The external estimate of error, s_{ext}, is given by $s_{ext}^2 = \sum (y - \bar{y})^2/n$, where y is log K observed, $\bar{y}$ is log K calculated from the equation, and n is the degrees of freedom ($n = 14$ for eq. [1] and 13 for eq. [3]).

significantly. Rubin and Panson (29), however, have shown that substituents in phenols do produce significant changes in the strength of intermolecular hydrogen bonds with pyridine. The ρ value for this complex formation in carbon tetrachloride is about +1. It would therefore seem probable that substituents should have a significant effect on the strength of chelation in salicylic acids.

An extension of the above argument suggests that an electronic effect which makes the phenolic group more acidic (strengthening chelation) will make the carboxylate group less basic (weakening chelation), so that the intramolecular hydrogen bond will be little affected by substituents. No doubt these opposing effects do exist, but they strengthen the expectation that the data should fit eq. [3] rather than eq. [1]. This can perhaps best be seen by considering them in an equation of the Hammett form. The total effect of a substituent on the ionization constant of a substituted salicylic acid would then involve three terms, which could be represented by

$$\log K/K_0 = \rho_1\sigma_1 + \rho_2\sigma_2 + \rho_3\sigma_3. \qquad [5]$$

The first term ($\rho_1\sigma_1$) corresponds to the usual substituent effect found in benzoic acids, the second term represents the substituent effect on the acidity of the phenolic group, and the third term represents the effect of the substituent on the basicity of the carboxylate ion. Since the first and third terms represent processes taking place at the carboxyl group, σ_1 applies to both; but since the second term represents the acidity of the phenolic group, σ_2 is different. For example, a 4-substituted acid has $\sigma_1 = \sigma_p$ and $\sigma_2 = \sigma_m$, whereas a 5-substituted acid will require $\sigma_1 = \sigma_m$ and $\sigma_2 = \sigma_p$. Hence, eq. [5] reduces to

$$\log K/K_0 = (\rho_1 + \rho_3)\sigma_1 + \rho_2\sigma_2,$$

which is equivalent to eq. [3]. Furthermore, since ρ_3 will be negative and ρ_1 positive, some cancellation will occur between ρ_1 and ρ_3, and this will tend to diminish the importance of the "direct" route for substituent influence in comparison with the "indirect" one via the intramolecular hydrogen bond.

Another obvious way to explain the absence of an "indirect" substituent effect is to suppose that in aqueous solution intramolecular hydrogen bonding is replaced by intermolecular hydrogen bonds between anion and solvent. The probability of the survival of chelate hydrogen bonds in aqueous solutions of carboxylic acids has been debated much (30, 32), but remains uncertain. Concerning salicylate ion, there is very little evidence, except that from ionization constants. Voroshin and Vlasov interpret the ultraviolet spectrum of sodium salicylate as indicating the presence of a chelate hydrogen bond in ethanol solution (31), and Chapman *et al.* reach similar conclusions from an infrared study of sodium salicylate in heavy water (32). Certainly, it is very difficult to account for the enhanced ionization of *o*-hydroxybenzoic acid over the para acid without recourse to chelation in the anion. It is true that other benzoic acids having bulky ortho substituents show a similarly enhanced ionization in aqueous solution, as shown in Table IV, and this is usually attributed to destabilization of the un-ionized acid by steric interference, with conjugation between the carboxylic group and the aromatic ring (4, 5, 8, 30, 33). However, the hydroxy group is much smaller than any of the other ortho groups which increase benzoic acid ionization, and its effect is larger. It is possible that in aqueous solution solvation of the phenolic group may increase its effective size, but whether this could be large enough to account for the enhanced acidity of salicylic acids is, at present, impossible to say. Further work on the transmission of substituent effects through chelation is in progress.

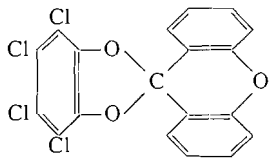
CYANOESTERS AND DINITRILES

I. SYNTHESIS OF MALONONITRILES FROM METHYLENE ETHERS

N. LATIF AND N. MISHRIKY
National Research Center, Dokki, Cairo, United Arab Republic

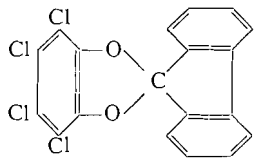
Received July 13, 1965

ABSTRACT



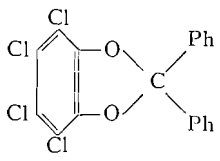
α-(9-Fluorenylidene) malononitrile (V) is obtained by the interaction of malononitrile and 9,9-(tetrachloro-*o*-phenylenedioxy) fluorene (II) in boiling *n*-butanol. Whereas fluorenone phenyl- or benzoyl-hydrazone is similarly obtained by the action of the corresponding hydrazine on II, the latter also undergoes reductive cleavage by hydrazine hydrate to give fluorene and tetrachlorocatechol. The heteropolar structures of methylene ethers are stressed.

Methyl-, ethyl-, isopropyl-, and benzyl-magnesium halides react readily with V to give the 9-dicyanomethyl-9-alkylfluorenes (VII*b*–VII*e*), respectively, which give, upon oxidation with alkaline potassium permanganate, the corresponding 9-alkylfluorene-9-carboxylic acids.



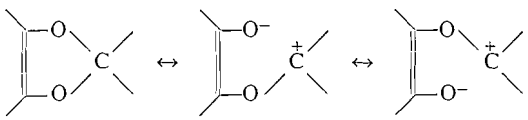
α-(9-Xanthenylidene) malononitrile (VI*a*) reacts similarly with alkylmagnesium halides to give the corresponding 9-xanthenylmalononitriles (VIII*b*–VIII*d*). However, V and VI are reduced by isobutylmagnesium iodide to give 9-fluorenyl- (VII*a*) and 9-xanthenyl-malononitrile (VIII*a*), respectively.

Whereas the infrared spectra of unsaturated malononitriles and cyanoesters show strong absorption in the 4.5 μ region, the spectra of the saturated analogues lack this absorption.



It has been reported throughout (1) that 9,9-(tetrachloro-*o*-phenylenedioxy) xanthene (I), in contrast to the fluorene analogue II, is cleaved readily by active hydrogen compounds in boiling ethanol to give the corresponding xanthenes. Cleavage of II is now brought about readily when the reaction is carried out in the higher boiling *n*-butanol. Thus, when II

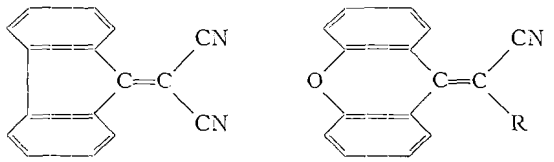
I



II

III

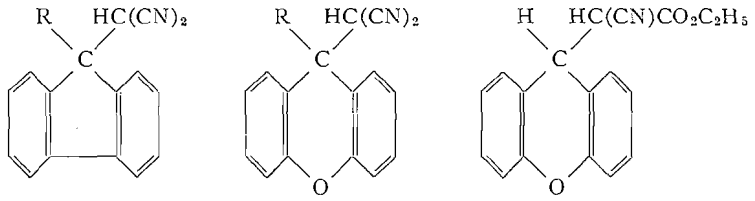
is refluxed with malononitrile, α-(9-fluorenylidene) malononitrile (V) is produced together with tetrachlorocatechol. With phenyl- or benzoyl-hydrazine, the corresponding fluorenone hydrazone is produced, possibly through the intermediate formation of an unstable open-chain ether by a β-elimination process (1). However, in contrast to other analogous methylene ethers previously investigated, II also undergoes reductive cleavage by hydrazine hydrate, yielding fluorene and tetrachlorocatechol, on prolonged boiling in *n*-butanol. The diphenylmethylene analogue III is not attacked by active hydrogen compounds under similar conditions. It is assumed that the methylene ether is a resonance



IV*a* IV*b* IV*c*

hybrid of various structures (2) (cf. IV), and the reaction proceeds through the nucleophilic attack of the active hydrogen compound. In the case of I, the heteropolar structure (IV*b* or IV*c*) is greatly stabilized by the strong resonance of the carbonium ion having

the unshared electron pair on the oxygen of the xanthene residue. In the case of II, the heteropolar structures contribute largely to the actual state of the molecule at higher temperatures.



Reaction of Alkylmagnesium Halides on Unsaturated Dinitriles

In an attempt to prepare substituted malononitriles for biological purposes and spectral investigation, the action of Grignard reagents on the unsaturated malononitriles (V and VI*a*) has been investigated. It is found that V reacts with methyl-, ethyl-, isopropyl-, and benzyl-magnesium halides to give 9-dicyanomethyl-9-methyl- (VII*b*), 9-dicyanomethyl-9-ethyl- (VII*c*), 9-dicyanomethyl-9-isopropyl- (VII*d*), and 9-dicyanomethyl-9-benzyl-

fluorene (VII*e*), respectively, in good yields. The analogous α-9-xanthenylmalononitriles VIII*b*, VIII*c*, and VIII*d* are similarly obtained by the action of the corresponding alkylmagnesium halides on α-(9-xanthenylidene) malononitrile (VI*a*). However, it is found that the latter is reduced by the action of isobutylmagnesium iodide in ether to give, in good yield, 9-dicyanomethylxanthene (VIII*a*), which is identical with the product obtained by the action of malononitrile on xanthydrol (3). V is similarly reduced by isobutylmagnesium iodide to give 9-dicyanomethylfluorene (VII*a*). Hook and Robinson (4) have reported the isolation of some α-cyano-β-alkylbutyric esters as reduction products from the reaction of alkylidene cyanoesters with Grignard reagents in the presence of cuprous iodide. The α-substituted malononitriles (VII*a*–VII*e* and VIII*a*–VIII*d*) are colorless, whereas V and VI are highly colored. Their infrared spectra do not show the frequency bands characteristic of NH or C=O groups, and thus support the structures given and exclude the possibility of 1,2-addition of the Grignard reagents to the cyano group. The 9-dicyanomethyl-9-alkylfluorenes or 9-dicyanomethyl-9-alkylxanthenes are oxidized by potassium permanganate to the corresponding 9-alkylfluorene- or 9-alkylxanthene-9-carboxylic acids, in good yields, and thus provide a new method for preparing these biologically important acids.[1] 1,4-Addition of Grignard reagents to unsaturated nitriles has previously been recorded (5);

[1]*Aminoesters of fluorene- and xanthene-9-carboxylic acids proved to have remarkable spasmolytic and related activities (6).*

however, as far as we are aware, nothing has been published on the action of these reagents on arylidene malononitriles.

When the infrared spectra of the substituted malononitriles were investigated, it was found that the spectra of the unsaturated derivatives V and VI*a* showed strong absorption in the 4.5 μ region characteristic of the cyano group (7), whereas the saturated analogues VII and VIII do not show absorption in this region. Similarly, the spectrum of the unsaturated cyanoester VI*b* shows strong absorption whereas that of the saturated analogue IX lacks absorption in this region.[2] Kitson and Griffith (8) have reported that the introduction of an oxygenated group into the molecule results in a quenching of the C≡N absorption intensity to a remarkable extent, or even in the absence of the frequency band characteristic of the cyano group when the oxygenated group is attached to the same carbon atom as the nitrile. It is clear, now, that monosubstituted malononitriles, where the same carbon atom is bonded to two cyano groups, also exhibit this quenching property, provided that, in all cases, this carbon atom is saturated. In the spectra of the unsaturated analogues where the rotation of the carbon atom is not free, strong absorption in the 4.5 μ region is observed.

EXPERIMENTAL

Melting points were not corrected. Infrared spectra were measured on a Perkin–Elmer infracord spectrophotometer, model 137 (Nujol).

Reaction of 9,9-(Tetrachloro-o-phenylenedioxy) Fluorene (II) with Hydrazine Hydrate

A mixture of the cyclic ether (1 g) and hydrazine hydrate (98–100%, 1 ml) in *n*-butanol (10 ml) was refluxed for 20 h and filtered while hot. The solid which separated out when the solution cooled (0.5 g) proved to be unchanged II. The mother liquor was evaporated to dryness, and the residue was crystallized from ethanol to give fluorene (0.12 g), m.p. 114 °C (undepressed when admixed with an authentic sample).

Reaction of II with Phenylhydrazine

The reaction was carried out as above with 1 g of II, 1 g of phenylhydrazine, and a reflux period of 3 h. The solution was filtered while hot, concentrated, and left to cool. The solid that separated out (0.3 g), m.p. 150–151 °C, proved to be fluorenone phenylhydrazone (melting point and mixed melting point).

Reaction of II with Benzoylhydrazine

The reaction was carried out as above with 1 g of II and 0.6 g benzoylhydrazine. The product that was obtained was recrystallized from alcohol to give fluorenone benzoylhydrazone (0.6 g), m.p. 171 °C (undepressed when admixed with an authentic sample (9)).

*Preparation of 9-Dicyanomethyl-9-methylfluorene (VII*b*)*

α-(9-Fluorenylidene) malononitrile (V) (2 g) was added slowly to an ethereal solution of methylmagnesium iodide (from magnesium (0.7 g) and methyl iodide); the mixture was refluxed for 3 h, cooled, decomposed with ice and dilute hydrochloric acid, and extracted with ether. The dried ethereal extract was evaporated to dryness, a few milliliters of methanol was added to the oily residue, and the mixture was cooled. The solid that formed was crystallized from methanol to give 9-dicyanomethyl-9-methylfluorene (VII*b*) as colorless crystals, m.p. 107 °C (yield 1.2 g).[3]

Anal. Calcd. for $C_{17}H_{12}N_2$: C, 83.6; H, 4.9; N, 11.5. Found: C, 83.2; H, 4.5; N, 11.8.

Oxidation of VIIb

A hot saturated solution of potassium permanganate was added dropwise to a suspension of the product (VII*b*) (0.5 g) in a solution of sodium hydroxide (2 *N*, 50 ml) heated on the water bath. The addition was continued until the pink color persisted; then the reaction mixture was heated on the boiling water bath for 30 min, left to cool, and filtered. The filtrate was acidified with dilute hydrochloric acid and the product that separated out was crystallized from methanol to give 9-methylfluorene-9-carboxylic acid, m.p. 170 °C (10).[3]

*Preparation of 9-Dicyanomethyl-9-ethylfluorene (VII*c*)*

The dinitrile V (2 g) was allowed to react with ethylmagnesium iodide (from 0.7 g of magnesium) as above. The dried ethereal extract was left to evaporate slowly at room temperature, and the solid that separated out was crystallized from methanol to give 9-dicyanomethyl-9-ethylfluorene (VII*c*) (1 g) as colorless prisms, m.p. 117 °C.[3]

Anal. Calcd. for $C_{18}H_{14}N_2$: C, 83.7; H, 5.4; N, 10.8. Found: C, 84.0; H, 5.5; N, 10.5.

[2]*Spectra of both malononitrile and cyanoacetic ester show absorption.*
[3]*This experiment is described in the Ph.D. thesis of one of us (N. L.).*

For personal use only.

Oxidation of VIIc

The substance was oxidized as above. The colorless product that was obtained was crystallized from petroleum ether (60–80°) to give 9-ethylfluorene-9-carboxylic acid (11), m.p. 145 °C.[3]

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.6; H, 5.9. Found: C, 80.3; H, 5.8.

Preparation of 9-Dicyanomethyl-9-isopropylfluorene (VIId)

This was prepared from V and isopropylmagnesium bromide as above. The dried ethereal extract was concentrated and cooled. The crystals that separated out were filtered off and recrystallized from methanol to give VII*d* as colorless needles (0.9 g), m.p. 159 °C.

Anal. Calcd. for $C_{19}H_{16}N_2$: C, 83.8; H, 5.9; N, 10.3. Found: C, 84.2; H, 6.0; N, 10.1.

When VII*d* was oxidized with potassium permanganate, 9-isopropylfluorene-9-carboxylic acid was obtained as colorless crystals (from benzene), m.p. 204 °C.

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.9; H, 6.4. Found: C, 81.1; H, 6.0.

Preparation of 9-Dicyanomethyl-9-benzylfluorene (VIIe)

The reaction between V and benzylmagnesium chloride was carried out as above. The dried ethereal extract was left to evaporate slowly at room temperature. The solid that formed was extracted with warm petroleum ether (40–60°) and the residue was crystallized from petroleum ether (60–80°) to give VII*e* as colorless crystals, m.p. 141 °C.[3]

Anal. Calcd. for $C_{23}H_{16}N_2$: C, 86.2; H, 5.0; N, 8.7. Found: C, 86.3; H, 4.9; N, 8.9.

Preparation of 9-Dicyanomethyl-9-methylxanthene (VIIIb)

The reaction between methylmagnesium iodide (from 0.7 g magnesium) and α-(9-xanthenylidene) malononitrile (VI*a*) (2.4 g) was carried out as usual. The ethereal extract was evaporated to dryness and a few drops of methanol was added to the oily residue. The solid that formed was crystallized from cyclohexane to give VIII*b* as colorless rods (1.1 g), m.p. 128 °C.

Anal. Calcd. for $C_{17}H_{12}N_2O$: C, 78.4; H, 4.7; N, 10.8. Found: C, 78.7; H, 4.7; N, 10.4.

When VIII*b* (1 g) was oxidized as above, 9-methylxanthene-9-carboxylic acid was obtained (0.5 g), m.p. 206 °C (12).

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 75.0; H, 5.0. Found: C, 75.3; H, 4.9.

Preparation of 9-Dicyanomethyl-9-ethylxanthene (VIIIc)

The reaction was carried out as above with ethylmagnesium iodide and VI*a*. VIII*c* was obtained as colorless prisms (from *n*-hexane), m.p. 97–98 °C.

Anal. Calcd. for $C_{18}H_{14}N_2O$: C, 78.8; H, 5.1; N, 10.2. Found: C, 79.2; H, 5.2; N, 10.0.

Preparation of 9-Dicyanomethyl-9-isopropylxanthene (VIIId)

Isopropylmagnesium bromide and VI*a* were allowed to react as above. The ethereal extract was evaporated to dryness. The residue was recrystallized from *n*-hexane several times to give VIII*d* as colorless rods, m.p. 92–94 °C (yield 0.8 g).

Anal. Calcd. for $C_{19}H_{16}N_2O$: C, 79.2; H, 5.6; N, 9.7. Found: C, 79.9; H, 5.7; N, 9.7.

Reduction of α-(9-Xanthenylidene) Malononitrile (VIa)

Isobutylmagnesium iodide (from magnesium (0.7 g) and isobutyl iodide (3.4 ml)) and VI*a* (2.4 g) were allowed to react together as usual. The dried ethereal extract was concentrated and cooled, and the solid that separated out was crystallized from methanol to give 9-xanthenylmalononitrile (VIII*a*) (1 g) as colorless rods, m.p. 186–188 °C (undepressed when admixed with an authentic sample (3)). When the reaction was carried out with V instead of VI*a*, 9-fluorenylmalononitrile (VII*a*) was obtained as colorless leaflets (from petroleum ether, 50–75°), m.p. 152 °C.

Anal. Calcd. for $C_{16}H_{10}N_2$: C, 83.5; H, 4.4; N, 12.2. Found: C, 83.3; H, 4.5; N, 12.8.

STRUCTURE OF A GALACTURONAN FROM SUNFLOWER PECTIC ACID[1]

V. ZITKO[2] AND C. T. BISHOP
Division of Biosciences, National Research Council, Ottawa, Canada

Received January 12, 1966

ABSTRACT

Fractions of sunflower pectic acid containing 89.8%, 94.2%, and 91.4% of D-galacturonic acid were carboxyl reduced as their methyl or ethylene glycol esters by potassium borohydride. Critical assessment of the effects of three different solvents (water, 80% aqueous dimethyl sulfoxide, and 80% aqueous methanol) on the efficiency of reduction showed that the latter solvent was best. The reductions caused a decrease in the degree of polymerization from 270 to 21. Measurement of the rates of hydrolysis of partially reduced pectic acids containing 90%, 41.6%, 19.9%, 11.0%, and 0.65% of D-galacturonic acid showed that the rate of hydrolysis was directly related to the proportion of galacturonosidic linkages present. Methylation and hydrolysis of the carboxyl-reduced pectic acid fractions yielded 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-galactose in an approximate molar ratio of 1:20. Results of the periodate oxidation of the carboxyl-reduced pectic acid supported the conclusion inferred from the methylation results that the pectic acid was a linear polymer of $1 \rightarrow 4$ linked α-D-galacturonic acid units.

There has been considerable evidence that the main structural feature of pectin is a linear chain of $1 \rightarrow 4$ linked α-D-galacturonic acid units (1–3). However, in most of the early work (1) the pectins examined were of uncertain homogeneity, and in one of the later investigations (2) there was evidence that the product examined was a mixture of closely related acidic polysaccharides. In the most recent work reported (3), it was shown that pectin from the bark of amabilis fir could be fractionated to yield a galacturonan which contained no neutral sugars. This galacturonan was shown to be a linear polysaccharide of $1 \rightarrow 4$ linked α-D-galacturonic acid units. However, the report of some $1 \rightarrow 3$ linkages in a galacturonoxyloglycan from mountain pine pollen (4) indicates that linkages other than $1 \rightarrow 4$ may occur in some galacturonans.

Sunflower seed heads provide an excellent source of galacturonan, which is obtained in good yield and relatively free of other polysaccharides (5). A previous publication (6) described the fractionation of pectic acids from sunflowers and other sources into two acidic polysaccharides: a galacturonan to which neutral sugars were attached glycosidically, and a galacturonan which yielded only D-galacturonic acid on hydrolysis. The present paper describes the structural investigation of the latter polyuronide.

Three of the fractions obtained from sunflower pectic acid (6) were chosen for this investigation: (I) the polysaccharide precipitated by 0.14 *M* sodium acetate, containing 89.8% of D-galacturonic acid and having $[\alpha]_D$ +280° and $[\eta]$ 256; (II) the polysaccharide precipitated by 0.12 *M* sodium acetate and reprecipitated by 0.14 *M* sodium acetate, containing 94.2% of D-galacturonic acid and having $[\alpha]_D$ +300° and $[\eta]$ 215; (III) the polysaccharide precipitated by 0.14 *M* sodium acetate and reprecipitated by 0.12 *M* sodium acetate, containing 91.4% of D-galacturonic acid and having $[\alpha]_D$ +291° and $[\eta]$ 200.

On moving-boundary electrophoresis polysaccharide I showed a main peak with a small shoulder. Polysaccharides II and III each showed a single, symmetrical peak under the same conditions of electrophoresis.

Because pectic acids are resistant to methylation and are subject to degradation under the strongly alkaline conditions used, the polysaccharides described above were each reduced to yield neutral galactans. This procedure has been used frequently in structural polysaccharide chemistry (2, 3, 7–9), but there has been no critical assessment of the conditions used. In the present study, both methyl and ethylene glycol esters of the galacturonans were used as starting materials and were reduced by potassium borohydride in 80% aqueous methanol, in water, or in 80% aqueous dimethyl sulfoxide. Because of weight changes caused by partial reduction and partial de-esterification of galacturonic acid units in the galacturonan during reduction, the direct analytical results did not permit valid comparisons. Comparisons can be made, however, with the proportions of reduced to de-esterified galacturonic acid units, and of reduced to original ester content. These proportions and recoveries on a theoretical basis are shown in Table I.

TABLE I

Reduction of esterified galacturonan

Reduction	A*	B*	Yield (% of theory)
Methyl ester of polysaccharide I			
1. In 80% aqueous methanol	0.835	0.620	90
2. In 80% aqueous methanol	0.720	0.550	90
3. In 80% aqueous methanol	0.630	0.410	92
4. In 80% aqueous methanol	0.577	0.320	88
In water†	0.580	0.580	67
In 80% aqueous dimethyl sulfoxide‡	0.720	0.719	69
Ethylene glycol ester of polysaccharide I			
In 80% aqueous methanol	0.723	0.576	94
In water	0.670	0.670	79

*A = reduced galacturonic acid/reduced + de-esterified galacturonic acid; B = reduced galacturonic acid/original esterified galacturonic acid.
†The starting product for this reduction had been reduced twice in 80% aqueous methanol.
‡The starting product for this reduction had been reduced three times in 80% aqueous methanol.

The results showed that reductions in 80% aqueous methanol were the most efficient; de-esterification was suppressed, a reasonably high proportion of the galacturonic acid units was reduced, and recoveries were good. In water, a high proportion of galacturonic acids was reduced but there was also considerable de-esterification and recoveries were low, undoubtedly because of the degradation of esterified galacturonan in alkaline media (10). In 80% aqueous dimethyl sulfoxide, de-esterification was greatly suppressed, and the highest proportion of reduced groups was obtained when a partially reduced product was taken for the reduction. These advantages were offset by the low recovery; indeed, when this solvent was used for the first reduction of a fully esterified galacturonan, complete degradation occurred and no product precipitable by methanol could be obtained. Reductions were only slightly more efficient with methyl esters than with ethylene glycol esters.

Another factor in these reductions was the efficiency of esterification. A heterogeneous esterification with diazomethane in ether can be used until the galacturonan is about 80% reduced. After that only 78% of the remaining carboxyl groups could be esterified, and at the next stage (galacturonic acid content, 11%) no more than 45%, even when the substrate was freeze-dried to provide a large surface area. Esterification with ethylene or propylene oxide gave good results but the products, when precipitated by organic solvents, tended to form gels which were difficult to handle. There was no evidence of hydroxyalkylation of alcohol groups by these reagents. Residual carboxyl groups in highly reduced galacturonans can be esterified effectively with diazomethane in dimethyl

For personal use only.

sulfoxide. In this procedure the esterified product need not be isolated before reduction, which can be done immediately afterwards in the same solution. A preparation containing 1.7% of D-galacturonic acid residues was obtained from one containing 6.8% in a yield of 54% by this procedure. Two esterifications and reductions were required to decrease the D-galacturonic acid content from 7.8% to 0.65%, with a recovery of 45%, when water was used as the solvent.

In summary, the best procedure for borohydride reduction of pectic acid methyl ester is heterogeneous esterification with diazomethane followed by borohydride reduction in 80% aqueous methanol until the product contains less than 20% of galacturonic acid. At that stage, both esterification and reduction can be carried out in 80% aqueous dimethyl sulfoxide to give the fully reduced product. In our hands, reduction of pectic acid by the diborane method (11) was incomplete and caused considerable degradation. Reduction of di-*O*-acetyl polyuronide methyl esters by lithium borohydride (12), reported while the present manuscript was in preparation, may offer a better route to carboxyl-reduced polysaccharides; however, possible degradative effects of the latter method have not been investigated.

Throughout this work, samples of polysaccharide I which were carboxyl reduced to varying extents became available, and their relative resistances to acid hydrolysis were determined. Rate constants were determined for acid hydrolysis (13, 14) with 0.5 *N* sulfuric acid in 95% (v/v) aqueous dimethyl sulfoxide at 100 °C. Plots of ln $(1 - \alpha)$ against time (α = percentage of hydrolysis) were linear. Figure 1 shows a plot of the rate constants as functions of the D-galacturonic acid content. There is a linear increase in rate constant with decreasing D-galacturonic acid content, indicating that the rate of acid hydrolysis is an additive property of the amounts of more resistant galacturonoside linkages (15) and less resistant galactoside linkages.

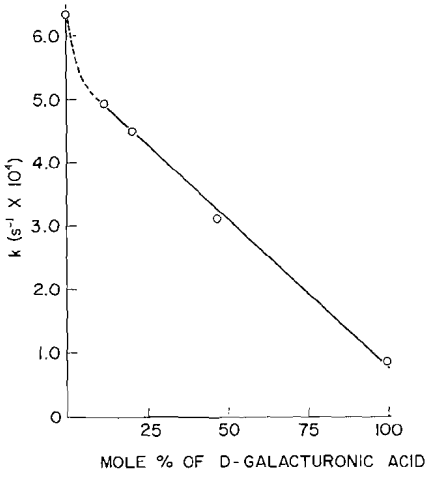

FIG. 1. Relation between rates of hydrolysis and D-galacturonic acid content for partially reduced pectic acid.

Reduction of polysaccharide I provided, in an overall yield of 37%, an α-galactan which contained 0.65% of D-galacturonic acid. The galactan had $[\alpha]_D$ +232° and showed a single, unsymmetrical peak on moving-boundary electrophoresis. The galactan contained 5.47% methoxyl and, on hydrolysis, yielded galactose and small amounts of two other components, which were probably 3-*O*- and 6-*O*-methyl-D-galactose. The *O*-methyl

For personal use only.

groups were a result of methylation by diazomethane during the esterification steps. A portion of the hydrolysate was methylated (16) and examined by gas–liquid chromatography (17). The only products found were the methyl glycosides of 2,3,4,6- and 2,3,5,6-tetra-*O*-methyl-D-galactose. Another portion of the hydrolysate was demethylated (18), and examination by paper chromatography showed that galactose was the only sugar present. The foregoing results established conclusively that the pectic acid was a polymer formed from D-galacturonic acid units exclusively.

Polysaccharides II and III were reduced in the same way as polysaccharide I but, because they were not available in as large a quantity, these two fractions were not analyzed during the reduction steps.

The three, reduced fractions were methylated by successive application of the procedures of Haworth (19), Falconer and Adams (20), and Purdie (21). The methylated products were isolated by precipitation with light petroleum and were purified, where necessary, by chromatography on silica gel. These procedures yielded the following main methylated polysaccharides: from polysaccharide I, yield 63%, methoxyl 45.2%, $[\alpha]_D$ +214°; from polysaccharide II, yield 55%, methoxyl 32.8%, $[\alpha]_D$ +126°; and from polysaccharide III, yield 16%, methoxyl 43.1%, $[\alpha]_D$ +146°. Hydrolysis of each of these methylated products yielded 2,3,4,6-tetra-*O*-methyl- and 2,3,6-tri-*O*-methyl-D-galactose, as shown by paper, thin-layer, and gas–liquid chromatography; the two compounds were also characterized by preparation of their crystalline derivatives. The fully methylated polysaccharide I also yielded small amounts of 2,3,5,6-tetra-*O*-methyl-D-galactose and di-*O*-methyl-D-galactoses. The latter consisted of at least three isomers, each amounting to less than 1.5% of the total hydrolysis products.

In addition to the main methylated products described above, methylation of polysaccharides I, II, and III provided some minor methylated products which were soluble in light petroleum or were separated from the main products by chromatography on silica gel. Each of these minor products had lower methoxyl contents (24% to 29%) and lower specific rotations (+60° to +70°). However, each of these minor products yielded 2,3,4,6-tetra-*O*-methyl- and 2,3,6-tri-*O*-methyl-D-galactose on hydrolysis; the only other methylated sugar found was a small amount of 2,3,5,6-tetra-*O*-methyl-D-galactose in the light petroleum soluble fraction from the methylation of polysaccharide I. The ratio of tetra- to tri-*O*-methyl-D-galactose was about 1:20 for each of these products. The lower methoxyl contents and specific rotations of the minor products from the methylation of the polysaccharides indicated the presence of considerable amounts of impurities. These impurities must have been polymeric artifacts, because no compounds other than the methylated galactoses mentioned above were detected in the hydrolysates by any of the chromatographic procedures. It is likely that these polymeric artifacts were formed during the reductions and methylations, which caused extensive degradation; the initial degree of polymerization of polysaccharide I was 270 (from the limiting viscosity number), whereas the methylated products had a degree of polymerization of 21 based on the ratio of tetra- to tri-*O*-methyl-D-galactose.

When reduced polysaccharide I was oxidized by periodate, it consumed 0.82 mole of oxidant per monomer unit, with production of 0.09 mole of formic acid. The oxidized polysaccharide I was reduced and hydrolyzed (22). Examination of the acetylated hydrolysis products by gas–liquid chromatography (17) showed the presence of the following components: ethylene glycol diacetate, glycerol triacetate, two unidentified compounds, and threitol tetraacetate. The latter compound was characterized as its tetra-*p*-nitrobenzoate (23). The molar ratio of the last four components was 9.5:3:22:266; the amount of ethylene glycol diacetate was not determined because ethylene glycol was added to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

oxidation to destroy excess periodate. An α-(1 → 4)-galactan should consume 1.00 mole of periodate per monomer unit, if one ignores the end groups. The observed value of 0.82 mole per mole is low, probably because of the 5.47% of methoxyl groups introduced during esterification. This may also account for the two unidentified components (retention times 1.17 and 2.15 min) in the hydrolysate described above. Traces of galactitol were found in the hydrolysate by paper chromatography, but the amounts were insignificant. The ratio of glycerol to threitol (1:28) from the periodate-oxidized product was close to the ratio of tetra- to tri-*O*-methyl-D-galactose (1:20) found in the methylated polysaccharides, indicating that the major degradation of the polysaccharide occurred during the reduction of the galacturonan methyl ester and not during the methylation.

The results of methylation and periodate oxidation showed that the polysaccharide fractions precipitated from sunflower pectic acid by low concentrations of sodium acetate were linear galacturonans formed by α-(1 → 4) linkages. Because the polyuronides suffered extensive degradation during reduction to neutral galactans, the possibility that some labile units or linkages were cleaved cannot be overlooked. Such a process may well account for the isolation of 2,3,5,6-tetra-*O*-methyl-D-galactose among the methylation products from polysaccharide I; units of D-galactose, split off during degradation, would be methylated preferentially in the furanose ring form (24). However, it is likely that the degradation of the polyuronides was a random process and would not be specific for glycosidic linkages other than α-(1 → 4). The linear α-(1 → 4) structure assigned to the degraded galactan may therefore be regarded as fairly representative of the galacturonan from which it was derived. The galacturonans from apples, citrus fruits, and sugar beets should also have similar structures, because of their close resemblance to sunflower galacturonan in both specific rotation and electrophoretic mobility (6).

EXPERIMENTAL

Paper chromatograms were run on Whatman No. 1 paper by the descending method in the following solvent systems (by volume): A, ethyl acetate – pyridine – water (10:4:3); B, ethyl acetate – acetic acid – formic acid – water (18:3:1:4); C, butanone half saturated with water; D, butan-1-ol–ethanol–water (4:1:5) (upper layer).

Paper electrophoreses were run on Whatman 3MM paper in 0.10 *M* sodium tetraborate at a potential gradient of 25–30 mA (25). A Tiselius-type, Spinco model H apparatus was used for moving-boundary electrophoresis; the buffer was 0.05 *M* sodium tetraborate (26). A Pye argon chromatograph was used for gas–liquid chromatography (17); the column packings were: (*a*) 10% Carbowax 6000 on Chromosorb W, 100–120 mesh, 164 °C, and (*b*) 15% polyphenyl ether on Gas Chrom A, 100–120 mesh, 190 °C. Retention times are given relative to that of methyl 2,3,4,6-tetra-*O*-methyl-β-D-glucoside unless otherwise stated. Thin-layer chromatograms were run on Adsorbosil 1 with benzene–acetone (4:6) as the developing solvent. Preparative thin-layer chromatograms were run on 0.8 mm layers of Adsorbosil 1, and the separated components were detected by a template technique (27). The *p*-anisidine hydrochloride (28) and alkaline silver nitrate (29) spray reagents were used to detect glycoses and alditols, respectively. Methods of analysis of galacturonans were described previously (6). Solvents were evaporated at 35–37 °C under diminished pressure, melting points are corrected, and specific rotations were measured at room temperature (24–26 °C).

Isolation of Polysaccharides

Sunflower pectic acid was prepared as previously described (5, 6). It was dissolved in water at pH 6.0, and 2.0 *M* sodium acetate was added to a concentration of 0.14 *M* sodium acetate. The precipitate which formed was washed with acidified 60% aqueous ethanol (5 ml of concentrated hydrochloric acid per l), and then with 60% aqueous ethanol until free of chlorides; it was then dried by solvent exchange with ethanol and ether. The precipitation by sodium acetate was repeated once to yield polysaccharide I (galacturonic acid, 89.8%; $[\alpha]_D$ +280° (*c*, 0.5 in water); $[\eta]$ 256; yield, 51% of the pectic acid; electrophoretic mobility, $\mu = 12.6 \times 10^{-5}$ cm^2 V^{-1} s^{-1}).

Polysaccharide II (galacturonic acid, 94.2%; $[\alpha]_D$ +300° (*c*, 0.5 in water); $[\eta]$ 215) and polysaccharide III (galacturonic acid, 91.4%; $[\alpha]_D$ +291° (*c*, 0.5 in water); $[\eta]$ 200) were isolated as described previously (6).

Reduction of Polysaccharide I

Polysaccharide I (20 g) was esterfied by dispersion in methanol which contained concentrated sulfuric acid to a concentration of 2 *N*. The mixture was kept at 0 to 2 °C for 19 days and yielded a product (21.2 g)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with a degree of esterification (percentage of galacturonic acid units esterified) of 87.3%. The ester (21 g) was suspended in 80% aqueous methanol (1 000 ml), and potassium borohydride (22 g) was added in small portions with vigorous stirring. After 18 h the product was filtered off, washed with 80% aqueous methanol, and dried by solvent exchange; yield, 17.4 g; degree of esterification, 48.8%; galacturonic acid, 42.7%.

The above preparation was esterified by diazomethane in ether (30) at 0 to 2 °C for 24 h. The resulting product (17 g; degree of esterification, 88.5%) was reduced by potassium borohydride (12 g) as described above to yield partially reduced polysaccharide I (15 g); degree of esterification, 41.6%; galacturonic acid, 19.0%. Another esterification by diazomethane and then reduction yielded a product (11.2 g) with a degree of esterification of 38.5%; galacturonic acid, 11.0%. This product was dissolved in water, freeze-dried, and esterified with diazomethane; after 1 week the degree of esterification was 45%. Reduction yielded a polysaccharide (8.8 g) with a degree of esterification of 21%; galacturonic acid, 7.8%. This product was esterified with ethylene oxide in water (3) for 6 days at room temperature. The ester was recovered by precipitation with acetone; yield, 8.7 g; degree of esterification, 99.0%. Reduction by potassium borohydride (2.5 g) in water (550 ml) yielded a product (5.2 g) with a degree of esterification of 0%; galacturonic acid, 4.3%. Esterification with ethylene oxide and reduction were repeated once more to yield reduced polysaccharide I (3.9 g); degree of esterification, 0%; galacturonic acid, 0.65%; methoxyl, 5.47%; $[\alpha]_D$ +232° (*c*, 0.5 in 95% aqueous dimethyl sulfoxide); electrophoretic mobility, $\mu = 3.04 \times 10^{-5}$ cm^2 V^{-1} s^{-1}.

The following alternative procedures for esterification and reduction were examined.

(i) Reduction of Ethylene Glycol Ester of Polysaccharide I

Polysaccharide I was esterified with aqueous ethylene oxide as described above; degree of esterification, 96.5%. The ester (0.7 g) was reduced by potassium borohydride (0.7 g) in 80% aqueous methanol (50 ml); yield, 0.53 g; degree of esterification, 43.2%; galacturonic acid, 35.1%.

Another sample of the ethylene glycol ester (0.65 g) was reduced by potassium borohydride (0.65 g) in water (50 ml); yield, 0.39 g; degree of esterification, 0%; galacturonic acid, 29.7%.

(ii) Esterification and Reduction in Dimethyl Sulfoxide

Partially esterified, partially reduced polysaccharide I (1 g; degree of esterification, 45%; galacturonic acid, 11%) was dissolved in dimethyl sulfoxide (75 ml); potassium borohydride (0.5 g) in water (25 ml) was added. The solution was stirred overnight and was then poured into four volumes of acidified methanol. The precipitated polysaccharide was washed with methanol and dried by solvent exchange; yield, 0.69 g; degree of esterification, 10.7%; galacturonic acid, 6.8%. This sample was dissolved in dimethyl sulfoxide, and ethereal diazomethane (2 ml) was added dropwise, with vigorous stirring, over 2 h. A solution of potassium borohydride (0.1 g) in dimethyl sulfoxide (10 ml) and water (5 ml) was then added and the solution was stirred overnight. The reduced polysaccharide was recovered as above; yield, 0.37 g; degree of esterification, 0%; galacturonic acid, 1.7%.

Polysaccharide I (1 g) was esterified in dimethyl sulfoxide by ethereal diazomethane as described above to yield a product (1 g) with a degree of esterification of 91.6%. When this product was reduced by potassium borohydride in dimethyl sulfoxide, no methanol-insoluble material could be recovered.

(iii) Reduction in Water

A solution of partially reduced polysaccharide I (2 g; degree of esterification, 78%; galacturonic acid, 19.9%) in water (200 ml) was added dropwise to a solution of potassium borohydride (2.5 g) in water (250 ml). The solution was stirred overnight and the reduced polysaccharide was then recovered by precipitation with acidified methanol; yield, 1.32 g; degree of esterification, 0%; galacturonic acid, 10.1%.

Reductions of Polysaccharides II and III

Polysaccharide II (0.75 g) was esterified with aqueous ethylene oxide (12.7%, 250 ml) and reduced by potassium borohydride to yield a partially reduced polysaccharide II (0.6 g). Two further reductions of the propylene glycol ester yielded the carboxyl-reduced polysaccharide II used for structural studies. The small amount (0.24 g) of this product precluded analysis for ester and galacturonic acid.

Polysaccharide III (6.5 g) was converted into its ethylene glycol ester between each reduction. It was reduced twice in 80% aqueous methanol and three times in water to yield carboxyl-reduced polysaccharide III (1.84 g); galacturonic acid, 5.8%.

Rates of Hydrolysis

The ethylene glycol esters of polysaccharide I and a series of partially reduced products containing 41.6%, 19.9%, 11.0%, and 0.65% of galacturonic acid were hydrolyzed by 0.5 *N* sulfuric acid in 95% aqueous dimethyl sulfoxide on a boiling water bath. The degree of hydrolysis was determined polarimetrically (14).

Periodate Oxidation of Carboxyl-Reduced Polysaccharide I

Carboxyl-reduced polysaccharide I (301 mg; galacturonic acid, 0.65%) was dissolved in water (40 ml), 0.1 *M* sodium metaperiodate (40 ml) was added, and the volume was adjusted to 100 ml with water. Aliquots (2 ml) were removed at intervals for an estimation of the periodate (31) and formic acid (32) content. Periodate consumption was 0.79, 0.80, and 0.82 mole per monomer unit after 17, 24, and 40 h, respectively. Formic acid production after 40 h was 0.09 mole per monomer unit. Ethylene glycol was added to the oxidation reaction to destroy excess periodate, and the solution was then deionized with exchange resins. Potassium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

borohydride (0.2 g) was added to the deionized solution and the reduction was left for 24 h. Excess borohydride was destroyed by cation-exchange resin, and boric acid was removed by repeated addition and evaporation of methanol. The syrupy residue was hydrolyzed with 0.5 *N* sulfuric acid on a boiling water bath for 4 h. The hydrolysate was neutralized with barium carbonate, barium salts were filtered off, and potassium borohydride (0.2 g) was added to the filtrate. The reduction was worked up as described above to yield a syrup (2.9 g). Part of this product was acetylated by acetic anhydride – pyridine (1:1) at 65 °C for 1 h and examined by gas–liquid chromatography (column *b*); the following components were found (retention times relative to that of glycerol triacetate): ethylene glycol diacetate (0.83), glycerol triacetate (1.00), two unidentified compounds (1.17, 2.15), and threitol tetraacetate (4.21). The rest of the reduced hydrolysate was examined by paper chromatography (solvents A and B), which showed the presence of threitol and traces of galactitol. Threitol (30 mg) was isolated by preparative paper chromatography in solvent B and was converted into tetra-*O*-(*p*-nitrobenzoyl)-D-threitol (23), m.p. 210 °C.

Anal. Calcd. for $C_{32}H_{20}O_{16}N_4$: C, 53.4; H, 3.1; N, 7.8. Found: C, 53.3; H, 3.3; N, 7.9.

Methylation of Carboxyl-Reduced Polysaccharide I

Carboxyl-reduced polysaccharide I (1.01 g; galacturonic acid, 0.65%) was methylated with dimethyl sulfate (20 ml) and 30% aqueous sodium hydroxide (50 ml) (19); four additions of reagents were made. The partially methylated product (1.05 g) was isolated by extraction into chloroform, and methylated by dimethyl sulfate (10 ml) and solid sodium hydroxide (10 g) in tetrahydrofuran (20); two additions of reagents were made. After extraction into chloroform the methylated product was precipitated by light petroleum (b.p. 30–60 °C) and gave a precipitated (680 mg) and a soluble fraction (354 mg). Both fractions showed hydroxyl absorption in the infrared. The two fractions were combined and methylated twice with methyl iodide and silver oxide (21). The product was again precipitated with light petroleum to yield an insoluble (633 mg) and a soluble (350 mg) fraction. The insoluble product had $[\alpha]_D$ +214° (*c*, 1.0 in chloroform) and a methoxyl content of 45.2%; the soluble fraction had $[\alpha]_D$ +60.5° (*c*, 1.9 in chloroform) and a methoxyl content of 25.8%. Methanolysis of each fraction by 4% methanolic hydrogen chloride at 100 °C for 12 h yielded identical products, as shown by gas–liquid chromatography (column *a*).

The fraction (633 mg) that was insoluble in light petroleum was hydrolyzed (33). Paper chromatography of the hydrolysate in solvent D showed the presence of components with the following mobilities relative to that of 2,3,4,6-tetra-*O*-methyl-D-galactose: 1.14 (very weak), 1.00, 0.82 (very strong), 0.59 (trace), and 0.18 (very weak). The methylated sugars in the hydrolysate were resolved by preparative thin-layer chromatography to give the following five fractions (in decreasing order of mobility).

Fraction 1

The syrup (66 mg) contained 2,3,5,6-tetra-*O*-methyl-D-galactose and an unidentified compound of high mobility on both paper and gas–liquid chromatograms. Rechromatography on thin layers yielded a syrup (18 mg) which had the same chromatographic mobility as an authentic sample of 2,3,5,6-tetra-*O*-methyl-D-galactose; demethylation (18) yielded galactose. The sample was oxidized by bromine, esterified by methanolic hydrogen chloride, and treated with ammoniacal methanol; the resulting amide failed to crystallize.

Fraction 2

This fraction (77 mg) contained a mixture of 2,3,4,6-tetra- and 2,3,6-tri-*O*-methyl-D-galactose. Methanolysis and gas–liquid chromatography showed the presence of components with retention times of 1.57, 3.06, 3.36, 3.93, and 4.16 on column *a*. Further purification by thin-layer chromatography yielded pure samples of the tetra-*O*-methyl (27 mg) and tri-*O*-methyl (34 mg) derivatives. 2,3,4,6-Tetra-*O*-methyl-D-galactose yielded a crystalline anilide (34), m.p. 194–196 °C, unchanged on admixture with an authentic sample.

Fraction 3

The syrup (429 mg) showed only one component corresponding to 2,3,6-tri-*O*-methyl-D-galactose on paper chromatography (solvent C). Gas–liquid chromatography of the methyl glycosides showed components with retention times of 3.06, 3.36, 3.93, and 4.16, corresponding to the anomeric methyl furanosides and pyranosides of 2,3,6-tri-*O*-methyl-D-galactose. Oxidation with bromine yielded 2,3,6-tri-*O*-methyl-D-galactono-(1 → 4)-lactone (35), m.p. 96–97 °C, $[\alpha]_D$ −41° → −32° (*c*, 1.26 in water). A syrup obtained from the mother liquors from the above crystallization contained a mixture of (1 → 4)- and (1 → 5)-lactones as shown by its infrared spectrum (36). This sample was esterified by methanolic hydrogen chloride and was then converted into the amide (37), m.p. 128–129 °C, unchanged on admixture with an authentic sample of 2,3,6-tri-*O*-methyl-D-galactonamide.

Fraction 4

This syrup (18 mg) contained at least three different compounds, as shown by thin-layer chromatography and by gas–liquid chromatography of the methyl glycosides; it was not examined further.

Fraction 5

This material (19 mg) was recovered from the starting line of the thin-layer chromatograms. Methanolysis and gas–liquid chromatography showed that 2,3,6-tri-*O*-methyl-D-galactose was the main product.

The portion of methylated, carboxyl-reduced polysaccharide I that was soluble in light petroleum (350 mg) was fractionated further by chromatography on silica gel to yield three products: the first (90 mg), eluted by chloroform, had $[\alpha]_D$ −3.5° (*c*, 0.9 in chloroform); the second (142 mg), eluted by chloroform–methanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(98:2), had $[\alpha]_D$ +76° (*c*, 1.4 in chloroform) and a methoxyl content of 28.9%; the third (45 mg), eluted by chloroform–methanol (75:25), had $[\alpha]_D$ +160° (*c*, 0.9 in chloroform) and a methoxyl content of 37.8%. Methanolysis and gas–liquid chromatography showed that each of these products contained the same methylated sugars as were present in the light petroleum insoluble fraction. The fraction with $[\alpha]_D$ +76° was found to contain methyl 2,3,5,6-tetra-*O*-methyl-D-galactosides before hydrolysis.

Methylation of Carboxyl-Reduced Polysaccharide II

Carboxyl-reduced polysaccharide II (207 mg) was methylated by the procedures of Haworth (19) and Purdie (21) to yield a product (114 mg) with $[\alpha]_D$ +126° (*c*, 2.28 in chloroform) and a methoxyl content of 32.8%; there was negligible hydroxyl absorption in the infrared. Paper chromatography (solvents C and D) and gas–liquid chromatography (columns *a* and *b*) of a hydrolysate and a methanolysate, respectively, showed the presence of only two compounds: 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-galactose in a molar ratio of 1:20 as determined by gas–liquid chromatography.

Methylation of Carboxyl-Reduced Polysaccharide III

Carboxyl-reduced polysaccharide III (1.6 g) was methylated by the procedures of Haworth (19) and Purdie (21) to yield light petroleum insoluble (608 mg) and soluble (472 mg) fractions. The latter, $[\alpha]_D$ +64° (*c*, 2.3 in chloroform), was not examined further. The fraction that was insoluble in light petroleum was chromatographed on silica gel to yield, first, a fraction (258 mg) eluted by chloroform–methanol (98:2) ($[\alpha]_D$ +146° (*c*, 1.29 in chloroform); methoxyl, 43.1%), and second, a fraction (167 mg) eluted by chloroform–methanol (95:5) ($[\alpha]_D$ +152° (*c*, 1.1 in chloroform); methoxyl, 39.0%). Each of these fractions contained only 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-galactose, as shown by paper chromatography (solvents C and D) of hydrolysates and gas–liquid chromatography (columns *a* and *b*) of methanolysates. The ratios of tetra- to tri-*O*-methyl-D-galactose were 1:24 and 1:36, respectively, in these two fractions.

STEROIDS AND RELATED NATURAL PRODUCTS

XXX. SELECTIVE REDUCTION OF ESTERS. PART A. BENZOATES[1]

GEORGE R. PETTIT,[2] BRIAN GREEN, GEORGE L. DUNN,[3] PETER HOFER, AND WILLIAM J. EVERS

Department of Chemistry, University of Maine, Orono, Maine, and Department of Chemistry, Arizona State University, Tempe, Arizona

Received January 5, 1966

ABSTRACT

Previously, reagents such as sodium borohydride – boron trifluoride were shown to be capable of reducing typical aliphatic esters and lactones to the corresponding ether derivatives. Under the same reaction conditions, a variety of benzoate esters (*Ib*, *IIb*, III, and V) were essentially unaffected. Resistance to attack was illustrated by conversion, with sodium borohydride – boron trifluoride, of 3-oxo-17β-benzoyloxy-5α-androstane (III) into 3β-hydroxy-17β-benzoyloxy-5α-androstane (IV) and of reserpine (V) into alcohol VI. With aryl–carbon–oxygen bonds of the ketone VII or alcohol IX*a* type, reaction with sodium borohydride – boron trifluoride was shown, in general, to cause reductive fission of the benzyl–oxygen linkage (e.g. X → XI). An exception was noted in the case of tertiary benzyl alcohols containing an available β-hydrogen (e.g. IX*c*). Here, dehydration to yield, for example, olefin XII*b* appears to be the more favorable reaction course. The marked difference in the reactivity of sodium borohydride – boron trifluoride toward benzoyl–oxygen vs. benzyl–oxygen bonds has been demonstrated.

Previous applications of diborane – boron halide[1] reagents for direct conversion of esters into ethers have involved a variety of aliphatic-type esters and lactones. In general, conversion into the ether derivative increased substantially as the alcohol segment of the ester varied from primary to tertiary.[4] Two phenyl esters, however, were found (1) to undergo only hydrogenolysis to the corresponding alcohol derivatives. More recently, Eliel and Daignault (2) have extended the reduction reaction to thiol esters and have obtained good yields of the corresponding thioethers. The present investigation was undertaken to determine whether the mesomeric effect of the aromatic ring in a benzoate-type ester would decrease the basicity[5] of the carbonyl group enough to substantially reduce the rate of reduction, or whether attack would proceed by one or more of the

[1] *For part XXIX in this series, see G. R. Pettit and W. J. Evers, Can. J. Chem., 44, 1097 (1966). The present study is based on part of the Ph.D. dissertation submitted by G. L. Dunn to the Graduate School, University of Maine, Orono, Maine, July 1962.*

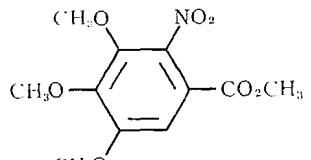
[3] *NDEA Predoctorate Fellow, 1960–1962.*

[4] *Dr. J. S. E. Holker and his colleagues have extended the reduction reaction to several steroid ring-D lactones derived from primary alcohols, and have obtained good yields of the corresponding tetrahydropyrans. We are grateful to Dr. Holker for providing us with this information before publication. One unsuccessful attempt to reduce a γ-lactone derived from a tertiary alcohol has also been noted (3a). Interestingly, extended platinum – perchloric acid catalyzed hydrogenation of 3β-acetoxy-5α-lanost-8-ene has been found to yield 3β-ethoxy-5α-lanostane (3b). We thank Professor J. T. Edward for bringing a similar, but unpublished, example to our attention. Both observations seem to be related to the recently reported (3c) preparation of ethers by reductive (platinum-catalyzed) condensation of alcohol–ketone mixtures.*

[5] *The increased π-bond overlap resulting from phenyl–carbonyl conjugation would be expected to inhibit association with boron trifluoride (compare with eq. [i]).*

[i] $$\mathrm{Ar{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}OR \xrightarrow{BF_3} Ar{-}\overset{\displaystyle \ominus OBF_3}{\overset{|}{\underset{\displaystyle \oplus}{C}}}{-}OR \leftrightarrow Ar{-}\overset{\displaystyle \ominus OBF_3}{\overset{|}{\underset{\displaystyle \oplus}{C}}}{=}OR}$$

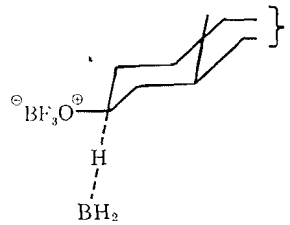


The reaction sequence illustrated in part by eq. [i] is assumed (4) to represent an important step in the reduction of esters to ethers by diborane – boron trihalide reagents.

following pathways: (*a*) reduction to the corresponding benzyl ether, or (*b*) hydrogenolysis to the corresponding alcohol derivatives.[6]

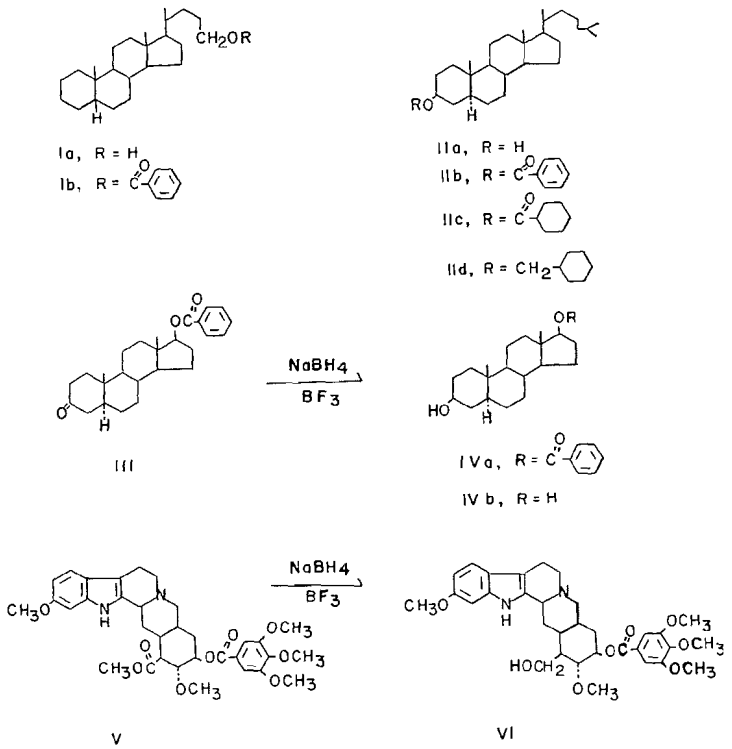
Subjecting 24-benzoyloxy-5β-cholane (I*b*, prepared from alcohol I*a*), in diethylene glycol dimethyl ether (diglyme) containing sodium borohydride, to treatment with boron trifluoride (in tetrahydrofuran) under conditions (1 h at ice-bath temperature and 1 h at room temperature) normally employed[1] in the ester → ether reduction sequence led to unreacted benzoate I*b* (79% recovery) accompanied by alcohol I*a* (20% yield). Extending the same reaction procedure to 3β-benzoyloxy-5α-cholestane (II*b*) gave comparable results: unreacted ester and alcohol II*a*. Under the same conditions 3β-cyclohexylcarbonyloxy-5α-cholestane (II*c*) was easily converted, in reasonable yield (50%), into ether II*d*. Comparing the benzoate and cyclohexanecarboxylate esters of alcohol II*a* provided a vivid illustration of differences in the reaction course.

Reduced reactivity of the benzoate esters toward sodium borohydride – boron trifluoride suggested that other more reactive carbonyl groups might be reduced selectively in their presence. Accordingly, two examples were studied. First, 3-oxo-17β-benzoyloxy-5α-androstane (III) was reduced (68% yield) with sodium borohydride – boron trifluoride to 3β-hydroxy-17β-benzoyloxy-5α-androstane (IV*a*). The remaining reaction product consisted primarily of diol IV*b* (20% yield). Sodium borohydride reduction of ketone III to alcohol IV*a* confirmed the structural and stereochemical assignments. The predominant formation of the C-3 equatorial alcohol when sodium borohydride – boron trifluoride is used is consistent with an earlier observation by Jones (9) involving diborane – boron trifluoride reduction of 4-*t*-butylcyclohexanone.[7] A second example of selective reduction, namely, conversion of reserpine (V) into alcohol VI, was of more practical importance.



[6]*Brown and Subba Rao reported (5) that reaction between sodium borohydride – boron trifluoride etherate (in diglyme) and ethyl benzoate, as well as two derivatives, proceeded slowly, but the products were not ascertained. During the same period, a similar study with diborane was summarized (6), and a potentially important observation concerning the unreactivity of diborane toward acid halides (5, attributable to the electron-withdrawing effect of the halogen, thereby reducing attack by the Lewis acid diborane) was noted. The amine borane derived from pyridine and diborane, however, appears to resemble a borohydride, and has been shown (7) to reduce benzoyl chloride easily to benzoyl alcohol.*

ii



Again, in 1960, Tarbell and his colleagues reduced methyl benzoate (ii) to the corresponding benzyl alcohol (68% yield) with sodium borohydride – aluminium chloride (known to generate diborane), and the same alcohol was obtained in excellent conversion (93%) from the corresponding carboxylic acid by employing sodium borohydride – boron trifluoride (8).

[7]*Diborane or diborane – boron trifluoride reduction of 4-t-butylcyclohexanone yielded, in each case, approximately 15–16% of the thermodynamically less stable (cis) axial alcohol. Interestingly, trimethylamine borane – boron trifluoride gave 46–52% yields of the axial alcohol. The stereochemical course of ketone reduction by diborane (10) appears, in general, to favor equatorial alcohol formation, and in the case of ketone III may proceed via an intermediate such as iii.*

iii

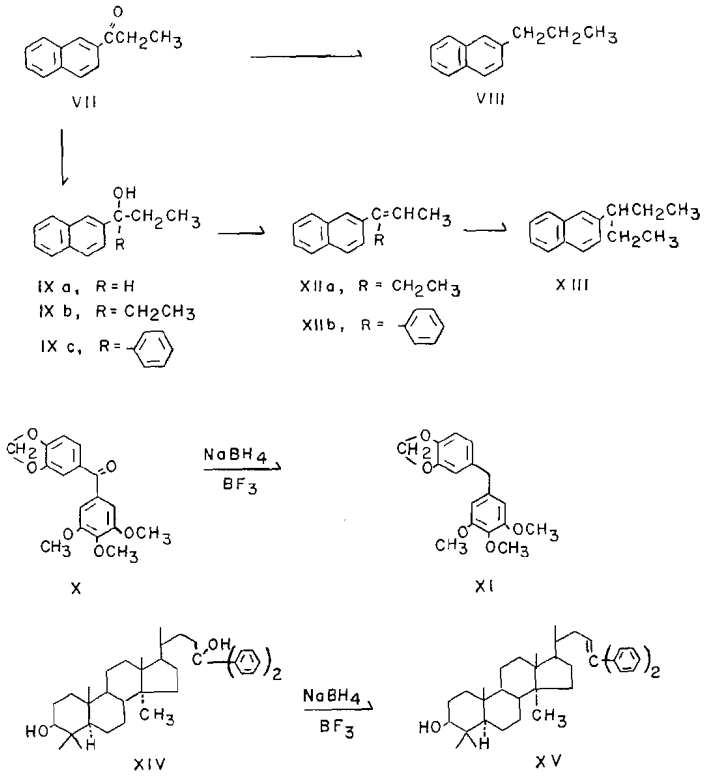
When reduction was attempted, in normal fashion, by adding a mixture of boron trifluoride and the alkaloid to sodium borohydride, a solid boron trifluoride – reserpine adduct separated from solution. Subsequently, a procedure based on adding boron trifluoride etherate to a mixture of reserpine and sodium borohydride provided alcohol VI. The results of infrared spectral and elemental analytical determinations supported structural assignment VI. Preferential reduction at the carbomethoxy group provides, in effect, a new means of further modifying the hypotensive and central nervous system activity of reserpine.[8]



At this point, the investigation was expanded to encompass effects of boron trifluoride – sodium borohydride on other types of benzyl–oxygen linkages.[9] Allowing both 2-naphthylethyl ketone (VII) and the corresponding alcohol (IX*a*) to react with boron trifluoride – sodium borohydride as in the case of, for example, benzoate I*b* yielded (good overall conversion) in both cases the product of complete hydrogenolysis: 2-(*n*-propyl)naphthalene (VIII). Benzyl alcohol IX*a* was obtained by lithium aluminium hydride reduction of ketone VII, and an authentic specimen of hydrocarbon VIII was prepared by catalytic hydrogenation (VII → VIII). Under similar conditions, diaryl ketone X was easily reduced to 3,4-methylenedioxyphenyl-3,4,5-trimethoxyphenylmethane (XI).[10]

[8]*Consult ref. 11 for leading literature citations pertinent to this point.*

[9]*A preliminary account of this study has been summarized in ref. 12. During the same period Venkataraman and his colleagues (13) reported boron trifluoride – sodium borohydride to be useful for the reduction of anthraquinones to anthracenes, and indicated that the reagent was also convenient for the analogous reduction of chromones and chromanones. Longer treatment with diborane was observed to give comparable results. Later, two additional examples (14) of the reaction with respect to chromanones were reported. Proposed mechanisms for this type of reduction reaction have been summarized (13b, 14b).*

[10]*It should be noted that other metal hydride techniques, particularly with aluminium chloride – lithium aluminium hydride, have been employed successfully for reductive cleavage of benzyl–oxygen bonds in various aryl ketones and in benzylic and allylic alcohols (see ref. 15 and footnotes 2 and 3 in ref. 12).*

For personal use only.

One limit to the utility of the hydrogenolysis reaction was found during routine extension to several tertiary-type benzylic alcohols. Treating ketone VII with ethylmagnesium bromide provided tertiary alcohol IX*b*. From the reaction between alcohol IX*b* and boron trifluoride – sodium borohydride, only a mixture of *cis* and *trans* olefins corresponding to structure XII*a* was isolated. The olefin mixture was not further characterized, but was instead hydrogenated in the presence of palladium on charcoal to hydrocarbon XIII. The latter compound (XIII) was identical with a specimen prepared in an unequivocal manner (acid-catalyzed dehydration followed by hydrogenation) from alcohol IX*b*. The analogous preparation (VII and phenylmagnesium bromide) of diaryl tertiary alcohol IX*c* and subsequent reaction with the hydride reagent yielded olefin XII*b*. The crystalline hydrocarbon was readily characterized and shown to be identical with a sample prepared by hydrochloric acid catalyzed dehydration of alcohol IX*c*. A reaction course terminating in dehydration was again encountered with tertiary alcohol XIV. Reaction with boron trifluoride – sodium borohydride gave only olefin XV, a substance previously characterized in our laboratory. The possibility of dehydration catalyzed by boron trifluoride taking precedence came into question when a solution of alcohol IX*b* in diglyme (containing sodium borohydride) was slowly treated with boron trifluoride etherate; the same result ensued (production of olefin XII*a*). These experiments also suggest that hydroboration of olefins such as XII and XV is a relatively slow process, or that they (the olefins) arise at a terminal stage.[11] In this regard, boron trifluoride – sodium borohydride reduction

[11]*Olefins are known to arise during lithium aluminium hydride reduction of certain aryl ketones; for example, see ref. 15a.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of triphenylcarbinol gave, as expected, triphenylmethane; however, no further effort was made to delineate the mechanism (13*b*, 14*b*) of olefin formation.

The preceding experiments served to extend the scope of reduction reactions with boron trifluoride – sodium borohydride to selective reduction in the presence of a benzoate ester, and with certain limitations (tertiary benzyl alcohols bearing an available β-hydrogen substituent) to reductive fission of benzyl–oxygen bonds. Later, carbonate-type esters were found to be similar to benzoates in their resistance to attack by boron trifluoride – sodium borohydride; a summary of these observations will appear in a later paper.

EXPERIMENTAL[12]

24-Benzoyloxy-5β-cholane (Ib)

To a cool (ice bath) solution of 24-hydroxy-5β-cholane (I*a*, 1.2 g) in pyridine (7 ml, distilled from potassium hydroxide) was added benzoyl chloride (1 ml). After 8 h at room temperature, the mixture was poured into water (50 ml) and extracted with diethyl ether. The combined ethereal extracts were washed successively with saturated sodium bicarbonate solution, water, 5% hydrochloric acid, and water. Removal of solvent *in vacuo* yielded a pale-yellow oil (1.7 g), which was dissolved in petroleum ether and chromatographed on a column of acid-washed alumina (30 g). Elution with petroleum ether and 3:1 petroleum ether – benzene gave a colorless oil, 1.4 g, 90%; ν_{max}^{neat} 1 720, 1 600, 1 580, 1 260, and 706 cm^{-1}. Crystallization from methanol – diethyl ether gave 1.35 g of crystals melting at 44–45°. After three recrystallizations from the same solvent mixture, an analytical specimen displayed the same melting point and had $[\alpha]_D^{20}$ +18.5° (*c*, 1.27). A thin-layer chromatogram (10:1 petroleum ether – ethyl acetate as the mobile phase) showed one spot.

Anal. Calcd. for $C_{31}H_{46}O_2$: C, 82.61; H, 10.29. Found: C, 82.25; H, 10.67.

Attempted Sodium Borohydride – Boron Trifluoride Reduction of 24-Benzoyloxy-5β-cholane (Ib)

A solution of ester I*a* (1.0 g) in tetrahydrofuran (20 ml) containing boron trifluoride etherate (7.5 ml) was added to a cool (ice bath) solution of sodium borohydride (0.17 g) in 20 ml of dry diglyme. Stirring was continued for 1 h at ice-bath temperature, and during a second hour while the solution was being heated at reflux. The solution was cooled (ice bath) and cautiously treated with 2 *N* hydrochloric acid, followed by dilution with water and extraction with diethyl ether. The combined ethereal extracts were washed with saturated sodium bicarbonate solution and water, and concentrated *in vacuo* to a colorless oil (1.2 g). A solution of the oily product in petroleum ether was chromatographed on acid-washed alumina (30 g). The petroleum ether and 1:1 petroleum ether – benzene fractions provided 0.79 g, m.p. 44–45°, of ester I*a*.[13] A fraction eluted with chloroform crystallized from methanol as needles (0.15 g, 20%) melting at 127–129°. The latter product proved[13] to be 24-hydroxy-5β-cholane (I*a*).

3β-Benzoyloxy-5β-cholestane (IIb)

Conversion of 3β-hydroxy-5α-cholestane (5.0 g) into benzoate ester II*b* by employing benzoyl chloride (8 ml) in dry pyridine (40 ml) was accomplished essentially as noted with ester I*b*. The crude product recrystallized from diethyl ether – methanol as colorless needles weighing 5.2 g and melting at 137–138° to an opaque liquid which cleared at 158–159° (ref. 17 reports m.p. 133–135° to 152–156°).

Attempted Reduction of 3β-Benzoyloxy-5α-cholestane (IIb)

Method A: Sodium Borohydride – Boron Trifluoride

A 1.0 g sample of ester II*b* was subjected to treatment with sodium borohydride (0.16 g) in the presence of boron trifluoride etherate (7.5 g) as described above for benzoate ester I*b*. A thin-layer chromatogram of the product indicated a two-component mixture. The first substance isolated weighed 0.92 g and proved[13] to be starting material (II*b*). The remaining product was found to contain, on the basis of comparative thin-layer chromatograms, 3β-hydroxy-5α-cholestane. No substance corresponding to ether II*d* was detected.

[12]*Acid-washed alumina refers to a Merck (Rahway) product. The petroleum ether employed was a fraction boiling at 65–70°. A summarized description of other general methods, solvents, reagents, and chromatographic procedures used in the present study appears in an introduction to the Experimental section of part XXVIII in this series (see G. R. Pettit, J. C. Knight, and W. J. Evers, Can. J. Chem., 44, 807 (1966)).*

Melting points reported for analytical specimens were recorded on a Kofler melting point apparatus. All other melting point determinations were performed with open Kimble glass capillaries in a silicone oil bath and are uncorrected. The purity of all analytical samples (colorless in each case) was confirmed by thin-layer chromatography on silica gel G, and the plates were developed with concentrated sulfuric acid.

Proton magnetic resonance (see ref. 16), ultraviolet (ethanol solution, Perkin–Elmer model 400 spectrometer), infrared spectra (potassium bromide, unless otherwise noted) and gas chromatographic data were provided by Dr. R. A. Hill (University of Maine). Specific rotation values (chloroform solution) were determined in the laboratories of Drs. Weiler and Strauss, Oxford, England, and P. Demoen, Janssen Pharmaceutica, Beerse, Belgium. Elemental analytical data was provided by Dr. A. Bernhardt, Max-Planck Institut, Mülheim, Germany.

[13]*The identity of this substance was established by mixture melting point determination and infrared spectral comparison with an authentic sample.*

For personal use only.

Method B: Lithium Aluminium Hydride – Boron Trifluoride

The preceding experiment (A) was repeated with lithium aluminium hydride (0.16 g) in place of sodium borohydride and with tetrahydrofuran (40 ml total) as solvent (1). The principal product, 0.80 g, was starting material,[13] and the residual mixture consisted largely of ester II*b* accompanied by a small amount of alcohol II*a*. A thin-layer chromatographic study of the mixture failed to reveal ether II*d*.

3β-Cyclohexylcarbonyloxy-5α-cholestane (IIc)

Method A

Platinum oxide (0.2 g) was added to a solution of commercial cholesteryl benzoate (8.7 g) and 70% perchloric acid (3 drops) in tetrahydrofuran (200 ml), and the mixture was shaken under a slight positive pressure of hydrogen for 2 h. At this time, an aliquot sample displayed a strong tetranitromethane test; thus, another 0.5 g quantity of platinum oxide was added and hydrogenation continued. Five hours later, hydrogen absorption appeared to be complete, and catalyst was removed by filtration. Dilution with water led to a solid which crystallized from chloroform–methanol as colorless needles, 4.2 g, m.p. 161–162°. An additional 0.62 g, m.p. 159–161°, of cyclohexylcarbonyloxy ester II*c* was obtained by recrystallization of the second and third crystal crops.

Method B

The cyclohexylcarbonyloxy ester II*c* of alcohol II*a* (0.5 g) was prepared from the acid chloride (by employing 10 ml of thionyl chloride, reflux for 1.5 h) derivative of cyclohexanecarboxylic acid (1.0 g) in pyridine (5 ml) as summarized with ester I*b*. The pale-yellow solid crystallized from chloroform–methanol as colorless needles, 0.5 g, m.p. 160–161° (ref. 18 reports m.p. 158.5–159°). The identical composition of both esters (obtained by methods A and B) was confirmed.[13]

3β-Cyclohexylmethyleneoxy-5α-cholestane (IId)

Reduction of cyclohexylcarbonyloxy ester II*c* (1.0 g in 50 ml of tetrahydrofuran) with sodium borohydride (0.19 g in 20 ml of diglyme) and boron trifluoride (12 ml) was accomplished by the procedure illustrated with ester I*a*. A petroleum ether solution of crude product was chromatographed on activated alumina (30 g). Elution with the same solvent (400 ml) gave a fraction (0.43 g) which crystallized from chloroform–methanol as colorless blades, 0.40 g, m.p. 157.5–158.5°. Further recrystallization from the same solvent mixture gave an analytical specimen with an unchanged melting point and with $[\alpha]_D^{20}$ +15.2° (*c*, 1.212); ν_{max} 2 900, 1 470, 1 450, 1 380, and 1 120 (broad) cm^{-1}.

Anal. Calcd. for $C_{34}H_{60}O$: C, 84.23; H, 12.47; O, 3.30. Found: C, 84.14; H, 12.39; O, 3.65.

Continued elution with chloroform gave 0.57 g of alcohol II*a*.

3-Oxo-17β-benzoyloxy-5α-androstane (III)

After one recrystallization from methanol, the pale-yellow solid (7.5 g, m.p. 150–160°) obtained from 3-oxo-17β-hydroxy-5α-androstane (7.0 g) and benzoyl chloride (6 ml) in pyridine (40 ml) was dissolved in 1:1 petroleum ether – benzene and chromatographed on acid-washed alumina. An initial fraction (0.45 g, m.p. 150–160°) eluted with the same solvent mixture was discarded, and subsequent fractions through 5:1 benzene–chloroform were collected. The colorless solid weighed 6.3 g (66%) and melted at 196–199°. Four recrystallizations from acetone gave an analytical sample in the form of rods, m.p. 201–202° (ref. 19 reports m.p. 201–202°), $[\alpha]_D^{20}$ +73.1° (*c*, 1.30); ν_{max} 1 710, 1 280, and 720 cm^{-1}.

Anal. Calcd. for $C_{26}H_{34}O_3$: C, 79.14; H, 8.68. Found: C, 79.11; H, 8.33.

3β-Hydroxy-17β-benzoyloxy-5α-androstane (IVa)

Method A

Reduction of ketone III (1.0 g) in diglyme (25 ml) – tetrahydrofuran (25 ml) with sodium borohydride (0.19 g) – boron trifluoride etherate (7.7 ml) was conducted as described for benzoate ester I*b*. The crude viscous oil was chromatographed on acid-washed alumina, and fractions eluted by benzene yielded a solid (0.73 g) melting at 170–180°. One recrystallization from acetone – petroleum ether gave colorless plates weighing 0.68 g (68%, m.p. 201–202°). Further recrystallization from the same solvent mixture gave a pure specimen melting at 202–203°, $[\alpha]_D^{20}$ +53.4° (*c*, 1.25).

Anal. Calcd. for $C_{26}H_{36}O_3$: C, 78.74; H, 9.15. Found: C, 78.99; H, 8.87.

The column was next eluted with chloroform and the resulting fraction allowed to crystallize from benzene – petroleum ether. The specimen of 3β,17β-dihydroxy-5α-androstane (IV*b*) that was obtained weighed 0.15 g (20%) and melted at 164–165° (ref. 20 reports m.p. 164°).

Method B

The preceding experiment (see method A) was repeated, omitting boron trifluoride etherate and tetrahydrofuran. The crude viscous oil (0.95 g) crystallized upon trituration with methanol to yield 0.90 g of crude alcohol IV*a* melting at 175–185°. A 0.10 g sample was purified as described above by column chromatography on acid-washed alumina (3 g). The fraction eluted by 5:1 benzene–chloroform yielded 0.08 g of alcohol IV*a* melting at 202–203°; ν_{max} 3 400, 1 710, 1 280, and 715 cm^{-1}. The specimen of alcohol IV*a* prepared by method B was identical[13] with that obtained by method A.

Sodium Borohydride – Boron Trifluoride Reduction of Reserpine (V)

In a typical experiment, reserpine (15.0 g) was dissolved in hot (100–110°) diglyme (750 ml) and, after the solution was cooled (ice bath), sodium borohydride (5.6 g) was added. Next, a solution composed of boron

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

trifluoride etherate (190 ml) and tetrahydrofuran (190 ml) was added dropwise over a 30 min period. Before the cool (20°) solution was cautiously treated with 2 *N* hydrochloric acid (250 ml), stirring was continued for 3 h at ice-bath temperature and for 1 h at reflux. The pH of the mixture was adjusted to 8–9 with ammonium hydroxide, and the solution was diluted with water and extracted with chloroform. After removal of solvent the red viscous oil was triturated with diethyl ether, and the yellow solid (10.5 g, giving a green Beilstein test) was collected, dissolved in methanol (475 ml) – concentrated hydrochloric acid (25 ml), and heated at reflux for 30 min. Concentration to a volume of ca. 200 ml and cooling (ice bath) provided 5.0 g of a straw-colored solid, decomposition point 265°, which recrystallized from 95% ethanol as cream-colored plates decomposing at 265°. Two additional recrystallizations from the same solvent did not change the appearance or decomposition point of *alcohol VI hydrochloride*, $[\alpha]_D^{22}$ −76.5° (*c*, 1.2); ν_{max} 3 400, 3 150, 2 600, and 1 708 cm^{-1} (in reserpine, the bands at 1 709 and 1 720 cm^{-1} correspond, respectively, to benzoate and methoxycarbonyl absorption).

Anal. Calcd. for $C_{32}H_{41}O_8N_2Cl$: C, 62.27; H, 7.00; Cl, 5.75; N, 4.54; O, 20.74. Found: C, 61.87; H, 6.58; Cl, 6.01; N, 4.76; O, 21.16.

A suspension of the hydrochloride in water – diethyl ether was shaken with 1 *N* sodium hydroxide. The mixture was diluted with benzene, and the upper phase was washed with water and concentrated. When the concentrate was allowed to stand at room temperature, *alcohol VI* separated from solution as rosettes of colorless needles, decomposition point 134–144° (Kofler block m.p. 144–148°). The free base (VI) was pure as evidenced by a thin-layer chromatogram, but quickly became yellow and impure on exposure to air and light. A pure specimen was preserved in the dark and exhibited $[\alpha]_D^{20}$ −55.7° (*c*, 0.88) and ν_{max} 3 400, 1 709, and 1 130 cm^{-1}.

Anal. Calcd. for $C_{32}H_{40}O_8N_2$: C, 66.20; H, 6.94; N, 4.83; O, 22.05. Found: C, 65.99; H, 6.88; N, 4.93; O, 21.95.

2-(n-Propyl)naphthalene (VIII)

Method A

By using the procedure outlined for the attempted reduction of benzoate *Ib*, a sample of 2-naphthylethyl ketone (3.0 g, VII (21)) was reduced with sodium borohydride (1.3 g) – boron trifluoride etherate (80 g). A solution of the crude product in petroleum ether was chromatographed on activated alumina (80 g). Elution with the same solvent yielded 2.2 g of a colorless mobile oil, b.p. 134° at 20 mm; λ_{max} 225, 276, and 319 mμ (log ε 4.23, 3.90, and 2.73). The ultraviolet spectrum of 2-methylnaphthalene has been reported (22) to be λ_{max} 220, 276, and 319 mμ (log ε 4.02, 3.68, and 2.71). Homogeneity of the hydrocarbon was confirmed by vapor phase chromatography. The *picrate* derivative (prepared in 95% ethyl alcohol) crystallized from ethanol as yellow needles, m.p. 89–91°. Boiling points of 273–274° at 760 mm and 135° at 12 mm have been reported (23) for hydrocarbon VIII, and the *picrate* derivative has been found (23*a*) to melt at 90–92°.

Method B

A solution of 2-naphthylethyl ketone (3.0 g) in tetrahydrofuran (20 ml) was reduced with lithium aluminium hydride (6.0 g) in tetrahydrofuran (50 ml) during 3 h at room temperature. The mixture was cautiously treated with 2 *N* sulfuric acid and extracted with chloroform. Removal of solvent from the combined chloroform extracts gave a nearly quantitative yield of 1-(2-naphthyl)propanol (IX*a*), b.p. 162° at 20 mm, ν_{max}^{neat} 3 480 cm^{-1}. A 0.92 g specimen of alcohol IX*a* was reduced by the sodium borohydride (0.38 g) – boron trifluoride etherate (22 g) technique as noted above in method A. After chromatographic purification, a 0.57 g quantity of 2-(*n*-propyl)naphthalene was isolated. The product (VIII) displayed the same ultraviolet spectrum as material prepared by method A, and both the hydrocarbon (VIII) and alcohol (IX*a*) precursor were pure as evidenced by vapor phase chromatography.

Method C

An authentic specimen of hydrocarbon VIII was prepared by catalytic (0.5 g of 10% palladium on charcoal) hydrogenation (4 h with a slightly positive pressure) of 2-naphthylethyl ketone (3.0 g) in methanol (100 ml). After catalyst and solvent were removed, the pale-yellow oily product was distilled *in vacuo*. The pure sample of hydrocarbon VIII (2.7 g) displayed ultraviolet and infrared (neat) spectra and vapor phase chromatographic behavior identical with those observed for the products from methods A and B. The *picrate* derivative, m.p. 89–91°, was identical[13] with the corresponding derivative described as part of method A.

3,4-Methylenedioxyphenyl-3,4,5-trimethoxyphenylmethane (XI)

Sodium borohydride (0.24 g) – boron trifluoride etherate (16 g) reduction of 3,4-methylenedioxy-3′,4′,5′-trimethoxybenzophenone (X, 1.0 g (12)) was performed as noted above (see VIII, method A). The product (XI, 0.58 g, m.p. 56–58°) crystallized from petroleum ether as colorless plates. Two recrystallizations from the same solvent provided an analytical sample melting at 55.5–56°.

Anal. Calcd. for $C_{17}H_{18}O_5$: C, 67.54; H, 6.00; O, 26.46. Found: C, 67.89; H, 5.94; O, 26.18.

3-Hydroxy-3-(2-naphthyl)pentane (IXb)

A solution of 2-naphthylethyl ketone (16.3 g) in diethyl ether (125 ml) was added during 30 min to a solution prepared from diethyl ether (35 ml), ethyl bromide (16 g), and magnesium (3.6 g). Twenty minutes later, reaction was complete and the mixture was treated with water (20 ml) followed by 10% aqueous sulfuric acid (100 ml). The ethereal layer was separated and successively washed with water, aqueous

potassium carbonate, and water. After removal of solvent, the residue was distilled through a 6 inch Vigreux column to yield 7.7 g of tertiary alcohol IX*b* boiling at 105–106° (0.08–0.09 mm); ν_{max}^{neat} 3 400, 3 010, 2 950, 2 900, 2 840, 1 598, 1 505, 1 460, 1 375, 1 270, 1 155, 1 132, 965, 915, 900, 860, 820, and 750 cm^{-1}.

Anal. Calcd. for $C_{15}H_{18}O$: C, 84.07; H, 8.46; O, 7.14. Found: C, 83.99; H, 8.22; O, 7.63.

3-(2-Naphthyl)pentane (XIII)

Method A

Reaction between 3-hydroxy-3-(2-naphthyl)pentane (2.0 g) and sodium borohydride (0.70 g) – boron trifluoride etherate (30 g) was attempted and the product isolated as was, for example, ketone VII. Again, when the reaction was repeated with a total reaction time of only 20 min, the following results were observed. A thin-layer chromatogram (hexane as the mobile phase) of the crude oily product indicated a major component (assumed to be olefin XII*a*) as a mixture of the two geometrical isomers, accompanied by a number of more polar materials. The presence of starting material was not detected. A solution of the product in hexane was chromatographed on activated alumina. Elution with the same solvent gave 1.14 g of an oily fraction displaying two spots (believed to be the geometrical isomers of olefin IX*a*) on a thin-layer chromatogram (hexane as the mobile phase). The olefin mixture was dissolved in hexane (20 ml) and hydrogenated (under a slightly positive pressure) in the presence of 10% palladium on charcoal (0.05 g). Next, the solution was filtered and chromatographed on activated alumina (35 g). Elution with hexane gave 1.1 g of 3-(2-naphthyl)pentane (XIII); ν_{max}^{neat} 3 010, 2 950, 2 900, 2 840, 1 600, 1 509, 1 460, 1 375, 890, 858, 820, and 750 cm^{-1}; proton magnetic resonance response ($CDCl_3$ solution): triplet (J = 7 c.p.s.) at 0.76 and complex signals at 1.40–1.87, 2.14–2.52, and 6.85–7.53 δ.

Anal. Calcd. for $C_{15}H_{18}$: C, 90.85; H, 9.15. Found: C, 90.81; H, 9.13.

Method B

A solution of alcohol IX*b* (1.6 g) in methanol (15 ml) containing 1 drop of concentrated hydrochloric acid was heated at reflux for 30 min. After dilution with water, the mixture was extracted with diethyl ether. The ethereal extract was washed with water and concentrated to an oily residue. A thin-layer chromatogram (hexane as the mobile phase) of the olefin mixture (XII*a*) displayed two principal spots with R_f values identical with those observed for the olefin described in method A (see above), and a number of lesser and more polar components. The crude olefin was partially purified by column chromatography and the mixture of geometrical isomers subjected to catalytic hydrogenation as described in the preceding experiment (see method A). Final purification was again achieved by column chromatography with hexane as solvent and eluent to yield 0.68 g hydrocarbon XIII as a colorless oil.

Anal. Found: C, 90.88; H, 9.13.

The infrared (neat) and proton magnetic resonance spectra of hydrocarbon VIII prepared by methods A and B were identical.

1-(2-Naphthyl)-1-phenylpropanol (IXc)

Conversion of 2-naphthylethyl ketone (5.0 g) into tertiary alcohol IX*c* was accomplished with the Grignard reagent prepared from magnesium (3.8 g) and bromobenzene (23 g) in tetrahydrofuran solution (80 ml). Except for a 2 h period at reflux and final dilution of the reaction mixture with saturated ammonium chloride solution, the reaction and isolation of crude alcohol were carried out as illustrated in the case of tertiary alcohol IX*a*. A pure specimen of alcohol IX*c* (4.9 g) crystallized from diethyl ether – petroleum ether as prismatic needles melting at 91–92°.

Anal. Calcd. for $C_{19}H_{18}O$: C, 86.98; H, 6.92. Found: C, 87.07; H, 7.04.

1-(2-Naphthyl)-1-phenyl-prop-1-ene (XIIb)

Method A

A sample of 1-(2-naphthyl)-1-phenylpropanol (IX*c*, 1.5 g) was treated with sodium borohydride (0.43 g) – boron trifluoride etherate (24 g) and the product isolated as summarized in the case of alcohol IX*b*. A solution of the crude olefin in hexane was chromatographed on activated alumina (40 g). The fraction eluted with hexane weighed 0.95 g (XII*b*) and crystallized from diethyl ether – petroleum ether as colorless prisms (0.35 g) melting at 104–106°; λ_{max} 239, 248, 276, 286, and 297 mμ (log ϵ 4.67, 4.64, 4.06, and 3.94); ν_{max} 3 000, 2 850, 1 500, 1 490, 1 440, 1 360, 900, 850, 825, 818, 770, 755, and 700 cm^{-1}; proton magnetic resonance response ($CDCl_3$ solution): doublet (J = 7 c.p.s. (CH_3)) at 1.78, quartet (J = 7 c.p.s. (=CH—)) at 6.33, and complex signals from 7.25 to 7.85 (12 aromatic H) δ.

Anal. Calcd. for $C_{19}H_{16}$: C, 93.40; H, 6.60. Found: C, 93.59; H, 6.73.

Method B

The acid-catalyzed dehydration of alcohol IX*c* (1.5 g) in methanol (30 ml) containing concentrated hydrochloric acid (2 ml) and isolation of olefin were executed as described for alcohol IX*b*. Recrystallizing the crude product (1.4 g) from diethyl ether – petroleum ether led to 0.40 g of hydrocarbon XII*b* melting at 104–106°. The ultraviolet spectra of olefin XII*b* prepared by methods A and B were identical, and both specimens were shown[13] to represent the same substance.

3β-Hydroxy-24,24-diphenyl-4,4,14α-trimethyl-5α-23-cholane (XV)

The sodium borohydride (0.008 g) – boron trifluoride etherate (0.46 g) reagent was allowed to react with 3β,24-dihydroxy-24,24-diphenyl-4,4,14α-trimethyl-5α-cholane (0.06 g, XIV) and the product isolated as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

summarized for alcohol IXc. Crystallizing the crude material from chloroform–acetone gave 0.045 g of colorless crystals melting at 237–239°. Recrystallization from the same solvent led to a pure sample of olefin XV melting at 244–246° (ref. 24 reports m.p. 244–247°). Olefin XV was identical[13] with an authentic sample.

Triphenylmethane

Triphenylcarbinol (1.0 g) was easily reduced by sodium borohydride (0.29 g) – boron trifluoride etherate (16 g) as noted above for ketone VII. A solution of the crude hydrocarbon in hexane was chromatographed on activated alumina. Elution with the same solvent gave 0.66 g of triphenylmethane, which crystallized from diethyl ether – methanol as colorless needles (0.36 g) melting at 93–94°. The hydrocarbon was identical[13] with an authentic sample.

ACKNOWLEDGMENTS

The investigation was supported in part by Public Health Service research grants Nos. CA-04074-04 to CA-08705-01 from the National Cancer Institute, and by Smith, Kline, and French Laboratories. We are also indebted to Professor C. Djerassi and the Department of Chemistry, Stanford University, for providing one of us (G. R. P.) with facilities during the initial preparation of this manuscript. Technical assistance provided by P. A. Whitehouse with several related experiments is also gratefully acknowledged.

STEROIDS AND RELATED NATURAL PRODUCTS

XXXI. SELECTIVE REDUCTION OF ESTERS. PART B. CARBONATES[1]

GEORGE R. PETTIT[2] AND WILLIAM J. EVERS[3]

Department of Chemistry, University of Maine, Orono, Maine, and Department of Chemistry, Arizona State University, Tempe, Arizona

Received January 26, 1966

ABSTRACT

Direct reduction of several pivalate esters to neopentyl ethers has been accomplished with boron trifluoride – sodium borohydride. The utility of the reduction reaction was illustrated with esters I*c*, II*b*, and IV*a*. Under the same conditions, a selection (I*d*, II*d*, and IV*a*) of carbonate esters was found to be relatively resistant to reduction. In this respect, the carbonate esters resembled benzoate esters, and selective reduction of a ketone (II*d*) or another ester (IV*a* → IV*b*) in their presence was possible. For comparison, one xanthate ester (I*e*) was allowed to react with boron trifluoride – sodium borohydride, and only the corresponding alcohol (I*a*) was isolated. Raney nickel desulfurization of xanthate I*a* was shown to provide alcohol I*a* and hydrocarbon I*f* as principal products.

Prior studies of ester → ether reduction reactions with diborane – boron trifluoride type reagents indicated that the alcohol segment of the ester influences the yield of ether while the carbonyl portion can influence the ease of reduction. For example, a series of otherwise equivalent *n*-, *s*-, and *t*-butyl esters, when allowed to react with boron trifluoride – sodium borohydride, were transformed to the corresponding ethers with marked increments in yield (7–76%) as alkyl branching adjacent to the ester alcohol group increased (2). Under the same conditions, benzoate esters were found to be essentially unaffected (1). To define further the scope of these observations and to increase biological knowledge of steroidal ethers (e.g. see ref. 3), we have examined the reaction between boron trifluoride – sodium borohydride and several pivalate- and carbonate-type esters.

Appropriate esters derived from primary alcohol I*a* were chosen for initial model experiments. The requirements for 24-hydroxy-5β-cholane (I*a*) were conveniently met by modifying a prior route (see ref. 2 for leading literature citations) to this substance. Cholic acid was oxidized to dehydrocholic acid by a modification of the Jones' chromic acid technique, and after Wolff–Kishner reduction, the 5β-cholanic acid was reduced with commercial diborane in tetrahydrofuran.[4] Treating alcohol I*a* in pyridine solution with pivaloyl chloride gave ester I*b*. Previous experience (2) suggested that reduction of pivalate I*b* would provide neopentyl ether I*c* in approximately 10% yield, and indeed 13% conversion was realized. Although the actual reagent used in this experiment was diborane – boron trifluoride,[5] all subsequent reduction reactions were carried out with a boron trifluoride – sodium borohydride reagent.[6] Next, pivalate ester II*b*, prepared from

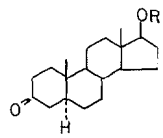
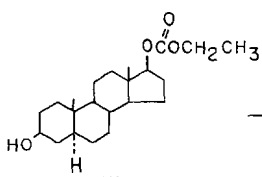
[4]*Carboxylic acids may even be reduced selectively by diborane in the presence of ketones (4a). For example, by employing a calculated amount of diborane, levulinic acid has been reduced to 4-oxopentanol (4b).*



[5]*Reaction between diborane, boron trichloride, and diethyl ether or tetrahydrofuran has been shown to yield a dichloroborane etherate with the composition* $HCl_2B \cdot OR_2$ *or, when a limited amount of boron trichloride is used, a monochloroborane etherate* ($H_2ClB \cdot OR_2$) *(5). At room temperature, chloroborane etherate was found to reduce (rapidly) certain ketones, but did not affect esters such as ethyl acetate (compare with ref. 6). Interestingly, Brown and Tierney (5a) did not detect a similar reaction between diborane and boron trifluoride. Boron trifluoride etherate has recently been expressed (5b) as* $F_2B[O(CH_2CH_3)_2]_2BF_4$.

[6]*The present series of experiments was performed by adding a solution of sodium borohydride in diglyme to the ester – boron trifluoride mixture. Except for possible lower overall ester → ether conversion (cf. ref. 2), no other important differences were noted when this "reverse" technique was used.*



3-oxo-17β-hydroxy-5α-androstane and trimethylacetyl chloride, was reduced by boron trifluoride – sodium borohydride in diglyme–tetrahydrofuran. The product was subjected to oxidation with an 8 *N* chromic acid reagent, and neopentyl ether II*c* was isolated in 55% yield. The oxidation step eliminated separation of the 3β- and 3α-hydroxy epimers formed during reduction. Interestingly, when reduction was repeated with diethyl ether in place of tetrahydrofuran, only 17% conversion into ether II*c* was noted and 21% of ester II*b* was recovered. The lower yield suggests that the rate of reduction is temperature dependent, but this point was not pursued further. Reduction of the pivalate esters illustrates a new and convenient route to neopentyl ethers[7] and further confirms that alkyl branching adjacent to the carbonyl moiety has little influence on the yield of corresponding ether(s).

Extending the reduction reaction to ethyl carbonate I*d*, prepared from alcohol I*a* and ethyl chloroformate,[8] was expected either to yield a methylenedioxy derivative or to provide an example of relative unreactivity.[9] In practice, ester I*d* was essentially unaffected (98% recovery), and when an attempt at reduction was repeated with boron trichloride (6*b*) in place of boron trifluoride, carbonate I*d* was recovered in 92% yield. Also, 3-oxo-17β-ethoxycarbonyloxy-5α-androstane (II*d*) was prepared and reduced, and the product reoxidized as with ester II*b*; a significant quantity (33%) of the starting ketoester was recovered. Decreased reactivity of carbonate ester II*d* was then demonstrated by a selective reduction sequence. Ketone II*d* was reduced by sodium borohydride in methanol

[7]*Recently, Eliel and Daignault (6a) have applied the lithium aluminium hydride – boron trifluoride reagent to reduction of thiol esters and have, for example, converted cyclohexyl thiopivalate into cyclohexyl neopentyl sulfide (33% yield).*

[8]*A recent review of reactions between chloroformates and alcohols has been prepared (7).*

[9]*If one assumes a molecular orbital picture for carbonate esters with the carbonyl group in an extended π bond overlap system, a reduced rate of reaction with diborane – boron trifluoride, as already experienced with benzoate esters (1), might be predicted.*

to a mixture of the corresponding C-3 epimeric alcohols. The more polar constituent, assumed to be equatorial alcohol III, was isolated by column chromatography and treated with trimethylacetyl chloride in pyridine. Applying the same reduction conditions (see II*b*) to diester IV*a* gave a mixture composed principally of neopental ether IV*b* and starting material (IV*a*) in essentially equal amounts (approximately 20% each). Results of the preceding reduction reactions suggest that carbonate esters, like benzoate esters, will, in general, display reduced reactivity.

The possibility that xanthate-type esters might be of greater utility than carbonates was discounted when thiocarbonate I*e* was found to yield (82%) alcohol I*a*. Since the fate of the alkoxy group during Raney nickel desulfurization of xanthate esters has, to our knowledge, not been determined (8), the present series of experiments was concluded by subjecting xanthate I*e* to desulfurization with an acid-washed (8*c*) W-4 Raney nickel. The major product was alcohol I*a* accompanied by 5β-cholane (I*f*).[10]

EXPERIMENTAL

All solvents were redistilled. A description of reagents and pretreatment of several solvents used in the present study appears in the Experimental sections of two prior contributions (1, 6*b*). Diborane (1 *M*) in tetrahydrofuran was employed as received from Metal Hydrides Division, Ventron Corp. Except for column chromatographic grade (0.02–0.5 mm) silica gel (E. Merck, A.G.) and Mallinckrodt chemical silicic acid (100 mesh), all other chromatographic and thin-layer techniques have been noted in refs. 1 and 6*b*.

After a crude reaction product had been partitioned between solvent and aqueous phase, the solvent layer was dried over anhydrous sodium sulfate or potassium carbonate. Each analytical sample was colorless, and its melting point was determined on a Kofler melting point apparatus. Unless otherwise indicated, the remaining melting points were determined in open Kimble glass capillary tubes immersed in a silicone oil bath. Optical rotation measurements (in the laboratory of Dr. C. Janssen, Beerse, Belgium) were conducted in chloroform solution. Infrared (in potassium bromide) and proton magnetic resonance (on a Varian Associates model A-60 nuclear magnetic resonance spectrometer) spectra were recorded by Dr. R. A. Hill, University of Maine. Elemental analyses were provided by Dr. A. Bernhardt, Mülheim, Germany.

3,7,12-Trioxo-5β-cholanic Acid

A solution of cholic acid (62 g) in acetic acid (370 ml) – acetone (1.5 l) was treated (room temperature, stirring) with an 8 *N* chromic acid reagent (9) until the orange color persisted for 15 min. Excess chromic acid was reduced with methanol, and solvent was removed (steam bath, *in vacuo*) until a precipitate began to separate. The solid was redissolved by adding acetic acid and the resulting solution was diluted with approximately 2 l of water. The solid product was collected, washed with water, and recrystallized from methanol (300 ml) to yield 40 g of dehydrocholic acid melting at 234–237° (ref. 10 reports m.p. 237–238°). The product was used without further purification for reduction.

24-Hydroxy-5β-cholane (Ia)

Commercial 1 *M* diborane in tetrahydrofuran (15 ml) was added to 5β-cholanic acid (2.7 g) in the same solvent (28 ml) at room temperature. Sixteen hours later the solution was diluted with water (15 ml) and diethyl ether (100 ml). The ethereal phase was separated, washed with water, and evaporated. The solid residue was recrystallized from ethyl acetate to give alcohol I*a* (2.2 g), m.p. 129.5–131° (ref. 10 reports m.p. 130.5–132.5°).

24-(2,2-Dimethyl)propionyloxy-5β-cholane (Ib)

A reaction mixture prepared from pyridine (16 ml), 24-hydroxy-5β-cholane (2.2 g), and 5 ml of 2,2-dimethylpropionyl chloride (11) was allowed to remain at room temperature for 1 h. After dilution with water (20 ml) – diethyl ether (60 ml), the ethereal solution was washed successively with water, 10% hydrochloric acid, and water. Removal of solvent (*in vacuo*) gave a viscous residue (2.3 g) which was crystallized from acetone–methanol to yield 1.8 g, m.p. 59.5–61.5°. Two recrystallizations from the same solvent system gave an analytical specimen as plates melting at 63–64°, $[\alpha]_D^{20}$ +9° (*c*, 5.63); ν_{max} 1 730, 1 282, and 1 158 cm^{-1}.

Anal. Calcd. for $C_{29}H_{50}O_2$: C, 80.86; H, 11.56; O, 7.43. Found: C, 81.34; H, 11.85; O, 6.90.

24-(2,2-Dimethyl)propoxy-5β-cholane (Ic)

Diborane (1 *M*) in tetrahydrofuran (4 ml) was added to pivalate ester I*b* (0.90 g) in tetrahydrofuran (10 ml) – boron trifluoride etherate (10 ml) and the solution was heated at reflux for 1 h. After it was cooled

[10]*Hydrocarbon If may have arisen by a Chugaev-type elimination leading to 5β-chol-23-ene, which would undergo ready hydrogenation in the presence of Raney nickel catalyst.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

water was added and the mixture extracted with hexane. The combined hexane extracts were chromatographed on activated alumina. Elution with the same solvent gave 0.12 g of neopentyl ether I*c*, which was recrystallized from acetone as plates melting at 69.5–70°, $[\alpha]_D^{20}$ +17° (*c*, 1.21), ν_{max} 1 120 cm^{-1}.

Anal. Calcd. for $C_{29}H_{52}O$: C, 83.58; H, 12.58. Found: C, 83.57; H, 12.46.

*3-Oxo-17β-(2,2-dimethyl)propionyloxy-5α-androstane (II*b*)*

Except for a 2 day reaction period at room temperature, 3-oxo-17β-hydroxy-5α-androstane (II*a*, 2.0 g) in pyridine (15 ml) – diethyl ether (20 ml) was converted into pivalate II*b* with pivaloyl chloride (5 ml) as noted for ester I*b*. Recrystallizing the product from ethyl acetate – ethanol yielded 1.4 g of ester II*b* melting at 199–200° (Fisher–Johns melting point apparatus). A pure sample was recrystallized from acetone–methanol as waxy needles, m.p. 194.5–196°, $[\alpha]_D^{20}$ +28° (*c*, 7.15); ν_{max} 1 720, 1 282, 1 171, and 1 032 cm^{-1}.

Anal. Calcd. for $C_{24}H_{38}O_3$: C, 76.96; H, 10.22; O, 12.82. Found: C, 76.94; H, 10.10; O, 12.86.

*3-Oxo-17β-(2,2-dimethyl)propoxy-5α-androstane (II*c*)*

Sodium borohydride (0.16 g) in diethylene glycol dimethyl ether (diglyme, 6 ml) was added to an ice-cold solution of pivalate II*b* (0.51 g) in tetrahydrofuran (20 ml) – boron trifluoride etherate (8 ml). Before the mixture was heated at reflux for 1 h, cooling was continued for 50 min. Next, water was added and the mixture extracted with chloroform. The combined extracts were washed with water and solvent removed *in vacuo*. Residual solid (0.47 g) was dissolved in acetone (50 ml) and treated with an 8 *N* chromic acid reagent (9) until the orange color remained for 5 min. After dilution with water (50 ml) and extraction with chloroform, removal (*in vacuo*) of solvent yielded 0.38 g of crystalline residue. A solution of the residue in benzene–chloroform (7:3) was chromatographed on activated alumina (13 g). Elution with the same solvent mixture gave 0.28 g of neopentyl ether II*c*. A thin-layer chromatogram (13:3 hexane – diethyl ether as the mobile phase) of the product displayed only one spot, and recrystallization from ethanol–water yielded 0.20 g melting at 189–191.5°. A second recrystallization from acetone gave crystals with the same melting point. The analytical sample exhibited $[\alpha]_D^{20}$ +13° (*c*, 0.73) and ν_{max} 1 715, 1 145, 1 119, and 1 102 cm^{-1}.

Anal. Calcd. for $C_{24}H_{40}O_2$: C, 79.94; H, 11.18; O, 8.88. Found: C, 79.80; H, 11.20; O, 8.82.

When the reduction was repeated with 0.27 g of pivalate ester II*b* and diethyl ether (20 ml) in place of tetrahydrofuran, only 0.047 g, m.p. 188–191°, of neopentyl ether II*c* was obtained. Continued elution of the column chromatogram with chloroform gave 0.06 g of starting ester II*b* melting at 193–195°.

*24-Ethoxycarbonyloxy-5β-cholane (I*d*)*

Ethylchloroformate (6 ml) was added during a 10 min period to 24-hydroxy-5β-cholane (I*a*, 2.0 g) in pyridine (15 ml) – benzene (40 ml). After the solution had stood for 5 min at room temperature, water (20 ml) was added, the aqueous phase discarded, and the benzene solution washed with 2 *N* hydrochloric acid and water. The benzene solution was concentrated to an oily residue, which was dissolved in 1:1 hexane–benzene and chromatographed on activated alumina (60 g). Elution with the same solvent mixture gave an oil which crystallized on standing. Recrystallization from methanol–acetone yielded 1.9 g melting at 69.5–72°. Three recrystallizations from the same solvent system gave a pure specimen as plates, m.p. 69.5–72°, $[\alpha]_D^{22}$ +28° (*c*, 1.23); ν_{max} 1 742, 1 250, 1 030, 1 010, 995, 953, 875, 859, and 792 cm^{-1}.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 77.45; H, 11.07; O, 11.46. Found: C, 77.74; H, 11.05; O, 11.47.

*Attempted Diborane – Boron Trihalide Reduction of 24-Ethoxycarbonyloxy-5β-cholane (I*d*)*

Procedure A

Reaction between carbonate ester I*d* (0.5 g) and sodium borohydride (0.11 g) – boron trifluoride etherate (13 g) was attempted essentially as described for ester II*b*, except that the hour at reflux (increased reductive cleavage) was not employed. After recrystallization from acetone–methanol, the product weighed 0.43 g, m.p. 69.5–71°, and was identical with ester I*d*.

Procedure B

The experimental approach summarized in procedure A was repeated with boron trichloride (7 ml) in place of boron trifluoride etherate. Here, reaction was carried out with diglyme (20 ml) as solvent and 0.59 g of carbonate ester I*d*. The product,[11] 0.50 g, m.p. 69.5–71°, was carbonate I*d*.

*3-Oxo-17β-ethoxycarbonyloxy-5α-androstane (II*d*)*

Preparation of ethyl carbonate II*d* (10 g crude yield, m.p. 129–136°) was accomplished by the method summarized above for obtaining ester I*d*, with appropriately adjusted quantities of reagents. The analytical specimen was recrystallized from 95% ethanol as fine plates, m.p. 138–139°, $[\alpha]_D^{22}$ +27° (*c*, 4.76); ν_{max} 1 738, 1 710, 1 270, 1 020, 992, 972, 890, 879, and 790 cm^{-1}.

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.89; H, 9.45; O, 17.65. Found: C, 72.80; H, 9.20; O, 17.86.

*Reaction of 3-Oxo-17β-ethoxycarbonyloxy-5α-androstane (II*d*) with Sodium Borohydride – Boron Trifluoride*

Ketone II*d* (1.1 g) was allowed to react with the boron trifluoride – sodium borohydride reagent as noted with pivalate ester II*b*. The crude product (1.1 g) was reoxidized with 8 *N* chromic acid reagent (cf. II*b*),

[11]*Identification was supported by the results of mixture melting point determination and infrared spectral comparison.*

and a solution of the oxidation product (0.85 g) in 17:3 benzene–chloroform was chromatographed on activated alumina (15 g). Elution with the same solvent mixture gave 0.33 g of starting carbonate ester (II*d*). Two recrystallizations from hexane gave 0.26 g of carbonate ester II*d* melting at 136–137°.[11] Continued elution with more polar solvents gave fractions with a combined weight of 0.39 g, but each was shown (by thin-layer chromatography) to contain substances considerably more polar than ester II*d*. The mixtures were not further separated.

3β-Hydroxy-17β-ethoxycarbonyloxy-5α-androstane (III)

A solution composed of 3-oxo-17β-ethoxycarbonyloxy-5α-androstane (II*d*, 8.0 g), sodium borohydride (3.0 g), and methanol (350 ml) was allowed to remain at room temperature for 3 h. After dilution with *N* hydrochloric acid (250 ml) and water (750 ml), the aqueous mixture was extracted repeatedly with diethyl ether. The combined extracts were washed with water and concentrated to a crystalline residue (6.0 g). A thin-layer chromatogram (1:1 hexane – diethyl ether as the mobile phase) of the residue indicated the presence of two substances with very similar R_f values: presumably the 3α- and 3β-isomers. A solution of the mixture in hexane – diethyl ether (3:2) was chromatographed on silica gel (430 g). A fraction eluted with the same solvent mixture gave 1.1 g of the more polar (on a thin-layer chromatogram) component. Two recrystallizations from hexane–chloroform and one from acetone led to a pure specimen of the 3β-isomer III, m.p. 132–133°, $[\alpha]_D^{20}$ +6° (*c*, 1.33); ν_{max} 3 500, 1 750, 1 740, 1 265 (broad), 1 050, 1 030, 1 014, 975, 881, and 790 cm^{-1}.

Anal. Calcd. for $C_{22}H_{36}O_4$: C, 72.49; H, 9.95; O, 17.56. Found: C, 72.52; H, 9.84; O, 17.56.

3β-(2,2-Dimethyl)propionyloxy-17β-ethoxycarbonyloxy-5α-androstane (IVa)

Alcohol III (0.16 g) was converted into pivalate ester IV*a* as described for ester II*b*. After recrystallization from 95% ethanol, ester IV*a* weighed 0.12 g and melted at 114–117°. A second recrystallization from the same solvent gave an analytical specimen as leaflets, m.p. 116–117°, $[\alpha]_D^{20}$ −10.9° (*c*, 1.83); ν_{max} 1 740, 1 720, 1 280 (broad with shoulders at 1 290 and 1 260), 1 172, 1 010, 969, 881, and 792 cm^{-1}.

Anal. Calcd. for $C_{27}H_{44}O_5$: C, 72.28; H, 9.88; O, 17.83. Found: C, 72.51; H, 10.01; O, 17.44.

3β-(2,2-Dimethyl)propoxy-17β-ethoxycarbonyloxy-5α-androstane (IVb)

Reduction of 3β-(2,2-dimethyl)propionyloxy-17β-ethoxycarbonyloxy-5α-androstane (IV*a*, 0.54 g) with boron trifluoride etherate (15 ml) – sodium borohydride (0.14 g) in tetrahydrofuran (25 ml) – diglyme (7 ml) was performed essentially as described for ester II*b*. However, 15 min at ice-bath temperature and 45 min at reflux were employed here. A solution of crude product (0.52 g) in hexane–benzene (1:1) was chromatographed on activated alumina (15 g). The same solvent eluted 0.1 g of neopentyl ether IV*b*, which was crystallized from ethanol–water as fine needles, m.p. 98–99°, $[\alpha]_D^{20}$ 0.0°; ν_{max} 1 740, 1 270, 1 109 (shoulder at 1 100), 1 018 (shoulder at 1 005), 980, 880, and 795 cm^{-1}.

Anal. Calcd. for $C_{27}H_{46}O_4$: C, 74.60; H, 10.59; O, 14.70. Found: C, 74.74; H, 10.59; O, 14.64.

A fraction eluted by 19:1 benzene–chloroform weighed 0.12 g and was identical[11] with starting diester IV*a*. Continued elution with 9:1 chloroform–methanol gave 0.23 g of a mixture of two alcohols (indicated by thin-layer chromatography), apparently arising from ester cleavage; these alcohols were not further characterized.

24-Methylthiolthiocarbonyloxy-5β-cholane (Ie)

A mixture of toluene (200 ml), 24-hydroxy-5β-cholane (I*a*, 15 g), and potassium (1.7 g) was heated at reflux for 16 h. After the solution was cooled to room temperature, carbon disulfide (5 g) was added, followed in 1 h by methyl iodide (5 ml). When a total of 4 h had elapsed, the solution was filtered and the solvent concentrated *in vacuo* to a red oil. The residue in hexane–benzene (1:1) was passed through a column of silicic acid to yield a yellow oil, which crystallized, m.p. 84–87°, upon trituration with methanol. When a thin-layer chromatogram (hexane as the mobile phase) indicated the presence of impurities, a 1.5 g portion of the product in hexane was chromatographed on acid-washed alumina (45 g). Of five fractions eluted by hexane–benzene (9:1), the fourth was pure as evidenced by a thin-layer chromatogram (hexane as the mobile phase); this fraction was recrystallized from 2-propanol–hexane to yield 0.35 g of needles melting at 87.5–89°, $[\alpha]_D^{20}$ +17.4° (*c*, 1.55); ν_{max} 1 379, 1 249, 1 225, 1 118, and 1 060 cm^{-1}.

Anal. Calcd. for $C_{26}H_{44}OS_2$: C, 71.50; H, 10.15; O, 3.66; S, 14.68. Found: C, 71.97; H, 10.10; O, 3.81; S, 14.08.

Reaction of 24-Methylthiolthiocarbonyloxy-5β-cholane (Ie) with Boron Trifluoride – Sodium Borohydride

Xanthate I*e* (2.0 g) was allowed to react with boron trifluoride (22 ml) – sodium borohydride (0.50 g) as described for ketone II*b*. A solution of crude product (1.6 g) in benzene–chloroform (4:1) was chromatographed on activated alumina. Elution with the same solvent gave 1.3 g of 24-hydroxy-5β-cholane (I*a*) melting at 130–131° after one recrystallization from ethyl acetate.[11]

Reaction of 24-Methylthiolthiocarbonyloxy-5β-cholane (Ie) with W-4 Raney Nickel

A sample (from 40 g of Raney nickel alloy) of W-4 Raney nickel (12) was washed successively with 0.4% acetic acid (2 × 500 ml), water (4 × 500 ml), 95% ethanol (2 × 100 ml), ethanol (3 × 150 ml), and tetrahydrofuran (3 × 150 ml). After the final washing, a mixture of xanthate I*e* (1.0 g) in tetrahydrofuran

(250 ml) and the nickel was heated at reflux for 14 h. The nickel residue was collected and washed with tetrahydrofuran (50 ml), and the combined filtrates were evaporated *in vacuo*. Chromatographing the crude product (0.96 g) in hexane on activated alumina and eluting with the same solvent gave 0.29 g of 5β-cholane melting at 91–92° (homogeneous on a thin-layer chromatogram with hexane as the mobile phase). Recrystallization from acetone gave 0.21 g, m.p. 91–92° (ref. 13 reports m.p. 90–91°); ν_{max} 2 950, 2 840, 1 450 (shoulder at 1 465), and 1 379 cm^{-1}; proton magnetic resonance (deuteriochloroform solution): broad response from 0.5 to 2.1 δ with methyl group signals at 0.65, 0.91, and 1.25 δ.

A series of fractions eluted by 13:7 hexane–benzene were found by thin-layer chromatography to consist of two or more components in small amounts, and were not further separated. However, the fraction eluted by chloroform provided 0.34 g of 24-hydroxy-5β-cholane[11] which melted at 130–131° after one recrystallization from ethyl acetate.

ACKNOWLEDGMENTS

This investigation was supported by Public Health Service research grants Nos. CA-04074-06 to CA-08705-01 from the National Cancer Institute, and in part by The Upjohn Co. We also thank Professor C. Djerassi and the Department of Chemistry, Stanford University, for providing facilities for one of us (G. R. P.) during the initial preparation of this manuscript.

STEREOCHEMICAL STUDIES

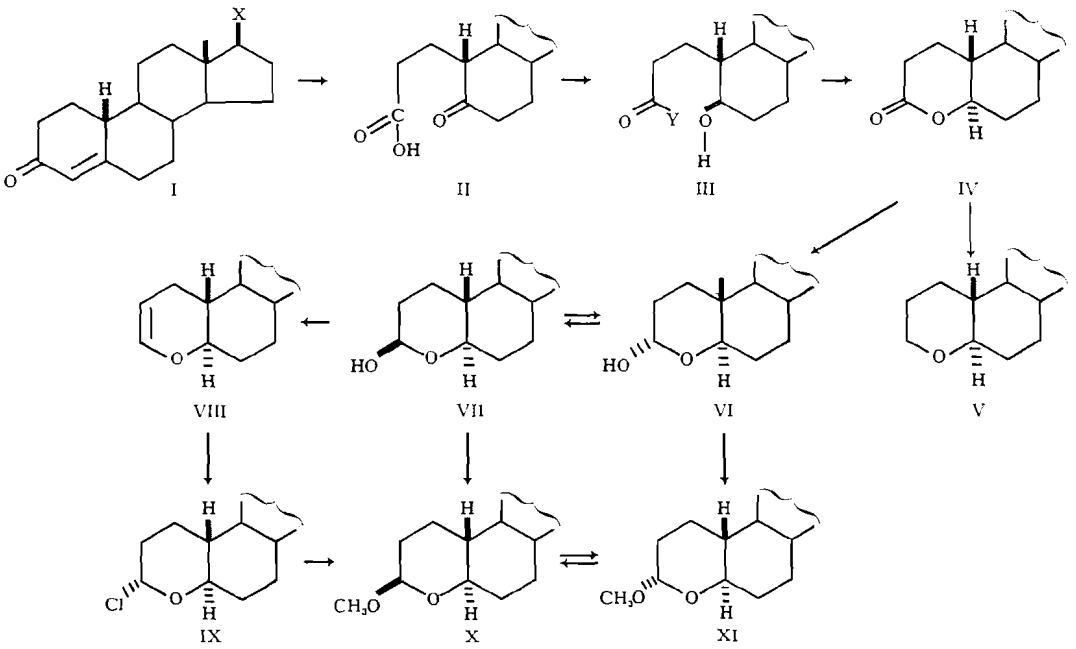
VI. REACTIONS OF 3β-HYDROXY-4-OXA-5α-ESTRANE AND 3α,17β-DIHYDROXY-4-OXA-5α-ESTRANE

J. T. EDWARD AND J.-M. FERLAND
Department of Chemistry, McGill University, Montreal, Quebec

Received November 1, 1965

ABSTRACT

The configurations at the 3 positions of 3β-hydroxy-4-oxa-5α-estrane and of 3α,17β-dihydroxy-4-oxa-5α-estrane were assigned from a study of the anomerizations of these compounds in aqueous tetrahydrofuran. 3α-Chloro-4-oxa-5α-estrane solvolyzed in alkaline methanol to give a mixture of 3α- and 3β-methoxy-4-oxa-5α-estrane, the former predominating. The difference in the solvolytic behavior of 3α-chloro-4-oxa-5α-steroids and of α-glycosyl halides is discussed.



The solvolysis of 3α-chloro-4-oxa-5α-cholestane in buffered or alkaline alcohols gives 3-alkoxy derivatives with predominant retention of configuration (1). The solvolysis of acylglycosyl halides, on the contrary, generally gives a product of inverted configuration (2) if participation by neighboring groups is avoided (3, 4) and if there is not excessive hindrance to approach of the substituting molecule (5). A possible explanation for the behavior of the steroidal chloroether was considered to be the shielding of the β face of ring A by the angular methyl group (1). Although the shielding of this ring is believed to be less complete than the shielding of rings C and D (6), it has been invoked frequently to explain cases of preferential reaction of ring A on its α face; a recent example is the hydroboration of Δ^1-, Δ^2-, Δ^3-, and Δ^4-cholestenes (7).

To test this possibility, we have synthesized a chloroether (IX, X = H) lacking the angular methyl group, and have studied the stereochemistry of its solvolysis in methanol.

Synthetic Routes

The synthetic route to the desired chloroether IX (X = H) is outlined in Reaction Scheme 1. The three-stage preparation from estrone of the unsaturated ketone I (X = H) is described in the literature (8). Ozonolysis of this ketone gave the keto acid II (X = H), which was reduced with sodium borohydride to the hydroxy acid III (X = H, Y = OH). On acidification, the latter formed the lactone IV (X = H). The α configuration at the 5 position of the lactone was indicated by its nuclear magnetic resonance (n.m.r.) spectrum (discussed in ref. 9), and by the negative shift in molecular rotation (Table I) when it was hydrolyzed in alkaline solution (10, 11). Hydrogenation of the lactone over platinum in acetic acid containing a small amount of perchloric acid gave the ether V (X = H), whereas reduction with lithium aluminium hydride (cf. refs. 1 and 12) or diborane (cf. ref. 13) gave the cyclic hemiacetal VII (X = H). The evidence for the β configuration of the hydroxyl group of the crystalline hemiacetal is discussed below. An examination of the ultraviolet and infrared spectra of the hemiacetal in solution and in the solid state revealed no detectable amount of hydroxyaldehyde present (cf. ref. 1).

Dehydration of the hemiacetal with phosphorus oxychloride in pyridine yielded the dihydropyran VIII (X = H), which in ether solution added hydrogen chloride (cf. refs. 1 and 14) to give the reactive chloroether IX (X = H). This reaction is known to be reversible (1, 15), and the sample of chloroether sent for analysis lost hydrogen chloride completely when allowed to stand, and analyzed as the dihydropyran. However, the

REACTION SCHEME 1.

freshly prepared chloroether used in our experiments was free from the dihydropyran, as shown by the absence from its n.m.r. spectrum of characteristic peaks at 3.74 τ (doublet, J 6.0 c.p.s.) and 4.47 τ (triplet, J 6.0 c.p.s.) caused by the 3- and 2-hydrogen atoms, respectively, of VIII (X = H). Instead, the spectrum showed a single one-proton peak at 3.77 τ having a half-width of 6 c.p.s., diagnostic of an equatorial hydrogen (16, p. 154; 17). Furthermore, the infrared spectrum showed a band at 581 cm^{-1} characteristic of an axial chlorine atom (18), and no trace of the peaks at 3 058 and 1 652 cm^{-1} found in the spectrum of the dihydropyran.

The α configuration of the chlorine atom indicated by these spectral data was in accord with the molecular rotation of the compound. The 3β-chloroether should have about the same molecular rotation as the parent ether V (X = H), and the 3α-chloroether should have a more positive molecular rotation (1, 19, 20). The chloroether obtained in our work did indeed have a more positive molecular rotation (Table II), although much less than anticipated from the rotation of 3α-chloro-4-oxa-6α-cholestane (1). This may indicate a small deformation in ring A when the angular methyl group is present (cf. ref. 21); Brewster (19) has already drawn attention to this possibility.

TABLE I

Molecular rotation ($[M]_D$) values of lactones and of compounds derived from them

Lactone	$[M]_D$	Derived compound	$[M]_D$	$\Delta[M]_D$

*THF = tetrahydrofuran.

This axial configuration of the chlorine atom was expected; the compound having equatorial chlorine would be less stable, because of the "anomeric effect" (1, 3, 15, 21–25), and would be expected to isomerize easily to the axial compound. For the same reason, glycosyl halides are generally more stable when the halogen is in an axial orientation (2, 3, 20, 24, 26), and frequently the equatorial halide is so unstable as to elude isolation. For compound IX (X = H), the data of Lemieux and Hayami (24) indicate that the 3β isomer, if in equilibrium with the 3α isomer, would be present to the extent of about 5%. Such an amount would be close to the limit of detection by our spectroscopic methods.

An attempt was made to synthesize 17β-acetoxy-3α-chloro-4-oxa-5α-estrane (IX, X = OAc) by a similar reaction sequence, starting with commercially available 19-nortestosterone acetate (I, X = OAc). This attempt succeeded as far as the hemiacetal VI (X = OH), but was frustrated by our failure to prepare a crystalline diacetate of this hemiacetal. The 5α configuration of the lactone IV (X = OH), and of the compounds derived from it, was indicated by its n.m.r. spectrum (9) and by the sign of the rotational shift when the lactone ring was opened to form the hydroxyamide (III; X = OH, Y = NH_2) or the sodium salt of the hydroxy acid (III; X = OH, Y = O^-) (Table I).

After most of this work was completed (27), Pettit *et al.* (28) described the synthesis of the lactone IV (X = OAc) by direct oxidation of 19-nortestosterone acetate with persulfuric acid, and its further conversion into the hemiacetal VI (X = OH). We had also used persulfuric acid to oxidize nortestosterone to the hydroxylactone IV (X = OH) in low yield (27). This reaction would be expected, on the basis of Pettit's mechanism (13) and of the known stereospecificity of the Baeyer–Villiger reaction (29), to yield a 5α-lactone, and hence may be construed as further evidence for the configurations shown in Reaction Scheme 1.

During the present work it was found that δ-lactones such as IV (X = H or OH) and others (see Experimental) were hydrogenolyzed over Adams' catalyst in acetic acid containing a small amount of perchloric acid to yield cyclic ethers.* The rate of the reaction varied greatly with different batches of catalyst. With any one batch it was strongly dependent on the concentration of perchloric acid, as shown in Table III. This unexpected

TABLE III

Effect of addition of differing volumes of 70% perchloric acid to the solvent acetic acid (5 ml) on the rate of absorption of hydrogen by 4-oxa-5α-cholestan-3-one*

Volume of perchloric acid (ml)	Initial rate (ml/min)
0	0.13
0.02	0.58
0.03	0.78
0.05	0.47
0.06	0.44
0.12	0.36

*Conditions: 20 mg lactone, 10 mg prereduced platinum oxide, magnetic stirring.

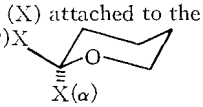
reaction accounts for the low yields of lactones sometimes obtained (e.g. refs. 11 and 31) from the hydrogenation of keto acids in acetic acid. Thus hydrogenation of II (X = OH) with 1 mole of hydrogen yielded a mixture of lactone IV (X = OH), ether V (X = OH), and starting material; hydrogenation with an excess of hydrogen gave the ether in good yield. The stereochemistry of this hydrogenation is discussed in ref. 9.

Solvolysis of 3α-Chloro-4-oxa-5α-estrane in Alkaline Methanol

Solvolysis of the chloroether IX (X = H) in alkaline methanol gave a mixture from which two isomeric methoxy compounds (X and XI; X = H) were isolated. The configurations of these methoxy compounds were shown by their differing n.m.r. spectra. For both compounds the peak at lowest field must be due to the anomeric 3-hydrogen atom, and numerous studies (17, 32) have shown that this peak is at higher field and has a greater width when the hydrogen atom is axial than when it is equatorial. Consequently, the isomer having this peak at 5.46 τ (half-width 4 c.p.s.) must be the 3α-methoxy derivative (XI, X = H), and the isomer having it at 5.83 τ (half-width 16 c.p.s.) must be the 3β-methoxy derivative (X, X = H). The latter peak was a poorly resolved quartet. These values of chemical shift and half-width agree closely with those found for the anomeric protons of 2-methoxy-4-methyltetrahydropyran (25).

These configurations were also indicated by the molecular rotations of the compounds, which agreed well with the values calculated by Brewster's method (19) (Table II). The calculations made use of group parameters (Table IV) that were slightly altered from Brewster's parameters to give better agreement between the calculated and observed rotations of 4-oxa-5α-steroids,† including compounds from previous studies (1, 15).

The proportions of 3-methoxy anomers obtained from the solvolysis of the chloroether IX (X = H) were: 78% of the α anomer (XI, X = H) and 22% of the β anomer (X, X = H). These are almost the proportions in which the 3α- and 3β-benzyloxy derivatives



*A preliminary account of this reaction has been published (30).

†The superiority, for our purposes, of the revised parameters in Table IV may be explained by the particular solvents used in our studies. Brewster's calculations take no account of the effect of solvent, although obviously the extent to which a group is solvated will affect its torsional asymmetry and hence its effect on molecular rotation. The large effect of changing solvent is apparent from the data in Table I, ref. 1.

TABLE IV

Contributions to molecular rotation of groups (X) attached to the tetrahydropyran ring in the conformation:

Group X	Brewster's parameters	Revised parameters
α-Hydroxyl	+100	+170
β-Hydroxyl	0	−30
α-Methoxyl	+205	+275
β-Methoxyl	−105	−115

were formed in the solvolysis of 3α-chloro-4-oxa-5α-cholestane in benzyl alcohol. The exact proportions of 3α- and 3β-methoxy derivatives formed from the solvolysis of the latter chloroether in methanol are not known, although the 3α-methoxy derivative clearly preponderated (1).

It thus becomes apparent that the angular methyl group at the 10 position has little or no effect on the stereochemistry of the displacement reactions of 3-chloro-4-oxa-5α-steroids. It would seem that the intermediate oxocarbonium ion (see ref. 1 for a detailed discussion of the mechanism) has an inherent tendency to react on its α rather than its β face. A similar tendency is shown by 19-nor-5α-steroids having a 3:4 double bond in adding diborane (33), although the absence of the angular methyl group makes the preference for reaction on the α face less complete (7). Various speculations based on stereoelectronic considerations may be advanced to explain this behavior (34), but discussion is best deferred until more experimental data have been accumulated.

If oxocarbonium ions derived from chlorotetrahydropyrans in the C1 conformation (35) have this tendency to react on their α face, the question arises: why do the ions derived from most α-glycosyl halides in this conformation react with alcohols on their β face? A possible explanation lies in the greater reactivity of the latter oxocarbonium ions, destabilized by many electron-withdrawing methoxy or acetoxy groups. For this reason these ions ("encumbered ions") will react with alcohol before the halide ion formed by rupture of the carbon–halogen bond has diffused away and while it is still blocking the α face.

Acid-Catalyzed Mutarotation of 3α- and 3β-Methoxy-4-oxa-5α-estrane

Although 3α- and 3β-methoxy-4-oxa-5α-estrane are stable in neutral or alkaline solution, in acidic methanol either one is rapidly converted into an equilibrium mixture, shown by its optical rotation to contain 67% of the 3α and 33% of the 3β compound (Fig. 1). About the same proportions (65% of 3α, 35% of 3β) were obtained by reaction of the hemiacetal VII (X = H) with methanol containing 3% hydrogen chloride, neutralization, and isolation of the products by chromatography. As expected (36), the 3β isomer, having the equatorial methoxyl group, was eluted more slowly than the 3α compound from the chromatographic column.

The proportions of the α and β anomers are about the same as those found from the equilibration of 3-alkoxy-4-oxa-5α-cholestanes (15).

Mutarotation of 3β-Hydroxy-4-oxa-5α-estrane and 3α,17β-Dihydroxy-4-oxa-5α-estrane

The optical rotation of 3β-hydroxy-4-oxa-5α-estrane (VII, X = H) dissolved in chloroform did not change when the solution was allowed to stand. However, in 90% (v/v) aqueous tetrahydrofuran the rotation increased, following a first-order rate equation (Fig. 2). This indicated a partial conversion into 3α-hydroxy-4-oxa-5α-estrane (VI,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

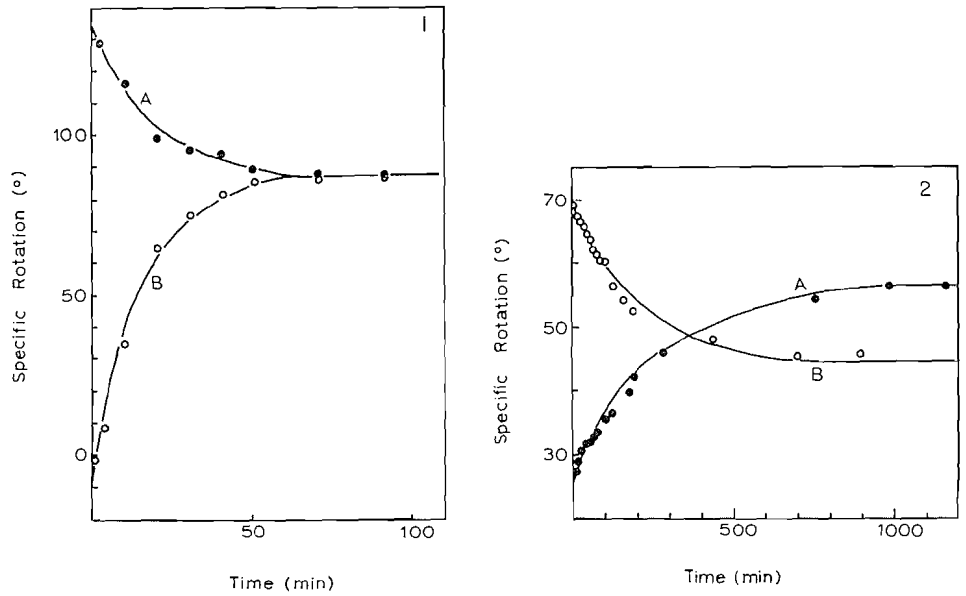

FIG. 1. Change in specific rotation of 3α- (A) and 3β-methoxy-4-oxa-5α-estrane (B) in methanol–tetrahydrofuran (1:1 v/v) containing 0.012 *M* hydrogen chloride at 24 ± 0.5°. Points: experimental; curves: theoretical for first-order reactions having $k = 0.063$ min^{-1}.

FIG. 2. Change in specific rotation of (A) 3β-hydroxy-4-oxa-5α-estrane and (B) 3α,17β-dihydroxy-4-oxa-5α-estrane in tetrahydrofuran–water (9:1 v/v) at 24 ± 0.5°. Points: experimental; curves: theoretical for first-order reactions having rate constants of (A) 0.0044 min^{-1} and (B) 0.0052 min^{-1}.

X = H), known from Hudson's rules of isorotation (37; cf. also ref. 19) to have a higher rotation. The molecular rotation of the 3α compound, estimated by Brewster's method (19) with the revised parameters of Table IV, is given in Table II. If this value is accepted, it may be calculated that the equilibrium mixture contains 41% of the 3α and 59% of the 3β isomer at equilibrium.

These results received a rough confirmation from n.m.r. analysis of equilibrated material isolated at a low temperature as quickly as possible (and so, it was hoped, with as little change in composition as possible during the isolation process). In pure, dry dimethyl sulfoxide this isolated material showed unresolved multiplets* at 3.83 and 4.26 τ caused by hydroxyl hydrogens, since they disappeared on treatment of the solution with deuterium oxide, and peaks at 5.00 and 5.56 τ caused by 3β and 3α protons. Pure 3β-hydroxy-4-oxa-5α-estrane showed only the peaks at 3.83 and 5.56 τ. The relative areas of peaks in the spectrum of the mixture indicated that it contained 38% of the 3α-hydroxy and 62% of the 3β-hydroxy anomers.

The chemical shifts of the anomeric hydroxyls are at higher field than the values for the anomeric hydroxyls of the common monosaccharides in dimethyl sulfoxide (39), as should be expected from the presence of many electron-withdrawing hydroxyl groups in the latter, but have the same order: axial hydroxyls absorb at higher field than equatorial hydroxyls. Thus, both n.m.r. data and optical rotation show the crystalline hemiacetal to have the 3β-hydroxy structure (VII, X = H). On the other hand, the crystalline hemiacetal isolated from the reduction of IV (X = OH) has the 3α-hydroxy structure (VI, X = OH). This is apparent from its molecular rotation (Table II), and from the

**The anomeric hydroxyl, perhaps because of its greater acidity, differs in this respect from the hydroxyl of secondary alcohols, which in dimethyl sulfoxide gives rise to a doublet (38).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

decrease in optical rotation of a solution in tetrahydrofuran–water (90:10 v/v) when it is allowed to stand (Fig. 2). If the calculated value shown in Table II for the molecular rotation of the 3β isomer is accepted, the final rotation indicates the equilibrium mixture to consist of 43% of the 3α and 57% of the 3β isomer.

The 3-hydroxy-4-oxa-5α-estranes thus differ from 3-hydroxy-4-oxa-5α-cholestane, in which the 3α isomer predominates at equilibrium (1). (If the revised molecular rotation for 3β-hydroxy-4-oxa-5α-cholestane given in Table II is accepted, the equilibrium mixture contains 61% of the 3α isomer, and not 55% as reported earlier (1).) However, the differences (in terms of free energy differences) are small, and may reflect slight changes in the shape of ring A brought about by the presence of the angular methyl group.

The predominance at equilibrium of the 3α-methoxy over the 3β-methoxy isomer is more decisive in both the 4-oxa-5α-cholestane and the 4-oxa-5α-estrane series. This predominance of the α isomer has also been noted in the mutarotation of methyl glycosides; in contrast, in the mutarotation of the parent sugars the β isomer may predominate (16, p. 411). It is apparent that in these equilibria the hydroxyl group behaves as a "larger" group than the methoxyl group, probably because of solvent interactions (25).

EXPERIMENTAL

Melting points were determined in a Gallenkamp apparatus and are corrected. Optical rotations were measured with a Carl Zeiss automatic polarimeter with chloroform as solvent. Infrared spectra were determined on a Perkin–Elmer 337 grating spectrophotometer with 1 mm sodium chloride cells and carbon tetrachloride as solvent. Nuclear magnetic resonance spectra were recorded on a Varian A-60 instrument with carbon tetrachloride as solvent. Woelm alumina was used for column chromatography, and Merck A.G. silica gel for thin- and thick-layer chromatography. Magnesium sulfate was used to dry all solvent extracts before concentration.

5-Oxo-3,5-seco-4-norestran-3-oic Acid (II, X = H)

A solution of 3-oxoestra-4-ene (I, X = H) (20 g (8)) in glacial acetic acid (300 ml) and ethyl acetate (300 ml) was cooled in an ice bath while being treated with oxygen containing ozone for 1.5 h. The solution was allowed to warm to room temperature, an aqueous 10% solution of hydrogen peroxide (60 ml) was added, and the mixture was left overnight. It was diluted with ether (2 l) and washed with water to remove acetic acid and hydrogen peroxide; the acidic product was then dissolved in 2% sodium hydroxide solution. Acidification of this solution gave an oil which was dissolved in ether and crystallized from hexane to give colorless crystals (13.9 g, 64%), m.p. 116–119°. After recrystallization several times from hexane – methylene chloride it melted at 117–119°, $[\alpha]_D^{20}$ −8.84° (*c*, 1.08).

Anal. Calcd. for $C_{17}H_{26}O_3$: C, 73.34; H, 9.41. Found: C, 73.12; H, 9.20.

3-Oxo-4-oxa-5α-estrane (IV, X = H)

The keto acid II (X = H) (4.00 g) in ethanol (300 ml) – water (100 ml) was treated with sodium borohydride (2.00 g) in water (20 ml) for 3 h at room temperature. The reaction mixture was poured into ice water, acidified with concentrated hydrochloric acid, and extracted with ether. Evaporation of the ether gave a solid which was crystallized from methanol–water to give a first crop (2.01 g), m.p. 128–130°, and a second crop (0.52 g), m.p. 125–129°; total yield, 70%. Two more recrystallizations from methanol–water gave an analytical sample, m.p. 135–136°, $[\alpha]_D^{24}$ +92.3° (*c*, 0.72), ν_{max} 1 748 cm^{-1}.

Anal. Calcd. for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99. Found: C, 77.74; H, 9.98.

4-Oxa-5α-estrane (V, X = H)

3-Oxo-4-oxa-5α-estrane (0.200 g) in acetic acid (15 ml) containing 70% perchloric acid (0.05 ml) was hydrogenated over platinum oxide (0.105 g) until there was no further uptake of hydrogen. The solution was filtered, diluted with ether, washed with 2% sodium hydroxide solution and with water, and dried. Evaporation of the ether left a solid which crystallized from methanol–ether as needles (0.162 g, 89% yield), m.p. 74–76°, $[\alpha]_D^{24}$ +37.5° (*c*, 1.08).

Anal. Calcd. for $C_{17}H_{28}O$: C, 82.20; H, 11.36. Found: C, 81.88; H, 10.86.

3β-Hydroxy-4-oxa-5α-estrane (VII, X = H)

(a) With Diborane

Diborane generated from sodium borohydride (5.00 g) and boron trifluoride etherate (27 ml) in diethylene glycol dimethyl ether (100 ml) was passed in a stream of nitrogen through dry tetrahydrofuran and then into a solution of lactone IV (X = H) (2.05 g) in dry tetrahydrofuran (100 ml). After 3 h the solution was poured

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

into ice water and extracted with ether. The oily residue from the extract was chromatographed on neutral alumina. Elution with benzene–ether (70:30 v/v) removed a solid (0.982 g, 49%) melting at 138–142°; on recrystallization from hexane – methylene chloride this solid melted at 143–144°, $[\alpha]_D^{24}$ +62.4° (*c*, 1.11), ν_{max} 3 610 cm^{-1}.

Anal. Calcd. for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67. Found: C, 76.96; H, 10.40.

(b) With Lithium Aluminium Hydride

Lithium aluminium hydride (58 mg) in anhydrous, peroxide-free tetrahydrofuran (50 ml) was added under nitrogen over a period of 5 min to a stirred solution of lactone IV (X = H) (2.00 g) in tetrahydrofuran (50 ml) cooled by an ice bath. The mixture was allowed to warm to room temperature and stirred for another 60 min. It was then poured into cold 1 *N* sulfuric acid (100 ml). A white solid precipitated and was removed by filtration, washed with water, and dissolved in ether. The ether solution was dried ($MgSO_4$) and evaporated, and the residue crystallized from hexane as a white solid (1.47 g, 74%), m.p. 139–142°. A recrystallized sample was shown by mixed melting point and infrared spectrum to be identical with the 3β-hydroxy-4-oxa-5α-estrane obtained above.

4-Oxa-5α-estra-2-ene (VIII, X = H)

A solution of 3β-hydroxy-4-oxa-5α-estrane (0.500 g) and phosphorus oxychloride (1.5 ml) in pyridine (5 ml) was refluxed for 1 h. The solution was cooled, diluted with water, and extracted with ether. The ethereal solution, on evaporation, gave an oily residue which crystallized from methanol–ether as plates (0.382 g, 81%), m.p. 59–62°. Recrystallization raised the melting point to 61–63°, $[\alpha]_D^{24}$ +125° (*c*, 0.66), ν_{max} 3 058 and 1 652 cm^{-1}, ϵ_{210} 5 000 (in cyclohexane; end absorption only).

Anal. Calcd. for $C_{17}H_{26}O$: C, 82.87; H, 10.64. Found: C, 83.13; H, 10.18.

3α-Chloro-4-oxa-5α-estrane (IX, X = H)

A solution of 4-oxa-5α-estra-2-ene (0.300 g) in anhydrous ether (20 ml) saturated with dry hydrogen chloride was kept under nitrogen for 2 h. Evaporation of the ether by a jet of dry nitrogen left crystals which sintered at 78°, m.p. 84–88°, $[\alpha]_D^{24}$ +74.0° (*c*, 1.00), ν_{max} 580 cm^{-1}. The compound contained chlorine, and was used immediately, without purification. A sample sent for analysis appeared to have decomposed to starting material.

3α- and 3β-Methoxy-4-oxa-5α-estrane (X and XI; X = H)

(a) From 3β-Hydroxy-4-oxa-5α-estrane

A solution of the hemiacetal VII (X = H) (0.360 g) in a mixture of anhydrous ether (15 ml) and anhydrous methanol (15 ml) containing 3% hydrogen chloride was refluxed for 30 min. To the cooled solution was added excess silver carbonate (40) (3 g), with stirring. The silver salts were removed by filtration and washed with anhydrous ether. The filtrate and washings, evaporated at reduced pressure, left an oil which was chromatographed on alumina (50 g, neutral, grade II). Elution with hexane removed 3α-methoxy-4-oxa-5α-estrane (XI, X = H) (0.234 g), m.p. 59–62°. This was purified by thick-layer chromatography to give a solid, m.p. 61–63°, $[\alpha]_D^{24}$ −8.2° (*c*, 0.75).

Anal. Calcd. for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86. Found: C, 77.61; H, 10.42.

Elution with hexane–benzene (80:20 v/v) removed the 3β isomer (X, X = H) (0.116 g) which, after purification by thick-layer chromatography, melted at 79–81°, $[\alpha]_D^{24}$ +125° (*c*, 0.71).

Anal. Calcd. for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86. Found: C, 77.97; H, 10.64.

(b) From 3α-Chloro-4-oxa-5α-estrane

Sodium (70 mg) was dissolved in absolute methanol (15 ml), and the 3α-chloro compound (IX, X = H) (0.250 g) was added. The solution was refluxed for 1 h, and the solvent then removed under reduced pressure. The residue was treated with water (15 ml) and ether (30 ml), and the ether layer was washed with water, dried, and evaporated. The oil thus obtained was chromatographed on alumina (50 g, neutral, grade II). Elution with hexane removed the 3α compound (XI, X = H) (0.179 g, 78%), m.p. 59–62°, identical (mixed melting point and infrared spectrum) with the 3α compound described above. Elution with hexane–benzene (80:20 v/v) removed the 3β compound (X, X = H) (0.050 g, 22%) as an oil. Thick-layer chromatography of this oil gave a solid which was identical (mixed melting point and infrared spectrum) with the 3β-methoxy compound described above.

17β-Hydroxy-5-oxo-3,5-seco-4-norestran-3-oic Acid (II, X = OH)

19-Nortestosterone acetate (I, X = OAc) (1.007 g) dissolved in ethyl acetate (60 ml) was treated with oxygen containing 6% ozone for 1 h at room temperature. Hydrogen peroxide (10%, 6 ml) and methanol (10 ml) were then added and the mixture was left overnight. It was concentrated to half volume, diluted with ether, and extracted with 2% sodium hydroxide. The alkaline extract, after standing for 12 h, was acidified and the keto acid dissolved in ether. Removal of the ether gave a crystalline solid (0.813 g, 95%), m.p. 85–92°. Two crystallizations from acetone–hexane gave the pure keto acid (II, X = OH), m.p. 108–109°, $[\alpha]_D^{24}$ +1.8° (*c*, 0.449), $\nu_{max}^{CHCl_3}$ 3 538 and 1 710 cm^{-1}.

Anal. Calcd. for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90. Found: C, 69.27; H, 8.79.

17α-Acetoxy-5-oxo-3,5-seco-4-norestran-3-oic Acid (II, X = $OCOH_3$)

Potassium carbonate (0.28 g) in water (4 ml) was added, with vigorous stirring, to a solution of 19-nortestosterone acetate (0.500 g) in *t*-butanol–water azeotrope (30 ml), followed by 5 ml of a solution prepared from sodium metaperiodate (2 g) and water (25 ml), and then 0.5 ml of 0.8% aqueous potassium permanganate. The rest of the periodate was added at a rate of 5 ml/min for 2 min and then 2 ml/min for 5 min. Permanganate solution was added as necessary to maintain the purple color.

After 1 h excess permanganate was destroyed with sodium bisulfite. The solution was concentrated at reduced pressure to 30 ml, cooled to 4°, acidified with ice-cold 50% sulfuric acid, and extracted with ether. The ethereal extract was washed with sodium bisulfite until free from iodine, and then with water. Evaporation gave an oil (0.446 g) which was chromatographed on 3% deactivated silica gel. Elution with ether removed a crystalline fraction (0.068 g, 12%), m.p. 80–89°, which, after two recrystallizations from methanol–water, gave keto acid II (X = $OCOCH_3$), m.p. 114–115°, $[\alpha]_D^{24}$ −3.8° (*c*, 0.457), ν_{max} 1 708 and 1 733 cm^{-1} (lit. (41) m.p. 113–115°, $[\alpha]_D^{28}$ −4.08°).

Anal. Calcd. for $C_{19}H_{28}O_5$: C, 67.83; H, 8.39. Found: C, 67.52; H, 8.33.

17β-Hydroxy-3-oxo-4-oxa-5α-estrane (IV, X = OH)

(a) With Sodium Borohydride

A mixture of keto acid II (X = OH) (1.00 g) in 25% aqueous ethanol (50 ml), and of sodium borohydride (1.00 g) in water (15 ml), was left overnight and then heated under reflux until decomposition of the borohydride was complete. The solution was acidified to pH 3, concentrated under reduced pressure to half volume, and diluted with ice-cold water. After 12 h a crystalline solid (0.404 g, 52%), m.p. 105–115°, was collected. Recrystallization from ethyl ether yielded pure 17β-hydroxy-3-oxo-4-oxa-5α-estrane, m.p. 131–132°, $[\alpha]_D^{24}$ +70.1° (*c*, 0.502), $\nu_{max}^{CHCl_3}$ 3 630 and 1 725 cm^{-1} (lit. (28) m.p. 132–134°, $[\alpha]_D^{20}$ +78.9°).

Anal. Calcd. for $C_{17}H_{26}O_3$: C, 73.31; H, 9.41. Found: C, 73.09; H, 9.13.

(b) With Lithium Aluminium Tri-t-butoxy Hydride

Keto acid II (X = OH) (0.972 g) dissolved in tetrahydrofuran (15 ml) was added to a suspension of lithium aluminium tri-*t*-butoxy hydride (4.0 g) in the same solvent (15 ml). The mixture was left at 0° for 30 min and at room temperature for 60 min, and then was poured into an excess of dilute hydrochloric acid. When allowed to stand overnight the solution deposited a solid (0.575 g, 61%) which, after recrystallization from ethyl ether, melted at 131–132°, $[\alpha]_D^{24}$ +70.1° (*c*, 0.504), $\nu_{max}^{CHCl_3}$ 3 630 and 1 725 cm^{-1}.

(c) With Potassium Persulfate

A solution of 19-nortestosterone acetate (0.999 g) in glacial acetic acid (22 ml) was treated with a mixture of potassium persulfate (1.3 g) and sulfuric acid (1.4 g) in acetic acid (22 ml) according to procedures already described (28). The product, after saponification with potassium hydroxide in aqueous dioxane, was obtained as an oil (0.158 g) which crystallized from ethyl ether, m.p. 131–132°, $[\alpha]_D^{24}$ +70.4° (*c*, 0.517), identical by mixed melting point and infrared spectrum with the product obtained in experiments *a* and *b* above.

5β,17β-Dihydroxy-3,5-seco-4-norestran 3-Carboxamide (III; X = OH, Y = NH_2)

A solution of 17β-hydroxy-3-oxo-4-oxa-5α-estrane (0.200 g) in methanol (20 ml) saturated with ammonia deposited needles of the hydroxyamide (III; X = OH, Y = NH_2) (0.165 g) which, after recrystallization from methanol, melted at 298–300°, $[\alpha]_D^{24}$ +18.8° (*c*, 0.461 in methanol); ν_{max}^{KBr} 3 465, 3 360, 3 180, 1 680, and 1 610 cm^{-1}.

Anal. Calcd. for $C_{17}H_{29}O_3N$: C, 69.11; H, 9.90; N, 4.74. Found: C, 69.31; H, 9.73; H, 4.91.

On treatment with dilute hydrochloric acid the amide regenerated the lactone (IV, X = OH), identified by melting point, mixed melting point, infrared spectrum, and optical rotation.

17β-Hydroxy-4-oxa-5α-estrane (V, X = OH)

(a) From Reduction of 17β-Hydroxy-3-oxo-4-oxa-5α-estrane with Lithium Aluminium Hydride – Boron Trifluoride

17β-Hydroxy-3-oxo-4-oxa-5α-estrane (0.262 g) dissolved in boron trifluoride – ether complex (0.840 g) was added to a suspension of lithium aluminium hydride (0.080 g) in ether (50 ml). The mixture was left at 0° for 1 h, refluxed for 2 h, and poured into an excess of dilute hydrochloric acid. The aqueous mixture was extracted with ether, and the extract washed with 2% sodium hydroxide and with water. Evaporation of the ether gave a crystalline solid (0.216 g, 86%), m.p. 166–168°, raised by two recrystallizations from ether to 173–175°, $[\alpha]_D^{24}$ +42.8° (*c*, 0.492) (lit. (26) m.p. 175–176°, $[\alpha]_D^{20}$ +28.8°).

Anal. Calcd. for $C_{17}H_{28}O_2$: C, 77.22: H, 10.67. Found: C, 77.15; H, 10.63.

(b) From Hydrogenation of 17β-Hydroxy-3-oxo-4-oxa-5α-estrane

17β-Hydroxy-3-oxo-4-oxa-5α-estrane (0.200 g) dissolved in glacial acetic acid (15 ml) was hydrogenated over Adams' catalyst (0.090 g) until no more hydrogen was absorbed (2 h). The catalyst was removed by filtration and the product, worked up as above, was obtained as a white crystalline solid (0.185 g, 90%), m.p. 173–175°, identical (mixed melting point, infrared spectrum, and optical rotation) with the product obtained above. The same compound was obtained in 87% yield by hydrogenation of the lactone in acetic acid (15 ml) containing 70% perchloric acid (0.1 ml), hydrogenation now being complete in 45 min.

(c) From Hydrogenation of 17β-Hydroxy-5-oxo-3,5-seco-4-norestran-3-oic Acid

Keto acid II (X = OH) (0.831 g) in glacial acetic acid (15 ml) was hydrogenated over Adams' catalyst (0.420 g) at room temperature and pressure. After 48 h, 3.7 moles of hydrogen/mole of keto acid had been absorbed. The catalyst was removed by filtration and the filtrate diluted with ether. The ether solution was washed with 2% aqueous sodium hydroxide and water. Evaporation gave colorless needles (0.545 g, 74%), m.p. 168–172°, raised by recrystallization from ether to 173–175°, $[\alpha]_D^{21}$ +42.6° (*c*, 0.496), $\nu_{max}^{CHCl_3}$ 1 103 and 1 093 cm^{-1}.

Hydrogenation of 17β-Hydroxy-5-oxo-3,5-seco-4-norestran-3-oic Acid with 1 Mole of Hydrogen

In the presence of Adams' catalyst (0.420 g), keto acid II (X = OH) (1.142 g) dissolved in glacial acetic acid (15 ml) absorbed the theoretical amount of hydrogen after 2½ h at room temperature and pressure. The catalyst was removed by filtration, and the filtrate diluted with ether and washed with 2% sodium hydroxide solution. The ether solution, on evaporation, gave an oil (0.142 g, 14%) that slowly crystallized and which, after recrystallization, was identified (melting point, mixed melting point, and infrared spectrum) as 17β-hydroxy-4-oxa-5α-estrane.

The sodium hydroxide solution was acidified and extracted with ether. The ether solution was washed with 5% sodium carbonate and with water, and dried. Evaporation of the ether gave an oil (0.487 g) which was chromatographed over activated silica gel. The fractions (0.287 g, 26%) eluted with benzene–ether (50:50 v/v) crystallized from ether to give 17β-hydroxy-3-oxo-4-oxa-5α-estrane, m.p. 125–129°, $[\alpha]_D^{21}$ +67.6° (*c*, 0.492), identified by mixed melting point, thin-layer chromatography, and infrared spectrum.

The sodium carbonate solution, after acidification, gave the starting keto acid II (X = OH) (0.456 g, 40%).

Preparation of Tetrahydropyrans by Hydrogenolysis of δ-Lactones

(a) 4-Oxa-5α-cholestane

3-Oxo-4-oxa-5α-cholestane (0.200 g) in acetic acid (15 ml) containing 70% perchloric acid (0.1 ml) was hydrogenated over Adams' catalyst (0.090 g) for 45 min. The product was obtained, after crystallization from methanol, as plates (0.187 g, 92%), m.p. 89–90°, $[\alpha]_D^{23}$ +43.4° (*c*, 0.577), identified as 4-oxa-5α-cholestane (12) by mixed melting point and infrared spectrum.

(b) 4-Oxa-5β-cholestane

Similar hydrogenation of 3-oxo-4-oxa-5β-cholestane (0.200 g) gave 4-oxa-5β-cholestane (0.175 g, 89%), m.p. 51–52°, $[\alpha]_D^{23}$ +3.5° (*c*, 0.629), identified by comparison (mixed melting point and infrared spectrum) with an authentic specimen (12).

(c) 1-Oxadecalin

2-Oxo-1-oxadecalin (42) (1.688 g), on hydrogenation, gave an oil (1.421 g, 80%), b.p. 184–185°, n_D^{27} 1.9686, ν_{max} 1 098 cm^{-1}.

Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 76.51; H, 11.23.

3α,17β-Dihydroxy-4-oxa-5α-estrane (VI, X = OH)

Lactone IV (X = OH) (2.2 g) was reduced with diborane according to Pettit *et al.* (28) to give the hemiacetal (0.8 g), m.p. 196–199°. After several recrystallizations from ether – ethyl acetate it had m.p. 202–205°, $[\alpha]_D^{21}$ +62° (*c*, 0.98) (lit. (28) m.p. 204–207°).

ACKNOWLEDGMENTS

We are grateful to Ayerst, McKenna and Harrison, Ltd., and to Wyeth Inc. for generous gifts of estrone and nortestosterone, respectively; to Professor G. R. Pettit for helpful discussions; and to the National Research Council for financial support.

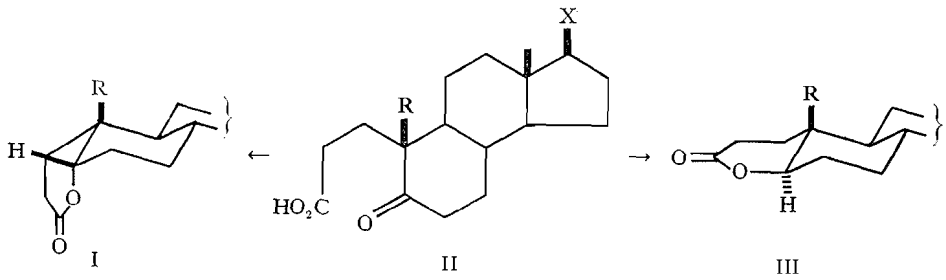
STEREOCHEMICAL STUDIES

VII. HYDROGENATION OF SOME STEROIDAL KETONES OVER ADAMS' CATALYST



J. T. EDWARD AND J.-M. FERLAND
Department of Chemistry, McGill University, Montreal, Quebec

Received November 1, 1965

ABSTRACT

The influence of the acidity of the solvent on the proportions of axial and equatorial alcohols obtained by hydrogenation of some steroidal ketones was investigated.

The hydrogenation of cyclic ketones over platinum in acetic acid generally gives axial alcohols (1, 2). This has been explained by the greater ease of adsorption of the ketone onto the catalyst from its less-hindered (equatorial) side, the hydrogen from the catalyst then being added to this side to produce the axial alcohol (3–6). Accordingly, it was expected that hydrogenation in acetic acid of keto acids of the general formula II would give *cis* lactones (I) in preference to *trans* lactones (III). This proved to be true for hydrogenation of Windaus' keto acid II (R = Me, X = C_8H_{17}) (7, 8); however, hydro-

I II III

genation of the keto acid II (R = H, X = OH) gave predominantly the *trans* lactone (9). It appeared, paradoxically, that the presence of the angular 19-methyl group made it easier for the catalyst to approach the top side of the molecule and add hydrogen to the carbonyl group.

A chair conformation of ring B of the keto acid II (R = Me, X = C_8H_{17}) and a boat conformation of ring B of the keto acid II (R = H, X = OH) offered a possible explanation of this curious result. Boat conformations have been postulated for some steroidal and triterpene ketones (10, 11), although in some cases the evidence for these conformations is contentious (11).

However, in the present case the optical rotatory dispersion curves indicated ring B to be in the chair form in both keto acids. The amplitude ([*A*]) predicted from the octant rule (12) for the Cotton effect of the keto acid II (R = H, X = OH) would be strongly negative if ring B were in the chair form, and weakly negative if it were in the boat form; in fact, it was strongly negative ([*A*] = −98). Similarly, the amplitude predicted for the keto acid II (R = Me, X = C_8H_{17}) would be weakly positive if ring B were in the chair form, and weakly negative if it were in the boat form; in fact, it was weakly positive ([*A*] = +14).

It was evident that hydrogenation of II (R = H, X = OH) in acetic acid gave predominantly the equatorial alcohol. Since the proportions of epimeric alcohols that are

obtained vary slightly with the sample of catalyst used, it became of interest to test our catalyst and reaction conditions with 3-oxo-5α-cholestane, previously studied by Vavon and Jakubowicz (13). At the same time, 3-oxolanost-8-ene (in which ring A has been claimed to assume the boat conformation (10)) and the keto acids II (R = Me, X = OCOPh) and II (R = H, X = OAc) were studied, in an attempt to discern the effect of structural changes on the proportions of axial and equatorial alcohols formed.

Effect of Acidity of Solvent on Rate and Stereochemistry of Hydrogenation

Vavon and Jakubowicz (13) obtained 50% of the 3α alcohol when 3-oxo-5α-cholestane was hydrogenated over platinum in butyl ether, 60% when it was hydrogenated in acetic acid, and 75% when it was hydrogenated in butyl ether containing hydrochloric acid. They used a melting point – composition diagram to determine the proportions of isomers in their product; this analytical method is unlikely to be very accurate. By the nuclear magnetic resonance (n.m.r.) method of analysis described below, we found that hydrogenation of 3-oxo-5α-cholestane with our catalyst gave only 35% of the 3α alcohol. It is apparent that hydrogenation in acetic acid does not always give the axial alcohol as the chief product. However, by adding small amounts of hydrochloric acid to the solvent it was possible to increase the proportion of axial alcohol, so that it effectively became the sole product of hydrogenation. The results are summarized in Table I. It is evident that steroidal ketones differ in the extent to which they yield axial alcohols on hydrogenation in acetic acid, but that for all of them the proportion of axial alcohol obtained goes up progressively when hydrochloric acid is added to the solvent.

TABLE I

Proportions (%) of α alcohols from hydrogenations of ketones in acetic acid containing varying amounts of mineral acid

II; R = H, X = OAc	40	65	90	—

*37% aqueous hydrochloric acid; percentages are by volume.
†70% aqueous perchloric acid.

The mechanism by which hydrochloric acid achieves this effect is obscure. It does not seem to be related to the rate of hydrogenation, as shown by the varying effect upon the latter of adding hydrochloric acid (Table II). The depressing effect of large amounts of hydrochloric acid upon the rate was due to the water being added. The use of acetic acid containing 2% hydrogen chloride (added as the dry gas) caused the time required for the hydrogenation of 3-oxo-5α-cholestane to drop to 4 min; use of acetic acid containing 10% hydrogen chloride caused it to drop to 3 min. In both cases, only the 3α alcohol could be detected in the product.

The addition of 70% aqueous perchloric acid was very effective in accelerating the rate of hydrogenation (Table II), but less effective in increasing the proportion of axial alcohol (Table I). This casts doubt on Brewster's suggestion (4) that the axial alcohol is formed by a hydride transfer from the catalyst to the protonated ketone, since the acetic acid

*37% aqueous acid.
†70% aqueous acid.

containing 10% of aqueous (70%) perchloric acid should be considerably more acidic than acetic acid containing 10% of aqueous (37%) hydrochloric acid.

The use of trifluoroacetic acid (14) in place of acetic acid as solvent caused the time required for the hydrogenation of 3-oxo-5α-cholestane to drop to 4 min, and the proportion of the 3α alcohol to rise to 62%. On the other hand, addition of 2% of sodium acetate to acetic acid lengthened the time to 17 min, and caused the proportion of the 3α alcohol to drop to 21%. The evidence for a relation between the acidity of the solvent and the proportion of axial alcohol formed is indisputable, but specific effects of different acids seem also to be involved. This general effect of acidity of solvent, although it has been known for a long time (13), is sometimes forgotten. Thus, a recent paper on the hydrogenation of ketoquinolizidines (15) attributed the greater proportion of axial alcohol obtained with an acidic solvent solely to protonation of the nitrogen so that it was prevented from "anchoring" the molecule on the catalyst.

Effect of Substrate Structure on Rate and Stereochemistry of Hydrogenation

It is evident from the results in Table I that the proportion of axial alcohol formed in the hydrogenation of the keto acid II (R = H, X = OH), the fact provoking the present studies, is unusually low, but that this proportion can be raised to respectable levels by addition of enough hydrochloric acid to the acetic acid. The 17β-hydroxy group apparently militates against formation of the axial alcohol, as shown by comparison with the results for II (R = H, X = OAc). No plausible reason can be advanced for this behavior. In comparison, the effects of the flanking 19-methyl group of II (R = Me, X = C_8H_{17} or OCOPh) seem to be minor. A study of the effect of the 17-hydroxyl group on the stereochemistry of hydrogenation of ketone groups at other positions would be desirable.

The results for 3-oxolanost-8-ene, very similar to those for 3-oxo-5α-cholestane, indicate only a minor effect from the two flanking methyl groups. The configuration of the resulting alcohols is best explained by postulating a chair rather than a boat conformation of ring A (cf. refs. 10 and 11).

Proof of Configurations of Hydrogenation Products

The configurations of the epimeric alcohols obtained by the hydrogenation of 3-oxo-5α-cholestane (10), 3-oxolanost-8-ene (16, 17), and Windaus' keto acid (II; R = Me, X = C_8H_{17}) (8) have already been established. The chemical shift of the proton at the epimeric center is at lowest field in the spectrum, and differs for each epimer in the direction already expected (18–20) for axial and equatorial protons, the axial being at higher field, as shown in Table III. A second difference lies in the half-widths of the peaks, those

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

TABLE III

Chemical shifts (τ) and half-widths ($w/2$, in cycles per second) of n.m.r. peaks of epimeric protons of alcohols, acetates, and lactones

Compound	Equatorial proton		Axial proton	
	τ	$w/2$	τ	$w/2$
Known configuration				
3-Hydroxy-5α-cholestane	6.20	8	6.71	17
3-Acetoxy-5α-cholestane	5.14	7	5.46	22
3-Hydroxylanost-8-ene	5.60	4.5	5.93	11
3-Acetoxylanost-8-ene	4.82	6	5.50	22

Uncertain configuration				
17β-Benzoyloxy-3-oxo-4-oxaandrostane (I and III; R = Me, X = OCOPh)	5.22	3.5	6.00	10
17β-Hydroxy-3-oxo-4-oxaestrane (I and III; R = H, X = OH)	5.57	6	6.39	10
17β-Acetoxy-3-oxo-4-oxaestrane (I and III; R = H, X = OAc)	5.53	*	6.00	12

*The half-width was not measurable because of overlapping of the peak with that of 17β-acetoxy protons.

from axial protons being about three times as great as those from equatorial protons (Table III). This is also in line with expectation (18, 21).

These differences may be used to assign configurations to hydrogenation products of uncertain configuration. Atwater and Ralls (22) reduced 17β-benzoyloxy-5-oxo-3,5-seco-4-norandrostan-3-oic acid (II; R = Me, X = OCOPh) with sodium borohydride to a mixture of lactones, tentatively formulated as 3-oxo-17β-benzoyloxy-4-oxa-5α-androstane (III; R = Me, X = OCOPh) for the major product and as the 5β epimer (I; R = Me, X = OCOPh) for the minor product. These structures are confirmed by the positions and widths of the peaks at lowest field. Similarly, the lactones obtained from the hydrogenation of 17β-hydroxy-5-oxo-3,5-seco-4-norestran-3-oic acid (II; R = H, X = OH) may be assigned structures I and III (R = H, X = OH).

An analytical method for mixtures of epimers based on the n.m.r. spectra of the compounds is described in the Experimental section.

The configurations assigned on the basis of n.m.r. spectra were confirmed by measurements of the molecular rotations of the lactones and of the sodium salts of the hydroxy acids derived from them, obtained by placing the lactones in methanolic sodium hydroxide. The direction of the shift in rotation (Table IV) was in the direction predicted by the

Klyne–Hudson "lactone rule" (23). The *trans* lactones III (R = Me, X = OCOPh) and III (R = H, X = OH) were more slowly attacked by alkali than the corresponding *cis* lactones, and required stronger alkali (see Table IV) to hydrolyze them in a convenient time. Neutralization of the solution of sodium salts to pH 6 caused almost no change in rotation, but acidification to pH 3 caused the rotation (in the 2–3 min required for measurement) to become that of the original lactone. Obviously, recyclization to the lactone was rapid.

EXPERIMENTAL

Materials

3-Oxo-5α-cholestane was a commercial product. 3-Oxolanost-8-ene (24), 5-oxo-3,5-seco-4-norcholestan-3-oic acid (II; R = Me, X = C_8H_{17}) (25), 17β-benzoyloxy-5-oxo-3,5-seco-4-norandrostan-3-oic acid (II; R = Me, X = OCOPh) (22), 17β-hydroxy-5-oxo-3,5-seco-4-norestran-3-oic acid (II; R = H, X = OH) (9), and 17β-acetoxy-5-oxo-3,5-seco-4-norestran-3-oic acid (II; R = H, X = OAc) (9, 26) were prepared by methods described in the literature. Johnson, Matthey and Mallory platinum oxide was used as catalyst; small differences were noted in the activity of different samples, but all results listed in any table were obtained with the same sample, so that comparative results are not affected.

General Hydrogenation Procedure

The ketone (200 mg) in acetic acid or acidified acetic acid (10 ml) was hydrogenated in an all-glass apparatus with a magnetic stirrer over prereduced platinum oxide (100 mg) at room temperature and atmospheric pressure. After absorption of hydrogen had ceased, the solution was filtered and diluted with ether. After several washings with water and with 5% sodium carbonate solution, the ether was evaporated and the crude product dissolved in carbon tetrachloride (3-hydroxy-5α-cholestane, 3-hydroxylanost-8-ene, and 3-oxo-4-oxacholestane) or deuteriochloroform (17β-benzoyloxy-3-oxo-4-oxaandrostane, 17β-hydroxy-3-oxo-4-oxaestrane, and 17β-acetoxy-3-oxo-4-oxaestrane) for n.m.r. analysis. It was found that hydrogenation in acetic acid containing perchloric acid or more than 2% (v/v) hydrochloric acid (37%) was accompanied by partial acetylation of hydroxyl groups. In these cases, the product was completely acetylated with acetic anhydride – pyridine before n.m.r. analysis.

The crude lactones obtained by hydrogenation of the keto acids were shown by thin-layer chromatography to contain only traces of ether resulting from further hydrogenolysis (27).

Analytical Procedure

The proportions of axial and equatorial alcohols obtained in hydrogenations were found by measuring with a planimeter the areas of the peaks caused by the epimeric protons. The accuracy of the method was tested by applying it to synthetic mixtures of lactones I and III (R = Me, X = C_8H_{17}) and of lactones I and III (R = H, X = OAc), made up from known weights of the pure compounds. The results showed the method to have an accuracy of about ±2%. However, when the minor constituent was present to the extent of less than 5%, it was impossible to measure the area of the n.m.r. peak with any confidence.

17β-Acetoxy-3-oxo-4-oxa-5β-estrane (I; R = H, X = OAc)

17β-Acetoxy-5-oxo-3,5-seco-4-norestran-3-oic acid (9, 26) (0.321 g) was hydrogenated over platinum oxide (0.155 g) in acetic acid (25 ml), and the product worked up as above. Crystallization of the crude product from ether–acetone gave a first crop of crystalline 17β-acetoxy-3-oxo-4-oxa-5α-estrane (58 mg, 18% yield), m.p. 210–212°, $[\alpha]_D^{26}$ +50.1° (*c*, 0.92 in chloroform) (lit. (28) m.p. 210–212°, $[\alpha]_D^{22}$ +46.9°).

A second crop crystallized as needles (0.127 g, 42% yield), m.p. 159–164°. Two recrystallizations from ether–acetone yielded pure 17β-acetoxy-3-oxo-4-oxa-5β-estrane, m.p. 169–170°, $[\alpha]_D^{26}$ +10.0° (*c*, 0.79), $\nu_{max}^{CHCl_3}$ 1 738 cm^{-1}.

Anal. Calcd. for $C_{19}H_{28}O_4$: C, 71.21; H, 8.88. Found: C, 71.06; H, 8.59.

The 5β lactone was also obtained by hydrogenation of the keto acid (1.00 g) in 90:10 glacial acetic acid – concentrated hydrochloric acid (50 ml) over platinum oxide (0.502 g). The crude product crystallized from ether–acetone as needles (0.672 g), shown by mixed melting point and infrared spectrum to be identical with the 5β lactone obtained above.

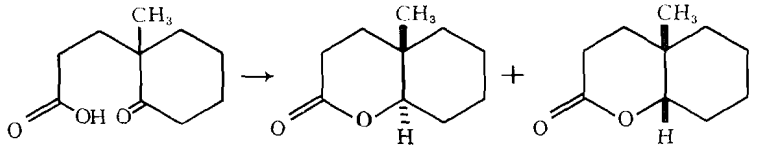
STEREOCHEMICAL STUDIES

VIII. SYNTHESIS OF *cis*-1-OXA-10-METHYLDECAL-2-ONE



J. T. EDWARD AND J.-M. FERLAND
Department of Chemistry, McGill University, Montreal, Quebec

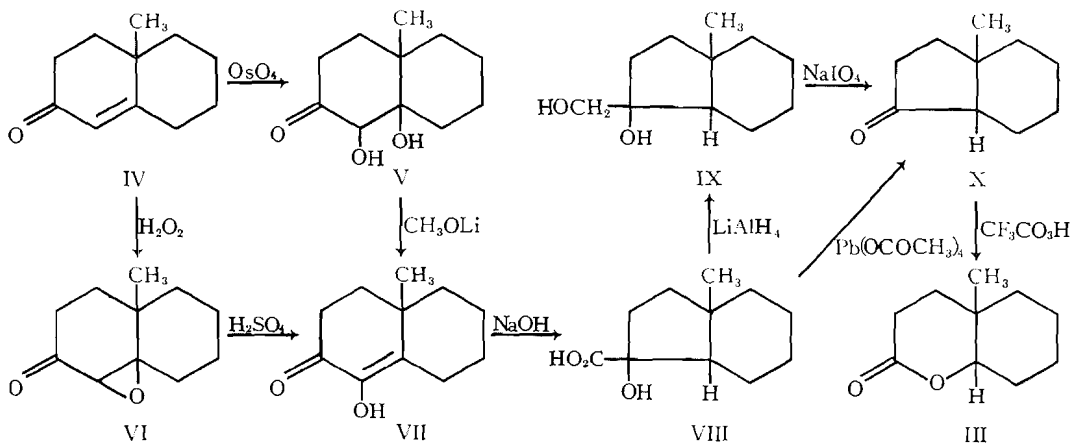
Received November 4, 1965

ABSTRACT

9-Methylhydrindan-1-one was obtained as a mixture (80% *trans*, 20% *cis*) in four steps from 10-methyl-$\Delta^{1,9}$-octal-2-one. In the presence of alkali it epimerized to *cis*-9-methylhydrindan-1-one containing less than 1% of the *trans* isomer. Oxidation of this *cis* ketone with peroxytrifluoroacetic acid gave *cis*-1-oxa-10-methyldecal-2-one.

House and Schellenbaum (1) reduced 3-(1′-methyl-2′-oxocyclohexyl)propionic acid (I) with sodium borohydride and obtained, after acidification of the product, a neutral material. From the nuclear magnetic resonance (n.m.r.) spectrum of this material they concluded that it was made up of *trans*- (II) and *cis*-1-oxa-10-methyldecal-2-one (III) in the ratio 35:65. A broad multiplet (one proton) centered at about 4.0 τ was attributed to

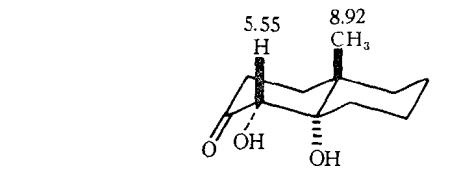
the C-9 hydrogens of II and III. Sharp, unsplit peaks at 9.05 τ and 8.95 τ (total area three protons; relative areas 35:65) were attributed to the angular methyl groups of the *trans* (II) and *cis* (III) isomers, respectively, by analogy with the positions of the peaks of angular methyl groups in the spectra of *trans* and *cis* decalols (2). The isomers could not be separated completely by vapor phase chromatography.



We have repeated this work and confirmed most of House and Schellenbaum's observations. The n.m.r. spectrum of our product had peaks at 8.94 τ and 9.03 τ; however, the peak at lowest field was a triplet at 5.93 τ (4.07 δ), and not at 4.0 τ. A peak at 5–6 τ for the C-9 hydrogens of II and III is to be expected from previous studies of δ-lactones (3).

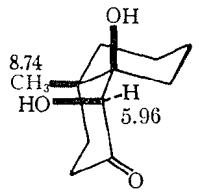
Hydrogenation of the keto acid I over Adams' catalyst in acetic acid gave a lactone mixture, indicated by its n.m.r. spectrum to be made up of II and III in the proportions 2:1. This ratio was not affected by addition of hydrochloric acid to the acetic acid solvent (cf. ref. 3).

For stereochemical studies the pure isomers II and III were required, and consequently a stereospecific synthesis of (±)-III was carried out by the route outlined in Reaction Scheme 1. The stereochemistry of the various intermediates (all (±) mixtures) is not shown in this scheme, but is discussed below, separately for each compound.

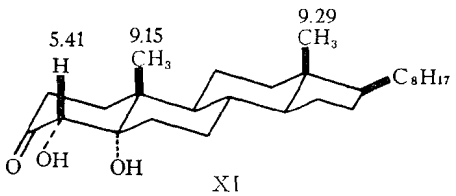


1,9-Dihydroxy-10-methyldecal-2-one (V)

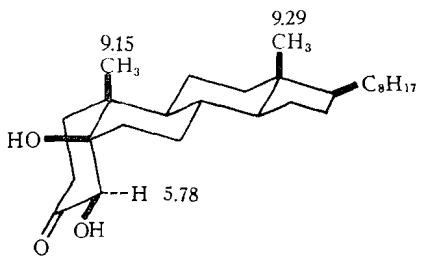
Osmium tetroxide hydroxylates a double bond *cis* (4), and consequently oxidation of the unsaturated ketone IV would be expected to yield a mixture of the diastereoisomeric diols V*a* and V*b*. This expectation was realized. Although the solid product of the reaction had a sharp melting point after one recrystallization, its n.m.r. spectrum showed it to be a



REACTION SCHEME 1.



mixture of V*a* and V*b* in the proportions 70:30. Two peaks at lowest field, at 5.55 τ and 5.96 τ, had a total area equivalent to one proton, and could be assigned to the protons at the 1 position of V*a* and V*b*. The two peaks at highest field, at 8.92 τ and 8.74 τ, with a total area equivalent to three protons, could be assigned to the angular methyl groups. In both cases the relative areas of the peaks were 70:30. The assignment of these peaks to the individual isomers V*a* and V*b* as shown in the formulae comes from a comparison with the n.m.r. spectra of the known compounds, 4α,5α-dihydroxycholestan-3-one (XI) and



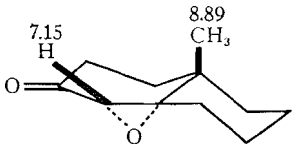
V*a*

V*b*

XI

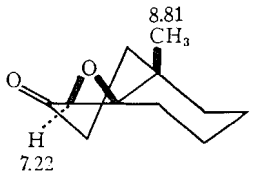
XII

4β,5β-dihydroxycholestan-3-one (XII) (5, 6). The various peaks of these spectra may be assigned on the basis of the known n.m.r. spectra of steroids (7), and the chemical shifts of the relevant peaks are shown in the formulae XI and XII. It is apparent that the *cis* decalone is either in the non-steroid conformation of V*b* (cf. refs. 2 and 8), or in a conformation in which one of the rings has become a twist-boat (9).



These results indicate the *trans* isomer V*a* to be the chief product from the oxidation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

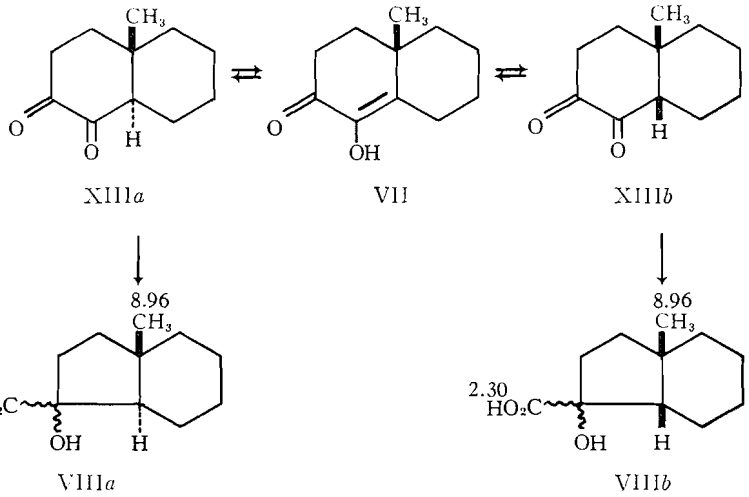


IV by osmium tetroxide, probably because the β-methyl group shields the β face of the molecule. Similarly, the oxidation of testosterone under the same conditions has been found to yield 70% of the 4α,5α-diol (10). However, when a mixture of osmium tetroxide and hydrogen peroxide was used to oxidize IV, the proportion of V*a* in the product decreased to 40%, again paralleling the behavior of steroidal compounds (6).

1,9-Epoxy-10-methyldecal-2-one (VI)

Oxidation of the unsaturated ketone IV with alkaline hydrogen peroxide according to published procedures (11, 12) gave a liquid product, indicated by its n.m.r. spectrum to contain two compounds. Two sharp peaks at highest field (8.89 τ and 8.81 τ; relative areas 1:2), having a total area equivalent to three protons, may be assigned with reasonable certainty (cf. ref. 8) to the angular methyl groups of the *trans* (VI*a*) and *cis* (VI*b*) isomers, respectively. The peaks at lowest field (7.15 τ and 7.22 τ; relative areas 1:2), corresponding to one proton, are then assigned to the protons on the 1 position, as shown below. This

VI*a*



VI*b*

ratio of 2:1 for the *cis* and *trans* isomers in the product agrees with the ratio of 70:30 obtained by Shaw and Stevenson (12) from the oxidation of cholest-4-ene-3-one.

Treatment of the epoxide mixture with sulfuric acid in acetic acid (cf. ref. 13) or of the diolones (V) with lithium methoxide in methanol (cf. ref. 6) yielded the diosphenol (VII), which gave a characteristic blue color with ferric chloride.

1-Hydroxy-9-methylhydrindan-1-carboxylic Acid (VIII)

Diosphenols undergo a benzilic acid type rearrangement in alkali (14, 15), presumably because of a small amount of diketone in equilibrium with diosphenol. In the present instance, the diketone can have either a *trans* (XIII*a*) or *cis* (XIII*b*) fusion of the rings (Reaction Scheme 2). It seems to be likely (cf. ref. 16) that both diones have about the

XIII*a* VII XIII*b*

VIII*a* VIII*b*

REACTION SCHEME 2.

same stability, and so are present in roughly equal amounts, but that the *trans* compound XIII*a* reacts more rapidly with hydroxide ion, because of the better solvation possible for the highly charged intermediate (17) leading from XIII*a* to VIII*a*. In fact, it proved to be impossible to determine the proportions of *trans* (VIII*a*) and *cis* (VIII*b*) products from the n.m.r. spectrum of the hydroxy acid, which showed only a single peak for the carboxyl (2.30 τ) and methyl (8.96 τ) protons; however, the products from the next stage of the synthesis showed the ratio of *trans* (VIII*a*) to *cis* (VIII*b*) to be about 80:20.

9-Methylhydrindan-1-one (X)

Lead tetraacetate oxidation of the hydroxy acid VIII gave 9-methylhydrindan-1-one (X). The n.m.r. spectrum of this compound showed two peaks at 8.81 τ and 9.21 τ, with a total area equivalent to three protons and with relative areas of 20:80. As shown below, these are due to the angular methyl groups of the *cis* and *trans* forms of X.

Because it was feared that some epimerization could have taken place under the acidic conditions of lead tetraacetate oxidation, the preparation of 9-methylhydrindan-1-one was carried out by an alternative route which avoided acidic conditions. The mixture of hydroxy acids (VIII) was reduced with lithium aluminium hydride to a mixture of diols (IX), which was then oxidized with sodium metaperiodate in neutral solution (14). Again, the ratio of *trans* to *cis* was shown by n.m.r. to be 80:20.

Treatment of this *cis*–*trans* mixture with sodium hydroxide in methanol gave a product showing a peak at 8.81 τ (three protons) and no peak at 9.21 τ. Evidently, under these conditions conversion of the *trans* into the *cis* compound was almost complete, because the n.m.r. spectrum would have revealed the *trans* compound if it had been present to the extent of more than about 1%. This isomerization took place very readily: after 2 days in a Pyrex container, the proportion of *cis* isomer had risen to 70%, and after 2 months to 90%.

These results are in accord with expectation. Although the proportion of *cis*- to *trans*-hydrindan-1-one at equilibrium is 75:25 (18), the addition of an angular methyl group would be expected to increase this ratio considerably (16, 19).

cis-1-Oxa-10-methyldecal-2-one (III)

The Baeyer–Villiger oxidation of *cis*-9-methylhydrindan-1-one (X) gave *cis*-1-oxa-10-methyldecal-2-one (III). This reaction proceeds with retention of configuration of the migrating groups (20) and almost always, as in the present case, involves migration of the more alkylated of the two carbons flanking the carbonyl group (21). The n.m.r. spectrum of the lactone III showed a sharp methyl peak (three protons) at 8.93 τ and a triplet ($J \sim 3.5$ c.p.s.) at 5.93 τ (one proton) caused by the proton at the 9 position. This confirms House's assignment of the methyl peak at lower field to III (1).

EXPERIMENTAL

Hydrogenation of 3-(1′-Methyl-2′-oxocyclohexyl)propionic Acid (I)

3-(1′-Methyl-2′-oxocyclohexyl)propionic acid (I) (2.014 g) in glacial acetic acid (2 ml) was hydrogenated over platinum oxide (0.794 g) at room temperature and atmospheric pressure. After 1½ h, uptake of hydrogen ceased. The solution was diluted with ether, filtered, and washed with 2% sodium hydroxide solution and with water. Distillation gave 1-oxa-10-methyldecal-2-one, b.p. 95–96° at 0.3 mm, n_D^{21} 1.4909 (lit. (1) b.p. 102–104° at 0.8 mm, n_D^{26} 1.4916).

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.26; H, 9.56.

1,9-Dihydroxy-10-methyldecal-2-one (V)

(a) With Osmium Tetroxide

A solution of 10-methyl-$\Delta^{1,9}$-octal-2-one (IV) (1.1 g) in pyridine (150 ml) was stirred at room temperature for 2½ h with osmium tetroxide (1.79 g). The black mixture was then stirred for 10 min with a solution of sodium bisulfite (2.8 g) in water (40 ml) and pyridine (30 ml). This mixture was extracted with ether, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the ether solution dried (K_2CO_3). Removal of the ether at reduced pressure left a black oil which was filtered through silica gel (20 g). Washing the silica gel with chloroform and concentration of the chloroform gave a brown solid (1.05 g), m.p. 85–89°, which, after several recrystallizations from hexane, was obtained as colorless needles, m.p. 90–92°; $\nu_{max}^{CCl_4}$ 3 580, 3 460, and 1 738 cm^{-1}.

Anal. Calcd. for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15. Found: C, 66.52; H, 8.99.

(b) With Osmium Tetroxide – Hydrogen Peroxide

Osmium tetroxide (2 g) was added to a solution of 10-methyl-$\Delta^{1,9}$-octal-2-one (15 g) in ether (200 ml), and the mixture allowed to stand in the dark for 5 h. Hydrogen peroxide (30%, 30 ml) was then added slowly and the mixture was stirred at room temperature for 4 days. Portions of hydrogen peroxide (10 ml) were added when the solution darkened. The excess of hydrogen peroxide was removed, and the ether solution was washed with water and then treated with a slow stream of hydrogen sulfide for 30 min. The solution was filtered, washed with 2% sodium bicarbonate and with water, and dried. The oily residue obtained on evaporation was chromatographed on silica gel. Benzene–ether (75:25 v/v) eluted an oily, crystalline material (8.2 g) which crystallized from hexane as a colorless solid, m.p. 90–92°. The compound was identical (mixed melting point and infrared spectrum) with the material prepared above, but its n.m.r. spectrum showed different proportions of the isomers V*a* and V*b*.

1,9-Epoxy-10-methyldecal-2-one (VI)

10-Methyl-$\Delta^{1,9}$-octal-2-one (29.7 g) in methanol (500 ml) was treated at 0° with ice-cold 30% hydrogen peroxide (308 ml) and then with ice-cold 10% sodium hydroxide solution (103 ml). The solution was kept at 0° for 48 h, and then diluted with water and extracted with ether. The ether solution was washed with water, dried, and evaporated, and the residue distilled to give 1,9-epoxy-10-methyldecal-2-one as an oil (22.5 g), b.p. 96–98° at 0.75 mm, n_D^{20} 1.4992; $\nu_{max}^{CCl_4}$ 1 720, 922, and 858 cm^{-1}.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95. Found: C, 73.27; H, 8.71.

1-Hydroxy-10-methyl-$\Delta^{1,9}$-octal-2-one (VII)

(a) From 1,9-Dihydroxy-10-methyldecal-2-one (V)

A solution of 4 *M* lithium methoxide in methanol (85 ml) was added to 1,9-dihydroxy-10-methyldecal-2-one (3.38 g) in methanol (200 ml), and the mixture was boiled under reflux for 2 h. The cooled solution was acidified to pH 3 with concentrated hydrochloric acid, diluted with a large excess of water, and extracted with ether. The ether was evaporated and the residue distilled to give an oil (2.3 g), b.p. 86–90° at 1.5 mm, which slowly crystallized. After recrystallization from hexane the diosphenol was obtained as a colorless solid, m.p. 84–85°, λ_{max}^{EtOH} 276 mμ (ϵ_{max} 20 000); $\nu_{max}^{CCl_4}$ 3 485, 1 720, 1 685, and 1 665 cm^{-1}.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95. Found: C, 73.38; H, 8.97.

(b) From 1,9-Epoxy-10-methyldecal-2-one (VI)

The epoxide (20 g) in glacial acetic acid (375 ml) containing concentrated sulfuric acid (37.5 ml) was left at room temperature for 24 h. The black solution was diluted with ice water (3 l) and neutralized with sodium bicarbonate. A solid separated and was distilled to give an oil, b.p. 90–100° at 2.8 mm, which slowly crystallized. After recrystallization from hexane the solid melted at 84–85°, and was shown by mixed melting point and ultraviolet and infrared spectra to be identical with the compound described in the preceding section.

1-Hydroxy-9-methylhydrindan-1-carboxylic Acid (VIII)

A solution of 1-hydroxy-10-methyl-$\Delta^{1,9}$-octal-2-one (3.9 g) in methanol (50 ml) and 5% aqueous sodium hydroxide (500 ml) was kept at 100° for 16 h under nitrogen. The cooled solution was acidified to pH 3 and extracted with ether, and the ether in turn extracted with 5% aqueous sodium bicarbonate. The latter solution was acidified and extracted with ether. Evaporation of the ether gave an oil which slowly crystallized. Recrystallization from hexane gave plates of the hydroxy acid (VIII) (2.11 g), m.p. 108–111°. Two more crystallizations from hexane raised the melting point to 112–113°; $\nu_{max}^{CCl_4}$ 3 575, 1 724, 1 448, and 1 272 cm^{-1}.

Anal. Calcd. for $C_{11}H_{18}O_3$: C, 66.69; H, 9.15. Found: C, 66.67; H, 8.91.

1-Hydroxymethyl-9-methylhydrindan-1-ol (IX)

Under dry nitrogen, a solution of 1-hydroxy-9-methylhydrindan-1-carboxylic acid (1.2 g) in ether (25 ml) was added, with stirring, over 15 min to a suspension of lithium aluminium hydride (1.5 g) in ether (100 ml). The mixture was refluxed for 2 h, and then water (5 ml) and 10% aqueous sodium hydroxide (4 ml) were added dropwise, with continued stirring. The inorganic precipitate was removed by filtration and washed with ether. The filtrate and washings, on concentration, gave the diol as an oil (1.1 g) which could not be crystallized.

9-Methylhydrindan-1-one (X)

(a) From 1-Hydroxy-9-methylhydrindan-1-carboxylic Acid (VIII)

A solution of the hydroxy acid (6.1 g) and lead tetraacetate (40 g) in methanol (200 ml) was left at room temperature overnight. The solution was concentrated, diluted with water, and extracted with ether. The ether solution was washed with 5% sodium bicarbonate and water, dried, and concentrated. Distillation of the residue (3.6 g) gave an oil (2.6 g), b.p. 60–68° at 1.3 mm, n_D^{20} 1.4804, $\nu_{max}^{CCl_4}$ 1 760 cm^{-1}. The n.m.r. spectrum showed this material to be a mixture of the *cis* and *trans* isomers.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.89; H, 10.59. Found: C, 78.62; H, 11.06.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(b) From 1-Hydroxymethyl-9-methylhydrindan-1-ol (IX)

The diol (1.0 g) in methanol (50 ml) was treated with sodium metaperiodate (2 g) in water (40 ml), followed by sufficient 5% aqueous sodium bicarbonate to adjust the pH of the mixture to about 6. The suspension was stirred overnight at room temperature. The methanol was removed at reduced pressure, and the residual mixture extracted with ether. The residue, after removal of the ether, was distilled to give an oil, b.p. 62–68° at 1.4 mm, n_D^{21} 1.4800, having an infrared spectrum identical with that of the ketone mentioned above.

cis-9-Methylhydrindan-1-one

The mixture of *trans-* and *cis*-9-methylhydrindan-1-one obtained above (3.0 g) was dissolved in 2.7% methanolic sodium hydroxide (220 ml) and left overnight. The solution was then acidified, diluted with water, concentrated at reduced pressure, and extracted with ether. Distillation of the residue from the ether gave *cis*-9-methylhydrindan-1-one as an oil (2.7 g), b.p. 70° at 1.25 mm, n_D^{20} 1.4812, $\nu_{max}^{CCl_4}$ 1 760 cm^{-1}.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.89; H, 10.59. Found: C, 78.81; H, 10.59.

cis-1-Oxa-10-methyldecal-2-one (III)

A solution of trifluoroperoxyacetic acid, prepared from trifluoroacetic anhydride (13 ml) and 90% hydrogen peroxide (2.6 ml) in methylene chloride (100 ml) (22), was added over a period of 1 h to a stirred solution of *cis*-9-methylhydrindan-1-one (2.6 g) in methylene chloride (160 ml) containing a suspension of disodiohydrogen phosphate (9 g). Stirring was continued for 2 h at room temperature. After dilution with ether and filtration, the solution was washed with 5% aqueous sodium bicarbonate and water, and dried. Slow distillation of the residue from evaporation of the ether gave starting material (0.23 g), b.p. 78–80° at 2.5 mm, followed by the lactone (III) (1.36 g), b.p. 130–134° at 2.5 mm, n_D^{20} 1.4892, $\nu_{max}^{CCl_4}$ 1 737 and 1 210 cm^{-1}.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.11; H, 9.46.

NOTES

1,8-DIACETYLNAPHTHALENE AND 3-METHYLPHENALENONE

D. F. TAVARES AND J. P. BORGER

This note describes a preparation of 1,8-diacetylnaphthalene (I), which was required in another problem, and the subsequent formation of 3-methylphenalenone (II). The usual

I II

method for the preparation of I involves cleavage of 1,2-dimethylacenaphthene-1,2-diol by lead tetraacetate (1). A modified chromic acid oxidation was found to be successful and more convenient.[1]

If 1,2-dimethylacenaphthene-1,2-diol was first dissolved in warm acetic acid and then cooled to room temperature, and 1 equivalent of chromic anhydride in water added, followed immediately by addition of water, 1,8-diacetylnaphthalene (I) was obtained in yields of 85–90%, which compare favorably with those obtained with lead tetraacetate (70–75%, in our hands).

If, on the other hand, 1.5 moles of chromic anhydride was used per mole of diol at 75° and water added after 10 min, the product was 3-methylphenalenone (II) in yields of 84–90%. At room temperature the use of this same excess of chromic anhydride yielded, after 10 min, 52% of I and 28% of II. Treatment of I in hot acetic acid with an excess of chromic acid to produce II in a quantitative yield established that I was a precursor of II.[2] Though a very facile cyclization of I, with piperidine, to form II is known (1), the acid-catalyzed cyclization has not been reported.

EXPERIMENTAL

All melting points are uncorrected; infrared spectra were determined in dilute chloroform solution with a Perkin–Elmer model 421 spectrophotometer; nuclear magnetic resonance spectra were measured at 100 Mc/s in deuteriochloroform, with tetramethylsilane as internal standard ($\tau = 10$); microanalyses were performed by Dr. C. Daessle, Montreal.

1,2-Dimethylacenaphthene-1,2-diol

The procedure is that of Maxim (3), with modification. Powdered acenaphthenequinone (15 g) was added in small portions to methylmagnesium iodide (50 g methyl iodide and 8.5 g magnesium) in anhydrous ether (100 ml), and the mixture was heated under reflux for 7 h. After hydrolysis with either 10% sulfuric acid or aqueous ammonium chloride solution, the combined, dried ($MgSO_4$) ether extracts were evaporated under reduced pressure. The residue of mixed *cis*- and *trans*-diols was crystallized from acetone and then chloroform to yield 4.0 g (23%) of *cis*-diol, m.p. 193–194° (lit. m.p. 187–189° (3)), as thick colorless plates from acetone, and 10.4 g (59%) of *trans*-diol, m.p. 186–187° (lit. m.p. 182–183° (3)), as fine white needles from chloroform.

[1]*For the preparation of large quantities of I, the lead tetraacetate method (1) requires large quantities of solvent (benzene).*

[2]*The formation of II is readily explained as an intramolecular acid-catalyzed aldol condensation. In the excellent review by Reid (2), 1,8-diacylnaphthalenes were not considered as precursors for phenalenones. In the particular case of II, the synthesis outlined here would appear to be the one of choice.*

1,8-Diacetylnaphthalene (I)

A mixture of *cis*- and *trans*-diols (6.4 g) was dissolved in acetic acid (175 ml) with heating, and then cooled to room temperature. Chromic anhydride (3.1 g) in water (30 ml) was added dropwise, as rapidly as possible and with good mixing, followed immediately by rapid dropwise addition of cold water, with good mixing, to precipitate I. Crystallization from acetone gave 8.1 g (89%) of colorless plates, m.p. 174–175° (lit. m.p. 171–172° (1)). The infrared spectrum showed carbonyl absorption at 1 683 cm^{-1}.

3-Methylphenalenone (II)

To a hot solution (75°) of diol (6.8 g) as described above was added an excess of chromic anhydride (4.7 g) in water (50 ml). The solution was kept at 75° for 10 min, and then cold water was added slowly, with stirring, to give II as pale-yellow crystals. After crystallization from an acetone–water mixture and then from ethanol the melting point was 151–152° (lit. m.p. 152° (1)); yield 5.4 g (90%). The infrared spectrum showed carbonyl absorption at 1 640 cm^{-1}. The nuclear magnetic resonance spectrum showed three methyl protons at 7.46 τ, one olefinic proton at 3.40 τ, and six aromatic protons (multiplet, 1.4–2.5 τ).

Anal. Calcd. for $C_{14}H_{10}O$: C, 86.56; H, 5.24. Found: C, 86.56, 87.00; H, 4.91, 5.22.

CONCERNING *cis*- AND *trans*-3-THIOCYANOPROPENAL AND THE SYNTHESIS OF ISOTHIAZOLE

R. Raap

The isothiazole ring system has received much attention lately and several methods leading to its synthesis have been developed (1). Recently, Wille *et al.* (2) reported the preparation of isothiazole by the reaction of either 3-thiocyanopropenal or sodium propenal-3-thiosulfate with liquid ammonia. This method is the most practical laboratory synthesis of this interesting compound, but full experimental details have not yet been reported. As stated by Slack and Wooldridge (3) (citing a personal communication from Wille), success is dependent on the reaction of the *cis* adducts with ammonia. The purpose of this publication is to supply practical details for obtaining optimal yields of isothiazole from both the thiocyanate and the thiosulfate.

When a solution of propynal in acetone was added to an aqueous solution of thiocyanic acid at 0°, an almost quantitative yield of 3-thiocyanopropenal, m.p. 93–94°, was obtained. The structural assignment was fully supported by the infrared spectrum and by the elemental analysis. However, when this compound was allowed to react with liquid ammonia, only a tar resulted, from which not a trace of isothiazole could be isolated. On examination of the compound's nuclear magnetic resonance spectrum (Table I), a coupling constant of 15 c.p.s. between the olefinic protons was revealed, indicating a *trans* relationship (4, 5). Attempts to isomerize *trans*-3-thiocyanopropenal (III) to the *cis* isomer were

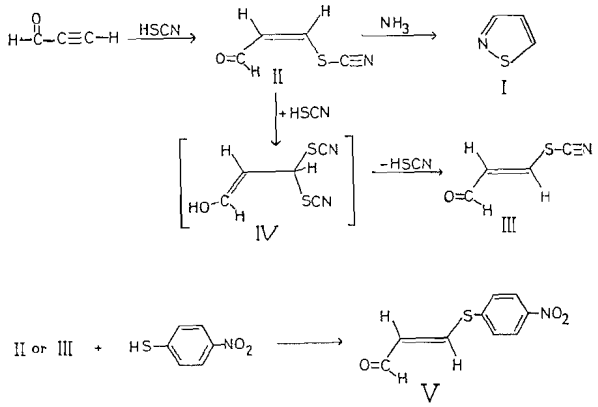
unsuccessful. Therefore, a search was made for conditions which would favor the formation and preservation of the *cis* isomer during the addition of the thiocyanic acid to the propynal. An optimum yield of *cis*-3-thiocyanopropenal was obtained when an aqueous solution of thiocyanic acid was *slowly* added to a solution of propynal in acetone at −10 to −15°. A mixture of the isomeric 3-thiocyanopropenals precipitated readily as the compounds formed (78% yield), and consisted predominantly (85–90%) of the *cis* isomer. When higher temperatures were employed the isomer ratio changed drastically in favor of the *trans* isomer.



cis-3-Thiocyanopropenal, m.p. 62–64°, could be purified by recrystallization. The assigned structure was fully supported by the infrared and nuclear magnetic resonance (Table I) spectra, the elemental analysis, and the compound's chemical behavior. The coupling constant, $J_{2,3}$ = 9 c.p.s., for the olefinic protons requires the *cis* relationship (4, 5). The compound was completely isomerized to the *trans* isomer ($J_{2,3}$ = 15 c.p.s.) when it was heated for 1 h at 100°.

In contrast to the *trans* isomer, *cis*-3-thiocyanopropenal reacted with liquid ammonia to give isothiazole (22% yield).

The results indicated that, similar to the addition of thiocyanic acid to propiolamides (5), the addition of thiocyanic acid to propynal proceeded in the usual *trans* manner and actually gave rise to *cis*-3-thiocyanopropenal, which, however, readily isomerized to the *trans* isomer under the reaction conditions. Thiocyanic acid was found to be responsible for this rapid isomerization. Acid alone did not cause the rapid isomerization, since II was recovered in high yield when left for 1 h in contact with either dilute sulfuric acid in aqueous acetone or with trifluoroacetic acid in ether solution, at room temperature. Also, when ammonium thiocyanate was added to a solution of II in aqueous acetone, no isomerization could be detected after 15 min at room temperature. However, when a few drops of dilute sulfuric acid was added to the latter solution, the isomerization to III was complete within a few minutes. The isomerization probably proceeds by way of the intermediate IV, which decomposes to the thermodynamically more stable *trans* isomer III. Evidence in support of this contention was provided by the observation that both *cis*- and *trans*-3-thiocyanopropenal react readily at room temperature with *p*-nitrothiophenol in ethyl acetate to give *trans*-3-*p*-nitrothiophenoxypropenal (V). Surely, the diadducts rather than the propynal were intermediate in these transformations.

Isothiazole can most conveniently be prepared from sodium *cis*-propenal-3-thiosulfate. The latter compound was obtained in 65% yield by the addition of an aqueous solution of sodium thiosulfate to a solution of propynal in aqueous acetone containing an equivalent

For personal use only.

amount of acetic acid. The nuclear magnetic resonance spectrum (Table I) revealed a coupling constant ($J_{2,3}$) of 9.5 c.p.s. for the olefinic protons. The thiosulfate adduct reacted with liquid ammonia to give a 61% yield of isothiazole.

EXPERIMENTAL

All temperatures are uncorrected. Infrared spectra were obtained on a Perkin–Elmer model 421 spectrophotometer. Nuclear magnetic resonance spectra were measured with a Varian Associates model A-60 spectrometer, with tetramethylsilane as a reference. Microanalyses were performed by Dr. G. Weiler and Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, England.

trans-3-Thiocyanopropenal (III)

An aqueous solution of thiocyanic acid was prepared by the addition of 160 ml of 3 *N* aqueous sulfuric acid to a solution (cooled in ice) of potassium thiocyanate (44.4 g, 0.457 mole) in 200 ml of water. The stirred solution was cooled in ice, and propynal (24.7 g, 0.457 mole) in 75 ml of acetone was added dropwise in 20 min. After the addition was complete, the stirring and cooling were continued for 40 min. The product, 50.0 g (97%) of white needles, m.p. 88–92°, was gathered by filtration, washed with ice water, and air-dried. The compound was recrystallized from benzene, m.p. 93–94°.

Anal. Calcd. for C_4H_3NOS: C, 42.46; H, 2.67; S, 28.34. Found: C, 42.44; H, 2.70; S, 28.45.

The infrared spectrum (in $CHCl_3$) showed strong bands at 2 180, 1 694, 1 572, 1 110, and 942 cm^{-1}. The nuclear magnetic resonance spectral parameters are reported in Table I.

cis-3-Thiocyanopropenal (II)

An aqueous solution of thiocyanic acid was prepared by the addition of 170 ml of 3 *N* hydrochloric acid to an ice-cold solution of potassium thiocyanate (48.5 g, 0.50 mole) in 220 ml of water. The solution was cooled in ice and then added dropwise to an efficiently stirred solution (maintained at −10 to −15°) of propynal (30.0 g, 0.55 mole) in 90 ml of acetone. The product precipitated during the addition, which was completed in approximately 1 h. The mixture was kept at −10 to −15° for an additional 30 min before the product was gathered by filtration and washed with ice water. The dried white solid, 43.9 g (78%), m.p. 50–56°, according to the nuclear magnetic resonance spectrum, consisted of 85–90% of *cis*-3-thiocyanopropenal (II) and 10–15% of the *trans* isomer (III). The pure *cis* isomer, m.p. 62–64°, was obtained after two recrystallizations from a 1:3 acetone–water mixture.

Anal. Calcd. for C_4H_3NOS: C, 42.46; H, 2.67; S, 28.34. Found: C, 42.51; H, 2.88; S, 28.60.

The infrared spectrum (in $CHCl_3$) had strong bands at 2 180, 1 670, 1 540, 1 110, 970, and 870 cm^{-1}, and the nuclear magnetic resonance spectral parameters are given in Table I. Whereas II is soluble in either ether or benzene in the cold, the *trans* isomer (III) is almost completely insoluble.

Conversion of cis-3-Thiocyanopropenal into the trans Isomer under the Influence of Thiocyanic Acid

Aqueous sulfuric acid (3 *N*, 1 ml) was added to a solution of potassium thiocyanate (0.50 g, 5 mmoles) in 25 ml of water. This mixture was then added to a solution of *cis*-3-thiocyanopropenal (1.13 g, 10 mmoles) in 10 ml of acetone. The reaction mixture was left at room temperature for 15 min, whereafter it was diluted with 20 ml of water and cooled. The precipitate was filtered off and air-dried to give 0.62 g of white solid, m.p. 87–91°. The melting point was not depressed by *trans*-3-thiocyanopropenal, and the infrared spectra were superimposable.

For personal use only.

trans-3-p-Nitrothiophenoxypropenal (V)

A mixture of 3-thiocyanopropenal (0.50 g, 4.4 mmoles) (either the *cis* or *trans* isomer) and *p*-nitrothiophenol (0.80 g, 5.1 mmoles) in 25 ml of ethyl acetate was left at room temperature for 1 h. The solution was next washed with a 5% aqueous sodium carbonate solution and dried. Removal of the solvent yielded 0.80 g (87%) of a yellow-colored solid, m.p. 109–115°. An analytical sample of fine yellow needles melting at 118–119° was obtained after two recrystallizations from ethyl acetate.

Anal. Calcd. for $C_9H_7NO_3S$: C, 51.67; H, 3.37; S, 15.33. Found: C, 51.80; H, 3.64; S, 15.39.

The nuclear magnetic resonance spectral parameters which require the *trans* configuration are reported in Table I. The infrared spectrum (in $CHCl_3$) had strong bands at 1 672, 1 562, 1 520, 1 345, 1 120, 945, and 853 cm^{-1}.

Sodium cis-Propenal-3-thiosulfate

A solution of sodium thiosulfate pentahydrate (505 g, 2.0 moles) in 600 ml of water was added dropwise in 1 h to a stirred mixture of propynal (97 g, 1.8 moles), acetic acid (111 g, 1.8 moles), water (370 ml), and acetone (185 ml). During the addition the temperature of the reaction mixture was kept at −5 to 0°. A white solid precipitated readily. After the addition was completed, the mixture was kept for an additional 30 min at 0°; then 400 ml of cold acetone was added and the white solid was filtered off and dried. The product amounted to 228 g (65%). The nuclear magnetic resonance spectral parameters are given in Table I.

Isothiazole (I)

(*a*) 3-Thiocyanopropenal (100 g, 0.89 mole; consisting of approximately 85% *cis* and 15% *trans* isomer) was added in portions, with stirring, to 500 ml of liquid ammonia at approximately −60°. The reaction mixture was left at this temperature for a few hours and was then allowed to come to room temperature. The dark-colored residue was steam-distilled until approximately 350 ml of distillate had been collected. The isothiazole layer was separated and the aqueous solution extracted with five 40 ml portions of ether. The combined organic layers were dried and fractionally distilled to give 14.0 g (22%, based on *cis*-3-thiocyanopropenal) of isothiazole, b.p. 111–112° at 700 mm (lit. (6) b.p. 113° at 770 mm).

(*b*) Sodium *cis*-propenal-3-thiosulfate (486 g, 2.56 moles) was added to liquid ammonia (approximately 1 l). The resulting mixture was stirred for a few hours at −60°, and then the ammonia was allowed to evaporate. Enough water was added to the residue to dissolve all the white solid material. The mixture was then extracted with four 150 ml portions of ether. The combined ether extracts were dried and fractionally distilled to give 133 g (61%) of isothiazole, b.p. 111–112° at 700 mm.

SOME NEW ROUTES FOR THE SYNTHESIS OF AROMATIC FLUORINE COMPOUNDS

H. L. Sharma, V. N. Sharma, and R. L. Mital

One of the important methods for the synthesis of aromatic fluorine compounds involves the exchange of fluorine for some other halogen atom (1–3), for some other univalent functional group like the hydroxyl, or for oxygen in the carbonyl and carboxyl groups (4).

SOME NEW ROUTES FOR THE SYNTHESIS OF AROMATIC FLUORINE COMPOUNDS

H. L. Sharma, V. N. Sharma, and R. L. Mital

One of the important methods for the synthesis of aromatic fluorine compounds involves the exchange of fluorine for some other halogen atom (1–3), for some other univalent functional group like the hydroxyl, or for oxygen in the carbonyl and carboxyl groups (4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A survey of the literature reveals that only a few references (5–7) deal with the methods for the synthesis of fluoronitrobenzenes via exchange of fluorine for some other halogen atom, and that practically no work has been done on their synthesis via exchange of fluorine for the *p*-toluenesulfonic ester group, though the latter method has been worked out for the synthesis of alkyl fluorides (8, 9).

The present note describes some new routes for the synthesis of fluoronitrobenzenes via exchange of fluorine for another halogen atom or for a *p*-toluenesulfonic ester group.

Several workers have shown that picryl and 2,4-dinitrophenyl carbonium ions are stabilized by heterocyclic bases (10, 11). Thus, when polynitrohalogenobenzenes are treated with pyridine or α-, β-, or γ-picoline, polynitrophenylpyridinium or polynitrophenyl-α-, -β-, or -γ-picolinium halides are obtained. It has been observed by us that these yield fluoronitrobenzenes when treated with anhydrous potassium fluoride in dry dimethylformamide or nitrobenzene.

Polynitrophenylpyridinium or polynitrophenyl-α-, -β-, or -γ-picolinium *p*-toluenesulfonates were obtained by treating polynitrophenyl *p*-toluenesulfonates with pyridine or α-, β-, or γ-picoline, and it has been found that these, under the conditions mentioned above, yield fluoronitrobenzenes. Even polynitrophenyl *p*-toluenesulfonates were successfully converted into fluoronitrobenzenes under these conditions. Thus this method provides a new route for the synthesis of fluoronitrobenzenes from polynitrophenols.

The exchange of fluorine in all these compounds has been found to be much easier in dimethylformamide than in nitrobenzene. This could be explained on the basis of the findings of Miller and Parker (12), who observed that there is a lower degree of solvation of F^- ions in dipolar aprotic solvents.

EXPERIMENTAL

Nitrophenyl p-Toluenesulfonates

4,6-Dinitro-3-methylphenyl, 2,6-dinitrophenyl, and 2,4-dinitrophenyl *p*-toluenesulfonates were prepared by the methods reported earlier (13–15).

Nitrophenylpyridinium and Nitrophenyl-α-, -β-, or -γ-picolinium Halides or p-Toluenesulfonates

A mixture of halogenonitrobenzene (0.01 mole) or nitrophenyl *p*-toluenesulfonate (0.01 mole) and one of the heterocyclic bases such as pyridine or α-, β-, or γ-picoline (0.012 mole) was heated at 90–95° in dry toluene (ca. 15 ml) under reflux for 4 h. The mixture was cooled, and the resulting solid was filtered off, washed successively with benzene and ether, and dried. The compounds are listed in Table I.

Only 2,6-dinitrochlorobenzene did not react with α-picoline, probably because the nitro groups hindered the approach of the attacking reagent.

Preparation of Fluoronitrobenzenes

(i) From Nitrophenylpyridinium or Nitrophenyl-α-, -β-, or -γ-picolinium Halides or p-Toluenesulfonates

(a) Reaction in dimethylformamide.—A mixture of nitrophenylpyridinium or nitrophenyl-α-, -β-, or -γ-picolinium halide or *p*-toluenesulfonate (0.01 mole) (as the case may be) and anhydrous potassium fluoride (0.012 mole) in dry dimethylformamide (ca. 20 ml) was heated at 110–115° for 1½ h. Dimethylformamide was removed under reduced pressure, and the residue was refluxed with 25 ml of ethanolic hydrochloric acid (1:1 v/v) for ½ h. The solution was then diluted with water (ca. 100 ml) and extracted with benzene. Removal of benzene by distillation yielded the fluoronitrobenzene.

(b) Reaction in nitrobenzene.—The same procedure was followed as described above, except that the reaction mixture was refluxed at 210° for 3 h.

(ii) From Nitrophenyl p-Toluenesulfonates

(a) Reaction in dimethylformamide.—A mixture of anhydrous potassium fluoride (0.015 mole) and nitrophenyl *p*-toluenesulfonate (0.01 mole) in dry dimethylformamide (ca. 25 ml) was heated at 150° for 2½ h. After dilution with water, the isolated product was extracted with benzene. Removal of benzene by distillation yielded the fluoronitrobenzene.

(b) Reaction in nitrobenzene.—A mixture of anhydrous potassium fluoride (0.015 mole) and the nitrophenyl *p*-toluenesulfonate (0.01 mole) in nitrobenzene (ca. 20 ml) was refluxed for 3½ h. The mixture was cooled and filtered, and the residue was washed well with hot toluene. The combined filtrate and washings were dried and vacuum-distilled to yield the fluoronitrobenzenes.

These compounds are listed in Table II.

SUGAR ESTERS
III. NEW REAGENT FOR DEOXYHALO SUGAR PREPARATION

J. B. LEE AND T. J. NOLAN

The need to prepare deoxyhalo analogues of certain sugar-containing natural products, together with the potential synthetic applications of deoxyhalo sugars, has prompted our examination of a number of possible routes to these compounds (1), including various modifications of Rydon's reagents (2). The latter reagents, of the type I (R = aryloxy or alkoxy, X = alkyl or halide, Y = halide), in principle offer ready means for conversion of

alcohols into halides. In practical use with natural products, we have found the original conditions used by Rydon to be unsatisfactory with respect to either yield, need for vigorous conditions, or necessitating tedious processes. These difficulties have been overcome by modification of the original conditions or reagents (3), but a need still exists for a reagent which would act rapidly in mild, essentially neutral, conditions.

Crofts and Downie (4) describe the reaction of triethyl phosphite with ethanol and carbon tetrachloride to give ethyl chloride, chloroform, and triethyl phosphate. Since

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

triethyl phosphite and carbon tetrachloride have been shown (5) to give diethyl trichloromethyl phosphonate, which is not attacked by alcohols under these conditions (4), it is likely that ethanol is reacting with an intermediate of type II to give III (plus chloroform), the latter intermediate (III) breaking down in an Arbusov-type (e.g. see ref. 6) reaction. We considered that, if we could induce an alcohol to react to form an analogous intermediate of type IV (where R'OH was the original alcohol), in which no competition for the halide ion in the final Arbusov reaction is possible (a condition satisfied when the R groups are aryl or alkyl, but not when they are alkoxy groups), then formation of the required halide should proceed readily.

We therefore examined the reaction of triphenylphosphine with alcohols in excess carbon tetrachloride. Model reactions with aliphatic primary and secondary alcohols proceeded in good yield, the reaction proceeding rapidly at the reflux temperature (approximately 80 °C) of the solution.

We then investigated the stability of acetal, ether, and ester groups (commonly used as protecting groups in the carbohydrate field) towards the reagent. For example, when 2,2-dimethyl-4-hydroxymethyl-1,3-dioxolane was heated under reflux with an equimolar amount of triphenylphosphine in excess carbon tetrachloride, the reaction was complete in 1 h, and a high yield (>80%) of the 4-chloromethyl derivative (correct analysis, identical in infrared and proton magnetic resonance spectra with authentic material) was obtained.

Under similar conditions (1 mole triphenylphosphine, excess carbon tetrachloride, reflux) the following ethers and esters were converted in high yield into the halo compound without effect upon the protecting groups: 2-acetoxyethanol, 4-acetoxybutanol, glycolic aldehyde diethylacetal, 2-hydroxyethyl ethyl ether, 2-hydroxyethyl methyl ether, 2-hydroxyethyl butyl ether, and 2-hydroxyethyl stearate.

The absence of rearrangement of the carbon skeleton of alcohols under the reaction conditions was confirmed by the conversion of neopentanol and 3-hydroxymethylheptane into neopentyl chloride and 3-chloromethylheptane, respectively, in good yield, their identity being confirmed by comparison with authentic material, and the absence of rearrangement being confirmed by examination of their proton magnetic resonance spectra.

When Rydon's reagents (e.g. triphenyl phosphite methiodide) are applied to sugars or polyols having two free hydroxyl groups sterically situated next to one another, the formation of phosphonate esters occurs in preference to halide formation (3). We showed that this disadvantage was eliminated by the use of our modified reagent.

Thus ethanediol reacted with triphenylphosphine and carbon tetrachloride to give a good yield of dichloroethane, together with some ethylene chlorohydrin. Similar behavior was observed with the butanediols.

In view of these observations, we proceeded to examine the reaction of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose with triphenylphosphine in excess carbon tetrachloride. From the reaction mixture we obtained, in good yield, 1,2;3,4-di-*O*-isopropylidene-6-deoxy-6-chloro-α-D-galactopyranose together with a little 1,2;3,4-di-*O*-isopropylidene-6-deoxy-5,6-didehydro-β-L-arabinohexopyranose.

We are examining the utility of this reaction in the preparation of other halo sugars and halopolyols.

To separate the sugar derivatives obtained in this and other work, we have applied the new technique of 'dry column' chromatography, which combines the selectivity of the thin-layer technique with the larger scale of normal column chromatography, without the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

disadvantages of cumbersome apparatus and large amounts of support needed for large-scale layer chromatography, or of large volumes of solvent required in normal column chromatography.

EXPERIMENTAL

Proton magnetic resonance spectra were measured with a Perkin–Elmer 40 Mc.p.s. instrument. Infrared spectra were measured on Unicam SP 100 and SP 200 instruments. Thin-layer chromatography used Kieselgel HF_{254} support. The solvents used were: A, 9:1 benzene–methanol; B, benzene; C, 19:1 benzene–methanol. Gas–liquid chromatography with a Perkin–Elmer 452, Shandon FB 4, or Wilkins Autoprep instrument employed Silicone, Carbowax, Apiezon L, or dinonyl phthalate (supported on Celite) liquid phases in 2 m columns. Materials were in most cases purified commercial samples. 1,2;3,4-Di-*O*-isopropylidene-α-D-galactopyranose was prepared by the method of Tipson (7). Melting and boiling points are uncorrected. We are indebted to P. Borda for microanalyses.

Typical Procedures

2,2-Dimethyl-4-chloromethyl-1,3-dioxolane

To a solution of triphenylphosphine (26 g) in carbon tetrachloride (15 ml) was added 2,2-dimethyl-4-hydroxymethyl-1,3-dioxolane (15 ml), and the solution was warmed under reflux on a water bath. After the initial vigorous reaction had moderated, the mixture was heated under reflux for a further 15 min. The mixture was fractionated under reduced pressure, and the fraction boiling at 64–78° at 17 mm was collected and redistilled at atmospheric pressure to give a fraction (13 g, b.p. 156–159°) identical in infrared and proton magnetic resonance spectra with authentic material (8).

2-Chloroethyl Methyl Ether

A mixture of redistilled 2-hydroxyethyl methyl ether (b.p. 122–124°, 7.2 g), dry triphenylphosphine (26 g), and anhydrous carbon tetrachloride (17 g) was warmed gently under reflux. A vigorous reaction ensued, and when this had moderated the mixture was kept at 80 °C for a further 10 min, and was then fractionated to give chloroform (contaminated with small amounts of carbon tetrachloride and chloroether) and 2-chloroethyl methyl ether (b.p. 92–94°, n_D^{18} 1.4108, 7.3 g), identical in retention (Silicone column, 50°) on gas–liquid chromatography, and in infrared and proton magnetic resonance spectra with authentic material.

1,2;3,4-Di-O-isopropylidene-6-deoxy-6-chloro-α-D-galactopyranose

A solution of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (6.5 g) and triphenylphosphine (6.56 g) in carbon tetrachloride (25 ml) was heated under reflux for 3 h. The solution was cooled, and the solid which had crystallized was separated and shown (by thin-layer chromatographic, spectral, and melting point comparison) to be triphenylphosphine oxide. Solvent was removed from the filtrate *in vacuo*, and the oily residue was extracted with ether (6 × 50 ml) to leave, as residue, a further amount of triphenylphosphine oxide.

TABLE I

Compound	Product* (physical constants)
2-Acetoxyethanol	2-Chloroethyl acetate (b.p. 144–146°)
4-Acetoxybutanol	4-Chlorobutyl acetate (b.p. 85–90° at 15 mm)
Glycolic aldehyde diethylacetal	Chlorodiethylacetal (b.p. 148–155°, n_D^{21} 1.4160)
2-Hydroxyethyl ethyl ether	2-Chloroethyl ethyl ether (b.p. 107–109°, n_D^{20} 1.4118)
2-Hydroxyethyl butyl ether	2-Chloroethyl butyl ether (b.p. 132–138°)
2-Hydroxyethyl stearate	2-Chloroethyl stearate (m.p. 47–49°)
Neopentyl alcohol	Neopentyl chloride (b.p. 80–83°)
1,3-Butanediol	1,3-Dichlorobutane (b.p. 130–135°, n_D^{20} 1.4458)
1,2-Butanediol	1,2-Dichlorobutane (b.p. 125–130°)
2,3-Butanediol	2,3-Dichlorobutane (b.p. 112–114°, n_D^{20} 1.4496)

*Comparisons of spectra with authentic material, and comparisons of gas–liquid chromatographic behavior, were made in each case.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Ether was removed from the extracts at the pump, and the clear yellow syrup that remained was subjected to 'dry column' chromatography upon Kieselgel HF_{254} (eluted with solvent B), the eluted fractions (1 ml fractions) being examined by thin-layer chromatography (solvents A and B).

1,2;3,4-Di-*O*-isopropylidene-6-deoxy-6-chloro-α-D-galactopyranose was obtained as a pale-yellow syrup showing only one component on thin-layer chromatography (Kieselgel HF_{254}; solvents A, B, and C) and on gas–liquid chromatography (Apiezon L column, 200 °C). This component analyzed correctly and had a correct infrared spectrum for the expected product.

Dichloroethane

A solution of carbon tetrachloride (50 ml) containing triphenylphosphine (26.5 g) was heated under reflux, with stirring, with ethanediol (3.1 g) for 12 h. The mixture was fractionated on a Silicone column to give ethylene chlorhydrin (n_D^{17} 1.4427, 0.8 g) and 1,2-dichloroethane (n_D^{18} 1.4458, 2.7 g), the products being identical in infrared spectra and in behavior on gas–liquid chromatography with authentic compounds.

INTRODUCTION

The degree of coplanarity achieved by a benzene ring and its conjugated substituents has been the subject of close scrutiny in recent years, and X-ray crystallographic results suggest that complete coplanarity is rarely achieved in the crystalline state (1–5). Non-coplanarity implies loss of resonance energy (6), which is presumably offset by the energy gain from relief of steric compression or improved molecular packing in the crystal. Some recent results for solutions have revealed non-coplanarity in aromatic solutes where solute–solvent interactions may provide compensation for the resonance energy lost by rotation of substituents about the bonds joining them to the ring. On the basis of dipole moment measurements in dioxane, it has been proposed that the carboxamido group of benzamide lies in a plane inclined at 37° to that of the benzene ring (7). Again, proton magnetic resonance measurements in pyridine have revealed that the amide and ring planes in N-methylacetanilide are orthogonal (2).

Some substituted formanilides have now been examined by proton magnetic resonance spectroscopy to measure the effects of ring substituents and the nature of the solvent on the orientation of the formamido group with respect to the aromatic ring. The *cis* (I) and *trans* (II) forms of formanilide have been shown to coexist in deuteriochloroform solution

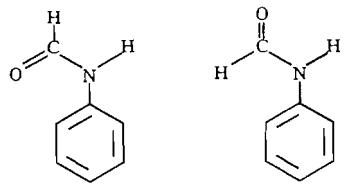
STEREOCHEMISTRY OF *o*-SUBSTITUTED FORMANILIDES

IAN D. RAE

INTRODUCTION

The degree of coplanarity achieved by a benzene ring and its conjugated substituents has been the subject of close scrutiny in recent years, and X-ray crystallographic results suggest that complete coplanarity is rarely achieved in the crystalline state (1–5). Non-coplanarity implies loss of resonance energy (6), which is presumably offset by the energy gain from relief of steric compression or improved molecular packing in the crystal. Some recent results for solutions have revealed non-coplanarity in aromatic solutes where solute–solvent interactions may provide compensation for the resonance energy lost by rotation of substituents about the bonds joining them to the ring. On the basis of dipole moment measurements in dioxane, it has been proposed that the carboxamido group of benzamide lies in a plane inclined at 37° to that of the benzene ring (7). Again, proton magnetic resonance measurements in pyridine have revealed that the amide and ring planes in N-methylacetanilide are orthogonal (2).



Some substituted formanilides have now been examined by proton magnetic resonance spectroscopy to measure the effects of ring substituents and the nature of the solvent on the orientation of the formamido group with respect to the aromatic ring. The *cis* (I) and *trans* (II) forms of formanilide have been shown to coexist in deuteriochloroform solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(8), and signals arising from both types of formyl proton are readily identifiable in the proton magnetic resonance spectrum because of the difference in coupling with the amide proton (J_{cis} ca. 2 c/s, J_{trans} ca. 11 c/s). If the formamido group itself remains planar and rotation is permitted about the bond joining the nitrogen and the aromatic ring, it is clear that the magnetic environment of formyl protons in the *trans* form (II) will change appreciably as rotation proceeds. Measurements from Dreiding models (or trigonometrical calculation) and use of the data of Johnson and Bovey (9) show that the changes in shielding of the formyl proton by the aromatic ring are dependent on the angle of rotation (ϕ) as follows ($\phi = 0$ for completely planar molecules).

Angle of rotation (ϕ)	0°	30°	45°	60°	90°
Relative shielding (p.p.m.)					
cis	0	0.01	0.02	0.05	0.08
trans	0	0.18	0.21	0.43	0.63

Since it had also been shown that the formyl proton resonances of formanilide were almost independent of concentration (8), the chemical shift of a *trans* formyl proton was seen as an excellent probe for investigating rotation about the Ar—N bond in formanilides. It was proposed to effect such a rotation by means of substituents placed ortho to the

I II

formamido group; also, to preserve the simplicity of the calculated relationship, it was necessary to choose substituents with low anisotropy and minimum electronic effect on the benzene ring. Halogen atoms and alkyl groups fulfilled both these conditions (10, 11), and the investigation was therefore confined to formanilides bearing substituents of these types. Further, the choice of solvents was influenced by the following factors: (*i*) the need to avoid the highly specific shielding effects of aromatic solvents (12, 13), (*ii*) the retention of slow exchange of the amide protons so that formyl proton signals might be clearly identified by means of coupling constants, and (*iii*) the solubility of formanilides. This last factor was doubly important since the ratio of *trans* to *cis* forms decreased markedly at low concentrations (cf. ref. 8); when the solubility of a formanilide was too low, only the *cis* form could be observed in solution.

RESULTS AND DISCUSSION

The *cis* formyl proton resonances (not recorded here) showed the small variation expected, thus confirming that the formyl protons may be regarded as electronically insulated from the aromatic ring. The *trans* proton resonances, however, showed a much greater variation with structure; they are recorded in the tables and form the basis for the discussion.

The results in Table I for dimethyl sulfoxide solutions are compatible with a model where the formamido group lies in the ring plane when no hindering substituents are present, and is orthogonal to the ring plane when both the 2′- and 6′-positions of the ring are occupied by substituents. In deuteriochloroform, the change in chemical shift of the formyl protons when two flanking substituents are introduced is somewhat smaller and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

leads to a calculated value of about 65° for the interplane angle ϕ. If this figure has any reality, the effect of solvent may be rationalized in terms of an increase in the "effective size" of the formamido group as outlined later in this section, but the paucity of data deters speculation.

TABLE I

Chemical shift of *trans* formyl protons for 4′- and 2′,6′-substituted formanilides

	Chemical shift (δ)	
Substituent	$CDCl_3$	CH_3SOCH_3
None	8.62	8.65
4′-Methyl	8.67	8.55
4′-Chloro	8.67	8.62
4′-Bromo	8.67	8.63
Mean of above values	8.66	8.61
2′,6′-Dimethyl	8.20	7.85
2′,6′-Dichloro	—*	8.02
2′,6′-Dibromo	—†	7.95
2′-Chloro-6′-methyl	8.17	7.95

*cis form predominates (>95%).
†Insufficiently soluble.

In the other solvents tried, the resonances for the 2′,6′-disubstituted formanilides could not be identified clearly, but 2′-substituted cases could be handled effectively; the data are reported in Table II. In each solvent the resonance positions for formanilide and three 4′-substituted formanilides were averaged to give a value for the coplanar standard ($\phi = 0$), and time-average values for the angles of rotation of 2′-substituted formanilides were computed on this basis. The varying limits of error result from the nonlinear dependence of shielding on ϕ and are based on an estimated error in the measurement of the chemical shift differences of 0.03 p.p.m.

TABLE II

Chemical shift of *trans* formyl protons and calculated angle ϕ for 2′-substituted formanilides

	$CDCl_3$		CH_3COCH_3		CH_3OH		CH_3SOCH_3	
Substituent	δ	ϕ	δ	ϕ	δ	ϕ	δ	ϕ
Planar standard	8.62	0	8.76	0	8.24	0	8.61	0
2′-Methyl	8.42	35±9°	8.50	50±3°	7.97	51±3°	8.22	58±2°
2′-Chloro	8.68	0	8.70	4±2°	8.12	12±4°	—*	
2′-Bromo	8.63	0	8.67	8±4°	8.10	16±6°	—*	
2′-Iodo	8.53	10±3°	8.52	48±3°	8.00	48±3°	—*	
2′,5′-Dimethyl	8.53	10±3°	8.40	57±2°	8.02	45±4°	8.25	57±2°

*Either predominantly *cis* isomer in solution, or coincident signal at 8.25 p.p.m. ($\phi = 57 \pm 2°$).

The data of Table II reveal a tendency towards increasing ϕ as the size of the 2′-substituent increases, and also as the solvent is changed from deuteriochloroform through methanol and acetone to dimethyl sulfoxide. The dependence of ϕ on steric factors is not unexpected, although the effect of a 2′-methyl group seems disproportionally large in view of the accepted covalent radii (14) of the chlorine and bromine atoms and the methyl group (1.80, 1.95, and 2.0 Å, respectively). In a study of N-substituted formanilides, a similar progressive increase in ϕ with the bulk of the N-alkyl substituent has been noted (15).

The dependence of ϕ on the nature of the solvent gives a solvent order which follows the dipole moment of the solvent molecules rather than the bulk property dielectric constant (see Experimental). In the more polar solvents it is proposed that a closer association of solvent molecules with the dipolar formamido group greatly increases its steric requirements and thus leads to higher ϕ values.

EXPERIMENTAL

No new compounds were employed in this study. With the exception of formanilide itself, which was commercially available, and 2′-methyl- and 2′,5′-dimethyl-formanilides, which were kindly supplied by Dr. L. Marion, the formanilides were prepared by the action of boiling 98% formic acid (16) or cold 4:1 formic acid – acetic anhydride (17) on the appropriately substituted anilines. The properties of the purified formanilides agreed with those reported in the literature (16, 18, 19), and further confirmation of their identity was obtained from infrared and proton magnetic resonance spectra.

Dielectric constants for the liquid state at 25° are: chloroform (20), 4.8; acetone (20), 20.7; methanol (20), 32.6; dimethyl sulfoxide (21), 45.5. Dipole moments for solutions in benzene (22) are: chloroform, 1.1; methanol, 1.6; acetone, 2.4; dimethyl sulfoxide, 3.9.

Proton magnetic resonance spectra were recorded for approximately 5% solutions on a Varian A-60 spectrometer at 25°. Tetramethylsilane was used as an internal (deuteriochloroform, acetone) or external (methanol, dimethyl sulfoxide) standard.

ACKNOWLEDGMENTS

The author thanks Dr. D. G. Gillies for discussion and communication of unpublished results, and Dr. L. Marion for generous samples of formanilides. This work was commenced during the tenure of a Postdoctorate Award at the National Research Council, Ottawa.

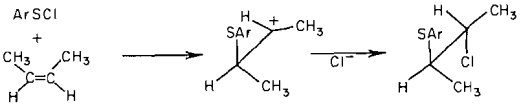
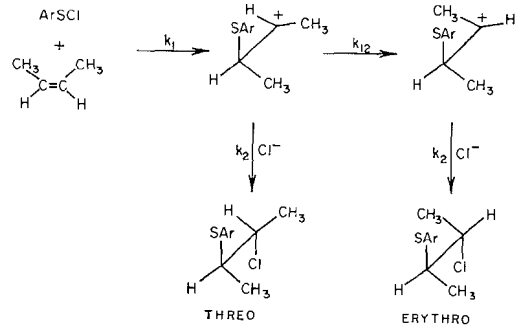
THE INFLUENCE OF TEMPERATURE ON THE STEREOCHEMISTRY OF THE ADDITION OF *p*-CHLOROBENZENESULFENYL CHLORIDE TO *cis*- AND *trans*-2-BUTENE



GEORGE H. SCHMID AND VALERIA M. CSIZMADIA[1]

The mechanism of the reaction of an arylsulfenyl chloride with an olefin has been postulated by Kharasch (1) to involve a cyclic sulfonium ion intermediate (I).



I

This intermediate has been invoked to account for the observed *trans* addition. Evidence that such an intermediate is capable of formation has been obtained by Pettitt and Helmkamp (2) and by Eliel (3). These results do not rule out the formation of an open carbonium ion (II) as an intermediate.

II

trans Addition will be favored because of the steric hindrance of the sulfur group and its substituent. This intermediate would retain its stereochemical integrity if the rate of rotation about the carbon–carbon single bond to form the isomeric carbonium ion is slower than the rate of attack by chloride ion. This mechanism is illustrated in Reaction Scheme 1. The bimolecular step is a reaction between ions of different charge. Such

REACTION SCHEME 1.

reactions have been shown to have extremely fast rates (4), and in addition, energy barriers to rotation in the range of 10 kcal are known (5). Thus, this mechanism cannot be rejected arbitrarily. A method to distinguish between these two mechanisms is to study the effect of temperature on the stereochemistry of the product of the addition of an arylsulfenyl chloride to a *cis* and *trans* olefin. The system chosen for study was the addition of *p*-chlorobenzenesulfenyl chloride to *cis*- and *trans*-2-butene.

Consider the kinetic scheme for the addition to *cis*-2-butene as illustrated in Reaction Scheme 1. The rates of formation of the threo isomer and the erythro isomer are given by eqs. [1] and [2], respectively.

$$[1] \qquad \frac{\mathrm{d[threo]}}{\mathrm{d}t} = \frac{k_1[cis\ \text{olefin}][\mathrm{ArSCl}]}{1 + (k_{12}/(k_2[\mathrm{Cl^-}]))}$$

$$[2] \qquad \frac{\mathrm{d[erythro]}}{\mathrm{d}t} = \frac{k_1[cis\ \text{olefin}][\mathrm{ArSCl}]}{(k_2[\mathrm{Cl^-}]/k_{12}) + 1}$$

Elimination of time as a variable (6) and integration gives eq. [3].

$$[3] \qquad \frac{[\text{erythro}]}{[\text{threo}]} = \frac{k_{12}}{k_2[\mathrm{Cl^-}]}$$

The relation between the [erythro]/[threo] ratio at any two temperatures is given by eq. [4].

$$[4] \qquad \frac{([\text{erythro}]/[\text{threo}])_{T_1}}{([\text{erythro}]/[\text{threo}])_{T_2}} = L = (k_{12}/k_2)_{T_1}(k_2/k_{12})_{T_2}$$

Replacement of the rate constants by the Arrhenius equation gives eq. [5].

$$[5] \qquad L = \frac{\exp \frac{E_a^{12}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)}{\exp \frac{E_a^{2}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)}$$

This can be simplified to eq. [6].

$$[6] \qquad \log L = \frac{E_a^{12} - E_a^{2}}{2.303R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

Equation [6] predicts that the ratio L will depend upon the relative activation energies of the two processes and the temperature range chosen to study the product composition. From eq. [6] it is possible to calculate the change in temperature necessary to observe a value of 5 for L if the difference in activation energies is but 2.0 kcal/mole. A temperature range of 150 degrees is predicted. Thus, eq. [6] gives a convenient method of testing the open carbonium ion mechanism. If the energy of activation of rotation is greater than the energy of activation of the bimolecular reaction by at least 2 kcal/mole, a significant change in the [erthyro]/[threo] ratio should be observed as the temperature of the reaction is increased over a range of 150 degrees.

The experimental results of the stereochemistry of the addition of *p*-chlorobenzenesulfenyl chloride to *cis*- and *trans*-2-butene in 1,1,2,2-tetrachloroethane over a temperature range of 180 degrees are given in Table I. The product composition was determined by vapor phase chromatography, which cleanly separated the *dl*-erythro and *dl*-threo isomers. Addition of oxygen, to suppress any free-radical reaction, had no effect upon the product composition. Control experiments showed that a minimum of 0.05% of one isomer could be detected in the presence of the other. The nearly constant 0.5% of threo isomer in the addition to *trans*-2-butene is due to *cis*-2-butene being an impurity in the starting material. The *cis*-2-butene contained less than 0.05% of *trans*-2-butene.

From the data in Table I it is clear that the ratio L given by eq. [4] has a value of 1. Therefore, if eq. [6] is to be consistent with the experimental observations, then $E_a^{12} = E_a^{2} = E$. This means that the difference in rates must be due to the pre-exponential factors.

TABLE I

Observed temperature effect on product stereochemistry

Temperature (°C)	*cis*-2-Butene		*trans*-2-Butene	
	dl-Erythro	*dl*-Threo	*dl*-Erythro	*dl*-Threo
−34	0.05	99.95	99.44	0.56
0	0.05	99.95	99.55	0.45
25	0.05	99.95	99.49	0.51
50	0.05	99.95	99.46	0.54
75	0.05	99.95	99.56	0.44
100	0.05	99.95	99.49	0.51
146	0.05	99.95	99.54	0.46

Equation [7] is obtained by substitution of the Arrhenius equations for k_{12} and k_2 into eq. [3], and relates the [erythro]/[threo] ratio and the pre-exponential factors.

$$[7] \qquad \frac{[\text{erythro}]}{[\text{threo}]} = \frac{A_{12}\exp(-E/RT)}{A_2\exp(-E/RT)[\text{Cl}^-]} = \frac{A_{12}}{A_2[\text{Cl}^-]}$$

Experimentally, the [erythro]/[threo] ratio is given by eq. [8].

$$[8] \qquad \frac{[\text{erythro}]}{[\text{threo}]} = \frac{0.05}{99.95} = 5 \times 10^{-4} = \frac{A_{12}}{A_2[\text{Cl}^-]}$$

For eq. [8] to be true, the product of the pre-exponential factor A_2 and the chloride ion must be 5×10^4 times the pre-exponential factor A_{12}. This seems to be unlikely. The concentration of chloride ion will be so small (approximately 10^{-8} mole/l) that, even if the pre-exponential factor is among the highest known (10^{19} l moles/s (4)), the product of the two will still be approximately equal to or less than a normal pre-exponential factor for a unimolecular process (10^{10} to 10^{12}/s) involving rotation (7). Thus, for an open carbonium ion mechanism to account for the observed results, it is necessary not only that the activation energies of the rotation and bimolecular steps be identical but also that the pre-exponential factor for the bimolecular step be extremely high.

It seems to be clear that the cyclic sulfonium ion intermediate mechanism originally postulated by Kharasch (1) and supported by the work of Pettitt and Helmkamp (2) and Eliel (3) explains more easily and more satisfactorily not only the *trans* addition but also the absence of a temperature effect upon the stereochemistry of the product.

EXPERIMENTAL

All melting and boiling points are uncorrected. Vapor phase chromatography was performed on a Wilkens Instruments model 705 chromatograph with helium as a carrier gas.

Bis-(4-chlorobenzene)disulfide

In a 2 l Erlenmeyer flask equipped with a magnetic stirrer were placed 1 000 ml of distilled water, 86.7 g (0.60 mole) of *p*-chlorothiophenol, and 24.0 g (0.60 mole) of sodium hydroxide. The crystalline *p*-chlorothiophenol dissolved as a fluffy precipitate of sodium *p*-chlorothiophenoxide was formed. To the mixture was added 450 ml of 3% hydrogen peroxide at such a rate that the temperature of the reaction mixture did not exceed 30 °C. The light-yellow disulfide precipitated as it was formed. After the addition of the hydrogen peroxide, the reaction mixture was stirred overnight at room temperature. The crystals were filtered, and washed with warm tap water and then distilled water until the filtrate was alkaline free. Recrystallization from 95% ethyl alcohol gave a 95% yield of pale-yellow plates, m.p. 73.0–73.5 °C (lit. m.p. 71–71.5 °C (8)).

p-Chlorobenzenesulfenyl Chloride

This compound was prepared by the method of Lawson and Kharasch (9) in 81% yield, b.p. 33–34 °C at 0.22 mm (lit. b.p. 86–90 °C at 5 mm (10)). The purity of the material was determined by the method of Kharasch and Wald (11) and found to be 99.8 ± 1%.

Reaction of p-Chlorobenzenesulfenyl Chloride with cis- and trans-2-Butene

The reaction was carried out in the dark in a 250 ml, three-necked, round-bottomed flask equipped with a thermometer, a $CaCl_2$ drying tube, a gas inlet tube, and a dry ice – acetone condenser. 1,1,2,2-Tetrachloroethane (40 ml) was placed in the flask and brought to the desired temperature by a liquid ammonia bath, water bath, or oil bath. During this time, dry nitrogen gas was bubbled through the solution. After the desired temperature had been reached, 0.6 g (0.0035 mole) of *p*-chlorobenzenesulfenyl chloride was added to the reaction vessel. As soon as the temperature of the reaction mixture returned to its former value, the butene gas was bubbled in slowly. The reaction was rapid and exothermic. The temperature of the reaction mixture rose by 2–4 °C at the beginning of the reaction. The reaction was judged to be complete upon disappearance of the yellow color of the *p*-chlorobenzenesulfenyl chloride. The time for complete reaction was 1 to 5 min, depending upon the temperature. The flask was removed from the bath and the reaction mixture was analyzed directly by vapor phase chromatography. The *dl*-erythro and *dl*-threo isomers were cleanly separated on a ¼ inch by 13 ft column of 5% Carbowax on Chromosorb G. The yield of product was determined at 25 °C by the same procedure, except that methylene chloride was used as solvent. The solvent was removed under reduced pressure to constant weight. The residue, representing a 99% yield, was shown by vapor phase chromatography to consist of one isomer.

Quantitative Determination of Threo- and Erythro-3-chloro-2-butyl-p-Chlorobenzenesulfide

Two stock solutions were prepared: one containing 60.1 mg of the pure threo isomer in 1.0 ml of 1,1,2,2-tetrachloroethane and another containing 60.6 mg of the pure erythro isomer in 1.0 ml of 1,1,2,2-tetrachloroethane. The pure erythro isomer was prepared from a sample of research grade *trans*-2-butene not previously available to us. By means of microliter syringes, several mixtures of known quantities of each component were prepared. These mixtures were analyzed by vapor phase chromatography under the identical conditions used to analyze the reaction product mixtures. It was found that the limit of detection was 0.05% of one component in the presence of the other.

PARACHORS AND OTHER PROPERTIES OF ORGANOTINS

ROBERT C. PUTNAM

Research Laboratory, M & T Chemicals Inc., Rahway, New Jersey

Received February 1, 1966

ABSTRACT

The parachors of a group of organotins were measured and compared with calculated values using both atomic constants and bond constants to obtain corresponding values for tin. The variation was found to be lower for the first method. The parachors were found to be about 8 times the molar refractions and could be approximately predicted from calculated molar refractions.

The refrachors of the organotins were calculated and a suitable series of additive constants devised to approximate the found values. Excellent correlation was obtained between the order of refrachors corrected for molecular weight and the order of dispersions as expressed by the Nu (ν) values. An initial indication of alternation in methylene group increments for both molar refraction and Nu values was found. For a constant dispersion ratio (Q value) the refractive indices for the F and C lines of hydrogen were calculated.

For many years, chemists have searched for ways to correlate physical properties with structure. The prediction of structure from physical properties and the prediction of physical properties from structure have been goals long sought, but only poorly realized.

It has been evident that more than one physical property will be needed, since all efforts using only one constant have ended far from the mark. The most promising combination of properties and the one most fruitful in results has been the parachor. This constant has been the subject of innumerable studies, and its value is generally available in most fields of chemistry. It is the purpose of this paper to present some new data in the field of organometallics relative to the parachor and certain other properties of organotins.

The parachor is a constant of great utility in studies on structures of closely related compounds. It has both additive and constitutive properties. It is affected by unsaturation, branching, rings, and hydrogen bonds and is related to several other constants. Over 2 000 parachors are listed in a review article by Quayle (1). A. I. Vogel has published more than 40 papers in which the parachor holds an important place.

The parachor was introduced by Sugden (2) in 1924 and may be defined as

$$P = M\gamma^{1/4}/D,$$

where M is the molecular weight, γ is the surface tension, and D is the density of the liquid.

The compounds investigated were certain organotins whose constants are given in Table I. The densities were determined on a Fisher–Davidson gravitometer at 25 °C and the surface tensions on a Fisher surface tensiometer at 25 °C with corrections applied according to the method of Zuidema and Waters (3). The compounds had purities exceeding 99%, most being 99.7 to 100% pure.

TABLE I
Physical constants of organotins

	D_4^{25}	γ^{25}	M
Me_4Sn	1.280	19.7	178.8
Et_4Sn	1.181	25.9	234.9
Pr_4Sn	1.092	24.5	291.0
iPr_4Sn	1.117	25.7	291.0
Bu_4Sn	1.040	26.2	347.1
iBu_4Sn	1.045	24.5	347.1
Vi_4Sn	1.254	24.1	226.8
Me_3EtSn	1.251	21.6	192.7
Me_3PrSn	1.206	22.2	206.9
Me_3iPrSn	1.198	21.4	206.9
Me_3ViSn	1.277	21.3	190.7
$Me_3CyhexSn$	1.216	25.3	247.0
$Me_3\phi Sn$	1.326	28.9	240.9

The parachors were determined and compared with calculated values in order to determine the constancy of a value for tin in the organotins. The constants used for the calculated values were mainly Sugden's (4), since they gave the most consistent results. They were C, 4.8; H, 17.1; C=C, 23.2; ring, 6.1; branch, −5.7. (A ring is also a branch.)

The values obtained are shown in Table II.

TABLE II
Parachors obtained using atomic constants

	P found	Calcd. Sn
Me_4Sn	295	70.6
Et_4Sn	451	70.6
Pr_4Sn	593	57.0
iPr_4Sn	588	74.4
Bu_4Sn	757	64.6
iBu_4Sn	739	69.4
Vi_4Sn	401	64.6
Me_3EtSn	333	69.6
Me_3PrSn	372	69.6
Me_3iPrSn	372	69.6
Me_3ViSn	322	69.6
$Me_3CyhexSn$	456	70.4
$Me_3\phi Sn$	422	69.4

The values for tin are quite consistent considering the structural differences represented. The average value found for Sn was 69.4, omitting tetrapropyl tin. The standard error of the mean was 1.1% of the mean, and the latter's value was 69.4 ± 1.7 (95%), omitting tetrapropyl tin.

Values for the parachor of tin have been previously reported by Kadomtzeff (5); these values showed a much greater variation and suggested a possible alternation with the number of carbon atoms. There appears to be no clear indication of an alternation of the parachors of tin in the few *n*-tetra-alkyl tins considered here. The abnormally low value found for tin in tetrapropyl tin suggests that there may be some anomaly in its structure. The parachor for tin would be 68, in line with the other values, if half the propyl groups were considered to be branched. Since parachors are very sensitive to structural differences, this implies the existence of a factor requiring another adjusting constant. Tetrapropyl tin has a feature not present in the lower homologues. The *n*-propyl group can have either of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

two internal torsional configurations, *trans* or *gauche*, with respect to orientation about the C_1C_2 bond. This isomerism is independent of the arrangement between alkyl groups or of interaction between them (6). The complexity of the spectrum of the compound is due in part to this factor and indicates that both forms are present in the liquid state.

When compared at temperatures where surface tensions are equal, parachors of compounds are proportional to molar volumes at those temperatures. If we assume that the presence of two forms affects the molar volume, then we can account for the anomaly in the parachor.

Instead of using additive atomic constants for computing the parachor, one may use bond constants. Those developed by Vogel and co-workers (7) for alkyl groups, and also the individual values from their work, were used to compute the parachors minus the Sn—C linkages in order to compare with the found values and to show the possible constancy of the Sn—C bond. The individual values obtained by Vogel *et al.* are: C—H, 17.85; C—C, 4.30; C=C, 28.5; C_{ar}—C_{ar}, 16.5; C—C (cyclohexane), 4.5.

Their values were established for 20 °C but have been applied without correction to the present work which was done at 25 °C. The error involved in the values is less than one part per thousand.

TABLE III

Parachors obtained using bond constants

	P

$Me_3CyhexSn$	456	383	18.3
$Me_3\phi Sn$	422	348	18.5
			Mean 18.0

The calculated parachors excluding the Sn—C bonds are listed in Table III with corresponding calculated values for the latter bond.

The standard error of the mean was 3.6% of the mean, and the latter's value was 18.0 ± 1.4 (95%).

MOLAR REFRACTIONS

The parachors of the organotins investigated were found to bear a constant relationship to the determined molar refractions. The average value of the ratio is 7.91. Since calculated molar refractions using Vogel (7) bond refractions closely approximate the found values, one may estimate the parachors from the calculated molar refractions. The pertinent data are listed in Table IV. The average ratio of parachor to calculated molar refraction is 7.95. As an approximation the parachor may be considered to be 8 times the calculated molar refraction. The bond refraction values used for the calculated molar refraction were those given by Vogel for alkyl groups (7) and the following (8): C—C, 1.296; Sn—C, 4.16; C—H, 1.676; Sn—C (ar.), 3.78; C=C, 4.17; C—C (ar.), 2.688; C—C (cyclohexane), 1.27.

$Me_3\phi Sn$	422	56.45	7.48	56.24	7.51
			Average 7.91		Average 7.95

Vogel's constants pertain to 20 °C, whereas all measurements here were at 25 °C. The error involved is less than one part per thousand. The refractions refer to the sodium D line.

Since $P = M\gamma^{1/4}/D$ and $N = \dfrac{n^2 - 1}{n^2 + 2} \cdot \dfrac{M}{D}$ (N = molar refraction)

$$P/N = \gamma^{1/4} \Big/ \frac{n^2 - 1}{n^2 + 2}$$

and the values listed under P/N represent this ratio.

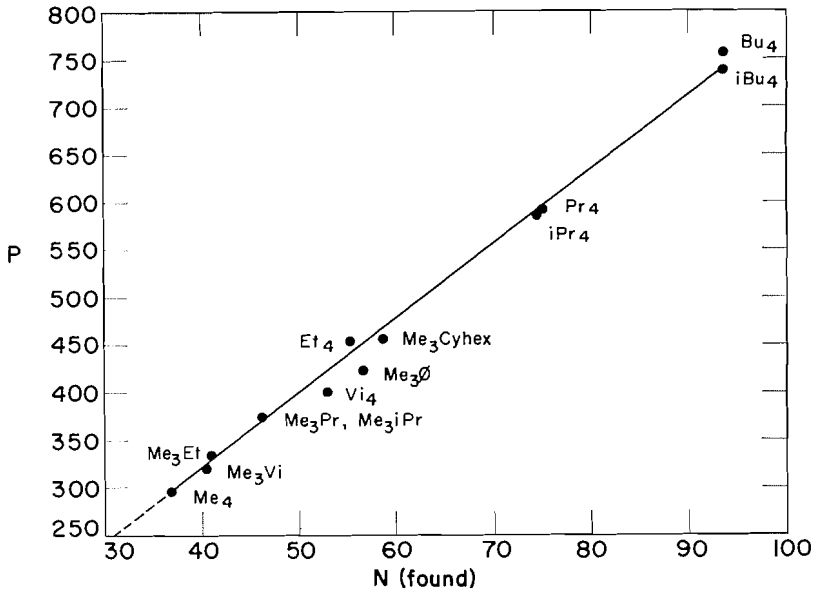

FIG. 1. Plot of parachor versus molar refraction.

Lagemann and Dunbar (9) discussed various relationships pertaining to the physical properties of liquids, and from their constants the following equation applying to *n*-alkanes may be derived,

$$P = 8.488N + 17.29,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

relating parachor and molar refraction. From a plot of the data relating to the alkyl tins, the corresponding equation in this field is:

$$P = 7.83N \text{ (calcd.)} + 7.3.$$

The per cent differences between the calculated and found values using the latter equation are approximately the same as those obtained using the relationship:

$$P = 7.95N \text{ (calcd.)}.$$

A plot of the parachor versus the found molar refraction is shown in Fig. 1.

REFRACHOR

The refrachor is a physical constant proposed by Joshi and Tuli (10) and is defined as

$$F = -P \log (n_D - 1),$$

where P is the parachor and n is the refractive index. It is very sensitive to structural variations and has the advantage that it combines both internal and external factors. They proposed a set of atomic, structural, and group refrachors. When these were applied to the tin compounds under study and compared with the determined refrachors, the values for tin were not found to be constant, viz.:

Compounds	F(Sn)
Me_4Sn	21.79
Et_4Sn	30.83
Pr_4Sn	36.98
iPr_4Sn	43.94
Bu_4Sn	34.74

When the following values were assigned to the bonds, reasonable agreement between found and calculated refrachors was obtained as shown in Table V: Sn—C, 38.4; C=C, 5; C—H, −4.3; branch, −2; C—C, 20.6; sat. ring, −48. (A ring is one branch.)

TABLE V

Refrachors of organotin compounds

	F found	F calcd.
Me_4Sn	105.5	102
Et_4Sn	148.3	150
Pr_4Sn	193.5	198
iPr_4Sn	185.9	190
Bu_4Sn	247.2	246
iBu_4Sn	239.1	238
Me_3EtSn	115.8	114
Me_3PrSn	128.4	126
Me_3iPrSn	128.8	126
$Me_3CyhexSn$	140.7	141
Me_3ViSn	109.4	107
$Me_3\phi Sn$	106.4	106
Vi_4Sn	121.5	122

The values show a mean deviation of two units on a whole number basis.

Since the parachor has been shown to have an average value of 7.91 times the measured molar refraction, this means that for the compounds studied the refrachor has the following average value:

$$F = -7.91N \log (n_D - 1)$$

ABBE NUMBER

The Abbe number or Nu (ν) value is a measure of the optical dispersion based on the determination of the refractive index using the D line of sodium, the C or red line of hydrogen, and the F or blue line of hydrogen. It is often characteristic of a given class of compounds and shows a greater variation within a class than the refractive index. It is defined as:

$$\nu = (n_D - 1)/(n_F - n_C).$$

It has been found that the compounds under study when arranged in order of decreasing ν correlate exactly with the order obtained by dividing the refrachor by the molecular weight. As shown in Table VI there was only one exception, trimethyl cyclohexyl tin.

TABLE VI

Specific refrachors and ν values of organotin compounds

A plot of F/M versus ν (in Fig. 2) shows reasonable correlation. The only important deviations are the two cyclic compounds, trimethyl phenyl and trimethyl cyclohexyl tin. Most of the compounds fall on or near a straight line whose equation is

$$Y = 1.154X + 18.8$$

where $Y = 100\ F/M$ and $X = \nu$.

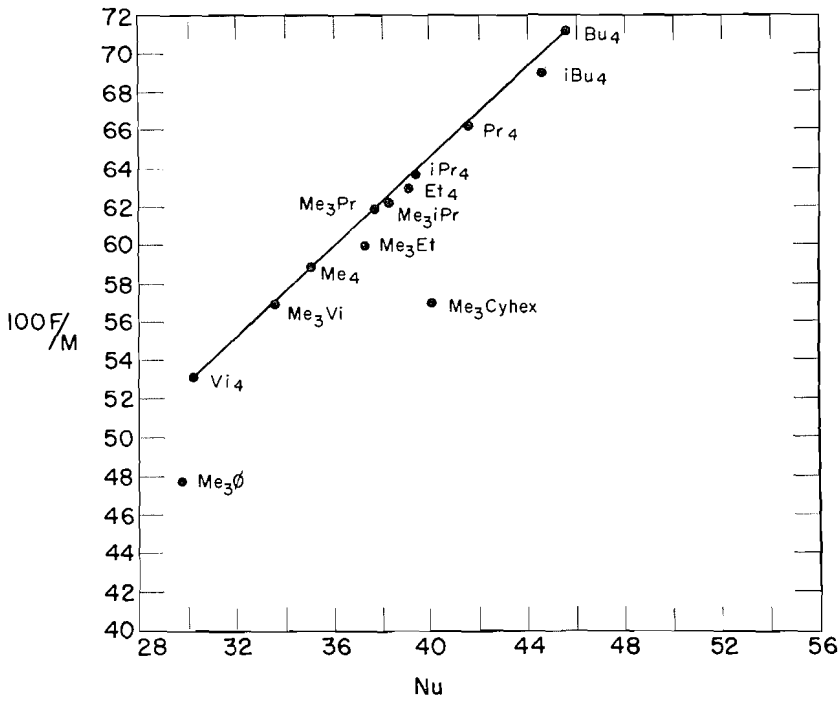

FIG. 2. Plot of F/M versus ν.

METHYLENE GROUP INCREMENTS

Work by Jones *et al.* (11) has indicated an alternation in the molar refraction increment in the *n*-tetra-alkyl tin series, and an initial indication of this is shown here for the lower members, the values being slightly different if the correction for air density (d) is included. The same effect is indicated by the ν values.

	Using $D - d$	Using D	ν
Me—Et	4.69	4.68	1.0
Et—Pr	4.78	4.79	0.6
Pr—Bu	4.69	4.67	1.0

Q VALUE

The Q value has been defined by Waldmann (12) as the ratio of the dispersions shown:

$$Q = (n_D - n_C)/(n_F - n_C).$$

Measurements on 100 organic materials gave an average value of $Q = 0.286$. The extremes varied from $+12$ to -10%, but most values deviated less than 5%. If we assume the stated value for Q, the individual calculated values n_F' and n_C' may be obtained from the measured values of n_D and the dispersion $n_F - n_C$. The data are given in Table VII. The average value of the mean specific dispersion times 10^4, omitting the unsaturated compounds, is 100.6.

REACTIONS OF THERMAL ENERGY IONS

II. RATES OF SOME HYDROGEN TRANSFER ION–MOLECULE REACTIONS[1]

A. G. HARRISON,[2] A. IVKO,[3] AND T. W. SHANNON[4]

Department of Chemistry, University of Toronto, Toronto, Ontario

Received December 20, 1965

ABSTRACT

The rate constants for the ion–molecule reactions forming the protonated molecule in CH_3CN, H_2, CH_4, and CH_3OCH_3, the equivalent reactions in the deuteriated species, and the reactions forming COD^+ in CO–CD_4 mixtures have been measured at thermal energies and at 10.5 V/cm repeller field strength. For H_2, HD, D_2 and the reactions in CO–CD_4 mixtures the rate constant for the thermal reaction is approximately 0.3–0.5 that of the 10.5 V/cm rate constant. For all other cases the ratio of rate constants is approximately unity as predicted by the ion-induced dipole model. The absolute values of the rate constants in most cases are considerably lower than predicted by theory.

INTRODUCTION

Although mass spectrometric studies of gaseous ion–molecule reactions have provided much qualitative information of interest in radiation chemistry and other fields, they have provided little reliable quantitative data on the rates of reaction of thermal energy ions. In conventional mass spectrometric methods the reactant ions undergo acceleration by the electric field required to withdraw the ions from the ionization chamber, with the result that the measured kinetic data represent an appropriately weighted average for reactant ions with velocities ranging from zero to the final exit velocity. Estimation of the rate constants for thermal energy ions thus requires a knowledge of the dependence of the cross section on the electric field (or ion velocity), and this information does not appear to be easily obtainable.

For ion–molecule reactions where the interaction is determined by ion-induced dipole forces Gioumousis and Stevenson (1) have derived the following expression for the macroscopic (or observed) cross section, Q.[5]

$$Q = 2\pi \left(\frac{2M_1\alpha e^2}{\mu}\right)^{1/2} \left(eEl\right)^{-1/2} \qquad [1]$$

where M_1 is the mass of the ion, α is the polarizability of the neutral species, μ is the reduced mass of the colliding pair, e is the electronic charge, E is the field strength, and l is the path length of the reactant ion. They have also shown that the rate constant, k, is given by

$$k = \left(\frac{eEl}{2M_1}\right)^{1/2} Q \qquad [2]$$

and is, in this case, independent of field strength. Such a result has been obtained experimentally for a number of systems by Stevenson and colleagues (1, 2) although Field *et al.* (3–5) have found the cross section to follow an E^{-1} dependence for both simple

[1] *Part I is considered to be Can. J. Chem. 43, 159 (1965).*

[2] *Alfred P. Sloan Fellow 1962–1964.*

[3] *Exchange student 1964–1965. Present address: Department of Chemistry, Byelorussian State University, Minsk, U.S.S.R.*

[4] *Present address: Department of Chemistry, Purdue University, Lafayette, Indiana.*

[5] *The variable Q is given experimentally by* $Q = (I_s/I_p)l$ [m] *where* I_s *is the secondary ion current,* I_p *is the reactant ion current, l is the path length of the reactant ion, and* [m] *is the concentration of neutral species.*

and complex systems. Hamill and colleagues (6–10) have shown for several systems that the energy dependence changes with ion velocity. Recently Giese and Maier (11), using a preselected ion beam of known energy, have reported that the velocity dependence of the cross section for reactions involving H^+ transfer differs from that for reactions involving H transfer. The discrepancies in the results obtained by conventional techniques probably result from instrumental problems. This is particularly true at low field strengths where space charge and discrimination effects can become more serious.

Since it thus appears that conventional studies have not yielded reliable data for the reactions of thermal energy ions, several groups (12–15) recently have undertaken studies of ion–molecule reactions using pulsing techniques which permit the direct measurement of the rates of reaction of thermal energy ions. In this technique a short pulse of electrons is admitted to a field-free ion source to produce the reactant ions by electron impact. A known (and variable) time later, a second pulse is applied, either to the ion repeller or to the draw-out plate, which removes for mass analysis both the primary ions and those formed by bimolecular reactions. In the time interval between the two pulses the ions react under field-free conditions, and from the variation with this time of the product/reactant ion ratios, the rate of reaction under thermal conditions can be obtained.

In a continuation of our studies of the reactions of thermal energy ions we report in the present paper the determination of the rate constants for a number of hydrogen transfer ion-molecule reactions. We have also compared the thermal rate constants with those obtained at 10.5 V/cm repeller field strength to obtain some indication of the variation of rate constant with field strength.

EXPERIMENTAL

The apparatus and experimental techniques for determining the thermal rate constants have been described previously (15). Cross sections at 10.5 V/cm were determined in the usual manner or, where more than one reaction contributed to the product ion, by the ratio-plot technique outlined earlier (16). The cross sections were converted to rate constants by eq. [2].

All chemicals were reagent grade and, with the exception of the labelled methanes, showed no detectable impurities in the mass spectra. Deuterium gas was obtained from The Matheson Co., Inc., while the other labelled samples were supplied by Merck, Sharp & Dohme of Canada Ltd. The mass spectra of the labelled methanes showed the presence of air impurity ranging up to 5%.

RESULTS AND DISCUSSION

The thermal rate constants, k(pulse), are compared in Table I with the rate constants obtained from the 10.5 V/cm data by eq. [2]. The thermal data for the methanes have been presented previously (15) as have the 10.5 V/cm data for the CO–CD_4 mixture (16), D_2, and CH_3CN (17). Each rate constant is an average of three or more determinations.

TABLE I

Rate constants for hydrogen transfer reactions

Reaction No.	k(pulse) (cm^3 molecule^{-1} s^{-1}) $\times 10^{10}$	k(10.5 V/cm) (cm^3 molecule^{-1} s^{-1}) $\times 10^{10}$	k(pulse)/k(10.5 V/cm)
[3]	5.8	15.0	0.38
[4a]	3.8	8.4	0.45
[4b]	2.9	6.9	0.42
[5]	5.9	13.3	0.44
[6]	6.12	7.58	0.81
[7a]	4.47	5.86	0.76
[7b]	1.30	1.73	0.75
[8a]	2.70	4.18	0.65
[8b]	2.16	3.36	0.65
[9a]	1.64	2.30	0.71
[9b]	3.36	4.90	0.69
[10]	4.71	6.35	0.74
[11]	1.96	5.22	0.38
[12]	2.67	5.57	0.48
[13]	18.7	21.5	0.87
[14]	9.49	8.24	1.15
[15a]	5.36	4.76	1.13
[15b]	4.39	4.13	1.07

For D_2, HD, and H_2, k(pulse) is considerably lower than k(10.5 V/cm), the ratio varying between 0.38 and 0.45. For H_2 and D_2, our results are in good agreement with the results of Ryan and Futrell (14) who reported k(pulse) = 4.73×10^{-10} for D_2, k(pulse) = 6.6×10^{-10} for H_2, and a ratio k(pulse)/k(10 V/cm) = 0.33 for both systems. As they have pointed out, these systems are unique in that the product and reactant ions differ by >50% in mass so that mass discrimination effects are difficult to avoid in the zero field work; furthermore, it is not possible to correct for these effects as was done for the methanes (15). Typical examples of the experimental results for the hydrogen isotopes are shown in Figs. 1 and 2 and it is apparent that mass discrimination effects are important, particularly in the H_2 and HD systems. For D_2 (Fig. 1) the ratio $I_{D_3^+}/I_{D_2^+}$ was linear with delay time to approximately 1 μs, following which an upward curvature was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

observed undoubtedly due to mass discrimination. For H_2 and HD, much more serious discrimination effects were observed and it was necessary to work with very short ionizing pulses ($\leqslant 0.1$ μs) and to limit the total delay time. As shown in Fig. 2 the plots of the ion current ratio versus delay time break upward after approximately 0.16 μs delay time. As would be expected the $I_{H_2D^+}/I_{HD^+}$ curve is linear over a longer region than that of $I_{HD_2^+}/I_{HD^+}$. We have taken the slopes of the initial linear portions to obtain the thermal rate constants.

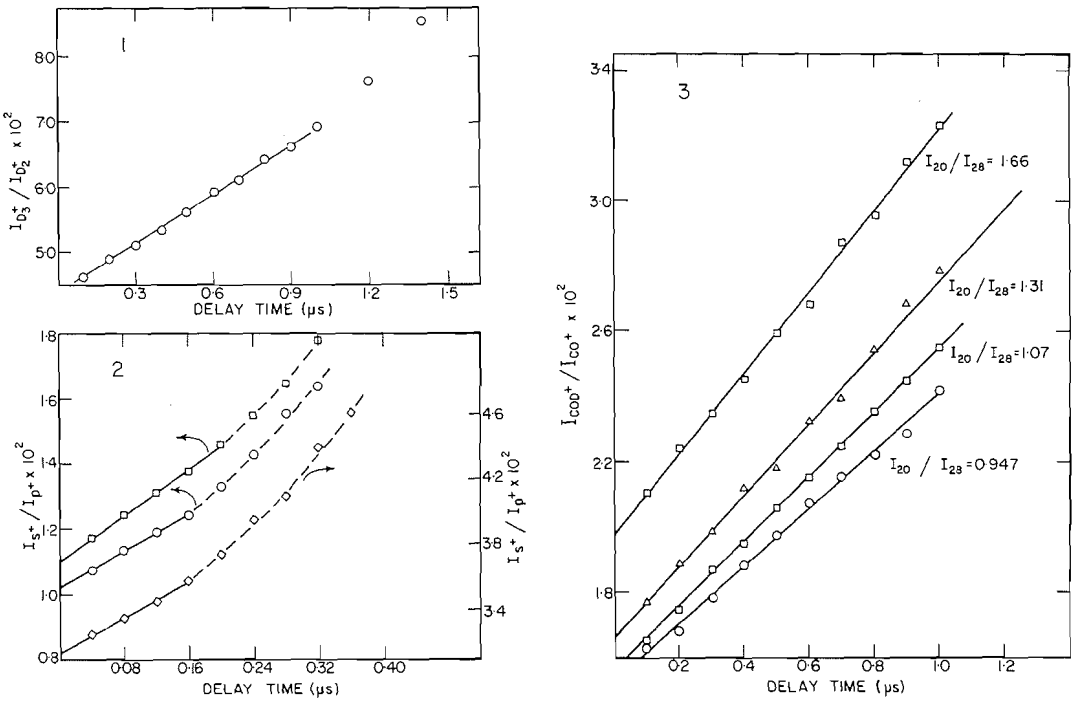

FIG. 1. Typical results for reaction $D_2^+ + D_2 \rightarrow D_3^+ + D$.
FIG. 2. Typical results for reactions in H_2 and HD: □, $I_{H_2D^+}/I_{HD^+}$ versus t in HD; ○, $I_{HD_2^+}/I_{HD^+}$ versus t in HD; ◇, $I_{H_3^+}/I_{H_2^+}$ versus t in H_2.
FIG. 3. Typical results for formation of COD^+ in CO–CD_4 mixtures.

Discrimination effects due to the higher thermal velocity of the reactant ion should vary considerably in this series since M_{s^+}/M_{p^+} varies from 1.33 (H_2D^+/HD^+) to 1.67 (HD_2^+/HD^+). The good agreement of the measured rate constants for the various isotopic reactions suggests that this is not a significant error. Further, such discrimination, if significant, would lead to erroneously high rate constants. Such considerations lead us to believe that the result k(pulse)/k(10.5 V/cm) ≈ 0.40 is not seriously in error.

The results obtained for the hydrogen transfer reactions in the methane series yield k(pulse)/k(10.5 V/cm) in the range 0.65–0.80. This result is not significantly lower than the ratio k(thermal)/k(10 V/cm) = 0.92 obtained for the reaction in CH_4 by Ryan and Futrell (18) using a modified pulsing technique.

It has been shown previously (16) that the formation of COD^+ in CO–CD_4 mixtures is the result of both reactions [11] and [12], and the cross sections and derived rate constants at 10.5 V/cm field strength have been reported. For the two concurrent reactions studied by the present pulsing techniques the secondary ion current observed after a time

For personal use only.

delay, t, can be expressed as the sum of two independent contributions, neglecting small differences in collection efficiencies

$$[16] \qquad I_{COD^+} = (k_{11}[CO]I_{CD_4^+} + k_{12}[CD_4]I_{CO^+})t + C$$

where C is a constant reflecting the COD^+ originating by reaction occurring during the ionizing and withdrawal pulses. Rearrangement of the above equation, as follows,

$$[17] \qquad \frac{I_{COD^+}}{I_{CO^+}} = \left[k_{11}[CO]\frac{I_{CD_4^+}}{I_{CO^+}} + k_{12}[CD_4]\right]t + C$$

shows that the slope of the I_{COD^+}/I_{CO^+} versus t plots should be a function of the primary ion current ratio $I_{CD_4^+}/I_{CO^+}$, for constant source concentration. Typical results are shown in Fig. 3 for $[CO] = 2.30 \times 10^{13}$ molecules cm^{-3} and $[CD_4] = 2.05 \times 10^{13}$ molecules cm^{-3}. The $I_{CD_4^+}/I_{CO^+}$ ratio was varied by changing the ionizing electron energy and, over the range of delay times used, remained constant for constant electron energy. The slopes of the lines, such as those in Fig. 3, are plotted in Fig. 4 against the $I_{CD_4^+}/I_{CO^+}$ ratio. Although the scatter is fairly large, a reasonable straight line is obtained which yields, by least squares analysis, the values of k_{11}(pulse) and k_{12}(pulse) recorded in Table I. Although these values are obviously subject to large errors, there seems to be little doubt that the thermal rate constants are significantly lower than the 10.5 V/cm rate constants.

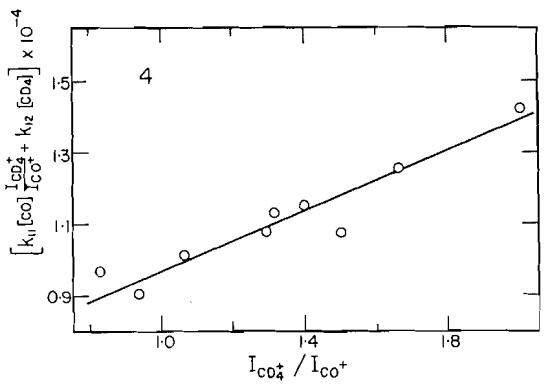

FIG. 4. Analysis of results for CO–CD_4 mixtures.

Typical results obtained in the study of reaction [13] are shown in Fig. 5. In this case the relatively high mass and small percentage mass difference permitted delay times up to 3 μs without any indication of mass discrimination. In view of the high rate constant for this reaction the rate constant was evaluated from the plot of

$$\log\left[1 + \frac{I_{CH_3CNH^+}}{I_{CH_3CN^+}}\right] \text{ versus } t.$$

The average of six determinations gave k(pulse) $= 18.7 \pm 2.1 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}, only slightly lower than k(10.5 V/cm) $= 21.5 \pm 2.1 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}. The ratio of rate constants is thus approximately unity.

In CH_3OCH_3 an abundant formation of the protonated ion $(CH_3)_2OH^+$ was observed. The ratio $I_{(CH_3)_2OH^+}/I_{(CH_3)_2O^+}$ was found to increase with increasing electron energy indicating occurrence of further reactions in addition to reaction [14]. The mass spectrum

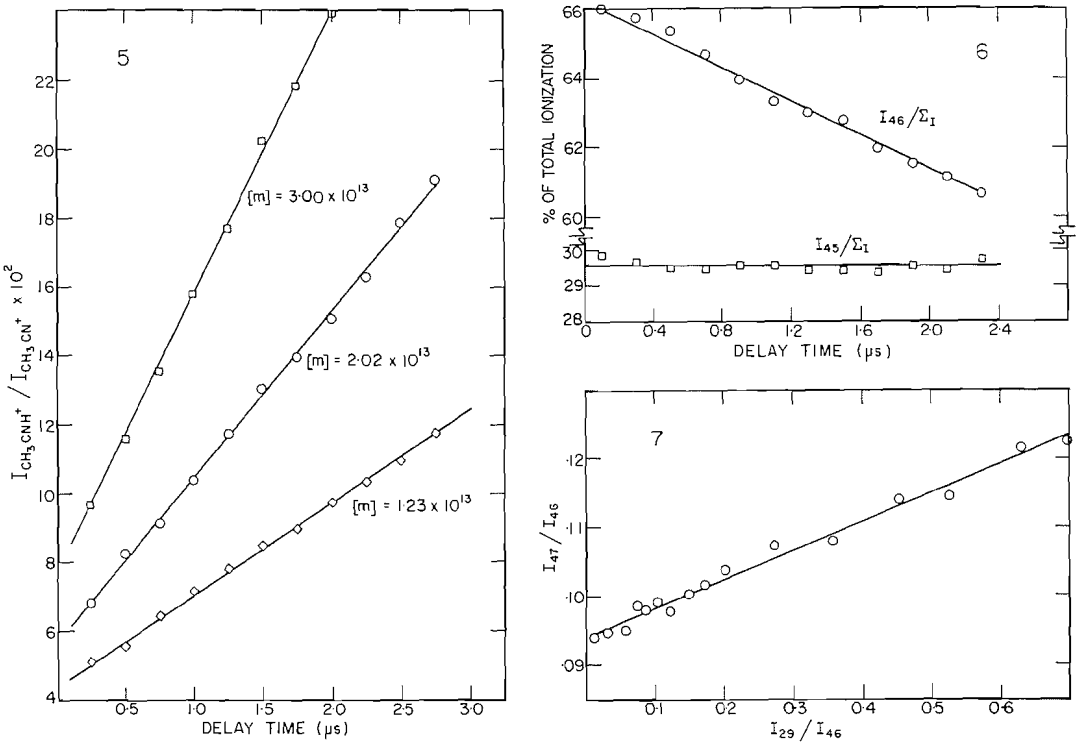

FIG. 5. Experimental results for the reaction $CH_3CN^+ + CH_3CN \rightarrow CH_3CNH^+ + CH_2CN$ where [m] refers to concentration of neutral species in molecules cm^{-3}.
FIG. 6. Ion intensities as a function of delay time for CH_3OCH_3.
FIG. 7. Plot of $I_{(CH_3)_2OH^+}/I_{(CH_3)_2O^+}$ versus $I_{CHO^+}/I_{(CH_3)_2O^+}$ for the CH_3OCH_3 system.

shows three major primary ions which must be considered as possible reactants in the following reactions.

[14] $$(CH_3)_2O^+ + (CH_3)_2O \rightarrow (CH_3)_2OH^+ + CH_3OCH_2$$

[18] $$CH_3OCH_2^+ + (CH_3)_2O \rightarrow (CH_3)_2OH^+ + ?$$

[19] $$CHO^+ + (CH_3)_2O \rightarrow (CH_3)_2OH^+ + CO$$

The occurrence of reaction [14] and the non-occurrence of reaction [18] was indicated by the ratio-plot technique (16) at low electron energies although the data were not very accurate due to the small range of ion current ratios which could be covered before the CHO^+ made a significant contribution. To provide further evidence the behavior of the $CH_3OCH_3^+$ and $CH_3OCH_2^+$ ion currents with delay time were examined at low energies where only these two ions and the $(CH_3)_2OH^+$ ion were significant. As shown in Fig. 6, $I_{CH_3OCH_2^+}$ remains a constant % of the total ion current with increasing reaction time while $I_{CH_3OCH_3^+}$ decreases as a percentage of the total. We thus conclude that reaction [14] occurs but that reaction [18] does not. At higher electron energies the occurrence of reaction [19] in addition to reaction [14] is indicated by the ratio plot (Fig. 7) obtained at 10.5 V/cm field strength. From such ratio plots we obtained $Q_{14} = 47.5 \times 10^{-16}$ cm^2 $molecule^{-1}$ and $Q_{19} = 27.5 \times 10^{-16}$ cm^2 $molecule^{-1}$ corresponding to rate constants of 8.24×10^{-10} cm^3 $molecule^{-1}$ s^{-1} and 5.66×10^{-10} cm^3 $molecule^{-1}$ s^{-1} respectively for the two reactions. In Fig. 8 we show typical results for variation of $I_{(CH_3)_2OH^+}/I_{CH_3OCH_3^+}$ with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

delay time and it can be seen that the slope is much greater at 50 eV than at 10 eV nominal electron energy where the CHO^+ ion was absent from the spectrum. From the low energy data k_{14}(pulse) was found to be 9.49×10^{-10} cm^3 molecule^{-1} s^{-1}. Analysis of the results for the rate of disappearance of $CH_3OCH_3^+$ gave rate constants in good agreement. From the 50 eV data one arrives at a rough estimate k_{19}(pulse) $\approx 8 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. It should be emphasized that at 50 eV further reactions in addition to [14] and [19] may occur (e.g. reaction of CH_3O^+) with consequent errors in the rate constant for reaction of CHO^+. Figure 8 also shows typical results obtained for the transfer reactions in CH_3OCD_3 at electron energies where the CHO^+ and CDO^+ ions were absent from the spectrum. At 50 eV both the rate of formation of $CD_3OCH_3H^+$ and $CD_3OCH_3D^+$ were considerably higher, again indicating reaction of other ions. As shown in Table I for the reactions studied in the ethers, k(pulse)/k(10.5 V/cm) is slightly above unity.

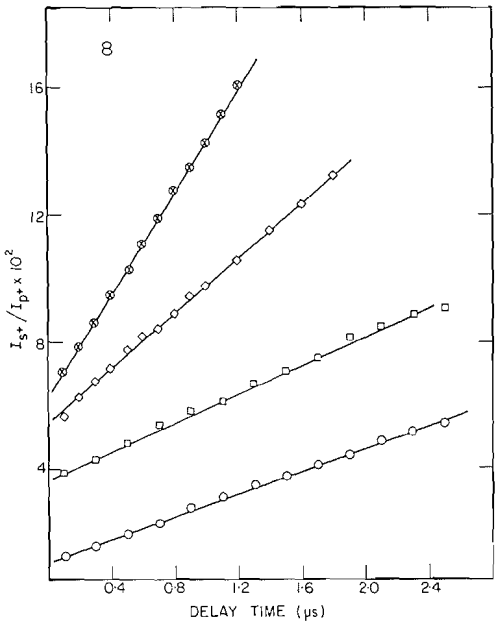

FIG. 8. Experimental results for dimethyl ether: ⊗, $I_{(CH_3)_2OH^+}/I_{(CH_3)_2O^+}$ versus t at 50 eV for CH_3OCH_3; ◇, $I_{(CH_3)_2OH^+}/I_{(CH_3)_2O^+}$ versus t at 10 eV for CH_3OCH_3; □, $I_{CH_3OCD_3H^+}/I_{CH_3OCD_3^+}$ versus t at 10 eV for CD_3OCH_3; ○, $I_{CH_3OCD_3D^+}/I_{CH_3OCD_3^+}$ versus t at 10 eV for CD_3OCH_3.

In summary, the thermal rate constants for the self-reactions in H_2, HD, and D_2 and for the reactions leading to COD^+ in CO–CD_4 mixtures are significantly lower than the rate constants obtained at 10.5 V/cm. The differences would appear to be outside the limits of error and thus we conclude that the ion-induced dipole model does not adequately describe these systems. For most of the remaining reactions listed in Table I, k(pulse)/k(10.5 V/cm) < 1. Since random experimental errors would not be expected to give ratios below unity, such a result must either be significant or due to some systematic error. In an examination of possible systematic errors we can immediately eliminate errors of ion source concentration since the thermal and 10.5 V/cm data usually were determined with a close time relationship so that flow characteristics and hence ion source concentrations did not vary. Discrimination effects in the pulsing experiments

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

either due to the higher thermal velocity of the primary ion or due to diffusion of secondary ions initially formed outside the ionizing volume into the ionizing volume (18) cannot account for the results for two reasons. Firstly, such discrimination effects cannot be important in the present work since usually $<20\%$ of the primary ions were lost at the longest delay times used and, secondly, such discrimination effects, if significant, would lead to erroneously high thermal rate constants and hence to ratios of rate constants greater than unity rather than less. On the other hand, a systematic error leading to the observed results could occur if the inherent mass spectrometer collection efficiency for secondary ions were lower in the pulsing mode than during continuous ion repulsion. The magnitude of such an effect cannot be assessed but would probably depend on the kinetic energy of the secondary ion and its position of formation.

INTRAMOLECULAR ISOTOPE EFFECTS

The results for HD, CD_3OCH_3, and the partially deuteriated methanes provide information in intramolecular H/D isotope effects in hydrogen transfer reactions. The isotope effects, summarized in Table II, are relatively small. At thermal energies it is probable

TABLE II

H–D isotope effects

Reactants	k_H/k_D(pulse)	k_H/k_D(10.5 V/cm)
$HD^+ + HD$	1.31	1.22
$CH_3D^+ + CH_3D$	1.15	1.14
$CH_2D_2^+ + CH_2D_2$	1.25	1.25
$CHD_3^+ + CHD_3$	1.46	1.41
$CD_3OCH_3^+ + CD_3OCH_3$	1.22	1.15

that the reactions proceed through formation of an intermediate collision complex and these small isotope effects undoubtedly arise in the decomposition of this complex. The good agreement of the isotope effects observed at 10.5 V/cm field strength with those observed at thermal energies suggests that there is no change in reaction mechanism over this energy range. It is interesting to note that the results for the deuteriated methanes show an apparent increase in the isotope effect with increasing deuterium substitution. Such an effect might be expected since increased deuterium substitution will increase the total non-fixed energy of the collision complex and thus lead to a more rapid H transfer process compared to the D transfer process. A similar effect is observed (19) in the fragmentation of the methane parent ion where increasing deuterium substitution leads to an increased probability of rupture of the C—H bond. For all the reactions studied it is impossible by the present techniques to determine whether the reaction proceeds by a neutral atom or a positive ion transfer process; thus more detailed consideration of these isotope effects does not appear justified. Further work is in progress to study the intramolecular isotope effects in neutral atom and positive ion transfer reactions.

COMPARISON OF EXPERIMENTAL AND THEORETICAL RATE CONSTANTS

For the ion-induced dipole model of ion–molecule reactions it has been shown (20) that the rate constant k is given by

$$k = 2\pi e \left(\frac{\alpha}{\mu}\right)^{1/2}, \qquad [20]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where the symbols are as defined previously. The experimental rate constants are compared in Table III with the values calculated by eq. [20]. For the reaction in CH_3CN

TABLE III

Comparison of experimental and calculated rate constants

Reactants	k(pulse) (cm^3 $molecule^{-1}$ s^{-1}) $\times 10^{10}$	k(10.5 V/cm) (cm^3 $molecule^{-1}$ s^{-1}) $\times 10^{10}$	k(calc)* (cm^3 $molecule^{-1}$ s^{-1}) $\times 10^{10}$
$H_2^+ + H_2$	5.9	13.3	20.8
$D_2^+ + D_2$	5.8	15.0	14.5
$CH_4^+ + CH_4$	6.12	7.58	13.36
$CD_4^+ + CD_4$	4.71	6.35	11.86
$CD_4^+ + CO$	1.96	5.22	9.51
$CO^+ + CD_4$	2.67	5.87	10.97
$CH_3CN^+ + CH_3CN$	18.7	21.5	11.0
$CH_3OCH_3^+ + CH_3OCH_3$	9.49	8.24	11.15

*k calculated on basis of ion-induced dipole interactions only.

the experimentally measured rate constants are considerably higher than the calculated value presumably because of the neglect of ion–dipole forces in calculating the rate constant. A similar neglect probably invalidates the calculations in the dimethyl ether case as well. For the other cases, where ion–dipole interactions should be negligible, it is found that the measured rate constants are markedly lower than predicted by theory. This indicates that a rather large proportion of the ion–molecule collisions does not lead to the protonated species. Whether this is due to reversion to reactants (transmission coefficient <1) or to competing reactions, such as charge exchange, is not known. It might be noted that for the self-reactions the charge exchange reaction is a resonance process and might be expected to occur with a relatively high cross section.

A METHOD FOR THE DETERMINATION OF WATER IN NONPOLAR LIQUIDS; THE SOLUBILITY OF WATER IN BENZENE

D. C. MOULE AND W. M. THURSTON
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario
Received February 8, 1966

ABSTRACT

A new method is described for the analysis of water in nonpolar organic liquids. It is based on an isotope dilution procedure and involves the exchange of the water present in the sample with D_2O. The change in isotopic composition of the D_2O is determined by infrared difference spectroscopy. The method appears to be accurate to $\pm 0.8\%$.

The principal advantage of this method is that the difficult problem of calibration with organic–water standards is avoided. It is restricted, however, to solvents which have a low solubility in water and do not have exchangeable hydrogens.

A series of solubility measurements were carried out for H_2O in C_6H_6 from 10 to 60 °C. The data were fitted to the usual interpolation equation $\ln (f/x) = -A/T + B \ln T + C$, and the thermodynamic functions of solution, ΔG, ΔH, ΔC_p, and ΔS, were computed for the transfer of 1 mole of water from the benzene phase to the vapor phase.

INTRODUCTION

A review of the profusion of papers published on water analysis indicates that there has been real difficulty in the determination of water solubility in hydrocarbons to an accuracy approaching 1%. This is partly because it is extremely difficult to prepare exact water concentrations in the organic materials used to calibrate and test an analytical method, and also because it is difficult to avoid contamination of the samples by atmospheric water, during and at the end point of an analysis. Methods which use tritiated water as a tracer may introduce errors associated with the tritium isotope effect, which are not easily accounted for.

We have developed an isotope dilution method for the determination of the solubility of H_2O in organic solvents which avoids some of these difficulties. It is based on a precision method for the determination of H_2O in D_2O which has recently been developed in these laboratories (1). Essentially, a quantity of benzene saturated with light water at a constant temperature is equilibrated with a known amount of heavy water and the change in heavy water concentration is determined by infrared difference spectroscopy. Water solubility is calculated from the concentration change in the heavy water, the quantities of heavy water and benzene involved, and a blank correction.

EXPERIMENTAL

1. *Materials*

Reagent grade benzene (Fisher Certified) was fractionally distilled twice and dried over molecular sieve (Linde No. 4A). Light water from the Ottawa River (0.0146 mole % D_2O) (2) was redistilled from alkaline permanganate. The reactor grade heavy water, 99.82 wt. % D_2O, used in this experiment had a specific conductance of $5 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ and was not purified further.

2. *Saturation of Benzene with Water*

In a typical experiment, 5 ml H_2O and 25 ml dry benzene were placed in a 50 ml volumetric flask, which was closed with a Teflon stopper and inserted into a constant temperature bath. Samples were agitated in the thermostat for 12 h to ensure that equilibrium between the two phases was complete. Before the benzene phase was decanted, the samples were left for another 24 h in the bath to allow the liquid layers to separate completely. The temperature was measured by a platinum resistance thermometer and controlled to ±0.02 °C.

3. Isotope Exchange

About 15 ml saturated benzene were withdrawn quickly from the thermostated liquid into a 30 ml hypodermic syringe (Multifit, Luer Lock) to which was added 2–10 ml reference D_2O solution, taken from the heavy water storage reservoir. The needle tip of the syringe was capped with a rubber stopper and the liquid phases agitated for 4 h on a wrist-action shaker until the isotope exchange between the H_2O dissolved in the benzene phase, and the D_2O phase, was complete. The weight of the benzene and heavy water phases was determined by weighing the syringe and contents during the sampling process.

It was necessary to soak the inside of the syringes with D_2O for 24 h before use, in order to eliminate H_2O absorbed on the surface of the glass by exchange with D_2O. After this treatment, syringes were dried in a vacuum oven and stored in a desiccator until required.

4. The Infrared Cell

Only a brief description of the infrared cell will be given here as complete details are given elsewhere (1). The cell was designed primarily to reduce temperature differences between the sample and reference compartments, which can be a serious limitation in infrared liquid analysis. A novel feature of the cell design was the union of the reference (A) and sample (B) compartments into a single cell (C), as illustrated in Fig. 1.

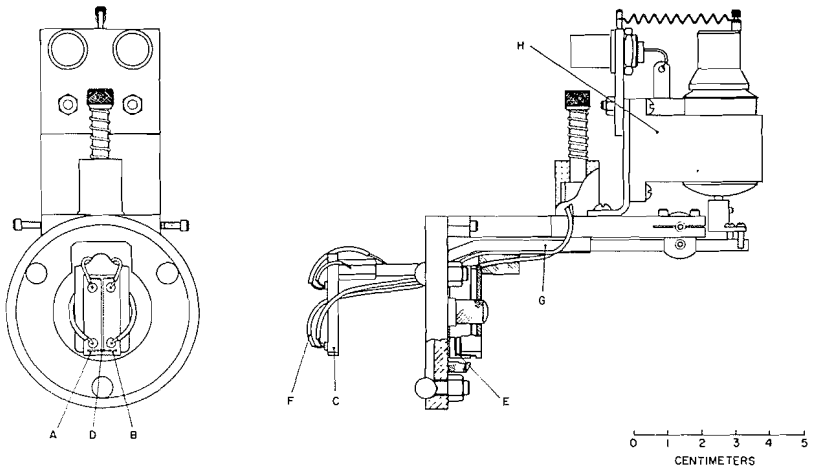

FIG. 1. The infrared cell.

Sample and reference compartments were formed between common sapphire windows and separated by a silver–epoxy divider (D). This arrangement allowed the liquids in the two compartments to come quickly to thermal equilibrium even though the cell was not at the temperature of the spectrometer. To reduce heating of the sample by the infrared radiation a bandpass filter (E) was inserted into the light beam. Sample and reference solutions were introduced into the cell compartments through Teflon leads (F) by displacing the heavy water within the cell out through the outlet tube (G). To measure the difference in optical density between sample and reference solutions, the compartments were interchanged in the front beam of the spectrometer by the motor drive (H). As the spectrometer operated on time drive, at fixed frequency, a square wave was traced on the chart paper. Ordinate scale expansion was used to magnify the amplitude of the square wave trace and thereby increase the precision to which the absorbance difference between the sample and reference compartments could be measured. The concentration of the unknown sample was calculated from the optical density difference between the sample and reference solution, the calibration factor, and the concentration of the reference solution.

5. Heavy Water Containers

Considerable care was given to the development of apparatus and techniques for the preparation, storage, and transfer of the heavy water standard solutions, as the accuracy of the analytical method is limited by the stability of the deuterium content of the heavy water. The containers for the heavy water standards, shown in Fig. 2, were of vacuum tight construction. The vessel consisted of a stainless steel beaker (A) closed at the top by a steel plate (B). Heavy water was introduced into the containers through a brass filling cap (C), which was sealed by O-ring (D). The vessel and contents were pressurized with helium to prevent atmospheric moisture from entering the system. Samples were removed from the containers by opening valve (E), the pressure within the vessel forcing the heavy water out through lead (I).

A cross section of the two-way valve is illustrated in Fig. 2. It was constructed mainly from brass and consisted of two grease-free metal valves joining side arms (J) and (K) to common arm (I). The side arm of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

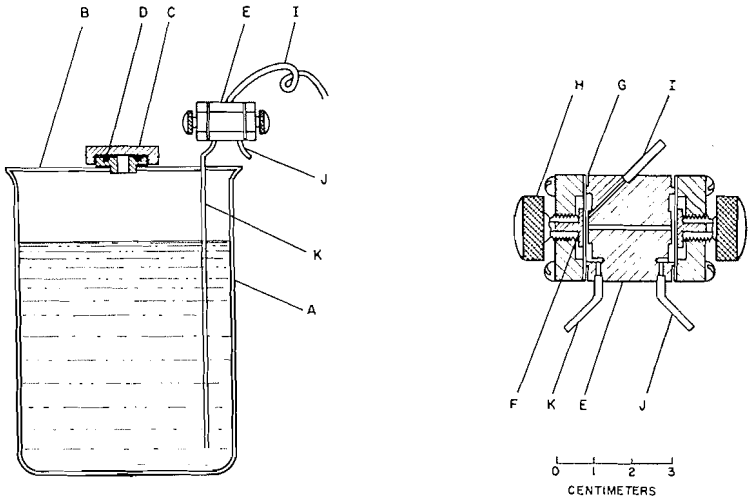

FIG. 2. Containers for storing heavy water reference and standard solutions.

the valve was closed to the outlet lead by tightening thumb screw (H) which applied pressure to disc (F) and forced neoprene diaphragm (G) into the valve seat. The rubber diaphragm was found to be sufficiently elastic to open the valve when the pressure from the thumb screw was released. The inside of the valve, and the Teflon tube (I) which lead to the infrared cell could be alternately flushed from side arm (J) with dry nitrogen and heavy water before the standard solution was withdrawn from the storage container.

Three 1-l vessels were constructed to contain the heavy water standard solutions (heavy water which had been diluted by the addition of 0.22–0.24 wt. % H_2O) and one 3-l vessel to hold the heavy water reference solution (undiluted heavy water, 99.82 wt. % D_2O).

6. Preparation of the D_2O Standard Solutions

The containers for the heavy water storage were carefully cleaned, dried, and treated with aliquots of heavy water over a period of several days to eliminate traces of light water. In a light-water-free atmosphere, 500 g D_2O was carefully weighed into each of the three standard solution containers. At about the same time 2 l D_2O was added to the reference solution vessel. The heavy water in the storage containers was degassed, pressurized slightly above 1 atm with helium, and then left for a week with intermittent shaking to allow the isotopic composition of the water to reach a constant value. The heavy water samples were compared against each other by infrared difference analysis to check for possible contamination by traces of water introduced during the cleaning and filling process. No evidence of heavy water degradation was found. Three heavy water standard solutions were prepared by adding weighed amounts of H_2O (1.1–1.2 g) to 500 g of the D_2O reference solution to give standard solutions of 0.2201, 0.2297, and 0.2401 wt. % H_2O relative to the undiluted reference solution.

7. Procedure for Filling the Infrared Cell

At least 24 h before an analysis the compartments of the infrared cell were filled with undiluted D_2O (reference solution) to offset the memory effect associated with H_2O absorbed on the metal and sapphire inside surfaces of the cell. Before the heavy water container was connected to the infrared cell, outlet lead (I) of Fig. 2 was dried with a stream of dry nitrogen introduced through side arm (J). The Teflon leads of the reference compartment of the infrared cell and the outlet lead from the heavy water standard container were connected by a length of hypodermic needle in such a fashion as to minimize air pockets at the junction. The valve of the heavy water container was slowly opened and the standard solution allowed to displace the liquid in the cell. Usually ~1 ml of heavy water flushed slowly through the cell compartment was sufficient to bring the isotopic concentration of the water in the cell to the concentration of the heavy water standard. It was necessary to reduce the helium pressure in the heavy water storage containers to ~1.01 atm in order to eliminate the formation of micro bubbles in the infrared cell created by the degassing of helium under the action of the infrared light. The flow of heavy water into the system was assisted by elevating the heavy water reservoir several feet above the infrared cell.

The unknown samples resulting from the equilibration of moist benzene with heavy water were removed from the wrist action shaker (see Section 3) and injected from the hypodermic syringes directly into the sample compartment of the infrared cell. A minimum of 0.5 ml of sample was used for each determination.

For personal use only.

8. Spectrometer Conditions

For the optical density measurements a Perkin-Elmer model 21 infrared spectrometer operated at a fixed frequency of 3 400 cm^{-1}, a slit width of 300 μ, and a time drive of 2 cm/min was used. Reference and sample cell compartments were interchanged in the front beam of the spectrometer about every 20 s, for a 5 min period. A variable density spiral filter (1) was inserted into the back beam of the spectrometer to compensate for absorption from the cell and its contents. The band pass filter transmitted at a frequency of 3 380 cm^{-1} with a full-width at half-maximum of 260 cm^{-1}. When scale expansion of 10 times was used, ordinate pen displacement of 5 cm or less was found to be directly proportional to optical density.

9. Experimental Procedure and Calculation of Data

The experimental procedure and the treatment of observed data may be illustrated from the results of a typical experiment shown in Table I. The second and third columns give the relative isotopic composition of

TABLE I

Results of a typical experiment to determine the solubility of light water in benzene at 24.54 °C

Run	Sample compartment (wt % H_2O)	Reference compartment (wt % H_2O)	$I_S - I_R$ (mm pen displacement) 1	2	3	Av.
1	0.2401	0.2401	6.0	7.0	7.0	6.7
2	0.2297	0.2201	65.4	63.4	65.4	64.7
3	0.2401	0.2297	76.9	76.4	76.9	76.7
4	Unknown	0.2201	87.4	84.4	85.4	85.7

the heavy water solutions in the sample and reference compartments of the infrared cell. The remaining columns list the optical density differences, in mm of pen displacement for 10× scale expansion between sample and reference compartments for three successive interchanges of the compartments in the front beam of the spectrometer. In run 1 the reference and sample compartments were filled with identical heavy water standard solutions. The observed infrared absorption, referred to as the cell constant, resulted from a mismatch in path length, geometry, and window transparency. To determine the slope of the Beer's law plot or the calibration factor, a comparison was made in runs 2 and 3 of the optical density difference between sets of heavy water standards. From the data of run 4, the concentration of a heavy water sample resulting from the exchange of 13.487 g benzene saturated with water at 24.54 °C with 4.236 g heavy water reference solution was determined.

The solubility of light water in benzene in parts per million by weight is given as

$$S = \left\{\left[I_S(C_u) - I_R(C_1) - I_C\right]\left[\frac{C_2 - C_1}{I_S(C_2) - I_R(C_1) - I_C}\right] + C_1\right\}\frac{\mathrm{wt}(C_u)}{\mathrm{wt}(C_6H_6)} \times 10^4,$$

where I_R and I_S refer to the optical densities of the reference and sample compartments, and C_1 and C_2 to the concentrations of a pair of standard heavy water solutions; C_u is the concentration of the heavy water resulting from the exchange of wt(C_u) grams of reference solution with wt.(C_6H_6) grams of moist benzene.

The cell constant $I_C = I_S(C_1) - I_R(C_1)$ which is determined in run 1 was found to be constant within the experimental error over the range of heavy water solutions employed. It did, however, tend to vary from day to day and was checked periodically during a set of runs. Run 2 comparing standard solution 0.2201 wt. % H_2O with standard solution 0.2297 wt. % gave a value of 1.65×10^{-4} wt. % H_2O per mm pen displacement for the calibration factor $[C_2 - C_1]/[I_S(C_2) - I_R(C_1) - I_C]$. Run 3 in a similar fashion yielded a value of 1.48×10^{-4}. The solubility of water in benzene at 24.54 °C was calculated to be 730.3 p.p.m. from the solubility equation and the data in Table I, run 4.

10. Blank Correction

It was necessary to correct for traces of light water and benzene contamination in the heavy water samples and for possible isotopic exchange between C_6H_6 and D_2O which were introduced during the sampling and exchange procedures. Blank samples were prepared by equilibrating dry benzene that had been pre-equilibrated with heavy water, with standard heavy water solution. When the blank samples were analyzed, the light water concentration of the blank was found to have increased by 0.59%. It was therefore necessary to divide the calculated solubility by the correction factor 1.0059.

11. Estimation of the Errors

A temperature uncertainty of 0.05 °C causes an error of 0.17% in the solubility results. The temperature, however, is known and controlled to within 0.02 °C. The optical density difference between the sample and reference cell-compartments can be measured to ±0.5 mm pen displacement (Table I) which limits sensitivity of the method to 0.03%. The accuracy to which the protium concentration of an unknown D_2O sample can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

determined is limited by the uncertainty in the concentration of the heavy water standards and is estimated from runs 2 and 3 to be 0.23%.

A standard deviation of 0.8% was obtained from a series of eight solubility measurements at 24.54 °C which indicates that the major component in the experimental uncertainty arises from contamination of heavy water sample by atmospheric moisture prior to the spectroscopic analysis.

RESULTS AND DISCUSSION

Results for the solubility of light water in benzene in parts per million by weight over the range 10 to 50 °C are recorded in Table II. Each value is the mean of three determinations and is estimated to be accurate to ±0.8% (Section 11).

TABLE II

The solubility of water in benzene as a function of temperature

T (°C)	S (p.p.m. by weight)	ln (f/x)
9.44	442.5	8.4527
14.98	530.2	8.6370
20.10	639.2	8.7786
24.54	726.0	8.9177
29.52	848.0	9.0521
34.88	1017.1	9.1821
40.06	1177.8	9.3159
43.78	1333.7	9.3796
49.45	1570.6	9.5033

An interpolation equation (ref. 3) of the form

$$\ln (f/x) = -A/T + B \ln T + C,$$

where x is the solubility of water in benzene expressed as mole fraction and f is the fugacity of the water vapor above the saturated solution, was fitted to the observed results. Fugacities were obtained from the second virial coefficient (4) and the vapor pressure data for water (5) which was corrected for the finite solubility of benzene in the aqueous phase (3). A least squares fit of the values of ln (f/x) listed in Table II to the interpolation equation gave $A = 5\,566.32\ °K^{-1}$, $B = -10.575$, and $C = 87.8429$ with a residual mean squared deviation of 0.5%. From the interpolation equation the thermodynamic quantities $\Delta G(298.16) = -5\,285$ cal mole^{-1}, $\Delta H(298.16) = 4\,793$ cal mole^{-1}, $\Delta S = 33.80$ cal deg^{-1} mole^{-1}, and $\Delta C_p = -21.00$ cal deg^{-1} mole^{-1} were obtained for the transfer of 1 mole of water from the benzene phase at unit mole fraction to the vapor phase at a fugacity of 1 mm.

The observed solubilities are plotted as a function of temperature in Fig. 3 along with the available literature data. Examination of Fig. 3 reveals that although there is considerable scatter in the combined data of Kirschenbaum (Karl Fischer titration) (6), Hill (silver perchlorate method) (7), and Grosschuff (turbidity method) (8), the overall agreement with our results may be considered to be reasonable.

The present results are also in excellent agreement with the recent tritium isotope tracer studies of Jones and Monk (9), providing an adjustment is made to their data to correct for the tritium isotope effect. If the fractionation factor $\alpha_1 = [(H_2O)/(HTO)]_{benz}/[(H_2O)/(HTO)]_{liq}$ is known for the equilibrium

$$(\text{water})_{liq} \overset{\alpha_1}{\rightleftarrows} (\text{water})_{benz}$$

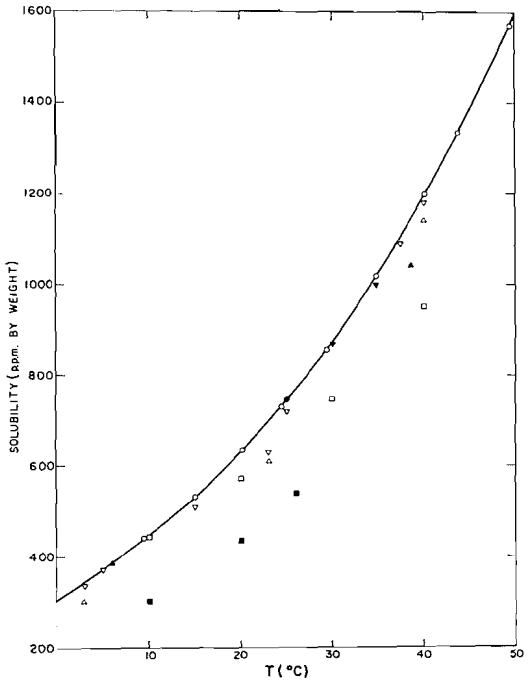

FIG. 3. Plot of the solubility of H_2O in C_6H_6 (parts per million by weight) against the temperature in degrees centigrade. ○ This research; □ Rosenbaum and Walton (15); ▽ Hill (7); △ Grosschuff (8); ■ Joris and Taylor (13); ▲ Kirshenbaum (6); ▼ Jones and Monk (as corrected) (9).

the solubility of H_2O in benzene is obtained as the product of α_1 and the observed solubility of HTO in benzene. Alternatively, given the fractionation factors $\alpha_2 = [(H_2O)/(HTO)]_{vap}/[(H_2O)/(HTO)]_{liq}$ and $\alpha_3 = [(H_2O)/(HTO)]_{benz}/[(H_2O)/(HTO)]_{vap}$ for the equilibrium

$$(water)_{liq} \overset{\alpha_2}{\rightleftarrows} (water)_{vap} \overset{\alpha_3}{\rightleftarrows} (water)_{benz}$$

then $\alpha_1 = \alpha_2 \cdot \alpha_3$. Values of α_2 are well known over the liquid range for water and at 25 °C α_2 is 1.11 (10). Although the fractionation factor α_3 has not been determined directly it may be estimated from the solubility relationships in the (H_2O–D_2O–C_6H_6) system. From the assumption that the isotope effect depends only on the molecular weight (11) it follows that $\alpha_3 = [(H_2O)/(D_2O)]_{benz}/[(H_2O)/(D_2O)]_{vap}$. We have measured (12) the solubility of D_2O in benzene by a method similar to the one described here. The solubility data for D_2O in benzene combined with the present results gave a value of $\alpha_3 = 1.05$. Therefore, $\alpha_1 = 1.16$ and the results of Jones and Monk must be increased by 16% to correct for the isotope effect. The excellent fit of the corrected points to our interpolation equation is shown in Fig. 3.

The results of Taylor and co-workers (13) are somewhat lower than those reported here. These authors absorbed the tritiated water saturated in benzene with calcium oxide and then exchanged the tritium with ethanol vapor for counting. It has been suggested (14), however, that incomplete exchange or isotope fractionation could be responsible for the low values obtained in this experiment.

The other work which is seriously out of line with the present study is that of Rosenbaum and Walton (15) who measured the volume of hydrogen liberated on the addition of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

calcium hydride to the moist benzene. Perryman (16) has found that the volume of hydrogen evolved is considerably lower than the value predicted by the reaction stoichometry, and has suggested that the method be calibrated with distilled water.

The principal advantage of the present method is that the difficult problem of calibration with water–organic standards is avoided since the heavy water reference solutions used in the infrared difference analysis were prepared as primary standards. The method also eliminates a correction for isotope effects as water is determined directly as H_2O. The chief limitation of the method is that it is restricted to solvents which have a low solubility in water and do not have exchangeable hydrogens. The method also is not rapid as the analyses are normally of several days' duration.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Dr. R. H. Betts for suggesting this problem.

ORGANIC COMPOUNDS OF SAMARIUM

II. REACTIONS OF SAMARIUM ISOPROPOXIDE WITH ETHYL ACETOACETATE

B. S. SANKHLA AND R. N. KAPOOR
Department of Chemistry, University of Jodhpur, Jodhpur, India

Received October 20, 1965

ABSTRACT

The reactions of samarium isopropoxide with ethyl acetoacetate have been carried out in benzene medium in different stoichiometric ratios and the compounds of the type $Sm(OPr^i)_2$(Etacac), $Sm(OPr^i)(Etacac)_2$, and $Sm(Etacac)_3$ have been isolated in quantitative yields. However, the reaction of samarium isopropoxide with excess of the acetoacetic ester lead to the formation of $Sm(Etacac)_3$.Etacac, which on heating under reduced pressure at 110 °C for $1\frac{1}{2}$ h loses its addition molecule of ester. The reactions are exothermic and the amount of heat liberated also increases with the increase in the concentration of the ester.

The interchange reactions of the products $Sm(OPr^i)_2(Etacac)$ and $Sm(OPr^i)(Etacac)_2$ with *t*-butyl alcohol have also been carried out; they are endothermic reactions. The compounds $Sm(OBu^t)_2(Etacac)$ and $Sm(OBu^t)(Etacac)_2$ have been obtained in quantitative yields from the reaction mixture. All the products are stable up to 200 °C at 0.5 mm, but at higher temperature they decompose to deep-red solids. Molecular weight determinations show that they are dimeric in nature.

INTRODUCTION

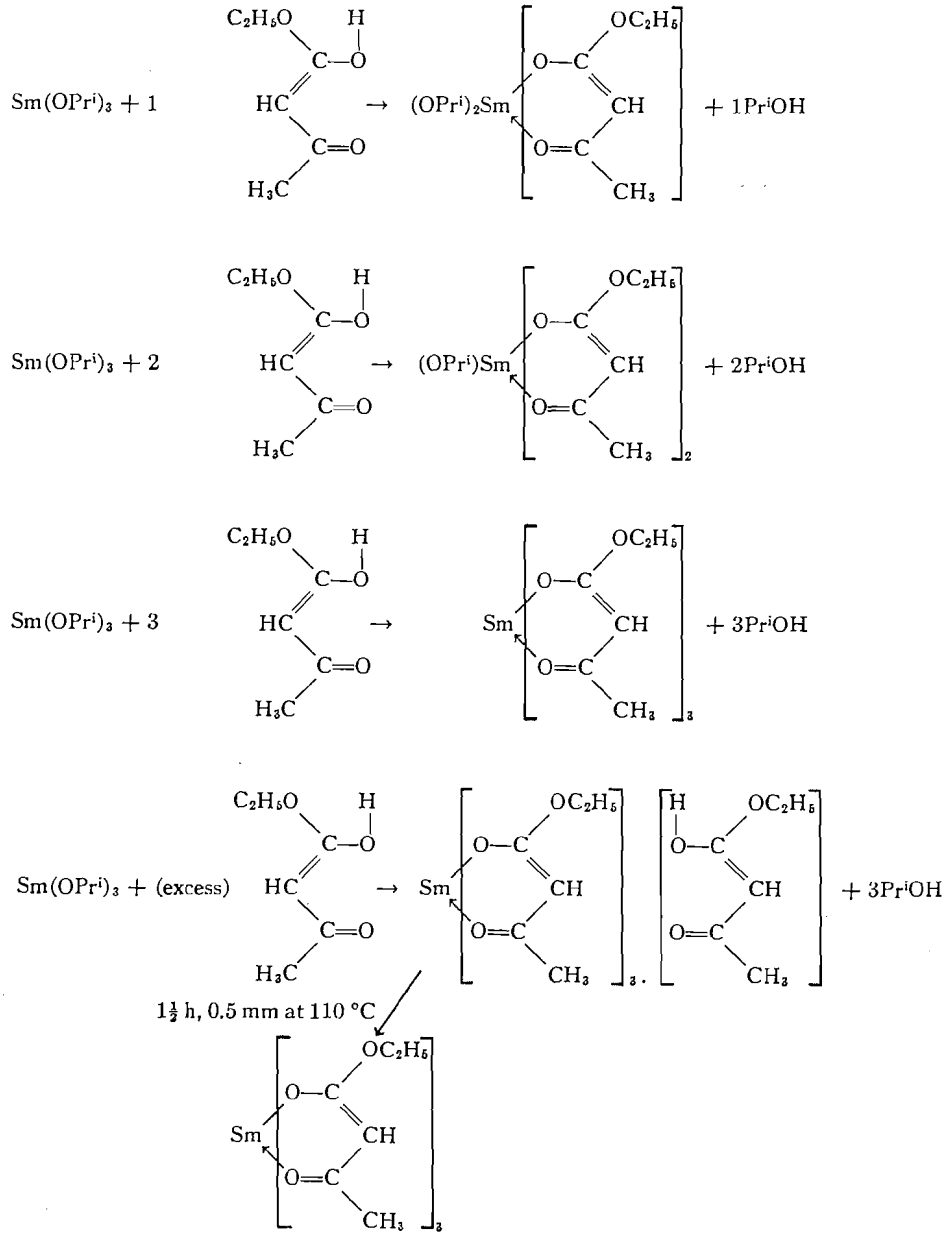
Recently the reactions of the alkoxides of aluminium (1), lanthanum, neodymium (2), praseodymium (3), titanium (4), niobium (5), tantalum (6), and uranium (7) with bidentate ligands have been carried out with interesting results regarding their volatility and coordination number. A survey of the literature reveals that no such type of work has been carried out with samarium alkoxides. It was, therefore, considered of interest to carry out the reaction of samarium isopropoxide with ethyl acetoacetate.

Kapoor *et al.* (8) were the first to report the synthesis of samarium alkoxides by a sodium alkoxide method. The reactions of samarium isopropoxide with ethyl acetoacetate may be represented by the following general equation:

$$Sm(OPr^i)_3 + n\text{Etacac} \rightarrow Sm(OPr^i)_{3-n}(Etacac)_n + nPr^iOH \ (n = 1, 2, \text{or } 3).$$

The experimental technique consists of adding the required amount of ethylacetoacetate to the solution of samarium isopropoxide in benzene, whereupon an exothermic reaction takes place. The reaction mixture was refluxed for about 5 h during which time the liberated isopropyl alcohol was collected azeotropically. The compounds were obtained on removal of the excess solvent under reduced pressure, 0.5 mm at 60 °C. From the analyses of the products formed, the reactions may be represented by the equations shown on the following page.

All these products are faint-yellow or deep-yellow crystalline solids, soluble in benzene.



The mixed isopropoxy ethyl acetoacetate derivatives were found to interchange their isopropoxy group on treatment with *t*-butyl alcohol, which can be represented as follows:

$$Sm(OPr^i)_2(Etacac) + 2Bu^tOH \rightarrow Sm(OBu^t)_2(Etacac) + 2Pr^iOH,$$

$$Sm(OPr^i)(Etacac)_2 + 1Bu^tOH \rightarrow Sm(OBu^t)(Etacac)_2 + 1Pr^iOH.$$

These reactions are endothermic and the corresponding *t*-butoxy derivatives, which are faint-yellow crystalline solids, can be obtained from their benzene solution in quantitative yields.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The thermal stability studies of these compounds have been studied. All these derivatives are stable to heat at low temperatures (200 °C at 0.5 mm), but when attempts were made to sublime them at higher temperatures (270–280 °C at 0.5 mm), they decomposed to deep-red solids.

The determination of molecular weights of these compounds in refluxing benzene suggests that they are dimeric in nature. In the mono- and di-derivatives, samarium shows the coordination number 6, and in tri-derivatives, it shows coordination number 8.

EXPERIMENTAL

Samarium isopropoxide was prepared by the sodium isopropoxide method (8) and was analyzed before use for samarium and isopropoxy contents. Ethyl acetoacetate (L. Light & Co.) was dried by reflux over aluminium isopropoxide and then distillation at 180 °C. Benzene (B.D.H. A.R.) was dried over sodium wire and then obtained by azeotropic fractionation in the presence of a little ethanol. *t*-Butyl alcohol (B.D.H.) was dried by careful distillation over the corresponding sodium alkoxide.

An all-glass apparatus with interchangeable standard joints was used throughout, special precautions being taken to exclude moisture from the system. Fractionations were carried out in a column packed with Raschig rings and fitted to a total condensation variable-takeoff stillhead. Molecular weights were determined ebulliometrically with a Gallenkamp semimicro ebulliometer.

Samarium was estimated by igniting the organic compounds and converting to the sesquioxide (Sm_2O_3). Isopropoxy constituents of the mixed isopropoxy acetoacetate derivatives were determined by estimating the isopropyl alcohol in the ternary azeotrope (benzene – water – isopropyl alcohol) by oxidation with normal dichromate solution in 12.5% sulfuric acid (9).

Reaction of Samarium Isopropoxide with Ethyl Acetoacetate in Benzene (Molar Ratio 1:1)

Ethyl acetoacetate (0.486 g) was allowed to react with samarium isopropoxide (1.225 g) in benzene (52 g); the reaction was exothermic. The binary azeotrope of benzene–isopropanol was collected at 72 °C, after refluxing the reaction mixture at 115–120 °C for 5 h. The excess benzene was removed under reduced pressure (0.5 mm at 60 °C). A faint-yellow crystalline solid was obtained. Yield 1.46 g. Found: isopropyl alcohol in the azeotrope, 0.224 g; Sm, 37.80%; OPr^i, 29.5%. Calcd. for $Sm(OPr^i)_2(Etacac)$: replacement of 1 mole requires 0.225 g isopropyl alcohol; Sm, 37.85%; OPr^i, 29.7%.

Other reactions of samarium isopropoxide with ethyl acetoacetate are given in Table I.

Reaction of Samarium Diisopropoxy Monoethyl Acetoacetate with t-Butyl Alcohol (Excess)

t-Butyl alcohol (7.92 g) was admitted to a solution of samarium diisopropoxy monoethyl acetoacetate (1.024 g) in benzene (45 g). The reaction was endothermic. After the mixture was refluxed slowly for about 5 h, the isopropanol–benzene azeotrope was collected slowly at 72 °C, and finally the *t*-butanol–benzene azeotrope at 74 °C. The excess benzene was also collected along with the azeotrope until the temperature reached 80 °C. After the compound was dried under reduced pressure, 0.5 mm at 60 °C, a faint-yellow crystalline solid was obtained. Yield 1.10 g. Found: isopropyl alcohol in the azeotrope, 0.311 g; replacement of 2 moles requires 0.308 g. Calcd. for $Sm(OBu^t)_2(Etacac)$: Sm, 35.30%. Found: Sm, 35.12%.

The interchange reactions with *t*-butyl alcohol are given in Table II.

ACKNOWLEDGMENT

The authors thank Prof. R. C. Mehrotra, Head of the Chemistry Department, and Dean, Faculty of Science, Rajasthan University, Jaipur, for valuable criticism, and Dr. S. N. Misra for helpful suggestions. We also thank Prof. R. C. Kapoor, Head of the Chemistry Department, and Dean, Faculty of Science, Jodhpur University, Jodhpur, for providing laboratory facilities; and the Ministry of Education, Government of India, for providing a research scholarship to B. S. S.

THERMAL DECOMPOSITION OF MOLECULAR COMPLEXES

IV. FURTHER STUDIES OF THE β-QUINOL CLATHRATES

H. G. McAdie
Department of Physical Chemistry, Ontario Research Foundation, Toronto, Ontario
Received January 21, 1966

ABSTRACT

The endothermal decomposition of 18 β-quinol clathrates has been studied by thermoanalysis, calorimetry, and X-ray diffraction, and the decomposition process shown to be

$$3\ \beta\text{-quinol}.x\text{M (s)} \rightarrow 3\ \alpha\text{-quinol (s)} + x\text{M (g)},$$

For those symmetrical guest molecules (M) which do not distort the β-quinol cavities from their normal dimensions, both temperatures and enthalpies of clathrate decomposition increase with increasing volume of the guest molecule. For those unsymmetrical guest species which require distortion of the cavities along their c-axis, temperatures and enthalpies of decomposition tend to decrease as the initial distortion required to accommodate the guest increases. Thermal stability of β-quinol clathrates is thus strongly influenced both by the size and shape of the guest molecule.

The mechanism of thermal decomposition is suggested to involve a combination of the loss of stabilizing guest–wall interactions, together with increased thermal motion of the interpenetrating networks of hydrogen-bonded quinol molecules.

An earlier paper in this series (1) described the thermal decomposition of four β-quinol clathrates, demonstrating that the endothermal loss of a given guest species from within the host β-quinol network occurs over a considerable temperature range. Thermal decomposition was shown to follow the general process

$$\text{clathrate (s)} \rightarrow \text{quinol (s)} + \text{guest (g)},$$

which occurs below the melting point of the host quinol. It was apparent that the size and shape of the guest species exerted considerable influence upon the thermal stability of the corresponding β-quinol clathrate and the present studies were undertaken to investigate further this influence of size and shape, through examination of a wide range of clathrates, and to clarify some details of the thermal decomposition process. A preliminary report of findings was made elsewhere (2).

EXPERIMENTAL

Clathrate Preparation

Reagent or C.P. grade materials were used throughout this work without further purification.

Clathrates of MeOH, HCOOH, and MeCN were prepared by slow crystallization from solutions of quinol in these solvents, saturated at 70 °C. The clathrates were filtered on sintered glass and air dried, the formic acid clathrate being dried over KOH (3).

Clathrates of H_2S, and SO_2, were prepared by passing these gases at about 2 atm pressure through stirred solutions of quinol in water, saturated at room temperature. The products were dried over KOH, the SO_2 clathrate having the yellow color previously reported (4). Clathrates of HCl, and HBr, were prepared by the same technique except that ether was used as solvent and the filtered products were washed sparingly with ether prior to drying over KOH.

Clathrates of the guest species listed in Table I were prepared with an Autoclave Engineers, Inc., 300 cc stainless steel autoclave equipped with a Magnedrive stirring unit and operable to 5000 p.s.i. at 650 °F. Approximately 66 gm of quinol and 100 ml of ethanol were placed in the autoclave and subjected to the initial pressures of guest species shown in Table I. In most cases these represented the maximum available supply pressure. The supply was then sealed off and the autoclave heated to 85–90 °C, followed by slow cooling overnight with continuous stirring. The products were filtered quickly and air dried.

TABLE I

Preparation of clathrates

Guest	Initial pressure (p.s.i.g.)
N_2	1 750
Ar	1 300
N_2O	600
CO	800
CO_2	700
CH_4	825
C_2H_2	200
C_2H_4	800
C_2H_6	500

Clathrates of MeCl and MeBr were prepared (5) by adding dry quinol to the autoclave, or to a 250 cc heavy-walled pyrex bomb, and condensing about 100 ml of the respective materials into the vessels at −75 °C. The vessels were sealed and heated to above 60 °C before slow cooling overnight. The MeBr clathrate initially possessed an orange tint which disappeared on drying in air.

α-Quinol was prepared by crystallization from ethanol according to the procedure of Evans and Richards (6). After drying, the material was heated for several hours at 150 °C to ensure the absence of β-quinol and solvent.

β-Quinol was also prepared as described (6), with air-free *n*-propanol as solvent. A seed crystal of the MeOH clathrate was used to facilitate crystallization, and the material was studied as soon as possible after preparation.

Analysis

The fraction of cavities within each clathrate occupied by guest molecules was determined by dissolving known weights of clathrate in ethanol and drying to constant weight at 40 °C. At this temperature loss in weight is due entirely to liberation of the guest species on dissolution of the clathrate, whereas higher temperatures resulted in some weight loss over long periods due to sublimation of the quinol.

Debye–Scherrer powder patterns were obtained with Cu K_α radiation. Patterns of samples heated to various temperatures were obtained by loading X-ray capillaries with about 2 mm depth of sample, and packing the tubes into the differential thermal analysis (DTA) block so that their open ends projected above the block. At the required temperature the tubes were sealed with a small flame and quickly removed to the X-ray camera.

Differential Thermal Analysis

Previous work (1) made no provision for atmosphere control within the DTA sample. To prevent access of air as well as to remove volatiles directly, the sample was purged continuously by an inert atmosphere using a modified version of the Stone dynamic atmosphere (7) sample block made of Inconel (Fig. 1). Reference

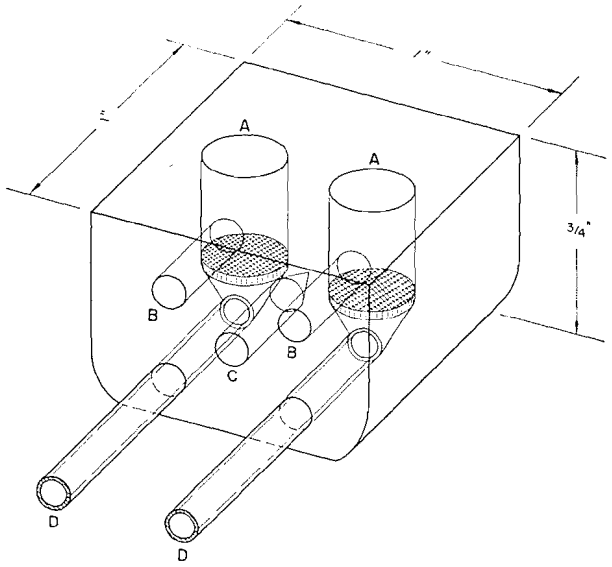

FIG. 1. Dynamic atmosphere DTA block.

For personal use only.

alumina, and samples diluted to 20% by weight in the same material, were packed in cavities A, the differential thermocouples entering through B. Sample and reference cavities were purged with separately controlled streams of dry nitrogen entering through tubes D, and passing through porous discs which formed the base of the cavities, at a flow rate of 6 cc min^{-1}. Differential temperature was amplified by a Leeds and Northrup 9835-B d-c. microvolt amplifier and fed into a Philips PR 2210A millivolt recorder. The usual display sensitivity was 0.8 $\mu V\ cm^{-1}$ chart width, with higher sensitivities being available. Block temperature was measured by a separate, calibrated, iron–constantan thermocouple located at C. A horizontal tubular-type furnace was employed and manually programmed at 3 °C min^{-1}.

All peak temperatures reported have been corrected to a value of 172.7 °C for the peak of the quinol fusion endotherm. Peak areas were estimated by tracing curves on semi-transparent graph paper and counting squares.

Calorimetry

Samples (0.5 gm) of clathrate were dissolved in 600 gm of 0.001 *N* HCl at 25 °C in a twin-type heat of solution calorimeter (8) calibrated against samples of potassium chloride.

Heats of solution of the individual pure guest species were obtained from standard tables (9), or were calculated from solubility data (10–12).

RESULTS

Thermograms

A typical differential thermogram for each of the β-quinol clathrates studied appears in Fig. 2. As the temperature increased, three main thermal effects were observed:

(i) a broad endotherm corresponding to the decomposition of the clathrate, i.e. liberation of the guest species from within the host β-quinol lattice, accompanied by the reversion of the residual quinol to the α-quinol crystal structure as shown by X-ray diffraction;

(ii) a relatively sharp endotherm due to the fusion of the residual α-quinol;

(iii) a broad, variable, endotherm which is associated with the volatilization of the molten quinol spread over the surface of the diluent alumina.

This latter peak was not observed previously (1) because sufficient air was present under the static atmosphere conditions then employed to permit oxidation and general exothermal degradation of the molten quinol. In the present work, the dynamic nitrogen atmosphere both prevents the access of air and purges any volatiles from the sample as they occur.

On the basis of heats of decomposition determined earlier (1) the thermal decomposition process was reported to produce solid β-quinol. It has now been possible to obtain X-ray diffraction patterns of samples heated through the clathrate decomposition endotherm. These patterns show the previous conclusions to be in error, and that the thermal decomposition of the clathrate produces residual quinol having the α crystal structure. Thus the thermal decomposition process may be represented as

$$3\ \beta\text{-quinol}.x\text{M (s)} \rightarrow 3\ \alpha\text{-quinol (s)} + x\text{M (g)}$$

for the clathrate where x moles of guest M are present.

That the first endotherm corresponds to loss of the guest species, accompanied by destruction of the β-quinol lattice, was further confirmed by simultaneous DTA–TGA (thermogravimetric analysis). Figure 3 shows the experimental record for the N_2 clathrate obtained for an undiluted sample heated in nitrogen at 4 °C min^{-1}. It may be noted that both DTA and TGA base lines begin to deviate prior to the decomposition endotherm and first rapid loss of weight. This represents the onset of sublimation of the host quinol at a measurable rate, and complicates any attempt to calculate decomposition kinetics and accompanying activation energies from TGA data. Decomposition of the clathrate through sublimation of the host lattice may be likened to dissolution of the clathrate in a solvent, i.e. the physical removal of quinol walls from about the guest molecule. However, the thermal decomposition process is complete at temperatures below which the rate of sublimation of quinol is sufficient to account for the decomposition, and the possibility of another mechanism will be discussed shortly.

For personal use only.

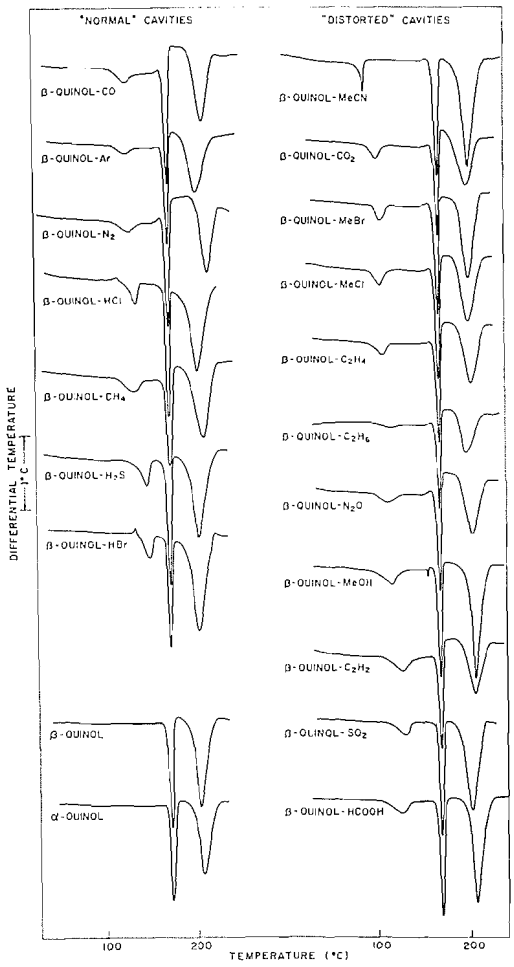

FIG. 2. Differential thermograms of β-quinol clathrates.

Two other minor thermal effects have been observed (Fig. 2). For the HCl and HBr clathrates a distinct indication of exothermal activity prior to the decomposition endotherm was found. This could suggest a small direct interaction of these guest species with the walls of the β-quinol clathrate cavities. Such exothermal activity was not observed with clathrates of the larger molecules MeCl and MeBr.

The other minor thermal effect has been observed only in the methanol clathrate. A small endotherm, equivalent to an enthalpy change of about $+0.2$ kcal mole^{-1} quinol, was found just prior to the quinol fusion endotherm, but X-ray diffraction patterns of samples heated to temperatures on either side of this endotherm showed only the α-quinol. Unfortunately, all X-ray diffraction patterns reported here were obtained ultimately at room temperature, and it is possible that the true structures prevailing before and after this endotherm have not been determined. In a further experiment, the methanol clathrate was decomposed isothermally at 120 °C and the residue of α-quinol (by X-ray diffraction) examined by DTA. No trace of the clathrate decomposition endotherm was observed, but a well-defined small endotherm was obtained just prior to quinol fusion. Because of the

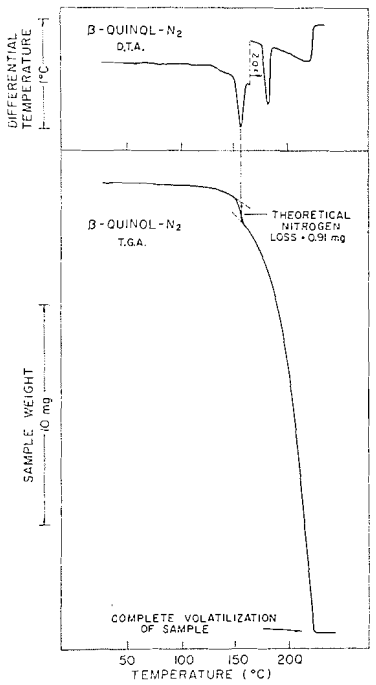

FIG. 3. Simultaneous DTA–TGA of the β-quinol–N_2 clathrate in N_2 atmosphere.

proximity of this endotherm to the onset of the quinol fusion, it has not been possible with the present equipment to verify whether a reversible process is associated with the small endotherm.

Thermograms of α- and β-quinol are also included in Fig. 2 and appear to be identical.

Decomposition Temperatures

Although clathrates of several of the guest species studied were prepared having more than one ratio of guest:host molecules, for brevity only those having the highest fraction of available cavities occupied are considered in Tables II and III. All decomposition temperatures reported are based on a peak temperature for the quinol fusion endotherm of 172.7 °C.

With some clathrates a small apparent increase in the average temperature of the clathrate decomposition peak (t_d) was found as the fraction of occupied cavities increased. Such increases in t_d were never more than 3 °C for an increase of 10% in the cavities occupied. It is possible to interpret these apparent changes in decomposition temperatures with composition on a purely kinetic basis, the clathrate having more cavities occupied requiring a somewhat longer time to reach the *rate* of decomposition represented by the peak of the decomposition endotherm. In dynamic techniques such as DTA, two competing rate processes are always present: the rate of the change under study, and the rate at which the conditions of the study themselves change.

Decomposition temperatures obtained in the present work were somewhat higher than reported previously (1) (Tables II and III), principally because of the conditions of the DTA experiment, viz. static vs. dynamic inert atmosphere. For the MeOH and MeCN clathrates, decomposition in a static atmosphere block allowed the accumulation of the

vaporized guest species, both of which in the liquid state are excellent solvents for quinol. One might reasonably expect both these materials in the vapor state to promote destruction of the β-quinol lattice under conditions where they were not removed promptly. In the case of the nitrogen clathrate, decomposition under 1 atm N_2 would be expected to occur at a slightly higher temperature than under the lesser, but unknown, pressure which prevailed in the static block. The decomposition temperature of the CO_2 clathrate is not appreciably different under the two techniques.

Palin and Powell (4) have reported that the formic acid clathrate melts at 160 °C. There is no evidence from the present studies to support this observation, and no indication that the host quinol melts at other than its normal temperature in this case.

Heats of Decomposition

From differential thermograms the heats of decomposition in kcal mole^{-1} *guest*, were estimated as previously (1). The average values are reported as ΔH_d (at t_d) in Tables II and III, and were generally reproducible to ±10% over a series of thermograms of clathrates having different fractions of occupied cavities.

It was also possible to calculate heats of decomposition of the clathrates, $\Delta H_d'$ (at 25 °C), from experimental heats of solution in 0.001 *N* HCl as follows

3 β-quinol.xM (s) → 3 α-quinol (aq.) + xM (aq.)	$+\Delta H_1$
3 α-quinol (aq.) → 3 α-quinol (s)	$-\Delta H_2$
xM (aq.) → xM (g)	$-\Delta H_3$
3 β-quinol.xM (s) → 3 α-quinol (s) + xM (g)	$+\Delta H_4$

$$\Delta H_d' = \Delta H_4/x$$

where ΔH_1 = experimental heat of solution of clathrate (kcal per 3 moles quinol), ΔH_2 = experimental heat of solution of 3 moles of α-quinol (kcal), ΔH_3 = heat of solution of x moles gaseous guest (kcal), ΔH_4 = heat of decomposition of clathrate (kcal per 3 moles quinol).

The heat of solution of α-quinol prepared by the method of Evans and Richards (6) was found to be +4.78 ± 0.03 kcal mole^{-1}, which compares favorably with their value of +4.7 kcal mole^{-1}. In certain cases x moles of guest exceeds the solubility of that substance at 1 atm, so that ΔH_3 then represents the enthalpy change to form a solution saturated with respect to guest under 1 atm pressure.

Since one of the objectives in this work was to produce clathrates with a large fraction of cavities occupied by guest species, no attempt was made to produce a systematic range of compositions. The observations of Evans and Richards (6) that the heats of solution of argon and oxygen clathrates are directly proportional to the fraction of available cavities filled was assumed to hold true for the other clathrates reported here.

For the clathrates of HBr, HCOOH, CO_2, N_2O, MeBr, and MeCN, $\Delta H_d'$ is significantly more endothermal than ΔH_d. Although the two quantities are measured at different temperatures, the temperature coefficient is not likely to be large, and this difference suggests secondary exothermal reaction between the liberated guest species and the residual quinol, or alumina diluent, prior to being completely purged from the system.

DISCUSSION

The spatial limitations imposed by the geometry of the clathrate cavity severely limit the choice of potential guest molecules. Thus, with few exceptions, it is not possible to compare two clathrates in which several parameters of the guest molecules have not been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

altered, and it becomes difficult to define the influence of any single parameter upon the thermal stability of β-quinol clathrates generally.

The thermal stability of these clathrates depends, among other factors, upon the initial distortion of the clathrate cavity required to accommodate the particular guest species. In cases for which the cell dimensions have been reported (4), present data indicate decreasing decomposition temperature and heat of decomposition with increasing initial distortion of the clathrate cavity as shown by its c-dimension (Fig. 4). A linear relationship has been fitted to these data to illustrate the overall trend, recognizing that with the many accompanying differences in guest parameters, and in their interaction with the β-quinol lattice, it would be fortuitous if such a linear relationship is entirely correct.

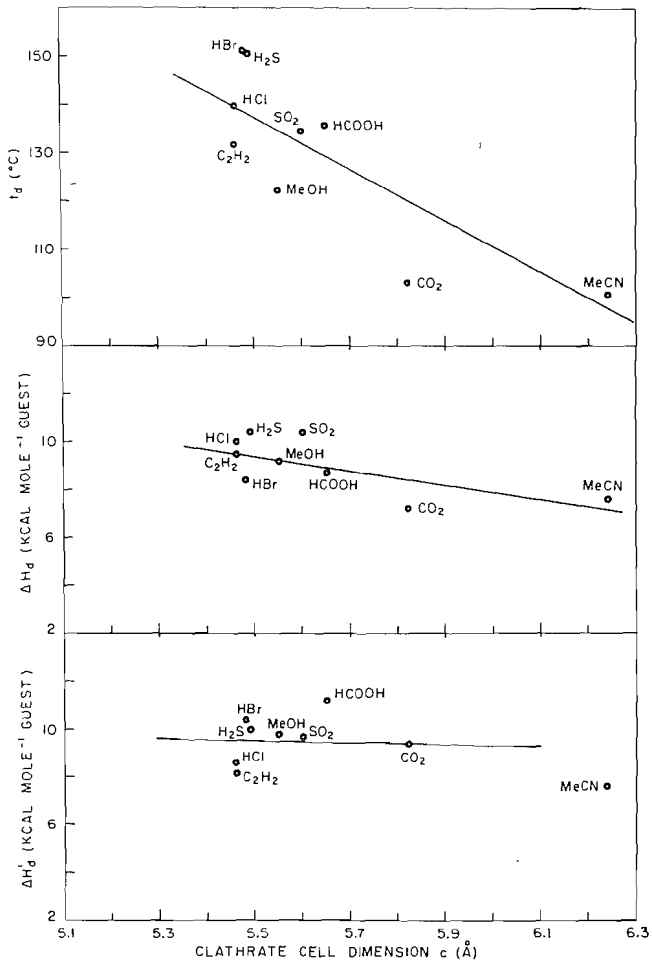

FIG. 4. Thermal stability of clathrates in relation to distortion of the clathrate cavity.

Two broad classes of β-quinol clathrates may then be considered: (i) those in which the clathrate cavity is essentially undistorted in accommodating the guest species, and (ii) those in which it is distorted. In Tables II and III guest species are therefore grouped on the basis of their influence upon the lattice parameters of the clathrate cell, determined from present diffraction patterns, and from available cell dimensions (4). The "normal" or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

undistorted cavity can accommodate those guest species listed in Table II without significant alteration in its dimensions. For simplicity these species may be considered to be generally spherical in shape, and to occupy a proportion of the available cavity volume in relation to their molecular volume. "Distorted" cavities result when the species shown in Table III are incorporated into the β-quinol lattice. Again for simplicity, these may be considered to be roughly "dumbbell" in shape. Not only will the length of the dumbbell vary from guest to guest, hence altering the extent to which the clathrate cavity is distorted, but the overall volume of the guest molecule in relation to the available cavity volume will vary, affecting its packing within the cavity.

"Normal" Clathrates

Since the group of clathrates in Table II have virtually the same cell dimensions, differences in thermal stability may be attributed to differences in the interaction of individual guest molecules with the cavity walls, arising not only from differences in the chemical nature of the various species but also from differences in the fraction of available cavity volume occupied by each guest. Further, since the environment of guest molecules is not strictly symmetrical (14), because of the grouping of oxygen atoms of the quinol at the poles of the cavity and carbon atoms at the equators, this may tend to give rise to preferred orientations of guest molecules within the cavities.

As a measure of the volume of these symmetrical guest molecules, the molar polarizability, α, calculated from refractive index (15) and vapor density (16) data is considered. Figure 5 shows that decomposition temperatures and heats of decomposition increase approximately linearly with the polarizability of these spherical guest molecules or, approximately, with the extent to which the available cavity volume is occupied. There is a maximum, as well as minimum, limit to which the undistorted cavity can be filled, and between these limits increasing thermal stability reflects increasing interaction of the guest with the cavity walls imparting increased stability to the entire lattice structure. These interactions are mainly van der Waals type, but differences due to the electronic structure of the guest species will result in different contributions from such effects as dipole–dipole interactions with the cavity walls. These should be relatively small since most of the guest molecules are small and relatively nonpolar. In a future paper it is hoped to present data for a series of the rare gas clathrates in which essentially only the volume of the guest molecule will vary.

In Fig. 5 heats of decomposition obtained from DTA and from heats of solution have been compared on a common basis with heat of formation data from the literature (1, 3, 13). A reasonable correlation was found in both cases, the calorimetric data showing somewhat less scatter than those obtained from DTA.

Although the magnitude of the guest–host interactions is considerably greater than the magnitude of guest–guest interactions, in the pure solid for instance, one might expect the thermal stability of β-quinol clathrates to be proportional to the heat of sublimation of the pure guest (3, 9). This is demonstrated in Fig. 6, indicating further that at least a portion of the forces which must be overcome by the guest molecule prior to escaping from the clathrate cavity are similar to those which must be overcome in removing individual molecules from their respective pure solids.

"Distorted" Clathrates

A group of guest species which generally distort the β-quinol clathrate cavity from its normal dimensions are listed in Table III. This comprises a very heterogeneous group of substances, about the only common feature being the more or less "dumbbell" shape of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

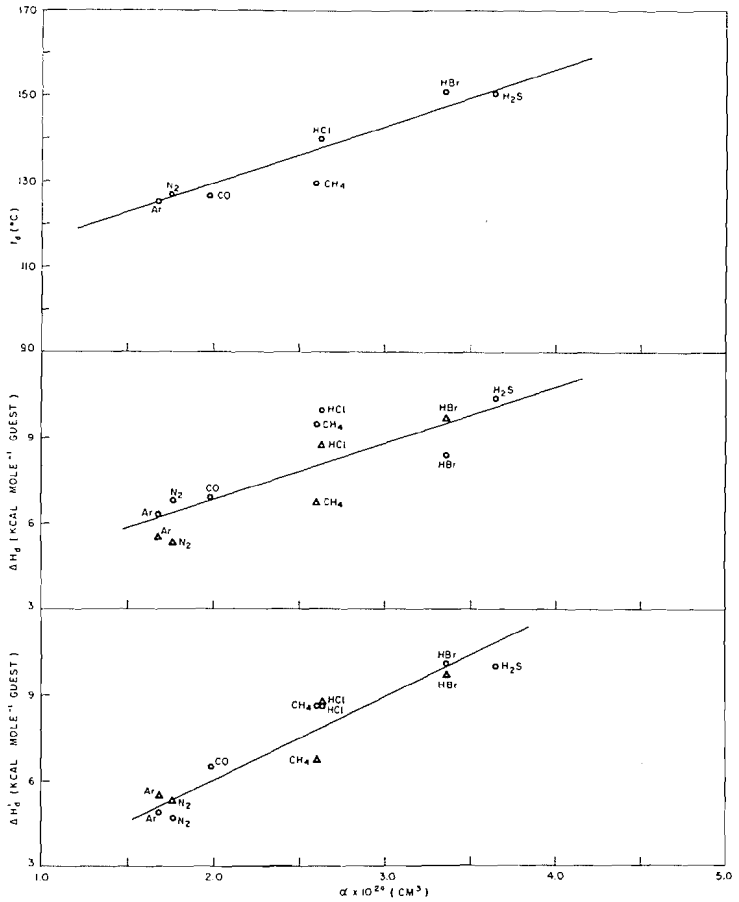

FIG. 5. Thermal stability of "normal" clathrates as a function of guest size: (○) present data, (△) literature data.

the molecules. For this reason the use of molar polarizability as a measure of molecular volume is not longer valid, and the van der Waals covolume, b, has been chosen as a measure of this parameter. As indicated by Fig. 7, there is a trend toward *decreasing* thermal stability with increasing molecular size. For the species investigated, increasing molecular size is generally accompanied by increasing extension of the cavity along its c-axis (Table III), complicated by differences in the overall fraction of available cavity volume occupied after the distortion. Such differences may be expected to be significant when comparing, for example, acetylene and methyl bromide and to contribute to differences in packing within the cavities. Another factor which contributes to the considerable scatter of data in Fig. 7 is the variation in the electronic structure among the different guest species.

The structures of the C_2H_2 and MeOH clathrates appear to be slightly anomalous, in that whereas one cell dimension is larger than normal for the undistorted case there is no compensating decrease in the other dimension as would be expected from the trellis-like architecture of the cell.

Despite an almost threefold difference in van der Waals b, CO_2 and MeCN form clathrates of remarkably similar thermal stability. CO_2 produces considerable distortion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

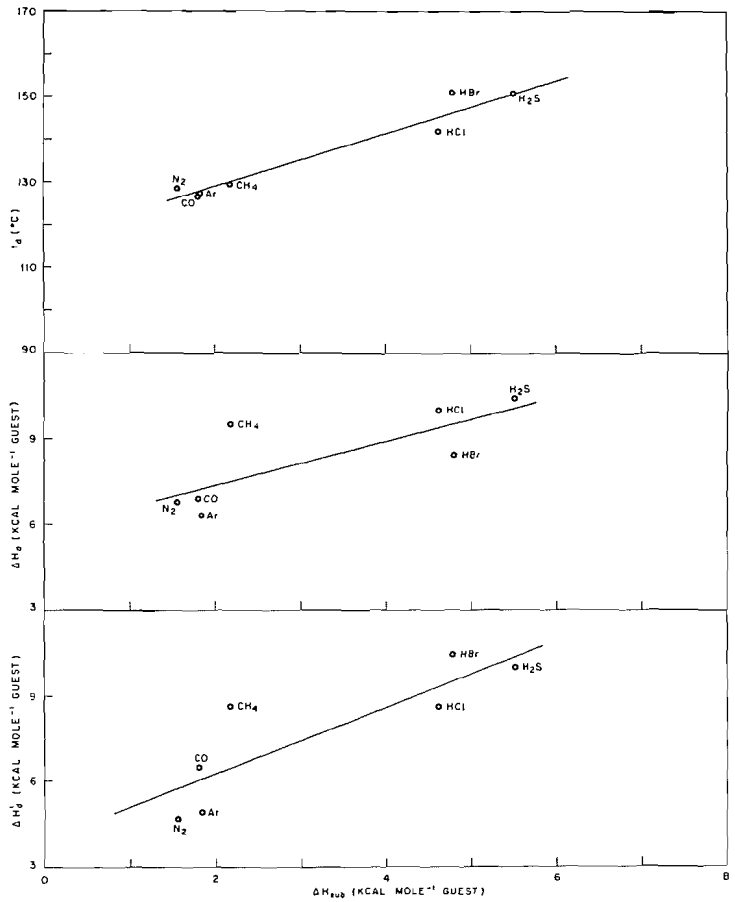

FIG. 6. Thermal stability of "normal" clathrates in relation to heat of sublimation of guest.

of the lattice and there appears to be a possible reduction in the O—H . . . O hydrogen-bond lengths in the quinol network from 2.8 to 2.72 Å (4) accompanying the packing of this guest molecule into the cavity. In the case of MeCN (17) a puckering of the hydrogen-bonded oxygen hexagons has been suggested.

From the relatively similar size and thermal stability of CO_2, N_2O, and their clathrates, one might suspect a packing situation prevails in the case of N_2O similar to that postulated for CO_2. These two clathrates are similar in other respects: (i) both guest species have roughly linear molecules with an axial length of about 5.2 Å (18, 19), and (ii) although increased pressure of guest during clathrate formation generally results in an increased fraction of the available cavities being filled, both N_2O and CO_2 are exceptional in that after a maximum of about 75% cavities filled has been reached further increase in pressure of guest during formation reduces the number of cavities occupied (18).

For those species which distort the clathrate cavity, the relation of thermal stability to heat of sublimation of the pure guest is poor, the scatter preventing any real conclusions from being drawn. It is interesting that for this group the heats of clathrate decomposition more nearly approximate the heats of sublimation of the pure guest, indicating that the removal of an individual guest molecule from the distorted clathrate cell is roughly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

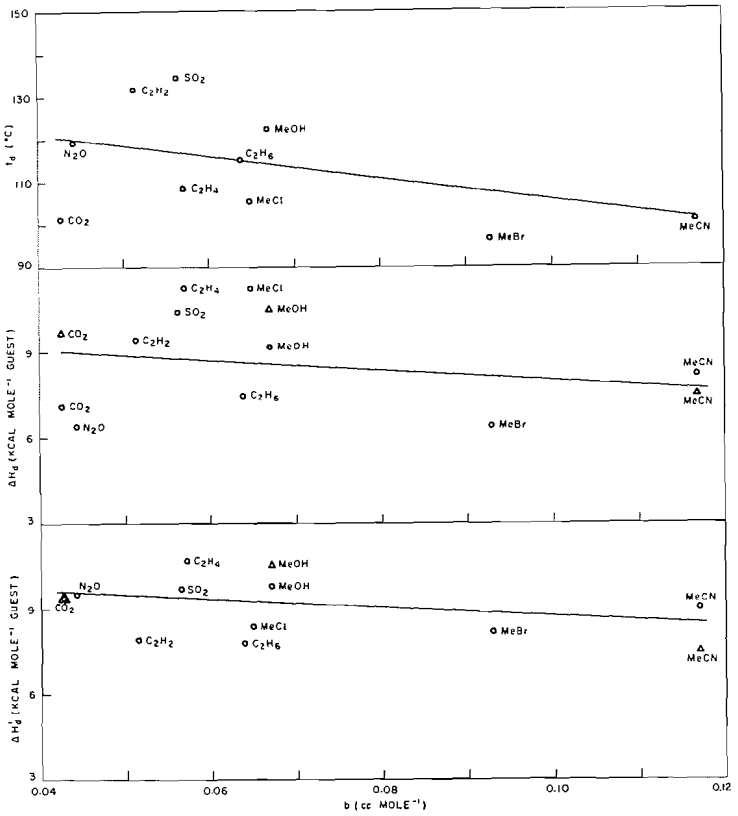

FIG. 7. Thermal stability of "distorted" clathrates as a function of guest size: (○) present data, (△) literature data.

equivalent to removal of that molecule from its pure solid state although the detailed nature of the interactions may be somewhat different in the two cases.

Comment

The size and shape of the guest molecule have a more pronounced effect upon the temperature at which the clathrate decomposes than upon the accompanying enthalpy change, suggesting that lattice vibration may play a significant role. In the clathrate structure there are no "holes" through which a guest molecule may escape from the cavity without approaching the walls closer than normal van der Waals distances; thus a high activation energy is required. Unfortunately, incipient sublimation of the quinol complicates calculation of experimental activation energies for thermal decomposition from TGA data. The fact that clathrates do decompose thermally, and do liberate guest molecules at temperatures well below the melting point of quinol where the rate of sublimation of quinol is measurable but not appreciable, requires (i) overcoming guest – cavity wall interactions and (ii) an opening of sufficient size to permit egress of the guest. It has been well established (14, 20, 21) that most guest species are capable of a considerable degree of motion within the clathrate cavity, even at low temperature, dependent upon the closeness of fit between cavity and guest. This motion may be expected to increase with temperature accompanied by a decrease in the extent to which the clathrate lattice is stabilized by interactions with the guest molecules in the cavities. At temperatures where these interactions have been overcome the contribution of the guest molecules to the stability of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

clathrate is virtually lost. Concurrently the interpenetrating quinol networks have acquired increasing energy of thermal motion and will vibrate with respect to one another at an increased frequency. The amplitude of these vibrations will also increase to the extent that there is general stretching of the O—H . . . O hydrogen bonds at the poles of the cavities, and the networks become somewhat more flexible with respect to one another. This combination of loss of the stabilizing influence of the guest upon the β-quinol structure, plus increased overall lattice vibration, results in destruction of the clathrate cavities with liberation of the individual guest molecules.

Thus, for an undistorted cavity, increasing the fraction of available cavity volume occupied by the guest molecule, or otherwise increasing the guest–wall interaction, will result in increased clathrate stability. Conversely, increasing distortion of the cavity by other types of guest species may be expected to overcome any increased stabilization of the lattice (due to dipole–dipole interactions or the like) rather readily, and loss of such internal stabilization will facilitate hydrogen-bond rearrangements at decreasing temperatures. It should be emphasized that these decomposition temperatures represent not thermodynamic transition points but temperatures at which the rates of the associated phenomena become measurable.

A PARAMAGNETIC RESONANCE STUDY OF HINDERED DIARYLMETHYL RADICALS AND RELATED COMPOUNDS

I. ANALYSIS OF THE SPECTRA

H. R. FALLE[1] AND F. C. ADAM
Department of Chemistry, University of Alberta, Calgary, Calgary, Alberta
Received April 30, 1965

ABSTRACT

Several ortho-substituted radicals of the benzhydryl type and a variety of diaryl ketyls have been studied through the nuclear hyperfine structure of their electron spin resonance spectra. A strong similarity is found between the spectra of a given ketyl and its hydrocarbon analogue. This suggests that when ketones are reduced, a very tight ion pair is formed between the ketyl anion and its cation. Although the coupling constants of the protons vary with different reducing agents, larger variations are observed when bulky groups are substituted into ortho positions. These larger changes are attributed to a forced internal rotation of the phenyl rings. The distortion results from the steric repulsion between the ortho groups. The effect of 'buttressing' of ortho methyl groups is also studied. Deuterium and ^{13}C substitutions have been effected in some of the compounds.

INTRODUCTION

The underlying purpose of this study was to determine the effect that ortho substituents have on the proton hyperfine structure of the electron spin resonance (e.s.r.) spectra of various compounds with a benzhydryl skeleton. Molecular models of the parent compound, diphenylmethyl, show that two of the four ortho protons are in positions which should give rise to large steric repulsions when the two rings are held in a coplanar configuration. The other pair of ortho protons is not constrained in this way, and steric interactions should not occur unless the carbon–carbon bond angles are severely distorted from the normal sp^2 hybrid angles of 120°. For convenience in the following text, the sterically hindered pairs of ortho groups will be termed the "inner" groups and those at the sterically inactive positions the "outer" groups. This distinction is unique for the diarylmethyl radicals, because for triphenylmethyl derivatives both inner and outer groups are sterically involved, whereas for the benzyl radical neither of the ortho protons is particularly effective in introducing steric repulsions.

The e.s.r. spectrum of triphenylmethyl may be analyzed in terms of six equivalent ortho protons, six meta protons, and three para protons (1). The implied threefold axis of symmetry would result if the steric strain at the ortho sites were relieved by symmetrical rotation of the three phenyl rings about the central bonds, resulting in a propellor configuration. Nuclear magnetic resonance (n.m.r.) studies of the carbanion and carbonium ions of diphenyl and triphenylmethyl derivatives support this conclusion because similar shifts are found for equivalent protons in each ring of these compounds (2, 3). The optical spectra of the ions also suggest a symmetrical structure for both diphenyl and triphenyl derivatives. The inferences here are less clear-cut, and the suggestion has been made that the optical spectrum results from transitions which do not involve all of the phenyl rings (4). This conclusion is based mostly on the lack of a bathochromic shift due to extension of conjugation in proceeding from the monophenyl to the triphenyl ions of this series. It has been shown theoretically (5) that this behavior is to be expected, and calculations

[1]*Present address: Department of Chemistry, Cambridge University, Cambridge, England.*

based on the transition intensities (6) appear to favor a structure in which all rings present contribute equally to the conjugation of the molecule.

It will therefore be assumed that the stable form of the radicals under consideration is of the form depicted in Fig. 1*a* rather than the unsymmetrical rotomer in Fig. 1*b*. Although this assumption leaves the question of the possible non-equivalence of the ortho substituents, the matter is not critical to the following discussion.

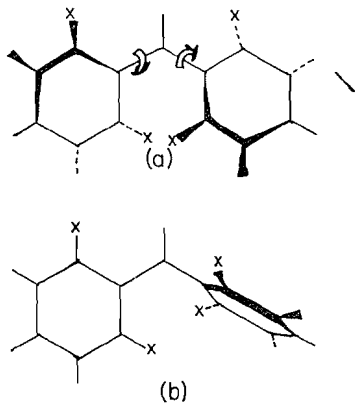

FIG. 1. Angular distortions of diphenylmethyl radicals. (*a*) Symmetrical, both rings rotated; (*b*) unsymmetrical, one of the four possible rotomers. The symbol X represents any sterically hindering group.

As can be seen from Fig. 1*a*, as the size of the ortho group, X, is increased, the additional steric strain may be partly relieved by rotation about the central carbon–carbon bonds. This will decrease the conjugation between the central carbon and each of the rings, with the result that the odd electron density will be confined more closely to the central position. In the extreme case of very large hindering groups, the phenyl rings would be held perpendicular to the plane of the central group. In all naivety it could be assumed that the unpaired electron would then be completely localized in the 2p orbital of the extracyclic carbon atom. According to the well-known formulation of McConnell (7), the coupling constant (a_i) of the ith aryl-type proton is given by the relationship

$$a_i = \rho_i Q(\mathrm{H})$$

where ρ_i is the spin density at the adjoining sp^2 hybridized carbon atom and $Q(\mathrm{H})$ is a constant of the order of 25 Oe. For the localized electron considered above, $\rho = 1$, so the hyperfine splitting of the lone proton on this central carbon atom would be ~ 25 Oe. There would be no hyperfine splittings from the ring protons. Smaller hindering groups would give smaller internal rotations, and greater delocalization of the unpaired spin density. Thus the lone proton splittings would decrease, whereas the contributions of the ring protons to the hyperfine spectrum would increase as the coplanar configuration is approached.

Unfortunately, the hydrocarbon radicals corresponding to diphenylmethyl dimerize more or less completely, unless wholly substituted in the ortho positions by fairly bulky groups (8). To obtain spectra for compounds with smaller hindering groups, the study has been extended to include the ketyls of the analogous substituted benzophenones, with which similar effects might be expected to occur.

Kinetic studies on the racemization of optically active biphenyls (9) have indicated that the size of a hindering ortho group may be effectively increased by "buttressing" this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

group with bulky substituents in the meta position. As applied to the situation under consideration here, 'buttressed' ortho groups should lead to a decrease in the ring-splitting constants by increasing the internal angle of rotation. Accordingly, compounds of this sort have been included in the present study.

EXPERIMENTAL

A variety of methylated and methoxylated benzophenones has been prepared. These appear in Table I, along with the source, or method of preparation, and the shorthand notation which will be used in this paper. The hydrocarbon radicals were obtained from the corresponding ketones by reduction to the carbinol with lithium aluminium hydride in ether solution. This carbinol was treated with dry HCl gas in acetyl chloride. On completion of the reaction, the solvent was removed on a vacuum line and replaced by toluene, along with a small amount of triethylamine (10). The chloride was reduced with amalgamated silver.

In addition to the precursors listed in Table I, the isotopically labeled species 4,4′-dideutero-2,3,6,2′,3′,6′-octamethylbenzophenone (i.e. dideutero diduryl ketone or DDK-d^2) and centrally substituted ^{13}C diduryl ketone (DDK-^{13}C) were prepared. Durene was dibrominated in chloroform at −10 °C and partially lithiated with *n*-butyl lithium in ether. Excess D_2O was added and the resulting monodeuterobromodurene isolated. The magnesium grignard of this material was then prepared in tetrahydrofuran. Half of it was carbonated with dry ice, hydrolyzed, and treated with thionyl chloride. To this product was added the remaining grignard, hydrolysis giving the desired ketone.

*Mathieson, Coleman and Bell.

^{13}C substitution was effected with gaseous $^{13}CO_2$ from 55.9 atom % $Ba^{13}CO_3$ (Isomet Corporation, Palisades, N.J.) and concentrated sulfuric acid, using a vacuum-line preparation. The gas was frozen in a thick-walled pyrex cell containing normal durylmagnesium bromide in tetrahydrofuran. This cell was then sealed off from the vacuum line and heated for 2 days on a steam bath. Hydrolysis of the product gave tetramethyl benzoic acid-^{13}C, which could then be treated as above to give DDK-^{13}C.

The spectra of the radical species were obtained with a TE_{011} tunable cylindrical cavity in a modified Strand Labs X-band spectrometer and a Harvey Wells magnet (L-128) system. Field modulation was at 6.2 kc/s. The magnetic field sweep had a nonlinearity of about a half a percent so that after each spectrum was run, the field was retraced at fixed microwave frequency and the spectrum of peroxylamine disulfonate superimposed on the sample spectrum. The hyperfine constants were determined from the averaged values of the field standard values. Low temperature spectra were obtained in a similar manner by the standard technique of blowing cold nitrogen gas past the sample in a quartz dewar insert set in the cavity. The ketyl spectra reported were obtained at room temperature, in dimethyoxyethane, whereas the hydrocarbon radicals spectra were taken in toluene at −60 °C. Electrolytic reductions were done in acetonitrile solution, with tetra *n*-propylammonium perchlorate as the supporting electrolyte and tungsten wire for the electrodes. The samples were prepared under vacuum. Three metals sodium, potassium, and calcium were also used as reductants. The first two were distilled into the system under vacuum by standard techniques (11), whereas calcium was cleaned as well as possible with emery paper and flamed thoroughly after introduction to the sample cell. The reductions with calcium were very slow and took several days at low temperatures, in some cases.

RESULTS

The analyses of the hyperfine spectra result in the coupling constants appearing in Tables II and III. The notation which is used follows from the notation used for the ketones in Table I. For example, DMKK-e is taken to mean 'dimesitylketone ketyl-produced electrolytically' and DMKK-Ca is the ketyl resulting from calcium metal reduction. DMM stands for dimesityl methyl, the neutral hydrocarbon species.

DDM	2.80	3.04*	2.16*	15.9

*Methyl protons.

The precise analysis of these compounds becomes very difficult and less certain as the number of ring substituents increases because of the proliferation of protons resulting from multiple methylations. To simplify the process the assumption has been made that if the substitution of methyl or methoxyl groups is made in sterically inactive positions, these substitutions do not materially change the spin distribution in the conjugated system, so that the magnitude of the splitting constants does not change from the order found in the parent ketyl of benzophenone. This latter spectrum is readily analyzed as being due to a triplet and two quintet splittings. The largest splitting is that of the triplet, and is due to the pair of para protons. This assignment is verified in the para-methylated and para-methoxylated derivatives of benzophenone, DTKK and DAKK, where the

triplet has been replaced by septets in both cases. In the spectrum of DAKK, the methoxyl splittings are very small, whereas for DTKK the methyl proton splittings are only slightly larger than the ring protons that have been replaced. The remaining two quintet splittings are due to the ortho and meta protons and do not change markedly as a result of either of these substitutions. This fact lends support to the contention that the spin densities are not markedly changed by substitution at unhindered sites. Alternatively, these substitutions produce only small perturbations to the ground state wave functions. It also appears that freely rotating methyl groups give splitting constants a_i(Me) which follow the approximate relationship (13)

$$a_i(\mathrm{Me}) = \rho_i Q(\mathrm{Me}),$$

where Q(Me) is but slightly larger than the value for ring protons (25 Oe) and ρ_i is the unperturbed spin density at the substitution site. Although on somewhat doubtful theoretical ground (14) this formulation will be assumed to hold in the present work.

It remains to be decided which of the two quintet splittings of DPKK is due to the ortho protons. If the spectrum of TMKK is considered, a large triplet splitting is obtained. Each line is further split by a single quintet. The ortho protons have been replaced by methoxyl groups from which no splittings were found. Contributions from these protons were unresolved within the rather broad lines ($\sim$ 0.4 Oe) of the absorption spectrum. The triplet splitting is similar to that of the para protons in DPKK, and the remaining quintet splitting corresponds to the smaller of the quintet splittings in DPKK. This latter structure is therefore assigned as due to the meta protons, and the larger quintet splittings in DPKK as due to the ortho protons. Thus the magnitudes of the splittings fall in the order $a_p > a_o > a_m$ for DPKK and its derivatives. This order does not appear to change when the ortho positions are completely methylated. The 13 line progressions due to these protons are quite apparent in the spectra of the ketyls of both DMK and DXK. Since the spectrum of DXKK-Ca is fairly well resolved it is possible to locate the subsidiary triplet and quintet due to para and meta ring protons. In the case of DMKK-Ca, essentially the same meta quintet splitting is found, along with the expected para methyl proton septet. Again the methyl proton splitting is only slightly larger than that of a ring proton at the same position. As with DTKK (compared to DPKK), para methylation would not be expected to alter the spin distribution in the ring nor effect the 'steric size' of the ortho group.

The spectrum of DDKK was not so amenable to the above cut-and-try method of analysis. The lines which appear in the spectrum may be interpreted in terms of two sets of 12 equivalent protons. The outer components of the triplet due to the para protons are of relatively lower intensity and appear to coincide with the progression of lines arising from the central component. As a result of this overlap a para proton coupling constant cannot be obtained except from a consideration of the relative intensities of the lines. Since the coincidences are probably not exact, this procedure would not give rise to an unequivocal assignment. On the other hand the ortho and meta methyl proton splitting constants must be considered anomalously large. This may result from the fact that these buttressed methyl groups interact very strongly; they may be interlocked in such a way as to allow only a concerted motion or may even be twisted out of the plane of the phenyl ring. In either case a different coupling constant from that obtained for freely rotating groups might be expected. For this reason, the para proton coupling constant would appear to be a more satisfactory index of the spin densities in the ring than would be the more readily available methyl splittings. Accordingly the para-deuterated DDKK was prepared.

The spectrum of this derivative was considerably different than that of the normal ketyl. The envelope of the hyperfine lines was symmetrical and bell shaped in the former case, but serrate in the latter. The 0.32 Oe spacing between adjacent lines was the same in both spectra. A number of possibilities exist. Firstly the deuterium splitting (1:2:3:2:1) may be very small compared to the linewidth. In this case one would expect the same symmetrical spectrum, or a 1:2:1 repetition of this symmetrical spectrum, for the normal derivative. Neither will give the characteristic spectrum observed. On the other hand, if the deuterium splitting corresponds to the 0.32 Oe interval (or a multiple of it), the symmetrical spectrum could result from the fivefold repetition of the basic 169 line pattern due to the ortho and meta methyl protons, with the coupling constants cited. Furthermore the proton coupling constant would be expected to be about $6\frac{1}{2}$ times the 0.32 Oe splitting, or an integral multiple of it. With this information it was possible to select the 'most likely' para proton coupling constant which appears in Table II. The ortho and meta coupling constants are assigned so that $a_o > a_m$ and correspond to the order found with the other compounds, but the reverse assignment may in fact be appropriate.

The spectra of the neutral hydrocarbon radicals are characterized by a large doublet splitting due to the lone central proton. However, the splitting is not so large as to prevent overlapping of the hyperfine components from the doublet states. This fact, along with a lack of symmetry between the high field and low field side of the spectrum, made the location of the central lines of the two halves of the spectrum rather uncertain. A striking similarity is to be observed between the intensity pattern of the ketyls and that of the corresponding neutral radicals. In fact the latter spectrum looks very much like the sum of two ketyl spectra displaced by the doublet separation. Comparison of the ketyl spectrum with that of the hydrocarbon radical leads to an assignment of the doublet splitting that is considerably more trustworthy than would have been obtained from the hydrocarbon data alone. The essential difference between the spectra of the two types of compound appears to be only in the doublet splitting and the fact that the coupling constants of the hydrocarbons are slightly larger than those of the ketyls. The assignments for the neutral radicals are set out in Table III. The same procedure was used in the case of DDM as was used for the corresponding ketyl; the para coupling constants were obtained from the comparison of the dideutero and the normal compound.

The lack of symmetry between the high and low field sides of the spectrum mentioned above was found in several of the cases studied. The situation with regard to the alteration of line intensities in these compounds is rather more difficult to cope with than in simpler spectra, where g value and residual dipolar anisotropies or intermolecular motional effects (15) serve to broaden the lines and so reduce the peak-to-peak amplitudes. The further complications arise because most of the lines observed result from the overlap of several transitions between different nuclear substates. The resulting line depends therefore not only on the width of the composite members but also on the degree of overlap. This complex matter is not considered further at present. However, to compare computed and observed spectra, an attempt was made to reduce intensity variation effects in the observed spectra by averaging the high and low field peak heights. This procedure will not yet give a true representation of the relative peak heights since these quantities will still be dependent upon the degree of superposition, and upon the intensities of the various components giving rise to the observed line. Plotted spectra corresponding to the suggested coupling constants have been drawn up for each of the compounds studied and have been compared to the averaged experimental intensities. Quite good agreement is found. While the computed intensities are generally somewhat higher than those observed, there is extremely

good agreement between the intensity patterns. The same procedure has been carried out for other assignments which correspond to other possible molecular arrangements. For instance, spectra have been computed for the situations where there is coupling in one ring only, or in two rings unequally, or where different inner and outer group splittings are assumed. In no case was the fit with the experimental data nearly as good as given by the results cited, nor was such reasonable internal consistency of the results obtained.

One further observation may be made about the spectrum of DMM. The spectrum of this compound and its analysis agree with that reported by Chestnut and Sloan (16) and, apart from intensity alteration effects, agree very closely with the calculated values. The line widths in this spectrum are of the order of 0.08 Oe, and in none of the lines is there the slightest indication of a splitting of the ortho lines due to differences between the inner and outer groups. It is also apparent that the methyl groups in this compound rotate freely, even in the sterically restrictive sites occupied by the inner groups.

The ^{13}C splitting for DDM-^{13}C was found to be 24.8 Oe, which compares very closely with the value of 24.5 Oe obtained by Adam and Weissman (17) for DMM-^{13}C. The spectrum of the corresponding diduryl ketyl was also taken, but although the resulting spectrum was different from the normal material, it proved impossible to analyze. However, from the increased width of the spectrum, an upper limit of some 15 Oe can be placed on the ^{13}C coupling constant in this compound.

DISCUSSION

As was outlined in the Introduction, it should be possible to assess gross changes in the molecular structure of diphenylmethyl radicals by a study of the proton hyperfine structure. In particular, substitution into the ortho positions should result in an increase in spin density at the central position and a decrease in the total density in the rings as a result of the decreased electronic coupling between the central position and the rings. It is hoped that the substitutions themselves do not produce changes in spin distribution and electron–proton interactions which are sufficient to mask any effects which are due to the steric factors alone. Since the spin density at the central position would be the least affected by perturbations within the rings, the lone proton splittings, and, to a lesser extent, the ^{13}C splittings, should therefore be the most reliable index of what is happening in the molecule as a result of chemical substitution. When the three compounds DXM, DMM, and DDM are compared on this basis, little change is observed in the lone proton splitting. The ^{13}C coupling constants for DMM and DDM are also very similar. One is forced to conclude that neither *p*-methylation nor buttressing of the sterically hindered groups produces much change in the interannular orientation. The ring densities for DXM and DMM are also quite similar. On the other hand DDM has coupling constants which show that considerable changes have occurred; apparently the buttressed groups affect each other much more than they do the remainder of the molecule. Although the para coupling constant decreases, it is suggested in this case that this results from distortion of the phenyl ring rather than from any large change in the dihedral angles of the ring relative to the central position.

The hydrocarbon results cannot be directly compared to those obtained with the ketyls because of the presence of the oxygen function and its possible interaction with the outer groups. With the absence of the lone proton one has to rely on the coupling constants of the ring substituents to indicate the distribution of spin within the ketyl radical. If xanthone ketyl (XKK) is considered in addition to the remaining examples of Table II, then a series of compounds is obtained which vary considerably in the disposition of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

two rings bonded to the ketone function. Xanthone ketyl (XKK-Ca) has splitting constants $a_o \approx a_p \approx 3.9$ Oe, and should be approximately planar by virtue of the oxygen bridge between the two rings. For DPKK-Ca, the value for a_p has dropped to 3.46 Oe, and for DXKK-Ca, to 2.52 Oe. The value of 2.34 Oe obtained for the buttressed form may or may not be real, since the coupling constant anomalies parallel those of its hydrocarbon analogue, which is also suspect. In any case this is the order predicted in the Introduction; as a result of steric repulsive forces, the odd electron population in the rings has decreased, planar > ortho hydrogens > ortho methyls. Whereas the meta coupling constants do not seem appreciably changed, the ortho values show a parallel decrease: XKK (3.9 Oe) > DPKK (2.77 Oe) > DXKK (1.49 Oe).

Attention must be drawn to the DAKK spectrum. The para coupling constant shows an increase over DPKK even though the ortho hydrogens have been replaced by methoxyl groups. It is not known whether this is due to a spin redistribution caused by the multiple substitution, or whether methoxyl has an intrinsically small steric effect in this particular situation where the methyl groups can get out of each other's way.

From the results in Table II, it can be seen that for each of the ketone samples for which the reducing agent is sodium, hyperfine coupling to that nucleus ($I = 3/2$) occurs. It is much smaller in the orthomethylated compounds than in the case of DPKK. The reverse situation would normally have been expected if the metal ion is associated with the oxygen atom which is, in turn, in a region of relatively higher spin density as a result of ortho methylation. This suggests that the ortho methyl groups interfere with the formation of a 'normal' bond between the metal and the oxygen atom. While the presence of metal nuclear coupling is strongly suggestive of a tight ion pair, there must be considerable difference in the structure of these complexes to give the order of magnitude variation which is observed. A further peculiarity may be observed in a comparison of the magnitudes of the splittings for various metals. Other recent work (18) reports lithium splittings for some of these compounds. For DPKK, $a_{Li}/a_{Na} = 0.37$, whereas for DTKK, $a_{Li}/a_{Na} = 0.36$. The ratio of the nuclear moments $\mu_{Li}/\mu_{Na} = 1.47$. Similarly from Table II, $a_{Na}/a_K = 4.8$, whereas $\mu_{Na}/\mu_K = 5.68$ for the same compounds. Thus the more electropositive elements have relatively higher spin densities, all other factors constant. Arguments based on relative ionic character for the metal–oxygen bond, or the length of the bond, and so on, all appear to favor a higher spin density with the more electronegative metal atoms. Sodium also has a relatively larger coupling constant compared to magnesium (19).

A further trend may be noticed within the sequence of splitting constants observed for a particular ketone. The values in Table II may be arranged in the arbitrary order $N(iPr)_4^{1+}$, Ca^{2+}, Na^{1+}, K^{1+} (which probably corresponds to the ionization potentials). For the metal reductions, the ring proton coupling constant for a given ketone decreases, or at worst remains unchanged, in the above order. On the other hand if the substituent is a methyl proton, the coupling constants increase in the same sequence.

Finally, reference should be made to the observation that in the spectra studied no evidence has been found which would indicate that there is any difference between the coupling constants of the inner and outer groups. Furthermore no differences appear to exist between the protons of each methyl group in these sterically restricted situations. Whereas it is reasonable to suppose that these methyl groups are free to rotate about the carbon–carbon axis even in severely hindered environments, there is no simple explanation of the apparent equivalence of the different groups. They are not related by symmetry, and exist in very different spin localities. This is especially true of the ketyls, where any

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

spin density on the oxygen atom would almost certainly be felt by the outer group. On the other hand the protons of the inner group are held close to the spin concentration of the adjacent ring. It is possible that these different sites may exchange places with sufficient rapidity to average out any field differences. The lack of high and low field symmetry may be a token of such an internal motion. The possibility of such an oscillation occurring at low energies of activation will be discussed in the second paper of this series.

Received July 30, 1965

ABSTRACT

This paper presents a model in which internal rotations of diphenylmethyl radical types effectively average out differences between the ortho and the meta substituent pairs in each ring. The process involves a very low energy of activation even though π-electron bonds are broken. The model is supported by valence bond (VB) and Huckel molecular orbital (HMO) calculations, and comparison is made with experimentally determined quantities wherever this is possible. Certain cases in which transannular pseudosymmetry has not been found are also discussed in relation to the above model.

INTRODUCTION

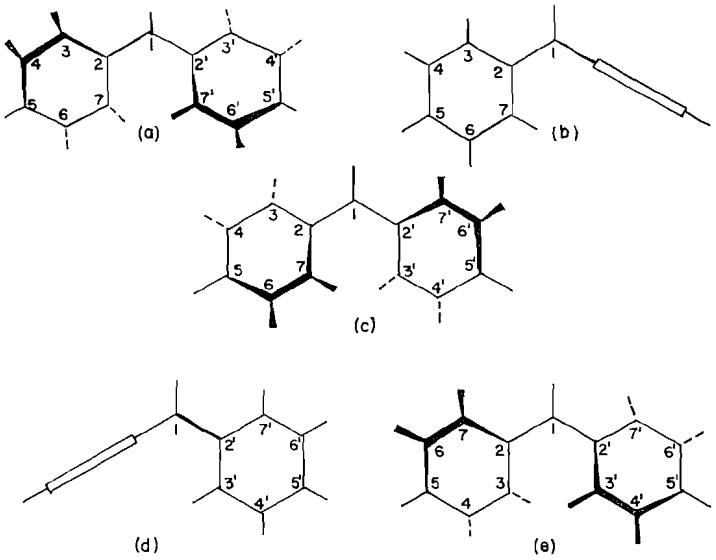
In this paper, a model will be developed to describe some of the phenomena which are observed with diarylmethyl systems. Of particular interest will be those molecules with a benzhydryl radical skeleton substituted with various saturated groups which do not formally extend the conjugated length of the system. A sequence of compounds with this property has been reported in an earlier paper (1), herein referred to as I, which describes the electron paramagnetic resonance (e.p.r.) spectra of a number of substituted diphenylmethyl hydrocarbon radicals and the spectra of the ketyls of the analagously substituted benzophenone derivatives. Strong similarities were observed between the proton hyperfine coupling constants of corresponding members of these two classes of compounds. Nuclear hyperfine structure for the counterion was found in a number of the ketyl spectra, suggesting that tight ion pairs are formed in these compounds. This observation, along with the similarities in the proton hyperfine structure, leads to the conclusion that the ketyls might profitably be studied as perturbed benzhydryl radicals, rather than as ketonic anion radicals perturbed by the electrostatic interaction with the counterion (2). Thus one basic model may be used to describe both types of radicals.

The sequence of compounds studied in I shows that substitutions at different positions in the rings produce markedly different effects. Whereas saturated para substituents such as methyl or methoxyl do not greatly change the coupling constants of the other ring protons, ortho substituents have the effect of reducing considerably the net spin density in the rings. The latter conclusion may be deduced from the hyperfine splittings by the well-known McConnell relationship (3) for ring protons, or that of McLachlan (4) for methyl groups. These relationships state that the coupling constants are proportional to the spin densities at the site of substitution, so that $a_i(\mathrm{H, or\ Me}) = \rho_i Q(\mathrm{H, or\ Me})$ where Q is a constant. According to the results of I, the value of Q for methyl protons is only slightly larger than its value for ring protons ($\sim$ 25 Oe).

The reason for the ortho substitution effect may be most readily seen from Fig. 1*a*. Introduction of bulky ortho groups at the 3, 3′, 7, and 7′ positions force internal rotation about the 1–2 extracyclic bonds. In this way the ortho groups can avoid one another and reduce the non-bonding repulsive forces between them. This loss in planarity occurs at the expense of the delocalization energy of the conjugated system, since the internal rotation

[1]*Present address: Department of Chemistry, Cambridge University, Cambridge, England.*

is accompanied by a decrease in exchange interaction (or overlap) between the central atom 1, and the ring carbon atoms at 2 and 2′. Thus the eventual ground state configuration will be that in which further rotation of the rings results in a loss of resonance energy greater than the gain in terms of the steric repulsion energy. The most likely configuration need not be the symmetrical rotomer where each ring has rotated through equal and opposite angles; it may even be a configuration in which one ring is perpendicular to the plane defined by the central carbon atom and the atoms of other rings (5). An acceptable model of the system would have to discriminate between these two extreme possibilities. The bulk of the evidence favors the former alternative (6), and the text immediately following will be based on this premise.



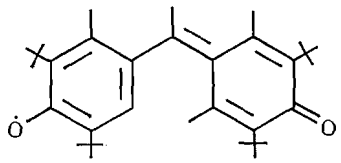


FIG. 1.

As may be seen from Fig. 1, ortho substituents at 3 and 3′ will not be particularly effective in introducing steric repulsion, unless there is also some fairly bulky substituent on the carbon atom at 1. The inner and outer groups are not related in the symmetry group (C_2) of the molecule. The 'outer' groups at 3 and 3′ are considerably further apart than the 'inner' group substituents at 7 and 7′ so that on complete ortho methylation of the benzhydryl skeleton, the protons of the inner methyl groups lie very close to the carbon atoms of the opposite rings, whereas the 'outer' methyl group protons point out and away from the center of the molecule. In the 20-odd radicals studied in I, a variety of ortho substituents was used as the hindering groups, but yielded the same coupling constants for both inner and outer groups. The equivalence of these groups seems even more unusual when it is considered in relation to the behavior of certain other radicals of different molecular structure. A number of species is known in which hyperfine structure is obtained from nuclei that are separated from the centers of electron spin density by a number of σ bonds (7, 8). The nuclear-electronic interactions appear to depend more critically upon the distance and position of the nucleus (or of the orientation of the σ bond involving the nucleus) relative to the orbital containing the unpaired electron spin. The peculiarities of the σ-bond system joining the centers do not seem to be at all important. Whereas the inner groups of a benzhydryl system are in a position to interact with the electron spin density in the π orbitals of the opposite ring, the outer groups are not.

The similarity between inner and outer groups is not restricted to studies involving the benzhydryl radicals. A similar situation is found in the nuclear magnetic resonance (n.m.r.) spectrum of the diphenylmethyl carbanion. In this case the inner and outer protons exhibit identical chemical shifts (9), although it seems unlikely that the inner protons should lie in a region which would give, in effect, a zero ring current contribution from the opposite phenyl ring (10).

There are, however, a few instances in which an apparent difference between inner and outer groups is known to be measurable. One is found in the recent work of Hyde and Maki (11) who have obtained an electron-nuclear double resonance (ENDOR) signal from the ortho ring protons of Coppinger's radical.

The signal is a doublet with a separation of about 0.06 Oe. This difference may be presumed to be between inner and outer ortho protons, rather than a difference arising from a lack of symmetry between the two rings. The resolution of the spectrum of dimesitylmethyl radical in I was only slightly larger than this value (0.08 Oe), yet no detectable broadening or splitting could be observed for the ortho lines. On the basis of the foregoing considerations, a much larger splitting than 0.06 Oe might have been expected for the latter compound if for no other reason than that the protons are much closer to the opposite ring than they are in Coppinger's radical.

Differences between the inner and outer proton hyperfine coupling constants are also observed in the electron spin resonance (e.s.r.) spectra of ortho-bridged benzophenone ketyl compounds. These are exemplified by the ketyl of xanthone which has an oxygen atom bridge between the two rings. The proton hyperfine spectrum may be explained in terms of a quartet of triplets so that the inner and outer protons are not equivalent in this compound. The observed difference probably does not result from the hetero atom substitution, since the proton coupling constants are not sensibly dependent upon the particular bridging group; the ketyl of thioxanthone has hyperfine coupling constants similar to those of the xanthone ketyl (12). It is apparent that the dichotomy with regard to inner and outer ortho group splittings persists when inner and outer meta protons are considered. It is hoped that some of the diversity in behavior may be explained by a model which will be discussed in the following sections.

THE BENZHYDRYL MODEL

For magnetic nuclei of the same molecule to exhibit the same hyperfine coupling constants, it is necessary that the totality of interactions with the unpaired electron distribution be identical for each nucleus. This may result simply from the requirements of molecular symmetry, so that the nuclei are situated in identical potential fields. Equivalence can also be observed under conditions where the nuclei are exchanged over non-equivalent positions in space. As long as the rate of exchange is rapid enough to average out completely the differences in potential energy during the measurement, the nuclei will appear to be equivalent. One example of such an averaging process is exhibited by the methyl protons studied in I. Although the protons interact instantaneously with the unpaired spin in an unsymmetrical way, rotation about the symmetry axis of these methyl groups is rapid enough to average the differences. There appear to be three equivalent

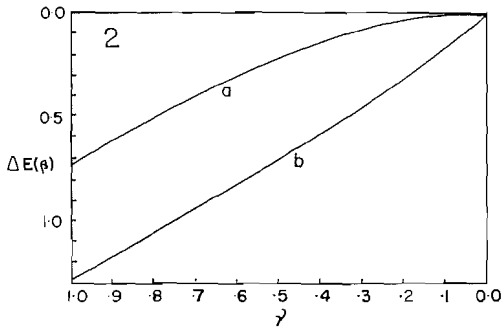
protons. The motion persists at very low temperatures (13) and in sterically unfavorable environments (1). The observed similarity between the coupling constants of inner and outer groups in the benzhydryl system would result from a similar process provided there were some mechanism by which these inner and outer groups could exchange positions. The situation would be considerably more complicated in this case, since such a process requires the breaking of π bonds, which for most conjugated systems involves very high activation energies. One would normally expect a very low exchange rate for such a process. However, the benzhydryl system is somewhat unique in that it is composed of two highly conjugated systems coupled together; if by some means the delocalization energy which is lost in one half of the molecule is gained by the other half during a distortion of the nuclear framework, then a considerable number of configurations may be possible in which there is little change in the total π-electron energy of the molecule. Consider the symmetrical isomer of Fig. 1*a*. The ortho groups are held apart by repulsive forces, and the same dihedral angle, θ, exists between the normal to each ring and the axis of the $2p\pi$ orbital of the central carbon atom. The molecule would have a resonance energy dependent to some extent upon this dihedral angle. Suppose now that the left-hand ring were to assume a coplanar configuration with the central carbon atom. The dihedral angle (θ_1) for the 1–2 bond would reduce to zero. The ortho groups of the second ring would be forced further out of the plane by steric forces, and the dihedral angle (θ_2) for the 1–2′ bond would approach the maximum value of 90°, as depicted in Fig. 1*b*. The system would now have the resonance energy of a planar benzyl radical plus that of an isolated benzene ring. If now the rotation were to be continued in the same direction, so that the group at 7, originally below the plane, were now to lie above the plane, then a symmetrical isomer would again be obtained as in Fig. 1*c*. The difference between the rotomers of Fig. 1*a* and Fig. 1*c* is that the inner and outer groups of the right-hand ring have exchanged positions. Further rotation in the same direction will result in the exchange of the inner and outer groups of the left-hand ring. This is shown in Figs. 1*d* and 1*e*.

The inner and outer groups at both ortho and meta positions are exchanged by this mechanism, and the question immediately arises concerning the amount of energy which must be expended in order to effect the exchange. It is easy to see that at least part of the delocalization energy lost to the out-of-plane ring may be compensated for by the increased resonance of the highly stable benzyl residue. The question then becomes one of determining the resonance energies for the systems benzyl plus benzene, and for benzhydryl. This is equivalent to finding the relationship between these energies and the dihedral angle θ, or equivalently the exchange energy of the 1–2 and 1–2′ π-electron bonds. Other interactions between the electrons in different rings may be neglected, as may the interactions of electrons on non-neighboring atoms. Values for the delocalization energy may then be obtained by simple valence bond (VB) or Huckel molecular orbital (HMO) techniques. The calculations are simple and straightforward, and one may set up appropriate secular equations in which the 1–2 and 1–2′ interactions are expressed in terms of the nearest neighbor interactions. Thus for the HMO treatment, $\beta_{12} = \gamma\beta_{\text{ring}}$, while for VB determinations, $\alpha_{12} = \gamma\alpha_{\text{ring}}$; β and α have their usual meaning (14). The parameter γ will have different meanings in the two methods, but will depend upon the 1–2 bond distance as well as upon the dihedral angle θ. In either case,

$$\gamma = f(r)g(\theta).$$



Although $g(\theta)$ may be taken to be $\cos\theta$ in a HMO treatment, it will be $\cos^2\theta$ in the VB method. The function $f(r)$ is a little more complicated, although theoretical estimates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

could be used if the bond lengths were known for these radical systems. However, both the HMO and VB treatments suggest that since the mobile bond order (or double bond character) is somewhat less than for normal benzene ring bonds, the 1–2 bond is somewhat elongated in these systems. Thus all that can be said is that $1 > f(r) > 0$. As will be seen an estimate of this parameter may be made in certain cases.

RESULTS

The results of HMO calculations appear in Fig. 2, and those of the VB calculations in Fig. 3. The π-electron delocalization energies are shown as functions of γ for both the symmetrical rotomer of the benzhydryl radical and the unsymmetrical rotomer corresponding to ω-phenyl benzyl radical. The latter is the transition state for the exchange process which switches the inner and outer groups of the benzhydryl system. The desired information is the low energy transition states available to a given symmetrical radical. Suppose this symmetrical molecule has inner ortho substituents of a size which requires the dihedral angles θ_1 and θ_2, at the 1–2 and 1–2′ bonds respectively, to accommodate their combined steric volumes. A certain bond length will also be pertinent to the given molecule, so that $\gamma_1 = f(r_1)\cos^2\theta_1 = f(r_2)\cos^2\theta_2 = \gamma_2$ or $\gamma_1 = \gamma_2$. This is denoted by γ in Fig. 3, and is the same for both extracyclic bonds. If now the rings were allowed to rotate as suggested in Fig. 1, the value of γ for the benzyl part of the system would increase and the γ value for the other bond would decrease. In the transition state, the bond extracyclic to the perpendicular ring would have a value $\gamma = 0$, by virtue of the cosine dependency. For the benzyl fragment, $\gamma = f(r)\cos^2\theta = \gamma' = f(r)$. γ' has also been indicated in Fig. 3. It pertains to the transition state whose energy is the same as that of symmetrical form, and therefore corresponds to a pure rotational isomer involving no energy of activation. The same symmetrical radical could exchange through a higher

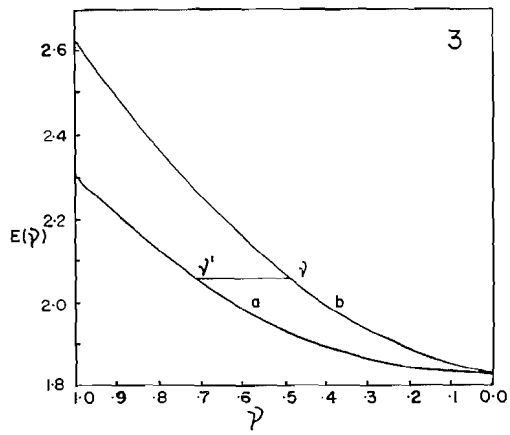


FIG. 2. Plot of $\Delta E(\beta)$ versus γ from HMO calculation.
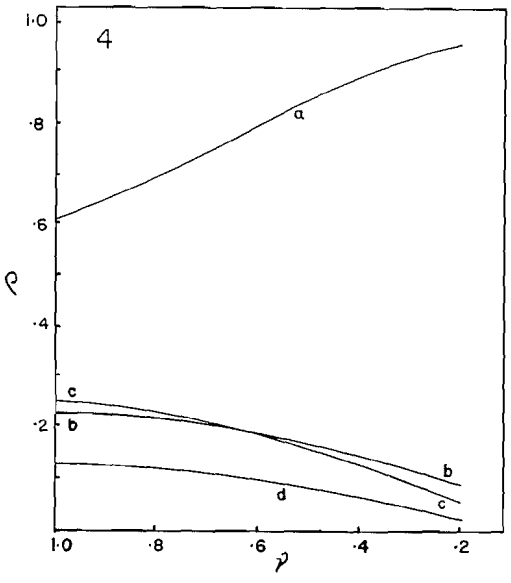
FIG. 3. Plot of $E(\gamma)$ versus γ from VB calculation.



energy transition state (i.e. a benzyl fragment with a smaller γ') but this would require the addition of energy to the system. It is also possible that the bond distance might shorten during the rotation, so that a given symmetrical radical could proceed through any of the transition states with a larger value of γ'. In this case the energy required to compress the σ bond must be supplied. All things considered, the range of γ' values which must be taken into account is probably fairly small. It may readily be seen that

$\gamma/\gamma' = \cos^2\theta$, where θ is the equilibrium angle dictated by the size of the ortho group. Similar considerations apply to the molecular orbital (MO) results in Fig. 2, but in this case $\gamma/\gamma' \approx \cos\theta$. From the same figure it may be seen that any symmetrical radical, with $f(r) \approx 1$, and a dihedral angle $\theta \gtrsim 60°$, may pass to the other symmetrical isomers with no energy of activation. By the same token, a planar radical ($\gamma = 1.0$) would require an energy of activation of 0.6 in units of β, or about 46.3 kcal/mole. As is apparent in both Figs. 2 and 3, the benzhydryl system is more stable than the corresponding benzyl fragment for any specific value of γ.

While neither of the above methods can lay any claim to great accuracy, it is encouraging that they predict similar trends. The variety of possible transition states is predicted to be smaller by the VB method.

The calculations may be extended to compute the spin densities for the symmetrical benzhydryl radicals. The VB results are shown in Fig. 4. They predict negative spin densities at the meta and bridgehead positions, and for the planar radicals ($\gamma = 1.0$), the ortho spin density is positive and larger than that at the para position. As γ decreases, the ortho densities decrease more rapidly than the para densities, with the result that they are the same at $\gamma = 0.65$. Thereafter the para position has the larger spin density. This is the region which applies to most of the radicals of I. The wave functions become badly behaved at about $\gamma = 0.1$, as has been reported by McLachlan (15). This probably results from the rather stringent constraints used in the VB treatment, but when many effects are collapsed into a single parameter, it is not surprising that peculiar effects should be predicted under certain circumstances. The fact remains that the trends predicted for the spin densities are indeed observed, and the range of applicability apparently goes from the planar ketyl radicals to the buttressed ortho methyl derivatives of the benzhydryl radicals.

The HMO predictions of spin densities as obtained by the McLachlan method (16) are a little less successful, at least in a system using only two adjustable parameters. The ortho spin densities are uniformly predicted to be greater than the para densities at all

values of γ. On the other hand, the general magnitudes are predicted fairly well if the value of the SCF mixing parameter, λ, is chosen correctly. The same cannot be said for the VB treatment. For instance for the ortho-methylated benzhydryl radicals, the observed 16 Oe splitting for the lone central proton corresponds to a spin density of about 0.64 and a γ value of ~ 0.9, as estimated from Fig. 4. For the same molecule a para proton splitting of 3.3 Oe is obtained. This corresponds to a spin density of ~ 0.13 and is supposed to occur at $\gamma = 0.3$. Clearly γ is a single-valued parameter, so that the results are inconsistent. It is likely that the poor quantitative agreement results from the neglect of many high energy long bond and ionic structures in the formalism used. According to the results of Simonetta (17) for the benzene molecule, these latter may amount to some 20% of the total. The wave function may be written in the form $\psi = a\psi(\text{covalent}) + b\psi(\text{ionic})$. If the covalent and ionic functions are considered to be orthogonal, then $a^2 + b^2 = 1$. The effect of the ionic structures is to 'steal' spin density from the covalent structures and to redistribute it more or less equally throughout the molecule. Thus the high spin density site at the central carbon atom will be decreased by a^2. This loss will be added to all of the sites of spin density (i.e. about $b^2/13$ at each carbon atom). The additive term is quite small, but would be important at the meta and bridgehead positions of negative spin density. At the other sites, this small term may be neglected, and the constant scaling factor may be eliminated by comparing the ratios of the computed spin densities. Thus ρ_p/ρ_o may be compared to the experimentally obtained ratio of the splitting constants a_p/a_o, and should lead to a more realistic value of γ. The use of such a ratio has the added advantage that it is independent of the particular value of Q which might pertain to the group under consideration as long as the substituents are the same at both positions. The computed ratios of spin density appear as a function of γ in Fig. 5. Four regions are marked off on this curve, and these correspond to the range of values of the ratios of the coupling constants a_p/a_o obtained in I for the various ketyls of xanthone, benzophenone, dimesityl ketone, and finally for the hydrocarbon, dimesitylmethyl. The ratio a_p/a_o for the calcium ketyl of xanthone was found to be 1.04, as indicated in Fig. 5 (12). The ketyl of xanthone is approximately planar because of the ortho oxygen bridge. The value of γ given from the above ratio is 0.5. Since the dihedral angle in this molecule is approximately zero, then $\gamma = f(r) = 0.5$. This value corresponds to rather a long bond, since the exchange integral is reduced to about 50% of that found in the phenyl rings. With the other derivatives, further elongation of this bond might be expected to occur as rotation about the 1–2 bond further weakens the π linkage. Thus $f(r) = 0.5$ represents a maximum value, and, no further information being available, must be used for the remaining compounds. It is easily found from Fig. 5 that $\cos^2\theta$ is therefore 0.5, 0.30, and 0.34 for the ketyls of benzophenone, dimesityl ketone, and dimesitylmethyl respectively. These values correspond to maximum dihedral angles of 45°, 58°, and 57° for these compounds. The distance between ortho protons at the 45° configuration is somewhat greater than the van der Waals diameter for hydrogen atoms (18), suggesting that $f(r) < 0.5$. On the other hand the distance between the centers of the carbon atoms in the 60° configuration is somewhat less than twice the CH bond lengths plus the van der Waals diameter of hydrogen. It appears the e.s.r. spectroscopy is not a very good method for predicting the constants of molecular geometry, at least in systems as complicated as the benzhydryl radicals.

DISCUSSION

The physical observations which have been made for the benzhydryl systems become more understandable on the basis of a model which allows rotation about the extracyclic bonds of these compounds. In one respect the benzhydryl system is quite different from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the other arylmethyl systems. In triphenylmethyl, for instance, all six ortho protons are in positions allowing steric interactions. In order for this molecule to execute an internal rotation similar to that presently being discussed, it would be necessary for two of the rings to assume perpendicular configurations simultaneously. This is a much less favorable proposition from the energetic point of view, but there appears to be a small range of equilibrium angles at large distortions where such would be possible. Because of the high symmetry of this molecule there are no 'inner' and 'outer' protons as such, and one could not use the present method to detect such a process. On the other hand, with the benzyl-type radicals such as the ketyls of benzaldehyde, there exists no axis of symmetry in the molecule, so that the pairs of ortho protons or meta protons are not equivalent. In this case, the rotation of the extracyclic ketyl group must involve the rupture of a π bond. There is no compensation for the loss in delocalization energy, and the process must then be one of high energy and low probability. This is reflected in the observations of Steinberger and Fraenkel (19) regarding the ketyl anions of this compound. For the free ion, the presence of a localized negative charge on the oxygen atom changes the electron distribution in the nearby ring, and hence the spin densities. Thus the two ortho splitting constants are different. Apparently when the ion associates, this coulombic interaction vanishes, and a second species is obtained which corresponds more closely to the benzyl-type systems mentioned here. The pseudosymmetry in this case results not from rotational averaging, but from the lack of a strong unsymmetrical potential field.

An attempt may now be made to explain the differences found between inner and outer groups in the xanthone ketyls and in Coppinger's radical. In the case of the xanthone ketyls, the two rings cannot rotate. The oxygen atom which bridges two of the ortho positions constrains the molecule to a fixed configuration. Coppinger's radical on the other hand exists largely in one of the two equivalent resonant forms illustrated in the Introduction; the lone proton splitting in this compound is only about 6 Oe as compared with the 15–16 Oe splitting found for the other diphenylmethyl derivatives. The quinoidal structure implies that the 1–2 bonds in this compound are shorter, being perhaps nearly the same as those in the aromatic rings. As a result the stable configuration is considerably 'more planar' than the remaining benzhydryl compounds, suggesting that a considerable amount of energy is required to effect the counter-rotation of the rings. The value of $f(r) \approx 0.5$ obtained from the xanthyl ketyls would appear to support this contention. If the value of $f(r) = 1$, and the same angular dependence as found for benzophenone, is taken, then with the curves of Fig. 2 one finds that an activation energy of $\sim 0.25\ \beta$ is required (i.e. ~ 20 kcal/mole).

The general trends observed for the compounds studied in I appear to fit in well with the present model. When there are no restraining influences such as interannular bridges, or exceptionally stable quinoidal ground states, the molecules apparently undergo a low energy libation which results in the appearance of a pseudosymmetry for the substituent pairs in each phenyl ring. For the ketyls, where there is a bulky oxygen-counterion substituent on the central position, the internal rotation may be hampered in that this group must also participate in the concerted motion. This may account in part for the relatively broad spectral lines of these compounds compared to the hydrocarbon species which have no large substituent at the central atom.

The ratios a_p/a_o compare very well to the ρ_p/ρ_o determined from the VB theory. The compounds lie in positions which are much as might be expected. The larger the hindering groups, the larger is the observed ratio. The insensitivity of the lone proton and ^{13}C splittings to buttressing of the ortho groups, which was mentioned in I, is also understandable. The spin density at carbon atom 1, upon which these splittings depend,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

changes relatively little as γ varies in the region of small γ. On the other hand, the spin densities at the ring sites are very sensitive to the γ value, as may be seen from a comparison of Figs. 4 and 5.

Although better quantitative agreement might have been hoped for, it is apparent that much more sophisticated computational techniques will be required. These appear to be prohibitively difficult for the present system of compounds. However, one cannot deny the excellence of the qualitative agreement.

ACKNOWLEDGMENTS

The authors would like to thank Dr. A. H. Reddoch for a preprint of his paper, and Mr. C. R. Kepford of this laboratory for his unstinting help. We would also like to recognize the enormous assistance that Mr. M. Williams of the University Computing Centre has given. STUDIES OF METAL COMPLEXES OF PYRIDINE DERIVATIVES

THE EFFECTS OF COORDINATION UPON INFRARED INTENSITY OF THE FUNCTIONAL GROUP IN β-CYANOPYRIDINE

D. G. Brewer and Patrick T. T. Wong

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received November 25, 1965

ABSTRACT

The infrared intensity of the C≡N group in β-cyanopyridine complexes with some first-row transition metal ions (Zn(II), Cu(II), Ni(II), Co(II), Fe(II), and Mn(II)) in aqueous solution has been measured. The coordination between the nitrogen atom on the pyridine ring and these metal ions exerts a marked change in the magnitude of the band intensity of the functional group. This can be interpreted in terms of a simple molecular orbital model and the relative magnitudes of σ-bonding and π-bonding involved in the complexes. A "coordination constant" is introduced for this system, and a linear correlation between these constants and the C≡N band intensities of the metal complexes is obtained from both the experimental data and theoretical considerations.

INTRODUCTION

The intensities of the infrared absorption band associated with the C≡N functional group vibration in aliphatic and aromatic cyanides have been studied to a considerable extent (1–5). In particular, studies of the C≡N band infrared intensities in a number of substituted benzonitriles showed that substituents on the ring exerted a pronounced effect on the magnitude of the functional group intensity; electron-releasing substituents enhanced the functional group intensity, whereas electron-attracting substituents lowered the intensity.

The correlation of the intensity variations in substituted benzonitriles with the so-called "substitution constants" (6) has also been studied. The results suggest that there is an essentially linear relation between the logarithm of the intensity and the substitution constant for both meta- and para-substituted compounds in various solvents.

In the present investigation, the intensities of the C≡N band in heterocyclic cyanides were studied. β-Cyanopyridine was chosen as a starting point for these studies. An attempt has been made to determine the effects of coordination between the nitrogen atom on the pyridine ring and some first-row transition metal ions on the C≡N band intensity. A simple molecular orbital model is presented; this model is used to give a quantitative treatment of the data for the system, for which purpose a "coordination constant" is introduced.

EXPERIMENTAL

Materials

β-Cyanopyridine, supplied by the L. Light and Co. Ltd., was recrystallized three times from ether – petroleum ether (60–68°) mixture.

Pyridine, reagent grade supplied by British Drug Houses (Canada) Ltd., was dried over potash overnight and then redistilled twice.

3-Pyridinol, supplied by Aldrich Chemical Co. Inc., was recrystallized twice in absolute alcohol and then purified by sublimation.

Most of the transition metal salts were nitrates supplied by the G. Frederick Smith Chem. Co., and were recrystallized from water several times.

Deuterium oxide was obtained from Merck Sharp and Dohme of Canada Ltd., and had an assay of 99.7% D_2O.

Carbonate-free potassium hydroxide solution for the pH titration was prepared by the method of Schwarzenbach (7).

Infrared Absorption Spectra

In the present study a Perkin-Elmer model 21 spectrometer was employed. The spectra were determined in aqueous solution with matched calcium fluoride cells (platinum foil spacers, 0.025 mm).

For all the intensity measurements, the slit width was held at a constant value to eliminate the error caused by the variations of slit width in each measurement. The resolution knob was set at 23.

The solution in the reference cell had a composition equal to that in the sample cell except for a certain amount of pyridine exchanged for β-cyanopyridine in the latter. In this way an almost complete compensation for the water absorption was obtained in the spectral region under investigation, 2 000 – 2 500 cm^{-1}.

The intensity of the C≡N band was estimated according to Ramsay's method (8). The intensity is given by

$$A = (1/CL)\ (1/2)\ 2.303 \Delta V_{1/2} \log\ (T_0/T)_{max}$$

where $\Delta V_{1/2}$ is the half-intensity width of the C≡N band, $\log\ (T_0/T)_{max}$ is the observed absorbance at band maximum, C is the total concentration of the ligand expressed in moles per liter of solution, and L is the cell length in cm.

All measurements for C≡N band intensities of β-cyanopyridine complexes were carried out using a 2:1 ratio for metal ion and ligand concentrations.[1]

The intensities of C≡N functional group, measured for β-cyanopyridine in the presence and absence of the first-row transition metal ions in the solution, are listed in Table I.

TABLE I

C≡N band intensities of β-cyanopyridine and its metal complexes

	A (10^3 $mole^{-1}$ l cm^{-2})	$A^{1/2}$ (10 $mole^{-1}$ l cm^{-2})
Ligand	7.57	8.70
Mn(II) complex	7.40	8.60
Ni(II) complex	6.07	7.79
Co(II) complex	5.67	7.53
Zn(II) complex	5.16	7.19
Cu(II) complex	3.54	5.95
Fe(II) complex	7.93	8.90

pH Titration

A Beckman model GS meter with glass and calomel electrodes was used to record the pH. The electrode system of the pH meter was calibrated against standard buffers supplied by British Drug Houses (Canada) Ltd.

Titrations were carried out in a 300 ml Berizeleus beaker closed by a rubber stopper with holes to accommodate a microburet, nitrogen inlet and outlet tubes, and the electrodes. The running nitrogen was washed beforehand by passing through Fieser's Solution, sodium hydroxide, and concentrated sulfuric acid.

The ionic strength was maintained constant by using 0.1 N KNO_3 as a supporting electrolyte. The concentration of 3-pyridinol used was 10^{-3} M and the concentration ratio of ligand to metal ion was 5:1. All measurements were made at a temperature of 25.0 °C in a thermostated bath.

Both the acid dissociation constants and the coordination constants of the metal complexes are shown in Table II.

TABLE II

Acid dissociation constants and coordination constants of 3-pyridinol and its metal complexes in aqueous solution at 25 °C

	k_{HA}	$\alpha \equiv \log k_{HA(ML)} - \log k_{HA(L)}$
Ligand	3.52×10^{-9}	0.00
Mn(II) complex	3.79×10^{-9}	0.03
Ni(II) complex	4.16×10^{-9}	0.07
Co(II) complex	4.33×10^{-9}	0.09
Zn(II) complex	4.50×10^{-9}	0.11
Cu(II) complex	5.49×10^{-9}	0.19

[1]*A study of the* C—N *and* C=N *band intensities of the pyridine ring in* D_2O *solution showed that both band intensities increased with increasing metal ion concentration and their intensities became constant when metal ion concentrations reached twice that of the ligand concentration.*

RESULTS AND DISCUSSION

Infrared Intensities

The C≡N band infrared intensities of β-cyanopyridine and its complexes of the first-row transition metal ions, Zn(II), Cu(II), Ni(II), Co(II), Fe(II), and Mn(II), were determined. The data in Table I show that the C≡N band intensity of β-cyanopyridine is enhanced when it forms a complex with ferrous ion, whereas the C≡N band intensities are lowered when it forms complexes with other first-row transition metal ions, Zn(II), Cu(II), Ni(II), Co(II), and Mn(II). The data also indicate that coordination between β-cyanopyridine and different metal ions gives different C≡N band intensities, and the relative magnitude of the C≡N band intensities follows the order:

$$\text{Zn(II)} > \text{Cu(II)} < \text{Co(II)} < \text{Ni(II)} < \text{Mn(II)} < \text{Ligand} < \text{Fe(II)}.$$

Comparing with Irving's order of stability for the complexes of these metal ions (9), the positions of Co(II) and Fe(II) are unexpected.

These observed results can be understood by a simple molecular orbital approach. For this purpose the energy levels of this system are required. The delocalized molecular orbital functions of pyridine can be written as (10):

$$\Psi_1 = 0.4208(\varphi_1 + \varphi_5) + 0.3540(\varphi_2 + \varphi_4) + 0.3219\varphi_3 + 0.5400\varphi_6$$

$$\Psi_2 = 0.1815(\varphi_1 + \varphi_5) - 0.3610(\varphi_2 + \varphi_4) - 0.6113\varphi_3 + 0.5475\varphi_6$$

$$\Psi_3 = 0.4970(\varphi_1 + \varphi_5) + 0.5030(\varphi_2 - \varphi_4)$$

$$\Psi_4 = 0.3383(\varphi_1 + \varphi_5) + 0.2728(\varphi_2 - \varphi_4) - 0.5893\varphi_3 - 0.5244\varphi_6$$

$$\Psi_5 = 0.5030(\varphi_1 + \varphi_5) - 0.4970(\varphi_2 - \varphi_4)$$

$$\Psi_6 = 0.4189(\varphi_1 + \varphi_5) - 0.4156(\varphi_2 + \varphi_4) + 0.4188\varphi_3 - 0.3662\varphi_6$$

where the φ's are Slater atomic orbitals. The energy level diagram of both pyridine and the C≡N group is shown in Fig. 1, in which the energies of the highest occupied orbitals were taken as equal to the first ionization potentials (10–18), and the energies of the lowest vacant orbitals were estimated approximately from a combination of the highest occupied levels and the experimental data of $\pi \rightarrow \pi^*$ or $n \rightarrow \pi^*$ absorption spectra (5, 19).

The interaction between the delocalized π-orbitals in the ring and the localized π-orbitals in the C≡N group presumably involves the highest occupied molecular orbital in the ring, H_{Py}, and the lowest vacant molecular orbital in the C≡N group, V_{CN}, rather than the orbitals H_{CN} and V_{Py}, since the energy difference between the former two is

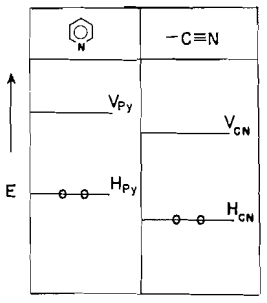

FIG. 1. The energy level diagram of pyridine and cyanide system.

much smaller than that of the latter two. Also, H_{CN} of the C≡N group is a non-bonding orbital predominantly localized on the nitrogen atom and is thus far from the pyridine ring. The interaction between the V_{CN} and H_{Py} orbitals gives two new orbitals which may be considered as a linear combination, $\Phi = a\phi_P \pm b\phi_{CN}$, and results in a migration of electrons from the pyridine ring towards the C≡N group. In addition, an interaction between V_{Py} and V_{CN} orbitals is also expected, since they are very close in energy and the interaction is symmetry allowed.

By means of this simple molecular orbital model, the effect of coordination on the C≡N band intensities of β-cyanopyridine may be interpreted. The coordination between pyridine derivatives and metal ions involves both σ-bonding and π-bonding contributions (20–23), which produce opposite effects on the C≡N band intensity; viz. σ-bonding lowers the C≡N band intensity, whereas π-bonding enhances the C≡N band intensity. The σ-bond in the metal complexes is formed by withdrawing the non-bonding electron pair from the pyridine ring to the metal ion. This lowers the H_{Py} energy level and the energy difference between H_{Py} and V_{CN} increases. Therefore the magnitude of the interaction between H_{Py} and V_{CN} is decreased, as is the electron density in $\Phi = a\phi_P + b\phi_{CN}$, and the dipole moment of the C≡N group is lowered. The π-bond is formed by the back donation of d electrons to the V_{Py} orbital. The interaction between V_{Py} and V_{CN} will also cause an electronic migration from the ring to the C≡N group and hence the dipole moment of the C≡N group is increased; thus the C≡N band intensity is increased. Moreover, the H_{Py} energy level is raised by the π-bonding, resulting in an increased interaction between H_{Py} and V_{CN}, and consequently an enhanced C≡N band intensity.

In complexes of pyridine and its derivatives, the relative magnitude of σ-bonding was deduced by F. A. Cotton to be much higher than that of π-bonding (20), and therefore the net effect of the σ-bonding and π-bonding in β-cyanopyridine complexes with Zn(II), Cu(II), Ni(II), Co(II), and Mn(II) is to lower the C≡N band intensity.

However, the intensity in the Fe(II) β-cyanopyridine complex was found to be higher than that of the free ligand. It seems probable that a polynuclear complex is formed in this system. A series of solutions with a constant concentration of the ligand and an increasing concentration of Fe(II) ion was prepared. Deuterium oxide (D_2O) was used for the preparation of all these solutions to avoid the interfering absorption bands of the H_2O molecule in the C—N, C=N region of the pyridine ring, 1 350 – 1 700 cm^{-1}. At equilibrium, the intensities of both the C—N and C=N bands of the pyridine ring should be increased by increasing the Fe(II) concentration (24, 25). The opposite results obtained in this laboratory suggest the presence of a polynuclear complex in this system.

In this polynuclear complex, Fe(II) ion could coordinate not only with the nitrogen atom on the pyridine ring, but also with the nitrogen atom on the nitrile group. This latter bond can be interpreted as resulting from the formation of a σ-molecular orbital between the occupied non-bonding orbital on the nitrogen atom and the vacant Fe atomic orbitals (26). This interaction lowers the energies of the π-orbitals in the C≡N group, and results in decreasing the energy difference between the V_{CN} orbital and the H_{Py} orbital and thus in increasing the interaction between these two orbitals. Therefore the C≡N band intensity of this system should be much higher.

The relative magnitude of the C≡N group infrared intensities in the β-cyanopyridine complexes studied were observed to be as follows:

$$Cu(II) < Zn(II) < Co(II) < Ni(II) < Mn(II).$$

According to earlier work (27), the relative magnitude of a σ-bond in a particular complex for the first-row transition metals can be estimated from the second ionization potentials of the metals. An estimate of the relative magnitude of π-bond in a particular complex for the first-row transition metals can be obtained from the first ionization potential of these metals. The lower the first ionization potential of a metal, the higher the relative magnitude of a π-bond in its metal complex. This suggestion is based on Pauling's electroneutrality rule of coordination (28); that is, when a metal ion forms a complex, its positive charge will be almost neutralized by the donation of electrons from the surrounding ligands. Therefore the "back donation" can be considered to have occurred from a neutral metal, and the magnitude of this back donation must be related to the first ionization potential. Moreover, this suggestion is supported by a comparison of the stabilities of some first-row transition metal complexes of the two classes of ligands (20) with the first and second ionization potentials (see Table III).

The first class of ligands, such as ammonia, ethylenediamine, etc., can act only as a donor in complex formation and thus only a σ-bond is present in their metal complexes. The second class of ligands, such as pyridine and its derivatives, cyanide, etc., coordinate with metal ions through both σ-bonding and π-bonding.

The second ionization potentials of the first-row transition metals in Table III show the relative magnitude of σ-bond in a particular complex is

$$\text{Cu(II)} > \text{Ni(II)} > \text{Zn(II)} > \text{Co(II)} > \text{Fe(II)} > \text{Mn(II)}.$$

Therefore the relative stability of the first-class complexes of these metal ions should follow the same order. The stability constants listed in Table III show this same result.

The first and second ionization potential data in Table III predict that the σ-bond magnitude in Zn(II) complexes with class two ligands is close to that in Co(II) complexes, whereas the π-bond magnitude in the same Zn(II) complexes is much lower than that in Co(II) complexes. Therefore the second class complexes of Co(II) should be more stable than those of Zn(II) and the stability of the first class complexes of Co(II) should be close to, or a little lower than, those of Zn(II). Similarly we may predict that the stability of Fe(II) complexes of both the first- and second-class ligands are lower than those of Co(II) complexes. Also, the Fe(II) complexes of the first-class ligands should be more stable than the corresponding Mn(II) complexes, whereas those of second-class ligands must be close to or a little lower in stability than those of the Mn(II) complexes. The first ionization potentials of Cu, Ni, and Mn are very similar, but the second ionization potential of Cu is much higher than those of Ni and Mn, and that of Ni is in turn much higher than that of Mn. Thus, we may predict that the relative stabilities of both the first- and second-class complexes of these three metal ions are mainly determined by the relative magnitude of σ-bonding in their complexes, and follow the order:

$$\text{Cu(II)} > \text{Ni(II)} > \text{Mn(II)}.$$

The stability constants of the first- and second-class complexes listed in Table III support the correlation between the relative magnitude of π-bonding in a particular complex of the first-row transition metals and the first ionization potentials of these metals.

From these studies we may conclude that the relative magnitudes of σ-bonding and π-bonding in β-cyanopyridine complexes for these first-row transition metal ions follow

TABLE III

The ionization potentials of the first-row transition metals (ref. 32) and the stability constants of some first- and second-class metal complexes (ref. 33)

Metals	First ionization potential (V)	Second ionization potential (V)	First-class ligands (σ)			Second-class ligands (σ, π)		
			Ammonia	Ethylenediamine		Pyridine	8-Hydroxyquinoline	
			log K_1	Log K_1	Log β_2	log K_1	Log K_1	Log β_2
Cu(II)	7.723	20.20	4.15	10.55	19.60	2.52	13.49	26.22
Ni(II)	7.633	18.13	2.79	7.66	14.06	1.78	11.44	21.38
Zn(II)	9.391	17.89	2.37	—	11.07	0.95	9.95	18.86
Co(II)	7.860	17.30	2.11	5.86	10.66	1.14	10.55	19.66
Fe(II)	7.896	16.50	1.40	4.28	7.53	0.71	9.83*	10.84*
Mn(II)	7.432	15.70	0.80	2.73	4.79	—	10.30*	20.40*

*In 75% dioxane–water, i.e., under conditions different from those for the other 8-hydroxyquinoline metal complexes.

the order:

σ-bond, $\quad$ Cu(II) > Ni(II) > Zn(II) ≈ Co(II) > Fe(II) > Mn(II),

π-bond, $\quad$ Zn(II) < Fe(II) ≈ Co(II) < Cu(II) < Ni(II) < Mn(II).

Since π-bonding contributions enhance, and σ-bonding contributions diminish, the C≡N band intensity, the observed order in the β-cyanopyridine complexes can now be interpreted.

The position of Zn(II), Cu(II), Ni(II), and Mn(II) are related to Irving's order (9), and agree with predictions made on the basis of σ- and π-bonding contributions. However, the position of Co(II) is perhaps unusual. The first ionization potential of cobalt is much higher than that of nickel, and even higher than that of copper. This means the relative magnitude of π-bonding in the Co(II) complex is lower than that in the Ni(II) complex. The net effect of both σ- and π-bonding effects results in the C≡N band intensity in the Co(II) complex being a little lower than that in the Ni(II) complex.

The intensity data in Table I also show that the intensity of the Co(II) complex is higher than that of Zn(II) complex. Again, from the ionization potential data we may expect the relative magnitude of the π-bond in Co(II) complex to be higher than that in Zn(II) complex, whereas the magnitudes of σ-bond in complexes of these two metal ions are almost the same. Thus the higher C≡N band intensity in Co(II) complex is expected.

Coordination Constant

The C≡N band intensities of substituted benzonitriles have been correlated with the Hammett constant (6). The effects of coordination on the free energy change involved in some functional groups of pyridine derivatives have been studied, and a coordination constant, similar to the Hammett constant, was introduced. The coordination constant is defined by

$$\alpha \equiv \log k_{ML} - \log k_{L},$$

where k_L is the acid dissociation constant of 3-pyridinol in H_2O at 25 °C, and k_{ML} is the acid dissociation constant of the metal complex of 3-pyridinol.

The acid dissociation constants of some metal 3-pyridinol complexes were determined by pH titrations of 3-pyridinol solution in the presence of metal ion, and are listed in Table II together with the coordination constants.

The formation of the monohydroxo complexes of these metal ions in aqueous solution have some influence on the equilibria being studied, although all titrations were carried out in a region where no precipitation of the metal hydroxide took place. An equation for the calculation of the acid dissociation constant taking account of this hydrolysis was deduced as in Appendix I.

If C_{HA} and C_M represent the total concentration of 3-pyridinol and metal ion, respectively, C_{KOH} represents the total concentration of KOH added and k_{L_mMOH} represents the dissociation constant of the monohydroxo complex, the acid dissociation constant may be calculated from the relationship

$$k_{HA} = \frac{[H^+]\{C_{KOH} - [OH^-] - (C_{M^{++}}[OH^-]/k_{L_mMOH^+} + [OH^-])\}}{C_{HA} - \{C_{KOH} - [OH^-] - (C_{M^{++}}[OH^-]/k_{L_mMOH^+} + [OH^-])\}}.$$

Correlation Between the Infrared Intensities and the Coordination Constants

When the square root of the measured intensity or the log (intensity) was plotted against the coordination constant, a straight line was obtained (Fig. 2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

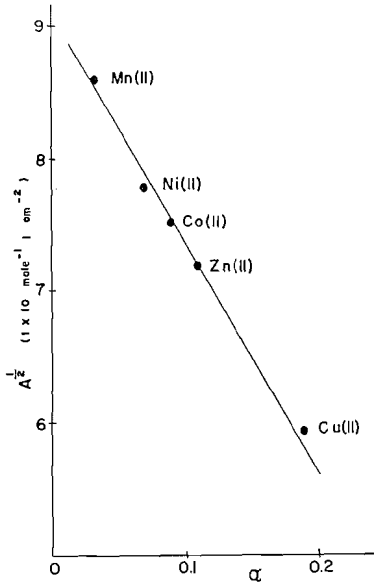

FIG. 2. A plot of square root of C≡N band intensities of β-cyanopyridine complexes vs. coordination constants.

As has been done for the substituted benzonitrile systems (5), this correlation can be predicted by a direct calculation (Appendix II) of the C≡N band infrared intensity based on the simple molecular orbital model.

The final equation of Appendix II correlated the square root of the intensity with the coordination constant:

$$A^{1/2} = \left[\left(\frac{N^2\pi}{3\,000\,c^2m}\right)^{1/2}\left(\frac{\partial\mu_0}{\partial q}\right)_{q=0}\right] + \left[\left(\frac{2exr^nE_LP}{GS}\right)\left(\frac{N^2\pi}{3\,000\,c^2m}\right)^{1/2}\right] - \left[\left(\frac{2exr^nP\gamma RT}{GS}\right)\left(\frac{N^2\pi}{3\,000\,c^2m}\right)^{1/2}\right]\alpha.$$

All the values inside the bracketed terms in this equation are constants. Therefore α is linearly related to $A^{1/2}$, as obtained experimentally.

APPENDIX I

For the equilibrium

$$(H_2O)_mMOH^+ \rightleftharpoons (H_2O)_nM^{++} + OH^-,$$

$$k_{(H_2O)_mMOH^+} = \frac{[(H_2O)_nM^{++}][OH^-]}{[(H_2O)_mMOH^+]}.$$

For the equilibrium

$$A_mMOH^+ \rightleftharpoons A_nM^{++} + OH^-,$$

where A is a ligand,

$$k_{A_mMOH^+} = \frac{[A_nM^{++}][OH^-]}{[A_mMOH^+]}.$$

Assume[2]

$$k_{(H_2O)_mMOH^+} = k_{A_mMOH^+} = k_{L_mMOH^+}.$$

[2]*A 10-fold change in order of magnitude of this constant leads to about 2–3% error in the k_{HA} of the most hydrolyzed copper complex.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Then

[1] $$k_{L_mMOH^+} = \frac{[L_nM^{++}][OH^-]}{[L_mMOH^+]},$$

where

$$[L_nM^{++}] = [(H_2O)_nM^{++}] + [A_nM^{++}],$$

$$[L_mMOH^+] = [(H_2O)_mMOH^+] + [A_mMOH^+].$$

For

$$(HA)_t \rightleftharpoons (A^-)_t + H^+,$$

[2] $$k_{HA} = \frac{[(A^-)_t][H^+]}{[(HA)_t]},$$

where

$$[(HA)_t] = n[(HA)_nM^{++}] + m[(HA)_mMOH^+] + [HA],$$

$$[(A^-)_t] = n[A_nM^{++}] + m[A_mMOH^+] + [A^-].$$

Materials balance:

[3] $$C_{HA} = [(HA)_t] + [(A^-)_t],$$

[4] $$C_{M^{++}} = [L_nM^{++}] + [L_mMOH^+],$$

[5] $$C_{KOH} = [OH^-] + [L_mMOH^+] + [(A^-)_t],$$

and from [4]

[6] $$[L_nM^{++}] = C_{M^{++}} - [L_mMOH^+].$$

Substitution of [6] into [1] gives

[7] $$[L_mMOH^+] = \frac{C_{M^{++}}[OH^-]}{k_{L_mMOH^+} + [OH^-]},$$

and from [3]

[8] $$[(HA)_t] = C_{HA} - [(A^-)_t].$$

Substitution of [8] into [2] gives

[9] $$[(A^-)_t] = \frac{C_{HA} - k_{HA}}{[H^+] + k_{HA}},$$

and substitution of [9] and [7] into [5] gives

$$k_{HA} = \frac{[H^+]\{C_{KOH} - [OH^-] - (C_{M^{++}}[OH^-]/k_{L_mMOH^+} + [OH^-])\}}{C_{HA} - \{C_{KOH} - [OH^-] - (C_{M^{++}}[OH^-]/k_{L_mMOH^+} + [OH^-])\}}.$$

APPENDIX II

The integrated infrared intensity was found to be related to molecular properties according to (31)

[10] $$A = \frac{\pi N}{3\,000\,c^2 m}\left(\frac{\partial \mu}{\partial q}\right)^2_{q=0}$$

where A represents the integrated intensity in units of mole^{-1} l cm^{-1}, N is Avogadro's number, c is the velocity of light, m is the reduced mass, $(\partial\mu/\partial q)_{q=0}$ represents the first derivative of the dipole moment change, and q is the displacement coordinate along the C≡N bond axis.

The molecular orbital formed by the interaction can be expressed as

$$\Phi = a\phi_P + b\phi_{CN}.$$

The dipole moment of the C≡N group is

$$\mu = \mu_0 + 2b^2ex,$$

where $2b^2ex$ represents the moment arising from the migration of charge from ϕ_P to ϕ_{CN}, x represents the distance separating the charge centers and μ_0 represents all other contributions to the moment, which keeps constant before and after β-cyanopyridine coordinates with the first-row transition metal ions. Then,

$$[11] \qquad \left(\frac{\partial\mu}{\partial q}\right)_{q=0} = \left(\frac{\partial\mu_0}{\partial q}\right)_{q=0} + 2b^2e\left(\frac{\partial x}{\partial q}\right)_{q=0} + 2ex\left(\frac{\partial b^2}{\partial q}\right)_{q=0}.$$

The quantity $\partial x/\partial q$ is very small, and the second term in eq. [11] can be dropped.

The energy of orbital Φ can be written as

$$E = \frac{\int \Phi^* H \Phi \mathrm{d}t}{\int \Phi^2 \mathrm{d}t} = \frac{\int (a\phi_P + b\phi_{CN}) H (a\phi_P + b\phi_{CN})\mathrm{d}t}{\int (a\phi_P + b\phi_{CN})^2 \mathrm{d}t}$$

$$= \frac{a^2\int \phi_P H \phi_P \mathrm{d}t + 2ab\int \phi_P H \phi_{CN}\mathrm{d}t + b^2\int \phi_{CN} H \phi_{CN}\mathrm{d}t}{a^2\int \phi_P{}^2\mathrm{d}t + 2ab\int \phi_P\phi_{CN}\mathrm{d}t + b^2\int \phi_{CN}{}^2\mathrm{d}t}.$$

Let

$$\int \phi_P H \phi_P \mathrm{d}t = H_{PP}, \quad \int \phi_{CN} H \phi_{CN}\mathrm{d}t = H_{CN}, \quad \int \phi_P H \phi_{CN}\mathrm{d}t = H_{PCN},$$

$$\int \phi_P{}^2\mathrm{d}t = \int \phi_{CN}{}^2\mathrm{d}t = 1, \quad \int \phi_P\phi_{CN}\mathrm{d}t = 0.$$

One obtains

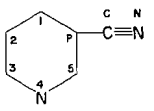
$$E = \frac{a^2H_{PP} + 2abH_{PCN} + b^2H_{CN}}{a^2 + b^2}.$$

Then

$$[12] \qquad \frac{\partial E}{\partial a} = a(H_{PP} - E) + b(H_{PCN}) = 0,$$

$$[13] \qquad \frac{\partial E}{\partial b} = a(H_{PCN}) + b(H_{CN} - E) = 0.$$

From [12] and [13]



$$[14] \qquad b = \frac{[H_{CN} - H_{PP}] - [(H_{PP} - H_{CN})^2 + 4(H_{PCN})^2]^{1/2}}{2/a[H_{PCN}]}.$$

If the atoms in β-cyanopyridine are labeled as in the diagram below, it follows that

$$[15] \qquad H_{PCN} = \int \phi_P H \phi_{CN}\mathrm{d}t$$

$$= \int (C_1\varphi_1 + C_2\varphi_2 + C_3\varphi_3 + C_4\varphi_4 + C_5\varphi_5 + C_P\varphi_P) H (C_C\varphi_C + C_N\varphi_N)\mathrm{d}t$$

$$= \int C_P\varphi_P H C_C\varphi_C \mathrm{d}t = C_PC_C\int \varphi_C H \varphi_P \mathrm{d}t = C_CC_P\beta.$$

Since

$$[16] \qquad a^2 + b^2 = 1,$$

combination of [14], [15], and [16] gives

$$b^2 = \frac{(H_{CN}-H_{PP})^2 - 2(H_{PP}-H_{CN})[H_{PP}-H_{CN})^2 + 4C_C{}^2C_P{}^2\beta^2]^{1/2} + [H_{PP}-H_{CN})^2 + 4C_C{}^2C_P{}^2\beta^2]}{(2C_CC_P\beta)^2 + (H_{CN}-H_{PP})^2 - 2(H_{PP}-H_{CN})[H_{PP}-H_{CN})^2 + 4C_C{}^2C_P{}^2\beta^2]^{1/2} + [(H_{PP}-H_{CN})^2 + 4C_C{}^2C_P{}^2\beta^2]}.$$

Then

$$[17]\quad (\partial b^2/\partial q)_{q=0} = -\Big(4C_C^2C_P^2\beta^2\{(H_{CN}-H_{PP})^2-(H_{CN}-H_{PP})[(H_{PP}-H_{CN})^2+4C_C^2C_P^2\beta^2]^{1/2}+2C_C^2C_P^2\beta^2\}(\partial H_{CN}/\partial q)_{q=0}\Big)\Big/\Big(\{16C_C^4C_P^4\beta^4+8C_C^2C_P^2\beta^2(H_{CN}-H_{PP})^2-8C_C^2C_P^2\beta^2(H_{CN}-H_{PP})\times[(H_{PP}-H_{CN})^2+4C_C^2C_P^2\beta^2]^{1/2}+(H_{CN}-H_{PP})^4+(H_{CN}-H_{PP})^3-2(H_{CN}-H_{PP})^3[(H_{PP}-H_{CN})^2+4C_C^2C_P^2\beta^2]^{1/2}\}\times[(H_{PP}-H_{CN})^2+4C_C^2C_P^2\beta^2]^{1/2}\Big).$$

In the LCAO model of C≡N bond (29), $(\partial H_{CN}/\partial q)_{q=0}$ can be written as

$$\left(\frac{\partial H_{CN}}{\partial q}\right)_{q=0} = -0.62\left(\frac{\partial \beta_{CN}}{\partial q}\right)_{q=0}.$$

Since $\beta_{CN} = k_{CN}\beta_{CC}$ and since $(\partial\beta_{CC}/\partial q)_{q=0}$ is approximately linear with a value of 6.25 eV/Å (30), the value of $(\partial H_{CN}/\partial q)_{q=0}$ can be easily calculated; suppose it to be P.

Let the coefficient of $(\partial H_{CN}/\partial q)_{q=0}$ in eq. [17] equal Q, then

$$[18]\qquad \left(\frac{\partial b^2}{\partial q}\right)_{q=0} = QP.$$

Combination of [10], [11], and [18] gives

$$[19]\qquad A^{1/2} = \left[\left(\frac{N^2\pi}{3\,000\,c^2m}\right)^{1/2}\left(\frac{\partial \mu_0}{\partial q}\right)_{q=0}\right] - \left[2ex\left(\frac{N^2\pi}{3\,000\,c^2m}\right)^{1/2}\right]QP.$$

Suppose that a process, such as protonation or hydration, occurs at the C≡N group of β-cyanopyridine. The activation energy which is contributed from electrostatic effects involved in this process can be written as E_L and E_{ML} for β-cyanopyridine and its metal complexes, respectively. In a particular process, E_L is a constant, whereas E_{ML} is varied with change of metal ion in the complex. E_{ML} arises from the interaction of the electrophile with the partial charge on the C≡N group, and can be written as

$$[20]\qquad E_{ML} = -\frac{2(b^2+\Delta b^2)G}{r^n},$$

where G and n are values depending on the nature of the electrophile (ion or dipole) attacking at the C≡N group, r represents the distance between the centers of the C≡N group and the electrophile in the transition state, and Δb^2 represents the change in the π-electronic interaction in the transition state from that in the ground state. From eq. [17]

$$[21]\qquad \Delta b^2 = -Q\Delta H_{CN}.$$

Substitution of [21] into [20] gives

$$[22]\qquad E_{ML} = -\frac{GQ}{r^n}\left[\frac{2\delta^2}{Q(1+\delta^2)} - 2\Delta H_{CN}\right],$$

where

$$\delta = \frac{(H_{CN}-H_{PP}) - [(H_{PP}-H_{CN})^2+4C_C^2C_P^2\beta^2]^{1/2}}{2C_CC_P\beta}.$$

In eq. [22] the bracketed term is very small, and ΔH_{CN} and $2\delta^2/Q(1+\delta^2)$ are changed in the opposite direction with complex formation, so that we may assume that this term is a constant,

$$\left[\frac{2\delta^2}{Q(1+\delta^2)} - 2\Delta H_{CN}\right] \equiv S.$$

Then

$$E_{ML} = -\frac{GQS}{\gamma^n}. \qquad [23]$$

Since the usual linear relation of free energy (6) is valid for the system being studied,[3] it follows that

$$\gamma\alpha = -\frac{E_{ML} - E_L}{RT}, \qquad [24]$$

where γ is a constant characteristic of the functional group, the attacking electrophile, and the reaction medium. Combination of [23], [24], and [19] gives

$$A^{1/2} = \left[\left(\frac{N^2\pi}{3\,000\,c^2m}\right)^{1/2}\left(\frac{\partial\mu_0}{\partial q}\right)_{q=0}\right] + \left[\left(\frac{2exr^nE_LP}{GS}\right)\left(\frac{N^2\pi}{3\,000\,c^2m}\right)^{1/2}\right] - \left[\left(\frac{2exr^nP\gamma RT}{GS}\right)\left(\frac{N^2\pi}{3\,000\,c^2m}\right)^{1/2}\right]\alpha.$$

THE COLLISION RATE IN A DILUTE CLASSICAL GAS

R. J. C. BROWN
Chemistry Department, Queen's University, Kingston, Ontario
Received January 26, 1966

ABSTRACT

The result given by Maxwell and by Boltzmann for the collision rate in a dilute classical gas has been widely accepted. Investigation of a stochastic model for the collisions indicates that the collision rate averaged over a macroscopic period of time is about 3% lower than the original result.

INTRODUCTION

One of the basic quantities of the classical kinetic theory of gases is the collision rate, and the result of Maxwell (1) and Boltzmann (2) has been widely accepted since it was first proposed (3, 4). This situation is in contrast with that of the mean free path, for which a number of different definitions and results have been given; as a result of these differing opinions, the mean free path is given an extended discussion in many textbooks while the collision rate is presented as if no ambiguity existed in its definition. The present work attempts to approach the collision problem by regarding the collisions of a single molecule as a stochastic process; it is shown that the collision rate averaged over a long period of time differs from the usual result given, and that the difference is analogous to that between the mean free paths calculated by Maxwell and by Tait (3).

COLLISION PROBABILITIES

Consider a gas of identical hard sphere molecules of mass m and diameter σ in thermal equilibrium at a temperature T, having a number density N molecules cm^{-3}. The velocity of a molecule selected at random in the gas is a random variable having the usual Maxwell–Boltzmann distribution (4): the probability that the velocity lies in the range $\boldsymbol{v}$ to $\boldsymbol{v} + \mathrm{d}\boldsymbol{v}$ is $F_1(\boldsymbol{v})\ \mathrm{d}\boldsymbol{v}$, where

$$[1] \qquad F_1(\boldsymbol{v}) = (\beta/\pi)^{3/2} \exp\{-\beta(v_x^2 + v_y^2 + v_z^2)\} \text{ and } \beta = m/2kT.$$

Suppose that a molecule having a particular velocity $\boldsymbol{v}$ is selected in the gas at the origin of time, $t = 0$; the next collision of this molecule is to be considered. The other molecules in the gas can be divided into groups such that each group contains molecules having essentially the same velocity; the number density of a group of molecules having velocities in the range $\boldsymbol{v}_1$ to $\boldsymbol{v}_1 + \mathrm{d}\boldsymbol{v}_1$ is $NF_1(\boldsymbol{v}_1)\ \mathrm{d}\boldsymbol{v}_1$. One can ask, what is the probability that the particular molecule considered collides with a molecule belonging to the specified group in the very short time interval between the times t, $t + \Delta t$? The probability is easily obtained if the gas is observed from a reference frame moving with velocity $\boldsymbol{v}_1$; the observer then sees the single molecule moving with velocity $\boldsymbol{w} = \boldsymbol{v} - \boldsymbol{v}_1$ through a group of almost stationary molecules whose centers are distributed at random. A collision occurs if the center of any one of the stationary molecules lies inside a particular cylindrical region of volume $\pi\sigma^2 w.\Delta t$, and the probability that this occurs is $\pi\sigma^2 w.\Delta t.NF_1(\boldsymbol{v}_1)\ \mathrm{d}\boldsymbol{v}_1$. Considering now all groups of molecules, the total probability that a collision occurs is

$$[2] \qquad \mu(v)\Delta t = N\pi\sigma^2\langle w|v\rangle.\Delta t,$$

where

$$\langle w|v\rangle = \int |\boldsymbol{v} - \boldsymbol{v}_1| F_1(\boldsymbol{v}_1)\, d\boldsymbol{v}_1 = (\pi\beta)^{-1/2}(\beta^{1/2}v)^{-1}\psi(\beta^{1/2}v), \quad [3]$$

and

$$\psi(x) = x\, e^{-x^2} + (2x^2 + 1) \int_0^x e^{-y^2}\, dy. \quad [4]$$

The quantity $\langle w|v\rangle$ is the average relative speed of two molecules in the gas, given that the speed of one of them is v. The following points may be noted in connection with the result [2]:

(i) It is implicitly assumed that Δt is small enough that the probability of more than one collision in the interval Δt is negligible, for the result is obtained formally by applying the theorem of total probability.

(ii) It is not meaningful to ask, "how many collisions per second are made by a molecule having velocity $\boldsymbol{v}$?" since the speed of the molecule changes at every collision. Conservation of energy and momentum require that the relative speed of the colliding molecules is the same after as before the collision; however, the molecules which were considered as stationary in the above argument were not rigidly fixed in space, and hence after the collision the speed of the incoming molecule relative to the rest of the group is altered and the probability associated with the second collision is different.

(iii) Since the speed of the molecule is specified, the interval of time Δt corresponds to an interval of path length $\Delta l = v.\Delta t$ and the probability that a collision occurs in this interval is

$$\mu'(v).\Delta l = N\pi\sigma^2\langle w|v\rangle.\Delta l/v. \quad [5]$$

COLLISIONS AS A STOCHASTIC PROCESS

The collisions which a molecule suffers occur at random times and can be regarded as events in a stochastic process; the probability law governing the distribution of collisions in time is given by eq. [2]. The probability density $\mu(v)$ is constant between collisions, but whenever a collision occurs, the speed of the molecule changes and hence the probability density changes to a new random value.

Define the probabilities $g_n(t)$ and $f_n(t).\Delta t$ by the following:

$g_n(t) = P\{n$ collisions in an interval of time $t\}$
$= P\{n, t\}$

$f_n(t).\Delta t = P\{1$ collision in an interval of time Δt *given* that n collisions occurred in the preceding interval of time $t\}$
$= P\{1, \Delta t|n, t\}$.

Let $F_2(v)$ be the distribution function for the speed of a molecule in a gas:

$$F_2(v) = 4\pi(\beta/\pi)^{3/2}v^2 \exp(-\beta v^2). \quad [6]$$

Then

$$g_0(t) = \int_0^\infty P\{0, t|v\} F_2(v)\, dv = \int_0^\infty e^{-\mu(v)\,t} F_2(v)\, dv, \quad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

since when v is specified, the "next" collision is distributed as in a Poisson process (5). For $n > 0$,

$$g_n(t) = \sum_{t_1=0}^{t} P\{n\text{th collision occurs between } t_1 - \Delta t_1 \text{ and } t_1\text{; and no collisions occur between } t_1 \text{ and } t\}$$
$$= \sum_{t_1=0}^{t} P\{n\text{th collision occurs between } t_1 - \Delta t_1 \text{ and } t_1\} \times P\{\text{no collisions occur between } t_1 \text{ and } t\}$$

since these two events are statistically independent. The first factor in each term of this expression can be further expanded using conditional probabilities:

$P\{n\text{th collision occurs between } t_1 - \Delta t_1 \text{ and } t_1\}$
$= P\{1 \text{ collision between } t_1 - \Delta t_1 \text{ and } t_1\text{; and } n-1 \text{ collisions between 0 and } t_1 - \Delta t_1\}$
$= P\{1 \text{ collision between } t_1 - \Delta t_1 \text{ and } t_1 | n-1 \text{ collisions between 0 and } t_1 - \Delta t_1\}$
$\times P\{n-1 \text{ collisions between 0 and } t_1 - \Delta t_1\}$
$= f_{n-1}(t_1 - \Delta t_1)\Delta t_1 . g_{n-1}(t_1 - \Delta t_1).$

Collecting these expressions and taking the limit as $\Delta t_1 \to 0$, one obtains the result

[8] $$g_n(t) = \int_0^t f_{n-1}(t_1) g_{n-1}(t_1) g_0(t - t_1)\, dt_1.$$

A differential equation involving the functions f_n and g_n may be obtained as follows: first it is noted that the probability of more than one collision occurring in a very short interval Δt is at least of order $(\Delta t)^2$ and hence

[9] $$P\{0, \Delta t | n, t\} + P\{1, \Delta t | n, t\} \cong 1.$$

The time development of $g_n(t)$ is governed by the expansion

$$P\{n, t + \Delta t\} = P\{n, t; 0, \Delta t\} + P\{n-1, t; 1, \Delta t\}$$
$$= P\{0, \Delta t | n, t\} P\{n, t\} + P\{1, \Delta t | n-1, t\} P\{n-1, t\},$$

and upon introducing eq. [9], and taking the limit as $\Delta t \to 0$, the following equation results:

[10a] $$\frac{dg_n(t)}{dt} = -f_n(t) g_n(t) + f_{n-1}(t) g_{n-1}(t).$$

For $n = 0$, the above argument yields

[10b] $$\frac{dg_0(t)}{dt} = -f_0(t) g_0(t).$$

Equations [7], [8], and [10] may now be solved for successive values of n, yielding the set of functions $\{g_n\}$ from which the average number of events in a time interval t, $\bar{n}(t)$, may be calculated:

[11] $$\bar{n}(t) = \sum_{n=0}^{\infty} n g_n(t).$$

This result is also obtainable by use of a suitable generating function,

[12] $$G(t, z) = \sum_{n=0}^{\infty} g_n(t) z^n,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

since

$$\bar{n}(t) = \left[\frac{\partial G(t, z)}{\partial z}\right]_{z=1} \quad [13]$$

Now

$$\frac{\partial G}{\partial t} = \sum_{n=0}^{\infty} \frac{\mathrm{d}g_n}{\mathrm{d}t} z^n$$

$$= \sum_{n} (-f_n g_n + f_{n-1} g_{n-1}) z^n$$

$$= (z - 1) \sum_{n=0}^{\infty} f_n g_n z^n,$$

and using this result and eq. [8] in the definition of $G(t, z)$, there results

$$G(t, z) = g_0(t) + \sum_{n=1}^{\infty} z^n \int_0^t f_{n-1}(t_1) g_{n-1}(t_1) g_0(t - t_1)\, \mathrm{d}t_1,$$

$$= g_0(t) + \frac{z}{z - 1} \int_0^t \frac{\partial G(t_1, z)}{\partial t_1} g_0(t - t_1)\, \mathrm{d}t_1.$$

Introducing the Laplace transform denoted by

$$\phi^*(s) = \int_0^{\infty} \phi(t)\, \mathrm{e}^{-st}\, \mathrm{d}t$$

and using the convolution theorem, one obtains

$$G^*(s, z) = g_0^*(s) + \frac{z}{z - 1} g_0^*(s)[sG^*(s, z) - G(0, z)].$$

Since

$$G(0, z) = 1,$$

$$G^*(s, z) = \frac{g_0^*(s)}{1 + z[sg_0^*(s) - 1]},$$

and hence from eq. [13],

$$\bar{n}^*(s) = \frac{1}{s^2 g_0^*(s)} - \frac{1}{s}.$$

The formal result for $\bar{n}(t)$ is

$$\bar{n}(t) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \frac{\mathrm{e}^{ts}\, \mathrm{d}s}{s^2 g_0^*(s)} - 1 \quad [14]$$

where the integration path lies to the right of the poles of the integrand, and

$$g_0^*(s) = \int_0^{\infty} \frac{F_2(v)\, \mathrm{d}v}{s + \mu(v)}. \quad [15]$$

The function $g_0^*(s)$ is non-zero and analytic everywhere in the complex s-plane except on the negative real axis to the left of $s = -2N\pi\sigma^2(\pi\beta)^{-1/2}$. Hence the contour in eq. [14] can be completed with any simple curve in the negative half-plane which excludes the real axis to the left of $s = -2N\pi\sigma^2(\pi\beta)^{-1/2}$, and then the only contribution to the integral over the whole contour is the residue at the double pole at the origin,

$$\frac{tg_0^*(0) - g_0^{*\prime}(0)}{[g_0^*(0)]^2}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The integral around the curve can be shown to vanish as $t \to \infty$ since the real part of s is negative, and hence

$$\lim_{t\to\infty} \frac{\bar{n}(t)}{t} = \frac{1}{g_0^*(0)} = \frac{1}{\langle 1/\mu \rangle} \tag{16}$$

since

$$g_0^*(0) = \int_0^\infty \frac{F_2(v)}{\mu(v)}\,dv = \langle 1/\mu \rangle. \tag{17}$$

On the other hand, for a very small value of t, $g_n(t)$ becomes vanishingly small for $n > 1$, and from the definition [11] of $\bar{n}(t)$,

$$\bar{n}(t) \cong g_1(t) \cong 1 - g_0(t) \cong \langle \mu \rangle t$$

$$\text{i.e.} \quad \lim_{t\to 0} \frac{\bar{n}(t)}{t} = \langle \mu \rangle \tag{18}$$

where

$$\langle \mu \rangle = \int_0^\infty \mu(v) F_2(v)\,dv. \tag{19}$$

Hence for this process, $\bar{n}(t)/t$ has different limiting values for very large and very small values of t. The average time from any arbitrary origin until the "next" collision is

$$\langle t_1 \rangle = \int_0^\infty t f_0(t) g_0(t)\,dt$$

$$= \int_0^\infty g_0(t)\,dt$$

$$= \langle 1/\mu \rangle, \tag{20}$$

which is exactly analogous to Tait's mean free path.

COLLISION RATE AND MEAN FREE PATH

The limiting value of the collision rate as $t \to \infty$ can be written explicitly using eqs. [2] and [3] in [17]:

$$\lim_{t\to\infty} \frac{\bar{n}(t)}{t} = \frac{N\pi\sigma^2\beta^{-1/2}}{I_3} \tag{21}$$

where

$$I_n = 4\int_0^\infty \frac{x^n \exp(-x^2)}{\psi(x)}\,dx. \tag{22}$$

The total number of collisions per cm^3 made by all molecules is obtained by multiplying the result [21] by $N/2$, the factor of $\frac{1}{2}$ being due to double counting of each collision.

The limiting value of the collision rate as $t \to 0$ is identical to the usual result quoted:

$$\lim_{t\to 0} \frac{\bar{n}(t)}{t} = N\pi\sigma^2\langle w \rangle$$

$$= N\pi\sigma^2\beta^{-1/2}(8/\pi)^{1/2}. \tag{23}$$

The status of the result [23] is clear: it is valid only for a period of time so short that $\bar{n}(t) \sim 0$, and except in a gas at exceedingly low pressures, such a period of time is very short.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The mean free path may also be discussed using the above stochastic model, using the probability density $\mu'(v)$ defined in eq. [5]; the number of collisions per cm of path length is

$$[24] \qquad \lim_{l\to\infty} \frac{\bar{n}(l)}{l} = \frac{1}{\langle 1/\mu' \rangle} = \frac{N\pi\sigma^2}{I_4}.$$

A mean free path may be defined as the inverse of this quantity, and is identical to the mean free path defined by Tait (6), as might be expected from eq. [20]; the Maxwell mean free path (3) may be obtained as the limit of $\bar{n}(l)/l$ as $l \to 0$. Thus the two collision rates defined above are entirely analogous to the two mean free paths.

Boltzmann calculated (6) the value of I_4 as 0.677464, which agreed in the first three figures with the result of Tait (7). The values of $I_{\bar{n}}$ for $n = 2$ up to $n = 6$ have been computed using Simpson's rule; the interval of subdivision was decreased until convergence to 8 decimal places was obtained, and only the basic arithmetic operations (using 22 digits) were employed in evaluating the exponential and error functions. The results are shown in Table I, and comparison with the usual results shows that the proposed collision rate [21] is smaller than the result [23] by about 3%.

THE PHOTOLYTIC AND PHOTOSENSITIZED DECOMPOSITION OF CHLOROFORM[1]

I. UNGER AND G. P. SEMELUK
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received November 22, 1965

ABSTRACT

The photolysis of $CHCl_3$, in the vapor phase, was carried out using the 1 849 Å line of Hg as the exciting radiation. The photosensitized reaction was also studied using benzene as a photosensitizer. In the latter case, the exciting wavelength was the 2 537 Å line of mercury, which $CHCl_3$ does not absorb.

The study was primarily concerned with establishing the initial steps of the direct photolysis and photosensitized reactions. Experimental observations rule out a molecular detachment of HCl in both the direct photolysis and photosensitized reactions at the wavelength used. The initial step of the photolysis appears to be a carbon–chlorine bond cleavage, but in the photosensitized reaction a carbon–hydrogen bond break is indicated as the primary step. It is concluded that in neither case does dissociation take place from the ground electronic state.

INTRODUCTION

Of the halogenated compounds those containing a carbonyl group have received the most attention. Very recently Majer and Simons published an excellent review of the photochemistry of halogenated compounds (2). Alkyl iodides have been studied more extensively than the other haloalkanes, perhaps because they are so easily dissociated. In the case of iodides it is now believed that two primary processes occur at different wavelengths; e.g., in ethyl iodide (3)

$$C_2H_5I \rightarrow \cdot C_2H_5 + I \text{ (at long wavelengths)}$$
$$\rightarrow C_2H_4 + HI \text{ (at shorter wavelengths)}$$

A molecular detachment mechanism has been suggested in the photodissociation of haloethylenes (4), although a radical mechanism may also be involved. More recently, the polyhalomethanes have been examined in an attempt to produce dichloro- and dibromocarbenes and to photograph their spectra (5). The photolysis of chloroform was studied by Hill (6), who identified only one product, HCl. Chloroform was photolyzed alone and in the presence of oxygen, hydrogen, and nitrogen. For chloroform alone the quantum yield was 3.99, and was not changed by the presence of hydrogen. Nitrogen increased the quantum yield to 23, while oxygen accelerated the reaction still more markedly.

Hill proposed the primary step of the reaction to be

[1] $$CHCl_3 \xrightarrow{h\nu} \cdot CHCl_2 + Cl$$

or

[2] $$CHCl_3 \xrightarrow{h\nu} \cdot CCl_3 + H$$

Shilov and Sabirova (7–9) have shown that in the pyrolysis of $CHCl_3$ the primary step of the reaction is

[3] $$CHCl_3 \rightarrow :CCl_2 + HCl$$

It is also interesting to note that in the radiolysis of $CHCl_3$ (10) the possibility of $:CCl_2$ formation by a "molecular mechanism" was used to explain the formation of one of the

[1]*Abstracted from the Ph.D. thesis (1963) of I. Unger. A preliminary report on this work has appeared as a note (1). In this communication we wish to present more extensive data as well as some experimental details.*

minor products, C_2Cl_4. On considering the above, it becomes evident that the primary step in the photolysis of $CHCl_3$ may be any one of reactions [1], [2], [3] or even the energetically less likely reaction [4].

$$[4] \qquad CHCl_3 \xrightarrow{h\nu} :CHCl + Cl_2$$

Neither should one exclude the possibility that more than one of the above reactions may participate in the initial dissociation.

Until recently, mercury has been used exclusively as a photosensitizer, but organic compounds are now becoming prominent as photosensitizers (11–13) perhaps because of the greater range of energies available and the broader knowledge of energy states of organic compounds made possible by the advent of flash photolysis. Ishikawa and Noyes (14) were able to show by an indirect method that all the benzene molecules which are excited by 2 537 Å radiation and do not fluoresce cross over to the triplet state, i.e., about 78%. This thesis has received support from the work of Cundall and Palmer (15) who used benzene to sensitize the isomerization of butene-2 and concluded that it was the triplet state of the benzene which sensitized this isomerization. We felt it was of interest to investigate the photolysis of chloroform, the possibility of a benzene-sensitized decomposition in a region of the spectrum where $CHCl_3$ does not absorb, and to perhaps relate the above dissociations to specific excited states, in the light of modern concepts and with the aid of modern instrumentation.

EXPERIMENTAL

Materials

C.P. chloroform was purified according to the method described by Vogel (16), degassed thoroughly, and stored in hermetically sealed ampoules under vacuum. Chloroform thus treated was found to be chromatographically pure and did not show any signs of decomposition even when stored for prolonged periods of time. Fisher Certified Thiophene-Free Spectranalyzed benzene was found to be chromatographically pure and was used without any further purification. Butenes and ethylene were Phillips Research Grade hydrocarbons, and *cis*- and *trans*-1,2-dimethyl-2,2-dichlorocyclopropane were prepared by the method described by Doering and Hoffman (17) and purified by several distillations. The fraction of *cis*-1,2-dimethyl-2,2-dichlorocyclopropane collected had a boiling point of 127–128 °C, while that of *trans*-1,2-dimethyl-2,2-dichlorocyclopropane collected had a boiling point of 121–122 °C. The 1,1-dichlorocyclopropane was prepared according to the method given by Stevens (18) and purified by distillation.

Pharmaceutical hydrogen (mercury-free), obtained from the Linde Air Products Co., was passed over hot finely divided copper to remove traces of oxygen and then passed through a phosphorus pentoxide drying tower. Linde nitrogen was treated in the same manner. Canadian Industries Limited anhydrous ammonia was purified by bulb-to-bulb distillation *in vacuo*.

The vacuum system was conventional but mercury-free, consisting essentially of three sections—storage, analytical, and reaction. Photolyses were carried out in a quartz cell 25 mm in diameter and 50 mm long and equipped with Suprasil windows. Pressure measurements were made using a Pyrex spiral gauge as a null instrument.

The lamp used for experiments at 1 849 Å was a custom made Hanovia low-pressure mercury arc, adjusted for optimum emission at 1 849 Å. A small heating tape, near the window of the lamp, was used to prevent mercury condensation on the window. This lamp was also used for experiments at 2 537 Å, in which case a Corning No. 9863 filter, 2 mm thick, effectively removed 1 849 Å radiation. For experiments in the presence of olefins a high-pressure mercury–xenon arc, Hanovia No. 908 B1 was used in conjunction with a Baird Atomic interference filter having a maximum transmission at 2 150 Å. Light emitted by the low-pressure mercury arc was monitored with a one stage platinum phototube (constructed at the N.R.C. laboratories in Ottawa) in conjunction with a Keithley electrometer. This phototube is insensitive to wavelengths above 2 100 Å.

When $CHCl_3$ or $CHCl_3$ plus a condensible were being studied, the reactants were admitted to the cell, frozen in the side arm of the cell, and then flash-vaporized, a half hour being allowed for efficient mixing. When $CHCl_3$ plus N_2 or H_2 were being studied, a period of 3 h was allowed for mixing following flash evaporation of the chloroform, since in this case mixing was much slower. After photolysis the products and reactants were collected in the analytical section. Hydrogen chloride was distilled into a trap containing sodium bicarbonate, and the carbon dioxide produced was collected in a short ampoule of 1 mm internal diameter, which was then detached while under vacuum and set aside to await analysis. The remaining

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

products and reactants were collected in a similar ampoule. In the benzene-photosensitized runs the dark-colored residue which was occasionally deposited on the window of the cell was removed by flaming the cell to a dull red, first in the presence of air and finally in the presence of hydrogen.

Most of the analyses were carried out using a model 500 F and M Linear Temperature Programmed Gas Chromatograph. An F and M SI-4 solid sample injector was used for ampoule injection. All the chlorinated hydrocarbon products were analyzed on a 10 ft column containing 10% silicone oil on 60/80 mesh Chromosorb W, temperature-programed from 65 to 225 °C at a rate of 15 deg/min, with a hydrogen carrier gas flow rate of 1 cc/s. A 3 ft 40/60 mesh silica gel column, at 105 °C, was used for carbon dioxide determination. A 12 ft column packed with 20% diisodecyl phthalate on 60/80 Chromosorb W held at 125 °C was used to identify chlorinated cyclopropanes. Hydrogen was determined on a 4 ft 40/60 mesh molecular sieve 5A column operating at room temperature, with a nitrogen carrier gas flow rate of 0.5 cc/s.

Actinometry

Ammonia was chosen as the chemical actinometer. Although an absolute quantum yield with it is uncertain because of the lack of data below 2 100 Å, it has some singular advantages (19). It is easily purified, the products of the reaction are H_2 and N_2 in the ratio 3:1 (at any extent of decomposition in a static system) and it is transparent to 2 537 Å radiation while absorbing 1 849 Å radiation strongly.

Wiig (20, 21) has calculated the quantum yield of NH_3 decomposition at 1 atm for a cell of the same geometry as the one used in the present study to be 0.163 at 2 100 Å. Our quantum yields are based on this value. It seems unlikely that the quantum yield of NH_3 decomposition at 1 849 Å will be sufficiently different from that at 2 100 Å to require a change in our interpretation of the chloroform photolysis. On the contrary, the available data (22) suggests that the quantum yield of NH_3 decomposition could be the same at both wavelengths, since the initial steps of the decomposition, the products, and the product ratios are nearly the same at both wavelengths. Should this not be the case, then our results may be corrected when an absolute value for ammonia photolysis at 1 849 Å is determined.

RESULTS AND DISCUSSION

Direct Photolysis

To establish whether the photolysis proceeds via a molecular mechanism, [3] and [4], or a radical mechanism, [1] and [2], numerous experiments were performed in the presence of olefins. If a biradical were formed in the first step, then in the presence of olefins one would expect a dichloro- or monochloro-cyclopropane among the products. When the photolysis was carried out in the presence of *cis*- or *trans*-butene-2, no evidence for the formation of the above-mentioned compounds could be obtained. The reactions of $:CH_2$ are fairly well characterized (23, 24) and are known to be very rapid. Those of heavier biradicals are not too well known and may be quite different. Frey (25) found that $CH_3CH:$ did not add to the double bond in *cis*- and *trans*-butene-2 but did react with propylene; he tentatively ascribed the reason to steric hindrance. One would, therefore, expect $:CCl_2$ to be even less reactive to *cis*- and *trans*-butene-2 than $CH_3CH:$ and for this reason several experiments were carried out in the presence of ethylene, which has the added advantage that its long wave limit of absorption is lower than that of any other olefin (26). None of these experiments showed any cyclopropanes among the products even when performed in a large excess of nitrogen.

Further evidence ruling out the molecular mechanism was obtained by performing photolyses in the presence of large amounts of H_2 and N_2 which should yield CCl_2H_2 and C_2Cl_4, respectively, if $:CCl_2$ is formed initially in a "hot" state according to the reactions

[5] $$:CCl_2^{**} + H_2 \rightarrow :CCl_2^{*} + H_2$$

[5a] $$:CCl_2^{*} + H_2 \rightarrow CCl_2H_2$$

[6] $$CCl_2^{**} + N_2 \rightarrow :CCl_2^{*} + N_2$$

[6a] $$2{:}CCl_2^{*} \rightarrow C_2Cl_4$$

Our observations indicate that the photolysis of $CHCl_3$ proceeds through an initial carbon–chlorine bond cleavage. Table I summarizes our results for varying $CHCl_3$

pressure. No products other than $C_2H_2Cl_4$, C_2HCl_5, C_2Cl_6 and HCl were detected. The mechanism (for small percentage conversions) can be described by

[1] $$CHCl_3 \xrightarrow{h\nu} \cdot CHCl_2 + Cl$$

[7] $$Cl + CHCl_3 \rightarrow HCl + \cdot CCl_3$$

[8] $$\cdot CHCl_2 + \cdot CCl_3 \rightarrow C_2HCl_5$$

[9] $$2 \cdot CHCl_2 \rightarrow C_2H_2Cl_4$$

[10] $$2 \cdot CCl_3 \rightarrow C_2Cl_6$$

TABLE I

13.9	9.2	19.8	10.1	2.15	1.09	0.54

If [7] is sufficiently rapid, then the steady state concentration of CCl_3 and $CHCl_2$ radicals will be equal and on a purely statistical basis it would be expected that C_2HCl_5, $C_2H_2Cl_4$, and C_2Cl_6 would be formed in the ratio 2:1:1 (27), which would be modified slightly for mass differences among these radicals, but changed more significantly if the activation energies for [8], [9], and [10] were different. The expected relationship between these activation energies $E_{10} > E_9 \geqslant E_8$ (27) is roughly confirmed by our observations, as shown in Table I.

An initial carbon–hydrogen bond rupture is shown to be unlikely by the absence of H_2 among the products and can be corroborated by photolyzing in the presence of an excess of H_2. If [1] applies, then this reaction would be followed rapidly by

[11] $$Cl + H_2 \rightarrow HCl + H$$

and then by

[12] $$H + CHCl_3 \rightarrow HCl + \cdot CHCl_2$$

or

[13] $$H + CHCl_3 \rightarrow H_2 + \cdot CCl_3$$

Hardwick (28) gives k_{12}/k_{13} as 7.3. Thus there would be an increase in the steady state concentration of $CHCl_2$ radicals relative to that of CCl_3 radicals and the product ratios should change in favor of $C_2H_2Cl_4$. In the case of carbon–hydrogen bond rupture, however, little change would be expected. The product ratios did indeed change significantly in the presence of H_2 (Fig. 1) though the quantum yield was very little affected (Fig. 2). Nitrogen, on the other hand, reduced the quantum yield slightly (Fig. 3) but hardly altered the product ratios (Fig. 4). The slight increase in favor of C_2Cl_6 in the presence of N_2 is also consistent with our mechanism, since if [1] is the first step of the sequence, the $CHCl_2$

radical is produced in the "hot" state, whereas the CCl_3 radical is not produced in a "hot" state. In the presence of N_2 some of the excess energy possessed by $CHCl_2$, which would otherwise be partly available for activation energy during a collision, would be removed and the amount of $C_2H_2Cl_4$ relative to C_2Cl_6 should decrease. This thesis is supported by data obtained at elevated temperatures, listed in Table II. Under these conditions the products arising from "hot" radicals should not be as strongly favored over those stemming from "cold" radicals and the product ratios should therefore change in favor of C_2Cl_6, as is illustrated in Fig. 5.

To make the mechanism a little more detailed, though by no means complete, the following reactions must be considered:

[14] $$CHCl_3 + h\nu \rightarrow CHCl_3^*$$

[15] $$CHCl_3^* \rightarrow CHCl_3 + h\nu$$

[16] $$CHCl_3^* + CHCl_3 \rightarrow 2CHCl_3$$

[17] $$CHCl_3^* + M \rightarrow CHCl_3 + M$$

[18] $$CHCl_3^* \rightarrow \cdot CHCl_2 + Cl\cdot$$

It is perhaps unusual to include [15], [16], and [17] in the scheme since in this spectral region chloroform apparently gives a continuous absorption band (29), and so implies that it finds itself in at least a repulsive part of the upper electronic state. The possibility exists, of course, that the band does have structure and that its appearance is the result of spectrographic insensitivity to small intensity differences, but it is also possible that the theoretical basis for understanding the relationship between dissociation and electronic spectra of polyatomic molecules is much less secure than it is for diatomic molecules. For example, fluorescence is observed when CF_4 is excited by radiation of about 900 Å, even though CF_4 absorption is continuous in this region (30).

It should be noted that the quantum yield of chloroform decomposition is significantly different from 2, the value which one would expect if dissociation took place from a completely repulsive state under the pressure conditions of this study. Although it is possible that our quantum yield is in error due to experimental shortcomings and to an incorrect value for the quantum yield of NH_3 dissociation, a careful consideration of the sources of error leads us to believe that any adjustment would likely result in a lower value than we report.

According to the proposed mechanism the quantum yield for the disappearance of $CHCl_3$ will be given by

[19] $$\Phi = \frac{2k_{18}}{k_{18} + k_{15} + k_{16}[CHCl_3] + k_{17}[M]}$$

In the presence of foreign gas, for constant $CHCl_3$ pressure, the denominator of [19] increases as foreign gas pressure increases and the quantum yield therefore decreases. This is graphically confirmed in Figs. 2 and 3, which also suggests that hydrogen is a more efficient quencher of excited $CHCl_3$ than is nitrogen, a behavior which has been observed in many other cases (31).

There is an apparent increase in the quantum yield of decomposition with increasing $CHCl_3$ pressure. There are several possible explanations for this phenomenon (wall quenching, dissociation from some state other than the one initially excited, etc.). We prefer to reserve judgement on this point until more accurate data become available.

Thus, the evidence presented here strongly supports an initial carbon–chlorine bond rupture and is in line with the view of Mulliken (32) that the continuous absorption band of $CHCl_3$, with maximum at 1 750 Å (29) is due to the excitation of an electron from a non-bonding orbital on the chlorine atom to a sigma carbon–chlorine antibonding orbital.

Benzene-Sensitized Photolysis

Chloroform and benzene when present separately in the cell did not show any detectable signs of decomposition when irradiated with 2 537 Å radiation, but when both were present simultaneously, chloroform decomposition did occur. The major organic products determined were hexachloroethane, methylene chloride, α,α,α-trichlorotoluene, and pentachloroethane. Much smaller quantities of tetrachloroethylene and tetrachloroethane were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

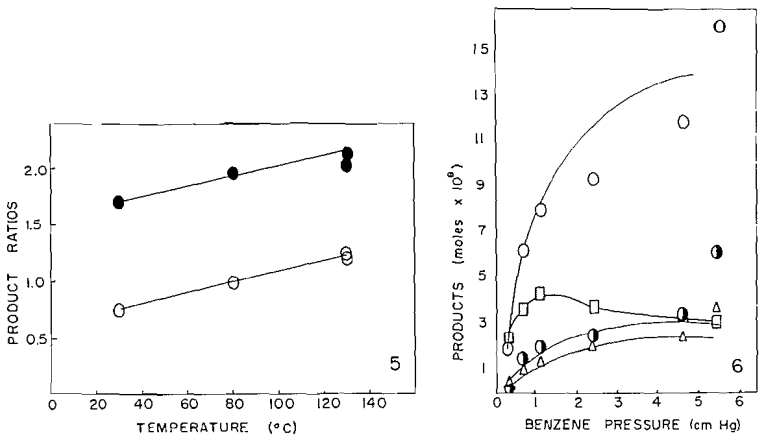

FIG. 5. Dependence of product ratios on temperature: ●, $[C_2HCl_5]/[C_2H_2Cl_4]$; ○, $[C_2Cl_6]/[C_2H_2Cl_4]$.
FIG. 6. Product dependence on benzene pressure: ○, $[C_2Cl_6]$; □, $[CH_2Cl_2]$; ◑, $[CCl_3{\cdot}C_6H_5]$; △, $[C_2HCl_5]$.

also found, but chlorobenzene and biphenyl which were expected products could not be detected in any experiment. The dependence of major organic products on benzene pressure is shown in Fig. 6. The inorganic products consisted of hydrogen chloride and, in marked contrast to the direct photolysis case, hydrogen. The quantitative determination of the inorganics has been more difficult and much less accurate, but it appears that hydrogen chloride production approximately parallels the production of methylene chloride.

In devising a mechanism for this reaction, the choice of radical reactions has been strongly influenced by the product distribution, and particularly by the absence of chlorobenzene among the products. This we have interpreted to mean that abstraction by phenyl radicals is not important in this system and that chlorine atoms do not significantly participate in the reaction.

Our results, then, are consistent with a mechanism based on a carbon–hydrogen bond split in $CHCl_3$ following energy transfer from an excited benzene molecule. In the following mechanism which is based on reactions of excited benzene discussed by Noyes (33), B represents benzene in the ground electronic state, $^1B^I$ represents electronically excited singlet benzene, $^3B^I_v$ represents electronically excited triplet benzene in a high vibrational energy-level, $^3B^I_0$ represents electronically excited triplet benzene in the ground vibrational level, M = $CHCl_3$ + B represents an 'energy-removing body', k_i represents the rate constant of the ith step in the mechanism, and T_a represents the absorbed intensity.

[20] $$B + h\nu \rightarrow {}^1B^I \qquad I_a$$

[21] $$^1B^I \rightarrow B + h\nu$$

[22] $$^1B^I + B \rightarrow 2B$$

[23] $$^1B^I \rightarrow {}^3B^I_v$$

[24] $$^3B^I_v + M \rightarrow {}^3B^I_0 + M$$

[25] $$^3B^I_0 + M \rightarrow B + M$$

[26] $$^3B^I_v + CHCl_3 \rightarrow B + \cdot CCl_3 + H$$

or

[26a] $$^1B^I + CHCl_3 \rightarrow B + \cdot CCl_3 + H$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[12] $H + CHCl_3 \rightarrow HCl + HCCl_2$

[13] $H + CHCl_3 \rightarrow H_2 + \cdot CCl_3$

[27] $H + B \rightarrow H_2 + \cdot C_6H_5$

[10] $2\cdot CCl_3 \rightarrow C_2Cl_6$

[28] $\cdot CHCl_2 + H \rightarrow CH_2Cl_2$

[29] $\cdot C_6H_5 + H \rightarrow B$

[30] $\cdot C_6H_5 + \cdot CCl_3 \rightarrow C_6H_5CCl_3$

[8] $\cdot CHCl_2 + \cdot CCl_3 \rightarrow C_2HCl_5$

If reaction [26] is responsible for the initial step of the decomposition of $CHCl_3$, then the steady state concentration of the triplet is given by

$$[31] \qquad [^3B^I_v] = \frac{k_{23}I_a}{\{(k_{24} + k_{21})[CHCl_3] + k_{24}[B]\}\{k_{21} + k_{23} + k_{22}[B]\}}$$

On the other hand if reaction [26*a*] is responsible, the steady state concentration of the singlet is given by

$$[32] \qquad [^1B^I] = \frac{I_a}{k_{21} + k_{23} + k_{26a}[CHCl_3] + k_{22}[B]}$$

If the sensitization rate is represented in general by $k_x[B^*][CHCl_3]$ where $k_x[B^*]$ is to be replaced by $k_{26a}[^1B^I]$ for singlet activation and by $k_{26}[^3B^I_v]$ for triplet activation, then the steady state concentration of hydrogen atoms is given by

$$[33] \qquad [H] = \frac{k_x[B^*][CHCl_3]}{(k_{12} + k_{13})[CHCl_3] + k_{27}[B] + k_{28}[CCl_2H\cdot] + k_{29}[C_6H_5\cdot]}$$

By using the average rate of formation of $C_2H_2Cl_4$ during the photolysis time, and a reasonable recombination rate constant of 10^{10} l mole^{-1} s^{-1}, it can be shown that $k_{28}[CCl_2H\cdot] \sim 0.1$. A similar evaluation of the production of C_2Cl_6 and $CCl_3\cdot C_6H_5$ indicates that $k_{29}[C_6H_5\cdot]$ will be no greater than $k_{28}[CCl_2H\cdot]$. On the other hand, from other similar reactions of hydrogen atoms (34, 35), and the known ratio k_{12}/k_{13} (28), it can be estimated that $k_{12} + k_{13}$ will have a value of $\sim 10^7$ l mole^{-1} s^{-1}. It would be expected that k_{27} would be somewhat smaller than k_{13} (36), so that under the experimental conditions we estimate that

$$(k_{12} + k_{13})[CHCl_3] + k_{27}[B] \sim 10^4$$

and therefore it may be assumed that

$$[34] \qquad [H] = \frac{k_x[B^*][CHCl_3]}{(k_{12} + k_{13})[CHCl_3] + k_{27}[B]}$$

The solutions for the remaining radicals and for the rates of formation of the products are now straightforward and give, for example

$$[35] \qquad \frac{d[C_2Cl_6]}{dt} = \frac{k_{13}k_x[B^*][CHCl_3]}{(k_{12} + k_{13}) + k_{27}[B]/[CHCl_3]}$$

A considerably more bulky expression results for the rate of formation of CH_2Cl_2, whose characteristic is that the denominator contains a higher order polynomial in [B] than does [35]. Simple substitution for $k_x[B^*]$ into these equations will yield two expressions for each

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rate depending on whether $^3B^I_v$ or $^1B^I$ causes sensitization. Both possible mechanisms of energy transfer predict

(*a*) the rate of formation of CH_2Cl_2 and C_2Cl_6 have maxima with respect to benzene pressure;

(*b*) at low benzene pressure the rate of production of C_2Cl_6 and CH_2Cl_2 should be the same;

(*c*) the maxima for CH_2Cl_2 occurs at lower benzene pressures than that for C_2Cl_6.

These predictions are qualitatively confirmed by the results, except at higher benzene pressure where the experimental conditions are complicated by the formation of heavy products which deposit on the cell windows. At present most of the rate constants in the above expressions are unknown and it is, therefore, impossible to determine which energy transfer mechanism is operative. However, data are available which narrow the possibilities.

Ground state decomposition of $CHCl_3$ proceeds via molecular elimination of HCl (7) and is incompatible with our observations. The dissociation of $CHCl_3$ must then take place in an excited singlet or an excited triplet state. We have previously discussed (1) the possibilities of either of these states being responsible for the reaction. The long lifetime of the benzene triplet (37) and its greater abundance, combined with the lack of an ultraviolet absorption spectrum for $CHCl_3$ at 2 537 Å leading to a singlet state (spin allowed), would favor photosensitization by the triplet.

It is interesting to note that work in this laboratory (G. P. Semeluk and A. K. Basak, unpublished results) with CH_2Cl_2 also indicates an initial carbon–chlorine bond cleavage in photolysis, and that both the benzene- and hexafluorobenzene-photosensitized reactions proceed via a carbon–hydrogen bond rupture. The possibility that hexafluorobenzene-sensitized decomposition of $CHCl_3$ will result in a much simpler sequence of reactions, as it does for CH_2Cl_2 (38), is being investigated.

THE REACTION OF METHANESULFONIC ACID WITH SULFUR TRIOXIDE

E. A. ROBINSON AND V. SILBERBERG
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario
Received December 14, 1965

ABSTRACT

The reaction of sulfur trioxide with methanesulfonic acid has been studied by examination of the nuclear magnetic resonance (n.m.r.) and Raman spectra of solutions containing up to 0.8 stoichiometric mole fraction of SO_3.

At relatively low SO_3 concentrations the polysulfonic acid $CH_3S_2O_6H$ is formed initially and reacts with excess methane sulfonic acid to give methanesulfonic anhydride.

$$CH_3S_2O_6H + CH_3SO_3H \rightleftharpoons (CH_3)_2S_2O_5 + H_2SO_4$$

$CH_3S_2O_6H$ and CH_3SO_3H exchange protons and SO_3 rapidly and a single methyl resonance peak only is observed for these species in the n.m.r. spectrum. A separate methyl resonance is observed for $(CH_3)_2S_2O_5$ at relatively low concentrations of SO_3, but at higher concentrations the peak merges with that due to CH_3SO_3H and $CH_3S_2O_6H$ because of the rapid equilibration of $(CH_3)_2S_2O_5$ with $H_2S_2O_7$.

$$(CH_3)_2S_2O_5 + H_2S_2O_7 \rightleftharpoons 2CH_3S_2O_6H$$

At higher concentrations of SO_3 it is likely that the system contains polymers of the three series $CH_3S_{n+1}O_{3n+3}H$, $(CH_3)_2S_{n+2}O_{3n+5}$, and $H_2S_{n+1}O_{3n+4}$ in rapid equilibrium. Free SO_3 is not found in the system at concentrations less than 60 mole %.

INTRODUCTION

In previous work it was shown that, at room temperature, solutions of sulfur trioxide in sulfuric acid, fluorosulfuric acid, or chlorosulfuric acid, contain the corresponding polysulfuric acids (1, 2).

$$H_2SO_4 + nSO_3 \rightleftharpoons H_2S_{n+1}O_{3n+4}$$

$$HSO_3F + nSO_3 \rightleftharpoons HS_{n+1}O_{3n+3}F$$

$$HSO_3Cl + nSO_3 \rightleftharpoons HS_{n+1}O_{3n+3}Cl$$

With the H_2SO_4–SO_3 system direct evidence was obtained for the formation of $H_2S_2O_7$ and $H_2S_3O_{10}$ by comparison of the Raman spectra with the spectra of the isoelectronic polysulfuryl fluorides $S_2O_5F_2$ and $S_3O_8F_2$, and detailed examination of the spectra provided strong support for the formation of $H_2S_4O_{13}$ and higher polysulfuric acids (1). Similarly for the HSO_3F–SO_3 and HSO_3Cl–SO_3 systems evidence was obtained from the Raman spectra for the formation of HS_2O_6F, HS_3O_9F, HS_2O_6Cl, HS_3O_9Cl, and higher polyacids (2). The fluorine nuclear magnetic resonance (n.m.r.) spectra of solutions of SO_3 in fluorosulfuric acid were also investigated. A single ^{19}F resonance only was observed which shifted to lower field as the concentration of SO_3 was increased and which was attributed to the rapid exchange of protons and SO_3 between the various polyacids $HS_{n+1}O_{3n+3}F$ (2). Addition of polysulfuryl fluorides, such as $S_2O_5F_2$ or $S_3O_8F_2$, to solutions of SO_3 in HSO_3F gave additional fluorine resonances in the n.m.r. spectra, and there was no evidence for any exchange between the polysulfuryl fluorides and the fluoro-polysulfuric acids. Thus it was clear that polysulfuryl fluorides were not present in the HSO_3F–SO_3 system at room temperature. However, when sulfuric acid and fluorosulfuric acid were heated to 100 °C in sealed tubes for several hours the n.m.r. measurements showed that polysulfuryl fluorides $S_nO_{3n-1}F_2$ (with n at least as high as 7) were formed.

In recent work van Wazer and his co-workers (3) have shown that dimethylsulfate and SO_3 react to give a liquid mixture of methoxy-terminated polysulfates, $CH_3O(SO_3)_nCH_3$, where n has values at least as high as 9. For each species a separate line was observed in the n.m.r. spectrum.

Complex formation between organic sulfonic acids and SO_3 was first postulated by Vicary and Hinshelwood (4) who found that the rate of sulfonation of nitrobenzene by sulfur trioxide was explicable if a 1:1 complex was postulated. Later work by Wadsworth and Hinshelwood (5) gave evidence that similar complexes are probably formed between the sulfonic acids of *p*-nitrotoluene and chlorobenzene, respectively, and SO_3.

The Raman spectrum of a solution of SO_3 in methanesulfonic acid has been examined previously by Sandeman (6) who compared the spectrum with those of solutions of SO_3 in sulfuric acid. He concluded that a complex acid, $CH_3S_2O_6H$, with structure similar to that of $H_2S_2O_7$ is formed. Sandeman also examined the phase diagram of the CH_3SO_3H–SO_3 system and obtained a freezing point maximum at the composition 21% SO_3 by weight. He assumed that this was due to a complex in which two molecules of methanesulfonic acid are hydrogen bonded to each $CH_3S_2O_6H$ molecule.

The present results are interpreted to show that both the polyacid $CH_3S_2O_6H$ and methanesulfonic anhydride, $(CH_3)_2S_2O_5$, are formed at low concentrations of SO_3 and the anhydride exchanges only slowly with the other components of the system under these conditions. At higher concentrations of SO_3 the anhydride is in rapid equilibrium with $H_2S_2O_7$ and higher polysulfuric acids which result from the reaction of SO_3 with the sulfuric acid formed in [2].

At very high concentrations of SO_3 it is probable that polysulfuryl compounds of the series $CH_3S_{n+1}O_{3n+3}H$, $H_2S_{n+1}O_{3n+4}$, free SO_3, and perhaps $(CH_3)_2S_{n+2}O_{3n+5}$ are in equilibrium.

RESULTS AND DISCUSSION

The results of the n.m.r. studies interpolated at round concentrations from large scale plots of the data are shown in Table I, and Figs. 1 and 2 show the original measurements. All chemical shifts are shown in c.p.s. relative to external tetramethylsilane.

Nuclear Magnetic Resonance Spectra

Whereas in the methylsulfate–SO_3 system van Wazer and co-workers (3) observed methyl resonances due to each of the species $CH_3O(SO_3)_nCH_3$, $9 \geqslant n \geqslant 1$, in the CH_3SO_3H–SO_3 system only two methyl resonance peaks were observed at concentrations less than 36 mole % SO_3. At SO_3 concentrations greater than this the two peaks collapsed to a single peak.

Pure methanesulfonic acid has its methyl resonance at 186.5 c.p.s. (relative to tetramethylsilane). On addition of SO_3 this peak gradually shifts to lower field with increasing concentration of SO_3. In the most dilute solution studied (4.35 mole % SO_3) the peak was at 187.8 c.p.s. A second peak was found in the spectrum of this solution, in the methyl region, at 202.4 c.p.s. This can be reasonably attributed to the methyl resonance of methanesulfonic anhydride since a dilute solution of $(CH_3)_2S_2O_5$ in methanesulfonic acid gave a single methyl resonance peak at 202.0 c.p.s. in addition to the methyl resonance peak of the acid. These resonances were observed immediately on mixing (in less than ca. 5 min) and were unchanged after several days. Furthermore the peak widths at half height were less than 1 c.p.s. Moreover it has been shown (E. A. Robinson, unpublished results) by cryoscopic and conductimetric measurements that $(CH_3)_2S_2O_5$ behaves as a nonelectrolyte in CH_3SO_3H, and a solution of the anhydride in chloroform gave a single

*R = ratio of areas of $CH_3(2)$ and $CH_3(1)$ peaks = $\frac{1}{2}[(CH_3)_2S_2O_5]:([CH_3SO_3H] + [CH_3S_2O_6H])$.
†Relative to external tetramethylsilane, uncorrected for changes in diamagnetic susceptibilities.

methyl resonance at 203.0 c.p.s. (relative to internal tetramethylsilane). Thus it appears that SO_3 reacts rapidly with CH_3SO_3H to give methanesulfonic anhydride.

The shift of the methyl resonance of CH_3SO_3H to lower field (curve A, Fig. 1*a*), and the shift of the acid proton (Fig. 1*b*), which is reminiscent of the behavior of the proton resonance in the HSO_3F–SO_3, HSO_3Cl–SO_3, and H_2SO_4–SO_3 systems (1, 2), is consistent with the simultaneous formation of the polyacid $CH_3S_2O_6H$. This suggests that the initial reaction of SO_3, at low concentrations, is to give $CH_3S_2O_6H$,

[1] $$CH_3SO_3H + SO_3 \rightleftharpoons CH_3S_2O_6H,$$

and that methanesulfonic anhydride is formed as a result of the reaction

[2] $$CH_3S_2O_6H + CH_3SO_3H \rightleftharpoons (CH_3)_2S_2O_5 + H_2SO_4.$$

A single methyl resonance only is observed for the acid species CH_3SO_3H and $CH_3S_2O_6H$, which shows that there is rapid exchange of protons and of SO_3 between them. The separate peak that is observed for the anhydride implies that the equilibrium established in [2] leads to only very slow exchange of the species involved.

On further addition of SO_3 to the system the resonance peak attributed to $(CH_3)_2S_2O_5$ ($CH_3(2)$) shifts *slightly* to lower field. It is at 205.4 c.p.s. in a solution containing 36 % SO_3. It would thus seem likely that the higher anhydrides, $(CH_3)_2S_3O_8$, $(CH_3)_2S_4O_{11}$, etc., are formed in the system by comparison with, for example, the $(CH_3O)_2SO_2$–SO_3 system where the following approximate shifts were observed: $(CH_3O)_2S_2O_5$, 247.5 c.p.s.; $(CH_3O)_2S_3O_8$, 252.0 c.p.s.; and $(CH_3O)_2S_4O_{11}$, 254.1 c.p.s. (3). Over the same concentration range the lower field methyl resonance peak ($CH_3(1)$) shifts towards that of the anhydride. At 36 mole % SO_3 it is at 202.8 c.p.s. The shift in the $CH_3(1)$ resonance peak is consistent with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the formation of $CH_3S_2O_6H$, and perhaps higher polyacids which exchange protons and SO_3 rapidly among themselves but *not* with the polyanhydrides. (Both the $CH_3(1)$ and the $CH_3(2)$ resonance peaks remain sharp up to 36 % SO_3.) However, on the basis of the above interpretation exchange of SO_3 between the methyl-polysulfuric acids and the polyanhydrides would certainly have been expected since they must exchange rapidly among themselves. It must therefore be concluded that the obvious interpretation of the results is incorrect and an alternative explanation must be sought.

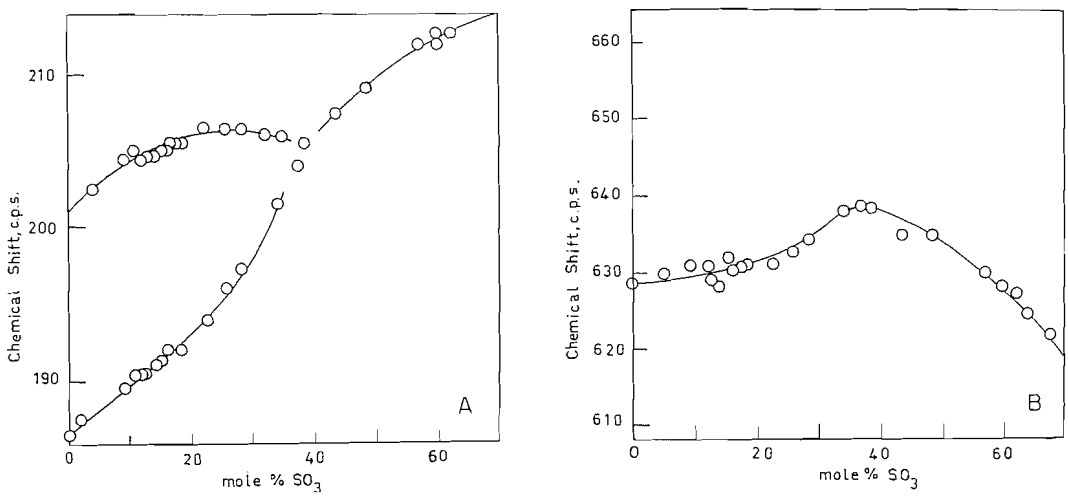

FIG. 1. Nuclear magnetic resonance shifts: (*a*) CH_3 protons, (*b*) —OH protons.

New evidence comes from the Raman spectra (see later) which significantly do not show the distinctive pattern of two lines in the 700 cm^{-1} region characteristic of the formation of a trisulfuryl compound (1) until the composition 40.2 % SO_3 is reached. Thus it would appear that trisulfuryl compounds are not present at lower concentrations in any appreciable amounts.

The difficulty appears to arise from the impossibility of using tetramethylsilane as an internal reference in this system because of its reaction.* Thus the chemical shifts quoted in Table I are uncorrected for changes in the diamagnetic susceptibilities of the solutions. Whereas the $CH_3(1)$ peak shifts quite rapidly to low field on the addition of SO_3, that due to $CH_3(2)$ shifts only very slowly to low field and indeed shows the reverse trend near 36 mole % SO_3 (Fig. 1*a*). It thus seems probable that $CH_3(2)$ is due solely to $(CH_3)_2S_2O_5$ and that its apparent shift is illusory. Indeed if we assume that this is so, and use $CH_3(2)$ as an internal reference from which to measure $CH_3(1)$ shifts, the results are explicable in terms of an equilibrium between CH_3SO_3H, $CH_3S_2O_6H$, $(CH_3)_2S_2O_5$, and H_2SO_4 at concentrations less than 36 mole % SO_3.

If reaction [1] followed by reaction [2] were the only reactions occurring then R (the ratio of the areas of the $CH_3(2)$ and $CH_3(1)$ peaks) would be expected to change as in curve A (Fig. 2). Only at low SO_3 concentrations are the results consistent with this model which supports writing reaction [2] as an equilibrium. If we assume that all the SO_3 in the system reacts with CH_3SO_3H to give $CH_3S_2O_6H$ which is then partly converted to $(CH_3)_2S_2O_5$ the value of R can then be used to calculate the concentrations of the species in the system (Table II). These give a value for the equilibrium constant of reaction [2] of 0.6 ± 0.1.

**Methanesulfonyl fluoride was found to be equally unsuitable.*

§Relative to $(CH_3)_2S_2O_5$.
‖$[CH_3SO_3H] + [CH_3S_2O_6H]$.

The chemical shifts for $CH_3(1)$ measured from $CH_3(2)$ are shown in Table II. If $CH_3(1)$ is due solely to the exchange between CH_3SO_3H and $CH_3S_2O_6H$, then we can write

$$[3] \qquad [CH_3SO_3H]\delta_1 + [CH_3S_2O_6H]\delta_2 = ([CH_3SO_3H] + [CH_3S_2O_6H])\delta,$$

which is more conveniently expressed as

$$[4] \qquad ([CH_3SO_3H] + [CH_3S_2O_6H])(\delta - \delta_1) = [CH_3S_2O_6H](\delta_2 - \delta_1),$$

where δ is the observed chemical shift, δ_1 is the chemical shift of CH_3SO_3H, and δ_2 is the chemical shift of $CH_3S_2O_6H$ (all shifts relative to that of $(CH_3)_2S_2O_5$ at 202.0 c.p.s.). Thus a plot of the left-hand side of eq. [4] versus $[CH_3S_2O_6H]$ should be a straight line with slope equal to $(\delta_2 - \delta_1)$. The data is shown in Table II and is plotted in Fig. 3. It gives a good straight line with a slope of 21 c.p.s., i.e. $\delta_2 = 207.5$ c.p.s. The magnitude of this chemical shift seems reasonable by comparison with those of the CH_3 groups in CH_3SO_3H, 186.5; $CH_3SO_2CH_3$, 178.0; and $(CH_3)_2S_2O_5$, 202.0 c.p.s. Thus below 36 mole % SO_3 it seems very likely the CH_3SO_3–SO_3 system contains principally the species CH_3SO_3H, $CH_3S_2O_6H$, $(CH_3)_2S_2O_6$, and H_2SO_4 in equilibrium.

At 37 mole % SO_3 the $CH_3(1)$ and $CH_3(2)$ peaks collapse into a single broad peak which continues to shift to lower field as the concentration of SO_3 increases. Clearly some additional species is now present which enables the exchange process between $CH_3S_2O_6H$ and $(CH_3)_2S_2O_5$ to become rapid. The most likely species is $H_2S_2O_7$ formed by the reaction of SO_3 with the H_2SO_4 resulting from reaction [2], i.e.

$$[5] \qquad (CH_3)_2S_2O_5 + H_2S_2O_7 \rightleftharpoons 2CH_3S_2O_6H.$$

Above 40 mole % SO_3 the single CH_3 resonance becomes sharp again and continues to move to lower field, showing that exchange is now rapid. It can probably now be attributed

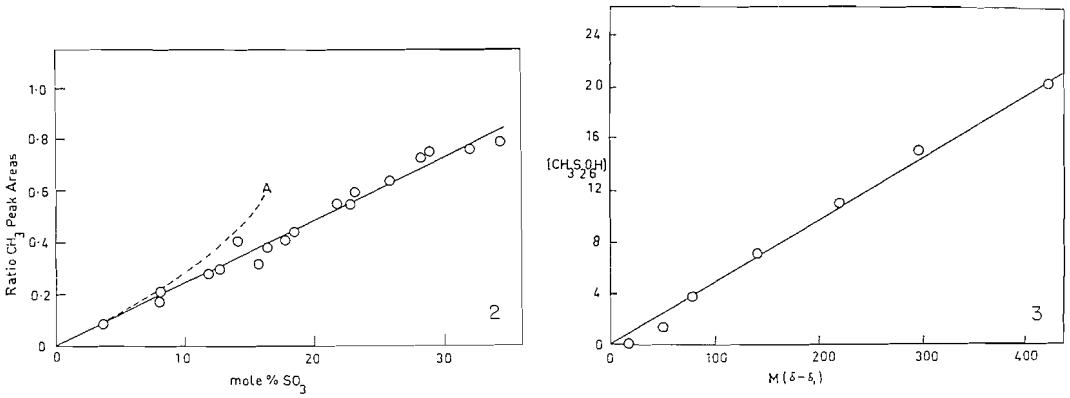

FIG. 2. Ratio of areas (R) of high- and low-field CH_3 peaks.
FIG. 3. Chemical shift plot to give $\delta_{CH_3S_2O_6H}$.

to a mixture of polyacids, $CH_3S_{n+1}O_{3n+3}H$, and polyanhydrides, $(CH_3)_2S_{n+2}O_{3n+5}$, in rapid equilibrium with each other and with polysulfuric acids, $H_2S_{n+1}O_{3n+4}$.

When samples were heated to 100 °C for several hours no change occurred in their n.m.r. spectra.

Raman Spectra

The above conclusions are supported by an analysis of the Raman spectra of solutions of SO_3 in CH_3SO_3H (Table III).

Sandeman (6) compared the Raman spectrum of a mixture of composition $3CH_3SO_3H$-SO_3 to that of disulfuric acid and showed that the spectra were similar in many respects. He claimed that these similarities support the proposal that $CH_3S_2O_6H$ is formed in the system. However, since many of the features of the spectra of $CH_3S_2O_6H$, structure I, and methanesulfonic anhydride, structure II, are expected to be similar a very careful examination of the results is necessary in order to unambiguously determine the nature of the products of the reaction.

I II

No evidence was found in the present work for the complex $CH_3S_2O_6H.2CH_3SO_3H$.

In the most dilute SO_3 solution studied (9.5 mole % SO_3) (Table III), new Raman lines were observed at 150, 263, 310, 370, 567, 661, 798, 890, 913, 1 200, 1 230, 1 380, and 2 775 cm^{-1} in addition to the frequencies of methanesulfonic acid. The new lines are to be compared with lines in the Raman spectrum of methanesulfonic anhydride (ref. 7 and E. A. Robinson, unpublished results) at 264, 308, 359, 572, 664, 800, 886, 1 209, and 1 384 cm^{-1}, and clearly show that this species is formed in the CH_3SO_3H–SO_3 system. The additional lines at 913, 1 230, and 2 775 cm^{-1} may probably be attributed to the polyacid $CH_3S_2O_6H$: 913 cm^{-1}, S—OH stretch; 1 230 cm^{-1}, SO_2 symmetric stretch; 2 775 cm^{-1}, C—H stretch. Many of the frequencies attributed to $(CH_3)_2S_2O_5$ are also doubtlessly common to $CH_3S_2O_6H$.

*Relative intensities in parenthesis.
†Robinson and Silberberg, unpublished experiments.

Additional lines appear in the spectrum of the 25.9 mole % SO_3 solution at 564, 1 450, and 2 846 cm^{-1} and in the spectrum of the 40.2 mole % SO_3 solution at 175, 230, 735, 955, and 1 240 cm^{-1}. The appearance of two lines near 700 cm^{-1} (695 and 735 cm^{-1}) is diagnostic of a trisulfuryl compound, and additional low frequency lines (cf. 170 and 230 cm^{-1}) are also expected for such a species (1). The absorption at 950 cm^{-1} can probably be assigned to the S—OH stretching frequency of $CH_3S_3O_9H$ and 1 240 and 1 460 cm^{-1} to the SO_2 symmetric and asymmetric stretching frequencies of this species.

In the 60.1 mole % SO_3 solution a very sharp line, which is diagnostic of SO_3 monomer (1), appears weakly at 1 075 cm^{-1} and shows that monomeric SO_3 is present in low concentration. There is no evidence that free SO_3 is present in any of the solutions of lower concentration. The spectrum of the 88.9 mole % SO_3 solution is complex and shows many

For personal use only.

additional lines that are diagnostic of SO_3 monomer and trimer (1). Presumably polymers higher than $CH_3S_2O_6H$ and $(CH_3)_2S_2O_5$ are present at relatively high mole % SO_3 since the lines assigned to the SO_2 stretching frequencies gradually move to higher frequencies (1 253 and 1 433 cm^{-1} in 88.9 mole % SO_3) (1).

EXPERIMENTAL

Sulfur trioxide was obtained by distillation of Sulphan B (Allied Chemical Corporation).

Methanesulfonic acid, m.p. 19.85 °C, was prepared by distillation of the commercial acid under reduced pressure followed by equilibration of the slightly aqueous acid so obtained with methanesulfonic anhydride.

Methanesulfonic anhydride, m.p. 70 °C, was obtained by dehydration of methanesulfonic acid. CH_3SO_3H and thionyl chloride were refluxed together for several hours and the excess thionyl chloride distilled off. The anhydride was recrystallized from anhydrous ether (8).

All the CH_3SO_3H–SO_3 solutions were made up by weight and they were handled in a dry box. Nuclear magnetic resonance measurements were performed at 35 °C on tightly stoppered samples with a Varian A-60 spectrometer. The Raman spectra were recorded photographically with a Hilger E 612 spectrometer in conjunction with a Toronto mercury arc lamp. The spectra were measured by comparison with a standard iron arc by means of a Joyce Loebl microdensitometer.

ACKNOWLEDGMENTS

Professor R. J. Gillespie and Mr. J. Bacon of McMaster University are thanked for helpful discussions, and the latter for his technical assistance in preliminary measurements.

We are indebted to the National Research Council of Canada, the Ontario Research Foundation, the Allied Chemical Corporation, and the University of Toronto for financial assistance.

KINETICS OF THE ABSTRACTION OF HYDROGEN ATOMS FROM HYDROGEN SULFIDE BY TRIFLUOROMETHYL RADICALS

N. L. ARTHUR AND T. N. BELL
Department of Physical and Inorganic Chemistry, University of Adelaide, South Australia
Received January 27, 1966

Trifluoromethyl radicals generated from the photolysis of hexafluoroacetone abstract hydrogen atoms from hydrogen sulfide.

$$CF_3 + H_2S \rightarrow CF_3H + SH$$

The rate constant of this reaction measured by comparing the rate with that for the recombination of trifluoromethyl radicals ($k = 2.3 \times 10^{13}$ cc mole^{-1} s^{-1}) is given by,

$$k = 10^{11.65\pm0.16}\, e^{-(3880\pm260)/RT} \text{ cc mole}^{-1}\text{ s}^{-1}.$$

INTRODUCTION

Free radicals interact rapidly with the S—H hydrogen atom of thiols, this transfer reaction being of importance in polymer chemistry. A knowledge of the rate constants of this type of reaction is of interest. The rate constant for the abstraction of hydrogen from HSH by trifluoromethyl has been measured and is compared with available information on the relevant systems, CH_3–HBr (2), CF_3–HBr (3), CH_3–HSH (4, 5), where the bond being attacked in the substrate molecule has similar properties.

EXPERIMENTAL

Materials

(*a*) Hydrogen sulfide, generated from ferrous sulfide and sulfuric acid, was fractionated through traps at −78°, −96°, −145°, and −196°. The fraction collecting at −145° was thoroughly degassed and stored in a blackened bulb.

(*b*) Hexafluoroacetone from a cylinder (Allied Chemical Corporation) was fractionated as above. The fraction condensing at −145° was thoroughly degassed at that temperature to remove traces of trifluoromethane and hexafluoroethane.

Apparatus

Photolysis experiments were carried out in a quartz reaction vessel (illuminated volume 173 ml) fitted with plane parallel windows which was suspended in a tubular furnace (37 cm long) fitted with quartz end windows. Radiation was through a Hanovia S500 mercury arc filtered with Corning filters, color specification 0-53 and 7-54. Light intensity was measured with an RCA 935 photocell and spot galvanometer. Temperature measurement was through six chromel–alumel thermocouples attached along the cell walls. Pressures in the reaction vessel were measured with a Pyrex spiral gauge used as a null instrument. The reaction vessel was connected through stainless steel Hoke 413 valves to the analytical and storage sections. The analytical section was fitted with Springham greaseless stopcocks.

In operation, either fresh mixtures of the two reactants or measured quantities of each reactant admitted singly were introduced into the reaction vessel. In the latter case a mixing time of 15 min was allowed.

After reaction the non-condensible products were measured in a gas burette and subsequently analyzed by gas chromatography. The condensible products were collected in a U trap, allowed to warm up, and then swept onto a ¼ in. absorption column sectioned with 30 cm alumina, 9 cm silver nitrate – ethylene glycol on firebrick, and 9 cm alumina, all 60–80 mesh. Nitrogen carrier at a flow rate 20 ml/min was used. The eluent was collected during a time of 10 min in a trap packed with glass wool. This trap was then evacuated and the eluent was transferred into a side arm, which could be sealed off ready for gas chromatographic analysis.

Using this method all reactants and products except trifluoromethane and hexafluoroethane were absorbed on the column. In the course of time two extra peaks appeared in the chromatographic analysis, at which stage hydrogen sulfide had reached the silver nitrate packing as determined by blackening of this phase. Removal of the silver nitrate packing resulted in elimination of these extra peaks whence it was concluded that a reaction between silver nitrate and hydrogen sulfide was occurring, possibly giving oxides of nitrogen. Consequently the absorption column was replaced by one consisting of alumina alone, this absorbent being sufficiently retentive to absorb the small quantities of hydrogen sulfide used.

Gas chromatographic analysis of the non-condensible fraction was carried out on a charcoal 2 m column (60–80 mesh) at 25°. Hydrogen was detected using nitrogen as carrier, and carbon monoxide was estimated with hydrogen carrier (flow rate 50 ml/min).

After the treatment described above, the condensible products were analyzed for CF_3H and C_2F_6 on an alumina column (60–80 mesh, length 1 m) with hydrogen carrier at a flow rate of 60 ml/min and temperature of 25°.

RESULTS AND DISCUSSION

The photolysis of hexafluoroacetone is described (6) by the equation

[1] $$(CF_3)_2CO \rightarrow 2CF_3 + CO,$$

the actual mass balance C_2F_6/CO being approximately 0.95 under our experimental conditions (7). The slight discrepancy may well be due to the addition of trifluoromethyl radicals to the carbonyl bond to yield $(CF_3)_3COCF_3$ (8). On the basis of the formation of trifluoroacetyl halides when hexafluoroacetone is photolyzed in the presence of bromine and chlorine, Tucker and Whittle concluded that the primary photolytic step yields the trifluoroacetyl radical (9). The instability of this radical is such, however, that in the absence of large amounts of radical scavengers, eq. [1] adequately describes the photolysis of hexafluoroacetone. The product of trifluoroacetyl radical scavenging in this work, namely trifluoroacetaldehyde, was not detected, but because of the difficulty of the analysis this does not constitute proof of the absence of this reaction.

A possible complication in the present work through the photolysis of hydrogen sulfide was considered; accordingly, hydrogen sulfide at 14 mm and 95° was photolyzed for 45 min with the filtered radiation used in the rate determinations. No hydrogen was detected; hence the photolysis of hydrogen sulfide may be ignored.

Experiments wherein hydrogen sulfide (1 mm) and hexafluoroacetone (39 mm) were heated for 9 min at 94°, were carried out to check for a possible dark reaction. Analyses for CO, C_2F_6, and CF_3H proved negative.

The volatile products from the photolysis of HFA/H_2S mixtures were analyzed by the method outlined in the Experimental section. The non-condensible products contained hydrogen and carbon monoxide, while the volatile products passing through the alumina absorption column consisted of hexafluoroethane and trifluoromethane. The efficiency of the abstraction process was such that the hexafluoroethane only became measurable at low concentrations of hydrogen sulfide.

The observed products may be accounted for in terms of the following reactions.

[1] $$(CF_3)_2CO \xrightarrow{h\nu} 2CF_3 + CO$$

[2] $$2CF_3 \rightarrow C_2F_6$$

[3] $$CF_3 + H_2S \rightarrow CF_3H + SH$$

[4a] $$SH + SH \nearrow H_2 + S_2$$

[4b] $$SH + SH \searrow H_2S + S$$

Darwent and Roberts (10), from work on the photolysis of hydrogen sulfide, concluded that $k_{4a}/k_{4b} \sim 0.15$.

The expected mass balance,

$$CO = \tfrac{1}{2}CF_3H + C_2F_6,$$

is seen from Table I not to hold, there being a deficiency of CF_3 radicals of some 18%. The formation of $(CF_3)_3COCF_3$ cannot account for this deficiency, but the efficiency of reaction [3] will lead to the formation of a relatively large number of SH radicals. Thus the occurrence of a hetero radical recombination step is highly probable.

100.5	6	1.04	43.6	433	17	9.3	658	2.678

*nm = not measured.

[5] $$CF_3 + SH \rightarrow CF_3SH$$

If reaction [5] plays a significant part in the reaction scheme, the expected mass balance is given by,

$$CO = \tfrac{1}{2}CF_3H + C_2F_6 + \tfrac{1}{2}CF_3SH,$$

which would account for $CO > \frac{1}{2}CF_3H + C_2F_6$ in these experiments.

If the CF_3H and C_2F_6 arise solely from [2] and [3] then,

$$k_3/k_2^{1/2} = R_{CF_3H}/R_{C_2F_6}^{1/2}[H_2S].$$

Thus measurement of R_{CF_3H} and $R_{C_2F_6}$ leads to a determination of $k_3/k_2^{1/2}$. In the absence of data to the contrary, it is assumed that the disproportionation reaction corresponding to [5] can be neglected as a source of CF_3H.

The results of the rate measurements are shown in Table I. A maximum temperature of 100° and maximum pressure of hydrogen sulfide of 1 mm ensured sufficient hexafluoroethane for analysis. Even so, the % reaction based on the ratio of the amount of CF_3H formed to H_2S present was somewhat higher than normal, being 5–8%. An Arrhenius plot of log $k_3/k_2^{1/2}$ against $1/T$ is shown in Fig. 1. Evaluation of the data by the method of least

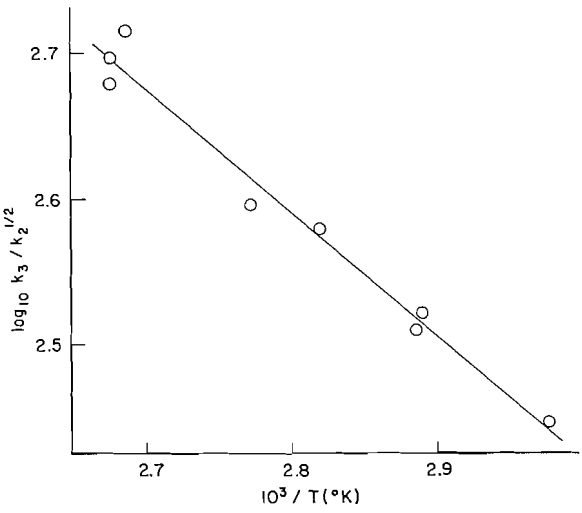

FIG. 1. Arrhenius plot of log $k_3/k_2^{1/2}$ against $1/T$.

For personal use only.

squares leads to $E_3 - \frac{1}{2}E_2 = 3.88 \pm 0.26$ kcal mole^{-1}. Using the value of $k_2 = 2.3 \times 10^{13}$ cm^3 mole^{-1} s^{-1} derived by Ayscough (1) for the recombination of trifluoromethyl radicals, and assuming $E_2 = 0$, leads to $\log A_3 = 11.65 \pm 0.16$. Thus the rate constant for the abstraction of H atoms from H_2S by CF_3 radicals is given by,

$$k_3 = 10^{11.65 \pm 0.16}\, e^{-(3880 \pm 260)/RT} \text{ cc mole}^{-1} \text{ s}^{-1}.$$

Using a collision diameter of 5 Å for CF_3 (assumed), and 4.6 Å for H_2S (calculated), the collision number for CF_3–H_2S collisions is 2.7×10^{14} cc mole^{-1} s^{-1}. Thus a steric factor of 1.6×10^{-3} is operative for reaction [3]. This is similar to the steric factors involved in hydrogen abstraction from many organic systems, and may be considered normal.

The high rate of reaction is thus due to the low activation energy which is considerably less than that for similar reactions of hydrocarbons. The ease of removal of the S—H hydrogen is well known, and Kerr and Trotman-Dickenson (11) have estimated an activation energy range of 4.9 to 5.6 kcal for removal of this hydrogen by methyl radicals from a series of thiols (*t*-butyl to methyl).

The reaction of methyl with hydrogen sulfide is more directly comparable, and Imai and Toyama have made two determinations of this abstraction. The first (4), based on product analysis from the acetone–H_2S system, gave $k_6 = 10^{11.4}\, e^{-2600/RT}$ cc mole^{-1} s^{-1}.

[6] $$CH_3 + H_2S \rightarrow CH_4 + SH$$

The second determination (5), where acetaldehyde was photolyzed in the presence of hydrogen sulfide, may be considered less reliable in that an overall rate of reaction based on pressure change was measured. The Arrhenius parameters of [6] were determined in comparison with the abstraction of hydrogen from acetaldehyde, reaction [7].

[7] $$CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO$$

A number of determinations of [7] have been made (12) allowing a range of possible values for E_6 between 2.8 and 4.0 kcal; A_6/A_7 was given as 1.7 ± 0.5. Reasonable agreement between the values for k_6 derived from the two methods is apparent, and the values are of the same order of magnitude as that for abstraction by trifluoromethyl.

Hydrogen bromide has a bond length 1.41 Å and bond strength 88 kcal; hydrogen sulfide has a bond length 1.34 Å, but its bond strength is a matter of some conjecture, reported values being: 92 ± 2 (13*a*), 95.3 (13*b*), 89 ± 4 (13*c*), $\leqslant 90.6$ (13*d*). A figure around 90 kcal might appear reasonable in view of these results. Thus it would be in order to compare hydrogen abstraction from HBr with that from H_2S, bearing in mind the different polarity of the H—Br bond compared with the S—H bond. Dipole moments are $\mu_{HBr} = 0.78 \times 10^{18}$ e.s.u. and $\mu_{H_2S} = 1.1 \times 10^{18}$ e.s.u.; hence for the S—H component $\mu = 0.79 \times 10^{18}$ e.s.u.

Assuming that iodine atom abstraction from I_2 has zero activation energy, Tucker and Whittle (3) find an activation energy for [8] of 3 kcal,

[8] $$CF_3 + HBr \rightarrow CF_3H + Br,$$

while for the corresponding methyl reaction, Fettis and Trotman-Dickenson (2) find $E_9 = 1.4$ kcal.

[9] $$CH_3 + HBr \rightarrow CH_4 + Br$$

The order of the magnitudes of the activation energies for [8] and [9] are very similar to those for the corresponding abstractions from H_2S. Compared to hydrogen abstraction from hydrocarbons, there is an inversion of the order of activation energies for methyl and

trifluoromethyl attack. This is considered (3) to arise through the polarity of the HBr system causing a repulsion with the attacking CF_3 radical.

If $E_{CH_3-H_2S} \sim 2.6$ kcal and $E_{CF_3-H_2S} \sim 3.9$ kcal, this argument could well be applied in the H_2S system.

RELATION BETWEEN ELECTRONS AND HOLES, AND THE VECTOR-COUPLING COEFFICIENTS FOR $p^m f^q$ AND $d^n f^q$ CONFIGURATIONS

GULZARI L. MALLI
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received January 25, 1966

ABSTRACT

The electrostatic energy of an atomic state arising from a configuration involving holes differs by ΔW from the energy expression of the same state arising from the configuration involving electrons where ΔW can be expressed in terms of Slater's integrals.

General formulas for ΔW are given for the $p^m f^q$ and $d^n f^q$ configurations. In addition, the vector-coupling (VC) coefficients useful for atomic self-consistent field (SCF) calculations are presented for all the states arising from the $p^m f^q$ and $d^n f^q$ configurations.

THEORETICAL DEVELOPMENT

Shortley (1) has shown that, aside from an array of coefficients common to the entire configuration, the energy expression of a state belonging to the configuration $l^{4l+2-N} l'^{4l'+2-N'}$ (involving holes) is given by the same equation as that for the *same* state arising from the configuration $l^N l'^{N'}$ (involving electrons); where N and N' are the number of electrons (occupation numbers) in the (nl) and (n'l') shells respectively.

In a previous publication (2) general formulas were given for these arrays of coefficients for atomic configurations consisting of all the possible combinations of s, p, and d shells, and for a single f shell.

In this section, we give the general formulas for any combination of p and f shells, and d and f shells. The necessity for considering the pf and df shells arises from the observation of Condon and Shortley (3) that 4f6p and 4f5d configurations occur for La(II).

For general theoretical development and notation we refer the reader to the previous publication (2).

For brevity, if we consider an atomic configuration then the energy expression of an atomic state (4) ^{2S+1}L is expressed as

$$E(^{2S+1}L) = E_{\text{Core}} + E_{\substack{\text{Core}\\ \text{open}}} + E_{\text{O}} + W(^{2S+1}L). \qquad [1]$$

$W(^{2S+1}L)$ is the only term which distinguishes the various states arising from the same configuration. Expressions for all the terms are given in the previous publication (2).

Let us now consider the configuration where *holes replace electrons in open shells only*, and the closed shell core is arbitrary; then for the same atomic state viz ^{2S+1}L the energy expression $E(^{2S+1}L)$ can be expressed by an equation analogous to eq. [1].

The term $\bar{W}(^{2S+1}L)$ depends upon the state only; and so if we define

$$\Delta W = \bar{W}(^{2S+1}L) - W(^{2S+1}L), \qquad [2]$$

we obtain

$$\Delta W = \sum_{k\neq 0}^{2(l_i,l_j)<} \Delta f^k F^k(n_i l_i, n_j l_j) - \sum_{k=|l_i-l_j|}^{l_i+l_j} \Delta g^k G^k(n_i l_i, n_j l_j). \qquad [3]$$

The ΔW of eq. [3] can be derived by evaluating the *difference* between the energies of *any two corresponding states* of the configuration with electrons and holes; however, a very convenient *state* to choose for this purpose is the state of highest total angular momentum

and highest multiplicity (in that order) since its wave function can be represented by a single Slater determinant. Thus it was found by a method analogous to that of a previous paper (2) that ΔW for $p^m f^q$ and $d^n f^q$ can be represented by *two* very simple formulas, namely:

$$[4] \quad \Delta W(p^{6-m}f^{14-q}) = (m-3)[(2/5)F^2(pp) + (3/5)G^2(pf) + (4/9)G^2(pf)] + (q-7)[(4/15)F^2(ff) + (2/11)F^4(ff) + (100/429)F^6(ff) + (9/35)G^2(pf) + (4/21)G^4(pf)]$$

VECTOR-COUPLING COEFFICIENTS

In a previous paper (5) general formulas were derived for the vector-coupling (VC) coefficients useful in atomic self-consistent-field (SCF) calculations; and tables of the (VC) coefficients for all the states arising from any combination of s, p, and d shells and a single f shell were prepared and are available elsewhere (6).

For personal use only.

We refer the reader to the paper (5) mentioned above for further details. We merely quote here the results; namely, that the vector-coupling coefficients $J_{\lambda\mu\nu}$ and $K_{\lambda\mu\nu}$ are given by the following expressions:

$$[6] \qquad \begin{cases} J_{\lambda\mu 0} = 0, \\ J_{\lambda\mu\nu} = -f^{\nu}(\lambda,\mu)/N_{\lambda}N_{\mu}, \quad \nu \neq 0 \end{cases}$$

$$[7] \qquad \begin{cases} K_{\lambda\lambda 0} = A_{\lambda\lambda 0} - 2/N_{\lambda}, \\ K_{\lambda\lambda\nu} = A_{\lambda\lambda\nu} + 4f^{\nu}(\lambda,\lambda)N_{\lambda}^{2}, \quad \nu \neq 0 \\ K_{\lambda\mu\nu} = A_{\lambda\mu\nu} + 2g^{\nu}(\lambda,\mu)/N_{\lambda}N_{\mu}, \quad \lambda \neq \mu \end{cases}$$

where the coefficients $A_{\lambda\mu\nu}$ are defined (7) as follows: viz

$$[8] \qquad A_{\lambda\mu\nu} = \frac{A_{\lambda+\mu-\nu}\, A_{\mu+\nu-\lambda}\, A_{\lambda+\nu-\mu}}{(\lambda+\mu+\nu+1)A_{\lambda+\mu+\nu}}$$

and

$$A_{\rho} = \frac{\rho!}{[(\rho)!]^{2}}$$

where ρ is always an even integer.

The eqs. [6] through [8] were used to derive the coefficients $J_{\lambda\mu\nu}$ from existing tabulations (3) of the Slater coefficients $f^{\nu}(\lambda,\mu)$ and $g^{\nu}(\lambda,\mu)$ for the pf and df configurations. The Slater coefficients for p^5f^{13} and d^9f^{13} were obtained from those of pf and df respectively by using the relations [4] and [5] respectively.

The results for the p^mf^q and d^nf^q configurations are presented in Tables I–VIII.

IONIZATION POTENTIALS OF ALKYL FREE RADICALS AND *n*-ALKANES THROUGH $C_{17}H_{36}$ BY ENERGY-CALIBRATED MOLECULAR ORBITAL METHODS[1]

CHARLES E. MELTON AND HUBERT W. JOY

Chemistry Division and Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

Received February 9, 1966

ABSTRACT

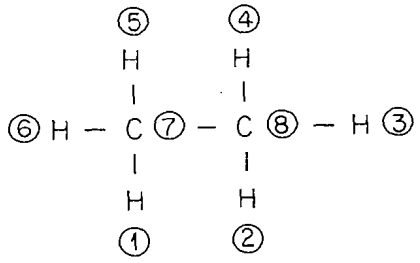
Ionization potentials are calculated by simple energy-calibrated molecular orbital techniques for the normal alkanes through $C_{17}H_{36}$ and for some normal and branched alkyl free radicals. A model is formulated which allows the computations to be extended to extremely large molecules by using "radical" orbitals as well as atomic orbitals in the expansion scheme. Auto-ionization levels as well as ionization potentials are calculated for the radicals. Computed and observed values are in good agreement where recent experimental data are available.

INTRODUCTION

Molecular orbital (MO) approaches to the properties of saturated hydrocarbons have been summarized recently by Pople and Santry (1), and some new calculations of their ionization potentials by the bond orbital (BO) method of Hall (2) have recently been made by Fueki (3). However, the reliability of these and other calculations and the validity of the models on which they are based is open to some question because their calibrations and comparisons were made on older experimental data which is well known to be of poor quality. In recent years several new and improved experimental techniques (4–8) have been used to obtain ionization potentials which may be accurate enough to eliminate some of the various models (9–13). Hence another semiempirical calculation seems not out of place, particularly if it uses new models and techniques.

In previous publications we have described a general model and a simple energy-calibrated molecular orbital scheme which was used to calculate ionization potentials and excitation levels for several free radicals (14), and ionization potentials for some simple halides (15). In this work we present similar results for some other free radicals, and the results of an extension of the approach to the ionization potentials of normal alkanes, this latter scheme being the same as the one applied to the halides. We consider the work an effort to determine the limits of reliability of the very simplest molecular orbital ideas in a context where the most adequate (obtained by least-squares fitting to experimental data on a computer) values of its parameters are used, and where attention is restricted to only one molecular property. We do not propose it as a contribution to molecular orbital theory per se; we offer it instead as a practical technique which we hope will provide good values of molecular orbital parameters and useful values of observable molecular properties.

MODELS



We here outline the structure of the secular equations which we used in the calculations on the *n*-alkanes, and the halides (15). The models for the radicals have already been described (14). Our problem is to assign values to the matrix elements of the usual (16) LCAO–MO (linear combination of atomic orbital – molecular orbital) secular equation

$$|H_{ij} - S_{ij}E| = 0 \qquad i,j = 1, \ldots, N,$$

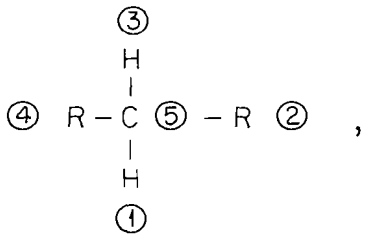
where $H_{ij} = \int \chi_i H \chi_j \, d\tau$, $S_{ij} = \int \chi_i \chi_j \, d\tau$, and χ_i is one of an N-membered set of atomic orbital wave functions, and H is some effective one-electron hamiltonian, in such a way as to obtain the minimum number of adjustable parameters and the minimum adjustment of them which will adequately correlate the ionization potentials of a set of similar molecules. After some experimentation with several physically more appealing alternatives we found that a model which takes the molecules to be planar and which invokes only one orbital per constituent atom is actually the most suitable for obtaining a set of transferable parameters. Within this model we use the ordinary approximations of zero off-diagonal overlap ($S_{ij} = \delta_{ij}$) and zero nonadjacent hamiltonian interaction to allow the secular equation for any n-alkane to be made up from seven different non-zero elements, all of which are found in the calculation for ethane,

,

whose secular equation is here of order 8. In an effort to give the maximum physical significance to the molecular orbital parameters

$$\alpha_i \equiv H_{ii} = \int \chi_i H \chi_i \, d\tau \quad \text{(coulomb integral)}$$



and

$$\beta_{ij} \equiv H_{ij} = \int \chi_i H \chi_j \, d\tau \quad \text{(resonance integral)},$$

we recognize that four of them may be identified as "independently known physical properties" and assigned fixed values, $\alpha_H = \alpha_1 = \ldots = \alpha_6$ = ionization potential of hydrogen, $\alpha_C = \alpha_7 = \alpha_8$ = ionization potential of carbon, $\beta_{CH}{}^0 = \beta_{17} = \ldots = \beta_{67}$ = C—H bond dissociation energy, $\beta_{CC}{}^0 = \beta_{78}$ = C—C bond dissociation energy. Thus the three allowed non-bonding interactions become the only adjustable parameters, $\beta_{HH}{}^1 = \beta_{16} = \ldots = \beta_{56}$ = interaction of adjacent hydrogens on the same carbon, $\beta_{HH}{}^2 = \beta_{12} = \beta_{45}$ = interaction of adjacent hydrogens on neighboring carbons, $\beta_{CH}{}^1 = \beta_{18} = \ldots = \beta_{58}$ = interaction of a hydrogen with an adjacent carbon. Values of these adjustable parameters are determined by the energy-calibration techniques (14), wherein the energy of the highest occupied molecular orbital is made equal to the (negative of the) ionization potential of the molecule used for calibration. We have in fact found a value for $\beta_{HH}{}^1$ from calibration on methane and values for $\beta_{HH}{}^2$ and $\beta_{CH}{}^1$ from calibration on ethane. These parameters are now fixed at this point and no further adjustments in them are made in treating the rest of the n-alkanes.

To try to keep the size of the secular equations within bounds when extending the approach to larger n-alkanes we have invoked the approximation of representing the molecular orbitals as linear combinations of atomic and "radical" orbitals (LCARO), where we introduce radical orbitals to replace hydrogen orbitals as needed. For example, we may treat pentane as methane with ethyl radicals in place of two of the hydrogens,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and make a calibration run to determine $\beta_{HR}^1 = \beta_{12} \ldots = \beta_{14}$ = interaction of hydrogen and ethyl on the same carbon, using for $\alpha_R = \alpha_2 = \alpha_4$ = ionization potential of ethyl, either an experimental or energy-calibrated value for the radical, and taking $\beta_{CR}^0 = \beta_{CC}^0$. Then, as usual, once a value for the interaction is found in one simple case it is fixed for all other cases. Nonane may be treated in a similar manner as methane with two attached butyl radicals. Thus the LCARO approximation greatly extends the upper limit on the size of molecules for which these calculations can be made. One merely needs to make calibration runs on the constituent radicals to find α_R values and on the first members of a series to find β_{HR}^1 values.

In the calculations on the halides (15) we also used planar models with one atomic orbital per constituent atom, and took ionization potentials for α values and bond dissociation energies for bonding β values. We made five calibration runs to obtain the non-bonding β values β_{HH}^1, β_{FF}^1, β_{ClCl}^1, β_{HF}^1, β_{HCl}^1, and assumed $\beta_{FCl}^1 = \beta_{ClCl}^1$.

In the next section we give our computed simplest-planar-model ionization potentials and our corresponding best sets of transferable molecular orbital parameters. We note here that, in every case we tried, more complex models which removed the restriction of planarity, or which allowed for non-nearest neighbor interactions, or which invoked more than one orbital per constituent atom or radical, led to sets of parameters which were significantly less transferable.

RESULTS AND DISCUSSION

In Table I we list, for the radicals (14), halides (15), and *n*-alkanes, the molecular orbital parameter values which were used as inputs to our calculations and those which were obtained as outputs from the calibration runs. In the calculations on the radicals we used several different values of α_C corresponding to various auto-ionization levels in carbon to obtain, as before (14), possible auto-ionizations in the radicals. In the other calculations we used only the lowest ionization potential of carbon. We were unable to find a single set of non-bonding H—H interactions common to all three cases, but this is not unexpected since these interactions would seem to be most dependent on intramolecular environment. For convenience in computation and tabulation we have made all elements (and thus all roots) in the secular equations positive (instead of negative, ref. 14). This does not affect the results except in a shift of the energy scale.

Alkyl Radicals

Calculated ionization potentials and auto-ionization levels for *n*-pentyl, *s*-propyl, *i*-butyl, *s*-butyl, and *t*-butyl free radicals are given in Tables II–VI together with available experimental results (5, 17). We also show all roots of the secular equations for each different value of α_C. They represent the ionization spectra as predicted by our models. The calculated values for ionization potentials tend to be lower than the electron impact values obtained by conventional techniques. This is not surprising, since experimental

values obtained by electron impact by conventional techniques are usually higher than the "true" or adiabatic ionization potentials. Experimental (obtained by RPD (retarding potenial difference)) (5, 8) and calculated auto-ionization levels for *s*-propyl are in excellent agreement over the limited range of the experimental data.

Normal Alkanes

Ionization potentials for the normal alkanes through heptadecane are given in Table VII. The calculated values are in excellent agreement with experimental ionization potentials measured by photon impact (18, 19) over the limited range of the experimental values. Electron impact values are not tabulated since most of the available data obtained by conventional techniques (20) tend to be higher and less reliable than the photon impact

data. Results from these calculations, for the heavier alkanes, indicate that the ionization potential for the homologous series decreases very slowly with increasing mass above decane.

CONCLUSIONS

It is interesting to compare our results with Fueki's (3), which were obtained from Hall's (2) "linear combination of bond orbital" (LCBO) (or "equivalent orbital") approach (21) (Table VIII). At first glance it would seem that there is little to choose between LCAO

and LCBO techniques, but it must be remembered that it is usually more difficult to give an "independent" physical interpretation to, as well as to find adequate values for, the α's and the β's when they are thought of as bond interactions rather than atom interactions. The LCBO α for a C—H bond must be related to the observed first ionization potential

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

and an estimated second ionization potential for methane, whereas the LCAO α for a C atom is simply its observed ionization potential. In addition, we can use (empirical) "independent" bond energy terms for the LCAO β's which describe bonding interactions, and then take recourse in data fitting only for non-bonding interactions. By contrast, all Fueki's LCBO β's must be obtained by data fitting. Because LCAO methods make more adequate use of physical quantities determined elsewhere, they may be said to use fewer adjustable parameters. Thus it would appear that they provide a simpler and more practical technique for correlating ionization potentials in a series of related molecules.

NOTES

DECARBOXYLATION OF STRONG ACIDS BY METAL ACETYLACETONATES

NEIL R. FETTER

INTRODUCTION

In a study of the reactions of carboranes with beryllium acetylacetonate, an attempt was made to prepare beryllium *o*-carboranylcarboxylic acid compounds from beryllium acetylacetonate and 1-methyl-2-*o*-carboranylcarboxylic acid with the elimination of acetylacetone. However, it was found that decarboxylation occurred and *o*-methylcarborane was formed.

The decarboxylations of trichloroacetate (1), trinitrobenzoate (2), and trifluoroacetate (3) anions in several solvents have been described by Verhoek and co-workers. The decarboxylations followed first order kinetics with respect to the anion concentration and occurred at mild temperatures, except with sodium trifluoroacetate, which required temperatures near 180 °C.

Because of the poor solubility of the carborane carboxylic acids in common solvents, the decarboxylations described below were conducted as melt reactions. The chloroacetic acids were treated with zinc acetylacetonate under similar conditions to see whether other strong carboxylic acids would behave similarly.

EXPERIMENTAL

Apparatus and Reagents

The zinc and beryllium acetylacetonates were obtained from Chemicals Procurement Laboratories, College Point, N.Y., and used without further purification.

The 1,2-*o*-carboranyldicarboxylic acid, $HOOC(C_2B_{10}H_{10})COOH$, was obtained from the Olin Mathieson Chemical Corp. through the courtesy of Dr. Theodore Heying. The 1-methyl-2-*o*-carboranylcarboxylic acid, $CH_3(C_2B_{10}H_{10})COOH$, was prepared from *o*-methyl carborane by reaction with butyllithium to form $CH_3(C_2B_{10}H_{10})Li$, followed by reaction with CO_2 and acidification (4). The crude product was recrystallized from CCl_4 before use. The chloroacetic acids were obtained from the Matheson, Coleman, and Bell Corp. and were used without further treatment.

The reactions were carried out on a standard high vacuum apparatus equipped with a Toepler pump for evolved gas measurement. The reaction vessel was a 50 ml, round-bottom flask, attached to a −20 °C cold finger to permit refluxing, connected to the vacuum line. In a typical experiment, approximately 1 g each of metal acetylacetonate and the carboxylic acid were heated under 200 mm of dry nitrogen at approximately 200 °C for about 3 h until gas evolution ceased.

After the reaction, the nitrogen was pumped off and the condensables, including CO_2, were retained in a −196 °C trap. The trap temperature was raised to −78 °C and the CO_2 was measured. The composition of the remaining condensables was determined by examination of the liquid phases with a Varian A-60 nuclear magnetic resonance spectrometer and the vapors with an infrared spectrophotometer. The crude products that remained in the reaction flasks were sublimed under vacuum (0.01 mm) at 75–80 °C onto a −20 °C cold finger where a solid carborane was deposited. The products were identified from infrared spectral comparison with authentic samples, melting point, and elemental analyses, which were performed by the Schwarzkopf Analytical Laboratories, Woodside, N.Y.

The results of the experimental work are summarized in Table I.

DISCUSSION

As can be seen from the data in Table I, the decarboxylation of $CH_3(C_2B_{10}H_{10})COOH$ and $HOOC(C_2B_{10}H_{10})COOH$ is quantitative with $Be(AcCHAc)_2$ and nearly so with $Zn(AcCHAc)_2$; however, recovery of a pure product was difficult when $Be(AcCHAc)_2$ was used, because unreacted portions of it co-sublimed with the carboranes.

TABLE I

Decarboxylation of strong acids by metal acetylacetonates

Carboxylic acid (mmoles)	Metal acetylacetonate (mmoles)	Reaction T (°C)	CO_2 evolved (mmoles)	Other products (mmoles)

$CHCl_2COOH$ (10.75)	$Zn(AcCHAc)_2$ (11.10)	200	2.09	Acetone (6.00)
$CH_2ClCOOH$ (22.80)	$Zn(AcCHAc)_2$ (22.60)	210	2.29	Acetone (11.7) Methyl chloride (1.25) Acetylacetone (1.00)
CF_3COOH (14.42)	$Zn(AcCHAc)_2$ (18.10)	195	No reaction	
C_6H_5COOH (5.48)	$Zn(AcCHAc)_2$ (5.57)	215	No reaction	
$CH_3C(B_{10}H_{10})CCOOH$ (4.45)	$Be(AcCHAc)_2$ (4.55)	190	4.10	Acetylacetone (0.184) Sublimate: mixture of $Be(AcCHAc)_2$ and $CH_3(C_2B_{10}H_{10})H$ (1.04 g) Anal. Found: B, 32.80; Be, 2.75
$HOOCC(B_{10}H_{10})CCOOH$ (2.37)	$Be(AcCHAc)_2$ (5.12)	200	4.47	Acetylacetone (0.455) Sublimate: mixture of $Be(AcCHAc)_2$ and carborane (0.470 g) Anal. Found: B, 17.84; Be, 3.55

To be sure that autodecarboxylation did not occur, samples of $CH_3(B_{10}H_{10}C_2)COOH$, $HOOC(B_{10}H_{10}C_2)COOH$, and Cl_3CCOOH were heated to 205 °C; no CO_2 evolution was observed.

Decarboxylations of the chloroacetic acids with $Zn(AcCHAc)_2$ were carried out to determine the effect of decreasing acid strength on the carbon dioxide yields. The carbon dioxide values obtained from Cl_3CCOOH, $CHCl_2COOH$, and $CH_2ClCOOH$ were 72.3, 19.4, and 9.3 mole % respectively, indicating that the ability of $Zn(AcCHAc)_2$ to effect decarboxylation depends upon the acids' strengths, whose pK_a values in water are 0.70, 1.48, and 2.85 (5), respectively. The quantitative decarboxylation of the carborane carboxylic acids suggests they are strong, with dissociation constants of 10^{-1} or larger.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The pK_a value of 1-methyl-2-*o*-carboranylcarboxylic acid has been reported (4) to be 2.74 in 50% aqueous ethanol, but insolubility of the carboranylcarboxylic acid in water has prevented measurement in this medium. Benzoic acid is apparently too weak to be affected by metal acetylacetonates.

The inability to decarboxylate trifluoroacetic acid at 195 °C is not readily explainable; however, the larger activation energy for the decarboxylation of trifluoroacetate ion (42.0 kcal/mole) vs. trichloroacetate ion (31.6 kcal/mole) in the same solvent, as reported by Verhoek (3), suggests that 195 °C may have been too low to decarboxylate trifluoroacetic acid in the presence of zinc acetylacetonate.

It is apparent from the variety of condensables obtained at −78 °C that the reaction mechanism is probably not a first order decarboxylation of the acid anions. For example, the reaction of the carborane carboxylic acid with $Be(AcCHAc)_2$ yielded acetylacetone as the primary condensable, but with $Zn(AcCHAc)_2$, acetone was obtained. Also, the decarboxylation of $Cl_2CHCOOH$ yielded no dichloromethane and $ClCH_2COOH$ produced only 5.5 mole % of the methyl chloride possible.

Although the evolution of acetylacetone or acetone would indicate the presence of the carborane carboxylic acid salts such as $CH_3(B_{10}H_{10}C_2)COOBeAcCHAc$, these compounds were not isolated because the evolution of acetylacetone and carbon dioxide occurred at approximately the same temperatures.

CHEMICAL DEACTIVATION BY HYDROCARBONS IN THE PHOTOLYSIS OF HEXAFLUOROACETONE[1]

S. N. KHANNA[2] AND K. O. KUTSCHKE

In a previous discussion (1) a distinction was made between the mode of action of "inert" gases, such as CO_2, C_4F_{10}, etc., and of a hydrocarbon (isobutane) in causing a reduction of the quantum yield, ϕ, for the photodecomposition of hexafluoroacetone. Experiments with the inert gases had been done by Ayscough and Steacie (2). They showed

CHEMICAL DEACTIVATION BY HYDROCARBONS IN THE PHOTOLYSIS OF HEXAFLUOROACETONE[1]

S. N. KHANNA[2] AND K. O. KUTSCHKE

In a previous discussion (1) a distinction was made between the mode of action of "inert" gases, such as CO_2, C_4F_{10}, etc., and of a hydrocarbon (isobutane) in causing a reduction of the quantum yield, ϕ, for the photodecomposition of hexafluoroacetone. Experiments with the inert gases had been done by Ayscough and Steacie (2). They showed

that, in the absence of added gas, ϕ decreased as the concentration of ketone, [A], increased and that it approached a limiting value, ϕ_∞, at sufficiently large [A]. The deactivation experiments were done with a fixed concentration, $[A]_1$, of ketone, corresponding in the absence of added gases to a quantum yield of ϕ', and yielded values of the quantum yield, ϕ_M, which decreased as the concentration, [M], of added gas was increased. The mechanism evolved (1) predicted that a plot of ϕ'/ϕ_M vs. [M] should rise from unity at [M] = 0 with a finite initial slope which decreased as the limiting value, ϕ'/ϕ_∞, of the function was approached at large [M]. The mechanism assumed that the inert gas acted only as a catalyst in the degradation of the vibrational energy in the excited singlet state; this mode of action can be termed physical deactivation. The limited data available were consistent with this prediction and a procedure was outlined to evaluate q, the efficiency of the inert gas as an agent for the transfer of vibrational energy relative to that for the ketone.

A few data with isobutane as the added species yielded a value of q greatly in excess of unity. It was suggested that a chemical reaction occurred between some excited state of the ketone and the added hydrocarbon; this reaction is designated as chemical deactivation. The present note reports additional data which support the hypothesis that chemical deactivation occurs.

Experiments were done in the usual type of apparatus. Light from a 550 W Hanovia Type A mercury arc was rendered approximately parallel and the group of lines near 3 130 Å was isolated by the combination of filters described by Kasha (3). The light beam just filled the cylindrical fused quartz cell (10 cm long, 5 cm diameter). All experiments with added gases were done at 79 °C with $[A]_1$ = 10.0 mm. Quantum yields were determined by acetone actinometry; values of ϕ' (= 0.70) and of ϕ_∞ (= 0.29) agreed closely with those obtained earlier (1, 2). Analysis was confined to the measurement of the amount of carbon monoxide formed. The data are shown in Fig. 1 as plots of ϕ'/ϕ_M vs. [RH] for the three hydrocarbons. The ordinate origin has been shifted for each gas to improve the clarity; the horizontal broken lines to the right of the figure indicate the position of ϕ'/ϕ_∞ (= 2.4) for the various ordinate origins.

The data have been treated in the manner outlined (1) to evaluate $q_{i\text{-}C_4H_{10}} = 1.6$, $q_{C_6H_{14}} = 2.9$, and $q_{C_6H_6} = 1.5$. All exceed unity but by rather smaller factors than did the $q_{i\text{-}C_4H_{10}} \simeq 30$ obtained earlier (1) when shorter wavelengths were used for excitation. It should also be noted that values of ϕ'/ϕ_M greatly in excess of ϕ'/ϕ_∞ are obtained even at moderate concentration of the hydrocarbons. This latter observation is strong evidence in favor of a chemical reaction of an excited molecule.

The nature of the chemical reaction cannot be specified with certainty at this time. The correlation which exists between the respective values of q and the number of tertiary hydrogen atoms on the two paraffins suggests that the reaction might be

$$A^* + RH \rightarrow AH + R \qquad [1]$$

where A* represents an excited state of the ketone molecule. In view of the slowness of reactions like [1] when free radicals attack benzene, it seems unreasonable to postulate [1] as the reaction involved in the present system when benzene is the added gas. By analogy with the reactions of free radicals, it is suggested that an addition reaction, [2], possibly followed by some rearrangement, operates in this case.

$$A^* + C_6H_6 \rightarrow AC_6H_6 \qquad [2]$$

A search for products of the species formed in [1] and [2] has not been made although such an investigation is an obvious extension of this work.

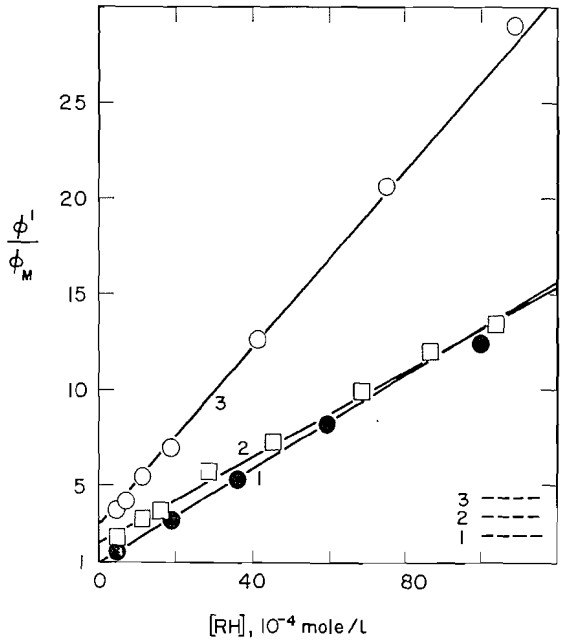

FIG. 1. Plots of ϕ'/ϕ_M vs. [RH]: (1) isobutane, (2) benzene, (3) 2,3-dimethylbutane. The ordinate origin is shifted upward by 1 unit for each successive plot. Broken lines to the right indicate the position of ϕ'/ϕ_∞ for each ordinate origin.

It also is impossible to identify A* on the basis of the data available. It is observed that plots of ϕ_M/ϕ' vs. $[RH]^{-1}$ pass through the origin within experimental error. However, this would be predicted if any of the excited states discussed previously (1) is involved. It seems reasonable to identify A* with the state designated $^3A_0$ in the previous discussion. Additional studies of the light emission will be of assistance in answering this question and these have been undertaken.

It should be noted that when a reaction like [1] or [2] is included in the mechanism, the procedure outlined previously (1) to evaluate q is no longer valid. This is a consequence of the fact that $S_M°$ then contains terms which cannot be evaluated by measurements of S_K' (see reference (1) for definitions of $S_M°$ and S_K'). It appears probable that the discrepancy between the value of $q_{t\text{-}C_4H_{10}}$ reported here and that reported earlier arises from differences in the degree of validity of the procedure used for the evaluation of q for the two sets of experimental conditions.

One final point should be made. It is conceivable that the phenomenon observed does not involve a reaction of the excited state of the ketone but rather involves a reaction such as [3] with an addition-type reaction occurring when unsaturated species are present.

[3] $$CF_3\dot{C}{=}O + RH \rightarrow CF_3CHO + R$$

Support for this suggestion is derived from the recent observation of CF_3COBr as a product of the photolysis of hexafluoroacetone in the presence of bromine (4). Although it is not possible to exclude this suggestion it should be noted that in the presence of relatively large amounts of isobutane the yield of C_2F_6 is negligible and the ratio CF_3H/CO is approximately 1.7 (5). Although this is smaller than the value of 2 expected if each CF_3CO radical decomposed, the decrement from 2 is explicable in terms of known reactions of CF_3

For personal use only.

radicals with the isobutene unavoidably produced in this system. Pearson and Szwarc (6) have discussed this point. Moreover, it should be noted that any reaction which inhibits the formation of CO from CF_3CO radicals leads to an expected increase in CF_3H/CO and cannot explain the observed decrement. It is concluded, therefore, that the lifetime of CF_3CO radicals with respect to decomposition is small enough to prevent the occurrence of a reaction such as [3] even at concentrations of hydrocarbon near atmospheric pressure.

Thus it seems reasonable to conclude that chemical deactivation is the most likely explanation of the phenomenon observed here. It would be desirable, however, to obtain analytical data to confirm or refute this conclusion.

ORGANIC COMPOUNDS OF URANIUM. PART I. REACTIONS OF URANIUM PENTAETHOXIDE WITH β-KETOESTERS

A. M. Bhandari and R. N. Kapoor

The reaction between alkoxides of aluminium (1), neodymium (2), praseodymium (3), titanium (4), niobium (5), tantalum (6), and samarium (B. S. Sankhla and R. N. Kapoor, private communication), and bidentate ligands like β-diketones and β-ketoesters have recently been studied in these and other laboratories with interesting results regarding the volatility and coordination number of the products. No reference appears to be available in the literature on the preparation of β-ketoester derivatives of pentavalent uranium. It was therefore considered of interest to carry out reactions between β-ketoesters and uranium pentaethoxide.

A systematic study was made of the reactions of uranium pentaethoxide with β-ketoesters (methyl acetoacetate and ethyl acetoacetate) in different stoichiometric ratios in benzene solution. The ethanol produced in these reactions was fractionated azeotropically and estimated by an oxidation method (7). It was found that the reaction proceeded comparatively easily up to the replacement of two ethoxy groups, but thereafter became very slow and required a larger amount of the β-ketoester. The final product appeared to be $(EtO)_2U(lig)_3$. All of the derivatives, $(EtO)_xU(lig)_{5-x}$ (where $x = 2$, 3, or 4), were dark-brown liquids or pasty solids. The viscosity increased as more ethoxy groups were replaced. These derivatives could be distilled under reduced pressure. In all of them the uranium was found to be pentavalent.

Description of the products of the reactions of uranium pentaethoxide with methyl acetoacetate and ethyl acetoacetate in different stoichiometric ratios are given in Table I.

On the basis of the analyses of the products formed, the various reactions of uranium pentaethoxide with β-ketoesters may be represented by the following equations, which probably involve an S_N2 type of mechanism (R = the methyl or ethyl group).

radicals with the isobutene unavoidably produced in this system. Pearson and Szwarc (6) have discussed this point. ORGANIC COMPOUNDS OF URANIUM. PART I. REACTIONS OF URANIUM PENTAETHOXIDE WITH β-KETOESTERS

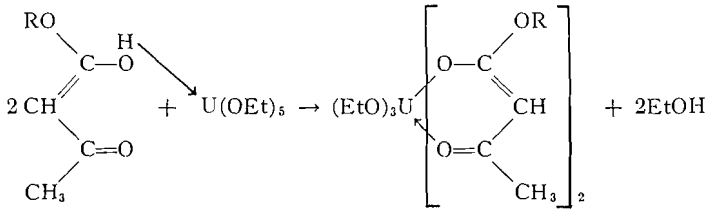
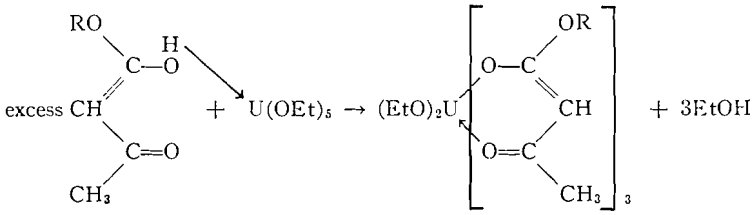
A. M. BHANDARI AND R. N. KAPOOR

The reaction between alkoxides of aluminium (1), neodymium (2), praseodymium (3), titanium (4), niobium (5), tantalum (6), and samarium (B. S. Sankhla and R. N. Kapoor, private communication), and bidentate ligands like β-diketones and β-ketoesters have recently been studied in these and other laboratories with interesting results regarding the volatility and coordination number of the products. No reference appears to be available in the literature on the preparation of β-ketoester derivatives of pentavalent uranium. It was therefore considered of interest to carry out reactions between β-ketoesters and uranium pentaethoxide.



A systematic study was made of the reactions of uranium pentaethoxide with β-ketoesters (methyl acetoacetate and ethyl acetoacetate) in different stoichiometric ratios in benzene solution. The ethanol produced in these reactions was fractionated azeotropically and estimated by an oxidation method (7). It was found that the reaction proceeded comparatively easily up to the replacement of two ethoxy groups, but thereafter became very slow and required a larger amount of the β-ketoester. The final product appeared to be $(EtO)_2U(lig)_3$. All of the derivatives, $(EtO)_xU(lig)_{5-x}$ (where $x = 2$, 3, or 4), were dark-brown liquids or pasty solids. The viscosity increased as more ethoxy groups were replaced. These derivatives could be distilled under reduced pressure. In all of them the uranium was found to be pentavalent.

Description of the products of the reactions of uranium pentaethoxide with methyl acetoacetate and ethyl acetoacetate in different stoichiometric ratios are given in Table I.



On the basis of the analyses of the products formed, the various reactions of uranium pentaethoxide with β-ketoesters may be represented by the following equations, which probably involve an S_N2 type of mechanism (R = the methyl or ethyl group).

(I)

(II)

(III)

The non-replacement of the fourth ethoxy group of uranium pentaethoxide, even in the presence of an excess of β-ketoesters, could be ascribed either to steric hindrance or to a saturated coordination state (coordination number 8) of compound III.

EXPERIMENTAL

Materials

Uranium pentaethoxide was prepared by the method described by Gilman and co-workers (8), and was distilled before use. Methyl acetoacetate and ethyl acetoacetate were dried by refluxing over aluminium isopropoxide, and distilled at 168–170 °C and 180 °C, respectively. Benzene (B.D.H.) was dried over sodium wire then subjected to azeotropic fractionation in the presence of a little ethanol.

Apparatus

All glass apparatus with interchangeable standard joints was used throughout, special precautions being taken to exclude moisture from the system. Fractionations were carried out in a column packed with Raschig rings and fitted to a total condensation variable takeoff still head.

Analytical Methods

Uranium was estimated as U_3O_8. The ethoxy constituent of the compounds was estimated by hydrolysis, and determination by chromic acid oxidation of the ethanol collected in the ternary azeotrope (7). The valency of the uranium was determined by double oxidation with ceric sulfate, as described by Bradley *et al.* (9).

Reactions

Reaction of Uranium Pentaethoxide with Methyl Acetoacetate in Molar Ratio of 1:1 in Benzene

Methyl acetoacetate (0.43 g) was added to uranium pentaethoxide (1.70 g) in benzene (60 g). The reaction mixture was refluxed for 4 h. The binary azeotrope of benzene–ethanol was collected slowly between 68 to 80 °C. The benzene was slowly distilled at 80 °C. When the mixture cooled, a dark-brown solution was obtained. When the excess solvent was removed under reduced pressure at room temperature, a dark-brown liquid (1.89 g) was left. The azeotrope collected between 68 and 80 °C was found to contain 0.17 g ethanol (calcd. for 1 mole = 0.17 g). The product was distilled under reduced pressure (b.p. 140–141 °C at 0.5 mm) and analyzed.

RARE-EARTH PICOLINATE AND PICOLINATE-N-OXIDE COMPLEXES

P. G. Manning

Stepwise stability constants for rare-earth picolinate and rare-earth picolinate-N-oxide complexes (Fig. 1) have been reported in two recent publications (1, 2). The *n*-dentate characters of the two ligands were discussed, but no unequivocal conclusions were drawn.

It has been shown in earlier publications (3, 4) that the magnitudes of ratios (P) of stepwise stability constants are useful in elucidating the structures of metal complexes, and in this paper the P values for the picolinate and picolinate-N-oxide systems are analyzed. The stepwise stability constant is defined as

$$b_m = [ML_m]/[ML_{m-1}][L],$$

where M and L are metal and ligand ions respectively. The ratios are given by

$$b_1{:}b_2 = P = S \times T \times R,$$

where S is a statistical factor calculable from a knowledge of the number of available cation sites and ligand groups, T is a measure of the electrostatic repulsion between the bound ligand (in ML_1) and the ligand about to bind (L_2), and R covers any change in the nature of the metal–ligand bonding in the first and second stages of ion association. The S, T, and R factors have been described in detail in earlier publications (3, 4). For the α-hydroxymonocarboxylate complexes of rare-earth, cupric, and zinc ions $T = 1.6$ and $R = 1.0$ (3), and it was postulated that a T value $= 1.6$ is valid for singly charged ligands binding to transition metal or rare-earth ions. This T value also holds for some transition metal halide and amino acid complexes (5).

P values for the presently studied systems may be calculated in the following manner. For a monodentate ligand binding to a six-coordinate rare-earth ion $S = 2 \times 6/5 = 2.40$. Table I lists P, S, and T values for monodentate and bidentate ligands associating with 6- and 8-coordinate cations. The experimentally determined P values are listed in Table II.

Picolinic acid

Picolinic acid-N-Oxide

FIG. 1.

TABLE I

Calculation of P values

	6-Coordinated		8-Coordinated*	
	Monodentate ligand	Bidentate ligand	Monodentate ligand	Bidentate ligand
S	2.4	4.8	2.3	3.5
T	1.6	1.6	1.6	1.6
P	3.85	7.7	3.7	5.6

*Dodecahedral structure. Also $S = 3.4$ for cube arrangement and bidentate ligandcy.

TABLE II

Log P(obs.) values for rare-earth complexes

Metal	Picolinate (1)	Picolinate (2)	N-Oxide (2)
La	0.80	1.11	0.77
Ce	0.92	1.53	
Pr	0.74	0.99	0.49
Nd	0.84	0.93	0.76
Sm	0.70	0.86	
Eu	0.66	0.87	0.65
Gd	0.78	0.70	0.66
Tb	0.68		
Dy	0.70	0.74	0.45
Ho	0.72		
Er	0.70		
Tm	0.74	1.14	0.47
Yb	0.74	0.90	0.55
Lu	0.70	1.43	0.64
Average P(obs.)	5.6	10	4.0

The P(calcd.) and P(obs.) are indicative of a monodentate picolinic acid-N-oxide. The pK_a value (3.31) for this ligand is of the same order as the pK_a values for the α-hydroxymonocarboxylic acids studied earlier. For a much weaker acid, however, the metal–ligand bond may have a lifetime greater than that of a metal–water bond, and chelation would then occur. The P(obs.) values for the picolinic acid ($pK = 5.34$) complexes are consistent with bidentate ligandcy (Tables I and II). Thompson's (1) P(obs.) values indicate an 8-coordinate cation whereas the data of Yoneda and co-workers (2) support a 6-coordinate structure. If we omit the two "wild" P(obs.) values for Ce and Lu picolinates, as determined by Yoneda and co-workers (2), the P(obs.) and P(calcd.)

values are in good agreement. Thompson's (1) data are extremely consistent, however, so that an unequivocal decision as to the coordination number of rare-earth ions cannot be reached. It is apparent, nevertheless, that the independent derivation of P values for the picolinate system should resolve the argument.

Yoneda and co-workers (2) suggested that the greater stability of the picolinate-N-oxide complexes relative to the acetate species was indicative of bidentate ligandcy. However, it was postulated in a recent publication (4) that the rare-earth acetates were ion pairs, and the greater stability of the picolinate-N-oxide complexes, therefore, is not proof of bidentate ligandcy.

The author is grateful to the referees for the interesting suggestion that the coordination number of the rare-earth ions depends on the nature of the medium. The data analyzed here could be interpreted in terms of an 8-coordinate structure in 0.1 M KNO_3 (ref. 1) and a 6-coordinate structure in 2.0 M $NaClO_4$ (ref. 2). An earlier examination of the rare-earth α-hydroxymonocarboxylate system (3) indicated that these ligands were monodentate. The S values for the 8- and 6-coordinate structures (2.3 and 2.4 respectively) were too close to give any information on the rare-earth coordination number.

T values seem to show little dependence upon ionic strength. In the α-hydroxymonocarboxylate system (3), experimental data determined at ionic strengths of 0.1 and 2.0 were analyzed with reasonable facility. Furthermore, T values for the cupric acetates (3) also seemed to be independent of ionic strength, at least within experimental error.

THE SIGN, TEMPERATURE, AND SOLVENT DEPENDENCE OF THE PROTON COUPLING CONSTANT AND CHEMICAL SHIFT IN α-CHLOROACRYLONITRILE

K. A. MCLAUCHLAN, L. W. REEVES, AND T. SCHAEFER

Solvent dependent geminal proton coupling constants, J, appear to decrease algebraically as the dielectric constant of the medium increases (1–4). Some workers (4) suggest a linear dependence of J on the reaction field (5) of the medium, whereas others (2) suggest specific interactions of solute molecules with donor or acceptor atoms in the solvent molecules. Further experiments are here reported on the solvent and temperature dependence of J and the chemical shift of the protons in α-chloroacrylonitrile. The sign of J is shown to be opposite to that of $J(^{13}C—H)$ in this molecule (see Experimental) and is taken as negative in the discussion that follows.

Temperature and Solvent Dependence of J

From Table I it is seen that in methylcyclohexane and toluene J increases appreciably as the temperature increases. The increase of J in methylcyclohexane may indicate that

The sign of J is shown to be opposite to that of $J(^{13}C—H)$ in this molecule (see Experimental) and is taken as negative in the discussion that follows.

Temperature and Solvent Dependence of J

From Table I it is seen that in methylcyclohexane and toluene J increases appreciably as the temperature increases. The increase of J in methylcyclohexane may indicate that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

self-association of solute molecules decreases as the temperature increases, but a corresponding change in the chemical shift is not observed. In toluene, association with solvent molecules is indicated since, at −80 °C, J is smaller than in the pure compound at 35 °C (1) and also smaller than in methylcyclohexane whose dielectric constant is nearly the same as that of toluene. The association with toluene molecules may be of a dipole–induced dipole type as discussed by Schneider (6). In both acetonitrile and dimethylformamide the temperature dependence of J is either very small or zero, although the chemical shift changes are appreciable.

Watts and Goldstein (4) suggest that the change in J parallels the reaction field of the medium as measured by the function $Z(\epsilon) = (\epsilon - 1)/(2\epsilon + 2.5)$. Their extrapolation of J to the limit $Z(1) = 0$ is based on the points for cyclohexane and dimethylformamide as solvents at 35 °C. They obtain $J = -1.4$ c/s. $Z(\epsilon)$ changes by only 0.02 to 0.03 for methylcyclohexane and toluene over the temperature range in Table I, but the $Z(\epsilon)$ dependence of J appears to be linear in both solvents. However, an extrapolation of such a plot to $Z(1) = 0$ yields $J = -0.7$ to -0.9 c/s, indicating the very approximate validity of such extrapolations.

*Temperature and Solvent Dependence of the Chemical Shift**

A graph of the mean chemical shift of the protons in Table I versus temperature indicates that at high temperatures the mean chemical shift approaches a common value, probably that in tetramethylsilane at infinite dilution (4). From this viewpoint it is natural that the largest changes in shift for a given temperature interval occur for those solvents (toluene and dimethylformamide) in which the low temperature value of the shift deviates most from the value in tetramethylsilane.

In toluene the ring-current effect, together with decreasing solute–solvent association, accounts for the large low-field shift observed as the temperature increases. In acetonitrile and dimethylformamide the shift changes are appreciable and as expected, if hydrogen bonds with the solvent molecules are being broken as the temperature increase shifts the equilibrium towards the non-bonded species. The shift change in acetonitrile is less than in dimethylformamide. In acetonitrile as solvent there is a *positive* contribution to the hydrogen bond shift of a proton donor by the magnetic anisotropy of the cyano group (7). It opposes the larger but comparable negative contribution from the electric field effect. Hence the total shift on hydrogen bonding may well be less than in dimethylformamide, where the anisotropy of the carbonyl group probably reinforces the low-field electric field shift. If the hydrogen bond energy is comparable in the two solvents, the relative temperature dependence of the shift in the two solvents appears reasonable.

Graphs of shift versus $Z(\epsilon)$ in the solvents toluene, acetonitrile, and dimethylformamide are linear for each solvent, but the $Z(\epsilon)$ dependence is much greater than that obtained by Watts and Goldstein (4) for different solvents at 35 °C. For the three solvents above it is very probable that there is an association with the solvent which is strongly temperature dependent. Correlations with $Z(\epsilon)$ are therefore of limited utility.

The reaction field model is valid only for a solute molecule in a medium which in no way interacts with solute molecules at the molecular level but simply presents a continuum of certain dielectric properties. For protons which are normally exposed to direct contact with solvent molecules, the reaction field model is probably realistic only for solvents of low dielectric constant. This was pointed out originally by Buckingham (5), but since then

**The low-field shift is consistently assigned to the proton trans to the chlorine atom for reasons discussed by Watts and Goldstein (4).*

†

.

‡Because of its high volatility, locking to the tetramethylsilane resonance peak was impossible. However, the shift change from −58 to 40 °C is very small so that the shift change from 40 to 72 °C will be almost negligible.

§Dielectric constant.

‖For cyclohexane (see Experimental).

¶$Z(\epsilon) = (\epsilon - 1)/(2\epsilon + 2.5)$.

this qualification has been largely ignored. Temperature studies are probably a good test of the model's validity for any particular solute–solvent system.

EXPERIMENTAL

Samples of α-chloroacrylonitrile were prepared as approximate 5% v/v solutions in the four solvents in Table I. Cyclohexane itself was not used because of its high melting point. Small amounts of tetramethylsilane were added to serve as an internal reference and locking signal. The proton resonance spectrum of each sample was recorded at three temperatures on an HA-100 Varian spectrometer. The temperature extremes depended on the liquid range of the solvent and were measured with an accuracy of 1 deg C by calibration with a methanol sample. Dielectric constant data are given in Table I for the pure solvents and were taken from refs. 8–11. The dielectric constant of methylcyclohexane at 20° is the same as that of cyclohexane (9, 10) and is here assumed to be that of cyclohexane at the other temperatures.

The sign of J was determined by a heteronuclear "tickling" (12) experiment performed on a modified Varian D.P.60 spectrometer operating at 56.4 Mc/s in the proton region. The modifications, which have been described elsewhere (13), consisted firstly in stabilizing the field/frequency ratio by a feedback loop operated from the signal of the internal reference compound. The probe was tuned both to the ^1H and ^{13}C (ca. 14.18 Mc/s) resonance frequencies and irradiating power was obtained at the lower frequency from a Rohde and Schwarz frequency synthesizer. The behavior observed in the "tickling" experiments was consistent only with the directly bonded ^{13}C—H coupling being of opposite sign to the geminal proton–proton coupling.

For personal use only.

preparation of O_4F_2 has been improved (3) and a number of its properties have been determined

METHOD OF PREPARATION OF TETRAOXYGEN DIFLUORIDE

Like O_2F_2 and O_3F_2, tetraoxygen difluoride is prepared from the elements in a high-voltage electric-discharge apparatus, but at much milder conditions. The reaction proceeds in accordance with the equation:

[1] $$2O_2 + F_2 \rightarrow O_4F_2 \quad .$$

The apparatus is shown in Fig. 1.

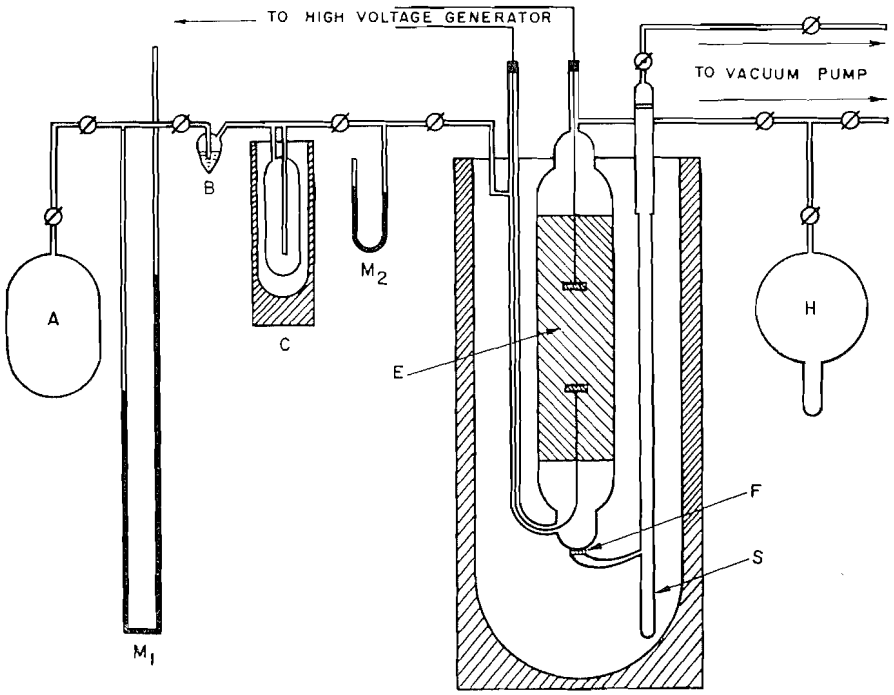

FIG. 1.

A 2:1 (by volume) mixture of oxygen and fluorine is fed from the stainless steel cylinder, A, through the flowmeter, B, containing Kel-F oil No. 3, and through the trap, C, cooled with Dry Ice, into the reaction vessel, E, cooled to 60–70 °K. M_1 and M_2 are the manometers for measuring the gas pressure in cylinder A and in reaction vessel E, respectively. They are filled with mercury covered with Kel-F oil No. 3.

A high voltage electric discharge is established in the reaction vessel between the copper electrodes which are fixed 4.5 cm apart. The discharges varied from 4 to 6 mA at 1 000 – 1 500 V; the power input should not exceed 6 W.

In distinction to the Pyrex glass reaction vessel (1, 2) used earlier, the main part of the reaction vessel in the new apparatus is made of copper. Copper was chosen as the material for the reaction zone walls because of its high thermal conductivity, since it is important to quench rapidly the O_4F_2 formed and thus avoid its decomposition.

The reaction vessel is 3 cm in diameter and 18 cm long. Its total volume, including connection tubes, is about 280 cm^3. Before use for preparation of O_4F_2, the reaction vessel and the whole apparatus must be prefluorinated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The feed rate of the $2O_2 + F_2$ mixture is adjusted so that the pressure in the reaction vessel is maintained below 15 mm Hg and is usually about 2 cm^3/min. Under these conditions normally all the oxygen–fluorine mixture is consumed and the O_4F_2 formed condenses on the walls of the reaction vessel. The maximum yield of O_4F_2 is about 3 mg/min. Flask H is for measuring and sampling the unreacted gas, in case all the gas fed is not consumed.

The product obtained can be either melted by warming the cooling bath to about 85 °K or dissolved and rinsed down (with an appropriate solvent), filtered through glass filter F, and collected in tube S. Carbon tetrafluoride (Freon-14) or oxygen difluoride can be used as solvents for O_4F_2. If commercially available Freon-14 is used, it is advisable to treat it (before use as a solvent for O_4F_2) with fluorine at room temperature to eliminate possible traces of oxidizable impurities.

Pure tetraoxygen difluoride or its solutions are stored cooled in liquid nitrogen.

The amount of SiF_4, usually formed as a by-product during preparation of O_4F_2, was reduced in the new reaction vessel to 2–4% by weight with respect to the amount of the tetraoxygen difluoride produced. Tetraoxygen difluoride is an explosive compound. Thus, corresponding safety precautions must be taken in its preparation, storage, and handling.

CHEMICAL ANALYSIS OF TETRAOXYGEN DIFLUORIDE

For chemical analysis, tetraoxygen difluoride is decomposed into oxygen and fluorine by warming it slowly to room temperature. The gas evolved is measured and analyzed for O_2 and F_2.

Fluorine can be determined by the Moissan method, namely by reaction with dry metallic mercury in a gas burette at room temperature. The gas mixture must be shaken with mercury until the volume of the remaining gas is constant. Fluorine reacts with mercury quantitatively, forming solid mercury fluorides, HgF and HgF_2. Thus, the decrease of the gas volume indicates the amount of F_2 present. This figure is then checked to determine the amount of F^- formed by reacting the mercury fluorides with a known amount of a standard solution of NaOH, in accordance with the equations

[2] $$Hg_2F_2 + 2NaOH \rightarrow 2NaF + Hg_2O + H_2O$$

or

[3] $$HgF_2 + 2NaOH \rightarrow 2NaF + HgO + H_2O \quad .$$

In any case, the amount of sodium hydroxide consumed corresponds to the amount of F_2 present. The excess NaOH is back-titrated with standard HCl. The residual gas (after absorption of F_2 with Hg) is analyzed for oxygen by absorption of O_2 with an alkaline pyrogallol solution. The decrease in the volume of gas indicates the amount of O_2 present. Fluorine may be determined also by reaction with dry potassium iodide

[4] $$F_2 + 2KI \rightarrow 2KF + I_2$$

and subsequent titration of the iodine evolved by a standard solution of $Na_2S_2O_3$.

The accuracy of the analysis depends upon the size of the sample and the accuracy of the measurements.

PROPERTIES OF TETRAOXYGEN DIFLUORIDE

Some of the properties of O_4F_2 have been described in earlier publications (1, 4–8). Additional characteristics are given here.

Thermal Stability

At 90 °K tetraoxygen difluoride decomposes with about a 16 day half-life to trioxygen difluoride and oxygen. Trioxygen difluoride decomposes, in turn, at 90–115 °K to O_2F_2 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

finally to O_2 and F_2. Pure O_4F_2, or its solidified solutions containing about 1 mole % of O_4F_2 in CF_4, has been kept at liquid nitrogen temperature for weeks without noticeable decomposition. O_4F_2 explodes at fast warming.

Vapor Pressure

In addition to the two values (5) obtained earlier, the vapor pressure of tetraoxygen difluoride at 90 °K was found to be 0.25 mm Hg.

Melting and Boiling Points

The melting point of O_4F_2 was found to be 82 ± 2 °K. The extrapolated normal boiling point of O_4F_2 is 194 °K. The compound decomposes completely below this temperature.

Solubility

Solid O_4F_2 is practically insoluble in liquid nitrogen at 77 °K, and in liquid argon at 85 °K, i.e. the solubility is less than 0.01 mole % (the limit of our detection). In liquid oxygen at 77 °K the solubility of O_4F_2 is about 0.05 mole %.

Carbon tetrafluoride (Freon-14) dissolves appreciable amounts of O_4F_2 at 90 °K (melting point of CF_4 = 89.2 °K). The solution containing 1 mole % of O_4F_2 is reddish brown. Reddish brown solutions of O_4F_2 have been obtained also in $CClF_3$ (Freon-13) at 90 °K. Mixtures of CF_4 with 50% $CClF_3$ (by volume, liquid), or with 3% O_2, or with 6% N_2, or with 15% NF_3, dissolve about 1 mole % of O_4F_2 at 77 °K.

Tetraoxygen difluoride is readily soluble in liquid oxygen difluoride, OF_2. At 77 °K, the solubility is about 2% by weight; at 90 °K, OF_2 dissolves 5% by weight (or 3 moles %), or more, of O_4F_2.

Reaction with Ozone

At 116 °K (melting point of Freon-12), tetraoxygen difluoride decomposes and, if there is contact with concentrated ozone, both explode.

Reaction with Tetrafluorohydrazine

With N_2F_4, tetraoxygen difluoride (dissolved in OF_2) reacts at 77 °K producing O_2F_2, NF_3, and oxygen.

Reaction with Xenon

If a mixture of tetraoxygen difluoride with xenon (prepared at 77 °K) is warmed slowly to 195 °K, O_4F_2 decomposes and a part of its decomposition products reacts with xenon forming xenon fluorides.

ACKNOWLEDGMENTS

Acknowledgment is due to Mrs. L. V. Streng for assistance in the experimental work and to Dr. A. V. Grosse for valuable suggestions.

COMPLEXES OF ALKYL AND ARYL CYANIDES. PART III.[1] THE FAR-INFRARED SPECTRA (500–200 CM^{-1}) AND ASSIGNMENT OF THE METAL–NITROGEN STRETCHING FREQUENCY IN COMPLEXES WITH PALLADIUM(II), PLATINUM(II), AND RHODIUM(III) HALIDES

R. A. WALTON[2]

In a recent study (2) of the infrared spectra (4 000 – 265 cm^{-1}) of the methyl and phenyl cyanide complexes of palladium(II) and platinum(II) halides, no bands were observed which could be assigned to the ν(Pd—N) and ν(Pt—N) modes. Similarly, ν(M—N) modes have not been observed in studies on the far-infrared spectra of alkyl cyanide complexes of a variety of metal halides (3–5). However, Evans and Lo (6) have assigned ν(Zn—N) to a strong band at 174 cm^{-1} in the infrared spectrum of $ZnCl_2.2MeCN$, and recently, Farha and Iwamoto (7) have examined the infrared spectra of several cyanopyridine complexes of copper(I), silver(I), and gold(I) perchlorates and, in the case of the nitrogen-bonded 2-cyanopyridine complexes, observed a new band in the 480–520 cm^{-1} region. This they point out is in the region where Lott (unpublished observations, quoted in ref. 7) has assigned ν(M—N) modes.

Although "metal–nitrogen" stretching vibrations have been assigned in several ammine (8, 9) and pyridine (10) complexes of the platinum metals, no such modes have yet been reported for the alkyl and aryl cyanide complexes of these metals. The present note reports the far-infrared spectra of several of these complexes in the 500–200 cm^{-1} region.

EXPERIMENTAL

Spectra were recorded in Nujol mulls between polythene plates on a Grubb-Parsons DM4 spectrophotometer which was calibrated with the spectrum of water vapor. The frequencies quoted are probably accurate to ± 2 cm^{-1}. The platinum(II) and palladium(II) were prepared as previously described (2) by the method of Hofmann and Bugge (11). Analytical data for the ethyl cyanide complexes, which were not reported previously (2), are shown below.

Dichlorobispropionitrileplatinum(II). Yellow crystals. Anal. Found: C, 20.30; H, 2.64; N, 7.60. $PtCl_2.2C_3H_5N$ requires C, 19.15; H, 2.68; N, 7.45.

Dibromobispropionitrileplatinum(II). Yellow crystals. Anal. Found: C, 15.72; H, 2.11; N, 6.64. $PtBr_2.2C_3H_5N$ requires C, 15.49; H, 2.17; N, 6.02.

For both complexes, the analytical data is consistent with the presence of a trace of "free" ligand, which was not readily removed on pumping *in vacuo*.

The alkyl cyanide complexes of rhodium(III) were those samples described in Part II of this series (1).

RESULTS AND DISCUSSION

Although metal–nitrogen stretching modes occur around 500 cm^{-1} in a variety of ammine complexes (8, 9), in other systems, e.g. metal halide – pyridine (py) complexes (10), these vibrations may occur as low as 200 cm^{-1}. Table I lists the principal infrared absorption bands recorded in the region 500–200 cm^{-1}. In addition, the infrared spectra of the 2,2-bipyridyl complexes MX_2.bipy, where M = Pd(II) or Pt(II) and X = Cl or Br, have been examined in this region and are included in Table I.

Durig *et al.* (12) have reported that for $PdCl_2$.bipy, the ν(Pd—N) modes occur as weak bands at 479 and 446 cm^{-1}. These workers also assigned ν(Pd—N) vibrations to bands $\sim$ 460 cm^{-1} in *cis*- and *trans*-$PdCl_2.2py$, whereas such modes are invariably found near

‡At the limit of the measurements.

200 cm^{-1} in pyridine complexes of transition metal halides (10). In the present study, a weak band was observed at 441 cm^{-1} in the spectrum of $PdCl_2.bipy$, but the presence of a band of similar intensity at 479 cm^{-1} could not be confirmed. These weak bands may arise from ligand vibrations activated by coordination, whereas medium-strong bands at ~410 cm^{-1}, observed in the complexes $MX_2.bipy$, are almost certainly the modified ligand vibration which occurs at ~400 cm^{-1} in free bipyridyl. The infrared spectra of the 2,2′-bipyridyl complexes also revealed bands at ~280, ~255, and ~200 cm^{-1}, which may be associated with the metal–nitrogen stretching vibrations. However, in other systems (13), such modes have not been observed above 200 cm^{-1}. These bands are unlikely to arise from modified ligand vibrations since no such absorptions are observed in the spectra of the free ligand (2, 13) or other bipyridyl complexes (4, 13, 14). The expected *cis*-planar configuration of the bromide complex $PtBr_2.bipy$ was confirmed by the observation of ν(Pt—Br) at 235 and 224 cm^{-1}; for a *cis*-planar configuration two such modes (symmetry $A_1 + B_1$) are expected.

In none of the alkyl cyanide complexes (Table I) were bands observed above 350 cm^{-1} which could be assigned to ν(M—N), thus contradicting the observations of Lott (unpublished observations, quoted in ref. 7). However, for the palladium(II) and platinum(II) complexes several bands, other than those assigned to ν(M—X), were observed between 350 and 200 cm^{-1} (see also ref. 2). Their number and position depended upon the particular halide and cyanide, and their assignment as ν(M—N) was not generally in keeping with the known stereochemistry of the complexes. Thus *trans*-$PdCl_2.2PhCN$, for which one ν(Pd—N) mode is predicted, had bands at 308 (m-s),* 281 (s),* and 247 (m-w)* cm^{-1}, whereas *cis*-$PtCl_2.2PhCN$ had only one band at 301 (m-s) cm^{-1} (with a weak shoulder at ~270 cm^{-1}) in the same region of the spectrum. Similarly, this difficulty was not resolved for the rhodium(III) complexes, $RhCl_3.3RCN$ (1), which in all cases had a single band below 290 cm^{-1}. Also, a comparison of the analogous chloride and bromide complexes of platinum(II) did not reveal bands which were independent of halogen, although most complexes had a band in the region 320–300 cm^{-1} which could possibly arise from the metal–nitrogen stretching vibration. In fact, in the case of $PtBr_2.2EtCN$ and $PtBr_2.2Ph$ CN, no prominent bands were observed below 350 cm^{-1} other than those due to ν(Pt—Br), although $PtBr_2.2EtCN$ had a very weak absorption at 307 cm^{-1}.

Bands in the 320–200 cm^{-1} region are unlikely to arise from ligand modes activated by coordination, since neither the infrared nor Raman spectra of the free ligands (15–17) reveal bands in this region. Also, since these bands are not independent of halogen for a particular metal ion, they cannot be associated with pure metal–nitrogen stretching vibrations. Thus the present study indicates that none of the infrared absorption bands above 200 cm^{-1} can be unambiguously assigned to ν(M—N). However, these modes may well occur below 200 cm^{-1}, as reported for $ZnCl_2.2MeCN$ (6).

REACTIONS OF SUGAR CHLOROSULFATES

VII. SOME CONFORMATIONAL ASPECTS

A. G. COTTRELL,[1] E. BUNCEL, AND J. K. N. JONES

Department of Chemistry, Queen's University, Kingston, Ontario

Received January 13, 1966

ABSTRACT

The reaction of sulfuryl chloride with several 1,6-anhydro-hexosans has yielded crystalline, fully chlorosulfated derivatives. Replacement of the chlorosulfate moieties by chlorodeoxy groups could not be achieved under the reaction conditions employed. This non-reactivity is discussed in terms of steric interactions in the transition state for substitution.

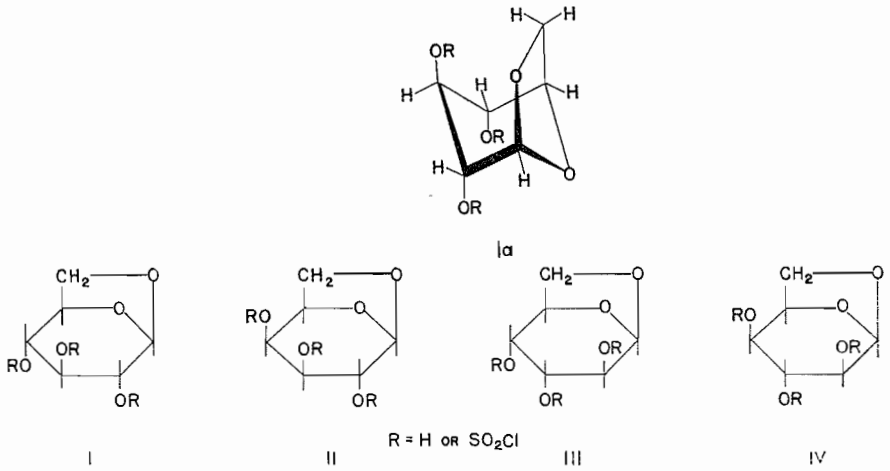
An examination of some chloro-substituted sugar chlorosulfates confirmed that an axial chlorodeoxy group in a glycopyranoside deactivates a neighboring equatorial chlorosulfate group and thus prevents further chlorodeoxy groups being introduced into such positions. Methyl α-D-altropyranoside, methyl α-L-rhamnopyranoside, methyl α-D-lyxopyranoside, L-rhamnose, and D-lyxose were reacted with sulfuryl chloride. The resulting products were those expected if these sugars reacted primarily in the C1 conformation.

INTRODUCTION

Previous work (1–5) has shown that the reaction of sulfuryl chloride with carbohydrates containing free hydroxyl groups gives derivatives containing both chlorodeoxy and chlorosulfate moieties, and that these products are formed via fully chlorosulfated derivatives. The chlorodeoxy groups are derived by the nucleophilic displacement (S_N2) of certain of the chlorosulfate groups by chloride ion. Kinetic studies carried out with model alkyl chlorosulfates have shown the remarkable facility with which the OSO_2Cl moiety can act as a leaving group (6).

It has been shown in the previous work carried out with hexopyranoses and hexopyranosides that the OSO_2Cl group at C-6 is the most reactive and is readily converted into a chlorodeoxy group. Preferential displacement at C-6 in hexopyranosides has been noted previously, for instance, with the tosyl derivatives (7).

Whether a secondary chlorosulfate group is replaced by the chloride ion depends on the conformation of the pyranoside of which it forms a part. Several steric factors have been demonstrated to affect adversely the replacement and may be summarized as: (*i*) 1,3-diaxial interactions to the approach of the chloride ion; (*ii*) deactivation of the C-2 position by anomeric chloro and methoxyl groups; and (*iii*) deactivation of an equatorial chlorosulfate ester group vicinal to an axial substituent which itself is resistant to substitution. The relevance of these factors to the synthesis of a fully chlorinated sugar glycoside was considered recently (8).



The present paper reports on a number of topics. For the first time, chlorosulfates of 1,6-anhydro-hexopyranoside derivatives have been investigated, with the view that the

[1]*Present address: Imperial Chemical Industries Ltd., Mond Division Research Laboratories, Runcorn Heath, Cheshire, England.*

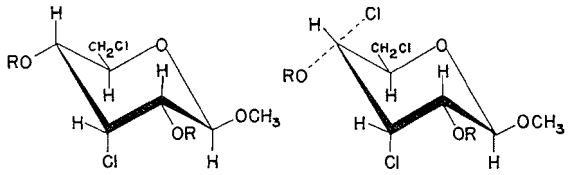
rigidity of these structures would impose stringent conditions on the substitution process. Secondly, a number of sugars have been examined in which chloro substituents were introduced into certain specific positions to learn more about steric and electronic effects in these substitution processes. Lastly, experiments have been performed with the aim of obtaining further information about the preferred conformation of certain sugars. Thus D-lyxose and D-altrose were considered by Reeves (9) to exist in both C1 and 1C conformations, but other workers (10, 11) have disagreed. It was considered that an examination of chlorosulfate substitution in these compounds might provide a chemical approach to this problem.

The Reaction of 1,6-Anhydro-hexosans

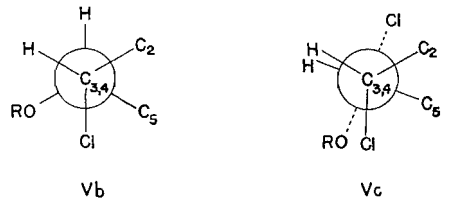
The following hexosans were studied: 1,6-anhydro-β-D-glucopyranose (I, R = H, or I*a*, R = H (conformational formula)), 1,6-anhydro-β-D-galactopyranose (II, R = H), 1,6-anhydro-β-D-altropyranose (III, R = H), and 1,6-anhydro-β-D-idopyranose (IV, R = H). The product obtained in each case was a crystalline 2,3,4-trichlorosulfate (I–IV, R = SO_2Cl). Treatment of the trichlorosulfates with pyridine hydrochloride in chloroform solution failed to introduce chlorodeoxy groups into the molecules under the conditions employed. Since substitution does not occur in any of the cases, it must be

concluded that the steric interactions are too great throughout or, of course, that the reaction conditions employed were not at an optimum. Another factor may contribute to the lower reactivity of the chlorosulfates of these bicyclic systems relative to that of the simple hexopyranosides, namely, that re-hybridization from sp^3 to sp^2 requisite for substitution (12) may be disfavored by the rigidity of this bicyclic system.

The Reaction of Some Substituted Methyl Glycopyranosides



When methyl α- and β-D-glucopyranosides were treated with sulfuryl chloride in pyridine, 4,6-dichloro-substituted derivatives were obtained which were resistant to further substitution (5). In the case of the methyl β-D-glycosidic derivative, in which the anomeric methoxyl group is equatorial, the resistance to further substitution was explained as being due to the deactivating effect of the axial chlorodeoxy group at C-4. It was decided in the current work to examine whether a chlorodeoxy group at C-3 would have the same deactivating effect. The known methyl 3-chloro-3-deoxy-β-D-allopyranoside



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was prepared from methyl 4,6-*O*-benzylidene-β-D-glucopyranoside. The methyl 3-chloro-3-deoxy-β-D-allopyranoside (V) was then treated with sulfuryl chloride in the usual way. The product was a syrup which, on dechlorosulfation, gave a crystalline compound that was most probably methyl 3,6-dichloro-3,6-dideoxy-β-D-allopyranoside. Elemental analysis showed the formation of a dichlorodideoxy compound, and periodate oxidation results indicated that the chlorodeoxy groups were at the C-3 and C-6 positions. The D-allo configuration is assumed, since in all cases examined hitherto the chlorodeoxy groups were observed to be introduced with inversion (3–5).

The observation that no further substitution by chloride ion occurred under these standard conditions to form a trichlorotrideoxy derivative indicates a deactivating effect of the axial chloro group at C-3. This is further evidence that an axial substituent which cannot itself be replaced deactivates a vicinal, equatorial chlorosulfate ester group. A possible explanation for this is shown in formulae V–V*c*. To introduce a chlorodeoxy

group at C-4 by S_N2 reaction, the transition state V*a* would have to be formed (13). The end-on representation of V and V*a*, viewed along the C-3, C-4 axis, is shown in V*b* and V*c*, and it is seen that steric interaction in V*c* between the chlorodeoxy group on C-3 and the large chlorosulfate group on C-4 would strongly hinder S_N2 reaction at C-4.

The Reaction of Methyl α-L-Rhamnopyranoside and L-Rhamnose

Methyl α-L-rhamnopyranoside has the anomeric methoxyl group on C-1 and the hydroxyl group on C-2 axially oriented, since its preferred conformation is 1C (9). The product obtained from its reaction with sulfuryl chloride in pyridine was a crystalline trichlorosulfate, and no further substitution could be obtained even when it was heated in chloroform solution with pyridine hydrochloride. A chlorodeoxy group might perhaps be introduced into methyl α-L-rhamnopyranoside at C-2 since this chlorosulfate group is axially oriented, by analogy with cyclohexyl derivatives where it is known that axial substituents are displaced at a faster rate than corresponding equatorial substituents. The axial methoxyl group at C-1 would further hinder substitution at C-2.

To verify the latter effect, L-rhamnose itself was reacted with sulfuryl chloride and pyridine. The product from this reaction was a crystalline compound which analyzed as (β?)-L-rhamnosyl chloride 2,3,4-trichlorosulfate. Treatment of this trichlorosulfate with pyridine hydrochloride yielded a syrup which, after dechlorosulfation, had the R_f value and chlorine content expected for a dichlorodideoxy compound. A periodate oxidation

showed no uptake of reagent within 2 days, as expected for 2,4-dichloro-2,4,6-trideoxy-L-galactose which would result if it is assumed that inversion takes place in the normal manner when the chlorodeoxy groups are introduced. The only other possible structure which would not be affected by periodate is a 2,3-dichloro-2,3,6-trideoxy compound, but the formation of the compound is unlikely on the basis of previous results.

The Reactions of Methyl α-D-Altropyranoside, Methyl α-D-Lyxopyranoside, and D-Lyxose

Glycosides and free sugars in the D-altropyranose and D-lyxopyranose configurations have been reported as existing in the C1 and 1C conformations.

Methyl 6-chloro-6-deoxy-α-D-altropyranoside was obtained from methyl α-D-altropyranoside after it was reacted with sulfuryl chloride in pyridine followed by dechlorosulfation. This is the product that would be formed if the glycoside reacted in the C1 conformation, since in this conformation the C-2 and C-3 hydroxyl groups are axially oriented. In the 1C conformation the OR (R = H or SO_2Cl) group at C-4 would be axially oriented, as would be also the CH_2Cl group on C-5. Substitution of the axial chlorosulfate group at C-4 is therefore prevented by the neighboring axial CH_2Cl group.

Proof of the structure of the methyl 6-chloro-6-deoxy-α-D-altropyranoside was given by its elemental analysis and periodate oxidation. The periodate oxidation of this compound was somewhat unusual. The consumption of 2 moles of periodate and the release of 1 mole of formic acid were consistent with the chlorodeoxy group being on C-6. However, unlike the periodate oxidation of the corresponding gluco compound, the rate of production of formic acid was much less than half the uptake of periodate during the first 6 h of the oxidation, and it was not until the reaction had been proceeding for about 1 day that the number of moles of formic acid released became approximately half the number of moles of periodate consumed. If an internal hemiacetal is postulated as an intermediate, these results may be explained.

Methyl α-D-lyxopyranoside in the C1 conformation has the axial glycosidic methoxyl group at C-1 and also an axial substituent at C-2. This situation is directly analogous to the situation in methyl α-D-mannopyranoside and methyl α-L-rhamnopyranoside, which also have axial groups at C-1 and C-2. Methyl α-D-mannopyranoside was shown to yield methyl 6-chloro-6-deoxy-α-D-mannopyranoside 2,3,4-trichlorosulfate when reacted with sulfuryl chloride (5). It was found in the present study that the reaction between methyl α-D-lyxopyranoside and sulfuryl chloride yielded methyl α-D-lyxopyranoside 2,3,4-trichlorosulfate; no chlorodeoxy groups could be introduced by reacting the product further with pyridine hydrochloride. However, if methyl α-D-lyxopyranoside reacted in the 1C conformation, the product might well be the same, since in this conformation the C-3 and C-4 hydroxyl groups would be axial.

To extend the analogy with the manno conformation further, it was decided to examine the reaction of D-lyxose with the sulfuryl chloride – pyridine mixture. D-Mannose had been found to yield a 6-chloro-6-deoxy-trichlorosulfate which, when reacted with pyridine hydrochloride, gave a trichlorotrideoxy compound whose methyl glycoside was assigned the structure methyl 2,4,6-trichlorotrideoxy-β-D-galactopyranoside (compare with L-rhamnose) (5). D-Lyxose also gave a chloro-trichlorosulfate derivative when reacted with sulfuryl chloride, and reaction with pyridine hydrochloride followed by treatment with sodium iodide solution now gave a syrup which was shown by thin-layer chromatography and chlorine analysis to be a dichlorodideoxy sugar. Periodate oxidation showed no uptake of periodate after 48 h, so that the compound was probably 2,4-dichloro-2,4-dideoxy-L-arabinose if the sugar is assumed to react in the pyranose form. The other possibility,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

2,3-dichloro-2,3-dideoxy-D-ribose, is considered to be unlikely, since the D-ribose configuration is known to undergo readily further substitution at C-4 (14). This indicates that D-lyxopyranose reacts primarily in the C1 conformation, as does D-mannopyranose. If it were in the 1C conformation, there would be an axial chlorosulfate at both C-3 and C-4 and an equatorial chlorosulfate group at C-2. This situation would be unlikely to lead to further introduction of chlorodeoxy groups.

EXPERIMENTAL[2]

Thin-layer chromatograms were run by the ascending technique on glass plates which had been coated with silica gel G and dried at 150–160° for 2 h. The following solvent systems were used: (*a*) benzene–methanol (10:1), (*b*) benzene–methanol (20:1), (*c*) benzene–methanol (50:1), and (*d*) benzene–isopropanol (2:1). The sugars were detected on chromatograms by spraying them with sulfuric acid and subsequent heating of the plate in an oven at 110°.

Three general procedures were used. (A) Sulfuryl chloride[3] was added dropwise to the stirred pyridine–chloroform reaction mixtures, cooled in an acetone – solid carbon dioxide bath (approximately −70°), and maintained at this temperature for 2 h, after which time the mixtures were allowed to come to room temperature and held at that temperature for 1 to 2 h. The products were then isolated in the usual way (1–5). (B) The experiment was repeated, except that the mixture was left for 8–12 h before the products were isolated. (C) If thin-layer chromatography (t.l.c.) indicated that further reaction had taken place, then the product was heated with pyridine hydrochloride in dry chloroform to complete, as far as the configuration would allow, the formation of chlorodeoxy groups.

Tetra-*n*-butylammonium chloride could be used as an alternative source of chloride ions to effect displacement (see below).

The Preparation of 1,6-Anhydro Sugars

1,6-Anhydro-β-D-glucopyranose was obtained by the pyrolytic distillation of starch (15) but with the following modification. The dry starch was mixed with copper powder to improve heat transfer through the decomposing starch, and a layer of glass wool was placed above the charge to reduce frothing. The yield was about 40 g from 150 g of starch (26.8%).

1,6-Anhydro-3,4-*O*-isopropylidene-β-D-galactopyranose was prepared from α-lactose monohydrate (16) except that copper powder was mixed with the charge to improve heat transfer through the decomposing lactose. 1,6-Anhydro-3,4-*O*-isopropylidene-β-D-galactopyranose (10 g) was dissolved in water, and the solution was treated with 8 g of Amberlite IR-120 (H^+) resin for 1½ h on a water bath at 70° and then filtered. The product, after evaporation, was recrystallized from alcohol–water (80:20). The yield of 1,6-anhydro-D-galactopyranose, m.p. 220°, was practically quantitative.

1,6-Anhydro-β-D-altropyranose was prepared as follows. A solution of syrupy methyl α-D-altropyranoside (17) in 200 ml of 6% hydrochloric acid was refluxed for 2 h. The solution was neutralized with lead carbonate and filtered, and the lead ions were removed from the filtrate as lead sulfide. The filtered solution was then deionized to yield 10.5 g of syrup. The syrup (6 g) was separated on a cellulose column (63 × 5 cm). The eluting solvent was butan-1-ol half saturated with water. The first fraction was nonreducing in character, and crystallized as long, needle-shaped crystals upon evaporation of the solvent. The relative speed of movement on paper of D-altrose and 1,6-anhydro-β-D-altropyranose is not great but was sufficient to follow the separation without difficulty. In solvent system *e* (ethyl acetate – acetic acid – formic acid – water (18:3:1:4 by volume)) the R_{Rh} of D-altrose was 0.70, and of 1,6-anhydro-β-D-altropyranose 0.95. The yield of 1,6-anhydro-β-D-altropyranose was 2 g (63%), and of D-altrose 1.5 g (58%), characterized as the penta-acetate (17). The yields are based on a 53:47 ratio of anhydro compound to free sugar. 1,6-Anhydro-β-D-altropyranose analyzed as the anhydrous sugar.

Anal. Calcd. for $C_6H_{10}O_5$: C, 44.4; H, 6.22. Found: C, 44.4; H, 6.07.

No definite melting point has previously been reported for 1,6-anhydro-β-D-altropyranose. The melting point of the above sample was 133°, with slight preliminary sintering. It had $[\alpha]_D$ −210° (*c*, 1.0 in water). A sample of 1,6-anhydro-β-D-altropyranose was also obtained from Dr. N. K. Richtmyer; this had a melting point and a mixed melting point with the above sample of 133°. The infrared spectrographs of the two samples were also identical. Dr. Richtmyer's sample was believed to have been the monohydrate before it was stored.

1,6-Anhydro-β-D-glucopyranose 2,3,4-Trichlorosulfate

1,6-Anhydro-β-D-glucopyranose (2 g, 0.012 mole) in dry pyridine (8 ml, 0.099 mole) and dry chloroform (25 ml) was treated with sulfuryl chloride (5 ml, 0.061 mole) and the product isolated according to

[2]*For details see refs. 1–5.*

[3]*The amount of sulfuryl chloride used to make the chlorosulfate ester was 1.5 to 2 moles per hydroxyl group. The pyridine – sulfuryl chloride ratio was in the range 1.5 to 2 moles per mole.*

For personal use only.

procedure A. Recrystallization from chloroform–petrol gave colorless needles, 3.6 g (66%), m.p. 144–146°, $[\alpha]_D$ −17° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_6H_7Cl_3O_{11}S_3$: C, 15.7; H, 1.54; Cl, 23.2; S, 21.0. Found: C, 15.6; H, 1.66; Cl, 23.1; S, 21.3.

The product gave a positive test for chlorosulfate groups. The infrared spectrum exhibited very sharp peaks at 1 200 and 1 435 cm^{-1} characteristic of chlorosulfate groups (18).

A small amount of crystalline 1,6-anhydro-β-D-glucopyranose 2,3,4-trichlorosulfate was dissolved in methanol (5 ml), and barium carbonate (1 g) was added. One drop of *N* sodium iodide solution was added to dechlorosulfate the product; after 8 h the liquor was co-chromatographed against 1,6-anhydro-β-D-glucopyranose on a paper run in solvent *f* (butan-1-ol–ethanol–water (3:1:1 v/v/v)). The only sugar detected was 1,6-anhydro-β-D-glucopyranose.

The reaction between 1,6-anhydro-β-D-glucopyranose and sulfuryl chloride was carried out according to procedure B. The only chloroform-soluble product obtained was 1,6-anhydro-β-D-glucopyranose 2,3,4-trichlorosulfate.

1,6-Anhydro-β-D-glucopyranose 2,3,4-trichlorosulfate (2 g, 0.043 mole) in dry chloroform (20 ml) and pyridine hydrochloride (2 g, 0.012 mole) was treated according to procedure C. The white crystals so obtained (0.6 g (40.0%)) were found to be identical with the starting material. A small amount of a reducing product (0.012 g) was also obtained but could not be identified.

1,6-Anhydro-β-D-galactopyranose 2,3,4-Trichlorosulfate

1,6-Anhydro-β-D-galactopyranose (1.5 g, 0.0093 mole) in dry pyridine (6 ml, 0.075 mole) and dry chloroform was reacted with excess sulfuryl chloride (4 ml, 0.049 mole) (procedure A). The product was recrystallized from chloroform – petrol (b.p. 35–60°) to give colorless needles, 1.7 g (40%), m.p. 105–106°, $[\alpha]_D$ −27° (*c*, 1.0 in chloroform). The material gave a positive test for chlorosulfate groups and the infrared spectrum exhibited very sharp peaks at 1 418 and 1 183 cm^{-1} corresponding to OSO_2Cl groups (18).

Anal. Calcd. for $C_6H_7Cl_3O_{11}S_3$: C, 15.7; H, 1.54; S, 21.1; Cl, 23.2. Found: C, 15.4; H, 1.64; S, 20.8; Cl, 23.0.

Procedure B gave 1,6-anhydro-β-D-galactopyranose 2,3,4-trichlorosulfate in somewhat lower yield.

1,6-Anhydro-β-D-altropyranose 2,3,4-Trichlorosulfate

1,6-Anhydro-β-D-altropyranose (0.67 g, 0.0041 mole) in pyridine (3 ml, 0.038 mole) and dry chloroform (10 ml) was treated with an excess of sulfuryl chloride (2 ml, 0.025 mole) according to procedure A. The product was recrystallized from chloroform – petrol (b.p. 40–65°) as white needles, 0.74 g (40%), m.p. 143°, $[\alpha]_D^{25}$ −130° (*c*, 0.1 in chloroform). It gave a positive test for chlorosulfate groups and the infrared spectrum exhibited very sharp peaks corresponding to OSO_2Cl groups.

Anal. Calcd. for $C_6H_7Cl_3O_{11}S_3$: C, 15.7; H, 1.54; Cl, 23.2; S, 21.1. Found: C, 15.3; H, 1.4; Cl, 23.0; S, 21.0.

Procedure B gave 1,6-anhydro-β-D-altropyranose 2,3,4-trichlorosulfate in somewhat lower yield.

1,6-Anhydro-β-D-idopyranose 2,3,4-Trichlorosulfate[4]

1,6-Anhydro-β-D-idopyranose (1.01 g from 2.0 g of the triacetate) in pyridine (4.5 ml) and dry chloroform (12.0 ml) was converted into the trichlorosulfate by addition of sulfuryl chloride (2.2 ml) to the mixture (procedure A). The crystalline product had m.p. 164–165° and $[\alpha]_D$ −41° (*c*, 1.8 in methanol).

Anal. Calcd. for $C_6H_7Cl_3O_{11}S_3$: C, 15.7; H, 1.54; Cl, 23.2; S, 21.1. Found: C, 16.1; H, 1.83; Cl, 22.9; S, 21.1.

Procedure C gave starting material as the main product. Some small quantities of other unidentified sugar derivatives were also produced.

Methyl 3,6-Dichloro-3,6-dideoxy-β-D-allopyranoside

Methyl 3-chloro-3-deoxy-β-D-allopyranoside (1.4 g, 0.007 mole), prepared from methyl 4,6-*O*-benzylidene-β-D-glucopyranoside, in pyridine (6 ml, 0.0075 mole) and chloroform was treated with sulfuryl chloride according to procedure A. The product was a syrup (2 g (88%)) which solidified but could not be recrystallized. Dechlorosulfation with sodium iodide gave a crystalline product which, after two recrystallizations, was shown to be pure by t.l.c. in solvent *f* (as used for paper chromatography), R_f 0.59, yield 1.0 g (75%), $[\alpha]_D$ −45°, m.p. 145–156° with some decomposition.

Anal. Calcd. for $C_7H_{12}Cl_2O_4$: C, 36.4; H, 5.23; Cl, 30.7. Found: C, 36.6; H, 5.37; Cl, 30.5.

Periodate oxidation of the methyl 3,6-dichloro-3,6-dideoxy-β-D-allopyranoside, determined in the usual way (19, 20), showed no consumption of periodate during 24 h.

Methyl α-L-Rhamnopyranoside 2,3,4-Trichlorosulfate

Methyl α-L-rhamnopyranoside (31) (0.5 g, 0.003 mole) in anhydrous pyridine (3 ml, 0.038 mole) and dry chloroform (10 ml) was treated with sulfuryl chloride (2 ml, 0.025 mole) (procedure A). The crystalline product was recrystallized from chloroform–petrol, 0.9 g (64%), m.p. 112–113°, $[\alpha]_D$ −2° (*c*, 1.0 in chloroform). Infrared analysis and the aniline–pyridine spray test confirmed the presence of chlorosulfate groups.

[4]*This experiment was carried out by Mr. S. S. Ali.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Anal. Calcd. for $C_7H_{11}Cl_3O_{11}S_3$: C, 17.8; H, 2.3; Cl, 22.5; S, 20.0. Found: C, 18.1; H, 2.1; Cl, 22.5; S, 20.1.

A portion of the above crystals (0.5 g, 0.002 mole) in chloroform and anhydrous pyridine hydrochloride (0.5 g, 0.044 mole) was treated according to procedure C. The melting point (112–113°) of the product (0.3 g) was undepressed on admixture with the starting compound.

(β?)-L-Rhamnosyl Chloride 2,3,4-Trichlorosulfate

L-Rhamnose (8 g, 0.05 mole) (dehydrated by heating it at 50° in a vacuum oven for several hours) in pyridine (30 ml) and chloroform (85 ml) was treated with 17 ml of sulfuryl chloride (procedure A). The crystalline product was recrystallized from chloroform – petrol (b.p. 40–60°), 8.5 g (35%), m.p. 140°, $[\alpha]_D$ +57.8° (*c*, 0.1 in chloroform).

Anal. Calcd. for $C_6H_8Cl_4O_{10}S_3$: C, 15.1; H, 1.69; Cl, 29.7; S, 20.1. Found: C, 14.8; H, 1.69; Cl, 29.6; S, 20.5.

The trichlorosulfate (5 g) was dissolved in a minimum of dry chloroform which contained an excess of pyridine hydrochloride, and the solution was heated for 12 h. The product, after dechlorosulfation, contained a major component with R_f 0.67 (solvent *e*). It was purified by preparative thin-layer chromatography and then distilled. The syrupy product had $[\alpha]_D$ −45° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_6H_{10}Cl_2O_3$: Cl, 35.3. Found: Cl, 35.8.

Periodate oxidation of the dichlorodideoxy compound showed no consumption of periodate during 48 h.

Methyl 6-Chloro-6-deoxy-α-D-altropyranoside 2,3,4-Trichlorosulfate

Methyl α-D-altropyranoside (1 g, 0.0052 mole) in anhydrous pyridine (5 ml, 0.062 mole) and chloroform (20 ml) was treated with sulfuryl chloride (3 ml, 0.037 mole) (procedure A). The crystalline product was recrystallized from chloroform–petrol to give colorless prisms, 2.1 g (79.5%), m.p. 156°, $[\alpha]_D$ +99.2° (*c*, 0.97 in chloroform).

Anal. Calcd. for $C_7H_{10}Cl_4O_{11}S_3$: C, 16.5; H, 1.98; Cl, 27.9; S, 18.9. Found: C, 16.8; H, 2.04; Cl, 28.1; S, 19.0.

Methyl 6-Chloro-6-deoxy-α-D-altropyranoside

The above crystals (2 g) were dissolved in methanol and dechlorosulfated with sodium iodide as previously described. The colorless syrup (1 g (60%)) was shown by t.l.c. to be one component with R_f 0.25 in solvent *b*, $[\alpha]_D$ +101° (*c*, 0.92 in chloroform).

Anal. Calcd. for $C_7H_{13}ClO_5$: C, 39.5; H, 6.16; Cl, 16.7. Found: C, 39.3; H, 6.07; Cl, 16.7.

Periodate Oxidation of Methyl 6-Chloro-6-deoxy-α-D-altropyranoside

A sample of the glycoside (39 mg) was oxidized in the usual way (20). The results are shown in Table I.

TABLE I

Periodate oxidation of methyl 6-chloro-6-deoxy-α-D-altropyranoside

Time	Periodate uptake (moles per mole)	Formic acid released (mole per mole)
20 min	0.99	0.19
1 h	1.24	0.29
3 h	1.36	0.37
6½ h	1.53	0.58
10 h	1.65	0.66
23 h	1.91	0.91
34 h	1.94	0.97
48 h	1.95	0.97
96 h	1.95	0.97

Methyl α-D-Lyxopyranoside 2,3,4-Trichlorosulfate

Methyl α-D-lyxopyranoside (21) (2 g, 0.012 mole) in anhydrous pyridine (10 ml, 0.02 mole) and chloroform (25 ml) was treated with sulfuryl chloride (6 ml, 0.074 mole) (procedure A). The crystalline product was methyl α-D-lyxopyranoside 2,3,4-trichlorosulfate, 3.3 g (60%). It was recrystallized from chloroform – petrol (b.p. 35–60°). The colorless plates had m.p. 129–130° and $[\alpha]_D$ −7° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_6H_9Cl_3O_{11}S_3$: C, 15.8; H, 1.96; Cl, 23.1; S, 20.8. Found: C, 15.8; H, 1.98; Cl, 23.5; S, 20.6.

A portion of the crystals (1 g, 0.006 mole) obtained from the previous experiment was treated according to procedure C. The crystalline product, 0.52 g (52%), m.p. 129–130°, was indistinguishable from the starting material.

D-Lyxosyl Chloride 2,3,4-Trichlorosulfate

D-Lyxose (2 g, 0.013 mole) in anhydrous pyridine (10 ml, 0.12 mole) and chloroform (25 ml) was treated with sulfuryl chloride (6 ml, 0.074 mole) according to procedure A and gave colorless crystals, 3 g (52%), m.p. 94–96°, $[\alpha]_D$ +20.4° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_5H_6Cl_4O_{10}S_3$: C, 13.0; H, 1.30; Cl, 30.6; S, 20.7. Found: C, 13.1; H, 1.37; Cl, 30.4; S, 20.6.

The Reaction of D-Lyxosyl Chloride 2,3,4-Trichlorosulfate with Pyridine Hydrochloride

The crystals (1.5 g, 0.003 mole) (above) in anhydrous chloroform and pyridine hydrochloride (1.3 g, 0.012 mole) gave (procedure C) a syrupy product containing several substances. A positive test for chlorosulfate groups was obtained. The syrup was dechlorosulfated with sodium iodide. A syrup was obtained which was shown by t.l.c. to contain one main substance, R_f 0.53 and R_{Rh} 2.5 in solvent *b*, and several minor substances. A small amount of the main substance was purified by t.l.c. followed by vacuum distillation. It had $[\alpha]_D$ +39.8°.

Anal. Calcd. for $C_5H_{10}Cl_2O_3$: Cl, 37.9. Found: Cl, 35.6.

Methyl 2-Chloro-2-deoxy-β-D-galactopyranoside[5]

Methyl 2-chloro-2-deoxy-β-D-galactopyranoside 2,3,4-triacetate (2.1 g, 0.007 mole), prepared from triacetyl D-galactal (22) in 19% yield according to the procedure of Lemieux and Fraser-Reid (23) except that silver carbonate was used in place of silver acetate, was dissolved in anhydrous methanol (25 ml) and cooled to 5°. It was de-*O*-acetylated catalytically with a cold, freshly prepared solution of sodium methoxide in the usual way. The methyl 2-chloro-2-deoxy-β-D-galactopyranoside, 0.95 g (72%), had m.p. 145–147° (mixed m.p. with a sample obtained from Dr. R. U. Lemieux 144–146°) and $[\alpha]_D$ +25° (*c*, 0.88 in water).

Methyl 2,3,4,6-Tetrachloro-2,3,4,6-tetradeoxy-β-D-alloside[5]

Methyl 2-chloro-2-deoxy-β-D-galactopyranoside (1.28 g, 0.006 mole) in pyridine (6 ml, 0.075 mole) and dry chloroform (24 ml) was treated with sulfuryl chloride (2.5 ml, 0.030 mole) (procedure A). The syrupy product (1 g) contained, as shown by t.l.c., one major component, R_f 0.94, and small amounts of two other components with R_f 0.83 and 0.75 (solvent *a*). Tests indicated that there was probably a small amount of material present containing the OSO_2Cl group. The syrup (1 g) in anhydrous chloroform and pyridine hydrochloride (0.5 g) was reacted according to procedure C and gave a syrupy product (0.85 g (54%)) which contained a single component, R_f 0.93 in solvent *a* and 0.62 in solvent *d* (t.l.c.). The volatile component was purified by vacuum distillation at 0.15 mm. The aniline–pyridine test for chlorosulfate groups was negative. The infrared spectrograph showed the absence of any hydroxyl peaks and confirmed the absence of any chlorosulfate groups.

Anal. Calcd. for $C_7H_{10}Cl_4O_2$: C, 31.4; H, 3.76; Cl, 52.9; OMe, 11.6. Found: C, 31.7; H, 3.7; Cl, 52.4; OMe, 11.9.

The Use of Tetra-n-butylammonium Chloride as a Source of Chloride Ions instead of Pyridine Hydrochloride

Methyl α-D-Glucopyranoside 2,3,4,6-Tetrachlorosulfate

Methyl α-D-glucopyranoside (10 g, 0.051 mole) was treated with sulfuryl chloride (26 ml, 0.32 mole) and pyridine in chloroform solution at −70° for 2 h. The mixture was allowed to warm up rapidly to −30° so that it became less viscous, while at this temperature an ice-cold 70% solution of sulfuric acid (500 ml) was added to the reaction mixture, with stirring. This modified method gave a considerably improved yield of the tetrachlorosulfate, 24 g (80%), m.p. 111–114°.

Methyl 4,6-Dichloro-4,6-dideoxy-α-D-galactopyranoside

The above material (2 g, 0.034 mole) in dry chloroform and anhydrous tetra-*n*-butylammonium chloride (2.06 g, 0.072 mole) was heated on a water bath at 50–60° for 5 h. From the chloroform solution was isolated a syrup which gave a positive test for chlorosulfate groups (aniline–pyridine test). The syrup was dechlorosulfated with sodium iodide to give a crystalline product, 0.70 g (85%), which, after recrystallization from chloroform–petrol, had m.p. 156–157°, undepressed on admixture with methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside (3, 4).

The previous experiment was repeated with a mole ratio of tetrachlorosulfate to tetra-*n*-butylammonium chloride of 1:4.4. The reaction was left for 24 h on the water bath at 50°. The only chloroform-soluble product obtained was methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-dichlorosulfate.

ACKNOWLEDGMENTS

The authors thank the National Research Council, Queen's University, and the Ontario Research Foundation for financial assistance. Dr. N. K. Richtmyer is thanked for a gift of 1,6-anhydro-D-idosan triacetate.

[5]*A short account of these reactions has been given (8).*

THE TRANSMISSION OF POLAR EFFECTS

IV. THE KINETICS OF ESTERIFICATION WITH DIAZODIPHENYLMETHANE OF SUBSTITUTED HETEROCYCLIC CARBOXYLIC ACIDS[1]

KEITH BOWDEN[2] AND D. C. PARKIN[2]

Department of Pure and Applied Chemistry, Royal College of Advanced Technology, Salford, Lancashire, England

Received December 30, 1965

ABSTRACT

The rate coefficients for the reaction with diazodiphenylmethane, in ethanol at 30.0°, of a number of substituted indole-2-carboxylic acids, indole-3-carboxylic acids, coumarin-3-carboxylic acids, coumarilic acids, and N-phenylglycines have been determined. The effect of substitution is assessed by use of adapted Hammett and Dewar–Grisdale relations. The relations give good correlations for oxygen-ring heterocyclic systems, and the relative ability of the systems to transmit π-electron effects has been determined. An anomalous perturbing effect appears to operate in the indole-carboxylic acid systems.

INTRODUCTION

The transmission of polar effects in heterocyclic systems has been reviewed recently by Jaffé and Jones (1). In particular, the ionization of carboxylic acids and the rates of the hydrolysis of the corresponding esters have been employed usefully. The esterification of carboxylic acids by diazodiphenylmethane has been employed successfully in investigating the transmission of polar effects (2–5). Other workers (6, 7) have extended this technique recently to simple heterocyclic systems. In the present studies we have made a series of measurements of the transmission of the polar effects of substituents in a benzenoid ring fused to a heterocyclic ring having a carboxylic acid group. The reaction chosen was that of the acids with diazodiphenylmethane, and the analysis of the substituent effects was made by use of linear free energy relations.

EXPERIMENTAL

Materials

The carboxylic acids used in this study were synthesized by standard methods or obtained commercially. The 6-nitroindole-3-carboxylic acid was prepared by nitration of the unsubstituted acid by the method of Majima and Kotake (8). The indole-3-carboxylic acids were prepared by the reaction of the substituted indole with methylmagnesium iodide, followed by reaction with solid carbon dioxide (9). The indole-2-carboxylic acids were obtained commercially. The coumarin-3-carboxylic acids were synthesized by the Knoevenagel reaction from diethyl malonate and a substituted salicylaldehyde, followed by acid hydrolysis (10). The coumarilic acids were prepared by Perkin's method from substituted coumarins (11). The reaction of a substituted aniline with ethyl bromoacetate was employed to prepare the N-phenylglycines (12).

The acids were recrystallized to a constant melting point and had melting points identical with or close to those in the literature. Neutralization equivalents were determined for the indole-carboxylic and coumarilic acids and were found to be within 1% of the theoretical values. The N-phenylglycines were difficult to prepare with satisfactory neutralization equivalents. This is probably due to their liability to decarboxylation (12). Neutralization equivalents were measured just before a rate determination and were between 1 and 4% high. These values were then used to calculate the rates. No apparent decrease in acid present over the reaction time at the reaction temperature was found. The coumarin-3-carboxylic acids appear to undergo alkaline ring fission and slowly reacted with alkali in excess of 1 equivalent.

Pure ethanol, b.p. 78.3° (lit. b.p. 78.3° (13)), was prepared by Smith's method (14). Solutions of diazodiphenylmethane, prepared as before (3, 15), were stored in a refrigerator. The solutions were all stored with careful exclusion of atmospheric moisture.

[1]*For part III in this series, see K. Bowden, Can. J. Chem., 44, 661 (1966).*

[2]*Present address: Department of Chemistry, University of Essex, Colchester, Essex, England.*

Measurements

The rate coefficients were determined, at 30 ± 0.05°, as described previously (3, 15), using a Unicam S.P.500 spectrophotometer. An approximately 5- or 10-fold excess of acid was used (0.015 or 0.03 *M*). The reaction was then studied as a first-order process by using eq. [i], where k is the second-order rate

$$k = k_1/a \qquad [i]$$

coefficient, k_1 is the observed first-order rate coefficient, and a is the acid concentration. The rate coefficients for a given acid obtained at either concentration were within the experimental reproducibility. The faster nitro acids were inconveniently fast for the latter method, and the reaction was studied as a second-order process. Equation [ii] was then used to calculate the rate coefficient k, where a is the initial concentration of the

$$k = \frac{2.303}{t(a - Rb)} \log \frac{b(a - Rx)}{a(b - x)} \qquad [ii]$$

acid, b the initial concentration of diazodiphenylmethane, and x the concentration of diazodiphenylmethane that has reacted at time t. R is the amount of diazodiphenylmethane consumed in the reaction with acid to give the ester compared with the total amount consumed. The ratio was determined as described previously (16), by a titration method. The values of R that were obtained were 0.56 ± 0.02 (indole-2-carboxylic acids), 0.59 ± 0.02 (indole-3-carboxylic acids), 0.59 ± 0.01 (coumarilic acids), and 0.59 ± 0.02 (N-phenylglycines). There is thus little change for these non-proximate substituents, as noted previously for similar systems (2, 17). Recent mechanistic studies (17) have demonstrated the meaningfulness of the rate coefficients. The results are summarized in Table I.

TABLE I

Rate coefficients for substituted carboxylic acids in diazodiphenylmethane in ethanol at 30.0°

Substituent	k	Substituent	k

NOTE: The rate coefficients, k (l mole^{-1} min^{-1}), are reproducible to ±3% or better and are the mean of at least two determinations.

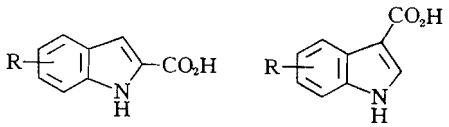
DISCUSSION

State of Acids in Solution

It has been shown that the normal acid form (I) of N-phenylglycines, in aqueous solution, exists in equilibrium with a zwitterionic form (II) (12). This becomes increasingly important as the electron-withdrawing capacity of the substituent decreases. The present

$$\underset{\text{I}}{RNHCH_2CO_2H} \rightleftharpoons \underset{\text{II}}{R\overset{+}{N}H_2CH_2CO_2^-}$$

measurements have been made in ethanol, where the tendency to the zwitterionic behavior is *greatly* reduced.[3] The substituted acids employed in this study are the least susceptible to this behavior, and it seems likely that the acids are completely in the form (I). Pyridine



[3]*See ref. 21, footnote on p. 424.*

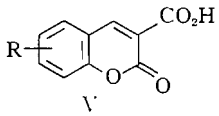
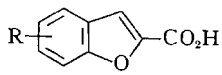
carboxylic acids exist predominantly as the zwitterionic species in aqueous solution (18), and apparently successful measurements have been made on the reaction of these acids with diazodiphenylmethane in ethanol (7).

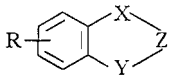


Linear Free Energy Relations

The systems under study are shown below (III to VI). Jaffé (1, 19) has adapted the Hammett equation (eq. [iii]) (20) to correlate the transmission of substituent effects



III



IV

V

VI

VII

through the two links X and Y to a reactive site Z (VII). The effect is then described by eq. [iv], where the substituent constants σ_X and σ_Y are the appropriate Hammett meta

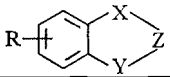
[iii] $$\log (k/k_0) = \rho\sigma$$

[iv] $$\log (k/k_0) = \rho_X\sigma_X + \rho_Y\sigma_Y$$

or para σ values for the position of the substituent R in relation to the link X or Y. The reaction constants ρ_X and ρ_Y describe the transmission by the links X and Y. The correlations were obtained by using the latter equation with the substituent constants recommended by McDaniel and Brown (21), and are shown in Table II.

A treatment similar to that of Dewar and Grisdale (22) can be used to analyze the results (3). The relative rates are assessed in terms of a field effect (F) and a π-inductive–resonance effect (M), as shown in eq. [v], where r_{ij} is the distance between the reactive group and

[v] $$\log (k/k_0) = \rho_D(F/r_{ij} + Mq_{ij})$$



the carbon atom bonded to it (measured in units of benzene carbon–carbon bond distances) and q_{ij} is the formal charge at the site produced by the substituent. The reaction constant found is ρ_D. The values of r_{ij} can be calculated for our systems, and are also shown in Table III. The values of q_{ij} are obtained, in this method, from the correlation itself, since these values are not available for these heterocyclic rings. The relation, as used here, has q_{ij} as an adjustable parameter.

However, these two treatments are basically similar. The substituent effect in the Dewar–Grisdale treatment has an a priori separation of the field and π-electron effects. This separation was made from the σ values of meta- and para-substituents. The Jaffé relation deals with the substituent as having a dual meta- and para-type nature. The parameters ρ_D and q_{ij} obtained by the former method can be compared usefully with those of the reference benzene system. On the other hand, the Jaffé treatment appears to imply transmission only via the links. The parameters ρ_X and ρ_Y are of more limited significance, and their relative values are very dependent on the substituents with quite different meta and para σ values, e.g. MeO. It seems likely that the total reaction constant ($\rho_X + \rho_Y$) is of more significance, in comparison to the reference benzene system, than the ratio ρ_X/ρ_Y.

The correlations (eqs. [iv] and [v]) have also been applied to data available for the pK values of the acids (series III, IV, and V) (1, 9, 23) in 50% aqueous ethanol and for the rates of the alkaline hydrolysis of the ethyl esters (series III and IV) (1, 23) in 85% ethanol–water. Jaffé (1) has previously made these correlations by using eq. [iv] for the latter data, and minor variations are caused by our use of different σ values (21). The furoic acid system has also been analyzed by applying eq. [v] to the pK_a values of 5-substituted-2-furoic acids in water and to the esterification of the acids with diazodiphenylmethane in ethanol (6). The N-phenylglycine system was also analyzed by using the normal Hammett equation (Table II). The results in Tables II and III cannot be compared directly because, whereas eq. [iv] applies to all substituents, eq. [v] is specific for any one position.

In all cases a satisfactory fit is obtained, *but* the standard deviation is particularly high for the results in Table II and for the indole-carboxylic acids in general. The results in Table II obtained by using the Jaffé relation show a confused picture, with the ratio of ρ_X to ρ_Y varying considerably; in view of the limits of the certainty, any conclusions are difficult to make. Although the total value of $(\rho_X + \rho_Y)$ in comparison to the reference system seems to give a more meaningful interpretation of the results, the conclusions can more clearly be drawn from the results of the Dewar–Grisdale relation in Table III.

The results for the latter correlations are very interesting. The Dewar–Grisdale reaction constant ρ_D should be comparatively constant for any stated reaction. The factor r_{ij} should, to a large extent, compensate for the change in situation of the substituent. The ρ_D values obtained for the coumarilic, coumarin-3-carboxylic, and furoic acid systems compare well with the reaction constant for the reference benzoic acid system. The transmission of the π-electron effects (q_{ij}) indicates the following order of efficiency: *trans*-acrylic (1, 2)[4] > furoic (2, 5) > benzoic (1, 4) > coumarilic (2, 5) > coumarin-3-carboxylic (3, 6).

The indole-carboxylic acids present a somewhat confusing picture. The ρ_D values, especially, are quite different from those expected. The variations are also not systematic. The results for the esterification of the indole-2-carboxylic acids and the ester hydrolysis of the latter system are reasonable, but the ionization reaction for both systems is particularly confused. It would appear that, in the indole system, there are interactions which perturb these relations.

It was therefore of interest to know the Hammett reaction constants for meta- and para-substituted N-phenylglycine and phenoxyacetic acids. The phenoxyacetic acids have already been studied in their esterification with diazodiphenylmethane and their ionization in water, where the reaction constants were equal to 0.247 and 0.341, respectively (24). In the present study, the rates of esterification of N-phenylglycines were measured. The correlation gives ρ equal to 0.180 and is shown in Table II. The correlation coefficient is *quite poor* for the esterification of the N-phenylglycines. Since our original study, the ionization of substituted N-phenylglycines has been studied (12) and the pK_a values of the acids estimated when they are ionizing as a normal acid (I). This correlation is also shown in Table II, and ρ equals 0.359. It thus seems to be quite possible that the effect of the proximate $\rangle$NH group may affect the application of these relations, e.g. by a hydrogen-bonding interaction (1). This latter explanation is not applicable to the indole-3-carboxylic acid system. Another possibility is that the zwitterionic behavior exists for

[4]*The value of q_{ij} for this system has been found to be between 0.25 and 0.30 (3).*

indole-carboxylic acids and persists even in aqueous ethanol and ethanol. A likely explanation is the occurrence of specific changes in electronic interactions which preclude the simple interpretations of the relations used here.

Our conclusions from this study are that (*a*) the equation of Jaffé (eq. [iv]) presents a satisfactory correlation of the data, although the physical significance of the reaction constants is in question; (*b*) the Dewar–Grisdale relation (eq. [v]) (as used herein) produces a useful correlation when applied to substitution in a single position; and (*c*) both treatments are empirical in nature and it is difficult to evaluate them on the limited data available.

ORGANIC AND BIOLOGICAL SPECTROCHEMICAL STUDIES

XXIII. CONFORMATION OF THE *p*-DIMETHOXYBENZENE CATION RADICAL IN CONCENTRATED SULFURIC ACID[1]

W. F. FORBES AND P. D. SULLIVAN

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received January 5, 1966

ABSTRACT

The electron spin resonance spectrum of the *p*-dimethoxybenzene cation radical in concentrated sulfuric acid is interpreted in terms of *cis–trans* isomerism. Empirical molecular orbital calculations support these assignments. The two isomers are found to possess slightly different "*g*" values, Δg (*cis* − *trans*) being ca. 1.8×10^{-5}.

Nuclear magnetic resonance and ultraviolet data show that the radical exists in equilibrium with the neutral non-radical species at room temperature, but that sulfonation occurs at higher temperatures. Nuclear magnetic resonance and electron spin resonance data of solutions of *p*-dimethoxybenzene in D_2SO_4 show that rapid exchange of the ring protons occurs.

INTRODUCTION

As part of an electron spin resonance (e.s.r.) study of some substituted aromatic compounds in 98% sulfuric acid, the cation radicals of *p*-dimethoxybenzene have been investigated. The relevant spectrum, and a partial interpretation, have previously been reported by Zweig *et al.* (1). The present paper represents a continuation of this work; in addition, the species formed are also investigated by nuclear magnetic resonance (n.m.r.) and ultraviolet spectroscopy. The results are divided into sections. Sections I and II describe the n.m.r. and ultraviolet work, respectively, section III summarizes the e.s.r. data, section IV gives the appropriate molecular orbital calculations, and section V represents a discussion of line widths and *g* value data.

EXPERIMENTAL

A commercially available sample of *p*-dimethoxybenzene was recrystallized and gave only one band on vapor phase chromatography. The concentrated sulfuric acid was best-grade commercially available 98% sulfuric acid. Dideuteriosulfuric acid was a commercially available sample (Merck).

The e.s.r. spectra were determined on a JES-3BX e.s.r. spectrometer at 100 kc/s modulation utilizing a field selector unit. The *g* values were obtained by simultaneously inserting in the cavity a solution of peroxylamine disulfonate with the sample under investigation. Parameters used for peroxylamine disulfonate were $g = 2.0055$[2] and $a_N = 13.07$ G. The magnetic field was also calibrated against a n.m.r. probe, and values of the splitting constants are believed to be accurate to ±0.5%. Radical concentrations were estimated by over-modulating the signal and comparing it, under the same conditions, with a standard diphenylpicrylhydrazyl (DPPH) sample of known spin concentration.

The e.s.r. spectra were determined in ca. 0.2 *M* solution, ca. 0.04 ml of which was inserted in a glass capillary tube which was then placed in the TE_{011} cavity of the spectrometer. This concentration was found to give minimum line width, consistent with a good ratio of signal to noise. All spectral traces represent the first derivative of the actual absorption curves.

The n.m.r. spectra were obtained on a JNM-3H-10 n.m.r. spectrometer, with 0.5 *M* solutions of *p*-dimethoxybenzene in concentrated H_2SO_4 or concentrated D_2SO_4.

The ultraviolet absorption spectra were determined by standard methods in 1 cm cells on a Beckman model DU and a Cary model 14 spectrophotometer. The accuracy of the λ_{max} values is estimated to be ±2 mμ.

[1]*For part XXII in this series, see E. J. Moriconi, J. P. St. George, and W. F. Forbes, Can. J. Chem., 44, 759 (1966).*

[2]*The g values were measured relative to peroxylamine disulfonate, taking g absolute = 2.005500. A recent, more accurate study by Fraenkel (2) for the anthracene positive ion gives g = 2.00256 ± 0.000006, whereas our work leads to a g value of 2.002506 ± 0.000012. The present g values may therefore be in error by −0.00006.*

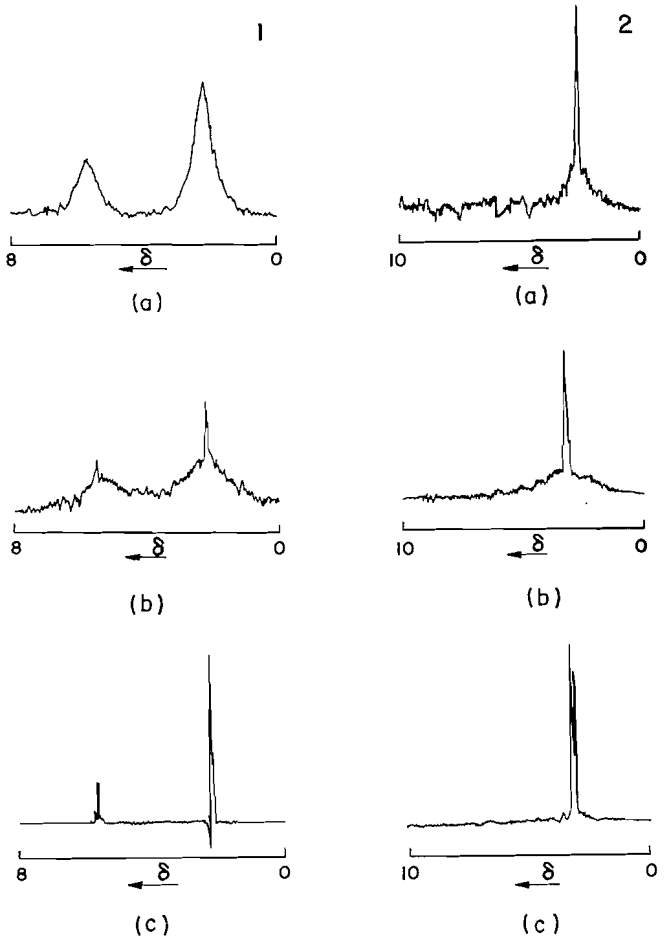
The e.s.r. spectra were simulated on an IBM 7040 computer, with a modified program kindly supplied by Dr. Lawrence C. Snyder of the Bell Telephone Laboratories. The output data from the IBM 7040, in the form of punched cards, were taken to an IBM 1710 computer and thence to a plotter.

Molecular orbital calculations were carried out by the self-consistent field method of McLachlan (3) on an IBM 7040 computer with a program kindly supplied by Dr. J. M. Fritsch (4) of the University of Kansas.

RESULTS AND DISCUSSION

I. Nuclear Magnetic Resonance Spectra

At room temperature in concentrated sulfuric acid, the n.m.r. spectrum consists of two broad absorption bands, of an approximate intensity ratio 3:2 (see Fig. 1*a*), together with some high-field bands caused by sulfuric acid (not shown). The two broad bands are assigned to the OCH_3 protons and ring protons, respectively. The band broadening is due to the presence of a free electron in the system which causes a perturbation of energy levels (cf. ref. 5). When the temperature is raised (see Figs. 1*b* and 1*c*) the lines sharpen, approximately in a manner parallel with the decrease in the e.s.r. signal intensity. If the temperature is maintained at 90 °C, the free radical decays, as shown by the disappearance of the e.s.r. signal and the appearance of a well-resolved n.m.r. spectrum.



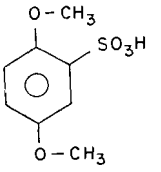


FIG. 1. Nuclear magnetic resonance spectra of *p*-dimethoxybenzene in concentrated sulfuric acid (*a*) at room temperature, (*b*) at 65 °C, and (*c*) at 90 °C after standing for 1 h.

FIG. 2. Nuclear magnetic resonance spectra of *p*-dimethoxybenzene in D_2SO_4 at room temperature (*a*) immediately after dissolution, (*b*) after standing for 3 h, and (*c*) after standing for 1 day.

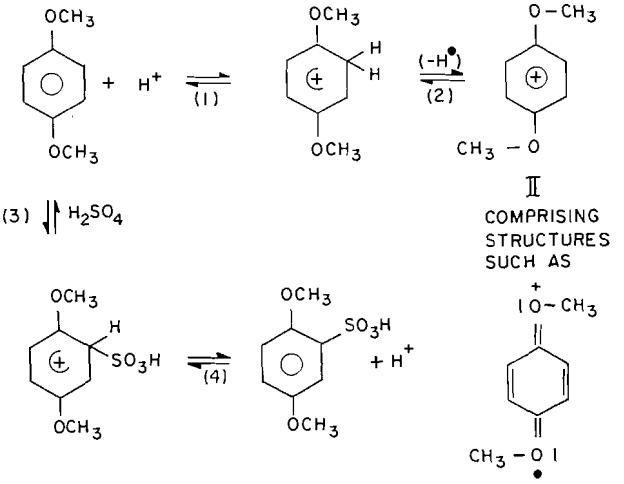
The species formed is the sulfonic acid (I), which can be isolated from the acid solution (6). Moreover, the ultraviolet and n.m.r. spectra of the heated solution are identical with the corresponding spectra of a solution of I in sulfuric acid.

I



In D_2SO_4 solution (see Figs. 2*a*–2*c*) the ring proton absorption disappears, indicating rapid H–D exchange of the ring protons.

When this solution is allowed to stand at room temperature, the absorption ascribed to the OCH_3 protons splits into a doublet (see Fig. 2*c*), suggesting again that sulfonation is taking place.

II. Ultraviolet Spectra

The spectrum of a solution of *p*-dimethoxybenzene in concentrated sulfuric acid shows intense bands at 280 mμ which are ascribed to *p*-dimethoxybenzene and to the sulfonic acid (I), and bands at 434 and 460 mμ which are ascribed to free-radical and (or) protonated species. By using the radical concentration obtained from e.s.r. data (0.025%), the molar absorptivity of these latter bands was found to be of the order of 5 000 (cf. the maximal absorption at 445 mμ for the durosemiquinone cation radical in concentrated sulfuric acid (7)).

The n.m.r. and ultraviolet data are consistent with the reactions shown below. At room temperature, reaction 1 is fast and reversible, whereas reaction 2, crudely represented as a one-step reaction, seems to be rate determining for the formation of the radical (II). Reactions 3 and 4 predominate as the temperature is increased. As judged from the intensity of the e.s.r. signal, species II contributes only about 0.025% to the postulated equilibrium at 20 °C. There is no evidence from the n.m.r. or ultraviolet data for secondary

For personal use only.

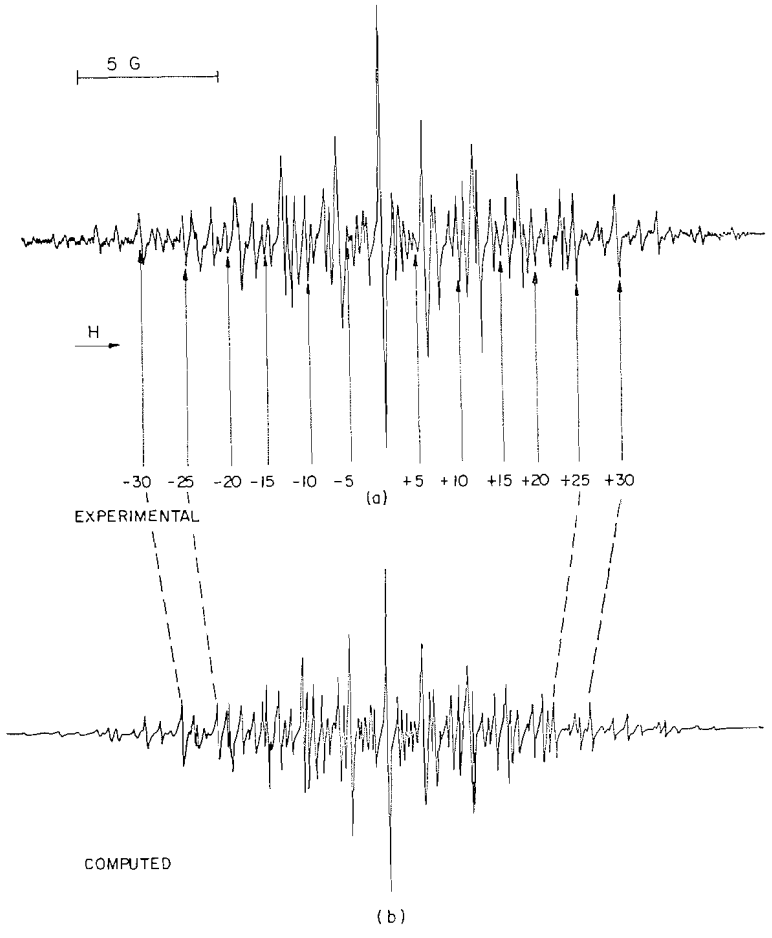
reactions such as diphenyl formation, although admittedly, *p,p'*-dimethoxydiphenyl in concentrated sulfuric acid did not give rise to an e.s.r. spectrum under our conditions (unpublished information).

III. Electron Spin Resonance Spectra

The e.s.r. spectrum (Fig. 3*a*) was found to contain a maximum of 87 lines at room temperature. By using increased modulation and carefully studying the wings of the spectrum, it was found that the spectrum could be represented as the sum of two species (A and B), possessing the following splitting constants (given in parentheses).

Species A	Species B
Six equivalent protons (3.45 G)	Six equivalent protons (3.33 G)
Two equivalent protons (2.99 G)	Two equivalent protons (2.68 G)
Two equivalent protons (1.49 G)	Two equivalent protons (1.81 G)

A spectrum computed by using these constants and assuming a displacement of 0.03 G between the two centers (see section V) is shown in Fig. 3*b*. By analogy with the e.s.r. spectrum of the anion radical of 1,4-diacetylbenzene (8) and of the durosemiquinone cation radical (9), where *cis–trans* isomerism has previously been postulated, the present



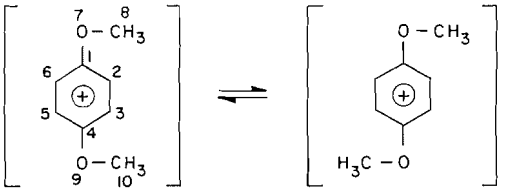


FIG. 3. (*a*) Electron spin resonance spectrum of a 0.2 *M* solution of *p*-dimethoxybenzene in concentrated sulfuric acid at room temperature. Lines are numbered as shown, proceeding from the center line. (*b*) A spectrum computed by using coupling constants as given in the text.

two species are associated with the *cis* and *trans* isomers of the *p*-dimethoxybenzene cation radical (II*a* and II*b*).

II a II b

An attempt to solve the problem of assigning splitting constants to the appropriate isomer was made by investigating line intensities. Lines 10 and 15 from the center of the spectrum (Fig. 3*a*) were found to belong to species B with no appreciable overlap from species A, whereas lines 11, 20, and 25 could be associated with species A. Theoretical intensities were then calculated and compared with the average of the experimental intensities; from this, the ratio of species A to species B was obtained. At +22 °C, this ratio was 1.19:1.00 (cf. Table II). Since the *trans* isomer would be expected to be more stable, species A is assumed to correspond to the *trans* form (see also a later discussion).

Effect of Temperature

Figures 4*a* and 4*b* show the changes of the e.s.r. spectrum with temperature. The changes were found to be reversible up to 80 °C for short periods of time. It is possible to explain the changes by using the model proposed by Bolton and Carrington (9) for the durosemiquinone cation. At room temperature, since both *cis* and *trans* forms are observed, τ (the lifetime of a particular conformation) must be large compared with $1/\Delta\omega$, where

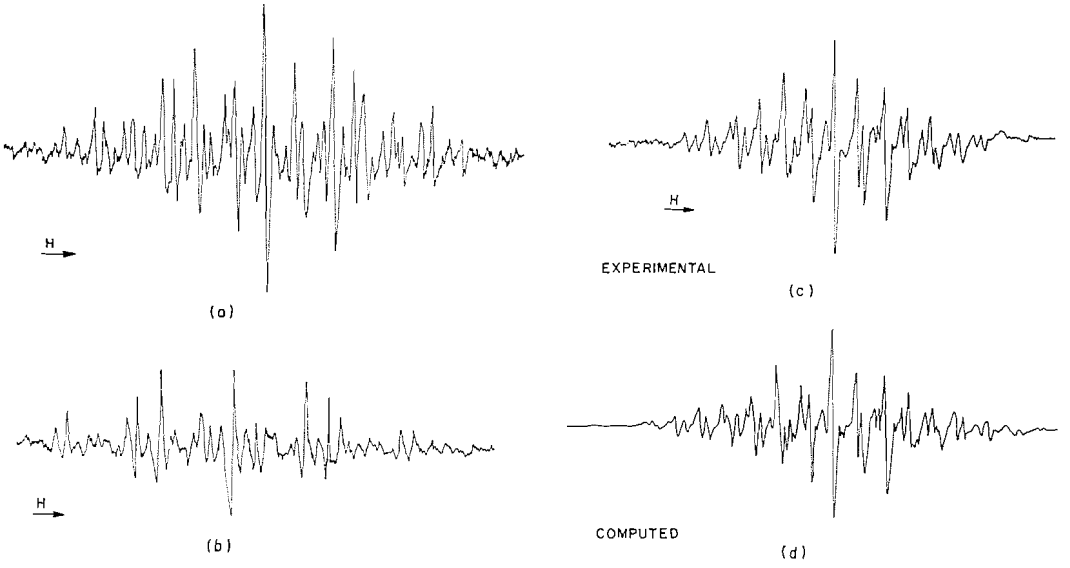

FIG. 4. (*a*) Electron spin resonance spectrum of a 0.2 *M* solution of *p*-dimethoxybenzene in concentrated sulfuric acid at 54 °C. (*b*) The same spectrum at 68 °C. (*c*) Electron spin resonance spectrum of a 0.2 *M* solution of *p*-dimethoxybenzene in a 50:50 (by volume) mixture of concentrated sulfuric acid and trifluoroacetic acid at room temperature. (*d*) A spectrum computed by using coupling constants given in the text and a line-width parameter of 0.25 G.

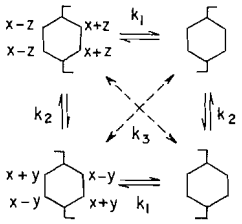

FIG. 5. Schematic representation of *cis* and *trans* forms of *p*-dimethoxybenzene at different temperatures.

$\Delta\omega$ is the frequency separation between corresponding lines of the separate isomers. Under these conditions, $k_1 \simeq k_2 \gg k_3$, and k_1 and k_2 must be slow compared with τ. Since the smallest frequency separation between the isomers corresponds to that between the OCH_3 protons (i.e. 0.12 G), a lower limit can be placed on the lifetimes of the *cis* and *trans* isomers, namely, ca. 3.0×10^{-6} s. As the temperature increases, k_1 and k_2 also increase and τ decreases. Since $\Delta\omega$ for the ring protons corresponds to $\tau = 2.4 \times 10^{-7}$ s, an intermediate state should exist with $\tau \simeq 10^{-6}$ s, when an uncertainty in the energy levels of the OCH_3 protons causes the lines from these protons to coalesce, whereas the lines caused by the ring protons are still discernible as *cis* and *trans* forms. This is shown in Fig. 4*a* (compare with the computed spectrum shown in Fig. 4*d*, which assumes a general broadening of each line to a half-width of 0.25 G, and a 50:50 ratio of the *cis* and *trans* isomers).

At still higher temperatures, τ approaches 10^{-7} s, thus leading to a condition when line-width alternation for the ring protons could occur (9, 10).

It has been shown theoretically that line-width alternation for four ring protons results in a broadening of the lines for which $\tilde{M}_{H(ring)} = \pm 1$;[3] hence, sharp lines at $\tilde{M}_{H(ring)} = \pm 2, 0$ would be expected. τ will be less than $1/\Delta\omega$ for the OCH_3 protons, and hence the splitting caused by these protons will be seen as the average of the *cis* and *trans* splittings (i.e. 3.39 G). The average splitting from the ring protons is 2.24 G, and sharp lines are therefore expected at ca. ± 4.48 G from the center of the spectrum, and broad lines at ca. ± 2.24 G. Figure 4*b* shows that the above predictions are being approached, since narrow lines at ± 4.48 G are actually observed. In addition, as the lines from the OCH_3 protons coalesce, the intensity of the outer lines (e.g. ± 12, ± 13, $\tilde{M}_{OCH_3} = \pm 1$, $\tilde{M}_{H(1)} = \tilde{M}_{H(2)} = 0$) should increase relative to that of the center line. The ratio of the intensities between line numbers ± 12 and the central line at room temperature is 2.18:1 (calculated 2.67:1), whereas at +68 °C the ratio between lines ± 12 and ± 13 (which have coalesced to one line) and the central line is 1.75:1 (calculated 1.33:1). The differences between the calculated and experimental ratios may be partly due to overlapping of lines and (or) differences in half-width, which makes the accurate determination of amplitudes difficult.

It is interesting to note that *p*-dimethoxybenzene is only just approaching line-width alternation for the ring protons at +70 °C, whereas the durosemiquinone cation shows this condition at +10 °C (9). As a first approximation, one might consider the barrier to rotation about the —C(ring)—O— bond to be similar in both molecules because steric

[3]*The field direction components of the nuclear spin angular momenta (M_{OCH_3}, $M_{H(1)}$, and $M_{H(2)}$) can have the following values: $M_{OCH_3} = \pm 3, \pm 2, \pm 1, 0$; $M_{H(1)} = \pm 1, 0$; $M_{H(2)} = \pm 1, 0$. Line positions can be specified in terms of 'spectral index' numbers: $\tilde{M}_{OCH_3}$, $\tilde{M}_{H(1)}$, and $\tilde{M}_{H(2)}$. The quantities are equal in magnitude to the respective quantum numbers, but are always defined so as to be positive on the high-field side of the spectrum. The spectral index numbers are identical with the absolute values if the splitting constant is negative, but $\tilde{M}_i = -M_i$ if a_i is positive (see ref. 18).*

interactions are similar. Moreover, the total spin density on the ring is approximately equal: $a_{CH_3} = 2.10$ G (9) and $a_{H(average)} = 2.24$ G (this paper). $1/\Delta\omega$ would therefore be expected to possess the same order of magnitude for both molecules. The main contribution causing the difference between the two molecules is therefore probably the relative rates (k_1 and k_2) of isomerization; i.e. for durosemiquinone k_1 and k_2 are greater than k_1, k_2 for *p*-dimethoxybenzene, presumably because of the differences in double bond character of the O-nuclear bond and (or) the differences in mass of the OH and OCH_3 groups.

The spectrum has also been recorded in a 50:50 mixture of trifluoroacetic and sulfuric acid (Fig. 4*c*); this spectrum can again be well represented by the simulated spectrum (Fig. 4*d*), which has an individual line-width parameter of 0.25 G (cf. the value of 0.075 G used in Fig. 3*b* in simulating the spectrum at room temperature).

The spectrum in D_2SO_4 is shown in Fig. 6*a*. It consists of seven groups of lines possessing fine structures. Since the spectrum is again slightly asymmetrical, and the fine structure within each group is not identical, this is consistent with the existence of *cis* and *trans* isomerism. The n.m.r. data show the ring protons to have exchanged, and the fine structure of the spectrum is therefore interpreted in terms of deuterium splittings. Such splitting gives a larger number of lines (the deuterium nucleus has a spin of 1), and the splitting caused by deuterium is approximately equal to 1/6.5 times the splitting caused by the proton. Figure 6*b* shows a simulated spectrum of *p*-dimethoxybenzene in D_2SO_4 with the following parameters (splitting constants in parentheses).

Species A		Species B	
Six equivalent protons	(3.45 G)	Six equivalent protons	(3.33 G)
Two equivalent deuterons	(0.482 G)	Two equivalent deuterons	(0.432 G)
Two equivalent deuterons	(0.242 G)	Two equivalent deuterons	(0.292 G)

IV. Molecular Orbital Calculations

The results of molecular orbital calculations are shown in Table I. Spin densities (ρ_1 (calcd.)) on the ring protons were calculated by choosing parameters which were consistent with normal interactions (11) and gave values which agreed approximately with the spin densities on the ring protons (ρ_1 (exptl.)); the latter were obtained from the splitting constants via McConnell's equation (12). Normally, such calculations on systems

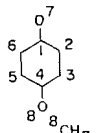
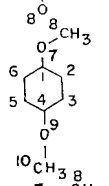
of this type will produce an equivalent amount of spin density on each of the ring positions. To rationalize the observed asymmetry in the ring splittings, an empirical approach was employed. Stone and Maki (13), in their treatment of the terephthalaldehyde anion, took into account two effects, which they called the α and β effects. The α effect was considered to be an electrostatic effect across space on the carbon atoms of the ring. In the present system, it was assumed that the OCH_3 protons may have a residual δ^+ charge and hence will change the Coulomb integrals of carbon atoms 2 and 3 in the *cis* isomer (II*a*), but of carbon atoms 2 and 5 in the *trans* isomer (II*b*). Incidentally, the sign of the α effect is now opposite to that in the terephthalaldehyde anion, where the effect was ascribed to a large negative charge on the oxygen atom.

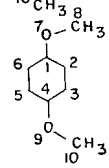
The β effect is assumed to reflect the tendency for overlap between carbon atoms 2 and 8 (and between carbon atoms 3 and 10) in the *cis* isomer. In the *trans* isomer, the tendency for overlap is between carbon atoms 2 and 8 (and between carbon atoms 5 and 10). This effect is thought to be small, compared with the α effect in this system, but in any case would be expected to lead to an asymmetry in the same direction as the α effect. In our calculations, only the α effect was considered. This seems to be justified, because significant spin density changes were obtained only if an exceptionally large β effect was assumed.

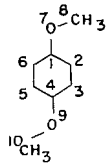
III IV

It may next be noted that interactions with the lone pair of electrons on the oxygen atoms have been ignored since their interactions with the ring hydrogens are probably small. This follows because the p orbitals presumably spend most of their time in a direction at right angles to the plane of the ring (cf. ref. 14). The equilibrium position for the CH_3 group will therefore tend to be in the plane of the ring, as shown in structures III and IV.









In Table I, the calculated spin density for the *p*-benzosemiquinone cation[4] is first used to obtain a proportionality constant between a_{OH} and ρ_o; i.e. $a_{OH}/\rho_o = Q_o$, giving $Q_o = 3.44/0.114 \approx 30$. This Q_o value is then used to estimate approximate spin densities for the oxygen atom of the OCH_3 group (values in parentheses in Table I). These spin density values are only estimates, since there is little theoretical justification to apply Q_o values obtained from the hydroquinone system to the *p*-dimethoxybenzene system (cf. the Q value variations obtained from the data reported for various quinones (15)). The calculated spin density values on the ring positions for the *cis* isomer agree to within $\sim$10% with the experimentally obtained values, whereas those for the *trans* isomer agree to within $\sim$1%. This indicates that some other interaction contributes to the observed spin densities in the *cis* isomer.

It may next be noted that the molecular orbital calculations indicate that the CH_3 splittings should be approximately equal in the *cis* and *trans* isomers (spin densities

[4]*Hydroquinone in concentrated sulfuric acid exists in equilibrium with the semiquinone cation radical; the concentration of this radical was calculated from the e.s.r. spectrum to be ca. 0.006%.*

*Parameters used were $h_{OO} = 2.00$, $k_{CO} = 1.30$, $h_{CH_3-CH_3} = 3.00$, $k_{O-CH_3} = 0.70$ (using the heteroatom model for the CH_3 groups and O—X (X = CH_3), giving $k_{XX} = 3.00$ and $k_{OX} = 0.70$ (cf. ref. 11)); $h_{CC(2)} = h_{CC(3)} = 0.10$ for *cis*, $h_{CC(2)} = h_{CC(5)} = 0.10$ for *trans*.

†Experimental ring proton spin densities (calculated from $a_i = \rho_i Q$, where $Q = 24$).

‡Energy of lowest unfilled orbital (calculated).

§See Experimental section.

‖Experimental spin densities of oxygen are estimated by assuming a relation $a_{OCH_3} = \rho_O Q$ for CH_3 splittings, with a Q value of 30 (from the hydroquinone spectrum).

¶Values taken from ref. 15.

**Values given are averages of experimentally obtained *cis* and *trans* splittings.

0.128 vs. 0.127), whereas in practice it is found that *trans* > *cis* (splittings 3.45 vs. 3.33 G; see Table I). This is probably because steric effects have been neglected, which would presumably be greater in the *cis* form, leading to an out-of-plane movement of the C(ring)—OMe bond and hence a decrease in the coupling to the OCH_3 protons. If it is assumed that this coupling is related to the angle of twist about the C(ring)—O bond by a $\cos^2\theta$ relationship (16), this leads to a value of $\theta = 7°$ (if one assumes $\cos^2\theta = 3.33/3.45$) for the equilibrium position of the *cis* isomer relative to that of the *trans* isomer.

The difference in energy between the *cis* and *trans* forms is calculated to be -0.0021β (see Table I). Therefore, if $\beta \approx 2$ eV, $\Delta E = 100$ cal/mole, which may be compared with the value of 110 cal/mole obtained from the experimental ratio of the two isomers at 22 °C.

V. Line Widths and g Value Variations

Closer inspection of Fig. 3*a* shows that, for example, lines 7 and 8, 12 and 13, and 24 and 25 appear to be better resolved on the low-field side than on the high-field side. If these lines are studied under slow-sweep conditions, the results show (Table II and Figs. 7*a*–7*d*) that the spectra of the two isomers are slightly displaced relative to one another, suggesting that $g_{trans} > g_{cis}$. The theory of g values (17) shows that they can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

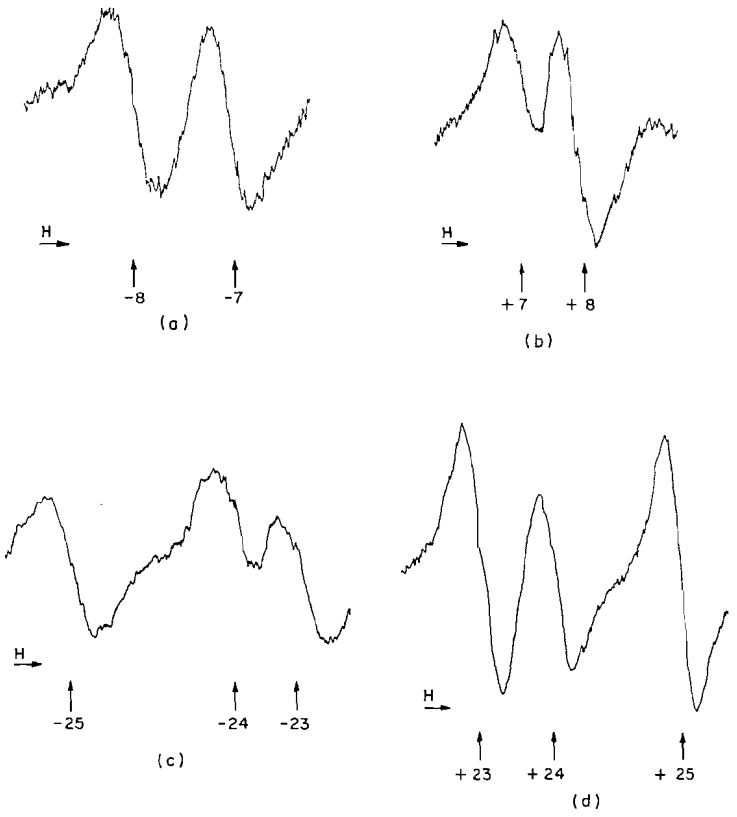

FIG. 7. Sections of the electron spin resonance spectrum (Fig. 3*a*) at low and high fields. Lines are numbered as in Fig. 3*a*.

be considered as the sum of a number of parameters. Since Δg (hydroquinone $-$ *p*-dimethoxybenzene) ≈ 0.0002 (see Table I), Δg (II*a* $-$ II*b*) would be expected to be much smaller, outside the limits of direct measurement. As a first approximation, *g* values for the *cis* and *trans* forms would be expected to be the same. However, since the splitting from the OCH_3 protons in the two isomers (3.33 and 3.45 G) is significantly different, probably because of steric interactions, the same interactions may also explain the *g* value difference. This follows, since, when the equilibrium value of θ is altered, some of the contributions to *g* would decrease and hence g_{cis} may be less than g_{trans}, as observed. From Table II the difference between the centers of the *cis* and *trans* isomers was calculated to be 0.029 ± 0.010 G as follows. Separation between $+7$, $+8$, and -7, -8 (see Figs. 7*a* and 7*b*) was found to be 0.098 G and 0.172 G on the high- and low-field sides, respectively. Hence, one line is shifted relative to the other by 0.074 G, corresponding to a displacement of the centers of 0.037 G. The average displacement of the centers as calculated from Table II was 0.029 ± 0.010 G, corresponding to Δg (*cis* $-$ *trans*) of 0.000018, an order of magnitude lower than the minimum difference which can be observed directly.

From Table II and from a separate line-width analysis it was found that, in almost every case, the low-field lines are broader than their high-field counterparts (the effect was temperature dependent, being more pronounced at low temperature, because of the

†Splitting between two *trans* lines should be constant on high- and low-field sides.

higher viscosity of the solution). Such line-width variations are well known (18, 19), and appropriate theories have been developed (10, 20). Unfortunately, because of lines overlapping, it has not been possible to carry out a complete line-width analysis. However, by analogy with other work (10, 20), it would seem to be plausible that the line-width variation is related linearly with the quantum number associated with the OCH_3 protons. Specific attention has not been paid to the anisotropic intramolecular dipolar g tensor interactions for the OCH_3 group from a theoretical point of view. Such interactions would be expected to result in the observed linear variation of line width across the spectrum. The linear variation of line width caused by a CH_3 group has been noted before, and has also been observed in a number of other related compounds (21 and unpublished information), when broad low-field lines were also found.

The results may be summarized in the following assignment of splitting constants, which can interpret completely the observed e.s.r. spectrum of *p*-dimethoxybenzene in concentrated sulfuric acid.

trans isomer	*cis* isomer
$a_{OCH_3} = +3.45$ G	$a_{OCH_3} = +3.33$ G
$a_{H(2,5)} = -2.99$ G	$a_{H(2,3)} = -2.68$ G
$a_{H(3,6)} = -1.49$ G	$a_{H(5,6)} = -1.81$ G

The isotropic splitting constants of the OCH_3 protons are considered to be positive, since a hyperconjugative mechanism is favored (22, 23).

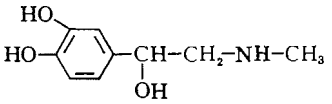
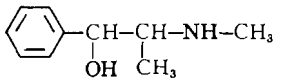
RÉACTIONS DE L'ÉPOXYSTYRÈNE AVEC LA GLYCINE ET SES DÉRIVÉS



CASIMIR BERSE ET KRZYSZTOF JANKOWSKI
Département de Chimie, Université de Montréal, Montréal, Québec

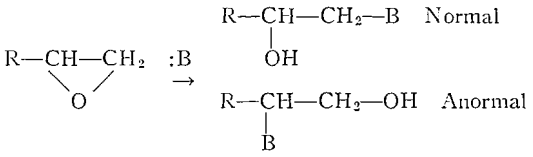
Reçu le 5 janvier 1966



RÉSUMÉ

La présente publication décrit une étude de l'ouverture du noyau oxirannique de l'époxystyrène par la glycine et ses dérivés. Les réactions ont été effectuées dans des conditions douces sans catalyseur. Les produits des réactions ont été isolés et identifiés, soit sous forme de dérivés de la dicéto-2,5 piperazine (formés par condensation des intermédiaires), soit sous forme de lactone (formée par réaction entre le carboxyle de l'acide aminé et la fonction alcool formée par ouverture de l'époxystyrène). Les structures des composés obtenus ont été déterminées. Le mécanisme de la réaction est discuté.

Il est connu qu'un grand nombre de composés qui contiennent les groupements aminé et hydroxyle possèdent une activité pharmacodynamique, par exemple, l'adrénaline ou l'éphédrine, qui sont des amino alcools aromatiques.



Adrénaline

Éphédrine

La recherche de nouveaux produits avec une activité semblable à été effectuée souvent utilisant la méthode d'ouverture des époxydes avec des amines aliphatiques et aromatiques (1). Nous avons donc pensé que les produits qui se forment dans la réaction d'ouverture des époxydes par les acides aminés pourraient posséder une activité pharmacodynamique particulière.

Les acides aminés libres ont assez rarement été utilisés pour ouvrir des époxydes. Kiprianov (2) et ses collaborateurs ont effectué l'ouverture de l'époxycyclohexène, de l'époxyéthylène et de l'époxybutylène avec certains dérivés de la glycine; Maekawa (3) a fait l'ouverture de l'époxyéthylène avec l'alanine. L'ouverture des époxydes donne presque toujours deux produits, qui ont été nommés par Krussuski (4) comme normal et anormal dépendant de la direction d'attaque de la fonction aminée sur le noyau oxirannique.

Les essais d'ouverture des époxydes avec les acides aminés libres n'ont pas donné, conformément à l'attente, de produits car la basicité du groupement aminé n'était pas suffisante pour ouvrir l'époxyde dans la réaction sans catalyseur. Nous avons donc utilisé des acides aminés dont le groupement carboxylique était protégé soit sous forme d'ester ou de sel sodé.

L'ouverture de l'époxystyrène avec le glycinate d'éthyle fournit quatre composés qui ont été isolés par cristallisation fractionnée: (*i*) la dicéto-2,5 piperazine (VIII), p.f. 260°,

provenant de la condensation de deux molécules de glycinate d'éthyle; (*ii*) la bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III), p.f. 275°; (*iii*) la (hydroxy-2 phényl-2 éthyl)-1 (hydroxy-2 phényl-1 éthyl)-4 dicéto-2,5 piperazine (IV), p.f. 206°; (*iv*) la lactone de la N-(hydroxy-2 phényl-2 éthyl) glycine (VI), p.f. 120–121°.

Les quatre produits ont été identifiés soit par hydrolyse, soit par synthèse et spectroscopie infrarouge.

La séparation des quatre produits a été effectuée par chromatographie sur alumine. Les résultats obtenus sont identiques avec ceux de la séparation par cristallisation. Deux autres produits possibles dans cette réaction (la bis-(hydroxy-2 phényl-1 éthyl)-1,4 dicéto-2,5 piperazine (V) et la lactone de la N-(hydroxy-2 phényl-1 éthyl) glycine (VII)) n'ont pu être isolés, ni par cristallisation ni par chromatographie.

Les structures des quatre composés ont été établies de la façon suivante. Le composé VIII a été identifié par synthèse par condensation de deux molécules de la glycine (5). Le composé III a été identifié par synthèse et hydrolyse. Le chloroacétate d'éthyle chauffé avec l'hydroxy-2 phényl-2 éthylamine (XI) donne le produit III, p.f. 275°, et le produit VI, p.f. 120–121°. L'hydrolyse du produit III par l'acide chlorhydrique concentré donne 80% de chlorhydrate de N-(hydroxy-2 phényl-2 éthyl) glycine (XIV), p.f. 186°. Ce dernier a été obtenu par la réaction du produit XI avec l'acide chloroacétique. La libération d'acide chlorhydrique à partir du produit XIV donne la N-(hydroxy-2 phényl-2 éthyl) glycine (IX), p.f. 210°. L'hydrolyse du produit III par l'acide chlorhydrique concentré dans l'éthanol donne 20% de chlorhydrate de N-(hydroxy-2 phényl-2 éthyl) glycinate d'éthyle (X), p.f. 165°. Le composé X libéré de son chlorhydrate donne le produit III. L'hydrolyse du produit III par une solution d'hydroxyde de sodium à 10% donne le composé IX, qui a été transformé par élimination d'eau dans le benzène en lactone VI et par la décarboxylation en N-(hydroxy-2 phényl-2) méthylamine (XV), p.f. 45°, identique avec le produit obtenu par l'action de la méthylamine sur l'époxystyrène.

La lactone VI a été hydrolysée et le produit IX a été obtenu. L'estérification du produit IX en présence d'acide chlorhydrique gazeux dans l'éthanol donne le produit X.

Le produit IV a été synthétisé à partir d'un mélange de 50% d'hydroxy-2 phényl-2 éthylamine (XI) et 50% d'hydroxy-2 phényl-1 éthylamine (XII); ce mélange étant mis en réaction avec le chloroacétate d'éthyle. Dans cette réaction il se forme aussi le produit III. L'hydrolyse du produit IV par l'acide chlorhydrique concentré donne le mélange de chlorhydrates suivants: 22% de chlorhydrate de N-(hydroxy-2 phényl-2 éthyl) glycine (XIV), p.f. 186°, et 26% de chlorhydrate de N-(hydroxy-2 phényl-1 éthyl) glycine (XIII), p.f. 152°.

Ce produit est identique avec le produit XIV déjà décrit. Le produit XIII est identique avec le produit obtenu par la réaction de XII avec l'acide chloroacétique. Ces données ont été confirmées par la chromatographie sur plaques minces. L'hydrolyse du produit IV par l'acide chlorhydrique concentré dans l'éthanol donne 11% du composé X; l'hydrolyse du produit IV par l'hydroxyde de sodium donne 18% du produit IX. Les autres produits de ces deux dernières hydrolyses n'ont pas été isolés.

La structure de la lactone de la N-(hydroxy-2 phényl-2 éthyl) glycine (VI) a été déterminée par la synthèse. Le produit XI chauffé avec le chloroacétate d'éthyl donne la lactone VI. Dans cette réaction le produit III se forme en majorité.

Le produit IX a été lactonisé dans le benzène anhydre et a donné le produit VI. Le produit IX laissé dans l'éthanol à 0° donne des petites quantités du produit III.

L'ouverture de l'époxystyrène avec le glycinate d'éthyle donne 20.9% de produit cristallin, dont 85.4% résulte de l'ouverture normale et 11% de l'ouverture anormale. Le

SCHÉMA 3.

rapport des produits normaux sur le produit anormal est 8:1. Les autres produits de la réaction sont très probablement des polymères. Le fait que les produits III et IV contiennent le même élément structurel, N-(hydroxy-2 phényl-2 éthyl) glycine (IX), a été établi comme suit. La quantité des produits IX, X ou XIV formés par hydrolyse du composé IV est environ deux fois plus petite que dans le cas de l'hydrolyse du composé III.

Mannich et Thiele (6) ont fait la réaction entre le produit XI et le chloroacétate d'éthyle en isolant seulement le produit VI, p.f. 121°, auquel ils ont attribué la structure III. Le spectre infrarouge du composé, p.f. 275°, montre à 1 635 cm^{-1} une bande carbonyle, suggérant la structure III pour ce produit.

Dans le cas du composé, p.f. 120–121°, une bande carbonyle à 1 720 cm^{-1} suggère la structure VI pour ce produit.

Pour compléter cette série de réactions nous avons fait la synthèse du produit V en condensant le chloroacétate d'éthyle avec le produit XII. Le produit attendu, p.f. 252°, fut isolé.

La glycine libre ne donne pas de produits d'ouverture dans la réaction avec l'époxystyrène. Aussi la dicéto-2,5 piperazine (VIII) ne réagit pas avec l'époxystyrène. Dans ces deux réactions on peut isoler seulement des produits de départ. Le glycinate de sodium (XVI) chauffé avec l'époxystyrène dans le diméthylformamide donne une petite quantité de produit IX, qui a été identifié d'après le point de fusion mixte et par son spectre infrarouge.

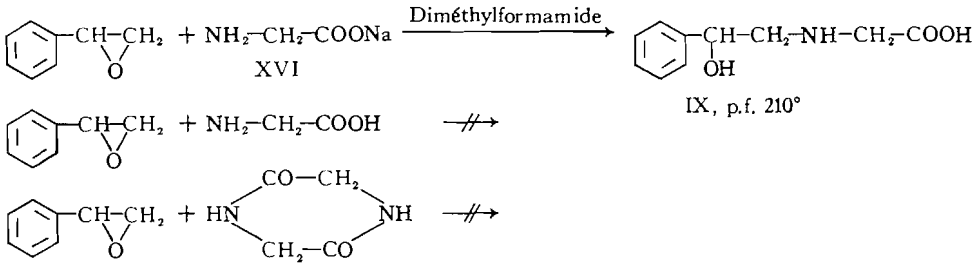

SCHÉMA 4.

Les résultats mentionnés plus haut permettent de supposer que le mécanisme réactionnel d'ouverture de l'époxystyrène est le suivant: les composés N-(hydroxy-2 phényl-2 éthyl) glycinate d'éthyle (I), qui correspondent à l'ouverture normale, et N-(hydroxy-2 phényl-1 éthyl) glycinate d'éthyle (II) (anormale) sont formés comme les intermédiaires qui à leur tour dimérisent pour donner les produits III et IV. Le produit VI est formé par lactonisation du composé I. Le deuxiéme mécanisme qu'on pourrait proposer serait la formation du dicéto-2,5 piperazine (VIII) qui réagira ensuite avec l'époxystyrène. Ce mécanisme peut être réfuté parce que la réaction entre dicéto-2,5 piperazine (VIII) avec l'époxystyrène ne donne que les produits de départ.

Il faut lier l'existance d'ouvertures normale et anormale au cours de la réaction avec la formation d'éthanol. La présence de l'éthanol comme solvant permet toujours la formation de deux produits d'ouverture des époxydes (7).

L'absence des produits V et VII il faut expliquer que l'hydroxyester II, qui pourrait donner par la dimérisation le produit V et par la lactonisation le produit VII, se forme avec un petit rendement. A la présence des plus grandes quantités du hydroxyesther I il réagit plus facilement avec les molécules du produit I que du produit II.

PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés dans l'appareil de Kofler et ne sont pas corrigés. Les spectres infrarouges ont été déterminés dans l'appareil de Beckman modèle IR-8 (en N-oil). Les analyses sont de J. Maciak, Indianapolis, de C. Daesslé, Montréal, et de nous-mêmes (micro-Kjeldahl). Les solvants ont été purifiés d'après les méthodes généralement utilisés. L'identité des composés dans la Partie Expérimentale a été prouvée par points de fusions mixtes et par superposition des spectres infrarouges.

Ouverture de l'époxystyrène avec le glycinate d'éthyle

Le glycinate d'éthyle (20.6 g, 0.20 mole) (8) et l'époxystyrène (24 g, 0.20 mole) ont été portés à reflux pendant 12 h. Le mélange refroidie à 0° donne les cristaux qui ont été triturés dans l'éthanol absolu et filtrés. Le précipité (9.3 g, 20.9%) a été cristallisé d'éthanol absolu. Les quatre fractions ont été séparées.

Fraction	Point de fusion	Rendement
a	260° (sublimation)	0.20 g, 2.2%
b	275°	6.98 g, 74.0%
c	206°	2.04 g, 22.0%
d	120–121°	0.037 g, 0.4%

(*a*) Le produit cristallisé d'éthanol–eau a été identifié comme dicéto-2,5 piperazine (VIII). Le spectre infrarouge est identique avec celui de la littérature (5).

Anal. Calc. pour $C_4H_6O_2N_2$ (114.10): N, 24.55. Trouvé: N, 23.90.

(*b*) Le produit cristallisé d'éthanol a été identifié comme bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III). Le spectre infrarouge: 1 635 cm^{-1} et 3 350 cm^{-1}.

Anal. Calc. pour $C_{20}H_{22}O_4N_2$ (354.39): C, 67.77; H, 6.25; N, 7.89. Trouvé: C, 68.03; H, 6.10; N, 8.23.

(*c*) Le produit cristallisé d'éthanol a été identifié comme (hydroxy-2 phényl-2 éthyl)-1 (hydroxy-2 phényl-1 éthyl)-4 dicéto-2,5 piperazine (IV). Le spectre infrarouge: 1 635 cm^{-1}, 3 350 cm^{-1} et 3 180 cm^{-1}.

Anal. Calc. pour $C_{20}H_{22}O_4N_2$ (354.39): C, 67.77; H, 6.25; N, 7.89. Trouvé: C, 67.69; H, 6.24; N, 8.21.

(*d*) Le produit cristallisé d'éthanol–eau a été identifié comme lactone de N-(hydroxy-2 phényl-2 éthyl) glycine (VI). Le spectre infrarouge: 1 720 cm^{-1} et 1 100 cm^{-1}.

Anal. Calc. pour $C_{10}H_{11}O_2N$ (177.19): N, 7.89. Trouvé: N, 7.67.

Hydrolyse acide du produit III

Une solution de bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III) (1.7 g, 0.005 mole) dans l'acide chlorhydrique concentré (20 ml) a été chauffée à reflux pendant 5 h. La solution a été évaporée *in vacuo* et le résidu a été cristallisé d'éthanol; rendement de chlorhydrate de N-(hydroxy-2 phényl-2 éthyl) glycine (XIV) 1.78 g (80%), p.f. 186°. Le spectre infrarouge: 1 650 cm^{-1}.

Anal. Calc. pour $C_{10}H_{14}O_3NCl$ (231.67): C, 51.83; H, 6.17; N, 6.13. Trouvé: C, 52.22; H, 6.07; N, 5.83.

Une solution de produit XIV (1.1 g, 0.005 mole) dans le diméthylformamide (20 ml) et la quantité équimoléculaire de triéthylamine ont été chauffées au bain-marie pendant 1 h et refroidies à 0° pendant 4 h. Le précipité de chlorhydrate de triéthylamine a été filtré et la solution a été triturée avec l'éther. La N-(hydroxy-2 phényl-2 éthyl) glycine (IX) a été filtrée et recristallisée d'éthanol; rendement 560 mg (56%), p.f. 210°. Le spectre infrarouge: 1 610 cm^{-1} et 1 570 cm^{-1}.

Anal. Calc. pour $C_{10}H_{13}O_3N$ (195.21): C, 61.55; H, 6.71; N, 7.17. Trouvé: C, 60.92; H, 6.82; N, 7.10.

Hydrolyse acide du produit IV

Une solution de (hydroxy-2 phényl-2 éthyl)-1 (hydroxy-2 phényl-1 éthyl)-4 dicéto-2,5 piperazine (IV) (500 mg, 0.0015 mole) dans l'acide chlorhydrique concentré (25 ml) a été chauffée pendant 5 h. Le mélange a été évaporé *in vacuo* et le résidu a été cristallisé d'acétone. Les deux produits ont été séparés par la cristallisation fractionnée.

(*a*) Chlorhydrate de N-(hydroxy-2 phényl-2 éthyl) glycine (XIV), rendement 152 mg (22%), p.f. 186°.

Anal. Calc. pour $C_{10}H_{14}O_3NCl$ (231.67): N, 6.13. Trouvé: N, 6.02.

(*b*) Chlorhydrate de N-(hydroxy-2 phényl-1 éthyl) glycine (XIII), rendement 180 mg (26%), p.f. 152°.

Anal. Calc. pour $C_{10}H_{14}O_3NCl$ (231.67): C, 51.83; H, 6.17; N, 6.13. Trouvé: C, 52.04; H, 6.41; N, 6.00.

La chromatographie sur couche mince dans le butanol – eau – acide acétique (4:4:1) donne les résultats suivants: R_f du produit XIII, 0.48; R_f du produit XIV, 0.71; R_f du mélange après l'hydrolyse, 0.48 et 0.70.

Le produit XIV a été libéré de son chlorhydrate dans le diméthylformamide avec le triéthylamine dans les mêmes conditions que déjà décrit. Le produit IX a été isolé; rendement 28 mg (22%), p.f. 209–210° (identique avec le produit IX obtenu par l'hydrolyse acide du produit III).

Hydrolyse acide du produit III dans l'éthanol

La bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III) (350 mg, 0.001 mole) dans l'éthanol (40 ml) a été chauffée avec l'acide chlorhydrique concentré (10 ml) à reflux pendant 5 h. La solution a été

évaporée *in vacuo*. Le chlorhydrate de N-(hydroxy-2 phényl-2 éthyl) glycinate d'éthyl (X) a été isolé. Le produit a été cristallisé d'éthanol–éther; rendement 208 mg (40%), p.f. 165°. Le spectre infrarouge: 1 730 cm^{-1}.

Anal. Calc. pour $C_{12}H_{18}O_3NCl$ (259.73): N, 5.39. Trouvé: N, 5.22.

Le titrage du produit avec $AgNO_3$ 0.1 *N* donne 13.8% HCl (théorie 14.1% HCl).

Hydrolyse acide du produit IV dans l'éthanol

L'(hydroxy-2 phényl-2 éthyl)-1 (hydroxy-2 phényl-1 éthyl)-4 dicéto-2,5 piperazine (IV) (272 mg, 0.007 mole) dans l'éthanol (30 ml) a été chauffée avec l'acide chlorhydrique concentré (10 ml) à reflux pendant 5 h. La solution a été évaporée *in vacuo*. Le produit X a été isolé et le composé cristallisé d'éthanol–éther; rendement 22 mg (11%), p.f. 163–165°.

Le produit X est identique avec celui obtenu par l'hydrolyse acide du produit III dans l'éthanol. Le spectre infrarouge: 1 730 cm^{-1}.

Anal. Calc. pour $C_{12}H_{18}O_3NCl$ (259.73): N, 5.39. Trouvé: N, 5.17.

Hydrolyse alcaline du produit III

La bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III) (350 mg, 0.001 mole) dans l'hydroxyde de sodium à 10% (25 ml) a été chauffée à reflux pendant 12 h. La solution a été lavée avec l'éther. Le résidu a été acidifié avec l'acide chlorhydrique concentré et évaporé *in vacuo*. Le résidu a été chauffé avec l'éthanol absolu (25 ml) pendant 1 h, et le chlorure de sodium a été séparé par filtration. La solution a été évaporée *in vacuo*. Le produit a été libéré de son chlorhydrate dans le diméthylformamide par la triéthylamine; rendement 171 mg (44%), p.f. 208–210°. Le spectre infrarouge est identique avec celui du produit IX.

Hydrolyse alcaline du produit IV

L'(hydroxy-2 phényl-2 éthyl)-1 (hydroxy-2 phényl-1 éthyl)-4 dicéto-2,5 piperazine (IV) (90 mg, 0.00025 mole) dans l'hydroxyde de sodium à 10% (10 ml) a été chauffée pendant 12 h à reflux. La procédure a été la même que décrite plus haut. Le produit IX a été isolé; rendement 9 mg (18%), p.f. 208–209°.

Bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III)

A une solution de chlorhydrate de N-(hydroxy-2 phényl-2 éthyl) glycinate d'éthyl (X) (250 mg, 0.001 mole) dans le diméthylformamide (20 ml), la triéthylamine a été ajoutée. Le mélange a été chauffé ½ h au bain-marie. Après avoir refroidi à 0°, le précipité de chlorhydrate de triéthylamine a été filtré. L'éther a été ajouté à la solution et le mélange a été agité pendant 2 h dans la température de la pièce. Le produit cristallise pendant 24 h à 0°; rendement 48 mg (27%), p.f. 275–276°. Le produit est identique avec le produit III isolé dans la réaction d'ouverture de l'époxystyrène.

Hydroxy-2 phényl-2 éthylamine (XI)

La solution de bisulfite de sodium (104 g, 1 mole) dans l'eau (500 ml) a été agitée avec le benzaldéhyde (106 g, 1 mole) jusqu'à ce que le composé d'addition se forme.[1] Une solution de l'hydroxyde de sodium (46 g, 1.1 moles) dans l'eau (200 ml) en présence du nitrométhane (66 g, 1.1 moles) a été ajoutée goutte à goutte à la solution de bisulfite de benzaldéhyde. Le mélange a été agité pendant 1 h à la température de la pièce, et abandonné pendant la nuit dans la même température. Le produit a été séparé par l'extraction avec l'éther. La couche éthérée a été lavée avec la solution saturée de bisulfite de sodium et séchée avec $MgSO_4$ anhydre. Après l'évaporation d'éther *in vacuo* le résidu a été distillé; rendement 23 g (14%), p.é. 120–123° à 3 mm Hg (litt. (10) p.é. 163–165° à 15 mm Hg).

A une solution d'hydroxy-2 phényl-2 nitroéthane (23 g, 0.15 mole) dans l'éthanol à 95% (90 ml), l'acide sulfurique à 33% (300 ml) et le zinc (80 g)[2] ont été ajoutés. Le mélange a été agité pendant 14 h à la température de la pièce et l'excès de l'hydroxyde de sodium à 25% a été ajouté. Le produit a été extrait avec l'éther; la solution éthérée a été séchée avec K_2CO_3 et évaporée *in vacuo*. Le résidu a été distillé à 144–147° et 6 mm; rendement du produit XI 7.1 g (38%) (litt. (12) p.é. 136–137° à 5 mm Hg).

Hydroxy-2 phényl-2 éthylamine (XI) et hydroxy-2 phényl-1 éthylamine (XII)

Le mélange des produits XI et XII a été séparé avec le rendement de 25% d'après la méthode décrite par Castro et ses collaborateurs (12).

Bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III) et lactone de N-(hydroxy-2 phényl-2 éthyl) glycine (VI)

Une solution du produit XI (7 g, 0.05 mole) dans l'éthanol (40 ml) a été chauffée avec le chloroacétate d'éthyle (6 g, 0.05 mole) pendant 12.5 h. L'éthanol a été évaporé *in vacuo*. Le résidu a été lavé avec l'éther, la solution saturée de K_2CO_3 et l'eau. Les deux produits formés ont été séparés par cristallisation.

(*a*) Le produit III; rendement 650 mg (8%), p.f. 275–276°.

Anal. Calc. pour $C_{20}H_{22}O_4N_2$ (354.4): C, 67.77; H, 6.25; N, 7.89. Trouvé: C, 67.85; H, 6.23; N, 7.67.

(*b*) Le produit VI; rendement 125 mg (1.5%), p.f. 120°.

Anal. Calc. pour $C_{10}H_{11}O_2N$ (177.2): C, 67.77; H, 6.25; N, 7.89. Trouvé: C, 67.57; H, 6.33; N, 7.74.

Ils sont identiques avec les composés III et VI de l'ouverture de l'époxystyrène.

[1]*La méthode de Kamlet (9).*

[2]*La préparation est analogue à celle de Hoover et Hass (11).*

For personal use only.

Bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III)

Une solution du produit XI (3.6 g, 0.025 mole) et du chloroacétate d'éthyle (3.0 g, 0.025 mole) dans le diméthylformamide (50 ml) a été chauffée avec la triéthylamine (2.5 g, 0.025 mole) au bain-marie pendant 2 h. Après avoir refroidi à 0°, le précipité du chlorhydrate de triéthylamine a été filtré et la solution évaporée *in vacuo* (60°). Le résidu a été cristallisé de l'éthanol absolu. Le produit obtenu (rendement 212 mg (5.3%), p.f. 273–275°) est identique avec le produit III.

Bis-(hydroxy-2 phényl-2 éthyl)-1,4 dicéto-2,5 piperazine (III), lactone de N-(hydroxy-2 phényl-2 éthyl) glycine (VI), N-(hydroxy-2 phényl-2 éthyl) glycine (IX) et chlorhydrate de N-(hydroxy-2 phényl-2 éthyl) glycine (XIV)

Une solution du produit XI (1.5 g, 0.01 mole) et d'acide chloroacétique (0.8 g, 0.01 mole) dans l'éthanol (20 ml) a été chauffée au bain-marie pendant 5 h. L'éthanol a été évaporé *in vacuo*. Le résidu a été lavé avec la solution saturée de K_2CO_3. Les quatre produits (IX, VI, III et XIV) ont été séparés par la cristallisation dans l'éthanol–eau; rendement respectif: 240 mg (11%), 82 mg (4%), 25 mg (1.2%) et 338 mg (13%).

Lactone de N-(hydroxy-2 phényl-2 éthyl) glycine (VI)

Une solution du produit IX (55 mg, 0.0025 mole) dans le benzène anhydre (50 ml) a été chauffée à reflux pendant 2 h. Les cristaux ont été dissous et le chauffage a été continué pendant 1 h. Le benzène a été évaporé *in vacuo* et le produit VI a été cristallisé d'acétate d'éthyle; rendement 28 mg (56%), p.f. 118–120°. Le spectre infrarouge: 1 723 cm^{-1} et 1 107 cm^{-1}.

Anal. Calc. pour $C_{10}H_{11}O_2N$ (177.2): N, 7.89. Trouvé: N, 7.58.

N-(Hydroxy-2 phényl-2 éthyl) glycine (IX)

Une solution du produit VI (120 mg, 0.006 mole) dans l'hydroxyde de sodium à 20% (10 ml) a été chauffée pendant 10 h à 60–70°. Le produit a été extrait avec l'éther; la solution éthérée a été acidifiée avec l'acide chlorhydrique concentré et évaporée *in vacuo*. Le résidu a été trituré avec l'éthanol absolu et le chlorure de sodium a été séparé par filtration; puis la solution a été évaporée *in vacuo* et le résidu lavé avec la solution saturée de K_2CO_3 et avec l'eau (25 ml). Le produit a été cristallisé de l'éthanol; rendement 18 mg (13%), p.f. 207–208°. Il est identique avec le produit IX.

Hydroxy-2 phényl-1 éthylamine (XII)

Une solution de phényl-2 glycine (13 g, 0.09 mole) dans l'éthanol absolu (400 ml) a été refroidie à 0° et l'acide chlorhydrique anhydre a été absorbé jusqu'à dissolution des cristaux. La solution a été chauffée pendant 2 h à reflux, abandonnée pendant 12 h à la température de la pièce et évaporée *in vacuo*. Le chlorhydrate de phényl-2 glycinate d'éthyle a été cristallisé d'éthanol–éther; rendement 10.5 g (57%), p.f. 199° (litt. (12) p.f. 197–198°).

Une solution du chlorhydrate de phényl-2 glycinate d'éthyle (10.5 g, 0.005 mole) dans l'éthanol absolu (50 ml) a été traitée avec l'éthanolate de sodium à 10% (50 ml), et le mélange a été chauffé pendant 1 h. Après refroidissement le chlorure de sodium a été filtré. La solution éthanolique a été évaporée *in vacuo* et distillé à 116–119° et 2 mm Hg; rendement 6.8 g (77%) (litt (12) p.é. 110–113° à 1.3–1.7 mm Hg).

Une solution de phényl-2 glycinate d'éthyl (8.6 g, 0.04 mole) dans l'éther absolu (15 ml) a été ajoutée à la solution du hydrure double de lithium et d'aluminium (2.3 g) dans l'éther absolu (100 ml). Le mélange a été chauffé pendant 1 h à reflux et l'eau a été ajoutée. La phase éthérée a été séparée et le résidu a été extrait deux fois avec l'éther. Les extractes éthérées combinées ont été séchés avec K_2CO_3 anhydre. L'éther a été évaporé *in vacuo* et le produit XII a été distillé à 140–145° et 6–7 mm Hg; rendement 3.6 g (54%) (litt. (12) p.é. 141–142° à 6 mm Hg).

Le composé XII a aussi été obtenu par réduction de l'oxime de la ω-hydroxyacétophénone avec l'amalgame de sodium. Les rendements ont été semblables à ceux décrits par Reiheln (13) et Gabriel (14).

Bis-(hydroxy-2 phényl-1 éthyl)-1,4 dicéto-2,5 piperazine (V)

Une solution du produit XII (6.06 g, 0.045 mole) dans l'éthanol (90 ml) a été chauffée à reflux avec le chloroacétate d'éthyle (4.8 g, 0.09 mole) pendant 12 h. La solution a été évaporée *in vacuo*, lavée de façon habituelle, séchée et évaporée à sec. Le résidu a été cristallisé plusieurs fois de l'éthanol; rendement 30 mg (0.5%), p.f. 252–254°. Le spectre infrarouge: 1 630 cm^{-1} et 3 182 cm^{-1}.

Anal. Calc. pour $C_{20}H_{22}O_4N_2$ (354.39): C, 67.77; H, 6.25; N, 7.89. Trouvé: C, 67.62; H, 6.38; N, 7.60.

Chlorhydrate de N-(hydroxy-2 phényl-1 éthyl) glycine (XIII)

Une solution du produit XII (1.4 g, 0.1 mole) dans l'éthanol absolu (25 ml) a été chauffée avec l'acide chloroacétique à reflux pendant 10 h. La solution a été évaporée et cristallisée de l'éthanol et ensuite de l'acétone; rendement 1.4 g (61%), p.f. 152°.

Anal. Calc. pour $C_{10}H_{14}O_3NCl$ (231.679): C, 51.84; H, 6.17; N, 6.17. Trouvé: C, 52.04; H, 6.41; N, 6.00.

N-(Hydroxy-2 phényl-2 éthyl) méthylamine (XV)

Le produit IX (0.25 g, 0.0008 mole) a été chauffé avec l'hydroxyde de sodium (0.1 g) jusqu'à ce que le dégagement du CO_2 ait été terminé (12 min). L'eau (15 ml) a été ajoutée et le produit a été séparé par extraction avec l'éther (3 × 15 ml). La solution éthérée a été séchée et évaporée à sec. Le produit XV a été cristallisé de l'éthanol–éther; rendement 21 mg (20%), p.f. 42–43° (litt. (15) p.f. 44–45°).

N-(Hydroxy-2 phényl-2 éthyl) méthylamine (XV)

Une solution de la méthylamine (6 g, 0.05 mole) à 50% dans l'eau a été chauffée avec l'époxystyrène (5 g, 0.04 mole) à reflux pendant 5 h. La solution a été extraite avec l'éther. L'extrait éthéré a été séché sur carbonate de potassium anhydre et saturé avec l'acide chlorhydrique gazeux anhydre. Le précipité a été séparé par filtration, lavé avec l'éther et repris dans l'hydroxyde de sodium à 1%. La solution alcaline a été extraite à l'éther. L'extrait éthéré a été séché sur carbonate de potassium anhydre et évaporé *in vacuo*. Le produit a été cristallisé de l'éthanol–éther; rendement 29 mg (3.9%), p.f. 41–44°. Il est identique avec le produit XV obtenu par décarboxylation du produit IX.

(Hydroxy-2 phényl-2 éthyl)-1 (hydroxy-2 phényl-1 éthyl)-4 dicéto-2,5 piperazine (IV)

Une solution du produit XI (0.5 g, 0.0036 mole) et du produit XII (0.5 g, 0.0036 mole) dans l'éthanol (25 ml) a été chauffée à reflux pendant 4 h avec le chloroacétate d'éthyle (0.65 g, 0.007 mole). La solution a été évaporée *in vacuo* et triturée avec l'éther, avec la solution saturée de carbonate de potassium et avec l'eau. Le résidu a été cristallisé et les deux produits ont été isolés: le produit III, rendement 52 mg (8%); le produit IV, rendement 17 mg (2.5%). Ils sont identiques avec les produits III et IV isolés dans la réaction d'ouverture de l'époxystyrène.

N-(Hydroxy-2 phényl-2 éthyl) glycine (IX)

Une solution de l'époxystyrène (10 g, 0.008 mole) avec le glycinate de sodium (XVI) (9 g, 0.009 mole) dans le diméthylformamide (100 ml) a été chauffée à reflux pendant 3 h. Le produit a été précipité avec l'éther et séparé par filtration. Le produit a été repris dans l'eau (40 ml), acidifié avec l'acide chlorhydrique concentré et évaporé *in vacuo*. Le résidu a été repris dans l'éthanol (25 ml) et le chlorure de sodium a été séparé par filtration. Le produit IX a été libéré de son chlorhydrate avec la triéthylamine dans le diméthylformamide; rendement 362 mg (2%), p.f. 209°. Il est identique avec le produit obtenu par l'hydrolyse acide du produit III.

Condensation de la glycine avec l'époxystyrène

Une suspension de la glycine (7.5 g, 0.01 mole) dans l'éthanol à 95% (100 ml) a été chauffée à reflux avec l'époxystyrène (12 g, 0.01 mole) pendant 12 h. Les trois produits ont été isolés: la dicéto-2,5 piperazine (VIII), rendement 1.2 g (30%), p.f. 260°; le phénylglycole, rendement 1.0 g (24%), p.f. 65.5°; la glycine, rendement 4.0 g (53%), p.f. 190°.

Condensation de la dicéto-2,5 piperazine (VIII) avec l'époxystyrène

Le produit VIII (1.1 g, 0.01 mole) a été chauffé à reflux avec l'époxystyrène (1.2 g, 0.01 mole) pendant 18 h. Le produit VIII a été isolé inchangé; rendement 0.9 g (82%). La fraction polymérique de l'époxystyrène a été aussi isolé; rendement 0.7 g (60%).

STUDIES ON PLANTS

XI. ALKALOIDS OF ASPIDOSPERMA SPEGAZZINII[1,2]

ORFEO O. ORAZI, RENÉE A. CORRAL, AND MARTA E. STOICHEVICH
Facultad de Química y Farmacia, Universidad Nacional de La Plata, La Plata, Argentina

Received December 17, 1965

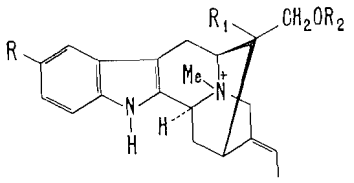
ABSTRACT

Extraction of the trunk bark of *Aspidosperma spegazzinii* Molf. ex Meyer yielded ajmaline and two quaternary alkaloids. One of the latter, characterized as the tetraphenylboride salt, was found to be identical with the N_b-metho derivative of akuammidine. Methylation of the phenolic group of the second quaternary alkaloid (named spegatrine) followed by thermal degradation led to the corresponding nor-base, which was identified as lochnerine; therefore, the structure and absolute stereochemistry of spegatrine are given by formula I. A confirmation was provided by N_b-methylation of sarpagine to spegatrine.

Five species of the genus *Aspidosperma* (Apocynaceae) may currently be recognized in the Argentinian flora, namely, *A. quebracho-blanco*, *A. chakensis*, *A. australe*, *A. polyneuron*, and the more recently described *A. spegazzinii* Molf. ex Meyer (1). Unlike the other species, no alkaloids have yet been isolated from *A. spegazzinii*, a tree 10–15 m high, indigenous to Argentina and Paraguay, and referred to by the vernacular names "quina" or "paratudo". The plant material examined in the present work (the trunk bark of old trees) was collected in Río Iguazú, Parque Nacional Iguazú (Misiones, Argentina).

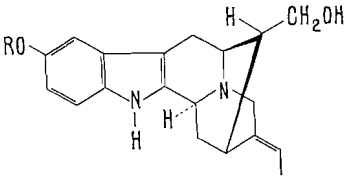
The alcoholic extract of the bark was separated into tertiary bases and quaternary chlorides. The tertiary bases consisted of a mixture of several alkaloids, from which ajmaline was isolated and identified as the ethanol solvate (about 0.3% yield based on dried bark).

The new alkaloid spegatrine (I), the major component (0.25% yield based on dried bark) of the quaternary alkaloidal fraction, was characterized as the crystalline chloride and perchlorate salts. Analytical data give the empirical formula $C_{20}H_{25}N_2O_2$ for the cation and indicate the presence of one N-methyl group, three active hydrogens, and no methoxyl groups. The nuclear magnetic resonance spectrum of the chloride of I, with a doublet centered at δ 1.80 p.p.m. (3H) and an unresolved multiplet at δ 5.95 p.p.m. (1H), suggests the existence of one ethylidene grouping. The quaternary nature of I and the number of active hydrogens require the presence of two OH groups and one NH group.



One of the oxygen atoms of I belongs to a phenolic function, as established by the following data. The chloride of I gives positive color reactions with aqueous ferric chloride and diazotized sulfanilic acid, and its ultraviolet spectrum suffers a bathochromic shift on addition of base; in addition, it may be methylated to compound II, which analyzes for one methoxyl group and shows identical ultraviolet absorption in neutral and basic media.

Acetylation of I gives compound III, which may easily be reconverted into the starting material. The acetylated product gave inconsistent results when subjected to repeated acetyl group analysis; however, the presence of infrared bands at 3 390 (NH) and 1 754 cm^{-1} (broad, ester carbonyls) coupled with the absence of amide absorption indicates that it is the O,O-diacetyl derivative of I rather than the O,N-diacetyl or O,O,N-triacetyl



[1]*Part of the doctoral thesis (1965) of M. E. S. is included in this paper.*
[2]*For part X in this series, see R. A. Corral and O. O. Orazi, Tetrahedron, in press.*

derivatives. Furthermore, when going from compound I to III, the nuclear magnetic resonance absorption in the range δ 2.10–2.70 p.p.m. shows the appearance of two sharp peaks (δ 2.25 and 2.50 p.p.m.) and an area increase corresponding to approximately six protons.

Thermal decomposition of the chloride of II gives, besides methyl chloride, its genuine nor-base as proved by a methylation experiment. Analytical and mass spectrometric data on the nor-base establish the molecular formula $C_{20}H_{24}N_2O_2$ and the presence of two active hydrogens and one methoxyl group; the Herzig–Meyer analysis also indicated one N-methyl group, but, as observed in several other instances (2), this is a fictitious result.

	R	R_1	R_2
I	OH	H	H
II	OCH_3	H	H
III	AcO	H	Ac
VI	H	CO_2Me	H

IV R = H
V R = CH_3

The ultraviolet absorption of the nor-base is typical of an indole chromophore, and its mass spectrum shows intense M-1 and M-31 peaks; these peaks suggest a tetrahydro-β-carboline structure and the presence of a primary alcoholic function, respectively (3). Moreover, all the strong peaks (Fig. 1) are displaced by 14 mass units from those of sarpagine (IV) (4).

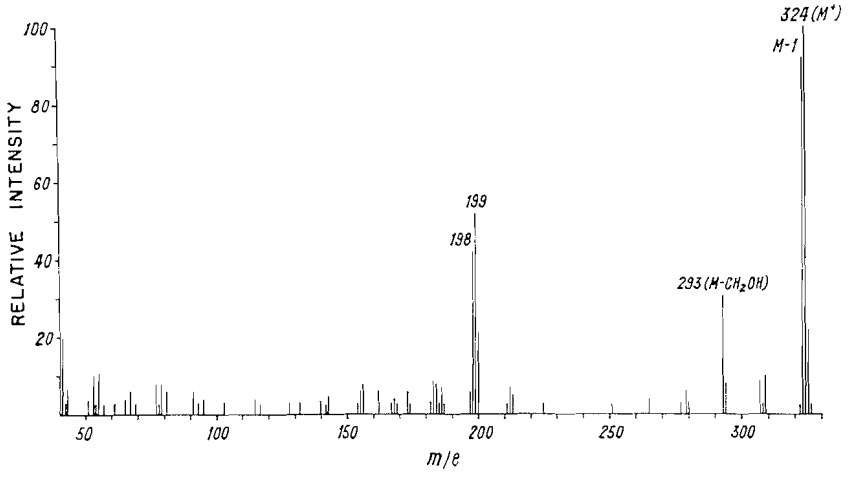


FIG. 1. The mass spectrum of the nor-base of II, inserted in the ion source; only peaks of intensity higher than 2% are plotted.

The nor-base was identical in all respects with the alkaloid lochnerine (10-O-methyl-sarpagine), the structure and absolute stereochemistry of which are shown in V (5); therefore, formula I is a complete description for the spegatrine ion. This result was confirmed by N_b-methylation of sarpagine (IV), the quaternary chloride that was obtained being identical with spegatrine chloride.

The foregoing structural elucidation also demonstrates that the ion II, characterized as the perchlorate salt, must be identical with the quaternary alkaloid lochneram, which was obtained as the iodide and tetraphenylboride salts (6).

The other quaternary alkaloid isolated from *A. spegazzinii*, characterized as the crystalline tetraphenylboride salt and then converted into the amorphous chloride salt, was available in much lesser amounts (0.01% yield based on dried bark). However, structure VI was brought into consideration by its co-occurrence with I and by the following data: ultraviolet absorption almost coincident with that of macusine-A (7); the tetraphenylboride salt shows infrared bands at 3 532, 3 357, and 1 728 cm^{-1} ascribable to alcoholic OH (ultraviolet measurements exclude the phenol group), indole NH, and CO_2Me (one methoxyl by analysis) groups, respectively; the presence of an ethylidene group according to the nuclear magnetic resonance spectrum (multiplets for one methyl group and one hydrogen at δ 1.78 and 5.9 p.p.m., respectively); the optical rotation of the chloride salt ($[\alpha]_D$ +12° (in water)) in comparison with those of macusine-A ($[\alpha]_D$ −58° (in water)) and the nonnatural akuammidine methoiodide ($[\alpha]_D$ +16° (in methanol)) (7, 8).

Methylation of akuammidine under the conditions used for the nor-base of II and sarpagine (IV) led to a quaternary tetraphenylboride salt identical (mixture melting points and superimposable infrared curves) with the sample obtained from the plant; the corresponding amorphous chlorides showed concordant chromatographic mobility, ultraviolet absorption, and optical rotation. The structure and absolute stereochemistry shown in VI are firmly established for the N_b-methylakuammidine cation (9) prepared by methylation of the natural tertiary base (8).

The complete formula VI has recently been assigned to the crystalline alkaloid macusine-C chloride, isolated from *Strychnos toxifera* bark (5); however, the sign and magnitude of the optical rotation ($[\alpha]_D$ −61° (in water)) indicate that it is not identical with the akuammidine methochloride here obtained.

The quaternary alkaloids found in *A. spegazzinii* belong to the sarpagine structural type; two tertiary bases of the same type, polyneuridine and normacusine-B, have recently been isolated from another *Aspidosperma* species (2*b*). On the other hand, the occurrence in this genus of alkaloids with the ajmaline skeleton is unprecedented; besides the biogenetic significance, this may be interesting from the chemical taxonomy viewpoint because of the peculiar anatomy of the *A. spegazzinii* bark (1*c*).

EXPERIMENTAL

Melting points were determined in sealed capillaries and are not corrected; all of the evaporations were carried out under reduced pressure. The ultraviolet spectra in neutral, acidic, or basic medium were recorded with 50% alcohol as the solvent; unless otherwise noted, the infrared spectra were taken in Nujol mulls. The nuclear magnetic resonance spectra were measured in trifluoroacetic acid at 60 Mc/s, the δ values (parts per million) being expressed downfield from internal $SiMe_4$ (δ = 0). The detection of spots in paper chromatograms and electrophoreses was made by fluorescence under ultraviolet light and by iodoplatinate reagent. The microanalyses were performed by Dr. A. Bernhardt (Mülheim, Germany) on samples dried, unless otherwise stated, to a constant weight (100° and a high vacuum) immediately before analysis.

Extraction of Alkaloids

The dried trunk bark (1 kg) of *Aspidosperma spegazzinii* Molf. ex Meyer was ground and extracted during 4 h with boiling 96% alcohol (4 l), with mechanical stirring; the liquid was separated by filtration and the process repeated three times. The combined alcoholic extracts, after concentration to a volume of 300 ml, were diluted at 0° with acetic acid (100 ml) in water (600 ml). The mixture was left in the refrigerator and then filtered; after addition of chloroform (250 ml), the aqueous layer was adjusted (ice bath) to pH 11 with aqueous sodium hydroxide.

The chloroform was decanted, and repeated extractions were made (15 × 100 ml) until the tertiary bases were completely separated. The total chloroform extracts, washed with water and dried over magnesium sulfate, gave, upon evaporation to dryness, the fraction of crude *tertiary alkaloids* (23 g).

The aqueous layer was acidified with 6 *N* hydrochloric acid to pH 2 and the quaternary alkaloids were precipitated by adding an excess of concentrated Mayer's reagent (10). The precipitate (22 g) was suspended in methanol (400 ml) and a current of hydrogen sulfide passed through until the Mayer complex had completely decomposed. The filtered methanolic solution was concentrated and passed successively through Dowex-3 (base form, 100 g) and Dowex-2 chloride (80 g); the eluate was adjusted to pH 6.5 by addition of 0.1 *N* hydrochloric acid, and subsequent removal of the solvent gave the fraction of crude *quaternary chlorides* (13 g).

Isolation of Ajmaline

A chloroform solution of the crude tertiary bases (1 g) was filtered through a column of neutral alumina (activity V, 10 g). Evaporation of the eluate left a solid (0.9 g), which was dissolved in hot absolute ethanol (2.5 ml); to obtain a very crystalline material the solution was allowed to stand undisturbed for several days and gradually cooled down to −10°. Thus was separated 125 mg of ajmaline ethanol solvate, m.p. 194–196° with apparent melting at 125° (gas evolution). A sample that was dried at 130° and 10^{-3} Torr melted at 194–196° without modification at lower temperatures.

The earlier procedure followed for the ajmaline isolation was based on adsorption chromatography. The crude tertiary bases (2 g) were fractionated over neutral alumina (activity II, 200 g); elution was carried out with benzene, benzene–chloroform (9:1 to 1:4), chloroform, and chloroform – absolute ethanol (24:1 to 1:4), and 200 samples (20 ml each) were collected. Eluates 124–167 from chloroform – absolute ethanol (15:1 to 5:1) contained essentially a single alkaloid, as indicated by paper chromatography; upon crystallization from absolute ethanol, 200 mg of ajmaline ethanol solvate, m.p. 191–193° (gas evolution at 125°), was obtained.

An analytical sample was prepared by repeated recrystallizations from the same solvent and dried at 76° and 10^{-3} Torr; $[\alpha]_D^{25}$ +130° (*c*, 1.11 in chloroform); λ_{max} 248 (log ϵ 3.96) and 291 mμ (log ϵ 3.50), λ_{min} 226 (log ϵ 3.58) and 271 mμ (log ϵ 3.20).

Anal. Calcd. for $C_{20}H_{26}N_2O_2 \cdot C_2H_5OH$: C, 70.93; H, 8.66; N, 7.52; O, 12.89; one OC_2H_5, 12.09; one $(N)CH_3$, 4.05; three active H, 0.81. Found: C, 71.23; H, 8.60; N, 7.67; O, 12.86; OC_2H_5, 12.02; $(N)CH_3$, 3.83; active H, 0.81; mol. wt. (by mass spectrum) 326 (calcd. for $C_{20}H_{26}N_2O_2$, 326.42).

An authentic specimen of ajmaline was recrystallized several times from absolute ethanol; it melted, showing the same behavior as the above samples. The identity was ascertained by chromatographic mobility, mixture melting point, and coincidence of the infrared absorptions.

Isolation of Quaternary Alkaloids

The first successful isolation of the alkaloids described below was attained by subjecting the crude quaternary chlorides to preparative paper chromatography; water-saturated methyl ethyl ketone plus 5% methanol was used as the developing solvent, and ultraviolet light and iodoplatinate reagent were used for detection of the bands. Fractionation attempts on powdered cellulose columns gave poorer results.

The work-up of subsequent batches was as follows. The mixture of crude chlorides (5 g) was chromatographed through a column of neutral alumina (activity III, 500 g); the elution was made with chloroform–methanol mixtures, methanol, 90% ethanol, and finally 80% ethanol, and 180 samples (20 ml each) were collected.

The weight distribution and paper chromatography (with the above-mentioned solvent system) showed the presence of several alkaloids; fractions 19–48 (800 mg) and the last 10 fractions (containing only a few milligrams) gave weak spots of mixtures of alkaloids. The most important fractions were fractions 62–101 (from chloroform–methanol (6:1 to 4:1), 250 mg) and fractions 102–170 (chloroform–methanol (4:1 to 90% ethanol), 1.9 g); each group of fractions gave principally a single alkaloid spot, the R_f values of which were 0.45 and 0.32, respectively.

N_b-Methylakuammidine (VI) Tetraphenylboride

(*a*) The combined fractions 62–101 were rechromatographed over neutral alumina (activity III, 25 g) with chloroform–methanol mixtures (19:1 to 1:1). The alkaloidal material of R_f 0.45 (130 mg) eluted with chloroform–methanol (7:1) was dissolved in water and mixed with an aqueous solution of sodium tetraphenylboride.

The precipitated salt (165 mg) was purified on an adsorption column of neutral alumina (activity II, 8 g); the fractions eluted with chloroform–acetone (19:1) were pure when examined by paper chromatography (150 mg). It was further purified by crystallization from alcohol to a constant melting point of 203–205° (decomp.); ν_{max} 3 532, 3 357, and 1 728 cm^{-1}.

Anal. Calcd. for $C_{22}H_{27}N_2O_3 \cdot (C_6H_5)_4B$: C, 80.45; H, 6.90; N, 4.08; one OCH_3, 4.52. Found: C, 80.63; H, 6.75; N, 3.99; OCH_3, 3.90.

This tetraphenylboride was identical with that obtained in experiment *b*, as shown by mixture melting point and complete coincidence of their infrared spectra (KBr).

The pure salt was converted into the corresponding chloride by means of Dowex-2 chloride with methanol as solvent. The resulting solid showed $[\alpha]_D^{20}$ +12° (*c*, 2.05 in water); in neutral or 0.01 *N* NaOH λ_{max} 219 (log ϵ 4.70), 271 (log ϵ 3.87), 277 (inflection) (log ϵ 3.86), and 288 mμ (log ϵ 3.75), λ_{min} 241 (log ϵ 3.55) and 285 mμ (log ϵ 3.72); ν_{max} 1 732 cm^{-1} (ester carbonyl).

(*b*) *From akuammidine.*—A solution of this base (25 mg) in a mixture of methanol (1.5 ml) and methyl iodide (1 ml) was heated in a sealed tube during 10 h at 100° in the dark (cf. ref. 8). After evaporation to dryness, the residue was dissolved in methanol and passed through Dowex-2 chloride. The crude chloride, after being washed with chloroform (2 × 1 ml) to remove unreacted akuammidine (2 mg, identified by paper chromatography), was purified by alumina chromatography as in experiment *a* and then transformed into the tetraphenylboride salt (39 mg); the latter was recrystallized from alcohol to a constant melting point of 203–205° (decomp.).

The amorphous chloride, prepared from the purified tetraphenylboride salt by ionic exchange, exhibited the same chromatographic mobility (R_f 0.45) as the sample obtained in experiment *a* when run on the same paper (water-saturated methyl ethyl ketone plus 5% methanol); $[\alpha]_D^{19}$ +13° (*c*, 1.01 in water); λ_{max} 219 (log ϵ 4.64), 270 (log ϵ 3.88), 276 (inflection) (log ϵ 3.86), and 288 mμ (log ϵ 3.74), λ_{min} 245 (log ϵ 3.68) and 285 mμ (log ϵ 3.70).

Spegatrine (I) Salts

The material of fractions 102–170, obtained from the alumina chromatogram of the crude quaternary alkaloids, was crystallized twice from absolute ethanol to give 1.1 g of spegatrine chloride, m.p. 283° (decomp.), increased to 294° (decomp.) by repeated recrystallizations. Its homogeneity was verified by paper chromatography with several solvent systems and by paper electrophoreses with buffers of pH 3 and pH 8.

It showed $[\alpha]_D^{17}$ +38° (*c*, 1.00 in methanol); in neutral or 0.3 *N* HCl λ_{max} 272 (log ϵ 3.87) and 296 mμ (inflection) (log ϵ 3.63), λ_{min} 245 mμ (log ϵ 3.43); in 0.01 *N* NaOH λ_{max} 270 (log ϵ 3.81), 309 (log ϵ 3.43), and 320 mμ (inflection) (log ϵ 3.34), λ_{min} 253 (log ϵ 3.66) and 293 mμ (log ϵ 3.34).

Anal. Calcd. for $C_{20}H_{25}N_2O_2Cl$: C, 66.56; H, 6.98; N, 7.76; O, 8.87; Cl, 9.83; one OCH_3, 8.60; one $(N)CH_3$, 4.17; three active H, 0.84. Found: C, 65.78; H, 7.08; N, 7.70; O, 8.52; Cl^-, 10.35; OCH_3, 0.61; $(N)CH_3$, 5.13; active H, 0.78.

Hot aqueous solutions of spegatrine chloride and magnesium perchlorate were mixed, thereby precipitating spegatrine perchlorate, constant m.p. 271° (decomp.) after several recrystallizations from butanol.

Anal. Calcd. for $C_{20}H_{25}N_2O_2 \cdot ClO_4$: C, 56.53; H, 5.93; N, 6.59; O, 22.60; Cl, 8.35. Found: C, 56.66; H, 6.02; N, 6.55; O, 22.55; Cl, 8.25.

10-O-Methylspegatrine (II) Perchlorate

A solution of spegatrine (I) chloride (100 mg) in methanol (2 ml) was mixed with anhydrous potassium carbonate (80 mg), and to the stirred solution was added dimethyl sulfate (125 mg) in portions.

After 12 h, the methanolic phase was decanted and evaporated to dryness. The residue was dissolved in water and a solution of ammonium reineckate (in water – acetic acid (2:1)) added; the precipitated reineckate salt was then converted into the corresponding chloride by ionic exchange. Purification by alumina chromatography (neutral, activity IV, elution with chloroform–methanol mixtures) provided the chromatographically pure quaternary chloride (100 mg), which was transformed into the perchlorate by adding an excess of magnesium perchlorate in water.

There was obtained 105 mg that, after repeated recrystallizations from butanol, melted at 147–150° (decomp.); the homogeneity was assessed by paper chromatograms and electrophoreses as indicated for the chloride of I. The perchlorate of II had $[\alpha]_D^{18}$ +45° (*c*, 1.03 in methanol); in neutral, acidic, or basic medium λ_{max} 272 (log ϵ 3.86), 291 (inflection) (log ϵ 3.63), and 303 mμ (inflection) (log ϵ 3.51), λ_{min} 245 mμ (log ϵ 3.44).

Anal. Calcd. for $C_{21}H_{27}N_2O_2 \cdot ClO_4$: C, 57.47; H, 6.20; N, 6.38; O, 21.87; Cl, 8.08; one OCH_3, 7.07; one $(N)CH_3$, 3.43. Found: C, 57.60; H, 6.33; N, 6.38; O, 21.32; Cl, 7.58; OCH_3, 6.72; $(N)CH_3$, 2.96.

10,17-O,O-Diacetylspegatrine (III) Perchlorate

A mixture of spegatrine (I) chloride (100 mg) and acetic anhydride (4 ml) was magnetically stirred at 90° for 10 h; the resulting solution was evaporated, and the solid residue was dissolved in water and mixed with a hot aqueous solution of magnesium perchlorate. The crude quaternary perchlorate (130 mg, m.p. 152–156°) was purified from alcohol to a constant melting point of 155–159°. It was homogeneous according to paper chromatograms and electrophoreses; $[\alpha]_D^{15}$ +34° (*c*, 1.89 in methanol); λ_{max} 223 (log ϵ 4.38), 268 (log ϵ 3.91), and 291 mμ (inflection) (log ϵ 3.73), λ_{min} 258 mμ (log ϵ 3.88); ν_{max} 3 390 and 1 754 (broad) cm^{-1}.

Anal. Calcd. for $C_{24}H_{29}N_2O_4 \cdot ClO_4$: C, 56.64; H, 5.74; N, 5.50; O, 25.15; Cl, 6.97. Found: C, 56.89; H, 5.78; N, 5.46; O, 25.14; Cl, 7.06.

A solution of the perchlorate of III (10 mg) in 2 *N* hydrochloric acid (1 ml) was maintained for 1 h at 90°; evaporation to dryness yielded a material which, when dissolved in methanol, was passed through Dowex-2 chloride. The eluted material was identified as spegatrine chloride by its chromatographic mobility and infrared absorption.

Degradation of 10-O-Methylspegatrine (II) Chloride

This salt, obtained above as an intermediate in the preparation of the corresponding perchlorate, was subjected to thermal degradation according to a literature technique (11).

It was heated (10 batches; in total, 330 mg) in a vacuum sublimation apparatus introduced into a bath at 250° and 10^{-4} Torr; the temperature was then increased to 280° in 1 h and the bath was maintained at this temperature for another hour.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The evolved gaseous product was condensed in an air–liquid trap and identified as practically pure methyl chloride by gas chromatographic and infrared absorption comparisons with an authentic specimen.

The combined sublimed material was extracted with several portions of chloroform; the extract was washed with water and dried, and the solvent was removed, leaving a residue (275 mg) which was purified either by column or thick-layer chromatography with thin-layer chromatograms (alumina Fluka D5F, chloroform–cyclohexane (1:1) plus 1% absolute ethanol) for analytical purposes.

In the former procedure the material (100 mg) was passed over neutral alumina (activity II, 10 g), elution being carried out with chloroform-cyclohexane (1:1) followed by the same system enriched with absolute ethanol. The main fraction (from eluant containing 0.5% ethanol, R_f 0.60) was homogeneous, and upon crystallization from methanol – ethyl ether gave 35 mg, m.p. 192–194°, increased to 204–205° by further recrystallizations. Similar results were obtained by the thick-layer procedure with chloroform–cyclohexane (1:1) plus 1% absolute ethanol as the solvent system.

The nor-base had $[\alpha]_D^{20}$ +70° (*c*, 0.62 in alcohol); λ_{max} 227 (log ϵ 4.50) and 278 mμ (log ϵ 3.94), λ_{min} 215 (log ϵ 4.47) and 250 mμ (log ϵ 3.48).

Anal. Calcd. for $C_{20}H_{24}N_2O_2$: C, 74.04; H, 7.46; N, 8.64; O, 9.86; two active H, 0.62; mol. wt. 324.41. Found: C, 73.53; H, 7.47; N, 8.94; O, 10.42; active H, 0.64; mol. wt. (by mass spectrum) 324.

A sample was dried *in vacuo* at 56°, but not quantitatively.

Anal. Calcd. for $C_{20}H_{24}N_2O_2 \cdot H_2O$: C, 70.15; H, 7.65; N, 8.18; O, 14.02; one OCH_3, 9.06. Found: C, 70.20; H, 7.42; N, 8.11; O, 14.07; OCH_3, 8.88.

The nor-base was identical with an authentic sample of the alkaloid lochnerine, as shown by mixture melting point and infrared spectra (KBr); furthermore, the values of the ultraviolet absorption and optical rotation (12) are virtually coincident.

The nor-base (10 mg) and methyl iodide (0.3 ml) in methanol (0.15 ml) were heated in a sealed tube at 100° for 10 h in the dark. Evaporation of the solution was followed by passage of the residue in methanol through Dowex-2 chloride; the material recovered from the eluate (11 mg) did not contain starting compound, as shown by a paper chromatogram.

The chloride salt was transformed into the perchlorate by magnesium perchlorate in water. The crude salt (13 mg) was crystallized from butanol, m.p. 148–150°, undepressed when admixed with a sample of the above 10-O-methylspegatrine (II) perchlorate. This identity was confirmed by coincidence of the chromatographic mobilities in several systems and of the infrared curves.

Spegatrine (I) Chloride from Sarpagine (IV)

Sarpagine was methylated as described above for the nor-base. The crude quaternary chloride was purified on neutral alumina (100 times by weight, activity III), chloroform–methanol mixtures (19:1 to 2:1) being used as eluants. The major fraction, coming from chloroform–methanol (4:1), gave a single spot on a paper chromatogram; crystallization from absolute ethanol gave N_b-methosarpagine chloride (68% yield) melting at 293° (decomp.); $[\alpha]_D^{20}$ +37° (*c*, 0.96 in methanol).

Anal. Calcd. for $C_{20}H_{25}N_2O_2Cl$: N, 7.76. Found: N, 7.86.

The quaternary salt thus obtained was identical with spegatrine chloride, as demonstrated by paper chromatographic behavior, mixture melting point, and superimposable ultraviolet and infrared spectra.

ACKNOWLEDGMENTS

The authors are grateful to the late Prof. J. F. Molfino, who supplied the plant material and made the corresponding botanical identification; and to Prof. M. G. Escalante (La Plata) for confirming the identification by an anatomicohistological study of the trunk bark. The generous support of the Consejo Nacional de Investigaciones Científicas y Técnicas (Argentina) is gratefully appreciated. Thanks are due to Prof. V. Deulofeu (Buenos Aires) and Prof. J. Le Men and Dr. L. Olivier (Paris), who kindly supplied samples of ajmaline, lochnerine, and akuammidine, respectively. The authors are also indebted to Prof. C. Djerassi (Stanford) for the mass spectra.

CHOLLA GUM

II. STRUCTURE OF THE UNDEGRADED CHOLLA GUM[1]

V. M. PARIKH[2] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 17, 1966

ABSTRACT

Cholla gum (*Opuntia fulgida*) has partially been degraded to yield several oligosaccharides and a degraded polymer. The structure of the degraded polymer was reported in an earlier paper.[1] Six of the oligosaccharides formed have been isolated in a pure state and identified. They are (*i*) 6-*O*-β-D-galactopyranosyl-D-galactose, (*ii*) 3-*O*-β-D-galactopyranosyl-D-galactose, (*iii*) 3-*O*-α-L-arabinofuranosyl-L-arabinose, (*iv*) 5-*O*-β-D-xylopyranosyl-L-arabinose, (*v*) 3-*O*-β-D-galactopyranosyl-L-arabinose (?), and (*vi*) a new trisaccharide *O*-β-D-xylopyranosyl-(1 → 5)-*O*-α-L-arabinofuranosyl-(1 → 3)-L-arabinose. The purified gum was subjected to Smith-type degradation, and the results of this experiment are compared with the methylation studies carried out earlier. On the basis of all this information plus the suggested structure for the degraded gum, it is proposed that the repeating unit of the polysaccharide consists of a total of 36 sugar residues with a backbone of 1 → 6 linked galactose residues.

In a previous paper (1) the results of the analysis of cholla gum (*Opuntia fulgida*) (Table I) and a probable structure (Diagram 1) of the repeating unit of the degraded gum were reported.

TABLE I
Analysis of cholla gum

Observations	Observed values
Ash	0.7%
Nitrogen	Absent
Methoxyl	Absent
Optical rotation	−86.2° (*c*, 1.8 in water)
Equivalent weight	1 734 (acidimetric)
Uronic anhydride	10.15% (acidimetric)
L-Arabinose	51.6% (18 moles)
D-Galactose	31.7% (9 moles)
D-Xylose	15.0% (5 moles)
L-Rhamnose	2–3% (1 mole)
D-Galacturonic acid	11.2% (3 moles)

In an earlier investigation, Anderson *et al.* (2) and Sands and Klass (3) isolated an aldobiouronic acid from this gum and identified it as D-galacturonosido-L-rhamnose. The presence of a second aldobiouronic acid, viz. 3-*O*-(β-D-galactopyranosyluronic acid)-D-galactose, was reported by us in part I (1). An investigation of the gum by the methylation procedure was carried out by Brown *et al.* (4), who were able to isolate, from the hydrolysate of the methylated gum, the following sugars: (*i*) 2,3,5-tri-*O*-methyl-L-arabinose (4 parts), (*ii*) 2,3,4-tri-*O*-methyl-D-xylose (2 parts), (*iii*) 2,3-di-*O*-methyl-L-arabinose (1 part), (*iv*) 2,4-di-*O*-methyl-D-galactose (3 parts), (*v*) L-arabinose (1 part), and (*vi*) 2-*O*-methyl-D-galacturonic acid (1 part). In the present communication we report the results of the partial hydrolysis and the Smith-type degradation of the gum and suggest a possible structure of the gum. Partial hydrolysis of the gum with cold acid produced

[1]*For part I in this series, see ref. 1.*
[2]*Present address: Department of Chemistry, Notre Dame University, Nelson, British Columbia.*

several oligosaccharides, six of which have been isolated and identified. A new trisaccharide, viz. *O*-β-D-xylopyranosyl-(1 → 5)-*O*-α-L-arabinofuranosyl-(1 → 3)-L-arabinose, was isolated and characterized.

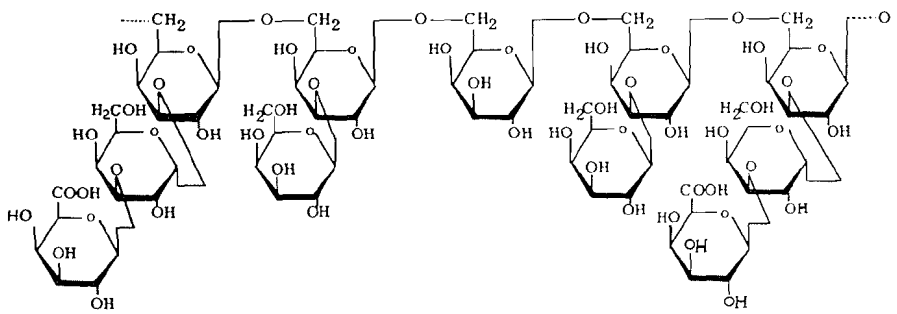

DIAGRAM 1. Proposed structure of the degraded gum.

Partial hydrolysis of the gum in cold 6 *N* sulfuric acid led to the isolation of a mixture of oligo- and mono-saccharides which was separated from the degraded gum by dialysis. Chromatographic examination showed the mixture to be composed of L-arabinose (ca. 60–65%), D-xylose (ca. 20–25%), D-galactose (ca. 5%), and several di- and oligosaccharides (total 8–10%). Most of the arabinose was crystallized from the mixture, and the rest was then removed almost completely on a cellulose column. The mixture of oligosaccharides thus obtained was further separated into six different oligosaccharides (Table II).

TABLE II

Neutral oligosaccharides from cholla gum

Oligosaccharide	Quantity (g)	R_{gal}	Color with *p*-anisidine hydrochloride spray
6-*O*-β-D-Galactopyranosyl-D-galactose	1.06	0.48	Yellow
3-*O*-β-D-Galactopyranosyl-D-galactose	0.158	0.62	Brownish-yellow
3-*O*-α-L-Arabinofuranosyl-L-arabinose	0.024	1.42	Red
5-*O*-β-D-Xylopyranosyl-L-arabinose	0.223	1.30	Pink
3-*O*-β-D-Galactopyranosyl-L-arabinose	0.018	0.76	Reddish-yellow
O-β-D-Xylopyranosyl-(1 → 5)-*O*-α-L-arabinofuranosyl-(1 → 3)-L-arabinose	0.098	1.20	Red

All of the above oligosaccharides, except *O*-β-D-xylopyranosyl-(1 → 5)-*O*-α-L-arabinofuranosyl-(1 → 3)-L-arabinose, have been reported earlier in the literature. The isolation of only two galactobioses and their identification as 1 → 6 and 1 → 3, β-linked disaccharides may be compared with the isolation of only 2,4-di-*O*-methyl-D-galactose residues from the methylated polymer by Brown *et al.* (4), and is consistent with the observation that the galactose residues in gums are usually 1 → 3 and (or) 1 → 6 linked. The isolation of trimethyl, dimethyl, and unsubstituted L-arabinose residues from the methylated polymer by Brown *et al.* had earlier indicated that the gum was a highly branched molecule with L-arabinose residues involved in several types of linkages. The isolation of four different oligosaccharides containing L-arabinose residues, in the present work, confirmed the variety of L-arabinose linkages. Because of the small amount of material available, the identification of 3-*O*-α-L-arabinofuranosyl-L-arabinose was based mainly on its optical rotation, its chromatographic mobility, and the ease with which it was hydrolyzed to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

produce only L-arabinose. An attempt to prepare a phenylosazone of the disaccharide resulted in the production of L-arabinose phenylosazone. The optical rotation of the disaccharide (−4°) was in close agreement with that reported for 3-*O*-α-L-arabinofuranosyl-L-arabinose, which was isolated by Smith and Stephen (5) from *Virgilia oroboides* gum. On the basis of this evidence and on the basis of the identification of a trisaccharide, *O*-β-D-xylopyranosyl-(1 → 5)-*O*-α-L-arabinofuranosyl-(1 → 3)-L-arabinose, a partial hydrolysis of which could produce 3-*O*-α-L-arabinofuranosyl-L-arabinose, it was assumed that the arabinobiose under study was the same as that isolated by Smith and Stephen (5). Although a very small quantity of this disaccharide was obtained from the hydrolysate of the gum, it has been possible to assign structural significance to it, particularly in view of the isolation of the new trisaccharide, which is discussed later.

The isolation and identification of 5-*O*-β-D-xylopyranosyl-L-arabinose from peach and cholla gum was earlier reported by Andrews and his co-workers (6). Since the methylation studies (4) have indicated that all the D-xylose residues in the gum occupy terminal positions, at least some of the L-arabinose residues form a layer underneath the outer D-xylopyranose residues. More information regarding the arabinose-containing part of the gum was obtained by the isolation of a trisaccharide which, on further mild hydrolysis, gave L-arabinose and 5-*O*-β-D-xylopyranosyl-L-arabinose. The trisaccharide was so unstable that a sample stored at 0° for 8–10 weeks decomposed partially into L-arabinose and the disaccharide mentioned above. Complete hydrolysis of a part of the pure trisaccharide by warm 1 *N* sulfuric acid produced L-arabinose and D-xylose in the ratio 2:1, respectively. When a part of the trisaccharide was reduced by sodium borohydride and hydrolyzed, xylose, arabinose, and arabinitol were obtained, thereby showing that one L-arabinose residue formed the reducing end of the trisaccharide. The trisaccharide and its fully methylated derivative had high negative optical rotations. Methanolysis and hydrolysis of the methylated trisaccharide gave a mixture containing equal proportions of 2,3,4-tri-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-L-arabinose, and 2,4-di-*O*-methyl-L-arabinose. A small amount of another sugar, probably 2,5-di-*O*-methyl-L-arabinose, was also detected. The three major sugars were separated chromatographically and were identified by their physical constants and by conversion into their respective *N*-phenylglycosylamines. The fourth sugar was extracted from the chromatogram in a quantity insufficient for further study. However, on the basis of the rate at which it moved on the chromatograms, this sugar is believed to be 2,5-di-*O*-methyl-L-arabinose. Its presence was not unexpected, because the terminal L-arabinose residue could exist in solution as either a pyranose or a furanose sugar. The linkage between D-xylopyranose and L-arabinofuranose residues was established to be of the β-type by Andrews and his co-workers (6). Application of Hudson's rules of isorotation (7) demanded that the nature of the glycosidic linkage between two arabinose residues in the trisaccharide be considered as of the α-type. Thus, on the basis of this evidence, the trisaccharide was identified as *O*-β-D-xylopyranosyl-(1 → 5)-*O*-α-L-arabinofuranosyl-(1 → 3)-L-arabinose (Diagram 2).

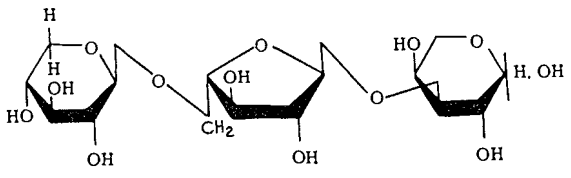

DIAGRAM 2. Neutral trisaccharide, *O*-β-D-xylopyranosyl-(1 → 5)-*O*-α-L-arabinofuranosyl-(1 → 3)-L-arabinose, from cholla gum.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

A disaccharide containing D-galactose and L-arabinose was also obtained in very small yield in the present study. It was not possible to prepare a crystalline derivative of this disaccharide, but on the basis of the melting range of the crude material and optical rotation of this compound it was tentatively identified as 3-*O*-β-D-galactopyranosyl-L-arabinose. The structural significance of this disaccharide is not clear, since its isolation was found not to be consistent with other observations, such as investigations of the structure of the degraded gum and Smith-type degradation of the polymer. Its origin might possibly be attributed to an acid reversion, although formation of a β-D-linked disaccharide by acid reversion has rarely been encountered.

Periodate Oxidation Studies

Oxidation of the polysaccharide by sodium metaperiodate was almost complete within 24 h, during which time the gum had consumed 0.73 mole of the oxidant and had released 0.14 mole of formic acid per average anhydro sugar unit. When the periodate-oxidized polymer was reduced by sodium borohydride and a small portion of the resulting polyalcohol was hydrolyzed, the hydrolysate was found chromatographically to be a mixture of seven components, among which those corresponding to D-galactose, L-rhamnose, D-galacturonic acid, and L-arabinose could easily be located. No spot corresponding to the presence of xylose was noticed. All the components of the hydrolysate were identified and estimated chromatographically (Table III).

TABLE III

Products of Smith-type degradation of cholla gum

Product	Approximate percentage	Product	Approximate percentage
D-Galactose	30±2	L-Arabinose	5–6
Glycerol	25±2	Ethylene glycol	5–6
Glycolaldehyde	20±2	L-Rhamnose	2–3
D-Galacturonic acid	10±2		

When the polyalcohol was partially hydrolyzed by cold 1 *N* sulfuric acid and the hydrolysate poured into ethanol, a sticky precipitate was obtained which was repeatedly extracted with hot ethanol. The precipitated material and the ethanol extracts were now separately hydrolyzed by hot dilute acid and the hydrolysates were examined chromatographically. The hydrolysate of the precipitated material contained D-galactose (ca. 70%), D-galacturonic acid (ca. 20%), and L-rhamnose (ca. 5%) with trace quantities of L-arabinose, glycerol, glycolaldehyde, and ethylene glycol. Hydrolysis of the alcohol-soluble syrup yielded mainly glycerol (ca. 50%) and glycolaldehyde (ca. 40%) together with L-arabinose (8–10%), ethylene glycol (8–10%), and trace quantities of L-rhamnose, D-galacturonic acid, and D-galactose.

The results obtained in the present investigations were found to be consistent with the results of the methylation studies of the polymer by Brown *et al.* (4). On the basis of all these results plus the suggested structure of the degraded gum (Diagram 1), it is proposed that one of many possible structures for the repeating unit of the polymer is as shown in Diagram 3.

DISCUSSION

Although the structure proposed in Diagram 3 explains a number of experimental results, it must be emphasized that it is just one of the several possible structures for the repeating unit of the polymer.

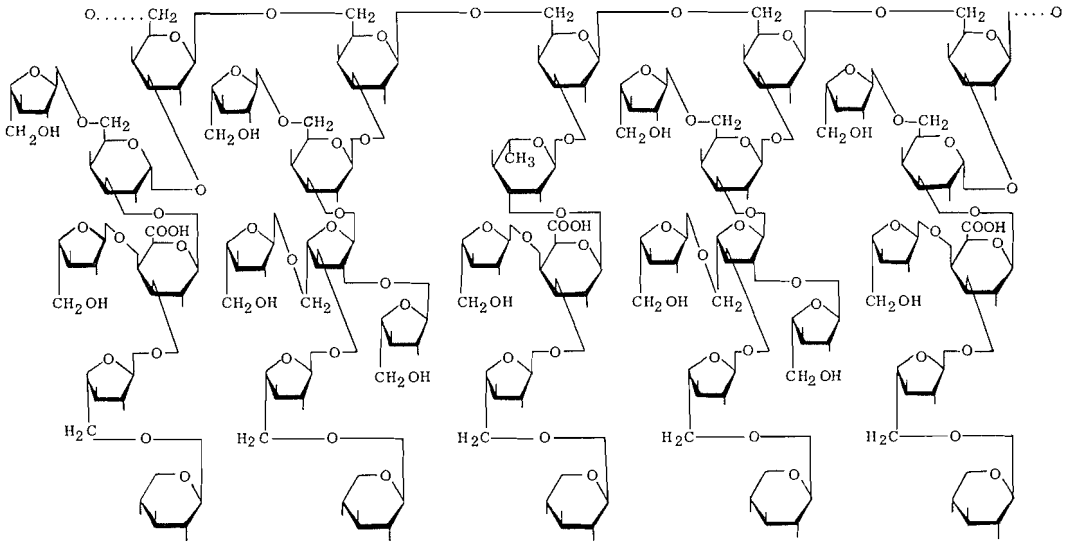

DIAGRAM 3. Proposed structure of cholla gum.

The analysis of the gum is given in Table I and is in fair agreement with a repeating unit of 36 sugar residues: 18 of L-arabinofuranose, 9 of D-galactopyranose, 5 of D-xylopyranose, 3 of D-galactopyranosyluronic acid, and 1 of L-rhamnose.

Methylated cholla gum (Diagram 3) gave, on hydrolysis, the methylated sugar derivative listed in Table IV. The quantities of methylated sugars anticipated from the hydrolysis of the methylated polymer are also in fair agreement with those isolated. The periodate results (a consumption of 0.73 mole of the oxidizing agent with the concomitant production of 0.14 mole of formic acid per average anhydro sugar residue) also support the above results. Further support for the proposed structure (Diagram 3) is obtained when the products resulting from the Smith-type periodate degradation of the gum are analyzed (Table V). It will be noted that all the D-xylose and most of the L-arabinose have been oxidized.

TABLE IV

A comparison of the methylation results with those expected according to the proposed structure

Product	Quantity (moles) expected according to the proposed structure	Quantity (moles) isolated experimentally (4)
2,4-Di-*O*-methyl-D-galactose	9	9
2,3,4-Tri-*O*-methyl-D-xylose	5	6
2-*O*-Methyl-D-galacturonic acid	3	3
2,3,5-Tri-*O*-methyl-L-arabinose	11	12
2,3-Di-*O*-methyl-L-arabinose	5	3
L-Arabinose (unsubstituted)	2	3
2,4-Di-*O*-methyl-L-rhamnose	1	Nil

The isolation of the trisaccharide (Diagram 2) gives an idea of the sequence of sugars from the end groups (D-xylopyranose) towards the inner portion of the molecule. Again it must be emphasized that the proposed structure of the gum (Diagram 3) is only one of many possibilities. Further work will be necessary before a specific structure can be advanced for cholla gum.

TABLE V

Comparison of the Smith-type degradation results with those calculated on the basis of the proposed structure

Substance	Quantity (%) expected according to the methylation studies	Quantity (%) obtained experimentally	Quantity (%) expected according to the proposed structure
D-Galactose	28.6	30±2	28.4
Glycerol	24.4	25±2	25.8
Glycolaldehyde	22.2	20±2	22.1
D-Galacturonic acid	10.3	10±2	10.2
L-Arabinose	8.0	5–6	5.3
Ethylene glycol	6.6	5–6	5.3
L-Rhamnose	Nil	2–3	2.9

Nature of Linkages and Optical Rotation

The proposed structure of the gum shows that the repeating unit of the gum is composed of a total of 36 sugar residues which are linked as follows: β-linked D-galactose (7 moles), α-linked D-galactose (2 moles), β-linked D-galacturonic acid (3 moles), α-linked L-rhamnose (1 mole), α-linked L-arabinose (18 moles), and β-linked D-xylopyranose (5 moles). The optical rotation of the polysaccharide, calculated on the basis of these data by the application of Hudson's rules (7), was found to agree reasonably well with the experimental value (−86°) for the gum.

EXPERIMENTAL

Methods

Paper chromatography was carried out on Whatman No. 1 filter paper with the following solvent systems (by volume): (*a*) butan-1-ol–ethanol–water (3:1:1); (*b*) butan-1-ol–ethanol–water (5:1:4), top layer cleared by addition of a minimum of ethanol; (*c*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (*d*) butan-1-ol–pyridine–water–benzene (5:3:3:1); (*e*) ethyl acetate – pyridine – water (10:4:3); and (*f*) butan-1-ol–ethanol–water (1:1:1). The spray reagents used were: (*i*) alkaline silver nitrate (8), and (*ii*) *p*-anisidine hydrochloride (9). Whatman 3 MM paper and columns packed with Whatman cellulose powder by the wet method were used for the separation of sugar mixtures. Optical rotations were observed in water, unless otherwise stated. All solutions were concentrated under reduced pressure at 40–45°.

Partial Hydrolysis of the Gum and Isolation of Neutral Oligosaccharides

The gum (100 g) was purified and hydrolyzed by cold dilute sulfuric acid as described in part I (1). The hydrolysate was neutralized with barium carbonate, filtered, and dialyzed against distilled water (3 × 4 l). The dialyzate, on concentration, yielded a mixture of mono- and oligo-saccharides (58.0 g). The chromatographic examination of the mixture revealed the presence of arabinose (60–65%), xylose (20–25%), galactose (ca. 5%), and several di- and oligo-saccharides (8–10%). The syrup was thinned with methanol seeded with L-arabinose, and was kept overnight at 0°, during which L-arabinose (19 g) crystallized out and was separated by filtration. Another crop of L-arabinose (5.8 g) subsequently crystallized out from the filtrate on concentration. The residual mixture (30.2 g) was found to contain L-arabinose (ca. 30%), D-xylose (ca. 30%), D-galactose (ca. 10%), and a mixture of at least four oligosaccharides (total ca. 20%). Attempts were made to remove monosaccharides from the mixture by carrying out the separation, on the basis of the molecular weights of the sugars, on columns containing Dowex-50-2 (Li salt) and eluting the sugars with water. These attempts, however, proved to be unsuccessful.

The syrupy mixture (29 g) was therefore divided into three equal portions and each portion (ca. 10 g) was passed through large cellulose columns (90 × 13 cm), butan-1-ol saturated with water being used as the solvent. The process of separation was extremely slow, and a mixture of L-arabinose and D-xylose was eluted from the column only after 4.8 l of the eluant had been collected from each column. The elution of the mixture of L-arabinose and D-xylose continued for a period of 7 days, during which time 4 l of the eluant was collected from each column. The total weight of the mixture of arabinose and xylose collected from the three columns was found to be 18.6 g. Elution of arabinose and xylose was followed by 1 l of the sugar-free eluant, after which D-galactose was eluted from the column; the elution was continued for a period of 5 days, during which time 3 l of the effluent containing a total of 2.8 g of galactose was collected.

At this stage the solvent system for chromatography was changed to butan-1-ol–ethanol–water (1:1:1 v/v/v), 4 l of which eluted all the oligosaccharides from each column in the form of a mixture (total 3.45 g). Chromatographic examination of this mixture in solvents *a*, *c*, *e*, and *f* revealed the presence of only trace quantities of monosaccharides, viz. arabinose, xylose, and galactose with at least five to six oligosaccharides.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The constituents of the mixture were separated chromatographically on 3 MM paper with solvent *e*. Their R_{gal} values in solvent *e*, yields, and identities are given in Table II. Higher oligosaccharides (R_{gal} 0.2), which were present only in trace quantities, were not examined and are not recorded.

Identification of the Oligosaccharides

Fraction 1: 6-O-β-D-Galactopyranosyl-D-galactose

This material (1.06 g) was chromatographically pure and showed R_{gal} values of 0.16, 0.48, and 0.65 in solvents *c*, *e*, and *f*, respectively. It crystallized from methanol–acetone (1:1 v/v) to give waxy, highly hygroscopic crystals which crumbled to an amorphous powder when kept in a desiccator. The white amorphous powder melted over a broad range of 98–106° and was therefore recrystallized from methanol. The colorless needles thus obtained softened at 98–99°, almost melted at 118°, but resolidified, when heated further, at 124–128°. The resolidified material melted, when heated further, at 169–171°.

The disaccharide reduced Fehling's solution and had $[\alpha]_D^{23}$ +26 → +35.2° (48 h) (*c*, 1.5 in water). On complete hydrolysis by 2 *N* sulfuric acid at 98° for 6 h, it produced only D-galactose (detected chromatographically). Its phenylosazone, prepared by heating the solution of the disaccharide (150 mg) in ethanol (5 ml) with freshly distilled phenylhydrazine (170 mg), sodium acetate (80 mg), and glacial acetic acid (105 mg) on a boiling water bath for 1 h, melted with decomposition at 201–202°. Freudenberg *et al.* (10), who have synthesized this disaccharide by the Köenigs–Knorr method (11), reported the following constants for the disaccharide and its phenylosazone: disaccharide, m.p. 115° and $[\alpha]_D^{17}$ +25.1 → +34.1° (48 h) (*c*, 3.20 in water); phenylosazone, m.p. 207° with decomposition.

Duplicate samples of the desiccated anhydrous disaccharide (38 mg each) were dissolved in distilled water (5 ml each). Sodium metaperiodate solution (0.3 *M*, 1 ml) was added to each flask, and the solutions were made up to 25 ml with distilled water and kept in the dark. The periodate uptake was determined by the thiosulfate method with phosphate buffer (12), and the formic acid by titration with standard sodium hydroxide solution (screened methyl red indicator) after addition of ethylene glycol. Found: periodate uptake 4.97 moles and formic acid yield 3.04 moles per mole.

Fraction 2: 3-O-β-D-Galactopyranosyl-D-galactose

This disaccharide (158 mg) was obtained in the form of a chromatographically pure syrup and had R_{gal} values of 0.27, 0.62, and 0.75 in solvents *c*, *e*, and *f*, respectively. It crystallized on trituration with ether–methanol (2:1 v/v), and had m.p. 159–161° and $[\alpha]_D^{23}$ +72 → +62° (10 h) (*c*, 1.0 in water). Hydrolysis of the disaccharide gave only galactose (detected chromatographically). The literature values (13) for 3-*O*-β-D-galactopyranosyl-D-galactose isolated from *Acacia pycnantha* gum are: m.p. 159–160.5° and $[\alpha]_D$ +62° (*c*, 0.58 in water).

Periodate oxidation of the disaccharide was carried out in the same manner as described for fraction 1, taking 35 mg duplicate samples for the experiments. Found: periodate uptake 3.02 moles and formic acid yield 0.96 mole per mole of the disaccharide.

Fraction 3: 3-O-α-L-Arabinofuranosyl-L-arabinose

A very small quantity (24 mg) of this disaccharide was isolated in the form of a colorless syrup having $[\alpha]_D^{23}$ −4° (*c*, 0.5 in water) and R_{gal} values of 1.2 and 1.42 in solvents *c* and *e*, respectively. It gave a pink spot on chromatograms sprayed with *p*-anisidine hydrochloride and also with the tetraazolium red reagent. It was hydrolyzed readily by 1 *N* sulfuric acid when heated to 98° for 3 h to give only L-arabinose. The attempted synthesis of its phenylosazone gave an impure crystalline material which melted at 184–200°. These crystals were probably those of L-arabinose phenylosazone. The optical rotation and the R_{gal} values of this disaccharide are in fair agreement with those reported for 3-*O*-α-L-arabinofuranosyl-L-arabinose isolated from *Virgilia oroboides* gum, by Smith and Stephen (5). The optical rotation reported for this disaccharide is 0°. The anomer of this disaccharide was isolated from a number of gums (14–16) and is reported to have $[\alpha]_D$ +94°.

Fraction 4: 5-O-β-D-Xylopyranosyl-L-arabinose

This fraction (223 mg) was obtained as a chromatographically pure, light-yellow syrup and had R_{gal} values of 0.92 and 1.30 in solvents *c* and *e*, respectively. The disaccharide could not be crystallized. When the chromatograms were sprayed with *p*-anisidine hydrochloride and warmed, the disaccharide was detected as an initial yellow spot which rapidly turned pink when heated further. On complete hydrolysis by 1 *N* sulfuric acid it produced arabinose and xylose in equal proportions. It had $[\alpha]_D^{23}$ −38° (*c*, 1.4 in water). A crystalline phenylosazone of the disaccharide, prepared in the usual manner, melted at 214° (decomp.) and had $[\alpha]_D^{23}$ +51° (*c*, 0.8 in pyridine–ethanol (3:2 v/v)). A portion of the osazone, on hydrolysis by 2 *N* sulfuric acid, gave only xylose and no arabinose. Andrews and his co-workers (6) have isolated 5-*O*-β-D-xylopyranosyl-L-arabinose from this gum and from cherry gum, and the constants reported by them are: disaccharide, $[\alpha]_D$ −34° (*c*, 6.0 in water); phenylosazone, $[\alpha]_D$ +48° (*c*, 0.25 in pyridine–water (3:2 v/v)) and m.p. 216°.

Fraction 5: 3-O-β-D-Galactopyranosyl-L-arabinose

The very small quantity (18 mg) of this fraction that was obtained solidified when kept at 0°, but several attempts to recrystallize the solid proved to be unsuccessful. The waxy material melted at 193–202°. It reduced Fehling's solution and was chromatographically pure, having R_{gal} values of 0.46 and 0.76 in solvents

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

c and *e*, respectively. On hydrolysis with 2 *N* sulfuric acid it produced galactose and arabinose in equal proportions. It had $[\alpha]_D$ +64° (*c*, 0.48 in water). Further examination of this material was not possible because of the very small amount available. However, on the basis of the available data the material appears to be 3-*O*-β-D-galactopyranosyl-L-arabinose. The literature values for this disaccharide are: m.p. 200–201° and $[\alpha]_D$ +60° (*c*, 1.8 in water) for the disaccharide isolated from *Albizzia zygia* (17); m.p. 204–205° and $[\alpha]_D$ +97 → +67° (2 h) (*c*, 0.45 in water) for the disaccharide isolated from *Anogeissus schimperi* gum (16).

Fraction 6: O-β-D-Xylopyranosyl-(1 → 5)-O-α-L-arabinofuranosyl-(1 → 3)-L-arabinose

This syrupy fraction (98 mg) was chromatographically pure when isolated, and showed a red spot with *p*-anisidine hydrochloride reagent. However, when the syrup was kept for a few weeks it decomposed, and the chromatographic examination of the fraction revealed it to be a mixture of the original material (80%) and two minor fractions (ca. 10% each). The minor fractions had the same chromatographic mobility as did fraction 4 (i.e. 5-*O*-β-D-xylopyranosyl-L-arabinose) and L-arabinose, respectively. The mixture was therefore separated chromatographically by passing its aqueous solution through a column containing Sephadex G-25, medium grain (45 × 5 cm). The pure material thus obtained had $[\alpha]_D^{24}$ −74.2° (*c*, 1.1 in water), and R_{gal} 1.2 in solvent *e*. Addition of a mixture of methanol and acetone to this syrup precipitated an amorphous solid melting at 131–140°. Hydrolysis of this material on a boiling water bath by 1 *N* sulfuric acid produced only arabinose and xylose in the proportion 2:1.

A small portion of the material (8 mg) in water (3 ml) was reduced by sodium borohydride (1%, 5 ml). The solution was passed through an ion-exchange column containing layers of Amberlite IR-120 (H^+ form) and Duolite A-4 (OH^- form), and the material thus obtained was hydrolyzed by 1 *N* sulfuric acid. Chromatographic examination of the hydrolysate showed that it contained equal proportions of xylose, arabinose, and arabinitol.

The rest of the material (40 mg) was dissolved in water (3 ml), and cooled to 0°; dimethyl sulfate (2 ml) followed by sodium hydroxide solution (30%, a few drops until the pH reached 9) was added and the solution was stirred until it became nonreducing. The solution was then brought to room temperature, and dimethyl sulfate (5 ml) and sodium hydroxide (8 ml) were simultaneously added dropwise over a period of 1 h. The excess dimethyl sulfate was decomposed by heating the mixture to 65–70° and the solution was brought to pH 7 by addition of dilute sulfuric acid. The methylated sugar thus obtained (42 mg) by extraction with chloroform was found to be chromatographically pure and had $[\alpha]_D$ −91.6° (*c*, 0.574 in chloroform). The infrared spectrum of the syrup in chloroform did not show any absorption in the hydroxyl region.

Hydrolysis of the methylated material by dilute sulfuric acid and chromatographic examination of the neutralized hydrolysate in solvent *a* revealed that four partially methylated sugars were produced. Three of these sugars travelled parallel, respectively, to authentic samples of 2,3,4-tri-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-L-arabinose, and 2,4-di-*O*-methyl-L-arabinose. The fourth sugar, which was present in only trace quantities (3–5%), travelled slightly faster than authentic 2,4-di-*O*-methyl-L-arabinose and was believed to be 2,5-di-*O*-methyl-L-arabinose, since the four sugars gave red spots on chromatograms sprayed with *p*-anisidine hydrochloride but none showed up when the chromatograms were sprayed with tetraazolium red reagent (18). The three components of the syrup were chromatographically separated on Whatman 3 MM filter paper with solvent *a* and were examined as follows.

Fraction 6A: 2,3,4-tri-O-methyl-D-xylose.—This fraction (11 mg) was a chromatographically pure syrup and was indistinguishable from an authentic sample of 2,3,4-tri-*O*-methyl-D-xylose. It had $[\alpha]_D^{22}$ +22° (equilibrium value) (*c*, 0.72 in water). Its *N*-phenylglycosylamine was prepared by treatment with aniline in ethanol. The crystalline derivative melted at 98–99° and had $[\alpha]_D^{22}$ −85 → +48° (*c*, 0.81 in ethanol). The literature values for 2,3,4-tri-*O*-methyl-D-xylose (19) and for its *N*-phenylglycosylamine (20) are: sugar, m.p. 91–92° and $[\alpha]_D$ +64 → +18° (in water); *N*-phenylglycosylamine, m.p. 102° and $[\alpha]_D$ −84 → +47°.

Fraction 6B: 2,3-di-O-methyl-L-arabinose.—This fraction (9 mg) was a chromatographically pure syrup and had $[\alpha]_D^{22}$ +98° (*c*, 0.52 in water). Conversion into its *N*-phenylglycosylamine in the usual manner gave tiny colorless crystals having m.p. 137–139° (undepressed). The literature values (21) for 2,3-di-*O*-methyl-L-arabinose and for its *N*-phenylglycosylamine derivative are: sugar, $[\alpha]_D$ +101° (in water); its *N*-phenylglycosylamine, m.p. 137–139°.

Fraction 6C: 2,4-di-O-methyl-L-arabinose.—This syrup was chromatographically pure and had $[\alpha]_D$ +116° (*c*, 0.52 in water). The *N*-phenylglycosylamine of the sugar, prepared in the usual manner and recrystallized from ethanol, had m.p. 143–145° (undepressed). The literature values (22) for 2,4-di-*O*-methyl-L-arabinose and for its *N*-phenylglycosylamine derivative are: sugar, $[\alpha]_D$ +129° (in water); its *N*-phenylglycosylamine, m.p. 145–146°.

ACKNOWLEDGMENTS

The authors thank Drs. B. A. Erukoff and K. Folkers for the gift of cholla gum. They also thank the National Research Council of Canada for a grant (N.R.C. T-19), Queen's University for financial assistance, and Dr. E. Buncel for helpful discussions.

LIGNANS OF WESTERN RED CEDAR (THUJA PLICATA DONN)

IV. THUJAPLICATIN AND THUJAPLICATIN METHYL ETHER[1]

HAROLD MACLEAN[2] AND KOJI MURAKAMI[3]

Forest Products Laboratory, Department of Forestry of Canada, Vancouver, British Columbia

Received February 17, 1966

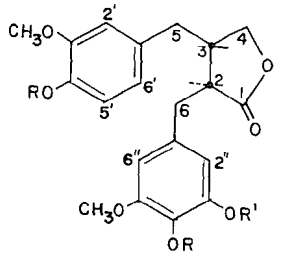
ABSTRACT

In addition to the already known plicatic acid and plicatin, five new lignans have been separated by thin-layer and column chromatography from the hot-water extractive of western red cedar (*Thuja plicata* Donn) heartwood, and two chemical structures have been identified. These are 2-(4″-hydroxy-3″,5″-dimethoxybenzyl)-3-(4′-hydroxy-3′-methoxybenzyl)-butyrolactone (thujaplicatin methyl ether) (I) and 2-(3″,4″-dihydroxy-5″-methoxybenzyl)-3-(4′-hydroxy-3′-methoxybenzyl)-butyrolactone (thujaplicatin) (II). The former is the first known example of a lignan containing a guaiacyl and a syringyl nucleus and the first example of a syringyl-group lignan isolated from a conifer. Proof of structure by synthesis, degradation, analysis, and various spectra is presented. The other components which apparently belong to this lignan series are still being investigated.

In previous papers (1–3) the structures of the lignans plicatic acid and plicatin, the main components of the hot-water extractive of western red cedar heartwood, were presented. Development of adequate thin-layer and preparative chromatographic systems has permitted the detection and separation of five new components of much lower concentration (Scheme 1), all of which appear to be related lignans. The structure of two of these components is reported in this paper. Investigation of the chemistry of the remaining compounds is continuing.

Because the first lignan of this series to be identified was the methyl ether of the second, and there are indications that the other lignans will also be derivatives of the second, the common names assigned are thujaplicatin methyl ether for I and thujaplicatin for II. The numbering and chemical naming systems follow the review of Hearon and MacGregor (4). The chemical names proposed by Freudenberg and Weinges (5) are given at the end of the discussion of each lignan.

Thujaplicatin Methyl Ether (I)



This compound gave approximately equal yields of vanillin and syringaldehyde on nitrobenzene oxidation (6). Analytical data obtained for this lignan and its di-*O*-methyl ether (III) were satisfactory; infrared spectra were as expected, showing no hydroxyl band after methylation. The ultraviolet spectrum of I had a maximum at 281 mμ shifting to 293 mμ in alkaline solvent. Nuclear magnetic resonance (n.m.r.) spectra with integrals accounted for all proton species in the dimethyl ether (III) and the diacetate (IV), the spectrum of the parent lignan being unsatisfactory because of low solubility in deuteriochloroform.

Synthesis of the dimethyl derivative (III) was accomplished by condensing (±)-3-(3′,4′-dimethoxybenzyl)-butyrolactone (V) (7) in sodium methoxide with 3,4,5-trimethoxybenzaldehyde (8, 9) to yield (±)-2-(3″,4″,5″-trimethoxybenzylidene)-3-(3′,4′-dimethoxybenzyl)-butyrolactone (VI) (10), the double bond of which was reduced by hydrogen over

VI

VII

a palladium chloride catalyst in methanol to the *cis* form of (±)-2-(3″,4″,5″-trimethoxybenzyl)-3-(3′,4′-dimethoxybenzyl)-butyrolactone (VII). This hydrogenation is directly analogous to Schrecker and Hartwell's conversion of savinin into (+)-isohinokinin (*cis* configuration) and the subsequent base-catalyzed epimerization to (−)-hinokinin (*trans* epimer) (11, 12). The *cis* epimer VII, which differed from the natural di-*O*-methyl ether III (shown by infrared and n.m.r. spectral comparison and by thin-layer R_f values), was dissolved in methanolic potassium hydroxide for 4 days at room temperature to yield, on acidification and purification, the *trans* epimer (±)-*trans*-2-(3″,4″,5″-trimethoxybenzyl)-3-(3′,4′-dimethoxybenzyl)-butyrolactone (III).

Additional evidence for the *cis–trans* configurations is indicated by comparing their Dreiding stereomodels and n.m.r. spectra. In the *trans* configuration, the four C5—C6 benzyl protons have free rotation and appear in the n.m.r. spectra as a singlet whereas the C2—C3 *trans* protons appear as a doublet at 7.03 and 7.10 τ. In the *cis* epimer, the rotation of the benzyl protons is sterically hindered, which, in conjunction with the 0° dihedral angle's larger coupling constant (13) for the C2—C3 protons, shows an unresolvable complex pattern totalling six protons in the 6.5 to 8.5 τ region of the n.m.r. spectra, as expected for the two overlapping ABX systems.

The *trans* epimer III was identical with natural di-*O*-methyl thujaplicatin methyl ether (III) as shown by ultraviolet, infrared, and n.m.r. spectral comparison. Although several crystals of the synthetic material had the same melting point as the natural product, the major part melted approximately 20° lower, which is indicative of a racemic mixture of individual crystals of each of the two enantiomers of the *trans* configuration (14). Thujaplicatin methyl ether (I) is therefore *trans*-2-(4″-hydroxy-3″,5″-dimethoxybenzyl)-3-(4′-hydroxy-3′-methoxybenzyl)-butyrolactone (4,4′-dihydroxy-3,3′,5′-trimethoxy-lignan-olid (9,9′) by the nomenclature of Freudenberg and Weinges (5)).

This is the first known lignan containing both a guaiacyl and a syringyl nucleus as well as the first isolated from a conifer containing a syringyl nucleus.

Thujaplicatin (II)

This compound has not been crystallized, but methylation of a chromatographically pure sample by diazomethane in methanol gave a good yield of tri-*O*-methyl thujaplicatin (III), identical with the product from the methylation of thujaplicatin methyl ether, di-*O*-methyl thujaplicatin methyl ether (III), as shown by mixed melting point, optical rotation, and infrared spectral comparison. The presence of a pyrocatechol group was indicated by a lower R_f value when chromatographed in butanol – acetic acid – water

(60:15:25 v/v/v) on molybdic acid treated paper rather than on untreated paper. Since nitrobenzene oxidation yielded only vanillin, and alkaline permanganate oxidation of the triethyl ether, prepared by diethyl sulfate and anhydrous potassium carbonate in acetone, produced 3,4-diethoxy-5-methoxybenzoic and 4-ethoxy-3-methoxybenzoic acids, this lignan was shown to be 2-(3″,4″-dihydroxy-5″-methoxybenzyl)-3-(4′-hydroxy-3′-methoxybenzyl)-butyrolactone (II) (4,3′,4′-trihydroxy-3,5′-dimethoxy-lignan-olid (9,9′) by the nomenclature of Freudenberg and Weinges (5)).

EXPERIMENTAL

Melting points were taken on a Fisher–Johns apparatus and are uncorrected. Carbon, hydrogen, and methoxyl analyses were performed by Clark Microanalytical Laboratories, Urbana, Illinois. The n.m.r. spectra were measured in deuteriochloroform with tetramethylsilane as internal reference ($\tau = 10$) on a Varian A.60 instrument at the Chemistry Department of the University of British Columbia. Ultraviolet spectra were taken in ethanol on a Beckman DK-2 spectrometer. Infrared spectra were taken as KBr disks, unless otherwise specified, on a Baird-Atomic KM-1 spectrometer. Molecular weights were determined on a Mechrolab osmometer, model 301A, with benzil and β-conidendrin as reference compounds. Thin-layer chromatography (t.l.c.) used silica gel G (Merck) as adsorbent with benzene–ethanol – acetic acid (100:10:1), unless otherwise shown, as developer, and with nitric acid – sulphuric acid (1:1) – heat and ultraviolet light as detectors. Preparative-layer chromatography (p.l.c.) used 2 mm layers of silica gel G and GF 254 (2:1) with ultraviolet light as detector and the t.l.c. developing solvent, unless otherwise indicated. All developing solvent mixtures are on a volume basis.

Fractionation of Extractive

As shown in Scheme 1, western red cedar heartwood meal (1 kg, moisture-free basis) ground to pass a 4 mm screen was extracted with water (8 l) for 5 h at 100 °C. The aqueous extract, after cooling, was extracted with chloroform (3 × 500 ml), and the aqueous layer retained for future work. The chloroform extract was evaporated to a light-colored oil (7.9 g) and triturated with petroleum ether (65–110 °C) (2 × 300 ml) to remove residual steam volatiles (thujaplicins, thujic acid, methyl thujate, etc.); the insoluble residue was subjected to silica gel column chromatography with benzene–isopropanol (100 : 2–5) as eluting solvent. Fractions were monitored by t.l.c. The fractions collected were: R_f 0.30, thujaplicatin methyl ether I (790 mg); R_f 0.25 (430 mg); R_f 0.21, thujaplicatin II (110 mg); and R_f 0.20 and 0.17 overlapping (2.5 g).

Thujaplicatin Methyl Ether (I)

Crude I (790 mg) was chromatographed first on a cellulose column to remove contaminating phenolic materials which have a low R_f value in carbonic acid paper chromatography, and then subjected to p.l.c. (R_f 0.30). The product reclaimed from the silica gel was crystallized from diethyl ether and recrystallized from acetone–water, m.p. 167–167.5 °C, $[\alpha]_D^{25}$ −48.7° (*c*, 3.94 in acetone).

Anal. Calcd. for $C_{21}H_{24}O_7$: C, 64.94; H, 6.23; OCH_3, 23.97; mol. wt. 388. Found: C, 64.86, 65.02; H, 6.06, 6.20; OCH_3, 24.02, 23.89; equiv. wt. (by back-titration) 380; mol. wt. 390.

Nitrobenzene oxidation according to Pepper and Siddiqueullah (6) yielded vanillin (3.5%) and syringaldehyde (4.2%). Spectra: λ_{min} 258 mμ (log ε 3.17), λ_{max} 281 mμ (log ε 3.60); in 0.025 *M* sodium ethoxide, λ_{min} 279 mμ (log ε 3.80), λ_{max} 293 mμ (log ε 3.86); ν_{max} 3 380 (phenol) and 1 747 (lactone) cm^{-1}.

To improve the solubility in deuteriochloroform and to remove the phenolic protons for a better n.m.r. spectrum, thujaplicatin methyl ether (150 mg) was acetylated with acetic anhydride (10 ml) in pyridine (30 ml) for 4 h at room temperature and purified by p.l.c. to yield the noncrystalline diacetate IV (130 mg). Spectra: ν_{max} no hydroxyl band, 1 753 (broad, lactone and acetoxy) cm^{-1}; n.m.r. 3.06 (1H-C5′, doublet, $J = 8.5$ c.p.s.), 3.39 (1H-C2′, doublet, $J = 1.8$ c.p.s.), 3.40 (1H-C6′, quartet, $J = 1.8$ and 8.5 c.p.s.), 3.57 (2H-C2″,6″, singlet), 5.75–6.20 (2H-C4, multiplet), 6.24 (9H-methoxyl, singlet), 7.07 (2H-C2,3, doublet), 7.39 (4H-C5,6, broad singlet), 7.70 (3H-acetyl, singlet), and 7.73 τ (3H-acetyl, singlet).

Di-O-methyl Thujaplicatin Methyl Ether (III)

A suspension of thujaplicatin methyl ether (I) (100 mg) in methanol (1 ml) was treated with excess diazomethane in ether for 24 h at room temperature. The oily product (110 mg) was recovered by vacuum evaporation, purified by p.l.c. (R_f 0.54), and crystallized from ether by seeding with tri-*O*-methyl thujaplicatin (III) (later shown to be the identical compound). Recrystallization from ether gave colorless plates, m.p. 102–103 °C, $[\alpha]_D^{24}$ −37.4° (*c*, 0.64 in chloroform), R_f 0.24 (t.l.c., developed with benzene – ether – acetic acid (70:30:1)).

Anal. Calcd. for $C_{23}H_{28}O_7$: C, 66.34; H, 6.78; OCH_3, 37.26. Found: C, 66.10; H, 6.44; OCH_3, 37.00.

Spectra: λ_{max} 278 mμ (log ε 3.54); ν_{max} no hydroxyl band, 1 763 (lactone, 1 762 in chloroform) cm^{-1}; n.m.r. 3.21 (1H-C5′, doublet, $J = 8.5$ c.p.s.), 3.41 (1H-C6′, quartet, $J = 1.7$ and 8.5 c.p.s.), 3.44 (1H-C2′, doublet, $J = 1.8$ c.p.s.), 3.59 (2H-C2″,6″, singlet), 5.8–6.2 (2H-C4, multiplet), 6.17 (15H-methoxyl, singlet), 7.07 (2H-C2,3, doublet), and 7.41 τ (4H-C5,6, broad singlet).

SCHEME 1. Fractionation of chloroform extract of hot-water extractive of western red cedar heartwood (asterisk denotes development with benzene – ethanol – acetic acid (100:10:1 v/v/v) on silica gel).

Synthesis of Di-O-methyl Thujaplicatin Methyl Ether (III)

(±)-3-(3′,4′-Dimethoxybenzyl)-butyrolactone (3.1 g), prepared by the method of Rothe and Zimmer (7), b.p. 204–206 °C at 2 mm Hg, η_D^{20} 1.5416, was condensed with prepared 3,4,5-trimethoxybenzaldehyde (8, 9) (2.55 g), with sodium methoxide (0.73 g) in benzene (24 ml) as catalyst, in a stoppered bottle at room temperature for 6 days with occasional shaking according to the procedure of Zimmer *et al.* (10), except that the final neutral product was purified by p.l.c. with benzene – ethanol – acetic acid (100:10:1) (R_f 0.64), and crystallized from ethanol to yield (±)-2-(3″,4″,5″-trimethoxybenzylidene)-3-(3′,4′-dimethoxybenzyl)-butyrolactone (VI) (700 mg), m.p. 117–118 °C.

Anal. Calcd. for $C_{23}H_{26}O_7$: C, 66.67; H, 6.28; OCH_3, 37.44. Found: C, 66.71, 66.47; H, 6.30, 6.01; OCH_3, 37.20, 37.36.

Spectra: λ_{max} 314 mμ (log ε 4.26); ν_{max} 1 730 (lactone) and 1 635 (double bond) cm^{-1}.

This product, VI (200 mg), was hydrogenated in methanol (30 ml) with palladium chloride (100 mg) as catalyst. The catalyst was filtered off with Celite and washed with methanol. The filtrates were evaporated *in vacuo*, and the product was purified by p.l.c. with benzene – ether – acetic acid (70:30:1) (R_f 0.26) and crystallized from ether to yield (±)-*cis*-2-(3″,4″,5″-trimethoxybenzyl)-3-(3′,4′-dimethoxybenzyl)-butyrolactone (VII) (130 mg) (11, 12), m.p. 143–145 °C.

Anal. Calcd. for $C_{23}H_{28}O_7$: C, 66.34; H, 6.78; OCH_3, 37.26. Found: C, 66.18; H, 6.94; OCH_3, 37.11.

Spectra: λ_{max} 278 mμ (log ε 3.56); ν_{max} 1 752 (lactone, 1 763 in chloroform) cm^{-1}; n.m.r. 3.14–3.62 (3H-C2′,5′,6′, multiplet), 3.44 (2H-C2″,6″, singlet), 5.95 (2H-C4, doublet), 6.15 (15H-methoxyl, singlet), and 6.5–8.5 τ (6H, unresolved).

This *cis* lactone was dissolved in 4% methanolic potassium hydroxide (10 ml) and kept at room temperature for 4 days. After acidification with acetic acid and refluxing for 2 h to ensure lactonization, the solvent was removed by vacuum evaporation. The residue was dissolved in chloroform, washed with sodium carbonate and water, reclaimed by vacuum evaporation, purified by p.l.c. with benzene – ether – acetic acid (70:30:1) (R_f 0.24), and crystallized from ether to yield (±)-*trans*-2-(3″,4″,5″-trimethoxybenzyl)-3-(3′,4′-dimethoxybenzyl)-butyrolactone (III) (70 mg (64% yield)), m.p. (after drying at high vacuum (54 °C) to remove ether from crystals) 80.5–81.5 °C (several small crystals melted much higher at 102–103 °C (14))

Anal. Calcd. for $C_{23}H_{28}O_7$: C, 66.34; H, 6.78; OCH_3, 37.26. Found: C, 66.49; H, 6.97; OCH_3, 37.39.

The ultraviolet, infrared (KBr disk and $CHCl_3$), and n.m.r. spectra were identical with those of natural di-*O*-methyl thujaplicatin method ether (III).

Thujaplicatin (II)

Crude II (110 mg) from the extractive fractionation was chromatographed first on a cellulose column with dilute carbonic acid elution to remove contaminating materials which have a low R_f value in paper chromatography, and then by p.l.c. to yield amorphous II (50 mg). Repeated attempts at crystallization in a variety of solvents failed. Nitrobenzene oxidation of thujaplicatin (II) (6) yielded only vanillin (2.3%). Methylation as previously described produced a tri-*O*-methyl thujaplication in 78% yield, identical, as shown by mixed melting point, optical rotation, and infrared spectrum, with di-*O*-methyl thujaplicatin methyl ether (III).

Thujaplicatin (II) (180 mg) was refluxed in acetone (10 ml) containing anhydrous potassium carbonate with diethyl sulfate (0.4 ml) for 10 h, and purified by p.l.c. to yield amorphous tri-*O*-ethyl thujaplicatin (60 mg). Spectrum: ν_{max} no hydroxyl band, 1 756 (lactone) cm^{-1}. Alkaline permanganate oxidation was carried out as in previous work (2) to yield 3,4-diethoxy-5-methoxybenzoic and 4-ethoxy-3-methoxybenzoic acids, identified by mixed melting point and infrared spectral comparison with authentic samples (2).

ACKNOWLEDGMENT

We thank Dr. L. D. Hall, University of British Columbia, for helpful discussions concerning the nuclear magnetic resonance spectra.

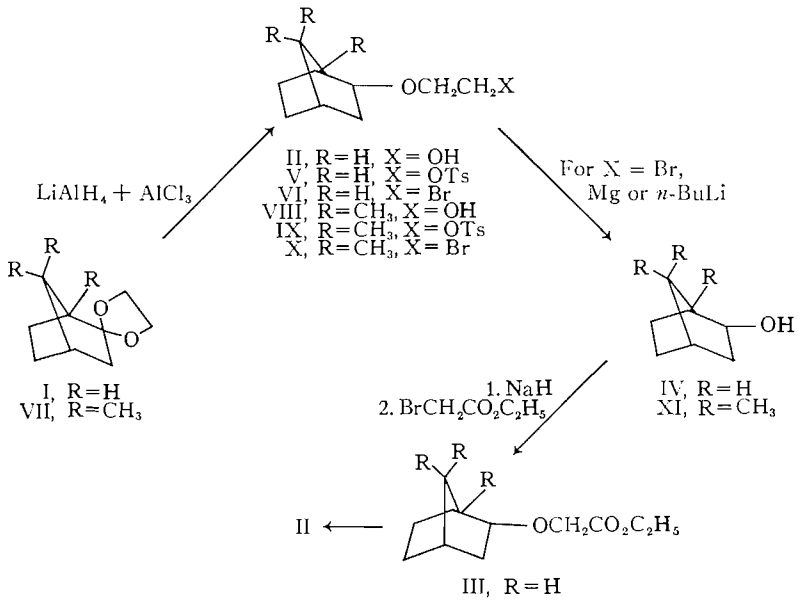
HYDROGENOLYSIS BY LITHIUM ALUMINIUM HYDRIDE – ALUMINIUM CHLORIDE OF ETHER SOLUTIONS OF CAMPHOR ETHYLENE KETAL AND NORCAMPHOR ETHYLENE KETAL

W. W. Zajac, Jr.,[1] B. Rhee, and R. K. Brown
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 3, 1966

ABSTRACT



The lithium aluminium hydride – aluminium chloride reductive cleavage of norcamphor ethylene ketal yields 2-(2-*endo*-norbornyloxy)ethanol in ⩾98% yield, whereas the similar reduction of camphor ethylene ketal gives 2-(2-isobornyloxy)ethanol in 78% yield and 2-(2-bornyloxy)ethanol in 22% yield. These are the products arising from steric approach control.

INTRODUCTION

As part of an investigation of the hydrogenolysis of acetals and ketals (1–3), we have examined the reductive cleavage by lithium aluminium hydride – aluminium chloride of ether solutions of the ethylene ketals of norcamphor and camphor. This paper describes the results of this work.

RESULTS AND DISCUSSION

The hydrogenolysis of norcamphor ethylene ketal, I, by the mixed reagent $LiAlH_4$–$AlCl_3$ was carried out according to the published procedure (3). Of the two isomeric products (II*a* and II*b*, Reaction Scheme 1) which may result from this cleavage, the 2-(2-*endo*-norbornyloxy)ethanol, II*a*, was the exclusive product. This was proven by independent syntheses of both II*a* and II*b* as well as by degradation of the hydrogenolysis product, II, to 2-norborneol by a method which avoided isomerization of the 2-norborneol so formed.

Reaction Scheme 1. *a* = *endo* isomer and *b* = *exo* isomer in each case.

[1]*On sabbatical leave from Villanova University, Villanova, Pennsylvania, U.S.A.*

For personal use only.

The synthesis of the two possible reduction products, II*a* and II*b*, was accomplished by lithium aluminium hydride reduction of the ethyl esters of 2-*endo*- and 2-*exo*-norbornyloxyacetic acid (III*a* and III*b*). The latter were prepared by reaction of the sodium salt of authentic 2-*endo*- and 2-*exo*-norborneol, IV*a* and IV*b*, with ethyl bromoacetate. Unfortunately, neither the isomeric esters III*a* and III*b* nor the hydroxyethers II*a* and II*b* could be separated by gas–liquid chromatography[2] using a variety of conditions and columns. However, the nuclear magnetic resonance spectra of the hydroxyethers II*a* and II*b* were sufficiently different to be clearly distinguishable. An examination of the nuclear magnetic resonance spectrum of the reduction product of the ketal I showed that most, if not all, of the hydrogenolysis product had the *endo* configuration II*a*. Compounds II*a* and II*b* show complex absorptions in the τ 8–9 region caused by the ring protons on carbons 3, 5, 6, and 7. The carbon 2 proton (*endo* or *exo*) absorbs in the τ 5.8–6.0 region but its identification is obscured by the absorption of the methylene protons (—OCH_2CH_2O—), which absorb in the same region. However, for the *endo* compound II*a*, the bridgehead protons on carbon 1 and carbon 4 give rise to *two* unresolved multiplets centered at τ 7.63 and τ 7.87 with half-widths of 8 c.p.s. and 11 c.p.s., respectively. The *exo* compound gives rise to only *one* unresolved multiplet centered at τ 7.83 with a half-width of 14 c.p.s.

To determine if a significant amount of the *exo* hydroxyether II*b* had actually been formed but been missed in the analytical method employed, the hydrogenolysis product II was degraded to the alcohol(s) IV, which are known to be separable quantitatively by gas–liquid chromatography (4–8). The key step in the degradation sequence was the elimination of the 2-norbornyloxy group from the bromoether VI with either magnesium (9) or *n*-butyllithium (10). That the degradation sequence of reactions truly reflects the proportion of *endo* isomer in the reduction product II was established by subjecting a synthetic mixture of known amounts of the *endo* and *exo* hydroxyethers II to the degradation reaction sequence. The proportion of *endo* and *exo* norborneols obtained agreed within $\pm 2\%$ of the proportion of *endo* and *exo* hydroxyethers in the synthetic starting mixture. The conditions of the degradation also exclude the possibility of a change in the configuration of the norborneol formed. Authentic *exo* or *endo* alcohol (IV) was found to remain unchanged under similar reaction conditions.

The product of the degradation of the material obtained by hydrogenolysis of the ketal I was shown by gas–liquid chromatography to consist of only one substance, identical in all respects with 2-*endo*-norborneol (IV*a*). Hence, the $LiAlH_4$–$AlCl_3$ reductive cleavage of the ketal I produces $\geqslant 98\%$ of the *endo* hydroxyether II*a*.

The hydrogenolysis of the ethylene ketal of camphor was carried out in the same manner as that for the norcamphor ketal. Degradation of the reduction product (VIII) was accomplished by the same reaction sequence as employed for II, i.e. VIII $\rightarrow$ IX $\rightarrow$ X $\rightarrow$ XI (Reaction Scheme 1). The borneol (XI*a*) and isoborneol (XI*b*) could also be analyzed quantitatively by gas–liquid chromatography (4, 5, 8, 11, 12). According to the results obtained from the degradation, the product of the reduction of the ethylene ketal of camphor is a mixture of $78 \pm 2\%$ of the hydroxyether with the *exo* configuration (VIII*b*) and $22 \pm 2\%$ of the hydroxyether with the *endo* configuration (VIII*a*).

The preceding results permit the conclusion that the hydride species enters from the least hindered side of the ketals I and VII. Since the hydroxyethers obtained from the $LiAlH_4$–$AlCl_3$ reductive cleavage of cyclic acetals and ketals are stable to our reaction conditions (1–3 and references therein), we are dealing with a case of steric approach

[2]*Although the individual, pure isomers II*a *and II*b *showed slightly different retention times (ca. 0.2 min) under some conditions, mixtures of the two isomers gave only one broad peak.*

control. The hydrogenolysis reactions studied in this investigation are analogous to the reduction of norcamphor and camphor to 2-norborneol (>90% *endo* isomer) and isoborneol (i.e. the *exo* isomer, >80%), respectively, with $LiAlH_4$ alone (5, 13, 14) or with $LiAlH_4$ in the presence of $AlCl_3$ (8) under kinetically controlled conditions, in that the course of reaction is governed by steric approach control (15).

This work presents a clear case in which steric factors are of predominant importance in controlling the approach of the *reducing species* during the hydrogenolysis of acetals and ketals (cf. refs. 16–18).

EXPERIMENTAL

All boiling points and melting points are uncorrected. Infrared spectra were obtained on a Perkin–Elmer model 421 spectrophotometer. Nuclear magnetic resonance spectra were obtained on a Varian Associates A-60 spectrometer with tetramethylsilane as an internal standard. In all cases the integrated nuclear magnetic resonance spectra were consistent with the assigned structures of the compounds. Gas chromatographic analysis was carried out on an Aerograph model A-700 instrument with a 20 ft by $\frac{1}{4}$ inch column packed with 25% Carbowax 20M on Gas Chrom P.

Norcamphor ethylene ketal was synthesized in 91% yield from norcamphor and ethylene glycol according to the method of Salmi (19), b.p. 78–80° at 14 mm, η_D^{25} 1.4319.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.09; H, 9.15. Found: C, 69.65; H, 8.52.

Camphor ethylene ketal was synthesized in 67% yield from camphor and ethylene glycol according to the method of Salmi (19), b.p. 64° at 1.5 mm, η_D^{25} 1.4770.

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Found: C, 73.47; H, 10.08.

Ethyl (2-exo-norbornyloxy)acetate was synthesized in 50% yield from 2-*exo*-norborneol, sodium hydride, and ethyl bromoacetate in benzene according to the procedure of Leffler and Calkins (20), b.p. 77° at 1 mm, η_D^{25} 1.4162.

Anal. Calcd. for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15. Found: C, 66.46; H, 9.04.

Ethyl (2-endo-norbornyloxy)acetate was synthesized in 53% yield from 2-*endo*-norborneol, sodium hydride, and ethyl bromoacetate in benzene according to the procedure of Leffler and Calkins (20), b.p. 80° at 1 mm, η_D^{25} 1.4160.

Anal. Calcd. for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15. Found: C, 66.42; H, 8.93.

2-(2-exo-Norbornyloxy)ethanol was synthesized in 60% yield by the reduction of the *exo* ester with lithium aluminium hydride in ether (21), b.p. 71° at 1 mm, η_D^{25} 1.4812.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.13. Found: C, 68.55; H, 10.08.

2-(2-endo-Norbornyloxy)ethanol was synthesized in 67% yield by the reduction of the *endo* ester with lithium aluminium hydride in ether (21), b.p. 72° at 1 mm, η_D^{25} 1.4815.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.13. Found: C, 69.17; H, 10.26.

This compound is identical with the hydrogenolysis product of norcamphor ethylene ketal.

Hydrogenolysis of Norcamphor Ethylene Ketal

This was carried out with lithium aluminium hydride and aluminium chloride in ether according to the method of Leggetter and Brown (1). The product was obtained in 95% yield. The tosylate of the reduction product was synthesized in 95% yield from *p*-toluenesulfonyl chloride in pyridine according to the method of Wiberg and Lowry (22), m.p. 49–51°.

Anal. Calcd. for $C_{16}H_{22}O_4S$: C, 61.91; H, 7.13. Found: C, 61.75; H, 7.06.

The *p*-toluenesulfonate was converted into the bromide with lithium bromide in acetone according to the method of Wiberg and Lowry (22). The bromide was used without further purification (98% purity by gas–liquid chromatography).

Degradation of Norcamphor Ethylene Ketal Reduction Product

(a) Grignard Method

The bromide (9.0 mmoles) in 100 ml of ether was added dropwise to a mixture of ether and magnesium turnings (9.0 mmoles). The reaction mixture was heated under reflux for 20 h. The mixture was cooled in an ice bath, and 30 ml of 2% ammonium chloride solution was added dropwise. The ether layer was removed and combined with the ether extracts of the aqueous phase. The dried ($MgSO_4$) ether solution was concentrated, whereupon the residue solidified. The residue was dissolved in a small quantity of chloroform and analyzed by gas–liquid chromatography, at a column temperature of 130° and a helium flow rate of 190 ml/min. The retention time of the product 2-*endo*-norborneol was 24.4 min. 2-*exo*-Norborneol had a retention time of 22.6 min under identical conditions. The only other product present in the reaction mixture was unreacted starting material, to the extent of 37%.

(b) n-Butyllithium Method

In a nitrogen atmosphere, 5 ml of a solution of 15% *n*-butyllithium in hexane was added dropwise to a stirred solution of 8.2 mmoles of the bromide in 50 ml of ether. The solution was stirred overnight, and 30 ml

For personal use only.

of ice water was added cautiously. The ether layer was separated and combined with the ether extracts of the aqueous phase. The dried ($MgSO_4$) ether solution was concentrated, whereupon the residue solidified. The residue was dissolved in a small quantity of chloroform and analyzed by gas–liquid chromatography as described above. The major product was 2-*endo*-norborneol. Unreacted starting material was present to the extent of 13%.

Hydrogenolysis of Camphor Ethylene Ketal

This was carried out with lithium aluminium hydride and aluminium chloride in ether according to the procedure of Leggetter and Brown (1). The product was obtained in 93% yield, b.p. 75–77° at 1.5 mm.

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18. Found: C, 73.20; H, 11.00.

The tosylate of the reduction product was prepared according to the method of Wiberg and Lowry (22) in 98% yield. This was converted into the bromide (yield 95%) according to published directions (22). The bromide was treated with *n*-butyllithium according to the procedure described above for the degradation of the norcamphor ethylene ketal reduction product. The reaction mixture was subjected to gas–liquid chromatographic analysis, at a column temperature of 150° and a helium flow rate of 90 ml/min. The retention time of isoborneol was 32.6 min, and of borneol 36.2 min. The product consisted of 78% isoborneol and 22% borneol. Unreacted starting material was present to the extent of 11%.

THE SYNTHESIS OF SOME IODOPHTHALAZINES AND PHTHALAZINECARBONITRILES

ARTHUR HIRSCH AND DEMETRIUS G. ORPHANOS
Canadian Technical Tape Ltd., Montreal, Quebec
Received February 21, 1966

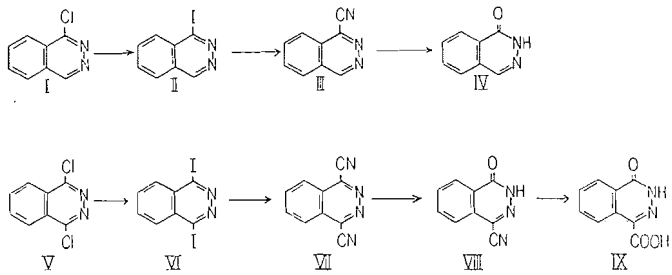
ABSTRACT

1-Iodo- and 1,4-diiodo-phthalazines were obtained by treating the corresponding chloro compounds with a solution of sodium (or potassium) iodide in acetone containing hydrogen iodide. These iodophthalazines, on reaction with copper cyanide in pyridine, gave the relevant phthalazinecarbonitriles.

INTRODUCTION

The preparation of 1,4-diiodophthalazine (VI) has not been described in the literature. It was reported that 1-iodophthalazine (II) can be obtained, in unspecified yield, from the corresponding chloro compound I by the action of boiling hydriodic acid, either alone or in the presence of red phosphorus. However, in our hands, these procedures gave unsatisfactory results.

Attempts to prepare the iodophthalazines II and VI by (*a*) treating the corresponding phthalazinones with phosphorus triiodide or (*b*) the action of sodium (or potassium) iodide on the relevant chloro compounds in acetone were not successful. However, halogen exchange occurred readily when a significant quantity of hydrogen iodide was present in the latter reaction mixture. Attempts to effect the same reaction by merely using a solution of hydrogen iodide in acetone proved to be fruitless.



A survey of the literature reveals no previous preparation of phthalazinecarbonitriles. Earlier attempts[1] to obtain these substances from the chloro- or bromo-phthalazines via the halogen–nitrile exchange method were unsuccessful.

It has now been possible to prepare 1-phthalazinecarbonitrile (III) and 1,4-phthalazinedicarbonitrile (VII) by heating the corresponding iodo compounds with copper cyanide in pyridine for a few minutes.

The infrared spectrum of III showed a very weak nitrile absorption at 2 240 cm^{-1}, whereas such an absorption was not present in the infrared spectrum of VII. It has been shown that this band is not always evident in the infrared spectra of a variety of nitrogen heterocyclic compounds (2, 3) or in aromatic nitriles with ortho and para electron-withdrawing groups (4).

Anomalous results were obtained on the attempted hydrolysis of the nitriles III and VII. When III was refluxed in 10% sodium hydroxide solution, ammonia was constantly evolved for 5 h. This observation suggested that normal hydrolysis of III to the corresponding 1-phthalazinecarboxylic acid was taking place. However, all attempts to isolate the suspected carboxylic acid were unsuccessful and no evidence for its presence could be found. In all cases, 1(2*H*)-phthalazinone (IV) and a viscous unidentifiable oily material were isolated. Since it was found that IV is quite stable under similar alkaline reaction conditions, it appears to be more likely that the 1-phthalazinecarboxylic acid decomposes as fast as it forms, thereby giving rise to oily products.

[1]*In those attempts a wide variation of solvents (pyridine, quinoline, all three picolines, dimethylformamide, dimethyl sulfoxide, and glycol) and cyanidation agents (potassium cyanide, sodium cyanide, silver cyanide, and copper cyanide) were used to no avail.*

On the other hand, alkaline treatment of the dicarbonitrile VII, at room temperature for 15 min, resulted in a quantitative yield of 4-cyano-1(2*H*)-phthalazinone (VIII). The resulting cyanophthalazinone, on further alkaline treatment, under heating, was quantitatively hydrolyzed to the corresponding 1(2*H*)-phthalazinone-4-carboxylic acid (IX), which had previously been prepared by a direct route (5–8). The cyanophthalazinone VIII, aside from its conversion into the known IX, was also confirmed by elemental analysis and its infrared spectrum (absorption at 2 240 cm^{-1}).

The enhanced susceptibility of a cyano group to displacement by nucleophiles has been described in many instances (9–11), and the conversion of III and VII into IV and VIII, respectively, should not be altogether unexpected.

The rapid displacement of the 1- (or 4-) cyano group in 1,4-phthalazinedicarbonitrile (VII) is explicable only by assuming that the intermediate in this nucleophilic aromatic substitution would derive stabilization from the electron-withdrawing benzene ring and the 4- (or 1-) cyano group, in addition to stabilization attributable to the azine group.

Carbonitriles III and VII, on treatment with concentrated sulfuric acid or 36% hydrochloric acid at 25° for 24 h, remained unaffected. Extensive decomposition of the starting material occurred after 2 h if temperatures of over 60 °C were applied.

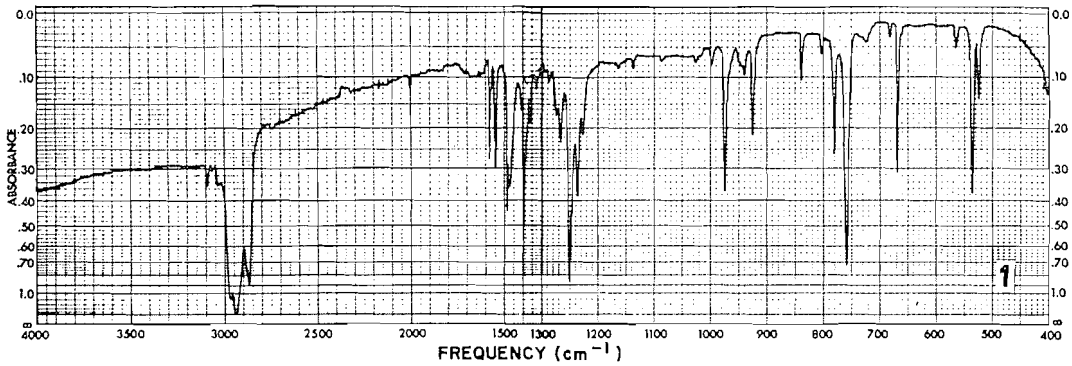
For identification purposes, the infrared spectra of II and VI are presented in Figs. 1 and 2, respectively.

EXPERIMENTAL

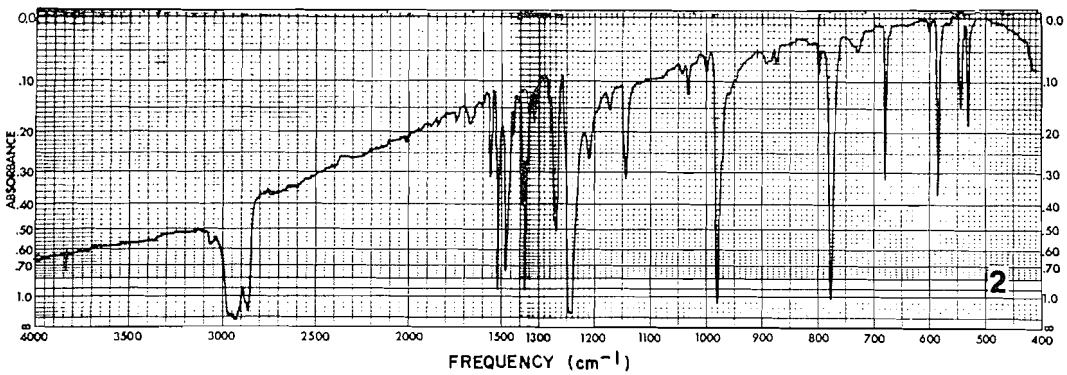
Melting points are uncorrected. Analyses were carried out by Dr. C. Daessle, Montreal, Quebec. Infrared absorption spectra were determined with a Perkin–Elmer model 337 spectrophotometer from Nujol mulls.

1,4-Dichlorophthalazine (V)

The procedure described previously by this laboratory was slightly modified (12). 2,3-Dihydro-1,4-phthalazinedione (16.2 g, 0.1 mole) and phosphorus pentachloride (85 g) were thoroughly mixed in an ordinary 6 fl. oz carbonated beverage bottle equipped with a magnetic stirring bar. The bottle was sealed with the appropriate metallic cap and placed in a cool oil bath. The temperature of the bath[2] was gradually brought up to about 180°. At this temperature the solid reaction mixture was slowly liquefied, and as soon as agitation became effective, the temperature of the oil bath was lowered to 140–150° and maintained there for 4 h. After the reaction bottle was cooled to room temperature,[3] it was refrigerated for a few hours and then carefully opened in a hood. The product was isolated as described in the original procedure (12). The yield and melting point were the same.



1-Iodophthalazine (II)



To a stirred mixture of potassium or sodium iodide (30 g), 1-chlorophthalazine (16.5 g) (13), and acetone (300 ml), a 50% aqueous solution of hydroiodic acid (20 ml) was added. The resulting yellow mixture was stirred at room temperature for 18 h. The canary-yellow precipitate was obtained by filtration, washed with diethyl ether, and dried *in vacuo*. This acidic product was apparently the hydroiodide salt. It was dissolved in ice-cold water (1 l), stirred for 15 min, and then neutralized carefully with dilute ammonium hydroxide. The faint-yellowish solid was collected, washed with cold water followed by petroleum ether,

[2]*The temperature of the oil bath should not be permitted to rise over 190° because of the explosion hazard. In any event, it should be recognized that any sealed glass vessel of this type constitutes a potential bomb and must be handled with extreme caution.*

[3]*The reaction bottle is removed from the oil bath when the latter has reached room temperature.*

FIGS. 1 and 2.

and dried *in vacuo*. It weighed 22.5 g (88%) and melted at 78° with decomposition (reported (1) m.p. 78°) 1-Iodophthalazine undergoes slow decomposition at room temperature to an amorphous yellow powder. This decomposition can be retarded by storing the substance in a freezer.

1,4-Diiodophthalazine (VI)

To a stirred mixture of potassium or sodium iodide (25 g), 1,4-dichlorophthalazine (9.95 g, 0.05 mole), and acetone (300 ml), a 50% aqueous solution of hydroiodic acid (20 ml) was added. The resulting yellow mixture was stirred at room temperature for 18 h. The canary-yellow solid was collected, washed with a little acetone followed by diethyl ether, and dried *in vacuo*. This acidic product was apparently the hydroiodide salt. It was dissolved in distilled water (2 l) and stirred until the initial yellow color of the solid had been discharged (about 1 h). The white solid was collected, washed with distilled water until the washing was no longer acidic, and dried *in vacuo*.

It melted at 156–157° with decomposition and was pure enough to be used for the next step, yield 14.5 g (76%). 1,4-Diiodophthalazine was crystallized from methylene chloride as hard white prisms melting at 161° with decomposition.

Anal. Calcd. for $C_8H_4I_2N_2$: C, 25.16; H, 1.05; N, 7.33; I, 66.45. Found: C, 25.35; H, 0.98; N, 7.53; I, 66.61.

1-Phthalazinecarbonitrile (III)

1-Iodophthalazine (12.8 g, 0.05 mole) was thoroughly mixed with copper cyanide (4.48 g, 0.05 mole). To this mixture was added dry pyridine (75 ml), and the resulting greenish suspension was placed in a preheated (110–120°) oil bath and kept there for 10 min under vigorous stirring. The black-colored reaction mixture was poured into chilled water (500 ml) and stirred for a few minutes.

Diethyl ether (500 ml) and some ice were added to lower the temperature to about 5–10°. To this chilled mixture, with vigorous stirring, dilute hydrochloric acid was added slowly until a pH of 2 was attained. Stirring was continued for an additional 20 min. (The aqueous layer must be maintained at all times at a pH of 2.)

The clear yellowish ether layer was separated and the aqueous layer extracted twice with 300 ml of diethyl ether each. The combined ether extracts were washed with water until neutral, dried over $MgSO_4$, shaken

For personal use only.

with charcoal, and filtered. The colorless filtrate, upon removal of the solvent under reduced pressure, left a white crystalline product melting at 148–149° and weighing 1.35 g (17.3%).

1-Phthalazinecarbonitrile was recrystallized from diethyl ether as fine white needles melting at 156–157°. The infrared spectrum showed a very weak, but sharp absorption at 2 240 cm^{-1} (C≡N).

Anal. Calcd. for $C_9H_5N_3$: C, 69.67; H, 3.25; N, 27.08. Found: C, 69.94; H, 3.43; N, 27.03.

1,4-Phthalazinedicarbonitrile (VII)

This substance was prepared by a procedure similar to that applied above for the preparation of 1-phthalazinecarbonitrile. Thus, from the reaction of 1,4-diiodophthalazine (19.1 g, 0.05 mole) and copper cyanide (9 g, 0.1 mole) in pyridine (80 ml) was obtained 3.2 g of 1,4-phthalazinedicarbonitrile. It melted at 201–204°, and recrystallization from diethyl ether gave yellowish shiny crystals melting at 204–205°. The infrared spectrum showed no evidence of the C≡N stretching frequency.

Anal. Calcd. for $C_{10}H_4N_4$: C, 66.66; H, 2.23; N, 31.10. Found: C, 66.87; H, 2.32; N, 31.39.

4-Cyano-1(2H)-phthalazinone (VIII)

To a solution of 1,4-phthalazinedicarbonitrile (1.8 g) in dioxane (5 ml), 10 ml of a 20% sodium hydroxide solution was added. The resulting orange-colored solution was stirred for 15 min at room temperature. The yellow suspension was dissolved in 80 ml of water. The clear yellow solution was extracted with diethyl ether to remove ether-soluble impurities. The alkaline layer was weakly acidified with dilute hydrochloric acid. The yellowish precipitate was collected on filter paper, washed with water, and dried. It melted at 269–270° and weighed 1.49 g. This material was dissolved in tetrahydrofuran, shaken with charcoal, and filtered. Removal of the solvent under reduced pressure left a white solid melting at 270°. The infrared spectrum showed characteristic bands at 3 175, 3 100, 2 240, 1 715, and 1 645 cm^{-1}.

Anal. Calcd. for $C_9H_5N_3O$: C, 63.16; H, 2.95; N, 24.55. Found: C, 63.46; H, 3.21; N, 24.46.

1(2H)-Phthalazinone-4-carboxylic Acid (IX) from 4-Cyano-1(2H)-phthalazinone (VIII)

A mixture of 4-cyano-1(2*H*)-phthalazinone (0.5 g), 4% sodium hydroxide solution (8 ml), and methanol (25 ml) was refluxed until evolution of ammonia ceased (tested with wet red litmus paper) (about 7 days). The yellowish solution was filtered and the filtrate concentrated to about 10 ml under reduced pressure. The remaining alkaline solution was cautiously acidified with dilute hydrochloric acid, and the precipitated white solid was collected, washed with diethyl ether, and dried. It melted at 234° with foaming, and weighed 0.51 g. 1(2*H*)-Phthalazinone-4-carboxylic acid was recrystallized from a mixture of methanol and dioxane (3:1) as hard white crystals melting at 236° with foaming (reported (5) m.p. 232°).

Alternatively, the substance can be prepared directly from 1,4-phthalazinedicarbonitrile under conditions identical with those described above. The time for the hydrolysis can be reduced to a few hours if a more concentrated sodium hydroxide solution is used and no methanol is present. In the latter case, the yield of pure product is much lower and its purification is achieved with difficulty. The infrared spectrum displayed characteristic absorptions at 3 250, 3 170, 1 680, and 1 640 cm^{-1}.

Anal. Calcd. for $C_9H_6O_3N_2$: C, 56.84; H, 3.18; N, 14.73. Found: C, 56.92; H, 3.01; N, 14.76.

1(2H)-Phthalazinone (IV) from 1-Phthalazinecarbonitrile (III)

1-Phthalazinecarbonitrile (0.2 g) in 10% sodium hydroxide solution (25 ml) was refluxed for 5 h. During this time ammonia was constantly evolved. The alkaline reaction solution was weakly acidified with dilute hydrochloric acid and then extracted with methylene chloride. The extract was dried over $MgSO_4$, decolorized with charcoal, and filtered. The colorless filtrate, upon removal of the solvent, left a semisolid material which, on trituration with a few milliliters of diethyl ether, separated out as a white crystalline material melting at 184–185°, yield 0.052 g. Its infrared spectrum was identical with that displayed by an authentic sample of 1(2*H*)-phthalazinone, and a mixed melting point with the latter compound showed no depression.

ACKNOWLEDGMENT

THE PHOTOINITIATED HALOGENATION REACTIONS OF N-BROMOACETANILIDE AND N-BROMO-2,4,6-TRICHLOROACETANILIDE[1]

DENNIS D. TANNER AND EUGENE PROTZ
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received June 30, 1965

ABSTRACT

The photoinduced rearrangement reaction of N-bromoacetanilide to *p*-bromoacetanilide in carbon tetrachloride was found to have a quantum efficiency approaching unity, and evidence is presented to indicate a chain component to the reaction process whose product-determining species is either the mesomeric acetanilide radical or the bromine atom. It was demonstrated that small variations in the solvent composition affected the product ratio of *p*- to *o*-bromoacetanilide. The reaction of N-bromoacetanilide in carbon tetrachloride with added toluene was found to be a long-chain process producing *p*-bromoacetanilide as well as acetanilide and benzyl bromide. The bromination of toluene by N-bromo-2,4,6-trichloroacetanilide was shown to proceed by a chain mechanism involving the bromine radical as the chain-propagating species, and this mechanism is used as a model to explain the reaction of N-bromoacetanilide in dilute carbon tetrachloride solutions of toluene.

INTRODUCTION

Because of the current interest in hydrogen abstraction reactions of divalent nitrogen (1–3), an investigation of the photoinitiated reactions of N-bromoacetanilide and N-bromo-2,4,6-trichloroacetanilide has been undertaken.

The ionic counterpart of the photoinitiated rearrangement of N-haloacetanilide to *p*-haloacetanilide, the Orton rearrangement, has been studied extensively by numerous groups of workers[2] (5–7), and has long been established to proceed, both in protic and aprotic solvents, by an acid-catalyzed intermolecular mechanism.

The photoinitiated rearrangement of N-chloroacetanilide has been studied by Blanksma (8), Mathews and Williamson (9), Chattaway and Orton (10), and Hodges (11). These workers have established that in aprotic solvents the reaction is accelerated by light, and that in the solvents cyclohexane, toluene, and decalin the main product of the reaction is not *p*-chloroacetanilide, but acetanilide itself. In the reactions which produced acetanilide, it was assumed that the higher boiling liquid fractions from the reaction mixtures were chlorinated solvents. Hodges has shown the rearrangement of N-chloroacetanilide to have a quantum efficiency of 5 in carbon tetrachloride, and that, in that solvent, traces of diacetylhydrazobenzene could be isolated.

The presence of nitrogen radical coupling products in the photolysis of N-chloroacetanilide suggested to us the possibility of nitrogen radical abstraction in the reaction of N-haloacetanilide with solvent.

To provide an adequate mechanistic explanation for the above results, and because of our interest (1) in hydrogen abstraction reactions, the present study was undertaken.

DISCUSSION AND RESULTS

We have found that carbon tetrachloride solutions of N-bromoacetanilide at 80° undergo a light-catalyzed reaction to produce as the major product *p*-bromoacetanilide. The solutions remain unchanged under these conditions in the absence of light for well over three half-lives of the light-catalyzed reaction.

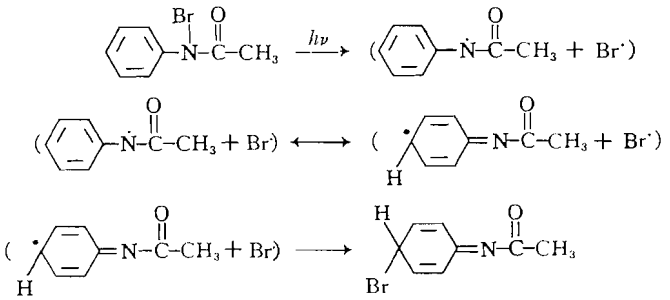
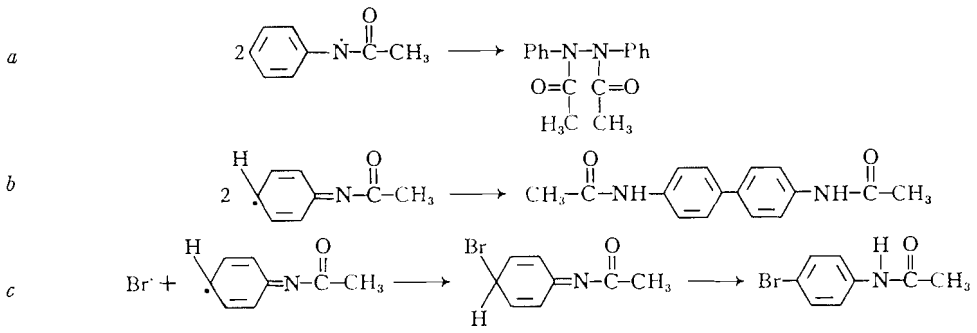
Three distinct light-catalyzed, free-radical mechanisms seem to be plausible for the N to C rearrangement of N-bromoacetanilide.

Mechanisms 1 and 2 are chain reactions for which the chain-propagation steps are shown. Mechanism 1 is a unique 1,5-displacement of a bromine atom by a bromine radical, whereas in mechanism 2 the chain-propagating species is the mesomeric carbon–nitrogen radical. Mechanism 3 depicts a reaction path which proceeds by a non-chain process to yield products by geminate cage recombination.

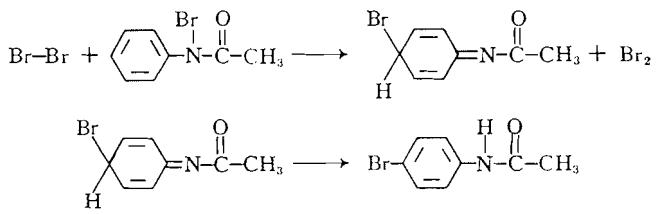


1.

2.



3.



Trace initiation experiments with benzoyl peroxide and azobisisobutyronitrile, and inhibition experiments with oxygen, gave inconclusive results about the chain or non-chain nature of the radical reaction, but the failure of these experiments established that the rearrangement reaction was not a long-chain process. Investigation of the quantum efficiencies for the disappearance of N-bromoacetanilide showed ($\Phi = 1.1 \pm 0.2$) the reaction to be a very short chain process indeed. The photolysis has a chain length which approaches unity, indicating a chain component to the mechanism since cage reactions of such high quantum efficiency are not very probable (12).

The products of the photoinduced decomposition of N-bromoacetanilide in carbon tetrachloride were *p*-bromoacetanilide, 78%; *o*-bromoacetanilide, 7%; acetanilide, ~5%; N,N′-diacetyl-4,4′-diaminobiphenyl, 3%; possibly diacetylhydrazobenzene; and traces of products resulting from dibromination. Since the chain length is so short, the formation of coupling products (reactions *a–c*) is feasible for all three of the proposed pathways, and could arise from the fate of the initiation products in mechanisms 1 and 2 or by escape from the solvent cage with subsequent recombination as in mechanism 3.

Further evidence against cage recombination was obtained from the observation that small amounts of added toluene (5–15%) can change the mechanism to a relatively longer chain process which is capable of trace initiation by benzoyl peroxide and in which the ortho to para ratio of bromoacetanilides is different from that when the reaction is run in 100% carbon tetrachloride. That the rearrangement is also involved in this chain reaction is evident from the observation that less than 9 mole % (per mole of N-bromoacetanilide) of the toluene reacted, and that the major product (>70%) was *p*-bromoacetanilide. Such marked effects are not likely to be observed if the reaction proceeded primarily by cage recombination.

The possibility existed that after preliminary initiation a subsequent ionic reaction took place as shown below, which would be indistinguishable from a free-radical chain.

When the photoinitiated reaction, both with and without added toluene, was stopped after approximately 15% completion by placing the reaction in the dark, the titer for the active bromine was found to remain constant for more than three half-lives of the rearrangement reaction. It therefore seems unlikely that, under our conditions, ionic reactions could determine a significant part of the reaction course.

We have shown bromine to be the chain-carrying species in the reaction of N-bromo-2,4,6-trichloroacetanilide (I) with toluene (see the next section). If this chain process is a suitable model for the reaction of N-bromoacetanilide with solvent, then the rearrangement of N-bromoacetanilide with added toluene, a process capable of trace initiation, can be assumed to be a rearrangement carried out in the presence of a low steady-state concentration of bromine. When the photorearrangement was carried out in a mixture of 15% toluene in carbon tetrachloride, the ortho to para ratio of bromoacetanilides decreased by 11% in comparison with the ortho to para ratio for the rearrangement carried out in pure carbon tetrachloride. In the reaction with added toluene, the product mixture contained, in addition to the normal products (>70% *p*-bromoacetanilide), acetanilide and benzyl bromide. An accompanying decrease in the amount of toluene that was originally added was observed (5–8 mole % per mole of N-bromoacetanilide). A change in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

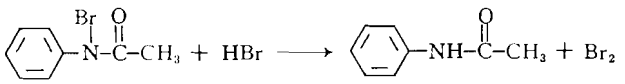
ortho to para ratio when the reaction is run under conditions where a steady-state concentration of bromine is present, i.e. with added toluene, can be interpreted as being due to a change in the mechanism for the formation of ortho- and para-brominated acetanilide.[1] Since bromine or acetanilide radicals are the product-determining species in the rearrangement, and the ortho to para ratio is concentration independent, a change in this ratio is equivalent to a change in the product-determining species. An alternative explanation for the change in the product ratio entails the formation of solvated radicals whose positional selectivity differs from the uncomplexed species. An investigation of the medium effects during the rearrangement reaction clearly substantiates this latter explanation. Photolysis of N-bromoacetanilide in carbon tetrachloride solutions containing chemically unreactive aromatic substrates had marked effects on the product ratio of *o*- to *p*-bromoacetanilide (Table I). The decrease in the amount of *o*-bromoacetanilide compared with the para-brominated isomer is consistent with complex formation between radicals and aromatic solvents (13–15). Steric considerations would predict a decrease in the ortho to para ratio by a bulkier, complexed, product-determining radical whether it were the acetanilide or the bromine radical. Although the structure of this complex cannot be defined, it is, at least in the case of the nitrobenzene–radical complex, most likely to involve the acetanilide radical, since complex formation between nitrobenzene and bromine radicals would not be favored (15).

TABLE I

Solvent effects on the product ratio of *o*- to *p*-bromoacetanilide

Solvent	% difference in ortho to para ratio‡	Number of experiments
100% CCl_4	0.0	4 to 12*
15% benzene in CCl_4	5±2	4
5% nitrobenzene in CCl_4	7±5	3
15% toluene in CCl_4	11±4	12
15% chlorobenzene in CCl_4	13±3	4
10% nitrobenzene in CCl_4	18±8	3
15% nitrobenzene in CCl_4	42±5 (43±5)†	6

*Standard experiments were run with each batch of N-bromoacetanilide used, because the purity of the reagent varied from 94 to 100%.
†Batches of differing purity gave different absolute numbers but the same percentage differences.
‡Experimental errors refer to standard deviations from average values.



The reaction with added toluene was found to be initiated by trace amounts of azobisisobutyronitrile or benzoyl peroxide as well as by light. Trace initiation indicated the involvement of a long-chain process. The propagation reactions most readily envisaged for the reaction with solvent are those involving bromine atom abstraction, 4, or hydrogen abstraction by the mesomeric acetanilide radical, 5.

To differentiate between mechanisms 4 and 5, measurements of the relative reactivities towards hydrogen abstraction from a number of meta- and para-substituted toluenes were attempted. Recently, relative reactivity data for bromine atom abstraction from substituted toluenes has become available where both bromine and N-bromosuccinimide were the sources of bromine atoms (16, 17, 19), and a comparison with values for the abstraction reaction of N-bromoacetanilide with these substrates was undertaken. Under the desired reaction conditions, 0.3 *M* in toluene and 0.2 *M* in brominating agent, it was found that less than 10% of the reaction proceeded by hydrogen abstraction from toluene. To eliminate the rearrangement process and maximize the amount of abstraction taking

4. $Br\cdot + RH \longrightarrow HBr + R\cdot$

$$R\cdot + Br_2 \longrightarrow RBr + Br\cdot$$

5. or

place, N-bromo-2,4,6-trichloroacetanilide (I) was used in place of N-bromoacetanilide. N-Bromo-2,4,6-trichloroacetanilide has the advantage that the ortho and para positions are blocked from rearrangement, and the abstraction reaction proceeds to completion.

The products for the photoinitiated decomposition of 0.275–0.300 *M* N-bromo-2,4,6-trichloroacetanilide in a 0.15–0.3 *M* solution of toluene in carbon tetrachloride were found to be benzyl bromide and 2,4,6-trichloroacetanilide. No indication of ring bromination products of toluene was detectable by vapor-phase chromatography.

N-Bromo-2,4,6-trichloroacetanilide was found to be stable under the reaction conditions (80° in a solution of carbon tetrachloride and toluene), and its reaction with toluene could be initiated by trace amounts of azobisisobutyronitrile or benzoyl peroxide. Photoinitiation gave reactions which were identical with those using trace initiation, and the former was therefore the method of choice.

Relative rates for hydrogen abstraction by N-bromo-2,4,6-trichloroacetanilide between toluene and substituted toluenes coincided very closely with the reactivity data present in the literature for bromine atom extraction (Table II).

A plot of the logarithm of the relative reactivities vs. σ^+ values[3] (Hammett correlation $\log k/k_0 = \rho\sigma$) shows $\rho = -1.52$ (correlation coefficient $r = 0.970$), which is in good

TABLE II

Relative reactivities (per H) of substituted toluenes toward radical abstraction at 80° in CCl_4*

	Source of radicals

m-Br	0.224 (17)	0.24 (16)	0.229±0.09 (3)
m-CN		0.11 (16)	0.062±0.007 (3)

*Our results, unless indicated by reference numbers (columns 2 and 3); numbers in parentheses in column 4 show the number of independent experiments. Experimental errors are average deviations from the mean.

[3]*The σ^+ values were taken from ref. 18.*

agreement with the values $\rho = -1.38$ (16) and $\rho = -1.46$ and -1.36 (17) previously reported in the literature for bromine atom abstraction (Fig. 1).

The excellent correlation between the relative reactivity data for N-bromo-2,4,6-trichloroacetanilide and the reactivity data in the literature indicates that the reaction of I with solvent proceeds by way of the bromine atom chain, which has been established for other N-halogenating reagents (16, 17, 19) (mechanism 4).

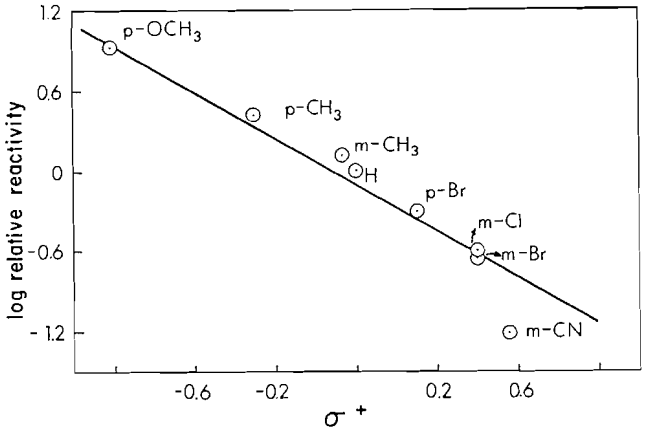

FIG. 1. Hammett $\rho\sigma$ correlation for N-bromo-2,4,6-trichloroacetanilide bromination of substituted toluenes (σ^+ = correlation, $\rho = -1.52$, and $r = 0.970$).

EXPERIMENTAL

Materials

The carbon tetrachloride used was residue-free, spectral grade Eastman reagent and its purity was checked by gas–liquid chromatography (g.l.c.) before use. Substituted toluenes were commercial materials. Before use they were distilled, the physical constants were determined, and their purity was checked by g.l.c. N-Bromoacetanilide was prepared by the method of Slosson (20) and could be obtained in 70.0–99% purity. The purity of the material was checked by iodometric titration (21). Different batches gave identical results, regardless of purity, for quantum efficiency, stability in solution, and reactivity. The product studies were carried out on material which was 99.0% pure as determined by titration. N-Bromo-2,4,6-trichloroacetanilide was prepared as pale-yellow crystals in 99.7–100% purity, as determined by iodometric titration, by using the method of Israel *et al.* (22) for the synthesis of N,2,4,6-tetrabromoacetanilide. After reaction of N-bromo-2,4,6-trichloroacetanilide in solution with added toluene, 2,4,6-trichloroacetanilide could be isolated from the reaction mixture in good yield. Different batches gave identical results for stability and relative reactivities.

Reactions of N-Bromoacetanilide and N-Bromo-2,4,6-trichloroacetanilide

The reactions were run in Pyrex cells or ampuls which had been degassed by the freeze–thaw method. Initiation experiments were carried out in the absence of light with 1–2% solutions of benzoyl peroxide or azobisisobutyronitrile. Inhibition experiments with oxygen were run in ampuls which contained atmospheric concentrations of oxygen. When irradiation was used to initiate the reaction, the light source was a Hanovia medium-pressure mercury arc (model No. 30620). All reactions of N-bromoacetanilide and N-bromo-2,4,6-trichloroacetanilide were run at 80.0 ± 0.1°, except for quantum efficiency experiments which were run at 28 ± 2°. All light-catalyzed reactions were determined by titration to be stable in the dark for over three half-lives of the light-catalyzed reactions. The average time required for the light-catalyzed reactions was approximately 4 h for the reaction of N-bromoacetanilide in carbon tetrachloride, and approximately 1 h for the reactions of N-bromoacetanilide in carbon tetrachloride with 5–15% added toluene. The photoinitiated reactions of N-bromo-2,4,6-trichloroacetanilide were irradiated for approximately 3 h for completion of the reaction.

Quantum Efficiency Measurements

Quantum yields were measured by uranyl oxalate actinometry according to the method of Forbes and Leighton (23). The apparatus and procedures used were essentially those described by Masson *et al.* (24). A Hanovia, model 30620, medium-pressure mercury arc was used as the light source. The filter used was an Eastman Kodak, No. 2B, Wratten gelatin filter, which transmits wavelengths longer than 4 000 Å. Because

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the wavelength of light used (>4 000 Å), a 20 cm actinometer cell was employed to measure the intensity of the light source. The actinometer cell was then replaced by a 1P28 photomultiplier tube whose output could be read directly from a 1 mV Sargent recorder. The filter employed was selected to alleviate the necessity to correct for the absorption of traces of products absorbing at longer wavelengths (trace absorbance was seen up to 3 700 Å). The quantum yield value used for uranyl oxylate at these wavelengths was 0.57 (23). The terminal absorbance of N-bromoacetanilide in the region 4 000 to 4 400 Å was sufficient, under our conditions, for the photolysis to proceed at a convenient rate to be measured.

Three independent determinations showed $\Phi = 1.1$, with a standard deviation of 0.2.

Expt.	% conversion	Φ
1	38	1.5

3	14	0.81

Reaction Products of N-Bromoacetanilide Photolysis

Sealed, degassed Pyrex ampuls of carbon tetrachloride, 0.324 *M* in N-bromoacetanilide (99.0% pure by titration), were placed in a thermostated water bath at 80.0° in the absence of light until they reached the bath temperature. The ampuls were then exposed to the irradiation of a Hanovia medium-pressure mercury arc for 4½ h. The pale-yellow solution turned amber and then a light brown on completion of the reaction. The amber color was shown not to be molecular bromine, since an amber-colored ampul could be shown not to contain a titratable amount of bromine. Attempts to identify the colored intermediate were unsuccessful.

After irradiation the ampuls were opened and the solvent was removed, leaving a light-brown residue. The products from the reaction were characterized and quantitatively determined in the following manner.

Diacetylhydrazobenzene

Mass spectral analysis of the product mixture showed a parent peak at *m/e* of 268 mass units. Under the operating conditions (220°), no introduction of a standard sample of N,N′-diacetyl-4,4′-diaminobiphenyl could be obtained (i.e. no ions observed), whereas an authentic sample of diacetylhydrazobenzene was easily introduced and showed a parent peak of 268 mass units. The cracking pattern of the reaction mixture was consistent with that of authentic diacetylhydrazobenzene. Retention times by thin-layer chromatography were consistent with the presence of diacetylhydrazobenzene, but attempts to isolate the compound from the reaction mixture were unsuccessful.

p-Bromoacetanilide

The major product, *p*-bromoacetanilide, was identified by its g.l.c. and thin-layer chromatography retention times. It was isolated by fractional recrystallization of the product mixture from ethanol, and its melting point and mixture melting point were identical with that of *p*-bromoacetanilide.

o-Bromoacetanilide

The retention times from thin-layer chromatography and g.l.c. indicated the presence of *o*-bromoacetanilide. Preparative thin-layer chromatographic separation of the reaction mixture, with 1.25 mm silica gel GF treated plates and a solvent system of ether – chloroform – ethyl acetate (1:1:0.8), allowed the isolation of pure *o*-bromoacetanilide after extraction from the silica gel with acetone. The melting point and mixed melting point showed the compound to be *o*-bromoacetanilide.

N,N′-Diacetyl-4,4′-diaminobiphenyl

Preparative thin-layer chromatography of 225 mg of the reaction mixture isolated 11 mg (5%) of N,N′-diacetyl-4,4′-diaminobiphenyl. The melting point (345°) was in agreement with the literature value (25), and the mixture melting point with an authentic sample showed no depression.

Products of Dibromination

Traces of products of dibromination could easily be detected in the mass spectrum of the reaction mixture. The characteristic isotopic ratios for bromine indicated a dibrominated anilinium ion (*m/e* 252, 250, and 248 mass units).

Acetanilide

Thin-layer and g.l.c. retention times indicated the presence of acetanilide. The yield (5.0%) of acetanilide was determined by adding to a weighed amount of the reaction mixture a weighed amount of an internal standard, octadecane. Analysis of the mixture by g.l.c. allowed a determination of the area ratios. The mole ratios were then calculated from a standard calibration curve, which had been determined by analysis of mixtures of known concentration analyzed under the identical conditions.

Ratio Measurements of o- and p-Bromoacetanilide

The ratio of *o*- to *p*-bromoacetanilide was determined quantitatively by g.l.c. analysis of a mixture of a weighed amount of the reaction mixture and weighed quantities of octadecane. The mole ratios were calculated from standard calibration curves. Twenty-four independent experiments were carried out: 12 reactions with 0.234 *M* N-bromoacetanilide in carbon tetrachloride and 12 reactions with 15% added toluene. The volatile components of the reaction mixture were removed and the residue dried. The analysis was carried out on acetone solutions of the dried residue. Triple analyses were carried out on each reaction mixture. The differences between the reaction mixtures, with and without added toluene, were consistent and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

showed a decrease in the ortho to para ratio of 11.0 ± 4.5%. The usual formula for propagation of errors was employed (26). The ratio measurements of *o*- to *p*-bromoacetanilide with other aromatic substrates were done in a similar manner, and the results are tabulated in Table II.

Competitive Brominations

Individual experiments consisted of weighing N-bromo-2,4,6-trichloroacetanilide into small Pyrex ampuls, adding aliquots of standard carbon tetrachloride solutions of substrates and internal standard, vacuum degassing the tubes, and sealing them. A typical reaction mixture was 0.23 *M* in brominating agent, 0.19 *M* in toluene, 0.24 *M* in the desired para- or meta-substituted toluene, and 0.10 *M* in Freon 113 or 0.23 *M* in chlorobenzene. Reactions were placed in a thermostat at 80° in the absence of light, and after temperature equilibration they were exposed to the irradiation of a Hanovia medium-pressure mercury arc. The reactions were usually complete within 1½ h. The tubes were cooled, opened, and subjected to g.l.c. analysis on the Aerograph, model 202, linear-temperature programmer with either a 10 ft silicone SF-96 on firebrick column or a 10 ft column packed with diethylene glycol succinate on firebrick. Gas–liquid chromatographic analyses were carried out in triplicate, comparing peak areas before and after reaction with that of the internal standard as in previously reported work (16, 27, 28).

Calculation of Relative Reactivities

Relative reactivities were calculated via the method described by Walling *et al.* (16), either directly or, where substrate reactivity differed greatly, by successive comparison of suitable pairs. Indirect comparisons were used for the *p*-methoxytoluene value (*p*-methoxytoluene–*p*-xylene = 3.21 ± 0.04 (3)) and for the *m*-cyanotoluene value (*m*-cyanotoluene–*m*-bromotoluene = 0.269 ± 0.02 (4)). Experimental errors are average deviations from the mean, and when successive comparisons were required to give the results in Table I, the usual statistical procedure for the propagation of errors was employed (26). Disappearance of substrate by paths other than hydrogen abstraction, i.e. nuclear bromination, were ruled out, because an examination of g.l.c. traces failed to show detectable amounts of these products.

THE REACTION OF *n*-BUTYLAMINE AND BENZYLAMINE WITH SOME β-NITROSTYRENES, DIETHYL BENZALMALONATES, AND CINNAMALMALONONITRILES[1,2]

C. E. Lough and D. J. Currie

Chemistry Section, Defence Research Board, Suffield Experimental Station, Ralston, Alberta

Received September 8, 1965

ABSTRACT

The relative rates of reaction of *n*-butylamine with 27 β-nitrostyrenes, 36 β-nitropropenylbenzenes, 20 β-nitrobutenylbenzenes and 7 related compounds, 11 diethyl benzalmalonates, and 4 cinnamalmalononitriles were measured in dioxane solution at 25 °C. In addition, the slower rates of reaction of benzylamine with 15 of these compounds were measured under identical conditions. The pseudo first order rate constants, $k_{overall}$, for all the reactions were adequately represented by the expression

$$k_{overall} = [RNH_2]^2/(A[RNH_2] + B),$$

where A and B are constants which, in general, could be correlated with Hammett sigma constants. A nitro group substituted in the ortho position or chlorines substituted in both ortho positions gave anomalous rate constants in some series but not in others. A mechanism is proposed for the amine additions.

INTRODUCTION

There are many factors which are of importance in determining the reactivity of amines with α,β-unsaturated systems. The qualitative effects of the nucleophilicity of the amine, of the steric factors associated with the amine, and of substituents on the phenyl ring and β-carbon atom of β-nitrostyrenes upon the product yields of amine–β-nitrostyrene reactions have previously been discussed.[3] For example, *o*-chloro-β-nitrostyrene will react with *p*-phenylenediamine but not with aniline, *m*-toluidine, or *p*-toluidine (1*a*). Moreover, the product yields from the addition of aromatic amines to 3-nitro-6-iodo-β-nitrostyrene appear to decrease in the order phenylhydrazine > *p*-toluidine > *m*-anisidine > *m*-toluidine > aniline > *o*-anisidine > *o*-toluidine (1*b*); therefore, in the absence of steric factors (which are operative with *o*-anisidine and *o*-toluidine), the more basic the amine, the more likely the reaction. The effects of substitution on the phenyl ring of β-bromo-β-nitrostyrenes and β-nitrostyrenes upon the product yields for a given amine reaction are such that a general correlation of the rate of reaction with Hammett sigma constants is indicated; electron-donating substituents oppose reaction and electron-withdrawing substituents favor reaction (1*a*–1*k*). Since a β-methyl group inhibits reaction whereas a β-bromine enhances reaction, the inductive effect of a substituent on the β-carbon of β-nitrostyrene is also important.

When water was a component of the solvent system, the aromatic amine adducts hydrolyzed and some polymer formation was noted. In anhydrous solvents, polymerization was unimportant and the adducts were relatively stable (1*j*). When allowed to stand, however, many of the colorless adducts became colored.

Proof of the mode of addition of aniline to β-nitrostyrene has been presented;[3] the same nitroamine is obtained from this reaction (1*j*) as is obtained from the reaction of

[1]*Issued as Suffield Technical Paper No. 320, D.R.B. project No. D52-20-20-28.*

[2]*This paper was presented in part at the 16th Defence Research Board Symposium, Ottawa, Canada, December 2–4, 1964.*

[3]*H. L. Holmes, unpublished work in this laboratory based on the research listed in ref. 1.*

benzylidene aniline and nitromethane (2). Addition products have been isolated from the reaction of benzylamine with β-nitropropenylbenzene (3), and by analogy with the above reaction it would be expected that aliphatic amines would add 1,4; nevertheless, this has not been established.

Southwick and Anderson (3) have shown that, when equimolar quantities of morpholine and β-nitropropenylbenzene react in anhydrous benzene – petroleum ether solution, two diastereomeric adducts are obtained. The unstable racemic erythro adduct is formed first, followed by the stable racemic threo adduct. The primary erythro form is probably converted into the stable threo form through the anion of the *aci*-nitro form in the presence of excess amine, or through the *aci*-form itself in ethanolic solution. When 2 mole equivalents of the stronger base pyrrolidine was used in the reaction in anhydrous ether, the pyrrolidinium salt of the *aci*-nitro form was isolated. These workers account for the primary formation of the unstable erythro adduct by steric factors favoring the approach of a proton donor on the side of the hydrogen-bonded, six-membered ring remote from the phenyl group. The present work has demonstrated that the transition state for the reactions of primary amines in anhydrous dioxane solutions involves one molecule of the unsaturated compound and two molecules of the amine. The second molecule of the amine may either form a salt as in the case of pyrrolidine, or be the hydrogen transfer agent in the conversion of the *aci*-nitro form into the nitro form. Steric factors governing the position of the second molecule of the amine for hydrogen transfer would favor the primary formation of the erythro racemate. This amine could then catalyze the conversion of this primary adduct into the stable racemate having the threo configuration.

Addition products indicating 1,4 addition have been isolated from the reaction of aromatic amines with diethyl benzalmalonate (4, 5), and 1,4 adducts are expected with *n*-butylamine. The products from the cinnamalmalononitrile reactions are assumed to arise by a 1,4 addition, although the possibility of 1,6 addition cannot be excluded.

EXPERIMENTAL

The preparation and purity of the unsaturated compounds will be described elsewhere. Fisher certified reagent dioxane was purified by the method of Fieser (6), and *n*-butylamine and benzylamine were purified by distillation from sodium hydroxide.

The experimental technique was essentially the same as that of Platford *et al.* (7). Dioxane solutions of the compound and the amine were mixed, and the solution, initially 5×10^{-4} to 5×10^{-3} *M* in the compound and 10^{-3} to 2 *M* in the amine, was transferred to a quartz absorption cell. The reaction of the unsaturated compound with *n*-butylamine or benzylamine destroys the long-wavelength ultraviolet absorption maximum and provides a method for following the reaction rate. The early runs were performed on a Beckman DU spectrophotometer equipped with a Spectracord recording attachment, and later runs were performed on a Cary model 15 spectrophotometer. When the Spectracord was used, successive spectra were recorded at appropriate time intervals; when the Cary instrument was used, the changes in optical density were recorded continuously as a function of time. The slower reactions were carried out in glass-stoppered flasks in a constant-temperature bath and aliquots taken to record the spectral data. The cell holder or compartment and bath were thermostatted at 25 ± 1 °C.

RESULTS

A plot of the logarithm of the change in the optical density at the long-wavelength absorption maximum of β-nitrostyrene (βNS) versus time during the reaction with excess *n*-butylamine (RNH_2) in dioxane showed that, although the rate of disappearance of β-nitrostyrene was first order with respect to β-nitrostyrene for a large portion of the reaction, the reaction did not go to completion but attained equilibrium, the position of which was dependent on the initial amine concentration. Unreacted β-nitrostyrene appeared to be the only absorbing species at equilibrium. The pseudo first order rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

constants, $k_{overall}$, that were calculated for the initial portion of the reaction are defined by the expression

$$-d[\beta NS]/dt = k_{overall}[\beta NS] = k[RNH_2]^x[\beta NS].$$

A plot of log $k_{overall}$ versus log $[RNH_2]$ can be used to determine the amine exponent x. For the reactions of β-nitrostyrene and substituted β-nitrostyrenes, the best straight line through the experimental points yielded non-integral values of x between 1.0 and 2.0. Moreover, these log-log plots were not strictly linear, and it soon became obvious that the apparent amine exponent was decreasing with increasing amine concentrations. This, and the desire to normalize the data, prompted the fitting of the results to the expression

$$k_{overall} = [RNH_2]^2/(A[RNH_2] + B),$$

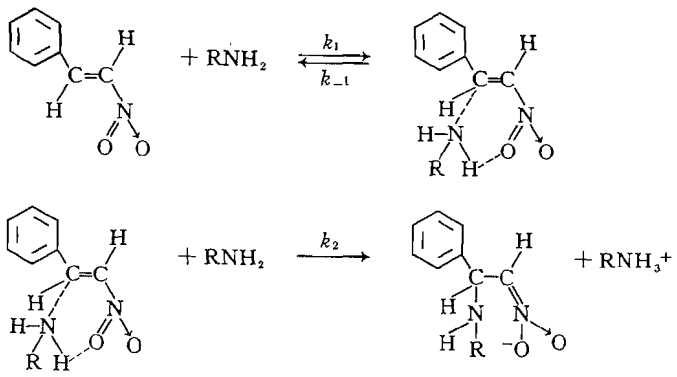
where A and B are constants. The units of $k_{overall}$ are second^{-1} when A is in molar seconds and B is in molar^2 seconds. The values of A and B given in Table I and thus defined adequately represent the rate data for the reactions of *n*-butylamine with substituted β-nitrostyrenes, β-nitropropenylbenzenes, and β-nitrobutenylbenzenes over the range of amine concentrations used. A limited number of compounds related to β-nitrostyrenes were also examined, and the rate data for the reactions of *n*-butylamine and also benzylamine were treated in the same manner (Table II). The reactions of substituted β-nitrostyrenes with benzylamine yielded the A and B constants given in Table III. The A and B constants for the reactions of diethyl benzalmalonates and cinnamalmalononitriles with *n*-butylamine are presented in Table IV. These tables have been placed in The Depository of Unpublished Data.[4] In general, only three values of $k_{overall}$ with different amine concentrations were employed to determine the constants.

DISCUSSION

The reaction rates for compounds of the form $C_6H_5CH{=}CRNO_2$, as measured by the A and B constants, were used to assess the relative reactivities of these compounds; Figs. 1 and 2 show plots of most of these constants versus Hammett sigma constants. The mechanism for the reaction which we propose is based on the following.

A bimolecular, quasi six membered ring intermediate has been suggested in the mechanism for the addition of amines to α,β-unsaturated ketones (8) and β-nitropropenylbenzene (3). Moreover, Southwick and Anderson (3) present evidence for the involvement of two amine molecules, since in a study of the addition of secondary amines to β-nitropropenylbenzene a second amine formed the *aci*-nitro salt.[5]

The product may either remain as the salt or add a proton to give the 1,4 adduct depending on the reaction conditions, as outlined in the Introduction. If $-d[\beta NS]/dt = k_2[complex][RNH_2]$ and $-d[complex]/dt = 0$, it can be shown that



$$-d[\beta NS]/dt = \{[RNH_2]^2/([RNH_2]/k_1 + k_{-1}/k_1k_2)\}[\beta NS],$$

and the constants A and B which were used to normalize the data can therefore be related to $1/k_1$ and k_{-1}/k_1k_2, respectively. When the constants for the reactions of *n*-butylamine

[4] *Photocopies of Tables I–V may be obtained, upon request, from: The Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada.*

[5] *The reactions of the secondary amines di-n-butylamine (0.3 to 4.7 M) and morpholine (2×10^{-2} to 5×10^{-1} M) with β-nitrostyrene and β-nitropropenylbenzene (10^{-3} M) in dioxane at 25 °C were, in fact, second order with respect to the amine, and for the reactions of seven β-nitropropenylbenzenes (βNPB) with morpholine, log ($k_{R_2NH} \times 10^2$) = $+1.34\sigma + 0.03$, where k_{R_2NH} (in molar^{-2} second^{-1}) is defined by $-d[\beta NPB]/dt = k_{R_2NH}[\beta NPB][R_2NH]^2$. The correlation coefficient (r) was +0.89, and the standard errors of the correlation coefficient (Δr) and the estimate (Δestimate) were +0.31 and +0.21, respectively. The rate constants appear in Table V.*[4]

with β-nitrostyrene and β-nitropropenylbenzene[6] are compared, it is seen that the presence of the methyl group *cis* to the phenyl group (9) slows down the rate of the reaction which forms the complex (greater A constants) by either hindering the approach of the amine to the alpha carbon or by reducing the positive charge on this carbon through an inductive effect, or both. The presence of this methyl group tends to prevent the phenyl ring from fully participating in resonance, its bulk causing the phenyl ring and the unsaturated linkage to assume a non-planar configuration (10). This reduced resonance participation would result in a reduction of the electronic effects associated with the substituents, and the ρ value for the reaction which forms the complex or for the A constants should be, and indeed is, less for the β-nitropropenylbenzenes than for the β-nitrostyrenes. It has been suggested[7] that the positive nature of the beta carbon atom in aryl nitro β-nitrostyrenes is evidenced by amine reaction on the terminal methylene of 4-nitrostyrene (12). In aryl nitro β-nitrostyrenes the opposed or cross-conjugated system probably reduces the positive charge on the alpha carbon atom and the rate of the complex formation reaction to a value close to that for the parent compound. In Figs. 1 and 2 the solid line was drawn from correlations omitting the A constants for these aryl nitro β-nitrostyrenes; the broken line accommodates these derivatives. Because of steric inhibition of resonance, the cross conjugation in aryl nitro β-nitropropenylbenzenes would be minimized, and so the correlations included these derivatives. The B constants are not subject to the aryl-substituted nitro group effects shown by the A constants in the β-nitrostyrene series, but weakly exhibit the effects of electronic isolation of the benzene ring in the β-nitropropenylbenzene series. Since $B = k_{-1}/k_1k_2$, in the β-nitrostyrenes either the effects of aryl substituents on k_{-1} parallel those on k_1 or the variation in k_2 compensates for the variation in k_1. The constants for the reactions of the β-nitrobutenylbenzenes with *n*-butylamine are very similar to those for the β-nitropropenylbenzenes, and the effects noted above appear to have reached a maximum with the methyl group.

The inductive effect of the bromine atom in the similarly constituted (10) β-bromo-β-nitrostyrene must override any steric effect, since the A and B constants for the reaction of this compound are less than those for β-nitrostyrene. Neither the greater conjugative

The reactions with benzylamine[8] and aniline demonstrate that the basicity of the amine determines the magnitude of the A and B constants: the more basic the amine, the faster the reaction and the smaller the numerical value of these constants. The steric factors associated with benzylamine do not appear to be significantly different from those associated with *n*-butylamine (Fig. 2).

The nature of the solvent exerts a pronounced effect on the apparent amine exponent, and for a given compound over a given range of amine concentrations it appears to be possible to alter this exponent from 1 to 2 by the proper choice of solvent. Aniline was reacted with a series of β-nitrostyrenes at 25 °C in 20% ethanol – 80% aqueous phosphate buffer (Sörensen, pH 7). The reactions were pseudo first order with respect to the β-nitrostyrenes with excess aniline during the initial stages of the reaction, and the amine exponent was unity.[9] If the kinetics of the reactions of aromatic amines in dioxane are the same as those for aliphatic amines, then water and hydroxylic solvents may be usurping the role of the second amine. The reactions of aniline, *p*-toluidine, and *o*-toluidine with β-nitrostyrene in ethanol–water showed that differences in the basicity and the steric effects of these amines had a minor effect on the rate of reaction.

The values of the A and B constants for the reactions of *n*-butylamine with substituted diethyl benzalmalonates[10] are intermediate between those of the corresponding β-nitrostyrenes and β-nitropropenylbenzenes or β-nitrobutenylbenzenes. The cross conjugation apparent in the aryl nitro β-nitrostyrenes does not operate to the same extent in the analogous β-nitropropenylbenzenes and diethyl benzalmalonates because of restricted rotation of the benzene ring; thus the A constants of the 4-nitro derivatives in the latter two classes of compounds are similar to those of the 3-nitro isomers.

The A and B constants for 2-nitro-β-nitropropenylbenzene ($A = 210$, $B = 450$; β-nitropropenylbenzene, $A = 76, B = 12$) and for diethyl 2-nitrobenzalmalonate ($A = 70$, $B = 1.55$; diethyl benzalmalonate, $A = 20$, $B = 0.37$) fall above the trend lines and are much greater than the constants for the parent compounds. Since any electronic interaction of the nitro group with the pendant methyl group in the β-nitropropenylbenzenes is unlikely, steric hindrance to nucleophilic attack caused by the bulky ortho substituent, *and* the non-planar configuration of the benzene ring and the ethylenic linkage appear to be the dominant causes of the reduced reaction rates. The constants for 2,6-dichloro-β-nitropropenylbenzene ($A = 220$, $B = 620$) were abnormal whereas those for 2-nitro-β-nitrostyrene ($A = 1.1, B = 0.0064$; β-nitrostyrene, $A = 1.1$, $B = 0.20$) and 2,6-dichloro-β-nitrostyrene ($A = 1.5$, $B = 0.019$) fell on the trend lines. A diminution in reaction rate is manifested to a lesser extent in other ortho-substituted β-nitropropenylbenzenes, β-nitrobutenylbenzenes, and diethyl benzalmalonates, but not in ortho-substituted β-nitrostyrenes.

The products of the reaction between cinnamalmalononitrile and *n*-butylamine absorb at 280 mμ, and therefore 1,4 addition is indicated. Separation of the *cis* phenyl and cyano groups in benzalmalononitrile by another ethenoid linkage minimizes the mechanical interference between the styryl system and the *cis* cyano group, and although there are insufficient data to discuss adequately these compounds, the Hammett plot would appear

[8]*For the β-nitrostyrenes* $\log A = -0.692\sigma + 0.75$, $r = -0.52$, $\Delta r = +0.36$, *and* $\Delta\text{estimate} = +0.51$, *and* $\log B = -2.43\sigma + 0.25$, $r = -0.98$, $\Delta r = +0.14$, *and* $\Delta\text{estimate} = +0.22$. *A correlation omitting aryl nitro derivatives gave* $\log A = -1.57\sigma + 0.65$, $r = -0.69$, $\Delta r = +0.58$, *and* $\Delta\text{estimate} = +0.47$.

[9]*For the reactions of eight β-nitrostyrenes with aniline,* $\log (k \times 10^2) = +1.99\sigma + 0.52$, $r = +0.95$, $\Delta r = +0.28$, *and* $\Delta\text{estimate} = +0.22$, *where the second-order rate constant, k (in* $\text{molar}^{-1}\ \text{second}^{-1}$*), is defined by* $-d[\beta NS]/dt = k[C_6H_5NH_2][\beta NS]$. *The rate constants are given in Table V.*[4]

[10]*The correlation omitting the 2-nitro derivative gave* $\log A = -1.11\sigma + 1.39$, $r = -0.95$, *and* $\Delta r = \Delta\text{estimate} = +0.13$, *and* $\log (B \times 10) = -2.42\sigma + 0.71$, $r = -0.79$, $\Delta r = +0.66$, *and* $\Delta\text{estimate} = +0.68$.

to be applicable. As expected, the rate constants for the 2-nitro derivative do not exhibit any anomalous effects. Therefore, in the amine reactions of conjugated heteroenoid compounds in which free rotation of the phenyl ring is unlikely, diortho substitution or ortho substitution by groups of sufficient bulk can greatly reduce the rate of the complex formation reaction (k_1) and, in addition, may either increase the rate of the reverse reaction (k_{-1}) or decrease the rate of the reaction leading to the final product (k_2).

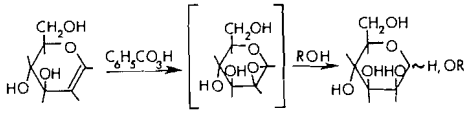
2-ALKOXY-3-HYDROXYTETRAHYDROPYRANS AND 2-ALKOXY-3-HYDROXYTETRAHYDROFURANS

I. PREPARATION, STRUCTURE, AND SOME DERIVATIVES[1]

F. SWEET AND R. K. BROWN

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 10, 1966



ABSTRACT

Oxidation of 2,3-dihydrofuran or 2,3-dihydropyran with peroxybenzoic acid or *m*-chloroperoxybenzoic acid in the presence of an alcohol has produced, respectively, *trans*-2-alkoxy-3-hydroxytetrahydrofurans in 59 to 64% yield and *trans*-2-alkoxy-3-hydroxytetrahydropyrans in 65 to 80% yield. In the presence of acids, these acetals isomerize readily to give an equilibrated mixture of *cis* and *trans* isomers.

INTRODUCTION

Simple models of pyranosides and furanosides which possessed, in addition to the anomeric hydroxyl or alkoxy group, only one hydroxyl group in the ring (and that specifically on C_2) were required for a study of the influence of substituents on the selective hydrogenolysis of acetals and ketals (1). The dihydroxylation of α,β-unsaturated ethers was considered to be a means to this end.

This approach has been used by several workers, but yields in general were not satisfactory. Glycals (2), which are α,β-unsaturated cyclic ethers, have in a number of cases been oxidized by peroxybenzoic acid to give, first, what is believed to be an intermediate epoxide. Under the reaction conditions this was rapidly converted into either a reducing sugar or a glycoside in the presence of water or an alcohol or a carboxylic acid (2–4) (Reaction Scheme 1).

R = H, alkyl, or benzoyl

REACTION SCHEME 1.

In a similar reaction, Bergmann *et al.* (5) showed that oxidation of 2-methyl-5,6-dihydropyran with peroxybenzoic acid provided the diol 2-methyl-2,3-dihydroxytetrahydropyran, isolated by these authors as the acyclic compound 4-hydroxy-4-aceto-1-butanol. Methanolysis of a dimer of this compound, obtained if the above product was isolated by distillation at 60° rather than 30°, gave 2-methyl-2,3-dimethoxytetrahydropyran.

Barker *et al.* (6) oxidized 5,6-dihydropyran with peroxybenzoic acid and obtained 2-benzoyloxy-3-hydroxytetrahydropyran, to which they tentatively assigned the *trans* configuration.

Recently (7), a mixture of hydrogen peroxide and a nitrile has been used to convert *n*-butyl vinyl ether in methanol into *n*-butyl β-hydroxy-α-methoxyethyl ether in 33% yield. Here also, the intermediate was considered to be an epoxide.

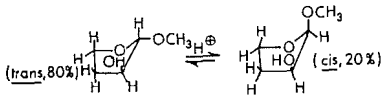
RESULTS AND DISCUSSION



With the work mentioned above as a basis, we have obtained a simple and more productive route to 2-alkoxy-3-hydroxytetrahydropyrans and 2-alkoxy-3-hydroxytetrahydrofurans, using either peroxybenzoic acid or *m*-chloroperoxybenzoic acid to oxidize dihydropyran or dihydrofuran dissolved in the appropriate alcohol. The results of these experiments are shown in Tables I and II. In all cases the nuclear magnetic resonance (n.m.r.) spectra of the compounds were consistent with the structures designated. Oxidation of *n*-butyl vinyl ether by this modified method gave a 92% yield of pure *n*-butyl β-hydroxy-α-methoxyethyl ether.

The proposal of initial formation of an intermediate epoxide as in Reaction Scheme 1 (5) is supported by the fact that the reaction product is almost exclusively the *trans*-2-alkoxy-3-hydroxytetrahydropyran or *trans*-2-alkoxy-3-hydroxytetrahydrofuran. This is in agreement with the known preferred *trans* opening of the epoxide ring (8). Since we have not yet been able to isolate the proposed epoxide intermediate, it is not certain that it actually does occur in this reaction. However, to account for the *trans* product, either such an intermediate must be formed or, alternatively, an "epoxide-like" transition state must be involved. Evidence for the *trans* assignment is shown below and is supported by n.m.r. data. A detailed account of this and the conformational preference of the structures is given in part II in this series.[2]

REACTION SCHEME 2.

If the reaction mixture, obtained from the epoxidation and alcoholysis of the α,β-unsaturated cyclic ether, was worked up immediately after completion of the reaction (about 12 to 14 h), the *trans* isomer was obtained, as shown by gas–liquid chromatography, contaminated by less than 1% of the *cis* isomer. If the reaction mixture stood for 2 days at room temperature before work-up, the amount of *cis* contaminant increased to about 5–10%, showing that isomerization had taken place, no doubt caused by the presence of the benzoic acid.[3] When pure *trans*-2-methoxy-3-hydroxytetrahydropyran, obtained by gas–liquid chromatography, was dissolved in the appropriate alcohol containing some *p*-toluenesulfonic acid, an equilibrium mixture (39:61) of *cis* and *trans* isomers was obtained. The same proportion of *cis* and *trans* isomers was found when pure *cis* isomer was equilibrated under the same conditions (Reaction Scheme 2). In a similar manner, the acid-catalyzed isomerization of *trans*-2-methoxy-3-hydroxytetrahydrofuran gave an equilibrium mixture of *cis* and *trans* isomers in the ratio of 20:80 (Reaction Scheme 3).

REACTION SCHEME 3.

The *trans* and *cis* assignments of the two isomeric 2-methoxy-3-hydroxytetrahydropyrans are supported by the n.m.r. signals for the respective anomeric protons. That for the *trans* isomer occurs as a doublet at τ 5.80 (J = 5.2 c.p.s.) whereas that for the *cis* isomer is a doublet centered at τ 5.43 (J = 3.2 c.p.s.). It is known that axial protons show signals at higher field than do those occupying an equatorial position (9). Furthermore, the coupling constant of 3.2 c.p.s. agrees with the axial–equatorial relation of the C_1 and C_2 protons found for *both* conformations of the *cis* isomer, and that of 5.2 c.p.s. is in agreement with an "average" signal obtained from two conformations of the *trans* isomer, one of which has a *trans* diaxial relation for the C_1C_2 protons, the other conformer having these two protons located diequatorially (9) (Reaction Scheme 2).

The *trans*-2-methoxy-3-hydroxytetrahydrofuran gave a singlet at τ 5.22 for the anomeric proton (unresolved even at high resolution). The signal for the anomeric proton of the *cis* isomer was a doublet centered at τ 5.05 (J = 6.3 c.p.s.). These figures support the *trans* and *cis* configurational assignments.

A more detailed discussion of the conformational arrangements will be given in part II in this series.[2]

EXPERIMENTAL

Melting points are uncorrected.

Analyses were carried out with a Burrell K-2 Kromo-Tog on a 2.5 m column packed with either 25% Carbowax 20 M on Gas Chrom P (60–80 mesh) or 20% butanediol succinate on Chromosorb B. Helium was used as the carrier gas at a flow rate of 60 ml/min, and the column temperature was 150°.

Separation of *cis* and *trans* isomers was accomplished with an Aerograph autoprep, model A-700, using a column packed with 25% Carbowax 20 M on Gas Chrom P (temperature 175°) and helium as the carrier gas at a flow rate of 110 ml/min. The equilibrium mixtures of *cis* and *trans* isomers were analyzed by gas–liquid chromatography on the butanediol succinate column by comparison of peak areas with those obtained from known and carefully weighed mixtures. These figures are consistent with those obtained by n.m.r. analyses.

Elemental analyses were carried out by Miss Darlene Roberts, Department of Chemistry, University of Alberta, Edmonton, and by Dr. C. Daessle, 5757 Decelles Avenue, Montreal.

Nuclear magnetic resonance spectra (in $CDCl_3$) were obtained with a Varian A-60 spectrometer. A Perkin–Elmer model 421 grating spectrophotometer was used to obtain infrared spectra of $CHCl_3$ solutions of the compounds.

4,5-Dihydrofuran was prepared, according to a modification (10) of published directions (11), by the base-catalyzed isomerization of commercially available 2,5-dihydrofuran. Fractional distillation in a spinning-band column gave an incomplete separation of the two isomers, as shown by gas–liquid chromatographic and n.m.r. spectroscopic analysis of each fraction. A 4 ft column packed with stainless-steel saddles gave an excellent separation. The 4,5-dihydrofuran boiled at 52.5° and 695 mm, η_D^{20} 1.4228, η_D^{25} 1.4204 (lit. b.p. 53–55° at 745, η_D^{20} 1.4200 (10); b.p. 54.3° at 760 mm, η_D^{20} 1.4282 (12)). The 2,5-dihydrofuran boiled at 63–65° and 700 mm, η_D^{25} 1.4292, η_D^{20} 1.4309.

General Procedure for the Preparation of 2-Alkoxy-3-hydroxytetrahydropyrans and 2-Alkoxy-3-hydroxytetrahydrofurans

To a cold (−10° to −5°) solution of 0.35 mole of commercial 5,6-dihydropyran or 4,5-dihydrofuran (10) in 350 ml of anhydrous alcohol[4] was added, over a period of 25 min with stirring, a suspension of 0.26 mole of peroxybenzoic acid (13) or *m*-chloroperoxybenzoic acid (FMC Corporation, 500 Roosevelt Avenue, Cartaret, New Jersey) in 150 ml of dry chloroform. The temperature during this addition was maintained at −10° to −5°. Stirring was continued at −5° for 15 min after complete addition of the oxidant. The cooling bath was then removed and the reaction mixture was stirred at room temperature overnight. The chloroform, alcohol, and excess dihydropyran (dihydrofuran) were removed under reduced pressure with a rotary evaporator and a water bath at 50°. The residue, consisting of a mixture of benzoic acid or *m*-chlorobenzoic acid and the 2-alkoxy-3-hydroxytetrahydropyran (2-alkoxy-3-hydroxytetrahydrofuran), was shaken vigorously with 400 ml of chloroform, and the mixture then cooled to 0° and filtered under suction. The benzoic acid residue in the funnel was washed twice with 25 ml portions of cold chloroform. The combined chloroform extracts and mother liquor were extracted with 10% aqueous sodium carbonate. Since these alcohols are water soluble, the aqueous sodium carbonate solution was saturated with sodium chloride and extracted in turn with chloroform to recover any of the alcohol. The combined chloroform extracts were dried (Na_2SO_4), filtered, and then freed from solvent (rotary evaporator). The colorless residue was

[4]*For the preparation of the t-butoxy analogue, the dihydropyran (dihydrofuran) was dissolved in a mixture of t-butyl alcohol (225 ml) diluted with chloroform (125 ml) to prevent solidification of the alcohol at these low temperatures.*

fractionally distilled under reduced pressure in a spinning-band column. The results are shown in Tables I and II.

The n.m.r. spectra (in deuteriochloroform) and the infrared spectra (in chloroform) of each product were consistent with the structures assigned.

The 3,5-dinitrobenzoates were prepared by the addition of 1.5 g of commercial 3,5-dinitrobenzoyl chloride to a solution of 500 mg of the alcohol in 5 ml of dry pyridine. The solution was heated in a water bath at 85° for 15 min and cooled, and then the bulk of the pyridine was removed by rotary evaporation. The residue, dissolved in diisopropyl ether or in chloroform, was washed successively with 5 ml quantities of water, 5% aqueous sodium carbonate, and water. The ether was removed, and the resultant glassy material was crystallized three times from aqueous methanol and simultaneously decolorized with charcoal. The solid was dried overnight in a vacuum desiccator at room temperature and 0.3 mm pressure.

2-Alkoxy-3-methoxytetrahydropyrans (2-Alkoxy-3-methoxytetrahydrofurans)

The alcohols were methylated by the silver oxide – methyl iodide procedure with dimethylformamide as solvent (14), or by the reaction of sodium hydride with a solution of the alcohol and methyl iodide in 1,2-dimethoxyethane. The latter method is similar to procedures which have appeared recently (15, 16). A typical experiment, with appropriate modifications, is described below for the methylation of 2-*t*-butoxy-3-hydroxytetrahydropyran. The pyran (16.0 g, 0.092 mole) was dissolved in 100 ml of 1,2-dimethoxyethane[5] containing 14.2 g (0.10 mole) of methyl iodide. The solution, in a 300 ml, three-necked flask equipped with a magnetic stirrer, an efficient condenser, and a thermometer, was cooled to 10° and four equal portions (total of 2.4 g, 0.10 mole) of sodium hydride[6] were added, with stirring, while the reaction mixture was kept at 5–10°. The mixture was then stirred for 2 h while it came to room temperature. The 1,2-dimethoxyethane was removed by distillation at atmospheric pressure until one-quarter of the volume of the mixture remained. The addition of 100 ml of dry diethyl ether precipitated the bulk of the sodium iodide. The filtered solution was freed from ether, and the residue was distilled in a spinning-band column to give 14.9 g (86%) of material boiling at 61–62° and 7 mm, n_D^{25} 1.4322.

The physical constants for the methylated compounds are shown in Tables I and II.

Isomerization of trans- and cis-2-Methoxy-3-hydroxytetrahydropyrans

A solution of pure *trans*-2-methoxy-3-hydroxytetrahydropyran in dry methanol containing a catalytic amount of concentrated hydrochloric acid was refluxed for 2 h. Analysis by gas–liquid chromatography indicated an equilibrium mixture of 61% *trans* and 39% *cis* isomers. Pure *cis*-2-methoxy-3-hydroxytetrahydropyran subjected to the same conditions gave the same proportion of *trans* and *cis* isomers.

The alcoholic solution of the equilibrated mixture was stirred with an excess of solid sodium carbonate as a suspension for half an hour until carbon dioxide evolution ceased. The solution was then filtered and freed from solvent on a rotary evaporator. The residue was dissolved in chloroform, washed with aqueous sodium carbonate (10%), dried (Na_2SO_4), filtered, and then freed from solvent. The isomers were separated with an Aerograph autoprep. It was more convenient to inject the mixture as a solution in an equal volume of solvent ($CHCl_3$), since the injector unit had a holdup of about 2–3 ml.

The *trans*- and *cis*-2-methoxy-3-hydroxytetrahydrofurans were isomerized in a similar manner.

BORON SULFIDE AS A SOURCE OF ACYLOXYBORANE

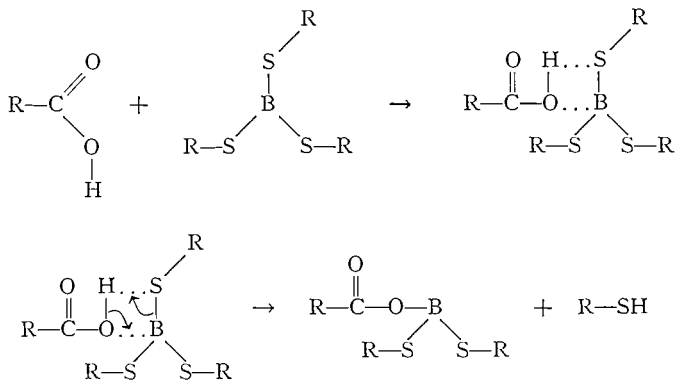
J. M. LALANCETTE, F. BESSETTE, AND J. M. CLICHE
Department of Chemistry, Faculty of Sciences, University of Sherbrooke, Sherbrooke, Quebec
Received March 9, 1966

ABSTRACT

Triacyloxyboranes ($(RCO_2)_3B$) are obtained in good yields by the action of organic acids on boron sulfide or on *o*-thioboric acid esters.

We have reported previously that functional groups bearing labile hydrogens, such as alcohols (1), mercaptans (2), and amines (3), react with boron sulfide to form B—O, B—S, and B—N bonds, respectively. Besides this sensitivity towards protons, boron sulfide can also react with aldehydic or ketonic carbonyls at room temperature to give the corresponding thioaldehydes or thioketones. Under more energetic conditions deoxygenation has been noted with esters (4). With *o*-thioboric acid esters, carbonyls are readily transformed into their corresponding thioacetals at room temperature (5). A study has been undertaken to determine the reactivity of the acid function towards boron sulfide and *o*-thioboric acid esters, the carbonyl group or the hydroxyl group or both being able a priori to react according to the pattern outlined above.

We have found that both aliphatic and aromatic organic acids react smoothly with boron sulfide to give the corresponding triacyloxyboranes (eq. [1]).



[1] $$6RCOOH + B_2S_3 \rightarrow 2(RCOO)_3B + 3H_2S$$

The triacyloxyborane is also obtained if an *o*-thioboric acid ester is used instead of boron sulfide (eq. [2]). We have noted that the carbonyl group is not affected by the *o*-thioboric acid ester.

[2] $$3RCOOH + (R'S)_3B \rightarrow (RCOO)_3B + 3R'SH$$

The mechanism of this reaction should call for the formation of a complex between the electron-poor boron atom and the acidic group, these groups being good acceptors and good donors, respectively. The formation of this complex should be facilitated by the assistance of hydrogen bonding between neighboring sulfur and hydrogen atoms. By subsequent electron shift, the rupture of the B—S bond and the formation of the B—O bond would follow (eq. [3]).

[3]

This S_N2 mechanism is much more attractive than the alternative S_N1 type, which would call for preliminary ionization of the B—S bond to give $=B^+$ and RS^-, a very unlikely step in view of the partial double bond character of the B—S bond induced by strong back-coordination of the electron pairs of the sulfur toward the boron atom.

Boron Acetates

These new methods of formation of acyloxyboranes offer interesting evidence concerning the structure of "boron acetate" obtained by the action of various acetylating agents on boric acid, and shed some light on the structural problems encountered with these compounds.

The first authors to report the formation of "boron acetate" indicated a triacetate structure for their compound (6, 7): $(CH_3COO)_3B$. This formulation has been challenged by Dimroth (8) and more recently by Gerrard (9), who favor a "pyro" structure for this compound: $(CH_3COO)_2B—O—B(CH_3COO)_2$. Gerrard, in his monograph on organoboron compounds (10), has been very categoric in rejecting the existence of the triacetate structure, indicating that he could not reproduce the experiments leading to the formation of the compound reported as the triacetate (m.p. 120°), obtaining instead (with a 99.3% yield in one case) a substance melting at 147–148°, the pyroacetate.

We agree that the product melting at 147–148° is in fact the pyroacetate, but we believe that it is formed from the triacetate by thermal decomposition.

The triacetate is produced by the reaction of acetic acid on boron sulfide or an *o*-thioborate, but cannot be obtained pure because it decomposes spontaneously and rather rapidly to give the "pyro" form (eq. [4]).

$$[4] \qquad 2(CH_3CO_2)_3B \rightarrow (CH_3CO_2)_2B—O—B(CO_2CH_3)_2 + (CH_3CO_2)_2O$$

The temperature and duration of contact seem to be the two factors determining the proportions of these two substances in the ultimate reaction mixture. The relative proportions of the tri- and tetra-acetates given by the reaction have been estimated by boron analysis. With the formation of boron acetate from boron sulfide or *o*-thioborates, the ultimate production of the tetraacetate cannot be explained without the transient existence of the triacetate, if the extreme sensitivity of the B—S bond towards labile protons is taken into account. This sensitivity is illustrated by the very fast reactions observed between alcohols, mercaptans, and boron sulfide. In the case of boron trifluoroacetate, the loss of trifluoroacetic anhydride has been observed at 100° under a vacuum (11), which indicates the feasibility of eq. [4].

Using special acetylating techniques, we have succeeded in reproducing a boron acetate melting at 120°, as reported by Ahmad (7). This material has a molecular weight of 325, not too far from the value for the tetraacetate. When kept in a desiccator, over KOH, it slowly loses acetic acid or acetic anhydride, which is absorbed by the base. After 2 weeks, the melting point has reached the correct value for the tetraacetate and the evolution of acetic fragments has stopped. In view of these results, we believe that the "triacetate" obtained by Ahmad was in fact the tetraacetate, which had retained acetic anhydride upon crystallization.

EXPERIMENTAL*

Reaction of Benzoic Acid with Boron Sulfide

A solution of 40 g (0.33 mole) of benzoic acid in 100 ml of anhydrous benzene was refluxed for 26 h in the presence of a suspension of boron sulfide (6.5 g, 0.055 mole). The reaction was accompanied by evolution

**Melting points were taken in sealed capillary tubes and are not corrected. Infrared measurements were made on a Perkin–Elmer spectrometer, model 125, with KBr cells.*

of H_2S. The crude mixture was filtered while hot, and after it was cooled, white crystals separated out, m.p. 195–197° (after recrystallization from benzene), yield 76% (reported (12) m.p. 145°). A sample of this material was analyzed by water hydrolysis and subsequent titration of the benzoic acid to a phenolphthalein end point, followed by addition of mannitol and titration of the boric acid to a phenolphthalein end point.

Anal. Calcd. for $(C_6H_5CO_2)_3B$: $C_6H_5CO_2$, 97.1; B, 2.9; mol. wt. 374.2. Found: $C_6H_5CO_2H$, 97; B, 3.0; mol. wt. (obtained by cryoscopy in ethylene dibromide) 396.

Ethylene dibromide had shown near ideal behavior in molecular weight determinations of *m*-dinitrobenzene and acetanilide. Infrared ($CHCl_3$): no bands in the region of 3 500 cm^{-1}; bands at 1 688 (very strong), 1 602 (medium), 1 420 (strong), 1 333 (very strong), and 1 282 cm^{-1} (strong).

By a similar technique, boron tripropionate (m.p. 110–113°) and boron tricinnamate (m.p. 160°) were obtained.

Anal. Calcd. for $C_{27}H_{21}O_6B$: cinnamic acid, 97.57; B, 2.40. Found: cinnamic acid, 97.2; B, 2.1.

Anal. Calcd. for $C_9H_{15}O_6B$: propionic acid, 95.22; B, 4.70. Found: propionic acid, 95.2; B, 5.0.

Reaction of Acetic Acid with Boron Sulfide

A method similar to the above was used except for the time of contact, which was 30 min instead of several hours. A mixture of two products was obtained after crystallization from glacial acetic acid, the first product melting at 120° and the second at 137–138°. Variations in the ratio of the two compounds (the tri- and pyro-acetates) have been estimated by boron analysis of the crude mixture obtained initially after the mixture was washed with dry petroleum ether to remove any excess of acetic acid.

Anal. Calcd. for $(CH_3CO_2)_3B$: B, 5.76. Calcd. for $(CH_3CO_2)BOB(CH_3CO_2)_2$: B, 7.87. Found: after a reaction period of 30 min B, 6.2; after a reaction period of 2 h B, 6.9; after a reaction period of 24 h B, 7.5.

Reaction of Acetic Acid with o-Thioboric Acid Esters

A mixture of 8.0 g (0.034 mole) of isopropyl *o*-thioborate and 25 ml (excess) of acetic acid was refluxed under a nitrogen atmosphere for 90 min. The excess of acetic acid was distilled under reduced pressure and the residue recrystallized from acetic acid. Two fractions melting at 120° and 146–148° were obtained. Similar mixtures were obtained by a prolonged contact at room temperature or a short reflux time, with *n*-butyl *o*-thioborate and acetic acid.

Acetylation of Boric Acid

A suspension of 5.0 g (0.081 mole) of boric acid in 30 g (0.29 mole, slight excess) of acetic anhydride was refluxed under a dry nitrogen atmosphere and with good stirring. The reaction took place suddenly, almost explosively, and the solid material dissolved completely. The reaction mixture was immediately cooled in an ice bath and a white solid crystallized out. This solid was filtered under a dry atmosphere, thoroughly washed with anhydrous ethyl ether, and kept for 1 h under a vacuum. The melting point was then 120°. A 5.7336 g sample of this material was kept for 2 weeks in a desiccator in the presence of KOH pellets. After a loss of 0.1905 g the weight remained constant and the melting point was then 145–147°. The increase in the weight of KOH was 0.1902 g. A molecular weight determination on the fresh material melting at 120° (cryoscopy in bromoform) was 325 ± 30; the calculated molecular weight for $(CH_3CO_2)_2BOB(CH_3CO_2)_2$ is 274. Molecular weight determinations of boron acetates proved to be a very delicate task because of their extreme sensitivity towards moisture.

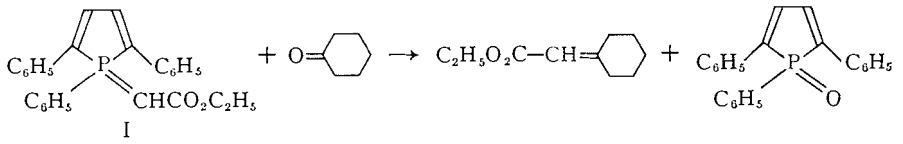
A 5-PHOSPHAFULVENE WITTIG REAGENT[1]

M. B. HOCKING
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received November 18, 1965



ABSTRACT

1,2,5-Triphenyl-1-carbethoxymethylenephosphole (I), a fairly stable isolable phosphorane, has been shown to undergo Wittig reactions with cyclohexanone, benzaldehyde, and acetaldehyde under a variety of conditions. Both the reactivity and stereoselectivity of I are less than the corresponding properties of triphenylcarbethoxymethylenephosphorane (II); these properties may be useful in certain applications.

INTRODUCTION

A new 1-phosphafulvene (I) has now been found to undergo Wittig reactions, and this capability has been examined to discover the latent advantages, if any, of this reagent over the analogous, more conventional triphenylphosphine Wittig reagent.

The carbethoxymethylene ligand was selected for the investigation of reactivity because of the adequacy of published work (2–4) on the reaction of triphenylcarbethoxymethylenephosphorane (II) with several aldehydes and ketones under widely differing conditions. The latter is also a stable phosphorane which does not require preparation *in situ*.

I

(Similarly, $(C_6H_5)_3P{=}CHCO_2C_2H_5$ (II))

The work was conducted in two phases, the first to give only indications of the reactivity of the phosphafulvene (I) relative to that of the triphenylphosphine phosphorane (II), whose reactivity is well established (see Tables I and II), and the second to determine any differences in the ratios of *cis* and *trans* olefins formed in reactions where geometrical isomerism is possible.

EXPERIMENTAL

Melting points and boiling points are not corrected. Benzene was dried by boiling it with $LiAlH_4$ for 2 h, and then was distilled. Ethanol was dried by the method of Lund and Bjerrum (5) and distilled to yield material containing less than 15 p.p.m. water. Acetonitrile containing 0.67% water was simply distilled, since the presence of a small percentage of polar impurity would not be detrimental. Acetaldehyde, benzaldehyde, and cyclohexanone were distilled immediately before use. Analyses were carried out by Dr. L. E. Swim and associates, The Dow Chemical Company, Midland, Michigan, and Dr. C. Daessle, Montreal, Quebec.

Ultraviolet spectroscopic data were obtained on a Unicam SP.700 recording spectrophotometer (for some of the phosphafulvene decomposition data) and on a Beckman DK-2 ratio recording spectrophotometer. Infrared data were recorded on Unicam SP.100 or Beckman IR-9 spectrophotometers. Proton resonance information was obtained on a Varian A-60 instrument fitted with a phase-detector integrator.

Phosphafulvene (I)

Several preparations of this compound were carried out as previously described (1) without interference from the reported complication, and analyses were considerably improved when carried out within 4 days of preparation.

Anal. Calcd. for $C_{26}H_{23}O_2P$: C, 78.4; H, 5.8; P, 7.8. Found: C, 78.6, 78.5; H, 5.4, 5.8; P, 7.8, 7.9.

The methyl ester of I, melting at 167–170°, was also prepared in a strictly analogous way.

Anal. Calcd. for $C_{25}H_{21}O_2P$: C, 78.1; H, 5.5; P, 8.1. Found: C, 77.8, 78.1; H, 5.3, 5.3; P, 8.1, 8.1.

It was not stable for long periods in the atmosphere (see the ultraviolet data), but kept satisfactorily in a desiccator (KOH). Distillation of 5.5 g of decomposed phosphafulvene failed to yield any diethyl fumarate or maleate (4). However, a small quantity of a hydrocarbon, m.p. 207–208°, was obtained (b.p. 200° at 0.04 mm), whose analysis and molecular weight corresponded to a formula of the type $C_{25}H_{16-18}$ or $C_{26}H_{18}$, but no correspondence with known compounds could be found (6) for the spectral properties (λ_{max}^{hexane} 274 mμ, ϵ_{molar} 43 500, mol. wt. 321).

Confirmation of the structure of the phosphafulvene (I) was obtained by hydrobromination back to the phosphonium salt. Excess gaseous HBr was passed into a solution of the phosphafulvene (1.0 g) in benzene (50 ml), thereby causing a yellow oil to separate. The mixture was purged with nitrogen for 15 min, the benzene decanted, and crystals obtained (1.15 g, 96%) from the oil in fresh benzene (50 ml). This salt, m.p. 128–132°, gave an infrared spectrum identical with that of the salt prepared directly from the phosphole (m.p. 167–168°). It was also completely soluble in water, and with aqueous base this solution yielded the starting phosphafulvene (m.p. and mixed m.p. 151–156°).

Reactivity Investigations

Cyclohexylideneacetic Acid via Phosphafulvene (I)

From an initial attempt in boiling benzene for 24 h on a 0.01 *M* scale with an excess of cyclohexanone in a nitrogen atmosphere, 93% of the Wittig reagent was recovered unchanged and no ethyl cyclohexylideneacetate could be isolated. A pressure reaction without solvent, however, was more successful.

The phosphafulvene (5.0 g) and cyclohexanone (6.25 g) were placed in a glass-lined stainless-steel reaction vessel which was then thoroughly flushed with nitrogen and closed. This was heated at 170° for 10 h. After the vessel was cooled to room temperature, the contents, which had partly crystallized, were rinsed into a suction filter with ethanol. The chunky yellow crystals of phosphole oxide (2.5 g) melted at 231–236°, which was raised to 232–236° after one recrystallization from ethyl acetate. Dilution of the filtrate with hexane caused small yellow needles to form (0.2 g, m.p. 178–183°) which, on recrystallization from chloroform, gave a melting point and mixed (with 1,2,5-triphenylphosphole) melting point of 183–185°. Solvents were stripped from the final filtrate by distillation on a boiling water bath, and the excess cyclohexanone (b.p. 48° at 15 mm) was subsequently removed by reducing the pressure. The dark gummy distillation residue was saponified in aqueous ethanolic sodium hydroxide, the excess alcohol was distilled off, the remaining mixture was diluted further with water, and the aqueous suspension was extracted with ether. The aqueous phase was acidified to pH 3 with HCl, and the oil which separated was extracted with ether. Evaporation of the ether gave 1.0 g of crude product. Distillation of this gum (90–146° bath at 0.05 mm) gave 169 mg (10%) of pure cyclohexylideneacetic acid, m.p. 81–88°, which, after one recrystallization from hexane, melted at 89–91° (lit. (7) m.p. 90–91.5°) and analyzed well.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.6; H, 8.6. Found: C, 68.9; H, 8.3.

Ethyl Cinnamate via Phosphafulvene

(a) At 80°.—The phosphafulvene (8.0 g) and freshly distilled benzaldehyde (2.1 g) in ethanol (90 ml) were boiled under reflux in a dry nitrogen atmosphere for 2 h. Crystals of the phosphole oxide (5.0 g, m.p. 236–239°) were filtered from the cooled reaction solution and washed with fresh ethanol. The ethanol was distilled from the combined filtrate and washings through a 50 cm Snyder column on a water bath under a very slightly reduced pressure. A further 0.6 g of phosphole oxide (m.p. 229–236°) was obtained from the residual oil on dilution with a small amount of hexane. The hexane solution was transferred to a small distilling flask and the hexane evaporated off. Distillation yielded ethyl cinnamate (2.7 g, 76%) at 262–269° (lit. (14) b.p. 265–267°) after a small forerun. The identity of the product was confirmed by comparison of its infrared spectrum with that of an authentic sample.

(b) At room temperature (23°).—The quantities of reagents used and the procedure were the same as in method *a* above, except that when the reagents were mixed the reaction mixture was left at room temperature for 48 h. Work-up as described in method *a* above yielded a total of 2.92 g (82%) of ethyl cinnamate and 6.5 g (98%) of the phosphole oxide.

Stereochemical Investigations

Preparation of the Ethyl Crotonates

(i) Ethyl trans-crotonate.—This was prepared by a method similar to that of Vogel (8). From 100 g of the crotonic acid was obtained 73 g of distilled product, b.p. 137–137.5° (lit. (8) b.p. 136.5°). The room temperature proton nuclear magnetic resonance (n.m.r.) spectrum in CCl_4 with tetramethylsilane as internal standard further established its purity and identity.

$$\underset{a}{CH_3}\text{—}\underset{b}{CH}\text{=}\underset{c}{CH}\text{—}\overset{\overset{O}{\|}}{\underset{}{C}}\text{—}O\text{—}\underset{d}{CH_2}\text{—}\underset{e}{CH_3}$$

The details were: vinyl proton (*b*) at δ 6.87 (1H, pair of overlapping quartets, J_{ba} = 6.4 and J_{bc} = 14.5 c.p.s.), vinyl proton (*c*) at δ 5.75 (1H, pair of quartets, J_{ca} = 1.5 and J_{cb} = 14.5 c.p.s.), ester methylene protons (*d*) at δ 4.08 (2H, quartet, J_{de} = 7.0 c.p.s.), vinylic methyl protons (*a*) at δ 1.83 (3H, pair of doublets, J_{ac} = 1.5 and J_{ab} = 6.4 c.p.s.), and ester methyl protons (*e*) at δ 1.22 (3H, triplet, J_{ed} = 7.0 c.p.s.).

(ii) Ethyl cis-crotonate.—*cis*-Crotonic acid[2] containing about 5% (by n.m.r.) of the *trans* isomer was cooled in an ice bath, and ice-cold 2.03 *N* ammonium hydroxide (10 ml) was added with stirring. Fifty milliliters of the ice-cold 0.4 *N* aqueous silver nitrate was then added in subdued light, with stirring, and the precipitated silver salt filtered off and dried (2.04 g). Ethyl iodide (2.5 ml) was added to a suspension of this silver salt in benzene (50 ml) and the mixture, shielded from light, was boiled under reflux for 1 h. (A preliminary run established that less time was insufficient.) The coagulated silver iodide was filtered off and the solvent evaporated from the filtrate to leave 1.0 g (52%) of a pale-yellow oil. Nuclear magnetic resonance established that this oil was ethyl crotonate, and the ratio of *cis* to *trans* was found to be 95:5, the same as in the starting acid.

The details of the n.m.r. spectrum, which was measured with the same solvent, internal standard, and conditions as for ethyl *trans*-crotonate, were: vinyl proton (*b*) at δ 6.26 (1H, pair of overlapping quartets, J_{ba} = 6.8 and J_{bc} = 11.1 c.p.s.), vinyl proton (*c*) at δ 5.72 (1H, pair of quartets, J_{ca} = 1.5 and J_{cb} = 11.1 c.p.s.), ester methylene protons (*d*) at δ 4.10 (2H, quartet, J_{de} = 7.0 c.p.s.), vinylic methyl protons (*a*) at δ 2.10 (3H, pair of doublets, J_{ac} = 1.5 and J_{ab} = 6.8 c.p.s.), and ester methyl protons (*e*) at δ 1.22 (3H, triplet, J_{ed} = 7.0 c.p.s.).

Analysis of cis–trans Mixtures of Ethyl Crotonates

To determine the *cis–trans* ratios of mixed ethyl crotonates by n.m.r. the resonance of protons on the vinylic methyl groups were used, for two reasons. Firstly, the bands caused by this resonance appeared at shifts which differed sufficiently between the *cis* and the *trans* isomers to enable integration of the peak areas for each individually, and secondly, this resonance was caused by a sufficiently high proportion of the protons in the molecules to still give an indication of the presence of as low as 3% of one of the isomers in the presence of the other. In one or two of the analyses an additional single resonance band appeared at 1.97 p.p.m., the cause of which could not be established. However, this was separated from the resonance bands being integrated for analysis by placing this portion of the spectrum on a sweep width of 100 cycles; integration could then be effected without interference from this trace impurity. Traces of 1,2,5-triphenylphosphole-1-oxide or triphenylphosphine oxide present in some of the samples analyzed had no effect on the accuracy of the ratio, since all the protons in these molecules resonate at much lower field strengths.

Parallel Wittig Reactions

1. In Boiling Benzene

(*a*) The phosphafulvene (6.0 g) and acetaldehyde (3.5 ml) in benzene (100 ml) were boiled together under reflux, with protection from atmospheric moisture, for 80 min. Further 3.5 ml portions of acetaldehyde were added at 40 min and 80 min reaction time. When the mixture was allowed to cool to room temperature crystals of the phosphole oxide (3.89 g) separated and were filtered off. The solvent was evaporated from the filtrate on a rotary evaporator with a 30 cm reflux head, using a water bath at 30° for heating and an aspirator vacuum. Residual oily yellow crystals remained which were washed with a few small portions of ether, dried, and identified (m.p. 230–233°) as a further crop of the phosphole oxide (0.89 g, total recovered 97%).

The ether was evaporated off and the residual oil (0.83 g), of which 0.67 g (39%) was ethyl crotonate, was examined by n.m.r., establishing a ratio of *cis* to *trans* of 23:77.

(*b*) As a control experiment in an attempt to demonstrate the lack of equilibration or fractionation of the isomeric crotonates the reaction was repeated with an initial addition of 0.190 g of ethyl *cis*-crotonate and on a smaller scale, but otherwise as described in method *a*. The use of 4 g of phosphafulvene and 2 ml portions of acetaldehyde gave a total of 0.68 g of crotonates, of which 33.5% was *cis*. This corresponded to a yield from the reaction of 0.49 g (43%), of which 8% was *cis*.

(*c*) The phosphorane (II) (6.0 g), acetaldehyde (10.5 ml, total), and benzene (100 ml) were reacted and worked up as described in method *a* above. Most of the triphenylphosphine oxide (4.39 g, 92%) was isolated and a yield of 1.62 g (82%) of ethyl crotonate obtained, of which 11% was *cis*.

2. In Boiling Ethanol

(*a*) The phosphafulvene (7.96 g) and acetaldehyde (2 ml) in ethanol (250 ml) were boiled under reflux for 1 h, with protection from atmospheric moisture. Two milliliter portions of acetaldehyde were added after 20 min and 40 min reaction time. The solvent and ester product were stripped off in a rotary evaporator, and the residual yellow crystals washed with a small quantity of ether and dried to yield 6.38 g (97%) of the phosphole oxide, m.p. 233–237°. The ethanol was then distilled from the ethyl crotonate through a 70 cm Vigreux column (70° bath at 120 mm). The yield of crotonate was 0.50 g (22%), of which 17% was *cis*.

(*b*) As a control experiment in a polar, protonating solvent the reaction described in method *a* above was carried out in essentially the same way, but with 0.118 g of ethyl *cis*-crotonate in addition to the quantities of reagents specified. The total ester recovery was 0.917 g (20% *cis*), of which that produced in the reaction was 0.79 g (35%) and 8% ethyl *cis*-crotonate.

(*c*) The phosphorane (II) (6.69 g) and acetaldehyde (6 ml, total) in ethanol (250 ml) were reacted and worked up as described in method *a* above. Triphenylphosphine oxide (5.17 g, 93%) was isolated and 0.44 g (19%) of ethyl crotonate obtained, of which 7% was *cis*.

(*d*) For a reproducibility test the reaction described in method *c* above was repeated with the same quantities. After the mixture was refluxed for 1 h the solvent was distilled through a 70 cm Vigreux column (70° bath at 120 mm). After the oily colorless crystalline residue was washed with petroleum ether (3 × 15 ml, b.p. 30–50°), the crystals were filtered off and dried to yield 5.45 g (98%) of triphenylphosphine oxide, m.p. 151–156°. The petroleum ether was distilled from the filtrate through a 70 cm Vigreux column (70° bath at 120 mm) to yield 0.24 g (12%) of ethyl crotonate, of which 6% was *cis*.

3. In Boiling Acetaldehyde

(*a*) The phosphafulvene (6.0 g) and acetaldehyde (150 ml) were boiled under reflux in a 40° water bath, with protection from atmospheric moisture, for 50 min. Initially most of the phosphafulvene was in solution, and during the reaction the solution became more yellow in color, accompanied by the precipitation of a yellow solid. The excess acetaldehyde was distilled (30° bath at 400 mm) through a 70 cm Vigreux column, and the residual yellow solid was washed free of oil with small portions of petroleum ether (b.p. 30–50°) and filtered off under suction. The yellow solid (4.68 g, 95%) was phosphole oxide, m.p. 233–237°. After the petroleum ether had been evaporated from the filtrate (same conditions as acetaldehyde) the residual yellow oil was distilled (b.p. $\simeq$ 40° at 10 mm), using a water bath at 80° and a receiver cooled to −15°. The yield was 0.59 g (35%), of which 26% was *cis*.

(*b*) The phosphorane (II) (5.23 g) and acetaldehyde (130 ml), in which the former was completely soluble, were boiled together under reflux in a 40° bath for 50 min. The work-up, which was carried out as described in method *a* above, yielded 4.00 g (93%) of triphenylphosphine oxide (m.p. 151–155°) and 0.56 g (33%) of ethyl crotonate, of which 8% was *cis*.

4. In Boiling Acetonitrile

(*a*) The phosphorane (II) (6.96 g) and acetaldehyde (2 ml) in acetonitrile (250 ml) were boiled together under reflux for 1 h. Additional 2 ml portions of acetaldehyde were added after 20 min and 40 min reaction time. Solvent and excess acetaldehyde were removed through a 70 cm Vigreux column (80° bath at 240 mm). The residual oil was distilled, keeping the pot temperature below 80° and the receiver at −15°, to yield 1.15 g of ethyl crotonate, of which 8% was *cis*. Crystallization of the solid distillation residue from benzene yielded 4.98 g (90%) of triphenylphosphine oxide, m.p. 153–156°.

(*b*) The phosphafulvene (I) (7.96 g) and acetaldehyde (2 ml) in wet acetonitrile as used in method *a* above gave no detectable yield of crotonates. However, when carried out on the same molar scale in dry acetonitrile (<20 p.p.m. water, by two treatments with P_2O_5 followed by distillation from the same drying agent) with the methyl ester of the phosphafulvene (I) a 14% yield of crotonates was obtained, of which 7% was *cis*.

5. Effect of Temperature

(*a*) The phosphafulvene was reacted and worked up essentially as described in section 2*a* above, except that the reaction was carried out at 23°, with stirring, for 24 h. The 0.54 g (24%) of ethyl crotonate obtained consisted of less than 3% *cis* ester.

(*b*) An experiment similar to the above, with the phosphorane (II) on the same scale as described in section 2*b* above, yielded 0.70 g (31%) of the mixed esters, of which 10% was ethyl *cis*-crotonate.

6. Equilibration Tests

One milliliter of a solution of ethyl *trans*-crotonate in benzene (50% by volume) was placed in each of three n.m.r. tubes. Nothing was added to the first, phosphole oxide (2 mg) was added to the second, and acetaldehyde (2 drops) and phosphafulvene (4 mg) were added to the third. One milliliter of another solution of mixed ethyl *cis*- and *trans*-crotonates (30.5% *cis*) in benzene (50% by volume) was placed in each of four n.m.r. tubes. To one tube nothing was added, to another phosphole oxide (2 mg) was added, to the third phosphole oxide (2 mg) and phosphafulvene (4 mg) were added, and to the fourth phosphole oxide (2 mg), phosphafulvene (4 mg), and acetaldehyde (2 drops) were added.

All seven tubes were then heated at 75° for 2½ h, followed by a further period of 64 h. Each tube was examined visually and by n.m.r. after each interval of heating. To those tubes starting with added acetaldehyde a further addition of the starting quantity was made after 2½ and 40 h heating, and to those starting with phosphafulvene a further 4 mg addition was made to each at 40 h. The ratio of *cis* ester to *trans* ester in each of the tubes remained the same throughout the test. However, all except one of the tubes starting as yellow solutions (containing added phosphole oxide and (or) phosphafulvene) became colorless by the end of the test, but did not after the short heating period. The one which retained most of its color contained the *trans* ester, acetaldehyde, and phosphafulvene.

RESULTS

Cyclohexanone seemed to be an ideal reagent for reactivity comparisons between the phosphafulvene (I) and the triphenylphosphine phosphorane (II). The latter reacts with cyclohexanone only slowly or under forcing conditions, yet gives better yields (9) than when it reacts with other ketones, whereas aldehydes form olefins with II so readily that a minor reluctance for the phosphafulvene to react would not be apparent.

The phosphafulvene reacted with cyclohexanone only under the most stringent conditions used with II, to give a similar yield of crude ethyl cyclohexylideneacetate, as indicated in Table I. Conditions of intermediate severity were insufficient to cause any detectable reaction.

Benzaldehyde reacted readily with the phosphafulvene in ethanol both at room temperature and in the boiling solvent, to give yields of ethyl cinnamate comparable to those obtained by others with II (Table II). No attempt was made to analyze the resulting ethyl cinnamate for *cis* and *trans* isomers, since Bergelson (15, 16) had already found the Wittig reagent II to yield virtually 100% ethyl *trans*-cinnamate regardless of conditions or additives.

Though the affinity of the phosphafulvene towards carbonyl reagents has been shown to be qualitatively somewhat lower than that of the triphenylphosphine phosphorane, experience indicates that the phosphafulvene is less stable towards atmospheric conditions. In the air fairly rapid decomposition of the phosphafulvene to 1,2,5-triphenylphosphole-1-oxide occurs, as shown by changes in the ultraviolet absorption and melting point with time (Table III). Also, it should be mentioned here that the phosphafulvene is much more sensitive to hydrolytic decomposition by moist solvents than II, as evidenced by difficulties in recrystallization (1), and by the lack of any detectable product from a reaction with the phosphafulvene in acetonitrile containing 0.67% water, conditions which little affected the phosphorane II.

Stereochemical investigations with the new Wittig reagent, it was felt, should be interesting for two reasons. The bulk of the phosphorus ligands in the phosphafulvene, though quantitatively similar to that of the three phenyls in triphenylphosphine, is unsymmetrically disposed about the phosphorus, as displayed by Stuart–Briegleb models. The other

point of difference is that the phosphorus in the phosphafulvene is in a more strained configuration than that in the triphenylphosphine phosphorane, which may in itself alter the ratio of geometrical isomers obtained in reactions with the former.

Two unsymmetrical ketones, ethyl methyl ketone and acetophenone (excess as solvent), have been found (9) to give mixtures of *cis* and *trans* isomers with II, but no accurate quantitative data were obtained. More recently, Russian workers (15) found that the steric course of the reaction of II and benzaldehyde was predominantly to ethyl *trans*-cinnamate, and was relatively unaffected by environment. House and his co-workers (17) have since published the results of clean-cut stereochemical investigations of the products from reactions of II (as the methyl ester) and acetaldehyde under a wide variety of conditions.

Originally, acetaldehyde was chosen by us for experiments to demonstrate the stereochemistry of the phosphafulvene, with the intention of using low-temperature vapor-phase chromatography for analysis of the *cis* to *trans* ratio. After this work was initiated, House (17) was successful in using vapor-phase chromatography to analyze analogous

cis–trans ester systems. However, a preliminary examination of ethyl *cis*- and *trans*-crotonates by proton n.m.r. established this method as being suitable for accurately determining the relative percentage of each in a mixture. Both the phosphafulvene (I) and the triphenylphosphine phosphorane (II) gave fair yields of mixed isomers of ethyl crotonate under identical conditions. By analysis of the integrals of the n.m.r. quadruplet caused by the respective vinylic methyl protons in the mixtures of *cis* and *trans* isomers, the relative amounts of each isomer were calculated.

Though under some conditions the triphenylphosphine phosphorane yielded a greater proportion of ethyl *cis*-crotonate than did the phosphafulvene, the tendency was to a product containing a greater proportion of *cis* ester from the phosphafulvene (Table IV). The insensitivity of the stereospecificity of II to solvent polarity was confirmed by our experiments in acetonitrile, a non-protonating polar solvent. This finding agrees with that of the Russian workers (16), and that found by House (17) with the methyl ester of II for *non-protonating* polar solvents. However, this insensitivity of II to solvent polarity cannot directly be applied to Wittig reactions of the phosphafulvene on the basis of our results.

TABLE IV

Effect of Wittig reagent, solvent, and temperature on yield and *cis* to *trans* ratio of ethyl crotonate from acetaldehyde

DISCUSSION

Important contributions to the mechanism outlined in Reaction Scheme 1 (4) have been made by many authors. Speziale and Bissing (18), for instance, have presented evidence to support the reversible formation of betaines from stable phosphoranes. Others have shown that both the inductive effect of the ylid substituents (19–21) of the phosphorane and the inductive effects of the other substituents on phosphorus (22, 23) play important roles, the first by changing the acidity of the α-hydrogen on the ylid, and the second by affecting the oxygen affinity of phosphorus. The recent X-ray determinations of the geometry of several phosphorus ylids (24 and references therein), particularly the findings revealing that the ylid α-carbon has little anionic character in at least the carbonyl- or sulfonyl-stabilized ylids (25),[3] also are relevant to any consideration of mechanistic pathways in the Wittig reaction.

The decreased stereoselectivity of the phosphafulvene can be attributed to one, or more, of several factors. If the main features of the mechanism (4) are accepted, slower equilibration of the two stereoisomeric betaines III*a* and IV*a* over III*b* and IV*b* will lead to a more nearly statistical distribution of *cis* and *trans* olefin product for the phosphafulvene, as

REACTION SCHEME 1. Pathways for betaine interconversion and decomposition.

found. Faster decomposition of the betaines III*a* and IV*a*, as they are formed, over the betaines III*b* and IV*b* would have the same net effect on the ratio of *cis* to *trans* olefin as slower equilibration.

Our stereochemical control experiments demonstrate that either equilibration or fractionation, or both, must have been occurring in our experiments with the phosphafulvene. Also, our small-scale tests failed to elucidate the cause of the suspected equilibration; yet equilibration is almost certainly the explanation of the low *cis* yields in the control reactions rather than fractionation, since there was only a decrease in the percentage of the *cis* isomer, not a simultaneous decrease in the yield. However ineffective the small-scale tests were in demonstrating equilibration, perhaps because of the relatively low proportion

For personal use only.

of additive to ester compared with the proportions present in the actual reactions, they did demonstrate a further consideration. Apparently, both the *cis* and the *trans* esters undergo Diels–Alder reactions with the phosphole oxide (1), as evidenced by the loss of color. However, the *cis* ester apparently, and not surprisingly, reacts faster than the *trans* ester (see Experimental). This preferential loss of *cis* ester could help to explain the low yields of the *cis* isomer in our control experiments, but probably only partly, since between $2\frac{1}{2}$ and 64 h was required for 2–8 mg of phosphole oxide to react completely with excess ester. At least the indications from the control experiments are that actually higher percentages of *cis* ester are formed than are indicated in Table IV.

Because of the conflict between the results of our control experiments and our other stereochemical results, there is little point in applying these to any mechanistic discussion of the Wittig reaction. However, empirical considerations may explain the higher *cis* yields obtained with the phosphafulvene. For instance, the 25% lower P=O bond dissociation energy for the phosphoryl group in pentaphenylphosphole-1-oxide as opposed to that in triphenylphosphine oxide (26) discourages the suggestion of faster decomposition for the intermediate betaines III*a* and IV*a*. On the other hand, in the respective intermediate betaines the apparent greater ease with which the oxygen anion can approach the phosphonium ion (Stuart–Briegleb models) in III*a* or IV*a* rather than in III*b* or IV*b* counteracts the suggestion based on bond dissociation energy. The greater of the foregoing effects (charge magnitude or the extent of charge delocalization) decides the relative rates of betaine decomposition according to its contribution to the overall scheme.

Since at least the reactive phosphoranes showed an enhancement of the *cis* to *trans* ratio when the polarity of the solvent was increased, we were hopeful of observing an enhancement of this ratio with the phosphafulvene. Unfortunately, no significant solvent effect was observed. Even in ethanol, with which we expected a significant *cis* effect based on the findings of House (17), a decrease, if anything, in the *cis* to *trans* ratio occurred. Several workers (3, 27) have reported that the higher the temperature at which a Wittig reaction is carried out the greater the yield of the *trans* olefin. Therefore, it was thought that this lack of a noticeable *cis* enhancement in ethanol in our experiments may be explicable on the basis of a temperature effect, since House and his co-workers (17) carried out their reactions at room temperature, whereas our initial experiments were at 80°. To prove this and to help explain the high percentage of *cis* ester obtained from the phosphafulvene reaction in acetaldehyde, Wittig reactions were repeated with the phosphafulvene and the phosphorane (II) in ethanol, but at room temperature. A slight *cis* enhancement was noticed with II, but only a trace of *cis* ester, if any, was obtained with the phosphafulvene. Therefore, a temperature effect alone cannot be the explanation for either our not finding any solvent effect, or for the high percentage of *cis* ester obtained from the phosphafulvene in acetaldehyde. Indeed, these experiments gave us yet another unanswered question: why should carrying out the phosphafulvene reaction at room temperature give us such a change in the isomer ratio?

Synthetic utility of this phosphafulvene Wittig includes the preparation of *cis* olefins not readily accessible by alternative methods. Another very specific possible application is the employment of successive Wittig reactions in placing different ligands on an aldehydic carbonyl and a ketonic carbonyl in the same molecule. A phosphafulvene Wittig reagent will probably give the product involving replacement of only the aldehydic oxygen, after which a triphenylphosphine Wittig reagent can be employed for replacement of the more hindered carbonyl oxygen, a sequence of reactions not as yet demonstrated to be within the capability of conventional Wittig reagents alone.

NOTES

A CONVENIENT METHYLATION PROCEDURE

U. E. Diner, F. Sweet, and R. K. Brown

The use of the more powerful solvents dimethylformamide and (or) dimethyl sulfoxide has permitted one-step complete methylation in good yield, with either silver oxide – methyl iodide or methyl sulfate – barium oxide (hydroxide), of a number of polyhydroxy compounds (1). This is a distinct improvement over the silver oxide – methyl iodide (2) or methyl sulfate – sodium hydroxide (3) procedures, which often required tedious, repeated methylations to produce the fully alkylated products. A recent report (4) illustrates rapid permethylation of a glycolipid and a polysaccharide by methyl iodide in the presence of the methylsulfinyl carbanion (5) obtained from the reaction of sodium hydride with dimethyl sulfoxide.

We wish to draw attention to a methylating procedure which we have employed for some time, and which is rapid and quite broadly applicable, resulting in a clean reaction providing consistently excellent yields of readily isolable, fully methylated material. It involves the addition of sodium hydride to a solution of the hydroxy compound in 1,2-dimethoxyethane, or in dimethylformamide if the solubility of the compound is low in 1,2-dimethoxyethane, or in a mixture of the two solvents. Methyl iodide is added shortly after, or it may be present advantageously in the solution before, the addition of the sodium hydride to the reaction mixture. Yields are above 80%.

A similar procedure has been reported by Eades *et al.* (6) for the preparation of 1,5-anhydro-2,3,4,6-tetra-*O*-methyl-D-mannitol with tetrahydrofuran as solvent, and by Tate and Bishop (7) for the preparation of benzyl ethers with excess benzyl chloride as solvent.

The convenience and utility of this method prompted us to point out the work noted in the last two papers as well as our own experience. Details of our procedure are illustrated by the following two examples.

6-Methoxymethyl-5,6-dihydropyran

To a solution of 6-hydroxymethyl-5,6-dihydropyran[1] (68.4 g, 0.6 mole) and methyl iodide (99.5 g, 0.7 mole) in 350 ml of dried ($LiAlH_4$), distilled 1,2-dimethoxyethane, all contained in a 1 l, three-necked flask equipped with a condenser, dropping funnel, drying tube, and magnetic stirrer, was added 15.6 g (0.65 mole) of sodium hydride[2] over a period of 30 min. Vigorous hydrogen evolution took place after addition of each of the small portions of the hydride. Heat was evolved and sodium iodide precipitated. Ten minutes after the last of the hydride had been added, a further quantity (10 ml) of methyl iodide was added and the solution stirred at room temperature for 1 to 2 h. The 1,2-dimethoxyethane and excess methyl iodide were removed by distillation at atmospheric pressure until the volume was reduced to one-third. Anhydrous ether (60 ml) was added, whereupon more sodium iodide precipitated. The mixture was filtered, the sodium iodide was washed

[1]*Kindly donated by J. A. Craig, Shell of Canada Limited, Winnipeg, Manitoba.*

[2]*The sodium hydride (Metal Hydrides Corporation) was a 56% suspension in mineral oil. The oil was washed out with ether and the hydride obtained by filtration. Satisfactory results were obtained if this was kept covered during the interval of addition to the solution.*

with 20 ml of ether, and the combined washings and filtrate were distilled at atmospheric pressure to remove the bulk of the solvent. Residual 1,2-dimethoxyethane was removed at 100 mm pressure with a spinning-band fractionating column. Further distillation gave the product boiling at 83–84° and 65 mm, yield 70 g (91%), η_D^{27} 1.4400.

Anal. Calcd. for $C_7H_{12}O_2$: C, 65.60; H, 9.44. Found: C, 65.41; H, 9.30.

Methyl 2,3,4,6-Tetra-O-methyl-α-D-glucopyranoside

Into a three-necked flask equipped with an efficient condenser and a mechanical stirrer was placed anhydrous methyl α-D-glucopyranoside (9.7 g, 0.05 mole) dissolved in a mixture of 130 ml of dry dimethylformamide and 70 ml of 1,2-dimethoxyethane (previously dried and distilled from $LiAlH_4$). Methyl iodide (32.5 g, 0.23 mole) was added and the solution cooled to −10° by immersion of the flask for a time in a dry ice – acetone bath. About half of the sodium hydride[2] (total amount: 4.8 g, 0.02 mole) was added in small portions over a period of 7–8 min to the stirred solution. A gentle evolution of gas occurred and the reaction temperature rose slowly. Then the rest of the hydride was added all at once. When the temperature reached 30°, the reaction became vigorous, whereupon the flask was immersed in the dry ice – acetone bath. A maximum temperature of 60° was reached and maintained for about 5 min, and then dropped rapidly. The cooling bath was removed, and then the mixture was stirred for a time (total reaction time ~1 h) and finally poured cautiously into 600 ml of water containing 100 g of dissolved sodium chloride. The resulting mixture was extracted with chloroform (5 × 100 ml). The combined extracts were dried (Na_2SO_4) and freed of solvents by rotary evaporation and finally by distillation under vacuum at 2 mm with a bath temperature of 70 °C. The crude residue (11.5 g, 92%), when analyzed by gas–liquid chromatography on a 6 ft column of 20% butanediol succinate on Gas Chrom P (60–80 mesh) at 200° with a helium flow rate of 70 ml/min, consisted of only two substances: dimethylformamide (~4% on a molar basis) and the fully methylated glucoside. Removal of the residual dimethylformamide was accomplished by passage of the crude product through a column of Woelm neutral alumina (150 g), using successively the eluants (200 ml of each) benzene–pentane (7:4), benzene–chloroform (1:1), and benzene–chloroform (1:3). The sequence of increasing polarity of eluants was used to avoid the possibility of elution of the contaminating dimethylformamide. The higher polarity was required to remove the last portion of the pentamethyl glucoside from the strongly adsorbing column. When British Drug Houses alumina was used, the eluant benzene–pentane (7:4) was sufficient to remove selectively all of the glucoside. The resulting pure methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucoside (10.5 g, 84%) was identical in all respects with an authentic sample (3, 8). The infrared spectrum (neat) showed no absorption in the 3 600 – 3 300 cm^{-1} region (OH).

FACILE METHYLATION OF HUMIC ACIDS FROM ORGANIC SOILS[1]

HIROKAZU MORITA

The application of classical techniques of organic chemistry to the structural elucidation of soil humic acid has been fraught with difficulties because of the intractable, labile features of the macromolecule. Partial amelioration has been sought in the conversion of the natural product into stable derivatives. The presence of polyphenolic functions in the compound (1) makes methylation an obvious choice for derivatization.

Existing methylation techniques, however, suffer from various shortcomings; none are satisfactory for the humic acid isolated from organic soils. We now describe an efficacious methylation procedure which has lead to promising results. The procedure, moreover, appears to be applicable to other polyphenolic materials.

The experiment described below is based on the one described by McCredie (2) for the one-step methylation of galactomannan with dimethyl sulfate and powdered sodium hydroxide in dioxane or dimethyl sulfoxide. In our hands, the best results were obtained with dimethyl sulfoxide as the solvent.

The advantage of the methylation procedure described herein is evident when the results are compared with those obtained by five successive Haworth methylations under conditions whereby gallic acid is completely methylated (3). Permethylation according to this procedure gave a methylated humic acid containing 16.59% methoxyl, whereas the more direct procedure involving an initial methylation in aqueous alkali followed by a methylation in dimethyl sulfoxide gave a product whose methoxyl content was 21.78%.

The importance of the solvent for an efficient methylation of humic acid is demonstrated by experiments in which dimethyl sulfoxide was replaced by other organic solvents. For example, in tetrahydrofuran and dimethylformamide the derivative had methoxyl values of 15.88% and 8.06%, respectively.

The infrared absorption spectra of the potassium bromide disks and Nujol mulls, as well as the attenuated total reflectance spectra, of the methylated humic acid containing 23.85% methoxyl showed a weak absorption at 3 400 cm^{-1}, indicating the presence of residual hydroxyl groups or absorbed moisture.

Modified Haworth methylations in organic media have been known for some time in carbohydrate chemistry (4). The utility of these procedures with phenolic materials appears to have been overlooked. The efficacy of methylations undertaken in dimethyl sulfoxide has been observed in this laboratory with unsaturated and polyphenolic acids which are fully methylated in one operation. For example, *p*-coumaric, caffeic, gallic, and *m*-digallic acids are smoothly converted into the corresponding dimethyl, trimethyl, tetramethyl, and hexamethyl derivatives.

EXPERIMENTAL

Starting Material

The soil samples, which were obtained from Alfred, Ontario, have been described earlier (5). The humic acid was isolated by a method described by Smith and Lorimer (6) involving five successive extractions with 0.2 *M* sodium hydroxide. The final freeze-dried product gave the following elemental analysis: C, 55.88%; H, 5.88%; N, 2.04%; OCH_3, 2.24%.

Methylation

Humic acid (1 g) was dispersed in 12% aqueous sodium hydroxide (20 ml) under nitrogen; after the addition of potassium borohydride (0.3 g), the reactants were set aside overnight, with continuous stirring.

[1]*Contribution No. 192 from the Soil Research Institute.*

To the reduced material cooled in a cold-water bath, 30% aqueous sodium hydroxide (17.5 ml) and dimethyl sulfate (17.5 ml) were added in portions and alternately over 6 h. Stirring, under nitrogen, was continued throughout the addition of the reagents and overnight.

Next, water (50 ml) was added to the reaction mixture and the aqueous solution heated on a steam bath for 1 h. After the methylation mixture was cooled in ice, it was acidified with 6 *N* sulfuric acid. The resulting light-brown precipitate was separated by centrifugation, thoroughly washed with water, freeze-dried, and finally dried *in vacuo*.

The partly methylated humic acid was dispersed in dimethyl sulfoxide (60 ml) (spectro grade, Eastman Kodak) and cooled. Then powdered sodium hydroxide (5.5 g) was added. The mixture was stirred under nitrogen, and dimethyl sulfate (12.5 ml) was added in portions periodically over 6 h. Stirring was continued overnight at room temperature.

The isolation of the permethylated product was accomplished by initially adding water (60 ml) to the reaction mixture to dissolve the alkali. The alkaline solution was then neutralized with 6 *N* sulfuric acid. Finally, the precipitate was isolated by centrifugation, washed thoroughly with water, freeze-dried, and dried *in vacuo*. The methylated derivative (1 g) gave the following analysis: C, 62.90%; H, 7.06%; N, 0.88%; OCH_3, 21.78%. A second methylation in dimethyl sulfoxide gave a product containing 23.85% methoxyl. The methoxyl contents of the methylated humic acids reported in the literature (1) have generally been less than 20%.

The substitution of an equal volume of tetrahydrofuran for dimethyl sulfoxide gave, after two successive methylations, a product whose elemental analysis showed C, 58.62%; H, 5.97%; N, 1.37%; OCH_3, 15.88%. When dimethylformamide was used, the methylated product contained C, 57.45%; H, 5.77%; N, 1.80%; OCH_3, 8.06%.

Haworth Methylation

Humic acid (1 g) was treated with potassium borohydride and methylated as described above. Subsequent methylations in aqueous media consisted of alternate additions of 30% aqueous sodium hydroxide (17.5 ml) and dimethyl sulfate (12.5 ml) to a solution of the partly methylated derivative in 0.3 *M* sodium hydroxide (50 ml), the reagents being added, with stirring, under nitrogen. The work-up and isolation of the product were performed as outlined in the previous methylation. Three methylations were carried out in this manner.

The final methylation was carried out by dissolving the partly methylated derivative in a solution of sodium hydroxide (3 g) and sodium carbonate (8 g) in water (50 ml), and adding dimethyl sulfate (12.5 ml) according to the procedure outlined for the preparation of methyl 3,4,5-trimethoxybenzoate (3). The resulting product gave the following analyses: C, 60.13%; H, 6.44%; OCH_3, 16.58%.

2,3;5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone was treated with diborane in tetrahydrofuran according to Brown and Subba Rao (1, 2). It was found that the original product was recovered. Reduction did not occur, probably owing to the steric hindrance of the substituent groups. Treatment of 2,3;5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone with diborane in the presence of acetic acid did not cause any reduction.

The reduction of 2,3;5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone, 2,3-*O*-isopropylidene-D-gulono-1,4-lactone, 2,3-*O*-isopropylidene-D-ribono-1,4-lactone, and 2,4-dihydroxy-3,3-dimethylbutanoic acid 1,4-lactone was effected in ether or tetrahydrofuran solution containing a suspension of sodium borohydride to which the calculated amount of acetic acid was added, to yield 75 to 80% of the corresponding derivatives of D-gulose, D-ribose, and butanal.

The new procedure offers an improved method for the reduction of substituted aldonolactones to aldose derivatives over the classical method involving reduction, in aqueous media, of aldonolactones with sodium amalgam (3, 4) or sodium borohydride under controlled pH conditions (5). It also offers a new and easy method for the preparation of substituted aldoses which are difficult to synthesize by other routes, particularly 2,3-*O*-isopropylidene derivatives.

EXPERIMENTAL

2,3;5,6-Di-O-isopropylidene-D-gulose

To a stirred mixture of 2,3;5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone (200 mg) and sodium borohydride (190 mg) in anhydrous ether (50 ml), glacial acetic acid (0.5 ml) in ether (10 ml) was added over 30 min. After 2½ h at room temperature, acetone (2 ml) was added and stirring was continued for 30 min. Sodium hydroxide (4.5 ml, 2 *N*) was then added followed by a saturated sodium chloride solution (10 ml). The ether layer was removed, dried (anhydrous Na_2SO_4), and filtered, and the filtrate concentrated. The residue was crystallized from an ether – light petroleum ether (40–60°) mixture to yield 2,3;5,6-di-*O*-isopropylidene-D-gulose (140 mg, 70%), which had m.p. 114–115° and $[\alpha]_D$ −6.3° (*c*, 0.9 in water) (6).

Anal. Calcd. for $C_{12}H_{20}O_6$: C, 55.4; H, 7.7. Found: C, 55.2; H, 7.9.

The hydrolyzed di-*O*-isopropylidene-D-gulose, when subjected to paper chromatographic analysis, showed a single spot having chromatographic behavior identical with that of authentic D-gulose.

2,3-O-Isopropylidene-D-gulose

To a stirred suspension of sodium borohydride (190 mg) in dry tetrahydrofuran (80 ml) containing 2,3-*O*-isopropylidene-D-gulono-1,4-lactone (200 mg), glacial acetic acid (0.45 ml) in tetrahydrofuran (5 ml) was added over 1 h at room temperature. After 3½ h acetone (2 ml) was added. After 15 min the solid material was filtered off and the filtrate was concentrated to a syrup. A chromatographic examination of the hydrolyzed (*N* sulfuric acid, 1 h at 100°) syrup showed three spots having chromatographic behavior identical with that of authentic D-gulose, D-gulono-1,4-lactone, and L-glucitol. D-Gulose was estimated by the colorimetric phenol – sulfuric acid method (7) to constitute 80% of the product.

2,3-O-Isopropylidene-D-ribose

To a stirred solution of 2,3-*O*-isopropylidene-D-ribono-1,4-lactone (600 mg) in anhydrous ether (50 ml), sodium borohydride (600 mg) and glacial acetic acid (1.5 ml) in ether (15 ml) were added simultaneously over 1 h. After 3 h acetone (6 ml) was added and stirring was continued for 30 min. The solid was removed by filtration and washed with ethyl acetate. The filtrate was evaporated to dryness, and the residue was dissolved in water (15 ml) and deionized by passing it through Amberlite IR-120 (H^+) and Duolite A_4 (OH^-) resins. The eluate was concentrated to a syrup (450 mg). The hydrolyzed syrup, when subjected to paper chromatographic analysis, showed two spots having chromatographic behavior identical with that of authentic D-ribose and ribitol, ribose (75%) being the main product.

N-Phenyl-D-ribopyranosylamine

The syrup (320 mg) containing D-ribose and ribitol was dissolved in water (2 ml), and aniline (200 mg) in ethanol (4 ml) was added. After the mixture was shaken for 10 min, it was kept at 5° for 18 h. The crystalline *N*-phenyl-D-ribopyranosylamine was collected by filtration and washed with cold ethanol (250 mg), m.p. 115–117°, $[\alpha]_D$ +63° → +48° (*c*, 1.1 in pyridine) (8, 9).

2,4-Dihydroxy-3,3-dimethylbutanal

To a stirred mixture of sodium borohydride (2 g) and pantoyllactone (2,4-dihydroxy-3,3-dimethylbutanoic acid 1,4-lactone) (2 g) in absolute ether (200 ml) was added acetic acid (5 ml) in ether (15 ml) over 4½ h. Powdered potassium carbonate (2.5 g) and acetone (10 ml) were added to the reaction mixture and the solid materials were removed by filtration. The concentrated filtrate was extracted with chloroform. Removal of

For personal use only.

the solvent gave a syrup (1.6 g) which failed to crystallize. The syrup was treated with 2,4-dinitrophenylhydrazine reagent (10) to yield the crystalline 2,4-dinitrophenylhydrazone derivative of 2,4-dihydroxy-3,3-dimethylbutanal, which, on recrystallization from an acetic acid – ether mixture and from benzene, gave a product (320 mg) which had m.p. 173–174°.

Anal. Calcd. for $C_{12}H_{16}O_6N_4$: C, 46.1; H, 5.2; N, 18.0. Found: C, 45.9; H, 5.6; N, 18.3.

*Attempted Reduction of 2,3;5,6-Di-O-isopropylidene-*D*-gulono-1,4-lactone with Diborane and with Diborane in the Presence of Acetic Acid*

Diborane was generated (1) by treating boron trifluoride etherate (4.1 g, 0.03 mole) and sodium borohydride (0.7 g, 0.02 mole), and was passed through a solution of 2,3;5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone (0.51 g, 0.002 mole) in tetrahydrofuran (50 ml) over 40 min under an atmosphere of nitrogen. The reaction mixture was allowed to stand at room temperature for 2½ h. Ethanol (5 ml) was added to destroy the excess of diborane. The solution was evaporated to dryness and the residue was recrystallized from an ether – light petroleum ether (40–60°) mixture to yield the starting material (0.4 g), m.p. 153–154°. The mixed melting point with the starting material was undepressed.

The above diborane reduction was repeated with tetrahydrofuran containing 0.1 ml of acetic acid as the solvent. Starting material was recovered from this reaction.

NUCLEAR MAGNETIC RESONANCE STUDY OF 2,3-QUINOXALINEDICARBOXALDEHYDE AND ITS CYCLIC MONOHYDRATE[1]

Emil J. Moriconi, James W. Young,[2] Thomas E. Brady, and Albert J. Fritsch

The formation of stable isolable hydrates of aldehydes and ketones requires the presence of a strong, electronegative atom bonded to the α-carbon (as in chloral, glyoxal, glyoxalic and mesoxalic acids, hexafluoroacetone, and triketoindane). Recently, we reported the preparation of 2,3-quinoxalinedicarboxaldehyde (I), which was isolated in the presence of water as the cyclic monohydrate II (1). In I, the electronic effects of the ring aza-atoms must enhance the additive power of the carbonyl groups such that reaction with water is rapid and complete. Since 2-quinoxalinecarboxaldehyde does not form a hydrate (2), the driving force for cyclic monohydrate formation must come not only from the severe dipole–dipole repulsions in I but also from the stability of the five-membered ring in II.

I II

This seems to be the first reported instance of the isolation and interconversion of an aromatic *o*-dialdehyde and its cyclic monohydrate in which 1 equivalent of water is chemically bound.[3] We now report on the structure and interconversion of I and II as determined by nuclear magnetic resonance (n.m.r.).

Compound II was prepared in 60% yield by the dimethyl sulfoxide (DMSO) oxidation of 2,3-bis(bromomethyl)quinoxaline. In the infrared (KBr), II showed no C=O band, but did display a strong, sharp, bonded OH absorption at 3.18 μ. The insolubility of II in the conventional solvents used to distinguish between inter- and intra-molecularly hydrogen-bonded OH groups precluded such measurements. Further, Dreiding models showed no special preference for either the *cis* or *trans* isomer. The *cis* isomer, however, would permit the formation of a weak intramolecular O—H · · · O bond. Compound II lost water when it was heated, and melted at 176.5–177° (decomp.). Sublimation of II at 110–120° and 2 mm then gave, as expected, I, m.p. 177–178° (decomp.); recrystallization of I from boiling water led to II as the only isolable product. Compound I showed a strong, sharp C=O band at 5.81 μ (KBr). Both I and II displayed typical quinoxaline absorption in the ultraviolet (1): I, $\lambda_{max}^{absolute\ EtOH}$ 238 mμ (ϵ 28 100) and 322 mμ (ϵ 9 100); and II, $\lambda_{max}^{95\%\ EtOH}$ 238 mμ (ϵ 30 400) and 322 mμ (ϵ 8 100).

Five n.m.r. spectra (60 Mc.p.s.) are compiled in Fig. 1. The spectrum (A) of I dissolved in DMSO-d_6 showed an aromatic multiplet centered at δ = 8.00 and aldehyde protons as a sharp singlet at δ = 10.28, with an intensity ratio of 2:1. In spectrum C, I was dissolved in DMSO and diluted with water; its spectrum displayed an aromatic multiplet centered at δ = 8.12, a pair of doublets centered at δ = 6.39 and 6.35, and a three-peak pattern centered at δ = 7.36, in the relative area ratio 2:1:1. Each of the doublets was assigned to a methine proton coupled with its respective hydroxyl proton; the appearance of a pair of doublets could be accounted for by the presence of a 1:1 *cis–trans* hydrate mixture in solution. The pattern centered at δ = 7.36 (assigned to OH protons) would then also be a pair of doublets (arising from OH being split by the CH) merging to appear as a triplet. In spectrum B, I was dissolved in DMSO-d_6 and diluted 40% by volume with D_2O. As expected, the aromatic multiplet (δ = 8.12, four protons) remained but the OH resonances had disappeared as a result of deuterium exchange. Also, the CH protons, no longer coupled, appeared as a pair of singlets (δ = 6.63 and 6.36, intensity ratio 1:1), each assignable to the pair of CH protons in each isomer of the 1:1 *cis–trans* mixture. Thus, the n.m.r. data suggested that solutions of I in DMSO with D_2O (spectrum B) and H_2O (spectrum C) consisted of 1:1 equilibrium mixtures of *cis* and *trans* hydrate.

Spectrum D, which is that of II dissolved in DMSO-d_6, showed, in addition to the aromatic multiplet (four protons), two doublets centered at δ = 7.36 (OH, two protons, J = 8 c.p.s.) and 6.48 (CH, two protons, J = 8 c.p.s.). The appearance of this simple AB pattern suggested that recrystallization of II from water had led to the isolation of only the single, and probably less soluble, *cis* or *trans* isomer. When the n.m.r. sample of spectrum D was diluted 40% by volume with D_2O, spectrum B was again obtained.

Finally, hydrate II was recrystallized from boiling D_2O, and the precipitated white, crystalline solid was separated and dried at room temperature for several days *in vacuo*.

[3]*Compare with the three examples of aliphatic cyclic monohydrate formation mentioned in ref. 3.*

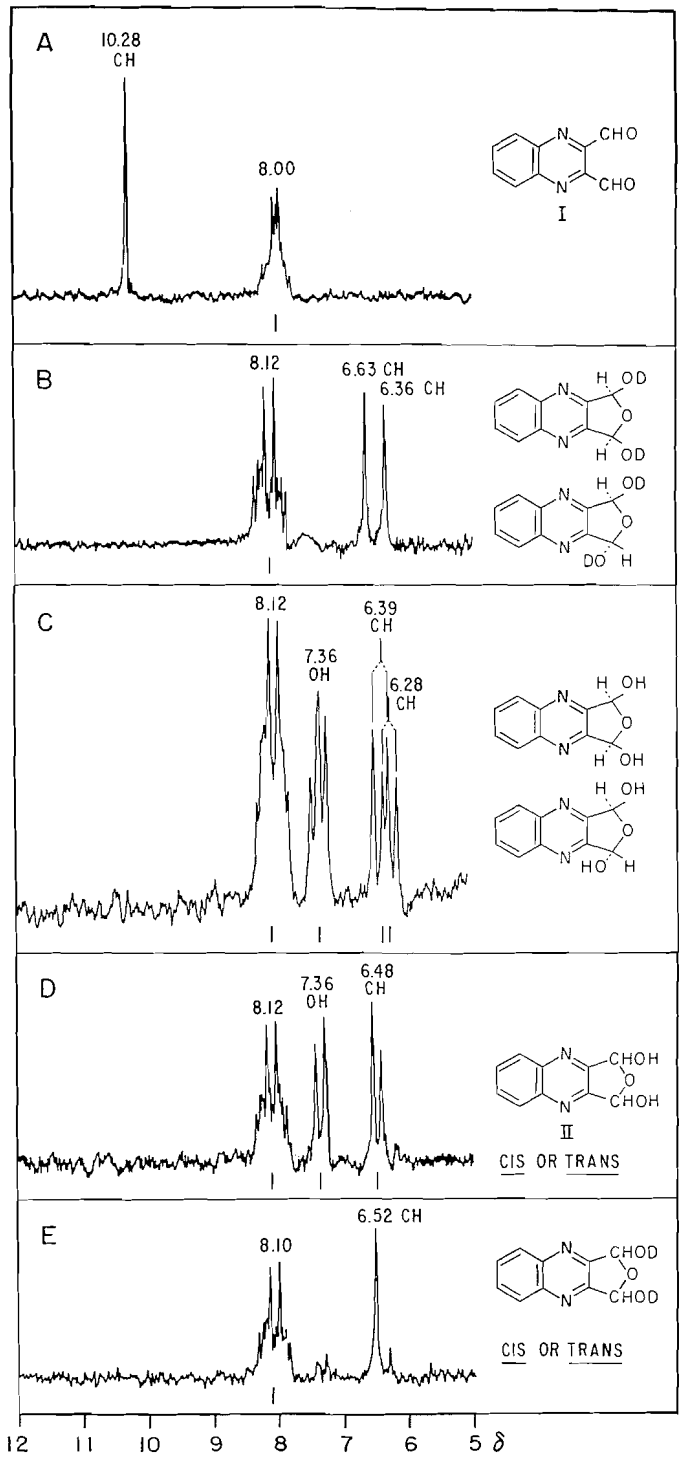

FIG. 1. All spectra were determined on a Varian A-60 spectrometer with tetramethylsilane as an internal reference. Spectrum A, I in DMSO-d_6; spectrum B, sample for spectrum A diluted 40% by volume with deuterium oxide; spectrum C, I in DMSO and diluted 40% by volume with water; spectrum D, II in DMSO; spectrum E, II recrystallized from deuterium oxide and dissolved in DMSO-d_6.

The n.m.r. spectrum of this material in DMSO-d_6 is recorded in spectrum E. The appearance of a sharp CH singlet at $\delta = 6.52$ confirmed the selective precipitation of only one of the two possible geometric isomers. As expected then, dilution of this last n.m.r. sample with D_2O led again to spectrum B.

AMÉLIORATION DE LA SYNTHÈSE DES DI- ET TRI-BROMHYDRINES DU PENTAÉRYTHRITOL

M. Saucier, C. Sauriol et R. L. Salvador

Un besoin de quantités appréciables des di- et tri-bromhydrines du pentaérythritol comme matières premières pour la synthèse de nouveaux composés cycliques nous incita à mettre au point une méthode mieux adaptée à la préparation de grandes quantités de ces dérivés bromés. Nous nous sommes principalement inspirés de la méthode proposée par Cheymol et ses collaborateurs (1) pour la synthèse de la tribromhydrine du pentaérythritol, laquelle est une modification de la méthode de Govaert et Beyaert (2) pour éviter l'opération en vase clos. Nous avons modifié cette méthode de façon à travailler avec le gaz bromhydrique anhydre en milieu acétique et à pression atmosphérique. Cette technique nous a permis de réduire le temps de réaction de 60 h à 20 h et d'obtenir des rendements plus élevés, soit 90% au lieu de 68% de la tribromhydrine du pentaérythritol V. Ces modifications nous ont aussi permis de préparer le dérivé dibromé VI en 12 h avec des rendements de l'ordre de 85%.

Les différentes étapes de la synthèse des dérivés di- et tri-bromés sont montrées dans le Schéma Réactionnel 1. La première étape (A) consiste en la transformation du pentaérythritol I en tétraacétate II ; en effet, la substitution des acétates par le brome se fait plus facilement que la substitution directe de la fonction hydroxylique (3, 4). Il n'est pas utile d'isoler le tétraacétate ainsi formé car il se trouve déjà dans le milieu réactionnel nécessaire à la bromuration. La deuxième étape (B) consiste en la bromuration du tétraacétate II. Quoique les deux premiers bromes se fixent assez facilement (IV), la substitution par le brome du troisième groupe acétate se fait difficilement (III). Cependant, en opérant en milieu acétique saturé d'acide bromhydrique, et en maintenant un flot constant d'acide bromhydrique, on peut ainsi obtenir des conditions aussi favorables qu'en tube scellé. SCHÉMA RÉACTIONNEL 1.

troisième étape (C) consiste en la régénération des fonctions hydroxyliques. Cette réaction s'effectue par transestérification à l'aide de l'alcool méthylique anhydre (5). La formation de la dibromhydrine VI nécessite des conditions réactionnelles moins vigoureuses. Pour prévenir la formation du dérivé tribromé V, il est important de ne pas opérer avec un trop grand excès d'acide bromhydrique. L'excès requis est de l'ordre de 10 à 12%. Celui-ci contribue à combler le déficit d'acide bromhydrique provenant de l'évaporation par chauffage de la réaction.

PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés au capillaire dans un appareil electrothermal à bloc d'aluminium et ne sont pas corrigés.

Tribromhydrine du pentaérythritol

Dans un ballon de 5 l à encolures multiples, muni d'un refrigérant dont l'extrémité supérieure est reliée à un système de trappes contenant de l'acide acétique glacial, on ajoue 544 g (4 moles) de pentaérythritol et 3 200 ml d'acide acétique glacial. On relie ensuite le ballon à un cylindre d'acide bromhydrique anhydre et on porte le mélange à l'ébullition pendant 20 h, tout en maintenant à un fort débit le flot d'acide bromhydrique. Le temps de chauffage écoulé, on évapore l'acide acétique sous pression réduite. On reprend le résidu par 800 ml de toluène que l'on évapore de même. Cette dernière opération a pour but d'entraîner azéotropiquement l'eau de la réaction. On ajoute alors au résidu 1 350 ml d'alcool méthylique anhydre, on y dissout une quantité catalytique d'acide bromhydrique anhydre et on distille lentement à pression atmosphérique. L'azéotrope d'acétate de méthyl – alcool méthylique passe à 53.8 °C. On poursuit cette distillation jusqu'à obtention de la quantité théorique d'acétate de méthyl soit environ 375 ml du mélange azéotropique. On élimine ensuite l'alcool méthylique résiduel par distillation rapide sous vide. On dissout alors le résidu solide dans 5 l de toluène bouillant et on traite au charbon décolorant (Darco G-60). On obtient, par refroidisement, comme produit secondaire, 60 g (6%) de bis-bromométhyl-2,2-propanediol-1,3, que l'on recrystallise dans le toluène, p.f. 109–110 °C (litt. (6) p.f. 110 °C).

On évapore le filtrat et on recrystallise le résidu dans le cyclohexane. On obtient ainsi 1 165 g (90%) de bis-bromométhyl-2,2-bromo-3-propanol-1, p.f. 68–69 °C (litt. (6) p.f. 70–71 °C).

Dibromhydrine du pentaérythritol

On prépare la dibromhydrine du pentaérythritol dans un ballon de 5 l comme pour le dérivé tribromé à partir de 4 moles de pentaérythritol dans 3 200 ml d'acide acétique glacial. On porte le mélange à l'ébullition et on sature avec l'acide bromhydrique anhydre jusqu'à obtention d'un gain de poids de 720 g, soit un excès de 72 g calculé pour deux bromes. On cesse alors l'addition d'acide bromhydrique et on continue le chauffage pendant 8 à 10 h. Après environ 4 h, on évalue par pesée la perte d'acide bromhydrique et on compense par une nouvelle addition du gaz jusqu'à obtention de l'excès initial. On poursuit alors le chauffage jusqu'à la fin de la réaction. On élimine l'acide acétique sous vide et on traite le résidu de la même façon que pour la tribromhydrine. La transestérification achevée, on dissout le residu solide dans le toluène à chaud, on traite au charbon et on obtient, par refroidissement, 890 g (85%) de bis-bromométhyl-2,2-propanediol-1,3, p.f. 109–110 °C.

PYROLYSIS OF DIMETHYLETHANOLAMINE OXIDE MONOHYDRATE

GARSON P. SHULMAN[1]

The pyrolysis of dimethylethanolamine oxide was selected as a means of generating acetaldehyde at moderate temperatures from a nonvolatile and relatively nonreactive precursor. The decomposition of trialkylamine oxides to olefin and dialkylhydroxylamine (Cope reaction) is known to proceed in good yield via a cyclic intramolecular transition state (1). The pyrolysis of some N,N-dimethyl-2-hydroxy-cycloalkylamine oxides has been reported (2). These give allylic alcohol and ketone (via enol), in a ratio ranging from 5:1 to 20:1, where stereochemical factors permit competitive elimination. Since only elimination toward the hydroxyl group is possible in dimethylethanolamine oxide, one would predict that the vinyl alcohol – acetaldehyde tautomeric system would be the principal product unless the rate of elimination were so slow that deoxygenation (3) or oxazoline formation (2) became significant. An explosion occurred during the initial preparative-scale pyrolysis. Experiments were then directed toward determination of the products and kinetics of the reaction to ascertain the cause of the violent reaction, and to see whether decomposition could be effected via a controlled reaction.

EXPERIMENTAL

Preparation of Amine Oxides

A mixture of 75 ml of isopropyl alcohol and 75 ml of 50% hydrogen peroxide was placed in a flask thermostatted at 50°. With vigorous stirring, 1.0 mole of amine was added dropwise. The homogeneous mixture was maintained at 50° for several hours; then stirring was resumed and volatile material was removed under reduced pressure. The products were analyzed for amine and amine oxide by nonaqueous acidimetric titration (3). The reaction times and analyses are shown in Table I.

Pyrolysis of Dimethylethanolamine Oxide Monohydrate

A 25 g sample was placed in a vacuum distillation apparatus, with the receiving flask cooled by dry ice – acetone. Heating with a microburner was continued until the temperature reached 110°. The temperature rose rapidly to about 180°; then the flask exploded.

A 0.5 g sample was placed in a flask fitted with a stopcock and a rubber seal. The flask was evacuated, a 10 ml hypodermic syringe (lightly greased) was inserted through the seal, and then the sample was heated with a microburner until the syringe was filled. The contents were immediately injected into the gas chromatograph (6 ft silicone oil column at 80°). Three peaks, identified as water, acetaldehyde, and dimethylhydroxylamine (by retention times), were obtained. These identities were confirmed by mass spectrometry of the eluted samples after degradation in a Perkin–Elmer pyrolysis unit at 200°. Because the water peak showed extensive tailing, a rigorous quantitative determination was not attempted. From peak areas, a molar ratio of water to acetaldehyde to dimethylhydroxylamine of about 2:1:1 was estimated.

The rate of reaction was determined at 127.5° in the manner described previously (3, 4). A rate constant of $(2.8 \pm 0.2) \times 10^{-5}$ s^{-1} was obtained.

A 3 μl sample was pyrolyzed in a duPont model 900 differential thermal analysis (DTA) apparatus (5) at a heating rate of 20°/min. The DTA curve is shown in Fig. 1.

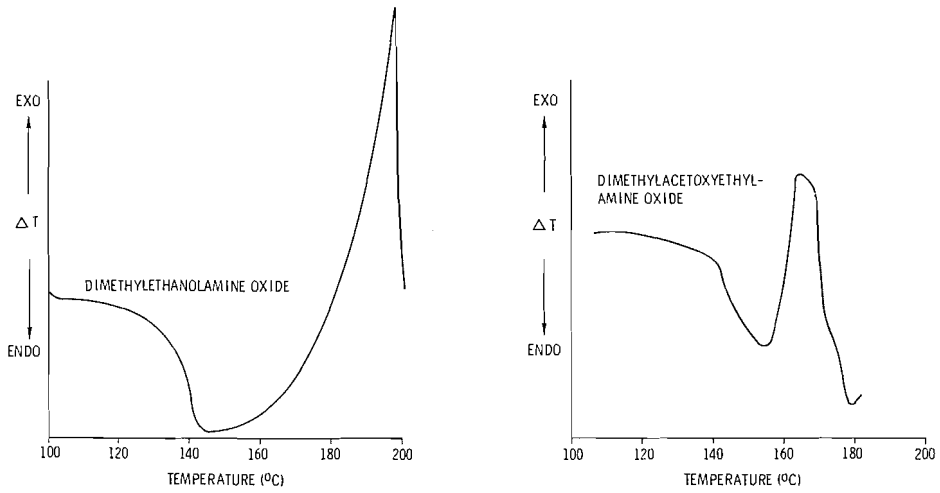

FIG. 1. DTA of dimethylethanolamine oxide and dimethyl-2-acetoxyethylamine oxide.

A 6.78 mg sample was placed in the tungsten crucible of the Knudsen cell inlet of a Bendix time-of-flight mass spectrometer and heated at a rate of 14°/min. Spectra were recorded at 1 min intervals; then the heights of peaks characteristic of each product were plotted versus temperature. The mass spectrometric thermal analysis (MTA) curve is shown in Fig. 2. The activation energies for the formation of each product were derived from the linear portion of semilogarithmic plots of peak height versus reciprocal temperature (water 6.2, acetaldehyde 32, dimethylhydroxylamine 36, and dimethylethanolamine 20 kcal $mole^{-1}$).

Differential Thermal Analysis of Dimethyl-2-acetoxyethylamine Oxide Monohydrate

A DTA taken on a 3 μl sample at a heating rate of 20°/min is shown in Fig. 1.

Pyrolysis of 2-Dimethyloxamino-2-methyl-1-propanol

A 5.0 g sample was added dropwise to a distilling flask (at 150 ± 5°) which formed part of a microdistillation apparatus. Gas chromatographic analysis (6 ft silicone oil column at 80°) of the distillate showed four components: dimethylhydroxylamine, water, and a 23:1 ratio of methallyl alcohol to isobutyraldehyde.

DISCUSSION

The expected products from the pyrolysis of dimethylethanolamine oxide monohydrate, i.e. water, dimethylhydroxylamine, and acetaldehyde, were observed gas chromatographically. Based on the mass spectra of the products, characteristic peaks of m/e 17 for water, 29 (CHO) for acetaldehyde, and 58 for dimethylhydroxylamine were selected for

For personal use only.

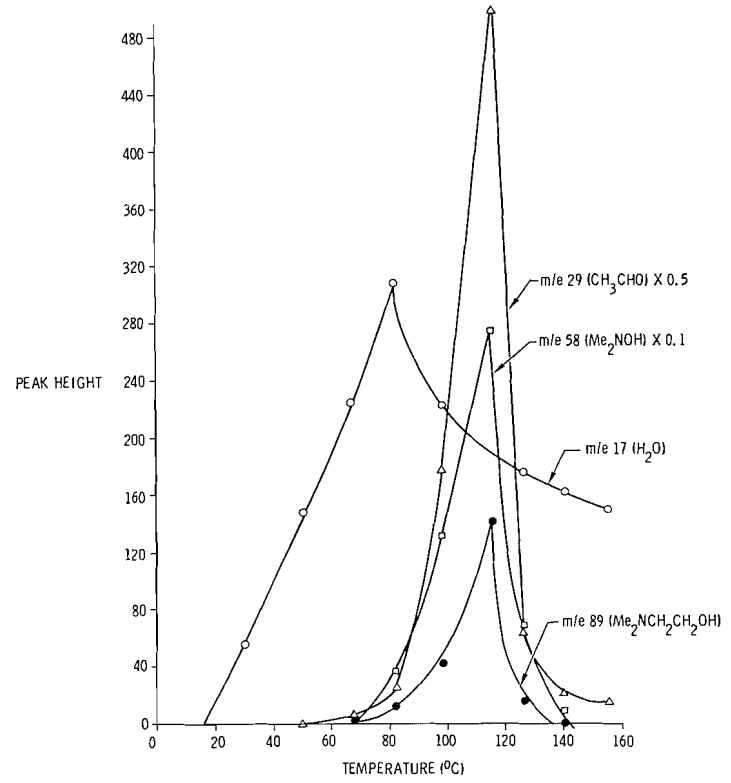

FIG. 2. MTA of dimethylethanolamine oxide.

the MTA.[2] The only identifiable peaks observed in the MTA in addition to those from fragmentation of the three principal products were peaks characteristic of an amine with a molecular ion at *m/e* 89. This must be dimethylethanolamine formed by deoxygenation of the amine oxide. No corresponding increase in the *m/e* 32 or 34 peaks was observed; hence, deoxygenation does not proceed with liberation of oxygen or hydrogen peroxide.

It is also possible to derive activation parameters from the MTA data. Based on the assumption that, in the rapidly pumped vacuum system of the mass spectrometer, the intensity of the characteristic ion is proportional to the rate of production of a species, a plot of log peak height versus reciprocal temperature should be linear as long as the concentration of the reactant is essentially unchanged. For olefin formation, an activation energy of 34 ± 2 kcal mole^{-1} was observed, based on the average for acetaldehyde and dimethylhydroxylamine; for deoxygenation the value is 20 kcal mole^{-1}, and for dehydration 6.2 kcal mole^{-1}. These values agree well with those of 36.3 and 20.6 kcal mole^{-1} determined for corresponding reactions of dimethyllaurylamine oxide. The activation energy for dehydration is in the range which one would expect for breaking a hydrogen bond.

It is clear from the MTA curve (Fig. 2) that dehydration precedes elimination, as has been postulated previously based on kinetic evidence (6). The DTA (Fig. 1) also shows

[2]*The m/e 18 peak for water was off scale. The m/e 43 peak was a major dimethylhydroxylamine fragment, and was therefore not characteristic for acetaldehyde. Only a minor molecular ion (61) peak was observed for dimethylhydroxylamine. The spectra of dialkylhydroxylamines will be reported subsequently.*

a two-stage reaction: an endotherm (dehydration) followed by an exotherm (degradation). Dimethylethanolamine oxide decomposition releases several times more energy than decomposition of its acetate ester. This extra energy must be derived from the isomerization of vinyl alcohol to acetaldehyde.

There seems to be a marked effect of pressure on the reaction. The preparative pyrolysis became uncontrollable at about 110°, and the maximum rate in the MTA is observed at 115°. In contrast, the DTA shows degradation occurring at 140–200°, and a slow rate of reaction was measured at 127.5° under atmospheric pressure. The enhanced rate *in vacuo*, which leads to an uncontrollable reaction on a preparative scale, is no doubt due to the greater use of removing water from the hydrate and the resulting rapid decomposition of anhydrous amine oxide, as shown by Sahyun and Cram (6).

Determination of the relative rates of aldehyde and allylic alcohol formation was accomplished by the competitive intramolecular reaction of 2-dimethyloxamino-2-methyl-1-propanol. The 23:1 ratio of methallyl alcohol to isobutyraldehyde shows that elimination of the methylol hydrogen is slower than that of the methyl hydrogen. If one compensates for the number of hydrogens of each type available (6:2), elimination toward a methylol group is about one-eighth as fast as that toward methyl. The corresponding factor for secondary alcohol – methylene competition ranges from 0.1 to 0.4 (2).

CHÉLATES DU GERMANIUM(IV) AVEC LA TROPOLONE, LE MALTOL, LA LAWSONE ET LA TRICHLOROHYDROXY *p*-BENZOQUINONE[1]

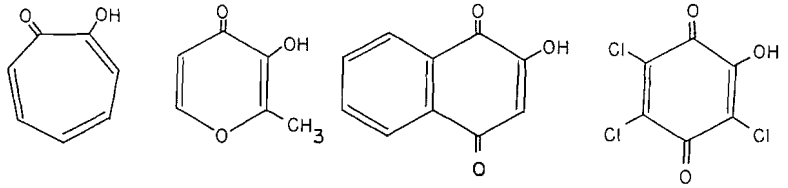
I. PROPRIÉTÉS ACIDES-BASES DES α-HYDROXYCÉTONES

A. BEAUCHAMP[2] ET R. L. BENOIT

Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 14 décembre 1965

RÉSUMÉ



Les constantes de dissociation k_1 des α-hydroxycétones HL tropolone, maltol, lawsone et trichlorohydroxy *p*-benzoquinone sont déterminées en milieu de force ionique 0.50; les valeurs des pk_1 obtenues sont respectivement: 6.67 ± 0.04; 8.36 ± 0.03; 4.00 ± 0.04; 1.05 ± 0.04. La formation d'acides conjugués H_2L^+ en milieu fortement acide est également étudiée et les valeurs des constantes pk_2 basées sur la fonction d'acidité H_0 sont: −0.53 ± 0.10; −0.71 ± 0.10; −5.6 ± 0.2; −8.8 ± 1.0.

ABSTRACT

The acidity constants k_1 of the following α-hydroxyketones HL tropolone, maltol, lawsone, and trichlorohydroxy *p*-benzoquinone have been determined at ionic strength 0.50 (HCl, NaCl). The values of pk_1 are respectively: 6.67 ± 0.04; 8.36 ± 0.03; 4.00 ± 0.04; 1.05 ± 0.04. The formation of conjugated acids H_2L^+ in strongly acidic media has also been studied. The values of pk_2 defined in terms of the acidity function H_0 are: −0.53 ± 0.10; −0.71 ± 0.10; −5.6 ± 0.2; −8.8 ± 1.0.

INTRODUCTION

En vue d'une étude des chélates de la tropolone (I), du maltol (II), de la lawsone (III) et de la trichlorohydroxy *p*-benzoquinone (TCHQ) (IV) avec le germanium(IV), nous avons examiné en premier lieu les propriétés acides–bases de ces α-hydroxycétones HL. Les valeurs des constantes des équilibres acides–bases sont requises pour caractériser les chélates en solution et permettent d'établir des corrélations entre les propriétés basiques des atomes d'oxygène coordinés et la stabilité des chélates.

I II III IV

Il s'est révélé nécessaire de redéterminer les valeurs des constantes d'acidité k_1, celles relevées dans la littérature correspondant au milieu eau–dioxanne (1) ou à des forces ioniques différentes (2–8). A notre connaissance, la formation des acides conjugués H_2L^+

[1]*Tiré d'une communication présentée lors du 48ième Congrès de l'Institut de Chimie du Canada, tenu à Montréal les 31 mai – 2 juin 1965.*

[2]*Boursier du Conseil National de Recherches 1964–1965 et de l'Hydro-Québec 1965–1966.*

n'a été étudiée précédemment que dans le cas de la tropolone (2). Nous avons donc déterminé les constantes de dissociation k_2 de ces acides H_2L^+.

PARTIE EXPÉRIMENTALE

Réactifs

Tropolone.—Le produit brut a été sublimé à 25–30° (0.5 Torr) et il a un p.f. 49–50° (litt. (5) 49–50°). L'analyse élémentaire (Galbraith Lab.) indique 68.59% C, 4.86% H (calc. pour $C_7H_6O_2$: 68.84% C, 4.95% H). La densité optique des solutions est sensible à la présence d'air dissous, particulièrement en milieu basique. Les solutions ont été préparées immédiatement avant l'expérience, avec de l'eau bouillie et saturée d'azote et les mesures ont été faites sous atmosphère d'azote.

Maltol.—Le produit de Aldrich Chemical Co., sublimé deux fois à 60 ± 5° (0.2–1.5 Torr), a un p.f. 159° (litt. (9) 158–160°) et l'analyse élémentaire indique 57.09% C, 4.83% H (calc. pour $C_6H_6O_3$: 57.15% C, 4.80% H). Les solutions-mères neutres ou peu acides sont conservées au maximum 5 jours durant lesquels la densité optique reste constante.

Lawsone.—Le produit de Aldrich Chemical Co. a un p.f. 195–196° (décomp.) (litt. (10) 195–196° (décomp.). Le titrage par NaOH du produit dissous dans l'acétone à 50% indique une pureté de 99.6 ± 0.4%. Le produit a été utilisé sans autre purification.

TCHQ.—Le produit a été préparé à partir du chloranil, selon la méthode suggérée par Hancock *et al.* (11). Le produit de la réaction a été extrait par CH_2Cl_2 et le solvant a été évaporé: l'acide chloranilique présent comme impureté dans le produit ainsi traité à trois reprises (p.f. 197–198°, litt. (11) 198–199°) est inférieur à 0.7%, comme l'indique l'examen du spectre d'une solution à pH 4 dans la région de 325 mμ. Les solutions-mères ont été préparées en milieu acide, immédiatement avant l'expérience.

Les autres produits utilisés sont des réactifs purs pour analyse.

Technique expérimentale

Les mesures de densité optique ont été effectuées au moyen des spectrophotomètres Zeiss QII et Bausch & Lomb 505, avec une gamme de cuvettes de quartz dont l'épaisseur varie de 0.20 à 10.0 mm.

La concentration des ions H^+ a été mesurée au moyen d'un potentiopHmètre Radiometer 4, avec des électrodes de verre et de calomel – KCl saturé. La linéarité de l'électrode a été vérifiée dans l'intervalle $2.0 \leqslant -\log [H^+] \leqslant 9.2$, et des solutions de concentration $[H^+]$ connue et de force ionique 0.50 (NaCl–HCl) ont servi à la standardisation.

Toutes les expériences ont été effectuées à 25.0 ± 0.2°.

RÉSULTATS EXPÉRIMENTAUX ET DISCUSSION

(A) Détermination des constantes de dissociation k_1 de HL

Deux méthodes ont été utilisées.

(a) Spectrophotométrie

Dans les Figs. 1–4, on donne pour chacun des composés, les spectres des diverses espèces L^-, HL et H_2L^+, obtenus en opérant dans des conditions d'acidité appropriées. Les spectres des espèces L^- et HL présentent des différences importantes qui permettent de déterminer k_1 par spectrophotométrie.

Dans chacun des cas, la densité optique est mesurée à plusieurs longueurs d'onde. La concentration totale du composé C_L est maintenue constante ($1–3 \times 10^{-4}$ M), de même que la force ionique (0.50 (NaCl + HCl)). On varie l'acidité au moyen de HCl, NH_3 ou NaOH concentrés (tropolone, maltol) ou en ajoutant à une solution acide des volumes croissants de solution plus basique de même concentration C_L (lawsone, TCHQ).

On définit ϵ_L, le coefficient d'extinction molaire moyen, tel que $\epsilon_L = A_s/C_L$, où A_s est la densité optique correspondant à une épaisseur de 1.00 cm. La constante d'acidité k_1, définie de la façon habituelle, peut être calculée d'après l'équation

$$[1] \qquad -\log [H^+] = pk_1 + \log \frac{\epsilon_1 - \epsilon_L}{\epsilon_L - \epsilon_0}$$

où ϵ_0 et ϵ_1 sont les coefficients d'extinction molaire de L^- et HL, obtenus respectivement à $-\log [H^+] \sim pk_1 + 3$ et $pk_1 - 3$. L'équation [1] est celle d'une droite de pente unité, dont l'ordonnée à l'origine est égale à pk_1. On donne dans le Tableau I les valeurs de la pente et

de pk_1 obtenues à partir de cette équation, ainsi que les régions de longueurs d'onde où les mesures ont été effectuées. Les constantes k_1 sont définies à partir des concentrations.

TABLEAU I

Résultats des déterminations de pk_1

	Pente	λ, mμ	pk_1 Potentiométrie	pk_1 Spectrophotométrie
Tropolone	1.02±0.04	330, 335, 380–390	6.70±0.04	6.64±0.03
Maltol	1.03±0.03	260–276, 285–315	8.36±0.03	8.37±0.03
Lawsone	1.05±0.04	310, 420–500	4.02±0.04	3.97±0.04
TCHQ		500–600, 320–325	1.05±0.04	

Le coefficient ϵ_1 de TCHQ ne peut être obtenu directement, puisqu'en milieu HCl 0.50 M il existe une proportion importante de L^-. On a toutefois mesuré ϵ_0 à $-\log [H^+] = 3.8$, puis A_s en fonction de l'acidité entre $0.50 \geqslant [H^+] \geqslant 10^{-3.8}$. La constante k_1 a été déterminée graphiquement à partir de la pente de la droite correspondant à l'équation:

$$[2] \qquad A_s = \epsilon_1 C_L + k_1 \frac{\epsilon_0 C_L - A_s}{[H^+]}.$$

La valeur de pk_1 ainsi obtenue est égale à 1.05 ± 0.04.

(b) Potentiométrie

Les résultats précédents ont été confirmés par potentiométrie. On a déterminé les courbes de neutralisation par NaOH de solutions diluées (0.5 à 1.0×10^{-3} M) de maltol, de tropolone et de lawsone. On donne dans le Tableau I les valeurs de pk_1 obtenues d'après l'équation [3], $[Na^+]$ étant la concentration de soude ajoutée.

$$[3] \qquad -\log [H^+] = pk_1 + \log \frac{[Na^+] + [H^+]}{C_L - [Na^+] - [H^+]}$$

Les courbes de neutralisation de TCHQ sont telles que les valeurs de $-\log [H^+]$ diminuent régulièrement avec le temps au voisinage du point équivalent. On n'a donc pas utilisé de méthode potentiométrique dans ce cas.

On note un bon accord entre les résultats des méthodes spectrophotométrique et potentiométrique. Les valeurs données dans la littérature pour des milieux ioniques différents sont généralement voisines (2, 6, 8). Dans le cas de la lawsone, la valeur obtenue par Zozulya et Peshkova (7) ($pk_1 = 2.38$) n'est pas confirmée.

(B) Détermination des constantes de dissociation k_2 de H_2L^+

Les α-hydroxycétones étudiées peuvent également, en milieu très acide, accepter un proton sur l'oxygène du carbonyle pour former un acide conjugué H_2L^+. Les constantes de dissociation k_2 de H_2L^+ ont été déterminées par spectrophotométrie. On a mesuré l'extinction de solutions de concentration C_L constante, en des milieux de concentration H_2SO_4 variable. Les valeurs de pk_2 sont obtenues d'après l'équation

$$[4] \qquad H_0 = pk_2 - \log \frac{\epsilon_2 - \epsilon_L}{\epsilon_L - \epsilon_1} = pk_2 - \log R'.$$

L'acidité est ici définie au moyen de la fonction d'acidité H_0, dont les valeurs sont données par Paul et Long (12). ϵ_2 et ϵ_1 sont les coefficients d'extinction molaire de H_2L^+ et HL respectivement et le rapport R' est tel que $R' = [H_2L^+]/[HL]$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Il est difficile de connaître avec précision les valeurs de ϵ_1 et ϵ_2 pour chaque concentration H_2SO_4, puisque ces valeurs varient quelque peu avec la nature du milieu. De telles variations sont souvent observées au cours de mesures de ce genre.

On a déterminé pour chacun des composés le spectre d'absorption à diverses concentrations de H_2SO_4. On a choisi, après examen des courbes donnant ϵ_L en fonction de H_0, les longueurs d'onde qui semblent les moins influencées par les changements de milieu, c'est-à-dire celles qui donnent une courbe comportant deux branches relativement horizontales. On obtient ϵ_1 et ϵ_2 à partir de points expérimentaux situés vers $H_0 = pk_2 \pm 2.3$ et on calcule pour toutes ces longueurs d'onde le facteur $\log R'$. La valeur moyenne de $\log R'$ pour toutes les longueurs d'onde choisies est portée sur la Fig. 5. L'équation [4] correspond à une droite de pente -1 et l'ordonnée à l'origine donne la valeur pk_2. Les résultats obtenus à partir de ces droites sont donnés dans le Tableau II, pour la tropolone, le maltol et la lawsone. Les valeurs calculées en utilisant la méthode de Davis et Geissman (13) sont identiques à celles du Tableau II. L'emploi de HCl au lieu de H_2SO_4 pour la mesure de la constante k_2 du maltol n'introduit pas de différences appréciables (-0.66 ± 0.10).

TABLEAU II

Résultats des déterminations de pk_2

	Pente	pk_2	λ, mμ
Tropolone	-1.01 ± 0.05	-0.53 ± 0.10	260–274, 290–300
Maltol	-1.18 ± 0.05	-0.71 ± 0.10	356–364
Lawsone	-1.19 ± 0.07	-5.6 ± 0.2	256, 275, 305–310, 400–420
TCHQ		$-8.8 \pm 1.$	500

La valeur obtenue par Dyrssen (2) pour l'ion tropolonium ($pk = 0.03$) correspond à une force ionique 3 ($HClO_4$, $NaClO_4$); ce résultat est comparable au nôtre ($pk_2 = -0.53$) si l'on considère de plus que l'acidité est définie de façon différente. La stabilité relativement grande du cation est reliée à des effets de résonance importants. Cook (14) a montré, par examen de spectres infra-rouges de sels de pyrilium, que la fixation du proton a lieu sur l'oxygène du groupe carbonyle des γ-pyrones. L'acide conjugué du maltol, comme celui de la tropolone, est stabilisé par résonance.

On note sur le spectre de la TCHQ, donné sur la Fig. 4, pour H_2SO_4 86%, un épaulement vers 500 mμ qui correspond vraisemblablement à H_2L^+. Les spectres à concentrations d'acide sulfurique inférieures présentent des variations régulières entre 15 et 65%: la solution reste jaune, avec un maximum d'absorption vers 445 mμ, mais ε varie quelque peu (435 à 360); dans l'ultra-violet, la bande se déplace de quelques mμ sans changement notable d'intensité. Ces variations sont peu importantes et du même type que celles qu'on retrouve avec la tropolone, le maltol et la lawsone et qui ont été notées par Handa (15) pour une série de composés quinoniques: elles ne correspondent apparemment pas à un changement de nature des espèces. La détermination de k_2 de TCHQ impliquerait l'emploi de milieux H_2SO_4 très concentrés (> 96%) dans lesquels le composé est peu stable. En supposant que l'épaulement observé pour la solution dans H_2SO_4 86% ($H_0 = -7.8$) correspond à une formation $1\% \leqslant H_2L \leqslant 50\%$, on peut conclure que pk_2 de TCHQ se situe dans l'intervalle -7.8 à -9.8. La TCHQ, comme la lawsone, est probablement protonée sur l'oxygène en position 4 (—OH étant en position 2): la stabilisation par résonance de tels cations serait plus grande que pour l'espèce protonée sur l'oxygène en position 1 (6).

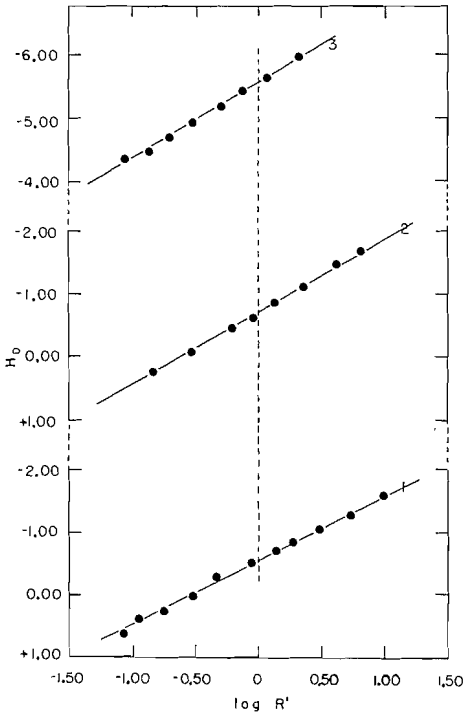

FIG. 5. Détermination des constantes k_2 de la tropolone, du maltol et de la lawsone. (1) Tropolone; (2) maltol; (3) lawsone.

Les quinones sont généralement peu basiques: anthraquinone (pk −7.5), naphtoquinone (−7.2) (15). Biedermann (16) déduit de la mesure des potentiels de l'électrode de quinhydrone en milieu acide, la formation d'un cation HL^+ de la *p*-benzoquinone, avec un pk = −1.0. Handa (15) prétend au contraire que la *p*-benzoquinone est détruite dans les milieux H_2SO_4 concentrés où elle pourrait accepter un proton. La présence d'une proportion importante de l'acide conjugué H_3L^+ de la dichloro-2,5 dihydroxy-3,6 *p*-benzoquinone (acide chloranilique H_2L) en milieu $HClO_4$ 1 *N* a été récemment avancée par Nazarenko et Flyantikova (17). Nous avons toutefois mesuré les spectres, entre 200–700 mμ, du composé dissous dans l'acétone et le dioxanne, solvants peu polaires dans lesquels l'acide chloranilique est vraisemblablement sous forme de l'espèce H_2L. Ces spectres sont semblables à ceux que l'on obtient pour le même composé dissous dans H_2SO_4 40% ce qui semble indiquer que le cation H_3L^+ ne se forme qu'en milieu très acide. Schwarzenbach et Suter (18) ont d'ailleurs étudié, par une méthode analogue à la nôtre, les propriétés basiques de la dihydroxy-2,5 *p*-benzoquinone et donnent pk = −7.0.

CHÉLATES DU GERMANIUM(IV) AVEC LA TROPOLONE, LE MALTOL, LA LAWSONE ET LA TRICHLOROHYDROXY *p*-BENZOQUINONE[1]

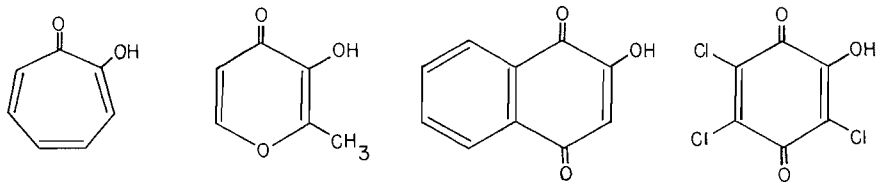
II. NATURE ET STABILITÉ DES CHÉLATES

A. BEAUCHAMP[2] ET R. L. BENOIT

Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 25 février 1966

RÉSUMÉ



On a étudié par spectrophotométrie la formation de chélates entre le germanium(IV) et une série d'α-hydroxycétones (HL). Avec la tropolone et le maltol, on a mis en évidence la présence d'espèces $Ge(OH)_2L_2$ et GeL_3^+ et déterminé les constantes d'équilibre correspondantes β_2 et β_3. Les composés $Ge(OH)_2(tropolonate)_2.2H_2O$, $Ge(tropolonate)_3ClO_4$ et $Ge(maltolate)_3ClO_4$ ont été isolés à l'état solide. Aucun complexe n'a été observé avec la lawsone et la trichlorohydroxy *p*-benzoquinone. On examine les relations entre la stabilité des chélates, la nature du germanium(IV) en solution et les propriétés acides–bases des α-hydroxycétones.

ABSTRACT

The formation of chelates between germanium(IV) and a series of α-hydroxyketones (HL) has been examined spectrophotometrically. Tropolone and maltol have been shown to give the species $Ge(OH)_2L_2$ and GeL_3^+; the corresponding equilibrium constants β_2 and β_3 have been determined. The following solid compounds have been isolated: $Ge(OH)_2(tropolonate)_2.2H_2O$, $Ge(tropolonate)_3ClO_4$, and $Ge(maltolate)_3ClO_4$. There was no evidence of complex formation with lawsone and trichlorohydroxy *p*-benzoquinone. Relations are discussed between the chelate stability, the state of germanium(IV) in solution, and the acid–base properties of the α-hydroxyketones.

INTRODUCTION

Les complexes du germanium(IV) avec la dichloro-2,5 dihydroxy-3,6 *p*-benzoquinone (acide chloranilique) ont fait l'objet d'une étude antérieure (1). On examine maintenant la formation de complexes avec les quatre autres α-hydroxycétones cycliques simples de formules suivantes:

On a voulu préciser le comportement des deux α-hydroxyquinones, lawsone et TCHQ, afin d'effectuer des comparaisons avec la dichloro-2,5 dihydroxy-3,6 *p*-benzoquinone et son analogue non-chloré (1). En ajoutant à cette étude deux autres α-hydroxycétones, la tropolone et le maltol, on s'est proposé de rechercher une relation entre les propriétés acides–bases de ces ligands et la stabilité des complexes formés avec le germanium. On pourrait s'attendre à obtenir une relation analogue à celle établie par Fernelius *et al.* (2) entre les constantes d'acidité d'hydroxycétones et les constantes de stabilité des chélates d'ions métalliques M^{2+}.

[1]*Tiré d'une communication présentée lors du 48ième Congrès de l'Institut de Chimie du Canada, tenu à Montréal, les 31 mai – 2 juin 1965.*

[2]*Boursier du Conseil National de Recherches 1964–1965 et de l'Hydro-Québec 1965–1966.*

Kimura *et al.* (3), Oka et Matsuo (4) et Kanno (5) ont déjà noté que la présence de germanium(IV) modifie les spectres de certaines hydroxycétones de la famille des fluorones, naphtoquinones, coumarines, tropones et flavones. Des chélates solides ont été récemment isolés par réaction de $GeCl_4$ avec la tropolone (6). Les réactions de la tropolone, du maltol et de la lawsone avec plusieurs cations M^{2+} ont été caractérisées par d'autres auteurs (2, 7, 8).

PARTIE EXPÉRIMENTALE

Les solutions de germanium(IV) environ 4×10^{-2} *M* sont préparées par dissolution de bioxyde GeO_2 de haute pureté, fourni par le "Germanium Research Center" et dosées par titrage potentiométrique avec de la soude non-carbonatée en présence de mannitol.

Les autres réactifs et la technique expérimentale sont décrits dans l'article précédent.

RÉSULTATS EXPÉRIMENTAUX

Les composés étudiés comportent une ou plusieurs bandes d'absorption dans la région 200–800 mμ et les réactions avec le germanium(IV) ont été caractérisées au moyen de méthodes spectrophotométriques.

I. Chélates avec la tropolone et le maltol

La formation de chélates lors de l'addition de GeO_2 à des solutions peu acides (pH 4) de tropolone ou de maltol (HL) s'accompagne de modifications dans les spectres d'absorption des ligands. La présence de germanium affecte de façon importante les diverses bandes d'absorption de la tropolone (Fig. 1) et déplace le maximum du maltol de 275 mμ vers 290 mμ (Fig. 2). Lorsque deux espèces absorbantes seulement sont présentes, les spectres peuvent présenter des points isobestiques; ainsi cinq tels points sont présents dans les spectres de la tropolone, deux dans ceux du maltol.

En milieu plus acide (HCl 0.50 *M*) les spectres sont différents et l'influence de l'acidité sur la formation de chélates a d'abord été considérée. La densité optique A_s d'une solution de

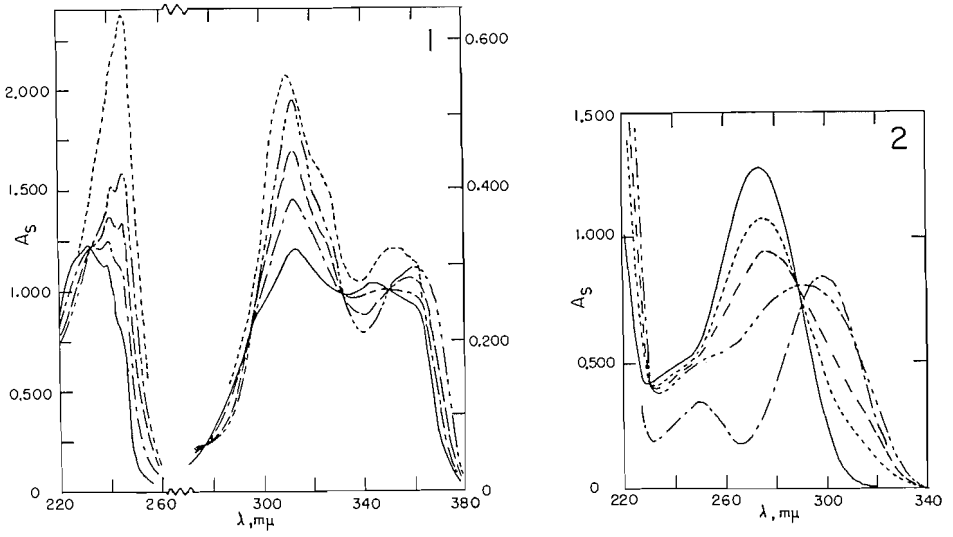


FIG. 1. Spectres de la tropolone en présence de germanium(IV). $C_L = 2.30 \times 10^{-3}$ *M*; pH = 4.0 ± 0.1; NaCl = 0.50 *M*; e (épaisseur) = 0.20 cm. (—) $C_M = 0$; (-·—·-) $C_M = 3.54 \times 10^{-1}$ *M*; (— — —) $C_M = 7.04 \times 10^{-1}$ *M*; (— · · · — · · · —) $C_M = 1.06 \times 10^{-2}$ *M*; (--) $C_L = 2.86 \times 10^{-3}$ *M*, HCl = 0.50 *M*, $C_M = 2.86 \times 10^{-2}$ *M*.

For personal use only.

maltol et de GeO_2 a été mesurée pour des milieux d'acidité variable. Les concentrations totales du ligand ($C_L = 1.88 \times 10^{-3}\ M$) et du germanium ($C_M = 4.08 \times 10^{-2}\ M$) sont maintenues constantes, ainsi que la force ionique (HCl + NaCl = 0.50 M). Les résultats obtenus pour plusieurs longueurs d'onde sont donnés sur la Fig. 3. Dans un domaine d'acidité compris entre $2.5 \leqslant -\log [H^+] \leqslant 6$, l'acidité est sans effet sur les équilibres, comme l'indique la valeur constante de la densité optique. A $-\log [H^+] > 6$, les équilibres sont modifiés par la neutralisation du maltol ($pk_1 = 8.38$) et de l'acide germanique ($pk_1 = 9.2$). Les variations d'extinction observées pour $-\log [H^+] < 2.5$ ne peuvent s'expliquer seulement par la formation du cation H_2L^+, puisqu'à $-\log [H^+] = 1$, par exemple, le ligand est protoné à moins de 2%. Il se forme donc, en milieu acide, d'autres chélates dont la concentration dépend de l'acidité. La tropolone se comporte de façon analogue: les spectres ne dépendent pas de l'acidité dans le domaine $3 \leqslant -\log [H^+] \leqslant 6$. Les chélates présents en milieu peu acide ont d'abord été caractérisés, en opérant à $-\log [H^+] = 3.5$–4.5.

(a) Chélates formés en milieu peu acide

La méthode de variations continues permet dans les cas simples de déterminer la composition de complexes. Des mesures ont été effectuées à plusieurs longueurs d'onde et les courbes donnant $\Delta A_s = A_s - \epsilon_L C_L$ en fonction du rapport $C_L/(C_M + C_L)$ sont représentées sur la Fig. 4, ϵ_L étant le coefficient d'extinction molaire du ligand à l'acidité choisie. Toutes les courbes correspondant à un milieu peu acide présentent un maximum pour un rapport $C_L/(C_M + C_L)$ voisin de 0.67. Ces résultats indiquent que le maltol et la tropolone forment avec le germanium des chélates de type M_mL_{2m}. Comme il a été vérifié par la suite que l'indice de polymérisation m est égal à 1, la réaction suivante rend compte des faits observés:

$$[1] \qquad Ge(OH)_4 + 2HL \rightleftarrows Ge(OH)_2L_2 + 2H_2O \qquad \beta_2 = \frac{[Ge(OH)_2L_2]}{[Ge(OH)_4][HL]^2}.$$

De plus, les résultats de la Fig. 3 ayant indiqué que l'acidité est sans effet sur les équilibres dans ce domaine, on peut conclure que les —OH liés au germanium ne possèdent pas de propriétés acides–bases notables.

L'absence de quantités appréciables d'espèces de stoechiométrie différente, suggérée par l'observation de points isobestiques (Figs. 1 et 2) et par la valeur constante de l'abscisse du maximum des courbes de variations continues (Fig. 4), est confirmée par la méthode des rapports molaires. On mesure l'extinction de solutions de tropolone de concentration constante et élevée en présence de quantités croissantes de GeO_2. Les résultats obtenus sont donnés sur la Fig. 5, où on porte ΔA_s en fonction du rapport C_M/C_L. Les deux droites de pentes 0 et $2\Delta A_{s(max)}$ se coupent à un rapport C_M/C_L égal à 0.50, ce qui est caractéristique de la présence d'une seule espèce ML_2. Des proportions importantes de chélate ML_3 conduiraient à une courbure pour $C_M/C_L < 0.50$, tandis que des variations de ΔA_s seraient observées pour $C_M/C_L > 0.50$, dans le cas où il y aurait formation de ML ou d'espèces polynucléaires.

Les constantes d'équilibre β_2 ont été déterminées par la méthode de McConnell–Davidson modifiée, décrite antérieurement (1). On mesure la densité optique de solutions de tropolone ou de maltol à concentration C_L constante, en faisant varier la concentration du germanium. On porte ensuite sur la Fig. 6, $(\Delta A_s/C_M)^{1/2}$ en fonction de ΔA_s. La concentration C_M est généralement telle que $C_M \gg C_L$ et l'approximation $C_M \sim [M]$ est justifiée. Les valeurs des constantes β_2 et des coefficients d'extinction molaire ϵ_2 de ML_2 sont calculées à partir de la pente et de l'ordonnée à l'origine des droites de la Fig. 6. On

Acide chloranilique (H_2L)	6.57* (1)	2.37 (1)	0.66† (1)	3.03	11.31

$^*\beta_2 = \dfrac{[Ge(OH)_2L_2^{2-}]}{[Ge(OH)_4][HL^-]^2}$.

$\dagger k_2 = \dfrac{[H^+][HL^-]}{[H_2L]}$.

obtient pour la tropolone $\beta_2 = 10^{8.03 \pm 0.05}$ et pour le maltol $\beta_2 = 10^{3.90 \pm 0.04}$ (Tableau I). On a vérifié par ailleurs que les fonctions analogues correspondant à ML, ML_3 et M_mL_{2m} où $m \neq 1$ conduisent à des courbes avec les résultats expérimentaux obtenus.

(b) Chélates formés en milieu acide

L'existence d'autres équilibres en milieu acide est suggérée par les spectres dans HCl 0.50 M (Figs. 1 et 2) et par les variations de l'extinction pour $-\log [H^+] < 2.5$ (Fig. 3). L'abscisse des maxima des courbes de variations continues du maltol à cette acidité

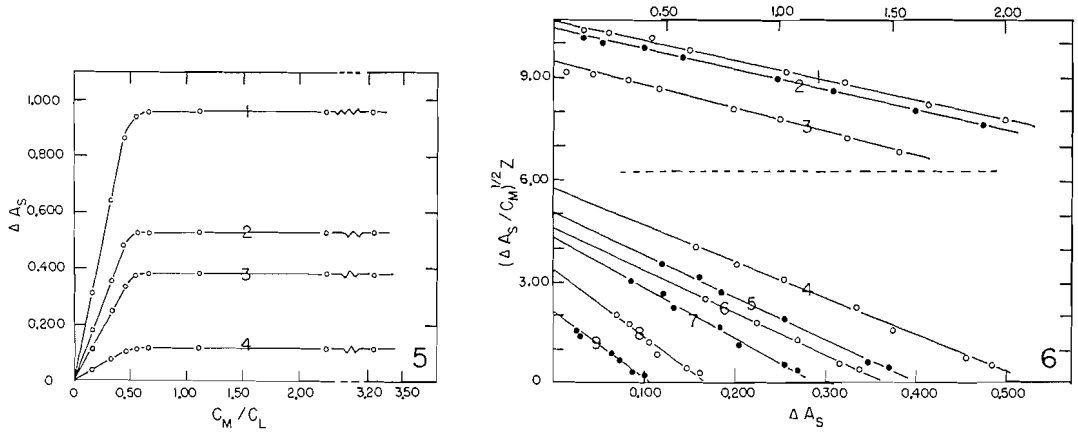

FIG. 5. Méthode des rapports molaires pour le système germanium(IV)–tropolone. $C_L = 6.41 \times 10^{-3}$ M; NaCl = 0.50 M; $-\log [H^+] = 4.34 \pm 0.05$; e = 0.20 cm. (1) 256 mμ; (2) 314 mμ; (3) 370 mμ; (4) 380 mμ.

FIG. 6. Méthode McConnell–Davidson modifiée. Maltol: $Z = 1$; $C_L = 9.97 \times 10^{-4}$ M; NaCl = 0.50 M; $-\log [H^+] = 4.02 \pm 0.03$. (1) 305 mμ; (2) 310 mμ; (3) 315 mμ. Tropolone: $Z = 10$; $C_L = 2.81 \times 10^{-5}$ M; NaCl = 0.50 M; $-\log [H^+] = 4.34 \pm 0.05$. (4) 249 mμ; (5) 252 mμ; (6) 245 mμ; (7) 254 mμ; (8) 256 mμ; (9) 314 mμ.

varient entre 0.65 et 0.75 selon la longueur d'onde. Un autre chélate est donc vraisemblablement formé en milieu acide, selon la réaction:

$$[2] \qquad Ge(OH)_4 + 3HL + H^+ \rightleftarrows GeL_3^+ + 4H_2O \qquad \beta_3 = \frac{[GeL_3^+]}{[Ge(OH)_4][HL]^3[H^+]}.$$

Les constantes d'équilibre β_3 ont été déterminées par spectrophotométrie, en utilisant une réaction compétitive avec le fer(III).

L'ion ferrique forme avec la tropolone (9) et les hydroxy-3 pyrones-4 (10) des chélates colorés qui absorbent entre 450 et 600 mμ, région où les chélates du germanium n'interfèrent pas. Les équilibres entre le germanium et ces ligands peuvent être étudiés indirectement en mesurant l'extinction due aux chélates du fer. Les résultats d'une expérience type, effectuée à 515 mμ, sont représentés sur la Fig. 7. La concentration totale de fer(III) est maintenue constante ($C_{Fe} = 7.04 \times 10^{-4}$ M) ainsi que l'acidité (HCl = 0.50 M). La densité optique est mesurée en fonction de la concentration de maltol ajoutée et on porte le rapport $Y = A_s/C_{Fe}$ en fonction de cette concentration C_L (courbe 1). Les mesures sont répétées pour des solutions qui contiennent en plus une concentration C_M de germanium(IV) (courbes 3 et 4). Cette méthode est comparable à la méthode "ferri" utilisée couramment en potentiométrie (11). On peut démontrer qu'à une valeur donnée de Y, la concentration de ligand libre [L] est constante et le nombre moyen de ligands par germanium $\bar{n}_M$ est calculable d'après l'équation $C_L' - C_L^0 = \bar{n}_M C_M$, où C_L' et C_L^0 sont les concentrations de ligand ajoutées à la solution ferrique en présence et en absence de germanium respectivement. La concentration de HCl étant constante et telle que $C_{Cl} \gg C_{Fe}$, la formation de complexes chlorhydriques du fer ne gêne pas. On obtient ainsi des paires de valeurs ($\bar{n}_M$, Y). La concentration [L] correspondant à chacune des valeurs de Y est obtenue par la méthode des solutions correspondantes (11). On détermine une autre courbe en l'absence de germanium en utilisant une concentration différente C_{Fe} (courbe 2) et on calcule [L] d'après l'équation $C_L = [L] + \bar{n}_{Fe} C_{Fe}$. A partir des paires de valeurs ($\bar{n}_M$, [L]) ainsi

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

obtenues, on trace la courbe de formation $\bar{n}_M = f(-\log [L])$ du système germanium(IV)–maltol à HCl 0.50 *M*. Ces résultats, de même que ceux qui correspondent à d'autres longueurs d'onde, sont donnés sur la Fig. 8. Les courbes calculées à partir de $\beta_2^* = 10^{4.4\pm0.8}$ et $\beta_3^* = 10^{7.74\pm0.06}$ donnent le meilleur accord avec les points expérimentaux.

Dans le cas de la tropolone, les conditions expérimentales ont été choisies de façon à obtenir la portion de la courbe de formation dans la région $\bar{n}_M = 2$ (Fig. 8). La constante β_1 d'un chélate ML étant négligeable, la valeur de β_3^* peut être calculée à partir de l'équation:

$$\beta_3^*[L]^3_{\bar{n}_M=2} = 2.$$

La valeur β_3^* $10^{13.0\pm0.1}$ est obtenue pour la tropolone. La constante β_2^* $10^{8.7\pm0.9}$ estimée au moyen des autres points expérimentaux est obtenue avec une mauvaise précision puisque la concentration de chélate ML_2 est très inférieure à celle de ML_3 dans les conditions de l'expérience.

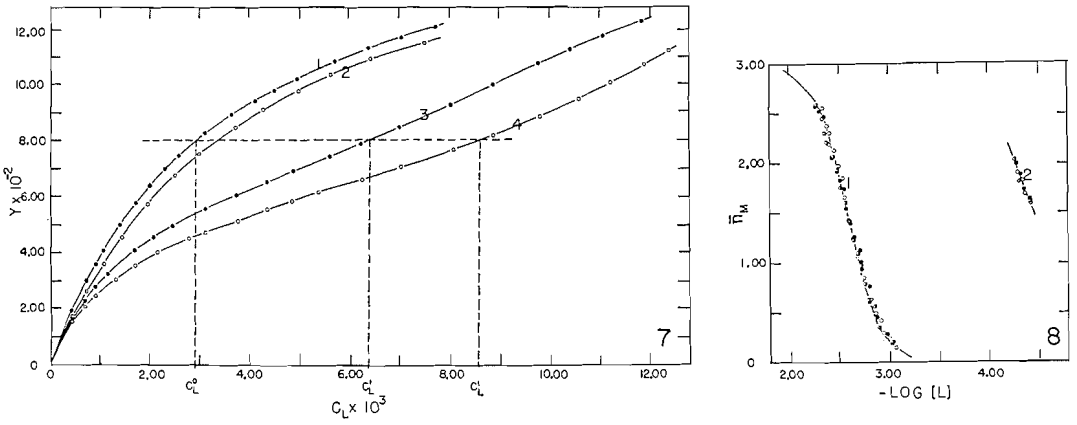

FIG. 7. Méthode compétitive Fe(III)/Ge(IV) – maltol. HCl = 0.50 *M*; e = 1.00 cm; 515 mμ. (1) $C_{Fe} = 7.04 \times 10^{-4}$ *M*, $C_M = 0$; (2) $C_{Fe} = 1.409 \times 10^{-3}$ *M*, $C_M = 0$; (3) $C_{Fe} = 7.04 \times 10^{-4}$ *M*, $C_M = 3.57 \times 10^{-3}$ *M*. (4) $C_{Fe} = 7.04 \times 10^{-4}$ *M*, $C_M = 7.14 \times 10^{-3}$ *M*.

FIG. 8. Courbes de formation des chélates du germanium(IV) en milieu HCl 0.50 *M*. (1) Maltol: (○) 530 mμ, (●) 515 mμ, (◑) 500 mμ; (2) tropolone: (○) 545 mμ, (●) 525 mμ, (◑) 480 mμ.

Les valeurs des constantes β_3 sont calculées à partir des constantes apparentes β_3^*, valables en milieu HCl 0.50 *M*, d'après la relation

$$\beta_3 = \beta_3^*(1 + (10^{-H_0}/k_2))/[H^+]$$

où k_2 est la constante d'acidité de l'acide conjugé H_2L^+, déterminée précédemment en se basant sur la fonction d'acidité H_0: $pk_2 = -0.71$ pour le maltol, -0.53 pour la tropolone; $[H^+] = 0.50$, $H_0 = 0.99$. Les constantes sont $\beta_3 = 10^{8.05\pm0.07}$ (maltol); $10^{13.3\pm0.1}$ (tropolone).

(c) Chélates solides

Quelques espèces identifiées en solution ont été isolées dans des composés solides. L'évaporation d'une solution aqueuse de GeO_2 et de tropolone (1:2 respectivement) a fourni un solide blanc de composition $Ge(OH)_2(tropolonate)_2.2H_2O$. Le germanium a été estimé gravimétriquement par calcination du chélate en GeO_2 et la tropolone a été analysée par spectrophotométrie à 330 mμ et 390 mμ sur une solution basique (NaOH 0.04 *M*). Ce composé est à rapprocher de $GeCl_2(tropolonate)_2$ isolé par réaction de la tropolone avec $GeCl_4$ (6). Dans ces mêmes conditions, le chélate $Ge(OH)_2(maltolate)_2$, dont la constante de stabilité est faible, n'est pas obtenu à l'état pur. Le spectre ultra-violet

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

d'une solution dans CH_2Cl_2 du mélange recueilli après évaporation, comporte un maximum vers 275 mμ, caractéristique du maltol, et un léger épaulement vers 300 mμ qui correspond vraisemblablement à un chélate. La présence d'une espèce complexe dans ce mélange est également indiquée par le spectre infra-rouge.

L'addition de $HClO_4$ (jusqu'à 1 *M*) à une solution de GeO_2 et de tropolone ou de maltol (1:3) (GeO_2:ligands) précipite des composés de formules $Ge(tropolonate)_3ClO_4$ et $Ge(maltolate)_3ClO_4$. Une bande vers 1 100 cm^{-1}, caractéristique de l'ion ClO_4^-, est observée et la bande —OH des ligands vers 3 400 cm^{-1} est absente dans les spectres infra-rouges des composés obtenus. D'autres sels de l'ion complexe $[Ge(tropolonate)_3]^+$ ont été isolés par Muetterties et Wright (6).

Les spectres ultra-violets de $Ge(OH)_2(tropolonate)_2.2H_2O$, $Ge(tropolonate)_3ClO_4$ et $Ge(maltolate)_3ClO_4$ ont été mesurés en solution dans CH_2Cl_2. Ils diffèrent peu de ceux qui ont été observés en solution aqueuse pour $Ge(OH)_2(tropolonate)_2$, $[Ge(tropolonate)_3]^+$ et $[Ge(maltolate)_3]^+$ respectivement, les faibles déplacements des maxima étant attribuables à des effets de solvant.

II. Réactions avec la lawsone et la TCHQ

Place (12) a étudié les réactions de $GeCl_4$ avec la lawsone et la TCHQ en milieu anhydre: dans des conditions où $GeCl_4$ donne lieu à la formation de chélates avec l'acide chloranilique et la dihydroxy-2,5-*p*-benzoquinone, aucun produit n'a été obtenu avec la lawsone et la TCHQ. L'absence de réaction entre le GeO_2 (3×10^{-5} *M*) et la lawsone (2.9×10^{-4} *M*) dans l'éthanol à 25% a été notée par Kimura (3). Nous nous sommes assurés que la lawsone et la TCHQ ne donnent pas de réaction détectable avec le germanium(IV) en solution aqueuse.

La présence d'une forte concentration de GeO_2 (2.9×10^{-2} *M*) dans une solution de lawsone (7.3×10^{-4} *M*) à pH 3.8 ou HCl 0.50 *M* est sans effet sur le spectre d'absorption. La lawsone est peu soluble à pH < 4 et aucun accroissement de sa solubilité n'a été noté en présence de GeO_2. A ces mêmes acidités, les spectres de solutions saturées de lawsone en présence de GeO_2(4×10^{-2} *M*) sont identiques à ceux qu'on obtient pour une solution saturée dans l'eau.

L'influence de GeO_2 sur le spectre de solutions concentrées de TCHQ (2.3×10^{-3} *M*) dans HCl 1 *M* et 0.1 *M* a été considérée. La présence de germanium (2.3×10^{-2} *M*) donne lieu à un léger épaulement dans le spectre vers 330 mμ. Cet épaulement est sans doute dû au chélate du germanium avec l'acide chloranilique présent comme impureté (0.7%) dans le produit de départ. Ceci est confirmé par le fait que les valeurs de la densité optique vers 330 mμ peuvent être expliquées quantitativement à l'aide des constantes d'équilibre et des coefficients d'extinction des chélates avec l'acide chloranilique (1).

Compte tenu de la précision de nos méthodes de détection, on peut donner pour les constantes hypothétiques de chélates du germanium avec la lawsone et la TCHQ les limites supérieures suivantes: lawsone, $\beta_2 \leqslant 10^3$; TCHQ, $\beta_2 \leqslant 10^{1.4}$.

DISCUSSION

La tropolone et le maltol réagissent avec le germanium(IV) en solution aqueuse pour former, suivant l'acidité, deux types de complexes, fort probablement des chélates, comportant soit deux, soit trois molécules de ligands par atome de germanium.

Les formules $Ge(OH)_2(tropolonate)_2$ et $Ge(OH)_2(maltolate)_2$, suggérées pour les chélates présents en milieu peu acide, rendent compte de la stoechiométrie et des propriétés observées. Cependent, l'étude des équilibres en solution ne permet pas de distinguer entre

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

les formules $Ge(OH)_2L_2$ et $GeOL_2$. L'étude du spectre infra-rouge du chélate solide dont la composition correspond à $Ge(OH)_2(tropolonate)_2.2H_2O$ n'a pas permis de mettre en évidence sans ambiguïté l'existence de groupes Ge—OH. La bande large vers 3 450 cm^{-1} pourrait être due à la fois à des vibrations de ces —OH et des molécules d'eau. Par ailleurs, les fréquences correspondant aux groupes Ge—O—H, Ge=O et Ge—O—C ne sont pas connues avec certitude. Clark *et al.* (13) attribuent à la vibration Ge—O—C une bande vers 940 cm^{-1}, observée dans les spectres de chélates du germanium avec des acides α-hydroxycarboxyliques, mais nous n'avons pas observé de telle bande dans les chélates de la tropolone et du maltol. Toutefois, comme on ne connaît apparemment pas de complexes comportant le groupe Ge=O (14), la formule $Ge(OH)_2L_2$ est retenue de préférence à $GeOL_2$. Elle est à rapprocher de $GeCl_2L_2$, formule du composé récemment obtenu en faisant réagir $GeCl_4$ avec la tropolone en milieu anhydre (6). L'étude effectuée ne permet pas par ailleurs de conclure quant à l'isomérie *cis–trans* de ces chélates.

On ne connait que peu de cations complexes du germanium(IV): $[GeOx_3]^+$ (où Ox^- est l'anion de l'hydroxy-8 quinoléine) présent dans $GeOx_3FeCl_4$ et stable dans certains solvants, semble avoir été le premier signalé (15). Nous avons mis en évidence l'existence des espèces $[Ge(tropolonate)_3]^+$ et $[Ge(maltolate)_3]^+$ en milieu acide et ces cations ont été isolés à l'état solide sous forme de perchlorates. Les composés sont vraisemblablement du même type que les sels $[Ge(tropolonate)_3]X$ (où $X = Cl^-$ ou tropolonate$^-$) isolés par Muetterties et Wright (6).

Les chélates du maltol et de la tropolone avec les ions métalliques sont généralement de stabilité voisine (7, 8). Il peut donc paraître surprenant que dans le cas du germanium, la constante d'équilibre β_2 du chélate de la tropolone ($\beta_2 = 10^{8.03}$) est beaucoup plus élevée que celle du composé du maltol ($\beta_2 = 10^{3.90}$). Ceci est dû au fait que la réaction [1] n'est pas strictement comparable à la réaction d'un ion métallique tel que M^{2+}, soit

$$[3] \qquad M^{2+} + 2L^- \rightleftarrows ML_2.$$

La réaction de formation de $Ge(OH)_2L_2$ formellement analogue à l'équation [3] est:

$$[4] \qquad Ge(OH)_2^{2+} + 2L^- \rightleftarrows Ge(OH)_2L_2 \qquad \beta_2^0 = \frac{[Ge(OH)_2L_2]}{[Ge(OH)_2^{2+}][L^-]^2}.$$

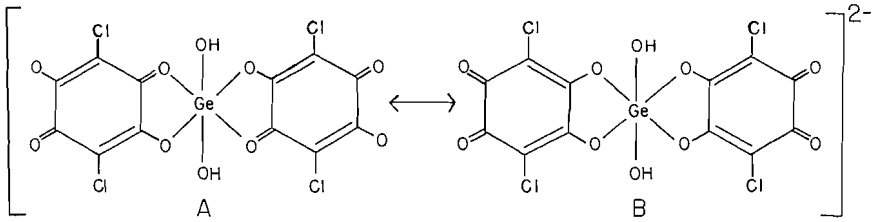
On peut relier le cation hypothétique $Ge(OH)_2^{2+}$ à l'acide germanique $Ge(OH)_4$ par l'équilibre:

$$[5] \qquad Ge(OH)_4 + 2H^+ \rightleftarrows Ge(OH)_2^{2+} + 2H_2O \qquad K_{Ge}'' = \frac{[Ge(OH)_4][H^+]^2}{[Ge(OH)_2^{2+}]}.$$

la constante K_{Ge}'' inconnue étant extrêmement élevée. La constante de stabilité observée β_2 se trouve ainsi reliée à β_2^0 par l'équation

$$[6] \qquad \beta_2^0 = K_{Ge}''\beta_2/K_a^2$$

où K_a est la constante d'acidité du ligand. On obtient maintenant pour β_2^0 des valeurs voisines pour les chélates du germanium avec la tropolone ($K_{Ge}'' \times 10^{21.43}$) et le maltol ($K_{Ge}'' \times 10^{20.62}$) comme dans le cas des ions M^{2+}.



Dans les conditions habituellement imposées par les solubilités de GeO_2 et des ligands et par les méthodes d'étude, la formation d'un complexe ML_2 du germanium n'est observable que si sa constante d'équilibre est telle que $\beta_2 \geqslant 1$. On peut voir, d'après l'équation [6], que la formation de chélates $Ge(OH)_2L_2$ avec les hydroxycétones et autres composés du même type ne sera détectable que si $\beta_2^0 K_a^2 \geqslant K_{Ge}''$. Ainsi, lorsque les réactions [3] et [4] sont

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

thermodynamiquement favorables, la réaction avec le germanium peut ne pas être observée à cause de la grande valeur de K_{Ge}'', c'est-à-dire de la grande stabilité du "complexe" $Ge(OH)_4$. Comme les facteurs qui influencent la stabilité des chélates de $Ge(OH)_2^{2+}$ et des ions M^{2+} sont vraisemblablement analogues, il ressort que les ligands les plus aptes à "réagir" avec le germanium seront ceux qui conduisent à des chélates très stables avec les cations métalliques. Ainsi, les chélates de la lawsone avec plusieurs cations étant beaucoup moins stables que ceux de la tropolone et du maltol (2, 7, 8), on comprend pourquoi le germanium ne donne pas de réaction avec la lawsone.

L'absence de chélates de type ML avec le germanium, déjà notée dans le cas de l'acide chloranilique (1), l'oxine* et ses dérivés†, se trouve ainsi confirmée. L'instabilité des chélates ML est apparemment aussi reliée à la grande stabilité du "complexe" $Ge(OH)_4$ en milieu aqueux.

De nombreux auteurs ont cherché à relier la stabilité de complexes formés avec des ligands voisins, à la basicité des ligands telle que mesurée par les pk de l'acide conjugué. Les résultats obtenus sont insuffisants pour pouvoir conclure à l'existence d'une relation, analogue à celle notée par Fernelius *et al.* (2), entre la stabilité des chélates $Ge(OH)_2L_2$ et le pk_1 du groupe hydroxy, c'est-à-dire la basicité de l'oxygène phénolique. Cependant, dans le cas de ligands bidentés, tels que les α-hydroxycétones, il semblerait que la basicité des deux atomes d'oxygène coordinés $-\overset{|}{\underset{|}{C}}-O^-$ et $\diagdown C{=}O \diagup$ soit à considérer et on pourrait la caractériser par p(k_1k_2) (16). On note que les anions du maltol et de la tropolone, ligands qui conduisent à des complexes du germanium(IV) relativement stables, possèdent des propriétés basiques assez prononcées, comme l'indiquent les valeurs de p(k_1k_2). Selon les valeurs des constantes β_2^0, la tropolone conduit à des chélates légèrement plus stables que le maltol, en dépit de propriétés basiques inférieures: la stabilité "anormalement" grande du chélate de la tropolone avec l'ion Cu^{2+} a également été notée (7).

La lawsone et la TCHQ qui ne donnent pas de réaction détectable avec le germanium (IV), possèdent au contraire des oxygènes nettement moins basiques. La constante pk_2 semble d'ailleurs correspondre à la protonation de l'oxygène en position 4: le carbonyle susceptible de conduire à un chélate serait probablement même moins basique que ne l'indiquent les valeurs des constantes pk_2.

Il est cependant surprenant que l'acide chloranilique et la dihydroxy-2,5 benzoquinone (DHQ), deux autres hydroxyquinones qui ont des propriétés acides–bases apparemment comparables à celles de la lawsone et de la TCHQ (1, 18), conduisent à des chélates stables avec le germanium(IV). Pour ces deux dihydroxyquinones (H_2L), les acidités fortes des chélates $Ge(OH)_2L_2H_2$ et dans une certaine mesure l'absence de chélates polynucléaires (1) suggèrent une redistribution électronique dans le chélate, conduisant à la coordination d'un

For personal use only.

deuxième oxygène phénolique, selon la structure prédominante B. La faible contribution d'une telle structure résonante pour la TCHQ et la lawsone expliquerait ainsi l'instabilité des chélates avec ces deux hydroxyquinones. On est alors conduit à suggérer que la basicité des oxygènes cétoniques de l'acide chloranilique et de la DHQ ($pk_{C=O} = -7.0$) (18) ne représente pas leur tendance à la coordination, mais que celle-ci correspondrait mieux au pk du deuxième groupe —OH. Il est intéressant de constater que les valeurs de log β_2^0/K_{Ge}'' et de $p(k_1k_2)$ de la DHQ diffèrent alors peu de celles du maltol. Les valeurs de log β_2^0/K_{Ge}'', pk_1, pk_2 et $p(k_1k_2)$ correspondant aux α-hydroxycétones étudiées sont rassemblées dans le Tableau I.

REMERCIEMENTS

Nous exprimons notre reconnaissance au Conseil National de Recherches qui nous a accordé un soutien financier sous forme d'une bourse (A. B.) et d'un octroi de recherches (R. L. B.). Nous sommes également reconnaissants à l'Hydro-Québec pour l'octroi d'une bourse (A. B.). Nous remercions le "Germanium Research Center" qui nous a fourni gracieusement l'oxyde de germanium.

ENERGETICS OF FORMATION OF SOME OXYGENATED IONS AND THE PROTON AFFINITIES OF CARBONYL COMPOUNDS

A. G. HARRISON,[1] A. IVKO,[2] AND D. VAN RAALTE
Department of Chemistry, University of Toronto, Toronto, Ontario
Received February 14, 1966

ABSTRACT

The energetics and mechanism of formation of ions of *m/e* 31, 45, and 59 from a number of alcohols, ethers, and esters have been studied. The following ionic heats of formation have been obtained: $CH_2{=}OH^+$, 176 kcal/mole; CH_3O^+, 213 kcal/mole; $CH_3CH{=}OH^+$, 145 kcal/mole; $CH_2{=}OCH_3^+$, 170 kcal/mole; $(CH_3)_2C{=}OH^+$, 125 kcal/mole; $CH_3CH_2CH{=}OH^+$, 131 kcal/mole; $CH_3CH{=}OCH_3^+$, 135 kcal/mole; $CH_2{=}OC_2H_5^+$, 144 kcal/mole. It is concluded that with the exception of CH_3O^+ the alkoxy ions probably are not formed by electron impact processes. The gas-phase proton affinities of a number of carbonyl compounds are estimated.

INTRODUCTION

The mass spectra of alcohols, ethers and, to a lesser extent, esters show prominent ions of general formula $C_nH_{2n+1}O^+$ appearing at *m/e* ratios of 31, 45, 59, 73, etc. The heats of formation of these ions and in many cases the structures are not known with certainty. During a recent study of the energetics of some gaseous oxygenated ions Munson and Franklin (1) have presented some results pertaining to the ions of *m/e* 31 and 45. During an extensive study (2–4) of the energetics and mechanism of ion formation in alcohols and esters, and related recent studies of ethers, we have accumulated a considerable body of data concerning ions of *m/e* 31, 45, and 59. This data both supplements the data reported by Munson and Franklin and serves, in some cases, to clarify points raised by their work. In addition, this data when combined with the data of Munson and Franklin (1) and others (5–9), permits more reliable estimates of the gas-phase proton affinities of a number of carbonyl compounds.

EXPERIMENTAL

Mass spectra and appearance potentials were measured with an AEI MS-2 mass spectrometer either as originally described (10) or as recently modified (11). Mass spectra were recorded at 50 V electron energy and 7–10 V/cm repeller field strength. Appearance potentials were measured in the usual manner (12) using xenon or krypton, admitted with the gas of interest, to calibrate the energy scale.

All chemicals were commercial samples of highest available purity and showed no detectable impurities in the mass spectra. The deuteriated samples studied were obtained from Merck, Sharp and Dohme, Montreal.

RESULTS AND DISCUSSION

Energetics of Formation and Structure of m/e = 31

The appearance potentials and resultant ionic heats of formation for *m/e* = 31 from a number of alcohols, ethers and esters are summarized in Table I. As can be seen there is reasonable agreement of the reported appearance potentials and therefore we have computed the ionic heats of formation using the unweighted average in each case with the exception of isopropyl alcohol where we have used the appearance potential obtained in the present work.

The first nine compounds listed in Table I give mutually consistent values for the ionic heat of formation suggesting a common structure, which we take to be $CH_2{=}OH^+$, and

[1]*Alfred P. Sloan Fellow 1962–1964. All correspondence should be addressed to this author.*
[2]*Exchange student 1964–1965. Present address: Department of Chemistry, Byelorussian State University, Minsk, U.S.S.R.*

leading to $\Delta H_f(CH_2{=}OH^+) = 176 \pm 3$ kcal/mole. This "best" value is only slightly higher than the value of 174 kcal/mole proposed by Munson and Franklin (1). The suggested structure, $CH_2{=}OH^+$, was first proposed by Cummings and Bleakney (13) and is supported by the observation of $CD_2{=}OH^+$ as the major fragment ion in the spectra of CD_3OH (14) and CH_3CD_2OH (15).

The neutral fragments postulated in column 5 require comment on the proposed fragmentation paths for some of the molecules. The proposed fragmentation path for isopropyl alcohol,

[1] $$(CH_3)_2CHOH^+ \rightarrow H + (CH_3)_2C{=}OH^+ \rightarrow CH_2OH^+ + C_2H_4,$$

is supported by the observation that in $(CD_3)_2CHOH$ the fragment ion appears as CD_2OH^+ which indicates loss of the secondary hydrogen in the rearrangement reaction. We suggest that the reaction may proceed through formation of a cationated cyclopropane as suggested (16) for a number of similar fragmentations.

The formation of $m/e = 31$ in the formate esters has been discussed previously (2) where it was shown by deuterium labelling that the formyl hydrogen was retained in the ion in all cases. This suggests, for methyl formate, the ionic structure $CH_2{=}OH^+$ with the neutral fragments assigned in Table I. The alternative formation of $CH_3O^+ + CHO$ would require a considerable rearrangement to be consistent with the labelling results.

Simple bond rupture in $CH_3OC_2H_5$ would be expected to lead to CH_3O^+ ($m/e = 31$) with C_2H_5 as the neutral fragment. That this does not occur is shown by the fact that in $CD_3OC_2H_5$ the fragment ion moves exclusively to $m/e = 33$ which indicates retention of only two deuteriums. The fragment ion is obviously formed by the rearrangement reaction

[2] $$CD_3OC_2H_5^+ \rightarrow D + CD_2OH^+ + C_2H_4.$$

There was no evidence that this was a two-step fragmentation i.e. there was no $(M{-}D)^+$ in the spectrum. This type of rearrangement has been postulated previously (17) to explain a number of prominent ions in the spectra of ethers including formation of $CH_2{=}OH^+$ in diethyl ether.

In contrast to the above cases the $m/e = 31$ ions from dimethyl ether, methyl acetate, and methyl nitrite lead to $\Delta H_f(m/e = 31) = 213 \pm 3$ kcal/mole. The high value and the structure of the molecules suggest that this heat of formation refers to the CH_3O^+ ion.

In summary, the ion of $m/e = 31$ has two possible structures, $CH_2{=}OH^+$ and CH_3O^+, with heats of formation of 176 and 213 kcal/mole respectively. The high heat of formation of CH_3O^+ means that fragmentation to form this ion is not a favorable route energetically and hence this ion is formed in relatively low abundance. A large intensity at $m/e = 31$ in a mass spectrum will thus usually indicate the $CH_2{=}OH^+$ structure for the ion rather than CH_3O^+. This is strikingly indicated in the mass spectrum of methyl formate and methyl ethyl ether where direct bond fission to yield CH_3O^+ does not occur but rather rearrangement to form $CH_2{=}OH^+$.

Energetics of Formation and Structure of $m/e = 45$

Deuterium-labelling studies and the structure of the molecules considered suggest three possible structures $CH_3CH{=}OH^+$, $CH_2{=}OCH_3^+$, and $CH_3CH_2O^+$ for the ion of $m/e = 45$. There is no evidence pointing to a fourth possible structure $HOCH_2CH_2^+$. The appearance potential data for $m/e = 45$ from a number of compounds are summarized in Table II. In this case the agreement of the reported appearance potentials is much poorer and we have chosen to calculate all ionic heats of formation using the appearance potentials measured in this laboratory.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Appearance potentials of $m/e = 45$ from ethyl alcohol, isopropyl alcohol, *s*-butyl alcohol, and diethyl ether lead to ionic heats of formation in mutual agreement and an average value of 145 ± 3 kcal/mole. The structure of the ion in this case is presumably $CH_3CH{=}OH^+$ as indicated by the loss of D in the spectra CH_3CD_2OH (15), CD_3 in the spectra of $(CD_3)_2CHOH$, and the ethyl group without isotopic mixing in the spectra of labelled *s*-butyl alcohols (18). We would suggest that the $m/e = 45$ ion from diethyl ether has the structure $CH_3CH{=}OH^+$ rather than $C_2H_5O^+$ as suggested by Munson and Franklin (1) and that it is formed by the rearrangement reaction

[3] $$[CH_3{-}CH{-}OH{-}CH_2{-}CH_2]^+ \rightarrow CH_3CHOH^+ + H + C_2H_4$$

although no deuterium labelling has been carried out to confirm this.

For ethyl and isopropyl formates, deuterium labelling (2) has shown formyl hydrogen retention indicating the fragmentation reaction

[4] $$CH_3{-}\underset{\displaystyle R}{\underset{|}{C}}H{-}O{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}H^+ \rightarrow R + CO + CH_3CH{=}OH^+ \ (R = H \text{ or } CH_3)$$

with the indicated structure for the ion rather than the $CH_3CH_2O^+$ structure postulated by Munson and Franklin (1). It is clear that the calculated ionic heats of formation are anomalously high which indicates that the fragmentation processes involve excess energy. From consideration of the structure of the neutral molecule, the ion formed from dimethyl ether, methyl ethyl ether, and dimethoxymethane should have the structure $CH_2{=}OCH_3^+$. The alternative fragmentation in methyl ethyl ether leading to $CH_3CH_2O^+$ was shown not to occur by the shift of the ion to $m/e = 48$ in the spectrum of $CD_3OC_2H_5$. The appearance potentials lead to a consistent value of $\Delta H_f(CH_2{=}OCH_3^+) = 170 \pm 3$ kcal/mole, considerably higher than $\Delta H_f(CH_3CH{=}OH^+) = 145 \pm 3$ kcal/mole. That the ions do indeed have different structures is indicated by differences in their further fragmentation reactions, the most striking difference being the fragmentation to form H_3O^+. It has been shown previously (3) that alcohols of the general formula $CH_3CH(R)OH$ form H_3O^+ upon electron impact by the fragmentation sequence

[5] $$CH_3CH(R)OH^+ \rightarrow R + CH_3CH{=}OH^+ \rightarrow H_3O^+ + C_2H_2.$$

The second step of this sequence is confirmed by observation of a metastable at $m/e = 8.03$. The ethers CH_3OCH_3 and $CH_3OC_2H_5$ show no H_3O^+ fragment ion and no metastable at 8.03 although the $m/e = 45$ ion is the most abundant ion in the mass spectra at 50 eV. Further fragmentation of $CH_2{=}OCH_3^+$ leads predominately to CH_3^+ and CHO^+.

The only molecule investigated which possibly forms the $CH_3CH_2O^+$ ion on electron impact is ethyl acetate where $m/e = 45$ is of rather low abundance. The reported appearance potentials are in reasonable agreement and suggest an ionic heat of formation of about 160 kcal/mole. When compared with $\Delta H_f(CH_3O^+) = 213$ kcal/mole, this value appears to be much too low to correspond to the ethoxy cation. For example, the corresponding sulfur-containing ions CH_3S^+ and $C_2H_5S^+$ have heats of formation of 222 and 213 kcal/mole respectively (19). It is thus probable that rearrangement to a thermodynamically more favorable structure has occurred. No reliable value for $\Delta H_f(CH_3CH_2O^+)$ can be established from present electron impact data.

Energetics of Formation of $m/e = 59$

The ion of $m/e = 59$ can have many possible structures, and the present work consists only of a preliminary examination of the energetics of formation of some of the most prominent ions. The nominal structures of these ions, given in column 2 of Table III, are

*Calculated using $\Delta H_f(H^+)$ = 365 kcal/mole, ref. 19.

based primarily on consideration of the structure of the neutral molecule and, obviously, a much more extensive investigation, including deuterium tracer studies, is desirable. The results do suggest some variation of ionic heat of formation with structure. From the present data one estimates $\Delta H_f(CH_3)_2C{=}OH^+ = 125$ kcal/mole and $\Delta H_f(CH_3CH_2\text{-}CH{=}OH^+) = 144$ kcal/mole. As will be shown in the following section, the former estimate appears reasonable but the latter value is probably 10–15 kcal/mole high.

The results in Table III also yield $\Delta H_f(CH_3CH{=}OCH_3^+) = 135$ kcal/mole and $\Delta H_f(CH_2{=}OC_2H_5^+) = 144$ kcal/mole, values which appear reasonable in comparison with $\Delta H_f(CH_2{=}OCH_3^+) = 170$ kcal/mole. These ions correspond in structure to cationated aldehydes; using well-established heats of formation (19, 20) and the above ionic heats of formation one can estimate values of 64 kcal/mole and 87 kcal/mole for the methyl ion affinity of formaldehyde and acetaldehyde respectively. The change in going from formaldehyde to acetaldehyde is also observed in the proton affinities calculated in the next section where the effect is of the same approximate magnitude. This suggests that the ionic heats of formation given above are not in serious error.

The heats of formation calculated for the ions with nominally the *n*-propoxy and isopropoxy structure again appear to be too low by comparison with CH_3O^+ which suggests rearrangement.

Proton Affinities of Carbonyl Compounds in the Gas Phase

The ions $CH_2{=}OH^+$, $CH_3CH{=}OH^+$, and $CH_3CH_2CH{=}OH^+$ can be considered (in the absence of rearrangement) as the ions formed on protonation of formaldehyde, acetaldehyde, and propionaldehyde respectively. It is of interest to use the thermochemical data on these ions to calculate the proton affinities of these aldehydes and to compare the proton affinities with those of the corresponding carboxylic acids. The proton affinity of X is given by the exothermicity of the reaction

$$H^+(g) + X(g) = HX^+(g) \qquad [6]$$

and hence a knowledge of $\Delta H_f(HX^+)$ is necessary for the calculation.

For the carboxylic acids the heat of formation of the protonated species, $RCOOH_2^+$, can be established from appearance potential studies of this ion which is observed as a rearrangement ion in the mass spectra of ethyl and higher esters. For some of the simpler esters extensive studies have been made of the mechanism (2, 4, 6, 8, 21–23) and energetics (1, 2, 4, 7–9) of this rearrangement reaction. The relevant data leading to estimates of $\Delta H_f(RCOOH_2^+)$ for R = H, CH_3, and C_2H_5 are summarized in Table IV. For the ethyl esters the neutral fragment generally has been assumed to be the vinyl radical and the calculations have been made using $\Delta H_f(\text{vinyl}) = 65$ kcal/mole (24). For the *n*-propyl and isopropyl esters both Munson and Franklin (1) and Harrison and Jones (4) have pointed out that the data are not reasonable if the neutral fragment is assumed to be the allyl radical but do give reasonable ionic heats of formation if an alternative structure of the C_3H_5 neutral fragment is considered. It has been pointed out (4) that the deuterium-labelling studies with isopropyl esters are consistent with a cyclopropyl structure for the C_3H_5 neutral. Accordingly the calculations have been made assuming $\Delta H_f(C_3H_5) = 53$ kcal/mole (1).

As can be seen in Table IV the ionic heats of formation calculated on this basis for the $CH_3COOH_2^+$ and $C_2H_5COOH_2^+$ ions from ethyl and propyl esters show reasonable internal agreement for each species. In the subsequent calculations (Table V) we have used the unweighted average of all determinations for these ions. For the formate esters the appearance potentials of $HCOOH_2^+$ from the propyl esters lead to considerably lower

$C_2H_5COOCH(CH_3)_2$	−123(9)	10.40		64	

ionic heats of formation than the average value obtained from the ethyl esters. The agreement is better in this case if the C_3H_5 neutral fragment is assumed to have the allyl structure, but it is unlikely that the fragmentation mechanism would be different for the ethyl and higher esters. Because of this inconsistency we have adopted for $\Delta H_f(HCOOH_2^+)$ the average value obtained from appearance potential measurements on ethyl formate.

Table V presents the calculations of the proton affinities of RCHO and RCOOH where R = H, CH_3, and C_2H_5. The results suggest that the proton affinities of H_2CO and HCOOH are identical as are the proton affinities of CH_3CHO and CH_3COOH. This agreement offers some support for our assignment of $\Delta H_f(HCOOH_2^+)$. The results also suggest that the proton affinity of C_2H_5CHO is considerably less than that of C_2H_5COOH and also less than the proton affinity of CH_3CHO. This is unlikely and indicates that our estimate of $\Delta H_f(CH_3CH_2CH{=}OH^+)$ is high by 10–15 kcal/mole. A more reasonable estimate would appear to be $\Delta H_f(CH_3CH_2CH{=}OH^+)$ = 131 kcal/mole leading to a proton affinity for C_2H_5CHO = 185 kcal/mole.

In addition to the proton affinities in Table V we estimate, from $\Delta H_f((CH_3)_2C{=}OH^+)$ = 125 kcal/mole (Table III), the proton affinity of acetone to be 188 kcal/mole. This value is slightly higher than that for acetaldehyde in agreement with the observation by Munson (25) that the ion–molecule reaction

[7] $$CH_3CH{=}OH^+ + (CH_3)_2C{=}O \rightarrow CH_3CHO + (CH_3)_2C{=}OH^+$$

occurs with a large rate constant. Since this indicates that the reaction has no activation energy the reaction cannot be endothermic and hence the proton affinity of acetone must be equal to or greater than that of acetaldehyde.

Throughout this paper we have written the protonated acid as $RCOOH_2^+$. We do not intend to imply by this symbolism that protonation necessarily occurs on the hydroxylic oxygen rather than the carbonyl oxygen. The present studies provide no information on the site of protonation.

AN IMPROVED METHOD OF HYDROGEN ISOTOPIC EXCHANGE WITH DEUTERIUM SULFATE, AND THE PREPARATION OF 9,10-ANTHRAQUINONE-d_8[1]

BRUNO LUNELLI AND CESARE PECILE
Institute of Physical Chemistry, University of Padua, Padua, Italy
Received February 22, 1966

ABSTRACT

An apparatus and improved conditions are described for using easily and efficiently sulfuric acid-d_2 as a deuterating agent. The preparation of 9,10-anthraquinone-d_8 with a high deuterium content is reported.

In a study of the vibrational spectrum of anthraquinone,[2] it was necessary to prepare anthraquinone-d_8 with high deuterium content. A careful consideration of the possible methods (1) convinced us that isotopic exchange would be the most convenient if a proper exchange agent could be found. The high stability of anthraquinone to concentrated sulfuric acid suggested the use of sulfuric acid-d_2.

Several deuterated aromatic compounds have been prepared by exchange with D_2SO_4 (2–7), but the operating conditions and yields are not always satisfactory. An examination of the methods used indicates that the disadvantages of using sulfuric acid-d_2 are to an important extent related to its activity as a sulfonating agent. Conditions for the isotopic exchange of a particular compound with sulfuric acid-d_2 are a concentration of the acid and a temperature at which the sulfonation rate is considerably lower than the exchange rate (5, 6). Such conditions are often attained at comparatively low temperatures and concentrations of sulfuric acid-d_2. These conditions (8) and the low solubility of the compound in sulfuric acid-d_2 (7) lead to low exchange rates. It is therefore necessary to use long exchange time and to renew the acid several times.

Because sulfonation is a reversible reaction, however, these difficulties can be avoided. The exchange can be allowed to take place at high temperature and high concentration of sulfuric acid. Under these conditions the exchange rate is high. After the exchange, the reaction mixture can be treated to hydrolyze the sulfonic acids formed. Because the solubility of many aromatic compounds is low in dilute, but appreciable in concentrated sulfuric acid, the presence of an organic solvent is not necessary (4, 6).

To apply this technique, we used an apparatus in which it is possible to obtain a gradient of both temperature and sulfuric acid concentration. The required quantity of sulfuric acid-d_2 was quite small. The method gave the fully deuterated product in high yield and isotopic purity, as shown by mass spectral analysis.

In our opinion, the procedure here described permits extension of the use of sulfuric acid-d_2, which is easy to handle, as a deuterating agent for aromatic compounds that do not undergo irreversible reactions (e.g. oxidation) under exchange conditions.

EXPERIMENTAL

Starting Materials

The anthraquinone used was a C. Erba (Milan) RP product, and the deuterium oxide was a Fluka "purissimum" product with a deuterium content of 99.7%.

[1]*This investigation was supported by the Consiglio Nazionale delle Ricerche (C.N.R., Rome).*
[2]*C. Pecile and B. Lunelli. To be published.*

Preliminary Experiments on the Exchange between Anthraquinone and Sulfuric Acid-d_2

An appreciable amount of anthraquinone dissolves in sulfuric acid of concentration higher than 80% (9), and gives oxonium salts (10). Sulfonation requires somewhat drastic conditions (11), and monosubstitution takes place principally in the β position, or in the α position if mercury salts are present. At temperatures above 230 °C, there is appreciable disulfonation and oxidation to polyhydroxylated compounds (11, 12).

Since for several aromatic compounds the exchange rates of hydrogen isotopes are appreciable at concentrations and temperatures lower than those required for sulfonation (2–7), we kept 500 mg of anthraquinone, dissolved in 5 ml of 95% D_2SO_4 (in D_2O), at 160 °C overnight. The infrared spectrum of the recovered anthraquinone (m.p. 286 °C, recrystallyzed from benzene) indicated that exchange had taken place and that no anthraquinone-d_0 was present.

To obtain larger quantities of deuterated anthraquinone, we allowed exchange and desulfonation to take place separately, in successive steps. Anthraquinone (2 g), deuterium oxide (5.5 ml), and sulfuric acid-d_2 (6.6 ml) were introduced into one arm of an inverted Y-shaped glass tube, which was then sealed under vacuum. The arm containing the mixture was heated until 5 ml of distillate had been collected in the other arm, kept at 0 °C. The arm containing the solution of anthraquinone in concentrated sulfuric acid was then kept for 20 min at 160 °C, cooled to room temperature, and poured slowly into the water which had distilled.

The same procedure[3] was repeated 4 times on the thick suspension obtained, then the apparatus was opened, 200 mg of mercury oxide were introduced, and the procedure was repeated 5 times more. Finally the whole apparatus was kept at 140 °C for 2 h, then opened; the anthraquinone was filtered off, and recrystallized from benzene. The series of 10 distillations, with introduction of mercury oxide after the fifth, was repeated twice more on the same sample, each time with fresh deuterium sulfate and deuterium oxide. At the end of these operations, 1.1 g of recrystallized anthraquinone, m.p. 286 °C, were obtained. With the quantities of reagents that were used, if we assume that the partition coefficient for deuterium between anthraquinone and sulfuric acid is 1 (6), the anthraquinone obtained in this experiment should have had a deuterium content of 99.7%. Its infrared spectrum, however, showed a number of weak bands which, when compared with the

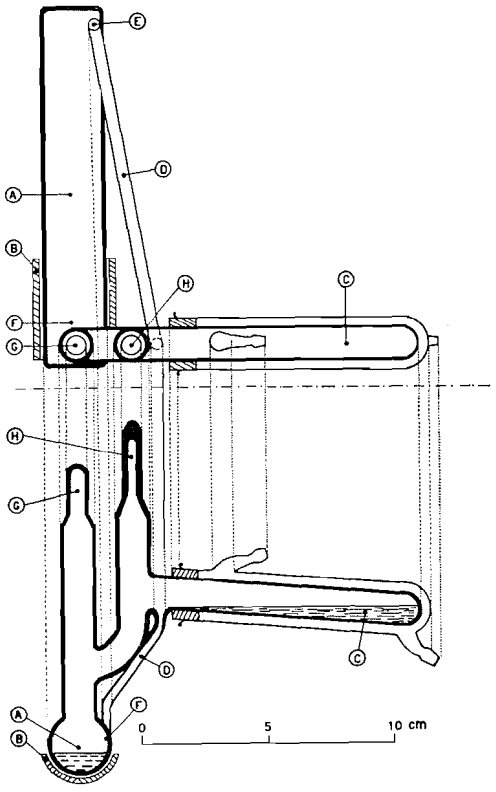

FIG. 1. Apparatus for the preparation of 9,10-anthraquinone-d_8.

[3]*At the beginning of each distillation, the concentration of sulfuric acid is low, and desulfonation takes place: at the end, the concentration is high, and both exchange and sulfonation of anthraquinone occur.*

spectra of the anthraquinone obtained at intermediate stages of the exchange, were recognized as having originated from partially deuterated anthraquinones.

This indication of low isotopic purity implied either that the partition coefficient for deuterium between anthraquinone and sulfuric acid-d_2 is less than 1, or that equilibrium distribution had not been attained. The latter seems more probable, since when the solution of anthraquinone in concentrated sulfuric acid is poured into the water, anthraquinone separates in finely divided form giving a thick suspension. This might limit mixing and therefore hydrogen isotope exchange between sulfuric acid and water. Moreover, since the partial rate factors for the exchange between anthraquinone and sulfuric acid were not known, the period allowed for exchange might have been too short.

These disadvantages and the long time required by this procedure induced us to seek another method. We designed an apparatus in which exchange sulfonation and desulfonation could take place at the same time, the reactions occurring in two separate parts of the apparatus.

Apparatus and Operating Conditions

The apparatus is made of borosilicate glass tubing. Figure 1 is a diagram of it.

The mixture of anthraquinone, deuterium sulfate, and deuterium oxide is placed in tube A. A small flame is placed under piece B (made of aluminium sheet 3 mm thick) and the water vapor produced condenses in C, which is cooled by flowing water. The condensate then flows down tube D and through E enters tube A, where it mixes with the solution of anthraquinone in sulfuric acid.

By varying the inclination of condenser C, it is possible to regulate the quantity of water held in it. An increase in the quantity of water held in C results in an increase in the concentration of the sulfuric acid in A, which causes the temperature of the mixture to rise. When the system reaches a steady state, there is a gradient of both temperature and sulfuric acid concentration from E to F. Near F, where the acid is concentrated, exchange and sulfonation of the anthraquinone occur; near E at the same time desulfonation of anthraquinone and exchange between sulfuric acid and water occur.

Several experiments were made with this apparatus to establish the proper operating conditions. It was found that the presence of mercury salts reduces considerably the quantity of recovered anthraquinone but

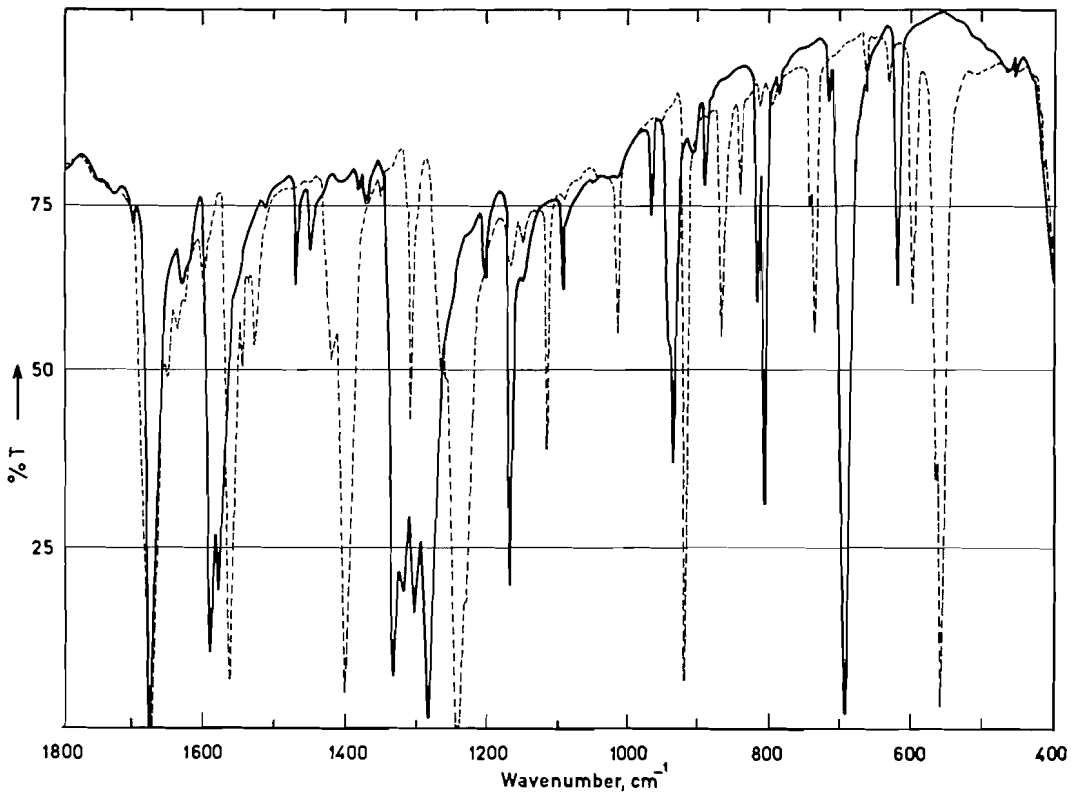

FIG. 2. Infrared spectra of 9,10-anthraquinone-d_0 (solid line) and 9,10-anthraquinone-d_8 (broken line) in KBr pellets (1 mg + 200 mg KBr). The spectra were measured on a Beckman model IR9 spectrometer.

has no influence on the degree of deuteration, and that an exchange period of 2½ h is sufficient for the attainment of equilibrium in hydrogen isotope distribution.

Preparation of Anthraquinone-d_8

An apparatus with the dimensions indicated in Fig. 1 was thoroughly degassed under vacuum, filled with dry nitrogen, and placed in a dry box. Anthraquinone (2 g) was melted in a thin glass tube, which was then broken; the compound was thus obtained free from moisture and in the form of a cylinder. It was introduced into the apparatus through tube G, which was then sealed. Deuterium oxide (5.4 ml) and deuterium sulfate (6.6 ml) were put in through tube H with a long hypodermic needle. The apparatus was immersed in liquid nitrogen and evacuated, and tube H was sealed. The apparatus was removed from the dry box, and heated for 2½ h. Because of the relatively high vapor pressure of anthraquinone at the temperatures of operation, it was necessary to discontinue heating every 30 min, and melt with a flame the anthraquinone which had sublimed on the walls. The indicated period of 2½ h does not include the time during which heating was stopped for this. The apparatus was then allowed to stand for 2 h at 130 °C in an oil bath, cooled to room temperature, and opened at G. The mixture of anthraquinone and 70% sulfuric acid was poured onto a sintered glass funnel in which a 3 mm layer of powdered glass had been placed, and filtered with suction. The product was washed repeatedly with sodium bicarbonate solution until the filtrate was no longer acid. Then it was dried, and crystallized twice from benzene with the addition of a little active charcoal. By this procedure, a yield of 1.8 g, m.p. 286 °C was obtained.

The procedure was repeated two more times. Finally, 1.4 g (yield 70%) of product, m.p. 286.8–287.2 (corr.) was obtained. The infrared spectrum is shown in Fig. 2 together with that of the light compound. The infrared spectrum of the product obtained after two exchanges differs from that indicated in Fig. 2 only by the presence of a few weak additional bands. The intensities of the C—H and the C—D stretching bands is very low and do not permit an estimate of the degree of deuteration.

The mass spectrometric analysis of the final product, made by Merck Sharp and Dohme of Canada Ltd., gave anthraquinone-d_8 95.38%, anthraquinone-d_7 4.62%, total deuterium 99.42%.

PREPARATION AND CHARACTERIZATION OF SOME BINARY AND TERNARY METAL COMPLEXES OF IMIDAZOLE AND AMINO ACIDS[1]

G. N. Rao and N. C. Li
Duquesne University, Pittsburgh, Pennsylvania
Received February 21, 1966

ABSTRACT

Five new ternary metal complexes containing imidazole and glycylglycine or amino acid have been prepared and characterized by proton magnetic resonance and infrared spectral studies. Seven new binary metal complexes have also been prepared and studied. The isolation of $Cd(imidazole)_6Cl_2.H_2O$ and $Ni(imidazole)_6.Cl_2.4H_2O$ provides evidence that the coordination number of these metal ions to imidazole in the solid state is six. The visible spectra of the Ni(II) complexes of amino acid and imidazole show that all these are octahedral in aqueous solution.

INTRODUCTION

The imidazole group of histidine is biologically of great importance, since it plays an important part in the binding of metallic ions to proteins and in the buffer action of proteins (1, 2). Koltun, Fried, and Gurd (3) measured the rates of hydrolysis of *p*-nitrophenyl acetate in the presence of imidazole (Im), $CuCl_2$, and glycylglycinate (GG), and calculated equilibrium constant for the reaction $CuGG + Im = CuGGIm$. These authors have pointed out that Cu(II) ion may bridge the N-terminus of a protein polypeptide chain to a side-chain imidazole group, so that studies on mixed imidazole–peptide complexes may serve to some degree as model for the protein complexes. From the effects of metal–peptide complexes on the imidazole catalysis of mutarotation of glucose and glucosamine, Tang and Li (4) reported the formation of ternary cadmium and nickel complexes containing imidazole and glycylglycinate. They found that the equilibrium constants for the reaction $MGG^+ + Im = MGGIm^+$ are $10^{2.78}$ and $10^{3.16}$ for M = Cd(II) and Ni(II), respectively.

In view of the importance of metal complexes containing imidazole and amino acid or peptide, we have prepared several binary and ternary metal complexes containing these biologically important ligands in the solid state, and have carried out proton magnetic resonance and absorption spectral studies on them. The results are presented in this paper.

EXPERIMENTAL

Materials

Imidazole and glycylglycine (from Aldrich Chemical Co.), and the amino acids (from Fisher Scientific Co.), were used without further purification. The other chemicals were of analytical reagent grade. Cadmium and nickel were analyzed by complexometric titration with EDTA; chloride by the Volhard titration method. Analysis for carbon, hydrogen, and nitrogen was done by A. Bernhardt, Germany.

Preparation of solid complexes

The following compounds have not been reported previously.

Cd(GG)(Im)(Cl)

To 0.01 mole of $CdCl_2.2\frac{1}{2}H_2O$ dissolved in 30 ml of water was added 30 ml of an aqueous solution containing 0.01 mole of sodium glycylglycinate. To this solution was added 30 ml of an aqueous solution containing 0.01 mole of imidazole, and the mixture was heated on a water bath for 1 h and filtered. The filtrate was evaporated to a volume of 25 ml and then placed in a refrigerator. The white precipitate formed was filtered, washed with water, and dried in a vacuum desiccator over P_2O_5.

Anal. Calcd. for $CdC_7H_{11}O_3N_4Cl$: Cd, 32.39; C, 24.21; H, 3.20; N, 16.15; Cl, 10.22. Found: Cd, 32.45; C, 24.11; H, 3.35; N, 15.98; Cl, 10.39.

[1]*This investigation was supported by a National Science Foundation grant, No. GB-4065.*

Cd(GG)(Im)$_2$(OH)

Cadmium hydroxide was prepared by mixing 0.02 mole of NaOH with 0.01 mole of $CdCl_2.2\frac{1}{2}H_2O$ in water, washing the precipitate formed with water, and centrifuging. The cadmium hydroxide formed in this manner was mixed with 0.01 mole of glycylglycine and 0.02 mole of imidazole in 100 ml of water, and digested on a water bath for 2 h. The mixture was then cooled and filtered to remove unreacted cadmium hydroxide. The filtrate was evaporated to a volume of 30 ml and then placed in a refrigerator. The white solid formed was filtered, washed with water, and dried in a vacuum desiccator over P_2O_5.

Anal. Calcd. for $CdC_{10}H_{16}O_4N_6$: Cd, 28.34; C, 30.25; H, 4.07; N, 21.19. Found: Cd, 28.48; C, 30.23; H, 4.27; N, 21.06.

Cd(GG)(Im)(NO_3).H_2O

This compound was prepared in the same way as Cd(GG)(Im)(Cl), except that cadmium nitrate was used instead of cadmium chloride.

Anal. Calcd. for $CdC_7H_{13}O_7N_5$: Cd, 28.71; C, 21.46; H, 3.34; N, 17.89. Found: Cd, 28.74; C, 21.60; H, 3.34; N, 17.69.

Cd(GG)$_2$.H_2O

0.01 mole of cadmium hydroxide was added to 100 ml of water containing 0.02 mole of glycylglycine, and the mixture was digested on a water bath for 2 h. After filtering off the unreacted cadmium hydroxide, the filtrate was evaporated to 30 ml and cooled. The white precipitate formed was filtered, washed with water, and dried in a vacuum desiccator over P_2O_5.

Anal. Calcd. for $CdC_8H_{16}O_7N_4$: Cd, 28.63. Found: Cd, 28.80.

Cd(asparaginate)$_2$

0.01 mole of cadmium oxide was mixed with 0.02 mole of the amino acid in 100 ml of water, and heated on a water bath until the oxide dissolved. The solution was filtered and the filtrate cooled. Ethanol was added to facilitate separation of the solid. The white precipitate formed was filtered, washed with water, and dried in air.

Anal. Calcd. for $CdC_8H_{14}O_6N_4$: Cd, 30.01; C, 25.63; H, 3.77; N, 14.96. Found: Cd, 30.11; C, 25.81; H, 3.89; N, 14.92.

Cd(α-alaninate)$_2$

This compound was prepared in the same way as Cd(asparaginate)$_2$.

Anal. Calcd. for $CdC_6H_{12}O_4N_2$: Cd, 38.96; C, 24.96; H, 4.19; N, 9.71. Found: Cd, 39.16; C, 24.83; H, 4.04; N, 9.90.

Cd(β-alaninate)$_2$

This compound was prepared in the same way as Cd(α-alaninate)$_2$, except that an excess (>0.02 mole) of the amino acid was necessary.

Anal. Calcd. for $CdC_6H_{12}O_4N_2$: Cd, 38.96; C, 24.96; H, 4.19; N, 9.71. Found: Cd, 38.91; C, 24.86; H, 4.04; N, 9.63.

Cd(Im)$_6$(Cl)$_2$.H_2O

To 0.01 mole of $CdCl_2.2\frac{1}{2}H_2O$ dissolved in 30 ml of warm water, was added 0.07 mole of imidazole in 30 ml of water, slowly with stirring. A white precipitate was obtained immediately and the mixture was digested on a water bath for 1 h and filtered. The white crystals were washed with water and ethanol, and dried in air.

Anal. Calc. for $CdC_{18}H_{26}ON_{12}Cl_2$: Cd, 18.44; C, 35.43; H, 4.30; N, 27.57; Cl, 11.64. Found: Cd, 18.40; C, 35.29; H, 4.32; N, 27.36; Cl, 11.46.

Ni(asparaginate)$_2$

0.01 mole of $NiCO_3$ was mixed with 0.02 mole of the amino acid in 100 ml of water and heated on a water bath for 1 h. The solution was evaporated to a volume of 20 ml and kept in a refrigerator. The blue crystals obtained were filtered, washed with water, and dried in a vacuum desiccator over P_2O_5.

Anal. Calcd. for $NiC_8H_{14}O_6N_4$: Ni, 18.29; C, 29.92; H, 4.40; N, 17.46. Found: Ni, 18.35; C, 30.49; H, 4.65; N, 17.65.

Ni(Im)$_6$.(Cl)$_2$.4H_2O

0.01 mole of $NiCl_2$ and 0.06 mole of imidazole were dissolved in 100 ml of water and evaporated on a water bath to about 20 ml. Blue-violet crystals appeared after the solution stood 4 d. The crystals were filtered, washed with water and ethanol, and dried in air.

Anal. Calcd. for $NiC_{18}H_{32}O_4N_{12}Cl_2$: Ni, 9.62; C, 35.41; H, 5.29; N, 27.55. Found: Ni, 9.56; C, 35.60; H, 5.43; N, 27.79.

Ni(glycinate)$_2$.(Im)$_2$

0.01 mole of $NiCO_3$, 0.02 mole of the amino acid, and 0.02 mole of imidazole were mixed in 100 ml of water and heated for 1 h on a water bath. The solution was then evaporated to a volume of 20 ml and let stand for 2 d. The violet crystals formed were filtered, washed with water and ethanol, and dried in a vacuum desiccator over P_2O_5.

Anal. Calcd. for $NiC_{16}H_{16}O_4N_6$: Ni, 15.49; C, 34.99; H, 4.71; N, 24.50. Found: Ni, 15.47; C, 35.23; H, 4.81; N, 24.38.

Ni(α-alaninate)$_2$.(Im)$_2$.H$_2$O

This compound was prepared in the same way as Ni(glycinate)$_2$(Im)$_2$.

Anal. Calcd. for $NiC_{12}H_{22}O_5N_6$: Ni, 14.43; C, 37.02; H, 5.70; N, 21.61. Found: Ni, 14.37; C, 37.14; H, 5.94; N, 21.85.

Instrumental

A Varian Associates Model A-60 n.m.r. spectrometer was used for proton magnetic resonance studies. Chemical shifts were measured with respect to tetramethylsilane (TMS) and are quoted as p.p.m. All lines are downfield from TMS. Infrared spectra were obtained with a Perkin-Elmer, model 137 spectrophotometer using Nujol mulls. Absorption spectra were taken on a Cary model 14 spectrophotometer with 5 cm cells.

RESULTS AND DISCUSSION

(A) Proton Magnetic Resonance and Infrared Studies

The proton magnetic resonance spectra of imidazole in 99.8% D_2O show a simple first-order AX_2 pattern consisting of two peaks in the intensity ratio 1:2. The more intense peak, at 7.6 p.p.m. for pH $\sim$ 8, is assigned to the single proton in the 2-position, while the other, at 6.9 p.p.m., is assigned to the two protons in the 4,5-positions. The protons in the 4- and the 5-position are equivalent because rapid NH proton exchange takes place with the solvent, and therefore only give rise to one line as observed. The NH proton does not give rise to a separate line because of the exchange (5).

At pH 3.5, the peak due to the 4,5-CH protons moves downfield to 7.6 p.p.m., while the peak due to the 2-CH proton moves to 8.2 p.p.m. At the lower pH, the imidazole is protonated and an electron redistribution results from the inductive electron-withdrawal operating at the 3-nitrogen position and causes a downfield shift of the proton signals.

The proton magnetic resonance spectra of Cd(GG)(Im)(Cl), Cd(GG)(Im)$_2$(OH), and Cd(GG)(Im)(NO_3).H$_2$O in 99.8% D_2O (a small amount of acid was added, pH $\sim$ 3.0, in order to facilitate solution of the ternary complexes) show four peaks at 4.0, 4.1, 7.8, and 8.5 p.p.m. The peaks at 4.0 and 4.1 p.p.m. (of equal intensity) are assigned to the protons of the two non-equivalent CH_2 groups in glycylglycine, because an acid solution of glycylglycine shows two peaks at these positions. The two peaks, 7.8 and 8.5 p.p.m., always in the intensity ratio 2:1, are ascribed to the 2-CH and the 4,5-CH protons, respectively, in the imidazole moiety of the ternary complexes.

The relative intensities of the peaks at 4.0, 4.1, 7.8, and 8.5 p.p.m. are in the ratios: 2:2:2:1, 2:2:2:1, and 1:1:2:1 for Cd(GG)(Im)(Cl), Cd(GG)(Im)(NO_3).H$_2$O, and Cd(GG)(Im)$_2$(OH), respectively. These are as expected since in Cd(GG)(Im)(Cl) and Cd(GG)(Im)(NO_3).H$_2$O, the ratio of GG to Im is 1:1, whereas in Cd(GG)(Im)$_2$(OH), the corresponding ratio is 1:2.

The infrared spectra of Cd(GG)(ImCl), Cd(GG)(Im)(NO_3).H$_2$O, and Cd(GG)(Im)$_2$-(OH) have been obtained. The general feature is an overlap of the spectra of the glycylglycinate and imidazole components. The N—H stretching band (2) at 3 125 cm^{-1} for imidazole persists in the spectra of the three ternary complexes, indicating that imidazole does not bind to cadmium(II) by way of the 1-nitrogen atom. By noting the similarity of the complex formation constants of imidazole and N-methylimidazole with Cu(II) and Cd(II), Li, White, and Doody (6) proposed that the binding site in imidazole is the 3-nitrogen atom. By comparing data on the N-methylimidazole complex with the imidazole complex of Ag(I), Bauman and Wang (7) came to the same conclusion regarding the site of complex formation of the imidazole molecule. It is interesting to note that in the infrared absorption spectra of the metal imidazolates which Bauman and Wang prepared, the highest frequency is around 1 600 cm^{-1}. In the metal imidazolates, therefore, the N—H stretching band is missing.

(B) Visible and Ultraviolet Spectral Studies

The absorption spectra of nickel(II) complexes of amino acids, glycylglycine, imidazole, and of ternary Ni(II) complexes of amino acids and imidazole, show four bands in the region of 9 700 to 28 000 cm^{-1}, as listed in Table I. These results may be interpreted in the light of the ligand field theory and Ni(II) can be shown to be in octahedral coordination, as follows:

Ballhausen (8) has derived the following equations for calculating the frequency of bands in the spectra of octahedral nickel(II) complexes

$$\nu_1 = 10Dq \quad [1]$$

$$\nu_2 = (9/5)(10Dq) \quad [2]$$

$$\nu_3 = 17\,000 + (6/5)(10Dq), \quad [3]$$

where ν is the frequency of the absorption band in cm^{-1} and $10Dq$ is the crystal field splitting parameter. Though the value of $10Dq$ for a particular configuration can be calculated from quantum mechanics, it is usually determined from the frequency of the first absorption band in the visible spectrum, eq. [1]. The frequencies of the remaining bands may then be calculated from eqs. [2] and [3], respectively, and if the calculated and observed frequencies agree, then the complex would be octahedral since the equations were obtained on the basis of this symmetry.

*A very weak band at 13 000 cm^{-1} (molar extinction coefficients $\epsilon < 2.0$) was observed for each of the nickel complexes.
†Values observed.
‡Values obtained from eqs. [1–3].
§Values obtained from eqs. [4–6].

Sharma, Mathur, and Biswas (9) modified Ballhausen's equations by introducing the correction factor, X, which accounts for perturbations due to higher energy transitions on the lowest energy transition. The equations become

$$X\nu_1 = 10Dq \quad [4]$$

$$\nu_2 = (9/5)(10Dq) = (9/5)(X\nu_1) \quad [5]$$

$$\nu_3 = 17\,000 + (6/5)(10Dq) = 17\,000 + (6/5)(X\nu_1). \quad [6]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

As an example of the use of these equations, $X = (5/9)(\nu_2/\nu_1) = (5/9)1.65$ for the spectrum of the Ni(glycinate)$_2$.2H$_2$O. The corrected value of $10Dq$ is therefore 8 910 cm^{-1}. If this value of $10Dq$ is used to calculate ν_2 and ν_3, the experimental and calculated values are in good agreement.

Jorgensen (10) has indicated that for octahedral nickel complexes there are in general four bands in the regions 8 000 – 11 000, 12 000 – 13 000, 15 000 – 19 000, and 25 000 – 29 000 cm^{-1}. The data of Table I show that there are indeed four bands in the nickel complexes listed, although the intensity of the band in the 12 000 – 13 000 region is very weak. The agreement between the calculated and observed frequencies, ν_2 and ν_3, in the spectra of the nickel complexes listed in Table I indicates that they are all octahedral.

Another characteristic feature of octahedral symmetry is the small molar extinction coefficients of the bands (of the order of 1–30) (10) and the ratio of ν_2/ν_1 is 1.8 (from eqs. 1 and 2). The values of the molar extinction coefficients and the ratio of ν_2/ν_1 in Table I again indicate the octahedral configuration.

Sharma, Mathur, and Biswas (9) have shown that if the nickel(II) complexes are tetrahedral, the first band would occur at $\nu_1 = 10Dq'$ (tetrahedral) $= (4/9)10Dq$ (octahedral) (11). In Table I, $10Dq$ is about 9 000. The first absorption band therefore should have occurred at about 4 000 cm^{-1} if the complexes were tetrahedral. Since no band is observed at 4 000 cm^{-1}, tetrahedral configuration can be ruled out. The spectra of the nickel glycinate and α-alaninate complexes in Table I cannot be compared with those reported by Jorgensen (12) and by Sharma, Mathur, and Biswas (9), since their spectra refer to triglycinate and tri-α-alaninate, respectively, while the present spectra refer to the diglycinate and di-α-alaninate complexes.

General Conclusion

The isolation and characterization of three solid ternary cadmium complexes containing glycylglycine and imidazole lend support to the finding of Tang and Li (4) on the existence of Cd(GG)(Im)$^+$ species in solution. The isolation of Ni(Im)$_6$Cl$_2$.4H$_2$O in the pure solid state supports the assumption of Li, Chu, Fujii, and White (13) that Ni(Im)$_6^{2+}$ exists in solution. The isolation of Cd(Im)$_6$(Cl)$_2$.H$_2$O in the pure solid state provides proof of the coordination number of six of cadmium in the solid state. Although Li, White, and Doody (6) find that the highest-order Cd(II) complex of imidazole is four, i.e., Cd(Im)$_4^{2+}$ in solution, other investigators have reported coordination number of six for cadmium in solution, when ligands are amines (14) and amino acids (15, 16). Proton magnetic resonance and infrared spectra are useful in the characterization of the ternary complexes. The visible spectra of binary Ni(II) complexes of amino acids, glycylglycine, imidazole, and ternary Ni(II) complexes of amino acids and imidazole, show that all these are octahedral in aqueous solution.

A SPECTROPHOTOMETRIC STUDY OF HEXA-, PENTA-, AND TETRA-COORDINATED HALOGENOCOPPER(II) COMPLEXES IN ACETONE – HYDROHALIC ACID MIXTURES

G. H. FAYE[1]

Mineral Sciences Division, Department of Mines and Technical Surveys, Ottawa, Canada

Received January 11, 1966

ABSTRACT

A spectrophotometric study of the Cu(II) – acetone – hydrochloric (hydrobromic) acid systems has revealed that at relatively high ratios of halide:copper there is a probable equilibrium between four-, five-, and six-coordinate halogenocopper(II) complexes. A distorted tetrahedral species is favored at the highest ratios. Ligand field bands of pseudo-octahedral monohalogenocopper(II) complexes and, in the visible region, a charge transfer band of the six-coordinate complex, $[CuCl_4(ac)_2]^{2-}$, have been identified. The results of the present work point to the important role of the solvent in determining the geometries and absorption spectra of the complexes, a factor that seems to have been misinterpreted by some previous workers.

INTRODUCTION

It is known that the tetrahalogenocopper(II) ion exists as a tetragonally distorted tetrahedron in crystalline solids such as Cs_2CuCl_4 (1), $[Ph_3MeAs]_2CuCl_4$ and $[Ph_3MeAs]_2CuBr_4$ (2), in molten chlorides (3, 4) and in certain aqueous and organic solvent media (5, 6). The structural information on the solids has been obtained largely through X-ray diffraction work and, on the solutions (including melts), by comparisons of the absorption spectra of the complexes in the two states of matter. In general, however, the absorption spectra of solutions of the halogen complexes of Cu(II) have been difficult to interpret because of "solvent effects" (7) and because of charge transfer bands arising in the visible region (8). In several cases these problems have led to the proposal of complexes that the present author finds difficult to reconcile with his own findings.

As a basis for discussion of previous work, it can be recalled that 3d transition metal complexes in solution exhibit absorption bands from the near ultraviolet to the near infrared region of the energy spectrum. Bands in the high energy region, with absorption coefficients, ϵ_{max}, $> \sim 500$ l/mole cm and oscillator strengths, f, $> \sim 10^{-2}$, are probably of the charge transfer type (ligand $\rightarrow$ metal), whereas bands in the visible to near infrared with $\epsilon_{max} < \sim 500$ l/mole cm and $< \sim 10^{-2}$ are the ligand field d–d bands.

Cu(II) has a d^9 configuration, which in a cubic field, gives rise to a single band due to the transition $T_{2g} \rightleftarrows E_g$. In an approximately octahedral field such as that in $Cu(OH_2)_6^{2+}$, this transition occurs at 12 500 cm^{-1} (800 mμ) (9). In a tetrahedral field, the transition should occur at a frequency less than 10 000 cm^{-1} because the ligand field splitting (Δ) for a tetrahedral complex should be about half as great as that for an octahedral complex (10). Felsenfeld (11), using theoretical considerations based on a tetrahedral model for $CuCl_4^{2-}$, showed that the complex should have a d–d band at 5 768 cm^{-1}.

Helmholz and Kruh (1) have shown that $CuCl_4^{2-}$ in crystalline Cs_2CuCl_4 is a flattened tetrahedron. These workers compared the absorption spectra (in the 10 000 – 45 000 cm^{-1} region) of a mull of powdered Cs_2CuCl_4 and that of an aqueous solution of cupric chloride, and concluded that the structure of the aqueous ion was not the same as that in the crystal. Both spectra obtained by Helmholz and Kruh show charge transfer bands ($> 2 \times 10^{-2}$) above 20 000 cm^{-1}, but the only d–d band resolved was that of the solution

[1]*Senior Scientific Officer, Analytical Chemistry Sub-division, Mineral Sciences Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada.*

at about 13 000 cm^{-1} ($\sim$ 770 mμ). It will be evident later in the paper that this band probably should have been drawn with a maximum near 11 000 cm^{-1}; but in either case, according to the criteria outlined above, one may be led to conclude that copper probably did not exist in the solution mainly as a tetrahedral complex. It may be noted, however, that in a theoretical paper on the intensities of spectral bands in tetrahedral complexes, Ballhausen and Liehr (12) state that they considered the "$CuCl_4^{2-}$" complex in solution to be rigorously tetrahedral.

Antipova-Karataeva and Nainshtein (7) studied the spectra of solutions of cupric chloride in acetone and noted a relatively intense band at about 21 000 cm^{-1} (475 mμ), which they attributed to a solvated complex of low symmetry and implied that it contained less than four chlorines per copper. Because of the attempted structure assignment, it would appear that Antipova-Karataeva and Vainshtein considered this maximum to be due to a d-orbital transition because charge transfer bands do not readily permit such assignments.

Gažo (13) also observed the maximum at 21 000 cm^{-1} and showed that it was due to a tetrachloro complex; however, he did not identify the band as being either charge transfer or d–d in character. It will be shown later in this paper that it is a charge transfer band.

Furlani and Morpurgo (6) obtained the spectra of nitromethane solutions of certain salts of the general formula R_2CuCl_4, and under some conditions these show an absorption peak at 21 900 cm^{-1}. Furlani and Morpurgo attribute this charge transfer band to a "solvolysis product" and imply that the complex contained less than four chlorines per copper (a conclusion similar to that of Antipova-Karataeva and Vainshtein).

In nitromethane solutions of R_2CuX_4 (X = Cl or Br) containing excess X^-, the spectra measured by Furlani and Morpurgo show broad bands with maxima at 8 000 – 9 000 cm^{-1} and these are considered to be the d–d bands of pseudo-tetrahedral tetrahalogeno complexes. However, in the spectra of similar solutions not containing excess halide, maxima appear at 11 500 – 12 000 cm^{-1} and Furlani and Morpurgo assign these to distorted square planar solvolysis products, i.e. di- and (or) tri-halide species such as CuX_2L_2.

Gill and Nyholm (2) studied the complexes $[Ph_3MeAs]_2CuCl_4$ and $[Ph_3MeAs]_2CuBr_4$ but did not publish their crystal or solution spectra. However, they did indicate that they found absorbance maxima for "$CuCl_4^{2-}$" and "$CuBr_4^{2-}$" in nitromethane solutions at 11 200 and 11 500 cm^{-1} respectively, with corresponding ϵ_{max} values of 88 and 122 l/mole cm. From the arguments presented earlier, the above spectral data suggest that the two complexes, in solution, were of approximately octahedral symmetry. Gill and Nyholm suggest that in nitromethane solution a tetrahedral arrangement is not at all certain for their tetrahalogen complexes.

Barnes and Hume (5) have established the existence of the distorted tetrahedral $CuBr_4^{2-}$ ion in both aqueous and organic solvents and this has been considered to be the only example of such a geometry for Cu(II) complexes in liquid solutions (4). According to Barnes and Hume, the d–d band of the purple tetrabromo complex has its maximum at 9 100 cm^{-1} (1 100 mμ) with ϵ_{max} = 160, both parameters in the accepted range for tetrahedral (approximately) complexes.

Barnes and Hume also investigated a green complex which in acetone solutions was found to have its d–d band at about 11 400 cm^{-1} (880 mμ) with ϵ_{max} = 160. Apparently the green complex had been studied previously by Yatsimirskii and Malkova (14), who concluded that it was $CuBr_4^{2-}$. However, Barnes and Hume consider the species to be the five-coordinate entity, $CuBr_3^-$.2solvent. As we will see later, it is probably a pseudo-octahedral tetrabromo complex.

From the foregoing it is evident that further experimental work is required to elucidate the spectra and structure of the halogenocopper(II) complexes, especially in coordinating solvents such as acetone. The present paper describes studies directed to that end.

It will be shown that in acetone solutions, containing an excess of Cl^- or Br^-, an equilibrium exists between octahedral and tetrahedral (both distorted) tetrahalogenocopper-(II) complexes, the four-coordinate species being favored in solutions having the highest halide ion activity. The experimental evidence, although not conclusive, suggests that a five-coordinate (probably pentachloro) complex participates in the overall equilibrium.

The important role of solvent molecules as "primary" ligands is indicated in the present study where the six-coordinate complexes are considered to be $[CuCl_4(ac)_2]^{2-}$ and $[CuBr_4(ac)_2]^{2-}$. Information on monohalogenocopper(II) species has been obtained and it seems that these are more thermodynamically stable than the higher halogeno pseudo-octahedral complexes.

EXPERIMENTAL

Stock Solution of $CuCl_2.2H_2O$ in Acetone

This was prepared by dissolving an accurately weighed quantity of analyzed (37.5% Cu) reagent grade $CuCl_2.2H_2O$ in the required volume of reagent grade acetone. Recent studies in this laboratory have shown that in such solutions the coordination sphere of the dissolved copper species changes with time through the formation of monochloro complexes. For example, after approximately 5 days a green gelatinous material containing Cu(II) and Cl^- in a 1:1 ratio is produced in solutions that were originally 10^{-2} to 10^{-3} *M* in Cu(II). Thus to avoid complications due to the formation of such material, freshly prepared solutions only were used in the present studies.

Stock Solution of $Cu(ClO_4)_2$ in Acetone

This was prepared by dissolving high-purity copper turnings in concentrated nitric acid, evaporating the resulting solution just to dryness, and then treating the salt with several milliliters of concentrated perchloric acid. The solution was evaporated until copper perchlorate had crystallized and nearly all free perchloric acid had been driven off. After the solution had cooled, the residue was treated with acetone and several drops of concentrated perchloric acid (just sufficient to produce a clear solution) and diluted to a known volume with acetone.

Apparatus

All spectrophotometric measurements were made with a Beckman DK-2 recording spectrophotometer equipped with matched 1 cm cells.

Experimental Procedure

Most sample solutions were prepared by mixing aliquots of the appropriate copper stock solution with aliquots of either concentrated hydrochloric or hydrobromic acids, or of solutions of known concentration of each acid in acetone. The resulting mixtures were diluted to 25 ml with acetone, cooled to room temperature, and examined spectrophotometrically. In obtaining the spectra, copper-free reference solutions containing all ingredients in the same concentration as the corresponding samples were used.

During the course of the experimental work it was established that the spectra were reproducible except, as noted in the text, under conditions where Cu(II) was reduced to Cu(I) by Br^-.

It is known that at room temperature concentrated hydrochloric acid reacts relatively slowly with acetone; however, this did not complicate the present study. For example, it was found that absorbance values of the spectra of solutions in which $[Cl^-]/[Cu^{2+}] \sim 8$ decreased by 10% in 5 h, whereas in the same period the decrease in absorbance was 1–3% for solutions in which $[Cl^-]/[Cu^{2+}]$ ranged from approximately 150 to 600.

Because of the high absorbance of the solvent medium, the spectra could not be examined above approximately 31 000 cm^{-1} ($\sim$ 320 mμ) or below approximately 6 000 cm^{-1} ($\sim$ 1 700 mμ).

Extinction coefficients (ϵ_{max}) were calculated using total copper concentrations.

RESULTS AND DISCUSSION

Chlorocopper(II) Complexes in Acetone–Hydrochloric Acid Solutions: Monochlorocopper(II) Complex

From the spectra in Fig. 1 it is evident that as the ratio of the total molar concentrations of Cl^- to Cu^{2+} is increased from 0 to about 1.3 there is a gradual increase in the intensity of the d–d band and a shift of the band maximum from 12 500 to about 12 200 cm^{-1}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(820 mμ). In the mole ratio range 1.3 to 2.5 (not shown), the intensity increase continues and there is a sudden shift of the maximum to 11 500 cm^{-1} (870 mμ), at which value it remains constant up to a ratio of approximately 20:1 (see B of Fig. 2).

Absorbance data from Fig. 1, together with that from additional spectra, have been plotted against $[Cl^-]/[Cu^{2+}]$ in Fig. 3*a* and from this it is clear that Cu(II) and chlorine are present in a 1:1 ratio in the complex with d–d band maximum at 12 200 cm^{-1} (820 mμ).

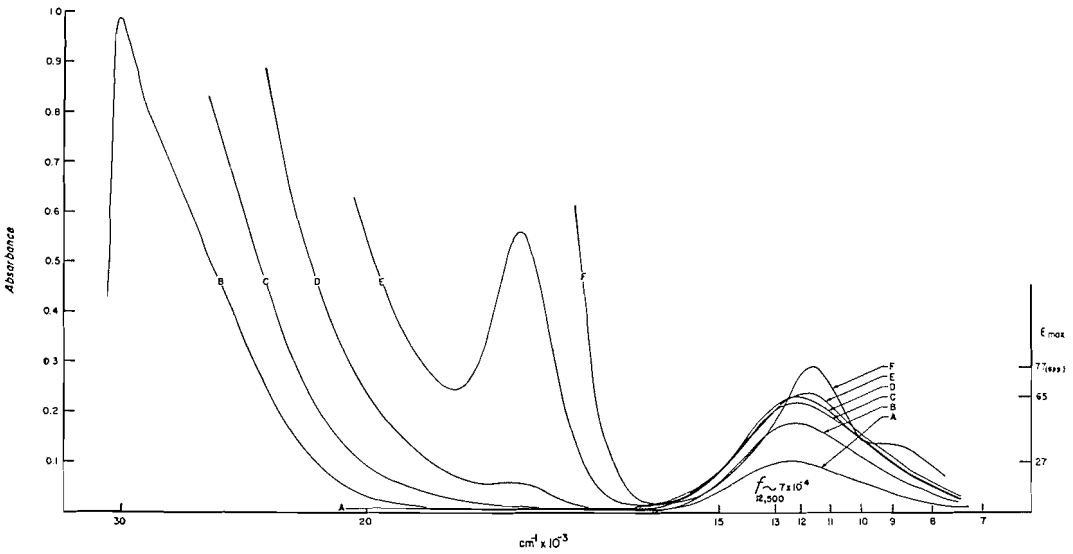

FIG. 1. Spectra of octahedral complexes. $[Cu]_{total} = 3.76 \times 10^{-3}$ *M*; $[Cl^-]/[Cu^{2+}]$ = (A) 0, (B) 0.64, (C) 0.96, (D) 1.28, (E) 1.92, and (F) 3.20.

In the interpretation of these spectral changes, it is assumed that spectrum A in Fig. 1 is that of a distorted (Jahn–Teller effect) octahedral complex $[Cu(OH_2)_4(ac)_2]^{2+}$ (where ac = acetone). Friedman and Plane (15) have shown that such a complex is present in acetone solutions of copper perchlorate containing small amounts of water. Since no free water was added to the initial system in the present work, it is possible that more than two molecules of acetone were present in the inner coordination sphere. However, the acetone used may well have contained as much as 0.05% water and because $\epsilon_{max} = 27$ l/mole cm at 12 500 cm^{-1} is similar to the value given by Friedman and Plane for $[Cu(OH_2)_4(ac)_2]^{2+}$, it is reasonable to assume that this is the complex responsible for the 12 500 cm^{-1} band. It is worth noting here that $[Cu(OH_2)_4(ac)_2]^{2+}$ has its d–d band maximum at the same energy as $Cu(OH_2)_6^{2+}$ because of the similar ligand fields of acetone and water (15).

From the above considerations it can be concluded that the monochlorocopper(II) complex is probably $[CuCl(OH_2)_3(ac)_2]^+$, or in the extreme, $[CuCl(ac)_5]^+$. Because acetones are preponderant in the system, it is felt that water molecules in the coordination sphere are replaced preferentially by chlorines. The decrease of approximately 300 cm^{-1} in Δ_{oct} accompanying the introduction of a chlorine into the coordination sphere is consistent with its position in the spectrochemical series.

At energies higher than approximately 20 000 cm^{-1} certain spectra in Figs. 1 and 2 show bands which, because of their intensity (and energy), are considered to be of the charge transfer type. Because these bands arise with chloride ligandcy it is reasonable to

assume that they are due to electronic transitions from ligand orbitals to orbitals centered on coppers. It is to be noted that the band at approximately 21 000 cm^{-1} (475 mμ) is not apparent until $[Cl^-]/[Cu^{2+}]$ exceeds 1:1; this band will be discussed more fully later in the paper.

Equilibrium Involving Four-, Five-, and Six-Coordinate Complexes

Pseudo-Octahedral Complex

Figure 3*b* shows the variation in absorbance at 11 500 cm^{-1} (see also B of Fig. 2) with the ratio $[Cl^-]/[Cu^{2+}]$; the plot indicates that the absorbing species contains four chlorines per copper. There seems to be little doubt that the complex is approximately octahedral and thus it can be formulated as $[CuCl_4(ac)_2]^{2-}$. From Fig. 1 it is evident that Δ_{oct} of this species is 1 000 cm^{-1} smaller than that of $[Cu(OH_2)_4(ac)_2]^{2+}$, i.e. an average decrease of 250 cm^{-1} for each chlorine.

The band maxima between 12 200 and 11 500 cm^{-1} in Fig. 1 are probably due to distorted octahedral complexes containing two and three chlorines per copper.

The oscillator strength, *f*, of the 11 500 cm^{-1} transition is approximately 10^{-3}, as calculated from the expression $f = 4.6 \times 10^{-9}\ \epsilon_{max}\ \nu^{1/2}$ ($\nu^{1/2}$ is the band width where $\epsilon_\nu = \frac{1}{2}\epsilon_{max}$) (16), and this is appropriate for an octahedral complex (cf. $\sim 7 \times 10^{-4}$ for $[Cu(OH_2)_4(ac)_2]^{2+}$).

The value of the oscillator strength and the relatively high degree of symmetry of the band at 11 500 cm^{-1} are indicative of a complex of high octahedral symmetry, one in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

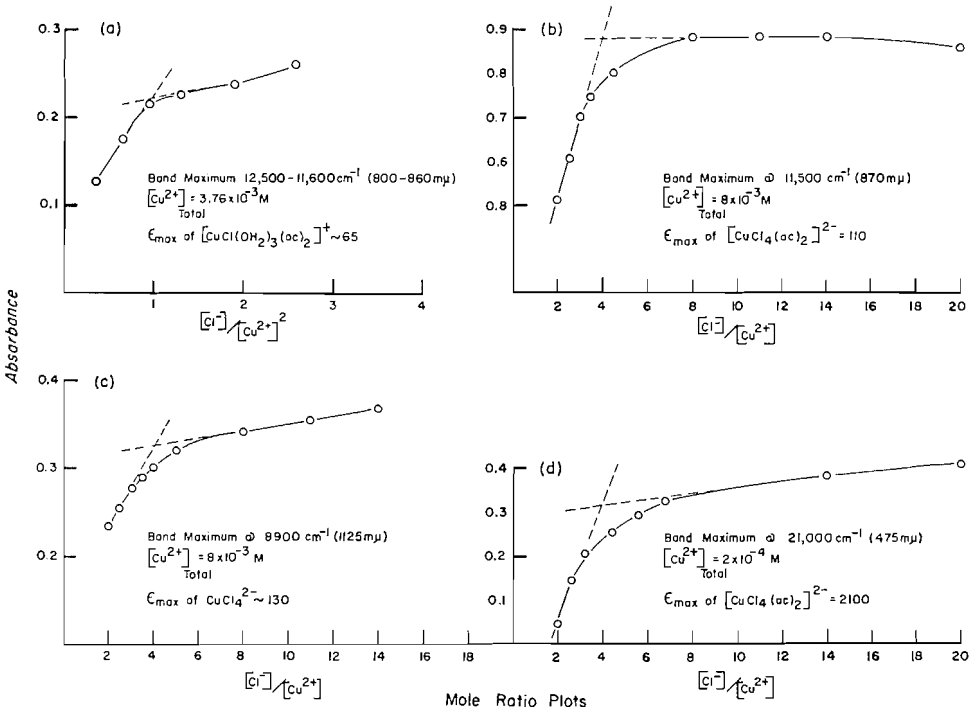

FIG. 3. Mole ratio plots.

which the four halide ions bind in a square plane. This is in accord with the previous findings that singly charged ligands are similarly bound (17).

Pseudo-Tetrahedral Complex

Spectrum B in Fig. 2 shows that even at relatively low values of $[Cl^-]/[Cu^{2+}]$, an appreciable proportion of the copper in the system is present as a species with an absorbance maximum at approximately 8 900 cm^{-1}. As indicated by the mole ratio plot in Fig. 3*c*, this band is also due to a 4:1 complex. The d-orbital splitting interval, Δ, for this complex is appreciably less than that for the pseudo-octahedral species described above, but it is larger than that calculated ($\sim$ 5 800 cm^{-1}) from theoretical considerations based on a tetrahedral model (11). It is known (1, 3, 6) that in certain systems $CuCl_4^{2-}$ is distorted, tending toward a planar structure; because of this distortion a value greater than Δ_{tetr} is to be expected for the complex. Therefore, it is reasonable to assume that the 8 900 cm^{-1} band is due to a complex having distorted tetrahedral symmetry. The change in absorbance at 8 900 and 11 500 cm^{-1} with variation in chloride ion concentration strongly suggests the existence of an equilibrium between the four- and six-coordinate species.

The asymmetry of the 8 900 cm^{-1} band (see D, especially in Fig. 2) indicates that there is one or more components at lower energies (the result of factors that cause further splitting of the d-orbital energy levels). As we will see later, the d–d band of tetrahedral $CuBr_4^{2-}$ (G and H in Fig. 2) in acetone media can be resolved into two peaks and there is reason to believe that the spectrum of $CuCl_4^{2-}$ would be analogous if it could be examined at sufficiently low energy. By extrapolation of spectrum D it is estimated that the low energy peak would lie between 5 500 and 6 000 cm^{-1}. Such a spectrum would be very similar to that of $CuCl_4^{2-}$ in Cs_2CuCl_4 at room temperature, in which Ferguson (18) found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

two major peaks at 9 050 and 5 550 cm^{-1}. (At 20 °K, Ferguson observed four d–d bands for the complex and made transition assignments for each.)

Close inspection of spectra B, C, and D of Fig. 2 reveals that the band maximum near 9 000 cm^{-1} (1 100 mμ) shifts slightly to higher energies in solutions that are relatively

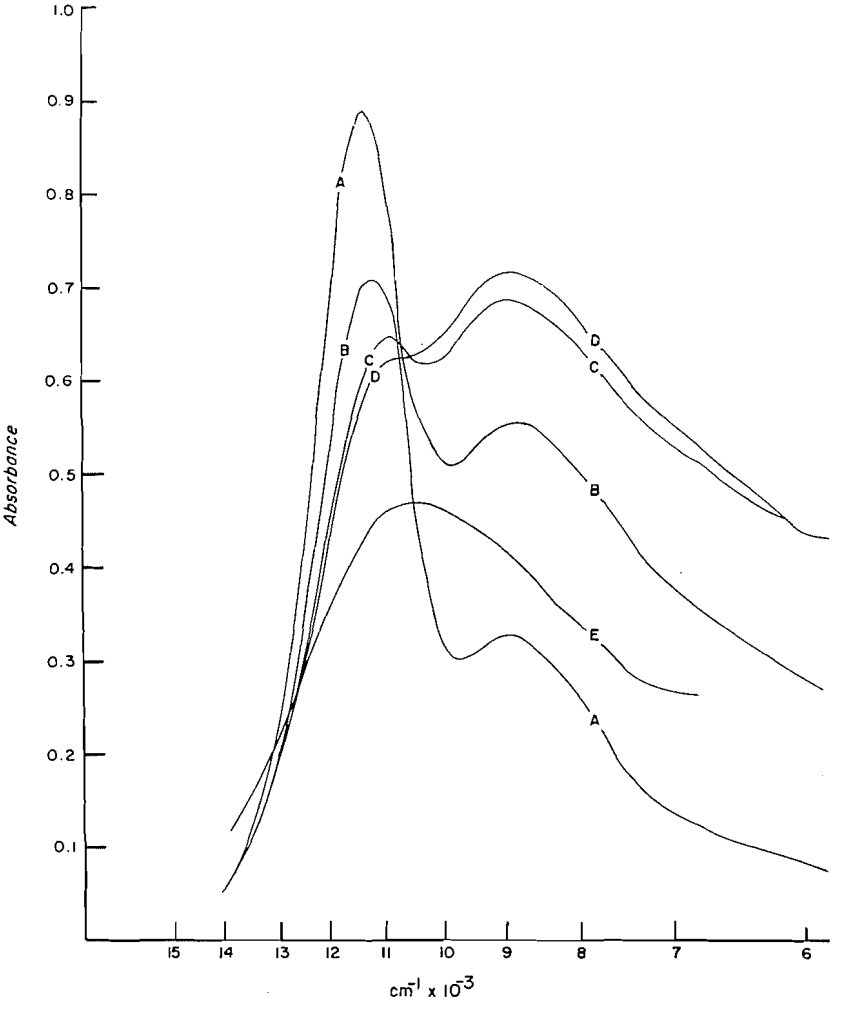

FIG. 4. d–d bands of hexa-, penta-, and tetra-coordinated species. $[Cu^{2+}]_{total} = 8 \times 10^{-3}$ *M*; $[Cl^-]/[Cu^{2+}]$ = (A) 8, (B) 62, (C) 120, (D) 154, and (E) 2×10^{-3} *M* solution of $CuCl_2.2H_2O$ in 12 *M* HCl.

concentrated with respect to hydrochloric acid (i.e. $> \sim 2$ *M*). This behavior is to be expected because such solutions contain enough water (from 12 *M* HCl) for it to compete effectively with chlorines for sites in the complex and thus the "blue shift" possibly represents the formation of a distorted tetrahedral complex having fewer than four chlorines per copper.

Evidence for Five-Coordinate Complex

At first glance, the shoulder in both spectra C and D of Fig. 4 appears to be a "remnant" of the d–d band of $[CuCl_4(ac)_2]^{2-}$. However, its maximum in D lies approximately 800 cm^{-1} lower than that of the six-coordinate complex, and, as we will see later (Fig. 5), its intensity is not consistent with the extinction coefficient of the band for $[CuCl_4(ac)_2]^{2-}$. Spectra C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and D in Fig. 4 intersect at an isobestic point at approximately 10 600 cm^{-1} and this clearly indicates that the shoulder is not due to the distorted tetrahedral complex. Therefore, from the above evidence, it seems necessary to invoke the existence of a third complex to account for the shoulder.

From Fig. 5 (the calculation of the values on the abscissa to be explained later) it is evident that when the total concentration of hydrochloric acid in the solution is 1–1.3 *M* (i.e. when $[Cl^-]/[Cu^{2+}]$ is 120–160) approximately 30% of Cu(II) is present as the pseudo-octahedral species $[CuCl_4(ac)_2]^{2-}$ with d–d band maximum at 11 500 cm^{-1}. The limiting value of the absorbance for this band is 0.89 (Figs. 2 and 3*b*) and therefore, in the mole ratio range mentioned above, it would be expected that the absorbance at the band maximum would be approximately 0.3 in the absence of other species absorbing appreciably at the same energy. However, the absorbance of the shoulder at 10 500 – 11 000 cm^{-1} in spectra C and D of Fig. 4 is over twice as high and this can be accounted for by the presence of a complex of appreciable intensity other than the six- and four-coordinate species already characterized.

It is tempting to postulate the existence of a five-coordinate complex (possibly pentachloro) as an "intermediate" in the overall structural transition from approximately octahedral $[CuCl_4(ac)_2]^{2-}$ to distorted tetrahedral $CuCl_4^{2-}$.

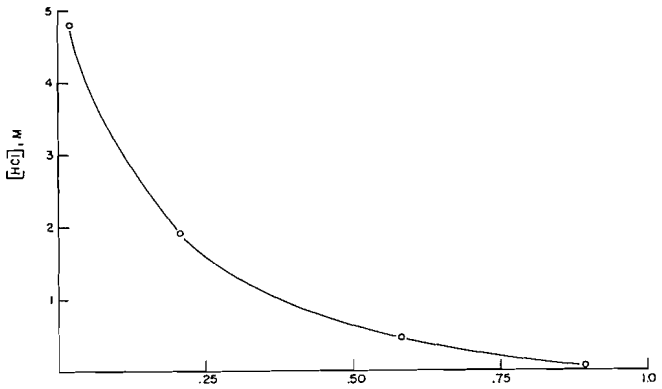

FIG. 5. Fraction of total copper present as $[CuCl_4(ac)_2]^{2-}$.

The $CuCl_5^{3-}$ ion (trigonal bipyramidal) has been identified in certain crystalline solids and its absorption spectrum shows a charge transfer band at approximately 27 000 cm^{-1} (19) and d–d bands at 10 400 and 8 200 cm^{-1} (20), the former being comparable to the shoulder of spectrum D at 10 700 cm^{-1}.

If it is assumed that the five-coordinate complex proposed in the present work is essentially trigonal bipyramidal, then consideration of a d-orbital splitting scheme for such a structure indicates that two bands due to the dx^2-y^2, $dxy \rightarrow dz^2$ and dxz, $dyz \rightarrow dz^2$ transitions should occur in the spectrum (21). It is also reasonable to expect that the band resulting from the latter transition (the higher energy of the two) should lie between those of the distorted octahedral and tetrahedral tetrachloro complexes. If the 10 700 cm^{-1} shoulder is taken to be due to the dx^2-y^2, $dxy \rightarrow dz^2$ transition, then the band due to the dxz, $dyz \rightarrow dz^2$ transition can be calculated to lie at approximately 8 500 cm^{-1}; however, at this energy it would be largely obscured by the band due to the pseudo-tetrahedral tetrachloro complex in spectra C and D of Fig. 4.

Of considerable interest are the spectra of solutions of $CuCl_2.2H_2O$ in 12 *M* HCl shown

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in Figs. 2(I) and 4(E). These show, respectively, a charge transfer band at approximately 27 000 cm^{-1} and a d–d band at approximately 10 500 cm^{-1}; thus one is led to conclude that, in the solutions studied, an appreciable proportion of the copper probably existed as $CuCl_5^{3-}$. The asymmetry of the d–d band may be due to the dx^2-y^2, $dxy \rightarrow dz^2$ transition in $CuCl_5^{3-}$ and (or) to a "contribution" from the distorted $CuCl_4^{2-}$.

Charge Transfer Bands

Charge transfer bands in the spectra of the tetrachlorocopper(II) complexes in the visible to near ultraviolet region are shown in Fig. 2 (E and F).

The mole ratio plot in Fig. 3*d* indicates that the complex responsible for the 21 000 cm^{-1} (475 mμ) band has four chlorines per copper and this is in agreement with the findings of Gažo (13) but not those of Furlani and Morpurgo (6). Because the band rises and falls in concert with the d–d band at 11 500 cm^{-1}, it can be concluded that it is due to the complex $[CuCl_4(ac)_2]^{2-}$. From the estimated limiting value of the absorbance ($\sim$ 0.42) and the total copper concentration indicated in Fig. 3*d*, ϵ_{max}, at 21 000 cm^{-1}, is calculated to be approximately 2 100 l/mole cm. With this value together with absorbance readings at various hydrochloric acid concentrations, the proportion of the total copper in the system that is present as $[CuCl_4(ac)_2]^{2-}$ has been calculated from absorbance/2100$[Cu^{2+}]_{total}$. Figure 5 shows how this varies with the hydrochloric acid concentration.

Figure 2 shows that the 21 000 cm^{-1} band virtually disappears at high Cl^- concentrations and is replaced by a new charge transfer band at approximately 25 000 cm^{-1}. The new band is similar to, but of slightly lower energy than, that observed for chlorocopper(II) complexes at very high Cl^- concentration (9–12 *M*) in aqueous solutions. It is probable that the band is analogous to that found at 24 800 cm^{-1} by Ferguson (18) in the spectrum of tetrahedral $CuCl_4^{2-}$ in Cs_2CuCl_4.

The wedge-shaped band with a maximum between 30 000 and 32 000 cm^{-1} (and which appears to contain several components) also seems to be associated with the octahedrally coordinated complexes, for it appears at low $[Cl^-]/[Cu^{2+}]$ ratios and decreases in intensity in accord with the 21 000 and 11 500 cm^{-1} bands of $[CuCl_4(ac)_2]^{2-}$ at high ratios.

Bromocopper(II) Complexes in Acetone – Hydrobromic Acid Solutions

A brief spectrophotometric study was made of bromocopper(II) complexes formed in the copper perchlorate – acetone – hydrobromic acid (8.2 *M*) system. The following are some of the findings obtained with experimental techniques similar to those described earlier and their interpretation:

(*a*) When $[Br^-]/[Cu^{2+}] < \sim 1$, a relatively stable six-coordinate complex, $[CuBr(OH_2)_3(ac)_2]^+$, is formed. The d–d band of this complex has its maximum at 12 000 cm^{-1} (835 mμ) and $\epsilon_{max} \sim 60$ l/mole cm.

(*b*) Rapid reduction of Cu(II) to Cu(I) by Br^- occurs when $[Br^-]/[Cu^{2+}]$ is in the range 1–150 (i.e. when [HBr] = 0.01–1.5 *M*) and thus it is possible to obtain only semi-quantitative spectral data, at best. However, the transient spectra of the green solutions produced under these conditions show a low-intensity band between 11 800 and 11 100 cm^{-1} (845–900 mμ). By analogy to the chloride system, it is felt that absorption in this region is due to pseudo-octahedral species containing from two to four bromines per copper and these complexes are unstable with respect to cuprous complexes (probably tetrahedral).

Barnes and Hume (5) found a band maximum at about 11 000 cm^{-1} in the spectrum of the green species in acetone solutions and they ascribed this band to the complex "$CuBr_3^-$.2 solvent". In view of the present findings, it seems more probable that the complex is $[CuBr_4(ac)_2]^{2-}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(*c*) At high hydrobromic acid concentrations (1.5 to at least 3.5 *M*) a purple complex, presumably tetrahedral $CuBr_4^{2-}$ (5), is formed. Compared with the six-coordinate 1:2, 1:3, and 1:4 bromo complexes the purple species seems to be relatively stable to reduction by Br^-.

The d–d bands (G and H of Fig. 2) of the $CuBr_4^{2-}$ complex show two peaks that lie somewhat closer together in acetone – hydrobromic acid solutions than in 8.2 *M* hydrobromic acid. The peaks are similar to those observed in the spectrum of $CuCl_4^{2-}$ in $CsCuCl_4$ (18).

(*d*) The spectra of acetone solutions of Cu(II) containing hydrobromic acid in intermediate concentrations reveal maxima at both approximately 11 000 and 8 400 cm^{-1} thus suggesting that the system is directly analogous to that of the chlorocopper(II) complexes, i.e. there is an equilibrium between six- and four-coordinate tetrabromocopper(II) complexes.

It is noteworthy that the ligand field bands of the octahedral and the high-energy component of the band of tetrahedral bromocopper complexes appear at lower energies than those of the corresponding chloro complexes and this is to be expected from the position of the halogens in the spectrochemical series.

Previously it was mentioned that octahedral bromocopper(II) complexes containing more than one bromine are unstable with respect to reduction to cuprous species. The reduction process also results in the formation of a tetrahedral structure (22) in which Cu(I) exists as a d^{10} ion with all electrons occupying relatively stable orbitals. It is probable that charge transfer processes in $[CuBr_4(ac)_2]^{2-}$ are more efficient than in $[CuCl_4(ac)_2]^{2-}$ since the lowest energy charge transfer bands observed for these complexes appear at approximately 15 000 and 21 000 cm^{-1} respectively; this accounts for the greater stability of the pseudo-octahedral tetrachlorocopper(II) species with respect to reduction of copper.

Comparison of Spectra of Halogenocopper(II) Complexes in Acetone Solution with Those in Chloride Melts and Crystalline Solids

For comparison purposes, spectral and structural data from the present study and from various other sources, previously cited, are listed in Table I.

The results of the present study, indicating an equilibrium between six- and four-coordinate tetrachloro (bromo) Cu(II) complexes in an acetone medium, are similar to those of Gruen and McBeth (3), who studied the absorption spectra of Cu^{2+} in LiCl–KCl melts. However, Gruen and McBeth did not find evidence for, or postulate the presence of, a five-coordinate complex participating in the equilibrium.

The halide ion activity in acetone – concentrated hydrochloric acid mixtures, having a final concentration of approximately 1–4 *M* for the acid, is comparable to that in chloride melts such as those used by Gruen and McBeth. For example, these workers estimate that the ratio of the concentrations of the tetrahedral and octahedral chlorocopper species in a LiCl–KCl melt at 1 000 °K is 2.2. In the present work (Fig. 4) this ratio corresponds to a solution in which the total molar concentration of hydrochloric acid is 1–1.5 *M*.

ACKNOWLEDGMENT

The author wishes to express appreciation to Dr. P. G. Manning for his sincere interest and for his valuable advice during the course of this work.

ION–MOLECULE REACTIONS IN METHYL ALCOHOL AND METHYL-d_3 ALCOHOL

J. C. J. THYNNE,[1] F. K. AMENU-KPODO, AND A. G. HARRISON
Department of Chemistry, University of Toronto, Toronto, Ontario

Received March 10, 1966

ABSTRACT

The rate constants for the hydrogen-transfer ion–molecule reactions

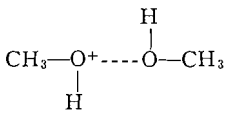
[*a*] $CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_3O$ (or CH_2OH)

[*b*] $CH_2OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_2O$

have been measured at thermal ion energies and found to be 12×10^{-10} cm^3 molecule^{-1} s^{-1} and 8.0×10^{-10} cm^3 molecule^{-1} s^{-1} respectively. The rate coefficients at higher ion energies (3.7 eV ion exit energy) show little change from these values. Reactions [*a*] and [*b*] have also been studied using CD_3OH and it is found that in reaction [*a*] the hydroxyl hydrogen is transferred 2.5 times more readily at low ion energies and 1.8 times more readily at high ion energies than a methyl hydrogen. This rather small specificity would appear to preclude formation of a "locked-in" collision complex even at low ion energies.

INTRODUCTION

Although the ion–molecule reaction producing $CH_3OH_2^+$ in the high-pressure mass spectrum of methyl alcohol originally was assumed (1, 2) to be



[1] $$CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_2OH \text{ (or } CH_3O),$$

Moran and Hamill (3) have shown that the apparent cross section decreases with decreasing electron energy, near the threshold, indicating reactions involving ions with appearance potentials higher than that of CH_3OH^+. Lindholm and Wilmenius (4, 5), using mass spectrometric selection of the reactant ions, observed both reaction [1] and reaction [2]

[2] $$CH_2OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_2O$$

in methyl alcohol. More recently, Ryan *et al.* (6) have re-investigated the reactions in methyl alcohol and methyl-d_3 alcohol using conventional mass spectrometric techniques and have reported cross sections for both reactions [1] and [2].

Our interest in the methyl alcohol system arose from the fact that the reactant species contain non-equivalent hydrogens and as a result one might expect to observe selectivity in the transfer reactions. In particular, the CH_3OH^+ ion is formed by removal of a non-bonding oxygen electron and ion–dipole interaction of this species with the polar CH_3OH molecule might be expected to lead to a collision complex (Structure I) in which the two hydroxyl groups are adjacent. Such a "locked-in" complex, if formed, would be

I

more probable at low ion energies, since as the ion energy increases a random orientation in the collision complex would be anticipated. In such a "locked-in" complex one would anticipate predominately hydroxyl-hydrogen transfer, whereas a random orientation of

[1]*Visiting Scientist. Permanent Address: Department of Chemistry, University of Edinburgh, Edinburgh, Scotland.*

the complex (at higher ion energies) or a stripping mechanism would probably result in a much less specific hydrogen transfer. Thus one might anticipate predominate hydroxyl-hydrogen transfer at low (or thermal) ion energies with this specificitiy decreasing to essentially a random selection of hydrogens as the ion energy increases. This argument presupposes that no other factors such as bond dissociation energies determine the detailed course of the reaction.

The hydrogen transferred in reaction [1] can be determined by suitable deuterium labelling and some experiments along these lines have been carried out. Using a preselected beam of CD_3OH^+ impinging on CD_3OH, Lindholm and Wilmenius (5) found $I_{CD_3OH_2^+}/I_{CD_3OHD^+} = 0.66$ at a reactant ion energy of 5 eV. Ryan *et al.* (6) report that reaction [1] in CD_3OH leads to $I_{CD_3OH_2^+}/I_{CD_3OHD^+} = 0.92$. This ratio represents a mean value for reaction of ions with energies ranging from zero to the final exit energy of 2.3 eV. Although the latter workers reported that no variation of the ratio with ion exit energy could be observed, a more detailed investigation, particularly at low ion energies, appeared desirable. We therefore have undertaken a detailed study of the ion–molecule reactions in CH_3OH and CD_3OH at thermal ion energies and over a range of repeller voltages corresponding to a range of final ion energies. The reactions were studied at thermal energies using the pulsing techniques previously described (7, 8), while for ions accelerated by the repeller field the ratio plot technique (9) was used to estimate the contributions of the various reactions occurring.

EXPERIMENTAL

The mass spectrometer used was an A.E.I. MS-2 instrument modified as previously described (7). The techniques for determining kinetic data for reactions of thermal energy ions have been adequately described (7, 8) as has the use of the ratio plot technique (9) for the study of concurrent reactions under conditions of constant ion acceleration.

The methyl alcohol used was a reagent grade sample. The methyl-d_3 alcohol was obtained from Merck Sharp and Dohme, Montreal, and had an isotopic purity of ~99% as determined by low-energy analysis.

RESULTS AND DISCUSSION

For the two concurrent reactions, [1] and [2], studied under conditions of constant ion acceleration, the total secondary ion current, $I_{CH_3OH_2^+}$, is given by eq. [3] where Q_X is the macroscopic cross section for reaction [X], d is the distance of reactant ion travel in the ion source, and the square brackets denote concentrations in units molecule cm^{-3}. In formulating eq. [3] we have neglected the small differences (9) in collection efficiencies.

$$[3] \qquad I_{CH_3OH_2^+} = Q_1 d[CH_3OH] I_{CH_3OH^+} + Q_2 d[CH_3OH] I_{CH_2OH^+}$$

Division of eq. [3] by $I_{CH_3OH^+}$ yields eq. [4]

$$[4] \qquad \frac{I_{CH_3OH_2^+}}{I_{CH_3OH^+}} = Q_1 d[CH_3OH] + Q_2 d[CH_3OH] \frac{I_{CH_2OH^+}}{I_{CH_3OH^+}}$$

which predicts that a plot of $I_{CH_3OH_2^+}/I_{CH_3OH^+}$ versus $I_{CH_2OH^+}/I_{CH_3OH^+}$ should yield a straight line with the relevant cross sections being obtainable from the slope and intercept. Division of eq. [3] by $I_{CH_2OH^+}$ leads to an analogous equation, and in practice the experimental data were analyzed by both equations.

Figure 1 shows typical results obtained for CH_3OH at 10.5 V cm^{-1} repeller (3.7 eV ion exit energy) plotted in the manner indicated by eq. [4]. The ion current ratios were varied by changing the ionizing electron energy and all measurements were made at energies where only CH_2OH^+ and CH_3OH^+ were significant primary ions. The non-zero intercept and slope clearly show the occurrence of both reactions [1] and [2]. The $CH_3OH_2^+$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ion current at $m/e = 33$ has not been corrected for $^{13}CH_3OH^+$ with the result that the intercept of Fig. 1 actually gives $0.011 + Q_1d[CH_3OH]$. Table I summarizes the experimental cross sections obtained by least squares analysis and the rate constants calculated by the relation (10)

$$[5] \qquad k = \frac{Qd}{\tau},$$

where τ is the primary ion residence time.

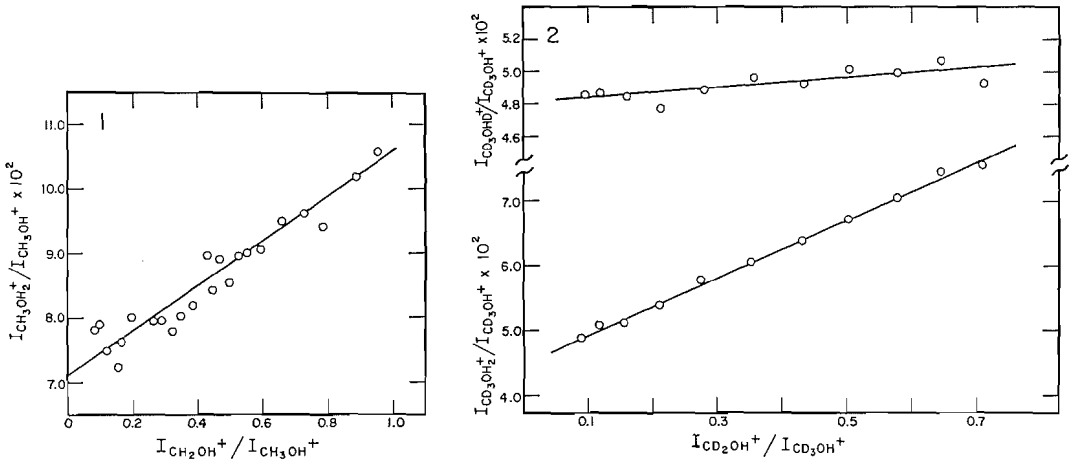


FIG. 1. Ratio plot for CH_3OH.
FIG. 2. Ratio plots for CD_3OH.

TABLE I

Cross sections and derived rate constants at 3.7 eV ion energy

	Reaction	Q (cm^2 molecule^{-1} $\times 10^{10}$)	k (cm^3 molecule^{-1} $s^{-1} \times 10^{10}$)
[1]	$CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_3O$ (CH_2OH)	62.3	14.6
[2]	$CH_2OH^+ + CH_3OH \rightarrow CH_3OH_2^+ CH_2O$	34.9	8.3_5
[6]	$CD_3OH^+ + CD_3OH \rightarrow CD_3OH_2^+ + CD_3O$	28.2±0.6	6.3_0
[7]	$CD_3OH^+ + CD_3OH \rightarrow CD_3OHD^+ + CD_2OH$	36.9±0.2	8.2_5
[8]	$CD_2OH^+ + CD_3OH \rightarrow CD_3OH_2^+ + CD_2O$	29.3±0.7	6.6_8
[9]	$CD_2OH^+ + CD_3OH \rightarrow CD_3OHD^+ + CDOH$	2.0±0.3	0.4_5

In CD_3OH both $CD_3OH_2^+$ and CD_3OHD^+ are observed as the products of ion–molecule reactions. Since the ion corresponding to CH_2OH^+ is predominately (>95%) CD_2OH^+ in the labelled alcohol, only the following four reactions need be considered at low electron energies.

$$[6] \qquad CH_3OH^+ + CD_3OH \rightarrow CH_3OH_2^+ + CD_3O$$

$$[7] \qquad CD_3OH^+ + CD_3OH \rightarrow CD_3OHD^+ + CD_2OH$$

$$[8] \qquad CD_2OH^+ + CD_3OH \rightarrow CD_3OH_2^+ + CD_2O$$

$$[9] \qquad CD_2OH^+ + CD_3OH \rightarrow CD_3OHD^+ + CDOH$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A treatment similar to the above leads to the following ratio equations for $I_{CD_3OH_2^+}$ and $I_{CD_3OHD^+}$.

$$[10] \qquad \frac{I_{CD_3OH_2^+}}{I_{CD_3OH^+}} = Q_6 d[CD_3OH] + Q_8 d[CD_3OH]\frac{I_{CD_2OH^+}}{I_{CD_3OH^+}}$$

$$[11] \qquad \frac{I_{CD_3OHD^+}}{I_{CD_3OH^+}} = Q_7 d[CD_3OH] + Q_9 d[CD_3OH]\frac{I_{CD_2OH^+}}{I_{CD_3OH^+}}$$

Figure 2 shows typical results obtained for the CD_3OH system plotted in the manner of eqs. [10] and [11]. The cross sections obtained by least squares analysis are summarized in Table I, where the limits of error represent the mean deviation of three separate runs. The results show that the CD_2OH^+ ion transfers predominately the hydroxyl hydrogen, in agreement with earlier conclusions (5).

The results for the labelled and unlabelled alcohols are internally consistent and any small differences should not be attributed to isotopic effects since the results were obtained some months apart and experimental conditions may have changed slightly. The present value for k_1 is considerably lower than the value of 24.5×10^{10} cm^3 molecule^{-1} s^{-1} reported by Ryan *et al.* (6) although our ratio $k_6/k_7 = 0.767$ is in reasonable agreement with their value of 0.92. The reasons for the discrepancies in the rate coefficients are not apparent. For reaction [2] our rate constant of $8.3_5 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} is in reasonable agreement with Ryan *et al.*'s value of 6.8×10^{-10} cm^3 molecule^{-1} s^{-1}.

The rate coefficients for the reactions of thermal energy ions were obtained by the pulsing techniques described previously (7, 8), where reaction time is the experimental variable. For the unlabelled alcohol the total secondary ion current observed after a time delay, t, between the ionizing and ion withdrawal pulses can be expressed as follows (for a small extent of reaction)

$$[12] \qquad I_{CH_3OH_2^+} = (k_1[CH_3OH]I_{CH_3OH^+} + k_2[CH_3OH]I_{CH_2OH^+})t + C$$

where k_1 and k_2 are the thermal rate constants for reactions [1] and [2] and C is a constant reflecting the $CH_3OH_2^+$ formed during the ionizing and withdrawal pulses. Rearrangement of eq. [12] gives

$$[13] \qquad \frac{I_{CH_3OH_2^+}}{I_{CH_3OH^+}} = \left(k_1[CH_3OH] + k_2[CH_3OH]\frac{I_{CH_2OH^+}}{I_{CH_3OH^+}}\right)t + C'$$

which predicts that the slopes of the experimental $I_{CH_3OH_2^+}/I_{CH_3OH^+}$ versus t plots should be a linear function of the reactant ion current ratio $I_{CH_2OH^+}/I_{CH_3OH^+}$ at constant ion source concentration. Figure 3 shows typical results obtained for CH_3OH and shows the increase in slope with increasing primary ion current ratio. This ratio was varied by changing the ionizing electron energy and was independent of delay time over the time range covered. The experimental slopes are shown in Fig. 4 plotted against the ratio $I_{CH_2OH^+}/I_{CH_3OH^+}$. Although the scatter is rather large a satisfactory least squares line can be drawn. Two such determinations yielded the values of k_1(thermal) and k_2(thermal) tabulated in Table II.

For the $CD_3OH_2^+$ and CD_3OHD^+ ions formed in CD_3OH, eqs. [14] and [15] can be written expressing the time dependence of the ion current ratios.

$$[14] \qquad \frac{I_{CD_3OH_2^+}}{I_{CD_3OH^+}} = \left(k_6[CD_3OH] + k_8[CD_3OH]\frac{I_{CD_2OH^+}}{I_{CD_3OH^+}}\right)t + B$$

$$[15] \qquad \frac{I_{CD_3OHD^+}}{I_{CD_3OH^+}} = \left(k_7[CD_3OH] + k_9[CD_3OH]\frac{I_{CD_2OH^+}}{I_{CD_3OH^+}}\right)t + B'$$

TABLE II
Rate constants at thermal ion energies

	Reaction	k(thermal) (cm^3 molecule^{-1} $s^{-1} \times 10^{10}$)	k(10.5 V/cm) (cm^3 molecule^{-1} $s^{-1} \times 10^{10}$)
[1]	$CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_3O$ (CH_2OH)	13.4_4, 10.9_8	14.6
[2]	$CH_2OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_2O$	8.5_6, 7.3_7	8.3_5
[6]	$CD_3OH^+ + CD_3OH \rightarrow CD_3OH_2^+ + CD_3O$	4.7_8, 5.1_6	6.3_0
[7]	$CD_3OH^+ + CD_3OH \rightarrow CD_3OHD^+ + CD_2OH$	6.0_7, 5.9_1	8.2_5
[8]	$CD_2OH^+ + CD_3OH \rightarrow CD_3OH_2^+ + CD_2O$	7.0_9, 7.2_9	6.6_8
[9]	$CD_2OH^+ + CD_3OH \rightarrow CD_3OHD^+ + CDOH$	0.01, 0.3	0.4_5

Typical results for $CD_3OH_2^+$ plotted in the form of eq. [14] are shown in Fig. 5 where the increase in slope with increasing $I_{CD_2OH^+}/I_{CD_3OH^+}$ is clearly evident. The slopes of such plots are shown in Fig. 6 plotted against the $I_{CD_2OH^+}/I_{CD_3OH^+}$ ratio. Also shown in Fig. 6 are the slopes of the experimental plots of eq. [15] as a function of the primary ion current ratio. The relevant rate constants obtained by least squares analyses of two sets of runs are summarized in Table II.

Again the results for the labelled and unlabelled alcohols are in reasonable agreement with each other. The thermal rate constants are compared in Table II with the rate constants derived from the data at 10.5 V/cm. On the whole the thermal rate constants are slightly lower than the 10.5 V/cm data. This result is in agreement with the results obtained previously (8) for the hydrogen transfer reactions in methane, CH_3CN, CH_3OCH_3, and some deuteriated equivalents.

The two sets of thermal data give $k_6/k_7 = 0.79$ and 0.87 while the average results at 3.7 eV ion exit energy $k_6/k_7 = 0.67$. Although these data suggest little change in the hydrogen selectivity with ion energy, a more extensive study of reactions [6], [7], and [8]

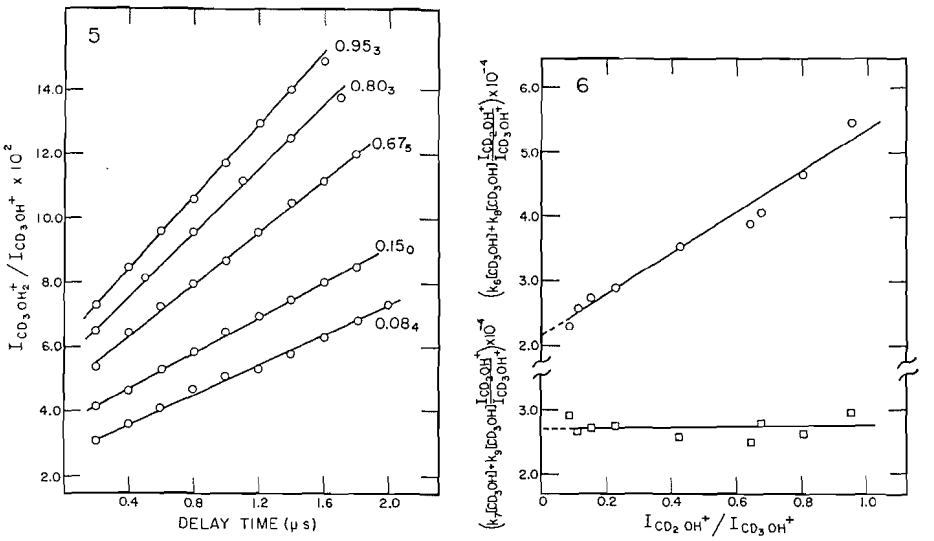

FIG. 5. $I_{CD_3OH_2^+}/I_{CD_3OH^+}$ versus delay time for CD_3OH. The successive plots are displaced upwards for clarity, and the numbers give the $I_{CD_2OH^+}/I_{CD_3OH^+}$ ratio.
FIG. 6. Analyses of delay time plots for CD_3OH.

was undertaken by the ratio plot technique over a range of repeller voltages from 4 V to 36 V. The cross sections obtained are summarized in Table III. As can be seen by the last column the ratio Q_6/Q_7 (and hence k_6/k_7) decreases from ~0.83 at the lowest ion exit energy to 0.59 at 13.3 V ion exit energy. Neglecting any isotopic effects and allowing for the 3:1 ratio of methyl to hydroxyl hydrogens, these results show that a hydroxyl hydrogen is transferred 2.5 times more readily at thermal and low ion energies and 1.8 times more readily at the highest ion exit energies than a methyl hydrogen. Although these results show a preference for hydroxyl-hydrogen transfer and also the expected trend with ion energy neither the magnitude of the rate constant ratio nor its energy dependence appear to be sufficiently large to support the suggestion of a "locked-in" collision complex. The factors which determine the hydrogen transferred would thus appear to other than the primary interaction forces. In this regard we might point out that reaction [2] (and the equivalent reactions [8] and [9]) involves exclusively the hydroxylic

hydrogen and this is undoubtedly due to the greater stability of the $H_2C{=}O$ neutral compared to HC—OH. Further we have found (Thynne and Harrison. To be published) that the reaction analogous to reaction [1] in CH_3SH proceeds predominately by transfer of the mercaptyl hydrogen over the whole range of ion energies studied and in this case we would suggest that the specificity arises primarily from bond strength effects.

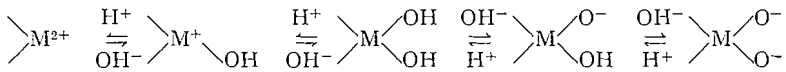
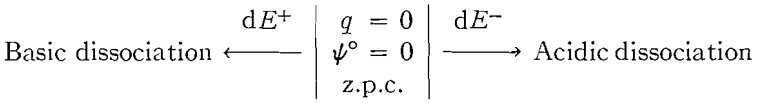
STUDIES OF THE DISSOCIATION OF OXIDE SURFACES AT THE LIQUID–SOLID INTERFACE[1]

SYED M. AHMED[2]
Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada

Received October 13, 1965



ABSTRACT



The dissociation of surface hydroxyl groups of crystalline SiO_2, ZrO_2, and ThO_2, in aqueous suspensions, has been studied as a function of pH_s at different ionic strengths of KNO_3. The surface groups of quartz dissociate as weak acids, while those of ZrO_2 and ThO_2 dissociate amphoterically. A reversible double layer is formed at the oxide–solution interface, and H^+ and OH^- function as the potential-determining ions. Quantitative data have been obtained on (*a*) surface charge densities, (*b*) zero point of charge, (*c*) differential capacities of the double layer on quartz and ZrO_2, and (*d*) the effect of surface charge density and ionic strength on the interfacial tension. The differential capacities indicate specific adsorption of NO_3^- on ZrO_2 and ThO_2 while NO_3^- has zero affinity for quartz surfaces. At low negative charge densities, solvated K^+ are adsorbed on quartz and ZrO_2 through coulombic interactions while at $pH_s > 10$ specific adsorption of K^+ predominates. ThO_2 appears to exhibit a greater tendency for the specific adsorption of K^+.

INTRODUCTION

The double layer at an oxide–solution interface can be investigated by studying the equilibrium distribution of the potential-determining ions (H^+ and OH^-) between the interface and the bulk solution, as a function of pH_s and ionic strength. The experimental and thermodynamic principles underlying this method are well established in the earlier works of others on AgI (1, 2), Ag_2S (3, 4), and Fe_2O_3 (5). The present work, using crystalline samples of quartz, ZrO_2, and ThO_2 of low and known surface areas, is based on similar principles but uses different techniques so as to minimize any secondary effects that may arise from slime formation and solubility of the material. The work is primarily aimed at deriving information on the nature of interactions at the interface from the double layer characteristics. The thermodynamic principles from this point of view are outlined below for the purpose of the discussion to follow.

The origin of charge ($\pm$) at an amphoteric oxide–solution interface may be attributed to the basic or acidic dissociation of the metal hydroxide groups on the surface. The equilibria are

The pH_s (6) at which the surface is undissociated is the zero point of charge (z.p.c.), where the charge density q is zero. It is seen from the above equilibria that addition of the oxide to a solution in the region of acidic dissociation will decrease the pH_s of the bulk solution and the surface will have a negative charge. In the region of basic dissociation, however, the pH_s of the bulk solution will increase on adding an amphoretic oxide and

the surface acquires a positive charge. It is the extent of these changes in pH_s of the solution at a constant ionic strength that are measured in the present work. Applying Gibbs' adsorption equation to the system at constant temperature, pressure, and ionic strength, the latter controlled by KNO_3, it can be shown that

$$[1] \qquad d\gamma = -F[\Gamma_{H^+} - \Gamma_{OH^-}]_{\mu_{K^+,NO_3^-}} \cdot dE^{\pm},$$

where γ is the interfacial energy, Γ_{H^+} and Γ_{OH^-} are the surface excess (1, 7) of H^+ and OH^- respectively in moles/cm^2 and the rest of the terms have their usual meaning. The change dE in the electrochemical potential of H^+ and OH^- in solution is measured using a standardized glass electrode, and, when taken from the z.p.c., may also be identified with the variation of potential in the double layer. The charge density q, which is a result of surface dissociation, can be regarded as the difference in the adsorption densities of H^+ and OH^- on the surface, so that

$$[2] \qquad d\gamma = -(q^{\pm}./dE^{\pm})_{\mu_{K^+,NO_3^-}} \quad \text{or} \quad (d\gamma/dE^{\pm})_{\mu_{K^+,NO_3^-}} = -q^{\pm}.$$

The charge density q is positive, zero, or negative in sign depending on whether $\Gamma_{H^+} > = \text{or} < \Gamma_{OH^-}$. The charge density q is zero (z.p.c.) when the interfacial energy is a maximum. The differential capacity C of the entire double layer can be written from eq. [2] as

$$[3] \qquad (d^2\gamma/dE^2)_{\mu_{K^+,NO_3^-}} = -(dq/dE)_{\mu_{K^+,NO_3^-}} = C.$$

By following the variation in C, inferences can be drawn as to the nature of interactions at the interface. A good discussion on this subject is available elsewhere (7–12). Assigning a hypothetical value γ_0 (the absolute value is not known) for the interfacial energy when $q = 0$, and taking into account chemisorption of K^+ and NO_3^- on the surface at the z.p.c., the integration of the more general form of eq. [2] gives

$$[4] \qquad \gamma - \gamma_0 = \left(\int_{E_0}^{E} q^{\pm}\, dE^{\pm}\right)_{\mu_{K^+,NO_3^-}} = -\infty - \left(\int_{-\infty}^{\mu} \Gamma_{K^+,NO_3^-} \cdot d\mu_{K^+,NO_3^-}\right)_E.$$

If the chemisorption of K^+, NO_3^-, is neglegible, the last term in eq. [4] may be omitted. At a constant pH_s ($dE^{\pm} = 0$), the degree of dissociation of the surface is constant and the effect of changing the ionic strength of the indifferent electrolyte on the interfacial energy can be described according to eqs. [5] and [6], which follow from the more general form of eq. [1].

$$[5] \qquad d\gamma_{H^+/OH^-} = -\Gamma_{K^+} \cdot d\mu_{K^+} \quad \text{for } q^- \text{ and}$$

$$[6] \qquad d\gamma_{H^+/OH^-} = -\Gamma_{NO_3^-} \cdot d\mu_{NO_3^-} \quad \text{for } q^+.$$

It is assumed that ions having the same charge as that on the surface have no influence on γ.

In the present work quantitative data have been obtained on the double layer characteristics considered above, and inferences have been drawn qualitatively as to the nature of interactions at the surface. Such information would be of considerable practical value in various fields of studies such as adsorption, adhesion, flotation, etc., dealing with nonmetallic substances.

EXPERIMENTAL

Materials

Brazilian quartz and crystalline forms of fused ZrO_2 and ThO_2 were used, the two latter being supplied by The Norton Co., Chippawa, Ontario. The material in −100+150 mesh size was leached for 24 h with 20% HCl in an all-glass Soxhlet. The samples were washed free of chloride, deslimed, and stored in degassed conductivity water, which was replaced frequently. For desliming, the material was packed in a long glass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tube with a fritted-glass bottom and elutriated with a rising current of distilled water. Quartz and ThO_2 samples were found by spectrographic analysis to be >99.9% pure. ZrO_2 contained ~0.5% trace impurities mainly TiO_2, SiO_2, Fe_2O_3, and CaO. These impurities may, however, be leached out of the surface in the acid treatment. X-Ray diffraction analysis indicated that quartz was the usual α form (hexagonal) and that ZrO_2 and ThO_2 were single phase baddelyite (monoclinic) and thorianite (cubic) respectively. Analytical reagent grade KNO_3 was recrystallized from water. HNO_3 (A.R.) was purified from any dissolved oxides of nitrogen by bubbling argon through a hot 1:2 solution of the acid and stored cool in the dark.

Method

The oxide samples were given a blank stirring treatment in water under the same conditions as used in the experiment. The specific areas of the resultant material were determined by the B.E.T. krypton gas adsorption method (13). The specific areas of quartz, ZrO_2, and ThO_2 were found to be 429, 1 438, and 192 cm^2/g respectively. A Beckman Research pH meter that could be read with a relative accuracy of 0.002 pH unit was enclosed in a constant humidity (~50%) box leaving the electrodes outside. The dissociation studies were carried out in a Pyrex glas tube ($2\frac{1}{8}$ in. × $1\frac{1}{8}$ in.) provided with an outer jacket for the circulation of water at 25 ± 0.05 °C. An inert atmosphere was maintained above the solutions by passing argon through two side vents fitted to the main chamber which was also closed to the open air by a flexible covering. Argon was purified to remove traces of CO_2 and other acidic impurities. A Beckman micro glass electrode and a KCl – saturated calomel electrode were used, the latter being separated from the experimental solution by a saturated KNO_3 solution bridge through a fiber junction. A series of oxide samples (1.5 to 3 g each) were rewashed and freshly dried at room temperature in a vacuum desiccator that was subsequently opened in an atmosphere of argon. Published information (14, 15) indicates that the chemisorbed water is retained on the surface of quartz through the formation of hydroxyl bonds, and ZrO_2 and ThO_2 are assumed to behave similarly. The glass electrode was calibrated against Beckman and Coleman buffers in the pH range 2.4 to 11.0.

A 10 ml solution of KNO_3 was taken in the reaction vessel and the dissolved CO_2 was first expelled by rapid stirring under a current of argon. The pH_s was adjusted as required by means of HNO_3 or KOH and the variation in pH_s on stirring of the blank solution was followed at time intervals of 2 min. When the solution attained a steady pH_s, a sample of the prepared oxide was added and the variation in pH_s with time again followed at intervals of 2 min. Fresh samples of oxides and solution were used for each run. Smaller quantities (~1.5 g) of oxide were used near the z.p.c. than at other pH_s (~2.5–3.0 g). It was found that almost all the change in pH_s occurred within 2–6 min of the addition of oxide. This was followed by a much slower variation (<5% of the initial change) in the pH_s that was attributed to secondary effects such as slime formation and solubility of the material. Corrections for these effects and for the blank were made. Verwey (16) has also reported that equilibrium is attained almost immediately in such oxide systems. The solubility[3] of the oxides under similar experimental conditions was also studied as a function of pH_s and time, using standard colorimetric methods. No dissolved material could be detected (sensitivity 1 μmole/l) under the present conditions of experiments, whereas stirring for prolonged periods (about half an hour or longer) produced dense colloidal solutions in the case of ZrO_2 and ThO_2. Stirring was found to cause random variation in the liquid junction potentials and, hence, in the pH_s; stirring was therefore interrupted at the time of reading the meter at high sensitivity. It was also noted that any stirring method which crushed the material and produced more slimes, gave erratic results. In the present work a tiny glass stirrer was used.

The activity coefficients of H^+ and OH^- in 10^{-3} *M* and 1 *M* KNO_3 solutions were experimentally determined for each buffer over the relevant pH_s range, and the factors $1/f_{H^+}$ and $1/f_{OH^-}$ below and above pH_s 7 respectively were calculated. These factors are markedly dependent on ionic strength of the solution and to a lesser degree on pH_s.

RESULTS

In solutions of pH_s > the z.p.c. of the oxide, a decrease in pH_s occurred on adding quartz, ZrO_2, or ThO_2. In this range of pH_s, q is assigned a negative charge as per the mechanism already considered. In solutions of pH_s < the respective z.p.c. of the oxide, an increase in pH_s occurred on adding ZrO_2 and ThO_2 and their surfaces are assigned a positive charge. The decrease in pH_s on adding quartz to 1 *M* KNO_3 solutions, as stated above, occurred only above pH_s 4, but below this pH_s no change could be observed experimentally. From the initial and final pH_s (if <7) or pOH_s (if pH_s > 7), the respective values of a_{H^+} or a_{OH^-} are calculated. The necessary corrections for blank, solubility, and slime formation if any, are made. The activities are converted into concentration terms

[3]*Similar studies of the solubility of specular hematite near the z.p.c. indicate that in a period of 1 h about 10^{-5} mole of Fe/l goes into solution, whereas in the first few minutes, during which almost all the change in pH_s occurs, the solubility of iron was below detection limits (1 μmole/l).*

c_{H^+} or c_{OH^-}, by multiplying with the respective activity coefficient factors $1/f_{H^+}$ (for $pH_s < 7$) and $1/f_{OH^-}$ (for $pH_s > 7$). From the resulting data one can calculate (Δc_{H^+} or Δc_{OH^-})/10 ml cm^{-2} oxide, and hence the charge densities q.

In Figs. 1, 2, and 3 the positive and negative charge densities for the oxides (only q^- for quartz) are plotted on a linear scale against the final pH_s and the potential difference in mV relative to the z.p.c. The plotted values of q^- for quartz in 10^{-3} M KNO_3 solution (Fig. 1) have been expanded in order to show finer details. The differential capacity C ($\mu F/cm^2$) of the whole double layer on quartz and zirconia in 10^{-3} M KNO_3 solutions has been obtained by the graphical differentiation of the smoothened charge density curves of

Figs. 1 and 2. The results are shown plotted in Fig. 4. The q^- values for quartz below pH_s 7 in 10^{-3} M KNO_3 solutions are too low for an accurate measurement of the slopes, and, hence, the C values obtained at and above pH_s 7 are shown in Fig. 4. The C values obtained similarly for ThO_2 were comparatively higher in magnitude and this behavior will be discussed later. The changes in the interfacial energy, $(\gamma - \gamma_0)$ in ergs/cm^2, have been obtained by the graphical integration of the charge density plots of Figs. 1, 2, and 3. The results are plotted for the three oxides in Figs. 5, 6, and 7.

DISCUSSION

The Charge Densities and the Zero Point of Charge

The silanol groups on quartz surfaces dissociate as acids and the surface therefore has a negative charge throughout the pH_s range shown in Fig. 1. It is also evident from the experimental results that NO_3^- has no affinity for quartz surfaces in the presence of H^+ and OH^-, and, hence, the silanol groups show no signs of basic dissociation. Although no change in pH_s of 1 *M* KNO_3 solutions could be experimentally detected below pH_s 4 on adding quartz, an extrapolation of the charge density plot (Fig. 1) to zero charge gives a $pH_s = 3.6 \pm 0.05$ as the z.p.c. of quartz. Since there is no evidence of specific adsorption of K^+ or NO_3^- on quartz at low pH_s (cf. discussion on *C*), this value for the z.p.c. of quartz is acceptable. It is in close agreement with the isoelectric point (pH 3.7) of coarse and crystalline quartz obtained by electrokinetic measurements (17). The hydroxyl groups on ZrO_2 and ThO_2 dissociate amphoterically (Figs. 2 and 3) and as a result the surface could be either positively or negatively charged. The charge density plots of quartz and ZrO_2 in 10^{-3} *M* KNO_3 solutions show a sharp change in slope at $pH_s \approx 9$ and 10 respectively. The significance of this behavior could be best discussed in light of the differential capacities. The z.p.c. of ZrO_2 and ThO_2 in 10^{-3} *M* KNO_3 solutions occur at pH_s 5.5 ± 0.05 and 5.9 ± 0.05 respectively and the corresponding values in 1 *M* KNO_3 are 6.2 ± 0.05 and 6.8 ± 0.1. The glass electrode in this range of pH_s was found to record a somewhat lower value on increasing the ionic strength of the solution from dilute to 1 *M* KNO_3. Hence the actual shift in the z.p.c. could be somewhat more than what is noted above. This shift in the z.p.c. towards a more negative potential can be attributed to the specific adsorption of NO_3^- and also of any dissolved complexes, at the z.p.c. (eq. [6]). There is clear evidence from the differential capacity curves that NO_3^- is specifically adsorbed on positively charged ZrO_2 and ThO_2, particularly at high charge densities.

A comparison of q^- values with the total number of sites available per cm^2 of quartz ($\sim$2 sites/23.4 Å^2) indicates an almost monolayer dissociation of quartz surfaces at $pH_s \approx 11.5$, whereas the fraction of the surface groups on ZrO_2 and ThO_2 dissociated at this pH_s is much less. At very high and low pH_s solubility effects may become considerable and the measurements less accurate because of small changes in pH_s. As a result of surface heterogeneity, some groups on the surface of a given oxide may dissociate as acids and others as bases giving an overall neutral reaction. It is then possible that the experimental values obtained for the z.p.c. of ZrO_2 and ThO_2 may not be accurate; they should, nevertheless, be good approximations.

The Differential Capacity Curves

The minimum values of the differential capacity, *C*, obtained for quartz and ZrO_2 in 10^{-3} *M* KNO_3 solutions at the z.p.c. are in agreement with the theoretically expected value (6 μF/cm^2) (7) in the absence of specific adsorption. As the *C* curves were obtained by the graphical differentiation of the smoothened charge density curves, no quantitative precision, either in the upper range of *C* values or in the shape of the curves can be expected. The following conclusions can, however, be drawn qualitatively. The positive branch of the *C* curve for quartz is absent for reasons already discussed. The *C* curves on positively charged ZrO_2 (and also ThO_2) indicate considerable specific adsorption of NO_3^- on the surface, even at low charge densities. Above pH_s 9 and 10 for quartz and ZrO_2 respectively, there is a relatively steep rise in *C* with increasing pH_s, indicating specific adsorption of K^+. Such behavior is not encountered on Hg except in the rare cases, such as Tl^+ and to some extent Cs^+ (18, 19). However, there is considerable evidence for a similar behavior on the

cathodic surfaces of metals, particularly those bearing an oxide film (19, 11 p. 670). It has been reported (11 p. 670) that on removing the oxide film from the metal such as Pt, the metal behaves like Hg in its differential capacity curves. Super-equivalent adsorption (18) of cations on the cathodic surface of Hg through specifically adsorbed anions is also known. In the present case of oxides, specific adsorption of cations may be said to occur on the metal through chemisorbed O^{2-}. Further evidence for the specific adsorption of cations on oxides at high pH_s is obtained from the adsorption of Ca^{2+} on quartz (20), which has been found to increase sharply at $pH_s > 9$. This effect is also indicated by a drop in the negative zeta-potential (17) (which is approximately the difference in potential between the outer Helmholtz plane and the bulk solution) of quartz at $pH_s > 10$.

Compared to the other oxides, higher values of C (cf. higher $q^{\pm}$ values) were obtained for ThO_2 in 10^{-3} M KNO_3 solutions. This effect could be due to a higher tendency for the specific adsorption of K^+ and NO_3^- on ThO_2 than on the other oxides. It may also be partly due to a greater tendency of ThO_2, as noticed experimentally, to form slimes and colloidal solutions even in short time intervals. If the formation of slimes and the solubility of the material are not checked and corrected for, abnormal values of q and C could be obtained. Also, the slimes may have a different z.p.c. from the coarse and crystalline material. The dissolved hydroxy complexes may have different degrees of hydration and dissociation and a different isoelectric point from those of the surface. The polyvalent ions could also increase the ionic strength of the solution considerably, and all these effects could be different in magnitude at different pH_s.

The Interfacial Energy Curves

The $(\gamma - \gamma_0)$ against pH_s curves shown in Figs. 5, 6, and 7 are very similar to the electrocapillary curves of Hg (7), with a maximum at the z.p.c. as predicted from theory (eq. [2]). The decrease in $(\gamma - \gamma_0)$ on the positive or negative side of the z.p.c. may be attributed to the dissociation of OH^- or H^+ and the subsequent adsorption of anions or cations respectively on the surface as counter ions. The more negative value of $(\gamma - \gamma_0)$ on the surfaces of ThO_2 is probably due to the high specific adsorption of K^+ and NO_3^-. There is also a shift in the maxima of these curves corresponding to the shift in the z.p.c. on changing the ionic strength from 10^{-3} M to 1 M KNO_3.

Applications

The information thus obtained on the double layer characteristics of non-metallic substances will be useful in practical problems such as flotation. The nature and the amount of collectors, activators, and depressants (anionic, cationic, or neutral) that are used in the flotation of minerals depend on the nature (+ or −) and the magnitude of the surface charge, the role of the potential determining ions, the indifferent electrolytes, the ionic strength and the degree of specific interactions. In a mixture of solids, whose z.p.c. are sufficiently apart, the surface of one will be positively charged and of the other negatively charged in the range between their z.p.c. In such a case, a selective or a collective flotation may be brought about by choosing collectors and activators of suitable charge. It is hoped to discuss this aspect in greater detail in a future publication.

ACKNOWLEDGMENTS

The author is grateful to the National Research Council of Canada for awarding the fellowship and to Mines Branch, Department of Mines and Technical Surveys, for providing the research facilities. The X-ray and spectrographic analyses were performed by the respective sections of the Mines Branch. Helpful discussions on the subject with

THE POLYMERIZATION OF STYRENE BY ANHYDROUS PERCHLORIC ACID AND THE SPECTRA OF BENZYLIC CARBONIUM IONS[1]

S. BYWATER AND D. J. WORSFOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received March 24, 1966

ABSTRACT

A spectroscopic investigation of the reaction of anhydrous perchloric acid with styrene in methylene chloride solution has been carried out, together with a study of the spectra of styrene and its derivatives dissolved in sulfuric acid. From the results it was decided that the absorbing species formed at the end of the reaction in methylene chloride are derivatives formed from the cyclized end groups of the polymer chain, and not the polystyrylcarbonium ion. It is not thought possible to determine from spectroscopic studies whether the polymerization reaction goes via a true ionic intermediate or a perchlorate ester.

The established view that the polymerization of vinyl compounds by acidic catalysts goes via an ionic intermediate has recently been challenged by Gandini and Plesch (1) who have proposed that the intermediate is an ester in some of the systems they have studied. In particular they have studied the reaction of perchloric acid with styrene in methylene chloride solution. From previous kinetic studies by Pepper and Reilly (2), confirmed by Gandini and Plesch, the simplest reaction scheme involves the rapid reaction of the acid with monomer to form the reaction centers, which then propagate and transfer, but have no effective kinetic termination step. Pepper suggested that the reaction centers were ion pairs, but Gandini and Plesch noted that no color developed during the polymerization and hence concluded that no appreciable concentration of polystyrylcarbonium ions could be present, and that the active centers must be perchlorate esters. Color does develop after the styrene has been consumed, caused by an absorption band ~ 420 mμ which was identified as that of the polystyrylcarbonium ion. The fact that the color formed only after polymerization, together with a large increase in electrical conductivity, was the major evidence for the absence of carbonium ions during polymerization.

Doubt of the validity of the assignment of this absorption band suggested that some further work on the subject was warranted.

EXPERIMENTAL

The purification of styrene has been described before (3).

Methylene chloride was stirred with concentrated sulfuric acid for 3 days, washed with water and dilute alkali, and dried with calcium hydride. Since vapor phase chromatographic analysis showed the impurity level to be very low, the solvent was then stored over fresh calcium hydride on the vacuum line.

Anhydrous perchloric acid was prepared in an all-glass apparatus (4), and in the same apparatus metered as the vapor into small fragile bulbs which were frozen and sealed off. The bulbs were stored in a freezer.

The polymerization reactions were performed under normal high vacuum conditions in an all-glass apparatus containing a quartz optical cell. The solvent was distilled in under vacuum and the apparatus sealed off. The styrene and perchloric acid were contained in fragile bulbs, broken with a glass-covered magnetic bar.

The spectra in sulphuric acid were measured in cells open to the atmosphere. Measurements were made immediately (20 s) after mixing. The acid was added to neat α-methylstyrene derivatives, but to 0.1% acetic acid solutions of the styrene derivatives to avoid polymer precipitation and to obtain more reproducible spectra.

The spectra for a duplicate experiment was measured in vacuum with degassed sulfuric acid; the result was the same. All spectra were measured on a Bausch and Lomb 505 spectrophotometer at room temperature, except for a few measured at low temperatures where the reaction vessel was immersed in a quartz dewar vessel with flat windows.

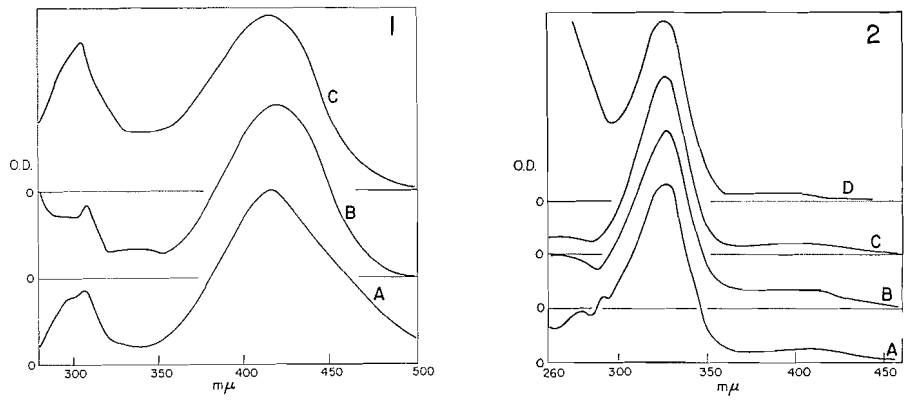
RESULTS AND DISCUSSION

(a) Spectra of Styrene and Its Derivatives in the Presence of Acids

Gandini and Plesch assigned to the polystyrylcarbonium ion an absorption whose major maximum was near 420 mμ from spectral measurements in $HClO_4/CH_2Cl_2$ (Fig. 1A). Molecular orbital theory suggests the position of absorption bands of corresponding carbonium ions and carbanions to be similar and this is found to be true for di- and tri-phenylmethyl ions, and also for allylic ions. The assignment of an absorption maximum at 420 mμ to the polystyrylcarbonium ion is greatly at variance with the well-established absorption of the polystyryl carbanion near 340 mμ (5).

Deno (6) has recently questioned the validity of assignments of ultraviolet spectra of benzyl-type cations except for certain α,α-alkyl-substituted benzyl ions, suggesting that the former were too unstable to measure under the conditions used. Recently, apparently reliable nuclear magnetic resonance (n.m.r.) spectra have been obtained of α,α-dimethylbenzyl and some polymethyl ring substituted benzyl carbonium ions in $SbF_5/FHSO_3$ at low temperature (7) and their ultraviolet spectra have been measured (R. Waack, private communication). All spectra showed a major maximum in the region 320–370 mμ ($\epsilon \sim 10^4$), with a much smaller absorption at longer wavelengths (ca. 400 mμ).



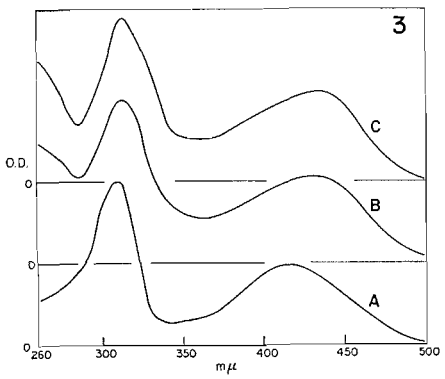


FIG. 1. (A) Spectrum obtained when 5×10^{-3} *M* $HClO_4$ was reacted with 0.2 *M* styrene in CH_2Cl_2 solution and the absorption at 420 mμ had reached its maximum. The carbonium ion was destroyed by adding methanol (in vacuum), and the polystyryl background absorption subtracted ($\epsilon_{420} = 1.3 \times 10^3$ based on $HClO_4$). (B) Spectrum immediately formed from 7×10^{-3} *M* saturated dimer of styrene and 3×10^{-3} *M* $HClO_4$ in CH_2Cl_2 solution ($\epsilon_{420} = 6.5 \times 10^2$ based on $HClO_4$). (C) Spectrum from 3×10^{-4} *M* saturated dimer of styrene in 96% H_2SO_4 ($\epsilon_{410} = 1.1 \times 10^3$).

FIG. 2. Spectra in 96% sulfuric acid. (A) 10^{-3} *M* α,α-dimethylbenzyl alcohol ($\epsilon_{327} = 8 \times 10^2$). (B) 2×10^{-4} *M* unsaturated dimer of α-methylstyrene ($\epsilon_{327} = 1.9 \times 10^3$). (C) 10^{-3} *M* α-methylstyrene ($\epsilon_{327} = 1.4 \times 10^3$). (D) 4×10^{-4} *M* α-methylstyrene in 30% fuming sulfuric acid ($\epsilon_{327} = 7 \times 10^2$).

Spectra obtained when α-methylstyrene (8), α,α-dimethylbenzyl alcohol, or the unsaturated dimer of α-methylstyrene are dissolved in concentrated H_2SO_4 (Fig. 2) have the same maxima as those found for the α,α-dimethylbenzyl carbonium ion in $SbF_5/FHSO_3$, except for a somewhat lower extinction coefficient (10^3 as compared with 10^4 (R. Waack, private communication)). When the sulfuric acid solution of α,α-dimethylbenzyl alcohol was added to iced dilute alkali, the products were a mixture of the saturated and unsaturated dimer of α-methylstyrene, and the spectrum in Fig. 2 is probably that of the 1:3 dimethyl, 1:3 diphenylbutyl carbonium ion. Its main absorption is close, as expected, to that of the corresponding poly α-methylstyryl carbanion (342 mμ in tetrahydrofuran) in poly α-methylstyryllithium.

When a large excess of sulfuric acid is added to a dilute acetic acid solution of styrene, or the corresponding alcohol or unsaturated dimer, the spectra in Fig. 3 are obtained, and are similar to those found by others (9). The spectrum in general is similar to that expected for the polystyrylcarbonium ion except the longer wavelength band is larger than expected, but since it appears variable in size and position it may well be due at least partly to a side product. The apparent extinction coefficient of the major peak at 318 mμ is low, near 3×10^3. Isolation of the products by adding to iced alkali solution gave low molecular weight polystyrene containing some unsaturation. Although there can be no certainty that this is the spectrum of the polystyrylcarbonium ion, it is greatly different from that obtained by Gandini and Plesch, or in general in $HClO_4/CH_2Cl_2$ systems, but the conditions here are likely to give a more nearly correct spectrum than those used by Gandini and Plesch. The only times that a spectrum resembling that in Fig. 3 was obtained in the $HClO_4/CH_2Cl_2$ system were in reactions at low temperatures, $< -50°$, where Gandini and Plesch report anomalous behavior. When the cell was warmed, the spectrum became similar to Fig. 1A.

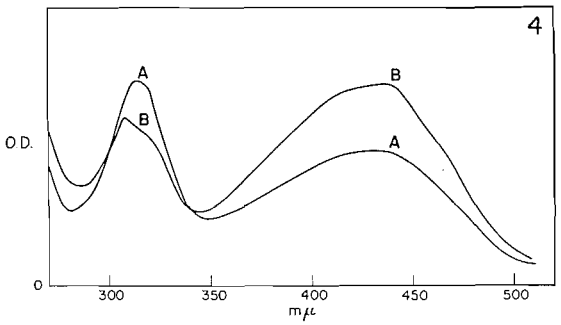

FIG. 3. Spectra in 96% sulfuric acid. (A) 3×10^{-4} *M* unsaturated dimer of styrene ($\epsilon_{314} = 10^3$). (B) 10^{-4} *M* α-methylbenzylalcohol ($\epsilon_{314} = 3 \times 10^3$). (C) 10^{-4} *M* styrene ($\epsilon_{314} = 2 \times 10^3$).

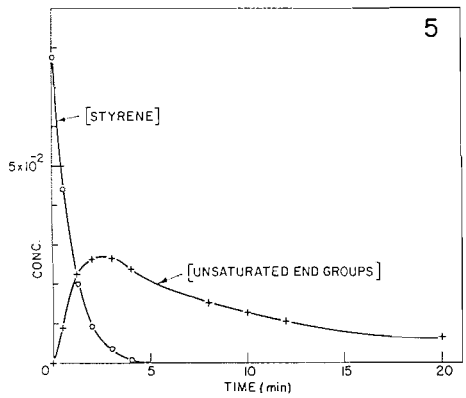
FIG. 4. Spectra of 10^{-4} *M* styrene in 10% H_2SO_4 in CF_3COOH solution. (A) After 4 min ($\epsilon_{314} = 2.8 \times 10^3$). (B) After 2 days.

If the medium in which the spectrum derived from styrene was formed is made less acidic by diluting the sulfuric acid with trifluoracetic acid, it is found at moderate dilution that the spectrum formed initially is similar to that in 96% sulfuric acid. But if the sulfuric acid content is reduced to 1%, the absorption obtained is similar to that found by Gandini and Plesch in methylene chloride (Fig. 1). In an intermediate solvent, say 10% sulfuric acid in trifluoracetic acid, the initially formed spectrum, which is similar to that in 96% sulfuric acid (Fig. 4A), slowly changes to that found in the 1% sulfuric acid solution (Fig. 4B). This suggests that the spectrum observed by Gandini and Plesch is at best caused by a secondary product.



In summary, it would seem that the spectra in sulfuric acid offer the closest approach to that of the true polystyrylcarbonium ion, although some side reactions may have occurred even in this case. The spectra of α-substituted derivatives in strong acids all show the major absorption around 320 mμ and so it is unlikely that strong absorption around 420 mμ would be characteristic of the polystyrylcarbonium ion, since shifts of this magnitude on α-methyl substitution are unknown. Rapid rearrangements in media of low acidity and low dielectric constant must be held responsible for the spectra observed under these conditions.

(b) Observations on the Polymerization of Styrene by $HClO_4$

If the spectrum of the reaction mixture of styrene with anhydrous perchloric acid in methylene chloride is observed in the region of 260–300 mμ, it is seen that as the styrene is consumed the absorption of styrene decreases and is replaced by an absorption of the type associated with the unsaturated dimer of styrene. This is a small change, but readily observable as the sharp peak of styrene at 291 mμ changes to a sharp peak at 294 mμ together with other changes near 280 mμ. This is attributed to the formation of low molecular weight polystyrene with an unsaturated end group. When all the styrene has gone, it is seen that the spectrum of the unsaturated end group itself decreases and the comparatively low intensity spectrum of low molecular weight polystyrene with a saturated cyclized indane end group emerges. The disappearance of styrene and the appearance and disappearance of the unsaturated end group is illustrated in Fig. 5.

It is during the second period, as the unsaturated end group disappears and is replaced by a cyclized end group, that the absorption near 420 mμ observed by Gandini and Plesch grows. To see if there is any connection between the cyclized end groups and the appearance of this spectrum, both the saturated and unsaturated dimer of styrene were prepared, and reacted with perchloric acid in methylene chloride. The saturated dimer instantly gave the spectrum as in Fig. 1B, whereas the unsaturated dimer only gave it slowly (as it cyclized). Moreover, when the dimers were dissolved in concentrated sulfuric acid, the unsaturated dimer gave the spectrum in Fig. 3A (major abs. 320); the saturated dimer gave the spectrum in Fig. 1C (major abs. 420). From the similarity of the spectra in Fig. 1 to that of the diphenylmethyl carbonium ions in Fig. 6A, it can be suggested that the absorption at 420 mμ is due to a diphenyl-substituted carbonium ion derived from the cyclized end group, the exact nature of which is not known.

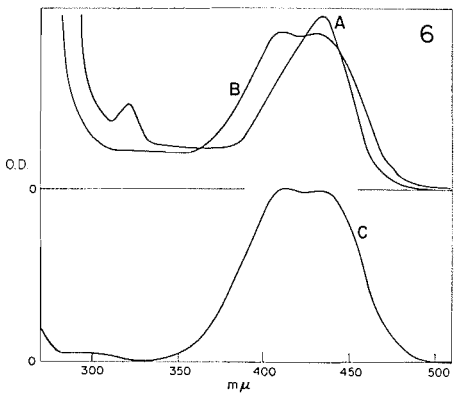

FIG. 5. Reaction curve of styrene with ca. 10^{-3} *M* $HClO_4$ showing rise and fall of the unsaturated end group concentration.

FIG. 6. (A) Spectrum formed initially when 5×10^{-2} *M* diphenylethylene is added to 10^{-3} *M* $HClO_4$. (B) The same reaction mixture after 2 days. (C) Spectrum formed from triphenylcarbinol with H_2SO_4 in CH_2Cl_2 solution.

This interpretation is strengthened by experiments carried out on diphenylethylene and α-methylstyrene. When 1,1-diphenylethylene is polymerized in methylene chloride solution with anhydrous perchloric acid, the initially formed diphenylethyl carbonium ion spectrum (Fig. 6) changes slowly, and after several days becomes identical to that of the triphenylcarbonium ion (Fig. 6C). During this time the initially formed unsaturated dimer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cyclizes to the saturated dimer. α-Methylstyrene gives a very similar reaction with perchloric acid to rapidly produce a saturated dimer. No corresponding visible spectrum is observed, probably because the extra methyl group blocks the reactive diphenyl-substituted carbon atom in the saturated dimer.

Previous interpretations of the mechanism of $HClO_4$-initiated polymerization assume that the acid is consumed rapidly. This requirement has never been confirmed directly, so three experiments were performed to check this point. In the first a methylene chloride solution of anhydrous perchloric acid was half distilled from one part of an evacuated reaction vessel to another. A styrene bulb was broken into the distillate, and the styrene polymerized normally with subsequent formation of the 420 mμ absorption. This indicated that, as expected, the perchloric acid distilled over with the solvent. The same experiment was repeated, but instead of only a solution of perchloric acid being used, a solution in which styrene had been polymerized by perchloric acid and allowed to cyclize and form the 420 mμ absorption was distilled. Again when a styrene bulb was broken into the distillate, the styrene polymerized and the 420 mμ absorption appeared. In the third experiment, the solution distilled was a polymerizing solution of styrene and the distillation stopped before absorption at 420 mμ appeared. The distillate was found to contain a little styrene. In this case no color appeared in the distillate, even on adding a further bulb of styrene, but the styrene did polymerize very slowly, at about 1% of the normal rate. It appears that during the polymerization the perchloric acid is in a combined, nonvolatile form, and is released again as the end groups cyclize. The suggestion of Gandini and Plesch that an ester is formed would be in accord with the experiments, although it might be suggested that the perchloric acid is tied up as a π-complex with styrene.

Regardless of the exact position of the polystyrylcarbonium ion absorption, it is possible to show that under the best conditions, during the polymerization of styrene with anhydrous perchloric acid in methylene chloride solution at room temperature, there is no appreciable absorption from the foot of the styrene absorption between 300 and 310 mμ and out through the visible spectrum, not merely at 420 mμ as stated by Gandini and Plesch. If an extinction coefficient of 10^4 is assumed for the polystyrylcarbonium ion, the highest concentration that could be undetected would be less than 10^{-6} mole/l. To give the propagation reaction rates suggested by the kinetics, a concentration of ions of 10^{-6} M would require a rate constant of 10^4–10^5 moles/l s. This is in the region found for the propagation rate constant for the free polystyrylcarbanion in tetrahydrofuran (11), and considerably less than the 10^6 suggested recently by Ffrancon Williams (11) for the free polystyrylcarbonium ion rate constant. Thus the absence of absorption in this region by no means excludes the possibility of an ionic mechanism. It is possible that if the rate constant of ionic propagation is at the high end of the suggested values, it may approach that of the carbonium ion with water, and account for the seeming insensitivity of the reaction to water concentrations, low compared with the styrene.

If the reaction does go through an ionic intermediate, it is likely to be the free carbonium ion because any ion pairing in the probable concentration range will be very slight in this solvent with a dielectric constant near 9. It is, in fact, possible to show that the ionic species (of comparatively high concentration) formed when the styrene has been consumed are fully dissociated, since there is a linear relationship between the increase in optical density at 420 mμ and the increase in electrical conductance of the solution.

If we assume, according to the above evidence, a covalent perchlorate is formed almost instantaneously, any equilibrium between free ions and the proposed ester would cause the order of the polymerization reaction to be half in the initial perchloric acid concentration,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

instead of first order as found. But if the rate-determining step is the rate of ionization of the ester, the rate would be first order in the ester concentration.

It is possible to write such schemes, which give the appropriate kinetics, as below.

$$HClO_4 + PhCH{=}CH_2 \xrightarrow{\text{fast}} CH_3PhCHClO_4$$

$$CH_3PhCHClO_4 \xrightarrow{\text{slow}} CH_3PhCH^+ + ClO_4^-$$

$$\sim CH_2PhCH^+ + PhCH{=}CH_2 \rightarrow \sim CH_2PhCHCH_2PhCH^+$$

$$\sim CH_2PhCHCH_2PhCH^+ \xrightarrow{\text{normal propagation and transfer reaction}} \sim CH_2PhCHCH{=}CHPh + H^+$$

$$H^+ + ClO_4^- \rightarrow HClO_4$$

The major transfer process is probably monomer transfer, and gives an unsaturated end group, although it has been suggested that some cyclized end groups are formed during the polymerization (12). In this scheme the overall rate constant would be a composite of the initiation, propagation, and termination constants.

CONCLUSIONS

It has been shown that the polystyrylcarbonium ion probably shows maximum absorption around 320 mμ and not at 420 mμ. The latter absorption is associated with the reaction products from cyclic end groups in the polymer. During the polymerization of styrene with $HClO_4$ in CH_2Cl_2 there is not only no measurable absorption at $\sim$ 420 mμ, as shown by Gandini and Plesch, but none at 320 mμ, so the concentration of carbonium ions (if any) is very low. It has been confirmed that there is little free $HClO_4$ during the polymerization, which suggests that Gandini and Plesch's deduction that most of the $HClO_4$ is present as a perchlorate ester may very well be correct. The spectral and kinetic evidence cannot distinguish between chain propagation by perchlorate esters or by free carbonium ions if the latter have a very high rate constant as is suggested by recent evidence. Only the insensitivity of the polymerization rate to small concentrations of water suggests that the propagation by esters is more likely. The fact that the rate of polymerization is very sensitive to the dielectric constant of the medium (2), however, is more in accord with carbonium ion intermediates as reactive species.

PHOTOLYSIS OF SOLID CARBONYL SELENIDE AND CARBON DISELENIDE

D. A. STILES, W. J. R. TYERMAN, O. P. STRAUSZ, AND H. E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 4, 1966

ABSTRACT

Samples of COSe and CSe_2 were photolyzed at 77 °K, either pure or in matrices of Xe or *trans*-2-butene. Observed electron spin resonance spectra are assigned to $Se(4^3P)$, to Se_2, and to chains of selenium atoms, $\cdot Se(Se)_nSe\cdot$. The selenium chains exhibit metallic behavior intermediate between that of sulfur and tellurium. It is suggested that polymeric chains of CSe are formed on warming photolyzed samples containing CSe_2. The ultraviolet absorption spectrum of COSe vapor is reported.

INTRODUCTION

By comparison with sulfur-containing species, radicals containing selenium atoms have received little attention by electron spin resonance (e.s.r.) spectroscopy. The presence of free radicals in elemental selenium, both pure and with added impurities, has been inferred from the observation of two e.s.r. lines at $g = 2.00$ and $g = 2.04$ (1). Windle, Wiersema, and Tappel (2) photolyzed a number of selenomercaptans at 77 °K and postulated that C—H cleavage was preferred to rupture of a bond to selenium. After several hours irradiation of the substrates ($\lambda = 2\,537$ Å), the selenide spectra were weaker than those produced from sulfides after much shorter periods of photolysis. The low intensity and the broadness of the selenide spectra handicap identification of the carriers and obscure hyperfine splitting (3) due to $^{77}Se(I = 1/2)$ which has a natural abundance of 7.5%. For this reason most authors have preferred to identify their spectra by analogy with the sulfides.

During an earlier investigation of COS photolysis in various matrices at 77 °K (4), three intense e.s.r. lines with an average g-value of 2.024 were observed. This spectrum was assigned to unbranched chains of $\sim 10^3$ sulfur atoms. These possess an unpaired electron on each terminal atom, sufficiently separated to behave independently, i.e. the radicals exist in double doublet rather than triplet electronic states. No spectra were attributed to the anticipated precursors of the S chains, the triplet species $S(^3P)$ and $S_2(^3\Sigma)$. Since Se and Se_2 are larger than S and S_2, they should migrate less readily through a matrix at 77 °K, and recombination should be slower. We have therefore extended the investigation to COSe and CSe_2, which have been previously studied in the gas phase by flash photolysis (5). Photolysis of CSe_2 vapor yields triplet atoms, $Se(4^3P)$, but there was chemical evidence for formation of excited singlet atoms, $Se(4^1D_2)$, by photolysis of COSe. The distinction is analogous to that between CS_2(6) and COS vapor (7).

To assist interpretation of our results, experiments were also performed with allotropes of selenium. Long-chain polymers exist in selenium at its melting point (8), and contain about 10^4 atoms. The e.s.r. spectrum is unlike that of sulfur samples but the line at $g = 2.00$ (1) may be the analog of that observed at the same value in metallic tellurium (9), and assigned to free holes in its valence band.

RESULTS

Ultraviolet Spectrum of COSe Vapor

To check that this compound absorbs light at wavelengths emitted by the photolysis lamps, the ultraviolet spectrum of the vapor was determined (Fig. 1). Under low dispersion the spectrum appears very similar to those of the analogous compounds CS_2 (6, 10) and

CSe_2 (5), exhibiting intense transitions in the far ultraviolet and weaker systems in the near ultraviolet regions. It is interesting to note that the 1 940 Å system of COSe is banded, although the spectrum at 2 500 Å exhibits little sign of structure. The solid phase absorption spectra of COSe and CSe_2 were not studied.

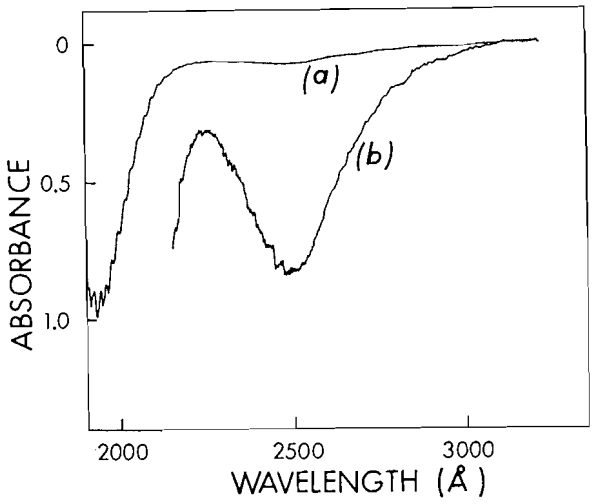

FIG. 1. Ultraviolet absorption spectrum of carbonyl selenide for a path-length of 10 cm: (*a*) 1 Torr COSe, (*b*) 15 Torr COSe.

Electron Spin Resonance Spectra

The observed e.s.r. signals will be separated into six distinct spectra. These are listed in Table I, together with assignments which will be discussed below.

TABLE I

Assignments of observed e.s.r. signals

Spectrum	Source	g	Assignment
A	Unirradiated amorphous selenium	2.0	Free electrons or conduction band
B	*In situ* photolysis of COSe	3	Se(4^3P)
C	*In situ* photolysis of COSe	2.2	Se_2
D	Photolysis of COSe or CSe_2	2.0	Selenium chains
E	Photolysis of CSe_2	2.05	$\cdot(CSe)_n\cdot$
F	Photolysis of COSe (1% in Xe)	2.3	Unassigned

Selenium

A degassed sample of amorphous selenium was melted in a sample tube, and rapidly cooled by plunging into liquid nitrogen. A comparatively narrow e.s.r. line (5 G half-line width) at $g = 2.00$ was detected at temperatures between 77 and 512 °K (Fig. 2) (A). When the sample was melted in the cavity a very broad e.s.r. absorption also appeared at lower fields. The line at $g = 2.04$ reported by Gager (1) was absent. Unlike sulfur, which in amine solutions exhibits a spectrum characteristic of sulfur chains (11), no spectra were obtained at 77 °K or at room temperature from solutions of selenium in piperidine or CS_2.

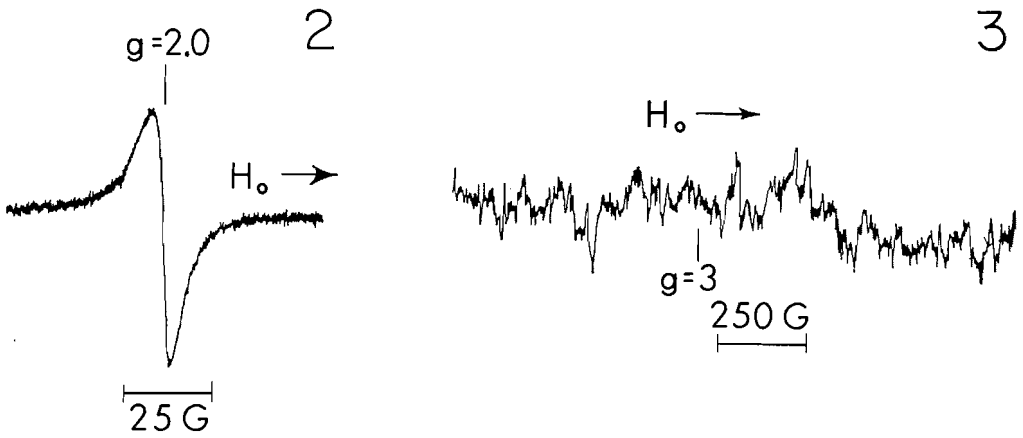

FIG. 2. Electron spin resonance spectrum of elemental selenium (A) for an integrative time constant of 0^{-4} s and an amplifier gain of 320 (arbitrary scale).

FIG. 3. Electron spin resonance absorption near $g = 3$ observed during *in situ* photolysis of COSe (1% in Xe) (B) for an integrative time constant of 0.3 s and an amplifier gain of 4 000 (arbitrary scale).

Selenides

The following mixtures were photolyzed for 24 h at 77 °K:

COSe	100%; 1% in Xe; 1% in *trans*-2-butene
CSe_2	5% in Xe; 0.1% in Xe.

During irradiation samples gradually reddened, suggesting the formation of elemental selenium. Samples containing CSe_2 became distinctly darker than those containing COSe.

In addition, a sample of COSe (1%) in Xe was photolyzed in the microwave cavity. During this *in situ* photolysis, three weak absorption signals were observed. A broad, ill-defined signal centered close to $g = 3$ (Fig. 3) (B), formed very rapidly and reached its maximum intensity after a few minutes irradiation. Meanwhile, a single line (C) at $g = 2.2$ built up, as well as a broad signal which appeared to contain spectrum A, partially obscured by a line at $g = 2.0$ due to radicals trapped in the wall of the quartz insert Dewar. When the mercury lamp was extinguished, the spectra at $g = 3.0$ and $g = 2.2$ decayed very rapidly.

The spectra obtained from COSe and CSe_2 matrices were generally very similar, particularly when the samples were warmed above 77 °K. When COSe (100%) was irradiated through a 7910 Vycor filter, which cut off light with $\lambda < 2\,300$ Å, no spectrum was observed. Since the sample remained colorless throughout the irradiation it was assumed that photolysis had been prevented (COSe vapor is decomposed by λ 2 537 Å. W. J. R. Tyerman. Unpublished results). No e.s.r. spectrum was obtained from irradiated COSe–*trans*-2-butene mixtures, although these samples became red during irradiation. In the gas phase, selenium atoms react very rapidly with *trans*-2-butene (A. B. Callear and W. J. R. Tyerman. To be published), forming an adduct which decomposes in ~1 s. Evidently *trans*-2-butene acts as a scavenger of Se during solid-phase photolysis, although elemental selenium is still ultimately produced. From the results of Windle, Wiersema, and Tappel (2), we anticipate that e.s.r. absorption of any selenide radical intermediate would be of very low intensity.

At 77 °K, both COSe and CSe_2 samples displayed the broad and narrow signals A and D (Fig. 4). A line also formed at $g = 2.2$ in some samples. In the COSe–Xe matrix a very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

intense asymmetric line appeared at $g = 2.3$ (half-line width ~130 G) (Fig. 5) (F), and the signals at $g = 2.0$ were absent.

Two types of warm-up experiment were performed; first the spectrum of the sample was run at the temperature cited (internal warm-up) and then the sample was returned to 77 °K and a second spectrum was obtained (external warm-up). The significance of changes in spectra at different temperatures has been discussed by Ingram (12). At 93 °K, all samples showed some alteration in their spectra, the most striking change being the appearance of a strong line at $g = 2.3$, similar to F. This line decreased markedly in intensity when the sample was returned to 77 °K. Upon further warming between 93 and 130 °K, however, the general characteristics of this line altered little.

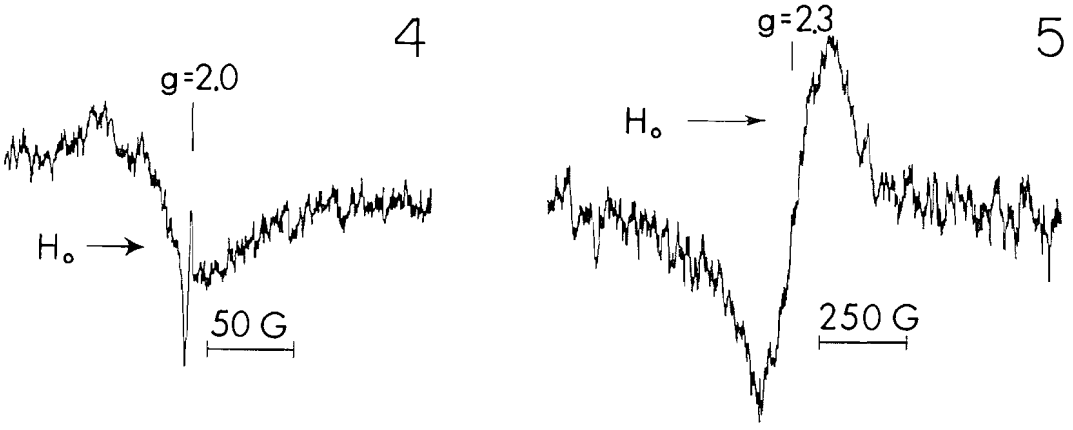

FIG. 4. Electron spin resonance spectrum observed in CSe_2 (5% in Xe) after photolysis (A, D, and E) for an integrative time constant of 0.3 s and an amplifier gain of 2 000 (arbitrary scale).
FIG. 5. Electron spin resonance line at $g = 2.3$ detected in photolyzed COSe (1% in Xe) (F) for an integrative time constant of 0.3 s and an amplifier gain of 2 000 (arbitrary scale).

Significant changes were also observed in spectrum D as the temperature was increased from 93 to 130 °K (internal and external warm-up) (Fig. 6). In addition slight differences appeared between the COSe and CSe_2 matrices. The spectrum broadened considerably, developing a structure similar to that of sulfur chains (4). Near $g = 2.05$ a broad line (E) was evident in CSe_2 samples, but absent in those of COSe.

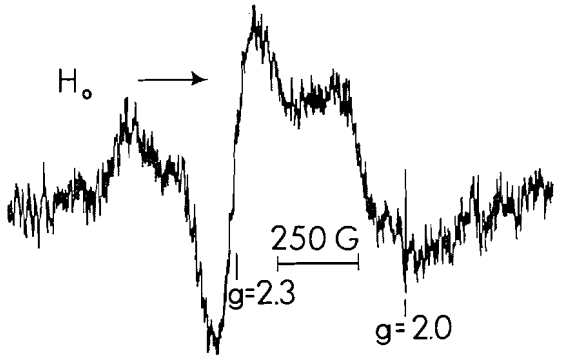

FIG. 6. Electron spin resonance spectrum of photolyzed COSe (1% in Xe) after warm-up of sample to 130 °K (A, D, and F) for an integrative time constant of 0.3 s and an amplifier gain of 4 000 (arbitrary scale).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The narrow line at $g = 2.0$ did not change appreciably up to 130 °K, which was the highest temperature at which our experiments were performed.

DISCUSSION

Most of the observed spectra are broad and lack structure; we must therefore attempt to identify their carriers from chemical and physical evidence, rather than by analysis of the line positions. However, it is useful first to predict the g-values at which we might expect to detect resonance. A ground state selenium atom (4^3P_2) contains two unpaired electrons in 4p orbitals, and the corresponding Landé g-factor is 1.5. A half-field transition (in which both electron spins are simultaneously reversed) should also appear at $g = 3.0$; this is expected to be less broad and therefore more readily detectable than the line at $g = 1.5$ (E. Wasserman. Private communication). The ground state of Se_2 approaches Hund's case c (13) in the gas phase and the Zeeman effect for such molecules has been described (14). At low rotational quantum numbers it is equivalent to that of a case b molecule such as O_2; e.s.r. transitions will therefore occur at $g = 2.0$ and $g = 4.0$, if the zero-field splitting of Se_2 is small. In the gas phase, O_2 displays paramagnetic resonance at $g = 1.9998$ (15); g-values observed in O_2 – quinol clathrates are slightly lower (16). Selenium chains, $\cdot Se(Se)_nSe\cdot$, might also be produced and, if n is sufficiently large, these behave as biradicals (double doublet states and not triplets), with e.s.r. signals near $g = 2.0$. Additionally in CSe_2 samples we might expect $(CSe)_n$ polymers to form; these will behave also as double doublet species. Interaction of the electrons with the d-orbitals or nuclei of Se act as further perturbations, tending to increase the g-value of a doublet radical by about 5% (2, 3).

During *in situ* photolysis of COSe, a signal appeared weakly at $g = 3.0$ (B), relatively more intense than the lines near $g = 2.0$, and decayed rapidly when irradiation ceased. This is therefore borne by a precursor of the carriers of the spectra, and on the basis of the g-values suggested above, we assign it to $Se(4^3P)$. Evidently, $Se(4^1D_2)$, produced by photolysis of COSe, is rapidly relaxed in the matrix to the triplet state. A similar conclusion was derived from the work on COS (4). In the gas phase, the abstraction reaction

$$Se(4^1D_2) + COSe \rightarrow CO + Se_2$$

may be important, although it is spin-forbidden if a product is $Se_2(X^3\Sigma)$. The spin rule will be somewhat relaxed for Hund's case c coupling, where the spin quantum number is no longer a 'good' quantum number.

The dissociation energy of COSe is unknown, but the gas-phase reaction

$$COSe + Se(4^3P) \rightarrow CO + Se_2$$

would probably be almost thermoneutral; abstraction from CSe_2 is ~40 kcal endothermic, and is therefore unlikely to occur under our conditions. Se_2 formed by combination of two (4^3P) atoms bears 73 kcal/mole (13) and may therefore induce local melting of the matrix, facilitating migration prior to polymerization. At 77 °K, we therefore expect atomic selenium to polymerize, either by abstraction of Se from COSe or by combination of free atoms. The first product in either case is Se_2, and it seems reasonable to assign the spectrum at $g = 2.2$, observed in *in situ* photolyses of COSe, to Se_2 in spite of there being no resonance at the half-field value, $g = 4.4$. This spectrum and B decay very rapidly, showing that polymerization of Se and Se_2 is fast, even in the solid state at 77 °K.

The spectrum at $g = 2.0$ is more interesting because it contains two distinct lines, one of which, A, was also observed in elemental selenium. This comparatively narrow line (half-line width 5 G) in the photolyzed selenides cannot correspond to the same radical as the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

broader signal, since the relative intensities of the two lines varied with temperature. A very broad line (half-line width 225 G) from metallic tellurium has been reported, and is attributed to the presence of free holes in the valence band (9). We propose that this signal in selenium corresponds either to free electrons (F centers) or to free holes (V centers), which may have line-widths of the order of a few gauss (12, 17). It is surprising that no signal in elemental selenium could be assigned to selenium chains, as these are known to be present in molten Se (8). It is reasonable, however, to assign spectrum D from photolyzed selenides to selenium chains, which must ultimately form by combination of Se_2, etc., and which would account for the red coloration of the samples. When the samples were warmed to 113 °K, this spectrum developed structure which was very similar to that of sulfur chains between 77 and 298 °K (Fig. 6); this is evidence in support of our assignment. A very crude estimate of the chain-length is made by assuming that the signals correspond to at least ten times the minimum that can be detected by the spectrometer ($\sim 10^{14}$ free spins). About 2×10^{-6} moles of Se atoms were produced in the COSe matrices during 24 h irradiation (as determined from the amount of CO formed, each mole of which corresponds to one mole of Se atoms). Each chain bears two free spins, and therefore we were detecting $\sim 5 \times 10^{14}$ chains, and 12×10^{17} atoms. If no ring polymers exist, an upper limit for the average chain length is 2 400 atoms, which may be compared with the value of 10^4 atoms at 490 °K (8).

Presumably the free electrons in $(CSe)_n$ chains are localized on C, rather than Se, atoms; their g-value is therefore expected to lie closer to 2.0 than that of free electrons in a selenium chain. We therefore assign the spectrum at $g = 2.05$, (E) observed in CSe_2 samples, to $\cdot(Se)\cdot_n$.

We have been unable to assign spectrum F, at $g = 2.3$. At 77 °K, this signal and that at $g = 2.0$ are both very broad, and their overlap probably results in the appearance of the line at $g = 2.2$ in samples externally photolyzed; i.e. this signal is quite distinct from the signal at $g = 2.2$ observed during *in situ* photolysis and attributed to Se_2. The very large reversible temperature effects of the spectrum at $g = 2.3$ indicate that it is carried by a simple species rather than, for example, a long-chain polymer.

CONCLUSION

Polymeric chains of selenium build up in photolyzed samples of COSe and CSe_2 at 77 °K; $Se(4^3P)$ and Se_2 were identified as precursors, by e.s.r. spectroscopy. The e.s.r. spectrum of selenium contains a line which is attributed to free electrons or free 'holes' in its valence bands; this is an example of metallic behavior intermediate between that of sulfur and tellurium.

EXPERIMENTAL

Spectra were recorded as the first derivative of the resonance absorption using a Varian E.P.R. spectrometer (type 4502), operating at a nominal frequency of 9.5 Gc/s and using 100 kc/s magnetic field modulation. The spectrometer was fitted with a dual cavity (V4532), a variable temperature accessory, and a Fieldial (V-FR-2503) magnetic field regulator. The g-values of the spectra were measured by extrapolation from the three lines of Fremy's salt (18). It was not necessary to calibrate the spectrometer precisely at g-values far removed from 2.0 because the spectra were too broad for accurate measurements of line centers. All spectra, except those from Fremy's salt, were recorded with a modulation amplitude of about 2 G. Those from the calibrating standard were recorded using 0.2 G modulation. Other experimental parameters for each spectrum are listed with the corresponding figure.

Gas mixtures were prepared in 5 l bulbs and left for several hours to equilibrate, before being distilled into thin-walled quartz sample tubes and degassed. Despite large differences in the boiling points of the components, no difficulty was encountered due to separation of the mixtures in handling. Each sample was irradiated in a quartz Dewar cooled by liquid N_2 (77 °K), using the output of a Hanovia medium-pressure mercury arc, which emits discontinuously at $\lambda > 2\,200$ Å. The usual period of irradiation was 24 h. In one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

series of experiments, the sample was photolyzed in the microwave cavity, by focussing light from a high-pressure mercury arc through a slotted plate which formed one boundary of the cavity. All samples were stored at 77 °K after irradiation.

Materials

Assayed reagent grade xenon (Airco), ethylene, and *trans*-2-butene (Phillips Petroleum Co. Research Grade) were used without further purification.

CSe_2 was prepared by the reaction of CH_2Cl_2 with molten Se at 500 °C (19). The product was separated from CH_2Cl_2 by distillation at 193 °K. COSe was obtained in low yield by passing dry CO over molten selenium (20); the product was distilled and degassed, and the infrared spectrum of the vapor showed no bands which could not be assigned to COSe (21), apart from CO_2 bands observed at low intensity. The ultraviolet absorption spectrum of COSe was obtained with a Perkin-Elmer model 202 recording spectrophotometer. Selenium was obtained from Fisher, and was >99.9% pure.

THE DESCRIPTION AND USE OF A SPIN-ECHO SPECTROMETER TO STUDY CHEMICAL EXCHANGE[1]

K. H. Abramson, P. T. Inglefield, E. Krakower, and L. W. Reeves
Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received February 1, 1966

ABSTRACT

A spin-echo spectrometer, suitable for studies of chemical exchange, is described. The performance of the apparatus is described and illustrated. From a Carr–Purcell sequence of pulses T_2 measurements have been made using two alternative schemes for the correction of cumulative error in the width of π pulses. Agreement is satisfactory and the standard errors in each method are $\pm 5\%$ of the average T_2. The Meiboom and Gill method of phase-shifting the r.f. in the first pulse has the advantage of more flexibility in the choice of pulse intervals.

A theory developed by Bloom, Reeves, and Wells for the dependence of T_2 measured in a Carr–Purcell experiment on pulse intervals in the presence of a suitable exchange process has been tested experimentally for two molecules. The rate constants for the hindered internal rotation about the N=N bond in *N,N*-dimethylnitrosamine agree for the following sets of data: (*a*) a previous high-resolution study by Phillips, (*b*) a repeated high-resolution study made in this work, (*c*) spin-echo studies using the complete closed expression for a two site exchange process, and (*d*) the approximate expression derived for the limit of fast pulse repetition rates.

A similar study by the spin-echo method of the rates of internal rotation about the C=N bond in *N,N*-dimethyltrifluoroacetamide does not agree with a previous high-resolution study. Since the chemical shift between the inequivalent methyl groups is so small, it is suggested that the rates of rotation in this molecule are much better evaluated by the spin-echo method.

The spin-echo method can more easily take account of variations with temperature of the natural relaxation time and the chemical shift. The non-selective nature of an experiment with such a large H_1 field remains a disadvantage at this time. The selective deuteration of sites unaffected by exchange is in general difficult enough to limit the scope of the spin-echo method when protons are observed.

INTRODUCTION

The time constant for the decay of echo amplitudes in a Carr–Purcell spin-echo experiment (2) is affected by the pulse interval, even in a homogeneous magnetic field, if there is a chemical exchange which modulates the Larmor frequencies at a rate comparable to the frequency difference (17, 3, 4). The general solution for the decay of echo amplitudes has been presented by Bloom, Reeves, and Wells (1) for the case of exchange involving two Larmor frequencies in the absence of spin-coupling. From considerations of simple probability theory for phase angle distribution in the $x'y'$ plane and the use of a matrix operator technique to generate the amplitude of alternate echoes, it can be shown that the magnetization at a time $4n\tau$ is related to the initial magnetization by an expression involving the sum of two exponentials;

$$[1] \qquad M(4n\tau) = A_1 \exp(-r_1 4n\tau) + A_2 \exp(-r_2 4n\tau)$$

where $\tau = \frac{\pi}{2}$, π pulse interval, $n = 0, 1, 2 \ldots$ etc., A_1 and A_2 are constants which depend upon the initial conditions, and r_1 and r_2 are two time constants, which are independent of the initial conditions. A similar relationship has been derived (5) by the use of the Bloch equations (6).

In this paper, experimental results will be presented for two special cases when the

[1]*Paper presented in part at International Symposium on Nuclear Magnetic Resonance, Tokyo, Japan, September 3, 1965.*

population of one site is equal to that of the other. In this event a single time constant r_1 dominates the decay of echo amplitudes and this is given by (1)

$$[2] \qquad r_1 = k - \frac{1}{2\tau}\sinh^{-1} F$$

where

$$\text{if } \omega > k,\ F = \frac{k}{(\omega^2 - k^2)^{1/2}} \sin 2\tau(\omega^2 - k^2)^{1/2}$$

$$\text{if } \omega < k,\ F = \frac{k}{(k^2 - \omega^2)^{1/2}} \sinh 2\tau(k^2 - \omega^2)^{1/2}$$

$$\text{if } \omega = k,\ F = 2k\tau$$

$$k = \frac{k_a + k_b}{2} = \text{mean rate constant for the exchange process}$$

$$\omega = \frac{\omega_a - \omega_b}{2} = \text{half chemical shift in radians } s^{-1}$$

$$\tau = \frac{\pi}{2},\ \pi \text{ pulse interval.}$$

In much of the experimentation described here a further simplification can be made if $k\tau \ll 1$ and $\omega\tau \ll 1$:

$$[3] \qquad r_1 = \tfrac{2}{3}k\omega^2\tau^2.$$

This assumption is valid for $\omega > k$ and $k > \omega$ and applies in the region of small pulse intervals (short τ limit). The time constants r result entirely from the exchange effect, and in the actual experiments account is taken of the additional natural relaxation processes expressed as the time constant $1/T_{2_0}$.

$$[4] \qquad \frac{1}{T_{2(\mathrm{CP})}} = \frac{1}{T_{2_0}} + r_1$$

where $1/T_{2(\mathrm{CP})}$ = time constant of exponential decay observed in the Carr–Purcell experiment.

The application of spin-echo methods to the study of chemical exchange have been made previously by Reeves and co-workers (3, 4) and Luz and Meiboom (7). The latter workers derived an approximate expression for a multi-site exchange process for the limit of short pulse intervals and fast exchange, $k \gg \omega$. This equation will not be used here. A considerable volume of work by Gutowsky and co-workers has appeared while this present study was in progress (8–11). Insofar as the present study applies our original equations (1) to different rate processes, there is no overlap in the two parallel investigations. This paper should serve as an independent evaluation of the advantages and limitations of the spin-echo method to the study of chemical kinetics in the simplest cases (8–11).

EXPERIMENTAL

Chemicals

N,N-dimethylnitrosamine was prepared by the reaction of dimethylamine hydrochloride and sodium nitrite in acid solution. The mixture was distilled to dryness and the distillate was treated with an excess of solid potassium carbonate. The nitrosamine appeared as a yellow oil which was further treated with potassium carbonate to remove water. The dimethylnitrosamine, b.p. 150–151 °C, was then doubly distilled.

The overall reaction is given as:

$$(CH_3)_2NH + HNO_2 \rightarrow (CH_3)_2NNO + H_2O.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

N,N-dimethyltrifluoroacetamide was prepared by the reaction of methyl trifluoroacetate and dimethylamine gas at −7 °C. The solution was then left at room temperature for 12 h and the product *N,N*-dimethyltrifluoroacetamide (b.p. 134–136 °C) was distilled out to 81% yield:

$$CF_3CO.OMe + NMe_2H \xrightarrow[\text{saturate}]{-7\ ^\circ C} MeOH + CF_3CO.NMe_2.$$

The steady state spectrum of pure *N,N*-dimethylnitrosamine was studied at 60 Mc/s on a Varian A60 spectrometer at temperatures in the range 125–195 °C. The exchange-modified spectrum was similar to that reported by Phillips (12) and Blears (13). The equations of Piette and Anderson (14) were used to derive rate constants from the line widths in the slow exchange limit.

Spin-Echo Apparatus

The spin-echo spectrometer operated at 40 Mc/s and was constructed in our own laboratories. It has not been reported previously, hence some description will be given here. The magnetic field was provided by a Varian 12 in. magnet shimmed for high-resolution experiments and with additional homogeneity trimming provided by a Varian V-4365 field homogeneity control unit. The non-spinning samples had a T_2^* (measured from the free induction tail) of 150 ms.

Figure 1 illustrates the generation of the Carr-Purcell pulse sequence. The r.f. generator, Fig. 2, consisted of a highly stable 10 Mc/s crystal oscillator, a pulse modulator stage, two frequency doublers, a 40 Mc/s driver stage and a push-pull final amplifier stage. The 10 Mc/s crystal was thermostatically maintained at

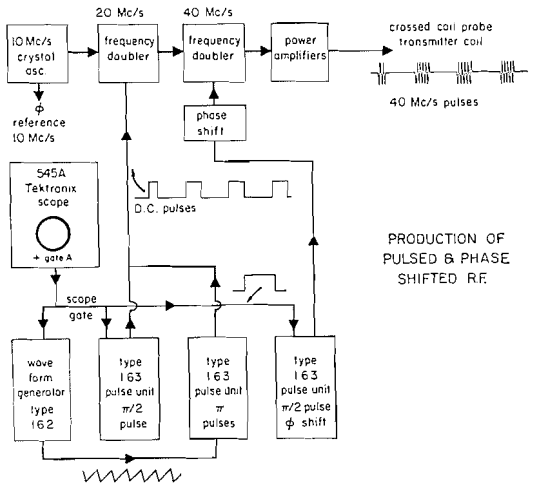

FIG. 1. Generation of the Carr–Purcell pulse sequence.

85 °C in a crystal oven. Careful interstage shielding was used to virtually eliminate 40 Mc/s leakage during the "pulse off" period. Phase coherent 40 Mc/s r.f. pulses were obtained by allowing the 10 Mc/s oscillator to run continuously while pulse-modulating the first doubler stage. A 90 degree r.f. phase shift during the $\frac{\pi}{2}$ pulse was accomplished in the second doubler grid circuit by means of the Meiboom and Gill method (15). In this method a pulse, identical to the $\frac{\pi}{2}$ modulation pulse, switches a back-biased semiconductor diode into its conductive stage; this procedure effectively places a phase-changing capacitor across the tuned circuit for the duration of the $\frac{\pi}{2}$ pulse. The 90 degree r.f. phase shift during the $\frac{\pi}{2}$ pulse served to minimize the effect of accumulative error which might occur in the width of the π pulses. The peak r.f. output power of this unit was approximately 250 W, giving a π rotation of magnetization in ~15 μs.

The modulating pulse train was synthesized by the combined use of a Tektronix 545A oscilloscope, a Tektronix Type 162 waveform generator and three Type 163 pulse generators. A positive gate voltage was fed from the +Gate A terminal of the oscilloscope to the trigger inputs of two Type 163 pulse generators (modified to give pulse amplitudes of +90 V peak). These two generators produced the single $\frac{\pi}{2}$ modulating pulse and the 90 degree r.f. phase shifting pulse. The $\frac{\pi}{2}$ and r.f. phase shift pulses were thus synchronized with

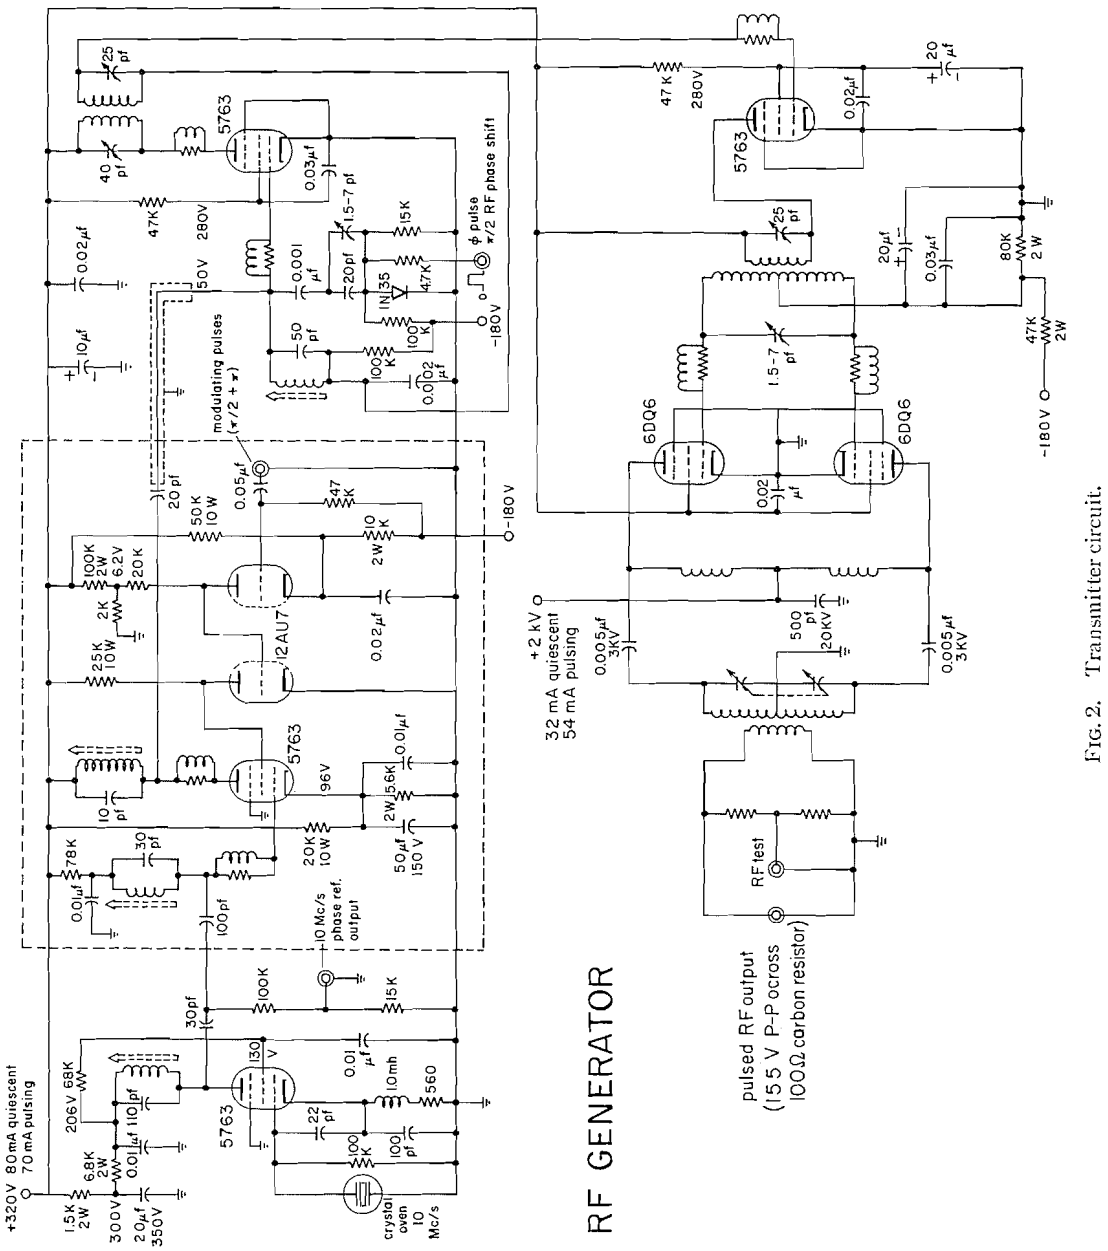

FIG. 2. Transmitter circuit.

the beginning of the oscilloscope sweep. To produce the modulating train of π pulses at times τ, 3τ, 5τ, etc., the same + Gate A from the oscilloscope was used to gate a Type 162 waveform generator, producing a negative sawtooth train of variable frequency. This negative sawtooth train was used to trigger the remaining Type 163 pulse generator ("negative trigger" mode), producing the train of π modulating pulses. The train of π pulses could be delayed from the $\frac{\pi}{2}$ pulse simply by adjusting the "output pulse delay" control. The π pulse repetition period was adjusted by means of the "pulse interval" control on the waveform generator (Type 162).

A Varian crossed coil probe was used and modified by appropriate changes of capacitors in the transmitter coil circuit to facilitate impedance matching. The probe can be used both for high-resolution and spin-echo experiments. The Varian probe, although quite inefficient in coupling r.f. energy from the transmitter coil to the sample, did give a homogeneous H_1 field as indicated by the complete disappearance of the induction tail after a π pulse in a $\frac{\pi}{2}$, π pulse sequence. Receiver coil orthogonality and the leakage paddles used normally for high-resolution studies could be adjusted to obtain excellent isolation between the transmitting and receiving coils. This adjustment was made such that the central portion of the r.f. pulse sensed by the receiver was negligible and only the high-frequency components (the leading and trailing edges) of the pulse were detected (as two small spikes). This optimal isolation condition facilitated quick receiver recovery time ($\sim$3 μs) and avoided inducing into the receiver coil large "ringing currents" which could distort the overall H_1 from the transmitter coils. Such optimal conditions were not required for all of the present work, but were maintained as a matter of routine. The experiments described here were performed in a relatively homogeneous H_0 field so that a continuous signal of detected pulses and echoes occurred.

The receiver was a modified L.E.L.-I.F. amplifier which was used as a 40 Mc/s broadband receiver (Figs. 3*a*, 3*b*). The preamplifier section used cascaded 5 842 stages. Manual control of receiver gain was provided by varying the grid bias of the third and fourth stages. Two means of signal detection were provided: ordinary diode detection and phase detection. In the phase detection mode, any attempt to draw more power from the transmitter oscillator to achieve frequency quadrupling resulted in loss of drive to the subsequent stages of the transmitter with loss of and varying power to the probe. An amplifying stage was used

to raise the power available from the transmitter oscillator to that required for frequency modulating (V1 in Fig. 3*c*). To achieve efficient frequency multiplication with reasonably uniform output amplitude, two stages of frequency doubling were used (Fig. 3*d*). The original tube Type 6AH6 was used for all three stages; V1 as a 10 Mc/s amplifier, V2 doubling to 20 Mc/s, and V3 doubling to 40 Mc/s. An additional advantage of this method is the minimizing of the risk of self-oscillation present when more than one stage is tuned to the same frequency. Reference to the paper by W. Gilbert Clark (24) was made to achieve good control of the phasing and attenuation for the system (Fig. 3*c*). In most cases the experiments presented here did not require the use of the phase detector. The maximum receiver gain was 2×10^5 with a bandwidth of 3 Mc/s.

The echo amplitudes were photographed with a Polaroid oscilloscope camera on 3 000 A.S.A. film. Photographs were subsequently measured for echo amplitudes. Typical experiments are illustrated to indicate the performance of the apparatus. The π pulse interval was timed on a Hewlett Packard 522B electronic counter.

RESULTS

Some attempt has been made in this work to investigate the precision of our T_2 measurements in the Carr–Purcell experiment. The measurement is very sensitive to the resonance condition (16), the inclusion of a $\frac{\pi}{2}$ phase shift, and the homogeneity of the H_1 field.

The resonance condition in such a homogeneous field is quite difficult to maintain. The oscillator frequency was certainly stable enough but small magnetic field drifts over a period of even 5 min necessitated readjustments. These were easily achieved by observation of the free induction decay with phase sensitive detection. The field was swept to give zero beat each time. The measurements of T_2 values >5 s were appreciably shortened for slight field drifts from resonance. Satisfying the resonance condition is the most tedious part of the experimental procedure, and in future work, further precautions concerning this field drift will be taken. The magnitude of the magnetic field instability may be only 1 c.p.s. per minute but deterioration in performance can be detected after 15 min.

The accumulated error in echo amplitudes due to error in the width of the π pulse can also be corrected by working at certain off resonance conditions without a $\frac{\pi}{2}$ r.f. phase shift in the first pulse (18). In the off resonance experiment we have to observe the condition that the π–π pulse spacing is given by

$$2\tau = (2n + 1 \pm \tfrac{1}{2})T \qquad [5]$$

where $T = 2\pi/(\Delta\omega)_0$, 2τ is the 180°/180° pulse spacing, n is an integer, and $(\Delta\omega)_0$ is the angular frequency difference between the resonance condition and the applied frequency.

We found it satisfactory to work at about 4.5 Kc/s off resonance where the above condition could be satisfied for a range of 2τ between 1 and 10 ms. It must be noted that these off resonance experiments have far less flexibility in the pulse interval range and we found them much more difficult to perform when the pulse intervals were greater than 10 ms. All kinetic experiments reported here are repeated using both methods of obtaining T_2 and agreement to $\pm 5\%$ on T_2 is claimed. The performance of the apparatus, while using the Meiboom and Gill (15) phase shift is shown in Fig. 4. The column of figures on the left of this figure indicates the pulse interval 2τ. Experimental Carr–Purcell trains are given in the next column corresponding to these pulse spacings. The computed T_2 values in the third column vary, in this particular experiment performed on *N*,*N*-dimethylnitrosamine at 135 °C, from 10.1 s to 0.2 s. The time calibration for the decay can be obtained from the figures in column 4. The decays are all accurately exponential and with the large pulse spacing of 40.75 ms the individual echoes can be resolved.

A typical experiment such as that illustrated was performed at a series of temperatures

for each of the two molecules under study. The results in the form of log $1/T_{2(CP)}$ versus log $1/2\tau$ are plotted in Figs. 5 and 6 for *N,N*-dimethylnitrosamine and *N,N*-dimethyltrifluoroacetamide respectively. The general shape for the complete dependence of $T_{2(CP)}$ upon pulse separation 2τ is best seen in Fig. 6. When $1/2\tau$ is large the value of $1/T_2$ approaches the natural value in the absence of chemical exchange. At large pulse separations (2τ) the curve approaches the line width in the exchange-broadened steady state spectrum for the fast exchange limit. Both off-resonance and on-resonance results are plotted in Fig. 5. A considerable temperature dependence of T_{2_0}, the natural relaxation time in *N,N*-dimethylnitrosamine, can be seen in Fig. 5, which is very unusual because it indicates a shorter T_{2_0} as the temperature increases. This unusual behavior can be associated with the equilibrium

$$(CH_3)_2NNO \rightleftharpoons (CH_3)_2N\text{–}N(CH_3)_2 + 2NO,$$

which produces small but increasing amounts of paramagnetic nitric oxide as the temperature is raised. This unusual temperature dependence of T_{2_0} is not observed in *N,N*-dimethyltrifluoroacetamide. The requirement of a rather more homogeneous field is important for *N,N*-dimethylnitrosamine because it is necessary to extend measurements to the relatively high temperature of 190–195 °C where diffusion processes are rapid.

The value of the rate constant k was obtained by use of eq. [2]. The experimentally observed value of r was obtained from eq. [4]. The value of T_{2_0} was equated to T_1 measured in a separate experiment or was estimated by using the T_{2_0} indicated from Fig. 5 and 6 at infinitely fast pulse rates (a third method of estimating T_{2_0} from eq. [3] is described below.) An iterative FORTRAN program for an I.B.M. 7040 was used in which trial values of ω and k were inserted and for the experimental values of (2τ) the value of r was computed. These values of r were compared to experimental values and deviations were sensed by the computer. Changes in trial values of k were then made in order to minimize deviations from experimental values. The deviations were finally minimized by small changes in the choice of ω. The best overall values of k to fit as many as 20 experimental determinations of T_2 were found.

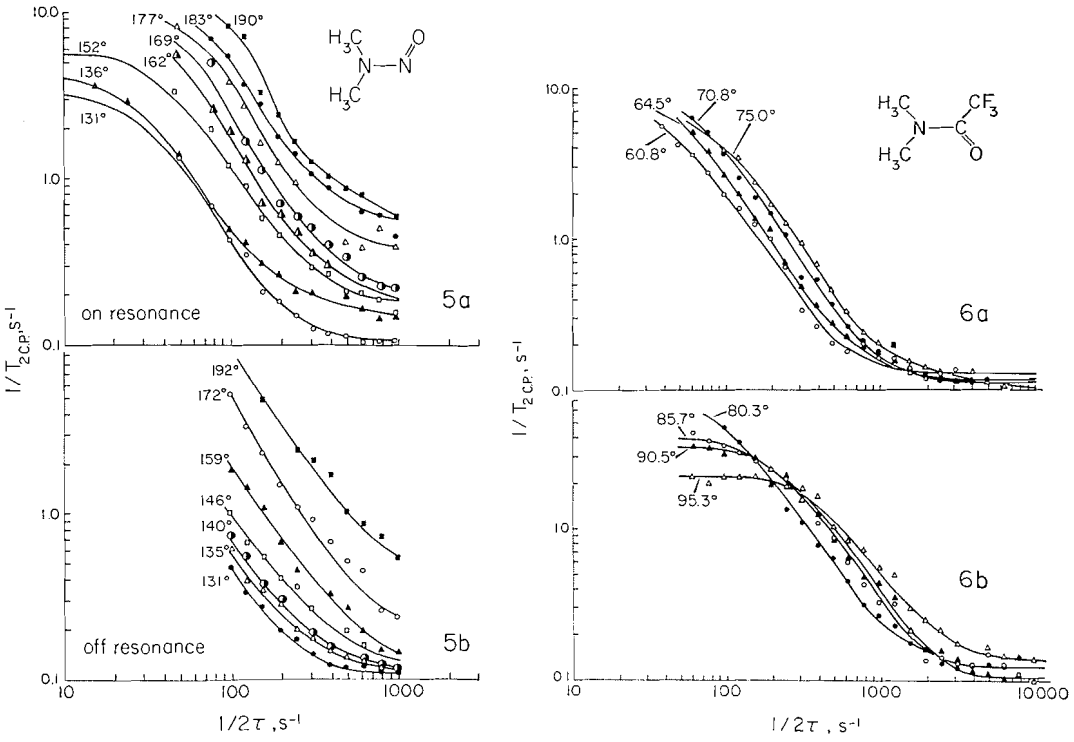

FIG. 5. Dependence of $T_{2(CP)}$ upon the pulse interval 2τ for *N,N*-dimethylnitrosamine: (*a*) on resonance, (*b*) off resonance.

FIG. 6. Dependence of $T_{2(CP)}$ upon the pulse interval 2τ for *N,N*-dimethyltrifluoroacetamide, on resonance: (*a*) 60.8 to 75.0 °C; (*b*) 80.3 to 95.3 °C.

It is of some interest to compare these values of k with those from the equation for the fast pulsing limit. Within the validity of eq. [3] the value of $1/T_{2(CP)}$ was plotted against $(\omega\tau)^2$ and a straight line was obtained for each temperature. The results for the two compounds studied are given in Figs. 7 and 8. Note that in Fig. 8, to avoid crowding, the values of $1/T_2$ are plotted without a scale and each temperature is vertically displaced on the diagram. The value of $1/T_2$ when $(\omega\tau)^2 = 0$ gives the natural relaxation time T_{2_0} which may be used also in the curve-fitting procedure for the full dependence of $1/T_{2(CP)}$ on

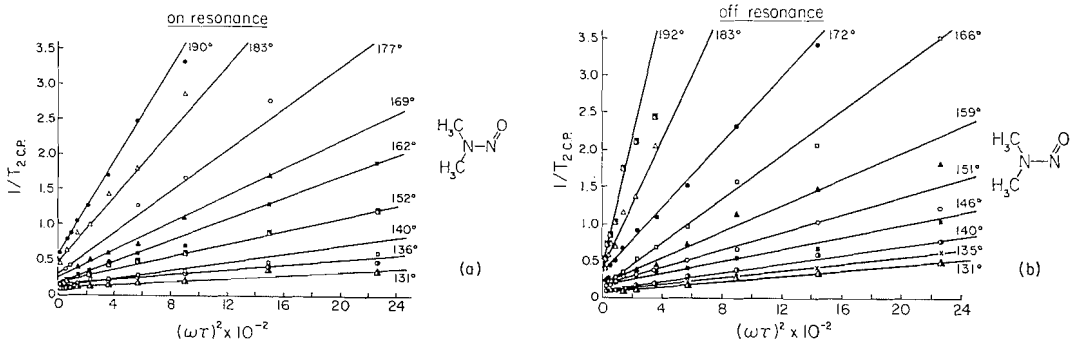

FIG. 7. "Short τ" limit plot for *N,N*-dimethylnitrosamine: (*a*) on resonance; (*b*) off resonance.

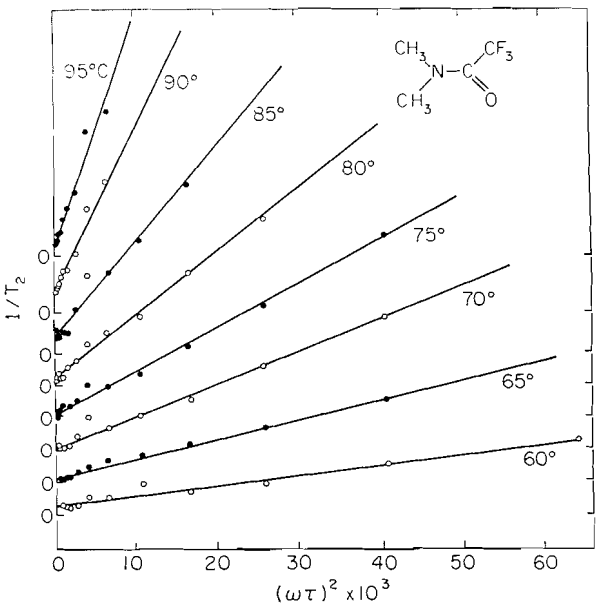

FIG. 8. "Short τ" limit plot for *N,N*-dimethyltrifluoroacetamide, on resonance.

$1/2\tau$. The values of ω chosen were those obtained in high-resolution experiments. A simple computer program was devised to obtain a least squares fit to the straight lines in Figs. 7 and 8 and the resulting slopes were converted to rate constants for each temperature. Then a least squares fit to the usual Arrhenius temperature dependence was used to evaluate the activation energy and frequency factor.

The important information derived from these experiments is the rate constant, k, and we compare the values of k for *N,N*-dimethylnitrosamine and *N,N*-dimethyltrifluoroacetamide in Tables I and II. The comparison with the high-resolution method

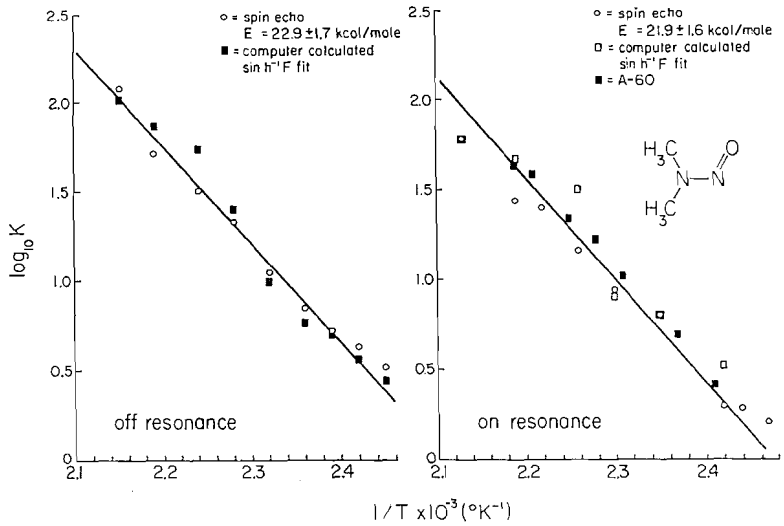

FIG. 9. Activation energy determination for *N,N*-dimethylnitrosamine.

In Figs. 9 and 10 the activation energies are determined as least squares lines to all rate constant determinations. In Fig. 9 the origin of the T_2 measurements is from both on- and off-resonance experiments for *N,N*-dimethylnitrosamine.*

In Table III the best activation parameters are quoted for the two molecules studied.

DISCUSSION

The spin-echo method for determining rate constants is now fairly well established and will serve as an independent check on high-resolution studies of rate constants. When both methods are in agreement a satisfactory set of activation parameters can be established for a given rate process. Unless this is the case, however, caution should be exercised in using the results. Abnormal frequency factors for simple hindered rotation barriers should be regarded with suspicion. In *N,N*-dimethyltrichloroacetamide, Gutowsky and Allerhand (19) were not able to obtain satisfactory agreement between steady state and spin-echo

**In Fig. 10, the on-resonance activation energy determination is illustrated for N,N-dimethyltrifluoroacetamide.*

techniques. The case of the activation parameters for inversion in c-$C_6D_{11}H$ (8) can be considered to be solved. The rate constants have been determined over a spectacularly large range of temperature and agreement with the high-resolution studies is now complete (20, 21). A quantum mechanical theory of the spin-echo experiment on an exchanging system has now been given (22). The primary disadvantage of the spin-echo method is its lack of selectivity. Usually all nuclei of one type are in or near the resonance condition during pulses.

ACKNOWLEDGMENTS

The research was generously supported by the Petroleum Research Fund of the American Chemical Society and the National Research Council of Canada. The authors are grateful for discussions with Professor Myer Bloom and Dr. E. J. Wells and for help with computer programs from Mr. Robert Wolfe. Thanks are also accorded to Mr. E. Fisher for help in the construction of the spin-echo spectrometer.

INFRARED SPECTRUM AND STRUCTURE OF LIQUID WATER[1]

MICHAEL FALK[2]

AND
T. A. FORD[3]
Chemistry Department, Dalhousie University, Halifax, Nova Scotia
Received February 18, 1966

ABSTRACT

The infrared spectrum of HDO at low concentrations in H_2O and in D_2O was studied between 0° and 130° by a double-beam technique. Each of the three fundamentals of HDO shows nearly Gaussian contours, complete absence of shoulders, and a single maximum at a frequency intermediate between those of HDO in ice and in vapor. Increase of temperature causes a gradual shift of each band in the direction of the frequency in vapor. These observations fully support the "continuum" models of the structure of liquid water and present strong evidence against the "mixture" models. It is concluded that hydrogen bonds in liquid water have a broad, smooth, single-peaked distribution of strengths which gradually shifts with temperature. The hydrogen bonds at one end of this distribution have strengths comparable to those in ice, whereas those at the other end are very weak. These extremes do not correspond to distinct molecular species. Every description of liquid water in terms of "broken" and "unbroken" bonds, or "monomers" and "clusters", is therefore arbitrary.

INTRODUCTION

"Mixture" Models and "Continuum" Models

There exists a very considerable amount of evidence that hydrogen bonds in liquid water form an extensive, though short-lived three-dimensional network (1–14). This network must differ from the corresponding network in ice by an absence of long-range order, denser overall packing, and lower average strength of hydrogen bonding. A structure which meets the above conditions may arise in a variety of ways and a number of structural models have been postulated for liquid water. Most of these models can be grouped into two general categories: "mixture" models and "continuum" models.

By *mixture models* we understand those (5, 9, 12, 13, 15–31) which describe liquid water as an equilibrium mixture of molecular species with different numbers of hydrogen bonds per molecule. Such a description implies the disruption of a well-defined proportion of hydrogen bonds at any temperature. Some estimates of the percentage of broken hydrogen bonds in water are recorded in Table I. A similar table has been compiled by Luck (10).

By *continuum models* we mean those (2–4, 6, 44) which describe liquid water as a still essentially complete hydrogen-bonded network, with a distribution of hydrogen-bond energies and geometries. These models consider the average strength of hydrogen bonds in water to be weaker than in ice as a result of irregular distortion and elongation, both of which increase with temperature.

Evidence from Spectroscopic Studies

It should be possible to choose between the two types of structural models on the basis of the vibrational spectrum, which is highly sensitive to the strength and extent of hydrogen bonding. The vibrational spectrum also represents a nearly instantaneous "picture" of water, in that it allows the detection of species having a lifetime as short as 10^{-13} s.

Stevenson (43)	0.1	25	Far ultraviolet

The frequency of OH stretching vibrations is known to *decrease* in a regular manner with the strength of hydrogen bonding (45). Thus every Raman or infrared fundamental, overtone, or combination band, which involves OH stretching, may serve as a probe of hydrogen bonding. Frequencies of bending vibrations *increase* upon hydrogen bonding but the shifts are much smaller, hence somewhat less useful as a structural probe.

If liquid water consists of a mixture of molecules with broken and unbroken hydrogen bonds, then every OH stretching band would consist of two sub-bands. The sub-band corresponding to the non-hydrogen-bonded OH groups should occur at a frequency considerably higher than that of the sub-band due to the hydrogen-bonded OH groups, and ought to be detectable. Moreover, the relative intensity of this high-frequency sub-band would increase rapidly with temperature as the proportion of broken hydrogen bonds increased.

If, on the contrary, liquid water contains a continuous distribution of hydrogen-bond energies, then a single, broad band would be expected, which would shift gradually towards higher frequencies as the temperature increased and the average strength of hydrogen bonding decreased.

Thus, in principle, the changes of the band shape with temperature for any Raman or infrared vibrational band which involves OH stretching should allow a choice between the mixture and continuum models. Unfortunately, the bands in the spectra of liquid H_2O and D_2O are extremely broad, overlap considerably, and have a highly complicated temperature dependence, which makes distinction between the two predicted types of behavior extremely difficult. Some of the causes for these complications are:

1. The frequencies of the two fundamental OH stretching vibrations, ν_1 and ν_3, and of the first overtone of the bending vibration, $2\nu_2$, happen to lie very close to one another in liquid H_2O.

2. A similar, but even more complex situation holds for higher overtone and combination bands, so that the spectrum in fact consists not of single bands but of "band

For personal use only.

clusters", which contain a rapidly increasing number of contributing vibrational transitions (Fig. 1).

3. The situation in D_2O is the same as in H_2O, all the vibrational frequencies being simply shifted down by a nearly constant factor of about 1.36.

4. Because of the asymmetry of the local field of force about a water molecule in the liquid, the effective symmetry of water molecules is lowered from C_{2v} to C_s. Therefore the vibrations ν_1 and ν_3 are no longer purely the symmetric and antisymmetric stretching vibrations, and both may enter into Fermi resonance with the overtones of ν_2 (46).

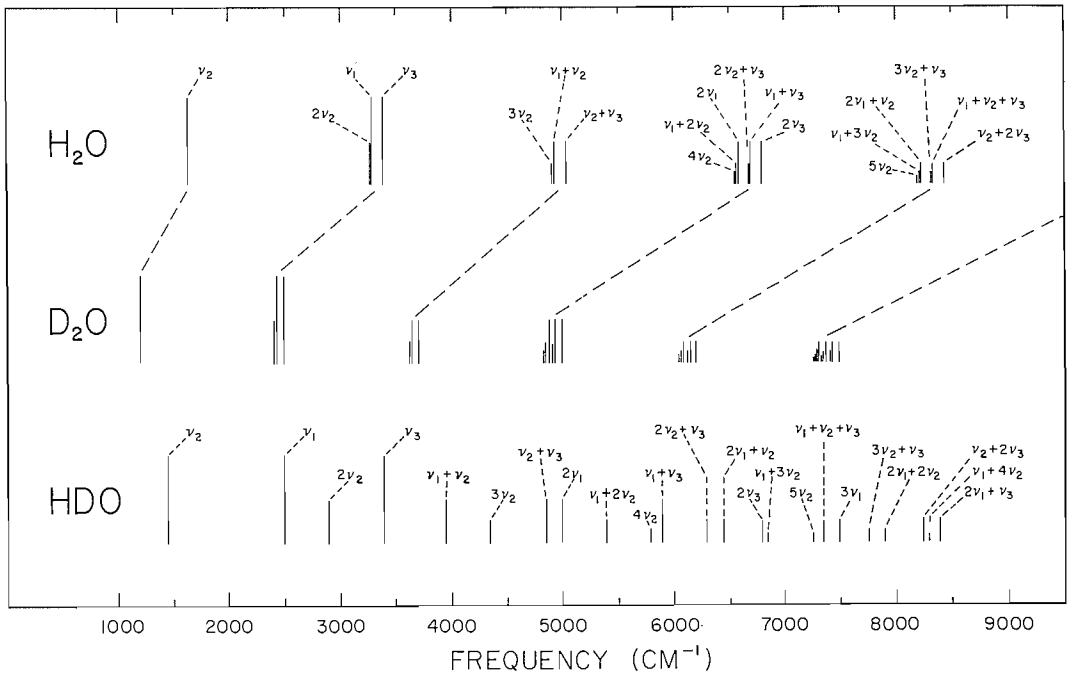

FIG. 1. Intramolecular vibrations of H_2O, D_2O, and HDO in liquid water (*highly schematic*). The frequencies of the overtone and combination bands were computed from the three fundamental frequencies, neglecting anharmonicity and Fermi resonance effects.

5. Fermi resonance within each "band cluster" may produce intensity borrowing and frequency shifts which will vary with temperature in a complex manner, since the frequencies of the three fundamentals vary differently with temperature.

6. Intermolecular coupling occurs between like vibrations of neighboring molecules, leading to a general broadening and distortion of all band shapes.

Many workers have neglected the above complications and have treated the complex changes of the shapes of some infrared or Raman "band clusters" of water as if they were due to changes in equilibria between various hydrogen-bonded and non-hydrogen-bonded water molecules (25, 27, 28, 34, 36–38, 47). Some of these studies, notably that by Cross, Burnham, and Leighton (34) and the more recent one by Buijs and Choppin (36), have been widely quoted in support of the mixture models of water (7–10). The naive interpretation of the very complex bands of H_2O and D_2O in terms of distinct species differing in hydrogen bonding must be ruled out by the far simpler spectra of HDO (48).

Some of the advantages of the study of HDO have been pointed out before (48–51). The main advantage is that in HDO the three fundamentals and many of the overtone and

For personal use only.

combination bands are widely separated (Fig. 1) so that Fermi resonance does not occur. In addition, the spectra of *dilute* HDO in H_2O and in D_2O are free from intermolecular coupling of vibrations and thus have narrower bands of simple shapes. A further important advantage of dilute HDO solutions in H_2O and D_2O is that they make it possible to record infrared spectra in the fundamental region for films having a thickness of about 50 μ, which can be accurately measured. In contrast, the corresponding spectra of pure liquid H_2O or D_2O require the use of extremely thin films (1 to 5 μ). The thickness of such films is not usually known accurately, nor can it be kept constant when temperature is varied.

EXPERIMENTAL

The spectra were recorded on a Perkin–Elmer Model 521 grating spectrophotometer equipped with an automatic frequency indicator. The spectrometer was flushed with dry air or dry nitrogen in the regions of absorption of atmospheric water vapor and carbon dioxide. Matched liquid cells with barium fluoride windows and with an optical path of 0.050 mm were supplied by the Research and Industrial Instruments Co., London. Doubly distilled H_2O, and D_2O from the Merck, Sharp, and Dohme Company, Montreal, were used. The deuterium content of the D_2O, calculated from the HDO absorbance at 3 400 cm^{-1} was 99.85 mole %. Mixtures of H_2O and D_2O were prepared by weighing and were degassed immediately before use to prevent the formation of bubbles at higher temperatures. This incidentally allowed superheating of the samples above 100°. The sample cell, which contained a dilute solution of HDO in H_2O or in D_2O, and the reference cell, which contained pure H_2O or D_2O, were placed in an insulated aluminium chamber designed to fit the spectrometer. The chamber could be heated electrically or cooled with a mixture of dry ice and acetone. The temperature of each cell was measured with a mercury thermometer in thermal contact with the windows. The indicated temperatures were the same to within 1° for the two cells and were probably correct to within 2°, as checked by freezing the H_2O or D_2O films in the cells and observing their melting points.

The spectrometer calibration was accurate to ± 1 cm^{-1}. Centers of broad bands could be determined with an accuracy of ± 2 cm^{-1} graphically by joining the midpoints of "tie lines" drawn parallel to the base line and extrapolating the line joining these midpoints to intersect with the band.

The concentrations of HDO were chosen so as to obtain bands with absorbance of about 0.3 (50% transmittance) at a path length of 0.050 mm. The corresponding HDO concentrations were approximately 1.6 mole % for the OH stretching band (ν_3), 2.0 mole % for the OD stretching band (ν_1), and 4.0 mole % for the bending band (ν_2).[4] To calculate the concentrations of HDO the equilibrium constant for the equilibrium $H_2O + D_2O \rightleftharpoons 2HDO$ was assumed to have the value 3.96 (52).

RESULTS

The spectra of pure H_2O and D_2O at room temperature and at a thickness of 0.050 mm are shown in Fig. 2. At this thickness, the transmission of H_2O near 2 500 cm^{-1} and of D_2O near 3 400 and 1 450 cm^{-1} is high enough to observe conveniently all three fundamental bands of HDO in compensated double-beam spectra. Because of the excellent compensation of the absorption of H_2O (or D_2O), the present spectra of HDO have better band contours than those obtained previously (50–53). Moreover, the earlier spectra were recorded either at a single temperature (51–53) or over a very small temperature range (50).

Fig. 3 shows typical spectra of the three fundamental bands of HDO recorded at a high and a low temperature at a standard resolution. Figure 4 shows a typical portion of the HDO spectrum in the particularly important region of 3 550 to 3 750 cm^{-1}, recorded at a higher resolution and a higher HDO concentration.

The spectra of the three fundamental bands of HDO were recorded in several series of measurements at ascending and descending temperatures. The frequencies of the three band maxima are plotted in Fig. 5. The absorptivities and the half-widths (the band widths at half the maximum absorbance) of the three bands at 22° and 120° are recorded in Table II. Our data are in reasonable agreement with most values of frequency, absorptivity, and half-width of the bands reported in the earlier studies (Fig. 5 and Table II).

[4]*The present numbering of the three* HDO *fundamental vibrations was chosen to indicate as much as possible the correspondence with the vibrations of* H_2O *and* D_2O.

DISCUSSION

Choice between Mixture Models and Continuum Models

Each of the three fundamental bands of HDO shows a single maximum, nearly Gaussian contour, and a complete absence of shoulders at any temperature. Increase of temperature causes a gradual shift of the whole band, to higher frequencies for the stretching vibrations, ν_3 and ν_1, and to lower frequencies for the bending vibration, ν_2. The absorbance of ν_3 and ν_1 decreases with temperature, while the absorbance of ν_2 increases. These observations are consistent with a gradual weakening of the hydrogen bonds with increasing temperature. Particularly to be noted is the absence of shoulders at 3 550 to 3 750 cm^{-1} for the ν_3 band and at 2 600 to 2 700 cm^{-1} for the ν_1 band, where the absorption of any non-hydrogen-bonded OH and OD groups would occur. These regions were investigated with special care under the most favorable conditions of high temperature, high HDO concentration, high resolution, and low noise level (Fig. 4). The infrared spectra of HDO thus fully support the continuum models and *are incompatible with the existence in water of any discrete molecular species differing in the extent of hydrogen bonding.*

This conclusion agrees with that reached by Wall and Hornig (55) on the basis of the Raman spectra of HDO. The Raman spectra have the advantage that their intensity is relatively independent of the strength of hydrogen bonding (55). On the other hand, the present infrared spectra have the advantage of much higher resolution (by a factor of 30 to 60) and of higher signal-to-noise ratios (by an estimated factor of 50), which considerably improves the detectability of small shoulders. Our study and that of Wall and Hornig thus largely complement each other, strengthening our independently derived conclusions.

Distribution of Hydrogen-Bond Strengths in Water

The profiles of the three HDO bands were studied by analytical procedures (56, 57) and were found to be very close to Gaussian form at all temperatures. The broad and nearly Gaussian band profiles must reflect a broad, smooth, single-peaked distribution of the strengths of hydrogen bonds in liquid water. The band profiles do not correspond directly to this distribution, because of distortion caused by (*a*) the variation of absorptivity of molecules with frequency across the band (55), (*b*) possible contribution of combinations involving the continuum of low-frequency intermolecular vibrations to the band intensity,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

and (*c*) possible broadening due to short lifetimes of the hydrogen bonds in the liquid. The contribution of *a* is largely confined to the infrared absorption spectrum, whereas *b* and *c* tend to distort both the infrared and the Raman bands. This distortion makes it difficult to evaluate quantitatively the distribution of hydrogen-bond strengths from the profiles of the vibrational bands. Fortunately, the distortion is not very serious[5] and may be neglected in the first approximation, allowing the following *qualitative* deductions about the structure of liquid water:

The distribution of the strengths of hydrogen bonds in water is very broad. At one end of this distribution are hydrogen bonds having strengths comparable with those of hydrogen bonds in ice. These correspond to the HDO absorption at frequencies close to those of HDO in ice, which are 3 300 and 2 440 cm^{-1} at 0° (59) and 3 277 and 2 421 cm^{-1} at −170° (58). At the other end of the distribution are very weak hydrogen bonds, which correspond to the small but appreciable absorption at frequencies approaching those of non-hydrogen-bonded OH or OD groups. These frequencies are 3 705 and 2 719 cm^{-1} in the vapor (60) and 3 670 and 2 695 cm^{-1} in dilute solution in CCl_4 (59). These two extremes are simply the "wings" of a broad distribution of bond strengths and cannot be considered to correspond to distinct molecular species. Most hydrogen bonds in water fall between the two extremes. The whole distribution shifts towards lower bond strengths as temperature increases, the width of the distribution remaining essentially constant.

Quantitative estimates of the distribution of the strengths of hydrogen bonds must await a careful evaluation of the distortion inherent in the contours of the Raman and infrared bands.

Distribution of Geometries

The geometry of the hydrogen bond in water is determined by the O···O distance and by angular parameters which determine the deviation of the hydrogen bond from linearity (3). The smooth, single-peaked distribution of hydrogen-bond strengths in water appears to reflect a smooth, single-peaked distribution of geometries, with the stronger bonds corresponding to short O···O distances and small deviations from linearity, and the weaker bonds corresponding to long O···O distances and larger deviations from linearity.

Because several geometrical parameters are involved and each may be expected to have a broad distribution of values, gradually shifting with temperature, the detailed shapes of these distributions will be even more difficult to derive from the band contours than the form of the distribution of the strengths of hydrogen bonds. There is also some uncertainty as to how the distributions relating to OH···O (or OD···O) bonds of HDO dissolved in D_2O or H_2O compare with the distributions relating to pure H_2O or D_2O. Nevertheless, even when the nonlinearity of the hydrogen bonds is completely neglected and a rough correlation between O···O distances and the OH stretching frequency is used, the distribution of O···O distances in water, as derived from the contours of the Raman bands of HDO, is in surprisingly good agreement with the distribution derived from X-ray diffraction measurements (55).

"Monomers" and "Clusters"

The basic assumption underlying the mixture theories of water has been that the hydrogen bonds in water at any instant can be divided into "broken" and "unbroken" bonds. Such a division must now be rejected as completely arbitrary, in view of the broad,

[5]*That the distortion is not serious is shown by (i) the close correspondence of the band profiles in the infrared and Raman spectrum of* HDO *in water (55), (ii) the relatively narrow* HDO *bands in ice (58, 59), and (iii) the near constancy of* HDO *band-widths over a 130° range of temperature observed in this work.*

smooth, single-peaked distribution of hydrogen-bond strengths. The arbitrariness of the division into broken and unbroken bonds may have been inferred already from the scatter of the estimates by various earlier workers for the percentage of broken hydrogen bonds in water (Table I). Each such estimate is in fact based on a different "operational definition" (43) of what constitutes the rupture of a hydrogen bond, and it is not surprising that the estimates vary from 0 to 71%.

The definitions of "monomers" and "clusters" in water are of course derived from the definition of what constitutes a broken hydrogen bond and, consequently, are equally arbitrary. Depending on one's operational definition of a "broken hydrogen bond", the average size of a "cluster" may thus vary from one to an infinite number of water molecules at any temperature, while the fraction of molecules present as "clusters" may vary from 0 to 1.

Addendum

In a recent publication, K. A. Hartman, Jr. presents the infrared spectra of the OH band of HDO over a 73° range of temperature and the spectrum of the OD band of HDO at room temperature (61). Hartman's spectra are less extensive, and lack double-beam compensation above room temperature but are otherwise very similar to ours. Hartman uses his data to calculate the mole fraction of "non-hydrogen-bonded OH groups" in water. Hartman estimates that such OH groups would absorb at 3 635 cm^{-1}, and, assuming that all the absorbance at this frequency is due to such groups, derives an upper limit of 7% for HDO in D_2O at 25°. Hartman's estimate should not be taken as spectroscopic evidence for the existence of up to 7% of some *distinct molecular species* with non-hydrogen-bonded OH groups. Our approach stresses the absence of such species as shown by the lack of any shoulders in the region of 3 635 cm^{-1} in both our spectra and Hartman's.

In another recent paper (62), G. E. Walrafen obtains the value of 38% for the fraction of "unbound" water molecules at 0°. In his 1964 paper (41), Walrafen obtained the very different value of 10.5% for the same quantity. The two publications also provide vastly different estimates of the enthalpy change for the process $H_2O_{(bound)} \rightarrow H_2O_{(unbound)}$. The two sets of calculations are based on the same questionable assumption that the intensity of the Raman band of water near 175 cm^{-1} is proportional to the fraction of "bound" water molecules. Walrafen's 1966 paper makes no comment about his earlier results, and in both publications close agreement is claimed with other workers' data. This inconsistency illustrates the difficulties encountered in attempts to evaluate what is an inherently arbitrary quantity.

HEATS OF ASSOCIATION OF AQUEOUS COPPER, NICKEL, AND COBALT IONS WITH HALIDE IONS

M. B. KENNEDY AND M. W. LISTER
Department of Chemistry, University of Toronto, Toronto, Ontario

Received September 20, 1965

ABSTRACT

Calorimetric measurements are reported for the heats of formation of $CoCl^+$, $NiCl^+$, $CuCl^+$, $CoBr^+$, $NiBr^+$, and $CuBr^+$ from simple aqueous ions. Values of ΔF, ΔH, and ΔS for these reactions at 25 and 40 °C, and an ionic strength of 2.0 were found. It was noted that ΔH and ΔS seem to be related by the equation: $\Delta H = 254\Delta S + 201$, for values at both temperatures.

In two recent papers (1, 2), one of the present writers measured the equilibrium constants for the formation of complex chlorides and bromides of divalent copper, nickel, and cobalt. The reactions were all of the type:

$$M^{++} + X^- \rightleftharpoons MX^+$$

and the equilibria were measured by means of spectrophotometry or cell voltages. The variation of the equilibrium constants with temperature in general deviated from the integrated equation:

$$\ln K = A - \Delta H/RT.$$

It was suggested that this was caused by either (i) rapid variation of ΔH with temperature, or (ii) the formation of other types of complex ions in appreciable amounts. These other complex ions would presumably have the general formula M_2X^{3+}, since in the experiments mentioned above the concentrations of metal ions were high, and those of halide ions low. It was not possible to distinguish between these two alternatives from the earlier experiments, so it was decided to attempt to measure the heats of reaction directly by calorimetry. The present paper reports the results of such measurements.

The experiments took the general form of measuring the temperature change when solutions of a metal perchlorate and a sodium halide were mixed in a differential calorimeter. However, it is not reasonable to attribute all the heat change to complex ion formation, since the surroundings of the various ions are altered on mixing two solutions even when no reaction occurs. The method used to allow for this was essentially that of Austin, Matheson, and Parton (3), who studied the heat of association for lead halide complex ions, PbX^+. They assumed that this was the difference between the heat changes when a given potassium halide solution was mixed firstly with lead perchlorate and secondly with perchloric acid solutions. In the present work we have similarly compared the heat changes when a given sodium halide solution was mixed firstly with copper (or nickel or cobalt) perchlorate and secondly with magnesium perchlorate. The ionic strengths were the same in the two compared experiments. Magnesium perchlorate was chosen because (i) the Cu^{++}, Co^{++}, Ni^{++}, and Mg^{++} ions are much the same size, and (ii) magnesium is reported to complex rather weakly with halide ions (4–6), though the evidence on this is a little uncertain. If (ii) is not correct, the results below might require some reinterpretation.

EXPERIMENTAL METHOD

Stock solutions used in the calorimetric experiments were prepared as follows. Reagent grade samples of the metal perchlorates, supplied by either the G. Frederick Smith Co. or Fisher Scientific Co., were dissolved in water, and made 0.02 *M* in perchloric acid to prevent hydrolysis. The solutions were then analyzed for

metal content. Copper perchlorate was analyzed iodometrically. Nickel and cobalt perchlorates were estimated by EDTA titration using murexide as indicator, as described by Vogel (7) or Schwarzenbach (8). In addition, the nickel was estimated with dimethylglyoxime; and cobalt by passing the solution through a cation exchange resin in its hydrogen form (Dowex 50W-X8), and titrating the perchloric acid produced with sodium hydroxide. This last method was also used for magnesium perchlorate. The stock sodium chloride and sodium bromide solutions were made from recrystallized reagent grade samples. The concentrations were checked by silver nitrate titration. These solutions were also made 0.02 M in perchloric acid.

The solutions were mixed in one half of a differential twin calorimeter of conventional design. The temperature change was measured by a 20-junction thermocouple of iron and constantan. This gave about 1 mV/deg which was measured on a Leeds and Northrup potentiometer sensitive to 0.1 μV. In a typical experiment, about 350 ml of the metal perchlorate solution was mixed with 50 ml of sodium halide solution. Both solutions were weighed to 0.01 g, and their densities were found in a separate experiment. It was assumed that the change in volume on mixing the two solutions was negligible. The heat capacity of the calorimeter plus mixed solutions was determined by electrical calibration. About 1.3 A at 4.2 V was passed for about 250 s, and the resulting temperature rise was about 0.8 °C. The voltage was measured on a potentiometer sensitive to 0.1 mV; and the current was measured by passing it through a standard 1 Ω resistance, and measuring the potential drop across the resistance, also to 0.1 mV. The time of heating was found to the nearest 0.05 s by an electrical timer operated by the same switch as the heating current. In each run, a second addition of 50 ml of sodium halide was made, and the electrical calibration was repeated. Experiments were made in which water (or some one solution) was used both in the pipette and the body of the calorimeter. The operation of the pipette was found to give a small heat change of 2.8 cal, with an average deviation of 0.2 cal (in six runs). This was not applied directly as a correction to the results, since the difference between the heat of mixing of (i) magnesium perchlorate and sodium halide solutions, and (ii) other metal perchlorate and sodium halide solutions, was taken to be the heat change due to complex formation.

The metal perchlorate solutions were about 0.67 M, and the sodium halide was about 2.0 M, so that both had an ionic strength of 2.0. This ionic strength was chosen to agree with that used in the earlier measurements of the equilibrium constants, so that these equilibrium constants could be used in the interpretation of the present results. This also permitted high enough concentrations to be used, so that considerable amounts of the complex species were formed. The number of moles of MX^+ formed varied, of course, with the particular ions being used, but was between 0.02 and 0.035 on the first addition, and between 0.015 and 0.025 on the second. If there are no other sources of error, the numbers given above would mean that the final value for ΔH was correct to 0.01 kcal/mole, allowing for the fact that four temperature measurements must be made to obtain one value of ΔH. However, the reproducibility of results was not as good as this, and suggest a possible error up to 0.05 kcal/mole. Part of this larger error is undoubtedly due to the assumption that heat changes due solely to mixing can be found from the behavior of magnesium perchlorate.

RESULTS

The primary experimental information consists of measurements of calories evolved or absorbed when two solutions are mixed. Its interpretation depends on (i) the complex species assumed to be formed; (ii) the values used for the stability constants of these complexes; and (iii) the method of correcting for the heat of mixing without chemical reaction. As mentioned above, this was done by measuring the heats of mixing of magnesium perchlorate and sodium halide solutions at the same concentrations, and subtracting them from the results with copper, nickel, or cobalt perchlorates. The results of the experiments with magnesium perchlorate are also given in Table I, and are each the mean of three experiments. The results after these subtractions are given in Tables I*a* and I*b* under the heading "Corrected heat change", and are used in the calculations reported in Tables I*a* and I*b* and later on. The different volumes of solution used in various runs were allowed for in making these subtractions. It was assumed that the correction should be proportional to the volume of the metal perchlorate solution used.

DISCUSSION OF RESULTS

Various assumptions can be made in order to interpret the data in Table I. These assumptions, and the conclusions they lead to, will now be considered. It was first assumed that only MX^+ complex ions were formed, and that the stability constants for these species are as given by Lister, Rosenblum, and Wilson (1, 2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

The values of the constants used are as follows:

25 °C: $NiCl^+$ 0.670, $NiBr^+$ 0.763, $CoCl^+$ 0.728, $CoBr^+$ 0.768, $CuCl^+$ 1.22, $CuBr^+$ 0.95;
40 °C: $NiCl^+$ 0.72, $NiBr^+$ 0.78, $CoCl^+$ 0.78, $CoBr^+$ 0.87, $CuCl^+$ 1.31, $CuBr^+$ 0.85.

From these the number of moles of complex formed in each run was calculated, and hence ΔH for the reactions

$$M^{++} + X^- \rightarrow MX^+.$$

The results of these calculations are also given in Tables I*a* and I*b*. ΔH obtained in this way may be compared with ΔH calculated from the equilibrium constants given above. In Table II the mean values of ΔH are compared with the values calculated from K at 25 and 40 °C. The average deviations are also given for the calorimetric results.

The values of ΔH obtained by the two methods agree only very moderately, though they are almost all small and positive (endothermic). ΔH for $CuBr^+$ is negative when calculated from K at 25 and 40 °C, but this equilibrium constant had an anomalous variation with temperature (1), and apparently went through a maximum between 25 and 30 °C. The calorimetric results are consistent in making the reaction endothermic, while the equilibrium constants only make it endothermic below 30 °C. While the comparison in Table II is perhaps not hopeless, it suggests that other explanations should be explored.

Firstly we may consider whether it would have been better to ascribe the total heat change to complex formation, and not make any allowance for mixing by means of measurements on magnesium perchlorate. The results are given in Table III. There is little to choose between the two, so far as agreement with ΔH calculated from K goes; however the corrected results vary much less with temperature, which is probably a point in their favor. In fact only the copper complexes show any appreciable change. The average deviations are less for the corrected results.

Secondly, it was suggested by Lister and Rosenblum (1) that ions of formula M_2X^{3+}, as well as MX^+, might be formed under their experimental conditions of a large excess of M^{++}. This explained some small drifts in K values that were observed. The best values of the equilibrium constants so found are given in Table IV. K_1 is the constant used above, and is $[MX^+]/[M^{++}].[X^-]$, while K_2 is $[M_2X^{3+}]/[M^{++}]^2.[X^-]$. The ΔH values calculated from K_1 and K_2 are listed as ΔH_1 and ΔH_2 respectively. These are ΔH for formation of the complexes from simple ions. These constants can be used to calculate amounts of MX^+ and M_2X^{3+} formed in the calorimetric experiments, and hence ΔH_1 and ΔH_2. The average values obtained are given in Table IV as ΔH_1 calorimetric and ΔH_2 calorimetric.

Agreement between the two methods of finding ΔH is appreciably worse than before and it is therefore improbable that the existence of M_2X^{3+} ions is the correct explanation for the anomalies in the equilibrium constant. All the calorimetric experiments were made at a considerable excess of metal over halide, and hence the solutions would not contain much MX_2. The possibility of this species cannot be entirely discounted as the halide concentrations could not be made too low, or the heat changes would have been too small. However, no systematic drifts that could be attributed to these species were detected.

Finally a more extensive calculation was made as follows. The possibility was considered that, in the original measurements of equilibrium constants by Lister, Rosenblum, and Wilson (1, 2), the extinction coefficients might vary slightly from one solution to another. These solutions were all at the same ionic strength, but the relative amounts of $M(ClO_4)_2$ and $NaClO_4$ varied. Accordingly the results on $CuBr^+$ were re-examined, and the % change in the extinction coefficient (ϵ) of $CuBr^+$ was found that would be necessary to keep

the equilibrium constant the same over the range of copper concentrations used (0.126 *M* to 0.315 *M*). This % change turned out to have a minimum value at $K = 0.79$ for 25 °C, when the range of variation of ϵ was 0.81%. This is for 280 mμ, which is the absorption maximum for $CuBr^+$.

This is not an implausibly large variation of ϵ, and consequently the calculations were extended to other wavelengths and temperatures, and to other complex ions. It was assumed that ΔH varied linearly with temperature:

$$\Delta H = \alpha + \beta T$$

so that $\mathrm{d} \ln k/\mathrm{d}T = \Delta H/RT^2$ could be integrated to give

$$\ln K = A - \alpha/RT + \beta \ln T/R.$$

The value of K at 25 °C was chosen as that which gave a minimum range of ϵ values, averaged over all the wave lengths used. This, in effect, chooses A in the above equation to give a minimum variation in ϵ. Then α and β were varied until values were found which gave the same values of ΔH at 25 and 40 °C, firstly when calculated from $\Delta H = \alpha + \beta T$; and secondly, when K obtained from the above equation was applied to the calorimetric data and used to calculate the number of moles of MX^+ formed, and hence ΔH. Where cell voltages had been used to determine K, the average value at 25 °C was used in the

$CuBr^+$	0.95±0.11	1.51±0.08

calculations. The results of these calculations are given in Table V. They require the extinction coefficients to vary over a range of about 1% between a solution about 0.12 M in $M(ClO_4)_2$ and 1.60 M in $NaClO_4$, and a solution about 0.32 M in $M(ClO_4)_2$ and 1.00 M in sodium perchlorate. Otherwise the ΔH values are self-consistent.

Table V also contains the final values of K, which are not very different from those used earlier, and hence ΔF and ΔS for the reactions. The results all refer to an ionic strength of 2.0. These are probably the most reliable values for these quantities. It may be noted that a plot of ΔH against ΔS (see Fig. 1) gives a straight line, whose equation from least squares is

$$\Delta H = 254\Delta S + 201$$

if we express ΔH in calories (not kcal). All ΔH values, both at 25 and 40 °C, lie within 80 cal of this line.

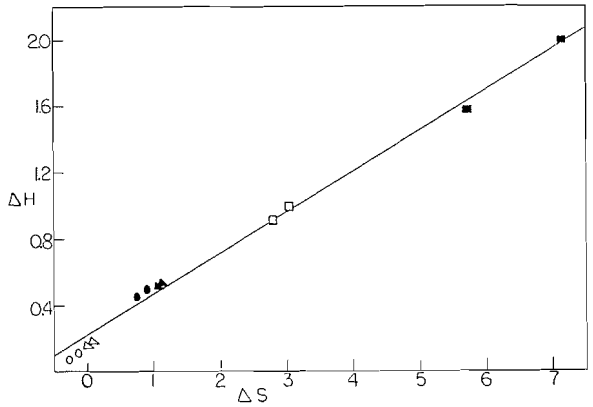

FIG. 1. H (kcal) plotted against ΔS (cal/deg) for formation of complex ions: ○, Ni (in bromide); ●, Ni (in chloride); △, Co (in bromide); ▲, Co (in chloride); □, Cu (in bromide); ■, Cu (in chloride).

$CuBr^+$	40	0.92	1.00	0.05	3.03

A possible explanation of this may be sought in terms of the strength of attachment of water molecules to the ions in solution. If the heat of hydration of the complex ion is high, ΔH for its formation will be more exothermic; but its ΔS will be lower, as the water is relatively less free. The heat of hydration presumably depends to a considerable extent on how the ionic charge is distributed between the M and X ions.

NOTES

KINETICS OF THE OXIDATION OF GLYCOLLIC ACID BY VANADIUM(V)

G. V. Bakore and Rama Shanker

Oxidation of glycollic acid by vanadium(V) in perchloric acid was investigated to see if the oxidation follows the scheme suggested by Jones, Waters, and Littler (1) for the oxidation of lactic, mandelic, and malic acids by vanadium(V).

An attempt was made to study the products of oxidation of glycollic acid by vanadium(V) in the presence of excess of glycollic acid. The product study was made by two independent methods.

(A) The formaldehyde produced by the oxidation of glycollic acid by vanadium(V) was estimated as its 2,4-dinitrophenylhydrazone in 2 *M* perchloric acid (2). To eliminate the possibility of low yield because of hydrolysis of the hydrazone, a control experiment was run along with the test experiment. The results are recorded in Table I.

TABLE I

Estimation of HCHO using 2,4-dinitrophenylhydrazine

Reaction mixture HCHO (g)*		Synthetic mixture, HCHO (g)†		% HCHO in the oxidized mixture
Expected	Found	Expected	Found	
0.0300	0.0024	0.0300	0.0242±0.0010	9.9±4.1
0.0375	0.0035	0.0375	0.0318±0.0013	11.0±4.0
0.0450	0.0044	0.0450	0.0412±0.0016	10.7±3.8

*Expected on the basis of the reaction $2V(V) + CH_2OHCO_2H \rightarrow HCHO + CO_2 + 2V(IV)$.
†Average of two to three runs.

(B) The oxidized mixtures were steam distilled to separate the formaldehyde produced. This was then estimated by its color reaction with chromotropic acid (3) by following the absorption at 570 mμ with a Bausch and Lomb Spectronic 20 colorimeter. A calibration curve was prepared by using standardized formaldehyde solution. From the relation between concentration and optical density, the amount of formaldehyde produced was evaluated. The results are summarized in Table II.

TABLE II

Estimation of HCHO by chromotropic acid (3)

Reaction mixture HCHO (g)*		Synthetic mixture HCHO (g)†		% HCHO in the oxidized mixture
Expected	Found	Expected	Found	
0.0500	0.0039	0.0500	0.0481±0.0018	8.1±3.7
0.0600	0.0047	0.0600	0.0550±0.0022	8.0±4.0

*Expected on the basis of the reaction: $2V(V) + CH_2(OH)CO_2H \rightarrow HCHO + CO_2 + 2V(IV)$.
†Average of three runs.

The total amount of formaldehyde and formic acid produced in the oxidized mixture was estimated both by bromometric (4) and permanganate (5) methods. From the control experiments, similar to those described in A and B, the amount of formaldehyde was estimated. This, when subtracted from the total amount of formaldehyde and formic acid, was taken to be a measure of the amount of formic acid produced in the reaction mixture.

Our results show that under these experimental conditions the amount of formaldehyde produced as a result of the oxidation of glycollic acid is about 10–15% of the yield expected on the basis of the equation and about 85% of the product is formic acid and not formaldehyde.

TABLE III

Dependence of rate on initial [V(V)] ([glycollic acid] = 0.058 M; [H^+] = 2.13 M; μ = 2.5 M; T = 38 °C)

[Vanadium(V)] (mole/l)	0.010	0.015	0.020	0.025
$k_1 \times 10^4$ (s^{-1})	1.40	2.10	2.80	3.20

TABLE IV

Dependence of rate on the concentration of glycollic acid ([vanadium(V)] = 0.02 M; [H^+] = 2.13 M; T = 38 °C)

[Glycollic acid] (mole/l)	0.060	0.083	0.165	0.250	0.350
$k_1 \times 10^4$ (s^{-1})	2.83	3.90	8.00	12.6	18.0
$k_1 \times 10^3$/[glycollic acid]	4.72	4.70	4.84	5.04	5.14

Average $k_2 (= k_1/[\text{glycollic acid}]) = 4.89 \pm 0.25 \times 10^{-3}$ l $mole^{-1}$ s^{-1}

Although the rate of disappearance of vanadium(V) follows first order kinetics for individual runs, the rate constant increases with an increase in the concentration of V(V). At higher concentrations of V(V), the rate constants tend to be independent of initial concentration of V(V) (cf. Table III). This indicates that consecutive reactions may be involved. The rate is proportional to the concentration of glycollic acid (cf. Table IV). The dependence of rate on hydrogen ion concentration in perchloric acid – sodium perchlorate mixtures of constant ionic strength follows the rate expression (1)

$$-\mathrm{d}[\mathrm{V(V)}]/\mathrm{d}t = k[\mathrm{V(V)}][\text{glycollic acid}](1 + ah_0),$$

where h_0 is the Hammett acidity function (cf. Table V).

TABLE V

Dependence of rate on acidity ([vanadium(V)] = 0.04 M; [glycollic acid] = 0.146 M; μ = 5.0 M; T = 25 °C)

[$HClO_4$] (moles/l)	h_0*	$k_1 \times 10^4$ (s^{-1})	
		Found	Calcd.†
1.0	28.2	1.25	1.30
1.5	47.9	2.00	2.07
2.0	69.2	3.00	2.90

Addition of formaldehyde has no effect on the rate of oxidation of glycollic acid by vanadium(V) (cf. Table VI).

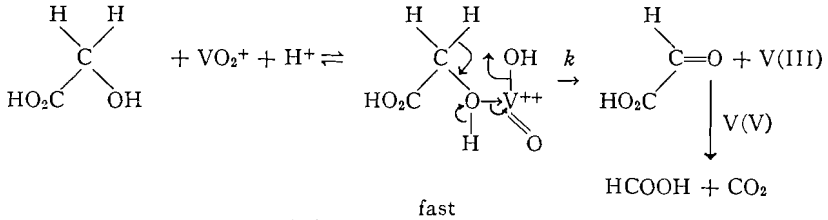

TABLE VI

Dependence of rate on initial [HCHO] ([vanadium(V)] = 0.0256 M; [glycollic acid] = 0.163 M; $[H^+]$ = 1.5 M; μ = 5.0 M; T = 38 °C)

[HCHO]$\times 10^2$ (moles/l)	0.00	2.24	4.88	11.2
$k_1 \times 10^4$ (s^{-1})	7.80	7.85	7.82	7.88

From our kinetic experiments we find that under similar conditions the rate of oxidation of glycollic acid is about 350 times the rate of oxidation of formaldehyde by vanadium(V), as observed by Kemp and Waters (6). This suggests that if the scheme suggested by Jones, Waters, and Littler (1) is correct, formaldehyde should be the main product of oxidation. The product study, however, indicates that this is not the case and that the main product of oxidation is formic acid and not formaldehyde. These facts suggest that oxidation of glycollic acid does not involve C—C fission to as great an extent as has been suggested by Jones, Waters, and Littler (1).

Shanker and Joshi (7) and Bhargava, Shanker, and Bakore (8) have suggested that vanadium(V) can act as a two-electron oxidant. Chromium(VI) also acts as a two-electron oxidant and by analogy with the oxidation of hydroxy acids by chromium(VI), the following mechanism, consistent with the facts reported here, may be suggested for the oxidation of glycollic acid by vanadium(V):

$$V(III) + V(V) \xrightarrow{\text{fast}} 2V(IV).$$

The fact that Kemp and Waters (9) have observed a kinetic isotope effect of 2.0 for the oxidation of mandelic acid and α-deuteromandelic acid by vanadium(V) indicates that C—H bond fission is appreciable in the oxidation of hydroxy acids by vanadium(V).

If the oxidation of glycollic acid and also lactic, mandelic, and malic acids involves C—H bond rupture, then a comparison of thermodynamic parameters for the oxidation of these acids with those for the oxidation of α-hydroxyisobutyric acid and pinacol, which involves C—C fission, may be expected to be different. Table VII summarizes these thermodynamic parameters.

TABLE VII

Thermodynamic parameters for the oxidation of α-hydroxy acids by vanadium(V)

Substrate	ΔE (kcal/mole)	ΔS (entropy units)	Reference
Glycollic acid	16.7	−16.0	—
Lactic acid	16.5	−20.0	(10)
Mandelic acid	14.0	−20.1	(11)
α-Hydroxyisobutyric acid	21.8	−0.4	*
Pinacol	22.8	+9.5	*
Oxalic acid	24.0	+0.6	(8)

*Data from present investigations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The entropy of activation for the oxidation of compounds like pinacol, oxalic acid, and α-hydroxyisobutyric acid, which is known to involve C—C fission, has values from -1.0 to $+10$ e.u. (entropy units). The observed entropy of activation ($\simeq -20$ e.u.) for the oxidation of glycollic, lactic, and mandelic acids suggests that the oxidation of these hydroxy acids involves considerable C—H fission in the rate-determining step.

The relative proportions of formaldehyde and formic acid in the products of oxidation of glycollic acid also agree with the suggestion that in the oxidation of glycollic acid C—H bond rupture becomes appreciably significant.

It, therefore, appears that oxidation of glycollic acid by vanadium(V) is similar to the oxidation of α-hydroxy acids by chromium(VI) (cf. Bakore and Narain (12)).

to the mean lifetime of the phosphorescence of hexafluoroacetone and to the effect of certain gases upon it.

The apparatus used was similar to that described by Kaskan and Duncan (3). Light from an argon flash discharge lamp (kindly provided by Dr. D. A. Ramsay of these laboratories) was filtered through the "3 130 filter" described by Kasha (4) and passed as a parallel beam ($\sim$ 0.5 cm diameter) through a T-shaped cell (15 cm long, 2 cm i.d.). The emitted light was focused through a Corning filter, C.S. 0-52, onto a 6256B EMI photomultiplier tube whose output was applied to the vertical plates of a Tektronix 545 oscilloscope. The signal from the photomultiplier triggered the horizontal sweep of the oscilloscope; the decay curves thus produced were photographed. The cell was permanently connected to the vacuum line. The effect of added gases was studied by starting an experiment with the pure ketone and by adding thereafter known amounts of the second compound; mixing was achieved with a glass piston pump operated electromagnetically. Mixing for periods longer than 15 min caused no further changes in the measured lifetimes.

The intensity of the flash from the lamp rose to a maximum in 5 to 7 μs and thereafter decreased exponentially with a lifetime of 5.9 $\pm$ 0.1 μs; a tungsten wire resistor in series with the lamp eliminated oscillations which were otherwise observed in the lamp output following the main pulse (5). The scattered light arriving at the photomultiplier, when the lamp was flashed into the empty cell or into as much as 400 mm of carbon dioxide, was negligibly small.

All experiments were conducted at 25 $\pm$ 1°.

Hexafluoroacetone (Allied Chemical), acetone (B. and A.), decafluorobutane (Columbia Organic Chemicals), isobutene (Matheson), benzene, isobutane, ethylene, and propylene (all Phillips research grade) were thoroughly degassed before use; isobutane contained less than 1 part in 15 000 of isobutene as determined by gas chromatography. Oxygen (Union Carbide, 99.99% purity) was used as obtained from the supplier.

The mean phosphorescence lifetime of acetone vapor has been measured by Kaskan and Duncan (6) in the pressure region 10 to 200 mm at 25°. We repeated these determinations as a test of the present apparatus; although the effect of acetone pressure upon the mean lifetime was similar to that found by Kaskan and Duncan, the actual values of the lifetime were consistently 15% higher than those reported. Two different batches of acetone were used for these determinations and gave the same results within experimental error. It is possible that this discrepancy was caused by the presence of triplet-quenching impurities in the acetone samples used by Kaskan and Duncan. It is unlikely that systematic errors in the time scale of the oscilloscopes could cause an error of this magnitude.

Hexafluoroacetone gave decay traces which clearly indicated, as in the case of acetone (7), the occurrence of two distinct emissions; the plots of the logarithm of the emission intensity versus time produced two straight lines with markedly different slopes. The larger, which was not very well resolved because of interference from the decay of the flash, gave a mean lifetime of about 12 μs; this is attributed to the fluorescence or emission from the first excited singlet state. This lifetime is longer than the radiative lifetime expected for a spin-allowed transition (an approximate integration of the extinction coefficients in the literature (8) yielded $\tau_0 \sim 6.7$ μs) and is much longer than that expected when paths other than fluorescence are available to dissipate the energy. Instances are known in which the measured lifetimes, extrapolated to zero pressure, are greater than those calculated from integrated absorption coefficients (9, 10). Mechanisms which might

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

be responsible for such effects have been discussed (11). The smaller slope, always much better defined, gave a mean lifetime of 286 ± 5 μs; this is attributed to the phosphorescence, or emission from the triplet state, since additions of a few millimeters of oxygen eliminated it completely.

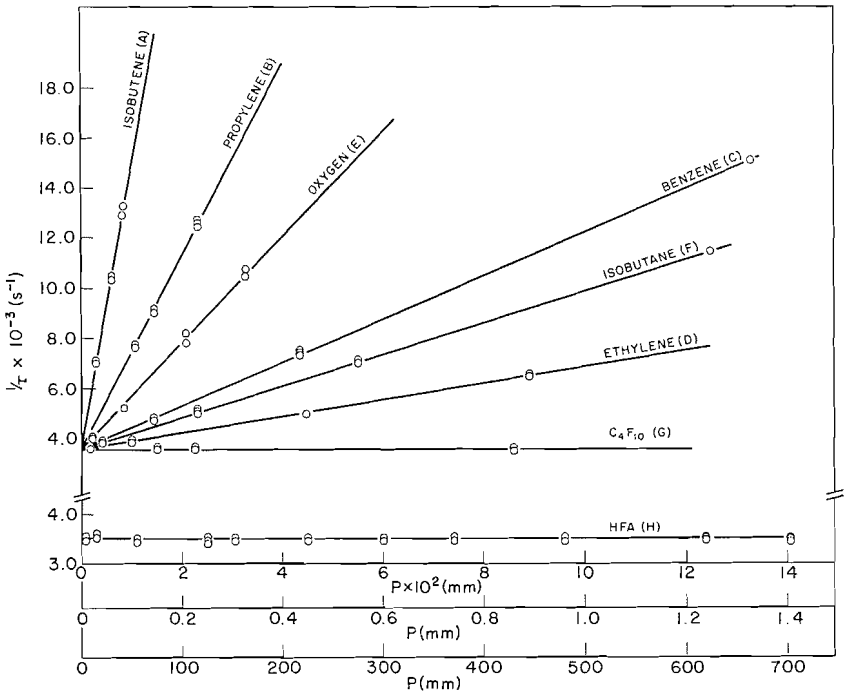

FIG. 1. The effect of various gases upon the phosphorescence lifetime of hexafluoroacetone at 25°. The top abscissa scale refers to A, B, C, and D; the middle scale to E and F; the bottom scale to G and H.

The pressure dependence of the phosphorescence lifetime was studied and the results are shown in Fig. 1. The lowest working pressure was that below which reasonable accuracy in determining lifetimes became technically unattainable. It must be pointed out that over 100 determinations were made in the pressure range shown in the graph and that they all fell within the scatter given above for the mean lifetime. It can be concluded that if there is any effect of pressure upon the phosphorescence of hexafluoroacetone between 4 and 704 mm, this must be less than the experimental scatter of ±2%. Several samples from one batch of the ketone were used; the degassing procedure varied greatly but no change in the lifetime was observed. Samples from other cylinders of the ketone gave this lifetime as a limiting value after rigorous purification which involved discarding the most volatile (at −110 °C) 80% of the sample. Similar results were obtained by Kaskan and Duncan (6) with biacetyl vapor, although the pressure range investigated by them was much more limited.

The effect of various gaseous compounds upon the mean lifetime of phosphorescence of hexafluoroacetone is also illustrated in Fig. 1 and the quenching rate constants given in Table I. The quenching effect always followed the simple relationship

$$1/\tau = k_1 + k_2[G],$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where τ is the mean lifetime of phosphorescence of the mixture, $1/k_1$ the mean lifetime of the pure ketone, and [G] the concentration of the added gas; k_2 represents the quenching rate constant.

TABLE I

Quenching efficiency of various gases upon the phosphorescence lifetime of hexafluoroacetone (HFA) at 25°

	$k_2 \times 10^{-11}$ $((\text{mole/ml})^{-1}\ \text{s}^{-1})$	P_{HFA} (mm)
Hexafluoroacetone	0.0	4 to 704
Decafluorobutane	0.0	76 and 302
Isobutane	1.2	142 and 362
Oxygen	4.5	209
Ethylene	5.9	153
Benzene	16.1	119
Propylene	72.6	190, 271, and 478
Isobutene	214	228

The following considerations must be included in an interpretation of these results

(*a*) The quenching effect of oxygen upon the triplet state of ketone vapors has been reported by several investigators (1, 6, 7, 12), although a clear understanding of the details of the quenching action has not been attained as yet. The present results show that oxygen is about 20 times more powerful in quenching the triplet state of acetone (7) than in quenching that of hexafluoroacetone, and that it displays approximately the same quenching efficiency with biacetyl (6) and with hexafluoroacetone, at 25°.

(*b*) Decafluorobutane has no effect upon the phosphorescence lifetime of hexafluoroacetone up to a ratio [fluorocarbon]/[ketone] of 6/1. Similar observations were made when studying the total emission of mixtures of these two compounds with a static system (13).

(*c*) The effect of the three olefins studied could in principle be interpreted according to one or more of the following mechanisms:

1. The ketone molecules in the triplet state transfer their energy to the olefin molecules.

[1] $$^3\text{A} + \text{O} \rightarrow \text{A} + {}^3\text{O}$$

2. Intersystem crossing to the ground state by collision with olefin molecules is the cause of the quenching.

3. The ketone molecules in the triplet state undergo a chemical reaction with the olefin.

A mechanism based on simple energy transfer to the triplet state of the olefin (reaction [1]) encounters energetic difficulties. The location of the O—O band of the T_1–S_0 transition for hexafluoroacetone is unknown, but, from the known (2) S_1–S_0 separation and by accepting a S_1–T_1 separation near 9 kcal/mole as is known for formaldehyde (14), the T_1–S_0 separation becomes 71 kcal/mole. The only monoolefin for which this separation is known from spectroscopic data is ethylene; Evans (15) gave a value of 82 kcal/mole. Triplet state levels for higher homologs are expected to lie somewhat lower; thus values of k_2 are expected to be greater for propylene and isobutene than for ethylene, as indeed is observed. However, the magnitudes involved become quite unreasonable if only low vibrational levels of the ketone triplet state are involved. For example, if the rate constant for [1] is written as $k_2 = A_2 \exp(-E_2/RT)$ and if E_2 is taken as the endothermicity of the reaction ($\sim$ 11 kcal/mole), the experimental value of k_2 for ethylene requires that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$A_2(C_2H_4) \simeq 10^{20}$ (mole/ml)$^{-1}$ s^{-1}, which suggests a collision cross-section of $\sim 8 \times 10^6$ Å^2. More reasonable values of A_2 are obtained if smaller values of E_2 are involved; in the case of ethylene if E_2 is ~ 5 kcal/mole, the collision cross-section is reduced to about 300 Å^2. A lower E_2 implies a higher triplet state energy for the ketone, or that higher vibrational levels of the triplet state are involved. Neither suggestion is unreasonable, although the latter is not supported by the lack of effect of ketone pressure on k_2 (Table I). Because of the uncertainty in the energetics it is not possible to rule out the energy transfer mechanism, although at present it seems not to provide a completely satisfactory explanation of the experimental data. Studies of the temperature dependence of k_2, soon to be undertaken, should provide further insight into the energetics of these systems.

The second possibility seems highly improbable, since other molecules of not too different size, such as decafluorobutane and hexafluoroacetone itself, have no such effect on the lifetime even at very much higher concentrations.

The possibility of a chemical interaction seems the most plausible interpretation, although it is not possible to offer any evidence on the actual mode of attack; presumably both the double bond and the methyl groups of the higher olefins must play a role. This concept is supported by the fact that ethylene and isobutane, both of which lack one of the two structures, display a finite efficiency.

The effect of isobutene on the phosphorescence of hexafluoroacetone was confirmed by static measurements on the total emission (13).

The fact that Okabe and Steacie (2) did not observe any phosphorescence emission from hexafluoroacetone is possibly explained by the presence of small quantities of ethylene in the ketone used. These could have been generated during the dehydration of the commercial ketone hydrate; it has since been observed in these laboratories that most samples of the hydrate contained some ethanol. Less than 1 mm of ethylene would have been sufficient to quench the entire phosphorescence emission.

(*d*) The deduction of a quenching mechanism for isobutane is easier, since both collisional deactivation and energy transfer can be safely ruled out in this case. A chemical reaction seems to be the only alternative. Khanna and Kutschke (16) have recently come to a similar conclusion in considering the effect of isobutane upon the quantum yield of the decomposition of hexafluoroacetone. It should be noted that the maximum isobutene impurity in the isobutane used here could have caused less than about 1% of the quenching observed. Moreover, the total level of impurities was such that quenching constants larger than the collision number would have been required for these to interfere significantly with the effect of isobutane itself.

(*e*) The effect of benzene upon the phosphorescence lifetime of hexafluoroacetone is again explained in terms of chemical reaction. Rebbert and Ausloos (17) have found that benzene produces no observable reduction of the emission yield of acetone and explained this by showing that energy transfer was too endothermic. The same can be said in the present instance, since the O—O band of the S_0–T_1 transition for benzene corresponds to 84 kcal/mole. The ratio of the values of k_2 for benzene and isobutane differs considerably from the value of $q_{i\text{-}C_4H_{10}}/q_{C_6H_6} \simeq 1$ found by Khanna and Kutschke (16). This suggests that the same quantity is not being measured in these two sets of experiments.

It will be noticed from Table I that in some instances the effect of an added gas was studied at more than one pressure of ketone and that this did not alter the efficiency of the added compound. This confirms the observation that the mean lifetime of phosphorescence of hexafluoroacetone is independent of the pressure of the ketone.

Further work on both emissions of hexafluoroacetone is in progress.

NOTE ADDED IN PROOF: The present experiments were done in an apparatus in which mercury was present near its saturation pressure at 25 °C. Very recently we measured τ at $\sim$ 50 mm HFA under mercury-free conditions and obtained $\tau = 2.3 \pm 0.2$ ms in two experiments. Moreover when a drop of mercury was added to the cell τ returned to less than 300 μs; condensation of the mixture at −196 °C followed by reevaporation produced no significant changes in τ. These observations suggest that mercury vapor acts as a quencher. The quenching constants in Table I should not be greatly affected by the presence of this second quencher at an essentially constant concentration. Quantum yields of decomposition of HFA probably also are affected by the presence of mercury vapor, however. Under mercury-free conditions τ for acetone remained near the value found in the presence of mercury.

THE HIGH RESOLUTION NUCLEAR MAGNETIC RESONANCE SPECTRUM OF THE NONRIGID AB_2X_2 SYSTEM

R. G. Jones

The high resolution nuclear magnetic resonance (n.m.r.) spectrum of the rigid ABB′XX′ (1, 2) and AB_2X_2 (2) systems have been studied in some detail. The ABB′XX′ system provides a good example of the application of the principles of sub-spectral analysis (2) and the AB_2X_2 system illustrates the special case of effective frequency spectra (3, 4).

The nonrigid AB_2X_2 system received a mention by Diehl *et al.* (2) as a further system in which the special conditions of effective frequencies apply because of the magnetic equivalence of the two B nuclei and the two X nuclei as a result of intramolecular torsional oscillations. However, the basic symmetry wave function diagram was not derived because the appropriate point group was not determined.

It is the purpose of this paper to show the way in which it is possible to elucidate the

NOTE ADDED IN PROOF: The present experiments were done in an apparatus in which mercury was present near its saturation pressure at 25 °C. Very recently we measured τ at $\sim$ 50 mm HFA under mercury-free conditions and obtained $\tau = 2.3 \pm 0.2$ ms in two experiments. Moreover when a drop of mercury was added to the cell τ returned to less than 300 μs; condensation of the mixture at −196 °C followed by reevaporation produced no significant changes in τ. These observations suggest that mercury vapor acts as a quencher. The quenching constants in Table I should not be greatly affected by the presence of this second quencher at an essentially constant concentration. Quantum yields of decomposition of HFA probably also are affected by the presence of mercury vapor, however. Under mercury-free conditions τ for acetone remained near the value found in the presence of mercury.

THE HIGH RESOLUTION NUCLEAR MAGNETIC RESONANCE SPECTRUM OF THE NONRIGID AB_2X_2 SYSTEM

R. G. Jones

The high resolution nuclear magnetic resonance (n.m.r.) spectrum of the rigid ABB′XX′ (1, 2) and AB_2X_2 (2) systems have been studied in some detail. The ABB′XX′ system provides a good example of the application of the principles of sub-spectral analysis (2) and the AB_2X_2 system illustrates the special case of effective frequency spectra (3, 4).

The nonrigid AB_2X_2 system received a mention by Diehl *et al.* (2) as a further system in which the special conditions of effective frequencies apply because of the magnetic equivalence of the two B nuclei and the two X nuclei as a result of intramolecular torsional oscillations. However, the basic symmetry wave function diagram was not derived because the appropriate point group was not determined.

It is the purpose of this paper to show the way in which it is possible to elucidate the

symmetry point group for the nonrigid AB_2X_2 system (from first principles) with particular regard to the specific requirements of the n.m.r. problem involved.

The paper by Longuet-Higgins (5) provides the basic ideas and definitions necessary for the extrapolation of our ideas about the symmetry point groups of rigid molecules to those of nonrigid molecules. Longuet-Higgins suggests that the clearest and most useful definition of the molecular symmetry point group appears to be, all feasible permutations of the positions and spins of identical nuclei or any product of such permutations, including E, the identity, and all feasible P^* ($PE^* = E^*P$) not necessarily including E^*. E^* is defined as the inversion of all particle positions, through the center of mass.

The simple product spin functions used as a representation of an n.m.r. problem are invariant under E^* (5). They are, therefore, transformed by P^* in the same way as by P. Hence it is only necessary to use the P elements of the group to characterize the symmetry point group for the n.m.r. problem. This point group is usually a sub-group of the molecular symmetry point group.

The feasible P for the nonrigid AB_2X_2 system can be defined using the numbering notation of Fig. 1.

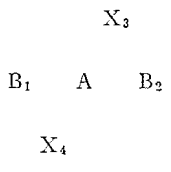

FIG. 1. Model for nonrigid AB_2X_2 systems.

The feasible P are E, (12), (34), and (12)(34). The multiplication table for the group is shown in Table I.

TABLE I

Transformations of the elements E, (12), (34), and (12)(34)

	E	12	34	12 34
E	E	12	34	12 34
12	12	E	12 34	34
34	34	12 34	E	12
12 34	12 34	34	12	E

Every element of the group is conjugate with itself but no other element and therefore each element belongs to a unique class (6). There are four classes and therefore there are four irreducible representations.

It is possible to derive the characters of these four irreducible representations on the basis of the vector properties of the representations and four important rules (6, p. 64). A basis for a representation of a group may be any set of algebraic functions or vectors. Let the vectors $\overrightarrow{12}$ and $\overrightarrow{34}$ be the basis, at least in part, for the group under consideration. These vectors transform as follows

E	(12)	(34)	(12)(34)
$\overrightarrow{12}$	$-\overrightarrow{12}$	$\overrightarrow{12}$	$-\overrightarrow{12}$
$\overrightarrow{34}$	$\overrightarrow{34}$	$-\overrightarrow{34}$	$-\overrightarrow{34}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The matrix representations are

$$\begin{array}{cccc} E & (12) & (34) & (12)(34) \\ \begin{bmatrix} 1, & 0 \\ 0, & 1 \end{bmatrix} & \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix} & \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} & \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix} \end{array} .$$

Hence $$(12)\begin{bmatrix} \overrightarrow{12} \\ \overrightarrow{34} \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} \overrightarrow{12} \\ \overrightarrow{34} \end{bmatrix} = \begin{bmatrix} -\overrightarrow{12} \\ \overrightarrow{34} \end{bmatrix} .$$

The vectors 12 and 34 are not mixed by the elements E, (12), (34), (12)(34) and therefore each forms an independent representation of the group

	E	(12)	(34)	(12)(34)	
$\Gamma_{\overrightarrow{12}}$	1	−1	1	−1	$\overrightarrow{12}$
$\Gamma_{\overrightarrow{34}}$	1	1	−1	−1	$\overrightarrow{34}$

These representations are orthogonal and the sums of the squares of the characters in these representations equal the order of the group (four elements). Thus they satisfy two of the four rules. The product of their characters within each class produces a new representation,

	E	(12)	(34)	(12)(34)
$\Gamma = \Gamma_{12} \times \Gamma_{34}$	1	−1	−1	1

which is orthogonal to both of them and therefore independent. The remaining independent representation which must be orthogonal to those defined above has the dimension $\chi(E) = 1$ (third rule (6)).

E	(12)	(34)	(12)(34)
1	1	1	1

The character table for the point group of the nonrigid AB_2X_2 system is therefore

	E	(12)(34)	(34)	(12)	
Γ_1	1	1	1	1	
Γ_2	1	1	−1	−1	$\overrightarrow{34}$
Γ_3	1	−1	1	−1	$\overrightarrow{12}$
Γ_4	1	−1	−1	1	

This point group is isomorphic with C_{2v}, the point group of the rigid AB_2X_2 system. It is obvious therefore that the factorization of the secular determinant will be identical both for the rigid and nonrigid AB_2X_2 systems (2). The AB_2 part of the spectrum is composed of three superimposed ab_2 sub-spectra corresponding to $F_s(X_2) = 1, 0, -1$ with statistical weight 1:2:1 respectively, as predicted by the effective frequency method (3, 4).

THE HYDROLYSIS OF DIMETHYLSULFATE AND DIETHYLSULFATE IN WATER[1]

R. E. ROBERTSON AND S. E. SUGAMORI

In this note we supply kinetic data for the hydrolysis of dimethylsulfate and diethylsulfate in water for a range of temperatures and compare the derived parameters with similar terms from the hydrolysis of the corresponding methanesulfonates and benzenesulfonates.

At one time questions were raised as to whether solvolysis involved the cleavage of the O—S or O—C bond or most probably both in varying proportion depending on reaction conditions (1, 2). Results of research on this question by Ader (3), by Kaiser (4*, 5), and by Lauder, Wilson, and Zerner (6) show that the reaction involves C—O cleavage only. Kaiser (4) has shown that $MeSO_4^-$ ion will exchange with $H_2{}^{18}O$ and that the conflicting evidence based on ^{18}O tracer techniques is removed if the sulfate ion is precipitated as quickly as formed.

In the hydrolysis of dimethylsulfate, some degree of nucleophilic interaction with a single water molecule is indicated by the k_{OH^-}/k_{H_2O} ratio of 45–50 and the inverse secondary α-deuterium isotope effect (7) ($k_H/k_D = 0.97$). These values lie in the general range of the benzenesulfonates rather than that of the methyl halides, but it may be significant to note here that the k_{OH^-}/k_{H_2O} ratio and the k_H/k_D ratio for dimethylsulfate are both a little closer to unity than for the corresponding sulfonates. Moreover, the solvent isotope effect (k_{H_2O}/k_{D_2O}) 0.899 lies at the low end of the sulfonate range (8) a value which indicates less availability of the unshared electrons on the oxygens for hydrogen bonding. Because we shall have reason to return to this point later, we note here that a difference in hydrogen bonding ability of the sulfonates and the sulfates has been clearly indicated by the careful infrared investigation of Kartha *et al.* (9) on the relative hydrogen bonding to *p*-chlorophenol in CCl_4.

EXPERIMENTAL SECTION

Distilled water was purified by passage through an acid–base ion exchange column. A backing electrolyte (potassium methylsulfate) was added to give a 0.002 *M* solution.

Dimethylsulfate.—Matheson dimethylsulfate b.p. 75–77 °C (15 mm) was redistilled under vacuum and the distillate repeatedly purified by partial freezing to give a product with m.p. −26.9 and n_D^{25} 1.3858.

THE HYDROLYSIS OF DIMETHYLSULFATE AND DIETHYLSULFATE IN WATER[1]

R. E. ROBERTSON AND S. E. SUGAMORI

In this note we supply kinetic data for the hydrolysis of dimethylsulfate and diethylsulfate in water for a range of temperatures and compare the derived parameters with similar terms from the hydrolysis of the corresponding methanesulfonates and benzenesulfonates.

At one time questions were raised as to whether solvolysis involved the cleavage of the O—S or O—C bond or most probably both in varying proportion depending on reaction conditions (1, 2). Results of research on this question by Ader (3), by Kaiser (4*, 5), and by Lauder, Wilson, and Zerner (6) show that the reaction involves C—O cleavage only. Kaiser (4) has shown that $MeSO_4^-$ ion will exchange with $H_2{}^{18}O$ and that the conflicting evidence based on ^{18}O tracer techniques is removed if the sulfate ion is precipitated as quickly as formed.

In the hydrolysis of dimethylsulfate, some degree of nucleophilic interaction with a single water molecule is indicated by the k_{OH^-}/k_{H_2O} ratio of 45–50 and the inverse secondary α-deuterium isotope effect (7) ($k_H/k_D = 0.97$). These values lie in the general range of the benzenesulfonates rather than that of the methyl halides, but it may be significant to note here that the k_{OH^-}/k_{H_2O} ratio and the k_H/k_D ratio for dimethylsulfate are both a little closer to unity than for the corresponding sulfonates. Moreover, the solvent isotope effect (k_{H_2O}/k_{D_2O}) 0.899 lies at the low end of the sulfonate range (8) a value which indicates less availability of the unshared electrons on the oxygens for hydrogen bonding. Because we shall have reason to return to this point later, we note here that a difference in hydrogen bonding ability of the sulfonates and the sulfates has been clearly indicated by the careful infrared investigation of Kartha *et al.* (9) on the relative hydrogen bonding to *p*-chlorophenol in CCl_4.

EXPERIMENTAL SECTION

Distilled water was purified by passage through an acid–base ion exchange column. A backing electrolyte (potassium methylsulfate) was added to give a 0.002 *M* solution.

Dimethylsulfate.—Matheson dimethylsulfate b.p. 75–77 °C (15 mm) was redistilled under vacuum and the distillate repeatedly purified by partial freezing to give a product with m.p. −26.9 and n_D^{25} 1.3858.

[1]*Issued as N.R.C. No. 9010.*
**We wish to acknowledge receipt of Dr. Kaiser's thesis prior to publication.*

Diethylsulfate.—Diethylsulfate was redistilled and subsequently fractionated by partial freezing; m.p. −24.0–24.5, D_0^{25} 1.1725. Neither compound gave kinetic evidence of the presence of significant impurity.

Rate data were obtained by a conductance method. The experimental method, calculations, and details of temperature measurement and control have been described elsewhere (10, 11). In the present instance there is the theoretical possibility that the rate data might be confused by the subsequent hydrolysis of the methyl sulfuric ion. Lewis, Mason, and Morgan (12) showed many years ago that the latter reaction is much slower than the hydrolysis of the first methyl group, and we have not been able to detect any appreciable reaction of the methyl ion at 100 °C in 10 h. Since hydrolysis occurs readily at this temperature in concentrated solutions (6), it must be concluded that in the latter case it is the un-ionized acid which is reacting. In no case were our initial concentrations of sulfuric ester higher than 0.005 M, hence the hydrolysis reaction of the methyl sulfuric ion can be safely neglected.

Individual rate determinations for a range of temperatures have been deposited with the Depository of Unpublished Data.* These rates could be fitted by least mean squares to the usual three constant equation $\log_{10} k = A/T + B \log_{10} T + C$. The corresponding values of the empirical constants are given in Table I, and provide a means of calculating the rate for any particular temperature. The constants of these empirical equations give† corresponding values of $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta C_p^{\neq}$, granted transition state assumptions are accepted and $d\Delta C_p^{\neq}/dT$ is assumed to be small. Corresponding values of these terms and some comparable values of analogous compounds are given in Table II.

TABLE I

Empirical constants for the rate equation $\log_{10} k = A/T + B \log_{10} T + C$

Compound	A	B	C
Dimethylsulfate	−7609.092	−22.1323	76.5044
Diethylsulfate	−7548.588	−20.7590	72.7329

TABLE II

Kinetic parameters derived from rate–temperature relationships at 25 °C

	$k_1 \times 10^5$* (s^{-1})	$\Delta H^{\neq}$ (cal/mole)	$\Delta S^{\neq}$ (cal/mole deg)	$\Delta C_p^{\neq}$ (cal/mole deg)
Dimethylsulfate	16.60	21 110	−5.03	−46
Diethylsulfate	11.15	21 650	−4.0	−43

negative by about 10 cal/mole deg. Part of the difference in $\Delta S^{\neq}$ can be attributed to a statistical factor due to symmetry ($2.3R \log 2 \simeq 1.4$ e.u.) and part may be attributed to a somewhat more stable solvent shell about the sulfate than about the sulfonate group. The latter difference is probably marginal, as indicated by the similar kinetic solvent isotope effects noted above. We believe that the most important factor contributing to this difference may be the enhanced probability of nucleophilic attack due to the enhanced polarizability of the  system, but this effect is difficult to estimate by independent means.

The more negative $\Delta C_p^{\neq}$ for the two sulfates compared with the values for the sulfonates is consistent with the suggestion that the initial state solvation shell is somewhat more stable about the former solutes. The more positive entropy due to a greater degree of disruption of solvent in the transition state would be consistent with this suggested hypothesis (13). This difference is not nearly large enough to suggest a similarity to that accompanying a change of mechanism from SN2 to SN1 (14) and hence we cannot agree with the suggestion of Lauder and co-authors (6) that the hydrolysis of these compounds in water follows the latter mechanism.

ADDENDUM: STEREOCHEMISTRY AND SEVEN COORDINATION[1]

T. A. CLAXTON AND G. C. BENSON

(Ref. Can. J. Chem. 44, 157 (1966))

In our paper (1) attention was drawn to the importance of the nuclear repulsion and *net* electron attraction (2) terms in deciding molecular structure. Application of the arguments to the fluorine compounds of xenon suggests that the structure of XeF_6 is determined by the *net* electron attraction term, since XeF_7^- and XeF_8^{2-} presumably are present in the corresponding alkali metal salts (3). In this case the methods used by Gillespie (4) are applicable and the accumulating evidence for a distorted XeF_6 (5, 6) appears to provide

The latter difference is probably marginal, as indicated by the similar kinetic solvent isotope effects noted above. We believe that the most important factor contributing to this difference may be the enhanced probability of nucleophilic attack due to the enhanced polarizability of the  system, but this effect is difficult to estimate by independent means.

The more negative $\Delta C_p^{\neq}$ for the two sulfates compared with the values for the sulfonates is consistent with the suggestion that the initial state solvation shell is somewhat more stable about the former solutes. The more positive entropy due to a greater degree of disruption of solvent in the transition state would be consistent with this suggested hypothesis (13). This difference is not nearly large enough to suggest a similarity to that accompanying a change of mechanism from SN2 to SN1 (14) and hence we cannot agree with the suggestion of Lauder and co-authors (6) that the hydrolysis of these compounds in water follows the latter mechanism.

(Ref. Can. J. Chem. 44, 157 (1966))

In our paper (1) attention was drawn to the importance of the nuclear repulsion and *net* electron attraction (2) terms in deciding molecular structure. Application of the arguments to the fluorine compounds of xenon suggests that the structure of XeF_6 is determined by the *net* electron attraction term, since XeF_7^- and XeF_8^{2-} presumably are present in the corresponding alkali metal salts (3). In this case the methods used by Gillespie (4) are applicable and the accumulating evidence for a distorted XeF_6 (5, 6) appears to provide

substantiation. XeF_6 is therefore different from the relatively small number of known examples of molecules of the type MX_6, except the isolectronic IF_6^- ion, with M containing seven electron pairs in the valence shell, in that the *net* electron attraction term is dominant. We should emphasize that XeF_6 is distinctive in that it is the only molecule of the type discussed that has been studied in the vapor phase. Furthermore, it should be noted that in the other cases the crystal forces may be important in determining the shape.

It is also not surprising that there are indications from the Raman spectrum of IF_6^- in solution in anhydrous hydrogen fluoride[2] that this ion too is distorted; there appeared to be more Raman bands than one would expect for an octahedral ion. This distortion is consistent with the hypothesis that the *net* electron attraction term is dominant, since IF_7 exists. The Raman spectrum in the solid state also indicated[2] that IF_6^- is distorted. Thus it seems in this case that crystal forces do not provide an alternative explanation to the one proposed (1) for the existence of octahedral complexes with the central atom having seven electron pairs in the valence shell.

ORGANIC SULFUR COMPOUNDS

II. CATALYZED SODIUM BOROHYDRIDE REDUCTIONS OF SELECTED α-(*o*-NITROPHENYLTHIO) ACIDS[1]

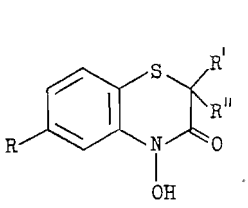
R. T. COUTTS, D. L. BARTON, AND ELIZABETH M. SMITH

College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan

Received February 28, 1966

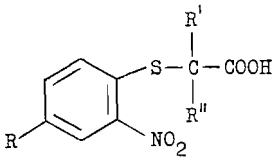
ABSTRACT

The products obtained when α-(*o*-nitrophenylthio) acids are reduced by means of sodium borohydride and palladium–charcoal depend on (*a*) the reaction temperature, (*b*) the solvent, (*c*) the length of time in which the α-(*o*-nitrophenylthio) acid is in contact with the reducing agent, and (*d*) the nature of the substituents on the α-(*o*-nitrophenylthio) acid. By varying these conditions, benzothiazine hydroxamic acids (i.e. substituted 3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazines), the corresponding lactams (3,4-dihydro-3-oxo-2*H*-1,4-benzothiazines), and derivatives of 2-carboxymethylthioazobenzene can be prepared.



In two cases, additional products were obtained. When (*o*-nitrophenylthio)acetic acid was catalytically reduced for 30 min in dioxane, 3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine-1,1-dioxide (VI*c*) was an unexpected product, and when α-(4-trifluoromethyl-2-nitrophenylthio)-isobutyric acid was left for a prolonged time in contact with sodium borohydride and palladium–charcoal, a derivative of hydrazobenzene, namely, 2-carboxy(α,α-dimethyl)methylthio-5-trifluoromethylhydrazobenzene (V), was one of the three identified products.

When reduced by means of sodium borohydride and palladium–charcoal, certain aromatic nitro compounds which possess an ester group in a position suitably orientated with respect to the *o*-nitrophenyl group are converted into cyclic hydroxamic acids (1–3); the nitro group is reduced to a hydroxylamino group which then cyclizes with the ester function. When two nitro acids were reduced by similar means, however, complete reduction to the corresponding amines occurred, and in both cases, lactamisation resulted on acidification (1).



We have recently reported (3) that 2*H*-1,4-benzothiazine hydroxamic acids (I) are readily obtained by reducing suitably substituted (*o*-nitrophenylthio)acetates by means of sodium borohydride and palladium–charcoal. On the supposition that reduction of the corresponding acids would yield the related lactams (III), which could be expected to possess anthelmintic properties (4, 5), substituted (*o*-nitrophenylthio)acetic acids were reduced with sodium borohydride and palladium–charcoal. The resulting products depended on (*a*) time, (*b*) solvent, (*c*) nature of the substituents, and (*d*) temperature.

When α-(4-trifluoromethyl-2-nitrophenylthio)propionic acid (II*f*) was reduced in dioxane or methanol over a period of 30 min with excess sodium borohydride in the presence of palladium–charcoal, the corresponding amino compound was not formed (6). The isolation of 6-trifluoromethyl-3,4-dihydro-4-hydroxy-2-methyl-3-oxo-2*H*-1,4-benzothiazine (I*f*) in good yield, on acidification of the filtrate, indicated that reduction had proceeded only as far as the hydroxylamino stage. This reaction is a general one. A total

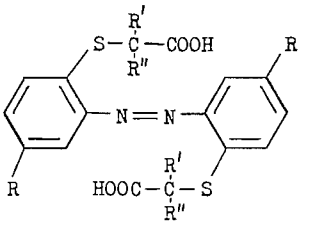
of 13 acids having the general formula II (i.e. II*a*–II*m*) were reduced by this method. In every case, the corresponding hydroxamic acid (I*a*–I*m*) was obtained, usually in good yield, regardless of whether methanol or dioxane was used as solvent (Table I).



A different result was obtained, however, when simple derivatives of (*o*-nitrophenylthio)acetic acid were left in contact with sodium borohydride and palladium–charcoal for extended periods of time. Reduction of (4-trifluoromethyl-2-nitrophenylthio)acetic acid (II*e*) in aqueous dioxane by this method gave initially an almost colorless solution which slowly darkened when left to stand at room temperature. After an interval of 72 h the solution was orange-red in color; at this stage the catalyst was removed and the filtrate acidified. No hydroxamic acid was obtained. Chromatographic analysis of the product showed that it was a mixture containing 6-trifluoromethyl-3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine (III*a*), 2-carboxymethylthio-5-trifluoromethylazobenzene (IV*a*), and other unidentified material. In the same way, prolonged reductions of α-(4-bromo-2-nitrophenylthio)propionic acid (II*d*), α-(4-trifluoromethyl-2-nitrophenylthio)propionic acid (II*f*), α-(4-methyl-2-nitrophenylthio)propionic acid (II*h*), α-(*o*-nitrophenylthio)propionic acid (II*j*), and α-(4-bromo-2-nitrophenylthio)isobutyric acid (II*l*) with sodium borohydride and palladium–charcoal gave derivatives of 3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine (III*b*–III*f*, respectively), and azo compounds (IV*b*–IV*f*, respectively). Yields were generally poor, and other unidentified products were also obtained. A similar prolonged reduction of α-(4-trifluoromethyl-2-nitrophenylthio)isobutyric acid (II*m*) again failed to give hydroxamic acid. In this case, the solution had darkened appreciably after the reagents had been in contact for only 24 h. At this stage, the solution was filtered and acidified. Three identifiable products were isolated, two of which were the expected 2-carboxy-(α,α-dimethyl)methylthio-5-trifluoromethylazobenzene (IV*g*) and 6-trifluoromethyl-3,4-dihydro-2,2-dimethyl-3-oxo-2*H*-1,4-benzothiazine (III*g*). The third product has been deduced to be the hydrazo compound (V). Such a structure is compatible with elemental analysis and with equivalent and molecular weight determinations. Evidence from infrared studies also suggests this molecular structure. The infrared spectra of IV*g* and V are similar, except for absorption peaks attributable to the NH group, which occur only in compound V. The infrared spectra of azobenzene and hydrazobenzene were recorded for comparison purposes. As expected, they also showed many similarities, with differences mainly in the regions where NH absorption occurs.

In addition to the expected hydroxyl and carbonyl absorption, it was noticeable that the infrared spectra of all the azo compounds (IV*a*–IV*g*) in potassium bromide had an absorption band of weak to medium intensity in the range 1 418 – 1 444 cm^{-1}. Such a band may be ascribed to the azo group (7). The mechanism involved in the formation of the azo and hydrazo compounds from the hydroxylamino intermediates is being investigated at present.

The products obtained from the reduction of (*o*-nitrophenylthio)acetic acid were also dependent on the rate of reduction and on the nature of the solvent used. A fast reduction (30 min) in dioxane gave 3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazine (VI*a*) as the major product, though some of the corresponding lactam 3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine (VI*b*) was also formed. In addition to these products, an unexpected third product, namely, 3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine-1,1-dioxide (VI*c*), was isolated from the reaction mixture. One explanation for the formation of VI*c* is a concurrent oxidation and reduction of the intermediate VII*a* to yield VII*b* and VII*c*, which cyclize on acidification. A prolonged reduction of (*o*-nitrophenylthio)acetic acid in dioxane gave the lactam in very good yield, and rather surprisingly, no azo compound was obtained. The lactam (VI*b*) was also the only product isolated when the same acid was reduced over a 15 min period in methanol. A similar result was obtained when *o*-chloro-*α*-(*o*-nitrophenylthio)cinnamic acid (VIII) was reduced with an excess of sodium borohydride and palladium–charcoal. A fast reduction in dioxane yielded the hydroxamic acid (IX*a*) as the major product; some lactam (IX*b*) was also isolated. The lactam was the only product obtained when the fast reduction was repeated with methanol as solvent or when the reduction in dioxane was prolonged.

This is not the first instance of solvent influencing the nature of the product obtained when sodium borohydride and palladium–charcoal are employed to reduce nitro compounds. We have previously reported (1) that the reduction of methyl (*o*-nitrobenzoyl)-cyanoacetate in sodium hydroxide solution gave 3-cyano-1,2-dihydro-1,4-dihydroxy-2-oxoquinoline (X*a*) in excellent yield. We have since found[2] that, when the solvent is changed to methanol, the hydroxamic acid does not form. The product is then the lactam (X*b*).

When α-(4-trifluoromethyl-2-nitrophenylthio)propionic acid (II*f*) was reduced in dioxane with sodium borohydride and palladium–charcoal over a period of 15 min at room temperature and left at 0° for 72 h before filtering and acidifying, the reaction mixture did not darken appreciably. On acidification, the hydroxamic acid (I*f*) was obtained as the major product, even though an excess of sodium borohydride was employed in the reaction. The corresponding lactam (III*c*) was the minor product of this reaction.

The results of this study should be compared with those of Neilson *et al.* (6), who showed that aromatic nitro compounds were smoothly reduced to amines with sodium borohydride and palladium–charcoal. These authors were unable to isolate any intermediate compounds in the reduction and they presented evidence that by-products of the azobenzene, azoxybenzene, or hydrazobenzene type were not formed and subsequently reduced to the amine.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were recorded on a Unicam SP200 spectrophotometer. Palladium–charcoal refers to 10% palladium on charcoal.

Preparation of α-(o-Nitrophenylthio) Acids (IIa–IIm)

With the exception of compounds II*b* and II*c*, the preparations of the acids used in this study were reported in part I (3).

(4-Chloro-2-nitrophenylthio)acetic acid (II*b*) was obtained in 96% yield by the previously described (3) general method for preparing 2-(*o*-nitrophenylthio) acids. It was a yellow solid, m.p. 209°, when recrystallized from methanol (lit. (8) m.p. 209–210°).

α-(4-Chloro-2-nitrophenylthio)propionic acid (II*c*) was prepared by the method described for II*b*. The title compound was obtained as a yellow solid (95% yield), m.p. 134–135°, when recrystallized from methanol. Infrared spectrum (KBr disk): broad absorption 2 400 – 3 300 (m) (OH); 1 700 (s) (C=O); 1 525 (s), 1 340 (s), and 832 (m) (NO_2) cm^{-1}.

Anal. Calcd. for $C_9H_8ClNO_4S$: C, 41.30; H, 3.07. Found: C, 41.63; H, 3.05.

Fast Reductions of α-(o-Nitrophenylthio) Acids (IIa–IIm)

The method of reduction was similar to the one previously used for the reduction of the corresponding esters (3). Palladium–charcoal (0.2 g), suspended in water (10 ml), was added carefully to a solution of sodium borohydride (1 g) in water or 2% sodium hydroxide solution (10 ml) (see Table I). The suspension was diluted with dioxane or methanol (20 ml), and nitrogen was passed through the mixture while a solution of the acid (1 g) in dioxane or methanol (20–40 ml) was added dropwise over a period of 15 min. The reaction was

[2]*R. T. Coutts and S. J. Storey, unpublished results.*

For personal use only.

allowed to continue for a further 15 min in an atmosphere of nitrogen; then the catalyst was removed by filtration and the hydroxamic acid was isolated from the filtrate by the methods reported earlier (3).

The yields of hydroxamic acids are recorded in Table I. Four hydroxamic acids (I*b*, I*c*, I*g*, and I*i*) have not been reported previously. Apart from these four compounds, all the hydroxamic acids listed in Table I had properties identical with those already reported (3) for these compounds.

6-Chloro-3,4-dihydro-4-hydroxy-3-oxo-2H-1,4-benzothiazine (I*b*) was a colorless compound, m.p. 179–180°, when recrystallized from ethanol. Infrared spectrum (KBr disk): 3 180 (m) (OH); 1 675 (s) and 1 628 (m) (free and hydrogen-bonded C=O) cm^{-1}.

Preparation of o-Chloro-α-(o-nitrophenylthio)cinnamic Acid (VIII)

The title compound was prepared by the reported (9) method. It was a yellow solid, m.p. 213–215°, when recrystallized from methanol (lit. (9) m.p. 215–217°).

Reduction of o-Chloro-α-(o-nitrophenylthio)cinnamic Acid

Method a

A fast reduction of the title compound (1.007 g) was carried out in dioxane by the previously described general method for the reduction of α-(*o*-nitrophenylthio) acids. The filtrate was acidified with concentrated hydrochloric acid, and 2-(*o*-chlorobenzylidene)-3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazine (IX*a*) was precipitated as a yellow solid (0.506 g), m.p. 140–143°, which gave a violet color when treated with ethanolic ferric chloride solution. Two recrystallizations from methanol raised the melting point to 143–144°. Infrared spectrum (KBr disk): broad absorption 2 500 – 3 400 with maximum at 3 220 (m) (OH); 1 665 (m) and 1 624 (s) (free and hydrogen-bonded hydroxamate C=O) cm^{-1}.

Anal. Calcd. for $C_{15}H_{10}ClNO_2S$: C, 59.30; H, 3.32; N, 4.67. Found: C, 59.40; H, 3.29; N, 4.76.

The aqueous acidic filtrate remaining after removal of the above hydroxamic acid was completely extracted with ether, and then the combined ether extracts were re-extracted with 10% sodium carbonate solution. Evaporation of the ether solution gave 2-(*o*-chlorobenzylidene)-3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine (IX*b*) (0.27 g) as a yellow solid, m.p. 229–230°, after recrystallization from methanol (lit. (9) m.p. 225–227°).

Anal. Calcd. for $C_{15}H_{10}ClNOS$: C, 62.60; H, 3.50; N, 4.87. Found: C, 62.99; H, 3.58; N, 4.89.

The sodium carbonate extract was acidified with concentrated hydrochloric acid and extracted with ether. Removal of the ether gave a brown oil (0.1282 g) which was rejected.

Method b

The title compound (1.003 g) was reduced as described in method *a*, except that methanol was used as solvent. The filtrate was acidified with concentrated hydrochloric acid, and when the solution was cooled,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

2-(*o*-chlorobenzylidene)-3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine (IX*b*) (0.346 g) separated as a pale-yellow solid, m.p. 229–230° after recrystallization from methanol. A further yield of IX*b* (0.360 g) was obtained by means of ether extraction of the aqueous acidic filtrate as described in method *a*.

Method c

The title compound (3.04 g) in dioxane (150 ml) was added in small portions over a period of ½ h to a suspension of palladium–charcoal (0.5 g) in 50% aqueous dioxane (50 ml), in which was dissolved sodium borohydride (2.5 g). Nitrogen was passed through the mixture during the addition of the solution of the title compound. The mixture was left for 72 h; then the solution was filtered and the filtrate acidified with concentrated hydrochloric acid. 2-(*o*-Chlorobenzylidene)-3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine (0.928 g) precipitated as a yellow solid, m.p. 214–217°, raised to 228–230° when recrystallized from methanol. The infrared spectrum was identical with that of an authentic sample. A further yield of IX*b* (0.896 g) was obtained from an ether extraction of the aqueous acidic filtrate as described in method *a*.

Reduction of (o-Nitrophenylthio)acetic Acid

This compound was reduced by methods which were essentially the same as those described under the reduction of *o*-chloro-α-(*o*-nitrophenylthio)cinnamic acid.

(*o*-Nitrophenylthio)acetic acid (1.06 g) in dioxane (50 ml) was reduced as described in method *a*, the solution filtered, and the filtrate acidified. A white solid (0.157 g), m.p. 187–189°, separated. Two recrystallizations from methanol gave 3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine-1,1-dioxide as a colorless solid, m.p. 208–209° (lit. (10) m.p. 207–208°). Infrared spectrum (KBr disk): broad absorption 2 800 – 3 400 with maxima at 3 090 (m) and 3 210 (m) (lactam NH); 1 682 (s) (C=O) cm^{-1}.

Anal. Calcd. for $C_8H_7NO_3S$: C, 48.72; H, 3.58; N, 7.10; S, 16.26. Found: C, 49.02; H, 3.28; N, 6.92; S, 16.00.

The acidic filtrate remaining after removal of the above product was extracted with ether; then the ether solution was re-extracted with 10% sodium carbonate solution. Evaporation of the ether solution gave 3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazine (0.482 g), m.p. 179–180°, when recrystallized from methanol (lit. (11) m.p. 179°). The sodium carbonate solution was acidified and extracted with ether. Removal of the ether gave 3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazine (0.482 g) as colorless crystals, m.p. 149–150°, when recrystallized from methanol (lit. (1) m.p. 151–152°). The infrared spectra of both compounds were identical with those of authentic samples, and only the latter compound, m.p. 149–150°, gave a violet color when alcoholic ferric chloride solution was added.

This reduction by method *a* has been repeated a number of times. On two occasions, no product separated when the initial filtrate was acidified. The acidic solution was then extracted with ether and the ether-soluble material separated into neutral and acidic products. The neutral material was shown to contain 3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine (VI*b*) and the corresponding dioxide (VI*c*) by subjecting the mixture to chromatography on Whatman No. 1 paper with methanol–water (1:4) as solvent and locating the spots by means of ultraviolet light. The R_f values for VI*b* and VI*c* are 0.61 and 0.45, respectively.

When the title compound (1.02 g) was reduced by method *b*, a total yield of 0.581 g of 3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine was obtained and no hydroxamic acid was isolated.

When the title compound (3.032 g) was reduced by method *c*, a total yield of 1.990 g of 3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine was isolated.

Prolonged Reductions of α-(o-Nitrophenylthio) Acids

General Method

The α-(*o*-nitrophenylthio) acid (3 g) was dissolved in dioxane (minimum volume) and the resulting solution was added in small portions over a period of 15 min to an aqueous dioxane solution of sodium borohydride (3 g) in which was suspended palladium–charcoal (0.6 g). Nitrogen was passed through the mixture while the solution of the α-(*o*-nitrophenylthio) acid was added and for a further 15 min. The reaction mixture was then left exposed to the atmosphere at room temperature for 72 h, during which time the almost colorless solution turned dark red in color. The solution was then filtered and the filtrate was acidified with concentrated hydrochloric acid. This gave a dark-colored solid. The solid and the filtrate which remained after its removal were treated as described in individual examples.

Prolonged Reduction of (4-Trifluoromethyl-2-nitrophenylthio)acetic Acid (IIe)

The title compound (2.906 g) was reduced by the general method, and a pale-brown precipitate (2.118 g), m.p. 211–218°, was obtained. A portion (0.522 g) was recrystallized from ethanol and gave 2-carboxymethylthio-5-trifluoromethylazobenzene (IV*a*) (0.155 g) as an orange solid, m.p. 252–253°. Infrared spectrum (KBr disk): broad absorption 2 400 – 3 300 with maxima at 3 050 (m) and 2 900 (m) (OH); 1 700 (s) (C=O); 1 426 (m) (azo) cm^{-1}.

Anal. Calcd. for $C_{18}H_{12}F_6N_2O_4S_2$: C, 43.37; H, 2.43; N, 5.62; S, 12.87. Found: C, 43.68; H, 2.64; N, 5.57; S, 12.83.

A second portion (0.404 g) of the product, m.p. 211–218°, was chromatographed on alumina (8 cm × 1 cm). Elution with benzene gave 6-trifluoromethyl-3,4-dihydro-3-oxo-2*H*-1,4-benzothiazine (III*a*) (0.077 g) as a white solid, m.p. 186–187°. Infrared spectrum (KBr disk): broad absorption 2 700 – 3 350 with maxima at 3 190 (m) and 3 095 (m) (lactam NH); 1 672 (s) (C=O) cm^{-1}.

Anal. Calcd. for $C_9H_6F_3NOS$: C, 46.35; H, 2.59; N, 6.01. Found: C, 46.76; H, 2.71; N, 5.57.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The solvent was then changed to methanol, which eluted unidentified material (0.105 g, m.p. 265–285°). Finally a mixture of methanol – 5% sodium hydroxide solution (19:1) was used as eluant. A dark-red solution was obtained which was concentrated to a small volume, diluted with water, acidified with hydrochloric acid, and extracted with ether. Evaporation of the ether solution gave a further quantity of 2-carboxymethylthio-5-trifluoromethylazobenzene (IV*a*) (0.134 g), m.p. 243–251°, raised to 251–253° when recrystallized from methanol–benzene. The infrared spectrum was superimposable on that of the earlier fraction of IV*a* obtained as described above.

*Prolonged Reduction of α-(4-Methyl-2-nitrophenylthio)propionic Acid (II*h*)*

The title compound (2.995 g) was reduced by the general method, and an orange-brown solid (1.092 g), m.p. 170–180°, was obtained. Three recrystallizations from methanol gave 2-carboxy(α-methyl)methylthio-5-methylazobenzene (IV*d*) as a pale-orange solid, m.p. 205–208°. Infrared spectrum (KBr disk): broad absorption 2 400 – 3 300 with maximum at 2 940 (m) (OH); 1 698 (s) (C=O); 1 442 (w) (azo) cm^{-1}.

Anal. Calcd. for $C_{20}H_{22}N_2O_4S_2$: C, 57.39; H, 5.30; N, 6.69. Found: C, 57.63; H, 5.20; N, 6.63.

The filtrate remaining after removal of the above solid, m.p. 170–180°, was extracted with ether. The product obtained on evaporation of the ether was dissolved in methanol and chromatographed on alumina (8 cm × 1 cm). Eluate (100 ml) was collected and evaporated. The resulting product was dissolved in ether (ca. 100 ml) and extracted with 10% sodium bicarbonate solution (3 × 50 ml). Evaporation of the washed and dried ether solution gave 3,4-dihydro-2,6-dimethyl-3-oxo-2*H*-1,4-benzothiazine (III*d*) as a pale-brown solid (0.541 g), m.p. 146–152°, raised to 158–159° when recrystallized from aqueous methanol. Infrared spectrum (KBr disk): broad absorption 2 800 – 3 400 with maxima at 3 225 (w) and 3 110 (w) (lactam NH); 1 660 (s) (C=O) cm^{-1}.

Anal. Calcd. for $C_{10}H_{11}NOS$: C, 62.14; H, 5.75; N, 7.25; S, 16.59. Found: C, 62.09; H, 6.28; N, 6.90; S, 16.06.

Acidification of the aqueous sodium bicarbonate extract gave an ether-soluble brown oil (0.277 g) which was rejected. A similar oil (0.179 g) was obtained when the eluant for the column was changed to methanol – 5% sodium hydroxide (19:1). It was also rejected.

*Prolonged Reduction of α-(4-Trifluoromethyl-2-nitrophenylthio)propionic Acid (II*f*)*

Method a.—After the title compound (3.018 g) was reduced by the general method, acidification of the filtrate gave no precipitate, and so the solution was concentrated and extracted with ether. The product remaining after removal of the ether was chromatographed on alumina (8 cm × 1 cm) with methanol as eluant. Eluate (100 ml) was collected and evaporated to give product A, which was treated as described below. The eluant was then changed to methanol – 5% aqueous sodium hydroxide solution (19:1), and 100 ml was collected. The solvent was removed and the resulting product (product B) was treated as described below.

Product A was dissolved in ether (100 ml) and the ether solution was extracted with 10% sodium bicarbonate solution. Evaporation of the washed and dried ether solution gave 6-trifluoromethyl-3,4-dihydro-2-methyl-3-oxo-2*H*-1,4-benzothiazine (III*c*) (0.502 g), m.p. 166–167°, as a pale-brown solid after two recrystallizations from aqueous methanol. Infrared spectrum (KBr disk): broad absorption 2 800 – 3 400 with maxima at 3 180 (w) and 3 080 (w) (lactam NH); 1 660 (s) (C=O) cm^{-1}.

Anal. Calcd. for $C_{10}H_8F_3NOS$: C, 48.58; H, 3.26; N, 5.67. Found: C, 48.20; H, 3.29; N, 5.15.

Acidification of the aqueous sodium bicarbonate extract with concentrated hydrochloric acid gave 2-carboxy(α-methyl)methylthio-5-trifluoromethylazobenzene (IV*c*) (0.980 g) as an orange solid, m.p. 243–245°, after two recrystallizations from methanol. Infrared spectrum (KBr disk): broad absorption 2 400 – 3 700 with maximum at 2 950 (m) (OH); 1 704 (s) (C=O); 1 432 (m) (azo) cm^{-1}.

Anal. Calcd. for $C_{20}H_{16}F_6N_2O_4S_2$: C, 45.62; H, 3.06; N, 5.32; S, 12.18. Found: C, 45.38; H, 3.31; N, 5.65; S, 12.19.

A solution of product B in water was acidified with concentrated hydrochloric acid, and a further 0.355 g of IV*c* was obtained, m.p. 227–230°, raised to 242–244° when recrystallized from methanol. The infrared spectra of this and the previous product were identical.

Method b.—The title compound (3.012 g) in dioxane (100 ml) was reduced by the general method, except that the reaction mixture was left at 0 °C for the 72 h period. The yellow filtrate was acidified and extracted with ether; the ether solution was re-extracted with 10% sodium carbonate solution. Evaporation of the resulting ether solution left an orange-brown oil which, on trituration with methanol, gave 6-trifluoromethyl-3,4-dihydro-2-methyl-3-oxo-2*H*-1,4-benzothiazine (0.156 g), m.p. 158–161°, raised to 165–167° when recrystallized from methanol.

The sodium carbonate solution was acidified with concentrated hydrochloric acid, and then extracted with ether. The ether solution, on evaporation, gave 6-trifluoromethyl-3,4-dihydro-4-hydroxy-2-methyl-3-oxo-2*H*-1,4-benzothiazine (I*f*) (1.438 g) as a pale-yellow solid, m.p. 105–109°. Recrystallization from methanol raised the melting point to 124–126° (lit. (3) m.p. 126–128°). The infrared spectrum was identical with that of an authentic sample of the hydroxamic acid.

*Prolonged Reduction of α-(o-Nitrophenylthio)propionic Acid (II*j*)*

The method used to reduce the title compound (3.034 g) was similar to that described for the reduction of α-(4-trifluoromethyl-2-nitrophenylthio)propionic acid (method *a*). With methanol as eluant, acidic and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

neutral products were isolated. The acidic material, 2-carboxy(α-methyl)methylthioazobenzene (IV*e*) (0.902 g), was obtained initially as a red oil which solidified (m.p. 138–142°) when triturated with methanol. Recrystallization from aqueous methanol gave an orange solid, m.p. 151–152°. Infrared spectrum (KBr disk): broad absorption 2 400 – 3 300 with maximum at 2 920 (m) (OH); 1 700 (shoulder) (s) and 1 688 (s) (C=O); 1 422 (w) (azo) cm^{-1}.

Anal. Calcd. for $C_{18}H_{18}N_2O_4S_2$: C, 55.36; H, 4.65; N, 7.17. Found: C, 55.72; H, 4.37; N, 7.58.

The neutral material, 3,4-dihydro-2-methyl-3-oxo-2*H*-1,4-benzothiazine (III*e*) (0.508 g), was obtained as an orange solid, m.p. 117–120°. Recrystallization from aqueous methanol gave a pale-brown solid, m.p. 126–128°. Infrared spectrum (KBr disk): broad absorption 2 700 – 3 400 with maxima at 3 215 (w) and 3 080 (w) (lactam NH); 1 662 (s) (C=O) cm^{-1}.

Anal. Calcd. for C_9H_9NOS: N, 7.82. Found: N, 7.79.

With methanol – 5% sodium hydroxide (19:1) as eluant, a red acidic oil (0.205 g) was obtained which was not investigated further.

Prolonged Reduction of α-(4-Bromo-2-nitrophenylthio)propionic Acid (IId)

This compound (3.052 g) was reduced by the general method, and the subsequent treatment was similar to that described for the prolonged reduction of α-(4-methyl-2-nitrophenylthio)propionic acid. 5-Bromo-2-carboxy(α-methyl)methylthioazobenzene (IV*b*) (1.707 g) was obtained initially as a red-brown solid, m.p. 167–170°. Two recrystallizations gave an orange solid, m.p. 235–236°. Infrared spectrum (KBr disk): broad absorption 2 400 – 3 700 with maxima at 2 990 (m) and 3 080 (m) (OH); 1 702 (s) (C=O); 1 424 (w) (azo) cm^{-1}.

Anal. Calcd. for $C_{18}H_{16}Br_2N_2O_4S_2$: C, 39.43; H, 2.94; N, 5.11; S, 11.70. Found: C, 39.21; H, 2.86; N, 5.10; S, 11.90.

The neutral product was initially obtained as an orange oily solid which was triturated with methanol. In this way, 6-bromo-3,4-dihydro-2-methyl-3-oxo-2*H*-1,4-benzothiazine (III*b*) (0.696 g) was obtained as a colorless solid, m.p. 188–190°, raised to 192–193° when recrystallized from methanol. Infrared spectrum (KBr disk): broad absorption 2 500 – 3 400 with maxima at 2 980 (m), 3 110 (m), and 3 210 (m) (lactam NH); 1 674 (s) (C=O) cm^{-1}.

Anal. Calcd. for C_9H_8BrNOS: C, 41.87; H, 3.12; N, 5.43. Found: C, 42.18; H, 3.20; N, 5.17.

Prolonged Reduction of α-(4-Bromo-2-nitrophenylthio)isobutyric Acid (IIl)

The title compound (2.89 g) was reduced by the general method. The acidified filtrate was extracted with ether, and the combined ether extracts were re-extracted with 2% sodium hydroxide solution. The dried ether solution, on evaporation, gave 6-bromo-3,4-dihydro-2,2-dimethyl-3-oxo-2*H*-1,4-benzothiazine (III*f*) (0.564 g) as a cream-colored solid, m.p. 178–181°. Recrystallization from benzene gave a colorless solid, m.p. 188–189°. Infrared spectrum (KBr disk): broad absorption 2 700 – 3 350 with maxima at 3 000 (m), 3 130 (m), and 3 230 (m) (lactam NH); 1 670 (s) (C=O) cm^{-1}.

Anal. Calcd. for $C_{10}H_{10}BrNOS$: C, 44.13; H, 3.70; N, 5.15. Found: C, 44.34; H, 3.66; N, 5.20.

The aqueous alkaline extract was acidified and extracted with ether. The dark-red ether extract was dried and evaporated to give a purple solid (1.740 g) which was triturated with methanol, in which a portion (0.820 g) was insoluble. This insoluble portion was recrystallized from methanol to give 5-bromo-2-carboxy-(α,α-dimethyl)methylthioazobenzene (IV*f*) as purple prisms, m.p. 220–222°. Infrared spectrum (KBr disk): broad absorption 2 400 – 3 300 with maxima at 2 970 (m) and 3 075 (m) (OH); 1 688 (s) (C=O); 1 418 (w) (azo) cm^{-1}.

Anal. Calcd. for $C_{20}H_{20}Br_2N_2O_4S_2$: C, 41.68; H, 3.50; N, 4.86; S, 11.13. Found: C, 41.32; H, 3.52; N, 4.82; S, 11.43.

The portion of the purple solid which dissolved when triturated with methanol was not investigated further.

Prolonged Reduction of α-(4-Trifluoromethyl-2-nitrophenylthio)isobutyric Acid (IIm)

The title compound (3.026 g) was reduced by the general method, except that the reaction was allowed to continue for only 24 h, at which time the solution was dark orange in color. The filtrate was acidified with concentrated hydrochloric acid and extracted with ether. The combined ether extracts were dried and evaporated to give a dark-red solid (2.457 g), m.p. 110–121°. A portion (1.40 g) of this solid was chromatographed on alumina (8 cm × 1 cm) with methanol as solvent. Suitable volumes of eluate were collected and evaporated, and the following fractions were collected.

Fraction No.	Weight	Color	Melting point
1	0.089 g	Colorless	139–142°
2	0.364 g	Colorless	135–139°
3	0.376 g	Pink	158–163°
4	0.077 g	Pink	157–160°
5	0.009 g	Cream	136–139°
6	0.065 g	Pink	135–149°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The eluant was changed to methanol – 5% sodium hydroxide (19:1), and the following fractions were isolated after evaporation and acidification.

Fraction No.	Weight	Color	Melting point
7	0.252 g	Pink	151–160°
8	0.061 g	Pink	179–200°

Fractions 1 and 2 were combined and recrystallized from aqueous ethanol to give 6-trifluoromethyl-3,4-dihydro-2,2-dimethyl-3-oxo-2*H*-1,4-benzothiazine (III*g*) as a cream-colored solid, m.p. 144–145°. Infrared spectrum (KBr disk): broad absorption 2 800 – 3 400 with maxima at 3 095 (m) and 3 200 (m) (lactam NH); 1 665 (s) (C=O) cm^{-1}.

Anal. Calcd. for $C_{11}H_{10}F_3NOS$: C, 50.57; H, 3.86; N, 5.36. Found: C, 50.80; H, 3.79; N, 5.29.

Fractions 3, 4, and 6 were mixtures and not investigated further at this time. Fraction 7 was recrystallized from aqueous ethanol to give 2-carboxy(α,α-dimethyl)methylthio-5-trifluoromethylhydrazobenzene (V) as a pale-pink solid, m.p. 166–168°. To enable direct comparison with the infrared spectrum of IV*g* (see later), the infrared spectrum of V (KBr disk) is given in detail (main peaks only): broad absorption 2 350 – 3 500 with maxima at 3 340 (w), 2 980 (m), 1 686 (shoulder) (s), 1 678 (s) 1 610 (m), 1 585 (m), 1 520 (m), 1 452 (s), 1 424 (s), 1 376 (w), 1 336 (s), 1 276 (s), 1 172 (s), 1 138 (s), 1 128 (s), 1 090 (s), 936 (m), 904 (m), 892 (m), 836 (m), 830 (m), 724 (w), and 678 (w) cm^{-1}.

Anal. Calcd. for $C_{22}H_{22}F_6N_2O_4S_2$: C, 47.48; H, 3.98; N, 5.03; S, 11.52; mol. wt. 556.5; equiv. wt. 278.3. Found: C, 47.55; H, 3.97; N, 4.92; S, 11.66; mol. wt. (vapor pressure) 552; equiv. wt. (direct titration with barium hydroxide in aqueous methanol) 282 ± 12.

Fraction 8 recrystallized from aqueous methanol as a red solid, m.p. 211–213°. It was 2-carboxy(α,α-dimethyl)methylthio-5-trifluoromethylazobenzene (IV*g*). Infrared spectrum (KBr disk): broad absorption 2 300 – 3 500 with maxima at 2 950 (m), 1 692 (s), 1 600 (w), 1 470 (m), 1 444 (w), 1 416 (m), 1 406 (m), 1 376 (w), 1 332 (s), 1 294 (s), 1 186 (s), 1 136 (shoulder) (s), 1 126 (s), 1 088 (s), 954 (m), 924 (shoulder) (s), 918 (s), 850 (s), 826 (w), 736 (w), and 682 (w) cm^{-1}.

REARRANGEMENT OF ALLYL 2,6-DICHLOROPHENYL ETHER ON COLUMN PACKINGS DURING GAS–LIQUID CHROMATOGRAPHIC ANALYSIS[1]

M. J. BALDWIN AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 7, 1966

ABSTRACT

At temperatures above 175° and with packed columns, rearrangement of allyl 2,6-dichlorophenyl ether occurs during gas–liquid chromatographic analysis with a contact time of no more than 4 min. For example, at a temperature of 205° with Gas Chrom P as packing material, about 7% of the ether is changed, but the packing 20% Apiezon L on Gas Chrom P increases this to about 50%. Products characteristic of both thermal and acid-catalyzed rearrangements are obtained. The number of such products increases to a maximum of five as the temperature is increased to 228°.

Accordingly, the results of gas–liquid chromatographic analysis of mixtures obtained from the Claisen rearrangement of allyl phenyl ethers must be interpreted with care if unchanged ether is present.

INTRODUCTION

The products of rearrangement and halogen elimination obtained from the Claisen rearrangement of allyl 2,6-dichlorophenyl ether have been found to be stable under reaction conditions, and also remain unchanged during analysis by gas–liquid chromatography (1). However, the extent, if any, of rearrangement of allyl 2,6-dichlorophenyl ether itself during gas–liquid chromatographic analysis is not known. This paper describes the results obtained in experiments designed to discover whether such rearrangement does occur during analysis by gas–liquid chromatography.

RESULTS AND DISCUSSION

Pure allyl 2,6-dichlorophenyl ether (1) was passed through a column packed with 20% Apiezon L on Gas Chrom P (60–80 mesh) (column No. 1) at a helium flow rate of 100 ml/min. The number of peaks obtained, increasing from two to a maximum of five, was dependent upon the temperature of the column. The influence of temperature on the number of compounds formed and their relative molar amounts are shown in Table I.

TABLE I

The influence of temperature on the number of compounds formed from allyl 2,6-dichlorophenyl ether during analysis by gas–liquid chromatography*

	% of total product as:				
Column temperature (°C)	2,6-Dichlorophenol (peak A)	2-Allyl-6-chlorophenol (peak B)	Allyl 2,6-dichlorophenyl ether (peak C)	4-Allyl-2,6-dichlorophenol (peak D)	7-Chloro-2-methylcoumaran (peak E)
176	0	2.4	97.6	0	0
195	0	29.1	70.9	0	0
205	Trace	49.7	50.0	Trace	Trace
215	2.4	63.4	24.3	4.7	4.9
228†	4.3	70.0	6.3	9.7	10.1

*Peaks are arranged in order of increasing retention time at a helium flow rate of 100 ml/min. Quantitative analyses were made against the standard, nitrobenzene.
†Retention times for peaks A to E at 228° are, respectively, 45, 85, 105, 165, and 190 s.

[1]*Part of the work of M. J. Baldwin to be submitted to the Graduate School, University of Alberta, Edmonton, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

A column temperature lower than 176° gave peaks which were too broad and had too long a retention time for convenient analysis; hence the temperature range of 176° to 228° was employed. Peaks A, B, and C were identified by collecting small amounts of the actual substances represented by these peaks. Each of the isolated materials A and B was reinjected separately, and each gave only a single peak having the same retention time as before, thus showing that these products are stable under gas–liquid chromatography conditions. Compound C gave the same pattern of five peaks found upon injection of the original ether.

The infrared and nuclear magnetic resonance spectra, refractive indices, and gas–liquid chromatography retention times showed that A, B, and C were, respectively, 2,6-dichlorophenol, 2-allyl-6-chlorophenol, and the original allyl 2,6-dichlorophenyl ether. Substances D and E were not as clearly resolved. This fact, plus their presence in only small amounts, prevented their isolation in the pure state. However, their retention times were identical with those of authentic 4-allyl-2,6-dichlorophenol and 7-chloro-2-methylcoumaran, respectively. These products can be expected, since 4-allyl-2,6-dichlorophenol is one of the major products from the *thermal* rearrangement of allyl 2,6-dichlorophenyl ether, and 7-chloro-2-methylcoumaran is obtained from the *acid-catalyzed* cyclization of 2-allyl-6-chlorophenol (peak B) (1, 2).

Rearrangement of allyl 2,6-dichlorophenyl ether was found to occur also when this ether was passed through the following columns: column No. 2, 25% silicone rubber on Gas Chrom P (60–80 mesh); column No. 3, a 1:1 mixture of 20% Apiezon M on Chromosorb W (nonacid-washed) and 20% butanediol succinate on Chromosorb W (nonacid-washed); column No. 4, 20% Carbowax 20 M on Chromosorb W (acid-washed, 60–80 mesh). Several peaks were observed when columns 2 and 4 were used, but they were too poorly resolved for isolation of products. Column No. 3, on the other hand, gave a single peak when the ether was injected under test conditions (column temperature 205°, helium flow rate 100 ml/min). This substance, when collected and analyzed, proved to be 2-allyl-6-chlorophenol. For our purposes, column No. 1 gave the best separation of products, and hence was used throughout this work.

The rearrangement on these columns is quite rapid, since the contact time is no more than 4 min. Usually, thermal rearrangement requires considerable time (2, 4).[2] Hence it is apparent that the column material has catalyzed the rearrangement as well as strongly directed the course of the reaction.[3]

To observe the effect of the packing for column No. 1 under other conditions, some allyl 2,6-dichlorophenyl ether was mixed in a round-bottomed flask with 2 g of column packing No. 1 (20% Apiezon L on Gas Chrom P (60–80 mesh)). The vessel and contents were heated rapidly to 190° with stirring, while under an atmosphere of nitrogen, and then quickly cooled. The total heating time was 15 min. The temperature of 190° was chosen since, from Table I, temperatures in this region had led to the production of only two substances, whose separation by fractional distillation would thus be much simpler. Considerable hydrogen chloride was evolved, a fact which would account for the acid-catalyzed effects noted above. Distillation under vacuum gave fractions whose analyses indicated that 94.8% of the total product was unchanged ether and 5.2% was 2-allyl-6-chlorophenol. This is about one-sixth the extent of rearrangement found at 195° during gas–liquid chromatographic analysis.

[2]*Compare with 90 min for the rearrangement of this ether to 4-allyl-2,6-dichlorophenol (2, 4).*

[3]*A column used for several weeks caused considerably less rearrangement, but even under these conditions of column aging, the major product was 2-allyl-6-chlorophenol.*

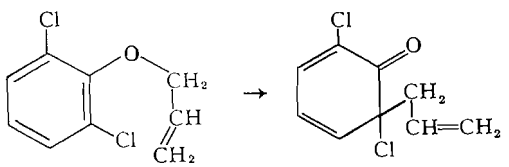
Passage of the ether through an unpacked column under otherwise identical gas–liquid chromatography conditions (temperature 205°) failed to cause rearrangement, whereas a packing of just Gas Chrom P was found to produce 7.6% rearrangement (cf. 50% rearrangement found for a column containing Apiezon L on Gas Chrom P at 205° (Table I)).

It is clear that the "inert" solid support promotes some rearrangement within the 4 min contact time, but that the coated solid support is much more effective.



The above results are of twofold interest. They show that (*a*) allyl 2,6-dichlorophenyl ether does rearrange quite extensively on a column at a temperature above 176° during analysis by gas–liquid chromatography, and (*b*) the facility of rearrangement and the pattern of products obtained are indicative of catalysis by an acidic species.

Previous work (expt. 1 of Table II in ref. 2) has shown that the *thermal* rearrangement of allyl 2,6-dichlorophenyl ether (at 193–200°) gave most of the product (91.3%) as 4-allyl-2,6-dichlorophenol (the result of rearrangement of only the allylic group), 6.7% as 2-allyl-6-chlorophenol (from halogen elimination and allyl rearrangement), and 2.0% as 2-allyl-4,6-dichlorophenol (from both halogen and allyl rearrangement). No 2,6-dichlorophenol was found as a reaction product. On the other hand, the presence of the Lewis acid zinc chloride not only hastened the rearrangement of the ether but also changed the course of the reaction markedly, so that (at 150–155°) most of the product (88.3%) was 2-allyl-4,6-dichlorophenol (from halogen *and* allyl migration); in addition, 4.1% of the product was 2,6-dichlorophenol (the result of ether cleavage) and 7.7% was 5,7-dichloro-2-methylcoumaran. Neither 2-allyl-6-chlorophenol (the result of halogen elimination and allyl migration) nor 4-allyl-2,6-dichlorophenol (from only allyl migration) was found in the zinc chloride catalyzed reaction (expt. 3 of Table I in ref. 2).

In the present case, as the column temperature was increased from 176° to 228°, the extent of conversion of allyl 2,6-dichlorophenyl ether rose from 2.4% to 93.7%. Two of the products, 2,6-dichlorophenol (peak A) and 7-chloro-2-methylcoumaran (peak E), are those which arise characteristically from the presence of acidic substances such as zinc chloride (2). Most of the product (70% at 228°), however, is 2-allyl-6-chlorophenol, a product obtained previously from only the *thermal* rearrangement, and then merely in small amounts (see above). This compound arose from loss of halogen as well as allyl migration. Such loss of halogen has been attributed to reaction with some oxidizable material such as the solvent used for the reaction, a catalyst such as stannous chloride, or the phenolic products of rearrangement (1). What constitutes the oxidizable species during gas–liquid chromatographic analysis is not known. When nitrobenzene was used as the standard, the yield of products obtained from the injection of a known amount of ether was found to be practically quantitative, thus suggesting that the phenolic products are not lost extensively by oxidation in this case.

Reductive removal of halogen is most likely to occur at the intermediate dienone stage (eq. [1]), where the allylic halide structure is formed (1). All attempts to isolate for study the intermediate 6-allyl-2,6-dichlorocyclohexa-2,4-dienone, as had been done for the analogous 6-allyl-2,6-dimethylcyclohexa-2,4-dienone (3), have failed, and only 4-allyl-2,6-dichlorophenol was obtained.

[1]

This work shows that estimation by gas–liquid chromatography of the amount of unchanged allyl 2,6-dichlorophenyl ether and of the products obtained in experiments involving the Claisen rearrangement of this ether may lead to erroneous conclusions. Of even more significance is the pattern of products obtained from rearrangement of the ether on the column employed. The very large preponderance of 2-allyl-6-chlorophenol obtained in this case, compared with the relatively small proportion obtained during *thermal* rearrangement, and its total absence in the zinc chloride catalyzed rearrangement (2) are quite striking. Their significance with respect to the mechanism of halogen elimination during the Claisen rearrangement of allyl 2,6-dichlorophenyl ether is being examined.

EXPERIMENTAL

Rearrangement of Pure Allyl 2,6-Dichlorophenyl Ether During Analysis by Gas–Liquid Chromatography

Via a Burrell K-2 Kromo-Tog (Fitted with an Integrator and a Fraction Collector)

A 2 m glass column was packed with Gas Chrom P (60–80 mesh) previously coated with Apiezon L (20%). Ten microliter quantities of allyl 2,6-dichlorophenyl ether (2) were injected at various column temperatures (see Table I) with the helium flow rate at 100 ml/min. Reaction products representing the first three peaks (A to C), which were clearly resolved, were collected with a fraction collector cooled in a dry ice – acetone bath. These three peaks as well as the smaller and poorly resolved peaks D and E were identified as described in Results and Discussion.

Via an Aerograph Autoprep

Fifty microliter quantities of allyl 2,6-dichlorophenyl ether were injected into the Autoprep equipped with a 20 ft × $\frac{3}{8}$ inch (inside diameter) aluminium column packed with 20% Apiezon L on Gas Chrom P (60–80 mesh). The helium flow rate was 300 ml/min and the column temperature was 205°. Although three peaks (A to C) were obtained, the products represented by only the two major peaks, B and C (Table I), were collected automatically. The substances represented by peaks B and C were identified as 2-allyl-6-chlorophenol and allyl 2,6-dichlorophenyl ether by comparison of their nuclear magnetic resonance and infrared spectra, as well as gas–liquid chromatography retention times, with those of authentic samples. The refractive indices (η_D^{25} 1.5441 and 1.5393 for B and C, respectively) agreed with the literature values (4).

Via an Aerograph Autoprep Containing either an Unpacked Column or One Packed with Only Gas Chrom P

Either a clean aluminium column (20 ft × $\frac{3}{8}$ inch (inside diameter)) with no packing or one packed with only Gas Chrom P (60–80 mesh) was used, under gas–liquid chromatography conditions identical with those stated immediately above. In each case, only a single peak was observed. Analysis of the material collected was conveniently accomplished by nuclear magnetic resonance. Since the characteristic doublet for the allylic methylene group attached directly to the aromatic ring occurs at τ 6.7 (J = 7.0 c.p.s.) (tetramethylsilane as internal standard; neat) whereas that for the allylic methylene group attached directly to oxygen is found at τ 5.5 (J = 6.0 c.p.s.), it was easy to obtain the relative amounts of unchanged allyl 2,6-dichlorophenyl ether and the rearranged products from the integrated areas. The material obtained when an unpacked column was used showed a doublet at τ 5.5 (J = 6.0 c.p.s.), and none at τ 6.7. The material obtained from the column packed with only Gas Chrom P showed doublets at τ 5.5 and τ 6.7 whose integrated areas were in the ratio of 92.4 to 7.6.

The Effect of Column Packing Alone on the Rearrangement of Allyl 2,6-Dichlorophenyl Ether

To a 100 ml, three-necked, round-bottomed flask fitted with a stirrer and reflux condenser was added 20 g of pure allyl 2,6-dichlorophenyl ether along with 2 g of 20% Apiezon L on Gas Chrom P (60–80 mesh). The flask and contents were then heated rapidly, over a period of 10 min, to 190°, and this temperature was maintained for an additional 5 min. The mixture, quickly cooled to room temperature, was freed from the solid packing by filtration under suction. Fractional distillation at 3 mm pressure gave the following results.

Fraction	Boiling range	Amount (g)
I	80–85°	2.7
II	85–95°	3.4
III	95–100°	10.3
Residue		2.8

The gas–liquid chromatographic spectra of fractions I, II, and III were compared with those obtained under identical conditions from known amounts of pure allyl 2,6-dichlorophenyl ether, with nitrobenzene as the internal standard. The proportions of products obtained from definite quantities of the ether under identical conditions were repeatedly the same. Hence, by measuring the amounts of the products obtained in the analyses of fractions I–III, one can, by comparison with standard spectra, estimate the amount of ether present in the original material (fractions I–III) which would give the proportion of products found.

For personal use only.

Only two products were obtained: allyl 2,6-dichlorophenyl ether and 2-allyl-6-chlorophenol, in the ratio of 94.8 to 5.2.

Attempted Preparation of 6-Allyl-2,6-dichlorocyclohexa-2,4-dienone

The literature procedure for the preparation of 6-allyl-2,6-dimethylcyclohexa-2,4-dienone (3) was employed in the attempted preparation of the dichloro dienone, but with some modification. When all the methanol had been removed, 30 ml of pure, dry toluene was added, and to the resulting solution, first cooled to −5°, was added cold (−5°) allyl bromide. The whole mixture was stirred at −5° for 80 h under nitrogen. Fractional distillation under vacuum gave a material boiling at 76–77° and 0.5 mm. This was the only product obtained and proved to be identical with authentic 4-allyl-2,6-dichlorophenol (4).

OXIDATION OF POLYSACCHARIDES BY LEAD TETRAACETATE IN DIMETHYL SULFOXIDE[1]

V. ZITKO[2] AND C. T. BISHOP
Division of Biosciences, National Research Council, Ottawa, Canada

Received March 25, 1966

ABSTRACT

Neutral polysaccharides can be oxidized by lead tetraacetate in dimethyl sulfoxide if 15–20% of glacial acetic acid is added to prevent oxidation of the solvent. The oxidation proceeds at a rate which is several times faster than that of periodate oxidation in aqueous solution, and the same amount of oxidant is consumed. Polysaccharides oxidized by lead tetraacetate in dimethyl sulfoxide can be recovered in excellent yield by precipitation with alcohol, and have been shown to contain free aldehyde groups. Identification of the products of reduction and hydrolysis of the oxidized polysaccharides showed that the oxidation followed the normal glycol-cleavage pattern given by lead tetraacetate in other solvents. Addition of potassium acetate to the oxidations in dimethyl sulfoxide decreased the consumption of lead tetraacetate by dextran (mainly α-(1 $\rightarrow$ 6) and α-(1 $\rightarrow$ 4)). Reduction and hydrolysis of dextrans oxidized in the presence and absence of potassium acetate yielded glycerol and erythritol in the respective ratios of 3.8:1 and 8.7:1. This result indicated that potassium acetate inhibited oxidation of the C-3, C-4 glycol groups in the dextran. Acidic polysaccharides behaved atypically in this oxidation system, and those containing a high proportion of uronic acid units were resistant to oxidation.

Oxidation of polysaccharides by lead tetraacetate has received little attention, undoubtedly because this oxidant must be used in nonaqueous solvents, in which most polysaccharides are insoluble (1, 2). Oxidations of pulps (3–5) and of a spruce-wood glucomannan (6) by lead tetraacetate under heterogeneous conditions have been studied; evidence was obtained that the D-mannose units in the polysaccharides were attacked preferentially. In cellulose acetates of various degrees of substitution it appeared that unsubstituted end groups were attacked by lead tetraacetate (7). Cellulose, starch, amylose, and amylopectin are only partially oxidized, at a very slow rate, by lead tetraacetate in aqueous acetic acid (8).

For another project we wished to obtain substantial quantities of polysaccharides which had been oxidized by a glycol-cleaving oxidant. Yields of products recovered from periodate oxidations are often low, probably because of hydrolysis of the very labile acetal linkages during deionization procedures and subsequent loss of low molecular weight material. Dimethyl sulfoxide is an excellent solvent for many polysaccharides. If lead tetraacetate could be used as an oxidant in this solvent, the oxidized polysaccharides should be recoverable directly by precipitation with alcohol, in which the other reactants would be soluble.

Solutions of lead tetraacetate in dimethyl sulfoxide have a red color, apparently because of decomposition of lead tetraacetate. Under these conditions polysaccharides were oxidized, but so was the solvent, and the amount of oxidant consumed by the polysaccharide could not be determined. Addition of 15–20% of glacial acetic acid to the dimethyl sulfoxide solution eliminated completely both of these undesirable side reactions. It was observed previously that acetic acid inhibits the hydrolysis of lead tetraacetate in other solvents (9).

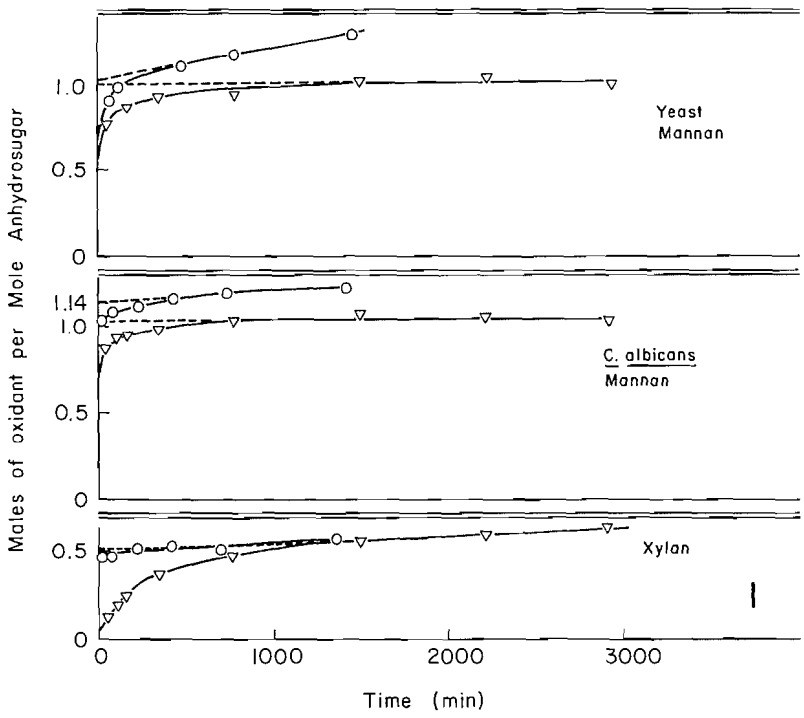
The results of oxidations of several polysaccharides by lead tetraacetate in dimethyl sulfoxide – acetic acid and by aqueous sodium metaperiodate are shown in Figs. 1–4. With only two exceptions there was excellent agreement between the amounts of the two oxidants consumed by these neutral polysaccharides. The levan from *L. mesenteroides* 1149 consumed substantially higher amounts of lead tetraacetate than periodate and showed significant overoxidation (Fig. 3), possibly because of the acid lability of fructofuranoside units. Potato starch was resistant to oxidation by lead tetraacetate (Fig. 4), possibly because it was insoluble in dimethyl sulfoxide. However, insolubility had no effect on the oxidation of cotton linters, and the lead tetraacetate system was slightly more active than aqueous periodate (Fig. 4).



Since the consumptions of the two oxidants by the polysaccharides were the same, it was apparent that formic acid, produced by cleavage of a triol, was not oxidized by lead tetraacetate under these conditions. In separate experiments we found that formic acid added to dimethyl sulfoxide was oxidized by lead tetraacetate but that methyl formate was resistant to oxidation. It seems likely that HCO^+ species is generated by lead tetraacetate oxidation of triols and reacts immediately with dimethyl sulfoxide in a Pummerer-type reaction to give an ester which is resistant to oxidation (10–12).

The presence of potassium acetate catalyzes the oxidation of formic acid by lead tetraacetate in glacial acetic acid. However, when potassium acetate was added to oxidations by lead tetraacetate in dimethyl sulfoxide – acetic acid, it had no effect on the oxidation of amylose but caused a *decrease* in the consumption of oxidant by dextran. These results are shown in Fig. 5, and it can be seen that a 4.5-fold molar excess of potassium acetate over lead tetraacetate is as effective as a 9-fold excess in inhibiting the oxidation. The lower limits of concentration of potassium acetate required for inhibition were not investigated. Dextrans oxidized by lead tetraacetate in the presence and absence of potassium acetate were reduced and hydrolyzed to yield glycerol and erythritol in the respective molar ratios of 3.8:1 and 8.7:1. The decrease in the amount of glycerol in the product from the inhibited oxidation showed that the potassium acetate interfered in some way with the oxidation of the C-3, C-4 glycol groupings in the α-(1 $\rightarrow$ 6) linked D-glucopyranose units. This conclusion was supported by the lack of inhibition by potassium acetate in the oxidation of amylose (Fig. 5), which is an α-(1 $\rightarrow$ 4) linked glucan and therefore contains only C-2, C-3 glycol groups.

The addition of other salts (potassium chloride, lithium chloride, lithium fluoride, or mercuric chloride) catalyzed the oxidation of dimethyl sulfoxide by lead tetraacetate and promoted a fast decomposition of the oxidant.

The oxidation of acidic polysaccharides by lead tetraacetate in dimethyl sulfoxide was less straightforward than the oxidations of neutral polysaccharides. Thus, methyl or ethylene glycol esters of pectin consumed only 0.2 mole of lead tetraacetate per mole of anhydrogalacturonic acid as compared with 0.6–0.7 mole of periodate per mole of anhydrogalacturonic acid (Fig. 6). As also shown in Fig. 6, the consumption of lead tetraacetate by a series of carboxyl-reduced pectins (13) increased with decreasing D-galacturonic acid content but was always less than the consumption of periodate by the same products. Two other acidic polysaccharides, a 4-*O*-methylglucuronoxylan from beech wood (14) and the acidic capsular polysaccharide from pneumococcus type VIII (15), were both insoluble in dimethyl sulfoxide and were resistant to oxidation by lead tetraacetate in that solvent, consuming only 0.2 mole of oxidant per mole of anhydrosugar. However, esterification of these two polysaccharides with propylene oxide yielded products which were soluble in dimethyl sulfoxide. Figure 7 shows the rates of oxidation of the propylene glycol esters of these two polysaccharides by lead tetraacetate in dimethyl

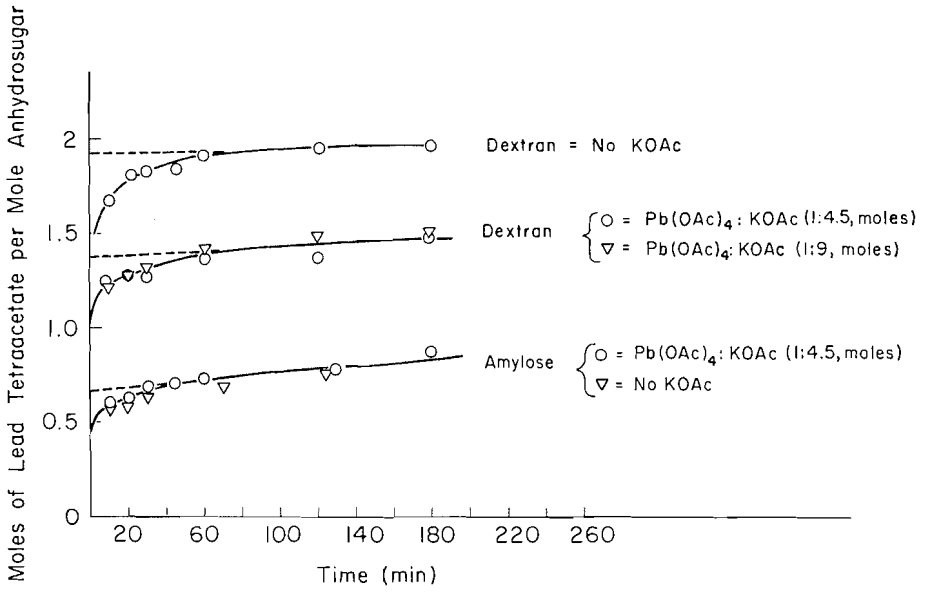

FIG. 5. Effect of potassium acetate on oxidations of dextran and amylose by lead tetraacetate.

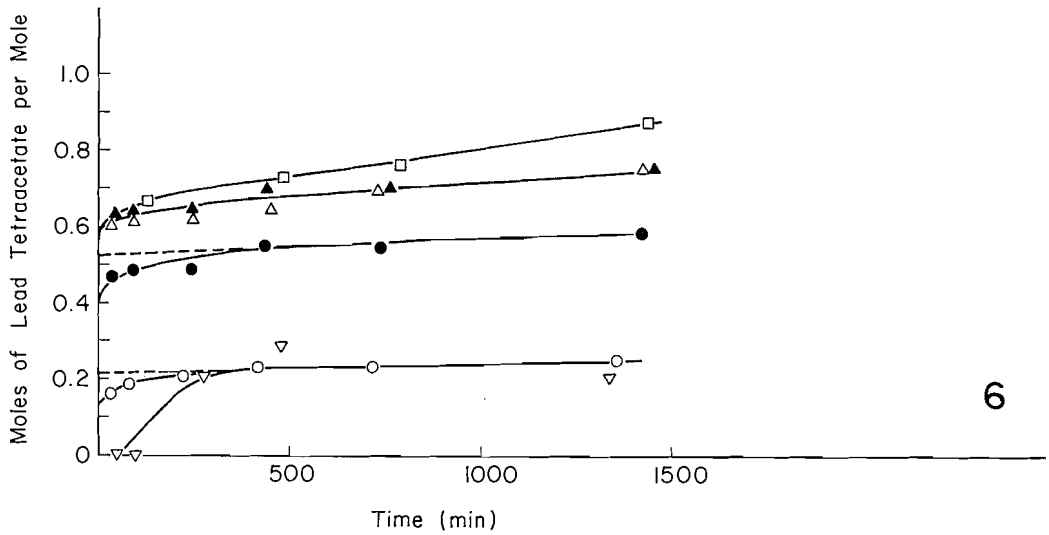
sulfoxide – acetic acid and by aqueous periodate. The results for the 4-*O*-methylglucuronoxylan are in fair agreement; the esterified pneumococcus type VIII polysaccharide consumed more lead tetraacetate than it did periodate. It is clear that solubility is a major factor in the oxidation of acidic polysaccharides by lead tetraacetate in dimethyl sulfoxide and that insoluble products are not oxidized. Esterification of acidic polysaccharides promotes solubility in dimethyl sulfoxide, but even then the oxidations are atypical, vary with uronic acid content (Fig. 6), and apparently depend on variations in the secondary structure.



Identification of the products from the successive oxidation, reduction, and hydrolysis of the polysaccharides (16) showed that the lead tetraacetate oxidations in dimethyl sulfoxide followed the normal pattern of glycol cleavage. As described above, oxidized dextrans were reduced and hydrolyzed to yield glycerol and erythritol. A yeast mannan, oxidized by lead tetraacetate in dimethyl sulfoxide – acetic acid, was reduced and hydrolyzed to yield glycerol and a small amount of mannose. The products obtained from starch by the same procedures were erythritol (as the main component) and small amounts of glycerol. These were the products that would be expected from glycol-cleavage oxidations of these polysaccharides.

The major advantage of the oxidation of polysaccharides by lead tetraacetate in dimethyl sulfoxide – acetic acid rather than by aqueous periodate was the ease of recovery of the oxidized product. Addition of ethanol precipitated the oxidized polysaccharides in excellent yield, as shown in Table I. The low yield from the carboxyl-reduced pectin was caused by the low degree of polymerization of this material (13), which made the oxidized product partly soluble in alcohol. The oxidized polysaccharides contained only small amounts of ash and showed high contents of dialdehyde units. Some of these dialdehyde units were present as free aldehyde groups, since infrared spectroscopy of the oxidized polysaccharides showed strong absorption at 1 730 cm^{-1}. As far as we are aware, this is the first time that the presence of free aldehyde groups has been demonstrated in the

polysaccharides oxidized by glycol-cleaving reagents. Polysaccharides oxidized by aqueous periodate show no absorption at 1 730 cm^{-1}, and the "dialdehyde" groups have been shown to be involved in a cyclic acetal structure (17).

EXPERIMENTAL

Paper chromatograms were run by the descending method in *n*-butanol–pyridine–water (6:4:3 v/v/v). A Pye argon chromatograph was used for gas–liquid chromatography (18); the column packing was 10% neopentylglycol sebacate on Gas Chrom Z, 100–120 mesh; the column temperature was 180 °C. Sugars and glycols were detected on paper chromatograms by *p*-anisidine hydrochloride (19) and alkaline silver nitrate (20), respectively. Iodometric methods were used to determine concentrations of periodate (21) and lead tetraacetate (22).

Analytical Oxidations with Lead Tetraacetate

Lead tetraacetate (2 g) was dissolved in a 1:1 (v/v) mixture (100 ml) of dimethyl sulfoxide and glacial acetic acid. The polysaccharide sample (20–30 mg) was dissolved or suspended in dimethyl sulfoxide (10 ml) in a 25 ml volumetric flask, the lead tetraacetate solution (10–13 ml) was added, and the solution was made up to 25 ml with dimethyl sulfoxide. Blanks without polysaccharides were prepared in the same way. At intervals aliquots (2 ml) were pipetted into an aqueous solution (10 ml) containing sodium acetate (250 g/l) and potassium iodide (20 g/l), and liberated iodine was titrated with 0.05 *N* sodium thiosulfate, with Thyodene as indicator.

When potassium acetate was used in the oxidations it was dissolved with the lead tetraacetate in the 1:1 mixture of dimethyl sulfoxide and glacial acetic acid.

Analytical Oxidations with Periodate

The polysaccharide sample (20–30 mg) was dissolved or dispersed in water (10 ml) in a 25 ml volumetric flask. Aqueous sodium metaperiodate (5 ml, 0.12 *M*) was added and the solution was made up to volume with water. At intervals aliquots (2 ml) were pipetted into phosphate buffer of pH 7.0 (20 ml), solid potassium iodide was added, and liberated iodine was titrated as described above.

Preparative Oxidations with Lead Tetraacetate

The polysaccharide (500 mg) was dissolved in dimethyl sulfoxide (37 ml), and glacial acetic acid (13 ml) was added dropwise followed by solid lead tetraacetate (4.4 g). The mixture was stirred until all the solid had dissolved and was then stored in the dark for 3 h. The solution was then poured into ethanol (150 ml) to precipitate the oxidized polysaccharide, which was washed three times with ethanol and once with ether, and then air-dried. The 3 h period for the preparative oxidations was the time at which most of the polysaccharides had consumed the theoretical amount of oxidant. For polysaccharides which are only partly soluble in dimethyl sulfoxide or are prone to overoxidation, the course of the reaction should be followed titrimetrically or by polarimetry. Dialdehyde units in the oxidized products were determined by the method of Hofreiter *et al.* (23). Infrared spectra of the oxidized products were obtained by the potassium bromide disk technique.

Reduction and Hydrolysis of Oxidized Polysaccharides

Samples (100 mg) of oxidized dextrans, mannan, and starch were reduced by potassium borohydride (100 mg) in aqueous solution (5 ml). Excess borohydride was destroyed by Rexyn 101 (H^+) ion-exchange resin and the solutions were evaporated to dryness. Boric acid was removed by repeated addition and evaporation of methanol. The residual syrups (average yield, 70 mg) were hydrolyzed by 0.5 *N* hydrochloric acid (2 ml) on a boiling water bath for 4 h. The hydrolysates were neutralized by Duolite A4 (OH^-) and examined by paper chromatography. Portions of the hydrolysates were evaporated to dryness and acetylated by acetic anhydride and pyridine (1:1 v/v) at 60 °C for 30 min. The acetates were examined by gas–liquid chromatography to give the quantitative estimates of glycerol and erythritol.

Polysaccharides

Dextran 500 was a commercial product obtained from Pharmacia, Uppsala; xylan and amylose were obtained from Nutritional Biochemicals Corp. Soluble starch was a Merck preparation and potato starch was a commercial sample from an unidentified source. *L. mesenteroides* 1149 dextran and levan, yeast mannan, cotton linters, *C. albicans* mannan, *C. tropicalis* mannan, and *C. parapsilosis* glucan were laboratory samples. Sunflower pectin and its carboxyl-reduced fractions were prepared previously in this laboratory (13). Beech-wood 4-*O*-methylglucuronoxylan (14) and pneumococcus type VIII polysaccharide (15) were donated by Dr. G. A. Adams and Dr. M. B. Perry, respectively. The method for esterification of acidic polysaccharides by propylene oxide has been published (24).

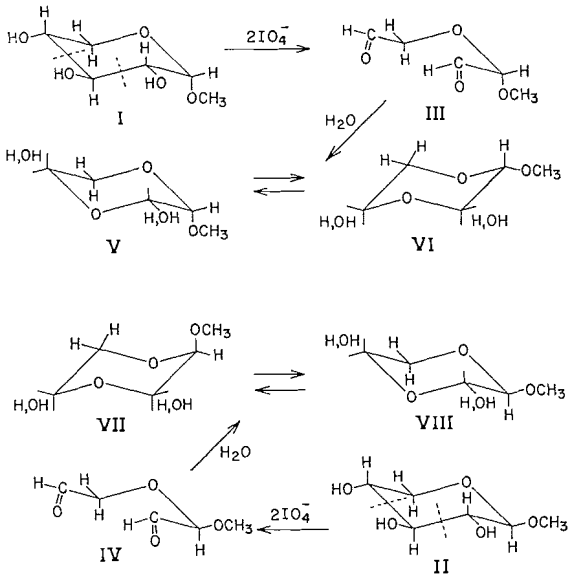
NUCLEAR MAGNETIC RESONANCE SPECTRA OF GLYCOL-CLEAVAGE OXIDATION PRODUCTS OF METHYL ALDOPENTOPYRANOSIDES[1]

A. S. PERLIN

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan
Received March 24, 1966

ABSTRACT

The products obtained by the periodate oxidation of methyl α- and β-D-xylopyranosides have been examined by nuclear magnetic resonance spectroscopy. In deuterium oxide each product exists mainly in two forms, one of which is a hydrated dialdehyde and the other a hemialdal (1,4-dioxane derivative). In dimethyl sulfoxide the dialdehyde cyclizes slowly to yield the hemialdal which, at equilibrium, is found to be by far the most stable of the many isomeric forms possible. The spectrum of this hemialdal in both solvents provides an example of a degenerate ABX type of pattern. The spectra of the products prepared from 5-deuterated xylosides show that the 1-methoxyl group of each hemialdal is axial and the 4-hydroxyl group equatorial, and that the one derived from the β-anomer possesses an inverted chair conformation relative to that of the other hemialdal and of the glycoside itself. The 2-hydroxyl group of each hemialdal appears to be axially oriented. The data support the long-standing view that glycol scission of anomeric aldopentopyranosides leads to products that are mirror images.



It has been found also that each product yields a mixture of several *p*-nitrobenzoates.

Glycol-cleavage oxidation of a pair of anomeric methyl aldopentopyranosides, e.g. methyl α- and β-D-xylopyranoside (I and II, Reaction Scheme 1), leads to a pair of syrupy products having numerically equal optical rotations, but of opposite sign (1). By appropriate treatment these products are converted into enantiomorphic dicarboxylic acids (1, 2), diols (3), and hydrazones (4). Although they may be regarded as enantiomorphic dialdehydes (III and IV), many of their properties are more consistent with the hemialdal (1,4-dioxane) type of structure (V or VI and VII or VIII, and stereoisomers of these) (5, 6). Guthrie (7) has discussed these properties in detail. In a recent paper, Chittenden and Guthrie (4) describe di-*p*-nitrobenzoates of hemialdal forms, but those derived from the different anomeric glycosides are not enantiomorphs, suggesting that the mirror-image relationship depicted for compounds II–VIII does not necessarily hold true. Hence, these diverse data provide only a partial, and at present conflicting, characterization of the glycol-cleavage products themselves.

In seeking additional information, especially about the structure of these oxidation products in solution, their nuclear magnetic resonance (n.m.r.) spectra have been examined. Deuterium oxide solutions of the compounds derived from the α- and β-anomers of methyl D-xylopyranoside are indistinguishable. As seen in Fig. 1B, the multiplicity of signals and their widely varied relative intensities show that a mixture of several forms is present. Since a hemialdal (e.g. V–VIII) contains two hydroxyl groups whereas a hydrated form of the acyclic dialdehyde (III or IV) has four hydroxyl groups, the hydroxyl proton signals in dimethyl sulfoxide (8) have been examined as a possible means for assessing the relative populations of these two structural types (9).[2] However, these signals are not well resolved for a freshly prepared dimethyl sulfoxide solution, and a change in composition soon becomes evident (9). At equilibrium, only two hydroxyl proton doublets of significant intensity are found (Fig. 2), and after deuterium exchange a relatively simple proton spectrum emerges (Fig. 3B). Aside from the signals for the methoxyl protons, there are a

[2]*The author acknowledges his indebtedness to an anonymous referee who, in reviewing this earlier paper, made comments which have proven to be very helpful to the current study.*

REACTION SCHEME 1. Schematic representation of the periodate oxidation of methyl α-D-xylopyranoside (I) and of its β-anomer (II) to yield dialdehyde and hemialdal products.

triplet and three doublets, the relative intensities of which are approximately 1:1:1:2. By spin decoupling, the triplet (spacings of 5.3 c.p.s.) is shown to be associated with the upfield two-proton doublet (spacing of 5.3 c.p.s.), and since it also reflects hydroxyl coupling before deuterium exchange (Fig. 2), these signals are ascribed to H-4 and the methylenic 5-protons, respectively (retaining the numerical order of the parent glycoside). Similarly, the two doublets (spacings of 1.8 c.p.s.) are due to spin-coupled protons and are attributed to H-1 and H-2, the pair being distinguished by the fact that the latter is coupled to a hydroxyl proton before deuterium exchange (Fig. 2). The two minor upfield singlets are ascribed to methoxyl protons of minor components; at 60–80° these signals tend to merge whereas the major signals are not noticeably altered. Signals comprising the spectrum shown in Fig. 3B have their counterpart in the spectrum shown in Fig. 1B, this relationship being emphasized by inset tracings (Fig. 1A). Hence, the data indicate that one component of the aqueous oxidation mixture becomes overwhelmingly dominant in dimethyl sulfoxide solution, and that this component has a hemialdal structure (and hence only two hydroxyl groups (Fig. 2)).

The small H-1 and H-2 spacing is consistent with a gauche interaction in 1,4-dioxane (10), as well as in related sugar derivatives (11), and shows that the methoxyl or 2-hydroxyl group (or both) is axially oriented. Since the methylene protons would not be expected to be equivalent, they, together with H-4, should comprise an ABX system (12). Although the signals appear to be those of an A_2X system, it has been shown that spectra of the ABX type sometimes become deceptively simple in form (13).[3] Thus, the X proton can give a triplet rather than a higher multiplet when, for example, $J_{AX} = J_{BX}$ or when δ_{AB} approaches zero. In terms of a hemialdal molecule, the case $J_{AX} = J_{BX}$ would be consistent with an axially oriented 4-hydroxyl group whereas the second condition could

[3]*Dr. H. J. Bernstein has pointed out (private communication) that a system of this latter type would be anticipated from the fact that the line width at half height for the H-4 signal (in Fig. 1A or 1B) is considerably larger (1.7 c.p.s.) than that (1.0 c.p.s.) for the* O—CH_3 *singlet (inset, Fig. 1A).*

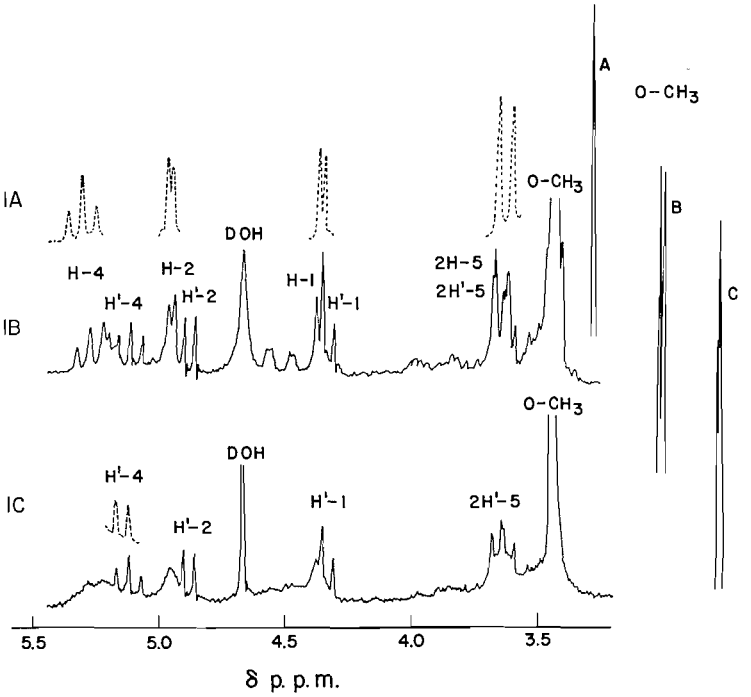

FIG. 1. Nuclear magnetic resonance spectra at 100 Mc.p.s. of the periodate oxidation products from methyl α- and β-D-xylopyranoside (B) in an equilibrated deuterium oxide solution, and (C) in a freshly prepared deuterium oxide solution. The inset signals (A) are taken from Fig. 3B for comparison. The primed numbers refer to proton signals common to spectra B and C; the inset H'-4 doublet in C is due to the 5-deuterio isomer. The other numbers refer to signals common to the spectra shown in Figs. 1B and 3B. Signals designated O—CH_3 are the upper portions of methoxyl proton signals corresponding to 1A, 1B, or 1C.

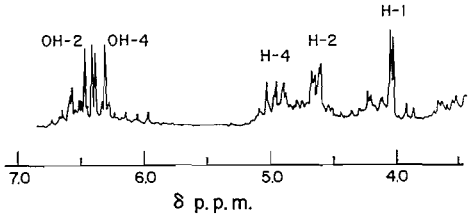

FIG. 2. Partial n.m.r. spectrum at 100 Mc.p.s. of the periodate oxidation product from methyl α- or β-D-xylopyranoside in dimethyl sulfoxide-d_6 (OH refers to hydroxyl proton signals).

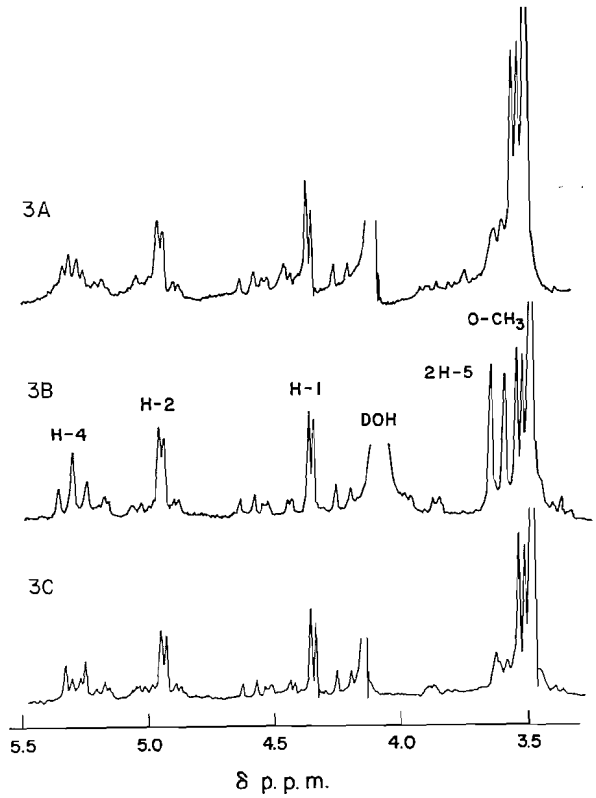
arise also when the 4-hydroxyl is equatorial. With an ABX system of this kind, a change of solvent may substantially alter the spectrum (13), but such a criterion could be unreliable in the present instance since several components are in equilibrium.

A choice between these possibilities has been provided by the use of 5-deuterated methyl α- and β-D-xylopyranosides. The latter were prepared from D-xylose-5-*d* in which two-thirds of the isotope has been introduced equatorially and one-third axially (14). Oxidation products of these glycosides, after equilibration in dimethyl sulfoxide, give the spectra shown in Figs. 3A and 3C. Consistent with the assignments made above, only the H-4 and H-5 signals are modified, and particularly pertinent is the fact that they vary in appearance depending on the anomer used.



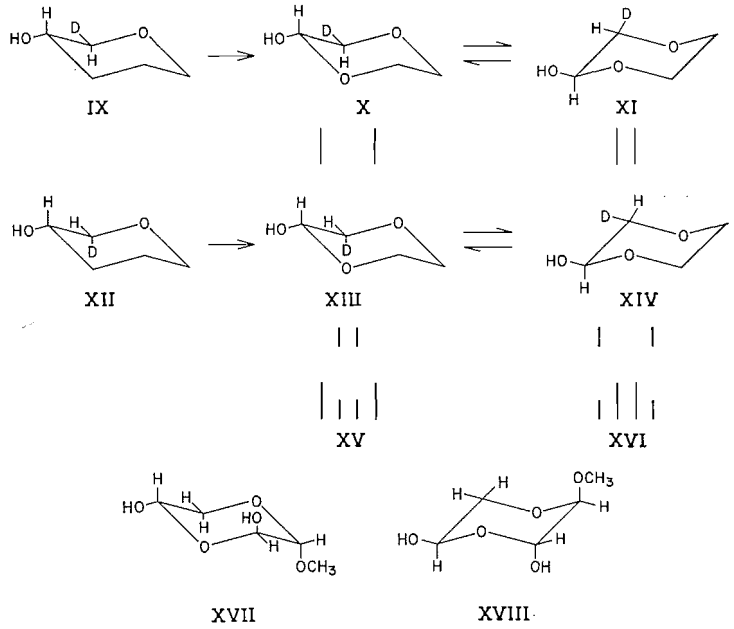


FIG. 3. Nuclear magnetic resonance spectra at 100 Mc.p.s. of dimethyl sulfoxide-d_6 solutions (at equilibrium) of the periodate oxidation products from (A) methyl α-D-xylopyranoside-5-*d*, (B) methyl α- or β-D-xylopyranoside, and (C) methyl β-D-xylopyranoside-5-*d*. Signal designations apply to all three spectra.

These results have been interpreted as follows. The multiplet structure of H-4 must be due basically to both a small (gauche) and a large (diaxial) coupling with H-5. Hence OH-4 must be equatorially oriented. Consider, for example, the oxidation of methyl D-xylopyranoside-5-*d*, in which the isotope is equatorial (IX), i.e. two-thirds of the material. Hemialdal X should give a H-4 doublet of $\frac{2}{3}$ proton intensity having a large (diaxial) spacing (10, 11), whereas XI should show a doublet with a narrow (gauche) spacing (if hydrogen–deuterium coupling is ignored for the moment). Simultaneously, the xyloside component in which the deuterium is axial (XII) (i.e. one-third of the material) yields a hemialdal (XIII) characterized by a H-4 doublet of $\frac{1}{3}$ proton intensity having a narrow spacing, or XIV, in which the spacing is broad. Therefore, the 2:1 mixture of X and XIII should give a composite H-4 signal consisting of a relatively strong ($\frac{2}{3}$ proton) broad doublet upon which a weak ($\frac{1}{3}$ proton) narrow doublet is superimposed, e.g. as in quartet XV. In contrast, the mixture of XI and XIV should show a quartet as in XVI, with the relative intensities of the two superimposed signals reversed.

According to these considerations, the spectrum in Fig. 3C shows that the hemialdal derived from methyl α-D-xyloside may be formulated, *in part*, by XVII. Its chair conformation must be the same as in the parent glycoside, since the H-4 signal is of the type represented by quartet XV, the OH-4 group is equatorial, and the axial orientation of the methoxyl group must be retained. Analogous considerations apply for the β-D-xyloside.

For personal use only.

Since the signal observed for H-4 in Fig. 3A corresponds to quartet XVI, the oxidation product of II may be represented by XVIII, the mirror image of XVII. Its formation thus involves a ring-chair inversion.

The configuration of OH-2 has not been deduced from these data. However, its arrangement should be of considerable significance because of the remarkable stability in dimethyl sulfoxide of the one particular form that is detected, relative to the stabilities of the other seven isomers that are possible for each product. A comparison of all eight possibilities has been made in a semiquantitative way by conformational analysis along the lines formulated especially by Angyal (15) and by Lemieux (16). The main factors taken into account are the anomeric effect, the 1,3-diaxial interactions of *O*-substituents, and the gauche O—O interactions. On this basis structure XVII or XVIII, in which OH-2 is axially oriented, appears to be a most likely possibility, since it lacks both of the unfavorable factors and incorporates two stabilizing anomeric effects. Also pertinent in this connection is the observation that a 1,2-diaxial orientation (as in α-D-mannose and related compounds) is particularly favored in dimethyl sulfoxide solution (unpublished data). In addition, there is the fact that the halogen atoms of *trans*-2,3-dibromo-1,4-dioxane prefer the 1,2-diaxial orientation (17).

The hydroxyl proton signals may also yield some information about the configuration of OH-2. In Fig. 2 the OH-2 doublet has a spacing of 5.5 c.p.s., and that of OH-4 a spacing of 7.5 c.p.s. The equatorial orientation of the latter is consistent with a relatively large spacing of this magnitude for equatorial anomeric hydroxyl protons (spacings of 6.5–8 c.p.s.), whereas the OH-2 spacing is closer to that found for axial anomeric hydroxyl groups (4–5 c.p.s.) (9 and unpublished data). Hence, these values suggest that XVII and XVIII should be formulated as shown.

Outer spacings caused by the 4,5-diaxial interactions observed for the H-4 signals in Figs. 3A and 3C are 8.0 c.p.s. Since the 10.6 c.p.s. total spacing of the H-4 triplet (Fig. 3B) is $J_{AX} + J_{BX}$ (13), the gauche interaction must involve a coupling of about 2.6 c.p.s. This,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in fact, is close to the spacing (2.8 c.p.s.) observed for the inner component of the H-4 signals in Figs. 3A and 3C. However, small additional splittings caused by axial hydrogen–deuterium coupling would be expected. It is pertinent, therefore, that these signals are relatively broad doublets as compared with the outer doublet components. This becomes more obvious when the scale of the signals is expanded several fold over that shown; a multiplet structure is then discernible. Mention also should be made of the H-5 proton signals in Figs. 3A and 3B. Although these are obscured somewhat by overlapping signals for the methoxyl protons, their general characteristics parallel those of the corresponding H-4 protons, in agreement with expectation.

As noted above, the signals in Fig. 3B correspond very closely to some of those in Fig. 1B. A similar relationship holds when the spectra of the deuterated products are compared in the two solvents. In particular, despite the overlap of other signals, multiplets closely resembling those for H-4 in Figs. 3A and 3C are evident in the spectra of the deuterium oxide solutions. By relating these two groups of spectra, a second pattern of signals becomes apparent in Fig. 1B. Fortuitously, it has been possible to delineate this group even more clearly by examining the (thoroughly dried) syrupy oxidation products soon after solution in deuterium oxide, since the other signals are remarkably diffuse under these conditions (Fig. 1C). Both I and II give the same result, and on equilibration each spectrum slowly reverts to that represented by Fig. 1B. Two doublets and a triplet, each of about the same intensity, are found in Fig. 1C, together with a stronger high-field multiplet. Spin decoupling shows that the latter is associated with the triplet (spacings of 4.7 c.p.s.), these signals being ascribed to the 4- and 5-protons. Similarly, the spin-coupled doublets (spacings of 4.3 c.p.s.) are attributed to H-1 and H-2. The intermediate magnitude of the spacings indicates that this group of signals is due to the acyclic dialdehyde (hydrated III or IV), or else to a hemialdal undergoing a rapid chair interconversion (see, for example, ref. 18). Of these possibilities, the dialdehyde structure is the more likely. This follows from the fact that in the spectra of the 5-deuterio compounds each H-4 signal appears as a doublet of 4.7 c.p.s. spacing (inset, Fig. 1C), i.e. in this instance the product from each anomer gives the same type of signal. If the compound were a hemialdal, however, the product derived from each anomer should give a different result. That is, the spacings of the H-4 doublet should be either smaller or larger than that of the H-4 triplet, because the uneven isotope distribution would result in disproportionate contributions from the H-4 and H-5 gauche and diaxial interactions to the average values.

On this basis it is concluded that an almost equimolar mixture of open-chain (III or IV) and hemialdal (XVII or XVIII) forms is present in the aqueous solution after periodate oxidation of I and II, together with more minor, unidentified components. In dimethyl sulfoxide, however, the equilibrium is displaced almost entirely in favor of the hemialdal.

The foregoing data are clearly consistent with the view that the oxidation products derived from two anomeric aldopentopyranosides are enantiomorphic. Although this disagrees with the recent findings of Chittenden and Guthrie (4), the fact that the oxidation products can exist in more than one form enhances the possibility that the preparation of certain derivatives could conceivably involve mixtures of products. Preliminary results show that a situation of this kind can arise. Thus, amorphous *p*-nitrobenzoates have been prepared as described by the above workers, from the syrupy oxidation products obtained from I and II. Each of these products gives a n.m.r. spectrum consisting of a profusion of signals that undoubtedly reflects the presence of several admixed components; in particular, three singlets attributable to methoxyl groups are readily evident in each spectrum. All of the signals are common to both spectra, although their relative intensities vary

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

slightly from one to the other. However, these small compositional differences have little overall effect on the optical rotatory values, which, for the two products, are almost equal and of opposite sign. On balance, therefore, there appears to be little reason to doubt Jackson and Hudson's original postulate that the products derived by glycol-cleavage oxidation of anomeric aldopentopyranosides are enantiomorphic.

EXPERIMENTAL

Nuclear magnetic resonance signals were recorded on a Varian HA-100 high-resolution spectrometer, with tetramethylsilane contained in a coaxial capillary as the internal control reference signal. Chemical shift values obtained in this way are about 45 c.p.s. higher than when tetramethylsilane is present in the solution; hence the values reported herein have been corrected by −0.45 p.p.m. Spin-decoupling experiments were carried out with the frequency-sweep facility of this instrument.

Methyl α- and β-D-Xylopyranoside-5-d

D-Xylose-5-*d* was prepared essentially according to the procedure described by Lemieux and Howard (14). In the present study, 1,2-*O*-isopropylidene-α-D-glucofuranose was used as the starting material (instead of the 3-*O*-benzyl derivative) and the 5-oxoxylose intermediate was reduced with sodium borodeuteride in water (instead of with lithium aluminium deuteride in ether). The 1,2-*O*-isopropylidene-α-D-xylofuranose-5-*d* was treated directly with 1% methanolic hydrogen chloride under reflux for 6 h to prepare the anomeric xylosides according to Hudson's conditions (19). Methyl β-D-xylopyranoside, m.p. 154–156°, was obtained by crystallization from ethanol. As found for the configerationally related 1,2,3,4-tetra-*O*-acetyl-β-D-xylose (14), methyl β-D-xyloside (in deuterium oxide) gives a quartet (spacings of 4.4 and 10.3 c.p.s.) for the equatorial 5-proton well shifted (4.0 p.p.m.) from that of the axial proton (ca. 3.4 p.p.m.). Also, in the spectrum of the deuterated compound this signal appears as a broad doublet, its intensity being approximately 35% of that of the nearby H-1 doublet, in agreement with the data of Lemieux and Howard (14).

Methyl α-D-xylopyranoside-5-*d* was difficult to obtain in a crystalline form, although several solvents, including methyl ethyl ketone (19), were tested as crystallization media. However, repeated precipitation from ethyl acetate – ether solution gave the pure compound, as judged from its n.m.r. spectrum and by paper chromatography. The H-5 signals of methyl α-D-xylopyranoside and of its deuterated counterpart are not well resolved; hence, the distribution of isotope was not cross-checked in this way.

Periodate Oxidation of Glycosides

These oxidations were carried out with periodic acid as described by Jackson and Hudson (1), except that the iodate and excess of the oxidant were removed with Dowex-1 resin (bicarbonate form). In the deionization step the suspension was shaken with an excess of resin for several hours; otherwise, when the syrupy oxidation product was dissolved in dimethyl sulfoxide, iodine was slowly released.

p-Nitrobenzoates of the Oxidation Products

The syrupy product (0.2 g) obtained by oxidation of either methyl α- or β-D-xylopyranoside was dissolved in pyridine (15 ml). (A n.m.r. spectrum of a more concentrated solution, which differed somewhat from those shown in Figs. 1 and 3 but was the same for each product, indicated that a mixture of components was present, although one component greatly predominated.) *p*-Nitrobenzoyl chloride (0.6 g) was added, and after 20 h at room temperature the solution was treated with 2–3 ml of ice water and then poured onto cracked ice admixed with an excess of sodium bicarbonate. The suspension was stirred for 30 min, and filtered; then the precipitate was washed on the filter with ice water and dried *in vacuo*. The yields of cream-colored powder were 0.31 g (from the α-anomeric product) and 0.30 g (from the β-anomeric product). The derivative was dissolved in chloroform, ether was added to turbidity, a small quantity of dark precipitate was filtered off, and on removal of the chloroform a white crust was obtained; $[\alpha]_D$ +58° (α-product) and −53° (β-product) (*c*, 3 in chloroform) (these solutions gave plain optical rotary dispersion curves which were virtually mirror images).

In the n.m.r. spectrum of each product (recorded in chloroform) three sharp singlets ascribable to methoxyl protons were found at 3.45, 3.48, and 3.53 p.p.m., respectively. The relative intensities of these signals, as well as of some other signals present, differed slightly in the two spectra. The spectra were found to be unaltered after the products had been treated with *p*-nitrobenzoyl chloride (as above) to ensure complete esterification.

ACKNOWLEDGMENTS

The author expresses sincere thanks to M. Mazurek, who recorded the spectra, and to Dr. H. J. Bernstein and Dr. W. Quail for very helpful discussions.

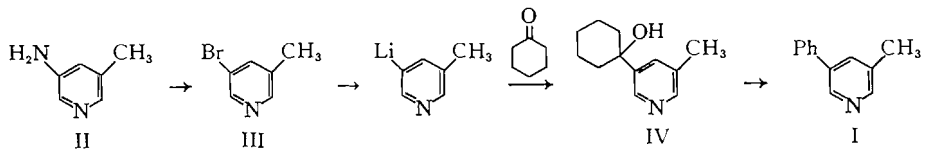
AROMATIC SUBSTITUTION

XIV. THE HOMOLYTIC PHENYLATION OF 3- AND 4-PICOLINE. A QUANTITATIVE STUDY OF ISOMER AND TOTAL RATE RATIOS[1]

R. A. Abramovitch and Maitreyi Saha
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan
Received March 15, 1966

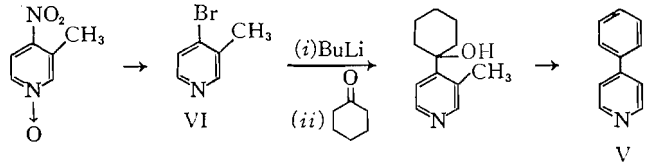
ABSTRACT

The homolytic phenylation of 3- and 4-picoline under the conditions of the Gomberg–Hey reaction has been studied quantitatively. The methyl group in both picolines was found to activate the nucleus to the same extent. All the nuclear positions in both systems, except for C_5 in 3-picoline, were slightly activated as compared with any one position in benzene. The significance of these results is discussed.



In previous parts of this series (1, 2), the effects of substituents in the aryl radical upon the isomer ratio and upon the relative reactivities of the nuclear positions in pyridine towards free-radical arylation have been studied. On the other hand, the effects of substituents present in the pyridine nucleus upon the reactivity of the various positions towards homolytic attack have received little attention. A qualitative analysis of the products formed in the substitution of 4-picoline by 3-pyridyl radicals showed that both the 2- and 3-(3′-pyridyl) isomers were formed in the ratio of 3:11 (3). Similar results were obtained with 4-ethylpyridine (3). Ethyl isonicotinate is reported to give only ethyl 2-(3′-quinolyl)isonicotinate with the 3-quinolyl radical (4). The alkylation of 3-picoline by methyl radicals (from lead tetraacetate) is said to give a mixture of 2,3- and 2,5-lutidine (5), though the other isomers are undoubtedly present as well (6). Methylation of 3-*n*-butylpyridine with lead tetraacetate in acetic acid (in which the pyridine is undoubtedly *N*-protonated to a large extent) has been examined semiquantitatively (7). The main product of monomethylation (60% of total) was 3-*n*-butyl-2-methylpyridine, and about equal amounts (slightly less than 20%) of each of the 4- and 6-methyl derivatives were obtained. About 2% of the total product was thought to consist of 3-*n*-butyl-5-methylpyridine. A small amount of the dimethylated 3-*n*-butylpyridines was obtained together with an appreciable quantity of a high-boiling residue.

The present work reports a quantitative study of the homolytic phenylation of 3- and 4-picoline under the conditions of the Gomberg–Hey reaction. Since the reactivities of the various nuclear positions of pyridine (1) and toluene (8, 9) towards attack by phenyl radicals are known, it was of interest to determine whether the effects of the nitrogen atom and of the methyl group in the picolines were additive in this reaction.



Of the possible products from the phenylation of 3-picoline, 4-phenyl-3-picoline was not known. 5-Phenyl-3-picoline (I) had previously been prepared by the condensation of phenylacetaldehyde, propionaldehyde, and ammonia, and had been obtained as a mixture with 3,5-diphenylpyridine, 3,5-diphenyl-2-ethylpyridine, and 2-ethyl-3-methyl-5-phenylpyridine (10). A more conventional approach to this compound was used here, starting with 3-methyl-5-pyridyllithium and cyclohexanone. 5-Bromo-3-picoline (III) was required and was prepared from 5-amino-3-picoline (II) by the Craig perbromide procedure. An attempt to make use of the Gattermann reaction for this purpose gave a basic product

[1]*For part XIII in this series, see ref. 2.*

whose picrate did not analyze correctly for that of III. When the bromination of 3-picoline with bromine and aluminium chloride (swamping catalyst method (11)) was carried out, a mixture of three products was obtained, more than 85% of which was 5-bromo-3-picoline. The formation of I from 1-(3′-methyl-5′-pyridyl)cyclohexanol (IV) with concentrated sulfuric acid and glacial acetic acid was unexceptional.

4-Phenyl-3-picoline (V) was prepared similarly from 3-methyl-4-pyridyllithium and cyclohexanone. A number of attempts were made at preparing pure 4-bromo-3-picoline (VI). 4-Bromo-3-picoline 1-oxide, m.p. 112–113° (reported (12) m.p. 72–73°), decomposed very readily and could not be used conveniently. Reduction of 4-nitro-3-picoline 1-oxide with iron and acetic acid gave 4-amino-3-picoline which, in turn, gave 4-bromo-3-picoline (VI) by the Craig method. The yields of VI were very poor and the compound obtained in this way underwent self-addition very readily, a process probably catalyzed by some impurity that was present. On the other hand, a reasonably good yield (47%) of VI was obtained on treatment of 4-nitro-3-picoline 1-oxide with phosphorus tribromide in ethyl acetate. The product could be distilled without decomposition.

EXPERIMENTAL

Melting points are uncorrected. Only the main peaks are reported for the infrared spectra.

5-Bromo-3-picoline

(a) From 5-Amino-3-picoline

A solution of 5-amino-3-picoline (2.0 g) (13) in constant-boiling hydrobromic acid (8.0 ml) was treated with bromine (2.4 ml) dropwise at 0°, stirring was continued for 15 min, and then a solution of sodium nitrite (4.0 g) in water (12.0 ml) was added at such a rate as to keep the temperature at 0–5°. A vigorous evolution of gas occurred at the end of the addition. When the effervescence had subsided the mixture was made alkaline and then steam-distilled. The distillate was extracted with ether, the ethereal layer was dried (Na_2SO_4) and evaporated, and the residue was distilled to give 5-bromo-3-picoline (1.38 g), b.p. 108–110° at 25 mm. Infrared spectrum (liquid film): 1 595 (m), 1 445 (s), 1 165 (m), 1 105 (s), 1 035 (s), 1 005 (w), 870 (s), 860 (s), 700 (s), and 665 (w) cm^{-1}. The picrate crystallized from ethanol and was recrystallized from the same solvent. It had m.p. 180–181°.

Anal. Found: C, 36.25; H, 2.47. $C_6H_6NBr \cdot C_6H_3N_3O_7$ requires C, 35.91; H, 2.24.

The use of the Gattermann reaction in the synthesis of this compound gave a very impure material which did not analyze correctly.

(b) By the Swamping Catalyst Method

Anhydrous 3-picoline (4 g, 0.041 mole) was added dropwise to stirred anhydrous aluminium chloride (14 g, 0.103 mole) (calcium chloride guard tube). Heat was evolved and bromine (4.0 g) was added to the mixture over a period of 1.5 h while the temperature was maintained at 95–100°. After being kept at room temperature overnight the mixture was decomposed with ice water, made alkaline, and extracted with ether. The ether layer was dried ($MgSO_4$), the solvent evaporated, and the residue distilled at 112–114° and 60 mm to give a yellow oil (1.22 g). This was analyzed by gas chromatography with a 6 ft × ¼ inch 15% asphalt on Chromosorb W column operated at 165° and a helium inlet pressure of 45 p.s.i. Three peaks were observed; the substance giving rise to the major peak (>85%) was collected and shown to be identical with 5-bromo-3-picoline by a comparison of its infrared spectrum with that of a sample prepared by method *a* above.

The attempted bromination of 3-picoline in the presence of thionyl chloride gave a complex mixture of at least four products which was not examined further.

1-(3′-Methyl-5′-pyridyl)cyclohexanol

A solution of *n*-butyllithium in hexane (3.5 ml of a 14.9% solution) and dry ether (2.0 ml) was stirred vigorously under dry, oxygen-free nitrogen and cooled to −62° to −74°. 5-Bromo-3-picoline (1.0 g) in dry ether (2.0 ml) was added dropwise over a period of 15 min, the mixture was stirred for a further 15 min, and a solution of freshly distilled cyclohexanone (3.0 ml) in dry ether (2.0 ml) was then added slowly during 30 min. After being stirred for another 3 h at −62° to −74° the reaction mixture was allowed to come to room temperature, poured onto crushed ice, and extracted with ether. The dried ($MgSO_4$) ether extract was evaporated to give 1-(3′-methyl-5′-pyridyl)cyclohexanol (0.97 g) which, after recrystallization from acetone, had m.p. 144–144.5°. Infrared spectrum (KBr disk): 3 250 (s), 1 595 (m), 1 440 (s), 1 395 (s), 1 320 (m), 1 272 (s), 1 180 (s), 1 145 (s), 1 045 (s), 995 (s), 870 (s), 815 (m), 795 (w), 715 (s), and 695 (w) cm^{-1}.

Anal. Found: C, 74.94; H, 8.97. $C_{12}H_{17}NO$ requires C, 75.35; H, 8.96.

5-Phenyl-3-picoline

1-(3′-Methyl-5′-pyridyl)cyclohexanol (0.2 g) was boiled under reflux with a mixture of concentrated sulfuric acid (1.0 ml) and glacial acetic acid (3.0 ml) for 4 h. Most of the acetic acid was then distilled off, the residue was poured into water, and the solution was made basic and extracted with ether. The dried ($MgSO_4$) ether extract was evaporated and the residue distilled to give 5-phenyl-3-picoline (0.14 g), b.p. 208–210° at 60 mm. Infrared spectrum (liquid film): 3 070 (m), 1 505 (w), 1 425 (m), 1 155 (m), 1 035 (m), 840 (m), 815 (s), 760 (s), 710 (s), 695 (s), and 660 (w) cm^{-1}. The picrate was recrystallized from ethanol and had m.p. 200–201°. Farley and Eliel (10) give m.p. 191–192° for this picrate.

Anal. Found: C, 53.80; H, 3.88. $C_{12}H_{11}N \cdot C_6H_3N_3O_7$ requires C, 54.27; H, 3.54.

3-Benzylpyridine

Because the red phosphorus and hydriodic acid method of reduction of 3-benzoylpyridine (14) proved to be unsatisfactory in our hands, a Wolff–Kishner reduction was used.

3-Benzoylpyridine (3.6 g) was dissolved in diethylene glycol (30.0 ml), and 90% hydrazine hydrate (3.0 ml) and potassium hydroxide (4.0 g) were added. The mixture was boiled under reflux for 6–7 h, cooled, and extracted with ether. The dried ($MgSO_4$) ether layer was evaporated and the residue distilled. The fraction (0.92 g), b.p. 285–288°, crystallized in the refrigerator and gave a picrate, m.p. 124–126° when crystallized from ethanol. Tschitschibabin (14) reported m.p. 34° for 3-benzylpyridine and m.p. 126–127° for its picrate.

4-Bromo-3-picoline 1-Oxide

4-Nitro-3-picoline 1-oxide (1.0 g) (15) was heated under reflux with constant-boiling hydrobromic acid (40 ml) for 24 h. The reaction mixture was poured onto crushed ice and neutralized with aqueous sodium hydroxide. The product was extracted with chloroform, the extract dried (Na_2CO_3), and the solvent evaporated to give a light-yellow solid (0.92 g) which, after recrystallization from light petroleum (b.p. 60–80°), gave fine white needles of the bromo *N*-oxide, m.p. 112–113°. Infrared spectrum (KBr disk): 3 400 (m, br), 1 450 (s), 1 400 (s), 1 390 (w), 1 290 (s), 1 245 (s), 1 205 (m), 1 155 (s), 1 005 (m), 850 (w), 845 (w), 835 (w), 745 (s), and 695 (m) cm^{-1}.

Anal. Found: C, 38.80; H, 3.51. C_6H_6NOBr requires C, 38.32; H, 3.19.

Hai and Ogura (12) reported m.p. 72–73° for this compound. The picrate was recrystallized from benzene and had m.p. 117–118°, depressed on admixture with picric acid.

4-Bromo-3-picoline

(a) By the Craig Procedure

4-Amino-3-picoline (2.0 g) (15) in constant-boiling hydrobromic acid (8 ml) was cooled to 0° and treated with bromine (2.4 ml) dropwise. Stirring at 0° was continued for 15 min, and a solution of sodium nitrite (4.0 g) in water (12 ml) was then stirred in at such a rate that the temperature of the mixture remained at 0–5°. At the end of the addition a vigorous evolution of gas occurred. The solution was made basic with 10% sodium hydroxide solution, the temperature not being allowed to rise above 25°, and then steam-distilled. The distillate was extracted with ether, the organic layer dried ($MgSO_4$), and the solvent evaporated. The residue was distilled to give 4-bromo-3-picoline (0.185 g, 5.8%), b.p. 108–110° at 60 mm. The picrate (crystallized from benzene) was recrystallized from ethanol and had m.p. 139–141°.

Anal. Found: C, 35.75; H, 2.55. $C_6H_6NBr \cdot C_6H_3N_3O_7$ requires C, 35.91; H, 2.24.

(b) From 4-Nitro-3-picoline 1-Oxide

Phosphorus tribromide (36.0 g) was added to a mixture of 4-nitro-3-picoline 1-oxide (5.0 g) and dry ethyl acetate (300 ml), and the mixture was boiled under reflux for 30 min. The reaction mixture was poured into water and the solution extracted with ether. The aqueous layer was made alkaline, care being taken to maintain the temperature at 25–30°. The solution was extracted with ether, the ether layer was dried (Na_2CO_3) and evaporated, and the residue was distilled under vacuum to give 4-bromo-3-picoline (2.06 g), b.p. 104–107° at 60 mm. The picrate had m.p. 137–138°, undepressed on admixture with a sample prepared by method *a* above. Infrared spectrum of the free base (liquid film): 3 040 (m), 1 600 (w), 1 520 (s), 1 470 (m), 1 440 (m), 1 380 (m), 1 350 (s), 1 230 (s), 1 065 (s), 840 (s), 790 (s), 750 (s), 715 (w), 690 (s), and 670 (s) cm^{-1}.

1-(3′-Methyl-4′-pyridyl)cyclohexanol

A solution of *n*-butyllithium in ether was prepared from lithium (0.07 g), *n*-butyl bromide (4 ml), and dry ether (25 ml) at −62° to −74°. A solution of 4-bromo-3-picoline (0.860 g) in dry ether (5 ml) was added dropwise, with stirring, to the butyllithium solution over a period of 30 min, the temperature being maintained at −62° to −74°. Cyclohexanone (3.0 g) in dry ether was added dropwise over a period of ½ h, and then stirring was continued for another 3 h, during which time the reaction mixture was allowed to come to room temperature. The resulting mixture was poured onto crushed ice and extracted with ether. The dried ($MgSO_4$) ethereal layer was evaporated to give the alcohol (0.418 g), which was vacuum-distilled at 205–209° and 60 mm and then recrystallized from light petroleum (b.p. 60–80°). It was obtained as colorless prisms, m.p. 95°. Infrared spectrum (KBr disk): 3 180 (s), 1 590 (s), 1 255 (m), 1 210 (m), 1 165 (s), 1 125 (s), 1 065 (s), 965 (s), 822 (s), 805 (w), 755 (w), 745 (m), and 645 (s) cm^{-1}.

Anal. Found: C, 75.64; H, 8.81. $C_{12}H_{17}NO$ requires C, 75.35; H, 8.96.

4-Phenyl-3-picoline

1-(3′-Methyl-4′-pyridyl)cyclohexanol (0.20 g) was boiled under reflux with concentrated sulfuric acid (1.0 ml) and glacial acetic acid (3.0 ml) for 4 h, and the reaction mixture worked up as described for 5-phenyl-3-picoline. The product (0.054 g) had b.p. 195–198° at 60 mm. Infrared spectrum (liquid film): 3 340 (m, br), 1 585 (s), 1 475 (m), 830 (m), 805 (w), 760 (s), 735 (m), and 695 (s) cm^{-1}. Nuclear magnetic resonance spectrum (in CCl_4): τ 7.80 (3H, singlet, CH_3—Ar), 2.67 (5H, singlet, phenyl protons), 2.1 (1H, doublet, J = 5 c/s, C_5—H), and 1.4 (2H, multiplet caused by the superimposed singlet and doublet of C_2—H and C_6—H). The picrate (crystallized from benzene) had m.p. 168–169°.

Anal. Found: C, 54.07; H, 3.70. $C_{12}H_{11}N \cdot C_6H_3N_3O_7$ requires C, 54.27; H, 3.54.

General Method Used for the Phenylation of the Picolines and the Determination of the Isomer Ratios

A mixture of aniline (0.5 g) and concentrated hydrochloric acid (1 ml) was cooled to 0–5° and diazotized below 5° with a solution of sodium nitrite (0.42 g) in water (0.75 ml). The diazonium salt solution was slowly added over a period of 15 min to the picoline (100 ml), which was being stirred vigorously in a thermostat maintained at 40 ± 1°; the solution was then stirred at that temperature for a further 6 h. Sodium carbonate (5 g) was now added, the mixture was stirred at room temperature for 15 min and, after being allowed to stand for some time, was filtered into a distillation flask, and the solids were washed thoroughly with ether until free of picoline. The combined filtrates were concentrated carefully with a fractionating column to a volume of 20–30 ml. This was transferred quantitatively to a conical flask with the help of ether, the total volume being kept below 50 ml, and this solution was used directly for the quantitative analyses of the isomer ratios by gas–liquid chromatography.

For the quantitative analyses, the internal standard method (16) was used. The introduction of a known weight of internal standard in the final reaction mixture also permitted the yield of products to be determined. The authentic samples prepared as described above were all gas chromatographically pure. The conditions for the gas–liquid chromatographic analyses are given in each individual case.

Phenylation of 3-Picoline

The diazonium salt solution, prepared as described above, was added to 3-picoline (100 ml) at 40 ± 1° and worked up as usual. The reaction mixture was best resolved on a 5 ft × ¼ inch column packed with asphalt (15% w/w) on Chromosorb W (80–100 mesh) and operated at 220° and a helium inlet pressure of 40 p.s.i. (flow rate 75 ml/min). Under these conditions, four peaks were well resolved and had retention times of 24.5, 28.5, 39.5, and 45.0 min, respectively. These correspond to 2-phenyl-3-picoline, 4-phenyl-3-picoline, 6-phenyl-3-picoline, and 5-phenyl-3-picoline, respectively, and were identified by collecting samples corresponding to the individual peaks and comparing their infrared spectra with those of authentic samples. 2-Phenyl-3-picoline and 6-phenyl-3-picoline were available from a previous study (17). No 3-benzylpyridine (retention time 12.5 min) could be detected in the reaction mixture. The thermal detector responses of the four isomeric phenylpicolines were found to be the same, so that the relative areas under the chromatographic peaks could be used directly in the determination of the isomer ratios. 2-Methylbiphenyl was used as the internal standard. The percentage composition thus obtained (average of two runs in triplicate) was: 2-phenyl-, 43.3 ± 0.5%; 4-phenyl-, 28.7 ± 0.6%; 5-phenyl-, 6.9 ± 0.8%; and 6-phenyl-3-picoline, 21.1 ± 0.5%.

Phenylation of 4-Picoline

The reaction mixture was best resolved on a 6 ft × ¼ inch column packed with precipitated asphalt (25% by weight) on Chromosorb W (60–80 mesh) and operated at 175° and a helium inlet pressure of 40 p.s.i. (flow rate 80 ml/min). Under these conditions 3-phenyl-4-picoline had a retention time of 19.3 min and 2-phenyl-4-picoline a retention time of 27.4 min. Only two peaks were observed. Coumarin (retention time 22.2 min) was used as the internal standard. The compound giving rise to the peak corresponding in retention time to 2-phenyl-4-picoline was collected and found to be identical (melting point and infrared spectrum) with a sample prepared from phenyllithium and 4-picoline (18). The compound giving rise to the peak corresponding to 3-phenyl-4-picoline was collected and gave a picrate, m.p. 145°, undepressed on admixture with an authentic sample of the picrate of this base kindly supplied by Dr. J. N. Chatterjee (19). Infrared spectrum of the free base (liquid film): 1 610 (s), 1 475 (m), 1 455 (m), 1 415 (m), 1 225 (m), 1 015 (s), 830 (s), 765 (s), 730 (w), and 700 (s) cm^{-1}.

The molar thermal responses of the two isomers were different, so that the internal standard had to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

introduced in all the samples being analyzed. The percentage composition thus obtained (two runs in triplicate) was: 2-phenyl-, 44.9 ± 1.0%; and 3-phenyl-4-picoline, 55.1 ± 0.6%.

Determination of ${}^{3\text{-Pic}}_{C_6H_6}K$ *for the Phenylation of 3-Picoline*

(i) With a Molar Ratio of 3-Picoline to Benzene of 4:1

The ratio of aniline to total solvent was 1:200.

The diazonium salt solution from aniline (0.5 g), concentrated hydrochloric acid (1.0 ml), sodium nitrite (0.42 g), and water (0.7 ml) was added over a period of 15 min, with vigorous stirring, to a mixture of 3-picoline (83.0 ml) and benzene (19.0 ml) maintained at 40 ± 1° in a thermostat. The reaction mixture was stirred for a further 6 h and then worked up as described in the determination of the isomer ratios. It was analyzed by gas–liquid chromatography on a 6 ft × ¼ inch column packed with precipitated asphalt (15% w/w) on Chromosorb W (80–100 mesh) and operated at 220° and a helium inlet pressure of 40 p.s.i. Under these conditions biphenyl had a retention time of 8.3 min. Advantage was taken here of the fact that the phenyl-3-picolines have the same thermal detector response, so that no special calibrations were necessary. 2-Bromobiphenyl was used as the internal standard. The mean of the results of three runs carried out in duplicate gave ${}^{3\text{-Pic}}_{C_6H_6}K = 1.39 \pm 0.05$.

(ii) With a Molar Ratio of 3-Picoline to Benzene of 6:1

The same proportions of amine to total solvent were used. In this way, ${}^{3\text{-Pic}}_{C_6H_6}K$ was found to be 1.40±0.06.

Determination of ${}^{4\text{-Pic}}_{C_6H_6}K$ *for the Phenylation of 4-Picoline*

The reaction was carried out as described above, but with 4- instead of 3-picoline. The mixtures were analyzed on a 6 ft × ¼ inch column packed with precipitated asphalt (25% w/w) on Chromosorb W and operated at 175° and a helium inlet pressure of 40 p.s.i. (flow rate 80 ml/min). Under these conditions biphenyl had a retention time of 8.3 min, and 2- and 3-phenyl-4-picolines retention times of 22.6 and 16.4 min, respectively. Coumarin was used as the internal standard. The average of the results of three runs carried out in duplicate gave ${}^{4\text{-Pic}}_{C_6H_6}K = 1.39 \pm 0.1$.

DISCUSSION

Since the reaction mixtures were homogeneous in all cases, the argument sometimes levelled (20) against the suitability of the Gomberg–Hey reaction for quantitative work that, with the usual aromatic solvents, the reaction is a heterogeneous one does not apply. Selective solvation was not important within the range of solvent ratios used. The validity of isomer ratios obtained in the Gomberg–Hey arylation has already been discussed (1), and the conclusion was reached that the σ-complexes formed are not selectively removed by dimerization or disproportionation. No high-boiling products could be isolated in the reactions with the picolines. In view of the work-up and analytic procedure used the errors in the quantitative estimations are small and the results are reproducible within ±2% (in most cases much better than this).

The averaged proportions of isomeric phenylpicolines are given in Table I, which also includes the data for the phenylation of pyridine (1). The values of the total rate ratios

TABLE I

Averaged percentage ratios of phenylated pyridines formed at 40 ± 1° and total rate ratios

Compound	Isomer distribution					${}^{XC_5H_4N}_{C_6H_6}K$
	2-	3-	4-	5-	6-	
Pyridine (1)	52.4	29.6	18.0	—	—	1.14
3-Picoline	43.3	—	28.7	6.9	21.1	1.39
4-Picoline	44.9	55.1	—	—	—	1.39

${}^{XC_5H_4N}_{C_6H_6}K$ relative to benzene are also given (corrected for the statistical relative amounts of benzene and XC_5H_4N used in the competitive reactions). A previous study (1) had shown that the most convenient molar ratio of pyridine to benzene to use in the competitive runs was 4:1. Under such conditions the mixtures were homogeneous and no selective solvation of the diazonium salt or covalent diazo compound was occurring. This was also found to be the case here in the competitive runs with the picolines and benzene. Increasing the molar ratio of 3-picoline to benzene to 6:1 had no effect upon the total rate ratio.

The results indicate that the 3- and 4-methyl groups activate the pyridine nucleus slightly (as expected) towards attack by phenyl radicals, and to the same extent (${}^{Plc}_{Pyr}K$ = 1.22). This is about the same degree of activation as is imparted by a methyl substituent onto a benzene ring (${}^{C_6H_5CH_3}_{C_6H_6}K$ = 1.23) (21). (See, however, the more recent results with triphenylbismuth as the source of phenyl radicals to substitute toluene, in which ${}^{CH_3}_{H}K$ was found to be 1.99 on the assumption that there is no side-chain attack (9). This value appears to be too high. Abramovitch and Saha (22), using benzenediazonium tetrafluoroborate and pyridine as the source of phenyl radicals, obtained a value of 1.20 for this total rate ratio.)

The most abundant isomers obtained in the phenylation of the picolines are those in which the phenyl group enters ortho to the methyl group, which is consistent with the orientation observed in previous homolytic substitutions of 3- and 4-alkylpyridines (3, 5, 7). The effect of the methyl group may be seen more clearly from a consideration of the partial rate factors for the phenylations. These are given in Table II together with the data for pyridine itself (1).

TABLE II

Partial rate factors for phenylation at 40 ± 1°

	Partial rate factors				
Compound	F_2	F_3	F_4	F_5	F_6
Pyridine (1)	1.83	1.00	1.18	—	—
3-Picoline	3.5	—	2.37	0.57	1.74
4-Picoline	1.87	2.29	—	—	—

If the principle of additivity (23) is presumed to hold in these substitutions, then the partial rate factors for the various positions in the picolines can be calculated from the partial rate factors for the phenylation of pyridine and of toluene. The data for toluene are, as mentioned above, not definitive. The latest values of the isomer ratios as obtained from the phenylation with triphenylbismuth (9) have been confirmed in our laboratories with benzoyl peroxide as the source of phenyl radicals, the analysis being carried out by gas–liquid chromatography, using the internal standard technique. The isomer ratio so obtained is: *o*-, 57%; *m*-, 25%; and *p*-, 18% (24). If the values for the partial rate factors originally given by Hey *et al.* (21) are used in conjunction with our data for pyridine, the values calculated for 3-picoline are: F_2 = 4.58, F_4 = 2.95, F_5 = 0.71, and F_6 = 1.83; and those for 4-picoline are: F_2 = 1.30 and F_3 = 2.50. If the partial rate factors based on ${}^{C_6H_5CH_3}_{C_6H_6}K$ = 1.99 (9) are used, then the calculated values for 3-picoline are: F_2 = 6.22, F_4 = 4.0, F_5 = 1.6, and F_6 = 3.48; and those for 4-picoline are: F_2 = 2.93 and F_3 = 3.4. These values are obviously much too high and confirm that the total rate ratio for toluene is probably close to 1.23. Using this figure and our data for the isomer ratios (24) leads to the following predicted values for 3-picoline: F_2 = 3.85, F_4 = 2.47, F_5 = 0.92, and F_6 = 2.43; and for 4-picoline: F_2 = 1.69 and F_3 = 2.10. Except for F_5 in 3-picoline (and perhaps F_6 as well), these agree reasonably well with the experimentally found values. This additivity of the substituent effects supports the assumption that formation of the σ-complexes is the rate-determining step in such substitution reactions.

The apparent deactivation of C_5 in 3-picoline towards attack by phenyl radicals is unexpected. The proportion of 5-isomer obtained in the methylation of 3-*n*-butylpyridine was similarly low (2%) (7), but partial rate factors are not available in this case. A similar, though lesser, deactivation of the meta position in toluene has been reported (F_m = 0.71 (21), F_m = 0.76 (22)) but the data from the reaction with triphenylbismuth give F_m = 1.6

For personal use only.

(9). Again, using our data for the isomer ratio (24) and ${}^{C_6H_5CH_3}_{C_6H_6}K = 1.23$, one gets $F_m = 0.92$, which is close enough to 1 to be well within the experimental error. The still lower yield of 3-*n*-butyl-5-methylpyridine obtained in the methylation of 3-*n*-butylpyridine is readily explained on the basis that methyl radicals are more nucleophilic than phenyl radicals (20), so that a deactivation of the pyridine β-position is to be expected towards "nucleophilic" attack. The low value of F_5 found for the phenylation of 3-picoline might be due to a systematic experimental error and could be without real significance. This seems to be rather unlikely at the moment. Another possibility worth considering is that phenyl radicals have a slight nucleophilic character. All substituents activate the benzene nucleus towards attack by phenyl radicals, barring steric hindrance (25). This is probably due to the fact that substituents, whether electron attracting or donating, can delocalize a single electron in the σ-complexes obtained by attack at the ortho and para positions. When the substrate is pyridine, attack by the radical at the α- and γ-positions will eventually lead to σ-complexes in which one of the contributing structures has the odd electron on the nitrogen atom. No further delocalization is, however, possible. It has tentatively been suggested (2) that, if anything, the phenyl radical has to be slightly nucleophilic to account for the slightly greater reactivity of pyridine compared with that of benzene. Although this would explain the deactivation of C_5 in 3-picoline, it would leave other data unaccounted for, e.g. F_m for nitrobenzene is reported to be 0.86 (25). Since many of these values are very close to 1, however, the slight variations around this figure may, in some cases, be within the limits of experimental error and not be significant at all. In any event, no firm statement is warranted at this time.

The formation of the 3-phenyl derivative as the main product in the phenylation of 4-picoline is another example of a case in which the 3-isomer is the predominant one formed. Other examples are the *o*-nitrophenylation (1) and the *o*-bromophenylation (2) of pyridine.

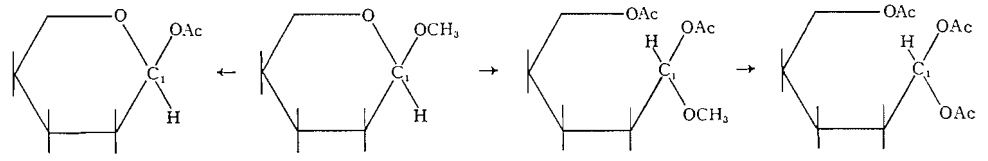
SUBSTITUTION OF ACYCLIC SUGAR ACETALS

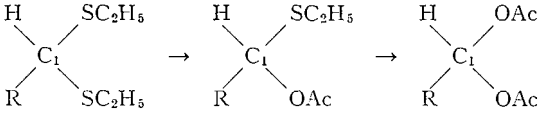
RATE OF PERCHLORIC ACID CATALYZED ACETOLYSIS OF 2,3,4,5,6-PENTA-*O*-ACETYL-D-GLUCOSE DIETHYL DITHIOACETAL AND 1,2,3,4,5,6-HEXA-*O*-ACETYL-D-GLUCOSE *S*-ETHYL MONOTHIOACETAL



NORMAN H. KURIHARA AND EDGAR PAGE PAINTER
Department of Chemistry, University of California, Davis, California

Received February 2, 1966

ABSTRACT



The rate constants for the perchloric acid catalyzed substitution of one ethylthio group of 2,3,4,5,6-penta-*O*-acetyl-D-glucose diethyl dithioacetal (V*a*) and the acetoxy group bonded to C_1 of 1,2,3,4,5,6-hexa-*O*-acetyl-D-glucose *S*-ethyl monothioacetal (VI*a*) have been measured when the substrates were dissolved in solutions of acetic acid and acetic anhydride. The rate-determining step is interpreted to be the dissociation of the substrate conjugate acid to give a carbonium–sulfonium cation. The rate constants indicate that acyclic sugar derivatives are substituted faster than cyclic (pyranose) derivatives, and that an acetoxy group is substituted faster than an ethylthio group.

Acetals dissolved in mixtures of acetic acid and acetic anhydride which contain a strong acid give substitution products which arise by cleaving either C—O bond of the substrate. The product has a C—OAc bond in place of the C—O bond cleaved. Thus methyl 2,3,4-tri-*O*-acetyl-β-arabinoside (I) gave both II and III when the acid was zinc chloride or 0.16% sulfuric; and gave the C_1 *gem*-diacetate (IV), a product which required cleavage of both the C_1—OCH_3 and C_1—O ring bonds of I, when the catalyst was 4% sulfuric acid (1).

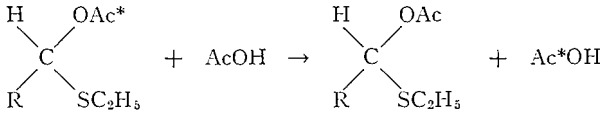
[1] 

II I III IV

Poly-*O*-acetyl diethyl dithioacetals of the common monosaccharides behave in much the same way. Pirie (2) dissolved dithioacetals (V) in acetic anhydride which contained 1.8 *M* sulfuric acid, and isolated products (C_1 *gem*-diacetates (VII)) formed by substitution after cleavage of each ethylthio group. Similar to the observation of Montgomery *et al.* (1) when I was the substrate, acids at low concentration catalyze a fast substitution of one

[2] 

V VI VII



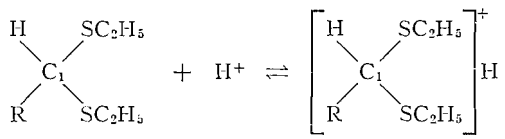
SC_2H_5 group of V to give VI (3). The products of a single substitution by an acetoxy group (II, III, and VI) are diastereomeric pairs (1, 3). Strong acids in acetic acid epimerize to give equilibrium mixtures. A C_1—OAc bond is broken in the process. *gem*-Diacetates are acetolysis products formed by cleavage of a C_1—OCH_3 bond (of III) or a C_1—SC_2H_5 bond (of VI). The rate of substitution of the monoacetals (III and VI) to give *gem*-diacetates is several powers of 10 slower than the rate of substitution of the acetals (I and

V) or the rate of epimerization of the monothioacetals. Since relative rates differ so greatly, the reaction can be quenched after the initial fast substitution of V, so that good yields of monothioacetals are obtained (3, 4). When dilute perchloric acid was the catalyst, we were unable to isolate a *gem*-diacetate which would show that the substitution VI → VII took place.

We cannot find in the literature rate constants for the substitution of dithioacetals or for the substitution (at C_1) of a single acyclic sugar derivative. We therefore measured concentration changes when 2,3,4,5,6-penta-*O*-acetyl-D-glucose diethyl dithioacetal (V*a*) was converted into 1,2,3,4,5,6-hexa-*O*-acetyl-D-glucose *S*-ethyl monothioacetal (VI*a*). To compare the rate of acetoxy substitution of an acyclic sugar with that of a pyranose,

[3] $$Va \rightarrow VIa\ (\alpha + \beta)$$

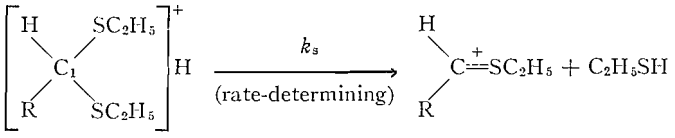
VI*a* has been prepared with ^{14}C-acetoxy at C_1 and reaction [4] followed by measuring the loss of ^{14}C from the substrate. The experimental conditions for reactions [3] and [4] were



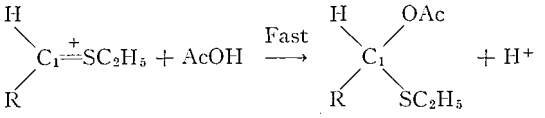
[4] 

α-VI*a* VI*a* (α + β)

those previously used to obtain data for a comparison of inversion and substitution rates of pyranose pentaacetates. Lemieux *et al.* (5) demonstrated, by measuring ^{14}C-acetoxy exchange of pentaacetates, that substitution rate constants may be much larger than inversion rate constants.



No studies comparable to those on the hydrolysis of oxygen acetals (6–9) have been reported on the hydrolysis of sulfur acetals. Hydrolysis rates of many α-halo thioethers (10–12) have, however, been measured. Bordwell *et al.* (12) gave convincing evidence that the rate-determining step for the solvolysis of α-halo thioethers is the formation of a sulfonium ion ($>C^{+}=SR$) by a unimolecular ionization analogous to the formation of the oxonium ion ($>C^{+}=OR$) which Newth and Phillips (13) proposed to explain the solvolysis of α-haloethers. Dissociation of an acetal conjugate acid to give the above oxonium ion is the rate-determining step when acetals are hydrolyzed by acids (6–9). Based on the similar behavior of the α-halo derivatives and the experimental observation that thioacetals are hydrolyzed under the same conditions as oxygen acetals, we believe that the rate-determining step for the substitution of our substrates is a first-order dissociation of the substrate conjugate acid to give a sulfonium ion.



The conjugate acids of the dithioacetal (V) and monothioacetal (VI) give the same sulfonium ion by the mechanism proposed. The former will be used to illustrate the steps shown in eqs. [5] to [7] (R = $AcOCH_2$—$(CHOAc)_4$—). Both substrates have an acetoxy group in a position to give anchimeric assistance, but we will limit our example to the cationic species without neighboring acetoxy participation.

VI ($\alpha + \beta$)

Since a new asymmetric carbon is formed by the substitution of the dithioacetal, the product is a pair of diastereomers. Both isomers (called α and β: the absolute configuration at C_1 is not known) were obtained from three sugar dithioacetals (3, 4). The diastereomer composition given by dithioacetals under conditions whereby the monothioacetal product is stable may be different from that given under conditions (such as the presence of perchloric acid) which give an equilibrium between the diastereomeric pairs. When, however, the substrate is the glucose dithiodiacetal, the product composition at epimeric equilibrium

$$\alpha\text{-VI} \underset{k_\beta}{\overset{k_\alpha}{\rightleftharpoons}} \beta\text{-VI}$$

is almost identical with the composition obtained by substitution under conditions whereby the substitution product is stable (3). The rate measurement on the glucose dithioacetal is then not complicated by consecutive reactions, so that $k_\alpha + k_\beta$ can be ignored.

RESULTS

Based on the steps given for the substitution we have described, the rate (V is now written as RSC_2H_5) is given by

$$\text{rate} = k[(RSC_2H_5)H^+]. \quad [8]$$

Substrate conjugate acid concentration is dependent upon the equilibrium

$$RSC_2H_5 + AcOH_2^+ \underset{}{\overset{K_1}{\rightleftharpoons}} (RSC_2H_5)H^+ + AcOH. \quad [9]$$

If we consider that perchloric acid is completely dissociated in acetic acid,[1] the concentration of substrate conjugate acid is given by eq. [11].

$$[HClO_4]_0 = [(RSC_2H_5)H^+] + [AcOH_2^+] \quad [10]$$

$$[(RSC_2H_5)H^+] = \frac{K_1[RSC_2H_5][HClO_4]_0}{[AcOH] + K_1[RSC_2H_5]} \quad [11]$$

By eq. [11] the rate constant will be first order with respect to perchloric acid. Provided that K_1 is small, the first-order constant will vary as 1/[AcOH]. The data in Table I show that the rate constant is first order with respect to acid, as observed when perchloric acid anomerized glucose pentaacetates (15) in mixtures of acetic acid and acetic anhydride.

[1]*Kolthoff and Bruckenstein (27) give experimental evidence that perchloric acid is half ionized (to ion pairs) in acetic acid, i.e.* $HClO_4 = AcOH_2^+ \cdots ClO_4^-$. *Including an additional term for undissociated perchloric acid and considering acetic acid as a dimer does not lead to a more useful equation than eq. [11].*

8.30×10^{-3}	1.50×10^{-2}	1.81
4.15×10^{-3}	7.35×10^{-3}	1.77

We have no measure of the relative basic strength of the solvent acetic acid and the substrate. Unless K_1 (eq. [9]) is large, the concentration of $AcOH_2^+$ is greater than that of $(RSC_2H_5)H^+$ because the concentration of solvent molecules is in large excess. If the $K_1[RSC_2H_5]$ term in the denominator (eq. [11]) is small compared with the [AcOH] term, the rate constant should increase when the concentration of acetic acid is reduced by increasing the substrate concentration, and also when part of the acetic acid is replaced by an aprotic solvent. The solubility of the substrate (molecular weight = 496) is great enough to reduce the acetic acid concentration to one-half the concentration at dilute substrate concentrations. Concentrated solutions become so colored soon after the addition of perchloric acid that the reaction cannot be followed polarimetrically. The rate was measured at different concentrations of acetic acid by replacing part of the acetic acid with methylene chloride. Qualitatively, the rate constant (Table II) increased as required by eq. [11], provided that the $K_1[RSC_2H_5]$ term can be neglected.

TABLE II

Rate constants for the conversion of dithioacetal (V*a*) into 1-acetoxy monothioacetal (VI*a*) in mixtures of acetic acid and methylene chloride at 25°

AcOH (% by volume)	$[HClO_4]$ (*M*)	$k_{obs.}$ (min^{-1})	$k/[HClO_4]$ Observed	$k/[HClO_4]$ Calculated

33.4	0.0185	0.086	4.15	2.90
23.8	0.0185	0.15	8.1	4.06

NOTE: The substrate concentration was 0.31 *M*. The acetic acid contained a small amount of acetic anhydride to ensure the absence of water.

While exploring synthetic procedures for the preparation of poly-*O*-acetyl 1-acetoxy-*S*-ethyl monothioacetals of sugars from the diethyl dithioacetals, we observed that the substitution rate was faster in acetic acid – acetic anhydride (equal volume mixtures) than in acetic acid alone. To determine whether the rate was influenced by solvent composition in the same way as anomerization (15) of glucose pentaacetates (also a substitution process), we measured the rate in mixtures of the two solvents (Table III).

A plot of some of these rate constants and anomerization rate constants measured in the same solvents shows how much the relative magnitude of the rates is influenced by the ratio of acetic acid to acetic anhydride.

DISCUSSION

Provided that the $K_1[RSC_2H_5]$ term in eq. [11] is small compared with the [AcOH] term, the calculated rate constants will be first order with respect to perchloric acid and will vary as 1/[AcOH]. The rate constant for the substitution of the dithioacetal is first order with respect to acid in all solvent mixtures tested. Replacing part of the acetic acid with the non-basic solvent methylene chloride produces an increase in the rate constant which follows eq. [11] until about one-half the solvent volume is non-basic solvent. At higher volume fractions of non-basic solvent, the rate constants become progressively larger than predicted by eq. [11]. The effect of methylene chloride on the rate constant is almost identical with that observed when the reaction is the substitution of the acetoxy group of glucose pentaacetate (15).

Replacing a given volume of acetic acid by acetic anhydride resulted in a greater rate increase than replacing the same volume by methylene chloride. This result is surprising. Even though $K_2 > K_1$, acetic anhydride must be a base in our solutions; if it is a very weak

[12] $$RSC_2H_5 + Ac_2OH^{+} \overset{K_2}{\rightleftharpoons} (RSC_2H_5)H^{+} + Ac_2O$$

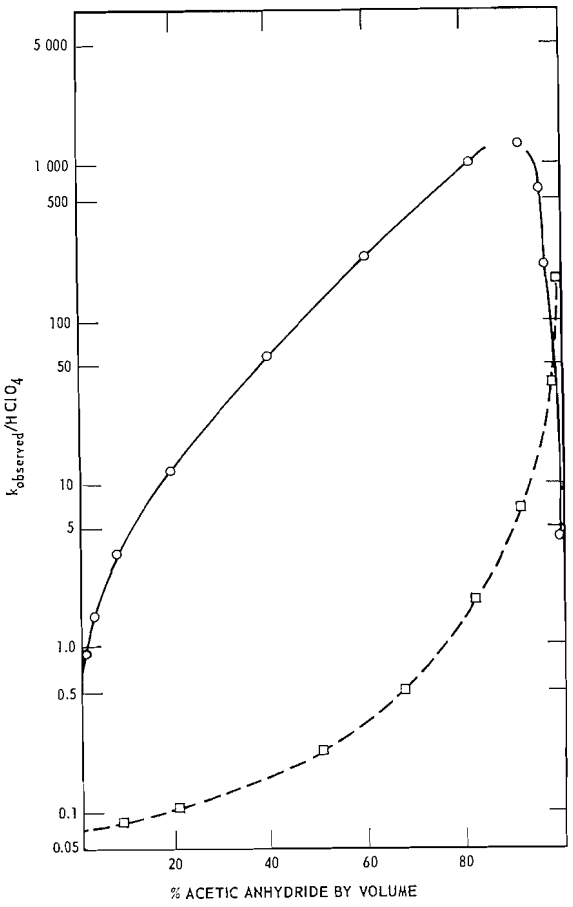

FIG. 1. Effect of solvent composition on the acetolysis rates of V*a* (○) and glucose pentaacetate (□).

base, eq. [11] should be obeyed. The rate constants calculated from the experimental data increased much faster when the solvent fraction of acetic anhydride increased than was predicted by eq. [11].

The data plotted in Fig. 1 show that the substitution of the dithioacetal increases much faster than the substitution of the pyranosyl acetoxy as the ratio of acetic anhydride to acetic acid increases. The rate constant increases faster than a measured acidity function (H_0) (16) in the solvent mixture, and the rate constant for dithioacetal substitution, unlike anomerization, reaches a maximum near 90% acetic anhydride. At this solvent composition, acetic acid (in acetic anhydride) is almost completely dissociated to monomer (16). Apparently the ratio of f substrate conjugate acid to $f^{\pm}$ becomes larger (at higher acetic anhydride concentration) when the substrate is the dithioacetal than when the substrate is glucose pentaacetate. One difference in the two reactions should be noted: acetoxy, presumably from acetic acid, is consumed when thioacetals are substituted but not when acetoxy substitutes for acetoxy in the anomerization step. With the solvent composition where the rate constant begins to decrease, acetic acid should not be limiting because the ratio of acetic acid to substrate is approximately 25.

Since the rate of acetoxy substitution of β-glucose pentaacetate is larger than the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

anomerization rate (based on experimental data (5, 17) the factor is within the range 11.4 to 15.5), the differences between the rate constants for the two substrates plotted in Fig. 1 are larger than the differences between the substitution rate constants. At concentrations of acetic anhydride greater than 50%, the relative substitution rates of the two substrates are uncertain because ^{14}C-acetoxy exchange has not been measured for glucose pentaacetate in solutions which have acetic anhydride as the major component.

The available data do not permit an unqualified decision about which substrate, the one giving the oxonium ion or the one giving the sulfonium ion, will be substituted by the faster rate. Solvolysis of α-haloethers indicates that oxygen is the better electron donor: the oxonium cation is more stable than the sulfonium cation. Relative solvolysis rates (10, 11) measured in dioxane–water were: α-chloromethyl ether/α-chloro-*S*-methyl ether = 1–2 $\times$ 10^4. The difference in the methanolysis rate of α-haloethers with oxygen or sulfur in a pyranose ring (18) was much less: 2,3,4-tri-*O*-acetyl-α-xylopyranosyl bromide/2,3,4-tri-*O*-acetyl-α-xylothiopyranosyl bromide = 40.

A comparison of the rate constants for the acid-catalyzed substitution of oxygen acetals with those for acetals which have both sulfur and oxygen (—S—C(—)—O—) reveals data which places in doubt the relative donor capacity of sulfur and oxygen. Horton and Hutson (19) state that "1-thioglycosides are more resistant to acid hydrolysis than their glycoside analogs". Methyl and ethyl oxygen xylosides and glucosides were hydrolyzed only 2–3 times faster than their sulfur analogues (18, 20). When, however, sulfur was in the pyranose ring, the acetal was substituted faster than when oxygen was in the ring. Methyl β-xylothiopyranoside was hydrolyzed nearly 30 times faster (by acid catalysis) than methyl β-xylopyranoside (18). The Lewis acid aluminium chloride cleaved a C—O bond of dioxolanes but not a C—S bond of dithiolanes (21).

The data in Table V summarize the acid-catalyzed substitution rate constants of di- and mono-acetal substrates in solutions of acetic acid and acetic anhydride. The substrates are poly-*O*-acetyl derivatives of glucose (both acyclic and pyranose), and in all cases an acetoxy group from the solvent substitutes for one of the groups bonded to the anomeric carbon. To aid the comparison, some of the rate constants for substitution in the 1:1 solvent mixture have been recorded as the value estimated, had perchloric acid been the catalyst.[2]

The data in Table V show that, when measured in equal volumes of acetic acid and acetic anhydride, acetoxy bonded to C_1 was substituted 36 times faster than methoxyl when oxygen in a pyranose ring was the electron donor. Acetoxy was substituted only 4 times faster than ethylthio when sulfur bonded to C_1 in the acyclic substrate was the electron donor. When measured in acetic acid with 4% acetic anhydride, acetoxy was substituted 116 times faster than ethylthio. It is tempting to say that acetoxy is the better leaving group (as acetic acid), but the concentration of substrate conjugate acids [—Y—C(—)—X]H$^+$, where Y = O or S and X = CH_3O, C_2H_5S, or CH_3CO, is dependent upon equilibria we cannot measure.

The data (Table V) show that, when the leaving group was the same, acyclic derivatives were substituted faster (about 190 times) than pyranose derivatives. Rate differences

[2]*Both substitution and inversion rate constants have been calculated for the sulfuric acid catalyzed reactions of glucose pentaacetates when measured in the 1:1 solvent (17). Inversion rate constants for the same substrate have been calculated from measurements with both sulfuric and perchloric acids in mixtures of acetic acid and acetic anhydride (15). For the 1:1 mixture* $k_{obs.}/[HClO_4] = 3.5k_{obs.}/[H_2SO_4]$.

*$3.5k_{obs.}/[H_2SO_4]$.
†Anomerization rate constant for M $HClO_4$ × ^{14}C-acetoxy exchange/inversion rate in 1:1 solvent.

caused by the relative conjugate acid concentrations of these substrates seem to be unlikely. The differences are not those expected if the relative rates are solely dependent upon oxygen or sulfur as electron donors. We attribute the rate constant differences to steric factors in the step leading to the cationic intermediates VIII and IX. To attain the

planar carbonium ion VIII requires eclipsing of more bulky groups (which are staggered in the substrate conformer of lowest energy) than is required to form IX. The potential energy difference (ground state → carbonium ion) caused by steric factors must be less for our acyclic substrates than it is for pyranose substrates. The activation energy (E_a) is smaller when the reaction is the substitution of glucose dithioacetal by acetoxy than when the reaction is the substitution of glucose pentaacetate by acetoxy (23, 24). The activation energy for the hydrolysis of thioglycosides (20) is slightly larger than that for oxygen glycosides.

In case the substitution at C_1 is anchimerically assisted, a conformation with the acetoxy group at C_2 *trans* to the group substituted (X in X) is energetically favored when the substrate is an acyclic derivative (V or VI). When, however, the substrate is a 2,3,4,6-tetra-*O*-acetyl β-glucopyranose derivative, the conformer with the group at C_1 *trans*-diaxial to the acetoxy group at C_2 has all polar groups axial, so that this conformer is far less stable than the conformer (the major species) which has all polar groups equatorial.

EXPERIMENTAL

Acetic acid was purified by partial freezing, and displacing the melt with dry nitrogen. This step was repeated 3 times on the solid. Acetic anhydride (99.5% pure, as determined by the supplier) was purified in the same way to remove the small amount of acetic acid.

Perchloric acid in acetic acid or acetic anhydride was prepared by dissolving silver perchlorate (dried at 110 °C) in the solvent and by gassing the solution with dry hydrogen chloride to precipitate silver chloride. Excess hydrogen chloride was removed by a stream of dry nitrogen. The perchloric acid concentration was measured by titration with potassium acid phthalate (25).

The dithioacetal substrate was dissolved in solvents with the compositions listed in the tables, and the flasks containing the solutions were placed in a constant-temperature bath. When the bath temperature was reached, a measured volume of perchloric acid in acetic acid was added and the solution poured into jacketed polarimeter tubes held to within ±0.1° by circulating water from the constant-temperature bath. Rotation was measured until equilibrium was reached. Rate constants were calculated from the equation

$$k_{obs.} = \frac{2.3}{t} \log \frac{a_0 - a_\infty}{a_t - a_\infty}.$$

*1,2,3,4,5,6-Hexa-O-acetyl-*D*-glucose 1-*^{14}*C-Acetoxy-S-ethyl Monothioacetal*

The preparation of α-1,2,3,4,5,6-hexa-*O*-acetyl-D-glucose *S*-ethyl monothioacetal (VI*a*) from the dithioacetal (V*a*) by a modification of the method of Wolfrom *et al.* (14) has been described (3, 4).

The source of ^{14}C-acetoxy used to label VI*a* was acetic acid-1-^{14}C obtained by distilling the solvent from a solution of sodium acetate (0.41 g containing 1 mcurie of ^{14}C) in 100 cc of acetic acid plus 5% acetic anhydride.

The ^{14}C-acetoxy group was incorporated by an exchange reaction with unlabeled substrate (VI*a*). VI*a* (5 g) was dissolved in 20 cc of acetic acid-1-^{14}C which was 4% in acetic anhydride, perchloric acid was added to give a concentration of 2.44×10^{-4} *M*, and the reaction mixture was allowed to stand for 48 h at 24°. The reaction was then quenched by neutralizing the perchloric acid with anhydrous sodium acetate. The excess acetic acid was removed *in vacuo*, the resulting solid material was extracted with 100 cc of hot methylene chloride, and the solution was filtered to remove suspended sodium acetate. Removal of the solvent at reduced pressure gave a white crystalline residue. Two recrystallizations from 95% ethanol yielded 3.04 g, m.p. 103–104°, of labelled VI*a*.

Kinetics of Acetoxy Exchange

One gram of labeled VI*a* was dissolved in each of the solvents listed in Table IV. These solutions were placed in a constant-temperature bath kept at 25 ± 0.1°. Perchloric acid catalyst was added until the concentration given in Table IV was reached, and at 5 min intervals 5 cc aliquots were removed and quenched in 5 cc of acetic acid saturated with sodium acetate. The acetic acid in each sample was removed *in vacuo* and the resulting solid was extracted with 30 cc of chloroform. The chloroform extract was washed 3 times with 30 cc portions of water. Crystalline material was obtained after final removal of the chloroform at reduced pressure. This material was assayed by the technique of liquid scintillation counting in a Packard Tri-Carb liquid scintillation spectrometer.

The scintillation fluid consisted of 60 g of naphthalene, 4 g PPO (2,5-diphenyloxazole) (scintillation grade), 0.2 g POPOP (1,4-bis-2-(5-phenyloxazolyl)-benzene) (scintillation grade), 20 cc ethylene glycol, and 100 cc methanol made up to a volume of 1 l with dioxane (26). The samples assayed were each 0.1000 g and were dissolved in 20 cc of the scintillation fluid. Low-potassium vials were used. The experimental data for a run in acetic acid and first-order rate constants calculated at the time intervals listed are given in Table VI.

TABLE VI

Acid-catalyzed loss of ^{14}C activity from C_1-labeled VI in acetic acid

Time (min)	Activity (mcurie/mole)	$10^2 k_{obs.}$ (min^{-1})
0	0.1949	
5	0.1564	4.46
10	0.1274	4.31
15	0.1009	4.53
20	0.0850	4.22
∞	0.0022	

The first-order rate constants recorded in Table IV were estimated from the slope of the line obtained by plotting log $(\alpha_t - \alpha_\infty)$, where α = activity, against time.

To be confident that the exchange is specific for C_1—OAc, we dissolved glucose heptaacetate in a solution containing acetic acid-1-^{14}C and added perchloric acid (2×10^{-4} *M*). The count of the heptaacetate isolated was 64 c.p.m./0.1 g (count of blank was 41 c.p.m./0.1 g). A sample of *S*-ethyl monothioacetal treated in the same way gave 10 635 c.p.m./0.1 g.

ÉTUDE DE LA FLUORESCENCE DES DÉRIVÉS DE LA PHÉNOTHIAZINE

E. Adonai Martin
Faculté de Pharmacie, Université de Montréal, Montréal, Québec

Reçu le 9 mars 1966

RÉSUMÉ

Certains dérivés de la phénothiazine développent en milieu sulfurique, après dilution par le diméthylsulfoxyde, une fluorescence qui permet un dosage fluorométrique d'une très grande sensibilité variant, suivant les substances employées, de 0.01 à 0.06 μg/ml.

Les radicaux fixés sur le noyau influencent l'intensité de la fluorescence. En général, une substitution sur l'atome de carbone de ce dernier, par certains radicaux, produit un effet extinctif plus marqué que celle, par différentes chaînes, sur l'atome d'azote de la phénothiazine. Cette méthode pourrait servir à déterminer ces substances dans les liquides biologiques.

L'identification des dérivés de la phénothiazine par la fluorescence a déjà été signalée par Mellinger et Keeler (1). Ces derniers, en effet, identifient ces substances sur chromatogrammes, en utilisant de l'acide sulfurique à 40% comme révélateur. De plus, Udenfriend et ses collaborateurs soulignent que certains composés de la phénothiazine possèdent une légère fluorescence naturelle (2, 3).

Comme la spectrophotofluorométrie s'avère un procédé analytique de très grande précision dans l'étude des substances biologiques et médicamenteuses, nous avons entrepris à la lumière de ces références d'étudier la fluorescence des dérivés de la phénothiazine afin de mettre au point une méthode de dosage de ces composés, si utilisés en thérapeutique.

PARTIE EXPÉRIMENTALE

A partir d'une solution contenant 0.1 μg de substance à doser/ml, dissoute dans le dichlorométhane, on introduit respectivement dans cinq petits tubes à essai 0.3, 0.5, 1.0, 1.5 et 2.5 ml. Après avoir complété le volume à 2.5 ml avec le même solvant, on évapore à sec sous vide, on introduit 0.5 ml d'acide sulfurique concentré et on place les tubes dans un bain-marie à la température de 75 °C durant 15 min. Alors on ajoute 0.3 ml de diméthylsulfoxyde tout en refroidissant dans de l'eau glacée, et on porte de nouveau les tubes au bain-marie durant 15 min. Après refroidissement, on dilue par 0.2 ml d'eau bidistillée.

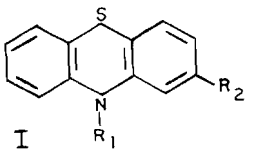
La solution de chaque spécimen présente alors, après 10 min de repos, une certaine fluorescence dont l'intensité est déterminée à l'aide du spectrophotofluoromètre Aminco. La gamme d'échantillons permet de repérer les longueurs d'onde optima et la limite du dosage, et d'élaborer une courbe de référence pour les déterminations subséquentes.

RÉSULTATS ET DISCUSSION

Tous les dérivés de la phénothiazine figurant aux Tableaux I et II, sauf la thiopropérazine (Majeptil), développent, en concentration suffisante, en présence d'acide sulfurique concentré, une réaction colorée dont l'intensité varie suivant les radicaux fixés sur le noyau. La limite de sensibilité de cette réaction colorimétrique est de l'ordre de 0.1 mg.

Toutes les substances étudiées développent, suivant les conditions énumérées plus haut, une fluorescence jaune verdâtre dont la longueur d'onde d'excitation et d'émission, pour l'obtention de l'intensité maximale de fluorescence, se situent respectivement à 350 et 500 mμ, sauf pour la trifluopérazine, la trifluopromazine et la fluphénazine, qui accusent un maximum d'intensité à 500 mμ lorsque l'excitation maximale s'effectue à 325 mμ. Le radical —CF_3 retenu en position R_2 par ces substances causerait cette variation. Une autre longueur d'onde d'excitation a été repérée, mais son intensité énergétique lumineuse semble altérer la structure chimique du dérivé obtenu, car l'intensité de la fluorescence diminue progressivement durant la lecture des déterminations. De façon

générale, les dérivés qui fournissent une coloration rouge ou violette en milieu sulfurique développent plus de fluorescence que ceux qui donnent une coloration jaune.



La limite de sensibilité de la fluorescence définie par Duggan et ses collaborateurs (4) s'établit à 10% de la déflection de l'échelle galvanométrique de l'appareil Aminco en utilisant une bande de $\frac{1}{16}$ de pouce; comme une bande de $\frac{1}{32}$ de pouce a été employée, nous l'avons fixée à 7%. Dans ces conditions, la limite de sensibilité varie, suivant les substances étudiées,[1] de 0.01 μg/ml à 0.06 μg/ml (Tableaux I et II, Figs. 1 et 2).

Si l'on compare les dérivés dont R_1 représente un radical aliphatique non cyclique (Tableau I et Fig. 1), on en déduit les constatations suivantes. Les deux substances de cette catégorie qui développent le maximum de fluorescence sont la promazine et la diéthazine dont R_1 désigne respectivement le radical $-CH_2CH_2CH_2N(CH_3)_2$ et $-CH_2CH_2N(C_2H_5)_2$, et R_2 désigne dans les deux cas l'atome d'hydrogène. La limite de fluorescence de ces composés s'établit à 0.02 μg/ml. Par contre, une substitution sur ces deux derniers radicaux par un groupement méthyle ou diméthylamino cause une diminution dans l'intensité de la fluorescence; en effet, la triméprazine, la prométhazine, la profénamine et l'aminopromazine illustrent bien ce fléchissement.

En outre, lorsque R_2 représente un radical ou un élément autre que l'hydrogène, l'intensité de la fluorescence diminue dans l'ordre $Cl < CF_3 < OCH_3 < SO_2N(CH_3)_2$.

‡A, B et X représentent des noyaux cycliques.

Les dérivés dont R_1 désigne un radical renfermant une chaîne aliphatique (Tableau II et Fig. 2) soudée à un noyau pipéridyle (II et III) ou pipérazinyle (IV) développent aussi de la fluorescence, et le noyau hétérocyclique ne semble pas influencer de façon appréciable son intensité. La prochlorpérazine produit, dans les conditions mentionnées plus haut, la substance la plus fluorescente de tous les composés étudiés. En effet, elle permet de détecter 0.01 μg/ml. Cependant, la substitution du radical $-CH_2CH_2OH$ au groupement CH_3 terminal soudé au noyau hétérocyclique de la prochlorpérazine donne un dérivé moins fluorescent, la perphénazine.

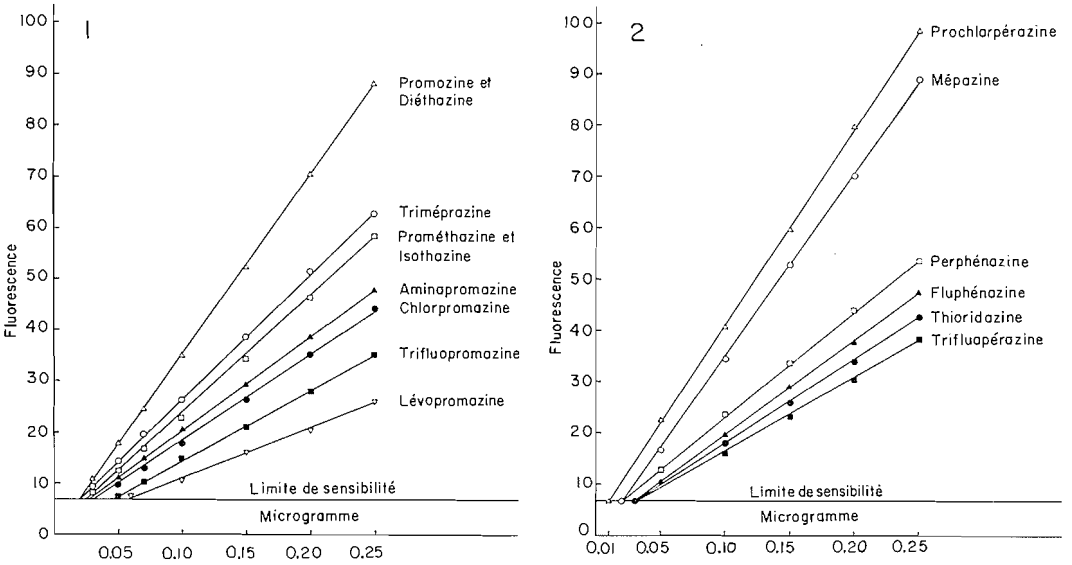

FIG. 1. Fluorescence des dérivés de la phénothiazine dont l'atome d'azote du noyau porte une chaîne aliphatique saturée.

FIG. 2. Fluorescence des dérivés de la phénothiazine dont l'atome d'azote du noyau porte une chaîne aliphatique saturée contenant un radical hétérocyclique.

For personal use only.

L'examen du Tableau II révèle, comme précédemment, que la substitution de l'atome d'hydrogène en position R_2 (I) par un autre élément ou un radical produit un effet d'extinction beaucoup plus marqué que celle effectuée, par différentes chaînes, sur l'atome d'azote du noyau de la phénothiazine. Quant au radical $—SO_2N(CH_3)_2$, son effet extinctif sur la fluorescence s'avère tellement intense qu'il relègue au second plan, le dosage fluorométrique des composés qui le portent. De plus, le radical $—SCH_3$ confère à la thioridazine une fluorescence fugitive qui oblige à effectuer le dosage durant les quinze minutes qui suivent la dilution aqueuse.

Ces expériences ne permettent pas de discuter la structure chimique du composé fluorescent obtenu. Cependant, l'oxydation du soufre du noyau de la phénothiazine ne semble pas donner une substance fluorescente. En effet, l'oxomémazine (R.P.) (dioxo-9,9 (diméthylamino-3 méthyl-2 propyl)-10 phénothiazine), qui ne diffère de la triméprazine (Tableau I) que par deux atomes d'oxygène, fixés sur le soufre du noyau, ne développe aucune fluorescence dans les conditions énumérées plus haut, ni dans les solvants ou réactifs utilisés. Il faut donc conclure que le composé fluorescent répond à une formule chimique différente.

La dilution par l'alcool et l'addition d'une quantité d'eau ou de diméthylsulfoxyde supérieure à celle qui a été mentionnée diminuent la fluorescence. De plus, l'exposition prolongée de 2 ou 3 min de la cellule aux rayons de la source lumineuse de l'appareil peut entraîner, dans certains cas, une diminution de la fluorescence.

Pour vérifier la précision de cette méthode de dosage, cinq échantillons de 5 ml de sérum additionnés de 100 μg de chlorpromazine ont été traités suivant la technique d'extraction élaborée par la compagnie Poulenc. La méthode nous a permis de retrouver en moyenne 91% de la substance ajoutée au sérum ; ce qui prouve que ce procédé analytique pourrait servir à déterminer ces substances médicamenteuses dans les liquides biologiques.

Ces résultats démontrent avec évidence que ces composés de la phénothiazine, à l'état pur, sauf le composé 8599 (R.P.) et la thiopropérazine, peuvent être dosés par méthode fluorométrique avec une sensibilité variant, suivant les substances, de 0.01 à 0.06 μg/ml.

REMERCIEMENTS

Ce travail a été réalisé grâce à un octroi du Conseil National de Recherches du Canada, que nous remercions sincèrement.

L'auteur désire exprimer sa reconnaissance aux compagnies pharmaceutiques suivantes, qui ont fourni gracieusement les substances utilisées dans ces expériences: Sandoz, Schering, Smith Kline & French, Squibb, Warner-Chilcott, Wyeth et Poulenc.

PREPARATION AND STEREOCHEMISTRY OF 1,2-*O*-(2′-HYDROXYETHYLIDENE)- AND 1,2-*O*-(HYDROXYISOPROPYLIDENE)-GLYCEROLS[1]

P. A. J. GORIN AND T. ISHIKAWA[2]

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received February 17, 1966

ABSTRACT

The *cis*- and *trans*-isomers of 1,2-*O*-(2′-hydroxyethylidene)-glycerol (I and II) and 1,2-*O*-(hydroxyisopropylidene)-glycerol (V and VI) were prepared and their configurations assigned by stereospecific chemical synthesis. Equilibration of 1,2-*O*-(2′-*cis*-hydroxyethylidene)-L-glycerol (I) in acidified chloroform gave mainly 1,3-*O*-(2′-*cis*-hydroxyethylidene)-glycerol (III). In the 1,2-*O*-(hydroxyisopropylidene)-glycerol series, equilibration data and infrared absorption studies showed that hydrogen bonding of the *O*-(hydroxyisopropylidene) hydroxyl group was more pronounced in the *cis*-isomers.

Starch polyalcohol, prepared by oxidation of starch with sodium periodate followed by reduction of the polyaldehyde with sodium borohydride, was treated with aqueous acid at 100°. An apparently stereospecific acetal migration resulted which gave 1,2-*O*-(2′-*cis*-hydroxyethylidene)-DL-erythritol (1). This compound has been characterized by oxidation with periodic acid followed by reduction with sodium borohydride to give 1,2-*O*-(2′-*cis*-hydroxyethylidene)-DL-glycerol (I), which has a nuclear magnetic resonance (n.m.r.) spectrum identical with that of the L-isomer (2) prepared from 1,6-anhydro-D-glucopyranose (1). Since acetal isomerization may have taken place during the above reactions, it was necessary to obtain the n.m.r. spectrum of 1,2-*O*-(2′-*trans*-hydroxyethylidene)-glycerol (II) for comparison purposes. This compound was prepared, as a minor product, by treating D′-methoxyhydroxymethyldiethylene glycol (3) at 100° in an aqueous solution adjusted to pH 2. The main product was shown by thin-layer chromatography (t.l.c.) on silica gel to be faster moving 1,2-*O*-(2′-*cis*-hydroxyethylidene)-glycerol (DL-isomer of I, 4.0% yield), and the mixture was fractionated by cellulose column chromatography to obtain the required slower moving minor component. The first fraction was characterized by conversion into 1,2-*O*-(2′-*cis*-hydroxyethylidene)-DL-glycerol bis-*p*-nitrobenzoate. The second fraction (DL-isomer of II, 1.3% yield) consisted of the *trans*-isomer contaminated with an unidentified material. Methylation of a small portion followed by acid hydrolysis gave a mixture shown to consist of 1- and 2-*O*-methyl glycerol in a 4:1 ratio by gas–liquid chromatography (g.l.c.) of their acetates. The contaminant, probably 1,3-*O*-(2′-hydroxyethylidene)-glycerol, could be removed by fractional crystallization of the derived *p*-nitrobenzoates, and the resulting *trans*-bis-*p*-nitrobenzoate was clearly distinguishable from the *cis*-isomer by its n.m.r. spectrum. The 1,2-*O*-(2′-hydroxyethylidene)-DL-glycerols obtained on saponification were similarly distinguishable.

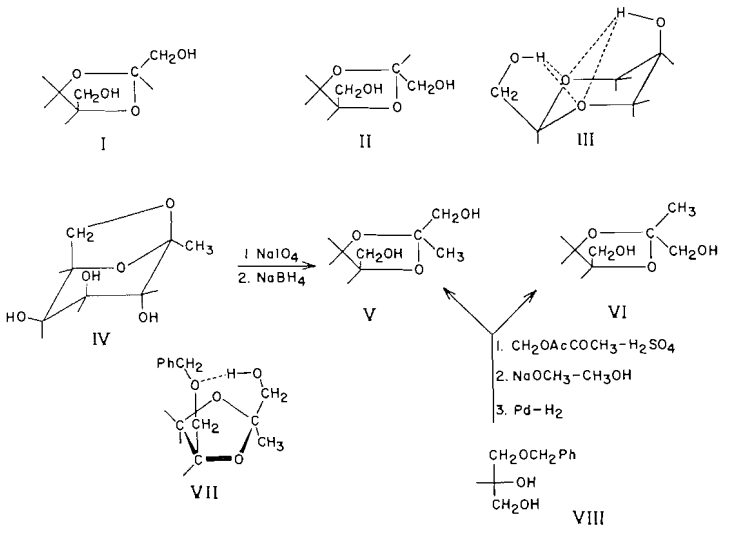
An alternative synthesis of 1,2-*O*-(2′-*trans*-hydroxyethylidene)-glycerol (II) was attempted by isomerization of 1,2-*O*-(2′-*cis*-hydroxyethylidene)-L-glycerol (I) in chloroform containing hydrogen chloride. Equilibration was readily followed by n.m.r. spectroscopy, since the C-1′ proton signals of the four isomeric *O*-(2′-hydroxyethylidene)-glycerol components in chloroform were distinguishable. At equilibrium the mixture contained, presumably in the DL-form, 1,2-*O*-(2′-*trans*-hydroxyethylidene)-glycerol (12%; triplet,

[1]*Issued as N.R.C. No. 9043.*
[2]*National Research Council Postdoctorate Fellow, 1964–1966.*

4.78 τ) and its *cis*-isomer (26%; triplet, 4.97 τ). Also formed were two 1,3-*O*-(2′-hydroxyethylidene)-glycerols, one in 55% yield (triplet, 5.68 τ) and the other in 7% yield (triplet, 6.05 τ). Cellulose column chromatography of the mixture only partially purified the major 1,3-*O*-isomer; a pure sample was obtained after fractional crystallization of its relatively insoluble bis-*p*-nitrobenzoate. Methylation followed by hydrolysis gave 2-*O*-methyl glycerol, as shown by g.l.c. of its diacetate.

No acetal migration or change in stereochemistry was observed on treatment of 1,2-*O*-(2′-*cis*-hydroxyethylidene)-L-glycerol at 100° in an aqueous solution at pH 2.

The isolated 1,3-*O*-(2′-hydroxyethylidene)-glycerol (III) should have the *cis*-configuration according to the results of Baggett and his co-workers (4), who showed that 1,3-*O*-*cis*-benzylidene glycerol was more stable than its *trans*-isomer in hot isopropanol and acetone containing aluminium isopropoxide. The stability of the *cis*-isomer was attributed to the observed hydrogen bonding, which was more general in the *cis*-isomer than in the *trans*-isomer. Similarly, the 1,3-*O*-*cis*-isomer is more stable than its *trans*-isomer in acidified chloroform. Nuclear magnetic resonance spectral evidence showed that equilibration of benzylidene glycerols gave the 1,3-*O*-*cis*-isomer (44%), the 1,3-*O*-*trans*-isomer (15%), and two 1,2-*O*-isomers in equal proportions (42% total). III produced infrared absorption (chloroform) at 3 600 cm^{-1}, which was consistent with the intramolecularly hydrogen bonded hydroxyl groups as depicted.



The equilibrium composition of *O*-(2′-hydroxyethylidene)-glycerols is in agreement with previous work carried out on the relative stabilities of cyclic glycerol acetals. There was no marked preference for the formation of either the five- or six-membered *O*-(2′-hydroxyethylidene) acetals, a result similar to the reaction of glycerol with trimethylacetaldehyde, which gave six- and five-membered acetals in a 2:3 ratio (5). Similarly, both five- and six-membered *O*-methylene glycerols were formed on condensation of formaldehyde with glycerol (6). In the five-membered series, Barker and his co-workers (7) have assigned configurations to isomeric 2,4-dimethyl-1,3-dioxolanes by comparing their boiling points, refractive indices, and stabilities, and by correlating these physical properties with those of known *cis*- and *trans*-1,3-dimethylcyclopentanes (8). *cis*-2,4-Dimethyl-1,3-dioxolane is more stable than the *trans*-isomer since they were formed in a ratio of 13:7, thus agreeing with the relative stabilities of 1,2-*O*-(2′-*cis*-hydroxyethylidene)-glycerol and its *trans*-isomer.

The preceding chemical proof of the stereochemistry of 1,2-*O*-(2′-hydroxyethylidene)-acetals of glycerol could be extended to the 1,2-*O*-(hydroxyisopropylidene)-ketals of glycerol (V and VI). These compounds have been obtained by saponification of the mixed 1,2-*O*-(acetoxyisopropylidene)-DL-glycerols, which Evlampiev prepared by condensation of acetoxyacetone with glycerol in the presence of acid (9). 1,2-*O*-(Hydroxyisopropylidene)-DL-glycerols were separated by cellulose chromatography and were converted into crystalline bis-*p*-nitrobenzoates.

The key compound in stereochemical assignments in the five-membered *O*-hydroxyisopropylidene series was 2,7-anhydro-1-deoxy-β-D-galactoheptulopyranose (IV), prepared by pyrolysis of 1-deoxy-D-galactoheptulose under reduced pressure. The anhydride, isolated as crystals in 0.5% yield by cellulose column chromatography, had carbon and hydrogen contents and a molecular weight which corresponded to the molecular formula $C_7H_{12}O_4$, and consumed 2 moles of sodium periodate with concomitant production of 1 mole of acid. On a preparative scale, the resulting dialdehyde was reduced with sodium borohydride to 1,2-*O*-(*cis*-hydroxyisopropylidene)-L-glycerol (V).

The two optically active, stereoisomeric 1,2-*O*-(hydroxyisopropylidene)-L-glycerols (V

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and VI) were prepared by condensation of acetoxyacetone and 1-*O*-benzyl-D-glycerol (VIII) with sulfuric acid as catalyst followed by saponification of the resulting mixture with sodium methoxide in methanol. 3-*O*-Benzyl-1,2-*O*-(*cis*-hydroxyisopropylidene)-L-glycerol and its *trans*-isomer were present in equal amounts, and had R_F 0.70 and 0.49, respectively, on silica gel t.l.c. The isomers were separated by silicic acid column chromatography. Hydrogenolysis of the isomers in the presence of palladium on barium sulfate gave syrupy 1,2-*O*-(hydroxyisopropylidene)-L-glycerols, which could be converted into their crystalline bis-*p*-nitrobenzoates. The bis-*p*-nitrobenzoate arising from the 3-*O*-benzyl-1,2-*O*-(hydroxyisopropylidene)-L-glycerol, with R_F 0.70, was identical with that prepared from 2,7-anhydro-1-deoxy-β-D-galactoheptulopyranose.

The n.m.r. spectra of 1,2-*O*-(*cis*-hydroxyisopropylidene)-L-glycerol (V) and its *trans*-isomer (VI) in deuterium oxide were virtually identical in that part of the spectrum attributable to the protons on C-1, C-2, and C-3, thus indicating conformational similarity. In chloroform, however, this part of the n.m.r. spectra was readily distinguishable, thus suggesting that the *cis*- and *trans*-stereoisomers are conformationally different in this solvent, likely because of hydrogen bonding. However, infrared studies on hydrogen bonding were hindered in this series, since assignment of OH absorptions to either of the two hydroxyl groups was difficult. Instead, the OH absorptions of 3-*O*-benzyl-1,2-*O*-(hydroxyisopropylidene)-L-glycerols were measured in 0.005 *M* solutions. The spectrum of the *trans*-isomer in carbon tetrachloride showed absorption at 3 625 cm^{-1}, a frequency shift ($\Delta\nu$) of 17 cm^{-1} from the value of 3 642 cm^{-1} expected for unbonded primary hydroxyl groups (10). The spectrum of the *cis*-isomer showed, in addition to a band at 3 616 cm^{-1} ($\Delta\nu$ 26 cm^{-1}), absorption at 3 480 cm^{-1} ($\Delta\nu$ 162 cm^{-1}), thus indicating strong hydrogen bonding. Similarly, the spectrum of the *trans*-isomer in chloroform solution showed absorption at 3 620 cm^{-1}, and that of the *cis*-isomer showed bands at 3 620 cm^{-1} and 3 480 cm^{-1}. The large spectral shift of the *cis*-isomer is comparable to those of long-range hydrogen bonds which occur in 1,4-diols ($\Delta\nu$ 100–200 cm^{-1}) (11) and which are caused by bonding between the two hydroxyl groups. In the *O*-*cis*-hydroxyisopropylidene derivative the hydroxyl group can form a bond with the oxygen atom of the *O*-benzyl group (VII), an association which is not sterically allowed in the *trans*-isomer. The weaker hydrogen bonds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

appear to be formed by chelation between the hydroxyl groups and the ring oxygens of the 1,3-dioxolane rings.

Hydrogen bonding appears to influence the equilibrium position of isomeric 3-*O*-benzyl-1,2-*O*-(hydroxyisopropylidene)-glycerols in chloroform containing hydrogen chloride. The ratio of *cis*- to *trans*-isomer, as determined by n.m.r. spectroscopy, was 57:43, whereas treatment of 1-*O*-benzyl-D-glycerol with acetoxyacetone in the presence of sulfuric acid gave equal amounts of 1,2-*O*-(*cis*-acetoxyisopropylidene)-3-*O*-benzyl-L-glycerol and its *trans*-isomer. Similar considerations probably govern the equilibration of 1,2-*O*-(hydroxyisopropylidene)-L-glycerols, which favors the *cis*- over the *trans*-isomer in the surprisingly high ratio of 2:1.

The n.m.r. spectra of various five-membered *O*-2′-hydroxyethylidene and *O*-hydroxyisopropylidene derivatives of glycerol have been examined. In general, protons in groups *cis* to the C-3 hydroxymethyl group gave signals at lower field than the corresponding proton(s) in the *trans*-position. This property is also true of *O*-ethylidene derivatives of glycerol and 1-*O*-benzyl-D-glycerol after assignment of signals to the *cis*- and *trans*-isomers. Brimacombe and his co-workers (12) have predicted that the reaction of acetaldehyde with 1-*O*-benzyl-D-glycerol would give mainly 3-*O*-benzyl-1,2-*O*-*cis*-ethylidene-L-glycerol and a smaller proportion of the *trans*-isomer, assignments which were later confirmed chemically by Triggle and Belleau (2). The n.m.r. spectrum of the 1,2-*O*-*cis*,*trans*-ethylidene-D-glycerols formed on hydrogenolysis contains predominant signals (63:37 ratio) at low field which should correspond to the *cis*-isomer.

EXPERIMENTAL

Specific rotations were measured at 25°. Nuclear magnetic resonance spectra were obtained on a Varian A-100 high-resolution spectrometer with tetramethylsilane as standard.

Preparation of 1,2-O-(2′-trans-Hydroxyethylidene)-DL-glycerol and its cis-Isomer from D′-Methoxyhydroxymethyldiethylene Glycol

An aqueous solution (100 ml) of D′-methoxyhydroxymethyldiethylene glycol prepared by successive treatments of methyl α-D-glucopyranoside with periodate and sodium borohydride (15 g (3)) was adjusted to pH 2 with hydrochloric acid and heated at 100° for 30 min. After neutralization (Ag_2CO_3) and filtration the solution was extracted continuously with chloroform for 3 days. The extract (2.1 g) was examined by t.l.c. on silica gel G (solvent: chloroform–methanol (9:1 v/v); spray: 50% sulfuric acid), and a spot with R_F 0.41 corresponding to 1,2-*O*-(2′-*cis*-hydroxyethylidene)-glycerol and a minor spot with R_F 0.33 were detected. The mixture was fractionated by cellulose column chromatography with benzene–ethanol–water (1000:50:1 v/v/v) as eluent. The component with R_F 0.41 (0.48 g) was eluted initially followed by a mixed fraction (0.10 g) and the component with R_F 0.33 (0.16 g). The initial fraction was converted into 1,2-*O*-(2′-*cis*-hydroxyethylidene)-DL-glycerol bis-*p*-nitrobenzoate, which had m.p. 97–98° and $[\alpha]_D$ 0° (*c*, 1.0 in $CHCl_3$) after two recrystallizations from ethyl acetate – *n*-hexane. Its n.m.r. spectrum was identical with that of an authentic specimen (1).

Anal. Calcd. for $C_{19}H_{16}O_{10}N_2$: C, 52.78; H, 3.73. Found: C, 52.7; H, 3.75.

A portion of the fraction with R_F 0.33 (10 mg) was methylated by refluxing it for 3 days in methyl iodide (5 ml) containing silver oxide. The product was hydrolyzed for 1 h in refluxing methanol (5 ml) containing water (1 ml) and *N* hydrochloric acid (0.1 ml). The solution was neutralized (Ag_2CO_3), filtered, and evaporated to a syrup which was acetylated at 100° in acetic anhydride containing sodium acetate. The reagent was destroyed in ice-cold aqueous sodium bicarbonate, and the resulting *O*-methyl glycerol diacetates were extracted with chloroform. These were examined by g.l.c., using 2% silicone nitrile gum XE-60 on Chromosorb W (80–100 mesh) in a 4 ft × ¼ inch (outside diameter) copper tube at 100°, helium (30 p.s.i.) as the carrier gas, and a g.l.c. apparatus of conventional design with thermal conductivity detectors. The product contained 1-*O*-methyl glycerol diacetate (retention time 9.7 min (80%)) and 2-*O*-methyl glycerol diacetate (retention time 12.0 min (20%)). A derivative of the major component of the fraction with R_F 0.33 (0.10 g) was obtained by conversion into 1,2-*O*-(2′-*trans*-hydroxyethylidene)-DL-glycerol bis-*p*-nitrobenzoate (96 mg), which had m.p. 116–117° and $[\alpha]_D$ 0° (*c*, 1.0 in $CHCl_3$) after two recrystallizations from ethyl acetate – *n*-hexane.

Anal. Calcd. for $C_{19}H_{16}O_{10}N_2$: C, 52.78; H, 3.73. Found: C, 52.9; H, 3.85.

Methylation of the deesterified product followed by hydrolysis gave 1-*O*-methyl glycerol, as shown by g.l.c. of its diacetate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The bis-*p*-nitrobenzoates of 1,2-*O*-(2′-*trans*-hydroxyethylidene)-DL-glycerol and its *cis*-isomer were examined by n.m.r. spectroscopy in chloroform. Each specimen contained a C-1′ proton triplet (*cis*-isomer: 4.72 τ, J 2.0 c.p.s.; *trans*-isomer: 4.55 τ, J 1.8 c.p.s.) and a C-2′ CH_2 doublet (*cis*-isomer: 5.54 τ; *trans*-isomer: 5.58 τ). The derived 1,2-*O*-(2′-*cis*-hydroxyethylidene)-glycerol and its *trans*-isomer in D_2O gave C-1′ proton triplets (*cis*-isomer: 4.51 τ, J 1.7 c.p.s.; *trans*-isomer: 4.44 τ, J 1.7 c.p.s.) and C-2′ CH_2 doublets (*cis*-isomer: 5.86 τ; *trans*-isomer: 5.93 τ). All τ values for multiple signals refer to the average τ value.

Equilibration of O-(2′-Hydroxyethylidene)-glycerols

A solution of 1,2-*O*-(2′-*cis*-hydroxyethylidene)-L-glycerol (50 mg) in chloroform (1 ml), adjusted to 0.1 *N* with hydrogen chloride, was examined at intervals by n.m.r. spectroscopy. In addition to the triplet corresponding to starting material, three new triplets appeared, one of them corresponding to 1,2-*O*-(2′-*trans*-hydroxyethylidene)-glycerol. The equilibration was virtually complete after 4 h, and at 24 h the mixture contained the *cis*-1,2-isomer (26%; 4.97 τ, J 2.5 c.p.s.), the *trans*-1,2-isomer (12%; 4.78 τ, J 3.5 c.p.s.), and two other isomers (55%; 5.68 τ, J 3.6 c.p.s., and 7%; 6.05 τ, J 4.0 c.p.s.).

The equilibration products obtained from 0.60 g of the *cis*-1,2-*O*-isomer were chromatographed on a cellulose column with benzene–ethanol–water (1000:50:1 v/v/v) as eluent, and the separation was followed by t.l.c. on silica gel G. The first fraction contained the *cis*-1,2-*O*-isomer as the main component, and the second fraction contained every component except the *cis*-1,2-*O*-isomer. The first fraction was converted into mixed bis-*p*-nitrobenzoates which, after three recrystallizations from ethyl acetate, gave 1,3-*O*-(2′-hydroxyethylidene)-glycerol bis-*p*-nitrobenzoate, with m.p. 179–181° and $[\alpha]_D$ 0° (*c*, 1.0 in $CHCl_3$).

Anal. Calcd. for $C_{19}H_{16}O_{10}N_2$: C, 52.78; H, 3.73. Found: C, 52.7; H, 3.7.

(The infrared spectrum of a 0.005 *M* solution of the derived diol in chloroform showed absorption at 3 600 cm^{-1}. Under these conditions the infrared spectrum of cyclohexanol showed absorption at 3 630 cm^{-1}, and that of *n*-butyl alcohol showed absorption at 3 642 cm^{-1}.) Its n.m.r. spectrum in $CHCl_3$ contained a C-1′ proton triplet (4.96 τ, J 3.2 c.p.s.), a C-2′ CH_2 doublet (5.56 τ), and complex signals at 5.09 τ corresponding to the C-2 proton. The free diol in D_2O gave a triplet (4.78 τ, J 2.1 c.p.s.) coupled to a doublet (5.99 τ). Methylation of the free diol followed by hydrolysis gave 2-*O*-methyl glycerol, as shown by g.l.c. of its diacetate.

Equilibration of O-Benzylidene Glycerols

Equilibration of 1,3-*O*-*cis*-benzylidene glycerol under conditions similar to those described above gave four isomers. Nuclear magnetic resonance spectroscopic examination of the chloroform solution revealed *O*-benzylidene ring proton signals at 4.10 τ and 4.23 τ (1,2-*O*-isomers, 21% each), 4.50 τ (1,3-*O*-*cis*-isomer, 44%), and 4.66 τ (1,3-*O*-*trans*-isomer, 15%).

Condensation of Acetoxyacetone with Glycerol

Glycerol (0.50 ml) was shaken for 4 h in acetoxyacetone (13) (10 ml) containing sulfuric acid (0.1 ml). The solution was neutralized ($BaCO_3$), filtered, and evaporated to a syrup (0.89 g) which was deacetylated with 0.1 *N* sodium methoxide (3 ml). The product was fractionated on a cellulose column with benzene–ethanol–water (1000:50:1 v/v/v) as eluent. The eluate was examined by t.l.c. on silica gel (solvent: chloroform–methanol (9:1 v/v)). The first fraction contained components with R_F 0.61 and 0.63 (0.49 g); the former, which was 1,2-*O*-(*cis*-hydroxyisopropylidene)-DL-glycerol, was isolated as its bis-*p*-nitrobenzoate, which had m.p. 125–127° after crystallization from ethyl acetate – *n*-hexane.

Anal. Calcd. for $C_{20}H_{18}O_{10}N_2$: C, 53.81; H, 4.06. Found: C, 53.6; H, 4.2.

The second fraction (0.15 g), R_F 0.50, contained 1,2-*O*-(*trans*-hydroxyisopropylidene)-DL-glycerol, which was converted into its bis-*p*-nitrobenzoate, m.p. 125–127° after crystallization from ethyl acetate – *n*-hexane.

Anal. Calcd. for $C_{20}H_{18}O_{10}N_2$: C, 53.81; H, 4.06. Found: C, 54.0; H, 4.3.

The above structures were assigned since their n.m.r. spectra were respectively identical with those of 1,2-*O*-(*cis*-hydroxyisopropylidene)-L-glycerol bis-*p*-nitrobenzoate and its *trans*-isomer.

Preparation of 2,7-Anhydro-1-deoxy-β-D-galactoheptulopyranose and 1,2-O-(cis-Hydroxyisopropylidene)-L-glycerol

1-Deoxy-*keto*-D-galactoheptulose pentaacetate (14) was deacetylated in methanolic sodium methoxide, and the solution was evaporated and deionized in water containing approximately equal amounts of Amberlite IR-120 and Dowex-1. The resulting syrupy 1-deoxy-D-galactoheptulose (11.8 g) was heated in a small tube for 2–3 h at 300–350° and a pressure of <0.1 mm (15). The amber-colored distillate (0.60 g) was fractionated on a cellulose column with benzene–ethanol–water (400:50:1 v/v/v) as solvent. A crystalline fraction was obtained which, after two recrystallizations from ethyl acetate – ether, gave 2,7-anhydro-1-deoxy-β-D-galactoheptulopyranose (60 mg), m.p. 124–127°, $[\alpha]_D$ −25° (*c*, 1 in EtOH), $[\alpha]_D$ −26.5° (*c*, 1 in H_2O).

Anal. Calcd. for $C_7H_{12}O_5$: C, 47.72; H, 6.87; mol. wt. 176. Found: C, 47.7; H, 6.8; mol. wt. (in H_2O) 175.

Oxidation with sodium periodate for 24 h resulted in consumption of 2.03 moles of oxidant and formation of 0.98 mole of acid.

The anhydride (40 mg) was oxidized for 20 h in sodium periodate (200 mg) and water (5 ml), and the solution was adjusted to pH 7 with sodium carbonate and evaporated. The residue was extracted with acetone and the syrupy extract was treated with sodium borohydride (0.20 g) in a few milliliters of water for 2 h. The pH was adjusted to 8 and the solution was extracted continuously with chloroform to give a syrup

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

which contained a little boric acid. Repeated evaporations in methanol gave 1,2-*O*-(*cis*-hydroxyisopropylidene)-L-glycerol (31 mg). Its bis-*p*-nitrobenzoate derivative had m.p. 139–141° and $[\alpha]_D$ −42° (*c*, 2.0 in $CHCl_3$) after crystallization from ethyl acetate – *n*-hexane.

Anal. Calcd. for $C_{20}H_{18}O_{10}N_2$: C, 53.81; H, 4.06; N, 6.27. Found: C, 53.6; H, 4.1; N, 6.2.

Condensation of 1-O-Benzyl-D-glycerol with Acetoxyacetone

1-*O*-Benzyl-D-glycerol was prepared from 1,2-*O*-isopropylidene-D-glycerol by the method of Schmidt and Blank (16), who worked on the corresponding racemates. 1-*O*-Benzyl-D-glycerol (2.0 g) was treated with acetoxyacetone (20 ml) and sulfuric acid (0.1 ml) for 4 h, and the reaction mixture was added to aqueous sodium bicarbonate. Extraction with chloroform and evaporation with heat *in vacuo* gave a mixture of 1,2-*O*-(*cis*-acetoxyisopropylidene)-3-*O*-benzyl-L-glycerol and its *trans*-isomer, which was treated for 2 h in 0.1 *N* sodium methoxide in methanol (5 ml). The deacetylated mixture was examined by t.l.c. on silica gel with chloroform as solvent, and spots with R_F 0.49 and 0.70 were detected. The 3-*O*-benzyl-1,2-*O*-(hydroxyisopropylidene)-glycerols in chloroform gave a n.m.r. spectrum showing C—CH_3 proton signals at 8.66 τ and 8.72 τ in a ratio of 1:1.

The mixture was chromatographed on a silicic acid column with hexane–chloroform (3:2 v/v) as solvent, and the syrupy *cis*-isomer (0.75 g) with R_F 0.70 was isolated. It had a C—CH_3 proton signal at 8.72 τ, $[\alpha]_D$ +10° (*c*, 2.0 in EtOH), and infrared absorptions at 3 616 and 3 480 cm^{-1} (0.005 *M* in CCl_4) and at 3 620 and 3 480 cm^{-1} (0.005 *M* in $CHCl_3$). These frequencies were unchanged after hydrogen chloride was bubbled into the CCl_4 and $CHCl_3$ solutions.

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61. Found: C, 65.3; H, 7.4.

After a mixed fraction (0.48 g) was eluted, the syrupy *trans*-isomer (0.90 g) with R_F 0.49 appeared. It had a C—CH_3 proton signal at 8.66 τ, $[\alpha]_D$ +13° (*c*, 2.0 in EtOH), and infrared absorption at 3 625 cm^{-1} (0.005 *M* in CCl_4) and at 3 620 cm^{-1} (0.005 *M* in $CHCl_3$). These frequencies were also unchanged after hydrogen chloride was bubbled into the solutions.

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61. Found: C, 65.15; H, 7.55.

Hydrogenolysis Products of 3-O-Benzyl-1,2-O-(hydroxyisopropylidene)-L-glycerols

These were hydrogenolyzed over palladium – barium sulfate according to the method of Mozingo (17). The *cis*-isomer gave rise to syrupy 1,2-*O*-(*cis*-hydroxyisopropylidene)-L-glycerol, with $[\alpha]_D$ +9° (*c*, 1.3 in EtOH) and R_F 0.61 on t.l.c. (solvent: chloroform–methanol (9:1 v/v)). Its n.m.r. spectrum in D_2O was identical with that of an authentic specimen obtained from 2,7-anhydro-1-deoxy-β-D-galactoheptulopyranose. The derived bis-*p*-nitrobenzoate, crystallized twice from ethyl acetate – *n*-hexane, had m.p. and mixed m.p. 138–139° and $[\alpha]_D$ −36° (*c*, 1.8 in $CHCl_3$), and gave a X-ray diffraction pattern identical with that of an authentic specimen. Its n.m.r. spectrum was identical with that of authentic material, with a C—CH_3 signal in chloroform at 8.52 τ.

Anal. Calcd. for $C_{20}H_{18}O_{10}N_2$: C, 53.81; H, 4.06. Found: C, 54.0; H, 4.0.

The *trans*-isomer gave rise to syrupy 1,2-*O*-(*trans*-hydroxyisopropylidene)-L-glycerol, with $[\alpha]_D$ +17° (*c*, 1.3 in EtOH) and R_F 0.50 on t.l.c. Its bis-*p*-nitrobenzoate, after two recrystallizations from ethyl acetate – *n*-hexane, had m.p. 85–86° and $[\alpha]_D$ +15° (*c*, 2.0 in $CHCl_3$).

Anal. Calcd. for $C_{20}H_{18}O_{10}N_2$: C, 53.81; H, 4.06. Found: C, 53.6; H, 4.25.

Its n.m.r. spectrum in $CHCl_3$ contained a C—CH_3 signal at 8.47 τ. The n.m.r. spectrum of 1,2-*O*-(*cis*-hydroxyisopropylidene)-L-glycerol in D_2O contained a C—CH_3 signal at 8.22 τ and a hydroxyisopropylidene CH_2 signal at 6.02 τ. The *trans*-isomer had a C—CH_3 signal at 8.18 τ and a hydroxyisopropylidene CH_2 signal at 6.06 τ.

Equilibration of 1,2-O-(Hydroxyisopropylidene)-L-glycerol and 3-O-Benzyl-1,2-O-(hydroxyisopropylidene)-L-glycerols

A solution of 1,2-*O*-(*cis*-hydroxyisopropylidene)-L-glycerol (50 mg) in chloroform (1 ml), adjusted to 0.1 *N* with hydrogen chloride, was examined by n.m.r. spectroscopy at intervals. The C—CH_3 proton signals showed that, at equilibrium (1 day), the *cis*- and *trans*-isomers were present in a ratio of 2:1 (8.22 τ and 8.18 τ, respectively, in D_2O).

Under similar conditions equilibration of the 3-*O*-benzyl derivatives resulted in a ratio of *cis*- to *trans*-isomer of 57:43 (C—CH_3 signals at 8.72 τ and 8.66 τ, respectively).

Nuclear Magnetic Resonance Spectra of 1,2-O-cis,trans-Ethylidene-L-glycerol and its 3-O-Benzyl Derivative

In chloroform, 3-*O*-benzyl-1,2-*O*-*cis*,*trans*-ethylidene-L-glycerol gave two superimposed C-1′ proton quadruplets, the larger at higher field at approximately 5.02 τ and the minor component at approximately 4.98 τ. Doublets from C-2′ methyl protons appeared at 8.63 τ (average value; *J* 2.4 c.p.s., major signal) and at 8.68 τ (*J* 2.4 c.p.s.).

In deuterium oxide, 1,2-*O*-*cis*,*trans*-ethylidene-L-glycerol gave two C-1′ proton quadruplet signals, one at 4.33, 4.37, 4.43, and 4.47 τ (37%) and the other at 4.42, 4.47, 4.52, and 4.5 τ (63%). Doublets corresponding to the C-2′ methyl protons appeared at 8.16 τ (average value; *J* 2.2 c.p.s., major signal) and at 8.20 τ (average value; *J* 2.2 c.p.s.).

THE SYNTHESIS OF SOME 6,7-METHYLENEDIOXY- AND 6,7-DIMETHOXY-1,4-BENZOXAZIN-2-ONES[1]

D. G. Orphanos and A. Taurins
Department of Chemistry, McGill University, Montreal, Quebec
Received February 22, 1966

ABSTRACT

3,4-Methylenedioxy-6-aminophenol (I) and 3,4-dimethoxy-6-aminophenol (IV) were condensed with various α-ketoesters to give the corresponding 6,7-methylenedioxy- and 6,7-dimethoxy-1,4-benzoxazin-2-ones.

Wislicenus and his co-workers (1, 2) discovered that *o*-aminophenols reacted with α-ketoesters to give the ring system of 1,4-benzoxazin-2-ones. Biekert *et al.* (3) investigated the scope of this reaction by varying both components. The objective of our work was the extension of this reaction to *o*-aminophenols containing either a methylenedioxy group or two ortho dimethoxy groups, to synthesize 1,4-benzoxazin-2-ones carrying these substituents on the benzenoid ring.

The synthesis was accomplished by the condensation of 3,4-methylenedioxy-6-aminophenol (I) (4) and 3,4-dimethoxy-6-aminophenol (IV) (4) with a number of α-ketoesters. A general reaction scheme illustrating the synthesis of 6,7-methylenedioxy- and 6,7-dimethoxy-1,4-benzoxazin-2-ones is given in Reaction Scheme 1. The structures of the products III*a*–III*e* and V*a*–V*e* were assigned on the basis of analogy, analytical data, and infrared spectra.

The starting materials I and IV were prepared readily by catalytic reduction of the corresponding nitrophenols (4). The 6-aminophenols I and IV, being extremely sensitive to oxidation, were filtered under a nitrogen atmosphere into a glacial acetic acid solution of the appropriate α-ketoester, and converted directly into the stable 1,4-benzoxazin-2-ones. Although the condensation of *o*-aminophenols with α-ketoesters proceeds at a slow rate in the absence of acids, in most cases it is speeded up by the presence of glacial acetic acid. However, the synthesis of 6,7-methylenedioxy- and 6,7-dimethoxy-1,4-benzoxazin-2-ones possessing methyl or phenyl substituents in the 3-position could not be accomplished without the presence of glacial acetic acid in the reacting mixture.

6,7-Methylenedioxy-1,4-benzoxazin-2-ones were obtained in high yields in an almost pure state, at temperatures ranging from room temperature to 60°, and a reaction time of 1 to 6 h. On the other hand, the preparation of all 6,7-dimethoxy-1,4-benzoxazin-2-ones required heating at 70° for a long period of time, and considerable amounts of dark decomposition products were formed, which could be removed only with difficulty. All the dialkoxybenzoxazinones that were prepared were highly colored. The nature of the substituent in the 3-position appears to be responsible for the color. Substitution of a phenyl group in the 3-position causes the substances, in acetone, to show a strong blue-green fluorescence. This effect, but with less intensity, is also observed when these compounds are dissolved in several other polar and inert solvents.

Catalytic hydrogenation of benzoxazin-2-ones to give 2-phenomorpholones has been reported to occur at a pressure of 50 atm (5). In this work, a much lower hydrogen pressure (0.2 atm) was used and the 6,7-substituted 2-phenomorpholone derivatives VI*a*, VI*b*,

VII	6,7-Dimethoxy-3-phenyl-2-phenomorpholone	$C_{16}H_{15}NO_4$, 116–117°, white needles	90	67.35	5.30	4.91	67.17	5.23	5.15	3 335 1 748

for a certain length of time (refer to Table I), with occasional shaking. Heat was not applied unless noted in the table. The crystalline product was isolated by filtration and purified as outlined in Table I. By this general procedure, the following five methylenedioxybenzoxazinones were prepared and characterized: III*a*, 6,7-methylenedioxy-3-methyl-1,4-benzoxazin-2-one; III*b*, 6,7-methylenedioxy-3-phenyl-1,4-benzoxazin-2-one; III*c*, 6,7-methylenedioxy-1,4-benzoxazin-2-one-3-acetic acid ethyl ester; III*d*, 6,7-methylenedioxy-3-acetonyl-1,4-benzoxazin-2-one; and III*e*, 6,7-methylenedioxy-3-phenacyl-1,4-benzoxazin-2-one.

Condensation of α-Ketoesters with 3,4-Dimethoxy-6-aminophenol (IV)

At room temperature and in a nitrogen atmosphere, a methoxyethylene glycol solution of IV (0.01 mole) was added to a solution of α-ketoester (10% excess) in glacial acetic acid. The reaction mixture was heated at 65–70° for 12 h, with occasional shaking. The deep-orange reaction solution was concentrated under reduced pressure to one-half its volume, and then refrigerated for 2–3 h. The solid product was collected and purified (refer to Table II). By this method, the following five dimethoxybenzoxazinones were prepared and characterized: V*a*, 6,7-dimethoxy-3-methyl-1,4-benzoxazin-2-one; V*b*, 6,7-dimethoxy-3-phenyl-1,4-benzoxazin-2-one; V*c*, 6,7-dimethoxy-1,4-benzoxazin-2-one-3-acetic acid ethyl ester; V*d*, 6,7-dimethoxy-3-acetonyl-1,4-benzoxazin-2-one; and V*e*, 6,7-dimethoxy-3-phenacyl-1,4-benzoxazin-2-one.

Preparation of 6,7-Methylenedioxy-2-phenomorpholones (VI)

A suspension of 6,7-methylenedioxy-3-R-1,4-benzoxazin-2-one (R = CH_3, $CH_2COOC_2H_5$, or C_6H_5) (0.5 g) in absolute ethanol (50 ml) was hydrogenated for 30 min at room temperature and 0.3 atm pressure with 10% palladium on charcoal (0.05 g) as a catalyst. Removal of the catalyst by filtration in a nitrogen atmosphere gave a colorless solution, which was then concentrated to one-quarter its volume under reduced pressure at room temperature. White crystalline material separated from the residual solution. The mixture was cooled in an ice-water bath and filtered in a nitrogen atmosphere. The white crystalline product was washed with 5 ml of light petroleum ether and dried *in vacuo*. The melting points of the individual compounds were not improved after recrystallization from benzene. These substances, on contact with air, slowly dehydrogenated to their parent 6,7-methylenedioxy-1,4-benzoxazinones; in glacial acetic acid solution the same reaction occurred in a few hours. The methylenedioxyphenomorpholones obtained are recorded in Table III.

6,7-Dimethoxy-3-phenyl-2-phenomorpholone (VII)

6,7-Dimethoxy-3-phenyl-1,4-benzoxazin-2-one (V*b*) (0.5 g) was hydrogenated to VII by a procedure similar to that used for the reduction of the analogous methylenedioxy compounds. The method of isolation and the physical and chemical properties of VII are comparable to those of VI (Table III).

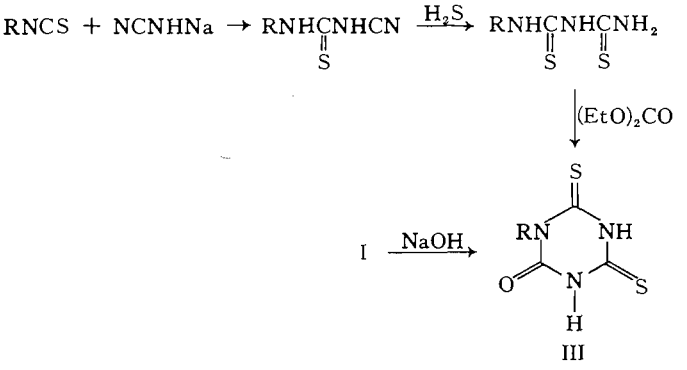
DERIVATIVES OF ISOTRITHIOCYANURIC ACID

D. L. GARMAISE
Research Department, Abbott Laboratories Limited, Montreal, Quebec
Received March 31, 1966

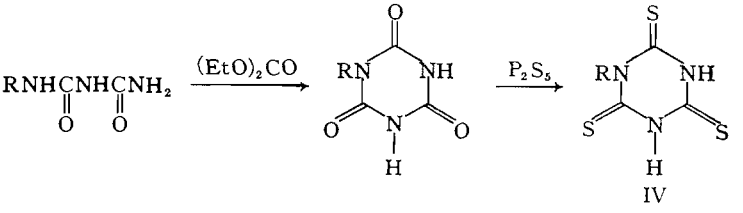
ABSTRACT

A by-product isolated in low yield from the reaction of *p*-chlorobenzyl chloride with potassium thiocyanate and sodium iodide in dimethylformamide was shown to be the isotrithiocyanuric acid derivative I (R = *p*-chlorobenzyl). I gave the isodithiocyanuric acid ester (III) on alkaline hydrolysis, and mono-*p*-chlorobenzyl isotrithiocyanurate (IV) on reduction with sodium hydrosulfite. Treatment of I with sodium hypochlorite in aqueous alcoholic medium resulted in the direct replacement of the sulfhydryl group by an alkoxyl group. The *N,S,S*-triester VIII rearranged, on heating, to the symmetrical *S,S,S*-triester IX; this behavior is opposite to that shown by the oxygen analogues.

During the preparation of *p*-chlorobenzyl isothiocyanate by treatment of *p*-chlorobenzyl chloride with potassium thiocyanate and sodium iodide in dimethylformamide at 150° for 30 min, a mixture of two crystalline by-products separated out in low yield. The major component, which was isolated by extracting the mixture with alcoholic sodium hydroxide and acidifying the alcoholic extract, was a pale-yellow solid with the formula $C_{17}H_{13}Cl_2N_3S_4$. Evidence obtained during this work has led to the assignment of structure I (1-(*p*-chlorobenzyl)-6-(*p*-chlorobenzyldithio)-*s*-triazine-2,4(1*H*,3*H*)-dithione) to this substance. The minor component, which was insoluble in alcoholic sodium hydroxide solution, was an orange-colored substance with the formula $C_{16}H_{12}Cl_2N_2S_4$. When the reaction temperature was maintained at 150° for 3 h instead of 30 min, apparent interaction with dimethylformamide led to the disappearance of I, and a neutral compound (II), which is presumed to have one of the isomeric structures indicated, was isolated.



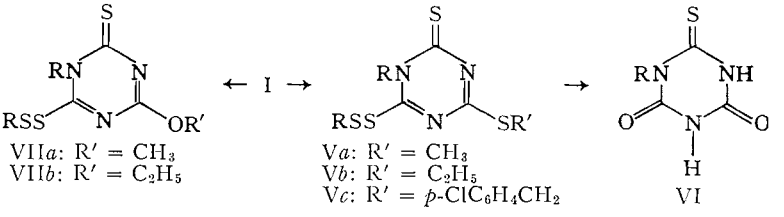
R = *p*-chlorobenzyl throughout



Alkaline hydrolysis of I resulted in the loss of the 4-chlorobenzyldithio group, and the formation of an acidic substance (III) with the formula $C_{10}H_8ClN_3OS_2$. III was shown to be 1-(*p*-chlorobenzyl)-2,4-dithio-*s*-triazine-2,4,6(1*H*,3*H*,5*H*)-trione by synthesis from 1-*p*-chlorobenzyldithiobiuret and diethyl carbonate. The dithiobiuret was prepared by adding *p*-chlorobenzyl isothiocyanate to sodium cyanamide followed by hydrogen sulfide (1).

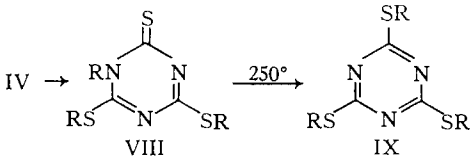
Reduction of I with sodium hydrosulfite in alkaline medium yielded *p*-chloro-α-toluenethiol (isolated as the disulfide) and 1-(*p*-chlorobenzyl)-*s*-triazine-2,4,6(1*H*,3*H*,5*H*)-trithione (IV), along with some III arising from alkaline hydrolysis of I.

The structure of compound IV, which appears to be the first monoester of isotrithiocyanuric acid to have been described, was confirmed by direct synthesis. 1-*p*-Chlorobenzylbiuret was treated with diethyl carbonate (2) to give mono-*p*-chlorobenzyl isocyanurate.



The isocyanurate was not affected by treatment with phosphorus pentasulfide in refluxing pyridine, but fusion with the reagent at 265 °C gave IV in 51% yield.

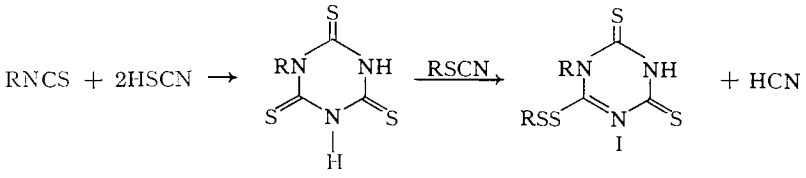
I was readily alkylated in alkaline alcoholic medium to give the neutral esters V*a*–V*c*. When the methyl ester V*a* was treated with hot concentrated sodium hydroxide solution, both the 4-thio and 6-dithio substituents were hydrolyzed, and 1-(*p*-chlorobenzyl)-2-thio-*s*-triazine-2,4,6(1*H*,3*H*,5*H*)-trione (VI) was obtained.



Treatment of I with sodium hypochlorite in aqueous methanol caused the direct replacement of the sulfhydryl group by methoxyl to give VII*a* in good yield; the ethoxy derivative VII*b* was obtained in lower yield by performing the reaction in aqueous ethanol. This rather unexpected replacement reaction is presumed to proceed via the chloro derivative as an intermediate, and its possible application to other thiols is being investigated.

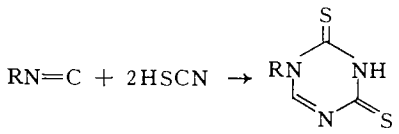
The mixed triester VIII (m.p. 171°), which was prepared by the esterification of IV, rearranged, on heating, to the symmetrical tri-*p*-chlorobenzyl trithiocyanurate (IX), m.p. 122°. The direction of the rearrangement is in interesting contrast to the behavior of the oxygen analogues, since alkyl and aralkyl cyanurates rearrange, on heating, to the isocyanuric acid esters (3, pp. 398–421). The difference in behavior between the thioxo and oxo analogues is consistent with the relative instability of doubly bound sulfur as compared with doubly bound oxygen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



The ultraviolet spectrum of VIII (λ_{max} 288 and 330 mμ) showed peaks at higher wavelengths than that of the normal ester IX (λ_{max} 263 mμ). A similar though smaller difference was observed with mono-*p*-chlorobenzyl isotrithiocyanurate (IV) (λ_{max} 292 mμ) and mono-*p*-chlorobenzyl trithiocyanurate (XII) (λ_{max} 280 mμ).

VIII IX

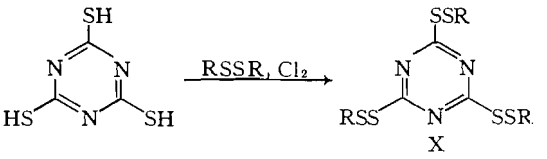


Relatively few derivatives of isotrithiocyanuric acid have been described. Alkyl and aralkyl thiocyanates have long been known to trimerize readily to the normal trithiocyanurates (3, p. 111), but little has been reported on the comparable trimerization of isothiocyanates. In a recent publication (4) it was stated that heating methyl isothiocyanate at 200° in dioxane gave 1,3,5-trimethyl dithioisocyanurate, but the corresponding isotrithiocyanurate has never been described. With respect to monoesters of isotrithiocyanuric acid, no examples could be found in the literature.

The reaction mixture from which I was isolated contains, among other components, *p*-chlorobenzyl isothiocyanate, *p*-chlorobenzyl thiocyanate, and excess thiocyanate ion. The initial reaction in the sequence leading to the formation of I may be the condensation of *p*-chlorobenzyl isothiocyanate with thiocyanic acid to give mono-*p*-chlorobenzyl isotrithiocyanurate (IV), followed by condensation with *p*-chlorobenzyl thiocyanate with the elimination of hydrogen cyanide.

IV I

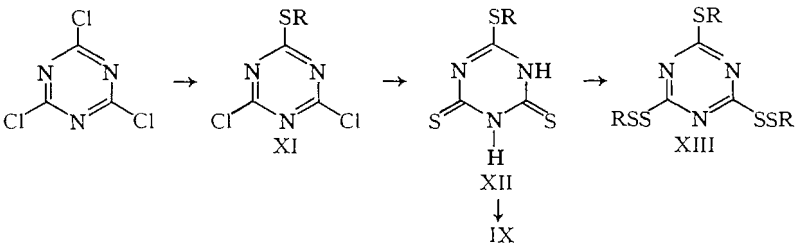
The suggested cyclization reaction is similar to the recently described condensation of isonitriles with thiocyanic acid to give 1-substituted-*s*-triazine-2,4(1*H*,3*H*)-dithiones (5).



These condensations are stated to occur readily at −20 °C in ether solution, giving the triazine-2,4-dithiones in high yield.

The reaction between thiols and thiocyanates to give disulfides, with the elimination of hydrogen cyanide, has been studied by several investigators (6, 7). This reaction is distinguished from the standard preparation of disulfides by the alkaline hydrolysis of thiocyanates to thiols followed by air oxidation, since it was shown to proceed in a nitrogen atmosphere. Thus, heating *p*-chlorothiophenol and *p*-chlorophenyl thiocyanate at 100° in nitrogen gave a nearly quantitative yield of the disulfide in 8 h.

For purposes of comparison with the isotrithiocyanurate I and its derivatives, a number of derivatives of trithiocyanuric acid with *p*-chlorobenzylthio and *p*-chlorobenzyldithio

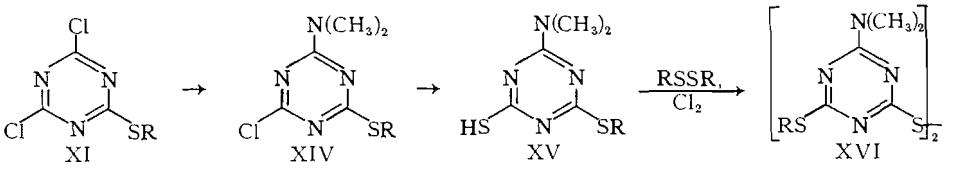


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

substituents were synthesized. Some tri(alkyldithio)-*s*-triazines have been prepared (8) by treating alkanethiols with excess chlorine to give the alkylsulfenyl chlorides, which were then allowed to react with trithiocyanuric acid. This procedure did not work with *p*-chloro-α-toluenethiol, but it was found that addition of the calculated amount of chlorine to bis-(*p*-chlorobenzyl) disulfide and trithiocyanuric acid gave 2,4,6-tri-(*p*-chlorobenzyldithio)-*s*-triazine (X) in fair yield.

X

Cyanuric chloride was converted into 2-(*p*-chlorobenzylthio)-4,6-dichloro-*s*-triazine (XI) by treatment with *p*-chloro-α-toluenethiol in the presence of lutidine at −40° by the method of Koopman *et al.* (9).



XI XII XIII

↓

IX

Reaction of XI with sodium hydrosulfide gave mono-(*p*-chlorobenzyl) trithiocyanurate (XII). This monoester melted at a higher temperature than its isomer IV, but was considerably more soluble in ether and ethanol. It was readily esterified to the symmetrical triester (IX) (which could also be prepared from cyanuric chloride and *p*-chloro-α-toluenethiol). Treatment of XII with bis-(*p*-chlorobenzyl) disulfide and chlorine gave the di-disulfide (XIII).

XI XIV XV XVI

In an attempt to prepare a compound containing both a *p*-chlorobenzyldithio and a dimethylamino substituent, as in the by-product II, the dichloro derivative (XI) was first treated with dimethylamine to give XIV, and the remaining chlorine was replaced by a sulfhydryl group to yield the monothiol XV. The reaction of XV with bis-(*p*-chlorobenzyl) disulfide and chlorine, however, yielded the bis-(triazinyl) disulfide (XVI) instead of the desired *p*-chlorobenzyldithio derivative.

EXPERIMENTAL

All melting points are uncorrected. Analytical data were supplied by Dr. C. Daessle, Montreal, Quebec, and by the Microanalytical Department, Abbott Laboratories, North Chicago, Illinois.

1-(p-Chlorobenzyl)-6-(p-chlorobenzyldithio)-s-triazine-2,4(1H,3H)-dithione (I)

p-Chlorobenzyl chloride (500 g, 3.1 moles) was added to a solution of potassium thiocyanate (330 g, 3.4 moles) and sodium iodide (23 g, 0.15 mole) in dimethylformamide (250 ml) at 130° over a period of 15 min.

The temperature was allowed to increase to 150°, and the reaction was maintained at that temperature for 30 min. The hot reaction mixture was poured onto ice, and the mixture was extracted with chloroform (250 ml). The chloroform solution was washed with water and dried. Petroleum ether (500 ml) was added and the solution was allowed to stand at 5° overnight. The precipitated solid (5.7 g, m.p. 190–204°) was extracted with sodium hydroxide (*N*, 30 ml) in ethanol (250 ml), giving an orange-colored residue, yield 0.4 g, m.p. 170–175°. Recrystallization from dimethylformamide raised the melting point to 174–175°.

Anal. Calcd. for $C_{16}H_{12}Cl_2N_2S_4$: C, 44.54; H, 2.81; Cl, 16.44; N, 6.49; S, 29.72. Found: C, 44.50; H, 2.42; Cl, 16.80; N, 6.32; S, 29.70.

Acidification of the alkaline filtrate with 5% hydrochloric acid gave crude I, m.p. 205–206°, yield 5.2 g (0.8%). Recrystallization from dimethylformamide raised the melting point to 207–208°.

Anal. Calcd. for $C_{17}H_{13}Cl_2N_3S_4$: C, 44.53; H, 2.86; Cl, 15.41; N, 9.17; S, 27.97. Found: C, 44.52; H, 2.90; Cl, 15.31; N, 9.19; S, 27.56.

1-(p-Chlorobenzyl)-4(or 2)-dimethylamino-6-(p-chlorobenzyldithio)-s-triazine-2(or 4)(1H)-thione (II)

The reaction was performed as described above, except that the period of heating at 150° was extended to 3 h. The reaction mixture was worked up in the same way, resulting in the isolation of a neutral product, m.p. 225–229°, yield 8.5 g. Recrystallization from dimethylformamide raised the melting point to 232–233°.

Anal. Calcd. for $C_{19}H_{18}Cl_2N_4S_3$: C, 48.61; H, 3.86; Cl, 15.10; N, 11.94; S, 20.49. Found: C, 48.32; H, 4.08; Cl, 15.13; N, 12.08; S, 20.25.

1-(p-Chlorobenzyl)-2,4-dithio-s-triazine-2,4,6(1H,3H,5H)-trione (III)

By Hydrolysis of I

I (1.5 g) was added to a solution of sodium hydroxide (7.5 g) in water (30 ml) and methanol (60 ml), and the mixture was heated on the steam bath for 2 h. The methanol was distilled off slowly as the hydrolysis proceeded. The solution was cooled and acidified, giving the crude product, m.p. 254–262°, yield 0.51 g (51%). Recrystallization from methanol raised the melting point to 280–282 °C.

Anal. Calcd. for $C_{10}H_8ClN_3OS_2$: C, 42.03; H, 2.82; Cl, 12.41; N, 14.70; mol. wt. 285.76. Found: C, 42.34; H, 3.31; Cl, 12.69; N, 14.16; mol. wt. 283.

Via 1-p-Chlorobenzyldithiobiuret

Cyanamide (2.1 g, 0.05 mole) was added to a solution of sodium methoxide (prepared from 1.15 g sodium) in ethanol (20 ml). *p*-Chlorobenzyl isothiocyanate (9.1 g, 0.05 mole) was added and the solution was refluxed for 30 min. The solution was evaporated to dryness and the solid residue was dissolved in 75 ml H_2O, to which was added 2.4 g ammonium chloride and 8.0 ml concentrated ammonium hydroxide. Hydrogen sulfide was bubbled through the solution at 90° for 6 h, giving the crude dithiobiuret, m.p. 160–165°, yield 8.1 g (62%). Recrystallization from methanol raised the melting point to 167–169 °C.

Anal. Calcd. for $C_9H_{10}ClN_3S_2$: C, 41.61; H, 3.88; Cl, 13.65; N, 16.18; S, 24.68. Found: C, 41.75; H, 3.96; Cl, 13.84; N, 16.14; S, 24.47.

Sodium (0.23 g) was dissolved in 10 ml ethanol, and diethyl carbonate (1.2 g, 0.1 mole) and 1-*p*-chlorobenzyldithiobiuret (1.3 g, 0.05 mole) were added. The solution was refluxed for 40 min and then evaporated to dryness. The residue was dissolved in water (100 ml) and the solution was washed with ether to remove the unreacted diethyl carbonate. Acidification of the aqueous solution gave a precipitate which was extracted with chloroform (100 ml) and recrystallized from ethanol to give the pure product, m.p. 270–272°, yield 0.25 g (18%). There was no melting point depression on admixture with the product obtained from I, and the ultraviolet and infrared spectra were identical.

1-(p-Chlorobenzyl)-s-triazine-2,4,6(1H,3H,5H)-trithione (Mono-p-chlorobenzyl Isotrithiocyanurate) (IV)

By Reduction of I

Sodium hydrosulfite (17.4 g, 0.1 mole) was added to a solution of I (2.5 g, 0.0055 mole) in 50% methanol (300 ml) containing sodium hydroxide (1.2 g, 0.03 mole). The solution was refluxed for 2 h, and *N* sodium hydroxide was added continuously to maintain a pH of 8. After being allowed to stand overnight, the solution deposited crystals of bis-(*p*-chlorobenzyl) disulfide (10), m.p. 58°. Acidification of the filtrate gave a mixture (2.1 g) of compounds I, III, and IV. The mixture was extracted with boiling absolute ethanol (100 ml), in which only the isodithiocyanurate III was soluble. The residue, consisting of I and IV, was suspended in 20 ml *N* aqueous sodium hydroxide, and the insoluble sodium salt of I was removed by filtration. Acidification of the alkaline filtrate gave pure IV, m.p. 320° (decomp.) (crystal change at 275°), yield 0.26 g (16%).

Anal. Calcd. for $C_{10}H_8ClN_3S_3$: C, 39.79; H, 2.67; Cl, 11.75; N, 13.92; S, 31.87. Found: C, 40.05; H, 2.86; Cl, 11.66; N, 13.74; S, 31.71.

From Mono-p-chlorobenzyl Isocyanurate

p-Chlorobenzylamine (24 g, 0.17 mole) and nitrobiuret (25 g, 0.17 mole) were heated in 150 ml water at 95° for 1 h. Filtration of the hot solution gave 1-(*p*-chlorobenzyl)-biuret, m.p. 190–192°.

Anal. Calcd. for $C_9H_{10}ClN_3O_2$: C, 47.48; H, 4.43; Cl, 15.58. Found: C, 47.55; H, 4.58; Cl, 15.71.

The biuret (22.8 g, 0.1 mole) and diethyl carbonate (23.6 g, 0.2 mole) were added to a solution of sodium methoxide (0.2 mole) in methanol (200 ml), and the solution was refluxed for 2 h. The precipitated solid was

filtered off and extracted with 600 ml water; acidification of the filtrate gave mono-*p*-chlorobenzyl isocyanurate, m.p. 249–251°.

Anal. Calcd. for $C_{10}H_8ClN_3O_3$: C, 47.35; H, 3.18; Cl, 13.98; N, 16.57. Found: C, 47.47; H, 3.20; Cl, 13.70; N, 16.49.

A mixture of mono-*p*-chlorobenzyl isocyanurate (8.8 g, 0.035 mole) and phosphorus pentasulfide (8.0 g, 0.036 mole) was heated at 255–265° for 20 min. Water (50 ml) was added, and the suspension was boiled for 10 min and filtered. The precipitate was extracted with 4% sodium hydroxide (300 ml) and the alkaline extract was acidified to give the product (8.8 g, 83%), m.p. 295–300°. Recrystallization from dimethylformamide–methanol raised the melting point to 320°; the ultraviolet and infrared spectra were identical with those of the product obtained by reduction of I.

1-(p-Chlorobenzyl)-4-methylthio-6-(p-chlorobenzyldithio)-s-triazine-2(1H)-thione (Va)

I (498 mg, 1.09 mmoles) was dissolved in a solution of sodium hydroxide (*N*, 1.8 ml) in methanol (40 ml), and methyl iodide (1.0 ml) was added at 0°. The product separated out immediately, giving 425 mg (82%), m.p. 163–165°. Recrystallization from dimethylformamide raised the melting point to 169–170°.

Anal. Calcd. for $C_{18}H_{15}Cl_2N_3S_4$: C, 45.75; H, 3.20; Cl, 15.01; N, 8.89; S, 27.14. Found: C, 45.73; H, 3.72; Cl, 14.88; N, 9.08; S, 26.94.

1-(*p*-Chlorobenzyl)-4-ethylthio-6-(*p*-chlorobenzyldithio)-*s*-triazine-2(1*H*)-thione (V*b*), prepared in the same way with ethyl iodide, melted at 115–116° after recrystallization from methanol.

Anal. Calcd. for $C_{19}H_{17}Cl_2N_3S_4$: C, 46.90; H, 3.52; Cl, 14.58; N, 8.64. Found: C, 47.09; H, 3.77; Cl, 14.91; N, 8.89.

1-(*p*-Chlorobenzyl)-4-(*p*-chlorobenzylthio)-6-(*p*-chlorobenzyldithio)-*s*-triazine-2(1*H*)-thione (V*c*), m.p. 120–122°, was obtained in 87% yield.

Anal. Calcd. for $C_{24}H_{18}Cl_3N_3S_4$: C, 49.44; H, 3.11; Cl, 18.24; N, 7.21; S, 22.00. Found: C, 49.82; H, 3.17; Cl, 17.79; N, 6.90; S, 21.64.

1-(p-Chlorobenzyl)-2-thio-s-triazine-2,4,6(1H,3H,5H)-trione (VI)

A suspension of the methyl derivative V*a* (730 mg) in methanol (50 ml) and 50% sodium hydroxide solution (16 g) was heated on the steam bath for 2 h, and the methanol was evaporated. The alkaline solution was diluted with water (150 ml) and filtered, and the filtrate was acidified. The crude precipitate (185 mg) was recrystallized from glacial acetic acid to a constant melting point of 279–281°, yield 132 mg (32%).

Anal. Calcd. for $C_{10}H_8ClN_3O_2S$: C, 44.53; H, 2.99; Cl, 13.15; N, 15.58; S, 11.89. Found: C, 44.54; H, 3.05; Cl, 13.19; N, 15.55; S, 11.76.

1-(p-Chlorobenzyl)-4-methoxy-6-(p-chlorobenzyldithio)-s-triazine-2(1H)-thione (VIIa)

I (0.68 g, 1.48 mmoles) was dissolved in methanol (60 ml) containing 3.4 ml of aqueous *N* sodium hydroxide, and sodium hypochlorite solution (9 ml, available chlorine 5%) was added. The suspension was stirred at room temperature for 2 days. The precipitated product (0.51 g, 75%) melted at 142–143° after recrystallization from methanol.

Anal. Calcd. for $C_{18}H_{15}Cl_2N_3OS_3$: C, 47.36; H, 3.31; Cl, 15.54; N, 9.21; S, 21.07. Found: C, 47.11; H, 3.43; Cl, 15.35; N, 9.07; S, 21.25.

1-(p-Chlorobenzyl)-4-ethoxy-6-(p-chlorobenzyldithio)-s-triazine-2(1H)-thione (VIIb)

Sodium hypochlorite (10 ml, available chlorine 5%) was added to a solution of I (458 mg, 1 mmole) and aqueous sodium hydroxide (*N*, 1.5 ml) in ethanol (50 ml). After being allowed to stand for 1 day, the reaction solution was evaporated, and the residue was extracted with chloroform (50 ml). The chloroform was washed with water, dried, and evaporated, and the residue was crystallized from ethanol to give the product, m.p. 130–131°, yield 108 mg (23%).

Anal. Calcd. for $C_{19}H_{17}Cl_2N_3OS_3$: C, 48.51; H, 3.64; Cl, 15.07; N, 8.93; S, 20.44. Found: C, 48.27; H, 3.65; Cl, 15.21; N, 9.04; S, 20.23.

1-p-Chlorobenzyl-4,6-di-(p-chlorobenzylthio)-s-triazine-2(1H)-thione (VIII)

A solution of III (91 mg, 0.3 mmole) in 0.66 ml of *N* sodium hydroxide (0.66 mmole) was added to *p*-chlorobenzyl chloride (106 mg, 0.66 mmole) in ethanol (6 ml). The product separated out after the solution had stood for 12 h, yield 166 mg (70%), m.p. 172–174° after recrystallization from methanol.

Anal. Calcd. for $C_{24}H_{18}Cl_3N_3S_3$: C, 52.32; H, 3.29; N, 7.63; S, 17.46. Found: C, 52.01; H, 3.30; N, 8.04; S, 17.89.

Rearrangement of VIII to 2,4,6-Tri-(p-chlorobenzylthio)-s-triazine (IX)

A sample of VIII (m.p. 174°) (10 mg) was heated in a tube sealed *in vacuo* at 250° for 1 h. The product was crystallized from ether–alcohol, m.p. 117 °C. The product was identical with the triester prepared by esterification of either trithiocyanuric acid or the monoester XI with *p*-chlorobenzyl chloride. The analytical sample melted at 120–122°.

Anal. Calcd. for $C_{24}H_{18}Cl_3N_3S_3$: C, 52.32; H, 3.29; Cl, 19.31; N, 7.63; S, 17.46. Found: C, 52.26; H, 3.23; Cl, 19.70; N, 7.80; S, 17.59.

2,4,6-Tri-(p-chlorobenzyldithio)-s-triazine (X)

Chlorine (0.55 ml, 0.025 mole) was added to bis-(*p*-chlorobenzyl) disulfide (7.89 g, 0.025 mole) in carbon tetrachloride (20 ml) at −8° to −10° over a period of 25 min. This solution was added to trithiocyanuric acid (0.7 g, 0.004 mole) suspended in a mixture of carbon tetrachloride (20 ml) and chloroform (10 ml) at −10° with stirring, and the stirring was continued for 1 h at 10°. The solution was evaporated at room temperature and the residue was crystallized from ethanol, giving 1.2 g (46%), m.p. 119–120°.

Anal. Calcd. for $C_{24}H_{18}Cl_3N_3S_6$: C, 44.54; H, 2.80; Cl, 16.44; N, 6.49; S, 29.73. Found: C, 44.04; H, 2.79; Cl, 16.61; N, 6.50; S, 29.79.

2-(p-Chlorobenzylthio)-4,6-dichloro-s-triazine (XI)

To a stirred solution of cyanuric chloride (29.1 g, 0.158 mole) in acetone (200 ml) was added dropwise a mixture of *p*-chloro-α-toluenethiol (25 g, 0.158 mole) and lutidine (20 ml) at −40° over a 15 min period. The stirring was continued at −25° for a further 2 h. The reaction mixture was poured into ice water (1 000 ml) and the precipitated solid was recrystallized from heptane, giving 21.0 g (38%), m.p. 72–75 °C. The analytical sample melted at 75–77 °C.

Anal. Calcd. for $C_{10}H_6Cl_3N_3S$: C, 39.17; H, 1.97; Cl, 34.69; N, 13.71; S, 10.46. Found: C, 39.08; H, 1.89; Cl, 34.83; N, 13.81; S, 10.77.

2-(p-Chlorobenzylthio)-s-triazine-4,6(3H,5H)-dithione (XII)

A solution of XI (13.0 g, 0.0424 mole) in dioxane (20 ml) was added to aqueous sodium hydrosulfide (50%, 20 ml) in methanol (40 ml). The solution was boiled briefly, cooled, and acidified, and the precipitated product was recrystallized from dimethylformamide, yield 8.4 g (65%). The purified product underwent a crystal change at 239–240°, and did not melt below 330 °C.

Anal. Calcd. for $C_{10}H_8ClN_3S_3$: C, 39.79; H, 2.67; Cl, 11.75; N, 13.92; S, 31.87. Found: C, 39.91; H, 2.75; Cl, 11.89; N, 13.77; S, 32.18.

2-(p-Chlorobenzylthio)-4,6-di-(p-chlorobenzyldithio)-s-triazine (XIII)

A solution of chlorine (0.11 ml, 5 mmoles) and bis-(*p*-chlorobenzyl) disulfide (1.58 g, 5 mmoles) in carbon tetrachloride (4 ml) was prepared at −10 °C. A suspension of XII (0.245 g, 0.81 mmole) in carbon tetrachloride (10 ml) was added at the same temperature, and the clear solution was allowed to stand at 10° for 30 min. The solution was evaporated and the residue was crystallized from petroleum ether to give the product, m.p. 93–95°, yield 85 mg (17%).

Anal. Calcd. for $C_{24}H_{18}Cl_3N_3S_5$: C, 46.86; H, 2.95; Cl, 17.29; N, 6.83; S, 26.07. Found: C, 46.88; H, 2.99; Cl, 17.64; N, 6.73; S, 26.38.

2-Chloro-4-(p-Chlorobenzylthio)-6-dimethylamino-s-triazine (XIV)

To a solution of X (3.07 g, 0.01 mole) in acetone (350 ml), aqueous dimethylamine solution (1.43 *N*, 70 ml, 0.01 mole) and 60 ml of aqueous sodium bicarbonate (1.18 g, 0.02 mole) were added at 25–35° over 1 h. The pH of the reaction mixture was kept at 8–8.5. The reaction temperature was allowed to rise to 35–40° for 10 min. Water (300 ml) was added to precipitate the product, yield 2.65 g (84%), m.p. 128–130°. The analytical sample was recrystallized from methanol, m.p. 129–130°.

Anal. Calcd. for $C_{12}H_{12}Cl_2N_4S$: C, 45.72; H, 3.83; Cl, 22.50; N, 17.77; S, 10.17. Found: C, 45.58; H, 3.77; Cl, 22.86; N, 17.55; S, 10.12.

4-(p-Chlorobenzylthio)-6-dimethylamino-s-triazine-2(1H)-thione (XV)

A solution of XIV (2.3 g) in dioxane (50 ml) was added to sodium hydrosulfide (0.84 g) in water (25 ml), and the reaction mixture was boiled for 5 min. The solution was cooled and acidified, and the product was purified by crystallization from chloroform, yield 1.5 g (66%), m.p. 250–253°.

Anal. Calcd. for $C_{13}H_{13}ClN_4S_2$: C, 46.07; H, 4.18; Cl, 11.33; N, 17.91; S, 20.50. Found: C, 45.71; H, 4.00; Cl, 11.62; N, 18.04; S, 20.61.

2,2'-Dithiobis-(4-(p-chlorobenzylthio)-6-dimethylamino-s-triazine) (XVI)

Treatment of XV with bis-(*p*-chlorobenzyl) disulfide and chlorine as described for the preparation of XII and XIII gave the ditriazinyl disulfide, yield 88%, m.p. 183–184° after crystallization from dimethylformamide.

Anal. Calcd. for $C_{24}H_{24}Cl_2N_8S_4$: C, 46.21; H, 3.88; Cl, 11.37; N, 17.97; S, 20.57. Found: C, 45.98; H, 3.98; Cl, 11.63; N, 17.76; S, 21.00.

ACID-CATALYZED REACTIONS OF VINYL COMPOUNDS

IV. MECHANISM OF FORMATION OF THE PRODUCTS OF THE REACTION OF VINYL ACETATE AND BENZENE[1]

J. M. PEPPER AND B. P. ROBINSON

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received February 23, 1966

ABSTRACT

In part II of this series the isolation and identification of nine products from the reaction of vinyl acetate with benzene and aluminium chloride were described. This paper presents a discussion of the mechanism of formation of these compounds.

A comparison of the aluminium chloride catalyzed reactions of benzene with vinyl acetate and ethyl acetate is described. The reaction with ethyl acetate gave all the monocyclic products obtained from the reaction involving vinyl acetate, as well as *m*-diethylbenzene. The ratio of the ortho and para isomers of ethylacetophenone is the same in both reactions, which suggests that the same acetylating species is involved. The fact that none of the three polycyclic products is obtained from the reaction involving ethyl acetate suggests that the vinyl moiety of the ester is involved in the formation of these compounds from vinyl acetate. The use of ^{14}C-labelled vinyl acetate confirmed the fact that the synthesis of 9,10-dimethylanthracene involved only the vinyl part of the ester.

A study of the reactions of ethyl acetate and vinyl acetate with aluminium chloride showed that ethyl chloride and vinyl chloride, respectively, may be intermediates in the alkylation of benzene with these reagents. Evidence is presented that 1-phenylethyl chloride may also be an intermediate product in the reaction of vinyl acetate and benzene. 1,1-Diphenylethane is believed to be involved in the formation of 9,10-dimethylanthracene, the final step of which is thought to occur by the dehydrogenation of 9,10-dihydro-9,10-dimethylanthracene.

The isolation and characterization of nine products from the aluminium chloride catalyzed interaction of vinyl acetate and benzene have been described in an earlier communication (1). These products were ethylbenzene, acetophenone, *o*- and *p*-ethylacetophenone, 2,4- and 3,4-diethylacetophenone, 1,1-diphenylethane, 1,1-diphenylethene, and 9,10-dimethylanthracene. This communication describes experiments that were carried out in an attempt to obtain information regarding the mechanism of their formation.

There appeared to be a close similarity between the products obtained from the reaction of ethyl acetate and benzene in the presence of aluminium chloride (2–9) and those obtained from the corresponding reaction with vinyl acetate. A detailed study was therefore made, under identical conditions, of these two reactions, and the nature and relative yields of the products were compared. The ester was added slowly to a cooled mixture of benzene and aluminium chloride, and the resulting mixture was heated under reflux for 3 h before decomposition. From the ethyl acetate reaction, the liquid product was analyzed by gas–liquid chromatography. From the reaction involving vinyl acetate, 9,10-dimethylanthracene was separated by filtration from the semisolid crude product (10) and the filtrate was analyzed by gas–liquid chromatography. The identities of the products from the vinyl acetate reaction had already been established (1), and those from the ethyl acetate reaction were confirmed by isolation and infrared analysis. The identities and yields of products are given in Table I. There are significant variations in the nature of the products obtained from the two reactions. The absence of the polycyclic compounds and higher yields of all products containing the ethyl group are characteristic of the reaction

[1]*Presented at the 46th annual conference, Chemical Institute of Canada, Toronto, Ontario, June 1963. For parts I, II, and III of this series, see refs. 10, 1, and 30, respectively.*

TABLE I

Products of the reactions of vinyl acetate and ethyl acetate with benzene*

Product	Vinyl acetate			Ethyl acetate		
	Yield (g)		% yield (average)	Yield (g)		% yield (average)
	Run 1	Run 2		Run 1	Run 2	
Ethylbenzene	0.09	0.10	0.85†	0.37	0.47	3.95†
m-Diethylbenzene	—	—	—	0.19	0.14	2.45‡
Acetophenone	3.09	3.03	25.5†	0.99	1.08	8.6†

*Ester (0.1 mole), benzene (1 mole), and aluminium chloride (0.3 mole).
†If it is assumed that 1 mole of ester is required to produce 1 mole of product.
‡If it is assumed that 2 moles of ester is required to produce 1 mole of product.

involving ethyl acetate, whereas high yields of acetophenone and the presence of the polycyclic derivatives are associated with the vinyl acetate reaction.

In an attempt to establish the nature of the alkylating and acylating species which may be responsible for these products, the reactions of ethyl acetate and vinyl acetate with aluminium chloride (in the absence of benzene) were studied. In equimolar proportions, ethyl acetate and aluminium chloride formed a complex which was stable at 80°. If the aluminium chloride were in excess, decomposition occurred with evolution of ethyl chloride and hydrogen chloride. The yield of ethyl chloride increased, reaching a maximum (0.7–0.8 mole/mole of ester) if the molar ratio of aluminium chloride to ester were 2:1. Under these conditions, the amount of hydrogen chloride evolved was about 0.2 mole/mole of ester.

An attempt to determine if, as a result of the indicated alkyl–oxygen type of fission, acetic acid would result from hydrolysis of the residue resulted in only a small amount being isolated. If, however, the residue from the reaction of ethyl acetate (1 mole) and aluminium chloride (2 or more moles) was treated with benzene, acetophenone (0.6 mole) was obtained. This molar yield compared well with the amount of ethyl chloride obtained under similar conditions. On the other hand, the reaction of vinyl acetate and aluminium chloride led to extensive polymerization. As expected, no vinyl chloride was detected, since it is known to polymerize under these conditions (11). The residue from a reaction involving 1 mole of vinyl acetate and 3 moles of aluminium chloride, on treatment with benzene, gave only 0.2 mole of acetophenone.

On the basis of this study, the reaction of ethyl acetate and aluminium chloride may be formulated as shown in eq. [1].

[1] $$MeCO_2Et + AlCl_3 \rightarrow \underset{\text{I}}{MeC(OEt)(O^+-AlCl_3)} \xrightarrow{AlCl_3} MeC(O^+-AlCl_3)(OAlCl_2) + EtCl$$

The formation of hydrogen chloride is not accounted for by this sequence of reactions, and it may result from decomposition of ethyl chloride by aluminium chloride (12, 13). The isolation of ethyl chloride suggests that it may be the alkylating agent in the reaction of

For personal use only.

ethyl acetate with benzene. In a similar way, vinyl chloride may be the reactive intermediate in the reaction involving vinyl acetate. Such conclusions are supported by the work of Baddeley (14), who reported that alkylation with ethers and alcohols requires an excess of aluminium chloride and is probably effected by alkyl halide. Alternatively, Takegami and Shingu (15), who studied the reaction of ethyl acetate with aluminium bromide at 20°, reported that ethyl acetate is only slightly decomposed (4–9%), even in the presence of an excess of aluminium bromide, and that no ethyl bromide is produced. These authors concluded that the alkyl cation alkylates benzene and that no alkyl halide is involved.

The results reported by Illari (16), who studied the reaction of ethyl acetate with aluminium chloride, are not in accord with those obtained in this study. He reported that, even in the presence of an excess of the ester, hydrogen chloride (0.56 mole/mole of aluminium chloride) is liberated. This difference may not be real, since he added the ester slowly to the metal halide and hence, regardless of the final molar ratio of ester to halide, the metal halide was always initially in excess, and decomposition would occur. Norris and Arthur (7) also believed that ethyl chloride was the alkylating species in the aluminium chloride catalyzed reaction of ethyl acetate with benzene. They considered that the ethyl chloride arose by the decomposition of an equimolar complex of the ester and the metal halide, but since this occurs only at a temperature of 140–170°, it is more reasonable to assume, for the low-temperature reaction, that the decomposition is effected by the excess of aluminium chloride. The suggestion of Bowden (5) that the alkylation of benzene by ethyl acetate in the presence of aluminium chloride proceeds via the intermediate formation of ethylene is not supported by any experimental evidence.

The observed isomer distributions of $6.5 \pm 0.5\%$ and $93.5 \pm 0.5\%$ for the *o*- and *p*-ethylacetophenone, respectively, were the same for both the vinyl acetate and the ethyl acetate reactions, which would suggest that the same acylating species was involved. The acylating species might be formulated as shown in structure I. Alternatively, acetyl chloride may be formed *in situ* and may be responsible for the acylation reaction. Other workers have presented evidence for the intermediate formation of acyl halide in acylation reactions involving acid anhydrides and carboxylic acids (17–20).

Consideration was given to the possibility that vinyl chloride could react to give either styrene or 1-phenylethyl chloride, which could react further to give the final polycyclic products. To test the first suggestion, the reaction of styrene with aluminium chloride and benzene was investigated. None of the products of the vinyl acetate – benzene reaction was detected, except for a very small amount (0.2%) of ethylbenzene. It was therefore concluded that styrene is not an intermediate. Schramm (21) reported that 1-phenylethyl chloride reacted with benzene in the presence of aluminium chloride at 0° to give 1,1-diphenylethane, ethylbenzene, and 9,10-dihydro-9,10-dimethylanthracene.[2] In the present investigation, this reaction gave ethylbenzene, *m*-diethylbenzene, 1,1-diphenylethene, and 1,1-diphenylethane at room temperature. If, on the other hand, the reaction were carried out at reflux temperature, ethylbenzene, *m*-diethylbenzene, and 9,10-dimethylanthracene were obtained. The conversion of 1-phenylethyl chloride into ethylbenzene may occur in a manner analogous to the decomposition of other alkyl halides (12, 13) and as indicated in eqs. [2]–[4]. This sequence of reactions would also explain the formation of 1,1-diphenylethene. The almost exclusive formation of the *m*-diethylbenzene would indicate an isomerization of either the *o*- or *p*-diethyl isomer, or disproportionation of ethylbenzene (22).

[2]*This compound was actually 9,10-dimethylanthracene (see ref. 10).*

[2] $$PhCHClCH_3 + AlCl_3 \rightleftharpoons Ph\overset{+}{C}HCH_3AlCl_4^-$$

[3] $$PhCHClCH_3 + Ph\overset{+}{C}HCH_3AlCl_4^- \rightarrow Ph\overset{+}{C}ClCH_3AlCl_4^- + PhCH_2CH_3$$

[4] $$Ph\overset{+}{C}ClCH_3AlCl_4^- \rightarrow HCl + AlCl_3 + PhCCl{=}CH_2$$

The formation of the polycyclic products, 1,1-diphenylethene, 1,1-diphenylethane, and 9,10-dimethylanthracene, from the vinyl moiety of vinyl acetate and benzene was indicated by the fact that these compounds were not obtained from the reaction involving ethyl acetate. Further evidence that 9,10-dimethylanthracene and 1,1-diphenylethane are derived by a reaction involving the vinyl group is provided by the fact that these compounds may be obtained by the reaction of vinyl halides with benzene and Friedel–Crafts catalysts (23–28). The reaction of vinyl formate with benzene and aluminium chloride also gives 9,10-dimethylanthracene (10).

Experiments with ^{14}C-labelled vinyl acetate confirmed the fact that the *meso* carbon atoms in 9,10-dimethylanthracene originated from the vinyl group. When vinyl-1,2-^{14}C acetate was used the activity was incorporated into the 9,10-dimethylanthracene. The use of vinyl acetate-1-^{14}C resulted in the formation of inactive 9,10-dimethylanthracene. The formation of 9,10-dimethylanthracene could occur by one of three possible routes, as shown in Reaction Scheme 1. All of the three possible routes are consistent with the fact that the yield of 9,10-dimethylanthracene decreases if a very large excess of benzene is used (10). All three routes involve the intermediate formation of 9,10-dihydro-9,10-dimethylanthracene.

REACTION SCHEME 1. Possible routes for the formation of 9,10-dimethylanthracene.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Korshak *et al.* (27) found that the yield of 9,10-dimethylanthracene increased and of 1,1-diphenylethane decreased as the time of the vinyl acetate – benzene reaction increased. They suggested that 1,1-diphenylethane is an intermediate in the formation of 9,10-dimethylanthracene. These same authors (27) also reported the isolation of 9,10-dihydro-9,10-dimethylanthracene[2] by treatment of 1,1-diphenylethane with aluminium chloride, and suggested that the anthracene derivative was formed by disproportionation of 1,1-diphenylethane. Further, Radziewanowski (29) has reported that the treatment of 1,1-diphenylethane with aluminium chloride in the absence of benzene gives rise to the dihydroanthracene derivative.[2] The conversion of 1,1-diphenylethane into 1-phenylethyl chloride, followed by elimination of hydrogen chloride, was proposed to account for the reaction.

Experiments carried out during the present investigation did not result in the formation of 9,10-dimethylanthracene by the action of aluminium chloride on 1,1-diphenylethane, under the conditions described by Korshak *et al.* (27). However, when 1,1-diphenylethane was treated with aluminium chloride in the presence of benzene, 9,10-dimethylanthracene was obtained. This indicates that the anthracene derivative may be formed by route 3*b* (Reaction Scheme 1). 9,10-Dimethylanthracene was also obtained when 1,1-diphenylethane was treated with vinyl acetate and aluminium chloride, which indicates that the anthracene derivative may be formed by route 3*a*.

It was concluded that 1,1-diphenylethene is not an intermediate in the formation of 9,10-dimethylanthracene, because this compound, when treated with aluminium chloride either in the presence or absence of benzene, did not give rise to the anthracene derivative. Further, no 9,10-dimethylanthracene was obtained by treating 1,1-diphenylethene with vinyl acetate and aluminium chloride.

The formation of 9,10-dimethylanthracene by routes 3*a* and 3*b* is supported by studies on the reaction of toluene with vinyl acetate and aluminium chloride (30). In this case 2,7,9,10-tetramethylanthracene is formed. The final step in the formation of 9,10-dimethylanthracene involves the dehydrogenation of the dihydro compound. This dehydrogenation will be discussed in a forthcoming communication.

EXPERIMENTAL

Melting points are uncorrected. The infrared spectra were measured on a Perkin–Elmer model 21 instrument with sodium chloride optics. Gas–liquid chromatography was effected with a Beckman GC-2 chromatograph which had a thermal conductivity detector unit and which had been modified by placing the injection system as close as possible to one end of the column and by making it more comparable electronically to the GC-2A.

In all the reactions involving the use of anhydrous aluminium chloride, the ingress of moisture into the apparatus was prevented by the use of calcium chloride drying tubes.

The Reaction of Ethyl Acetate with Aluminium Chloride

The apparatus consisted of a three-necked flask fitted with a dropping funnel, a mercury-sealed stirrer, and a reflux condenser. A suitable attachment was connected to the top of the condenser for trapping the gaseous products. The exit gases were passed successively through a U-tube containing calcium chloride to prevent ingress of moisture into the flask, two scrubbers containing sodium hydroxide solution (to trap hydrogen chloride), a calcium chloride tube, an acetone – dry ice trap (to trap ethyl chloride), and finally another calcium chloride tube.

The procedure for a typical experiment was as follows. Aluminium chloride (40 g, 0.3 mole) was placed in the reaction flask. Ethyl acetate (8.8 g, 0.1 mole) was added dropwise, with stirring. During the addition heat was evolved and the evolution of gas was observed (bubbling through the scrubbers). At the end of the addition there was 0.4 ml of condensate in the acetone – dry ice trap. Five minutes after the end of the addition, bubbling of gas through the scrubbers ceased, and the mixture was heated to 80°. Gas started to bubble through the scrubbers when the temperature reached 60°. The mixture was maintained at 80° until bubbling ceased (ca. 1 h).

The reaction flask was allowed to cool and the system was flushed out with nitrogen. The condensate in the acetone – dry ice trap was allowed to warm up to about 0° and then measured. The volume of condensate was 5.3 ml at 2°. The infrared spectrum of the condensate was identical with that reported for ethyl chloride (31). Titration of the sodium hydroxide solution in the scrubbers indicated that 0.016 mole of hydrogen chloride had been produced by the reaction.

The residue in the reaction flask was treated as follows. Benzene (15.6 g, 0.2 mole) was added to the reaction flask over a period of 10 min. The mixture was stirred for 1 h at room temperature and then heated under reflux for 1 h. The reaction mixture was decomposed and worked up in the usual manner. Distillation of the crude product under reduced pressure gave acetophenone (2.75 g), b.p. 82–84° at 12 mm.

The Reaction of Vinyl Acetate with Aluminium Chloride

The apparatus and procedure were the same as for the corresponding reaction of ethyl acetate. There was evidence of polymerization in the condenser, and no vinyl chloride was isolated.

Vinyl acetate (0.1 mole) and aluminium chloride (0.3 mole) gave hydrogen chloride (0.025 mole). The residue, when heated under reflux for 3.5 h with benzene (15.6 g), gave, after the usual treatment, acetophenone (2.2 g, 18%), b.p. 80–83° at 12 mm.

The Reaction of Styrene with Benzene and Aluminium Chloride

Styrene (10.4 g, 0.1 mole) was added slowly over a period of 1 h to a stirred mixture of benzene (78 g, 1.0 mole) and aluminium chloride (40 g, 0.3 mole) in a 200 ml, three-necked flask equipped with a reflux condenser, a dropping funnel, and a mechanical stirrer. Both the condenser and dropping funnel were fitted with calcium chloride drying tubes. Throughout the addition, the flask was cooled in an ice bath, but after the addition the mixture was heated under reflux for 3 h. The reaction mixture was decomposed and worked up in the usual manner, whereby a black liquid was obtained.

The crude product was analyzed by gas–liquid chromatography on a Beckman silicone column, No. 17,449 (6 ft), at a temperature of 210° with a helium flow rate of 27 ml/min. Peaks corresponding to benzene, ethylbenzene, and styrene were observed. No peaks corresponding to diethylbenzene, diphenylethane (1,1- or 1,2-), or 1,1-diphenylethene were obtained. Analysis with a SE 30 (5%) on Chromosorb W column at a temperature of 210° with a helium flow rate of 23 ml/min showed the absence of 9,10-dimethylanthracene. Quantitative analysis by gas–liquid chromatography showed that the size of the peak corresponding to ethylbenzene indicated that 0.03 g ((0.28%) of ethylbenzene was formed. The peak corresponding to styrene was very small (comparable in size to that corresponding to ethylbenzene), which indicated that almost all the styrene had reacted.

The Reaction of Styrene with Benzene, Aluminium Chloride, and Hydrogen Chloride

The procedure was the same as for the above experiment, except that hydrogen chloride gas was bubbled through the reaction mixture throughout the reaction. As in the above experiment, gas–liquid chromatography showed the absence of diethylbenzene, diphenylethane (1,1- and 1,2-), 1,1-diphenylethene, and 9,10-dimethylanthracene. Peaks corresponding to benzene, ethylbenzene, and styrene were detected. The peaks corresponding to ethylbenzene and styrene were of comparable size. Quantitative analysis indicated that 0.015 g (0.14%) of ethylbenzene was formed.

The Reaction of 1-Phenylethyl Chloride with Benzene and Aluminium Chloride

Run 1

1-Phenylethyl chloride (7.25 g, 0.05 mole) was added slowly over a period of 1 h to a stirred, cooled mixture of benzene (39 g, 0.5 mole) and aluminium chloride (20 g, 0.15 mole) in a three-necked flask equipped with a reflux condenser, a dropping funnel, and a mechanical stirrer. Both the condenser and the dropping funnel were fitted with calcium chloride drying tubes. After the addition the mixture was heated under reflux for 3 h, and then decomposed and worked up in the usual manner. The crude product (9.65 g) consisted of a yellow solid and an orange liquid. The yellow solid was removed by filtration and washed with methanol to yield 2.35 g, m.p. 178–180°, which was readily shown to be 9,10-dimethylanthracene by a mixed melting point with an authentic sample and by determination of its infrared spectrum.

The filtrate was analyzed by gas–liquid chromatography on a Beckman silicone column, No. 17,449 (6 ft), at a temperature of 210° with a helium flow rate of 27 ml/min. Peaks corresponding to ethylbenzene and *m*-diethylbenzene were observed. The fact that these peaks were due to ethylbenzene and *m*-diethylbenzene was confirmed by collection of samples (gas–liquid chromatography). These two samples had infrared spectra which were identical with those of authentic samples of ethylbenzene and *m*-diethylbenzene, respectively. Quantitative analysis showed that the yield of ethylbenzene was 0.29 g (5.5%) and of *m*-diethylbenzene 0.215 g (6.4%). Analysis with a SE 30 (5%) on Chromosorb W column at a temperature of 210° showed that the filtrate contained a negligible amount of 9,10-dimethylanthracene.

Run 2

An experiment similar to the above was carried out in which the reaction mixture was not heated under reflux. 1-Phenylethyl chloride (7.25 g, 0.05 mole) was added, in the manner described in run 1 above, to benzene (39 g, 0.5 mole) and aluminium chloride (20 g, 0.15 mole). After the addition the mixture was stirred for 0.5 h at room temperature, and then decomposed and worked up. The crude product (9.5 g), an orange

oil, was analyzed by gas–liquid chromatography. Peaks corresponding to ethylbenzene, *m*-diethylbenzene, 1,1-diphenylethane, and 1,1-diphenylethene were observed. The presence of these four compounds was confirmed by collection of samples. The infrared spectra of these samples were identical with those of the authentic compounds. Gas–liquid chromatography showed the absence of 9,10-dimethylanthracene. Quantitative analysis showed that the yields of ethylbenzene, *m*-diethylbenzene, 1,1-diphenylethane, and 1,1-diphenylethene were 0.59 g (11.2%), 0.59 g (17.6%), 0.50 g (5.5%), and 0.82 g (9.1%), respectively.

The Reaction of ^{14}C-Labelled Vinyl Acetate with Benzene and Aluminium Chloride

Vinyl-1,2-^{14}C acetate[3] (8.6 g, 0.1 mole, ca. 0.1 mcurie) was treated with benzene (78 g, 1.0 mole) and anhydrous aluminium chloride (40 g, 0.3 mole) in the same manner as previously described (1). The 9,10-dimethylanthracene obtained after recrystallization was shown to be pure by elemental analysis.

Anal. Calcd. for $C_{16}H_{14}$: C, 93.16; H, 6.84. Found: C, 93.14; H, 6.91.

The activities of the 9,10-dimethylanthracene and its oxidation product anthraquinone (9) were determined. The activity of the vinyl-1,2-^{14}C acetate was determined by the conversion of this compound into iodoform (32). The ratio of the activities of 9,10-dimethylanthracene, anthraquinone, and vinyl acetate was 2.05:1.0:1.04.

When vinyl acetate-1-^{14}C[4] was used the 9,10-dimethylanthracene obtained was essentially inactive.

The Reaction of 1,1-Diphenylethane with Aluminium Chloride

(*i*) 1,1-Diphenylethane (1.8 g) was treated with aluminium chloride (1.3 g) according to the procedure of Korshak *et al.* (27). Distillation of the crude product gave 1,1-diphenylethane (0.2 g), b.p. 146–155° at 13 mm. No more material distilled over until the temperature reached 230–240° (at 15 mm). This indicated the absence of 9,10-dimethylanthracene, b.p. 180–182° at 15 mm (27).

(*ii*) 1,1-Diphenylethane (3.64 g) and aluminium chloride (2.7 g) were heated together at 60–70° for 3 h. The mixture was decomposed and worked up in the usual manner. Unchanged 1,1-diphenylethane (0.45 g), b.p. 148–156° at 15 mm, was recovered by distillation of the crude product (1.85 g). The residue (1.33 g) was chromatographed on alumina (50 g). Nothing was eluted from the column by light petroleum (700 ml). Since 9,10-dimethylanthracene is readily removed from alumina by this solvent, it is clear that no 9,10-dimethylanthracene was present.

(*iii*) 1,1-Diphenylethane (1.8 g), aluminium chloride (1.3 g), and benzene (10 ml) were heated together under reflux for 3 h. The mixture was decomposed and worked up in the usual manner. The crude product (0.75 g) was a brown waxy solid. Gas chromatographic analysis of the crude product, with a SE 30 (5%) on Chromosorb W column (6 ft) at 205° with a helium flow rate of 21 ml/min, indicated the presence of 9,10-dimethylanthracene. 9,10-Dimethylanthracene was obtained by chromatography of the crude product on alumina (30 g), with light petroleum as eluent. Recrystallization from benzene gave yellow needles (0.08 g, 8%), m.p. 178–180°.

The Reaction of 1,1-Diphenylethane with Vinyl Acetate and Aluminium Chloride

(*i*) Vinyl acetate (0.86 g) was added dropwise to a stirred mixture of 1,1-diphenylethane (4.0 g) and aluminium chloride (4.0 g). The mixture was heated at 80° for 3 h, and then decomposed and worked up in the usual manner. Distillation of the crude product (2.8 g) gave 9,10-dimethylanthracene (crude), b.p. ca. 180° at 15 mm. Recrystallization from benzene gave 9,10-dimethylanthracene (0.24 g, 11.5%), m.p. 178–180°.

(*ii*) Vinyl acetate (0.86 g) was added dropwise to a stirred mixture of 1,1-diphenylethane (5.0 g) and aluminium chloride (4.0 g). The mixture was heated at 70–80° for 3 h, and then decomposed and worked up in the usual manner. The crude product (3.0 g) was chromatographed on alumina (50 g). Elution of the column with light petroleum gave 9,10-dimethylanthracene, m.p. ca. 170–176°. Recrystallization from benzene gave yellow needles (0.26 g, 12.5%), m.p. 178–180°.

The Reaction of 1,1-Diphenylethene with Aluminium Chloride

(*i*) 1,1-Diphenylethene (1.8 g) and aluminium chloride were heated together at 70–80° for 3 h. The mixture was decomposed and worked up in the usual manner. Distillation of the crude product did not give 9,10-dimethylanthracene (b.p. 180–182° at 15 mm (27)).

(*ii*) 1,1-Diphenylethene (3.6 g) and aluminium chloride (2.7 g) were heated together at 70–80° for 3 h. The mixture was decomposed and worked up in the usual manner. The crude product (3.6 g) was chromatographed on alumina (50 g). The column was eluted with light petroleum. No 9,10-dimethylanthracene was obtained, but a colorless oil, which crystallized (when washed with methanol) to give a white solid (0.5 g), m.p. 143–145°, was obtained. Schoepfle and Ryan (34) reported that 1,1-diphenylethene, when treated with aluminium chloride, was converted into 1,1,3-triphenyl-3-methylhydrindene, m.p. 143°.

(*iii*) 1,1-Diphenylethene (1.8 g), aluminium chloride (1.3 g), and benzene (10 ml) were heated together under reflux for 3 h. The mixture was decomposed and worked up in the usual manner. The crude product was a dark-colored, viscous liquid (1.56 g). Gas chromatographic analysis of the crude product, with a SE 30 (5%) on Chromosorb W column (6 ft) at 205° with a helium flow rate of 21 ml/min, showed that no 9,10-dimethylanthracene was present.

[3]*Vinyl-1,2-^{14}C acetate (208 mg, 0.5 mcurie) was diluted with inactive vinyl acetate (50 ml); 8.6 g of this material was used.*

[4]*Prepared from acetic acid-1-^{14}C and acetylene (33).*

The Reaction of 1,1-Diphenylethene with Vinyl Acetate and Aluminium Chloride

Vinyl acetate (0.86 g) was added dropwise to a stirred mixture of 1,1-diphenylethene (4.8 g) and aluminium chloride (4.0 g). The mixture was heated at 70–80° for 3 h, and then decomposed and worked up in the usual manner. The crude product (4.3 g) was chromatographed on alumina (100 g). The column was eluted with light petroleum (700 ml). No eluate was obtained, which indicated that no 9,10-dimethylanthracene was present.

ACKNOWLEDGMENTS

Grateful acknowledgment is made of the financial assistance provided by Imperial Oil Limited. The authors thank both the University of Saskatchewan and Canadian Industries Limited for the award to one of them (B. P. R.) of a graduate assistantship (1961–1962) and a fellowship (1962–1963), respectively. The molecular weights and radioactivities were determined by Mr. E. Mazurek and Mr. J. Dyck, National Research Council, Saskatoon.

ABSTRACT

The kinetics, at room temperature, of the oxidation of cyclohexene in the presence of benzaldehyde have been measured, and the nature of the products when this oxidation was performed at 70 and 110 °C has been studied. The results indicate that the attack of benzoyl peroxy radical on the double bond of cyclohexene retards the rate of oxygen absorption and also causes epoxidation of cyclohexene. The epoxidation of cyclohexene by peroxybenzoic acid (produced from aldehyde) seems to proceed simultaneously with the epoxidation by peroxy radicals during the oxidation of cyclohexene in the presence of benzaldehyde.

INTRODUCTION

It is known that the autoxidation of olefin in the presence of aldehyde gives a quite sizable amount of epoxide (1–3) and ester (4, 5), and also that the olefin retards (6) the oxidation of aldehyde.

We have reported (7) that retardation of the liquid-phase oxidation of benzaldehyde caused by the addition of a small amount of non-olefinic compounds (tetralin and cumene) can be explained reasonably well by the co-oxidation scheme postulated by Walling (8), and also (9) that acetaldehyde works as the most effective reaction accelerator for the air oxidation of propylene, doubling the yield of propylene oxide.

The purpose of this paper is to clarify (*a*) the retarding effect of cyclohexene on the rate of oxidation of benzaldehyde, and (*b*) the reaction mechanism of the epoxidation of cyclohexene in the presence of benzaldehyde.

The mechanism of retardation was examined kinetically, and the mechanism of epoxidation was investigated by means of the reaction products.

EXPERIMENTAL

Materials

Cyclohexene was purified by distillation under a nitrogen stream. Benzene was washed successively with concentrated sulfuric acid, dilute alkali, and distilled water, and then dried with sodium metal. Benzaldehyde was purified just before use by fractional distillation under a nitrogen stream at 60 mm Hg pressure and 99.8–100.3 °C.

Oxygen and nitrogen, both 99.9% pure, were dried with calcium chloride. Peroxybenzoic acid was prepared from benzoyl peroxide according to Braun's procedure as modified by Kolthoff *et al.* (10). The following materials were used as reference substances for gas chromatographic analysis: cyclohexene oxide and benzoic acid were used without further purification; cyclohexane-1,2-diol was prepared (11) from cyclohexene and hydrogen peroxide; cyclohexane-1,2-diol monobenzoate was prepared from cyclohexane-1,2-diol and benzoic acid by Owens' procedure (12); cyclohexene-3-ol and cyclohexene-3-on were obtained from the autoxidation of cyclohexene.

Kinetic Measurements at Room Temperature

The rate of oxygen absorption was measured in an oxygen atmosphere with benzene as solvent without cobalt catalyst by the same method as already described in a previous paper (7). The reaction temperature and the concentration of benzaldehyde were kept constant at 19 °C and 3.5 moles/l, respectively, in each run.

Product Study at High Temperatures

The general procedure was essentially the same as described in a previous paper (9). Benzene was added to a mixture of 20 cc of cyclohexene and 6–20 cc of benzaldehyde, up to a total volume of 100 cc. This solution was placed in an autoclave having a 200 cc volume and a magnetic stirrer. Nitrogen was introduced into the autoclave up to 5 kg/cm^2, with and without cobalt acetate. To keep the partial pressure of oxygen at about 3 kg/cm^2, oxygen was occasionally added from an oxygen accumulator. Unreacted cyclohexene, unreacted benzaldehyde, cyclohexene oxide, cyclohexene-3-ol, and cyclohexene-3-on were analyzed by gas chromatography on a 3 m column of P.E.G. 1000 at 110 °C with a hydrogen flow rate of 50 cc/min. Cyclohexene-1,2-diol monobenzoate, cyclohexylbenzoate, and benzoic acid were analyzed on a 2 m column of P.E.G. 20 M at 200 °C with a hydrogen flow rate of 50 cc/min. The retention times of these compounds were 2.3, 52, 10, 43.5, 37, 53, 10.5, and 14 min, respectively. The total acid was measured by titration with alcoholic potassium hydroxide. Carbon dioxide was found to be the major gaseous product on the gas chromatogram. The amount of cyclohexane-1,2-diol dibenzoate was not measured.

Epoxidation of Cyclohexene with Peroxybenzoic Acid

A solution of 20 cc of cyclohexene and 0.165 g of cobalt acetate dissolved in 100 cc of benzene was refluxed in a 250 cc glass flask at 70 °C under a nitrogen atmosphere, a benzene solution containing 0.345 mole peroxybenzoic acid/100 cc being added at the rate of 0.05 mole peroxybenzoic acid/h during 2 h.

RESULTS

Kinetic Measurements

The reaction conditions and results of the kinetic study are summarized in Table I. Since the amount of oxygen absorbed during each measurement was not large, the concentrations of cyclohexene and benzaldehyde could be considered to be constant. Therefore, without any further reaction of peroxides affecting the oxygen absorption, the rate of oxygen absorption should be constant. Typical absorption curves are shown in Fig. 1. The initial absorption rate was different in each run under the same reaction conditions, probably because of a trace of impurity in the reactants. However, at steady state the same rate was obtained under the same reaction conditions. Absorption rates were calculated from the slopes of the straight lines. Since cyclohexene is considered to be an inhibitor during the oxidation of benzaldehyde, the antioxidation during sufficient oxygen pressure can be represented by eqs. [1]–[5] (13).

TABLE I

Reaction conditions and results of the kinetic measurements

Run No.	Initial concentration of benzaldehyde (mole/l)	Observed rate of oxygen absorption (mole/l s)	k_5 (l/mole s)	Calculated rate of oxygen absorption (mole/l s)
1	0	6.61×10^{-5}		
2	0.000395	5.28	2.51×10^{3}	5.66×10^{-5}
3	0.00158	3.67	1.63	3.51
4	0.00395	2.1	1.46	1.87
5	0.0079	1.1	1.50	1.11
6	0.0158	0.77	1.08	0.79
7	0.0790	0.108	1.57	0.095
8	0.197	0.0285	2.39	0.038

Steady-state methods lead to the rate equation shown in eq. [6].

The rate constant k_1 was calculated to be 0.48×10^{-8} l/mole s from the equation of the oxidation rate of pure benzaldehyde. By using values of k_1 and k_3 equal to 2.2×10^3 l/mole s (14) and $k_4 = 2.3 \times 10^8$ l/mole s (14) and the observed oxidation rates of the mixture at 19 °C, the values of k_5 are calculated from eq. [6] (Table I). The values of k_5 should be constant regardless of the concentration of reactant; the calculated values of k_5 appear to be roughly constant. By using the k values noted above and k_5 (mean) = 1.79

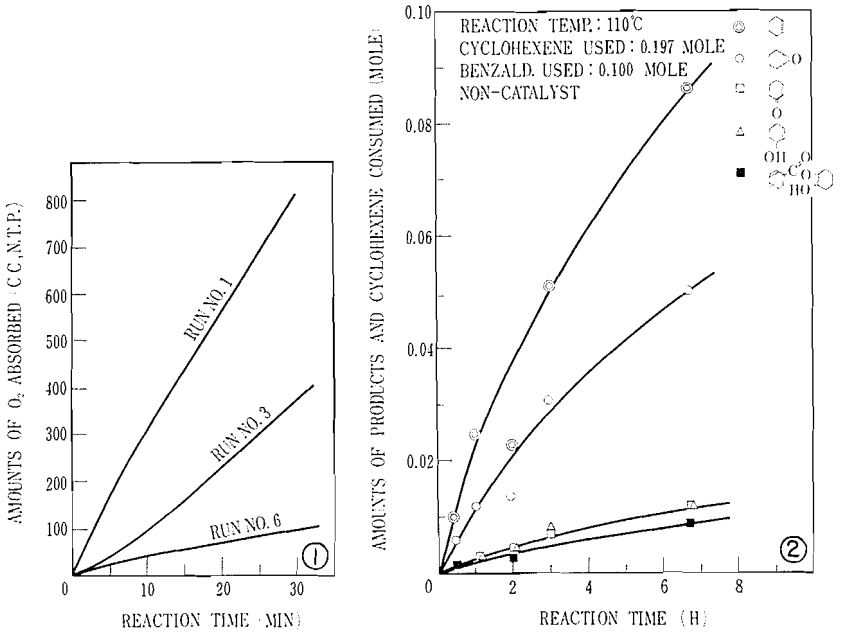

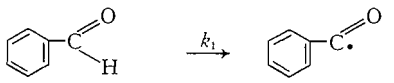

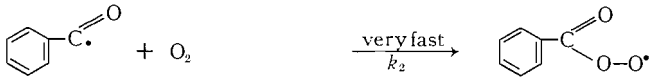

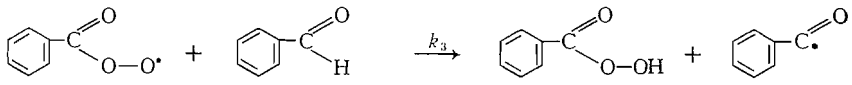

FIG. 1. Oxidation of binary system.
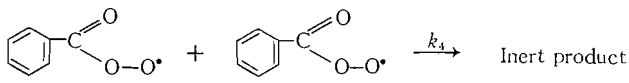
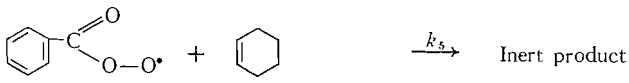
FIG. 2. Products versus reaction time.



$\times 10^3$ l/mole s, the rates of oxygen absorption are calculated (Table I); the results were in good agreement with the observed values. The reaction schemes of the co-oxidation suggested by Walling (8) and by Ikawa *et al.* (7), in addition to other assumptions, have been applied to this reaction system, but the retardation of the oxidation rate could not be explained very well. It therefore seems that cyclohexene combines with benzoyl peroxy radical as shown in eq. [5], and reduces the oxidation rate.



It was difficult to analyze accurately the reaction products at room temperature, because only a small amount of cyclohexene had reacted. Therefore, the products were

analyzed at high temperatures. It is uncertain whether the reaction mechanism at room temperature holds at 70–100 °C, but it can serve to clarify the mechanism of epoxidation at high temperatures.

Product Study at High Temperatures

The reaction conditions and results are presented in Table II. The rate of oxidation without catalyst was so slow at 70 °C that oxidation had to be carried out at 110 °C. The variations in the yields of products and in the amounts of cyclohexene and benzaldehyde consumed are shown in Figs. 2 and 3. The effect of the concentration of benzaldehyde on the selectivities of products is shown in Fig. 4. Cyclohexene oxide was obtained in a good

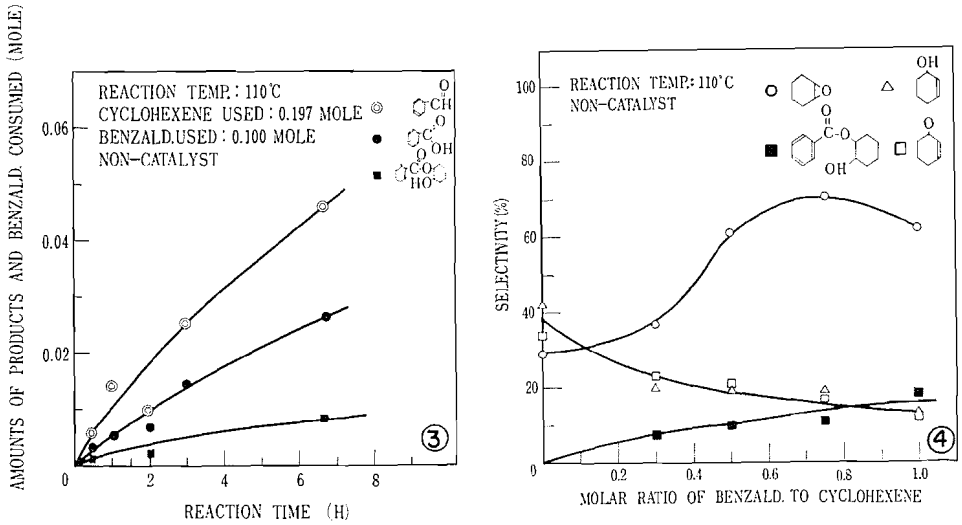

FIG. 3. Products versus reaction time.
FIG. 4. Selectivity of products.

yield. The selectivity of the epoxide was increased by adding benzaldehyde. Although the rate of oxygen absorption has not been measured exactly, during the oxidation of pure cyclohexene the rate was different in every run, but the selectivities of products remained roughly constant. Run 20 (Table II) is an example of these runs. By adding cobalt acetate or benzaldehyde the reproducibility of this procedure became satisfactory. A trace of cyclohexylbenzoate but no cyclohexane-1,2-diol was found on the gas chromatogram, and a trace of peroxide was detected by iodometry. Acid and carbon dioxide appear to have been formed from benzaldehyde, since they were detected in only small amounts in the oxidation products of pure cyclohexene. A sizable amount of polymerized product was found in the residue after distillation of the products.

Epoxidation with Peroxybenzoic Acid

The most probable reaction mechanism for epoxidation during the autoxidation of olefin in the presence of aldehyde seems to be the reaction of olefin with peracid produced by aldehyde. However, it must also be considered that benzoyl peroxy radical reacts directly with cyclohexene to form the epoxide by a mechanism similar to that postulated by Twigg (15) for the oxidation of pure olefin and confirmed by Brill (16, 17) and Roch (18). To ascertain which of these processes was of importance, epoxidation by peroxybenzoic acid was studied in the presence of cobalt acetate. No peroxide and peracid were detected

in the product by iodometry. In spite of a high rate of epoxidation, only 3% of the peracid reacted with cyclohexene to form cyclohexene oxide in the presence of cobalt acetate. This result shows that the rate of catalytic decomposition of peroxybenzoic acid is much larger than the rate of epoxidation.

DISCUSSION

The results of the kinetic study indicate that cyclohexene works as an acceptor for benzoyl peroxy radical and reduces the rate of oxygen absorption at room temperature.

If the results of the epoxidation of cyclohexene with peracid in the presence of cobalt acetate are considered, it is unlikely that epoxidation with peracid is the main epoxidation route in the actual cobalt-catalyzed oxidation. Cyclohexenyl or benzoyl peroxy radical seems to take part in epoxidation. Brill (16) reported that cyclohexenyl peroxy radical combined with a double bond of cyclohexene to form cyclohexene oxide and cyclohexenyl alkoxy radical, which were converted into cyclohexenol and cyclohexenone. We have obtained cyclohexene oxide in the products of the oxidation of pure cyclohexene, and a fair amount of cyclohexene-3-ol and cyclohexene-3-on in the products of the catalytic oxidation in the presence of benzaldehyde. These results indicate the considerable contribution of cyclohexenyl peroxy radical in epoxidation, whereas increasing the selectivity of the epoxide by the addition of benzaldehyde supports the contribution of benzoyl peroxy radical in epoxidation. It is considered that benzaldehyde reacts easily to form benzoyl peroxy radical, which then attacks the hydrogen atom of cyclohexene and causes the increase in the concentration of cyclohexenyl peroxy radical, the latter contributing to the epoxidation. This reaction scheme may be negligible at room temperature, if the results of the kinetic study are taken into account. It is usually considered (19) that most of the additions of radicals at double bonds of olefins involve very low activation energies; consequently, at low temperatures their rates exceed those of the competing abstraction of hydrogen from the olefins. This situation is reversed at high temperatures, abstraction then becoming dominant. Therefore, cyclohexenyl peroxy radical appears to contribute much to the epoxidation at high temperatures. The increase in the molar ratio of cyclohexene oxide to cyclohexenol and cyclohexenone, both of which result from cyclohexenyl peroxy radical, with the addition of benzaldehyde is shown in Fig. 5, and the decrease in the selectivities of cyclohexenol and cyclohexenone with the addition of benzaldehyde is shown in Table II. These results indicate that the attack of benzoyl peroxy radical on the hydrogen of cyclohexene is not dominant at 70–110 °C, and lead to the speculation that benzoyl peroxy radical plays a considerable role directly in the epoxidation during the cobalt-catalyzed oxidation. A probable reaction scheme for the epoxidation during the cobalt-catalyzed oxidation is the attack of benzoyl peroxy radical on a double bond of cyclohexene to form the epoxide and benzoyl alkoxy radical; this mechanism is similar to that postulated by Twigg (15).

The increase in the selectivity of the epoxide in the non-catalytic oxidation compared with that in the cobalt-catalyzed oxidation will result from the epoxidation of cyclohexene with peroxybenzoic acid, the rate of which (20) is larger than the rate (21) of the thermal decomposition of the peracid and the rate (22) of the Baeyer–Villiger reaction of benzaldehyde with the peracid.

Since the kinetic study has shown that the rate of reaction [5] is comparable with that of reaction [3] at room temperature, it may be concluded that the combination of benzoyl peroxy radical with a double bond of cyclohexene also contributes more than a little to the epoxidation during the non-catalytic oxidation at 70–110 °C.

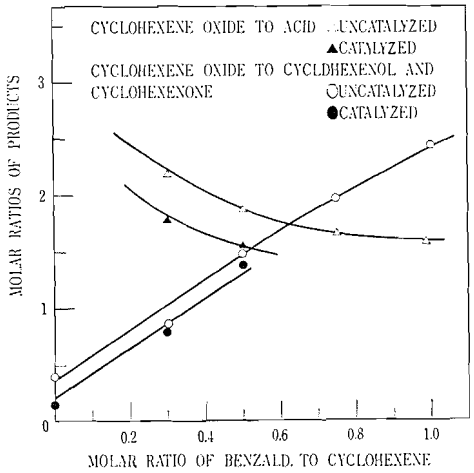

FIG. 5. Molar ratio of products.

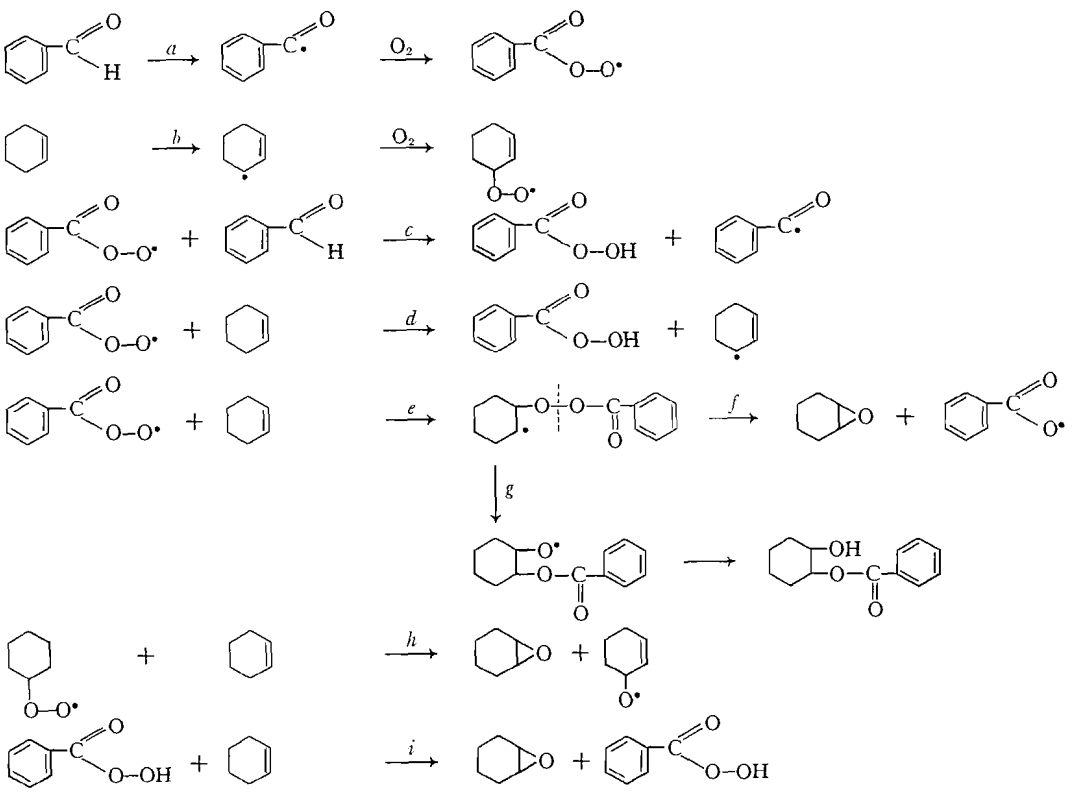
Most of the benzoyl alkoxy radical may be converted into benzoic acid, and the rest of it seems to combine with a double bond of cyclohexene, possibly to form esters. However, the latter is unlikely because (*a*) cyclohexane-1,2-diol monobenzoate is obtained at the same selectivity in the non-catalytic and the catalytic oxidation (in the latter case there is a greater concentration of benzoyl alkoxy radical in the reaction mixture than in the former case because of a sizable amount of benzoyl alkoxy radical produced by the catalytic decomposition of peroxybenzoic acid), and (*b*) a trace of cyclohexyl benzoate is obtained.

If one considers the fact (4) that cyclohexene gives a large amount of cyclohexane-1,2-diol monobenzoate at 50 °C in the oxidation with benzaldehyde, the ester seems to be produced by reaction [5] at low temperatures. At 110 °C, the ester appears to be produced by the reaction of cyclohexene oxide with benzoic acid, because no cyclohexane-1,2-diol is found in the oxidation products and the calculated amount of the ester is of about the same order of magnitude as that obtained in the actual oxidation at 110 °C by using the observed rate of esterification of cyclohexene oxide with benzoic acid and the assumed rate of formation of the epoxide and the acid. Unbalanced benzaldehyde and cyclohexene are considered to be polymerized product and the unknown products on the gas chromatogram.



Based on the speculation described above, the probable reaction schemes for the epoxidation will be as shown in Reaction Scheme 1.

The fact that propylene gives propane-1,2-diol monoacetate (5) at low temperatures and propylene oxide (9) at high temperatures in the air oxidation with acetaldehyde, and the fact that cyclohexene gives cyclohexane-1,2-diol monobenzoate (4) at 50 °C in the oxidation with benzaldehyde, support reactions *e*, *f*, and *g*.

In the non-catalytic oxidation at room temperature, the rates of reactions *b* and *d* are so slow that they can be neglected, and the concentration of cyclohexenyl peroxy radical is low in the reaction system. Therefore, the oxidation scheme consists of reactions *a*, *c*, and *e*, and the rate equation shown in eq. [6] can be derived. The reactivity of the radical $C_6H_5CO_2OC_6H_{10}\cdot$ could be considered to be not too high.

The rate of reaction *d* is considered during the oxidation at 70–110 °C, but if it is assumed that this rate is slower than those of reactions *c* and *e*, the increase in the molar

REACTION SCHEME 1.

ratio of the epoxide to cyclohexenol and cyclohexenone and the decrease in the selectivities of cyclohexenol and cyclohexenone with the addition of benzaldehyde are consistently explained.

Finally, concerning the mechanism of the formation of the epoxide, the main reaction occurs between benzoyl peroxy radical and cyclohexene (reactions *e* and *f*) in the case of cobalt-catalyzed oxidation. It seems that the minor reaction between cyclohexenyl peroxy radical and cyclohexene (reaction *h*) could occur besides the main reaction. However, the minor reaction would not contribute very much at a high concentration of benzaldehyde. In the non-catalytic oxidation, besides the above two reactions, the reaction between peroxybenzoic acid and cyclohexene (reaction *i*) would be added to the epoxidation; thus the overall selectivity of the epoxide has been increased.

ACKNOWLEDGMENTS

The authors express their appreciation to Prof. Ikuzo Tanaka, Tokyo Institute of Technology, for his helpful discussions. The authors also thank Mr. Takashi Shintani for his technical assistance. One of the authors (T. I.) thanks the Tōyō Sōda Manufacturing Co., Ltd., for its financial support.

LIGNANS OF WESTERN RED CEDAR (THUJA PLICATA DONN)

V. HYDROXYTHUJAPLICATIN METHYL ETHER

HAROLD MACLEAN[1] AND KOJI MURAKAMI[2]

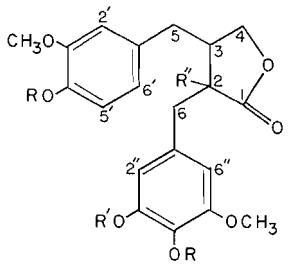
Forest Products Laboratory, Department of Forestry of Canada, Vancouver, British Columbia

Received March 3, 1966

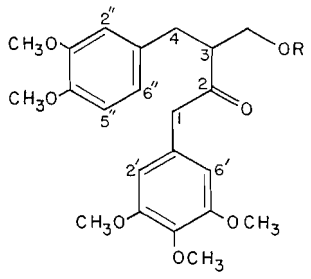
ABSTRACT

The structure of another guaiacyl–syringyl type lignan, which was previously separated from the hot-water extractive of western red cedar (*Thuja plicata* Donn), has now been determined as 2-hydroxy-2-(4″-hydroxy-3″,5″-dimethoxybenzyl)-3-(4′-hydroxy-3′-methoxybenzyl)-butyrolactone (III). This lignan is the third member of the thujaplicatin series and has been given the name of hydroxythujaplicatin methyl ether. Analytical data and degradational and spectral studies of the parent compound and its methylated derivatives are presented as proof of structure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



The separation of several new components from the hot-water extractive of western red cedar (*Thuja plicata* Donn) heartwood as well as the structural characterization of two of them, thujaplicatin (I) and thujaplicatin methyl ether (II), was reported in a previous paper (1). Another of the components whose separation was reported in the foregoing paper (R_f 0.25 by thin-layer chromatography) has now been determined as hydroxythujaplicatin methyl ether (III).



The aromatic rings of III were identified by nitrobenzene oxidation, which yielded both vanillin and syringaldehyde (2). Hydroxythujaplicatin methyl ether (III) and its dimethyl ether derivative (IV) both gave the expected infrared and ultraviolet spectra. Nuclear magnetic resonance (n.m.r.) spectra with integrals of both compounds accounted for all protons and proton species. The four (C5-C6) methylene protons and the one (C3) methine proton could not be assigned with certainty, but occurred in the expected range in both cases, 2.4–3.3 δ. The methylene protons of the lactone ring (C4) were shifted downfield as expected, and appeared as a doublet centered near 4.0 δ with unresolved splitting indicative of the AB portion of an ABX spectrum. Carbon–hydrogen, methoxyl, and equivalent and molecular weight data agreed with the theoretical calculations for both compounds III and IV. The equivalent weight titration was carried out by dissolving hydroxythujaplicatin methyl ether in sodium hydroxide solution to open the lactone ring, and then back-titrating with acid. The product reclaimed from the solution was identical with the starting material. Thus no change of configuration had taken place. A plot of this back-titration curve showed hydroxythujaplicatin methyl ether (III) to be a stronger acid than thujaplicatin methyl ether (II), and indicated that the alcoholic hydroxyl group was alpha to the carbonyl group. Since reaction with manganese dioxide failed to form a ketone group (3), a benzyl alcohol group was not present on either carbon 5 or carbon 6.

Periodate oxidation of dimethyl ether derivative IV at pH 5 was slow and yielded 1-(3′,4′,5′-trimethoxyphenyl)-4-(3″,4″-dimethoxyphenyl)-3-hydroxymethyl-2-butanone (V). Since formaldehyde was not produced in this reaction, the alcoholic hydroxyl group was not attached to carbon 3 of the di-*O*-methyl compound (IV). Slow periodate oxidation at this pH was indicative of an α-hydroxy acid (4). Infrared spectral comparison of IV

[1]*Research Officer, Forest Products Laboratory, Department of Forestry of Canada, Vancouver, British Columbia.*

and V showed the disappearance of the lactone carbonyl and appearance of a ketone carbonyl at 1 700 cm^{-1}. Acetylation of the butanone V to form the butanone acetate (VI) shifted the hydroxymethylene protons downfield from the 3.7–3.9 δ region, where they were obscured by the methoxyl protons, to form a doublet centered at 4.19 δ. This shift allowed the unambiguous assignment of all protons and proton species in both V and VI (see Experimental). The fact that V was an oxidation product proved that the

I R,R′,R″ = H

II R,R″ = H; R′ = CH_3

III R = H; R′ = CH_3; R″ = OH

IV R,R′ = CH_3; R″ = OH

V R = H

VI R = CH_3CO

alcoholic hydroxyl group and the carbonyl of the lactone ring were attached to carbon 2 of the original compound (III). Periodate oxidation of V at pH 8–9 yielded 3,4,5-trimethoxybenzaldehyde, identical with an authentic sample. The formation of this aldehyde, as a result of periodate reaction with the active methylene group (5) at carbon 1 of the butanone derivative V, proved that the syringyl group of the original compound was attached as shown in III.

Hydroxythujaplicatin methyl ether is therefore 2-hydroxy-2-(4″-hydroxy-3″,5″-dimethoxybenzyl)-3-(4′-hydroxy-3′-methoxybenzyl)-butyrolactone (4,4′,8′-trihydroxy-3,3′,5-trimethoxy-lignan-olid (9,9′) by the nomenclature of Freudenberg and Weinges (6)).

EXPERIMENTAL

The following equipment was used: melting points, Fisher–Johns heated block; infrared spectra, Baird-Atomic KM-1 spectrometer (KBr disks); ultraviolet spectra, Beckman DK-2 spectrophotometer (ethanol); n.m.r. spectra, Varian A.60 spectrophotometer with tetramethylsilane ($\delta = 0$) as internal standard in deuteriochloroform; molecular weights, Mechrolab osmometer 301A with benzil and β-conidendrin as reference compounds. Analyses were carried out by Clark Microanalytical Laboratories, Urbana, Illinois. The thin-layer chromatography values were obtained with silica gel G (Merck) as adsorbent and with benzene – ethanol – acetic acid (100:10:1 v/v/v) as solvent; the spots were detected by ultraviolet light followed by nitric acid – sulfuric acid (1:1) spray and heat. For preparative layer chromatography a mixture of silica gel G and GF 254 (Merck) (2:1) was used as adsorbent with the thin-layer chromatographic solvent, and the spots were detected by ultraviolet light.

Hydroxythujaplicatin Methyl Ether (III)

Separation of this compound (R_f 0.25) from the hot-water extractive of western red cedar heartwood has been described previously (1). The crude hydroxythujaplicatin methyl ether (430 mg) was purified by cellulose column chromatography with carbon dioxide saturated water, and crystallized from ether (110 mg). The crystals contained ether, and melted at 55–60 °C with foaming. After the crystals were dried for 2 h under vacuum at 54 °C, the melting point was raised to 128.5–129.5 °C. Nitrobenzene oxidation yielded vanillin (3.9%) and syringaldehyde (6.5%) by the modified method of Pepper and Siddequeullah (2).

Anal. Calcd. for $C_{21}H_{24}O_8$: C, 62.38; H, 5.98; OCH_3, 23.02; mol. wt. 404. Found: C, 62.42, 62.31; H, 5.98, 6.00; OCH_3, 22.74, 22.96; equiv. wt. (by back-titration) 396; mol. wt. 409.

Spectra: λ_{max} 281 mμ (log ϵ 3.58); in 0.025 *N* sodium ethoxide, 292 mμ (log ϵ 3.87); ν_{max} 3 500 (OH) and 1 768 cm^{-1} (lactone); n.m.r. 6.86 (1H-C5′, doublet, $J = 8.5$ c.p.s.), 6.67 (1H-C6′, quartet, $J = 1.7$ and

8.5 c.p.s.), 6.65 (1H-C2′, doublet, J = 1.7 c.p.s.), 6.40 (2H-C2″,6″, singlet), 5.62 and 5.55 (2H-phenols, singlets, quenched by deuterium exchange), 4.05 (2H-C4, doublet, separation of 6.0 c.p.s., with unresolved fine structure), 3.85 and 3.86 (9H-OCH_3, singlets), 2.78 (1H-hydroxyl, singlet, shifted to 2.65 by increasing the temperature to 50 °C and quenched by deuterium exchange), and 2.4–3.1 δ (5H-C3,5,6, unresolved multiplet). $[\alpha]_D^{25}$ −54.8° (c, 0.88 in chloroform).

Di-O-methyl Hydroxythujaplicatin Methyl Ether (IV)

Hydroxythujaplicatin methyl ether (III) (300 mg) in methanol (0.7 ml) was treated with excess diazomethane in ether at room temperature for 24 h. The reaction was monitored during its early stages, when it showed spots at R_f 0.25 (unreacted III), R_f 0.36 and 0.41 (the two monomethyl derivatives), and R_f 0.51 (the dimethyl product IV). At the end of the reaction, only the dimethyl product was detected. The product was reclaimed by evaporation (304 mg) and recrystallized from ether (225 mg), m.p. 113.5–114.5° C, $[\alpha]_D^{25}$ −50.0° (c, 0.92 in chloroform).

Anal. Calcd. for $C_{23}H_{28}O_8$: C, 63.89; H, 6.50; OCH_3, 35.88; mol. wt. 432. Found: C, 63.55, 63.65; H, 6.43, 6.45; OCH_3, 35.80, 35.99; mol. wt. 432.

Spectra: ν_{max} 3 500 (hydroxyl, 3 588 in $CHCl_3$) and 1 776 cm^{-1} (lactone); n.m.r. 6.6–6.9 (3H-C2′,5′,6′, unresolved multiplet), 6.44 (2H-C2″,6″, singlet), 4.07 (2H-C4, doublet, separation of 6.0 c.p.s., with unresolved fine structure), 3.85 and 3.86 (15H-OCH_3, singlets), 3.34 (1H-hydroxyl, singlet, quenched by deuterium oxide with trifluoroacetic acid), and 2.4–3.3 δ (5H-C3,5,6, unresolved multiplet).

Periodate Oxidation of Di-O-methyl Hydroxythujaplicatin Methyl Ether (IV)

Dimethyl derivative IV (600 mg) was dissolved in an equivalent amount of 0.6 N methanolic sodium hydroxide and refluxed for several minutes. Water (10 ml) and 0.1 M sodium metaperiodate (14 ml) were added and the pH was adjusted to 5 with 1 N acetic acid. The reaction mixture was maintained at 0 °C overnight, acidified with dilute hydrochloric acid to pH 2–3, and left for another hour at room temperature. It was then extracted with chloroform (5 × 30 ml), and the chloroform extracts were combined, dried over sodium sulfate, and concentrated. The products were separated by preparative layer chromatography to yield, on crystallization from carbon tetrachloride and recrystallization from ether, the butanone V (R_f 0.30) (65 mg), m.p. 101–101.5 °C, as well as unreacted crystalline starting material (430 mg). No formaldehyde was detected by dimedone precipitation (7).

Anal. Calcd. for 1-(3′,4′,5′-trimethoxyphenyl)-4-(3″,4″-dimethoxyphenyl)-3-hydroxymethyl-2-butanone (V) ($C_{22}H_{28}O_7$): C, 65.35; H, 6.95; OCH_3, 38.37. Found: C, 65.07; H, 6.91; OCH_3, 38.14.

Spectra: ν_{max} 3 450 (hydroxyl) and 1 700 cm^{-1} (carbonyl); n.m.r. 6.82 (1H-C5″, doublet, J = 8.6 c.p.s.), 6.65 (1H-C2″, doublet, J = 1.7 c.p.s.), 6.63 (1H-C6″, quartet, J = 1.7 and 8.6 c.p.s.), 6.27 (2H-C2′,6′, singlet), 3.79, 3.81, and 3.83 (15H-OCH_3, singlets), 3.7–3.9 (2H-hydroxymethylene, overlapping methoxyl), 3.52 (2H-C1, singlet), 2.95–3.30 (1H-C3, multiplet), 2.77 (2H-C4, doublet, J = 6.0 c.p.s.), and 2.41 δ (1H-OH, broad singlet). $[\alpha]_D^{22}$ −72.0° (c, 0.20 in chloroform).

1-(3′,4′,5′-Trimethoxyphenyl)-4-(3″,4″-dimethoxyphenyl)-3-acetoxymethyl-2-butanone (VI)

The butanone (V, 50 mg) from the foregoing periodate oxidation was treated with acetic anhydride in pyridine (1:2 v/v, 0.8 ml) overnight. The solvents were evaporated and the product was purified by preparative layer chromatography. The acetate (VI) was recovered from the silica gel with CCl_4 and, on solvent removal by vacuum evaporation, crystallized spontaneously (45 mg), m.p. 67–68.5 °C. Spectra: ν_{max} no hydroxyl band, 1 730 (acetoxyl) and 1 708 cm^{-1} (carbonyl); n.m.r. 6.76 (1H-C5″, doublet, J = 8.5 c.p.s.), 6.60 (1H-C2″, doublet, J = 1.7 c.p.s.), 6.59 (1H-C6″, quartet, J = 1.8 and 8.5 c.p.s.), 6.21 (2H-C2′,6′, singlet), 4.19 (2H-hydroxymethylene, doublet, J = 6.4 c.p.s.), 3.82 and 3.79 (15H-OCH_3, singlets), 3.43 (2H-C1, singlet), 3.05–3.40 (1H-C3, multiplet), 2.72 (2H-C4, doublet, J = 6.8 c.p.s.), and 1.95 δ (3H-acetyl, singlet).

Periodate Oxidation of 1-(3′,4′,5′-Trimethoxyphenyl)-4-(3″,4″-dimethoxyphenyl)-3-hydroxymethyl-2-butanone (V)

Periodate oxidation of V at pH 5 was unsuccessful. The butanone derivative V (42 mg) was dissolved in water containing 20% methanol (10 ml), and potassium metaperiodate (80 mg) was added. The reaction mixture was adjusted to pH 8–9 with sodium carbonate and left at room temperature for 2.5 h. After acidification with dilute hydrochloric acid, the reaction products were reclaimed by chloroform extraction and subsequent evaporation. These products were purified by preparative layer chromatography to yield crystalline 3,4,5-trimethoxybenzaldehyde (R_f 0.70) (2 mg), m.p. 72–73.5 °C, identical by mixed melting point and infrared spectral comparison with an authentic sample prepared from gallic acid trimethyl ether (8, 9). No other discrete spots capable of being identified, other than that of unreacted V, were found by thin-layer chromatography.

PYRROLE CHEMISTRY

V. FRIEDEL–CRAFTS ISOPROPYLATIONS OF SOME PYRROLE DERIVATIVES

HUGH J. ANDERSON AND L. CAMERON HOPKINS
Department of Chemistry, Memorial University, St. John's, Newfoundland

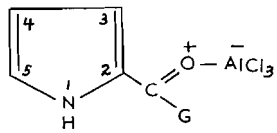
Received March 4, 1966

ABSTRACT

The Friedel–Crafts isopropylations of methyl 2-pyrrolecarboxylate, 2-pyrrolecarboxaldehyde, and 2-pyrryl methyl ketone have been investigated under a variety of conditions. Products have been isolated and identified. The effects of different Lewis acid catalysts, solvents, and reaction times upon conversion and product isomer distribution have been determined. These results support the sequence of mechanistic steps suggested in an earlier publication. Further experiments have involved attempted rearrangements and disproportionations under alkylation conditions. The evidence indicates that Lewis acid complexing of the carbonyl oxygen deactivates position 4 in electrophilic substitution less than it does positions 3 and 5. The extent of deactivation of the different positions varies from 2-ester to 2-ketone to 2-aldehyde. Some proton nuclear magnetic resonance investigations of the Lewis acid complexes of these 2-carbonyl pyrroles are also reported.

INTRODUCTION

In a previous publication (1) we have discussed the Friedel–Crafts isopropylation of methyl 2-pyrrolecarboxylate catalyzed by aluminium chloride with carbon disulfide as solvent. It was suggested that electrophilic attack occurred primarily at the 4-position, leading to the formation of methyl 4-isopropyl-2-pyrrolecarboxylate as the major product, and that methyl 5-isopropyl-2-pyrrolecarboxylate arose mainly from the concurrent or consecutive intramolecular rearrangement of the isopropyl group. The third reaction product, methyl 4,5-diisopropyl-2-pyrrolecarboxylate, appeared to result principally from isopropylation of the 5-isopropyl-2-ester. In the present work we have extended the study to include 2-pyrrolecarboxaldehyde and 2-pyrryl methyl ketone (2-acetylpyrrole) as substrates, and have used a wider range of solvents and Lewis acid catalysts with all three carbonyl compounds.



2-Pyrryl methyl ketone was prepared by the reaction of acetic anhydride with pyrrylmagnesium bromide as described by Oddo and Dainotti (2), and 2-pyrrylcarboxaldehyde by a Vilsmeier synthesis (3).

The structures of the 4-isopropyl-, 5-isopropyl-, and 4,5-diisopropyl-2-esters have already been established (1). Isopropylation of 2-pyrrolecarboxaldehyde gave only the 4-isopropyl derivative. The nuclear magnetic resonance (n.m.r.) spectra and elemental analyses were in agreement with the assigned structure, and oxidation with silver oxide produced the known 4-isopropyl-2-pyrrolecarboxylic acid (1, 4).

Gas–liquid partition chromatography of the isopropylation product from 2-acetylpyrrole indicated three products. These were isolated by column chromatography on alumina and identified by their elemental analyses and n.m.r. spectra as the 4-isopropyl-, 5-isopropyl-, and 4,5-diisopropyl-2-pyrryl methyl ketones by analogy with the corresponding esters. In addition, the reaction of acetic anhydride with the Grignard reagent from a mixture of isopropylpyrroles, of which more than 80% was the 2-isomer, gave as the major product a compound having the same retention time on the gas chromatograph as the product we presumed to be the 5-isopropyl-2-pyrryl methyl ketone.

Before the results of the isopropylation reactions are discussed, it seems useful to consider two other related studies, since they indicate possible explanations for many of the observed facts.

In the earlier publication (1) it was suggested that the predominant electronic effect in compounds of this sort should be electron withdrawal by the 2-substituent. This would be expected to be enhanced greatly by the complexing of the carbonyl oxygen with a Lewis acid (see structure I). The consequent deactivation of positions 3 and 5 should lead to predominantly 4-isopropylation, as observed.

G = H, CH_3, OCH_3

I

This simple picture was supported by Hückel molecular orbital calculations (5) of the localization energies for electrophilic substitution at the 3-, 4-, and 5-positions of 2-pyrrolecarboxaldehyde. These calculations indicated that the localization energy required at position 4 was substantially less than that required at positions 3 and 5. Further, as the carbonyl oxygen was made increasingly electronegative, the localization energies at all open aromatic carbons increased. However, the increase was proportionately far greater at the 3- and 5-positions than at the 4-position. Thus, Lewis acid complexing should lead to an even higher proportion of the 4-isomer in electrophilic substitution. However, the complexing does deactivate all aromatic positions to some extent.

It was found that Lewis acid complexing of these 2-carbonyl compounds had a marked effect on the n.m.r. chemical shift positions of the aromatic (and other) protons, as indicated in Tables I and II. The signal positions obtained from each of the parent compounds were assigned (Table I) through their coupling constants (Table II) and by other means (6), and were found to be 5, 3, and 4 in order of increasing field. When these carbonyl compounds, in the same solvent, were complexed with a Lewis acid the signal positions of aromatic protons were all moved to lower field, with the 3- and 5-signals moving nearly twice as far as the 4-signal in each system (Table III).

The chemical shift positions of the 4- and 5-protons in the complexed ester spectrum were closer together than was found with either the complexed aldehyde or the complexed ketone. It was also observed that the downfield shift of the proton signal positions caused by complexing the ester was much less than that caused by complexing the aldehyde and ketone. It is interesting that these observations, referring as they do to electron density in the ground state, parallel some of the calculations discussed above involving the transition state. The most deactivated positions show the greatest change in shift with complexing. This is possibly indicative of a similarity between ground and transition states for 4- and 5-substitution in these compounds.

The inductive withdrawal of electrons caused by complex formation was also observed in the movement to lower field of the n.m.r. signals of the ketone CH_3 and ester OCH_3 protons. However, the aldehyde proton signal was moved instead to higher field by Lewis acid complexing. Complex formation should lead to a withdrawal of electrons from the carbonyl bond, changing the bond order and decreasing the strength of the deshielding induced magnetic field, thus moving the resonance signal to higher field as observed.

Alkylation Experiments

The effects of substituent, catalyst, solvent, and time on the rate of reaction and product distribution were determined for the three 2-carbonyl pyrroles. The results of these experiments are presented in Table IV.

2-Pyrrolecarboxaldehyde·$AlBr_3$	$C_2H_4Cl_2$	−0.89	−0.52	−0.86	+0.80 (CHO)

*Values are in parts per million; positive is to higher and negative to lower field from the uncomplexed chemical shift positions given in Table I.

Most of these reactions were carried out under the standardized conditions reported earlier (1). As Table IV indicates, the aldehyde appeared to be the most reactive in all such experiments and formed only the 4-isopropyl-2-aldehyde under nearly all experimental conditions. However, the 2-ketone generally gave small amounts of both the 5-isopropyl and 4,5-diisopropyl derivatives (but far less than had been obtained with the 2-ester), along with the 4-isopropyl-2-ketone.

Under the same conditions the order of reactivity of these carbonyl compounds was aldehyde > ketone > ester. However, the physical states of the reaction mixtures were at least partly responsible for this. The reactions in carbon disulfide with aluminium chloride as a catalyst produced a heterogeneous mixture which formed a "red oil" layer below the carbon disulfide. This took place quite slowly with the ester, whereas both the aldehyde and the ketone rapidly formed the red oil.[1] In this highly polar and acidic medium with a high concentration of reactants, the reaction would be expected to occur much faster than in the less polar and more dilute carbon disulfide layer. In fact, the reactions proceeded very much more rapidly as soon as this layer formed. Separate preliminary examinations of the red oil and solvent phases by gas chromatography revealed

[1]*The actual color of the oil obtained from the 2-ester was yellow-amber, whereas the oils separating in the aldehyde and ketone experiments were red.*

a higher proportion of product in the oil layer than in the carbon disulfide. This was found to be qualitatively true for reactions of all three carbonyl compounds, and will be investigated further. Olah and Meyer (7) discuss previous investigations concerning the nature of the red oil. However, these studies have mainly involved aromatic hydrocarbons.

Presumably, a complex between the carbonyl oxygen and the Lewis acid has been formed when the red oil separates. If complex formation is not complete, then both free and complexed substrate are present, and the former would be expected to react very much more rapidly and to form both 4- and 5-substituted products. This would require different equilibrium constants for each substrate – Lewis acid complex. There is no real evidence to support this. Indeed, the ester in carbon disulfide forms the red oil most slowly and reacts more slowly than the aldehyde (even with $AlBr_3$), but produces the most 5-isomer.

If, however, all three carbonyl compounds are completely complexed, we are dealing with the relative localization energies for electrophilic attack at positions 4 and 5 in each complex system. The Hückel molecular orbital calculations mentioned above support the idea that Lewis acid complexing of the carbonyl group greatly increases the required energy at all positions, but most markedly at positions 3 and 5. The isopropylation results indicate that this effect is felt most in the aldehyde and least in the ester. Thus the barrier to 5-substitution, either by direct attack or by rearrangement, is lowest for the complexed ester. The fact that the observed behavior of the 4- and 5-proton signals in the n.m.r. spectra of the complexed carbonyl compounds indicates that this is the order of electron density in the ground state is interesting and supports this idea.

Both aluminium bromide and gallium chloride were soluble in carbon disulfide, and a very rapid formation of the red oil layer with the ester and a very much more rapid isopropylation took place than when aluminium chloride was used. With these last two catalysts the degree of rearrangement and diisopropylation of the ester was significantly less. However, the ketone and the aldehyde product distributions in isopropylations with these catalysts were not particularly different from those obtained with aluminium chloride.

Under the conditions used in the rearrangement (1) of the 4-isopropyl- to the 5-isopropyl-2-ester, no change took place with the 4-isopropyl-2-aldehyde. Similar attempted rearrangements of the 4-isopropyl-2-ketone were inconclusive, but gas chromatography indicated that the extent of rearrangement must be very much less than that observed for the corresponding ester. The 4,5-diisopropyl-2-ketone did not disproportionate under these conditions, in agreement with the behavior of the correspondingly substituted 2-ester (1).

The complete absence of 5-isopropylation of the 2-aldehyde and the very low percentage with the 2-ketone may be linked with the failure of the rearrangement experiments with the 4-isopropyl-2-aldehyde and 4-isopropyl-2-ketone. Complexing of these two compounds with the Lewis acid catalyst leads to electron withdrawal from the 5-position to such an extent that the π-electron localization energy for the sigma complex precludes, or nearly precludes, 5-substitution either by direct attack or by rearrangement from the 4-position. The corresponding electron withdrawal at the 4-position is apparently much less.

On the other hand, the 2-ester seems to have a lower energy sigma complex for Friedel–Crafts isopropylation at the 5-position and may undergo 5-isopropylation by both rearrangement and direct attack. As indicated in the earlier publication, rearrangement appears to be a much more important pathway.

The use of a swamping amount of catalyst in 2-ester isopropylations led to methyl 5-isopropyl-2-pyrrolecarboxylate almost exclusively. Reactions of 2-ketone and 2-aldehyde under the swamping catalyst conditions led to a much smaller increase in the percentage

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of 5-isopropyl-2-ketone and none of the 5-isopropyl-2-aldehyde. These alkylation experiments with a swamping amount of catalyst appear to be analogous to the behavior of monoalkylbenzenes and phenol on alkylation. In each example it is the most basic isomer which forms the most stable sigma complex (8, 9). Thus, migration will occur unless the alternate position is too deactivated.

The use of ethylene chloride as a solvent with aluminium chloride catalyst once again produced a homogeneous solution with the ester and thus a much more rapid reaction with the usual products, although somewhat more diisopropylation than before. However, the rate of the aldehyde reaction was much slower and, as usual, only 4-isopropylation was observed. Significantly, only very small amounts of the red oil formed in this solvent. Thus, in this solvent where the catalyst and carbonyl compounds were soluble, the order of reactivity was ester > aldehyde.

The use of nitromethane as solvent produced the very mild nitromethane – aluminium chloride complex and homogeneous reaction conditions. Here, only the ester reacted, and then only to a small extent. The aldehyde and ketone were sufficiently deactivated by complexing to prevent isopropylation when this weak Friedel–Crafts catalyst was used. All aromatic positions of the ester would be the least deactivated in this basic medium at the low concentrations used. However, mainly 5-isopropyl- and 4,5-diisopropyl-2-ester were obtained. Olah *et al.* (10) have found that isopropylations in nitromethane were highly selective and that the basic conditions of reaction largely eliminated consecutive rearrangement, except where "water-promoted" aluminium chloride was used (11). Thus it might be expected that such a highly selective species would attack the 2-ester exclusively at the 4-position. The observed results, however, suggest that the first-formed 4-sigma complex rearranges rapidly to the 5-isomer, which can undergo further alkylation to form the 4,5-diisopropylated product. It would appear that rearrangement before deprotonation may be quite important.

Finally, ferric chloride was found to be ineffective as a catalyst for isopropylation of the ester, and only moderately successful for the aldehyde. Titanium tetrachloride catalysis failed for both, although it produced an intense red color with the aldehyde. The addition of aluminium chloride and isopropyl chloride to the red aldehyde – titanium tetrachloride complex produced only a minor amount of alkylation.

The results of these experiments seem to be consistent with our earlier description of the reaction path (1). That is, the carbonyl group is complexed by the Lewis acid catalyst, and then electrophilic attack takes place primarily at the least deactivated 4-position, forming a sigma complex. This complex can then lose a proton; rearrange to give, eventually, the 5-isomer; or disproportionate through attack by a molecule of the 5-isopropyl derivative to form one molecule each of diisopropyl and unsubstituted compound. The extent to which the secondary reactions take place will depend upon the degree of deactivation of the 5-position. As indicated above, solubility factors also play an important role.

EXPERIMENTAL

General

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Ultraviolet spectra were determined with a Beckman DK-2A recording spectrophotometer; samples were dissolved in ethanol (95%) at a concentration of 10 mg/l. Nuclear magnetic resonance spectra were determined at 60 Mc.p.s. in the solvents stated in Tables I and III, with a Varian A-60 instrument. The chemical shifts are in parts per million on the δ scale from tetramethylsilane as internal reference.

Analyses of reaction mixtures were carried out by means of gas–liquid partition chromatography with a Beckman GC-2A gas chromatograph, equipped with a 30 in. column (No. 70007) packed with Carbowax 4000 dioleate on fire brick, with helium as the carrier gas. Analyses were accurate to $\pm 2\%$, as shown by gas chromatographic examination of a series of known mixtures.

Elemental analyses were determined by Alfred Bernhardt, Mülheim (Ruhr), Germany.

The Lewis acids used were aluminium chloride (Fisher reagent grade), aluminium bromide (Fluka purum), gallium chloride (Fluka puriss), and ferric chloride (British Drug Houses anhydrous). These were all used without further purification and with no precautions beyond those required for ordinary handling. The solvents used were reagent grade and were not further purified.

Methyl 2-pyrrolecarboxylate, m.p. 72–73° (crystallized from methanol), was prepared as described previously (1). 2-Pyrrolecarboxaldehyde, m.p. 44–45° (crystallized from petroleum pentane), was prepared by the method of Silverstein *et al.* (3). 2-Pyrryl methyl ketone (2-acetylpyrrole), m.p. 88–89° (crystallized from methanol), was prepared by the method of Oddo and Dainotti (2).

These carbonyl compounds were all purified until they showed only a single peak on gas–liquid partition chromatography. In addition, the n.m.r. spectrum showed no impurity within the limits of its sensitivity.

General Procedure for Alkylations

The reaction vessel was a 100 ml, three-necked, round-bottomed flask equipped with a stirrer, a dropping funnel, and a condenser with a drying tube, and immersed in an oil bath maintained at 50°. The 2-carbonyl compound (0.01 mole) and the anhydrous catalyst (0.012 mole) were placed in the reaction vessel with 40 ml of carbon disulfide. Isopropyl chloride (0.01 mole) in 10 ml of carbon disulfide was added after 15 min, and the reaction mixture was refluxed and stirred for the required period. The reaction was quenched by pouring the mixture onto ice. The aqueous layer was separated, saturated with sodium chloride, and extracted with ether. The combined organic extracts were washed with sodium acetate (saturated aqueous solution) and dried over anhydrous sodium sulfate. The solvent was removed by distillation and the residue analyzed by gas chromatography. The results are tabulated in Table IV.

Isolation of Alkylation Products

After preparative-scale isopropylation of the three substrate molecules, the dried ether layer was evaporated to dryness and the products separated by column adsorption chromatography on alumina (Fisher reagent grade). Purifications were accomplished through recrystallization from methanol and occasionally sublimation.

The analyses, physical constants, and proofs of structure for the isopropylation products from methyl 2-pyrrolecarboxylate are given in an earlier paper (1).

4-Isopropyl-2-pyrrolecarboxaldehyde, m.p. 31°. Ultraviolet: λ_{max} 257.5 mμ (log ε 3.84) and 302 mμ (log ε 4.20).

Anal. Calcd. for $C_8H_{11}NO$: C, 70.04; H, 8.09; N, 10.20. Found: C, 70.42; H, 8.06; N, 10.16.

Oxime, m.p. 124° (crystallized from ethanol).

Anal. Calcd. for $C_8H_{12}N_2O$: C, 63.14; H, 7.95; N, 18.40. Found: C, 63.20; H, 7.76; N, 18.39.

Semicarbazone, m.p. 173–175° (crystallized from ethanol–water).

Anal. Calcd. for $C_9H_{14}N_4O$: C, 55.66; H, 7.26; N, 28.84. Found: C, 55.85; H, 7.82; N, 28.24.

4-Isopropyl-2-pyrryl methyl ketone, m.p. 46.5–47.5°.

Anal. Calcd. for $C_9H_{13}NO$: C, 71.52; H, 8.61; N, 9.27. Found: C, 71.51; H, 8.85; N, 9.40.

5-Isopropyl-2-pyrryl methyl ketone, m.p. 58–59°.

Anal. Calcd. for $C_9H_{13}NO$: C, 71.52; H, 8.61; N, 9.27. Found: C, 72.15; H, 8.42; N, 9.24.

4,5-Diisopropyl-2-pyrryl methyl ketone, m.p. 103–104°.

Anal. Calcd. for $C_{12}H_{19}NO$: C, 74.57; H, 9.91; N, 7.25. Found: C, 74.58; H, 9.85; N, 7.41.

The n.m.r. proton chemical shifts are given in Table I, and the aromatic proton coupling constants in Table II. The latter values are in agreement with those reported by Gronowitz *et al.* (12).

At no time was there any indication, in gas chromatography or n.m.r. spectra, of the presence of propyl products along with the isopropyl products.

Oxidation of 4-Isopropyl-2-pyrrolecarboxaldehyde

4-Isopropyl-2-pyrrolecarboxaldehyde was oxidized to the corresponding acid with alkaline silver oxide (6). This acid had a melting point of 182–184°. The mixed melting point with a sample of 4-isopropyl-2-pyrrolecarboxylic acid obtained by hydrolysis of the corresponding ester (1) was not depressed from this value. The infrared spectra showed no significant difference.

Attempted Disproportionation of 4,5-Diisopropyl-2-pyrryl Methyl Ketone

4,5-Diisopropyl-2-pyrryl methyl ketone (0.001 mole) and 2-pyrryl methyl ketone (0.001 mole) were dissolved in 10 ml carbon disulfide together with aluminium chloride (0.0024 mole). The mixture was refluxed for 4 h in the presence of a continuous stream of dry hydrogen chloride. The reaction mixture was worked up in the usual manner and the products analyzed by gas chromatography. No elimination or disproportionation of isopropyl groups was observed.

Attempted Rearrangement of 4-Isopropyl Derivatives

4-Isopropyl-2-aldehyde or 4-isopropyl-2-ketone (0.001 mole) and aluminium chloride (0.0024 mole) in 10 ml carbon disulfide were refluxed (50°) for 2 h in the presence of a continuous stream of dry hydrogen chloride. The reaction mixture was worked up in the usual manner and the products analyzed by gas chromatography. The amount of rearrangement to 5-isopropyl-2-ketone was very small, but apparently greater than the limits of experimental error. The 4-isopropyl-2-aldehyde showed only a trace of a new product, whose retention time indicated that it could have been the 5-isopropyl-2-aldehyde.

ACKNOWLEDGMENT

LONG CARBON CHAIN CARBOHYDRATE POLYMERS

1,3-(BIS-5-ALDOXYLOSYLIDENE-1)-ACETONE AND ITS POLYMER WITH 1,3-DICARBETHOXYACETONE

PHILIPPOS E. PAPADAKIS AND S. M. PHILIP

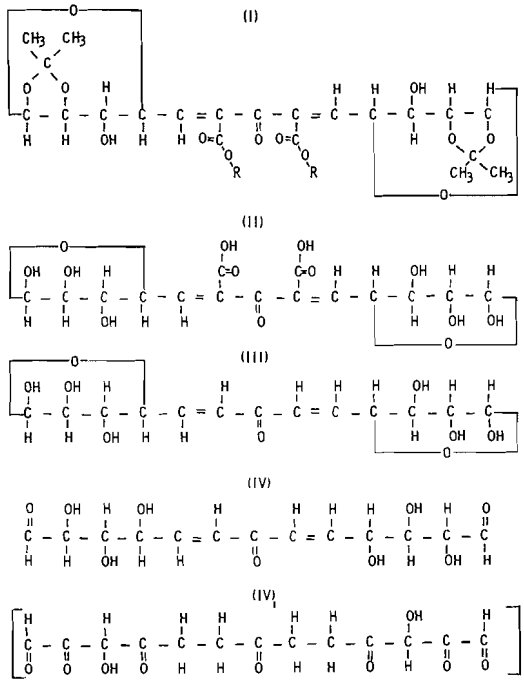
Received March 10, 1966

ABSTRACT

1,3-Dicarbethoxy-1,3-(bis-(4′,5′-*O*-isopropylidene-D-xylofuranosylidene))-acetone was hydrolyzed and decarboxylated to produce 1,3-(bis-D-xylofuranosylidene-5)-acetone (III) and 1,3-(bis-5-aldoxylosylidene-1)-acetone (IV). Compound IV reacted with 1,3-dicarbethoxyacetone in 75% methanol, with piperidine as catalyst, to give polymers V and VI and some intermediates. The main component of polymer V had a molecular weight between 2 000 and 4 000, and there were six to seven components with molecular weights of less than 2 000. Because the molecular weight of the repeating unit is approximately 500, a polymer with a molecular weight of 2 500 would have 80 carbons in a continuous chain, and one with a molecular weight of 3 500 would have 112 carbons. The work presented in this article may open broad areas of further research.

INTRODUCTION

It has been shown previously that 1 mole of diethylacetonedicarboxylate condenses with 2 moles of an aldose in a 75% methanol solution, with piperidine as catalyst, to give long carbon chain sugars (1). In another method (2), diethylacetonedicarboxylate was condensed with an aldose in the molar proportions of 1:2 in concentrated hydrochloric acid at 0° to form long carbon chain sugars.



On one occasion, 2 moles of 1,2-*O*-isopropylidene-D-xylopentodialdose was condensed with 1 mole of diethylacetonedicarboxylate, with piperidine as catalyst, to give 1,3-dicarbethoxy-bis-(4′,5′-*O*-isopropylidene-D-xylofuranosylidene)-acetone, which is a dialdehydo unsaturated keto sugar with a chain of 13 carbon atoms (I) (1).

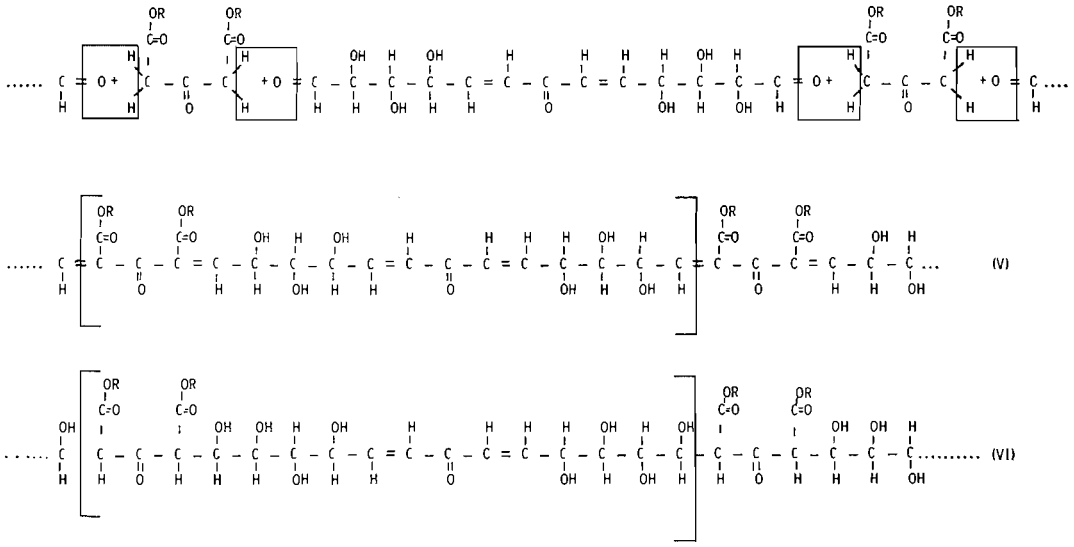
It was pointed out then that the hydrolysis of the isopropylidene groups of compound I could give rise to two free aldehyde groups in this compound, and might open the way for chain polymerization with diethylacetonedicarboxylate or other appropriate reagents.

Schaffer and Isbell (3) observed that the hydrogen on carbon 4 in 5-aldo-1,2-*O*-isopropylidene-D-xylopentodialdofuranose is alpha with respect to the aldehyde group, and helps to make the compound susceptible to aldol condensation. They observed the aldol reaction of two molecules of this compound to form a branched-chain 10-carbon sugar.

The present report deals with the hydrolysis of the isopropylidene and the carbethoxy groups of I to give compound II, the decarboxylation of the resulting β-ketonic acids to produce compound III, and the aldol condensation of the dialdehydo form of the resulting 13 carbon atom sugar (IV) with 1,3-dicarbethoxyacetone to give polymer V. An intermediate compound representing the first step of the aldol condensation was isolated and is represented by formula VI. The formulae may represent one of the possible *cis–trans* isomers.

Thus, 1,3-dicarbethoxy-1,3-(bis-(4′,5′-*O*-isopropylidene-D-xylofuranosylidene))-acetone (I) was hydrolyzed with 1% H_2SO_4. Both the isopropylidene and the carbethoxy esters were hydrolyzed. The latter gave rise to carboxylic groups (II), both of which have the keto group in the β-position. It is known that β-ketonic acids lose CO_2 when heated in an acid solution. Under such conditions, compound II was decarboxylated to give III, the alpha and beta forms of which are expected, in aqueous solution, to form an equilibrium with the dialdehydo form (IV).

In the next step, compound IV and 1,3-dicarbethoxyacetone, in the molar proportions of 1:1, were condensed in 75% methanol with piperidine as catalyst. After the product was processed, it analyzed as if polymerization had taken place. The polymer unit, taken x times, is shown within the brackets of formula V.



The approximate molecular weights were determined as follows by Dr. Wayne Ryan and James Dworak of the Eugene C. Eppley Institute for Research in Cancer and Allied Diseases. "The polymer was chromatographed on Bio-rad polyacrylamide gels with a 0.9 × 150 cm column and a flow rate of 20 ml/h, which was maintained with a Spinco accu-flow pump. The effluent from the column was monitored by a Spinco 135 Spectro-monitor programmed at 220 mμ and at 260 mμ. Polyacrylamide gels with exclusion limits of 2 000, 4 000, and 10 000 were used. The results of this study indicated that the polymer contained one component with a molecular weight between 2 000 and 4 000, and six to seven components with a molecular weight of less than 2 000."

The main product of the polymerization is the compound with a molecular weight between 2 000 and 4 000. On the basis of this information, the molecular weight of this component may have approximately one of the following values: 2 000, 2 500, 3 000, 3 500, or 4 000. With a molecular weight of 2 500 there would be 80 carbon atoms in the long carbon chain. A molecular weight of 3 500 would correspond to a carbohydrate with a chain of 112 carbon atoms.

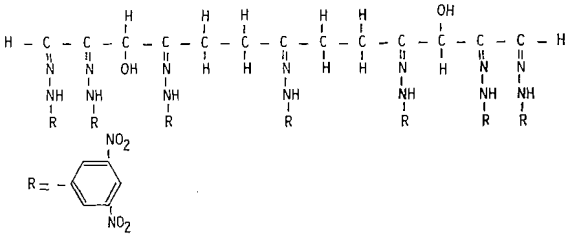
The ultraviolet and infrared spectra were taken and interpreted by Dr. Curtis Leicht, Chemistry Department, Creighton University.

The ultraviolet spectral data tentatively support the structural assignments given for V and VI. These polymers, as well as compound I, exhibited absorption in a region near 240 mμ, the intensity being somewhat greater for the polymers. Unfortunately, both ethylmethyleneacetoacetate, deemed to be an approximate model for compound V, and diethylacetonedicarboxylate, a model for formula VI, also exhibit absorption very near

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

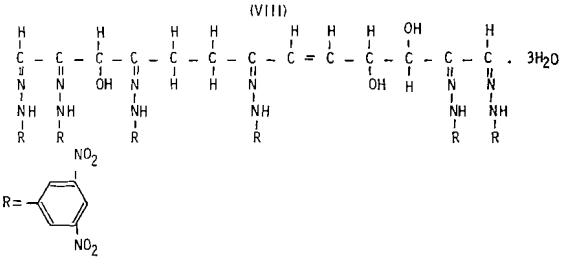
240 mμ, with very similar intensities (λ_{max} 239 mμ, log ε = 3.24 (4), and λ_{max} 237 mμ log ε = 3.5, respectively).

However, diethylacetonedicarboxylate dissolved in approximately 1% ethanolic KOH demonstrated a bathochromic shift of about 35 mμ, with a concomitant 12-fold increase in the absorption intensity (λ_{max} 272 mμ, log ε = 4.6). A very similar change in the wavelength and intensity of absorption was shown by compound VI with the same solvent change (λ_{max} 278 mμ, $E^{1\,cm}_{1\%}$ = 8 000). Although compounds I and V also demonstrated similar bathochromic shifts, the changes in intensity were much more modest (λ_{max} 282 mμ, log ε = 4.4, and λ_{max} 280 mμ, $E^{1\,cm}_{1\%}$ = 315, respectively). The tenuous nature of these interpretations is demonstrated by the fact that polymer VI and ethylmethyleneacetoacetate both exhibit somewhat similar longer wavelength absorptions (λ_{max} 324 mμ, $E^{1\,cm}_{1\%}$ = 17.5, and λ_{max} 307 mμ, log ε = 1.5, respectively). Furthermore, polymer VI and compound I show very similar longer wavelength absorptions in basic solution (λ_{max} 355 mμ, $E^{1\,cm}_{1\%}$ = 406, and λ_{max} 352 mμ, log ε = 3.7, respectively).



Since the infrared spectra of compounds V and VI were so similar, no further support for the structural assignments could be obtained by this means.

This work opens the way for several investigations. Further research will be carried out on the preparation of other polymers and the synthesis of derivatives analogous to those of the simpler carbohydrates which may have scientific, medicinal, or industrial importance.



During this investigation, the following derivatives (new compounds) were made and analyzed: (*a*) a crystalline 1,2-*O*-isopropylidene-3-*O*-(3,5-dinitrobenzoate)-D-xylopentofuranose; (*b*) a 3,5-dinitrobenzoate ester of I (the product corresponds to 1,2-*O*-isopropylidene-6,8-dicarbethoxy-7-oxo-3,11-di-(*O*-benzoate-3,5-dinitro)-5,8-diene-D-tridecadialdoxyfuranose; an *O*-diisopropylidene derivative was expected; apparently in the process one isopropylidene group was hydrolyzed); and (*c*) a 2,4-dinitrophenylhydrazine derivative of IV, 3,10,11-trihydroxy-hexakis-1,2,4,7,12,13-(2,4-dinitrophenylhydrazone)-tridecaene-8 (VIII) (osazone reaction and tautomerization of the hydrogens in IV and hydrazone reaction of the resulting carbonyl groups in $(IV)_1$ should result in compound VII; because of the inadequate amount of 2,4-dinitrophenylhydrazine used, only six 2,4-dinitrophenylhydrazines reacted, thereby giving compound VIII).

EXPERIMENTAL

Ultraviolet spectra were run on a Beckman DU spectrophotometer in 95% ethanol. Infrared spectra were run on a Beckman IR-8 instrument in chloroform solution.

*5-Aldo-1,2-O-isopropylidene-*D*-xylopentofuranose (5–7)*

This was prepared according to the method described by Grosheintz and Fischer.

*1,2-O-Isopropylidene-3-O-(3,5-dinitrobenzoate)-*D*-xylopentodialdose*

1,2-*O*-Isopropylidene-D-xylopentodialdose (1.88 g, 0.01 mole), 3,5-dinitrobenzoyl chloride (2.30 g, 0.01 mole), pyridine (1 ml), and dry ether (30 ml) were mixed at 0° for ½ h, and then allowed to stand at room temperature overnight. The mixture was then refluxed for 1 h, allowed to cool, and poured into ice water. A precipitate was collected and recrystallized from methyl alcohol, m.p. 150°.

Anal. Calcd. for $C_{15}H_{14}O_{10}N_2$: C, 47.12; H, 3.69. Found: C, 47.43; H, 3.32.

*1,2;12,13-O-Diisopropylidene-6,8-dicarbethoxy-7-oxo-3,11-dihydroxy-5,8-diene-*D*-tridecadialdoxylofuranose or 1,3-Dicarbethoxy-1,3-(bis-(4',5'-O-isopropylidene-*D*-xylofuranosylidene))-acetone (I)*

The title compound was prepared according to the method described by Papadakis (1). The analytical results agreed with the experimental values found previously (1) and with the theoretical values.

Anal. Calcd. for $C_{25}H_{34}O_{13}$: C, 55.35; H, 6.31. Found: C, 55.37; H, 6.34.

Specific rotation: $[\alpha]_D^{18}$ +45.62° (*c*, 3.051 in acetone); after 16 h $[\alpha]_D^{21}$ +22.9°; after 40 h $[\alpha]_D^{21}$ +22.9°. Ultraviolet spectrum: λ_{max} 234 and 247 mμ, log ε = 3.7 and 3.8, respectively. Infrared spectrum: absorption at 3 420, 3 020, 2 985, 2 940, 1 725, 1 655, 1 620, 1 370, 1 230, 1 080, and 1 020 cm^{-1}.

3,5-Dinitrobenzoyl Chloride Derivative of I

A mixture of 1.0 g (0.0018 mole) of I, 0.92 g (0.0036 mole) of 3,5-dinitrobenzoyl chloride, and 0.32 ml (0.0036 mole) of pyridine in a dry dioxane medium was kept at 0° for 1 h. After having stood at room temperature overnight, the mixture was heated at 60° under reflux for 1 h. The dioxane was removed under reduced pressure and the product poured over crushed ice. The residue was washed with 10 ml of 2% sodium bicarbonate. Recrystallization from ether – petroleum ether gave a white solid, m.p. 150–152°.

Anal. Calcd. for $C_{36}H_{36}O_{24}N_4$: C, 47.57; H, 3.99; N, 6.16. Found: C, 47.45; H, 4.26; N, 6.06. (In the process one isopropylidene was hydrolyzed.)

1,3-(Bis-5-aldoxylosylidene-1)-acetone (IV)

Hydrolysis of I was accomplished by heating with dilute acid. To a solution of 5 g of I in dioxane, 50 ml of 0.1 *N* sulfuric acid was added. The mixture was heated under reflux on a water bath at 75–80° for 2½ h. The sulfuric acid was neutralized with barium hydroxide, the $BaSO_4$ filtered off, and the filtrate evaporated to dryness. The residue was boiled with distilled water and filtered to remove any unhydrolyzed I, which is insoluble in water. The solution was evaporated again to dryness and the material was pulverized to an amorphous powder which softened at 93° and completely melted at 110°.

Anal. Calcd. for $C_{13}H_{18}O_9 \cdot 1\frac{1}{2}H_2O$: C, 45.21; H, 6.08. Found: C, 44.85; H, 6.31.

The analytical results correspond to a hydrated compound (IV).

For personal use only.

3,10,11-Trihydroxy-hexakis-1,2,4,7,12,13-(2,4-dinitrophenylhydrazone)-tridecaene-8 (VIII)

To 1.11 g (0.0056 mole) of 2,4-dinitrophenylhydrazine, 2.5 ml of concentrated sulfuric acid was added. Water was added dropwise, with stirring, until solution was completed. To a solution of 0.3 g (0.0008 mole) of crude IV in ethanol, the 2,4-dinitrophenylhydrazine – sulfuric acid solution was added, and the mixture was allowed to stand overnight. After centrifugation the red precipitate was collected and recrystallized from 95% alcohol. It sintered at 224° and melted at 229–235°.

Anal. Calcd. for $C_{49}H_{44}O_{30}N_{24}$: C, 40.60; H, 3.04; N, 23.20. Found: C, 40.48; H, 2.71; N, 23.76.

Preparation of the Long Carbon Chain Polymers V and VI

A quantity of 1.53 ml (0.008 mole) of diethylacetonedicarboxylate was added to 2.832 g (0.008 mole) of 1,3-(bis-5-aldoxylosylidene-1)-acetone (IV) in a benzene medium. After piperidine (five drops) was added to catalyze the reaction, the mixture was left at room temperature overnight. This was followed by heating under reflux in a water bath at 80° for 1 h. After a second day of standing, it was again heated for 1 h. The solution was then filtered and the filtrate evaporated to dryness. The hardened syrup was purified in the following manner. It was divided into two portions, one soluble in water and the other in 95% ethanol. A residue was precipitated from the former by the addition of 95% ethanol, and from the latter by the addition of water. The residue was removed by filtration (analysis later proved that it was not the polymer). This purification process was repeated several times. The amber solution of the water-soluble and alcohol-soluble materials containing the polymer was treated with Darco in an unsuccessful attempt to remove the color. This was followed by evaporation to dryness. The hardened amber syrups were pulverized.

The material from the first portion (represented by VI) softened at 72° and had completely melted at 85°. The material from the second portion (represented by V) melted at 78–81°.

Compound VI

Anal. Calcd. for $C_{22}H_{32}O_{14}$: C, 50.76; H, 6.15. Found: C, 50.86; H, 6.01.

Ultraviolet spectrum: λ_{max} 238 (4) and 324 mμ, $E^{1\,cm}_{1\%}$ = 406 and 17.5, respectively. Infrared spectrum: absorption at 3 400, 3 010, 2 980, 1 720, 1 580 (broad), 1 440, 1 370, 1 220, 1 090, and 1 030 cm^{-1}.

Compound V

Anal. Calcd. for $C_{22}H_{28}O_{12}$: C, 54.54; H, 5.78. Found: C, 54.77; H, 6.07.

Ultraviolet spectrum: λ_{max} 240 mμ (4), $E^{1\,cm}_{1\%}$ = 180. Infrared spectrum: absorption at 3 400, 3 010, 2 920, 1 720, 1 615 (broad), 1 440, 1 370, 1 220, and 1 020 cm^{-1}.

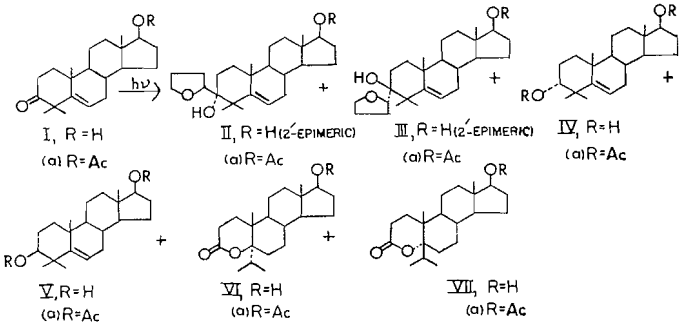
THE PHOTOLYSIS OF 4,4-DIMETHYLANDROST-5-EN-17β-OL-3-ONE[1]

RONALD T. TAYLOR[2] AND GEORGE JUST
Department of Chemistry, McGill University, Montreal, Quebec

Received March 16, 1966

ABSTRACT

The photolysis of 4,4-dimethylandrost-5-en-17β-ol-3-one (I) in aqueous tetrahydrofuran has been shown to give products of reduction, adducts with tetrahydrofuran, and 5-isopropyl-lactones VI and VII.



It is well known that the carbonyl chromophore of a β,γ-unsaturated ketone can overlap with the carbon–carbon double bond chromophore, giving rise to an exalted intensity of the $n \rightarrow \pi^*$ transition or to a shift towards longer wavelength of the chromophore. From this type of data, conformations of ring A of 4,4-dimethylcholest-5-en-3-one have been deduced (1, 2).

We were interested in determining whether this type of interaction would lead to products analogous to those formed in the solvolysis of cholesteryl derivatives in which the double bond of a β,γ-unsaturated tosylate interacts with the incipient carbonium ion. We therefore studied the photolysis of 4,4-dimethylandrost-5-en-17β-ol-3-one, which is readily available from testosterone (3).

RESULTS

Photolysis of a 0.033 *M* aqueous tetrahydrofuran solution of 4,4-dimethylandrost-5-en-17β-ol-3-one (I) in a helium atmosphere gave a mixture of products, which could be resolved by chromatographic means only with difficulty. When the crude reaction mixture was steam distilled, a reasonable separation of the residue was effected by a combination of chromatography on alumina and thin-layer chromatography (t.l.c.), with silica gel as the adsorbent. The purity of the components and the yields were established by gas–liquid chromatography (g.l.c.). The details of the separation procedure, as well as relevant analytical and spectral data, are described in the Experimental section.

Diols IV and V were obtained as a mixture which was not resolved. Oxidation with chromium trioxide in pyridine (4) gave in good yield 4,4-dimethylandrost-5-ene-3,17-dione (VIII), identical with the oxidation product of I. The diol mixture (IV and V) was then

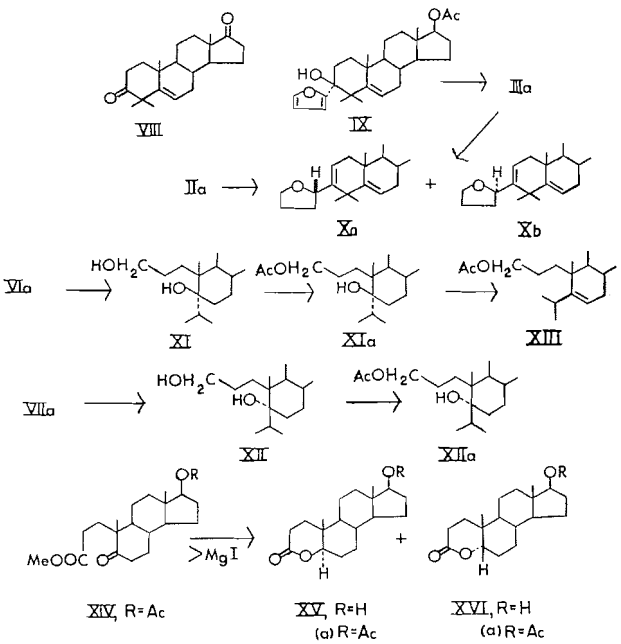
For personal use only.

acetylated. Gas–liquid chromatographic analysis of this mixture indicated the presence of two components (IV*a* and V*a*), with retention times identical with those of an authentic mixture of IV*a* and V*a*, obtained by sodium borohydride reduction of ketone I (3) followed by acetylation.

Diol III was characterized in the following manner. Acetylation with acetic anhydride in pyridine at room temperature gave a diol monoacetate III*a*. The mass spectrum of III*a* indicated it to be an adduct of ketone I*a* and tetrahydrofuran. The proton magnetic resonance (p.m.r.) spectrum[3] of III*a* showed the C_6-olefinic proton at 5.68 p.p.m. and a three-proton signal centered at 3.89 p.p.m., characteristic of the low-field protons in tetrahydrofuran. The most probable mode of attachment of the tetrahydrofuryl moiety was as depicted in III*a*. The synthesis of III*a* was therefore undertaken. Ketone I*a* was reacted with an ethereal solution of 2-furylmagnesium iodide (5). After acetylation, a low yield (high conversion) of product IX was obtained. Catalytic reduction of IX gave, after acetylation, the tetrahydrofuryl derivative III*a* in very low yield.



Diol II was apparently the C_3-epimer of diol III. It gave, upon acetylation, a diol monoacetate II*a*. Dehydration of this monoacetate with thionyl chloride in pyridine gave product X, identical with the product obtained by dehydration of diol monoacetate III*a*. Product X was a mixture of the 2′-epimers X*a* and X*b*. It could be resolved into its constituents[4] by t.l.c., with silver nitrate impregnated silica gel as the adsorbent and hexane–ether (6.5:3.5 v/v) as the developing solvent.

The configurational assignment at C-3 of II and III was based on the following arguments. The 3α-alcohol (axial) II had a higher chromatographic mobility on alumina (column). This criterion has often and successfully been applied for this type of assignment (6, 7). Similarly, II*a* had a larger R_f value than III*a* on t.l.c. with alumina as adsorbent (8, 9). Gas–liquid chromatography gave similar results when applied to II*a* and III*a* (10). Comparison of the mode of addition of 2-furylmagnesium iodide and ketone I*a* to that of similar Δ^5-3-ketones and Grignard reagents (11) confirmed the stereochemical assignment at C-3 of II and III.

Lactones VI and VII, which absorbed in the infrared at 1 740 cm^{-1}, were the third type of compound obtained. Both lactones gave monoacetates (VI*a* and VII*a*), which could be converted into triols (XI and XII) by lithium aluminium hydride treatment. Acetylation of XI and XII gave triol diacetates XI*a* and XII*a*, whose infrared spectra were superimposable and displayed hydroxyl bands at 3 620 cm^{-1}. The p.m.r. spectra of XI*a* and XII*a* showed a two-proton signal (triplet) at 4.09 p.p.m. (C—CH_2—OAc). Dehydration of XI*a* gave olefinic diacetate XIII (δ 5.62 p.p.m. (1H)). The mass spectrum of VII*a* showed a very small parent peak at *m/e* 376 and the base peak at *m/e* 333, corresponding to the loss of an isopropyl radical. The subsequent fragmentation pattern was essentially identical with the mass spectrum of the mixture of lactones XV*a* and XVI*a*.[5]

The stereochemical assignment at C-5 in lactones VI*a* and VII*a* was based on (*i*) differences in the molecular rotations (ΔM_D (VI*a* − VII*a*) = 308°) of these substances compared with those of the corresponding lactones (ΔM_D (XV − XVI) = 237°) described by Atwater and Ralls (12); (*ii*) the relative R_f values of triol diacetates XI*a* (0.87) and XII*a* (0.98) on t.l.c.[6] (8, 9); and (*iii*) the chemical shift of the 19-CH_3, which is more deshielded in the *trans*-lactone VI*a* (1.15 p.p.m.) than in the *cis*-lactone VII*a* (1.09 p.p.m.).

[3]*The p.m.r. spectra were taken in* $CDCl_3$ *(tetramethylsilane = 0 p.p.m.).*
[4]*A stereochemical assignment at C-2′ is discussed in the Ph.D. thesis of R. T. T.*
[5]*Lactones XV*a *and XVI*a *were obtained as a mixture from the attempted synthesis of lactones VI*a *and VII*a *outlined in the Experimental section.*
[6]*The procedure for the comparison is described in the Experimental section.*

The yields of the photoproducts in tetrahydrofuran–water (3:1 v/v) and in tetrahydrofuran were established by g.l.c. of the crude, steam distilled, and acetylated reaction mixtures, and are summarized in Table I.

TABLE I

Photoproduct	% yield: Tetrahydrofuran–water (3:1)	% yield: Tetrahydrofuran	Retention times* (min)

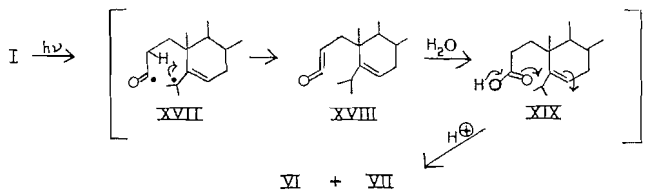
†Product A was not isolated.

DISCUSSION

Diols IV and V are products of photoreduction, a well-documented (13, 14) occurrence in ketone photochemistry. Adducts II and III find complete analogy in the photochemical addition of tetrahydrofuran to acetone observed by Shima and Tsutsumi (15). Both reduction and adduct formation arise from $n \rightarrow \pi^*$ excitation of the ketone (I) carbonyl to a biradical triplet state (16). The intermediate biradical reacts with solvent molecules to give IV, V, II, and III in yields of 8, 8, 7, and 6%, respectively. When the photolysis of I was performed in tetrahydrofuran, the yields of IV, V, and II were 16, 4, and 3%, respectively, and no III could be detected.[7] This alteration in product distribution from



[7]*The irradiation was performed in a standard quartz water-cooled immersion apparatus.*

For personal use only.

aqueous tetrahydrofuran to tetrahydrofuran most probably reflects the differences in solvation of the electronically excited species.

That the C_3—C_4 bond in ketone I underwent cleavage during the photolysis is evident from the presence of lactones VI (7%) and VII (6%).[7] The α-cleavage of ketones also arises from a biradical state, from which is generated an acyl and alkyl radical (17). It is to be expected that cleavage would occur between C-3 and C-4 to give the more stable biradical, e.g. lanostanone yields ca. 34% primary acid (18).

Lactones VI and VII are most likely formed by the known process outlined below. A similar transformation has recently been described (19). An olefinic acid (such as XIX) is known to give a δ-lactone under acidic conditions (20); recently, Mousseron-Canet *et al.* (21) explained their isolation of a δ-lactone from the photolysis of an olefinic acid similar to XIX on the basis of lactonization catalyzed by traces of acid.

Inspection of the g.l.c. spectrum showed that all major components but one were accounted for. This product A, present in approximately 7% yield, was not isolated. The balance of the isolated compounds indicated that no participation of the double bond has to be invoked to explain the products formed.

EXPERIMENTAL

Proton magnetic resonance spectra were recorded on a Varian A-60 (60 Mc.p.s.) spectrometer with deuteriochloroform as solvent and tetramethylsilane (0 p.p.m.) as internal standard. Infrared spectra were taken on Perkin–Elmer grating spectrophotometers, models 337 and 521, with carbon tetrachloride as solvent. Melting points were determined in open capillary tubes on a Gallenkamp apparatus, and are corrected. Optical rotations were measured on a Carl Zeiss photoelectric precision polarimeter. Ultraviolet absorption spectra were taken on a Beckman DK 1 recording spectrophotometer. Schwarzkopf Microanalytical Laboratories, Woodside 77, New York, and Dr. A. Bernhardt, Mülheim, Germany, performed the microanalyses. Mass spectra were recorded by S. Meyerson, American Oil Co., Whiting, Indiana, and by Morgan–Schaffer, Montreal, Quebec. Gas–liquid chromatographic determinations were made on a F and M model 700 gas chromatograph. All acetylations were performed with acetic anhydride in pyridine at room temperature. Silica gel 0.75 mm thick on 8 × 8 in. glass plates was used for plate chromatography, with water as the detector.

Irradiation of Ketone I (3) in Tetrahydrofuran–Water

Ketone I (6.67 g) dissolved in 500 ml of tetrahydrofuran–water (3:1 v/v) was irradiated[7] with a Hanovia 450 W lamp until no starting material remained by t.l.c. analysis (72 h). The addition of 4 g of sodium chloride to the reaction solution gave two layers, which were separated. The tetrahydrofuran layer was dried with magnesium sulfate and concentrated to give 13.03 g of viscous oil. This product was steam distilled and the residue extracted with 1% sodium hydroxide solution, which removed 0.975 g of acidic material. The remaining 7.17 g of oil was chromatographed on 300 g of alumina (activity II–III).

Elution with 120 ml of benzene–ether (9:1 v/v) gave 0.118 g of oil which was not characterized.

Further elution (320 ml) gave 0.321 g of an oil which was then acetylated. Plate chromatography with benzene–ether (4:1 v/v) as the developing solvent gave a major band with R_f 0.78. Ether elution of this band yielded 0.276 g of 17β-acetoxy-4,4-dimethyl-3β-(2-tetrahydrofuryl)androst-5-en-3α-ol (11*a*), m.p. 159.5–161°. Recrystallization from methanol raised the melting point to 160–162°; $[\alpha]_D^{25}$ −94° (*c*, 0.52 in $CHCl_3$); ν_{max} 3 592 (OH) and 1 052 cm^{-1} (C—O—C); δ 5.57 (1H, C=C$_6$—H), 3.80 (3H, poorly resolved CH_2—O—CH), and 1.21 and 1.16 p.p.m.; g.l.c. retention time 12.0 min.

Anal. Calcd. for $C_{27}H_{42}O_4$: C, 75.31; H, 9.83. Found: C, 75.73; H, 9.99.

Continued elution (360 ml) with the same solvent gave 1.25 g of oil, which crystallized overnight from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

methanol, m.p. 167–180°. Four recrystallizations from methanol provided 0.205 g of 4,4-dimethyl-3α-(2-tetrahydrofuryl)androst-5-ene-3β,17β-diol (III), m.p. 183–184°; $[\alpha]_D^{25}$ −73° (*c*, 1.37 in $CHCl_3$); ν_{max} 3 562 (tertiary OH) and 1 052 cm^{-1}; δ 5.62 (1H, broad) and 3.75 p.p.m. (4H, broad, O—C_{17}H and CH_2—O—CH).

Anal. Calcd. for $C_{25}H_{40}O_3$: C, 77.27; H, 10.38. Found: C, 77.52; H, 10.38.

Further elution (160 ml) gave 0.830 g of oil. Acetylation followed by plate chromatography in benzene–ether (4:1 v/v) gave two bands at R_f 0.85 and 0.73. The band with R_f 0.85 provided 0.085 g of epimeric 3-acetoxy-4,4-dimethylandrost-5-en-17β-ol acetate (IV*a* and V*a*), m.p. 157–160°; δ 4.58 (1H, triplet, AcO—C_{17}H) and 4.42 p.p.m. (1H, triplet, AcO—C_3H); g.l.c. retention times 2.6 and 2.2 min, respectively.

Anal. Calcd. for $C_{25}H_{38}O_4$: C, 74.59; H, 9.52. Found: C, 74.77; H, 9.62.

The band at R_f 0.73 gave 0.337 g of 17β-acetoxy-4,4-dimethyl-3α-(2-tetrahydrofuryl)androst-5-en-3β-ol (III*a*), m.p. 199–201°. An analytical sample was prepared by recrystallization from methanol, m.p. 201–202°; $[\alpha]_D^{25}$ −78° (*c*, 0.87 in $CHCl_3$); ν_{max} 3 562 (OH) and 1 052 cm^{-1}; δ 4.67 (1H, triplet, AcO—C_{17}H), 3.89 (3H, approximating a triplet, CH_2—O—CH), and 2.47 p.p.m. (OH, exchanged with D_2O); g.l.c. retention time 15.2 min.

Anal. Calcd. for $C_{27}H_{42}O_4$: C, 75.31; H, 9.83. Found: C, 75.78; H, 10.08; mol. wt. 430 (mass spectrometry).

Continued elution (280 ml) provided an oil (0.563 g), from which III*a*, IV*a*, and V*a* were isolated by t.l.c. as described above.

Further elution (80 ml) gave 0.102 g of epimeric 3-hydroxy-4,4-dimethylandrost-5-en-17β-ol (IV and V), m.p. 201–204° (crystallization from ether). Three recrystallizations from acetone gave an analytical sample having m.p. 204–206°; ν_{KBr} 3 500 – 3 452 (broad) and 3 053 cm^{-1} (olefinic C—H); δ (pyridine) 3.87 (1H, triplet, O—C_{17}H), 3.48 (1H, triplet, O—C_3H), and 1.40 and 1.32 p.p.m. (3H each, two singlets, 4,4-dimethyl).

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.19; H, 10.76. Found: C, 78.97; H, 10.82.

Elution (160 ml) with benzene–ether (8.5:1.5 v/v) gave 1.34 g of oil. Acetylation followed by hexane trituration of the recovered oil provided long fibers melting at 151–156°. Crystallization from hexane gave 0.184 g of 17β-acetoxy-5α-isopropyl-4-oxaandrostan-3-one (VI*a*), m.p. 162–163°; $[\alpha]_D^{25}$ +87° (*c*, 0.13 in $CHCl_3$); ν_{max} 1 740 (acetate carbonyl and δ-lactone), 1 425 (C—H of CH_2COO), and 1 391 and 1 382 cm^{-1} (isopropyl group); δ 2.62 (2H, AB system, CH_2—COO),[8] 1.20 and 1.12 (3H each, two doublets, J = 7 c.p.s., isopropyl Me_2), and 1.15 p.p.m. (19-Me); g.l.c. retention time 9.3 min (broad, with decomposition).

Anal. Calcd. for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64. Found: C, 73.29; H, 9.77.

Elution with 250 ml of benzene–ether (1:1 v/v) gave 0.51 g of oil. Acetylation followed by plate chromatography in benzene–ether (3:1 v/v) gave a major band with R_f 0.51. Ether elution of this band provided 0.252 g of 17β-acetoxy-5β-isopropyl-4-oxaandrostan-3-one (VII*a*), m.p. 121–123.5° (crystallization from hexane); $[\alpha]_D^{25}$ +5° (*c*, 1.38 in $CHCl_3$); δ 2.48 (2H, AB system, CH_2—COO), 1.09 (19-Me), and 1.05 and 1.01 p.p.m. (3H each, two doublets, J = 7 c.p.s., isopropyl Me_2); g.l.c. retention time 4.7 min (with decomposition).

Anal. Calcd. for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64. Found: C, 73.40; H, 9.57; mol. wt. 376 (mass spectrometry).

Oxidation of Epimeric 3-Hydroxy-4,4-dimethylandrost-5-en-17β-diol (IV and V) with Chromium Trioxide (4)

Chromium trioxide (61 mg) dissolved in 5 ml of pyridine was added to a solution of 140 mg of the mixture (IV and V) in 7 ml of pyridine. After having stood overnight, the reaction mixture was filtered through an asbestos pad and the inorganic residue was washed with two 10 ml portions of benzene. The usual work-up and plate chromatography of the recovered oil with benzene–ether (4:1 v/v) gave 99 mg of powder, m.p. 151–154°. One recrystallization from hexane–ether gave 83 mg of dione VIII, m.p. 161–162°; ν_{max} 1 734 and 1 705 cm^{-1} (ketones having five- and six-membered rings, respectively). No depression in the melting point was observed on admixture with the product obtained from the corresponding oxidation of I.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62. Found: C, 80.41; H, 9.63.

17β-Acetoxy-4,4-dimethyl-3α-(2-furyl)androst-5-en-3β-ol (IX)

A mixture of I*a* (1.1 g) in 15 ml of ether and 2-furylmagnesium iodide (prepared by reacting 0.425 g of magnesium with 2.4 g of 2-iodofuran (5) in 6 ml of ether) was heated under reflux for 7 h. Ammonium chloride (20 ml of a 5% solution) was added to the cooled reaction mixture, followed by filtration through an asbestos pad. The ether layer was dried and concentrated to give 1.3 g of oil, which was then acetylated. Plate chromatography of the recovered oil with 15% ether in benzene gave two bands at R_f 0.61 and 0.54. The band at R_f 0.61 provided 0.401 g of I*a* (identified by mixed melting point and infrared spectrum). The band with R_f 0.54 gave an oil which provided a partially crystalline material when passed through 20 g of alumina (activity I) with benzene–ether (1:1) as eluent. Crystallization from methanol yielded 0.410 g of IX as platelets, m.p. 213–215°. Five recrystallizations from methanol raised the melting point to 215–216° (yellow color persisted); $[\alpha]_D^{25}$ −37° (*c*, 0.40 in $CHCl_3$); $\lambda_{max}^{Et_2O}$ 223 mμ (ϵ 4 700); ν_{max} 3 620 (OH) and 3 045 and 1 047 cm^{-1}; δ 7.23 (1H, complex splitting, C=$C_{5'}$H—O), 6.28 (2H, complex multiplet, C=$C_{3'}$H—$C_{4'}$H=C), and 2.58 p.p.m. (OH).

Anal. Calcd. for $C_{27}H_{38}O_4$: C, 76.02; H, 8.98. Found: C, 76.51; H, 8.47.

[8]*When the p.m.r. spectrum of lactone VIa was taken in 30% deuterium oxide in pyridine, the AB system (in* $CDCl_3$*) became a two-proton triplet centered at 2.79 p.p.m.*

Hydrogenation of IX

A mixture of Raney nickel (45 mg), acetate IX (150 mg), and ethanol (50 ml) was hydrogenated (3 100 p.s.i.) at 160 ± 4° for 17 h. Filtration and concentration gave 135 mg of oil. Acetylation followed by plate chromatography, with 30% ether in benzene, gave a series of closely moving bands with R_f values ranging from 0.98 to 0.17. Collection of the bands between R_f 0.98 and 0.55 and separation by plate chromatography with benzene–ether (4:1) gave a band at R_f 0.73 which provided 8 mg of oil. The oil crystallized from methanol, m.p. 196–198°, and was identical with III*a* obtained from photolysis (mixture melting point, comparison of t.l.c. behavior and infrared spectrum).

Dehydration of IIIa (or IIa) with Thionyl Chloride

Thionyl chloride (0.8 ml) was added dropwise to a stirred solution of 184 mg of III*a* in 6 ml of dry pyridine at 0°. After addition, stirring was continued at room temperature for 1 h. Ice chips were then added cautiously and 115 mg of oil was recovered by ether extraction. The oil crystallized from ethanol after 5 days, m.p. 148–151°. Plate chromatography of the product (X) with silver nitrate impregnated silica gel[9] as the adsorbent and 35% ether in hexane as the developing solvent gave two bands, detected by ultraviolet light at R_f 0.62 and 0.57, respectively. The band at R_f 0.62 provided 23 mg of 17β-acetoxy-4,4-dimethyl-3-(2-tetrahydrofuryl)androsta-2,5-diene (X*a*), m.p. 154–156°; $[\alpha]_D^{25}$ −59° (*c*, 0.96 in $CHCl_3$); ν_{max} 3 030 and 1 048 cm^{-1}; δ 5.84 (1H, unresolved, C=C$_2$—H), 5.60 (1H, broad, C=C$_6$—H), 4.32 (1H, triplet, O—C$_{2'}$H—C=O), and 3.87 p.p.m. (2H, poorly resolved, O—C$_{5'}$H$_2$—C); g.l.c. retention time 8.0 min.

Anal. Calcd. for $C_{27}H_{40}O_3$: C, 78.59; H, 9.77. Found: C, 78.78; H, 9.77.

The band with R_f 0.57 gave 20 mg of X*b*, m.p. 171–172.5°; $[\alpha]_D^{25}$ −74° (*c*, 0.94 in $CHCl_3$). The infrared and p.m.r. spectra were essentially the same as those for X*a*.

Anal. Calcd. for $C_{27}H_{40}O_3$: C, 78.59; H, 9.77. Found: C, 78.48; H, 9.74.

3,4-Seco-4,4-dimethylandrostane-3,5β,17β-triol (XI)

A solution of 318 mg of VI*a* in 10 ml of dry ether was added slowly to 126 mg of lithium aluminium hydride in 4 ml of ether. The mixture was heated under reflux for 1 h and worked up in the usual way to give 306 mg of XI, m.p. 184–187°. Three recrystallizations from ether–acetone raised the melting point to 196–198.5°; $[\alpha]_D^{25}$ +4° (*c*, 0.98 in pyridine).

Anal. Calcd. for $C_{21}H_{38}O_3$: C, 74.51; H, 11.32. Found: C, 74.35; H, 11.25.

Acetylation of XI (100 mg) gave 104 mg of 3,17β-diacetoxy-3,4-seco-4,4-dimethylandrostan-5β-ol (XI*a*) as an oil, which was shown to be homogeneous by t.l.c.; ν_{max} 3 620 (free OH) and 1 740 cm^{-1} (intense); δ 4.69 (1H, triplet, AcO—C$_{17}$H) and 4.09 p.p.m. (2H, triplet, C—CH$_2$—OAc).

3,17β-Diacetoxy-3,4-seco-4,4-dimethylandrost-5-ene (XIII)

The dehydration of 104 mg (oil) of XI*a* was carried out as described for III*a*. The resulting oil was purified by plate chromatography with 35% ether in hexane to give XIII, R_f 0.98; m.p. 116–116.5°; ν_{max} 1 742 cm^{-1} (intense); δ 5.62 (1H, poorly resolved, C=C$_6$—H), 4.67 (1H, triplet, AcO—C$_{17}$H), and 4.03 p.p.m. (2H, triplet, C—CH$_2$—OAc).

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.21; H, 9.97. Found: C, 74.19; H, 9.54.

3,4-Seco-4,4-dimethylandrostane-3,5α,17β-triol (XII)

Lactone VII*a* (112 mg) was treated as described for VI*a*. Triol XII (91 mg) was isolated, m.p. 143–144.5°; $[\alpha]_D^{24}$ +41° (*c*, 0.94 in pyridine).

Anal. Calcd. for $C_{21}H_{38}O_3$: C, 74.51; H, 11.32. Found: C, 74.18; H, 11.14.

Acetylation of 65 mg of XII provided 61 mg of 3,17β-diacetoxy-3,4-seco-4,4-dimethylandrostan-3α-ol (XII*a*), m.p. 141–143° after crystallization from methanol; $[\alpha]_D^{24}$ +1° (*c*, 0.6 in $CHCl_3$). The infrared spectrum was indistinguishable from that of XI*a*. The p.m.r. spectrum was also very similar to that of XI*a*.

Anal. Calcd. for $C_{25}H_{42}O_5$: C, 71.09; H, 9.95. Found: C, 70.97; H, 10.26.

Thin-Layer Chromatographic Comparison of XIa and XIIa

Both XI*a* and XII*a* were spotted on a microscope slide coated evenly (0.5 mm) with Woelm neutral alumina (for t.l.c.). With ethyl acetate – hexane (3:2 v/v) as the developing solvent, XII*a* had a R_f value of 0.98 whereas XI*a* was at R_f 0.87.

Attempted Synthesis of Lactones VIa and VIIa; Lactones XVa and XVIa

An ethereal solution of isopropylmagnesium iodide was added to 431 mg of 17β-acetoxy-5-oxo-3,5-seco-A-norandrostan-3-oic acid methyl ester (XIV)[10] in 35 ml of dry ether until t.l.c. analysis indicated that only a trace of XIV remained. Ammonium chloride (10 ml of a 3% solution) was then introduced and the ether solution dried and concentrated. Acetylation of the residual oil followed by plate chromatography with 30% ether in benzene gave two bands at R_f 0.77 and 0.54. Ether elution of the band at R_f 0.77 provided 120 mg

[9]*The plates ordinarily used for plate chromatography were sprayed with 5% silver nitrate solution until the adsorbent was saturated. The plates were then air dried overnight.*

[10]*Prepared from testosterone acetate in accordance with a procedure described by Atwater and Ralls (12), followed by treatment with diazomethane.*

of starting material (identified by infrared and p.m.r. spectra and mixed melting point), m.p. 90–91.5°. The other band (R_f 0.54) gave a mixture of 17β-acetoxy-4-oxa-5α-androstan-3-one (XV*a*) and the 5β-epimer (XVI*a*), m.p. 150–164°; ν_{max} 1 740 cm^{-1} (intense); δ 4.22 (0.6H, triplet, 5β-hydrogen of XVI*a*) and 3.70 p.p.m. (0.5H, broad, 5α-hydrogen of XV*a*).[11]

Anal. Calcd. for $C_{20}H_{30}O_4$: C, 71.85; H, 8.98. Found: C, 72.05; H, 9.01; mol. wt. 334 (mass spectrometry).

The Grignard reaction therefore resulted in only reduction and enolization.

ACKNOWLEDGMENTS

We thank Mr. K. Valentin for taking the p.m.r. spectra; Dr. G. Schilling and Mr. J. Kastner, Ayerst Laboratories, Montreal, for providing g.l.c. supports and performing the high-pressure catalytic reduction of IX; Mr. S. Meyerson, American Oil Co., for taking a mass spectrum; and G. D. Searle and Co., Syntex Corporation, and Ayerst Laboratories for generous gifts of starting material.

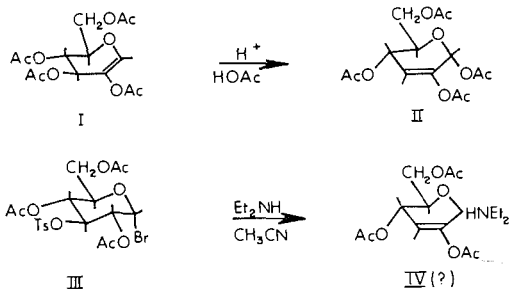
REACTIONS OF 2-ACETOXY-4,6-DI-*O*-ACETYL-3-*O*-(2,6-DICHLOROBENZOYL)-D-GLUCAL, TRI-*O*-ACETYL-3-DEOXY-α-D-*erythro*-HEX-2-ENOPYRANOSYL CHLORIDE, AND RELATED COMPOUNDS

R. U. LEMIEUX AND R. J. BOSE[1]

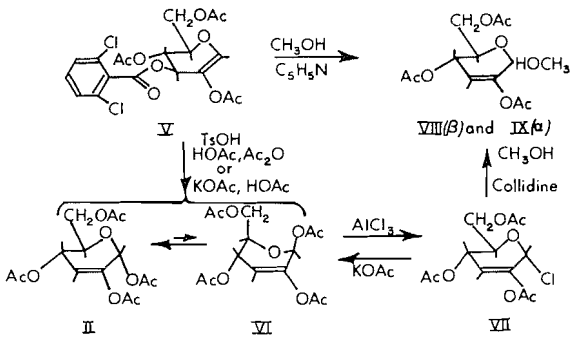
Department of Chemistry, University of Alberta, Edmonton, Alberta



Received March 15, 1966

ABSTRACT

Attempts to dehydrobrominate tri-*O*-acetyl-3-*O*-tosyl-α-D-glucopyranosyl bromide with diethylamine led directly to products resulting from the replacement of the tosyloxy group by the diethylamine. It was readily possible to prepare 2-acetoxy-di-*O*-acetyl-3-(2,6-dichlorobenzoyl)-D-glucal (V). Acetolysis of this compound gave an equimolar mixture of the α- and β-anomers (II and VI, respectively) of 2-acetoxy-di-*O*-acetyl-pseudo-D-glucal as the first products of the reaction. Compound V reacted only reluctantly with methanol in pyridine to give a mixture of the anomeric methyl di-*O*-acetyl-3-deoxy-D-*erythro*-hex-2-enopyranosides. These glycosides were readily prepared by reaction of tri-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranosyl chloride with methanol in the presence of pyridine. 2-Acetoxy-di-*O*-acetyl-3-*O*-mesitoyl-D-glucal was prepared from 3-*O*-mesitoyl-β-D-glucose. The anomerizations of compounds II and VI were examined with both sulfuric acid in 1:1 acetic acid – acetic anhydride and potassium acetate in acetic acid. The conformations of II and VI are discussed, as are a number of the mechanistic features of the reactions studied.



Lemieux *et al.* (1) have reported the acid-catalyzed isomerization of tetra-*O*-acetyl-1-deoxy-D-*arabino*-hex-1-enopyranose (I) (2-acetoxy-D-glucal triacetate) to tetra-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranose (II) (2-acetoxy-pseudo-D-glucal triacetate). The main objective of this research was to prepare a 3-*O*-derivative of 4,5-di-*O*-acetyl-2-acetoxy-D-glucal wherein the substituent at the 3-position was a sufficiently good leaving group for the compound to undergo solvolysis in the absence of acid, with attack of the entering group at the anomeric center. It was anticipated that if this could be accomplished the stereochemical route of the reaction could be established and compared with the S_N2' mechanism (2). Furthermore, the compound could conceivably be useful as a reagent for the synthesis of 2,3-unsaturated glycopyranosides, which could then presumably be converted into 2-ketoglycosides and so on.

In the first attempt, the tosyloxy group was chosen for the 3-substituent. Tri-*O*-acetyl-3-*O*-tosyl-α-D-glucopyranosyl bromide (III) was readily prepared by established procedures (3) from 1,2;5,6-di-*O*-isopropylidene-α-D-glucose. By use of the optimum conditions developed by Lemieux and Lineback (4) for dehydrobromination, the tosyloxy group was

[1]*Corn Industries Research Foundation Postdoctorate Fellow, 1964–1965. Present address: Fisheries Research Board of Canada, Technological Research Laboratory, Vancouver 8, British Columbia.*

removed and derivatives of the diethylamine were obtained in about 80% yield. Evidently, the initially formed 2-acetoxy-3-*O*-tosyl-D-glucal diacetate underwent extremely facile replacement of the tosyloxy group by the amine, most probably with migration of the double bond from the 1,2- to the 2,3-position. The nuclear magnetic resonance (n.m.r.) spectrum of the crude product showed the presence of at least two main components. As judged from the relative intensities of the signals, 1 mole of diethylamine had replaced the tosyloxy group. The product was very unstable and readily consumed about 2 moles of hydrogen when hydrogenated in the presence of palladium. These properties are consistent with those expected for an unsaturated glycosylamine (IV). The actual structures were not established, since the separation and purification of the compounds were not accomplished. Also, the product from the hydrogenation was found, by gas–liquid preparative chromatographic examination, to be a complex mixture.

The use of the mesyloxy rather than the tosyloxy group in the above sequence of reactions gave comparable results. This experience is analogous to that of Stork and White (2), who were unable to prepare *trans*-4-alkyl-3-tosyloxycyclohexene. Since these authors found the 2,6-dichlorobenzoyloxy group to be a useful leaving group in their research on the S_N2' reaction, 2-acetoxy-3-*O*-(2,6-dichlorobenzoyl)-D-glucal diacetate (V) was prepared by conventional methods. That the 2,6-dichlorobenzoyl group was, in fact, at the 3-position of V was demonstrated by conversion of the compound into the equilibrium mixture of the anomeric forms of 2-acetoxy-pseudo-D-glucal diacetate (II and IV) in a nearly quantitative yield (n.m.r.) by treatment with *p*-toluenesulfonic acid in a 1:5 acetic anhydride – acetic acid mixture under the conditions reported (1) for the isomerization of 2-acetoxy-D-glucal triacetate. Also, the n.m.r. spectrum of V was in complete agreement with that of a compound having the assigned structure.

Extensive reaction of compound V with methanol in the presence of pyridine occurred after 3 h at 100°. However, much decomposition to intractable material took place and the reaction showed no promise as a synthetic approach to glycosides. Nuclear magnetic resonance examination of the crude product indicated that the α- and β-methyl glycosides (IX and VIII, respectively) described below were present along with starting material (V).

Ferrier *et al.* (5) have recently reported the β-anomer (VI) of II. As was anticipated (1), the use of *p*-toluenesulfonic acid (0.05 *M*) in 1:5 acetic anhydride – acetic acid to isomerize I to II caused the equilibration of II and VI at a rate much faster than that of the isomerization. However, the equilibration reaction was followed with 0.00037 *M* sulfuric acid in 1:1 acetic acid – acetic anhydride. The half-life of the reaction was about 14 min at 23°. It is of interest to note that the half-life for the anomerization of the tetra-*O*-acetyl-2-deoxy-D-glucopyranoses under these conditions, but with 0.001 *M* acid,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is 4 min (6). Thus the increased opportunity for charge delocalization provided by the allylic double bond effectively cancels the effect of the 2-acetoxy group (7). The solvent itself did not cause equilibration at a measurable rate. The equilibrium constant was about 4.0 in favor of the α-anomer, both by n.m.r. analysis and from the optical rotation of the mixture. As indicated by Ferrier and his co-workers, the anomeric effect (8) may be mainly responsible for the greater stability of the α-form. In this regard, it is of interest to note the n.m.r. parameters for II and VI listed in Table I. In view of the differences in both $J_{3,4}$ and $J_{4,5}$, it is evident that the pyranose ring has different conformations for these compounds. From the value of $J_{4,5}$ for the α-anomer (9 c.p.s.), it follows that the 4-acetoxy and 4-acetoxymethyl groups are in an equatorial orientation and that the compound resides in the "regular" half-chair conformation, with the 1-acetoxy group in a quasi-axial orientation. Since these compounds have two trigonal carbons and an oxygen atom in the pyranose ring, the destabilizing interactions between opposing axial groups must be much less than in a chair conformation. Thus, it is reasonable to expect that the β-anomer may closely achieve a conformation which has the 4- and 5-substituents in a quasi-axial orientation to decrease the non-bonding interaction between these substituents. In fact, the n.m.r. data require that the 4- and 5-substituents be much further apart in the β- than in the α-anomer. Evidently, for the α-form, the anomeric effect is sufficiently great to overcome the gauche interaction between the 4- and 5-substituents.

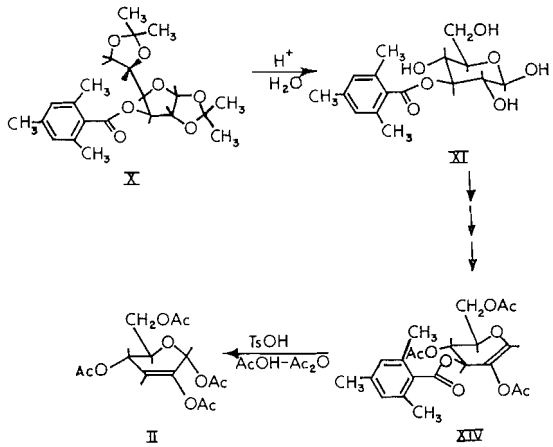
TABLE I

Nuclear magnetic resonance parameters for derivatives of 2-acetoxy-pseudo-D-glucal

Compound	Chemical shifts (τ)			Coupling constants (c.p.s.)	
	H^1	H^3	H^4	$J_{3,4}$	$J_{4,5}$
α-Tri-*O*-acetyl (II) (1)	3.69	4.13	4.47	2.2	9
β-Tri-*O*-acetyl (VI)	3.63	4.04	4.69	5.5	~1
α-Di-*O*-acetyl-1-*O*-methyl (IX)	5.07	4.28	4.58	2	~9
β-Di-*O*-acetyl-1-*O*-methyl (VIII)	4.85	4.23	4.69	4.7	4.5
α-Di-*O*-acetyl-1-chloro-1-deoxy (VII)	3.72	4.19	4.4	2	~9

The anomeric compounds II and VI could also be equilibrated by heating them in acetic acid with potassium acetate, although substantial decomposition to other products occurred. The equilibrium constant was, within experimental error, the same as that observed under the acid conditions. The half-life of the reaction with M potassium acetate in acetic acid at 100° was about 100 min.

Di-*O*-acetyl-2-acetoxy-3-*O*-(2,6-dichlorobenzoyl)-D-glucal (V) also gave the anomeric tri-*O*-acetyl-2-acetoxy-pseudo-D-glucals (II and VI) on treatment with potassium acetate in acetic acid at 100°. The half-life of the reaction was about 10 min. Thus, this reaction is about 10 times faster than the anomerization of the products, and the stereochemistry of the reaction was readily established. In fact, compound V could be converted into an almost exactly equimolar mixture of the anomeric acetates (II and VI) in 27% yield by heating it for 5 min at 100° in M potassium acetate in acetic acid, conditions which left the products virtually unchanged. Thus, unlike the S_N2' reaction (2), this transformation was devoid of stereospecificity. This is not surprising since the ring oxygen must participate in the reaction to help delocalize the developing positive charge, and thus obviates the need for an attack by the entering nucleophile in *cis*-relationship to the leaving group to maximize the stability of the transition state. The molecularity of the reaction was not



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

established, and it is possible that the reaction proceeds by way of an ionic intermediate (S_N1).

Reaction of 2-acetoxy-pseudo-α-D-glucal triacetate (II) with aluminium chloride in chloroform under carefully controlled conditions gave the highly reactive tri-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranosyl chloride (VII). The syrupy product appeared (n.m.r.) to be over 80% pure. The same product was obtained from 2-acetoxy-pseudo-β-D-glucal triacetate (VI).

The structure of the chloride (VII) was substantiated by reaction with sodium acetate in acetic acid to yield a mixture of II and VI in the ratio of 1:2, respectively. Thus, it was apparent that the compounds underwent replacement of the chlorine predominantly with inversion of the reacting center, as is normally found in these reactions (9).[2] The configuration of the chloride (VII) was established by the n.m.r. parameters listed in Table I.

At one point in this research, it was thought of interest to prepare 3-*O*-mesitoyl-2-acetoxy-D-glucal diacetate (XIV) to test the leaving power of the mesitoyloxy group. This preparation was readily possible by using the recently published method for preparing esters of hindered acids, which employs the use of trifluoroacetic anhydride as the activating reagent (10). It was remarkable to find that crystalline 1,2;5,6-di-*O*-isopropylidene-3-*O*-mesitoyl-α-D-glucose (X) was readily prepared in this way in 94% yield. The compound was hydrolyzed to crystalline 3-*O*-mesitoyl-β-D-glucose (XI), which was converted in the usual manner by way of the acetobromo derivative (XIII) into compound XIV. The compound seemed to be as stable as the tetraacetate (I), and underwent conversion into the 2-acetoxy-pseudo-D-glucal triacetates (II and VI) in 5:1 acetic acid – acetic anhydride 0.05 *M* in *p*-toluenesulfonic acid (1) at 0.34 times the rate of I and 6.7 times the rate of V.

Although this research failed to yield a 3-*O*-substituted-2-acetoxy-D-glucal diacetate of sufficient reactivity to serve as a useful reagent for the synthesis of 2,3-unsaturated glycosides, the tri-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranosyl chloride (VII) described above shows considerable promise in this regard. The compound is extremely reactive, as shown by the fact that its reactions with methanol and ethanol to form glycosides were complete within minutes at room temperature in the presence of *sym*-collidine as buffer. The α- and β-anomers were formed in about equal amounts.

EXPERIMENTAL

Unless otherwise stated, the optical rotations were measured in 1 dm tubes at the D-line of sodium and room temperature (23–24°). The n.m.r. spectra were determined in deuterated chloroform on the spectrometers previously described (4). The melting points were determined on a microstage and are uncorrected.

Attempts to Prepare a 3-O-Sulfonyl Derivative of 4,6-Di-O-acetyl-2-acetoxy-D-glucal

The 2,4,6-tri-*O*-acetyl-3-*O*-tosyl (3) and 2,4,6-tri-*O*-acetyl-3-*O*-mesyl (11) derivatives of α-D-glucosyl bromide were prepared as previously described. The physical constants were in close agreement with those published for these compounds. Furthermore, the n.m.r. spectra were in complete agreement with those of compounds having the assigned structures.

When the compounds were treated with diethylamine in acetonitrile according to the directions reported by Lemieux and Lineback (4) for the dehydrobromination of tetra-*O*-acetyl-α-D-glucopyranosyl bromide, a syrupy product was obtained which darkened rapidly when allowed to stand. The n.m.r. spectra showed the products to be devoid of the sulfonate ester grouping and to be virtually identical. Although integration showed the presence of one diethylamino group per tri-*O*-acetyl sugar residue, it was evident that the product was a mixture of at least two compounds. Attempts to obtain a pure compound failed. Hydrogenation in ethanol in the presence of 5% palladium on charcoal led to extensive hydrogenolysis as well as hydrogenation, as indicated by the rapid consumption of 2 moles of hydrogen. The product was deacetylated and converted into the trimethylsilyl derivative for analysis by gas–liquid preparative chromatography. Although a band corresponding to 80% of the mixture appeared to provide a single component, the n.m.r. spectrum required this fraction to be a mixture of several compounds.

Reaction of the crystalline 2,4,6-tri-*O*-acetyl-3-*O*-tosyl-α-D-glucosyl bromide with 1 mole equivalent of diethylamine and 3 moles of methanol in acetonitrile led to a reaction which was complete after 10 h. The observed decrease in rotation was 0.76°. When 2 more mole equivalents of diethylamine was added, the rotation decreased 0.89° in 10 h and then remained constant. The product of this reaction was identical with that described above, obtained in the absence of methanol and with a large excess of diethylamine. Increased concentrations of methanol had no effect on the course of the reaction.

1,2;5,6-Di-O-isopropylidene-3-O-(2,6-dichlorobenzoyl)-α-D-glucose

1,2;5,6-Di-O-isopropylidene-α-D-glucose (1.0 g, 3.00 mmoles) was dissolved in 3 ml dry pyridine containing 1 ml 2,6-dichlorobenzoyl chloride (2). The reaction mixture was heated for 2.5 h on the steam bath, cooled, and poured onto ice. The mixture was extracted with chloroform. Evaporation of the chloroform extract gave a deep-red syrup which was extracted with ether. The red ethereal solution was concentrated to a syrup (2.26 g) which was subsequently fractionated on a column of 30 g silicic acid (Mallinckrodt, 100 mesh, analytical reagent) with chloroform as the eluting solvent. A pale-yellow syrup (1.06 g) was obtained from the fast-moving zone; this syrup crystallized when allowed to stand and was recrystallized from ethanol as long needles, m.p. 122–123°, $[\alpha]_D$ −14.45° (*c*, 1.4 in chloroform).

Anal. Calcd. for $C_{19}H_{22}Cl_2O_7$: C, 52.67; H, 5.12. Found: C, 52.51; H, 5.11.

4,6-Di-O-acetyl-2-acetoxy-3-O-(2,6-dichlorobenzoyl)-D-glucal (V)

1,2;5,6-Di-*O*-isopropylidene-3-*O*-(2,6-dichlorobenzoyl)-D-glucose was heated on the steam bath under reflux for 2 h in 1:1 ethanol – 2 *N* sulfuric acid. Thin-layer chromatography of the resulting hydrolysate showed only one spot. The reaction mixture was diluted with water and neutralized with barium carbonate. The filtrate was concentrated to a syrup, $[\alpha]_D^{23}$ −29.1° (*c*, 2.6 in ethanol), which was directly acetylated in the usual manner with sodium acetate and acetic anhydride.

In a typical experiment, the syrupy 1,2,4,6-tetra-*O*-acetyl-3-*O*-(2,6-dichlorobenzoyl)-D-glucose (0.41 g, $[\alpha]_D$ +24.4° (*c*, 3 in chloroform)) was dissolved in an ice-cold mixture of 5 ml 32% hydrogen bromide in glacial acetic acid containing 1 ml of acetic anhydride. The reaction mixture remained overnight at room temperature and then was poured onto 100 g ice. The amorphous precipitate was recovered by filtration, washed with ice water, and dissolved in chloroform. The solution was washed with ice-cold sodium bicarbonate solution and then water, and finally dried over sodium sulfate. Evaporation gave a syrup, 0.28 g, $[\alpha]_D$ +120° (*c*, 2.8 in acetonitrile), which resisted crystallization. The n.m.r. spectrum in deuterated chloroform required the substance to be virtually pure 2,4,6-tri-*O*-acetyl-3-*O*-(2,6-dichlorobenzoyl)-α-D-glucopyranosyl bromide. The chemical shifts for H^1, H^2, H^3, and H^4 were τ 3.27, 5.07, 4.03, and 4.66, and the spacings in the closely first-order spectrum indicated $J_{1,2} = 4.0$, $J_{2,3} = J_{3,4} = 10.0$, and $J_{4,5} = 9.5$ c.p.s. The relative intensities of the signals in the spectrum were as expected. The three protons on the benzene ring gave a sharp singlet at τ 2.63.

2,4,6-Tri-*O*-acetyl-3-*O*-(2,6-dichlorobenzoyl)-α-D-glucopyranosyl bromide (0.282 g, 0.52 mmole) was dissolved in 10 ml dry acetonitrile. Dry diethylamine (0.4 ml, 3.9 mmoles) was added and the change in rotation observed. From an initial observed rotation of +3.39°, a final rotation of 1.11° was reached in 11 h. The reaction mixture was poured into 150 ml of ice-cold chloroform and washed successively with 100 ml 0.2 *N* hydrochloric acid (ice-cold) and ice-cold sodium bicarbonate solution. When the chloroform solution was concentrated a syrup (0.21 g) was obtained, $[\alpha]_D$ −11.35° (*c*, 3.13 in chloroform), which discolored when allowed to stand. In a separate experiment 4.24 g of the syrup was applied to a 30 g silicic acid column and

eluted with chloroform. A single, sharp band appeared on the column which was recovered as a single fraction (4.02 g). The pale-yellow syrup (V), $[\alpha]_D$ −9.32° (*c*, 2 in chloroform), was dried for 12 h at 100° and 0.5 mm pressure without appreciable darkening.

Anal. Calcd. for $C_{19}H_{18}O_9Cl_2$: C, 49.47; H, 3.93. Found: C, 48.99; H, 3.96.

Although the compound resisted crystallization, the n.m.r. spectrum in deuterated chloroform indicated a high degree of purity. Only the expected signals, having the proper relative intensities, were observed. The signals for H^1 (singlet), H^3 (doublet), and H^4 (triplet) were at τ 3.28, 4.06, and 4.58, respectively, with $J_{3,4} = J_{4,5} = 5$ c.p.s. The signals for the three acetyl groups were well separated, and the three protons on the benzene ring gave a sharp singlet at τ 2.67.

*Tetra-O-acetyl-β-*D*-erythro-hex-2-enopyranose (VI)*

The α-anomer (II) was prepared from 65 g of tri-*O*-acetyl-2-acetoxy-D-glucal according to the directions of Lemieux and his co-workers (1), with *p*-toluenesulfonic acid as catalyst. The reaction mixture was poured onto 2 l of crushed ice. The crude crystalline α-anomer was isolated by filtration and recrystallized from 600 ml of 1:1 ethanol–water to give 39.5 g of pure compound. The mother liquors from the above filtrations were combined and thoroughly extracted with chloroform. The neutralized and dried extract was concentrated to a syrup (23.2 g), which was a 1.6:1 mixture of VI and II, respectively. The β-anomer (VI) crystallized readily when the mixture was seeded with an authentic sample kindly provided by Dr. R. J. Ferrier, Birkbeck College. The compound, m.p. 81.5–83.5°, $[\alpha]_D$ +146° (*c*, 2.4 in chloroform), was purified by repeated recrystallizations from 95% ethanol. Ferrier and his co-workers (5) reported m.p. 81–83°, $[\alpha]_D$ +156° (*c*, 1 in chloroform). The n.m.r. parameters measured at 100 Mc.p.s. are reported in Table I.

Anomerization Reactions of Compounds II and VI

Acid-Catalyzed

When 0.2 g of II was dissolved at 25° in 3 ml of 1:1 acetic acid – acetic anhydride 0.37 *M* in sulfuric acid, the rotation fell from an initially observed value of +4.6° to 3.28° in 5 min and eventually to a nearly constant value of −3.12°. Since these observed rotational changes were in the direction opposite to that expected for anomerization, it was evident that these strongly acid conditions had caused rapid changes other than anomerization. Solutions of compounds II and VI in 1:1 acetic acid – acetic anhydride showed no change in rotation during 24 h at 25°. It was found that reactions limited to anomerization could be achieved by using 0.00037 *M* sulfuric acid. Under these conditions, the rotation increased from 3.2° after 3 min to a constant value of +4.02° in 30 min. The rate of change in rotation followed first-order kinetics ($k_\alpha + k_\beta = 5 \pm 1 \times 10^{-2}$ min^{-1}). After 80 min, 0.1 ml of collidine was added and the product isolated in the usual manner. The n.m.r. spectrum showed the product to be a 4:1 mixture of the α- and β-anomers, respectively. Based on the rotations at zero time obtained by plotting the rotational data for both II and VI, the equilibrium rotation for the 4:1 mixture is expected to be 4.10°.

Anomerization of compound VI under the above conditions gave a change in rotation from +8.40° at zero time to a nearly constant value of +4.05° in 60 min. The velocity of the reaction was, within experimental error, the same as that when the α-anomer was used.

Base-Catalyzed

Solutions (0.1 *M*) of II and VI were made up at room temperature in acetic acid 1 *M* in potassium acetate, and placed in sealed tubes. At zero time, the tubes were immersed in a boiling water bath. After various intervals of time, the solutions were added to cold chloroform and the mixtures immediately washed with water and then sodium bicarbonate solution, dried, and evaporated to the syrupy products. The compositions of the products were determined by n.m.r. The β-anomer (VI) was anomerized to a 2:1 mixture of the α- and β-forms, respectively, in 180 min. After 5 min, only 5% anomerization had occurred. The α-anomer (II) was isomerized to a 4:1 mixture of II and VI, respectively, after 16 h. The isolated yield of the product was 40%.

*Conversions of 4,6-Di-O-acetyl-2-acetoxy-3-O-(2,6-dichlorobenzoyl)-*D*-glucal (V) into the Anomeric Tetra-O-acetyl-*D*-erythro-hex-2-enopyranoses (II and VI)*

Acid Catalysis

Compound V (a 0.1 *M* solution in 1:5 acetic anhydride – acetic acid containing 0.05 *M* *p*-toluenesulfonic acid) was treated at 25° as described by Lemieux and his co-workers (1) for the isomerization of I. The rate of rotational change indicated a velocity constant of 2×10^{-2} h^{-1}. The product of reaction was a 4:1 equilibrium mixture of II and VI. The velocity constants for the conversions of compounds I and XIV were 40×10^{-2} and 13.5×10^{-2} h^{-1}, respectively.

Base Catalysis

Compound V was allowed to react in acetic acid 1 *M* in potassium acetate at 100° as described above for compounds II and VI. Products were isolated after reaction times of 5, 15, 30, and 180 min and contained 73, 29, 11, and 0% of the starting material, respectively, as indicated by the n.m.r. spectra. Compounds II and VI were the sole products of the reaction and were present in the products in ratios (α/β) of 1.08, 1.27, 1.54, and 2.70, respectively.

Tri-O-acetyl-3-deoxy-α-D-erythro-hex-2-enopyranosyl Chloride (VII)

Compound II (5.08 g, 15.4 mmoles) was dissolved in 100 ml of alcohol-free dry chloroform. Powdered aluminium chloride (2.1 g, 15.8 mmoles) was added and the mixture was vigorously shaken for 1 h at room temperature. The mixture was poured into 300 ml of dry benzene and filtered through a cotton plug. Evaporation of the solvents under reduced pressure left 3.07 g of a colorless syrup, $[\alpha]_D$ +53.4° (*c*, 2.5 in chloroform). The n.m.r. spectrum (see Table I) left no doubt that the product was virtually one compound. Characterization as VII is based on its n.m.r. spectrum and conversion into II and VI in high yield. Virtually the same product as described above was obtained when the β-anomer (VI) was treated with aluminium chloride.

The syrupy chloride (VII) (0.25 g) was dissolved in 5 ml of acetic acid containing 0.5 g of anhydrous sodium acetate and 1 ml of acetic anhydride. After 75 min at room temperature, 0.225 g of the product was isolated in the usual manner. Examination by n.m.r. showed the presence of a 2:1 mixture of VI and II, respectively, along with some impurity, giving rise to minor signals, particularly at τ 2.75.

Methyl Di-O-acetyl-3-deoxy-β-D-erythro-hex-2-enopyranoside (VIII)

Compound VII (3.07 g) was dissolved in a mixture of 5 ml of dry *sym*-collidine and 25 ml of anhydrous methanol. The observed rotation changed from an initial value of +7.74° to a constant value of +6.30° in 1 h. The solvents were largely removed by evaporation *in vacuo*, the residue was dissolved in ether, and the ethereal solution was washed with water, decolorized with charcoal, and evaporated to dryness in a high vacuum. The residue, 2.58 g (96% yield), had a n.m.r. spectrum consistent with that expected for an equimolar mixture of VIII and its α-anomer IX. A 0.91 g sample of the product was chromatographed on a 50 g column of silicic acid with chloroform as the eluting solvent. Although a clear separation was not obtained, a 0.07 g fraction had a n.m.r. spectrum (see Table I) consistent with that of a pure compound in the β-D-configuration. The specific rotation was +104° (*c*, 4 in chloroform) and showed a strongly plain, positive rotatory dispersion curve, as found by Ferrier and his co-workers (5) for the related β-anomer (VI).

1,2;5,6-Di-O-isopropylidene-3-O-mesitoyl-α-D-glucose (X)

Mesitoic acid (1.01 g, 0.1 mmole) (I) was dissolved in 5 ml trifluoroacetic anhydride and the mixture cooled in an ice bath. 1,2;5,6-Di-*O*-isopropylidene-α-D-glucose (1.82 g, 7.0 mmoles) was added and, after 30 min, the yellowish reaction mixture was diluted with 100 ml dry benzene. The solution was washed with ice-cold 10% aqueous sodium hydroxide and then with ice water. The benzene solution was dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo* to a pale-yellow, viscous syrup, 2.66 g, $[\alpha]_D$ −28.8° (*c*, 1.8 in chloroform). The n.m.r. spectrum was in complete agreement with that of a compound having the assigned structure.

3-O-Mesitoyl-β-D-glucose (XI)

1,2;5,6-Di-*O*-isopropylidene-3-*O*-mesitoyl-α-D-glucose (X) was dissolved in 20 ml of refluxing methanol, and 20 ml of 2 *N* sulfuric acid was added dropwise during 10 min. The mixture was refluxed for a further 60 min, cooled, and diluted with 50% aqueous methanol. The solution was shaken with Dowex 3 (OH^-) until neutral, filtered, and concentrated to a syrup, 1.615 g (98% yield). The compound was crystallized from water, and after two recrystallizations from this solvent melted at 153–154°, $[\alpha]_D$ +17.1° → +49.8° after 20 h (*c*, 1.55 in 95% ethanol 0.2% in pyridine).

Anal. Calcd. for $C_{16}H_{22}O_7$: C, 58.89; H, 6.79. Found: C, 58.95; H, 6.60.

1,2,4,6-Tetra-O-acetyl-3-O-mesitoyl-β-D-glucose (XII)

3-*O*-Mesitoyl-β-D-glucose (XI) (6.54 g) was heated for 2.5 h on the steam bath with 7 g of anhydrous sodium acetate and 70 ml of acetic anhydride. The mixture was poured onto 500 g of crushed ice, and the resulting solid product was washed with cold water. Recrystallization from 95% ethanol gave 5.36 g of fine needles, m.p. 170–171°, $[\alpha]_D$ +9.4° (*c*, 2.9 in chloroform). The n.m.r. spectrum was in complete agreement with that of a compound having the assigned structure.

Anal. Calcd. for $C_{24}H_{30}O_{11}$: C, 58.29; H, 6.12. Found: C, 58.21, H, 5.86.

2,4,6-Tri-O-acetyl-3-O-mesitoyl-α-D-glucosyl Bromide (XIII)

Compound XII was treated with 32% hydrogen bromide in glacial acetic acid in the usual manner to give a colorless syrup, in a nearly quantitative yield, which failed to crystallize. The high rotation ($[\alpha]_D$ +149° (*c*, 1.5 in acetonitrile)) and the n.m.r. spectrum were in complete agreement with those of a compound having the assigned structure.

4,6-Di-O-acetyl-2-acetoxy-3-O-mesitoyl-D-glucal (XIV)

Compound XIII was reacted with diethylamine in acetonitrile according to the directions described by Lemieux and his co-workers (1) for the preparation of I. The crude product was virtually pure XIV and was obtained in a nearly quantitative yield. The compound crystallized readily on trituration with methanol. Recrystallization from methanol gave pure material, m.p. 114–116°, $[\alpha]_D$ −39.6° (*c*, 1.2 in acetonitrile). The n.m.r. spectrum was in complete agreement with that of a compound having the assigned structure.

Anal. Calcd. for $C_{22}H_{26}O_9$: C, 60.82; H, 6.03. Found: C, 61.2; H, 6.04.

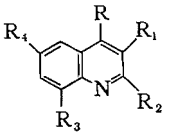
4-HYDROXYQUINALDINES IN THE MANNICH REACTION[1]

I. NABIH AND M. NASR

Many quinoline derivatives possess chemotherapeutic activity, but their usefulness may be interfered with by water insolubility. It was anticipated that introduction of a basic side chain would overcome the difficulty through hydrochloride formation. Quinaldine itself had been treated with formaldehyde and a primary or secondary amine hydrochloride to form 2-B-aminoethylquinoline derivatives (1). A German patent reported that treatment of 2-methyl-8-nitroquinoline with a primary amine hydrochloride gave a product having the basic side chain at the 2-position (2).

The same patent claims that, in the case of 4-hydroxyquinaldine, the reaction involves the methyl group at the 2-position (3). Price and Jackson carried out the reaction with 7-methoxy-4-hydroxyquinaldine, formaldehyde, and di-*n*-butylamine; they obtained the 3-dibutylaminomethyl derivative (4). Ghosh and Chandhuri treated 4-hydroxyquinaldine with diethylamine and formaldehyde and obtained 3-diethylaminomethyl-4-hydroxyquinaldine (5) (I), but they did not demonstrate its structure.

In the present work, 4-hydroxyquinaldine was treated with paraformaldehyde and diethylamine in 95% alcoholic solution at room temperature for 24 h. The product was assigned structure I, with the basic side chain attached to the 3-position. The methyl group at the 2-position remained intact, as shown by its condensation with *p*-dimethylaminobenzaldehyde in the presence of zinc chloride to give the carbostyryl derivative II. Also, hydrogenolysis of I with copper chromite catalyst gave 2,3-dimethyl-4-quinolinol (6) (III). The 4-hydroxyl group of I, in contrast to that of 4-hydroxyquinaldine, could be acetylated. When the product IV was treated with alkali, it hydrolyzed to regenerate I. Also, I, when condensed with chloroacetic acid, gave V.



I: R = OH, R_1 = $CH_2N(C_2H_5)_2$, R_2 = CH_3
II: R = OH, R_1 = $CH_2N(C_2H_5)_2$, R_2 = $CH{=}CHC_6H_5N(CH_3)_2$
III: R = OH, R_1 = R_2 = CH_3
IV: R = $OCOCH_3$, R_1 = $CH_2N(C_2H_5)_2$, R_2 = CH_3
V: R = OCH_2COOH, R_1 = $CH_2N(C_2H_5)_2 \cdot HCl$, R_2 = CH_3

When diethylamine hydrochloride was used in place of diethylamine, the product was the hydrochloride of I. When diethylamine was used in the presence of excess concentrated hydrochloric acid, the reaction failed to occur.

The Mannich reaction was carried out with 6- and 8-methyl-4-hydroxyquinaldine to give VI and VII, respectively. Upon hydrogenolysis, the corresponding 3-methyl derivatives VIII and IX were obtained. Both were identical with authentic samples prepared by condensation of α-methyl acetoacetic ester with *p*- and *o*-toluidine, respectively, followed by cyclization of the resulting crotonate derivatives.

EXPERIMENTAL

All melting points are uncorrected and were determined on a Kofler hot stage.

3-Diethylaminomethyl-4-hydroxyquinaldine (I)

A mixture of 1.6 g of paraformaldehyde (0.017 mole), 25 ml of 95% ethyl alcohol, and 20 ml (14.22 g, 0.194 mole) of diethylamine was refluxed until the paraformaldehyde had dissolved. To this solution was added 7.95 g (0.05 mole) of 4-hydroxyquinaldine (7) dissolved in the least amount of 95% ethanol; then the mixture was kept for 48 h at room temperature. White needles were formed. Recrystallization from alcohol gave 10.98 g (90% yield) of I, which decomposed at 348–350° (lit. (5) no melting until 300°).

Anal. Calcd. for $C_{15}H_{20}ON_2$: C, 73.73; H, 8.25; N, 11.47. Found: C, 73.60; H, 8.30; N, 11.36.

3-Diethylaminomethyl-4-hydroxyquinaldine Hydrochloride (Ia)

The foregoing procedure was applied, except that diethylamine was replaced by its hydrochloride. The reaction mixture was refluxed for 5 h. The solvent was then evaporated and the residue was recrystallized from aqueous alcohol to give a 95% yield of I*a*, m.p. 313–315°.

Anal. Calcd. for $C_{15}H_{21}ON_2Cl$: N, 9.98; Cl, 12.65. Found: N, 9.65; Cl, 12.14.

When I*a* was heated with 10% potassium hydroxide solution, I was recovered.

Condensation of I with p-Dimethylaminobenzaldehyde

A mixture of 2.44 g (0.01 mole) of I, 1.49 g (0.01 mole) of *p*-dimethylaminobenzaldehyde, and 0.5 g of zinc chloride was heated in an oil bath at 180 °C for 3 h. The reaction mixture was dissolved in alcohol. Upon addition of sodium hydroxide solution, a yellow substance was precipitated. Recrystallization from alcohol gave 2.6 g (70% yield) of 2-(*p*-dimethylaminostyryl)-3-diethylaminomethyl-4-quinolinol (II), m.p. 185–187°, which was soluble in alcohol but insoluble in water, ether, and petroleum ether.

Anal. Calcd. for $C_{24}H_{29}ON_3$: C, 76.59; H, 7.73; N, 11.20. Found: C, 76.44; H, 7.54; N, 11.12.

Hydrogenolysis of I

A mixture of 7.32 g (0.03 mole) of I, 150 ml of absolute ethyl alcohol, and 5 g of copper chromite was placed in a bomb, hydrogen was added, and the mixture was shaken and heated gradually to 175° at an equilibrium pressure of 3 000 lb, for 4 h, until the calculated amount of hydrogen was consumed (0.045 mole). The bomb was allowed to cool to room temperature. The reaction mixture was filtered from the catalyst, concentrated, and cooled in ice. Precipitation by addition of ether and recrystallization from water gave 1.7 g (34% yield) of III, m.p. 319–320°. Its melting point was identical with that of an authentic sample of III and showed no depression upon admixture (lit. (6) m.p. 319–320°).

Acetylation of I

A mixture of 1.55 g (0.012 mole) of I and 2 ml of acetic anhydride was heated in an oil bath at 180 °C for 3 h. The reaction mixture changed to a dark-red syrup. When this was poured into boiling water, a brown solid separated. This was filtered off, dried, and then recrystallized from absolute ethyl alcohol to give 1.5 g (85% yield) of 3-diethylaminomethyl-4-acetoxyquinaldine (IV), m.p. 314–316°, as yellow crystals insoluble in water, ether, petroleum ether, and chloroform, and soluble (with difficulty) in alcohol.

Anal. Calcd. for $C_{17}H_{22}O_2N_2$: C, 71.30; H, 7.74; N, 9.79. Found: C, 71.15; H, 7.59; N, 9.61.

Acetylation of III

The above procedure was applied to III, which was recovered unchanged (no depression in mixed melting point).

Attempt to Acetylate 4-Hydroxyquinaldine

The foregoing procedure was applied to 4-hydroxyquinaldine but the compound was recovered unchanged (no depression in melting point when mixed with starting material).

Hydrolysis of IV

A mixture of 0.15 (0.0006 mole) of IV, 0.2 g (0.0036 mole) of potassium hydroxide, and 5 ml of ethyl alcohol was refluxed on the water bath for 3 h, cooled, and poured into cold water. The precipitated solid was 3-diethylaminomethyl-4-hydroxyquinaldine (I), which decomposed at 348–350° (undepressed upon admixture with an authentic sample).

Reaction of I with Chloroacetic Acid

A mixture of 2.44 g (0.01 mole) of I and 0.945 g (0.01 mole) of chloroacetic acid was heated in an oil bath until solution was complete. The mixture was cooled and made alkaline with aqueous sodium hydroxide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The yellow solid that separated was filtered off, dissolved in alcohol, and precipitated by a stream of hydrogen chloride to give 2.1 g (70% yield) of 3-diethylaminomethyl-4-carboxymethoxyquinaldine hydrochloride (V). It was recrystallized from absolute alcohol, and had m.p. 360–363°.

Anal. Calcd. for $C_{17}H_{23}O_3N_2Cl$: C, 60.26; H, 6.84; N, 8.27. Found: C, 60.12; H, 6.71; N, 8.41.

Attempted Reaction of Chloroacetic Acid with 4-Hydroxyquinaldine

The foregoing procedure was applied to 4-hydroxyquinaldine, but only unchanged starting material was obtained.

6-Methyl-3-diethylaminomethyl-4-hydroxyquinaldine (VI)

A mixture of 1.6 g (0.017 mole) of paraformaldehyde, 25 ml of 95% ethyl alcohol, and 20 ml (14.22 g, 0.194 mole) of diethylamine was refluxed on the water bath until the paraformaldehyde had dissolved, and then allowed to cool to room temperature. To this solution was added 8.65 g (0.05 mole) of 2,6-dimethyl-4-quinolinol dissolved in the least amount of 95% ethanol; then the mixture was refluxed for 3 h and allowed to cool to room temperature. White needles insoluble in water and alkali but soluble in 5% hydrochloric acid were formed. Recrystallization from ethyl alcohol gave 11.52 g (90% yield) of VI, which decomposed at 320°.

Anal. Calcd. for $C_{16}H_{22}ON_2$: C, 74.40; H, 8.58; N, 10.85. Found: C, 74.39; H, 8.47; N, 10.78.

Hydrogenolysis of VI

The hydrogenolysis of VI was effected in a manner similar to that used for the hydrogenolysis of I. The resulting reaction product was recrystallized from aqueous alcohol to give needles, m.p. 349–352°, easily soluble in alcohol and soluble (with difficulty) in water. The product showed no depression in the melting point upon admixture with an authentic sample of 3,6-dimethyl-4-hydroxyquinaldine (VIII) prepared by an alternative synthesis.

Anal. Calcd. for $C_{12}H_{13}ON$: C, 77.01; H, 6.95; N, 7.49. Found: C, 76.87; H, 7.37; N, 7.25.

8-Methyl-3-diethylaminomethyl-4-hydroxyquinaldine (VII)

The foregoing procedure for VI was applied to 2,8-dimethyl-4-quinolinol. The reaction product was recrystallized from alcohol to give VII (90% yield), m.p. 338–340°, soluble in 5% hydrochloric acid and insoluble in water and alkali.

Anal. Calcd. for $C_{16}H_{22}ON_2$: C, 74.40; H, 8.58; N, 10.85. Found: C, 74.39; H, 8.59; N, 10.64.

Hydrogenolysis of VII

The same procedure as described above for I was applied. The resulting reaction product was recrystallized from aqueous alcohol. The product melted at 325–327°. It showed no depression in the mixture melting point with 3,8-dimethyl-4-hydroxyquinaldine (IX).

Anal. Calcd. for $C_{12}H_{13}ON$: C, 77.01; H, 6.95; N, 7.49. Found: C, 76.94; H, 7.10; N, 7.52.

3,6-Dimethyl-4-hydroxyquinaline (VIII)

A mixture of 10.7 g (0.1 mole) of *p*-toluidine and 14.41 g (0.1 mole) of α-methylacetoacetate ester, to which was added two drops of concentrated hydrochloric acid, was kept at room temperature for 24 h. After separation of water, the residual *p*-toluidino-α-methylcrotonate was added dropwise to hot paraffin oil (150 ml) at 240°. The temperature was raised to 265°, and the mixture was then cooled. The white crystalline product was filtered off and washed with petroleum ether. It had m.p. 347°. Recrystallization from alcohol gave 12 g (64% yield) of VIII, m.p. 349–352°.

Anal. Calcd. for $C_{12}H_{13}ON$: C, 77.01; H, 6.95; N, 7.49. Found: C, 76.95; H, 6.95; N, 7.54.

3,8-Dimethyl-4-hydroxyquinaldine (IX)

A mixture of 10.7 g (0.1 mole) of *o*-toluidine and 14.41 g (0.1 mole) of α-methylacetoacetic ester was treated similarly as above, and the isolated product was recrystallized from alcohol to give 8.4 g (45% yield) of IX, m.p. 325–327°.

Anal. Calcd. for $C_{12}H_{13}ON$: C, 77.01; H, 6.95; N, 7.49. Found: C, 76.82; H, 6.54; N, 7.61.

ACKNOWLEDGMENT

The authors express their gratitude to Professor J. H. Burckhalter, University of Michigan, Ann Arbor, for his suggestions during his visit to this laboratory.

DECOMPOSITION PRODUCTS OF 5-OXO-3,5-SECO-A-NORCHOLESTAN-3-OIC ACID *p*-TOLUENESULFONYLHYDRAZONE

J. T. EDWARD,[1] DAPHNE L'ANGLAIS,[2] AND SEYMOUR MEYERSON[3]

The decomposition of 5-oxo-3,5-seco-A-norcholestan-3-oic acid *p*-toluenesulfonylhydrazone (I) was carried out in diethyl Carbitol containing sodium methoxide (the "aprotic" Bamford–Stevens reaction (1, 2)) in the hope of obtaining the unsaturated acid III. An intractable oil was obtained which appeared, from its nuclear magnetic resonance spectrum (no olefinic protons), to contain little or none of this acid. The decomposition of the *p*-toluenesulfonylhydrazone in alkaline ethylene glycol (the "protic" Bamford–Stevens reaction) also yielded a mixture that was largely intractable, but from which small amounts of several crystalline compounds were isolated. Three of these proved to be identical with compounds previously isolated from the solvolysis of 5α- or 5β-*p*-toluenesulfonyloxy-3,5-seco-A-norcholestan-3-nitrile and formulated as the lactones IX, X*a* (m.p. 114–115°), and XII (3). A fourth compound X*c*, m.p. 105–106°, is apparently a stereoisomer of X*a*.

In the earlier work, so little of the lactone XII had been obtained that it could not be analyzed. Thus, its formula was based only on the close similarity of its infrared spectrum to that of the lactone IX, the stereochemical assignments being very tentative. In the

present study, larger amounts of the compound were obtained, and the analytical data and mass spectrum give additional support to the formulation XII, though without stereochemical implications. The mass spectrum, shown in Table I, is generally similar to that of the isomer IX (3); the most pronounced difference occurs at mass 370, corresponding to loss of H_2O, where the relative intensity of XII is far lower than that of IX. The higher intensity of the parent ion relative to that of the fragment ions suggests that XII is the more stable of the two isomers.

TABLE I

Partial mass spectra of lactones

	Relative intensity*				
Mass	XII	IX†	X*c*	X*a*†	Loss‡

*Scale of relative intensities defined by assigning a value of 100.0 to the most intense peak of mass greater than 90 in each spectrum.
†From ref. 3.
‡Probable composition of neutral particle(s) lost from parent ion.

The mass spectrum of X*c*, also shown in Table I, is similar enough (especially at masses 99, 287, and 289) to that of X*a*, known to be a pendant lactone, to indicate that X*c* is also a pendant lactone. The higher intensity of the parent ion relative to that of the fragment ions suggests that X*c* is the more stable isomer. Its infrared spectrum is likewise closely similar to that of X*a*, and also to that of X*b*, a stereoisomer of X*a* with m.p. 89–90° (3). Hence, X*c* is most likely another stereoisomer of these compounds. Too little of it was obtained (5 mg of crude product) to permit more detailed experimentation.

Some unsaturated acidic material was also formed, containing perhaps VIII, since oxidation of the oily fraction with osmium tetroxide gave a hydroxylactone previously formulated as XI (3). In the earlier work (3), the major unsaturated acid was believed to be III, since a large amount of a hydroxy-δ-lactone was formed when the acid fraction was oxidized with osmium tetroxide. In the present experiments, this lactone was not detected (infrared spectrum) after oxidation of the crude acidic product.

The mechanism of the "protic" Bamford–Stevens reaction is believed to involve the formation of a diazo compound (II, in the present instance) which then adds a proton from the solvent to form a diazonium ion. Possibly, addition of a proton from an equatorial direction to give the diazonium ion V proceeds more easily than addition from an axial direction to give IV. This would explain why the spiro lactones IX and XII, which probably originate from V via the stereospecifically generated carbonium ion VI (cf. ref. 3), are formed in greater amount than the pendant lactones (X), which probably originate from IV via the carbonium ion VII. The apparent failure to form any unsaturated acid III from the diazonium ion V remains puzzling, particularly since Elks *et al.* (4) obtained about a 25% yield of unrearranged olefin from the decomposition of hecogenin acetate *p*-toluenesulfonylhydrazone. This compound, like I, has a hydrazone group flanked by methylene and quaternary carbon atoms, and might be expected to display about the same propensity to rearrangement in competition with elimination.

EXPERIMENTAL

5-Oxo-3,5-seco-A-norcholestan-3-oic Acid p-Toluenesulfonylhydrazone (I)

A mixture of 5-oxo-3,5-seco-A-norcholestan-3-oic acid (9.9 g) (5) and *p*-toluenesulfonylhydrazine (8.9 g) in hexane–benzene (1:1 v/v) (500 ml) containing one drop of concentrated hydrochloric acid was refluxed for 1 h. The solution was then filtered from a small amount of unreacted *p*-toluenesulfonylhydrazine, and concentrated to 200 ml under reduced pressure. A white solid, m.p. 158–166°, was removed from the cooled solution and recrystallized twice from hexane–benzene to yield white crystals (12.1 g), m.p. 172–173°, ν_{max}^{KBr} 1 372 and 1 160 cm^{-1}.

Anal. Calcd. for $C_{33}H_{52}O_4N_2S$: C, 69.20; H, 9.15; N, 4.89. Found: C, 68.72; H, 8.88; N, 4.89.

Decomposition of 5-Oxo-3,5-seco-A-norcholestan-3-oic Acid p-Toluenesulfonylhydrazone

The *p*-toluenesulfonylhydrazone (10 g) was suspended in ethylene glycol (500 ml) to which sufficient sodium had been added to give a 1 *N* solution of alkoxide, and then heated slowly to 170°. After 30 min the solution was cooled, diluted with water (2 l), acidified with concentrated hydrochloric acid to pH 4, and extracted five times with ether. The ether solution was washed with water, dried, and evaporated to yield an oil (6.8 g). The oil was chromatographed on alumina (grade III) and yielded the following oily fractions: A (1.75 g), a clear mobile oil, $\nu_{max}^{CCl_4}$ 1 740 cm^{-1}, eluted with hexane–benzene (9:1); B (1.09 g), $\nu_{max}^{CCl_4}$ 1 770 cm^{-1}, eluted with hexane–benzene (2:1); and C (3.9 g), a series of fractions eluted with benzene–ether (1:1), ether, and ether – acetic acid – water (96:3:1), showing essentially the same infrared spectrum, with a prominent peak at 1 720 cm^{-1} and a minor peak at 1 770 cm^{-1}.

Further chromatography of fraction A on neutral alumina (grade II or grade I) effected no further purification. It did not react with 2,4-dinitrophenylhydrazine or ethanolic ammonia (cf. ref. 6). Its nature remains obscure.

Fraction B was chromatographed on alumina (grade II). Elution with hexane–benzene (14:1) removed the following fractions: 1–3 (60 mg), an oil, $\nu_{max}^{CCl_4}$ 1 740 cm^{-1}; 4–13 (90 mg), a solid, m.p. 90–95°, $\nu_{max}^{CCl_4}$ 1 770 cm^{-1}; 14–15 (200 mg), a solid, m.p. 120–126°, $\nu_{max}^{CCl_4}$ 1 770 cm^{-1}; and 16–18 (200 mg), a solid, m.p. 138–140°, $\nu_{max}^{CCl_4}$ 1 770 cm^{-1}. Elution with hexane–benzene (26:4), followed by mixtures richer in benzene and finally by pure benzene, removed fractions 19–27 (600 mg), a solid, m.p. 143–145°, $\nu_{max}^{CCl_4}$ 1 770 cm^{-1}.

The solid from fractions 4–13, after three recrystallizations from ethanol, melted at 112–113° (65 mg), and was identified by mixed melting point and infrared spectrum as the lactone X*a*, m.p. 114–115° (3).

The solid from fractions 16–27 was recrystallized four times from ethanol to give needles (530 mg), m.p. 152–153°, identical (mixed melting point and infrared spectrum) with the lactone IX (3).

The residue from the mother liquors of these crystallizations was combined with fractions 14 and 15, and fractionally crystallized from ethanol to yield further amounts of IX (81 mg, m.p. 151–152°) and X*a* (10 mg, m.p. 111–112°), and finally a small amount of the material formulated as X*c* (5 mg, m.p. 103–104°, $\nu_{max}^{CCl_4}$ 1 770 cm^{-1}). The melting point was raised to 105–106° by four recrystallizations from ethanol; it was depressed on admixture with X*a*.

Fraction C was shown by its infrared spectrum to contain aromatic sulfonyl and carboxylic ($\nu_{max}^{CCl_4}$ 1 720 cm^{-1}) compounds. It formed a gummy benzylisothiouronium salt, from which a small amount of solid was obtained by recrystallization. However, on treatment with hydrochloric acid, the latter gave only a gummy product. A portion of fraction C (1.6 g) was oxidized with osmium tetroxide (1.0 g) in anhydrous ether (40 ml) and dry pyridine (4 ml). After 6 days at room temperature, the mixture was worked up in the usual way with sodium sulfite (3) to yield an orange oil (1.3 g), which was chromatographed on neutral alumina (grade II). The following fractions were collected: D (25 mg), an oil showing no hydroxyl or carbonyl peaks in the infrared spectrum, eluted with hexane–benzene (6:4); E (103 mg), white needles, m.p. 95–98°, eluted with hexane–benzene (1:1); F (42 mg), a solid, m.p. 21–26°, eluted with hexane–benzene (28:32); G (86 mg), a solid, m.p. 105–116°, eluted with benzene–ether (2:1); and H (70 mg), an oil, $\nu_{max}^{CCl_4}$ 1 720 cm^{-1}, eluted with ether and ether – acetic acid, this could not be crystallized.

Fraction E, after two recrystallizations from ethanol, melted sharply at 97–98° (80 mg), and was identical (mixed melting point and infrared spectrum) with the compound formulated as XII (3).

Anal. Calcd. for $C_{26}H_{44}O_2$: C, 80.35; H, 11.41. Found: C, 80.54; H, 11.36.

Fraction G, after three recrystallizations from hexane–ether, melted at 201° and was identical (mixed melting point and infrared spectrum) with the hydroxylactone tentatively formulated as XI (3).

Anal. Calcd. for $C_{26}H_{44}O_3$: C, 77.17; H, 10.96. Found: C, 77.02; H, 11.07.

Mass Spectrometry

Mass spectra were measured with 70 V electrons on a modified (7) Consolidated model 21-103*c* instrument, with the sample-introduction system at 250°.

ACKNOWLEDGMENTS

We are grateful to N. E. Lawson for preparing a pure sample of 5-oxo-3,5-seco-A-norcholestan-3-oic acid *p*-toluenesulfonylhydrazone. The financial support of the National Research Council of Canada for the work performed at McGill University is gratefully acknowledged.

ORGANIC SULFUR MECHANISMS

5. PHOTOLYSIS OF UNSATURATED SULTAMS AND THE QUESTION OF ABNORMAL ADDITION TO SULFENES

T. DURST AND J. F. KING

As would be predicted by analogy with ketenes, those products which may be derived in a simple manner from a nucleophilic reaction on sulfenes are those stemming from attack of the nucleophile on the sulfur atom of the sulfene, rather than the carbon atom (cf. refs. 1–3). However, whereas simple nucleophilic attack at the olefinic carbon of ketene would lead to a virtually unprecedented carbanion, the corresponding reaction at the carbon atom of a sulfene would give a comparatively low-energy species, a sulfinate anion. This consideration suggested that the possibility of the reaction of nucleophilic reagents at the carbon atom of a sulfene (referred to as "abnormal" attack in this note) warranted an investigation, especially since our work on the formation of the oxythiobenzoyl chlorides (4–6) led us to wonder whether a proposed precursor of these compounds might not be derived from such an abnormal attack.

One possible way of detecting the abnormal addition would be to carry out the reaction under conditions in which normal attack (i.e. at the sulfur atom) would lead only to a trivial change, such as return to the starting material, which could occur many times and still allow the sulfene to be formed anew in the reaction mixture. Under such circumstances the abnormal process might manifest itself even though it were orders of magnitude slower than the normal process.

De Mayo and his co-workers (1, 7) have shown that the irradiation of unsaturated, six membered ring sultones leads to the formation of products derivable from nucleophilic addition to a photochemically generated sulfene. In addition, Helferich *et al.* (8) have observed that pyrolysis of unsaturated, six membered ring sultams leads to the corresponding pyrroles with loss of sulfur dioxide. It occurred to us that, if the pyrrole formation were to take place via a sulfene (whether generated by heat or light), then the reaction would easily be explained on the basis of abnormal attack on the sulfene as shown in eq. [1]. Accordingly, we sought to determine whether pyrroles could be produced by photolysis of sultams and whether we could obtain evidence that sulfenes might be

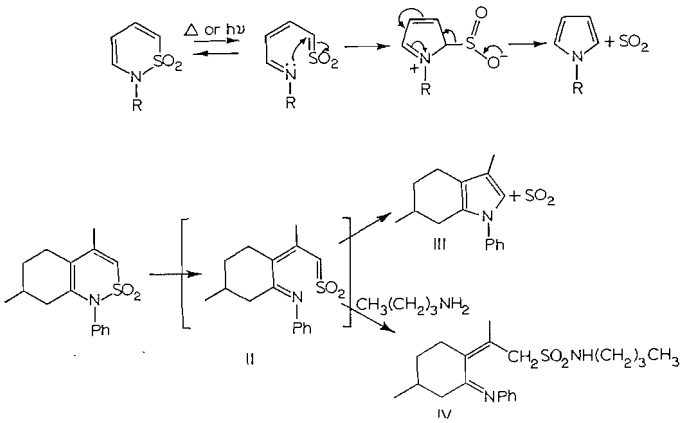
ORGANIC SULFUR MECHANISMS

5. PHOTOLYSIS OF UNSATURATED SULTAMS AND THE QUESTION OF ABNORMAL ADDITION TO SULFENES

T. DURST AND J. F. KING

As would be predicted by analogy with ketenes, those products which may be derived in a simple manner from a nucleophilic reaction on sulfenes are those stemming from attack of the nucleophile on the sulfur atom of the sulfene, rather than the carbon atom (cf. refs. 1–3). However, whereas simple nucleophilic attack at the olefinic carbon of ketene would lead to a virtually unprecedented carbanion, the corresponding reaction at the carbon atom of a sulfene would give a comparatively low-energy species, a sulfinate anion. This consideration suggested that the possibility of the reaction of nucleophilic reagents at the carbon atom of a sulfene (referred to as "abnormal" attack in this note) warranted an investigation, especially since our work on the formation of the oxythiobenzoyl chlorides (4–6) led us to wonder whether a proposed precursor of these compounds might not be derived from such an abnormal attack.



One possible way of detecting the abnormal addition would be to carry out the reaction under conditions in which normal attack (i.e. at the sulfur atom) would lead only to a trivial change, such as return to the starting material, which could occur many times and still allow the sulfene to be formed anew in the reaction mixture. Under such circumstances the abnormal process might manifest itself even though it were orders of magnitude slower than the normal process.

De Mayo and his co-workers (1, 7) have shown that the irradiation of unsaturated, six membered ring sultones leads to the formation of products derivable from nucleophilic addition to a photochemically generated sulfene. In addition, Helferich *et al.* (8) have observed that pyrolysis of unsaturated, six membered ring sultams leads to the corresponding pyrroles with loss of sulfur dioxide. It occurred to us that, if the pyrrole formation were to take place via a sulfene (whether generated by heat or light), then the reaction would easily be explained on the basis of abnormal attack on the sulfene as shown in eq. [1]. Accordingly, we sought to determine whether pyrroles could be produced by photolysis of sultams and whether we could obtain evidence that sulfenes might be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

formed under these conditions. It was recognized that a sulfene formed by the photochemical opening of the unsaturated sultam ring would differ from that formed from a sultone in that the former would have a much stronger internal nucleophile (the anil nitrogen rather than the carbonyl oxygen). In the absence of external nucleophilic reagents capable of competing with it, the internal base could conceivably react with the sulfene end in two ways: (*i*) normal attack on the sulfur atom to regenerate starting material, and (*ii*) abnormal attack on the carbon atom to give the pyrrole as shown in eq. [1].

[1]

The irradiation of the sultam I (9), when carried out in dry ether, cyclohexane, or dry methanol, gave a good yield of the pyrrole III, which was identified by comparison of its infrared and nuclear magnetic resonance spectra and R_f value on thin-layer chromatography with those of an authentic sample prepared by pyrolysis of the sultam according to Helferich *et al.* (8). The reaction in methanol is noteworthy because irradiation of the unsaturated sultones in that solvent invariably led to the corresponding esters; also, in inert solvents the sultones showed little reaction on irradiation under comparable conditions (1, 7).

When the irradiation was carried out in the presence of *n*-butylamine (a strong external nucleophile), the pyrrole formation was diminished, though a 10–20% yield was obtained even when *n*-butylamine was the solvent. In addition to the pyrrole III, the reaction in *n*-butylamine gave a white crystalline compound in 60% yield. The analytical data for the crystalline material corresponded to the empirical formula $C_{20}H_{30}N_2O_2S$, thereby suggesting that the compound was the sulfonamide IV (no specification of stereochemistry is implied), derivable from 1,2 addition of *n*-butylamine to the sulfene II. This view was confirmed by the infrared and nuclear magnetic resonance spectra of the compound. The former showed bands at 1 325 and 1 138 cm^{-1} appropriate to the sulfonyl group, NH absorption at 3 360 cm^{-1}, and a band at 1 635 cm^{-1} ascribable to the conjugated carbon–nitrogen double-bond system. In addition to complex absorption between 3.3 and 0.9 p.p.m. caused by methylene and methyl protons, the nuclear magnetic resonance spectrum showed the following bands: (*i*) aromatic hydrogen absorption between 6.7 and 7.4 p.p.m., (*ii*) a broadened signal around 5.6 p.p.m. attributed to NH, (*iii*) an AB quartet, $\delta_A = 4.05$ and $\delta_B = 4.38$ p.p.m., $J_{AB} = 13$ c.p.s., assigned to a $C{=}\overset{C}{\underset{|}{C}}{-}CH_2{-}SO_2{-}$ grouping, and (*iv*) a singlet at 2.03 p.p.m. assigned to a methyl group attached to an olefinic carbon; the relative areas of the peaks agreed with these assignments.

The formation of the sulfonamide IV from the sultam[1] is exactly parallel to the production of sulfonamides and other sulfonic acid derivatives by irradiation of the sultones. There are, to be sure, differences between the reactions, but they are readily explained on the basis of the greater nucleophilicity of the anil nitrogen atom. If a sulfene is in fact formed in the sultone reaction, then one is almost certainly formed in the irradiation of the sultam, and it is reasonable to postulate that both the sulfonamide and the pyrrole arise from the proposed sulfene intermediate. In the latter case, this is most simply accounted for by abnormal attack of the nitrogen on the sulfene as shown in eq. [1].

EXPERIMENTAL

Melting points were determined on a Kofler block and are uncorrected. Infrared spectra were obtained with a Beckman IR-5 spectrophotometer equipped with sodium chloride optics. Nuclear magnetic resonance spectra were determined with a Varian A-60 instrument. The silica gel referred to is British Drug Houses "suitable for chromatography" grade.

Irradiation of N-Phenyl Pulegone Sultam (5,6,7,8-Tetrahydro-4,7-dimethyl-1-phenyl-1H-2,1-benzothiazine 2,2-Dioxide) (I)

N-Phenyl pulegone sultam (225 mg), prepared according to Helferich *et al.* (9), was dissolved in methanol (15 ml) and irradiated in a Vycor flask for 150 min in the apparatus described by de Mayo (10). During this time the solution became red. The methanol was evaporated, the residue dissolved in carbon tetrachloride, and the solution filtered through a short silica gel column. The yield of 1-phenyl-3,6-dimethyl-4,5,6,7-tetrahydroindole (III) was 105 mg (61%), identified by comparison of its infrared and nuclear magnetic resonance spectra and R_f value on thin-layer chromatography with those of a sample obtained by pyrolysis of *N*-phenyl pulegone sultam (8).

Similar irradiation of the sultam in either ether or cyclohexane solution gave a similar product.

Irradiation of N-Phenyl Pulegone Sultam in n-Butylamine Solution

N-Phenyl pulegone sultam (250 mg) was irradiated in *n*-butylamine (8 ml) for 75 min. The *n*-butylamine was evaporated under reduced pressure and the product analyzed by thin-layer chromatography. Development with 3:1 benzene–ether yielded three fractions: (*i*) 1-phenyl-3,6-dimethyl-4,5,6,7-tetrahydroindole (III) (20 mg, 11% based on utilized starting material), identified by comparison of its infrared spectrum and R_f value on thin-layer chromatography with those of a sample obtained by pyrolysis of *N*-phenyl pulegone sultam; (*ii*) starting material (22 mg); and (*iii*) sulfonamide IV (164 mg, 60% based on utilized starting material). Recrystallization of the latter compound from ether–pentane gave white crystals, m.p. 139–141°.

Anal. Calcd. for $C_{24}H_{30}N_2O_2S$: C, 66.27; H, 8.34; N, 7.73; S, 8.84. Found: C, 65.92; H, 8.53; N, 8.20; S, 9.24.

Infrared peaks ($CHCl_3$) were at 3 360, ~1 635 (broad), 1 593, 1 325, and 1 138 cm^{-1}. Nuclear magnetic resonance bands ($CDCl_3$) were at 6.7 to 7.4 p.p.m. (complex aromatic absorption, relative area 5); 5.6 p.p.m. (broad singlet, relative area 1); AB quartet, $\delta_A = 4.05$ and $\delta_B = 4.38$ p.p.m. ($J_{AB} = 13$ c.p.s., relative area 2); 2.03 p.p.m. (singlet, relative area 3); and 0.98 to 0.85 p.p.m. (complex multiplet including two similar methyl groups).

In a repeat of the experiment, *N*-phenyl pulegone sultam (285 mg) yielded pyrrole III (32 mg, 17%), starting material (45 mg), and sulfonamide IV (173 mg, 58%).

Reaction of N-Phenyl Pulegone Sultam with n-Butylamine in the Absence of Light

N-Phenyl pulegone sultam (I) (25 mg) was dissolved in dry *n*-butylamine (5 ml). The flask was wrapped in aluminium foil and heated for 2 h at 55°. The *n*-butylamine was evaporated under reduced pressure. The infrared spectrum of the product was identical with that of the starting material.

ACKNOWLEDGMENTS

Acknowledgment is made to the donors of The Petroleum Research Fund, administered by the American Chemical Society, for support of this research, and to the National Research Council of Canada for a studentship. We cordially thank Professor Paul de Mayo for his valuable discussions and for lending us equipment.

[1]*Though no attempt has been made to delineate the full scope of these reactions, the formation of the corresponding pyrrole has also been observed on irradiation of 3,5-dimethyl-2-phenylthiazine 1,1-dioxide (D. J. H. Smith and J. F. King, unpublished observations).*

ALKYLATION OF CYCLIC AMIDINES WITH MANNICH BASES

C. PODESVA AND K. VAGI

In a recent communication Craig and Moyle (1) reported a simple method for the preparation of Mannich bases from aromatic amines by heating an equimolecular mixture of an aromatic amine and β-diethylaminopropiophenone hydrochloride in ethanol–water. In the same paper these authors reported the isolation of β-(2-pyridylamino)-propiophenone in a 74% yield from the reaction between β-diethylaminopropiophenone hydrochloride and 2-aminopyridine; this seems to be the only reported case of an alkylation of a cyclic amidine with a Mannich base.

We now report the products obtained from a reaction of Mannich bases or their salts with 2-aminothiazoles, 2-aminobenzoxazole, and adenine. These products are summarized in Table I. (The yields indicated are pure but not optimum yields, as the optimum reaction conditions were not investigated.)

The alkylations were carried out in refluxing 50% aqeuous ethanol with equimolecular amounts of the reagents. Free Mannich bases were found to be equivalent to their salts, and β-dimethylaminopropiophenones could be used instead of β-diethylaminopropiophenones with equal success.

Alkylation of 2-aminothiazole by means of β-diethylaminopropiophenone hydrochloride yielded β-(2-thiazolylamino)-propiophenone (ν_{max} (KBr) 3 200, 1 690, 1 600, 1 575, and 1 495 cm^{-1}; λ_{max} (methanol) 245 and 206 mμ (log ε 4.18 and 4.03, respectively)), plus a yellow crystalline substance, m.p. 227–229°, analyzing for $C_{21}H_{17}NO_2S$. A corresponding product, analyzing for $C_{25}H_{19}NO_2S$, was obtained, together with the expected product, from the reaction between 2-aminobenzothiazole and β-diethylaminopropiophenone hydrochloride. Similarly, β-(2-benzoxazolylamino)-propiophenone was accompanied by a yellowish substance analyzing for $C_{25}H_{19}NO_3$. These higher molecular weight products, whose structure will be reported in a separate communication, were not formed when free Mannich bases instead of their salts were used for the alkylation. It is also noteworthy that they were not formed in reaction mixtures in which either 2-amino-5-nitrothiazole or β-diethylamino-*p*-nitropropiophenone was one of the reactants.

Surprisingly, with adenine, the alkylation was found to take place at N_9 rather than on the exocyclic nitrogen. The reaction product of β-diethylaminopropiophenone and adenine exhibited infrared absorption bands at 3 270, 3 100, 1 680 – 1 670 (a doublet), 1 600, and 1 575 cm^{-1}. The peak at 1 672 cm^{-1} in adenine has been assigned by Angell (2) to the deformation vibration of the NH_2 group. This peak obviously forms a part of the doublet at 1 680 – 1 670 cm^{-1} together with the propiophenone carbonyl, thus excluding any substitution on the 6-amino group. Further evidence for the presence of the primary amino group in β-adenylpropiophenone was obtained from the infrared spectra of the alcohol prepared by reduction of adenylpropiophenone with sodium borohydride, where the characteristic bands appeared at 3 275, 3 150, 1 707, 1 620, and 1 575 cm^{-1}. It is rather difficult to speculate about the reasons for the shift of the NH_2 deformation vibration to the higher frequency. The explanation given by Angell (2) for a similar shift in adenine hydrochloride involving protonation of N_1 cannot apply in the present case. Also, in 9-(3′-hydroxypropyl)-6-aminopurine, NH_2 deformation vibration occurs at 1 670 cm^{-1} (3), which is in good agreement with the NH_2 deformation frequency of 1 675 cm^{-1} we found for 9-(3′-phenyl-3′-hydroxy-2′-methyl)-propyladenine, obtained from the sodium borohydride reduction of the corresponding ketone.

The attachment of the propiophenone moiety to N_9 of adenine follows from the ultraviolet spectra of the ketone and the corresponding alcohol. The ketone exhibits maxima at 249 and 212 mμ (log ε 4.32 and 4.28, respectively), which are obviously composite peaks of adenine (261 mμ (log ε 4.08) and 214 mμ (log ε 3.90)) and acetophenone (243 mμ (log ε 3.99)) (4). The corresponding alcohol shows bands at 215 and 262 mμ (log ε 4.28), unaffected by pH. As the position of the ultraviolet maximum in 1-methyladenine has been shown to be dependent on pH (5), substitution on N_1 has to be excluded. Neither N_3 nor N_7 substitution can be considered seriously in view of the fact that several 3- or 7-alkyladenines exhibit a maximum in the range of 272–274 mμ (5–7). On the other hand, 9-methyladenine has been shown to possess a maximum at 260 mμ in both acidic and alkaline solutions (5), and 9-(3′-hydroxypropyl)-adenine has been reported to absorb at 259 mμ (3).

EXPERIMENTAL

The ultraviolet spectra were obtained with a Unicam SP 800 recording instrument in methanol solutions. The infrared spectra were recorded on a Perkin–Elmer 237 apparatus in Nujol, unless otherwise stated. The melting points were determined in capillaries on a Mel-Temp apparatus and are uncorrected. Microanalyses were performed by Organic Microanalysis, Dr. C. Daessle, Montreal. Starting materials were obtained from commercial sources and were used without prior purification.

General Procedures

Reactions of β-Dialkylaminopropiophenone Hydrochlorides with 2-Aminothiazoles or 2-Aminobenzoxazole

An approximately 30% solution of equimolar amounts of the reactants in 50% aqueous ethanol was refluxed for the periods of time specified in Table 1. A mixture of two products precipitated when the solution was cooled (addition of acetone was necessary in the case of 2-aminobenzoxazole), and was collected by filtration. The crystalline material was dissolved in hot acetone (in hot benzene in the case of 2-aminobenzothiazole) and allowed to cool to room temperature. The high molecular weight products were removed by filtration and the filtrates evaporated to dryness. The residues were then crystallized from the appropriate solvents. β-(2-Benzothiazolylamino)- and β-(2-benzoxazolylamino)-propiophenone melted at 137–140° and 139–140°, respectively. Because these products failed to analyze within acceptable limits even after repeated crystallizations, they were transformed into picrates by treatment with methanolic picric acid.

Reactions of β-Dialkylaminopropiophenones (Bases) with 2-Aminothiazoles or 2-Aminobenzoxazole

The same concentration of the reactants was used as described above. After the reaction mixture was cooled to room temperature, it was diluted with water and extracted with chloroform. The solvent was removed *in vacuo* and the residue purified by crystallization.

Reactions of β-Dialkylaminopropiophenone Hydrochlorides with Adenine

Because adenine is only slightly soluble in alcohol–water, the whole reaction was carried out in suspension. The crystalline reaction product was collected by filtration and recrystallized several times.

Reduction of β-(9-Adenyl)-propiophenone

A mixture of the ketone (1 g) and sodium borohydride (0.2 g) in 55 ml of isopropanol containing 5 ml of water was stirred at room temperature over the weekend. After dilution with water the reaction product was extracted with chloroform, the solvent was removed *in vacuo*, and the resin-like residue (0.9 g) was crystallized from ethyl acetate. The analytically pure product (0.66 g, 66%) had a melting point of 139–142°.

Anal. Calcd. for $C_{14}H_{15}N_5O$: C, 62.44; H, 5.62; N, 26.01. Found: C, 62.18; H, 5.86; N, 26.24.

Reduction of β-(9-Adenyl)-α-methylpropiophenone

A mixture of the ketone (4 g) and sodium borohydride (0.3 g) in methanol–isopropanol–water (1:1:0.2, 66 ml) was stirred for 17 h at room temperature. The reaction mixture was worked up as above to give 1.5 g (37%) of pure alcohol, m.p. 229–231° (crystallized from methanol – ethyl acetate).

Anal. Calcd. for $C_{15}H_{17}N_5O$: C, 63.58; H, 6.05; N, 24.72. Found: C, 63.76; H, 6.17; N, 24.56.

ACKNOWLEDGMENT

PREPARATION OF 3,4-METHYLENEDIOXY- AND 3,4-DIMETHOXY-6-AMINOPHENOL

D. G. Orphanos and A. Taurins

The work on the synthesis of 6,7-dialkoxy-1,4-benzoxazin-2-ones (1) required the preparation of 3,4-methylenedioxy- (I) and 3,4-dimethoxy-6-aminophenol (II), which had not been described in the literature. These aminophenols proved to be very sensitive to air oxidation, and could not be isolated from solutions in a pure state. Therefore, their solutions were brought directly into reactions with other components in a nitrogen atmosphere. 3,4-Methylenedioxy- and 3,4-dimethoxy-6-aminophenol were characterized as their acetanilides, which were prepared by reductive acetylation (2) of the corresponding nitro compounds. Most of the intermediates used in the preparation of I and II have been described previously; however, in the present work they were synthesized either by a modification of the known method, or by a new procedure.

3,4-Methylenedioxy-6-aminophenol (I) was prepared from piperonal (3,4-methylenedioxybenzaldehyde) (III) in five steps (Reaction Scheme 1): (*a*) oxidation of piperonal (III) with peracetic acid to give 3,4-methylenedioxyphenol (IV) (sesamol), (*b*) acetylation of sesamol, (*c*) nitration of the acetyl derivative (VI) to obtain 3,4-methylenedioxy-6-nitrophenyl acetate (VII), (*d*) hydrolysis of the latter compound to produce a free nitrophenol (VIII), and (*e*) catalytic hydrogenation of the nitro compound to obtain I. The aminophenol I was characterized as its *N*-acetyl derivative, prepared by reductive acetylation (2) of the nitro compound (VIII).

Reduction of β-(9-Adenyl)-propiophenone

A mixture of the ketone (1 g) and sodium borohydride (0.2 g) in 55 ml of isopropanol containing 5 ml of water was stirred at room temperature over the weekend. After dilution with water the reaction product was extracted with chloroform, the solvent was removed *in vacuo*, and the resin-like residue (0.9 g) was crystallized from ethyl acetate. The analytically pure product (0.66 g, 66%) had a melting point of 139–142°.

Anal. Calcd. for $C_{14}H_{15}N_5O$: C, 62.44; H, 5.62; N, 26.01. Found: C, 62.18; H, 5.86; N, 26.24.

Reduction of β-(9-Adenyl)-α-methylpropiophenone

A mixture of the ketone (4 g) and sodium borohydride (0.3 g) in methanol–isopropanol–water (1:1:0.2, 66 ml) was stirred for 17 h at room temperature. The reaction mixture was worked up as above to give 1.5 g (37%) of pure alcohol, m.p. 229–231° (crystallized from methanol – ethyl acetate).

Anal. Calcd. for $C_{15}H_{17}N_5O$: C, 63.58; H, 6.05; N, 24.72. Found: C, 63.76; H, 6.17; N, 24.56.

REACTION SCHEME 1.

3,4-Dimethoxy-6-aminophenol (II) (5, 6) was similarly synthesized from veratraldehyde (3,4-dimethoxybenzaldehyde).

The oxidation of piperonal with peracetic acid was reinvestigated because the experimental observations did not agree with the literature data (3, 9). According to previous views, peracetic acid oxidation of piperonal gave sesamol acetate (3), or sesamol acetate and formate (9); therefore, the oxidation product was subjected to alkaline hydrolysis to obtain a uniform substance.

In the present work, neither sesamol acetate nor formate was found to be present. Instead, the oxidation product consisted of sesamol and unreacted piperonal in a ratio of 4:1, and a small amount of piperonylic acid (3,4-methylenedioxybenzoic acid) (V). This mixture could not be separated even by fractional distillation with a spinning-band column. The oxidation of piperonal was studied under a variety of experimental conditions, and it was observed that the reaction never goes to completion. If a greater amount of peracetic acid was used than that established as an optimum, the yields of the product were noticeably lower and more resinous by-products were formed. Freshly prepared peracetic acid was decidedly most efficient, and the best yields of sesamol (45–49%) were obtained when the reaction temperature was between 32 and 38°.

3,4-Methylenedioxy- (VI) and 3,4-dimethoxy-phenyl acetate (XI) were prepared by an adaptation of a method involving the treatment of the sodium salts of phenolic substances with acetic anhydride (8). The yields of VI and XI were 92% and 88%, respectively.

Nitration of 3,4-methylenedioxyphenyl acetate (VI) was carried out by an improved method in which the mixture of nitric and acetic acids was added to the solution of VI in glacial acetic acid at 30–45°. This procedure gave a yield of 88% of pure 3,4-methylenedioxy-6-nitrophenyl acetate (VII), compared with a yield of 67% obtained by a previous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

method (9). 3,4-Dimethoxy-6-nitrophenyl acetate (XII), a new compound, was prepared by a method analogous to that used for preparing VII.

Both VII and XII were hydrolyzed to give free phenols by reaction with 20% sulfuric acid for 40 min, instead of by the previous method (9) in which VII was refluxed for 20 h with ethanolic sodium hydroxide solution. Acidic hydrolysis of VII and XII produced quantitative yields of VIII and XIII as pure crystalline products.

Low-pressure catalytic hydrogenation of 3,4-methylenedioxy- (VIII) and 3,4-dimethoxy-6-nitrophenol (XIII) produced the desired products, 3,4-methylenedioxy- (I) and 3,4-dimethoxy-6-aminophenol (II), which were characterized and analyzed as their acetanilides (*N*-acetylamino derivatives). I and II were not isolated in a pure state from solutions because of their sensitivity to oxidation, but were used directly in syntheses (1).

EXPERIMENTAL

The melting points were determined in a Thiele–Dennis melting point tube containing Dow Corning silicone fluid No. D.C. 550, and are uncorrected. The analyses were carried out in the laboratory of C. Daessle, Montreal, Quebec. Infrared spectra were determined in potassium bromide, on a Perkin–Elmer model 21 double-beam instrument equipped with a sodium chloride prism.

20% Peracetic Acid Solution

This solution, containing catalytic amounts of *p*-toluenesulfonic acid, and being free of explosive Ac_2O_2, was always freshly prepared according to Böeseken *et al.* (3), and used within 24 h.

3,4-Methylenedioxyphenol (Sesamol) (IV)

To a solution of piperonal (III) (50 g, 0.333 mole) in glacial acetic acid at 32°, 20% peracetic acid solution (145 g, 0.38 mole) was added in portions of 20–30 ml, with occasional shaking. After the addition of the first portion, the temperature rose slowly to about 38°. It was allowed to fall to 32° before the next portion was added. When the addition had been completed, the reaction mixture was left at room temperature for 24 h, and then distilled under reduced pressure to free it from acetic acid. The dark-brown viscous oil was mixed with toluene (250 ml) and stirred for 15 min, during which time most of the resinous by-products separated as a viscous mass. After separation and distillation of the solvent, the residual dark-brown oil was subjected to vacuum distillation, and gave 40.5 g of a yellow oil boiling at 110–114° and 2 mm Hg. At the end of this distillation, the temperature was raised to 130–145° and piperonylic acid was distilled over. This acid, collected and crystallized from methanol, weighed 1.2 g and melted at 229°. The yellow oil obtained from the vacuum distillation was shaken with 150 ml of 10% sodium hydroxide solution and extracted three times with 50 ml portions of diethyl ether. The combined ether extracts, washed with water and dried over potassium sulfate, left 13.1 g of pure unreacted piperonal after removal of the solvent. The alkaline layer, acidified with 20% sulfuric acid solution, was then extracted with diethyl ether (200 ml). The ether extract, washed three times with 50 ml portions of 5% sodium bicarbonate solution and then with water, was dried over potassium sulfate. Removal of the ether gave a colorless to light-yellow oil which, with evolution of heat, rapidly solidified to pure sesamol (22.5 g), m.p. 64–65° (lit. (3) m.p. 65.8°). The yield of pure product, when the recovery of 13.1 g of pure unreacted piperonal was considered, amounted to 67.5%.

3,4-Dimethoxyphenol (X)

Oxidation of 55.5 g (0.333 mole) of veratraldehyde (IX) with peracetic acid was carried out under the conditions described above. Distillation of the reaction product gave 39.8 g of a yellow oil boiling at 118–127° and 2 mm Hg. Purification of the oil gave 25.8 g of crude 3,4-dimethoxyphenol, m.p. 71–76°. Crystallization from carbon tetrachloride raised the melting point to 79–80° (lit. m.p. 78–80° (6), 80–81° (7), 81.5° (5)); 11.5 g of pure unreacted veratraldehyde was isolated.

3,4-Methylenedioxyphenyl Acetate (VI)

3,4-Methylenedioxyphenol (IV) (13.8 g, 0.1 mole) was dissolved in 10% sodium hydroxide solution (60 ml), and to the cooled solution acetic anhydride (15 g, 0.15 mole) was added, with stirring, over 10 min. The reaction mixture was extracted with carbon tetrachloride. The extract was neutralized with sodium carbonate solution and dried over magnesium sulfate. The solvent was removed under reduced pressure, and the residue, 3,4-methylenedioxyphenyl acetate, was distilled at 112° and 2.5 mm Hg, yield 16.6 g (92%), n_D^{20} 1.5281 (lit. (4) n_D^{25} 1.5265).

3,4-Dimethoxyphenyl Acetate (XI)

3,4-Dimethoxyphenol (X) (15. g, 0.1 mole) was acetylated by a similar procedure. The crude acetate distilled at 128° and 2 mm, yield 17.8 g (88%). 3,4-Dimethoxyphenyl acetate forms colorless plates when crystallized from dilute ethanol, m.p. 44° (lit. (7) m.p. 44°).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

3,4-Methylenedioxy-6-nitrophenyl Acetate (VII)

3,4-Methylenedioxyphenyl acetate (VI) (18 g, 0.1 mole) dissolved in glacial acetic acid (60 ml) was treated at room temperature gradually with a solution of concentrated nitric acid (11 g, 0.12 mole, specific gravity 1.42) in glacial acetic acid (20 ml). The solution was stirred for 3 h and then poured into cold water (400 ml). After 1 h the pale-yellow crystalline precipitate was separated by filtration, washed with water, and dried. 3,4-Methylenedioxy-6-nitrophenyl acetate (VII) was crystallized from ethanol, yield 19.8 g (88%), m.p. 104–105° (lit. (9) m.p. 104–105°).

3,4-Dimethoxy-6-nitrophenyl Acetate (XII)

Nitration of 3,4-dimethoxyphenyl acetate (XI) (19.6 g, 0.1 mole) was carried out by the method used for the preparation of VII. 3,4-Dimethoxy-6-nitrophenyl acetate was crystallized from ethanol as yellow prisms, m.p. 117–118°, yield 20.7 g (85.4%).

Anal. Calcd. for $C_{10}H_{11}NO_6$: C, 49.79; H, 4.59; N, 5.81. Found: C, 49.51; H, 4.47; N, 6.08.

The structure of XII was confirmed by its infrared spectrum and hydrolysis of the acetate to the known XIII.

3,4-Methylenedioxy-6-nitrophenol (VIII)

3,4-Methylenedioxy-6-nitrophenyl acetate (VII) (22.5 g, 0.1 mole), ethanol (220 ml), and 20% (by volume) sulfuric acid solution (125 ml) were heated on a water bath for 40 min. The solution deposited golden-yellow needles when cooled. The product VIII was separated by filtration, washed with cold water, and dried, yield 18.1 g (98.3%), m.p. 95–96° (crystallized from 60% ethanol) (lit. (9) m.p. 93–94°).

3,4-Dimethoxy-6-nitrophenol (XIII)

3,4-Dimethoxy-6-nitrophenyl acetate (XII) (24.1 g, 0.1 mole) was hydrolyzed under conditions similar to those employed for the preparation of VIII. The compound XIII formed yellow crystals, m.p. 145–146° (crystallized from 60% ethanol) (lit. (10) m.p. 143°).

3,4-Methylenedioxy-6-aminophenol (I) (in Ethanol Solution)

3,4-Methylenedioxy-6-nitrophenol (VIII), dissolved in 25 times its weight of 96% ethanol, was reduced at room temperature with either platinum oxide or palladium on charcoal as catalyst, and with hydrogen at 3 atm pressure, until 3 molecular equivalents had been absorbed. The time required was about 10 min. When Raney nickel was used as a catalyst, the hydrogenation was carried out at 80–90°, and the time required was 1 h. Removal of the catalyst by filtration in a nitrogen atmosphere gave a colorless solution. Many efforts to isolate the reduction product I as a solid were unsuccessful. The amino compound I was characterized as its acetanilide and hydrochloride.

3,4-Methylenedioxy-6-hydroxyacetanilide

3,4-Methylenedioxy-6-nitrophenol (VIII) (1.83 g, 0.01 mole) was mixed with glacial acetic acid (50 ml) and acetic anhydride (1.1 g, 0.011 mole). The nitro group was reduced and acetylated at room temperature and 3 atm hydrogen pressure with 10% palladium on carbon (0.015 g) as catalyst. The reaction mixture was dissolved in hot ethanol and the catalyst removed by filtration. The solution was concentrated under reduced pressure to a small volume (10 ml), and diluted with water (100 ml); the solid which precipitated was separated by filtration, washed with water, and dried. 3,4-Methylenedioxy-6-hydroxyacetanilide was crystallized from 50% ethanol as cotton-like white crystals, m.p. 209–211°, yield 1.78 g (91%); ν_{max} 3 270, 3 090, 1 648 (sh), 1 635, and 1 565 cm^{-1}.

Anal. Calcd. for $C_9H_9NO_4$: C, 55.39; H, 4.64; N, 7.18. Found: C, 55.17; H, 4.75; N, 7.33.

3,4-Methylenedioxy-6-aminophenol Hydrochloride

A mixture of VIII (0.5 g), 10% palladium on carbon (0.01 g), and anhydrous diethyl ether (250 ml) was shaken with hydrogen under 3 atm pressure at room temperature. The reduction of the nitro group was completed in about 2 h. The catalyst was filtered under a nitrogen atmosphere, and hydrogen chloride gas was introduced into the filtrate. The white crystalline hydrochloride of I was separated by filtration, washed with benzene (5 ml), and dried *in vacuo* (0.45 g yield), m.p. 195–210° (decomp.); ν_{max} 3 540 (sh), 3 450, 3 160, 2 620, 1 595, and 1 298 cm^{-1}.

Anal. Calcd. for $C_7H_7NClO_3$: N, 7.39. Found: N, 7.51.

3,4-Dimethoxy-6-aminophenol (II) (in Methoxyethylene Glycol Solution)

The procedure employed for the reduction of 3,4-dimethoxy-6-nitrophenol (XIII) was similar to that used for the preparation of I, except that methoxyethylene glycol was used as the solvent because of the low solubility of XIII in ethanol. The resulting aminophenol II was characterized as its acetanilide.

3,4-Dimethoxy-6-hydroxyacetanilide

This derivative of II was prepared by reductive acetylation of XII, in a yield of 90%. It was crystallized from benzene as colorless needles, m.p. 137–138°; ν_{max} 3 365, 3 145, 1 648, and 1 630 (sh) cm^{-1}.

Anal. Calcd. for $C_{10}H_{13}NO_4$: C, 56.86; H, 6.20; N, 6.63. Found: C, 57.08; H, 6.04; N, 6.41.

PROTON MAGNETIC RESONANCE AND INFRARED SPECTRA OF SOME COMPLEXES OF N,N-DIMETHYLACETAMIDE

A. J. CARTY

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received April 12, 1966

ABSTRACT

Proton magnetic resonance spectra of some complexes of In, Zn, Cd, and Sn halides and perchlorates with N,N-dimethylacetamide (DMA) have been measured in acetone-d_6. Low field shifts of the methyl resonances of DMA on complex formation are dependent on metal and anion. The similarity of the spectra of all the complexes suggests only oxygen-coordinated DMA in solution. Infrared spectra in the range 2 000 – 625 cm^{-1} are recorded. Changes in the C—O and C—N stretching frequencies of the ligand on coordination are consistent with oxygen-bonded DMA both in the solid complexes and in solution.

The new compounds $Zn(ClO_4)_2.6DMA$, $Cd(ClO_4)_2.6DMA$, $CdI_2.2DMA$, and $SnCl_4.2DMA$ are reported.

INTRODUCTION

N,N-Dimethylacetamide (DMA) is well known to form complexes with a wide range of metal salts (1–7). In general, metal perchlorates form complexes in which the metal ion exhibits its maximum coordination number; $La(ClO_4)_3.8DMA$ and $In(ClO_4)_3.6DMA$ are typical. Metal halide complexes are often unusual in that 1.0, 1.5, or 2.5 moles of amide may be coordinated per mole of salt as in $CdCl_2.DMA$, $InI_3.1.5DMA$, and $UCl_4.2.5DMA$.

The nature of the bonding in amide complexes has been the subject of some discussion. On the basis of infrared and conductivity evidence, Bull *et al.* (1) postulate that DMA is coordinated to metals via the carbonyl oxygen. Other authors interpret spectral results for complexes of related amides in terms of nitrogen bonding (8, 9). Bridging or bidentate DMA has been suggested to account for the unusual stoichiometries of some metal halide complexes (3, 10).

Proton magnetic resonance has recently been used to establish that N,N-dimethylformamide coordinates to boron trihalides (11) and to decarborane (12) via the carbonyl oxygen.

This paper describes the proton magnetic resonance (p.m.r.) spectra of some DMA complexes of non-transition metal halides and perchlorates; the results are correlated with infrared spectral measurements and discussed in terms of metal–ligand bonding and the structure of coordinated DMA.

EXPERIMENTAL

B.D.H. reagent grade DMA was dried over Linde molecular sieve type 5A and distilled under reduced pressure. Anhydrous indium trihalides were prepared as described elsewhere (13). Indium, zinc, and cadmium perchlorates were prepared from the metals and perchloric acid and were dried *in vacuo* over potassium hydroxide. Other salts were Fisher reagent grade materials.

The new compounds $CdI_2.2DMA$, $Cd(ClO_4)_2.6DMA$, $Zn(ClO_4)_2.6DMA$, and $SnCl_4.2DMA$ were prepared as follows:

(1) $CdI_2.2DMA$.—Excess DMA was added to a suspension of cadmium iodide in hot ethyl acetate and the solution filtered. On standing, colorless crystals of the complex were formed. The product was recrystallized from methanol/acetone and dried *in vacuo*.

Anal. Calcd. for $CdI_2.2(C_4H_9NO)$: C, 17.76; H, 3.40; N, 5.18; I, 47.15; Cd, 20.69. Found: C, 17.41; H, 3.52; N, 5.27; I, 46.71; Cd, 20.80.

(2) $Cd(ClO_4)_2.6DMA$.—The hydrated perchlorate was dissolved in excess DMA. Excess ligand was removed under vacuum and the viscous liquid allowed to crystallize over phosphorus pentoxide. The hygroscopic product was recrystallized from anhydrous acetone.

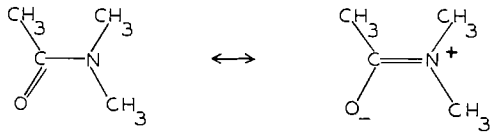
Anal. Calcd. for $Cd(ClO_4)_2.6(C_4H_9NO)$: C, 34.56; H, 6.48; N, 10.08; Cd, 13.49. Found: C, 34.19; H, 6.46; N, 10.01; Cd, 13.79.

(3) $Zn(ClO_4)_2.6DMA$.—An ethanolic solution of DMA was added to a solution of hydrated zinc perchlorate in the same solvent. The solution was allowed to crystallize over phosphorus pentoxide and the hygroscopic product dried *in vacuo*. Washing with ether or recrystallization led to decomposition.

Anal. Calcd. for $Zn(ClO_4)_2.6(C_4H_9NO)$: C, 36.63; H, 6.87; N, 10.69; Zn, 8.31. Found: C, 36.45; H, 6.31; N, 10.52; Zn, 8.51.

(4) $SnCl_4.2DMA$.—Addition of anhydrous tin tetrachloride in chloroform to a chloroform solution of DMA gave colorless crystals of the complex. The compound was recrystallized from acetone and dried *in vacuo*.

Anal. Calcd. for $SnCl_4.2(C_4H_9NO)$: C, 22.09; H, 4.14; N, 6.44; Cl, 32.67; Sn, 27.31. Found: C, 22.39; H, 4.13; N, 6.52; Cl, 32.54; Sn, 27.18.



Indium complexes were prepared by literature methods (10), as were the remaining zinc and cadmium complexes (1). Microanalyses were carried out by A. Bernhardt (Mulheim).

Proton magnetic resonance spectra were measured on a Varian A60 spectrometer operating at 60 Mc/s and equipped with a Varian temperature control assembly. Tetramethylsilane (TMS) was used as an internal reference. Samples were made up in a dry box and concentrations were 0.1 *M*.

Infrared measurements were made on a Perkin–Elmer 237B spectrophotometer. Spectra were measured as Nujol mulls and as solutions in methylene chloride.

RESULTS

The structure of DMA is best described as a resonance hybrid of the primary structures.

I ⟷ II

Significant contributions from II to the ground state of the molecule result in considerable double-bond character for the C—N bond (14). Restricted rotation about the C—N bond and the planar configuration of DMA give rise to two non-equivalent N-methyl groups and a p.m.r. spectrum in acetone-d_6 at 60 Mc/s consisting of a single C-methyl resonance at δ 1.99 and two N-methyl resonances centered at δ 2.93. The N-methyl resonance to high field can be assigned to the group *cis* to the carbonyl oxygen since the high anisotropy of the carbonyl bond causes greater shielding of the *cis* than the *trans* N-methyl group. At high resolution, a slight broadening of the high field N-methyl signal can be detected which can be attributed to a small *trans* spin–spin coupling between the N-methyl and C-methyl groups. Similar couplings have been noted in ethylenic systems (15).

Data for DMA and complexes are summarized in Table I.

In a study of this type it is necessary to show that the ligand remains coordinated to the metal ion in the solvent chosen. Proton magnetic resonance spectra of the DMA complexes of Sn(IV), In(III), Zn(II), and Cd(II) in acetone-d_6, methylene chloride, or deuterochloroform show considerable low field shifts, relative to free DMA in the same solvent (Table I). Furthermore, the chemical shifts of the ligand protons are almost independent of solvent, the signals being shifted slightly to high field for solutions in the halogenated compounds. For solutions of the complexes in the strong donor solvent

†Downfield shifts measured as $\delta_{DMA} - \delta_{complex}$ p.p.m.
‡Solution in deuteromethanol.

dimethylsulfoxide-d_6, which forms complexes with the above metal ions (16, 17), both N-methyl and C-methyl resonances appear only 2 c.p.s. to low field of the corresponding signals for free DMA. It seems reasonable to assume that in this solvent, complete replacement of DMA from the coordination sphere has occurred, whereas in acetone, chloroform, and methylene chloride, DMA remains coordinated to the metal. Finally, the spectra were shown to be independent of concentration. For example, no change in relative peak position was observed for solutions of $InI_3.1.5DMA$ for the concentration range 0.01 *M* to 0.1 *M* in acetone-d_6.

The p.m.r. spectra of all the complexes studied are very similar at probe temperature (about 36°). Figure 1 illustrates the p.m.r. spectra of $In(ClO_4)_3.6DMA$ and $ZnCl_2.2DMA$ in acetone-d_6, which are typical of the perchlorate and halide complexes. A single C-methyl resonance and two N-methyl resonances occur in all cases. Perchlorates generally gave broader signals than halides and the downfield shifts of the resonances vary both with cation and anion.

For the perchlorate complexes, traces of perchloric acid remaining from the preparations caused collapse of the two N-methyl signals into a single broad resonance. Reasons for this are discussed later.

Addition of free ligand to solutions of the complexes caused high field shifts of both N-methyl and C-methyl resonances but in no case were separate signals for complexed and free DMA observed.

We have qualitatively investigated the effect of temperature on the p.m.r. spectra of these compounds. Up to the boiling point of acetone-d_6, none of the complexes prepared showed marked changes in either the N-methyl or C-methyl resonances. The barrier to internal rotation about the C—N bond in bonded DMA must be somewhat higher than in the free ligand, where broadening of the N-methyl resonances begins at $\sim 40°$ and coalescence is complete at $\sim 70°$ (18). When the complexes were cooled below −20°, whereas only slight broadening of the methyl resonances in the perchlorate complexes occurred, the indium halide complexes showed marked resolution of both N-methyl and C-methyl signals. The spectra of $InBr_3.1.5DMA$ at normal temperature (36°) and −30° are shown in Fig. 2. The indium trichloride and triiodide complexes showed similar spectral changes at low temperature but signals from the zinc and cadmium halide complexes remained unresolved.
