0.72 mole % HCl	4.15 mole % HCl

$CF_2H\cdot$‡	0.66	0.57	0.62

*Corrected for competitive quenching.
†Substrate pressure = 27.7 Torr; exposure time = 5 min; cell temperature = 120 °C; light intensity = 3.16×10^{15} quanta/s.
‡The contribution of the C_3 products was neglected (see text).

To examine the effect of incident light intensities on the reaction, three runs were performed at different intensities, covering a tenfold range. The data in Table II show a large change in the overall quantum yield. Thus $\Phi(CF_2H)$ and $\Phi(CF_2Cl)$ increased from 0.33 and 0.19 at 8.9×10^{15} quanta/s to 0.74 and 0.32 at 9.8×10^{14} quanta/s, respectively. This intensity effect can be attributed largely to an efficient back reaction of Cl atoms with difluoromethyl radicals.

[8] $$CF_2H + Cl \rightarrow CF_2HCl.$$

This indicates that although [3] is faster than [2], it is still not sufficiently rapid to suppress [8], even when assisted by Cl-atom scavenging by mercury atoms:

[9] $$Hg + Cl + M \rightarrow HgCl + M.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Alternatively, the cause of the intensity effect could be a decrease in light absorption in the cell at high intensities, owing to the depletion of mercury vapor through [9] and [16]. In the runs with added HCl, there was an increase in the Cl-atom concentration because of the increased importance of reaction [7]. Despite this there was no significant change in the total yield of CF_2H-containing products. From the data in Table I, with pure substrate, $\Phi(CF_2H) = 0.66$ while with 4.15 mole % added HCl (where $\Phi(CF_2H_2)$ increased tenfold), $\Phi(CF_2H) = 0.62$. This indicates that reaction [8] is the predominant factor in the effect of light intensity.

†I_a (quanta/s × 10^{14}) = 9.8; exposure time (min) = 16.2.
‡I_a (quanta/s × 10^{14}) = 33; exposure time (min) = 28.2.
§I_a (quanta/s × 10^{14}) = 89; exposure time (min) = 10.0.
‖Obtained from the following relation, on the assumption that CF_2H_2 arises from the disproportionation reaction of the CF_2H radical (see text), $\Phi(CF_2H) = \Phi(C_2F_4HCl) + 2\Phi(C_2F_4H_2) + 2\Phi(CF_2H_2)$.
¶Obtained from the following relation, on the assumption that CF_2Cl_2 arises from the disproportionation reaction of the CF_2Cl radical (see text), $\Phi(CF_2Cl) = \Phi(C_2F_4HCl) + 2\Phi(CF_2Cl_2) + 2\Phi(C_2F_4Cl_2)$.

The yield of calomel could be estimated roughly, neglecting the minor C_3 products of the reaction (*vide infra*), from the following equation:

$$\Phi(\text{calomel}) = \Phi(CF_2H) + \Phi(CF_2H_2) - \Phi(CF_2Cl) - \Phi(CF_2Cl_2).$$

The Φ(calomel) values in Table II were calculated on this basis.

The values for the rate constant ratio, $k_6/(k_4k_5)^{1/2}$, appearing in the last row of the table were obtained from the product yield ratios and are reasonably close to two, as expected for reactions without activation energy (10).

For personal use only.

The reaction was also examined as a function of substrate pressure in the range, 76 to 313 Torr. From the data given in Table III only a very small dependence on pressure appears. If the back reaction of chlorine atoms with difluoromethyl radicals is truly represented by step [8] the overall quantum yield should rise with increasing substrate pressure. This discrepancy dictates a third body restriction on the recombination step and instead of [8] we should write

[10] $$CF_2H + Cl + M \rightarrow CF_2HCl + M.$$

Additional evidence for the importance of reaction [10] comes from the results of experiments with added CH_3SH which are presented in Table IV. It is seen that upon addition of 4.98 mole % mercaptan, $\Phi(CF_2H_2)$ increases from 0.04 to 0.63. Under these conditions the primary quantum efficiency rises to 0.94. The mercaptan provides an easily abstractable H atom ($D(CH_3S—H)$ = 77 kcal (11)) leading to the rapid reaction:

[11] $$CF_2H + CH_3SH \rightarrow CF_2H_2 + CH_3S.$$

The methanethiol is also an efficient scavenger for Cl atoms and, at relatively low concentrations, completely suppresses secondary calomel formation (5).

TABLE IV

Quantum yields* of products as a function of mole % added methanethiol in the decomposition of chlorodifluoromethane

	Φ,† mole/einstein

CF_2HSCH_3	—	0.26	0.21
CF_2H	0.66‡	0.88	0.94

*Corrected for competitive quenching.
†Substrate pressure = 27.2 Torr; exposure time = 5 min; cell temperature = 120 °C; light intensity = 3.16×10^{15} quanta/s.
‡The additional contribution from CF_2HCF_2Cl must be included. Here $\Phi(CF_2HCF_2Cl) = 0.18$.

The effect of temperature on the reaction was examined in three runs performed at 140, 180, and 230°. The results are given in Table V. With rising temperature $\Phi(CF_2H)$ increases slightly from 0.30 at 140 °C to 0.47 at 230 °C, but $\Phi(CF_2H_2)$ increases nearly threefold. These increases are evidently due to the higher efficiency of the abstraction reactions [2] and [3] at elevated temperatures.

It should be noted that the rate constant ratios, $k_6/(k_4k_5)^{1/2}$, for the present system show no temperature effect, as was reported for the cross recombination reactions of methyl and trifluoromethyl radicals (12). However, from our data a small pressure effect is evident. Thus at 25 Torr pressure these ratios have a mean value of 1.9 (cf. Tables II and VI), but at the higher pressures, 200–313 Torr, their mean value is 2.4 (cf. Tables III and V). It is unlikely that this pressure trend is due to a secondary mercury photosensitized decomposition of the products, in view of the reported quenching efficiency of these compounds.*

In addition to the products already mentioned, $CF_2HCF_2CF_2H$, $CF_2HCF_2CF_2Cl$, and $CF_2ClCF_2CF_2Cl$ are also formed and account for approximately 10% of the product yield. They appeared as very broad peaks under the g.c. column conditions used, and were difficult to measure in short runs. Sufficient quantities of the first two were produced in

*The pertinent quenching cross section values are CF_2HCl = 19.1 Å²; C_2F_4HCl = 14.7 Å²; $C_2F_4Cl_2$ = 23.6 Å²; and $C_2F_4H_2$ estimated to be negligibly small (13).

†Temperature = 140 °C; I_a (quanta/s × 10^{15}) = 8.9.
‡Temperature = 180 °C; I_a (quanta/s × 10^{15}) = 7.2.
§Temperature = 230 °C; I_a (quanta/s × 10^{15}) = 7.2.

high conversion experiments to permit their identification by mass spectrometry. This was not feasible in the case of 1,3-dichlorohexafluoropropane since its yield was small. However, there was only one unidentified peak on the chromatogram and it had a retention time that one would expect for $C_3F_6Cl_2$. Unfortunately, standard samples were not available to check the retention times of these C_3 products.

It is unlikely that these C_3 compounds are formed in secondary quenching reactions at the pressures and conversions used. Since the products formed in largest yield are those arising from radical–radical recombination reactions, it is reasonable to suppose that radical–radical disproportionation reactions might be the source of the C_3 products. A scheme analogous to that proposed by Bowles, Majer, and Robb (14) would certainly explain the experimental findings.

[12] $$2CF_2H \rightarrow CF_2H_2 + CF_2$$

[13] $$2CF_2Cl \rightarrow CF_2Cl_2 + CF_2$$

[14] $$CF_2H + CF_2Cl \rightarrow CF_2HCl + CF_2$$

[15] $$CF_2 + CF_2H \rightarrow C_2F_4H$$

[16] $$CF_2 + CF_2Cl \rightarrow C_2F_4Cl$$

[17] $$C_2F_4H + CF_2H \rightarrow CF_2HCF_2CF_2H$$

[18] $$C_2F_4H + CF_2Cl \rightarrow CF_2HCF_2CF_2Cl$$

[19] $$C_2F_4Cl + CF_2H \rightarrow CF_2HCF_2CF_2Cl$$

[20] $$C_2F_4Cl + CF_2Cl \rightarrow CF_2ClCF_2CF_2Cl$$

It is now evident why a quantum efficiency of unity is never observed for the primary reaction. The importance of a substrate-reforming step [10] has already been discussed. Reaction [14] also reforms substrate. Lastly, CF_2H contributions from the C_3's formed were not considered. Consequently, it is not unreasonable to suggest that the primary step proceeds with perfect quantum efficiency.

From runs performed at very low conversions (reported in Table VI) where the occurrence of reaction [7] can be neglected, a value of about 0.19 can be deduced for the rate of disproportionation to recombination, k_d/k_r, for CF_2H radicals. (The values for C_2H_5 and n-C_3H_7 radicals are, respectively: 0.14 and 0.16 (10).) A similar estimate for CF_2Cl radicals is not feasible since the contribution of

is not known. This reaction must occur to some extent since, as has been shown above, reaction [10] is important. Nonetheless, an upper limit of 0.5 for k_d/k_r for CF_2Cl radicals may be estimated.

The radicals, C_2F_4H and C_2F_4Cl formed in [15] and [16] respectively, owing to their high C—H bond energies, may undergo hydrogen-abstraction reactions with HCl. This would have a slight influence on the $k_6/(k_4k_5)^{1/2}$ ratio. But even the possible occurrence of these reactions would not explain the observed pressure dependence of the rate constant ratios. Thus it would appear that at 25 Torr pressure the recombination reactions [4], [5], and [6] become third body dependent, although this might be spurious owing to the complexity of the overall mechanism.

CONCLUSION

The primary step in the mercury photosensitization of chlorodifluoremethane is C—Cl bond cleavage with a probable quantum efficiency of unity. The CF_2H radicals formed in the primary process and the CF_2Cl radicals formed in the subsequent abstraction by Cl-atoms undergo disproportionation and recombination reactions. The ratio $k_{AB}/(k_{AA}k_{BB})^{1/2}$ for the recombination rate constants of CF_2H and CF_2Cl radicals is 2.4 and the rate constant ratio for the disproportionation to recombination of the CF_2H radicals is 0.19. For the CF_2Cl radicals only an upper limit of ca. 0.5 could be derived for the disproportionation–recombination ratio. The disproportionation reactions of both radicals presumably yield difluorocarbene, which through combination reaction with the monoradicals present gives rise to C_3 products.

HYDROGENOLYSIS BY $AlCl_3$–$LiAlH_4$ OF ETHER SOLUTIONS OF *cis* AND *trans* ISOMERS OF 2,4-DISUBSTITUTED-1,3-DIOXOLANES[1]

B. E. LEGGETTER AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received November 30, 1964

ABSTRACT

Hydrogenolysis by $LiAlH_4$–$AlCl_3$ of ether solutions of the *cis* and *trans* isomers of both 2,4-dimethyl-1,3-dioxolane and 2-ethyl-4-methyl-1,3-dioxolane have been carried out.

The *cis* isomers are hydrogenolyzed respectively about 6.8 times and 10 times faster than are the corresponding *trans* isomers. The ratio of C_2—O_1 to C_2—O_3 bond cleavage in the *cis* isomers is at least 15 to 1 while that for the *trans* isomers is about 1 to 2. Isomerization during the aluminium chloride catalyzed hydrogenolysis is not detectable for the *trans* isomers. Slight indications of isomerization are discerned for the *cis* isomers.

INTRODUCTION

It has been found (1) that electron donor substituents on C_4 of the 1,3-dioxolane ring system cause hydrogenolysis, by a mixture of $LiAlH_4$ and $AlCl_3$ in ether, to occur predominantly at the C_2—O bond remote from the C_4 position (eq. [*a*]). However, it was noted that with the 2,4-disubstituted-1,3-dioxolanes, which are capable of *cis–trans* isomerism, the extent of C_2—O_1 vs. C_2—O_3 cleavage depended upon the proportion of *cis* and *trans* isomers present in the mixture subjected to hydrogenolysis.

IV. (*a*) R = R′ = methyl
(*b*) R = ethyl
R′ = methyl

This paper describes the results of a study of the reductive cleavage by $LiAlH_4$–$AlCl_3$ of ether solutions of the *cis* and *trans* isomers of both 2,4-dimethyl-1,3-dioxolane (I*a*, *b*) and 2-ethyl-4-methyl-1,3-dioxolane (II*a*, *b*).

RESULTS AND DISCUSSION

A configurational assignment for the isomeric 2,4-dimethyl-1,3-dioxolanes has been made by Barker *et al.* (2) by taking advantage of the similarity of the geometry of 2,4-dimethyl-1,3-dioxolane to that of 1,3-dimethylcyclopentane. Since the 1,3-dimethylcyclopentane isomer which has both the higher boiling point and greater density has been assigned the *trans* configuration, the isomeric 2,4-dimethyl-1,3-dioxolane which also has the higher boiling point as well as greater density was considered to be the *trans* isomer. We have accepted this reasonable configurational assignment in the work discussed below.

[1]*Taken from the thesis of B. E. Leggetter, submitted to the Graduate School, University of Alberta, Edmonton, Alberta, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

Preferred Direction of Ring Cleavage of cis and trans Isomers

Equimolar quantities (0.1 mole each) of lithium aluminium hydride, aluminium chloride, and the dioxolane in ether solution were allowed to react for 1 h, a time sufficient to ensure complete hydrogenolysis to the hydroxy ethers (III or IV). Reductions were carried out identically for each of *cis*- and *trans*-2,4-dimethyl-1,3-dioxolane (I*a* and *b*) and *cis*- and *trans*-2-ethyl-4-methyl-1,3-dioxolane (II*a* and *b*). As well reductions were carried out on 0.1 *M* amounts of the equilibrium mixtures of *cis*- and *trans*-2,4-dimethyl-1,3-dioxolane (63%:37% respectively) and of *cis*- and *trans*-2-ethyl-4-methyl-1,3-dioxolane (68%:32% respectively). Results of these experiments (Table I) show that the ratio of C_2—O_1 to C_2—O_3 cleavage in the *cis* isomers is at least 15 to 1 while for the *trans* isomers this ratio is about 1 to 2.

TABLE I

Hydrogenolysis of *cis* and *trans* isomers of 2,4-disubstituted-1,3-dioxolanes by lithium aluminium hydride and aluminium chloride*

		2-*n*-Propoxy-1-propanol	68

*Each hydrogenolysis was carried out in ether solution and allowed to proceed for 60 min.

The Possibility of Isomerization during Hydrogenolysis

We have found that *cis*-2,4-dimethyl-1,3-dioxolane, left at room temperature in ether solution in contact with a catalytic amount of aluminium chloride, in a few hours reaches an equilibrium composition of 63% *cis* and 37% *trans* very much like the equilibrium ratio of 65:35 found for this material by Barker *et al.* (2). The occurrence of isomerization simultaneously with reductive cleavage would give a false impression of the extent of preferential C_2—O bond cleavage of the *cis* and *trans* isomers. To discover whether isomerization does in fact occur during hydrogenolysis, partial reductions were carried out on both *cis*- and *trans*-2,4-dimethyl-1,3-dioxolane. The product from these separate reductions was then analyzed by gas–liquid chromatography (g.l.c.) for the expected reduction products and for the unreduced dioxolane. The latter would reveal the occurrence of any isomerization since the *cis* and *trans* isomers have different retention times. Table II contains the results of these experiments.

It is seen that over the limited ranges of reduction (controlled by the addition of limited amounts of $LiAlH_4$ and $AlCl_3$) the *trans* isomer shows no evidence of conversion to the *cis* isomer. The *cis* isomer isomerizes to the *trans* very slightly, but this occurs only when the molar proportion of aluminium chloride approaches that of the lithium aluminium

7	0.05	0.035	0.03	96	4	Trace (plus)

*The total reaction time was 30 min in all cases. Total recovery was of the order of 80% in all cases. The extent of reduction was limited by a deficiency in both the $LiAlH_4$ *and* $AlCl_3$.
†IIIa is 2-ethoxy-1-propanol; IVa is 1-ethoxy-2-propanol.

hydride. Since isomerization must occur by C_2—O bond breaking, a step which is considered to be rate determining in the hydrogenolysis reaction (1), the above observations might be interpreted as indicating that the irreversible reduction step is much faster than the isomerization step and as long as the hydride is in excess, little or no isomerization takes place. The detection of some conversion of *cis* to *trans* but none of *trans* to *cis* could be due to a greater rate of hydrogenolysis of the *cis* than of the *trans* isomer. Thus the *cis* isomer would reduce as quickly as it was formed, while the *trans* isomer would survive to some extent. Evidence that the *cis* isomer does hydrogenolyze faster than the *trans* isomer is shown in the following work.

Relative Rate of Hydrogenolysis of cis- and trans-2,4-Dialkyl-1,3-dioxolanes

Absolute rates of hydrogenolysis have not yet been obtained due to the failure to find a satisfactory method of following this heterogeneous reaction. However, an approximate value for the *relative rate* of reduction of the *cis* and *trans* isomers was found by use of a competitive reduction of mixtures of these isomers, with the amount of reducing agent limited so as to permit only 10 to 15% reduction. The more reactive isomer should be consumed to a greater extent and yield a greater quantity of its particular proportion of the two isomeric hydroxy ethers. From Table I it is seen that *cis*-2,4-dimethyl-1,3-dioxolane gives a reduction product which has the composition 96% of 2-ethoxy-1-propanol and 4% of 1-ethoxy-2-propanol while the product from the reduction of *trans*-2,4-dimethyl-1,3-dioxolane is composed of 35% of 2-ethoxy-1-propanol and 65% of 1-ethoxy-2-propanol. Since little or no isomerization occurs, then in a competitive and very limited reduction of a mixture of *cis* and *trans* isomers, if X moles of *cis* isomer is reduced for every mole of *trans* isomer, the ratio of 2-ethoxy-1-propanol to 1-ethoxy-2-propanol obtained is $(96X + 35):(4X + 65)$. From a knowledge of the initial amounts of isomers subjected to reduction and a measurement of the relative amounts of the two alcohols in the reduction product, both X and the relative rate of reduction of the isomers can be calculated. The results, shown in Table III, reveal that the *cis* isomer is reduced about 6.8 times faster than is the *trans* isomer. This observation is confirmed by noting that following a partial reduction of an equimolar mixture of the two isomers, the amount of *cis* isomer in the remaining unchanged dioxolanes was diminished to a far greater extent than was the *trans* isomer. Similar studies on the relative rate of hydrogenolysis of the *cis* and *trans* isomers of 2-ethyl-4-methyl-1,3-dioxolane showed the *cis* isomer to be reduced approximately 10 times faster than the *trans*.

TABLE III

The relative rates of hydrogenolysis of the *cis* and *trans* isomers of 2,6-dimethyl-1,3-dioxolane with lithium aluminium hydride and aluminium chloride

Expt. No.	Rates of *cis* to *trans* in starting material	Composition of reduction product, %	Rates of *cis* to *trans* isomer reduced	Relative rate of reduction of *cis* isomer (*trans* = 1)
1	50:50	1-Ethoxy-2-propanol, 11 2-Ethoxy-1-propanol, 89	7.7	7.7
2	50:50	1-Ethoxy-2-propanol, 12 2-Ethoxy-1-propanol, 88	6.6	6.6
3	65:35	1-Ethoxy-2-propanol, 9 2-Ethoxy-1-propanol, 91	11.2	6.1
4	35:65	1-Ethoxy-2-propanol, 17 2-Ethoxy-1-propanol, 83	3.7	6.9
			Average	6.8

In view of the fact that acid-catalyzed equilibration of *cis*- and *trans*-2,4-dimethyl-1,3-dioxolane results in a ratio of *cis* to *trans* of about 65:35, the observation that the *cis* isomer is reduced faster than the *trans* is surprising. However, our results agree with the finding by Salomaa (3) that acid-catalyzed hydrolysis of *cis*-2,4-dimethyl-1,3-dioxolane is about 4 times faster than that of *trans*-2,4-dimethyl-1,3-dioxolane. Any plausible explanation of these results must account for (*1*) the different proportions of products obtained on hydrogenolysis of the *cis* and *trans* isomers, (*2*) the enhanced rate of Lewis acid catalyzed hydrogenolysis and also acid-catalyzed hydrolysis of the *cis* isomer with respect to the *trans* isomer, (*3*) the acid-catalyzed 65:35 equilibration ratio of *cis* to *trans* isomers.

It is noteworthy that the 96:4 ratio of C_2—O_1 to C_2—O_3 bond cleavage obtained in the hydrogenolysis of *cis*-2,4-dimethyl-1,3-dioxolane (Table I) is comparable with that of other 1,3-dioxolanes containing an electron donor alkyl group at C_4 (Table I in ref. 1). For example 2,2,4-trimethyl-1,3-dioxolane, 2,4,4-trimethyl-1,3-dioxolane, 4-methyl-1,3-dioxolane, and 4,4-dimethyl-1,3-dioxolane gave respectively 82%, 90%, 93%, and 92% of C_2—O_1 bond cleavage. One might then consider that C_2—O_1 bond cleavage is the "normal" or expected course and that the *cis* isomer then follows the expected preferential C_2—O_1 bond breakage. Thus C_2—O_1 bond breakage in the *trans* isomer can then be considered as retarded, permitting more of C_2—O_3 bond cleavage. No explanation for such a retardation of C_2—O_1 bond cleavage in the *trans* isomer is apparent to us. Relevant to this is the finding that 2,2,4,4-tetramethyl-1,3-dioxolane cleaves "abnormally" to yield 1-isopropoxy-2-methyl-2-propanol (94%) and only 6% of the expected compound 2-isopropoxy-2-methyl-1-propanol (4).

Of interest also is our observation that in parallel reductions of 2,4,4-trimethyl-1,3-dioxolane using either boron trifluoride or aluminium chloride as the Lewis acid but with otherwise identical reaction conditions, no difference could be observed in the proportion of C_2—O_1 to C_2—O_3 bond cleavage. This ratio in each case was 82:18. If approach of the Lewis acid to the dioxolane were influenced by steric factors, and if this were part of the rate-controlling step, then one should expect differences in the proportion of C_2—O_1 to C_2—O_3 bond cleavage due to these two Lewis acids. The inference from these results is that steric effects are not significant in the attack of the Lewis acids upon the *cis* and *trans* isomers during the hydrogenolysis reactions. It should be pointed out, however, that since the exact structure of these Lewis acids in ether solution is not known, boron

For personal use only.

trifluoride may still be "large" enough to produce closely similar steric effects to these shown by aluminium chloride. Hence one cannot be certain that steric effects do not play an important role in this reaction.

EXPERIMENTAL

All boiling points are uncorrected.

Gas–liquid chromatography analyses were done with a Burrell K-2 Kromo-Tog apparatus using a 2 m column packed with 25% of carbowax 20 M on Gas-Chrom P. Helium at a flow rate of about 80 ml/min was the carrier gas. The column temperature employed was dependent upon the boiling point of the compounds analyzed. All compounds were identified by comparison of their g.l.c. retention times, as well as by their isolation and comparison of the infrared and nuclear magnetic resonance (n.m.r.) spectra and boiling points with those of authentic compounds. Quantitative analyses were made by measuring peak areas and comparison of these with the areas obtained by use of carefully measured amounts of the known compounds. Infrared spectra were recorded on a Perkin–Elmer Model 221 instrument. Nuclear magnetic resonance spectra were obtained with a Varian Associates A-60 spectrometer.

Preparation of Compounds

2,4-Dimethyl-1,3-dioxolane was prepared by the following modification of Fischer and Pfahler's procedure (5). Acetaldehyde (100 g, 2.3 mole) was added portionwise to a stirred mixture of 1,2-propanediol (152 g, 2.0 mole), anhydrous magnesium sulfate (60 g), and *p*-toluenesulfonic acid (1 g). The temperature of the reaction mixture was maintained below 20° by ice cooling during the addition. After complete addition of the reagents the reaction mixture stood at 0° for 16 h, and was then filtered free of the magnesium sulfate. The product was distilled to give 121 g (59%) of material boiling at 88–89°. Lit. b.p. 92.8° (6). Analysis of this material by g.l.c. showed it to be a mixture of two components, the *cis* and *trans* isomers of 2,4-dimethyl-1,3-dioxolane in the ratio of 63% to 37% (cf. 65%:35% obtained by Barker *et al.* (2)). Separation of these isomers was effected by several fractional distillations through a 1 m column packed with stainless steel saddles. The course of the distillation was followed by g.l.c. analyses. The isomers so obtained were finally distilled from sodium hydroxide pellets. The lower boiling *cis* isomer distilled at 87° and 700 mm. Lit. b.p. 89.7(2). The higher boiling *trans* isomer distilled at 89–90° and 700 mm. Lit. b.p. 93.5°(2).

2-Ethyl-4-methyl-1,3-dioxolane was prepared by a procedure similar to that employed for the preparation of 2,4-dimethyl-1,3-dioxolane, starting with propionaldehyde and 1,2-propanediol. Boiling point of the mixture of *cis* and *trans* isomers, 114–117° at 700 mm. Lit. b.p. 113–118°(7). The two isomers in the equilibrium ratio of 68:32 were separated by several distillations through a spinning band column. The pure isomers were stored over sodium hydroxide pellets. Boiling point of *trans* isomer, 117° at 700 mm. Boiling point of *cis* isomer, 115° at 700 mm. Configurational assignment was made on the same bases as used for the assignment of the configurations to the low and high boiling isomeric *cis*- and *trans*-2,4-dimethyl-1,3-dioxolanes (2).

1-n-Propoxy-2-propanol was made by a modification of a literature procedure (8). 1,2-Epoxypropane (Eastman Kodak Company) (15 g, 0.26 mole) was added dropwise to a solution of sodium *n*-propoxide (from 2 g of sodium in 70 ml of 1-propanol). The resulting solution was allowed to stand at 25° for 16 h and then poured into cold water. The organic layer was separated, washed with water, and then dried ($MgSO_4$). After removal of the solvent, the remaining oil was distilled under reduced pressure to yield 22.0 g (72%) of material boiling at 73° and 45 mm. Lit. b.p. 148.5–149° at 730 mm (9).

1-Ethoxy-2-propanol was prepared by the same method used to make 1-*n*-propoxy-2-propanol starting with 1,2-epoxypropane and sodium ethoxide in ethanol. Boiling point 130° at 700 mm. Lit. b.p. 130–130.8° (8).

2-Ethoxy-1-propanol was made by a standard literature procedure (10) involving lithium aluminium hydride reduction of the corresponding ester or acid as described below. The precursor, *ethyl α-ethoxypropionate* was prepared in 64% yield from sodium ethoxide and ethyl α-bromopropionate (Eastman Kodak Company) according to the procedure advocated by Nieman *et al.* (11) for the preparation of methyl α-methoxypropionate. Boiling point 70° at 30 mm. Lit. b.p. 66–68° at 27 mm (12). Ethyl α-ethoxypropionate (28.0 g, 0.19 mole) was added dropwise to a stirred suspension of lithium aluminium hydride (7.7 g, 0.2 mole) in 200 ml of dry ether. After complete addition of the reagents, the reaction mixture was stirred for 1 h and then cold water cautiously added to decompose any excess hydride and aluminium salts. After removal of the inorganic solid by filtration, the ether solution was separated and dried over anhydrous magnesium sulfate. Removal of the ether afforded an oil which was purified by distillation to give 16.1 g (81%) of 2-ethoxy-1-propanol boiling at 143° and 700 mm. Lit. b.p. 137.5–138° (8).

2-n-Propoxy-1-propanol.—A mixture of α-chloropropionic acid (Fischer Scientific Co.) (1.0 mole), 1-propanol (400 ml), and concentrated sulfuric acid (20 ml) was refluxed for 3 h, then cooled and poured into aqueous sodium carbonate. The organic layer was separated, dried over anhydrous sodium carbonate, and then distilled to give a 70% yield of *n-propyl α-chloropropionate* boiling at 68° and 23 mm. Lit. b.p. 57° at 12 mm (13). *n-Propyl α-n-propoxypropionate* was made in 79% yield from sodium *n*-propoxide and *n*-propyl α-chloropropionate in 1-propanol as solvent according to the general procedure of Nieman *et al.* (11). Boiling

point 85° at 16 mm. Lit. b.p. 187–188° (14). Reduction of *n*-propyl α-*n*-propoxypropionate by lithium aluminium hydride according to the same procedure employed above for the preparation of 2-ethoxy-1-propanol gave 2-*n*-propoxy-1-propanol in 58% yield. Boiling point 154–155° at 700 mm. Lit. b.p. 150.5–151° at 730 mm (9).

Determination of the Relative Rates of Reductions of the Dioxolanes

The following description of the competitive partial reduction of *cis*- and *trans*-2-ethyl-4-methyl-1,3-dioxolane is typical of the general procedure used to obtain *relative rates* of hydrogenolysis of the 1,3-dioxolanes. The hydroxy ethers obtained were found to be stable under the reaction conditions, hence their relative amounts in the product can be considered as an indication of the relative rates of formation via hydrogenolysis.

A solution of *cis*-2-ethyl-4-methyl-1,3-dioxolane (2.9 g, 0.025 mole) and *trans*-2-ethyl-4-methyl-1,3-dioxolane (2.9 g, 0.025 mole) in 50 ml of dry ether was stirred whilst lithium aluminium hydride (0.95 g, 0.025 mole) was added. Then a solution of aluminium chloride (0.7 g, 0.005 mole) in ether (10 ml) was added dropwise over a period of 3 min. The reaction mixture was stirred for 30 min and then water was cautiously added to decompose the hydride and aluminium complexes. The inorganic solid was removed by filtration and the ethereal filtrate dried over anhydrous sodium carbonate. Removal of the ether afforded 5.4 g (92%) of material which was analyzed by g.l.c. to determine the composition of the product of reduction. Of the reduced product, 89% was 2-*n*-propoxy-1-propanol and 11% was 1-*n*-propoxy-2-propanol. Of the unreacted dioxolanes, 62% was the *trans* isomer and 38% the *cis* isomer, showing that more of the *cis* than the *trans* isomer had been reduced. Results for similar reductions of a mixture of *cis* and *trans* isomers of 2,4-dimethyl-1,3-dioxolane are given in Table III.

Typical Procedure for Hydrogenolysis of 1,3-Dioxolanes

The dioxolane (0.1 mole) was added to a stirred suspension of lithium aluminium hydride (0.1 mole) in 300 ml of dry ether. The resulting mixture was stirred whilst an ether solution of aluminium chloride (0.1 mole) was added dropwise over about a 10 min period. The reaction mixture was stirred for 1 h after complete addition of the chloride, then cautiously treated with cold water to decompose the aluminium complexes and the excess hydride. The inorganic material was removed by filtration and the ethereal filtrate dried over anhydrous magnesium sulfate. Removal of the ether afforded an oil which was analyzed by g.l.c. Results of these reactions are shown in Table I.

Partial Reductions of cis- and of trans-2,4-Dialkylated-1,3-dioxolanes

These reductions were carried out in a manner identical to that described immediately above, but with a limited amount of reducing agent and aluminium chloride present. A 30 min reaction time was allowed in each case. Amounts of reagents and results of each experiment are shown in Table II.

SUBSOLUTIONS IN MULTICOMPONENT SYSTEMS: APPLICATIONS TO SOME TERNARY AQUEOUS ACID SULFATE SYSTEMS AT UNIVARIANCE

A. J. SUKAVA
Department of Chemistry, University of Western Ontario, London, Ontario
Received January 20, 1964

ABSTRACT

A method is described by which univariant composition data for multicomponent solutions may be tested for consistency or accuracy, and used to estimate or verify invariant points, by reference to the vapor pressure data for an appropriate binary subsolution derived from the system. A subsolution is defined as any homogeneous part of a multicomponent solution, such that it is composed of a smaller number of the components than the total but in which the relative masses of these components are the same as in the parent solution.

Published data for ternary systems containing sulfuric acid, water, and the metal sulfates $MnSO_4$, $FeSO_4$, $ZnSO_4$, $BeSO_4$, Na_2SO_4, and $CuSO_4$ are examined. Some new data for the $CuSO_4$ system are also presented. The subsolution in each case is the binary H_2SO_4–H_2O solution, for which adequate vapor pressure data are available.

INTRODUCTION

The composition of any multicomponent solution can be expressed in terms of the relative masses of the various components that are present, and therefore any array of mass ratios can be written as a function of the independent state variables as shown by

$$[1] \qquad m_2/m_1,\ m_3/m_1,\ \ldots,\ m_c/m_1 = f(x, y, \ldots)$$

where the m's are the masses of the different components 1, 2, . . . c and x, y, . . . are the state variables that determine the composition. The number of these variables is the variance, or number of degrees of freedom, of the system.

If a mixture of components is considered such that it consists of any smaller number of the components than the total present in a given multicomponent solution, but with the restriction that the relative masses of these fewer components must be the same as in the parent solution, then it is a consequence of eq. [1] that the composition of such a *part mixture* is also a function of the same independent variables. This can be shown for any choice of part mixture by writing

$$[2] \qquad \begin{aligned} m_2/m_1 &= g(x, y, \ldots), \\ m_3/m_1,\ m_5/m_1 &= h(x, y, \ldots), \text{ etc.} \end{aligned}$$

It can happen of course that a part mixture derived in this way could constitute a solution at the prevailing values of x, y, ... Such a *subsolution** might be unsaturated or supersaturated in practice, depending upon the substances present, but in any case its particular state will be determined by these variables.

SUBSOLUTIONS AT UNIVARIANCE

One consequence of eqs. [1] and [2] offers some practical advantages. If a multicomponent solution is univariant, then the properties of any subsolution derived from it will vary in a regular manner as single-valued functions of the one independent state variable. Since the subsolution will be univariant too by reason of the restriction on its composition, it

**The term "subsolution" is adopted as sufficiently appropriate to describe the physical consequence of eqs. [1] and [2] in the case of any homogeneous part mixture derived from a multicomponent parent solution in the manner shown. The geometric term "projection" might also be used since the functions in [2] are projections of the array in [1].*

would follow, for example, that its vapor pressure might show a dependence on temperature somewhat like any typical Clausius–Clapeyron log P vs. $1/T$ relation for a (univariant) pure liquid or for a solution at constant composition. This possibility is examined in this paper, with emphasis on two main practical applications, (i) detection of errors in original multicomponent composition data and (ii) estimation of invariant points.

The vapor pressure of a binary subsolution can be related very simply to the composition of the multicomponent parent. If components 1 and 2 of a multicomponent solution constitute a subsolution, then

$$P_1 = P_1^0 \gamma_1 X_1, \qquad [3]$$

where P_1^0 is the vapor pressure of pure 1 and P_1, X_1, and γ_1 are the vapor pressure, mole fraction, and activity coefficient of 1 in the subsolution. Since the ratio of the mole numbers (n) of components 1 and 2 is the same in the subsolution and multicomponent parent, one can write

$$X_1 = \frac{n_1}{n_1 + n_2} = \frac{n_1'}{n_1' + n_2'} = \frac{X_1'}{X_1' + X_2'}, \qquad [4]$$

where the unprimed quantities are those for the subsolution and the primes identify corresponding quantities in the parent. Equation [4] is obviously valid for any number of components in the multicomponent solution.

Under univariant conditions the vapor pressure can be considered a function of temperature and composition, with the composition also a function of temperature. Thus, to get the log P vs. $1/T$ relation, the dependence of P_1 on temperature and composition can be written as

$$\log P_1 = f(1/T, X_1)$$

to give the desired derivative

$$\frac{\mathrm{d} \log P_1}{\mathrm{d}(1/T)} = \left(\frac{\partial \log P_1}{\partial(1/T)}\right)_{X_1} + \left(\frac{\partial \log P_1}{\partial X_1}\right)_{1/T} \left(\frac{\mathrm{d}X_1}{\mathrm{d}(1/T)}\right). \qquad [5]$$

The first term on the right in eq. [5] can be obtained by differentiating [3] with respect to $1/T$, giving

$$\left(\frac{\partial \log P_1}{\partial(1/T)}\right)_{X_1} = \frac{\mathrm{d} \log P_1^0}{\mathrm{d}(1/T)} + \left(\frac{\partial \log a_1}{\partial(1/T)}\right)_{X_1} \qquad [6]$$

where a_1 is the activity. Since the first term on the right in [6] is the Clausius–Clapeyron slope for pure 1, and since the second term can be easily shown to be

$$\left(\frac{\partial \log a_1}{\partial(1/T)}\right)_{X_1} = \frac{\bar{H}_1 - H_1^0}{2.3R},$$

where H_1^0 and $\bar{H}_1$ are the molal enthalpy of pure 1 and the partial molal enthalpy of 1 in the subsolution, eq. [6] becomes the simple Clausius–Clapeyron expression for component 1 in a binary solution at constant composition:

$$\left(\frac{\partial \log P_1}{\partial(1/T)}\right)_{X_1} = \frac{-(H_1^{\mathrm{v}} - \bar{H}_1)}{2.3R},$$

where H_1^{v} is the molal enthalpy of the equilibrium vapor. When the major component in the subsolution is 1, the value of $\bar{H}_1$ does not differ greatly from H_1^0. Under these conditions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the second term in eq. [5] can be interpreted as the difference in slope between the log P vs. $1/T$ curve for the subsolution and the log P vs. $1/T$ curve for pure 1.

Adequate vapor pressure data are available for binary mixtures of sulfuric acid and water (1). Multicomponent systems containing these two components can therefore be readily tested for the log P vs. $1/T$ behavior of the H_2SO_4–H_2O subsolution provided the univariant compositions are available for the same phase equilibrium for at least three different temperatures. These conditions are met by published data for the ternary systems composed of sulfuric acid, water, and the metal sulfates $MnSO_4$ (2, 3), $FeSO_4$ (4–8), $ZnSO_4$ (9, 10), $BeSO_4$ (11), Na_2SO_4 (12, 13, 14), and $CuSO_4$ (12, 15, 16). The compositions of the subsolutions were calculated and the vapor pressures were found by graphical interpolation from the literature values (1), with the results shown in Figs. 1 to 6. It is evident that the downwardly concave log P vs. $1/T$ curves are in many cases almost linear over wide ranges of temperature, especially when the sulfuric acid concentration of the subsolution is low. Greater non-linearity tends to occur with the higher concentrations of acid.

Examination of other univariant data shows that the near linearity of the log P vs. $1/T$ curves is a general property of subsolutions. A good example is a univariant equilibrium in the quaternary system $(NH_4)_2SO_4$–Li_2SO_4–C_2H_5OH–H_2O (17). The log P vs. $1/T$ curve for the ethanol–water subsolution derived from the upper quaternary liquid layer is nearly linear whether P is the partial pressure of the ethanol or of the water. Easier empirical plots such as log X_1 or X_2/X_1 vs. temperature are considerably more curved, in general.

ACCURACY OF UNIVARIANT MULTICOMPONENT COMPOSITION DATA

If the composition of a subsolution is abstracted from the data for some multicomponent solution at univariance, and if the vapor pressure of the subsolution is plotted against the temperature, then the plotted points must lie on a smooth curve if the multicomponent data are accurate or at least self-consistent. Scatter of the points for a given phase equilibrium will indicate error or inconsistency, provided of course that the computation of vapor pressures for the subsolution does not also introduce error in significant amount. The near linearity of the log P vs. $1/T$ curves for the subsolutions offers an advantage in detecting such errors, and specific errors can be found if the multicomponent composition data are sufficient to establish the trend of the log P vs. $1/T$ relation with the necessary certainty. Numerous examples are given in the diagrams.

BINARY TRANSITION POINTS FROM UNIVARIANT TERNARY DATA

Any univariant ternary acid sulfate system in which there are two different hydrates of a normal metal sulfate in equilibrium with a liquid and a vapor phase reduces to the invariant binary system with the same two solids when the concentration of sulfuric acid in the liquid phase becomes zero with rise in temperature. (One of the equilibrium solids can of course be the normal anhydrous salt.) Therefore, for any such univariant normal-sulfate equilibrium, the log P vs. $1/T$ curve for the H_2SO_4–H_2O subsolution ends at the log P vs. $1/T$ curve for pure water as temperature rises. The point at which the two curves meet then corresponds to the invariant binary transition temperature for the particular hydrate mixture in the equilibrium.

Figures 1 to 6 include the log P vs. $1/T$ curve for pure water, the uppermost curve in each diagram, to allow estimation or verification of binary transition points in this way. This method provides an obvious advantage if the curves are sufficiently linear and if the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

angle of intersection is sufficiently large. In the most favorable cases simple geometrical calculation could give the transition point more precisely from the appropriate ternary composition and binary vapor pressure data. Extrapolating the sulfuric acid concentration of the univariant ternary solution to zero provides a more obvious method of locating a binary transition point in sulfate systems, but this has the disadvantage of greater and uncertain curvature.

TERNARY QUINTUPLE POINTS FROM UNIVARIANT DATA

An invariant quintuple point in any ternary aqueous acid–sulfate system involves three solid phases in equilibrium with one liquid, and the associated univariant equilibria can in theory involve any two of these solids. It follows that the quintuple point can be found as the point of intersection of either two or three log P vs. $1/T$ curves for the univariant H_2SO_4–H_2O subsolutions, the number depending on which solid phases form the experimentally stable pairs at the different temperatures near the quintuple point. Various circumstances shown in the diagrams illustrate both of these possibilities. As before, the advantage lies in the near linearity of many of the curves.

TREATMENT OF PUBLISHED DATA

The System $MnSO_4$–H_2SO_4–H_2O

Some univariant compositions for the system $MnSO_4$–H_2SO_4–H_2O, reported by Taylor (2), are represented in Fig. 1 by log P vs. $1/T$ plots for the H_2SO_4–H_2O subsolutions, with each different equilibrium designated by letter. Equilibrium A involves the normal salt only, B normal and acid salts, and C and D acid salts only. In A, the necessary third point for the graphical plot is provided by the limiting binary equilibrium at 24.5°, credited to Krepelka and Rejha (3).

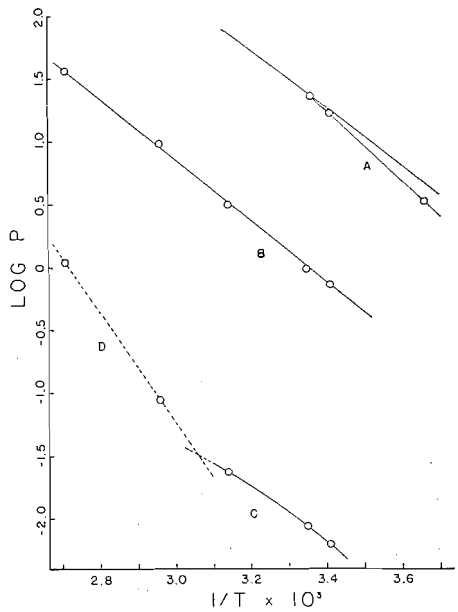

FIG. 1. Log P vs. $1/T$ relations for H_2SO_4–H_2O subsolutions in the system $MnSO_4$–H_2SO_4–H_2O at univariance (2, 3): (A) $MnSO_4 \cdot 5H_2O$ – $MnSO_4 \cdot H_2O$ – solution – vapor, (B) $MnSO_4 \cdot H_2O$ – $MnSO_4 \cdot H_2SO_4 \cdot H_2O$ – solution – vapor, (C) $MnSO_4 \cdot H_2SO_4 \cdot H_2O$ – $MnSO_4 \cdot 3H_2SO_4$ – solution – vapor, (D) $MnSO_4 \cdot H_2SO_4 \cdot H_2O$ – $MnSO_4 \cdot H_2SO_4$ – solution – vapor.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The three points for equilibrium A appear to lie on a reasonably good straight line. The five points for B, despite some irregularity, show the same trend. The scatter is an indication of experimental or computational error, or both. Curve C, which shows marked downward concavity, is based on somewhat uncertain graphically estimated small vapor pressure values. It may not be correct as drawn. Curve D, for lack of sufficient data, cannot be established with certainty. The broken line in the diagram is included merely to provide a rough estimate of the invariant quintuple-point temperature for the ternary equilibrium

$$MnSO_4 \cdot H_2SO_4 \cdot H_2O - MnSO_4 \cdot H_2SO_4 - MnSO_4 \cdot 3H_2SO_4 - \text{ternary solution} - \text{vapor}.$$

If curves C and D are at least approximately correct, their intersection places this quintuple point at about 55°.

The System $FeSO_4$–H_2SO_4–H_2O

Univariant data for the system $FeSO_4$–H_2SO_4–H_2O are represented in Figs. 2*a* and 2*b*. These were obtained from several sources (4–8), one reason for the wide interest being that the waste "pickle liquor" of the steel industry is primarily an acid iron(II) sulfate solution. The symbols used for the individual plots identify the source of the original data.

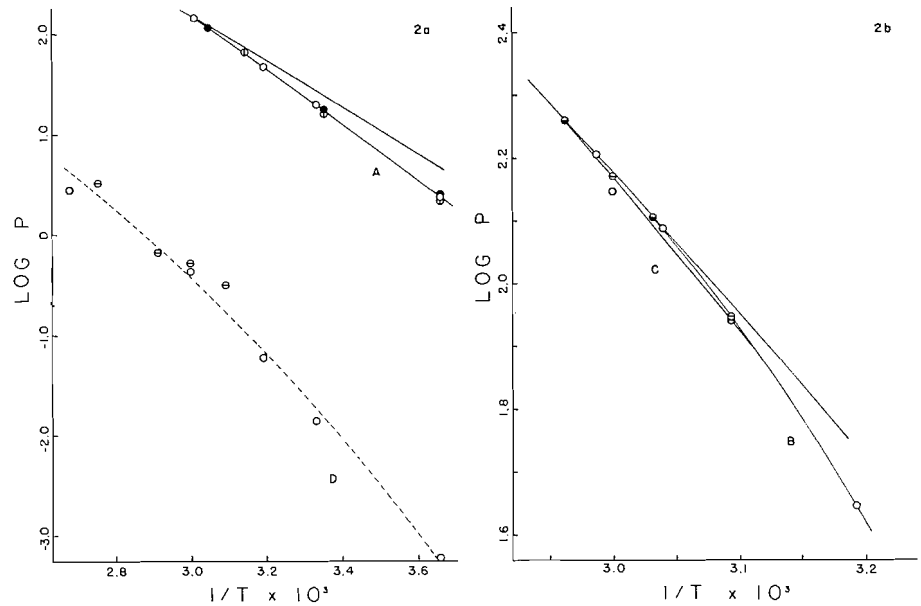

FIG. 2. Log P vs. $1/T$ relations for H_2SO_4–H_2O subsolutions in the system $FeSO_4$–H_2SO_4–H_2O at univariance: (A) $FeSO_4 \cdot 7H_2O$ – $FeSO_4 \cdot H_2O$ – solution – vapor, (B) $FeSO_4 \cdot 7H_2O$ – $FeSO_4 \cdot 4H_2O$ – solution – vapor, (C) $FeSO_4 \cdot 4H_2O$ – $FeSO_4 \cdot H_2O$ – solution – vapor, (D) $FeSO_4 \cdot H_2O$ – $FeSO_4$ – solution – vapor. ⦶ Bullough *et al.* (5), ● Cameron (6), ○ Kobe and Fredrickson (8), ⊖ Belopol'skii and Shpunt (4), ◒ Fraenckel (7).

Curve A in Fig. 2*a* is best represented as slightly concave downward. Except for some disagreement at 0° and at 25°, the data from the different sources seem to be in reasonable accord. The Kobe and Fredrickson value for the invariant heptahydrate–monohydrate transition point, given as 59.0° (8), appears to be verified.

Curve B in Fig. 2*b* is also concave downward. No definite conclusion can be drawn about the better accuracy of one or the other of the two values reported for the heptahydrate–tetrahydrate transition point, 56.6° (7) and 56.0° (8), except that both values, in good agreement anyway, are obviously reasonable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The two sets of data for equilibrium C (Fig. 2*b*) reported by Belopol'skii and Shpunt (4) produce a good straight line with the Fraenckel value for the tetrahydrate–monohydrate transition temperature, given as 64.4° (7). The extrapolated Kobe and Fredrickson value of 61.7° (8) for this point appears to be too low. The Kobe and Fredrickson data for the univariant ternary tetrahydrate–monohydrate equilibrium at 60° (8) are definitely in error.

Despite the small angle between curves B and C, their point of intersection can be estimated at about 49°. This is then the approximate quintuple point for the equilibrium

$$FeSO_4 \cdot 7H_2O - FeSO_4 \cdot 4H_2O - FeSO_4 \cdot H_2O - \text{ternary solution} - \text{vapor}.$$

Because of the solids present, curve A in Fig. 2*a* must also pass through this point, and it may be noted that equilibria A and B occur experimentally both above and below this temperature while equilibrium C has been found above it only.

At least some of the data for equilibrium D, as represented in Fig. 2*a*, must be quite inaccurate. The broken curve shows the approximate trend only.

The System $ZnSO_4$–H_2SO_4–H_2O

Data for some univariant and invariant equilibria in the system $ZnSO_4$–H_2SO_4–H_2O, reported by Copeland and Short (9) and by Joshi and Devadatta (10), are represented in Fig. 3. Some of the data for equilibrium A appear to be slightly inaccurate, while all points for B indicate good accuracy. The heptahydrate–hexahydrate transition at 39° and the ternary quintuple point at 21° are both consistent with the univariant data.

The Joshi and Devadatta data for equilibrium C are in poor agreement with those of Copeland and Short. The latter appear to be self-consistent, but the curve cannot be taken as evidence of accuracy for the two highest points. The 60° value for the hexahydrate-monohydrate transition seems to be too high. Lorimer has pointed out recently (18) that extrapolating the curve obtained by plotting the sulfuric acid concentration of the ternary solution against reciprocal temperature gives a value of 52.5° for this transition. It is also worth noting that the four lower Copeland and Short points for equilibrium C, including the quintuple point, all lie on a nearly linear curve that meets the water curve at 51°. This is shown by the alternative (broken) curve in the diagram.

The System $BeSO_4$–H_2SO_4–H_2O

Data for one univariant equilibrium in the system $BeSO_4$–H_2SO_4–H_2O, reported by Campbell and co-workers (11), are represented in Fig. 4. The overall trend of the log P vs. $1/T$ curve indicates only very slight downward concavity. The data may be judged accurate, except perhaps at 75°. The tetrahydrate–dihydrate transition point is verified at about 89°.

The System Na_2SO_4–H_2SO_4–H_2O

Figure 5 shows some univariant data for the more complicated system Na_2SO_4–H_2SO_4–H_2O. These were compiled from papers by Foote (12), Faust and Esselmann (13), and Luk'yanova (14). To make the diagram as complete as possible, some univariant data which were not found in the literature were estimated by extrapolating the ternary bivariant data. No great precision can be claimed for these extrapolations, and the diagram in such respects should be taken only as a very rough approximation.

For lack of sufficient data, only three of the curves in Fig. 5 can be established with any certainty. These are B, D, and E. The first is nearly linear and the other two are markedly concave downward. The curves for the other three equilibria, A, C, and F, are shown as broken lines to suggest approximation only. These enable rough estimates of the quintuple

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

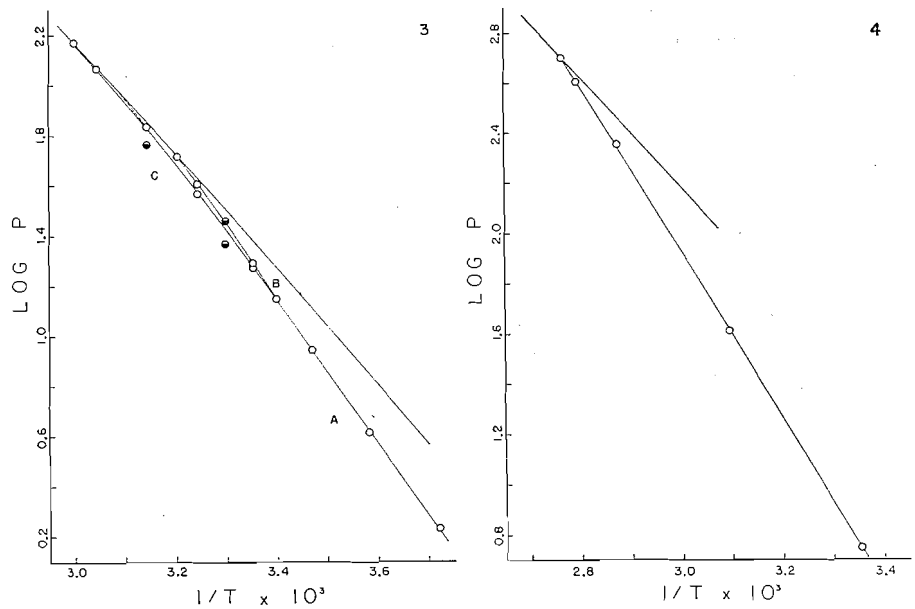

FIG. 3. Log P vs. $1/T$ relations for H_2SO_4–H_2O subsolutions in the system $ZnSO_4$–H_2SO_4–H_2O at univariance: (A) $ZnSO_4 \cdot 7H_2O$ – $ZnSO_4 \cdot H_2O$ – solution – vapor, (B) $ZnSO_4 \cdot 7H_2O$ – $ZnSO_4 \cdot 6H_2O$ – solution – vapor, (C) $ZnSO_4 \cdot 6H_2O$ – $ZnSO_4 \cdot H_2O$ – solution – vapor. ○ Copeland and Short (9), ● Joshi and Devadatta (10).

FIG. 4. Log P vs. $1/T$ relation for H_2SO_4–H_2O subsolution in the system $BeSO_4$–H_2SO_4–H_2O at univariance (11). Equilibrium phases: $BeSO_4 \cdot 4H_2O$ – $BeSO_4 \cdot 2H_2O$ – solution – vapor.

point temperatures, one of which may be taken as reasonably correct. This point, the intersection of curves A, B, and C, shows the quintuple point for the equilibrium

$$Na_2SO_4 \cdot 10H_2O - Na_2SO_4 - Na_3H(SO_4)_2 - \text{ternary solution} - \text{vapor}$$

to be about 16°.

The System $CuSO_4$–H_2SO_4–H_2O

The curves in Fig. 6 represent univariant equilibria in the system $CuSO_4$–H_2SO_4–H_2O. Ternary data from Foote (12), Crockford and Warrick (15), and Posnjak and Tunell (16) are included together with the results of some new analyses shown in Table I.* The three equilibria are identified by letter in both table and diagram.

Equilibration in this system is a very slow process, especially at low temperatures and high concentrations of acid. It is therefore not surprising that the data show rather poor agreement. The differences in color and rates of settling of the solid phases nevertheless favor establishment of the univariant conditions experimentally. This is done by careful adjustment of the sulfuric acid concentration of the equilibrium liquid to give visual evidence of the simultaneous presence of two solids.

All three log P vs. $1/T$ curves show only slight downward concavity. Some of the older data for the pentahydrate–trihydrate equilibrium at the lower temperatures (curve A) are obviously in error. The new data for the higher temperatures are reasonably consistent with the known binary transition point, 95.9° (19).

The data for equilibrium B are not sufficient to allow accurate extrapolation to the

Credit for the new data goes to the following students: R. G. Benbow, L. B. Bezeau, M. A. Clarke, and G. W. Gray.

TABLE I

Univariant data for the system $CuSO_4$–H_2SO_4–H_2O

		Ternary liquid	
Equilibrium	Temp. (°C)	$CuSO_4$ (%)	H_2SO_4 (%)
A	50	8.42	37.31
A	75	22.83	21.05
A	95	37.92	3.95
B	0	0.25	64.82
B	25	2.07	56.47
B	50	5.39	48.00
B	75	13.92	36.69
B	95	25.71	22.56
C	0	0.39	91.57

water curve. The average trend gives a value of about 120° for the trihydrate–monohydrate transition. The new data alone give 115°.

In view of the general downward concavity of the log P vs. $1/T$ curves, the one new point for equilibrium C seems to agree with the Posnjak and Tunell data (16). This suggests that the three lowest-temperature Crockford and Warrick points are in error. If the curve is reasonably correct as shown, the monohydrate–anhydrous transition lies in the supercritical region.

NUCLEAR MAGNETIC RESONANCE STUDIES OF THE PROTONATION OF WEAK BASES IN FLUOROSULFURIC ACID

V. KETONES, CARBOXYLIC ACIDS, AND SOME OTHER OXYGEN BASES

T. BIRCHALL AND R. J. GILLESPIE
Department of Chemistry, McMaster University, Hamilton, Ontario
Received October 19, 1964

ABSTRACT

The proton n.m.r. spectra of the conjugate acids of some ketones and carboxylic acids, and of ethyl acetate, nitromesitylene, and ethyl alcohol have been observed. A correlation has been found between the chemical shift of the C=OH^+ proton of the conjugate acids of some para-substituted acetophenones and their pK_{BH^+} and σ^+ values. The rates of proton loss from these conjugate acids have been obtained.

INTRODUCTION

The proton n.m.r. spectra of the conjugate acids of acetone, ethyl alcohol, and water were first observed in solutions of the bases in anhydrous hydrogen fluoride saturated with boron trifluoride at −75° (1). The successful observation of the C=OH^+ resonances in the n.m.r. spectra of the conjugate acids of amides and related compounds in solution in fluorosulfuric acid at low temperatures (2) has led us to the examination of the low-temperature spectra of some other oxygen bases in this solvent.

RESULTS AND DISCUSSIONS

Ketones

The n.m.r. spectra of a series of para-substituted acetophenones in fluorosulfuric acid were recorded at various temperatures. It is possible to observe the spectrum of the conjugate acid in all cases, although in the case of para-nitroacetophenone it is not possible to completely stop exchange with the solvent even at −88°. The chemical shifts are recorded in Table I. No spin–spin coupling is observed between the captured proton and the protons of the methyl group.

TABLE I

Chemical shifts of the conjugate acids of some ketones

	Temp., °C	$-\delta$, p.p.m. from external tetramethylsilane			
		=OH^+	Phenyl	$OC\cdot CH_3$	CH_3

Acetone‡	25	14.45		3.25	

*Phenyl spectrum not resolved.
†Only the chemical shifts of the most prominent phenyl peaks are recorded.
‡Spectrum in SbF_5/HSO_3F.

A notable feature of these spectra is the very large chemical shift, from tetramethylsilane, of the captured proton. We note that the C=OH^+ resonance shifts to lower field as

the para-substituent becomes more electron attracting. Figure 1 shows that there is a very satisfactory linear correlation between the chemical shift of the captured proton and the pK_{BH^+} values. Since a linear relation has been found between pK_{BH^+} and the substituent constant σ^+ (3) there is also a good correlation between the chemical shift and σ^+ (Fig. 2).

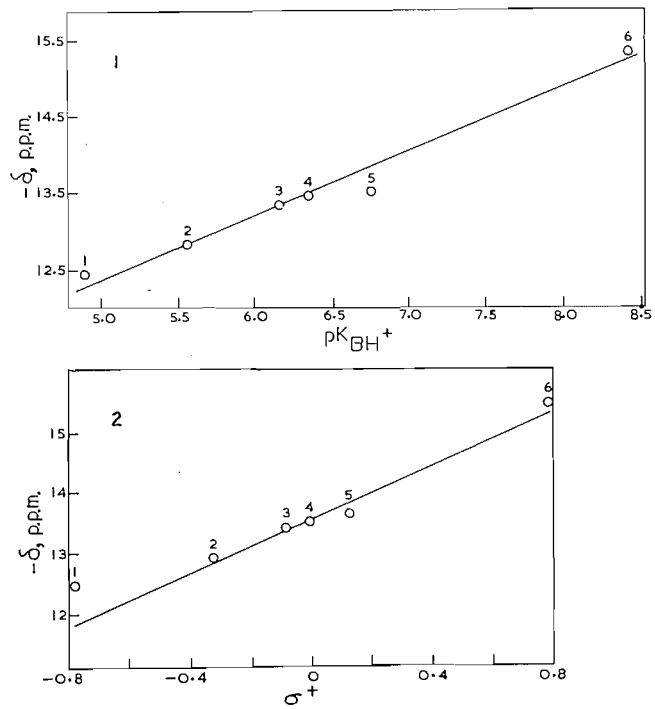

FIG. 1. Chemical shift of the $=OH^+$ proton of the conjugate acids of some para-substituted acetophenones vs. pK_{BH^+}: (1) p-OCH_3, (2) p-CH_3, (3) p-F, (4) p-H, (5) p-Cl, (6) p-NO_2.

FIG. 2. Chemical shift of the $=OH^+$ proton of the conjugate acids of some para-substituted acetophenones versus σ^+: (1) p-OCH_3, (2) p-CH_3, (3) p-F, (4) p-H, (5) p-Cl, (6) p-NO_2.

The ring portion of the spectra of the protonated acetophenones would be expected to be of the A_2B_2 type. Presumably because cross-ring coupling is weak, the actual spectra approximate to $(AB)_2$ spectra (Fig. 3). As the electron-withdrawing character of the para-substituent is increased from OCH_3 to NO_2, the chemical shift between the A and B protons decreases until in the latter case it becomes very small indicating that the electron-withdrawing powers of the NO_2 and $HO^+{=}C\cdot CH_3$ groups are very similar.

The n.m.r. spectrum of the conjugate acid of acetone, obtained in an SbF_5/HSO_3F solution, consists of two peaks, one due to the proton on the carbonyl oxygen and the other due to the methyl protons: the shifts are given in Table I.

Carboxylic Acids

Stewart and Yates (4) have found a close correlation between the basicities of a number of substituted benzoic acids and their acetophenone analogues and they conclude that the site of protonation in benzoic acid and its derivatives is the carbonyl oxygen. In an attempt to obtain confirmation of their conclusion, carboxylic acids have been examined in SbF_5/HSO_3F solution. The chemical shifts are given in Table II.

TABLE II

Chemical shifts of the conjugate acids of some carboxylic acids and ethyl acetate in HSO_3F/SbF_5

Base	Temp., °C	−δ, p.p.m. from external tetramethylsilane			
		OH	Phenyl	CH_2	CH_3
Acetic acid	−75	12.89, 12.28			3.12
	−25	12.56			3.12
Propionic acid	−77	12.62, 12.39		3.40	1.67
Benzoic acid	−84.5	12.10	8.42, 8.32, 7.95, 7.82		
Ethyl acetate	−75	12.75		5.14	2.97, 1.82

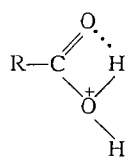
The n.m.r. spectrum of benzoic acid in SbF_5/HSO_3F solution shows, in addition to peaks arising from the phenyl protons, another peak with a chemical shift similar to that observed for the $=OH^+$ peak of protonated ketones. That this low-field peak is the result of protonation is confirmed by the measurement of the relative areas of the peaks which were found to be 1.89:5.0. One cannot on the basis of this evidence decide between structures I and II for the conjugate acid provided that there is free rotation about the $C—OH_2^+$ bond in II.

I II

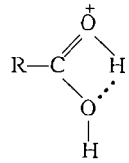
The conjugate acid of acetic acid in SbF_5/HSO_3F shows, at low temperature, two peaks at low field and a peak due to the methyl protons; the relative areas of the peaks were found to be 1.08:0.96:3.0. Raising the temperature results in broadening of the low-field peaks which eventually collapse together and merge with the solvent. Similar results were obtained for the conjugate acid of propionic acid (Table II). Unlike protonated benzoic acid, where both OH protons appear equivalent, the OH protons of the conjugate acids

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of these aliphatic acids are non-equivalent, presumably because of the formation of a very strong hydrogen bond between one of the hydrogens and the oxygen atom to which it is not directly attached (III).



IIIa



IIIb

Again, it is not possible to distinguish between IIIa and IIIb. Consideration of the donor and acceptor properties of oxygen would lead one to conclude that hydrogen bonding would be considerably stronger in IIIa than in IIIb and that IIIa might therefore be favored. However no spin–spin coupling between the non-equivalent hydrogens is observed.

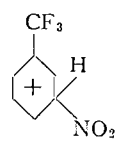
Ethyl Acetate

In the n.m.r. spectrum of the conjugate acid of ethyl acetate, a new peak is observed at low temperature in addition to peaks due to the CH_3 and CH_2 protons of the ethyl group and the single sharp peak due to the CH_3 protons of the acetate group. One might expect that protonation of the ether oxygen would result in a change in the CH_2 quartet due to additional spin–spin coupling with the captured proton only three bonds removed. No change in the pattern is observed, even at very low temperatures, and the signal from the captured proton remains a single sharp line. It is concluded that protonation takes place on the carbonyl oxygen, and by analogy we might conclude that the conjugate acids of acetic and propionic acids have structure IIIb rather than IIIa.

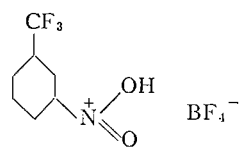
Nitromesitylene

The n.m.r. spectrum of nitromesitylene in CCl_4 consists of a single line A, due to the phenyl protons and two overlapping lines, B and C, due to the ortho and para methyl groups. In a strongly acidic solution at low temperatures peaks A, B, and C are again observed and in addition a new peak, D, appears at −14.86 p.p.m. from tetramethylsilane (Fig. 4): the relative areas were found to be D:A:B+C:: 0.93:1.85:9.0. The chemical shift (Table III) between the non-equivalent methyl groups increases from 0.05 p.p.m. in CCl_4 to 0.24 p.p.m. in acid solution. The absence of any peaks in the "methylene" region of the spectrum which would result from protonation of the aromatic ring (5, 6), the area measurements, and the fact that the new peak has a chemical shift characteristic of an $=OH^+$ proton, indicate that protonation takes place on one of the oxygen atoms of the nitro group.

It is interesting to compare the structure of the conjugate acid of nitromesitylene with the structure IV proposed by Oláh (7) for the compound formed by the reaction of trifluoromethylbenzene, NO_2F, and BF_3.



IV



V

In the light of our n.m.r. evidence V appears to be a more likely structure than IV.

Ethyl Alcohol and Water

The chemical shifts obtained for solutions of ethyl alcohol and water in fluorosulfuric acid are given in Table III. In the case of ethyl alcohol only the CH_2 and CH_3 peaks are visible at room temperature but on cooling the solution a new peak appears, as was found by MacLean and Mackor in HF/BF_3 solution (1). However, we were unable to observe any fine structure in the new peak. At −95° the relative areas of the three peaks were found to be 1.74:1.89:3.0 which agrees reasonably well with the values 2.0:2.0:3.0 expected for $H_2O^+ \cdot CH_2 \cdot CH_3$.

Only a single peak was observed in the spectra of solutions of water in fluorosulfuric acid or in SbF_5/HSO_3F solutions even at low temperatures. MacLean and Mackor (1) have found that the peak due to H_3O^+ in hydrogen fluoride occurs 0.52 p.p.m. to lower field than the H_2O^+ signal from protonated ethyl alcohol, and it is very likely therefore that the H_3O^+ peak in HSO_3F solutions is very close to the solvent. Since the solvent line is quite broad at these low temperatures, it is not unreasonable to suppose that the peak due to H_3O^+ is overlapped by the solvent peak and is therefore not observable.

Rates of Proton Exchange and Activation Energies

Raising the temperature of solutions of these bases in HSO_3F results in a broadening of the OH^+ peak due to a decrease in the lifetime of the conjugate acid. Since there is no overlapping of the OH^+ and solvent peaks, the conditions for slow exchange may be applied

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and the rates of proton exchange calculated. If $1/T_2'$ is the measured line width at any particular temperature, $1/T_2$ is the line width in the absence of exchange, and $1/\tau$ is the lifetime of the conjugate acid, then

$$1/T_2' = 1/T_2 + 1/\tau.$$

The first-order rate constant for proton loss by the conjugate acid is given by

$$k = \tau^{-1}$$

and the dependence of the rate of deprotonation on the temperature can be expressed by the Arrhenius equation

$$k = k_0 \, e^{-E/RT}.$$

Rate data for the substituted acetophenones is given in Table IV. In the case of *p*-nitroacetophenone it was not possible to stop the exchange process completely and hence $1/T_2$ could not be measured. In this case a value for $1/T_2$ was estimated from the results for the other ketones. Plots of log k against $1/T$ (Fig. 5) for these acetophenones give straight lines from which the activation energies were obtained. Except for the *p*-nitro compound the activation energies fall in the range 11–12 kcal. Whether or not the large deviation from this value in the case of *p*-nitroacetophenone is real, or is due to the choice of an incorrect value for T_2, could perhaps be answered by carrying out a comparable investigation in a more acidic solvent than HSO_3F so that proton exchange by the conjugate acid of *p*-nitroacetophenone could be stopped completely.

TABLE IV

Rate data for solutions of acetophenones in fluorosulfuric acid

Base	Conc., mole %	E, kcal/mole	Log k_0	Log k ($-60°$)	$-pK_{BH^+}$
p-Nitroacetophenone	3.28	7.6	10.89	3.10	8.43
p-Chloroacetophenone	2.93	11.4	12.89	1.17	6.77
Acetophenone	3.36	11.1	12.64	1.49	6.36
p-Fluoroacetophenone	2.94	12.9	14.14	0.90	6.29
p-Methylacetophenone	3.22	11.4	12.57	0.87	5.57
p-Methoxyacetophenone	3.10	11.6	12.97	1.08	4.91

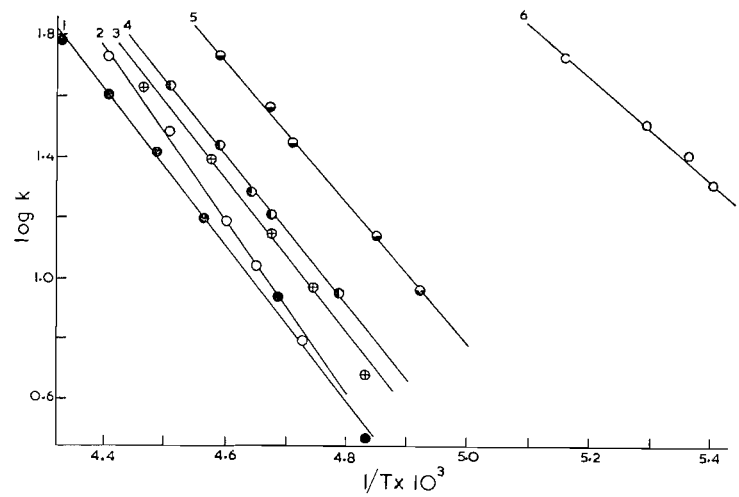

FIG. 5. Log k against $1/T$ for solutions of acetophenones in fluorosulfuric acid: (1) *p*-CH_3, (2) *p*-F, (3) *p*-OCH_3, (4) *p*-Cl, (5) *p*-H, (6) *p*-NO_2.

For personal use only.

There is no obvious correlation between the rate of proton loss and pK_{BH^+} or σ^+. Although *p*-nitroacetophenone exchanges more rapidly than the other acetopheones, *p*-methoxyacetophenone does not exchange as slowly as might be expected. It is possible, however, that in this latter case the calculated rate may not be correct, as the $=OH^+$ peak is much closer to the solvent peak than for the other bases studied, and when exchange becomes appreciable some merging of the $=OH^+$ and solvent peaks is apparent, and therefore the conditions for slow exchange may not apply.

EXPERIMENTAL

The bases were commercial samples; solid samples were recrystallized from suitable solvents, while the liquids were dried and then distilled. All samples were prepared in the manner reported previously (2).

The spectra were recorded on a Varian HR60 n.m.r. spectrometer equipped with a low-temperature probe and integrator.

ELECTROCRYSTALLIZATION

I. SURFACE DIFFUSION

S. K. RANGARAJAN
Central Electrochemical Research Institute, Karaikudi, India

Received October 19, 1964

ABSTRACT

A solution of the boundary value problem posed by Fleischmann and Thirsk is presented here for a generalized time dependence of $\eta(t)$, the overpotential. The results for various techniques have been derived. Expressions for the transients have also been obtained. The formulations reported earlier for the potentiostatic, the faradaic impedance, and the galvanostatic techniques are deduced as special cases. It has also been shown that in the 'potential step method' a relatively simple relationship exists between the first and the second overpotentials.

Recent investigations* have suggested that two important paths to be reckoned with in the discussion of the kinetics of electrocrystallization can formally be idealized as follows:

(*a*) The ions (or the reactive species) are discharged (or transferred) from the solution so as to form the so-called adions (or adatoms). This stage is the one involving electrochemical reactions. Adatoms, then, diffuse over the surface to the sites where the lattice formation is facilitated and accomplished.

(*b*) The reactive species is first to be transferred to the pre-electrode layer before the electrochemical reaction can occur. The discharge takes place at the sites where the lattice building takes place.

Formally (*a*) and (*b*) can be termed "surface diffusion" and "direct deposition" models respectively—implying that these are the probable rate-controlling steps in the sequence of events characterizing the two paths. It is to be noted that the stages characterizing (*a*) and (*b*) are not to be considered mutually exclusive. Usually the point of interest is to determine which of these eclipses the other in any particular study. It must be emphasized again that (*a*) and (*b*) themselves are "simplified versions" and the actual physical situation may be too complicated to elude both of these cleverly (1, 2). Attempts have been made to interpret the experimental results in terms of the models (*a*) and (*b*). Interpretations based on simplified versions of (*a*) have been put forward (1, 3, 4, 5) and, obviously, are limited in scope. A rigorous approach may have to take into account simultaneously (i) the mass transfer processes in the solution (not neglecting the double layer structure), (ii) the details of the reaction mechanisms (homogeneous chemical reactions following or preceding, adsorption etc.), (iii) surface diffusion of adatoms (whose 'ionic nature' (6) also is to be detailed), (iv) a description of the surface dislocations and their dependence on the applied field, the effect of the nature of the surface, the interference of impurities in the step motion etc. (2, 7, 8)—to mention a few. It is obvious that such a theory is very difficult, if not impossible. Nevertheless, quantitative formulations worked out for well defined models can themselves be of significant value in interpreting the results. The most systematic attempt available as regards the model (*a*) is by Fleischmann and Thirsk (1*b*) who have, besides formulating the problem that is solved in this paper, worked out an exact solution for the potentiostatic case and a

**For a critical discussion of this problem and comprehensive bibliography see refs. 1a, 1b.*

formulation for the faradaic impedance when the amplitude of the sinusoidal wave is sufficiently small. Fleischmann and Thirsk (1*b*) have also suggested some possible experiments. The diffusion process of the adatoms over the surface as assumed in this model (1*b*) is as follows.

The steps are spaced at a distance $2l$ and at the steps the density of Kossel kinks is high and the mean displacement of the adsorbed species on the surface is much greater than the mean distance between the kinks so as to maintain an equilibrium for the 'exchange *at* the kinks' and consequently to ensure a uniform concentration along these. This enables one to consider a step as 'a continuous line-sink' (cf. p. 304 of ref. 7). The mass transfer process in the solution does not interact or influence this.

Under these assumptions, a mathematical representation of the diffusion phenomenon becomes considerably simplified. If the steps are represented as $x = 0$, $x = 2l$, and the concentration of the adatoms at any position x and any instant t is $C(x, t)$, we have

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} + k_1(t) - k_2(t)C. \qquad [1]$$

Herein, $k_1(t)$, the rate of deposition, is equal to $i_0(zF)^{-1}\exp[\alpha zF\eta(t)/RT]$, $k_2(t)$, the rate of removal, is equal to $i_0C(zFC_0)^{-1}\exp[(\alpha - 1)zF\eta(t)/RT]$, where $\eta(t)$ is the overpotential and C_0 is the concentration at $\eta = 0$.

The initial condition is

$$C(x, t) = C_0 \text{ when } t = 0, \qquad [2]$$

and the boundary conditions are

$$C(x, t) = C_0,\ x = 0,\ t \geqslant 0; \qquad [3]$$

$$\partial C(x, t)/\partial x = 0,\ x = l,\ t \geqslant 0. \qquad [4]$$

In this paper, we solve eq. [1] with [2–4] for *any* given functional form of $\eta(t)$ and all values of α (Section 1). The limitations of the solutions, if any, are then those of the model. We also present explicit dependence of the current on time t for the following techniques, besides rederiving the results of Fleischmann (1) for the potentiostatic conditions (Section 2).

A. Potentiodynamic (or potentiokinetic) (Section 3),

$$\eta(t) = \eta_0 + \omega t. \qquad [5]$$

B. Potential step method ((Section 4), wherein

$$\eta(t) = \eta_0',\ 0 < t < t_1;\ \eta(t) = \eta_0,\ t_1 \leqslant t. \qquad [6]$$

C. Faradaic impedance (Section 5),

D. Faradaic rectification (Section 6),

$$\eta(t) = \eta_0 + v_0\cos\omega t. \qquad [7]$$

Cases A and B have been solved exactly. In the case of C and D, v_0 is assumed to be small but the results can be expected to be valid over a wider range than that allowed for the known linearization model (1*b*). The significance of the approximation made earlier (1*b*) is discussed. The expressions for the transients in all these cases have been explicitly stated so as to be useful in the experiments dealing with transients. Besides

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the analysis with reference to the mathematical significance of the general solutions and the degeneracy of these into special cases, a brief discussion of the results of Fleischmann (1*b*) and Gerischer and Tischer (9) with reference to the potential step method is presented. It is indeed shown that eq. 40 of ref. 1*b* can be simplified resulting in an elegant relationship between the two overpotentials, η_0' and η_0 of eq. [6].

As the galvanostatic experiments (3, 4) are usually confined to small excursions of the current i and time t from their zero values, a simple, trivial expression relating $i(t)$ and $\eta(t)$ is given for various functional forms of $i(t)$ which, we hope, would be valid for sufficiently small t. Though this expression might be useful for such experiments in transients with $i(t)$ as any *known function* of time, the limitations are many and one has to be aware of them before applying the expression. Of course, an exact inversion of $\eta(t)$ for *any* given $i(t)$ remains a tricky and laborious question. Aside from rederiving the earlier results (1, 6, 7), we do not present in this paper any important results concerning the galvanostatic experiments (Section 7).

Lastly it may be mentioned here that the results for various techniques have been presented more as illustrations—with emphasis on the 'mathematical completeness'—than as suggestions for further experimentation. This paper confines itself to theoretical derivations and no comparison is made with experimental results. The discussion of models and numerical representation of some of the expressions derived here will be communicated later.

1. General Solution

The differential equation [1] is solved with the initial and boundary conditions [2–4] and the concentration distribution of adatoms $C(x, t)$ is found to be (cf. Appendix I),

$$C(x, t) = C_0 + \frac{C^*(x, t) - \mathscr{K}(t)}{K(t)}, \qquad [8]$$

where

$$C^*(x, t) = C_0 - \frac{D}{l}\frac{\partial}{\partial x}\left\{\int_0^t [C_0 - \mathscr{K}(t)]\theta_1\left[\frac{l-x}{2l}, \frac{\pi D(t-\tau)}{l^2}\right] d\tau\right\} \qquad [9]$$

$$C(x, t) = C_0 - \frac{D}{K(t)}\frac{\partial}{\partial x}\left\{\int_0^t [C_0 - \mathscr{K}(t)]\theta_1\left[\frac{l-x}{2l}, \frac{\pi D(t-\tau)}{l^2}\right] d\tau\right\} + \frac{1}{K(t)}\int_0^t [k_1(\tau) - k_2(\tau)C_0]K(\tau)\, d\tau \qquad [10]$$

$$K(t) = \exp\left[\int_0^t k_2(\tau)\, d\tau\right] \qquad [11]$$

$$\mathscr{K}(t) = C_0K(t) - \int_0^t k_1(\tau)K(\tau)\, d\tau$$

$$= C_0 - \int_0^t [k_1(\tau) - k_2(\tau)C_0]K(\tau)\, d\tau \qquad [12]$$

$$\theta_1(v, t) = 2\sum_0^\infty (-1)^{n+1} \exp[-\pi(n + \tfrac{1}{2})^2 t] \sin[(2n + 1)\pi v] \qquad [13]$$

is the theta function.

The current $i(t)$ is given by

$$[14] \qquad i(t) = zFl^{-1} \int_0^l [k_1 - k_2 C(x, t)]\, dx.$$

We give below three alternate forms for $i(t)$ which would prove to be useful under appropriate conditions:

$$[15] \qquad i(t) = zF \frac{d}{dt}\left[\frac{1}{K(t)} \int_0^t [k_1(\tau) - k_2(\tau)C_0]K(\tau)\, d\tau\right] + \frac{2ZFDk_2(t)}{K(t)l^2} \sum_{n=0}^{\infty} \exp\left[-\frac{\pi^2 Dt}{4l^2}(2n+1)^2\right] \cdot \left\{\int_0^t [C_0 - \mathscr{K}(\tau)] \exp\left[\frac{\pi^2 D\tau}{4l^2}(2n+1)^2\right] d\tau\right.$$

(cf. Appendix, A.22),

$$[16] \qquad \frac{i(t)}{zF} = [k_1(t) - k_2(t)C_0] - \frac{8}{\pi^2} \sum \frac{k_2(t)}{(2n+1)^2} \exp\left[-\left(\frac{\pi^2 Dt}{4l^2}(2n+1)^2 + \int_0^t k_2(\tau)\, d\tau\right)\right] \cdot \left\{\int_0^t [k_1(\tau) - k_2(\tau)C_0] \exp\left[\frac{\pi^2 D\tau}{4l^2}(2n+1)^2 + \int_0^\tau k_2(z)\, dz\right] d\tau\right\}$$

(cf. Appendix, A.24),

$$[17] \qquad \frac{i(t)}{zF} = [k_1(t) - k_2(t)C_0] - \frac{32l^2}{\pi^2} k_2(t) \sum \frac{k_1(t) - k_2(t)C_0}{[4l^2 k_2(t) + \pi^2 D(2n+1)^2](2n+1)^2} + \frac{32l^2}{\pi^2} k_2(t) \sum \frac{k_1(+0) - k_2(+0)C_0}{[4l^2 k_2(+0) + \pi^2 D(2n+1)^2](2n+1)^2} \cdot \exp\left[-\left[\frac{\pi^2 Dt(2n+1)^2}{4l^2} + \int_0^t k_2(\tau)\, d\tau\right]\right] + \frac{32l^2}{\pi^2} k_2(t) \sum \exp\left[-\left[\frac{\pi^2 Dt(2n+1)^2}{4l^2} + \int_0^t k_2(\tau)\, d\tau\right]\right] / (2n+1)^2 \left\{\int_0^t \frac{d}{d\tau}\left[\frac{k_1(\tau) - k_2(\tau)C_0}{4l^2 k_2(\tau) + \pi^2 D(2n+1)^2}\right] \exp\left[\frac{\pi^2 D\tau(2n+1)^2}{4l^2} + \int_0^\tau k_2(z)\, dz\right] d\tau\right\}$$

(cf. Appendix, A.25). It can be shown (cf. Appendix I) that eqs. [15], [16], and [17] are equivalent. Equation [15] is particularly useful in approximations involving $t \to 0$ (cf. Section 7), eq. [16] is more easily integrable than [15] and can be used with advantage for $t \to \infty$, while [17] suggests how successive approximations can be adopted in problems involving a complicated dependence of $\eta(t)$ on time t (also cf. Section 4). If $\alpha = 1$, the expressions are considerably simplified since $k_2(t) = i_0/(zFC_0)$, a constant, and $K(t) = \exp[i_0 t/(zFC_0)]$. The resulting expression under these conditions can be seen to be identical with that given earlier (2)*.

*The sign of one of the terms will have to be corrected in eq. 21, p. 154 of ref. 1a.

(i) As $\pi Dt/l^2$ tends to zero, one approximates [1] as

$$\partial C/\partial t = k_1(t) - k_2(t)C \qquad [18]$$

with the conditions [2–4]. It is easily seen that

$$i(t) = \frac{zF}{l}\int_0^t [k_1(t) - k_2(t)C(x,t)]\,dx = \frac{d}{dt}\left\{\frac{1}{K(t)}\int_0^t [k_1(\tau) - k_2(\tau)C_0]K(\tau)\,d\tau\right\}. \qquad [19]$$

(ii) As t tends to infinity and

$$\int_0^t k_2(\tau)\,d\tau \ll \pi^2 D\tau(4l^2)^{-1}, \qquad [20]$$

eq. [16] gives

$$i(t) \rightarrow [k_1(t) - k_2(t)C_0]. \qquad [21]$$

When $zF\eta(t)/RT$ is a constant, δ_0 say, eq. [21] results as a steady state if

$$k_2{}^0 = (i_0/zFC_0)\exp[(\alpha - 1)\delta_0] \ll \pi^2 D(4l^2)^{-1}.$$

(iii) As t tends to infinity (steady state), i.e.,

$$\pi^2 Dt(4l^2)^{-1}, \quad \int_0^t k_2(z)\,dz \rightarrow \infty.$$

Then,

$$i(t) \simeq [k_1(t) - k_2(t)C_0] - \frac{32l^2}{\pi^2}k_2(t)\sum\left[\frac{k_1(t) - k_2(t)C_0}{[4l^2k_2(t) + \pi^2 D(2n+1)^2](2n+1)^2} - \frac{1}{(2n+1)^2}\frac{1}{k_2(t) + \pi^2 D(4l^2)^{-1}(2n+1)^2}\frac{d}{dt}\left\{\frac{k_1(t) - k_2(t)C_0}{4l^2k_2(t) + \pi^2 D(2n+1)^2}\right\}\right]. \qquad [22]$$

For the sake of brevity, a discussion on the magnitude of the approximations expressed through eqs. [19], [21], and [22] is not given.

2. Potentiostatic Case

If

$$zF\eta(t)/RT = \delta_0, \text{ a constant}, \qquad [23]$$

$$k_1(t) = i_0/(zF)\exp(\alpha\delta_0) = k_1{}^0, \qquad [24]$$

and

$$k_2(t) = i_0/(zFC_0)\exp[(\alpha - 1)\delta_0] = k_2{}^0, \text{ say} \qquad [25]$$

$$K(t) = \exp(k_2{}^0 t). \qquad [26]$$

When eqs. [23–26] are substituted in [16], one obtains,

$$\frac{i(t)}{zF} = (k_1{}^0 - k_2{}^0C_0) - \frac{8k_2{}^0}{\pi^2}(k_1{}^0 - k_2{}^0C_0)\cdot\sum\frac{1 - \exp[-(\pi^2 Dt(4l^2)^{-1} + k_2{}^0 t)]}{(2n+1)^2[\pi^2 D(2n+1)^2(4l^2)^{-1} + k_2{}^0]}. \qquad [27]$$

Observing that

$$\sum \frac{1}{(2n+1)^2[A(2n+1)^2+B]} = \frac{1}{B}\left[\sum \frac{1}{(2n+1)^2} - \sum \frac{A}{A(2n+1)^2+B}\right]$$

$$= \frac{\pi^2}{8B}\left[1 - \sum \frac{2}{\pi^2(2n+1)^2/4 + \pi^2 B/4A}\right]$$

$$= \frac{\pi_2}{8B}\left[1 - \frac{\tanh(\pi/2\sqrt{B/A})}{\pi/2\sqrt{B/A}}\right], \quad [28]$$

eq. [27] becomes

$$\frac{i(t)}{zF} = (k_1^0 - k_2^0 C_0)\frac{\tanh(\sqrt{k_2^0/D}\cdot l)}{\sqrt{k_2^0/D}\cdot l} + 32(k_1^0 - k_2^0 C_0)k_2^0 l^2 \sum \frac{\exp[-(\pi^2 D(2n+1)^2(4l^2)^{-1} + k_2^0 t)]}{(2n+1)^2[4l^2 k_2^0 + \pi^2 D(2n+1)^2]} \quad [29]$$

a result identical with that derived earlier (1*b*). Except for the derivation of [29] as a special case of [16], no discussion is presented since this has been dealt with in detail by Fleischmann and Thirsk (1).

3. Potentiokinetic Technique

We consider here the derivation of the faradaic current $i(t)$ when the applied potential varies linearly with time. It is of interest to note here that lately this technique has assumed important significance in the studies of electrode kinetics. (For a review see refs. 10 and 11.)

Writing $zF\eta(t)/RT = \delta_0 + \delta_1 t$,

$$k_1(t) = k_1^0 \exp(\alpha\delta_1 t) \quad [30]$$

$$k_2(t) = k_2^0 \exp[(\alpha - 1)\delta_1 t] \quad [31]$$

and

$$K(t) = \exp(k_2^0(\alpha-1)^{-1}\{\exp[(\alpha-1)\delta_1 t] - 1\}). \quad [32]$$

With [30–32] made use of in [16], an expression for $i(t)$ is derived (cf. Appendix II). The steady state of $i(t)$ is

$$i_{st}(t) = zF[k_1(t) - k_2(t)C_0] - \frac{8zFk_2(t)}{\pi^2}\sum\left\{\frac{k_1(t)}{(2n+1)^2}\frac{\Phi(1, A_n+1; k_2(t)/(1-\alpha)\delta_1)}{[\pi^2 D(4l^2)^{-1}(2n+1)^2 + \alpha\delta_1]} - \frac{k_2(t)C_0}{(2n+1)^2}\frac{\Phi(1, A_n+1+(1-\alpha)^{-1}; k_2(t)/(1-\alpha)\delta_1)}{[\pi^2 D(4l^2)^{-1}(2n+1)^2 + (\alpha-1)\delta_1]}\right\}, \quad [33]$$

while the transient is

$$i_{tr}(t) = \frac{8zFk_2(t)}{\pi^2}\exp\left[\frac{k_2(t) - k_2^0}{(1-\alpha)\delta_1}\right]\sum\{\exp[-\pi^2 D(4l^2)^{-1}(2n+1)^2 t]\}/(2n+1)^2 \cdot \left\{\frac{k_1^0\Phi[1, A_n+1; k_2^0/(1-\alpha)\delta_1]}{\pi^2 D(4l^2)^{-1}(2n+1)^2 + \alpha\delta_1} - \frac{k_2^0 C_0\Phi[1, A_n+1+(1-\alpha)^{-1}; k_2^0/(1-\alpha)\delta_1]}{\pi^2 D(4l^2)^{-1}(2n+1)^2 + (\alpha-1)\delta_1}\right\}. \quad [34]$$

The instantaneous faradaic current $i(t)$ is then $i_{st}(t) + i_{tr}(t)$ where the steady state and the transient currents are given through equations [33–34]. In [33–34], $\Phi(a, c; x)$ represents the confluent hypergeometric function defined by

$$\Phi(a, c; x) = 1 + \frac{a}{c}x + \frac{a(a+1)}{c(c+1)}\frac{x^2}{2!} + \ldots \qquad [35]$$

and

$$A_n = -\left[\frac{\pi^2 D(2n+1)^2}{4l^2(1-\alpha)\delta_1} + \frac{\alpha}{1-\alpha}\right]. \qquad [36]$$

Equations [33–34] can as well be expressed in terms of incomplete gamma functions (cf. Appendix II).

An Approximate Expression for $i(t)$

Considering the time dependence of $\eta(t)$ on t as a perturbation so that $(\delta_1 t)$ is assumed to be quite small, we approximate,

$$K(t) = \exp\left[\frac{k_2^0}{(\alpha-1)\delta_1}\{\exp[(\alpha-1)\delta_1 t] - 1\}\right] \simeq \exp(k_2^0 t). \qquad [37]$$

With the approximation implicit in [37], the result [16] then takes a particularly simple form:

$$\frac{i(t)}{zF} = [k_1(t) - k_2(t)C_0] - \frac{8}{\pi^2}\sum \frac{k_2(t)}{(2n+1)^2}\exp\left[-\frac{\pi^2 Dt(2n+1)^2}{4l^2} + \frac{k_2^0 - k_2(t)}{(1-\alpha)\delta_1}\right] \cdot\left\{\int_0^t [k_1(\tau) - k_2(\tau)C_0]\exp\left[\frac{\pi^2 D\tau(2n+1)^2}{4l^2} + k_2^0\tau\right]d\tau\right\} = i_{st}(t) + i_{tr}(t); \qquad [38]$$

with

$$i_{st}(t) = zF[k_1(t) - k_2(t)C_0] - \frac{8zF}{\pi^2}k_2(t)\sum\left\{\frac{k_1(t)}{[\pi^2 D(4l^2)^{-1}(2n+1)^2 + k_2^0 + \alpha\delta_1](2n+1)^2} - \frac{k_2(t)C_0}{[\pi^2 D(2n+1)^2(4l^2)^{-1} + k_2^0 + (\alpha-1)\delta_1](2n+1)^2}\right\}; \qquad [39]$$

and

$$i_{tr}(t) = \frac{8zF}{\pi^2}k_2(t)\exp\left[\frac{k_2(t) - k_2^0}{(1-\alpha)\delta_1}\right] \sum \frac{\exp(-\pi^2 Dt(4l^2)^{-1}(2n+1)^2)}{(2n+1)^2}\left\{\frac{k_1^0}{\pi^2 D(4l^2)^{-1}(2n+1)^2 + k_2^0 + \alpha\delta_1} - \frac{k_2^0 C_0}{\pi^2 D(4l^2)^{-1}(2n+1)^2 + k_2^0 + (\alpha-1)\delta_1}\right\}. \qquad [40]$$

With the help of [28], eq. [39] is rewritten as

$$i_{st}(t) = zF[k_1(t) - k_2(t)C_0] - \frac{zFk_1(t)k_2(t)}{k_2^0 + \alpha\delta_1}\left[1 - \frac{\tanh\sqrt{(k_2^0 + \alpha\delta_1)/D}\cdot l}{\sqrt{(k_2^0 + \alpha\delta_1)/D}\cdot l}\right] + \frac{zFk_2(t)^2 C_0}{k_2^0 + (\alpha-1)\delta_1}\left[1 - \frac{\tanh\sqrt{[k_2^0 + (\alpha-1)\delta_1]/D}\cdot l}{\sqrt{[k_2^0 + (\alpha-1)\delta_1]/D}\cdot l}\right]. \qquad [41]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Equations [39] and [41] become identical with the corresponding expressions for the potentiostatic case (cf. eq. [29]) by making $\delta_1 = 0$.

Some Particular Cases

(i)

[42] $$k_2(t) \ll \pi^2 D/(4l^2).$$

(ii)

[43] $$k_2(t) \gg \pi^2 D/(4l^2).$$

(iii)

$$k_2{}^0/[(1-\alpha)\delta_1] \to \infty, \quad \pi^2 D/[4l^2(1-\alpha)\delta_1] \to \infty \quad \text{while the ratio is finite.}$$

(iv)

$$\delta_1 \to 0 \text{ (potentiostatic case).}$$

(v)

$$\delta_1 \text{ is small (perturbation expressions [40–41]).}$$

(Note: a direct substitution of $\delta_1 = 0$ in the general equations [33–34] presents difficulties since both the parameters A_n and argument $k_2(t)/(1-\alpha)\delta_1$ of the hypergeometric function tend to infinity.)

For case (i), $k_2(t) \ll \pi^2 D/(4l^2)$, as

[44] $$\Phi(a, c; x) \to 1, \qquad \text{if } x/c \to 0 \ (a \text{ bounded}),$$

eq. [33] gives

[45] $$i_{st}(t) \to zF[k_1(t) - k_2(t)C_0] - zFk_2(t)\left\{\frac{k_1(t)}{\alpha\delta_1}\left[1 - \frac{\tanh\sqrt{\alpha\delta_1/D}\cdot l}{\sqrt{\alpha\delta_1/D}\cdot l}\right] - \frac{k_2(t)C_0}{(\alpha-1)\delta_1}\left[1 - \frac{\tanh\sqrt{(\alpha-1)\delta_1/D}\cdot l}{\sqrt{(\alpha-1)\delta_1/D}\cdot l}\right]\right\}.$$

Cases (ii–v) are all deduced by making use of the representation of $i(t)$ in terms of incomplete gamma function and making use of the asymptotic representation of these functions given by Tricomi (12).

Noting that the asymptotic behavior of gamma function is

[46] $$\gamma(1+\alpha, x+y) - \gamma(1+\alpha, x) \simeq \exp(-x)\cdot x^{1+\alpha}(x-\alpha)^{-1} - \exp[-(x+y)]\cdot(x+y)^{1+\alpha}(x+y-\alpha)^{-1},$$

if the parameter $z = \alpha^{1/2}/(x-\alpha)$ is small, the parameter

$$z^2 = \alpha/(x-\alpha)^2 = \frac{\pi^2 D(4l^2)^{-1}(1-\alpha)\delta_1}{[k_2(t) + \pi^2 D(4l^2)^{-1} + \alpha\delta_1]^2} \ll 1,$$

if (i) $\delta_1 \to 0$ and $k_2(t), \pi^2 D/4l^2 \gg \delta_1$

or (ii) $k_2(t) \gg \pi^2 D(4l^2)^{-1}(1-\alpha)\delta_1$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Condition (i) allows us to attain the limit corresponding to the potentiostatic condition ($\delta_1 = 0$) whatever be the relative magnitudes of $k_2(t)$ and $\pi^2 D/4l^2$. An approximate result for small δ_1 can also be derived under these conditions.

If $k_2(t) \gg \pi^2/4l^2$ and $k_2^0 \gtrsim \delta_1$, the same asymptotic approximation can be used. Thus one arrives at the same limiting expression under varied conditions depending upon the parameters of interest. Thus,

$$\left[\frac{k_2^0}{(1-\alpha)\delta_1}\right]^{-A_n}\left[\frac{1}{(1-\alpha)\delta_1}\right]\left\{\gamma\left[A_n, \frac{k_2^0}{(1-\alpha)\delta_1}\right] - \gamma\left[A_n, \frac{k_2(t)}{(1-\alpha)\delta_1}\right]\right\}$$

and

$$\left[\frac{k_2^0}{(1-\alpha)\delta_1}\right]^{-(A_n+(1-\alpha)^{-1}}\left[\frac{1}{(1-\alpha)\delta_1}\right]\left\{\gamma\left[A_n + \frac{1}{1-\alpha}, \frac{k_2^0}{(1-\alpha)\delta_1}\right] - \gamma\left[A_n, \frac{k_2(t)}{(1-\alpha)\delta_1}\right]\right\}$$

are approximated with the help of [22] and it can be proved that [B.11] then becomes

$$[47]\quad \frac{i(t)}{zF} = [k_1(t) - k_2(t)C_0]$$
$$- \frac{8}{\pi^2}k_2(t)\left\{\sum \frac{1}{(2n+1)^2}\left[\frac{k_1(t)}{k_2(t) + \pi^2 D(4l^2)^{-1}(2n+1)^2 + \alpha\delta_1}\right]\right.$$
$$\left. - \sum \frac{1}{(2n+1)^2}\left[\frac{k_2(t)C_0}{k_2(t) + \pi^2 D(4l^2)^{-1}(2n+1)^2 + (\alpha-1)\delta_1}\right]\right\}$$
$$+ \frac{8}{\pi^2}k_2(t)\exp\left[\frac{k_2(t) - k_2^0}{(1-\alpha)\delta_1}\right]\left\{\sum \frac{k_1^0 \exp[-\pi^2 D(4l^2)^{-1}(2n+1)^2 t]}{(2n+1)^2[k_2^0 + \pi^2 D(4l^2)^{-1}(2n+1)^2 + \alpha\delta_1]}\right.$$
$$\left. - \sum \frac{k_2^0 C_0 \exp[-\pi^2 D(4l^2)^{-1}(2n+1)^2 t]}{(2n+1)^2[k_2^0 + \pi^2 D(4l^2)^{-1}(2n+1)^2 + (\alpha-1)\delta_1]}\right\}.$$

It may be observed here that the approximate treatment made earlier (cf. eqs. [39] and [41] gives a result identical with [47] if the approximations made in deriving the former are properly introduced in [47].

4. Potential Step Method

Let us assume that

$$[48]\quad \eta(t) = \eta_0' \qquad 0 < t < t_1 \text{ and}$$
$$= \eta_0 \qquad t_1 \leqslant t$$

so that

$$[49]\quad k_1(t) = k_1^{0\prime} \qquad 0 < t < t_1 \text{ and}$$
$$= k_1^0 \qquad t_1 \leqslant t$$

and

$$[50]\quad k_2(t) = k_2' \qquad 0 < t < t_1 \text{ and}$$
$$= k_2^0 \qquad t_1 \leqslant t.$$

Obviously,

$$\frac{k_1(t) - k_2(t)C_0}{4l^2 k_2(t) + \pi^2 D(2n+1)^2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

has a discontinuity (a jump) of magnitude

$$\frac{k_1^0 - k_2^0 C_0}{4l^2 k_2^0 + \pi^2 D(2n+1)^2} - \frac{k_1^{0\prime} - k_2^{0\prime} C_0}{4l^2 k_2^{0\prime} + \pi^2 D(2n+1)^2}$$

at $t = t_1$.
Consequently

$$\frac{\mathrm{d}}{\mathrm{d}t}\left\{\frac{k_1(t) - k_2(t)C_0}{4l^2 k_2(t) + \pi^2 D(2n+1)^2}\right\}$$

can be represented as

[51] $$\left\{\frac{k_1^0 - k_2^0 C_0}{4l^2 k_2^0 + \pi^2 D(2n+1)^2} - \frac{k_1^{0\prime} - k_2^{0\prime} C_0}{4l^2 k_2^{0\prime} + \pi^2 D(2n+1)^2}\right\} \cdot \delta(t - t_1),$$

where $\delta(t)$ is Dirac's delta function. Also it is well known that

[52] $$\int_0^t \delta(\tau - t_1) f(\tau)\, \mathrm{d}\tau = f(t_1), \quad t > t_1.$$

Equation [17] then gives

[53] $$\frac{i(t)}{zF} = (k_1^0 - k_2^0 C_0)\frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l} + \frac{32l^2}{\pi^2} k_2^0 [k_1^{0\prime} - k_2^{0\prime} C_0] \sum \frac{\exp\{-[\pi^2 Dt(4l^2)^{-1}(2n+1)^2 + k_2^{0\prime} t_1 + k_2^0(t - t_1)]\}}{[4l^2 k_2^0 + \pi^2 D(2n+1)^2](2n+1)^2}$$
$$+ \frac{32l^2}{\pi^2} k_2^0 \sum \left[\frac{k_1^0 - k_2^0 C_0}{[4l^2 k_2^0 + \pi^2 D(2n+1)^2](2n+1)^2} - \frac{k_1^{0\prime} - k_2^{0\prime} C_0}{[4l^2 k_2^{0\prime} + \pi^2 D(2n+1)^2](2n+1)^2}\right] \cdot \exp\left\{-\left[\frac{\pi^2 D(t - t_1)}{4l^2}(2n+1)^2 + k_2^0(t - t_1)\right]\right\}.$$

The first term of [53] is the steady state value, viz.,

$$(k_1^0 - k_2^0 C_0)\frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l}$$

caused by the second overpotential. The other terms are transients. If the η_0 is applied only after the steady state due to the first η_0' has been attained, a limiting expression of [53] can be obtained by allowing $t, t_1 \to \infty$ while $t - t_1 = T$ remains finite. Under these conditions,

[54] $$\frac{i(t)}{zF} = [k_1^0 - k_2^0 C_0]\frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l} + \frac{32l^2}{\pi^2} k_2^0 [k_1^0 - k_2^0 C_0] \cdot \sum \frac{\exp[-(\pi^2 DT(4l^2)^{-1}(2n+1)^2 + k_2^0 T)]}{[4l^2 k_2^0 + \pi^2 D(2n+1)^2](2n+1)^2} - \frac{32l^2}{\pi^2} k_2^0 [k_1^{0\prime} - k_2^{0\prime} C_0] \cdot \sum \frac{\exp[-(\pi^2 DT(4l^2)^{-1}(2n+1)^2 + k_2^{0\prime} T)]}{[4l^2 k_2^{0\prime} + \pi^2 D(2n+1)^2](2n+1)^2}.$$

For personal use only.

The first two terms in [54] are identical with the response after a time T due to the application of the overpotential η_0 at $T = 0$. The last one is a 'cross term'.

The equation derived by Fleischmann and Thirsk (1*b*) for the problem corresponding to the solution [54] differs from that obtained here. After proper modifications (Appendix III) the two are shown to be identical.

It has been suggested by Gerischer (9) that the excess concentration polarization (that remaining after the corrections due to the mass transfer polarization in the solution) is to be accounted for by the concentration polarization of the adatoms. For the model discussed in this paper, one would write

$$[55] \qquad i(t_1 + 0) = zFl^{-1} \int_0^l [k_1^0 - k_2^0 C_1^*(x)]\, dx,$$

where $C_1^*(x)$ is the steady state concentration attained due to the application of η_0'.

$$[56] \qquad C_1^*(x) = C_0 + \frac{k_1^{0\prime} - k_2^{0\prime} C_0}{k_2^{0\prime}} \left[1 - \frac{\cosh \sqrt{k_2^{0\prime}/D} \cdot (l - x)}{\cosh \sqrt{k_2^{0\prime}/D} \cdot l}\right].$$

If η_0' has been so chosen as to make $i(t_1 + 0) = 0$,

$$[57] \qquad \frac{k_1^0}{k_2^0} = C_0 \exp\left[\frac{zF\eta_0}{RT}\right] = \frac{1}{l} \int_0^l C^*(x)\, dx = C_0 + \frac{k_1^{0\prime} - k_2^{0\prime} C_0}{k_2^{0\prime}} \left[1 - \frac{\tanh \sqrt{k_2^{0\prime}/D} \cdot l}{\sqrt{k_2^{0\prime}/D} \cdot l}\right].$$

Equation [57] demonstrates the dependence of the second overpotential on the average steady state concentration due to the first potential. The similarity with Nernst equation is too obvious.

In contrast to what has been stated earlier (1*a*, 1*b*) a relatively simple relationship* exists between the two overpotentials η_0' and η_0. As a matter of fact

$$[58] \qquad \exp\left(\frac{zF\eta_0}{RT}\right) = \exp\left(\frac{zF\eta_0'}{RT}\right) - \frac{\tanh \sqrt{k_2^0/D} \cdot l}{\sqrt{k_2^0/D} \cdot l} \left[1 - \exp\left(\frac{zF\eta_0'}{RT}\right)\right].$$

If the second overpotential has the equilibrium values, then $k_1^0 - k_2^0 C_0 = 0$, and one has

$$[59] \qquad i(t) = \frac{8i_0}{\pi^2} \left[1 - \exp\left(\frac{zF\eta_0'}{RT}\right)\right] \cdot \sum \frac{\exp\left[-(\pi^2 Dt(4l^2)^{-1}(2n+1)^2 + k_2^{0\prime} t)\right]}{[1 + \pi^2 D(4l^2 k_2^{0\prime})^{-1}(2n+1)^2](2n+1)^2}.$$

It has been suggested (2) that, if the second overpotential is chosen to be the reversible one, a study of the transient would provide a method of estimating i_0/C_0. But the dependence of [59] on t shows that the interpretation is not simple enough in the general case.

5. Faradaic Impedance

It is well known that superimposing a sinusoidal perturbation on a 'base value' and studying the alternating component of the response offers a wide scope in the interpretation of the kinetic processes.

**The same relationship results from eq. [40] of ref. 2 by using the identity given by eq. [28] of this paper.*

We assume that

[60] $$zF\eta(t)/RT = \delta_0 + \delta_1 \cos \omega t \qquad (\omega = \text{angular frequency})$$

Since the $i - \eta$ characteristics are fundamentally nonlinear, $i(t)$ contains the higher harmonic terms besides a transient and a 'fundamental response'. From the relationship [16] between $i(t)$ and $\eta(t)$ it is easy to see that $i(t)$ can be expressed as

[61] $$i_{st} + \sum_{n=1}^{\infty} i_n \cos (n\omega t - \phi_n) + i_{tr}(t)$$

($i_{tr}(t)$ tends to zero as t tends to infinity). As one would expect, i_n, ϕ_n, and i_{st} are complicated functions of the parameters.

As regards the magnitude of δ_1, the basic approximation made in the treatment reported here is contained in the assumption:

$$K(t) = \exp\left(\int_0^t k_2(\tau)\, d\tau \right)$$

$$\simeq \exp [\{k_2{}^0 I_0[1 - \alpha)\delta_1]t\} - 2k_2{}^0\omega^{-1} I_1[(1 - \alpha)\delta_1] \sin \omega t].$$

The explicit expressions for i_1 and ϕ_1 are (cf. Appendix IV)

[62] $$i_1 \cos (\omega t - \phi_1) = 2zF[k_1{}^0 I_1(\alpha\delta_1) - k_2{}^0 I_1(\alpha\delta_1 - \delta_1)] \cos \omega t$$

$$- \frac{zFA_1[k_1{}^0 I_0(A_2) - k_2{}^0 C_0 I_0(A_2')]}{I_0(\alpha\delta_1 - \delta_1)} \left[1 - \frac{\tanh [\sqrt{k_2{}^0 I_0(\alpha\delta_1 - \delta_1)/D} \cdot l]}{\sqrt{k_2{}^0 I_0(\alpha\delta_1 - \delta_1)/D} \cdot l} \right] \cos (\omega t + \chi_1)$$

$$- 2zFI_0 \left[\frac{2k_2{}^0}{\omega} I_1(\alpha\delta_1 - \delta_1) \right] . E'[k_1{}^0 I_1(A_2) \cos (\omega t - \chi_2 - \lambda')$$

$$- k_2{}^0 C_0 I_1(A_2') \cos (\omega t - \chi_2' - \lambda')].$$

(By simple manipulations, it is possible to reduce further the right hand side of [62] to the form $K \cos (\omega t - \kappa)$. But as the resulting expressions for K and κ would be more involved, this is not attempted.) In [62], $I_0(z)$ and $I_1(z)$ are the modified Bessel functions of argument z and orders zero and one respectively. In particular, $I_0[2k_2{}^0\omega^{-1} I_1(\alpha\delta_1 - \delta_1)]$ is the Bessel function of order zero and argument $2k_2{}^0\omega^{-1} I_1(\alpha\delta_1 - \delta_1)$. (Here the argument itself involves the Bessel functions).

[63] $$A_1{}^2 = [2I_0(\alpha\delta_1 - \delta_1) I_1\{2k_2{}^0\omega^{-1} I_1(\alpha\delta_1 - \delta_1)\}]^2$$

$$+ [2I_1(\alpha\delta_1 - \delta_1) I_0\{2k_2{}^0\omega^{-1} I_1(\alpha\delta_1 - \delta_1)\}]^2;$$

[64] $$\tan \chi_1 = \frac{I_0(\alpha\delta_1 - \delta_1) I_1[2k_2{}^0\omega^{-1} I_1(\alpha\delta_1 - \delta_1)]}{I_1(\alpha\delta_1 - \delta_1) I_0[2k_2{}^0\omega^{-1} I_1(\alpha\delta_1 - \delta_1)]}$$

[65] $$A_2{}^2 = \alpha^2\delta_1{}^2 + [2k_2{}^0\omega^{-1} I_1(\alpha\delta_1 - \delta_1)]^2$$

[66] $$A_2{}'^2 = (\alpha - 1)^2\delta_1{}^2 + [2k_2{}^0\omega^{-1} I_1(\alpha\delta_1 - \delta_1)]^2$$

[67] $$\tan \chi_2 = \frac{2k_2{}^0 I_1(\alpha\delta_1 - \delta_1)}{\alpha\delta_1\omega}$$

[68] $$\tan \chi_2' = \frac{2k_2{}^0 I_1(\alpha\delta_1 - \delta_1)}{(\alpha - 1)\delta_1\omega}$$

$$[69] \quad E' \exp(-i\lambda') = \frac{k_2{}^0 I_0(\alpha\delta_1 - \delta_1)}{k_2{}^0 I_0(\alpha\delta_1 - \delta_1) + i\omega}\left\{1 - \frac{\tanh\sqrt{[k_2{}^0 I_0(\alpha\delta_1 - \delta_1) + i\omega]/D}\cdot l}{\sqrt{[k_2{}^0 I_0(\alpha\delta_1 - \delta_1) + i\omega]/D}\cdot l}\right\}.$$

(Note: The relationship between E' and λ' defined here and E and λ of p. 40 of ref. 1*b* is $E'\exp(-i\lambda') = 1 - E\exp(-i\lambda)$ *provided* one substitutes $k_2{}^0 I_0(\alpha\delta_1 - \delta_1)$ for k_2 in eqs. [71–77] of ref. 1*b*.)

Considering δ_1 to be small such that quantities like $\delta_1{}^2$ and $[k_2{}^0(\alpha - 1)\delta_1\omega^{-1}]^2$ are neglected, one obtains the following limits for the parameters,

$$[70] \quad A_1 \rightarrow A_2'$$

$$[71] \quad \chi_1 \rightarrow \chi_2'$$

$$[72] \quad A_2{}^2 \rightarrow \alpha^2\delta_1{}^2 + [k_2{}^0(\alpha - 1)\delta_1\omega^{-1}]^2$$

$$[73] \quad A_2{}'^2 \rightarrow (\alpha - 1)^2\delta_1{}^2 + [k_2{}^0(\alpha - 1)\delta_1\omega^{-1}]^2$$

$$[74] \quad \tan\chi_2 \rightarrow k_2{}^0\omega^{-1}(\alpha - 1)\alpha^{-1}$$

$$[75] \quad \tan\chi_2' \rightarrow k_2{}^0\omega^{-1} = \tan\theta \text{ (say)}$$

$$[76] \quad E' \exp(-i\lambda') \rightarrow \frac{k_2{}^0}{k_2{}^2 + i\omega}\left[1 - \frac{\tanh\sqrt{(k_2{}^0 + i\omega)/D}\cdot l}{\sqrt{(k_2{}^0 + i\omega)/D}\cdot l}\right]$$

$$= 1 - E\exp(-i\lambda)$$

(E and λ are identical with those given in ref. 1).

$$[77] \quad I_0(A_2),\ I_0(A_2') \rightarrow 1$$

$$[78] \quad 2I_1(A_2) \rightarrow A_2;\quad 2I_1(\alpha\delta_1) \rightarrow \alpha\delta_1;\quad 2I_1(\alpha\delta_1 - \delta_1) \rightarrow (\alpha - 1)\delta_1;$$

$$[79] \quad 2I_1(A_2') \rightarrow A_2'.$$

The corresponding limiting expression for [62] is

$$[80] \quad i_1\cos(\omega t - \phi_1) = zF\delta_1\Big[[\alpha k_1{}^0 - (\alpha - 1)k_2{}^0 C_0]\cos\omega t$$

$$- [k_1{}^0 - k_2{}^0 C_0]\left[(\alpha - 1)\cos\omega t - \frac{k_2(\alpha - 1)}{\omega}\sin\omega t\right]\left(1 - \frac{\tanh\sqrt{k_2{}^0/D}\cdot l}{\sqrt{k_2{}^0/D}\cdot l}\right)$$

$$- E'[k_1{}^0\alpha - k_2{}^0 C_0(\alpha - 1)]\cos(\omega t - \lambda')$$

$$+ E'\frac{k_2{}^0(\alpha - 1)}{\omega}(k_1{}^0 - k_2{}^0 C_0)\sin(\omega t - \lambda')\Big]$$

$$[81] \quad = \delta_1\Big[[\alpha k_1{}^0 - (\alpha - 1)k_2{}^0 C_0]E\cos(\omega t - \lambda)$$

$$- (\alpha - 1)(k_1{}^0 - k_2{}^0 C_0)\left[\left\{1 - \frac{\tanh\sqrt{k_2{}^0/D}\cdot l}{\sqrt{k_2{}^0/D}\cdot l}\right\}\cos\omega t\right.$$

$$\left.+ \frac{k_2{}^0}{\omega}\frac{\tanh\sqrt{k_2{}^0/D}\cdot l}{\sqrt{k_2{}^0/D}\cdot l}\sin\omega t - \frac{k_2{}^0}{\omega}E\sin(\omega t - \lambda)\right]\Big]$$

If the superimposition of the alternating component is on the reversible potential, $\delta_0 = 0$ and $k_1^0 = k_2^0 C_0 = i_0/zF$; Hence,

$$[82] \qquad i_1 \cos(\omega t - \phi_1) \rightarrow i_0 \delta_1 (zF)^{-1} E \cos(\omega t - \lambda),$$

as derived by Fleischmann (1).

The above result [82] shows that expressions derived earlier (1) have assumed implicitly that δ_1^2 and $[k_2^0(\alpha - 1)\delta_1 \omega^{-1}]^2$ are to be neglected. This limitation should be taken note of especially when one is interested in the limiting case $k_2^0 \omega^{-1} \rightarrow \infty$ (very low frequencies). (For example, to apply eq. [82], under the conditions defined by $k_2^0 = i_0/zFC_0 \simeq 10^5\ s^{-1}$, $|\eta| = 1$ mV, one should have $\omega \gg 100$ cycles/s). Equation [62] can be expected to be valid over a wider range* of values of δ_1 (or $|\eta|$) in view of less stringent conditions imposed upon the parameters.

A detailed discussion of [62] and its implications will be given later.

6. Faradaic Rectification

Doss and Agarwal discovered that for small amplitudes of an alternating current a rectified component in the potential results in the steady state. They also pointed out how this phenomenon can be exploited in the study of the kinetic parameters.

Since then, many interesting techniques† have been developed based on this concept. We present here a derivation of an expression for $i_{st}(t)$ which is defined through the equation,

$$i(t) = i_{st}(t) + \sum i_n \cos(n\omega t - \phi_n) + i_{tr}(t).$$

Herein, $i_{st}(t) + i_{tr}(t)$ is the 'nonperiodic' part and $i_{tr}(t)$ is that which decays to zero with $t \rightarrow \infty$. As has been proved in Appendix IV,

$$\begin{aligned}[83] \quad i_{st}(t) = {} & [k_1^0 I_0(\alpha\delta_1) - k_2^0 C_0 I_0(\alpha\delta_1 - \delta_1] \\ & - I_0[2k_2^0 \omega^{-1} I_1(\alpha\delta_1 - \delta_1)][k_1^0 I_0(A_2) - k_2^0 C_0 I_0(A_2')] \\ & \qquad \left\{1 - \frac{\tanh\sqrt{k_2^0 I_0(\alpha\delta_1 - \delta_1)/D}\cdot l}{\sqrt{k_2^0 I_0(\alpha\delta_1 - \delta_1)/D}\cdot l}\right\} \\ & - I_0[2k_2^0 \omega^{-1} I_1(\alpha\delta_1 - \delta_1)] A_1 E' \{k_1^0 I_1(A_2) \cos(\lambda' + \chi_1 + \chi_2) \\ & \qquad - k_2^0 C_0 I_1(A_2') \cos(\lambda' + \chi_1 + \chi_2')\}.\end{aligned}$$

(For the definition of constants, refer to eqs. [63–69].) We hasten to remark here that the steady state direct component as given by eq. [83] is not entirely due to the superimposition of the sinusoidal overpotential, $RT(zF)^{-1}\delta_1 \cos\omega t$; it includes the contribution of the base potential $RT(zF)^{-1}\delta_0$ as well. The latter is given by, cf. eq. [29],

$$[84] \qquad i_{\eta_0}(t \rightarrow \infty) = (k_1^0 - k_2^0 C_0) \frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l}.$$

It may be noted from [83] that

$$[85] \qquad i(t) \rightarrow (k_1^0 - k_2^0 C_0) \frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l}$$

*That an earlier derivation of an expression for redoxokinetic potential (cf. J. Electroanal. Chem. 1, 396 (1960) is valid for a wider range of amplitudes than the limiting solution, has been shown by Oldham (Proc. Natl. Inst. Sci., Seminar on Electrochemistry, 1961. In press. 1964.)

†For a review see Chap. 3 of ref. 10b.

For personal use only.

as $\delta_1 \to 0$. Again for small values of δ_1,

$$I_0(\alpha\delta_1) \simeq 1 + (\alpha^2\delta_1^2/4),$$

$$I_0(\alpha\delta_1 - \delta_1) \simeq 1 + [(\alpha - 1)^2\delta_1^2/4],$$

$$I_0[2k_2^0 I_1(\alpha\delta_1 - \delta_1)/\omega] \simeq 1 + [k_2^0(2\omega)^{-1}(\alpha - 1)\delta_1]^2,$$

$$k_1^0 I_0(A_2) - k_2^0 C_0 I_0(A_2') \simeq (k_1^0 - k_2^0 C_0) + [k_1^0\alpha^2 - k_2^0 C_0(\alpha - 1)^2]\cdot\delta_1^2/4 + (k_1^0 - k_2^0 C_0)[k_2^0(2\omega)^{-1}(\alpha - 1)\delta_1]^2,$$

[86] $$1 - \frac{\tanh\sqrt{k_2^0 I_0(\alpha\delta_1 - \delta_1)/D}\cdot l}{\sqrt{k_2^0 I_0(\alpha\delta_1 - \delta_1)/D}\cdot l} \simeq \left[1 - \frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l}\right] \cdot \frac{\delta_1^2(\alpha - 1)^2}{8}\left[\operatorname{sech}^2(\sqrt{k_2^0/D}\cdot l) - \frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l}\right].$$

Therefore in the limiting case, $\omega \to \infty$, we write

[87] $$i_{st}(\omega \to \infty) - i_{\eta_0} = \frac{\delta_1^2}{4}[k_1^0\alpha^2 - k_2^0 C_0(\alpha - 1)^2]\frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l} + (k_1^0 - k_2^0 C_0)\frac{\delta_1^2(\alpha - 1)^2}{8}\left[\operatorname{sech}^2(\sqrt{k_2^0/D}\cdot l) - \frac{\tanh\sqrt{k_2^0/D}\cdot l}{\sqrt{k_2^0/D}\cdot l}\right].$$

(i) If $k_1^0 = k_2^0 C_0 = i_0/zF$; $\delta_0 = 0$,

[88] $$I_0(\omega \to \infty) \to i_0\left(\frac{zF\eta_1}{RT}\right)^2 \frac{(2\alpha - 1)}{4}\frac{\tanh(\sqrt{k_2^0/D}\cdot l)}{\sqrt{k_2^0/D}\cdot l}.$$

For sufficiently small values of l such that

[89] $$I_0(\omega \to \infty) \to i_0\left(\frac{zF\eta_1}{RT}\right)^2 \frac{(2\alpha - 1)^2}{4}$$

—a simple result that would result from

$$i(t) = zFl^{-1}\int_0^l (k_1^0 - k_2 C)\,dx$$

if one neglects the concentration polarization of the adatoms, i.e., if $C(x) = C_0$—a valid assumption for $\eta_0 = 0$, $l \to 0$ and $\omega \to \infty$.

The behavior of I_0 and the redoxokinetic potential χ with the frequency ω, δ_0 and a discussion of the various types of control will be presented later.

7. Galvanostatic Technique

Gerischer (3) and, independently, Bockris and Mehl (4) studied the kinetics under galvanostatic conditions assuming that surface diffusion is a significant step. A simple theory was suggested by these authors and this was later critically analyzed by Fleischmann and Thirsk (1*a*). It has been shown (1) that for $t \to 0$,

[90] $$zF(RT)^{-1}\eta(t) \simeq a + bt$$

where $a = i/i_0$ and $b = i/zFC_0$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Confining oneself to conditions where $\pi Dtl^{-2} \rightarrow 0$ but greater than τ_1, the relaxation time for the charging of the double layer, an approximate expression for $\eta(t)$ can be attempted under current-controlled conditions. Then, as $\pi Dtl^{-2} \rightarrow 0$,

$$[91] \qquad \frac{i(t)}{zF} = \frac{\mathrm{d}}{\mathrm{d}t}\left\{\frac{1}{K(t)} \int_0^t [k_1(\tau) - k_2(\tau)C_0]K(\tau)\,\mathrm{d}\tau\right\}$$

or

$$[92] \qquad \frac{q(t)}{zF}K(t) = \int_0^t [k_1(\tau) - k_2(\tau)C_0]K(\tau)\,\mathrm{d}\tau$$

$$[93] \qquad zF\left[k_1(t) - k_2(t)C_0\left(1 + \frac{q(t)}{zFC_0}\right)\right] = i(t)$$

$$[94] \qquad q(t) = \int_0^t i(\tau)\,\mathrm{d}\tau.$$

Equation [93] enables one to evaluate $\eta(t)$ for any given $i(t)$ as $t \rightarrow 0$.

In particular, let $i(t) = i$, a constant. Then $q(t) = it$ so that

$$[95] \qquad \frac{i}{i_0(1 + it/zFC_0)} = \exp\left[\frac{\alpha zF\eta(t)}{RT}\right] - \exp\left[\frac{(\alpha - 1)zF\eta(t)}{RT}\right].$$

Let us substitute $zF\eta(t)/RT = a + bt + \phi(t^2)$,
With a^2, $(bt)^2 \ll 1$, one deduces that,

$$[96] \qquad a = i/i_0 \quad \text{and} \quad b = i/zFC_0$$

as reported earlier (1*a*).

If $zF\eta(t)(RT)^{-1} = \delta$ is so small that δ^2 and higher powers can be neglected, a limiting expression for $\eta(t \rightarrow 0)$ can be derived for all $t \rightarrow 0$, relaxing the usual assumption, viz. $t \gg \tau_1$. It is easily proved that

$$[97] \qquad \eta(t) = \frac{q(t)}{C_a} + \left(\frac{1}{C_i} - \frac{1}{C_a}\right) \int_0^t \exp\left[-\left(\frac{t - \tau}{\tau_m}\right)\right] i(\tau)\,\mathrm{d}\tau$$

$$[98] \qquad \tau_m = \left[\frac{zF}{RT}\frac{i_0}{C_i} + \frac{i_0}{zFC_0}\right]^{-1}$$

and

$$[99] \qquad C_a = C_i\left(\frac{zFC_0}{i_0\tau_m}\right)$$

Three particular cases follow.

(*a*) If $i(t) = i$, a constant,

$$[100] \qquad \eta(t) = \frac{it}{C_a} + \left(\frac{1}{C_i} - \frac{1}{C_a}\right)\left[1 - \exp\left(-\frac{t}{\tau_m}\right)\right]$$

with

$$\frac{zF}{RTC_i} \gg \frac{i_0}{zFC_0}, \quad \frac{RT}{z^2F^2}\frac{C_i}{C_0} \ll 1,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and

$$t \gg \frac{RTC_l}{zFi_0} = \tau_1,$$

$$\frac{zF\eta(t)}{RT} \rightarrow \frac{it}{zFC_0} + \frac{i}{i_0} \qquad [101]$$

as has been proved above (cf. eq. [96]).
(*b*) If $i(t) = i_1$, $t < t_1$ and $= i_2$, $t_1 \leqslant t$;

$$[102] \quad \eta(t) = \frac{1}{C_l}[(i_1 - i_2)t_1 + i_2 t] + \tau_m\left(\frac{1}{C_l} - \frac{1}{C_a}\right)\left[(i_1 - i_2)\exp\left[-\left(\frac{t - t_1}{\tau_m}\right)\right] - i_1 \exp\left(-\frac{t}{\tau_m}\right) + i_2\right].$$

If $i_2 = 0$ in [102],

$$[103] \quad \eta(t) = \frac{1}{C_a}(i_1 t_i) + i_1\tau_m\left(\frac{1}{C_l} - \frac{1}{C_a}\right)\left[\exp\left[-\left(\frac{t - t_1}{\tau_m}\right)\right] - \exp\left(-\frac{t}{\tau_m}\right)\right].$$

(*c*) If $i(t) = Q\delta(t)$, where $\delta(t)$ is Dirac's delta function,

$$\eta(t) = \frac{Q}{C_a} + Q\left(\frac{1}{C_l} - \frac{1}{C_a}\right)\exp(-t/\tau_m). \qquad [104]$$

This can also be deduced from [103] by taking the limit when $t_1 \rightarrow 0$ and $i_1 \rightarrow \infty$ so that $i_1 t_1 = Q$.

APPENDIX I

DERIVATION OF THE GENERAL SOLUTION

The differential equation to be solved is

$$D\partial^2 C/\partial x^2 + k_1(t) - k_2(t)C = \partial C/\partial t. \qquad [A.1]$$

The initial and boundary conditions are

$$[A.2] \quad \begin{cases} C = C_0, & x = 0, \quad t > 0; \\ \partial C/\partial x = 0, & x = l, \quad t > 0; \\ C = C_0, & x > 0, \quad t = 0; \end{cases}$$

$$k_1(t) = (i_0/zF)\exp[\alpha zF\eta(t)/RT] \qquad [A.3]$$

and

$$k_2(t) = (i_0/zFC_0)\exp[(\alpha - 1)zF\eta(t)/RT]. \qquad [A.4]$$

The solution of [A.1] is accomplished by reducing [A.1] to a homogeneous form by the substitution,

$$C^* = C(x, t)K(t) - \int_0^t k_1(t)K(t)\,dt. \qquad [A.5]$$

Herein,

$$K(t) = \exp\left[\int_0^t k_2(t)\,dt\right].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Consequently, [A.1] transforms into

$$D\partial^2 C^*/\partial x^2 = \partial C^*/\partial x, \tag{A.6}$$

since

$$\partial C^*/\partial t = K(t)[\partial C/\partial t + k_2(t)C - k_1(t)] \tag{A.7}$$

and

$$\partial C^*/\partial x = K(t)\partial C/\partial x. \tag{A.8}$$

Also [A.2] now becomes

$$\begin{cases} (a)\ C^* = C_0K(t) - \int_0^t k_1(t)K(t)\,\mathrm{d}t,\ x = 0,\ t > 0; \\ (b)\ \partial C^*/\partial x = 0,\ x = l,\ t > 0; \\ (c)\ C^* = C_0,\ x > 0,\ t = 0. \end{cases} \tag{A.9}$$

Defining the Laplace transform of $f(t)$ as

$$L[f(t)] = \overline{f(p)} = p\int_0^\infty f(t)\exp(-pt)\,\mathrm{d}t, \tag{A.10}$$

we write [A.6] in the form,

$$D\partial^2\bar{C}^*/\partial x^2 - p\bar{C}^* = -pC_0; \tag{A.11}$$

Also,

$$\begin{aligned} \bar{C}^*(0,p) &= L[C_0K(t) - \int_0^t k_1(t)K(t)\,\mathrm{d}t] \\ &= L\left[C_0 - \int_0^t [k_1(t) - k_2(t)C_0]K(t)\,\mathrm{d}t\right] \\ &= L[\mathscr{K}(t)],\ \text{say.} \end{aligned} \tag{A.12}$$

$$\partial C^*/\partial x = 0,\ x = l,\ t > 0;$$

The solution of [A.11] with [A.12] is

$$\bar{C}^*(x,p) = C_0 + A(p)\cosh[\sqrt{p/D}(l-x)],$$

where

$$A(p) = L[\mathscr{K}(t) - C_0]\,\mathrm{sech}\,[\sqrt{p/D}\cdot l]$$

or

$$\bar{C}^*(x,p) - C_0 = L[\mathscr{K}(t) - C_0]\frac{\cosh[\sqrt{p/D}(l-x)]}{\cosh[\sqrt{p/D}\cdot l]}. \tag{A.13}$$

Observing that

$$L\left[\frac{\partial\theta_1(v,t)}{\partial v}\right] = -2\pi p\frac{\cosh(2v\sqrt{\pi p})}{\cosh(\sqrt{\pi p})} \tag{A.14}$$

and

$$L[f(\lambda t)] = \overline{f(p/\lambda)}, \tag{A.15}$$

we write

$$[A.16] \qquad \frac{D}{l} L\left\{\frac{\partial\theta_1[(l-x)/2l,\ \pi Dt/l^2]}{\partial x}\right\} = p\,\frac{\cosh\,[\sqrt{p/D}(l-x)]}{\cosh\,(\sqrt{p/D}\cdot l)}.$$

The theta function $\theta_1(v, t)$ in [A.14] is defined by

$$[A.17] \qquad \theta_1(v,t) = \sum_{-\infty}^{\infty} \exp\,[-\pi(n-\tfrac{1}{2})^2 t + 2\pi i(n-\tfrac{1}{2})(v+\tfrac{1}{2})]$$

$$= -t^{-1/2}\sum_{-\infty}^{\infty}(-1)^n \exp\,[-\pi(n+v+\tfrac{1}{2})^2/t]$$

$$= -2q^{1/4}\sum_{n=0}^{\infty}(-1)^n q^{n(n+1)} \sin\,[(2n+1)\pi v],$$

with $q = \exp\,(-\pi t)$.

Thus,

$$[A.18] \qquad C^*(x,t) = C_0 - \frac{D}{l}\frac{\partial}{\partial x}\left\{\int_0^t [C_0 - \mathscr{K}(t)]\theta_1\left[\frac{l-x}{2l}, \frac{\pi D(t-\tau)}{l^2}\right] d\tau\right\}$$

and

$$[A.19] \qquad C(x,t) = C_0 + [C^*(x,t) - \mathscr{K}(t)]/K(t)$$

with $C^*(x, t)$ completely determined by [A.18].

Equations [A.18] and [A.19] are the same as those given in equations [9] and [10] of the text. Again,

$$[A.20] \quad i = zFl^{-1}\int_0^l [k_1(t) - k_2(t)C(x,t)]\,dx$$

$$= zF[k_1(t) - k_2(t)C_0] - zFl^{-1}k_2(t)\int_0^l [C(x,t) - C_0]\,dx$$

$$= zF[k_1(t) - k_2(t)C_0] - \frac{zFk_2(t)}{K(t)}[C_0 - \mathscr{K}(t)]$$

$$- \frac{zFk_2(t)}{K(t)l}\int_0^l [C^*(x,t) - C_0]\,dx$$

$$[A.21] \quad = zF\frac{d}{dt}\left\{\frac{1}{K(t)}\int_0^t [k_1(\tau) - k_2(\tau)C_0]K(\tau)\,d\tau\right\}$$

$$- \frac{zFDk_2(t)}{K(t)l^2}\int_0^t [C_0 - \mathscr{K}(\tau)]\theta_1\left[\frac{1}{2}, \frac{\pi D(t-\tau)}{l^2}\right] d\tau$$

$$[A.22] \quad = zF\frac{d}{dt}\left\{\frac{1}{K(t)}\int_0^t [k_1(t) - k_2(t)C_0]\,dt\right\}$$

$$+ \frac{2zFDk_2(t)}{K(t)l^2}\sum \exp\,[-\pi^2 Dt(n+\tfrac{1}{2})^2/l^2]$$

$$\cdot\left\{\int_0^t [C_0 - \mathscr{K}(t)]\exp\,[\pi^2 D\tau(n+\tfrac{1}{2})^2/l^2]\,d\tau\right\}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(cf. eq. [15] of the text). Since

$$[A.23]\quad \int_0^t [C_0 - \mathscr{K}(\tau)] \exp\,[\pi^2 D\tau(n+\tfrac{1}{2})^2/l^2]\,d\tau = \frac{4l^2}{\pi^2 D(2n+1)^2}[C_0 - \mathscr{K}(\tau)] \exp\,[\pi^2 D\tau(2n+1)^2/4l^2] - \frac{4l^2}{\pi^2 D(2n+1)^2}\int_0^t [k_1(\tau) - k_2(\tau)C_0] \cdot \exp\left[\int_0^\tau k_2(t)\,dt + \pi^2 D\tau(2n+1)^2/4l^2\right] d\tau$$

and

$$\sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} = \frac{\pi^2}{8},$$

eq. [A.22] becomes

$$[A.24]\quad \frac{i(t)}{zF} = [k_1(t) - k_2(t)C_0] - \frac{8}{\pi^2}\sum \frac{k_2(t)}{(2n+1)^2} \exp\left\{-\left[\int_0^t k_2(t)\,dt + \pi^2 D(2n+1)^2/4l^2\right]\right\} \int_0^t [k_1(\tau) - k_2(\tau)C_0] \exp\left[\int_0^\tau k_2(t)\,dt + \pi^2 D\tau(2n+1)^2/4l^2\right] d\tau.$$

Again, by integrating by parts, [A.24] can be written as

$$[A.25]\quad \frac{i(t)}{zF} = [k_1(t) - k_2(t)C_0] - \frac{32l^2}{\pi^2}k_2(t)\sum \frac{k_1(t) - k_2(t)C_0}{[4l^2k_2(t) + \pi^2 D(2n+1)^2](2n+1)^2} + \frac{32l^2k_2(t)}{\pi^2}\sum \frac{k_1(+0) - k_2(+0)C_0}{[4l^2k_2(+0) + \pi^2 D(2n+1)^2](2n+1)^2} \cdot \exp\left\{-\left[\int_0^t k_2(t)\,dt + \pi^2 Dt(2n+1)^2/4l^2\right]\right\} + \frac{32l^2k_2(t)}{\pi^2}\sum \exp\left[-\left\{\int_0^t k_2(t)\,dt + Dt(2n+1)^2/4l^2\right\}\right] \int_0^t \frac{d}{d\tau}\left\{\frac{k_1(\tau) - k_2(\tau)C_0}{k_2(\tau) + [(\pi^2 D)/(4l^2)](2n+1)^2}\right\} \exp\left[\left\{\int_0^\tau k_2(t)\,dt + \pi^2 D\tau(2n+1)^2/4l^2\right\}\right] d\tau.$$

APPENDIX II
POTENTIOKINETIC METHOD

Since

$$[B.1]\quad zF\eta(t)/RT = \delta_0 + \delta_1 t,$$

we have

$$[B.2]\quad k_1(t) = (i_0/zF) \exp\,[\alpha(\delta_0 + \delta_1 t)] = k_1^0 \exp\,(\alpha\delta_1 t),$$

$$[B.3]\quad k_2(t) = k_2^0 \exp\,[(\alpha - 1)\delta_1 t],$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[B.4] $$\int_0^t k_2(t)\,dt = k_2^0[1 - \exp\{(\alpha - 1)\delta_1 t\}]/(1 - \alpha)\delta_1,$$

[B.5] $$\int_0^t [k_1(\tau) - k_2(\tau)\,C_0] \exp\left[\int_0^\tau k_2(z)\,dz + \pi^2 D(2n+1)^2\tau/4l^2\right] d\tau$$

$$= \exp[k_2^0/(\alpha - 1)\delta_1]\; k_1^0 \int_0^t \exp\left[\frac{k_2 \exp[(\alpha - 1)\delta_1\tau]}{(\alpha - 1)\delta_1} + \left(\frac{\pi^2 D(2n+1)^2}{4l^2} + \alpha\delta_1\right)\tau\right] d\tau$$

$$- k_2^0 C_0 \int_0^t \exp\left\{\left[\frac{k_2^0 \exp[(\alpha - 1)\delta_1\tau]}{(\alpha - 1)\delta_1} + \left(\frac{\pi^2 D(2n+1)^2}{4l^2} + (\alpha - 1)\delta_1\right)\tau\right\} d\tau,$$

[B.6] $$= \frac{1}{(1 - \alpha)\delta_1} \exp\left\{\frac{k_2^0}{(1 - \alpha)\delta_1}\right\} \left\{k_1^0\left[\frac{k_2^0}{(1 - \alpha)\delta_1}\right]^{-A_n}\left[\gamma\left(A_n, \frac{k_2^0}{(1 - \alpha)\delta_1}\right]\right.\right.$$

$$\left. - \gamma\left(A_n, \frac{k_2^0 \exp[(\alpha - 1)\delta_1 t]}{(1 - \alpha)\delta_1}\right)\right]$$

$$\left. - k_2^0 C_0 \left\{\frac{k_2^0}{(1 - \alpha)\delta_1}\right\}^{-(A_n + (1/1-\alpha))}\left[\gamma\left(A_n + \frac{1}{1 - \alpha}, \frac{k_2^0}{(1 - \alpha)\delta_1}\right)\right.\right.$$

$$\left.\left. - \gamma\left(A_n + \frac{1}{1 - \alpha}, \frac{k_2^0 \exp[(\alpha - 1)\delta_1 t]}{(1 - \alpha)\delta_1}\right)\right]\right\}.$$

In [B.1] to [B.6],

$$k_1^0 = (i_0/zF) \exp(\alpha\delta_0),$$

$$k_2^0 = (i_0/zFC_0) \exp[(\alpha - 1)\delta_0],$$

and $\gamma(\alpha, x)$ is the incomplete gamma function defined as

$$\int_0^x t^{\alpha-1} \exp(-t)\,dt$$

or through

[B.7] $$\gamma(\alpha, x) = \sum_0^\infty \frac{(-1)^n x^{\alpha+n}}{n!(\alpha + n)}, \alpha \neq 0, -1, -2, \ldots$$

(Note: if $A_n \to -m$, a negative integer, the limit of [B.6], which exists, is to be taken) and,

[B.8] $$A_n = -\left(\frac{\pi^2 D(2n+1)^2}{4l^2(1 - \alpha)\delta_1} + \frac{\alpha}{1 - \alpha}\right).$$

An alternate form for [B.6] which is more convenient for deriving an expression for the steady state is obtained through a relationship between the incomplete gamma function $\gamma(\alpha, x)$ and the confluent hypergeometric function $\Phi(1, 1 + \alpha; x)$, viz.,

[B.9] $$\gamma(\alpha, x) = \exp(-x)\, x^\alpha \Phi(1, 1 + \alpha; x)/\alpha$$

[B.10] $$\Phi(a, c; x) = 1 + \frac{a}{c}x + \frac{a(a+1)}{c(c+1)}\frac{x^2}{2!} + \ldots.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Since,

$$\frac{i(t)}{zF} = [k_1(t) - k_2(t)C_0] - \frac{8}{\pi^2}\sum \frac{k_2(t)}{(2n+1)^2}\exp\left[-\left\{\int_0^t k_2(t)\,dt + \pi^2 D(2n+1)^2 t/4l^2\right\}\right] \cdot \int_0^t [k_1(t) - k_2(t)C_0]\exp\left[\int_0^t k_2(t)\,dt + \pi^2 D(2n+1)^2 t/4l^2\right],$$

[B.11]
$$\frac{i(t)}{zF} - [k_1(t) - k_2(t)C_0] = -\frac{8}{\pi^2}\frac{k_2(t)}{(1-\alpha)\delta_1}\sum \frac{1}{(2n+1)^2}\exp\left\{-\left(A_n + \frac{\alpha}{1-\alpha}\right)(\alpha-1)\delta_1 t + \frac{k_2{}^0}{(1-\alpha)\delta_1}\exp[(\alpha-1)\delta_1 t]\right\} \cdot\left[\left\{\frac{k_2{}^0}{(1-\alpha)\delta_1}\right\}^{-A_n} k_1{}^0 \cdot\left\{\gamma\left(A_n, \frac{k_2{}^0}{(1-\alpha)\delta_1}\right) - \gamma\left(A_n, \frac{k_2{}^0\exp[(\alpha-1)\delta_1 t]}{(1-\alpha)\delta_1}\right)\right\} - \left\{\frac{k_2{}^0}{(1-\alpha)\delta_1}\right\}^{-(A_n+(1/1-\alpha))} k_2{}^0 C_0\left\{\gamma\left(A_n + \frac{1}{1-\alpha}, \frac{k_2{}^0}{(1-\alpha)\delta_1}\right) - \gamma\left(A_n + \frac{1}{1-\alpha}, \frac{k_2{}^0\exp[(\alpha-1)\delta_1 t]}{(1-\alpha)\delta_1}\right)\right\}\right]$$

[B.12]
$$= \frac{8k_2(t)}{\pi^2(1-\alpha)\delta_1}\sum\left[\frac{k_1(t)}{A_n(2n+1)^2}\Phi\left(1, A_n+1; \frac{k_2(t)}{(1-\alpha)\delta_1}\right) - \frac{k_2(t)C_0}{\left(A_n + \frac{1}{1-\alpha}\right)(2n+1)^2}\Phi\left(1, A_n+1+\frac{1}{1-\alpha}; \frac{k_2(t)}{(1-\alpha)\delta_1}\right)\right] - \frac{8k_2(t)}{\pi^2(1-\alpha)\delta_1}\sum\left[\frac{k_1(t)}{(2n+1)^2 A_n}\{\exp[(1-\alpha)\delta_1 t]\}^{A_n}\Phi\left(1, A_n+1; \frac{k_2{}^0}{(1-\alpha)\delta_1}\right) - \frac{k_2(t)C_0}{(2n+1)^2\left(A_n + \frac{1}{1-\alpha}\right)}[\exp(1-\alpha)\delta_1 t]^{A_n+(1/1-\alpha)} \cdot\Phi\left(1, A_n+1+\frac{1}{1-\alpha}; \frac{k_2{}^0}{(1-\alpha)\delta_1}\right)\right].$$

The confluent hypergeometric function $\Phi(a, c; x) \to 1$ as $x \to 0$ and hence, in the steady state,

[B.13]
$$\frac{i(t)}{zF} - [k_1(t) - k_2(t)C_0] \to -\frac{8k_2(t)}{\pi^2(1-\alpha)\delta_1}\left[\sum \frac{k_2(t)C_0}{(2n+1)^2(A_n + (1-\alpha)^{-1})} - \sum \frac{k_1(t)}{(2n+1)^2 A_n}\right].$$

Using eq. [28],

$$[B.14] \qquad i(t) = [k_1(t) - k_2(t)C_0] + k_2(t)\left[\frac{k_1(t)}{\alpha\delta_1}\left(\frac{\tanh l\sqrt{\alpha\delta_1/D}}{l\sqrt{\alpha\delta_1/D}} - 1\right) - \frac{k_2(t)C_0}{(\alpha-1)\delta_1}\left(\frac{\tanh l\sqrt{(\alpha-1)\delta_1/D}}{l\sqrt{(\alpha-1)\delta_1/D}} - 1\right)\right].$$

The steady state solution given by [B.14] is valid under the condition $t \to \infty$ *and*

$$[B.15] \qquad k_2(t) \ll \pi^2 D/4l^2.$$

In deriving [B.13] and [B.14], $zF\eta(t)/RT$ has been assumed to be equal to $\delta_0 + \delta_1 t$; hence, one may expect to deduce from these, expressions for the current under constant potential conditions by allowing $\delta_1 \to 0$; obviously [B.14] gives the corresponding steady state when $k_2^0 \ll \pi^2 D/4l^2$; [B.14] gives,

$$[B.16] \qquad i(t) = (k_1^0 - k_2^0 C_0)(1 + k_2^0 l^2/3D) \simeq (k_1^0 - k_2^0 C_0)\frac{\tanh(\sqrt{k_2^0/D}\cdot l)}{(\sqrt{k_2^0/D}\ l\cdot)},$$

as has been derived elsewhere (2) (cf. eq. [29] in this paper).

APPENDIX III

POTENTIAL STEP METHOD

The differential equation [1] or [A.1] is to be solved under the following boundary conditions,

$$[C.1] \qquad C(x,t) = \frac{k_1'}{k_2'} - \frac{k_1' - k_2'C_0}{k_2'}\frac{\cosh[\sqrt{k_2'/D}\cdot(l-x)]}{\cosh(\sqrt{k_2'/D}\cdot l)}$$

at $t = 0$, instead of eq. [3] of the text.

$$[C.2] \qquad D(\partial C/\partial x)_{x=l} = 0, \quad \text{and} \quad C(x,t) = C_0,\ x = 0.$$

As in Appendix I, we transform $C(x, t)$ to $C^*(x, t)$ through

$$[C.3] \qquad C^*(x,t) = C(x,t)K(t) - \int_0^t k_1(\tau)\,K(\tau)\,d\tau.$$

Conditions [A.9*a*] and [A.9*b*] remain valid while for [A.9*c*] we have, now,

$$[C.4] \qquad C^*(x,t) = C_0 + \frac{k_1' - k_2'C_0}{k_2'}\left[1 - \frac{\cosh[\sqrt{k_2'/D}\cdot(l-x)]}{\cosh\sqrt{k_2'/D}\cdot l}\right].$$

Consequently, we derive

$$[C.5] \qquad C^*(x,p) = C_0 + L[\mathscr{K}(t) - C_0]\cdot\frac{\cosh[\sqrt{p/D}\cdot(l-x)]}{\cosh(\sqrt{p/D})\cdot l} + \frac{k_1' - k_2'C_0}{k_2'}\left[1 - \frac{\cosh[\sqrt{k_2'/D}(l-x)]}{\cosh(\sqrt{k_2'/D}\cdot l)}\cdot\frac{p}{p-k_2'}\right] + \frac{k_1' - k_2'C_0}{p-k_2'}\cdot\frac{\cosh[\sqrt{p/D}\cdot(l-x)]}{\cosh(\sqrt{p/D}\cdot l)}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(*Apparently* eq. [C.5] suggests that a pole for $\bar{C}^*(x, p)$ exists at $p = k_2'$. Actually the residue can be proved to be zero at $p = k_2'$).

Inverting [C.5] and substituting in the expression for $i(t)$ one evaluates $i(t)$ as

$$i(t) = -I_1(t) + I_2(t),$$

where $I_1(t)$ is the transient due to the concentration polarization caused by the first pulse and equals

$$[C.6] \quad I_1(t) = \frac{8}{\pi^2} \frac{zFDk_2(t)}{k(t)} (k_1' - k_2'C_0) \cdot \sum \frac{\exp[-(\pi^2 Dt(4l^2)^{-1}(2n+1)^2)]}{(2n+1)^2 k_2' + \pi^2 D(4l^2)^{-1}(2n+1)^2}.$$

The quantity $I_2(t)$ is the current that would have been observed in the absence of the first pulse and is given by the eq. [29] of the text.

Thus eq. [40] of ref. (1*b*) will have to be modified as [C.6].

APPENDIX IV

Assuming $zF\eta(t)/RT = \delta_0 + \delta_1 \cos \omega t$,

$$[D.1] \quad k_1(t) = k_1^0 \exp(\alpha\delta_1 \cos \omega t)$$
$$= k_1^0[I_0(\alpha\delta_1) + 2I_1(\alpha\delta_1) \cos \omega t + 2I_2(\alpha\delta_1) \cos 2\omega t + \ldots].$$

Similarly,

$$[D.2] \quad k_2(t) = k_2^0 \exp[(\alpha - 1)\delta_1 \cos \omega t]$$
$$= k_2^0\{I_0[(\alpha-1)\delta_1] + 2I_1[(\alpha-1)\delta_1] \cos \omega t + 2I_2[(\alpha-1)\delta_1] \cos 2\omega t + \ldots\}.$$

$$[D.3] \quad \int_0^t k_2(z)\, dz = k_2^0 \left\{ I_0[(\alpha-1)\delta_1]t + 2I_1[(\alpha-1)\delta_1] \frac{\sin \omega t}{\omega} + 2I_2[(\alpha-1)\delta_1] \frac{\sin 2\omega t}{2\omega} + \ldots \right\}.$$

$$\frac{k_2(t)}{K(t)} = k_2(t) \exp\left[-\int_0^t k_2(z)\, dz \right]$$
$$= \frac{d}{dt}\left[-\exp\left\{ -\int_0^t k_2(z)\, dz \right\} \right]$$
$$= -\frac{d}{dt}\left[\exp\left\{ -k_2^0 \left(I_0[(\alpha-1)\delta_1]t + 2I_1[(\alpha-1)\delta_1] \frac{\sin \omega t}{\omega} + 2I_2[(\alpha-1)\delta_1] \frac{\sin 2\omega t}{2\omega} + \ldots \right) \right\} \right]$$

$$[D.4] \quad \simeq \exp(-k_2^0 I_0[(\alpha-1)\delta_1]t) \left[k_2^0 I_0[(\alpha-1)\delta_1] + 2k_2^0 I_1[(\alpha-1)\delta_1] \cos \omega t \right] \left[I_0\left\{ \frac{2k_2^0 I_1[(\alpha-1)\delta_1]}{\omega} \right\} - 2I_1\left\{ \frac{2k_2^0 I_1[(\alpha-1)\delta_1]}{\omega} \right\} \sin \omega t \right]$$

$$[D.5] \quad \simeq k_2^0 \exp\{-k_2^0 I_0[(\alpha-1)\delta_1]\} \left[I_0[(\alpha-1)\delta_1] I_0\left\{ \frac{2k_2^0 I_1[(\alpha-1)\delta_1]}{\omega} \right\} + A_1 \cos(\omega t + \chi_1) \right],$$

$$+ \text{ real part of } \frac{2I_1(A_2')\exp[i(\omega t - \chi_2)]}{B_n}$$

$$- k_2{}^0\left[\frac{I_0(A_2')}{\pi^2 D(2n+1)^2(4l^2)^{-1} + k_2{}^0 I_0(\alpha\delta_1 - \delta_1)} + \text{ real part of } \frac{2I_1(A_2')\exp(-i\chi_2')}{B_n}\right]\Bigg\}.$$

with

[D.14] $$A_2'^2 = (\alpha - 1)^2\delta_1{}^2 + \left[\frac{2k_2{}^0 I_1(\alpha\delta_1 - \delta_1)}{\omega}\right]^2,$$

[D.15] $$\tan\chi_2' = \frac{2k_2{}^0 I_1(\alpha\delta_1 - \delta_1)}{\omega(\alpha - 1)\delta_1},$$

and B_n as defined by [D.12].

Thus $i(t)$ is obtained by using eq. [16] of the text and substituting the expressions derived above. Writing,

[D.16] $$i(t) = i_{st}(t) + \sum_{n=1}^{\infty} i_n \cos(n\omega t - \phi_n) + i_{tr}(t),$$

and equating the Fourier coefficients, one obtains, formally, i_n and ϕ_n, $n = 1, 2, \ldots$; $i_{st}(t)$ is the steady state constant value attained by $i(t)$ whereas $i_{tr}(t)$ is the transient part of $i(t)$ tending to zero as t tends to infinity, For example, i_1 is found as follows:

The right hand side of eq. [16] is

[D.17] $$[k_1{}^0 I_0(\alpha\delta_1) - k_2{}^0 C_0 I_0(\alpha\delta_1 - \delta_1)] + 2[k_1{}^0 I_1(\alpha\delta_1) - k_2{}^0 C_0 I_1(\alpha\delta_1 - \delta_1)]\cos\omega t$$

$$+ \text{ terms in higher harmonics } - \frac{8}{\pi^2}k_2{}^0\left[I_0(\alpha\delta_1 - \delta_1)I_0\left(\frac{2k_2{}^0 I_1(\alpha\delta_1 - \delta_1)}{\omega}\right) + A_1\cos(\omega t + \chi_1)\right]\cdot\sum\frac{1}{(2n+1)^2}\left[\frac{k_1{}^0 I_0(A_2) - k_2{}^0 C_0 I_0(A_2')}{\pi^2 D(4l^2)^{-1}(2n+1)^2 + k_2{}^0 I_0(\alpha\delta_1 - \delta_1)}\right]$$

$$+ \sum\frac{1}{(2n+1)^2}\left[\text{real part of }\left\{\frac{2k_1{}^0 I_1(A_2)\exp[i(\omega t - \chi_2)]}{B_n} - \frac{k_2{}^0 C_0 I_1(A_2')\exp[i(\omega t - \chi_2')]}{B_n}\right\}\right] + \text{a transient } i_{tr}(t).$$

Also,

[D.18] $$\frac{8}{\pi^2}\sum\frac{k_2{}^0 I_0(\alpha\delta_1 - \delta_1)}{(2n+1)^2 B_n}$$

$$= \frac{8}{\pi^2}\sum\frac{1}{(2n+1)^2[\pi^2 D(2n+1)^2(4l^2)^{-1} + k_2{}^0 I_0(\alpha\delta_1 - \delta_1) + i\omega]}$$

$$= \frac{k_2{}^0 I_0(\alpha\delta_1 - \delta_1)}{k_2{}^0 I_0(\alpha\delta_1 - \delta_1) + i\omega}\left[1 - \frac{\tanh\sqrt{[k_2{}^0 I_0(\alpha\delta_1 - \delta_1) + i\omega]/D}\cdot l}{\sqrt{[k_2{}^0 I_0(\alpha\delta_1 - \delta_1) + i\omega]/D}\cdot l}\right]$$

$$= E'\exp(-i\lambda'), \text{ say.}^*$$

**The symbols E' and λ' are used in [D.17] to draw attention to the relationship between (E', λ') and (E, λ) used in ref. 1b; as a matter of fact, if one substitutes $k_2{}^0 I_0(\alpha\delta_1 - \delta_1)$ for $k_2{}^0$ in eqs. 71–77 of ref. 1b, $E'\exp(-i\lambda')$ and $[1 - E\exp(-i\lambda)]$ will be identical.*

CHARGE TRANSFER AND ELECTRON CAPTURE IN THE RADIOLYSIS OF ALIPHATIC HYDROCARBONS[1]

P. J. DYNE
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario
Received January 4, 1965

ABSTRACT

A mechanism is suggested for the radiolysis of hydrocarbons. Both ions and excited molecules are produced in the initial excitation. Ion–electron recombination leads to the formation of excited molecules which have similar properties to those formed initially; all subsequent decomposition proceeds through these excited molecules. In mixtures of hydrocarbons, ions and molecules may undergo positive charge exchange and additives reduce the hydrogen yield by capturing electrons or reacting with the positive ion. The mechanism provides a rationalization for a variety of observations.

This paper presents a mechanism for part of the radiolytic decomposition of hydrocarbons in which electron capture and charge exchange play a dominant role. There is no novelty in postulating these reactions as mechanistic steps. The significance of electron capture has been discussed on many occasions by Hamill and his colleagues (see, for instance, refs. 1, 2, 3). Charge exchange was proposed by Hardwick (4) as a mechanism for the reactivity transfer observed in mixtures of aliphatic hydrocarbons and has also been suggested by Hamill. The crux of this proposed mechanism lies in the combination of two hypotheses, first, that the initial act of excitation leads to the formation of both ions and excited molecules and secondly, that, in pure hydrocarbons, the recapture of the electron by the positive ion also leads to the formation of excited molecules which are, for practical purposes, identical to these formed in the initial excitation. The mechanism provides an explanation for a variety of phenomena; viz., the rapid inhibition of part but not all of the hydrogen yield by solutes, reactivity transfer in mixtures of aliphatic and alicyclic hydrocarbons, and the effects of additives on the isotopic composition of radiolytic hydrogen produced from mixtures containing deuterated hydrocarbons.

The Mechanism

(*1*) Radiolysis of a hydrocarbon A produces, initially, positive ions, an equivalent number of electrons, and excited, un-ionized molecules A*.

[1*a*] [1*b*]
$$A \rightsquigarrow \begin{cases} A^+ + e^- \\ A^* \end{cases}$$

The yields of ions and excited molecules are comparable and probably $\sim 3/100$ eV absorbed.

(*2*) The recapture of the electron by the positive ion produces an excited species which is, for the purposes of the present discussion, identical with A* produced in [1*b*].

[2]
$$A^+ + e^- \rightarrow A^*$$

(*3*) In mixtures of hydrocarbons, A and B, charge exchange may occur.

[3*a*]
$$A^+ + B \rightarrow B^+ + A$$

[3*b*]
$$B^+ + A \rightarrow A^+ + B$$

[1]*Issued as AECL No. 2174.*

The ionization potentials of the hydrocarbons will determine the preferred direction of charge exchange, that is, whether [3*a*] or [3*b*] is preferred.

(*4*) Solutes S may react rapidly with electrons formed in [1*a*] to give negative ions.

[4] $$S + e^- \rightarrow S^-$$

(*5*) When reaction [4] occurs electron capture [2] is replaced by electron transfer which does not lead to the excited species A*.

[5*a*] $$S^- + A^+ \rightarrow S + \text{not-A}^*$$

It is also possible that solutes S react with the positive ions A^+. In this process and the subsequent electron capture, products other than A* are formed.

[5*b*] $$S + A^+ \text{ (and later, } + e^-) \rightarrow \text{not-A}^*$$

(*6*) In a pure hydrocarbon the intermediate A* is therefore the precursor of all subsequent reactions. In the experiments we are discussing we shall be interested almost exclusively in the decompositions which give hydrogen gas. For this decomposition, we postulate that A* can decompose in two ways: (i) to give a reactive intermediate X_H which reacts further with other hydrocarbon molecules to give H_2, or (ii) to give hydrogen by molecular detachment.

[6*a*] $$A^* \nearrow X_H + \text{products}$$

[6*b*] $$A^* \searrow H_2 + \text{products}$$

[7] $$X_H + A \rightarrow H_2 + \text{products}$$

In a mixture of deuterated and non-deuterated hydrocarbons HD can only be formed through reactions [6*a*] and [7] and, for dilute solutions of the deuterated hydrocarbon, D_2 is only formed by [6*b*].

The number of excited states formed initially is, of course, large. This initial spectrum of excitation is, however, rapidly changed by processes of internal conversion to a more restricted spectrum of states which can decompose in relatively few ways. In studying hydrogen yields we observe only those excited states which decompose to give molecular hydrogen or its precursors. It happens that all these excited states appear alike, and we describe the spectrum as consisting of only one state, A*. Other experiments might, very well, resolve A* into a number of components.

Formal Structure of the Mechanism

It is useful to note the logical structure of this mechanism without identifying species as ions, electrons, or excited molecules, etc. Radiolytic decomposition of a hydrocarbon proceeds via two precursors A′ and A″.

[I*a*] [I*b*] $$A \rightsquigarrow \begin{cases} A' \\ A'' \end{cases}$$

A′ can relatively slowly be converted to A″.

[II] $$A' \rightarrow A''$$

In mixtures of hydrocarbons change of identity reactions can occur.

[III*a*] $$A' + B \rightarrow B' + A$$

or

[III*b*] $$B' + A \rightarrow A' + B$$

Solutes may react with A′.

[IV] $$S + A' \rightarrow \text{not-A}''$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A″ is the precursor of all subsequent reactions. Our mechanism makes the identification $A' \equiv A^+ + e^-$, $A'' \equiv A^*$. Any other species having the properties required by reactions [I] to [IV] above would provide satisfactory rationalizations of experiment.

Discussion of the Mechanism

We will now point out the features of hydrocarbon radiolysis which are rationalized by this mechanism. While some new experimental results are reported most of the data are already published.

1. Ions and Electrons in Liquids and Solids

The key hypothesis in the mechanism is firstly, that the yields of ions in a condensed phase is an appreciable fraction of the total product yield and, secondly, that the recombination of electron and positive ion may be slow compared to the rate of electron capture by solutes and to the rate of charge exchange processes. The major support for this comes from the work of Hamill and his colleagues on the radiolysis of organic glasses at liquid nitrogen temperature (3). They found that electrons can be captured by solutes in these glasses to give known anions. The maximum yield of anions, ~ 3, is equated to the yield of electrons. In some materials (methyl tetrahydrofuran, methyl pentene, and ethanol) the glass itself captures ("traps") electrons. Although trapped electrons are not observed in any significant yield in pure alkanes, solute anions can be observed in them (5). The non-appearance of trapped electrons in alkanes is, consequently, attributed to the absence of traps rather than to the absence of electrons.

Measurements of the conductivity of irradiated alkanes show a much lower yield (0.1–0.3) of electrons (6, 7). In these measurements an electric field is applied to the system to extract ions and electrons. These measurements only detect the fraction of electrons which escape recombination in the parent spur. It is assumed in the mechanism discussed here that efficient electron scavenging, at high concentrations of solute, takes place in the spur volume itself so that electrons undetected in conductivity measurements may, nevertheless, take part in reactions with electron scavengers.

2. Processes Which Reduce the Hydrogen Yield

Small concentrations of many substances reduce the yield of hydrogen and other products from aliphatic hydrocarbons. This effect has been intensively studied and we will first summarize the principal observations.

(*a*) A small concentration ($\sim 1\%$) of an additive produces a sharp decrease of the hydrogen yield; at a greater concentration ($\sim 3\%$), where the product yield is about half that in the pure material, the decrease in product yield with increasing concentration is much slower. This effect of concentration, which is found in so many systems that it seems to be a universal observation, is generally interpreted in terms of two decomposition modes, one of which is inhibited by the solute; the other is unaffected. We have called these modes respectively the inhibited and the residual yields (8). While these two modes have been identified in a variety of ways (8) there has been no clear demonstration from a product analysis in the radiolysis of a single aliphatic hydrocarbon that the decomposition paths of the two modes lead to different products; on the contrary, isotopic experiments showed that the decomposition paths were identical (9).

(*b*) Isotopic experiments (10) have also shown conclusively that, in many cases, the additive interacts by a physical mechanism (like energy transfer or charge transfer) on an intermediate which is the precursor of both molecular detachment processes and of bimolecular processes for the formation of molecular hydrogen. The clearest evidence that this physical process may be electron capture comes from the work of Scholes and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Simic (11) who have shown that nitrous oxide, a good electron scavenger, reduces $G(H_2)$ from cyclohexane. The rate constant for reaction of nitrous oxide with electrons is $\sim 10^5$ greater than that for reactions with hydrogen atoms (12, 13). Solutions of nitrous oxide in cyclohexane showed a reduced hydrogen yield and a yield of nitrogen which is somewhat greater than the reduction in hydrogen yield. They further found that in solutions of nitrous oxide with either carbon tetrachloride or benzene, the nitrogen yields were consistent with a further competition for electrons between nitrous oxide and the other solutes. The ratio of the electron affinities of N_2O:CCl_4:C_6H_6 was in accord with other measurements.

These conclusions are in accord with several experimental studies performed in these laboratories. Detailed product analyses in the cyclohexane–benzene (14) and cyclohexane – carbon tetrachloride (15) systems have shown that the primary interactions in reactions giving hydrogen gas are physical and not chemical, i.e. they do not involve the making or breaking of a chemical bond. For carbon tetrachloride, electron capture was one of the possible physical interactions which was suggested by direct chemical evidence (the yield of Cl^-). There is, therefore, a considerable body of interlocking evidence supporting the hypothesis that electron capture is, for several solutes, a significant mode of interaction. If this is accepted then most of the other steps in this mechanism are logically required by the experimental evidence.

The yield of hydrogen occupies a crucial position in this mechanism as we suppose that its formation is directly related to the formation of the excited state A*. While it appears that many solutes inhibit the formation of hydrogen it does not follow that all other decompositions are inhibited. On the contrary, reactions following electron capture may lead to a net increase in decomposition (as is shown in the detailed product analysis of the C_6H_{12}–CCl_4 system (15)) even though the yields of some products, hydrogen in particular, may be reduced. The two decomposition modes are now interpreted as being due to the formation of ions and electrons (the inhibited yield) and to the formation of excited molecules (the residual yield). Since, however, the whole decomposition proceeds after electron–ion recombination through the same excited species, there is no essential difference in products in the two regimes.

The formation of ions and excited species should be a general phenomenon, not restricted to hydrocarbons. The separation of the yields into two parts should therefore be observable in other systems. This has indeed been found by Lee and Armstrong in the radiolysis of HCl and HBr (16). Part of the hydrogen yield was produced via the reaction of electrons with positive ions; this was inhibited by electron scavengers such as bromine or sulfur hexafluoride. The rest of the yield proceeds via decompositions which do not involve thermal electrons. Our proposed mechanism for hydrocarbons has several features in common with those suggested by Armstrong for hydrogen halides.

While we are emphasizing in this paper the role of electron capture processes in the radiolysis of hydrocarbons, it should be noted that the positive ion is also an intermediate which may have a high reactivity. As pointed out, reaction [5*b*], a reaction with the positive ion would also prevent the formation of A* and lead to many effects which, in simple experiments such as measurements of the hydrogen yield, would be indistinguishable from those produced by electron capture.

3. Electron Scavenging and Spur Reactions

In organic glasses the electron, formed in the initial ionizing step, is trapped at a small distance, 100 Å or less, from the positive ion. If this distance is appropriate to liquid hydrocarbons then the process of electron capture by a solute is competing with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

recombination of ions and electrons in a spur, or in the geminate recombination of an ion–electron pair. The competition is kinetically equivalent to the reactions of radical scavengers in the radiolysis of water where the scavenger competes for free radicals (H, e_{aq}^-, or OH) preventing their recombination in spurs to give molecular products H_2 and H_2O_2. We shall now show that the hydrogen yield in benzene–cyclohexane mixtures is predicted by the theories of diffusion-controlled kinetics which have been worked out for water.

Schwarz (17) found empirically that for a large number of solutes in water, the values of G/G_0 (where G_0 is the yield at infinitely low concentration of the additive and G the yield at concentration C) fall on a universal curve when plotted against log kC. The constant k is proportional to the rate constant for the reaction between the solute and the free radical. Schwarz also made a theoretical calculation where the constant k is found to be equal to BT where B is the rate constant for the solute – free radical reaction and T is a time related to (and defining) the initial size of the spur. This theoretical curve is shown in Fig. 1 with $BT = 0.1$. The experimental values of G/G_0 for the hydrogen yield in benzene-cyclohexane mixtures are in good agreement with the theoretical predictions.

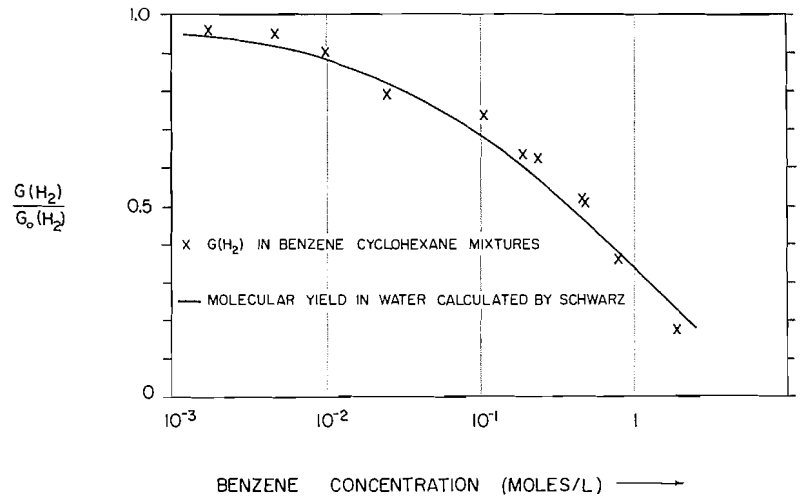

FIG. 1. Hydrogen yields from benzene–cyclohexane mixtures. The calculated curve is taken from Schwarz (17) with a correction to the concentration scale described in the text.

This agreement does not, however, mean that spur sizes and diffusion constants appropriate to water are equally relevant to the reactions of ions and electrons in organic systems. A rigorous treatment for the reactions we are postulating must include, amongst other things, the effect of Coulomb attraction in ion–electron recombination and the effect of electron energy, the rate of electron thermalization, and the energy dependence of the electron capture cross section on the probability of electron capture by a solute. The data in Fig. 1 indicate that inclusion of these effects has not made a large difference to the shape of the yield curve. This is, perhaps, to be expected when it is noted, from Kuppermann's review (18), that the shape of this yield curve is not markedly altered by quite drastic changes in the parameters of the model.

These conclusions are very similar to those proposed by Ffrancon Williams (19) to explain the kinetics of the formation of HD from solutions of ND_3 in cyclohexane. At

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

low concentrations of ND_3 ($< 10^{-3}$ M) ammonia reacts with positive ions which have not undergone recombination. At high concentrations, ND_3 competes in a spur reaction with the recombination of positive ions and electrons in spurs. The yield of HD, plotted against log [ND_3] is similar in shape to our figure except that G(HD) increases with scavenger concentration where, in our experiments $G(H_2)$ decreases. One curve is, as it were, the complement of the other. This interpretation implies that the distinction between the yields of ions and the yields of excited molecules is, in part, artificial; some ion–electron pairs have such a high probability of recombining that, except at very high scavenger concentrations, they, for all practical purposes, contribute to the yield of excited molecules and not to the ionic yield. The rigorous kinetic separation of the two yields is also made difficult by Freeman's observations (20) that there are other weak interactions observable at high additive concentrations which can be attributed to another energy transfer process. This corresponds, in our mechanism, to an interaction between A* and S.

The effects of solutes on yields in hydrocarbon systems have, hitherto, been calculated on the assumption that the reactions occurred homogeneously. While the experimental data do follow the predictions of many homogeneous mechanisms over a limited concentration range it is now clear that this agreement is fortuitous. Typical of these predictions is the 'scavenger plot' which states that $1/(G_0(H_2) - G(H_2)) \equiv 1/\Delta G(H_2)$ is a linear function of $1/c$ where $G_0(H_2)$ is the yield in the pure hydrocarbon and $G(H_2)$ is the yield at the concentration c (21). Klots, Raef, and Johnsen (22) have, however, recently shown that this function is not accurately obeyed over a wide concentration range. It is easy to verify that theoretical curves of the type calculated by Schwarz have all the numerical properties of the yield curves (G vs. concentration) found in organic systems, and for instance give linear plots of $1/\Delta G$ vs. $1/c$ over certain concentration ranges with a second segment at low concentrations as observed by Stone and Dyne (14).

4. Charge Exchange Processes

In the radiolysis of a hydrocarbon containing a small amount of a deuterated hydrocarbon the decomposition of the deuterated component is readily seen from the isotopic composition of the radiolytic hydrogen. Such experiments show a very large variation in the reactivity of cyclohexane-d_{12} and methyl-cyclohexane-d_{14} when mixed with other aliphatic and alicyclic hydrocarbons (23, 24). Recent experiments in this laboratory have shown that similar effects are found in mixtures of butane-d_{10}, propane-d_8, or ethane-d_6 with other aliphatic hydrocarbons (25). This reactivity transfer is not therefore restricted to cyclohexane or its derivatives.

From these experiments it appears that excitation produced in one component of a hydrocarbon mixture may be transferred to the second component. With the knowledge that electron capture processes can occur in hydrocarbons it is natural to suggest that this excitation transfer occurs by positive charge exchange. In a hydrocarbon mixture where components A and B are of comparable molecular weight then the ions A^+ and B^+ will be initially formed in a ratio close to that given by the mole ratio (or electron fraction). The number of ions A^+ and B^+ which decompose after charge transfer may be very different from this if one of the processes [3*a*] or [3*b*] is much more efficient than the other.

This charge transfer mechanism was first proposed by Hardwick (4) for these isotopic experiments and for others in which the total hydrogen yield in hydrocarbon mixtures was measured. Hardwick pointed out a general correlation: solvents with a higher ionization potential than the detector molecule (C_6D_{12} in our experiments) activated the detector molecule; solvents with a lower ionization potential deactivated it giving lower yields than for C_6D_{12} in C_6H_{12}. This correlation is also observed in the results obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

by Stone and Quirt (25) using butane-d_{10}, propane-d_8, and ethane-d_6. A correlation of this nature is reasonable since charge transfer can only go in the exothermic direction.

5. The Effects of Additives on the Charge Transfer Process

The role of excited molecules in the radiolysis of hydrocarbons is seen most clearly in the effects of additives on hydrocarbon mixtures in which there is considerable activation of one component by charge transfer. These effects were discussed in some detail by Dyne, Denhartog, and Smith (10) and this discussion elaborates some of the ideas presented in that paper.

We will first show that a mechanism involving reactions of positive ions alone (the independent formation of A* by reaction [1*b*] being omitted) is inadequate. Since charge transfer and electron capture are independent processes charge transfer will continue until the solute anion S^- reacts with the positive ion. If ions were the only precursors of decomposition then the effects of charge transfer would still be apparent in the presence of solutes even though the total hydrogen yield is reduced. Put another way; in an isotopic mixture positive charge transfer to the deuterated hydrocarbon can lead to high percentage of D_2 and HD in the radiolytic gas. An electron scavenger would inhibit the production of hydrogen but the percentages of D_2 and HD in the gas would be the same as without the scavenger. This, however, is not what is observed; in activating solvents the yields of $G_1(D)$ and $g(HD)$[2] are reduced more rapidly than the yields of hydrogen (the percentage of D_2 and HD decreases). This is shown in Fig. 2 for the effects of CCl_4 on solutions of C_6D_{12} in *n*-hexane. (Figure 3 of ref. (10) is an example of similar data for the addition of benzoquinone to *c*-C_6D_{12} – *n*-hexane mixtures.) In solvents which are deactivating (i.e. in which the D_2 and HD yields are considerably lower than for solutions of *c*-C_6D_{12} in *c*-C_6H_{12}) the converse is observed; the D_2 and HD yields are reduced less rapidly than the total hydrogen yield (Fig. 3). The solvent here is decalin.

The solution to this difficulty is most clearly seen through Stone's detailed study of products in mixtures of cyclohexane with cyclopentane (26). Cyclopentane is an activating

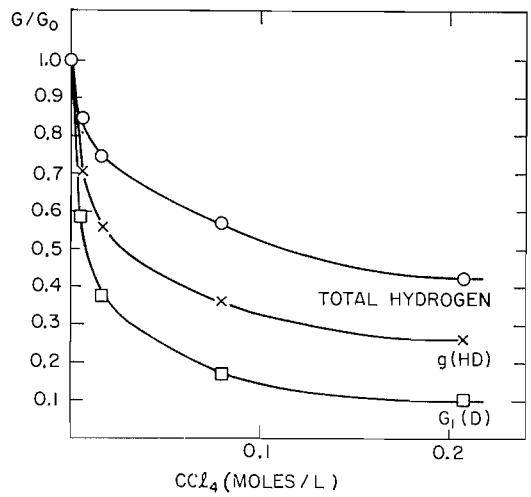

FIG. 2. Normalized yields of total hydrogen, $G_1(D)$, $g(HD)$ for additions of CCl_4 to cyclohexane-d_{12} – *n*-hexane mixtures. These data appear, in a different form, in ref. (10). The values of the normalizing constants G_0 are $G_0(H_2) = 5.1$, $G_1(D) = 2.6$, $g(HD) = 10.5$.

[2]*G_1(D) and g(HD) are, respectively, the yields of* D_2 *and* HD *per unit electron fraction of the deuterated hydrocarbon.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

solvent and so at low concentrations of cyclohexane the liquid products derived from cyclohexane, in particular cyclohexene, show enhanced yields. In the presence of solutes (iodine and carbon tetrachloride) no activation is observed; the yields of products derived from the two components are regular and follow the "mixture law."

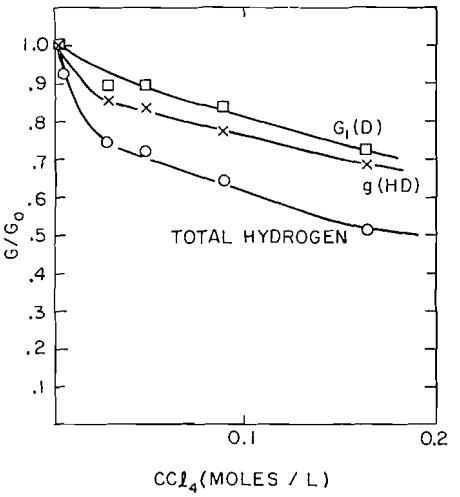

FIG. 3. Normalized yields of total hydrogen, $G_1(D)$, $g(HD)$ for additions of CCl_4 to cyclohexane-d_{12}–decalin mixtures. The values of the normalizing constants G_0 are G(total hydrogen) = 4.7, $g(HD)$ = 3.1, $G_1(D)$ = 0.15.

These observations lead us to postulate the existence of another precursor, other than the positive ion, which could not undergo a transfer reaction. This is the excited state A*. We shall now show that this mechanism predicts the effects of additives on the yields of D_2, HD, and D_2 for both activating and deactivating solvents. Suppose that the number of excited states and ions formed from the solvent are E_S and I_S and the numbers formed from the detector molecule (C_6D_{12}) are E_D and I_D. The yield of hydrogen from the pure solvent is then proportional to $(E_S + I_S)$, and

$$G_0(H_2) \simeq k(E_S + I_S).$$

In the presence of an electron scavenger which prevents the decomposition of some fraction of the ions the yield will be

$$G(H_2) \simeq k(E_S + \beta I_S)$$

when β is the fraction of ions unaffected by the solute. The reduction in the total yield, relative to the initial yield G_0 is

$$G(H_2)/G_0(H_2) \simeq (E_S + \beta I_S)/(E_S + I_S).$$

In the absence of charge transfer the same relation will apply to the detector molecule and the reduction in the D_2 yield, relative to $G_0(D_2)$, will be

$$\frac{G(D_2)}{G_0(D_2)} \simeq \frac{E_D + \beta I_D}{E_D + I_D}.$$

In an activating solvent the number of ions of the detector molecule will be increased by charge transfer by a number T.

$$G_0(D_2) \simeq k(E_D + I_D + T).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

If the concentration of the detector molecule is small then the effect of charge transfer on the number of solvent ions is negligible and I_S is effectively unaltered (i.e. $I_S - T \simeq I_S$). Since the quenched part of the D_2 yield ($I_D + T$) is a larger part of the yield the D_2 yield will be reduced more rapidly than the hydrogen yield, i.e.

$$\frac{E_S + \beta I_S}{E_S + I_S} > \frac{E_D + \beta(I_D + T)}{E_D + I_D + T} \quad \text{or} \quad \frac{G(H_2)}{G_0(H_2)} > \frac{G(D_2)}{G_0(D_2)}.$$

If the solvent is deactivating the converse applies. The reduction in the D_2 yield will be

$$\frac{G(D_2)}{G_0(D_2)} \simeq \frac{E_D + \beta(I_D - T)}{E_D + I_D - T},$$

which is now greater than $G(H_2)/G_0(H_2)$. The D_2 yield will be reduced less rapidly than the hydrogen yield.

The effect of an additive on the yield of HD will be intermediate between its effect on D_2 and H_2. Neglecting isotope effects we can expect that approximately equal amounts of HD come from the reaction $X_D + RH \rightarrow HD + ----$ and from $X_H + RD \rightarrow HD + ----$ (RH and RD are respectively the "light" solvent and deuterated detector). The yield of X_D is affected by the charge transfer process but, again in dilute solutions of the detector the yield of X_H is unaffected. In an activating solvent that part of the HD yield formed via X_D will be rapidly reduced to the same extent as the D_2 yield; the part formed via X_H will only be reduced as the H_2 yield. The normalized HD yield will therefore fall more rapidly than H_2 but less rapidly than D_2. These effects for activating and deactivating solvents are shown in Figs. 2 and 3.

Nitrous oxide and sulfur hexafluoride show the same qualitative effects when added to solutions of *c*-C_6D_{12} in *n*-hexane as do carbon tetrachloride (Figs. 4 and 5).

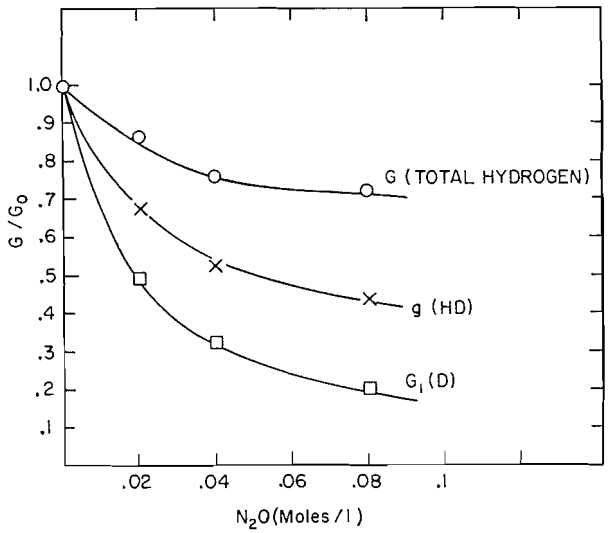

FIG. 4. Normalized yields of total hydrogen, $G_1(D)$ and $g(HD)$ for additions of nitrous oxide to cyclohexane-d_{12} – *n*-hexane mixtures. The normalizing constants are as for Fig. 2.

The simple theory presented here would predict a unique relation between G(total hydrogen) and $G_1(D)$; one is proportional to $E_S + \beta I_S$, the other is proportional to $E_D + \beta(I_D + T)$. Accordingly G(total hydrogen) and $G_1(D)$ should lie on a universal

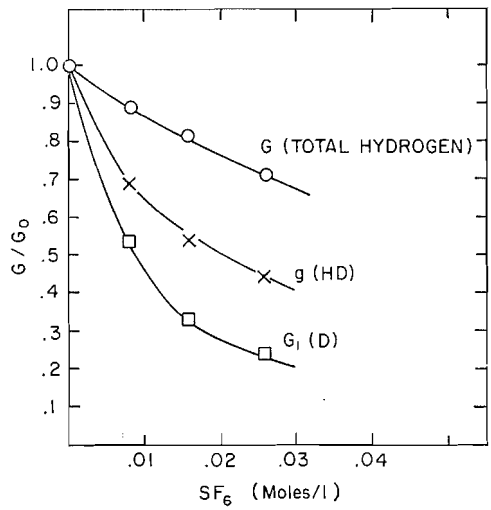

FIG. 5. Normalized yields of total hydrogen, G_1(D) and g(HD) for additions of sulfur hexafluoride to cyclohexane-d_{12} – n-hexane mixtures. The normalizing constants are as for Fig. 2.

curve for all solutes. This correlation was observed empirically in ref. (8). The data presented there are also shown in Fig. 6 with additional data for sulfur hexafluoride and nitrous oxide. This correlation is observed to a fairly high approximation. The data shown in Figs. 4 to 6 provide a link between our isotopic experiments for which we have hitherto presented a formal "physical" mechanism and the evidence for the electron capture step shown by the effects produced by N_2O and SF_6. As suggested by Toma and Hamill (3) some of the other additives we have studied, in particular cyclohexene and benzene, may undergo positive charge transfer with the positive ion ($C_6D_{12}^+$). The reaction [5*b*] would have, qualitatively, the same effect as electron capture in these isotopic experiments.

6. The Effect of Hydrogen Halides on the Radiolysis of Hydrocarbons

The yield of hydrogen from cyclohexane (and other aliphatic hydrocarbons) increases by about 1 G unit on the addition of hydrogen halides. Nash and Hamill (27) studied the isotopic composition of the hydrogen evolved from solutions of HI in C_6D_{12}. They suggested that the increase in yield arose from a competition between

$$C_6D_{12}^+ + e \rightarrow C_6D_{10} + D_2,$$
$$HI + e \rightarrow H + I^-,$$
$$I^- + C_6D_{12}^+ \rightarrow C_6D_{12} + I.$$

Electron capture by HI produces H atoms with a greater efficiency than the production of D_2 by neutralization of $C_6D_{12}^+$. The recombination of I^- and $C_6D_{12}^+$ produces no hydrogen. We would write Hamill's mechanism as follows (for HCl, the solute used in experiments carried out in this laboratory by J. Denhartog and M. G. Bailey).

$$C_6D_{12}^+ + e \rightarrow C_6D_{12}^* \begin{cases} \nearrow D_2 + \text{---} \\ \searrow X_D + \text{---} \end{cases}$$

[8] $$HCl + e \rightarrow Y_H + Cl^-, \; Y_H + C_6D_{12} \rightarrow HD$$

[9] $$Cl^- + C_6D_{12}^+ \rightarrow \text{not-}C_6D_{12}^*$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

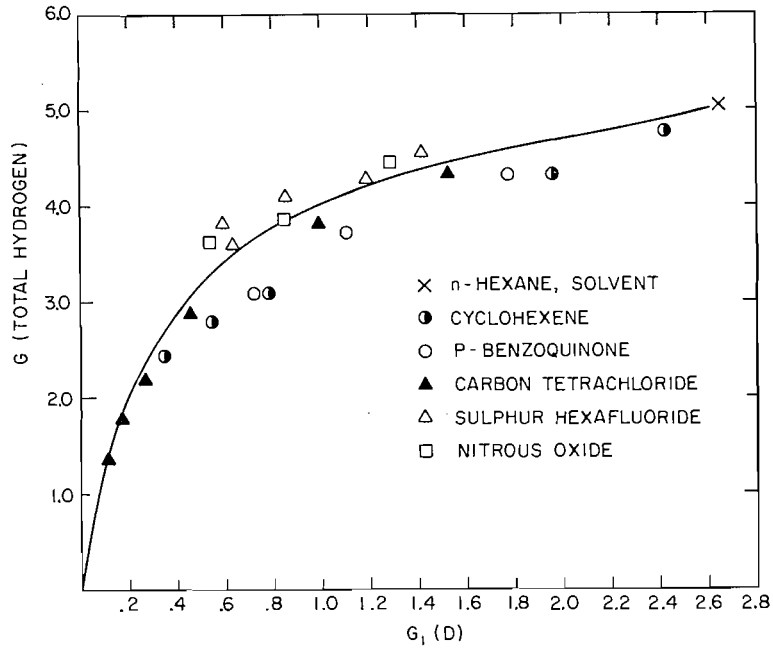

FIG. 6. Values of G(total hydrogen) from mixtures of C_6D_{12} in n-hexane plotted against G_1(D), the deuterium yield per unit mole fraction C_6D_{12}. The data for sulfur hexafluoride and nitrous oxide are new; other data were presented in ref. (10), Fig. 6.

We will now examine the effects of HCl on solutions of C_6D_{12} in an activating solvent, n-hexane. Using the notation of the previous section the yield of D_2 and HD will be proportional to $E_D + I_D + T$ and the yield of hydrogen will be proportional to $E_S + I_S$. If sufficient HCl is added to scavenge all electrons and prevent the reactions of all ions, then the D_2 yield will be reduced and will be proportional to E_D. The yield of ions $(I_D + T)$ is replaced by a somewhat larger yield $\gamma(I_D + T)$ of the intermediate Y_H where γ is the ratio of the efficiencies of processes [2] and [8], and the yield of ions I_S is replaced by a yield of $Y_H = \gamma(I_S)$. The yield of D_2 will be drastically reduced even though the total hydrogen yield is increased. This is observed experimentally (Fig. 7). The yield of HD will not be reduced as much for the following reasons. In the absence of HCl, HD is produced by the reaction of X_D on the light hydrocarbon and by the action X_H on the deuterated hydrocarbon. The presence of HCl suppresses the yield of X_D from decomposition of excited molecules. At the same time the yield of species Y_H (which will react to give HD as did X_H) will be increased in two ways. In the absence of HCl the ions $C_6H_{12}^+$ decompose after electron capture to give H_2 and X_H; i.e., only a fraction of the ions gave X_H. In the presence of HCl all ions give Y_H and in addition the efficiency of production of Y_H is greater than the total production of H_2 and X_H. There will, therefore, be a much larger yield of HD through the reactions of Y_H. The net effect will be a reduction of the yield of HD which is not as drastic as that for D_2.

This mechanism depends on the possibility that the efficiency of dissociative electron attachment (molecules decomposed / electrons captured) is greater for one molecule (HCl) than for the ion $C_6H_{12}^+$. There is evidence from other systems that dissociative electron attachment is less efficient for $C_6H_{12}^+$ than it is for other ions. Scholes and Simic (11) find that the yields of N_2 in solutions of N_2O in cyclohexane are greater than the

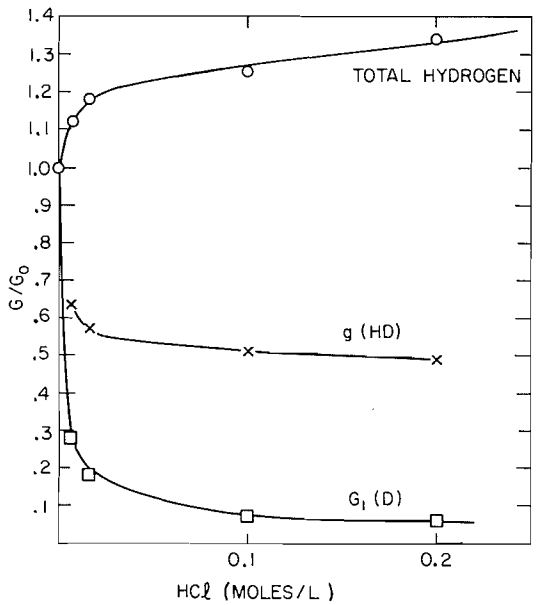

FIG. 7. Normalized yields of total hydrogen, $G_1(D)$, $g(HD)$ for additions of hydrogen chloride to cyclohexane-d_{12} – n-hexane mixtures. The normalizing constants are as for Fig. 2.

decrease in hydrogen yield and suggest that "N_2O can scavenge some electrons which do not normally lead to hydrogen gas." Stone and Dyne (15) found that, in solutions of CCl_4 in C_6H_{12}, the yield of HCl was greater than the decrease in hydrogen yield by as much as 1 G unit and that this was correlated with a larger number of cyclohexyl residues in the products. In their words "carbon tetrachloride enhances radiolytic action."

7. Problems Raised by this Mechanism

The main uncertainties in this mechanism stem from our ignorance of the rates or efficiences of ionic and electron capture reactions in liquids. In addition, as we believe that these reactions occur in spurs we have also to cope with the problems of non-homogeneous kinetics. Because of these difficulties we have so far only developed this mechanism qualitatively; much work has to be done before such a mechanism can be treated quantitatively. In this section we will review some of the problems which have to be treated in a quantitative theory.

Firstly, let us consider the efficiency of the charge transfer step. As can be seen from the following argument this efficiency is not very high in alkane mixtures. This efficiency can be estimated by comparing the sum of the yields of D_2 and HD in mixtures of c-C_6D_{12} in cyclohexane and n-hexane respectively. For a 5.5 mole % solution of c-C_6D_{12} the sum $G(D_2)$ and $G(HD)$ is 0.26 for cyclohexane as solvent and 0.7 for n-hexane as a solvent. The difference, 0.44 G units, is approximately the number of ions of C_6D_{12} formed by charge transfer from n-hexane ions. This is about one-tenth the total number of ions formed in the mixture if $G(e^-)$ is taken to be ~ 3. By contrast, Stone (28) finds very efficient charge transfer in solid mixtures of alkanes with krypton. In dilute mixtures of the hydrocarbon (~ 5 mole %) it appears that virtually all the krypton ions undergo charge transfer with neighboring hydrocarbon molecules since $G(H_2)$ in these mixtures is ~ 3. Although the efficiency of charge transfer is small in alkane mixtures the process must be fast compared to charge neutralization.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Charge transfer is exothermic and could presumably go to completion. What then limits the efficiency of the process? If it is limited by the time for charge neutralization then one would expect that more charge transfer might be observed in the presence of an electron-capturing solute since the negative ion will have a lower mobility than the free electron and would take longer to return to the positive ion. The efficiences of charge transfer processes in vapors are a related problem. We have shown that the activation processes observed in liquid mixtures are absent in the gas phase (10). According to this mechanism, therefore, charge transfer can occur in liquids but not in vapors. We have to conclude that charge transfer occurs slowly relative to the duration of a gas phase collision but can occur when the molecule and ion are held together in a solvent cage.

The kinetics of electron capture processes raises the perennial question of how far the electron gets away from the positive ion before it is thermalized and can be recaptured. When an electron-capturing solute is present, it must be remembered that the cross section for electron capture is energy dependent. With some solutes, electrons may more easily be captured before they are thermalized. For this reason it could be argued that, at certain concentrations, electron capture by a solute could even reduce the time for positive ion neutralization.

ACKNOWLEDGMENTS

The new experimental data on solutions containing N_2O and SF_6 were obtained by Mr. J. Denhartog. It is a pleasure to acknowledge his experimental work, and, in addition, the many entertaining and enlightening discussions I had with Dr. J. A. Stone on the substance of this paper.

THE STRUCTURE OF HOMOCHASMANINE[1]

O. ACHMATOWICZ, JR.[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received January 6, 1965

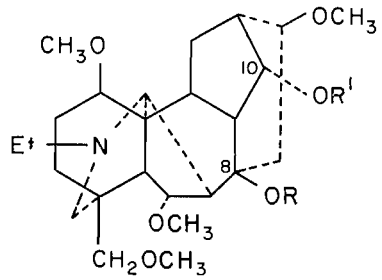
ABSTRACT

The structure of homochasmanine, a new alkaloid isolated from *Aconitum chasmanthum* Stapf, has been determined. Its empirical formula is $C_{26}H_{43}O_6N$ and the spectroscopic evidence shows that the base contains five methoxyl and one hydroxyl group. The presence of the hydroxyl group is confirmed by the formation of a monoacetyl derivative. That homochasmanine is 8-*O*-methylchasmanine has been shown by the synthesis of this substance from the previously known diacetylchasmanine.

Five alkaloids have been reported as occurring in *Aconitum chasmanthum* Stapf (1). The structure of four, i.e., indaconitine (2), chasmaconitine (1), chasmanthinine (1), and chasmanine (3) have already been determined. The fifth alkaloid, obtained from the fraction containing the strong bases, was initially identified as base A. It is now proposed to name it homochasmanine.

Homochasmanine has the empirical formula $C_{26}H_{43}O_6N$, m.p. 105–107°, $[\alpha]_D^{25}$ +19.2°. It is not stable and gradually decomposes on standing. Its infrared spectrum contains a band at 3 420 cm^{-1} indicative of a hydroxyl group, but no carbonyl absorption. The nuclear magnetic resonance (n.m.r.) spectrum shows five methoxyl signals (δ 3.36, 3.32, 3 30, 3.24, 3.23) and a triplet centered at δ 1.07 characteristic of an imino-ethyl group. The five methoxyl groups and one hydroxyl account for all the oxygen present in the molecule. The presence of a hydroxyl indicated by the infrared spectrum is confirmed by acetylation of the base to a monoacetate that could not be induced to crystallize, but was homogeneous in thin layer chromatography. In the infrared the monoacetate showed a carbonyl absorption band at 1 725 cm^{-1}, while its n.m.r. spectrum contained signals for five methoxyl groups, δ 3.32 (6H), 3.30 (3H), 3.22 (6H), a signal at δ 2.03 attributable to the three protons of the acetyl group, a triplet centered at δ 1.07 due to the imino-ethyl, and a poorly resolved triplet at δ 4.77 that will be referred to later.

The empirical formula of homochasmanine ($C_{26}H_{43}O_6N$) differs from that of chasmanine ($C_{25}H_{41}O_6N$) in that it contains an additional CH_2. Whereas chasmanine contains two hydroxyl and four methoxyl groups, homochasmanine contains one hydroxyl and five methoxyl groups. It was therefore assumed, as a working hypothesis, that homochasmanine was an *O*-methylchasmanine. From the structure of chasmanine I, it is obvious that the additional methyl group in homochasmanine can be linked to the oxygen only



I, R = R' = H
II, R = CH_3, R' = H
III, R = R' = Ac

[1]*Issued as N.R.C. No. 8360.*
[2]*National Research Council of Canada Postdoctorate Fellow.*

at C-8 or C-10. In the light of the assumption of the structure of homochasmanine, the poorly resolved triplet at δ 4.77 in the n.m.r. spectrum of monoacetylhomochasmanine would be attributable by analogy with many other cases (4) to a proton located on the carbon carrying the ester group. This carbon must be flanked by two neighboring protons to account for the splitting of the signal into a triplet. Of the two hydroxyls present in chasmanine only that at C-10 fills these conditions and hence it must be the C-8 position that carries a methoxyl so that homochasmanine should be 8-*O*-methylchasmanine II.

In order to confirm or disprove this conclusion we made use of the reaction whereby the acetoxy group at C-8 in aconitine (5) or in delphinine (6) is replaced by a methoxyl when the base is heated under pressure with methanol. Diacetylchasmanine III prepared from chasmanine (3) and heated in a sealed tube with methanol gave rise to an amorphous product which after saponification crystallized readily, m.p. 105–107°, $[\alpha]_D^{25}$ +19.4°. This base was identical in every respect with homochasmanine.

Homochasmanine, therefore, is 8-*O*-methylchasmanine and is represented by structure II. This is the first reported natural occurrence of a highly oxygenated diterpenoid alkaloid containing an *O*-methyl group in the C-8 position. It is conceivable that homochasmanine might be an artifact formed during the extraction of the alkaloids. It should be pointed out, however, that chasmanine itself was not methylated under the conditions in which diacetylchasmanine was converted into monoacetylhomochasmanine and also that no alkaloid corresponding to an ester of chasmanine was found in the plant.

EXPERIMENTAL

The infrared spectra were taken in Nujol mulls on a Perkin–Elmer double beam Model 21B spectrometer. The n.m.r. spectra were measured in chloroform solution containing tetramethylsilane as an internal reference on a Varian A-60 instrument. For column chromatography Woelm Grade IV neutral alumina was used, and for thin layer chromatography the adsorbent was Merck silica gel G, the developing solvent cyclohexane–chloroform–diethylamine. Melting points were taken on a Kofler hot stage and were not corrected.

Homochasmanine

The alkaloid was isolated from the crude basic extract of *Aconitum chasmanthum* Stapf as reported previously (1). It was purified by repeated crystallization in *n*-hexane from which it separated as clumps of colorless prisms, m.p. 105–107°, $[\alpha]_D^{25}$ +19.2° (*c*, 2.4 in EtOH). The base is unstable and decomposes gradually at room temperature. Found: C, 67.32; H, 9.07; N, 2.96. Calcd. for $C_{26}H_{43}O_6N$: C, 67.06; H, 9.31; N, 3.01%. Infrared: ν_{max} 3 420 cm^{-1} (OH), 1 110, 1 093 cm^{-1} (OCH_3). In the n.m.r. spectrum: singlets at δ 3.36 (3H), 3.32 (3H), 3.30 (3H), 3.24 (3H), 3.23 (3H), triplet centered at δ 1.07 (3H).

Acetylhomochasmanine

Homochasmanine (25 mg) and *p*-toluenesulfonic acid (20 mg) in acetic anhydride (2 ml) were heated for 1 h on a steambath. The reaction mixture, worked up as usual, gave a gummy monoacetate (21 mg). Infrared: ν_{max} 1 725 cm^{-1} (CO). In the n.m.r. spectrum: singlets at δ 3.32 (6H), 3.30 (3H), 3.22 (6H), 2.03 (3H), triplet at δ 1.07 (3H), and a poorly resolved triplet at δ 4.77.

Partial Synthesis of Homochasmanine

Diacetylchasmanine (52 mg), prepared as described previously (3), dissolved in methanol (5 ml) was heated in a sealed tube at 120–130° for 1 h. The solvent was evaporated and the residue, dissolved in *n*-hexane, was chromatographed on alumina. Elution first with *n*-hexane and then with *n*-hexane – benzene (1:1) produced a homogeneous gum (42 mg), the infrared spectrum of which contained a band at 1 725 cm^{-1}. In thin layer chromatography, it had the same mobility as the monoacetate described above. The product was refluxed for 30 min with 2% methanolic potassium hydroxide (5 ml), the solvent evaporated, and the residue dissolved in water. Extraction of the aqueous solution with chloroform and evaporation of the extract yielded a gum (31 mg) that solidified when triturated with *n*-hexane. The gum was dissolved in *n*-hexane, chromatographed on alumina, and eluted with the same solvent. The eluate on evaporation left a residue that crystallized from *n*-hexane as clumps of colorless prisms, m.p. 105–107°, $[\alpha]_D^{25}$ +19.4° (EtOH). This basic product proved to be identical with homochasmanine in every respect (melting point, mixture melting point, and infrared absorption spectra).

CATION EXCHANGE IN ANHYDROUS ETHYLENEDIAMINE

WALTER R. HEUMANN, ONIL DIONNE, AND GILLES TREMBLAY
Département de Chimie, Université de Montréal, Montreal, Quebec

Received October 16, 1964

ABSTRACT

The swelling of the strongly acid cation exchangers Dowex 50W of various degrees of cross-linking is markedly less in ethylenediamine than in water. However, it is sufficient for exchange reactions to occur. In contrast with aqueous solutions, electrolytes dissolved in ethylenediamine cause the swelling to increase, which is attributed to the low degree of dissociation attainable in this solvent. This explanation is supported by the observation that in water slightly dissociated electrolytes also produce a slight increase in swelling. Exchange reactions were carried out successfully with the slightly cross-linked resin Dowex 50W-X2. The bromide, ethoxide, aminoethoxide, and 2-aminoethylamide of lithium exchanged the latter cation with other alkali metals or tetrabutylammonium easily.

INTRODUCTION

Little is known on the behavior of ion exchange resins in strongly basic anhydrous solvents. Keenan and McDowell (1) reported briefly on the possibility of exchanging potassium and ammonium in anhydrous liquid ammonia. For ion exchange to take place between a resin and an electrolyte in solution, the solvent must be capable of penetration into the resin, and thus to cause swelling of the resin network. For a given exchange resin the maximum swelling in a particular solvent depends largely on the solvent's polarity as expressed by its dielectric constant ϵ, the degree of swelling being high with highly polar solvents and nil with nonpolar solvents. Ethylenediamine is only moderately polar, its dielectric constant being about 12.5 at 25 °C. Ion exchange resins could, therefore, not be expected to swell very much in this solvent, and it was by no means certain that ion exchange reactions would be easy to accomplish in this medium. It was the purpose of the present investigation to establish whether and under what conditions cation exchange in ethylenediamine could be possible.

The exchangers studied were the strongly acid cation exchangers Dowex 50W (sulfonated polystyrene divinylbenzene copolymers) of various degrees of cross-linking. All exchangers used had either lithium, a small inorganic ion, or tetrabutylammonium, a large organic ion, as their counterions. The extent of swelling of all samples in pure anhydrous ethylenediamine and its variation with the degree of cross-linking were determined. For the purpose of comparison, the swelling of identical samples was also determined in water, a highly polar solvent (ϵ = 78.5 at 25 °C), and in anhydrous methanol, a solvent of intermediate polarity (ϵ = 32.6 at 25 °C). To some extent, the influence of solutes in the ethylenediamine phase on the swelling was also investigated. Finally, several exchange reactions between the ions lithium, sodium, potassium, and tetrabutylammonium were carried out. These ions were present in the liquid phase either as alkoxides or amides.

EXPERIMENTAL

Exchangers

The exchangers used were the commercial resins Dowex 50W of 30–50 mesh/in. size of the dry material, having cross-linking degrees corresponding to 1, 2, 4, and 8% divinylbenzene (DVB) content respectively, and being labelled accordingly X1, X2, etc. The resins were thoroughly washed with deionized water, converted into either the lithium or tetrabutylammonium form, dehydrated by drying for at least 20 h at 115–120 °C, and weighed. Exchange capacities were determined by alkalimetric titration of the hydrogen form as described by Kunin (2).

Ethylenediamine

Anhydrous ethylenediamine was prepared from commercial material of at least 98% purity by first drying for several days with porous barium oxide (Barium and Chemicals, Inc., Willoghby, Ohio). The liquid was decanted into a vacuum distilling apparatus equipped with Teflon-sleeved ground glass joints and Teflon stopcocks. Liquid potassium–sodium alloy containing 78% potassium was added from a separatory funnel in successive portions until a persistent dark-blue coloration of the solution was obtained. This liquid alloy offers the advantage of dissolving much faster than either one of the two solid metals. It is easily prepared by mixing small pieces of the two metals in a separatory funnel under a high-boiling hydrocarbon having a density of less than 0.84, such as *n*-decane or *n*-dodecane. Vacuum distillation of the blue ethylenediamine solution at a temperature not exceeding 40 °C in presence of an excess of alkali metal finally gave the pure anhydrous solvent. Boiling at higher temperatures in presence of potassium can cause loss by polymerization (formation of dark-brown residues).

Lithium 2-Aminoethoxide $LiOC_2H_4NH_2$

A 0.5 *M* solution in ethylenediamine was prepared by first dissolving under anhydrous conditions 700 mg of pure lithium metal in 80–100 ml of liquid ammonia kept well below its boiling point in an ethanol – dry ice bath. After complete dissolution of the metal, which was attained after several minutes, anhydrous 2-aminoethanol (approximately 6 ml) was added slowly from a burette until the dark-blue solution became colorless. The reaction was complete within 15 min. The ammonia was allowed to evaporate from this solution of lithium 2-aminoethoxide and was gradually replaced by ethylenediamine until a volume of 200–220 ml was reached. The solution was transferred to a glove box containing dry nitrogen and filtered over a rapid filtering folded paper such as Whatman No. 40 or 541. This filtration removed any lithium hydroxide which could have formed, since it was found to be insoluble in ethylenediamine, forming a gelatinous precipitate.

Note. Pure alkali 2-aminoethoxides cannot be prepared by direct reaction of the metals with the amino-alcohol, as a side reaction takes place by which volatile decomposition products are formed.

Lithium 2-Aminoethylamide $LiNHC_2H_4NH_2$

The commercially available product of 97–98% purity (Foote Mineral Co., Exton, Pennsylvania) was used to prepare its ethylenediamine solution, which is dark-blue to violet. Its composition and purity were checked by decomposing a weighed sample with an excess of water and titrating the resulting aqueous solution conductometrically with standard hydrochloric acid. Three distinct equivalence points, corresponding to lithium hydroxide and the two basic functions of ethylenediamine respectively, could easily be established. The lithium content was determined by flame photometrical analysis of the aqueous solution.

Swelling Measurements

All experiments with both ethylenediamine and methanol were carried out in a glove box in an atmosphere of dry nitrogen. To determine volumes of swollen resins, weighed samples of anhydrous resins were placed in glass-stoppered graduated cylinders, mixed with solvent, and shaken from time to time until constant volumes were attained. The volumes of the resin layers as read by the cylinder graduation were taken as the volumes of the resin phase. These somewhat arbitrary measurements were considered satisfactory for the purpose of this investigation, although the true volumes of the resin were slightly smaller.

Exchange Columns

For the ion exchange reactions which were likewise carried out in a glove box, a glass column of 14 × 240 mm was used, fitted at the top with a 100 ml ampoule connected by a tapered joint with Teflon sleeve. The flow rate was controlled by a "Lab-Crest" Teflon needle valve (Fischer & Porter Co., Warminster, Pa.). All connections between glass tubes were of thin-walled Teflon tubing. This column was adequate for work with 25–30 milliequivalents (meq) of exchanger. Exchange reactions were carried out between this amount of exchanger and 2–5 meq of electrolyte in 0.1–0.3 *M* solutions in ethylenediamine with flow rates between 0.1 and 0.3 ml/min.

Analyses

The composition of both the resin samples and ethylenediamine solutions could always be found by flame photometric determination of one or two alkali metals, since in all experiments at least one alkali metal ion was involved. The resin samples to be analyzed were first digested in a Kjeldahl flask by boiling with a mixture of 4–5 volumes concentrated sulfuric acid and 1 volume concentrated nitric acid. Fresh portions of the latter were added several times until all organic matter was completely oxidized. The acids were then eliminated by evaporation, the residue taken up with water, and this solution analyzed with a Zeiss-PMQII spectrophotometer with flame attachment. Samples of the ethylenediamine solutions were diluted with water to five times their volume and analyzed directly. The presence of the organic solvent had the advantage of enhancing the sensitivity of the measurements.

RESULTS AND DISCUSSION

Swelling

The absorption of ethylenediamine by the exchangers is rather slow. The various samples took up to about 2 days to reach maximum swelling, whereas with water not

FIG. 2. Same data as in Fig. 1, but swelling expressed in moles of solvent (E_s) absorbed per 1 equivalent of resin (E_r).

more than a few minutes are usually required. Figure 1 shows the results obtained with both the lithium and the tetrabutylammonium forms in water, methanol, and ethylenediamine respectively. Swelling is expressed as is usual, i.e. in ml of swollen resin obtained from 1 g of dry resin. The variation of swelling as a function of the degree of cross-linking (% DVB) of the polymer is shown. As to be expected swelling is greatest in water and smallest in ethylenediamine. The tetrabutylammonium form seems to swell less than the lithium form in water and methanol, whereas in ethylenediamine the former tends to be more swollen. However, this presentation of the data does not take into account the equivalent weights of the two resin forms which are rather different, namely 190–200 for the lithium form and 430–440 for the other form. It would, therefore, appear more meaningful to express the swelling in moles of solvent absorbed by 1 mole of

For personal use only.

exchanger as is shown in Fig. 2. This "equivalent swelling" appears to be practically the same for both cation forms in water, whereas in the organic solvents the tetrabutylammonium form swells more strongly. This seems to indicate that the cation tetrabutylammonium, having a pronounced organic character, is more solvated in the organic solvents than is lithium. For the more cross-linked resins X4 and X8, however, this difference between the two cationic forms is rather small. An explanation for this was found in the fact that these more cross-linked resins cannot be converted completely into the tetrabutylammonium form. Table I gives the results obtained when the lithium forms were treated with 1 *M* solutions of tetrabutylammonium bromide in either water or ethylenediamine. In water only the little cross-linked resins are able to exchange all the lithium ions, while this capacity is reduced to 61% when cross-linking reaches a degree of X8. In ethylenediamine, where swelling is less than in water, even the slightly cross-linked resins cannot exchange completely, and the more cross-linked ones do not exchange at all. Therefore, it must be said that the swelling data given in Figs. 1 and 2 for the tetrabutylammonium forms of the resins X4 and X8 have been obtained with mixed resins containing a minor equivalent portion of lithium form. This limited capacity for large ions, which has already been reported for other tetraalkylammonium ions (3), seems to support the opinion that in commercial exchange resins there is considerable variation in pore size.

TABLE I

Exchange capacities of the exchangers Dowex 50W for the tetrabutylammonium ion $(C_4H_9)_4N^+$

Degree of cross-linking	Exchange capacity in % of total capacity	
% divinylbenzene	In water	In ethylenediamine
1	100	86
2	100	77
4	88	0
8	61	0

Some interesting observations were made of the effect solutes have on the swelling in ethylenediamine. When an exchange resin is swollen in pure water, swelling decreases upon contact with an electrolyte solution, whereas in ethylenediamine the reverse takes place. Table II shows the changes of swelling obtained with Dowex 50W-X2 both in water and ethylenediamine, when the pure solvent is changed to a 0.5 *M* solution of the bromide of the exchanger's counterion. It can be seen that the increase of swelling in ethylenediamine is as pronounced as the decrease in water. The explanation of this paradox lies probably in the fact that these electrolytes are present mainly as associated ion-pairs because of the ethylenediamine's low polarity. Schaap and co-workers (4) have determined the ion-pair association constants in ethylenediamine of several halides of alkali metals and of tetrabutylammonium, and all were found to have values between 1.5 and 6×10^3. That means that in the present experiments the degree of dissociation of the bromides of lithium and tetrabutylammonium could not be more than 2–3%. In water the penetration of nonexchanging strong electrolytes into the resin phase is subject to a Donnan equilibrium, which allows but a small fraction of the electrolytes to enter the resin. Weak electrolytes, however, behave more or less like nonelectrolytes and, therefore, are absorbed in considerable amounts. This has been reported for phenol, and a number of carboxylic acids and organic bases (5, 6), and could be explained, in part at least,

TABLE II

Influence of solutes on the swelling of the cation exchanger Dowex 50W-X2 in water and ethylenediamine

Cation form of exchanger	Solute	Solute concn. (*M*)	Change of volume %	
			In water	In ethylenediamine
Li	LiBr	0.5	−19.6	+17.6
$(C_4H_9)_4N$	$(C_4H_9)_4NBr$	0.5	−12.0	+10.4
H	CH_3COOH	0.5	+0.7	
H	CH_3COOH	1.0	+2.1	
H	C_6H_5OH	0.5	+1.7	
H	C_6H_5OH	1.0	+4.2	

by the common-ion effect of the resin's counterion, which will cause the weak electrolyte to be virtually undissociated in the resin phase. Such free absorption of the solute could be, if not the exclusive cause, at least a factor contributing to the increase of swelling in ethylenediamine. If this were so, then weak electrolytes in water should likewise cause the swelling to increase. As can be seen from Table II, this is indeed the case with acetic acid and phenol, each inducing a slight increase in swelling of the resin's hydrogen form.

Ion Exchange Applications

Since it was found that the exchange capacity of medium cross-linked resins for larger ions in ethylenediamine is limited, all reactions were carried out with the slightly cross-linked resin Dowex 50W-X2. Table III summarizes the reactions attempted of which only Nos. 1 through 3 were successful. In each of these cases the alkali cation originally present in the solution was removed quantitatively and could subsequently be eluted from the resin by drying and washing with 3 *M* hydrochloric acid. The solutions resulting from these exchanges were used to titrate potentiometrically ethylenediamine solutions of phenol as described by one of us earlier (7). In all three cases the titration curves were similar to those described in that report for a titrant solution of tetrabutylammonium ethoxide. No attempt was made to isolate these rather delicate reaction products, which are easily decomposed by both humidity and atmospheric carbonic acid. The flame photometric analyses of both the solution and the resin together with the potentiometrical titration were taken as satisfactory proof that the cations had been exchanged without any other chemical reaction. The three experiments lead thus to pure solutions of tetrabutylammonium ethoxide, potassium 2-aminoethoxide, and tetrabutylammonium 2-aminoethoxide respectively. None of these solutions or solutes seem to have been prepared hitherto, and earlier attempts by us at their preparation by other methods had failed. Only the preparation of tetrabutylammonium ethoxide by a precipitation reaction in a mixed benzene–ethylenediamine medium has been reported (7), but this method does not give pure solutions since the precipitation reaction is not quantitative.

The preparation of the potassium 2-aminoethylamide solution according to reaction

4 in Table III did not succeed, and that of the analogous sodium amide was only partly successful. When 50 ml of a 0.1 *M* solution of lithium 2-aminoethylamide in ethylenediamine (5 meq) was percolated through 29.2 meq of Dowex 50W-X2 in the potassium form at a rate of 0.3 ml/min, 45% of the lithium (2.25 meq) disappeared from the liquid phase without being replaced by potassium. However, this lithium fraction was recovered completely together with all the potassium from the dried resin by eluting it with 3 *M* aqueous hydrochloric acid. This seems to indicate that the exchange between lithium and potassium took place, but that the reaction product potassium 2-aminoethylamide is insoluble in ethylenediamine and precipitated in the resin. This precipitate will block certain exchange sites and thus prevent the reaction from becoming complete.

Since lithium 2-aminoethylamide is quite soluble in ethylenediamine, it seemed probable that the corresponding sodium amide should have an intermediate solubility. When 20 ml of a 0.258 *M* solution of the lithium amide (5.16 meq) was passed through 28.8 meq of the exchanger's sodium form at 0.1 ml/min, 65% of the lithium (3.36 meq) left the solution, whereas 16% of the total amount of lithium (0.83 meq) was replaced by sodium. In another experiment, where 90 ml of a 0.0272 *M* solution of the lithium amide (2.45 meq) was passed through the same column in the sodium form, 93.5% of the lithium (2.29 meq) left the solution, but only 4.5% of the total amount of lithium (0.110 meq) was replaced by sodium. In both these experiments the balance of both lithium and sodium was recovered from the dried resin by elution with hydrochloric acid. It was concluded that the sodium 2-aminoethylamide must be somewhat soluble in ethylenediamine, but no further attempt was made to determine its solubility. No explanation can be offered for the apparent difference in solubility in the two experiments. That the exchange between the three alkali metals potassium, sodium, and lithium is in principle possible was established by passing 0.05 *M* ethylenediamine solutions of sodium bromide through either the potassium or the lithium form of the exchanger and in both instances complete exchange was obtained. Here all three alkali bromides involved are sufficiently soluble in ethylenediamine.

REACTIONS OF THE ETHYL RADICAL

VI. ADDITION TO CONJUGATED DIENES

A. C. R. BROWN[1] AND D. G. L. JAMES

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia

Received December 7, 1964

ABSTRACT

Arrhenius parameters have been measured for the addition of the ethyl radical to the conjugated diene system in three representative molecular environments. Significant differences are found among the values of the energy of activation for addition, which are: 4.5 ± 0.2 kcal/mole for 2,3-dimethylbutadiene-1,3, 5.2 ± 0.3 kcal/mole for cyclohexadiene-1,3, and 6.6 ± 0.3 kcal/mole for 2,5-dimethylhexadiene-2,4. The increase in the energy of activation in this series is paralleled by an increase in the degree of shielding of the terminal carbon atoms of the conjugated system by substituent groups. The energy of activation for metathesis is significantly lower for cyclohexadiene-1,3 (5.4 ± 0.5 kcal/mole) than for 2,5-dimethylhexadiene-2,4 (7.6 ± 0.4 kcal/mole); the activated hydrogen atoms of the former are all secondary, whereas those of the latter are all primary. The ratio of the rate constants for addition and metathesis at 60° indicate that the radical homopolymerization of cyclohexadiene-1,3 and 2,5-dimethylhexadiene-2,4 should be subject to extensive degradative chain transfer.

INTRODUCTION

The reactivity of the conjugated diene system towards the addition of free radicals is likely to be profoundly influenced by its molecular environment. The aim of this investigation is to find a pattern of reactivity among substituted butadienes by measuring the Arrhenius parameters for the addition of the ethyl radical in the gas phase. These substituted butadienes were chosen so that the reactivity of the conjugated system could be studied in three characteristic molecular environments: extending the full length of the carbon chain (2,3-dimethylbutadiene-1,3); doubly substituted at each end by methyl groups (2,5-dimethylhexadiene-2,4); and as part of a six-membered carbon ring (cyclohexadiene-1,3).

The relative methyl affinity is the only systematic measure of reactivity towards the addition of free radicals which has included all three butadienes (1, 2). At 65 °C the methyl affinity is 2 230 for 2,3-dimethylbutadiene-1,3, 21.3 for 2,5-dimethylhexadiene-2,4, and 665 for cyclohexadiene-1,3. The reactivity of these dienes has also been demonstrated less comprehensively in relation to the addition of trichloromethyl (3) and thiyl (4, 5) radicals, and in homopolymerization (6–9) and copolymerization (10, 11, 12).

The high reactivity of 2,3-dimethylbutadiene-1,3 and cyclohexadiene-1,3 in radical copolymerization is conveyed by the Q values of the Alfrey–Price parameters, which are $Q = 5.86$ and $e = -1.81$ for 2,3-dimethylbutadiene-1,3 (13) and $Q = 1.76$ and $e = -1.18$ for cyclohexadiene-1,3 (12); the electron-donating nature of each monomer is evident from the negative values of e. The radical homopolymerization of 2,3-dimethylbutadiene-1,3 has been reviewed recently by Morton and Gibbs, who have measured the propagation constant, $k_p = 8.9 \times 10^7 \exp(-9\,000/RT)$ l mole^{-1} s^{-1} (6); the radical homopolymerization of cyclohexadiene-1,3 is kinetically complex (7, 8), and the propagation constant has not been measured (9). The structure of 2,5-dimethylhexadiene-2,4 is sterically unfavorable to the propagation reaction of radical polymerization, but its reactivity towards the methyl and thiyl radicals indicates that it should be included in this study as an example of complete substitution at the reactive sites for addition.

EXPERIMENTAL PROCEDURE

Ethyl radicals were generated in the presence of each olefin by the illumination of a gaseous mixture of diethyl ketone and the olefin with 3 130 Å radiation. To simplify the kinetics, the reaction conditions were controlled so that the ethyl radical was always present in great excess over all other radicals.

The apparatus and general method have been described previously (14). The reagents were of the purest grade commonly obtainable commercially; each was further purified by the Beckman Megachrom preparative gas chromatograph, and the purity of the selected fraction was then examined on the Perkin-Elmer Vapour Fractometer, model 154C. The only evidence of residual impurities was found for cyclohexadiene-1,3, which still contained 1% of benzene. Benzene was found to be unreactive towards the ethyl radical, but its presence among the reactants prevented the direct measurement of the rate of formation of benzene in the cyclohexadiene-1,3 system. A procedure which was devised to estimate this rate indirectly is described in the next section.

The analysis of the products followed the pattern of separation and measurement of CO, $C_2H_4 + C_2H_6$, and C_4H_{10} fractions. The purity of the fractions was established, and the composition of the C_2 fraction determined, by means of the Perkin-Elmer gas chromatograph.

THE KINETIC ANALYSIS

Under the experimental conditions of this investigation, the photolysis of diethyl ketone conforms to the following simple mechanism (14–19).

[1] $$CH_3CH_2COCH_2CH_3 + h\nu \rightarrow 2CH_3CH_2\cdot + CO$$

[2] $$2CH_3CH_2\cdot \rightarrow C_4H_{10}$$

[3] $$2CH_3CH_2\cdot \rightarrow C_2H_6 + C_2H_4$$

[4] $$CH_3CH_2\cdot + CH_3CH_2COCH_2CH_3 \rightarrow CH_3CH_3 + CH_3\dot{C}HCOCH_2CH_3$$

[5] $$CH_3CH_2\cdot + CH_3\dot{C}HCOCH_2CH_3 \rightarrow CH_3CH(CH_2CH_3)COCH_2CH_3$$

If a gaseous mixture of diethyl ketone and an olefin is illuminated, the ethyl radicals formed will also react with the olefin, and both addition and metathesis should be observed. If the olefin is cyclohexadiene-1,3 and the ethyl radical is present in great excess over all other radicals, then the following additional reactions may be expected.

[6] $CH_3CH_2^{\bullet}$ + → CH_3CH_3 +

[6c] $CH_3CH_2^{\bullet}$ + → ( and )

(I) (II)

[6d] → CH_3CH_3 +

[6e] → $CH_2{=}CH_2$ + (and)

[7] $CH_3CH_2^{\bullet}$ + → 
[7c] $CH_3CH_2^{\bullet}$ + → ( and )

(VI) (VII)

[7d] $\longrightarrow CH_3CH_3 +$  (I) and (III)

[7e] $\longrightarrow CH_2{=}CH_2 +$  (IV) and (V)

The cyclohexadienyl radical is formed by reaction [6], and the reactions of this radical with the ethyl radical are known from a study of the photolysis of a gaseous mixture of diethyl ketone and cyclohexadiene-1,4 (14). It was found that $k_{6d}/k_{6c} = 0.38 \pm 0.03$, and $k_{6e}/k_{6c} = 0$. The latter value is perhaps surprising, but it has been indirectly confirmed by the study of the photolysis of a gaseous mixture of diisopropyl ketone and cyclohexadiene-1,4; the value of the corresponding ratio was also found to be zero (20). Reaction [6*e*] should therefore be negligible in the present system, and this is confirmed by the absence of cyclohexadiene-1,4 from the products, especially as it could have been detected in trace quantity. We shall assume that the disproportionation reactions [7*d*] and [7*e*] can be neglected, so that the adduct radical, $C_8H_{13}^{\cdot}$, is consumed solely by combination with the ethyl radical. A parallel but more detailed study of the interaction of the isopropyl radical with cyclohexadiene-1,3, in which disproportionation reactions should be relatively more important, has shown that the neglect of the corresponding disproportionation reactions of the adduct radical has a negligible effect upon the values of the rate constants and the Arrhenius parameters (21). The significant reactions for the cyclohexadiene-1,3 system are therefore: [1–5, 6, 6*c*, 6*d*, 7, and 7*c*]. Ethane is formed only in reactions [3, 4, 6, and 6*d*], and therefore the rate constants may be calculated from the equations:

$$\frac{k_6}{k_2^{1/2}} = \frac{R(C_2H_6) - R(C_2H_4) - R(C_6H_6)}{[B]R(C_4H_{10})^{1/2}} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}}$$

$$= \left\{\frac{R(C_2H_6) - R(C_2H_4)}{[B]R(C_4H_{10})^{1/2}} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}}\right\} \Big/ \left(1 + \frac{k_{6d}}{k_{6c} + k_{6d}}\right) \qquad [I]$$

$$\frac{k_7}{k_2^{1/2}} = \frac{R(CO) + R(C_6H_6) - R(C_2H_6) - R(C_4H_{10})}{[B]R(C_4H_{10})^{1/2}}$$

$$= \left\{\frac{R(CO) - R(C_2H_6) - R(C_4H_{10})}{[B]R(C_4H_{10})^{1/2}}\right\} + \frac{k_{6d}}{k_{6c} + k_{6d}}\frac{k_6}{k_2^{1/2}}, \qquad [II]$$

where $R(Z)$ is the rate of formation of product Z, [D] and [B] are the concentrations of diethyl ketone and the olefin, respectively, and $k_4/k_2^{1/2}$ is known from previous work. Since $k_{6d}/k_{6c} = 0.38 \pm 0.03$ (14), $k_{6d}/(k_{6c} + k_{6d}) = 0.275$, and this value was used uniformly in equations [I] and [II]. The mechanisms proposed for the interaction of the ethyl radical with the other olefins of this study parallel the mechanism given above for cyclohexadiene-1,3 with the single difference that reaction [6*d*] is considered to be negligible for these other olefins. The validity of neglecting reaction [6*d*] has been discussed previously (14) with special reference to cyclooctadiene-1,5; it was concluded that reaction [6*d*] could be neglected except where it was particularly favored energetically by the formation of a highly stabilized product, as in the formation of benzene from the cyclohexadienyl radical in the cyclohexadiene systems. The significant reactions for the 2,3-dimethylbutadiene-1,3, 2,5-dimethylhexadiene-2,4, and octene-1 systems are therefore

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[1–5, 6, 6*c*, 7, and 7*c*]. Equations I and II may be used to calculate the rate constants by placing $k_{6d} = 0$, and the expression in curly brackets is then obtained in each case.

Rate constants for both addition and metathesis were obtained for each of the four olefins except 2,3-dimethylbutadiene-1,3; addition to this diene was too rapid to allow measurement of the rate of metathesis.

In the mechanism proposed for the reactions of the ethyl radical with the three dienes we have assumed that the ethyl radical will add to either of the terminal carbon atoms of the conjugated system. This assumption does not affect the validity of the kinetic analysis, but it does form the basis of our discussion of the influence of structure upon reactivity, and so we shall present below the evidence for addition at the terminal atoms of the conjugated systems in closely related reactions.

The mechanism of the addition of free radicals to substituted butadiene systems has been clarified recently by the analysis of the products of addition of bromotrichloromethane (3) and certain thiols (4, 5) to 2,3-dimethylbutadiene-1,3 and to 2,5-dimethylhexadiene-2,4.

The addition of bromotrichloromethane to 2,3-dimethylbutadiene-1,3 yields exclusively an equimolar adduct by a 1,4 addition process (3); exactly parallel results were obtained for the addition of diethyldithiophosphoric acid (5). The 1,4 addition patterns indicate initial attack of a trichloromethyl (or thiyl) radical at either terminal carbon atom (which we shall call $C_{(1)}$) of the conjugated chain; this point of addition yields the most stable adduct radical and is therefore favored energetically. The adduct radical then abstracts a bromine (or hydrogen) atom from a molecule of the addendum at either the $C_{(2)}$ or $C_{(4)}$ atom of the conjugated chain. Attachment to the primary $C_{(4)}$ atom is energetically much more favorable than attachment to the tertiary $C_{(2)}$ atom, and accordingly an exclusively 1,4 pattern of addition emerges.

Successive substitution of methyl groups at the terminal atoms of the conjugated diene chain increasingly favors the 1,2 pattern of addition over the 1,4. The single terminal methyl group of piperylene raises the proportion of the 1,2 adduct of diethyl dithiophosphoric acid to 50%, and the four terminal methyl groups of 2,5-dimethylhexadiene-2,4 raise the proportion of the 1,2 adduct to 85%, the remainder being the 1,4 adduct (5). A 1,2 pattern of addition to 2,5-dimethylhexadiene-2,4 is consistent with a mechanism of initial radical attack at the terminal atom $C_{(1)}$ of the conjugated system, and is supported by the energetics of the two successive steps of addition. Initial attack at $C_{(1)}$ is favored because it forms the more stable allylic radical. The $C_{(2)}$ atom of the resultant adduct is then secondary, whereas the $C_{(4)}$ atom is tertiary, so that hydrogen atom transfer to the $C_{(2)}$ site is favored energetically, causing the 1,2 pattern of addition to predominate. However, if the initial adduct radical were to engage in a bond-forming reaction of negligible activation energy, then the difference in the strengths of the bonds formed at the $C_{(2)}$ and $C_{(4)}$ atoms would be irrelevant to the kinetics; and if an exclusively 1,4 addition mechanism emerged in such a system, then the theory that the initial attack is at the terminal atom of the conjugated system would be vindicated. The low temperature co-oxidation of aromatic thiols and 2,5-dimethylhexadiene-2,4 by molecular oxygen conforms to a 1,4 pattern of addition (4). Crystalline 2,5-dimethyl-2-arylmercapto-hex-3-en-5-yl hydroperoxides were isolated; these products clearly indicate an initial addition of the thiyl radical at $C_{(1)}$, followed by addition of the oxygen molecule at $C_{(4)}$.

On the basis of the evidence given above we conclude that the addition of the ethyl radical to 2,3-dimethylbutadiene-1,3, 2,5-dimethylhexadiene-2,4, and cyclohexadiene-1,3 will occur at one of the terminal atoms of the conjugated system.

*The quantities B and C are the coefficients of the straight lines $13 + \log k_r/k_2^{1/2} = C - 10^3B/T$ fitted to the experimental results (r represents 7 for addition and 6 for metathesis). The units of k are cm^3 $molecule^{-1}$ s^{-1}; the limits of error are calculated at the 5% probability level.

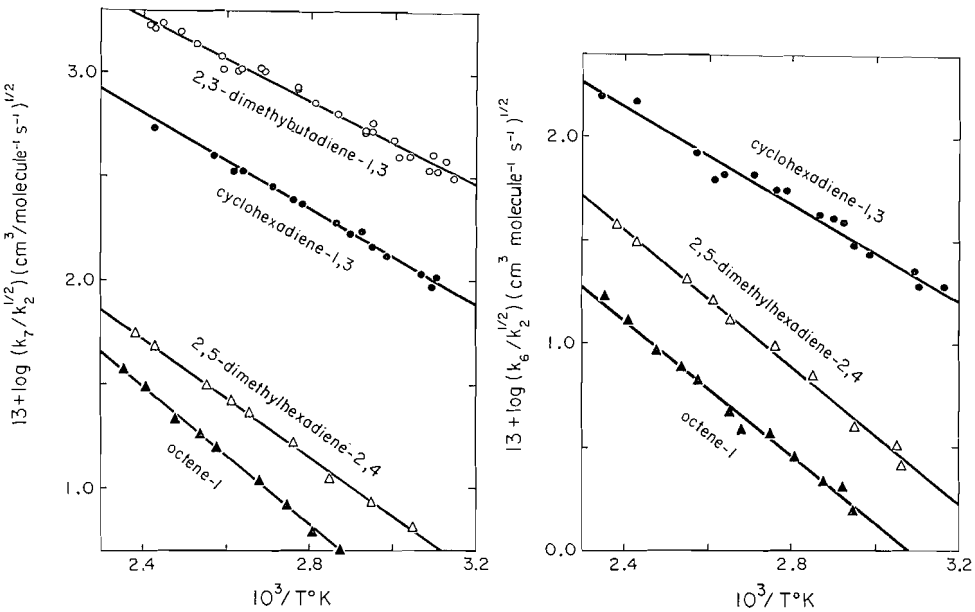

FIG. 1. Addition of the ethyl radical. Values for $E_7 - \frac{1}{2}E_2$ are: 2,3-dimethylbutadiene-1,3 = 4.5 ± 0.2 kcal/mole; cyclohexadiene-1,3 = 5.2 ± 0.3 kcal/mole; 2,5-dimethylhexadiene-2,4 = 6.6 ± 0.3 kcal/mole; octene-1 = 7.6 ± 0.2 kcal/mole.

FIG. 2. Metathesis with the ethyl radical. Values for $E_6 - \frac{1}{2}E_2$ are: cyclohexadiene-1,3 = 5.4 ± 0.5 kcal/mole; 2,5-dimethylhexadiene-2,4 = 7.6 ± 0.4 kcal/mole; octene-1 = 7.5 ± 0.5 kcal/mole.

RESULTS AND DISCUSSION

I. The Addition Reaction

The order of reactivity of the four hydrocarbons towards the addition of the ethyl radical is clear from the results of Table I*a* and Fig. 1:

2,3-dimethylbutadiene-1,3 > cyclohexadiene-1,3 > 2,5-dimethylhexadiene-2,4 > octene-1.

Moreover, each member of the series is significantly more reactive than its successor, whether the criterion of reactivity is the energy of activation ($E_7 - \frac{1}{2}E_2$) or the rate constant (given in the form $13 + \log k_7/k_2^{1/2}$ in Table I*a*). The dienes thus show the same order of reactivity towards the ethyl radical as towards the addition of the methyl radical at 65 °C (1, 2). Conjugation raises the reactivity of each of the dienes significantly above that of octene-1, although the terminal vinyl group of the latter is much less shielded from attack than the reactive position of 2,5-dimethylhexadiene-2,4. The terminal carbon atom of a conjugated diene system is normally the favored position for addition, as the allylic adduct is then the radical of lowest possible energy. The reactivity of the dienes decreases as the shielding of the terminal carbon atom of the conjugated system increases from two hydrogen atoms through a methylene group to two methyl groups. The effect of an increase in shielding upon the kinetics of the addition reaction is expressed mainly by an increase in the value of the energy of activation, but, furthermore, the pre-exponential factor for 2,5-dimethylhexadiene-2,4 is significantly lower than for the other dienes. The carbon atoms of the delocalized systems of cyclohexadiene-1,3 and of its adduct, the ethylcyclohexenyl radical, form part of a six-membered ring. It is probable that these carbon atoms are either coplanar or able to become coplanar very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

easily, and therefore that the energy of activation for addition to cyclohexadiene-1,3 does not include an appreciable contribution from the release of strain in the carbon ring.

Butadiene-1,3 and isoprene were not included in this investigation, but their reactivities towards the addition of the ethyl radical may be estimated from the results obtained for 2,3-dimethylbutadiene-1,3. Substituent methyl groups at the $C_{(2)}$ and $C_{(3)}$ atoms of the conjugated system increase the electron density at the terminal carbon atoms (22), but this appears to have little effect upon the reactivity of the diene system towards hydrocarbon radical addition. Thus, butadiene-1,3, isoprene, and 2,3-dimethylbutadiene-1,3 possess very similar methyl affinities (2 015 ± 30, 2 090 ± 50, and 2 230 ± 70, respectively, at 65 °C (1)), propagation rate constants (100, 50, and 120 l mole^{-1} s^{-1}, respectively, at 60 °C (6)) and propagation activation energies (9.3, 9.8, and 9 kcal/mole, respectively (6)). We conclude that the reactivity of these three butadienes towards the addition of the ethyl radical should be similar in magnitude and should stand in the same order as the methyl affinity.

The energy of activation for the addition of the ethyl radical to 2,3-dimethylbutadiene-1,3 lies over 4 kcal/mole below the energy of activation for the propagation of the radical polymerization of this diene. Such a difference is consistent with the difference in reactivity of an *n*-alkyl and a substituted allyl radical towards a common substrate.

II. The Metathetical Reaction

The order of reactivity towards metathesis with the ethyl radical is clear from the rate constants given in Table I*b* and Fig. 2:

cyclohexadiene-1,3 > 2,5-dimethylhexadiene-2,4 > octene-1.

Moreover, the value of $13 + \log k_6/k_2^{1/2}$ for each member of the series is significantly greater than for its successor. Cyclohexadiene-1,3 has a significantly lower energy of activation than the other olefins, but it alone possesses secondary hydrogen atoms activated by a conjugated system. The activation of the methylene groups is probably not reduced by the cyclic structure of cyclohexadiene-1,3, because the four carbon atoms of the conjugated system are not likely to deviate much from coplanarity and the carbon atoms of the cyclohexadienyl radical are known to be coplanar (23). The pre-exponential factor for 2,5-dimethylhexadiene-2,4 is significantly higher than for the other olefins when limits of error are assessed at the 10% probability level. If n denotes the number of equivalent hydrogen atoms, then $13 + \log (A_6/A_2^{1/2} n)$ takes the value of 4.4 for both 2,5-dimethylhexadiene-2,4 and for cyclohexadiene-1,3.

The Arrhenius parameters given in Table I for addition and metathesis between the ethyl radical and octene-1 differ from the previous values (24). In the earlier study the C_2 fraction was not analyzed, but $R(C_2H_4)$ was obtained from $R(C_4H_{10})$ by applying a uniform value of 0.136 for $R(C_2H_4)/R(C_4H_{10})$ to the results of each experiment. In the present study this ratio was found to be 0.137 ± 0.006, confirming the earlier value. Now if the rate constants are calculated from the values of $R(CO)$, $R(C_2)$, and $R(C_4H_{10})$ obtained in the present study using the original method, then the corresponding Arrhenius parameters are in agreement with the original values. However, if each rate constant is calculated using the known composition of the C_2 fraction, then the parameters of Table I are obtained. These revised parameters should be used in the comparative arguments of this discussion, as the Arrhenius parameters of all the other substrates have been calculated using the actual composition of the C_2 fraction of each experiment.

Chain transfer controls the course of the free radical homopolymerization of alkenes (25) and of cyclohexadiene-1,3 (7). The degree of polymerization is accordingly low;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

typical values are 7 for butene-1 at 130 °C and 20 000 p.s.i. (25), and 10–12 for cyclohexadiene-1,3 (9). Such behavior could be predicted from the values of the ratio k_7/k_6 listed for octene-1 and cyclohexadiene-1,3 in Table I*b*, assuming that this ratio gives a measure of k_p/k_t, the ratio of the rate constants for propagation and degradative chain transfer. On this basis we suggest that the radical homopolymerization of 2,5-dimethylhexadiene-2,4 should be subject to extensive chain transfer, and that as $E_7 - E_6 \approx 0$ for cyclohexadiene-1,3 and for octene-1, the corresponding degrees of polymerization should be relatively insensitive to temperature.

THE REACTIVITY OF THE CYCLIC POLYENES TOWARDS FREE RADICALS

III. ADDITION OF THE ETHYL RADICAL

A. C. R. BROWN[1] AND D. G. L. JAMES

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received December 7, 1964

ABSTRACT

Arrhenius parameters have been measured for the addition of the ethyl radical to cycloheptatriene-1,3,5 and to bicyclo[2.2.1]heptadiene-2,5 in the gas phase; the values for the energy of activation are distinct at 6.4 ± 0.2 and 7.0 ± 0.1 kcal/mole respectively. The addition of the ethyl radical to benzene, cyclohexadiene-1,4, and cyclooctadiene-1,5 proceeds too slowly to be detected. The significance of these results is considered in conjunction with those obtained previously for cyclohexadiene-1,3 and cyclooctatetraene, and the possibility of interpreting the reactivity of the cyclic polyenes in terms of molecular structure is discussed.

INTRODUCTION

A kinetic study of the addition of the ethyl radical to cycloheptatriene, bicycloheptadiene, cyclohexadiene-1,4, cyclooctadiene,1-5, and benzene completes our preliminary survey of the reactivity of the cyclic polyenes towards the ethyl radical. Arrhenius parameters could be measured for cycloheptatriene and bicycloheptadiene only, but, in conjunction with the corresponding results obtained previously for cyclohexadiene-1,3 (1) and cyclooctatetraene (2), they provide a quantitative basis for a discussion of the influence of structure upon the reactivity of the cyclic polyenes.

The most comprehensive study of the addition of a free radical to this group of compounds was limited to the measurement of the relative rate constant for the addition of the methyl radical in isooctane solution at 65 °C, but nevertheless a clear pattern of reactivity emerged (3). A kinetic study of the addition of the polyacrylonitrile radical to the four more reactive of the cyclic polyenes revealed that polar effects may dominate the pattern of reactivity for the addition of a highly electrophilic radical (4). Accordingly the polarographic half-wave potential has been measured for the cyclic polyenes wherever possible, and the results have been considered in relation to the enhanced reactivity of cyclooctatetraene towards the addition of the ethyl radical (2).

Under the experimental conditions of this investigation, the photolysis of diethyl ketone conforms to the following simple mechanism (2).

[1] $$CH_3CH_2COCH_2CH_3 + h\nu \rightarrow 2CH_3CH_2\cdot + CO$$

[2] $$2CH_3CH_2\cdot \rightarrow C_4H_{10}$$

[3] $$2CH_3CH_2\cdot \rightarrow C_2H_6 + C_2H_4$$

[4] $$CH_3CH_2\cdot + CH_3CH_2COCH_2CH_3 \rightarrow CH_3CH_3 + CH_3\dot{C}HCOCH_2CH_3$$

[5] $$CH_3CH_2\cdot + CH_3\dot{C}HCOCH_2CH_3 \rightarrow CH_3CH(CH_2CH_3)COCH_2CH_3$$

If a gaseous mixture of diethyl ketone and cycloheptatriene is illuminated with 3 130 Å light, and the ethyl radical is present in great excess over all other radicals, then the following additional reactions should be significant.

[1]*Present address: Petrochemical and Polymer Laboratory, Imperial Chemical Industries, Ltd., Runcorn, Cheshire, England.*

[6] $CH_3CH_2\cdot + C_7H_8 \rightarrow CH_3CH_3 + C_7H_7\cdot$

[6c] $CH_3CH_2\cdot + C_7H_7\cdot \rightarrow C_7H_7CH_2CH_3$

[7] $CH_3CH_2\cdot + C_7H_8 \rightarrow C_9H_{13}\cdot$

[7c] $CH_3CH_2\cdot + C_9H_{13}\cdot \rightarrow C_{11}H_{18}$

A similar set of reactions may be expected to describe the photolysis of a gaseous mixture of diethyl ketone and bicycloheptadiene under similar conditions, with the reservation that reaction [6] proceeds too slowly to be detected. Rate constants may be calculated from the equations:

[I] $$\frac{k_6}{k_2^{1/2}} = \frac{R(C_2H_6) - R(C_2H_4)}{[B]R(C_4H_{10})^{1/2}} - \frac{[D]}{[B]}\frac{k_4}{k_2^{1/2}}$$

[II] $$\frac{k_7}{k_2^{1/2}} = \frac{R(CO) - R(C_2H_6) - R(C_4H_{10})}{[B]R(C_4H_{10})^{1/2}},$$

where $R(Z)$ is the rate of formation of the product Z, [D] and [B] are the concentrations of diethyl ketone and the olefin respectively, and $k_4/k_2^{1/2}$ is known from previous work (5) to be given by

$$k_4/k_2^{1/2} = 10^{(-7.5\pm0.1)} \exp(-7\,800 \pm 200)/RT \quad (\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1})^{1/2}.$$

EXPERIMENTAL PROCEDURE

Ethyl radicals were generated in the presence of each olefin by the illumination of a gaseous mixture of diethyl ketone and the olefin with 3 130 Å radiation. To ensure that the kinetics should conform to the simple mechanism given above, the reaction conditions were controlled so that the ethyl radical was always present in great excess over all other radicals. The apparatus and procedure for purification of the reactants, conduct of the photolysis, and analysis of the products are given in Part II of this series (2).

Polarographic half-wave potentials were measured for the reduction of certain unsaturated compounds at the dropping mercury electrode, using a Sargent model XXI d-c. polarograph. Solutions, 1.0 mM, were prepared in acetonitrile containing 0.1 M tetrabutylammonium iodide as a supporting electrolyte. The acetonitrile and the tetrabutyl ammonium iodide were respectively of the Spectro and the White Label grade of the Eastman Chemical Company, and the mercury was freshly distilled before use. Each solution was held at 25 °C in a thermostat and deoxygenated by bubbling purified nitrogen through it for 20 min before making a measurement. The half-wave potentials were measured relative to the potential of the mercury pool. In certain systems the supporting electrolyte began to decompose before the completion of the polarographic step. To obtain an approximate result, a blank run was made first, and then the reduction of a 5 mM solution was recorded on the same chart; the difference of the two traces was evaluated.

RESULTS AND DISCUSSION

The Arrhenius parameters and rate constants for the addition of the ethyl radical to cycloheptatriene and bicycloheptadiene are given in Table I and Fig. 1; corresponding results obtained for cyclohexadiene-1,3 (1), cyclooctatetraene (2), and octene-1 (1) are included for reference. The principal aim of this section is to enquire whether the kinetic results reveal any general pattern of reactivity among the cyclic polyenes. Figure 2 reveals a satisfactory correlation between the relative methyl affinity and the rate constant for the addition of the ethyl radical; the scatter about the reference line of unit gradient is small. In a few cases the comparison has been made between the values for two closely related substrates; details are given in Table II.

In addition to the five olefins mentioned above, cyclohexadiene-1,4, cyclooctadiene-1,5, and benzene were examined but were found to be unreactive towards the addition of the ethyl radical. The monocyclic polyenes will be considered as a group first; the special problem of the reactivity of bicycloheptadiene then forms a natural sequel.

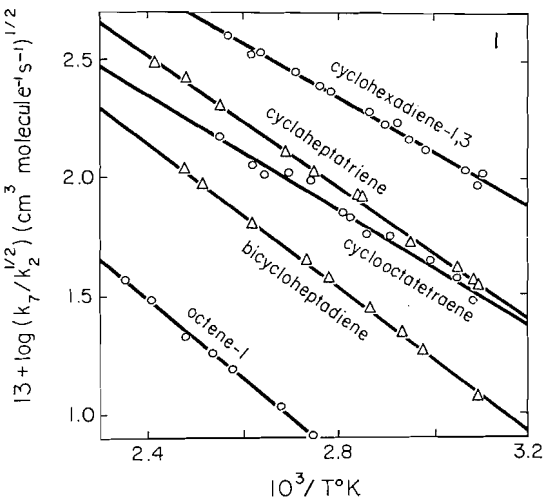

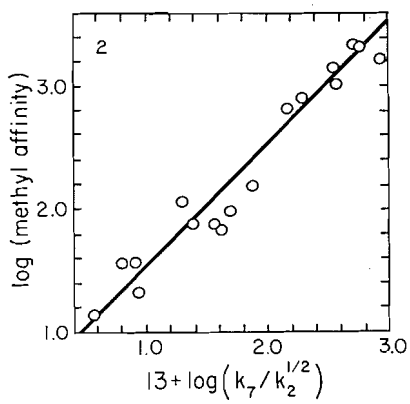

FIG. 1. Addition of the ethyl radical to cyclic polyenes. Values of $E_7 - \frac{1}{2}E_2$ are: cyclohexadiene-1,3, 5.2 ± 0.3 kcal/mole; cycloheptatriene, 6.4 ± 0.2 kcal/mole; cyclooctatetraene, 5.6 ± 0.6 kcal/mole; bicycloheptadiene, 7.0 ± 0.1 kcal/mole; octene-1, 7.6 ± 0.2 kcal/mole.

FIG. 2. Correlation of the rate constant for addition of the ethyl radical in the gas phase with the methyl affinity in solution, each at 65 °C. The values of the rate constants are listed in Table II. The reference line has unit gradient.

THE MONOCYCLIC POLYENES

Cyclohexadiene-1,3 is significantly more reactive than cycloheptatriene-1,3,5 with respect to both the energy of activation and the rate constant at 100 °C. The diene system of cyclohexadiene-1,3 is probably almost coplanar and fully delocalized. The triene system of cycloheptatriene is characterized by a dihedral angle of 40.5°, but even so a quite high degree of delocalization is indicated by the particularly short C—C single bonds of the conjugated system (13). Reactivity should therefore be high for both cycloheptatriene and cyclohexadiene-1,3, but higher for the latter, as it is more completely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

delocalized. Both molecules should show reactivity toward addition at the two terminal atoms of the conjugated system; furthermore cycloheptatriene may also be reactive at the medial atoms $C_{(3)}$ and $C_{(4)}$, as the adduct should then possess allylic stability. This is suggested by the values of the pre-exponential factor, which is twice as great for cycloheptatriene as for cyclohexadiene-1,3, and is supported by a study of the free radical arylation of cycloheptatriene, where medial addition appears to be important (14). The latter evidence should be treated with reserve, however, as an intramolecular 1,5-transannular hydrogen shift occurs readily in cycloheptatriene and its monophenyl derivatives between 100 and 140 °C, accompanied by a complementary migration of double bonds (15, 16).

The rate constants for addition to cycloheptatriene and cyclooctatetraene do not differ greatly over the temperature range of our experiments, but the energies of activation are significantly different at 6.37 ± 0.22 and 5.56 ± 0.58 kcal/mole respectively. These results should be considered in conjunction with Trætteberg's critical assessment (13) of the significance of the molecular parameters of the conjugated systems of butadiene-1,3, cycloheptatriene, and cyclooctatetraene obtained by electron diffraction studies in the gas phase. The relevant values are listed in order for butadiene-1,3, cycloheptatriene, and cyclooctatetraene:

single bond length, 1.483, 1.446, and 1.462 Å;
double bond length, 1.337, 1.356, and 1.334 Å;
dihedral angle, 0, 40.5, and 42.3°.

Comparison of the bond distances indicates a higher degree of delocalization in the cycloheptatriene molecule than in cyclooctatetraene molecule. On the other hand, the π-electron system of the cyclooctatetraene molecule extends around the entire molecule, whereas the π-electron system of the cycloheptatriene molecule is interrupted by the methylene group, which separates the $C_{(1)}$ and $C_{(6)}$ atoms by 2.511 Å. Perhaps a mutual compensation of these two effects leads to the similarity in the rate constants for cycloheptatriene and cyclooctatetraene. However, anomalies in the values of the molecular parameters above compel us to regard the question as open until the bond lengths of butadiene-1,3 and cyclooctatetraene have been confirmed or revised (13).

The energy of activation for the addition of the ethyl radical to cyclooctatetraene is sufficiently low to suggest that an explanation should be sought in terms of those properties of cyclooctatetraene which set it apart from the other cyclic polyenes. Electron affinity is such a property, and relative values may be obtained from the polarographic half-wave reduction potentials. Half-wave potentials relative to the mercury pool were measured for cyclooctatetraene and a variety of other unsaturated compounds in acetonitrile, and are listed in Table III with some corresponding literature values obtained under comparable conditions (17–19). The electron affinity of cyclooctatetraene is remarkably high for a non-aromatic hydrocarbon, and high in comparison with acrylonitrile. The electron spin resonance spectrum of the cyclooctatetrenyl radical-anion indicates that the electron spin density is the same at each of the eight carbon atoms of the ring (20). A planar conformation for the radical anion is consistent with the spectral parameters, with the position of the disproportionation equilibrium, and with the rates of the electron exchange reactions (20). The radical-anion resembles the dianion in conformation, but differs from cyclooctatetraene, which has D_{2d} symmetry with dihedral angles of 42.3° (21). However, a study of the rapid interconversion of the single and double bonds of cyclooctatetraene indicates that the molecule must very frequently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

assume the planar configuration of the transition state, having a compression energy of 13.7 kcal/mole, a strain energy of 20–30 kcal/mole, and a resonance energy of 5–15 kcal/mole (22). A possibly more accurate estimate of 21 kcal/mole for the compression energy was obtained from the polarographic results (18, 20).

In view of the properties of cyclooctatetraene and its radical-anion, it seems reasonable to propose that the high electron affinity of cyclooctatetraene, in conjunction with the ionization potential of 8.78 V for the ethyl radical (23), may introduce an appreciable and favorable polar effect into the addition reaction, and so contribute to the lowering of the activation energy for addition to cyclooctatetraene.

Addition of the ethyl radical to cyclooctatetraene is likely to follow a 1,4 pattern yielding 1,4-diethylcyclooctatriene-2,5,7. Certainly the α-cyanoisopropyl radical adds to cyclooctatetraene in solution at 80° yielding 1,4-bis(α-cyanoisopropyl)cyclooctatriene-2,5,7 without producing coloration, ring contraction, or polymerization (24). The ethyl radical should react more rapidly than the α-cyanoisopropyl radical with cyclooctatetraene, as the latter is both less reactive and subject to an unfavorable polar effect; ring contraction is therefore unlikely to accompany the addition of the ethyl radical to cyclooctatetraene.

TABLE III

Polarographic half-wave potentials relative to the mercury pool, measured for 1.0 mM solutions in acetonitrile containing 0.1 M tetrabutylammonium iodide at 25 °C

Compound	Half-wave potential (volts)	
	This work	Literature value
Cyclooctatetraene	−1.28	−1.12 in 96% dioxane–water (19)

trans-Crotononitrile	−1.95	—
Anthracene	−1.47	−1.48 in acetonitrile (20)
2,3-Dimethylbutadiene-1,3	−2.35*	—
2,5-Dimethylhexadiene-2,4	−2.35*	—
Cyclohexadiene-1,3	No wave	—
Bicycloheptadiene	No wave	—

*This value is approximate as the reduction wave was incomplete.

The addition of the ethyl radical to benzene, to cyclohexadiene-1,4, and to cyclooctadiene-1,5 proceeded too slowly to be detected by the methods of this investigation. Indeed, benzene appears to be generally unreactive towards the ethyl radical in the gas phase, as neither metathesis nor addition could be detected. However, an estimate can be made, for each experiment performed, of the maximum value (U_7) that the addition rate constant could have while addition remained undetectable. As

$$M = [R(C_2H_6) + R(C_4H_{10})]/R(CO) = 1.005 \pm 0.005$$

for the photolysis of pure gaseous diethyl ketone, it seems reasonable to assume that the rate of addition should be detectable if:

$$\frac{k_7}{k_2^{1/2}} > \frac{0.02R(CO)}{[B]R(C_4H_{10})^{1/2}} = U_7.$$

Each value of U_7 was compared with the value (V_7) of $k_7/k_2^{1/2}$ for octene-1 at the same temperature, obtained from the observed results by interpolation. Table IV shows that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the ratio U_7/V_7 may be as low as 0.006. Similarly we can estimate the maximum value (U_6) that the metathetical rate constant could have while metathesis remained undetectable in a given experiment. It was assumed that metathesis should be detectable if:

$$\frac{k_6}{k_2^{1/2}} > \frac{[D]k_4}{10[B]k_2^{1/2}} = U_6.$$

Each value of U_6 was compared with the value (V_6) of $k_6/k_2^{1/2}$ for octene-1 at the same temperature, obtained from the observed results by interpolation. Table IV shows that the ratio U_6/V_6 may be as low as 0.02. The radical displacement reaction:

$$CH_3CH_2\cdot + C_6H_6 \rightarrow CH_3CH_2C_6H_5 + H\cdot$$

may be ruled out as no hydrogen was found among the products. We conclude that benzene is generally unreactive towards the ethyl radical in the gas phase.

The low reactivity of benzene towards alkyl radicals is evident from the behavior of a mixture of benzene and ethylene under conditions which lead to the radical polymerization of ethlyene. In the presence of di-*tert*-butyl peroxide at 20 000 p.s.i. and 130 °C, polymer was formed containing a small but definite amount of benzene, but kinetic analysis showed that the benzene was incorporated entirely by chain transfer. Copolymerization failed because the polyethylene radical would not add to benzene; as this is the most reactive of the polymer radicals, it is unlikely that conventional methods will bring about the free radical copolymerization of benzene (25).

TABLE IV

Comparison of the reactivity of benzene and octene-1 towards the ethyl radical with respect to both addition and metathesis

Temp. (°C)	Addition			Metathesis		
	$U_7(C_6H_6)$	$V_7(C_8H_{16})$	U_7/V_7	$U_6(C_6H_6)$	$V_6(C_8H_{16})$	U_6/V_6
101	0.101	10.8	0.0093	0.082	4.6	0.018
104	0.111	11.8	0.0094	0.080	5.0	0.016
113	0.103	14.9	0.0069	0.111	6.3	0.018
130	0.130	22.7	0.0057	0.202	9.6	0.021

*The quantities U_i and V_i represent respectively an estimated upper limit and an actual value of $k_i/k_2^{1/2}$ for the species named, where $i = 7$ for addition and $i = 6$ for metathesis.

Metathesis with the ethyl radical is rapid for both cyclohexadiene-1,4 and cyclooctadiene-1,5. This raises the accessible lower limit of U_7 to relatively high values, as only those conditions which give accurate values of $k_6/k_2^{1/2}$, and thereby confirm that the simple mechanism remains valid, may be used for the calculation of U_7. Accordingly the values of U_7 may be many times greater than the corresponding values of $k_7/k_2^{1/2}$. With bicycloheptadiene as the reference substance, the values of U_7/V_7 for cyclohexadiene-1,4 included 0.13, 0.19, 0.16, and 0.17 at 74, 95, 118, and 133 °C respectively; for cyclooctadiene-1,5 the values included 0.11, 0.08, 0.07, 0.12, and 0.08 at 77, 99, 100, 111, and 129 °C respectively. Clearly, both cyclohexadiene-1,4 and cyclooctadiene-1,5 are significantly less reactive than bicycloheptadiene towards the addition of the ethyl radical.

In contrast, the radicals $CCl_3\cdot$, $CH_3CO\cdot$ and $(CH_3)_3CNHCO\cdot$ all add readily to cyclooctadiene-1,5 in solution. The adduct radicals isomerize by cycloaddition to a bicyclic structure, and derivatives of bicyclo[3.3.0]octane have been isolated (26). It is perhaps significant that all the radicals which add readily to cyclooctadiene-1,5 are markedly electrophilic. Conjugation between the double bonds of cyclooctadiene-1,5 is most

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

unlikely, but the *cis–cis* conformation appears to promote intramolecular cycloaddition. The bicyclocopolymerization of sulfur dioxide with cyclooctadiene-1,5 is a related radical addition reaction; the copolymer repeating unit contains two molecules of sulfur dioxide per molecule of cyclooctadiene-1,5, and includes a 1,5 transannular sulfur dioxide bridge indicating intramolecular cyclization (27). Intramolecular cyclization also occurs in the radical copolymerization of sulfur dioxide with bicycloheptadiene, leading to nortricyclyl units in the polymer (28). Indeed, intramolecular cyclization commonly accompanies radical addition to bicycloheptadiene, and will be discussed in the next section.

BICYCLO[2.2.1]HEPTADIENE-2,5

Bicycloheptadiene is significantly more reactive than octene-1 towards the addition of the ethyl radical. Table I shows that bicycloheptadiene has a significantly greater value for the energy of activation, the pre-exponential factor, and the rate constant at 100 °C; if the last value is divided by 4 on statistical grounds, the quotient is still greater than the corresponding rate constant for octene-1. Bicycloheptadiene is also significantly more reactive than cyclohexene (29) and cyclohexadiene-1,4 towards the addition of the ethyl radical.

Each of these cyclic olefins possesses formally isolated double bonds which form part of a six-membered ring. The pre-eminence of bicycloheptadiene is therefore remarkable, and it is paralleled in other systems, notably in the addition of methyl (3), thiyl (30, 31), acyl, and trichloromethyl radicals (31), and in the easy radical homopolymerization (32, 33) and copolymerization (4, 28, 33, 34) of bicycloheptadiene. The bicyclic structure of bicycloheptadiene is strained, and maintains the carbon atoms of the double bonds in greater continuous proximity than is possible in the molecule of cyclohexadiene-1,4. These two aspects of the molecular geometry provide the basis for two interpretations of the high reactivity of bicycloheptadiene towards radical addition: release of I-strain on the formation of the new bond, or stabilization of the adduct by the assumption of a non-classical mesomeric homoallylic structure. The second explanation is made plausible by the formation of both norbornenyl and nortricyclyl aryl thioethers on the addition of thiocresol (30) or thiophenol (31) to bicycloheptadiene under free radical conditions. However, kinetic studies indicate that a non-classical radical adduct is unlikely to be the common precursor of the nortricyclyl and norbornenyl isomers. First, the ratio of the isomers was not independent of the concentration of the reactants, but decreased substantially as the thiol concentration was increased (30). This is consistent with the slow isomerization of the initial radical adduct from a norbornenyl structure to a nortricyclyl structure. Secondly, the ratio of the rate constants for addition to bicyclo[2.2.1]-heptadiene-2,5 and to bicyclo[2.2.1]heptene-2 is 2.3 for the methyl radical (3) and 2.06 for the trichloromethyl radical (31). Homoallylic stabilization of the adduct cannot occur with bicycloheptene, and therefore cannot be important with bicycloheptadiene, and the effect of the second double bond upon the reactivity must be almost entirely additive. The release of I-strain upon the formation of the adduct remains as a plausible common basis for the reactivity of both bicyclic olefins (3). The absence of homoconjugative stabilization in the molecule of bicycloheptadiene has been confirmed by wave-mechanical calculations based upon the models of Pariser and Parr, and of Longuet-Higgins. Each method predicted that the ground state is the classical Kekulé structure with a delocalization energy of zero, and also predicted the wavelength of maximum absorption in the ultraviolet almost quantitatively (35). Heats of hydrogenation also give no indication of homoconjugative stabilization in bicycloheptadiene (36).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

We conclude that the addition of the ethyl radical to bicycloheptadiene will form initially the 2-ethylbicyclohept-5-en-3-yl radical, which will slowly isomerize to the 2-ethyl-3-nortricycl-6-yl radical. At the relatively high ethyl radical concentrations used, the initial adduct is probably consumed by the addition of a second ethyl radical before much isomerization has occurred, so that the principal product should be 2,3-diethylbicycloheptene-5.

Metathesis between the ethyl radical and bicycloheptadiene proceeds too slowly to be detected in our systems (2); this is not unexpected, as metathesis is very slow with both the methyl radical (3) and the trichloromethyl radical (31). The ratio k_7/k_6 is therefore high for bicycloheptadiene, and this is consistent with the ready formation of high polymer from this monomer with little chain transfer under free radical conditions (32, 33).

CONCLUSION

The observed reactivity of each of the cyclic polyenes may be rationalized in terms of its molecular structure, and a broad pattern of reactivity then emerges which includes each of the polyenes studied. However, this interpretation has a piecemeal character, and it would be more satisfactory to relate the energy of activation for addition to some clearly defined, calculable parameter, such as the maximum free valence or the localization energy at the reaction center. The latter appears to be the more reliable measure of the reactivity of unsaturated compounds towards the addition of alkyl radicals and hydrogen atoms. The energy of activation for the addition of the hydrogen atom to a group of olefins shows an approximately linear correlation with the localization energy but not with the free valence (37). In this type of correlation the logarithm of the rate constant at a given temperature may replace the energy of activation if the compounds examined have a common value for the pre-exponential factor, and therefore the success of the correlation of the methyl affinity of terminal olefins with the localization energy is meaningful (38), but its general significance is diminished. Preliminary calculations (39) of localization energy and free valence for the unsaturated molecules of this and parallel investigations are currently being revised and extended, and the degree of success attained in each of the possible correlations will be discussed elsewhere (40).

LA PYROLYSE DU PROPANE ET DE L'ISOPENTANE

INFLUENCE DE TRACES D'OXYGÈNE ET EFFETS DE PAROIS[1]

M. NICLAUSE, R. MARTIN, A. COMBES ET M. DZIERZYNSKI
Laboratoire de Chimie Générale, Université de Nancy, Nancy, France

Reçu le 16 novembre 1964

ABSTRACT

Results obtained in an analytical and kinetic study of propane or isopentane pyrolysis, either pure or in presence of trace amounts of oxygen, are reported. It is shown particularly, that oxygen accelerates or inhibits the reaction, depending upon wall conditions; an interpretation of this dual effect is proposed. The fact that the pyrolysis of these hydrocarbons can be inhibited almost completely under given conditions proves that any molecular mechanism of decomposition is negligible as compared to the chain reaction.

INTRODUCTION

Il a été montré (1) que des traces d'oxygène accélèrent fortement la pyrolyse de divers hydrocarbures saturés, du moins dans un réacteur "vide" en pyrex dont le rapport surface/volume (en abrégé: rapport s/v) est voisin de 1 cm^{-1}. Mais, dans ces travaux préliminaires, on n'a pas recherché si les parois du réacteur jouent ou non un rôle dans cette réaction, ni si la présence de traces d'oxygène modifie la composition des produits de pyrolyse de l'hydrocarbure; l'influence cinétique des pressions initiales de l'oxygène et de l'hydrocarbure n'a pas été étudiée non plus.

Aussi avons-nous entrepris, en 1959, une nouvelle étude comparée de la décomposition thermique d'hydrocarbures saturés, purs ou additionnés de traces d'oxygène. Nos premières observations et conclusions (relatives au propane) ont été présentées entre 1961 et 1964 (2).

Nous présentons ci-dessous les principaux résultats obtenus dans les cas du propane et de l'isopentane.

Ces réactions ont été examinées à faible avancement (inférieur à 10%) à l'aide d'un montage statique à volume constant. Pour suivre la réaction en fonction du temps, nous avons employé la technique de la chromatographie gazeuse et la méthode manométrique (manomètre différentiel à phtalate de butyle). La pyrolyse du propane a été étudiée dans des réacteurs en pyrex ou en silice, celle de l'isopentane seulement dans des réacteurs en pyrex.

PYROLYSE DU PROPANE PUR OU DE L'ISOPENTANE PUR

(1) Nous avons tout d'abord analysé, par chromatographie gazeuse, les produits de pyrolyse de ces hydrocarbures à faible avancement.

Dans le cas du propane, la réaction peut être essentiellement représentée par les deux équations stoechiométriques suivantes:

$$C_3H_8 = H_2 + C_3H_6$$
$$C_3H_8 = CH_4 + C_2H_4$$

qui, à moins de 5% d'avancement, ont des importances sensiblement égales vers 550 °C (2).

[1]*Communication présentée au symposium: The kinetics of pyrolytic reactions, qui s'est tenu à l'Université d'Ottawa, Canada, 9–11 septembre 1964.*

A 480 °C, les produits principaux de pyrolyse de l'isopentane (P_0 = 25 mm Hg) sont les suivants: hydrogène, méthane, éthane, propane, éthylène, propylène, butènes (isobutène, butène-1, butènes-2 *cis* et *trans*) et isopentènes. La réaction peut être essentiellement représentée par les cinq équations stoechiométriques suivantes, dont les importances relatives, vers 2% d'avancement, sont indiquées entre parenthèses:

$$i\text{-}C_5H_{12} = CH_4 + \text{butènes} \quad (73.2\%)$$

$$i\text{-}C_5H_{12} = H_2 + C_2H_4 + C_3H_6 \quad (14.4\%)$$

$$i\text{-}C_5H_{12} = C_2H_6 + C_3H_6 \quad (9.8\%)$$

$$i\text{-}C_5H_{12} = C_3H_8 + C_2H_4 \quad (2\%)$$

$$i\text{-}C_5H_{12} = H_2 + \text{isopentènes}. \quad (0.6\%)$$

Ces résultats analytiques vers 2% d'avancement (et à 480 °C) sont notablement différents de ceux observés récemment par Bryce et Chrysochoos (3) à 42% d'avancement (et à 510 °C).

(2) Nous avons ensuite cherché à voir si les parois du réacteur ont, ou non, une influence sur la vitesse de pyrolyse du propane pur ou de l'isopentane pur.

Voevodsky (4) signalait que la vitesse initiale de pyrolyse du propane (T = 610 °C; P_0 = 25 mm Hg) diminue fortement lorsqu'on augmente le rapport s/v d'un réacteur en silice (Fig. 1, courbe 2). Au contraire, Laidler, Sagert et Wojciechowski (5) observaient seulement de légers effets des parois en silice ($530 < T$ (°C) < 620; $30 < P_0$ (mm Hg) < 600).

Nos résultats expérimentaux montrent que la vitesse initiale de pyrolyse du propane ($525 < T$ (°C) < 600; $10 < P_0$ (mm Hg) < 150) est pratiquement indépendante du rapport s/v ($0.7 < s/v$ (cm^{-1}) < 16) du réacteur en pyrex ou en silice (Fig. 1, courbe 1, et Fig. 2) (les vitesses initiales V_0 portées dans les figures ont subi la correction d'espace mort).

De plus, la vitesse est pratiquement la même, que les parois aient été ou non traitées à l'acide fluorhydrique ou recouvertes de KCl ou de PbO (2).

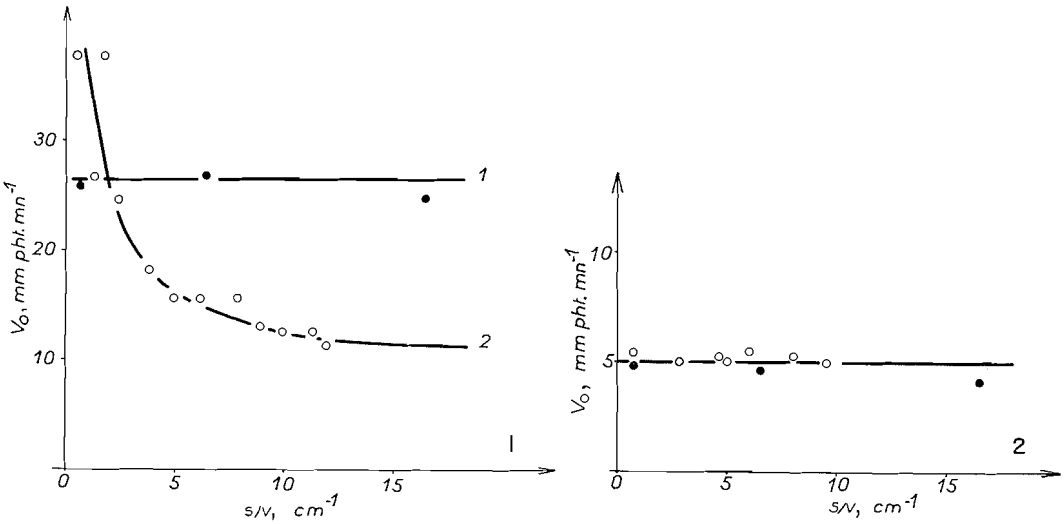

FIG. 1. Pyrolyse du propane (P_0 = 25 mm Hg), vitesse initiale en fonction du rapport surface/volume du réacteur en silice: (1) d'après nos expériences à 600 °C; (2) d'après Voevosdky (1959) à 610 °C.

FIG. 2. Pyrolyse du propane (P_0 = 25 mm Hg, T = 546 °C), vitesse initiale en fonction du rapport surface/volume du réacteur: ○ pyrex; ● silice.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

De même, la vitesse initiale de pyrolyse de l'isopentane dans des réacteurs en pyrex (T = 480 °C; P_0 = 25 mm Hg) est pratiquement indépendante du rapport s/v ($0.8 < s/v$ (cm^{-1}) < 12), contrairement à ce qui a été observé récemment par Bryce et Chrysochoos (3) dans des réacteurs en silice. Le dépôt de KCl ou de PbO sur les parois n'affecte pratiquement pas, non plus, la vitesse initiale de pyrolyse de l'isopentane (Fig. 3).

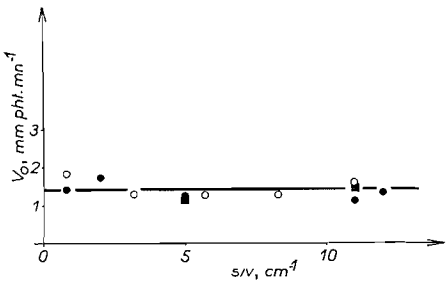

FIG. 3. Pyrolyse de l'isopentane (P_0 = 25 mm Hg, T = 480 °C), vitesse initiale en fonction du rapport surface/volume du réacteur: ○ pyrex; ■ pyrex traité à KCl; ● pyrex traité à PbO.

Il convient de noter que, dans certains cas, nous avons observé un léger abaissement de la vitesse de pyrolyse du propane ou de l'isopentane après introduction, dans le réacteur, d'un remplissage non spécialement nettoyé. Mais ce phénomène disparaissait après lavage du réacteur et de son remplissage au mélange sulfo-chromique ou, plus difficilement, après séjour d'oxygène (à la pression atmosphérique) dans le réacteur, à la température de l'expérience.

(3) Contrairement à l'opinion de Voevodsky (4), mais en accord avec celle émise en 1962 par Laidler, Sagert et Wojciechowski (5), nous pensons donc que la pyrolyse du propane pur est une réaction essentiellement homogène (du moins dans des réacteurs en silice, en pyrex et en pyrex traité à HF ou recouvert de KCl ou de PbO), comme la décomposition thermique du butane-*n* pur (dans des réacteurs en pyrex et en pyrex traité à HF ou recouvert de KCl) étudiée par Purnell et Quinn (6). Nous pensons qu'il en est de même de la pyrolyse de l'isopentane pur (dans des réacteurs en pyrex et en pyrex recouvert de KCl ou de PbO).

Comme l'ont fait remarquer Wojciechowski et Laidler (7) en 1963, l'éventualité de la participation à l'initiation et à la terminaison des chaînes, de processus hétérogènes, ne peut pas être totalement éliminée; mais elle nous paraît peu probable dans nos conditions expérimentales, car il faudrait alors que les divers traitements de parois envisagés modifient dans un même rapport les vitesses d'initiation et de terminaison.

Quant au désaccord entre les résultats de Voevodsky (4) et les nôtres relatifs au propane, nous allons voir qu'il pourrait s'expliquer par la présence de traces d'oxygène dans les expériences de Voevodsky.

PYROLYSE DU PROPANE OU DE L'ISOPENTANE EN PRÉSENCE DE TRACES D'OXYGÈNE

(1) Nous avons tout d'abord mis en évidence les faits suivants, à propos de la décomposition thermique du propane ou de l'isopentane ($480 < T$ (°C) < 550; $20 < P_0$ (mm Hg) < 100) en présence de traces d'oxygène (0.5 à 2%).

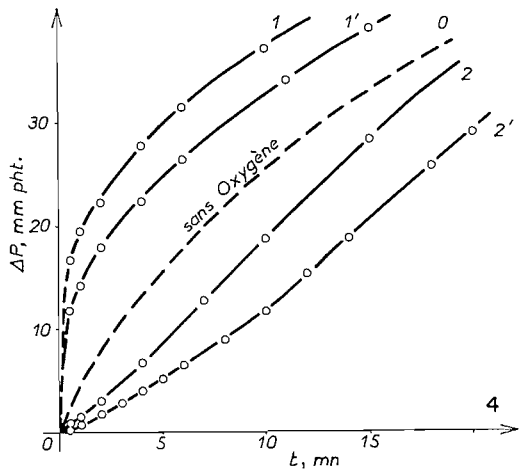
Dans un réacteur de faible rapport s/v, l'oxygène accélère considérablement la pyrolyse du propane ou de l'isopentane à ses débuts, mais cet effet accélérateur n'est observé que pendant un temps très court (Fig. 4 et 5, courbes 1). Lorsque le rapport s/v augmente,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

l'effet accélérateur de l'oxygène diminue (Fig. 4 et 5). Dans le cas du propane, il finit même, à de fortes valeurs du rapport s/v, par se transformer en un effet inhibiteur croissant, qui persiste alors pendant un certain temps (Fig. 4, courbes 2 et 2').

Autrement dit, la vitesse initiale de pyrolyse du propane ou de l'isopentane additionné de traces d'oxygène décroît très fortement lorsque le rapport s/v augmente, tandis qu'en l'absence d'oxygène, la variation de vitesse avec s/v est négligeable (Fig. 6 et 7).

L'allure des courbes 1 des Fig. 4 et 5 montre qu'il est très difficile—voire impossible—de mesurer la vitesse initiale réelle V_0 de la réaction, lorsque celle-ci est fortement accélérée



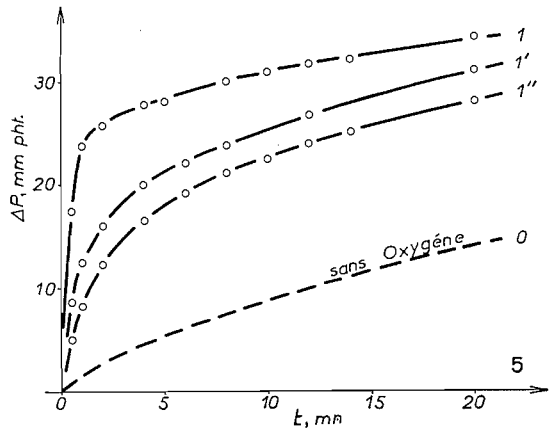


FIG. 4. Pyrolyse du propane (P_0 = 25 mm Hg, T = 546 °C) en présence de traces d'oxygène (0.5%); augmentation de pression en fonction du temps dans un réacteur en pyrex: (1) s/v = 0.7 cm^{-1}; (1') s/v = 5 cm^{-1}; (2) s/v = 8 cm^{-1}; (2') s/v = 9.5 cm^{-1}.

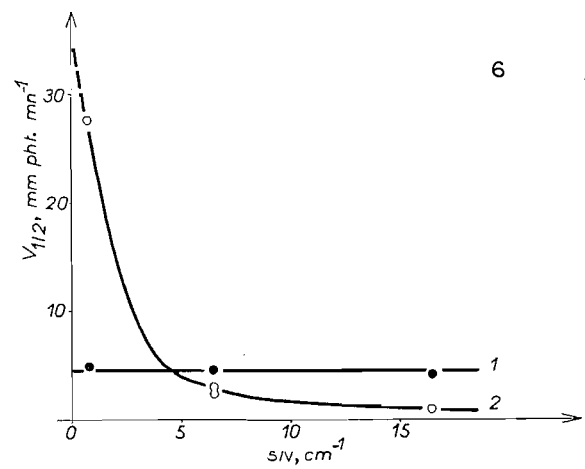
FIG. 5. Pyrolyse de l'isopentane (P_0 = 25 mm Hg, T = 480 °C) en présence de traces d'oxygène (1%); augmentation de pression en fonction du temps dans un réacteur en pyrex: (1) s/v = 0.8 cm^{-1}; (1') s/v = 5.7 cm^{-1}; (1'') s/v = 12 cm^{-1}.



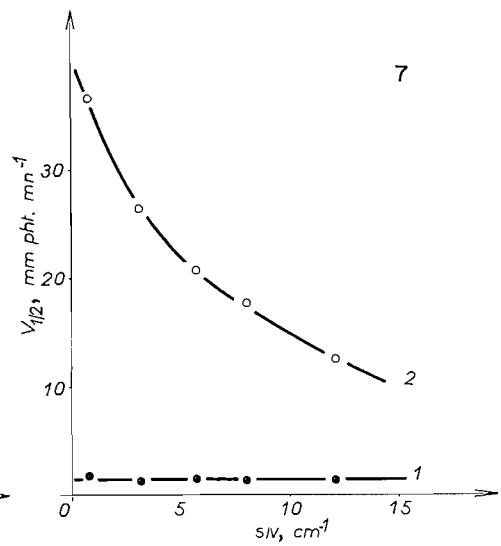


FIG. 6. Pyrolyse du propane (P_0 = 25 mm Hg, T = 546 °C); vitesse "initiale" $V_{1/2}$ en fonction du rapport surface/volume du réacteur en silice: (1) sans oxygène; (2) avec 0.5% d'oxygène.

FIG. 7. Pyrolyse de l'isopentane (P_0 = 25 mm Hg, T = 480 °C); vitesse "initiale" $V_{1/2}$ en fonction du rapport surface/volume du réacteur en pyrex: (1) sans oxygène; (2) avec 1% d'oxygène.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

par l'oxygène; en effet, la vitesse est alors initialement très grande et elle décroît très rapidement. Aussi avons-nous convenu (cf. Fig. 6 et 7) de déterminer la vitesse moyenne pendant les 30 premières secondes (1/2 mn):

$$V_{1/2} = \frac{\Delta P_{1/2}}{1/2} \text{ mm phtalate mn}^{-1}.$$

Cette vitesse "initiale" $V_{1/2}$ représente une valeur approchée par défaut de la vitesse initiale réelle V_0 de pyrolyse, lorsque celle-ci est accélérée par des traces d'oxygène; au contraire, $V_{1/2}$ représente une valeur légèrement approchée par excès de la vitesse initiale réelle V_0 de pyrolyse, lorsque celle-ci est inhibée par l'oxygène. Enfin, $V_{1/2}$ représente avec une bonne approximation la vitesse initiale réelle V_0 de pyrolyse de l'hydrocarbure pur (cf. réf. 2*d*).

Il convient de remarquer que la décroissance de la vitesse initiale de pyrolyse du propane signalée par Voevodsky (4) lorsque le rapport s/v augmente (Fig. 1, courbe 2) est analogue à celle que nous observons en présence de traces d'oxygène (Fig. 6, courbe 2). Le désaccord entre les résultats de Voevodsky (Fig. 1, courbe 2) et les nôtres relatifs au propane pur (Fig. 1, courbe 1) pourrait donc s'expliquer par la présence de traces d'oxygène (moins de 0.1%) dans les expériences de Voevodsky. De même, il est vraisemblable que la pyrolyse très rapide du propane observée par cet auteur en présence de parois recouvertes de perchlorate de magnésium (4), est due à l'oxygène provenant de la décomposition thermique de ce sel.

Par ailleurs, la vitesse de pyrolyse du propane ou de l'isopentane en présence de traces d'oxygène est très sensible à la nature et à l'état des parois du réacteur.

Par exemple, la réaction est plus rapide après lavage d'un réacteur en pyrex au mélange sulfo-chromique (2).

Au contraire, la réaction est plus lente après dépôt de KCl ou de PbO sur les parois d'un réacteur (2).

L'inhibition de la réaction peut même devenir quasi-complète, pendant un certain temps, dans un réacteur de fort rapport s/v traité à PbO (Figs. 8 et 9). Ce fait expérimental nouveau prouve clairement que tout processus moléculaire de décomposition est négligeable devant la réaction en chaînes.

(2) On note, par chromatographie gazeuse, que les parois ont également une influence inhibitrice sur la vitesse de consommation de l'oxygène. C'est ainsi que lorsqu'il accélère la pyrolyse du propane, l'oxygène est très rapidement consommé (l'effet accélérateur n'est alors observé que pendant un temps très court); au contraire, lorsqu'il inhibe la réaction, l'oxygène n'est consommé que lentement (l'effet inhibiteur persiste alors pendant un temps notable) (2).

Par ailleurs, l'étude analytique, par chromatographie gazeuse, montre que la nature des produits principaux de pyrolyse du propane ou de l'isopentane n'est pas modifiée par la présence de traces d'oxygène, que celui-ci soit accélérateur ou inhibiteur. Mais la présence de traces d'oxygène introduit une stoechiométrie d'oxydation de l'hydrocarbure et modifie les importances relatives des cinq équations stoechiométriques principales de décomposition de l'isopentane en début de réaction.

(3) Nous venons de montrer que, selon les conditions expérimentales, la vitesse initiale de pyrolyse du propane ou de l'isopentane est augmentée ou diminuée (parfois considérablement) par des traces d'oxygène.

Nous pensons que ce rôle double (accélérateur et inhibiteur) de l'oxygène moléculaire

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

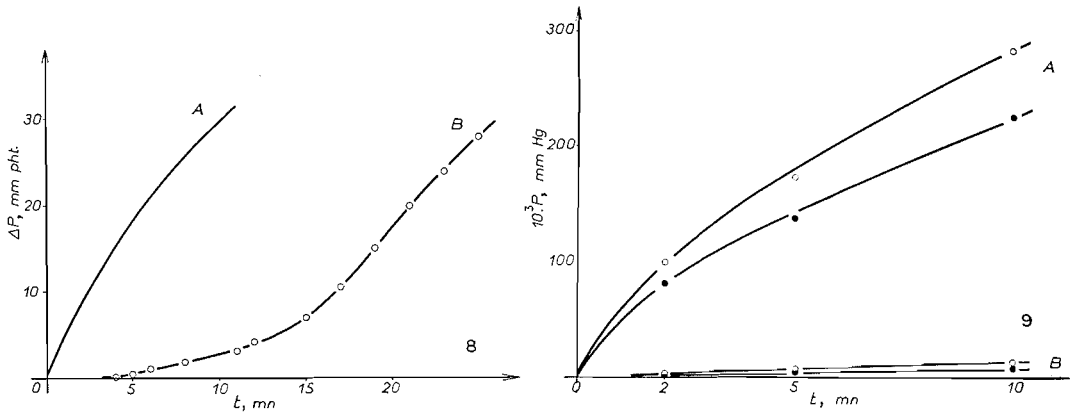

FIG. 8. Pyrolyse du propane (P_0 = 27 mm Hg, T = 551 °C); augmentation de pression en fonction du temps: (A) sans oxygène; (B) avec 1.8% d'oxygène dans un réacteur en pyrex (s/v = 4.6 cm^{-1}) traité à PbO.

FIG. 9. Pyrolyse de l'isopentane (P_0 = 25 mm Hg, T = 480 °C, pression d'échantillon = 10 mm Hg): ○ $P = C_2H_4 + C_3H_6$ + butènes: ● $P = CH_4 + C_2H_6 + C_3H_8$. (A) Sans oxygène dans un réacteur en pyrex (s/v = 0.8 cm^{-1}); (B) avec 1% d'oxygène dans un réacteur en pyrex (s/v = 11 cm^{-1}) traité à PbO.

peut s'expliquer comme suit, en partant de considérations relatives à la concurrence entre mécanismes en chaînes ayant un porteur de chaînes commun dans la réaction complexe entre l'oxygène et une substance organique (8).

(*a*) Par réaction avec l'hydrocarbure M, l'oxygène provoque l'apparition d'un processus d'induction, du type:

$$M + O_2 \rightarrow \text{radicaux libres};$$

ce nouveau processus d'initiation s'ajoutant au processus d'initiation normale:

$$M \rightarrow \text{radicaux libres}$$

l'oxygène tend à *accélérer* la pyrolyse de l'hydrocarbure.

(*b*) En l'absence d'oxygène, les radicaux libres hydrocarbonés R· ne peuvent propager que la décomposition en chaînes de l'hydrocarbure M. Mais, en présence d'oxygène, ils peuvent également s'oxyder en donnant naissance à d'autres radicaux libres R′·, oxygénés (par exemple: HO_2· et ·OH). Il se propage alors simultanément, dans le milieu, deux types de chaînes: une chaîne de décomposition et une chaîne d'oxydation de l'hydrocarbure M. La "chaîne globale complexe" qui en résulte comporte donc un certain nombre de "maillons" représentatifs de chacun des deux types de chaînes et il apparaît de nouveaux processus de terminaison des chaînes (disparition de radicaux libres oxygénés R′·). Du fait que la réaction de décomposition et celle d'oxydation ont des porteurs de chaînes communs (R·), ces deux réactions se font mutuellement concurrence et, par suite, l'oxygène peut aussi *inhiber* la pyrolyse de l'hydrocarbure M.

Rappelons que nos résultats expérimentaux mettent en évidence une influence inhibitrice des parois sur la réaction globale complexe (décomposition et oxydation) du propane ou de l'isopentane additionné de petites quantités d'oxygène. Ces faits indiquent que:

(*a*) le nouveau processus d'initiation provoqué par l'oxygène est essentiellement homogène;

(*b*) au contraire, les nouveaux processus de terminaison (qui apparaissent en présence d'oxygène) sont, en partie au moins, hétérogènes (aux parois).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Notre interprétation de la pyrolyse de l'hydrocarbure M, à l'instant initial, peut être schématisée comme indiqué ci-dessous, R· pouvant être un radical R_β· ou un radical R_μ· dans la terminologie de Goldfinger, Letort et Niclause (9).

Processus de pyrolyse de l'hydrocarbure pur.—

[1] Initiation: $M \rightarrow$ radicaux libres

[2] Propagation: $R_\mu\cdot\ (+X) \rightarrow R_\beta\cdot + P_1\ (+X)$

[3] $R_\beta\cdot + M \rightarrow R_\mu\cdot + P_2$

[4] Terminaison: $2R\cdot \rightarrow$ produits

Processus apparaissant en présence d'oxygène.—

[5] Terminaison: $R\cdot + R'\cdot \rightarrow$ produits

[6] $2R'\cdot \rightarrow$ produits

[7] $R'\cdot \xrightarrow{\text{parois}}$ produits

[8] Propagation: $R\cdot + O_2 \rightarrow R'\cdot\ (+P'_1)$

[9] $R'\cdot + M \rightarrow R_\mu\cdot + P'_2$

[10] Initiation: $M + O_2 \rightarrow$ radicaux libres

Cette représentation n'est que schématique, puisque les symboles R_β·, R_μ· et R'· peuvent, chacun, désigner plusieurs radicaux différents, étant donné que plusieurs équations stoechiométriques sont nécessaires pour représenter la réaction de décomposition du propane ou de l'isopentane.

La pyrolyse du propane ou de l'isopentane en présence d'oxygène serait donc une coréaction impliquant deux types de chaînes à interactions mutuelles, comme diverses autres réactions de décomposition, de polymérisation ou de chloration en présence d'oxygène (2*e*, 8) et comme la pyrolyse du butane-*n* en présence de propylène (10); mais, dans ce dernier cas, le propylène ne ferait pas apparaître de processus de terminaison aux parcis, ni de processus d'initiation appréciable.

A partir du schéma précédent, on peut calculer le rapport $(V_0)_{M,O_2}/(V_0)_M$ des vitesses initiales de pyrolyse de l'hydrocarbure M additionné ou non d'oxygène (toutes autres choses égales par ailleurs) dans le cas limite où l'on opérerait en l'absence de parois; que R· représente un radical R_β· ou un radical R_μ·, on trouve finalement:

$$\frac{(V_0)_{M,O_2}}{(V_0)_M} \simeq \left[\frac{1+\dfrac{k_{10}(O_2)_0}{k_1}}{1+\dfrac{k_5}{k_4}\dfrac{k_8(O_2)_0}{k_9(M)_0}+\dfrac{k_6}{k_4}\dfrac{k_8^2(O_2)_0^2}{k_9^2(M)_0^2}}\right]^{1/2}.$$

On voit que l'oxygène a non seulement une influence *accélératrice*, mais encore une influence *inhibitrice*, même en l'absence de parois.

Le rôle inhibiteur de l'oxygène est accentué par la présence de parois, puisque celles-ci font apparaître un processus hétérogène (processus 7) de terminaison des chaînes. Par conséquent, en présence de parois, on a:

$$0 < \frac{(V_0)_{M,O_2}}{(V_0)_M} < \left[\frac{1+\dfrac{k_{10}(O_2)_0}{k_1}}{1+\dfrac{k_5}{k_4}\dfrac{k_8(O_2)_0}{k_9(M)_0}+\dfrac{k_6}{k_4}\dfrac{k_8^2(O_2)_0^2}{k_9^2(M)_0^2}}\right]^{1/2};$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

en outre, la vitesse initiale de consommation de l'oxygène est elle-même plus faible qu'en l'absence de parois.

Notre représentation permet donc de concevoir que l'oxygène moléculaire joue un double rôle dans la pyrolyse du propane ou de l'isopentane—il est à la fois accélérateur et inhibiteur—et que l'importance relative de ces deux influences opposées et la nature de l'effet global qui en résulte (accélération ou inhibition) dépendent des conditions expérimentales.

(*a*) On comprend, en particulier, que la vitesse initiale de décomposition de l'hydrocarbure, en présence de traces d'oxygène, diminue lorsque le rapport s/v du réacteur augmente. Le dépôt de KCl ou de PbO sur les parois doit augmenter l'efficacité de ces parois vis-à-vis du processus hétérogène de terminaison, puisque l'influence inhibitrice de l'oxygène est accrue par de tels traitements des parois.

Remarquons que l'influence inhibitrice des parois mise en évidence ici pour la réaction globale complexe (décomposition et oxydation) du propane ou de l'isopentane, additionné de petites quantités d'oxygène, est analogue à celle observée dans les réactions d'oxydation proprement dite (en présence d'une concentration notable d'oxygène) de l'hydrogène et de divers hydrocarbures (cf. par exemple réf. 11).

(*b*) A partir de notre schéma de pyrolyse en présence d'oxygène, on peut prévoir les allures des variations de la vitesse initiale de décomposition, avec les concentrations initiales d'oxygène et d'hydrocarbure M (Fig. 10). Ce sont effectivement des allures de ce genre que l'on observe expérimentalement avec le propane (2) et avec l'isopentane.

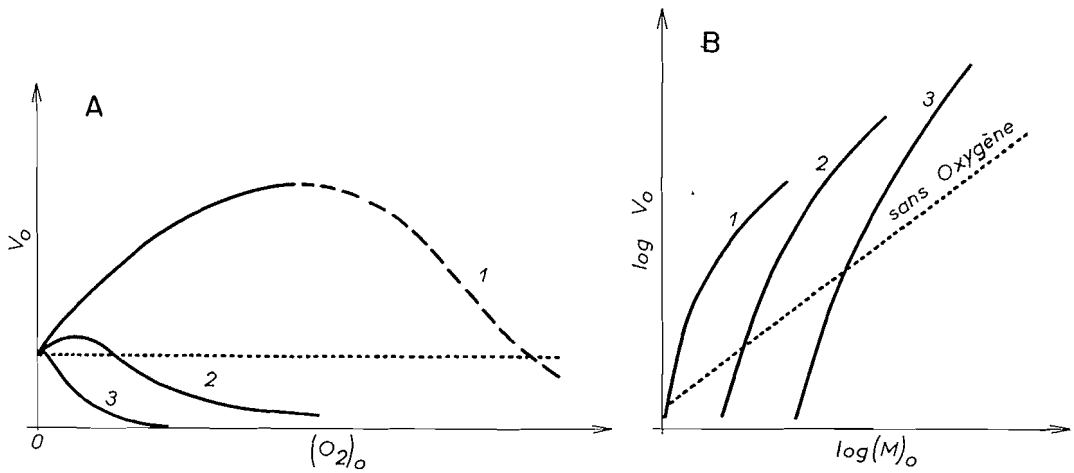

FIG. 10. Influence des concentrations initiales d'oxygène (A), dans le cas où $(M)_0 > k_1k_5k_8/k_{10}k_4k_9$, et d'hydrocarbure (B) sur la vitesse initiale V_0 de pyrolyse de l'hydrocarbure M en présence d'oxygène (représentation schématique d'après la théorie). (1) En l'absence de parois, (2) en présence de parois "moyennement efficaces", (3) en présence de parois "très efficaces" vis-à-vis du processus [7].

Remarque.—La Fig. 11 montre comment varie la vitesse instantanée V de pyrolyse du propane au cours d'une expérience: (*a*) dans le cas du propane pur, la réaction est très fortement auto-inhibée: l'ordre n au cours du temps [environ 17] est très supérieur à l'ordre initial n_0 [environ 1.25 (5)]; (*b*) en présence de traces d'oxygène (0.5%), on note, en début de réaction, une importante inhibition ou une très forte accélération de la pyrolyse selon les conditions de parois; mais la vitesse de la réaction en présence d'oxygène finit par devenir égale à celle de pyrolyse du propane pur (à même avancement). On observe des phénomènes semblables dans le cas de l'isopentane.

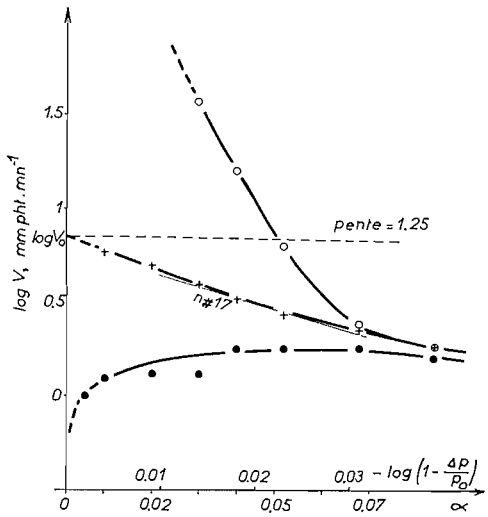

FIG. 11. Pyrolyse du propane (P_0 = 26 mm Hg, T = 547 °C, réacteur en pyrex); variations de la vitesse instantanée V au cours d'une expérience: × $(O_2)_0$ = 0% et s/v = 9.5 cm^{-1}; ● $(O_2)_0$ = 0.5% et s/v = 9.5 cm^{-1}; ○ $(O_2)_0$ = 0.5% et s/v = 0.7 cm^{-1}.

Etant donné, d'une part que la pyrolyse du propane ou de l'isopentane est une réaction très fortement auto-inhibée, d'autre part que sa vitesse initiale est très sensible aux traces d'oxygène et qu'en présence de telles traces elle dépend beaucoup des conditions de parois, il nous a paru très difficile de déterminer, avec précision, les caractéristiques cinétiques (ordre et énergie d'activation), à l'instant initial, de la pyrolyse homogène de ces hydrocarbures purs. C'est pourquoi nous n'avons pas étudié systématiquement cette question. De nos résultats expérimentaux, on peut toutefois déduire les caractéristiques cinétiques approximatives, dans certaines conditions, de la pyrolyse du propane ou de l'isopentane. En particulier, l'ordre initial n_0 est compris entre 1 et 3/2, en accord avec les observations de Laidler et coll. (5) relatives au propane. Nos résultats expérimentaux ne mettent toutefois pas en évidence des variations de n_0 si prononcées que celles observées par Laidler et coll. (5) dans le cas de la pyrolyse du propane dans un réacteur vide en silice. D'ailleurs, de brusques changements d'ordre n_0 (avec la pression initiale d'hydrocarbure) nous sembleraient difficiles à interpréter uniquement: soit par des variations des importances relatives des processus de terminaison des chaînes; soit par le fait que la décomposition d'un radical $R_\mu\cdot$, d'ordre 2 à basse pression, devient d'ordre 1 à haute pression.

CONCLUSIONS

La pyrolyse du propane pur est une réaction essentiellement homogène, du moins dans des réacteurs en silice, en pyrex et en pyrex traité à HF ou recouvert de KCl ou de PbO. Il en est de même de la pyrolyse de l'isopentane pur dans des réacteurs en pyrex et en pyrex recouvert de KCl ou de PbO.

Nous avons montré expérimentalement qu'il est possible d'inhiber de façon pratiquement complète la pyrolyse du propane ou de l'isopentane; ceci prouve que tout processus moléculaire de décomposition est négligeable devant le mécanisme en chaînes.

Il avait déjà été signalé que des traces d'oxygène accélèrent certaines réactions, tandis qu'elles en inhibent d'autres. Mais nous avons montré, avec le propane et l'isopentane, que, selon les conditions expérimentales, l'effet inhibiteur de l'oxygène sur la pyrolyse d'une

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

substance organique peut l'emporter ou non sur son effet accélérateur. Nous avons proposé une interprétation de cette double influence de l'oxygène. Elle postule que la pyrolyse du propane ou de l'isopentane en présence de petites quantités d'oxygène est une co-réaction impliquant deux types de chaînes à interactions mutuelles et que l'oxygène fait apparaître un nouveau processus d'initiation essentiellement homogène (qui traduit le rôle accélérateur de O_2) et de nouveaux processus de terminaison, en partie au moins hétérogènes (qui traduisent le rôle inhibiteur de O_2).

Nos expériences attirent l'attention sur le fait qu'il est très difficile de déterminer, avec précision, les caractéristiques cinétiques, à l'instant initial, de la pyrolyse homogène de ces hydrocarbures purs.

Nous poursuivons actuellement l'étude de ces phénomènes avec d'autres hydrocarbures saturés.

REMERCIEMENTS

PROTON SPIN RELAXATION BY PARAMAGNETIC MOLECULAR OXYGEN

M. E. MIRHEJ[1]

Institute of Oceanography, University of British Columbia, Vancouver, British Columbia

Received October 22, 1964

ABSTRACT

The proton spin–lattice relaxation time, T_1, was measured for oxygen solutions of water, methanol, and acetone at different temperatures and resonance frequencies of 10.8, 20.0, and 29.8 Mc/s. The contribution of O_2 to the relaxation was assumed to be due to the dipole–dipole and hyperfine interaction between the proton spins and the unpaired spins of the O_2 molecule. The correlation times of the two interactions were related to the motion and the size of the polymeric cluster of the solvent. Activation energies for the two correlation times were obtained for the oxygen–water system from the dependence of the relaxation time on the resonance frequency. No separation of the two terms was possible for either the oxygen–methanol or oxygen–acetone systems because of their independence of magnetic field variations. The correlation time of the hyperfine term was postulated to be a measure of the extent of solvent–oxygen hydrogen bond strength in all the measured systems.

INTRODUCTION

Earlier studies on the influence of paramagnetic substances on the proton spin–lattice relaxation time, T_1, in water solutions, were interpreted assuming that the relaxation was due to dipole–dipole interactions between electron and nuclear spins, where fluctuations in such interactions are governed by viscosity and diffusion. Bloembergen *et al.* (1) found the addition of paramagnetic ions to water to decrease both the spin–lattice and the spin–spin relaxation time, T_1 and T_2 respectively. The additional contribution to the relaxation rates was found to be proportional to the concentration of the paramagnetic ions concentrations. Later, Conger (2) and Morgan *et al.* (3) concluded from measurements of relaxation times in water–glycerol solutions of several aquated ions that the observed changes were not entirely attributable to the change in viscosity according to the early theory. It was suggested that the difference observed might well provide an insight into the nature of molecular interactions in those and similar solutions. Bloembergen (4), on the other hand, followed with comparison of the ratio of T_1 to T_2 in paramagnetic ion solutions and found a deviation from unity for most ions to as high as 7.1 for Mn^{++}. The interpretation advanced emphasized that a spin exchange interaction was contributing to the relaxation due to the formation of a hydrated complex between the paramagnetic ions and water molecules. This was extended by Bloembergen and Morgan (5) to interpret the different effect on relaxation between various paramagnetic ions and the role played by the electron spins of the ions.

The influence of paramagnetic but nonionic substances in water was studied by Guilotto (6). By measuring T_1 of water in the presence and absence of oxygen, he demonstrated the change in T_1 at 20 °C and the linear dependence of the reciprocal of the spin–lattice relaxation time on the concentration of oxygen. Recently, Gutowsky and Tai (7) investigated the solvent–proton and fluorine nuclear relaxation mechanisms in solutions of organic free radicals. Their findings confirmed further the presence of a spin exchange or a hyperfine relaxation mechanism between electron and nuclear spin in these systems.

It was attempted in this work to investigate the existence of any hyperfine interaction between the two unpaired electrons of dissolved molecular oxygen and the protons of

[1]*Present address: Research and Development Division, Polymer Corporation Limited, Sarnia, Ontario, Canada.*

different liquid solvents. For this purpose, T_1 was measured for oxygen solutions of water, methanol, and acetone at different temperatures and three different resonance frequencies. Employing the Solomon–Bloembergen equation (5), the experimental results were fitted to its various forms as deemed by the dependence of the relaxation times on the variation of resonance frequency.

EXPERIMENTAL

A. Apparatus

(i) Nuclear Magnetic Resonance Free Induction Technique

The apparatus used was a conventional pulsed n.m.r. instrument (8), operated at the proton Larmor precession frequencies of 29.8, 20.0, and 10.8 Mc/s.

(ii) Thermostated Induction Coil Chamber

A copper coil 1/4 in. in diameter was helically shaped to a height of 6 cm and an o.d. of 3 cm. It was insulated with aluminium foil on the outside and placed in a wooden sample holder block leaving a small opening at the top for the sample entrance. The induction coil was fitted between the copper coil and the sample tube. The ends of the copper coil were joined to a circulating water bath with a temperature range of 1 to 90 °C and a temperature control of 0.1 °C. A thermocouple was placed inside the induction coil to determine the temperature. The measured temperatures fluctuated by an amount of the order of 0.5 °C at low temperatures and 1.0 °C at high temperatures during the course of the measurements.

(iii) Degassing Instrument

A 1 l bulb with two openings was joined to a high-vacuum line at one end, and to the sample tube at the other. The bulb contained a Teflon-covered bar magnet and was placed over a magnetic stirrer.

(iv) Sample Tubes

These were of pyrex glass 0.6 cm i.d. and about 8 cm in length. Two designs of tubes were used. One, for oxygen-free solvent, which was sealed off from the degassing bulb and used permanently, and the second for oxygenated solvents. The latter contained two small openings, one for the introduction of air or oxygen and the other for its escape.

B. Reagents

(*i*) Double distilled water.

(*ii*) Compressed air. The 'Liquid Air' cylinder contained 21% oxygen. The remaining gases were the same as atmospheric gas content.

(*iii*) Compressed oxygen. The 'Liquid Air' cylinder contained 99.5% oxygen and 0.5% nitrogen.

(*iv*) Acetone. Fisher 'Spectranalyzed' reagent grade.

(*v*) Methanol absolute. This was prepared in the laboratory from the reaction of methylphthalate and sodium hydroxide (9) and was kept in a dry box until used.

C. Procedures

(i) Degassing Method

Approximately 100 ml of water, methanol or, acetone was placed in the degassing bulb. The stopcock to the high vacuum line was opened and the magnetic stirrer started. Degassing was carried out normally from 1/2 to 1 h depending on the rate of solvent evaporation. The stopcock was closed, and the bulb was tilted until 4 or 5 ml of liquid solvent entered the sample tube at the other side. The sample tube content was frozen with liquid nitrogen and the tube sealed off. Sample tubes prepared in this manner were used for relaxation time measurements of oxygen-free solvents.

(ii) Oxygen Concentration Method

Two oxygen concentrations were employed for water and only one concentration for acetone and methanol. The solvent was saturated at a particular temperature with either air containing 21% oxygen, or with oxygen under 1 atm pressure. The degassed sample tubes were placed in the circulating water bath with the open tubes, each containing 5 or 6 ml of the solvent, after the thermoregulator has been adjusted for the desired temperature. A polyethylene tube, 0.2 cm o.d. was connected to one of the gas cylinders through a series of drying and carbon dioxide absorbing tubes. The polyethylene tube was inserted in the open sample tube until it reached the bottom, and then either air or oxygen was bubbled slowly through allowing the solvent to come to equilibrium with the ambient temperature and the gas saturation point at the same time. At the end of 10–15 min the polyethylene tube was withdrawn, and the sample tube stoppered, dried carefully, and placed quickly in the induction coil chamber, which was then at the same temperature, for relaxation time measurements.

The oxygen concentrations were checked occasionally on water samples by the micro-gasometric technique of Scholander *et al.* (10). The results were 2.5% of the theoretical concentration at any particular temperature. This is of the same order of magnitude as the usual error in estimating oxygen concentration by this method.

(iii) Measurement of Spin–Lattice Relaxation Time, T_1

While the three sample tubes were being brought to the desired temperature and pressure, a glycerine sample tube was placed in the induction coil chamber, and the Larmor frequency of the protons was adjusted to an optimum height signal. The glycerine tube was then replaced by a sample tube, and T_1 was determined. Using a $\pi/2$–$\pi/2$ pulse sequence, the amplitude of the first pulse signal or that of the echo, A, was read at $A(\infty)$ and at various $A(t)$'s. T_1 was deduced from the usual relation:

$$A(t) = A(\infty)\ [1 - \exp\ (-t/T_1)],$$

where $A(\infty)$ is the value of $A(t)$ for $t \gg T_1$.

THEORETICAL CONSIDERATION

The Solomon–Bloembergen equation (5) for the proton spin–lattice relaxation time, T_1, in the presence of molecular oxygen in a protonic solvent, may be written as:

$$[1] \qquad \frac{1}{T_1} = \frac{4}{15}\frac{Ng^2\beta^2\gamma_I{}^2N_h}{N_p r^6}\left[3\tau_c + \frac{7\tau_c}{1+\omega_S{}^2\tau_c{}^2}\right] + \frac{4}{3}\left(\frac{A}{\hbar}\right)^2\frac{NN_h}{N_p}\frac{\tau_e}{1+\omega_S{}^2\tau_e{}^2}.$$

Where ω_S refers to the electron Larmor precessional frequency; γ_I, the nuclear gyromagnetic ratio; g, the electron spectroscopic splitting factor; β, the Bohr magneton; N, the molar concentration of paramagnetic ions; N_h, the number of protons in the hydration sphere; N_p, the molar concentration of protons in solution; A, the spin exchange constant; τ_c and τ_e, the correlation times for dipoles and spin exchange interactions respectively; and r, the effective separation between the nucleus and the electron. The correlation time τ_c is related to the dipole–dipole interaction which depends on the vector $\boldsymbol{r}$ joining the proton–O_2 pair, while τ_e is a function of the scalar $\boldsymbol{I.S}$. interaction and is independent of the orientation of the pair. The spin-lattice relaxation time

$$[2] \qquad \frac{1}{T_1} = \frac{1}{T_1(O_2)} - \frac{1}{T_1(\text{pure})},$$

where T_1(pure) indicates the spin–lattice relaxation in oxygen-free solvent, and $T_1(O_2)$ the spin–lattice relaxation in the presence of oxygen.

Equation [1] contains three approximations: (*a*) $\omega_S \gg \omega_I$, i.e. $\omega_S \pm \omega_I \approx \omega_S$; (*b*) $\omega_I{}^2\tau_c{}^2 \ll 1$; and (*c*) the spin temperature of the S system of the electrons is taken to be the same as the lattice temperature; where ω_I is the proton Larmor precessional frequency.

If the electron spins of the dissolved paramagnetic substance are relaxed in a time τ_s, the electron spin relaxation time, then the values of τ_c and τ_e are as follows:

$$[3] \qquad \frac{1}{\tau_c} = \frac{1}{\tau_r} + \frac{1}{\tau_s},$$

$$[4] \qquad \frac{1}{\tau_e} = \frac{1}{\tau_h} + \frac{1}{\tau_s}.$$

In general τ_s is a function of temperature and magnetic field, while τ_r and τ_h are functions of temperature only (5).

For the oxygen molecule, however, it is assumed that τ_s is much larger than either τ_r or τ_h for all the investigated systems and that τ_c is mainly dependent on τ_r, and τ_e on τ_h. This assumption is supported by the knowledge that electron relaxation times of free radicals are generally much longer than those of paramagnetic ions (7). Therefore, at magnetic field strengths of 2 540, 4 700, and 7 000 gauss (G), ω_S is 0.45×10^{11},

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

0.83×10^{11}, and 1.24×10^{11} s^{-1}, respectively. τ_c is considered to be less than 10^{-11} s and τ_e of the order of 10^{-11} s for the water–oxygen system but much smaller than 10^{-11} s for either the methanol– or the acetone–oxygen system.

For the situation where τ_c is determined mainly by τ_r, and τ_c by τ_h, an exponential temperature dependence may be written after the fashion of Bloembergen and Morgan (5) as:

$$\tau_c = \tau_c^0 \exp (E_c/RT), \quad [5]$$

$$\tau_e = \tau_e^0 \exp (E_e/RT). \quad [6]$$

E_c is considered a measure of the activation energy of the tumbling of the oxygen-solvent complex, and E_e a measure of the hydration or solvation of molecular oxygen.

RESULTS AND DISCUSSION

A. Water–Oxygen System

(i) Determination of T_1

The spin–lattice relaxation time was measured in oxygen-free double distilled water and in gas-saturated water under 1 atm of air and 1 atm of oxygen. The range of temperature employed was 10 to 75 °C. Three different proton resonance frequencies were used, 10.8, 20.0, and 29.8 Mc/s. At least three separate runs were made for each temperature at any resonance frequency. Figure 1 shows the actual scatter of the points at 20.0 Mc/s, while Fig. 2 represents all the obtained data at the three frequencies and three oxygen concentrations based on a similar treatment of the data. There was essentially no change in the value of oxygen-free water when the frequency was varied at any particular temperature; however, a marked change in T_1 values resulted from frequency

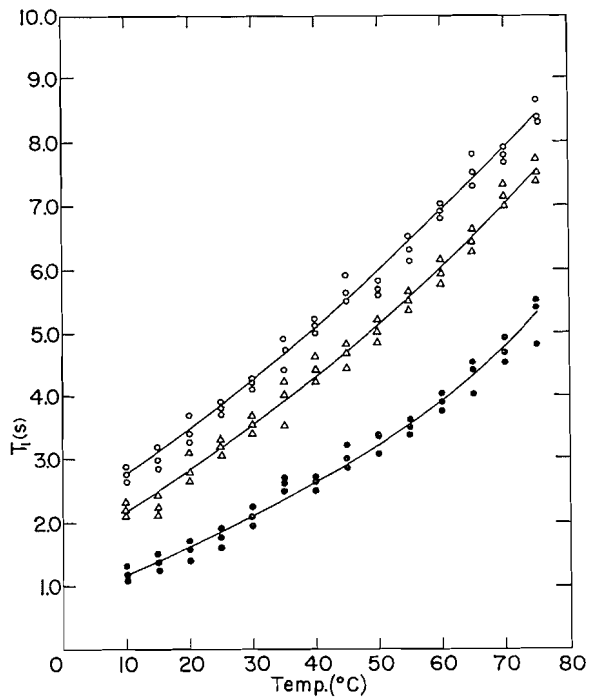

FIG. 1. Values of T_1 in water at 20.0 Mc/s in oxygen free, ○; under 1 atm of air, △; and under 1 atm of oxygen, ●.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

alteration for any of the oxygen-containing samples. T_1 decreased with increase of oxygen concentration, but increased with the increase of frequency at constant concentration of oxygen.

The estimated maximum error for T_1 data for the smoothed curves was of the order of $\pm 5\%$. Comparison of T_1 values for oxygen-free water was made with those of Simpson and Carr (11), who measured T_1 and the diffusion coefficient D of proton in water at temperatures between 0 and 100 °C. The agreement above 40 °C was very apparent and of the order of 1–2%. At lower temperatures, the difference was more pronounced. Simpson and Carr's T_1 values were lower by 19% at 10 °C, 13% at 20 °C, and 10% at 30 °C. Better agreement at lower temperature was obtained with Guilotto's (6) value, where the two T_1's were of the order of 1% at 20 °C.

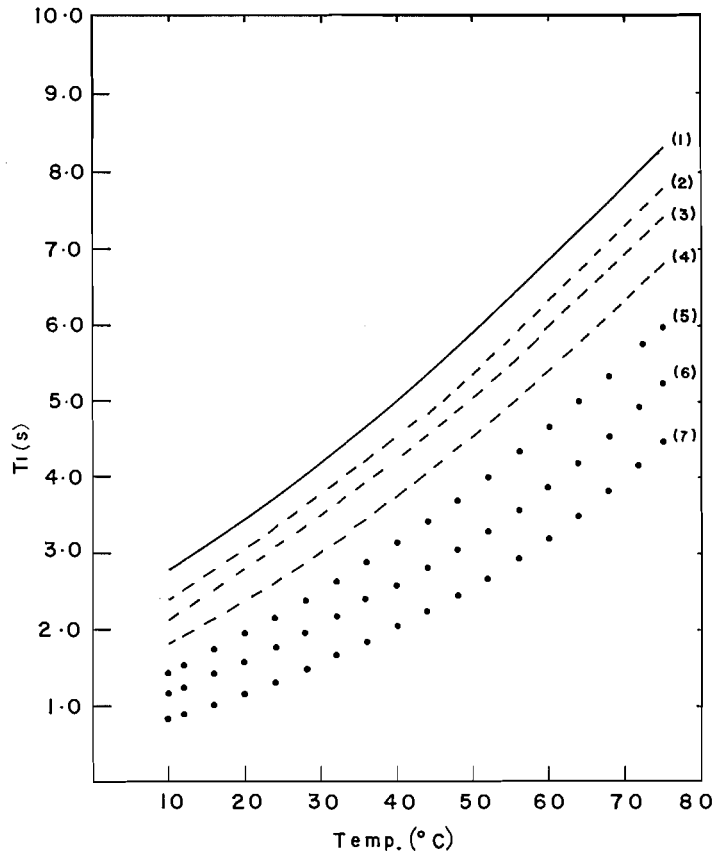

FIG. 2. Values of T_1 in water at 10.8 Mc/s ((1), (4), and (7)), 20.0 Mc/s ((1), (3), and (6)), and 29.8 Mc/s ((1), (2), and (5)) in oxygen free (—); under 1 atm of air (- - -); and under 1 atm of oxygen (●).

The inability of obtaining constant oxygen concentrations at different temperatures warranted the use of an indirect approach whereby $1/T_1$ was plotted vs. dissolved oxygen concentration at the various temperatures (6). The slopes of the line between zero and 10^{-3} mole/l were computed for $1/T_1N$ at each temperature of measurement and for the three resonance frequencies and listed in Table I.*

**The solubility values of oxygen in distilled water were obtained from the 'Handbook of physics and chemistry', 1960, p. 1706.*

70	195	140	100	55	40
75	190	140	100	50	40

(ii) Relaxation Terms

It was shown that $1/T_1N$ for dissolved oxygen in water varies with the magnetic field strength, H_0. This is related in turn to the dependence of the electron precession frequency, ω_S, on H_0. The best fit for the experimental results obeyed the relationship.

[7] $$R = 1/T_1N = \alpha\tau_c + B\tau_e/(1 + \omega_S{}^2\tau_e{}^2)$$

where

$$\alpha \text{ is } \frac{40}{15}\frac{g^2\beta^2\gamma_I{}^2N_h}{N_p r^6}$$

and

$$B \text{ is } \frac{4}{3}\left(\frac{A}{\hbar}\right)^2\frac{N_h}{N_p}$$

at any particular temperature and $\omega_S{}^2\tau_c{}^2 \ll 1$.

The magnitude sequence of the three correlation times, τ_h, τ_s, and τ_r, which are related to τ_c and τ_e by eqs. [3] and [4], for the protons in presence of paramagnetic molecular oxygen, should differ from their sequence in paramagnetic ions solutions. Whereas in the latter they follow the order $\tau_h \geqslant \tau_s \gg \tau_r$ (5), they should possess, in the former, a new order of magnitude, $\tau_s \gg \tau_h \geqslant \tau_r$. This is based on two considerations. 1. Because τ_s for a free radical is usually much larger than that of a paramagnetic ion (7). 2. Because the O_2 molecule is nonpolar and thus is incapable of forming a hydration layer of the same strength as a charged ion in solution. Furthermore, paramagnetic, nonionic molecules may participate in the relaxation mechanism without disruption of the normal cluster arrangement of the solvent. On this basis, eq. [7] was solved at three different magnetic field strengths from the plot of $R = 1/T_1N$ vs. temperature, using the relationship:

[8] $$\frac{R_1 - R_2}{R_2 - R_3} = \frac{(\omega_{S2}{}^2 - \omega_{S1}{}^2)}{(\omega_{S3}{}^2 - \omega_{S2}{}^2)}\frac{(1 + \omega_{S3}{}^2\tau_e{}^2)}{(1 + \omega_{S1}{}^2\tau_e{}^2)}.$$

The square of the correlation time, $\tau_e{}^2$ and hence τ_e were evaluated. An average value for $B\tau_e$ was obtained from both $(R_1 - R_2)$ and $(R_2 - R_3)$ and was used to determine $\alpha\tau_c$ (average), at the three different frequencies. The values are shown in Table II.

TABLE II

Evaluation of the correlation times

Temp. (°C)	$\tau_c \times 10^{11}$ (s)	$\beta\tau_c$ (mole^{-1} s^{-1})	$\alpha\tau_c$ (mole^{-1} s^{-1})
10	2.0	830	100
15	2.1	750	90
20	1.9	690	60
25	1.9	620	50
30	1.7	540	45
35	1.7	490	40
40	1.5	440	30
45	1.4	390	28
50	1.3	350	23
55	1.2	320	20
60	1.2	280	15
65	1.2	260	12
70	1.1	230	8
75	1.0	220	5

Due to the presence of the 3/7 term in the dipole–dipole interaction expression, it is reasonable to expect that if the hyperfine term did not contribute to T_1, i.e. if $<A>$ was zero, the proper expression could be written as follows:

[9] $$\frac{1}{NT_1} = \frac{3}{10}\alpha\tau_c + \frac{(7/10)\alpha\tau_c}{1 + \omega_S^2\tau_c^2}.$$

However, neither this consideration nor the reversal of the assumption that $\omega_s^2\tau_c^2 \ll 1$ was found to be capable of suitable correlation with the data. In accordance with such findings it was discovered that the variation in τ_c^2 values were only of the order of 30%.

(iii) Activation Energies

It was assumed that $\tau_s \gg \tau_e$ or τ_c, as postulated earlier, and the exponential temperature dependence for the two latter correlation times follow eqs. [5] and [6]. The two activation energies E_e and E_c were obtained as 6.5 kcal mole^{-1} and 2.5 kcal mole^{-1} respectively. Furthermore, the validity for the assumption that $\tau_c < 10^{-11}$ s in water may be reasoned as follows: τ_c is proportional to τ_D where $\tau_D = 4\pi\eta a^3/kT$. From data of dielectric relaxation (12), neutron diffraction (13), and diffusion and viscosity (14), τ_D or its equivalent was estimated to be not more than 10^{-11} s at 0 °C. Also τ_D was found to be equal to $3\tau_c$ (15) and both τ_D and τ_c to decrease with increase in temperature.

Both τ_D and τ_c should vary proportionally with η/T of water. This relation is demonstrated by the linear variation of $\alpha\tau_c$ with η/T. Accordingly, it is believed that τ_c is principally a measure of the hydrogen bond breaking between water molecules in the process of the cluster tumbling in the body of the solvent.

The energy of activation E_c being 6.5 kcal mole^{-1}, is viewed as the energy required for one hydrogen bond breaking between two water molecules, within the accumulated experimental error of 30–40%. Comparison of this value with various other experimental values of hydrogen bond breaking in water at temperatures between −65 and 100 °C shows a similar order of magnitude with those of Scatchard (16), 3.4 kcal mole^{-1}, Rowlinson (17), 4.4 kcal mole^{-1}, and Lambert (18), 5.7 kcal mole^{-1}. Also, the activation energy for dielectric absorption in ice was found by Auty and Cole (19) to be 13.2 kcal mole^{-1} and was interpreted as the breaking of three hydrogen bonds each being 4.5 kcal mole^{-1}. The activation energy of hydration or solvation, E_e, on the other hand, is believed to be due to solvent–solute bond breaking between water and oxygen molecules. This was found to have the value of 2.5 kcal mole^{-1} for the range of temperature from 10 to 75 °C.

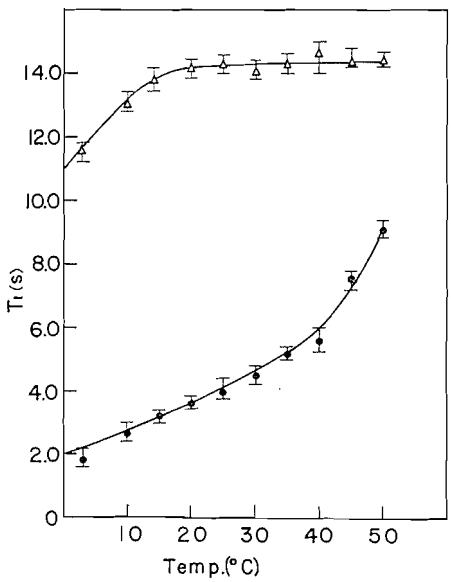
B. The Methanol– and Acetone–Oxygen Systems

(i) Measurement of T_1

The spin–lattice relaxation time measurements of the methanol– and acetone–oxygen systems were carried out in the same manner as that for water–oxygen except for two variations. 1. Only two magnetic field strengths of 7 000, and 2 540 G were used since no apparent change in the value of T_1 was found within the experimental error to necessitate the use of a third field strength. 2. One concentration of oxygen under 1 atm of air was employed. Figures 3 and 4 show the influence of temperature variation between 0 and 50 °C on T_1 for the oxygen-free and oxygen-containing acetone and methanol respectively. The inverse value of $1/T_1N$ was again obtained from the slope of $1/T_1$ vs. O_2 concentration. The concentration of dissolved oxygen in acetone was obtained from Horiuti (20) and in methanol from Seidell (21) as the Ostwald coefficient, γ, and were converted to moles of O_2 per liter of solvent.



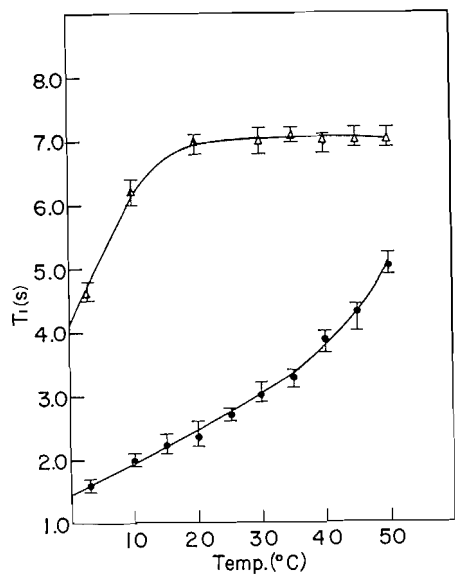


FIG. 3 (left). Values of T_1 in acetone at 29.8 Mc/s and 10.8 Mc/s in oxygen free, △ and under 1 atm of air, ●.

FIG. 4 (right). Values of T_1 in methanol at 29.8 Mc/s and 10.8 Mc/s in oxygen free, △ and under 1 atm of air, ●.

(ii) Relaxation Terms and Activation Energies

The independence of $1/T_1N$ of magnetic field variations in acetone and methanol, in contrast to that of water, indicates that either $AI.S.$ is zero or that both $\omega_S^2\tau_c^2$ and $\omega_S^2\tau_e^2$ are much less than unity. To verify either of these indications $1/T_1N$ was plotted vs. η/T. (Viscosity data, as for water, were obtained from the International critical tables (22).) If $1/T_1N$ is only a function of τ_e then a linear relationship should exist between the two quantities. The non-linear behavior, however, for both systems led to the conclusion that in all probability, $1/T_1N = \alpha\tau_c + B\tau_e$. The magnitude of τ_e and the extent of its variation were nevertheless expected to be small.

The large values of τ_e point to strong solvation or hydration and a large E_e, while small values ultimately involve a smaller activation energy. Since the oxygen molecule is nonpolar, but polarizable nevertheless, the contribution to hydrogen bond strength

For personal use only.

between the solvent and solute will depend chiefly on the polarity of the solvent cluster at any particular temperature. The decrease in the solvent cluster size should reduce the resultant polarity of the cluster and thus the hydrogen bond strength between solvent and solute.

CONCLUSION

It is concluded that the solvation of paramagnetic molecular oxygen in protonic solvents decreases the spin–lattice relaxation time by two mechanisms, a dipole–dipole and a hyperfine interaction. The extent of each depends on the capacity of polymeric cluster formation and the strength of the O_2–solvent hydrogen bond. In solvents where hydrogen-bonding potential is small, the dipole–dipole mechanism predominates, while the converse is true in solvents of higher hydrogen-bonding capacity. Because of the nonionic nature of the oxygen molecule, no disruption of solvent cluster formation is expected, and the dipole–dipole interaction is considered to be independent of the molecular oxygen size contribution.

ACKNOWLEDGMENTS

The author wishes to thank Professor M. Bloom for his generous contribution of time and equipment towards this study as well as for his many helpful suggestions and criticisms. Thanks is also extended to Mr. I. M. Kristensen for his assistance in the evaluation of the variability of τ_e^2.

REFINEMENT OF THE CRYSTAL STRUCTURE OF β-$Mg_2P_2O_7$

CRISPIN CALVO
Department of Chemistry, McMaster University, Hamilton, Ontario
Received September 14, 1964

The crystal structure of $Mg_2P_2O_7$ reported by Lukaszewicz has been refined by least squares analysis. Data of the *hkl* type with $0 \leqslant k \leqslant 6$ have been used to obtain improved atomic parameters. The central oxygen atom of the $P_2O_7^{-4}$ is found to have enhanced thermal motion in the plane perpendicular to the P—P vector. Thus the P—O—P bond angle appears to be linear in this phase because of a thermal averaging of the position of the central oxygen atom. This conclusion is in agreement with that obtained by Lazarev from infrared studies.

INTRODUCTION

β-$Mg_2P_2O_7$ is one of a series of chemically and crystallographically related pyrophosphate compounds. Included in this series are $Mn_2P_2O_7$, $Cu_2P_2O_7$, $Mg_2P_2O_7$, and $Zn_2P_2O_7$. Each of these pyrophosphates except that of Mn^{++} shows a phase transition. $Zn_2P_2O_7$ has a first order phase transition at 132 °C featuring an increase in symmetry from I*c* or I2/*c* and roughly a halving and a thirding of the *c*- and *a*-axes respectively (1). A further gradual phase transition was found at 155 °C and proposed to be of second order. No substantial change occurred in the lattice parameters across this transition but the crystal symmetry increased to *C*2/*m* beyond 155 °C. A phase transformation in $Cu_2P_2O_7$ is found at $\sim$72 °C with the space group changing from *C*2/*c* to *C*2/*m* (2). Here the *c*-axis is halved in passing through the transition.

An apparent first order phase transition was noted near 68 °C in $Mg_2P_2O_7$. The crystal parameters seemed to change discontinuously (3) and an enthalpy change of 729 cal/mole at the transition has been found (4). However, a detailed examination of the powder pattern suggested that a gradual phase transition occurs as did the fact that the specific heat anomaly was spread over more than 20° in temperature. Thus the true thermodynamic nature of the transition remains uncertain. The space group transition is from $B2_1/c$ (5) at room temperature to *C*2/*m* above the transition with a simultaneous having of the *a*- and *c*-axes.

Lazarev (6) has investigated the infrared absorption of $Mg_2P_2O_7$ from −150 to 150 °C. He found that the anion in the low temperatures phase showed a symmetry no greater than C_s or C_2 and suggested that the P—O—P bond angle was no larger than 160°. Further he concluded that in the high temperature form the central oxygen atom vibrates across a potential surface containing at least a double minima.

Because of the multiplicity of related phases, this system of pyrophosphates should be important in any attempt to "read" chemical bonding information from the geometry of the $P_2O_7^{-4}$. A correlation between these bond lengths and the $p\pi$–$d\pi$ bond order has been proposed by Cruickshank (7). He investigated the overlap possibilities of the available oxygen and phosphorus orbitals for the cases of a linear and nearly 120° P—O—P bond angle. Further delocalization to the cations was ignored. The two strongly coupled π-bonding systems that can occur in an isolated PO_4 group are found to differ in their ability to extend throughout the $P_2O_7^{-4}$. This ability is determined by the central bond angle. On a simple valence bond picture Cruickshank proposes that the outer P—O bond should have a bond order of 1.60 and the inner P—O bond a bond order 1.20

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in the case of a nearly 120° bond angle. In the linear case, these values are 1.53 and 1.40 respectively. From an assumed linear relationship of bond order to bond length one can predict bond lengths from bond order estimations and vice versa.

Lazarev (8) has proposed that the force constants obtained from molecular vibration studies are a more sensitive measure of the actual bond character. Based upon these constants he concludes that the magnitude of the central angle in pyro compounds should be a measure of the $p\pi$–$d\pi$ bonding. The influence of the cations on this bonding and, therefore, on the angle arises from the degree of covalency of the bond between the cation and the oxygen atoms. The greater the basic character of the cation, the smaller should be the covalency of the M—O bond which, in turn, favors a decrease in the X—O—X bond order and, therefore, a decrease in the bond angle. The influence of the cation on the nature of the bonding in the pyrophosphate anion can be monitored in a study of crystallography of the pyrophosphate compounds.

Lukaszewicz has shown the β-$Mg_2P_2O_7$ at 80 °C is isostructural with thortveitite (9) ($Sc_2Si_2O_7$). Unfortunately the rather large residual suggests an incomplete refinement. Further suggestive evidence has been provided by the resolution of the crystal structure of β-$Zn_2P_2O_7$ (10) where the central oxygen atom undergoes considerable enhanced motion. The resolution of the detail structure of β-$Mg_2P_2O_7$ is desirable because the low scattering power of the cation would permit the most reliable determination of the "true" shape of the $P_2O_7^{-4}$ in these high temperature phases.

EXPERIMENTAL

Crystals of $Mg_2P_2O_7$ doped with either Mn^{++} or Cu^{++}, for concurrent electron paramagnetic resonance (e.p.r.) work, were prepared by slow cooling of the melt obtained from the decomposition of precipitated $MgNH_4PO_4$ (11). These crystals consisted of thin plates of diamond cross section. The twofold axis lies parallel to the small diagonal and the plate face has a Miller index of (001).

The crystal chosen for study was Cu^{++} doped and had dimensions of 0.08 mm × 0.12 mm × 0.15 mm. Mo K_α radiation was used to minimize absorption effects. This crystal was also used in obtaining data on the α-phase whose crystal structure is presently being resolved. The lattice parameters were determined from films calibrated with TiO_2 lines (a = 4.594 Å, c = 2.959 Å) (12). The parameters obtained at ~ 95 °C were a = 6.494 ± 0.007 Å, b = 8.28 ± 0.01 Å, c = 4.522 ± 0.005 Å, β = 103.8 ± 0.1°, and z = 2. These values vary slightly from those reported by Lukazewicz. The X-ray extinctions of β-$Mg_2P_2O_7$ (I_{hkl} = 0 if $h + k$ = odd) restrict the space group choice to among $C2$, Cm, or $C2/m$. Electron paramagnetic resonance experiments with $Mg_2P_2O_7$:Mn^{++} (13) have shown only one active site above 64 °C and this result has been interpreted as indicating a space group symmetry of $C2/m$. The arguments supporting this are the same as were used in the discussion of the e.p.r. of $Zn_2P_2O_7$ (1). Supporting evidence for the e.p.r. method of establishing the space group has been provided by a recent complete investigation of the spectra of α-$Mg_2P_2O_7$:Mn^{++} (13). In this case the space group symmetry $B2_1/c$ is uniquely determined by the pattern of the scattered X-rays. This suggests that the e.p.r. spectra should show four Mn^{++} sites related in pairs by the mirror operation associated with the glide plane.

The crystal was heated to 95 ± 5 °C with a hair dryer inserted along the axis of the Weissenberg camera and photographs of the first seven layer lines about the b-axis were recorded using Mo K_α radiation. Photographs of the [100] and [001] zones were obtained with the precession camera. The intensities of these reflections, visually estimated, were corrected for Lorentz and polarization effects and converted into scaled structure factors. These data were directly inserted into a modified Busing, Martin, and Levy (14) least squares program with the atomic parameters obtained from two least square refinement cycles on the $h0l$ and $hk0$ data of Lukaszewicz. The value of the residual for these data had decreased from the reported value of 0.26 to 0.15 when the calculated structure factors were adjusted for anisotropic thermal vibrations of the atoms. The new data were substituted for those of Lukaszewicz and the refinement carried through until no further significant shifts in the atomic parameters were obtained. The weights were assigned by the method of Ibers (15). At this point the residual was 0.108 for the 340 observed reflections and 0.15 if the 148 unobserved reflections were included. The large number of unobserved reflections are due to the use of Mo K_α radiation combined with short exposure times (4 h). The electron density of the final structure projected onto the y = 0 plane is shown in Fig. 1.

The calculated and observed structure factors are compared in Table I. In Table II the positional parameters obtained in this study are compared with those obtained by Lukaszewicz. The largest change is seen to be a shift of about 0.2 Å in the position of O_{II}; significant shifts, however, are found for all other

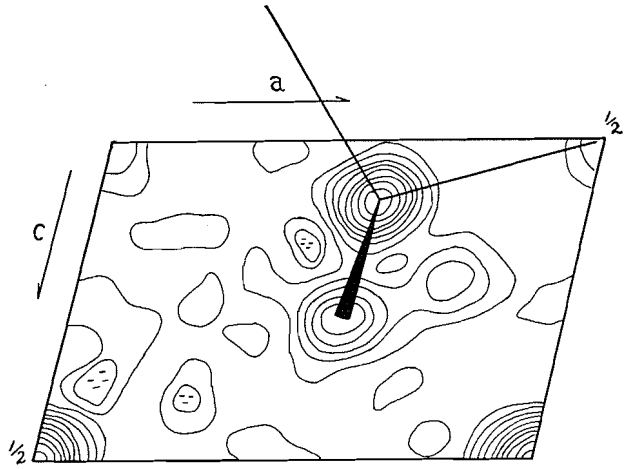

FIG. 1. Electron density projected onto the $y = 0$ plane. The electron density of β-$Mg_2P_2O_7$ is shown projected onto the $y = 0$ plane. The contours are at equal intervals and the regions of negative electron density are depicted with negative signs. The projected position of half of the anion is shown. O_I is at the origin and O_{II} falls outside of the cell boundary.

atoms (except O_I, of course). The new nonthermally adjusted bond distances are collected in Table III and the thermal parameters in the form of mean square displacements in Table IV. The magnitudes of these quantities clearly show the enhanced thermal activity of O_I. The direction of this thermal motion is in the plane perpendicular to the P—P vector with the major component along the *b*-direction. The motion of the other oxygen atoms are modest and restricted primarily to the *a*–*c* plane. These "raw" temperature parameters yield nonpositive definite values for some of the minors of the thermal matrix for every one of the atoms. This means that the effective thermal motion cannot be represented as an ellipsoid and this, in turn, may result from an absorption effect or from the nonharmonic nature of the thermal motion. That is, if we have a double well potential energy minima, we are attempting to represent a function of the form

$$\tfrac{1}{2}f_j\, e^{-\mathbf{H}\cdot B\cdot \mathbf{H}}\, e^{2\pi i \mathbf{H}\cdot(\mathbf{r}_j+\Delta\mathbf{r}_j)} + \tfrac{1}{2}f_j\, e^{-\mathbf{H}\cdot B\cdot \mathbf{H}}\, e^{2\pi i \mathbf{H}\cdot(\mathbf{r}_j-\Delta\mathbf{r}_j)}$$

by a function

$$f_j\, e^{2\pi i \mathbf{H}\cdot\mathbf{r}_j}\, e^{-\mathbf{H}\cdot B'\cdot \mathbf{H}},$$

where $\mathbf{H}$ is a reciprocal lattice vector, B is the thermal motion dyadic for the atom in the potential well and displaced from the average position by $\pm\Delta\mathbf{r}_j$, and B' the thermal parameter when the nature of the potential surface is ignored. Equating the two expressions permits us to relate B and B' as in

$$\mathbf{H}\cdot B'\cdot\mathbf{H} = \mathbf{H}\cdot B\cdot\mathbf{H} - \log\cos 2\pi\mathbf{H}\cdot\Delta\mathbf{r}_j.$$

Clearly the value of B' will not represent B very well. In the light of this discussion, it is clear that these thermal parameters have only qualitative significance if the thermal motion is a disordering. This would be consistent with the fact that the hyperfine lines of Mn^{++} are not resolved in $Mg_2P_2O_7$ until a temperature of 174 °C is reached (13).

The fact that so many of the U_{22} values are significantly negative might be suggestive of erroneous space group choice. In this regard an attempt was made to establish the space group by the more traditional means of seeking a solution within one of the subgroups of $C2/m$. Since the anion in α-$Mg_2P_2O_7$ nearly possesses a twofold axis, a refinement was sought in the $C2$ space group where the anion necessarily lies on the twofold axis. Trial parameters were manufactured from the atomic parameters obtained from the partially refined α-$Mg_2P_2O_7$ structure. The minimum residual obtained was 0.27.

PHASE TRANSITION

The temperature of the phase transition was determined by recording oscillation photographs while heating the crystal. In addition, by this experiment we hoped to determine whether the gradual phase transition reported by Roy *et al.* for a powdered sample

could be seen in a single crystal pattern. Again the same crystal used in the structure analysis was used for this study. Hour-long exposures were recorded at various temperatures with the camera slightly displaced between exposures. By this technique a transition was found to occur abruptly at 62 ± 1 °C. At 63.5 ± 1 °C, however, two patterns were found superimposed on, in particular, a $h2l$ type photograph. One pattern had lattice parameters similar to those of the β-phase whereas the second appeared contracted along the $(10\bar{1})$ direction. However, a one to one correlation existed between reflections of the two patterns. The coexisting phases reported by Hummel *et al.* (3) appears to involve two β-like phases with a much suppressed range of coexistence for our crystal.

Weissenberg photographs of the α- and β-phases for the [010] zone were superimposed on a single film. These showed the contraction of the β-angle with small changes in the lengths of the $\mathbf{b}_1$ and $\mathbf{b}_3$ axes. The major change was clearly seen to be a contraction along the $\mathbf{b}_1 + \mathbf{b}_3$ direction and an expansion along the $\mathbf{b}_1 - \mathbf{b}_3$ direction in reciprocal space. Further comments on the details of the phase transition will soon be published together with the crystal structure of α-$Mg_2P_2O_7$ and the e.p.r. study of the phase transition of $Mg_2P_2O_7$:Mn^{++}.

DISCUSSION

Since β-$Mg_2P_2O_7$ is an isostructure of $Sc_2Si_2O_7$ and β-$Zn_2P_2O_7$ and both of these structures have previously been discussed in some detail we will only comment on the relevant points of comparison. Again as in β-$Zn_2P_2O_7$ the central oxygen atom manifests enhanced thermal activity in the plane perpendicular to the P—P vector of the anion. Any reasonable correction for the effects of this motion will result in a substantially enlarged central P—O bond and thus lead to a significant difference between the terminal and inner P—O bond distance. Good agreement is found among the anion bond distances obtained for the refined structures of $Mn_2P_2O_7$ (16, 17), β-$Mg_2P_2O_7$, and β-$Zn_2P_2O_7$. The bond distances of β-$Zn_2P_2O_7$ are compared with those reported here in Table III.

The cation environment is an irregular octahedral arrangement of the oxygen atoms. The major distortions from a perfect octahedron arise from a rotational displacement of $\sim 30°$ of the O_{III}—O_{III}' pair from the ideal octahedral position and an elongation of the Mg—O_{III}' bond as compared to the other cation oxygen bond distances. The mean positions of O_{II} and O_{III} are found to lie very nearly in the same plane as the two cations and phosphorus to which it is ligated. This suggests the possibility of sp^2 hydribization of the oxygen atoms with a lone p_z orbital available for π-bonding to the cation. Such a contribution would of course change the amount of $p\pi$–$d\pi$ bonding within the anion. This structural feature, which is common to these β-phase pyrophosphates, implies that electron delocalization between the cation and the anion can play a significant role in the detailed properties of the individual compounds. The only crystallographic suggestion of such a possibility lies in the fact that the average nonthermally corrected average P—O bond distance exceed the predicted value of 1.54 Å for an isolated anion. This value, when corrected for thermal motion, would probably lie significantly outside the range of error.

It appears that the phase transformations are triggered or at least paralleled by an enhanced disorder for the central oxygen atom. Whether this is actually a time disordering or a positional disorder is at present immaterial. The wide dispersion found in the transition temperatures of the four phases together with the similar but unique low temperature phases implies that indeed the cations play a role in the bonding beyond what is generally implied in terms of their effective size and charge. Unfortunately questions like the nature of the disordering, thermal corrections, and a more definitive manifestation of the role of the environment must await the resolution of the α-structures in this series.

THE CRYSTAL STRUCTURE AND PHASE TRANSITIONS OF β-$Zn_2P_2O_7$

CRISPIN CALVO
Department of Chemistry, McMaster University, Hamilton, Ontario
Received August 13, 1964

ABSTRACT

β-$Zn_2P_2O_7$ crystallizes in the $C2/m$ space group with lattice parameters $a = 6.61 \pm 0.01$ Å, $b = 8.29 \pm 0.01$ Å, $c = 4.51 \pm 0.01$ Å, $\beta = 105.4° \pm 0.2°$ and $z = 2$. The anion, $P_2O_7^{-4}$, is centered with its mirror plane coinciding with the mirror plane of the space group. The central oxygen atom, however, shows high anisotropic thermal motion and thus it appears that the P—O—P bond angle is linear only as a result of thermal averaging. The cations are found on twofold axes in irregular sixfold coordination and these ZnO_6 groups share three edges with neighboring cations. This cation coordination is, therefore, consistent with that predicted from the red emission of β-$Zn_2P_2O_7$:Mn^{++}.

INTRODUCTION

An investigation of the structures of the α- (low temperature) and the β-forms (high temperature) of $Zn_2P_2O_7$ was undertaken (*a*) to determine whether the correlation found between the cation coordination and the luminescence of the Mn^{++}-activated zinc orthophosphate (1, 2) could be extended to zinc pyrophosphate and (*b*) to determine the structural nature of the reported phase transition between the α- and β-phases (3). Additional impetus for this study has been provided by Cruickshank's study of the relationship of the P—O bond length and the π-bonding through the 3d orbitals of the phosphorus (4). In this paper, we will deal primarily with the crystal structure of β-$Zn_2P_2O_7$ although some comment on related phases will be necessary.

The pyrophosphate of Zn, Mg (5), Cu (6), and Mn (7) have isostructural high temperature forms and save for $Mn_2P_2O_7$ related but distinct low temperature structures. No phase transition has been found in this latter compound above −60 °C. Qualitatively the *c*-axes of the unit cells of the low temperature phases of Zn, Mg, and Cu are twice that of the high temperature structure and the *a*-axes are thrice; twice and the same length as found for the β-cells, respectively. The lengths of the *b*-axes and the β-angles remain substantially the same through the transition. The space group symmetry is lowered from $C2/m$ to Ic (8), $B2_1/c$ (9), and $C2/c$ (6) respectively for unit cell axes chosen parallel to those of the high temperature cells. In addition to the reversible first order phase transition at 132° in $Zn_2P_2O_7$ a gradual (in temperature) transition has been identified near 155 °C by electron paramagnetic resonance (e.p.r.) studies (10). In $Mg_2P_2O_7$ a gradual phase transition near 68 °C was reported by Roy, Middleswarth, and Hummel (11) and recently confirmed by the specific heat measurements of Oetting and McDonald (12). However, the changes in the unit cell symmetries of $Mg_2P_2O_7$ do not readily support the type of phenomena reported in $Zn_2P_2O_7$. Larazev (13–16) has extensively studied the infrared adsorption of pyrocompounds and has proposed a thermal excitation across a double well potential barrier to explain the phase transition in $Mg_2P_2O_7$. No such study has been reported for $Zn_2P_2O_7$. Further comment on the relevance of these studies to the results reported here will be presented below.

Previous crystallographic studies of pyrophosphate structures have indicated that the geometric configuration of the $P_2O_7^{-4}$ ion is not independent of the environment in which it appears. For example, the P—O—P bond is 133.6° in $Na_4P_2O_7.10H_2O$ (17) with inner and average outer P—O bond lengths of 1.61 Å and 1.51 Å respectively. In ZrP_2O_7

For personal use only.

(18, 19) the P—O—P bond angle appears to be fixed by the crystal symmetry at 180°; the inner P—O bond length is 1.56 Å and the outer 1.52 Å. Studies by Larazev (13), however, indicated a phase transition in this compound near 300 °K and thus a further crystallographic examination is indicated. The structure of β-$Zn_2P_2O_7$, to be discussed here, appears to have a linear P—O—P bond fixed by the crystal symmetry. A similar result has been obtained in the partial resolution of the crystal structures of β-$Mg_2P_2O_7$ (5) and $Mn_2P_2O_7$ (7). It will be shown that the enhanced thermal motion of the central oxygen atom suggests that the bond is, in fact, bent, but appears linear as a result of the thermal motion.

EXPERIMENTAL

Crystals of $Zn_2P_2O_7$ were prepared by crystallization from a melt obtained from the decomposition of precipitated zinc ammonium phosphate. These crystals had their (110), (001), and (10$\bar{1}$) faces sufficiently developed to permit optical alignment. Photographs of both the α- and β-forms were obtained with the Weissenberg camera using Cu K_α and Mo K_α radiation. To obtain photographs from the β-form, the crystals were heated by a soldering iron placed on the axis of the camera at a distance of about 2 mm from the crystal. In later experiments, the crystals were heated by the air flow from a pair of hair dryers arranged in series. The temperatures were estimated from e.m.f. readings from a thermocouple attached to the collimator and placed near the crystal. Temperature stabilities of the order of ±2 °C in an hour could easily be maintained with this hair dryer technique.

The lattice parameters for the β-phase were obtained from photographic films calibrated with reflections from the identical crystal in the α-phase. The parameters for the α-phase, $a = 19.59$ Å, $b = 8.28$ Å, $c = 9.103$ Å and $\beta = 100.17°$, have been obtained by deWolff (20) from powder data. Note that on the basis of this cell the α-space group would be face centered rather than body centered as indicated above. The lattice parameters obtained for the β-phase are, $a = 6.61 \pm 0.01$ Å, $b = 8.30 \pm 0.01$ Å and $c = 4.51 \pm 0.01$ Å and $\beta = 105.4°$. From the measured density for the α-phase, 4.1 g/cm^3, it was concluded that the β-phase had two molecules per unit cell. Only those reflections labelled by hkl with $h + k =$ odd were systematically absent and thus the space group must lie among the choices $C2$, Cm, or $C2/m$. The centric space group was chosen on the basis of e.p.r. experiments (10). In this space group the cation, the phosphorus atom, and at least 6 of the 14 oxygen atoms must be located in special positions. The special position for the cation is on the twofold axis and, in addition, all the cations are either translationally equivalent or related by the inversion operation. The magnetic moment tensor is invariant to these operations and thus only one e.p.r.-active site should be seen in the spectrum. Such was the case for $Zn_2P_2O_7$ above $\sim$ 155 °C. This method of establishing the space group is to be contrasted with the traditional crystallographic method. Customarily, one attempts a refinement of the crystal structure separately in each of the possible space groups. Ideally, all these refinements should ultimately lead to the same "correct" structure. Such a precedure was applied to $Sc_2Si_2O_7$ (21), an isostructure of β-$Zn_2P_2O_7$, with the result that chemical considerations ultimately were necessary for the resolution of the space group symmetry.

Historically, work was first begun on the structure of α-$Zn_2P_2O_7$. The Patterson functions prepared from the $h0l$ data and $hk0$ data strongly suggested the existence of a superstructure. Once the lattice parameters and space group had been established for the β-$Zn_2P_2O_7$ phase, these Patterson functions were interpreted for a trial structure for the β-phase. This trial structure consisted of cations on the twofold axis, related in pairs by the mirror plane, in an octahedral environment of oxygen atoms. Each of these ZnO_6 groups shares three edges with three neighboring cations. These cations are related to it by the mirror plane and the C-centering and this arrangement extends as sheets along the x- and y-directions. These ZnO_6 groups form a hexagonal network similar to that found in $CdCl_3$ (see Wells (22), Fig. 51 (*iii*)). Adjacent sheets are held by the $P_2O_7^{-4}$ groups. The anion, of course, consists of a pair of corner-shared PO_4 groups. As a trial arrangement these $P_2O_7^{-4}$ groups were placed on the mirror plane with the central oxygen atom at the origin in a manner which proved to be analogous to the thortveitite structure. This trial structure, seen in Fig. 1, was used in subsequent refinements.

The crystals selected for intensity measurements had dimensions of the order of 0.1 mm × 0.1 mm × 0.15 mm. Data of the type hnl with $n = 0$, 1, and 2 were recorded with Cu K_α and Mo K_α radiation. In addition, data indexed as $hk0$, $0kl$, and hhl were also recorded with Mo K_α radiation. The temperature of the crystal was not monitored while the intensity photographs were taken. However, the heating elements were arranged in a manner that yielded temperatures well above 160 °C in previous experiments. These reflections were visually estimated and these data, suitably corrected for Lorentz and polarization effects, were used in a detailed refinement of the crystal structure. Early refinements used only Fourier and difference Fourier techniques. Recently an IBM-7040 (20K) became available and thus the final refinements were carried out on this unit with a modified Busing, Martin, and Levy least squares program (23). Weights were assigned to the structure factors according to the criterion suggested by Ibers (24). In this procedure

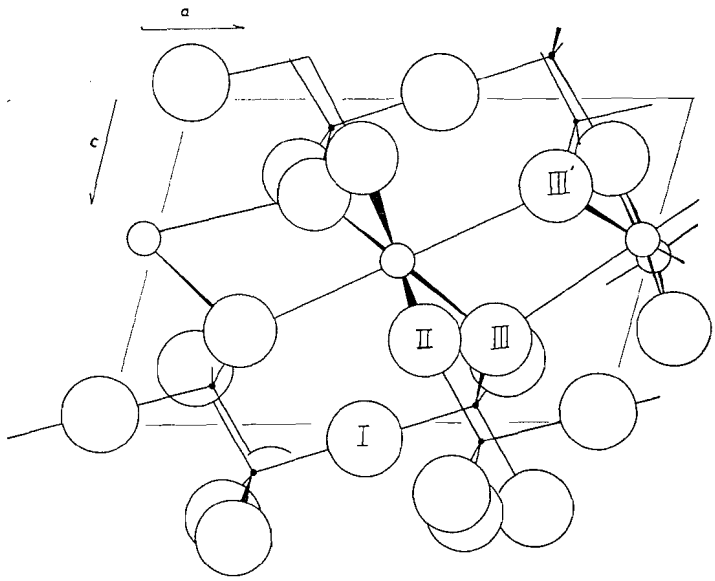

FIG. 1. A view of structure of β-$Zn_2P_2O_7$. The large circles represent the oxygen atoms, the full circles the phosphorus atoms, and the small open circles the cations. No attempt has been made to represent the motion of O_I. The axial directions are represented on the figure.

weights are assigned according to values determined from a curve of the standard deviation versus F_{obs} for multiply observed reflections. Least squares refinements were also carried through with unit weights and weights as suggested by Hughes (25). Some of the results of these refinements will be discussed below. The final R-factor for all 217 unique reflections is 0.137 and for the observed reflections only, it is 0.098. The observed and calculated structure factors are compared in Table I. The atomic parameters, including both positional and thermal coordinates are collected in Table II.

Crystals of $Zn_2P_2O_7$ were studied through the range of temperatures corresponding to the two reported phase transitions. Oscillation photographs were taken with a crystal rotating about the [110] axis near 132 °C to ascertain whether the halving of the c-axis and the thirding of the a-axis occurred simultaneously. Both changes occurred at 132 ± 1 °C. The transition near 155 °C was more difficult to detect since the unit cell dimension and extinctions remain the same. Two 180° oscillation photographs were superimposed on the same film with the camera displaced translationally by 2 mm between exposures. These exposures were of equal duration (4 h); the first was taken with the temperature maintained between 135 and 145 °C and the second with the temperature above 160 °C. The crystal was disaligned by about 2° to prevent the reflections from superimposing on the photograph. The intensities from the crystal at the lower temperatures were found to be more diffuse and, except for the stronger intensities, this set was found to be of consistently weaker intensity.

DISCUSSION

The cations in this structure are coordinated irregularly to six oxygen atoms. Although the Zn^{++} lies on the twofold axis they are not at the center of the oxygen atom environment. In fact, the Zn^{++} lies displaced by about 0.3 Å from a line joining $O_{III'}$ to its mate generated by the twofold axis. This, no doubt, results from the fact that the y-parameter for $O_{III'}$ is fixed by the requirements of the bonding to the phosphorus atom and the existence of the mirror plane. The $O_{III'} - O_{III''}$ separation is 2.59 Å, a distance of approach too small for neighboring Zn^{++}. The distance actually found between the cations along the b-axis is 3.17 Å, a somewhat shorter distance than that found between cations related by C-centering (3.44 Å). The cation–oxygen atom bond lengths are 2.06 Å, 2.00 Å, and 2.27 Å for the cation to $O_{II'}$ O_{III}, and $O_{III'}$ displacements respectively with no correction applied for correlated thermal motion. The oxygen atom environment

about the cation deviates substantially from that of a perfect octahedron. The major component of these distortions arises from a rotation of the O_{III}—O_{III}''' edge from its ideal position by $\sim 30°$ about the twofold axis. Such a distortion arises from the constraints placed upon the positions of the oxygen atoms by the requirements of its bonding to the phosphorus atom.

TABLE III

Bond distances and angles

Bond distances, Å		Bond angles, °	
ZnO_6 group			
Zn—O_{II}	2.061		
Zn—O_{III}	2.001		
Zn—O_{III}'	2.275		
P_2O_7 group			
P—O_I	1.569	O_I—P—O_{II}	102.1
P—O_{II}	1.556	O_I—P—O_{III}	110.0
P—O_{III}	1.554	O_{II}—P—O_{III}	110.9
O_I—O_{II}	2.430	O_{III}—P—O_{III}'	112.6
O_I—O_{III}	2.558		
O_{II}—O_{III}	2.561		
O_{III}—O_{III}'	2.586		

The pyrophosphate ion is also quite irregular. The three unique uncorrected P—O bond lengths are P—O_I = 1.569 Å, P—O_{II} = 1.557 Å, and P—O_{III} = 1.554 Å with estimated standard deviation (e.s.d.) of 0.005 Å, 0.019 Å, 0.013 Å, respectively. See Table III. These distances cannot be used directly to estimate $p\pi$–$d\pi$ bond character since the thermal motions of the atoms are high and probably highly correlated. The large values of thermal parameters for the central oxygen atom in the plane perpendicular to the P—P vector indicates that the P—O—P bond is essentially non-linear. It is not at all clear whether the motion is real or represents a statistical disordering in the order–disorder sense, and if real whether it represents vibrational or rotational motion.

For any of the proposed sources of the high thermal parameters of the central oxygen

For personal use only.

atom, the apparent P—O_I bond length will be significantly shorter than the true internuclear distance. The effect of the apparent thermal motion on the other P—O bonds will be much smaller. The structure thus appears to manifest different distances for the inner and outer P—O bonds. However, the difference is not as large as found in $Na_4P_2O_7.10H_2O$.

The value obtained for the P—O_{II} bond distance is very sensitive to the details of the weighting used. If constant weights are used the value is 1.48 Å whereas with weights assigned as suggested by Hughes a value of 1.51 Å is obtained. In general, except for the position of O_{II} all the atoms lie within the range determined from the sum of the e.s.d. These latter quantities are about 50% higher than the values shown in Table II for these two weighting schemes.

A detailed analysis of the effect of the thermal motion on the "true" bond lengths is not feasible without a better knowledge of the molecular source of this motion. It may be that β-$Zn_2P_2O_7$ features a disordering of the central oxygen atom across a double well potential as has been suggested for the phase transition in $Mg_2P_2O_7$ (15). In this latter case the specific heat anomaly, according to Tisza (26) is suggestive of an entropy-driven anomaly. The transition of the second kind found at 155 °C in $Zn_2P_2O_7$ together with the line broadening (10) would be consistent with the requirement of continuity for this type of transition (27) arising from a positional disordering of a bent $P_2O_7^{-4}$ ion. A better representation for the structure would then be a split central oxygen atom, the details of which would be determined by the anion configuration found for the α-$Zn_2P_2O_7$ phase. It seems prudent to postpone any attempt to analyze the $p\pi$–$d\pi$ bond character in the anion, the role of the environment together with the nature of the disorder until the low temperature structure is resolved.

This investigation further substantiates the correlation between the red emission of Mn^{++} and the octahedrally coordinated site in phosphate systems. In this case e.p.r. evidence proves that the Mn^{++} substitutes directly for the cation. Hummel and Katnack (28) have determined the emission intensity versus wavelength for α-$Zn_2P_2O_7$. This emission peaks at 6 900 Å but the emission curve appears to be composed of at least two major peaks. In the case of β-$Zn_2P_2O_7$:Mn the emission is definitely red under X-ray bombardment but no details of the curve shapes are available.

SPECTRES INFRAROUGES DE COMPOSÉS RICHES EN AZOTE

MÉÜDE TREMBLAY
Centre Canadien de Recherches et Perfectionnement des Armes, Québec, Québec
Reçu le 3 décembre 1964

RÉSUMÉ

L'étude des spectres infrarouges des dérivés de la guanidine et du tétrazole obtenus par synthèse a permis de vérifier leur structure. Les sels suivants de diazotétrazole, contenant de 72 à 86% d'azote, ont été préparés; le sel d'aminoguanidine, de triaminoguanidine, de cyanoguanidine, d'aminotétrazole et de diaminotétrazole.

INTRODUCTION

Les substances qui contiennent un haut pourcentage d'azote sont habituellement très instables et difficiles à caractériser. Les groupes azotés présents peuvent pour la plupart être déterminés par spectrophotometrie infrarouge permettant d'établir la structure des composés qui les contiennent.

Au cours du présent travail nous avons tenté la synthèse de diazocyanures (—N=N—CN). Le guanidinyldiazocyanure (NH_2—C(=NH)—NH—N=N—CN) a été synthétisé à partir de l'azide d'amidine (1). Nous avons essayé de synthétiser le cyanoguanidinyl diazocyanure et le nitroguanidinyl diazocyanure. Nous croyions pouvoir former le dérivé cyano à partir de l'azide de cyanamidine (2) et de l'acide cyanhydrique. D'autre part le dérivé nitro aurait dû se former à partir de l'azide de nitroamidine (3) et l'acide cyanhydrique. Le dérivé cyano n'a pas été isolé et la structure du 5-cyanamidotétrazote formé à été étudiée à l'aide de son spectre infrarouge. Le produit obtenu à partir du dérivé nitro a été identifié comme étant du 5-nitroaminotétrazole.

Nous avons synthétisé une autre série de composés à partir du sel de potassium du diazotétrazole et de substances riches en azote tels que l'aminoguanidine, la triaminoguanidine, la cyanoguanidine, le 5-aminotétrazole et le 1,5-diaminotétrazole.

SPECTRES INFRAROUGES

Nous avons déterminé les spectres infrarouges du diazocyanure de guanidine et du bis-diazoguanidinyl diazotétrazole. Le spectre de diazocyanure de guanidine est donné dans la littérature (4) mais le spectre de son dérivé, le bis-diazoguanidinyl-diazotétrazole n'est pas décrit. Le premier spectre fut déterminé dans un but d'identification et aussi dans l'intention de le comparer à nos dérivés diazocyanures. Le dérivé bis-diazoguanidinyl-diazotétrazole d'autre part a été comparé à nos sels de diazotetrazole. Nous avons aussi déterminé le spectre du produit isolé à partir de l'azide de cyanamidine et de l'acide cyanhydrique, les spectres du 1,5-diaminotétrazole et des sels de diazotétrazole. Nous voulions ainsi confirmer leur structure et éventuellement les caractériser.

Notre attention s'est porté plus particulièrement sur la région de 3 800 à 500 cm^{-1}, où apparaissent les bandes dues aux groupement azotés. D'après la littérature (4, 5) le groupe imino (C=NH), la double liaison azote (—N=N—) et l'anneau du tétrazole (—CN_4H) ont des bandes d'absorption infrarouges caractéristiques. Une bande relativement forte entre 1 620 et 1 650 cm^{-1} est attribuée au groupe imino, des bandes très fortes et très étroites dans la région de 1 575 à 1 630 cm^{-1} caractérisent la double liaison azote–azote, et trois bandes d'à peu près la mêne intensité entre 975 et 1 150 cm^{-1} sont carac-

téristiques de l'anneau tétrazolique. Les bandes caractéristiques observées chez les produits étudiés sont données dans le Tableau I.

TABLEAU I

Frequences d'absorption (en cm^{-1}) des composés étudiés

Composés	N—H	C≡N	C=NH	NH_2	N=N	Tétrazole
Guanidinyl diazocyanide (4)	3 325, —	2 300	1 655	1 640	1 575	
5-Cyanamidotétrazole	3 325, —	2 300				— , 1 065, 1 030, 980
1,5-Diaminotétrazole	3 325, 3 325			1 640		1 110, 1 075, 1 000, —
Bis-diazoguanidinyl-diazotétrazole	3 325, —		1 680	1 640	1 570	1 095, 1 045, — —
Sel de diazotétrazole						
Aminoguanidine	3 450, 3 125		1 667		1 600	1 120, 1 065, 1 010, —
Triaminoguanidine	3 325, 3 225		1 680	1 640	1 600	— , 1 035, 1 010, 1 000
Diaminotétrazole	3 325, 3 125			1 640	1 587	1 115, 1 085, 1 010, —

Le produit de la réaction de l'azide de cyanamidine et de l'acide cyanhydrique donne un spectre infrarouge possédant une bande de forte intensité à 2 300 cm^{-1} attribuable à un groupe CN, et trois bandes de même intensité à 980 et 1 030 et 1 065 cm^{-1} qui indiqueraient la présence d'un anneau tétrazolique. Au surplus la bande située à 3 325 cm^{-1} serait dûe aux vibrations du groupe NH. L'étude spectrographique, la méthode de synthèse et l'analyse élémentaire nous porte à croire que ce composé est le 5-cyanamidotétrazole formé par cyclisation de l'azide de cyanamidine.

Le spectre obtenu du 1,5-diaminotétrazole se caractérise par une bande double à 3 225 et 3 325 cm^{-1}, attribuable aux vibrations NH, une autre bande à 1 640 cm^{-1} dûe aux groupes amino et trois petits pics 1 000, 1 075 et 1 110 cm^{-1} caractéristiques de l'anneau tétrazolique. Sa méthode de formation à partir du 1-benzalamino-5-aminotétrazole et son analyse spectrale sont en accord avec la structure proposée.

Tous les sels de diazotétrazole étudiés dans l'infrarouge ont donné des spectres possédant une forte bande entre 1 570 et 1 600 cm^{-1} attribuable au groupe diazo venant du diazotétrazole. Les bandes à 3 450 et 1 667 cm^{-1} du spectre du sel d'aminoguanidine étaient caractéristiques des groupements NH_2 et C=NH respectivement. Le spectre du sel de triaminoguanidine possède des bandes à 3 325, 1 680 et 1 640 cm^{-1} caractéristiques de la triaminoguanidine. De même le spectre du sel de diaminotétrazole révèle des bandes à 3 325, 3 125 et 1 640 cm^{-1} dûes aux groupements amino. L'analyse des spectres des sels de diazotétrazole, la solubilité de ces produits dans l'eau et l'analyse élémentaire des composés isolés nous porte à croire que nous sommes en présence de sels formés par double échange du potassium avec les dérivés de la guanidine ou du tétrazole selon le cas. Par exemple le chlorohydrate de triaminoguanidine et le sel de potassium du diazotétrazole donne le bis-triaminoguanidinium-5,5′-diazotétrazole sans perte de groupement fonctionnel, au contraire du composé suivant qui pendant la réaction perd un groupe cyano.

Le spectre du bis-diazoguanidinyl diazotétrazole préparé d'après la méthode de Thiele (6, 7) a été étudié dans le but de déterminer si dans ce cas nous sommes en présence d'un sel de diazotétrazole. Nous remarquons dans ce spectre l'absence de la bande à 2 300 cm^{-1}, ce qui indiquerait la disparition du groupe C≡N dans le diazocyanure de guanidine de départ.

Une comparaison de ce spectre avec celui du diazocyanure de guanidine décrit dans

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

la littérature (4) indique la présence du diazotétrazole en plus de l'absence du groupe C≡N. D'après l'analyse élémentaire, la nature non-ionique du produit et l'insolubilité dans l'eau, nous croyons que le radical diazoguanyl s'est substitué sur l'anneau de tétrazole par élimination de KCN et formation du composé suivant:

$$NH_2—C(=NH)—NH—N=N—N_4C—N=N—CN_4—N=N—NH—C(=NH)NH_2$$

le 1,1′-diazoguanyl-5,5′-diazotétrazole, tout comme l'avait supposé Thiele (1).

PARTIE EXPÉRIMENTALE

Technique générale

Les points de fusion ont été déterminés sur le "Melt-Pointer Vanderkamp" (Scientific Glass Apparatus Co., Inc.) et ne sont pas corrigés.

Les analyses élémentaires ont été faites par le Dr. C. Daessle, 5757 ave Decelles Montreal, Canada.

Les produits de départs excepté le sel de potassium du diazotétrazole et le 1,5-diaminotétrazole sont vendu dans le commerce. Le sel de potassium fut obtenu d'après la méthode de Thiele (6, 7) et le 1,5-diaminotétrazole connu sous forme de dérivé benzal (8) a été isolé comme amine libre par hydrazinolyse. Le contenu en azote des sels de diazotétrazole formés variait entre 72 et 86%.

Les spectres infrarouges ont été déterminés à l'aide du spectrographe Perkin–Elmer, Modèle 21, en pulvérisant des échantillons de 10 à 30 mg dans l'huile Nujol. Il n'a pas toujours été possible d'obtenir des échantillons très finement pulvérisés, en raison de la sensibilité de certains sel à la friction, mais en variant la concentration de l'échantillon il a été possible de minimiser l'effet de dispersion de la lumière et de choisir les meilleures courbes.

5-Cyanamidotétrazole

(a) On ajoute goutte à goutte une solution d'azide de cyanamidine (28.5 g, 0.25 mole) dans l'acide chlorhydrique dilué (25 g d'HCl dans 100 ml d'eau) et refroidi à 0 °C à une solution de KCN (16.2 g dans 50 ml d'eau). Lorsque le mélange est complété à température de la pièce, on extrait trois fois à l'éther. Par refroidissement de la solution aqueuse, on obtient 7.2 g de solide qu'on recrystallise de l'eau. Rendement 25.2%; p.f. = 147 °C.

Anal. Calc. pour $C_2H_2N_6$: C, 21.8; H, 1.8; N, 76.3. Trouvé: C, 22.0; H, 2.06; N, 75.9

(b) On dissout l'azide de cyanamidine (10 g, 0.09 mole) dans l'éther, dans laquelle on fait barboter l'acide cyanhydrique gazeux (27 g, 0.09 mole). Après évaporation de l'éther et crystallization de l'eau, 8 g de solide fondant à 147 °C sont obtenus. Rendement 80%.

Anal. Calc. pour $C_2H_2N_6$: C, 21.8; H. 1.82; N, 76.3. Trouvé: C, 22.5; H, 2.06; N, 75.6.

1,5-Diaminotétrazole

On dissout le 1-benzalamino-5-aminotétrazole (2.0 g) préparé d'après la méthode de la littérature (6) dans l'alcool éthylique absolu (25 ml). Après l'addition d'hydrazine anhydre (95%+, 1 g) on chauffe à reflux pendant 24 h. Le mélange après concentration et refroidissement donne, une fois recrystallisé, 0.7 g de solide (rendement de 80%); p.f. = 187–188 °C.

Anal. Calc. pour CH_4N_6: C, 12.0; H, 4.03; N, 83.9. Trouvé: C, 11.9; H, 3.81; N, 84.3.

Sel d'aminoguanidine du 5,5′-diazotétrazole

On ajoute une solution du sel de potassium du diazotétrazole pentahydraté (3.32 g, 0.01 mole) dans l'eau (10 ml) à une solution aqueuse de nitrate d'aminoguanidine (2.74 g, 0.02 mole). Le solide jaune obtenu est crystallisé de l'eau jusqu'à ce que la solution mère soit libre de nitrate; p.f. = 209 °C.

Anal. Calc. pour $C_4H_{14}N_{18}$: C, 15.3; H, 4.49; N, 80.2. Trouvé: C, 16.7; H, 5.0; N, 78.7.

Sel de triaminoguanidine du 5,5′-diazotétrazole

On mélange une solution de sel de potassium du diazotétrazole pentahydraté (3.32 g, 0.01 mole) dans l'eau (10 ml) à une solution aqueuse (10 ml) du chlorhydrate de triaminoguanidine (2.88 g, 0.02 mole) préparé d'après une méthode connue (9). Après plusieurs cyrstallisations de l'eau et élimination complète du chlorure, le solide obtenu, légèrement jaune, fond à 190 °C.

Anal. Calc. pour $C_4H_{18}N_{22}$: C, 12.9; H, 4.85; N, 82.3. Trouvé: C, 12.6; H, 4.5; N, 82.6.

Sel de cyanoguanidine du 5,5′-diazotétrazole

On mélange une solution de cyanoguanidine (1.68 g, 0.02 mole) dans 50 ml d'eau à une solution de sel de potassium du diazotétrazole pentahydraté (3.32 g, 0.01 mole). Le mélange est acidulé par addition d'acide chlorhydrique (1.7 cc d'HCl conc.). Par refroidissement un solide crystallise; p.f. = 195 °C avec décomposition. Le mélange de ce composé avec le bis-diazoguanyl-5,5′-diazotétrazole fondant à la même température et préparé par Thiele (1) fondait à 179 °C.

Anal. Calc. pour $C_6H_{10}N_{18}$: C, 21.5; H, 3.01; N, 75.4. Trouvé: C, 21.5; H, 3.8; N, 74.8.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Sel de 5-aminotétrazole du 5,5'-diazotétrazole

On mélange les solutions aqueuses du sel de potassium du diazotétrazole (3.32 g, 0.01 mole) et du chlorhydrate d'aminotétrazole (2.4 g, 0.02 mole). Le solide obtenu crystallise de l'eau; p.f. = 150 °C avec décomposition.

Anal. Calc. pour $C_4H_8N_{20}$: C, 14.2; H, 2.39; N, 83.3. Trouvé: C, 14.6; H, 2.9; N, 83.2.

Sel de 1,5-diaminotétrazole du 5,5'-diazotétrazole

On mélange une solution de sel de potassium du diazotétrazole (0.83 g) dans l'eau à une solution de 1,5-diaminotétrazole (0.59 g) dans HCl dilué (0.5 ml HCl dans 25 ml d'eau). Le solide obtenu crystallise de l'eau; p.f. = 176 °C.

Anal. Calc. pour $C_4H_{10}N_{22}$: C, 13.1; H, 2.61; N, 84.6. Trouvé: C, 13.0; H, 2.7; N, 85.0.

APPLICATION OF THE EXTENDED HAMMETT RELATIONSHIP TO THE IONIZATION CONSTANTS OF SUBSTITUTED ANTHRANILIC ACIDS[1]

P. LEGGATE[2] AND G. E. DUNN
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received November 30, 1964

ABSTRACT

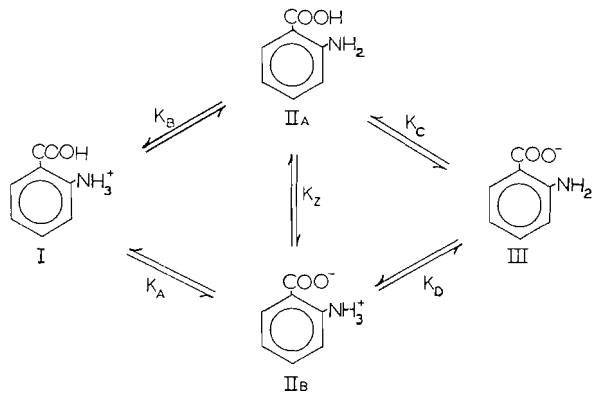
The overlapping ionization constants of the carboxyl and amino groups in 14 substituted anthranilic acids have been determined by a spectrophotometric method. The results have been fitted to the extended Hammett relationship $\log K_1K_2/K_1^0K_2^0 = \rho_1\sigma_A + \rho_2\sigma_B$, where A and B refer to ionization of the carboxyl and amino group, respectively. The values of ρ_1 and ρ_2 so obtained have been used to estimate K_Z^0, the equilibrium constant for ionization of neutral anthranilic acid to zwitterion.

An earlier paper (1) described an investigation of the rates of decarboxylation of 4- and 5-substituted anthranilic acids in nitrobenzene. Recently a parallel study of the decarboxylation of substituted salicylic acids in nonaqueous solvents has been performed (2). The extension of this work to the decarboxylation of anthranilic acids in water requires, as a first step, the determination of the two overlapping ionization constants of the acids. The complex character of the ionization equilibria of such acids in aqueous solution provides the opportunity for a somewhat unusual application of a linear free energy relationship.

THE HAMMETT EQUATIONS

In aqueous solutions of anthranilic acids there are assumed to exist four ionic and molecular species in equilibria (3, 4). These are shown in the diagram below with the accompanying hydronium ions omitted.

[1]



The ionization constants K_1 and K_2, which are obtained experimentally, define the equilibria:

[2] $$RH_2^+ \overset{K_1}{\rightleftarrows} RH + H^+,$$

[3] $$RH \overset{K_2}{\rightleftarrows} R^- + H^+.$$

[1]*Presented at the 1962 Chemical Institute of Canada Conference, Edmonton, Alberta.*
[2]*N.R.C. Postdoctorate Fellow, 1960–1962.*

RH_2^+ and R^- are the species I and III, respectively, of eq. [1], RH is a mixture of zwitterion, $RH^{\pm}$ (II*B*), and 'non-zwitterion', RH^0 (II*A*). However, in the equilibria of eqs. [2] and [3], RH can be treated as a single species since the ratio of $RH^{\pm}$ to RH^0 is independent of pH.

The experimental ionization constants K_1 and K_2 are related to the 'true' constants K_A, K_B, K_C, and K_D by the equations:

$$K_1 = K_A + K_B, \quad [4]$$

$$1/K_2 = 1/K_C + 1/K_D, \quad [5]$$

$$K_1K_2 = K_AK_D = K_BK_C. \quad [6]$$

Furthermore,

$$K_Z = \frac{K_A}{K_B} = \frac{K_C}{K_D}, \quad [7]$$

where

$$K_Z = \frac{[RH^{\pm}]}{[RH^0]}.$$

For a series of substituted anthranilic acids, each of the ionization constants K_A, K_B, K_C, and K_D should obey a Hammett relationship. If, however, there is strong hydrogen bonding between the amino and carboxyl groups, then two electronic pathways are available for transmitting the substituent effect. The extension of the Hammett equation to reaction series of this type has been discussed by Jaffe (5) who proposes the use of an equation of the form:

$$\log \frac{K}{K^0} = \rho_1\sigma_1 + \rho_2\sigma_2. \quad [8]$$

This equation provides the means of estimating the relative importance of the two possible electronic paths in reactions in which, either two side chains react with one another, or the site of reaction is linked to the benzene ring at two points. The ionization of ortho-substituted benzoic acids represents a special case of the latter type. In this special case a hydrogen bond provides one of the two electronic pathways and a distinction can be made between a 'direct' substituent effect and an 'indirect' (and presumably less potent) effect exerted through the hydrogen bond. Jaffe showed (5) that, among the acids so far investigated, only the *o*-(hydroxymethyl)-benzoic acids provide evidence of a significant 'indirect' effect. However, as there is almost certainly a strong interaction between the amino and carboxyl groups of anthranilic acids, the possibility of indirect effects must be taken into account.

If we consider as an example the ionization constant K_A, a substituent in, say, the 4-position will behave as if para to the reaction site in exerting a direct effect on the ionization of the —COOH group and as if meta in exerting an indirect effect via the $-NH_3^+$ group. The Hammett equation* is:

$$\log \frac{K_A}{K_A^0} = {}_D\rho_A\sigma_A + {}_I\rho_A\sigma_B. \quad [9a]$$

**In this and subsequent equations ρ_A and ρ_B are the Hammett constants for a given substituent considered in relation to the —COOH (or —COO^-) and the $-NH_3^+$ (or $-NH_2$) groups, respectively. Reaction constants are defined by a suffix (A, B, C, or D) referring to the constants K_A, K_B, K_C, and K_D of eq. [1], and a prefix (I or D) indicating whether a direct or indirect effect is involved. In other cases where it is necessary to distinguish between two or more ρ or σ values, numerical suffixes are used.*

For personal use only.

The corresponding equations for K_B, K_C, and K_D are:

$$[9b] \qquad \log \frac{K_B}{K_B^0} = {}_I\rho_B\sigma_A + {}_D\rho_B\sigma_B$$

$$[9c] \qquad \log \frac{K_C}{K_C^0} = {}_D\rho_C\sigma_A + {}_I\rho_C\sigma_B$$

$$[9d] \qquad \log \frac{K_D}{K_D^0} = {}_I\rho_D\sigma_A + {}_D\rho_D\sigma_B.$$

Equation [9*a*] can be rewritten as:

$$[10] \qquad K_A = K_A^0 10^{({}_D\rho_A\sigma_A + {}_I\rho_A\sigma_B)},$$

and K_B, K_C, and K_D can be redefined in a similar manner. Substitution of these expressions for K_A, K_B, K_C, and K_D in eqs. [4] and [5] enables K_1 and K_2 to be expressed in terms of Hammett parameters:

$$[11a] \qquad K_1 = K_A^0 10^{({}_D\rho_A\sigma_A + {}_I\rho_A\sigma_B)} + K_B^0 10^{({}_I\rho_B\sigma_A + {}_D\rho_B\sigma_B)},$$

$$[11b] \qquad \frac{1}{K_2} = \frac{1}{K_C^0} 10^{-({}_D\rho_C\sigma_A + {}_I\rho_C\sigma_B)} + \frac{1}{K_D^0} 10^{-({}_I\rho_D\sigma_A + {}_D\rho_D\sigma_B)}.$$

These equations are obviously too complex to be fitted to the ionization constants, but fortunately a very much simpler Hammett equation is available. Thus, from eq. [6] there may be obtained the logarithmic relationships:

$$[12] \qquad \log \frac{K_1K_2}{K_1^0K_2^0} = \log \frac{K_AK_D}{K_A^0K_D^0} = \log \frac{K_BK_C}{K_B^0K_C^0}.$$

Combining eqs. [12], [9*a*], and [9*d*] gives:

$$[13] \qquad \log \frac{K_1K_2}{K_1^0K_2^0} = \sigma_A({}_D\rho_A + {}_I\rho_D) + \sigma_B({}_I\rho_A + {}_D\rho_D).$$

Similarly, from eqs. [12], [9*b*], and [9*c*]:

$$[14] \qquad \log \frac{K_1K_2}{K_1^0K_2^0} = \sigma_A({}_I\rho_B + {}_D\rho_C) + \sigma_B({}_D\rho_B + {}_I\rho_C).$$

However, if two or more sets of experimental data are available, a linear equation of general form:

$$\log \frac{K_1K_2}{K_1^0K_2^0} = A\sigma_A + B\sigma_B,$$

in which A and B are constants, must have a unique solution providing σ_A and σ_B are not themselves linearly related. Equations [13] and [14] can therefore be rewritten as a single equation.

$$[15] \qquad \log \frac{K_1K_2}{K_1^0K_2^0} = \rho_1\sigma_A + \rho_2\sigma_B,$$

where

$$[16a] \qquad \rho_1 = {}_D\rho_A + {}_I\rho_D = {}_I\rho_B + {}_D\rho_C,$$

$$[16b] \qquad \rho_2 = {}_I\rho_A + {}_D\rho_D = {}_D\rho_B + {}_I\rho_C.$$

Equation [15] defines a simple relationship between the experimental ionization constants and the Hammett parameters and it is, therefore, of importance that the chemical significance of this equation be defined. For this purpose it is convenient to consider the 'specific' case in which the postulated indirect substituent effects are assumed to be negligible. (Henceforth the 'general' case is that in which the indirect effects are taken into account and the 'specific' case is that in which indirect effects are assumed to be negligible.)

In the specific case the identities [16*a*] and [16*b*] simplify to:

[17*a*] $$\rho_1 = {}_D\rho_A = {}_D\rho_C,$$

[17*b*] $$\rho_2 = {}_D\rho_B = {}_D\rho_D.$$

(For the remainder of this paper only ρ_A and ρ_B are referred to; the argument could equally well be pursued in terms of ρ_C and ρ_D.)

The identity [17*a*] implies that the effect of a substituent on the ionization of the —COOH is the same whether an NH_2 or NH_3^+ group occupies the ortho position and the identity [17*b*] carries the same implication for the ionization of the $-NH_3^+$ group. These conclusions are related to the principle, proposed by Jaffe (6), that the effect of a substituent is independent of a second substituent in an ortho position relative to the reacting side chain, provided that this ortho substituent does not participate in the reaction. The independence of the reaction constant on the nature of an ortho substituent should include the case where there is no ortho substituent. It follows, therefore, that within the limits of experimental error, ${}_D\rho_A$ should have the value 1.00 which is by definition the ρ-value for benzoic acid. Similarly, the value of ${}_D\rho_B$ should show reasonable agreement with the experimentally determined value (7) of 2.889 for the Hammett reaction constant of the anilinium ion. From the identities [17*a*] and [17*b*] it follows that in the specific case eq. [15] becomes:

[18] $$\log \frac{K_1K_2}{K_1^0K_2^0} = {}_D\rho_A\sigma_A + {}_D\rho_B\sigma_B.$$

This equation is mathematically identical to the eq. [8], proposed by Jaffe (5), for reactions in which the substituent effect can be transmitted by two electronic pathways. Equation [18], however, possesses a very different chemical significance. As implied by eq. [12], this equation provides a Hammett relationship for both the experimental constants K_1 and K_2 and the true constants K_A and K_D (or K_B and K_C). When expressed in the latter terms it is seen as an application of the Hammett equation to two successive equilibria which are not readily distinguished by experimental means. The two equilibria may be represented (for example) by the lower half of eq. [1] which may be rewritten in an abbreviated form:

$$\text{I} \overset{K_A}{\rightleftarrows} \text{II}B \overset{K_D}{\rightleftarrows} \text{III}.$$

The character of the system requires that a substituent para (or meta) to the reaction center (the carboxyl group) in I is meta (or para) to the reaction center (the anilinium group) in II*B*. The above interpretation can be extended to the general case represented by eq. [15]; this is an abbreviated form of eq. [13] which contains four Hammett reaction constants and represents the application of the Hammett relationship to a system of two successive equilibria, in each of which both indirect and direct substituent effects are assumed to operate. Whether or not the indirect effects are significant, eq. [15] enables

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

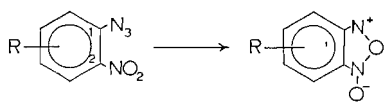
the product of the two experimental ionization constants to be fitted to a Hammett equation which can be solved for ρ_1 and ρ_2. Relationships between the individual constants (K_1 or K_2) and the Hammett parameters are provided by eqs. [11] in the general case or in the specific case, by the equations

$$K_1 = K_A^0 10^{\rho_A\sigma_A} + K_B^0 10^{\rho_B\sigma_B}, \qquad [19a]$$

$$\frac{1}{K_2} = \frac{1}{K_C^0} 10^{-\rho_A\sigma_A} + \frac{1}{K_D^0} 10^{-\rho_B\sigma_B}. \qquad [19b]$$

Thus, if a significant fit of the experimental data to eq. [15] is obtained, then the values of ρ_1 and ρ_2 required by this equation can be used to solve eqs. [11] or [19] for the true ionization constants K_A^0, K_B^0, K_C^0, and K_D^0 of anthranilic acid. Finally, by use of eq. [7] the zwitterion constant K_Z^0 and therefore the zwitterion content can be obtained. Providing that there is a statistically significant agreement between experimental data and the theoretical equations then we have a most unusual method for determining the zwitterion content of an aromatic amino acid. Furthermore, the fit of the experimental data to eqs. [11] or [19] could provide a criterion as to whether or not the indirect substituent effects are significant. However, this criterion must be used with caution as the extended computational sequence will greatly magnify errors in both the experimental data and the Hammett substituent constants. Lack of agreement between experiment and theory may well be due to these errors rather than indicative of indirect substituent effects.

In the above discussion the possible application of the Hammett equation to the zwitterion constant K_Z has been ignored. Actual K_Z values are difficult to determine and any such relationship could not be easily verified experimentally. Nevertheless, this equilibrium is of interest in that it involves the interaction of two side chains and is therefore subject to two 'direct' substituent effects. In this respect it is closely analogous to the intramolecular reaction of the *o*-nitroazides.



Andersen *et al.* (8) have recently correlated the rate constants for a series of substituted *o*-nitroazides by the use of a two-parameter Hammett equation of the type proposed by Jaffe (5):

$$\log \frac{K}{K^0} = \rho_1\sigma_1 + \rho_2\sigma_2. \qquad [8]$$

The σ_1 and σ_2 terms are the substituent constants of R relative to positions 1 and 2, the points of attachment of the nitro and azido groups. Anderson found that ρ_1 is positive and ρ_2 negative in agreement with the rule that ρ-values are negative when a high electron density favors the reaction. Similarly, the tautomeric equilibrium defined by K_Z involves simultaneously the release of a proton from the —COOH group (favored by low electron density) and the acceptance of a proton by the —NH_2 group (favored by high electron density). The expected Hammett equation would be:

$$\log \frac{K_Z}{K_Z^0} = \rho_1\sigma_A + \rho_2\sigma_B,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where ρ_1 is positive and ρ_2 negative. In the specific case in which the indirect substituent effects on the other equilibrium constants are ignored, ρ_1 and ρ_2 can be identified with the reaction constants ρ_A and ρ_B. Thus

$$[20] \qquad \log \frac{K_Z}{K_Z^0} = \rho_A\sigma_A - \rho_B\sigma_B.$$

Both ρ_A and ρ_B are assumed to be positive as they are defined for reactions which are favored by a low electron density—the ionizations of the —COOH and $-NH_3^+$ groups respectively. Equation [20] can also be deduced directly from eq. [7] on the assumption that K_A, K_B, K_C, and K_D each obey a simple Hammett relationship.

Equation [15] is crucial to the present work in that it provides the simplest experimentally verifiable Hammett relationship for the system. However, in deducing this and other relationships, it has been assumed that eq. [1] is a valid representation of the equilibria existing in aqueous solutions of an anthranilic acid. The possibility must be considered that there are alternatives to this hypothesis. The only chemically reasonable alternative assumption is that the interactions between —COOH (or $-COO^-$) and $-NH_2$ (or NH_3^+) groups are so strong that it is impossible either to consider the zwitterion (II*B*) and non-zwitterion (II*A*) as separate species or to distinguish between ionizations from the —COOH and $-NH_3^+$ groups. In such circumstances the ionic equilibria could be represented as:

[21] 
Experimental and true ionization constants are now identical. The substituent effects will be somewhat similar to those found in reactions of the nitroazides, two 'direct' effects at a single reaction center. The Hammett equations would be:

$$[22] \qquad \log \frac{K_1}{K_1^0} = \rho_1\sigma_A + \rho_2\sigma_B,$$

$$[23] \qquad \log \frac{K_2}{K_2^0} = \rho_3\sigma_A + \rho_4\sigma_B.$$

A combination of eqs. [22] and [23] gives an equation which is mathematically identical to eq. [15]. This equation is therefore still valid even if the existing equilibria are represented by eq. [21]. However, if eq. [21] rather than eq. [1] represents the equilibria existing in aqueous solutions of anthranilic acids, then the data should fit eqs. [22] and [23] individually as well as eq. [15].

DETERMINATION OF IONIZATION CONSTANTS

A spectrophotometric method for the determination of the overlapping ionization constants of dibasic acids was first described by Thamer and Voigt (9). This method was modified by Kok-Peng Ang (10) and, in this latter form, has been applied to aromatic amino acids by Bryson and Matthews (11). In the present work some further modifications were made, particularly as regards the method of computation.

The extinction coefficient, ϵ, of an aqueous solution of a dibasic acid at any given wavelength is related to the hydrogen ion activity, α, by the equation:

$$\alpha^2(\epsilon - \epsilon_1) + \alpha K_1(\epsilon - \epsilon_2) + K_1K_2(\epsilon - \epsilon_3) = 0.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In the present case ϵ_1, ϵ_2, and ϵ_3 are the extinction coefficients of RH_2^+, RH, and R^- respectively, and K_1 and K_2 are the first and second ionization constants as defined in eqs. [2] and [3]. ϵ_1 and ϵ_3 can be determined directly by measurements in acid or alkaline solutions, but ϵ_2 is not directly available. In the present work all the solutions used in the determination of K_1 and K_2 for any particular acid were of the same concentration and it is therefore convenient to use D, the optical density, in place of ϵ in describing the method and carrying out the calculations. The above equation can therefore be rewritten:

$$[24] \qquad \alpha^2(D - D_1) + \alpha K_1(D - D_2) + K_1K_2(D - D_3) = 0.$$

Kok-Peng Ang's solution of this equation for K_1 and K_2 requires that some wavelength be found for which the variation of D with pH exhibits a maximum or minimum (Fig. 1). Any value of D corresponding to the 'steep' portion of the curve will then define two values (α_1, α_2) of α and thus provide two simultaneous equations of the form of eq. [24]. Combining these equations gives

$$[25] \qquad D = D_2 + K_2P,$$

where

$$P = \frac{(D_3 - D)(\alpha_1 + \alpha_2)}{\alpha_1\alpha_2}$$

and

$$[26] \qquad D = D_1 + K_1Q,$$

where

$$Q = \frac{D_2 - D}{\alpha_1 + \alpha_2}.$$

A plot of D against P is linear with slope K_2 and intercept D_2. The value of D_2 is inserted into eq. [26] and D is plotted against Q to give K_1.

In the present work an IBM 1620 computer was available and computational labor

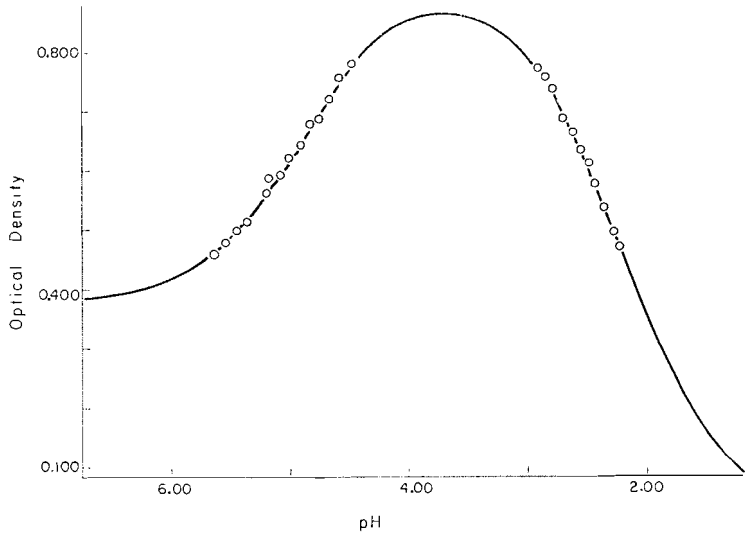


FIG. 1. Variation of optical density with pH at $\lambda = 345$ mμ for anthranilic acid. Circles represent the experimental points of Table I and the line is calculated from eq. [24] using the parameters of Table II.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was not an important consideration. It was therefore possible to eliminate the following, otherwise unavoidable, weaknesses in the method of computation.

(*i*) The value of K_2 is highly dependent upon D_3, the optical density of an alkaline solution, which must therefore be determined with extreme accuracy to avoid undetectable, systematic error in K_2.

(*ii*) Similarly, and as previously pointed out by Bryson and Matthews (11), an error in the computed value of D_2 introduces a systematic error into the calculation of K_1.

(*iii*) The usual 'least squares' procedure for determining the slope and intercept of a line assumes that only $y(= D)$ is in error and that $x(= P$ or $Q)$ is inerrant; this is clearly not true in the present case.

For the computation used in the present work eqs. [25] and [26] are rearranged;

[27] $$D = \frac{D_2 + K_2D_3A}{1 + K_2A} \quad \text{from [25]},$$

where $$A = 1/\alpha_1 + 1/\alpha_2;$$

[28] $$D = \frac{D_1 + K_1D_2A^1}{1 + K_1A^1} \quad \text{from [26]},$$

where $$A^1 = 1/(\alpha_1 + \alpha_2).$$

Equations [27] and [28] were solved on the computer by Dolittle's least squares method (12, 13) which takes into account errors in both D and α and thus provides more reliable estimates of the standard errors of the parameters. By this method independent values for K_1 and K_2 are obtained without the necessity of determining either D_1 or D_3. Furthermore two independent estimates of D_2 are available as a test of the consistency of the calculations.

The method of obtaining the values of D, α_1, and α_2 for use in the computation of K_1K_2 was also modified. Kok-Peng Ang's procedure required that a continuous curve be constructed through the experimental points (pH, D). The values of α_1 and α_2 are then read *from the curve*. However, the responsibility of drawing a 'true' curve can be avoided. Thus, in the present work, using the determination of K_2 as the example, the values of D and α_2 which are used in the calculation are the actual experimental points. To obtain the corresponding values of α_1 it is still necessary to draw a curve through the experimental points on the low pH side of the maximum. However, in eq. [27] the terms α_1 and α_2 appear only in the function $A = 1/\alpha_1 + 1/\alpha_2$. For most values $1/\alpha_2 \gg 1/\alpha_1$, and errors in α_1 due to inaccurate curve construction have a negligible effect on the accuracy of the overall calculation.

Similarly for K_1, D and α_1 are experimental points and α_2 is obtained from a constructed curve.

EXPERIMENTAL

(A) Preparation of the Substituted Anthranilic Acids

The 5-chloro, 5-hydroxy, and 5-methyl anthranilic acids, and anthranilic acid itself, were commercial products. The 5-bromo, 4-chloro, 4-nitro, and 5-nitro acids were prepared as described by Dunn and Prysiazniuk (1). The compound described in that paper as the 4-bromoanthranilic acid was found to be the 5-bromo isomer; an unambiguous synthesis of the 4-bromo acid is described in the present paper.

All the anthranilic acids were purified by one or more recrystallizations from aqueous ethanol in the presence of animal charcoal. The melting points given are for the recrystallized acids. All melting points were determined with a Hershberg melting point apparatus (14) using Anschutz thermometers and are expressed in °C.

'Analar' acetone was purified for use in the permanganate oxidations by distillation from solid potassium permanganate.

4-Methylanthranilic Acid

4-Methyl-2-nitrobenzoic acid was prepared by the procedure described by Grob (15). 4-Methyl-2-nitroaniline was diazotized and the diazonium solution treated with cuprous cyanide to yield the 4-methyl-2-nitrobenzonitrile, which was hydrolyzed to the 4-methyl-2-nitrobenzoic acid. The crude nitro acid (10 g) in ethanol (75 ml) was hydrogenated during 20 min at 3 atm pressure in the presence of 10% palladium-on-charcoal (1.0 g). 4-Methylanthranilic acid (6.0 g, 65%) was recovered from the reaction mixture and, after recrystallization from aqueous ethanol, had m.p. 181–182° (lit. (15) 178–180°).

4-Methoxyanthranilic Acid

4-Methoxy-2-nitrobenzoic acid, m.p. 192–193°, was prepared from 4-methoxy-2-nitroaniline by the procedure of Steven *et al.* (16) who give m.p. 195–196°. The nitro acid was hydrogenated under conditions already described (for the 4-methyl-2-nitro acid) to give a 73% yield of 4-methoxyanthranilic acid, m.p. 180–181° (lit. (16) 180–181°).

5-Methoxyanthranilic Acid

4-Methoxy-2-methylaniline (93 g) was dissolved in 0.4 *N* hydrochloric acid (1.7 l) to give a dark-brown solution which was stirred with animal charcoal and filtered. To this filtrate at 50° were added acetic anhydride (82 ml) and then sodium acetate trihydrate (109 g). The solution was cooled to 15° to precipitate the 4-methoxy-2-methylacetanilide (100 g, 82%) which had m.p. 135–136° (lit. (17) 132–134°). The anilide (10.00 g) in acetone (500 ml) was treated with potassium permanganate (27.0 g) and magnesium sulfate during 48 h at room temperature. Sodium sulfite was then added to destroy excess permanganate and the reaction mixture was filtered. The filtrate was evaporated to 100 ml, diluted with water, and extracted with chloroform to remove unreacted starting material. Acidification yielded N-acetyl-5-methoxyanthranilic acid (3.9 g, 85% of reacted material), m.p. 165–166° (lit. (18) 165–166°). Hydrolysis of the acetylanthranilic acid (7.6 g) was accomplished by warming for 30 min with 6 *N* sodium hydroxide solution. Acidification of the alkaline solution precipitated 5-methoxyanthranilic acid (2.5 g, 42%), m.p. 151–152° (lit. (19) 151°).

4-Fluoroanthranilic Acid

The preparation of this acid from 5-fluoro-2-methylaniline followed the published procedure of Steck and Fletcher (20). The 4-fluoroanthranilic acid so prepared had m.p. 198–199° (lit. (20) 192.5–193.0°).

5-Fluoroanthranilic Acid

The 5-fluoro acid was obtained from 4-fluoro-2-methylaniline by the successive acetylation, oxidation, and hydrolysis steps which are described in detail for the preparation of 5-methoxyanthranilic acid. Acetylation of the aniline gave an 87% yield of 4-fluoro-2-methylacetanilide, m.p. 110–112° (lit. (21) 113°), which was oxidized in 43% yield to 5-fluoro-N-acetylanthranilic acid, m.p. 178°. Hydrolysis of this compound gave a 91% yield of the 4-fluoroanthranilic acid, m.p. 183–184° (lit. (22) 180°).

5-Phenoxyanthranilic Acid

2-Nitro-5-chlorobenzoic acid (25 g) was reacted with potassium phenoxide in nitrobenzene solution as described by Süs and Möller (23) to give 5-phenoxy-2-nitrobenzoic acid (14 g, 65%), m.p. 154–155° (lit. (23) 157°). Hydrogenation of the crude nitro acid (14 g) under conditions already described in the present paper gave 5-phenoxyanthranilic acid (9 g, 70%), m.p. 148–149° (lit. (23) 148°). Attempts to apply the same method to the preparation of the 4-phenoxyanthranilic acid were unsuccessful, even though the more reactive 2-nitro-4-bromobenzoic acid was used in place of the 4-chloro compound. This failure is to be expected in the absence of an activating nitro group para to the halogen atom.

4-Bromoanthranilic Acid

4-Bromo-2-nitrobenzoic acid was prepared from *o*-nitroaniline by the three stage procedure of Erickson *et al.* (24). Bromination of the *o*-nitroaniline gave an 84% yield of 4-bromo-2-nitroaniline, m.p. 105–106° (lit. (24) 111–112°), which was then diazotized and the diazonium solution treated with cuprous cyanide to give 4-bromo-2-nitrobenzonitrile in 67% yield. The nitrile was hydrolyzed to 4-bromo-2-nitrobenzoic acid, m.p. 161–162° (lit. (24) 164–165°). The nitroacid (10.8 g) was dissolved in ammonium hydroxide solution and treated with ferrous ammonium sulfate hexahydrate (100 g) in water (200 ml). The reaction mixture was boiled briefly, cooled, and filtered. Acidification of the filtrate gave 4-bromoanthranilic acid (7.0 g, 83%), m.p. 225° (lit. (25) 222°). A melting point depression was observed on mixing with 5-bromoanthranilic acid (m.p. 215–216°).

A small quantity of the 4-bromo compound was converted by a diazotization procedure to 4-bromosalicylic acid, m.p. 203–204° (lit. (26) 214°). This compound was readily distinguished both by melting point and mixed melting point from the 5-bromo isomer which has m.p. 169°. It is of interest that in one recent paper (27) a melting point of 164–165° is quoted for 4-bromosalicyclic acid; it is almost certain that this was in fact the 5-isomer.

(B) pK_a Determinations

All measurements were made on solutions of ionic strength $\mu = 0.10$ since for the stronger acids it was necessary to measure optical densities at pH's as low as 1. Consequently, only apparent pK values are reported. These are adequate for the present purpose since the Hammett relationships always concern differences between the pK's of substituted and unsubstituted aromatic acids where the activity coefficients will be very similar and cancel.

Experimental Procedure

Stock solutions of each acid were prepared by dissolving the appropriate weight of the acid in a slight excess of sodium hydroxide (0.1 *N*) and then diluting to 1 l with distilled water containing sufficient potassium chloride to give an ionic strength of 0.10. Aliquots (10 ml) of this stock solution, delivered from an automatic burette, were diluted to 50 ml with the appropriate buffer to give the solutions on which pH and optical density (*D*) determinations were made. Preliminary experiments were performed on solutions of each acid in 10 to 12 buffers spanning the range 1.0–5.5. The absorption spectra of these solutions in the range 2 750 – 4 500 Å were recorded. These spectra indicated the optimum wavelength for a pK_a determination, the required concentration of the stock solution, and the approximate pH ranges of the 'steep' portions of pH/*D* curve at the chosen wavelength. In the actual pK_a determinations the buffers were chosen so as to concentrate the experimental points in these steep portions.

Solutions of all the acids eventually became colored on standing, but in the case of the 5-methoxy, 5-hydroxy, and 5-bromo acids and in particular the 5-phenoxy acid, discoloration was observed within a few hours and anomalous optical density readings resulted. Stock solutions of these acids were therefore prepared in oxygen-free water and stored in opaque bottles under nitrogen. Under these conditions no significant variations in optical density were observed during the course of the pK_a determination.

Buffer Solutions

Hydrochloric acid (pH 1.0–1.8), chloroacetate (1.9–3.6), acetate (3.7–5.4), and phosphate (5.7, 6.0, 6.8) buffers were used. All buffers were adjusted to ionic strength 0.10 by addition of potassium chloride. In some initial experiments citrate buffers were used. It was found, however, that the optical density of an acid in a citrate buffer was significantly higher than that in hydrochloric acid or acetate buffers of the same pH and it was assumed that some degree of complex formation was occurring.

pH Measurements

These were made with a Radiometer Model 4C pH meter with shielded glass and silver chloride electrodes in a water bath thermostatically controlled at 25.0 ± 0.1°. The instrument was standardized at pH's 1.68, 4.01, and 6.80 with potassium tetroxalate (0.1 *N*), potassium hydrogen phthalate (0.1 *N*), and sodium hydrogen phosphate – potassium hydrogen phosphate (0.25 *N*) buffers prepared from the corresponding National Bureau of Standards pH standards.

Optical Density Measurements

A Beckman DK1 spectrophotometer was used with matched cells contained in a thermostated cell holder at 25.0 ± 1.0°. The appropriate buffer solution was used as a standard in the reference cell. In making a pK_a determination the instrument was set at the predetermined optimum wavelength throughout the determination. For each solution a record was made of the optical density over a period of several minutes during which the temperature of the cell oscillated between 24° and 26° several times. This temperature variation produced changes in the optical density of not more than 0.001 absorbance units, except in the case of strongly acid solutions of the nitro acids, in which slightly larger variations were observed.

RESULTS

Table I details the experimental data for anthranilic acid itself. Solutions Nos. 1–11 define the steep portion of the curve on the low pH side of the maximum and solutions Nos. 12–25 the steep portion on the high pH side. These data were used to solve eqs. [27] and [28] by the methods already described.

The values of pK_1 and pK_2 (and K_1 and K_2) calculated from these data are given in Table II, row 1, which also shows the excellent agreement between the two values obtained for D_2, and between the computed value for D_3 and an experimental value. The values of K_1 and K_2 from a second, independent experiment using a different concentration of anthranilic acid are also given in Table II. The mean values of K_1 and K_2 from the two experiments are seen to be in agreement with previously published values.

Figure 1 compares the experimental data of Table I with a pH vs. *D* curve defined by eq. [24], using the computed values for the parameters K_1, K_2, D_1, D_2, and D_3. (The mean of the two computed values of D_2 was used.) A test of the degree of coincidence between experimental data and theoretical equation is given by the value of s(ext.), the external estimate of error.* This is 0.005 for both equation [27] which gives K_2 and eq. [28] which

**Throughout this paper, for any set of experimentally derived data, $y, x_1, x_2, \ldots$, which are used to determine the constant parameters $a_1, a_2, \ldots$ of an equation $y = f(x_1, x_2 \ldots a_1, a_2 \ldots)$, the "external estimate of error" is defined as $s^2(\text{ext.}) = \sum (y - \tilde{y})^2/(\text{degrees of freedom})$, where $\tilde{y}$ is the value of y calculated by inserting the computed values of $a_1, a_2, \ldots$ into the equation.*

			25	5.634	0.460
			26	0.1 N NaOH	0.390

gives K_1. The actual experimental uncertainty in the optical density, D, (i.e., the internal estimate of error) is about 0.005.

Ionization constants were obtained for 15 substituted anthranilic acids. Values of K_1, K_2, and D_2 are given in Table III, including duplicate determinations which were made for four of the acids. For these acids the weighted mean of the duplicate values of K_1 and K_2 were used in the calculations of the Hammett relationships described in the next section. No value of K_1 is given for the 5-nitro acid, which exhibited a very broad maximum at a very low pH. The determination of K_1 would have required the use of very strongly acidic solutions for which sufficiently accurate pH data were unobtainable.

The third ionization constant of 5-hydroxyanthranilic acid, involving ionization of the hydroxyl group, was readily accessible from our data so it was calculated although it was not needed for the purposes of this paper.

$$K_3 = \frac{[A^{=}][H^{+}]}{[A^{-}]}.$$

On the assumption that there is no significant overlapping of the second and third ionization constants, K_3 may be determined approximately by use of the relationship:

$$K_3 = \frac{(D - D_3)a}{D_4 - D},$$

where D_3 and D_4 are optical densities of solutions of the same concentration containing only A^- and $A^=$ respectively. D is the optical density at hydrogen ion concentration a. A value of D_3 has already been computed in the calculation of K_2; D_4 was obtained by measurement of a solution in 0.10 N sodium hydroxide. Using $D_3 = 0.154$, $D_4 = 0.929$, $D = 0.414$ at pH = 9.069, the values $K_3 = 4.31 \times 10^{-10}$, $pK_3 = 9.36$ were obtained.

DISCUSSION

Equation [15] can be written in the form:

$$[15] \qquad \log K_1K_2 = \rho_1\sigma_A + \rho_2\sigma_B + \log K_1^0K_2^0.$$

This equation was solved for the constant terms ρ_1, ρ_2, and log $K_1^0K_2^0$ by application of Dolittle's least squares procedure (12, 13) to the experimental data for 13 of the 14 acids for which both K_1 and K_2 had been determined. Data for the 5-phenoxy acid were rejected for reasons given below. The σ-values which were used are listed in Table IV and are those given by McDaniel and Brown (30) with the exception of the σ_B values for the 5-fluoro and 5-nitro acids. The values reported by Biggs and Robinson (7) are used for these two σ_B's which define the effect of a *p*-fluoro and of a *p*-nitro substituent, respectively, on the amino group. Statistical weights were calculated from an assumed standard deviation (30) of 0.020 for all the σ's, and from standard deviations of log K_1K_2 values which were calculated from the standard deviations given in Table III for each of the individual ionization constants.

Solution of eq. [15] gave $\rho_1 = 0.751$, $\rho_2 = 3.111$, and $\log K_1^0K_2^0 = -7.039$. These calculated constants were inserted into eq. [15] to obtain calculated values ($\tilde{y}$) of $\log K_1K_2$ which are listed, together with the corresponding experimental values (y), in Table IV.

When data for all 14 acids were fitted to eq. [15] the difference, $y - \tilde{y}$, between the experimental and the calculated values for the 5-phenoxy acid was several times larger than the corresponding value for any other acid and also its own standard deviation. The K_1 and K_2 constants for this acid were, therefore, not used in subsequent calculations. This large discrepancy between observed and calculated values of $\log K_1K_2$ for 5-phenoxyanthranilic acid is shown in Table IV where the Hammett parameters defined by the other 13 acids have been used to calculate $\log K_1K_2$ for the 5-phenoxy acid.

The data for the same 13 acids were also fitted to the four other equations following.

[22] $$\log K_1 = \rho_1\sigma_A + \rho_2\sigma_B + \log K_1^0,$$

[23] $$\log K_2 = \rho_1\sigma_A + \rho_2\sigma_B + \log K_2^0,$$

[29] $$\log K_1K_2 = \rho_1\sigma_A + \log K_1^0K_2^0,$$

[30] $$\log K_1K_2 = \rho_1\sigma_B + \log K_1^0K_2^0.$$

Table V gives the calculated parameters for these equations. Equations [22] and [23] are valid only if the existing equilibria can be represented by eq. [21] rather than the generally accepted eq. [1]. Equations [29] and [30] have no obvious physical significance; they are included only for purposes of comparison in estimating the significance of the fit of the data to eq. [15].

TABLE V

Comparison of Hammett equations

Eq.	ρ_1	ρ_2	s^2(ext.)*	s^2(int.)†	R‡	F§	F′‖
[15]	0.751±.084	3.111±.071	0.0039	0.0057	0.997	1 560	73
[22]	0.491±.146	1.727±.114	0.0091	0.0024	0.981	255	
[23]	0.426±.144	1.254±.130	0.0113	0.0009	0.949	93	
[29]	2.086±.121		0.640	0.0057	0.481		
[30]	3.331±.019		0.0419	0.0057	0.983		

*s^2(ext.) $= \Sigma (y - \tilde{y})^2/(n - 3)$, where the numerator is the sum of the squares of the deviations from the estimated regression equation and the denominator is the degrees of freedom.
†s^2(int.) $= \Sigma$ (observed standard error of $y)^2/(n - 3)$.
‡R = multiple correlation coefficient.
§F is the variance ratio comparing the equation in question with a completely random distribution and tests the hypothesis $\rho_1 = 0$, $\rho_2 = 0$.
‖F' is the variance ratio between the three-parameter eq. [15] and the two-parameter eq. [30] and indicates whether the former gives a significantly better fit to the data.

The statistics of Table V, which describe the significance of the fit of the data to each equation, amply demonstrate the superiority of eq. [15] as an accurate interpretation of the experimental results. Only for this equation is s^2(int.), calculated from the known experimental uncertainties, greater than s^2(ext.) which is calculated from the fit of the data to the theoretical equation. The data give a considerably less significant fit to eqs. [22] and [23], indicating that the zwitterion and neutral acid cannot be treated as a single species.

The multiple correlation coefficient and the F-test show eq. [15] to be significant within the 99% confidence limit. Jaffe (5) has pointed out that equations of the same mathematical form as eq. [15] may give an excellent but entirely fallacious fit of the data if σ_A and σ_B are highly correlated. He has proposed that equations of this type should only be considered to give a meaningful interpretation of the data if $r_{AB} < 0.9$, where r_{AB} is

the correlation coefficient between σ_A and σ_B. The value of $r_{AB} = 0.590$ for our substituents amply fulfills this condition and, indeed, is lower than in any of the cases discussed by Jaffe.

It was pointed out earlier that in the specific case, where indirect effects are negligible, $\rho_1 = {}_D\rho_A$ and $\rho_2 = {}_D\rho_B$. Furthermore, ${}_D\rho_A$ and ${}_D\rho_B$ should, in theory, be approximately equal to 1.00 and 2.89, respectively. These theoretical values are outside the standard deviations of $\rho_1(= 0.751 \pm 0.084)$ and $\rho_2(= 3.111 \pm 0.071)$ shown in Table V. This might be considered evidence for the existence of an indirect effect, although the differences between theoretical and experimental values are no greater than some reported by Jaffe (6) for ortho-substituted systems where chelation is impossible. However, it may be worthwhile to explore the possibility of indirect effects as an explanation for the discrepancy. In that case eq. [16] would give

$$\rho_1 = {}_D\rho_A + {}_I\rho_D = 0.751,$$

$$\rho_2 = {}_I\rho_A + {}_D\rho_D = 3.111.$$

If ${}_D\rho_A$ and ${}_D\rho_D$ were given their theoretical values of 1.000 and 2.889, respectively, the indirect effects would become ${}_I\rho_D = -0.249$ and ${}_I\rho_A = +0.222$. Since the former of these represents the indirect effect of substituents via chelation upon the ionization of a NH_3^+ group, it would be expected to be positive. It seems unlikely, therefore, that the deviation from the theoretical values is really the result of an indirect effect. This conclusion is reinforced by the fact that no indirect effect is observed in the similar but simpler system of salicylic acids (5, 31).

A further test of the indirect effect would be to compare the fit of the experimental K_1's and K_2's to eqs. [11*a*] and [11*b*] which include the indirect effect, with the fit of the same data, to [19*a*] and [19*b*] which do not. This was attempted using ${}_D\rho_A = 1.000$, ${}_I\rho_A = 0.222$, ${}_D\rho_D = 2.889$, and ${}_I\rho_D = -0.249$ for eqs. [11], or $\rho_A = 0.751$ and $\rho_B = 3.111$ for eqs. [19], and weighting the K's inversely as the squares of their standard deviations. Table VI compares the observed pK_1's and pK_2's with those calculated by the two methods. It is seen that, while the pK_1's fit eq. [11] somewhat better than eq. [19], there is little to choose between [11] and [19] as methods for calculating pK_2. Since for both

series s^2(ext.) is at least double s^2(int.), the better fit to eq. [11] can hardly be taken as evidence for an indirect effect.

TABLE VII

Calculated ionization constants for eq. [1]

Eq.	$K_A^0 \times 10^3$	$K_B^0 \times 10^3$	$(K_A^0 + K_B^0) \times 10^3$	Experimental $K_1^0 \times 10^3$	K_Z^0
[11*a*]	3.2±.3	3.4±.6	6.6±.8	6.7±.4	1.0±.3
[19*a*]	1.9±.2	3.9±.6	5.9±.8	6.7±.4	0.5±.1
Eq.	$K_C^0 \times 10^5$	$K_D^0 \times 10^5$	$(1/K_C^0 + 1/K_D^0) \times 10^{-5}$	Experimental $1/K_2^0 \times 10^{-5}$	K_Z^0

[19*b*]	2.7±.1	3.2±.3	0.68±.04	0.70±.04	0.9±.1

In fitting the K_1's and K_2's to eqs. [11] and [19] the data for 5-phenoxyanthranilic acid were omitted, as indicated previously, because of their poor fit to eq. [15]. The values of K_A^0, K_B^0, K_C^0, and K_D^0 obtained from the remaining 13 acids were used to calculate pK_1 and pK_2 for the 5-phenoxy acid and these are shown in parentheses in Table VI. It is seen that the calculated pK_1 agrees reasonably well with experiment but that pK_2 is widely out. Examination of eq. [19*b*] shows that the calculated value of K_2 for this acid is largely determined by the second term of the equation, which depends upon σ for the para-phenoxy group. It appears, therefore, that either the experimental value of K_2 is grossly in error or σ_{para} is incorrect. In order to fit the experimental K_2 into eqs. [15] and [19*b*] a value of $\sigma = -0.088$ would be required for the *p*-phenoxy group, and it is interesting to note that this is in good agreement with the σ_p reported by Jaffe (6) for reactions other than ionization constants of benzoic acids. However, our data ought, in principle, to correlate with the ionization constants of benzoic acids, and the 5-phenoxy acid is particularly susceptible to oxidative side reactions, so that it is probably not safe to attach any particular significance to our apparent σ-value.

Table VII shows the values for K_A^0, K_B^0, K_C^0, and K_D^0 obtained from eqs. [11] and [19] and for the values of K_Z^0 derived from these by means of eq. [7]. The extended series of computations from the original data causes an accumulation of uncertainties in the quantities presented in Table VII but it is seen that they are consistent within their standard deviations. For example, eq. [4], which requires that $K_A^0 + K_B^0 = K_1^0$, and eq. [5], which requires that $1/K_C^0 + 1/K_D^0 = 1/K_2^0$, are both satisfied. The uncertainty in K_Z^0 is correspondingly large, but K_Z^0 evidently lies in the region 0.4–1.5, with the theoretically preferable eq. [19*a*] giving a range of 0.4–1.0, equivalent to 30–50% zwitterion.

Previous calculations giving $K_Z^0 = 0.2$, or 17% zwitterion, have been based on the assumption that K_A^0 may be equated to the ionization constant of the methyl ester of anthranilic acid, p$K_E = 2.09$ (3). This assumption, as applied to *p*-aminobenzoic acid, has been criticized by Bryson and Matthews (11) on the grounds that the various alkyl esters have different ionization constants and that among these the methyl ester is out of line. The assumption may be particularly questionable when applied to anthranilic acid esters because of the known acid-strengthening effect of bulky ortho substituents in anilinium ions (32). The reported ionization constant of the ester, $K_E = 8.13 \times 10^{-3}$, is indeed larger than our K_A^0, whether one considers its most probable value of 1.9×10^{-3} or the maximum value of 3.5×10^{-3} obtained by inclusion of indirect substituent effects

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

via eq. [11*a*]. In fact, Table II shows that the ionization constant of the ester is larger than most modern estimates of K_1^0, which, since $K_1^0 = K_A^0 + K_B^0$, makes the assumption that $K_E = K_A^0$ untenable.

Finally, it may be pointed out that, although the equilibrium constant for zwitterion formation by anthranilic acid is still not known with great precision, the relative equilibrium constants for zwitterion formation by substituted anthranilic acids may be calculated from eq. [20] with considerable certainty. If K_Z^0 is assumed to be 1.0, then among our acids K_Z varies from 17.5 (95% zwitterion) for 5-hydroxy to 0.019 (2% zwitterion) for 4-nitroanthranilic acid.

SUMMARY

The ionization constants of substituted anthranilic acids give an excellent fit to the two-parameter Hammett eq. [15], showing that these acids at the isoelectric point are better represented as a mixture of zwitterion and neutral acid than as a single hybrid species; previous estimates of the % zwitterion are low because of the erroneous assumption that the ionization of the amino group is the same in anthranilic acid as in its methyl ester; and indirect transmission of substituent effects via chelation is very improbable since in some cases it would have to act in the sense opposite to that predicted by theory.

ACKNOWLEDGMENT

The authors are grateful to Mr. Immo E. Scheffler for assistance with the experimental work,

SPECTRAL PROPERTIES OF *p*-SUBSTITUTED BENZOYLTRIPHENYLSILANES

A. G. Brook, Ryan Kivisikk, and G. E. LeGrow[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received October 26, 1964

ABSTRACT

A series of *p*-substituted benzoylsilanes have been synthesized and their infrared and ultraviolet spectra determined. Correlations of both the infrared carbonyl stretching frequency and the n–π^* ultraviolet absorption with Hammett substituent constants have been found. Benzoylsilanes are generally unstable in ethanol undergoing light-catalyzed decomposition. Benzoyldiphenylphosphine was found to give spectra similar to those of benzoylsilanes.

The yellow color and general spectral properties of benzoylsilanes are of some interest since the analogous carbon compounds are colorless and since the benzoylsilanes represent the only known group of colored silicon-containing compounds in which the silicon atom is obviously acting as part of the chromophoric system (1–4). As part of our continuing investigation of the behavior of silyl ketones we were led to synthesize a number of substituted benzoyltriphenylsilanes, where substituents were present either on the para position of the benzoyl group or on the para positions of all three phenyl groups attached to silicon. All of the substituted silanes were varying shades of yellow. The infrared and ultraviolet spectral data are given in Tables I and II.

TABLE I

Infrared carbonyl stretching frequency

For Ph_3SiCO–C$_6$H$_4$–X		For (Y–C$_6$H$_4$–)$_3$SiCOPh	
X	cm^{-1}	Y	cm^{-1}
H	1 617	H	1 617
NO_2	1 624	Cl	1 617
Br	1 618	CF_3	1 617
Cl	1 618		
F	1 617.5		
OCH_3	1 616		
$C(CH_3)_3$	1 616		

The carbonyl infrared stretching frequency for all ketones occurred near 1 617 cm^{-1} (6.18 μ). An approximately linear correlation between the stretching frequency and σ, the Hammett substituent constant, was found for the *p*-substituted benzoyltriphenylsilanes (Fig. 1), as had been observed previously for the corresponding acetophenones (5) except that in the present case the σ^- value for the *p*-nitro group fitted the data better. Since the frequencies for all compounds occurred over a range of only 8 cm^{-1} a more precise correlation could not be expected.

One difference noted between the acetophenones and the benzoylsilanes was in the slope of the ν vs. σ plot; in the acetophenones the slope $\Delta\nu/\Delta\sigma$ was 16.6, whereas in the benzoylsilanes the slope was 5.4, indicating considerably less sensitivity of the carbonyl

[1]*Dow Corning Silicones of Canada Predoctorate Fellow, 1962–1964.*

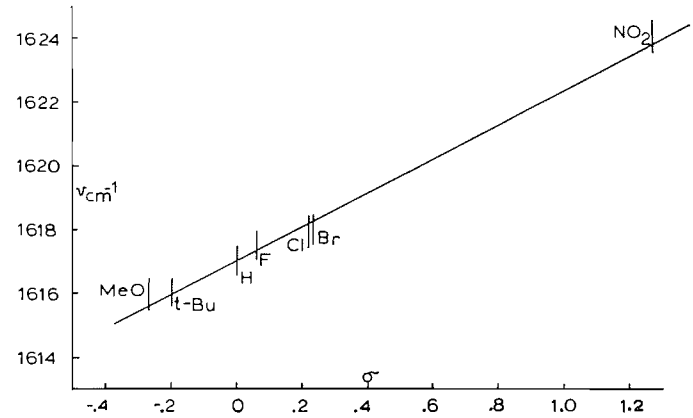

FIG. 1. Infrared carbonyl stretching frequency vs. Hammett σ (or σ^-) constant for *p*-substituted benzoylsilanes.

group in the latter compounds to inductive and mesomeric effects of the *p*-substituent. This is to be expected because of the significant degree of single bond or polar character present in the carbonyl group of these compounds. The carbonyl stretching frequencies of the tris-*p*-substituted phenylbenzoylsilanes occurred in the same position as the unsubstituted compound within experimental error. The insensitivity of the stretching frequency to the nature of the group attached to silicon has been observed before, triphenyl- and trimethyl-benzoylsilanes, as well as mixed methylphenylbenzoylsilanes, absorbing at the same frequency (2).

In the ultraviolet and visible region benzoylsilanes have two absorptions, one in the region of 260 mμ assigned as a π–π^* transition and the other occurring at about 420 mμ ascribed as an n–π^* transition of the carbonyl group involving interaction with the silicon d-orbitals (3, 4). The high intensity π–π^* band occurs in essentially the same position as that of its carbon analog β-benzpinacolone (2), while the n–π^* transition is, of course, at much longer wavelength. Comparing the absorption data with that of the related acetophenones (6), we found, with the exception of the *p*-nitrobenzoylsilane, where the shift in wavelength is rather smaller, that the π–π^* absorption maxima of *p*-substituted benzoylsilanes occurs at 17–18 mμ longer wavelength than that of the corresponding acetophenones, suggesting that the silicon atom adjacent to the carbonyl group is not significantly involved in the π–π^* transition, and that the *p*-substituents are acting in their normal manner as far as their effects on the position of absorption maxima are concerned. The extinction coefficients of benzoylsilanes are, however, slightly larger than those of the corresponding acetophenones. On the other hand, the n–π^* absorption band of the benzoylsilanes occurs at approximately 100 mμ longer wavelength, and with a considerably greater extinction coefficient than the n–π^* band for the corresponding acetophenones. Unfortunately, the position of this band in acetophenones has not always been reported, but from the available data (7), the minor changes in wavelength caused by *p*-substituents appear to vary in the same way with both benzoylsilanes and acetophenones.

An interesting correlation between the wavelength of the most intense n–π^* band and σ, the Hammett substituent constant, was noted (Fig. 2). Although it is recognized that ultraviolet data, which involve both ground and excited states, cannot normally be

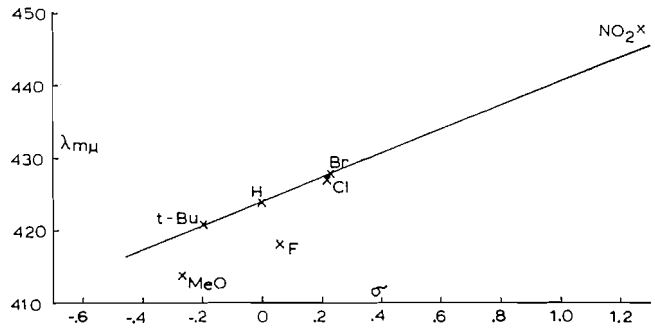

FIG. 2. n–π^* Carbonyl absorption wavelength vs. Hammett σ (or σ^-) constant for *p*-substituted benzoylsilanes.

related to Hammett substituent effects, which involve ground states only, the apparent correlation appears worthy of comment. A linear correlation of wavelength with σ was found for benzoyltriphenylsilane and its *p-tert*-butyl, *p*-chloro, and *p*-bromo derivatives. The *p*-nitro, *p*-fluoro, and *p*-methoxy compounds deviate significantly from this correlation: in other cases involving Hammett correlations of kinetic data, compounds with these same substituents have been observed to deviate in the same direction. Thus *p*-nitro compounds fitted the data better here, and in Eaborn's work (8) if σ^- values were used, and in both base-catalyzed hydrolyses of benzylsilanes (9) and in base-catalyzed isomerizations of α-silylcarbinols (10), the *p*-fluoro and *p*-methoxy compounds required, as here, more negative σ values than those normally employed to fit the correlation. Further data seems desirable, before the significance of the correlation and the deviations from it can be assessed. We believe that this deviation is a real and significant effect and will be discussed in more detail in a future publication.

The ultraviolet data reported in Table II were measured in cyclohexane, and in some cases, in ethanol as well. In ethanol, the solvent employed in previous studies (2), the 420 mμ band appears as one peak, with shoulders on each side, whereas in cyclohexane all the ketones showed three clearly resolved bands as well as a shoulder on the short wavelength side of the shortest wavelength band. This fine structure, previously observed with simple carbonyl compounds in nonpolar solvents (11), is presumably associated with various vibrational levels of the n–π^* excitation. A comparison of the data in cyclohexane and ethanol showed small changes in wavelength of both absorption bands. The n–π^* transition occurred at 5–10 mμ shorter wavelength in ethanol than in cyclohexane (blue shift) whereas the π–π^* transition generally occurred at 1–2 mμ longer wavelength in changing to the more polar solvent (red shift). These changes follow the pattern usually observed in carbonyl compounds in changing from nonpolar to polar solvents and hence substantiate the assignment of the spectroscopic transitions as π–π^* and n–π^* (12).

Apart from the enhanced resolution of the n–π^* band an additional reason for changing the solvent from ethanol to cyclohexane was the observation that some of the ketones appeared to be unstable in ethanol; different extinction coefficients were found for new and aged solutions, and in extreme cases, the yellow color of the solutions faded rapidly to colorless. It was shown that this decomposition was light catalyzed. Thus several grams of benzoyltriphenylsilane in methanol were irradiated with a lamp rich in near ultraviolet radiation and in 1–2 h the yellow color was entirely bleached. Distillation of

the solution gave triphenylmethoxysilane in high yield, a small amount of benzaldehyde and a much larger yield of benzaldehydedimethylacetal, identified by its infrared and nuclear magnetic resonance (n.m.r.) spectra, and physical properties.

$$Ph_3SiCOPh \xrightarrow[MeOH]{h\nu} Ph_3SiOMe + PhCH(OMe)_2$$

This decomposition occurs much more slowly, if at all, in the dark in methanol and is completely avoided in nonpolar solvents such as cyclohexane.

It has been reported in the literature that benzoyldiphenylphosphine is a yellow solid although no spectral data is reported (13). Because of the obvious analogy between benzoylsilanes and benzoylphosphines the synthesis was repeated and a yellow solid was obtained. The material could not be entirely freed of benzaldehyde, and the compound was found to be rather less stable than the original literature suggested. In air, it decomposed yielding benzoic acid and diphenylphosphonic acid. As expected the yellow (impure)

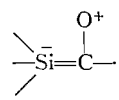
For personal use only.

material, freshly distilled, showed a low frequency carbonyl stretching band (1 645 cm^{-1}) although the frequency was higher than that of benzoylsilanes, and the ultraviolet spectra showed π–π^* absorption at 265 mμ, and n–π^* absorption centered about 390 mμ, rather lower than that of a benzoylsilane. It seems clear in view of the similar spectra that benzoylsilanes and benzoylphosphines are closely related species subject to the same sort of group interactions.

It now seems quite clear that the abnormally low infrared carbonyl stretching frequency in benzoylsilanes is a result of significant single bond character in the carbonyl group caused by inductive release of electrons by the adjacent silicon atom. In accord with this Yates and Agolini (14) have established that benzoyltriphenylsilane is significantly more basic than benzoyltriphenylmethane. Also, Brook and Pierce (3) have shown that β- but not γ-silyl ketones absorb at a lower frequency than their carbon analogs, a result consistent with inductive electron release acting through a single intervening methylene group. Thus in the ground state benzoylsilanes must have a significant negative charge associated with the carbonyl-oxygen atom. Back bonding of this charge from oxygen into the available d orbitals on silicon forming n–d π-bonding seems inconsistent with the basicity studies, but cannot be excluded on the present available data. As noted before, the π–π^* transition is little affected in ketones by replacement of carbon by silicon, wherease the n–τ^* is significantly affected by this change. West has explained these effects as due to a general lowering of both the π and π^* levels, relative to the n energy level in silyl ketones (4) which implies stabilization of the excited state by contributions from structures such as



through charge delocalization from carbon into the adjacent unoccupied silicon d orbitals. At the same time, it seems probable that the n level is raised relative to the π^* level, by virtue of the strong inductive electron release of the adjacent silicon atom, as characterized by the infrared stretching frequency. These two effects in concert result in π–π^* transitions at about the same wavelength for ketones and benzoylsilanes, while at the same time the n–π^* wavelength is raised significantly. Superimposed on these two effects are the general effects of para substituents (6) which appear to influence both transitions in the same way and to about the same extent in both ketones and benzoylsilanes.

The new ketones employed in this study were all prepared from the appropriately substituted benzylsilane by dibromination with N-bromosuccinimide followed by hydrolysis in aqueous organic solvent mixtures employing either silver acetate (1) or silver trifluoroacetate (3), the latter effecting hydrolysis much more rapidly. The triphenylbenzylsilanes were prepared by one of several general routes; viz. (*a*) coupling of a *p*-substituted benzyl Grignard reagent with triphenylchlorosilane (X = *p*-*tert*-butyl, *p*-methoxy), (*b*) reaction of a *p*-substituted benzyl Grignard reagent with silicon tetrachloride, followed by coupling of the benzyltrichlorosilane with 3 mole equivalents of phenyl Grignard reagent (X = *p*-fluoro, *p*-chloro), (*c*) bromination of benzyltrichlorosilane, followed by coupling with phenyl Grignard reagent (X = *p*-bromo), (*d*) nitration of benzyltriphenylsilane (X = *p*-nitro). The properties of these compounds and of their intermediates are given in Table III.

The tris-*p*-substituted phenylbenzylsilanes were synthesized by similar routes; viz. (*a*) coupling of the appropriately tris-*p*-substituted phenylchloro- or bromo-silane with

benzyl magnesium chloride (X = *p*-Me_2N, *p*-Me, *p*-Cl,), or (*b*) of the methoxysilane with benzyl magnesium chloride (X = *p*-CF_3), (*c*) coupling of benzyltrichlorosilane with 3 equivalents of the appropriate *p*-substituted phenyl Grignard reagent (X = *p*-Me). The benzylsilanes were converted in the ordinary way to the ketones. In the case of tri-*p*-tolylbenzylsilane bromination probably occurred both on the methylene hydrogens and also on the methyl group. The dibromide isolated was crystallized to give an apparently pure product which analyzed correctly, but hydrolysis gave a yellow oil with the characteristic spectrum of a benzoylsilane but which was contaminated with unhydrolyzable bromine-containing material and acetate esters from which it could not be separated by crystallization or chromatography. Properties of the compounds are given in Table IV.

EXPERIMENTAL

All reactions involving organometallic reagents were carried out under an atmosphere of nitrogen.

Infrared spectra were obtained on a Perkin–Elmer 221 instrument run at very slow speed using carbon tetrachloride as solvent and are probably accurate to 1–2 cm^{-1}. Ultraviolet spectra were determined in ethanol on a Beckmann DK 1 instrument or in cyclohexane on a Perkin–Elmer 350 instrument.

Reagents

p-Bromobenzyltrichlorosilane was prepared by bromination of benzyltrichlorosilane (15).

p-Fluorobenzyltrichlorosilane, b.p. 56° at 0.13 mm, was prepared in 56% yield by reaction of silicon tetrachloride in 1:5 ether–hexane at 0° with the Grignard reagent of *p*-fluorobenzyl bromide in ether.

Anal. Calcd. for $C_7H_6SiCl_3F$: Cl (titratable), 43.5. Found: Cl, 43.5.

The *p*-fluorobenzyl bromide was prepared in 63% yield by treatment of *p*-fluorotoluene with 1 equivalent of N-bromosuccinimide in CCl_4, b.p. 29.3–31° at 0.035 mm, n_D^{22} 1.5480. *p*-Chlorobenzyltrichlorosilane was similarly prepared from the Grignard reagent of *p*-chlorobenzylchloride and silicon tetrachloride in 64% yield, b.p. 80° at 0.10 mm.

Anal. Calcd. for $C_7H_6SiCl_4$: Cl (titratable), 40.4. Found: Cl, 41.3.

Tri-(p-trifluoromethylphenyl)-methoxysilane

A solution of *p*-trifluoromethylphenylmagnesium bromide, prepared from 60.8 g (0.27 mole) of *p*-bromobenzotrifluoride and 6.55 g (0.27 g-atom) of magnesium in 250 ml of dry ether, was added over 1 h to 10.0 g (0.074 mole) of trichlorosilane in 50 ml of dry ether. There was immediate evolution of heat. After 4 h reflux, the reaction mixture was cooled and drowned in ice water and dilute acid, and was ether extracted. Bubbles of gas were evolved during the extraction. The organic phase was dried over anhydrous sodium sulfate and then distilled to give 18.3 g of product, b.p. 136–146° at 0.15 mm. The infrared spectrum had a strong band at 2.7 μ (SiO—H) but no band at 4.7 μ (Si—H). Crystallization from methanol gave 18.8 g (51.5%) of tri-(*p*-trifluoromethylphenyl)-methoxysilane, m.p. 123°, which was raised to 130–131° by further recrystallization. Evidently, the silanol reacted with the methanol since the product had no SiO—H peak at 2.7 μ but a new peak at 3.5 μ (CH_3O) had appeared.

Anal. Calcd. for $C_{22}H_{15}SiOF$: C, 53.4; H, 3.06. Found: C, 53.4; H, 3.16.

Synthesis of Benzyl- and Benzoyl-silanes

Typical procedures for the synthesis of the benzyl- and benzoyl-silanes are described below.

Method A. Coupling of p-Methoxybenzylmagnesium Chloride with Triphenylchlorosilane

To 11.8 g (0.040 mole) of triphenylchlorosilane in 150 ml of tetrahydrofuran was added over 45 min 160 ml of 0.25 *N* *p*-methoxybenzylmagnesium chloride (0.04 mole) prepared by the method of Van Campen *et al.* (19) except that tetrahydrofuran was employed as solvent. The reaction was refluxed for 1 h and then stirred overnight. After hydrolysis with dilute acid the organic phase was water washed, dried, and evaporated to dryness. Addition of ethanol gave 12.2 g (80%) of *p*-methoxybenzyltriphenylsilane, m.p. 107–108° after recrystallization from 1:1 ethanol–hexane.

Method B

To 2.73 g (0.011 mole) of *p*-fluorobenzyltrichlorosilane in ether was added slowly at 0° 3 equivalents of phenyllithium in ether. A negative color test was obtained at the end of the addition. After hydrolysis with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dilute acid and work-up 3.30 g (79%) of *p*-fluorobenzyltriphenylsilane was obtained, m.p. 98–99° after recrystallization from absolute ethanol.

Method C. Nitration of Benzyltriphenylsilane

To a solution of 15.2 g (0.043 mole) of benzyltriphenylsilane in 150 ml of acetic anhydride was added over 45 min 5 g of red fuming nitric acid, specific gravity 1.59. The reaction became warm. After cooling to room temperature the reaction was poured into ice water and concentrated ammonium hydroxide. The crude product was filtered and crystallized from 1:1 ethanol – ethyl acetate to yield 9.40 g (55%) of *o*-nitrobenzyltriphenylsilane, m.p. 155–156°. This material was shown to be the ortho-nitro compound as follows.* A mixture of 4.0 g (0.01 mole) of the nitro compound, m.p. 155–156°, in 50 ml of a solution prepared from 1 volume of 50% aqueous sodium hydroxide and 7 volumes of ethanol was refluxed for 30 h. After addition of water and ether extraction, the dried ether layers were concentrated and then distilled to yield 1.0 g (73%) of *o*-nitrotoluene, b.p. 50° at 1 mm, identified by the identity of its infrared and n.m.r. spectra with those of an authentic sample. The filtrate from which the ortho-nitro compound was isolated was evaporated to dryness leaving an oil which crystallized from absolute ethanol to give 4.75 g (28%) of *p*-nitrobenzyltriphenylsilane, m.p. 105–115°. Several recrystallizations raised the m.p. to 114.5–116.5°.

p-(N-Acetylamino)-benzyltriphenylsilane.—A suspension of 3.75 g (0.0075 mole) of *p*-nitrobenzyltriphenylsilane in 120 ml of glacial acetic acid and 20 ml of acetic anhydride was shaken under 30 p.s.i. of hydrogen in the presence of PtO_2 for 24 h. Work-up gave 3.35 g of crude water-insoluble product which after recrystallization from methanol gave white *p*-(N-acetylamino)-benzyltriphenylsilane, m.p. 207–208°. Attempted reduction under the same conditions but using glacial acetic acid or ethanol as solvents failed.

Halogenation of Benzylsilanes

p-tert-Butyl-αα-dibromobenzyltriphenylsilane

A mixture of 12.2 g (0.030 mole) of *p-tert*-butyl benzyltriphenylsilane, 10.7 g (0.060 mole) of N-bromosuccinimide and 200 ml of carbon tetrachloride was refluxed for 3 h. A trace of benzoyl peroxide was added to initiate the reaction. On cooling 6.7 g (107%) of succinimide was filtered off, the filtrate was evaporated to dryness under reduced pressure, and the residue on crystallization from ethanol–petroleum ether (90–100°) gave 14.95 g (92%) of product, m.p. 138.5–139.5°.

Other benzylsilanes were similarly halogenated. *o*-Nitrobenzyltriphenylsilane gave only a monobromide even when refluxed for prolonged periods, presumably due to steric hindrance.

Hydrolysis of αα-Dibromobenzylsilanes

Hydrolyses with silver acetate or silver trifluoroacetate were carried out in benzene–acetone–water or ethanol–water media according to previously described techniques (1, 3). Silver trifluoroacetate, prepared by reaction of trifluoroacetic acid with a slurry of silver oxide in benzene, appeared to react more rapidly with dibromides than did silver acetate.

Light-catalyzed Decomposition of Benzoyltriphenylsilane

A solution of 2.5 g (0.0069 mole) of benzoyltriphenylsilane in 50 ml of dry reagent grade methanol was exposed for 4 h to radiation from a General Electric "Bonus Line Mercury Reflector Spot" lamp, by which time the solution was entirely colorless. The excess methanol was removed under reduced pressure, and the residue (a mushy solid below room temperature) was distilled. Two main fractions were obtained. (*a*) Benzaldehyde dimethylacetal, 0.5 g (48%), b.p. 82° at 14 mm, n.m.r. 3.21 δ, singlet (CH_3—O), 5.35 δ, singlet (C—H), and 7.2-7.6 δ, multiplet (C—H aromatic), areas 5.7:1:5.5 (calcd. 6:1:5). The materialw as slightly contaminated with benzaldehyde, as judged by odor, and the presence of weak infrared absorption peaks at 3.65 and 5.85 μ (CH + C=O). (*b*) Triphenylmethoxysilane, 1.7 g (85%), b.p. 165–175° at 0.5 mm, m.p. 56–57°, identified by mixed melting point with an authentic sample.

Benzoyldiphenylphosphine

The compound was prepared as described in the literature (13) and the yellow product was twice distilled to give a 20% yield of material, m.p. 71–80°, b.p. 162–164° at 0.12 mm. An odor of benzaldehyde was noted after distillation, and was observable in the infrared spectrum as bands at 3.65 and 5.85 μ. When air was bubbled through 0.65 g of benzoyldiphenylphosphine in carbon tetrachloride for 15 min, 0.35 g (71%) of white solid, shown by mixed melting point to be diphenylphosphonic acid, m.p. 185°, precipitated. The filtrate was evaporated to dryness and was recrystallized from boiling water to yield 0.10 g (37%) of benzoic acid, m.p. 118–120°, identified by mixed melting point.

CYCLOHEXENE-3,3,6,6-d_4

A USEFUL COMPOUND FOR THE STUDY OF MECHANISM AND STRUCTURE[1]

SAUL WOLFE AND P. G. C. CAMPBELL[2]
Department of Organic Chemistry, Gordon Hall, Queen's University, Kingston, Ontario
Received November 17, 1964

ABSTRACT

The title compound (I) was prepared by Diels–Alder reaction of butadiene-1,1,4,4-d_4 with ethylene. The considerations which led to the synthesis of I are presented and some examples are then given of how use of I can simplify the study of, and provide new information about, a number of different kinds of problems. In the proton magnetic resonance (n.m.r.) spectra of the products of additions to I, the tertiary protons usually appear as clearly defined quartets. Since $|J_{AB}|$ can be read directly from these spectra, both the stereochemistry of the additions and the conformations of the products can be deduced. Thus, oxymercuration of I is clearly a *trans* addition and Na/Hg reduction of the mercury takes place with retention of configuration. When the second step is performed in D_2O, the oxymercuration–reduction sequence represents a convenient route for the *trans* addition of DOH to a double bond. Deuteroboration provided an example of *cis* addition of DOH to I. Acid-catalyzed hydration of I resulted in scrambling of the deuterium atoms. The value of $G_{Hg/OH}$ is small; $G_{Br/OH}$ is 600 cal/mole. The position of the double bond in a product resulting from allylic substitution of I is determined by integration of the n.m.r. spectrum. Relative to I, the possibilities are no rearrangement, 50% rearrangement, and 100% rearrangement of the double bond. The first product of allylic substitution by *N*-bromosuccinimide shows no rearrangement; therefore, this reaction does not require a "free" radical intermediate. The structure of an adduct formed during allylic acetoxylation of I by mercuric acetate (the Treibs reaction) has been determined.

INTRODUCTION

This is Part I of a series which will deal with the use of selectively deuterated cyclohexenes in the study of mechanism and structure. The purpose of this paper is to present the considerations which led to the synthesis of cyclohexene-3,3,6,6-d_4 (I) along with some of the ways in which the compound seems to be useful. Subsequent papers in this series will be concerned with detailed consideration of specific reactions.

APPLICATION OF I TO THE STUDY OF ALLYLIC SUBSTITUTION

The replacement of a hydrogen allylic to a double bond by oxygen or halogen represents an established method for the introduction of additional functionality into an organic compound; however, it is often observed that substitution is accompanied by rearrangement of the allylic system. Though rearrangements of allylic compounds are well known and have been the subject of numerous investigations (1), it is perhaps less well appreciated that varying amounts of rearrangement can also occur during the initial substitution, with the result that the product may have the new substituent at one end of the original double bond. In fact, we do not know of any reaction which will lead to allylic substitution of an olefin without rearrangement. Among the more common reagents which can effect allylic substitution, *t*-butylperesters[3] (2), lead tetraacetate[4] (7), unsensitized photooxygenation (10), *N*-bromosuccinimide (11), and chromium trioxide (12) are reported to

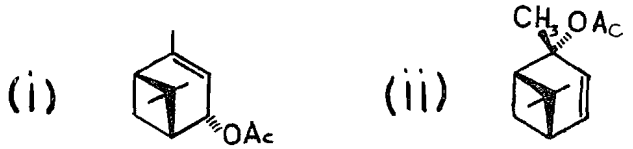
[1]*Presented in part at the 47th Annual Conference of the Chemical Institute of Canada, Kingston, June 1964.*
[2]*Holder of a Woodrow Wilson Fellowship, 1963–1964, and of a National Research Council Studentship, 1964–1965.*
[3]*The original reports (3, 4) suggested that t-butylperesters gave substitution without rearrangement and a rather elaborate mechanism had to be proposed (3); this mechanism was subsequently made invalid by the finding that products of rearrangement are present in the reaction mixtures (5, 6).*
[4]*Oxidation of α-pinene was reported by Criegee (7, 8) to give trans-verbenol acetate (i), the unrearranged product;*

give partial rearrangement; sensitized photooxygenation (13) and mercuric acetate (14, 15) afford mainly rearranged products.

Though some workers have utilized rather ingenious methods to move a new substituent from the synthetically less desirable end of an allylic system[5] (16), on the whole it is difficult to predict the position of the new substituent or to know which reaction will best suit a given synthetic requirement.

From the foregoing it would appear that the synthetic utility of allylic substitution might be improved if the timing of rearrangement or the relationship between substrate structure and the position of the new substituent could be determined. Compound I should be useful for the study of these problems for two reasons: first, the extent of rearrangement during allylic substitution of this compound can be easily determined by nuclear magnetic resonance spectroscopy (n.m.r.); secondly, if rearrangement does occur, it can be predicted that either 50% or 100% rearrangement will be observed. The rationale is shown in Chart 1. A priori, five different mechanisms can be considered: *A*, a carbonium ion mechanism in which the reagent, acting as an electrophile (17), removes a deuteride ion from the allylic position. The resulting carbonium ion should be mesomeric (18) and, unless the deuterium atoms exert an unusually large secondary isotope effect, the substituent, Z, will then be found with equal probability at positions *a* and *b*. This corresponds to 50% rearrangement. In fact, it has been found (*vide infra*) that the deuterium atoms do not display an observable isotope effect. In mechanism *B*, the reagent can remove a deuterium atom; the resulting radical should be mesomeric and, as with mechanism *A*, the product will correspond to 50% rearrangement. In mechanism *C*, the reagent, Z, attacks the double bond; concerted rearrangement of the resulting π-complex will then lead to 100% rearrangement, with the new substituent exclusively at position *a*. It would be anticipated that processes *A*–*C* would be more important than *D*, the direct replacement of allylic deuterium. Finally, as shown in *E*, substitution might be the result of addition of the reagent YZ, followed by elimination of DY or DZ. Mechanism *E* would lead to 100% rearrangement but should be distinguishable from *C* if the intermediate can be detected.

subsequent work (9), however, suggests that the initial product is actually cis-2-acetoxypin-3-ene (ii), the rearranged compound, and that (ii) is converted to (i) upon distillation.



[5]*In their total synthesis of dl-atisine, Nagata et al. (16) accomplished the transformation as follows:*

For personal use only.

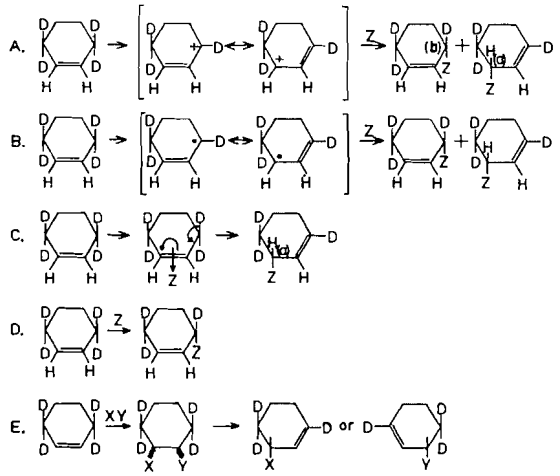

CHART 1. The various possible mechanisms for allylic substitution of I: *A*, carbonium ion mechanism; *B*, free radical mechanism; *C*, π-complex mechanism; *D*, direct displacement mechanism; *E*, addition–elimination mechanism.

With compound I as the substrate, determination of the extent of rearrangement in any given reaction can be performed by integration of the n.m.r. spectrum. Products formed without rearrangement will have two vinyl protons and no allylic protons; products of 50% rearrangement will show a vinyl:allyl proton ratio of 3; and products of 100% rearrangement will show a vinyl:allyl proton ratio of 1.

APPLICATION OF I TO THE STUDY OF ELECTROPHILIC ADDITIONS TO A DOUBLE BOND

The use of n.m.r. spectroscopy to determine configuration and conformation is based on experimental (19) and theoretical equations (20) relating vicinal coupling constants to dihedral angle. Although no single equation can be applied to all organic compounds (21), for substituted cyclohexanes it is well established that $|J_{aa}|$ is of the order of 10–11 c/s, and $|J_{ee}|$ ($\cong |J_{ea}|$) is 2.5–3.5 c/s (22). Therefore, if $|J_{AB}|$ could be determined for the product of addition of XY to the double bond of cyclohexene (where H_A and H_B are the protons geminal to X and Y respectively in the product), then it should be possible to deduce the stereochemistry of the addition. However, since H_A and H_B are also coupled to protons at C_3 and C_6, in practice the experimental determination of $|J_{AB}|$ is too difficult. Several methods have been developed to overcome this problem. The spectra can be simplified by the use of lower temperatures (23); structural information can be obtained by measurement of the widths of the unresolved multiplets (24, 25). But clearly the most useful simplification that could be introduced would be the removal of the factors which complicate the AB pattern in the n.m.r. spectra, i.e., the removal of the protons at C_3 and C_6.

Thus it would seem that I should be a useful compound for the study of additions to a double bond. The rationale for a number of different situations is shown in Chart 2. If an unsymmetrical reagent XY adds *cis* to the double bond of I, then, regardless of the position of the conformational equilibrium, $|J_{AB}|$ will be 2.5–3.5 c/s.[6] On the other hand,

[6]*Unless the molecule adopts a true boat conformation. However, it is now recognized that the boat is disfavored relative to the twist conformation (26, 27) and in this conformation the dihedral angle (33°) between* H_A *and* H_B *would lead to a* $|J_{AB}|$ *of 6–7 c/s.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the observed $|J_{AB}|$ for *trans* addition of XY will depend on the position of the conformational equilibrium between the ee and aa isomers; if X and Y are axial, then $|J_{AB}|$ will be 2.5–3.5 c/s; if X and Y are equatorial, $|J_{AB}|$ should be 10–11 c/s. It would be anticipated that only rarely should the conformational situation make the interpretation of $|J_{AB}|$ ambiguous (e.g., *trans* addition and substituents diaxial or *cis* addition and the ring in a twist conformation), but for these cases determination of $|J_{AB}|$ at various temperatures should remove the ambiguity. A corollary of these considerations is that once the stereochemistry of the addition of XY to cyclohexene is known, then the magnitude of $|J_{AB}|$ can be used to obtain information concerning the conformational equilibria.

For *trans* addition of X_2 to I, H_A and H_B are equivalent and do not couple. One would expect a single peak at room temperature (corresponding to the averaged chemical shift of the aa and ee conformers) splitting into two peaks at lower temperatures as the rate of the aa $\rightleftarrows$ ee interconversion is slowed down. For *cis* addition of X_2 to I, one would expect a single peak at room temperature, splitting to a quartet at lower temperatures because of the different chemical shifts of the equatorial and axial protons (28, 29).

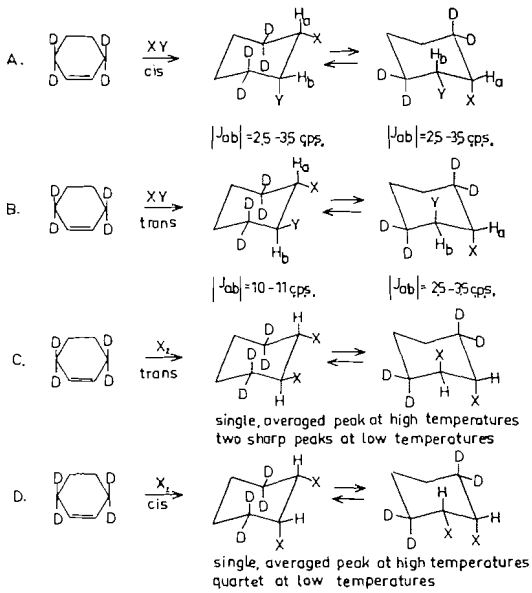

CHART 2. The various possibilities for electrophilic additions of XY and X_2 to the double bond of I; *A*, *cis* addition of XY; *B*, *trans* addition of XY; *C*, *trans* addition of X_2; *D*, *cis* addition of X_2.

RESULTS AND DISCUSSION

The preparation of cyclohexene from butadiene and ethylene was reported a number of years ago (30), but the Diels–Alder reaction as a route to deuterated cyclohexenes does not seem to have been tried. For the synthesis of cyclohexene-3,3,6,6-d_4 the required reagents are ethylene and butadiene-1,1,4,4-d_4. Since the latter compound is now available through the elegant procedure of Cope and co-workers (31), it was anticipated that the preparation of I would be straightforward. Because we do not have the equipment which is required for the Diels–Alder reaction, we asked Merck, Sharp and Dohme of Canada to undertake the synthesis of I. The product which we received had the n.m.r. spectrum shown in Fig. 1; the spectrum of ordinary cyclohexene is also shown in Fig. 1. The integrated intensities of the two peaks of the deuterated compound were 1:2, as required

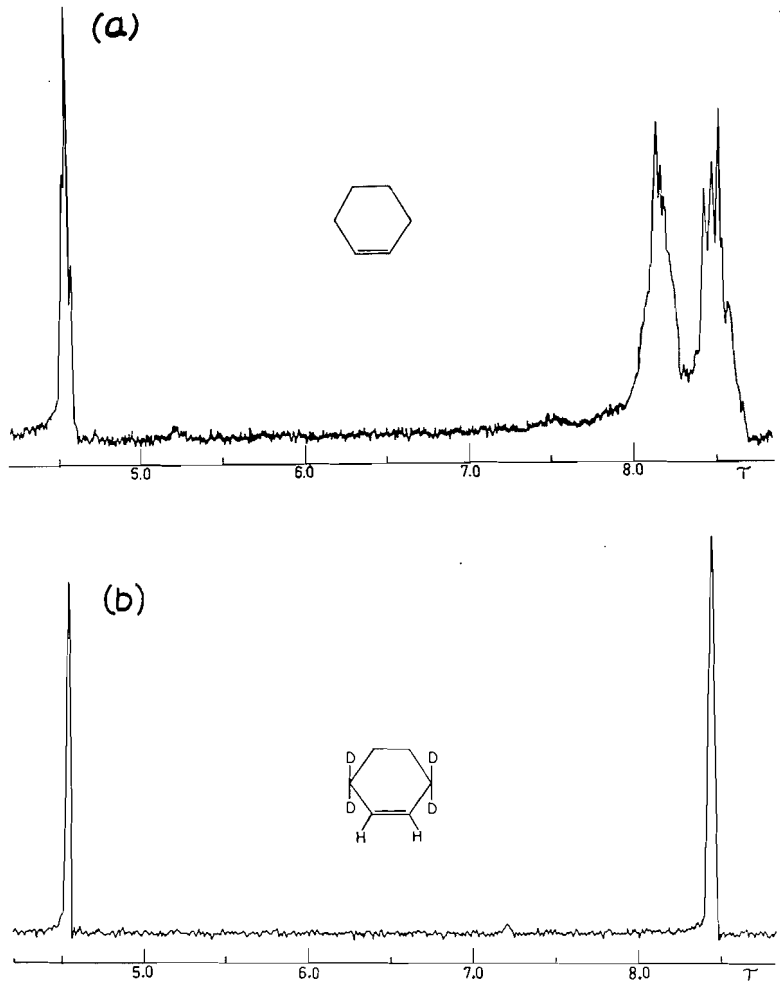

FIG. 1. (*a*) Nuclear magnetic resonance spectrum of cyclohexene in CCl_4; (*b*) n.m.r. spectrum of I in CCl_4.

for cyclohexene-3,3,6,6-d_4. It is clear that the Diels–Alder reaction took place without scrambling of the deuterium atoms.[7]

The n.m.r. spectrum of 2-deuteroxycyclohexylmercuric acetate, prepared by treatment of cyclohexene with mercuric acetate in D_2O, is shown in Fig. 2*a*; the proton geminal to the —OD appears as an unresolved multiplet at τ 5.85; the proton geminal to mercury is the sextet centered at τ 7.1. First order analysis of this sextet indicates that this proton is coupled (ca. 10 c/s) large to two other protons and small (ca. 3 c/s) to a third. The product of oxymercuration of I gives the much simpler spectrum shown in Fig. 2*b*. The AB quartet shows a coupling constant of 10.3 c/s.[8] The magnitude of this coupling constant is near the maximum expected for two vicinal axial protons; therefore, the reaction of mercuric acetate with cyclohexene in D_2O proceeds by *trans* addition (33, 34).

[7]*Compound I is available from Merck at a cost of about $42 per gram.*

[8]*The spectrum of Fig. 2a is apparently identical with one described by Anderson and Henry (32). These authors concluded that the oxymercuration of cyclohexene is trans. While we are in agreement with Anderson and Henry, it should be recognized that their interpretation is qualitative only since $|J_{AB}|$ cannot be obtained from the spacings of the sextet.*

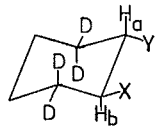
TABLE I

Oxymercuration of cyclohexene-3,3,6,6-d_4



X	Y	Solvent	$\|J_{AB}\|$, c/s
HgOAc	OD	D_2O	10.3
HgCl	OD	Pyridine	10.0
HgOAc	OCH_3	$CDCl_3$	10.1
HgCl	OCH_3	$CDCl_3$	10.1

Jensen has reported (35) that the A-value ($F_{(axial)} - F_{(equatorial)}$) for the chloromercuric grouping is zero. Assuming 90% of the diequatorial conformation for the product of oxymercuration of I, we have, at 40°,

$$\Delta F = -2.303RT \log 90/10 = 1\,400 \text{ cal/mole} = A_{Hg} + A_{OH} - G_{Hg/OH},$$

where G is the parameter introduced by Lemieux and Lown (19) to estimate *gauche* interactions. Using our experimental value of 1 400 cal for ΔF, Jensen's value of 0 for A_{Hg}, and Anet's value of 1 250 cal/mole for A_{OH} in D_2O (36), we conclude that the G-value for the hydroxyl–mercury interaction is approximately 0.

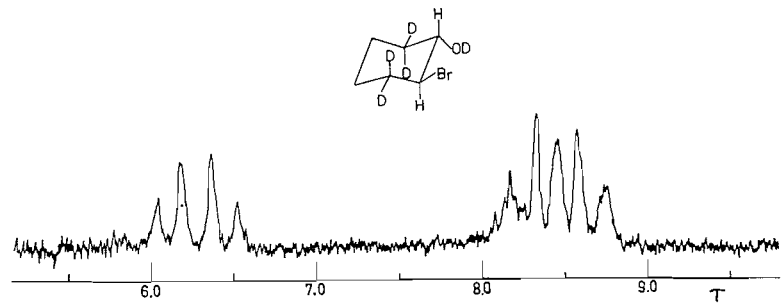


FIG. 3. Nuclear magnetic resonance spectrum of *trans*-2-deuteroxycyclohexyl bromide-3,3,6,6-d_4 in CCl_4.

Figure 3 shows the n.m.r. spectrum in CCl_4 of the *trans*-2-deuteroxycyclohexyl bromide prepared by treatment of I with N-bromosuccinimide in D_2O (37). Here $|J_{AB}|$ is 9.0 c/s; this means that the ratio of ee to aa conformers is approximately 85/15. Using the values A_{Br} = 600 cal/mole (38) and A_{OH} = 1 000 cal/mole (CCl_4), we estimate that $G_{Br/OH}$ is ca. 600 cal/mole. Clearly it is possible to extend this method of estimation of G-values to many pairs of groups. Studies of this nature are underway.

Various methods have been reported for the replacement of mercury by hydrogen. These include Na/Hg in water (39) and sodium borohydride (40). We were unable to convert *trans*-2-hydroxycyclohexylmercuric acetate or the derived mercuric chloride to cyclohexanol with either sodium borohydride or lithium aluminium hydride. Instead, under all conditions tried, reductive *elimination* to cyclohexene was observed (41). We had hoped, using the corresponding deuterohydrides, to determine the stereochemistry of the reduction. However, the oxymercuration products were smoothly converted to cyclohexanol by shaking with Na/Hg in water. Figure 4 shows the n.m.r. spectrum in carbon tetrachloride of the product obtained by treatment with Na/Hg in D_2O of the

For personal use only.

trans-2-deuteroxycyclohexylmercuric acetate derived from I. The doublet at τ 6.55 represents the proton geminal to the deuteroxy grouping, and the coupling constant (9.5 c/s) is just that expected *if the replacement of mercury by deuterium occurred with retention of configuration.* This may be calculated as follows: from the A-value for hydroxyl of 1 000 cal (36), the proportions of equatorial and axial hydroxyl are 88:12; therefore, the hydrogen geminal to deuteroxyl in the hexadeuterocyclohexanol formed by *trans* addition of D_2O to I should show a coupling constant of $0.88 \times 10.5 + 0.12 \times 3.5 = 9.7$ c/s, a value which is in good agreement with the above, observed value.[9]

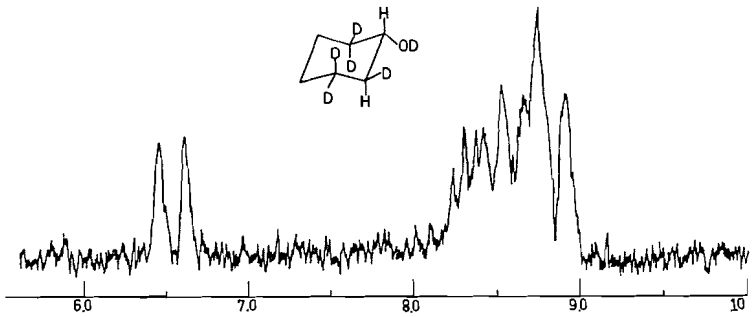

FIG. 4. Nuclear magnetic resonance spectrum in CCl_4 of cyclohexanol-2,3,3,6,6-d_5 from the Na/Hg reduction.

Although it has been pointed out by others (42) that the combination of oxymercuration followed by reductive displacement of mercury represents a useful and experimentally easy method for the addition of HOR to a double bond, the above results provide the further information that the overall addition is *trans*. Clearly, it is now possible by *trans* addition of DOR onto a double bond to effect stereospecific deuterium labelling and thus provide compounds which may be useful for further work.

The hydroboration reaction has been reported to proceed by *cis* addition of HOH to a double bond (43, 44). The n.m.r. spectrum shown in Fig. 5 is that of the 2,3,3,6,6-pentadeuterocyclohexanol obtained by treatment of I with lithium aluminium deuteride and boron trifluoride etherate, followed by oxidation with alkaline hydrogen peroxide (44). The hydrogen geminal to hydroxyl shows the doublet with $|J| = 3.8$ c/s at τ 6.55. The doublet shows considerable line broadening due to coupling of this proton with the adjacent deuterium atoms. Confirmation of this was obtained by a deuterium decoupling experiment[10] which led to the sharp doublet, $|J| = 3.8$ c/s, also shown in Fig. 5. The magnitude of this coupling constant is in agreement with expectation (part A of Chart 2).[11]

Since the two pentadeuterocyclohexanols resulting from *cis* and *trans* addition of DOH to I were available, it seemed that it was now possible to study the stereochemistry of acid-catalyzed hydration of cyclohexene. The conversion of ordinary cyclohexene to cyclohexanol could be performed by shaking cyclohexene for 1 h at 50° with a mixture

[9]*No mechanistic significance should be attached to this conclusion. Though retention of configuration is commonly observed in the cleavage of organomercury compounds (35),* Na/Hg *reduction is a heterogeneous reaction. Traylor and Baker (34) found retention in the* Na/Hg *reduction of exo-cis-3-hydroxy-2-norbornylmercuric chloride; in this case retention would be sterically favored.*

[10]*We thank Professor F. A. L. Anet for assistance with this experiment.*

[11]*Actually, the cis addition of* DOH *observed here is the result of two reactions: reaction of I with* B_2D_6 *to form a trialkylborane, followed by oxidation of the borane to cyclohexanol. An overall cis addition could occur by a (generally accepted) route involving cis addition of* B_2D_6 *and retention of configuration during the oxidation, or by trans addition of* B_2D_6 *followed by inversion of configuration during the oxidation.*

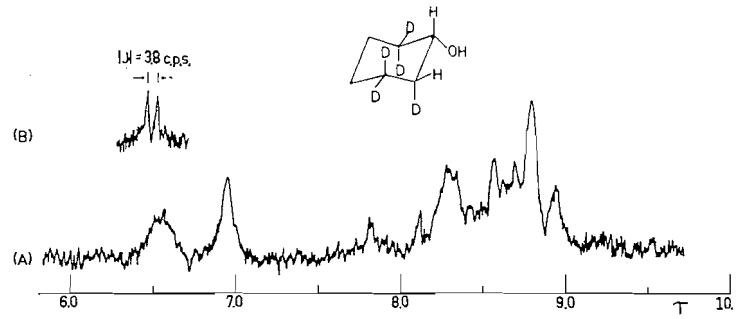

FIG. 5. Nuclear magnetic resonance spectrum in CCl_4 of cyclohexanol-2,3,3,6,6-d_5 from deuteroboration of I.

of 75% H_2SO_4 and CCl_4. However, repetition of the experiment with I and D_2SO_4/CCl_4 gave a cyclohexanol whose n.m.r. spectrum, after deuterium decoupling,[10] showed that considerable scrambling of deuterium had occurred. This reaction is presently being examined in more detail.

The results described above show that useful information can be obtained from studies of additions of unsymmetrical reagents onto the double bond of I. We now turn to some results obtained from allylic substitution experiments. Figure 6*a* shows the n.m.r. spectrum of the CCl_4 reaction mixture obtained by treatment of a 1% w/v solution of I with *N*-bromosuccinimide under the usual conditions for allylic bromination (45); Fig 6*b* shows the spectrum obtained upon concentration or further warming of this solution. The spectrum of an authentic sample of 3-bromocyclohexene is shown in Fig. 7; the

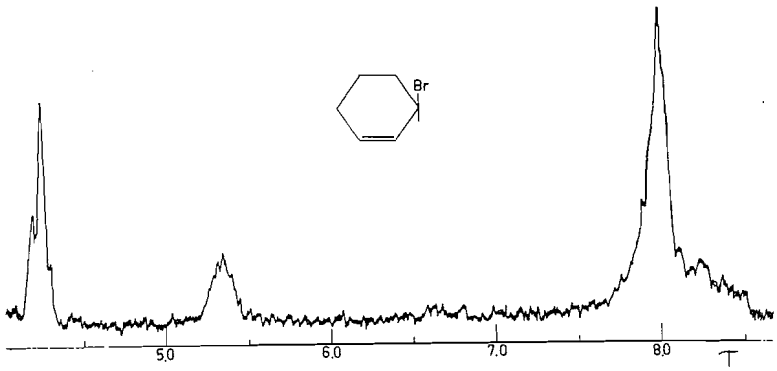

FIG. 7. Nuclear magnetic resonance spectrum of 3-bromocyclohexene in CCl_4.

multiplet (2H) at τ 4.25 represents the vinyl protons and the multiplet (1H) at τ 5.35 is the proton geminal to the allylic bromine. Figure 6*a* shows some unreacted I, as well as absorption at τ 4.25 and weak absorption at τ 5.35. *The integral at τ 5.35 is considerably less than one-third of the integral at τ 4.25.* This experiment has been repeated many times, with essentially the same result. Differences between experiments seemed to be related to the time interval between the end of the reaction and the taking of the n.m.r. spectrum. This result means that the initial product of the *N*-bromosuccinimide reaction contained less than 50% of II. On the other hand, the integrated intensities (3:1) of the peaks at τ 4.25 and τ 5.35 in the spectrum of Fig. 6*b* is just that expected for a 1:1 mixture

II:  III: 
of II and III. Gas chromatography confirmed that the mixture which gave the spectrum in Fig. 6*a* contained only I and 3-bromocyclohexene. Thus the primary product of allylic bromination of I with *N*-bromosuccinimide is III, which subsequently rearranges to a mixture containing equal amounts of II and III. Three conclusions may therefore be drawn. (i) The formation of 3-bromocyclohexene is not the result of a "free" radical reaction; (ii) the rearrangement of the primary product does proceed via a symmetrical intermediate; (iii) the deuterium atoms do not affect the expected 1:1 product distribution when a mesomeric intermediate is formed. Several interpretations of this result can be suggested, but it appears to us that the most reasonable explanation is that the radical chain reaction which is known to lead to allylic bromination (46, 47, 48), *occurs on the surface of the N-bromosuccinimide* (45). Detailed discussion of this point and the results of other experiments which we have carried out to test this explanation will be presented separately.

The demonstration that oxymercuration of I is a *trans* addition is in accord with the view that the reaction proceeds via a π-complex (IV) which collapses to a mercurinium ion (V) (34, 49). We felt that the Treibs reaction (14) should also involve the intervention of these initial steps. In water or alcohol the mercurinium ion then opens to give the product of *trans* addition while in hot acetic acid a different series of steps starting with IV or V leads to cyclohexenyl acetate.

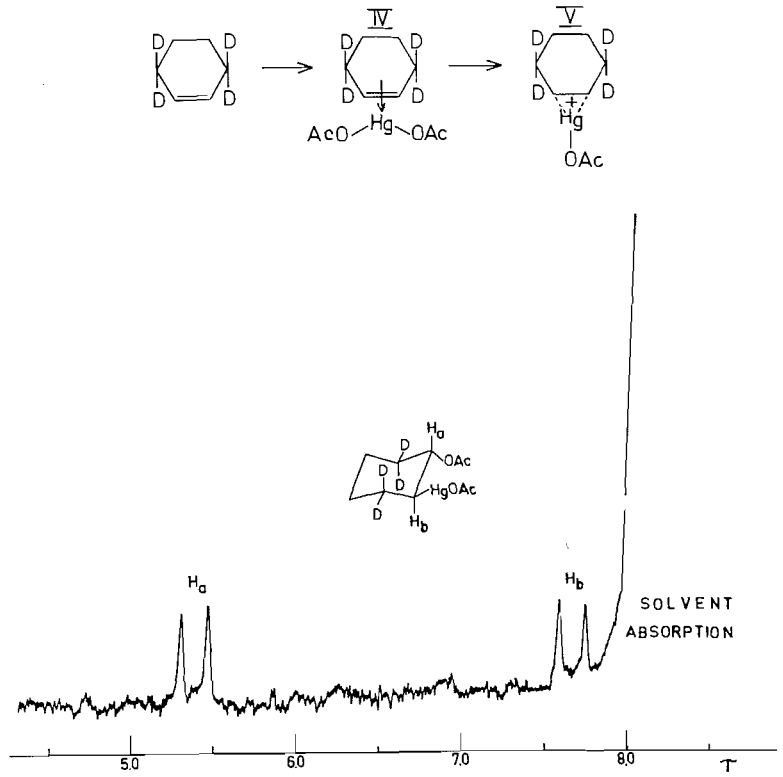

FIG. 8. Nuclear magnetic resonance spectrum of the mixture obtained upon treatment of I with $Hg(OAc)_2$ in glacial acetic acid at 70°.

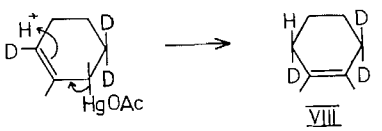
Treatment of I with mercuric acetate in acetic acid at 65° resulted in the immediate and complete disappearance of the vinyl protons from the n.m.r. spectrum and the concomitant appearance of a new series of peaks; the spectrum is shown in Fig. 8. There was no further change in this spectrum during the next 20 h. Though the reaction mixture at this stage apparently contained no unreacted olefin, attempted isolation of the product gave mainly cyclohexene with less than 10% of 3-acetoxycyclohexene. This result along with the n.m.r. spectrum suggested that either VI or VII was formed during the Treibs reaction.

VI VII

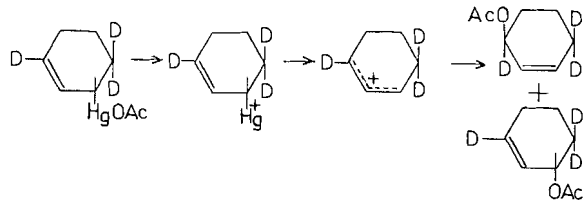
Either VI or VII could show the observed AB quartet in the n.m.r. spectrum with the indicated chemical shifts for the A and B protons. The reversion of VI to cyclohexene could then occur as shown (50).



VIII

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

On the other hand, solvolysis of VI would give 3-acetoxycyclohexene (51).



Conversion of VII to cyclohexene is the usual acid-catalyzed demercuration reaction (52); decomposition of VII to 3-acetoxycyclohexene could occur in several ways (15).

That the compound formed during the Treibs reaction is VII was established by a study of the n.m.r. spectrum of the recovered deuterated cyclohexene. As indicated above, reversion of VI to cyclohexene gives VIII, while demercuration of VII gives I. In practice, the conversion of the intermediate to cyclohexene was best accomplished by warming the mercuric acetate – cyclohexene – acetic acid reaction mixture with zinc dust; under these conditions quantitative reversion to cyclohexene occurred. The cyclohexene thus obtained was identical with I. If VI had been the intermediate, reaction with zinc in ordinary acetic acid could not have restored the deuterium atom lost in the formation of VI. Therefore, the Treibs reaction involves the quantitative formation of an *adduct*. The mechanism by which the mercuric acetate – olefin adduct decomposes to give an allylic acetate is presently being studied. It is not yet known whether the adduct is a necessary intermediate or is formed reversibly from a mercurinium ion which can also decompose irreversibly to allylic acetate.[12]

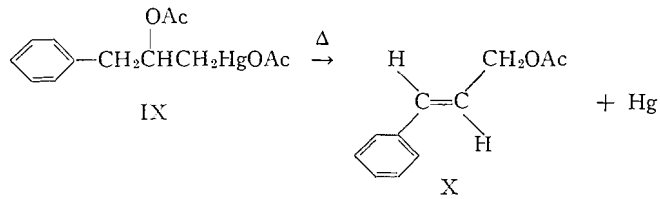
EXPERIMENTAL

The n.m.r. spectra were obtained on a Varian A-60 spectrometer, with tetramethylsilane (10% in chloroform) as an external standard. The deuterium decoupling experiment on cyclohexanol-2,3,3,6,6-d_5 was performed by Professor F. A. L. Anet on a 40 Mc instrument at the University of Ottawa. The solvents for n.m.r. samples were dried by conventional means. Gas chromatographic separations were made on a GC-2 instrument; the column packing was 1% SE-30 on Embacel.

Reaction of I with Mercuric Acetate in Deuterium Oxide

To 70 mg (0.82 mmole) of I in a 1 ml vial were added 270 mg (0.85 mmole) of mercuric acetate and 1 ml of deuterium oxide. The vial was then capped and shaken vigorously for 20 min, whereupon the solution became clear. The solution was allowed to stand for 70 min with occasional shaking. The reaction mixture then gave the n.m.r. spectrum shown in Fig. 2*b*. To the above solution of *trans*-1-deuteroxy-2-acetoxymercuricyclohexane-3,3,6,6-d_4 was added a solution of 0.65 g of sodium chloride in 4 ml of water. A copious

[12]*From the reaction of allylbenzene with mercuric acetate the adduct IX can be isolated in 90% yield. Heating this compound in refluxing acetic acid leads to quantitative precipitation of mercury and formation of X in 80–90% yield. Deuterium-labelling experiments show that the secondary acetate group is lost during the transformation of IX to X (53).*



After this paper was submitted for publication, a paper by Wiberg and Nielsen appeared (54) with some additional observations on the Treibs reaction. These workers observed 50% rearrangement in the conversion of cyclohexene-1,2-^{13}C to cyclohexenyl acetate; this result means that a mesomeric intermediate is formed during the reaction. Wiberg and Nielsen suggest that a mercurinium ion partitions itself between addition of acetate to form an adduct and loss of a proton to give an allylmercuriacetate. The mesomeric intermediate is then formed during the solvolysis of the latter.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

white precipitate formed immediately. The mixture was cooled to 0°; the precipitate was collected and dried *in vacuo* at 80°. The yield of *trans*-1-hydroxy-2-chloromercuricyclohexane-3,3,6,6-d_4 was 238 mg (85%). This product was dissolved in 0.7 ml of dry pyridine for determination of the n.m.r. spectrum.

Reaction of I with Mercuric Acetate in Methanol

A solution was prepared containing 60 mg (0.70 mmole) of I in 2.5 ml of absolute methanol. To this solution was added 233 mg (0.73 mmole) of mercuric acetate. The resulting solution was stirred at room temperature for 1 h. The solvent was then completely removed *in vacuo*, and the resulting viscous oil was dissolved in 0.7 ml of deuterochloroform and the n.m.r. spectrum was obtained. The deuterochloroform was then removed *in vacuo*. To the residue was added a solution of 0.56 g of sodium chloride in 5 ml water. The resulting mixture was shaken for 5 min and was then cooled to 0°. The precipitate which formed was collected and dried. The yield of *trans*-1-methoxy-2-chloromercuricyclohexane-3,3,6,6-d_4 was 241 mg (96%). This product was dissolved in 0.8 ml of deuterochloroform for determination of the n.m.r. spectrum.

Reaction of I with N-Bromosuccinimide in Deuterium Oxide

A mixture of I (60 mg, 0.7 mmole), *N*-bromosuccinimide (130 mg, 0.7 mmole) and deuterium oxide (1 ml) was shaken for 20 min, by which time the *N*-bromosuccinimide had dissolved. Carbon tetrachloride (1 ml) was added and the organic layer, after drying, gave the n.m.r. spectrum shown in Fig. 3.

Reduction of trans-1-Hydroxy-2-chloromercuricyclohexane-3,3,6,6-d_4 with Sodium Amalgam in Deuterium Oxide

Freshly prepared *trans*-1-hydroxy-2-chloromercuricyclohexane-3,3,6,6-d_4 (270 mg) was stirred in 1 ml of water with 50 mg of sodium bicarbonate to remove traces of the acetic acid produced during the oxymercuration. The mixture was cooled in an ice bath and the precipitate was collected. After drying *in vacuo* at 80° the yield was 226 mg. This relatively large loss was due in part to the partial conversion of the water-insoluble chloromercuricyclohexane to the water-soluble hydroxymercuricyclohexane. The 226 mg (0.67 mmole) of *trans*-1-hydroxy-2-chloromercuricyclohexane-3,3,6,6-d_4 were transferred to a 5 ml volumetric flask. Into this flask were weighed 7.5 g of 2% sodium amalgam and 1.45 g of deuterium oxide. The flask was securely stoppered and was then shaken at room temperature for 6 h. The deuterium oxide layer was decanted and was then extracted with 2 ml of carbon tetrachloride. The carbon tetrachloride extract was dried by filtration through a column of anhydrous sodium sulfate. The n.m.r. spectrum of the filtrate is shown in Fig. 4.

Deuteroboration of I

A solution of 100 mg (1.16 mmole) of I in 3 ml of diethyl ether (freshly distilled from $LiAlH_4$) was placed in a three-necked 25 ml flask. This flask was fitted with a stirrer, a dropping tube, and a condenser with a nitrogen inlet. The reaction flask was maintained at 0°. A solution of 178 mg (1.25 mmole) boron trifluoride etherate in 2 ml of dry diethyl ether was added to the ether solution of I. Then a suspension of 94 mg (2.45 mmole) of lithium aluminium deuteride in 5 ml of dry diethyl ether was gradually added with vigorous stirring. The addition required 1 h. The ice bath was then removed, and the reaction mixture was stirred for an additional 2 h. The mixture was then cooled again to 0°, and 0.75 ml of acetone was added to destroy any excess lithium aluminium deuteride. Saturated sodium sulfate (2 ml) was then added followed by 1.5 g of solid sodium sulfate. The solution was decanted from the precipitated inorganic salts and the solvent was removed *in vacuo*. The residual oil was dissolved in 3 ml of 90% ethanol and 100 mg of sodium hydroxide were added, followed by six 0.2 ml portions of 30% hydrogen peroxide, the solution being warmed at 70° for 5 min between each addition. The mixture was diluted with 9 ml of water and extracted with three 10 ml portions of diethyl ether. The combined ether extracts were washed with water, dried over anhydrous sodium sulfate, and concentrated *in vacuo*. The oil remaining after the complete removal of the diethyl ether was dissolved in 0.7 ml of carbon tetrachloride. This solution gave the n.m.r. spectrum shown in Fig. 5.

Reaction of I with N-Bromosuccinimide in Carbon Tetrachloride

To a solution of I (60 mg, 0.7 mmole) in carbon tetrachloride (5 ml) were added *N*-bromosuccinimide (130 mg, 0.7 mmole) and benzoyl peroxide (2 mg). The mixture was then heated to reflux temperature and the heat source was removed while the mixture was illuminated with a 100 W Photoflood No. 2 lamp. The illumination was stopped after 6 min. Filtration of the reaction mixture then gave a solution whose n.m.r. spectrum is shown in Fig. 6*a*; concentration of this solution to 1 ml led to the n.m.r. spectrum shown in Fig. 6*b*.

Reaction of I with Mercuric Acetate in Glacial Acetic Acid

A solution was prepared containing 60 mg (0.70 mmole) of I in 0.85 ml of glacial acetic acid. The n.m.r. spectrum of this solution showed the characteristic strong unsplit absorption of the olefinic protons in I at τ 4.5. The solution was then decanted from the n.m.r. tube and 230 mg (0.70 mmole) of mercuric acetate were added. The mixture was warmed to aid solution of the mercuric acetate, and was then returned to the n.m.r. tube. The n.m.r. spectrum (70 s after mixing) now showed no olefinic absorption, but did show two new doublets at τ 5.4 and τ 7.6 forming a quartet with $|J_{AB}|$ 10.0 c.p.s. This spectrum is shown in Fig. 8. The reaction mixture was kept at 65 °C for 20 h and there was no further change in the n.m.r. spectrum. Then 140 mg (2.14 mmole) of zinc dust and 1 drop of water were added. This mixture was warmed for 12 h

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

at about 35 °C in a sealed vial, with occasional shaking. The clear supernatant liquid was decanted into a n.m.r. tube. The n.m.r. spectrum showed the olefinic absorption of I at τ 4.5; on a 50 cycle sweep width there was no observable splitting of the peak. The remainder of the spectrum was largely overrun by the acetic acid solvent. This solution was then diluted with an equal volume (0.8 ml) of carbon tetrachloride, and the resulting solution was distilled from a water bath, the bath temperature being slowly raised from 50 to 90°. The distillate (0.75 ml) was condensed at 0°, washed with a solution of 150 mg of sodium bicarbonate in 1 ml of water, and dried over anhydrous sodium sulfate. The n.m.r. spectrum of this solution was identical with that of I (Fig. 1*b*). Repetition of the above experiment using deuteroacetic acid (AcOD) as the solvent and 1 drop of deuterium oxide in the zinc dust treatment gave the same results.

Acid-Catalyzed Hydration of Cyclohexene

To a solution of 150 mg (1.83 mmole) of cyclohexene in 0.5 ml of carbon tetrachloride was added 0.3 ml of a 75% (by weight) solution of sulfuric acid in water. The reaction flask was stoppered and shaken at 50 °C for 90 min. Dilution with 2 ml of water, followed by saturation with sodium chloride and steam distillation, gave a distillate which was then saturated with sodium chloride and extracted with carbon tetrachloride. The carbon tetrachloride extract was dried over anhydrous sodium sulfate and concentrated *in vacuo* to a pale-yellow oil. The infrared and n.m.r. spectra of this oil were identical with those of an authentic sample of cyclohexanol. When the above procedure was repeated using I and a 75% solution of deuterosulfuric acid in deuterium oxide, a pale-yellow oil was again obtained. The n.m.r. spectrum of a carbon tetrachloride solution of this oil was correct for a cyclohexanol, but not for cyclohexanol-2,3,3,6,6-d_5, the expected product of simple addition. Deuterium decoupling indicated that considerable scrambling of deuterium had occurred.

ON THE FORMATION OF "Ag_2O_3" ON SILVER ELECTRODES[1]

E. J. Casey and W. J. Moroz
Defence Chemical, Biological, and Radiation Laboratories, Defence Research Board, Ottawa, Canada

Received November 20, 1964

ABSTRACT

"Ag_2O_3" was examined electrochemically in eutectic KOH–H_2O at −40 °C by coulombic measurements of quantities formed, open circuit potential decays, variation of potential as a function of anodic current density, and temperature coefficients of decomposition rates. It can be formed directly from Ag_2O on Ag at current density (c.d.) > 15 $\mu A/cm^2$, with a maximum thickness during the first oxidation cycle (25 layers, assuming a surface roughness factor of one) occurring at 65 $\mu A/cm^2$. Potential decay ($-\partial E/\partial \log t \equiv b$) curves have protracted linear regions where $0.045 < b < 0.078$, sometimes higher. One-tenth of a layer of adsorbed species superimposed on the higher oxide exists on the surface during O_2 evolution. Reduction curves show a minimum in the potential decay of the higher oxide preceding the formation of Ag_2O. The "Ag_2O_3" decomposes in approximately 1 h at −40 °C to either AgO or Ag_2O. The activation energy for its thermal decomposition is 12.0 ± 2.0 kcal/mole. Under most experimental conditions studied the results indicated that the material is not true Ag_2O_3 but it is probably better described as $Ag_2O[O]$ where [O] is trapped oxygen.

The evidence does point to the probable existence of a thin layer, which may be true Ag_2O_3, on the surface in a steady state which is maintained at high anodic current density (> 100 $\mu A/cm^2$ at −40°).

INTRODUCTION

About 100 papers have been published in which the existence of higher oxides of silver (i.e. Ag^{+3}) are discussed, implied, or claimed. The papers fall into two groups. In one there is a definite claim or implication that the compound studied was Ag_2O_3; in the other there is concern over the proximity of the oxygen electrode, the presence of peroxides on the surface, and the influence which foreign ions such as nitrate and sulfate have on the crystal structure and stability of a material which behaves like a higher oxide of silver. However, the question of whether a pure phase of trivalent silver oxide exists still remains. This question is not only of intrinsic interest but is also a practical one, as it concerns charge acceptance in the zinc – silver oxide battery, and the use of silver oxide catalyzed oxygen electrodes in fuel cells. Sections of three excellent reviews discuss Ag_2O_3 (1, 2, 3).

The present investigation was undertaken at low temperature (−40 °C), where the rate of decay of "Ag_2O_3" is slow enough to permit study over an hour or two. We use the symbol "Ag_2O_3" to indicate the uncertainty about the chemical composition and structure of the material under study. We use the symbol 'Ag_2O_3' when the experimental indications are such that the material may be in fact the stoichiometric compound Ag_2O_3.

EXPERIMENTAL METHODS

The test cell consisted of a test electrode, a counter electrode, and a reference electrode (Hg/HgO) with a luggin capillary, immmersed in eutectic KOH–H_2O in a cylindrical glass vessel equipped with a Teflon covered magnetic stirrer. The cell contained 125 ml of electrolyte made from deionized water. The carbonate content of the electrolyte was of the order of 0.5%.

The silver electrodes were cut from rolled sheet 0.005 in. thick and 99.99% pure, and measured 1.27 × 2.54 cm. The apparent surface area exposed to the electrolyte was 6.46 cm^2. Before use, all electrodes were degreased in hot acetone, and then etched in dilute nitric acid or scraped with glass. A silver wire mounted in a glass capillary tube was forge welded to a tab at the top of the test electrode. The tab, wire, and capillary tube were then sealed off from the electrolyte with stop-off lacquer. The counter electrode was a commercially available porous silver electrode of large area. Formed into the shape of a cylindrical tube, it completely

[1]*Issued as DCBRL Report No. 454.*

surrounded the test electrode. During the course of the experiments the counter electrode was always kept at or near the potential of the AgO/Ag_2O electrode by periodic oxidation.

Some experiments were carried out with porous silver test electrodes for purposes of comparison with data obtained using the planar or sheet electrodes.

Temperature control was $\pm 1°$ at $-40°$ in a Tenney two-stage freon low temperature cabinet, with the cell temperature cycling at $\pm 0.2°$. Potential measurements were made on a General Radio DC Amplifier, type 1230-A, used with an Esterline-Angus Model AW, continuous recording DC Milliammeter. The input resistance of the G.R. amplifier was set at 10^{10} ohms. The ammeters used were calibrated against our own secondary standard. All oxidations and reductions were carried out using constant current techniques, with manual control, direct current being supplied from a 6 V storage battery through the appropriate resistors. Amounts of materials formed on or removed from the surface were thus easily determined.

RESULTS AND DISCUSSION

Anodic Oxidation at −40°

The oxidation curve of voltage vs. time for a planar or a porous silver electrode can take one of two shapes depending upon the rate of oxidation. If the oxidation current density is below a critical value, the peak which generally precedes AgO formation is evident and the oxidation curve can be considered normal. However, if the oxidation current density is above the critical value, the electrode potential rises quickly through the peak without inflection (4) (there is no evidence of the usual AgO plateau) and continues to rise until oxygen evolution commences.

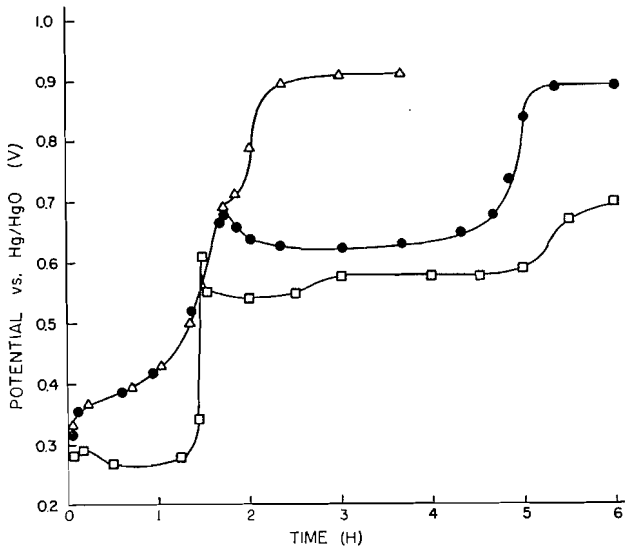

FIG. 1. Anodic oxidation curves of planar silver electrodes illustrating Ag_2O_3 and AgO formation △, ●, oxidation at c.d. of 15 $\mu A/cm^2$ at $-40°$; □, oxidation at 75 $\mu A/cm^2$ at 25 °.

In Fig. 1 are shown the two types of curves. The critical current densities were found to be 15 $\mu A/cm^2$ for the planar electrode and $\sim 10^3$ $\mu A/cm^2$ for the porous electrode (apparent areas). Electrolytic reduction following a charge shows the presence of AgO, as would be expected after a normal charge, but no evidence of AgO following oxidation at higher than critical current densities. In the latter case the usual mechanism by which Ag_2O is oxidized to AgO is obviously missing or altered as evidenced by the absence of the peak, and also of any AgO potential plateaus during forced or open circuit (o.c.) potential decays. The presence of a new, well-defined voltage plateau at approximately 725 mV with respect to (w.r.t.) Hg/HgO/KOH reference electrode during oxidation, and

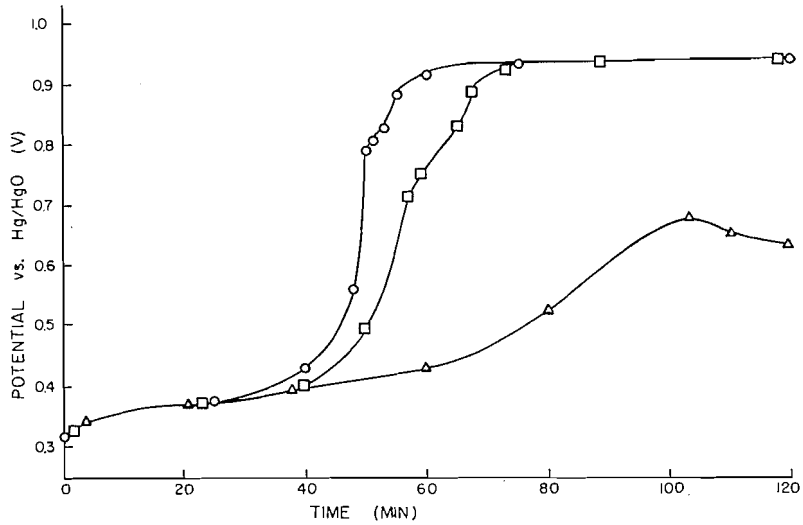

FIG. 2*a*. Consecutive anodic oxidations of a *planar* silver electrode at −40° showing transition from Ag_2O_3 to AgO formation. Oxidation c.d. was 15 $\mu A/cm^2$.

a similar well-defined potential arrest both on forced and o.c. decay in the 800–600 mV region, lead one to suspect that a new intermediate stage may be occurring in this potential region.

Three successive oxidation curves on a planar electrode are shown in Fig. 2*a*. The electrode was alternately oxidized and reduced (to O_2 evolution and Ag, respectively) at the critical current density of 15 $\mu A/cm^2$. As can be seen, both types of oxidation curves were obtained and the transition from the one type to the other is clearly evident. Successive oxidations at higher current densities produced changes of degree, but not of kind, in the shape of the oxidation curve. Generally speaking the result of repetitive oxidation–reduction cycles on planar electrodes is to increase the depth of the oxidation layer and increase the area of the electrode surface. At the apparent critical current density used above, this was equivalent to reducing the actual current density by the third cycle to somewhat below the critical value. The necessary conditions for higher oxide formation were not sustained, and the formation of AgO resulted.

Fig. 2*b* shows tracings of potential during two successive oxidations of a *porous* silver electrode at its critical current density at −40°. The fine structure in the vicinity of the peak is much better developed than in the case of the planar electrode.

The Oxygen Precursor

The decay of o.c. potential at −40° of an anodically polarized planar electrode which has been evolving O_2 for some time is linear with the logarithm of time from about the fifth second to the time (up to as long as an hour or so later) when it falls to the next potential plateau (Fig. 3). However, within the first 5 s, curvature of the E vs. log t plot occurs, concave upward. If the linear plot is extrapolated back to very small values of time, and the extrapolated values are subtracted from the measured ones, a set of potential differences ΔE at the different times can be obtained. These values can be considered to refer to an oxygen precursor superimposed on the higher oxide, and can be described by a diffusion-controlled model of O_2 liberation. Thus, if one assumes that the activity of the reduced form (OH^-?) is constant in the double layer, that the decay is governed by

Fick's second law of diffusion, that the Nernst equation holds, and that the boundary conditions must be consistent with a source on a plane diffusing normal to the plane; the potential E decays as the sum of two terms, $1/t + C \log t$. It was found that ΔE vs.

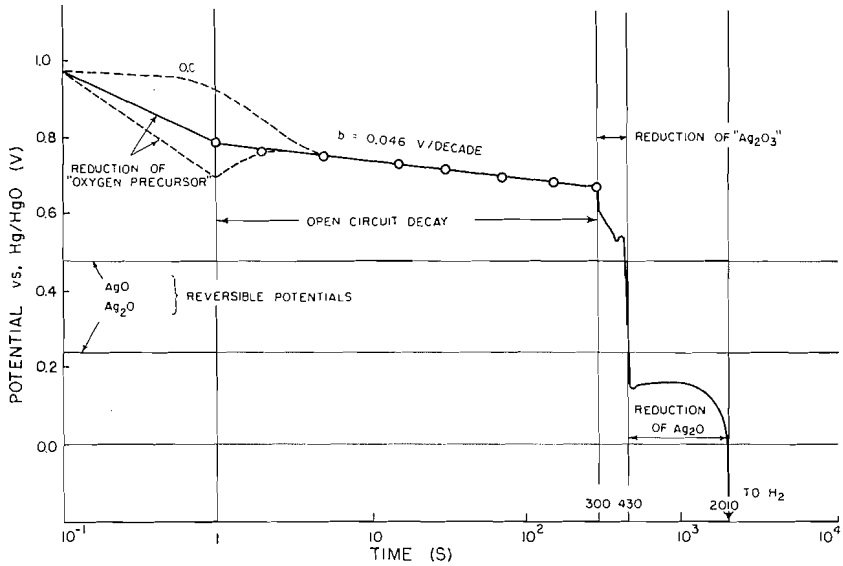

FIG. 4. Coulombic measurements of oxygen precursor, Ag_2O_3 and Ag_2O, following anodic oxidation at $-40°$ at a c.d. of 30 $\mu A/cm^2$.

$1/t$ was linear for planar electrodes over the first two or three cycles. Hence qualitatively the early stages of potential decay, during the first few cycles of a planar electrode, can be interpreted as being diffusion controlled.

By rapid reduction immediately following anodic oxidation to O_2 evolution, it was possible to obtain a rough estimate ($\pm 25\%$) of the amount of oxygen precursor that had been present in the steady state of current flow. The value of the reduction current was chosen so that in a 1 s reduction the potential was lowered to that value obtained by extrapolating, back to $t = 1$ s, the E vs. log t decay which exists beyond 5 s. In this way it was found that 0.1–0.3 of the passivated electrode surface had been covered with oxygen precursor. This measurement is illustrated on the left half of Fig. 4. Note that if the number of coulombs required to reduce the oxygen precursor have been exceeded, the potential on subsequent o.c. decay will recover to that of the higher oxide. The right half of Fig. 4 deals with coulombic measurements, to be discussed later. For the present simply note the little "hitch", or potential minimum, in the reduction curve of Ag_2O_3, between 300 and 430 s.

Open Circuit and Cathodic Potential Decays

In Fig. 5 are shown a group of o.c. potential decays (Fig. 5*b*) taken from a planar electrode at $-40°$. Each decay curve followed anodic polarization at c.d. 780 $\mu A/cm^2$ to a preselected potential value, (Fig. 5*a*). Then after approximately 100 s of o.c. decay a cathodic current was used to reduce any of the oxides on the electrode to silver. The potential values selected (points 1 to 12 on Fig. 5*a*) were taken over a period of time from just after the start of anodic polarization to a time when the electrode was vigorously evolving O_2.

These curves clearly show the absence of AgO on the electrode. There is no potential arrest evident at or near the usual AgO/Ag_2O potential of 0.49 V (see Fig. 5*b*). The buildup of the higher oxide can be traced stepwise with the help of the o.c. decay curves.

From many other o.c. decay curves obtained during the course of the experiments it was found that the decay of the higher oxide could take any one of the following paths: (i) Decay to Ag_2O from the Ag_2O_3/AgO potential level (calculated as 0.64 V w.r.t. Hg/HgO) (4, 5, 6). (ii) Decay to Ag_2O from the Ag_2O_3/Ag_2O potential level (calculated as 0.56 V w.r.t. Hg/HgO) (5, 6). (iii) Decay to Ag_2O from the Ag_2O_3/Ag_2O potential level, but with the presence of a "hitch". (iv) Decay to AgO from either the Ag_2O_3/AgO or Ag_2O_3/Ag_2O potential levels.

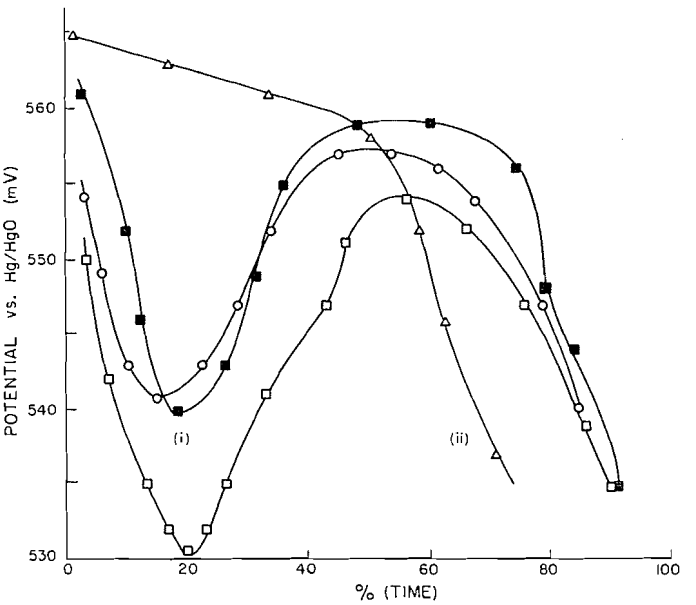

FIG. 6. Normalized curves showing details of potential minimum (i) during cathodic reduction of a planar silver electrode at −40°. Hitch does not occur (ii) if sufficiently large quantities of Ag_2O_3, Ag_2O, or nuclei of AgO are present.

Details of the "hitch" which occurs during discharge of the higher oxide, or under certain conditions on o.c. decay, can be seen on an expanded scale of the decay of potential vs. time in Fig. 6. The time scale has been normalized (100% being the time required for the potential to fall during cathodic reduction to 480 mV) so that several reduction curves which referred to different amounts of "Ag_2O_3" could be compared directly. At times no minimum occurred, and the decay curve was then of the type represented by curve (ii) in Fig. 6.

Generally it was found that this minimum in the potential–time curve did not occur if the quantities of "Ag_2O_3" and Ag_2O on the electrode were large, or if AgO was present. The hitch did occur during the cathodic reduction of small quantities of "Ag_2O_3", or even on o.c. decay if the amount of "Ag_2O_3" on the surface was small. In most cases the total amount of coulombs passed to the bottom of the minimum (assuming a surface roughness factor of one) amounted to 3–5 layers of higher oxide being reduced on the electrode surface. From the potential region in which the minimum occurs ($\sim$ 560 mV, Ag_2O_3/Ag_2O rev. pot.) and from the magnitude of the potential drop, $\sim$ 30 mV, one is inclined to believe that first the higher oxide is reduced to Ag_2O (high specific resistance) which then either breaks regularly or is reduced further to Ag as further charge is passed. From

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the minimum value the potential rises again to a maximum before decaying precipitously to the Ag_2O/Ag potential as the higher oxide becomes exhausted. The discharge might be represented by

$$Ag_2O_3 + 2H_2O + 4e^- \rightarrow Ag_2O + 4OH^-.$$

When the coherent Ag_2O film breaks or is otherwise removed, the depleted oxygen content of the surface layer is restored from underneath (7), and the potential rises from the minimum towards the maximum of the hitch. In those cases in which the hitch is not present, the rapid formation of the coherent, passivating layer of Ag_2O is in some manner prevented. The presence of large quantities of Ag_2O, "Ag_2O_3", or the presence of AgO were found to discourage the formation of this passivating surface layer. Large quantities of "Ag_2O_3" (> 50 layers), perhaps approaching in stoichiometry the formula Ag_2O_3, when present on the electrode, due to very favorable forming conditions, probably exhibit a different, more stable crystal structure in which oxygen atoms are more tightly bound to the crystal lattices on the surface and the solid phase remains during reduction.

In those cases in which AgO was present on the electrode in sufficient quantities to show its presence during discharge, no evidence of a hitch in the decay curve was observed which would accompany the formation of a coherent surface layer of Ag_2O. It appears therefore that in the presence of nuclei of AgO the higher oxide discharges preferentially to AgO.

$$Ag_2O_3 + H_2O + 2e^- = 2AgO + 2OH^-.$$

Hence, the discharge of "Ag_2O_3" can proceed to either AgO or Ag_2O.

Coulombic Measurements

A composite measurement of the amounts of oxygen precursor, higher oxide and Ag_2O, as well as the o.c. "*b*" value are shown following the first oxidation of a planar electrode in Fig. 4. The results on this first cycle are typical of the behavior of this electrode at $-40°$ and are listed in Table I. The number of layers of silver which oxidized to form

TABLE I

Quantities of oxides formed anodically (30 $\mu A/cm^2$) during the first cycle on a planar silver electrode at $-40°$ in eutectic KOH–H_2O

Measured capacity on reduction (C/cm^2)	Region	Layers of Ag oxidized (calcd.)
2.6×10^{-5}	O_2 precursor	0.1
3.6×10^{-3}	Ag_2O_3	13
Nil	AgO	Nil
4.2×10^{-2}*	Ag_2O	156

*4.3×10^{-2} on oxidation.

Ag_2O and the higher oxide were calculated from the measured coulombic capacity, the silver radius 1.26 Å (8) and a surface roughness arbitrarily chosen as unity. If the ratio of real area to apparent area is taken even as high as 10, as Hickling did (4), then the thickness of the higher oxide would still be at least a monolayer thick on the surface of the Ag_2O oxide layer.

The amounts of "Ag_2O_3" and Ag_2O formed at $-40°$ vary with the oxidation c.d. (Figs. 7 and 8) and are dependent on the state of the electrode surface prior to oxidation. The formation of maximum amounts of "Ag_2O_3" (Fig. 7) and Ag_2O (Fig. 8) occur at different

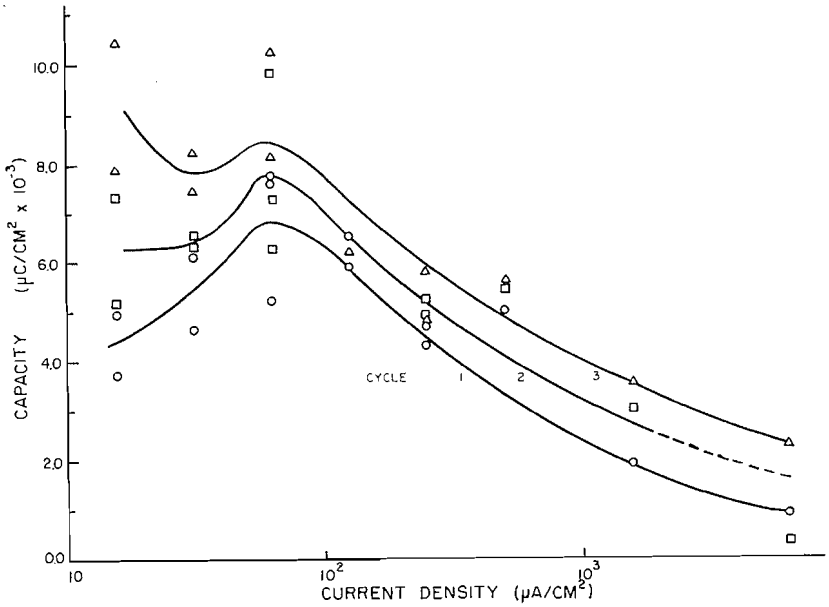

FIG. 7. Ag_2O_3 capacity at −40° as a function of the current density of anodic oxidation, and the effect of cycling on this capacity.

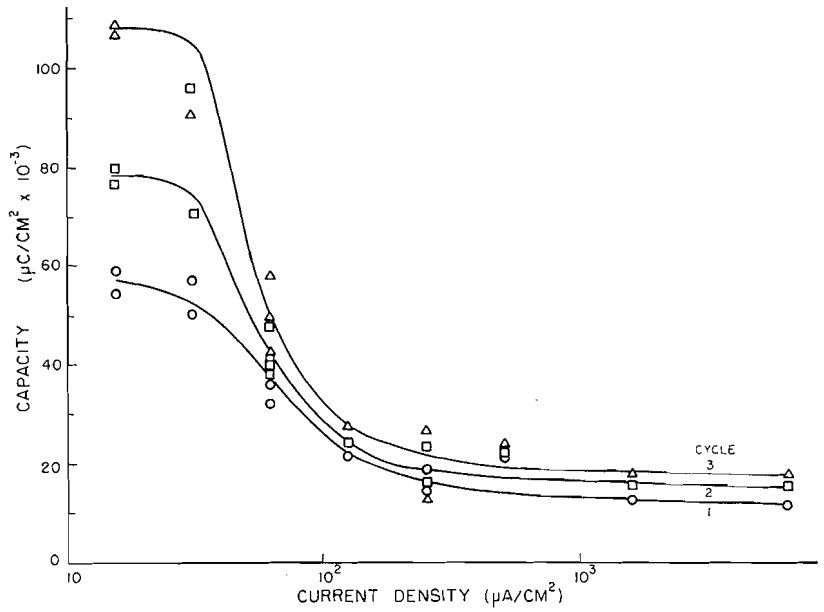

FIG. 8. Ag_2O capacity at −40° as a function of the current density of anodic oxidation and the effect of cycling on this capacity.

current densities. From data collected on 13 fresh planar electrodes, over the range of current densities shown, it was found that maximum amounts of "Ag_2O_3" and Ag_2O were formed at c.d.'s of 62 $\mu A/cm^2$ and below about 30 $\mu A/cm^2$, respectively. During the first cycle on a fresh electrode, maximum amounts of 25 layers of Ag oxidized to "Ag_2O_3", and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

215 layers (if the surface roughness factor is taken as unity) of Ag oxidized to Ag_2O were found. The quantity of Ag_2O formed decreases very quickly at c.d. greater than 30 $\mu A/cm^2$. Repeated cycling had the effect of increasing the amounts of "Ag_2O_3" and Ag_2O formed per cycle by about 15 and 25% respectively, from the first to the third cycle. This held true for all current densities studied.

Let us now introduce a conceptually significant quantity, the ratio of the amounts (equivalents) of "Ag_2O_3" and Ag_2O formed under different conditions. This ratio, C_r, is the amount of "Ag_2O_3" formed per unit amount of underlying Ag_2O substrate. The results plotted in Fig. 9 show that above the critical current density for AgO formation (15 $\mu A/cm^2$) C_r increases *linearly* with log anodic c.d. up to $\sim$ 140 $\mu A/cm^2$, and then decreases, *again linearly*, with further increase in c.d., at least up to 6 200 $\mu A/cm^2$. Thus the amount of "Ag_2O_3" formed per unit of underlying Ag_2O has a maximum value at what we shall call the *transition current density of formation*; and this maximum is determined by two competing processes one of which increases linearly and one of which decreases linearly with increasing log c.d.

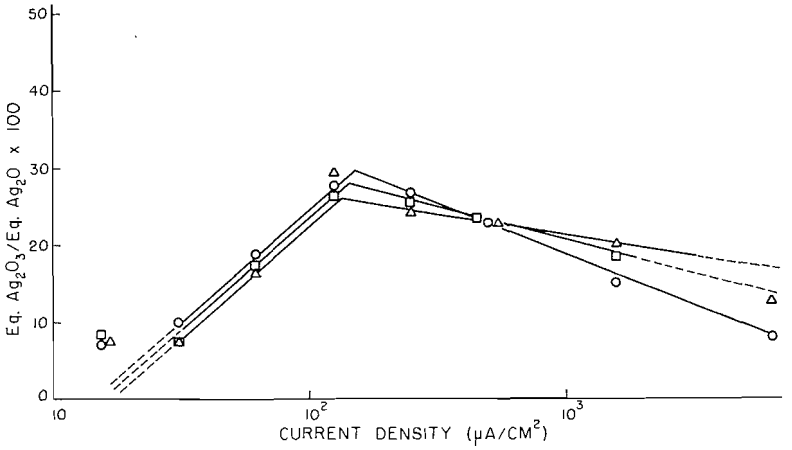

FIG. 9. The effect of anodic current density on the ratio (C_r) of the equivalents of Ag_2O_3:Ag_2O formed on a planar silver electrode at −40° during the first three cycles (○, cycle 1; □, cycle 2; △, cycle 3).

Unfortunately, so far we have been unable to account quantitatively for the linearities in the plot of C_r vs. log t. Not surprisingly, the overpotential for oxygen evolution shows a discontinuity just preceding this same maximum value of C_r (Fig. 10), indicating a change in the mechanism by which O_2 is evolved. Thus above C_r the Tafel slope was found to be 100 mV/decade; below C_r it was 160 mV/decade. At c.d.'s > 10^4 $\mu A/cm^2$, the curve deviates from linearity and the potential values begin to rise very rapidly until, beyond 10^6 $\mu A/cm^2$ the slope of the curve is almost infinite. At these very high current densities the processes become diffusion controlled.

Three other facts complete the basis for an interpretation.

1. At the current density of 60 $\mu A/cm^2$, which forms the lower end of the discontinuity and is the beginning of the transition between the two oxygen evolution processes, prolonged (18 h) anodic oxidation results in the formation of some AgO. By contrast no AgO was formed during prolonged oxidation at current densities of 30 and 15 $\mu A/cm^2$.

2. *Both E and C_r increase* linearly with log c.d. below the c.d. of maximum C_r. Above this value E increases while C_r *decreases* with increasing log c.d. (See Fig. 9.)

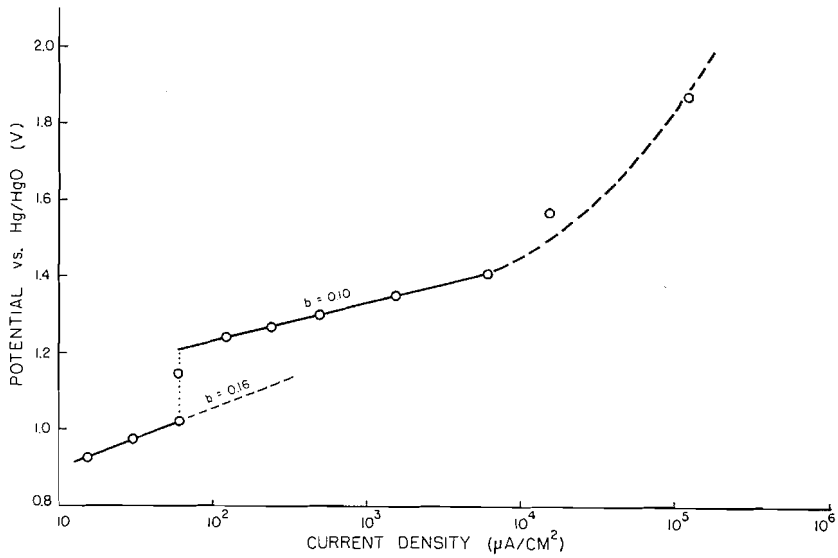

FIG. 10. The end of charge potential for oxygen evolution as a function of the anodic current density (Tafel curve) for planar silver electrodes at −40°.

3. Whatever the value of the reversible oxygen potential at −40°, it is obvious from Fig. 10 that the exchange current for the high current process of oxygen evolution must be lower than the exchange current for the low current process. In other words, whatever the high current process is, once it is instituted it can be maintained at lower c.d. than can the low current process. This is perhaps due to the formation of a "blanket" of an oxygen-precursor species (Ag_2O_3?) which is tightly bound during anodic oxidation, and which also gives rise to hysteresis behavior to be discussed later.

From these facts one can picture O_2 being evolved *primarily* off Ag_2O[O] sites at c.d.'s below 60 μA/cm^2, and *primarily* off filled Ag_2O_3 sites at c.d.'s above 120 μA/cm^2; that below this lower value the "Ag_2O_3" is substantially Ag_2O plus trapped oxygen; above the higher value the crystal form has shifted more towards true Ag_2O_3. In the current density region between 60 and 120 μA/cm^2 the process of crystal deformation is continuously occurring, and results, whenever the configuration is favorable, in an alternative crystalline transition to AgO. Above this transitional region the mass is protected by the blanket of what *may be* true Ag_2O_3 but which we shall call 'Ag_2O_3'. Below the transitional region the Ag_2O lattice does not become strained enough to form true Ag_2O_3. Above this region the 'Ag_2O_3' is so thermally unstable at −40° that more oxygen forced in at the interface causes less to be retained in the thin, coherent blanket in the steady state, while below it, more [O] can be stored by the Ag_2O the higher the steady state current.

If these inferences are correct, it would follow that the true crystalline phase Ag_2O_3 is likely face-centered cubic, like Ag_2O, and not monoclinic like AgO (9). Indeed the structures of the nitrate- and sulfate-stabilized higher oxides, Ag_7NO_{11} and Ag_7SO_{12}, and often confused with Ag_2O_3, are close to that of Ag_2O (7, 8).

Tafel Slopes

Fully charged *porous* electrodes at room temperature show two limiting slopes in the overpotential vs. log current plots, viz. 0.05 and 0.25 V per decade (Fig. 11). The hysteresis introduced in the previous section of this paper was observed during Tafel

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

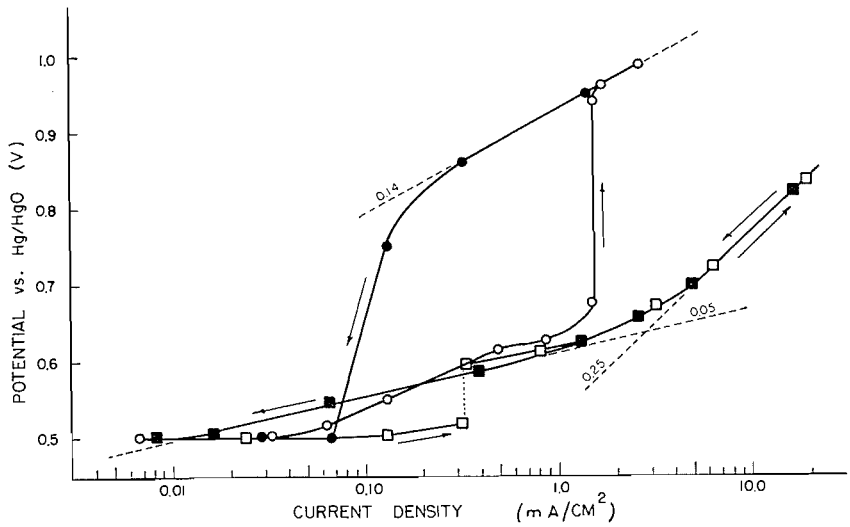

FIG. 11. Tafel curves on a porous silver electrode at 25° and −40° (○, ●, −40°; □, ■, +25 °C).

measurements, when the current was being reduced from large to smaller values. The hysteresis is much larger at −40°. As mentioned already, this behavior is taken as evidence for the formation of a protective blanket ('Ag_2O_3'?) which is relatively slow to form, but once formed is relatively slow to decay. It seems to decay rapidly when present in a small quantity, but much more slowly if it has been formed gradually and has had an opportunity to form well-defined crystallites.

Planar electrodes oxidized at current densities below the critical value (AgO forms) show hysteresis at −40° (Fig. 12*a*), and have high *b* values. If no AgO forms (Fig. 12*b*),

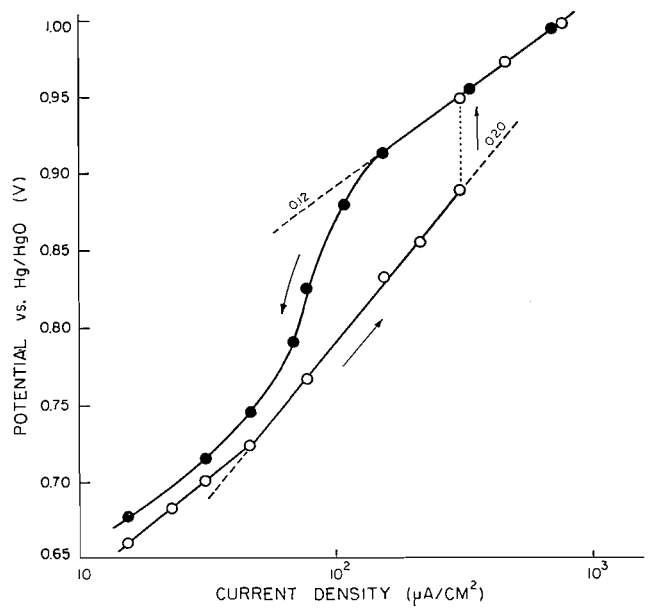

FIG. 12*a*. Tafel curve on a planar silver electrode at −40°; AgO present on the electrode.

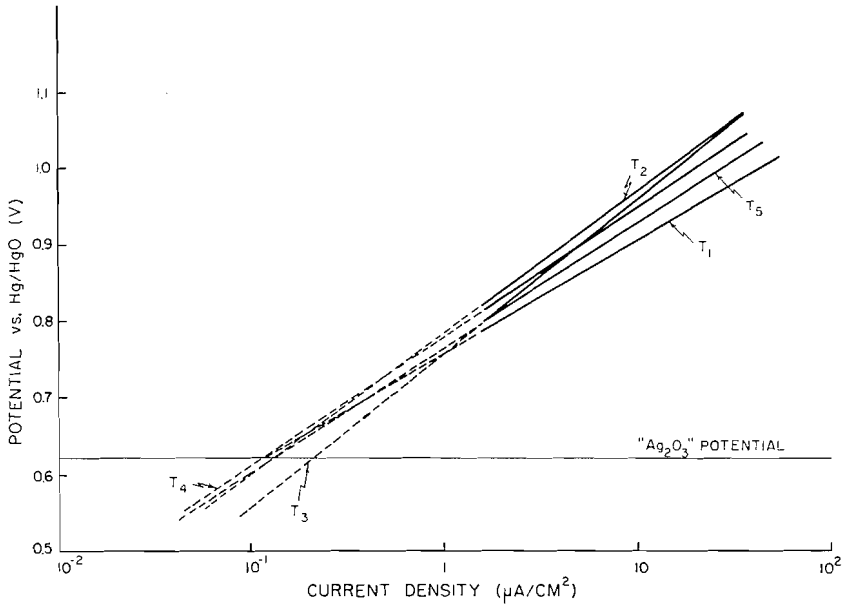

FIG. 12*b*. Tafel curves on a planar silver electrode at −40°; no AgO present on the electrode. T_1, T_2, etc. refer to the order in which the Tafel curves were taken.

hysteresis may not occur. The curves of Fig. 12*b* show that both the slope and the intercept at 0.62 V change unpredictably with time. This is one indication that the area from which oxygen is being electrochemically evolved is changing with time during the experiment. However if it were only a change in the *area* of the oxygen precursor, the *b* values, at least, should remain constant. Since they are not constant, then the rate of thermal decomposition of the higher oxide must also be changing in an uncontrollable and unpredictable manner or perhaps decomposing by parallel but different paths. Since these trends on oxide electrodes are well known at room temperature, it is not likely that the −40° temperature in itself makes much difference; and whether or not these trends lead to steady values of current after prolonged periods is of little importance. The important point is that the changes that do occur are unpredictable, uncontrollable, and very slow. These facts are taken as further evidence that there may be a great many (perhaps an infinite gradation of) metastable, intermediate states represented by $Ag_2O[O]$.

Temperature Coefficient of Decomposition Rate

If the higher oxide is decomposing thermally, then the current required to maintain the electrode at any selected potential in the higher oxide region should be a measure of the rate of its thermal decomposition. From the shape of the potential vs. time curves for oxidation, reduction, and open circuit decay in the higher oxide region, the average potential of the higher oxide was estimated to be about 0.62 V vs. Hg/HgO or 130 mV positive to the AgO electrode. The temperature coefficient of current needed to maintain the potential at 0.62 V was easily obtained on porous electrodes (Fig. 13) and was found to be 12.0 ± 2.0 kcal/mole from −40 to +10 °C. The course of the experiment is indicated by the arrows in the figure. Note that the current required to maintain a potential was much lower early in the experiment, but that after AgO had formed at +10° or thereabouts the current required to maintain the higher oxide on top of AgO was much higher.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

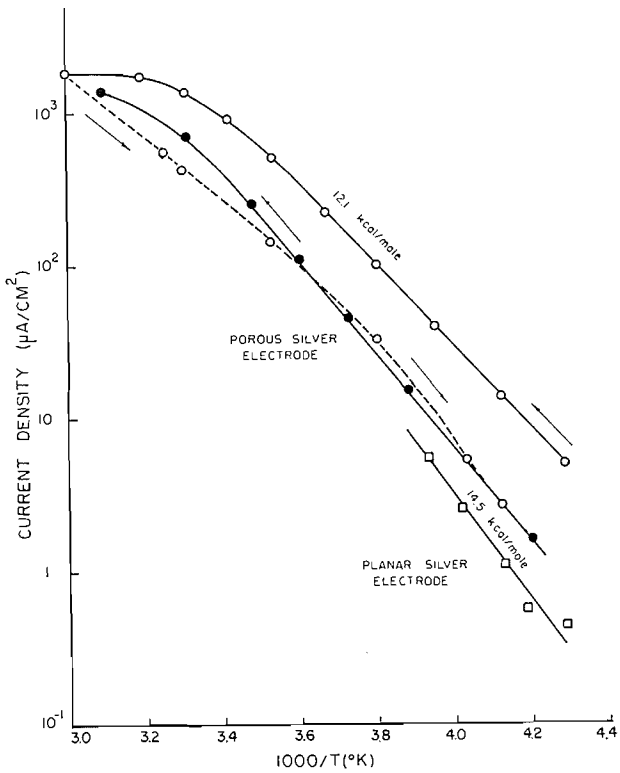

FIG. 13. Temperature coefficient of current required to maintain the electrode at a steady state at 0.62 V vs. Hg/HgO ($\sim Ag_2O_3$ reversible potential).

The same measurement on a planar sheet was difficult to make, probably for two reasons. First of all, the electrode surface was all free to the electrolyte and the area of the precursor (as interpreted by wanderings of the current required to maintain a constant potential) was changing by as much as a factor of 10 over a period of a week before settling to a steady value. Secondly, the thicknesses of Ag_2O and "Ag_2O_3" were small and probably subject to mechanical strains related to conductivity, porosity, and repair. In any case, perseverance yielded five points between -40 and -17.8 °C which gave an activation energy of about 14 kcal/mole, in the same range as found on the porous electrode.

It was thought that if the higher oxide was simply chemisorbed oxygen, then a higher potential should correspond to a greater surface coverage by adsorbate, which would be more weakly held to the surface. However a determination of activation energy on a planar electrode at a potential of 0.72 V still resulted in an activation energy of about 12 kcal/mole for the same temperature range. Thus the evidence seems to point again toward a higher oxide, a new phase.

More rapid activation energy measurements on the same planar electrode taken over a temperature range of -40 to -50 °C gave values of 8 to 9.5 kcal/mole at a potential of 0.72 V. The implication here is that when the temperature is low enough that modification and repair of the surface is slow, the outer layers of adsorbate are less tightly bound. Conversely, it would follow that the less tightly bound oxygen (chemisorbed?)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

contributes little to the potential. In other words, it is electrochemically relatively inactive, or has a very low exchange current, perhaps because of some barrier to electron transfer right at the site of adsorption.

SEMICONDUCTOR ELECTRODES

The higher oxides of silver seem to belong to a class of materials in which both electrons and ions can move, and in which oxygen-containing species can be trapped into or onto the base material. During the anodic formation of "Ag_2O_3" on Ag_2O at low temperatures, extra oxygen, perhaps in the form of O atoms (12), penetrates the Ag_2O mass, either interstitially or at grain boundaries. The stability of the higher oxide should be dependent upon the energy with which the extra oxygen is bound into the Ag_2O lattice. Although this value does not seem to vary with experimental conditions (constant E^*), apparently the number of paths by which the trapped oxygen can escape does vary (varying rate of decay), as does also the contribution of parallel electrochemical paths (varying b value) through more than one oxygen-containing species (O, OH, HO_2). The time and space distribution of these species in the crystal defines the semiconduction paths which are essential to the electrochemical processes.

The class contains also the oxy-hydroxides of manganese, nickel, vanadium, iron, cobalt, and possibly lead. Further knowledge of the complex fundamental physical and electrochemical processes of one would doubtless contribute rapidly to a better understanding of the whole class.

SUMMARY

In eutectic KOH–H_2O at $-40°$, the higher oxide formed anodically on silver decomposes slowly, and some properties of this oxide, called for convenience, "Ag_2O_3", can be measured.

1. At $-40°$, Ag_2O forms readily on Ag. If the c.d. is $> 15\ \mu A/cm^2$, AgO does not form readily and the electrode passes immediately from Ag_2O formation to O_2 evolution. Two intermediate states are indicated, one that can be attributed to be "Ag_2O_3", the other to an oxygen precursor, possibly adsorbed HO_2.

2. Decay of o.c. potential through the Ag_2O_3 region is slow ($\sim$ 1 h) and electrochemical reduction completed within 5 min of anodic oxidation shows the stored capacity of the higher oxide to be up to $\sim 9 \times 10^3\ \mu C/cm^2$ if formed within the first three cycles. The largest number of layers of silver which were formed to higher oxide on rolled, etched, or polished silver sheet, after much cycling was 70 (assuming a surface roughness factor of one).

3. Similar measurements, less accurate, however, because of the much faster decay at the oxygen precursor potential, indicated that about one-tenth of a layer of an adsorbed species (HO_2, O, OH?) exists on the surface during O_2 evolution.

4. The temperature coefficient of the current required to maintain the potential of a porous electrode at 130 mV above the AgO/Ag_2O potential (that is, in the region of the Ag_2O_3 reversible potential) was 12.0 ± 2.0 kcal/mole. This value can be considered to be the energy by which oxygen atoms are bound in the higher oxide. Activation energy measurements on planar electrodes [although more difficult to make] were about the same at both 130 and 230 mV above the AgO/Ag_2O potential, i.e. 14.0 ± 2.0 kcal/mole.

5. Tafel slopes and intercepts were measured and recorded, but they are difficult to interpret since they change unpredictably with time. However, they do underline the complex nature and the time variance of the reactions taking place on the electrode surface.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

6. Open circuit potential decay curves, with their protracted linear regions of $\partial E/\partial \log t$, have many slopes and potential regions which seem to be typical of the non-stoichiometric type of oxide.

7. The evidence for a higher oxide phase can be summed up by the following: (i) the presence of voltage plateaus in oxidation and reduction curves in a region well above the AgO potential; (ii) the recovery of the potential if reduction is interrupted in the higher oxide region; (iii) the substantial electrochemical capacity of this phase and its thickness on the surface of the electrode; and (iv) the activation energy of 12 kcal/mole, not a function of the potential in the higher oxide region.

8. The variation of the amount of "Ag_2O_3" formed per unit amount of Ag_2O substrate under various experimental conditions suggests that as the material $Ag_2O[O]$ becomes filled up with oxygen atoms to form stoichiometric Ag_2O_3, an abrupt change occurs in the structure of the higher oxide which results in an abrupt change in the mechanism of oxygen evolution.

THE ELECTRICAL CONDUCTIVITIES OF SOME TETRA-*n*-ALKYLAMMONIUM SALTS IN ACETONITRILE[1]

A. C. HARKNESS AND H. M. DAGGETT, JR.
Department of Chemistry, The University of British Columbia, Vancouver, British Columbia
Received October 28, 1964

ABSTRACT

The conductances of a number of tetra-*n*-alkylammonium bromides and iodides have been measured in acetonitrile. Limiting equivalent conductances and dissociation constants have been evaluated by two methods. Limiting equivalent ionic conductances have been evaluated from these results. Correlations have been made of the effect of ion size on the ionic conductances and on the relative order of magnitude of the dissociation constants. In an appendix the limiting ionic conductances of a number of other ions have been collected from the existing literature.

INTRODUCTION

There has been no systematic study made of the effect of ion size on the conductance of salts in acetonitrile. The few investigations that have been carried out deal with the conductances of a variety of salts, but the data are such that no correlations can be made regarding the effect of ion size. It is the purpose of this paper to report on some measurements made on solutions of the tetra-*n*-alkylammonium bromides and iodides from methyl to *n*-amyl. From the results of these measurements the limiting equivalent conductances and dissociation constants have been evaluated using the Shedlovsky method (1). Ionic conductances have been evaluated using the method suggested by Coplan and Fuoss (2). Using these results a correlation is made of the effect of ion size on conductances and dissociation constants in the solvent acetonitrile.

EXPERIMENTAL

Solvent

Acetonitrile (Carbide and Carbon Chemicals Co.) was purified as follows. The middle two thirds of the product obtained by a preliminary distillation from silver nitrate was collected over freshly activated alumina. After standing for 2 d, this product was distilled from activated alumina. The product from this distillation had a specific conductance of $0.8–1.0 \times 10^{-8}$ mhos as compared to $10^{-6}–10^{-5}$ mhos for the starting material. The boiling point of the solvent was 81.5–82.0 °C. Its density was determined to be 0.7768 g/ml at 25 °C, in satisfactory agreement with the literature (3). The dielectric constant was taken to be 36.1 (the average of values reported in refs. 4–8) and the viscosity was taken to be 0.3442 cP (the average of values reported in refs. 4–7).

Salts

Tetra-*n*-alkylammonium bromides and iodides were prepared by allowing equivalent amounts of redistilled tertiary amine and of alkyl halide to react at room temperature until the mixture solidified. The product was then repeatedly recrystallized from appropriate solvents until the conductance results from successive recrystallizations were in agreement. The recrystallization solvents and the melting points of the various salts are listed in Table I.

Procedure

Conductivity cells of the flask type described by Kraus and Fuoss (9) were used. The electrodes were lightly platinized. They were intercompared and finally standardized against aqueous solutions of purified potassium chloride. The specific conductivities of the solutions were calculated from the concentrations by means of the empirical Shedlovksy equation (10) corrected to the Jones and Bradshaw standard (11). A correction was made for the conductivity of the water used.

[1]*Based on a thesis submitted by A. C. Harkness in partial fulfillment of the requirements for the degree of Master of Science in the Faculty of Graduate Studies of the University of British Columbia.*

TABLE I

Recrystallization solvents and melting points

Salt*	Recrystallization solvent	m.p. (°C)†
Me_4NI	60% Ethanol/water	375–380 d.
Et_4NI	Ethanol	275–276 d.
Pr_4NI	Ethanol	291 d.
Bu_4NI	Ethanol ppt. with ether	145–146
Am_4NI	Ethanol ppt. with ether	134–135
Me_4NBr	60% Ethanol/water	351–353 d.
Et_4NBr	Ethanol	276 d.
Pr_4NBr	Ethanol	261–262 d.
Bu_4NBr	Benzene	116–117
Am_4NBr	Benzene	99–101

*The following abbreviations are used in this paper: Me = methyl, Et = ethyl, Pr = *n*-propyl, Bu = *n*-butyl, Am = *n*-amyl.
†Melting points are uncorrected.

Measurements of cell resistances were made using a precision a-c. resistance bridge constructed in this laboratory. Polarization effects were eliminated by making measurements at several frequencies and extrapolating to infinite frequency. All measurements were made at 25.000 ± 0.002 °C; an oil thermostat was used to achieve a constant temperature.

Measurements were carried out by the dilution method, all dilutions being made by weight. In calculating concentrations the densities of the solutions were assumed to be the same as that of the solvent. All measured specific conductivities were corrected by subtracting the specific conductivity of the pure solvent from those of the solutions.

RESULTS

The results are tabulated in Tables II and III and are shown graphically in Figs. 1 and 2. It should be noted that the phoreograms are all catabatic.

These results were analyzed in two different ways. In the first, the data were treated by the method of least squares using the relationship:

$$\Lambda = \Lambda_0 - \mathscr{S}\sqrt{C}$$

where Λ is the equivalent conductance at a concentration of C g equiv/l, Λ_0 is the limiting equivalent conductance, and $\mathscr{S}$ is the slope of the $\Lambda - \sqrt{C}$ plot. From this treatment Λ_0 and $\mathscr{S}$ were evaluated. In the second method used in dealing with the data the results were treated by the Shedlovsky method (1) yielding Λ_0 and the dissociation constant K. In these calculations the dielectric constant was taken to be 36.1 and the viscosity 0.3442 cP. An IBM 1620 computer was used to facilitate these calculations. The results of these calculations are given in Table IV.

DISCUSSION

Consistency of the Results

To test the consistency of the results, Kohlrausch's law of independent migration of ions was applied to the Λ_0-values tabulated in Table IV. Taking the differences $\Lambda_0(R_4NI) - \Lambda_0(R_4NBr)$, the average value of the differences was found to be 1.7 ± 0.5 Λ-units when the Λ_0-values based on the $\Lambda - \sqrt{C}$ plot were used and 2.0 ± 0.5 Λ-units when the Shedlovsky values were used. Thus the Λ_0-values are consistent to within about 0.3%.

The values of Λ_0 for Et_4NI was 0.43 Λ-units lower than that found by Kortüm (8) and by Walden (12). The values of Λ_0 for Me_4NBr, Me_4NI, Et_4NBr, Et_4NI, and Pr_4NI were from 1.24 to 5.07 Λ-units higher than those found by other investigators (12, 13, 14,). Data for the other salts do not appear in the literature.

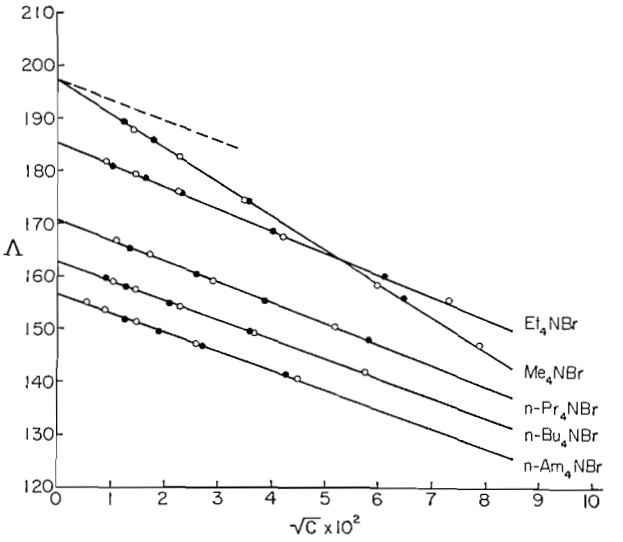

FIG. 1. Phoreograms of some tetra-*n*-alkylammonium bromides in acetonitrile at 25 °C. The dotted line represents the theoretical Onsager slope for tetramethylammonium bromide.

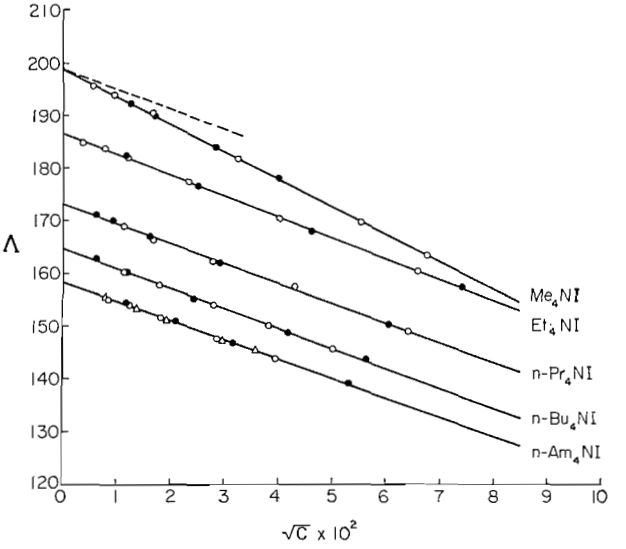

FIG. 2. Phoreograms of some tetra-*n*-alkylammonium iodides in acetonitrile at 25 °C. The dotted line represents the theoretical Onsager slope for tetramethylammonium iodide.

Experimental Slopes

All of the experimental slopes of the $\Lambda - \sqrt{C}$ plots were greater than theoretical, the ratios $\mathcal{S}_{exp}/\mathcal{S}_{th}$ varying from 1.699 to 1.038 (i.e. the phoreograms are all catabatic). This indicates a substantial degree of association of the ions, the degree of association being greatest with the methyl salts and least with the amyl salts. This trend is to be expected, for the electrical field around the small Me_4N^+ ion would be greater than that around the larger Am_4N^+ ion and hence there would be a greater degree of association with the counterions Br^- and I^- with Me_4N^+. The ratio $\mathcal{S}_{exp}/\mathcal{S}_{th}$ is unexpectedly high for Bu_4NI. There seems to be no logical explanation for this.

TABLE IV

Results of the analysis of the conductance data

*See first footnote to Table I.

Dissociation Constants

The dissociation constants obtained by application of the Shedlovsky method to the data vary in the manner predicted in the previous section. The *dissociation* constants for the methyl salts are the lowest (indicating a high degree of association of the ions), while those for the other salts increase regularly to amyl. The only exception to this trend is Bu_4NI, where the dissociation constant is unexpectedly low (as was indicated in the previous section).

It is also of interest to compare the dissociation constants for the bromide series with those for the iodide series. The values of K for the bromide series are lower than those for the iodide series (the exception again being Bu_4NI). These trends are easily interpreted on the basis of the higher electrical field around Br^- due to its smaller size. This higher field would cause more interaction between R_4N^+ and Br^- than between R_4N^+ and I^-, leading to a greater degree of association and hence a lower value of K for the bromide series.

Ionic Conductances

Ionic conductances were evaluated by the method suggested by Coplan and Fuoss (2). In this method tri-*i*-amyl-*n*-butylammonium tetraphenylboride is taken as the standard. The limiting ionic conductances for $(i\text{-Am})_3BuN^+$ and Ph_4B^- are each assumed to be one half of the limiting conductance for the salt. The argument is based on the fact that the ionic radii of the two ions are nearly the same and hence should have the same values for the limiting ionic conductance, for they would meet with the same resistance in passing through the solution. We have adopted the value of 116.1 ± 0.1 Λ-units for the limiting equivalent conductance for the salt (15). Thus the value of Λ_0^+ for the tri-*i*-amyl-*n*-butylammonium ion is 58.0 Λ-units which is the same as that for the tetraphenylboride ion. Using these Λ_0-values, we have determined the Λ_0^+-values for the tetra-*n*-alkylammonium ions and for the Br^- and I^- ions in acetonitrile, using the results of Fuoss and coworkers (4, 5, 6) for Bu_4NPh_4B. The results (based on Shedlovsky Λ_0-values) are presented in Table V.

It is to be noted from Table V that the Λ_0^--value for Br^- is smaller than that for I^- in spite of the fact that the Br^- ion is smaller and so should have the greater ionic conductance. This apparent discrepancy is easily explained by the fact that the Br^- ion will have a higher electrical field around it (because of its smaller size) and so will interact more strongly with the polar solvent leading to a greater hydrodynamic radius. Thus its

TABLE V

Limiting ionic conductances based on $\Lambda_0^+(Bu_4N^+) = 61.3 \pm 0.1$*

Ion	Λ_0 value
Br^-	101.3±0.1
I^-	103.3±0.1
Me_4N^+	94.2±0.3
Et_4N^+	83.6±0.2
Pr_4N^+	69.6±0.3
Bu_4N^+	61.3±0.1
Am_4N^+	55.1±0.1

*See first footnote to Table I.

conductance will be smaller than that of the I^- ion where the interaction with the solvent will not be as great.

The trend of Λ_0^+-values for the R_4N^+ ions is in line with the change in ionic radius—the smaller the radius the greater will be the conductance of the ion.

APPENDIX I

The ionic conductances reported in Table V enable us to evaluate ionic conductances for a large number of ions from results reported in the literature. To effect this evaluation all conductance data were reprocessed by the Shedlovsky function to gain consistent values for the limiting equivalent conductance of the various salts in acetonitrile. The results are reported in Table VI.

NOTES

A COMPARISON OF THE RAMAN CRYSTAL AND SOLUTION SPECTRA OF THE HEXANIOBATE AND HEXATANTALATE IONS

R. STUART TOBIAS

INTRODUCTION

About a decade ago, Lindqvist, in reviewing methods for studying inorganic polyions in aqueous solution (1), noted that efforts to explain the relatively complicated Raman spectra of solutions of polyanions had not been very successful. On the positive side, he commented that "the most important result is the confirmation, in some cases, of the identity of the ions in crystals and in solution." He also noted that such measurements "may give valuable information about the ions in solution if the interpretation of the spectra can be related to the known structure of the ions in the solid state."

During the past ten years, few Raman studies of polycondensed inorganic species have been made in spite of the availability now of more crystallographic information and of commercial Raman equipment with double-grating monochromators and photoelectric detection. These permit accurate recording of the rather weak scattering from inorganic oxyanions in solution as well as the determination of the spectra of powdered crystalline samples. While it would not be expected that the spectra would show appreciable changes with small variations in the degree of polymerization of, for example, a large polyphosphate, they should be sensitive to significant changes in the species symmetry. That this much is true seems to be supported by the recent observations of Aveston, Anacker, and Johnson (2) on the Raman spectra of different polymolybdates.

On the basis of light scattering and ultracentrifugation, it has been suggested recently that solutions prepared by dissolving $K_{14}Nb_{12}O_{37}\cdot 27H_2O$ (3) and $K_8Ta_6O_{19}\cdot 16H_2O$ (4, 5) contain polyanions with the same degree of polymerization, $[M_6O_{19}^{-8}]$, M = Nb(V), Ta(V). In the case of the niobate, the conclusion is supported by the e.m.f. measurements of Neumann (6). Single crystal X-ray studies on the niobate (7) and tantalate (8) indicate that the crystals contain isostructural anions $[M_6O_{19}^{-8}]$ with cubic symmetry. The Raman spectrum of the tantalate has been published (9), and this note reports a comparison of the niobate and tantalate solution and crystal spectra made to ascertain whether the same structural unit exists in the niobate and tantalate crystals and solutions.

EXPERIMENTAL

Materials

The preparations and analyses of the $K_8Ta_6O_{19}\cdot 16H_2O$ and $K_{14}Nb_{12}O_{37}\cdot 27H_2O$ have been described earlier (3, 4). Solutions of the niobate and tantalate were prepared by saturating carbonate-free KOH solution with the salt.

Raman Spectra

The Raman spectra were recorded photoelectrically with a Cary Model 81 spectrophotometer. The general procedure has been described elsewhere (10). Crystal spectra were measured using a conical cell patterned after that described by Busey and Keller (11), for this was found far superior to straight cells. All spectra were excited with the 4 358 Å mercury line.

RESULTS AND DISCUSSION

Figure 1 illustrates the Raman spectra for 1 *M* KOH saturated with $K_{14}Nb_{12}O_{37}\cdot 27H_2O$ and with $K_8Ta_6O_{19}\cdot 16H_2O$. In Fig. 2 are given the corresponding crystal spectra. Our

tantalate spectra are virtually identical with those given earlier by Aveston and Johnson and are shown only for comparison. One exception arises from the use of 1 *M* KOH as the solvent in this work. Its use leads to an increase in intensity of the 450 cm^{-1} librational mode of water, and this tends to obscure this region in our spectra. Values of the frequencies and the state of polarization are tablulated in Table I. The 260 cm^{-1} line in our tantalate crystal spectra was so weak that it was only identified by comparison with Aveston and Johnson's spectrum. The pronounced similarity of all of the spectra make it seem very likely that the isostructural niobate and tantalate anions found in the crystals are also present in the solutions.

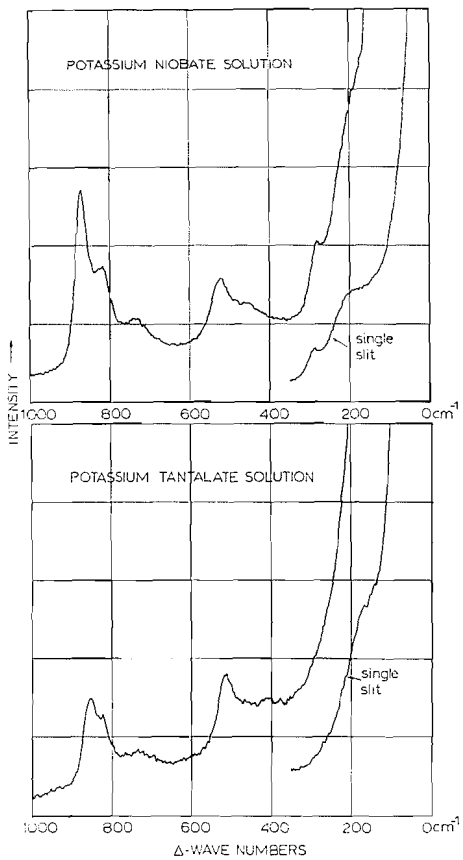

FIG. 1. Niobate and tantalate solution spectra.

Because of the complexity of the anions (there are 69 vibrational degrees of freedom) it is not possible to discuss any detailed assignments. If one assumes the structure suggested by Lindqvist (7, 8) to be correct, the representation of the normal coordinates can be obtained using the relations given by Herzberg (12) as

$$\Gamma_{vib} = 3A_{1g} + A_{2g} + A_{2u} + 4E_g + E_u + 3F_{1g} + 7F_{1u} + 4F_{2g} + 4F_{2u}.$$

On this basis, as noted by Aveston and Johnson (9), 11 Raman active and 7 infrared active normal modes would be predicted. Fewer lines might appear because of accidental degeneracy resulting from the very heavy metal atoms and because many of the bending

*A line was observed by Aveston and Johnson at 466 cm^{-1}.

modes would be expected at very low frequencies, and no more than three polarized lines should be observed. In these spectra, two lines were polarized. In addition for a cubic point group where the polarizability ellipsoid reduces to a sphere, the A_{1g} modes should be completely polarized, i.e., $\rho = 0$. Under these conditions the Rayleigh scattering should also be completely polarized, and it was noted earlier that no depolarization was detected (3). Unfortunately it is very difficult to make precise measurement of the degree of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

depolarization for either Rayleigh or Raman scattering. The depolarization ratio for the 878 cm^{-1} line of the niobate solution, $\rho = 0.23$, was comparable to the values obtained for other ions belonging to cubic point groups using similar experimental conditions.

The polarized niobate and tantalate lines at 878 and 853 cm^{-1}, respectively, in solution can be assigned to an A_{1g} mode. While no precise description of the normal mode can be given, it would be expected to consist of symmetrical metal–oxygen bond stretching involving mainly the six unshared peripheral oxygens. The very similar frequencies for the niobate and tantalate are to be expected if one considers the similarity in the frequencies of the breathing modes, ν_1, of the tetrahedral $MoO_{4(aq)}^{-2}$ and $WO_{4(aq)}^{-2}$ anions which appear at 894 and 928 cm^{-1} (13). The fact that these niobate and tantalate lines arise from relatively straightforward bond stretching is supported by similarity of the frequencies to the value for the breathing mode of VO_4^{-3}, 870 cm^{-1} (13).

It might be expected that the metal–oxygen stretching force constants would be considerably smaller with the octahedrally coordinated niobium(V) and tantalum(V) than with tetrahedrally coordinated molybdenum(VI) and tungsten(VI) or technetium(VII) and rhenium(VII). There does not seem to be a pronounced effect, for only a rather regular trend with the metal oxidation state is observed for the highest frequency totally symmetrical mode: $Nb_6O_{19(aq)}^{-8}$, 878 cm^{-1}; $MoO_{4(aq)}^{-2}$, 894 cm^{-1} (13); $TcO_{4(aq)}^{-}$, 912 cm^{-1} (11); and $Ta_6O_{19(aq)}^{-8}$, 853 cm^{-1}; $WO_{4(aq)}^{-2}$, 928 cm^{-1} (13); $ReO_{4(aq)}^{-}$, 971 cm^{-1} (11).

THE ACIDITY OF SOME SUBSTITUTED ACETONITRILES[1]

Ross Stewart, J. P. O'Donnell, and Keith Bowden

In connection with the establishment of an acidity scale for strongly basic solutions (1–4) several nitriles have been examined as possible indicators.

$$RCH_2CN + OH^- \rightarrow RCHCN^- + H_2O.$$

[1]*Part VI of the series "Strongly Basic Systems".*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

One of these, *p*-nitrobenzyl cyanide has been frequently used as an indicator in mixed solvent systems in the critical area spanning the completely aqueous and partly aqueous regions. We have found this compound to be an unreliable indicator because of the complicated spectral changes that accompany its ionization. These are shown in Figs. 1 and 2. The behavior of this carbon acid is in marked contrast to that of the other nitriles reported herein and the nitrogen acids reported earlier. In all these cases a simple ionization process (proton loss) was indicated by the spectral changes.

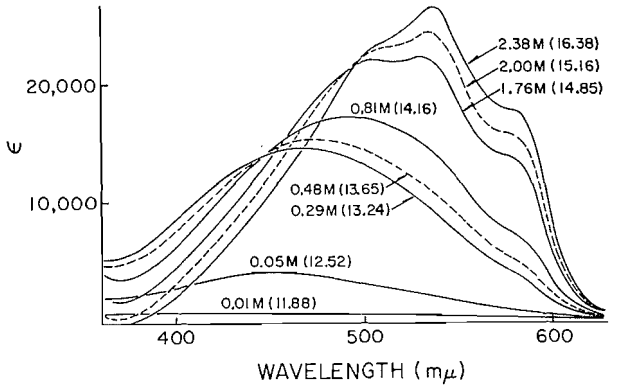

FIG. 1. The spectrum of *p*-nitrobenzyl cyanide in various concentrations of aqueous benzyltrimethylammonium hydroxide.

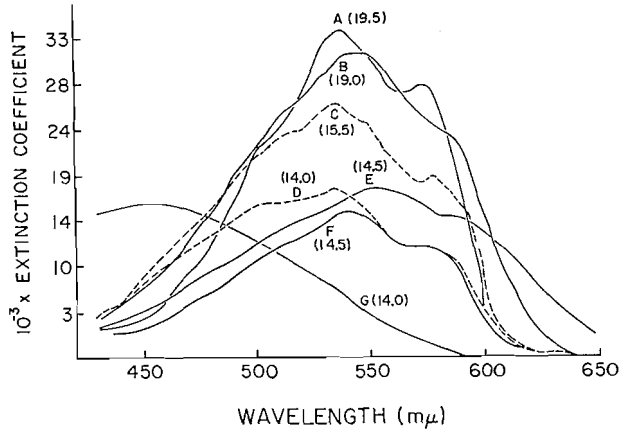

FIG. 2. The spectrum of *p*-nitrobenzyl cyanide in various solvent systems. The bracketed quantity is the H_- value of the system. A. 95 mole % sulfolane in water containing 0.11 *M* tetramethylammonium hydroxide. B. 30 mole % pyridine in water containing 1.19 *M* benzyltrimethylammonium hydroxide. C. 73.2% hydrazine in water. D. 45.3% hydrazine in water. E. 1.0 *M* aqueous phenyltrimethylammonium hydroxide. F. Anhydrous ethanolamine. G. 1.0 *M* aqueous sodium hydroxide.

Figure 1 shows the spectral changes that occur as the concentration of benzyltrimethylammonium hydroxide is increased and Fig. 2 the changes that occur when the solvent is altered. Each of these curves is labelled with the H_- value of the solution (3) and it is clear that the spectrum continues to change over the H_- region from 12 to 20. Schaal has suggested that two successive ionizations occur (5) to give, finally, the ion $p\text{-}NO_2C_6H_4CCN^{=}$. Although the loss of the second proton may occur in strongly basic solution the variety of spectra that can be obtained in moderately basic solution show that this is not the sole answer.

O'Ferrall and Ridd (6) have shown that *p*-nitrobenzyl cyanide reacts in different ways with aqueous and methanolic base. None of the nitrogen acids used in the development of the H_- scale (1–4) nor the other nitriles reported herein behave in this way and we suspect that nucleophilic addition to the aromatic ring (7, 8) must be competing with proton removal in this case. The other nitriles lack the nitro substituent and nucleophilic addition to the ring does not occur.

TABLE I

Ionization data for cyano compounds

Compound	pK_a	Anion absorption maxima λ_{max} (mμ)	ϵ	Solvent
Malononitrile	11.14 (4)	226	20 800	Ethanol
9-Cyanofluorene	11.41 (4)	410	2 220	Ethanol
3-Chlorobenzyl cyanide	18.18	348	18 200	Ethanol–DMSO*
	18.10	346	18 500	Water–DMSO*

*Dimethyl sulfoxide.

Table I lists the ionization data for the other nitriles. In addition to these, diphenylacetonitrile was examined but this compound decomposes rapidly in basic aqueous dimethyl sulfoxide after the appearance of a transient yellow color that is due, presumably, to the carbanion.

EXPERIMENTAL

The compounds used were commercially available or were prepared by standard methods, as described elsewhere (4). The pK determinations were made as previously described (3).

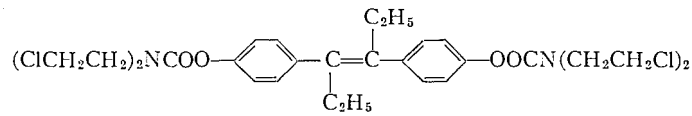
series of derivatives of that type have been synthesized, starting from natural or synthetic estrogenic hormones, estrone (10), stilbestrol (I) (1, 5, 10), and hexestrol (1, 5, 10).



(I)

Danielli showed that tumors treated with urethanes with cytostatic properties became urethane resistant owing to the appearance of an enzyme in the tumor tissue which hydrolyzed and inactivated the urethanes (6). Urethane-type nitrogen mustards remain active since they are hydrolyzed by the enzyme previously formed inside the tumor tissue (5, 6). In the case of urethanes derived from estrogenic hormones (natural or synthetic) such a hydrolysis might also set free in the tumor the base estrogen, e.g. in the case of compound I the diethylstilbestrol, known to have cytostatic properties for some hormone-dependent tumors. There is no proof that this mechanism is responsible for the anticancerous effect observed on urethane-nitrogen mustards of the stilbestrol and hexestrol type. If the hypothesis of enzymatic hydrolysis is correct, there might exist a direct relationship between the anticancer activity of urethane-type nitrogen mustards and the estrogenic activity of the initial *p,p'*-dihydroxydiaryl derivatives.

To elucidate the point a study was undertaken on the anticancer activity of some urethane-type nitrogen mustards, derived from compounds of the *p,p'*-dihydroxydiaryl derivatives class with various estrogenic effects but with similar structures (II) (see Table I).

(II)

The following new urethane-type nitrogen mustards of the symmetrical *p,p'*-dihydroxydiaryl derivatives were therefore synthesized (see Table II).

*Spectra were carried out by pastillation in KBr, on a spectrophotometer URIO Zeiss-Jena–RDG.
†Two hours at reflux.

To obtain nitrogen mustard carbamates, the condensation of the above *p,p'*-dihydroxydiarylic derivatives with nitrogen mustard chloroformate, prepared according to Childs *et al.* (4), was used. The condensation was carried out in pyridine (10) and has the advantage of directly and efficiently yielding easily crystallized products.

Infrared spectra from the synthesized products present a characteristic peak in the range of 1 740 – 1 710 cm^{-1} corresponding to the carbamate function. The synthesis was performed according to Nogrady's method (10). For some products the reaction lasted up to 6–7 days (see Table II).

The carbamates were recrystallized from anhydrous methanol or ligroin.

SUMMARY

This work was carried out to study the relationship between the estrogenic activity of *p,p'*-dihydroxydiaryl derivatives and the possible anticancer activity of their tetrakis N,N,N',N'-(2 chlorethyl)urethanes. New nitrogen mustard-type urethanes were synthesized from: 4,4'-dihydroxystilbene (*trans*); 4,4'-dihydroxydibenzil; 4,4'-dihydroxydiphenylmethane; 4,4-dihydroxy-1,1-diphenyl-2,2,2,-trichlorethane; 4,4'-dihydroxydiphenyl; 4,4'-dihydroxyazobenzene; 4,4'-dihydroxydiphenyl ether; 4,4'-dihydroxydiphenyl sulfide; 4,4'-dihydroxydiphenyl sulfone; 4,4'-dihydroxydibenzeliden acetone; 4,4'-dihydroxydiphenyl sulfoxide; 4,4'-dihhydroxybenzophenone; and 4,4'-dihydroxy-1,1-diphenyl-2,2-dichloroethylene. Infrared spectra were obtained. Substances are under biological tests.

SYNTHESIS OF SOME TETRAZOLE SALTS

Méude Tremblay

INTRODUCTION

The objective of the synthesis work was to prepare solid organic compounds consisting mainly of nitrogen and hydrogen, and containing the smallest amount of carbon and oxygen.

Three 5-nitroaminotetrazole salts were prepared by the reaction of nitroguanylazide or potassium 5-nitroaminotetrazole with the mineral salts of guanidine derivatives or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

5-aminotetrazole. The guanidium 5-nitroaminotetrazole, formed by the condensation of guanidine carbonate and nitroguanylazide, is described in the literature (1). This compound contains 4.5 moles of nitrogen per mole of carbon or oxygen. By a similar method, other salts of 5-nitroaminotetrazole containing higher percentages of nitrogen were synthesized. Aminoguanidinium 5-nitroaminotetrazole was formed from aminoguanidine bicarbonate and nitroguanylazide. Triaminoguanidinium 5-nitroaminotetrazole was obtained by the condensation of triaminoguanidine nitrate and potassium 5-nitroaminotetrazole. 5-Aminotetrazolyl-5′-nitroaminotetrazole was also obtained from 5-aminotetrazole nitrate and potassium 5-nitroaminotetrazole. The compounds obtained formed monobasic salts that display slightly acidic properties as in the case of guanidinium 5-nitroaminotetrazole (1, 2). Most starting materials were available except nitroguanylazide (3) and triaminoguanidine (4). These salts contained between 68 and 73% nitrogen, and by decomposition, liberated large volumes of hydrogen, nitrogen, and carbon monoxide. Upon combustion a large amount of heat is also evolved, owing to the positive heat of formation of these salts, i.e. +26.59 kcal/mole for guanidinium 5-nitroaminotetrazole (5).

The shock sensitivity of 5-nitroaminotetrazole salts was determined on the Bruceton impact machine with a 2 kg weight. It is given as the minimum height (cm) at which the hammer should fall to give 50% detonation. Their shock sensitivity varied from 30 cm / 2 kg for aminoguanidinium 5-nitroaminotetrazole to 8 cm / 2 kg for triaminoguanidinium 5-nitroaminotetrazole. The infrared absorption spectra of tetrazole derivatives were determined in Nujol emulsion and absorption bands were obtained which were assigned on the basis of data published in the literature (6). The spectra of nitroaminotetrazole salts of aminoguanidine, triaminoguanidine, and aminotetrazole have shown the presence of tetrazole rings together with the functional groups present in the individual guanidines.

EXPERIMENTAL

The elemental analyses for carbon, hydrogen, and nitrogen were made by C. Daessle, Micro Analyses, Montreal. In some instances explosions occurred upon combustion.

Aminoguanidinium 5-Nitroaminotetrazole

To aminoguanidine bicarbonate (3.4 g, 0.025 mole) dissolved in water (25 ml) and ethanol (40 ml) was added nitroguanylazide (3.3 g, 0.025 mole). There was an evolution of CO_2 with formation of a salt which was insoluble in the alcoholic solution. After recrystallization from water, m.p. 214–215 °C.

Anal. Calcd. for $C_2H_8N_{10}O_2$: C, 11.7; H, 3.94; N, 68.6. Found: C, 11.4; H, 3.73; N, 67.6.

Triaminoguanidinium 5-Nitroaminotetrazole

To the potassium salt of 5-nitroaminotetrazole (2.3 g, 0.0137 mole) dissolved in water (25 ml) was added triaminoguanidinium nitrate (2.3 g, 0.0137 mole), and the mixture heated. Upon cooling a white solid (melting at 184–186 °C) was obtained.

Anal. Calcd. for $C_2H_{10}N_{12}O_2$: C, 10.2; H, 4.3; N, 71.8. Found: C, 9.3; H, 4.7; N, 71.0.

5-Aminotetrazolyl-5′-nitroaminotetrazole

(*a*) To nitroguanylazide (1.5 g, 0.0115 mole) dissolved in ethanol (25 ml) was added aminotetrazole monohydrate (1.2 g, 0.0115 mole). The mixture was warmed, filtered, and upon cooling a solid melting at 171 °C (explodes) was obtained. Several recrystallizations from water yielded a compound melting at 178 °C (decomp.).

Anal. Calcd. for $C_2H_5N_{11}O_2$: C, 11.1; H, 2.34; N, 71.6. Found: C, 11.0; H, 2.10; N, 71.1.

(*b*) To 5-aminotetrazole nitrate (1.48 g, 0.01 mole), prepared by the literature method (7), dissolved in water (25 ml). An aqueous solution was added to potassium salt of 5-nitroaminotetrazole (1.68 g, 0.01 mole, 25 ml). The 5-aminotetrazole-5′-nitroaminotetrazole precipitated. Yield, 1.5 g (70%). After recrystallization from water, m.p. 178 °C (decomp.). An admixture with the previous compound did not depress the melting point.

Triaminoguanidinium 5-Nitroaminotetrazole from Aminoguanidinium 5-Nitroaminotetrazole

To a solution of aminoguanidinium 5-nitroaminotetrazole (2.04 g, 0.01 mole) in water (50 ml), anhydrous hydrazine (95%, 0.6 g, 0.02 mole) was added. The mixture was heated under reflux in a water bath for 2 h, partially evaporated, cooled, and filtered. The solid obtained melted at 184–186 °C. A mixed melting point with authentic triaminoguanidinium 5-nitroaminotetrazole was not depressed.

SYNTHESIS OF α-ALKYL-SUBSTITUTED AMINO ACIDS AND DERIVATIVES

C. J. Abshire and L. Berlinguet

The interesting biological properties of some α-substituted amino acids (1–5) made their preparation and pharmacological study of interest to us. We describe two such preparations starting from the available ketones.

α-(2-Furyl)-alanine was prepared from 2-furyl methyl ketone via the corresponding hydantoin 5-(2′-furyl)-5-methylhydantoin.* This new amino acid is an isomer of β-(2-furyl) alanine, β-(3-furyl) alanine, and β-(2-furyl)-β-alanine, all of which have been previously reported (8–10). The amino acid was characterized by its N-phenylcarbamyl derivative which was converted to the 3-phenylhydantoin by treatment with boiling glacial acetic acid. Although stable toward alkali each of these three compounds were decomposed by mineral acids, owing presumably to the lability of the furan nucleus. This instability resulted in the failure of the attempted cyclization of the N-phenylcarbamyl derivative to the 3-phenylhydantoin by hydrochloric acid.

α-Ethylserine has been prepared previously from 2-amino-2-hydroxymethyl-1-butanol (11, 12), from α-aminobutyric acid by the action of formaldehyde (13), and by a long route from ethyl α-acetylbutyrate (14). We report the convenient synthesis of this amino acid from 1-acetoxy-2-butanone via the hydantoin in an overall yield of 38%. α-Ethylserine was characterized by its cupric salt. Probably because of its high solubility, the hydantoin could not be isolated as an intermediate but was obtained from the pure amino acid. Reaction of α-ethylserine with phenyl isocyanate yielded N-phenylcarbamyl-α-ethylserine which in turn was cyclized to 3-phenyl-5-ethyl-5-hydroxymethylhydantoin.

Biological Evaluation

The amino acids and their carbamyl derivatives were nontoxic to rats on intraperitoneal injection and had no effect on Walker-cancer bearing rats. The amino acids had no effect on growth curves when fed to rats at a 1% concentration in the diet. The hydantoins (as their sodium salts) had no visible effects on metrazole-induced epileptic fits in rats.

**This hydantoin has been previously reported in two patents (6, 7).*

EXPERIMENTAL

5-(2'-Furyl)-5-methylhydantoin

The use of ammonium chloride with potassium cyanide in this preparation is a departure from the patent procedures (6, 7). To a stirred solution of 13.75 g of 2-furyl methyl ketone and 10 g of ammonium chloride in 200 ml of ethanol–water (1:1) was added a solution of 12.2 g of potassium cyanide in 20 ml of water; this was stirred at room temperature for 3 h. Then a mixture of 48 g of ammonium carbonate and 100 ml of water was added during 1 h; the resulting mixture was stirred overnight at 50–70°. Excess ammonium carbonate was decomposed by heating and the solution was concentrated *in vacuo* until a precipitate began to form. The cooled solution afforded 17 g (75%) of white crystals, m.p. 178–180° (lit. (6) 176–178°).

Anal. Calcd. for $C_8H_8N_2O_3$: N, 15.55. Found: N, 15.63.

α-(2-Furyl) Alanine

A mixture of 7 g of 5-(2'-furyl)-5-methylhydantoin and 14.2 g of barium hydroxide in 150 ml water was boiled under reflux in a stainless steel flask overnight. Addition of 2.4 ml of concentrated sulfuric acid precipitated barium sulfate which was removed by filtration. The filtrate was concentrated to a yellow gum, which crystallized after trituration with acetone. A 4.9 g yield (82%) of white solid melting at 194–200° was obtained; the crystals began to darken and decompose slowly at 174°. The amino acid gave the usual purple color with ninhydrin. A circular paper chromatogram developed in pyridine–water (4:1) gave an R_f of 0.71 for the compound.

Anal. Calcd. for $C_7H_9NO_3$: N, 9.14. Found: N, 9.15.

N-Phenylcarbamyl-α-(2-furyl) Alanine

α-(2-Furyl) alanine (1.55 g, 0.01 mole) in an equivalent of 4% sodium hydroxide was shaken for 1/2 h with a slight excess of phenyl isocyanate (1.55 g, 0.014 mole). The reaction mixture was filtered, the filtrate acidified with concentrated hydrochloric acid, and the white precipitate collected and washed with water. Crystallization from ethanol–water afforded 1.55 g (57%) of pure product, m.p. 159–161°; neutralization equivalent, found 276 (calcd. 274).

Anal. Calcd. for $C_{14}H_{14}N_2O_4$: N, 10.21. Found: N, 10.26.

3-Phenyl-5-(2'-furyl)-5-methylhydantoin

A solution of 6 g of N-phenylcarbamyl-α-(2-furyl) alanine in 50 ml glacial acetic acid was refluxed for 10 min then quickly cooled; if heating is continued for a longer period of time some darkening of the solution occurs probably due to decomposition of the furan ring. Excess water was added; the precipitate was filtered and recrystallized from ethanol–water. Yields in the range of 27 to 36% of a product melting at 170–172° were obtained. Cyclization had taken place because the product is now neutral in alcohol solution to bromothymol blue, whereas the starting material requires 1 equivalent of base for neutrality.

Anal. Calcd. for $C_{14}H_{12}N_2O_3$: N, 10.93. Found: N, 10.67.

α-Ethylserine and Its Copper Salt

Potassium cyanide (65 g, 1 mole) was added, with stirring, to a solution of 1-acetoxy-2-butanone (87 g, 0.67 mole) and ammonium chloride (53.5 g, 1 mole) in a 1:1 ethanol–water mixture (600 ml). The resulting mixture was stirred at room temperature for 3 h; then ammonium carbonate (300 g) was added and the mixture was stirred overnight at 50–70°. Residual ammonium carbonate was decomposed by refluxing 3 h, following which the solution was concentrated *in vacuo* to a brown oil; this was triturated with hot acetone and filtered, the filtrate being subsequently concentrated again. The residue, presumably a hydantoin, consisted of 152.8 g of a brown oil. Numerous attempts to crystallize it failed, so 87.6 g of it was hydrolyzed; this was added to a solution of 165.8 g of barium hydroxide in 500 ml of water and the solution was refluxed overnight in a steel vessel. Excess ammonium carbonate was added; the solution was refluxed 3 h and filtered, and concentrated to an oil *in vacuo*. This was subsequently dissolved in 171 ml of water and divided into two parts: 57 ml to make the copper salt, and 114 ml to isolate the free amino acid.

The 114 ml of solution above were added to 700 ml of acetone and allowed to crystallize slowly. The large white crystals were filtered and recrystallized from ethanol–water to yield 12 g (38%) of α-ethylserine melting at 257–259°. In electrophoresis using a buffer of pH 8.6, the product remained at the point of origin. A circular paper chromatogram employing pyridine–water (4:1) as solvent gave an R_f of 0.63 for the amino acid.

Anal. Calcd. for $C_5H_{11}NO_3$: N, 10.52. Found: N, 10.75.

The remaining 57 ml of the above solution was boiled for 15 min with excess cupric carbonate, then filtered. The copper salt was precipitated by the addition of acetone–ethanol and an 8.5 g yield (41%) was obtained. The compound does not melt below 300°; it turns from blue to brown gradually upon heating at about 194°. The product was dried at 100° for 2 h, then analyzed.

Anal. Calcd. for $C_{10}H_{20}N_2O_6Cu$: N, 8.55. Found: N, 8.75.

5-Ethyl-5-hydroxymethylhydantoin

A solution of α-ethylserine (2 g, 0.015 mole) and potassium cyanate (1.22 g, 0.015 mole) in 14 ml of water was stirred at 60–70° for 2 h. Then 14 ml of concentrated hydrochloric acid was added and the solution was

refluxed for 1 h, following which the solvent was removed by vacuum leaving a clear oily residue. This was triturated with hot alcohol; the inorganic salts were filtered and the filtrate again concentrated to an oil which crystallized on standing. An 800 mg yield (34%) of the hydantoin melting at 165–168° was obtained.

Anal. Calcd. for $C_6H_{10}N_2O_3$: N, 17.71. Found: N, 17.23.

N-Phenylcarbamyl-α-ethylserine

α-Ethylserine (1 g, 0.00752 mole) was dissolved in an equivalent of 10% aqueous sodium hydroxide (3 ml) and about 20 ml of water. To this was added a slight excess of phenyl isocyanate (1.07 g, 0.01 mole). The mixture was shaken vigorously for 1/2 h and then filtered. Acidification of the filtrate with concentrated hydrochloric acid precipitated a white solid which was filtered, washed with water, recrystallized from ethanol–water, and dried. A 1.3 g (69%) yield of pure material melting at 150–152° was obtained. The compound is acidic and requires 1 mole of sodium hydroxide for neutralization; neutralization equivalent, found 264 (calcd. 252).

Anal. Calcd. for $C_{12}H_{16}N_2O_4$: N, 11.11. Found: N, 10.64.

3-Phenyl-5-ethyl-5-hydroxymethylhydantoin

A solution of 350 mg of N-phenylcarbamyl-α-ethylserine in 20 ml of 6 *N* hydrochloric acid was refluxed 1 h, then concentrated *in vacuo* until a precipitate began to form. A small amount of water (10 ml) was added; the mixture was cooled and filtered, and the precipitate was dried. A 220 mg yield (68%) of a product melting at 155–156° was obtained. Cyclization had occurred because the product is now neutral.

Anal. Calcd. for $C_{12}H_{14}N_2O_3$: N, 11.96. Found: N, 11.62.

STUDIES OF SODIUM CUPRATE(III) STABILITY

J. S. Magee, Jr.[1] and R. H. Wood

We have recently completed a study of the stability of sodium dioxocuprate(III) in various alkali bases at several different base strengths. In no case did we find that the salt was stable in solution and, in fact, the half-life of the CuO_2^- ion was estimated to be only 25 s. Thus, it appears that tervalent copper can be present in aqueous solution only in the presence of large stabilizing anions such as periodate or tellurate (1–3) or in the presence of large concentrations of hypobromite (4).

EXPERIMENTAL

One of the methods reported by Scholder and Voelskow (4) for preparing $NaCuO_2$ was modified and used throughout this study. This procedure involves oxidation of copper(II) hydroxide with sodium hypobromite in strong base, the sodium cuprate(III) precipitating as a reddish-brown precipitate.

All reagents used were C.P grade. The sodium hypobromite and microcrystalline copper(II) hydroxide used were prepared according to the procedure of Scholder and Voelskow (4).

The analytical procedure used was a modification of Park's (5) method for determining Cu(II) in the presence of As(III). An ice-cold mixture of 30 ml of 3.3 *N* NaOH and 15.00 ml of standard 0.2 *N* arsenic(III) solution was added to a sample of about 0.15 g solid sodium cuprate(III). The mixture, which contained a fine precipitate of copper(II) oxide was diluted with 90 ml of ice-cold water and acidified with 15 ml of cold 12 *N* sulfuric acid. Excess arsenic(III) was determined by titration with standard cerium(IV) solution using ferrous orthophenanthroline as the indicator and osmium tetraoxide as catalyst (meq Cu(III) = meq As(III) − meq Ce(IV)). Three grams of potassium acid phthalate was added to the solution and the pH was adjusted to 3.5 with concentrated ammonium hydroxide (28% NH_3). Ten grams of potassium iodide, dissolved in a minimum quantity of water, was added and the solution was titrated with standard sodium thiosulfate to a light-orange end point. Starch solution was used as the indicator. The number of equivalents of sodium thiosulfate used equalled the number of moles of copper.

The decomposition of sodium cuprate(III) may be represented by the following equation:

$$4NaCuO_2 + 2H_2O \rightarrow 4NaOH + 4CuO + O_2.$$

In this study, we followed the rate of decomposition of solid sodium cuprate(III) in the presence of base using a Warburg apparatus (6). A small sample of $NaCuO_2$ was placed in a glass vial which was inserted in a Warburg flask containing a known volume of base. After the flask had come to equilibrium in a constant temperature bath, the contents of the vial were mixed with the base and the mixture was shaken vigorously until an equilibrium pressure reading was obtained. Oxygen pressure readings were taken as a function of time during the decomposition. When decomposition was complete the solution of base and copper(II) was acidified and the amount of copper(II) was determined iodometrically. Decomposition of sodium cuprate(III) in 1 *N* NaOH by this technique was used to check the analytical method given above.

RESULTS AND DISCUSSION

Products prepared by the above procedure contained 95 to 99% of the copper as copper(III). As a check on the accuracy of the arsenic(III) method of analysis, duplicate analyses of the same sample of sodium cuprate(III) gave a ratio of copper(III) to total copper of 0.796 and 0.800 by the gas volume method and 0.796 by the arsenic(III) method. As a check on possible air oxidation of the arsenic(III) solutions a series of blank runs were performed. Under the conditions of the analysis dissolved copper(II) is an excellent catalyst for the air oxidation of arsenic(III). However, solid copper(II) oxide and decomposed sodium cuprate(III) produced a maximum of 0.5 mole % oxidation in 1 h.

Scholder and Voelskow report that moist sodium cuprate(III) decomposes slowly. Analysis of a sample prepared by the method previously given showed 10% decomposition when stored for 8 days at room temperature. A portion of the same sample stored at 5 °C showed only 1% decomposition in the same period. In an effort to both dry and purify the sodium cuprate(III), samples were leached with various solvents. With freshly dried ethyl alcohol, dioxane, and acetone extensive decomposition occurred. Ethyl ether caused a slight decomposition (about 6%) but did not remove any moisture from the solid. Sodium cuprate(III) samples dried in a vacuum desiccator using either $Mg(ClO_4)_2$ or silica gel showed partial decomposition (20 to 35%). However, once dried the sodium cuprate(III) did not show further decomposition when stored in a desiccator over silica gel for 2 months at room temperature. These results are consistent both with the results of Scholder and Voelskow, who report a partial decomposition on drying the solid, and with those of Klemm and Wahl (7), who report that dry solid potassium dioxocuprate(III) is stable.

The results of the study of the decomposition of sodium cuprate(III) in the presence

of base are given in Table I. Inspection of Table I shows that sodium cuprate(III) decomposes more rapidly when in contact with KOH than NaOH and that the extent of decomposition increases as base strength decreases. Further, as may be expected, decomposition is more rapid at room temperature than at 0 °C.

TABLE I

Decomposition rate of sodium cuprate(III) in base*

	0.0 °C decompositions		25.2 °C decompositions	
Base	meq Cu present	Time (min) for 50% decomposition	meq Cu present	Time (min) for 50% decomposition
Satd. KOH	0.630	None in 40	0.510	25
10 *M* KOH	0.664	14	0.685	1.5
7.5 *M* KOH	0.619	7	0.452	1.0
0.5 *M* KOH	0.878	5	—	—
0.01 *M* KOH	0.633	4	—	—
Satd. NaOH	0.773	None in 150	0.736	50
10 *M* NaOH	0.595	None in 150	0.448	47
5 *M* NaOH	1.00	100	0.529	10
Satd. LiOH	0.633	40	0.597	15

*In all cases 20.0 ml base was used.

Except in the case of decompositions in lithium hydroxide, the rate of O_2 evaluation appears reasonably linear. In 10 *M* and saturated NaOH however, we observed a 10 min period in which essentially no decomposition occurs followed by a constant rate of O_2 evolution to the equilibrium pressure reading. In saturated LiOH at 25.2 °C, the rate of O_2 evolution is equivalent to that observed in 5 *M* NaOH up to a point corresponding to about 45% of the equilibrium O_2 pressure reading. The O_2 evolution rate then becomes progressively smaller so that complete decomposition in saturated LiOH requires 60 min compared to 20 min in 5 *M* NaOH.

Qualitative observations of the precipitates indicated that the decomposition rate was primarily influenced by the rate of solution. This observation is confirmed by the fact that saturated potassium hydroxide at both 0 °C and 25 °C in which $NaCuO_2$ was dissolving and decomposing gave no indication of Cu(III) in solution when we titrated a rapidly filtered portion of the $NaCuO_2$–base mixture with a known amount of excess As(III) followed by standard Ce(IV). More than 0.02 meq of copper(III) in solution with a solid sample containing 0.60 meq of copper(III) would have been detected. These results show that the cuprate(III) ion is so unstable in basic solutions that it can not have a half-life of more than a fraction of a minute.

Lister's study (3) of the rate of oxygen evolution in a copper(III) hypochlorite solution at 20 °C can be used to give a lower limit to the half-life of a copper(III) solution assuming that 4 moles of copper(III) give 1 mole of oxygen and that no hypochlorite complexes are present. At 20 °C Lister finds a rate of oxygen evolution of 0.25 ml of oxygen per minute for 2.77×10^{-5} moles of copper. This represents a half-life of about 25 s. This result is approximately the upper limit given by our experiments and would fix the half-life of cuprate(III) ion at about 25 s. However, Lister's results can also be explained by assuming that only a small fraction of the copper is present as copper(III), and that the rest of the copper is present as a hypochlorite complex.

Scholder and Voelskow have shown that solutions of copper(III) are stable in the presence of both excess base and excess hypobromite. This indicates that the hypobromite is either stabilizing the cuprate(III) ion by forming a complex ion or the rate of oxidation of copper(II) by hypobromite is greater than the rate of copper(III) decomposition.

A PROTON MAGNETIC RESONANCE STUDY OF SODIUM 3,5,5-TRIMETHYL HEXANOATE

T. J. R. CYR AND B. A. DUNELL

Continuing with an investigation of molecular motion of fatty acids and their salts, we have examined the broad line nuclear magnetic resonance (n.m.r.) spectra of the sodium salt of 3,5,5-thrimethyl hexanoic acid. A commercial sample of the acid was distilled at 1 atm. Most of the acid distilled over between 226 and 228 °C and a portion of this central cut was taken for neutralization with an alcoholic solution of reagent grade sodium hydroxide. The solvent was partially evaporated and the precipitated soap was filtered and dried for some 24 h under vacuum. The precipitate was crushed to a powder, packed into pyrex sample tubes, and heated in the tubes for a further 24 h at 200° under vacuum before the tubes were sealed off.

Spectra were obtained on a Varian dual purpose spectrometer mainly at 60 Mc/s, although a few were run at 40 Mc. The depth of modulation varied from 0.14 gauss (G) to approximately 1 G, but most spectra were run at 0.14, 0.24, or 0.38 G modulation. Line shape and width were not observed to depend on the depth of modulation, and more specifically they were independent of modulation depth over the range 0.14 to 1 G at liquid nitrogen temperature and at 154 °K. This fact provides evidence that the narrowing of the absorption signal between 100 and 160 °K is not a spurious effect caused by the presence of an impurity whose absorption signal narrows at this temperature and obscures the still broad absorption of the main substance. Increasing the depth of modulation to 1 G from 0.14 G should produce at least some change in line shape at 154 °K if there is a broad as well as a narrow component of absorption actually present in the spectrum (1). The temperature of the sample was controlled by passing heated air or tank nitrogen cooled by passage through a cryostatic bath over the sample which was held in a dewar vessel within the n.m.r. probe. The temperature was measured by thermocouples placed in the airflow both upstream and downstream from the sample.

Typical spectra are presented in Fig. 1, and line width and second moment are shown as a function of temperature in Fig. 2. Three steps are distinguishable in the decrease of each of these parameters. The first and most obvious step begins immediately above liquid oxygen temperature and continues to about 160 °K. The second step is marked by a clear decrease in line width between 450 and 470 °K and a levelling off of the second moment at approximately 1.2 G^2 at 470 °K after a gradual decrease from some 4.5 G^2 at 350 °K. At temperatures above the third step, which occurs sharply at 538 °K, the line width is determined by depth of modulation and field homogeneity, and the second

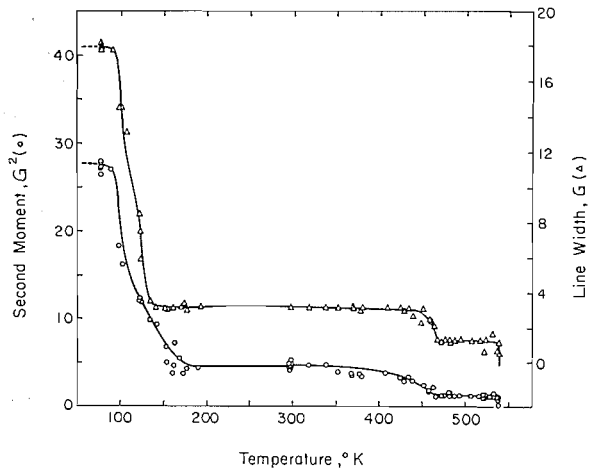

FIG. 2. Variation of line width and second moment of sodium 3,5,5-trimethyl hexanoate with temperature.

moment becomes vanishingly small. The final melting point was measured on a hot stage microscope as approximately 580 °K.

The intramolecular contribution to the rigid lattice second moment was calculated from proton positions, which were determined on the assumption that all bond angles were tetrahedral, that C—C bond lengths were 1.54 Å, and that C—H bond lengths were 1.10 Å. In the *t*-butyl group, one C—H bond of each CH_3 was assumed to be parallel to the C_4—C_5 bond direction. For interproton distances less than 5 Å, the intramolecular contribution was found to be 24.7 G^2. The magnitude of the intermolecular contribution is a matter for speculation since no crystallographic data were known for this salt. For potassium caprate to caproate the intermolecular contribution, from known crystal structure, is some 6.3 G^2 (2), and for sodium stearate it is estimated to be 9.4 G^2 (3).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

It would be reasonable to assume that the intermolecular contribution in this compound is 7.5 ± 2 G^2. One might therefore estimate the total second moment to be 32 ± 3 G^2. The experimental value at 77 °K is 27 ± 1 G^2, and the difference between this and the theoretical value is 5 ± 4 G^2. The internal contribution of a methyl group to the second moment is 3.76 G^2 if it is rigid and 0.94 G^2 if it rotates. It is thus reasonable (2) to consider that the theoretical rigid lattice second moment is decreased by 3.5 G^2 for each methyl group which rotates. Construction of the molecule from Fisher–Hirschfelder atom models shows that free reorientation of all the methyl groups simultaneously is sterically impossible. In some conformations two methyl groups are strongly hindered and two rotate easily. If two methyl groups are rotating at 77 °K the difference between experimental and theoretical second moments should be 7 G^2, a value which is consistent with the estimated difference 5 ± 4 G^2. Until information is available concerning the crystal structure of this salt, the n.m.r. results cannot distinguish between one and two methyl groups rotating at liquid nitrogen temperature. The second moment does indicate, however, that it is improbable that no methyl groups rotate, and very improbable that more than two rotate. Alternatively, limited reorientation of all the methyl groups and of the whole *t*-butyl group, in which the possibility of motion of one group is dependent on reorientation of another, cannot be excluded as an interpretation of the results. Reorientation of the whole acid anion about the axis joining the carboxyl carbon and the central carbon atom of the *t*-butyl group reduces the intramolecular second moment to 5.5 G^2 if no other motion is considered. Addition of 0.6 of the estimated rigid lattice intermolecular contribution gives a total second moment of 10 ± 1 G^2 for rotation of the whole hydrocarbon chain. Simultaneous, limited reorientation of methyl groups would lower the second moment further, bringing it into the vicinity of the value of 4.5 G^2, which is observed experimentally over the temperature range of 180 to 340 °K. Molecular motion continues to increase above 340 °K, until by about 470 °K the experimental second moment of 1.2 G^2 indicates that only diffusional motion is not yet taking place at a frequency sufficient to influence the n.m.r. line, i.e. at about 10^4 s^{-1} (4). At approximately 537 °K line width and second moment approach zero, and we may assume that diffusion becomes significant above this sharply defined transition temperature, which is still some 40° below the melting point as it can be observed visibly with a hot stage microscope. It is, of course, also understood that the rate of rotational reorientation increases with increasing temperature over a wide temperature range, passing through the frequency range which is critical for n.m.r. line narrowing, viz., the order of the line width expressed as frequency (some 10^4 to 10^5 s^{-1}), in the temperature region in which line narrowing is observed.

The subsidiary maximum and minimum in the derivative curves at liquid nitrogen temperature may be attributed to a comparatively large contribution to the total signal from three-proton groups, broadened by large interactions from beyond the groups (5). It is established that increasing molecular motion with rise in temperature smooths out even this residual structural detail in the line shape of the three-proton system (5), and this is indeed observed in our spectra. A very narrow component of the spectrum appears at room temperature and increases in intensity as the temperature rises. We attribute this, as in other fatty acids and their salts (6), to premelting or to an abnormally early occurrence of the transition which is observed at 537 °K. The fact that the intensity of this narrow component does not increase especially rapidly with rise in temperature after its appearance at 300 °K may be taken as supporting evidence that the sample has a good degree of purity.

MAGNETIC STUDIES ON COPPER(II) TRIFLUOROACETATE

R. C. THOMPSON AND D. B. W. YAWNEY

Magnetically dilute copper(II) compounds have magnetic moments essentially temperature independent and in the range 1.8–2.0 Bohr magnetons (B.M.) (1). Most of the alkyl- and aryl-carboxylates of copper(II), however, have abnormally low magnetic moments which vary with temperature in a manner indicative of the presence of antiferromagnetic interactions in these compounds (2–4). Extensive magnetic and structural studies have shown that one of the major factors affecting the magnetic properties is whether the compound has a binuclear structure, as has copper(II) acetate monohydrate, or a polymeric structure, as has copper(II) formate tetrahydrate. In carboxylate compounds of copper(II) which have the binuclear configuration, the magnetic interaction is relatively large as it arises through overlap of atomic orbitals on pairs of copper ions held in close proximity by four bridging carboxylate groups. Magnetic moments at room temperature for this type of compound range from approximately 1.4 B.M. observed for copper(II) acetate and the higher homologous alkanoates to 1.0 B.M. observed for copper(II) formate hemidioxane (5). In the group of compounds with polymeric configurations the magnetic interaction is much weaker since it occurs, not from direct metal–metal bonding but via the bridging carboxylate groups by a super-exchange mechanism. Room temperature moments observed here range from the value 1.61 B.M. for the power-blue form of copper(II) formate to 1.90 B.M. for the royal-blue form of the same compound (3).

In a review article on copper(II) complexes with subnormal magnetic moments, Kato, Jonassen, and Fanning (6), referring to unpublished work, report copper(II) trifluoroacetate to have a room temperature moment of 1.9 B.M. No further details were given. The magnetic properties of this compound have now been studied over the temperature range 90–300 °K. The criterion that carboxylates of copper(II) which have a binuclear configuration will exhibit magnetic interactions of a magnitude at least of the order of that observed in copper(II) acetate, or possibly larger, has been used to deduce structural information on copper(II) trifluoroacetate.

EXPERIMENTAL

Copper(II) trifluoroacetate was prepared by mixing copper(II) carbonate with a slight excess of trifluoroacetic acid in the form of a concentrated aqueous solution. The resulting blue solution, when placed in a desiccator containing phosphoric oxide, was reduced to a blue glassy residue and further dehydration under vacuum yielded anhydrous copper(II) trifluoroacetate, a pale-green, exceptionally hygroscopic solid.

Anal. Calcd. for $CuC_4F_6O_4$: Cu, 21.94; C, 16.59; F, 39.36; H, 0.0. Found: Cu, 21.6; C, 16.46; F, 39.37; H, 0.25.

Magnetic susceptibilities were determined by the Gouy method using an apparatus described previously (7). Calibration was achieved using a gravimetrically analyzed nickel(II) chloride solution (8). Measurements made at field strengths of approximately 8 500, 7 000, and 4 500 G gave no evidence for the dependence of the susceptibility of copper(II) trifluoroacetate upon the strength of the magnetic field. The diamagnetic contribution to the magnetic susceptibility of copper(II) trifluoroacetate was estimated from Pascal's constants (9) to be 89×10^{-6} c.g.s., e.m.u. Infrared spectra in Nujol were obtained using a Perkin–Elmer model 137 spectrophotometer.

DISCUSSION

The magnetic susceptibility data are given in Table I. A plot of reciprocal molar susceptibility versus temperature yields a straight line which intercepts the temperature abscissa at -42 °K. A slight curvature in the plot is noticeable at high temperatures, a type of behavior which has been observed in other copper(II) compounds and explained by the presence of a temperature-independent paramagnetic contribution to the susceptibility (1). The compound, therefore, obeys Curie–Weiss law of the form $\chi_M \alpha (T - \theta)^{-1}$ with a Weiss constant, θ, of $-42°$. The magnetic moment at 24 °C, calculated using the formula $\mu = 2.84[(\chi_M - 60)T]^{1/2}$ which includes a temperature-independent paramagnetic correction for copper(II) of 60×10^{-6} c.g.s., e.m.u., is 1.81 B.M.

TABLE I

Experimental gram and molar susceptibilities (c.g.s., e.m.u.) at various absolute temperatures

Temp. (°K)	$10^6\chi_g$	$10^6\chi_M$
296.8	4.64	1 430
291.1	4.73	1 460
233.2	5.45	1 670
223.7	5.64	1 720
208.7	6.11	1 860
189.7	6.57	1 990
180.0	6.83	2 070
151.3	7.97	2 400
122.3	9.33	2 790
94.5	11.45	3 400

The small, negative θ value observed for copper(II) trifluoroacetate probably arises through weak antiferromagnetic interactions, a result which strongly suggests that this compound does not have the binuclear configuration but may have a polymeric structure.

On comparing the infrared spectra of several copper(II) carboxylates with those of the corresponding sodium salts it has been observed that, where the copper salt has a binuclear configuration, the COO^- antisymmetric stretching frequencies, ν_a, are higher for the copper compounds than for the sodium compounds (6). The value of ν_a for copper(II) trifluoroacetate (1 650 cm^{-1}) is lower than the value (1 680 cm^{-1}) observed for sodium trifluoroacetate (10), a result supporting the conclusion reached by the magnetic studies that copper(II) trifluoroacetate does not adopt the binuclear configuration.

The fact that copper(II) trifluoroacetate is not binuclear while copper(II) acetate is lends strong support to the ideas of Martin and Waterman concerning the effect of the

donor properties of the ligands on the structures of copper(II) carboxylates (3). These authors suggest that one of the factors determining whether or not a copper(II) carboxylate adopts the binuclear configuration is the residual charge left on the copper ions after bonding with the carboxylate ligand. The separation of the two copper ions in the binuclear unit is small compared to the copper–copper distances in the polymeric configuration and hence a large residual charge on the metal ions may result in a repulsion between them which is strong enough to render the binuclear configuration unstable with respect to the polymeric configuration. The trifluoroacetate group is similar in size to the acetate group; however, due to the large inductive effect of the fluorine atoms, the former is a much weaker base. Hence the residual charge left on the copper ions is greater for copper(II) trifluoroacetate than for copper(II) acetate and the binuclear configuration is expected to be less stable for the former compound.

STRUCTURAL DETERMINATIONS BY NUCLEAR MAGNETIC RESONANCE. 3-SUBSTITUTED PROPIONYL CHLORIDES

George H. Schmid and Larry S. J. Weiler

The possibility that 3-substituted propionyl chlorides might exist in a cyclic form or in equilibrium with a cylic form has been previously considered (1–8). In particular, succinyl dichloride (I*a*) and levulinyl chloride (I*c*) have received considerable attention (1, 2).

Various physical measurements have indicated that succinyl dichloride exists predominantly in the open chain form I*a*. These measurements have included infrared spectroscopy (1), refractivity (4), molecular volume (5), parachor (6), and dipole moments (7).

The structure of levulinyl chloride has been the subject of considerable work which has not firmly established its structure. Various workers have concluded that levulinyl chloride exists in the open chain form (4) while others concluded that the structure was cyclic (8). The nuclear magnetic resonance (n.m.r.) spectra of succinyl dichloride, levulinyl chloride, and 3-carbomethoxypropionyl chloride were taken in an attempt to provide

donor properties of the ligands on the structures of copper(II) carboxylates (3). These authors suggest that one of the factors determining whether or not a copper(II) carboxylate adopts the binuclear configuration is the residual charge left on the copper ions after bonding with the carboxylate ligand. The separation of the two copper ions in the binuclear unit is small compared to the copper–copper distances in the polymeric configuration and hence a large residual charge on the metal ions may result in a repulsion between them which is strong enough to render the binuclear configuration unstable with respect to the polymeric configuration. The trifluoroacetate group is similar in size to the acetate group; however, due to the large inductive effect of the fluorine atoms, the former is a much weaker base. Hence the residual charge left on the copper ions is greater for copper(II) trifluoroacetate than for copper(II) acetate and the binuclear configuration is expected to be less stable for the former compound.

STRUCTURAL DETERMINATIONS BY NUCLEAR MAGNETIC RESONANCE. 3-SUBSTITUTED PROPIONYL CHLORIDES

George H. Schmid and Larry S. J. Weiler

The possibility that 3-substituted propionyl chlorides might exist in a cyclic form or in equilibrium with a cylic form has been previously considered (1–8). In particular, succinyl dichloride (I*a*) and levulinyl chloride (I*c*) have received considerable attention (1, 2).

Various physical measurements have indicated that succinyl dichloride exists predominantly in the open chain form I*a*. These measurements have included infrared spectroscopy (1), refractivity (4), molecular volume (5), parachor (6), and dipole moments (7).

The structure of levulinyl chloride has been the subject of considerable work which has not firmly established its structure. Various workers have concluded that levulinyl chloride exists in the open chain form (4) while others concluded that the structure was cyclic (8). The nuclear magnetic resonance (n.m.r.) spectra of succinyl dichloride, levulinyl chloride, and 3-carbomethoxypropionyl chloride were taken in an attempt to provide

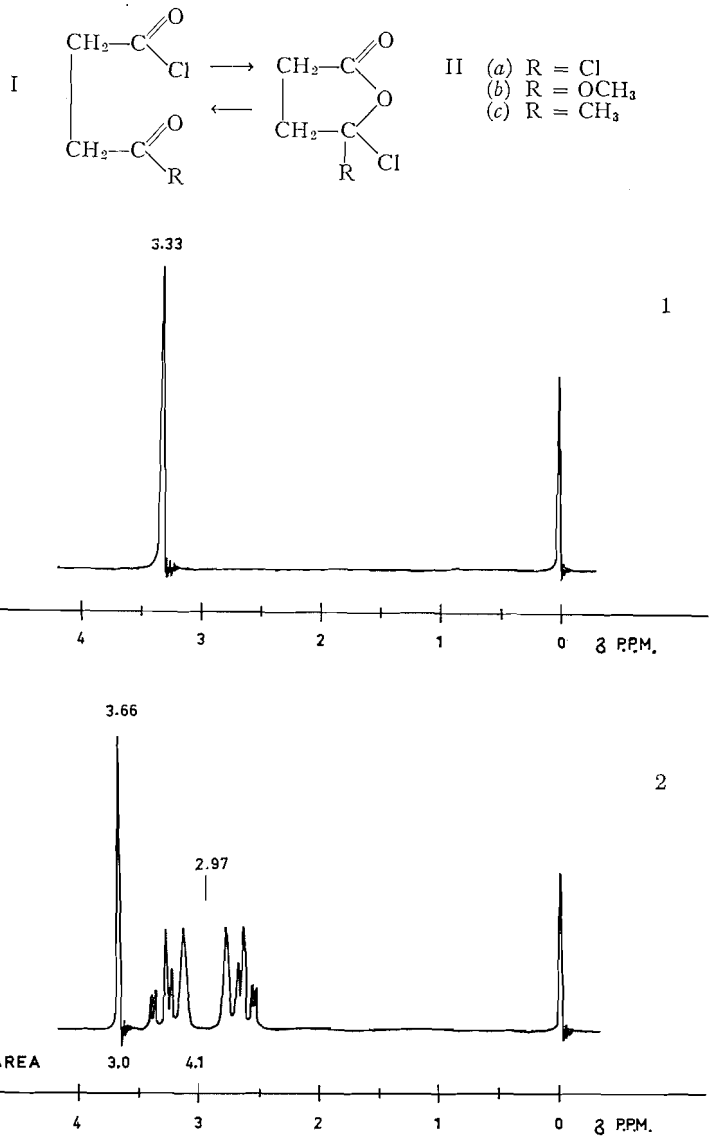

FIGS. 1 and 2. Nuclear magnetic resonance spectrum of succinyl dichloride and 3-carbomethoxypropionyl chloride.

further evidence for the structure of these compounds. The evidence from nuclear magnetic resonance spectra for a cyclic or an acyclic structure for the 3-substituted propionyl chlorides rests on the following two points: (*i*) the methylene splitting pattern for a cyclic structure should be an asymmetric ABCD type and (*ii*) there should be a difference between the chemical shift of the methylene, methyl, and methoxy protons in a cyclic as compared with an acyclic structure. The nuclear magnetic resonance spectra of succinyl dichloride, 3-carbomethoxypropionyl chloride, and levulinyl chloride are shown in Figs. 1, 2, and 3 respectively. Figures 4 and 5 show the nuclear magnetic resonance spectra of the pseudo-ester (III), prepared from levulinyl chloride by the method of Langlois

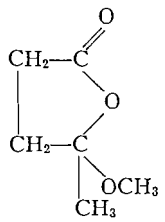
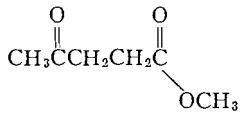
and Wolff (2), and the normal ester (IV), prepared from levulinic acid by the method of Frank (9).

III



IV



Figures 4 and 5 show clearly the different splitting pattern of the methylene protons in the pseudo-ester (III), as compared to the acyclic normal ester (IV). A comparison of the chemical shifts of the protons in (III) and (IV) shows that the methylene, methyl, and methoxy protons of the cyclic pseudo-ester (III) are all further upfield than those in (IV). This indicates that the protons in (III) are more shielded, which is consistent with a cyclic structure. Thus the structure of the pseudo-ester (III) derived from levulinyl chloride is clearly cyclic while the structure of methyl levulinate (IV) derived from levulinic acid is acyclic. The asymmetric methylene proton pattern in Fig. 3 leads to the conclusion that levulinyl chloride exists predominantly in the cyclic form. The replacement of a methoxy group by a chlorine atom (compare Figs. 3 and 4) leads to a downfield shift of the methyl group and a decrease in the spread of the methylene proton pattern, indicating that chlorine is less shielding than a methoxy group. While the methylene proton splitting pattern is consistent with a cyclic structure, the ratio of the integrated areas of methyl to methylene protons is in poor agreement with the theoretical ratio of 4:3. There is the possibility that an appreciable concentration of the acyclic form is present in the neat liquid. The methyl and the methylene protons of the acyclic form would be found approximately 0.3 p.p.m. to 0.6 p.p.m. downfield from the cyclic methyl and methylene proton peaks. This would place them in the region of the cyclic methylene protons and could account for the discrepancy in the ratio of the integrated areas. If it is assumed that only the cyclic and the acyclic forms are present, this indicates that 15.5% of levulinyl chloride may exist in the open chain form.

The nuclear magnetic resonance spectrum of 3-carbomethoxypropionyl chloride (Fig. 2)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

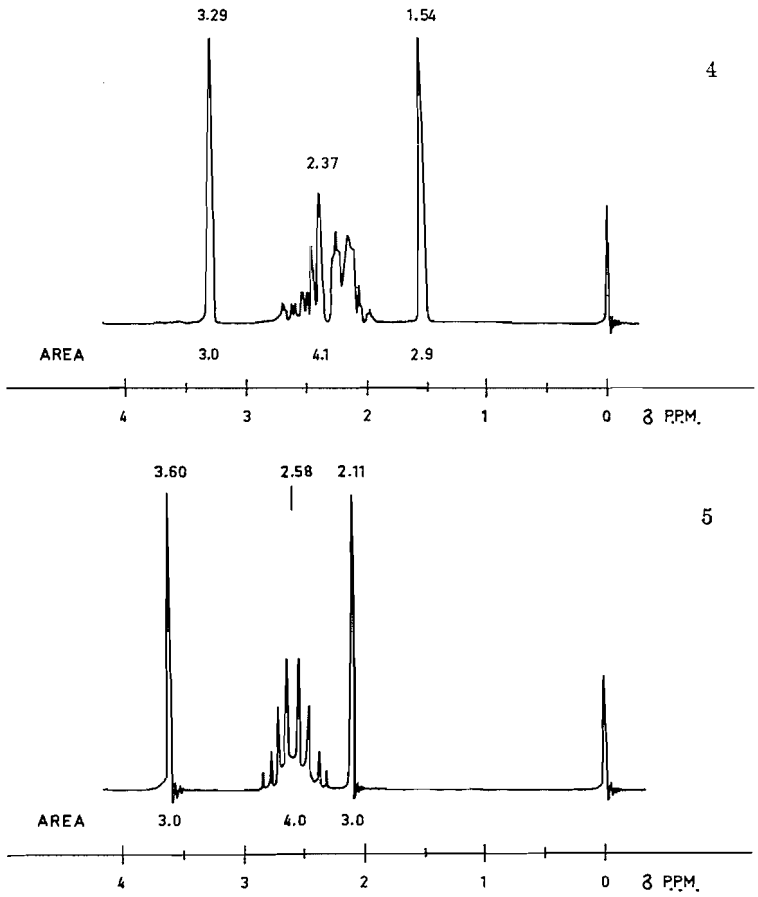

FIGS. 4 and 5. Nuclear magnetic resonance spectrum of pseudo-methyl ester of levulinic acid and methyl levulinate.

is in accord with an acyclic structure for this compound. The excellent agreement between the theoretical ratio and the ratio of the integrated areas of the methylene and methoxy protons tends to rule out the presence of an appreciable concentration of the cyclic form whose methoxy and methylene protons would be hidden by the acyclic methylene protons. Furthermore the chemical shift of the methoxy protons are in the positions expected for an open chain structure. Thus the methoxy protons are found at 3.66 p.p.m., a position similar to that of the methoxy group in methyl levulinate.

The nuclear magnetic resonance spectrum of succinyl dichloride (Fig. 1) shows only a singlet at 3.33 p.p.m. in accord with an open chain structure for this compound. The possibility exists that the complex multiplet of a small amount of the cyclic form might be hidden under the singlet. Such a possibility cannot be ruled out until the pure cyclic form is prepared and its spectrum determined. However, the sharpness of the singlet indicates that succinyl dichloride exists predominantly in the acyclic form.

The use of nuclear magnetic resonance has not conclusively established that an equilibrium exists between an open and a cyclic form of 3-substituted propionyl chlorides since in no case has it been possible to detect proton signals from both forms simultaneously. It is interesting to notice that the structure of the 3-substituted propionyl chloride is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

dependent upon the substituent R. When R is methoxy or chlorine the structure is predominantly acyclic while when R is methyl the structure is largely cyclic. This can be explained on the basis of the electronegativity of the substituent. The more electronegative the substituent, the greater the decrease in the stability of the cyclic form relative to the open chain form resulting in the observed structures.

EXPERIMENTAL

All melting and boiling points are uncorrected. Nuclear magnetic resonance spectra were taken on a Varian A-60 Spectrometer on the neat compounds unless otherwise stated with tetramethylsilane as internal standard. Vapor phase chromatography (v.p.c.) was performed on a F and M Model 500 Gas Chromatograph using helium as a carrier gas.

Succinyl dichloride (Ia) was prepared by the method of Cason and Reist (1) in 77% yield. Boiling point 65–66° at 2 mm; lit. b.p. 65° at 5 mm.

Levulinyl chloride (IIc) was prepared by the method of Cason and Reist (1) in 95% yield. Since this acid chloride is very sensitive to heat, it was not distilled. Excess thionyl chloride was removed at reduced pressure below 50°. The last traces of thionyl chloride were removed by an azeotrope with benzene at reduced pressure. The nuclear magnetic resonance was taken of the yellow residual acid chloride.

Pseudo-methyl levulinate (III) was prepared by the method of Langlois and Wolff (2) in 27% yield. Boiling point 83° at 2 mm; lit. b.p. 90–92° at 15 mm. Vapor phase chromatographic analysis showed the product to be contaminated by a small amount of the normal ester. The pure pseudo-ester for spectral studies was obtained by isolation from v.p.c. on an 8 ft diisodecyl phthalate column at 120°. The nuclear magnetic resonance spectrum was taken in carbon tetrachloride.

β-Carbomethoxypropionyl chloride (Ib) was prepared according to the method of Cason (10) in 92% yield. Boiling point 44–45° at 0.5 mm; lit. b.p. 58–59° at 2.5 mm.

Methyl levulinate (IV) was prepared by the method of Frank *et al.* (11) in 16% yield. Boiling point 82–85° at 8 mm; lit. b.p. 89–91° at 15 mm (2).

CARBONYL AND THIOCARBONYL COMPOUNDS. IX. SYNTHESIS OF BENZOXANTHENE ETHERS BY THE ACTION OF TETRAHALO-*o*-BENZOQUINONES[1]

N. Latif and I. Fathy

Recently, it has been shown that methylene ethers derived from xanthene can be directly obtained by the action of tetrahalo-*o*-benzoquinones on ketohydrazones (1). In the present study, the 1,2-benzoxanthene ethers I*a* and I*b* are similarly produced by the interaction of 1,2-benzoxanthone hydrazone with tetrachloro- and tetrabromo-*o*-benzoquinones, respectively, in dry ether at room temperature. It is believed that the reaction

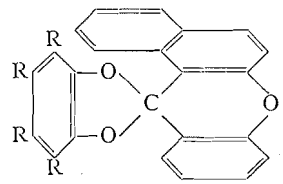
proceeds through the intermediate formation of an unstable 9-diazo-1,2-benzoxanthene, which reacts with the tetrahaloquinone to give the methylene ether. The production of the corresponding tetrahalocatechol in this reaction together with the evolution of gas supports this suggestion. Constitution of the products is based on analogy (2, 3), analytical data and lack of color, and on the fact that they could be produced by condensing 9,9-dichloro-1,2-benzoxanthene with the corresponding tetrahalocatechol.



I*a*; R = Cl
I*b*; R = Br

1,2-Benzoxanthone hydrazone is prepared by the action of hydrazine hydrate on 1,2-benzoxanthione, which is obtained readily by the action of phosphorus pentasulfide on 1,2-benzoxanthone. The latter is synthesized by condensing salicylic acid with β-naphthol in presence of polyphosphoric acid. The product obtained by Desai *et al.* (4) from a similar experiment and described by them as 2,3-benzoxanthone is shown, in the present investigation, to be actually the 1,2-analogue. It is identical with the product obtained by von Dilthey *et al.* (5) from *o*-iodobenzoyl-β-naphthol, and different from 2,3-benzoxanthone (5, 6).

The benzoxanthene ethers exhibit remarkable chemical reactivity towards different nucleophiles resulting in cleavage of the dioxole ring. Thus, I*a* undergoes, quite readily, reductive cleavage by lithium aluminium hydride in boiling ether yielding 1,2-benzoxanthene and tetrachlorocatechol. The ease of cleavage, compared with the parent xanthene analogues (7), might be rationalized by assuming that the carbonium ion intermediate is stabilized by resonance with the ethereal oxygen and the conjugated naphthalene nucleus (cf. II). Delocalization of charge via π-orbitals is enhanced by the fused 1,2-benzenoid ring and this promotes stability of the carbonium ion formed.

The dioxole ring of the benzoxanthene ethers is also readily cleaved by active hydrogen compounds furnishing the corresponding 1,2-benzoxanthylenes. Thus, I*a* and I*b* react with hydrazines in boiling ethanol to give the corresponding hydrazones. In the case of hydrazine itself, 1,2-benzoxanthone azine is found among the products formed presumably through the action of a part of the hydrazone first formed on the cyclic ether. With malononitrile and ethyl cyanoacetate, the unsaturated nitriles III*a* and III*b* are readily produced. It is believed that cleavage proceeds, for example in the case of hydrazine, through the intermediate formation of IV which gives directly the hydrazone together with tetrachlorocatechol by a β-elimination process (8). Authentic samples of the

benzoxanthylenes are prepared by two established procedures: (*a*) by condensing 1,2-benzoxanthione with malononitrile or ethyl cyanoacetate in presence of a desulfurizing agent, or (*b*) by the reaction of 1,2-benzoxanthone dichloride with the cyanocompounds. The fused 1,2-benzenoid ring seems to have no retarding steric effect on the reactivity of the benzoxanthene analogues as compared with the parent xanthene ethers.

EXPERIMENTAL

Microanalyses were performed by A. Bernhardt, Germany, and the Microanalysis Unit, National Research Center, Cairo.

Preparation of 1,2-Benzoxanthone

A mixture of salicyclic acid (12 g), β-naphthol (12 g), and polyphosphoric acid (from 50 ml orthophosphoric acid and 80 g phosphorus pentaoxide) was heated at 140–145 °C (oil bath) for 6 h with occasional shaking. The reaction mixture was left to cool, poured onto crushed ice, then strongly stirred. The separated solid was filtered off, and washed with water several times. It was then heated with 10% sodium hydroxide solution for 15 min in a boiling water bath, left to cool, and filtered off. The solid obtained was washed with hot water till free from alkali, dried, and crystallized from ethanol to give 1,2-benzoxanthone (4.5 g) as colorless crystals m.p. 142 °C (undepressed when admixed with an authentic sample prepared according to von Dilthey *et al.* (5)).

Preparation of 1,2-Benzoxanthione

A finely powdered mixture of 1,2-benzoxanthone (2 g) and phosphorus pentasulfide (2.5 g) was heated at 120 °C for 1 h. The reaction mixture was left to cool, and extracted with hot benzene. The extract was filtered, concentrated, and left to cool. The separated solid (1.4 g) was recrystallized from benzene to give 1,2-benzoxanthione as dark-green crystals m.p. 145 °C (undepressed when admixed with an authentic sample (9)).

Anal. Calcd. for $C_{17}H_{10}OS$: C, 77.86; H, 3.81; S, 12.21. Found: C, 78.12; H, 3.95; S, 11.98.

Preparation of Benzoxanthone Hydrazone

To a boiling solution of 1,2-benzoxanthione (2 g) in absolute alcohol (50 ml), hydrazine hydrate (80%, 0.5 ml) was added. The solution was refluxed for 1 h, filtered, concentrated, and left to cool. The separated solid (1.5 g) was recrystallized from ethanol to give 1,2-benzoxanthone hydrazone as pale-yellow crystals m.p. 146 °C.

Anal. Calcd. for $C_{17}H_{12}ON_2$: N, 10.76. Found: N, 10.29.

Preparation of 9,9-(Tetrachloro-o-phenylenedioxy)1,2-benzoxanthene (Ia)

Tetrachlorocatechol (2 g) and 9,9-dichloro-1,2-benzoxanthene (from 2 g 1,2-benzoxanthone and thionyl chloride) were heated together, for 1 h, in a round bottom flask protected from moisture at 120 °C (oil bath). The reaction mixture was left to cool, washed with acetone several times, and recrystallized from xylene to give I*a* as colorless crystals m.p. 333–334 °C.

Anal. Calcd. for $C_{23}H_{10}O_3Cl_4$: C, 57.98; H, 2.10; Cl, 29.81. Found: C, 58.15; H, 2.53; Cl, 29.74.

Reaction of Tetrachloro-o-benzoquinone with 1,2-Benzoxanthone Hydrazone

To a dry ethereal solution of the quinone (2 g), the hydrazone (1 g) was added in portions at room temperature. After each addition a vigorous reaction with evolution of gas occurred. When all the hydrazone had been added, a colorless crystalline product separated out. This was filtered off, and recrystallized from xylene to give I*a* as colorless crystals m.p. 333–334 °C (undepressed when admixed with an authentic sample prepared as above). The ethereal mother liquor was evaporated to dryness, extracted with methanol, and the extract poured onto ice and acidified with hydrochloric acid. The separated solid was shown to be tetrachlorocatechol as before.

Reaction of Tetrabromo-o-benzoquinone with 1,2-Benzoxanthone Hydrazone

The reaction was carried out as in the case of the chloro analogue. The separated product was filtered off and recrystallized from benzene to give I*b* as colorless crystals which decompose at 344 °C.

Anal. Calcd. for $C_{23}H_{10}O_3Br_4$: C, 42.20; H, 1.52; Br, 48.92. Found: C, 42.12; H, 1.42; Br, 48.24.

Tetrabromocatechol was isolated from the ethereal mother liquor as described in the case of the chloro analogue, and was identified as its diacetate (melting point and mixed melting point).

Reaction of Ia with Lithium Aluminium Hydride

The reaction was carried out as in the case of the parent xanthene ether (7). The reaction mixture was decomposed with ethanol, then with dilute hydrochloric acid, and extracted several times with ether. The combined ethereal extracts were dried over anhydrous sodium sulfate and then filtered, and the ether was driven off. The solid which separated was recrystallized from methanol to give 1,2-benzoxanthene (0.26 g) as colorless crystals m.p. 92–93 °C (undepressed when admixed with an authentic sample (9)). The alcoholic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mother liquor was poured onto ice-cold water and acidified with hydrochloric acid. The precipitate formed was shown to be tetrachlorocatechol as before.

Preparation of 1,2-Benzoxanthone Azine

A solution of 1,2-benzoxanthone hydrazone (1 g) in benzene (20 ml) was refluxed with yellow mercuric oxide (1 g) for 1 h. The reaction mixture was filtered while hot, concentrated, and cooled. The product obtained was crystallized from benzene to give the azine as orange-yellow crystals m.p. 314 °C.

Anal. Calcd. for $C_{34}H_{20}O_2N_2$: C, 83.60; H, 4.10; N, 5.73. Found: C, 83.49; H, 4.35; N, 6.03.

Reaction of Ia with Hydrazine Hydrate

I*a* (0.2 g) and hydrazine hydrate (99–100%, 0.2 ml) in absolute alcohol (20 ml) were refluxed together for 3 h. The reaction mixture was filtered while hot, and the solid obtained (0.02 g) was shown to be 1,2-benzoxanthone azine (melting point and mixed melting point). The filtrate was concentrated and left to cool; a yellow crystalline solid separated (0.07 g) and proved to be 1,2-benzoxanthone hydrazone (melting point and mixed melting point). Tetrachlorocatechol was identified in the main alcoholic mother liquor as above.

Reaction of Ia with Benzoylhydrazine

The reaction was carried out as above using 1 g of I*a* and ½ g of benzoylhydrazine. The solution was filtered, concentrated, and left to cool. The separated product (0.45 g) was recrystallized from methanol to give 1,2-benzoxanthone benzoylhydrazone as pale-yellow crystals m.p. 164 °C.

Anal. Calcd. for $C_{24}H_{16}O_2N_2$: C, 79.10; H, 4.39; N, 7.69. Found: C, 78.93; H, 4.36; N, 8.44.

Reaction of Ia with Phenylhydrazine

The reaction was carried out as above when 1,2-benzoxanthone phenylhydrazone was obtained as yellow crystals (from methanol) m.p. 124 °C (decomp.).

Anal. Calcd. for $C_{23}H_{16}ON_2$: N, 8.33. Found: N, 7.70.

Preparation of Δ^9,α-1,2-Benzoxanthenemalononitrile (IIIa)

Method A.—A mixture of 9,9-dichloro-1,2-benzoxanthene (from 1 g 1,2-benzoxanthone) and malononitrile (0.5 g) was heated at 120 °C (oil bath) for 3 h in absence of moisture. The reaction mixture was left to cool, washed with methanol, and extracted with boiling benzene. The benzene extract was concentrated and cooled when III*a* (0.9 g) was obtained as yellow crystals m.p. 224–225 °C.

Anal. Calcd. for $C_{20}H_{10}ON_2$: C, 81.63; H, 3.40; N, 9.53. Found: C, 81.41; H, 3.58; N, 9.76.

Method B.—A suspension of 1,2-benzoxanthione (0.5 g), malononitrile (0.5 g), and yellow mercuric oxide (1 g) in dry benzene (20 ml) was heated under reflux for 5 h. The reaction mixture was filtered while hot, concentrated, and left to cool. The separated yellow crystals (0.26 g) proved to be III*a* (melting point and mixed melting point).

Preparation of Δ^9,α-1,2-Benzoxantheneacetic Acid, α-Cyanoethyl Ester (IIIb)

9,9-Dichloro-1,2-benzoxanthene (from 2 g 1,2-benzoxanthone) and ethyl cyanoacetate (1 ml) were allowed to react together as above. The reaction mixture was extracted with methanol, and the alcoholic extract was concentrated and cooled. The separated solid was recrystallized from acetone to give III*b* (1.2 g) as yellow crystals m.p. 118–120 °C.

Anal. Calcd. for $C_{22}H_{15}O_3N$: C, 77.41; H, 4.39; N, 4.10. Found: C, 77.30; H, 4.64; N, 3.77.

III*b* could be also obtained by the reaction between 1,2-benzoxanthione and ethyl cyanoacetate.

Reaction of Ia with Malononitrile

Malononitrile (0.2 g) and I*a* (0.4 g) in absolute alcohol (30 ml) were refluxed together for 6 h. The reaction mixture was filtered, concentrated, and cooled. The separated yellow crystals (0.1 g) proved to be III*a* (melting point and mixed melting point). Tetrachlorocatechol was identified in the main alcoholic mother liquor as usual.

When the reaction was carried out using ethyl cyanoacetate, instead of malononitrile, III*b* was similarly produced.

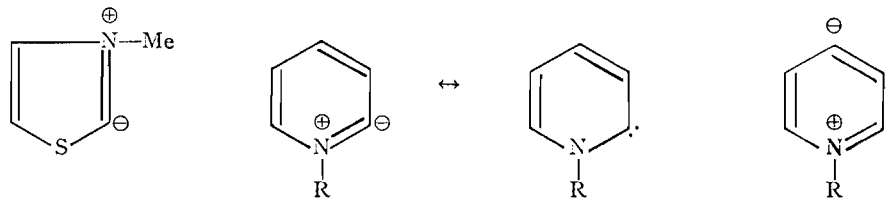
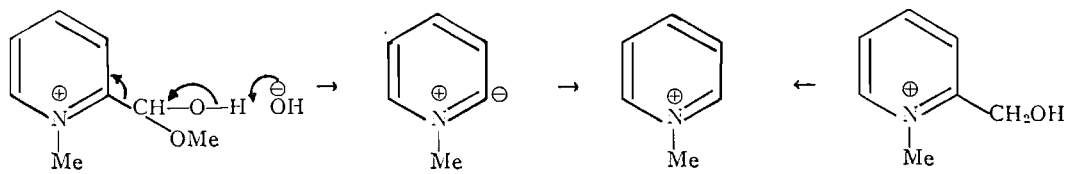
HETEROCYCLONIUMYL ZWITTERIONS. PART I. THE ALKALI-CATALYZED CLEAVAGE OF 2-HYDROXYMETHYL- AND 2-FORMYL-PYRIDINIUM CATIONS

S. GOLDING AND A. R. KATRITZKY



I II III

Heterocycloniumyl zwitterions of type I are well known to be of importance in the biological activity of thiamine (1), and recently azolonium zwitterion intermediates have received attention (2). Certain pyridinium derivatives have been shown to exchange α-hydrogen atoms by way of zwitterions of type II (3). We have now shown that the relative stability of such species facilitates the reaction sequences (IV $\rightarrow$ VI) and (VII $\rightarrow$ VI).



IV V VI VII

1-Methyl-2-formylpyridinium iodide has been previously reported as an oil (4), or as a solid of m.p. 174° (5) or 178–179° (6), but in none of these references is there mention of any analytical data. 1-Methyl-4-formylpyridinium iodide was reported (5) as a "low melting solid", but was apparently not characterized. Repetition of these procedures gave ill-defined products. Attempted preparation of the aldehyde methiodides in methanol solution gave crystalline derivatives which were shown by analysis and spectroscopy to be the corresponding methyl hemi-acetals.
